# A Joint Experimental and Computational Study on the Electronic Communication in Diethynylaryl-Bridged ($\eta^5$-$C_5H_5$)Fe($\eta^2$-dppe) and ($\eta^5$-$C_5H_5$)-Fe$(CO)_2$ Units

**Laura Medei,[a] Laura Orian,[b] Oleg V. Semeikin,[c] Mikhail G. Peterleitner,[c] Nikolai A. Ustynyuk,[c] Saverio Santi,*[b] Christian Durante,[b] Antonella Ricci,[d] and Claudio Lo Sterzo*[d]**

**Keywords:** Mixed-valence compounds / Iron / Electron transfer / Electronic communication / Ethynylaryl bridging ligand

A family of bimetallic complexes [$Cp(CO)_2Fe$–C≡C–Ar–C≡C–$Fe(CO)_2Cp$] {Cp = $C_5H_5$; **6a**–**g**: Ar = $C_4H_2S$ (**a**), 3-($C_4H_9$)-$C_4HS$ (**b**), 3-($C_{16}H_{33}$)-$C_4HS$ (**c**), $C_6H_4$ (**d**), 2,5-bis-($OC_4H_9$)-$C_6H_2$ (**e**), 2,5-bis($OC_8H_{17}$)-$C_6H_2$ (**f**), ($C_6H_4$)$_2$ (**g**)} was prepared by the three-step Pd-catalysed *extended one-pot* (EOP) synthetic protocol from $Bu_3Sn$–C≡CH, X–Ar–X (X = I, Br) and $Cp(CO)_2FeI$. Complexes **6a**,**d**,**g** were then exposed to ultraviolet irradiation in the presence of an equivalent amount of 1,2-bis(diphenylphosphanyl)ethane (dppe) to form the corresponding bimetallic complexes [Cp(dppe)Fe–C≡C–Ar–C≡C–Fe(dppe)Cp] (**7a**,**d**,**g**). Compounds **6a**–**g** and **7a**,**d**,**g** were characterised by cyclic voltammetry (CV). The most significant electrochemical information comes from the oxidation of the dppe derivatives. The $\Delta E°$ separations between the subsequent reversible waves suggest that the efficiency of the metal–metal electronic coupling decreases in the order **7a** > **7d** > **7g**. Complexes **7a** and **7g** were also chemically oxidised with [$Fe(Cp^*)]_2[BF_4]$ {$Cp^*$ = $C_5(CH_3)_5$} and $[Fe(Cp)]_2[BF_4]$ respectively, and the near infrared (NIR) spectra of the mixed-valence species **7a**$^+$ and **7g**$^+$ were recorded. A strong intervalence transition (IT) band was observed only for the radical cation **7a**$^+$. While this finding confirms the existence of an electronic interaction between the two termini when a 2,5-thiophene group is present in the spacer, the NIR spectrum of **7g**$^+$ reveals a reduced efficiency in conveying electrons when the $C_4H_2S$ moiety is replaced by a 4,4′-biphenyl. In order to rationalise and quantify the extent of electronic communication, ruled by geometrical and electronic factors, density functional computational results on selected [Cp $(PH_3)_2$Fe] and [$Cp(CO)_2Fe$] binuclear model complexes are reported.

## Introduction

Highly ethynylated organic or organometallic compounds are currently providing new opportunities in projecting materials to be used in electronics, optics and ceramics.[1]

The attention devoted to such compounds arises from unique chemical and physical properties due to *facile* electron transfer along rod-like unsaturated molecular chains (eventually) incorporating metal centres.[2] The possibilities of extended delocalisation through the π networks can hardly influence physical properties such as polarisability, conductivity, and so forth, making these complexes suitable as active components in optoelectronic devices.[3]

We have recently disclosed a new one-pot route to poly(acetylide)s and poly(metallaacetylide)s based on palladium-catalysed carbon–carbon and metal–carbon bond formation (Scheme 1).[4]

By this procedure, named *extended one-pot* (EOP), a great variety of organic co- and homopolymers can be straightforwardly obtained with few steps and very good yields, with no need to isolate intermediate compounds (see path $a_1$ and path b in Scheme 1). Moreover, taking advantage of a new performance of Pd catalysts we discovered, allowing the formation of metal–carbon bonds, also organometallic oligomers and polymers can be conveniently accessed by this procedure[4a,4b,5] (path $a_2$ in Scheme 1).

With such versatile synthetic methodology at our disposal, we pursued our study by aiming for the valuation of the electrochemical and optical properties of some spacers

commonly used as building blocks in the preparation of opto- and electroactive polymers. To achieve this purpose, insertion of different spacers between two iron centres [CpFe(dppe)-] was planned, in order to exploit the electronic interaction between the metallic nuclei in a given redox state and the bridging ligand.

Actually, depending on both the redox state of the molecule and its structure, electron transfer and magnetic exchange can occur along the intermetallic bridge.

Several compounds with different metallic termini, that is iron and rhenium, bridged by unsaturated all-carbon chains ($C_4$ to $C_{20}$),[6a–6j], or iron, ruthenium and osmium, bridged by σ-acetylides intercalated by different aryl cores,[6k–6m] have been prepared and evaluated for their physical properties by other authors. Elegant studies on the possibility of tuning the electronic communication by lengthening the polyalkynyl bridging ligand and/or by changing the metallic termini have been presented by

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Lapinte,[7] Gladysz[8] and Bruce[9] and their co-workers. In a few cases aryl cores have been intercalated in the hydrocarbon spacer.[7g,7h,7k,7l,7o,7p,7s]

In this paper new binuclear $Fe^{II}$ compounds incorporating aromatic groups are presented. Aromatic groups to be introduced between iron centres have been chosen in order to keep the rigid-rod geometry of the carbon chain, to increase the chemical stability of the compounds and to maintain a high level of electronic coupling. The availability of compounds that differ for the aryl core in their bridge and the metal ancillary ligands allows discussion of the effects of structural and electronic molecular features on the extent of metal–metal communication. Particularly interesting are the effects on the metal–metal interaction resulting from (i) the replacement of a thiophenyl core by a phenyl core, a structural change in the bridge which does not greatly affect the intermetallic distance, (ii) the insertion of a 4,4′-biphenyl core, which significantly increases the length of the hydrocarbon linker and (iii) the presence of different ancillary ligands, that is CO and dppe.

The physical–chemical study was performed by electrochemical (CV) and spectroscopic techniques [IR, near infrared (NIR), UV/Vis] on selected synthesised dppe complexes.

Cyclic voltammetry (CV) results give information on the stability of the oxidation products but are not sufficient to determine the extent of electronic coupling between the metal termini. Actually, in a typical redox process involving symmetric bimetallic complexes, the separation between the two subsequent reversible waves, in the chemical and electrochemical sense, $\Delta E°$, allows a quantitative estimate of the thermodynamic stability of the intermediate oxidation state with respect to disproportionation (i.e., the comproportionation constant $K_c$).[10] $\Delta E°$ is only a qualitative indicator of an interaction between the two sites. According to the classification proposed by Robin and Day,[10a] $\Delta E°$ values close to zero are characteristic of noninteracting metal sites, that is of class I complexes. Small $\Delta E°$ separations correspond to a weak interaction between the metals and this situation is described by a mixed-valence state involving trapped-valence systems (class II). Finally, larger $\Delta E°$ values correspond to a stabilisation of the mixed-valence complexes involving the totally delocalised class III systems. Although the larger the conjugation along the intermetallic bridge is, the easier the transfer of electronic information between metal centres is, the greater $\Delta E°$ tends to be, the more CV separations are influenced by other factors, in particular the medium (solvent and support electrolyte), which can modify the electrostatic interaction in the dications.[10n] Thus, the CV analysis should always be integrated with spectroscopic investigation, in particular in the NIR region where mixed-valence species typically absorb.

While CV provides no information on the thermodynamic stability in the carbonylated species because of the irreversible nature of their waves, the dppe derivatives are studied in detail. In particular, the two dppe-substituted compounds, including the thiophenyl core and the 4,4′-biphenyl core respectively, exhibit very different reversible electrochemical behaviour. Thus they were also chemically oxidised and their products were studied by near infrared (NIR) spectroscopy. A quenching of the NIR absorption band, which is characteristic of mixed-valence species, occurs when the thiophenyl core is replaced by the 4,4′-biphenyl moiety.

Theoretical calculations, based on state-of-the-art density functional theory (DFT) methods, were carried out on selected $(PH_3)_2$ and $(CO)_2$ model derivatives and provided (i) reliable structures for the title complexes, for which crystallographic data are not available yet, (ii) a detailed description of the electronic structure of the neutral and radical cation species, and (iii) prediction and interpretation of the experimental NIR bands based on the model radical cations.

## Results and Discussion

The synthesis of dppe-substituted bimetallic compounds **7a**–**g** (Scheme 2) was first attempted using the EOP synthetic strategy outlined in path $a_2$ of Scheme 1; however, all the attempts to couple CpFe(dppe)I (**4**) with the different in situ generated $Bu_3Sn–C≡C–Ar–C≡C–SnBu_3$ (**3a**–**g**) in the presence of Pd failed (step 3 of path $a_2$). The failure in the formation of the Fe–C≡C bond was probably due to the strong electron-donating effect of dppe groups on the metal, which decreases the electrophilicity of the Fe–I bond, a basic requirement for oxidative addition to the Pd catalyst, thus the disclosure of the coupling process leading from **4** and **3a**–**g** to **7a**–**g**.[7j,11]

As direct EOP formation of **7a**–**g** proved not to be possible, we decided first to form the (CO)-substituted bimetallic compounds **6a**–**g**, then to subject these compounds to photolytic substitution in the presence of dppe as reported for similar compounds.[7d,12]

### Synthesis of (CO)-Substituted Bimetallic Compounds 6a–g

In Scheme 2 the EOP route to the bimetallic compounds **6a**–**g** and the subsequent conversion into the dppe derivatives **7a**–**g** are outlined. The EOP transformations were performed in dioxane solvent using 2–4% of $Pd^0$ catalyst (single addition at the beginning of step 1). While step 1 and step 2 were rapidly accomplished (20–30 min overall time) with quantitative formation of **3a**–**g**, the accomplishment of step 3 was revealed to be a critical event because of the delicate nature of the bimetallic complexes **6a**–**g**. Although the reaction temperature was lowered to 50–80 °C, with consequent prolongation of reaction times, monitoring of the reaction progress by $^1H$ NMR revealed that formation of the expected product was always accompanied by unidentified side products and a small amount of starting materials always remained.

Isolation of products **6a**–**g** was not straightforward. Chromatographic separation proved to be always detrimental, therefore products had to be isolated and purified by repeated crystallisation (see Experimental Section), which affected the yields of recovered products.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

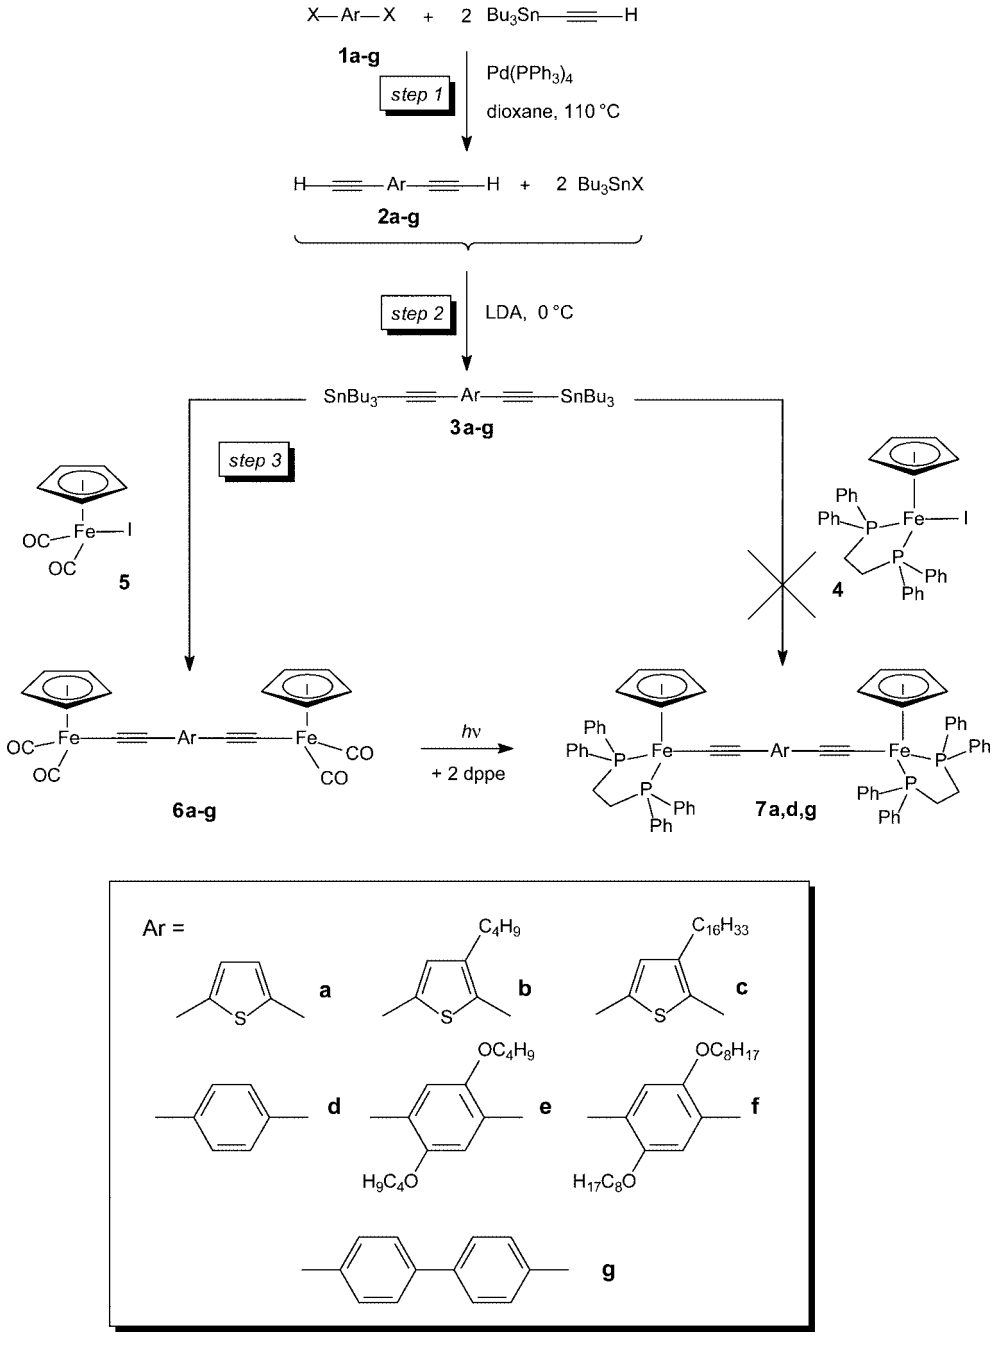
### Synthesis of (dppe)-Substituted Bimetallic Compounds 7a,d,g

Complexes **6a**,**d**,**g** were subjected to ultraviolet irradiation (Scheme 2) to obtain the corresponding dppe-substituted bimetallic complexes. All reactions were carried out in distilled benzene using an equivalent amount per iron centre of 1,2-bis(diphenylphosphanyl)ethane, which readily replaces all the carbonyl groups.

Concerning the recovery of products in a pure form, chromatographic purification proved always too aggressive, and isolation of complexes **7a**,**d**,**g** was achieved only by repeated cycles of precipitation from hexane and following dissolution of residues in toluene (or benzene), which allowed free dppe to be removed. By this method, products could be isolated and obtained in a satisfactory pure state, but the numerous cycles of precipitation/dissolution caused the yields to be drastically decreased.

### Cyclic Voltammetry (CV)

The CV at the platinum electrode, at scan rate 0.1 $V s^{-1}$, of a 2-mM solution of complex **7a** in $CH_2Cl_2$ in the presence of 0.1 M $nBu_4NPF_6$ exhibits two reversible (in the chemical and electrochemical sense) one-electron waves at $E_{pa}$ =



Scheme 2.

Table 1. Cyclic voltammetric data for $[Cp(dppe)Fe–C\equiv C–Ar–C\equiv C–Fe(dppe)Cp]^+[BF_4^-]$.[a]

| Complex | Ligand $L_2$ | Spacer Ar | $\Delta E^0 = E_2^0 - E_1^0$[b] | $E_1^0(0/+1)$[b] | $E_{pa}–E_{pc}$[c] | $E_2^0(+1/+2)$[b] | $E_{pa}–E_{pc}$[c] |
|---|---|---|---|---|---|---|---|
| **7a** | dppe | | 0.29 | –0.19 | 56 | 0.10 | 70 |
| **7d** | dppe | | 0.22 | 0.09 | 60 | 0.31 | 60 |
| **7g** | dppe |  | – | 0.04 | 70 | – | – |

[a] Solvent $CH_2Cl_2$/0.2 M $nBu_4NBF_4$; potential scan rate 0.1 V s$^{-1}$ at a 0.5-mm diameter platinum disk electrode; $T$ = 20 °C. [b] Volts vs. SCE. [c] Data are in mV.

–0.16 V and 0.14 V versus saturated calomel electrode (SCE), current ratio ($i_{pa}/i_{pc}$) = 1 (Figure 1, a). These two waves correspond to the formation of **7a**$^+$ and **7a**$^{2+}$. The anodic and cathodic peak separations ($E_{pa}–E_{pc}$) are 56 and 70 mV at scan rate 0.1 V s$^{-1}$ (Table 1).

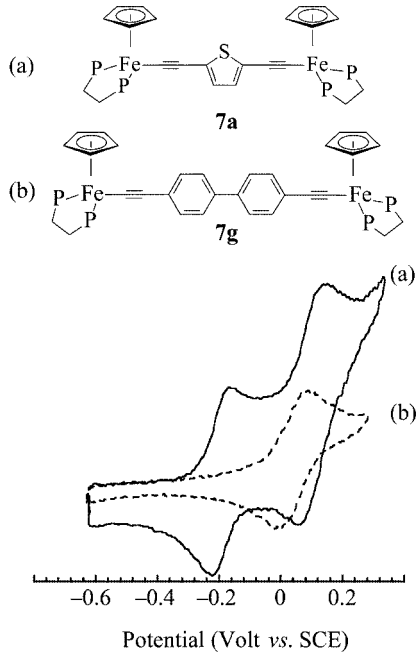

Figure 1. Cyclic voltammetric scan at a 0.5-mm diameter platinum disk electrode, $T$ = 20 °C. Solvent $CH_2Cl_2$/0.1 M $nBu_4NBF_4$; scan rate of 0.1 V s$^{-1}$; (a) solid line, 1 mM **7a**; (b) dashed line, 1 mM **7g**.

Similarly the CV of complex **7d** in the same conditions is characterised by two reversible one-electron waves in the oxidation scan from 1.5 to –1.5 V ($E_{pa}$ = 0.12 V and 0.34 V vs. SCE) and shows a wave separation $\Delta E°$ of 0.22 V and peak separations ($E_{pa}–E_{pc}$) of 60 mV (Table 1). On the contrary, the CV of complex **7g** (Figure 1, b) reveals only one reversible wave at $E_{pa}$ = 0.08 V with ($E_{pa}–E_{pc}$) = 70 mV and current ratio ($i_{pa}/i_{pc}$) = 1 (Table 1).

The low values of the oxidation potentials show that these binuclear complexes are electron-rich compounds. More interesting the quite large wave separations found for complexes **7a** and **7d** ($\Delta E°$ = 0.29 V and 0.22 V, respectively) reveal a significant degree of metal–metal interaction when the 2,5-thiophene and 1,4-phenylene groups are present in the diethynylaryl spacer. The presence of a single wave in the CV of complex **7g** suggests that the intercalation of a 4,4′-biphenyldiyl spacer drastically reduces the electronic communication between the metal sites.

We have also measured by CV the CO-substituted precursors **6a**–**g**. Such compounds are unstable in redox cycles, as expected from the absence of the bidentate phosphane ligands, which guarantee the reversibility of the process for **7a**,**d**,**g**. As a consequence, the possibility of obtaining analogous information about their electrical behaviour and the metal–metal electronic interaction is compromised. The CVs of all (CO)-substituted complexes (except for **6c**, this compound is very weakly soluble in most of the commonly used solvents) are characterised in the anodic scan by two irreversible waves. The CV in Figure 2 (a) is representative of the anodic scan of complexes **6a**,**b** and **6d**–**g**; in Table 2 the values of $E_p$ are reported. The first waves correspond to the formation of $[Cp(CO)_2Fe–C\equiv C–Ar–C\equiv C–Fe(CO)_2Cp]^+$ in the range of $E_p$ = 0.84–1.15 V; potentials as high as expected on the basis of the electron-poor nature of the $CpFe(CO)_2$ moiety. Concerning the second oxidation waves, they cannot be definitely assigned to the formation of $[Cp(CO)_2Fe–C\equiv C–Ar–C\equiv C–Fe(CO)_2Cp]^{2+}$ because of the irreversible nature of the preceding peaks. It is easily seen from Figure 2 that the height of the second oxidation peak is noticeably smaller than that of the first oxidation peak. The CVs at higher scan rates up to 100 V s$^{-1}$ did not

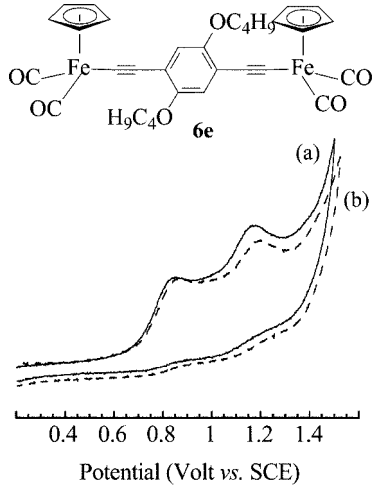

Figure 2. Cyclic voltammetric scan of 1 mM **6e** at a 0.5-mm diameter platinum disk electrode, $T$ = 20 °C. Solvent $CH_2Cl_2$/0.1 M $nBu_4NBF_4$; (a) solid line, scan rate of 0.1 V s$^{-1}$; (b) dashed line, scan rate 0.5 V.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

allow unequivocal analysis of the variation of the intensity of the second waves because of the intrinsic slowness of the corresponding electron transfer. However, by increasing the scan rate from 0.1 to 0.5 $V s^{-1}$, the intensity of this wave, $i \times v^{-1/2}$ ($v$ = scan rate), decreases (Figure 2, b). One can suggest that the second oxidation process does not correspond to the oxidation of the radical cation of the neutral ethynylaryl binuclear complexes, but rather indicates the oxidation of other intermediates formed at the potential of the first wave. In this context, the separation between the two subsequent waves does not furnish sound information on the electronic interaction between the $CpFe(CO)_2$ units.

## IR, UV/Vis, NIR Analysis

The mixed-valence radical cation **7a**$^+$ was generated at room temperature in $CH_2Cl_2$ by chemical oxidation of a 3.4-mM wine-coloured solution of the neutral complex with 1 equiv. of decamethylferrocenium tetrafluoroborate, $[Fe(Cp^*)]_2[BF_4]$ {$Cp^* = C_5(CH_3)_5$}. The resulting solution was deep-blue coloured.

The IR analysis of **7a**$^+$ shows a single vibration mode for the C≡C stretches (1981 $cm^{-1}$), at an intermediate frequency between those found for **7a** (2031 $cm^{-1}$) and **7a**$^{2+}$ (1929 $cm^{-1}$). Averaging of the vibration modes of the triple bonds is expected in homobimetallic class III complexes containing a polyalkynyl bridge, as the unpaired electron is fully delocalised and the resulting structure is symmetrical.

Conversely, for the previously reported [Cp*(dppe) Fe–C≡C–Ar–C≡C–Fe(dppe)Cp*] analogue (Ar = 2,5-$C_4H_2S$), Lapinte and co-workers[7h] found that the two metal sites are not equivalent on the basis of the presence of two separate C≡C vibration modes in the IR spectrum (1983 and 1927 $cm^{-1}$), predicting that the unpaired electron is partially localised on the IR time scale ($10^{-13}$ s). Alternatively, in this latter case, the lower energy band could not be a consequence of a symmetry breaking associated with the localisation of the odd electron. Possibly this band could be due to a Fermi coupling or to a harmonic combination with another absorption mode at lower energy.[13] These results reveal that substitution of the Cp* with the Cp groups in the metal sites renders more efficient the electronic coupling between the metal groups, the difference presumably coming from the metal/carbon ratio in the frontier orbitals because of the presence of the methyl groups.

The NIR spectrum of **7a**$^+$ (Figure 3) displays a band with a maximum at 5640 $cm^{-1}$ and a shoulder at 6500 $cm^{-1}$.

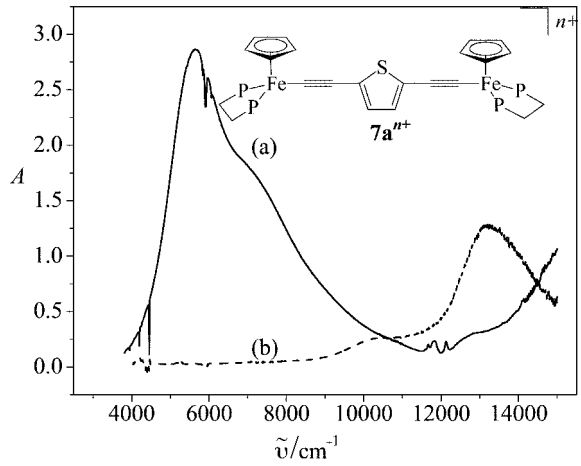

Figure 3. NIR spectra in $CH_2Cl_2$ at 20 °C of (a) 3.41 mM **7a**$^+$ and (b) **7a**$^{2+}$; optical path, $b$ = 0.100 cm.

The bands in this spectral region are considered diagnostic for an intervalence transfer process.[10] A detailed theoretical overview on the presence of two or more bands, as previously discussed for the closely related Cp* derivatives[7h] and other mixed-valence complexes,[8a] is given by Meyer et al.[11] As shown in Figure 4, the deconvolution of the spectrum has been satisfactorily obtained by considering three Gaussian components (5500, 6500, 7900 $cm^{-1}$) and the tail of the UV/Vis absorption. The effect of the polarity and ionic strength of the medium, which is generally employed to distinguish between class II and class III behaviour, was tested. The spectra of **7a**$^+$ in $CH_3CN$ ($\varepsilon$ = 37.5) and $CH_2Cl_2$ ($\varepsilon$ = 10.7) are almost identical, that is no variation of the band energy and shape was observed. Moreover, there is no dependence of the band energy and shape on ionic strength up to an electrolyte concentration of 0.2 M in $[nBu_4N][BF_4]$.[6i,7h,10] The analysis of the bands gives a bandwidth for the lower energy band **I** (Figure 4), $\Delta\tilde{\nu}_{1/2}$ = 1000 $cm^{-1}$, which is much below the theoretical value (3630 $cm^{-1}$) predicted by the Hush equation for a localised mixed-valence (class II) symmetric system,[14] $\Delta\tilde{\nu}_{1/2} = (2310\tilde{\nu}_c)^{1/2}$ $cm^{-1}$, where $\tilde{\nu}_c$ is the frequency of the maximum. By analogy with the data reported by Lapinte and co-workers on the Cp* analogues,[7h] band **I** of **7a**$^+$ could be an intervalence transfer (IT) transition and **7a**$^+$ is assigned to class III, at least on the timescale of the NIR spectroscopy ($10^{-14}$ s). The value of the $H_{ab}$ parameter,[14,15] calculated using the formula $H_{ab}$ ($cm^{-1}$) = $\tilde{\nu}_{max}/2$, is 2750 $cm^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

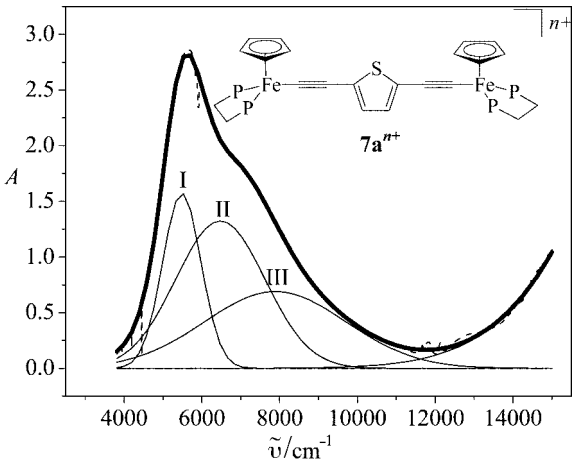

Figure 4. Gaussian deconvolution of the NIR bands of **7a**$^+$ (dashed line, experimental curve; solid lines, deconvoluted bands **I**, **II**, **III**; bold line, the sum of **I**, **II**, **III** components).

The addition either in $CH_3CN$ or $CH_2Cl_2$ of a second equivalent of ferrocenium, whose oxidation potential is sufficiently high to oxidise the second metal group forming a green solution of **7a**$^{2+}$, causes the disappearance of the bands of the monocation and the appearance of a less intense absorption at 13100 cm$^{-1}$ (Figure 3), likely because of a ligand-to-metal charge transfer (LMCT) transition. Under the same condition, we have found that $Cp_2Fe^+$ and $Cp^*_2Fe^+$ show bands at 13600 and 12900 cm$^{-1}$ respectively.

Also the oxidation of **7g** was monitored by NIR spectroscopy (Figure 5). The oxidation with 1 equiv. of ferrocenium gives a green solution whose spectrum in this region presents a very weak band at about 6000 cm$^{-1}$ and a more intense band at 12500 cm$^{-1}$, which could be assigned to the IT process of **7g**$^+$ and to an LMCT transition of the dication **7g**$^{2+}$, respectively, indicating that the mixed-valence state is not stable with respect to the disproportionation to the **7g** and **7g**$^{2+}$ states, in agreement with the presence of a single oxidation wave in the CV of complex **7g**.

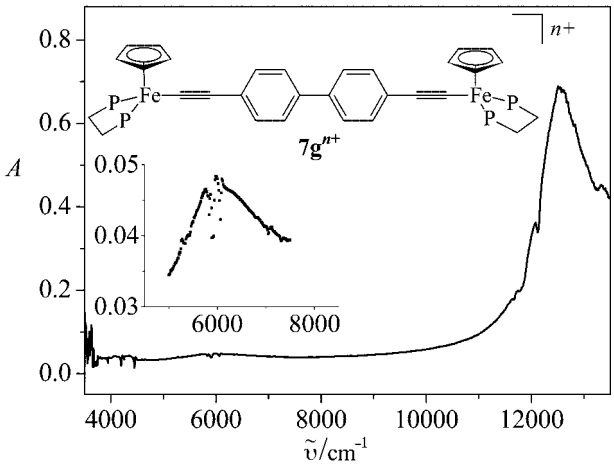

Figure 5. NIR spectra in $CH_2Cl_2$ at 20 °C of 3.4 mM **7g** oxidised with 1 equiv. of ferrocenium.

The couple **7a**/**7a**$^+$ was also studied in the UV/Vis spectroscopic region. The solution of **7a** in $CH_2Cl_2$ presents a very strong absorption at $\lambda$ = 410 nm, a wavelength quite similar to that reported for the Cp* analogue (418 nm), and attributed to a metal-to-ligand charge transfer (MLCT) transition.[7h] The spectrum of the deep-blue solution of **7a**$^+$ is totally different from its precursor **7a**. In fact, two new strong bands appears at 612 and 765 nm, which are responsible for the deep-blue colour of the mixed-valence species. They might be ascribed to LMCT transitions, similarly to what Lapinte and co-workers previously proposed for the absorptions at 588 and 653 nm of the Cp* mixed-valence analogous species.[7h] In that case, the intense MLCT transition observed for the neutral complex is still present in the spectrum of the monocation at a slightly red-shifted wavelength (423 nm), indicating that the characteristic absorptions of both $Fe^{II}$ and $Fe^{III}$ metal groups coexist (trapped valence, class II). On the contrary, in the UV/Vis spectrum of **7a**$^+$ the MLCT band, which is characteristic of a $Fe^{II}$ species, is absent, clearly showing that in **7a**$^+$ the valence is delocalised on the very fast UV/Vis timescale ($10^{-15}$ s).

## Density Functional Theory (DFT) Analysis

In order to gain insight on the factors ruling the extent of electronic communication and possibly to deconvolute the effects due to the structural parameters (i.e., metal–metal distance) from those related to the peculiar electronic features (i.e., the nature of the bridge and the nature of the ancillary ligands), we investigated systematically selected model complexes by DFT calculations.[16]

DFT optimisations were performed at B3LYP/LANL2DZ,6-31G** level of theory without any restriction in symmetry and tight conditions (see Computational Details) for neutral and oxidised $PH_3$ analogues of **7a**$^{0/+1}$, **7d**$^{0/+1}$ and **7g**$^{0/+1}$, which differ in the nature of the conjugated spacer. A *transoid* conformation of the metal centres is found to be more stable for $PH_3$-**7a** and $PH_3$-**7d**. Instead, in the fully optimised $PH_3$-**7g** the phenyl rings are oriented in distorted *cisoid* conformation.[17] It is worth noticing that the orientation of the metal fragments is such that the plane of the aromatic cores bisects the dihedral angle P–Fe–P. Consequently the conformation calculated for $PH_3$-**7g** is directly related to the torsion angle between the two phenyl rings. The calculated geometries of the neutral complexes are shown in Figure 6 (I–III). Significant interatomic distances and bond angles are reported in Table 3. In several cases the crystallographic data of structurally similar compounds are indicated and the good agreement with the analogous computed parameters enhances our confidence in the quality of the optimised geometries. A distinct alternation of single and multiple bonds is predicted in the three complexes. The average bond length of the alkyne units of the linkers is 1.232 Å, a value that nicely compares to the triple bond length in acetylene, that is 1.212 Å. The localised double bonds of the rings have an average value of 1.386 Å, which is also comparable to the ethylene double bond length (1.320 Å).

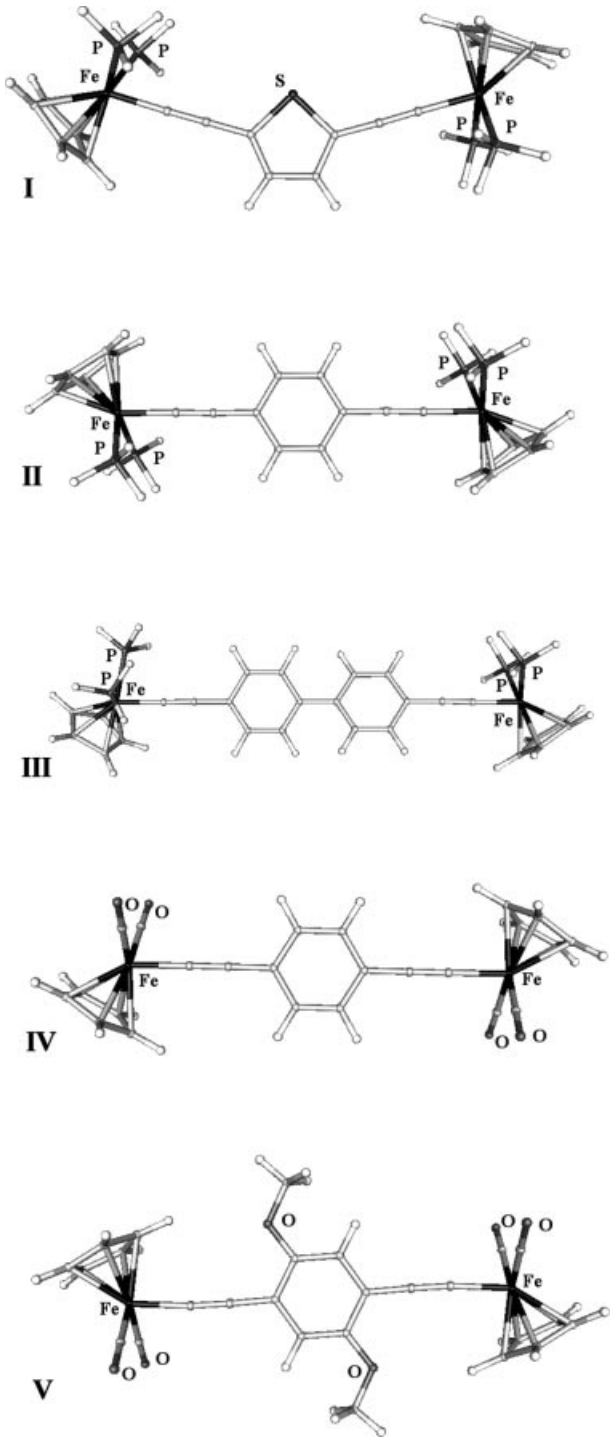

Figure 6. Calculated molecular structures of neutral model complexes: $PH_3$-**7a** (I), $PH_3$-**7d** (II), $PH_3$-**7g** (III), **6d** (IV) and $CH_3O$-**6e** (V). Heteroatoms are labelled for sake of clarity.

The ground-state electronic structures of $PH_3$-**7a**, $PH_3$-**7d** (the electronic structure of this complex was previously reported by Lapinte et al.[7o]) and $PH_3$-**7g** exhibit similar features.

Several authors have reported their theoretical studies on polyalkynyl- and alkynylaryl-bridged bimetallic complexes; thus the bonding between group 8 metal centres and acetylides is well documented.[18] A qualitative fragment analysis reveals that the cationic $[Cp(PH_3)_2Fe]^+$ fragments bond by strong σ-type interactions between unoccupied high-lying metallic frontier orbitals and low-lying occupied orbitals of the bridge (electron donation from the bridge to the metal fragments). Metal–carbon π-type interactions occur between occupied metal frontier orbitals and unoccupied carbon levels (weak π-type back-donation). The Kohn–Sham HOMOs are mainly localised on the metal centres and the ethynyl groups, and, to a less extent, on the aromatic rings. They result from out-of-phase combination of metal dπ orbitals and out-of-plane π orbitals of the linker; they exhibit *anti* bonding character between adjacent multiple bonds. The LUMO and LUMO+1 are almost degenerate and localised on the metal fragments. The topologies of Kohn–Sham frontier orbitals of $PH_3$-**7d** are shown in Figure 7.

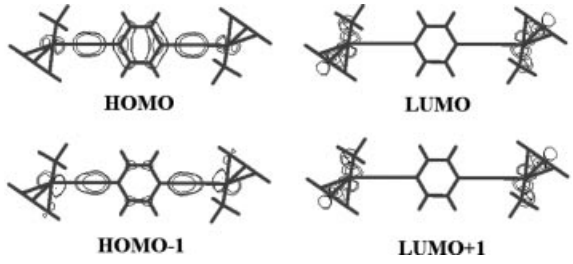

Figure 7. Top view of the contour plot of the frontier Kohn–Sham MOs of $PH_3$-**7d**. Contour values are ±0.035, ±0.04 and ±0.05 (e/bohr$^3$)$^{1/2}$.

A rather large energy gap separates the occupied and empty orbital sets in $PH_3$-**7a**, $PH_3$-**7d** and $PH_3$-**7g** (see Figure 8). The HOMO–LUMO gap in $PH_3$-**7d** is larger by about 0.2 eV than that of $PH_3$-**7a** (3.50 vs. 3.30 eV), and this is mainly due to the fact that the energy of HOMO of $PH_3$-**7d** is lower than that of HOMO of $PH_3$-**7a**. The HOMO–LUMO gap of $PH_3$-**7g** is 3.69 eV.

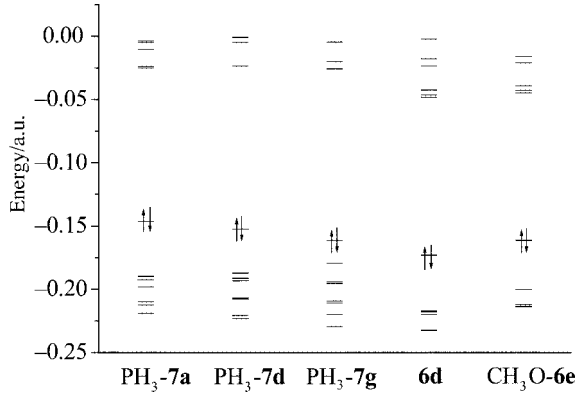

Figure 8. Frontier MOs for complexes $PH_3$-**7a**, $PH_3$-**7d**, $PH_3$-**7g**, **6d** and $CH_3O$-**6e**. HOMOs are indicated by double occupancy arrows; bold lines indicate almost degenerate energy levels.

Upon oxidation no significant conformational changes are observed. Both in $PH_3$-**7a**$^+$ and $PH_3$-**7d**$^+$ the metal units

[a] Average values. [b] X-ray data of $(\eta^5\text{-}C_5Me_5)(\eta^2\text{-dppe})Fe\text{–}C\equiv C\text{–}C_6H_5$.[7j] [c] Single $C_\beta$–C bond in the ethynyl bridge. [d] Average crystallographic values of $[Fe(\eta^5\text{-}C_5Me_5)(\eta^2\text{-dppe})(C\equiv C)]_3(\mu\text{-}1,3,5\text{-}C_6H_3)$.[7o]. [e] Triple $C_\alpha \equiv C_\beta$ bond in the ethynyl bridge. [f] Torsion angle between the two rings, around the bond $C_d$–$C_{d'}$. [g] By indicating the centroids of the Cp rings as Q and Q′, a torsion angle $\gamma$ can be defined as Q–Fe1–Fe2–Q′, so that $\gamma = 0$ corresponds to a *cis* conformation of the metal termini and $\gamma = 180$ indicates a *trans* conformation.

are still oriented *trans* with respect to the bridging ligand, while in $PH_3$-**7g**$^+$ the *cisoid* conformation is still more stable. Upon going from the neutral to the corresponding oxidised species, the Fe–$C_\alpha$ bond and the bond between $C_\beta$ and the adjacent carbon atom of the aryl core shorten, while the alkyne bond $C_\alpha \equiv C_\beta$ elongates. The cation $PH_3$-**7a**$^+$ is generated by removal of one electron from the HOMO of the neutral parent compound. In $PH_3$-**7d**$^+$ and $PH_3$-**7g**$^+$ there is a rearrangement of the energy levels, because their HOMOs (118β and 138β) correspond to HOMOs–1 of the neutral parent complexes. The trend in stability, based on the HOMO–LUMO gap, is inverted in the series of cations, $PH_3$-**7a**$^+$ being the most stable, as expected on the basis of the lower resonance energy of the thiophenyl unit compared to that of the phenyl unit, because of the mixing of sulfur d orbitals with carbon pπ orbitals. The HOMOs of the cations $PH_3$-**7d**$^+$ and $PH_3$-**7g**$^+$ are characterised by an in-phase contribution of metal dπ orbitals disposed in an *anti* bonding fashion with respect to the out-of-plane pπ orbitals of the linker. While the extent of delocalisation is large in $PH_3$-**7a**$^+$, the contribution of p(π) carbon orbitals of the phenyls to HOMO is poorer both in $PH_3$-**7d**$^+$ and $PH_3$-**7g**$^+$. The Kohn–Sham HOMOs of $PH_3$-**7a**$^+$, $PH_3$-**7d**$^+$ and $PH_3$-**7g**$^+$ are shown in Figure 9.

The effect of replacing the ancillary ligands $PH_3$ with CO groups was investigated theoretically on the couple **6d**$^{0/+1}$ by direct comparison with $PH_3$-**7d**$^{0/+1}$. In addition, the influence of alkoxy groups on the phenyl core was explored by calculating the electronic structures of the methoxy analogues of **6e**$^{0/+1}$, to be compared with those of **6d**$^{0/+1}$. The full geometry optimisations of **6d**$^{0/+1}$ and of $CH_3O$-**6e**$^{0/+1}$ were calculated at B3LYP/LANL2DZ,6-31G** level of

theory. The neutral species are shown in Figure 6 (IV, V) and their significant structural data are reported in Table 4. The full optimisations converged in both neutral complexes with a *trans* conformation of the metal groups. As for the $PH_3$ neutral derivatives, the calculations predict a distinct alternation of adjacent single and multiple bonds (see Table 4). In particular, a contraction of the alkyne bond length $C_\alpha{\equiv}C_\beta$ is observed compared to the $PH_3$-substituted species, which is a consequence of the electron density loss of the metal (1.225 vs. 1.232 Å).

Another effect of replacing the phosphanes with carbonyl groups is a reduction in energy of the frontier orbitals, as expected on the basis of the electron-poorer nature of the metal centres in the carbonylated complexes due to backbonding from the occupied metal orbitals to the empty π* of the carbonyl ligands (Figure 8). The HOMOs of **6d** and $CH_3O$-**6e**, resulting from out-of-phase combination of metal dπ orbitals and out-of-plane π orbitals of the linker, are strongly localised on the bridge, with minor metal contribution, and show *anti* bonding character between adjacent multiple bonds. The LUMOs and LUMOs+1 are almost degenerate and localised on the end-capping termini. The HOMO–LUMO gap of $CH_3O$-**6e** (3.17 eV) is smaller that that of **6d** (3.39 eV) and this is mainly the result of the destabilisation of the HOMO of the former complex, caused by the presence of the methoxy substituents (Figure 8). The variation in bond lengths occurring upon oxidation is reported in Table 4. No rearrangements of the frontier electronic levels are observed: the electron is removed from the HOMO of the neutral parent compound, as found for $PH_3$-**7a**.

[a] Alkyne carbon atom linked to iron. [b] Alkyne carbon atom linked to the aromatic ring. [c] Carbon atom of the aromatic core; the labelling is reported in the schemes above.

The extent of delocalisation of the unpaired electron in the radical cations was estimated on the basis of Mulliken spin densities, which are reported in Table 5.

The distribution of the spin density is symmetric in all the radical cations, although symmetry was not taken into account in the calculations. The spin density is well delocalised on the iron centres and on the $C_\alpha$ atoms in $PH_3$-**7a**$^+$ and in $PH_3$-**7d**$^+$. In $PH_3$-**7a**$^+$ the spin density is distributed also on the carbon atoms adjacent to S in the thiophenyl core, while in both $PH_3$-**7d**$^+$ and $PH_3$-**7g**$^+$ the spin density values on the phenyl rings are rather small. In **6d**$^+$ and $CH_3O$-**6e**$^+$ the significant decrease of the spin density on the metals as compared to $PH_3$-**7d**$^+$ is accompanied by its increase on the two α carbons and on two carbon atoms of the rings (see Table 5).

The extent of delocalisation is in favour of a stronger metal–metal interaction,[7m] and decreases in the $PH_3$ derivatives in the order $PH_3$-**7a**$^+$ > $PH_3$-**7d**$^+$ > $PH_3$-**7g**$^+$, in agreement with the trend based on the experiments.

To investigate the presence and the nature of the NIR absorptions of these model di-iron cations we have carried out time-dependent density functional theory (TDDFT) calculations,[19] which have been recently employed with success for mixed-valence organometallic species.[20] The level of theory is B3LYP/LANL2DZ,6-31+G* (see Computational Details). The lowest excitation energy computed for $PH_3$-**7a**$^+$ in the NIR region is 8560 cm$^{-1}$ (0.47), with an error comparable to those reported in a similar analysis.[20a] It corresponds to the lowest energy deconvoluted experimental absorption at 5500 cm$^{-1}$. The detailed composition is shown in Table 6. Its most relevant components involve the couples of levels 120α–121α and 119β–120β, that is the highest occupied α/β levels and the lowest unoccupied α/β levels respectively (pictures of the couples of MOs involved in the calculated excitation energies are given in the Supporting Information), which have significant contributions from d orbitals of both iron centres and p(π) carbon orbitals of the bridge.

In the case of $PH_3$-**7d**$^+$, an absorption is computed at 6859 cm$^{-1}$ ($f$ = 0.62) corresponding mainly to the HOMO (118β)–LUMO (119β) transition. The experimental spectrum of the Cp* analogue of **7d**$^+$ exhibits a single band at 4960 cm$^{-1}$.[7l] Also in this case the couple of orbitals involved in the monoelectronic transition are delocalised all over the molecular backbone.

By TDDFT calculations we also found an allowed low-energy absorption for $PH_3$-**7g**$^+$ at 5216 cm$^{-1}$ ($f$ = 0.83) assigned mainly to HOMO (138β)–LUMO (139β) and HOMO–1 (137β)–LUMO (139β) transitions. This excitation energy in the NIR region corresponds to the weak

[a] The HOMO is 120α, the LUMO is 120β. [b] The HOMO is 118β, the LUMO is 119β. [c] The HOMO is 138β, the LUMO is 139β. [d] The HOMO is 111α, the LUMO is 111β. [e] The HOMO is 127α, the LUMO is 127β. [f] The most relevant monoelectronic transitions are indicated; values in brackets are the CI coefficients.

absorption experimentally detected for **7g**$^+$ around 6000 $cm^{-1}$. It should be noted that in $PH_3$-**7d**$^+$ and $PH_3$-**7g**$^+$ the strongest NIR absorptions have an important contribution from the HOMO–LUMO transition and are thus shifted toward lower frequencies, as compared to that of $PH_3$-**7a**$^+$. Most importantly, no charge transfer character between the metal termini is observed, as reported recently for other organometallic binuclear systems,[20a] but these NIR absorptions are better interpreted as allowed electronic transitions between filled and empty delocalised frontier levels. The oscillator strengths increase with the length of the alkynylaryl bridge, as already noticed in previous theoretical studies.[20c,20d]

TDDFT calculations on the carbonylated model cations **6d**$^+$ and $CH_3O$-**6e**$^+$ do not reveal any low-energy transition. In the former an absorption is predicted at 11481 $cm^{-1}$ ($f$ = 0.52), while in the latter the calculated excitation energy is 12361 $cm^{-1}$ ($f$ = 0.39). In both cases the transitions involve the highest occupied α/β levels and the lowest unoccupied α/β levels, as for $PH_3$-**6a**$^+$. Also in these species no metal–metal charge transfer character is observed.

## Conclusions

The combination of the EOP synthetic protocol and the Pd-catalysed metal–carbon bond formation procedure offers suitable synthetic access to a large family of bimetallic complexes (**6a**–**g**) characterised by the presence of different conjugated (bis-ethynyl)aromatic spacers bridging two iron centres. Our EOP synthetic route represents a complementary approach to alkynylaryl-bridged bimetallic complexes with respect to Lapinte's method.[7q] In our procedure the straightforward formation of the bis(tributylethynyltin)aromatic derivatives **3a**–**g** and their direct in situ use to form complexes **6a**–**g** prevent the formation and isolation of the corresponding bis(trimethylsilylethynyl) derivatives as required by Lapinte's procedure.[7u]

Although substitution of carbonyls with dppe is conveniently performed only in some cases, the dppe derivatives of such organometallic assembly (**7a**,**d**,**g**) proved to be a useful manifold to study the electrical and optical properties of the conjugated spacer and the interaction between the metal centres, and thus, in perspective, the properties of polymeric materials incorporating such building blocks in the backbone.

On the basis of the electrochemical and optical properties of complexes **7a**,**d**,**g**, a correlation between the extent of the metal–metal electronic interaction and the nature of the diethynylaryl bridge can be pointed out. In fact, the $\Delta E°$ separations between the two subsequent reversible waves increase in the order **7a** > **7d** > **7g**, as does the efficiency of the metal–metal electronic coupling. The previously reported [Cp*(dppe)Fe–C≡C–Ar–C≡C–Fe(dppe)-Cp*] analogue (Ar = 2,5-$C_4H_2S$) displayed a somewhat more pronounced $\Delta E°$ (0.35 V) than **7a**. This indicates a higher thermodynamic stability of the corresponding monocationic intermediate with respect to disproportionation, probably due to the electron-donating effect of the methyl substituents of Cp*, which stabilise the positive charge on the metal groups. A similar trend can be established on the basis of the spectroscopic results for the mixed-valence species **7a**$^+$, **7d**$^+$ and **7g**$^+$. In the case of **7a**$^+$, the IR data, the shape and the solvent effect of the NIR band and the UV/Vis spectrum indicate unambiguously that the cation is a delocalised (class III) mixed-valence system on the timescale of $10^{-15}$ s. The comparison with the analogous 2,5-bis{[$\eta^5$-$C_5(CH_3)_5$]Fe($\eta^2$-dppe)($\sigma^1$-C≡C)}-$C_4H_2S$, which is valence-trapped on the IR timescale, highlights the important effect of replacing Cp* with Cp in the metal termini. On the basis of its electrochemical behaviour and the spectroscopic data reported in the literature, **7d**$^+$ can also be assigned to class III. The analysis of **7g**$^+$ is less clear-cut, because of the low stability of this mixed-valence cation in solution. $PH_3$-**7g**$^+$ has a certain extent of delocalisation, but the metal–metal interaction is hampered with respect to $PH_3$-**7d**$^+$ because of the increase of the distance and the greater flexibility of the bridge. DFT calculations support the experimental findings and allow deconvolution

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of geometric effects, such as the intermetallic distance ($PH_3$-**7d**$^+$ vs. $PH_3$-**7g**$^+$), from electronic effects, that is the different nature of the incorporated aryl core ($PH_3$-**7a**$^+$ vs. $PH_3$-**7d**$^+$), on the extent of electronic delocalisation. On the basis of the computational results on the carbonylated model cation **6d**$^+$ a less efficient electron delocalisation is observed with respect to the corresponding $PH_3$ analogue (**6d**$^+$ vs. **7d**$^+$). In addition, in the presence of the methoxy substituents on the aryl core in $CH_3O$-**6e**$^+$ the spin density decreases further on the iron centres and moves to the phenyl ring ($CH_3O$-**6e**$^+$ vs. **6d**$^+$).

TDDFT calculations predict that NIR absorptions, which are a sort of fingerprint of mixed-valence species, occur only in $PH_3$-**7a**$^+$, $PH_3$-**7d**$^+$ and $PH_3$-**7g**$^+$, and that they do not exhibit dominant charge transfer character between the metal termini, but are better described as allowed electronic transitions between filled and empty frontier levels.

Finally the efficiency of the dialkynyl–thiophenyl unit in conveying electron information is further recognised and associated to the large extent of delocalisation in the radical cations bearing this aryl core.[6l,6m] Work is in progress to employ this functional unit, intercalated also by different metal centres, in larger molecular wires.

## Experimental Section

**General:** All manipulations were carried out under argon using Schlenk techniques. Dioxane and benzene were dried and distilled respectively over Na and Na/K alloy, and argon-saturated prior to use. The following chemicals were prepared according to the published procedure: 1,4-diiodo-2,5-dioctyloxybenzene,[4] 1,4-diiodo-2,5-dibutoxybenzene,[4] 2,5-diiodo-3-hexadecylthiophene[4] and 2,5-diiodo-3-butylthiophene.[4] Other chemicals were used as received. Routine NMR spectra were recorded with a AC-300 P Bruker spectrometer (300, 121 and 75 MHz respectively for $^1H$, $^{31}P$, $^{13}C$). Chemical shifts are given in parts per million (ppm) relative to tetramethylsilane (TMS) for $^1H$ NMR and $^{13}C$ NMR spectra and 85% $H_3PO_4$ for $^{31}P$ NMR spectroscopy. Cyclic voltammograms [except the ones of complexes **6d**,**g** and **7a**,**d**, performed by Dr. Mikhail G. Peterleitner of Nesmeyanov Institute of Organoelement Compounds (INEOS), Russian Academy of Science, Moscow] were recorded with an AMEL 500 potentiostat. Transmittance FTIR spectra were recorded with a Nicolet FT 510 instrument in the solvent subtraction mode, using a 0.1-mm $CaF_2$ cell. NIR spectra were recorded with a Bruker Equinox55 FTIR spectrometer equipped with an optical fibre for NIR measurements on liquids. Elemental analyses were performed by the Servizio Microanalisi of the Dipartimento di Chimica of Università di Roma "La Sapienza".

**2,5-Bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]C$_4$H$_2$S (6a). Step 1:** In a Schlenk tube $Bu_3SnC{\equiv}CH$ (0.962 g, 3.05 mmol), 2,5-diiodothiophene (0.500 g, 1.49 mmol) and $Pd(PPh_3)_4$ (40 mg, 0.035 mmol) were stirred in dioxane (30 mL) at 110 °C for 20 min.

**Step 2:** The brown solution was then cooled (ca. 0 °C) and LDA (1.8 mL, 2 M) was slowly added.

**Step 3:** This mixture was left for about 30 min at room temperature, ($\eta^5$-$C_5H_5$)Fe(CO)$_2$I (0.914 g, 3.01 mmol) was added and the resulting dark solution was heated (50 °C) for 7 h, then filtered through a thin Celite layer and dried under vacuum. The residue was dissolved in a small amount of $CH_2Cl_2$ and then precipitated with pentane. After filtration and repeated washings with pentane, a dark brown powder (0.533 g, 74% yield) was obtained. IR ($CH_2Cl_2$): 2095 (w) $\tilde{\nu}_{C\equiv C}$, 2044 (s), 2000 (s) $\tilde{\nu}_{CO}$ cm$^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.60 (2 H, thioph.), 5.02 (10 H, Cp) ppm. Spectroscopic data correspond to the reported data.[4]

**2,5-Bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]-3-($C_4H_9$)-C$_4$HS (6b):** This complex was prepared as described for **6a**, from $Bu_3SnC{\equiv}CH$ (0.837 g, 2.55 mmol), 2,5-diiodo-3-butylthiophene (0.500 g, 1.28 mmol) and $Pd(PPh_3)_4$ (30 mg, 0.03 mmol) in dioxane (30 mL), LDA (1.5 mL, 2 M) and ($\eta^5$-$C_5H_5$)Fe(CO)$_2$I (0.799 g, 2.55 mmol). Step 3 was accomplished by stirring at 70 °C for 10 h. After repeated precipitation cycles from $CH_2Cl_2$/pentane the product (0.352 g, 51% yield) was recovered as described for **6a** as a coffee-brown powder. IR ($CH_2Cl_2$): 2095 (w) $\tilde{\nu}_{C\equiv C}$, 2042 (s), 1997 (s) $\tilde{\nu}_{CO}$ cm$^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 7.73 (thioph.), 4.04 (Cp), 2.85, 1.70–0.80 ($C_4H_9$) ppm. $^{13}C$ NMR ([$D_7$]DMF): $\delta$ = 213.2, 141.9, 131.3, 128.4, 107.3, 89.5, 85.9, 71.7, 66.3, 31.8, 21.7, 13.1 ppm. $C_{26}H_{20}Fe_2O_4S$ (540.20): calcd. C 57.81, H 3.73; found C 57.60, H 3.83.

**2,5-Bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]-3-($C_{16}H_{33}$)-C$_4$HS (6c):** This complex was prepared as described for **6a**, from $Bu_3SnC{\equiv}CH$ (0.586 g, 1.79 mmol), 2,5-diiodo-3-hexadecylthiophene (0.500 g, 0.89 mmol) and $Pd(PPh_3)_4$ (16 mg, 0.01 mmol) in dioxane (30 mL), LDA (1.1 mL, 2 M) and ($\eta^5$-$C_5H_5$)Fe(CO)$_2$I (0.559 g, 1.78 mmol). Step 3 was accomplished by stirring at 65 °C for 23 h. After repeated precipitation cycles from $CH_2Cl_2$/methanol the product (0.09 g, 15% yield) was recovered as described for **6a** as a coffee-brown powder. IR ($CH_2Cl_2$): 2096 (w) $\tilde{\nu}_{C\equiv C}$, 2042 (s), 1997 (s) $\tilde{\nu}_{CO}$ cm$^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 7.52 (thioph.), 4.08 (Cp), 1.70–0.80 ($C_{16}H_{33}$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 249.6, 230.2, 158.8, 121.6, 90.6, 85.3, 31.9, 29.7, 29.4, 22.7, 22.3, 14.1 ppm. $C_{38}H_{44}Fe_2O_4S$ (708.52): calcd. C 64.42, H 6.26; found C 64.30, H 6.15.

**1,4-Bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]C$_6$H$_4$ (6d):** This complex was prepared as described for **6a**, from $Bu_3SnC{\equiv}CH$ (0.985 g, 3.00 mmol), 1,4-diiodobenzene (0.500 g, 1.5 mmol) and $Pd(PPh_3)_4$ (35 mg, 0.03 mmol) in dioxane (25 mL), LDA (1.8 mL, 2 M) and ($\eta^5$-$C_5H_5$)Fe(CO)$_2$I (0.940 g, 3.00 mmol). Step 3 was accomplished by stirring at 60 °C for 6 h. After repeated precipitation cycles from $CH_2Cl_2$/pentane the product (0.406 g, 57% yield) was recovered as described for **6a** as a dark yellow powder. IR ($CH_2Cl_2$): 2107 (w) $\tilde{\nu}_{C\equiv C}$, 2043 (s), 1996 (s) $\tilde{\nu}_{CO}$ cm$^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 7.56 (benzene), 4.06 (Cp) ppm. $^{13}C$ NMR ([$D_7$]DMF): $\delta$ = 213.6, 131.7–124.9, 115.6, 91.1, 85.9 ppm. $C_{24}H_{14}Fe_2O_4$ (478.07): calcd. C 60.30, H 2.95; found C 60.53, H 2.91.

**1,4-Bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]-2,5-bis($OC_4H_9$)C$_6$H$_2$ (6e):** This complex was prepared as described for **6a**, from $Bu_3SnC{\equiv}CH$ (0.692 g, 2.11 mmol), 1,4-diiodo-2,5-dibutoxybenzene (0.500 g, 1.05 mmol) and $Pd(PPh_3)_4$ (25 mg, 0.02 mmol) in dioxane (25 mL), LDA (1.3 mL, 2 M) and ($\eta^5$-$C_5H_5$)Fe(CO)$_2$I (0.661 g, 2.11 mmol). Step 3 was accomplished by stirring at 50 °C for 7 h. After repeated precipitation cycles from $CH_2Cl_2$/hexane the product (0.320 g, 49% yield) was recovered as described for **6a** as a coffee-brown powder. IR ($CH_2Cl_2$): 2106 (w) $\tilde{\nu}_{C\equiv C}$, 2041 (s), 1994 (s) $\tilde{\nu}_{CO}$ cm$^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 7.72 (benzene), 4.19 (Cp), 3.75 ($OCH_2$), 1.62–0.92 [$OCH_2(CH_2)_2CH_3$] ppm. $^{13}C$ NMR ([$D_7$]DMF): $\delta$ = 213.6, 130.4, 116.8, 86.5, 68.0, 19.1, 13.3 ppm. $C_{32}H_{30}Fe_2O_6$ (622.28): calcd. C 61.77, H 4.86; found C 61.90, H 4.81.

**1,4-Bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]-2,5-bis($OC_8H_{17}$)C$_6$H$_2$ (6f):** This complex was prepared as described for **6a**, from $Bu_3SnC{\equiv}CH$ (0.896 g, 2.73 mmol), 1,4-diiodo-2,5-dioctyloxybenzene (0.800 g, 1.36 mmol) and $Pd(PPh_3)_4$ (32 mg, 0.03 mmol) in dioxane (25 mL),

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

LDA (1.7 mL, 2 M) and ($\eta^5$-$C_5H_5$)Fe(CO)$_2$I (0.855 g, 2.73 mmol). Step 3 was accomplished by stirring at 80 °C for 12 h. After repeated precipitation cycles from $CH_2Cl_2$/methanol the product (0.521 g, 52% yield) was recovered as described for **6a** as a brown powder. IR ($CH_2Cl_2$): 2106 (w) $\tilde{\nu}_{C\equiv C}$, 2042 (s), 1996 (s) $\tilde{\nu}_{CO}$ cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 4.20 (Cp), 3.70 (OC$H_2$), 1.50–0.90 [OCH$_2$(C$H_2$)$_6$C$H_3$] ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 212.5, 154.0–110.0, 85.4, 69.2, 29.4–22.6, 14.1 ppm. $C_{40}H_{46}Fe_2O_6$ (734.50): calcd. C 65.41, H 6.31; found C 65.32, H 6.27.

**4,4′-Bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]($C_6H_4$)$_2$ (6g):** This complex was prepared as described for **6a**, from $Bu_3SnC{\equiv}CH$ (1.031 g, 3.14 mmol), 4,4′-dibromobiphenyl (0.500 g, 1.57 mmol) and $Pd(PPh_3)_4$ (37 mg, 0.03 mmol) in dioxane (30 mL), LDA (1.9 mL, 2 M) and ($\eta^5$-$C_5H_5$)Fe(CO)$_2$I (0.984 g, 3.14 mmol). Step 3 was accomplished by stirring at 80 °C for 9 h. After repeated precipitation cycles from $CH_2Cl_2$/pentane the product (0.728 g, 84% yield) was recovered as described for **6a** as a dark orange powder. IR ($CH_2Cl_2$): 2106 (w) $\tilde{\nu}_{C\equiv C}$, 2041 (s), 1994 (s) $\tilde{\nu}_{CO}$ cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 7.66–7.01 (biph), 4.10 (Cp) ppm. $^{13}$C NMR ([$D_7$]-DMF): $\delta$ = 213.6, 136.2–125.5, 115.3, 92.5, 86.0 ppm. $C_{30}H_{18}Fe_2O_4$ (554.16): calcd. C 65.02, H 3.27; found C 65.15, H 3.29.

**2,5-Bis[($\eta^5$-$C_5H_5$)Fe(dppe)($\sigma^1$-C≡C)]$C_4H_2S$ (7a):** A rust colour mixture of 2,5-bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]$C_4H_2S$ (**6a**) (0.247 g, 0.51 mmol) and 1,2-bis(diphenylphosphanyl)ethane (0.406 g, 1.02 mmol) in benzene (200 mL) was exposed to ultraviolet irradiation for 2 h at room temperature. The dark brown reaction mixture was then filtered and dried under vacuum. The black residue was washed with hexane, dissolved in toluene and precipitated with hexane. This treatment was repeated three times to isolate a crystalline black powder (0.137 g, 23% yield). IR ($CH_2Cl_2$): 2052 (w) $\tilde{\nu}_{C\equiv C}$ cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 7.96, 740–6.90, 4.21 (Cp), 2.50–0.40 ppm. $^{13}$C NMR ($C_6D_6$): $\delta$ = 142.7–128.0, 114.2, 99.7, 81.7, 30.2, 28.6 ppm. $^{31}$P NMR ($C_6D_6$): $\delta$ = 106.9 ppm. $C_{70}H_{60}Fe_2P_4S$ (1168.90): calcd. C 71.93, H 5.17; found C 72.05, H 5.09.

**1,4-Bis[($\eta^5$-$C_5H_5$)Fe(dppe)($\sigma^1$-C≡C)]$C_6H_4$ (7d):** A yellow-orange mixture of 1,4-bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]$C_6H_4$ (**6d**) (0.200 g, 0.42 mmol) and 1,2-bis(diphenylphosphanyl)ethane (0.345 g, 0.42 mmol) in benzene (200 mL) was exposed to ultraviolet irradiation for 3.5 h at room temperature. The dark red reaction mixture was then filtered and dried under vacuum. The residue was washed with hexane, dissolved in toluene and precipitated with hexane. This treatment was repeated ten times, and the pure complex (0.056 g, 12% yield) was finally recovered as a crystalline black powder. IR ($CH_2Cl_2$): 2065 (w) $\tilde{\nu}_{C\equiv C}$ cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 7.98, 7.69, 6.99, 4.28 (Cp), 2.68–0.90 ppm. $^{31}$P NMR ($C_6D_6$): $\delta$ = 107.1 ppm. $C_{72}H_{62}Fe_2P_4$ (1162.87): calcd. C 74.37, H 5.37; found C 74.64, H 5.81.

**4,4′-Bis[($\eta^5$-$C_5H_5$)Fe(dppe)($\sigma^1$-C≡C)]($C_6H_4$)$_2$ (7g):** A brick-red mixture of 4,4′-bis[($\eta^5$-$C_5H_5$)Fe(CO)$_2$($\sigma^1$-C≡C)]($C_6H_4$)$_2$ (**6d**) (0.150 g, 0.26 mmol) and 1,2-bis(diphenylphosphanyl)ethane (0.222 g, 0.54 mmol) in benzene (200 mL) was exposed to ultraviolet irradiation for 2 h at room temperature. The yellow-orange reaction mixture was then filtered and dried under vacuum. The light-orange residue was washed with hexane, dissolved in toluene and precipitated with hexane. This treatment was repeated ten times, and the pure product (0.060 g, 19% yield) was finally recovered as a dark yellow powder. IR ($CH_2Cl_2$): 2059 (w) $\tilde{\nu}_{C\equiv C}$ cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 8.01, 7.25–6.90, 4.30 (Cp), 2.57–0.43 ppm. $^{13}$C NMR ([$D_7$]DMF, ppm): $\delta$ = 133.5–120.3, 105.2, 84.8, 78.6, 66.9, 29.9 ppm. $^{31}$P NMR ($C_6D_6$): $\delta$ = 107.1 ppm. $C_{78}H_{66}Fe_2P_4$ (1238.97): calcd. C 75.62, H 5.37; found C 75.40, H 5.11.

**[{Fe($\eta^5$-$C_5H_5$)($\eta^2$-dppe)(C≡C)}$_2${2,5-$C_4H_2S$}][$BF_4$] (7a$^+$):** [Fe($\eta^5$-$C_5Me_5$)$_2$][$BF_4$] (0.0033 g, 0.0081 mmol, 0.95 equiv.) was added at room temperature to a stirred solution of [{Fe($\eta^5$-$C_5H_5$)($\eta^2$-dppe)(C≡C)}$_2${2,5-$C_4H_2S$}] (**7a**) (0.01 g, 0.0085 mmol) in $CH_2Cl_2$ (10 mL). The wine-coloured mixture immediately became blue and was stirred at room temperature for 1.5 h. The solution was filtered through Celite, reduced in vacuo to about 2 mL, and hexane (15 mL) was added, allowing precipitation of a blue solid. After decantation of supernatant pale yellow liquid, the precipitate was washed several times with 5 mL of hexane, and dried under vacuum yielding the pure [{Fe($\eta^5$-$C_5H_5$)($\eta^2$-dppe)(C≡C)}$_2${2,5-$C_4H_2S$}]-[$BF_4$] as blue microcrystals (0.0102 g, 95%). IR ($CH_2Cl_2$): 2059 (s) $\tilde{\nu}_{C\equiv C}$ cm$^{-1}$. $C_{70}H_{60}BF_4Fe_2P_4S$ (1255.70): calcd. C 66.96, H 4.82; found C 66.64, H 4.63.

**Computational Details:** Full geometry optimisations with tight conditions were performed at B3LYP level of theory, as implemented in Gaussian03.[21] The hybrid functional is Becke's three-parameter nonlocal exchange functional[22] with the local correlation functional of Lee, Yang and Parr et al.[23] The choice of this functional is motivated by the successful results obtained in geometry calculations of both neutral and charged similar complexes[7p] and by its performance reported in very recent studies on the electronic coupling in mixed-valence organometallic complexes.[20a,24] In both spin-restricted and spin-unrestricted calculations the 6-31G** basis set was used for S, P, O, C and H and the standard LANL2DZ-ECP was employed for Fe (B3LYP/LANL2DZ, 6-31G**).[25] This choice is suitable for accurate results at an acceptable computational expenditure. In charged species the total spin values do not show significant spin contamination for doublet ion states. TDDFT excitation energies were calculated at B3LYP level of theory; standard LANL2DZ-ECP basis set was used for Fe and 6-31+G* was employed for all the other atoms (B3LYP/LANL2DZ, 6-31+G*).[25]

**Supporting Information** (see footnote on the first page of this article): UV/Vis spectra of **7a** and **7a$^+$**; B3LYP/LANL2DZ,6-31G**-optimised geometries of the studied model complexes, and pictures of MOs involved in the NIR transitions.

## Acknowledgments

This work was supported by the Consiglio Nazionale delle Ricerche (CNR, Roma) within the CNR/RAS (Russian Academy of Science, Moscow) bilateral agreement for financial support and by the Ministero dell'Istruzione, dell'Università e della Ricerca (MIUR) within the PRIN 2003 research project. We are grateful to Patrizia Gentili (Università "La Sapienza", Roma) for her very useful cooperation. CINECA (Consorzio Interuniversitario di Calcolo del Nord-Est, Casalecchio di Reno, Italia) is greatly acknowledged for the generous allocation of their computational facilities.

# Redox-Active Coordination Polymers from Esterified Hexavanadate Units and Divalent Metal Cations

Jong Woo Han,[a] Kenneth I. Hardcastle,[a] and Craig L. Hill*[a]

**Keywords:** Polyoxometalates / Coordination polymers / Vanadium

The redox-active bis(pyridyl)-capped hexavanadate $[V_6O_{13}\{(OCH_2)_3C(4\text{-}CONHC_5H_4N)\}_2]^{2-}$ (**1**) reacts with divalent first-row transition-metal cations ($Mn^{II}$, $Co^{II}$, $Ni^{II}$, or $Zn^{II}$) to yield crystalline linear zwitterionic coordination polymers (**1**M). The zwitterionic coordination chains are connected to each other by hydrogen bonds to form a 3D network. Microporous channels are formed along the packing axes of the 2D networks. All four compounds exhibit almost identical cell parameters, space group ($P\bar{1}$) and crystal morphology. The materials have been characterized by X-ray crystallography, $^1H$ and $^{51}V$ NMR, IR, UV/Vis, elemental analysis, and TGA. All compounds **1**M are reversibly reduced by chemical reductants such as phenylhydrazine and $NaBH_4$ in $CCl_4$ in which the hexavanadates are insoluble.

## Introduction

Supramolecular coordination chemistry as a means to construct sophisticated solid materials has been a topic of intense research.[1] Recently, coordination polymers based on organic polyoxometalate (POM) derivatives and metal ions have attracted increasing attention because of the extensive and diverse properties of POMs.[2] In coordination polymers, POM units are generally formed under hydrothermal conditions, so it is difficult to relate the final structure and composition to the starting materials.[3] There are examples of applying preformed complete[4] or lacunary POMs[5] as ligands to metal ions to construct coordination polymers. However, the coordination modes of the POM oxo groups in the coordination polymers are complex and not defensibly predictable. By using pre-formed organic POM derivatives with a well-defined coordination mode as linking ligands, one can expect to design the morphologies and properties of the products from an understanding of the geometrical possibilities from the building units. Recently, coordination polymers using pre-formed organic POM derivatives have been reported. The first supramolecular coordination network materials[6] with pre-formed organic POM derivatives were reported by Stein et al. using organic POM derivatives with aniline moieties, $[W_6O_{25}H(AsC_6H_4\text{-}4\text{-}NH_2)_2]^{5-}$ and $[Mo_{12}O_{46}(AsC_6H_4\text{-}NH_2)_4]^{4-}$. In these materials, both the aniline moieties and POM oxo groups are coordinated to transition-metal ions. Stein et al. reported another coordination network assembled with $Cu^{II}$, (4,4′-bipyridyl)ethylene, and a preformed POM derivative, $[Mo_{12}O_{46}(AsC_6H_4NH_2)_4]^{4-}$.[7] In the network, the POM derivative behaves as a non-coordinating anion. Presumably because of the weak coordinating ability of the aniline, the coordination modes of the POM building units are complicated. More recently, Hasenknopf et al. reported the assembly of the polyoxomolybdate $[MnMo_6O_{18}\{(OCH_2)_3CNHCO(4\text{-}C_5H_4N)\}_2]^{3-}$ and $[PdCl_2(PhCN)_2]$, that yields a transparent and birefringent gel.[8] The design and construction of materials based on a redox-active building block with a pre-defined coordination mode and transformation into a crystalline coordination material would constitute an advance.

Here we report the preparation of a pyridine-terminated bis(trialkoxo)hexavanadate complex, $[V_6O_{13}\{(OCH_2)_3C(4\text{-}CONHC_5H_4N)\}_2]^{2-}$ (**1**), and the assembly of **1** with divalent transition-metal cations, M = $Mn^{II}$, $Co^{II}$, $Ni^{II}$, or $Zn^{II}$, to form POM-based coordination polymers. We are interested in the hexavanadate units esterified in a linear fashion with two chelating triols, $[V_6O_{13}\{(OCH_2)_3CR\}_2]^{2-}$, because the alkoxy groups of the chelating (triester)$V_3$ units are quite stable to hydrolysis,[9] and bis(triester)$V_6$ units can be extensively and reversibly reduced.[10] Unfortunately, the terminal R groups on the triester "caps" of the compounds reported to date, R = $CH_3$, $CH_2CH_3$, $NO_2$, and $CH_2OH$, bind metal ions poorly if at all.[10,11] Complex **1** can be viewed as a tunable, redox-active analogue of organic linking molecules such as 4,4′-bipyridine. A larger goal of this study, which we document, is the reversible reduction of POM-based open-framework coordination networks, and in particular oxidative regeneration (re-oxidation) by air. The latter phenomenon typically implies the ability of the POM-based

material to catalyze air-based oxidations, an area of considerable interest in context with removal of pollutants, decontamination of toxic agents, environmental remediation, and green chemistry.[12–14]

## Results and Discussion

The triol derivative $(HOCH_2)_3CNHCO(4\text{-}C_5H_4N)$ was prepared by the reaction of $(HOCH_2)_3CNH_2$ and isonicotinoyl chloride hydrochloride, $(4\text{-}C_5H_4N)COCl{\cdot}HCl$, in DMA under $N_2$ in the presence of $K_2CO_3$ at 60 °C for 72 h. The bis(pyridyl)-capped hexavanadate **1** was prepared by the reaction of $(HOCH_2)_3CNHCO(4\text{-}C_5H_4N)$ with $[(n\text{-}C_4H_9)_4N]_3[H_3V_{10}O_{28}]$[15] in DMA under $N_2$ at 80 °C for 60 h, a modification of the method used by Zubieta and co-workers for the $\text{-}CH_3$, $\text{-}CH_2CH_3$, $\text{-}NO_2$, and $\text{-}CH_2OH$ derivatives,[10] and characterized by various spectroscopic methods and X-ray crystallography. Coordination polymers, $[M(DMF)_2(H_2O)_2(V_6O_{13}\{(OCH_2)_3CCONH(4\text{-}C_5H_4N)\}_2)]_n$ (M = Mn, Co, Ni, or Zn), were synthesized in 70–80% yield, by adding the appropriate transition-metal ion, dissolved either in methanol or in acetonitrile, to the stock solution of **1** in DMF and storing the solution at room temperature for 4–7 d. Regardless of the molar ratio of metal ion/**1**, zwitterionic (1:1 = divalent metal ion/**1**) compounds were obtained. In the case of **1**Ni and **1**Zn, single crystals suitable for X-ray diffraction were obtained by carefully layering the stock solution of **1** with a solution of the metal ion. In the case of **1**Mn and **1**Co, the formation of the product was relatively slow, so dilute solutions of each metal ion and the solution of **1** were mixed and the resulting solution was left undisturbed at room temperature for 4 d to afford single crystals suitable for X-ray diffraction.

All four coordination polymers **1**M (M = Mn, Co, Ni, or Zn) are nearly isostructural and exhibit almost identical unit cell parameters, space group ($P\bar{1}$) and crystal morphology. The metal atom, M, is in a symmetry-unique position in all four coordination polymers. This d-electron-containing metal center is located in a crystallographic inversion center and is six-coordinate with 2 DMF, 2 water, and 2 pyridine ligands all *trans* to each other (Figure 1). The divalent transition-metal ions and the pyridine-terminated triesterified polyoxovanadates form one-dimensional (1D) coordination chains. Interestingly, the 1D coordination chains are connected to each other by weak hydrogen bonds involving C–H moieties of the pyridine units to form microporous channels. Four different types of hydrogen bonds connect the 1D chains in a direction nearly parallel to the crystallographic *c* axis to form a two-dimensional (2D) network (Figure 2): (1) a relatively strong hydrogen bond between a coordinated water molecule and a bridging oxo group of the POM (O–O distance ca. 2.7 Å), weak hydrogen bonds between either pyridine hydrogen atoms and (2) bridging oxo groups of the POM (O–O distance ca. 3.3 Å) or (3) a terminal oxo group of the POM (O–O distance ca. 3.7 Å), and (4) hydrogen bonds between pyridine hydrogen atoms and carbonyl oxygen atoms of amide units (N–O distance ca. 3.7 Å). The 2D networks, in turn, are linked to each other in a direction nearly parallel to the crystallographic *a* axis by hydrogen bonds between a methyl hydrogen atom of the coordinated DMF molecule and a terminal oxo group (O–O distance ca. 3.4 Å) of the POM. Microporous channels are formed along the crystallographic *c* axis of the 2D networks (Figure 3).

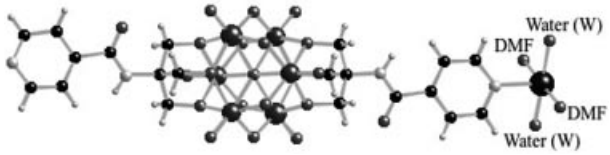

Figure 1. Structure of the repeating coordination unit of **1**Co. Selected distances [Å] and angles [°]: Co–O(DMF) 2.065(3), Co–O(W) 2.067(2), Co–N(pyridine) 2.157(2); O(DMF)–Co–O(W) 88.91(10), O(DMF)–Co–N(pyridine) 86.69(11), O(W)–Co–N(pyridine) 90.84(10).

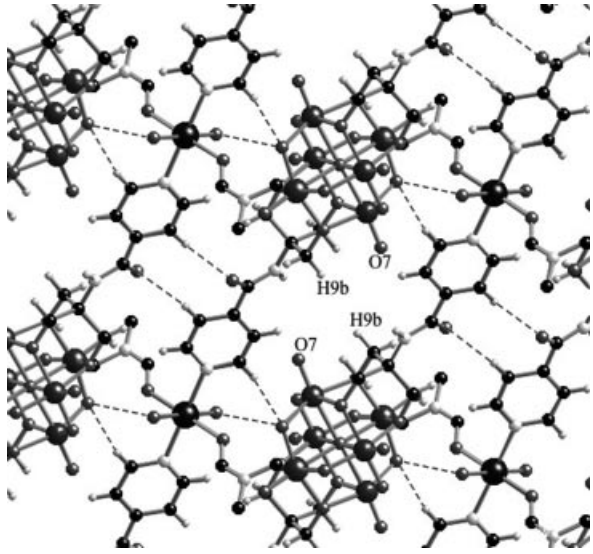

Figure 2. View parallel to the *a* axis. DMF molecules and some hydrogen atoms are omitted for clarity. Longest dimension (O7–O7) 5.54 Å, shortest dimension (H9b–H9b) 2.76 Å.

Bond valence sum (BVS) calculations[16] confirm that all six symmetry-distinct vanadium atoms in the hexavanadate unit are in the +5 oxidation state (values 5.0–5.1). The infrared and UV/Vis spectroscopic data are also consistent with vanadium(V).[17]

All the product polymers are slightly soluble (0.04–0.2 mM in the repeating unit) in polar aprotic solvents such as DMSO, DMF and $CH_3CN$ and insoluble in non-coordinating solvents such as dichloroethane and chloroform. Both the $^1H$ and $^{51}V$ NMR spectra of **1**Zn and **1**Mn (see Figures S1 and S2 in the Supporting Information) clearly show that only the signals for the monomer are observed, and that these signals have effectively identical chemical shifts to that for **1** only. Expectedly, the $^1H$ NMR spectra of the polymers with paramagnetic centers (**1**M; M = Mn, Co, or Ni) exhibit broader signals than those of **1**Zn. Dissolution clearly involves dissociation of the pyridine–metal coordination bond in **1**M. The slow kinetics of formation/

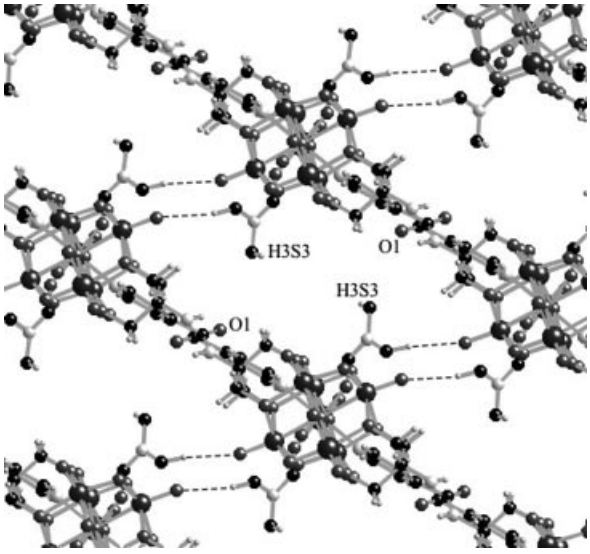

Figure 3. View parallel to the crystallographic *c* axis. Longest dimension (O1–O1) 8.89 Å, shortest dimension (H3S1–H3S1) 4.27 Å. Channel-filling DMF molecules and some hydrogen atoms are omitted for clarity.

crystallization as well as solubilization of all compounds **1**M precluded quantification of the dissociation equilibrium constants: $K$ = [soluble monomer]. Dynamic light scattering (DLS) was attempted in order to corroborate the findings but the low solubility of dissociated monomers precluded acquisition of acceptable data.[18]

Thermogravimetric analysis (TGA) shows that the polymers **1**M are thermally less stable than the monomeric hexavanadate **1**. The polymers lose 20–30% of their total weight from 30 to 160 °C which correlates with the loss of the DMF molecules in the pores and the two DMF molecules coordinated to the metal ion in each formula unit. The differential scanning calorimetry (DSC) data supports the implications of TGA data. The IR spectra of **1**Zn at different temperatures were obtained to confirm the stability of the compound (see Figure S5).

The phase purity of the bulk material was evaluated by X-ray powder diffraction pattern (XRPD). The measured XRPD pattern matches well with that of the calculated one from the single crystal data (see Figure S6). Unfortunately, XRPD data of all compounds **1**M dried under vacuum ($10^{-2}$ Torr for 2 d) indicated loss of crystallinity, consistent with the complete loss of framework structure upon the evacuation of the channel-occupying solvent molecules.

All compounds **1**M are reversibly reduced by chemical reductants such as phenylhydrazine and $NaBH_4$ in tetrachloromethane in which the compounds **1**M are insoluble. Reduction by $NaBH_4$ is much slower than that by phenylhydrazine. The reduced compounds **1**M are reoxidized without decomposition by any of the following: $O_2$, $Br_2$, $Ce^{IV}$, and $S_2O_8^{2-}$ (reoxidation by $O_2$ is very slow but accelerated in the presence of HCl vapor). The reduction and reoxidation of the hexavanadate unit can be easily detected from the distinctive change in color (red in fully oxidized state and blue in reduced species) and by the characteristic $\nu_{V-O-V}$ stretch for the fully oxidized hexavanadate unit at 790–810 $cm^{-1}$ that shifts to a lower energy (750 $cm^{-1}$) upon reduction. The shift to a lower frequency upon reduction is consistent with protonation. Zubieta and co-workers documented longer V–O distances relative to those of fully oxidized hexavanadate units and protonated oxygen atoms by BVS calculations in the X-ray structure of the reduced forms of tris(alkoxo)hexavanadates.[19] The number of reduced vanadium atoms in the bis(triester)hexavanadate unit reproducibly determined by titration with $Br_2$ averages 2.5.

## Conclusions

In conclusion, we have prepared a new class of POM-based supramolecular materials composed of the linear pyridine-terminated redox-active esterified hexavanadate units and divalent transition-metal cations ($Mn^{II}$, $Co^{II}$, $Ni^{II}$, or $Zn^{II}$). The terminal linking groups on the triester "cap" of the bis(triester)$V_6$ units, the metal composition of the POM units and the linking cations should all be independently variable affording a fairly diverse family of redox-active open-framework materials.

## Experimental Section

**General Methods and Materials:** All chemicals were obtained from Aldrich. Dimethylacetamide (DMA) was dried with molecular sieves (3 Å) before use. Other chemicals were used as received. $^1H$ and $^{13}C$ NMR spectra were recorded either with a Varian INOVA 400 MHz instrument or a Mercury 300 MHz instrument. $^{51}V$ NMR spectra were recorded with a Varian Unity 600 MHz instrument. $^1H$ and $^{13}C$ NMR spectra were referenced to the deuterated solvent itself, and chemical shifts are reported relative to $(CH_3)_4Si$. $^{51}V$ NMR spectra were referenced externally by the sample replacement method to a 10 mM solution of $H_4PVMo_{11}O_{40}$ in 0.60 M NaCl ($\delta$ = –533.6 ppm relative to neat $VOCl_3$), and chemical shifts are reported relative to $VOCl_3$. IR spectra were recorded with a Nicolet 510 FT-IR instrument. Electronic absorption spectra were collected with a Hewlett-Packard 8452A UV/Vis spectrophotometer. Thermal gravimetric analyses (TGA) were performed with an ISI TGA 1000 instrument under $N_2$ flow from 25 to 400 °C at a rate of 10 °C/min. Differential scanning calorimetry (DSC) data were recorded with an ISI DSC 100 instrument under $N_2$ flow from 25 to 400 °C at a rate of 10 °C/min. Elemental analyses for C, H, and N were conducted by Atlantic Microlab, Norcross, GA, and elemental analyses for all other elements were conducted either by Desert Analytics, Tucson, AZ or by Kanti Lab Ltd., Mississauga, Ontario.

**Preparation of $(HOCH_2)_3CNHCO(4\text{-}C_5H_4N)$:** A solid mixture of $K_2CO_3$ (6.08 g, 44.0 mmol) and $(HOCH_2)_3CNH_2$ (2.42 g, 20.0 mmol) was added to a solution of isonicotinoyl chloride hydrochloride, $(4\text{-}C_5H_4N)COCl{\cdot}HCl$ (3.81 g, 21.4 mmol) in 30 mL of DMA under $N_2$. The resulting yellow solution and $K_2CO_3$ pellets were stirred under $N_2$ at 60 °C for 72 h. During the reaction, a decrease of the amount of $K_2CO_3$ pellets and the formation of a fine powder was observed. After the reaction batch was cooled to room temperature, the fine powder was filtered with a fine fritted glass filter. Acetone (150 mL) was added to the filtrate. After 1 d, the resulting crystalline material (needle morphology; isonicotinic acid, confirmed by $^1H$ NMR and IR) was filtered off, and the fil-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trate was concentrated to about 25 mL. Acetone (100 mL) was added to the concentrated solution. After 1 d, the resulting crystalline material was filtered off, and the filtrate was concentrated under vacuum to about 4 mL. To this concentrate was added 20 mL of acetone. After 1 d, a crystalline solid was obtained (2.8 g, 62%). The product was used for further reaction without additional purification. [Note 1: A small amount of isonicotinic acid (2–5% based on the integration of the $^1$H NMR spectrum of the product) observed in the product could be removed by repeated (2–3 times) crystallization in DMA/acetone. Note 2: When the product was used for further reaction without additional purification, the impurity was successfully removed during the crystallization of the subsequent material, **1**.] $^1$H NMR ([D$_6$]DMSO): $\delta$ = 3.68 (d, 12 H), 4.67 (t, 6 H), 7.49 (s, 1 H), 7.69 (d, 2 H), 8.69 (d, 2 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 60.47 ($HOCH_2$), 63.78 (CNH), 122.16 (β-Py), 143.02 (γ-Py), 150.66 (α-Py), 166.19 (CO) ppm. $C_{10}H_{14}N_2O_4$ (226.23): calcd. C 53.09, H 6.23, N 12.38; found C 52.58, H 6.13, N 12.13. IR (KBr, 400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3422 (s, br.), 3261 (w), 3097 (w), 3028 (w), 2920 (m), 2849 (w), 1733 (w), 1641 (s), 1607 (w), 1581(m), 1552 (m), 1493 (w), 1453 (w), 1418 (w), 1374 (w), 1054 (m), 1024 (m), 962 (w), 895 (w), 845 (w), 757 (w), 700 (m) cm$^{-1}$.

**Preparation of [(*n*-$C_4H_9)_4N]_2[V_6O_{13}\{(CH_2O)_3CNHCO(4$-$C_5H_4N)\}_2]$·1.8DMF {[(*n*-$C_4H_9)_4N]_2$1·1.8DMF}:** The bis(pyridyl)-capped hexavanadate **1** was prepared by a modification of the method reported by Zubieta and co-workers.[10] DMA (62 mL) was transferred to the solid mixture of $(HOCH_2)_3CNHCO(4$-$C_5H_4N)$ (1.21 g, 5.40 mmol) and $[(n$-$C_4H_9)_4N]_2[H_3V_{10}O_{28}]$ (3.01 g, 1.80 mmol). An orange solution resulted and the flask was wrapped with aluminum foil to protect the solution from potential photoreduction; stirring was continued under $N_2$ at 80–90 °C for 60 h. After the reaction batch was cooled to room temperature, the resulting deep reddish brown solution was filtered with a fine fritted glass filter. The filtrate was added to 180 mL of diethyl ether in ca. 1-mL portions using a Pasteur pipette. The dark brown precipitate was filtered and washed with diethyl ether. The pure product was obtained by repeated (normally two) crystallization [dimethylformamide (DMF)/acetonitrile/ether = 2:1:6]. After filteration and washing with diethyl ether, the resulting crystalline product was dried under vacuum at room temperature for 1 d. The yield (2.1 g, 45%) was calculated based on the amount of vanadium. The amount of the solvent in the crystal was confirmed by TGA. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 0.92 (t, 24 H), 1.30 (sext, 16 H), 1.55 (quint, 16 H), 3.15 (t, 16 H), 5.27 (d, 12 H), 7.69 (d, 4 H), 8.05 (s, 2 H), 8.67 (d, 4 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 14.20, 19.89, 23.75, 53.92 (CNH), 58.17, 82.71 ($HOCH_2$), 122.35 (β-Py), 142.66 (γ-Py), 150.61 (α-Py), 166.49 (CO) ppm. $^{51}$V NMR ([D$_6$]DMSO): $\delta$ = –494.9 ppm. $C_{57.4}H_{106.6}N_{7.8}O_{22.8}V_6$ (**1**·1.8DMF, 1576.73): calcd. C 43.71, H 6.82, N 6.93, V 19.40; found C 43.61, H 6.80, N 6.95, V 19.49. UV/Vis (DMF): $\lambda_{max}$ (ε) = 360 (6000 M$^{-1}$ cm$^{-1}$) nm. IR (KBr, 400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3345 (m, br.), 3272 (w), 2962 (m), 2934 (m, sh), 2876 (m), 1730 (w), 1669 (s), 1597 (w), 1540 (m), 1486 (m), 1407 (w), 1384 (w), 1322 (m), 1280 (w), 1188 (w), 1153 (w), 1102 (s),1050 (s), 953(s), 811 (s), 798 (m), 723 (s), 639 (m), 583 (m), 515 (w), 460 (w), 417 (m) cm$^{-1}$.

### Preparation of Coordination Polymers

**General Preparation:** A 10.2 mM stock solution of **1** was used for the preparation of the polymers. The stock solution was prepared by dissolving 1.60 g (1.02 mmol) of **1** in 100 mL of DMF. Coordination polymers were synthesized by adding the appropriate transition-metal ions dissolved either in methanol or in acetonitrile to the stock solution of **1** (yield 70–80%). In the case of **1**Ni and **1**Zn, single crystals suitable for X-ray diffraction study were obtained by careful layering of a stock solution of **1** with the solution of each metal ion. In the case of **1**Mn and with **1**Co, dilute solutions of each metal ion and a solution of **1** were mixed, and the resulting solution was left undisturbed at room temperature for several days. Single crystals suitable for X-ray diffraction analysis were produced. Samples for elemental analysis were dried under vacuum for 2 d. The crystalline materials appeared to lose crystallinity when dried (the crystals lose luster when dried).

**Preparation of $[Co(H_2O)_2(DMF)_2(V_6O_{13}\{(CH_2O)_3CNHCO(4$-$C_5H_4N)\}_2)]_n$ (1Co):** A solution of $Co(NO_3)_2$ (5.2 mM) in acetonitrile and a stock solution of **1** (diluted from 10.2 mM to 5.1 mM) were mixed and left undisturbed for several days to form crystals suitable for X-ray diffraction. $C_{38.6}H_{69.4}CoN_{10.3}O_{29.2}V_6$ (**1**Co·4.2DMF, 1509.61): calcd. C 30.72, H 4.64, Co 3.91, N 9.47, V 20.27; found C 30.18, H 4.75, Co 4.01, N 9.44, V 19.5. The amount of solvent was consistent with the TGA data. IR (KBr, 400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3399 (m, br.), 3261 (m), 2928 (m), 2860 (w), 1653 (s), 1543 (m), 1495 (w), 1438 (w), 1417 (w), 1386 (m), 1324 (w), 1283 (w), 1255 (w), 1101 (m), 1049 (m), 957 (s), 810 (m), 800 (m),720 (m), 622 (w), 618 (w), 583 (w), 417 (m) cm$^{-1}$.

**Preparation of $[Mn(H_2O)_2(DMF)_2(V_6O_{13}\{(CH_2O)_3CNHCO(4$-$C_5H_4N)\}_2)]_n$ (1Mn):** Complex **1**Mn was prepared according to the same procedure as described above for **1**Co except using $Mn(NO_3)_2$·$x$H$_2$O ($x$ = 4–6) (in calculations $x$ was taken as 6) in methanol as a metal source instead of $Co(NO_3)_2$·6H$_2$O in acetonitrile. $C_{33.8}H_{58.2}MnN_{8.6}O_{27.6}V_6$ (**1**Mn·2.6DMF, 1387.26): calcd. C 29.25, H 4.23, Mn 3.96, N 8.68, V 22.04; found C 28.68, H 4.33, Mn 4.25, N 8.55, V 21.6. The amount of solvent was consistent with the TGA data. IR (KBr, 400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3251 (m, br.), 3060 (w), 2929 (w), 2867 (w), 1654 (s), 1545 (m), 1496 (w), 1438 (w), 1417 (w), 1387 (w), 1323 (w), 1284 (w), 1255 (w), 1187 (w), 1101 (m), 1050 (s), 958 (s), 809 (s), 795 (m), 718 (s), 641 (m), 586 (w), 515 (w), 420 (m) cm$^{-1}$.

**Preparation of $[Ni(H_2O)_2(DMF)_2(V_6O_{13}\{(CH_2O)_3CNHCO(4$-$C_5H_4N)\}_2)]_n$ (1Ni):** Single crystals suitable for X-ray diffraction were prepared by a solution diffusion method as follows. DMF (1.0 mL) was layered on top of 1.0 mL of a stock solution of **1** (10.2 mM) in a 5-mL test tube. To the layered DMF solution, 1.5 mL of a solution of $Ni(NO_3)_2$·6H$_2$O in acetonitrile (6.6 mM) was carefully added. After several days, single crystals suitable for X-ray diffraction were obtained. $C_{32.6}H_{55.4}N_{8.2}NiO_{27.2}V_6$ (**1**Ni·2.2DMF, 1361.78): calcd. C 28.75, H 4.10, N 8.44, Ni 4.26, V 22.47; found C 28.15, H 4.22, N 8.23, Ni 4.11, V 21.91. The amount of solvent was consistent with the TGA data. IR (KBr, 400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3423 (m, br.), 2929 (w), 2863 (w), 1650 (s), 1541 (m), 1495 (w), 1436 (w), 1417 (w), 1384 (w), 1325 (w), 1282 (w), 1101(m), 1049(m), 958(s), 811(m), 723(m), 645 (w), 586 (w), 555 (w), 417(m) cm$^{-1}$.

**Preparation of $[Zn(H_2O)_2(DMF)_2(V_6O_{13}\{(CH_2O)_3CNHCO(4$-$C_5H_4N)\}_2)]_n$ (1Zn):** Single crystals suitable for X-ray diffraction were prepared according to the same method described for the crystallization of **1**Ni. $C_{31.4}H_{53.6}N_{7.8}O_{26.8}V_6Zn$ (**1**Zn·1.8DMF, 1340.25): calcd. C 28.16, H 4.04, N 8.16, V 22.84, Zn 4.78; found C 28.51, H 3.80, N 8.16, V 20.9, Zn 4.5. The amount of solvent was consistent with the TGA data. IR (KBr, 400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3418 (s, br.), 3026 (w), 2921 (w), 2866 (w), 1733 (w), 1655 (s), 1539 (m), 1494 (w), 1451 (w), 1420 (w), 1385 (w), 1327 (w), 1282 (w), 1100 (m), 1066 (m), 1047 (s), 960 (s), 810 (s), 792 (s), 699 (s), 646 (m), 584 (w), 569 (w), 420 (m) cm$^{-1}$.

**X-ray Crystallography:** Suitable crystals of **1** and **1**M (M = Mn, Co, Ni, or Zn) were coated with Paratone N oil, suspended on a small fiber loop, and placed in a cooled nitrogen stream at 100 K

of a Bruker D8 SMART APEX CCD sealed tube diffractometer with graphite-monochromated Mo-$K_\alpha$ (0.71073 Å) radiation. Redundant data were measured using a series of combinations of $\varphi$ and $\omega$ scans with 10 s frame exposures and 0.3° frame widths. Data collection, indexing, and initial cell refinements were handled using SMART software.[20] Frame integration and final cell refinements were carried out using SAINT software.[21] The final cell parameters were determined from least-squares refinements, and the SADABS program[22] was used to carry out absorption corrections. The structures were solved by direct methods and difference Fourier techniques. All atoms were refined anisotropically, except where noted (see data deposited in the crystal structure data base). The final *R*1 scattering factors and anomalous dispersion corrections were taken from the *International Tables for X-ray Crystallography*.[23] Additional details for **1** and **1**Co are provided in Table 1 (see crystallographic details for **1**Mn, **1**Ni, and **1**Zn in the crystal structure data base). CCDC-229734 to -229738 contain the supplementary crystallographic data for the structures reported upon in this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Reduction and Reoxidation of 1M:** To **1**M suspended in $CCl_4$, where **1**M is completely insoluble, either chemical reductant, $NaBH_4$ or phenylhydrazine, was added, and the suspension was stirred for 36 h or 24 h, respectively. The reduction of **1**M can be easily observed from the distinctive change in the color of **1**M (red in fully oxidized state and blue in reduced state). Reduced **1**M was reoxidized in a separate reaction by $O_2$, $Br_2$, $Ce^{IV}$, or $S_2O_8^{2-}$.

**Titration of Reduced 1Zn with $Br_2$:** The number of reduced vanadium atoms in the bis(triester)hexavanadate unit was evaluated by titration with $Br_2$. To phenylhydrazine hydrochloride (104 mg, 0.720 mmol), suspended in 6.0 mL of chloroform, triethylamine (100 mL, 0.720 mmol) was added to obtain a homogeneous solution. Solid **1**Zn (160 mg, 0.120 mmol of repeating unit) was suspended in 10.0 mL of chloroform. To the suspension, the phenylhydrazine solution was added, and the mixture was stirred for 24 h. The initial red solid turned bluish green over the reaction period. The powder was then filtered and washed with methanol (2 × 5 mL) and diethyl ether (2 × 5 mL) and was suspended in 10.0 mL of tetrachloromethane ($CCl_4$). To this suspension, 0.10 M of $Br_2$ in $CCl_4$ was added slowly until the decoloration of $Br_2$ was no longer observed. The titration gives reproducible values within the experimental error (< 0.1 mL). An average of 3.0 mL of the $Br_2$ solution was added in the titrations. Therefore, the number of reduced vanadium atoms in the hexavanadate unit averages 2.5.

**Supporting Information** (see footnote on the first page of this article): $^1$H and $^{51}$V NMR of **1**Zn, $^1$H NMR of **1**Mn, TGA of monomer and **1**Zn, DSC of monomer and **1**Zn, FT-IR of **1**Zn as a function of temperature, simulated and measured powder X-ray diffraction pattern, cyclic voltammetry data of **1** and analogous compounds.

# Redox-Active 17- and 19-Membered Metallamacrocycles Incorporating Tetrathiafulvalene

Grégory Gachot,[a] Pascal Pellon,[a] Thierry Roisnel,[a] and Dominique Lorcy*[a]

**Keywords:** Metallamacrocycle / Tetrathiafulvalene / Diphosphane ligands / Molybdenum / Tungsten

Redox-active 17- and 19-membered metallamacrocycles were prepared thanks to the chelating ability of bis[(diphenylphosphane)alkylthio]TTF towards the $M(CO)_4$ fragment (M = Mo, W). The TTF unit can adopt either a *cis* or a *trans* configuration as can the phosphorus atoms coordinated to the metal center. Moreover, an element of planar chirality is generated by the *trans* isomer of the TTF. Thus, the reaction affords six stereoisomers as evidenced by $^{31}P$ NMR and X-ray crystallographic analyses. The electrochemical properties of the title compounds have been investigated by cyclic voltammetry. Within the 19-membered metallamacrocycles, no significant influence of the two redox moieties was detected, whereas in the 17-membered metallamacrocycles, the oxidized TTF modifies the redox behavior of the metal center. Two crystalline complexes obtained with tetracyanoquinodimethane (TCNQ) and the tungsten 17- and 19-membered metallamacrocycles are reported. Comparison of the crystal structures shows that these metallamacrocycles appear to be rather flexible even with strained structures.

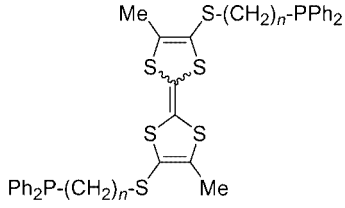
## Introduction

Various cyclophanes or cage molecules incorporating one or more electroactive units such as a tetrathiafulvalene core (TTF) have been studied with the aim of creating, through intramolecular or intermolecular interactions, nanoelectronic devices.[1] Among the electroactive macrocycles described so far, none of them contain a metallic fragment. Association of the TTFs with one appropriate metal will lead to a macrocycle with multiple redox sites and the possibility of interaction between the inorganic and organic moieties.[2] Various potential applications can be envisioned for these hybrid molecules, as molecular materials or in catalytic systems as it is well known that the steric and electronic properties of the ligand have an enormous effect on the reactivity of metal complexes.[3] A simple route toward the formation of large metallamacrocycles involves the coordination of a bidentate α,ω-diphosphane ligand to the transition metal center.[4] Therefore, we have studied the ability of bis-substituted [(diphenylphosphanyl)propylthio]-TTF **1**[5] to form metal carbonyl complexes upon chelation of the $Mo(CO)_4$ and $W(CO)_4$ fragments. Moreover, we also present the synthesis of the diphosphanyl ligand **2** where the phosphane moieties are linked to the donor core through a longer spacer group such as a thiobutyl one and the influence of this longer chain on the structural and electrochemical properties of the metallamacrocycles. Comparison of the effect of the length of the spacer group on the molecular structure and the redox behavior will then be discussed. Another interesting feature that will be presented is the influence of the complexation with TCNQ on the conformation of these metallamacrocycles.



**1** *n* = 3 *cis*/*trans*
**2** *n* = 4 *cis*/*trans*

## Results and Discussion

The synthesis of the ligand **2** was accomplished as depicted in Scheme 1 according to the chemical pathway used for the synthesis of bis[(diphenylphosphanyl)propylthio]-TTF **1** using the preformed TTF derivative **3** as the starting material.[5] The methodology consists first of the synthesis of the bis[(boronatodiphenylphosphanyl)butylthio]TTF **5**. The use of phosphane–borane substituents in the synthesis of the target TTFs presents several advantages as they are very stable compared to phosphane derivatives towards the

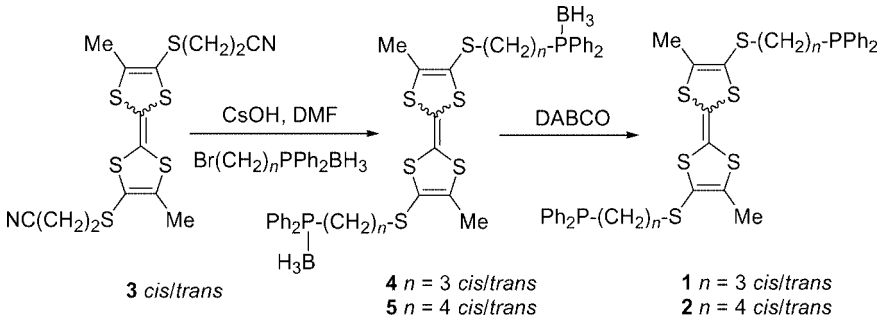

Scheme 1.

usual oxidizing or electrophilic reagents, and very easy to handle and to purify.[6,7] The bis(cyanoethylthioTTF) **3** was treated with cesium hydroxide and reacted with the bromobutyldiphenylphosphane–borane leading to TTF **5**. Decomplexation of the phosphane–borane complex was performed in the presence of DABCO under an inert atmosphere to give the bis[(diphenylphosphanyl)butylthio]TTF **2**.[8] These TTFs **1**–**2** should be kept under an inert atmosphere to avoid the formation of the corresponding phosphane oxides. Note that all these TTFs **1**–**5** are obtained as a mixture of the *cis* and *trans* isomers and attempts to separate these isomers are worthless as TTFs are prone to isomerization in solution upon light exposure or in the presence of traces of acid.[9,10]

In order to form metal carbonyl complexes with these TTF ligands, we used *cis*-$M(CO)_4(C_5H_{10}NH)_2$ derivatives (M = Mo, W) where the two labile piperidine ligands can be easily replaced by other ligands such as two phosphanes.[11] As mentioned earlier for monosubstituted phosphanylTTF derivatives, the metal carbonyl complexation can be realized directly from the phosphane–borane TTF complexes,[12] in a one-pot procedure by a two-step chemical synthesis: firstly decomplexation of the phosphane–borane complex in the presence of DABCO and then addition of one equivalent of *cis*-$M(CO)_4(C_5H_{10}NH)_2$ in the medium where the bis[(diphenylphosphanyl)alkylthio]TTFs were formed. The solution was warmed at 80 °C for 2 h. Actually, because of the flexibility of the alkylthio spacer groups, two types of metal carbonyl complexes were obtained, the expected metallamacrocycles **6**–**9** (Scheme 2) but also polymeric derivatives resulting respectively from an intramolecular and an intermolecular complexation. The mononuclear metallamacrocycles formed can be easily isolated after column chromatography upon silica gel in an overall yield of 20–33%.

Analysis of the fraction containing the mononuclear complexes by $^{31}P$ NMR, after the chromatographic separation, reveals the presence of four signals for each of the four investigated derivatives **6**–**9** (Table 1). Indeed, besides the *cis*/*trans* isomerism of the TTF core, the phosphorus atoms can also be either *cis* or *trans* coordinated to the metal center. For the tungsten metallamacrocyles **6** and **8**, a small doublet due to the coupling of the phosphorus atom with the $^{183}W$ isotope is associated with the four singlets. Thanks to the coupling constant, it is possible to distinguish the *cis*-P–W–P isomers from the *trans*-P–W–P ones.[13] Indeed, the phosphorus atoms resonate at high field for **6** and **8** with $^1J_{PW}$ = 230 Hz characteristic for the *cis*-P–W–P isomers while the two signals observed at low field for **6** and **8** exhibit a $^1J_{PW}$ = 279 Hz characteristic for the *trans*-P–W–P one. For the molybdenum metallamacrocycles, by analogy with previous results on monodiphenylphosphanylpropylthioTTF (P–TTF) *cis* coordinated to the $Mo(CO)_4$, *cis*-$Mo(CO)_4$-$(P–TTF)_2$,[12] where the phosphorus atoms resonated at $\delta$ = 26.6 ppm, the singlets observed at high field for **7** and **9** can be attributed to *cis*-P–Mo–P isomers while the signals observed at low field for **7** and **9** are assigned to the *trans* isomers.

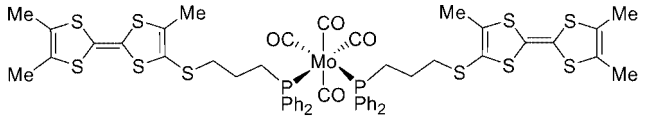
Table 1. $^{31}P$ chemical shifts for compounds **6**–**9** in $CDCl_3$ solution.

| Compound (metal, *n*) | $\delta$ = $^{31}P$ ppm ($^1J_{PW}$ [Hz]) |
|---|---|
| **6** (W, 3) | 5.9 (230), 6.9 (230), 13.5 (279), 14.6 (279) |
| **7** (Mo, 3) | 24.2, 24.7, 38.4, 39.3 |
| **8** (W, 4) | 8.0 (230), 8.6 (230), 14.8 (279), 14.9 (279) |
| **9** (Mo, 4) | 25.5, 25.7, 39.0, 39.1 |

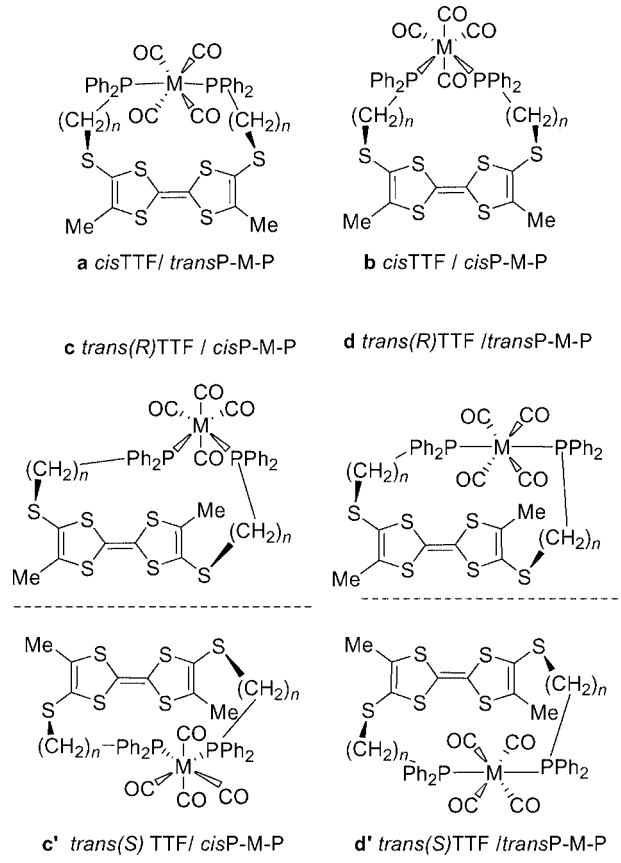


*cis*-$Mo(CO)_4$(P-TTF)$_2$

Interestingly, the intensity of the various signals observed indicates that a majority of the *trans* isomers on the metal center are formed in all the cases with an estimated *trans* P–M–P/*cis* P–M–P ratio of 5:2. The obtention of *cis*/*trans* isomers on the metal center, starting from the *cis*-$M(CO)_4$-(piperidine)$_2$ derivatives (M = Mo, W), finds its origin in the temperature used to form these metallamacrocycles.[11] Indeed, when the reaction was performed at 50 °C, no isomerization occurs as previously observed for monosubstituted TTF but the reaction rate is very low, while at 80 °C substitution of the two piperidine ligands occurs, especially for the *cis*-$W(CO)_4$(piperidine)$_2$ derivative, but also isomerization on the metallic center. The TTF core can also adopt either a *cis* or *trans* configuration. The presence of isomers on the TTF moiety is not surprising as we started from a mixture of *cis* and *trans* isomers for both TTFs **4** and **5**. Moreover, the *trans* form of the TTF introduces an element of planar chirality. Therefore, as depicted in Scheme 3, six stereoisomers can be envisioned for each metallamacrocycle, **6**–**9**, corresponding to the following isomers: (i) **a** *cis* TTF/*trans* P–M–P, (ii) **b** *cis* TTF/*cis* P–M–P, (iii) **c** *trans* (R)TTF/*cis* P–M–P and **c′** *trans* (S)TTF/*cis* P–M–P and (iv) **d** *trans* (R)TTF/*trans* P–M–P, and **d′** *trans* (S)TTF/*trans* P–M–P, hence the four $^{31}P$ NMR signals since the enantiomers **c/c′** and **d/d′** can not be distinguished in this way.

Crystals of the metallamacrocyles **6**, **7**, and **8** were isolated from a mixture of dichloromethane and methanol. The crystal structure determinations reveal that in the case of the macrocycles **6** (*n* = 3, M = W) and **8** (*n* = 4, M = W), the isomers **a** (*cis* TTF/*trans* P–W–P), were isolated (Figure 1), while for **7** (*n* = 3, M = Mo) the two enantiomeric forms **7 c/c′** [*trans* (R/S) TTF/*cis* P–Mo–P] (Figure 2) were crystallized in the racemic mixture.

All the TTF moieties adopt a boat conformation within these metallacyclophanes where both dithiole rings are folded along the S···S vector with asymmetric folding angles, which are more pronounced for the most strained 17-membered metallamacrocycles **6a** (17 and 28°) and **7c/c′** (19 and 36°) than for the 19-membered metallamacrocycle **8a** (9 and 11°). Comparison of the crystal structure of **6a** (*n* = 3) with **8a** (*n* = 4), where the difference is only due to the length of the spacer group between the TTF and the phosphorus atoms, shows that in both cases, the W–P distances and P–W–P interligand angles are similar and in the



Scheme 3.

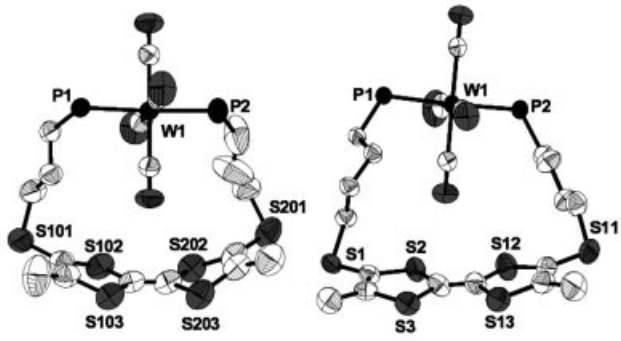


Figure 1. Molecular structure of (left) **6a** and (right) **8a**. The hydrogen atoms and the phenyl rings are not shown for clarity (thermal ellipsoids set at 50% probability). Selected bond lengths [Å] and angles [°]: W(1)–P(1) 2.4636(12), W(1)–P(2) 2.4644(14), P(1)–W(1)–P(2) 177.36(5) for **6a** and: W(1)–P(1) 2.4717(8), W(1)–P(2) 2.4652(8), P(1)–W(1)–P(2) 176.20(2) for **8a**.

usual range. Therefore, constrains brought by the formation of the metallamacrocycle are more effective on the fulvalene skeleton than on the inorganic part. Analysis of the crystals **6a** and **8a**, dissolved in $CDCl_3$, by $^{31}P$ NMR reveals that the isomers **a** (*cis* TTF/*trans* P–W–P) exhibit only one set of signals at $\delta$ = 13.5 ppm for **6a** and at $\delta$ = 14.8 ppm for **8a**. The same $CDCl_3$ solution left under ambient light exposure and analyzed again one day later exhibits this time two sets of signals caused by the presence of the *cis* and *trans* TTF isomers.[9]

The redox properties of the metallacyclophanes **6**–**9** were studied by cyclic voltammetry and peak potentials of the various complexes are collected in Table 2 together with the data for the starting ligands TTF **1** and **2**. In order to obtain an insight into the effect of the ligand environment on the redox potentials of the metal center, we also added to Table 2 the data for complexes $Mo(CO)_4(PPh_3)_2$ and $W(CO)_4(PPh_3)_2$. It is worth noting that *cis*-$M(CO)_4(PPh_3)_2$ and *trans*-$M(CO)_4(PPh_3)_2$ (M = Mo, W) present almost identical $E°$ values [15] and exhibit cyclic voltammograms which are partially reversible for the molybdenum complex and irreversible for the tungsten one because of the loss of carbon monoxide on the metallic center upon oxidation.[15] Concerning the various metallamacrocycles, two oxidation waves are observed. The first reversible oxidation step corresponds to the oxidation of the TTF in its radical cation while the second oxidation process is due to the concomitant oxidation of the TTF radical cation into the dication and the oxidation of the metallic center. However, this process is not fully reversible due to the loss of the carbonyl ligand upon oxidation (Figure 3). This concomitant oxidation of the organic and inorganic moieties was also observed on phosphane TTF linked to a metal via a nonconjugated spacer group, such as *cis*-$Mo(CO)_4(P–TTF)_2$.[12] Within the metallamacrocycles of the same size, the nature of the metal center, Mo or W, does not modify the redox potentials. Moreover, comparison of the first redox potentials of the complexes with those of the starting ligands (**1** and **2**) shows that there is no significant influence of the cyclization despite the strained structures described above. Interestingly, comparison can also be made with TTF cyclophanes where fully covalent bridges of various lengths link the two dithiole moieties leading to 14-, 18-, and 20-membered rings.[16–18] Indeed, among those cyclophanes, the most constrained one with the shortest bisthioalkyl link ($–S(CH_2)_6S–$[16] and $–SCH_2C_6H_4CH_2S–$[16,17]) were found to exhibit a single irreversible oxidation wave, while by contrast, longer links [$–S(CH_2)_{10–12}S$][18] or the redox active metallamacrocycles described here display a first fully reversible oxidation wave. The lack of reversibility of the redox system on the 14-membered TTF cyclophanes was attributed to the severe bending of the TTF core as for instance the *cis*-substituted TTF with a bisthiohexyl bridge, [$–S(CH_2)_6S$], is folded by 47 and 34° along the S···S vector.[16b] Although, in **6**–**9**, the metallic fragment with the CO ligands brings a novel inner constraint to the TTF unit, the bridge is long enough to enable the two typical redox waves of a TTF core.

Table 2. Oxidation potentials V vs. SCE, Pt-working electrode with $nBu_4NPF_6$ (0.1 M) in $CH_2Cl_2$, scanning rate 0.1 V/s.

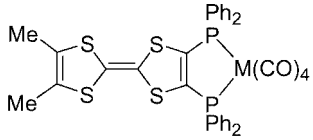
[a] Irreversible process.



[P2][M(CO)4] (M = Mo, W)

Considering the second redox process, the comparison of the anodic peak potential $E_{pa}^2$ in the complexes **6**–**9** with the value of the noncyclic $Mo(CO)_4(PPh_3)_2$ and $W(CO)_4(PPh_3)_2$ shows a significant positive shift of $E_{pa}^2$ in the 17-membered cyclic compounds **6** and **7** (+60 mV for Mo, W) while the $E_{pa}^2$ potentials are almost identical in the less-constrained **8** and **9** molecules. This indicates that through-space interactions occur between the two−organic and organometallic−redox moieties in the smallest metallamacrocycles. This effect on $E_{pa}^2$ is most probably due to electrostatic repulsion and the close proximity of the TTF dication to the bound metal. Note that by contrast, when the phosphane is directly linked to the TTF core, as in [P2][$M(CO)_4$] (M = Mo, W), oxidation of the coordinated metallic center occurs at a more positive potential than the $TTF^+/TTF^{2+}$ redox system because of even stronger electrostatic interactions.[19] In this case the donating ability of the TTF core within the complexes was also significantly decreased as a positive shift of about 200 mV was observed, while in our metallamacrocycle **6**–**9** the redox properties of the donor are conserved.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

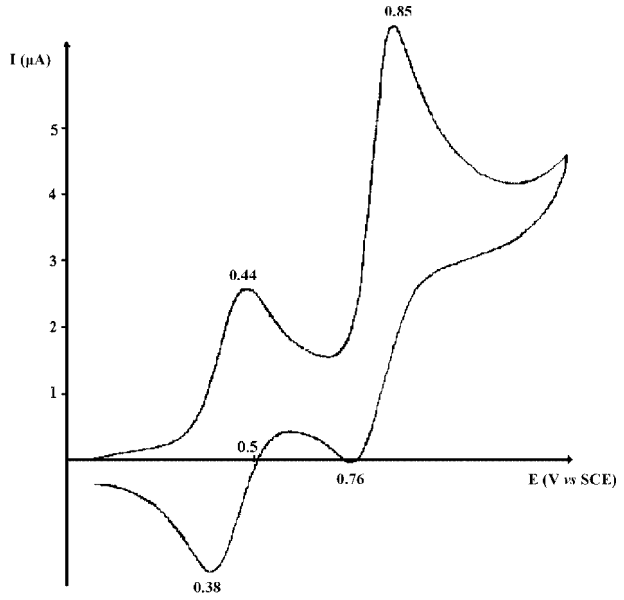


Figure 3. Cyclic voltammogram of **9**, $n$Bu$_4$NPF$_6$ (0.1 M) in $CH_2Cl_2$, scanning rate 0.1 V/s.

Formation of charge transfer salts with TCNQ depends on the relative redox potentials of the donor ($E_D^1$) and TCNQ ($E_A^1$ = 0.18 V vs. SCE). These metallamacrocycles with their first redox potentials above 0.40 V are a rather borderline case as precursors of such charge transfer salts since $E_D^1$-$E_A^1 > 0.22$ V. Indeed, it is known that a partial or full charge transfer is only possible when $E_D^1$-$E_A^1 < 0.25$ V.[20–21] Mixing a dichloromethane solution of the metallamacrocycles **6** or **8** with an acetonitrile solution of TCNQ afforded deep purple shiny single crystals after slow evaporation. X-ray crystal structure determinations reveal a stoichiometry of two metallamacrocycles for one TCNQ in each case with inclusion of acetonitrile, that is (**6**)$_2$(TCNQ)·(CH$_3$CN)$_3$ and (**8**)$_2$(TCNQ)·(CH$_3$CN)$_2$. The former complex with **6** ($n$ = 3) crystallizes in the triclinic system, space group $P\bar{1}$, with molecule **6** in a general position in the unit cell, one TCNQ located on an inversion center, one acetonitrile disordered on an inversion center, and one acetonitrile in a general position. Complex (**8**)$_2$(TCNQ)·(CH$_3$CN)$_2$ crystallizes in a triclinic system, space group $P\bar{1}$, with molecule **8** in a general position in the unit cell, TCNQ located on an inversion center with only one acetonitrile in a general position. In the solid state, the TCNQ molecule is, in each case, sandwiched by two TTF cores of the metallamacrocycles in a ···DAD··· (D = **6** or **8** and A = TCNQ) motif. The TCNQ ring overlaps the central C=C bond of the TTF core and the interplanar separations between the donor and the acceptor are 3.48 and 3.53 Å for (**6**)$_2$(TCNQ)·(CH$_3$CN)$_3$ and (**8**)$_2$(TCNQ)·(CH$_3$CN)$_2$, respectively (Figure 4). Using the empirical formula of Kistenmacher, which correlates the bond lengths to the formal charge of the TCNQ in various charge transfer salts,[22] we found that in both complexes the TCNQ is neutral. This is supported by the EPR analyses carried out on the crystals and no EPR signal was observed from room to liquid helium temperature. This is also confirmed by the diamagnetic behavior found in the whole temperature range by SQUID susceptibility measurements. Therefore, both complexes, (**6**)$_2$(TCNQ)·(CH$_3$CN)$_3$ and (**8**)$_2$(TCNQ)·(CH$_3$CN)$_2$, are neutral donor/acceptor complexes. Concerning (**8**)$_2$(TCNQ)·(CH$_3$CN)$_2$, the DAD motifs form stacks with a lateral slip between two neighboring TTF cores with S···S distances at 4.499(9) Å, while for (**6**)$_2$(TCNQ)·(CH$_3$CN)$_3$ the DAD motifs are isolated from each other by the inorganic moieties of the macrocycles (Figure 5).

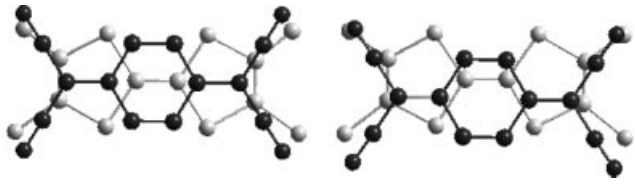

Figure 4. TTF/TCNQ overlap in (**6a**)$_2$(TCNQ)·(CH$_3$CN)$_3$ (left) and (**8a**)$_2$(TCNQ)·(CH$_3$CN)$_2$ (right).

Also noticeable, among the six possible stereoisomers for each metallamacrocycle **6** and **8** present in the starting solution for the elaboration of the TCNQ complexes, the isomers that crystallized within these complexes are the isomers **a** (*cis* TTF/*trans* P–W–P), which were independently crystallographically characterized and described above. The complexation with TCNQ has a significant influence on the conformation of the metallamacrocycles **6a** and **8a** as depicted in Figure 6. Comparison of the molecular structures shows that the TTF core for the 17-membered metallamacrocycle **6a** is more planar within the complex as the folding angles along the S···S vector for the dithiole rings are smaller (11 and 15° instead of 17 and 28°). The planarization of the TTF core in $(\mathbf{6a})_2(TCNQ)\cdot(CH_3CN)_3$ brings the metal closer to the TTF core with a distance of about 5.85 vs. 6.25 Å in the starting complex. Contrariwise, for the 19-membered metallamacrocycle **8a**, the folding angles are in the same range (10 and 10° instead of 11 and 9°). Actually, the difference brought by the complexation on **8a** lies in the location of the metal in relation to the TTF core. Indeed, within the complex $(\mathbf{8a})_2(TCNQ)\cdot(CH_3CN)_2$ the side chain with the metallic moiety is located in a plane perpendicular to the plane of the TTF core, while before complexation the chain with the metallic fragment was located more on the side of the TTF (Figure 6).

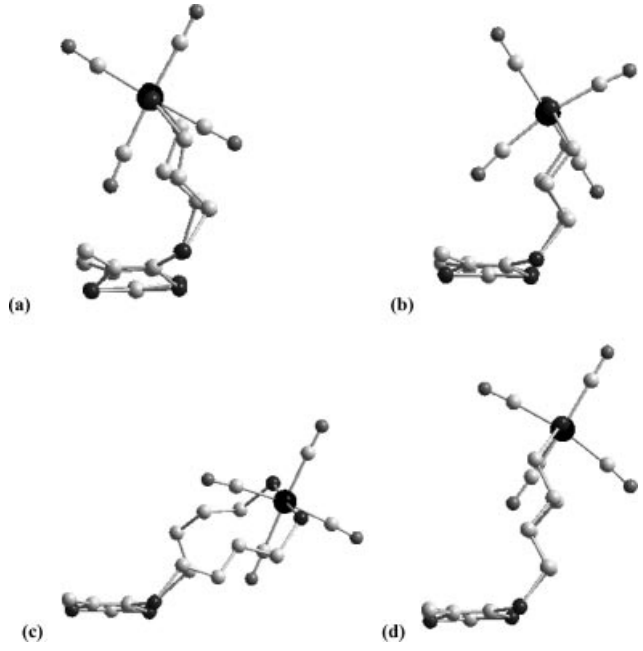

Figure 6. Side view of the metallamacrocycles, (a) **6a**, (b) $(\mathbf{6a})_2(TCNQ)\cdot(CH_3CN)_3$, (c) **8a**, (d) $(\mathbf{8a})_2(TCNQ)\cdot(CH_3CN)_2$.

Analysis of the bond lengths of the metallamacrocycles within the TCNQ complexes shows that in both cases the bond lengths of the TTF core are in the usual range for neutral TTF moieties with the central C=C bond lengthened by 1.340 Å, but still within the range for the neutral TTF core. Similarly, the W–P distances are not significantly modified (Table 3). On the contrary, the P–W–P angles are altered and for **6a** it amounts to 169.16(3)° instead of 177.36(5)° and for **8a** 176.20(2)° instead of 172.58(4)°, accounting for the consequences of the complexation with TCNQ (Table 3). Therefore, even with a constrained structure such as **6a** these metallamacrocyles remain flexible and the planarization of the TTF core, within the TCNQ complexes, induces a transfer of the constraints onto the metallic fragment.

Table 3. Significant bond lengths [Å] and angles [°].

| Compound | *d* W–P | *d* C=C | Angle P–W–P | Folding angles along S···S vector |
|---|---|---|---|---|
| **6a** | 2.4636(12) | 1.310(9) | 177.36(5) | 17 |
| | 2.4644(14) | | | 28 |
| $(\mathbf{6a})_2(TCNQ)$ | 2.4655(10) | 1.340(6) | 169.16(3) | 11 |

## Conclusions

In this study, redox active 17- and 19-membered metallamacrocycles incorporating one TTF unit have been synthesized through the coordination of the bidentate [(diphenylphosphanyl)alkylthio]TTFs to the $Mo(CO)_4$ and $W(CO)_4$ fragments. As a consequence of the possible *cis*/*trans* isomerization of the TTF core and the metallic fragment six stereoisomers were formed. As evidenced by the X-ray diffraction studies, the central TTF unit in these metallamacrocycles is not planar, however it is significantly less folded in the 19-membered ring than in the 17-membered ring. Nevertheless, the bending of the TTF is not sufficient to negate the electron-donating ability of this redox unit. Furthermore, in the 17-membered metallamacrocycles, the close proximity of the metallic fragment to the TTF produces electrostatic interactions as evidenced by the shift of the oxidation peak potentials of the metallic fragment to more positive potentials. Two TCNQ complexes with the 17- and 19-membered metallamacrocycles (M = W) have been obtained and crystallographically analyzed. Although no charge transfer was observed, comparison of the crystal structures provide valuable information on the relative flexibility of these strained structures. An attractive feature of these metallamacrocycles lies in the modification of the TTF core upon oxidation which should modify the molecular organization in the neighborhood of the metal fragment and attempts at isolating cation radical salts are currently under way.

## Experimental Section

$^1H$ NMR and $^{31}P$ NMR spectra were recorded with a Bruker AC 300P spectrometer. Chemical shifts are reported in ppm referenced to TMS for $^1H$ NMR and to $H_3PO_4$ for $^{31}P$ NMR spectroscopy. Elemental analyses were obtained from the Laboratoire Central de Microanalyse du CNRS, Lyon. Mass spectra were recorded with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a ZABSpec TOF instrument by the Centre Régional de Mesures Physiques de l'Ouest, Rennes. $CH_2Cl_2$ was distilled from $P_2O_5$. Toluene was dried with sodium wire. Chromatography was performed using silica gel Merck 60 (70–260 mesh). $Mo(CO)_6$ and 1,4-diazabicyclo[2.2.2]octane (DABCO) were purchased from ACROS Organics, $W(CO)_6$ was purchased from Aldrich. $M(CO)_4(NHC_5H_{10})_2$ was prepared from $M(CO)_6$ according to published procedures.[11] Cyclic voltammetry was carried out in dichloromethane, containing 0.1 M $nBu_4NPF_6$ as the supporting electrolyte. Voltammograms were recorded at 0.1 $Vs^{-1}$ on a platinum disk electrode ($A$ = 1 $mm^2$). The potentials were measured vs. a saturated calomel electrode. TTF **2** was prepared following known procedures.[5]

**General Procedure for the Synthesis of Complexes 6–9:** To a solution of the TTF **4** or **5** (0.5 mmol) in dried, degassed toluene (30 mL) DABCO (112 mg, 1 mmol) was added under argon. The mixture was stirred for 4 h at 50 °C after which $M(CO)_4(NHC_5H_{10})_2$ (0.5 mmol) in degassed $CHCl_3$ (10 mL) was added. The resulting solution was stirred at 80 °C for 2 h and then the solvent was removed under reduced pressure. The solid residue was dissolved in $CH_2Cl_2$, washed with water, and dried with $Na_2SO_4$. The solvent was removed and chromatography of the residue over silica gel (3:1 $CH_2Cl_2$/PE) afforded the complexes **6**–**9** as a mixture of isomers.

**Complex 6:** Yield 170 mg (33%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.20–1.40 (4 m, 4 H), 1.99, 2.01, 2.09, 2.14 (4 s, 6 H), 2.25–2.64 (4 m, 4 H), 2.70–3.0 (4 m, 4 H), 7.19–7.70 (m, 20 H) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 5.9 ($^1J_{PW}$ = 230 Hz), 6.9 ($^1J_{PW}$ = 230 Hz), 13.5 ($^1J_{PW}$ = 279 Hz), 14.6 ($^1J_{PW}$ = 279 Hz) ppm. $C_{42}H_{38}O_4P_2S_6W$: HRMS calcd. 1044.0075; found 1044.0075. $C_{42}H_{38}O_4P_2S_6W{\cdot}CH_3OH$: calcd. C 47.95, H 3.90, S 17.84; found C 47.58, H 3.80, S 17.53.

**Complex 7:** Yield 100 mg (20%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.20–1.40 (4 m, 4 H), 1.98, 2.02, 2.14, 2.16 (4 s, 6 H), 2.25–2.64 (4 m, 4 H), 2.70–3.0 (4 m, 4 H), 7.19–7.70 (m, 20 H) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 24.2, 24.7, 38.4, 39.3 ppm. $C_{42}H_{38}MoO_4P_2S_6$: HRMS calcd. 957.9626; found 957.9626.

**Complex 8:** Yield 120 mg (22%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.18–1.80 (4 m, 8 H), 2.00, 2.02, 2.10, 2.12 (4 s, 6 H), 2.41–2.62 (4 m, 8 H), 7.15–7.50 (m, 20 H) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 8.0 ($^1J_{WP}$ = 230 Hz), 8.6 ($^1J_{WP}$ = 230 Hz), 14.8 ($^1J_{WP}$ = 279 Hz), 14.9 ($^1J_{WP}$ = 279 Hz) ppm. $C_{44}H_{42}O_4P_2S_6W$: HRMS calcd. 1072.0392; found 1072.0395.

**Complex 9:** Yield 100 mg (20%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.18–1.40 (4 m, 4 H), 1.40–1.55 (4 m, 4 H), 1.92–2.09 (4 s, 6 H), 2.38–2.62 (4 m, 8 H), 7.12–7.49 (m, 20 H) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 25.5, 25.7, 39.0, 39.1 ppm. $C_{44}H_{42}MoO_4P_2S_6$: HRMS calcd. 985.9940; found 985.9946.

Crystallization of the derivatives **6**, **7**, and **8** from $CH_2Cl_2$/MeOH afforded prisms of complexes **6a**, **7c/c′**, and **8a** that were suitable for X-ray crystal structure analyses.

**Single-Crystal Structure Determination:** A single crystal of each compound was carefully selected under a polarizing microscope and glued to a thin fiber glass. Single crystal data collection was performed at room temperature with a Nonius KappaCCD diffractometer (Centre de Diffractométrie, Université de Rennes, France), with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). A crystal-to-detector distance of 25.0 mm was used for all the crystals and the data collection strategy (determination and optimization of the goniometer positions) was performed with the help of the COLLECT program.[23] Experimental details of the data collection are summarized in Table 4.

The integration process and data reduction was carried out using the DENZO-SCALEPACK[24] program. Numerical absorption corrections were performed using the multiscan procedure[25a] implemented in the WinGX program suite.[25b] Structure determination was performed with the direct methods solving program SIR97,[26] which revealed all the non-hydrogen atoms. SHELXL 97[27] was used to refine the structure. Finally, hydrogen atoms were placed geometrically and held in the riding mode in the least-square

# An Entry to Novel Platinum Complexes: Carboxylation of Dihydroxoplatinum(IV) Complexes with Succinic Anhydride and Subsequent Derivatization

**Michael Reithofer,[a] Markus Galanski,*[a] Alexander Roller,[a] and Bernhard K. Keppler[a]**

**Keywords:** Antitumor agents / Bioinorganic chemistry / Carboxylate ligands / Drug design / Platinum

An improved carboxylation method of (*OC*-6-33)-dichloro-(ethane-1,2-diamine)dihydroxyplatinum(IV) based on succinic anhydride is reported. Reaction of the uncoordinated carboxylic acid with simple amines and alcohols leads to the corresponding amides and esters in the presence of 1,1′-carbonyldiimidazole. The resulting new complexes are characterized by IR, $^{1}H$, $^{13}C$, $^{15}N$, and $^{195}Pt$ NMR spectroscopy, mass spectrometry, and elemental analysis. This reaction provides an entry to a new class of kinetically inert platinum(IV) complexes.

## Introduction

Cisplatin, *cis*-diamminedichloroplatinum(II) (Figure 1),[1,2] is a highly effective platinum-based anticancer agent that is used in nearly 50% of all tumor therapies all over the world. Cisplatin alone, or in combination with other antineoplastic drugs, is used against a series of solid tumors, including ovarian cancer, non-small cell lung cancer, and head and neck cancer. Cure rates above 90% have been reported in the case of testicular germ-cell cancer, depending on the point of diagnosis; it is thus one of the few anticancer drugs with real curative potential. Nevertheless, severe adverse effects such as a dose-limiting nephrotoxicity, peripheral neuropathy, tinnitus, and hearing loss in the high frequency range are known.[3] Additionally, acquired or intrinsic resistance of tumors to cisplatin therapy narrows the use of this drug.[4] After evaluation of thousands of platinum compounds in preclinical settings during the last 40 years, the second- and third-generation platinum complexes carboplatin [*cis*-diammine(1,1-cyclobutanedicarboxylato)-platinum(II)] and oxaliplatin [(*trans*-*R*,*R*-cyclohexane-1,2-diamine)platinum(II)] were successfully introduced into clinical practice.[5,6]

Besides platinum(II) complexes, which have to be administered intravenously due to their instability in the gastrointestinal tract, platinum(IV) complexes have also been investigated, thereby opening up the possibility of an oral absorption. In this context it has to be mentioned that, in principle, an orally administrable drug offers some advantages in the clinical routine, such as a reduction of the hospitalization costs and a better acceptance of chemotherapy by the patient. From the chemical point of view, octahedrally coordinated platinum(IV) complexes exhibit a higher coordination number than their square-planar platinum(II) counterparts, and therefore variation in the ligand sphere is more easily accessible. This is of great significance in order to fine-tune important properties such as lipophilicity, stability, reduction behavior, and biological activity.[7] Platinum(IV) complexes are kinetically inert and therefore show a significantly decreased reactivity. It is generally accepted that platinum(IV) complexes act as prodrugs by extra- or intracellular reduction to the more reactive platinum(II) complexes upon release of the axial ligands (activation by reduction).[8,9] The first platinum(IV) complexes, tetraplatin and iproplatin (Figure 1), which were investigated in phase-I clinical trials both showed an unfavorable pharmacokinetic behavior in vivo. Tetraplatin (two axial chloro ligands; reduction potential: –90 mV)[10] displays a high systemic

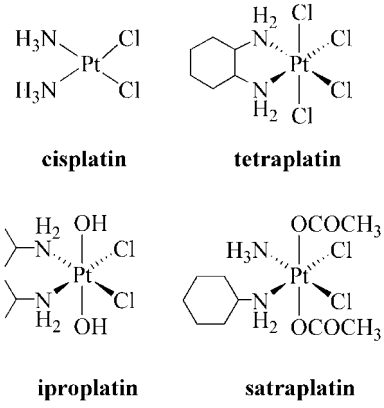

Figure 1. Chemical structures of the anticancer drug cisplatin and of tumor inhibiting platinum(IV) complexes in clinical evaluation. Tetraplatin and iproplatin were abandoned.

toxicity due to a very fast reduction of the platinum(IV) complex in the blood stream, whereas iproplatin (two axial hydroxy ligands; reduction potential: –730 mV) was found to be inactive because it is not reduced fast enough to the more (re)active platinum(II) species in the body. A breakthrough was reached with the synthesis of satraplatin (Figure 1), which contains two carboxylate ligands in the axial positions. Satraplatin is currently being investigated in phase-III clinical trials in hormone refractory prostate cancer.[11] The reduction potential (which is most influenced by the axial ligands) of satraplatin adopts an average value with –250 mV, but the lipophilicity of this complex also seems to be in an appropriate range. Very recently, a close analogue to satraplatin, namely LA-12, a platinum(IV) complex with a bulky and hydrophobic 1-adamantylamine ligand instead of cyclohexylamine, entered clinical phase I trials.[12,13] LA-12 shows high cytotoxic potential in leukemia, melanoma, and colorectal cancer cells and has been found to overcome acquired resistance to cisplatin in human ovarian A2780cisR cells.[14]

The success of satraplatin is a direct consequence of progress in the synthesis and derivatization of platinum(IV) complexes. Some years ago, the design of platinum(IV) coordination compounds was limited to oxidation of the corresponding platinum(II) species with hydrogen peroxide or chlorine gas:[15,16] selective ligand substitution was difficult to perform since platinum(IV) complexes are kinetically inert (substitution of chloride for hydroxide, for example works under comparatively drastic conditions in the presence of hydrochloric acid at high temperature). With the knowledge that hydroxide coordinated to platinum(IV) has nucleophilic properties and therefore can be carboxylated with classical agents known from synthetic organic chemistry, a new class of platinum(IV) complexes was accessible, which resulted in the development of satraplatin. Carboxylation of *trans*-dihydroxoplatinum(IV) by anhydrides, pyrocarbonates, isocyanates, and even by carboxylic acid chlorides in the presence of pyridine has recently been described in the literature,[17–21] leading to numerous new and interesting platinum(IV) derivatives. Very recently, the carboxylation with cyclic anhydrides (succinic, maleic, glutaric, and phthalic anhydride) under different reaction conditions was reported. Carboxylation in $CH_2Cl_2$ over 1–2 days,[22] reaction in DMSO at 70 °C with a considerably large amount (3.3 g) of the dihydroxoplatinum(IV) starting complex,[23] and the unsuccessful use of molten phthalic anhydride[24] have been reported. The yields were reported to be in the range of 40 to 70%. The use of cyclic anhydrides offers a further advantage, besides the fact that novel platinum(IV) compounds are prepared: it provides an uncoordinated carboxylic acid moiety for subsequent derivatization, although in only one case has derivatization to the amide been described; amine-modified estrogens were coupled to the uncoordinated carboxylic acid by the use of a common peptide coupling reagent, namely diisopropylcarbodiimide/4-(dimethylamino)pyridine.

Here we report an improved carboxylation method based on succinic anhydride. Additionally, reaction of the uncoordinated carboxylic acid with simple amines and alcohols, leading to the corresponding amides and esters in the presence of 1,1′-carbonyldiimidazole, is described. The platinum(IV) complexes have been synthesized for the first time and were characterized in detail by multinuclear NMR spectroscopy.

## Results and Discussion

Derivatization of kinetically inert platinum(IV) complexes is an attractive entry to novel platinum compounds. Besides the well-established carboxylation of hydroxide coordinated to the $Pt^{IV}$ center, derivatization of peripheral hydroxo groups in diaminetetrachloroplatinum(IV) complexes has also been reported.[25] With the use of cyclic anhydrides, a further functional group is now accessible in the axial position. In order to set up a general reaction procedure, synthesis of the bis(carboxylato)platinum(IV) complex **2** was improved and subsequent derivatization of the uncoordinated carboxylic acid group was evaluated (Figure 2).

The starting (*OC*-6-33)-dichloro(ethane-1,2-diamine)dihydroxoplatinum(IV) complex **1** was prepared by reaction of $K_2PtCl_4$ with ethane-1,2-diamine; the dichloroplatinum(II) compound was then oxidized with hydrogen peroxide. The carboxylation reaction with succinic anhydride was performed in DMF at 70 °C, affording **2** in a good yield of 85%. This is in clear contrast to the synthetic procedures described recently. The use of DMSO at higher temperatures seems to be especially problematic since it often leads to decomposition of the platinum complexes. The subsequent derivatization of **2** was carried out in DMF by activation of the carboxylic acid with 1,1′-carbonyldiimidazole (CDI). The formed imidazolide was used directly without isolation for the next reaction step. Contrary to our synthetic procedure, Lippard and co-workers have used another typical peptide coupling reagent, namely diisopropylcarbodiimide/4-(dimethylamino)pyridine, which could cause problems in the workup of the reaction mixture and may lead to unfavorable side-reactions. Reaction of the imidazolide with amines afforded the corresponding amides, whereas the use of alcohols, which were converted in part to the alkoxides by catalytic amounts of sodium, produced the esters. In the case of ethanolamine (in the absence of a strong base), only the amide was produced, thus demonstrating the selectivity of the reaction.

The new complexes **2**, **3a**–**c**, **4a**, and **4b** were characterized in detail by elemental analysis, IR, $^1H$, $^{13}C$, $^{15}N$, and $^{195}Pt$ NMR spectroscopy, mass spectrometry, and also by X-ray diffractometry in the case of **2**. The carboxylation of **1** and its subsequent derivatization to the amide or ester can be followed by significant changes in the infrared spectra. The *trans*-dihydroxoplatinum(IV) starting complex exhibits a characteristic very sharp and intense O–H stretch at 3483 $cm^{-1}$, which disappears after carboxylation with succinic anhydride. As a result, two C=O stretches, at 1654 $cm^{-1}$ for the coordinated carboxylato moiety and at 1719 $cm^{-1}$ for the uncoordinated carboxylic acid group, are

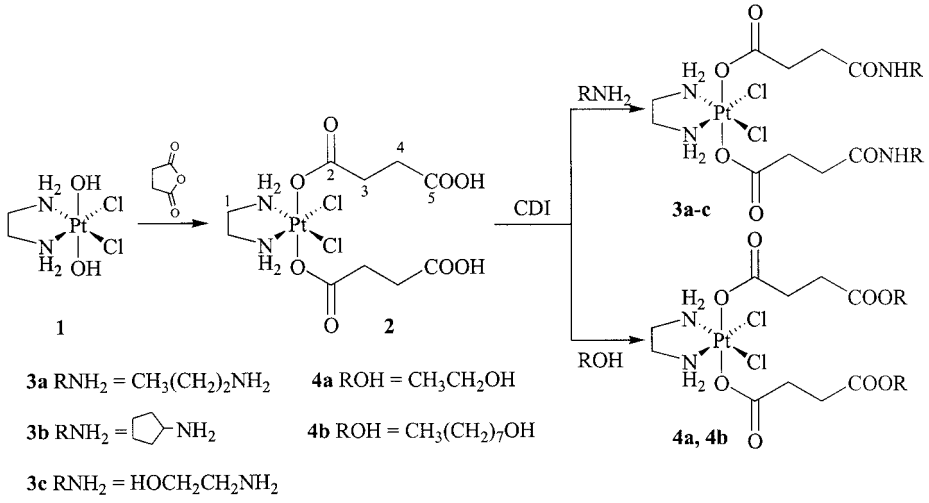

Figure 2. Synthesis of novel bis(carboxylato)platinum(IV) complexes and NMR numbering scheme.

detectable. The shift of the C=O band of the coordinated carboxylate to smaller wavenumbers is in good agreement with previously published data for analogous complexes (1633–1669 $cm^{-1}$).[19] Derivatization with amines, leading to complexes **3a**–**c**, is reflected by two characteristic absorptions (1633–1640 and 1664–1675 $cm^{-1}$) for the coordinated carboxylate and the amide C=O stretch, respectively, whereas the ester formation is accompanied by C=O absorption bands in the range of 1650 and 1658 $cm^{-1}$ for the PtOC=O stretch and between 1739 and 1745 $cm^{-1}$ for the C=O stretch of the ester moiety. Remarkably, in the case of ethanolamine the amide formation (vs. ester formation) could be confirmed by infrared spectroscopy.

$^{1}H$, and $^{195}Pt$ as well as gradient-enhanced two-dimensional $^{1}H$,$^{13}C$- and $^{1}H$,$^{15}N$-COSY NMR spectra of complexes **2**, **3a**–**c**, **4a**, and **4b** were acquired in [$D_7$]DMF. The ligand sphere around the platinum center can best be judged by the chemical shift of the $^{195}Pt$ nucleus, which spans a wide range of several thousand ppm, depending on the coordinated atoms, the geometry, and the oxidation state of the metal center. The $^{195}Pt$ resonances of the novel platinum(IV) complexes were found between $\delta$ = 2621 and 2630 ppm, which is indicative of a *cis*,*cis*,*trans*-$Pt^{IV}N_2Cl_2O_2$ ligand sphere (Table 1). These values are in good agreement with literature data {$\delta$ = 2658 ppm for [$PtCl_2$(en)-($OCOCH_3$)$_2$]}.[26] As expected, the $^{195}Pt$ chemical shifts as well as the $^{1}H$ ($\delta$ = 8.88–8.92 ppm) and $^{15}N$ resonances ($\delta$ = –3.3 to –4.2 ppm) of the coordinated amine moiety are not significantly influenced by derivatization at the uncoordinated carboxylic acid group. Nevertheless, a trend in the $^{195}Pt$ and $^{1}H$ (of the $NH_2$ group) chemical shifts seems to be obvious. In the $^{13}C$ NMR spectra, two resonances for the quaternary carbon atoms of the coordinated carboxylate (C-2 at around $\delta$ = 180 ppm and C-5 in the region between $\delta$ = 169.9 and 172.3 ppm) are detected, with an apparent upfield shift of C-5 upon derivatization of the uncoordinated carboxylic acid. Amide formation, especially in the case of the bifunctional ethanolamine, was verified by significant $^{1}H$ and $^{15}N$ shift differences. In complexes **3a**–**c** the proton resonances of the amide protons are found at around $\delta$ = 7.96 ppm, with $^{15}N$ chemical shifts in the region between $\delta$ = 90 and 109 ppm (typical region for amide nitrogens: $\delta$ = 63–113 ppm). Values between $\delta$ = 1 and 3 ppm ($^{1}H$) and –15 to +15 ppm ($^{15}N$) are found in the free amines, thus demonstrating the success of amide formation. In both **3a**–**c** and **4a**/**4b**, long-range shift correlation signals between the derivatized C=O quaternary carbon atom and the amine- or alcohol-derived residue could also be detected, additionally proving the amide or ester formation. Furthermore, these cross peaks in the two-dimensional shift correlated spectra allowed us unequivocally to distinguish between the two $^{13}C$=O resonances.

Table 1. $^{1}H$, $^{13}C$, $^{15}N$, and $^{195}Pt$ NMR spectroscopic data for the new complexes **2**, **3a**–**c**, **4a**, and **4b**.

| | $^{1}H$ | | $^{13}C$ | | $^{15}N$ | | $^{195}Pt$ |

Crystals suitable for X-ray diffraction analysis were grown by vapor diffusion of diethyl ether into a solution of **2** in acetone. The result of the X-ray diffraction study of complex **2**·2($CH_3$)$_2$CO is shown in Figure 3. Crystal data, data collection parameters and structure-refinement details are given in the Experimental Section. The compound crystallizes in the monoclinic space group *P*2/*c*, with the platinum atom lying on a twofold rotation axis that also goes through the center of the C–C bond of the ethane-1,2-diamine ring. The platinum(IV) atom has an octahedral coordination geometry with ethane-1,2-diamine and two chloro ligands bound in the equatorial plane and two succinic acids coordinated in a monodentate fashion in the axial positions. The Pt–N1, Pt–Cl1, and Pt–O1 bond lengths

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[2.0541(10), 2.3175(5), and 2.0113(12) Å, respectively] are well comparable with those in *cis,trans*-[Pt(en)$Cl_2$-($OCOCH_3$)$_2$] [2.040(5), 2.315(1), and 2.017(5) Å, respectively].[27] A five-membered chelate ring, with a bite angle of 83.66(6)°, is formed upon coordination of ethane-1,2-diamine to $Pt^{IV}$. A zigzag arrangement of the ligand atoms alternately above and below the mean least-squares plane through $PtCl_2N_2$ is observed. The dihedral angle $\Theta_{N1-C1-C1^i-N1^i}$ (superscript i denotes $-x + 1$, $y$, $1/2 - z$), which serves as a measure of the deviation of the corresponding chelate ring from planarity, is –55.8°.

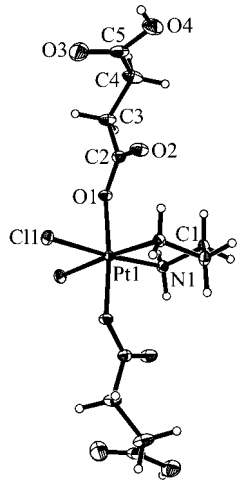

Figure 3. ORTEP diagram of **2** displaying thermal ellipsoids at 50% probability (the solvent molecule has been omitted). Selected bond lengths [Å] and angles [°]: Pt–N1 2.0541(10), Pt–Cl1 2.3175(5), Pt–O1 2.0113(12), O1–C2 1.3095(16), C2–O2 1.2235(16), C2–C3 1.5122(19), C3–C4 1.519(2), C4–C5 1.497(2), C5–O3 1.234(2), C5–O4 1.3070(18); O1–C2–O2 126.42(13), O3–C5–O4 123.13(15).

## Conclusions

It has been demonstrated that carboxylation of (*OC*-6-33)-dichloro(ethane-1,2-diamine)dihydroxoplatinum(IV) with succinic anhydride results in a platinum complex with coordinated carboxylato ligands, which contains further uncoordinated carboxylic acid groups for subsequent derivatization. Improved reaction conditions have allowed synthesis of this new complex in a pleasingly high yield of 85%. Reaction of the uncoordinated carboxylic acid with simple amines and alcohols, which leads to the corresponding amides and esters in the presence of 1,1′-carbonyldiimidazole, has been shown to be generally applicable to this kind of platinum complex, and provides entry to a new class of kinetically inert platinum(IV) complexes with potentially useful anticancer properties.

## Experimental Section

All chemicals were obtained from commercial suppliers and were used as received. The $^1$H, $^{195}$Pt and two-dimensional $^1$H,$^{13}$C- and $^1$H,$^{15}$N-COSY NMR spectra were recorded with a Bruker Avance DPX 400 spectrometer (Ultrashield™ Magnet) at 400.13, 86.11, 100.62, and 40.55 MHz, respectively, in [$D_7$]DMF at 25 °C, using standard pulse programs; two-dimensional spectra were measured in a gradient-enhanced mode. $^{15}$N and $^{195}$Pt chemical shifts are referenced relative to external $NH_4Cl$ and $K_2PtCl_4$, respectively. Half-height line widths of $^{195}$Pt resonances are given in parentheses. IR spectra were measured in a KBr matrix (4000–400 $cm^{-1}$) with a Perkin–Elmer Spectrum 2000 FT-IR spectrometer. Mass spectra (ESI-MS) were recorded with a Bruker $ESQUIRE_{3000}$ ion-trap mass spectrometer in the negative- as well as in the positive-ion mode. The elemental analyses were performed with a Perkin–Elmer 2400 CHN elemental analyzer by the microlaboratory of the Institute of Physical Chemistry, University of Vienna. Silica gel 60 (Fluka) was used for column chromatography. (*OC*-6-33)-Dichloro-(ethane-1,2-diamine)dihydroxoplatinum(IV) (**1**) was synthesized according to standard literature procedures by mixing equivalent amounts of ethane-1,2-diamine and $K_2PtCl_4$ in aqueous solution and subsequent oxidation with $H_2O_2$.[16]

**(*OC*-6-33)-Bis(3-carboxypropanoato)dichloro(ethane-1,2-diamine)-platinum(IV) (2):** Succinic anhydride (114 mg, 1.139 mmol) was added to a suspension of **1** (100 mg, 0.278 mmol) in DMF (2 mL) and the reaction mixture was stirred at 70 °C for 24 h. During this time the solid material dissolved to form a yellow-brown solution. DMF was then removed under reduced pressure. The residue was dissolved in acetone and filtered to give a clear, yellow solution. This solution was concentrated under reduced pressure, and subsequent addition of diethyl ether led to precipitation of a pale-yellow solid. The product was dried in vacuo. Yield: 131.5 mg (85%). $C_{10}H_{18}Cl_2N_2O_8Pt$ (560.24): calcd. C 21.44, H 3.24, N 5.00; found C 21.72, H 3.18, N 4.89. ESI-MS: *m*/*z* 561.1 [M + $H^+$]$^+$, 583.1 [M + $Na^+$]$^+$, 598.1 [M + $K^+$]$^+$, 559.1 [M – $H^+$]$^-$. IR: $\tilde{\nu}$ = 3445 ($\nu_{COO-H}$), 3202 ($\nu_{N-H}$), 3039–2927 ($\nu_{C-H}$), 1719, 1654 ($\nu_{as\ C=O}$) $cm^{-1}$. $^1$H NMR: $\delta$ = 12.52 (s, 2 H, COO*H*), 8.93 (s, $^2J_{H,Pt}$ = 52.7 Hz, 4 H, N$H_2$), 3.15 (s, 4 H, 1-H), 2.70 (m, 4 H, 3-H/4-H), 2.67 (m, 4 H, 3-H/4-H) ppm. $^{13}$C NMR: $\delta$ = 180.0 (C-2), 172.3 (C-5), 47.6 (C-1), 28.1, 29.5 (C-3/C-4) ppm. $^{15}$N NMR: $\delta$ = –3.8 ppm. $^{195}$Pt NMR: $\delta$ = 2630 (420 Hz) ppm. Crystals suitable for X-ray data collection were grown by vapor diffusion of diethyl ether into a solution of **2** in acetone.

**(*OC*-6-33)-Dichloro(ethane-1,2-diamine)bis{(4-propylamino)-4-oxobutanoato}platinum(IV) (3a):** 1,1′-Carbonyldiimidazole (CDI; 237.3 mg, 1.464 mmol) in DMF (16 mL) was added to a solution of **2** (400 mg, 0.714 mmol) in DMF (8 mL) and the mixture heated to 60 °C. After 10 min stirring, the solution was cooled down to room temperature and $CO_2$ was removed by flushing with argon. Propylamine (120.8 μL, 1.464 mmol) in DMF (24 mL) was added to the solution and stirred for 24 h at room temperature. DMF was then removed under reduced pressure to form a yellow-brown oil. The crude product was purified by column chromatography (EtOAc/MeOH, 4:1) to yield a white powder. Yield: 253.1 mg (55%). $C_{16}H_{32}Cl_2N_4O_6Pt$ (642.43): calcd. IR: $\tilde{\nu}$ = 3210 ($\nu_{N-H}$), 2958, 2927, 2856 ($\nu_{C-H}$), 1745, 1650 ($\nu_{as\ C=O}$) $cm^{-1}$. $^1H$ NMR: $\delta$ = 8.92 (br. s, 4 H, N*H*$_2$), 4.21 (t, $^3J_{H,H}$ = 6.7 Hz, 4 H, 6-H), 3.16 (br. s, 4 H, 1-H), 2.74 (m, 4 H, 3-H/4-H), 2.69 (m, 4 H, 3-H/4-H), 1.77 (m, 4 H, 7-H), 1.46 (br. s, 20 H, 8-H to 12-H), 1.04 (t, $^3J_{H,H}$ = 6.6 Hz, 6 H, 13-H) ppm. $^{13}C$ NMR: $\delta$ = 179.7 (C-2), 170.9 (C-5), 62.6 (C-6), 47.7 (C-1), 29.5, 28.1 (C-3/C-4), 26.9 (C-7), 30.1, 27.5$_2$, 27.4$_8$, 24.1, 20.8 (C-8 to C-12), 12.0 (C-13) ppm. $^{15}N$ NMR: $\delta$ = –3.5 ppm. $^{195}Pt$ NMR: $\delta$ = 2628 (420 Hz) ppm.

X-ray diffraction measurements were performed on a Bruker X8APEX II CCD diffractometer at 100 K. Single crystals were positioned 37.5 mm from the detector and 813 frames were measured, each for 80 s over a 1° scan. The data were processed using the Denzo-SMN software package.[28] Crystal data, data collection parameters, and structure-refinement details for **2**·2$CH_3COCH_3$ are given in Table 2. The structures were solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms were calculated and allowed to ride. Computer programs: structure solution: SHELXS-97;[29] refinement: SHELXL-97;[30] molecular diagrams: ORTEP.[31] Computer: PC, Pentium II; scattering factors taken from the literature.[32]

# Monomeric and Polymeric Amines as Dual Reductants/Stabilisers for the Synthesis of Gold Nanocrystals: A Mechanistic Study

**Michael J. Richardson,*[a] James H. Johnston,[a] and Thomas Borrmann[a]**

**Keywords:** Amines / Nanostructures / Phase diagram / Colloids

Uniform, monodisperse gold nanocrystals have been prepared in a single-step synthesis by the addition of secondary and tertiary alkylamines, or a cationic polymer containing these moieties, to dilute solutions of gold tetrachloraurate. The acidic pH resulted in the formation of quaternary ammonium sites, scavenging loosely bound chloride ions from the tetrachloraurate species, lowering the overall potential and reducing $Au^{III}$ to nanocrystalline $Au^0$. The secondary amino groups then served to stabilise the particles, preventing aggregation and collapse of the colloidal system. Addition of further capping groups was thus not required. The particles were characterised by UV/Visible spectroscopy, HR-TEM, X-ray diffraction, electrochemical potential and pH measurements (Eh-pH) and FTIR.

## Introduction

Nanoscale metallic particles exhibit characteristics at variance with those of the bulk metal.[1] Increased surface area, susceptibility towards Brownian motion and restricted plasmon oscillation are observed. Interaction with electromagnetic radiation (Mie theory) and biological systems allows for potential applications in the next generation of data storage disks,[2] photovoltaic and photochemical devices, catalysis and antimicrobial surfaces.[3]

In general, nanocrystalline gold is prepared either by physical means, for example vapour deposition, or chemically through the reduction of tetrachlorauric acid. The latter is now accepted as being more flexible, due to the remarkable influence that the type and molar ratio of reductant to $Au^{III}$, in addition to reaction time and temperature, exert over the size and shape of the particles formed.[4] The reductant supplies the necessary electrons to affect the reduction from the ionic through to the metallic state. Use of trisodium citrate provides particle sizes of 1.6 to 140 nm with a relatively narrow size distribution, tuneable according to the molar excess of reductant present.[5] Sodium borohydride in conjunction with either an alkanethiol capping group[6] or a branched polyamine[7] to ensure the stability of the colloidal system, provides particles of 6 to 20 nm. Interestingly, glucose in the presence of sodium hydroxide has been shown to reduce $Au^{III}$ to $Au^0$.[8] Alternatively, photochemical reduction may be employed[9] with the incoming photons generating the necessary electrons.

However, due to the precarious stability of the Au–Cl–$H_2O$ system (Figure 1) weaker reductants may be employed to initiate the transition to the metallic state. While $AuCl_4^-$ is stable over a wide pH range (0–7.5), any slight reduction in electrochemical potential will result in destabilisation of the system with a subsequent transition to $AuCl_2^-$ at 920 mV. Further lowering of the overall potential will then cause a further redistribution of electrons, favouring $Au^0$ as the stable species. This change in potential may result from a change in concentration of one or more species present, the addition of a new compound, a deviation in temperature or pH.

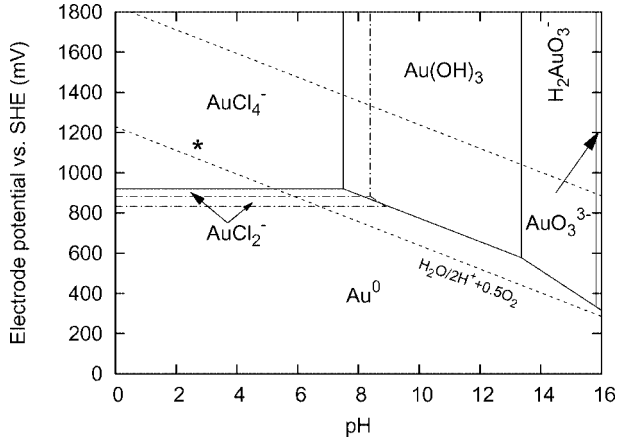

Figure 1. Pourbaix diagram for the Au–Cl–$H_2O$ system at 298 K.[10] $a_{Au} = 10^{-3}$ and $a_{Cl} = 1$ (—), $a_{Cl} = 5$ (– · – ·), chloride treated as electro-inactive. Water metastability region (- - -) calculated assuming standard conditions. The resting potential for the $AuCl_4^-$ used in the present study is indicated at *.

While commonly used for the steric stabilisation of nanocrystals, polymeric amines have recently received attention for their potential role as dual reductants/stabilisers.[11,12] In a few studies the mechanistic route is reasonably clear, for

example the degradation of *N*,*N*-dimethylacetoacetamide,[12] however in many it is not. This is particularly so when the amine is relatively stable towards oxidation compared to the metal complex that is to be reduced. Oxidation to an imine has been suggested,[13] however, no evidence of this route has yet been published. Furthermore, it is not difficult to disprove this hypothesis (see below).

Due to the difficulties in observing individual proton chemical shifts in highly branched polymers, an initial investigation was made into the ability of simple primary, secondary and tertiary amines to reduce $AuCl_4^-$, or at least destabilise the system such that metallic $Au^0$ would become the favoured species. In the present work, primary, secondary and tertiary amino groups are investigated as potential dual reductants/stabilisers for the synthesis of nanocrystalline gold. This allows some conclusions to be drawn regarding the use of cationic alkylamino polymers containing these groups.

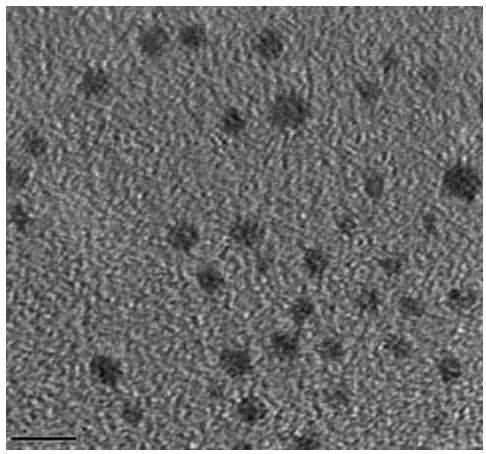

Figure 2. HR TEM of seed gold nanocrystals prepared with diethylamine. The scale bar represents 5 nm.

## Results and Discussion

**Monomeric Amines:** No reaction was observed between the primary amines, methylamine, ethylamine, and $AuCl_4^-$, either when heated to boiling or left under ambient conditions for several days. However, the secondary amine, diethylamine, reacted relatively slowly with the gold complex over 48 hours to form stable seed nanocrystals of 1.7 nm mean diameter, standard deviation 0.2 nm (Figure 2). The tertiary amine, trimethylamine, reacted relatively quickly to form nanocrystals within one hour; however, these began to aggregate immediately.

Examination of the proton nuclear magnetic resonance (NMR) spectrum of trimethylamine before and after nanocrystal formation showed a partial splitting of the single peak at $\delta$ = 3.35 ppm into two tiers of peaks over the range 2.20 to 3.60 ppm. It is believed that this is due to partial coordination of the gold to the nitrogen, as no coupling constants were able to be distinguished. A similar effect was observed for diethylamine, with the exception that coupling constants of 7 Hz were observed, consistent with methylene protons (Figure 3). By contrast, the proton NMR spectrum of ethylamine was found to be unchanged after addition of $AuCl_4^-$ (save for the expected shift of the triplet and quartet peaks due to the change in pH).

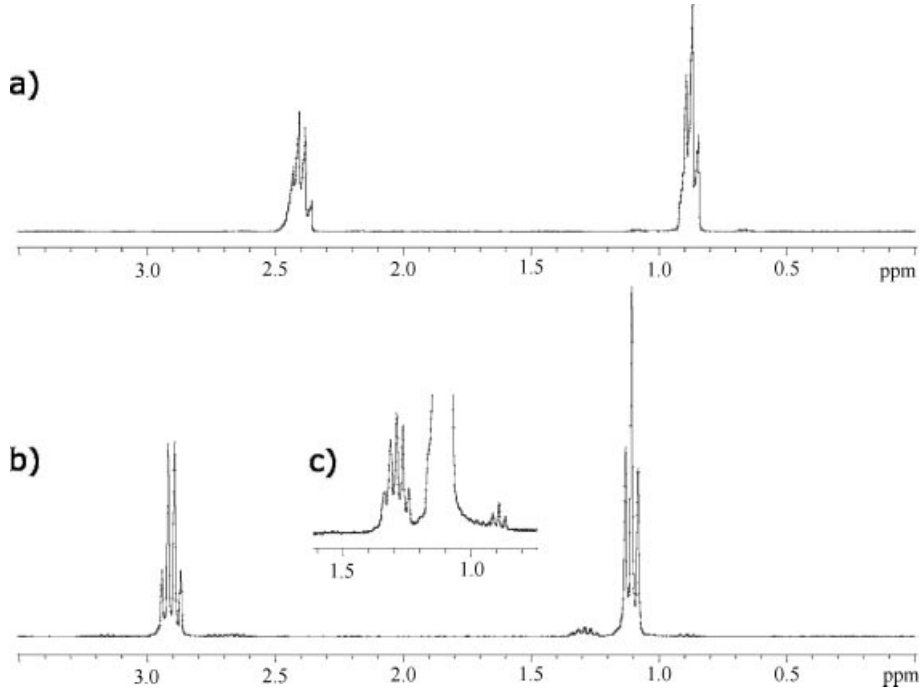

Figure 3. $^1$H NMR spectra of a) diethylamine, b) nanocrystalline gold prepared with diethylamine, c) expansion of spectrum b) showing the 7 Hz coupling-constant multiplet downfield of the triplet.

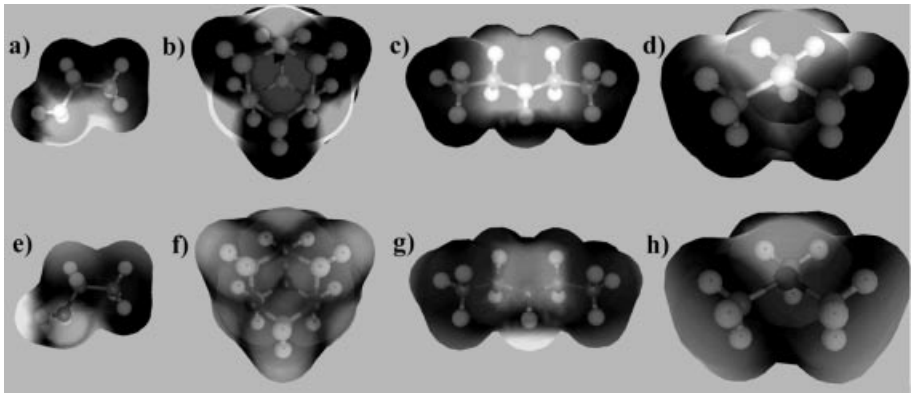

Figure 4. Molecular models of a) ethylamine (–0.18), b) hexamethylenetetramine (–0.20), c) diethylamine (–0.16) and d) trimethylamine (–0.13) showing the Van der Waals shell shaded white in areas of high electrostatic potential. Models on the second row represent e) ethylamine, f) hexamethylenetetramine, g) diethylamine and h) trimethylamine, respectively, redrawn to show areas of low electrostatic potential shaded white. Nitrogen charge in parentheses.

Length of the alkyl chain was also found to affect the ability of the amine to form nanocrystalline gold from the $AuCl_4^-$ solution. When the primary chain length was increased linearly to eight methylene (octylamine) units, colloid formation was observed. When the alkyl chain was cyclised (cyclohexylamine), however, no reaction was observed. Conversely, a longer alkyl chain in the secondary amines (dipropylamine, dibutylamine, dioctylamine) resulted in the formation of flakes of metallic gold. No reaction was observed with a shorter secondary amine chain length (dimethylamine). For the tertiary amines, the use of triethylamine rather than trimethylamine, while decreasing the volume of amine from 10 to 2 μL resulted in a colloid, which was stable for several days. The colloid was unstable with a greater volume of amine. No nanocrystal formation was observed with hexamethylenetetramine.

The differences in reactivity of the amino groups may be attributed to a combination of steric hinderence and extent of charge separation, in addition to their slightly different levels of basicity. Molecular modelling of the charge on the nitrogen and the steric hinderence (Figure 4) suggests that compounds better suited to interaction with gold nanocrystals are those with a charge on the nitrogen greater than than –0.16, in addition having the areas of minimum and maximum charge well separated. Access to the nitrogen atom is necessary if nanocrystal growth is to proceed. For example, addition of pyridine resulted in immediate formation of an unstable colloid, while the sterically hindered 1-methylpyridine provided a colourless solution – indicative of reduction to monoatomic gold. Gold colloid formation was not observed with the remaining amines.

Potential dissociation of the ammonium ion is also likely to affect formation of the nanocrystals. Diethylamine (as the ammonium ion) has the highest p$K_a$ (10.94) while ethylamine and trimethylamine have p$K_a$ values of 10.64 and 10.72, respectively.[15] While the increase in reactivity observed for longer chained secondary amines may be explained by their higher p$K_a$, only a minimal change in p$K_a$ in the primary amines is observed as the chain length is increased. Greater intramolecular interaction, exemplified by the increase in boiling point from 16.6 to 176 °C as the chain length is increased from one to eight methylene units, is expected to take an additional role.

The aromatic amines aniline, methoxyanilinesulfonate and benzylamine were also found to react readily with the $AuCl_4^-$ to form polyaniline (for the former) and nanocrystalline gold, in a similar fashion to that previously observed for 2-methoxyaniline[16] and pyrrole.[17] However, due to the ease of oxidation of these compounds relative to those discussed above, no further work was continued with these compounds.

While the above constitutes only an introductory investigation into the use of saturated monomeric amines as dual reductant/stabilising functional groups, it may tentatively be concluded that for short alkyl chains it is the tertiary amines that are the most effective at reducing $Au^{III}$, followed by longer chained secondary amines. However, secondary amines are more effective at providing the necessary coordination required for stabilisation of the nanocrystals as they are formed.

**Polymeric Amines:** No reaction was observed with polyacrylamide or polyvinylpyrrolidone containing primary and tertiary amino groups, respectively. The branched polyethylenimine (PEI) containing primary, secondary and tertiary amino groups reacted over a period of three hours to form the characteristic deep red colloid, stable over several months. Previous studies have confirmed its stabilising effect on nanocrystalline gold.[7] Due to the success observed with PEI, the remainder of the study focused on the use of this polyamine for nanocrystal synthesis.

Figure 5 shows the increase in the UV/Visible band at 525 nm associated with the transverse plasmon resonance[18] for these colloids (denoted type I, for the purposes of distinguishing the various colloids in the paper presented here). The mean particle size measured was 11 nm, with a standard deviation of 4 nm. Figure 6 and Figure 7 show the crystalline particles formed, together with a typical X-ray diffraction pattern. Type II colloids were prepared fortuitously when investigating the effect of temperature on formation of type I particles. On reaching 70 °C the solution

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rapidly underwent a colour change to deep red, which on examination under HR TEM showed that reduction had occurred and nanocrystals had formed. For comparison, similar colloids (denoted type III) were also synthesised according to the method of Sun[7] using $NaBH_4$ as reductant. Interestingly, the particles appeared more encumbered by the PEI used to stabilise the colloids when the reducing agent had been used, relative to the type I and II colloids.

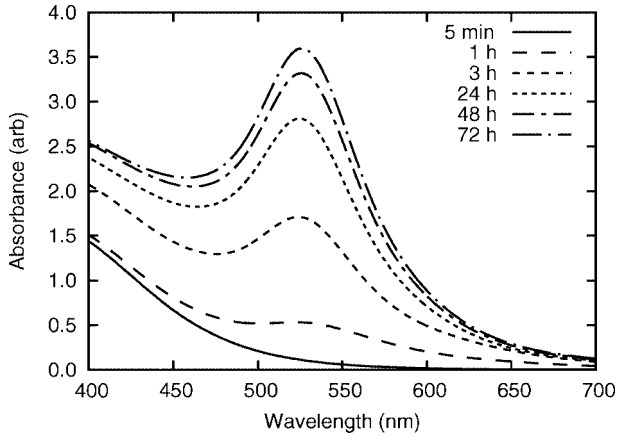

Figure 5. UV/Visible spectra of gold colloids (type I) prepared with PEI (N/Au ratio of 33:1) over the first three days, showing the development of the peak at 525 nm.

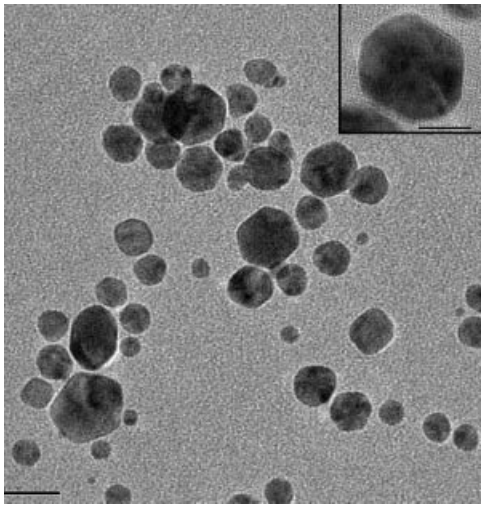

Figure 6. HR TEM of gold nanocrystals prepared with polyethylenimine (type I, N/Au 33:1). The scale bar represents 20 nm for the main picture, 10 nm for the inset.

Use of a lower concentration of PEI, measured as the average number of amino groups present, resulted in the formation of some metallic gold (though none at the nanometer scale) which settled rapidly to the bottom of the vial Figure 7. With a 1:1 N/Au ratio, the colloid aggregated within several hours – a minimum ratio of 33:1 was required to ensure stability of the system. As the ratio of N to Au was increased from 33:1 to 330:1, a gradual colour change from red to blue was observed in the colloidal system. This is seen in the UV/Visible spectra (Figure 8) as a broadening towards higher wavelengths of the principle absorbance

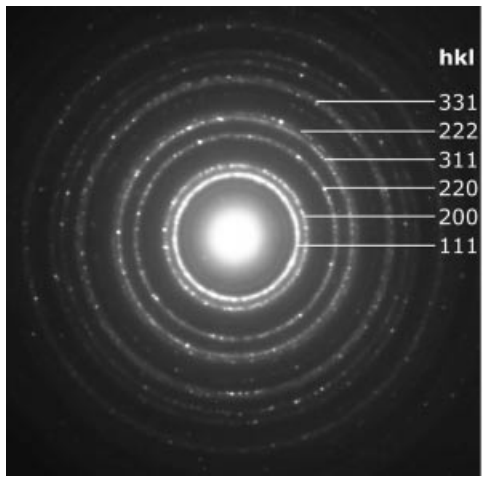

Figure 7. Typical diffraction pattern of multi-crystalline nanoparticulate gold prepared with PEI (type I, 33:1 N/Au, camera height = 80 cm).

peak. The change in absorbance was due in part to a slightly higher mean particle size; however, a greater tendency towards aggregation into larger "clumps" of 50 to 100 nm, was the over-riding factor. Increasing the N/Au ratio further had no noticeable effect. However, if the ratio of N/Au was kept at 33:1 and the colloid aged for up to four months, then a decrease in size distribution (standard deviation 1 nm) and concurrent increase in mean particle size (13 nm) due to Ostwald ripening, is observed. A corresponding shift in absorbance to longer wavelengths was also noted.

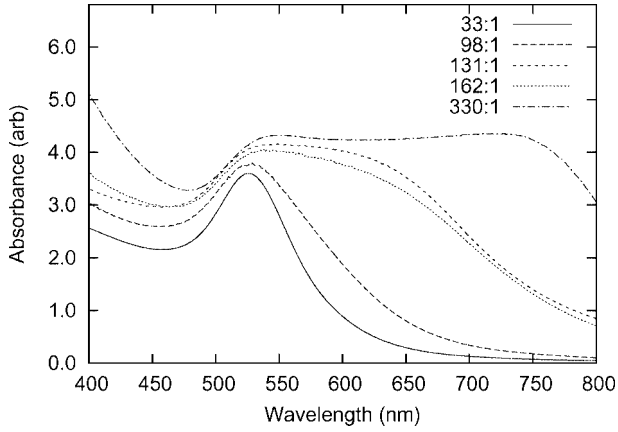

Figure 8. UV/Visible spectra of type I colloids at increasing molar ratios of amino nitrogen to gold, after four days.

The mechanism by which the reduction occurs is likely to be complex and remains unresolved at present. It has been postulated that the amino groups on the polymer are oxidised to imino moieties,[13] and indeed this is the obvious source of electrons by which the reduction of $Au^{III}$ could take place. No evidence for the required carbon–nitrogen double bond has been published, however. NMR analysis of the PEI–colloid system before and after synthesis of the colloid should show the appearance of a proton bound to a carbon with a carbon–nitrogen double bond. However,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

proton and HSQC NMR spectra lack such a peak in the polymer both before and after reduction of the $Au^{III}$, confirming the absence of the imine group.

It has also been suggested that the loss of the peak at 1570 $cm^{-1}$ in the IR spectrum after ten days[13] attributed to the N–H bending vibration, is evidence for the oxidation of the amino groups. Considering that nanocrystal formation is observed in less than three hours and is essentially complete within 24 hours, this is unlikely. Furthermore, the expected concurrent appearance of the carbon–nitrogen double-bond at 1700 $cm^{-1}$ is not observed. Oxidation of the amino groups to nitrate was eliminated as a possibility by the negative "Brown Ring" test.[14]

However, some suggestions towards a mechanism must be made. Formation of type I and II particles is believed to proceed initially through transfer of protons from the acidic gold solution to the nitrogen groups of the polymer to form quaternary ammonium sites, the resulting cationic species attracting the chloride ions initially complexed to the gold. In order to test the hypothesis that this "doping" of the amino groups on the polymer was required for the reduction, parallel experiments were conducted where the polymer was first treated with excess chloride before addition of the gold. Upon subsequent addition of $AuCl_4^-$ no reaction was observed. This suggests that availability of the nitrogen lone electron pairs, as cationic quaternary ammonium sites under acid pH, is requisite to formation of the nanocrystals. Revisiting the secondary and tertiary amines, a similar effect was found, with no reduction of the tetrachloraurate.

The main difficulty is locating the source of the electrons required for reduction of $Au^{III}$ to $Au^0$. Analysis of the oxidation–reduction potential (ORP) of the $H_2O$–PEI–$AuCl_4^-$ system with various concentrations of PEI, corresponding to multiples of the number of moles of chloride ion present, shows that at a molar ratio of nitrogen to gold ions of approximately 1:1, a lowering of the potential is observed (Figure 9). A slight reduction in pH is observed concurrently, followed by an increase to a pH of 7.3. Due to the potential of the system initially being in that where water is

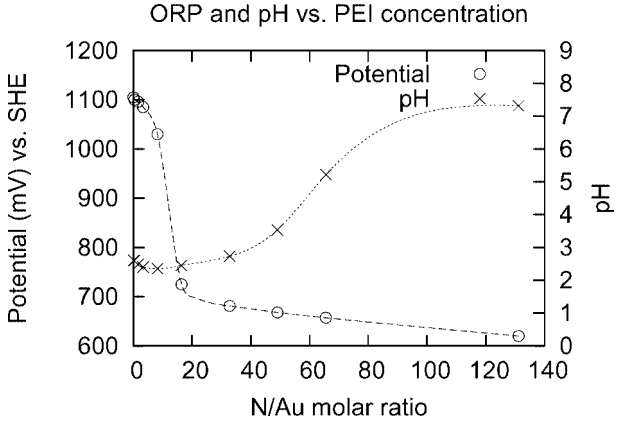

Figure 9. Oxidation–reduction potential vs. the standard hydrogen electrode (SHE) and pH as a function of the molar ratio of polymeric amino nitrogen to gold.

only metastable (Figure 1) some water may have been oxidised concurrently with the initial stages of nanocrystal formation. Nanoparticulate gold is known to catalyse the reduction of oxygen to peroxide[19] thus it is possible that the equivalent oxidation may also be thus affected. The resulting protons would lead to the observed lower pH, simultaneously providing the electrons required for the reduction of the gold. Once all required electrons have been provided and the reaction with the gold species is complete, the presence of additional, excess amino groups only serves to increase the overall system pH.

## Conclusions

Crystalline gold nanocrystals of 6 to 100 nm diameter have been prepared using both monomeric and polymeric amines in a dual reductant/stabilising role, the latter containing both primary, secondary and tertiary amino groups. The secondary groups were found to be the most amenable to the synthesis and stabilisation of the nanocrystals, while the tertiary amines were able to reduce the $Au^{III}$ but unable to stabilise the colloid. The mechanism by which reduction takes place is expected to be complex, but is believed to involve the formation of quaternary ammonium sites on the monomer or polymer, together with possible oxidation of water to provide the necessary electrons. A significant advantage of the processes used to form the nanocrystals is the simplicity of the synthesis (one pot, one step). This allows ready scale-up of the synthesis. Additionally, the three compounds used are relatively benign at the concentrations used, leaving no undesirable by-products for disposal or further treatment.

## Experimental Section

### Synthesis of Colloids

**Monomeric Amines:** $HAuCl_4$ (40 μL, 1.24 wt.-%) was added to Millipore water (5 mL, 15 MΩ·$cm^{-1}$) with rapid stirring. After one min, the amine [methylamine (40 wt.-%, aqueous), ethylamine (70 wt.-%, aqueous), octylamine, cyclohexylamine, benzylamine, ethylenediamine, phenylethylamine, 1,1,3,3-tetramethylguanidine, dimethylamine (26 wt.-%, aqueous), diethylamine, dipropylamine, dibutylamine, dioctylamine, aniline, methoxyanilinesulfonate, pyrrole, pyridine, 1-methylpyridine, trimethylamine (25 wt.-%, aqueous), triethylamine, hexamethylenetetramine](1 to 10 μL) was added and stirring continued for a further minute before leaving to stand for 2 to 72 hours. A duplicate sample of the diethylamine-Au colloid was evaporated to dryness before dispersion in $D_2O$ in preparation for $^1H$ NMR analysis (300 MHz, $D_2O$, 25 °C): $\delta$ = 1.11 (t, $J_{H,H}$ = 7 Hz), 1.29 (m, $J_{H,H}$ = 7 Hz), 2.90 (m, $J_{H,H}$ = 7 Hz), in addition to a further sample of the trimethylamine-Au colloid (300 MHz, $D_2O$, 25 °C): $\delta$ = 2.42 (s), 2.49 (s), 2.55 (s), 2.60 (s), 2.67 (s), 2.73 (s), 2.80 (s), 2.83 (s), 2.87 (s), 2.91 (s), 2.97 (s), 3.05 (s), 3.22 (s), 3.24 (s), 3.53 (s) ppm.

**Polymeric Amines:** Stock solutions of surfactant were prepared using dry polyethylenimine (PEI) (A: 18 wt.-%, B: 0.18 wt.-%, average Mw 25000, Aldrich), polyvinylpyrrolidone (C: 1 wt.-%), polyacrylamide (D: 1 wt.-%) and Millipore water (15 MΩ·$cm^{-1}$).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Type I nanocrystals were prepared by the addition of $HAuCl_4$ (40 μL, 1.24 wt.-%) to Millipore water (5 mL) with rapid stirring, followed by the required amount of solution A to D. The reaction mixture was left to stand for a minimum of 24 hours in a sealed vial, whereupon a characteristic colour change to deep red was observed. NMR samples were prepared by evaporating to dryness a duplicate volume (5 mL) of the PEI–Au colloid, prior to redispersion in $D_2O$. $^1H$ NMR (300 MHz, $D_2O$, 25 °C): $\delta$ = 4.74 (s), 4.67 (s), 4.61 (s), 4.41 (s), 3.33 (m), 3.21 (s), 3.17 (m), 3.02 (m), 2.83 (m), 2.28 (s), 2.13 (s), 2.06 (s), 2.00 (s), 1.85 (s), 1.80 (s) ppm. $^{13}C$ NMR (from HSQC at 300 MHz, $D_2O$, 25 °C): $\delta$ = 35.5 (s), 36.7 (s), 43.9 (s), 44.0 (s), 45.1 (s), 49.7 (s), 72.9 (s), 138.1 (s), 153.5 (s) ppm. Type II nanocrystals were formed in the same manner as type I, with the PEI/$HAuCl_4$ solution being heated momentarily to 70 °C. The vial was cooled to ambient temperature prior to further analysis. Type III nanocrystals were prepared according to the method of Sun (2003).[7] $HAuCl_4$ (80 μL, 1.24 wt.-%) was added to a 15 mL glass vial containing water (10 mL) and a magnetic stirring bar. After stirring rapidly for one min, PEI (20 μL, 18 wt.-%) was added to the mixture, whereupon a colour change to faint red was noted. After a further minute of stirring, $NaBH_4$ (2.0 M in dimethyl ether/ethylene glycol, Aldrich) was added dropwise until a colour change to deep red was observed.

### Analysis

High-resolution transmission electron micrographs (HR TEM) and diffraction patterns were recorded with a Jeol 2010 instrument at 200 keV acceleration voltage with the samples mounted on carbon-coated copper grids (200 mesh). Ultra-violet/visible (UV/Visible) spectra were measured using matched quartz curvettes and a Varian Cary 100 system. A Bruker Tensor 27 system attached to a Pike Technologies single-reflectance horizontal-attenuated total reflectance (ATR) attachment was used to obtain Fourier Transform infra-red (FTIR) spectra. pH and oxidation–reduction potentials (ORP) were measured using Mettler Toledo and Hanna probes, respectively, with a Hanna 8521 instrument. $^1H$ and gradient heteronuclear single quantum correlation (HSQC) nuclear magnetic resonance (NMR) spectra were recorded on a Varian Inova spectrometer at 300 MHz.

### Molecular Modelling

Modelling of the charge density on the compounds was undertaken using the Polak Ribiere conjugate gradient algorithm, on HyperChem. 7.5 (Gainesville, Florida). Rendering of the molecular models was achieved using Ghemical 1.91[20] and the Massively Parallel Quantum Chemistry system (MPQC).[21]

## Acknowledgments

Funding from the School of Chemical and Physical Sciences, Victoria University is gratefully acknowledged. The authors would also like to thank Dr. Richard Tilley and Mr. David Flynn for their valuable assistance with HR TEM sample preparation and analysis.

# Synthesis and Characterization of $MoOI_2(PMe_3)_3$ and Use of $MoOX_2(PMe_3)_3$ (X = Cl, I) in Controlled Radical Polymerization

**José A. Mata,[a] Sébastien Maria,[a] Jean-Claude Daran,[a] and Rinaldo Poli*[a]**

**Keywords:** Molybdenum / Oxido ligands / Phosphane ligands / Halide exchange / Atom transfer radical polymerization

Complex $MoOCl_2(PMe_3)_3$ smoothly reacts with NaI in acetone to produce $MoOI_2(PMe_3)_3$ in good yields. The geometry of the compound is *mer-cis* octahedral, that is, identical to that of the dichloride precursor, as shown by NMR spectroscopy and by an X-ray crystallographic study. Electrochemical investigations of $MoOX_2(PMe_3)_3$ show irreversible oxidation waves at $E_{p,a}$ = +0.18 and +0.39 V for X = Cl and I, respectively. A study of the halide exchange between $MoOCl_2(PMe_3)_3$ and NaI, or between $MoOI_2(PMe_3)_3$ and $Bu_4NCl$, shows two equilibrated isomers for the mixed halide intermediate $MoOICl(PMe_3)_3$. The diiodide complex rapidly exchanges the iodo ligands with chloride upon dissolution in chloroform at room temperature, and with bromide from (1-bromoethyl)benzene (BEB) under more forcing conditions. The equilibrium favors the softer halide (I) on C and the harder one (Cl or Br) on $Mo^{IV}$. Both oxido compounds catalyze the atom transfer radical polymerization (ATRP) of styrene in combination with the BEB initiator, yielding polymers with quite narrow molecular weight distributions (down to 1.11). The apparent polymerization rate constant is approximately doubled in the presence of 1 equiv. of the $Al(OiPr)_3$ cocatalyst. On the other hand, the system is not capable of efficiently controlling the radical chain growth for methyl acrylate polymerization.

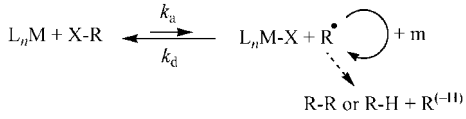
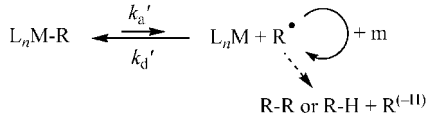
## Introduction

In recent years, a number of coordination and organometallic compounds based on different transition metals have been proven capable of controlling the radical polymerization of activated olefins. The phenomenon is accomplished by maintaining the active radical concentration at very low levels through a fast reversible equilibrium with a dormant species, thereby reducing the incidence of bimolecular terminations. The equilibrium may implicate a halogen atom transfer (see Scheme 1), thus the term atom transfer radical polymerization (ATRP).[1,2] In this respect, the process corresponds to a transition-metal-catalyzed multiple insertion of olefins into the carbon–halogen bond of the initiator molecule. A metal complex, however, may also yield a dormant species by reversibly forming a metal–carbon bond (see Scheme 2). This process is termed, somewhat inappropriately, stable free radical polymerization (SFRP). Indeed, the stable transition-metal complex acting as a spin trap need not possess a radical character. We have recently proposed a new term for this process, organometallic radical polymerization (OMRP), because it involves the reversible formation of a metal–carbon bond.[3]



Scheme 1.



Scheme 2.

The various metals so far shown to be effective include $Ti^{III}$,[4] $Mo^{III}$,[5,6] $Re^{V}$,[7] $Fe^{II}$,[8,9] $Ru^{II}$,[10] $Ni^{II}$,[11] $Ni^{0}$,[12] and $Cu^{I}$.[13] Although no system currently appears to parallel the activities and practical advantages of certain $Cu^{I}$ complexes, the investigation of other metal systems is useful in order to shine additional light on the mechanistic details of the process. For instance, by using $CpMoCl_2L_2$ complexes (L = tertiary phosphanes or $L_2$ = diene), we have demonstrated how the two trapping processes in Schemes 1 and 2 may simultaneously take place when the polymerization is carried out under ATRP conditions.[5] Furthermore, the use of $MoX_3(PMe_3)_3$ catalysts (X = Cl, Br, I) has revealed that the oxidized metal complex (ATRP spin trap) need not be a thermodynamically stable species in order for the catalyst to ensure good control.[14] In fact, whereas the $Mo^{IV}$ complexes $MoX_3Y(PMe_3)_3$ (X, Y = Cl, Br) could be isolated

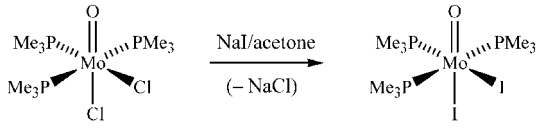
and fully characterized, no such complex containing an iodo ligand was shown to exist, because it would decompose by an internal redox process to an $Mo^{III}$ complex and $I_2$. As a further example, a comparison of the rates of halide exchange between various ATRP catalysts [i.e. $MoX_3(PMe_3)_3$, $CpMoCl_2(RN{=}CHCH{=}NR)$ (R = *i*Pr), $RuCl_2(PPh_3)_3$] and initiator molecules, in the presence and in the absence of $Al(O{i}Pr)_3$, has revealed two possible mechanisms for this exchange process.[15,16]

The results of DFT calculations have shown that the Mo–X and Mo–R bond strengths decrease upon raising the metal oxidation state, the computed values suggesting that the $Mo^{III/IV}$ redox couple is ideally placed to insure appropriate equilibrium positions for both ATRP and SFRP processes. Indeed, no radical polymerization occurs in the presence of the complex $CpMo(CH_2SiMe_3)_2(\eta^4\text{-}C_4H_6)$, showing that this particular $Mo^{III}$–R bond is too strong.[5] On the other hand, preliminary evidence, which will be reported separately, has indicated the possible implication of $Mo^{IV/V}$ couples in ATRP. For this reason, we have decided to test some typical $Mo^{IV}$ coordination compounds as ATRP catalysts. In this paper, we report our results obtained by using a well-known $Mo^{IV}$ coordination compound, $MoOCl_2(PMe_3)_3$. In addition, we also report the results obtained with the related compound $MoOI_2(PMe_3)_3$, whose synthesis and characterization is reported here for the first time. Our interest in this compound was twofold. From the point of view of ATRP catalysis, we have shown that some iodo derivatives of certain $Mo^{III}$ ATRP catalysts, for example, $CpMoI_2(RN{=}CHCH{=}NR)$ (R = *i*Pr) are more active than the corresponding chloro derivatives.[15] From the coordination chemistry point of view, we have demonstrated the incompatibility between iodo ligands and $Mo^{IV}$ in complexes of type $MoX_nY_{4-n}(PMe_3)_3$ (vide supra).[14] Yet, stable iodide derivatives of molybdenum in higher oxidation states do exist when the metal electronic deficiency is satisfied by strong donor ligands (e.g. $Cp^*Mo^{IV}I_4^-$ and $Mo^{V}OI_4^-$).[17,18] Therefore, it was of interest to see whether compound $MoOI_2(PMe_3)_3$ would be stable, to investigate its redox properties, and to test its catalytic properties in ATRP.

## Results and Discussion

### Syntheses and Characterization

The new complex $MoOI_2(PMe_3)_3$ was obtained by halide exchange from the dichloride precursor as described in Scheme 3. The reaction is driven by the precipitation of the less soluble NaCl and is relatively rapid at room temperature. The spectroscopic properties of the isolated compound indicate an identical structure to that of the precursor. In particular, the $^{31}P$ NMR spectrum shows two types of phosphane ligands in a 2:1 ratio, whereas the virtual triplet pattern for the $^1H$ NMR resonance of the two equivalent $PMe_3$ ligands establishes their mutual *trans* arrangement (the spectral parameters are collected in Table 1). This clearly identifies the *mer* arrangement of the $Mo(PMe_3)_3$ moiety. The $^{31}P$ NMR spectrum is qualitatively different in [$D_6$]acetone and in $C_6D_6$. Whereas the doublet/triplet pattern expected for an $AX_2$ spin system is relatively unperturbed in the former solvent, a more complex pattern, which is indicative of second-order coupling for an $AB_2$ system, is evident in $C_6D_6$ (see Figure 1). This difference is caused by the closer proximity of the two $^{31}P$ resonances in $C_6D_6$. The values reported in Table 1 result from the successful simulation of the spectrum.



Scheme 3.

Table 1. $^1H$ and $^{31}P\{^1H\}$ NMR parameters ($\delta$ in ppm, $J$ in Hz) for compounds $MoOXY(PMe_3)_3$ (X, Y = Cl or I).

The relative *cis* arrangement of the two iodo ligands is unambiguously confirmed by the single-crystal X-ray diffraction study, but is also indicated by the NMR monitoring of the halide exchange process, notably by the presence of *two* different stereoisomers for the mixed halide complex (vide infra). When using a sufficiently large excess of NaI (>5 equiv.), the isolated product is devoid of any mixed halide impurity. It is also devoid of the known[19] $Mo^{III}$ complex $MoI_3(PMe_3)_3$, a problem that often affects its dichloride precursor $MoOCl_2(PMe_3)_3$.[20] Indeed, the latter is usually obtained from $MoCl_4(THF)_2$ and $PMe_3$ in the presence of water,[21] giving a product whose color (varying from blue to green) depends on the level of contamination by yellow $MoCl_3(PMe_3)_3$. By replacing the $Mo^{IV}$ tetrachloride precursor with the bis(ether) complex, $MoCl_4(Et_2O)_2$,[22] we have obtained a blue material that is also contaminated by minor amounts of the $Mo^{III}$ trichloride complex, as evidenced by $^1H$ NMR spectroscopy. A better synthesis of pure $MoOCl_2(PMe_3)_3$ is that reported by Galindo et al., from $MoO_2Cl_2(MeOCH_2CH_2OMe)$ and $PMe_3$.[23] Our synthesis of $MoOI_2(PMe_3)_3$ was carried out from a dichloride precursor obtained by the latter procedure.

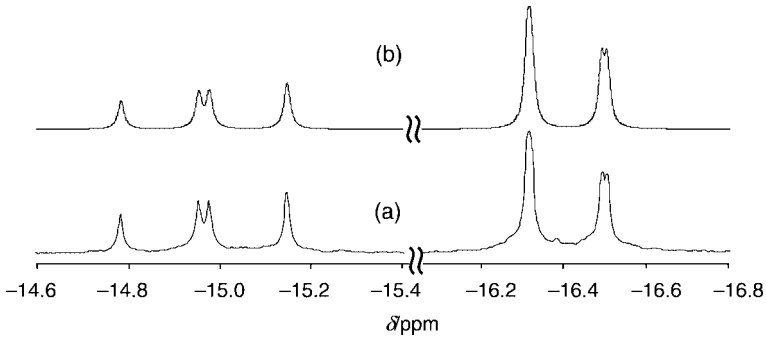

Figure 1. Experimental (a) and simulated (b) $^{31}P$ NMR spectrum of $MoOI_2(PMe_3)_3$ in $C_6D_6$.

A view of the molecule resulting from the X-ray diffraction study is shown in Figure 2. Selected geometric parameters are collected in Table 2. The thermal ellipsoids are well behaved, showing no evidence for positional disorder, in agreement with the NMR evidence for the absence of $MoI_3(PMe_3)_3$. In addition, the presence of iodide in the oxido position would have a notable effect on the refined Mo=O distance, whereas the experimental value of 1.685(4) Å is quite short. Moreover, this distance is identical within experimental error to the distance reported for the corresponding complex *cis-mer*-$MoOCl_2(PMe_2Ph)_3$ [1.675(3) Å].[20] Therefore, these results show that there is no compositional I/O disorder, contrary to previous reports for the dichloro analogues.[20] The Mo–P distances [2.494–2.513 Å] are within the normal range for related compounds.

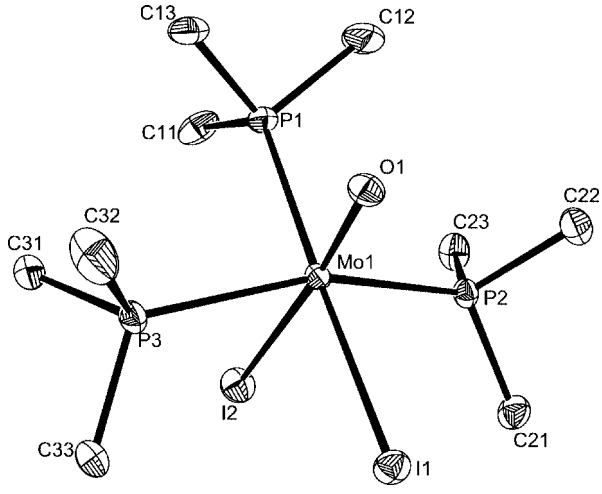

Figure 2. ORTEP view of $MoOI_2(PMe_3)_3$. The ellipsoids are drawn at the 50% probability level.

From a benzene/*n*-pentane solution of $MoOCl_2(PMe_3)_3$ set aside for several days, crystals of compound $[MoOCl(PMe_3)(OPMe_3)]_2(\mu\text{-}O)$ were obtained, possibly by adventitious contact with air and moisture. As the resulting structure is more accurately determined and is in a different crystal system than one reported previously for the same compound,[24] we report it here but do not comment on it any further. No analogous compound was obtained from the corresponding oxido diiodide complex.

Table 2. Selected bond lengths [Å] and angles [°] for compound $MoOI_2(PMe_3)_3$.

The existence and stability of the $MoOI_2(PMe_3)_3$ compound [cf. the nonexistence of $MoI_4(PMe_3)_3$][14] indicates that the oxido ligand is a much stronger electron donor than two iodo ligands toward the Mo center, raising the energy of the LUMO and thereby making the metal center a less powerful oxidizing agent. Indeed, qualitative MO considerations lead to the expectation of an interaction as shown in Scheme 4, where the energy of the $d_{xz}$ and $d_{yz}$ orbitals of the pseudo-$t_{2g}$ set (octahedral coordination environment) is raised through the π-donation mechanism.

An electrochemical investigation of compounds $MoOX_2(PMe_3)_3$ yields irreversible oxidation processes at $E_{p,a}$ = +0.18 and +0.39 V for X = Cl and I, respectively (see Figure 3). The lack of reversibility indicates the occurrence of a fast chemical process after oxidation to the cationic $Mo^V$ complex $[MoOX_2(PMe_3)_3]^+$, probably involving solvent coordination. The voltammogram recorded on the chloride complex shows that a new and broad cathodic peak is generated after the oxidation peak (this feature is not observed during the first cathodic scan prior to the oxidation peak). In the presence of chloride ions, the oxidation peak shifted slightly toward less positive potentials, but the overall shape of the voltammogram was otherwise unaffected. This result can be rationalized by a follow-up coordination of $Cl^-$ to $[MoOCl_2(PMe_3)_3]^+$, with generation of the putative ATRP spin trap, $MoOCl_3(PMe_3)_3$. The same phenomenon was previously observed by us for the oxidation of $MoX_3(PMe_3)_3$ in the presence of $X^-$ (X = Cl, Br) and verified by an independent study of the isolated $MoX_4(PMe_3)_3$ products.[14] In the present case, a similar verification is impossible because, to the best of our knowl-

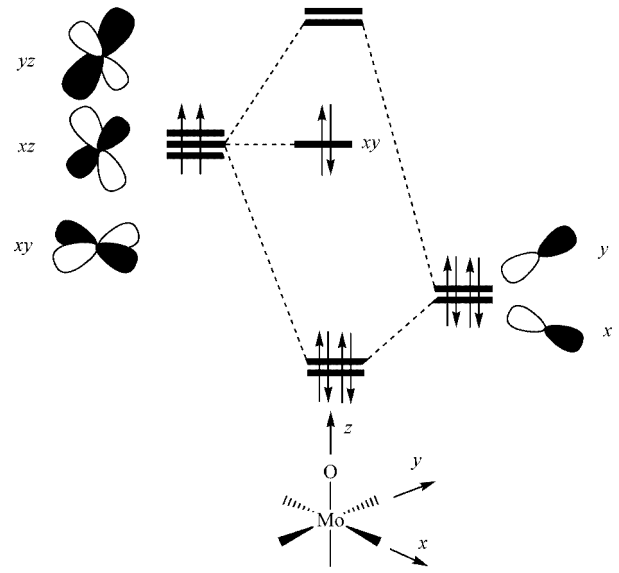

Scheme 4.

edge, complex $MoOCl_3(PMe_3)_3$ is nonexistent. Indeed, the voltammetric response in the presence of $Cl^-$ shows that such a compound is unstable under the conditions of the CV experiment (THF solution) and decomposes in a similar way to that of the $[MoOCl_2(PMe_3)_3]^+$ complex.

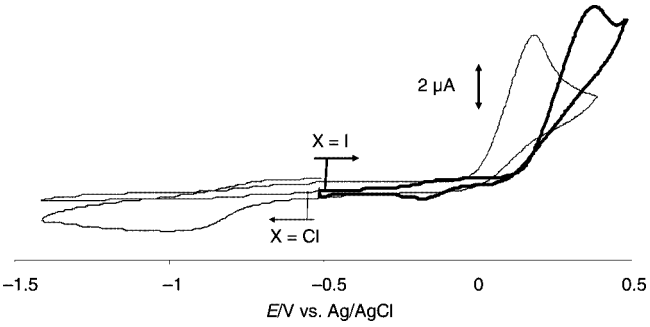

Figure 3. Cyclic voltammogram of $MoOX_2(PMe_3)_3$ in THF. Thinner curve: X = Cl; thicker curve: X = I. $C_{Mo} = 4 \times 10^{-3}$ M. Scan rate = 100 mV/s.

Concerning the voltammogram of the diiodide complex, the greater oxidation potential relative to the dichloride analogue parallels the corresponding shift for the $Mo^{III}$ complexes $MoX_3(PMe_3)_3$ upon going from X = Cl to I.[14] Note the presence of a small reversible wave at about –0.1 V in this voltammogram. This corresponds to the oxidation of $I^-$ to $I_3^-$ (as verified by the deliberate addition of $I^-$ to the solution) and grows with the time lapse between the solution preparation and the voltammetric study. Even upon rapidly recording the voltammogram (as in the example shown in Figure 3), this feature could not be completely eliminated, suggesting the establishment of a slow ligand substitution equilibrium between iodide and THF. The other important observation is that the oxidation of $I^-$ occurs at a less positive potential relative to the oxidation of the (oxido)$Mo^{IV}$ complex. This has implications for the ATRP process (vide infra).

It is interesting to compare the oxidation potentials of $MoOX_2(PMe_3)_3$ with those of the corresponding $MoX_4(PMe_3)_3$. Because of its nonexistence, the $E_{1/2}$ for the oxidation of $MoI_4(PMe_3)_3$ could not be established, but those of the analogous $MoX_4(PMe_3)_3$ complexes are –0.15 V (X = Cl) and –0.06 V (X = Br), allowing extrapolation to a value of about +0.05 for X = I. Thus, we can observe that the replacement of two X ligands by one O ligand has the effect of raising the oxidation potential by about 0.3 V. This change can be related to a lower energy of the HOMO for the oxido compound (Scheme 4), resulting from the greater electronegativity of the oxygen atom. In other words, there is less electron donation by one O atom relative to two I atoms by the σ-bonding mechanism.

## NMR Study of the Halide Exchange Reactions

The conversion of the dichloride to the diiodide complex was monitored by $^1H$ and $^{31}P$ NMR in the presence of NaI in [$D_6$]acetone. Figure 4 shows representative $^{31}P\{^1H\}$ NMR spectra recorded during the transformation. The resonance values for the different compounds are collected in Table 1. Given the *mer-cis* coordination, there are two possible stereoisomers for the mixed halide intermediate, **A** and **B** (see Scheme 5). A *mer-trans* or a *fac* arrangement would only allow a single stereoisomer. The monitoring clearly shows the preferential formation of isomer **A**. The structural assignment of **A** and **B** as shown in Scheme 5 is strongly suggested by the $\delta_P$ resonance pattern, especially the chemical shift of the unique P nucleus, which is expected to be most sensitive to the nature of the *trans*-halide ligand. This resonance shifts very little during the first substitution for isomer **A**, whereas it shifts by a large amount for isomer **B**, to a position close to that observed for the final product. The two mutually *trans*-P nuclei (*cis* to both halide coordination positions), on the other hand, shift gradually with the halide substitution.

A preferential formation of **A** would seem consistent with kinetic control of the halide exchange, as the oxido ligand should exert a stronger *trans* effect relative to the $PMe_3$ ligand. However, the conversion in the opposite direction, which occurs in the presence of $Bu_4N^+Cl^-$ in [$D_6$]acetone, again yields isomer **A** as the *major* intermediate. If the exchange process had been under kinetic control, the prevalence of isomer **B** was expected. Therefore, we conclude that the halide exchange process is under thermodynamic control and that the position *trans* to the oxido ligand is preferentially occupied by the softer iodo ligand.

In order to gain further insight on this issue, we have also carried out a reaction between $MoOI_2(PMe_3)_3$ and NaBr in [$D_6$]acetone. The reaction qualitatively follows the same pathway (see Scheme 6). The use of a small excess amount of NaBr (about 1.3 equiv.) leads to rapid equilibration (4 h at room temperature) with the two mixed halide intermediates having structures **A′** and **B′**, the former being predominant, plus a small amount of the corresponding dibromide.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

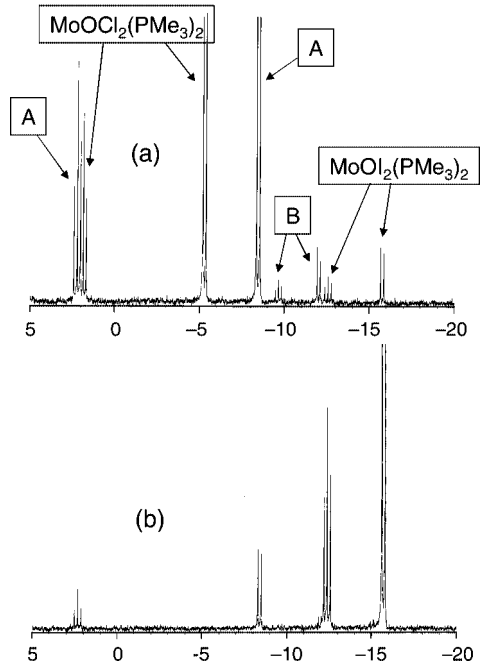

Figure 4. Room-temperature $^{31}P\{^1H\}$ NMR spectra of $MoOCl_2(PMe_3)_3$ (50 mg, 0.12 mmol) and NaI in [$D_6$]acetone (0.6 mL). (a) After 5 h with 1 equiv. NaI; (b) 2.5 h after spectrum (a) with excess NaI.

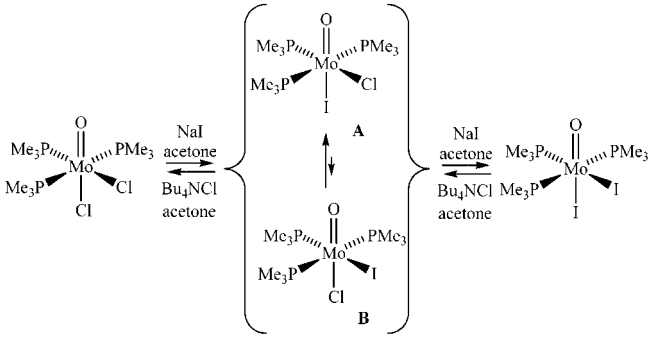
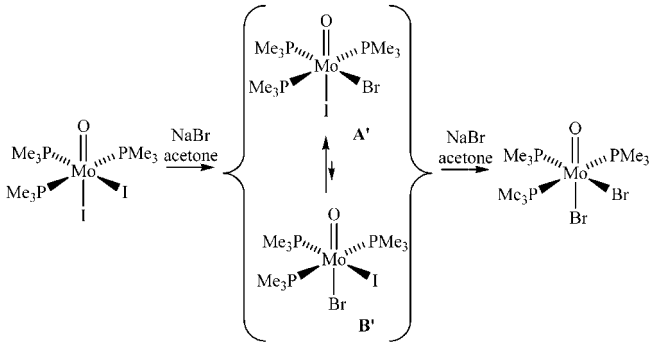


Scheme 5.

Treatment with an excess of NaBr increases the amount of dibromide product. The $^{31}P$ resonance of the unique $PMe_3$ ligand shifts from $\delta$ = –12.5 ppm for the diiodide complex to $\delta$ = –3.6 ppm for **A′** and only to $\delta$ = –10.3 ppm for **B′**. The same nucleus resonates at $\delta$ = –2.8 ppm for the dibromide complex. Once again, the *trans* position to the oxido ligand shows a thermodynamic preference for the softer iodo ligand.



Scheme 6.

It is interesting to note that complex $MoOI_2(PMe_3)_3$ rapidly undergoes halide exchange when dissolved in chloroform (about 50% in 30 min at room temperature). The NMR monitoring indicates the intermediate formation of the mixed halide isomers **A** (major) and **B** (very minor), though the exchange is eventually complete. In dichloromethane, this exchange is much slower, as no significant amount of mixed halide species (**A**) is formed after 20 h of stirring at room temperature. This phenomenon could either take place by an internal nucleophilic substitution assisted by solvent coordination to the metal center, as we have recently pointed out for other transition-metal complexes,[16] or by reversible atom transfer. In the latter case, the phenomenon would suggest that this system could serve as a good catalyst in atom transfer radical polymerization. This has indeed been verified experimentally (vide infra).

As $MoOI_2(PMe_3)_3$ rapidly exchanges its halogen atoms with chloroform, we have also tested the halogen exchange with the initiator molecule used in ATRP, namely (1-bromoethyl)benzene, $PhCH(Br)CH_3$ (BEB). The reaction (Scheme 7) was monitored by $^1H$ NMR, as the C*H* proton is very sensitive to the nature of the halogen atom. At 90 °C in [$D_8$]toluene and using a stoichiometric BEB/Mo ratio (same conditions used for the ATRP experiments, vide infra), the exchange process is essentially complete after 40 min (see Figure 5). A slower exchange is also observed at room temperature. $^{31}P$ NMR monitoring shows that the reaction proceeds through the same intermediates seen

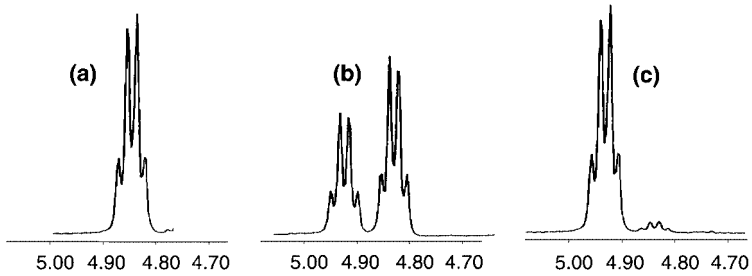


Figure 5. $^1H$ NMR monitoring of the halogen exchange between $MoOI_2(PMe_3)_3$ and BEB in [$D_8$]toluene at 90 °C ([Mo] = [BEB] ≈ 0.1 mol/L). (a) $t$ = 0 min. (b) $t$ = 20 min. (c) $t$ = 40 min.

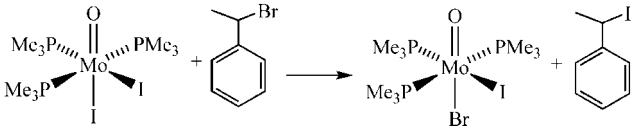
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

when using NaBr, namely $MoOBrI(PMe_3)_3$ (**A′** and **B′**, the former being predominant). The quantitative nature of the exchange illustrates the thermodynamic preference for placing the heavier halogen on the carbon atom and the lighter one on the metal atom. On the basis of Pearson's HSAB theory,[25] this result may be interpreted in terms of a harder character for the $Mo^{IV}$ center with respect to carbon.



Scheme 7.

### Controlled Radical Polymerizations

Complexes $MoOX_2(PMe_3)_3$ were tested as catalysts for the controlled radical polymerization of styrene and methyl acrylate under ATRP conditions. The experimental conditions and apparent polymerization rates for the styrene polymerization are summarized in Table 3. In each case, the first-order monomer consumption rate was verified by the linearity of the $\ln([M]_0/[M])$ versus time plot, indicating that the concentration of active radical remains constant throughout the polymerization process, as expected for a controlled process. The polymerization was carried out both in the absence and in the presence of an equivalent amount of the $Al(OiPr)_3$ cocatalyst, whose effectiveness in ATRP seems quite general. In fact, it has been demonstrated that the apparent polymerization rates increase by factors up to 10 or more when 1 equiv. of this compound is used in conjunction with a variety of different catalysts based on Group 6–11 metals, including $CpMoCl_2(i\text{PrN=CH–CH=N}i\text{Pr})$,[6] $MoX_3(PMe_3)_3$,[14] $ReIO_2(PPh_3)_2$,[7] $CpFeX(CO)_2$ (X = Br, I),[8] $RuCl_2(PPh_3)_3$,[10] $NiBr_2(PPh_3)_2$,[11] $Ni(PPh_3)_4$,[12] and CuBr/bipy.[13] The proposed mode of action of this cocatalyst consists of a shift of the atom transfer equilibrium, caused by the stronger interaction of the Al Lewis acid with the halogen lone pairs in the more polarized Mo–X bond, relative to the C–X bond of the initiator/dormant species.[16] Table 3 shows that $Al(OiPr)_3$ is also effective in conjunction with the $MoOX_2(PMe_3)_3$ catalysts, although by a smaller margin. In each case, the apparent polymerization rate approximately doubles when 1 equiv. of $Al(OiPr)_3$ is added. Note also that the diiodide system is about twice as fast as the dichloride system.

Table 3. ATRP of styrene using $MoOX_2(PMe_3)_3$ (X = Cl, I) catalysts.[a]

| Entry | X | Mo/I/Al/S[b] | $k_{app}$ [$min^{-1}$] |
|---|---|---|---|
| 1 | Cl | 1:1:–:200 | $2.18\times10^{-4}$ |
| 2 | Cl | 1:1:1:200 | $4.38\times10^{-4}$ |
| 3 | I | 1:1:–:200 | $4.26\times10^{-4}$ |
| 4 | I | 1:1:1:200 | $9.54\times10^{-4}$ |

[a] All polymerizations were carried out in toluene at 90 °C. [b] I: initiator (BEB); Al: $Al(OiPr)_3$ cocatalyst; S: styrene.

For each dihalide catalyst and in the absence of $Al(OiPr)_3$, the experimentally determined number-average molecular weights ($M_n$) of the polymer grow linearly with the monomer conversion and correspond closely to the theoretical molecular weights on the basis of the monomer/initiator ratio (see Figure 6a, c). These characteristics are as expected for a controlled radical polymerization process. Furthermore, the polydispersity indexes (PDI = $\bar{M}_w/\bar{M}_n$) are quite low, down to 1.11. These are the lowest PDIs reported to date for an Mo-based catalyst, underlining the excellent level of control exerted by these oxidomolybdenum(IV) complexes. At high conversions, the experimental $M_n$ value is slightly lower than the theoretical one for the dichloride system, whereas it is slightly higher for the diiodide system. The former effect could result from the slight intervention of chain transfer processes, whereas the latter one could find a rationalization in an initiator efficiency slightly lower than 100% ($f < 1$). In the presence of $Al(OiPr)_3$, the dichloride catalyst appears to insure a less effective control, as the PDIs are higher (about 1.3 at 75% conversion), although $M_n$ still grows linearly with conversion (see Figure 6b), and the monomer consumption follows first-order kinetics. In addition, the experimental $M_n$ value is about two times larger than the calculated one (i.e. $f \approx 0.5$). The diiodide catalyst also controls the polymerization a little less effectively in the presence of $Al(OiPr)_3$, but $f$ remains close to 1 (see Figure 6d). At the moment, we are not able to rationalize why the nature of the halogen has such a large effect on the initiator efficiency, and only for the experiments carried out in the presence of $Al(OiPr)_3$.

The putative coordination compounds produced by the atom transfer process could not be characterized. From the electrochemical study, we have established that the oxidation potential of complex $MoOCl_2(PMe_3)_3$ is less positive than those of the free $Cl^-$ or $Br^-$ ions.[14] Therefore, the oxidized complex $[MoOCl_2(PMe_3)_3]^+$ is compatible with the presence of these ions or, in other words, complex $MoOCl_2X(PMe_3)_3$ (X = Cl, Br) is predicted to be a stable system from the redox point of view. Nonetheless, the electrochemical study indicates instability for $MoOCl_3(PMe_3)_3$, at least in the THF solvent used for the cyclic voltammetric investigation. On the other hand, the free iodide ion is oxidized at a less positive potential than both complexes $MoOX_2(PMe_3)_3$ (X = Cl, I). This means that the putative ATRP spin trap, namely an (oxido)$Mo^V$ complex of type $MoOX_2Y(PMe_3)_3$, is thermodynamically unstable when either X or Y is an iodine atom, relative to an internal redox process leading to the reduction of $Mo^V$ to $Mo^{IV}$ and oxidation of $I^-$. This observation might seem inconsistent with the ability of $MoOI_2(PMe_3)_3$, in combination with a bromide initiator, to catalyze the ATRP of styrene with a controlled chain growth. However, our recently published investigation of the $MoI_3(PMe_3)_3$ ATRP catalyst, for which the same apparent contradiction was observed, provides the basis to rationalize this phenomenon.[14] In essence, the oxidized $MoOI_2Br(PMe_3)_3$ complex is capable of efficiently acting as a spin trap for the growing radical chain for kinetic reasons, its decomposition being a bimolecular reaction

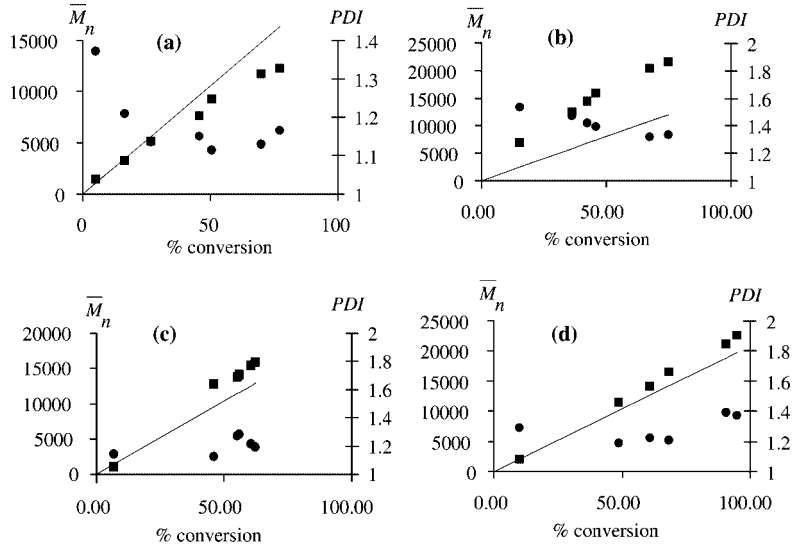

Figure 6. $M_n$ vs. conversion and PDI for the ATRP of styrene catalyzed by $MoOX_2(PMe_3)_3$ (X = Cl, I). Conditions are given in Table 3 (Entries 1–4). Squares: experimental $M_n$; circles: PDI; straight line: theoretical $M_n$. (a) X = Cl, no Al(O*i*Pr)$_3$ (Entry 1); (b) X = Cl, with Al(O*i*Pr)$_3$ (Entry 2); (c) X = I, no Al(O*i*Pr)$_3$ (Entry 3); (d) X = I, with Al(O*i*Pr)$_3$ (Entry 4).

and involving a greater activation barrier than the radical trapping process.

The polymerization of methyl acrylate was not well controlled by these (oxido)$Mo^{IV}$ complexes. Initial experiments carried out with each dihalide complex at 90 °C with ethyl 2-iodopropionate as an initiator gave very fast polymerizations, with greater than 90% conversion after the first 300 min. The reaction was therefore repeated at a lower temperature (35 °C). Even under these conditions, however, the polymerization process remained quite fast. With complex $MoOCl_2(PMe_3)_3$ the conversion was initially high and slowed down at later times (the monomer decay did not follow a first-order rate law), reaching about 60% conversion in 6 d. With complex $MoOI_2(PMe_3)_3$, the process was even faster, reaching 100% conversion in about 18 h. In both cases, the molecular weights were much larger than expected on the basis of a controlled process, and the PDIs were quite high (>1.5), see for instance Figure 7 for the chloride system. This behavior is consistent with an atom transfer process that is not sufficiently shifted toward the dormant species. Further studies under different conditions (nature of the initiator, different cocatalysts) will need to be carried out in order to optimize this process.

In order to check whether the OMRP equilibrium also plays a role in the ATRP catalyzed by $MoOX_2(PMe_3)_3$, the polymerization of styrene was also carried out using AIBN as a thermal initiator in the presence of these compounds. After heating at 100 °C for 30 min to decompose most of the initiator, the temperature was set to 80 °C for the rest of the experiment. The polymerizations were not controlled, with conversions reaching 30% within the first 4 h and then increasing slowly to 65% over the next 4 d. There was no first-order monomer consumption, and the PDIs remained consistently high throughout the experiment. These results are typical of an uncontrolled free radical process. Only a minor retardation effect was noted in the presence of the

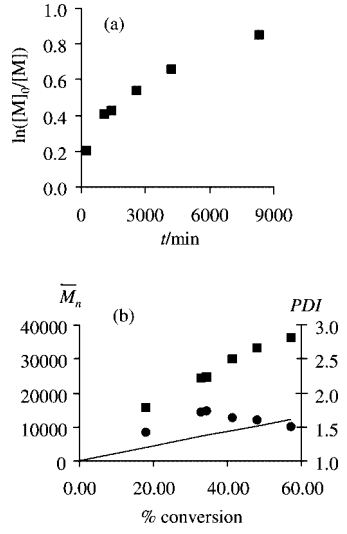

Figure 7. Polymerization of methyl acrylate catalyzed by $MoOCl_2(PMe_3)_3$ at 35 °C. Conditions: Mo/I/Al/MA = 1:1:1:250 [MA: methyl acrylate; I (initiator): ethyl 2-iodopropionate; Al: Al(O*i*Pr)$_3$]. (a) Kinetics plot. (b) $M_n$ vs. conversion and PDI. Squares: experimental $M_n$; circles: PDI; straight line: theoretical $M_n$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metal complexes (e.g. see Figure 8). This suggests the possibility of a radical-trapping process by the $MoOX_2(PMe_3)_3$ complex, but the stability of the adduct is insufficient. In conclusion, the $MoOX_2(PMe_3)_3$ complexes are not capable of efficiently trapping the reactive radical of polystyrene and form sufficiently persistent dormant species.

## Conclusions

The current investigation has shown, for the first time, the ability of $Mo^{IV}$ complexes to function as ATRP catalysts. Both the well-known dichloro complex and its newly developed diiodo analogue are equally capable of producing polystyrenes with rather narrow polydispersities. The diiodide catalyst gives higher apparent polymerization rates, and the rate is further doubled in the presence of 1 equiv. of $Al(OiPr)_3$ for each catalyst. We could not isolate and characterize the metallic spin traps, which are expected to be $Mo^{V}$ complexes of the formula $MoOX_2Y(PMe_3)_3$ (X, Y = Cl, Br, I). The electrochemical studies indicate instability for these complexes, at least in THF. In addition, the iodide-containing system is thermodynamically unstable with respect to an intramolecular redox process. However, as we have recently demonstrated for a related catalyst,[14] it is not necessary for the spin trap to be a thermodynamically stable compound. It remains capable of performing the radical-trapping function, thereby regulating the concentration of the active organic radical, for kinetic reasons. We are now interested in testing these oxidomolybdenum(IV) complexes as well as other similar compounds in the polymerization (under ATRP and SFRP conditions) of other monomers.

## Experimental Section

**General:** All manipulations were carried out under dry and oxygen-free argon with standard Schlenk techniques. Styrene was washed with aqueous NaOH (10%), neutralized with water, dried with $MgSO_4$ and then distilled at 25 °C under reduced pressure. Toluene and pentane were purified by distillation under argon after drying with sodium/benzophenone ketyl. $CH_2Cl_2$ was purified with $P_4O_{10}$ and distilled under argon. 1-Bromo-1-phenylethane [or (1-bromoethyl)benzene, BEB] and $Al(OiPr)_3$ were purchased from Aldrich Chemical Co., and used as received. Complex $MoOCl_2(PMe_3)_3$ was prepared according to the literature.[21,23] A slight modification of the procedure described in ref.[21] with use of complex $MoCl_4(EtO)_2$ instead of $MoCl_4(THF)_2$ as starting material gave the product in the form of a blue solid containing a small percentage of the $MoCl_3(PMe_3)_3$ byproduct, as shown by $^1H$ NMR spectroscopy.[20] The procedure described in ref.[23] afforded a pure product (deep blue solid) in 70% yield.

**Physical Measurements:** The cyclic voltammograms were obtained with an EG&G 362 potentiostat connected to a Macintosh computer through MacLab hardware/software. The electrochemical cell was fitted with an Ag/AgCl reference electrode, a platinum disk working electrode and a platinum wire counter electrode. $[Bu_4N]PF_6$ (about 0.1 M) was used as supporting electrolyte. The ferrocene standard was added to each solution and measured at the end of the experiments. Its potential was $E_{1/2}$ = +0.50 V under our experimental conditions. NMR spectra were recorded with a Bruker DRX 400 MHz spectrometer. The peak positions are reported with positive shifts in ppm downfield of TMS, as calculated from residual solvent peaks. Digital simulation of the $^{31}P$ NMR spectrum was carried out with MestReC.[26] The molecular weight distribution, $\bar{M}_n$ and $\bar{M}_w/\bar{M}_n$ of the polymers, was measured by size-exclusion chromatography (SEC) using THF as eluent (1 mL/min) at room temperature on a 300 × 7.5 mm PLgel 5-μm Mixed-D column (Polymer Laboratories), equipped with multiangle light scattering (miniDawn Tristar, Wyatt Technology Corp.) and refractive index (RI2000, Soparès) detectors.

**Synthesis of $MoOI_2(PMe_3)_3$:** An excess of NaI (795 mg, 5.3 mmol) was added to a solution of $MoOCl_2(PMe_3)_3$ (435 mg, 1.06 mmol) in freshly distilled THF (15 mL). The solution was then stirred at 50 °C for 2 h to achieve completion, although after 10 min it was possible to observe the formation of a white precipitate of NaCl. After removing the volatiles under reduced pressure, the crude residue was redissolved in toluene (15 mL) to eliminate the insoluble salts of NaI and NaCl. Then pentane (25 mL) was added to the toluene solution to precipitate complex $MoOI_2(PMe_3)_3$ as an emerald-green solid, which was filtered and washed with pentane (2 × 10 mL). Yield 314 mg, 50%. Single crystals for X-ray diffraction were obtained by slow diffusion of pentane into a concentrated solution of the product in toluene. The NMR properties are collected in Table 1. $C_9H_{27}I_2MoOP_3$ (593.98): calcd. C 18.20, H 4.58; found C 18.30, H 4.28. The compound was soluble and stable in THF, acetone, and aromatic hydrocarbons. It dissolved in $CDCl_3$ but gave rise to rapid halogen exchange in this solvent.

**X-ray Structural Studies:** A single crystal of each compound was mounted under inert perfluoropolyether on the tip of a glass fiber and cooled in the cryostream of either a Stoe IPDS diffractometer [for $MoOI_2(PMe_3)_3$] or an Oxford-Diffraction XCALIBUR CCD diffractometer [for $\{MoCl_2O(PMe_3)(OPMe_3)\}_2O$]. The structures were solved by direct methods (SIR97)[27] and refined by least-squares procedures on $F^2$ using SHELXL-97.[28] All H atoms attached to carbon atoms were introduced in idealized positions and treated as riding models. The absolute structure for $MoOI_2(PMe_3)_3$ was confirmed by the refinement of Flack's enantiopole parameter[29,30] and by careful examination of the sensitive reflections. The drawing of the molecules was realized with the help of ORTEP32.[31] Crystal data and refinement parameters are shown in Table 4. CCDC-294667 and -294668 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Controlled Radical Polymerizations:** All ATRP polymerization reactions were conducted according to the same experimental procedure. A typical procedure is described as a representative example. $MoOCl_2(PMe_3)_3$ (54 mg, 0.13 mmol) was added to a 25-mL Schlenk tube equipped with a stirring bar. Styrene (3 mL, 26 mmol), toluene (6 mL), and (1-bromoethyl)benzene (17.7 μL, 0.13 mmol) were added to the reaction flask by a syringe after a 20-min Ar purge. The Schlenk tube was immersed in an oil bath heated at 90 °C. Aliquots were withdrawn periodically for monitoring. All OMRP polymerization reactions were conducted according to the same experimental procedure. A typical procedure is described as a representative example. $MoOI_2(PMe_3)_3$ (21 mg, 0.035 mmol) and AIBN (2.9 mg, 0.018 mmol) were added to a 15-mL Schlenk tube equipped with a stirring bar. Styrene (1 mL, 8.7 mmol) and toluene (2 mL) were added to the reaction flask by a syringe after a 20-min Ar purge. The Schlenk tube was immersed during 30 min in an oil bath heated at 100 °C and at 80 °C for the

# Stepwise Sulfuration of the Terminal Phosphido Complex *trans*-[PtCl(PHCy$_2$)$_2$(PCy$_2$)]: Synthesis of [Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$)(PHCy$_2$)$_2$]Cl and [Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$){κ*P*-P(S)Cy$_2$}(PHCy$_2$)] and Crystal Structure of [Pt(κ$^2$-*S*,*S*-PCy$_2$S$_2$)(κ-*S*-PCy$_2$S$_2$)(PHCy$_2$)]

**Vito Gallo,[a] Mario Latronico,[a,b] Piero Mastrorilli,*[a] Cosimo Francesco Nobile,[a] Giuseppe Ciccarella,[c] and Ulli Englert[d]**

**Keywords:** Platinum / Terminal phosphides / Phosphanyl sulfides / Phosphanyldithioates / Phosphorus

The terminal phosphido complex *trans*-[PtCl(PHCy$_2$)$_2$(PCy$_2$)] (**1**) has been prepared, exploiting the reversibility of the reaction with HCl, by action of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) on [PtCl(PHCy$_2$)$_3$]Cl, and its reactivity towards elemental sulfur studied. The first product obtained by reaction of **1** with 1 equiv. of sulfur is *trans*-[PtCl(PHCy$_2$)$_2${κ*P*-P(S)Cy$_2$}] (**2**), which rapidly isomerises in halogenated solvents into *cis*-[PtCl(PHCy$_2$)$_2${κ*P*-P(S)Cy$_2$}] (**3**). Further addition of sulfur causes the formation of a mixture of [Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$)(PHCy$_2$)$_2$]Cl (**4**) and [Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$){κ*P*-P(S)Cy$_2$}(PHCy$_2$)] (**5**), which could be selectively synthesised; the first upon sulfuration of pure **3** and the second by reaction of **4** with 1 equiv. of sulfur in the presence of DBU. Complex **5** can be further sulfurated to [Pt(κ$^2$*S*,*S*′-PCy$_2$S$_2$)(κ*S*-PCy$_2$S$_2$)(PHCy$_2$)] (**6**), which is fluxional in solution and was also characterised by single-crystal X-ray diffraction.

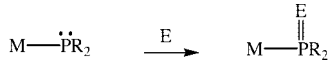
## Introduction

Terminal phosphides are interesting albeit rare ligands, the reactivity of which depends mainly on the characteristics of the lone pair on the phosphorus atom. The first terminal phosphido complexes were prepared in 1968 by reaction of CpFe(CO)$_2^-$ or CpMo(CO)$_3^-$ with P(C$_6$F$_5$)$_2$Cl to give Cp(CO)$_2$Fe[P(C$_6$F$_5$)$_2$] and Cp(CO)$_3$Mo[P(C$_6$F$_5$)$_2$], respectively.[1] From then on, a number of terminal phosphido complexes have been prepared mainly by two routes: (i) the reaction of diorganometal phosphides with a metal species;[2–16] (ii) the deprotonation of a coordinated phosphane bearing at least a P–H bond by means of an appropriate base {1,8-diazabicyclo[5.4.0]undec-7-ene (DBU),[17–19] methoxide, OH$^-$,[20–24] *t*BuO$^-$,[25–29] [N(SiMe$_3$)$_2$]$^-$,[30–32] NEt$_3$,[33] BuLi[34]} that, in some instances, was previously coordinated onto the metal atom.[35–39]

The reactivity of terminal phosphido complexes is determined by the presence of the lone pair on the phosphorus atom, which renders such molecules highly nucleophilic. Such high nucleophilicity has been exploited for the synthesis of phosphido-bridged heterodimetallic species,[40] and is also responsible for the ease of protonation of the three-coordinate phosphorus atom[13,20,41–43] as well as for its reactivity with MeI.[41,43–47]

The typical reaction of coordinated terminal phosphides with chalcogens transforms the trivalent into a pentavalent phosphorus atom bound to the chalcogen as in Scheme 1.



Scheme 1. Typical addition of chalcogens E to coordinated terminal phosphides.

Such reactivity is shown by Ir(CO)(Cl)$_2$(PEt$_3$)$_2$(PF$_2$) (reaction with O$_2$, S$_8$ or Se),[48] (η$^5$-C$_5$H$_5$)Ru(PEt$_3$)$_2$(PPh$_2$) (reaction with O$_2$),[25] (η$^5$-C$_5$H$_5$)Re(NO)(PPh$_3$)$_2$(PR$_2$) (R = Ph, *t*Bu, reaction with O$_2$),[28] (η$^5$-C$_5$H$_5$)Fe(CO)$_2$[P(CF$_3$)$_2$] (reaction with S$_8$),[49] (η$^5$-C$_5$H$_5$)M(CO)$_3$(PCl$_2$) (M = Cr, reaction with S$_8$; M = W, reaction with S$_8$, Se)[50] and (η$^5$-C$_5$H$_5$)M(CO)$_2$(L)(PPh$_2$) (L = CO or PMe$_3$, M = Mo, reaction with S$_8$; M = W, reaction with S$_8$, Se).[41,51]

We have recently described the synthesis and characterisation of *trans*-[PtCl(PHCy$_2$)$_2$(PCy$_2$)Cl] (**1**) obtained by reaction of *cis*-PtCl$_2$(PHCy$_2$)$_2$ with LiPCy$_2$.[52] Complex **1** is stable under inert gases but reacts promptly with dry dioxygen to give the hydrogen-bound bis(phosphinito) complex [PtCl(PHCy$_2$){P(O)Cy$_2$}$_2$H][53] and with hydrogen peroxide to give *trans*-[PtCl(PHCy$_2$)$_2${κ*P*-P(O)Cy$_2$}Cl].[54]

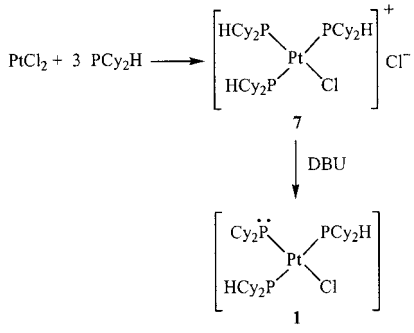
Herein we describe the stepwise sulfuration of **1** leading to the compounds *trans*-[PtCl(PHCy$_2$)$_2${κ*P*-P(S)Cy$_2$}] (**2**), *cis*-[PtCl(PHCy$_2$)$_2${κ*P*-P(S)Cy$_2$}Cl] (**3**), [Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$)(PHCy$_2$)$_2$]Cl (**4**), [Pt(κ$^2$*S*,*S*′-PCy$_2$S$_2$)(PHCy$_2$){κ*P*-P(S)Cy$_2$}] (**5**) and [Pt(κ$^2$*S*,*S*′-PCy$_2$S$_2$)(κ*S*-PCy$_2$S$_2$)(PHCy$_2$)] (**6**).

## Results and Discussion

### Reversible Protonation of 1

Reaction of *trans*-[PtCl(PHCy$_2$)$_2$(PCy$_2$)] (**1**) with gaseous HCl results in the fast and complete protonation of the coordinated terminal phosphide with formation of the cationic Pt$^{II}$ complex [PtCl(PHCy$_2$)$_3$]Cl (**7**). In order to test the reversibility of the protonation reaction of **1**, a toluene suspension of **7** was treated with DBU, leading to the quantitative formation of **1** as the only soluble product, so that the reaction sequence shown in Scheme 2 represents the most convenient way for preparing **1**.

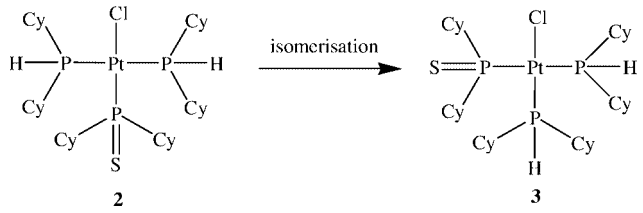


Scheme 2.

### Reaction with $S_8$

Reaction of **1** with sulfur carried out in toluene at room temperature using an S/Pt molar ratio of 1.0 resulted in the formation of the *P*-bound thiophosphinito complex *trans*-[PtCl(PHCy$_2$)$_2${κ*P*-P(S)Cy$_2$}] (**2**).[54] Dissolving **2** in halogenated solvents, the irreversible isomerisation into the thermodynamically favoured *cis* complex **3** took place as indicated in Scheme 3. This isomerisation was completed in 5 min by heating the reaction mixture at 40 °C.

When an excess of sulfur (S/Pt molar ratio of 8) was treated with **1** in toluene, the reaction led, after 1 h, to a mixture of two new sulfur-containing platinum complexes, **4** and **5**, along with *cis*-PtCl$_2$(PHCy$_2$)$_2$ and dicyclohexylphosphane sulfide P(S)HCy$_2$ (Scheme 4).



Scheme 3.

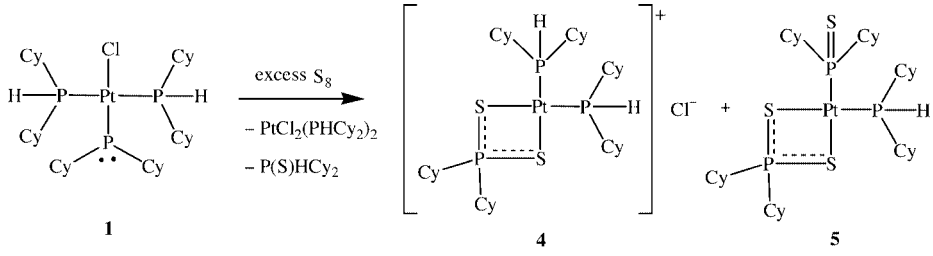
Complex **4**, which incorporates two S atoms, showed two $^{31}$P{$^1$H} NMR signals in CDCl$_3$ at $\delta$ = 136.6 ($^2J_{P,Pt}$ = 151 Hz) and $\delta$ = 2.0 ($^1J_{P,Pt}$ = 3048 Hz), which support a structure in which the sulfur atoms are bound to the phosphide P atom and chelate the platinum atom. The remaining coordination sites are occupied by two PHCy$_2$ ligands, mutually *cis*. Accordingly, the $^{195}$Pt{$^1$H} NMR spectrum in CDCl$_3$ consists of a triplet ($^1J_{Pt,P}$ = 3048 Hz) of doublets ($^2J_{Pt,P}$ = 151 Hz) centred at $\delta$ = –4596 ppm. Compound **4** can be therefore formulated as [Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$)(PHCy$_2$)$_2$]Cl, a dithiophosphinato complex of Pt$^{II}$. ESI-MS analysis confirmed this formulation by comparison of the measured isotope pattern centred at 852.35 Da with that calculated on the basis of the natural abundances.

Recording the $^{31}$P{$^1$H} and $^1$H NMR spectra of **4** in different solvents, we noticed that the resonance of (PS$_2$Cy$_2$) remained almost unchanged ($\delta$ = 134–138 ppm), whilst the chemical shift of the coordinated PHCy$_2$ ligand ranged from $\delta$ = –5.9 to 10.0 ppm ($^{31}$P) and from $\delta$ = 4.3 to 6.8 ppm ($^1$H) (Table 1).

Table 1. $^{31}$P{$^1$H} and $^1$H NMR spectroscopic data of **4** in different solvents.

| | *P*S$_2$ | *P*H | P*H* |
|---|---|---|---|
| C$_6$D$_6$ | 134 | –5.9 | 6.83 |
| CDCl$_3$ | 137 | 2.0 | 5.15 |
| CD$_2$Cl$_2$ | 139 | 9.3 | 4.32 |
| CD$_3$CN | 140 | 10.0 | 4.43 |

Such behaviour could be explained invoking a hydrogen bond interaction between the P–H of the cationic complex and the chloride anion, an interaction already found for [PtCl(PCy$_2$H)$_3$]Cl.[54] In order to confirm such a hypothesis we have compared the $^{35}$Cl NMR spectra recorded in CD$_2$Cl$_2$ before and after the addition of CD$_3$OD as a hydrogen bond breaker. No signal could be observed in the $^{35}$Cl NMR spectrum recorded in CD$_2$Cl$_2$, as expected for a



Scheme 4.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

quadrupolar nucleus surrounded by an asymmetric electron cloud. However, the addition of a few drops of $CD_3OD$ caused the rupture of the ion pairs, leaving the chloride anion in a nearly symmetric solvation sphere, and permitted the observation of a broad $^{35}Cl$ NMR signal centred at $\delta$ = –18 ppm after the same number of scans (Figure 1).

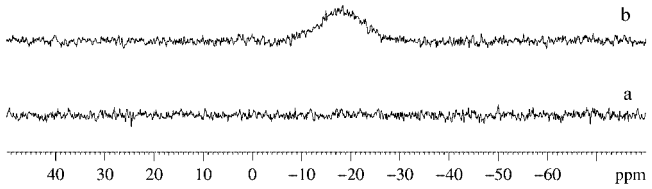


Figure 1. $^{35}Cl$ NMR spectrum of **4** (39 MHz, 295 K); a) in $CD_2Cl_2$; b) after the addition of a few drops of $CD_3OD$.

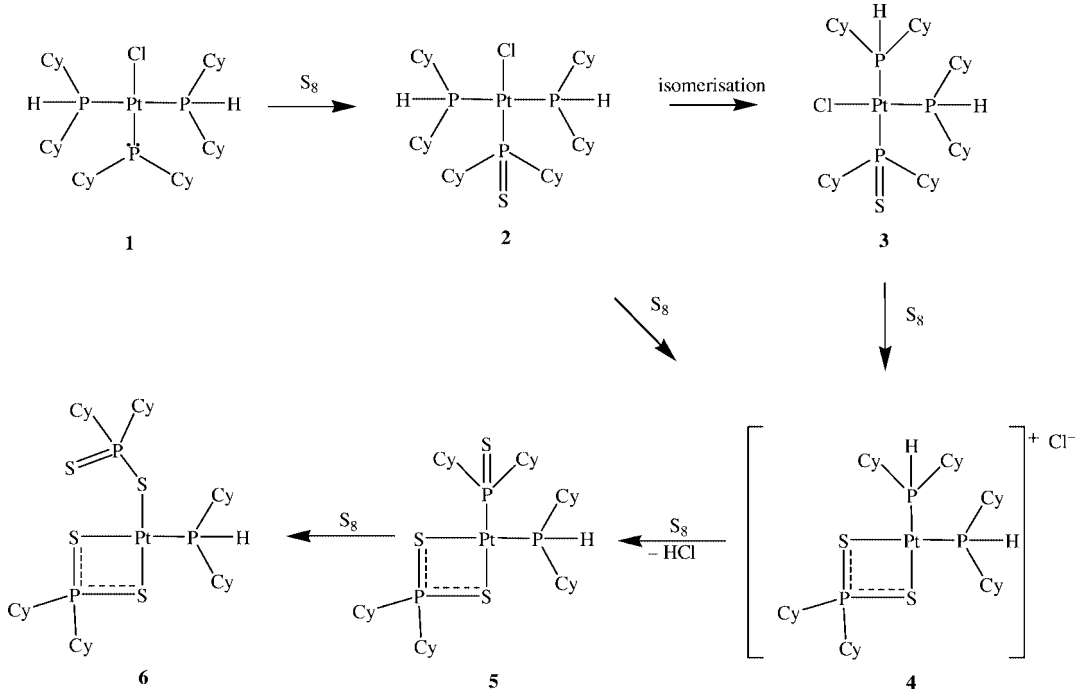
Pure **4** could be isolated from the reaction of **3** with 1 equiv. $S_8$ in dichloromethane at room temperature and showed IR bands ascribable to PH (2272 $cm^{-1}$) and $PS_2$ stretchings (591, 553 $cm^{-1}$).

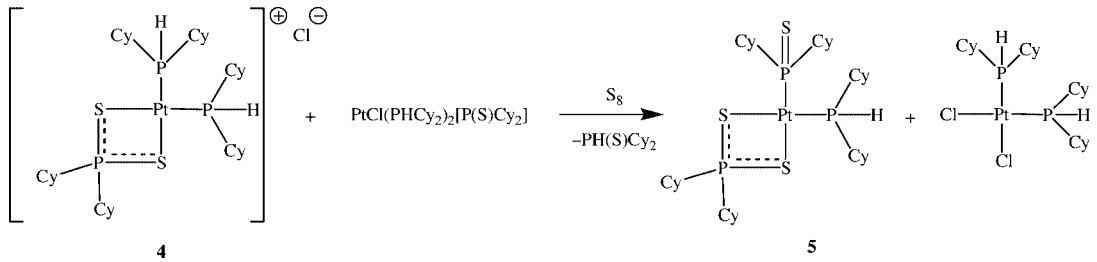
Complex **5** incorporates three atoms of S and gives in $C_6D_6$ three $^{31}P\{^1H\}$ NMR signals flanked by $^{195}Pt$ satellites at $\delta$ = 127.2, 48.4 and 38.9 ppm. Of these, that at $\delta$ = 38.9 ppm can be attributed to a coordinated $PHCy_2$ ligand (proton-coupled spectrum gave $^1J_{P,H}$ = 424 Hz) and that at $\delta$ = 48.4 ppm can be attributed, on the basis of its chemical shift and $^1J_{P,Pt}$ value (2977 Hz), to a *P*-bound $P(S)Cy_2$ ligand *cis* to $PHCy_2$. The remaining signal at $\delta$ = 127.2 ppm is flanked by satellites from which a $^2J_{P,Pt}$ value of 137 Hz was extracted and can be attributed to a chelating dithiophosphinate ligand, $PS_2Cy_2$. The $^{195}Pt\{^1H\}$ NMR spectrum consists of a doublet of doublets of doublets centred at $\delta$ = –4522 ppm and the proposed structure for **5** is [Pt($\kappa^2$*S*,*S*′-$PS_2Cy_2$){κ*P*-$P(S)Cy_2$}($PHCy_2$)].

Complex **5** could be obtained in high yield by treating **4** with $S_8$ in the presence of DBU as proton scavenger, and showed P=S (of the thiophosphinite ligand) and PH IR stretchings at 597 and 2366 $cm^{-1}$ respectively. Comparison of the IR features of complexes **2**, **4** and **5** allowed us to assign the $\nu PS_2$ bands of **5** at 556 ($\nu_{sym.}$) and 597 ($\nu_{asym.}$). Such assignments are consistent with those reported for $R_2PS_2$ complexes.[55–57]

A mechanism for the reaction of **1** with excess sulfur in $CH_2Cl_2$ is depicted in Scheme 5. The initially formed **2** par-



Scheme 5. Stepwise sulfuration of **1**.



Scheme 6.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tially isomerises into **3**. Both **2** and **3** can incorporate one more S atom yielding **4**. The subsequent sulfuration of **4** into **5** requires a proton scavenger, as confirmed by the lack of reaction between **4** and $S_8$ in the absence of DBU.

In the reaction medium, possible proton scavengers are the thiophosphinite complexes **2** and **3**, whose products of HCl formal addition are P(S)HCy$_2$ and Pt(PHCy$_2$)$_2$Cl$_2$, effectively found as byproducts (Scheme 6).

Compound **5** reacted slowly (several weeks) with elemental sulfur in toluene solution to give the bis(dithiophosphinato)phosphane product Pt(κ$^2$*S*,*S*-PCy$_2$S$_2$)(κ*S*-PCy$_2$S$_2$)(PHCy$_2$) (**6**, Scheme 5), which precipitated from the reaction medium.

Complex **6** showed IR bands in the PS region (650–500 cm$^{-1}$) attributable to bidentate (620 and 527 cm$^{-1}$) and unidentate (598 and 559 cm$^{-1}$) PCy$_2$S$_2$ ligands (Table 2).[55,58]

Table 2. Characteristic IR bands in the PS region.

| Complex | P(S)Cy$_2$ | PS$_2$Cy$_2$ Bidentate | | PS$_2$Cy$_2$ Monodentate | |
|---|---|---|---|---|---|
| | $\nu$ | $\nu_{sym.}$ | $\nu_{asym.}$ | $\nu_{sym.}$ | $\nu_{asym.}$ |
| **2** | 579 | | | | |
| **3** | 577 | | | | |
| **4** | | 553 | 591 | | |
| **5** | 597 | 556 | 597 | | |
| **6** | | 559 | 598 | 527 | 620 |
| **8** | | 561 | 595 | | |

The $^{31}$P{$^1$H} NMR spectrum of **6** in C$_6$D$_6$ showed three resonances at $\delta$ = 124.8, 81.8 and 2.5 ppm ascribable to bidentate PCy$_2$S$_2$, unidentate PCy$_2$S$_2$ and PHCy$_2$, respectively. Complexes of the general formula M(PS$_2$)$_2$(P) (where PS$_2$ represents a dithiophosphinato and P a tertiary phosphane) have long been known as the reaction products between M(PS$_2$)$_2$ and P in polar solvents[55] and, in fact, we could prepare **6** in high yield also starting from [Pt(κ$^2$*S*,*S*′-PCy$_2$S$_2$)$_2$] (**8**) and 1 equiv. of PHCy$_2$ in toluene.

As already noticed for related complexes,[59–61] dynamic $^{31}$P{$^1$H} and $^{195}$Pt{$^1$H} NMR experiments (Figures 2 and 3) demonstrated the existence, for compound **6**, of a rapid interchange of bidentate and unidentate dithiophosphinates (Scheme 7).

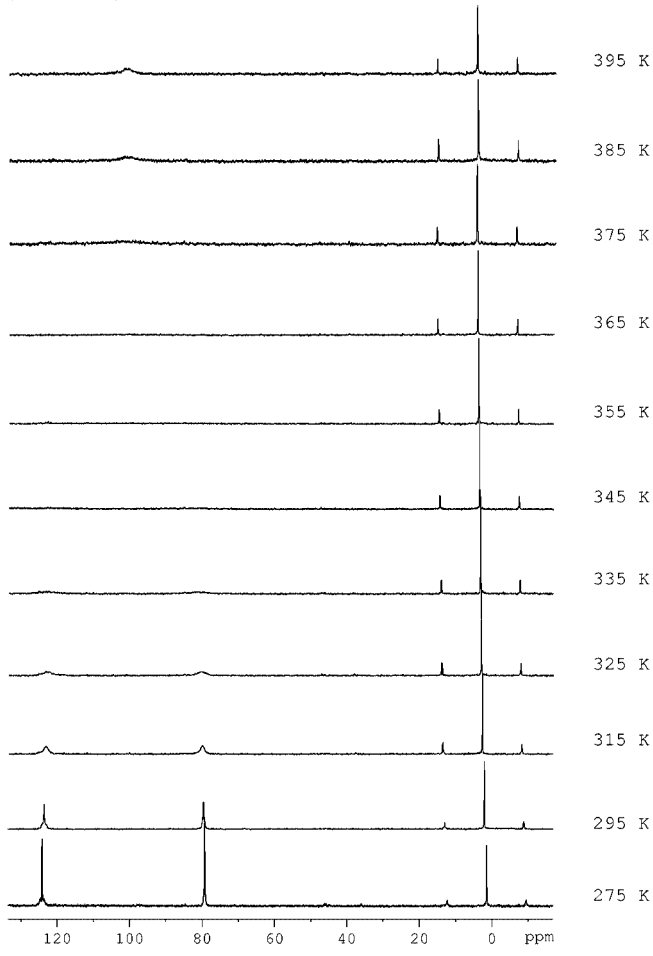


Figure 2. Variable-temperature $^{31}$P{$^1$H} NMR spectra of **6** in 1,2-dichlorobenzene.

Accordingly, the $^{31}$P EXSY experiment showed an intense exchange cross-peak between the signals at $\delta$ = 124.8 ppm (bidentate PS$_2$Cy$_2$) and $\delta$ = 81.8 ppm (uniden-

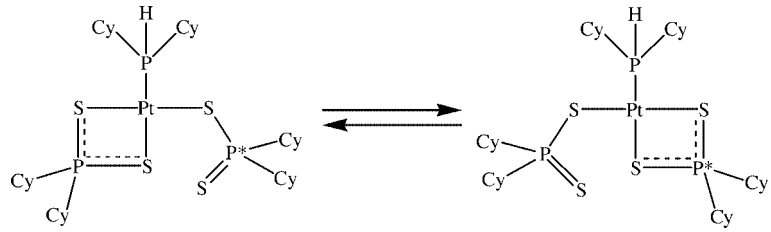

Scheme 7.

tate $PS_2Cy_2$) (Figure 4). Variable-temperature $^{31}P\{^1H\}$ NMR spectra allowed us to calculate an activation $\Delta G^{\ddagger}$ value of 59 ± 1 kJ/mol. Such a value is fully consistent with those obtained in the related complexes $Pt(Me_2PS_2)(PPh_3)$ ($\Delta G^{\ddagger}$ = 56 kJ/mol),[60,62] $Pt(Me_2PS_2)(PPh_2C_6F_5)$ ($\Delta G^{\ddagger}$ = 55 kJ/mol)[62] and $Pt\{(OEt)_2PS_2\}(PPh_3)$ ($\Delta G^{\ddagger}$ = 52 kJ/mol).[60,61]

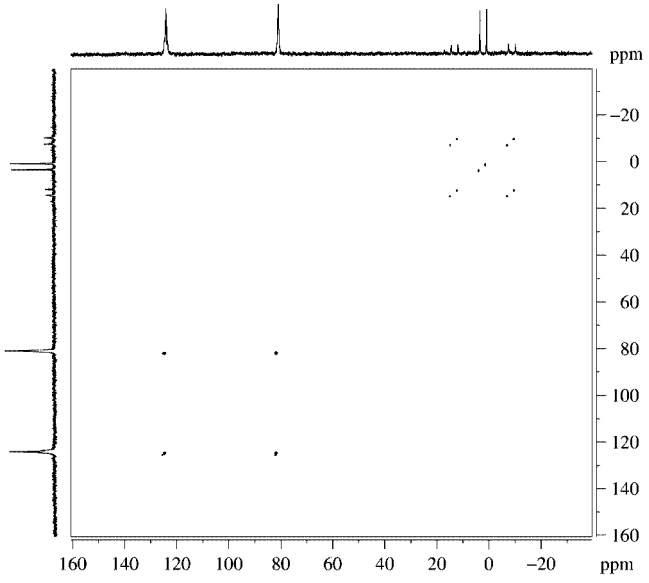

Figure 4. $^{31}P$ EXSY spectrum of **6** in $C_6D_6$.

Yellow crystals of **6** suitable for single-crystal X-ray diffraction were deposited upon slow concentration of a toluene solution. Complex **6** crystallises in the monoclinic space group $P2_1/c$ with one complex molecule in the asymmetric unit. The molecular structure, depicted in Figure 5, is characterised by a distorted square-planar geometry around the Pt atom. The Pt atom is bound to two $PCy_2S_2^-$ ligands, one of which is chelating whereas the other one is unidentate. The Pt–S(1) [2.3419(16) Å] and Pt–S(3) [2.3024(15) Å] bond lengths are shorter than Pt–S(2) [2.4134(15) Å], as expected on the basis of the different *trans* influences of P and S. The structure of **6** resembles that found for the related complex $Pt[(OEt)_2PS_2]_2(PPh_3)$.[61] Both complexes show one uncoordinated sulfur atom at a Pt···S distance of more than 4 Å. The interaction between H(3) and the sulfur atom S(4) not coordinated to Pt is certainly weak: the interatomic distance amounts to 2.91 Å, to be compared with several intra- and intermolecular C–H···S contacts in the range between 2.8 and 3.0 Å. Selected bond lengths and angles are listed in Table 3.

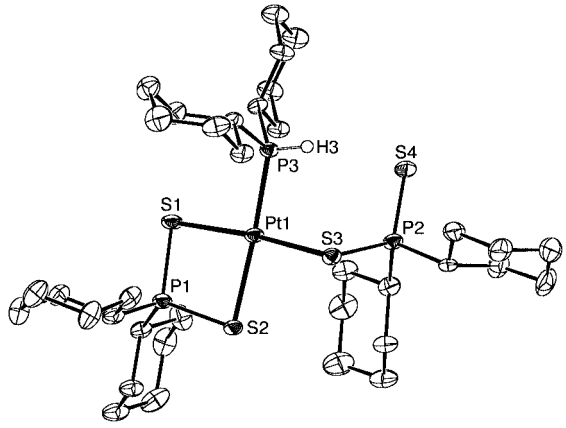

Figure 5. Displacement ellipsoid plot of **6**.[63] Ellipsoids are scaled to 50% probability. Only the phosphorus-bonded hydrogen atom is shown with arbitrary radius; the other H atoms are omitted for clarity.

Table 3. Selected bond lengths [Å] and angles [°] for **6**.

## Conclusion

We have demonstrated that the sulfuration of complex **1** occurs stepwise, and involves first the terminal phosphide giving rise to the formation of complexes **2**, **3** and **4** and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

subsequently one of the coordinated PHCy$_2$ ligands with formation of products **5** and **6**.

## Experimental Section

**General:** All manipulations were carried out under pure argon, using freshly distilled and oxygen-free solvents. Dicyclohexylphosphane (Strem) and $PtCl_2$ (Acros) were used as received. Complexes **2** and **7** were prepared as described elsewhere.[54] Melting points were determined with Gallenkamp equipment and are uncorrected. C, H and S elemental analyses were carried out with a Eurovector CHNS-O Elemental Analyser. Cl elemental analysis was performed by potentiometric titration using a Metrohm DMS Titrino. Infrared spectra were recorded with a Bruker Vector 22 spectrometer. All the ESI-MS spectra were recorded with an Agilent LC-MS SL series instrument adopting the following general conditions: electrospray, positive ions, flow rate 0.200 mL/min, drying gas flow 4.0 L/min, nebuliser pressure 25 psi, drying gas temperature 300 °C, capillary voltage 4000 V, mass range $m/z$ = 400–1400. $CH_2Cl_2$ solutions of the complexes were infused with a Cole-Parmer syringe pump. The isotopic pattern was calculated by the Isotope Pattern Viewer software available free of charge from the www.surfacespectra.com Web site. NMR spectra were recorded with a BRUKER Avance DRX400 spectrometer; frequencies are referenced to $Me_4Si$ ($^1$H and $^{13}$C), 85% $H_3PO_4$ ($^{31}$P), $H_2PtCl_6$ ($^{195}$Pt) and aqueous 1 M NaCl ($^{35}$Cl). The reported temperatures of variable-temperature NMR experiments were calibrated from the chemical shift difference of the signals in the $^1$H NMR spectrum of a standard sample of methanol. The uncertainty in the $\Delta G^{\ddagger}_{Tc}$ value (±1 kJ/mol) was estimated on the basis of the assumption that there is an error of 5 °C in the determination of the coalescence temperature. 2D $^{31}$P EXSY spectra were recorded with a gradient-selected NOESY pulse program from Bruker (noesygpph) with a mixing time of 10 or 50 ms and a relaxation delay of 1.0 s. The spectra were phased to give positive peaks along the diagonal.

***trans*-[Pt(PHCy$_2$)$_2$(PCy$_2$)Cl] (1):**[52] DBU (131 μL, 0.86 mmol) was added to a suspension of **7** (0.74 g, 0.86 mmol in 15 mL of toluene) and the mixture stirred at room temperature for 5 min. The resulting yellow suspension was filtered and pure **1** was obtained as a yellow solid after solvent evaporation (0.63 g, 0.77 mmol, 89%).

**Isomerisation of *trans*-[Pt(PHCy$_2$)$_2${P(S)Cy$_2$}Cl] (2) into *cis*-[Pt(PHCy$_2$)$_2${P(S)Cy$_2$}Cl] (3):** A dichloromethane solution of **2** was stirred at room temperature for 1 h. Pure **3** was obtained after evaporation of the solvent under reduced pressure. The complex is very soluble in halogenated solvents, fairly soluble in toluene, and scarcely soluble in hexane. $C_{36}H_{68}ClP_3PtS$ (856.44): calcd. C 50.49, H 8.00, Cl 4.14, S 3.74; found C 50.92, H 7.85, Cl 4.35, S 3.72. LC-MS: exact mass calcd. for $C_{36}H_{68}ClP_3PtS$: 855.36 amu; found 856 [M + H]$^+$. M.p. 186 °C (dec.). IR (Nujol mull): $\tilde{\nu}_{max}$ = 2272 (w, PH), 1344 (w), 1297 (m), 1268 (m), 1201 (m), 1176 (m), 1115 (m), 1074 (w), 1005 (s), 918 (m), 895 (m), 870 (m), 848 (m), 819 (w), 736 (s), 577 (s, P=S), 511 (m), 411 (w), 400 (w), 388 (w), 298 (m, Pt–Cl), 227 (m) cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$, 295 K): $\delta$ = 5.39 (m, $^1J_{P,H}$ = 383 Hz, P*H trans* Cl), 5.22 [m, $^1J_{P,H}$ = 373, $^2J_{H,Pt}$ = 67 Hz, P*H trans* P(S)] ppm. $^{31}$P{$^1$H} NMR (162 MHz, $CDCl_3$, 295 K): $\delta$ = 67.4 [dd, $^1J_{P,Pt}$ = 1733, $^2J_{P,P}$ = 252, $^2J_{P,P}$ = 16 Hz, P(S)], 11.6 (br. s, $^1J_{P,Pt}$ = 3540, P *trans* Cl), 10.9 [dd, $^1J_{P,Pt}$ = 2822, $^2J_{P,P}$ = 252, $^2J_{P,P}$ = 14 Hz, P *trans* P(S)] ppm. $^{195}$Pt{$^1$H} NMR (86 MHz, $CDCl_3$, 295 K): $\delta$ = –5329 (ddd, $^1J_{P,Pt}$ = 3540, $^1J_{P,Pt}$ = 2822, $^1J_{P,Pt}$ = 1733 Hz) ppm.

**[Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$)(PHCy$_2$)$_2$]Cl (4):** A dichloromethane solution of sulfur (9.0 mg, in 2 mL) was slowly added to a stirred $CH_2Cl_2$ solution of **3** (0.230 g, 0.268 mmol in 5 mL) at room temperature. After 2 h, the solvent was removed under reduced pressure and the residue was treated with toluene (5 mL). Addition of *n*-hexane caused the precipitation of **4** as a yellow solid, which was isolated by filtration, washed with *n*-hexane and dried under vacuum. Yield: 0.170 g (71%). The complex was very soluble in halogenated solvents and toluene and scarcely soluble in *n*-hexane. $C_{36}H_{68}ClP_3PtS_2$ (888.51): calcd. C 48.66, H 7.71, Cl 3.99, S 7.22; found 48.45, H 7.83, Cl 4.05, S 6.95. LC-MS: exact mass calcd. for the cationic $C_{36}H_{68}P_3PtS_2$: 852.36 amu; found 852. M.p. 214 °C (dec.). IR (Nujol mull): $\tilde{\nu}_{max}$ = 2274 (w, P–H), 1345 (w), 1296 (m), 1268 (m), 1201 (w), 1172 (m), 1120 (m), 1074 (w), 1005 (s), 918 (s), 888 (m), 850 (m), 820 (m), 752 (w), 727 (m), 591 (m, $\nu$PS$_2$), 553 (s, $\nu$PS$_2$), 515 (m), 466 (s), 406 (m) cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$, 295 K): $\delta$ = 4.19 (m, $^1J_{P,H}$ = 402, $^2J_{Pt,H}$ = 88 Hz, P*H*) ppm. $^{31}$P{$^1$H} NMR (162 MHz, $CDCl_3$, 295 K): $\delta$ = 136.6 (s, $^2J_{P,Pt}$ = 151 Hz, *P*S$_2$Cy$_2$), 2.0 (s, $^1J_{P,Pt}$ = 3048 Hz, *P*HCy$_2$) ppm. $^{35}$Cl NMR (39 MHz, $CD_2Cl_2$, 295 K): $\delta$ = –18 (br.) ppm. $^{195}$Pt{$^1$H} NMR (86 MHz, $CDCl_3$, 295 K): $\delta$ = –4596 (td, $^1J_{P-Pt}$ = 3048, $^2J_{P-Pt}$ = 151 Hz) ppm.

**[Pt(κ$^2$*S*,*S*′-PS$_2$Cy$_2$){κ*P*-P(S)Cy$_2$}(PHCy$_2$)] (5):** DBU (30 μL, 0.202 mmol) was added to a stirred dichloromethane solution (5 mL) containing **4** (0.180 g, 0.202 mmol) and sulfur (7.5 mg). After 10 min, the solvent was removed under reduced pressure and the residue was treated with toluene (5 mL). The resulting suspension was filtered and **5** was obtained as a white solid (0.16 g, 89% yield) after evaporation of the filtrate under reduced pressure. The complex is very soluble in toluene and halogenated solvents, and scarcely soluble in hexane and methanol. $C_{36}H_{67}P_3PtS_3$ (884.11): calcd. C 48.91, H 7.64, S 10.88; found C 48.67, H 7.54, S 11.08. LC-MS: exact mass calcd. for $C_{36}H_{67}P_3PtS_3$: 883.33 amu; found 884 [M + H]$^+$. M.p. 248–250°°C. IR (Nujol mull): $\tilde{\nu}_{max}$ = 2366 (w, PH), 1342 (w), 1328 (w), 1296 (m), 1175 (m), 1111 (m), 1075 (m), 1025 (s), 1002 (s), 889 (m), 848 (s), 817 (m), 756 (m), 736 (s), 597 (s, $\nu$P=S and $\nu$PS$_2$), 556 (s, $\nu$PS$_2$), 510 (m), 467 (w), 403 (m), 400 (m), 352 (w), 316 (m) cm$^{-1}$. $^1$H NMR (400 MHz, $C_6D_6$, 295 K): $\delta$ = 5.24 (br. d, $^1J_{P,H}$ = 424, $^2J_{Pt,H}$ = 72 Hz) ppm. $^{31}$P{$^1$H} NMR (162 MHz, $C_6D_6$, 295 K): $\delta$ = 127.2 (br., $^2J_{P,Pt}$ = 137 Hz, PS$_2$Cy$_2$), 48.4 [br., $^1J_{P,Pt}$ = 2977 Hz, P(S)Cy$_2$], 38.9 (br., $^1J_{P,Pt}$ = 3977 Hz, PHCy$_2$) ppm. $^{195}$Pt{$^1$H} NMR (86 MHz, $C_6D_6$, 295 K): $\delta$ = –4522 (ddd, $^1J_{P,Pt}$ = 3977, $^1J_{P,Pt}$ = 2977, $^2J_{P,Pt}$ = 137 Hz) ppm.

**[Pt(κ$^2$*S*,*S*′-PCy$_2$S$_2$)(κ*S*-PCy$_2$S$_2$)(PHCy$_2$)] (6):** A toluene solution of PHCy$_2$ (0.180 mmol in 2 mL) was slowly added to an orange toluene suspension of **8** (0.133 g, 0.184 mmol in 5 mL). After 10 min, the obtained yellow suspension was filtered, the filtrate was concentrated to dryness and the resulting yellow solid was washed with *n*-hexane (3 × 2 mL). Yield: 0.128 g, 76%. Complex **6** is very soluble in halogenated solvents, slightly soluble in toluene and scarcely soluble in *n*-hexane. $C_{36}H_{67}P_3PtS_4$ (916.18): calcd. C 47.19, H 7.37, S 14.0; found C 47.25, H 7.45, S 14.4. LC-MS: exact mass calcd. for $C_{48}H_{90}OP_4Pt_2$: 915.30 amu; found 916 [M + H]$^+$, 718 [M – PHCy$_2$ + H]$^+$. M.p. 208–210 °C. IR (Nujol mull): $\tilde{\nu}_{max}$ = 2367 (w, P–H), 1297 (w), 1267 (w), 1178 (m), 1113 (m), 1075 (w), 999 (m), 919 (w), 885 (m), 849 (m), 819 (m), 748 (m), 620 (s, $\nu$ of unidentate PS$_2$), 598 (m, $\nu$ of bidentate PS$_2$), 559 (s, $\nu$ of bidentate PS$_2$), 527 (m, $\nu$ of unidentate PS$_2$), 473 (w), 356 (w), 310 (w) cm$^{-1}$. $^1$H NMR (400 MHz, $C_6D_6$, 295 K): $\delta$ = 5.94 (br. m, $^1J_{P,H}$ = 417 Hz, P*H*) ppm. $^{31}$P{$^1$H} NMR (162 MHz, $C_6D_6$, 295 K): $\delta$ = 124.8 (br. s, $^2J_{P,Pt}$ = 195 Hz, κ$^2$*S*,*S*′-PCy$_2$S$_2$), 81.8 (br. s, κ*S*-PCy$_2$S$_2$), 2.5 (s, $^1J_{P,Pt}$ = 3551 Hz, PHCy$_2$) ppm. $^{195}$Pt{$^1$H} NMR (86 MHz, $CDCl_3$, 265 K): $\delta$ = –4052 (ddd, $^1J_{P,Pt}$ = 3551, $^2J_{P,Pt}$ = 184, $^2J_{P,Pt}$ = 116 Hz) ppm.

**Pt(κ$^2$*S*,*S*′-PCy$_2$S$_2$)$_2$ (8):** Dicyclohexylphosphane sulfide,[64] prepared by addition of 1 equiv. of elemental sulfur to a toluene solu-

tion of $PHCy_2$ at room temperature, was converted into $P(Cy)_2S_2Na$ by further reaction with 1 equiv. of sulfur and subsequent deprotonation by NaH. $NaP(Cy_2S_2)$ (0.193 g, 0.678 mmol)[65] was then poured into an ethanol suspension of $K_2PtCl_4$ (0.141 g, 0,339 mmol in 5 mL) and the mixture was vigorously stirred at room temperaturefor 24 h. Complex **8** was isolated by filtration as a pale orange solid, washed with *n*-hexane (4×2 mL) and dried under vacuum. Yield: 0.181 g, 74%. The complex is fairly soluble in halogenated solvents and insoluble in hexane and ethanol. $C_{24}H_{44}P_2PtS_4$ (717.90): calcd. C 40.15, H 6.18, S 17.87; found C 40.65, H 6.31, S 18.05. LC-MS: exact mass calcd. for $C_{24}H_{44}P_2PtS_4$: 717.14 amu; found 718 $[M + H]^+$. M.p. 279 °C (dec.). IR (Nujol mull): $\tilde{\nu}_{max}$ = 1266 (w), 1180 (m), 1113 (w), 1078 (w), 1023 (w), 1001 (m), 887 (m), 850 (w), 818 (w), 742 (m), 595 (m, *ν* of bidentate $PS_2$), 561 (s, *ν* of bidentate $PS_2$), 524 (w), 401 (w), 298 (m) $cm^{-1}$. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$ 295 K): $\delta$ = 134.5 (s, $^2J_{P,Pt}$ = 279 Hz) ppm. $^{195}Pt\{^1H\}$ NMR (86 MHz, $CDCl_3$, 295 K): $\delta$ = –3025 (t, $^2J_{P,Pt}$ = 279 Hz) ppm.

**X-ray Data Collection, Structure Solution and Refinement of 6:** Crystal data, parameters for intensity data collection and convergence results are compiled in Table 4. A pale yellow platelet of approximate dimensions 0.30×0.20×0.20 mm was studied at 110 K with a BRUKER-AXS SMART APEX diffractometer. An empirical absorption correction (min. trans. 0.40, max. trans. 0.52) was applied before averaging symmetry-equivalent data [*R*(int) = 0.0815]. After merging, 11370 independent reflections remained for the structure solution by direct methods.[66] The structure model was completed by Fourier difference syntheses and refined with full-matrix least squares on $F^2$.[67] CCDC-299582 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 4. Crystal data and structure refinement for **6**.

| | |
|---|---|
| Empirical formula | $C_{36}H_{67}P_3PtS_4$ |
| Formula mass | 916.14 |
| Temperature [K] | 110(2) |
| Wavelength [Å] | 0.71073 |
| Crystal system | monoclinic |
| Space group | $P2_1/c$ |
| Unit cell dimensions: | |
| *a* [Å] | 15.731(2) |
| *b* [Å] | 11.1000(16) |
| *c* [Å] | 27.258(3) |
| *β* [°] | 121.060(5) |
| *V* [Å$^3$] | 4077.2(9) |
| *Z* | 4 |
| $D_{calcd.}$ [Mg/m$^3$] | 1.492 |
| Absorption coeff. [mm$^{-1}$] | 3.788 |
| *θ* range for data coll. [°] | 2.25–29.70 |
| Reflections measured | 51300 |
| Independent reflections | 11370 |
| Observed reflections [$I > 2\sigma(I)$] | 8705 |
| Data/parameters | 11370/397 |
| Goodness-of-fit on $F^2$ | 1.102 |
| $R$[a] [$I > 2\sigma(I)$] | 0.0581 |
| $wR_2$[b] (all data) | 0.1208 |
| Largest diff. peak/hole [e/Å$^3$] | 1.934/–2.962 |

[a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

**Supporting Information** (see footnote on the first page of this article): $^{31}P\{^1H\}$ NMR spectra of **3**, **4**, **5** and **8**, $^{195}Pt\{^1H\}$ NMR spectrum of **8**, ESI-MS spectra of **3**, **4**, **5**, **6** and **8**.

# New Palladium Complexes with S- or Se-Containing Schiff-Base Ligands as Efficient Catalysts for the Suzuki–Miyaura Cross-Coupling Reaction of Aryl Bromides with Phenylboronic Acid under Aerobic Conditions

**Ioannis D. Kostas,*[a] Barry R. Steele,*[a] Aris Terzis,[b] Svetlana V. Amosova,[c] Alexander V. Martynov,[c] and Natalia A. Makhaeva[c]**

**Keywords:** Homogeneous catalysis / Suzuki / C–C coupling / Schiff bases / Tridentate ligands

Four palladium chelate complexes with S- or Se-containing substituted salicylaldehyde Schiff-base derivatives have been synthesized. Spectroscopic and crystallographic data indicate that, in the complexes, the deprotonated salicylaldehyde ligand is bound to the metal in an O,N,S (or Se)-tridentate coordination mode, forming one six- and one five-membered chelate ring. The complexes are thermally and air stable and efficiently catalyze the Suzuki–Miyaura cross-coupling of aryl bromides with phenylboronic acid in air.

## Introduction

Palladium-catalyzed carbon–carbon coupling reactions have now become essential tools for the organic synthetic chemist,[1] and one of the most important of these is the Suzuki–Miyaura cross-coupling of aryl halides with organoboronic acids.[1,2] This reaction now represents a key process for the synthesis of biaryls, which play an important role as intermediates in organic synthesis and as functional groups in natural products.[3] Intensive research efforts are being made into finding ways of improving and expanding the scope of this process, and one aspect that has received particular attention is the development of new ligands. As a consequence, a large number of phosphorus ligands,[4] and phosphane-free ligands,[5] have been reported that are applicable to the conventional thermal Suzuki–Miyaura reaction.

We have previously reported several nitrogen- and/or sulfur-containing phosphorus ligands and their applications to transition-metal homogeneous catalysis.[6] However, as efficient catalysis under phosphane-free conditions represents a challenge of high current importance, our interest has focused on the development of new phosphane-free ligands and recently, for the first time, we used thiosemicarbazones as effective catalyst precursors for palladium-catalyzed coupling reactions under aerobic conditions.[7] In a previous paper, we reported a synthetic route for the preparation of chalcogen (S,Se,Te)-containing substituted salicylaldehyde Schiff-base derivatives.[8] Taking into account the potential of these Schiff bases as tridentate ligands,[9] in this paper we report the synthesis of palladium complexes with S- or Se-containing Schiff-base ligands, two crystal structures of which were determined by X-ray analysis. These phosphane-free systems were applied to the Suzuki–Miyaura coupling of aryl bromides with phenylboronic acid under aerobic conditions.

## Results and Discussion

### Synthesis and Characterization of the Palladium Complexes with S- or Se-Containing Schiff-Base Ligands

The synthesis of the palladium complexes **3a**–**d** is outlined in Scheme 1. Chalcogen-containing Schiff bases 2-(1-ethylpropyl)-6-({[2-(methylsulfanyl)ethyl]imino}methyl)-benzenol ("emSib", **2a**), 2-({[2-(methylsulfanyl)ethyl]imino}-methyl)benzenol ("mSib", **2b**), 2-(1-ethylpropyl)-6-({[2-(methylselanyl)ethyl]imino}methyl)benzenol ("emSEib", **2c**), and 2-({[2-(methylselanyl)ethyl]imino}methyl)benzenol ("mSEib", **2d**) were prepared by treatment of salicylaldehyde derivative **1a** or salicylaldehyde **1b** with 2-(methylsulfanyl)- or 2-(methylselanyl)ethylamine (or their hydrochlorides), according to a procedure recently published by us.[8] In the $^1$H NMR spectra of **2a**–**d**, the signal of the phenolic proton at $\delta$ = 13.30 ppm (**2b**,**d**) or 13.50 ppm (**2a**,**c**) is consistent with hydrogen bonding between the hydroxy and the nitrogen of the imine group.[10] The syntheses of the palladium complexes **3a**–**d** were achieved by the reaction of li-

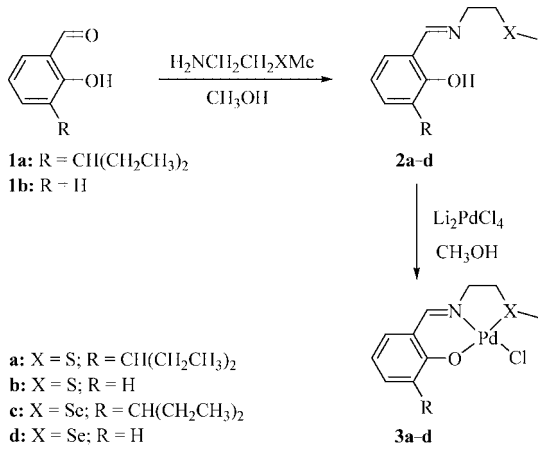
gands **2a**–**d** with $Li_2PdCl_4$, prepared in situ from $PdCl_2$ and LiCl. Spectroscopic studies indicate that the ligands are bound to palladium in an O,N,S (or Se)-terdentate coordination mode. In the $^1H$ NMR spectra of **3a**–**d**, the signal of the phenolic proton is absent because of deprotonation and complex formation. In the $^1H$ and $^{13}C\{^1H\}$ NMR spectra of **3a**–**d**, the $CH_2N$ and $XCH_3$ resonances are shifted to low field compared to the corresponding resonances in the free ligands, indicating Pd–N as well as Pd–X coordination (Table 1).



Scheme 1. Synthesis of the palladium complexes [PdCl(emSib)] (**3a**), [PdCl(mSib)] (**3b**), [PdCl(emSEib)] (**3c**), and [PdCl(mSEib)] (**3d**).

Yellow-orange crystals of complexes **3a** and **3c** suitable for X-ray determination were obtained by slow diffusion of diethyl ether through a diluted solution of the complexes in dichloromethane. The two complexes are isostructural and, for that reason, only the structure of **3c** is presented here. As shown in Figure 1, the monoanionic ligand is coordinated to palladium in a terdentate fashion by the phenoxy oxygen, the azomethine nitrogen and the selenium atom, forming one six- and one five-membered chelate ring. In both complexes, the coordination geometry at the metal center can be regarded as slightly distorted square-planar, and the four Pd–heteroatom distances have normal values, according to the selected data presented in Table 2.

## Suzuki–Miyaura Coupling Reactions Catalyzed by Palladium Complexes with S- or Se-Containing Schiff-Base Ligands under Aerobic Conditions

Complexes **3a**–**d** were applied to the Suzuki–Miyaura reaction of phenylboronic acid with some representative aryl bromides (from electron-rich to electron-poor) at 100 °C for 24 h, in DMF, using $K_2CO_3$ as base, without addition of free ligand or any promoting additive (Scheme 2, Table 3). All reactions were performed in air. As it is known that addition of water enhances the activity of the catalyst,[4b,7b] catalysis was performed in the presence of a small amount of water (close to 1 equiv. with respect to the substrates). Catalysts seem to be air stable at 100 °C, and palladium-black, which could indicate the degradation of the catalysts, was not observed. The reaction was performed using a 1:1000 catalyst/aryl halide molar ratio. As expected, the catalytic activity depended on the halide, while electron-withdrawing groups on the aryl ring increased the reaction rate. According to the GC and GC–MS analysis of the reaction mixtures resulting from the coupling of 4-substituted aryl halides, homocoupling of phenylboronic acid to give unsubstituted biphenyl was observed in a low yield (3–4%) only for the substrate with an electron-donating group. For the deactivated 4-bromoanisole, the reaction proceeded with conversions to the coupled product, MeO–$C_6H_4$–Ph,

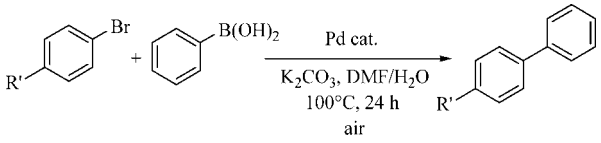
in the range 21–25% (entries 1–4), and for the nonactivated bromobenzene in the range 40–45% (entries 5–8). The narrow ranges for the yields for entries 1–4 and also 5–8 do not permit conclusions to be drawn concerning the influence of the bulky substituent $CHEt_2$ on the salicylaldehyde moiety or on the effect of replacing sulfur with selenium on the catalytic activity of the complexes. For the activated 4-bromobenzonitrile (entries 9–12) and 1-bromo-4-nitrobenzene (entries 13–16), the reaction proceeded with high or even quantitative yield. The results in these entries provide evidence that the presence of the $CHEt_2$ group on the aryl ring, situated away from the coordination sphere around the metal, does not significantly influence the activity of the complex. This observation is not in contrast with that broadly accepted concerning the increased reactivity of a ligand by the presence of a bulky electron-donating group, thereby making the ligand more electron-rich, because in our systems the ligand is in an anionic form. On the other hand, the presence of a selenium donor in the complex was found to promote its catalytic activity slightly compared to the sulfur analogue. For comparison purposes, coupling of 4-bromobenzonitrile with phenylboronic acid was also achieved by using $Li_2PdCl_4$ or $Pd(OAc)_2$ as catalysts under the same reaction conditions as those described above. The reactions proceeded with 95% ($Li_2PdCl_4$ as catalyst) and 92% [$Pd(OAc)_2$ as catalyst] yields of coupling product, but, in contrast to complexes **3a**–**d**, unsubstituted biphenyl was also observed (5% and 8%, respectively) because of homocoupling of phenylboronic acid. Although it is known that these simple palladium compounds may produce nanoparticles under these reaction conditions,[11] it remains to be established whether this is the case for the complexes reported here.



Scheme 2. Suzuki–Miyaura cross-coupling of aryl bromides with phenylboronic acid catalyzed by palladium complexes **3a**–**d**, in air.

[a] Reaction conditions: ArBr (2.0 mmol), $PhB(OH)_2$ (3.0 mmol), $K_2CO_3$ (4.0 mmol), $H_2O$ (3.3 mmol), Pd complex in DMF (0.5 mM, 4 mL), 100 °C, 24 h; ArBr/Pd = 1000:1. [b] Conversion to coupled product R′-$C_6H_4$–Ph, based on aryl bromide (GC, decane as internal standard). [c] Conversion to unsubstituted biphenyl because of homocoupling of phenylboronic acid.

## Conclusions

We have shown that new palladium chelate complexes with S- or Se-containing substituted salicylaldehyde Schiff-base derivatives, in which the ligand is bound to the metal in an O,N,S (or Se)-terdentate coordination mode, can serve as efficient catalysts for the Suzuki–Miyaura cross-coupling of aryl bromides with phenylboronic acid under mild reaction conditions. Se-containing ligands are slightly more active than the S-containing analogues. Although the activity is not as high as some other palladium systems, these phosphane-free catalysts are thermally and air stable, and offer the advantage of the successful coupling of aryl bromides and the synthesis of biaryls under aerobic conditions.

## Experimental Section

**General:** 3-(1-Ethylpropyl)-2-hydroxybenzenecarbaldehyde (**1a**),[12] 2-(methylsulfanyl)ethylamine,[13] and 2-(methylselanyl)ethylamine[8] were prepared by known procedures. Syntheses of ligands emSib (**2a**) and emSEib (**2c**) have been described by us elsewhere.[8] Ligands mSib (**2b**) and mSEib (**2d**) were prepared according to the same procedure. All other chemicals were commercially available. Coupling reactions were performed on a Radleys Carousel Reactor™ with 12 tubes of about 45 mL in two stacked aluminum blocks. The lower block was placed on a heater–stirrer and maintained at a constant temperature by means of a thermostat, while water circulated in the upper block, which served to cool the tops of the tubes. NMR measurements were made using a Bruker AC 300 (300.13 MHz and 75.47 MHz for $^1H$ and $^{13}C\{^1H\}$, respectively). Distinction of the CH, $CH_2$, and $CH_3$ carbons in the $^{13}C\{^1H\}$ NMR spectra was performed by DEPT NMR experiments. Gas chromatography was undertaken using a Varian Star 3400 CX with a 30 m × 0.53 mm DB5 column. Electron impact gas chromatography–mass spectrometry was carried out using a Varian Saturn 2000 with a 30 m × 0.25 mm DB5-MS column. Elemental analyses for C, H, N were carried out on a Perkin–Elmer PE 2400 II instrument.

**2-({[2-(Methylsulfanyl)ethyl]imino}methyl)benzenol ("mSib", 2b):**[14] Reaction of salicylaldehyde **1b** (2.01 g, 16.48 mmol) with 2-(methylsulfanyl)ethylamine (1.50 g, 16.48 mmol) in MeOH (15 mL) yielded **2b** (3.09 g, 96%). $^1H$ NMR (300.13 MHz, $CDCl_3$): $\delta$ = 13.31 (s, 1 H, OH), 8.35 (s, 1 H, C*H*=N), 7.30 (m, 2 H, ArH), 6.95 (d, $^3J$ = 8.5 Hz, 1 H, ArH), 6.87 (t, $^3J$ = 7.3 Hz, 1 H, ArH), 3.78 (t, $^3J$ = 6.7 Hz, 2 H, $CH_2$N), 2.81 (t, $^3J$ = 6.7 Hz, 2 H, $CH_2$S), 2.12 (s, 3 H, S$CH_3$) ppm. $^{13}C\{^1H\}$ NMR (75.47 MHz, $CDCl_3$): $\delta$ = 165.9 (*C*H=N), 161.0 (*C*-OH), 132.3, 131.3, 118.5, and 116.9 (ArC), 58.8 ($CH_2$N), 34.9 ($CH_2$S), 15.9 (S$CH_3$) ppm.

**2-({[2-(Methylselanyl)ethyl]imino}methyl)benzenol ("mSEib", 2d):**[15] Reaction of salicylaldehyde **1b** (1.05 g, 8.61 mmol) with 2-(methylselanyl)ethylamine (1.19 g, 8.62 mmol) in MeOH (10 mL) yielded **2d** (1.98 g, 95%). $^1H$ NMR (300.13 MHz, $CDCl_3$): $\delta$ =

13.30 (s, 1 H, OH), 8.37 (s, 1 H, C*H*=N), 7.30 (m, 2 H, ArH), 6.96 (d, $^3J$ = 8.5 Hz, 1 H, ArH), 6.88 (t, $^3J$ = 7.3 Hz, 1 H, ArH), 3.87 (t, $^3J$ = 6.7 Hz, 2 H, C$H_2$N), 2.84 (t, $^3J$ = 6.7 Hz, 2 H, C$H_2$Se), 2.02 (s, 3 H, SeC$H_3$) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, $CDCl_3$): $\delta$ = 165.5 (*C*H=N), 161.1 (*C*-OH), 132.3, 131.4, 118.6, and 117.0 (ArC), 59.7 (*C*$H_2$N), 25.9 (*C*$H_2$Se), 4.7 (Se*C*$H_3$) ppm.

**Typical Procedure for the Preparation of the Palladium Complexes 3a–d:** $PdCl_2$ (0.10 g, 0.56 mmol) was stirred with LiCl (0.075 g, 1.76 mmol) in MeOH (10 mL). Ligand **2a** (0.15 g, 0.56 mmol) was added to the dark brown-red solution formed, yielding a yellow-orange suspension after stirring at room temperature overnight. The reaction mixture was allowed to settle and an orange solid was isolated by filtration in air, washed with small amounts of methanol and diethyl ether, and recrystallized from dichloromethane/ether yielding **3a**.

**[PdCl(emSib)] (3a):** Reaction of ligand **2a** with $Li_2PdCl_4$, prepared in situ from $PdCl_2$ and LiCl in MeOH, in the quantities indicated above, yielded **3a** (0.18 g, 79%). $^1$H NMR (300.13 MHz, $CDCl_3$): $\delta$ = 7.37 (s, 1 H, C*H*=N), 7.16 (d, $^3J$ = 7.5 Hz, 1 H, ArH), 6.84 (d, $^3J$ = 7.5 Hz, 1 H, ArH), 6.54–6.49 (m, 1 H, ArH), 4.04–3.96 and 3.90–3.81 (m, m, 2 H, C$H_2$N), 3.13–3.07 and 3.03–2.95 (m, m, 2 H, C$H_2$S), 2.65 (s, 3 H, SC$H_3$), 2.58–2.50 [m, 1 H, C*H*(C$H_2$C$H_3$)$_2$], 1.73–1.54 [m, 4 H, CH(C$H_2$C$H_3$)$_2$], 0.81–0.75 [m, 6 H, CH(CH$_2$C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, $CDCl_3$): $\delta$ = 163.02 (ArC), 160.50 (*C*H=N), 135.91, 133.61, 132.06, 118.38, and 115.07 (ArC), 63.35 (*C*$H_2$N), 41.87 [*C*H(CH$_2$CH$_3$)$_2$], 37.60 (*C*$H_2$S), 26.99 and 26.79 [CH(*C*$H_2$CH$_3$)$_2$], 20.97 (S*C*$H_3$), 12.24 and 12.07 [CH(CH$_2$*C*$H_3$)$_2$] ppm. $C_{15}H_{22}ClNOPdS$ (406.28): calcd. C 44.35, H 5.46, N 3.45; found C 44.56, H 5.53, N 3.77.

**[PdCl(mSib)] (3b):** Reaction of ligand **2b** (0.12 g, 0.62 mmol) with $Li_2PdCl_4$, prepared in situ from $PdCl_2$ (0.10 g, 0.56 mmol) and LiCl (0.075 g, 1.76 mmol) in MeOH (10 mL), yielded **3b** (0.15 g, 79%). $^1$H NMR (300.13 MHz, [D$_6$]DMSO): $\delta$ = 8.19 (s, 1 H, C*H*=N), 7.39–7.29 (m, 2 H, ArH), 6.80 (d, $^3J$ = 8.5 Hz, 1 H, ArH), 6.61–6.56 (m, 1 H, ArH), 4.28–4.19 and 4.03–3.95 (m, m, 2 H, C$H_2$N), 2.98–2.89 and 2.74–2.66 (m, m, 2 H, C$H_2$S), 2.53 (s, 3 H, SC$H_3$) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, [D$_6$]DMSO): $\delta$ = 163.43 (ArC), 160.78 (*C*H=N), 135.32, 134.93, 119.60, 119.47, and 114.94 (ArC), 63.60 (*C*$H_2$N), 36.33 (*C*$H_2$S), 19.57 (S*C*$H_3$) ppm. $C_{10}H_{12}ClNOPdS$ (336.14): calcd. C 35.73, H 3.60, N 4.17; found C 36.15, H 3.96, N 4.59.

**[PdCl(emSEib)] (3c):** Reaction of ligand **2c** (0.18 g, 0.58 mmol) with $Li_2PdCl_4$, prepared in situ from $PdCl_2$ (0.10 g, 0.56 mmol) and LiCl (0.075 g, 1.76 mmol) in MeOH (10 mL), yielded **3c** (0.17 g, 68%). $^1$H NMR (300.13 MHz, $CDCl_3$): $\delta$ = 7.34 (s, 1 H, C*H*=N), 7.16 (d, $^3J$ = 7.5 Hz, 1 H, ArH), 6.84 (d, $^3J$ = 7.5 Hz, 1 H, ArH), 6.54–6.49 (m, 1 H, ArH), 4.30–4.20 and 4.14–4.05 (m, m, 2 H, C$H_2$N), 3.16–3.01 (m, 2 H, C$H_2$Se), 2.52 (s, 3 H, SeC$H_3$), 2.50–2.44 [m, 1 H, C*H*(CH$_2$CH$_3$)$_2$], 1.69–1.58 [m, 4 H, CH(C$H_2$CH$_3$)$_2$], 0.83–0.76 [m, 6 H, CH(CH$_2$C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, $CDCl_3$): $\delta$ = 163.08 (ArC), 160.82 (*C*H=N), 135.52, 133.32, 132.25, 118.51, and 114.78 (ArC), 65.61 (*C*$H_2$N), 41.64 [*C*H(CH$_2$CH$_3$)$_2$], 28.99 (*C*$H_2$Se), 26.95 and 26.70 [CH(*C*$H_2$CH$_3$)$_2$], 12.66 (Se*C*$H_3$), 12.24 and 12.07 [CH(CH$_2$*C*$H_3$)$_2$] ppm. $C_{15}H_{22}ClNOPdSe$ (453.18): calcd. C 39.76, H 4.89, N 3.09; found C 39.58, H 5.01, N 3.38.

**[PdCl(mSEib)] (3d):** Reaction of ligand **2d** (0.15 g, 0.62 mmol) with $Li_2PdCl_4$, prepared in situ from $PdCl_2$ (0.10 g, 0.56 mmol) and LiCl (0.075 g, 1.76 mmol) in MeOH (10 mL), yielded **3d** (0.12 g, 56%). $^1$H NMR (300.13 MHz, [D$_6$]DMSO): $\delta$ = 8.13 (s, 1 H, C*H*=N), 7.36–7.28 (m, 2 H, ArH), 6.79 (d, $^3J$ = 8.0 Hz, 1 H, ArH), 6.59–6.54 (m, 1 H, ArH), 4.40–4.21 (m, 2 H, C$H_2$N), 2.94–2.85 and 2.73–2.66 (m, m, 2 H, C$H_2$Se), 2.45 (s, 3 H, SeC$H_3$) ppm. $^{13}$C{$^1$H} NMR (75.47 MHz, [D$_6$]DMSO): $\delta$ = 163.76 (ArC), 161.04 (*C*H=N), 135.16, 134.93, 119.44, and 114.58 (Ar), 65.57 (*C*$H_2$N), 28.53 (*C*$H_2$Se), 11.58 (Se*C*$H_3$) ppm. $C_{10}H_{12}ClNOPdSe$ (383.03): calcd. C 31.36, H 3.16, N 3.66; found C 30.98, H 2.90, N 4.07.

**General Procedure for the Suzuki–Miyaura Cross-Coupling Reactions:** A mixture of aryl bromide (2.0 mmol), $PhB(OH)_2$ (0.366 g, 3.0 mmol), $K_2CO_3$ (0.553 g, 4.0 mmol), water (60 μL, 3.3 mmol), and a stock solution of palladium complex **3a–d** in DMF (0.5 mM, 4 mL, $2\times10^{-3}$ mmol) was heated at 100 °C for 24 h, and then cooled to room temperature. After addition of water and extraction with dichloromethane, the organic phase was washed with brine, dried with $Na_2SO_4$, filtered, passed through Celite, and analyzed by GC and GC–MS. All the biaryls prepared were known compounds.[4b]

**X-ray Crystallographic Study of 3a and 3c:** Slow crystallization from $CH_2Cl_2/Et_2O$ yielded yellow-orange crystals of **3a** ($0.20\times0.25\times0.55$ mm) and **3c** ($0.10\times0.20\times0.50$ mm), which were mounted in air. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo radiation. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11 < 2\theta < 23°$ and they appear in Table 4. Intensity data were recorded using a $\theta$–$2\theta$ scan. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization, and absorption corrections were applied using Crystal Logic software. The structures were solved by direct methods using SHELXS-86[16] and refined by full-matrix least-squares methods on $F^2$ with SHELXL-97.[17] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located by difference maps and were refined isotropically (except those on C13 and C15 in **3a**, which were introduced at calculated positions as riding on bonded atoms). Crystal data and experimental details for the crystals of compounds **3a** and **3c** are given in Table 4.

Table 4. X-ray experimental data of compounds **3a** and **3c**.

| | **3a** | **3c** |
|---|---|---|
| Empirical formula | $C_{15}H_{22}ClNOPdS$ | $C_{15}H_{22}ClNOPdSe$ |
| Formula mass | 406.25 | 453.15 |
| Crystal system | monoclinic | monoclinic |

# A Prospective Study of the Use of the $[Os(tpy)_2]^{2+}$ (tpy = 2,2′;6′:2′′-Terpyridine) Core as Signalling Scaffolding for the Development of Chemical Sensors

**Jose V. Ros-Lis,[a] Ramón Martínez-Máñez,*[a] Juan Soto,[a] Colette McDonagh,*[b] and Adrian Guckian[b]**

**Keywords:** Chemosensors / Osmium terpyridines / Macrocyclic ligands / Fluorescent probes / Thin films

The heteroleptic osmium(II) complex $[Os(L^1)(Me\text{-}phtpy)][PF_6]_2$ ($L^1$ = 1-[4′-*p*-tolyl-(2,2′:6′,2′′-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane, Me-phtpy = 4′-*p*-tolyl-2,2′:6′,2′′-terpyridine) has been prepared, characterized and its potential use for chemical sensing purposes studied. The complex contains a polyazacycloalkane as "binding site" and a $Os(tpy)_2^{2+}$ core that acts as a "signalling subunit". The emission intensity of the osmium complex was quenched in acetonitrile/water (1:1 v/v) by $Cu^{2+}$ and $Ni^{2+}$. Potentiometric titrations of $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ in the presence of $Cu^{2+}$ were carried out in order to determine thermodynamic binding constants in acetonitrile/water (70:30 v/v, 0.1 mol·dm$^{-3}$ tetrabutylammonium perchlorate). With $Cu^{2+}$ the receptor $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ forms the complex $\{Cu[Os(L^1)(Me\text{-}phtpy)]\}^{4+}$ at neutral pH. Moreover it undergoes two stepwise protonation processes at acid pH related to the partial protonation of the cyclam core and forms two hydroxo complexes at basic pH. The $Ni^{2+}$ complexes of the osmium receptor $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ are able to act as an anion fluorogenic chemosensor in acetonitrile/water mixtures. A displacement of the quenching effect to more acidic pH in the $Ni^{2+}$–$[Os(L^1)(Me\text{-}phtpy)]^{2+}$ system was observed for anions in the order ATP > AMP > chloride. A prospective study of the use of the $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ complex as a fluorogenic sensor for oxygen was also carried out by incorporation of the complex in sol-gel silica films made with TEOS and MTEOS. Significant quenching of the osmium fluorescence by oxygen was observed. The oxygen response of the films showed good stability and repeatability. The study suggested that the $Os(tpy)_2^{2+}$ core might act as suitable signalling scaffolding in chemical sensing systems of cations, anions and gases.

## Introduction

The development of new chemosensors for the selective sensing of cations and anions based on the covalent or non-covalent coupling of binding sites and signalling subunits is an area of interest. These programmed molecular systems, when appropriately designed, are capable of transducing guest binding processes into suitable signalling events such as changes in colour, fluorescence or redox properties of the formed molecular ensemble. Among different output signals, those based on changes in emission properties are especially attractive and a number of different fluorogenic chemosensors have been described for anion[1] and cation[2] sensing. Both all-organic and metal-based fluorogenic subunits have been widely used. Among metal-based luminescent systems, the complexes of ruthenium and rhenium are well known and have been used as signalling subunits in a considerable number of reported chemosensors.[3] In fact, the polypyridyl complexes of $d^6$ metal cations, with their strong metal-to-ligand charge transfer absorptions and emitting excited states, are good candidates as signalling reporters. In this sense, the most widely used metal-based signalling framework has been the $Ru(bpy)_3^{2+}$ core.[4] In contrast, the analogous $Ru(tpy)_2^{2+}$ scaffolding has been used as a signalling unit in very few cases.[5–10] $Ru(tpy)_2^{2+}$ might show certain advantages versus $Ru(bpy)_3^{2+}$, that is, it is relatively easy to functionalise the terpyridine core. The most serious drawback in using the $Ru(tpy)_2^{2+}$ scaffolding is its usually very low quantum yield when compared with that found for the $Ru(bpy)_3^{2+}$ systems. In order to maintain the use of the terpyridine framework but in an attempt to enhance the emission properties of the signalling unit at room temperature, we have moved in this paper from ruthenium to osmium as an alternative metal centre. Thus, for instance, the quantum yield at room temperature of the Ru(tolyl-tpy)$_2^{2+}$ complex (tolyl-tpy = bis[4′-(*p*-tolyl)-2,2′:6′,2′′-terpyridine]) is $3.2 \times 10^{-5}$, whereas that observed with osmium as the metal centre, Os(tolyl-tpy)$_2^{2+}$, is more than 500 times larger ($\varphi$ = 0.021).[11] Although the osmium–terpyridine complexes have received less consideration than other metal–terpyridine systems, their photophysical properties

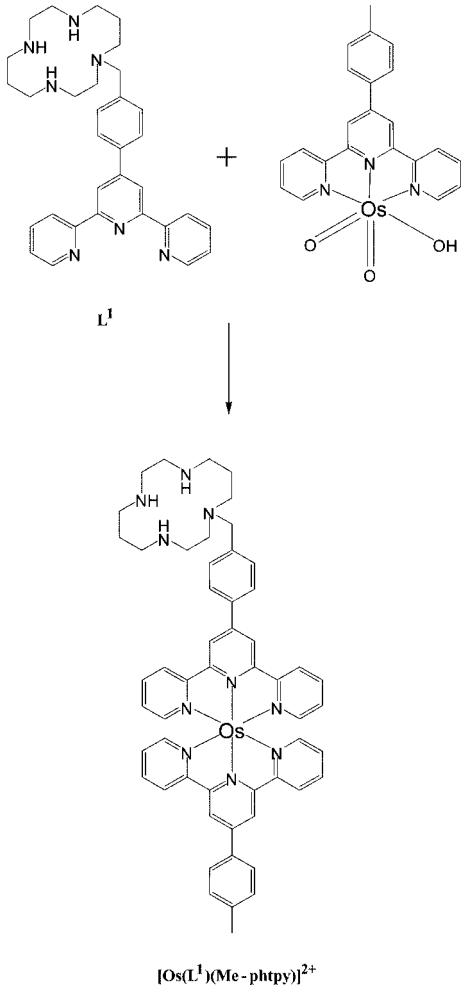
are well known because of comparative studies with the ruthenium analogues.[12]

Some of us have previously reported ruthenium bis-terpyridine functionalised systems as chemosensors for metal cations and anions.[6–10] However, and as far as we know, there are very few examples of the use of the $Os(tpy)_2^{2+}$ core as a signalling subunit for chemosensing purposes. As part of our interest in the development of chemical sensors for cations,[13] anions[14] and neutral guests,[15] we report here a prospective use of the osmium–terpyridine scaffolding as signalling reporter for the fluorogenic sensing of metal cations, anions and gases.

## Results and Discussion

### Synthesis and Characterisation

The ligand $L^1$ was synthesised following previously reported procedures[7] by reaction of 4′-[(4-bromomethyl)-phenyl]-2,2′:6′,2′′-terpyridine with an excess of cyclam in dichloromethane in the presence of $NEt_3$ at 30 °C for 24 h. Equimolar amounts of $L^1$ and [Os(Me-phtpy)$O_2$OH·-$(NO_3)_2$] (Me-phtpy = 4′-*p*-tolyl-2,2′:6′,2′′-terpyridine) were reacted in a THF/water (1:1 v/v) mixture in the presence of hydrazine hydrate as reductant to yield a complex mixture containing several Os–tpy derivatives. The desired heteroleptic derivative $[Os(L^1)(Me\text{-}phtpy)][PF_6]_2$ was isolated from the reaction mixture by column chromatography in silica using a mixture of acetonitrile/water/saturated aqueous solution of $KNO_3$ (85:10:5 v/v/v) as eluent and further precipitation with ammonium hexafluorophosphate (see Scheme 1). The high-resolution FAB mass spectrum of the $[Os(L^1)(Me\text{-}phtpy)][PF_6]_2$ complex showed peaks at *m*/*z* 1325, 1180 and 1033 corresponding to $[Os(L^1)(Me\text{-}phtpy)][PF_6]_2$, $[Os(L^1)(Me\text{-}phtpy)][PF_6]$ and $[Os(L^1)(Me\text{-}phtpy)]$ fragments, respectively. The high-resolution FAB mass spectra also showed the expected isotopic distribution of peaks corresponding to the Os(192), Os(190) and Os(189) isotopes. The $^1H$ NMR spectra of the osmium complex were also in agreement with the proposed formulation.



Scheme 1. $L^1$ and synthesis of $[Os(L^1)(Me\text{-}phtpy)]^{2+}$.

### Fluorogenic Sensing of Metal Cations

The synthesised osmium(II) complex $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ contains a polyazacycloalkane as "binding site" and an $Os(tpy)_2^{2+}$ core able to act as a "signalling subunit". In the first step, the studies shown below were carried out to identify the effect that the coordination of metal cations on the cyclam fragment has on the emission properties of the signalling osmium–terpyridine reporter. The electronic spectrum of the $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ complex is as expected for an $Os(tpy)_2^{2+}$ chromophore[11] with two bands in the visible region because of the spin-allowed d→π metal-to-ligand charge transfer (MLCT) transition ($\lambda_{max}$ = 470 nm) and the spin-forbidden MLCT band ($\lambda_{max}$ = 670 nm).

The studies below were performed in acetonitrile–water mixtures because of the insolubility in pure water of the $[Os(L^1)(Me\text{-}phtpy)][PF_6]_2$ complex in a wide pH range. Excitation at 670 nm resulted in the emission at 740 nm. This emission of the $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ complex remains unaltered within 5% in the 2–12 pH interval (see Figure 1). This behaviour is similar to that found for some ruthenium–terpyridine–polyamine analogues.[8] This indicates that in these systems there are no pH-dependent PET processes from the lone pair of the cyclam nitrogens to the photoexcited fluorophore as is usually found in polyazaalkanes bearing polycyclic aromatic hydrocarbons as signalling units.[2]

Steady-state fluorescence experiments as a function of the pH in the presence of equimolar amounts of metal cations $M^{2+}$ ($M^{2+}$ = $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, $Hg^{2+}$, $Pb^{2+}$ and $Ni^{2+}$) resulted in noticeable changes only in the presence of $Cu^{2+}$ and $Ni^{2+}$, whereas the emission intensity versus pH profile stayed unaltered in the presence of the remaining cations. The metal cation $Cu^{2+}$ induced an important quenching of the $Os(tpy)_2^{2+}$ emission in the 3–12 pH range, whereas $Ni^{2+}$ gave a similar quenching at basic pH (see Figure 1). This behaviour is significantly different to that found for the

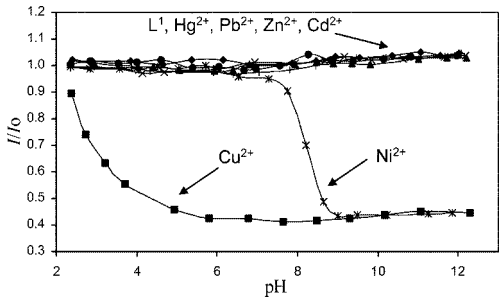

Figure 1. Emission intensity of the system [Os(L$^1$)(Me-phtpy)]$^{2+}$–M$^{2+}$–H$^+$ as a function of the pH in acetonitrile/water (70:30 v/v) mixture, [{Os(L$^1$)(Me-phtpy)}$^{2+}$] = $10^{-4}$ mol·dm$^{-3}$, in the presence of 1 equiv. of metal cation ($\lambda_{ex}$ = 670 nm, $\lambda_{em}$ = 740 nm).

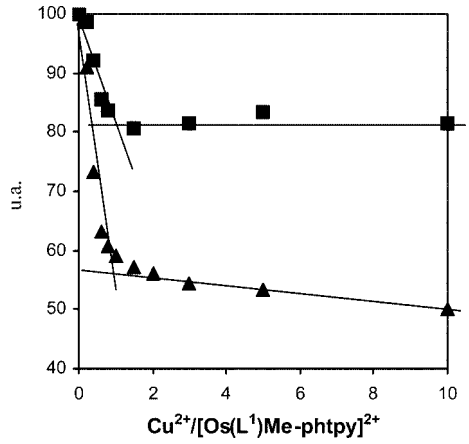

Figure 2. Steady-state fluorescence intensity (▲) and contribution of the lifetime of the free [Os(L$^1$)(Me-phtpy)]$^{2+}$ to the global decay (■) as a function of the Cu$^{2+}$ equivalents in acetonitrile/water (70:30 v/v) mixture.

analogous [Ru(L$^1$)(Me-tpy)]$^{2+}$ compound (Me-tpy = 4′-methyl-2,2′:6′,2′′-terpyridine),[9] for which quenching was observed in a narrower pH window (5–9 pH range). In recent years a certain number of fluorogenic molecular probes for copper and nickel have been reported.[16–18] When compared with them, the complex [Os(L$^1$)(Me-phtpy)]$^{2+}$ shows some advantages; it displays fluorogenic sensing properties in mixed aqueous solutions and shows emission properties in the far end of the visible window where usually few fluorescence interferences are found.

Additional time-resolved emission studies of the ligand [Os(L$^1$)(Me-phtpy)]$^{2+}$ in the presence of Cu$^{2+}$ were carried out in acetonitrile and in acetonitrile/water (70:30 v/v) solutions at neutral pH. In both cases the concentration of the osmium complex was $3\times10^{-5}$ M. The ligand [Os(L$^1$)(Me-phtpy)]$^{2+}$ shows a monoexponential decay in both acetonitrile and acetonitrile/water mixtures with lifetime values of 107 ns and 112 ns, respectively. In the presence of certain amounts of Cu$^{2+}$, a biexponential decay was observed. One of the species has the same lifetime as [Os(L$^1$)(Me-phtpy)]$^{2+}$, whereas the other showed significantly shorter lifetime values of 22 and 28 ns respectively for acetonitrile and acetonitrile/aqueous solutions. This second lifetime was assigned to the formation of Cu$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ complexes. In fact, when we compare the intensity of steady-state fluorescence and the contribution of the 107 ns component to the global decay, we observe that they follow the same tendency (see Figure 2), which is in agreement with the assignment of the 25 ns species to the copper complex that induced the quenching of the fluorescence of the Os(tpy)$_2^{2+}$ core. Upon increasing amounts of Cu$^{2+}$, in water, the lifetime at 112 ns does not undergo significant changes. On the contrary, when only acetonitrile is employed as solvent, the lifetime at 108 ns decreases to a value lower than 95 ns in the presence of an excess of Cu$^{2+}$. This suggests that in acetonitrile the free Cu$^{2+}$ displays some kind of additional interaction with the fluorogenic group that is avoided in the presence of water, probably because of a stronger solvation of the metal. The curves in Figure 2 also reach an asymptotic behaviour between 1 and 2 equiv., suggesting the formation of [Os(L$^1$)(Me-phtpy)]$^{2+}$:Cu$^{2+}$ 1:1 complexes.

In order to obtain more information about the nature of the cation–ligand interaction, we have performed additional coordination studies for the Cu$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ system by the use of potentiometric titrations.

## Potentiometric Studies

The protonation and coordination behaviour of the [Os(L$^1$)(Me-phtpy)]$^{2+}$ complex was studied by potentiometric titrations with KOH of previously acidified acetonitrile/aqueous solutions (70:30 v/v, 0.1 mol·dm$^{-3}$ tetrabutylammonium perchlorate) of [Os(L$^1$)(Me-phtpy)][PF$_6$]$_2$. The resulting protonation constants are shown in Table 1. For comparison purposes, the protonation constants of the ligand L$^1$[9] are also included in Table 1. Os$^{II}$–terpyridine complexes are very stable and kinetically inert, therefore titration experiments could be carried out without observing demetallation on the Os(tpy)$_2^{2+}$ framework. L$^1$ gives rise to five protonation constants in acetonitrile/aqueous solutions. The first two correspond to protonation of the cyclam fragment whereas the remaining three are more difficult to assign and might correspond to either protonation of the terpyridine or the cyclam units. The existence of a large number of protonation sites in L$^1$ makes the last two protonations too acidic and those constant values could not be determined. For the [Os(L$^1$)(Me-phtpy)]$^{2+}$ complex only three protonations were observed. This is in agreement with the results found for cyclam in acetonitrile/water (70:30 v/v) mixtures, in which only three protonation processes (log $K$ = 11.6, 9.49 and 2.01, respectively) were found.[9] The protonation constants for the [Os(L$^1$)(Me-phtpy)]$^{2+}$ complex are very close to those reported for the analogous Ru-containing complex [Ru(L$^1$)(Me-tpy)]$^{2+}$.[9] This was an expected behaviour that indicated that the simple modification of the metal centre in the M–terpyridine core does not significantly affect the protonation of the anchored cyclam unit.

Table 2 shows the stability constants obtained for the formation of $Cu^{2+}$ complexes with $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ in acetonitrile/water (70:30 v/v) mixtures from potentiometric titrations with KOH of previously acidified solutions of 1:1 mixtures of $Cu^{2+}$ and $[Os(L^1)(Me\text{-}phtpy)][PF_6]_2$. The distribution diagram of $[Os(L^1)(Me\text{-}phtpy)]^{2+}$–$H^+$–$Cu^{2+}$ is shown in Figure 3. The receptor $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ forms the complex $\{Cu[Os(L^1)(Me\text{-}phtpy)]\}^{4+}$ that exists at neutral pH (see Figure 3). This complex undergoes two stepwise protonation processes at acid pH and forms two hydroxo complexes at basic pH. The hydroxo complexes are formed by $OH^-$ coordination to the $Cu^{2+}$ centre to give most likely an octahedral configuration, whereas protonation processes at acidic pH involve the partial protonation of the cyclam subunit. The logarithm of the stability constant for the formation of the $\{Cu[Os(L^1)(Me\text{-}phtpy)]\}^{4+}$ complex is 14.2. This value is very close to that found for the formation of the analogous ruthenium complex $\{Cu[Ru(L^1)(Me\text{-}tpy)]\}^{4+}$ (log$K$ = 13.30), in agreement with the almost identical nature of the receptor.[9] The constant for the formation of the $\{Cu[Os(L^1)(Me\text{-}phtpy)]\}^{4+}$ complex can be compared with that found, under similar conditions (acetonitrile/water, 70:30), for the formation of the complex $[Cu(tmfcyclam)]^{2+}$ (log$K$ = 19.06), where tmfcyclam is a cyclam-substituted derivative [tmfcyclam = 1,4,8,11-tetrakis(ferrocenylmethyl)-tetraazacyclotetradecane].[9] Despite the somewhat different nature of both coordination sites in these complexes, the lower stability constants found for the former with $Cu^{2+}$ are in agreement with the electrostatic repulsions imposed by the $Os(tpy)_2^{2+}$ core on the $Cu^{2+}$–cyclam coordination process.

Table 2. Logarithms of the stability constants of the system $[Os(L^1)(Me\text{-}phtpy)]^{2+}$–$H^+$–$Cu^{2+}$ in acetonitrile/water (70:30 v/v) (298 K, 0.1 mol·dm$^{-3}$ tetrabutylammonium perchlorate).

| $[Os(L^1)(Me\text{-}phtpy)]^{2+} + Cu^{2+} + 2H_2O \leftrightarrows$ $[Os(L^1)(Me\text{-}phtpy)Cu(OH)_2]^{2+} + 2H^+$ | –5.45(7) |

From the stability constants obtained from potentiometric methods and emission studies shown in Figure 1 it is possible to determine which species are responsible for the quenching observed in the interaction of $Cu^{2+}$ with the $Os(tpy)_2^{2+}$ signalling unit. This can be seen in Figure 3, which shows both the distribution diagram and the emission intensity versus pH profile for the $[Os(L^1)(Me\text{-}phtpy)]^{2+}$–$H^+$–$Cu^{2+}$ system. It can be observed that the quenching of the emission of the $Os(tpy)_2^{2+}$ core is related to the formation of $Cu^{2+}$–$[Os(L^1)(Me\text{-}phtpy)]^{2+}$ complexes independently of the nature of the species formed. Neither the partial coordination of the cyclam macrocycle by the protons to form $\{Cu[Os(HL^1)(Me\text{-}phtpy)]\}^{5+}$ and $\{Cu[Os(H_2L^1)(Me\text{-}phtpy)]\}^{6+}$ nor the coordination of $OH^-$ to the $Cu^{2+}$ cation to form $\{Cu(OH)[Os(L^1)(Me\text{-}phtpy)]\}^{3+}$ and $\{Cu(OH)_2[Os(L^1)(Me\text{-}phtpy)]\}^{2+}$ produce significant changes in the emission intensity of the $Os(tpy)_2^{2+}$ core. The enhancement at acid pH is due to demetallation of the $Cu^{2+}$ to recover the emissive $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ species.

This behaviour contrasts significantly with that observed for the $Cu^{2+}$–$[Ru(L^1)(Me\text{-}tpy)]^{2+}$ system, for which the quenching of the emission intensity of the $Ru(tpy)_2^{2+}$ core was only found at neutral pH and attributed to the existence of the $\{Cu[Ru(L^1)(Me\text{-}tpy)]\}^{4+}$ complex in the solution.[9] In that case, the partial protonation of the macrocycle or $Cu^{II}$ coordination with $OH^-$ induced the recuperation of the emission intensity. In our system the different complexes formed have no effect on the emission of the $Os(tpy)_2^{2+}$ core in the $[Os(L^1)(Me\text{-}phtpy)]^{2+}$–$H^+$–$Cu^{2+}$ system, suggesting that the deactivation path should be different to that of $Ru(tpy)_2^{2+}$ in the analogous $[Ru(L^1)(Me\text{-}tpy)]^{2+}$–$H^+$–$Cu^{2+}$ ensemble. For the latter, a deactivation by energy transfer (ET) mechanisms was suggested, bearing in mind that photoelectron transfer (PET) processes were unlikely because of the large difference between the reduction of the $Cu(cyclam)^{2+}$ fragment and the oxidation of the $Ru^{II}$ core.

From a simple thermodynamic cycle the free energy associated to a photoelectron transfer from the excited state of the Os or Ru complex to the Cu–cyclam core can be calculated from the redox potentials of the metal–terpyridine and copper–cyclam cores and the $\lambda_{em}$ from the excited state of the metal–terpyridine group by using the equation: $\Delta G = -F[E_{Cu^{II}/Cu^{I}} - E_{M^{III}/M^{II}}] - hcN_A/\lambda_{em}$ where M = Os or Ru. The oxidation of the $Ru^{II}$ core in $[Ru(Me\text{-}tpy)_2]^{2+}$ is +1.3 V versus SCE, whereas the oxidation of the $Os^{II}$ metal centre in $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ is found at +0.84 V versus SCE. Additionally, the $\lambda_{em}$ for the Os and Ru complexes is 740 and 670 nm, respectively. Unfortunately, the Os system did not show any defined reduction peak for the $Cu^{II}$–cyclam core. Nevertheless, it might be possible to get some conclusion from the comparison between the oxidation potentials and $\lambda_{em}$ from the Ru and Os complexes. Thus, from the above equation it can be observed that a reduction in the oxidation potential of the $M(tpy)_2^{2+}$ core would favour the occurrence of photoelectron transfer processes, whereas a reduction of the energy of the excited state (longer $\lambda_{em}$) would disfavour this. When we move from Ru to Os there

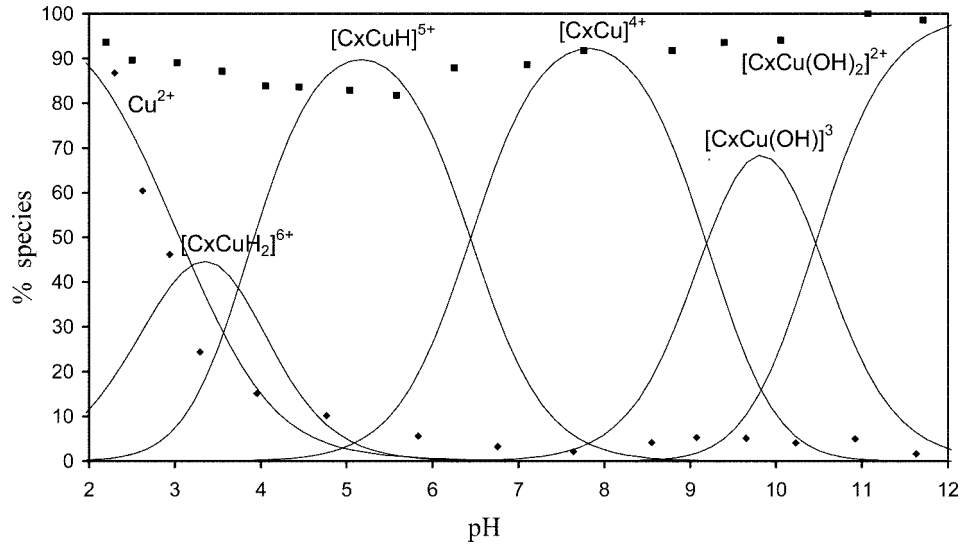

Figure 3. Species distribution diagram of the system [Os(L$^1$)(Me-phtpy)]$^{2+}$–H$^+$–Cu$^{2+}$ in acetonitrile/water (70:30 v/v) from the data of Table 2. The experimental values of intensity of fluorescence of [Os(L$^1$)(Me-phtpy)]$^{2+}$ (■) and [Os(L$^1$)(Me-phtpy)]$^{2+}$–Cu$^{2+}$ (♦) [Cx = Os(L$^1$)(Me-phtpy)] are also included.

is a fall in the oxidation potential of almost 500 mV that is not compensated by the difference in $\lambda_{em}$ from the excited states of Os and Ru ($\lambda_{em}$ at 740 and 670 nm), which correspond to an energy of only 180 mV. This indicates that a PET process from the excited state of the M(tpy)$_2^{2+}$ core to the Cu$^{II}$–cyclam moiety is thermodynamically more favourable to occur for Cu$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ than for the analogous ruthenium Cu$^{2+}$–[Ru(L$^1$)(Me-phtpy)]$^{2+}$ complex.

Attempts to determine stability constants from potentiometric titrations for the Ni$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ system were unsuccessful, most likely because of the presence of kinetically slow coordination processes. Nevertheless, the Ni$^{2+}$ cation would be expected to form similar complexes to those found for Cu$^{2+}$, that is, the formation of the {Ni[Os(L$^1$)(Me-phtpy)]}$^{4+}$ complex at near neutral pH and the formation of hydroxo complexes and protonation of the cyclam macrocycle at basic and acidic pH, respectively. Assuming this general behaviour it might tentatively be suggested that the quenching in the case of the Ni$^{2+}$ cations occurs in the pH range where the square-planar 1:1 {Ni[Os(L$^1$)(Me-phtpy)]}$^{4+}$ complex and the corresponding hydroxo complexes exist in solution.

## Anion Sensing

As we have found above, the complex [Os(L$^1$)(Me-phtpy)]$^{2+}$ can protonate in acetonitrile/water media to give highly positively charged species. We believed that some of these formed species in mixed aqueous environments might be used as chemosensors for the fluorogenic sensing of anions. In order to check this possibility, certain anions were added to acidified solutions of [Os(L$^1$)(Me-phtpy)]$^{2+}$ and the emission of the Os(tpy)$_2^{2+}$ core monitored at different pH values. Unfortunately, the emission versus pH profile of the [Os(L$^1$)(Me-phtpy)]$^{2+}$ complex remained unaltered in the presence of the anions studied (Br$^-$, Cl$^-$, phosphate, sulfate, ATP, ADP and GMP). As an alternative, we also carried out similar studies with the Cu$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ systems. However, unfortunately no change in the emission intensity of the Os(tpy)$_2^{2+}$ core was observed at any pH in the presence of the above-mentioned anions. This might be because, as we have found above, to observe a recovery of emission intensity in the Cu$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ system it appears necessary to remove the copper from the macrocycle, whereas none of the anions is able to produce an interaction strong enough to take out the Cu$^{2+}$ from the cyclam.

The research in this section has been completed by studying the effect that the presence of anions has on the emission behaviour of the Ni$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ system (see Figure 4). As can be seen, the anions ATP, ADP and chloride show a remarkable behaviour and are able to significantly change the emission intensity versus pH profile of the Ni$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ ensemble. Other anions (Br$^-$, phosphate, sulfate and GMP) are not shown but they did not induce significant emission changes. In all cases the Ni$^{2+}$ quenching effect is shifted to the acidic range, suggesting these anions stabilise the formation of the nickel complex. In fact, the interaction of the Ni$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ complex with anions would reduce the neat charge of complex. This would decrease the repulsion with the protonated cyclam core at acidic pH, resulting in a stabilization of the Ni$^{2+}$–[Os(L$^1$)(Me-phtpy)]$^{2+}$ system in a wider pH range with the concomitant fluorescence quenching due to the presence of the Ni$^{2+}$ cation in the cyclam core. On the contrary, it seems that the anions are not able to produce an extra stabilisation of Cu$^{2+}$ in the macrocycle because the quenching effect of Cu$^{2+}$ is not shifted in the presence of anions (see above). The pH value at which the

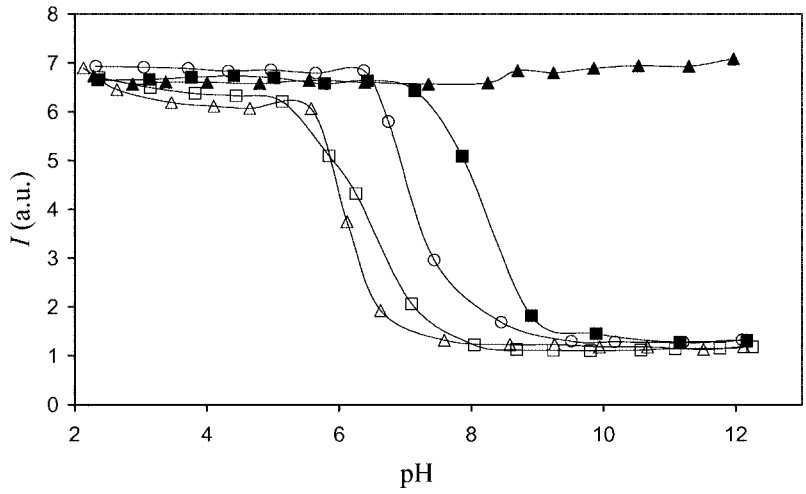

Figure 4. Emission intensity of the system $[Os(L^1)(Me\text{-}phtpy)]^{2+}$–$Ni^{2+}$–$H^+$–$A^{n-}$ as a function of the pH in acetonitrile/water (70:30 v/v) mixture, $[\{Os(L^1)(Me\text{-}phtpy)\}^{2+}] = 10^{-4}$ mol·dm$^{-3}$, in the presence of 1 equiv. of anion unless otherwise noted ($\lambda_{ex}$ = 670 nm, $\lambda_{em}$ = 740 nm). $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ (▲), $Ni^{2+}$ (■), chloride (○), ADP, (□) and ATP (△).

demetallation is produced (about 4 units lower than in the case of $Ni^{2+}$) is probably too low and the compensation of charge with anions is too weak to produce a significant effect in the fluorescence emission.

Selectivity can, for example, be achieved by changing the pH. For instance, addition of anions to the $Ni^{2+}$–$[Os(L^1)(Me\text{-}phtpy)]^{2+}$ system at pH 6.5 would result in a significant quenching only in the presence of ATP and ADP anions. A displacement of the quenching effect to more acidic pH is observed for anions in the order ATP > AMP > chloride. A similar sequence would also be expected (ATP > ADP > chloride) in relation with the strength of the interaction of these anions with the $\{Ni[Os(L^1)(Me\text{-}phtpy)]\}^{4+}$ complex. This is a somewhat attractive behaviour that indicated that the $Ni^{2+}$ complex of the $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ system acts as an anion fluorogenic chemosensor in mixed aqueous environments.

## Oxygen Sensing

Finally, we have also tested the oxygen-sensing properties of the osmium complex $[Os(L^1)(Me\text{-}phtpy)]^{2+}$. There are a certain number of examples in the literature of the use of ruthenium–polypyridyl complexes for the detection of oxygen both in air[19] and as dissolved oxygen in water.[20] These studies are usually carried out either by immobilising the complex in polymer films or in sol-gel-derived films. In these systems the oxygen concentration is proportional to the degree of quenching of the ruthenium complex emission in the presence of oxygen. In most of the cases the complexes used for the preparation of oxygen sensors are $Ru(bipy)_3^{2+}$. On the contrary, there are very few examples of oxygen sensors using osmium complexes.[21]

Thus, we have performed studies directed to test the use of the $[Os(L^1)(Me\text{-}phtpy)]^{2+}$ complex as a gas-phase oxygen

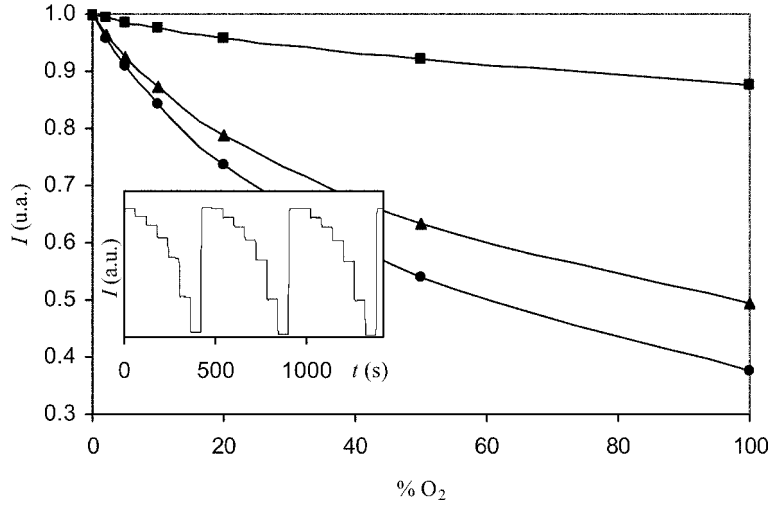

Figure 5. Emission intensity in different $N_2$:$O_2$ mixtures. MTEOS (■), MTEOS/TEOS, 1:1 (▲), TEOS (●).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sensor. The studies have been carried out using sol-gel silica films in which the osmium complex has been immobilised. Additionally, in order to study the influence of the sol-gel matrix we have used two different silica precursors, tetraethoxysilane (TEOS) and methyl tryethoxysilane (MTEOS). These precursors have a different number of hydrolysable positions and different speed of hydrolysis. Furthermore, the MTEOS precursor has a methyl group that increases the hydrophobicity of the final matrix. The emission intensity of the [Os(L$^1$)(Me-phtpy)]$^{2+}$ complex in the presence of different $O_2/N_2$ mixtures ($\lambda_{ex}$ = 470 nm, $\lambda_{em}$ = 740 nm) was measured and it was observed that oxygen produced a significant quenching of the osmium fluorescence. Figure 5 plots the emission intensity of the osmium core as a function of the concentration of oxygen for three different films made with TEOS, MTEOS and TEOS/MTEOS in 1:1 molar ratio. Table 3 shows the characteristics of the films prepared. As can be seen in Figure 5 and Table 3, the choice of precursor has a significant effect on the sensor response. Thus, films made with TEOS display a larger quenching (63% of the original emission intensity) in the presence of oxygen than that found for films with MTEOS (13% of the original osmium emission). As can also be seen in Table 3, the response time (time for the intensity to drop to 90% of the original value for a certain concentration of $O_2$) for films fabricated with TEOS was approximately 10 times larger than for the films made with MTEOS. This is most likely due to the presence of silanol groups in the former films that are able to retain some water in the structure hence slowing the sensor response time. The presence of the hydrophobic $CH_3$ groups in the matrix made with MTEOS avoids this effect and enhances the accessibility of the gas in the films, resulting in shorter response times. The films prepared showed a good stability and repeatability, indicating a very reversible process (see inset of Figure 5).

Table 3. Response parameters of the films.

| Film | Quenching $O_2$ [%] | Response time 90% [s] |
|---|---|---|
| MTEOS | 13 | 6.7 |
| MTEOS/TEOS, 1:1 | 52 | 4.4 |
| TEOS | 63 | 44.1 |

## Conclusions

A new osmium bis-terpyridine derivative attached to a cyclam receptor unit has been prepared and its ability to act as a fluorogenic chemosensor has been studied. The osmium complex [Os(L$^1$)(Me-phtpy)]$^{2+}$ is able to act as a fluorogenic sensor of copper and nickel in mixed aqueous environments, whereas the emission of the osmium–terpyridine core remains unaltered in the presence of other metal cations. Additionally, changes in the emission of the nickel complex have shown to be capable of sensing anions such as ATP, ADP and chloride in mixed aqueous solutions. Finally we have demonstrated good gas-phase oxygen sensitivity of sol-gel-based thin films in which the complex has been immobilised. All these studies indicate that osmium–terpyridine systems might behave as suitable and versatile signalling subunits for different sensing purposes.

## Experimental Section

**General Remarks:** [Os(Me-phterpy)$O_2$OH·$(NO_3)_2$], 4′-[4-methylphenyl]-2,2′:6′,2′′-terpyridine and 1-[4′-*p*-tolyl-(2,2′:6′,2′′-terpyridyl)]-1,4,8,11-tetraazacyclotetradecane (L$^1$) were prepared according to published methods. All other reagents were obtained from commercial sources and were used as received.

**Synthesis of [Os(L$^1$)(Me-phtpy)][$PF_6$]$_2$:** The synthesis of the osmium complex [Os(L$^1$)(Me-phtpy)]$^{2+}$ was carried out following a general procedure described previously.[22] A mixture of L$^1$ (195.06 mg, 0.35 mmol), [Os(Me-phterpy)$O_2$OH·$(NO_3)_2$] (238.6 mg, 0.35 mmol) and hydrazine hydrate (0.65 mL) as a reducing agent in water/THF (1:1 v/v) were heated to 50 °C for 10 min. Ammonium hexafluorophosphate was added to the resulting deep red solution and the THF was eliminated under reduced pressure until the appearance of a precipitate that was filtered. This precipitate was purified by column chromatography over silica using acetonitrile/aqueous/saturated $KNO_3$ aqueous solution 85:10:5 as eluent. The product was finally isolated as its $PF_6^-$ salt (19 mg, 4.1% yield). The osmium complexes are toxic and they should be handled carefully. $^1$H NMR (300 MHz, $CD_3CN$, 25 °C) $\delta$ = 2.5–3.5 (m), 4.1 (s, 2 H), 7.13–7.20 (m, 4 H), 7.368 (t, 4 H), 7.61–7.70 (m, 4 H), 7.864 (t, 4 H), 8.137 (d, 2 H), 8.282 (d, 2 H), 8.699 (t, 4 H), 9.082 (s, 2 H), 9.109 (s, 2 H). FAB$^+$: 1325 [Os(L$^1$)(Me-phtpy)]$^{2+}$·2$PF_6^-$, 1180 [Os(L$^1$)(Me-phtpy)]$^{2+}$·$PF_6^-$, 1033 [Os(L$^1$)(Me-phtpy)]$^{2+}$. High resolution FAB$^+$ $C_{54}H_{57}F_{12}N_{10}OsP_2$ (192) calcd. 1327.36662, found 1327.36961. $C_{54}H_{57}F_{12}N_{10}OsP_2$ (190) calcd. 1325.36358, found 1325.35995. $C_{54}H_{57}F_{12}N_{10}OsP_2$ (189) calcd. 1324.36328, found 1324.38587.

**Preparation of the Films for Oxygen Sensing:** Aqueous HCl (0.1 M) and the corresponding Si precursor were added to [Os(L$^1$)(Me-phtpy)][$PF_6$]$_2$ (20 mg, 15 μM) solved in acetonitrile (see Table 4). The solution was stirred for 30 min at room temperature and aged in the oven at 70 °C for several hours. Glass slides were coated by dip coating (3 mm·s$^{-1}$), and the films aged in the oven at 70 °C for 24 h.

Table 4. Details for the preparation of the oxygen-sensing films.

| TEOS [%] | ACN [mL] | HCl [mL] | MTEOS [mL] | TEOS [mL] | Oven [h] |
|---|---|---|---|---|---|
| 0 | 3.280 | 0.630 | 1.800 | – | 1 |
| 50 | 2.995 | 0.536 | 0.847 | 0.946 | 4 |
| 100 | 2.840 | 0.563 | – | 1.800 | 5 |

**Physical Measurements and Instrumentation:** Photochemical data were obtained with a FS900CDT steady-state T-Geometry Fluorometer from Edinburgh Analytical Instruments. $^1$H NMR spectra were recorded with a Varian Gemini spectrometer. Potentiometric titrations were carried out in acetonitrile/water (70:30, v/v, 0.1 mol·dm$^{-3}$ tetrabutylammonium perchlorate) under nitrogen using a vessel water-thermostatted at 25.0 ± 0.1 °C. The tritant was added by means of a Crison microburette 2031. Further details of the potentiometric experiments have been published previously.[23] The concentrations of the metal ions were determined using standard methods. The computer program SUPERQUAD[24] was used to calculate the protonation and stability constants. The titration curves for each system (about 250 experimental points, correspond-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing to at least three titration curves; pH range investigated 2.5–10.2; ligand and metal ions concentration about $1.0\times10^{-3}$ mol·dm$^{-3}$) could be treated either as a single set or as separate entities without significant variation in the values of the stability constants. Finally, the sets of data were merged together and treated simultaneously to give the quoted stability constants.

Oxygen sensitivity was measured employing a Nichia blue LED (470 nm) as an excitation source and S1223 photodiode from Hamamatsu as detector placed at 90° to the LED. Appropriate optical filters were used to isolate the excitation from the emission light. Oxygen/nitrogen mixtures were delivered using computer-controlled mass-flow controllers from Kinetic Systems, Dublin, Ireland.

# Synthesis, Structures and Catecholase Activity of a New Series of Dicopper(II) Complexes of Reduced Schiff Base Ligands

**Bellam Sreenivasulu,[a] Fei Zhao,[b] Song Gao,[b] and Jagadese J. Vittal*[a]**

**Keywords:** Biomimetic studies / Copper / Reduced Schiff-base complexes / Tridentate ligands / Catecholase activity / Magnetic properties

A series of dinuclear $Cu^{II}$ complexes of reduced Schiff bases from substituted salicylaldehydes and amino acids have been synthesized and characterized. They are: $[Cu_2(RScp11)_2(H_2O)_2]$ {$H_2RScp11$ = 1-[(2-hydroxy-5-R-benzyl)amino]cyclopentane-1-carboxylic acid; R = H (**1**), Cl (**2**), $CH_3$ (**3**), OH (**4**)}, $[Cu_2(RSch11)_2(H_2O)_x]$ {$H_2RSch11$ = 1-[(2-hydroxy-5-R-benzyl)amino]cyclohexane-1-carboxylic acid; R = H and *x* = 1 (**5**), R = Cl and *x* = 2 (**6**), R = $CH_3$ and *x* = 2 (**7**)}, $[Cu_2(RSch12)_2(H_2O)_2]$ {$H_2RSch12$ = 2-[(2-hydroxy-5-R-benzyl)amino]cyclohexane-1-carboxylic acid; R = H (**8**), $CH_3$ (**10**) and $[Cu_2(ClSch12)_2]\cdot 2H_2O$ (**9**)}, $[Cu_2(Diala5)_2(H_2O)_2]\cdot H_2O$ [$H_3$Diala5 = *N*-(2,5-dihydroxybenzyl)-L-alanine] (**11**), $[Cu_2(Diala4)_2(H_2O)_2]\cdot H_2O$ [$H_3$Diala4 = *N*-(2,4-dihydroxybenzyl)-L-alanine] (**12**), and $[Cu_2(Diala3)_2(H_2O)_2]\cdot H_2O$ [$H_3$Diala3 = *N*-(2,3-dihydroxybenzyl)-L-alanine] (**13**). They were isolated and characterized by chemical and spectroscopic methods. Single crystal X-ray crystallographic studies have revealed that $[Cu_2(Scp11)_2(MeOH)_2]$ (**1a**), $[Cu_2(ClScp11)_2(DMF)(H_2O)]\cdot MeCN$ (**2a**), $[Cu_2(MeScp11)_2(MeOH)_2]\cdot 2MeOH$ (**3a**), $[Cu_2(ClSch11)_2(MeOH)_2]\cdot 2MeOH$ (**6a**), $[Cu_2(ClSch12)_2]\cdot 2MeOH$ (**9a**), and $[Cu_2(Diala4)_2(DMSO)_2]\cdot 2DMSO\cdot 2$acetone (**12a**) have 1D hydrogen-bonded polymeric structures while **4** has a 3D hydrogen-bonded network structure. Complex **8** displays a 2D coordination polymeric network structure. The complexes **1**–**13** have been investigated as functional models for the catechol oxidase by employing 3,5-di-*tert*-butylcatechol as a model substrate. Electron-withdrawing substituents reduced the activity while electron-donating substituents enhanced the activity. Variable-temperature magnetic studies conducted on compound **8** suggest the presence of strong inter-dimer antiferromagnetic coupling.

## Introduction

Among the well-known representatives of Type III copper proteins, catechol oxidase with active dicopper(II) sites is a ubiquitous enzyme in living systems for catalyzing the oxidation of a wide range of *ortho*-diphenols to *ortho*-diquinones. The subsequent auto polymerization of the highly active quinones into polyphenolic catechol melanins is considered to be responsible for the defense mechanism observed in plants against pathogens or pests.[1] In fact, the two copper atoms of dicopper(II) bio-active centers present in different metalloenzymes are found to act cooperatively within the proximity of ca. 3.5 Å with each $Cu^{II}$ center coordinated by three histidine donors.[2,3] As confirmed by the recent X-ray crystal structure analysis, catechol oxidase in the *met* oxidized form contains dicopper centers with a Cu···Cu distance of 2.9 Å.[3] Modeling the features of bio-relevant dinuclear active sites through synthetic analogues basically involves the judicious design of binucleating ligands to meet the conditions such as bridging mode controlling the metal–metal distance, steric-electronic properties, and geometry around the metal centers.[4] Consequently, dinuclear copper(II) complexes of the binucleating ligands have been extensively documented as bimetallic catalysts due to their potential ability to mimic the functions of the so-called catechol oxidase.[2,4–5]

Our research group has been interested in the coordination chemistry of reduced Schiff-base ligands, *N*-(2-hydroxybenzyl)-amino acids, which have the potential to form dinuclear complexes through a bridging phenolate group. In addition, these ligands can also afford the choice of coordination environments that determine the nature of metal ions that can be bound within the closest proximity. Apart from the studies illustrating interesting solid-state supramolecular transformation of $Cu^{II}$ and $Zn^{II}$ complexes,[6] and the novel helical stair-case structure in the $Ni^{II}$ complex,[7] our research group has reported several dicopper(II) complexes derived from reduced Schiff bases as functional models for catechol oxidase.[8] Very recently, we have also demonstrated that the dicopper(II) complexes containing the weakly coordinating sulfonate donor group are more active

catalysts towards the oxidation of 3,5-DTBC compared to their carboxylate analogues.[9]

In this paper, we report a new series of dicopper(II) complexes of reduced Schiff-base ligands formed between various substituted salicylaldehydes and aminocyclopentane/cyclohexanecarboxylic acids and L-alanine (Scheme 1). Our previous studies discussing the effect of chelating side arms[8] and the weakly coordinating sulfonate group[9] on the activity, prompted us to investigate and evaluate the activity of these closely related yet distinct series of dicopper(II) complexes with substituted phenyl rings under similar experimental conditions. Despite the plethora of reports on catecholase activity of various dicopper(II) complexes, studies modulating the activity in terms of electronic properties via substituted bridging phenolates have not been well documented.[10] Such an investigation of the structure-reactivity patterns is essential to enhance the mechanistic understanding of the parameters affecting the catecholase activity. In this paper, we present the salient structural features and the details of catecholase activity of the dicopper(II) complexes of various reduced Schiff-base ligands containing the substituted phenolate moiety. Further, variable temperature magnetic studies of a selected complex have also been discussed.

## Results and Discussion

Copper complexes **1**–**13** have been synthesized in good yields by the complexation of $Cu^{II}$ salts with the corresponding reduced Schiff-base ligands according to the procedures described in the experimental section. Owing to their poor solubility in common solvents except in DMF and DMSO, our attempts to obtain single crystals of the

bulk as such were not successful. However, the single crystals obtained were different from the bulk due to lattice and coordinated solvents in the case of $[Cu_2(Scp11)_2(MeOH)_2]$ (**1a**), $[Cu_2(ClScp11)_2(DMF)(H_2O)]\cdot MeCN$ (**2a**), $[Cu_2(MeScp11)_2(MeOH)_2]\cdot 2\,MeOH$ (**3a**), $[Cu_2(ClSch11)_2(MeOH)_2]\cdot 2\,MeOH$ (**6a**), $[Cu_2(ClSch12)_2]\cdot 2\,MeOH$ (**9a**), and $[Cu_2(Diala4)_2(DMSO)_2]\cdot 2\,DMSO\cdot 2\,acetone$ (**12a**); however, complexes **4** and **8** afforded single crystals that were the same as the bulk during single crystal growth.

The IR absorption bands of the newly synthesized complexes **1**–**13** in the range of 3398–3458 $cm^{-1}$ indicate the presence of coordinated or lattice water molecules in the compounds.[11a,11c] This can be further supported by the weight loss observed in thermo gravimetric (TG) analysis. The sharp bands observed in the range of 2927–2960 $cm^{-1}$ are due to ν(N–H). The absorption bands observed in the region of 1597–1640 and 1360–1460 $cm^{-1}$ are due to the asymmetric [$\nu_{as}COO^-$] and symmetric [$\nu_sCOO^-$] stretching frequencies of the carboxylate group, respectively. The difference (Δν) between the asymmetric and symmetric stretching frequencies of carboxylate groups can be used to determine their binding mode in the metal complexes.[11a] In general, Δν for monodentate carboxylate is greater than 200 $cm^{-1}$ and for a bridging carboxylate Δν is less than 200 $cm^{-1}$.[12] This observation has been confirmed for the 2D coordination polymeric structure in **8** showing the bridging ($\Delta\nu$ = 115) mode of carboxylate.

The initial weight loss in TG of **4** in the temperature range of 134–177 °C corresponds to the two water molecules coordinated to the $Cu^{II}$ ions, which is corroborated by the crystal structure of **4**. The complex **8** showed weight loss for all six water molecules in the temperature range 80–119 °C and the crystal structure of **8** contains two aqua ligands and four lattice water molecules. The loss of metal bound water molecules along with lattice waters is similar to the observed behavior during the solid-state supramolecular transformations via thermal dehydration.[6a–b] The TG of the bulk **1**–**3**, **5**–**7**, and **9**–**10** showed weight loss in the temperature range of 60–168 °C due to the loss of two metal-bound aqua ligands. The observed dehydration temperature below 120 °C for **11** and **12**, and 130 °C for **13** also suggests similar behavior of metal bound aqua ligands as in **8**. Thus, in the light of the observed thermal dehydration behavior, UV/Vis, IR, and ESI-MS studies the molecular formulae of the bulk have been proposed.

## Solution Studies

The structural behavior of the complexes **1**–**13** in solution has been investigated using UV/Vis, ESI-MS spectroscopic techniques.

### *UV/Vis Spectroscopy*

Electronic spectra of the complexes **1**–**13** recorded in DMF solution and Nujol mull are shown in Table 1. The absorption bands observed in the range 620–703 nm correspond to *d-d* transitions and the strong bands at 358–402 nm are due to ligand-to-metal charge transfer. For an octahedral geometry the expected $^2E_g$ to $^2T_{2g}$ transition takes place at around 800 nm. This band will undergo a significant blue shift when the octahedral geometry distorts to a square pyramidal and square planar structure.[13] For the reduced Schiff base copper(II) complexes with square pyramidal geometry, the *d-d* transitions and charge transfer transitions generally occur in the range 620–720 and 360–450 nm, respectively.[8–9,14a–14d]

The medium intensity bands occurring in the range 356–401 nm are due to phenolate-to-copper(II) charge transfer.[14a–14d] As the present complexes contain the *para* substituents on the bridging phenolate, definitive assignment of CT bands can be provided based on the electronic effects induced by the substituents. Electron-donating groups are expected to decrease the Lewis acidity of the copper center thus shifting the phenoxo-to-copper CT band to lower energies while electron-withdrawing groups are expected to increase the Lewis acidity and shift the phenolate-to-copper CT bands to higher energies.[10a,14d] Accordingly, we observe the electron-donating *para* $-CH_3$ group shifting the LMCT band to lower energy and the electron-withdrawing *para* –OH and –Cl groups causing the shift of the LMCT

Table 1. Summary of the UV/Vis spectroscopic data of **1**–**13**.

band to higher energy. On the basis of the crystal structure of **9a**, the geometry around the copper(II) centers in **9** is assumed to have a square-planar geometry. The observed *d-d* transitions in **9** at 623 nm also indicate square planar $Cu^{II}$ centers. This behavior is similar to that recorded for the structurally well-characterized square planar copper(II) complexes.[13] The electronic spectra of **1**–**13** do not change much in DMF solution and Nujol mull, and appear to indicate that the coordination number and geometry observed in the solid state are retained in solution.

### *ESI-MS Studies*

The structural behavior of the complexes **1**–**13** in solution has been investigated by ESI mass spectral analysis. ESI mass spectra of the complexes were recorded in MeOH except for **2**, **7**, and **9** for which the spectra were recorded in a 1:1 solvent mixture of MeOH and DMSO because of a solubility problem. As indicated by the masses of both positive and negative ions in the spectra, all the complexes are found to exist in solution mainly as dicopper(II) species. For example, the positive ion ESI masses observed for **8** shows the existence of dicopper(II) species predominantly in solution as $[Cu_2(Sch12)_2Na]^+$ (643, 100). The other less intense peaks found were $[Cu(Sch12)Na]^+$ (333, 27); $[Cu_3(Sch12)_3Na]^+$ (954, 55); $[Cu_4(Sch12)_4Na]^+$ (1267, 25); $[Cu_5(Sch12)_5Na]^+$ (1574, 20). Our attempts to obtain consistent electrochemical data using CV were unsuccessful owing to the solubility problem. Nonetheless, it maybe noted that the concentration levels in methanolic solutions were just enough for the activity studies.

## General Description of Crystal Structures

The crystal structures of complexes **1a**, **2a**, **3a**, **4**, **6a**, **8**, **9a**, and **12a** were determined by single-crystal X-ray crystallographic analysis. In all these complexes, the reduced Schiff-base ligands display a tridentate coordination mode while bridging the two copper ions through phenolate oxygen atoms forming $Cu_2O_2$ cores with a Cu···Cu distance of ca. 3 Å. The crystal structure of **9a** displayed $Cu^{II}$ centers with a square-planar geometry while the other complexes contain square pyramidal $Cu^{II}$ centers.

In all the square pyramidal complexes, the basal plane of the square pyramid is completed by the coordination of each $Cu^{II}$ to the two bridging phenolate oxygen atoms, imine nitrogen, and carboxylate oxygen. The Cu–O bond lengths due to the coordination of each $Cu^{II}$ to the bridging phenolate and carboxylate oxygen atoms in the basal plane fall in the range of 1.934(2)–2.002(3) and 1.876(2)–1.982(7) Å, respectively, while the bond lengths due to Cu–N (imine nitrogen) are observed in the range of 1.950(2)–2.004(8) Å. The apical position is occupied by solvents. A crystallographic center of inversion is present in the dimeric structure of **1a**, **3a**, **4**, **6a**, and **9a**. Selected bond lengths and angles as well as hydrogen bond parameters have been compiled in Table 2 and Table 3 respectively.

With respect to the ligands, **1a**, **2a**, **3a**, and **4** contain a 1-aminocyclopentanecarboxylate side arm but different

[a] Symmetry transformations used to generate equivalent atoms: $-x+1, -y+1, -z+1$ (**1a**); $-x+1, -y+1, -z+1$ (**3a**); $-x+1, -y+1, -z+1$ (**4**); $-x+1, -y+1, -z+1$ (**6a**); $-x+1, -y+1, -z+1$ (**8**); $-x+1, -y+1, -z+1$ (**9a**). [b] $-x, -y, -z$ (**8**). [c] $-x+1, -y+1, -z$ (**8**).

substituents on the 5-position of the benzene ring; H in **1a**, Cl in **2a**, $CH_3$ in **3a**, and OH in **4a**. All these complexes, **1a**, **2a**, **3a**, and **4** display $Cu^{II}$ centers with a distorted square pyramidal geometry ($\tau$ = 0.168, 0.043, 0.038, 0.228, and 0.003, respectively).[15] The common 1-aminocyclopentanecarboxylate side arm of the ligands in **1a**, **2a**, **3a**, and **4** resulted in the formation of five-membered rings. The complex **1a** as a methanol adduct crystallized with two methanol molecules in the monoclinic system with space group *C*2/*c* with a Cu···Cu separation of 3.0245(7) Å. The apical positions of the square pyramid of the two $Cu^{II}$ atoms are occupied by methanol molecules in *trans* fashion (Figure 1). Complementary MeOH···O=C (O4–H4···O2) and N–H···O=C (N1–H1···O3) intermolecular hydrogen bonding generates a 1D polymeric structure in **1a** in the solid state (Figure 2).

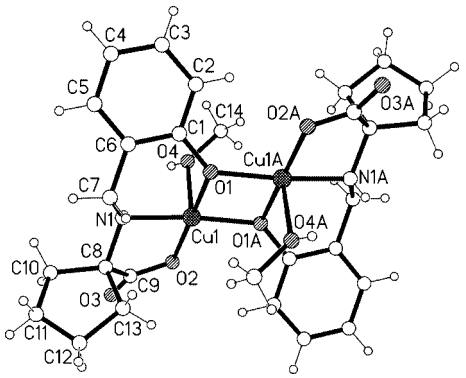

Figure 1. A perspective view of the dimer **1a** (symmetry equivalent positions: $-x+1$, $-y+1$, $-z+1$).

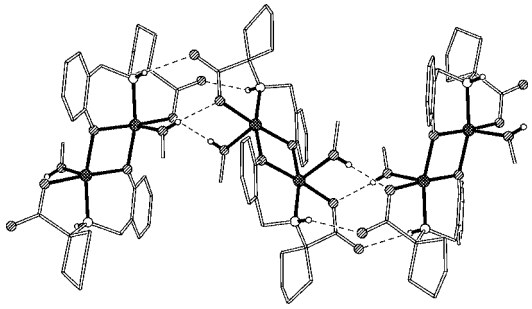

Figure 2. A view showing a portion of the 1D hydrogen-bonded structure in **1a**.

In **2a** the two copper atoms in the dimer are separated by a distance of 3.0428(6) Å. The apical site of the square pyramid is occupied by DMF [Cu(1)–O(8), 2.230(3) Å] with Cu(1) and the aqua ligand [Cu(2)–O(7), 2.299(3) Å] with Cu(2) in *trans* to each other. Each dimer is associated with two molecules of acetonitrile solvent in the asymmetric unit. There are very weak interactions between the carbonyl oxygen atoms and the copper atoms [Cu(1)···O3(1 – *x*, 1 – *y*, 1 – *z*), 2.885 Å and Cu(2)···O6(1 – *x*, *y*, *z*), 2.922 Å] that are about the sum of the van der Waals radii, 2.9 Å. These Cu···O interactions generate a 1D polymer along the *b*-axis sustained by hydrogen bonds between carboxylate oxygen and the aqua ligand, O(7) H(7B)···O(3). Further O(7)–H(7A)···N(4S) hydrogen bonds have also been observed.

The complex **3a** displays square pyramidal geometry at each $Cu^{II}$ center with a Cu···Cu distance of 3.0056(5) Å. The apical sites of the square pyramid at each $Cu^{II}$ center are occupied by methanol molecules in *trans* fashion with a Cu···O distance of 2.59 Å. Packing of dimers along the *a* axis displays a 1D hydrogen-bonded polymer in **3a** supported by intermolecular hydrogen bonds generated between imine H atoms and methanol oxygen [N–H···O(5)], methanolic hydrogen, and carboxylate oxygen atoms [O(4)–H(4)···O(3) and O(5)–H(5)···O(2)] as well as weak interactions of neighboring carboxylate oxygen atoms with each $Cu^{II}$ ion (Cu···O, 2.885 Å) in *syn-anti* fashion.

In the crystal structure of **4** the two lattice water molecules are in close interaction with $Cu^{II}$ atoms [Cu–O, 2.66(3) Å] occupying the apical positions to complete the square pyramidal geometry around each $Cu^{II}$ center (Figure 3) with a Cu···Cu distance of 2.9924(8) Å. Intermolecular hydrogen bonds generated by the hydroxy group on the phenolate moiety with the aqua ligand (O4–H4B···O5, O5–H5···O4) and carboxylate oxygen atom (O4–H4A···O3) and by the imine hydrogen with another carboxylate oxygen (N1–H1···O3) have resulted in a 3D hydrogen-bonded network in **4** as shown in Figure 4.

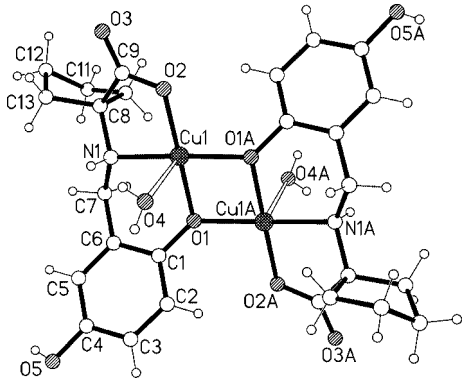

Figure 3. A perspective view of the dimer **4** (symmetry equivalent positions: $-x+1$, $-y+1$, $-z+1$).

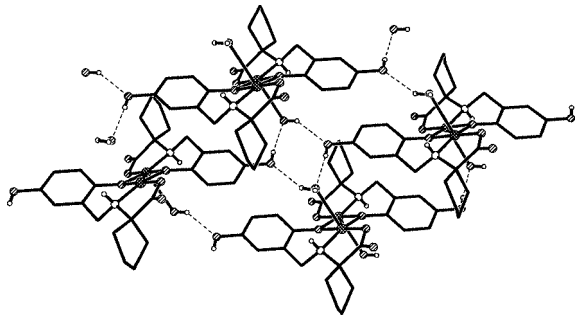

Figure 4. Packing diagram of **4**.

The compound **6** crystallized in triclinic space group $P\bar{1}$ with two methanol molecules in the crystal lattice and **6a** is isomorphous to **3a**, i.e. the arrangement of molecules in the crystal lattice, but not isostructural. The hydrogen bonding pattern in **6a** is also similar to that observed in **3a**. The solid-state crystal packing along the *b* axis revealed that the complex is a 1D polymer that resulted from weak Cu···O interactions and intermolecular hydrogen bonding. Further, carboxylate oxygen atoms of the neighboring dimeric units maintain weak interactions with each $Cu^{II}$ ion (Cu···O, 2.95 Å) in *syn-anti* mode. In addition to these interactions, crystal packing also reveals that N–H hydrogen atoms are involved in the intermolecular hydrogen bonding to methanolic oxygen atoms [N(1)–H(1)···O(5)] and the methanolic hydrogen atoms maintain intermolecular hydrogen bonds to carboxylate oxygen atoms [O(4)–H(4)···O(3) and O(5)–H(5)···O(2)].

In the crystal structure of **8** for $Z = 3$ in the triclinic space group $P\bar{1}$, there are three independent $Cu^{II}$–Sch12 units and each one is near an inversion center (1/2, 1/2, 1/2), (0,0,0), and (1/2, 1/2, 0) as illustrated in Figure 5. Of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

these Cu3 has an aqua ligand in the apical position. The O9 of the carboxylate group from this unit is bonded to Cu2 with the Cu2–O9 distance of 2.51(1) Å. Similarly, O6 occupies the apical axial position of the Cu1 [Cu1–O6, 2.36(1) Å] with a distorted square pyramidal geometry. On the other hand, the oxygen atom of the third carboxylate group, O3, is only involved in hydrogen bonding to a hydrogen atom, H13D of lattice water. The axial bonding of the carbonyl oxygen atoms O6 and O9 from neighboring dimeric units to Cu1 and Cu2 centers produces a 2D coordination polymeric structure and the interdimer connectivity leads to the formation of a 2D (4, 4) network structure as shown in Figure 6 and these (4, 4) nets are well known in coordination polymeric structures.[16]

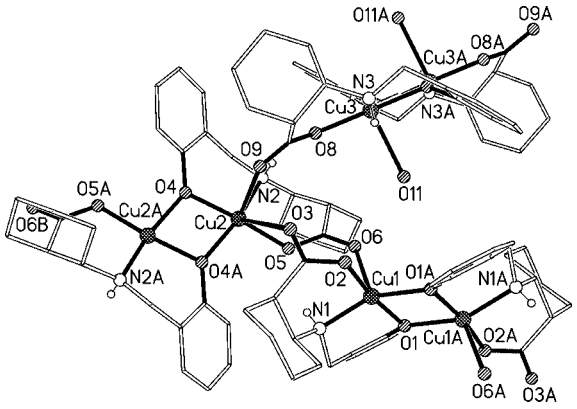

Figure 5. Perspective view of the unit cell contents in **8**. The lattice water molecules are omitted for clarity.

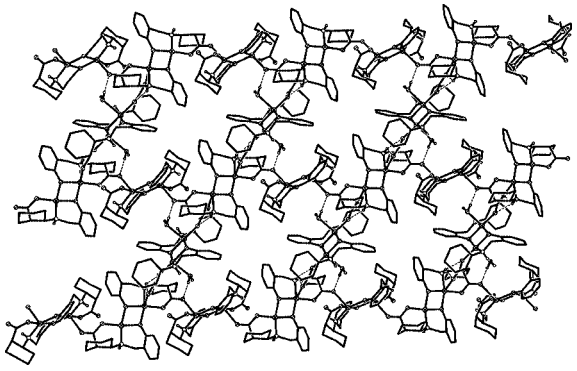

Figure 6. Portion of packing diagram of **8** showing the 2D connectivity. The hydrogen atoms and lattice water molecules have been omitted for clarity.

In this series, the only compound that displays a square-planar geometry at the $Cu^{II}$ atoms is **9a**. The unit cell contains two methanol molecules involved in hydrogen bonding via imine nitrogen [N(1)–H(1)···O(1S)] and carboxylate oxygen [O(1S)–H(1S)···O(3)], which lead to the formation of a 1D polymeric structure. The hydrogen bond lengths observed in the solid-state packing of **9a** are found to vary between 1.90 and 2.38 Å. Table 3 contains selected hydrogen bond parameters. These hydrogen bonds are considered to be normal as compared to the available literature on N–H···O and O–H···O hydrogen bond parameters.[17]

The dimer **12a** crystallized with four DMSO molecules of which two are bonded at the apical positions of each $Cu^{II}$ in the dimer and two are hydrogen-bonded to the imine hydrogen atoms through N–H···O interactions. The two DMSO molecules are disposed in *anti* fashion probably due to the bulkiness of the axial substitution. This causes the dimer to have a pseudo-center of inversion which is unprecedented in these types of structure having chiral reduced Schiff-base ligands.[6] A ribbon-like 1D hydrogen-bonded polymeric structure is produced by complementary O–H···O bonds between phenolic hydrogen and oxygen atoms of the carboxylate group. All these polymers are aligned parallel to the (1$\bar{1}$0) plane. Acetone molecules filled the empty cavities between these strands.

### Magnetic Studies of $[\{Cu_2(Sch12)_2\}_2Cu_2(Sch12)_2(H_2O)_2]\cdot 4H_2O$ (8)

It is evident from the previous section that only complexes **4** and **8** furnished the single crystals that represent the structures of the bulk. Further, the inter-dimer connectivity in **8** generated an interesting 2D (4, 4) coordination polymeric network structure. Hence, we investigated the variable temperature magnetic moments for **8** in order to understand the inter-dimer magnetic coupling interactions mediated by *syn-anti* carboxylate bridging.

The temperature dependences of $\chi_m$ and $\chi_m T$ for crystalline samples of **8** per $Cu_2$ unit are presented in Figure 7. On lowering the temperature, $\chi_m$ decreases gradually, there is an increase below ca. 70 K; while the $\chi_m T$ value even at 330 K (0.383 $cm^3 mol^{-1} K$) is quite small compared with the expected value 0.75 $cm^3 mol^{-1} K$ for two noninteracting $Cu^{II}$ ions, upon cooling it decreases rapidly to a value close to zero at 2 K. The increase of $\chi_m$ at low temperature should be due to trace paramagnetic impurity ($\rho$). Overall, the data suggest a strong antiferromagnetic coupling between the adjacent Cu ions in **8**. The coupling between the dinuclear moiety in the 2D layer of **8** is negligible, as expected, because of both the *syn-anti* carboxylate bridging

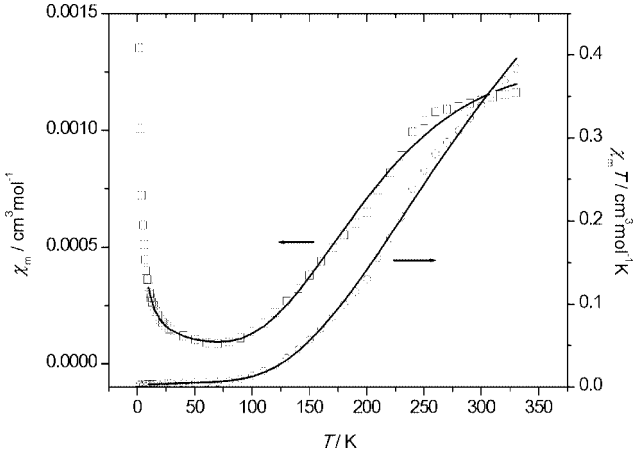

Figure 7. The temperature dependences of $\chi_m$ and $\chi_m T$ in the range of 2–350 K for **8**. The solid lines represent the fit using a $Cu_2$ dimer model.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mode and the orthogonal relationship of the planes of the neighboring $Cu_2O_2$.[14b] Therefore, the magnetic data of **8** can be analyzed by fitting the susceptibilities to an equation calculated using an $H = -2JS_1S_2$ Hamiltonian for a dimer plus impurity of the monomer model.[14e–14f] The parameters have their usual meanings. As shown in Figure 7, a reasonable fit was obtained with the results: $J = -230(3)\ cm^{-1}$, $g = 2.29(2)$, $\rho = 0.0056$; $N_\alpha = 4.9\times10^{-6}$ with $R = 1.4\times10^{-3}$ $\{R = \sum[(\chi_m)_{obs} - (\chi_m)_{calc}]^2/\sum[(\chi_m)_{obs}]^2\}$.

### Catecholase Biomimetic Studies

In order to gain deeper insight into the various parameters that determine the copper-mediated substrate oxidations and bimetallic reactivity both in natural metalloenzymes and in synthetic analogues, quite a number of mono- and dinuclear copper(II) complexes have been investigated as biomimetic catalysts for catechol oxidation.[18–23] In all these investigations, a common and convenient model substrate, 3,5-DTBC was used due to its low redox potentials.[20] Some of the crucial factors dictating the catecholase activity can now be highlighted based on many investigations correlating various structural parameters of the dicopper(II) complexes with their activity; viz., the distance between the $Cu^{II}$ centers,[24] the nature of the bridging group between the copper ions,[25] electronic properties of the complexes,[10,26] and the geometric changes of the dicopper core.[27] Furthermore, the factors such as the number of donor sites, nature of the donors, and the rigidity of the ligand or the bridging moiety imposing strain in the complex have also been found to play a vital role.[28] However, the studies correlating the activity with electronic effects due to substituents on the bridging phenolate have not been well explored.[10] Since the present series of complexes contain both electron-donating and -withdrawing substituents on the phenyl ring we have attempted to investigate their activity.

On the basis of the chemical and spectroscopic characterizations of the complexes **1**–**13** and the crystal structures of selected compounds, all these complexes are characterized by active $Cu_2O_2$ centers with a Cu···Cu distance of ca. 3 Å, which is favorable for the efficient binding of the substrate. Minor changes observed in the UV/Vis spectra recorded in DMF solution compared to Nujol mull indicate that the coordination number and geometry of **1**–**13** are retained in solution. Further, ESI-MS studies confirm the existence of copper(II) dimers in solution. Subsequently, all the complexes exhibit significant activity due to the presence of active dicopper(II) cores. The course of oxidation of 3,5-DTBC catalyzed by **8** is shown in Figure 8. The kinetic parameters have been determined by applying the Michaelis–Menten approach. A linear relationship for the initial rates and the concentration of the complexes has been obtained for **1**–**13**, which shows a first-order dependence of the rate on the catalyst concentration. An example of a Lineweaver–Burk plot[18f] is given in Figure 9 for **8**. Kinetic parameters of the complexes are given in Table 4.

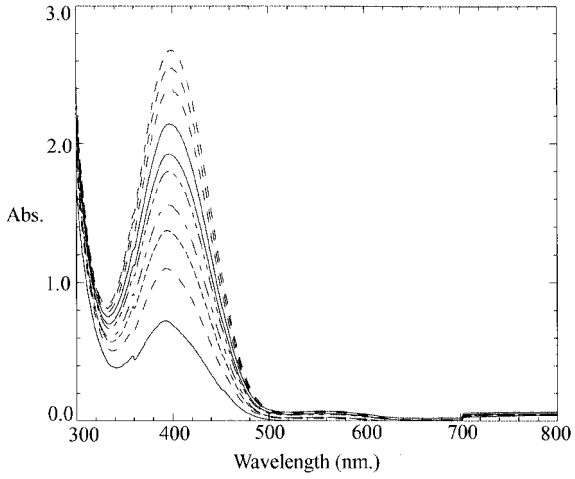

Figure 8. Oxidation of 3,5-DTBC by **8** monitored by UV/Vis spectroscopy. Higher concentrations were used only to emphasize the bands for the oxidation process.

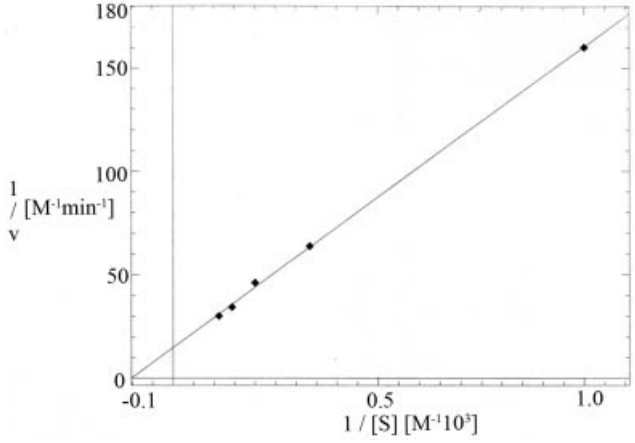

Figure 9. Lineweaver–Burk plot for the catalysis by **8**.

Table 4. Kinetic parameters for the oxidation of 3,5-DTBC by the complexes **1**–**13**.[a]

| Complex | Substituent (R) | $K_{cat}$ [$h^{-1}$] | $K_m$ [mM] | $V_{max}$ [$10^6\ Ms^{-1}$] |
|---|---|---|---|---|
| **1** | –H | 850(28) | 22.3(4) | 30.2(6) |
| **2** | –Cl | 694(32) | 26.2(3) | 22.4(1) |
| **3** | $-CH_3$ | 1003(59) | 15.4(6) | 34.3(6) |
| **4** | –OH | 773(30) | 20.6(7) | 26.7(3) |
| **5** | –H | 863(28) | 18.5(5) | 30.2(1) |
| **6** | –Cl | 785(49) | 20.3(8) | 24.5(5) |
| **7** | $-CH_3$ | 1080(30) | 14.6(3) | 36.1(2) |
| **8** | –H | 2006(44) | 9.2(1) | 68.5(4) |
| **9** | –Cl | 883(33) | 17.7(3) | 29.3(3) |
| **10** | $-CH_3$ | 3120(28) | 4.3(1) | 104.6(6) |
| **11** | *para* –OH | 595(27) | 21.4(4) | 22.3(7) |
| **12** | *meta* –OH | 513(21) | 28.6(4) | 19.4(8) |
| **13** | *ortho* –OH | 460(14) | 31.3(3) | 17.6(5) |

[a] The values were obtained from three measurements.

It is obvious from Table 4 that the activity of **1**–**4** follows the order **3** > **1** > **4** > **2** with **3** showing higher activity ($K_{cat}$ = 1003 $h^{-1}$). Further, the activity of **2** has noticeably

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

decreased due to the strong electron-withdrawing nature of *Cl* when compared to the activity of **4** containing the *–OH* group.[29] Thus, with respect to the substituents on the bridging phenolate, the activity of the corresponding complexes followed the order: $CH_3 > H > OH > Cl$. A similar trend (**7** > **5** > **6**) has been observed (Table 4) for $Cu^{II}$ complexes of RSch11 ligands, **5**–**7**. Among **8**–**10**, the *methyl*-substituted **10** exhibited significantly higher activity ($K_{cat}$ = 3120 $h^{-1}$) while *chloro*-substituted **9** with $Cu^{II}$ in a square-planar geometry showed a lower activity ($K_{cat}$ = 883 $h^{-1}$) following a similar trend. Earlier investigations on the activity of copper(II) systems have shown that the square planar copper(II) complexes are weak catechol-oxidase catalysts.[19,22,24d,28,31] However, reports are also available on square planar dicopper(II) complexes showing very high activity.[18f,25] On the same grounds, **9** with a similar geometry exhibiting significant activity can be another example for the latter.

The six-membered chelate rings facilitate strain-free substrate binding compared to the five-membered rings[9,18f,28] by offering a flexible and relaxed coordination sphere at $Cu^{II}$ centers thus enhancing the activity of **8** compared to the activities of **1** ($K_{cat}$ = 850 $h^{-1}$), and **5** ($K_{cat}$ = 863 $h^{-1}$) forming five-membered rings. Furthermore, it is also the formation of six-membered rings that significantly enhanced the activity of **10** ($K_{cat}$ = 3120 $h^{-1}$) compared to **3** ($K_{cat}$ = 1003 $h^{-1}$) or **7** ($K_{cat}$ = 1080 $h^{-1}$) which contain five-membered rings. It may be noted that these complexes (**3**, **7**, and **10**) have *para* methyl phenyl rings.

In the case of **11**–**13** containing Diala ligands, the trend in $K_{cat}$ is **11** > **12** > **13** (Table 4). The activity of **11** ($K_{cat}$ = 595 $h^{-1}$) with a *para*-hydroxy bridging phenolate is found to be higher than that of **12** ($K_{cat}$ = 513 $h^{-1}$) and **13** ($K_{cat}$ = 460 $h^{-1}$) containing *meta*- and *ortho*-hydroxy bridging phenolate moieties, respectively. These variations in the activity maybe attributed to the differences in the steric match[18,27,28] caused by the respective changes in the position of the *–OH* group on the bridging phenolate. Further, comparing the activity ($K_{cat}$ = 666 $h^{-1}$), under similar experimental conditions, of our previously reported unsubstituted complex $[Cu_2(L\text{-}Sala)_2(H_2O)]$[8] with the activity ($K_{cat}$ = 595 $h^{-1}$) of the present *para* hydroxy-substituted **11** it is obvious that the decrease in the activity of **11** can be attributed to the effect of the electron-withdrawing *-OH* group on the phenyl ring of the ligand.

The kinetic data for **1**–**13** presented in Table 4 shows that the substitution of phenolate by electron-donating substituents increased the activity while the substitution by electron-withdrawing groups decreased the activity. In the absence of electrochemical data for **1**–**13**, it is difficult to conclude that the catalytic efficiency is solely governed by the electronic influence of the substituents except envisaging a rough correlation. Moreover, no clear and direct correlation has been established so far between the rates of reaction, redox potentials, and electronic effects of the complexes.[10,26,28] However, other factors such as geometry, steric factors, and interactions between the substrate and catalyst can also influence the overall efficiency. It should also be noted that the exact Cu···Cu separation in solid-state structures need not be retained in the solution, and direct correlation between the Cu···Cu distance and catalytic activity need not be expected. However, based on the information regarding the geometries and molecular species obtained from the solution studies involving the techniques such as UV/Vis spectroscopy and ESI-MS at least some correlations can be achieved.

Recently, Wegner et al. reported the most active catalyst among the known functional model complexes so far, with a turnover number or $K_{cat}$ of 9927 $h^{-1}$.[5h] When compared mainly with the turnover numbers of 1188 $h^{-1}$, 2804 $h^{-1}$, and 5470 $h^{-1}$, reported by Monzani et al.,[31–32] Meyer et al., [27] and Mukherjee et al.[25a] respectively, and with the other lower to moderate turnover values,[5,10,18–19,22–30] the observed turnover rates of 460 to 3120 $h^{-1}$ may suggest moderate to high catalytic activity of the present complexes. However, all activity studies on the model complexes synthesized so far have only achieved turnover numbers of about several thousand-fold lower when compared to the turnover number of native enzymes[31,26a] (for example catechol oxidase from sweet potatoes has been found to be highly active with a $K_{cat}$ of 2293 $s^{-1}$ especially towards catechol).[33] The current high activity in **10** ($K_{cat}$ = 3120 $h^{-1}$) observed among the present model catalysts has been found to be ca. 2600-fold slower towards the oxidation of 3,5-DTBC when compared to the natural enzyme. Finally, these findings suggest that significant differences in the catalytic ability of dicopper(II) complexes can be induced by the judicious choice of different sets of binucleating ligands.

## Summary

A new series of dicopper(II) complexes **1**–**13** containing reduced Schiff-base ligands formed between different substituted salicylaldehydes and amino acids have been synthesized and characterized by physicochemical and spectroscopic methods. On the basis of the single-crystal X-ray crystallographic studies of selected compounds, it can be suggested that all the complexes contain $Cu_2O_2$ cores with a Cu···Cu distance of ca. 3 Å. In view of the interesting 2D coordination polymeric structure, variable temperature magnetic studies carried out on **8** suggested the presence of strong intradimer antiferromagnetic coupling.

The catecholase activity of the complexes **1**–**4**, **5**–**7**, **8**–**10**, and **11**–**13** containing 1-aminocyclopentane-1-carboxylate, 1-aminocyclohexane-1-carboxylate, 2-aminocyclohexane-1-carboxylate, and L-alanine side chains, respectively, in the corresponding reduced Schiff-base ligands has been evaluated and systematically compared. It has been found that the presence of electron-withdrawing groups decreased the activity while the electron-donating groups enhanced the activity of the complexes. Under similar experimental conditions the activity shown by the current series of dicopper(II) complexes can be considered moderate to high as observed in our previous results.[8–9]

## Experimental Section

### Materials and Physical Measurements

All the chemicals were purchased from commercial sources and used as received for syntheses. All the solvents used were of reagent grade. The yields are reported with respect to the metal salts.

The $^1$H NMR spectra were recorded with a Bruker ACF 300FT-NMR spectrometer using TMS as an internal reference at 25 °C and the infrared spectra (KBr pellet) were recorded using a FTS 165 Bio-Rad FTIR spectrometer in the range 4000–400 cm$^{-1}$. The electronic transmittance spectra were recorded with a Shimadzu UV-2501/PC UV/Vis spectrometer in DMF and Nujol mull. ESI-MS spectra were recorded using a Finnigan MAT LCQ Mass Spectrometer using the syringe-pump method. The elemental analyses were performed in the Micro Analytical Laboratory, Department of Chemistry, National University of Singapore. Water present in the compounds was determined using a SDT 2960 TGA Thermal Analyzer with a heating rate of 10 °C min$^{-1}$ using a sample size of 7–10 mg per sample run. Room-temperature magnetic susceptibility measurements were carried out with a Johnson–Mathey Magnetic Susceptibility balance with Hg[Co(SCN)$_4$] as the standard. Variable temperature magnetic studies were made using a Quantum Design MPMS-XL5 SQUID magnetometer operating in an applied field of 5 kOe. Corrections for diamagnetism were made using Pascal's constants. Optical rotation was measured on the specified solutions in a 0.1-dm cell at 27 °C using a Perkin–Elmer model 341 polarimeter. The concentration of the solutions was 5.5 mg mL$^{-1}$ for both the ligands (in MeOH) and complexes (in DMSO). The optical rotation of the ligands was recorded at the wavelength of 365 nm where as for the complexes the measurements were conducted at the wavelength of the D line (578 nm) of sodium.

### Ligands

All the ligands except $H_3$Diala5, $H_3$Diala4, and $H_3$Diala3 have been synthesized using the same molar quantities according to the procedure described for $H_2$Scp11 in our earlier report.[6c]

**1-[(5-Chloro-2-hydroxybenzyl)amino]cyclopentane-1-carboxylic Acid ($H_2$ClScp11):** This compound was prepared from 1-aminocyclopentane-1-carboxylic acid and 5-chlorosalicylaldehyde. Yield: 0.92 g (73%). m.p. 271–272 °C. $C_{13}H_{16}ClNO_3$ (269.7): calcd. C 57.8, H 5.9, N 5.2; found C 57.2, H 6.0, N 5.7. IR (KBr): $\tilde{\nu}$ = 2966 m (NH), 1566 s $\upsilon_{as}$(COO$^-$), 1384 s $\upsilon_s$(COO$^-$), 1276 s (phenolic CO) cm$^{-1}$. $^1$H NMR (CD$_3$OD): $\delta$ = 1.83–2.28 (m, 8 H, -C$_5$H$_8$), 4.12 (s, 2 H, benzylic), 6.83–7.36 (m, 3 H, Ar-H). $^{13}$C NMR (CD$_3$OD): $\delta$ = 25.9, 37.3, 47.5, 48.1, and 48.4 (-C$_5$H$_8$), 72.9 (benzylic), 119.4, 122.3, 127.4, 129.1, 129.5, and 160.6 (aromatic), 182.7 (-COOH). EI-MS: *m*/*z* (%) = 269.2.

**1-[(2-Hydroxy-5-methylbenzyl)amino]cyclopentane-1-carboxylic Acid ($H_2$MeScp11):** This compound was prepared from 1-aminocyclopentane-1-carboxylic acid and 5-methylsalicylaldehyde. Yield: 0.92 g (76%). m.p. 272–273 °C. $C_{14}H_{19}NO_3$ (249.3): calcd. C 67.4, H 7.6, N 5.6; found C 67.0, H 7.7, N 5.9. IR (KBr): $\tilde{\nu}$ = 3447 m (OH), 2956 m (NH), 1571 s $\upsilon_{as}$(COO$^-$), 1383 s $\upsilon_s$(COO$^-$), 1277 s (phenolic CO) cm$^{-1}$. $^1$H NMR (CD$_3$OD): $\delta$ = 1.89–2.11 (m, 8 H, -C$_5$H$_8$), 2.35 (s, Ar–CH$_3$), 3.62 (s, 2 H, benzylic), 6.53–6.83 (m, 3 H, Ar-H). $^{13}$C NMR (CD$_3$OD): $\delta$ = 20.6 (Ar–CH$_3$), 24.3, 26.1, 37.6, 47.4, and 48.2 (-C$_5$H$_8$), 72.8 (benzylic), 118.4, 126.0, 127.1, 129.6, 130.6, and 160.3 (aromatic), 184.0 (-COOH). ESI-MS: *m*/*z* (%) = 249.2.

**1-[(2,5-Dihydroxybenzyl)amino]cyclopentane-1-carboxylic Acid ($H_2$(OH)Scp11):** This compound was prepared from 1-aminocyclopentane-1-carboxylic acid and 5-hydroxysalicylaldehyde. Yield: 0.75 g (63%). m.p. 263–264 °C. $C_{13}H_{17}NO_4$ (251.6): calcd. C 62.1, H 6.8, N 5.5; found C 62.0, H 6.9, N 5.6. IR (KBr): $\tilde{\nu}$ = 3398 m (OH), 2960 m (NH), 1582 s $\upsilon_{as}$(COO$^-$), 1390 s $\upsilon_s$(COO$^-$), 1276 s (phenolic CO) cm$^{-1}$. $^1$H NMR (CD$_3$OD): $\delta$ = 1.73–2.11 (m, 8 H, -C$_5$H$_8$), 3.83 (s, 2 H, benzylic), 6.43–6.51 (m, 3 H, Ar-H). $^{13}$C NMR (CD$_3$OD): $\delta$ = 24.7, 26.1, 36.0, 37.6, and 40.9 (-C$_5$H$_8$), 72.7 (benzylic), 117.6, 118.7, 119.6, 126.3, 148.2, and 159.6 (aromatic), 184.1 (-COOH). ESI-MS: *m*/*z* (%) = 251.

**1-[(2-Hydroxybenzyl)amino]cyclohexane-1-carboxylic Acid ($H_2$Sch11):** This compound was prepared from 1-aminocyclohexane-1-carboxylic acid and salicylaldehyde. Yield: 1.06 g (90%). m.p. 296–297 °C. $C_{14}H_{19}NO_3$ (249.3): calcd. C 67.4, H 7.6, N 5.6; found C 67.4, H 7.7, N 5.5. IR (KBr): $\tilde{\nu}$ = 2941 m (NH), 1577 s $\upsilon_{as}$(COO$^-$), 1388 s $\upsilon_s$(COO$^-$), 1272 s (phenolic CO) cm$^{-1}$. $^1$H NMR (CD$_3$OD): $\delta$ = 1.43–2.03 (m, 10 H, -C$_6$H$_{10}$), 3.70 (s, 2 H, benzylic), 6.41–7.02 (m, 4 H, Ar-H). $^{13}$C NMR (CD$_3$OD): $\delta$ = 23.0, 27.0, 34.5, 37.1, 48.1, and 48.4 (-C$_6$H$_{10}$), 64.3 (benzylic), 117.7, 118.3, 127.0, 129.3, 130.0, and 162.5 (aromatic), 182.8 (-COOH). ESI-MS: *m*/*z* (%) = 249.2

**1-[(5-Chloro-2-hydroxybenzyl)amino]cyclohexane-1-carboxylic Acid ($H_2$ClSch11):** This compound was prepared from 1-aminocyclohexane-1-carboxylic acid and 5-chlorosalicylaldehyde. Yield: 0.88 g (66%). m.p. 290–291 °C. $C_{14}H_{18}ClNO_3$ (283.7): calcd. C 59.3, H 6.4, N 4.9; found C 59.0, H 6.5, N 4.9. IR (KBr): $\tilde{\nu}$ = 3462 m (OH), 2940 m (N–H), 1568 s $\upsilon_{as}$(COO$^-$), 1495 s $\upsilon_s$(COO$^-$), 1273 s (phenolic CO) cm$^{-1}$. $^1$H NMR (CD$_3$OD): $\delta$ = 1.41–2.03 (m, 10 H, -C$_6$H$_{10}$), 3.70 (s, 2 H, benzylic), 6.60–7.01 (m, 4 H, Ar-H). $^{13}$C NMR (CD$_3$OD): $\delta$ = 23.4, 26.9, 34.3, 37.0, 46.1, and 48.2, (-C$_6$H$_{10}$), 64.61 (benzylic), 119.6, 121.7, 128.2, 128.9, 129.4, and 161.5 (aromatic), 182.2 (-COOH). 3 H, Ar-H). $^{13}$C NMR ($CD_3OD$): $\delta$ = 21.4, 22.2, 25.5, 26.3, 44.5, and 45.4 (-$C_6H_{10}$), 55.3 (benzylic), 117.0, 117.4, 117.7, 124.4, 126.3, and 161.5 (aromatic), 179.2 (-COOH). ESI-MS: *m*/*z* (%) = 283.3.

**2-[(2-Hydroxy-5-methylbenzyl)amino]cyclohexane-1-carboxylic Acid ($H_2$MeSch12):** This compound was prepared from 2-aminocyclohexanecarboxylic acid and 5-methylsalicylaldehyde. Yield: 60%. m.p. 285–286 °C. $C_{15}H_{21}NO_3$ (263.3): calcd. C 68.4, H 8.0, N 5.3; found C 68.1, H 8.0, N 5.0. IR (KBr): $\tilde{\nu}$ = 2941 m (N–H), 1632 s $\upsilon_{as}(COO^-)$, 1459 s $\upsilon_s(COO^-)$, 1272 s (phenolic CO) cm$^{-1}$. $^1$H NMR ($CD_3OD$): $\delta$ = 1.34–2.17 (m, 8 H, -$C_6H_{10}$), 2.37 (Ar–$CH_3$), 2.57 (t, 1 H, HC–N), 2.97 (t, 1 H, HC–$COO^-$), 3.96 (s, 2 H, benzylic), 6.55–6.87 (m, 3 H, aromatic). $^{13}$C NMR ($CD_3OD$): $\delta$ = 20.5 ($CH_3$), 25.1, 28.0, 29.1, 37.0, 47.1, and 48.4 (-$C_6H_{10}$), 57.1 (benzylic), 117.4, 117.8, 123.4, 127.4, 130.2, and 159.3 (aromatic), 182.0 (-COOH). ESI-MS: *m*/*z* (%) = 263.4.

The ligands $H_3$Diala5, $H_3$Diala4, and $H_3$Diala3 were synthesized as described below.

***N*-(2,5-Dihydroxybenzyl)-L-alanine ($H_3$Diala5):** A mixture of L-alanine (0.9 g, 10.1 mmol) and NaOH (0.4 g, 10.1 mmol) in methanol (20 mL) was stirred for 20 min to get a clear solution. To this was added 2,5-dihydroxybenzaldehyde (1.4 g, 10.1 mmol). After stirring for 1 h, the resulting yellow solution was cooled in an ice bath and then treated with $NaBH_4$ (0.42 g, 11.11 mmol). The yellow color slowly disappeared. After 45 min, the pH of the solution was brought to 5 by adding acetic acid. Upon stirring for 40 min, a pale-brown solid separated out. Filtration followed by washing with methanol (2 × 5 mL), diethyl ether (2 × 5 mL), and then drying under vacuum afforded pure $H_3$Diala5. Yield: 1.82 g (85%). m.p. 268–270 °C. $C_{10}H_{13}NO_4$ (211.2): calcd. C 56.8, H 6.2, N 6.6; found C 56.3, H 6.3, N 6.5. IR (KBr): $\tilde{\nu}$ = 3438 m (OH), 2487 m (NH), 1635 s $\upsilon_{as}(COO^-)$, 1511 s $\upsilon_s(COO^-)$, 1285 s (phenolic CO) cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 1.31 (m, 3 H, $CH_3$), 3.21 (m, 1 H, -CH), 3.92 (m, 2 H, benzylic), 6.61–6.72 (m, 3 H, Ar-H). $^{13}$C NMR: $\delta$ = 15.7 ($CHCH_3$), 45.5 (benzylic), 56.2 (-$CHCH_3$), 116.0, 116.2, 116.9, 120.3, 148.6, and 149.6 (aromatic), 171.3 (-COOH). ESI-MS: *m*/*z* (%) = 211.4. $[\alpha]_D^{27}$: 7.4 (*c* = 5.5 mg mL$^{-1}$, MeOH).

***N*-(2,4-Dihydroxybenzyl)-L-alanine ($H_3$Diala4):** This ligand was synthesized according to the same procedure as $H_3$Diala4 except that 2,4-dihydroxybenzaldehyde was used instead of 2,5-dihydroxybenzaldehyde. Yield: 1.65 g (77%). m.p. 288–290 °C. $C_{10}H_{13}NO_4$ (211.2): calcd. C 56.8, H 6.2, N 6.6; found C 56.3, H 6.3, N 6.5. IR (KBr): $\tilde{\nu}$ = 3267 m (OH), 3085 m (NH); 1623 s $\upsilon_{as}(COO^-)$, 1522 s $\upsilon_s(COO^-)$, 1216 s (phenolic CO) cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 1.29 (d, 3 H, -$CH_3$), 3.20 (m, 1 H, -CH), 3.91 (s, 2 H, benzylic), 7.01–6.21 (m, 3 H, Ar-H). $^{13}$C NMR: $\delta$ = 15.4 ($CHCH_3$), 45.7 (benzylic), 56.6 (-$CHCH_3$), 116.1, 116.2, 117.0, 120.2, 148.7, and 149.5 (aromatic), 172.1 (-COOH). ESI-MS: *m*/*z* (%) = 211.3. $[\alpha]_D^{27}$: 8.0 (*c* = 5.5 mg mL$^{-1}$, MeOH).

***N*-(2,3-Dihydroxybenzyl)-L-alanine ($H_3$Diala3):** This ligand was prepared according to the same procedure as $H_3$Diala3 except that 2,3-dihydroxybenzaldehyde was used instead of 2,5-dihydroxybenzaldehyde. Yield: 1.41 g (66%). m.p. 262–264 °C. $C_{10}H_{13}NO_4$ (211.2): calcd. C 56.8, H 6.2, N 6.6; found C 56.7, H 6.0, N 6.4. IR (KBr): $\tilde{\nu}$ = 3367 m (OH), 3085 m (NH), $\upsilon_{as}(COO^-)$ 1623 s, 1522 s $\upsilon_s(COO^-)$, 1216 s (phenolic CO) cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 1.30 (d, 3 H, -$CH_3$), 3.26 (m, 1 H, -CH), 3.96 (s, 2 H, benzylic), 6.78–6.62 (m, 3 H, aromatic). $^{13}$C NMR: $\delta$ = 15.5 ($CHCH_3$), 45.8 (benzylic), 56.7 (-$CHCH_3$), 116.1, 116.2, 116.4, 120.6, 148.3, and 149.1 (aromatic), 170.5 (-COOH). ESI-MS: *m*/*z* (%) = 211.2. $[\alpha]_D^{27}$: 8.4 (*c* = 5.5 mg mL$^{-1}$, MeOH).

**Complexes**

The compound **[$Cu_2$(Scp11)$_2$($H_2O$)$_2$] (1)** was synthesized according to the procedure described earlier.[6c] Weight loss (60–115 °C) as per TGA: 5.1% [calculated for 2 $H_2O$: 5.7%]. $\mu_B$ = 1.55 B. M. Slow diffusion of methanol into a slightly turbid solution of **1** in water afforded single crystals of [$Cu_2$(Scp11)$_2$(MeOH)$_2$] (**1a**).

**[$Cu_2$(ClScp11)$_2$($H_2O$)$_2$] (2):** A clear solution containing of $H_2$Clscp11 (0.13 g, 0.5 mmol) and NaOH (0.04 g, 1.0 mmol) in methanol (20 mL) was obtained after stirring the mixture for 15 min. To this was added solid copper(II) acetate monohydrate in portions (0.10 g, 0.5 mmol). After stirring for another 2 h, a green solid separated out and was filtered off, washed with methanol (4 mL), diethyl ether (4 mL), and then in air. Yield: 0.31 g (88%). $C_{26}H_{32}Cl_2Cu_2N_2O_8$ (698.5): calcd. C 44.7, H 4.6, N 4.0; found C 45.1, H 4.7, N 3.7. IR (KBr): $\tilde{\nu}$ = 3400 m (OH), 2955 m (NH), 1619 s $\upsilon_{as}(COO^-)$, 1375 s $\upsilon_s(COO^-)$, 1266 s (phenolic CO) cm$^{-1}$. Weight loss (65–145 °C) as per TGA: 5.5% [calculated for 2 $H_2O$: 5.2%]. $\mu_B$ = 1.64 BM. Slow diffusion of acetonitrile into a saturated solution of **2** in DMF furnished dark green single crystals of [$Cu_2$(ClScp11)$_2$(DMF)($H_2O$)]·MeCN (**2a**).

**[$Cu_2$(MeScp11)$_2$($H_2O$)$_2$] (3):** To a clear solution of $H_2$MeScp11 (0.12 g, 0.5 mmol) and NaOH (0.04 g, 1.0 mmol) in a mixture of methanol (10 mL) and water (10 mL) was added copper(II) acetate monohydrate (0.10 g, 0.5 mmol) in portions. A green solid obtained after stirring for 2 h was filtered off, washed with water (2 × 2 mL), methanol (2 × 2 mL) and diethyl ether (2 × 2 mL) and then dried in air. Yield: 0.28 g (85%). $C_{28}H_{38}Cu_2N_2O_8$ (657.7): calcd. C 51.1, H 5.8, N 4.3; found C 51.2, H 5.9, N 4.1. IR (KBr): $\tilde{\nu}$ = 3399 m (OH), 2960 m (NH), 1621 s $\upsilon_{as}(COO^-)$, 1369 s $\upsilon_s(COO^-)$, 1264 s (phenolic CO) cm$^{-1}$. Weight loss (40–102 °C) as per TGA: 5.9% [calculated for 2 $H_2O$: 5.5%]. $\mu_B$ = 1.43 BM. Slow diffusion of methanol into a saturated solution of **3** in DMSO afforded single crystals of [$Cu_2$(MeScp11)$_2$(MeOH)$_2$]·2MeOH (**3a**).

**[$Cu_2$(OHScp11)$_2$($H_2O$)$_2$] (4):** A suspension of $H_2$(OH)Scp11 (0.04 g, 0.16 mmol) in methanol (6 mL) was allowed to slowly diffuse into a clear solution of copper(II) acetate monohydrate (0.03 g, 0.16 mmol) in water (3 mL) in a test tube. Dark brownish green single crystals of **4** were obtained after 2 days. Yield: 76% (0.08 g). $C_{26}H_{34}Cu_2N_2O_{10}$ (661.6): calcd. C 47.2, H 5.2, N 4.2; found C 47.1, H 5.2, N 4.2. IR (KBr): $\tilde{\nu}$ = 3481 m (OH), 2954 m (NH); 1625 s $\upsilon_{as}(COO^-)$, 1366 s $\upsilon_s(COO^-)$, 1264 s (phenolic CO) cm$^{-1}$. Weight loss (134–177 °C) as per TGA: 5.8% [calculated for 2 $H_2O$: 5.4%]. $\mu_B$ = 1.41 BM.

**[$Cu_2$(Sch11)$_2$]·($H_2O$) (5):** To a clear solution of $H_2$Sch11 (0.12 g, 0.50 mmol) and NaOH (0.04 g, 1.0 mmol) in methanol (20 mL) was added a solution of copper(II) acetate monohydrate (0.10 g, 0.50 mmol) in methanol (5 mL) and the solution was stirred for 3 h. The resulting green product was filtered, washed with methanol (2 × 2 mL), diethyl ether (2 × 2 mL), and then dried in air. Yield: 0.06 g (90%). $C_{28}H_{36}Cu_2N_2O_7$ (639.7): calcd. C 52.6, H 5.7, N 4.4; found C 52.4, H 5.7, N 4.3. IR (KBr): $\tilde{\nu}$ = 3435 m (OH), 2930 m (N–H), 1640 s $\upsilon_{as}(COO^-)$, 1373 s, $\upsilon_s(COO^-)$, 1272 s (phenolic CO) cm$^{-1}$. Weight loss (33–99 °C) as per TGA: 2.7% [calculated for $H_2O$: 2.8%]. $\mu_B$ = 1.57 BM.

**[$Cu_2$(ClSch11)$_2$($H_2O$)$_2$] (6):** To a clear solution of $H_2$ClSch11 (0.14 g, 0.50 mmol) and NaOH (0.04 g, 1.0 mmol) in methanol (20 mL) was added copper(II) acetate monohydrate (0.10 g, 0.5 mmol) and the solution was stirred for 1.5 h. The green product was filtered off, washed with methanol (2 × 2 mL), diethyl ether (2 × 2 mL), and then dried in air. Yield: 0.32 g (88%). $C_{28}H_{36}Cl_2Cu_2N_2O_8$ (726.6): calcd. C 46.3, H 5.0, N 3.9; found C

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

46.7, H 5.0, N 3.5. IR (KBr): $\tilde{\nu}$ = 3447 m (OH), 2937 m (N–H), 1622 s $\upsilon_{as}(COO^-)$, 1382 s $\upsilon_s(COO^-)$, 1266 s, (phenolic CO) $cm^{-1}$. Weight loss (65–168 °C) as per TGA: 4.4% [calculated for $2H_2O$: 4.9%]. $\mu_B$ = 1.32 BM. Slow diffusion of methanol into a saturated solution of **6** in DMSO afforded dark green single crystals of $[Cu_2(ClSch11)_2(MeOH)_2]\cdot 2MeOH$ (**6a**).

**$[Cu_2(MeSch11)_2(H_2O)_2]$ (7):** A clear solution of copper(II) acetate monohydrate in methanol (5 mL) was added to a clear solution containing a mixture of $H_2$MeSch11 (0.26 g, 1.0 mmol) and NaOH (0.08 g, 2.00 mmol) in methanol (20 mL). Upon stirring this reaction mixture for 1.5 h, the resulting greenish product obtained was filtered, washed with methanol (4 mL), diethyl ether (4 mL), and then dried in air. Yield: 0.46 g (67%). $C_{30}H_{42}Cu_2N_2O_8$ (685.7): calcd. C 52.5, H 6.2, N 4.1; found C 53.2, H 6.2, N 4.1. IR (KBr): $\tilde{\nu}$ = 3436 m (OH), 2932 m (NH), 1624 s $\upsilon_{as}(COO^-)$, 1381 s $\upsilon_s(COO^-)$, 1262 s (phenolic CO) $cm^{-1}$. Weight loss (68–127 °C) as per TGA: 5.5% [calculated for $2H_2O$: 5.2%]. $\mu_B$ = 1.40 BM.

**$[\{Cu_2(Sch12)_2\}_2Cu_2(Sch12)_2(H_2O)_2]\cdot 4H_2O$ (8):** The ligand $H_2$Sch21 (0.12 g, 0.50 mmol) along with NaOH (0.04 g, 1.0 mmol) was added to a solvent mixture of water (15 mL) and acetonitrile (15 mL) and stirred for 15 min to obtain a clear solution. To this was added copper(II) nitrate trihydrate (0.12 g, 0.50 mmol) and the solution was stirred for another 3.5 h. The clear dark-green solution obtained was filtered. Dark green single crystals were formed from the clear filtrate upon slow evaporation for 4–5 days. Yield: 0.26 g (79%). $C_{84}H_{114}N_6O_{24}Cu_6$ (1973.1): calcd. C 51.1, H 5.8, N 4.3; found C 51.4, H 5.7, N 4.2. IR (KBr): $\tilde{\nu}$ = 3429 m (OH), 2928 m (NH), $\upsilon_{as}(COO^-)$ 1597 s 1360 s $\upsilon_s$ $(COO^-)$, 1265 s (phenolic CO) $cm^{-1}$. Weight loss (64–119 °C) as per TGA: 5.9% [calculated for $6H_2O$: 5.5%]. $\mu_B$ = 1.31 BM.

**$[Cu_2(ClSch12)_2]\cdot 2H_2O$ (9):** To a clear solution of $H_2$ClSch12 (0.14 g, 0.5 mmol) and NaOH (0.04 g, 1.0 mmol) in methanol (10 mL) was added water (10 mL) followed by the addition solid copper(II) nitrate trihydrate (0.12 g, 0.5 mmol) and the mixture was stirred for 1.5 h. The dark green product obtained was filtered, washed with water (2 × 2 mL), methanol (2 × 2 mL) and diethyl ether (4 mL) and then dried in air. Yield: 0.31 g (85%). $C_{28}H_{36}Cl_2Cu_2N_2O_8$ (726.6): calcd. C 46.3, H 5.0, N 3.9; found C 47.0, H 5.2, N 4.0. IR (KBr): $\tilde{\nu}$ = 3396 m (OH), 3115 m (NH), 1603 s $\upsilon_{as}(COO^-)$, 1384 s $\upsilon_s(COO^-)$, 1264 s (phenolic CO) $cm^{-1}$. Weight loss (80–146 °C) as per TGA: 5.8% [calculated for $2H_2O$: 5.0%]. $\mu_B$ = 1.25 BM. A clear saturated solution of **9** in the solvent mixture of methanol/dichloromethane (1:1) afforded single crystals of $[Cu_2(ClSch12)_2]\cdot 2MeOH$, **9a** upon slow evaporation for 3 days.

**$[Cu_2(MeSch12)_2(H_2O)_2]$ (10):** A clear solution of $H_2$MeSch12 (0.26 g, 1.0 mmol) and NaOH (0.08 g, 2.0 mmol) in methanol (20 mL) was obtained on stirring the mixture for 15 min. To this was added solid copper(II) nitrate trihydrate (0.24 g, 1.0 mmol) in one portion. The reaction mixture was stirred for another 1 h. The greenish product obtained was filtered, washed with methanol, $Et_2O$, and then dried in air. Yield: 0.48 g (70%). $C_{30}H_{42}Cu_2N_2O_8$ (685.7): calcd. C 52.5, H 6.17, N 4.1; found C 52.4, H 6.25, N 4.1. IR (KBr): $\tilde{\nu}$ = 3458 m (OH), 2936 m (NH), 1601 s $\upsilon_{as}(COO^-)$, 1396 s $\upsilon_s(COO^-)$, 1262 s (phenolic CO) $cm^{-1}$. Weight loss (60–107 °C) as per TGA: 5.2% [calculated for $2H_2O$: 5.3%]. $\mu_B$ = 1.34 BM.

**$[Cu_2(Diala5)_2(H_2O)_2]\cdot H_2O$ (11):** To a clear solution of copper(II) acetate monohydrate (0.20 g, 1 mmol) in water (20 mL) $H_3$Diala5 (0.21 g, 1 mmol) was added directly and stirred for 3 h. The green solid obtained after stirring for 3 h was filtered, washed with methanol (2 × 2 mL), diethyl ether (2 × 2 mL), and then dried in air. Yield: 0.38 g (63%). $C_{20}H_{28}Cu_2N_2O_{11}$ (599.5): calcd. C 40.1, H 4.7, N 4.6; found C 40.2, H 4.8, N 4.2. IR (KBr): $\tilde{\nu}$ = 3406 m (OH), 2920 m (NH), 1611 s $\upsilon_{as}(COO^-)$, 1462 s $\upsilon_s(COO^-)$, 1299 s (phenolic CO) $cm^{-1}$. $[a]_D^{27}$: 97.4 ($c$ = 5.5 mg$mL^{-1}$, DMSO). Weight loss (24–101 °C) as per TGA: 8.6% [calculated for $3H_2O$: 9.0%]. $\mu_B$ = 1.51 BM.

**$[Cu_2(Diala4)_2(H_2O)_2]\cdot H_2O$ (12):** To the clear solution of copper acetate (0.20 g, 1 mmol) in methanol (20 mL) $H_3$Diala4 (0.21 g, 1 mmol) was added directly and stirred. The green precipitate that formed after 10 min was subjected to further stirring for 3.5 h and then filtered off, washed with methanol, $Et_2O$, and dried in air. Yield: 0.36 g (61%). $C_{20}H_{28}Cu_2N_2O_{11}$ (599.5): calcd. C 40.1, H 4.7, N 4.6; found C 40.1, H 4.5, N 4.4. IR (KBr): $\tilde{\nu}$ = 3406 m (OH), 2920 m (NH), 1611 s $\upsilon_{as}(COO^-)$, 1462 s $\upsilon_s(COO^-)$, 1299 s (phenolic CO) $cm^{-1}$. $[a]_D^{27}$: 32.4 ($c$ = 5.5 mg$mL^{-1}$, DMSO). Weight loss (23–106 °C) as per TGA: 8.2% [calculated for $3H_2O$: 9.0%]. $\mu_B$ = 1.25 BM. Slow diffusion of acetone into a saturated solution of **12** in DMSO afforded dark-green single crystals of $[Cu_2(Diala4)_2(DMSO)_2]\cdot 2DMSO\cdot 2$acetone (**12a**).

**$[Cu_2(Diala3)_2(H_2O)_2]\cdot H_2O$ (13):** To a clear solution of copper acetate (0.40 g, 2 mmol) in methanol (30 mL) $H_3$Diala3 (0.42 g, 2 mmol) was added directly and stirred. The dark-green solution was stirred for 5 h. The mixture was reduced to a small volume and then precipitated with excess of diethyl ether. The green product was dried in air. Yield: 0.82 g (68%). $C_{20}H_{28}Cu_2N_2O_{11}$ (599.5): calcd. C 40.1, H 4.7, N 4.6; found C 40.0, H 4.6, N 4.4. IR (KBr): $\tilde{\nu}$ = 3406 m (OH), 2920 m (NH), 1611 s $\upsilon_{as}(COO^-)$, 1462 s $\upsilon_s(COO^-)$; 1299 s (phenolic CO) $cm^{-1}$. $[a]_D^{27}$: 40.7 ($c$ = 5.5 mg$mL^{-1}$, DMSO). Weight loss (80–131 °C) as per TGA: 8.6% [calculated for $3H_2O$: 9.0%]. $\mu_B$ = 1.91 BM.

**Catecholase Activity and Kinetics Measurements:** The catecholase activity of the complexes **1**–**13** described here in has been measured by the reaction with model substrate 3,5-DTBC at 25 °C. The growth of absorption maximum at $\lambda_{max}$ = 390 nm, characteristic of the product of oxidation 3, 5-DTBQ, was measured as a function of time. For this purpose, $10^{-4}$ mol$dm^{-3}$ solutions of **1**–**13** were treated with 50 equivalents of 3,5-DTBC. The reaction was carried out in methanol because of the satisfactory solubility of 3,5-DTBC and 3,5-DTBQ. The course of the reaction was followed by UV/Vis spectroscopy. The UV/Vis spectra of the original solution directly after the addition and after 10, 20, 30, 40, 50, 60, 75, 90, 105, and 120 min were recorded and corrected for volume changes. The increase in the absorption due to the formation of DTBQ at 390 nm indicated significant catalytic activity for all the complexes. Kinetic parameters on the rate of catechol oxidation were determined by reaction of $1\,10^{-3}$ to $1.3\,10^{-2}$ M solutions of DTBC with $10^{-4}$ solutions of complexes in methanol. A kinetic treatment on the basis of the Michaelis–Menten approach was applied and the results were evaluated from Lineweaver–Burk double reciprocal plots. The errors in the kinetic parameters were obtained from at least three measurements.

**X-ray Crystallography:** The diffraction experiments were carried out with a Bruker AXS SMART CCD diffractometer. The program SMART[34a] was used for collecting frames of data, indexing reflections, and determining lattice parameters, SAINT[34a] for integration of the intensity of reflections and scaling, SADABS[34b] for absorption correction and SHELXTL[34c] for space group and structure determination, least-squares refinements on $F^2$. All the hydrogen atom positions of the imine groups, methanol, and water molecules were located and their positional parameters were refined in the least-squares cycles. One of the carbon atoms in **2a** (C12 with occupancies 0.65/0.35) and **3a** (C11 with occupancies 0.6/0.4) were found to be disordered. Selected crystallographic data

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

and refinement details are displayed in Table 5. The structure of **12a** can also be solved in the centrosymmetric space group $P\bar{1}$ with the methyl group of the alanine part of the ligand disordered. However, the optical activity of **12** containing the optically active Diala4 ligand is comparable to those of **11** and **13** and therefore, the chiral space group was retained.

CCDC-277306 to -277313 (for **1a**, **2a**, **3a**, **4**, **6a**, **8**, **9a**, and **12a**, respectively) contain the supplementary crystallographic data discussed in this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Structure diagrams, thermogravimetric curves, UV/Vis spectra of the oxidation of 3,5-DTBC, Lineweaver–Burk plots (1/v vs. 1/[S]) and ESI-MS data (total number of pages: 25).

# A Two-Step Spin Transition and Order–Disorder Phenomena in the Mononuclear Compound [Fe(Hpy-DAPP)]$(BF_4)_2$

**Galina S. Matouzenko,*[a] Dominique Luneau,[b] Gábor Molnár,[c] Nawell Ould-Moussa,[c] Samir Zein,[a] Serguei A. Borshch,[a] Azzedine Bousseksou,[c] and Frédéric Averseng[a]**

**Keywords:** Density functional calculations / Iron / Magnetic properties / Mössbauer spectroscopy / N ligands / Spin crossover

This paper reports the synthesis and detailed characterization of the mononuclear complex $[Fe^{II}(Hpy\text{-}DAPP)](BF_4)_2$ (Hpy-DAPP = {bis[*N*-(2-pyridylmethyl)-3-aminopropyl](2-pyridylmethyl)amine}), which manifests a two-step spin crossover accompanied by an ordering and a conformational transition in the ligand. The magnetic susceptibility measurements and Mössbauer spectra reveal that the two steps of the spin transition are separated by an inflexion point at about 130 K at which 50 % of the complex undergoes a spin conversion. The high-temperature step centered at 181 K is gradual, whereas the low-temperature one displays a thermal hysteresis with two transition temperatures ($T_{c\downarrow}$ = 119 and $T_{c\uparrow}$ = 123 K). The single-crystal X-ray structure has been determined for the HS (298 K) and LS (90 K) forms, as well as for the mixed form with an HS:LS ratio of 1:1 (130 K). The structural studies show that the crystal lattice contains a single $Fe^{II}$ crystallographic site over the whole temperature range. At room temperature, the most important peculiarity of the HS complex structure is the disorder of the N3 amino aliphatic atom, which is in the first coordination sphere of $Fe^{II}$, over two positions. The strong involvement of the N3 atoms in H-bonding with two neighboring counterions is considered as a possible origin of this disorder. At 130 K, the disorder is increased by the distribution of the N1 and C9 atoms over two positions, leading to the conformational disorder (*chair* and *twist-boat* conformations with a 1:1 ratio) in the six-membered N2C7C8C9N1Fe chelate cycle. At 90 K, the disorder in the positions of the N1, N3, and C9 atoms disappears and the N2C7C8C9N1Fe metallacycle adopts a unique *twist-boat* conformation. The results of structural studies suggest that the two-step spin-transition behavior of the complex $[Fe(Hpy\text{-}DAPP)](BF_4)_2$ is induced by two different geometries of the $[FeN_6]$ coordination core generated by the disorder in the ligand. The HS → LS transition is also associated with the conformational change in the chelate cycle. Both crystallographic data analysis and electronic structure calculations allow us to relate the disordered geometries of the $[FeN_6]$ coordination core to their HS and LS character.

## Introduction

The phenomenon of spin transition between low-spin (LS) and high-spin (HS) electronic states[1] is an important area in iron(II) coordination chemistry. Its theoretical and experimental aspects, as well as its potential applications, give rise to a permanent interest in this phenomenon. The bi-stable behavior (HS, $S = 2$, $^5T_2 \leftrightarrow$ LS, $S = 0$, $^1A_1$) underlies the design of new molecular materials for technological applications[1b,1d,2] and can be induced by a variation of temperature, pressure, light irradiation, or by application of a magnetic field. The potential applications of spin-crossover systems for information storage require an abrupt spin transition with a relatively large thermal hysteresis centered near to ambient temperature. Currently, two approaches are employed to design new cooperative spin-crossover compounds, namely supramolecular and polymeric approaches.[3] The use of new polydentate ligands containing nitrogen donor atoms with different chemical functions, which generate an intermediate ligand field that favors spin-state interconversion, is one of the possible synthetic strategies for engineering spin transition systems. However, the ligand-field splitting is not the only factor that determines the existence and character of a spin transition. The interplay of the spin pairing energy and the ligand-field strength is very sensitive to small structural perturbations in the metal environment, which may result from the existence of sterically demanding ligands and/or from minor crystal-packing changes associated with the nature of the counterions, or even the presence of a solvent of crystallization. As has been noted,[1i] even more subtle changes, such as the number of chelate rings and/or the replacement of five- with six-membered cycles, can also affect the spin state of the

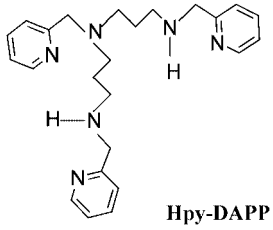
resulting iron(II) complex. In this context, polydentate ligands that are capable of generating one or more flexible six-membered metallocycles upon coordination with $Fe^{II}$ are of special interest. In this case, a high flexibility of the coordination sphere of a complex can manifest itself in different ways, one of which is the yield of several reaction products. For example, the enlargement of just one of three chelate cycles from five-membered in $[Fe(DPEA)(NCS)_2]$[4a] [DPEA = (2-aminoethyl)bis(2-pyridylmethyl)amine] to six-membered in $[Fe(DPPA)(NCS)_2]$[4b] [DPPA = (3-aminopropyl)bis(2-pyridylmethyl)amine] has allowed the isolation of four species with the DPPA ligand (three of them with the spin change), namely three polymorphic modifications and one solvated complex, instead of just one complex with DPEA. Another situation arises due to the conformational freedom of six-membered chelate cycles.[5] Recently, a new cooperative spin-crossover compound $[Fe(DAPP)(abpt)](ClO_4)_2$ [DAPP = bis(3-aminopropyl)(2-pyridylmethyl)-amine; abpt = 4-amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole], which displays simultaneous spin change and two order–disorder transitions (in the DAPP ligand and the counterion), has been reported.[6] At high temperatures, the disorder over two positions was observed for one carbon atom in the six-membered metallacycle, which is in a *half-boat* conformation. This peculiarity, i.e. the thermal ordering of the ligand directly coordinated to the metal, was documented for spin-crossover systems for the first time. The order–disorder phenomena and the spin transition in $[Fe(DAPP)(abpt)](ClO_4)_2$ were found to be interrelated. Both tuning of the ligand-field strength by the DAPP ligand and reinforcement of the cooperative interactions due to the thermal ordering in the perchlorate ions were proposed as initiators of the spin transition.

Following our studies on the role of metallocycle size on the spin-transition process, a new complex $[Fe(Hpy-DAPP)](BF_4)_2$ (Hpy-DAPP = {bis[*N*-(2-pyridylmethyl)-3-aminopropyl](2-pyridylmethyl)amine}) has been synthesized. The hexadentate Hpy-DAPP ligand (Scheme 1) was prepared starting from tetradentate DAPP. The modification of the DAPP ligand was motivated by its ability to form disordered six-membered chelate cycles upon coordination with $Fe^{II}$. The magnetic susceptibility measurements and Mössbauer spectra of the title compound display a two-step spin transition with thermal hysteresis in the low-temperature step. The single-crystal X-ray structure was determined for the HS (298 K) and LS (90 K) forms, as well as for the mixed form with an HS:LS ratio of 1:1 (130 K). The results of our experimental and theoretical studies suggest that $[Fe(Hpy-DAPP)](BF_4)_2$ can be considered as the first mononuclear complex with a unique $Fe^{II}$ crystallographic site for which the two-step spin transition occurs within the same space group and is accompanied by a ligand ordering in conjugation with a conformational transition.



Scheme 1. Representation of the Hpy-DAPP ligand.

## Results

### Magnetic Susceptibility Data

Magnetic susceptibility measurements were carried out on two different batches of freshly prepared samples of $[Fe(Hpy-DAPP)](BF_4)_2$ and also on some thermally cycled samples. Within the experimental precision, the magnetic susceptibility of these samples was the same at each temperature. Variable-temperature magnetic susceptibility data were measured in both cooling and warming modes in the range 15–290 K. The magnetic properties of the complex (Figure 1) display the HS ↔ LS transition. At 290 K, the magnitude of $\chi_M T$, where $\chi_M$ is the molar magnetic susceptibility, is 3.56 $cm^3 mol^{-1} K$ ($\mu_{eff}$ = 5.34 $\mu_B$) and corresponds to a quintet spin state. This value remains fairly constant with decreasing temperature until 230 K and then gradually decreases upon cooling to 1.78 $cm^3 mol^{-1} K$ at 130 K. Below 130 K, the $\chi_M T$ value descends more steeply to reach 0.53 $cm^3 mol^{-1} K$ at 90 K, and then it slowly decreases to 0.40 $cm^3 mol^{-1} K$ at 15 K. This weak paramagnetism may be related to a residual amount (about 10%) of the HS fraction. The presence of a residual paramagnetic HS fraction at low temperature was confirmed by Mössbauer spectroscopy (vide infra). The shape of the susceptibility curve reveals that the spin transition takes place in two steps, which are separated by an inflexion point at about 130 K at which 50% of the complex has undergone a thermal spin conversion. The gradual high-temperature step is centered at 181 K. The low-temperature step displays a thermal hysteresis. The observed transition temperatures are $T_{c\downarrow}$ = 119 and $T_{c\uparrow}$ = 123 K in the cooling and warming modes, respectively.

### Description of the Structure

The crystal structure of [Fe(Hpy-DAPP)]$(BF_4)_2$ was determined at 298, 130, and 90 K for the HS, mixed-spin states, and predominantly LS form, respectively. No change in the space group was observed at these three temperatures. All structures belong to the monoclinic $P2_1/c$ group with $Z = 4$. Selected bond lengths are given in Table 1. Six nitrogen atoms of Hpy-DAPP ligand constitute the first coordination sphere around the $Fe^{II}$ atom (Figure 2). The ligand, upon coordination to iron(II), forms three five-membered and two six-membered chelate cycles. It should be noted that three pyridine rings (or three aliphatic amino groups) of the Hpy-DAPP ligand can have either a facial or a meridional arrangement, which gives rise, in principle, to a number of isomers. An octahedral coordination leads to the possible existence of two stereoisomers (Δ or Λ configuration). In [Fe(Hpy-DAPP)]$(BF_4)_2$, the ligand adopts a *fac* configuration and the unit cell contains two pairs of symmetry-related left-handed and right-handed enantiomers.

Table 1. Selected bond lengths [Å] for [Fe(Hpy-DAPP)]$(BF_4)_2$.[a]

[a] Estimated standard deviations in the least significant digits are given in parentheses.

#### *High-Spin Complex Structure (T = 298 K)*

The $[FeN_6]$ coordination core is severely distorted at room temperature, and the Fe–N distances fall within the range 2.151(4)–2.238(2) Å (see Table 1). The average Fe–N distance is equal to 2.206 Å, typical for iron(II) in the HS state. The octahedron is axially elongated along the N2–Fe–N6 direction, which can be seen as a pseudo-Jahn–Teller distortion. The secondary N3 amino aliphatic atom is disordered over two positions (Figure 3, a), with an occupancy close to 0.5:0.5. The two Fe–N3(A) and Fe–N3(B) distances are rather different and equal to 2.151(4) and 2.217(5) Å, respectively. The N–Fe–N angles between the adjacent and the opposite nitrogen atoms fall within the range 73.7(2)–111.6(2)° and 160.5(2)–166.5(1)°, respectively. The largest deviation (74–78°) from 90° is observed in three five-membered chelate cycles due to steric strain. In contrast, the N–Fe–N angles in the FeN2C7C8C9N1 and FeN2C16C17C18N3(A/B) six-membered chelate cycles are close to the ideal octahedral value, probably owing to the flexibility of the amino aliphatic chain. The former metallocycle adopts a *chair* conformation (Figure 3, a).

The $BF_4$ counterions were found to be badly disordered at room temperature (Figure 2). This disorder was modeled over two orientations in a 0.5:0.5 occupation ratio. The disordered groups are represented as a superposition of two tetrahedra with a unique position for the B atoms and eight different orientations for the F atoms. However, the large values of the anisotropic displacement parameter for the F atoms indicate that the disorder model with only two positions for the $BF_4$ groups, derived from the SHELXS-97 program, is not fully satisfactory. It is therefore very likely that both counterions are disordered over several rather close orientations at room temperature.

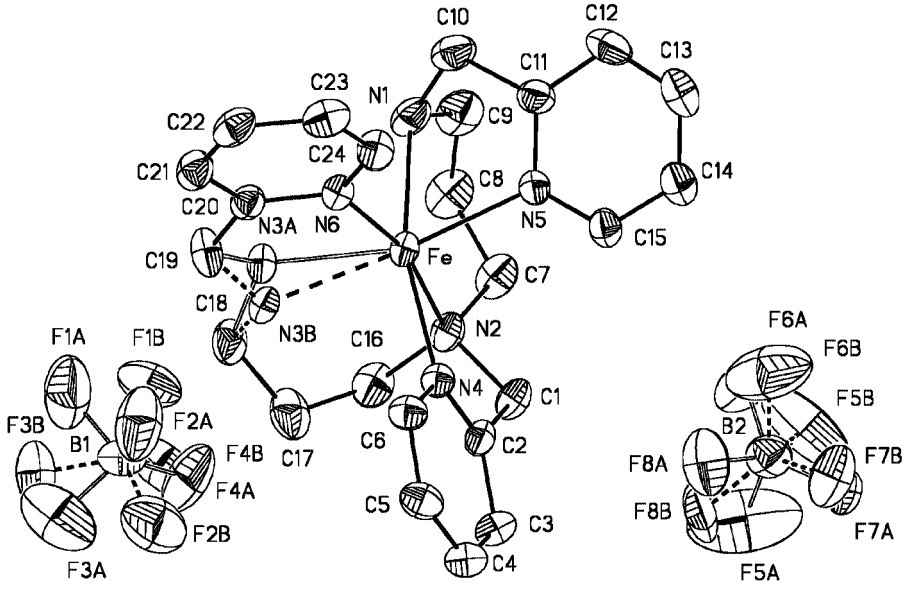

Figure 2. ORTEP view of [Fe(Hpy-DAPP)]$(BF_4)_2$ at 298 K. Ellipsoids enclose 30% probability. The hydrogen atoms have been omitted for clarity.

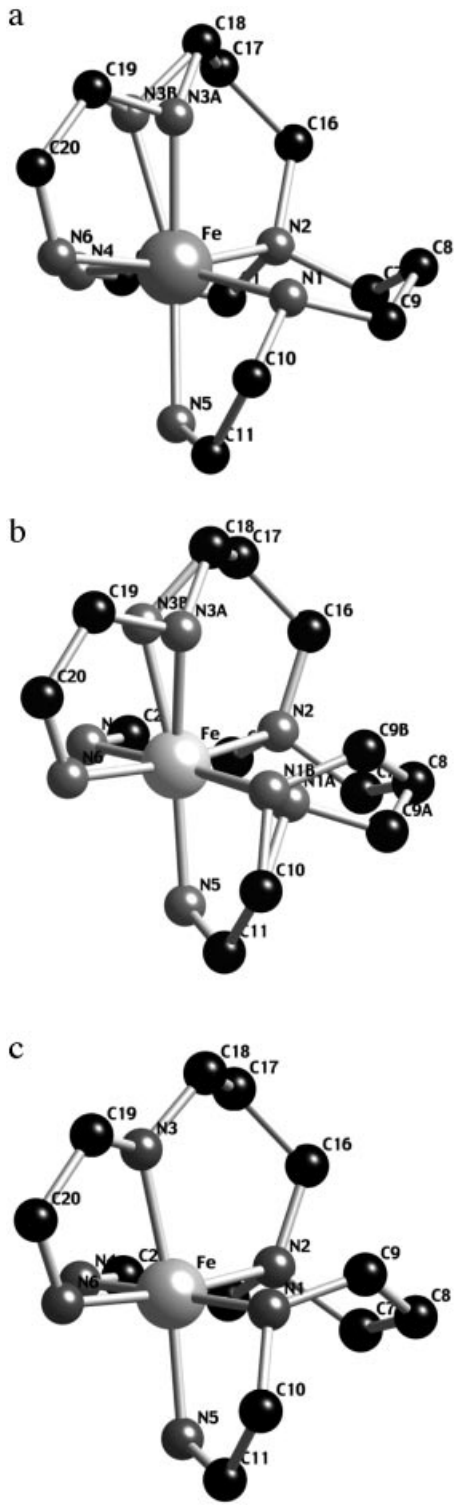

Figure 3. Fragment of the molecular structure of [Fe(Hpy-DAPP)]$(BF_4)_2$ at 298 K (a), 130 K (b), and 90 K (c).

Figure 4 displays a projection of the crystal structure on the *ac* plane. The cohesion between the cation complexes is achieved by numerous indirect hydrogen bonds passing via the fluorine atoms of both counteranions (Table 2). The fluorine atoms of the B1 tetrafluoroborate ion are strongly involved in the formation of sixteen H-bonds, namely four intramolecular bonds with the N1 atom, two intra- and two intermolecular bonds with the disordered N3 atom, and three intra- and five intermolecular bonds with C13 and C19 atoms, respectively. The intermolecular interactions concerning the B1 counterion link the molecules related by the symmetry operation $x$, $0.5 - y$, $0.5 + z$ into infinite chains that propagate in the *c* direction. The fluorine atoms of the B2 tetrafluoroborate anions, much less involved in the hydrogen bonding, take part in only a few H-bonds (Table 2). They link the molecules from neighboring infinite chains into a three-dimensional network. The H-bonds with the B2 counterions spread in the directions corresponding to the two diagonals in the *ab* plane.

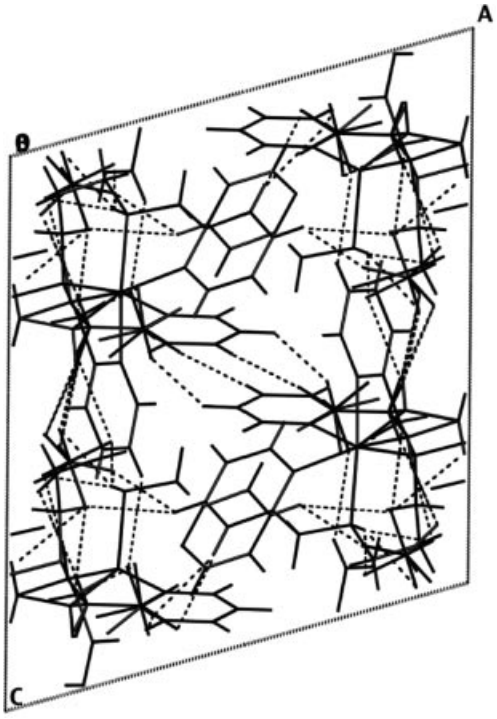

Figure 4. Projection of the molecular structure on the *ac* plane showing the H-bonding network at 298 K.

### *T = 130 K (Cooling Mode)*

The main feature of the structure is the disorder enhancement within the $Fe^{II}$ coordination core despite the lowering of the temperature. The disorder of the N3 amino aliphatic group over two equally occupied sites is retained (Figure 3, b). Moreover, the second amino aliphatic N1 atom, as well as the adjacent C9 methylene group, which are only slightly agitated at room temperature, were resolved to be also disordered over two A and B sites with a 0.5:0.5 occupancy ratio. At 130 K, the FeN2C7C8C9(A)N1(A) and FeN2C7C8C9(B)N1(B) six-membered chelate cycles adopt two different conformations. The former, as at room temperature, has a *chair* conformation, whereas the latter adopts a *twist-boat* conformation (Figure 3, b). At this temperature, the geometry of the $[FeN_6]$ octahedron reflects the changes conforming to a partial HS→LS transition. The distances in the coordination core decrease (Table 1) and the average Fe–N distance decreases to 2.087 Å.

Several models of splitting of the $BF_4$ anions at 130 K were tested. However, the best result was obtained for an ordered model. This suggests that the tetrafluoroborate anions undergo an order–disorder transition above 130 K. The anisotropic thermal parameters for the fluorine atoms are considerably reduced relative to 298 K. Nevertheless, they remain slightly higher than those for the other atoms.

Upon lowering the temperature to 130 K, the shortening of the unit-cell parameters and the bond lengths due to both thermal contraction and partial spin-transition occurs. Relative to 298 K, the unit-cell volume decreases by 5.3% (151 Å$^3$), although the crystal packing is similar to that at room temperature. The number of H-bonds is lower but the topology of their propagation in the crystal is quite similar (Table 2). As above, the B1 tetrafluoroborate anions participate in the formation of intra- and intermolecular interactions that result in infinite chains of H-bound complex cations spreading in the *c* direction. The intermolecular distances connected with H-bonding (Table 2) are slightly reduced, showing a relative strengthening of the intermolecular interactions upon cooling.

### *Low-Spin Complex Structure (T = 90 K)*

At this temperature, according to the magnetic and Mössbauer data (vide infra), the LS sample contains small amounts of the HS isomer (10%). Despite the presence of a residual HS fraction, the structural characteristics found at 90 K are close to those usually observed for LS complexes.

The main result of the structural determination at this temperature is the disappearance of disorder in the positions of both N1 and N3 secondary amino aliphatic nitrogen atoms observed at 130 K (Figure 3, c). Despite a general decrease, the anisotropic displacement parameter values for several atoms (N1, N3, and C9, as well as F2, F3, F5, and F6) remain slightly higher than those for the other atoms. This can be explained by the contribution of disorder introduced by the residual HS fraction. The FeN2C7C8C9N1 six-membered chelate cycle adopts a *twist-boat* conformation (Figure 3, c), whereas the FeN2C16C17C18N3 metallacycle has an intermediate conformation between the *chair* and *half-boat* ones.

Upon cooling, the metal–ligand distances in the $[FeN_6]$ coordination core become shorter (Table 1), in full accordance with the HS→LS transition. The reductions of the Fe–N distances are 0.199 (Fe–N1), 0.110 (Fe–N2), 0.099 (Fe–N3), 0.132 (Fe–N4), 0.158 (Fe–N5), and 0.174 Å (Fe–N6), relative to the room-temperature values. The N–Fe–N angles also vary in the direction of a more regular geometry of the $[FeN_6]$ octahedron.

At 90 K, the unit-cell volume decreases by 5.94% (168 Å$^3$) relative to that at 298 K due to both the lattice thermal contraction and the shortening of the Fe–N distances upon spin transition. The anisotropy of the unit-cell contraction amounts to 3.23, 1.01, and 1.48% for the *a*, *b*, and *c* axes, respectively, and 0.57% for the $\beta$ angle. The network of intermolecular contacts represented by hydrogen bonds is rather similar to that for the HS form (Table 2): the crystal packing consists of chains of molecules spreading in the *c* direction. The cohesion within the chains is provided by H-bonding through the B1 tetrafluoroborate anion, whereas between the chains it mainly occurs via the B2 counterion.

## Mössbauer Data

Mössbauer spectra for [Fe(Hpy-DAPP)]$(BF_4)_2$ were recorded on two different batches of freshly prepared sam-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ples. Within the experimental error, the Mössbauer parameters were found to be the same for the two syntheses. Figure 5 shows some representative spectra at different temperatures. The values of the main Mössbauer parameters obtained from a least-square fitting procedure are listed in Table 3 for the whole temperature range. The room-temperature Mössbauer spectrum consists of a unique quadrupole-split doublet with parameters typical for iron(II) in the HS state ($\delta$ = 0.955 mm s$^{-1}$, $\Delta E_q$ = 1.848 mm s$^{-1}$). The Mössbauer spectra at lower temperatures can be best fitted with two doublets corresponding to HS and LS iron(II) species. The Mössbauer area fraction [$A_{HS}/(A_{HS} + A_{LS})$] is plotted as a function of temperature (in the cooling mode) in Figure 6. It reveals the same two-step spin-crossover behavior as the magnetic measurements. The low-temperature residual HS fraction was found to be significantly different in the two series of Mössbauer measurements. We attribute this difference to the somewhat different cooling procedure in the two cases. To check this hypothesis, we carried out a series of thermal quenching experiments down to 80 K at different cooling rates (0.1, 1, 10, and 50 K min$^{-1}$). The HS fractions obtained at different cooling rates are included in Figure 6. At the lowest cooling rate we obtained about 8% HS residue, while at 10 and 50 K min$^{-1}$ the trapped HS fraction reached 31 and 32%, respectively.

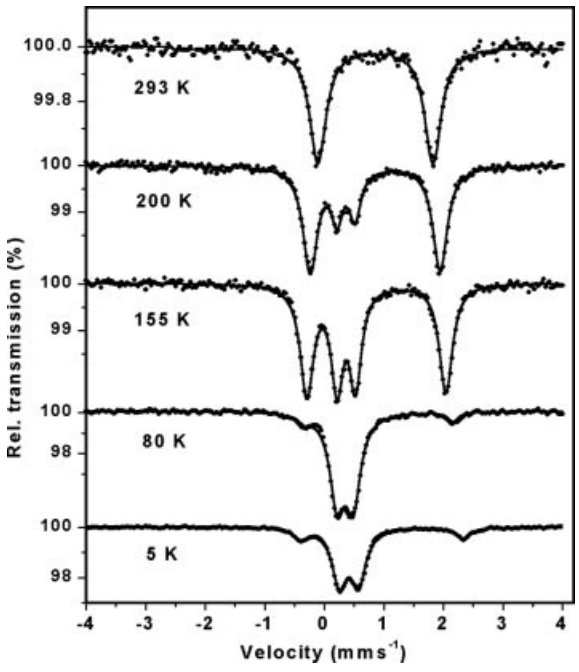

Figure 5. Representative Mössbauer spectra of [Fe(Hpy-DAPP)](BF$_4$)$_2$. The solid lines represent fitted curves.

The thermal variation of the Mössbauer parameters in the vicinity of the inflexion point (80–200 K) was carefully analyzed. Figures showing the evolution of the isomer shift ($\delta$), half-height width ($\Gamma$), quadrupole splitting ($\Delta E_q$) of the HS and LS Mössbauer lines, and the logarithm of the total Mössbauer spectrum area as a function of the temperature in the cooling cycle are provided as Supporting Information. Due to the second-order Doppler effect, both the HS and LS isomer shifts increase almost linearly with decreasing temperature. One can observe a slight deviation from the linear behavior around 125 K, but it hardly exceeds the experimental incertitude. The line widths of the HS and LS Mössbauer lines show an opposing tendency: while the former decreases, the latter increases slightly with decreasing temperatures. The thermal variation of $\Gamma_{LS}$ displays a jump between 125 and 117.5 K. For $\Gamma_{HS}$ the statistical errors become too high around these temperatures due to the small proportion of HS molecules. As a general ten-

dency, however, the HS quadrupole splitting increases between 200 and 80 K while it remains almost constant in the LS state. This behavior of $\Delta E_q$ is typical for iron(II) ions in the HS and LS spin states.[7] A closer inspection of quadrupole splittings reveals a jump in the $\Delta E_q^{LS}$ values between 125 and 117.5 K and a less monotonous increase of $\Delta E_q^{HS}$ below 132 K. This latter observation may, however, be hampered by increasing experimental errors when the HS fraction decreases. The natural logarithm of the Mössbauer line area as a function of temperature shows the continuous increasing tendency with decreasing temperature without any noticeable discontinuity.

### Electronic Structure Calculations

The molecular geometry of the isolated [Fe(Hpy-DAPP)]$^{2+}$ complex cation was firstly optimized in the HS and LS states. The optimized bond lengths in the LS and HS states reproduce the geometry found from the X-ray study at 90 K and 300 K, respectively, quite reasonably. All attempts to find another equilibrium geometry of the complex by modifying the departure geometry in the optimization procedure were unsuccessful. This means that the disorder in the spin transition complex is not due to the existence of several intrinsic complex conformations that are close in energy. At the next step, the single-point calculations were performed for the molecular structures obtained by X-ray crystallography at different temperatures. The calculations with the structure observed at 90 K correctly reproduce the ground LS state, with an energy gap to the HS state of 33 kJ mol$^{-1}$. If the molecular structures manifest a disorder, as is found at 300 and 130 K, the calculations were done for each observed geometry. Thus, with the 300-K structure the energies of the HS and LS states were calculated separately for the geometries with N3(A) and N3(B). In both cases, the HS state lies lower than the LS state of the same geometry. The energy gap is equal to 115 and 121 kJ mol$^{-1}$ for the N3(A) and N3(B) positions, respectively. These two values are quite similar, which suggests that the geometry with the N3(A) position is slightly closer to the spin transition. Disorder was observed for the two nitrogen atoms, as at 130 K, and as, a priori, we have no grounds to presume a correlation between the N1 and N3 positions, four geometries were considered, corresponding to the combinations N1(A)N3(A), N1(A)N3(B), N1(B)N3(A), and N1(B)N3(B). The ground HS state was obtained for the first two geometries with the energy gaps to the excited LS state equal to 23 and 14 kJ mol$^{-1}$ for N1(A)N3(A) and N1(A)N3(B), respectively. An inverse order of the spin levels was found for the N1(B)N3(A) and N1(B)N3(B) geometries, with the LS state stabilized by 6 and 17 kJ mol$^{-1}$, respectively.

The preference of the N1(B)N3(B) geometry for the formation of the LS state directly follows from comparison of Mulliken atomic charges, which are equal to –0.54 and –0.55 for N1(B) and N3(B), respectively, and to –0.48 for N1(A) and N3(A). These numbers indicate that the N1(B) N3(B) geometry corresponds to a stronger crystal field. This effect is also displayed in the energies of the molecular orbitals. All antibonding orbitals of the d block have about the same energies for N1(A)N3(A) and N1(B)N3(B), besides that originating from $d_{x^2-y^2}$, which is stabilized in N1(A)N3(A) by 55 kJ mol$^{-1}$. The antibonding character of the MO in the N1(A)N3(A) conformation is counterbalanced by a bonding behavior between the 2p atomic orbital of N1 and the $d_{x^2-y^2}$ atomic orbital of the Fe atom (Figure 7).

The results of calculations unambiguously show that the structural disorder revealed at 130 K by X-ray crystallography is accompanied by the coexistence in the crystal of complexes in the HS and LS states. Two statistically possible geometries result in the HS ground state, whereas for two others the order of spin states is the same as at low temperature.

## Discussion

The magnetic measurements of the [Fe(Hpy-DAPP)]$(BF_4)_2$ complex display a two-step spin transition. Such spin transitions have been reported for both binuclear[8] and mononuclear[9,10] $Fe^{II}$ spin-crossover compounds. Until now, the origin of two steps within the family of mononuclear compounds has been associated with the presence of two crystallographically inequivalent iron(II) sites in the unit cell. If two metal sites coexist whatever the temperature,[9] the thermal two-step spin transition can occur without change of the crystallographic symmetry group. The structural distinction between the two lattice sites leads to different transition temperatures. Two inequivalent $Fe^{II}$ sites can also appear upon cooling as a result of a crystallographic phase transition accompanied by a change of the space group.[10] It is interesting to note that the extensively studied mononuclear complex $[Fe(2\text{-pic})_3]Cl_2\cdot EtOH$[11] has been considered during the last 25 years as the only example of an iron(II) compound with a unique metal site[12] for which a two-step spin transition[13] takes place without any crystallographic phase transition. This phenomenon was interpreted in terms of coexisting positive and negative interactions,[8a] respectively, over a long and short range.[14a–14c] However, a recent detailed X-ray reinvestigation of $[Fe(2\text{-pic})_3]Cl_2\cdot EtOH$[10b] has shown that the expected negative correlations exhibit a long-range character in the plateau temperature range. Two steps on the thermal spin-transition curve result from two successive re-entrant structural phase-transitions of the order–disorder type. Nevertheless, the existence of HS-LS pairs with short correlation lengths was found for the photoinduced state.[14d]

The striking feature of the two-step spin-transition compound [Fe(Hpy-DAPP)]$(BF_4)_2$ consists in the absence of two crystallographically inequivalent iron(II) lattice sites, as well as a crystallographic phase transition accompanied by a change of space group. The most important peculiarity of the HS structure of the [Fe(Hpy-DAPP)]$(BF_4)_2$ complex is the disorder of the secondary N3 amino aliphatic atom over two positions (Figures 2 and 3a). A possible origin of the disorder of the N3 atoms, which constitute the first coordination sphere in iron(II), may be looked for in their strong involvement in H-bonding with their own and neighboring B1 counterions (Figure 8). Each B1 counterion is simultaneously attached by hydrogen bonds to the N3 atom belonging to its own complex cation and to the N3 atom of the neighboring complex (symmetry operation $x$, $0.5 - y$, $0.5 + z$), thus forming infinite chains of complexes in the $c$ direction. One can suppose that the strong H-bonding of the same N3 atom with two different counterions might produce appreciable constraint in the position of the N3 atom, thereby favoring a disorder between the A and B positions. This disorder is facilitated by a high flexibility of the N3-containing six-membered chelate cycle. At room temperature, the N1 amino aliphatic atom is also strongly involved in hydrogen bonding but only with its own B1 counterion. At room temperature, in contrast to the N3 atom, the position of the N1 atom is ordered.

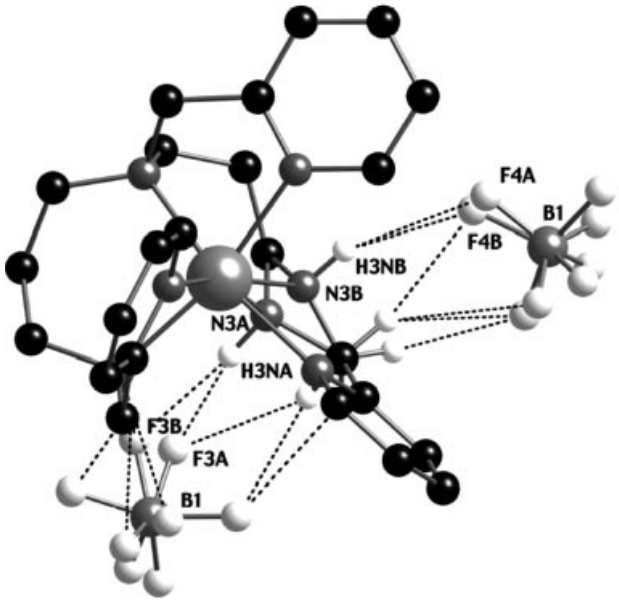

Figure 8. View of the hydrogen bonds of the N3 atom with its own and neighboring (symmetry operation: $x$, $0.5 - y$, $0.5 + z$) B1 counterions at 298 K. The labels for the other atoms have been omitted for clarity.

The structure determination at 130 K, corresponding to the inflexion point on the magnetic curve when the conversion from high to low spin reaches 50%, shows some new features. The disorder of the N3 amino aliphatic atom observed at room temperature is attended by the distribution

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the N1 atom between the two A and B positions. Moreover, the C9 methylene atom directly linked to the N1 atom is also equally distributed over C9(A) and C9(B) sites, which are stabilized by two new hydrogen bonds with the B1 and B2 counterions (Table 2). The two N1(A) and N1(B) positions are very close, whereas the C9(A) and C9(B) positions are rather distant one from another. The presence of the two sites for atoms N1 and C9 causes the two conformations of the N2C7C8C9N1Fe six-membered metallacycle (Figure 3, b). The N2C7C8C9(A)N1(A)Fe cycle has a *chair* conformation that is very close to that observed at room temperature (Figure 3, a), whereas the *twist-boat* conformation N2C7C8C9(B)N1(B)Fe appears in the course of spin conversion. This result strongly suggests that the spin conversion above the inflexion point is accompanied by the conformational change in the ligand. The crystallographic data obtained at 170 K confirm the coexistence of the C9(A) and C9(B) sites already at this temperature. However, the conformational motion in the complex is not drastic enough to modify the space group. It is important to underline that the 1:1 ratio of the HS and LS forms at 130 K coincides with the distribution of the N2C7C8C9N1Fe chelate cycle over two conformations.

Upon lowering the temperature to 90 K, the average metal–ligand distance becomes 0.142 Å shorter than at room temperature, which conforms to the occurrence of the HS→LS transition. The disorder found at 130 K for the positions of the N1, N3, and C9 atoms disappears at 90 K. The N2C7C8C9N1Fe metallacycle adopts a unique *twist-boat* conformation at 90 K (Figure 3, c). It should be noted that the geometry of the N2N7N8N9N1Fe chelate cycle in the LS complex is very close to that observed for the N2C7C8C9(B)N1(B)Fe metallacycle at 130 K (Figure 3, b). One may therefore conclude that the HS→LS transition in the complex is accompanied by order–disorder phenomena in conjugation with a conformational change in the ligand.

Let us now consider the relationship between the disorder in the [FeN$_6$] coordination core and the magnetic behavior of the system. A priori, the mononuclear [Fe(Hpy-DAPP)](BF$_4$)$_2$ complex without any crystallographic phase transition should be expected to display a one-step spin transition. Nevertheless, the magnetic measurements show the two steps in the spin transition. The presented X-ray data for [Fe(Hpy-DAPP)](BF$_4$)$_2$ do not contradict the basic assumption of two-step transition models, which involves the competition between positive and negative interactions[8a] possibly giving rise to short-range negative correlations[14a–14c] or to LS-HS sub-lattice ordering.[8a] However, our crystallographic data suggest that the origin of the two-step transition in [Fe(Hpy-DAPP)](BF$_4$)$_2$ can also be looked for in the [FeN$_6$] coordination core ordering. At room temperature, the distribution of the N3 amino aliphatic atom over two lattice positions preforms two geometries of the coordination core around the crystallographically unique Fe$^{II}$ center, with N3(A) and N3(B), respectively (Figure 3, a). Both geometries correspond to the HS state at 298 K. The systematic variation of the Mössbauer line widths for the HS doublet above 160 K (see Supporting Information) might suggest the existence of two different iron(II) environments with very similar Mössbauer parameters. However, these changes are very small and no reliable fit could be obtained with two doublets in the whole high temperature range. The congruency of two doublets corresponding to two different coordination geometries due to the high temperature disorder of counterions, as has been proposed for the compound [Fe(mtz)$_6$](BF$_4$)$_2$,[15] cannot, however, be excluded. Upon lowering the temperature from 298 to 230 K, the $\chi_M T$ value changes slightly, thus showing that the complex remains predominantly in the HS state. A further decrease of temperature leads to a continuous reduction of the $\chi_M T$ value, which indicates the beginning of spin transition. On cooling, both tetrafluoroborate counteranions become less agitated. The reduction of the counteranions' motion leads to their more regular arrangement in the crystal lattice, resulting in some modifications of the H-bonds between the B1 counteranions and the secondary amino aliphatic atoms. These modifications induce subtle perturbations of the N1 and N3 nitrogen atoms directly coordinated to the iron(II) center and affect the ligand field strength, initiating, in turn, the spin transition. The inflexion point on the magnetic curve denotes that at 130 K the spin transition is complete in half the sites whereas the other half remain in the HS state. At this temperature four possible coordination cores can be formally distinguished around the same Fe$^{II}$ atom. These four coordination cores may include, in addition to the N2N4N5N6 atoms, the pairs N1(A)N3(A), N1(A)N3(B), N1(B)N3(A), or N1(B)N3(B). The 0.5:0.5 occupation ratio for both the N1 and N3 atoms suggests that either all four combinations, or only two of them, namely N1(A)N3(A) and N1(B)N3(B), exist. The difference in the average Fe–N distances in the four cores (2.093, 2.096, 2.075, and 2.078 Å) is not significant enough to allow a proper identification of the HS and LS sites.

It has been demonstrated previously that not only metal–ligand distances but also angular distortions can modulate the ground-state spin.[16] As has been noted above, the geometries of the N2C7C8C9(B)N1(B)Fe chelate cycle at 130 K and the N2C7C8C9N1Fe chelate cycle in the LS complex at 90 K are very similar, with both being in the *twist-boat* conformation (see parts b and c in Figure 3). One may suppose that the LS coordination core at 130 K should involve the N1(B) atom. At 130 K, two coordination site geometries, from four formally possible, contain the N1(B) atom. The quantum-chemical calculations show that both the N1(B)N3(A) and N1(B)N3(B) pairs lead to the LS state. However, a very short distance (2.669 Å) between the N1(B) and N3(A) atoms, as well as between the attached hydrogen atoms (1.846 Å), should lead to an important steric strain (note that the van der Waals radii for the nitrogen and hydrogen atoms are 1.55 and 1.20 Å, respectively). Moreover, the presence of H-bonds between the N1(B) and N3(A) atoms must also be rejected due to the rather small N–H···N angles of 95.7° and 104.0°. Thus, it may be concluded that the LS site at 130 K contains the N1(B) and N3(B) atoms, i.e. the N1(B)N3(B) and N1(A)N3(A) pairs conform

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to the LS and HS isomers, respectively. The spin conversion in the N1(B)N2N3(B)N4N5N6 core is accompanied by a conformational transition in the ligand, whereas the high-spin N1(A)N2N3(A)N4N5N6 core retains a geometry close to that observed at room temperature.

The first step in the spin transition is very gradual but the second one is abrupt, with a hysteresis loop of 4 K. The change in the abruptness in the spin transition may be explained by the strengthening of intermolecular interactions, which leads to a higher cooperativity in the low-temperature step. The second step in the spin conversion is also associated with a conformational change in the ligand similar to that observed for the first step. So, two geometries of the $[FeN_6]$ coordination core, generated by order–disorder phenomena at room temperature, in the course of the spin transition converge to a unique geometry of the $Fe^{II}$ coordination site. The hysteresis in the low-temperature step is not connected either with a crystallographic phase transition or with strong changes of the unit-cell parameters and/or topology of the cooperative interactions.[6] One can suppose that the hysteresis results from a slow conformational transition in the ligand at low temperature. Indeed, the efficient quenching of the HS form indicates that the HS → LS relaxation is very slow at around 80 K. In order to throw more light on this phenomenon, further experiments will be necessary (magnetic measurements at different scan rates, thermal quenching and photoswitching experiments followed by relaxation studies).

In summary, we would like to underline that our studies suggest that $[Fe(Hpy\text{-}DAPP)](BF_4)_2$ is the first example of a spin-transition system that displays a disorder in the first coordination sphere of the metal center. Two different geometries of the $[FeN_6]$ coordination core generated by the disorder in the ligand may be at the origin of the two-step spin-transition behavior of the system. However, keeping in mind that it took 25 years to clarify the origin of the two-step transition in $[Fe(2\text{-}pic)_3]Cl_2{\cdot}EtOH$,[10b,12–14] we consider that further advanced crystallographic studies are needed to verify this hypothesis. The HS → LS transition is conjugated with the conformational change in the chelate cycle, and other examples of conformationally driven electronic transitions are known in the literature.[17] Conformational transformations in the solid state have been observed for thermochromic systems and electron-transfer mixed-valence complexes. However, this phenomenon for spin-transition systems in the solid state has not been described until now.

## Experimental Section

**Chemistry:** All reagents and solvents used in this study are commercially available and were used without further purification. All syntheses involving $Fe^{II}$ species were carried out in deoxygenated solvents under an inert atmosphere of $N_2$ using glovebox techniques. [Bis(3-aminopropyl)(2-pyridylmethyl)amine] (DAPP) was obtained according to the procedure we have recently reported.[6] $FeCl_2{\cdot}2H_2O$ was prepared as described elsewhere.[18] $^1H$ NMR spectra were recorded in $CDCl_3$ on a Bruker AC200 spectrometer operating at 200 MHz.

**Ligand Synthesis (Hpy-DAPP):** A mixture of DAPP (96 μL, 0.5 mmol) and 2-pyridinecarboxaldehyde (107 mg, 1 mmol) in methanol (15 mL) was refluxed under argon for 15 min. Then, an excess of $NaBH_4$ (100 mg) was added in several small portions. The solution was allowed to stand overnight at room temperature and the solvent was evaporated under vacuum. After successive extraction of the crude product with $CHCl_3$ and $Et_2O$, 180 mg of pure HpyDAPP was obtained as a pale-yellow oil. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.53–7.08 (m, 12 H, aromatic H's), 3.84 (s, 4 H, $CH_2$), 3.68 (s, 2 H, $CH_2$), 2.67–2.60 (t, 4 H, $CH_2$), 2.56–2.49 (t, 4 H, $CH_2$), 1.74–1.60 (q, 4 H, $CH_2$) ppm.

**Synthesis of the Iron(II) Complex:** $FeCl_2{\cdot}2H_2O$ (24.4 mg, 0.15 mmol) was dissolved in 2 mL of ethanol/methanol (1:1 mixture), and Hpy-DAPP (60.7 mg, 0.15 mmol) in 2 mL of the same mixture of alcohols was added. A light yellow-green solution was formed. The addition of 116.2 mg (0.30 mmol) of $NBu_4BF_4$ in 4 mL of ethanol/methanol turned the color of this solution to green. The solution was filtered and allowed to stand overnight at room temperature to give green crystals of $[Fe(Hpy\text{-}DAPP)](BF_4)_2$, which were collected by filtration, washed with ethanol, and dried in vacuo. The crystal used in the X-ray structure determination was selected from this sample. $C_{24}H_{32}B_2F_8FeN_6$ (634.01): calcd. C 45.47, H 5.09, Fe 8.81, N 13.26; found C 45.78, H 4.92, Fe 8.52, N 13.01.

**Magnetic Properties:** Magnetic susceptibilities were measured in the temperature range 15–300 K with a fully automated Manics DSM-10 susceptometer equipped with a TBT continuous-flow cryostat and an electromagnet operating at about 1.6 T. Data were corrected for magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.

**Mössbauer Spectra:** The variable-temperature $^{57}Fe$ Mössbauer measurements were carried out on a constant-acceleration spectrometer with a 50 mCi $^{57}Co(Rh)$ source. A powder sample (60 mg) was enclosed in a 12-mm-diameter cylindrical plastic sample holder, the size of which had been determined to optimize the absorption. Spectra were obtained at 5, 100, 150, 200, and 293 K using a custom-designed, liquid helium bath cryostat (DTA, Air Liquid). A second series of measurements was carried out in the 80–250 K range (in the cooling cycle) using a MD306 He exchange gas, liquid nitrogen bath cryostat (Oxford Instruments). A least-squares computer program was used to fit the Mössbauer parameters and to determine the standard deviations of statistical origin (given in parentheses).[19] The isomer shift values are given with respect to metallic iron at room temperature.

**Solution and Refinement of the X-ray Structure:** The data collection was made with a Nonius Kappa CCD diffractometer equipped with a normal monochromatized focus X-ray tube with a molybdenum target. The selected crystals were mounted on a thin glass fiber. The data were collected using the COLLECT software,[20] then were processed with the DENZO reduction software.[21] Three collections were made: the first one at room temperature (298 K), the second one at 130 K after a slow decrease of the temperature with a cool, dry nitrogen gas stream, and the third one at 90 K after cooling the crystal in a cold nitrogen gas flow. From 10 frames with 1° steps, the initial set of cell parameters was obtained for each measurement. A total of 12331 reflections were collected at room temperature, of which 6326 unique reflections were used for the structure determination. The second collection at 130 K is formed from 10356 measured reflections, 5738 of which were independent reflections. The third collection at 90 K concerns 8580 measured reflections, of which 5358 unique reflections were used for the hypothesis and refinement. The structures were solved by

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

direct methods with the SHELXS-97 program.[22] The structures were then refined by the least-squares method using SHELXL-97,[23] with anisotropic temperature factors for all non-H atoms. The hydrogen atoms were introduced at calculated positions and refined as riding on their carrier atoms. The final $R$ factor [with $I > 2\sigma(I)$] was 0.059, 0.091, and 0.091 at 298, 130, and 90 K, respectively. Crystal data and refinement results are summarized in Table 4. The perspective view of the asymmetric unit at three temperatures was calculated with PLATON[24] and is shown in Figure 2.

Table 4. Crystallographic data for $[Fe(Hpy\text{-}DAPP)](BF_4)_2$.

| | $T$ = 298 K | $T$ = 130 K | $T$ = 90 K |
|---|---|---|---|
| Formula | | $C_{24}H_{32}B_2F_8FeN_6$ | |
| $Fw$ | 634.03 | | |
| $a$ [Å] | 13.298(1) | 12.897(1) | 12.868(1) |
| $b$ [Å] | 14.368(1) | 14.251(1) | 14.223(1) |
| $c$ [Å] | 15.409(1) | 15.207(1) | 15.180(1) |
| $\beta$ [°] | 106.09(1) | 106.71(1) | 106.69(1) |
| $V$ [Å$^3$] | 2828.6(1) | 2676.9(2) | 2661.2(3) |
| $Z$ | 4 | 4 | 4 |
| Space group | $P2_1/c$ | $P2_1/c$ | $P2_1/c$ |
| $\lambda$ [Å] | 0.71073 | 0.71073 | 0.71073 |
| $\rho_{calcd.}$ [g cm$^{-3}$] | 1.489 | 1.573 | 1.583 |
| $\mu$ [cm$^{-1}$] | 6.12 | 6.47 | 6.51 |
| $R$[a] [$I > 2\sigma(I)$] | 0.059 | 0.091 | 0.091 |
| $wR_2$[b] [$I > 2\sigma(I)$] | 0.141 | 0.194 | 0.207 |

[a] $R = \sum(||F_o| - |F_c||)/\sum|F_o|$. [b] $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$.

CCDC-295576 to -295578 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Electronic Structure Calculations:** Calculations of the electronic structure of the isolated $[Fe(Hpy\text{-}DAPP)]^{2+}$ complex cation were performed using the formalism of density functional theory (DFT). Single-point calculations for molecular geometries, extracted from the X-ray crystallographic data for different temperatures, were carried out with the Gaussian 2003 package.[25] In each case, both HS and LS states were considered. The LANL2DZ basis set, including the double-ζ basis with the Los Alamos effective core potential for Fe and the Dunning–Huzinaga all-electron double-ζ basis set with polarization functions for the H, C, and N atoms[26,27] were used. The choice of exchange-correlation functional for calculations of the energy gap between HS and LS states is widely debated in the literature. The hybrid Hartree–Fock/GGA (generalized gradient approximation) B3LYP functional and its re-parameterized version B3LYP* are more often recommended.[28–30] In this work we firstly use the parameter-free density functional model PBE0 obtained by combining the so-called PBE GGA functional with a predefined amount of exact exchange.[31] The calculations with this functional result in a correct order of the HS and LS states for experimental structures obtained at different temperatures.

# Synthesis and Structure of Trialkyltantalum Complexes Stabilized by Aminopyridinato Ligands

**Awal Noor,[a] Winfried Kretschmer,[b] and Rhett Kempe*[a,c]**

**Keywords:** Amido ligands / Aminopyridinato ligands / N ligands / Olefin polymerization / Tantalum

(4-Methylpyridin-2-yl)(trimethylsilyl)amine (**1**), (6-methylpyridin-2-yl)(trimethylsilyl)amine (**2**), and (2,6-diisopropylphenyl)(pyridin-2-yl)amine (**3**) were deprotonated and used as ligands to synthesize trialkyltantalum complexes. The reaction of 2 equiv. of **1** or **2** with pentabenzyltantalum afforded tribenzyltantalum(V) complexes by toluene elimination. Analogous reaction using **3** failed. Lithiation of **3** followed by the reaction with tribenzyltantalum dichloride gave rise to the corresponding tribenzyl complex. Other alkyltantalum complexes stabilized by this ligand environment can be prepared by treating tantalum pentachloride with 2 equiv. of lithiated **3** to form a bis(aminopyridinato)tantalum trichloride. The reaction of this trichloride with 3 equiv. of alkyllithium compounds like methyllithium affords the corresponding trialkyltantalum complexes. X-ray diffraction studies of four of the synthesized complexes were carried out. They adopt two different coordination environments, either slightly distorted capped octahedrons (sterically less demanding aminopyridinato ligands) or pentagonal bipyramids (bulkier aminopyridinato ligands). The alkyl species were surprisingly stable at elevated temperatures and no formation of mixed alkyl/alkylidene complexes was observed. Alkyl cation formation and the behaviour of a selection of these compounds in olefin polymerization were explored.

## Introduction

Aminopyridinato ligands[1] are interesting amido ligands because of the flexibility of their binding mode and the ligand "asymmetry". The dominating binding mode in early transition metal and lanthanide chemistry[2] is the strained $\eta^2$ coordination (Scheme 1, left). The bridging binding mode (Scheme 1, right) is characteristic for late transition metal complexes. Of course, there are exceptions like homoleptic strained $\eta^2$-bound (aminopyridinato)palladium complexes.[3] The ligand "asymmetry" caused by the two different donor functionalities−the pyridine and amido function−might be considered as an additional interesting feature especially in comparison to the closest "relatives", the amidinates.[4]

Group 5 metal complexes stabilized by aminopyridinato ligands (Scheme 2, left) have been investigated to a lesser extent than related amidinate[5] complexes (Scheme 2, right).

The first Ap (Ap = aminopyridinato) group 5 metal complex was published by Gambarotta 15 years ago.[6] A more detailed investigation of some aspects of the coordination chemistry of these ligands was started by Polamo. He applied the "direct synthesis" method to prepare a variety of niobium and tantalum complexes stabilized by aminopyridinato ligands.[7–10] Interesting examples of aminopyridinato low oxidation state group 5 metal complexes have been described by Gambarotta and Cotton.[11] Reactivity studies employing organometallic species are still very rare.[12,13] Because of this lack of information we became interested in alkyltantalum complexes. We also expect an easy access into this chemistry because of the recently published Kol synthesis of $[Ta(CH_2C_6H_5)_5]$.[14,15] We report here on the synthesis and structure of organotantalum complexes stabilized by aminopyridinato ligands. The formation of organ-

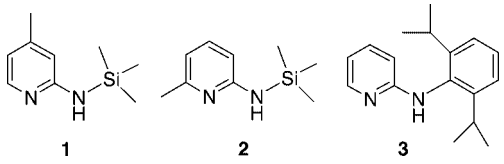
ocations and the relevance to olefin polymerization of a selection of these species is also discussed.

## Results and Discussion

### Synthesis of Ligands

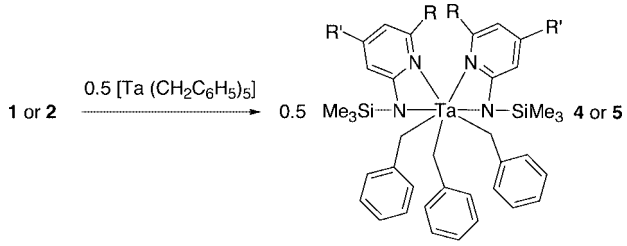
Compounds **1** and **2** were prepared as reported.[16,17] The aminopyridine **3** can be synthesized by palladium-catalyzed arylamination.[18] The reaction of 2-bromopyridine with 2,6-diisopropylaniline and sodium *tert*-butoxide in the presence of a Pd catalyst in toluene (90 °C, 48 h) leads after workup and purification by crystallization to compound **3** (Scheme 3) in good yield (70%).



Scheme 3. Applied aminopyridines.

### Synthesis and Structure of Tantalum Complexes

Reaction of 2 equiv. of **1** with $[Ta(CH_2C_6H_5)_5]$ in hexane at 60 °C results in the formation of **4** by toluene elimination (Scheme 4). No formation of benzylidene functionalities is observed by NMR spectroscopy in the course of this reaction. Complex **4** was isolated after workup in hexane in moderate yield as a yellow crystalline material.



Scheme 4. Synthesis of **4** and **5** (**4**: R = H, R′ = $CH_3$; **5**: R = H, R′ = $CH_3$).

The three benzyl groups show a broad doublet at $\delta$ = 2.96 ppm at room temperature indicative of a fast ligand exchange. Crystals suitable for X-ray analysis were grown from a hexane solution. Details of the X-ray crystal structure analysis are summarized in Table 3. The molecular structure of **4** is shown in Figure 1. The coordination of **4** is best described as a distorted capped octahedron. The methylene carbon atom of one of the benzyl ligands (C15) as well as the two pyridine nitrogen atoms occupy the first triangle and C8 as well as the two amido nitrogen atoms the second triangle. In order to apply a slightly increased steric bulk in close proximity to the metal center 2 equiv. of **2** were treated with $[Ta(CH_2C_6H_5)_5]$ under the same conditions as applied to **4**. The resulting benzyl complex **5** was obtained in moderate yield (Scheme 4). The three benzyl groups give two doublets at $\delta$ = 2.98 and 3.18 ppm. The product was characterized by X-ray analysis (molecular structure is shown in Figure 2) in addition to NMR spectroscopy. Details of the X-ray crystal structure analysis are summarized in Table 3. The coordination of **5** is best described as a capped octahedron (first triangle N1, N2, and N4; second triangle N3, C15, and C22). In both cases, the rigid aminopyridinato ligands induce distortion from the ideal symmetry. The Ta–C bond lengths lay in the ranges of 2.247–2.318 Å and 2.248–2.264 Å, respectively, for **4** and **5**, which clearly indicate $\eta^1$ binding of all benzyl groups in the solid state.

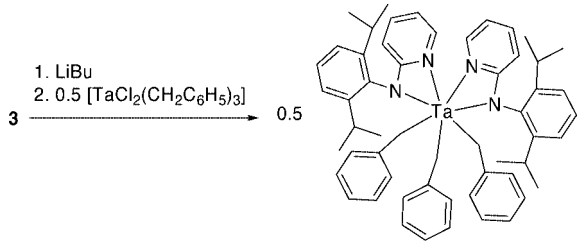
Figure 1. In order to increase the steric bulk of the used aminopyridinato ligands drastically we introduced the 2,6-diisopropylphenyl substituent at the amido nitrogen atom instead of the $SiMe_3$ group. Application of the toluene elimination route starting from $[Ta(CH_2C_6H_5)_5]$ was not successful and salt metathesis was adopted. The reaction of 2 equiv. of the lithium salt of **3** with $[TaCl_2(CH_2C_6H_5)_3]$[14] at room temperature (Scheme 5) resulted in the formation of the tribenzyl complex **6**. The $^1H$ NMR spectra of this compound shows two different sets of signals for benzyl protons. One signal corresponds to four methylene protons of the benzyl substituents and the other to the remaining two. We propose a pentagonal-bipyramidal arrangement in solution with the two amino and one of the benzyl moieties in the equatorial plane. Because of the steric bulk of the deprotonated **3** no exchange on the NMR time scale at room temperature is observed. Two benzyl resonances were found, one at $\delta$ = 3.60 ppm and the second at $\delta$ = 2.79 ppm.



**6**

Scheme 5. Synthesis of **6**.

The first Schrock-type alkylidene complex, $[Ta(CH_2tBu)_3(CHtBu)]$, was prepared in 1974.[19] Various mono- and polydentate ligand systems that support this functionality have been introduced in recent years and several synthetic methodologies are known that lead to the alkylidene complexes like, for instance, an α-elimination reaction sequence from dialkyl precursors.[20] However, the complexes **4**, **5**, and **6** do not form mixed benzyl/benzylidene complexes neither during the synthesis nor by treatment of the trialkyltantalum complexes at elevated temperatures (80 °C). In order to prepare other trialkyltantalum complexes supported by deprotonated **3** — the sterically most demanding of the three ligands described in this publication — we synthesized the corresponding tantalum trichloride species **7** (Scheme 6).

Compound **7** can be synthesized by the reaction of **3** with $TaCl_5$ (Polamo method "direct synthesis"[7]). Because of a relatively low yield using this "direct synthesis" salt metathesis (Scheme 6) was applied and gave rise to **7** in better yield. The success of salt metathesis using lithiated **3** and $TaCl_5$ is in contrast to Polamo's observations. He developed his method due to problems with the salt metathesis approach in similar reactions. The trimethyltantalum complex **8** results when 3 equiv. of LiMe were treated with **7**. The X-ray crystal structures of **7** (Figure 3) and **8** (Figure 4) revealed a distorted pentagonal-bipyramidal coordination. In **7** the two chloro ligands occupy the axial positions of the polyhedra and the two pairs of nitrogen and the third chloride ion form the pentagonal (equatorial) plane. In **8** methyl ligands adopt the same coordination sites as the chloro ligands in **7**. A distortion is caused by the small N–Ta–N angles due to the strained binding mode of the aminopyridinato ligands. In **7** they are 60.1(3) and 60.4(3)° and in **8** 59.25(2)°. Both lead to a situation in which all other angles in the pentagonal plane are over 72°. In **7** N–Ta–Cl(2) *cis* angles are 77.9(2) and 77.3(2)° and in **8** the N–Ta–C(1) *cis* angles are 77.43(10)°. N–Ta–N angles involving the amido bonds of the aminopyridinato ligands are the widest, 84.4(3)° in **7** and 86.65(18)° in **8**. The $Cl_{ax}$-Ta–$Cl_{eq}$ angles for **7** are 99.87(9)° and 99.64(9)° and the $C_{ax}$-Ta–$C_{eq}$ angles for **8** are 94.02(15)° and 93.23(16)°. Details of the X-ray crystal structure analyses of **7** and **8** are summarized in Table 3. The $^1H$ NMR spectrum shows two different sets of signals for methyl protons. The two methyl groups present above and below the pentagonal plane (axial positions) show a resonance at $\delta$ = 1.26 ppm and the in-plane methyl ligand at $\delta$ = 0.63 ppm. Similar observations have been made for **6**. The trimethyl complex **8** was found to be stable

towards elevated temperatures in terms of the formation of mixed methyl/methylidene species. Heating of **8** in toluene at 80 °C for 40 min did not affect the structure of the compound. When harsher conditions were employed, i.e., heating to 120 °C for 30 min, **8** started to decompose slowly without any signs of methylidene formation.

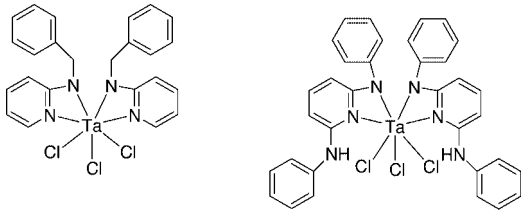
Figure 4. ### Formation of Organocations and Their Application in Ethylene Polymerization

Because of the high ethylene polymerization activity observed for the tantalum complexes **9** and **10**[12] (Scheme 7) we became interested in exploring the polymerization behavior of some of the complexes discussed in this study.



Scheme 7. Structures of **9** and **10**.

Ethylene polymerization studies were performed using **7** (Table 1) and **8** (Table 2) as pre-catalysts.

Table 1. Ethylene polymerization results, activation of **7** using PMAO [PMAO = polymethylaluminoxane $(AlOMe)_x$].[a]

| Pre-cat. [μmol] | PMAO [mmol] | PE [g] | Activity [kg(PE)mol(Ta)$^{-1}$h$^{-1}$bar$^{-1}$] |
|---|---|---|---|
| 10 | 5 | 0.2 | 16 |

[a] 260 mL of toluene as solvent, 5 bar of ethene, 50 °C, 15 min run time, Ta/Al = 1:500 (m/m).

Ethylene polymerization activity of **7** after activation with PMAO is low. This is in contrast to what was observed for **9** and **10**. Thus, we expected to see a significantly better catalyst performance when starting from the methyl complex **8** and activating with trialkylammonium tetrakis(pentafluorophenyl)borate. No significant improvement in terms of activity was found by changing the activation procedure. Because of the low activity no molecular weight analysis of the polymers was accomplished. The generation of cationic complexes was studied in an NMR scale reaction. Reaction of **8** with 1 equiv. of $B(C_6F_5)_3$ in $CD_2Cl_2$ results in the abstraction of one of the axial methyl groups. A new resonance at $\delta$ = 1.86 ppm was observed for this methyl group in the $^1$H NMR spectra. The resulting organocation is not stable in solution and decomposes rapidly into unidentified species.

Table 2. Ethylene polymerization results, activation of **8** using trialkylammonium tetrakis(pentafluorophenyl)borate.[a]

| Run no. | Pre-cat. [μmol] | $B(C_6F_5)_4^-$ [μmol] | TIBAO [mmol] | PE [g] | Activity [kg(PE)mol(Ta)$^{-1}$h$^{-1}$bar$^{-1}$] |
|---|---|---|---|---|---|
| 1 | – | 11 | 0.1 | 0.05 | – |
| 2 | 10 | 11 | 0.1 | 0.06 | 5 |
| 3 | 10 | 22 | 0.1 | 0.16 | 13 |

[a] 260 mL of toluene as solvent, 5 bar of ethene, 80 °C, 15 min run time, Ta/Al = 1:20 (m/m); TIBAO = tetraisobutylaluminoxane ($[iBu_2Al]_2O$).

## Conclusions

Trialkyltantalum complexes stabilized by aminopyridinato ligands can be synthesized by salt metathesis or toluene elimination. They adopt the coordination of either a capped octahedron or a pentagonal bipyramid depending on the steric demand of the aminopyridinato ligand. These trialkyltantalum complexes are thermally unusually stable towards α-H elimination. They form rather unstable organocations and the instability of these cations might be the reason for the low activity in ethylene polymerization.

## Experimental Section

### General Procedures

**Synthesis and Structure Analysis:** All manipulations were performed with rigorous exclusion of oxygen and moisture in Schlenk-type glassware on a dual manifold Schlenk line or in an argon-filled glove box (mBraun 120-G) with a high-capacity recirculator (<0.1 ppm $O_2$). Non-halogenated solvents were dried by distillation from sodium wire/benzophenone. Commercial $TaCl_5$ (Lancaster) was used as received. Deuterated solvents were obtained from Cambridge Isotope Laboratories and were degassed, dried, and distilled prior to use. NMR spectra were recorded with a Bruker ARX at 250 MHz and chemical shifts are reported in ppm relative to the deuterated solvent. Elemental analyses (CHN) were carried out using a Vario EL III instrument. X-ray crystal structure analyses were performed by using a STOE-IPDS II diffractometer equipped with an Oxford Cryostream low-temperature unit. Crystal structure data are presented in Table 3. Structure solution and refinement was accomplished using SIR97,[21] SHELXL97,[22] and WinGX.[23] CCDC-297697 (**4**), -297698 (**5**), -297699 (**7**), and -297700 (**8**) contain the supplementary crystallographic data for

**Polymerization:** Toluene (Aldrich, anhydrous, 99.8%) was passed through columns of $Al_2O_3$ (Fluka), BASF R3-11 supported Cu oxygen scavenger, and molecular sieves (4 Å, Aldrich). Ethylene (AGA polymer grade) was passed over BASF R3-11 supported Cu oxygen scavenger and molecular sieves (4 Å, Aldrich). PMAO (4.9 wt.-% Al in toluene, Akzo Nobel), *N*,*N*,*N*-trialkylammonium tetrakis(pentafluorophenyl)borate [6.2 wt.-% $B(C_6F_5)_4^-$ in Isopar, DOW Chemicals], and TIBA (Witco) were used as received. TIBAO was prepared according to published procedures.[24]

**Synthesis of 3:**[25] Toluene (25 mL) was added to a Schlenk vessel charged with tris(dibenzylideneacetone)dipalladium (0.082 g, 0.09 mmol), NaO*t*Bu (0.750 g, 7.8 mmol), and 1,3-bis(diphenylphosphanyl)propane (0.074 g, 0.18 mmol). To the resulting suspension 2-bromopyridine (0.57 mL, 6 mmol) and 2,6-diisopropylaniline (1.47 mL, 7.8 mmol) was added. The solution was stirred and heated to 90 °C for 48 h. On cooling to room temperature, water and diethyl ether were added to the resulting red solution. The organic phase was extracted and the remaining inorganic phase was further washed with diethyl ether (3 × 20 mL). The combined organic phases were washed with a saturated sodium chloride solution and dried with sodium sulfate. The solvent was removed under reduced pressure and the resulting reddish solid was purified using silica gel chromatography (eluent: dichloromethane). The solvent was removed under reduced pressure and the product was recrystallized from pentane as a white crystalline material. Yield 1.07 g (70%). $C_{17}H_{22}N_2$ (254.37): calcd. C 80.27, H 8.72, N 11.01; found C 80.30, H 8.75, N 10.82. $^1$H NMR ($C_6D_6$, 298 K): $\delta$ = 1.10 [d, 12 H, $CH(CH_3)_2$], 3.39 [sept, 2 H, $CH(CH_3)_2$], 5.88 (d, 1 H, Py-3-H), 6.20 (dd, 1 H, Py-5-H), 6.89 (t, 1 H, Py-4-H), 7.17–7.29 (m, 3 H, Ar-CH), 7.99 (dd, 1 H, Py-6-H), 8.34 (br. s, 1 H, NH) ppm. $^{13}$C NMR ($C_6D_6$, 298 K): $\delta$ = 23.98 [4 $CH_3$, $CH(CH_3)_2$], 28.67 [2 CH, $CH(CH_3)_2$], 105.62 (CH, Py-C-5), 112.94 (CH, Py-C-3), 124.22 (2 CH, Ar-C-9,11), 134.69 (CH, Py-C-4), 137.68 (2 CH, Ar-C-8,12), 148.45 (1 C, Ar-C-7), 148.57 (1 CH, Py-C-6), 160.51 (1 CH, Py-C-2) ppm.

**Synthesis of 4:** Compound **1** (0.380 g, 2 mmol, 425 μL) in hexane (5 mL) was added slowly to a stirred solution of $[Ta(CH_2C_6H_5)_5]$ (0.636 g, 1 mmol) in hexane (15 mL) at –33 °C. The mixture was warmed to room temperature and was further heated at 60 °C for 2 h as a color change was observed from brown to deep red. The mixture was filtered and the volume of the solvent was reduced in vacuo. The solution was cooled at –25 °C overnight to afford a yellow crystalline material. Yield 0.365 g (43%). $C_{39}H_{51}N_4Si_2Ta$ (812.97): calcd. C 57.62, H 6.32, N 6.89; found C 57.36, H 6.62, N 6.29. $^1$H NMR ($C_6D_6$, 298 K): $\delta$ = 0.40 [s, 18 H, $Si(CH_3)_3$], 1.61 (s, 6 H, $CH_3$), 2.96 (br. d, 6 H, $CH_2$), 5.76 (d, 2 H, Py-5-H), 5.88 (s, 2 H, Py-3-H), 6.74 (t, 3 H, Ar-4-H), 6.89–7.10 (m, 14 H, Py-6-H, Ar-2, 3, 5, 6 H) ppm. $^{13}$C NMR ($C_6D_6$, 298 K): $\delta$ = 2.45 (6 C, 6 $CH_3$), 21.6 (2 C, 2 $CH_3$), 99.40 (br. and flat s, 3 $CH_2$), 111.87 (2 CH, Py-C-3/5), 114.05 (2 CH, Py-C-3/5), 122.49 (3 CH, Benz-C-4), 126.83 (6 CH, Benz-C-3,5), 128.20 (6 CH, Benz-C-2,6), 141.51 (3 C, Benz-C-1), 151.53 (2 C, Py-C-4), 153.26 (2 CH, Py-C-6), 164.91 (2 C, Py-C-2) ppm.

**Synthesis of 5:** Compound **2** (0.463 g, 2.57 mmol, 546 μL) in hexane (5 mL) was added slowly to a stirred solution of $[Ta(CH_2C_6H_5)_5]$ (0.817 g, 1.28 mmol) in hexane (15 mL) at –33 °C. The mixture was warmed to room temperature and further heated at 60 °C for 2 h. The mixture was filtered and the volume of the solvent was reduced in vacuo. The solution was cooled at –25 °C overnight to afford a yellow crystalline material. Yield 0.460 g (44%). $C_{39}H_{51}N_4Si_2Ta$ (812.97): calcd. C 57.62, H 6.32, N 6.89; found C 56.73, H 6.24, N 6.54. $^1$H NMR ($C_6D_6$, 298 K): $\delta$ = 0.27 [s, 18 H, $Si(CH_3)_3$], 1.92 (s, 6 H, $CH_3$), 3.15–2.96 (2 d, 6 H, $CH_2$), 5.65 (d, 2 H, Py-5-H), 5.83 (d, 2 H, Py-3-H), 6.69 (dd, 6 H, Benz-2,6-H), 7.00 (t, 6 H, Benz-3,5-H), 7.44 (t, 2 H, Py-4-H) ppm. $^{13}$C NMR ($C_6D_6$, 298 K): $\delta$ = 2.57 (6 C, 6 $CH_3$), 21.56 (2 C, 2 $CH_3$), 100.34 (3 $CH_2$), 108.34 (2 CH, Py-C-3/5), 113.95 (2 CH, Py-C-3/5), 122.66 (3 CH, Benz-C-4), 126.67 (6 CH, Benz-C-3,5), 129.42 (6 CH, Benz-C-2,6), 138.32 (3 C, Benz-C-1), 151.97 (2 CH, Py-C-4), 153.17 (2 C, Py-C-6), 161.49 (2 C, Py-C-2) ppm.

**Synthesis of 6:** To a stirred solution of **3** (0.557 g, 2.14 mmol) in diethyl ether (10 mL), *n*BuLi (1.34 mL, 1.6 M, 2.14 mmol) was added at 0 °C. This "ligand solution" was warmed slowly to room temperature and stirred for 2 h. This solution was slowly added to $[TaCl_2(CH_2C_6H_5)_3]$ (0.562 g, 1.07 mmol) in hexane (10 mL) at room temperature. The mixture was stirred overnight and a color change from red to dark brown was observed. LiCl was filtered off

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and the volume of the solvent was reduced in vacuo. The solution was cooled at –25 °C overnight to afford an orange crystalline material. Yield 0.564 g (55%). $C_{55}H_{63}N_4Ta$ (961.06): calcd. C 68.74, H 6.61, N 5.83; found C 67.44, H 6.64, N 5.51. $^1$H NMR ($C_6D_6$, 298 K): $\delta$ = 1.15–1.27 [dd, 24 H, 2 $CH(CH_3)_2$], 2.79 (s, 2 H, $CH_2$), 3.60 (s, 4 H, 2 $CH_2$), 3.85 [sept, 4 H, 4 $CH(CH_3)_2$], 5.52 (d, 2 H, Py-3-H), 5.81 (t, 2 H, Py-5-H), 6.22 (d, 4 H, Ar-H), 6.27 (d, 2 H, Py-4-H), 6.62 (dd, 2 H, Py-6-H), 6.78–6.67 (m, 5 H, Ar-H), 6.94–6.86 (m, 6 H, Ar-H), 7.19–7.16 (m, 6 H, Ar-CH) ppm. $^{13}$C NMR ($C_6D_6$, 298 K): $\delta$ = 23.22 [8 $CH_3$, $CH(CH_3)_2$], 26.28 [2 CH, $CH(CH_3)_2$], 28.80 [2 CH, $CH(CH_3)_2$], 83.50 (3 C, $CH_2$), 106.53 (2 CH, Py-C-3/5), 112.39 (2 CH, Py-C-3/5), 123.18 (4 CH, Ar-C-9,11), 125.31 (6 CH, Benz-C-3,5), 126.57 (6 CH, Benz-C-2,6), 127.09 (3 CH, Benz-C-4), 129.96 (4 CH, Ar-C-8,12), 139.55 (2 CH, Ar-C-10), 141.87 (2 CH, Py-C-4), 143.08 (2 C, Ar-C-7), 146.36 (3 C, Benz-C-1), 148.46 (2 CH, Py-C-6), 169.21 (2 CH, Py-C-2) ppm.

**Synthesis of 7. Method I:** $TaCl_5$ (1.432 g, 4 mmol) and **3** (2.035 g, 8 mmol) were heated at 110 °C. The melt started to turn dark brown immediately. During the reaction gas formation was observed. After 1 h, toluene (30 mL) was added and the dark-red reaction mixture was further refluxed for 2 h. The solution was filtered while hot and the volume was reduced until red crystals began to appear. The solution was cooled and a red crystalline material was obtained overnight. Yield 1.103 g (35%). $C_{34}H_{42}Cl_3N_4Ta$ + 0.5 $C_7H_8$ (840.10): calcd. C 53.61, H 5.51, N 6.67; found C 53.67, H5.54, N 6.08. $^1$H NMR ($C_6D_6$, 298 K): $\delta$ = 1.13–1.48 [dd, 24 H, $CH(CH_3)_2$], 2.10 (s, 3 H, toluene) 3.86 [sept, 4 H, $CH(CH_3)_2$], 5.74 (d, 2 H, Py-3-H), 6.05 (t, 2 H, Py-5-H), 6.83 (t, 2 H, Py-4-H), 7.28–7.16 (m, 6 H, Ar-H), 8.06 (d, 2 H, Py-6-H) ppm. $^{13}$C NMR ($C_6D_6$, 298 K): $\delta$ = 24.73 [4 $CH_3$, $CH(CH_3)_2$], 24.95 [4 $CH_3$, $CH(CH_3)_2$], 28.22 [4 CH, $CH(CH_3)_2$], 107.56 (2 CH, Py-C-3/5), 113.50 (2 CH, Py-C-3/5), 124.46 (4 CH, Ar-C-9,11), 140.19 (2 CH, Ar-C-10), 140.66 (CH, Py-C-4), 141.15 (2 C, Ar-C-7), 147.37 (4 C, 2 CH, Ar-C-8,12, Py-C-6), 169.86 (2 C, Py-C-2) ppm. **Method II:** Lithiated **3** (1.041 g, 4 mmol) in diethyl ether (20 mL) was added to $TaCl_5$ (0.716 g, 2 mmol) in toluene (5 mL) at room temperature and the reaction mixture was stirred at room temperature overnight. The solution was filtered and the solvent was removed in vacuo. The red residue was washed with hexane (5 mL) and dried under vacuum. Yield 0.92 g (58%).

**Synthesis of 8:** LiMe (1.88 mL, 1.6 M, 3 mmol) was added to a stirred suspension of **7** (0.794 g, 1 mmol) in hexane (20 mL) at –40 °C. The red suspension was warmed to room temperature as the color started changing from red to yellow. The suspension was further stirred for 2 h. The brown solution was filtered and the residue washed with diethyl ether (5 mL). The volume was reduced in vacuo and the solution was cooled at –25 °C overnight to afford a yellow crystalline material. Yield 0.432 g (59%). $C_{37}H_{51}N_4Ta$ (732.78): calcd. C 60.65, H 7.02, N 7.65; found C 60.37, H 7.04, N 7.50. $^1$H NMR ($C_6D_6$, 298 K): $\delta$ = 0.63 (s, 3 H, $CH_3$), 1.13 [d, 12 H, $CH(CH_3)_2$], 1.26 (s, 6 H, 2 $CH_3$),1.34 [d, 12 H, $CH(CH_3)_2$], 3.61 [sept, 4 H, $CH(CH_3)_2$], 5.54 (d, 2 H, Py-3-H), 6.18 (dd, 2 H, Py-5-H), 6.86 (t, 2 H, Py-4-H), 7.24–7.17 (m, 6 H, Ar-8,9,10-H) ppm.$^{13}$C NMR ($C_6D_6$, 298 K): $\delta$ = 24.10 [4 $CH_3$, $CH(CH_3)_2$], 24.18 [4 $CH_3$, $CH(CH_3)_2$], 25.10 (3 $CH_3$), 27.75 [2 CH, $CH(CH_3)_2$], 27.93 [2 CH, $CH(CH_3)_2$], 105.67 (2 CH, Py-C-3/5), 113.36 (1 CH, Py-C-3/5), 113.56 (1 CH, Py-C-5), 124.45 (4 CH, Ar-C-9,11), 127.09 (1 CH, Ar-C-10), 127.14 (1 CH, Ar-C-10), 138.91 (1 CH, Py-C-4), 139.11 (1 CH, Py-C-4), 141.32 (4 CH, Ar-C-8,12), 146.09 (4 CH, Py-C-6, 2 C, Ar-C-7), 168.32 (1 C, Py-C-2) ppm.

**General Description of Polymerization Experiments:** The catalytic ethylene polymerization reactions were performed in a stainless steel 1-L autoclave (Medimex) in semi-batch mode (ethylene was added by replenishing flow to keep the pressure constant). The reactor was temperature- and pressure-controlled and equipped with separated toluene, catalyst, and cocatalyst injection systems and a sample outlet for continuous reaction monitoring. At 5 bar of ethylene pressure multiple injection of the catalyst with a pneumatically operated catalyst-injection system was used. During a polymerization run the pressure, ethylene flow, inner and outer reactor temperature, and the stirrer speed were monitored continuously. In a typical semi-batch experiment, the autoclave was evacuated and heated at 125 °C for 1 h prior to use. The reactor was then brought to the desired temperature with stirring at 600 rpm and charged with 230 mL of toluene together with either the required amount of PMAO [2.76 g, Ta/Al = 1:500 (m/m)] or TIBAO scavenger [1 mL of a 0.1 M stock solution in toluene, Ta/Al = 1:20 (m/m)]. After pressurizing with ethylene to reach 5 bar total pressure the autoclave was equilibrated for 5 min. Subsequently 1 mL of a 0.01 M stock solution of the tantalum complex in toluene was injected together with 30 mL of toluene, to start the reaction. In the case where trialkylammonium tetrakis(pentafluorophenyl)borate was the activator, 1 mL of the tantalum complex stock solution and the appropriate amount of borate [0.12 g, Ta/B = 1:1.1 (m/m)] were premixed before injection. During the run the ethylene pressure was kept constant to within 0.2 bar of the initial pressure by replenishing flow. After the desired reaction time, the reactor was vented and the residual PMAO/TIBAO was destroyed by addition of 20 mL of ethanol. Polymeric product was collected, stirred in acidified ethanol for 30 min, and rinsed with ethanol and acetone on a glass frit. The polymer was initially dried in air and subsequently in vacuo at 80 °C.

# Oxovanadium(IV) Complexes with Pyrazinecarboxylic Acids: The Coordinating Properties of Ligands with the ($N_{aromatic}$, $COO^-$) Donor Set

**Eugenio Garribba,*[a] Giovanni Micera,*[a] Elzbieta Lodyga-Chruscinska,[b] and Daniele Sanna[c]**

**Keywords:** Vanadium / N,O ligands / Isomers / Magnetic properties / EPR spectroscopy

Complex formation between the $V^{IV}O$ ion and four pyrazine derivatives, 2-pyrazinecarboxylic acid (pzc), 5-methyl-2-pyrazinecarboxylic acid (5-Mepzc), 2,3-pyrazinedicarboxylic acid (3-COOHpzc) and 5-hydroxy-2-pyrazinecarboxylic acid (5-OHpzc), was studied in aqueous solution and in the solid state through the combined application of potentiometric and spectroscopic (EPR and FT-IR) techniques. The results indicate that in acidic and neutral aqueous solution all the ligands form mono(chelated), bis(chelated) and dinuclear species of composition VOL, $VOL_2$ and $(VO)_2L_2H_{-2}$. Hexacoordinated $VOL_2$ complexes are characterised by a *cis*/*trans* isomerism, where *cis* and *trans* are the species with a water molecule bound in the *cis* or *trans* position with respect to the V=O group. The *trans* arrangement is favoured over the *cis* arrangement. Three solid derivatives, $[VO(5\text{-}Mepzc)_2]$ (**1**), *cis*-$[VO(pzc)_2(H_2O)]$ (**2**) and *cis*-$[VO(3\text{-}COOHpzc)_2(H_2O)]$ (**3**), were isolated and characterised. Based on the experimental results and on the data in the literature, the stability of *cis* and *trans* isomers in aqueous solution and in the solid state has been discussed, showing that with ligands of comparable basicity and size of the chelate ring the hydrophilicity favours the *cis* species and determines the relative amount of the two isomers. The analysis of the magnetic properties of the hydroxo-bridged $V^{IV}O$ dimers suggests that for the $(VO)_2L_2H_{-2}$ species the *anti*-coplanar arrangement is realised.

## Introduction

Vanadium plays a number of roles in biological systems.[1] Among others, a growing interest is devoted to the insulin-mimetic activity of its compounds.[2] Initially, both $V^V$ and $V^{IV}$ inorganic salts were extensively used as insulin mimics, but the introduction of $V^{IV}$ complexes has considerably improved their pharmacological potential by minimising the dose required for effective diabetic control.[2b]

The insulin-mimetic properties of complexes with coordination modes $VO(O_4)$,[3,4] $VO(N_2S_2)$,[3,5] $VO(S_4)$,[6] $VO(S_2O_2)$,[7] $VO(N_4)$[8] and $VO(N_2O_2)$[9,10] have been examined. Generally, N,O ligation is more efficient than O,O or O/N,S coordination, irrespective of the vanadium oxidation state.[11]

$V^{IV}O$ compounds with $N_2O_2$ coordination are very promising in the treatment of insulin-dependent diabetes mellitus.[12] In particular, $V^{IV}O(picolinato)_2(H_2O)$ and $V^{IV}O(6\text{-methylpicolinato})_2$ are strong inhibitors of the mobilisation of fatty acids and effective in the treatment of rats affected by diabetes induced with streptozotocin (STZ).[9,10] In addition, the complex formed by 6-methylpicolinate, with long-acting character and low toxicity, is the most effective in the treatment of insulin-dependent diabetes mellitus (IDDM) as well as non-insulin-dependent diabetes mellitus (NIDDM) when administrated orally.[13]

In the last few years several studies have been devoted to the complexation of the $V^{IV}O$ ion by bidentate ligands provided with an aromatic nitrogen atom and a carboxylate oxygen atom as donors.[14] Usually, VOL and $VOL_2$ species are formed in aqueous solution, with the possibility of *cis*/*trans* isomerism for the hexacoordinate bis(complexes) (Scheme 1).[15] The presence of di-μ-hydroxo EPR-silent species of composition $(VO)_2L_2H_{-2}$ has been proposed in some systems.[14b,14c,14e]

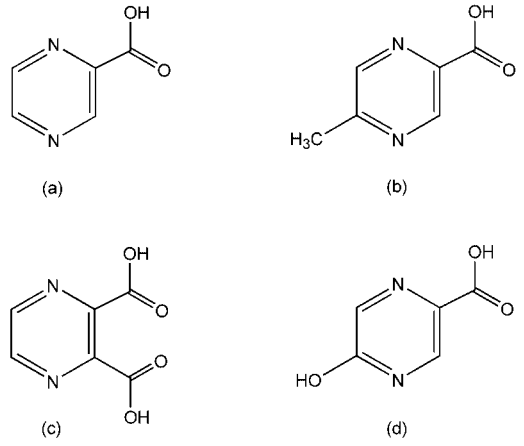
In this work we investigated the $V^{IV}O$ complex formation with four pyrazine derivatives: 2-pyrazinecarboxylic (pzc), 5-methyl-2-pyrazinecarboxylic (5-Mepzc), 2,3-pyrazinedicarboxylic (3-COOHpzc) and 5-hydroxy-2-pyrazinecarboxylic (5-OHpzc) acids (Scheme 2). Only one potentiometric study, although not supported by spectroscopic measurements, is available on the interaction of the $V^{IV}O$ ion with 2-pyrazinecarboxylic and 2,3-pyrazinedicarboxylic acids in aqueous solution.[16] To the best of our knowledge, no data on the formation of solid complexes have been reported. Here, the behaviour in aqueous solution and in the solid state of the four ligands is presented together with a discussion of the coordinating properties of ligands provided with the ($N_{aromatic}$, $COO^-$) donor set.



Scheme 2. Ligands: (a) 2-pyrazinecarboxylic acid (pzc), (b) 5-methyl-2-pyrazinecarboxylic acid (5-Mepzc), (c) 2,3-pyrazinedicarboxylic acid (3-COOHpzc) and (d) 5-hydroxy-2-pyrazinecarboxylic acid (5-OHpzc).

## Results

### Studies in Aqueous Solution

Fully protonated forms of 2-pyrazinecarboxylic and 5-methyl-2-pyrazinecarboxylic acids in aqueous solution can be denoted as $H_3L^{2+}$ and those of 2,3-pyrazinedicarboxylic and 5-hydroxy-2-pyrazinecarboxylic acids as $H_4L^{2+}$.

Two deprotonation processes are measurable for pzc, 5-Mepzc and 3-COOHpzc in the titrable pH range with p$K_a$ values of 1.83 and 2.73 for pzc, 2.06 and 3.13 for 5-Mepzc, and 1.50 and 3.25 for 3-COOHpzc (Table 1). The two processes can be assigned to the pyrazine $–NH^+$ and the –COOH groups, respectively. The values measured for pzc and 3-COOHpzc are in very good agreement with those previously reported.[16] Owing to its very high acidity, the deprotonation of the first $–NH^+$ group is not detectable. A comparison with 2-pyridinecarboxylic acid, for which p$K_a$ values of about 1 and 5.19 are reported,[14b] indicates that the presence of a second nitrogen atom in the aromatic ring significantly reduces the basicity of the $–NH^+$ group. On the other hand, the carboxylic group slightly increases the basicity of the second $–NH^+$ group with respect to pyrazine, for which a p$K_a$ of 0.65 is reported.[17] The increase in basicity is due to the formation of a cyclic structure, which stabilises the $–NH^+$ form through an internal hydrogen bond between the protonated pyrazine nitrogen atom and the –COOH group. The value for the deprotonation of the carboxylic group of pzc is comparable with that measured by Toma and Borges (2.82).[18] The electron-releasing effect of the methyl group reduces the acidity of both the $–NH^+$ and –COOH groups in 5-Mepzc (Table 1).

Table 1. Protonation constants of the ligands (log $K$) and stability constants of the $V^{IV}O$ complexes (log $\beta_{pqr}$) at 25.0 ± 0.1 °C and $I$ = 0.1 M ($KNO_3$).

| log $K$/log $\beta_{pqr}$ | pzc | 5-Mepzc | 3-COOHpzc | 5-OHpzc |
|---|---|---|---|---|
| $–N1_{pyr}H^+$ | <1 | <1 | <1 | <1 |
| $–N2_{pyr}H^+$ | 1.83 | 2.06 | 1.50 | <1 |
| –COOH1 | 2.73 | 3.13 | 3.25 | 3.44 |
| –COOH2 | – | – | <1 | – |
| –OH | – | – | – | 7.78 |
| VOL | 3.42(2) | 3.49(2) | 3.99(2) | 7.01(2) |
| $VOL_2$ | 6.09(2) | 6.99(2) | 7.02(3) | 12.97(2) |
| $(VO)_2L_2H_{-2}$ | 0.11(3) | 0.58(2) | 1.79(3) | 5.85(3) |

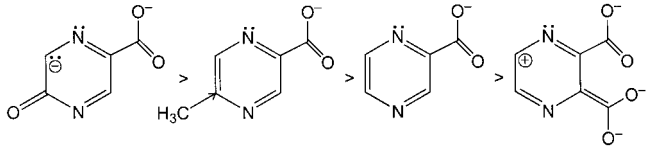
Only two deprotonation steps, of the four possible ones, can be determined for 2,3-pyrazinedicarboxylic acid. Owing to the strong internal hydrogen bond between COOH and $COO^-$, one of the two carboxylic groups is protonated only at pH < 1. This effect had already been observed for 2,3-pyridinedicarboxylic[19] and 4,5-imidazoledicarboxylic acids.[14a] For the same reason, the deprotonation of the second –COOH group takes place at higher pH values with respect to pzc and 5-Mepzc. Moreover, the electron-withdrawing properties of the carboxylic group increase the acidity of the pyrazine nitrogen atom in comparison with pzc and 5-Mepzc.

The carboxylic group of 5-OHpzc is more basic than in other ligands for the presence of an –OH group in the *para* position according to the Hammett equation;[20] p$K_a$ values of 0.1 and 8.23 are reported for the $–NH^+$ and –OH groups in 2-hydroxypyrazine,[17] and of 6.85 for the –OH group in 2-hydroxy-5-nitropyridine.[21] The presence of –COOH, more efficient in the electron-withdrawing effect than –H and less than $–NO_2$, explains the value of 7.78 measured for 5-OHpzc, intermediate between the other two p$K_a$ values.

According to the potentiometric results, all the ligands form VOL, $VOL_2$ and $(VO)_2L_2H_{-2}$ species, in which five-membered chelate rings are formed by the ($N_{pyr}$, $COO^-$) donor set. The formation constants of the complexes are listed in Table 1 and the order of stability is 5-OHpzc >> 5-Mepzc > pzc ≈ 3-COOHpzc. For example, the higher stability of the bis(chelated) species formed by 5-OHpzc is reflected by the values of the stability constant for the reaction VOL + HL → $VOL_2$ + $H^+$ (2.52 for 5-OHpzc, 0.37 for 5-Mepzc, –0.06 for pzc and –0.22 for 3-COOHpzc). The amount of $(VO)_2L_2H_{-2}$ dimers increases in solution with decreasing stability of VOL and $VOL_2$ species; in equimolar solutions at pH = 6 with a $V^{IV}O$ concentration of $5 \times 10^{-2}$ M, it is 88.5% with 3-COOHpzc, 65.9% with pzc, 63.4% with 5-Mepzc and 38.2% with 5-OHpzc. The

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

strength of the ligands can be explained by the effect of the substituents on the aromatic ring of their fully deprotonated forms, displayed in Scheme 3: $-O^-$ is the most effective electron-releasing group, followed by $-CH_3$, whereas –COOH is an electron-withdrawing group. To reduce the hydrolytic processes, the EPR spectra were recorded with a ligand/metal molar ratio of 2 with 5-OHpzc, 5 with 5-Mepzc and 10 with pzc and 3-COOHpzc.



Scheme 3. Resonance forms of the fully deprotonated ligands.

The distribution curves of the species as a function of pH, calculated from the stability constants reported in Table 1, for the weaker (3-COOHpzc) and the stronger ligand (5-OHpzc) are shown in Figures 1 and 2, respectively.

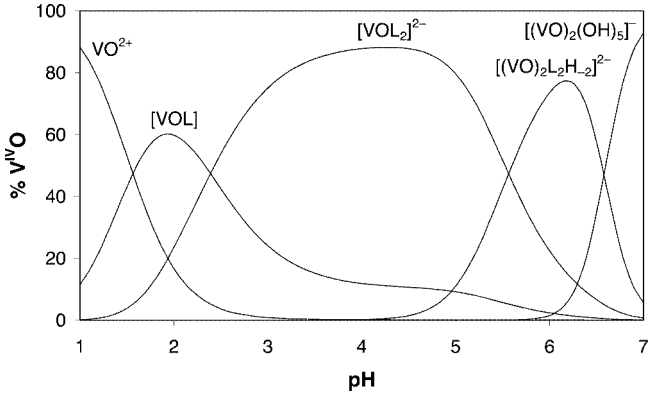


Figure 1. Species distribution for the $V^{IV}O$/3-COOHpzc system with a metal/ligand molar ratio of 1:10 and a $V^{IV}O$ concentration of 1 mM.

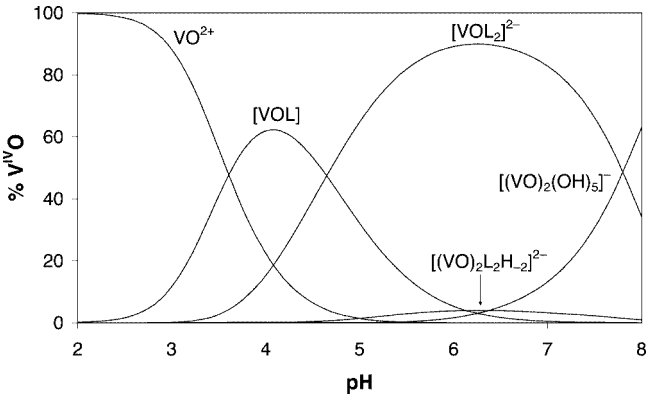

Figure 2. Species distribution for the $V^{IV}O$/5-OHpzc system with a metal/ligand molar ratio of 1:3 and a $V^{IV}O$ concentration of 1 mM.

The $g_\parallel$ and $A_\parallel$ values (Table 2) of the mono(chelated) complexes VOL (**I** in Figure 3) are consistent with the donor set ($N_{pyr}$, $COO^-$).[14b] By applying the additivity rule of Chasteen,[22] corrected for carboxylate by Kiss and Costa Pessoa,[23] a value of about $174 \times 10^{-4}$ $cm^{-1}$ is predicted for $A_\parallel$.

In the range of existence of the bis(chelated) complexes, the EPR spectra show two partly overlapped resonances, indicating the presence of the *cis* and *trans* isomers (**II** and **III** in Figure 3). The $A_\parallel$ value of the *trans* species (Table 2) is similar to that measured with 4-imidazoleacetic acid[14a] and corresponds to an [($N_{pyr}$, $COO^-$); ($N_{pyr}$, $COO^-$); $H_2O^{ax}$] set, with a water molecule weakly coordinated in the axial position (see Scheme 1a).

Two different arrangements of the two ligand molecules are possible for the *cis* species (Scheme 1b and c): one with two aromatic nitrogen atoms and one carboxylate oxygen atom, and another with one aromatic nitrogen atom and two carboxylate oxygen atoms in the equatorial plane of the vanadyl ion. The additivity rule assigns to an aromatic nitrogen atom a lower contribution to the parallel hyperfine coupling constant ($40.7 \times 10^{-4}$ $cm^{-1}$)[22] in comparison with

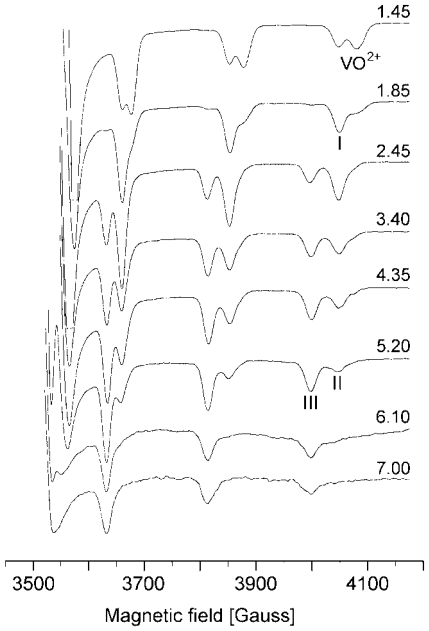

Figure 3. High-field region of the X-band anisotropic EPR spectra recorded at 140 K as a function of pH on an aqueous solution of $V^{IV}O$ and 5-Mepzc with a metal/ligand molar ratio of 1:5 and a $V^{IV}O$ concentration of 4 mM. **I**, **II** and **III** denote VOL, *cis*-$VOL_2$ and *trans*-$VOL_2$ complexes.

a carboxylate oxygen atom ($42.1\times10^{-4}$ $cm^{-1}$).[23] Therefore, a lower value of $A_{\parallel}$ is expected for the set [($N_{pyr}$, $COO^{-}$); ($N_{pyr}$, $COO^{-ax}$); $H_2O$] than for [$N_{pyr}$, $COO^{-}$); ($N_{pyr}^{ax}$, $COO^{-}$); $H_2O$]. The experimental data are in agreement with the first possibility. This is in agreement with the structures in the solid state formed by 5-methoxycarbonylpicolinic acid (5MeOpicH), *cis*-[$V^{IV}O(5MeOpic)_2(H_2O)$],[14e] and by 4,5-dicarboxy-1-methylimidazole ($H_2MDCI$), *cis*-[$V^{IV}O(HMDCI)_2(H_2O)$].[24] They have two aromatic nitrogen atoms in the equatorial plane and $A_{\parallel}$ values of 168 and $171\times10^{-4}$ $cm^{-1}$, comparable with those measured in this study for the *cis* isomers.

As an example, the anisotropic EPR spectra of the system with 5-Mepzc as a function of pH are presented in Figure 3.

At pH ≈ 7, the potentiometric titrations show a deprotonation process. The fitting of the data is improved considerably by the insertion of a $(VO)_2L_2H_{-2}$ species into the model. This suggests that the hydrolytic processes transform $VOL_2$ complexes into the di-μ-hydroxo $(VO)_2L_2H_{-2}$ dimers, according to the principle established by Felcman and Fraústo da Silva.[25] Differently from the usual behaviour of the $V^{IV}O$ systems, a ferromagnetic interaction between the two $S = 1/2$ ions is observed with a distinctive EPR signal superimposed to the resonances of $VOL_2$. A forbidden signal at half field (ca. 1650 G) in the $\Delta M = \pm2$ region is also detected (see Discussion). The spectra recorded on an equimolar solution of $V^{IV}O$ and pzc, in both the $\Delta M = \pm1$ and $\Delta M = \pm2$ regions, are shown in Figures 4 and 5.

The possible configurations of a $[VO(\mu\text{-}OH)_2VO]^{2+}$ core in complexes consisting of two edge-sharing octahedrally coordinated $V^{IV}O$ ions are classified according to the orien-

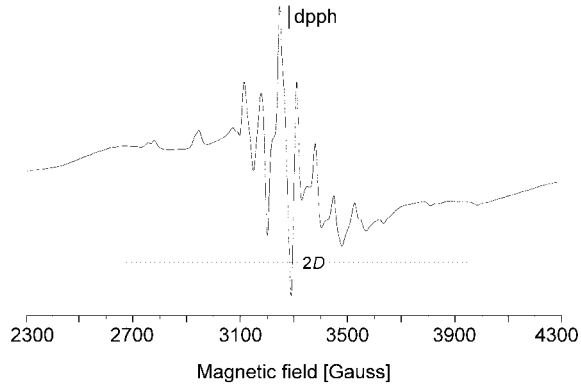

Figure 4. $\Delta M = \pm1$ region of the X-band anisotropic EPR spectrum recorded at 140 K and pH = 5.65 on an equimolar aqueous solution of $V^{IV}O$ and pzc with a concentration of $5\times10^{-2}$ M.

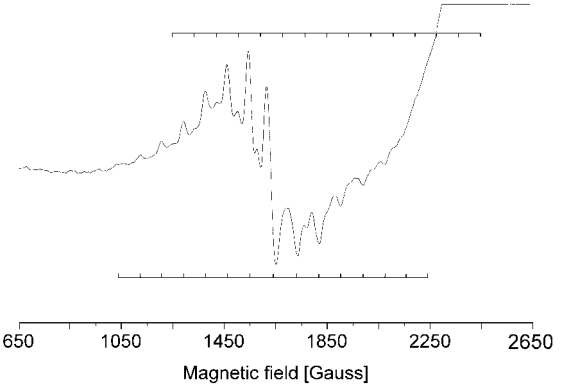

Figure 5. $\Delta M = \pm2$ region of the X-band anisotropic EPR spectrum recorded at 140 K and pH = 5.65 on an equimolar aqueous solution of $V^{IV}O$ and pzc with a concentration of $5\times10^{-2}$ M.

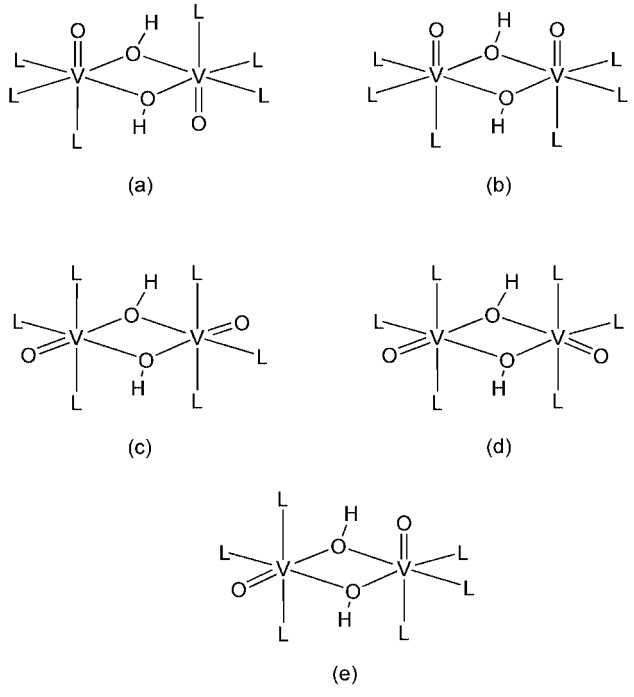

Scheme 4. Possible arrangements of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ core: (a) *anti*-orthogonal, (b) *syn*-orthogonal, (c) *anti*-coplanar, (d) *syn*-coplanar, and (e) twisted.

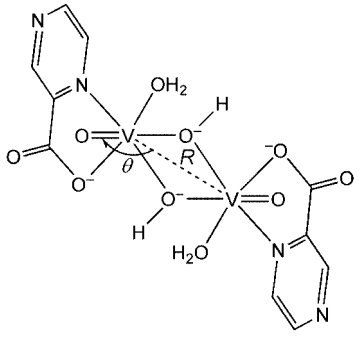
tation of the V=O group with respect to the plane defined by the two vanadium atoms and the two bridging oxygen atoms (orthogonal, coplanar and twisted) and the orientation of the two V=O bonds (*syn* or *anti*) (Scheme 4).[26]

The magnitude of the coupling constant in the $\Delta M = \pm 2$ region is nearly half of that expected for $A_{\parallel}$ in the monomeric species with the same equatorial donors. Values of about $84 \times 10^{-4}$ cm$^{-1}$ for the set [($N_{pyr}$, $COO^-$); $H_2O$; $OH^-$] (*anti*-coplanar arrangement) and of about $80 \times 10^{-4}$ cm$^{-1}$ for [($N_{pyr}$, $COO^-$); $OH^-$; $OH^-$] (*anti*- or *syn*-orthogonal arrangement) are expected. The experimental values, in the range $85–86 \times 10^{-4}$ cm$^{-1}$ (Table 2), are consistent with the structure depicted in Scheme 5, where two $OH^-$ ions bridge two metal ions in one equatorial and one axial position, with the remaining three equatorial sites occupied by the ($N_{pyr}$, $COO^-$) set and a $H_2O$ molecule in an *anti*-coplanar arrangement.



Scheme 5. Structure of the dimeric complex $(VO)_2L_2H_{-2}$ formed by pzc. *R* is the distance between the two $V^{IV}O$ ions and $\theta$ the angle formed by the V=O and V–V directions.

## Studies on the Solid Compounds

The solid compounds **1**, **2** and **3** were characterised by thermogravimetric, elemental, FT-IR and EPR analyses. Attempts to obtain solid compounds with reproducible stoichiometry with 5-OHpzc were unsuccessful.

Thermogravimetric and elemental analyses indicate a [$VOL_2$] composition for 5-Mepzc, and a [$VOL_2(H_2O)$] stoichiometry for pzc and 3-COOHpzc. The presence of a water molecule strongly bound to the metal ion in **2** and **3** is supported by the decomposition step at $> 150$ °C to yield the five-coordinate species [$VO(pzc)_2$] and [$VO(3\text{-}COOHpzc)_2$]. This temperature value is typical of vanadyl complexes containing equatorially coordinated water.[14e] On the contrary, the thermogravimetric analysis of **1** indicates the absence of water and the decomposition of the complex starts above 300 °C.

IR spectroscopy shows the presence of water in **2** and **3** and its absence in **1**. The V=O stretching frequency is normal for $V^{IV}O$ complexes. The separation between the asymmetrical ($\nu_{as}$) and symmetrical ($\nu_s$) stretching vibrations of the carboxylate group, $\Delta(\nu_{as} - \nu_s)$, for complexes **1**, **2** and **3**, in the range 212–243 cm$^{-1}$, suggests a monodentate coordination to the $V^{IV}O$ ion and allows a bridging behaviour to be ruled out.[27] In compound **3** the band at 1729 cm$^{-1}$ indicates that the carboxylic group in position 3 of the aromatic ring is protonated (Table 3).

The solid compounds **1**–**3** were dissolved in an anhydrous weakly coordinating solvent ($CH_3OH$) or in a mixture of non-coordinating solvent ($CHCl_3$/toluene, 60:40, v:v) in order to study the geometry and the coordination mode of the ligands through EPR spectroscopy (Figure 6). Anisotropic spectra exhibit an axial symmetry with two *g* and two *A* values (Table 4). No traces of mono(chelated) or dimeric complexes are observed.

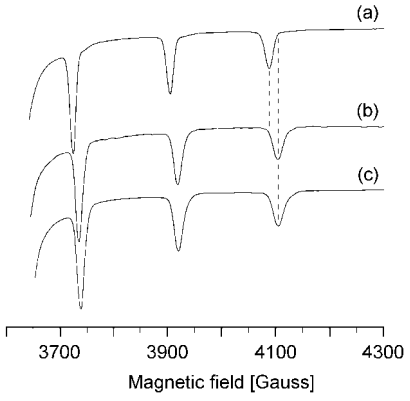


Figure 6. High-field region of the X-band anisotropic EPR spectra recorded at 140 K in $CH_3OH$. (a) [$VO(5\text{-}Mepzc)_2$] (**1**); (b) *cis*-[$VO(pzc)_2(H_2O)$] (**2**); and (c) *cis*-[$VO(3\text{-}COOHpzc)_2(H_2O)$] (**3**).

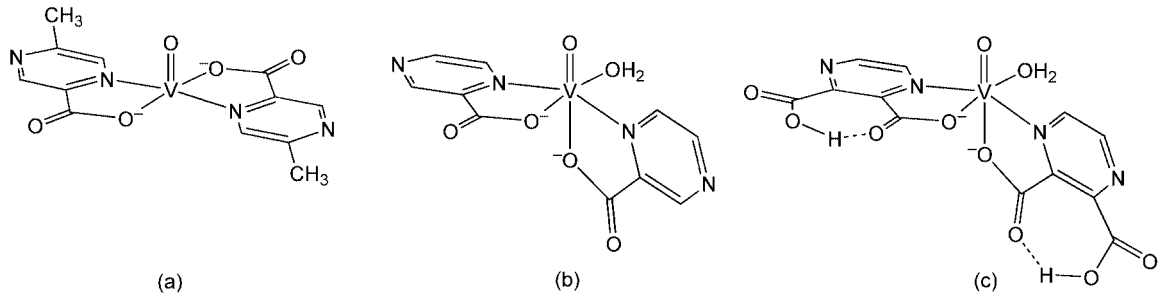

Scheme 6. Structure of the solid complexes **1** (a), **2** (b) and **3** (c).

The $A_{\parallel}$ value measured for the methyl derivative **1** is $163 \times 10^{-4}$ cm$^{-1}$, indicative of an equatorial [($N_{pyr}$, $COO^-$); ($N_{pyr}$, $COO^-$)] coordination mode. The value is comparable with those reported for [$V^{IV}O$(8-quinolinecarboxylato)$_2$] in a $CH_2Cl_2$/toluene mixture ($161 \times 10^{-4}$ cm$^{-1}$)[14d] and for $V^{IV}O$-doped [$Ti^{IV}O$(8-quinolinecarboxylato)$_2$] ($161 \times 10^{-4}$ cm$^{-1}$).[14d] For the analogous complex formed by 2-pyridylacetate a value of $162 \times 10^{-4}$ cm$^{-1}$ was measured.[28] The coincidence of $A_x$ and $A_y$ values allows a distortion of the pentacoordinate square-pyramidal structure towards the trigonal bipyramid to be ruled out.[29]

The spectra of **2** and **3** are characterised by a larger hyperfine coupling constant ($168 \times 10^{-4}$ cm$^{-1}$) than for **1** (Table 4), because of the presence of weaker donors in the equatorial plane of the vanadyl ion. This clearly indicates that water replaces one of the two equatorially bound carboxylate ions, increasing the value of $A_{\parallel}$ by about $4 \times 10^{-4}$ cm$^{-1}$,[22,30] and that one ligand molecule switches its coordination mode from an (equatorial–equatorial) to an (equatorial–axial) arrangement. In the absence of single-crystal X-ray determinations, the three structures shown in Scheme 6 can be proposed.

The carboxylic group in position 3 of the pyrazine aromatic ring in **3** is protonated, similarly to the results obtained with the bis(chelated) complexes of $Co^{II}$[31] and $Ni^{II}$.[32,33] The structure is stabilised by an intramolecular hydrogen bond between the protonated carboxylic group and the coordinating deprotonated carboxylate ion in position 2 of the aromatic ring (Scheme 6). An analogous hydrogen bond is exhibited by *cis*-[$V^{IV}O$(HMDCI)$_2$($H_2O$)],[24] formed by 4,5-dicarboxy-1-methylimidazole ($H_2$MDCI) similar to 3-COOHpzc. A further stabilisation of **2** and **3** could be provided by a network of intermolecular hydrogen bonds between the coordinated water molecules, as happens with the $Co^{II}$ ion.[31]

## Discussion

### Stability of the *cis* and *trans* Isomers of Bis(chelated) $V^{IV}O$ Complexes

Few $V^{IV}O$ compounds with ($N_{aromatic}$, $COO^-$) coordination are known compared to those with ($N_{imino}$, $O^-$) coordination. A search in the Cambridge Structural Database[34] for monomeric vanadyl complexes formed by bidentate ligands with N,O donors yields 22 structures; among them, 18 do not exhibit water molecules coordinated to the $V^{IV}O$ ion and show a square-pyramidal geometry. Six-membered chelate rings characterise all the structures except [$V^{IV}O$(2-methyl-5-methylthio-8-hydroxyquinolato)$_2$],[35] [$V^{IV}O${2-[(–)-(1*S*,2*S*,5*R*)-menthylpyridine}$_2$][36] and [$V^{IV}O$(2-methyl-8-quinolinolato)$_2$].[37]

Rather surprisingly, the only four structures with the ($N_{aromatic}$, $COO^-$) donor set exhibit a water molecule bound to the $V^{IV}O$ ion. Two are characterised by a *cis* arrangement of the $H_2O$ molecule with respect to the V=O bond: *cis*-[$V^{IV}O$(5-methoxycarbonylpicolinato)$_2$($H_2O$)][14e] and *cis*-[$V^{IV}O$(1-methyl-4,5-dicarboxyimidazolato)$_2$($H_2O$)].[24] In the other two, *trans*-[$V^{IV}O$(6-ethylpicolinato)$_2$($H_2O$)][38] and *trans*-[$V^{IV}O$(2-quinolinecarboxylato)$_2$($H_2O$)],[39] $H_2O$ is *trans* to the V=O bond. This indicates that the ($N_{aromatic}$, $COO^-$) set favours the binding of water, probably for the high polarity of the carboxylate group, which makes the solvation of the complexes easier. In addition, other binary structures with the ($N_{aromatic}$, $COO^-$) donor set have been fully characterised in the solid state without single-crystal X-ray determination.[9,10,14c,14d,40–42]

Finally, three mixed complexes, in which one of the two bidentate donor sets is ($N_{aromatic}$, $COO^-$), have been described. One of them is *cis*-[VO(Hhpic-O,O)(Hhpic-O,N)($H_2O$)], with $H_2$hpic = 3-hydroxy-2-pyridinecarboxylic acid,[43] where one of the two $Hhpic^-$ anions coordinates the vanadyl ion through the phenolate and carboxylate groups in the equatorial plane and the other one through the carboxylate group in *trans* position and the pyridine nitrogen atom in *cis* position with respect to the V=O bond, whereas the remaining equatorial site is occupied by a water molecule. The other two complexes are [$V^{IV}O$(dipic)(HDMCI)]$^-$ and *cis*-[$V^{IV}O$(acac)(HDMCI)($H_2O$)], with $H_2$dipic = 2,6-pyridinedicarboxylic acid and Hacac = 2,4-pentanedione.[24] These last three examples highlight the preference of the ($N_{aromatic}$, $COO^-$) donor set to assume an orientation *cis* with respect to the V=O bond, with the aromatic nitrogen atom in the equatorial plane and the carboxylate oxygen atom in the axial position.

It is worth noting that the *cis* complexes are formed with more hydrophilic ligands (5-methoxycarbonylpicolinate,[14e] 4,5-dicarboxy-1-methylimidazolate,[24] picolinate,[9,14b,40] 3-hydroxy-2-pyridinecarboxylate[43]), whereas the *trans* structures are favoured by more hydrophobic ligands (6-methylpicolinate,[10,14c,41] 8-hydroxy-2-methylquinoline,[37] 6-ethylpicolinate[38]) and six-membered chelate rings (8-quinoline-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

carboxylate,[14d] 2-pyridylacetate[28]). The results are confirmed by this study: the hydrophobic 5-methyl derivative forms the anhydrous pentacoordinate complex **1**, whereas the more hydrophilic pzc and 3-COOHpzc ligands form the *cis* complexes **2** and **3** with a water molecule coordinated in the equatorial plane of the $V^{IV}O$ ion.

The preference of a ligand for the *trans* or *cis* arrangement is not easily predictable. For instance, picolinate forms only the *cis* complex,[14b] 6-methylpicolinate the *trans* and *cis* isomers in comparable amounts,[14c] and 2-pyridylacetate only the *trans* species.[28] Generally, stronger ligands and six-membered chelate rings favour the *trans* isomer, as demonstrated by the comparison of carboxylates, pyrones and catechols,[44,45] and of oxalate and malonate[44] or picolinate[14b] and 2-pyridylacetate.[28]

For the four systems considered in this work, the amount of the *cis* isomer (**I** in Figure 7) increases in the order: 5-Mepzc < pzc < 5-OHpzc < 3-COOHpzc. With ligands yielding the same size and steric hindrance of the chelate ring, the order of stability does not follow the basicity of the donors, but the relative amount of the two isomers depends on the hydrophilicity of the species; in particular, the hydrophilicity of the complexes favours the *cis* isomer. Indeed, the *cis* arrangements are mainly formed by the two more hydrophilic ligands, 3-COOHpzc and 5-OHpzc, whereas the most hydrophobic, 5-Mepzc, gives almost exclusively the *trans* structure (Figure 7). The hydrophobicity of the complex hinders the approach and the coordination of a water molecule to the $V^{IV}O$ ion and, therefore, the formation of the *cis* complex: for instance, picolinate forms only the *cis* isomer,[14b] whereas the less hydrophilic 6-methyl derivative forms both the *trans* and *cis* complexes.[14c]

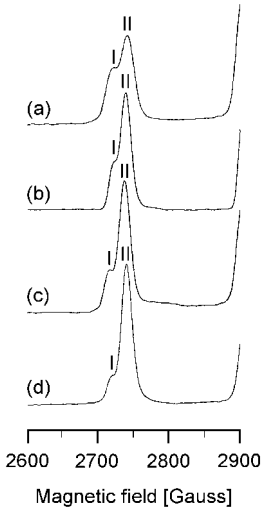

Figure 7. Low-field region of the X-band anisotropic EPR spectra of the bis(chelated) complexes formed by pzc, 5-Mepzc, 3-COOHpzc and 5-OHpzc recorded on aqueous solutions at 140 K with a $V^{IV}O$ concentration of 4 mM. (a) 3-COOHpzc, L/M = 10, pH = 5.05; (b) 5-OHpzc, L/M = 2, pH = 5.25; (c) pzc, L/M = 10, pH = 4.35; (d) 5-Mepzc, L/M = 5, pH = 5.00. **I** and **II** denote *cis*-$VOL_2$ and *trans*-$VOL_2$ complexes.

## Magnetic Properties of the Hydroxo-Bridged $V^{IV}O$ Dimeric Complexes

A qualitative interpretation of the magnetic interactions in transition-metal dimers is given by the Goodenough–Kanamori rules,[46] based on the interactions between pairs of magnetic orbitals (the unpaired electron for $V^{IV}O$ generally resides in the $d_{xy}$ orbital). The magnetic interaction of two ions with spin $S_1$ and $S_2$ is described by the Heisenberg Hamiltonian $\hat{H} = -J\hat{S}_1 \cdot \hat{S}_2$, where $J$ is the exchange coupling constant. If $S = 1/2$, as for $V^{IV}O$ dimers, the energy difference between the triplet ($S = 1$) and the singlet ($S = 0$) spin states is about $J$. Thus, if the $J$ value is positive, the triplet state is more stable than the singlet one, the interaction is ferromagnetic and an EPR spectrum can be detected; in the opposite case, the singlet state is more stable, the interaction is antiferromagnetic and no EPR signal is observed. Plass demonstrated that for the two orthogonal configurations of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ core (Scheme 4) either a direct interaction or a superexchange mechanism between the magnetic orbitals can be expected to be operative, yielding rather strong antiferromagnetic coupling.[26] However, the configuration of the core, the nature of the terminal ligands and the structural distortions can influence the exchange coupling constant.[47,48] It has been found that for certain combinations of the V–O–V angle and V···V distance, the value of $J$ can become positive.[48]

In order to find examples of magnetic coupling between two $V^{IV}O$ ions in the literature, two searches have been performed on the Cambridge Structural Database.[34] The first, on the dimeric $[VO(\mu\text{-}OH)_2VO]^{2+}$ core, yielded six structures, four with an *anti*-orthogonal,[49] one with a *syn*-orthogonal[50] and one with a *syn*-coplanar arrangement.[51] All show antiferromagnetic behaviour with $-J$ values in the range 6–177 $cm^{-1}$. The second search, on the $[VO(\mu_2\text{-}OR)_2VO]^{2+}$ core, yielded 31 structures, 15 with an *anti*-orthogonal,[52] 10 with a *syn*-orthogonal,[53] 5 with an *anti*-coplanar[26,53j,54] and 1 with a twisted configuration.[26] Magnetic measurements are reported for 15 of them. The four structures with an *anti*-orthogonal and the seven with a *syn*-orthogonal arrangement show antiferromagnetic coupling with $-J$ values in the range 6–212 $cm^{-1}$. On the other hand, the six structures with an *anti*-coplanar and a twisted configuration display ferromagnetic coupling with $J$ values in the range 3–56 $cm^{-1}$. This confirms the suggestions of Plass that for edge-shared dinuclear units, only the relative orientation of the vanadyl groups is necessary to qualitatively predict their magnetic behaviour in terms of antiferro- (*anti*- and *syn*-orthogonal and *syn*-coplanar) or ferromagnetic interactions (*anti*-coplanar and twisted) between the metal centres.[26]

A ferromagnetic interaction leads to a detectable EPR signal. For a system with tetragonal symmetry the anisotropic EPR spectrum consists of four bands, whose separation depends on the molecular interactions. The external lines, corresponding to the V=O orientation parallel to the magnetic field direction, are separated by $2D$, whereas the internal lines corresponding to the perpendicular orienta-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion are separated by $D$, where $D$ is the zero-field splitting. In the case of weak paramagnetic interaction the zero-field splitting has contributions of only dipolar origin and can be correlated to the distance between the two vanadium interacting centres ($R$) and to the angle formed by the V=O and V–V directions ($\theta$) through the Stevens equation (1):[55]

$$D = 0.325 g^2 \frac{\left|1 - 3\cos^2\theta\right|}{R^3} \quad (1)$$

with $D$ in $cm^{-1}$ and $R$ in Å. Usually two broad transitions in the $\Delta M = \pm 1$ region centred at $g \approx 2$ and a well-resolved $^{51}V$ hyperfine structure in the $\Delta M = \pm 2$ region at $g \approx 4$ are detectable.[56] If the symmetry of the complex is axial, two sets of 15 lines, partially overlapping, are observed in the forbidden $\Delta M = \pm 2$ region, with the magnitude of the coupling constant nearly half of that expected for $A_{\parallel}$ in the monomeric species with the same equatorial donors (Figure 5).

All four $(VO)_2L_2H_{-2}$ complexes formed by pzc, 5-Mepzc, 3-COOHpzc and 5-OHpzc exhibit a separation of the parallel components ($2D$) in the range 1312–1328 G between the high-field resonance at about 3990 G and the low-field resonance at about 2670 G, corresponding to a $D$ value of about 660 G or 0.06 $cm^{-1}$ (Table 2). In the literature, no agreement exists on the attribution of these transitions to the perpendicular or parallel components of the ***D*** tensor. In Figure 8, the $D$ value derived from the Stevens equation is represented as a function of the $\theta$ angle for five $R$ distances; the $g$ value has been approximated to 2. For five of the six di-μ-hydroxo-bridged $V^{IV}O$ compounds reported in the literature, $R$ is in the range 2.965–3.122 Å;[49,50] only the sixth compound is characterised by a higher value (3.45 Å), but this is due to the presence of a $\mu_2$-squarato-$O,O'$ bridging ligand, which keeps the metal ions distant.[51] Therefore, we believe that an estimate of about 2.9–3.1 Å for $R$ is reasonable also for 2-pyrazinecarboxylic acid and its derivatives. For $R > 2.9$ Å, values higher than 0.11 $cm^{-1}$ should result in $\cos^2\theta > 1$ and are not to be expected for $D$ (Figure 8). This is a very important conclusion because it demonstrates that the separation measured on the experimental EPR spectrum cannot be attributed to the perpendicular components of the ***D*** tensor, to which a value of about 1320 G or 0.12 $cm^{-1}$ would correspond.

From Figure 8 it is worth noting that if $D \approx 0.06$ $cm^{-1}$ and $R$ = 2.9–3.1 Å, only the angles in the range 27.2–32.7 and 147.3–152.8° satisfy the Stevens equation. These values are consistent with an *anti*-coplanar arrangement of the two $V^{IV}O$ ions (angles of 130.7 and 132.8° for the two *anti*-coplanar complexes $[\{V^{IV}O(Hsabhea)\}_2]\cdot 2CH_3OH$ and $[\{V^{IV}O(Hsabhea)\}_2]\cdot CH_3OH$, with $H_3$sabhea = *N*-salicylidene{2-[bis(2-hydroxyethyl)amino]ethyl}amine, were reported[26]), but not with an *anti*- or a *syn*-orthogonal configuration, for which much lower values of $\theta$ are expected ($\theta$ is in the range 101.0–111.4° for the five di-μ-hydroxo structures in the literature[49,50]).

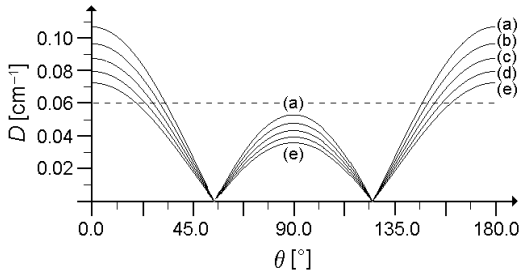

Figure 8. $D$ value derived from the Stevens equation as a function of the $\theta$ angle: (a) $R$ = 2.9 Å; (b) $R$ = 3.0 Å; (c) $R$ = 3.1 Å; (d) $R$ = 3.2 Å; and (e) $R$ = 3.3 Å. The $g$ value has been approximated to 2.

In conclusion, an *anti*-coplanar arrangement with an aromatic nitrogen atom and a carboxylate oxygen atom, one water molecule and an $OH^-$ ion in the equatorial plane and a second $OH^-$ ion of another unit in the axial position of each $V^{IV}O$ ion is realised for the $(VO)_2L_2H_{-2}$ species formed by pzc, 5-Mepzc, 3-COOHpzc and 5-OHpzc (Scheme 5). These findings are supported by recent results[28] with hyphetri-COOH {4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzoic acid} and hyphetri-$SO_3H$ {4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzenesulfonic acid}.[57] In weakly acidic aqueous solutions, they give $\Delta M = \pm 1$ (at $g \approx 2$) and $\Delta M = \pm 2$ (at $g \approx 4$) EPR signals analogous to those of pzc and its derivatives. Because they are tridentate chelating ligands, which occupy three equatorial positions of the $V^{IV}O$ ion with the donor set ($O^-_{aromatic}$, $N_{aromatic}$, $O^-_{aromatic}$), they enforce the formation of an *anti*-coplanar arrangement for the corresponding $(VO)_2L_2H_{-2}$ species with the two bridging $OH^-$ ions in *cis* and *trans* positions with respect to the V=O bond.

## Conclusions

2-Pyrazinecarboxylic acid and three of its derivatives (5-methyl-2-pyrazinecarboxylic, 2,3-pyrazinedicarboxylic and 5-hydroxy-2-pyrazinecarboxylic acids) coordinate the $V^{IV}O$ ion forming VOL, $VOL_2$ and $(VO)_2L_2H_{-2}$ species in acidic and neutral solutions. Bis(chelated) species are hexacoordinate and are characterised by a *cis*/*trans* isomerism, with the *trans* arrangement favoured with respect to the *cis* one. The application of the additivity rule[22] allows identification of the donors coordinated in the equatorial plane of the $V^{IV}O$ ion. The relative stability of the two isomers in aqueous solution is influenced by a number of factors, like the ligand bite, the size of the chelate ring, the basicity and the steric requirements of the ligands. Generally, large ligand bites, six-membered chelate rings and strong ligands favour the *trans* isomer.[44,45] However, these rules are only effective if applied to ligands with different bite, basicity and size of the chelate ring. Instead, if ligands of the same series are compared, like those derived from 2-pyrazinecarboxylic acid (same size of the chelate ring, comparable ligand bite and basicity), the hydrophilicity of the complexes becomes determinant. This conclusion is supported by the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solid-state structures because the hydrophobic 5-methyl derivative forms the pentacoordinate *trans* complex **1**, whereas the more hydrophilic pzc and 3-COOHpzc form the hexacoordinate *cis* compounds **2** and **3**, with a water molecule in the equatorial plane of the $V^{IV}O$ ion. The hydrophilicity, because of the presence of the polar carboxylate group, explains the reason why the only four monomeric $V^{IV}O$ complexes with a water molecule coordinated, among 22 structures found formed by bidentate ligands with an N,O coordination,[34] are characterised by an ($N_{aromatic}$, $COO^-$) donor set.

In weakly acidic solutions a $(VO)_2L_2H_{-2}$ species is detected by EPR spectroscopy and potentiometry. The rule established by Felcman and Fraústo da Silva suggests that the hydrolysis of a mono(chelated) $V^{IV}O$ complex with two adjacent equatorial sites occupied by water molecules gives a di-μ-hydroxo-bridged dimer,[25] but there are different possibilities for their geometrical arrangement (Scheme 4). Usually, these species are EPR-silent, as proved in several cases, for example with picolinic[14b] and 6-methylpicolinic acids.[14c] Plass demonstrated that an *anti*- and a *syn*-orthogonal configuration results in an antiferromagnetic coupling, whereas an *anti*-coplanar and a twisted arrangement give rise to a ferromagnetic coupling.[26] An *anti*-coplanar configuration for a ferromagnetically coupled $V^{IV}O$ complex can also be predicted through the Stevens equation.[55] Moreover, an analysis of this equation suggests that the signals present in the $\Delta M = \pm 1$ region of the EPR spectrum belong to the parallel components of the ***D*** tensor. These findings are supported by the value of the coupling constant in the $\Delta M = \pm 2$ region, which must be half of that expected for $A_{\parallel}$ in the monomeric species with the same equatorial donors. In this case, it allows the set [($N_{pyr}$, $COO^-$); $H_2O$; $OH^-$], expected for an *anti*-coplanar arrangement, to be distinguished from [($N_{pyr}$, $COO^-$); $OH^-$; $OH^-$], characteristic of an *anti*- or *syn*-orthogonal configuration. In conclusion, the theoretical and experimental results, compared with the data in the literature, suggest an *anti*-coplanar configuration for $(VO)_2L_2H_{-2}$ species, with two bridging $OH^-$ ions in the equatorial and axial positions and the ($N_{pyr}$, $COO^-$) set and an $H_2O$ molecule completing the coordination sphere of the $V^{IV}O$ ion (Scheme 5).

At the moment, the factors that favour the *anti*-coplanar configuration with respect to the *anti*- or *syn*-orthogonal are not clear to us. Although for bidentate ligands the simplest and more common *anti*- or *syn*-orthogonal arrangements of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ core should be expected, this is not the case for 2-pyrazinecarboxylic acid and its derivatives. So, one of the next challenges in the chemistry of the $V^{IV}O$ ion is to try to understand the factors that stabilise each of the five configurations of the $[VO(\mu\text{-}OH)_2VO]^{2+}$ core and determine the ferromagnetic or antiferromagnetic coupling.

## Experimental Section

**Chemicals:** All the ligands were Aldrich or Fluka products of puriss. quality. Their purity and their concentration in solution were determined by the Gran method.[58] $V^{IV}O$ solutions were prepared according to a procedure described in the literature.[59] All operations were performed under purified argon in order to avoid oxidation of the $V^{IV}O$ ion.

**Potentiometric Measurements:** The protonation constants of the ligands ($\log K$) and the stability constants of the $V^{IV}O$ complexes were determined by pH-potentiometric titrations of 2.0-mL samples. The ligand/metal molar ratio was in the range 1:1–10:1. The concentration of $V^{IV}O$ was 0.001 M. Measurements were carried out at 25 ± 0.1 °C and at a constant ionic strength of 0.1 M $KNO_3$ with a MOLSPIN pH-meter equipped with a digitally operated syringe (Molspin DSI 0.250 mL) controlled by a computer. The titrations were performed with a carbonate-free NaOH solution of known concentration (about 0.1 M) using a Russel CMAWL/S7 semimicro combined electrode, calibrated for hydrogen ion concentration by the method of Irving et al.[60] The number of experimental points was 100–150 for each titration curve. The reproducibility of the titration points included in the evaluation was within 0.005 pH units in the whole pH range examined (2–10). The stability constants of the complexes, reported as the logarithm of the overall formation constants $\beta_{pqr} = [VO_pL_qH_r]/[VO]^p[L]^q[H]^r$, where VO is the vanadyl ion, L is the deprotonated form of the ligand and H is the proton, were calculated with the aid of the SUPERQUAD program.[61] Standard deviations were calculated by assuming random errors. The conventional notation has been used. Negative indices for H in the formulas indicate either the dissociation of groups that do not deprotonate in the absence of $V^{IV}O$ coordination, or hydroxo ligands. Hydroxo complexes of $V^{IV}O$ were taken into account in the calculations. The following species were assumed: $[VO(OH)]^+$ ($\log\beta_{10-1} = -5.94$), $[(VO)_2(OH)_2]^{2+}$ ($\log\beta_{20-2} = -6.95$), with stability constants calculated from the data of Henry et al.[62] and corrected for the different ionic strengths by use of the Davies equation,[63] $[VO(OH)_3]^-$ ($\log\beta_{10-3} = -18.0$) and $[(VO)_2(OH)_5]^-$ ($\log\beta_{20-5} = -22.0$).[64]

***trans*-[VO(5-Mepzc)$_2$]:** $VOSO_4 \cdot 5H_2O$ (0.1265 g), dissolved in MeOH (5 mL), was added at room temperature to 5-Mepzc (0.1480 g), dissolved in MeOH (5 mL). The resulting solution was stirred at 50 °C. After 1 h, $CH_3CN$ (20–30 mL) was added and the suspension was stirred at room temperature for 1 h. The dark brown solid was filtered under vacuum, washed with diethyl ether and dried under $N_2$. $C_{12}H_{10}N_4O_5V$ (341.18): calcd. C 42.25, H 2.95, N 16.42, $V_2O_5$ 26.6; found C 41.56, H 3.21, N 16.87, $V_2O_5$ 25.8.

***cis*-[VO(pzc)$_2$(H$_2$O)]:** Pzc (0.1316 g) was dissolved in MeOH (10 mL) by heating at 50 °C. $VOSO_4 \cdot 5H_2O$ (0.1265 g), dissolved in MeOH (5 mL), was added to the ligand. The mixture was stirred at 50 °C for 1 h. Subsequently, acetone (30 mL) was added and the suspension was stirred at room temperature for 1 h. The greenish solid was filtered under vacuum, washed with acetone and diethyl ether and dried under $N_2$. $C_{10}H_8N_4O_6V$ (331.14): calcd. C 36.27, H 2.43, N 16.92, $H_2O$ 5.4, $V_2O_5$ 27.5; found C 36.73, H 2.65, N 17.02, $H_2O$ 6.0, $V_2O_5$ 28.0.

***cis*-[VO(3-COOHpzc)$_2$(H$_2$O)]:** 3-COOHpzc (0.1480 g) was dissolved in MeOH (10 mL) at room temperature. $VOSO_4 \cdot 5H_2O$ (0.1265 g), dissolved in MeOH (5 mL), was added to the ligand. The solution was stirred at 50 °C for 1 h. Subsequently, diethyl ether (30 mL) was added and the suspension was stirred at room temperature for 1 h. The dark green solid was filtered under vacuum, washed with diethyl ether and dried under $N_2$. $C_{12}H_8N_4O_{10}V$ (419.16): calcd. C 34.39, H 1.92, N 13.37, $H_2O$ 4.3, $V_2O_5$ 21.7; found C 34.54, H 1.75, N, 13.07, $H_2O$ 5.0, $V_2O_5$ 21.2.

**Spectroscopic and Analytical Measurements:** Anisotropic EPR spectra were recorded on aqueous solutions with an X-band (9.15 GHz)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Varian E-9 spectrometer in the temperatures range 120–140 K. The spectra were simulated with the computer program Bruker WinEPR SimFonia. Infrared spectra (4000–600 $cm^{-1}$) were obtained with a JASCO FT-IR 480 Plus interferometer using KBr disks. Elemental analyses (C, H, N) were performed with a Perkin–Elmer 240 B analyser. The thermogravimetric studies, which allowed the determination of the $H_2O$ and $V_2O_5$ content, were carried out with a Perkin–Elmer TGS-2 instrument under nitrogen.

[15] In this work the *cis* nomenclature refers to the bis(chelated) complexes in which the two ligand molecules adopt an (equatorial–equatorial) and an (equatorial–axial) arrangement with respect to the V=O bond of the vanadyl ion; *cis* isomers are hexacoordinate with one solvent molecule coordinated in the fourth equatorial position; *trans* isomers are bis(chelated) complexes in which both ligand molecules adopt an (equatorial–equatorial) arrangement with respect to the V=O group; *trans* isomers can be pentacoordinate or hexacoordinate according to the absence or presence of a solvent molecule bound in the axial position.

# New Heterometallic ($Cu^{II}$ and $Cr^{III}$) Complexes – First Crystal Structure of an Oxalate-Bridged Ferromagnetically Coupled [$Cu^{II}Cr^{III}Cu^{II}$] System

**Marijana Jurić,[a] Pavica Planinić,[a] Nevenka Brničević,*[a] Dalibor Milić,[b] Dubravka Matković-Čalogović,[b] Damir Pajić,[c] and Krešo Zadro[c]**

**Keywords:** Crystal structure / Copper complexes / Chromium complexes / Oxalate bridges / Ferromagnetic interaction

Two new heterotemetallic complexes [{Cu(μ-$C_2O_4$)(bpy)$_2$}$_2$-Cr($C_2O_4$)]$NO_3$·$H_2O$ (**1**) and [Cu(bpy)$_3$][Cr($C_2O_4$)$_3$]$NO_3$·$9H_2O$ (**2**) (bpy = 2,2′-bipyridine) have been synthesized. The crystal structures were determined and magnetic and spectroscopic (IR, UV/Vis) characterization accomplished. In **1**, the central [Cr($C_2O_4$)$_3$]$^{3-}$ unit acts as a bridge between two copper(II) ions, each of them having a distorted octahedral geometry. The apical positions are occupied by one oxygen atom belonging to the bridging oxalate anion [Cu–O2 = 2.6439(18) Å] and one nitrogen atom from one of the bpy ligands [Cu–N1 = 2.1079(18) Å]. The $N_3O$ equatorial environment consists of three bpy nitrogen atoms [Cu–N = 1.995 Å (mean value)] and the second oxygen atom from the bridging oxalate anion [Cu–O1 = 2.1168(15) Å]. The chromium(III) atom is in a slightly distorted octahedral environment of four oxygen atoms from two bridging oxalate groups [Cr–O = 1.988 Å (mean value)] and two oxygen atoms from the terminally bonded bidentate oxalate group [Cr–O = 1.9454(16) Å]. Complex **2** consists of two mononuclear [Cu(bpy)$_3$]$^{2+}$ cations, one mononuclear [Cr($C_2O_4$)$_3$]$^{3-}$ anion, one $NO_3^-$ anion and nine molecules of water of crystallisation. The copper(II) ions in two crystallographically independent [Cu(bpy)$_3$]$^{2+}$ cations are in a tetragonally distorted octahedral coordination environment of six N atoms from the bpy ligands. The chromium(III) ion in [Cr($C_2O_4$)$_3$]$^{3-}$ has a slightly distorted octahedral environment of oxygen atoms from three oxalate groups [with the Cr–O bond lengths ranging from 1.964(3) to 1.982(3) Å]. Analysis of the magnetic properties (1.8–290 K) of **1** showed a ferromagnetic exchange interaction between $Cu^{II}$ and $Cr^{III}$ with $J$ = +1.20 $cm^{-1}$ [using $\mathbf{H}_{INT} = -J(S_{Cu1}S_{Cr} + S_{Cu2}S_{Cr})$].

## Introduction

The design of molecule-based magnetic materials has become one of the most stimulating challenges for chemists nowadays.[1,2] A generally accepted strategy for synthesizing these materials consists of assembling paramagnetic metal centres in such a way that the resulting solid lattices, with their components properly arranged, exhibit desired physical properties such as magnetic exchange interactions. In designing homo- and heteropolynuclear complexes, a very essential role belongs to the oxalate ion, $C_2O_4^{2-}$, because of its ability to adopt a bis(chelating) coordination mode as well as to mediate magnetic interactions between paramagnetic metal centres. On this account, stable mononuclear anionic oxalate complexes are often used as ligands toward the second metal ion, an approach known as "complexes as ligands" or "building-blocks chemistry".

One of the possibilities for the synthesis of molecule-based ferromagnetic materials, developed in the early 1990's, is based on the use of the tris(oxalato)chromate(III) anion, [Cr($C_2O_4$)$_3$]$^{3-}$,[3] as one of the starting components. The advantage of using this anion is its stability towards ligand substitution as well as good control over the reaction products. By using [Cr($C_2O_4$)$_3$]$^{3-}$ as a building block, a series of mixed-metal assemblies {[$NR_4$][$M^{II}Cr^{III}$($C_2O_4$)$_3$]}$_n$ (R = *n*-butyl; $M^{II}$ = Mn, Fe, Co, Ni, Cu, Zn) was obtained, for which the ferromagnetic phase transition was observed up to 14 K;[3a] the crystal structures of these assemblies were not known. Shortly afterwards, determination of the crystal structures of {[$NR_4$][$Mn^{II}Cr^{III}$($C_2O_4$)$_3$]}$_n$ (R = *n*-butyl, *n*-propyl)[4] and {[$PR_4$][$Mn^{II}Cr^{III}$($C_2O_4$)$_3$]}$_n$ (R = phenyl)[5] revealed a 2D structure, and ferromagnetic behaviour was confirmed. The anion [Cr($C_2O_4$)$_3$]$^{3-}$ was also used in the preparation of the cubic 3D coordination polymers [$M^{I}Cr^{III}$($C_2O_4$)$_3$]$_n^{2n-}$ ($M^{I}$ = Li, Na)[6] or [$M^{II}Cr^{III}$-($C_2O_4$)$_3$]$_n^{n-}$ ($M^{II}$ = Mn, Fe, Co, Ni, Cu, Zn)[7] in which the charge was counterbalanced by a tris(chelated) transition-metal (M′) diimine, [M′(bpy)$_3$]$^{m+}$ (bpy = 2,2′-bipyridine; *m* = 2, 3). Other anionic oxalate complexes of chromium(III)

have also served as building blocks: the mono(oxalato) complexes $[CrL(C_2O_4)]^-$ [L = *N*,*N*′-ethylenebis(salicylideneaminate)][8] and $[CrL_2(C_2O_4)]^-$ (L = acetylacetonate)[9] have been used for the synthesis of heterodinuclear compounds, whereas the bis(oxalato) complexes $[CrL(C_2O_4)_2]^-$ (L = 2,2′-bipyridine,[10] 1,10-phenanthroline,[10d,11] 2,2′-bipyrimidine[12]) produced heterodinuclear as well as heteropolynuclear species of different dimensionalities.

Recently, the $[Cr(C_2O_4)_3]^{3-}$ and $[Fe(C_2O_4)_3]^{3-}$ anions were used in the synthesis of some oxalate-bridged trinuclear complexes such as $[Cu_2M^{III}(C_2O_4)_3(Mephen)_2]ClO_4$ ($M^{III}$ = Cr, Fe; Mephen = 5-methyl-1,10-phenanthroline).[13a] The magnetic susceptibility data revealed an intramolecular ferromagnetic interaction between the copper(II) and chromium(III) ions through the oxalate bridge and an antiferromagnetic interaction between the copper(II) and iron(III) centres with spin-coupling constants of $+14.9\ cm^{-1}$ and $-12.7\ cm^{-1}$ [using $\mathbf{H}_{INT} = -2J(S_{Cu1}S_M + S_{Cu2}S_M)$], respectively. Slightly reduced values were obtained for similar complexes when Mephen was substituted by tmen (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine).[13b] The occurrence of intramolecular ferromagnetic interactions between the copper(II) and chromium(III) ions through the oxalate bridge with spin-coupling constants of $+6.36\ cm^{-1}$ and $+7.02\ cm^{-1}$ [using $\mathbf{H}_{INT} = -2J(S_{Cu1}S_{Cr} + S_{Cu2}S_{Cr} + S_{Cu3}S_{Cr})$], has also been found for the tetranuclear complexes $[Cu_3Cr(C_2O_4)_3L_3](ClO_4)_3$ with L = diaminoethane and 1,3-diaminopropane, respectively.[13c] All of these complexes[13] were prepared as polycrystalline solids. Because of the lack of single crystals suitable for X-ray structural analysis, their structures remain unknown.

In relation to our current magneto-structural studies on the polynuclear transition-metal complexes, we report in this paper on two new heterometallic complexes, $[\{Cu(\mu\text{-}C_2O_4)(bpy)_2\}_2Cr(C_2O_4)]NO_3\cdot H_2O$ (**1**) and $[Cu(bpy)_3]_2[Cr(C_2O_4)_3]NO_3\cdot 9H_2O$ (**2**), which have been obtained by using the $[Cr(C_2O_4)_3]^{3-}$ anion as building block. To the best of our knowledge, the complex $[\{Cu(\mu\text{-}C_2O_4)(bpy)_2\}_2Cr(C_2O_4)]NO_3\cdot H_2O$ is, so far, the first heterotrinuclear oxalate-bridged copper(II)–chromium(III)–copper(II) compound for which the crystal structure has been determined. The structural data of the complexes have been correlated with magnetic and other measurements.

## Results and Discussion

### Preparation

Complex **1** was obtained in the form of dark-green crystals from the reaction of aqueous solutions of $K_3[Cr(C_2O_4)_3]\cdot 3H_2O$ and $Cu(NO_3)_2\cdot 3H_2O$ and an ethanolic solution of 2,2′-bipyridine in the ratio 1:2:4. Single crystals of **2** were formed as the only solid by slow concentration of the aqueous solution containing $K_3[Cr(C_2O_4)_3]\cdot 3H_2O$ and $[Cu(bpy)_3](NO_3)_2\cdot 6H_2O$ in the ratio 1:1. When this reaction was performed with a 1:2 ratio of the precursors, crystals of **1** and **2** formed simultaneously. Both compounds are moderately stable in air and rather insoluble in common organic solvents.

### Description of the Structures

#### *[{Cu(μ-C$_2$O$_4$)(bpy)$_2$}$_2$Cr(C$_2$O$_4$)]NO$_3$·H$_2$O (1)*

The structure of **1** consists of trinuclear $[\{Cu(\mu\text{-}C_2O_4)(bpy)_2\}_2Cr(C_2O_4)]^+$ cations, nitrate anions and uncoordinated water molecules. The trinuclear cation (Figure 1) can be considered as being composed of two $[Cu(bpy)_2]^{2+}$ moieties bridged by the $[Cr(C_2O_4)_3]^{3-}$ complex anion, which acts as a bidentate ligand towards each of the copper atoms.

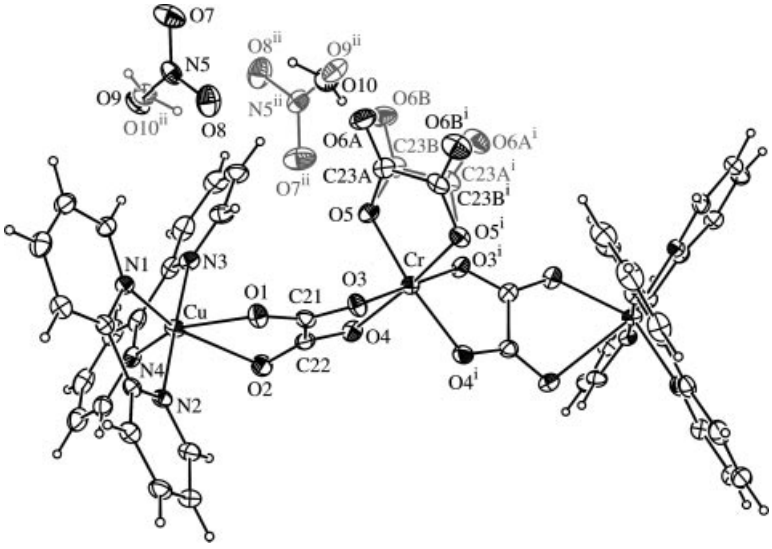

Figure 1. Asymmetric unit of **1** with atom numbering scheme and displacement ellipsoids drawn at the 50% probability level. Two halves of the $[\{Cu(\mu\text{-}C_2O_4)(bpy)_2\}_2Cr(C_2O_4)]^+$ cation are related by the symmetry operator (i) $1-x, y, 1/2-z$. The carboxylate groups of the terminal oxalate ligand are disordered (see text for explanation). The water molecule and nitrate ion are disordered over two sites related by the symmetry operator (ii) $1-x, -y, -z$. Atoms in the alternative sites and their numbering scheme are shown in grey.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Although compound **1** crystallises in the space group *C*2/*c* (see Exp. Sect.) with the chromium atom situated on the twofold axis, the trinuclear cation possesses only approximate $C_2$ symmetry: atoms C23 and O6 of the terminal oxalate group (which is intersected by the crystallographic twofold axis) are disordered over two sites (denoted A and B). The distance between C23A and the equivalent atom generated by the twofold symmetry C23A(1 – *x*, *y*, 1/2 – *z*) is 1.657(18) Å, whereas the distance C23A–C23B(1 – *x*, *y*, 1/2 – *z*) is 1.572(18) Å and is closer to the value for a C–C single bond.[14] This suggests that the two atoms from one of the carboxylate groups are in the A site and the corresponding atoms from the other carboxylate group of the terminal oxalate ligand are in the B site (Figure 1). This oxalate group is, therefore, statistically disordered, and the occupancies of the C23A, C23B, O6A and O6B atoms were fixed at 0.50 during refinement. Furthermore, the lattice water molecules and nitrate ions are disordered over two sites related by the inversion centre, so that the occupancy of each site equals exactly one half (Figure 1).

The apical positions in the distorted octahedron around Cu are occupied by the O2 and N1 atoms. The Cu–O2 bond [2.6439(18) Å] is significantly longer than the Cu–O1 bond [2.1168(15) Å]. The Cu–N1 bond [2.1079(18) Å] is the longest one among the four Cu–N bonds (Table 1). The remaining three bpy nitrogen (N2, N3 and N4) atoms having an average Cu–N bond length of 1.995 Å as well as the O1 atom are located in the equatorial plane. The pyridyl rings of the bpy ligands are slightly tilted towards each other. The dihedral angles between the planes of the pyridyl rings are 15.78(10)° (for the bpy ligand including N1 and N2) and 4.52(11)° (for the ligand including N3 and N4).

Table 1. Selected bond lengths [Å] and angles [°] for compound **1**.

[a] Symmetry code: (i) 1 – *x*, *y*, 1/2 – *z*.

The Cr atom in **1** is bonded to six oxygen atoms arranged in a slightly distorted octahedron. As already observed in similar complexes,[10a,15,16] the Cr–O bonds are longer for the bridging oxalate ligands [1.9866(16) Å and 1.9900(16) Å] than for the terminal one [1.9454(16) Å], but they are all shorter than the Cu–O bonds (Table 1). The carboxylate groups of the oxalate ligands are not coplanar; instead, they are rotated around the C–C bond by 14.05(12)° in the bridging ligands and by 6.0(17)° in the terminal one.

The complex cations, mutually related by the twofold axis, are stacked in columns parallel to the *c* axis because of the offset π–π interactions between pyridyl moieties. The columns of the complex cations are further connected with the neighbouring columns by zipper-like offset π–π stacking interactions between the pyridyl moieties: in this way, layers parallel to (010) are formed. These layers consist of pyridyl rings with two different orientations alternating in the *a*-direction: (a) the rings almost parallel to (012) and (b) those almost parallel to (01$\bar{2}$) (Figure 2). The contact distances between atoms involved in the pyridyl π–π stacking interactions range from 3.324(3) Å to 3.594(3) Å, which indicates that these are strong to modest π–π interactions.[17] The two layers of the complex cations are held together by the C–H···O hydrogen bonds and other interactions mediated by the nitrate ions and water molecules: each water molecule bridges the complex cation and the nitrate anion by forming two hydrogen bonds: O10–H101···O6A of 2.92(2) Å and O10–H102···O8 of 2.814(19) Å, (Figure 3; Table 2). Additionally, the carboxylate group of the terminal oxalate ligand occupying the B site and the nitrate ion are in close contact [N5···O6B(1 – *x*, –*y*, –*z*) = 3.201(7) Å; O7···C23B(1 – *x*, –*y*, –*z*) = 3.103(14) Å] and exhibit a π–π stacking interaction [the angle between the plane of the nitrate ion and that of the carboxylate group B equals 18.7(9)°]. In the proposed structural model, the carboxylate group nearest to the nitrate ion always occupies the B site; otherwise, unacceptably short contacts between the nitrate ion and carboxylate group at the A site [N5···O6A(1 – *x*, –*y*, –*z*) = 2.588(8) Å; O7···C23A(1 – *x*, –*y*, –*z*) = 2.775(16) Å] would be present.

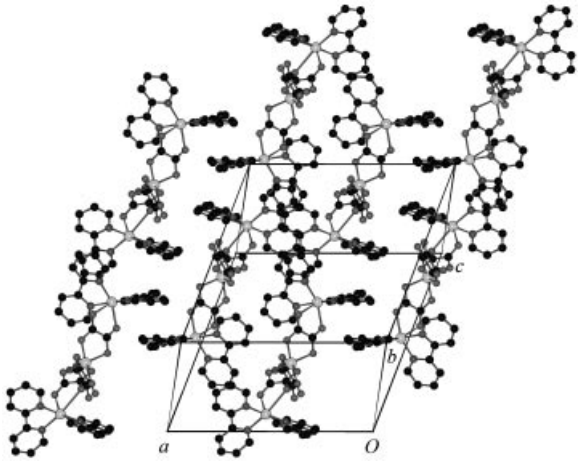

Figure 2. Pyridyl π–π stacking in **1**. The stacking almost parallel to (012) alternates in the *a*-direction with the stacking almost parallel to (01$\bar{2}$). Hydrogen atoms are omitted for clarity.

The Cu···Cr distance across the bridging oxalate group is 5.4605(5) Å. It is similar to the corresponding values found elsewhere: in the dinuclear complex [(bpy)($C_2O_4$)Cr-(μ-$C_2O_4$)Cu(Hfsaaep)($H_2O$)]·2$H_2O$ {$H_2$fsaaep = 3-[*N*-2-(pyridylethyl)formimidoyl]salicylic acid; Cu···Cr =

5.506 Å},[16] in the trinuclear complex $[CuCr_2(bpy)_2(C_2O_4)_4(H_2O)_2]\cdot 1.5H_2O$ (Cu···Cr = 5.288 Å)[10a] or in the tetranuclear compound $[Cr_2Cu_2(bpy)_4(C_2O_4)_5]\cdot 2H_2O$ [Cu···Cr = 5.4473(17) Å].[15b] The oxalate bridging mode in all of these complexes is the same as that in **1**. The shortest intermolecular Cu···Cu, Cu···Cr and Cr···Cr distances in the structure of **1** are 6.0311(6) Å [Cu···Cu(1 – *x*, *y*, –1/2 – *z*)], 7.6473(8) Å [Cu···Cr(1 – *x*, 1 – *y*, –*z*)] and 9.4527(7) Å [Cr···Cr(3/2 – *x*, 1/2 – *y*, 1 – *z*)], respectively.

### *[Cu(bpy)$_3$]$_2$[Cr(C$_2$O$_4$)$_3$]NO$_3$·9H$_2$O (2)*

The asymmetric unit of **2** is composed of two mononuclear, crystallographically independent $[Cu(bpy)_3]^{2+}$ cations, a mononuclear $[Cr(C_2O_4)_3]^{3-}$ anion, a nitrate anion and nine molecules of water of crystallisation, two of which are disordered over two positions (Figure 4). Each copper atom is coordinated by six nitrogen atoms of the three chelating bpy ligands. The two axial Cu–N bonds in each of the $[Cu(bpy)_3]^{2+}$ cations [Cu1–N2 = 2.247(3) Å and Cu1–N5 = 2.291(3) Å; Cu2–N8 = 2.171(3) Å and Cu2–N11 = 2.200(4) Å] are significantly longer than the other four [ranging from 2.027(3) Å to 2.055(5) Å for Cu1 and from 2.068(5) Å to 2.088(5) Å for Cu2; Table 3]; thus an elongated octahedron is formed (as expected as a result of the Jahn–Teller effect). The dihedral angles between pyridyl moieties are smaller for the ligands coordinated to Cu1 [5.0(3)°, 5.19(18)° and 6.23(19)°] than for those coordinated to Cu2 [10.4(2)°, 9.76(19)° and 6.6(3)°]. The geometrical parameters of $[Cu(bpy)_3]^{2+}$ in **2** are significantly different from those found in some other $[Cu(bpy)_3]^{2+}$ complexes {the apical Cu–N distances in $[Cu(bpy)_3][Ni(tdtdt)_2]_2$ (tdtdt = 2-thioxo-1,3-dithiole-4,5-dithiolate)[18] are longer than the equatorial ones by only 0.02 Å; the octahedral geometry in $[Cu(bpy)_3](ClO_4)_2$[19] is more distorted than in **2**; the coordination polyhedron around Cu in $[Cu(bpy)_3][Hg_2I_6]$[20] is a flattened octahedron}, but they are similar to those found in $[Cu(dmbpy)_3](BF_4)_2\cdot C_2H_5OH$, where the ligand dmbpy indicates 5,5-dimethyl-2,2′-bipyridine.[21] The Cr atom in $[Cr(C_2O_4)_3]^{3-}$ is coordinated by six oxygen atoms of the three bidentate oxalate ligands in a slightly distorted octahedral arrangement. The Cr–O bond lengths range from 1.964(3) Å to 1.982(3) Å, and the structure of the

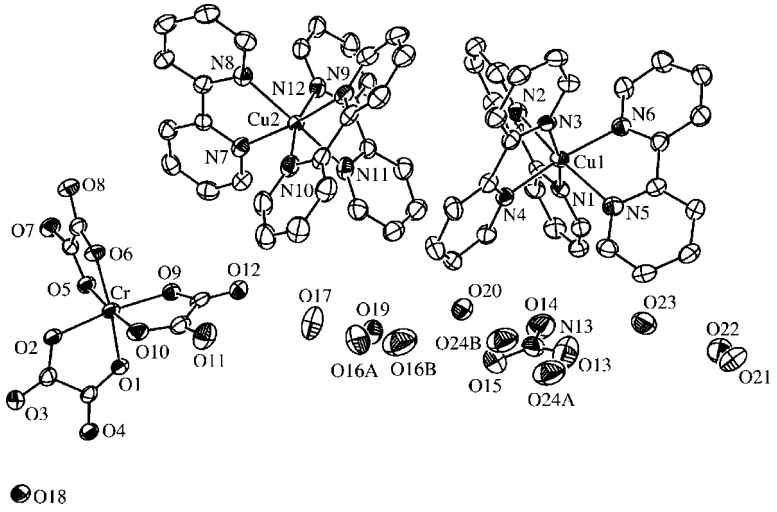

Figure 4. Asymmetric unit of **2** with atom numbering scheme and displacement ellipsoids drawn at the 50% probability level. Two water molecules are disordered over two positions, namely O16A and O16B, O24A and O24B. Occupancies of the oxygen atoms at the A and B sites are 0.84 and 0.16, respectively. Hydrogen atoms are omitted for clarity.

The crystal structure of **2** consists of hydrophobic and hydrophilic regions. The $[Cu(bpy)_3]^{2+}$ cations are arranged in honeycomb-like hydrophobic layers parallel to $(10\bar{1})$ (Figure 5). The cations are interconnected by the aromatic–aromatic interactions with C···C contact distances in the 3.417(9)–3.598(7) Å range. Each hydrophobic layer is sandwiched between two hydrophilic layers composed of $[Cr(C_2O_4)_3]^{3-}$, nitrate anions and water molecules; all of them are involved in an extensive hydrogen-bonding network (Table 4). The water molecule situated in each hexagonal cell of the "hydrophobic honeycomb" (O18) links two hydrophilic layers by forming hydrogen bonds with the oxalate ligands of $[Cr(C_2O_4)_3]^{3-}$ units from different layers (Figure 6). The crystal structure is additionally stabilised by

many C–H···O interactions at the interface between two layers.

The shortest Cu···Cu, Cu···Cr and Cr···Cr distances in the structure of **2** are 7.7558(10) Å [Cu2···Cu2(1 – *x*, –1/2 + *y*, 3/2 – *z*)], 8.0770(10) Å [Cu2···Cr(*x*, 1/2 – *y*, 1/2 + *z*)] and 10.7121(15) Å [Cr···Cr(1 – *x*, –*y*, 1 – *z*)], respectively.

## Spectroscopic Properties

### *Infrared Spectra*

Inspection of the IR spectra of **1** and **2** clearly indicates the presence of the absorption bands of the bidentate oxalate group, the bipyridine ligands, the ionic nitrate group and the water molecules in both complexes, in addition to the absorption bands of bis(bidentate) bridging oxalate group in compound **1**. In the spectrum of **1** the absorption bands at: 1717, 1705, 1672, 1663 $cm^{-1}$ [$\nu_{as}$(CO)], 1370, 1251 $cm^{-1}$ [$\nu_s$(CO)] and 801, 795 $cm^{-1}$ [δ(OCO)] are characteristic of bidentate oxalate,[23] whereas those due to the bis(bidentate) bridging oxalate at 1625 $cm^{-1}$ [$\nu_{as}$(CO)], 1338 $cm^{-1}$ [$\nu_s$(CO)] and 817 $cm^{-1}$ [δ(OCO)] agree well with the values reported for dinuclear[8] or tetranuclear[15b] bis(bidentate) bridging oxalate $Cu^{II}Cr^{III}$ complexes. The latter three bands are absent from the spectrum of **2**, and those originating from the bidentate oxalate ligand are found at similar positions as those observed in **1** (see Exp. Sect.).

### *Electronic Spectra*

Electronic spectroscopic data for **1** and **2** were obtained from aqueous solutions and are presented in Table 5. Data for $[Cu(bpy)_3](NO_3)_2{\cdot}6H_2O$ and $K_3[Cr(C_2O_4)_3]{\cdot}3H_2O$ are included for comparison. For the new complexes, the spectra were also recorded as KBr pellets, but this method resulted in essentially the same UV/Vis absorption maxima as those recorded in solution, which indicates that the structures of the complex ions in **1** and **2** are preserved in aqueous media.

The electronic spectra of **1** and **2** exhibit very similar patterns, which confirms the similarity of the local coordination environments around the metal centres in the two complexes. The spectra show the superposition of bands characteristic for both the $Cu^{II}$ and $Cr^{III}$ six-coordinate ions. In the visible region, they are dominated by a broad absorption band with a pronounced shoulder on the lower energy side (of the spectra), which corresponds to the presence of a $Cu^{II}$ ion in a more or less distorted octahedral environment. The unsymmetrical absorption bands for **1** and **2**, having maxima at ca. 715 and ca. 675 nm, respectively, are in good agreement with the spectrum of the starting $[Cu(bpy)_3](NO_3)_2{\cdot}6H_2O$ compound (Table 5), which must have essentially a distorted octahedral geometry. The type of the distortion of the $[Cu(bpy)_3]^{2+}$ ion is significantly dependent on the counteranion present,[18–20] and, in general, does not influence a lot the position of the band maxima. Therefore, the shift of the main absorption maximum in the spectrum of **1** towards the lower energy side relative to the spectrum of **2** could be perceived as a consequence of the different chromophores present in **1** and **2**, namely $[Cu^{I}{}^{I}N_4O_2]$ and $[Cu^{II}N_6]$ (nitrogen ligands exerting higher field strength), rather than as a result of somewhat different geometrical parameters found for $Cu^{II}$ in the two complexes (see Description of the Structures). The presence of an octahedrally coordinated $Cr^{III}$ ion is indicated by the two shoulders, one appearing at the higher energy side of the main visible absorption band (at ca. 565 and 580 nm for **1** and **2**, respectively) and the other observed at the lower energy side of the strong UV band of the spectra (at ca. 415 nm in both cases). The two shoulders in the spectra of **1** and **2** agree well in positions and intensities with the two main absorption bands in the electronic spectrum of $K_3[Cr(C_2O_4)_3]{\cdot}3H_2O$ (maxima appearing at 420 and 570 nm) and can account for the two spin-allowed d–d transitions, $^4A_{2g}(F) \rightarrow {}^4T_{1g}(F)$ and $^4A_{2g}(F) \rightarrow {}^4T_{2g}(F)$, in the octahedral ligand field of a $d^3$ configuration. An extremely narrow and very weak band observed at ca. 700 nm in both spectra could be ascribed to the spin-forbidden $^4A_{2g} \rightarrow {}^2T_{2g}(F) + {}^2E_g$ transition, characteristic of chromium(III) six-coordinate compounds.

Very strong absorptions (with ε of the order of magnitude of several tens of thousands) in the UV region of the spectra (at ca. 240 and ca. 300 nm) originate from ligand-specific and charge-transfer metal-to-ligand transitions.[24,25]

## TG Analysis

As is evidenced from the thermogravimetric analysis, the thermal behaviour of the two compounds is significantly different. Complex **1**, with bridging oxalate groups, is thermally more stable than complex **2**, in both synthetic air and under nitrogen. In synthetic air, the decomposition of **1** starts only after 170 °C by a distinctive step visible in the TG curve and corresponding to the loss of approximately one water molecule (calcd. 1.57%; found 1.75%). The next large step (ca. 58%) in the decomposition curve, in the tem-

perature range of ca. 200–300 °C, comprises the removal of bipyridine molecules together with the $NO_3^-$ group. Decomposition of the oxalate groups proceeds in a rather narrow temperature range of 300–400 °C as a strongly exothermic process. Afterwards, the remaining mass stays constant and corresponds to a mixture of copper(II) and chromium(III) oxides.

The elimination of water molecules in **2** proceeds in two well-separated steps taking place in the temperature intervals 40–105 °C and 110–145 °C, both followed by an endothermic peak in the DTA curve. In the first step, six lattice water molecules are expelled (calcd. 6.75%; found 7.05%), the remaining three (calcd. 3.37%; found 3.62%) are lost at higher temperature. The further course of the decomposition process follows that of complex **1**.

## Magnetic Properties

The results of magnetic measurements on **1** and **2** are shown in Figure 7, in terms of the dependence of the product of molar susceptibility and temperature, $\chi_M T$, on temperature. The value of $\chi_M T$ for **1** at temperatures above 50 K is almost constant at an average of 2.84 $cm^3 mol^{-1} K$. This corresponds to the effective magnetic moment per molecule $\mu = 4.77\beta$, where $\beta$ stands for the Bohr magneton. Generally, the spin-only value of the effective magnetic moment for three uncoupled spins is obtained according to the expression:

$$\mu = \beta\sqrt{g_1^2 S_1(S_1 + 1) + g_2^2 S_2(S_2 + 1) + g_3^2 S_3(S_3 + 1)}$$

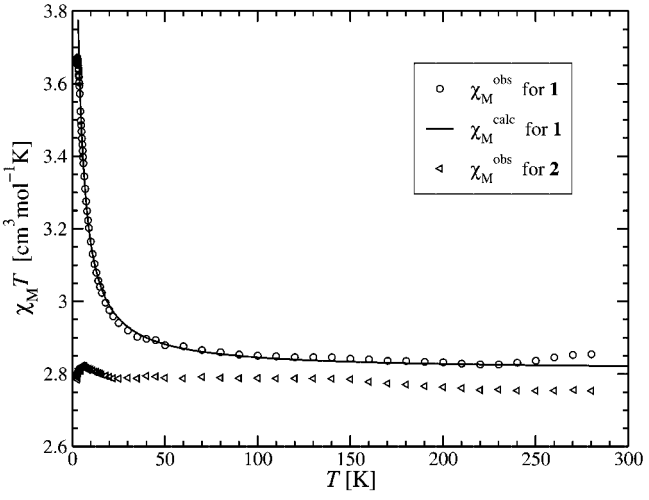

Figure 7. Plots of $\chi_M T$ vs. $T$ for compounds **1** and **2**. The solid line represents the curve of best fit.

For compound **1**, with ($S_{Cu1}$, $S_{Cr}$, $S_{Cu2}$) = (1/2, 3/2, 1/2) and taking $g_{Cu} = g_{Cr} = 2$, the above expression gives a value of $\mu = 4.58\beta$. The measured value is slightly higher and corresponds to $g_{Cu,Cr} = 2.08$. As shown in Figure 7, on cooling the compound below 50 K, the $\chi_M T$ product increases rapidly, and at 2.8 K it attains a value of 3.67 $cm^3 mol^{-1} K$, corresponding to $\mu = 5.42\beta$. This increase of $\chi_M T$ points to the emergence of a ferromagnetic interaction. Below 2.8 K, a very slight decrease of $\chi_M T$ is observed.

The value of the $\chi_M T$ product for **2** at temperatures above 30 K is almost constant and equals 2.77 $cm^3 mol^{-1} K$, which is very close to that of **1**. On cooling the sample below 30 K, first an increase in $\chi_M T$ was observed, but this increase was much smaller than the corresponding increase for **1**. A value of 2.82 $cm^3 mol^{-1} K$ was reached at 5.7 K. With further cooling, the $\chi_M T$ product decreased abruptly to 2.79 $cm^3 mol^{-1} K$ at 3 K. The room temperature effective magnetic moment per molecule for **2** is $\mu = 4.71\beta$. The corresponding $g$ factor which gives this value of $\mu$ for the (1/2, 3/2, 1/2) uncoupled spin system is $g_{Cu,Cr} = 2.06$.

The good linear dependences of the reciprocal magnetic susceptibilities, $\chi_M^{-1}$, on temperature (above 50 K) give the Weiss constants ($\theta = 0.8 \pm 0.1$ K for **1** and $\theta = 0.3 \pm 0.1$ K for **2**) which point to a negligible long-range ordering interaction. The absence of a 3D interaction is also in agreement with the value of the effective molecular magnetic moments at the measured temperatures. Therefore, the observed ferromagnetic interaction should be analyzed on the molecular level.

On the basis of the structure of the compound **1** and the magnetic properties of $Cu^{II}$ and $Cr^{III}$ ions, it is reasonable to write the interaction Hamiltonian as in Equation (1):

$$\mathbf{H}_{INT} = -J(S_{Cu1}S_{Cr} + S_{Cu2}S_{Cr}) \quad (1)$$

where $J$ is the exchange interaction between $Cu^{II}$ and $Cr^{III}$ ions in the same molecule, whereas $S$ is the spin operator for the ions labelled by indices.

In the above Hamiltonian only the isotropic Heisenberg exchange term appears, as the $Cu^{II}$ ion does not have zero-field splitting, and for the $Cr^{III}$ ion it is negligible in a first approximation,[1] as shown by the observed magnetic and structural properties. Therefore, the anisotropic and antisymmetric exchange terms are omitted.

Taking $g_{Cu} = g_{Cr} = g$, the following formula is obtained [Equation (2)]:

$$\chi_M = \frac{N\beta^2}{4k}\cdot\frac{g^2}{T}\cdot\frac{10 + e^{-\frac{5J}{2T}} + 10e^{-\frac{J}{T}} + 35e^{\frac{3J}{2T}}}{2 + e^{-\frac{5J}{2T}} + 2e^{-\frac{J}{T}} + 3e^{\frac{3J}{2T}}} \quad (2)$$

The nonlinear fitting of the susceptibility vs. temperature dependence for **1** in the temperature range 2.8–300 K gave the following results: $J = +1.20$ $cm^{-1}$, $g = 2.07$. The discrepancy factor $R$, defined as $R = \Sigma[(\chi_M T)_{obsd.} - (\chi_M T)_{calcd.}]^2 / \Sigma[(\chi_M T)_{obsd.}]^2$, equals $1.8 \cdot 10^{-5}$. A small decrease of the magnetic moment below ca. 2.5 K may be generally attributed to an intermolecular antiferromagnetic interaction and/or a zero-field splitting on $Cr^{III}$.[8,10a]

In order to describe the mechanism of the spin-exchange interaction in oxalate-bridged transition-metal complexes, several models have been considered.[26–28] According to these models only a strict orbital orthogonality results in a ferromagnetic interaction. In the structure of **1** (Figure 1)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the O1 and O1$^{i}$ atoms from the bridging oxalate groups are located in the equatorial planes [consisting of the O1, N2, N3 and N4 atoms for Cu and O1$^{i}$, N2$^{i}$, N3$^{i}$ and N4$^{i}$ for Cu$^{i}$ ($i = 1 - x, y, 1/2 - z$)] of the distorted Cu octahedra, whereas the O2 and O2$^{i}$ atoms from the corresponding bridging oxalate ligands occupy the apical positions. The significantly shorter Cu–O1 bond relative to the Cu–O2 bond (Table 1) indicates a strong orbital interaction in the equatorial planes of the two Cu coordination polyhedra, which are mutually related by the twofold axis through the chromium atom. It is clear that the unpaired electron on each copper(II) ion should be described by the $d_{x^2-y^2}$ as the highest energy orbital[1] that will interact with the σ-type oxygen orbitals, forming one of the magnetic orbitals. Simultaneously, the chromium(III) $t_{2g}$ orbitals, with three unpaired electrons, interact with the π-type oxygen orbitals, also resulting in magnetic orbitals. Consequently, a ferromagnetic spin coupling results from the orthogonality of the magnetic orbitals involved. A similar explanation was given for the appearance of a ferromagnetic interaction in [(bpy)($C_2O_4$)Cr(μ-$C_2O_4$)Cu(Hfsaaep)($H_2O$)]·2$H_2O$.[16] In the absence of necessary symmetry conditions, the magnetic interaction in $Cu^{II}Cr^{III}$ oxalate-bridged complexes is antiferromagnetic.[10a,15] For the ferromagnetic $Cu^{II}Cr^{III}Cu^{II}$ compounds mentioned in the introduction,[13a,13b] the values for $J$ were found to be higher than that for **1**. Because the crystal structures of these complexes are still unknown, it is not possible to comment on their $J$ values. Structurally, the coordination environment of $Cu^{II}$ in **1** is similar to that found in the dinuclear compound [(bpy)($C_2O_4$)Cr(μ-$C_2O_4$)-Cu(Hfsaaep)($H_2O$)]·2$H_2O$, for which the ferromagnetic spin-coupling constant $J = +1.4\ cm^{-1}$ (using $\mathbf{H}_{INT} = -JS_{Cu}S_{Cr}$) has been measured.[16] The ferromagnetic interaction with $J = +2.8\ cm^{-1}$ (using $\mathbf{H}_{INT} = -2JS_{Cu}S_{Cr}$) has also been found for the dinuclear complex [Cr(salen)(μ-$C_2O_4$)Cu(acpy)].[8] The exchange constant ($J = +1.2\ cm^{-1}$) obtained for **1** is comparable to these two values.

Appearance of a slight increase followed by a slight decrease of $\chi_M T$ for the compound **2** when lowering the temperature may come from the zero-field splitting on $Cr^{III}$ and/or from a 3D interaction effect. However, it is not quantitatively well understood at present and is the subject of further investigations.

## Conclusion

We have prepared two new heterometallic ($Cu^{II}$ and $Cr^{III}$) complexes. In **1**, metal atoms are oxalate-bridged in the trinuclear [{Cu(μ-$C_2O_4$)(bpy)$_2$}$_2$Cr($C_2O_4$)]$^+$ cation, whereas **2** consists of two [Cu(bpy)$_3$]$^{2+}$ cations and two {[Cr($C_2O_4$)]$^{3-}$ and $NO_3^-$} anions. Compound **1** is the first trinuclear $Cu^{II}Cr^{III}Cu^{II}$ complex with solved crystal structure. This fact allowed us to explain the pathway of a ferromagnetic exchange interaction between the $Cu^{II}$ and $Cr^{III}$ metal ions mediated through the bridging oxalate groups. We are currently engaged in a more detailed study aiming to understand the magnetic behaviour of **2** at low temperature.

## Experimental Section

**General Remarks:** All the reagents used in the syntheses were purchased from commercial sources and used without further purification. K$_3$[Cr($C_2O_4$)$_3$]·3$H_2O$ and [Cu(bpy)$_3$]($NO_3$)$_2$·6$H_2O$ were prepared according to the literature methods.[29,30]

**Synthesis of [{Cu(μ-$C_2O_4$)(bpy)$_2$}$_2$Cr($C_2O_4$)]$NO_3$·$H_2O$ (1):** To an aqueous solution (15 mL) of K$_3$[Cr($C_2O_4$)$_3$]·3$H_2O$ (146.7 mg, 0.301 mmol) were added an aqueous solution (12 mL) of $Cu(NO_3)_2$·3$H_2O$ (145.8 mg, 0.603 mmol) and an ethanolic solution (10 mL) of bpy (188.4 mg, 1.206 mmol) dropwise with stirring at room temperature. Slow concentration of the resulting solution at ambient conditions led to the formation of dark-green single crystals of **1** as the only solid with a yield of 297.1 mg (86%). $C_{46}H_{34}CrCu_2N_9O_{16}$ (1147.90): calcd. C 48.13, H 2.98, N 10.98; found C 47.74, H 3.14, N 10.93. IR data (KBr): $\tilde{\nu}$ = 3434 (w, br), 3073 (w), 1717 (m), 1705 (m), 1672 (vs), 1663 (vs), 1625 (vs), 1607 (m), 1598 (s), 1493 (m), 1474 (m), 1444 (s), 1415 (s), 1382 (vs), 1370 (sh), 1338 (m), 1314 (m), 1276 (m), 1251 (m), 1226 (m), 1175 (w), 1162 (w), 1105 (w), 1029 (w), 1013 (w), 898 (w), 817 (sh), 801 (m), 795 (m), 773 (vs), 732 (m), 534 (m), 460 (w), 419 (m), 410 (m), 304 (w) $cm^{-1}$.

**Synthesis of [Cu(bpy)$_3$]$_2$[Cr($C_2O_4$)$_3$]$NO_3$·9$H_2O$ (2):** To an aqueous solution (15 mL) of K$_3$[Cr($C_2O_4$)$_3$]·3$H_2O$ (103.3 mg, 0.212 mmol) was added an aqueous solution (10 mL) of [Cu(bpy)$_3$]($NO_3$)$_2$·6$H_2O$ (162.0 mg, 0.212 mmol) dropwise with stirring at room temperature. The green-blue plate-like crystals of **2** were formed in the solution in a period of three days. The yield was 125.8 mg (37%, based on Cr). $C_{66}H_{66}CrCu_2N_{13}O_{24}$ (1604.40): calcd. C 49.41, H 4.15, N 11.35; found C 49.14, H 4.40, N 11.71. IR data (KBr): $\tilde{\nu}$ = 3415 (m, br), 3074 (w), 1708 (m), 1681 (s), 1650 (m), 1594 (m), 1491 (w), 1472 (m), 1441 (s), 1384 (vs), 1372 (m), 1312 (w), 1257 (sh), 1248 (m), 1176 (w), 1158 (w), 1101 (w), 1062 (w), 1043 (w), 1015 (m), 910 (w), 806 (m), 797 (m), 776 (vs), 734 (m), 650 (m), 538 (m), 475 (w), 411 (m), 307 (w) $cm^{-1}$.

When the reaction of K$_3$[Cr($C_2O_4$)$_3$]·3$H_2O$ and [Cu(bpy)$_3$]($NO_3$)$_2$·6$H_2O$ was performed in a molar ratio of 1:2, crystals of both **1** and **2** formed simultaneously.

**Physical Techniques:** Infrared absorption spectra were recorded by using KBr pellets with an ABB Bomem FT model MB 102 spectrometer, in the 4000–200 $cm^{-1}$ region. Thermogravimetric measurements were carried out with a Shimadzu DTG-60 analyzer, with a heating rate of 10 °C $min^{-1}$ in a stream of synthetic air. Electronic spectra were measured with a Cary 50 Probe spectrophotometer. Solution spectra were recorded in $H_2O$ by using 1-cm silica cells. For solid-state spectra, the samples were prepared as KBr pellets which were mounted in the pathway of the radiation beam. A weighed pure-KBr pellet was used as the reference.

Magnetic moments were measured with a commercial SQUID magnetometer (MPMS-5, Quantum Design). Measurements were performed in the temperature range 1.8–290 K at an applied magnetic field of 1 T. The field dependence of the magnetic moment was checked up to 5 T, and both samples showed linearity up to more than 1 T even at 2 K, so the susceptibilities analyzed here are field-independent. The calculated molar magnetic susceptibilities were corrected for the diamagnetic contributions of the constituent atoms, which are $-560 \cdot 10^{-6}\ cm^3\ mol^{-1}$ for **1** and $-874 \cdot 10^{-6}\ cm^3\ mol^{-1}$ for **2** according to Pascal's constants.[31] Also, a correction was made for temperature-independent paramagnetism, which is $110 \cdot 10^{-6}\ cm^3\ mol^{-1}$ for $Cr^{III}$ and $60 \cdot 10^{-6}\ cm^3\ mol^{-1}$ for $Cu^{II}$ ions.[10d]

**X-ray Crystallographic Study:** Each of the selected single crystals of **1** and **2** was glued on the tip of a glass fibre and coated with a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thin layer of silicone grease. The X-ray data were collected at 100(1) K by $\omega$ scans with an Oxford Diffraction Xcalibur 3 CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data reduction including the absorption correction was performed with the CrysAlis software package.[32] Crystal data, experimental conditions and final refinement parameters are summarized in Table 6. Solution, refinement and analysis of the structures was performed by using the programs integrated in the WinGX system.[33] Both structures were solved by direct methods (SIR92)[34] and refined by the full-matrix least-squares method based on $F^2$ against all reflections (SHELXL-97).[35] All non-hydrogen atoms were refined anisotropically. The anisotropic displacement parameters of the disordered atoms were restrained during refinement, except those of the atoms C23B in **1** and O24B in **2** which were constrained to equal the anisotropic displacement parameters of C23A and O24A, respectively (EADP). Additionally, in **1**, the geometries of the two parts of the disordered non-bridging oxalate ligands were restrained to be equal. Furthermore, the atoms in each of the sets {O5, O6A, C23A, C23B($1-x$, $y$, $1/2-z$)} and {O5, O6B, C23B, C23A($1-x$, $y$, $1/2-z$)} were restrained to be coplanar. In both structures, the hydrogen atoms bound to the carbon atoms were treated as riding in idealized positions, with C–H = 0.95 Å, and displacement parameters were assigned as $U_{iso}(H) = 1.2U_{eq}$ of the attached C atom. Initial positions of the water H atoms in **1** as well as those of some of the H atoms of the water molecules in **2** were found in the difference Fourier map. Other modelled water H atoms of **2** were obtained by combined geometric and force-field calculations on the basis of hydrogen-bonding interactions (CALC-OH).[36] For all water H atoms, the O–H vector directions were kept fixed, while the O–H distances were restrained (DFIX 0.85 0.02) during refinement. Prior to applying the mentioned constraints and restraints to the water molecules, those having the calculated H atoms were additionally refined as rigid bodies by using the O atoms as the pivot ones. Displacement parameters of all water H atoms were assigned as $U_{iso}(H) = 1.5U_{eq}$ of the joined O atom. Geometrical calculations were performed using PLATON[37] and the figures were produced by using ORTEP-3[38] and SCHAKAL99.[39]

## COVER PICTURE

**The cover picture shows** the two types of complexes formed by the reaction of diethylzinc and tripodal monoanionic amine mono(phenolate) ligand precursors bearing two methoxy sidearm donors. The ligand precursor bearing bulky (*t*Bu) phenolate substituents leads cleanly to a mono(ethyl) mononuclear zinc complex in which the two methoxy sidearm donors are bound to the metal atom as confirmed by spectroscopic data and X-ray structure analysis. The ligand precursors bearing less bulky phenolate substituents lead cleanly to dinuclear pentacoordinate complexes that are bridged by phenolate oxygen atoms, and only one of the two sidearm donors is bound. Details are discussed in the article by M. Kol et al. on p. 2739 ff.

# Tetrahedra, Super-Tetrahedra, Bipyramids, Boxes and More: Polymetallic Clusters of Benzotriazole

**David Collison,[a] Eric J. L. McInnes,*[a] and Euan K. Brechin*[b]**

**Keywords:** Benzotriazole / Clusters / Transition metals / Large spin ground states / Single-molecule magnets

The syntheses, structures and magnetic properties of a host of polymetallic 3d transition-metal clusters made with the pro-ligand benzotriazole (BtaH) and its analogues are reported. These range from a family of tetradecametallic clusters with spin ground states as large as $S \approx 25$, to decametallic vanadium "boxes", to iron and manganese tetra- and super-tetrahedra, to hexaicosametallic manganese single-molecule magnets.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The synthesis and characterization of polynuclear clusters of paramagnetic metal ions has attracted intense study since the discovery that such molecules can display the phenomenon of single-molecule magnetism.[1] In these molecules there exists an energy barrier to the relaxation of the magnetization due to the combination of a large ground-state spin multiplicity and significant negative magnetoanisotropy. This imparts a molecular magnetic memory effect that can be observed as temperature- and sweep-rate-dependent hysteresis loops in $M$ vs. $H$ studies.[2]

Single-Molecule Magnets (SMMs) have many potential applications including high-density information storage in

which each bit of information is stored as the magnetization orientation of an individual molecule, and as qubits for quantum computation where the required arbitrary superposition of quantum states with opposite projections of spin are produced by either quantum tunneling of the magnetization (QTM), intermolecular exchange, or multi-frequency EPR pulses.[3]

Single-molecule magnetism spans areas as diverse as physics, theoretical chemistry, spectroscopy, materials chemistry and synthetic coordination chemistry, as demonstrated by the several hundred papers published on the topic over the last ten years. There are now several species displaying such behavior – formed by a multitude of successful synthetic strategies ranging from the self-assembly of 3d-metal carboxylate clusters, to molecular Prussian Blues, to heterometallic 3d–4f complexes and most recently to simple 4f monometallic species.[4] By far the most productive route has been by the self-assembly of 3d transition metals with flexible organic bridging ligands such as carboxylates and alkoxides. Here we describe some of our efforts toward the synthesis of large polymetallic 3d clusters using the ligand benzotriazole (and its analogues), including some of the largest nuclearity and highest-spin ground-state molecules known.

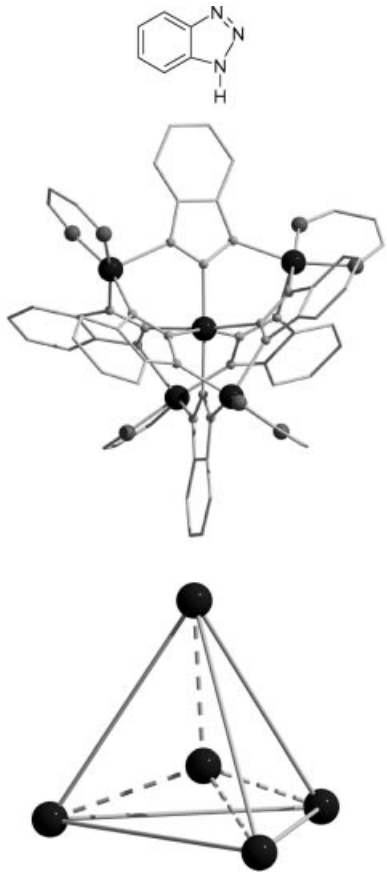

Figure 1. The structure of benzotriazole (BtaH, top); the structure of the complex $[Cu_5(Bta)_6(acac)_4]$ (middle); and its centered tetrahedral $\{Cu_5\}$ core (bottom). The $-CH_3$ groups of the $acac^-$ ligands have been removed for clarity.

Benzotriazole (BtaH, $C_6H_5N_3$; Figure 1) and substituted benzotriazoles are well established corrosion inhibitors for copper and its alloys,[5] and as a result the coordination chemistry of benzotriazoles with various $M^{2+}$ species has been thoroughly investigated, producing many new cluster compounds. Of these the most well-known and thoroughly studied are the family of compounds of general formula $[M_5(OH)_x(R)_{6-x}(L)_4(H_2O)_{4x}]$ [where M = Cu, Zn, Ni; R = $Bta^-$, $Me_2Bta^-$ (5,6-$Me_2$-$bta^-$); L = β-diketonate, $x$ = 0, 1].[6] These pentametallic species consist of a tetrahedral arrangement of four $M^{2+}$ ions centered on a fifth, with each $\mu_3$-benzotriazole spanning an edge of the tetrahedron (Figure 1). Magnetic studies have shown that weak antiferromagnetic exchange between the metals leads to spin ground states equal to that of the *"isolated"* central $M^{2+}$ ion.

Although a number of other $Ni^{2+}$,[7] $Cu^{2+}$,[8] $Hg^{2+}$,[9] $Re^{5+}$,[10] and $Ag^{+}$[11] complexes have been reported, the chemistry of BtaH and its derivatives with $M^{3+}$ species has, until now, not been investigated.

## Our Work

Despite the large numbers of $M^{2+}$ pentamers structurally characterized, only one "related" $M^{3+}$ pentamer has been reported.[12] The complex $[HNEt_3]_x[Fe_5O_2(OMe)_2(Bta)_4(BtaH)_{1-x}(MeOH)_{5-x}Cl_{5+x}]$ (1, $x$ = 1, 0; Figure 2) consists of an elongated tetrahedral array of four $Fe^{3+}$ ions centered on a fifth. The central Fe ion is attached to the apical Fe ions by two $\mu_3$-$O^{2-}$ ions forming a $[Fe_5O_2]^{11+}$ core, with the two $OMe^-$ ligands bridging between the apical Fe ions on each short edge of the elongated tetrahedron and the $Bta^-$ ligands bridging in a $\eta^1$:$\eta^1$:$\mu_2$-fashion between the central Fe ion and the apical Fe ions along the long edges of the elongated tetrahedron. The coordination geometry of the apical Fe ions is completed by a combination of terminal $Cl^-$ and MeOH ligands. The central Fe is antiferromagnetically coupled to the peripheral Fe ions resulting in an $S$ = 15/2 spin ground state (Figure 2), with the best fit obtained for the two independent exchange interactions being $J_1 = -7.3\ cm^{-1}$, $J_2 = 8.6\ cm^{-1}$.[12] As expected, this suggests that the interaction between the central Fe ion and the apical Fe ions by the $\mu_3$-$O^{2-}$ ions is antiferromagnetic and the interaction between the two apical Fe centers mediated by the $\mu_2$-$MeO^-$ is ferromagnetic. A spin ground state of $S$ = 15/2 can thus be rationalized by assuming the central Fe is "spin-up" and the apical Fe ions are "spin-down" (Figure 2).

The only other iron cluster containing benzotriazole is the tetradecametallic complex $[Fe_{14}O_6(OMe)_{18}(Bta)_6Cl_6]$ (**2**, Figure 3) – formed from the reaction between $[Fe_3O(OAc)_6(H_2O)_3]Cl$ and BtaH in MeOH at 100 °C in a Teflon-lined autoclave.[13] The structure comprises a hexa-capped hexagonal bipyramid of $Fe^{3+}$ ions with caps on alternate faces (Figure 4). The $Bta^-$ ligands coordinate in the maximal $\mu_3$-mode to form two $\{Fe_4(Bta)_3\}$ moieties which sandwich a central $\{Fe_6\}$ ring, bridged by eighteen $\mu_2$-$OMe^-$ and six $\mu_4$-$O^{2-}$ ions. The $\{Fe_4(Bta)_3\}$ fragment is reminiscent of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

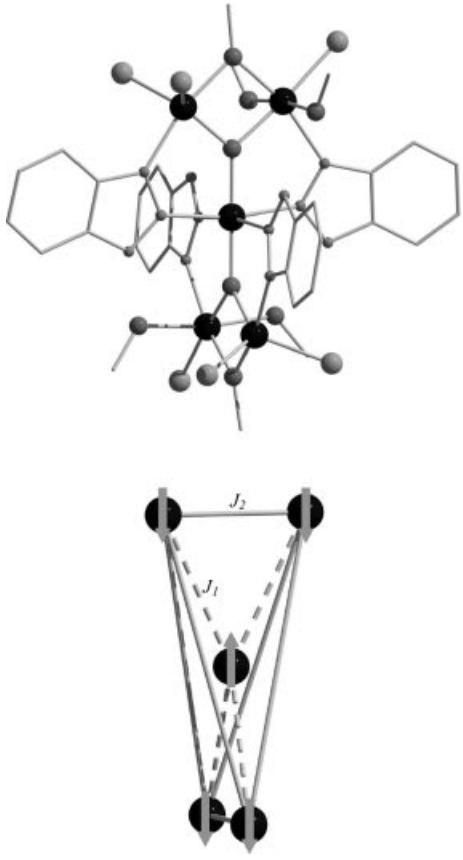

Figure 2. The molecular structure of complex **1** and its elongated, centered tetrahedral $\{Fe_5\}$ core showing the two independent exchange interactions and the resultant spin topology.

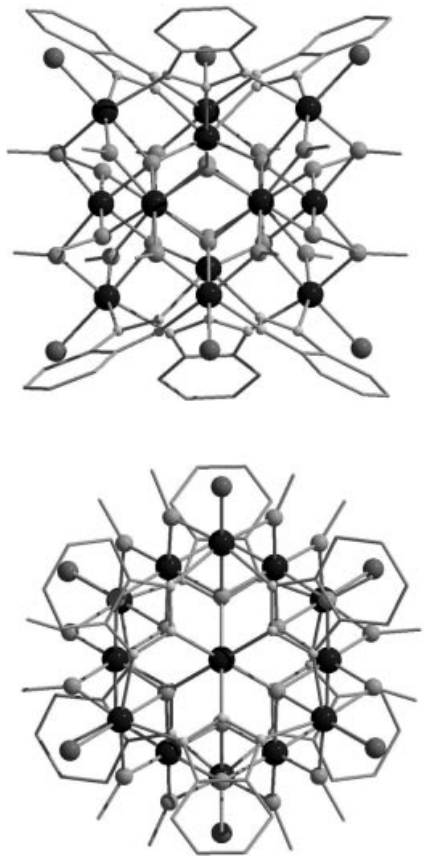

Figure 3. Molecular structure of $[Fe_{14}O_6(OMe)_{18}(Bta)_6Cl_6]$ (**2**) viewed perpendicular (top) and parallel (bottom) to the apical Fe ions.

$M^{2+}$ pentamers above (Figure 1) and here they act to stop the growth of the Fe–oxide–alkoxide cluster. Complex **2** exhibits one of the largest spin ground states yet seen with magnetization data suggesting $S \approx 25$ and $D \approx 0$ cm$^{-1}$ (Figure 5).[13–15] An $S = 25$ ground state can be rationalized from competing antiferromagnetic exchange interactions within the cluster: the relative magnitude of the four chemically distinct, nearest-neighbor exchange pathways via $\mu_4$-$O^{2-}$ ions and/or $\mu^2$-$OMe^-$ ions can be predicted on the basis of the Fe–O–Fe angles (Figure 4). The Fe(apex)–Fe(face cap) [$J_1$] and Fe(apex)–Fe(ring) [$J_3$] interactions are expected to be the most antiferromagnetic because they are defined by the largest angles and therefore dominate over the much weaker antiferromagnetic Fe(face-cap)–Fe(ring) [$J_2$] and Fe(ring)–Fe(ring) [$J_4$] interactions. This would lead to a very simple spin structure in the ground state with the two apical Fe ions of the bipyramid "spin down" and all other Fe ions "spin up". Conventional fitting of the experimental magnetic susceptibility data to a spin Hamiltonian to derive $J_1$–$J_4$ is not possible, but DFT calculations in tandem with Monte Carlo simulations support this model giving: $J_1 = -22$ cm$^{-1}$, $J_2 = -8.7$ cm$^{-1}$, $J_3 = -29.7$ cm$^{-1}$ and $J_4 = -3.7$ cm$^{-1}$.[14]

Despite its huge ground state S, **2** does not behave as an SMM. This is due to the near isotropic nature of this ground state ($D \approx 0$). However, this is interesting in itself as it gives rise to an unusually large magnetocaloric effect (MCE) below 10 K.[15] The 51-fold degeneracy of the (isotropic) ground state gives rise to very large magnetic entropy changes $\Delta S_m$ on magnetization. If isothermal magnetization (at temperature $T_i$) is followed by adiabatic demagnetization then magnetic cooling can be achieved with a characteristic temperature change $\Delta T_{ad}$. The huge spin of **2** (combined with an additional entropy contribution from low-lying excited states) gives rise to $\Delta S_m(T)$ and $\Delta T_{ad}(T)$ values ($\Delta T_{ad} = 5.8$ K for $T_i = 6$ K) that are not only much larger than those displayed by other molecular clusters but more than 30% larger than any other material for $T_i <$ 10 K, including the best intermetallic materials such as $[(Dy_xEr_{1-x})Al_2]$.[16] Thus **2** has potential applications in low temperature magnetic refrigeration.

The analogous clusters $[Cr_{14}O_6(OMe)_{18}(Bta)_6Cl_6]$ (**3**) and $[V_{14}O_6(OMe)_{18}(Bta)_6Cl_6]$ (**4**) can be made in an identical manner,[17] but in both cases magnetic measurements indicate the complexes to have $S = 0$ spin ground states. This (presumably) arises because of small changes in the relative magnitudes of the four exchange interactions such that the order $|J_3| > |J_1| > |J_2| > |J_4|$ seen in $[Fe_{14}]$ is not maintained in either $[Cr_{14}]$ or $[V_{14}]$.[17] If the reaction mixture leading to **4** is exposed to atmospheric $O_2$ then $[(V^{IV}O)_6V^{III}{}_8O_6(OMe)_{18}(Bta)_6]$ (**5**) can be isolated, in which each face cap is oxidized from a $[V^{III}–Cl]^{2+}$ moiety to the isoelectronic

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

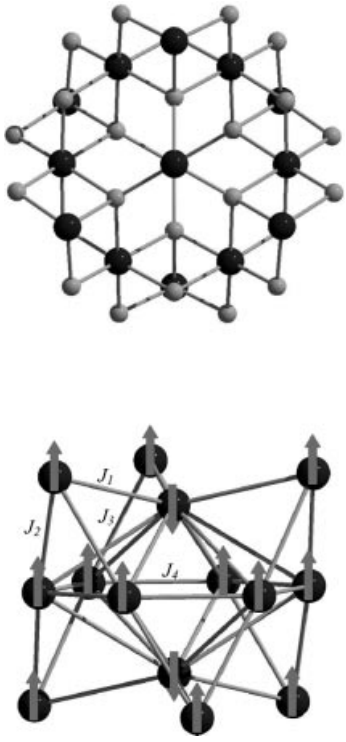

Figure 4. The metal–oxygen core of **2** viewed parallel to the apical Fe ions (top); the hexacapped hexagonal bipyramidal metallic skeleton of **2** (bottom) showing the four independent exchange interactions and the resultant spin topology.

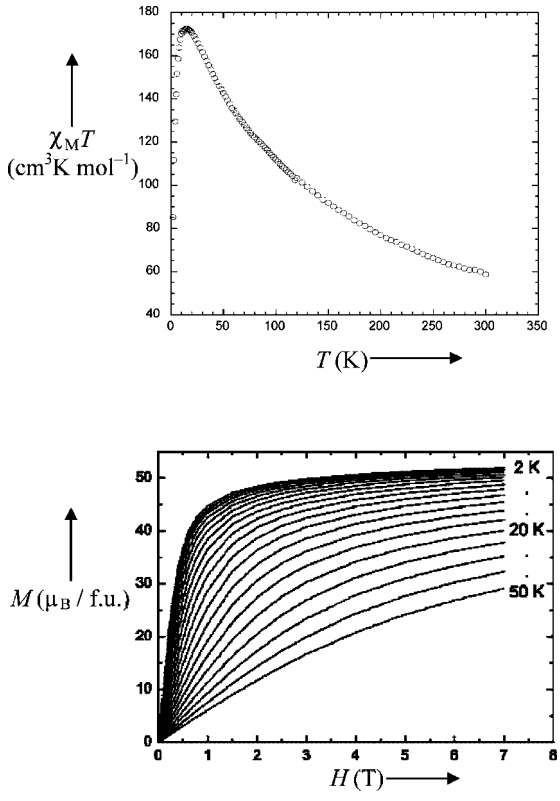

Figure 5. Plot of $\chi_M T$ vs. $T$ for complex **2** in the 300–1.8 K temperature range, and isothermal $M(H)$ curves measured in the temperature range 2–50 K.

vanadyl $[V^{IV}{=}O]^{2+}$ unit. If these reactions are performed under non-solvothermal, lower temperature conditions then the "box-like" complex $[V^{IV}_8V^{III}_2O_8(OH)_4(OMe)_{10}(Bta)_8]$ (**6**) forms (Figure 6).[18] The complex consists of a square-prism of vanadyl ions where the square faces are bridged through the 1,3-bridging mode of the $Bta^-$. The "box" surrounds two $V^{III}$ ions that form a $[V^{III}_2(OMe)_2]$ dimer that bind to the vertices of the square-prism by the four $\mu_3$-hydroxides. The topology, and the highly reduced $[V^{IV}_8V^{III}_2]$ state, of **6** is unique for a polyoxoalkoxovanadate. This chemistry also highlights the importance of exploring a wide temperature range in cluster chemistry – under the higher temperature, solvothermal conditions this reaction gives a less oxidized, higher nuclearity product.

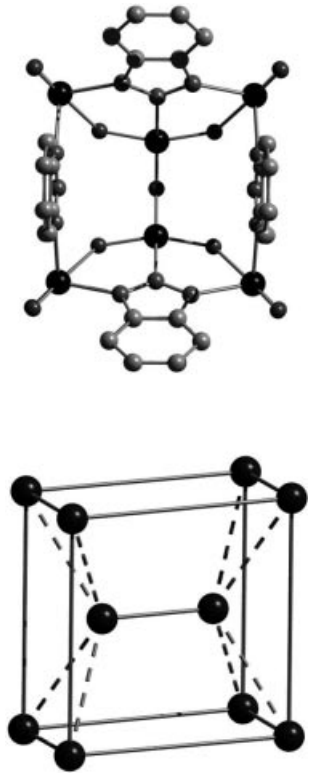

Figure 6. The molecular structure of complex **6** (top); and the $\{V^{IV}_8\}$ box encapsulating the $\{V^{III}_2\}$ fragment (bottom). Some of the $MeO^-$ ions have been removed for clarity.

The magnetic properties of **6** are dominated by strong antiferromagnetic interactions: the room temperature $\chi_M T$ value of 3.3 $cm^3{\cdot}K{\cdot}mol^{-1}$, is well short of the value expected for eight uncoupled $V^{4+}$ and two $V^{3+}$ ions, and is already rapidly decreasing with decreasing temperature. The low temperature value tends towards zero indicating a diamagnetic ground state for the cage. This strong antiferromagnetic coupling is consistent with the structure – very strong coupling is expected for the face-sharing $(VO)_2$ pairs on the short edges of the box.

The majority of Single-Molecule Magnets (SMMs) reported to date have been clusters containing $Mn^{3+}$ ions.[4,19] In each case the clusters have been made, at least initially, via the serendipitous assembly of Mn starting materials

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with flexible organic bridging ligands such as carboxylates or alkoxides. Manganese clusters often display "*unusually*" large spin ground states with respect to other 3d transition metals, and large and negative magnetoanisotropies resulting from the presence of Jahn–Teller distorted $Mn^{3+}$ ions. However this presents a synthetic problem: there are few *simple* readily available sources of $Mn^{3+}$. This has resulted in the use of two alternative techniques. The first is the use of the basic metal carboxylates of general formula, $[M_3O(RCO_2)_6L_3]^{0/+}$, which can contain either two or three $Mn^{3+}$ ions, and the second is the oxidation of $Mn^{2+}$ salts with permanganate, $MnO_4^-$.[4] Both of these techniques have been successful, particularly the former. An alternative approach is to use $MnF_3$. The main disadvantage of using metal fluorides is their relative insolubility and therefore the apparent need for more "complicated" synthetic procedures – indeed the majority of fluoride-containing clusters have been isolated at elevated temperatures.[20] For $MnF_3$ this insolubility can be easily overcome by using either a "melt" reaction whereby the BtaH acts as the solvent (MPt = 100 °C) in which the $MnF_3$ dissolves as the reaction proceeds,[21] or by the simple reflux of the reaction mixture in a particular solvent. For example the complex $[Mn^{III}{}_{26}O_{17}(OH)_8(OMe)_4F_{10}(Bta)_{22}(MeOH)_{14}(H_2O)_2]$ (**7**, Figure 7) is made by simply mixing $MnF_3$ and BtaH in MeOH at ca. 60 °C. The rather complicated $[Mn^{III}{}_{26}O_{17}(OH)_8(OMe)_4]^{32+}$ core of **7** can be described as a central distorted tetra-face-capped octahedron either side of which are attached vertex-sharing tetrahedra. The $O^{2-}$ ions all bridge in their usual $\mu_3$-fashion, forming $\{Mn_3O\}^{7+}$ triangular units. The $OH^-$ ions are of two types: four are $\mu_3$-bridging and are situated within the tetra-face-capped octahedron, while the remaining ions are $\mu_2$-bridging and are situated both in the tetra-face-capped octahedron and within the two vertex-sharing tetrahedra. The 22 deprotonated $Bta^-$ ligands are of two types: four use all three nitrogens to bond to three $Mn^{3+}$ centers while the remaining 18 use only two nitrogen atoms to bond to two $Mn^{3+}$ centers, the third nitrogen atom H bonds to adjacent MeOH, $H_2O$ or $OH^-$ ligands. The four $MeO^-$ ions are all $\mu_2$-bridging, but rather unusually there are also two MeOH molecules which act as $\mu_2$-bridges, whilst the ten $F^-$ ions are bonded terminally. Fitting the magnetization ($M$ vs. $H$) data for complex **7** gives $S = 4$, $g = 2.0$ and $D = -0.90\ cm^{-1}$. Ac susceptibility measurements performed on **7** in the 1.8–4.00 K range show the presence of out-of-phase ac susceptibility signals, but no peaks. Low-temperature single-crystal studies performed on **7** on an array of micro-SQUIDS[22] show the time and temperature-dependent hysteresis loops indicative of single-molecule magnetism behavior (Figure 8). Below 1.2 K, hysteresis loops are observed in magnetization vs. field studies whose coercivities increase with decreasing temperature, at a sweep rate of 0.14 T/s. The loops do not show the step-like features associated with quantum tunneling of magnetization (QTM), and appear typical for a cluster with a distribution of energy barriers. The steps may be present but broadened out, due to the inherent disorder associated with the crystal of **7**,[21] resulting in a distribution of $Mn^{3+}$ environments. These observations have been reported for other large SMMs.[23] Relaxation data at very low temperatures were determined from dc relaxation decay measurements (Figure 9). The relaxation of crystals of SMMs is often very complicated, leading to non-exponential relaxation laws, and the $M/M_s$-vs-$t$ curves for **7** cannot be fitted by a simple-exponential, stretched-exponential or square-root law. In order to extract the temperature dependence of the mean relaxation time $\tau(T)$, it is necessary to use a single scaling function $f[t/\tau(T)]$.[24] This scaling analysis allows $\tau(T)$ to be determined without making any particular assumption about the relaxation law, and allows the mean relaxation time $\tau(T)$ to be extracted. Fitting of these data to the Arrhenius law (Figure 9) gives an effective mean barrier for the reversal of magnetization of approximately 15 K and a pre-exponential factor of $\tau_0 = 3 \cdot 10^{-9}$ s. Below ca. 0.2 K, the relaxation rates become temperature-independent, strongly suggesting the presence of QTM in the ground state. The experimentally derived $U_{eff}$ value of 15 K is comparable to the theoretical value ($U = S^2|D| \approx 21$ K). Indeed, $U$ is expected to be larger than $U_{eff}$ as the reversal of magnetization has two components: thermally activated relaxation over the barrier and quantum tunneling of magnetization (QTM) through the barrier.

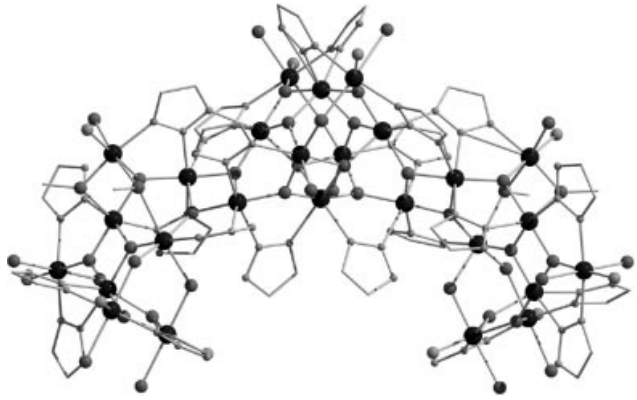

Figure 7. The molecular structure of complex **7**.

Repeating the reaction that produces complex **7** but in the presence of pyridine affords the decametallic complex $[Mn_{10}O_6(OH)_2(Bta)_8(py)_8F_8]$ (**8**), while the same reaction in the presence of triethylamine produces the trimetallic species $[NHEt_3]_2[Mn_3O(Bta)_6F_3]$ (**9**).[21,25] Complex **8** (Figure 10) consists of a "supertetrahedral" $[Mn^{III}{}_{10}]$ core bridged by six $\mu_3$-$O^{2-}$ ions, two $\mu_3$-$OH^-$ ions, four $\mu_2$-$F^-$ ions and eight $\mu_2$-$Bta^-$ ions, while complex **9** (Figure 11) has a structure analogous to that of the basic metal carboxylates of general formula $[M_3O(RCO_2)_6L_3]^{0/+}$, consisting of an oxo-centered metal triangle with $\mu_2$-$Bta^-$ ligands bridging each edge of the triangle and the fluoride ions acting as the terminal "L" ligands. Both complexes display dominant antiferromagnetic exchange interactions resulting in small spin ground states. For complex **9**, the best fit to the experimental $\chi_M T$ vs. $T$ data was obtained for the following pa-

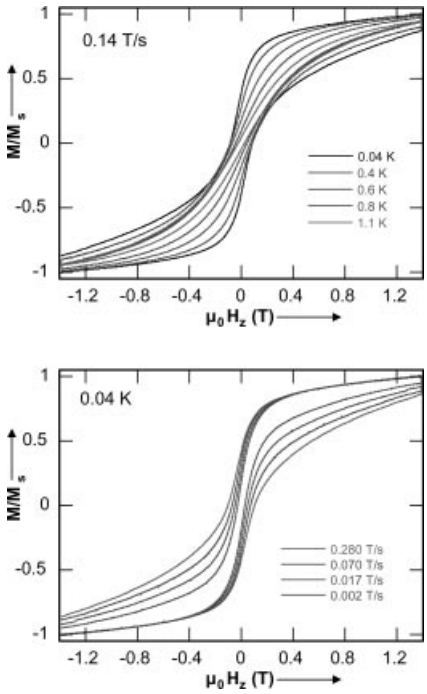

Figure 8. Magnetization ($M$) of **7** vs. applied magnetic field ($\mu_0 H$). The magnetization is normalized to its saturation value. The resulting hysteresis loops are shown at different temperatures and different field sweep.

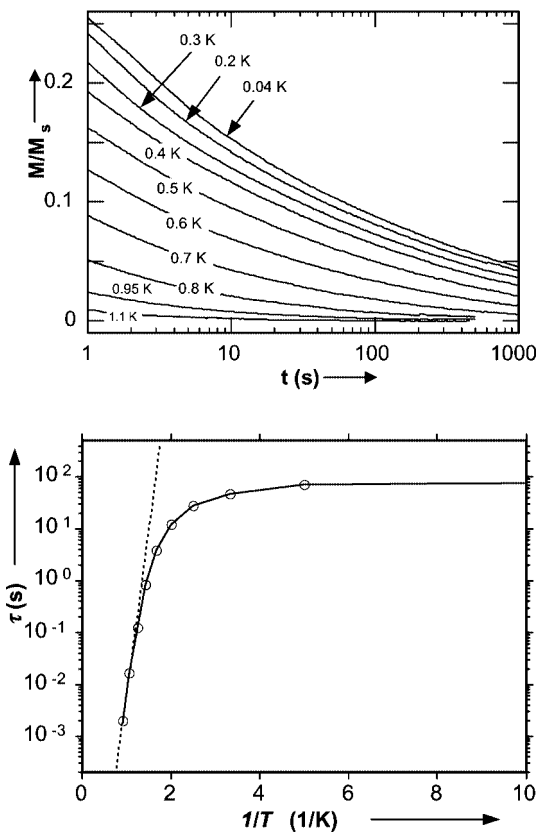

Figure 9. Relaxation data for **7** plotted as $M/M_s$ vs. time, $M$ is normalized to its saturation value (top); Arrhenius plot for **7** using dc decay data on a single crystal. The dashed line is the fit of the data in the thermally activated region.

rameters: $J_a = -5.01$ cm$^{-1}$; $J_b = +9.16$ cm$^{-1}$ and $g = 2.00$, resulting in an $S = 2$ spin ground state. DFT calculations, however, suggest an $S = 0$ ground state with $J_a = -2.95$ cm$^{-1}$ and $J_b = -2.12$ cm$^{-1}$ with two $S = 1$ states at 1.46 cm$^{-1}$ and 5.9 cm$^{-1}$, and an $S = 2$ state at 6.1 cm$^{-1}$ above the ground state.[21] The presence of low-lying excited states leads to obvious problems when trying to satisfactorily fit the experimental data. The ground state of this molecule can be changed from $S = 0$ to $S = 2$ by small changes in the exchange interaction $J_b$. The ratio of $J_a/J_b$ vs. the Eigen values obtained for these exchange parameters is shown in Figure 11. For a value of $J_a/J_b < 1$, the ground state spin value varies from $S = 2$ to $S = 1$; for $J_a/J_b = 1$ the ground state becomes $S = 0$, and for $J_a/J_b > 1$ the ground state varies from $S = 0$ to $S = 2$. For the DFT calculated values, the $J_a/J_b$ ratio is found to be 1.37 and the ground state is $S = 0$. However, it is also clear that for $J_a/J_b > 1$ the energy levels are very closely separated, and the fact that the ground state depends on the ratio of $J_a/J_b$ reveals that a degree of spin frustration exists in the triangle. At lower and higher values of $J_a/J_b$ the degree of spin frustration is minimal, giving rise to an $S = 2$ ground state which can be accounted for by a simple pairwise exchange interaction. At intermediate values of $J_a/J_b$, spin frustration causes a net spin vector alignment, which cannot be accounted for by considering a simple pairwise exchange interaction, and the value of the ground state depends on the degree of spin frustration.[21,25]

By replacing BtaH with its dimethyl derivative ($Me_2$-BtaH; 5,6-dimethylbenzotriazole) in otherwise similar reactions to those above affords completely different clusters: the octametallic complex $[Mn_8O_4(OMe)_2(Me_2Bta)_6F_8$-

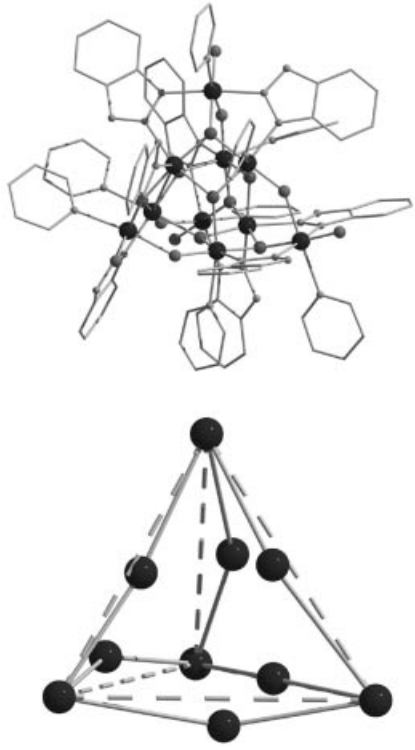

Figure 10. The molecular structure of complex **8** (top) and its supertetrahedral metallic core (bottom).

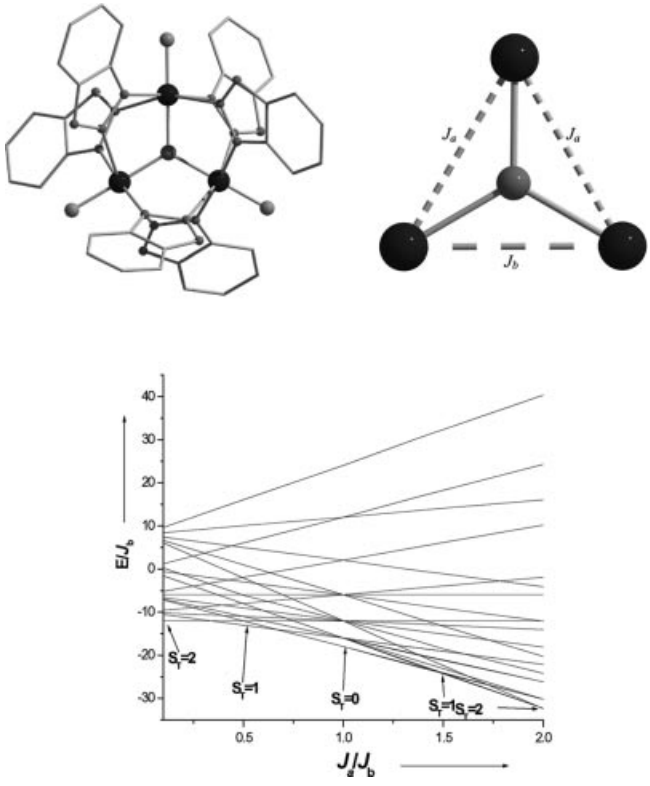

Figure 11. Top: Molecular structure of complex **9** and the two independent exchange interactions; bottom: Plot of calculated Eigen values vs. $J_a/J_b$ for complex **9**. The experimental data was fitted with a two-*J* model that employed the spin Hamiltonian $\hat{H} = -2[J_a(\hat{S}_3\hat{S}_2) + J_a(\hat{S}_3\hat{S}_1) + J_b(\hat{S}_2\hat{S}_1)]$. For more details see ref.[21]

$(Me_2BtaH)(MeOH)_8]$ (**10**), and the tridecametallic complex $[Mn_{13}O_{12}(Me_2Bta)_{12}F_6(MeOH)_{10}(H_2O)_2]$ (**11**).[25] The core of **10** (Figure 12) consists of a central $[Mn_4O_2]^{8+}$ butterfly unit, the body atoms of which are also part of a peripheral $[Mn_3O]^{4+}$ triangular unit. The $[Mn_4O_2]$ butterfly is near planar with the two peripheral $[Mn_3O]$ triangles perpendicular to this plane, attached via an $O^{2-}$ ion forming a $[Mn_8O_4]^{16+}$ core. Two $MeO^-$ and two $F^-$ ions act as $\mu_2$-bridges, the $MeO^-$ bridging one side of the $[Mn_3O]$ unit and the $F^-$ linking the $[Mn_3O]$ unit to the central $[Mn_4O_2]$ butterfly. The $F^-$ bridges are asymmetric as, in each case, one Mn–F bond lies on a Jahn–Teller axis. The six $Me_2Bta^-$ ligands all bond in a $\mu_2$-fashion and the remaining six $F^-$ ions and eight MeOH molecules all are terminal. The core of **11** (Figure 13) consists of a $[Mn^{IV}_3Mn^{III}_4O_{12}]$ centered hexagon. The $Mn^{4+}$ ions form a linear $[Mn_3O_4]$ trimer through the centre of the hexagon with the $Mn^{3+}$ ions attached on either side. The twelve $O^{2-}$ ions are all $\mu_3$-bridging and are of two types: six are bound to the central $Mn^{4+}$ ion and link this ion to the outer six Mn ions of the hexagon. The remaining six $O^{2-}$ ions bridge between the outer Mn ions of the centered-hexagon and the remaining six $Mn^{3+}$ ions that are located, alternately, above and below the plane of the $[Mn^{IV}_3Mn^{III}_4O_{12}]$ core. The $\mu_2$-$Me_2Bta^-$ ligands are all deprotonated and link the Mn ions in the central hexagon to the Mn ions above and below this plane.

The coordination of these six Mn ions is completed by a terminal $F^-$ ion and either two MeOH molecules or one MeOH and one $H_2O$ molecule. The central $[Mn^{IV}_3Mn^{III}_4O_{12}]$ core of **11** is reminiscent of the hexagonal close-packed structure present in $CdI_2$ and is similar to the cores found in several large cluster compounds.[26] Magnetic studies reveal that both **10** and **11** have small spin ground states.

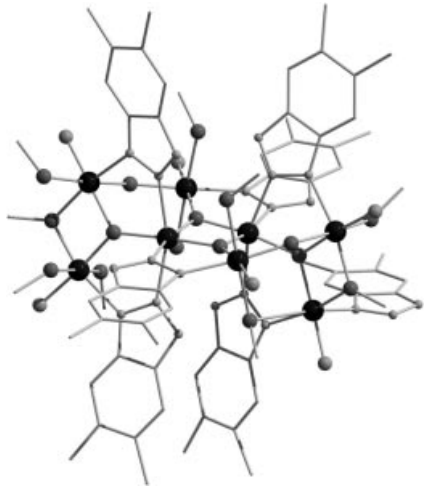

Figure 12. The molecular structure of complex **10**.

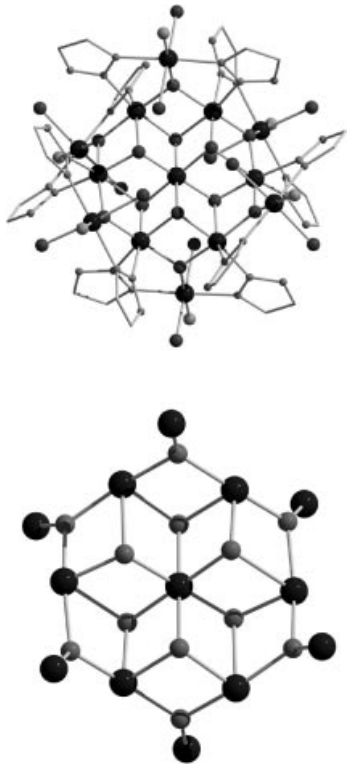

Figure 13. The molecular structure of complex **11** (top) and its metal–oxygen core (bottom).

Complexes **7**–**11** can all be described as aggregated $\{Mn_3O\}$ triangular units: compound **7** consists of twenty triangular units; **8** is made from eight edge-sharing units; **9** consists of one triangular unit; **10** contains four edge- and vertex-sharing units; and **11** contains twelve such units. This perhaps suggests that triangular $[Mn_3OF_3]^{4+}$ units may be present in all of the above solutions and that the identity of the isolated crystalline product is then dependent on the nature of the added base. Indeed complex **10** could be thought of as an "intermediate" in the formation of **11**: both clusters are comprised of aggregated $\{Mn_3O\}$ units and the $\{Mn_8O_4\}$ unit present in **10** can be seen three times in the core of **11**.

## Conclusions

The work here clearly illustrates that the use of benzotriazole and its analogues is a successful synthetic strategy for the formation of large polymetallic cluster compounds. The complexes isolated thus far range in nuclearity from three to twenty six and in topologies (amongst others) ranging from simple triangles and tetrahedra, to rectangular boxes, supertetrahedra and hexacapped hexagonal prisms. Some of these complexes have displayed interesting magnetic properties including some of the largest spin ground states ever seen and single-molecule magnetism behavior. The science remains in its infancy, but given our initial results the future promises many more exciting complexes.

## Acknowledgments

We would like to thank the EPSRC, Leverhulme Trust and Lloyd's of London Tercentenary Foundation for financial assistance (UK). The EC (HPRN-CT-1999-00012)/TMR network "Molnanomag", and MRTN-CT-2003-504880 "QuEMolNa". The work described has been done in collaboration with a number of groups. In particular, the authors would like to thank Prof George Christou (University of Florida), Dr Wolfgang Wernsdorfer (Laboratoire Louis Néel), Prof Talal Mallah (Université Paris-Sud), Drs Marco Evangelisti and Marco Affronte (INFM-CNR, Modena), Drs Guillem Aromí and Joan Cano (Universitat de Barcelona). EKB, EJLM and DC would also like to thank Drs Leigh Jones, David Low, Rebecca Laye and Gopalan Rajaraman for their invaluable contribution to this work.

# Bis-Ruthena(III)cycles $[Ru(C^{\frown}N)_2(N^{\frown}N)]PF_6$ as Low-Potential Mediators for PQQ Alcohol Dehydrogenase ($C^{\frown}N$ = 2-phenylpyridinato or 4-(2-tolyl)-pyridinato, $N^{\frown}N$ = bpy or phen)

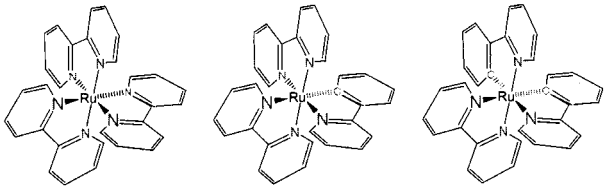
**Ronan Le Lagadec,[a] Larissa Alexandrova,[b] Hebert Estevez,[a] Michel Pfeffer,[c] Valdas Laurinavičius,[d] Julija Razumiene,[d] and Alexander D. Ryabov*[e]**

**Keywords:** Ruthenium / Metallacycles / X-ray diffraction / Biosensors / PQQ dehydrogenase

Bis-cyclometalated analogs of tris(2,2′-bipyridine)ruthenium(II), namely $[Ru^{III}(C^{\frown}N)_2(N^{\frown}N)]PF_6$ complexes **3**, are prepared in 52–57% yield from the mono-cyclometalated *N*,*N*-dimethylbenzylamine (dmbaH) derivatives $[Ru^{II}(dmba)(N^{\frown}N)(MeCN)_2]PF_6$ ($N^{\frown}N$ = bpy or phen) and mercurated 2-phenylpyridinato- or 4-(2-tolyl)pyridinato ($C^{\frown}N$) species $Hg(C^{\frown}N)Cl$. Two new bis-ruthenacycles studied by X-ray crystallography revealed a $C_1$ symmetry, with the C and N atoms of different $C^{\frown}N$ ligands *trans* to the nitrogen atoms of the $N^{\frown}N$ ligand. The reduction potential of the $Ru^{II/III}$ feature of **3** is as low as ca.–0.2 V (vs. SCE in MeCN). Complexes **3** display a unique mediating ability in moving electrons from the reduced active site of PQQ-dependent alcohol dehydrogenase (PQQ-ADH) to an electrode with 1,2-propanediol as a substrate at a working potential of +0.1 V.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

The $Ru^{II/III}$ reduction potential for $[Ru^{II}(bpy)_3]^{2+}$ is +1.34 V in MeCN (vs. SCE).[1] The structurally similar mono-cyclometalated complex $[Ru^{II}(phpy)(bpy)_2]^+$ (Scheme 1), in which one N donor is replaced by a σ-bound $sp^2$ carbon, has a drastically lower $Ru^{II/III}$ reduction potential (+0.52 V).[2] The new bis-cyclometalated species $[Ru^{III}(phpy)_2(bpy)]^+$ (**3a**), the central atom of which is σ-bound to two $sp^2$ carbon atoms, has the lowest $Ru^{II/III}$ potentials of ca. –0.2 V. The synthesis, X-ray structural study, and electrochemistry of a new family of $Ru^{III}$ bis-cyclometalated complexes **3** and their record mediating ability in moving electrons from the reduced active site of PQQ-dependent alcohol dehydrogenase (PQQ-ADH) to an electrode are described here. Examples of *bis-cyclometalated Ru complexes* are very limited; those known are the $Ru^{II}$ derivatives of benzo[*h*]quinoline,[3] azobenzene,[4] benzylidene aniline,[5] and $P(OPh_3)_3$.[6] SciFinder tracks the term that is italicized[7] but the species listed do not have two Ru–C bonds at one metal center as in **3**.



Scheme 1. A family of related cations discussed in this work. Charges in structures are omitted for clarity.

Two approaches were explored for the synthesis of the blackish-green compounds **3** (Scheme 2). The precursor bis(acetonitrile) ruthena(II)cycles are cyclometalated 2-phenyl- or 4-(2-tolyl)pyridine (**1**) and *N*,*N*-dimethylbenzylamine (**2**, dmbaH).[8] Their labile nitrile and dmba ligands are readily substituted in hot methanol by 2-phenylpyridinato or 4-(2-tolyl)pyridinato $C^{\frown}N$ chelates, which are transferred from the corresponding organomercurial compounds **4** or **5**.[9] Complexes **1** have to be treated with the symmetric organomercurial compound **4**, whereas the reactivity of the asymmetric molecule **5** is sufficient to convert **2** into **3** in 52–57% yield. It is worth noting that the formation of **3** by path **B** resembles the exchange of cyclometalated ligands[10] at $Ru^{II}$. Pincer $N^{\frown}C^{\frown}N$ ligands were previously replaced by $P^{\frown}C^{\frown}P$ fragments at $Ru^{II}$.[7c] Path **B** in Scheme 2 illustrates the exchange between bidentate $C^{\frown}N$ chelates.

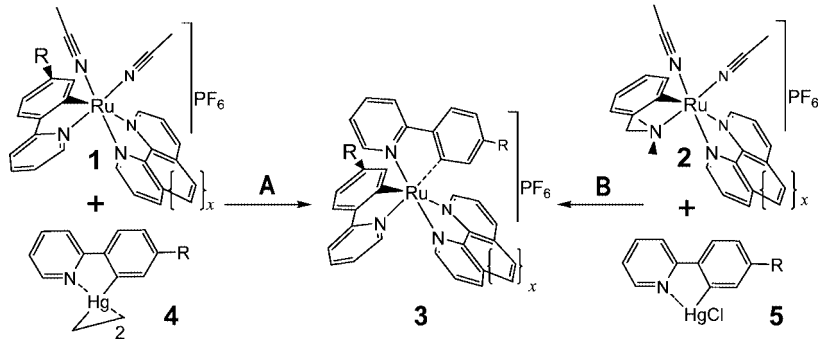

Scheme 2. Syntheses of complexes **3** (**a**: $x$ = 0, R = H; **b**: $x$ = 1, R = H; **c**: $x$ = 0, R = $CH_3$; **d**: $x$ = 1, R = $CH_3$).

Two C^N ligands of charge –1 make the complexes susceptible to oxidation, and hence the isolated compounds **3** are paramagnetic $Ru^{III}$ species. Their study by $^1H$ NMR spectroscopy is complicated, and hence, in addition to the combustion, mass-spectral, and electrochemical analyses, X-ray crystal-structure analysis of **3a** and **3d** was performed. The study on **3a** confirmed its composition (see Supporting Information), but the true stereoisomer (A, B, or C) could not be determined because the three ligands of **3a** are crystallographically identical, and the four nitrogen atoms are indistinguishable from the two carbon atoms.[11]

The X-ray data for **3d** indicates structure B with $C_1$ symmetry, which was established by the long Ru–N bond *trans* to the Ru–C σ-bond and by the $CH_3$ groups at the C^N chelates. There are two different donor atoms, i.e. N and C, *trans* to the nitrogen atoms of the phen ligand in the distorted octahedron. Accordingly, the $sp^2$ C1 atom is located *trans* to N21 of the second C^N ligand. The Ru–N21 and Ru–N38 bonds are longer than the other Ru–N bonds, as expected. This reflects the ground state *trans*-influence of the σ-bound $sp^2$ atoms C1 and C14, respectively (Figure 1).

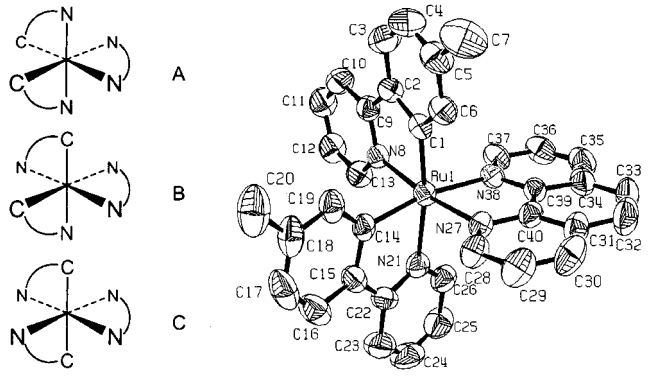

Figure 1. Possible geometric isomers of **3**, A, B, and C, and ORTEP diagram of **3d**. Selected bond lengths: Ru–C1 1.999(3), Ru–N8 2.059(2), Ru–C14 2.0209(3), Ru–N21 2.174(2), Ru–N27 2.067(2), Ru–N38 2.164(2) Å. For X-ray structure of **3a**, see SI.

It is perhaps worth noting that the properties of **3** were previously theoretically investigated.[12] The bis-ruthenacycles were unknown then, and the calculations were performed for arbitrary selected isomers A and C of $C_2$ symmetry. Properties of nonexistent species were thus simulated.

Rich cyclic voltammograms of complexes **3** that consist of three one-electron quasi-reversible and one irreversible features (Figure 2, Table 1) were interpreted by using the previously obtained data for mono-cyclometalated species such as $[Ru(phpy)(bpy)_2]^{+}$[2,13] and $[Ru(bpy)_3]^{2+}$.[1,14] The peaks around –0.2 V represent the $Ru^{II/III}$ couple, since each replacement of bpy by $phpy^-$ causes ca. 0.7 V decrease. The peaks at ca. –1.9 and +1.5 V could be assigned to the $Ru^{I/II}$ (alternatively, to a ligand-centered reduction) and $Ru^{III/IV}$ couples, respectively. Irreversible peaks at 0.9–1.0 V are presumably due to a ligand-centered oxidation. Post-peaks of lower and variable intensity that follow each peak of **3a** might be due to adsorption; they are not observed for complexes other than **3a**.

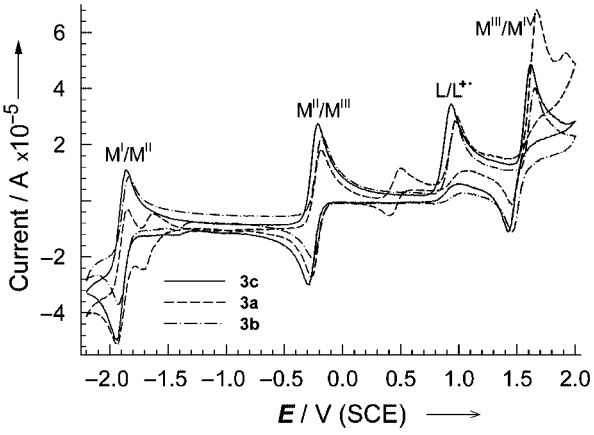

Figure 2. Cyclic voltammograms of ruthena(III)cycles **3** in MeCN (0.1 M $nBu_4NPF_6$, 0.1 V $s^{-1}$, 25 °C, glassy carbon, $N_2$; background subtraction is applied, $E_0$ = –2.2 V).

Table 1. Assignment of reduction potentials for **3** (in V vs. SCE) from the CVA data in Figure 2 in MeCN.

| **3** | $M^I/M^{II}$ | $M^{II}/M^{III}$ | $L/L^{\cdot+}$[a] | $M^{III}/M^{IV}$ |
|---|---|---|---|---|
| **3a** | –1.90 (–1.67)[b] | –0.23 (+0.45)[b] | 0.98 | 1.56 (1.91)[b] |
| **3b** | –1.88 | –0.21 | 0.97 | 1.56 |

*Pseudomonas putida* HK5 by using screen-printed carbon paste electrodes.[16] Remarkably, the largest currents (Figure 3) were registered for the new complexes **3** than for mono-metalated Ru and Os[17] species, though the optimal electrode potential for **3** was around 0.35 V vs. Ag/AgCl (see Figure S2 of the Supporting Information). Currents in Figure 3 depend hyperbolically on the alcohol concentration ($I = I_{M,app}[S]/(K_{M,app} + [S])$), and the values of $I_{M,app}$ (in parenthesis in Figure 3) emphasize a superior performance of the bis-cycloruthenated species **3**. The major advantage of complexes **3** as mediators of PQQ-ADH is that they are remarkably efficient at a low working electrode potential, i.e. 0.1 V. A decrease in the current because of the voltage drop is minor, and $I_{M,app}$ equals 2290 and 2110 nA for complexes **3a** and **3b**, respectively (cf. with the data in Figure 3).

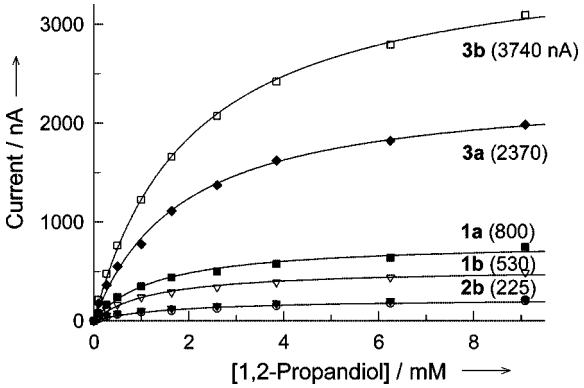

Figure 3. Current as a function of [1,2-propanediol] at 0.5 V for screen-printed electrodes incorporating PQQ-ADH and complexes **1**–**3**; pH 6, 1 mM $Ca^{2+}$, 22 °C. Numbers in parentheses are calculated values of $I_{M,app}$, which for mono-cyclometalated complexes [Ru(phpy)(phen)(MeCN)$_2$]X and [Ru(dmba)(phen)$_2$]X are close to that of **2b** and for [Os(phpy)(phen)$_2$]X is that for **1b** (X = $PF_6$).

In conclusion, the synthesis, full characterization, and numerous properties of previously anticipated but unknown complexes **3** are reported here. The X-ray study of **3d** reveals a structural type B. A "cyclometalation" tool has demonstrated its virtue again by showing how the electronic properties of compositional analogs of $[Ru(bpy)_3]^{2+}$ can further be coarsely altered by replacing N by C donors. An illustrative example of a bioanalytical use of the new complexes **3** highlighted their potential as efficient mediators of enzymatic electron transport which are capable of functioning at low electrode potentials.

## Experimental Section

**General Procedures for Preparation of [Ru(C^N)$_2$(N^N)]PF$_6$ (3) – Path B:** $Ru^{II}$ precursors **1** and **2** were described elsewhere;[8] **5** and **4** were synthesized according to the procedure of Black et al.[18] In a Schlenk tube fitted with a condenser, a solution of complex **2** (0.313 mmol) and organomercurial compound **5** (0.313 mmol) in dry methanol (30 mL) was heated at reflux for 20 h. The solvent was evaporated to dryness under vacuum, and the residue was purified by column chromatography on alumina by using a MeCN/$CH_2Cl_2$ (1:6) mixture as the eluent. The dark green band was collected, and the solvent removed. Blackish crystals were obtained by a slow diffusion of $Et_2O$ into a concentrated solution of the compound in 1:1 MeCN/$CH_2Cl_2$. Crystals were washed with $Et_2O$ (3 × 10 mL) and dried under vacuum. Reaction of **2** with **4** (Path **A**) under the same conditions gave compounds **3a**–**d** in lower yields.

**Complex 3a:** Yield 52% (115 mg) from 193 mg of **2** and 268 mg of **5**. MS: *m*/*z* (%) = 566 (13) $[M+H]^+$, 410 (20) $[M+H-bpy]^+$, 255 (4) $[M+H-bpy-phpy]^+$. IR: 839 (s, $PF_6$) $cm^{-1}$. $C_{32}H_{24}F_6N_4PRu$ (711.07): calcd. C 54.09, H 3.40, N 7.88; found C 53.89, H 3.61, N 7.69%.

**Complex 3b:** Yield 57%. MS: *m*/*z* (%) = 590 (100) $[M+H]^+$, 436 (23) $[M+H-phpy]^+$, 410 (35) $[M+H-phen]^+$, 255 (7) $[M+H-phen-phpy]^+$. IR: 841 (s, $PF_6$) $cm^{-1}$. $C_{34}H_{24}F_6N_4PRu$ (735.07): calcd. C 55.59, H 3.29, N 7.63;. found C 55.10, H 3.29, N 7.51%.

**Complex 3c:** Yield 50%. MS: *m*/*z* (%) = 594 (55) $[M+H]^+$, 438 (20) $[M+H-bpy]^+$, 426 (20) $[M+H-tolpy]^+$. IR: 836 (s, $PF_6$) $cm^{-1}$. $C_{34}H_{28}F_6N_4PRu$ (739.10): calcd. C 55.29, H 3.82, N 7.59; found C 55.20, H 3.91, N 7.69%.

**Complex 3d:** Yield 54%. MS: *m*/*z* (%) = 618 (65) $[M+H]^+$, 450 (10) $[M+H-tolpy]^+$, 438 (13) $[M+H-phen]^+$. IR: 840 (s, $PF_6$) $cm^{-1}$. $C_{36}H_{28}F_6N_4PRu\cdot 1/2(C_2H_5)_2O$ (800.13): calcd. C 57.07, H 4.16, N 7.01; found C 56.71, H 4.78, N 6.69%.

**Preparation of Biosensors:** The screen-printed carbon electrodes (CE) were designed as described.[16] A carbon paste electrode (working area 0.125 $cm^2$) was impregnated with 4 μL of a solution of mediator **1**–**3** (1 mg in 1 mL acetone). The enzyme was immobilized on the electrode surface by adsorption of 3 μL of enzyme solution for 1 h. Soluble PQQ-dependent alcohol dehydrogenase (Type II ADH IIG) from *Pseudomonas putida* HK5 (activity 1.54 U/0.2 mL) was used.

**Electrochemical Measurements:** These were performed with a three-electrode system containing a screen-printed carbon electrode as a working electrode, a Pt wire as a counter electrode, and a saturated KCl Ag/AgCl reference electrode. Steady-state currents were recorded at 0.5 or 0.1 V on a polarographic analyzer PGZ 402 (Radiometer Analytical). Acetate buffer (0.05 M, pH 6.0, 1 mM $Ca^{II}$) was used. Experimentally measured steady-state currents ($I$) as a function of the concentration of the substrate of the enzymatic reaction ([S]) were fitted to: $I = I_{M,app}[S]/(K_{M,app}+[S])$, where $I_{M,app}$ is the apparent maximal current and $K_{M,app}$ is the apparent Michaelis constant.

**Crystallography:** The crystals were mounted on the top of glass fibers and transferred to a Bruker SMART-APEX CCD diffractometer. Crystal data and details of data collection and structure refinement are given in Table S1. Absorption corrections were based on face-indexed measurements (program XPREP in SHELXTL).[19] The structures were refined anisotropically on $F^2$ with SHELXTL.[19] For both complexes, hydrogen atoms were included using a riding model. For more details, see Supporting Information. CCDC-606516 and -606515 contain the supplementary crystallographic data for **3a** and **3d**, respectively. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Crystal data and structure refinement parameters, details for **3a**, bond lengths and bond angles in Tables S1, S2, and Figure S1; current as a function of applied potential (Figure S2).

# Zinc Complexes of Amine Mono(phenolate) [$NOO_2$] Ligands: Controlling Coordination Modes by Bulk of Phenolate Substituents

**Stanislav Groysman,[a] Ekaterina Sergeeva,[a] Israel Goldberg,[a] and Moshe Kol*[a]**

**Keywords:** Zinc / N,O ligands / Tripodal ligands / Polynuclear complexes

The coordination chemistry of three tripodal monoanionic amine mono(phenolate) ligands bearing two methoxy sidearm donors with ethylzinc(II) is reported. Reacting diethylzinc with the ligand precursor bearing bulky (*t*Bu) phenolate substituents led cleanly to a mono(ethyl) mononuclear $C_s$-symmetric zinc complex according to spectroscopic data. X-ray structure analysis revealed a semi-pentacoordinate complex as one of the methoxy sidearm donors was tightly bound whereas the other one was weakly bound. The ligand precursors bearing less bulky electron-donating (Me) or electron-withdrawing (Br) phenolate substituents led cleanly to dinuclear pentacoordinate complexes, bridged by phenolate oxygens, in which only one of the two sidearm donors was bound, and in a weak manner.

## Introduction

Zinc plays a major role in bioinorganic chemistry, fulfilling structural and catalytic functions in various enzymes.[1,2] When coordinated by S-based (cysteinate) ligands, or by a mixed set of S- and N-based (histidine) ligands, the role of zinc is mainly structural.[2] On the other hand, a coordination sphere containing O-based ligands is characteristic for a catalytic metal site, as the O-based hard donors ($H_2O$ or $HO^-$) are readily replaced at the zinc metal center, providing a vacant coordination site to be occupied by a substrate.[2] According to these general observations, simple analogues of the zinc biological active sites are sought.

In such research, controlling the nuclearity of metal species is a major goal. For many applications, mononuclear species are desired, as they lead to better-defined catalytic performance in comparison to multinuclear species. The most practical route toward such species is the utilization of chelating multidentate ligands such as the "tripodal" ligands, having three donor arms, which have become very abundant in the last two decades.[3] One particular family of tripodal ligand, that attracts ever-increasing attention, is the family of tripodal ligands possessing a central nitrogen donor atom, in addition to the three donor arms. Several ligand families of this type have been employed in zinc chemistry, including neutral tris(picolyl)amine ([$NN_3$]),[4,5] *N*-bis[2-(methylthio)ethyl]-*N*-[(6-neopentylamino-2-pyridyl)-methyl]amine ([$NS_2N$]),[6] and tris[(*N*-*tert*-butylcarbamoyl)-methyl]amine ([$NN_3$]) ligands,[7] or monoanionic dipicolylglycinate ([$NON_2$]),[8] and 2-mercaptobenzyl-bis(2-pyridylmethyl)amine ([$NN_2S$]) ligands [9] (Figure 1).

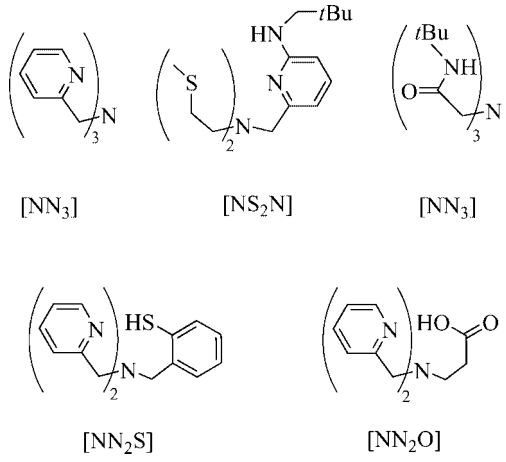

Figure 1. Various tripodal ligands, having a central nitrogen donor employed in zinc chemistry.

The zinc chemistry of monoanionic amine mono(phenolate) ligands, carrying two additional arms, has been investigated in the last decade, mainly by the groups of Fenton and Vahrenkamp.[10–13] The advantages of the amine mono(phenolate) ligands include their straightforward synthesis, and their broad structural diversity.[10–17] Yet, until now, the zinc chemistry of these ligands was limited to ligands having two additional pyridine arms,[10–12] or pyridyl and pyrrolidinyl arms (Figure 2).[13] The [$NON^{py}_2$] ligands, having no substituents, or *t*Bu substituents at the phenolate ring, were shown to bind the metal firmly through all four donors, with the three "tripodal" donors lying in the equatorial plane.[11,12] Both ligands led to neutral mononuclear complexes, possessing an additional, monodentate ligand in

the fifth position: Cl, Br, I, OPh, and SPh. In this study, we were aiming at extending the chemistry of tripodal monoanionic [$NOX_2$] ligands. Specifically, we wanted to reveal structural effects on coordination chemistry of [$NOO_2$]-zinc complexes, in which zinc binds to labile oxygen donors.

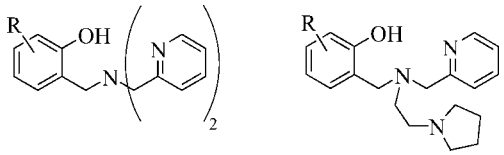

Figure 2. Two tripodal amine mono(phenolate) ligands, employed in zinc chemistry.

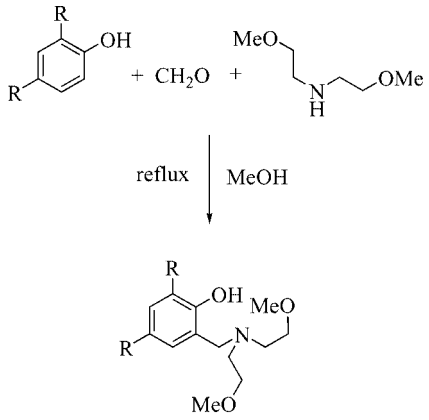
## Results and Discussion

We previously reported the preparation of the ligand precursor $Lig^1H$.[17] $Lig^2H$ and $Lig^3H$ ligand precursors were prepared in a similar way, via a single-step Mannich condensation between the respective phenol, secondary amine, and formaldehyde (Scheme 1). The ligand precursors were obtained as yellow oils, and their identity was confirmed by NMR and elemental analyses.



$Lig^1H$: R = *t*Bu; $Lig^2H$: R = Me; $Lig^3H$: R = Br

Scheme 1. Synthesis of ligand precursors $Lig^1H$–$Lig^3H$.

Diethylzinc provides a convenient entry into zinc chemistry with sufficiently acidic ligands.[18,19] An ethereal solution of $Lig^1H$ was added to a hexane solution of diethylzinc at –30 °C, followed by warming to room temperature and stirring for 1 h. Subsequent removal of solvent and recrystallization from pentane led to pure **1** in 80% yield, obtained as colorless crystals. According to its NMR spectra, **1** contains a single type of phenolate ring, and a single type of metal-bound ethyl group. As anticipated, the zinc-bound methylene group gives rise to high-field NMR signals [$\delta(^{13}C)$ –1.8 ppm; $\delta(^1H)$ 0.58 ppm]. The $^1H$ and $^{13}C$ NMR spectra of this compound clearly signify a $C_s$-symmetrical species at room temp. Thus, the $^1H$ spectrum featured a single resonance for the O$CH_3$ groups at $\delta$ = 2.85 ppm [$\delta(^{13}C)$ 58.7 ppm], and a sharp singlet for the two benzyl (Ar$CH_2$N) protons at $\delta$ = 3.31 ppm (these groups are reflected by a mirror plane). The N$CH_2CH_2$OMe protons appear as four distinct signals, of ddd (or dt) multiplicity, whose connectivity pattern was validated by a 2D $^1J_{C,H}$ (HMQC) experiment. This indicates that all four methylene protons of a particular "sidearm" are different; thus, the ligand seems to wrap around the metal in a well-defined fashion, in which the two sidearms are reflected by a mirror plane. However, the possibility of a fast (on the NMR timescale) exchange process, in which only one of the sidearms is bound at a given time, cannot be excluded a priori.

To distinguish between these two possibilities, we carried out a VT NMR experiment for **1** in [$D_8$]toluene. For the latter scenario, two different sidearms should be observed at low temperatures. In contrast, for the compound containing an effective mirror plane, no significant difference between proton spectra at room temp. vs. low temperatures should be anticipated. Upon cooling to as low as 210 K, no splitting in the peak attributed to the O$CH_3$ groups was observed; the N$CH_2CH_2$OMe appeared as four distinct signals as well, though all signals were somewhat broadened. The signals attributed to the ethyl group also underwent no change. This data is consistent with a $C_s$-symmetrical complex in solution, featuring binding of both sidearms (Figure 3). The slight broadening of peaks is attributed to a low-barrier conformational flip of the methylene-phenolate group. A freezing of this flip would result in a $C_1$-symmetrical complex, as revealed from the X-ray structure of **1**. The X-ray structure also reveals different MeO–Zn bond lengths (vide infra).

The complex of the nonbulky [$NOO_2$] electron-donating ligand $Lig^2$ was prepared in a similar way, by a protonolysis reaction between the ligand precursor $Lig^2H$ and $Et_2Zn$ (Figure 3). Complex **2** was obtained as colorless crystals upon recrystallization from ether. Even at room temp. the NMR spectrum of **2** in deuteriobenzene displays different features: the methylene N$CH_2CH_2$OMe protons appear as two broad signals vs. four sharp signals of ddd (dt) multiplicity for **1** (Figure 3). The O$CH_3$ protons appear as a single resonance at $\delta$ = 2.85 ppm at room temp. and the ethyl group gives rise to single triplet and quartet resonances, at $\delta$ = 0.39 and 1.56 ppm, respectively. However, in contrast to **1**, cooling **2** to 210 K causes splitting of the O$CH_3$ resonance into two discrete signals (coalescence at 221 K). The quartet signal attributed to the metal-bound methylene was split into two multiplets at that temperature as well, signifying a different chemical environment for the two methylene protons. Thus, a different binding of the nonbulky [$NOO_2$] ligand to the metal should be anticipated, according to the VT-NMR spectroscopic data (Figure 3).

The X-ray structure determination of these complexes provided a solid evidence for the different coordination modes of these [$NOO_2$] ligands around zinc. According to our expectations for the structure of **1**, the ligand is bound to the metal through all four donors, forming a mononuclear, pentacoordinate species of highly distorted TBP geometry (Figure 4, Table 1). In the previously disclosed zinc complexes featuring the [$NO(N^{py})_2$] ligand,[11,12] the three

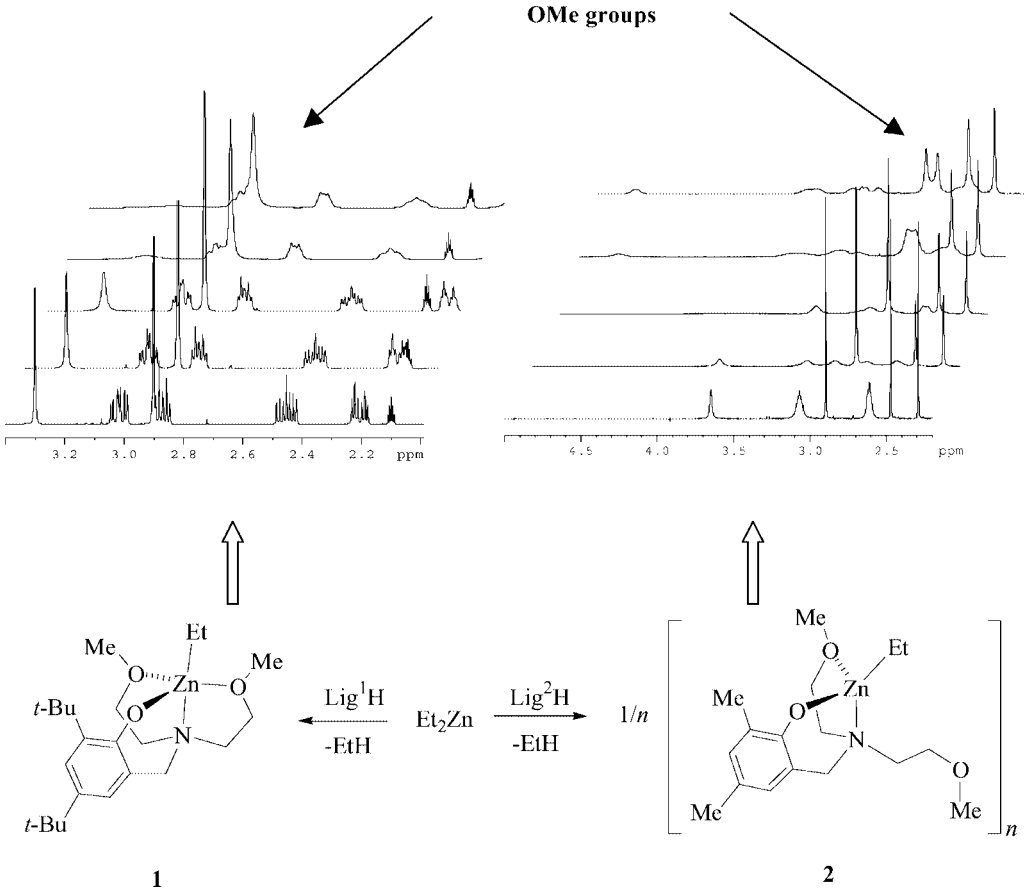

Figure 3. Syntheses of the amine mono(phenolate) complexes **1** and **2**, and their proposed structures; (bottom), based on VT $^1$H NMR spectra (top). See text for details.

arms of the tripodal ligand occupied the equatorial positions, while the central amine and the additional monodentate ligand were located in the axial positions. In the present case, the phenolate oxygen, the central nitrogen, and the ethyl methylene carbon are located in the equatorial plane, whereas the methoxy donors occupy the axial positions. The phenolate oxygen, amine donor, and the ethyl methylene carbon all feature strong bonding to the metal center. In contrast, the two methoxy groups are inequivalent, displaying weak binding to the metal: 2.308 vs. 2.598 Å. The pronounced difference in bond lengths may result from the conformation of the ethyl group, as its methylene carbon points toward the remote methoxy group, or from the conformation of the phenolate ring, as the *t*Bu group points toward that group as well, or by a combination of both. It may also signify an "arrested" dynamic process equilibrating bound and unbound sidearm donors. The Zn–O–C(Ph) angle is narrow (114.9°), as is anticipated for a $d^{10}$ metal complex experiencing no π-donation from the phenolate oxygen to the metal, vs. 128–148° in $d^0$ or $d^2$ ($Ta^V$, $V^{III}$, $V^V$, or $Ti^{IV}$) complexes.[20–22]

In a sharp contrast to the structure of **1**, **2** is a dinuclear complex of $C_i$-symmetry, in which the two nearby zinc atoms (Zn···Zn separation of 3.108 Å) are bridged by the two phenolate oxygen atoms (Figure 5, Table 1). This

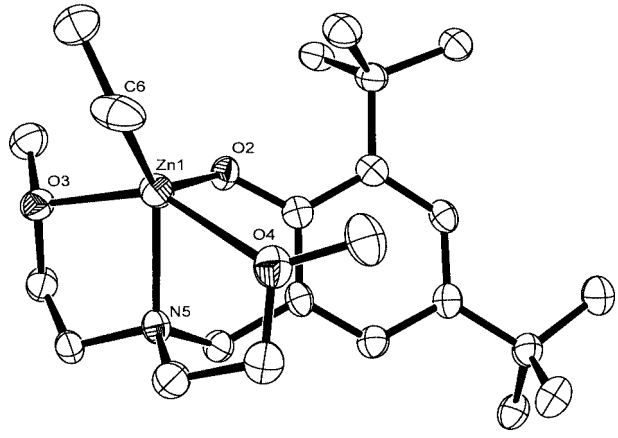

Figure 4. The X-ray structure of **1**. ORTEP representation, 50% probability.

$Zn_2O_2$ core is a common structural motif in zinc coordination chemistry, found frequently in zinc-phenolate species.[23–27] The Zn–O(Ph) bond lengths are not identical, being 2.018 and 2.123 Å, respectively. One of the sidearms is unbound, creating a pentacoordinate, nearly TBP geometry at each metal center. One of the phenolate oxygen atoms and the methoxy donor are in the axial position [O(Ph)-Zn-

(R)OMe 159.0°], whereas the second phenolate oxygen, the ethyl methylene carbon, and the central nitrogen are in the equatorial positions. Consistently with the previous structure, the central amine is bound tightly (2.169 Å), and the methoxy donor is bound very weakly (2.549 Å).

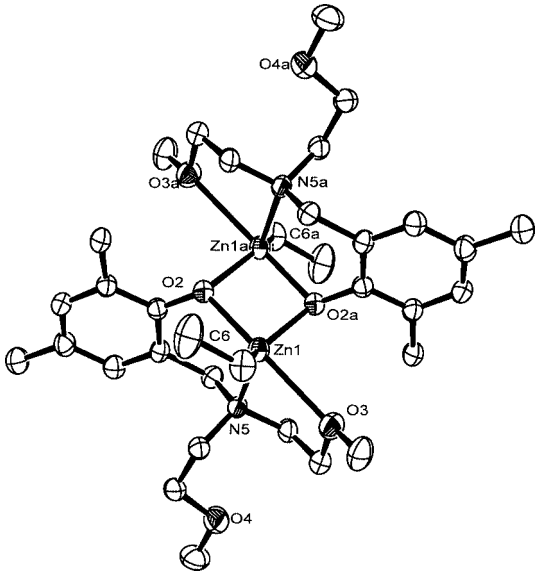

Figure 5. The X-ray structure of **2**. ORTEP representation, 40% probability. The asymmetric unit contains only half of the *Ci*-symmetric dimer, and the second half is generated by a symmetry operation. The structure also contains a disordered solvent molecule, not shown here.

An additional ligand, employed in this research, was Lig[3], carrying *ortho*, *para* bromo substituents, that are comparable in size to the methyl groups, yet are electron-withdrawing and may reduce the tendency of the phenolate oxygen atoms to act as bridging groups. The ligand precursor Lig[3]H was treated with diethylzinc in analogy to Lig[1]H and Lig[2]H; the product **3** was obtained in a good yield after washing out of the impurities with pentane and ether. In general, the room temp. $^1$H NMR spectrum of **3** displays similar features to that of **2**. In both cases, the NC$H_2$C$H_2$O methylene protons give rise to two resonances: For **2**, these are represented by two broad peaks; for **3**, one of these signals is broad, while the second appears as a relatively sharp triplet. The VT NMR behavior of **3** was not identical to the spectrum of **2**: for example, the methylene NC$H_2$C$H_2$O protons were observed in **2** at 278 K as four broad multiplets, while in **3** they gave rise to two broad signals at that temperature. Moreover, in spite of a significant broadening in the OC$H_3$ and Zn-C$H_2$ resonances, no splitting was observed down to 200 K, which may indicate a lower-energy process in **3** than in **2**; it does not exclude, however, the possibility of a mononuclear, nearly $C_s$-symmetrical complex.

The X-ray structure analysis provided a clear evidence for the dinuclear nature of **3** (Figure 6). In the solid state, the *Ci*-symmetric **3** possesses a very similar structure to that of **2**, displaying two pentacoordinate metal centers in close proximity (Zn···Zn separation of 3.163 Å), bridged by the phenolate oxygen atoms. The bond lengths in **3** are reminiscent of those in **2**; the major structural difference between these structures lies in the Zn–O(R)Me bond lengths [2.451(5) in **3** vs. 2.549(3) Å in **2**]. The stronger bonding of the weak donor in **3** may be traced back to the electron deficiency at the metal center, as a result of the electron-poor ligand.

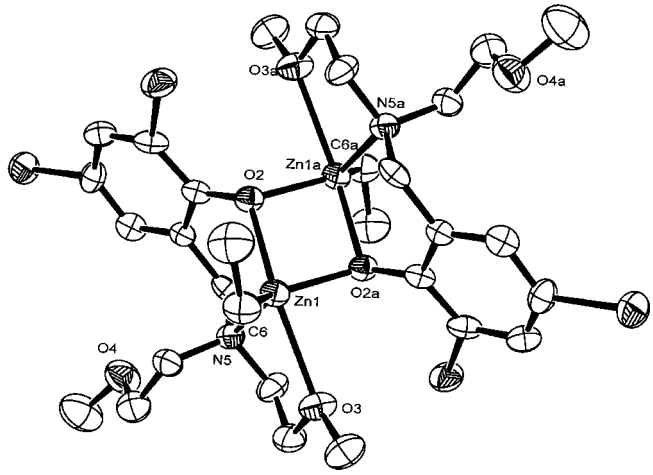

Figure 6. The X-ray structure of **3**. ORTEP representation, 40% probability. The asymmetric unit contains only half of the *Ci*-symmetric dimer, and the second half is generated by a symmetry operation.

On the basis of the above results, we propose that a point of divergence for the different nuclearity in [$NOO_2$]ZnEt species lies in a delicate balance between the weakness (lability) of the dative Zn–O(R)Me bond and the steric bulk imposed by the groups in the *ortho* positions of the phenolate ring. Presumably, formation of a dinuclear phenolate-bridged species in the [$NOO_2$] zinc complexes is favorable due to the weakness of the Zn–O(R)Me dative bond. However, the formation of dinuclear species is precluded by sufficient steric bulk at the *ortho* positions of the phenolate group.[28] As a result, mononuclear species arise, in which the weak, yet nonbulky, second O(R)Me donor is able to bind to the metal center, accomplishing a pentacoordinate geometry.

To summarize, we investigated the coordination chemistry of zinc(II) in the environment of the amine mono(phenolate) ligands, carrying two neutral oxygen-type arms, in addition to the anionic phenolate oxygen. A neutral oxygen donor, known to bind weakly to zinc, was found to display varying coordination modes, influenced by the steric bulk

at the phenolate ring. In the case of small groups at the phenolate ring, formation of a dinuclear complex was observed, in which every metal atom was bound to two phenolate oxygen atoms, at the expense of binding of a second weak donor. In contrast, utilization of bulkier, *t*Bu, groups at the phenolate ring prohibited the formation of a dinuclear complex, leading to a mononuclear species instead, in which both neutral oxygen donors were bound.

## Experimental Section

**General:** All manipulations of the metal complexes were performed under dry nitrogen in a nitrogen-filled glovebox. 2,4-Di-*tert*-butylphenol, bis(2-methoxyethyl)amine, formaldehyde (37% in water), and diethylzinc (1.0 M in hexane) were obtained from Aldrich and used without purification. Lig$^1$H was prepared as described previously.[17] Ether was purified by reflux and distillation under dry Ar from Na/benzophenone. Pentane was washed with $HNO_3/H_2SO_4$ prior to distillation from Na/benzophenone. [$D_6$]-Benzene was flushed with Ar and stored on molecular sieves in the glovebox. [$D_8$]Toluene was dried on Na before being used. NMR spectroscopic data for the metal complexes were collected with Bruker AC-200 and AC-400 spectrometers, and referenced to protio impurities in [$D_6$]benzene and [$D_8$]toluene ($\delta$ = 7.15 and 2.1 ppm, respectively) and to the $^{13}$C chemical shift of benzene ($\delta$ = 128.06 ppm). Routine characterization of metal complexes consisted of $^1$H, BB, and DEPT-135 $^{13}$C NMR experiments, performed in [$D_6$]benzene at 298(2) K. VT NMR experiments were performed in [$D_8$]toluene. X-ray diffraction measurements were performed with a Nonius Kappa CCD diffractometer system, using Mo-$K_\alpha$ ($\lambda$ = 0.7107 Å) radiation. The analyzed crystals were embedded within a drop of viscous oil and freeze-cooled to 110 K. The structures were solved by a combination of direct methods and Fourier techniques using SIR-92 software,[29] and were refined by full-matrix least-squares with SHELXL-97.[30] The crystal and experimental data are summarized in Table 2. CCDC-294424 (for **1**), -294425 (for **2**), and -294426 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Elemental analyses were performed in the microanalytical laboratory in the Hebrew University of Jerusalem.

**Synthesis of Lig$^2$H:** 2,4-Dimethylphenol (5.5 mL, 46 mmol), bis(2-methoxyethyl)amine (13 mL, 89 mmol), and formaldehyde (13 mL, 37% in water) were mixed in MeOH (20 mL). The mixture was heated to 110 °C in a pressure flask and stirred for 48 h, yielding a deep orange biphasic solution. The crude reaction mixture was poured into water/$CH_2Cl_2$ (40 mL each), the organic phase was separated, dried with anhydrous $MgSO_4$, and the solvent was removed under reduced pressure. The traces of amine were removed under vacuum (0.5 mbar), while heating to 80 °C, yielding the desired product as orange oil (9.243 g, 35 mmol, 76%). $C_{15}H_{25}NO_3$ (267.36): calcd. C 67.38, H 9.42, N 5.24; found C 67.31, H 9.71, N 5.44. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 10.32 (s, 2 H, O-*H*), 6.74 (br. s, 2 H, Ar-H), 6.52 (br. s, 2 H, Ar-H), 3.69 (s, 2 H, ArC$H_2$N), 3.43 (t, $^3J_{H,H}$ = 5.5 Hz, 4 H, NC$H_2$C$H_2$O), 3.23 (s, 6 H, OC$H_3$), 2.70 (t, $^3J_{H,H}$ = 5.5 Hz, 4 H, NC$H_2$C$H_2$O), 2.11 (s, 6 H, Ar-C$H_3$) ppm. $^{13}$C NMR (50.29 MHz, $CDCl_3$): $\delta$ = 153.7 (*C*O), 130.6 (*C*H), 127.6 (*C*), 126.9 (*C*H), 124.8 (*C*), 121.5 (*C*), 70.5 (*C*H$_2$), 58.8 (O*C*H$_3$), 58.6 (*C*H$_2$), 53.4 (*C*H$_2$), 20.5 (C*H*$_3$), 15.8 (C*H*$_3$) ppm.

**Synthesis of Lig$^3$H:** 2,4-Dibromophenol (1.97 g, 7.8 mmol), bis(2-methoxyethyl)amine (2 mL, 13.6 mmol), and formaldehyde (3.2 mL, 37% solution in water) were mixed in MeOH (20 mL). The mixture was stirred and refluxed for two weeks. The crude reaction mixture was poured into water/$CH_2Cl_2$ (20 mL each), the organic phase was separated, dried with anhydrous $MgSO_4$, and the solvent was removed under reduced pressure. The remaining product was dried (0.5 mbar, 100 °C) for 2 h, yielding the desired product as brown oil (2.86 g, 7.2 mmol, 92%). $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 7.57 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H, Ar-*H*), 6.79 (d, $^4J_{H,H}$ = 2.4 Hz, 2 H, Ar-*H*), 3.23 (s, 2 H, ArC$H_2$N), 3.01 (t, $^3J_{H,H}$ = 5.1 Hz, 4 H, NC$H_2$C$H_2$O), 2.94 (s, 6 H, OC$H_3$), 2.34 (t, $^3J_{H,H}$ = 5.4 Hz, 4 H, NC$H_2$C$H_2$O) ppm. $^{13}$C NMR (100.58 MHz, $CDCl_3$, 300 K): $\delta$ = 154.4 (*C*O), 134.1 (*C*H), 130.4 (*C*H), 125.3 (*C*), 111.1 (*C*), 110.5 (*C*), 70.4 (*C*H$_2$), 59.2 (O*C*H$_3$), 58.4 (*C*H$_2$), 53.6 (*C*H$_2$) ppm.

**Synthesis of 1:** Lig$^1$H (86 mg, 0.25 mmol) was dissolved in ether (1 mL) and cooled to –35 °C. While cold, it was added slowly to a pre-cooled solution of $ZnEt_2$ in hexane (1.0 M, 0.25 mL). The resulting bright yellow solution was warmed to room temp. and stirred for 1 h. The solvent was removed under reduced pressure, the resulting bright yellow solid was dissolved in pentane and the solution was left at –35 °C overnight. Colorless crystals of X-ray quality were separated from the solution, washed with cold pentane and dried under reduced pressure to afford **1** (91 mg, 0.20 mmol, 80%). $C_{23}H_{41}NO_3Zn$ (444.97): calcd. C 62.08, H 9.29, N 3.15; found: C 61.85, H 9.31, N 3.25. $^1$H NMR (400 MHz, $C_6D_6$, 298 K): $\delta$ = 7.58 (d, $^4J_{H,H}$ = 2.7 Hz, 2 H, Ar-*H*), 6.88 (d, $^4J_{H,H}$ = 2.7 Hz, 2 H, Ar-*H*), 3.31 (s, 2 H, PhC$H_2$N), 2.96 (ddd, $^2J_{H,H}$ = 10.1, $^3J_{H,H}$ = 9.0, $^3J_{H,H}$ = 3.7 Hz, 2 H, NCH$_2$C$H_2$O), 2.85 (s, 6 H, OC$H_3$), 2.81 (dt, $^2J_{H,H}$ = 10.1, $^3J_{H,H}$ = 4.5 Hz, 2 H, NCH$_2$C$H_2$O), 2.41 (ddd, $^2J_{H,H}$ = 13.3, $^3J_{H,H}$ = 8.9, $^3J_{H,H}$ = 4.5 Hz, 2 H, NC$H_2$CH$_2$O), 2.17 (dt, $^2J_{H,H}$ = 13.3, $^3J_{H,H}$ = 4.0 Hz, 2 H, NC$H_2$CH$_2$O), 1.86 [s, 9 H, C(C$H_3$)$_3$], 1.63 (t, $^3J_{H,H}$ = 8.1 Hz, 3 H, Zn-CH$_2$C$H_3$), 1.46 [s, 9 H, C(C$H_3$)$_3$], 0.59 (q, $^3J_{H,H}$ = 8.1 Hz, 2 H, Zn-C$H_2$CH$_3$) ppm. $^{13}$C NMR (100.58 MHz, $C_6D_6$, 298 K): $\delta$ = 164.4 (*C*O), 138.5 (*C*), 135.1 (*C*), 125.3 (*C*H), 124.1 (*C*H), 122.4 (*C*), 68.5 (C$H_2$), 59.6 (C$H_2$), 58.7 (OC$H_3$), 56.5 (C$H_2$), 35.9 [*C*(CH$_3$)$_3$], 34.2 [*C*(CH$_3$)$_3$], 32.4 [C(*C*H$_3$)$_3$], 30.2 [C(*C*H$_3$)$_3$], 13.5 (Zn-CH$_2$*C*H$_3$), –1.8 (Zn-*C*H$_2$CH$_3$) ppm. $^1$H NMR (400 MHz, $C_7D_8$, 301 K, selected resonances): $\delta$ = 3.30 (s, 2 H, PhC$H_2$N), 3.01 (ddd, $^2J_{H,H}$ = 10.0, $^3J_{H,H}$ = 9.0, $^3J_{H,H}$ = 3.7 Hz, 2 H, NCH$_2$C$H_2$O), 2.90 (s, 6 H, OC$H_3$),

# Novel Coordination Polymers Generated from Angular 2,2′-Dipyridyl Ligands and Bis(hexafluoroacetylacetonate) Copper(II): Crystal Structures and Magnetic Properties

**Salomé Delgado,*[a] Aitor Barrilero,[a] Agustín Molina-Ontoria,[a] Manuela E. Medina,[b] Cesar J. Pastor,[b] Reyes Jiménez-Aparicio,[c] and José L. Priego[c]**

**Keywords:** Coordination polymers / Copper / N ligands

The synthesis of the ligand 2,5-bis(2-pyridylethynyl)thiophene (**L2**) is described and the coordination chemistry of the 2,2′-long conjugated bidentate ligands 1,2-di(2-pyridyl)-butadiyne (**L1**), 2,5-bis(2-pyridylethynyl)thiophene (**L2**), and 2,2′-dipyridyl disulfide (**L3**) with $Cu(hfac)_2$ (hfac = hexafluoroacetylacetonate) is investigated. Three new coordination polymers $\{[Cu(hfac)_2L]_n$ (**1** for L = **L1**, **2** for L = **L2** and **3** for L = **L3**)} are prepared and fully characterized by infrared spectroscopy, elemental analysis, thermogravimetric analysis, and X-ray diffraction. They are obtained by a combination of **L1**, **L2**, or **L3** with $Cu(hfac)_2{\cdot}H_2O$ in dichloromethane ($CH_2Cl_2$) as the solvent. When $CH_2Cl_2$ solutions of **3** were left standing for longer than one day or were refluxed for two days, rearrangements took place and **3** was transformed into **4** and **5**. Compounds **1**–**3** adopt a one-dimensional chain structure with the copper atom in a six-coordinate 4+2 pseudooctahedral geometry. In **1** and **2**, four equatorial sites Cu–O/N and two axial sites Cu–O are found with an unusual *cis* orientation of two $\mathbf{L_1}$ or $\mathbf{L_2}$ ligands, respectively, while in **3** the four equatorial sites are defined by four oxygen atoms from two hfac chelating ligands and the axial sites by two nitrogen donors from two *trans*-**L3** ligands. Compound **4** contains a (1-hydro-2-pyridinio)thio group that is bound to a hexafluoroacetylacetonate anion through a S–C bond and **5** is a molecular compound where the $Cu^{II}$ ion is pentacoordinate to two oxygen atoms of the hfac anion, two nitrogen atoms of two 2-pyridyl sulfide fragments, and one carbon atom of the $CC(O)CF_3$ fragment, which has been inserted into the S–S bond of the 2,2′-dipyridyl disulfide ligand, giving a new tridentate ligand. The reaction of **L3** with copper acetate leads to the molecular 1:2 adduct $Cu_2(\mu\text{-}OAc)_4(L3)_2$ (**6**), where the $Cu^{II}$ ion is pentacoordinate to four oxygen atoms of four different acetate anions and one nitrogen atom from the pyridine ring of **L3** to form a square-pyramidal geometry.

## Introduction

The rational design of new coordination polymers is of current interest in the field of supramolecular chemistry and crystal engineering because of their exploitable properties; these include magnetism,[1] catalysis and separation,[2] non-linear optics,[3] and molecular sensing.[4] Coordination polymers with diverse architectures, such as linear or zigzag chains, helices, honey-combs, square grids, ladders, brick walls, and interwoven diamondoids have been extensively developed.[5] In particular, much research has been concentrated on the use of bridging 4,4′-bipyridyne-based rodlike ligands,[6] whereas bent ligands are relatively less frequently used as building blocks because of the difficulty in predicting the structure. Recently, crystalline polymers have been synthesized by using 1,2-di(3-pyridyl)ethyne or 2,5-di(3-pyridyl)-1,3,4-oxadiazole and $Cd^{II}$, $Co^{II}$, $Cu^{II}$ salts.[7] Moreover, unsaturated metal complexes such as bis(hexafluoroacetylacetonate)metal(II) are promising metal building blocks and have proved to be very useful precursors in the synthesis of several types of molecular materials including thin metallic and oxide films and magnetic materials.[8–10]

With this in mind, the aim of this work is to study the effect of the 2,2′-positional orientation of the nitrogen atoms in *N*,*N*′-bidentate ligands on the coordination framework and to affect the polymeric architectures of the crystalline materials. Ligands with nitrogen atoms at the 2-position of the pyridyl ring do not readily form polymeric compounds, as is the case for ligands with nitrogen atoms at the 3- and 4-positions. Therefore, the reaction between 1,2-di(2-

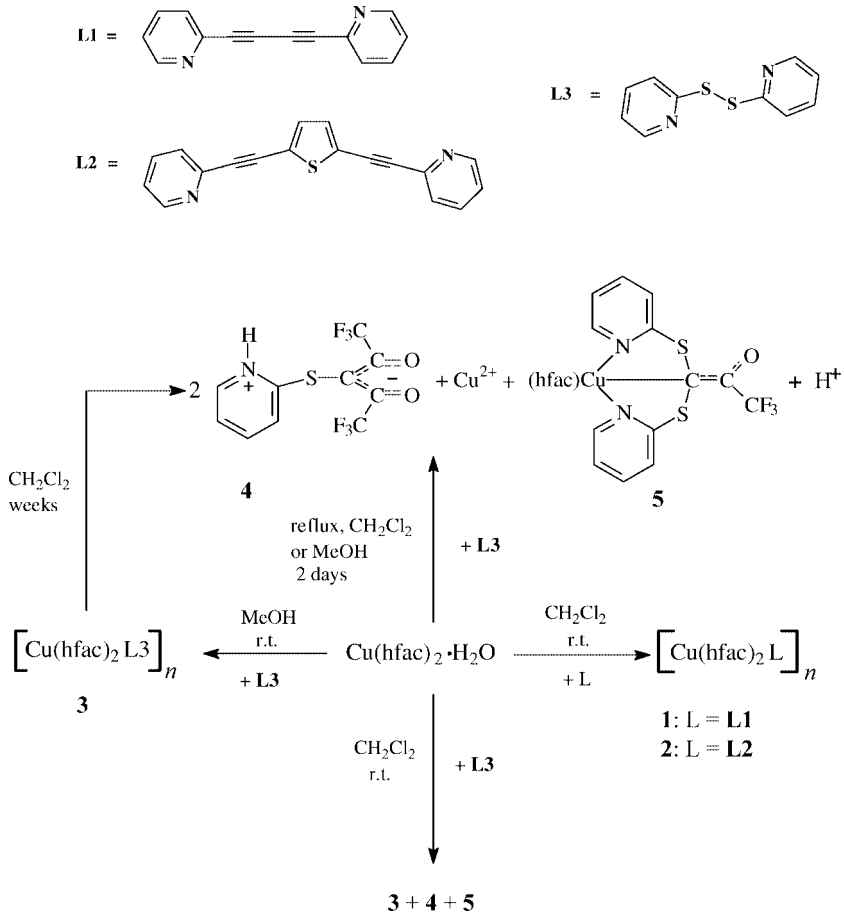
pyridyl)ethyne and $Cu(hfac)_2$ only formed solutions when a methanol solution of ligand was layered over a dichloromethane solution of copper(II) hexafluoroacetylacetonate.[11]

In this report, we focus on 1,2-di(2-pyridyl)butadiyne (**L1**), 1,2-bis(2-pyridylethynyl)thiophene (**L2**), and 2,2′-dipyridyl disulfide (**L3**), in which the first two are rigid ligands and the last one is a flexible ligand that may assume a twisted conformation because of the flexible –S–S– bridging group. The C–S–S–C torsion angles in aromatic disulfides are known to be generally within a range of 70–90°.[12a] Further, oxidation of 2,2′-dipyridyl disulfide to pyridine-2-sulfinate in the presence of the $Cu^{II}$ ion and water has been reported.[12b] Here we describe the synthesis, structures, and properties of new $Cu^{II}$ coordination polymers. The 1,2-bis(2-pyridylethynyl)thiophene ligand was synthesised and used first as a linker.

## Results and Discussion

When dichloromethane solutions of **L1** and **L2** were allowed to diffuse, at room temperature, into a solution of $Cu(hfac)_2$ in the same solvent (ratio 1:1), the infinite coordination polymers **1** and **2** were afforded as green and yellow crystalline materials, respectively, within 2–3 days. Similar results were obtained when layering the dichloromethane solution of copper(II) hexafluoroacetylacetonate over a solution of **L1** or **L2**.

Treatment of $Cu(hfac)_2$ with 2,2′-dipyridyl disulfide (**L3**), depending on the conditions, leads to the formation of different products. When a methanol solution of **L3** is allowed to diffuse, at room temperature, into a solution of $Cu(hfac)_2$ in the same solvent, the coordination polymer **3** is obtained as a green solid after one day. By contrast, when the reaction is carried out in $CH_2Cl_2$, under similar conditions, **3** is also isolated together with the orange organic compound **4** and the violet mononuclear compound **5** as minor products. The amount of **3** diminished significantly and the yield of **4** and **5** increased up to 50% after prolonged standing in contact with $CH_2Cl_2$. If the same reagents are allowed to react together under reflux in $CH_2Cl_2$ or MeOH for two days, only **4**, as the major product, and **5** are obtained. During this process **3** is converted into 2-[(1-hydro-2-pyridinio)thio]hexafluoroacetylacetonate (**4**) and the mononuclear compound **5**, where a new copper–carbon bond is formed (Scheme 1). Crystals of **3** can be stored unchanged at room temperature. It is also stable in ether or $CCl_4$ solutions but slowly decomposes to **4** and **5** in acetone solutions. In order to explain the formation of complexes **4** and **5** from **3**, we have carried out additional experiments. In order to test whether $H_2O$ or $O_2$ play a role in the formation of the final products, we have repeated the



Scheme 1.

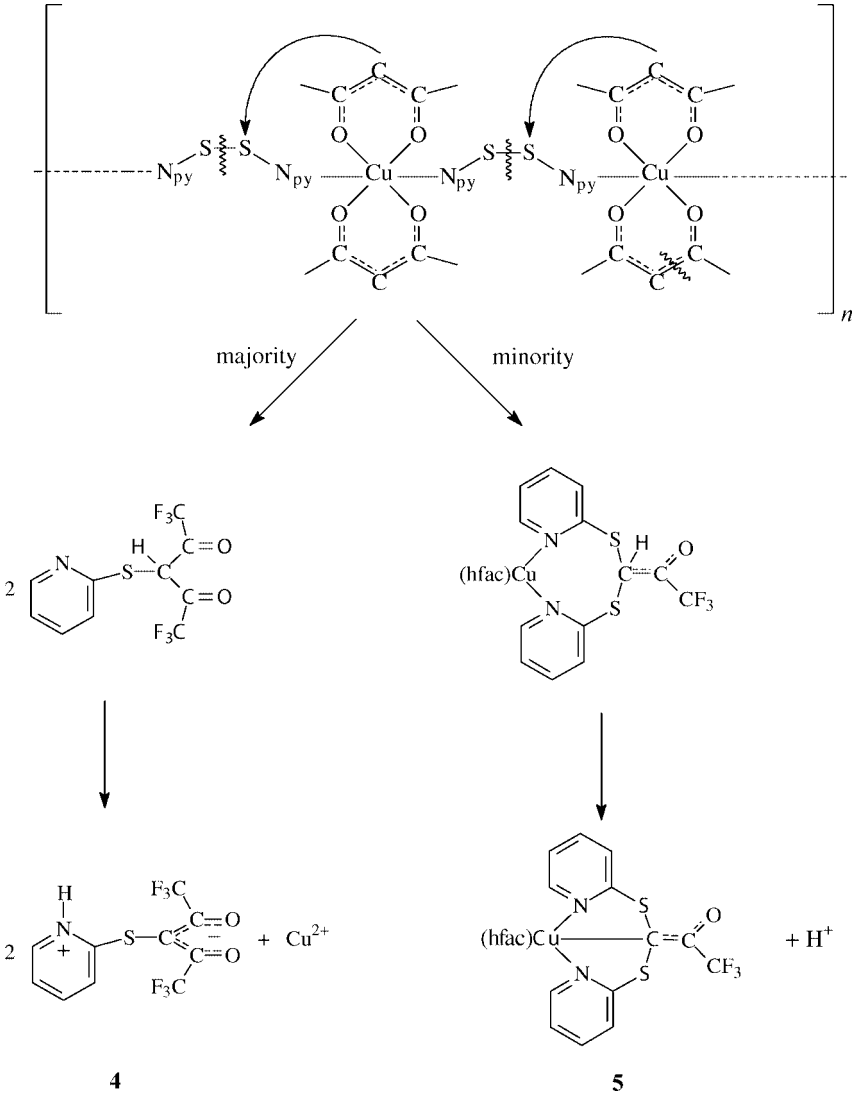
reactions, in $CH_2Cl_2$ at reflux, under both anaerobic and anhydrous conditions, and monitored the reactions by FT-IR spectroscopy until the strong $\nu_{C\equiv O}$ band at 1641 $cm^{-1}$ assigned to **3** disappeared. However, the results were similar to those previously obtained.

One possible mechanism that could explain the formation of **4** and **5** from **3** involves the homolytic cleavage of the S–S bond in the **L3** ligand, probably promoted by the $Cu^{II}$ ion. It is known that the disulfide bond in R–S–S–R–systems is broken by metal ions.[12b] The attack of the imine carbon atom of the $hfac^-$ anion on the sulfur atom of the pyridyl sulfide radical leads to the formation of **4**. This pathway is predominant because **4** is obtained in higher yield than **5**. Along with this, some $hfac^-$ is broken apart and $C(H)C(O)CF_3$ fragments are bonded to the sulfur atom of pyridyl sulfide to give **5**, probably via the formation of an intermediate with an acid proton, which is easily removed by the stabilization that allows the formation of two five-membered rings. The $CF_3$–C(O) fragments could be recombined to produce the 1,2-diketone $F_3C$–C(O)–C(O)–$CF_3$, which could not be detected because of its high volatility (b.p. = 19 °C). Some of the $CF_3$–C(O) fragments could also lead to $CHF_3$ and CO, but neither of these were detected during the reaction (Scheme 2).

Finally, when $Cu(OAc)_2{\cdot}H_2O$ dissolved in methanol is reacted at room temperature with **L3** in methanol in a 1:1 molar ratio, a green solution is obtained. After workup, green crystals of the molecular 1:2 adduct $Cu_2(\mu\text{-}OAc)_4(L3)_2$ (**6**) were obtained. The polymeric compound was not formed. This complex dissociates to $Cu(OAc)_2{\cdot}H_2O$ and **L3** after prolonged standing in contact with the solution.

All compounds have been characterized by analytical and IR spectroscopic data. Details are given in the Experimental Section. In the IR spectra of **1** and **2**, the $\nu$(CO) stretching bands appear to be split into two bands (1654, 1592 $cm^{-1}$and 1644, 1594 $cm^{-1}$, respectively) while in **3** only one $\nu$(CO) is observed (1641 $cm^{-1}$). This is consistent with a pseudooctahedral geometry around the copper(II) ion (see the description of the structures). In **1** and **2** the former bands are assigned to the stretching of C(4)=O(3),



Scheme 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

C(24)=O(3) and C(3)=O(2), C(21)=O(2), respectively; these oxygen atoms are more strongly bonded to the $Cu^{II}$ ion, and the latter to C(1)=O(1), C(19)=O(1) and C(6)=O(4), respectively. In **3**, the four (C=O) distances of the two hfac rings have similar values. In the IR spectrum of **4** a single $\nu$(CO) band is observed at 1679 $cm^{-1}$, at a higher energy than those for polymers **1**–**3**, which is in accordance with the shorter (C–O) bond. Moreover, a $\nu$(N–H) band is located at 3103 $cm^{-1}$, and a $\nu$(C=N) band and three $\nu$(C=C) bands at 1606, 1583, 1452, and 1420 $cm^{-1}$, respectively, are observed. The latter four bands are shifted to a higher energy with respect to the free ligand (1570, 1556, 1443, and 1416 $cm^{-1}$, respectively); the same behavior is observed when pyridine and pyridinium ligands are compared. Finally, at 838 $cm^{-1}$ a new band appears that can be attributed to a (C–S) vibration of the new bond, which has formed. In the IR spectrum of **5**, two types of $\nu$(CO) stretching bands are observed. A single (CO) band at 1673 $cm^{-1}$, attributed to the stretching of C(30)=O(6) from the –C–C(O)–$CF_3$ fragment and a (CO) stretching band with two peaks at 1650 and 1611 $cm^{-1}$ from the chelating hfac ligand. As in **1** and **2**, the first band is assigned to the stretching of C(32)=O(4), which is more strongly bonded to the $Cu^{II}$ ion, and the second to C(34)=O(5).

For **6** the characteristic bands of the acetate anions appear at 1620 $\nu_{as}$(C–O), 1427 $\nu_{sym}$(C–O) and 682 $\delta$(O–C–O) $cm^{-1}$ together with the absorption bands resulting from the aromatic rings in the 1400–1600 $cm^{-1}$ range. The $\Delta$ value ($\nu_{as} - \nu_{sym}$) indicates that the acetate anion coordinates to the $Cu^{II}$ center in a bridging mode.

## Description of the Crystal Structures

### *[Cu(hfac)$_2$L1]$_n$ (1)*

The crystallographic data are given in Table 1 (compounds **1**–**3**). An ORTEP view of a copper center is shown in Figure 1 (a), together with the atom numbering scheme. Selected bond lengths and angles are listed in Table 2. The coordination geometry of the copper(II) ion is pseudooctahedral in which four oxygen atoms from two hfac ligands chelate to the $Cu^{II}$ center, while the other two sites are occupied by two nitrogen atoms from two *cis*-1,2-di(2-pyridyl)-butadiyne ligands. The pyridyl groups of the **L1** ligand are coplanar through the diyne portion. Usually a *trans* orientation of the pyridine rings is adopted in these types of complexes [Cu(hfac)$_2$L$_2$] [L = pyrazine,[13] 1,2-di(2-pyridyl)-ethyne][7] or the analogous 1,2-bis(3-pyridyl)butadiyne ligand.[14] This different behavior suggests that the relative orientation of the pyridyl nitrogen donors can control the coordination framework and influence the polymeric architectures of the crystalline materials. To the best of our knowledge, a *cis* orientation has only been found in [Cu(hfac)$_2$(4-PDS)] (4-PDS = 4,4′-dipyridyl disulfide).[15] As already known, $Cu^{II}$ is Jahn–Teller-active, so it is expected to adopt a 4+2 coordination environment with two long bond lengths and four shorter ones, as is usually observed. As a result of this, the bond angles within the $CuO_4N_2$ octahedra deviate appreciably from 90° and vary from 81.61(5) to 100.57(6)° for O(2)–Cu(1)–O(1) and N(2)–Cu(1)–O(4), respectively. Similar types of distorted coordination geometries are reported for [Cu(hfac)$_2$L]$_n$ complexes.[16,17] In addition to this, the N(2)–Cu(1)–N(1) bond angle, which is 96.37(6)°, deviates from a perfect right angle.

The Cu–N bond length of 2.0438(2) Å in **1** is intermediate between the Cu–N bond length found in the Cu(hfac)$_2$ complexes with 1,2-bis(3-pyridyl)ethyne {2.061(3) Å}[7] and 1,2-bis(3-pyridyl)butadiyne {2.026(2) Å};[15] and significantly longer than that in the polymeric compound [Cu(hfac)$_2${1,2-bis(4-pyridyl)ethane}]$_n$ [Cu–N 2.014 (7) Å].[13]

Two copper centers bond through the N1 and N2 atoms of two $\mathbf{L_1}$ molecules in a *transoid* conformation forming dimers. As a result of this, the extended structure consists of polymeric 1D chains that run parallel to the *b* axis as is shown in Figure 2, where the **L1** ligand links the Cu(hfac)$_2$ moieties together. The intra- and interpolymer Cu···Cu distances are 8.950 Å and 8.221 Å, respectively. Because **L1** affords close contact between neighboring polymeric chains, the interpolymeric Cu···Cu distance is significantly shorter than that in the polymer constructed from the 1,2-bis(3-pyridyl)butadiyne ligand (13.88 Å).[14] Surprisingly, no interpolymer hydrogen-bonding interactions were found.

### *[Cu(hfac)$_2$L2]$_n$ (2)*

The crystallographic data are given in Table 1 (compounds **1**–**3**). Selected bond lengths and angles are listed in Table 3. The structure, emphasizing the coordination environment around the copper atom, is shown in Figure 1 (b). As in **1**, the copper atom has a six-coordinate 4+2 pseudo-octahedral geometry defined by two nitrogen donors from two *cis*-**L2** ligands and four oxygen donors from two hfac chelating ligands. In contrast, the pyridyl groups of the **L2** ligand are not coplanar through the diyne portion and form an angle of 68°. The Cu–N and Cu–O bond lengths are very close to those found in compound **1**. In contrast to **1**, the two Cu(hfac)$_2$ units of compound **2** are joined by the **L2** ligand in a *cisoid* conformation. The structure of **2** consists of one-dimensional chains running parallel to the *a* axis, as is shown in Figure 3. The intra- and interpolymer Cu···Cu distances are 9.421 Å and 10.983 Å, respectively. Interpolymer hydrogen bonding was not observed.

### *[Cu(hfac)$_2$L3]$_n$ (3)*

An ORTEP view of the copper center is shown in Figure 4 (a), together with the atom numbering scheme. Table 1 (compounds **1**–**3**) gives the crystallographic data for **3**, while selected bond lengths and angles are listed in Table 4. In this compound the copper atom has a six-coordinate 4+2 pseudooctahedral geometry, where the four equatorial sites are defined by four oxygen atoms from two hfac chelating ligands (1.9365 Å to 1.9572 Å), but in contrast to compounds **1** and **2**, the axial sites have two nitrogen donors from two *trans*-**L3** ligands. This is unusual because four equatorial sites Cu–O/N and two axial sites Cu–O are

found in $L_2Cu(hfac)_2$ type complexes. The Cu–N bond lengths are 2.4587(19) and 2.5968(19) Å, unexpectedly longer than distances found in copper dipyridyl disulfide compounds[14,15,18] or in N-donor-coordinated $Cu(hfac)_2$ complexes, including **1** and **2**. A similar distance is reported for $[Cu(hfac)_2(pyz)]$ [2.529(9) Å][19a] and $Cu(hfac)_2$(ted) [2.566(7) Å].[19b] One possible explanation for these very long Cu–N bonds is the interaction of the pyridine rings with the hfac ring (see part a in Figure 4). The intramolecular geometry of the **L3** ligand shows a C–S–S–C torsion angle of 79.8(10)°, smaller than that in the free ligand (87.1°) and in the analogous $Cu(hfac)_2$(4,4′-dipyridyl disulfide)[15] [88.1(2)°], which seems to indicate a slight deformation when **L3** is coordinated to the metal ion. The S–S bond length of 2.0369(8) Å is in close agreement with the value found in the free **L3** ligand [2.016(2)].[20] The angle between the two pyridyl rings is 79.83(10)°. Compound **3** assumes a one-monodimensional zigzag chain structure, as shown in part b of Figure 4, where each copper center is bridged by the twisted ligands of 2,2′-dipyridyl disulfide in a *cisoid* conformation. The interchain and intrachain Cu–Cu distances are 8.139 and 9.573 Å, respectively.

### *2-[(1-Hydro-2-pyridinio)thio]hexafluoroacetylacetonate (4)*

The structure is shown in Figure 5 (a) together with the atom numbering scheme. Crystallographic data are given in Table 1 (compounds **4**–**6**), and the selected bond lengths and angles are listed in Table 5. The molecule adopts a nonplanar disposition. The pyridinium ring is oriented almost perpendicular to the hexafluoroacetylacetonate anion (89.75°). The intramolecular geometry of the hexafluoroacetylacetonate anion shows O–C–C, C–C–C, and C–S–C torsion angles of 126.40(13), 118.66(12), and 104.84(7)°, respectively; these values are comparable to those found for compound **3** [128.2(2), 121.1(2), and 104.64(8)°, respectively] and indicates that the $hfac^-$ moiety seems to maintain its characteristic shape. The C–S distances are 1.7573(15) and 1.7601(14) Å, which are similar to those found in other copper dipyridyl disulfide compounds[15,18] and slightly

shorter than the **L3** ligand [1.785(2) Å]. Two molecules of **4** are linked through hydrogen bonds between the hydrogen atom of the pyridinium ring and oxygen atoms of the hexafluoroacetylacetonate anion resulting in dimers (Figure 5, b).

### *[(hfac)Cu($C_{13}H_8N_2S_2OF_3$)] (5)*

The molecular structure is shown in Figure 6. Table 1 (compounds **4**–**6**) shows the crystallographic data, while selected bond lengths and angles are summarized in Table 6. The $Cu^{II}$ ion is pentacoordinated to two oxygen atoms of the hfac anion, two nitrogen atoms of two 2-pyridyl sulfide fragments and one carbon atom of the $CC(O)CF_3$ fragment that has been inserted into the S–S bond of the **L3** ligand, giving a new tridentate ligand with two five-membered rings and coordination to the copper atom through nitrogen atoms of the pyridine rings and the terminal carbon atom of the $CC(O)CF_3$ fragment. Although the S–S bond in **L3** is reactive and can undergo several transformations,[13,19b] to the best of our knowledge, this is the first example of rearrangement that involves scission and insertion into the disulfide S–S bond. The environment of the copper atom is of particular interest. The geometry may be described as a highly distorted trigonal bipyramidal with N4, N3, and O4 atoms at the equatorial position and O5 and C29 atoms at

the axial positions. In copper(II) pentacoordinate complexes, trigonal-bipyramidal and square-pyramidal structures are well known; the structures are mostly square pyramidal with various degrees of distortion.[21] Generally, the Cu–$L_{axial}$ bond is longer than the Cu–$L_{equatorial}$ bond in square-pyramidal structures while the opposite is true for the trigonal-bipyramidal geometry. In this compound, all Cu–L distances are similar [2.0034(14) to 2.1461(14) Å]. The Cu–N bond lengths of 2.0074(2) Å and 2.0439(2) Å are very close to the Cu–N bond lengths found in **1** and **2** and are shorter than those in **3**. The ($C_{pyridine\ ring}$–S) and ($C_{29}$–S) distances are 1.7546(19), 1.7502(19) Å and 1.7915(19), 1.8033(19) Å, respectively, and are similar to those found for **3**, **4**, and **L3**. The (C–Cu) distance is 2.0857(19) Å. The C24–S4–C29 and C19–S3–C29 torsion angles of each of the five-membered rings are similar [102.32(9) and 102.22(9)°], respectively, and these rings are not coplanar [C24–S4–C29–S3 and C19–S3–C29–S4 torsion angles are 102.21(11) and 158.59(10)°, respectively]. Both of the five-membered rings form an angle of 54.94(0.04)°.

lographic data, and selected bond lengths and angles are summarized in Table 7. The structure consists of the molecular 1:2 adduct $Cu_2(\mu\text{-}OAc)_4(L3)_2$ where the $Cu^{II}$ ion is pentacoordinate to four oxygen atoms of four different acetate anions and one nitrogen atom from the pyridine ring of **L3** to form a square-pyramidal geometry. The Cu(II) center deviates from the mean equatorial plane, defined by four coordinated oxygen atoms, toward the apical nitrogen atom by 0.1536 Å. The Cu–O distances [1.956(2)–1.981(3) Å] are similar to those in its analogous compounds[22] and the Cu–N [2.252(3) Å] distance is shorter than that in **3** but longer than those in **1** and **2** and similar to $[Cu(hfac)_2]_2(pyz)$ [2.25(2) Å].[19a] Four acetate anions bridge two $Cu^{II}$ centers in *syn-syn* fashion to form a $[Cu_2(OAc)_4]$ dinuclear building unit with a Cu–Cu distance of 2.6229(9) Å, which is linked by two **L3** ligands in a *trans* disposition. A similar structure is observed in $[Cu_2(\mu\text{-}OAc)_4(bpt)_2]$bpt [bpt = 1-(2-pyridyl)-2-(2-pyridylsulfanyl)ethane].[23]

Two pyridyl rings within each **L3** ligand are in a *cisoid* arrangement with a C–S–S–C torsion angle of 89.37(17)°, almost similar to that in the free ligand (87.1°). Steric factors produced by the 2,2′-dipyridyl orientation could explain why the molecular compound $[Cu_2(\mu\text{-}OAc)_4(L3)_2]$ (**6**) is formed instead of the polymeric compound $[Cu_2(\mu\text{-}OAc)_4(L3)]_n$. Reactions with dipyridyl ligands with an orientation different from 2,2′ are in progress in order to test how the nature of the ligand affects the structure of the compound.

## Magnetic Properties

The magnetic moment of complex **6** at room temperature is 2.05 $\mu_B$. This magnetic moment is smaller than that expected for two magnetically isolated spin $S = 1/2$ centers per molecule. The representation of the magnetic moment versus temperature shows a pronounced decrease until 100 K and drops more slowly to 0.43 $\mu_B$ at 2 K. The decrease of the magnetic moment could result from a strong antiferromagnetic coupling. The existence of antiferromagnetic interactions in this complex is also supported by the variation of the magnetic susceptibility with the temperature. Thus, a broad maximum from room temperature to 125 K is observed in the plot of $\chi_M$ vs. $T$. This feature is characteristic of antiferromagnetically coupled $Cu^{II}$ pairs.[24] A paramagnetic tail at very low temperatures is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

also observed, which indicates the presence of a paramagnetic impurity. Similar paramagnetic impurities are usually present in complexes with strong antiferromagnetic coupling. Thus, the magnetic data of complex **6** have been analyzed[25] with the isotropic spin Hamiltonian of Equation (1) with $S_1 = S_2 = 1/2$.

$$H = -JS_1S_2 \quad (1)$$

From this spin Hamiltonian the Bleaney–Bowers formula has been derived in which terms corresponding to a paramagnetic impurity (P) and temperature independent paramagnetism (TIP) have been added [Equation (2)]. $N$, $g$, $\beta$, $k$, and $T$ have the usual meaning and $P$ is the molar fraction of the noncoupled paramagnetic impurity. In this expression it is assumed that the paramagnetic impurity follows the Curie law and has the same molecular weight and the same $g$ value as complex **6**.

$$\chi_M = \{2Ng^2\beta^2/kT[3 + \exp(-J/kT)] + TIP\}(1 - P) + (Ng^2\beta^2/2kT)P \quad (2)$$

A very good agreement between the experimental and calculated curves of the magnetic moment and the molar susceptibility for complex **6** was observed with this model. The magnetic parameters obtained in the best fit are: $g$ = 2.21, $J$ = –352 cm$^{-1}$, $TIP = 2.83 \times 10^{-4}$, and $P$ = 2.53%. The agreement factor is $2.95 \times 10^{-5}$. Figure 8 shows the experimental and calculated curves for complex **6**.

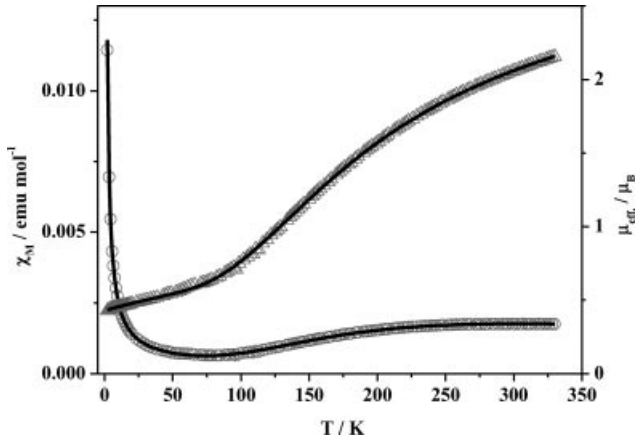

Figure 8. Experimental and calculated curves of $\chi_M$ and $\mu_{eff}$ vs. $T$ for complex **6**.

The $J$ value indicates that the Cu$^{II}$ centers of each molecule are very strongly antiferromagnetically coupled. This coupling constant is in good agreement with those observed in other tetracarboxylatodicopper(II) complexes.[24–26] Because of the large Cu–Cu distance the antiferromagnetic interaction is probably produced through the carboxylate groups. In fact, it has been pointed out[26d] in similar compounds that the $J$ parameter is more related to the O–Cu–Cu–O bond angles and the O–C–O planes than the Cu–Cu distance.

On the other hand, **1**–**3** shows magnetic moments corresponding to the presence of one unpaired electron per mol of copper at room temperature. The magnetic moment remains almost constant with the temperature and decreases sharply only at very low temperatures. This decrease could be explained by Zeeman level depopulation effects in the applied magnetic field. However, as these complexes form monodimensional systems with very long Cu–Cu distances, mediated by the size of the organic ligands, a weak antiferromagnetic coupling between the Cu$^{II}$ centers could also be possible. Thus, to fit these magnetic data we have considered the molecular field approximation applied to a paramagnetic model with $S$ = 1/2 [Equation (3)]. $\chi_{Cu} = Ng^2\beta^2/4kT$, $z$ is the number of neighbors and $J$ is the magnitude of the interaction of the Cu$^{II}$ centers.

$$\chi_M = \frac{\chi_{Cu}}{1 - [2\,zJ/N\,g^2\,\beta^2]\chi_{Cu}} \quad (3)$$

The parameters of the best fits are collected in Table 8. Figure 9 shows the experimental and calculated curves for complex **2**. Similar curves have been obtained for the other complexes. The $zJ$ values (from –0.45 to –0.16 cm$^{-1}$) are very low, in accordance with the presence of a very weak antiferromagnetic interaction between the copper(II) centers.

Table 8. Magnetic parameters for complexes **1**–**3** obtained from the fits of the magnetic moment as a function of temperature.

| Compound | $g$ | $J$ [cm$^{-1}$] | $\sigma^{2}$[a] |
|---|---|---|---|
| **1** | 2.20 | –0.45 | $4.33 \times 10^{-5}$ |
| **2** | 2.20 | –0.24 | $7.55 \times 10^{-5}$ |
| **3** | 2.17 | –0.16 | $9.39 \times 10^{-5}$ |

[a] $\sigma^2 = \Sigma(\mu_{eff.\ calcd.} - \mu_{eff.\ exp.})^2 / \Sigma\mu_{eff.\ exp.}{}^2$, [$\sigma^2 = \Sigma(\chi_{mol\ calcd.} - \chi_{mol\ exp.})^2 / \Sigma\chi_{mol\ exp.}{}^2$].

### Thermal Properties

The thermal properties of the compounds were examined by thermal gravimetric analysis (TGA/DTA) and differential scanning calorimetry (DSC). Compounds **1**–**3** and **6** were heated to 600 °C under a nitrogen atmosphere. TGA data suggest that the framework of **1** is stable up to 170° and show a weight loss of 60.80% (calcd. 60.30%) from 170 to 325 °C corresponding to the loss of one 1,2-di(2-pyridyl) butadiyne (**L1**) and one hfac chelating ligand per formula unit. Further weight loss is observed above 325 °C, with CuO remaining as a black powder (observed 11.82%, calcd. 11.67%). Compound **2** is also stable up to 170 °C, and in the temperature range 170–435 °C it undergoes two weight loss steps corresponding to one 1,2-bis(2-pyridylethynyl)-thiophene ligand (**L2**) and one hfac chelating ligand (found 64.42%, calcd. 64.57%). Above 435 °C, weight loss is also observed and the black powdery product once again is CuO (found 10.62%, calcd. 10.40%). Compound **3** is stable up to 80 °C, and up to 415 °C undergoes three weight loss steps; the first two (up to 160 °C and up to 215 °C) produce a loss of 15.60% and 15.45%, respectively, each corresponding to a 2-pyridyl sulfide fragment (calcd. 15.77%). In the range 215–415 °C, the loss of one hfac anion is observed (found 29.50, calcd. 29.67%). Above 415 °C, the weight loss observed is assigned to CuO (obsd. 11.20%, calcd. 11.39%). Compound **6** is stable up to 125 °C; in the 125–260 °C and 260–400 °C ranges, a loss of two 2,2′-dipyridyl disulfide (**L3**) ligands and three acetate anions, respectively, is observed. Above 400 °C, weight loss is also observed (10.35%) and is attributed to CuO (calcd. 10.52%).

This behavior is common for organic–inorganic coordination polymers consisting of $Cu(hfac)_2$ cations and *N*,*N*′-bidentate-type ligands.[13] DSC analyses of hermetically sealed samples of **1** and **2** display sharp endothermic peaks at 126.4 °C and 177.2 °C, respectively, which correspond to the melting point.

## Conclusions

Six new compounds generated from the reactions of 1,2-di(2-pyridyl)-1,3-butadiyne (**L1**), 2,5-bis(2-pyridylethynyl)-thiophene (**L2**), and 2,2′-dipyridyl disulfide (**L3**) with $Cu(hfac)_2$ and copper acetate have been synthesized and structurally characterized by X-ray diffraction.

The **1**–**3** coordination polymers described in this paper are some of the first reported examples of polymers based on dipyridyl ligands in 2,2′-positions and illustrate that the positional orientation of pyridyl nitrogen atoms and the nature of the ligands (**L1** and **L2** are rigid, **L3** is flexible) affects the structure during the self-assembly process. Moreover, new interesting transformations take place from 2,2′-dipyridyl disulfide (**L3**), because of the reactivity of the S–S bond, and the organic and mononuclear copper compounds **4** and **5** are obtained. In **5**, as a result of rearrangement, a copper–carbon bond is formed. The reaction of **L3** with copper acetate does not lead to polymeric compounds but a molecular complex **6** (1:2 adduct). Further studies of these ligands with transition metal salts are in progress in our laboratories.

## Experimental Section

**General:** All the solvents were of reagent grade quality and were used as received. 2,5-Dibromothiophene (Aldrich), 2-ethynylpyridine (Aldrich), tetramethylethylenediamine (Aldrich), $PdCl_2$ (Aldrich), CuI (Aldrich), $Cu(hfac)_2{\cdot}H_2O$ (hfac = hexafluoroacetylacetonate) (Aldrich), and 2,2′-dipyridyl disulfide (**L3**) (Lancaster) were used as received. $Et_3N$ (Fluka) was distilled from KOH immediately before use. $Pd(PPh_3)_4$[27] and the **L1** ligand[28] were prepared according to a literature procedure and **L2** was synthesized by us from a literature method.[29] The $^1H$ and $^{13}C$ NMR spectra were recorded with Bruker AMX-300 or 500 instruments. Solid-state NMR measurements were performed at room temperature with a Bruker AV 400WB (9.4 T) with a 4 mm MAS probehead. Infrared spectra were measured with a Perkin–Elmer 1650 infrared spectrometer. Elemental analyses were performed by the Microanalytical Laboratory of the University Autónoma of Madrid with a Perkin–Elemer 240 B microanalyzer. The Mass spectrum was measured with a VG-Autospec mass spectrometer for FAB by the Mass Laboratory of the University Autónoma of Madrid. Single-crystal diffraction experiments were performed with samples mounted on a glass fiber and transferred to a Bruker SMART 6 K CCD area-detector three-circle diffractometer with a Rigaku Rotating Anode (Cu-$K_\alpha$ radiation, $\lambda$ = 1.54178 Å) generator equipped with Goebel mirrors at settings of 50 kV and 100 mA. X-ray data were collected at 100 K, with a combination of six runs at different $\varphi$ and $2\theta$ angles, 3600 frames. The data were collected using 0.3° wide $\omega$ scans with a crystal-to-detector distance of 4.0 cm.

The substantial redundancy in data allows empirical absorption corrections (SADABS) to be applied using multiple measurements of symmetry-equivalent reflections.

The raw intensity data frames were integrated with the SAINT program, which also applied corrections for Lorentz and polarization effects.

The software package SHELXTL version 6.10 was used for space group determination, structure solution, and refinement. The space group determination was based on a check of the Laue symmetry and systematic absences and was confirmed using the structure solution. The structures were solved by direct methods (SHELXS-97), completed with difference Fourier syntheses, and refined with full-matrix least-squares using SHELXL-97 minimizing $\omega(F_o^2 - F_c^2)^2$. Weighted *R* factors ($R_w$) and all goodness of fits *S* are based on $F^2$; conventional *R* factors (*R*) are based on *F*. All scattering factors and anomalous dispersion factors are contained in the SHELXTL 6.10 program library. Table 1 contains crystal data for complexes **1**–**6**.

CCDC-264487, -264488, -287409, -287410, -287412, and -287878 contain the supplementary crystallographic data for complexes **1**–**6**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. The variable-temperature magnetic susceptibilities were measured on polycrystalline samples with a Quantum Design MPMSXL SQUID (Superconducting Quantum Interference Device) susceptometer over a temperature range of 2 to 300 K (Complutense University of Madrid). All data were corrected for the diamagnetic contribution of both the sample holder and the compound to the susceptibility. The molar diamagnetic corrections for the complexes were calculated based on Pascal's constants.

The thermal properties were examined by thermal gravimetric analysis (TGA) and differential scanning calorimetry (DSC). The gravimetric data were obtained on a Seiko DTA/TG 320 U using an open pan, which was purged with $N_2$ and at a heating rate of 5 °C/min. The calorimetric data were obtained with a Perkin–Elmer Pyris 1DSC instrument using a sealed pan with a heating rate of 5 °C/min. The melting points were also obtained by using a conventional melting point apparatus.

**Synthesis of 1,2-Bis(2-pyridylethynyl)thiophene (L2):** A mixture of 2,5-dibromothiophene (1.75 g, 7.27 mmol), 2-ethynylpyridine (3.00 g, 29 mmol), $Pd(PPh_3)_4$ (1.26 g, 1.09 mmol), and CuI (0.192 g, 1.0 mmol) in triethylamine (40 mL) and THF (40 mL) was stirred under Ar at 70 °C for 20 h. The solution was cooled to room temperature and after evaporation of the solvent a brown solid was obtained. The crude product was extracted with several portions of ether, filtered and evaporated at reduced pressure. The residue was purified by chromatography on silica gel eluting with ether/$CH_2Cl_2$ (1:1). The product 1,2-bis(2-pyridylethynyl)thiophene (**L2**) was isolated as a yellow solid (1.78 g, 85%); m.p. 115–116 °C. (KBr): $\tilde{\nu}$ = 2204 (s, $\nu_{C\equiv C}$), 1576 and 1556 (s, $\nu_{C=C,}$ $\nu_{C=N}$, conj), 987 (vs, py), 774 (m) and 737 (s, py-H) $cm^{-1}$. $^1H$ NMR ([D$_6$]acetone, 300 MHz): $\delta$ = 8.63 (d, $J$ = 4.3 Hz, 2 H), 7.85 (td, $J$ = 2.7and 0.67 Hz, 2 H), 7.64 (dt, $J$ = 2.7 and 0.3 Hz, 2 H), 7.45 (s, 2 H), 7.40 (td, $J$ = 2.0 and 0.3 Hz, 2 H) ppm. $^{13}C$ NMR (500 MHz, $CDCl_3$): $\delta$ = 81.9 (C8), 93.1 (C7), 123.1(C3), 124.6 (C5), 127.1 (C9), 136.2 (C4), 133.2 (C10), 142.8 (C2), 150.2 (C6) ppm. MS (FAB$^+$): $m/z$ (%) = 286 [M$^+$]. $C_{18}H_{10}N_2S$ (287): calcd. C 75.52, H 3.49, N 9.79; found C 75.58, H 3.43, N 9.70.

**Synthesis of $[Cu(hfac)_2L1]_n$ (1):** A solution of $Cu(hfac)_2{\cdot}H_2O$ (110 mg; 0.245 mmol) in $CH_2Cl_2$ (5 mL) was slowly layered onto a solution of **L$_1$** (50 mg; 0.245 mmol) in $CH_2Cl_2$ (5 mL). The solution was allowed to stand at 0 °C for 2 d. Green crystals were obtained (150.3 mg, 90%). M.p. 133 °C. IR (KBr): $\tilde{\nu}$ = 3077 (w), 1654 (s), 1592 (m), 1574 (s), 1561 (s), 1525 (s), 1475 (s), 1459 (vs), 1425 (s), 1258 (vs), 1240 (m), 1197 (vs), 1146 (vs), 798 (m), 774 (vs), 733 (s), 666 (s), 629 (m), 583 (m), 532 (s) $cm^{-1}$. $C_{24}H_{10}CuF_{12}N_2O_4$ (681.88): calcd. C 42.47, H 1.48, N 4.11; found C 42.24, H 1.50, N 4.08.

**Synthesis of $[Cu(hfac)_2L2]_n$ (2):** A solution of **L2** (40 mg, 0.139 mmol) in $CH_2Cl_2$ (2 mL) was slowly added to a $CH_2Cl_2$ solution (2 mL) of $Cu(hfac)_2{\cdot}H_2O$ (66.8 mg, 0.139 mmol). The solution was allowed to stand at room temperature. After 2 d a yellowish solution appeared. The solvent was then slowly evaporated over a period of 1 d to half the initial volume. The solution was allowed to stand at 0 °C for 2 d and yellow crystals were obtained (90.26 mg, 85%). M.p. 175 °C. IR (KBr): $\tilde{\nu}$ = 3100 (w), 2209 (vs), 1644 (vs), 1594 (vs), 1561 (vs), 1546 (vs), 1523 (vs), 1471 (vs), 1433 (s), 1337 (m), 1320 (m), 1250 (vs), 1196 (vs), 1132 (vs), 1084 (vs), 808 (vs), 790 (vs), 771 (vs), 756 (s), 740 (s), 667 (vs), 583 (vs), 521 (s) $cm^{-1}$. $C_{28}H_{12}CuF_{12}N_2O_4S$ (764): calcd. C 44.00, H 1.57, N 3.67; found C 43.98, H 1.54, N 3. 63.

**Synthesis of $[Cu(hfac)_2L3]_n$ (3), Zwitterionic Compound 4 and $[(hfac)Cu(C_{13}H_8N_2S_2OF_3)]$ (5). Method (a):** A solution of **L3** (100 mg, 0.455 mmol) in $CH_2Cl_2$ (3 mL) was added to a $CH_2Cl_2$ solution (8 mL) of $Cu(hfac)_2{\cdot}H_2O$ (217 mg, 0.455 mmol). After the mixture was left for 2 d at room temperature, the solvent was evaporated. After recrystallization in $CH_2Cl_2$/hexane (1:1), **3** was obtained as a green solid (206.2 mg, 65%), **4** as a yellow solid (36.08 mg, 25%), and **5** as a violet solid (13.65 mg, 5%). X-ray quality crystals of **3** and **4** were grown by slow evaporation of $CH_2Cl_2$ solutions at –10 °C and room temperature, respectively. Crystals suitable for X-ray analysis of **5** were obtained by slow evaporation of hexane solutions at room temperature.

**3:** M.p. 88 °C. IR (KBr): $\tilde{\nu}$ = 3055 (w), 1641 (vs), 1611 (w), 1580 (s), 1561 (s), 1535 (m), 1485 (vs), 1472 (vs), 1455 (vs), 1420 (vs), 1255 (vs), 1224 (vs), 1210 (vs), 1147 (vs), 807 (s), 799 (s), 760 (s), 679 (s), 596 (s), 527 (m) $cm^{-1}$. $C_{20}H_{10}CuF_{12}N_2O_4S_2$ (697.96): calcd. C 34.41, H 1.43, N 4.01, S 9.17; found C 34.32, H 1.48, N 3.97, S 9.23.

**4:** M.p. 102 °C. IR (KBr): 3103 (w), 3070 (w), 1679 (vs), 1606 (m), 1583 (s), 1507 (m), 1452 (s), 1420 (s), 1260 (m), 1203 (vs), 1203 (vs), 837 (m), 803 (m), 758 (s), 722 (s), 520 (m) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 MHz): $\delta$ = 8.40 (d, $J$ = 4.3 Hz, 1 H), 7.56 (dd, $J$ = 3.7 and 1.0 Hz, 1 H), 7.33 (dd, $J$ = 2.3 and 1.8 Hz, 1 H) ppm. $^1H$ NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.68 (d, $J$ = 4.2 Hz, 1 H),8.20 (t, $J$ = 2.6 Hz, 1 H), 7.74 (d, $J$ = 1.05 Hz, 1 H), 7.62 (t, $J$ = 2.24 Hz, 1 H) ppm. $C_{10}H_5NO_2SF_6$ (317.21): C 37.82, H 1.58, N 4.42, S 10.10; found C 3.72, H 1.61, N 4.37, S 9.99.

**5:** M.p. 150 °C. IR (KBr): $\tilde{\nu}$ = 3076 (w), 1673 (vs), 1650 (vs), 1611 (w), 1593 (s), 1559 (s), 1522 (m), 1486 (vs), 1457 (vs), 1421 (vs), 1302 (s), 1285 (s), 1260 (vs), 1203 (vs), 1205 (vs), 1147 (vs), 1051 (s), 1013 (s), 879 (m), 807 (m), 797 (m), 789 (s), 770 (vs), 760 (vs), 729 (s), 703 (s), 679 (s), 668 (s), 586 (m), 527 (m), 486 (m), 410 (m) $cm^{-1}$. $^1H$ NMR ($CDCl_3$, 300 MHz): 8.00 (br. s, 2 H), 7.63 (br. s, 2 H) ppm. $C_{18}H_9CuO_3N_2S_2F_9$ (599.93): calcd. C 36.00, H 1.50, N 4.07, S 10.67; found C 36.18, H 1.47, N 4.06, S 10.58.

**Method (b):** A solution of **L3** (100 mg, 0.455 mmol) in MeOH (2 mL) was added to a solution of $Cu(hfac)_2{\cdot}H_2O$ (217 mg, 0.455 mmol, 6 mL) in the same solvent. After the solution was slowly evaporated at room temperature for 2 d, only green crystals of **3** were obtained (285.8 mg, 90%).

**Method (c):** $Cu(hfac)_2{\cdot}H_2O$ (434 mg, 0.91 mmol) in $CH_2Cl_2$ (15 mL) was added to a solution of **L3** (200 mg, 0.91 mmol) in $CH_2Cl_2$ (6 mL). The reaction was monitored by FT-IR spectroscopy. After the mixture was refluxed for 48 h, the pH was checked and an acidic pH was observed. The solvent was removed under vacuum and the residue was extracted with hexane giving a violet solution. Slow evaporation of the solvent gave crystals of **5** (49.13 mg, 18%) suitable for X-ray analysis. The insoluble residue in hexane was redissolved in $CH_2Cl_2$ and stood for about 3 d at –10 °C. Yellow crystals of **4** were obtained (101.0 mg, 70%). Similar results were obtained when the reaction was carried out in MeOH.

**Synthesis of $[Cu_2(\mu\text{-}OAc)_4(L3)_2]$ (6):** A solution of $Cu(OAc)_2{\cdot}H_2O$ (55 mg, 0.28 mmol) in $CH_3OH$ (15 mL) was added to a solution of **L3** (62 mg, 0.28 mmol) in $CH_3OH$ (3 mL). The solution was left for 2 d at room temperature and for about 2 d in the refrigerator (–10 °C). Blue crystals of copper acetate were isolated by filtration; the solution was filtered off, the solvent was removed under vacuum and the residue was washed several times with hexane/$CH_2Cl_2$ (10:2) to isolate **L3**. Extraction of the solid with $CH_2Cl_2$/$CH_3OH$ (1:1), followed by slow solvent evaporation afforded green crystals of **6** (87 mg, 50%). M.p. 205 °C. IR (KBr): $\tilde{\nu}$ = 3055 (w), 1618 (vs), 1573 (vs), 1561 (vs), 1457 (vs), 1427 (vs), 1418 (vs), 1347 (m), 1288 (m), 1163 (s), 1117 (s), 1051 (s), 1000 (s), 774 (vs), 754 (vs), 719 (s), 682 (vs), 627 (vs) $cm^{-1}$. $C_{28}H_{28}Cu_2N_4O_8S_4$ (803.86): calcd. C 41.84, H 3.49, N 6.97, S 15.94; found C 41.40, H 3.48, N 7.08, S 15.66.

## Acknowledgments

We express great appreciation to the Dirección General de Investigación Científica y Tecnológica (Grant n°. BQU 2002-02522, MAT 2004-22102-E Spain). We are grateful to the student J. Toledano for the help in the preparation of the compounds **L2** and **2**

# Solvothermal Synthesis, Crystal Structures, and Properties of New Selenidoantimonates $[Ln(en)_4(SbSe_4)]$ (Ln = La, Nd) and $[Sm(en)_4]SbSe_4 \cdot 0.5en$: The First Example of an $SbSe_4^{3-}$ Anion Acting as a Ligand to a Lanthanide Complex

**Ding-Xian Jia,*[a] Qian-Xin Zhao,[a] Yong Zhang,[a] Jie Dai,[a] and Jian Zhou[a]**

**Keywords:** Selenidoantimonates / Lanthanides / Antimony / Solvothermal synthesis / Crystal structures

Three new lanthanide selenidoantimonates $[Ln(en)_4(SbSe_4)]$ [Ln = La (**1**), Nd (**2**)] and $[Sm(en)_4]SbSe_4 \cdot 0.5en$ (**3**) (en = ethylenediamine) were first synthesized by treating $LnCl_3$, Sb, and Se in a stoichiometric ratio with en under mild solvothermal conditions. Compounds **1** and **2** are isostructural. The $Ln^{3+}$ ion has a nine-coordinate environment involving eight N atoms from four en ligands and one Se atom from the $SbSe_4^{3-}$ anion forming a distorted bicapped pentagonal bipyramid. $[La(en)_4(SbSe_4)]$ and $[Nd(en)_4(SbSe_4)]$ are the first examples of solvothermally synthesized selenidoantimonates with an $SbSe_4^{3-}$ anion acting as a ligand in a lanthanide complex. The crystal structure of **3** contains an isolated bicapped trigonal-prismatic coordinated $[Sm(en)_4]^{3+}$ cation, a tetrahedral $SbSe_4^{3-}$ anion, and half a free en molecule in its asymmetric unit. The bandgaps of 2.22 eV for **1**, 2.33 eV for **2**, and 2.54 eV for **3** have been derived from optical absorption spectra. Compound **1** loses the en ligands in one step, whereas compound **2** loses them in two steps.

## Introduction

The mild solvothermal reaction in amine has proven to be a versatile route for the synthesis of main group chalcogenometalates.[1–3] In the case of chalcogenoantimonates, since the compound $[Co(en)_3]CoSb_4S_8$[4] was prepared, a large number of thioantimonates have been synthesized using amino transition metal (TM) complexes $[TM(amine)_m^{n+}]$ as structural directors under solvothermal conditions, giving $[M(en)_3]Sb_2S_4$ (M = Co, Ni),[5] $[M(en)_3]Sb_4S_7$ (M = Mn, Co, Ni),[5,6] $Mn_2(en)Sb_2S_5$,[7] $[Co(en)_3]Sb_{12}S_{19}$,[8] $[Ni(dien)_2]Sb_4S_8$,[9] $[Fe(dien)_2]Sb_6S_{10} \cdot 0.5H_2O$,[10] $[Ni(dien)_2]Sb_4S_9$,[11] $[Ni(dien)_2]_9Sb_{22}S_{42} \cdot 0.5H_2O$,[12] $[Ni(dien)_2]_3(Sb_3S_6)_2$,[13] $[Fe(dien)_2]Fe_2Sb_4S_{10}$[14] (dien = diethylenediamine), $[M(tren)]Sb_2S_4$ (M = Co, Ni),[15] $[M(tren)]Sb_4S_7$ (M = Mn, Fe, Co, Zn),[16] $[Co(tren)]_2Sb_4S_8$,[17] $[Mn(tren)]_4Mn_2Sb_4S_{12}$,[18] and $[Mn(tren)]_2Sb_2S_5$[19] [tren = tris(2-aminoethyl)amine], for example. The thioantimonates exhibit rich structural diversity because of the variable coordination behaviors of $Sb^{III}$ atoms caused by the stereochemically active lone pair.[20] However, compared with the bewildering thioantimonates, the selenidoantimonates combined with transition metals are less explored under mild solvothermal conditions and only a few examples have been reported.[21–25]

The combination of lanthanide metals with chalcogenometalates should lead to new architectural features with unique properties. However, the chemistry explored involving the synthesis of chalcogenometalates integrating with lanthanide metal ions ($Ln^{3+}$) by the solvothermal methodology is very limited. It is a challenge to combine the $Ln^{3+}$ ion with the so-called soft-base chalcogenometalate anions in solution because of the weak coordination of chalcogenometalate anions and the hydrolysis of lanthanide ions. Very recently, templated by (en)lanthanide(III) complexes, two series of lanthanide thioantimonates(V), $[Ln(en)_3(H_2O)_x(\mu_{3-x}\text{-}SbS_4)]$ ($x$ = 0, 1; Ln = La, Nd, Sm) and $[Ln(en)_4]SbS_4 \cdot 0.5en$ (Ln = Sm, Eu, Dy, Yb),[26,27] were obtained from the synthetic system $Ln^{3+}$/Sb/S/en under solvothermal conditions during our systematic synthesis of chalcogenometalates in superheated en.[28–31] The present contribution reports the synthesis, crystal structures, and properties of new lanthanide selenidoantimonates(V) $[La(en)_4(SbSe_4)]$, $[Nd(en)_4(SbSe_4)]$, and $[Sm(en)_4]SbSe_4 \cdot 0.5en$, which were obtained from a solvothermal route. To the best of our knowledge, the present compounds are the only examples of selenidoantimonates combined with lanthanide(III) complex cations.

## Results and Discussion

The compounds **1** and **2** crystallize in the monoclinic space group $P2_1/n$ with four formula units in the unit cell and are isostructural. The molecular structure of **1** is de-

picted in Figure 1. The lanthanide(III) ion is coordinated by four bidentate en ligands and a monodentate $SbSe_4^{3-}$ anion leading to a neutral complex $[Ln(en)_4(SbSe_4)]$ [Ln = La (**1**), Ln = Nd (**2**)]. The central $Ln^{3+}$ ion lies within a nine-coordinate environment forming a distorted monocapped square antiprism $LnN_8Se$. The Ln–N bond lengths are 2.648(4)–2.773(3) Å for La–N and 2.628(3)–2.725(3) Å for Nd–N, and are consistent with those in other compounds containing (en)lanthanide(III) complexes.[27,32] The La–Se [3.3197(5) Å] and Nd–Se [3.2992(6) Å] bond lengths are comparable to those in multinary lanthanum and neodymium selenides [3.1070(12)–3.3625(12) Å for La–Se in $KLaP_2Se_6$[33] and 2.979(1)–3.245(1) Å for Nd–Se in $Nd_4MnOSe_6$[34]]. The Ln–N and Ln–Se bond lengths decrease from La to Nd, as expected from the lanthanide contraction. The $SbSe_4^{3-}$ anion is a distorted tetrahedron, as evidenced by Sb–Se bond lengths ranging from 2.4654(5) to 2.4851(7) Å and Se–Sb–Se angles ranging from 107.715(18) to 111.558(17)°. Both lengths and angles are comparable to those observed in other compounds containing tetrahedral $SbSe_4^{3-}$ anions.[21–24] The Sb–Se(1) bonds [2.4848(5) Å for **1**, 2.4851(7) Å for **2**] are expectedly longer than other Sb–Se bonds (Table 1) because of the coordination of Se(1) with the lanthanide(III) ion.

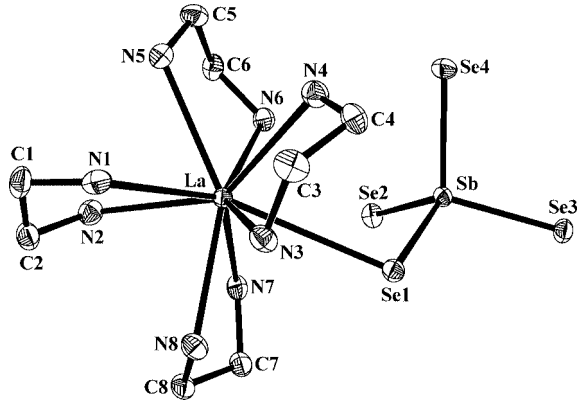

Figure 1. Crystal structure of **1** with labeling scheme; the probability ellipsoids are drawn at the 50% level. Hydrogen atoms are omitted for clarity.

In **1**, the terminal Se atoms of $[La(en)_4(SbSe_4)]$ are involved in intermolecular N–H···Se hydrogen bonding with adjacent molecules resulting in a chainlike arrangement of $[La(en)_4(SbSe_4)]$ moieties parallel to the *a* axis (Figure 2). The chains are further connected through N–H···Se hydrogen bonds leading to a three-dimensional network. The N···Se distances vary from 3.443(4) to 3.755(4) Å and the N–H···Se angles vary from 138.1 to 167.7° (Table 2), and are consistent with the values reported in the literature.[35] Similar intermolecular hydrogen bonding is observed in compound **2** (Table 2).

Compound **3** crystallizes in the space group $P2_1/n$ with four formula units in the unit cell. Its molecular structure is quite different from those of **1** and **2**, but it is isostructural to the thio analog of $[Sm(en)_4]SbS_4 \cdot 0.5en$.[26] The crystal structure of **3** consists of an isolated four-en-coordinated $[Sm(en)_4]^{3+}$ cation, a tetrahedral $SbSe_4^{3-}$ anion, and half a free en molecule in its asymmetric unit (Figure 3). The atom C(2) is disordered and the occupancies of disordered C and C′ are assigned as 55% and 45%, respectively. The $Sm^{3+}$ ion is in an eight-coordinate environment with eight amino N atoms from four bidentate en ligands forming a distorted bicapped trigonal prism. The Sm–N bond lengths [2.532(5)–2.576(6) Å] are comparable with those reported in the literature.[26] The Sb–Se distances and Se–Sb–Se angles are in agreement with those in **1** and **2** (see Tables 1 and 3). The Se atoms of the $SbSe_4^{3-}$ anion are in contact with $-NH_2$ groups with N···Se distances ranging from 3.402(5) to 3.764(5) Å and N–H···Se angles ranging from 142.1 to 171.9°, indicating weak hydrogen bonds. An N(6)–H(6A)···N(9) hydrogen bond is formed with an N(6)···N(9) distance of 3.100(8) Å and an N(6)–H(6A)···N(9) angle of 156.2°. The N–H···Se and N–H···N hydrogen-bonding interactions lead to a three-dimensional network structure. The crystal packing of **3** is illustrated in Figure 4.

In our systematic investigation of lanthanide thioantimonate compounds in superheated en, two types of compounds were obtained across the lanthanide series. The lighter (en)lanthanide(III) complex cations are bridged by $\mu_3$-$SbS_4$ or $\mu_2$-$SbS_4$ ligands to form one-dimensional neutral polymers $[Ln(en)_3(H_2O)_x(\mu_{3-x}\text{-}SbS_4)]$ (Ln = La, Nd, Sm),[26,27] whereas the heavier ones form compounds

[a] Symmetry code: $x + 1, y, z$. [b] Symmetry code: $-x + 3/2, y - 1/2, -z + 3/2$. [c] Symmetry code: $x + 1/2, -y + 3/2, z - 1/2$. [d] Symmetry code: $-x + 3/2, y + 1/2, -z + 1/2$.

$[Ln(en)_4]SbS_4 \cdot 0.5en$ (Ln = Sm, Eu, Dy, Yb)[26,27] that are constructed from isolated $[Ln(en)_4]^{3+}$ and $SbS_4^{3-}$ ions. The two types of thioantimonates are related to the stability of the (en)lanthanide(III) complexes, coordination number, and the radii of the metal ions.[27] A similar situation is observed in the case of selenidoantimonate. The (en)lanthanide(III) complexes also form two kinds of selenidoantimonates with the $SbSe_4^{3-}$ anion in en. In **1** and **2**, $[Ln(en)_4]^{3+}$ (Ln = La, Nd) cations combine with $SbSe_4^{3-}$ through an Ln–Se bond, while $[Sm(en)_4]^{3+}$ does not bond with $SbSe_4^{3-}$ in **3**. Although the lanthanide(III) ions do not exhibit restricted stereochemistry in coordination complexes and are characterized by variable coordination numbers and geometries in the solid state,[36] it is commonly observed that the lighter lanthanide ions prefer coordination numbers of nine and heavier ones prefer coordination numbers of eight in solution.[37] Because en is a bidentate ligand, the $[La(en)_4]^{3+}$ and $[Nd(en)_4]^{3+}$ ions are bonded to the monodentate ligand $SbSe_4^{3-}$ to maintain the coordination number of nine for $La^{3+}$ and $Nd^{3+}$, and $[La(en)_4(SbSe_4)]$ and $[Nd(en)_4(SbSe_4)]$ are formed. It is worth noting

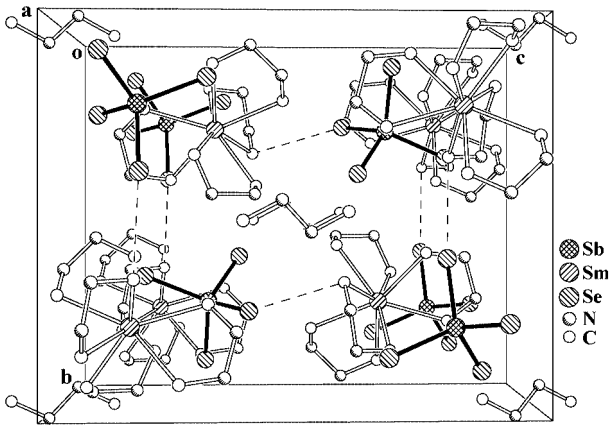

Figure 4. Crystal structure of $[Sm(en)_4]SbSe_4 \cdot 0.5en$ viewed along the *a* axis; hydrogen atoms are omitted for clarity.

that $SbS_4^{3-}$ and $SbSe_4^{3-}$ exhibit different coordination modes when bound to the same lanthanide ions. For example, in $[La(en)_3(\mu_3\text{-}SbS_4)]$, $SbS_4^{3-}$ acts as a $\mu_3$-$SbS_4$ tridentate ligand to interlink $[La(en)_3]^{3+}$ ions, while $SbSe_4^{3-}$ coordinates to the $[La(en)_4]^{3+}$ ion as a monodentate ligand in the compound $[La(en)_4(SbSe_4)]$. This structural difference can be interpreted in terms of the lower coordination ability of the $SbSe_4^{3-}$ anion with respect to $SbS_4^{3-}$. Compared with the $SbS_4^{3-}$ ligand, $SbSe_4^{3-}$is a soft-base ligand for the hard-acid cations of lanthanide(III) because of the larger radius of the selenium atom. Therefore, lanthanum can be coordinated with three sulfur atoms ($\mu_3$-$SbS_4$) and six nitrogen atoms to form the $\mu_3$-$SbS_4$ compound $[La(en)_3(\mu_3\text{-}SbS_4)]$ in a sulfide solution, but with one selenium atom and eight nitrogen atoms to form the mono-$SbSe_4$ compound $[La(en)_4(SbSe_4)]$ in a selenide solution.

## Optical Properties

The optical absorption spectra of compounds **1**–**3** show well-defined abrupt absorption edges from which the bandgaps were estimated as 2.22 eV for **1**, 2.33 eV for **2**, and 2.54 eV for **3** (see Figure 5). These bandgaps are larger than those of the multinary lanthanide polythioantimonates(III), such as $K_2La_2Sb_2S_9$ (2.20 eV)[38] and $La_2SbS_5Br$ (2.08 eV),[39] which are free of organic components.

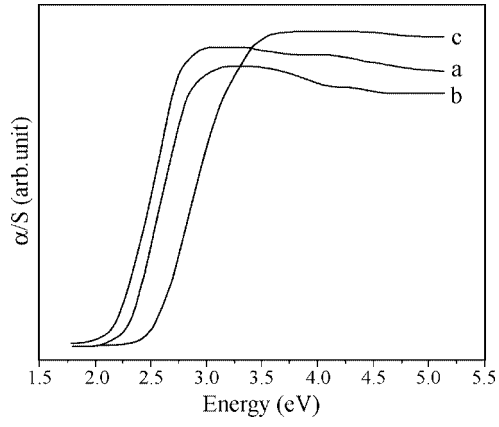

Figure 5. Optical absorption spectra of compounds **1** (a), **2** (b), and **3** (c).

## Thermal Investigations

On heating in a nitrogen stream, compound **1** starts to decompose at $T_{onset}$ = 190 °C with a weight loss of 29.2% (calcd. 29.4% for four en ligands) in one step. The weight loss is in good agreement with the theoretical value of 29.4% involving the complete removal of four en ligands. The decomposition process is accompanied by a strong endothermic signal in the DSC curve with peak temperature $T_p$ = 222 °C (Figure 6a). In the IR spectrum of the residue no H–N, H–C, C–N, and C–C vibrations could be detected. For **3**, thermal decomposition occurs in two steps with a weight loss of 3.0% (calcd. 3.5% for 0.5 en ligands) and 28.0% (calcd. 28.0% for four en ligands), which correspond with the removal of free en and coordinated en ligands, respectively. The two decomposition steps are accompanied by two endothermic signals in the DSC curve with peak temperatures of $T_p$ = 118 °C and $T_p$ = 236 °C (Figure 6b).

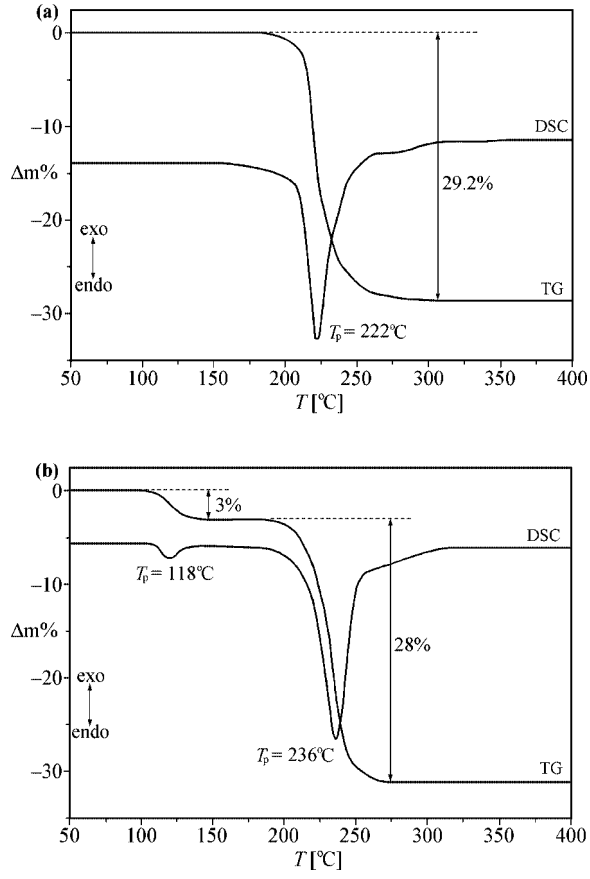

Figure 6. TG-DSC curves of compounds **1** (a) and **3** (b).

## Conclusions

The lanthanides(III) typically produce "hard"-acid cations, which preferentially bond to oxygen and nitrogen donor atoms in solution so it is a challenge to combine $Ln^{3+}$ ions with the so-called soft-base chalcogenometalate anions in an amine solvent. We have successfully synthesized novel selenidoantimonates containing lanthanide(III) in an en solvent under solvothermal conditions. $[Ln(en)_4(SbSe_4)]$ (Ln = La, Nd) and $[Sm(en)_4]SbSe_4{\cdot}0.5en$ are the first examples of solvothermally synthesized selenidoantimonates. The solvothermal method is a new route for the synthesis of multinary lanthanide selenides decorated by organic components. The synthesis and solid-state structural studies described in this article show that the soft-base ligand $SbSe_4^{3-}$ can coordinate to lanthanide(III) ions in an amine solution. This will shed light on a more complete understanding of the coordination chemistry of lanthanides(III) and preparation of lanthanide selenidometalates by mild solvothermal methods.

## Experimental Section

**General:** All analytical grade chemicals were obtained commercially and used without further purification. Elemental analysis was conducted with an MOD 1106 elemental analyzer. FT-IR spectra were recorded with a Nicolet Magna-IR 550 spectrometer using dry KBr discs in the 4000–400 $cm^{-1}$ range. Room-temperature optical diffuse reflectance spectra of the powdered samples were obtained with a Shimadzu UV-3150 spectrometer. The absorption ($\alpha$/S) data were calculated from the reflectance using the Kubelka–Munk function $\alpha/S = (1 - R)^2/2R$,[40] where $R$ is the reflectance at a given energy, $\alpha$ is the absorption, and S is the scattering coefficient. Thermoanalytical measurements were performed with a DCS-TGA microanalyzer of SDT 2960, and all the samples were heated under a nitrogen stream of 100 mL $min^{-1}$ with a heating rate of 5 °C $min^{-1}$.

**Synthesis of $[La(en)_4(SbSe_4)]$ (1):** The reactants $LaCl_3$ (122.6 mg, 0.5 mmol), Sb (61 mg, 0.5 mmol), and Se (158 mg, 2 mmol) were mixed in ethylenediamine (3 mL) whilst stirring. The mixture was loaded into a Teflon-lined stainless steel autoclave with an inner volume of 15 mL, and the sealed autoclave was then heated to 140 °C for 7 d. After cooling to ambient temperature, orange block crystals of **1** were obtained. The crystals were washed with ethanol and diethyl ether, dried and stored under vacuum. Yield: 188 mg (46%). $C_8H_{32}LaN_8SbSe_4$ (816.92): calcd. C 11.86, H 3.95, N 13.72; found C 11.81, H 3.92, N 13.66. IR (KBr): $\tilde{\nu}$ = 3383 (s), 3241 (s), 3106 (s), 2924 (s), 2870 (m), 1582 (vs), 1489 (s), 1454 (s), 1385 (m), 1327 (s), 1277 (m), 1146 (w), 1103 (w), 1007 (vs), 860 (w), 822 (w), 633 (m), 494 (m) $cm^{-1}$.

**Synthesis of $[Nd(en)_4(SbSe_4)]$ (2):** Orange-yellow platelet crystals of **2** were obtained by using a similar synthesis procedure to that used in **1** except that reactant $LaCl_3$ was replaced by $NdCl_3$. Yield: 226 mg (55%). $C_8H_{32}N_8NdSbSe_4$ (822.25): calcd. C 11.69, H 3.92, N 13.63; found C 11.54, H 3.88, N 13.60. IR (KBr): $\tilde{\nu}$ = 3335 (s), 3240 (s), 3167 (s), 2940 (s), 2870 (s), 1597 (s), 1578 (s), 1481, 1459 (s), 1385 (m), 1354 (s), 1214 (w), 1157 (w), 1080 (s), 1030 (vs), 822 (w), 779 (w), 640 (s), 513 (w), 440 (m) $cm^{-1}$.

**Synthesis of $[Sm(en)_4]SbSe_4{\cdot}0.5en$ (3):** Yellow prism crystals of **3** were obtained by using a similar synthesis procedure to that used in **1** except that reactant $LaCl_3$ was replaced by $SmCl_3$. Yield: 223 mg (52%). $C_9H_{36}N_9SbSe_4Sm$ (858.41): calcd. C 12.59, H 4.23, N 14.68; found C 12.54, H 4.25, N 14.62. IR (KBr): $\tilde{\nu}$ = 3301 (vs), 3280 (s), 3245 (s), 3132 (s), 2930 (vs), 2880 (s), 1570 (vs), 1515 (s), 1385 (m), 1331 (s), 1157 (w), 1007 (s), 868 (w), 814 (w), 776 (w), 660 (w), 498 (m) $cm^{-1}$.

**X-ray Crystal Structure Determinations:** A summary of crystal data and refinement parameters is given in Table 4. Data were collected with a Rigaku Mercury CCD diffractometer at 193(2) K using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) by an $\omega$-scan method with a maximum $2\theta$ value of 54.96°. An orange $0.22 \times 0.15 \times 0.10$ mm block crystal of **1**, an orange-yellow $0.46 \times 0.28 \times 0.05$ mm platelet crystal of **2**, and a yellow $0.35 \times 0.06 \times 0.05$ mm prism crystal of **3** were used for data collection. An absorption correction was applied for all the compounds using a multi-scan correction method. The structures were solved by direct methods using the SHELXS-97 program.[41] The refinement was performed against $F^2$ using the SHELXL-97 program.[42]

All the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were positioned with idealized geometries and refined with fixed isotropic displacement parameters using a riding model. The H atoms of C(1), C(2), and N(2) in **3** were not dealt with because of the disorder of atom C(2). CCDC-299097 (**1**), -299098 (**2**), and -299099 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Semicarbazide-Functionalized Silicate Nanoparticles for Peptide Ligation

Tristan Doussineau,[b] Jean-Olivier Durand,[c] Ouafâa El-Mahdi,[a] Céline Maillet,[a] Oleg Melnyk,[a] Christophe Olivier,[a] and Monique Smaïhi*[b]

**Keywords:** Zeolites / Colloids / Peptides / Fluorescence spectroscopy / Organic–inorganic composites

Monodisperse silicate nanoparticles have been used for the development of a site-specific ligation method that enables the control of the biomolecule orientation at the solid–liquid interface. Two types of zeolite nanoparticles were studied: zeolite β, which possesses a Si/Al ratio of 25, and silicalite-1, which is a fully silicic material. Zeolite-type materials are microporous silicate with pores of a well-defined size ranging from 2 to 20 Å. Semicarbazide-functionalized silicate colloids have been prepared for the site-specific ligation of COCHO-modified polypeptides. The obtained colloidal suspensions have been characterized by complementary techniques providing information on the size distribution, morphology, and porosity of the particles and chemical nature of the grafting. The specificity of the particles' surface for the semicarbazide group has been studied by fluorescence spectroscopy with two peptides labeled with rhodamine. A first peptide bares a COCHO functionality, which should bind covalently with the semicarbazide surface. The second peptide bares an amine end-group, which should interact by nonspecific adsorption with the surface. The results demonstrated that the peptide/colloids' reactivity is dramatically influenced by the chemical composition of the particles' surface. Indeed, while zeolite β (aluminosilicate) particles react indifferently with the two peptides, silicalite particles (pure silicate) anchor exclusively the peptide bearing the COCHO functionality. This particular physisorption phenomenon of zeolite β is attributed to the aluminum atoms present at the particles' surface, which have a specific affinity for peptides.

## Introduction

Nanoparticles (NPs) have great promise in bioanalysis and biotechnological applications because of their unique optical properties, high surface-to-volume ratio, and other size-dependent qualities.[1–3] When combined with surface modifications and composition control, these properties provide probes for highly selective and ultrasensitive bioassays.

The use of silica as a substrate in bioanalysis has a special advantage, as shown by its widespread use in biosensors and biochips. Silica can be synthesized by various preparation techniques to prepare NPs, transparent films, or solid flat materials.[4] Silica synthesis is governed by the chemical properties of the surface, which, in return, are based on the silanols and siloxanes present on the surface.[5] Silanol groups can be functionalized through different procedures.[6,7] Therefore, the versatility of silica in synthesis aspects as well as surface modifications offers a great advantage to the use of the materials in bioanalysis.

Among inorganic materials, the synthesis and studies of nanosized zeolites have attracted considerable attention in the last decade.[8] Zeolite-type materials are microporous silicate crystals with pores of a well-defined size ranging from 2 to 20 Å. This discrete pore system gives molecular sieve properties to these materials, which have found great utility as catalysts and sorption media. Lately, functionalized zeolite nanoparticles were envisaged for the preparation of controlled release capsules, artificial cells, chemical sensors, and adsorbents.

In many cases, covalent attachment of a biomolecule at the NPs' surface is preferred to avoid leaching of the biomolecules. The usual pathways for covalent attachment of biomolecules on silica surfaces consist of their functionalization by epoxides,[9] aldehydes,[10] or thiol groups.[11] However, as biomolecules usually possess more than one nucleophilic group, a random immobilization through multiple points of attachment is often observed.[12] Therefore, site-specific ligation methods are highly desired in order to control the biomolecule orientation at the solid–liquid interface.

Recently, we have described the preparation of α-oxo aldehyde (COCHO)- and semicarbazide-functionalized silica, for the site-specific ligation of hydrazinoacetyl- or COCHO-modified polypeptides.[13] Indeed α-oxo aldehyde peptides were shown to react chemoselectively and readily

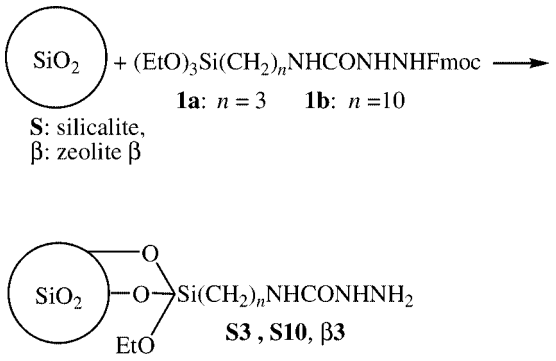
with the surface semicarbazide groups in very mild aqueous conditions. The α-oxohydrazone bond was readily formed and was very stable; no further reduction of the hydrazone bond was needed.

We have extended the α-oxo hydrazone chemistry to monodisperse silicate nanoparticles using α-oxo aldehyde peptides labeled with rhodamine. Two types of zeolite nanoparticles were studied: zeolite β and silicalite-1. Here, we describe the preparation of these nanoparticles, and their reactivity and selectivity for the covalent immobilization of COCHO-modified polypeptides.



Scheme 1. Semicarbazide grafting chemistry (Fmoc: fluorenylmethoxycarbonyl).

## Results and Discussion

Two types of samples have been used, differing mainly in their chemical composition: while silicalite is an "all-silica" zeolite, zeolite β contains aluminum atoms in its framework, with a Si/Al ratio that can be varied between 10 and 500. The zeolite β samples prepared in this study have a Si/Al ratio equal to 25.

As-synthesized zeolites contain an organic structure-directing agent (SDA) located in the framework channels. The SDA removal of zeolites through calcination is a common method employed to reveal the zeolite micropores, where the organic structure-directing agent is burned away. As-synthesized nanoparticles as well as template-free colloids have been used in this study as substrates for peptide ligation.

The anchoring of the peptides at the surface of these colloidal nanoparticles has been done in two steps. First, a semicarbazide coupling agent (SC) has been anchored at the colloids' surface followed by the grafting of peptides labeled with rhodamine. The specificity of the anchoring has been studied using two different peptides. One peptide molecule bares a COCHO functionality, which reacts covalently with the SC. The other peptide should only interact with the SC surface through physisorption, as it lacks the COCHO functionality.

Regardless of the zeolite framework and peptide used, stable colloidal suspensions were obtained for all samples. The different stages of the preparation procedure are presented in Scheme 1 and Scheme 2.

Subsequently, at each step of the preparation procedure, the size and morphology of the nanoparticles were studied by dynamic light scattering (DLS) and SEM. The influence of the various treatments on the porous characteristics of the samples has been analyzed by nitrogen sorption experiments.

$^{29}Si$ and $^{13}C$ NMR were performed also at each step of the preparation procedure in order to characterize the surface bonding.

Finally, the specificity of the peptide anchoring was investigated by fluorescence spectroscopy.

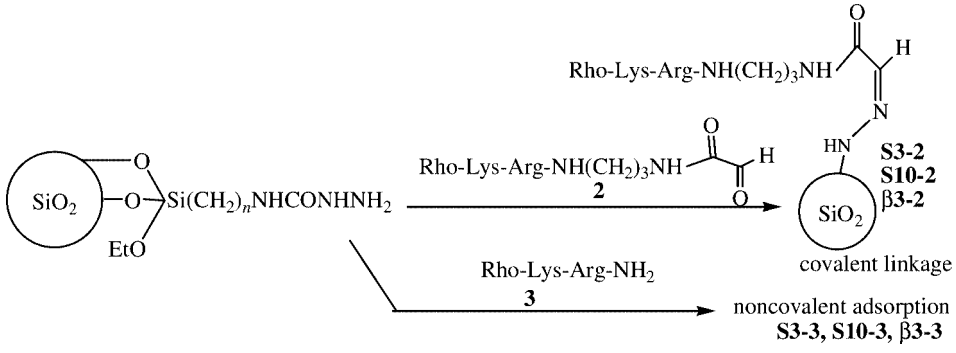
The zeolite β and silicalite-1 nanoparticles are called **β** and **S**, respectively, in the following text, and the template-free silicalite and zeolite β nanoparticles are named tf-**S** and tf-**β**, respectively.

As indicated in Scheme 1, functionalization of zeolite **β** and silicalite **S** with silane **1a** leads to **β3** and **S3**, respectively. Alternatively, reaction of silanes **1** on template-free zeolite nanoparticles gives tf-**β3**, tf-**S3**, and tf-**S10**.

As indicated in Scheme 2, grafting of peptides **i** on nanoparticles of zeolite **β3** and silicalite **S3** leads to samples **β3-i** and **S3-i**.

### Particle Size and Morphology

The DLS study performed after each step of the preparation procedure shows that the average diameter of the particles increases after the grafting procedure (Table 1, Fig-



Scheme 2. Peptide grafting chemistry.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 1). According to the DLS measurements, the average particle sizes of the initial zeolite β and silicalite-1 nanoparticles are about 57 and 64 nm respectively. After functionalization, the **β3**- and **S3**-grafted colloids show average particle sizes around 140 nm (Table 1). The same tendency is observed for template-free colloids. This increase in the average particle size does not only reflect the presence of anchored organic groups at the colloids' surface. Indeed, the maximum particle diameter increase in the case of SC10 functions would be about 4 nm. Therefore the average particle size increase is attributed to a modification of the colloids' surface reactivity after grafting, which leads to the adsorption of solvent molecules, which, in return, increases their hydrodynamic diameter. This effect is well known for silica colloids.[14] The stability of the final colloidal suspensions will enable the use of conventional spectroscopic techniques to study the particles grafted with rhodamine-labeled peptides.

SEM of the samples before and after functionalization (Figure 2) does not show morphological differences between the as-prepared and grafted samples. As these observations are performed on dry particles, sizes derived by this measurement do not take into account any adsorbed solvent crown. Therefore, the particle sizes observed by SEM can be considered as bulk (or core) sizes and are not in contradiction with those measured by DLS.

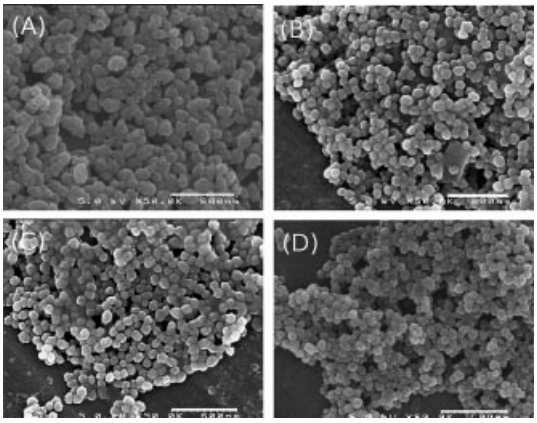


Figure 2. SEM micrographs of silicalite nanoparticles at various steps of the preparation: (A) as-synthesized **S** colloids, (B) **S3** particles, (C) tf-**S3** particles, and (D) tf-**S10** suspensions. Scale bar: 600 nm.

## Microporosity

In order to follow the influence of the various treatments on the porous characteristics of the zeolite samples, nitrogen gas sorption analyses were performed on the as-synthesized nanoparticles and the grafted nanoparticles. The zeolite microporosity is revealed by $N_2$ adsorption on template-free samples (ca. 0.2 $cm^3 \cdot g^{-1}$) and the specific surface area

Table 1. DLS, $N_2$ adsorption/desorption, and elemental analysis data obtained for the as-synthesized, calcined, and grafted particles.

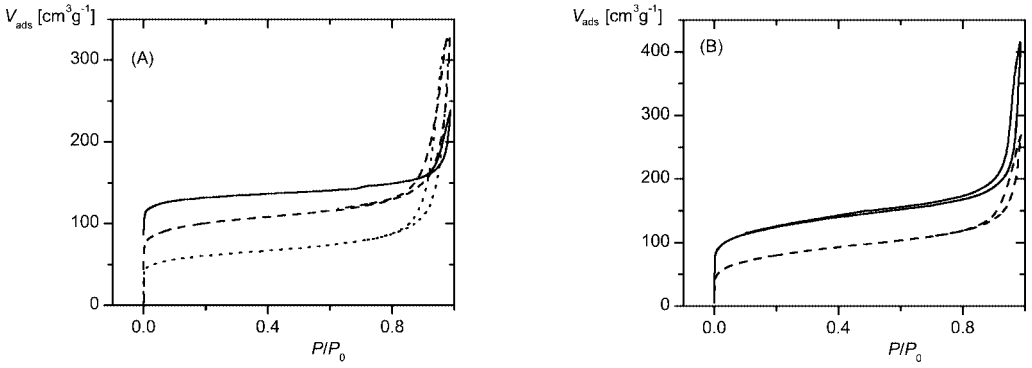

Figure 3. $N_2$ adsorption isotherms of silicalite nanoparticles (A) and zeolite β colloids (B): tf-**S** and tf-**β** (solid line), tf-**S3** and tf-**β3** (dashed line), tf-**S10** (dotted line).

is dramatically increased (ca. 3 times that of the as-synthesized samples) (Table 1). Grafting the zeolite nanoparticles, regardless of the structure used (β or silicalite-1), slightly decreases the specific surface area of the template-free sample (Table 1, Figure 3). This decrease of the micropore volume may indicate that some part of the grafting occurs inside the micropores. However, this decrease of the micropore volume is also observed for silane **1b**-grafted silicalite (tf-**S10** samples), although the size of this molecule forbids its entry through the pores. Therefore, the decrease of the measured micropore volume may be due to a decrease of its accessibility to $N_2$ (because of the presence of functional groups) instead of an actual decrease.

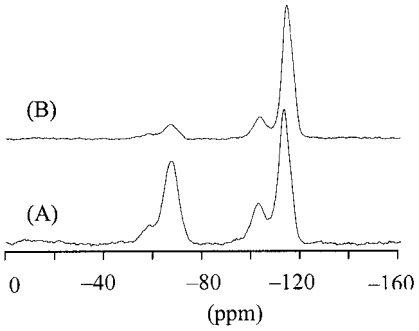

Figure 4. $^{29}$Si CP-MAS NMR spectra recorded for **S3** (A) and **S10** (B) samples.

### Grafting Quantification

Elemental analysis (N and C) allowed determination of the loading of the nanoparticles after the grafting procedure (Table 1). Assuming that each grafted silane molecule occupies 24 Å$^2$, the theoretical loading for a monolayer ranges between 0.55 and 2.4 mmol·g$^{-1}$ depending on the specific surface area of the particles (Table 1).[15–18] As the experimental loading is below a monolayer coverage for each sample, this shows that the microporosity of the nanoparticles is not accessible for silanes **1a** and **1b**.

### Grafting Analysis

CPMAS $^{29}$Si NMR spectra of **S3** and **S10** nanoparticles present signals at $\delta$ = –101 and –110 ppm (Figure 4). Around –110 ppm, the overlapping resonances for both samples are assigned to zeolite framework silicon atoms. Resonances around –113/–115 ppm and –109/–110 ppm are assigned to *Si*(OSi)$_4$, Q4 species with minor resolution of the crystallographic sites. The signal at $\delta$ = –100 ppm is assigned to *Si*(OSi)$_3$OH, Q3 species.[19] The presence of a signal between –60 and –70 ppm indicates that silane **1** is covalently linked to the zeolite framework silicon atoms. Two resonances are observed corresponding to Si attached to the organic chain in two different chemical environments [–67 ppm: C–*Si*–(OSi)$_3$, T3 and –60 ppm: C–*Si*–(OSi)$_2$OH, T2 species].[20]

The presence of T2–T3 species, the absence of T1, C–*Si*(OSi)(OH)$_2$ and Q2, *Si*(OSi)$_2$(OH)$_2$ species and finally the variation in signal intensity for species Q3 and Q4 relative to bare particles demonstrated the efficient grafting of silane **1** on the surface of **S3** and **S10** nanoparticles. Spectra recorded on samples **S3** and **S10** present significant differences in the relative intensity of these characteristic resonances. Although, in the case of CP-MAS spectra, the peak intensity is not directly proportional to the species abundance, this intensity difference may reflect a greater grafting loading for silane **1a** than silane **1b**. This is a further confirmation of the elemental analysis results, which gave a higher coverage for a functionalization with silane **1a** than silane **1b**.

The CPMAS $^{13}$C spectrum of **S3** nanoparticles presents three resonances situated at 9.7, 22.7 and 42.9 ppm corresponding to the propyl chain of silane **1a** (Figure 5). The additional resonance at $\delta$ = 162.1 ppm is attributed to the carbonyl group of the semicarbazide function. Signals corresponding to ethoxy groups or fluorenylmethoxycarbonyl (Fmoc) groups were not detected. This indicates the completion of the grafting reaction and the quality of the centrifugation–redispersion procedure.

$^{29}$Si and $^{13}$C MAS NMR characterization of zeolite β nanoparticles leads to similar spectra presenting the characteristic resonances of T species around –60 ppm for $^{29}$Si spectra and the carbonyl resonance at –162 ppm for $^{13}$C spectra.

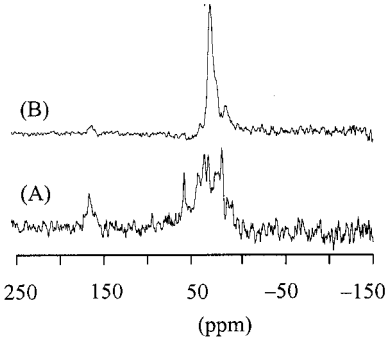

Figure 5. $^{13}C$ CP-MAS NMR spectra recorded for **S3** (A) and **S10** (B) samples.

### Fluorescence Analysis

The nature of the interaction of peptides **2** and **3** with substrates **S**, **β**, **β3**, tf-**β3**, **S3**, and tf-**S10** was analyzed by fluorescence spectroscopy.

First, we checked the eventuality of nonspecific adsorption of peptides **2** and **3** on bare nanoparticles of zeolite **β** and silicalite **S**. After mixing peptides **2** and **3** with zeolite **β** nanoparticles, an intense fluorescence is observed (Figure 6). Meanwhile, very weak fluorescence intensity is obtained for samples based on silicalite **S** (Figure 6). Therefore, this indicates that the zeolite **β** surface is able to immobilize peptides by noncovalent interactions. This physisorption phenomenon is attributed to the presence of aluminum atoms at the zeolite **β** surface, which have been reported to present an affinity for peptides.[21] Fluorescence spectra registered on functionalized samples, **β3** and tf-**β3** treated with peptides **2** and **3**, presented an intense fluorescence for all samples, regardless of the peptide's nature (Figure 7). Therefore, interactions between peptides **2** or **3** and the zeolite **β** surface occurred even after surface modification. Indeed, as the fluorescence intensity observed for samples prepared with peptide **3** is higher than that obtained with peptide **2**, nonspecific adsorption is a highly probable phenomenon for samples based on zeolite **β**.

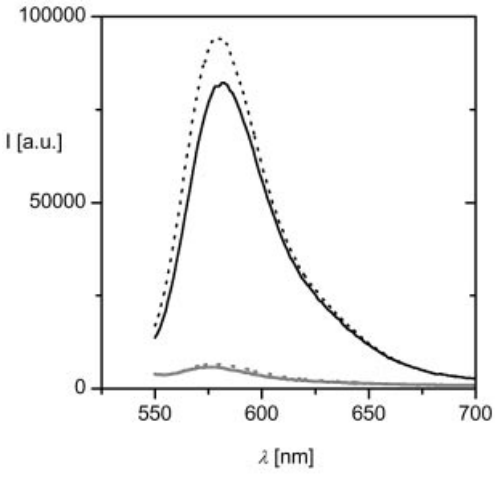

Figure 6. Fluorescence emission spectra of samples obtained after reaction between peptides **2** (dotted line) and **3** (solid line) with nanoparticles of zeolite **β** (black lines) and silicalite **S** (gray lines).

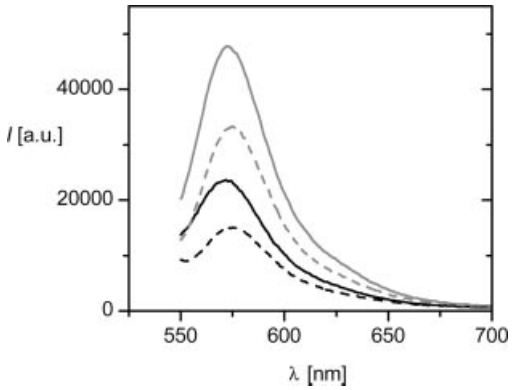

Figure 7. Fluorescence emission spectra of samples obtained after reaction between peptides **2** (dotted line) and **3** (solid line) with nanoparticles of zeolite **β3** (black lines) and tf-**β3** (gray lines).

By contrast, fluorescence spectra obtained with silicalite-based samples indicate a higher level of chemoselectivity. Therefore, for all these silicalite-based samples, the extent of physisorption was low and immobilization occurred mainly through the formation of a covalent bond between the semicarbazide groups on the surface and the α-oxo aldehyde group on the peptide molecule (Figure 8 and Figure 9). Fluorescence intensity ratio between samples **S3** obtained with peptide **3** and **2** (**S3-2/S3-3**) is around 40, showing that noncovalent interactions are rare with silicalite **S** (Figure 9).

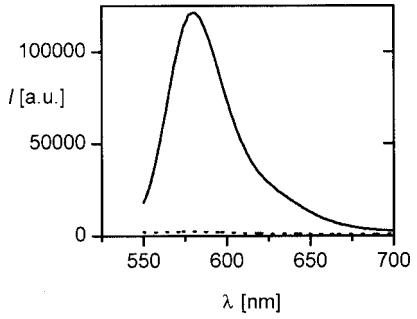

Figure 8. Fluorescence emission spectra of samples obtained after reaction between peptides **2** (dotted line) and **3** (solid line) with nanoparticles **S3**.

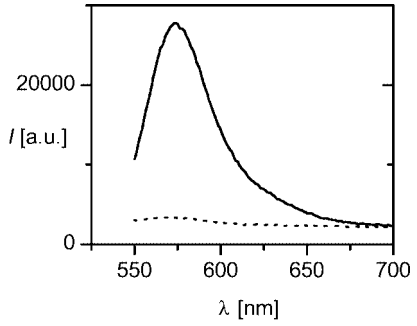

Figure 9. Fluorescence emission spectra of samples obtained after reaction between peptides **2** (dotted line) and **3** (solid line) with tf-**S10** nanoparticles.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

A similar fluorescence intensity ratio is obtained with tf-**S10** samples reacted with peptide **3** and **2** (Figure 9). Therefore, this demonstrates that whatever the micropore volume or the spacer length of the silicalite substrate, COCHO-modified polypeptides are specifically and covalently immobilized on silicalite surfaces.

Comparison of fluorescence spectra obtained for **S3**, tf-**S3**, and tf-**S10** samples of identical concentrations indicates a lower fluorescence intensity for tf-**S10** samples (Figure 10). This may be attributed to the lower loading obtained for these samples for silane **1b** than silane **1a** (Table 1).

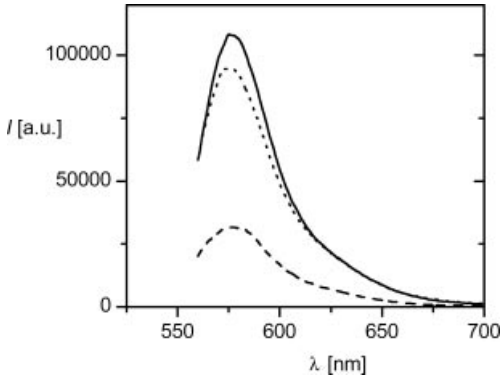

Figure 10. Fluorescence emission spectra of samples obtained after reaction between peptide **3** and **S3** (solid line), tf-**S3** (dotted line), and tf-**S10** nanoparticles (dashed line).

## Conclusions

Monodisperse zeolite nanoparticles have been used to develop colloids bearing polypeptides anchored on the solid surface by a site-specific ligation method, which enables the control of the biomolecule orientation at the solid–liquid interface.

Two types of nanoparticles were studied: zeolite β, which possesses a Si/Al ratio of 25, and silicalite-1, which is a fully silicic material.

Fluorescence spectroscopy results demonstrated that the specificity of the ligation is dramatically influenced by the chemical composition of the particles' surface. Indeed, while zeolite β (aluminosilicate) particles react by nonspecific adsorption with the peptides, silicalite particles (pure silicate) anchor exclusively a peptide bearing the COCHO functionality. This particular physisorption phenomenon of zeolite β is attributed to the aluminum atoms present at the particles' surface, which have a specific affinity for peptides.

These materials could find applications in immunodiagnostics and drug delivery.

## Experimental Section

Chemicals were purchased from commercial sources. They were reagent grade and used as received. Distilled deionized water (18 MΩ) was used for the preparation of all aqueous solutions.

### Nanoparticle Preparation

**Preparation of Colloidal Zeolite Nanoparticles:** Colloidal zeolite β nanoparticles with a Si/Al ratio of 18.5 were synthesized under mild hydrothermal conditions from a clear solution containing $0.28Na_2O/9.0(TEA)_2O/0.5Al_2O_3/25SiO_2/430H_2O$, where TEA is tetraethylammonium hydroxide, the structure directing agent (SDA) (Fluka, 20% in water). The synthesis was performed at 100 °C for 8 days. Colloidal zeolite β crystals were purified by a series of high-speed centrifugation and ultrasonic redispersion in water or ethanol.

Colloidal silicalite-1 nanoparticles were synthesized under mild hydrothermal conditions from a clear solution containing $9.0(TPA)_2O/25SiO_2/295H_2O$, where TPA is tetrapropylammonium hydroxide, the structure directing agent (SDA) (Fluka, 20% in water). The synthesis was performed at 100 °C for 24 h. Colloidal silicalite-1 crystals were purified by a series of high-speed centrifugation and ultrasonic redispersion in water or ethanol.

Template-free colloidal silicalite and zeolite β nanoparticles were obtained by using a procedure described previously.[22] This approach is based on surface-grafted organic ligands, for example (2-aminoethyl)phoshonic acid (APA) $[H_2N(CH_2)_2PO(OH)_2$ from Fluka, or (3-aminopropyl)triethoxysilane (APTS) $[H_2N(CH_2)_3Si(OC_2H_5)_3$, ABCR]. These compounds are used as aggregation inhibitors and crystallinity stabilizers during high-temperature combustion of SDA. The grafting and subsequent calcination processing has no influence on size, morphology, and crystallinity of the zeolite nanoparticles. This procedure provides stable colloidal template-free monodisperse zeolite nanoparticles with particle size distribution similar to the initial colloid.

### Semicarbazide Grafting of the Nanoparticles

We have recently described the preparation of semicarbazide-functionalized monodisperse silica ludox nanoparticles.[23] The same strategy was adopted here for each type of porous nanoparticle (silicalite and zeolite β). (Scheme 1).

First, silanes **1** were synthesized by reacting (3-isocyanatopropyl)- or (10-isocyanatodecyl)triethoxysilane[13] with $FmocNHNH_2$.[24] Then, silanes **1** were reacted as shown in Scheme 1, on the nanoparticles. The grafting of semicarbazide functionality was performed in DMF using silane **1** (3 mmol·g$^{-1}$) in the presence of piperidine, which permitted the in situ removal of the Fmoc-protecting group and improved the silanization process.[26] The nanoparticles were washed with DMF by centrifugation and stored at 4 °C, 1% (w/v) in DMF. The suspensions were found to be stable for months.

### Peptide Grafting of the Nanoparticles

The nanoparticles were then reacted with peptides **2** and **3** labeled with (5)-6-carboxymethylrhodamine. Detailed synthesis of the peptides has been reported elsewhere.[25] The peptide grafting (1 mL, 0.5–1 mM) was performed in acetate buffer (100 mM, pH = 5.51) at 37 °C. The excess of peptide was eliminated by five cycles of centrifugation (11000 rpm, 20 min). The final water suspension [1% (w/v)] was stored at 4 °C.

As peptide **2** bares a COCHO functionality, it should react with the semicarbazide surface, whereas immobilization of peptide **3**, which lacks the COCHO, should occur only through physisorption (Scheme 2).

### Sample Characterization

**Nanoparticle Size:** The mean particle size was determined by dynamic light scattering (DLS) using an argon laser (Spectra Physics Series 2000) operating at 632.8 nm. Light-scattering measurements

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were made at 25 ± 0.1 °C. Hydrodynamic measurements were performed at a 90° angle, after dilution of the sample to 10 μg·mL$^{-1}$ in water. The data were analyzed according to the method of cumulants for apparent mean diameter and polydispersity index.[26]

**Nanoparticle Morphology:** The morphology of the nanoparticles was investigated by scanning electron micrography (SEM, Hitachi S-4500) and transmission electron microscopy (TEM, JEOL 1200 EX with 120 keV accelerating voltage). SEM samples were prepared by depositing colloidal suspension on platinum-coated (2–3 nm) aluminum mounts fixed with carbon conducting tape. TEM samples were prepared by depositing 5 μL of silica nanoparticles water suspension (diluted 1:20) on 300 mesh copper grid with carbon film backing.

**Nanoparticle Microstructure:** The microstructure was studied by gas sorption experiments (Micromeretics ASAP 2010). Nitrogen was used as the adsorbate at 77 K. Samples were outgassed at 80 °C in dynamic vacuum ($3\times10^{-6}$ bar) before the adsorption. Determination of the specific surface was done by the BET method and total micropore volume was obtained by t-plot method based on the Harkins-Jura equation.

**Nanoparticle Grafting:** The nature of the functionalization was studied with $^{29}$Si and $^{13}$C CP-MAS NMR performed on the samples after each step of the preparation procedure. $^{29}$Si solid-state NMR spectroscopy gave useful information on the silanization step, as the chemical shift of $^{29}$Si was highly sensitive to number and nature of groups attached to it. $^{29}$Si CP-MAS NMR spectra of the solid samples were recorded with a Bruker spectrometer at 79.49 MHz using 5-μs single pulses (60° flip angle) with 10-s repetition rate and 15-ms contact time employing magic angle spinning at 3.5 kHz; 10000 scans were accumulated. All $^{29}$Si chemical shifts were referenced to tetramethylsilane (TMS). $^{13}$C CP-MAS NMR spectra were recorded with a Bruker spectrometer at 100.62 MHz using 10-μs single pulses (π/6) with 5-s repetition rate and 3-ms contact time employing magic-angle spinning at 3.5 kHz; 50000 scans were accumulated.

The powder samples were filled into 4-mm diameter zirconia rotors.

**Elemental Analysis:** Elemental analysis by the "Laboratoire Central d'Analyses du CNRS", Vernaison (France) enabled the evaluation of the grafting loading after functionalization.

**Photophysical Properties:** The optical properties of the particles were evaluated by recording static fluorescence spectra using a Spex Fluorolog 1681 spectrofluorimeter (scanning rate of 2 nm·s$^{-1}$). Spectra were recorded on 0.05% w/w particle suspensions.

## Acknowledgments

Funding of this work by the Ministère Délégué à la Recherche (ACI Nanosciences 045 270 and 042 130) is gratefully acknowledged. The authors thank Grace-Davidson for generously providing Ludox silica samples for the zeolite synthesis.

# Tin(IV) Fluoride Complexes with Tertiary Phosphane Ligands – A Comparison of Hard and Soft Donor Ligands

**Martin F. Davis,[a] Maria Clarke,[a] William Levason,*[a] Gillian Reid,[a] and Michael Webster[a]**

**Keywords:** Tin / Fluoride / Phosphane / Multinuclear NMR / Crystal structures

The first phosphane complexes of the hard Lewis acid $SnF_4$ have been synthesised including *trans*-$[SnF_4(PR_3)_2]$ (R = Me or Cy) and *cis*-$[SnF_4$(diphosphane)] [diphosphane = $R_2P(CH_2)_2PR_2$, R = Me, Et, Ph or Cy; *o*-$C_6H_4(PR_2)_2$, R = Me or Ph] and characterised by IR and multinuclear NMR ($^1H$, $^{19}F$, $^{31}P$, $^{119}Sn$) spectroscopy. The crystal structures of *trans*-$[SnF_4(PCy_3)_2]$ and *cis*-$[SnF_4\{Et_2P(CH_2)_2PEt_2\}]$ are reported. Tin(IV) fluoride complexes of 2,2′-bipyridyl, 1,10-phenanthroline, $MeO(CH_2)_2OMe$, $Me_2N(CH_2)_2NMe_2$, pyridine and THF have been characterised by multinuclear NMR spectroscopy, the structures of *cis*-$[SnF_4$(L–L)] (L–L = 1,10-phenanthroline and $MeO(CH_2)_2OMe$) determined, and the properties were compared with those of the phosphane complexes. Complexes of *o*-$C_6H_4(PMe_2)_2$, $Et_2P(CH_2)_2PEt_2$, and $MeC(CH_2AsMe_2)_3$ with $SnCl_4$ and $SnBr_4$ are also reported and the structures of *cis*-$[SnCl_4\{Et_2P(CH_2)_2PEt_2\}]$ and *cis*-$[SnBr_4\{\kappa^2$-$MeC(CH_2AsMe_2)_3\}]$ described. Attempts to prepare tertiary arsane complexes of $SnF_4$ have been unsuccessful.

## Introduction

Tin(IV) chloride is widely used in synthesis both as a source of tin(IV) and as a strong Lewis acid.[1,2] A very wide range of adducts of $SnCl_4$ with neutral ligands (L) are known, mostly six-coordinate $[SnCl_4L_2]$, and similar complexes are formed by $SnBr_4$ and $SnI_4$, although Lewis acidity decreases $SnCl_4 > SnBr_4 >> SnI_4$. The majority of these ligands have hard O or N donor atoms, but examples with softer P, As, S, Se or Te donors have also been characterised.[3–10] In marked contrast little is known about adducts of $SnF_4$ with neutral ligands. Some examples were reported in the period 1950–1975, often as part of larger surveys including the heavier tin(IV) halides, but little data were provided and only a single complex, $[SnF_4$(2,2′-bipy)], was structurally characterised.[11–16] There appear to be no reports of $SnF_4$ complexes with softer donor ligands. This neglect in part is similar to that of other p-block fluorides, whose Lewis acidity, except towards $F^-$ or in superacid media (for $MF_5$, M = As or Sb), is little explored, but also reflects the more difficult synthetic entry into the complexes. The $SnX_4$ (X = Cl, Br or I) are tetrahedral molecules readily soluble in weak or non-coordinating solvents such as chlorocarbons, hydrocarbons or arenes, and synthesis of $[SnX_4(L)_2]$ usually involves simply mixing the constituents in a solvent with precautions to avoid hydrolysis. In contrast, $SnF_4$ has a polymeric structure based upon vertex sharing $SnF_6$ octahedra,[17] and although readily hydrolysed, is otherwise rather unreactive and insoluble in weak donor solvents. Tudela and co-workers have reported[18] the preparation of $[SnF_4(MeCN)_2]$ from $SnF_2$ and $I_2$ in MeCN. We have found that this provides a convenient entry into the chemistry of $SnF_4$, and recently reported the synthesis and detailed spectroscopic and structural studies of a series of tin(IV) fluoride complexes of phosphane- or arsane oxides, including $[SnF_4(R_3EO)_2]$ ($R_3EO$ = $Ph_3PO$, $Ph_3AsO$, $Me_3PO$ or $Me_3AsO$) and $[SnF_4$(L–L)] {L–L = *o*-$C_6H_4[P(O)Ph_2]_2$, *o*-$C_6H_4[P(O)Me_2]_2$ or $Ph_2P(O)CH_2P(O)Ph_2$}.[19] These studies showed that toward pnictogen oxide ligands, $SnF_4$ was the strongest Lewis acid of the four tin(IV) halides, evidenced by shorter Sn–O and longer P–O bonds and larger $^{31}P$ NMR coordination shifts in the fluorides, compared to corresponding data in complexes with the heavier halides. Here we report the first investigations of the synthesis, structures and spectroscopy of tin(IV) fluoride adducts with tertiary phosphanes and arsanes. Comparisons of these complexes with $SnF_4$ species containing N- or O donor ligands and with the heavier $Sn^{IV}$ halides are described.

## Results and Discussion

**Phosphane Complexes:** The reactions of $[SnF_4(MeCN)_2]$ with $PMe_3$ or $PCy_3$ (L), in anhydrous dichloromethane under a dinitrogen atmosphere yielded $[SnF_4L_2]$ complexes in moderate to good yields. However we were unable to obtain a pure sample of $[SnF_4(PPh_3)_2]$ by this route. Since neither the $[SnF_4(MeCN)_2]$ nor the resulting complexes are easily soluble in this solvent, some care is needed to obtain pure

[a] School of Chemistry, University of Southampton, Southampton SO17 1BJ, UK

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

products. The complexes are both moisture and dioxygen sensitive in solution, although the dry solids only slowly decomposed in air (see below). They are much less soluble in chlorocarbons than corresponding complexes of the heavier tin halides, and prone to retain lattice solvent as evidenced in their $^1$H NMR spectra and in some of the X-ray structures.[19] $[SnF_4(THF)_2]$[18] was also explored as a synthon, but appeared to have no advantages over the acetonitrile complex. We also reacted $[SnF_4(MeCN)_2]$ with molten $PPh_3$, but the $^{31}P\{^1H\}$ and $^{19}F\{^1H\}$ NMR spectra showed a complex mixture of products, and it appears that some fluorination of the phosphane occurs under these conditions. The $[SnF_4L_2]$ complexes were identified as *trans* isomers from their $^{19}F\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra which are respectively triplets and quintets [in each case with weak satellites due to $^{119}$Sn and $^{117}$Sn ($^{117}$Sn: $I$ = 1/2, 7.7%, $\Xi$ = 35.63 MHz; $^{119}$Sn: $I$ = 1/2, 8.6%, $\Xi$ = 37.27 MHz)] (Table 1). The $^{119}$Sn NMR spectra are 15-line patterns (triplet of quintets) with the coupling constants shown in Table 1. The structure of $[SnF_4(PCy_3)_2]$ was determined and shows (Table 2, Figure 1) a centrosymmetric molecule with Sn–P = 2.654(1) Å and Sn–F = 1.959(2), 1.980(2) Å. The Sn–P is longer than that in *trans*-$[SnCl_4(PEt_3)_2]$ [2.615(5) Å],[20] and marginally longer than in *trans*-$[SnCl_4\{\kappa^1$-$Ph_2PCH_2PPh_2\}_2]$ [2.649(1) Å],[21] but shorter than found in *trans*-$[SnI_4(P\textit{i}Pr_3)_2]$ [2.69(1) Å],[22] although the differing steric requirements of the three phosphanes preclude a more detailed discussion.

[a] Symmetry operation, a: $-x$, $-y$, $2-z$.

The corresponding reactions of $[SnF_4(MeCN)_2]$ with the diphosphanes $Me_2P(CH_2)_2PMe_2$, $Et_2P(CH_2)_2PEt_2$, $Cy_2P(CH_2)_2PCy_2$, *o*-$C_6H_4(PPh_2)_2$, $Ph_2P(CH_2)_2PPh_2$ and *o*-$C_6H_4(PMe_2)_2$ (L–L) gave $[SnF_4(L–L)]$. The $[SnF_4\{Me_2P(CH_2)_2PMe_2\}]$ was essentially insoluble in chlorocarbons or nitromethane and decomposed by DMSO, and although it appeared to be similar to the other examples, we were unable to obtain any solution spectroscopic data and it will not be discussed further. The other examples are as expected *cis* isomers showing doublet of doublets of triplets in their $^{31}P\{^1H\}$ NMR spectra and two $^{19}F\{^1H\}$ resonances, a triplet of triplets for the $F_{trans\text{-}F}$ and a doublet of doublet of triplets for the $F_{trans\text{-}P}$, with the coupling constants shown in Table 1 (again all resonances have tin satellites). The $^{119}$Sn NMR resonances of the diphosphane com-

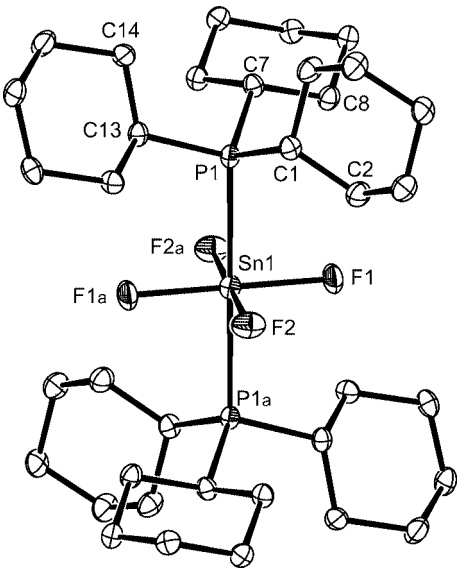

Figure 1. Structure of *trans*-[$SnF_4(PCy_3)_2$] showing a partial atom numbering scheme. Cyclohexyl groups are numbered cyclically starting at the P-bonded C atom. Ellipsoids are drawn at the 50% probability level and H atoms omitted for clarity. Sn1 is positioned on a centre of symmetry. Symmetry operation, a: $-x$, $-y$, $2-z$.

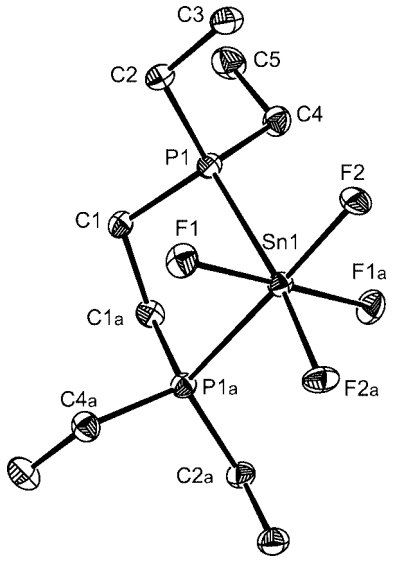

Figure 2. Structure of [$SnF_4\{Et_2P(CH_2)_2PEt_2\}$] showing the atom numbering scheme. Ellipsoids are drawn at the 50% probability level and H atoms omitted for clarity. A twofold axis passes through Sn1 and the centre of the C1–C1a bond. Symmetry operation, a: $-x$, $y$, $1/2-z$.

plexes are 27-line patterns (triplet of triplets of triplets), the spectra typically being recorded at 250 K to reduce any line broadening due to the onset of reversible ligand dissociation. The modest solubility necessitated long accumulations, and in some cases the weakest outer lines of the multiplets were rather unclear, although the various couplings were readily extracted (Table 1). The trends in the various NMR parameters will be discussed in a later section in comparison with those of related complexes (see below). The structure of [$SnF_4\{Et_2P(CH_2)_2PEt_2\}$] was determined and confirms the *cis* geometry deduced from the NMR studies (Table 3, Figure 2). The Sn–P distance is 2.606(1) Å, shorter than in the *trans*-[$SnF_4(PCy_3)_2$] [2.654(1) Å], and also shorter than the value in *cis*-[$SnCl_4\{Et_2P(CH_2)_2PEt_2\}$] [2.648(2) Å] described below. The Sn–$F_{trans\text{-}F}$ 1.986(2) Å is significantly longer than Sn–$F_{trans\text{-}P}$ 1.953(2) Å, a pattern which is found in most adducts of $SnX_4$ (X = Cl, Br or I) with soft donor ligands.[6–10]

**Other $SnF_4$ Complexes:** A small number of complexes of hard N- or O-donor ligands, previously obtained directly from $SnF_4$, were re-prepared in this study for comparison purposes from [$SnF_4(MeCN)_2$], viz [$SnF_4$(L–L)] (L–L = 2,2′-bipyridyl, 1,10-phenanthroline, *N*,*N*,*N*′*N*′-tetramethylethanediamine and 1,2-dimethoxyethane) and [$SnF_4$(pyridine)$_2$]. The complexes with N donor ligands are unaffected by exposure to air for several hours, although moisture-sensitive in solution. They are much less readily decomposed than the phosphane complexes. The solid [$SnF_4(L)_2$] [L = THF or $L_2$ = $MeO(CH_2)_2OMe$] are very deliquescent. The $^{19}F\{^1H\}$ and $^{119}Sn$ NMR spectroscopic data are shown in Table 1. Although the ranges overlap, there is a general shift to lower frequency in the $^{119}Sn$ NMR shifts with donor, P → N → O. The complexes with L–L = 2,2′-bipyridyl, 1,10-phenanthroline, $Me_2N(CH_2)_2NMe_2$ have the expected *cis* geometry, whilst the [$SnF_4$(pyridine)$_2$] is the *trans* isomer. In contrast to the N donor complexes, the ether adducts, [$SnF_4\{MeO(CH_2)_2OMe\}$] and [$SnF_4(THF)_2$], are undergoing rapid neutral ligand exchange in solution at ambient temperatures, and only at low temperatures was it possible to record $^{19}F\{^1H\}$ and $^{119}Sn$ NMR spectroscopic data. These revealed that in $CH_2Cl_2$ solution at 220 K the THF complex was a mixture of *cis* and *trans* isomers in approximately equal amounts. On the basis of IR and Mössbauer data Tudela[18] concluded that the [$SnF_4L'_2$] (L′ = pyridine or THF) were *trans* isomers in the solid state. Crystals of [$SnF_4\{MeO(CH_2)_2OMe\}$] and [$SnF_4$(1,10-phenanthroline)] were grown from $CH_2Cl_2$/*n*-hexane. The structure of the former shows (Table 4, Figure 3) the expected *cis* geometry with Sn–O = 2.156(2), 2.144(2) Å, which are shorter than those in *trans*-[$SnCl_4(THF)_2$][23] but significantly longer than the Sn–O distances in phosphane oxide adducts of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$SnF_4$, which lie in the range of ca. 2.045(3)–2.088(5) Å.[18] The latter complexes show no dissociation in solution, which is indicative of stronger binding of the phosphane oxide ligands compared to the ethers. The differences in the distances Sn–$F_{trans\text{-}F}$ [1.926(2), 1.927(2) Å] and Sn–$F_{trans\text{-}O}$ [1.921(2), 1.923(2) Å] are much less than in the phosphane complex described previously. The structure of [$SnF_4$(1,10-phenanthroline)] [Sn–N = 2.157(7) Å] (Table 5, Figure 4) may be compared with that of [$SnCl_4$(1,10-phenanthroline)],[24] which possess Sn–N = 2.234(7)–2.251(8) Å. One can also compare the literature data on [$SnX_4$(2,2′-bipyridyl)] for which Sn–N are X = F [2.181(3), 2.183(3) Å], X = Cl [2.247(4), 2.226(4) Å], X = Br [2.23(1), 2.23(1) Å], X = I [2.28(2) Å].[16,25,26] The 2,2′-bipyridyl series shows the longest Sn–N bonds in the iodide and the shortest in the fluoride, with the chloride and bromide less clearly discriminated, support for the fluoride being the strongest Lewis acid of the four halides.

dichloromethane, and the NMR spectra were recorded (Table 6). Like other complexes of this type, they are very moisture sensitive and also dioxygen sensitive to varying degrees in solution,[9,27] but also much more soluble in chlorocarbons than their tin(IV) fluoride analogues. The $^{119}Sn$ chemical shifts are surprisingly similar for corresponding complexes of $SnF_4$ and $SnCl_4$, but those of $SnBr_4$ and $SnI_4$ show much more deshielded resonances (Table 6). The $^1J(^{119}Sn\text{-}^{31}P)$ coupling constants fall with halogen F > Cl > Br > I. The structure of *cis*-$[SnCl_4\{Et_2P(CH_2)_2PEt_2\}]$ was determined (Table 7, Figure 5) and provides a direct comparison with the fluoride structure discussed above. Again there is a marked difference between $Sn–Cl_{trans\text{-}Cl}$ [2.453(1) Å] and $Sn–Cl_{trans\text{-}P}$ [2.408(1) Å] with Sn–P = 2.648(2) Å. Other structurally characterised phosphane complexes of $SnCl_4$ are *trans*-$[SnCl_4(PEt_3)_2]$ [Sn–P = 2.615(5) Å],[20] *trans*-$[SnCl_4(\kappa^1\text{-}Ph_2PCH_2PPh_2)_2]$ [Sn–P = 2.649(1) Å],[21] and *cis*-$[SnCl_4\{Ph_2P(CH_2)_2PPh_2\}]$ [Sn–P = 2.679(2), 2.653(2) Å, Sn–Cl = 2.402(2), 2.406(2), 2.408(2), 2.447(2) Å].[28]

**Reactions with Dioxygen:** We have reported elsewhere[9] that mixtures of phosphanes or diphosphanes and $SnX_4$ (X = Cl, Br or I) in chlorocarbon solution air-oxidise readily to the corresponding phosphane oxides. Catalytic amounts of $SnI_4$ can be used to cleanly generate phosphane oxides from the corresponding phosphanes using dry air or dioxygen, and whilst the mechanism remains obscure, the use of $^{18}O_2$ in these reactions showed that the source of the oxygen is $O_2$, not water as in a halogenation/hydrolysis mechanism.[27] The phosphane complexes of tin(IV) fluoride made in the present study also show varying degrees of oxygen sensitivity, especially in solution. The $[SnF_4(PCy_3)_2]$ is particularly sensitive and even brief exposure to air of a $CH_2Cl_2$ solution produced substantial oxidation. The $[SnF_4(PMe_3)_2]$ and the diphosphane complexes are less rapidly air-oxidised, but modest amounts of phosphane oxides can be detected by $^{31}P$ NMR in solutions exposed to air for some hours. In these systems the phosphane oxide binds strongly to the $SnF_4$ (cf. ref.[19]), and thus in contrast to the extensively dissociated $SnI_4$ systems[27] the formation of phosphane oxide is stoichiometric, because the phosphane oxides remove the $SnF_4$ by complexation preventing further reaction. Crystals of $[SnF_4(OPPh_3)_2]$ were obtained over several days from a $CH_2Cl_2$ solution of the products of melting $[SnF_4(MeCN)_2]$ with excess $PPh_3$. The structure (Figure 6, Table 8) shows it to be the *trans* isomer, and the bond lengths are entirely in keeping with our previous conclusions[19] that $SnF_4$ is the strongest Lewis acid of the four tin(IV) halides towards O donor phosphane oxide ligands.

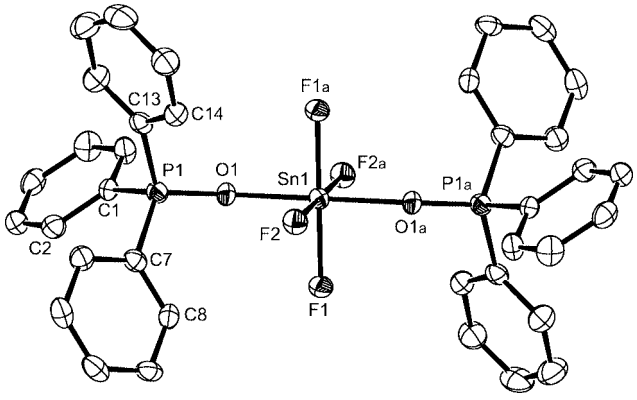

Figure 6. Structure of *trans*-$[SnF_4(Ph_3PO)_2]$ showing a partial atom numbering scheme. Phenyl groups are numbered cyclically starting at the *ipso* C atom. Ellipsoids are drawn at the 50% probability level and H atoms omitted for clarity. Sn1 is positioned on a centre of symmetry. Symmetry operation, a: $-x$, $1-y$, $1-z$.

**Attempted Preparation of Tertiary Arsane Complexes:** In contrast to the results with phosphane ligands, repeated attempts to isolate complexes of $SnF_4$ with tertiary arsanes including $AsMe_3$, *o*-$C_6H_4(AsMe_2)_2$ and $MeC(CH_2AsMe_2)_3$ were unsuccessful. The reaction of $[SnF_4(MeCN)_2]$ or $[SnF_4(THF)_2]$ in $CH_2Cl_2$ or toluene with *o*-$C_6H_4(AsMe_2)_2$,

which is a very strongly coordinating ligand towards many d-block metals,[29] resulted in white solids of variable composition which appeared to be mixtures of the starting complex, possibly $[SnF_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ and $SnF_4$. The IR spectra showed the presence of the diarsane, a broad υ(SnF) at ca. 570 $cm^{-1}$, and usually some MeCN or THF. The $^1H$ NMR spectra of these products in $CD_2Cl_2$ solution showed only MeCN or THF and "free" $o\text{-}C_6H_4(AsMe_2)_2$ [as $o\text{-}C_6H_4(AsMe_2)_2$ is a liquid, this is evidence for coordination of the diarsane to tin in the solids]. The $^{19}F\{^1H\}$ NMR spectra showed no resonances at room temperature, but below ca. 210 K, two new broad resonances at $\delta$ = –138 and –152 were observed, which seem reasonable for $[SnF_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$, but no F–F coupling was resolved even at 190 K. The data suggest that $[SnF_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ forms in the reaction, but that it is extensively dissociated in solution and even use of a substantial excess of diarsane does not produce a pure product. In the cases of $AsMe_3$ or $MeC(CH_2AsMe_2)_3$ there was little evidence for coordination to $SnF_4$. In contrast, arsane complexes of $SnX_4$ (X = Cl, Br or I) form readily,[9] and indeed $[SnI_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ is one of the very small number of structurally characterised neutral ligand adducts of $SnI_4$. The explanation of this marked difference to phosphanes probably arises from the fact the $SnF_4$ is a very hard Lewis acid with contracted tin acceptor orbitals, and correspondingly has less ability to bind the large soft arsenic centre. For many transition-metal systems the differences between binding corresponding phosphanes and arsanes is small, but becomes very significant with high oxidation state and/or harder metal centres of the 3d series such as $Fe^{IV}$, $Ni^{IV}$ or $Mn^{II}$, where the phosphanes result in significantly more stable complexes.[29] Our results suggest similar discrimination by $SnF_4$.

In the course of this work the $[SnX_4\{MeC(CH_2AsMe_2)_3\}]$ (X = Cl or Br) were prepared from the appropriate $SnX_4$ and triarsane in $CH_2Cl_2$ and their $^1H$ NMR spectra show the triarsane bound as a bidentate to a six-coordinate tin centre. The $^{119}Sn$ NMR chemical shifts of $\delta$ = –696 and –1290 ppm (Table 6) are typical of $SnX_4As_2$ donor sets.[9] The structures were confirmed by a X-ray study of $[SnBr_4\{MeC(CH_2AsMe_2)_3\}]$ (Table 9, Figure 7), which showed a distorted octahedral tin centre with $Sn–Br_{trans\text{-}Br}$ [2.5807(5), 2.6340(5) Å] longer than $Sn–Br_{trans\text{-}As}$ [2.5708(6), 2.5479(5) Å], and with the axial Br–Sn–Br unit bent towards the neutral ligand (Br3–Sn1–Br4 = 170.6°), as found in tin(IV) halide structures with a variety of soft donors.[6–9] The Sn–As [2.6932(5), 2.7095(6) Å] are slightly shorter than those in the only other structurally characterised tin–arsane complexes $[SnI_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ [2.716(2), 2.752(2) Å],[9] and *trans*-$[SnCl_4(AsPh_3)_2]$ [2.762(1) Å].[30] The wide As–Sn–As angle [86.79(2)°] in the present complex reflects the six-membered chelate ring present and compares with 78.43(7)° in $[SnI_4\{o\text{-}C_6H_4(AsMe_2)_2\}]$ which contains a five-membered ring.

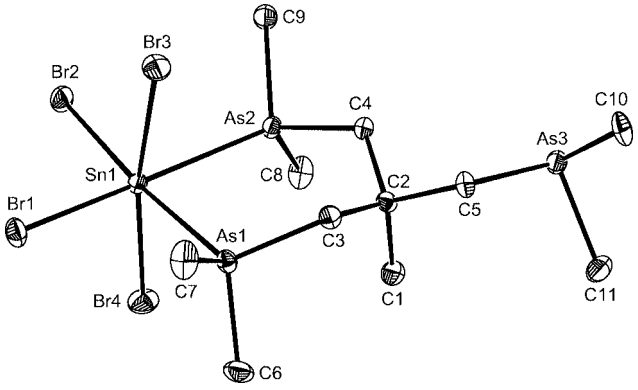

Figure 7. Structure of $[SnBr_4\{MeC(CH_2AsMe_2)_3\}]$ showing the atom numbering scheme. Ellipsoids are drawn at the 50% probability level and H atoms omitted for clarity.

## Comparisons and Conclusions

This work has provided the first examples of $SnF_4$ adducts with soft phosphane ligands and also a considerable amount of spectroscopic and structural data on comparable complexes with hard N- or O-donor ligands and with the heavier tin(IV) halides. The structural data discussed in preceding sections clearly show that for a fixed hard neutral ligand the Sn–ligand bond lengths are shortest in the fluoride complexes, consistent with $SnF_4$ being the strongest Lewis acid. The corresponding data for *cis*-$[SnX_4\{Et_2P(CH_2)_2PEt_2\}]$ (X = F or Cl), which are exact analogues (isostructural), also show the shortest Sn–P bond in the fluoride, indicating that similar trends hold with the soft (but strong σ-donor) phosphorus. The longer Sn–P

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bond in *trans*-$[SnF_4(PCy_3)_2]$ is almost certainly due to steric effects caused by the bulky cyclohexyl substituents ($PCy_3$ has a cone angle of ca. 170°). However, the instability of $SnF_4$ adducts of arsanes suggests that towards even softer ligands, $SnCl_4$ will be more strongly coordinated.

These studies have also produced a wealth of NMR spectroscopic data (Table 1 and Table 6), but although several empirical trends in the chemical shifts and coupling constants with change in halide or neutral ligand can be discerned, the patterns are complicated, indicating several competing factors are present. Thus, the $^{119}Sn$ chemical shifts show consistent low frequency shifts with X: Cl → F → Br → I, the same as observed in halostannates(IV),[31,32] evidence that electronegativity is not the dominant factor.[33] Low frequency shifts also occur with neutral donor atoms P → N → O. The $^{31}P$ chemical shifts and the coordination shifts ($\delta_{complex}-\delta_{ligand}$) for the phosphane complexes are not systematic with changes in halide co-ligand. Although phosphanes mostly show high frequency coordination shifts when bound to transition metals, both high and low frequency shifts have been observed in p-block element complexes, and the reasons remain obscure.[33,34] The $^1J(^{31}P\text{-}^{119}Sn)$ coupling constants are largest for the fluorides and much larger for *trans*-P–Sn–P than for *cis*-P–Sn–P arrangements (Table 1), whilst the $^1J(^{19}F\text{-}^{119}Sn)$ couplings are larger in the phosphane complexes than in the N- or O-donor ligand cases. The $^1J(^{19}F\text{-}^{119}Sn)_{F-trans-F}$ are markedly larger than $^1J(^{19}F\text{-}^{119}Sn)_{F-cis-F}$ in the phosphane complexes, but this difference is small or absent in the complexes with harder donor co-ligands. A more detailed understanding of the factors responsible for these trends must await further work on related systems.

Given that stable complexes of soft phosphane donor ligands have now been prepared for the hard Lewis acid $SnF_4$, similar complexes should be obtainable for other main-group fluorides. Studies to explore this are underway.

## Experimental Section

All compounds were made under dinitrogen using dry solvents and standard Schlenk and glove box techniques. $SnF_2$, $SnCl_4$, $SnBr_4$ and $SnI_4$ were obtained from Aldrich and used as received. $[SnF_4(MeCN)_2]$ was made as described.[18] Ligands were obtained from Aldrich: $PMe_3$, $PPh_3$, $PCy_3$, $AsMe_3$, $Me_2P(CH_2)_2PMe_2$, $Et_2P(CH_2)_2PEt_2$, $Cy_2P(CH_2)_2PCy_2$, or were made by literature methods: *o*-$C_6H_4(PPh_2)_2$, $Ph_2P(CH_2)_2PPh_2$, *o*-$C_6H_4(PMe_2)_2$, *o*-$C_6H_4(AsMe_2)_2$, $MeC(CH_2AsMe_2)_3$.[35–38] 2,2′-Bipyridyl and 1,10-phenanthroline were dried by heating in vacuo, 1,2-dimethoxyethane was dried with sodium and freshly distilled. Pyridine and $Me_2N(CH_2)_2NMe_2$ were dried by distillation from BaO, tetrahydrofuran was dried by distillation from Na-benzophenone ketyl, MeCN and $CH_2Cl_2$ from $CaH_2$. IR spectra were recorded as Nujol mulls on a Perkin–Elmer PE 983G spectrometer, $^1H$ NMR spectra in $CDCl_3$, $CD_2Cl_2$ or $CD_3NO_2$ solutions on a Bruker AV300, $^{31}P\{^1H\}$, $^{19}F\{^1H\}$ and $^{119}Sn$ NMR spectra on a Bruker DPX400 and referenced to 85% $H_3PO_4$, $CFCl_3$ and neat $SnMe_4$ respectively. The $^{119}Sn$ NMR spectra were recorded from solutions containing $[Cr(acac)_3]$ as a relaxation agent and without proton decoupling to avoid NOE diminution of the signal due to the negative magnetogyric ratio of the isotope. Microanalytical measurements on new complexes were performed by the microanalytical service at Strathclyde University.

**$[SnF_4\{o\text{-}C_6H_4(PMe_2)_2\}]$:** $[SnF_4(MeCN)_2]$ (0.276 g, 1.0 mmol) was dissolved in $CH_2Cl_2$ (20 mL) and *o*-$C_6H_4(PMe_2)_2$ (0.198 g, 1.0 mmol) added and the mixture stirred overnight at ambient temperatures. The white precipitate was filtered off and dried in vacuo. Yield 0.205 g, 52%. $C_{10}H_{16}F_4P_2Sn\cdot CH_2Cl_2$ (477.8): calcd. C 27.6, H 3.8; found C 26.9, H 3.8. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.87 (t, $^2J+^5J_{P-H}$ = 4 Hz, 12 H, Me), 5.4 ($CH_2Cl_2$), 7.75–7.81 (m, 4 H, $C_6H_4$) ppm. IR (Nujol): $\tilde{\nu}$ = 564 (s), 534 (s) $\upsilon$(SnF) $cm^{-1}$.

**$[SnCl_4\{o\text{-}C_6H_4(PMe_2)_2\}]$:** A solution of $SnCl_4$ (0.12 mL, 1.0 mmol) in $CH_2Cl_2$ (5 mL) was added to *o*-$C_6H_4(PMe_2)_2$ (0.198 g, 1.0 mmol) in $CH_2Cl_2$ (20 mL) producing an immediate white precipitate. After 30 min the solid was filtered off and dried in vacuo. Yield 0.427 g, 93%. $C_{10}H_{16}Cl_4P_2Sn$ (458.7): calcd. C 26.2, H 3.5; found C 25.9, H 3.2. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.97 (t, $^2J+^5J_{P-H}$ = 4.4 Hz, 12 H, Me), 7.75–7.81 (m, 4 H, $C_6H_4$) ppm. IR (Nujol): $\tilde{\nu}$ = 307 (s), 296 (s) $\upsilon$(SnCl) $cm^{-1}$.

**$[SnBr_4\{o\text{-}C_6H_4(PMe_2)_2\}]$:** Prepared similarly to the chloride as a yellow solid. Yield 93%. $C_{10}H_{16}Br_4P_2Sn$ (636.5): calcd. C 18.9, H 2.5; found C 18.7, H 2.4. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.95 (t, $^2J+^5J_{P-H}$ = 4.5 Hz, 12 H, Me), 7.75–7.81 (m, 4 H, $C_6H_4$) ppm. IR (Nujol): $\tilde{\nu}$ = 205 (sh), 202 (s), 199 (sh), 196 (s) $\upsilon$(SnBr) $cm^{-1}$.

**$[SnI_4\{o\text{-}C_6H_4(PMe_2)_2\}]$:** Prepared similarly to the chloride as a brown powder. Yield 80%. $C_{10}H_{16}I_4P_2Sn$ (824.5): calcd. C 14.6, H 2.0; found C 14.6, H 1.9. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.83 (t, $^2J+^5J_{P-H}$ = 4.8 Hz, 12 H, Me), 7.75–7.81 (m, 4 H, $C_6H_4$) ppm.

**$[SnF_4\{o\text{-}C_6H_4(PPh_2)_2\}]$:** $[SnF_4(MeCN)_2]$ (0.276 g, 1.00 mmol) was suspended in $CH_2Cl_2$ (20 mL) and a solution of *o*-$C_6H_4(PPh_2)_2$ (0.446 g, 1.00 mmol) in $CH_2Cl_2$ (5 mL) added and the mixture stirred for 8 h at ambient temperatures. The white precipitate was filtered off and dried in vacuo. Yield 0.17 g, 27%. $C_{30}H_{24}F_4P_2Sn$ (641.2): calcd. C 56.2, H 3.8; found C 56.9, H 4.1. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.30–7.68 (m, Ph) ppm. IR (Nujol): $\tilde{\nu}$ = 574 (s), 557 (s), 526 (s) $\upsilon$(SnF) $cm^{-1}$.

**$[SnF_4(PMe_3)_2]$:** $[SnF_4(MeCN)_2]$ (0.277 g, 1.00 mmol) was suspended in $CH_2Cl_2$ (10 mL), trimethylphosphane (0.167 g, 2.20 mmol) was added and stirred at room temperature for 1 h. Some of the $CH_2Cl_2$ was removed in vacuo and then dry hexane (20 mL) was added. A white solid precipitated out which was filtered off under nitrogen and dried in vacuo. Yield 0.250 g, 68%. $C_6H_{18}F_4P_2Sn\cdot 2CH_2Cl_2$ (516.7): calcd. C 18.6, H 4.3; found C 18.3, H 4.5. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.68 (m, Me), 5.4 ($CH_2Cl_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 546 (br) $\upsilon$(SnF) $cm^{-1}$.

**$[SnF_4(PCy_3)_2]$:** $[SnF_4(MeCN)_2]$ (0.277 g, 1.00 mmol) was suspended in $CH_2Cl_2$ (10 mL), tricyclohexylphosphane (0.588 g, 2.10 mmol) was added and stirred at room temperature for 3 h. No precipitation had occurred so the solution was reduced to ca. 5 mL in vacuo and then dry hexane (5 mL) was added. A white solid precipitated out which was filtered off under nitrogen and dried in vacuo. Yield 0.45 g, 60%. $C_{32}H_{66}F_4P_2Sn\cdot 1/2CH_2Cl_2$ (750.0): calcd. C 54.9, H 8.5; found C 54.4, H 8.8. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.29–2.34 (m, Cy), 5.4 ($CH_2Cl_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 557 (s), 535 (s) $\upsilon$(SnF) $cm^{-1}$.

**$[SnF_4\{Et_2P(CH_2)_2PEt_2\}]$:** $[SnF_4(MeCN)_2]$ (0.278 g, 1.00 mmol) was suspended in $CH_2Cl_2$ (20 mL), 1,2-bis(diethylphosphanyl)ethane (0.28 mL, 1.20 mmol) was added dropwise and stirred for 1.5 h.

The white precipitate was filtered off and dried in vacuo. Yield 0.32 g, 80%. $C_{10}H_{24}F_4P_2Sn$ (400.95): calcd. C 29.9, H 6.0; found C 29.0, H 6.0. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.13–2.07 (m, 2 H, $CH_2$), 1.37–1.26 (m, 6 H, Me) ppm. IR (Nujol): $\tilde{\nu}$ = 553 (m), 526 (s) $\upsilon$(SnF) $cm^{-1}$.

**[$SnF_4${$Cy_2P(CH_2)_2PCy_2$}]:** [$SnF_4(MeCN)_2$] (0.278 g, 1.00 mmol) was suspended in $CH_2Cl_2$ (10 mL), 1,2-bis(dicyclohexylphosphanyl)ethane (0.444 g, 1.05 mmol) in $CH_2Cl_2$ (5 mL) was added. This was stirred under nitrogen for 3 h. No precipitation had occurred so the solution was reduced to ca. 5 mL in vacuo and then dry hexane (5 mL) was added. Again no significant precipitate was observed so the solvent was removed in vacuo to give a white solid. Yield 0.51 g, 83%. $C_{26}H_{48}F_4P_2Sn{\cdot}1/2CH_2Cl_2$ (826.1): calcd. C 48.2, H 7.5; found C 49.2, H 8.3. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.21–1.255 (m, $CH_2$, Cy), 5.4 ($CH_2Cl_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 560 (s), 530 (s) $\upsilon$(SnF) $cm^{-1}$.

**[$SnF_4${$Ph_2P(CH_2)_2PPh_2$}]:** [$SnF_4(MeCN)_2$] (0.28 g, 1.0 mmol) was suspended in $CH_2Cl_2$ (15 mL), 1,2-bis(diphenylphosphanyl)ethane (0.42 g, 1.05 mmol) in $CH_2Cl_2$ (10 mL) was added and the mixture stirred for 3 h. Most of the solvent was removed in vacuo and the white precipitate was filtered off and dried in vacuo. Yield 0.46 g, 78%. $C_{26}H_{24}F_4P_2Sn{\cdot}1/2CH_2Cl_2$ (635.6): calcd. C 50.0, H 4.0; found C 49.6, H 3.7. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.89–7.45 (m, 5 H, Ph), 5.4 ($CH_2Cl_2$). 2.81 (br, 1 H, $CH_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 566 (br) $\upsilon$(SnF) $cm^{-1}$.

**[$SnCl_4${$Et_2P(CH_2)_2PEt_2$}]:** $SnCl_4$ (0.260 g, 1.00 mmol) was dissolved in $CH_2Cl_2$ (15 mL), 1,2-bis(diethylphosphanyl)ethane (0.245 mL, 1.05 mmol) was added and stirred for 2 h. Immediate precipitation occurred, and the solid was filtered off and dried in vacuo to give a white crystalline solid. Yield 0.45 g, 96%. $C_{10}H_{24}Cl_4P_2Sn{\cdot}CH_2Cl_2$ (551.7): calcd. C 23.95, H 4.8; found C 23.5, H 5.0. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.12–2.11 (m, 6 H, $CH_2$), 1.39–1.21 (m, 6 H, Me), 5.4 ($CH_2Cl_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 318 (sh), 307 (sh), 282 (br) $\upsilon$(SnCl) $cm^{-1}$.

**[$SnF_4$(2,2′-bipyridyl)]:** [$SnF_4(MeCN)_2$] (0.276 g, 1.00 mmol) was suspended in $CH_2Cl_2$ (10 mL) and a solution of 2,2′-bipy (0.156 g, 1.00 mmol) in $CH_2Cl_2$ (5 mL) added and the mixture refluxed for 2 h. The white precipitate was filtered off and dried in vacuo. Yield 0.365 g, 97%. $^1H$ NMR (300 MHz, $CD_3NO_2$, 25 °C): $\delta$ = 9.41 (s, 1 H), 9.15 (s, 1 H), 8.99 (s, 1 H), 8.49 (s, 1 H) ppm. IR (Nujol): $\tilde{\nu}$ = 580 (s), 560, 520 (sh) $\upsilon$(SnF) $cm^{-1}$.

**[$SnF_4$(1,10-phenanthroline)]:** Prepared similarly to the above. Yield 60%. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 9.35 (m, 2 H), 9.16 (m, 2 H), 8.45 (m, 4 H) ppm. IR (Nujol): $\tilde{\nu}$ = 587 (s), 566 (s) $\upsilon$(SnF) $cm^{-1}$.

**[$SnF_4${$MeO(CH_2)_2OMe$}]:** 1,2-Dimethoxyethane (0.1 mL, 1.0 mmol) was added to a solution of [$SnF_4(MeCN)_2$] (0.276 g, 1.0 mmol) in $CH_2Cl_2$ (10 mL), and the mixture stirred at reflux for 2 h. The white precipitate was filtered off and dried in vacuo. Yield 77%. $^1H$ NMR (300 MHz, $CDCl_3$, 200 K): $\delta$ = 3.98 (s, 3 H, Me), 4.25 (s, 2 H, $CH_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 609 (s), 584 (s), 540 (m) $\upsilon$(SnF) $cm^{-1}$.

**[$SnF_4$(pyridine)$_2$]:** Pyridine (0.16 g, 2.0 mmol) was added to a solution of [$SnF_4(MeCN)_2$] (0.186 g, 0.67 mmol) in $CH_2Cl_2$ (10 mL). This was stirred at reflux under nitrogen for 2 h. The white precipitate was filtered off and dried in vacuo. Yield 80%. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 9.00 (m, 2 H), 8.2 (m, 1 H), 7.7 (m, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 568 (s) $\upsilon$(SnF) $cm^{-1}$.

**[$SnF_4${$Me_2N(CH_2)_2NMe_2$}]:** [$SnF_4(MeCN)_2$] (0.276 g, 1.0 mmol) was suspended in $CH_2Cl_2$ (10 mL), *N*,*N*,*N*′*N*′-tetramethylethylenediamine (0.15 g, 1.00 mmol) was added and the mixture stirred for 12 h. The white precipitate was filtered off and dried in vacuo. Yield 0.14 g, 54%. $C_6H_{16}F_4N_2Sn{\cdot}1/2CH_2Cl_2$ (277.4): calcd. C 22.1, H 4.9, N 7.9; found C 22.3, H 5.1, N 8.1. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.89 (s, 12 H, Me), 3.02 (s, 4 H, $CH_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 570 (s), 547 (s) $\upsilon$(SnF) $cm^{-1}$.

**[$SnF_4$(THF)$_2$]:** Was made as described.[18] $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.1 (br., 2 H, $CH_2$), 4.4(br., 2 H, $CH_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 600 (vbr) $\upsilon$(SnF), 1013 (br), 845 (m) $\upsilon$(COC) $cm^{-1}$.

**[$SnCl_4${$MeC(CH_2AsMe_2)_3$}]:** $MeC(CH_2AsMe_2)_3$ (0.384 g, 1.0 mmol) was dissolved in $CH_2Cl_2$ (10 mL) under nitrogen. To this solution $SnCl_4$ (0.26 g, 1.0 mmol) was added and an immediate white precipitate formed. This was filtered off and dried in vacuo to give a white powder. Yield 0.21 g, 33%. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.03 (s, 6 H, AsMe), 1.35 (s, 3 H, CMe), 1.73 (s, 12 H, AsMe), 1.77 (s, 2 H, $CH_2$), 2.39 (d, $^2J$ = 12 Hz, 2 H, $CH_2$) 2.54 (d, $^2J$ = 12 Hz, 2 H, $CH_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 310 (sh), 302 (s), 280 (sh) $\upsilon$(SnCl) $cm^{-1}$.

**[$SnBr_4${$MeC(CH_2AsMe_2)_3$}]:** $MeC(CH_2AsMe_2)_3$ (0.384 g, 1.0 mmol) was dissolved in $CH_2Cl_2$ (10 mL) under nitrogen. To this solution $SnBr_4$ (0.438 g, 1.0 mmol) was added and an immediate yellow precipitate formed in a yellow solution. This was filtered and the filtrate was left to stand to give yellow crystals. Yield 0.18 g, 22%. $C_{11}H_{27}As_3Br_4Sn$ (822.4): calcd. C 16.1, H 3.3; found C 15.3, H 3.1. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.04 (s, 6 H, AsMe), 1.37 (s, 3 H, CMe), 1.70 (br., 12 H, AsMe), 1.78 (br., 2 H, $CH_2$), 2.32 (br., 2 H, $CH_2$) 2.55 (br., 2 H, $CH_2$) ppm. IR (Nujol): $\tilde{\nu}$ = 215 (sh), 207 (s), 199 (s) $\upsilon$(SnBr) $cm^{-1}$.

**X-ray Experimental:** Crystals were grown from anhydrous $CH_2Cl_2$ solutions of the complexes by vapour diffusion of *n*-hexane under dinitrogen. Brief details of the crystal data and refinement are given in Table 10. Data collections were carried out with a Bruker-Nonius Kappa CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and with the crystals held at 120 K in a nitrogen gas stream. Structure solution and refinement were routine[39–41] except as discussed below, with in all cases H atoms added in calculated positions. The [$SnF_4$(1,10-phenanthroline)]·MeOH complex showed, after identifying the tin residue, two peaks in the difference electron-density map associated with a solvent molecule. The larger of the peaks positioned on a twofold axis (proposed as an O atom) with the second peak and its symmetry related peak being a disordered C atom of an adventitious MeOH solvate molecule. No attempt was made to position H atoms on this residue.

# Zinc Thiolate Complexes $[ZnL_n(SR)]^+$ with Azamacrocyclic Ligands, Part II: Mechanism of the Reaction with $CS_2$[‡]

**Johannes Notni,[a] Stephan Schenk,[a] Arne Roth,[b] Winfried Plass,[b] Helmar Görls,[c] Ute Uhlemann,[d] Angela Walter,[d] Michael Schmitt,[d] Jürgen Popp,[d] Susana Chatzipapadopoulos,[d] Thomas Emmler,[e] Hergen Breitzke,[d] Jörg Leppert,[f] Gerd Buntkowsky,[d] Kristian Kempe,[a] and Ernst Anders*[a]**

**Keywords:** Zinc / Macrocyclic ligands / Enzyme models / Heterocumulenes / Density functional calculations

The thiolate complexes $[Zn([15]aneN_4)(S–CH_2–C_6H_5)]ClO_4$ (**1**) ([15]aneN$_4$ = 1,4,8,12-tetraazacyclopentadecane) and $[Zn(i\text{-}[14]aneN_4)(S–CH_2–C_6H_5)]ClO_4$ (**2**) (*i*-[14]aneN$_4$ = 1,4,7,11-tetraazacyclotetradecane) have been reacted with carbon disulfide. The trithiocarbonate complexes $[Zn([15]aneN_4)\{S–C(S)–S–CH_2–C_6H_5\}]ClO_4$ {**1a**, monoclinic, space group $P2_1/n$, $Z = 8$, $a = 13.2338(1)$ Å, $b = 12.9251(2)$ Å, $c = 30.1669(4)$ Å, $\beta = 101.463(1)°$, $V = 5057.1(1)$ Å$^3$} and $[Zn(i\text{-}[14]aneN_4)\{S–C(S)–S–CH_2–C_6H_5\}]ClO_4$ {**2a**, orthorhombic, space group $P2_12_12_1$, $Z = 8$, $a = 9.9936(1)$ Å, $b = 22.1261(4)$ Å, $c = 22.3192(4)$ Å, $V = 4935.2(1)$ Å$^3$} were obtained. The reaction of **1** with $CS_2$ is second order with a rate constant of $k = (57.6 \pm 2.4) \times 10^{-3}$ M$^{-1}$·s$^{-1}$ at 25 °C. The experimentally determined Eyring activation barrier is $\Delta H_{exp}^{‡} = 65.3 \pm 0.7$ kJ·mol$^{-1}$ ($\Delta S_{exp}^{‡} = -49.9 \pm 2.5$ J·mol$^{-1}$·K$^{-1}$) and a free energy of activation of $\Delta G^{‡} = 80.2 \pm 1.5$ kJ·mol$^{-1}$ at 25 °C. To discriminate between an associative and a dissociative mechanism the barriers for both processes were calculated using density functional theory at the C-PCM(B98/G3MP2Large)//B3LYP/6-311+G(d) level. The associative mechanism is clearly favored with a difference in free energies of activation of $\delta\Delta G^{‡} \approx 80$ kJ·mol$^{-1}$. Its calculated barrier $\Delta G_{theor}^{‡} = 114.3$ kJ·mol$^{-1}$ is in reasonable agreement with the experimental value.

## Introduction

Carbonic anhydrase (CA) is a ubiquitous zinc enzyme that accelerates the reversible hydration of $CO_2$ by a factor of up to $10^7$ when compared with the uncatalyzed reaction.[2–4] This enzymatic process is very important in all living organisms for the exchange of $CO_2$ with the atmosphere. (Detailed references to the numerous studies concerning the catalytic mechanism are given elsewhere.[2,5]) The rate-determining step of the reaction is the nucleophilic attack of a zinc-bound hydroxide ligand on carbon dioxide. From quantum mechanical calculations it has been concluded that the reaction proceeds via a four-center transition structure (see Scheme 1).[6,7]

Recent studies of Kesselmeier et al. have shown that CA is also implicated in the fixation of COS, a sulfur-containing heterocumulene that occurs as a trace gas in the atmosphere.[8] This process is performed by many organisms, such as higher plants,[9] algae,[10] lichens,[11] and even by components of the soil.[12] This interconversion has been reproduced experimentally by reacting an established CA model, $[Tp^{Ph,Me}ZnOH]$, with COS.[13] In the course of the reaction, $CO_2$ is released and the sulfur-analog complex $Tp^{Ph,Me}ZnSH$ is obtained. In addition, this complex is also formed by reacting $Tp^{Ph,Me}ZnOH$ with $CS_2$. In this case, COS is produced instead of $CO_2$, which in turn is capable of reacting with the zinc hydroxide complex to yield $CO_2$. This type of reaction, the fixation of sulfur-containing heterocumulenes by CA model compounds, has also been studied by us using computational methods.[5,14] In analogy to the fixation of $CO_2$, it has been found for all the studied systems that the insertion of the heterocumulene into the Zn–O bond via a four-center transition structure is the rate-determining step of the reaction.[5,6,14]

These studies show that the reaction of natural carbonic anhydrase is likely to result in the formation of a sulfur-analog enzyme with a hydrosulfide instead of a hydroxide

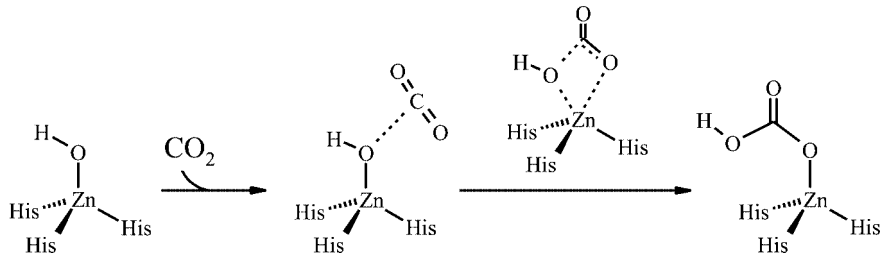


Scheme 1. Insertion of carbon dioxide into the Zn–S bond of CA.

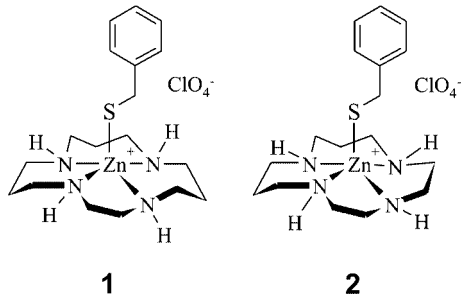
ligand. Since this reaction is exothermic, natural CA would become inactivated in this 'sulfurated state'.[5] Kesselmeier et al. have pointed out, though, that in the case of lichens, atmospheric sulfur compounds are the only available source of sulfur.[11] Apparently, the fixation of sulfur-containing compounds by CA is not a side reaction but rather essential for some organisms. This gives rise to the question of how CA can dispose of the sulfur in order to be reactivated. In a preceding theoretical study of a CA model system, a nucleophilic reaction of the Zn–SH moiety with $CO_2$ has been proposed for regeneration of the active catalyst.[5] However, until now this theory has not been supported by any experimental investigations.

In this work, we report on a reaction of the $CS_2$ with a zinc thiolate complex. We are fully aware that this may seem to be a large stretch of the subject. Nevertheless, the results are of value for the understanding of the reaction principles of a zinc-bound sulfur nucleophile with heterocumulenes in general. It is worth noting that a similar reaction has not previously been reported in the literature; even the available structural models for the sulfur-analog CA, e.g. $Tp^{Ph,Me}ZnSH$,[15] do not react with heterocumulenes. In the past, numerous computational studies have examined the fixation of heterocumulenes by zinc hydroxide complexes, but only one addresses zinc hydrosulfides and the mechanism of their heterocumulene reactions.[5] The results presented in this work are the first steps in elucidating the mode of heterocumulene fixation by sulfur-analog CA models. Investigations concerning the reactions of COS and $CO_2$ will be published soon.

## Results

### Heterocumulene Insertions

The starting materials, thiolate complexes **1** and **2** (see Scheme 2), are examples of a series of 24 novel zinc thiolate complexes.[1] The progress of the $CS_2$ insertion reaction can easily be monitored by the appearance of a yellow color from the formation of the trithiocarbonates. When reacting the neat substances with $CS_2$, only a very slow reaction was observed. This is not surprising, since the thiolates are virtually insoluble in $CS_2$. The reaction is obviously not possible while the complex cations are fixed in the crystal lattice. In contrast to this, the reaction proceeds quite fast when the starting materials are dissolved.



Scheme 2. Thiolate complexes **1** and **2**.

### *Structures*

Compounds **1a** (Figure 1) and **2a** (Figure 2) precipitated from concentrated dichloromethane solutions upon addition of a large excess of $CS_2$. Yellow crystals were obtained that were subjected to an X-ray crystallographic structure determination. The configuration of the four N atoms in the trithiocarbonates is the same as that found for the corresponding thiolates.[1] One of the N-bound hydrogens is found on the thiolate side of the ligand and three are located on the opposite side [the so-called (+ – – –)-configuration[16,17]]. For both compounds, the crystal lattices comprise two independent molecules with differences in conformation and bond lengths. In the case of **1a**, these

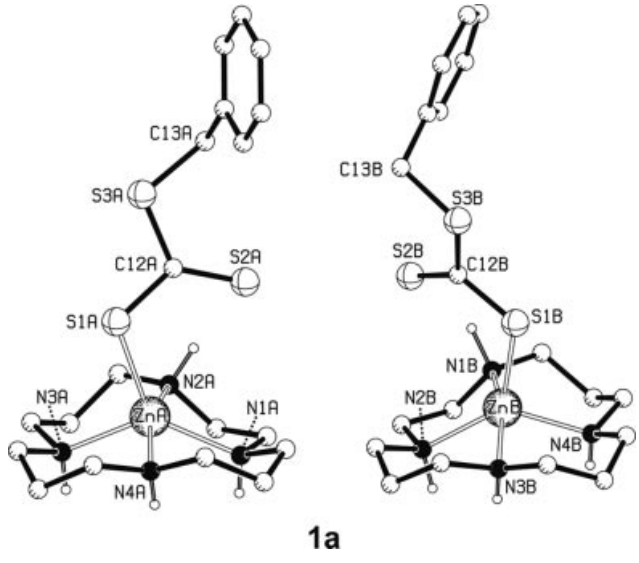


Figure 1. Molecular structures of the trithiocarbonate complex cation of **1a**.

two molecules are enantiomers because of the configuration of the nitrogen donors, which does not match the symmetry of the ligand, as was found for **2a**. However, the structural parameters of all trithiocarbonate moieties show very little variation and the Zn–S distances of both **1a** and **2a** are almost identical (Table 1).

### *NMR Spectra*

For the NMR spectroscopic investigations, chloroform solutions of **1** and **2** containing an equimolar amount and a 10-fold excess of $CS_2$ were analyzed. In these solutions, complexes **1a** and **2a** exist in a dynamic equilibrium with **1** and **2**, respectively (see Scheme 4). This causes all carbon atoms, particularly the trithiocarbonate carbons, to exhibit an increased line width in the $^{13}C$ spectra. Thus, their detection requires a large number of scans (>10.000) in order to reduce the signal-to-noise ratio.

Table 2 shows that upon addition of a 10-fold molar excess of $CS_2$ compound **1** is converted nearly completely to the trithiocarbonate **1a**, whereas the turnover is only two thirds for **2a** under the same conditions. This renders the reaction of **1** to **1a** suitable for the investigation of subsequent reactions and for determination of the thermal parameters of the insertion. Furthermore, it is worth noting that small changes of the macrocyclic ligand can have a dramatic effect on the reactivity of the thiolate, even though the structural parameters of the substrates and the products are nearly identical.

Table 2. Turnover of thiolates to trithiocarbonates in chloroform solutions containing different amounts of $CS_2$ (derived from $^1H$ NMR spectroscopic data).

| Mol. equiv. of $CS_2$ | **1a** [%] | **2a** [%] |
|---|---|---|
| 1 | 50 | 19 |
| 10 | >98 | 67 |

The $^{13}C$ NMR spectrum of **1a** shows 12 methylene signals. This indicates that the molecule has an asymmetric structure in a chloroform solution. It is most probable that the (+ – – –)-configuration is adopted, analogous with the solid-state structure. In contrast to the thiolate complex **1**,[1] the NMR spectra of **1a** do not provide any evidence for the presence of a second configurational isomer. As mentioned above, the zinc(II) ion of **1a** is chiral in nature due to the asymmetric configuration of the macrocyclic ligand. Thus, the benzyl protons of **1a** are in a diastereotopic environment. Nevertheless, the increased multiplicity of the corresponding NMR signals found for **1**[1] was not observed in the $^1H$ NMR spectrum of **1a**. This is a result of the spacer function of the trithiocarbonate moiety. The benzyl protons of **1a** are located at a much larger distance from the zinc atom than in complex **1**. The influence of the center of chirality is thus reduced to a minimum.

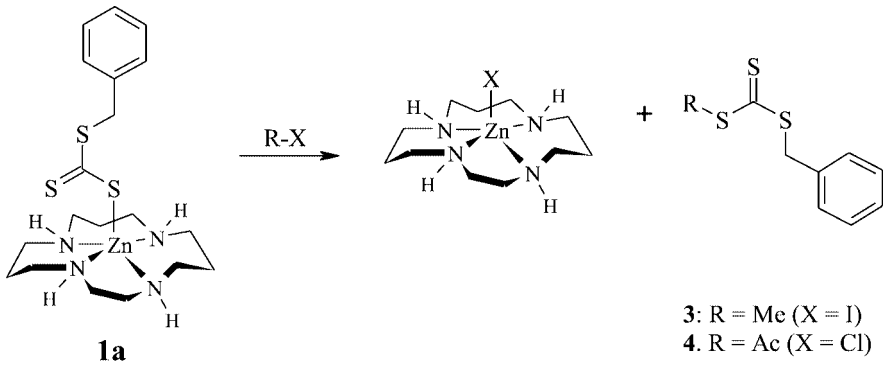
### *Solid-State NMR Spectroscopy*

While the thiolate complexes **1** and **2** do not have any spectral intensity in the range 230–240 ppm, the $^{13}C$ NMR spectra of the insertion products show strong signals in this spectral region. These lines show the formation of a thiocarbonyl group and thus corroborate the proposed structure of the trithiocarbonate moiety. Interestingly, both the thiocarbonyl line of **1a** and the line of the quaternary aromatic carbon C14 exhibit a splitting into an asymmetric doublet. These splittings reflect the conformational polymorphism of **1a**, which obviously is not as pronounced in **2a**. A splitting of the corresponding lines could not be observed in this case. (For graphical representations of all spectra and peak assignments see the Supporting Information.)

### *Raman Spectroscopy*

Complexes **1** and **1a** have also been investigated using Raman spectroscopy. Two strong signals at 507 and 1032 $cm^{-1}$ appear in the spectra of the reaction product **1a**. These are because of the symmetric (SCS) and the (C=S)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Reaction of the trithiocarbonate complex **1a** with electrophiles (only cations shown).

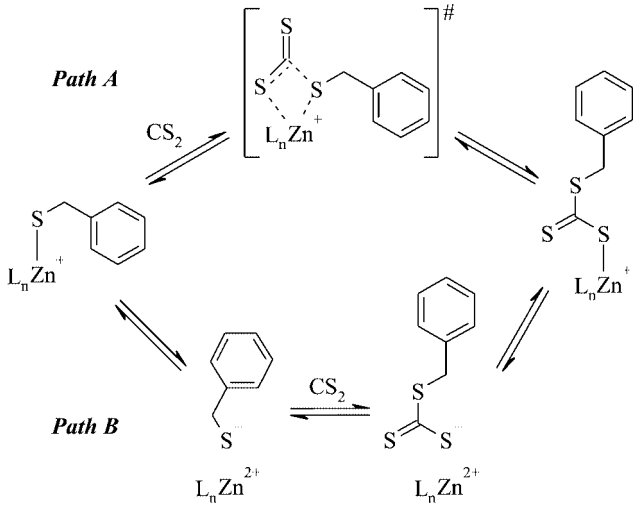
vibration, respectively, which correspond to the trithiocarbonate moiety of **1a**. At the same time, a signal at 1223 $cm^{-1}$ decreases in intensity. Raman monitoring of the reaction has shown that the formation of **1a** occurs in a clean reaction. Currently, we have no evidence for the formation of any intermediates or side products. (For a graphical representation of the spectra and a more detailed discussion see Supporting Information.)

### *Reactions of Complex 1a*

Similar to the thiolates, the trithiocarbonate complexes possess nucleophilic properties, as was found when reacting compound **1a** with electrophiles (see Scheme 3). Methyl iodide was added to a concentrated solution of **1** with a 10-fold excess of $CS_2$. As mentioned above, under these conditions the equilibrium is almost completely shifted to the insertion product **1a**. However, the reaction product of **1** with methyl iodide, which is benzyl methyl sulfide, was isolated in approx. 20% yield. Obviously, the thiolate **1** reacts several times faster than the trithiocarbonate **1a**, most likely because of the higher nucleophilicity of the thiolate sulfur in **1**. The quenching reaction with acetyl chloride results in the formation of the corresponding acetyl-substituted benzyltrithiocarbonate. The products were isolated and identified by their NMR spectra, which were known from authentic samples prepared for this purpose (see Exp. Sect.).

## Mechanism of $CS_2$ Insertion

The possible reaction mechanisms for the insertion of $CS_2$ into the Zn–S bond are outlined in Scheme 4. An attack of the zinc-bound thiolate on the carbon disulfide should result in clean second-order kinetic behavior of the reaction (path A). We assume that this is the preferred mechanism in a nonpolar solvent. An attack of the free thiolate (path B) should be much faster than the preliminary dissociation of the complex and result in clean first-order kinetics. Nevertheless, one could possibly observe second-order kinetics because of the perturbation effects or in the case where the dissociation step is unexpectedly not much slower than the $CS_2$ reaction. Thus, both mechanisms cannot be distinguished simply by comparing the order of their reaction kinetics. It is highly improbable, though, that the actual rate constants and activation barriers of both reaction modes are identical. Hence, we determined the activation barrier of this reaction and compared it with the calculated value for both of the possible pathways.



Scheme 4. Possible mechanisms for the formation of the trithiocarbonate complexes **1a** and **2a**.

### *Kinetic Study*

Since the insertion product **1a** absorbs at 434 nm the reaction progress could be monitored using electronic spectroscopy. At room temperature, the reaction proceeds on a time scale of minutes. Thus it was convenient to measure the rate constants at temperatures between 10 and 35 °C.

Because the reaction is an equilibrium reaction, the obtained data are a superposition of forward and backward reactions. In order to determine only the kinetic parameters of the insertion reaction, the perturbation effect of the back reaction must be eliminated. This was achieved by reacting **1** with $CS_2$ under pseudo first-order conditions. Only the data collected immediately after the start of the reaction were employed for the calculation of the rate constants.

A solution of **1** (0.05 M) was treated with a 20-fold excess of carbon disulfide. Under these conditions, the equilibrium is virtually completely shifted to the side of the insertion product. This was verified by NMR spectroscopy. The loga-

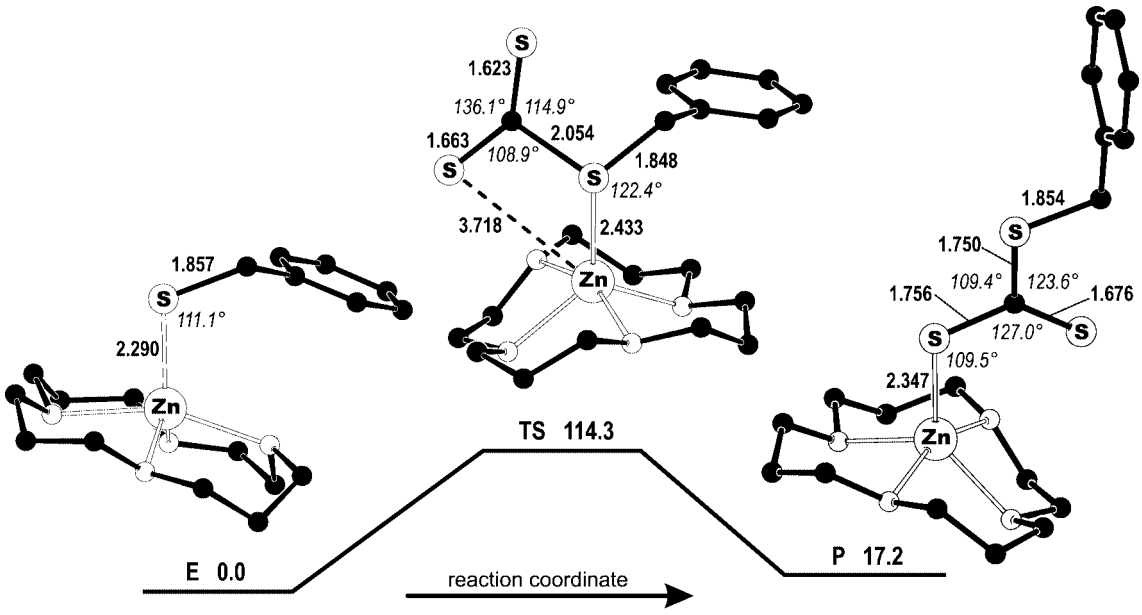

Figure 3. Structures and energy profile of the fixation of $CS_2$ by **1**, calculated at the C-PCM(B98/G3MP2Large)//B3LYP/6-311+G(d) level of theory. $\Delta G$ values are given in kJ·mol$^{-1}$.

rithmic plots employed for the calculation of the rate constants show only a very small variation from linearity with standard deviations of less than 1%. This emphasizes the clean pseudo first-order kinetic behavior of the observed reaction and proves that the perturbation effect of the back reaction is insignificant. Thus, the obtained kinetic and thermal parameters reliably represent the second-order insertion reaction. Analysis of a data set of 21 rate constants according to the Eyring theory resulted in $\Delta H^{\ddagger}$ = 65.3 ± 0.7 kJ·mol$^{-1}$ and $\Delta S^{\ddagger}$ = –49.9 ± 2.5 J·mol$^{-1}$·K$^{-1}$. The resulting free energy of activation at 25 °C is $\Delta G^{\ddagger}$ = 80.2 ± 1.5 kJ·mol$^{-1}$.

### *Quantum Mechanical Calculations*

The geometries of the starting material (**E**), the transition structure (**TS**), and the product (**P**) of the associative mechanism were optimized at the B3LYP/6-311+G(d) level of theory (Figure 3). For both **E** and **P** the X-ray structures of **1** and **1a**, respectively, served as starting points. The effect of the solvent chloroform on the reaction has been incorporated through the C-PCM model by B98/G3MP2Large single point calculations using the previously optimized B3LYP gas phase geometries. (For more detailed information see Computational Details.)

For the associative mechanism, the free energy of activation was calculated to be $\Delta G^{\ddagger}$ = 114.3 kJ·mol$^{-1}$. For comparison with the experimental results, the enthalpy of activation was computed to be $\Delta H^{\ddagger}$ = 60.7 kJ·mol$^{-1}$. The overall reaction is slightly endergonic ($\Delta_R G$ = 17.2 kJ·mol$^{-1}$).

For the dissociative mechanism a lower limit for the activation energy was estimated by calculating the energy required for the dissociation of **1** according to Equation (1) at the same level of theory. The initial dissociation of **E** requires $\Delta G$ = 191.8 kJ·mol$^{-1}$ and the barrier is thus quite substantial. Upon reaction with $CS_2$ the energy decreases slightly to $\Delta G$ = 165.4 kJ·mol$^{-1}$.

$$[Zn([15]aneN_4)(C_7H_7)]^+ \rightleftharpoons [Zn([15]aneN_4)]^{2+} + (C_7H_7)^- \quad (1)$$

## Discussion

The main issue we want to address in this work is the question of whether insertion of $CS_2$ proceeds via an associative mechanism or via a dissociative mechanism involving free thiolate. Preceding work has shown that the insertion of heterocumulenes into Zn–X (X = O, S) bonds usually involves a four-center transition structure.[5–7,13,14,18] For this type of reaction, this structure generally represents the rate-determining step. For the reaction we investigated, we thus proposed a mechanism that features a similar four-center transition structure, **TS**. In addition, it is highly improbable that the missing reaction step, the rearrangement (i.e. bond rotation) that leads to the reaction product **P**, involves an intermediate with a higher energy than the insertion step. No such example has been reported in the literature. Hence, we conclude that the free energy of the transition structure **TS** constitutes the actual reaction barrier and is thus comparable to the experimental value. Therefore, the different mechanisms can be distinguished by directly comparing the barriers and by comparison with the experimentally determined value.

From the calculations it is evident that the associative mechanism is favored by approximately 80 kJ·mol$^{-1}$ ($\Delta G^{\ddagger}$ = 114.3 kJ·mol$^{-1}$ for path A compared with $\Delta G^{\ddagger}$ > 190 kJ·mol$^{-1}$ for path B). Obviously, the entropy gain accompanying dissociation is not large enough to counterbal-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ance the unfavorable reaction enthalpy. Furthermore, the calculated barrier of path A ($\Delta G^{\ddagger}$ = 114.3 kJ·mol$^{-1}$) is in reasonable agreement, although somewhat larger, with the experimental value ($\Delta G^{\ddagger}$ = 80.2 kJ. mol$^{-1}$).

In addition, we would like to emphasize the good agreement of the values for the enthalpy of activation ($\Delta H^{\ddagger}$) obtained experimentally and theoretically. The correlation ($\Delta H_{exp}{}^{\ddagger}$ = 65.3 ± 0.7 kJ·mol$^{-1}$ versus $\Delta H_{theor}{}^{\ddagger}$ = 60.7 kJ·mol$^{-1}$) is striking, with a difference of only 5 kJ·mol$^{-1}$. Naturally, a very good agreement is therefore also obtained for the activation energy ($E_a$) according to the Arrhenius equation. The experimentally determined value is $E_{a(exp)}$ = 67.8 ± 0.8 kJ·mol$^{-1}$ compared to a computed value of $E_{a(theor)}$ = 63.2 kJ·mol$^{-1}$. (Admittedly, it is also possible that we benefit from some kind of fortuitous error cancellation here. However, with respect to the error margins of the computation this is not of significance concerning the overall conclusions of this work.)

The data presented above provides strong evidence that the insertion of $CS_2$ proceeds via an associative mechanism and that a dissociative mechanism is very unlikely under the chosen experimental conditions. Moreover, the applied technique of using gas-phase geometries and deriving energies from single-point C-PCM calculations can only yield results of restricted accuracy. We thus assume that the deviations of the calculated energies from experimental data are mainly caused by these deficiencies in the treatment of solvent effects.

## Conclusions

The chemistry of the $L_nZn$–XR motif (X = O, S; R = H, alkyl, aryl; $L_n$: 3 or 4 nitrogen donors) is highly relevant to biosystems. The heterocumulene reactions of these systems follow two basic principles: First, the nucleophilic attack of the zinc-bound heteroatom is facilitated by the polarizing effect of the Zn–X linkage on the heterocumulene. Second, the zinc(II) ion is able to accept a variety of coordination numbers and geometries and thus even severely distorted transition structures are possible. For these reasons, nucleophilic anions in zinc complexes can attack the heterocumulene in a zinc-bound state rather than acting as free (dissociated) anions. We would like to point out that in several studies an associative (zinc-bound) mechanism was invariantly found for heterocumulene reactions of widely different examples of $L_nZn$–XR complexes: for sterically unsaturated species such as $[(py)_nZn–OH]^+$ and $[(im)_nZn–OH]^+$ ($n$ = 1–3) with $CO_2$;[18] for several species resembling the 'classic' CA motif $[N_3Zn–OH]^+$ with $CO_2$,[6,7,19] COS,[5] and $CS_2$;[13,14] and for sterically demanding zinc thiolates with $CS_2$ (this work). Thus, we conclude that the principle of heterocumulene fixation involving a four-center transition structure is generally applicable and largely independent of the nature of the heterocumulene and the nucleophilic ligand (XR).

Currently, these investigations are being extended to other heterocumulene substrates, namely COS and $CO_2$. In this case, the elucidation of molecular structures of the products is much more difficult due to the fact that it is apparently not possible to obtain a standard NMR spectroscopic or an X-ray structural analysis. Thus, additional spectroscopic investigations are required, namely solid-state NMR and Raman spectroscopy. In the present work, these methods were applied for calibration purposes and appear to be of great value for determining structural details. A report on this continued study will be available soon.

## Experimental Section

**General:** All reagents used were of analytical purity. NMR spectra were recorded using a Bruker AC 250 or AC 400 spectrometer, respectively, at a temperature of 30 °C. IR data was collected from the neat substances using a Nicolet Avatar 320 FT-IR spectrometer. Elemental analysis was performed using a Heraeus Vario EL III system. Melting points were determined with a Büchi Melting Point B545 apparatus and are uncorrected. Raman measurements were performed on a LabRam HR inverse spectrometer (Jobin Yvon) with an excitation wavelength of 532 nm (Nd:YAG laser). A 100× objective was used to focus the laser beam on the sample. With a 300 lines/mm grating and a CCD detector, a spectral resolution of 5 cm$^{-1}$ was reached. The accumulation time was between 30 and 120 s.

**[Zn([15]aneN$_4$){S–C(S)–SCH$_2$C$_6$H$_5$}]ClO$_4$ (1a):** Complex **1** (250 mg) was dissolved in a minimal amount (ca. 0.5 mL) of dichloromethane. $CS_2$ (2 mL) was then added to this soulution. The mixture immediately turned yellow. After a short time, yellow crystals formed, which were separated and washed with a small amount of $CS_2$. Yield: 85%. M.p. = 112–113 °C. $C_{19}H_{33}N_4S_3ClO_4Zn$ (578.49): calcd. C 39.45, H 5.75, Cl 6.13, N 9.68, S 16.63; found C 39.27, H 5.92, Cl 6.27, N 9.69, S 16.63. IR: $\tilde{\nu}$ = 3252 (m), 2925 (m), 2864 (m), 1071 (vs), 1024 (vs), 821 (s), 706 (s), 620 (s) cm$^{-1}$. NMR: 25 mg of **1** in 0.4 mL chloroform with a 10-fold molar excess of $CS_2$, contains virtually exclusively complex **1a** and only traces of **1**. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.75–1.95 (range of multiplets, 7 H), 2.63–3.83 (range of multiplets, 21 H), 4.44 (s, 2 H, Ar-C*H*$_2$), 7.21–7.30 (multiplet, 5 H, Ar-*H*) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, 13911 scans): $\delta$ = 24.8, 27.9, 28.1, 46.2, 47.1, 48.3, 49.8, 51.4, 52.3, 52.4, 53.8, 54.0, 127.3, 128.5, 129.2, 135.8, 239.0 ppm.

**[Zn(*i*-[14]aneN$_4$){S–C(S)–SCH$_2$C$_6$H$_5$}]ClO$_4$ (2a):** The preparation was carried out similarly to that for **1a**. Yield: 81%. No melting point detectable; decomposition at 115–120 °C yields the thiolate complex **2**. $C_{18}H_{31}N_4S_3ClO_4Zn$ (564.47): calcd. C 38.30, H 5.54, Cl 6.28, N 9.96, S 17.04; found C 38.19, H 5.43, Cl 6.27, N 9.96, S 16.89. IR: $\tilde{\nu}$ = 3260 (m), 3165 (w), 2919 (m), 2866 (m), 1080 (s), 1076 (vs), 1033 (vs), 975 (s), 930 (s), 812 (s), 716 (m), 621 (vs) cm$^{-1}$. NMR: 25 mg of **2** in 0.4 mL chloroform with a 10-fold molar excess of $CS_2$, contains approx. 67% of complex **2a** and 33% of **2**. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.8–3.4 (range of multiplets), 4.48 (s, Ar-C*H*$_2$), 7.25–7.36 (multiplet, Ar-*H*) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 27.9, 45.8, 47.7, 49.1, 50.2, 51.9, 128.0, 128.5, 129.1, 135.8, 238.9 ppm.

### Crystal Structure Determination

The intensity data was collected on a Nonius Kappa CCD diffractometer, using graphite-monochromated Mo-$K_\alpha$ radiation. Data was corrected for Lorentz and polarization effects, but not for absorption effects.[20,21] The structures were solved by direct methods (SHELXS[22]) and refined by full-matrix least-squares

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

techniques against $F_o^2$ (SHELXL-97[23]). The hydrogen atoms of the amine groups were located by difference Fourier synthesis and refined isotropically. All other hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[23] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations. The drawings in the paper were generated using the program PLATON.[24]

**Crystal Data for 1a:**[25] $C_{19}H_{33}N_4S_3Zn{\cdot}ClO_4$, $M_r$ = 578.49 g·mol$^{-1}$, yellow prism, size 0.03 × 0.03 × 0.02 mm, monoclinic, space group $P2_1/n$, $a$ = 13.2338(1), $b$ = 12.9251(2), $c$ = 30.1669(4) Å, $\beta$ = 101.463(1)°, $V$ = 5057.1(1) Å$^3$, $T$ = –90 °C, $Z$ = 8, $\rho$(calcd.) = 1.520 g·cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 13.58 cm$^{-1}$, $F$(000) = 2416, 20403 reflections in $h$(–17/17), $k$(–16/15), $l$(–39/39), measured in the range 1.84° ≤ $\Theta$ ≤ 27.49°, completeness $\Theta_{max}$ = 98.5%, 11426 independent reflections, $R_{int}$ = 0.049, 6885 reflections with $F_o > 4(F_o)$, 608 parameters, $R1_{obs}$ = 0.049, $wR2_{obs}$ = 0.103, $R1_{all}$ = 0.1065, $wR2_{all}$ = 0.119, GOOF = 1.014, largest difference peak and hole: 0.676/–0.583 e·Å$^{-3}$.

**Crystal Data for 2a:**[25] $C_{18}H_{31}N_4S_3Zn{\cdot}ClO_4$, $M_r$ = 564.47 g·mol$^{-1}$, yellow prism, size 0.06 × 0.05 × 0.05 mm$^{-3}$, orthorhombic, space group $P2_12_12_1$, $a$ = 9.9936(1), $b$ = 22.1261(4), $c$ = 22.3192(4) Å, $V$ = 4935.2(1) Å$^3$, $T$ = –90 °C, $Z$ = 8, $\rho$(calcd.) = 1.519 g·cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 13.89 cm$^{-1}$, $F$(000) = 2352, 11275 reflections in $h$(–12/12), $k$(–28/28), $l$(–28/28), measured in the range 1.84° ≤ $\Theta$ ≤ 27.49°, completeness $\Theta_{max}$ = 99.7%, 11275 independent reflections, 9902 reflections with $F_o > 4(F_o)$, 591 parameters, $R1_{obs}$ = 0.045, $wR2_{obs}$ = 0.106, $R1_{all}$ = 0.057, $wR2_{all}$ = 0.113, GOOF = 1.047, Flack-parameter 0.08(1), largest difference peak and hole: 0.652/–0.534 e·Å$^{-3}$.

**Solid State NMR Spectroscopy:** The $^{13}C$ solid state NMR spectra were measured with three different solid state NMR spectrometers, namely a Bruker AMX 400, a Varian Unity 500, and a Varian CMX Infinity 600 plus at fields of 9.4, 11.7, and 14 T, respectively. All spectra were recorded under high power proton decoupling at ambient temperature. The spectra of **1**, **2**, and **1a** were measured employing a variable amplitude cross polarization with a contact time of 1.2 ms. For the insertion product **2a** we were not able to obtain a signal from the suspected thiocarbonyl group with this technique. We therefore did additional measurements employing $^{13}C$ 90° pulse excitation on this sample, using a recycle time of 100 s. In this experiment, we were able to reveal the thiocarbonyl signal (see Supporting Information). While the spectral assignment of the thiocarbonyl groups is obvious from the prominent chemical shift, the assignment of the aromatic and aliphatic carbons was done employing simulations with the NMR predictor program of ACDlabs.

### Reactions of 1a

**Methyl Iodide:** $CS_2$ (300 μL, 5 mmol) was added to a solution of **1a** (251 mg, 0.5 mmol) in chloroform (1 mL). After 30 min. methyl iodide (310 μL, 5 mmol) was added and the mixture was stirred overnight. The solvents were removed and the residue was washed several times with pentane. The combined pentane extracts were concentrated and chromatographed on 20 cm$^3$ of silica (eluent: pentane). After the elution of benzyl methyl sulfide (12 mg, 0.087 mmol), which was collected separately, benzyl methyl trithiocarbonate (**3**) (82 mg, 0.38 mmol, 76%) was obtained as a yellow oil. The substance was identified by NMR analyses and compared with data from the literature.[26] $^1H$ NMR (250 MHz, $CDCl_3$): $\delta$ = 2.78 (s, 3 H, $CH_3$), 4.66 (s, 2 H, $CH_2$), 7.26–7.41 (m, 5 H, $C_6H_5$) ppm. $^{13}C$ NMR (62.5 MHz, $CDCl_3$): $\delta$ = 20.2, 41.6, 127.8, 128.7, 129.3, 135.1, 224.2 ppm.

**Acetyl Chloride:** $CS_2$ (300 μL, 5 mmol) was added to a solution of **1** (251 mg, 0.5 mmol) in chloroform (1 mL). After 30 min. acetyl chloride (36 μL, 0.5 mmol) was added while stirring. After 20 min the mixture was subjected to chromatography on 20 cm$^3$ of silica (eluent: $CHCl_3$). **4** (88 mg, 72%) was isolated and identified by $^1H$ and $^{13}C$ NMR spectra.

**Synthesis of 4 (Reference Sample):** Benzyl mercaptan (205 mg, 1.65 mmol) was added to a solution of KOH (92.7 mg, 1.65 mmol) in methanol (10 mL),. After stirring for 30 min at room temp., the solvent was removed under reduced pressure. The residue was carefully dried in a desiccator. The salt was dissolved in dried THF (5 mL) and an excess of $CS_2$ (0.84 mL, 14 mmol) was added at 0 °C. The temperature was raised to 25 °C after stirring for 60 min. The reaction mixture was then cooled to –78 °C. Acetyl chloride (0.178 mL, 2.5 mmol) was added dropwise, whereupon the yellow solution turned red. After stirring for 20 min the solvent was evaporated. The residue was purified by chromatography on silica (eluent: $CHCl_3$), yielding 107 mg (27%) of a red oil that decomposed at room temp. within a few weeks. $C_6H_5$–$CH_2$–S–C(S)–S–C(O)–$CH_3$ ($C_{10}H_{10}OS_3$) (242.39): calcd. C 49.55, H 4.16, S 39.20; found C 50.28, H 4.10, S 39.20. $^1H$ NMR (250 MHz, $CDCl_3$): $\delta$ = 2.41 (s, 3 H, $CH_3$), 4.49 (s, 2 H, $CH_2$), 7.28–7.36 (m, 5 H, $C_6H_5$) ppm. $^{13}C$ NMR (62.5 MHz, $CDCl_3$): $\delta$ = 29.8, 42.9, 128.0, 128.8, 129.4, 133.8, 189.9, 212.4 ppm.

### Kinetics

**Experimental Setup:** The insertion of $CS_2$ was monitored by UV/Vis spectroscopy. Complex **1a** shows an absorption maximum at 434 nm, whereas the starting complex **1** does not show any absorption in the visible range at all. Measurements were performed using a Cary 5000 UV/Vis spectrometer from Varian. For keeping the temperature constant, a Cary dual cell peltier accessory from Varian was used. 1 cm quartz cuvettes were obtained from Hellma. During the reaction the mixture was stirred with a magnetic stirrer. The reaction temperature was determined with a sensor that was placed directly in the reaction medium.

**Measurements:** An amount of 2 mL was placed into a cuvette from a 20 mM stock solution (502.4 mg of **1** in 50 mL of chloroform). After the desired temperature was reached, 48 μL (61 mg, 800 μmol) of $CS_2$ was added and data collection was started. For the first 60 s, data were collected every second and later every 10 s. The reactions were monitored until no further alteration of the absorbance could be detected. For details on the data analysis see Supporting Information.

### Computational Details

Full geometry optimizations, i.e. without constraints, as well as frequency calculations on the stationary points thus obtained were carried out using the Gaussian03[27] program package. Depending on the number of imaginary modes all points on the hypersurface were rigorously characterized as true minima (no imaginary mode) or transition structures (exactly one).

All optimizations were performed using the hybrid B3LYP[28] density functional method, which includes the use of a term that accounts for the effect of dynamic electron correlation (Coulomb hole).[29] Geometries were optimized in the gas phase using the standard 6-311+G(d) basis set.

To estimate solvent effects, single point calculations in the presence of a dielectric field, as described by the C-PCM model,[30–32] were carried out on the gas phase geometries. In this model, the species of interest are embedded in a cavity of molecular shape surrounded by a polarizable continuum whose field is described by polarization

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

charges distributed on the cavity surface. This procedure is known to be very good at reproducing experimental hydration energies.[30] In the framework of the C-PCM model the default UA0 cavities (based on the united atom topological model) and the dielectric constant of chloroform ($\varepsilon$ = 4.9) were used.

For all single point calculations the B98[33] functional was used. The G3MP2Large basis set[34] was employed on all atoms except zinc where the 6-311+G(3df) basis set as implemented in Gaussian03 was applied. The B98 density functional was chosen for the calculation of the energies because it has recently been shown that it outperforms the more popular B3LYP functional, both for absolute energies and barrier heights, especially for larger molecules.[35–37] In all these studies the assessment was performed using single point calculations on some reference geometry, basically the same approach that we used in this work. We therefore believe that the use of the well-established B3LYP density functional for the geometry optimizations has only a minor effect on the calculated energies. This is even more plausible with respect to the fact that geometry relaxation effects from the dielectric field of the solvent are completely neglected. The absolute error of B98 on the G3/05 set is approximately 14 kJ·mol$^{-1}$,[35] but the relative errors are generally smaller.

All energies were calculated by adding the appropriate thermodynamic corrections [gas phase, B3LYP/6-311+G(d)] to the total free energy in solution (including electrostatic and nonelectrostatic terms) obtained from the single point calculations (B98/G3MP2Large). The gas phase correction values were calculated with the standard thermodynamic routines in Gaussian03 (with $T$ = 298.15 K and $p$ = 1 atm) using the frequencies computed at the B3LYP/6-311+G(d) optimal gas phase geometries.

**Supporting Information** (see footnote on the first page of this article): Details are given on the Raman spectroscopy (including two spectra), the solid-state NMR spectroscopy (including four spectra), and the analysis of the kinetic data (including two kinetic plots). The Cartesian coordinates and absolute energies of all calculated structures are provided.

# The Reactivity of Hexa(*N*-methylideneimine)Co$^{III}$ Complexes towards Nucleophiles: Structure and Mechanism[‡]

**Dirk Kuppert,[a] Peter Comba,[b] and Kaspar Hegetschweiler*[a]**

**Keywords:** Nucleophilic addition / Hydrogen transfer / N ligands / Cobalt / Chelates.

The reactivity of the ***h***exa(*N*-***m***ethylidene***i***mine)Co$^{III}$ complex [Co-hmi-(taci)$_2$]$^{3+}$ (taci = 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol) towards the nucleophiles ammonia, aniline and cyanide was investigated and the main products were identified by spectroscopic methods and by a crystal structure analysis. The relative energies of the complexes formed and those of possible stereo isomers were analysed by means of molecular mechanics calculations. In the reaction with $NH_3$, two condensation products, [Co(L$^a$)]$^{3+}$ and [Co(L$^b$)]$^{3+}$, were identified with the two taci moieties linked by one or two N=CH–N(H)-CH$_2$–NH bridges, respectively. The reaction with aniline yielded the complex [Co(L$^c$)(L$^d$)]$^{3+}$ (where L$^c$ is a mono-*N*-methylated and L$^d$ a phenylformamidine-substituted taci), whereas the reaction with cyanide resulted in the formation of [Co(L$^e$)]$^{3+}$ having an NH–CH$_2$–C(NH$_2$)=N bridge between the two taci subunits. A mechanism that accounts for the different types of products can be suggested as follows: In [Co(L$^a$)]$^{3+}$, [Co(L$^b$)]$^{3+}$ and [Co(L$^c$)(L$^d$)]$^{3+}$, *N*-methylation was observed and this can be interpreted in terms of an intramolecular Cannizzaro type hydride shift. For [Co(L$^a$)]$^{3+}$ and [Co(L$^b$)]$^{3+}$ two subsequent addition steps of the nucleophile to adjacent imino groups must take place prior to the hydride shift, whereas for [Co(L$^c$)(L$^d$)]$^{3+}$ the hydride shift appears to have already occurred after the first addition step of aniline to an imino group. Formation of [Co(L$^e$)]$^{3+}$ can be explained in terms of a nucleophilic attack of CN$^-$ to an imino group and a subsequent attack of a deprotonated amino group (which must have previously been formed by hydrolysis of a methylideneimino group) to the nitrile C-atom.

## Introduction

Polyaza macrocycles and polyaza macrobicycles are interesting classes of chelators for transition metal cations, since the complexes formed thereof are often of exceptionally high stability and inertness.[1] A variety of synthetic procedures have been established for the preparation of such ligands and among them the template method, in which a set of subunits is precoordinated to a metal centre, is particularly effective.[2] Sargeson discovered that the condensation of an (amine)Co$^{III}$ complex with formaldehyde under basic conditions, followed by a capping step, resulted in the formation of the corresponding cage complexes.[3] The capping reagent is usually a weakly acidic, tribasic component $H_3X$ such as ammonia or nitromethane[4] and the entire reaction may be performed either in an aqueous or a nonaqueous medium. The procedure was found to be particularly effective for the capping of [Co$^{III}$(en)$_3$]$^{3+}$ (en = ethane-1,2-diamine) where the two cages sepulchrate (sep, X = N) and sarcophagine (sar, X = C-NO$_2$) could be isolated in high yields. It is generally believed that the reaction proceeds via intermediate methylideneimine formation with the capping agent being finally added with subsequent deprotonation to the coordinated imines (Scheme 1).[5] Although the entire procedure is usually performed as a one-pot reaction without isolation of intermediates, some of the imines are of sufficient stability to allow their characterisation[6] and some of them could even be crystallised.[7,8] We reported the crystal structure of the ***h***exa(*N*-***m***ethylidene-***i***mine) (hmi) complex [Co-hmi-(taci)$_2$]$^{3+}$ (Scheme 2a, R = OH; taci = 1,3,5-***t***ri***a***mino-1,3,5-trideoxy-***c***is-***i***nositol) some years ago.[9]

Sargeson has already found that in complexes with sterically demanding diamine ligands such as *trans*-cyclohexane-1,2-diamine (*trans*-chxn), the capping reaction proceeds at a comparatively low rate.[10] Moreover, formation of a variety of by-products was noted. In particular, it was observed that some of the coordinated amino groups underwent methylation. It is thus apparent that, in general, the bridging process may be more complex than it appears at first glance.[11] After formation of the first two X–C bonds, additional deprotonation of XH can occur and the resultant anion could attack the electrophilic carbon atom of a third

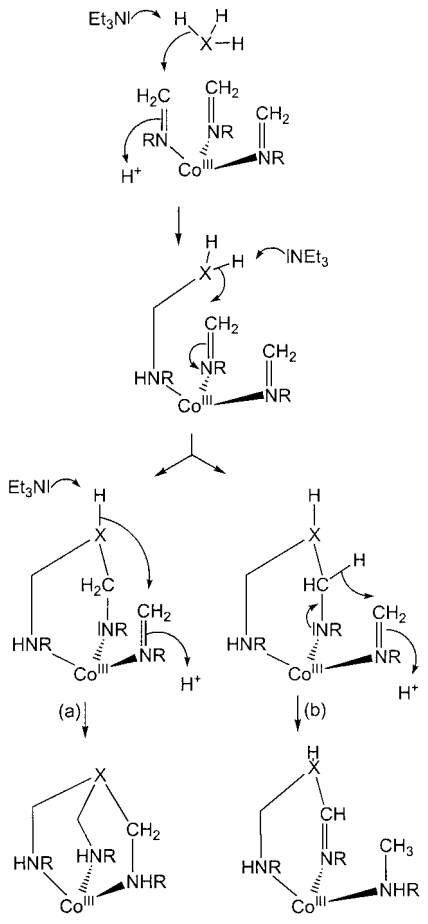
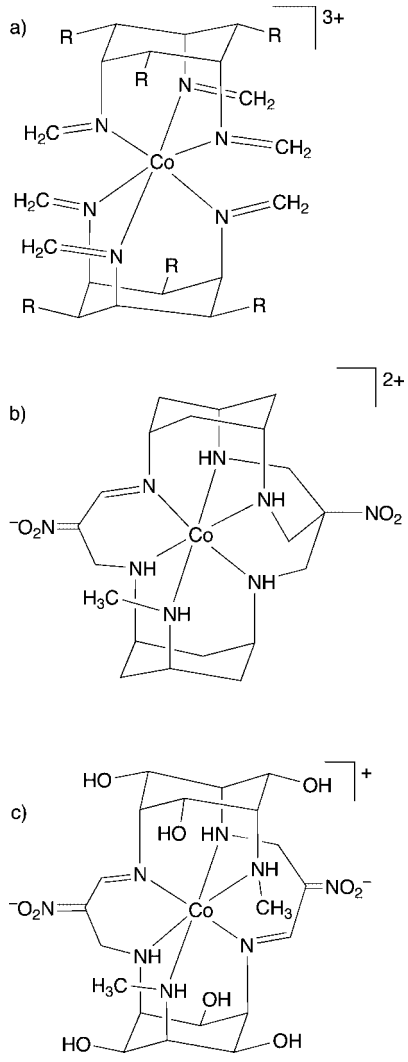


Scheme 1. Reaction of (hexaimine)$Co^{III}$ complexes with a capping reagent $H_3X$; mechanistic details for the formation of a cap (a) or a strap (b, Cannizzaro type hydride shift). Some of the charges are omitted for clarity.



Scheme 2. a) Structures of [Co-hmi-(*cis*-tach)$_2$]$^{3+}$ (R = H) and [Co-hmi-(taci)$_2$]$^{3+}$ (R = OH).[9] b) and c): Major products isolated from the condensation reaction of the two (hmi)$Co^{III}$ complexes with nitromethane. The reaction was carried out either in an alkaline aqueous medium (b)[12] or in acetonitrile using triethylamine as base (c)[9] (taci = 1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol, *cis*-tach = all-*cis*-cyclohexane-1,3,5-triamine).

imino group (Scheme 1a). It is also possible at this stage, however, that an N=C double bond could reform within the NH–$CH_2$–XH–$CH_2$–$N^-$ bridge in conjunction with hydride transfer from the methylene carbon to an adjacent imino group (Scheme 1b). Such an intramolecular, Cannizzaro type hydride shift would explain formation of the *N*-methylated by-products observed in the capping reaction of [$Co^{III}$-(*trans*-chxn)$_3$]$^{3+}$. In the corresponding reaction of [$Co^{III}$(*cis*-tach)$_2$]$^{3+}$ with formaldehyde and two equiv. of nitromethane, both types of reaction were observed within the same molecule (Scheme 2b).[12] The addition of one of the nitromethane molecules yielded an $O_2N$–C($CH_2$–NH)$_3$ cap whereas addition of the other resulted in the formation of an HN–$CH_2$–CH($NO_2$)–CH=N strap. The hydrogen atom of the CH($NO_2$) moiety was found to be strongly acidic and the complex was thus isolated as a dication with a carbanionic ligand having a delocalised $O_2N$=C–C=N π-system. Moreover, in the reaction of [$Co^{III}$-hmi-(taci)$_2$]$^{3+}$ with two equiv. of nitromethane, the resultant product was devoid of any $O_2N$–C($CH_2$–NH)$_3$ cap (Scheme 2c). Both nitromethane entities were incorporated as HN–$CH_2$–C($NO_2$)$^-$–CH=N straps.[9]

It is noteworthy that the rigidity of the ligand backbones increases in the order en < *trans*-chxn < *cis*-tach < taci. It appears, thus, that increasing the rigidity of the coordinated amine ligands tends to disfavour the capping reaction. Formation of such HN–$CH_2$–XH–CH=N straps has previously only been observed in the capping reaction with nitromethane.[9,12] It would be interesting to investigate the products formed when other types of nucleophiles are used. Such an investigation would not only shed light on the mechanism of this type of condensation processes but it could potentially open synthetic pathways to novel and interesting macrocyclic ligand systems. We therefore decided to extend our investigation of the capping of [$Co^{III}$-hmi-(taci)$_2$]$^{3+}$ using ammonia, aniline and cyanide as possible nucleophiles. In this paper, we describe the molecular structures of the products obtained and discuss the mechanism of the corresponding coupling reaction. We also carried out a series of molecular mechanics calculations to look for low-energy structures of the different possible stereoisomers.

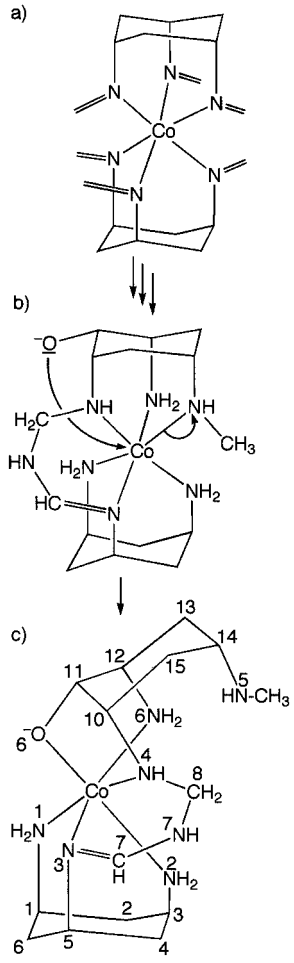
## Results

### Reaction of [Co-hmi-(taci)$_2$]$^{3+}$ with Ammonia

Formation of the well known (sepulchrate)Co$^{III}$ complex has been reported to occur readily upon mixing [Co$^{III}$-(en)$_3$]$^{3+}$ with formaldehyde and ammonia in an alkaline aqueous solution.[5] Consequently, initial attempts to carry out an analogous reaction of [Co$^{III}$-hmi-(taci)$_2$]$^{3+}$ (Scheme 2a, R = OH) with ammonia were performed in aqueous media. However, these experiments resulted in the complete hydrolysis of the imino groups, together with reduction of Co$^{III}$ to Co$^{II}$. The protonated H$_3$taci$^{3+}$ was the only product which could be isolated after acidification. Further experiments were therefore performed in acetonitrile. To achieve the required solubility, the chloride salt of [Co$^{III}$-hmi-(taci)$_2$]$^{3+}$ was converted into the corresponding triflate salt.[13] Reaction of [Co$^{III}$-hmi-(taci)$_2$](CF$_3$SO$_3$)$_3$ in acetonitrile with concentrated aqueous ammonia resulted in formation of a deep red solution containing a variety of different Co$^{III}$ complexes. After hydrolysis of the remaining imines, two main products were isolated by chromatographic techniques. The major red component, [Co(HL$^a$)]Cl$_4$ (L$^a$ = C$_{15}$H$_{33}$N$_7$O$_6$),[14] consisted of a complex in which the two taci-ligands are interlinked by an N=CH–NH–CH$_2$–NH bridge and where one of the coordinated amino group was methylated (Scheme 3). In a minor pink component, composed of [Co(H$_2$L$^b$)]Cl$_5$ (L$^b$ = C$_{18}$H$_{36}$N$_8$O$_6$),[14] the taci moieties were connected by two such N=CH–NH–CH$_2$–NH bridges and two methylated amino groups were formed. Both compounds were characterised by FAB$^+$ mass spectrometry in which the pseudo-molecular ions [Co$^{II}$-(H$_{-1}$L$^a$)]$^+$ (*m*/*z* = 465) and [Co$^{II}$(H$_{-1}$L$^b$)]$^+$ (*m*/*z* = 518)[15,16] could be observed with high intensities.



Scheme 3. Formation of [Co(H$_{-1}$L$^a$)]$^{2+}$.[14] A part of the numbering scheme of this complex is shown in c). The non-coordinating OH-groups are omitted for clarity.

### Characterisation of [Co(L$^a$)]$^{3+}$[14]

A $^1$H-$^1$H COSY NMR spectrum exhibited two independent spin systems each with six resonances for the H(-C) ring protons of the two taci frameworks. Clearly no element of symmetry of the $D_{3d}$ [Co$^{III}$-hmi-(taci)$_2$]$^{3+}$ precursor is retained in this complex. Four additional signals were indicative of one HC=N imino group, one N-CH$_3$ methyl group and one N–CH$_2$–N group. The $^{13}$C{$^1$H} NMR spectrum was consistent with this analysis exhibiting fifteen signals which, on the basis of a DEPT experiment, could be assigned to one CH$_3$, one CH$_2$ and 13 CH-carbon resonances.[17] One of the CH signals was strongly deshielded (170–173 ppm, depending on pD) and clearly originated from the imino group.[6] The remaining 12 CH signals were assigned to the two taci backbones. They appeared in the range of 52–80 ppm. Eleven of them were located in a comparatively narrow range of 52–68 ppm, whereas one single CH-resonance was displaced to a particularly high frequency ($\delta$ = 80.0 ppm at pD 8). Such a significant low-field shift of a single cyclohexane carbon atom is indicative of asymmetric $\kappa^3$-*O*,*N*,*O* or $\kappa^3$-*N*,*O*,*N* coordination (formation of two five-membered chelate rings).[18–20] The additional $^{13}$C-$^1$H HMQC and $^{13}$C-$^1$H HMBC experiments[17] provided evidence that the imine portion of the N=CH–NH–CH$_2$–NH bridge and the N-CH$_3$ group are not bound to the same taci-unit. These structural assignments were subsequently confirmed by a single-crystal X-ray analysis of a hydrated [Co(HL$^a$)][ZnBr$_4$]$_2$ salt (Table 1, Figure 1). Although serious disorder was observed for one of the [ZnBr$_4$]$^{2-}$ anions (see experimental section), the structure proved to be of sufficient quality to establish unambiguously the formation of the novel ligand L$^a$. Significant structural properties are: (i) Different coordination modes[21] of the two taci fragments with a $\kappa^3$-*N*,*N*,*N* coordination for the moiety with the imino group and a $\kappa^3$-*N*,*O*,*N* coordination for the moiety with the N–CH$_3$ group (the N–CH$_3$ group itself is detached from Co); (ii) Different conformations for the two cyclohexane rings: the $\kappa^3$-*N*,*N*,*N*-coordinating fragment forms a regular chair, whereas the $\kappa^3$-*N*,*O*,*N*-coordinating unit has a twisted boat conformation.[22] (iii) A planar geometry around the atoms N3, C7 and N7 (the sums of bond angles are 360.0 ± 0.1°), indicative of sp$^2$ hybridisation for all the atoms of the amidine fragment.

[a] Single-crystal X-ray structure analysis of $[Co(HL^a)][ZnBr_4]_2 \cdot 5H_2O$. [b] Molecular mechanics calculations using the MOMEC force field[46,47] together with the extension listed in Table 4.

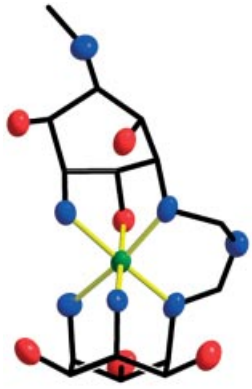

Figure 1. Molecular structure of $[Co(HL^a)]^{4+}$.[14] The carbon skeleton is shown as a stick model, other non-hydrogen atoms are shown as vibrational ellipsoids at the 30% probability level. Hydrogen atoms are omitted for clarity. Colour code: Co green, O red, N blue. The numbering scheme is shown in Scheme 3c.

$[Co(HL^a)][ZnBr_4]_2 \cdot 5H_2O$ was isolated from an acidic medium and, consequently, both the coordinated oxygen and the non-coordinating methylamino group are protonated as supported by charge balance considerations. In aqueous solution, however, the two sites could be deprotonated reversibly. Corresponding p$K_a$ values of 2.0(1) and 5.28(1) were determined by potentiometric titration (25 °C, 0.1 M KCl). The first value (deprotonation of the coordinated hydroxy group) agrees nicely with the value of 2.0(2) observed for the model complex [Co(*cis*-tach)(Htaci-κ$^3$-*O*$^1$,*N*$^2$,*O*$^3$)]$^{4+}$ (Supporting Information, Scheme S1b, structure O7).[20] However, the p$K_a$ of the methylammonium group is surprisingly low (the corresponding values for [Co(*cis*-tach)(Htaci)]$^{4+}$ are 7.23 and 8.84). An NMR titration experiment of $[Co(HL^a)]^{4+}$ (306 K, $D_2O$, no inert electrolyte) in the range 0.5 < pH < 8.5 (Figure 2) revealed a characteristic pD-dependence of the individual $^1$H resonances of the complex. The two protonation constants could be assigned as p$K_1$ = 1.16 and p$K_2$ = 5.60 which is in good agreement with the values determined by potentiometric measurements. In accord with a protonation of a nearby basic site, H(-C) resonances can be expected to shift to higher frequency upon protonation of this site and this effect should decrease with an increasing number of bonds between this site and the H(-C) group under consideration.[23] For the deprotonation of the coordinated hydroxy group, the resonances most affected (H10–H12) in the range 0.5 < pD < 2 are all in close proximity to O6; and H11, which is located in the α position, did indeed exhibit the most significant shift (see Scheme 3c for the numbering scheme). However, for the deprotonation of the methylammonium group the most significant shift can be observed for the hydrogen atoms in the β positions (H13 and H15). The shift observed for the α hydrogen atom (H14) is almost negligible. Moreover, in the range 4.5 < pD < 6.5, this signal is shifted to a higher frequency with increasing pD. This behaviour becomes understandable if a conformational change of the κ$^3$-*O*,*N*,*O*-coordinated cyclohexane residue takes place upon deprotonation of the methylammonium group. Below pD 4 the conformation of this ring corresponds to a twisted boat (Figure 1).[22] In terms of torsional strain, a corresponding chair conformation is expected to be of lower energy. However, as long as the non-coordinated nitrogen is protonated, such a geometry would give rise to dramatic repulsion between the three axial substituents (Scheme 4). This strain is released upon deprotonation because the methylamino group can act as a proton acceptor in an intramolecular hydrogen bond. A similar change in conformation has recently been described for a related complex with κ$^3$-*N*,*O*,*N*

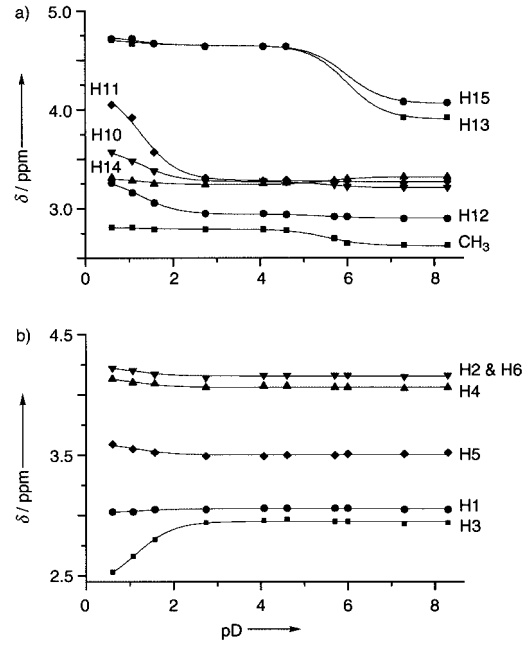

Figure 2. pD dependence of the $^1$H NMR resonances of $[Co(HL^a)]^{4+}$ ($D_2O$, 33 °C, TSP = 0 ppm).[14] a) κ$^3$-*O*,*N*,*O*-coordinated taci ring b) κ$^3$-*N*,*N*,*N*-coordinated taci ring. Squares, triangles and circles correspond to the experimental values, the lines are calculated (minimisation of $\Sigma[\delta_{obs} - \delta_{calcd}]^2$. The numbering scheme shown in Scheme 3c has been used.

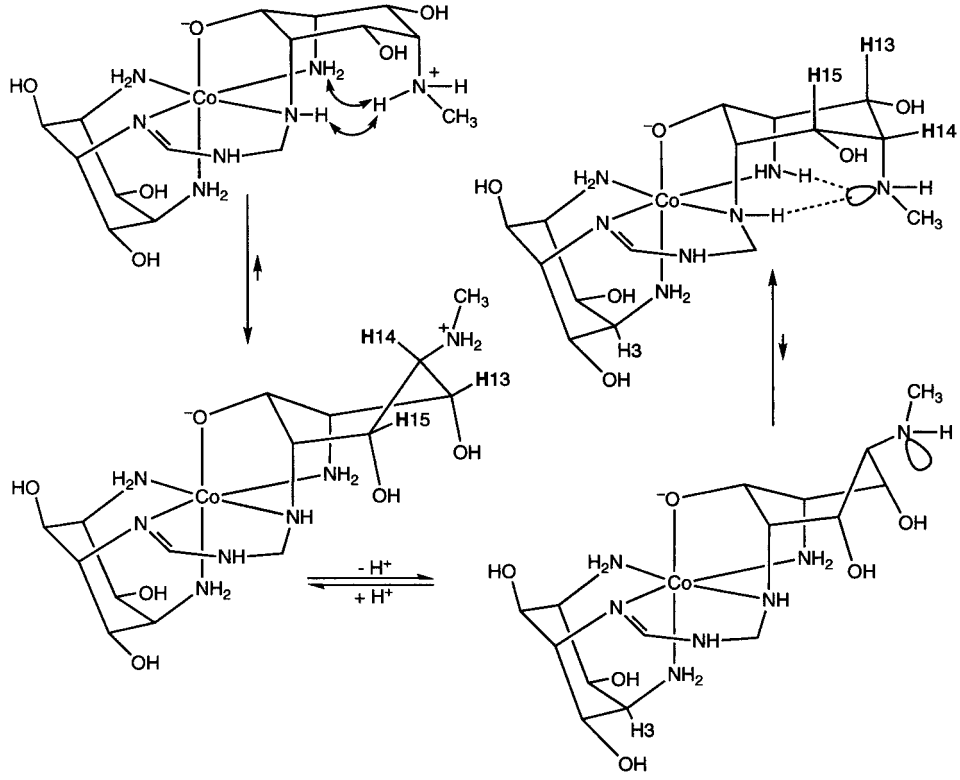


Scheme 4. The pH-dependent conformational equilibrium for the monobridged complex with a twisted boat conformation in acidic media ($[Co(HL^a)]^{4+}$ and $[Co(L^a)]^{3+}$) and a chair conformation at high pH ($[Co(H_{-1}L^a)]^{2+}$) as major species.[14] H–H Repulsion interactions are marked with arrows, possible hydrogen bonds are shown by dashed lines.

coordination in which hydrogen bonding to the non-coordinating amino group is suppressed by its conversion to an amide.[24] Molecular mechanics calculations support this interpretation, namely, for the fully deprotonated $[Co(H_{-1}L^a)]^{2+}$, the twisted boat conformer has a strain energy which is 17 kJ mol$^{-1}$ higher than for the corresponding chair conformation. The change from the twisted boat to the chair conformation brings H14 into an equatorial and H13/H15 into an axial position. It is well known that equatorial hydrogens in a cyclohexane moiety generally appear at higher frequencies. Clearly the two effects (change from an axial to an equatorial position and shielding by deprotonation) tend to the same direction for the hydrogens in the β position but to opposite directions for the hydrogen in the α position of the methylamino group. Consequently, the resultant shift is almost zero for H14 and twice as much as expected for H13 and H15. The release of strain which is caused by this conformational change represents an additional driving force for the deprotonation of the methylammonium group and helps to explain the above-mentioned rather low value of 5.3 for this p$K_a$. A conformational change is further supported by the observation that the resonances of H13, H15 and of the methyl group exhibited strong line broadening in the range $4.5 \leq pD \leq 6$, indicative of some dynamic behaviour within the molecule.

The pD-dependence of most of the resonances of the κ$^3$-*N*,*N*,*N*-bonded moiety is relatively minor as expected (Figure 2b). There is one remarkable exception, however. H3, which is *trans* to the coordinated oxygen donor, exhibits a strong shift in the range $0.5 < pD < 2$ and even more interestingly, this signal is shifted to *higher* frequency with increasing pD. The observed pD behaviour clearly implies that this effect must be due to the deprotonation of the coordinated hydroxy group. We recently demonstrated that such a specific *trans* effect is very characteristic for the deprotonation of a coordinated oxygen in Co$^{III}$ complexes with polyamino-polyalcohol ligands.[25]

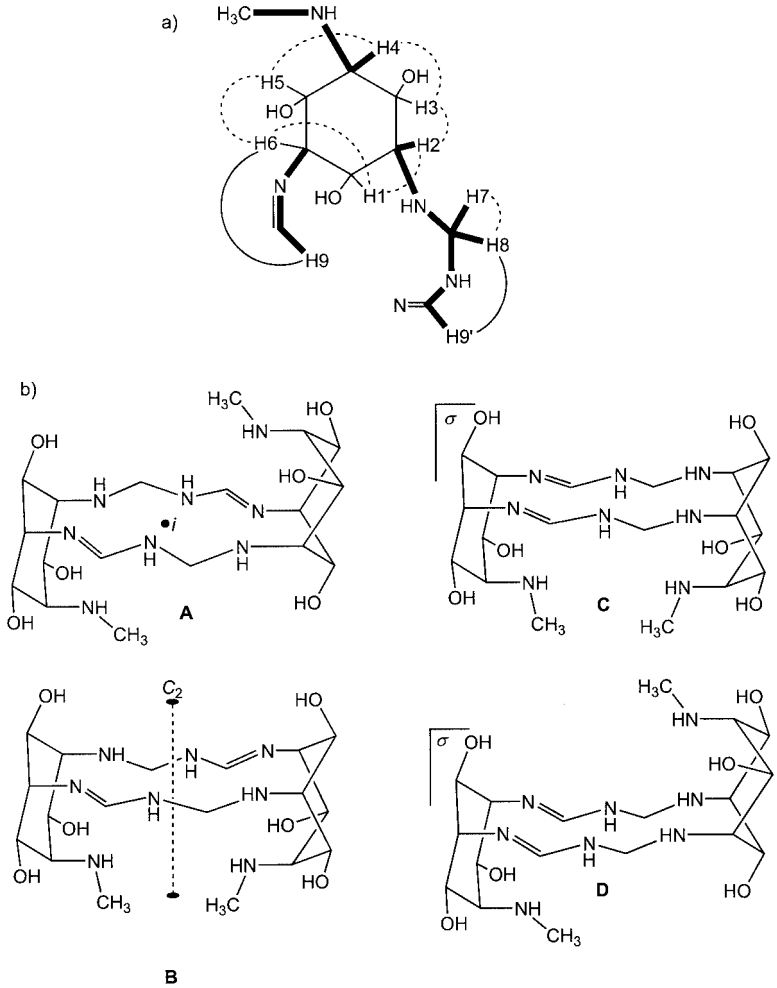
The $^1A_{1g}$–$^1T_{1g}$ transition of the $CoN_5O$ chromophore of $[Co(H_{-1}L^a)]^{2+}$ and $[Co(HL^a)]^{4+}$ can be observed at 508 nm (pH 12) and 513 nm (10 M HCl), respectively. These values are slightly higher than the corresponding values in the nonbridged [Co(*cis*-tach)(taci-κ$^3$-*N*,*O*,*N*)]$^{4+}$ ($\lambda_{max}$ = 484 nm).[20] Cyclic voltammetry (Hg-electrode) revealed quasi-reversible redox behaviour with a reduction potential $E_{1/2}$ (Co$^{III}$/Co$^{II}$) of –0.12 V (vs. NHE).

### Characterisation of $[Co(L^b)]^{3+}$[14]

The second pink coloured fraction was identified as a doubly bridged and dimethylated species.[15] The $^{13}C\{^1H\}$ NMR spectrum exhibited a total of nine signals for the 18 carbon atoms. They were assigned to one $CH_3$ resonance, one $CH_2$ resonance and seven CH resonances on the basis of DEPT experiments.[17] In the $^1H$ NMR spectrum two singlets, one of them at the low end and the other at the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

high end of the range observed for the chemical shifts, were assigned to the N–$CH_3$ methyl groups (6 H) and to the N=CH imine protons (2 H), respectively. The remaining eight resonances (each representing two hydrogen atoms) corresponded to the twelve cyclohexane ring protons and to the $CH_2$ groups of the bridges. Their mutual coupling pattern was established by a series of $^1$H-$^1$H and $^1$H-$^{13}$C correlation experiments (Scheme 5). The reduced number of signals is indicative of some symmetry. However, the $C_s$-symmetric forms **C** and **D** with the two imino groups attached to the same taci ring can be excluded from further consideration since a total of twelve rather than nine signals would be expected for such isomers in the $^{13}$C NMR spectrum. The $C_i$ and $C_2$ symmetric isomers **A** and **B** on the other hand are both consistent with the NMR characteristics. Further information about the structure of this complex can be obtained from the pD-dependence of the $^1$H NMR resonances (Figure 3). The $\delta$ vs. pD curves could be modelled successfully using the four p$K$ values p$K_1$ = 0.1, p$K_2$ = 2.4, p$K_3$ = 4.9 and p$K_4$ = 5.9. The exclusive and significant shift of H1 in the range $0 \leq$ pD $\leq 2$ is again indicative of a deprotonation of the α hydroxy groups and the low values for the two corresponding p$K_a$ values must be interpreted in terms of a coordination of these oxygen donors. p$K_3$ and p$K_4$ belong to the deprotonation of the non-coordinating methylammonium groups. Clearly, an asymmetric κ$^3$-*N*,*O*,*N*-binding mode, as already observed for $[Co(HL^a)]^{4+}$, has to be considered in the doubly bridged derivative and, based on symmetry arguments, both taci fragments must adopt such a coordination mode. As seen in the previous section, this type of coordination implies formation of five membered chelate rings and this is again clearly shown by the significant offset of C1 in the $^{13}$C NMR spectrum.[18–20] Similar to $[Co(L^a)]^{3+}$, the resultant $CoN_4O_2$ chromophore exhibits a $\lambda_{max}$ (525 nm in 12 M HCl, 517 nm at pH = 12) for the $^1A_{1g}$–$^1T_{2g}$ transition which is slightly higher than those of nonbridged analogues such as $[Co(cis\text{-tach})(taci\text{-}\kappa^3\text{-}O^1,N^2,O^3)]^{3+}$ ($\lambda_{max}$ = 498) and $[Co(taci\text{-}\kappa^3\text{-}N^1,N^3,N^5)(taci\text{-}\kappa^3\text{-}O^1,N^2,O^3)]^{3+}$ ($\lambda_{max}$ = 494).[20] The minor blue shift observed for this band upon an increase in pH is well established as an indicator for deprotonation of the coordinated ROH groups. The rearrange-



Scheme 5. a) The structural fragment of $L^b$ established by NMR spectroscopic measurements.[14] Selected $^1$H $^{13}$C long range couplings are depicted in bold, geminal and vicinal $^1$H $^1$H coupling interactions and long range $^1$H $^1$H coupling interactions are marked with dashed and full lines, respectively. The carbon atoms are labelled with the same numbering scheme as shown for the corresponding hydrogen atoms. b) Representations for **A** ($C_i$), **B** ($C_2$), **C** ($C_s$), and **D** ($C_s$) showing possible structures of $L^b$ as discussed in the text.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ment from a $\kappa^3$-*N*,*N*,*N* to a $\kappa^3$-*N*,*O*,*N* coordination mode appears to proceed in an analogous way to that of $[Co(L^a)]^{3+}$. However, it is worthy to note that in the mono-bridged complex only the moiety with three $sp^3$ nitrogen donors switches to a $\kappa^3$-*N*,*O*,*N*-mode (the moiety with the N=C group retains the adamantane-like triamine coordination), whereas in $[Co(L^b)]^{3+}$ both rings, although attached to an imine nitrogen, adopt a $\kappa^3$-*N*,*O*,*N* coordination.

For a further discussion of the stereochemistry of this complex, it should be kept in mind that the two NH bridge heads become stereogenic when coordinated to the $Co^{III}$ centre and, consequently, different diastereomers must be taken into account. Based on symmetry arguments, the two nitrogen atoms must have related configurations (*R*,*S* in the $C_i$ isomer **1** and *R*,*R* or *S*,*S* in the $C_2$ isomers **2** and **3** shown in Scheme 6). For the $C_i$ symmetric ligand **A** (Scheme 5), only structure **1** (Scheme 6) is compatible with these considerations. However, the $C_2$ symmetric macrocycle **B** can be wrapped around the $Co^{III}$ centre in two different ways resulting in distinct structures (**2** and **3**) where either the two $sp^2$ or the two $sp^3$ nitrogen donors have a *trans* orientation within the coordination sphere (for **B** the two oxygen donors of the $C_2$ symmetric ligand are always oriented *cis*). The observation that the deprotonation of the two coordinated hydroxy groups did not result in any reverse shift of any of the H(–C–N) ring protons (low-field shift upon in-

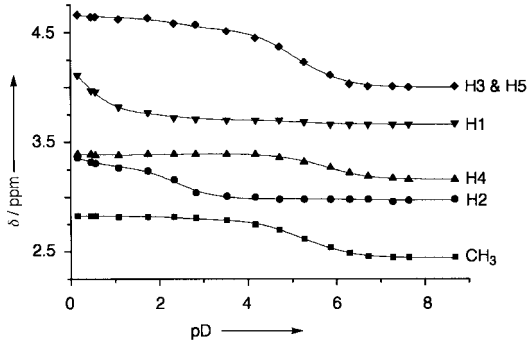


Figure 3. pD dependence of the $^1H$ NMR resonances of $[Co(H_2L^b)]^{5+}$ ($D_2O$, 33 °C, TSP = 0 ppm).[14] Squares, triangles and circles represent experimental values, the lines are calculated (minimisation of $\Sigma[\delta_{obs} - \delta_{calcd}]^2$. The numbering scheme of Scheme 5a has been used. The signal corresponding to H6 has been omitted due to pronounced line broadening around pD 5 (see text).

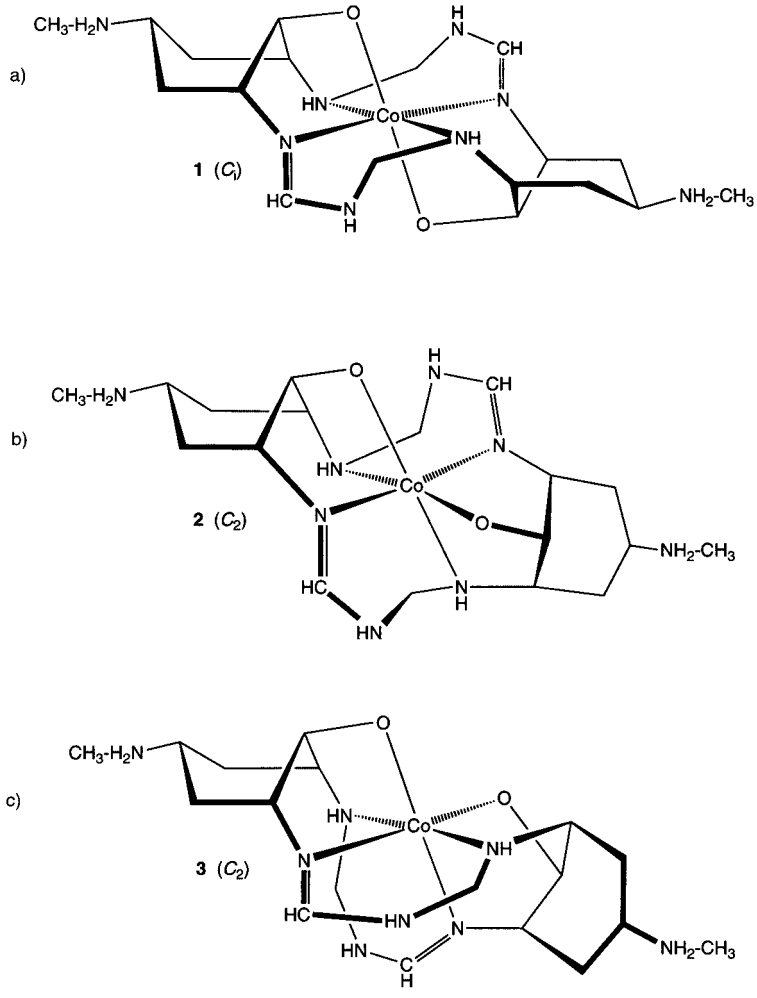

Scheme 6. Possible structures of $[Co(L^b)]^{3+}$ with $C_i$ (a) or $C_2$ symmetry (b and c).[14] Non-coordinating hydroxy groups and charges are omitted for clarity.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

creasing pD in the range $0 < pH < 2$, see the corresponding feature for H3 of $[Co(HL^a)]^{4+}$ in Figure 2) would exclude the presence of an O–Co–N–CH substructure with a *trans* O–Co–N orientation.[25] Consequently, the $C_i$ symmetric structure **1** remains as the only stereoisomer which is compatible with all the NMR spectroscopic characteristics.

Further inspection of the pH dependence of the $^1H$ NMR signals in the range $2.5 \leq pD \leq 7.5$ revealed considerable line broadening. Similar behaviour has already been noted for the monobridged species $[Co(HL^a)]^{4+}$, although the line broadening observed for the doubly bridged complex is much more pronounced and some of the signals such as H5 and H6 disappear completely around pH 5. We interpret this line broadening again in terms of a changeover from a twisted boat to a chair conformation of the two cyclohexane back bones. These structural changes are a consequence of the deprotonation of the two non-coordinated methylammonium groups, allowing N–H···N hydrogen bonding in the deprotonated form. Molecular mechanics calculations for the fully deprotonated $[Co(H_{-2}L^b)]^+$ predict that among the various possible isomers the $C_2$ symmetric form **2** (Scheme 6) is of the lowest energy (Table S2, supporting information). The $C_i$ symmetric isomer **1** has a slightly higher, and the $C_2$-symmetric isomer **3** a considerably higher strain energy. At first glance this result is in disagreement with the assignment of the centrosymmetric structure **1** for $[Co(L^b)]^{3+}$ as follows from the NMR spectroscopic data. However, it should be kept in mind that in analogy to the monobridged ion $[Co(L^a)]^{3+}$, the primary product of the condensation reaction is an $N_6$-coordinated complex and the $N_4O_2$-coordinated product is formed in a subsequent rearrangement (Scheme 3). Our calculations indeed revealed that the $N_6$-coordinated forms are all considerably more strained than the $N_4O_2$-coordinated species **1** and **2**. Furthermore, the $N_6$-coordinated complex with the $C_i$ symmetric ligand **A** (Scheme 5) is about 9 kJ mol$^{-1}$ less strained than the corresponding complex with ligand **B**. The calculations would thus be in full agreement with the experimental findings, if we assume formation of the $N_6$-coordinated species as the rate-limiting step in the entire reaction sequence.

### Coupling with Aniline

Aniline was used as an alternative nitrogen nucleophile to study the influence of an aromatic substituent on the coupling reaction with $[Co^{III}\text{-hmi-(taci)}_2]^{3+}$. However, a noticeable conversion was only observed if an additional base such as triethylamine was added to the reaction mixture. Workup under acidic conditions yielded a very complex mixture with a $^{13}C\{^1H\}$ NMR spectrum exhibiting more than forty resonances. After further treatment of this product with aqueous NaOH (pH 11), a single red $Co^{III}$ complex could be isolated as the major component by chromatographic methods. The $FAB^+$ mass spectrum showed an *m*/*z* value of 529 for the molecular ion which is consistent with the composition $[Co(C_{20}H_{36}N_7O_6)]^+$. The structure of this complex was again elucidated by NMR spectroscopy (Figure 4). Two independent spin systems were observed for the two cyclohexane rings. Additionally, one of the coordinated nitrogen donors bears a methyl group, another a $C_7H_7N$ substituent. The latter clearly contains the aniline component in the form of a coordinated formamidine moiety. The monosubstituted phenyl ring of this substituent could be readily recognised by its $^1H$ and $^{13}C$ NMR spectroscopic characteristics and the amidine functionality was identified by a strong C=N stretch vibration at 1658 cm$^{-1}$ and corresponding NMR resonances at $\delta$ = 8.74 ppm and 162.6 ppm in the $^1H$ and $^{13}C$ spectra.[6,26] Bridging of the two taci moieties was, however, not observed. The $^4J$ coupling between the H(–C)–imine proton and the cyclohexane proton H7 together with the $^3J_{C,H}$ coupling between H7 and the imine carbon atom enabled an unambiguous localisation of the amidine fragment. An additional long range coupling between H2 and the methyl group established that the amidine substituent and the methyl group are not attached to the same taci moiety. None of the $^1H$ resonances showed any pH dependence and we can therefore exclude a changeover from the $CoN_6$ to a $CoN_5O$ coordination. This contention is also supported by the $^{13}C$ NMR characteristics whereby a resonance above 70 ppm, indicative of five-membered chelate rings,[18] was not observed. The relative orientation of the methyl group and the $C_7H_7N$ substituent could not be deduced from experimental data. However, mechanistic considerations (hydride shift, see above) would clearly point to a *cis* arrangement of these two non-hydrogen substituents. Two different tautomers **I** and **II** are possible for the amidine moiety (Figure 4b) and, for each of them, a *Z* or *E* configuration of the C=N double bond and an *R* or *S* configuration of the stereogenic coordinated $sp^3$ amine donors must be taken into consideration. For the tautomers **I** with a coordinated imine, the methyl group of the NH–$CH_3$ donor can adopt a *syn* or *anti* orientation with respect to the amidine moiety. The reverse tautomers **II**, in which the C=N double bond is in conjugation with the phenyl ring, have two stereogenic nitrogen donors with either an *S*,*R*-, *R*,*S*-, *R*,*R*-, or *S*,*S* configuration. Once again, it was not possible to establish from experimental data which of the various isomers is predominantly formed. We therefore analysed the steric strain by means of molecular mechanics methods and these calculations established clearly that the tautomers with a coordinated imine (form **I**) are more stable (i.e. less strained) than the corresponding tautomers of the type **II** (Table 2). Moreover, form **I** enables the possibility for an extended π delocalisation within the N=C–NH–phenyl fragment which would not be possible in type **II**. A type **I** form is also in agreement with the structure observed for the organic analogue in which the Co centre and the taci subunit are replaced by two methyl groups.[27] Our calculations further revealed that the type **I** isomer with an *E* orientation for Co and NH-phenyl and a *syn* configuration of the amidine moiety and the methyl group is of lowest energy.[28] For this particular geometry, the calculations predicted $Co^{III}$–N bond lengths in the range of 1.95–1.99 Å (mean value 1.98 Å) with the 1.95 Å

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and the 1.99 Å distances corresponding to the bonds to the imine and methylamine nitrogen donor, respectively. For all possible isomers of $[Co(L^c)(L^d)]^{3+}$,[14] the increased strain is mainly caused by additional nonbonding interactions between the non-hydrogen substituents at the nitrogen donors and this is partially compensated for by an elongation of some of the Co–N bonds. As a matter of fact, it seems likely that these bonds are even somewhat longer than stated, since the calculations tend to slightly underestimate long $Co^{III}$–N distances.[29–31] The increased strain results in some weakening of the ligand field and this effect together with a possible conjugation between the 3d orbitals of Co and the extended π system of the amidine fragment supposedly contributes to the rather high $\lambda_{max}$ value of 510 nm observed for the $^1A_{1g}$–$^1T_{2g}$ transition.[32,33]

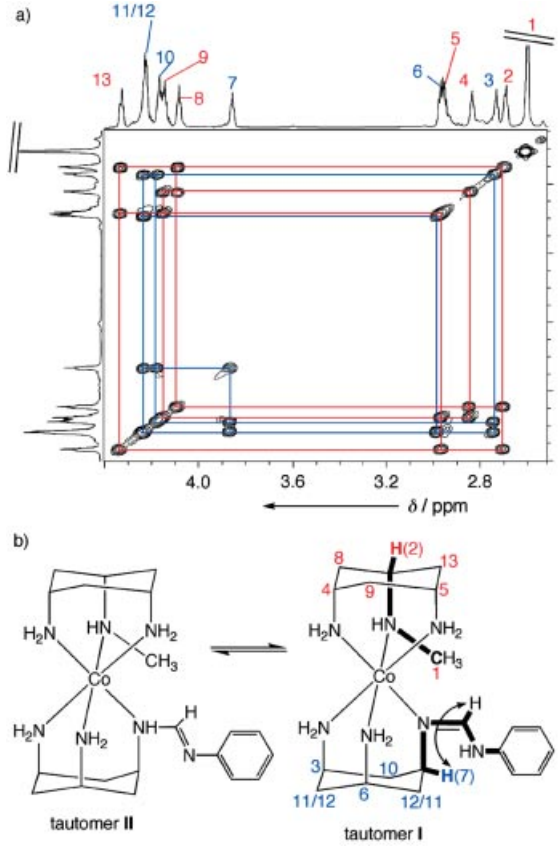

Figure 4. a) Section of the $^1$H-$^1$H COSY NMR spectrum of $[Co(L^c)(L^d)]^{3+}$ with the two independent spin systems shown in blue and red.[14] b) Structural representation of the two possible types of tautomers of $[Co(L^c)(L^d)]^{3+}$ (OH groups omitted) with numbering scheme. C–H long-range and H–H long-range coupling interactions are shown by bold bonds and by an arrow, respectively.

Hydrogenation of $[Co(L^c)(L^d)]^{3+}$ in an aqueous acidic medium on Pd/C (5 atm) resulted in decomposition of the complex and complete hydrolysis of the amidine moiety. As a consequence, the reaction product consisted of a 1:1 mixture of taci and its monomethylated derivative.

Table 2. Calculated strain energies and Co–N bond lengths of possible isomers for $[Co(taci)_2]^{3+}$ and $[Co(L^c)(L^d)]^{3+}$.[a]

| Complex | Relative strain energy [kJ mol$^{-1}$] | Co–N bond lengths [Å] range, mean |

[a] Molecular mechanics calculations using the MOMEC force field[46,47] together with the extensions listed in Table 4. [b] *E* and *Z* refer to the NH and Co substituents at the C=N double bond. Note that the free ligand $L^d$ and the complex $[Co(L^c)(L^d)]^{3+}$ have opposite stereo-descriptors: the *Z*-ligand[14] forms a complex with an *E* configuration and vice versa (Figure 4b). The descriptors *syn* and *anti* refer to the orientation of the methyl group with reference to the amidine moiety. [c] *E* and *Z* refer to the NH and $C_6H_5$ substituents at the C=N double bond, the two stereo-descriptors *R* and *S* refer to the configuration at the chiral amidine and methylamine nitrogen atoms, respectively, as shown in Figure 4b.

## Coupling with Cyanide

The reaction of $CN^-$ with $[Co^{III}$-hmi-$(taci)_2]^{3+}$ in aqueous solution again yielded a complex reaction mixture. Several different fractions could be separated on a Sephadex column but only the major red component could be identified unequivocally by means of MS and NMR spectroscopic measurements as a monobridged derivative $[Co^{III}(L^e)]^{3+}$ (Figure 5).[14] The $FAB^+$ spectrum exhibited signals of the pseudo-molecular ions $[Co^{II}(H_{-1}L^e)]^+$ and $[Co^{II}(L^e)Cl]^+$ ($L^e = C_{14}H_{31}N_7O_6$) with intensities of 100% and 13%, respectively. $[Co(L^e)]^{3+}$ is completely asymmetric as indicated by the $^1$H and $^{13}$C NMR spectra which contained a total of 10 and 11 signals for the two taci rings, respectively (one signal in the $^{13}$C NMR and two signals in the $^1$H NMR spectrum with double intensity corresponded to the resonances of two atoms). The $^1$H-$^1$H correlated 2D spectrum showed two independent spin system each consisting of six hydrogen atoms. The corresponding carbon atoms, which were identified as CH groups from a DEPT experiment,[17] were assigned by a $^1$H-$^{13}$C correlated spectrum. An additional $CH_2$ group with two diastereotopic hydrogen atoms was located and the $^{13}$C spectrum also exhibited a strongly deshielded signal at $\delta$ = 176 ppm, indicative of the formation of an imino group. Formation of a C=N double bond was further confirmed by a strong, sharp band at 1647 cm$^{-1}$ in the IR spectrum.[26] However, the DEPT experiment together with the $^1$H characteristics clearly show that, in contrast to the products obtained in the reaction with ammonia or aniline, the amidine-C is not bonded to any hydrogen atoms. Furthermore, the NMR spectroscopic

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

data gave no indication of the presence of an N–$CH_3$ group. The bridging position of the N=C($NH_2$)–$CH_2$–NH moiety was finally established from a long-range 2D C-H correlated experiment in which long range interactions from the bridging moiety to both cyclohexane entities could be observed. In analogy to $[Co(L^c)(L^d)]^{3+}$, it was not possible to conclude from the experimental data as to which of the two possible tautomers is formed. However, as outlined in the previous section it seems highly probable that the form with the imine nitrogen donor bonded to Co$^{III}$ is more stable. Indications for a $\kappa^3$-*N*,*O*,*N* coordination mode as described above for $[Co(HL^a)]^{4+}$ and $[Co(H_2L^b)]^{5+}$ have not been detected.

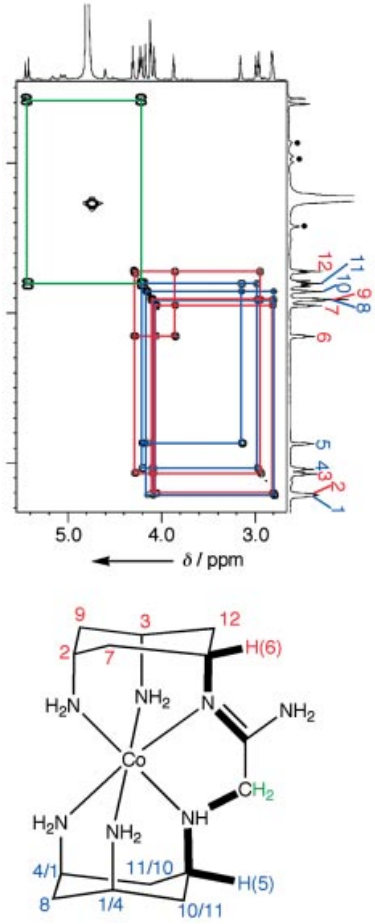

Figure 5. a) Section of the $^1$H-$^1$H COSY NMR spectrum of $[Co(L^e)]^{3+}$;[14] H(–N) protons of the coordinated amino groups are marked with black circles. b) structural representation of $[Co(L^e)]^{3+}$ with numbering scheme.[14] C–H long-range coupling interactions are shown in bold. The hydroxy groups in positions 7,9,12 and 8,10,11 are omitted for clarity.

The two doublets of the methylene group exhibited a rather large $^2J_{H,H}$ coupling constant of 18 Hz. Such unusually large coupling constants are known for spin systems with a π electron system attached to the $CH_2$ group as observed in cyclopentene-1,4-dione and it has been proposed that this enhancement is particularly large if the vector between the two protons is oriented parallel to the π orbitals[34] which is clearly the case for the N=C($NH_2$)–$CH_2$–NH bridge of $[Co^{III}(L^e)]^{3+}$. The $CH_2$-groups are weakly acidic and, if a solution of $[Co^{III}(L^e)]^{3+}$ in $D_2O$ is brought to a pD of about 11, the signals of the methylene group disappear in the $^1$H NMR spectrum and they do not reappear after addition of DCl. However, the DEPT spectrum still showed the presence of a methylene group indicative of H/D exchange. It is clear that the corresponding carbanion which is formed above pD 10 is stabilised by significant electron delocalisation.

The entire structure of $[Co^{III}(L^e)]^{3+}$ was again modelled by molecular mechanics calculations. In this model, the Co$^{III}$–$N_{imine}$ bond length proved to be relatively short (1.92 Å), whereas the remaining Co$^{III}$–$N_{amine}$ bonds lengths (1.96–1.97 Å) are consistent with the values reported in the literature for X-ray structures of a range of (hexaamine)-Co$^{III}$ complexes.[33] The high rigidity of the amidine-bridge resulted in some distortion of the octahedral coordination geometry with N–Co–N angles between 84° and 99°. The $^1A_{1g}$–$^1T_{2g}$ transition appeared at 497 nm which again indicates some weakening of the ligand field. Cyclic voltammetry showed a quasi-reversible redox process with a redox potential of –0.35 V (vs. NHE). A similar value has been observed for the parent system $[Co^{II/III}(taci)_2]^{2+/3+}$.[20,35]

## Discussion

The reaction of $[Co^{III}\text{-hmi-}(taci)_2]^{3+}$ with the three nucleophiles $NH_3$, aniline and $CN^-$ yielded three considerably different types of products. The reaction with $NH_3$ resembles the previously reported reaction with nitromethane insofar as formation of NH–$CH_2$–XH–CH=N bridges [XH = NH, C(H)-$NO_2$], connecting the two taci frames, coincides with methylation of an adjacent primary amino group.[9] The mechanism of this reaction has been discussed in terms of an intramolecular Cannizzaro reaction (Scheme 1, b) whereby a hydride is transferred from the methylene group of the initially formed NH–$CH_2$–XH–$CH_2$–$N^-$ bridge to an imino group. However, some characteristic differences are evident: (i) In the reaction with nitromethane (X = C-$NO_2$), the XH proton is finally abstracted by $NEt_3$ and the ligand appears in a carbanionic form, whereas in the reaction with $NH_3$, the nitrogen atom in the bridge (X = N) retains its proton. (ii) In the reaction with nitromethane, the doubly bridged complex was isolated as the main product while in the reaction with ammonia, the monobridged species was formed as the major product and the doubly bridged complex was only obtained as a very minor component. (iii) The bridging process with $NH_3$ was generally followed by a rearrangement of the coordination sphere of the Co$^{III}$ centre, i.e. the taci-moiety which becomes methylated switches from a $\kappa^3$-*N*,*N*,*N* to a $\kappa^3$-*N*,*O*,*N* coordination mode (Scheme 3). Consequently, an alkoxo-pentaamine coordination was observed for the monobridged complex and the doubly bridged derivative exhibits a dialkoxo-tetraamine coordination mode (Scheme 6). In the reaction with nitromethane, such a rearrangement of the coordination sphere was not observed. The isolated product

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

retains its hexaamine coordination. It has, however, been noted that the nitromethane adduct undergoes a characteristic structural rearrangement in strongly alkaline solutions and re-acidification leads to a species which was not identical with the initial condensation product. It is particularly interesting to note that in the initial product a total of 30 signals were observed in the $^{13}C$ NMR spectrum and that this number was reduced to a total of 10 at high pH. Moreover, in the initial reaction product, no resonance was observed above 70 ppm for the cyclohexane carbon atoms, whereas at high pH one of these signals shifted to 76 ppm. Based on the results presented in this paper, it thus appears highly probable that the previously observed[9] "low-energy isomer" has a doubly bridged structure with an analogous $CoN_4O_2$-coordination mode as reported here for $[CoL^b]^{3+}$.

For $[Co^{III}(cis\text{-tach})(H_{-1}ino)]^{2+}$ (ino = *cis*-inositol, Structure O6 in Scheme S1b), an equilibrium between two different stereoisomers has been observed in aqueous solution.[36] In the first isomer, the metal is bound to the three axial hydroxy groups of *cis*-inositol whereas in the second isomer the binding occurred by means of three hydroxy groups having a subsequent axial-equatorial-axial orientation. The kinetics of the isomerisation reaction have been investigated in detail and it has been found that (i) this reaction occurs at a considerably higher rate than complete dissociation of the inositol ligand, (ii) the isomerisation reaction becomes dramatically accelerated at high pH and (iii) the equilibrium between the triaxial and the axial-equatorial-axial coordination mode is influenced by the possibility of intramolecular O···H–O hydrogen bond formation. The higher rate of isomerisation compared with ligand dissociation was interpreted in terms of a mechanism in which the inositol ligand remains partially coordinated. For $[Co(L^a)]^{3+}$ and $[Co(L^b)]^{3+}$ with a hypothetical hexaamine coordination, the presence of an N–$CH_3$ group would generate significant strain due to nonbonding interactions between the methyl group and a hydrogen atom of a primary amino group of the neighbouring taci frame.[9] This strain is clearly responsible for the change to the $\kappa^3$-*N*,*O*,*N* axial-equatorial-axial coordination mode. By analogy with $[Co^{III}(cis\text{-tach})(ino)]^{3+}$, the rearrangement can occur without dissociation of the ligand (Scheme 3) and it is particularly fast in an alkaline medium. Similar to $[Co^{III}(cis\text{-tach})(ino)]^{3+}$, the pH has a significant influence on the possibility of intramolecular hydrogen bond formation: As long as the methylamino group remains deprotonated, it can act as a proton acceptor and can thus stabilise the corresponding cyclohexane chair. However, after protonation, significant nonbonding N–H···H–N repulsive interactions would arise. In contrast to $[Co^{III}(cis\text{-tach})(ino)]^{3+}$, this conflict cannot be resolved by a return to the double-adamantane-type structure and the only way for strain to be minimised is by the adoption of a twisted boat conformation (Scheme 4).

The reaction of $[Co^{III}\text{-hmi-}(taci)_2]^{3+}$ with aniline is remarkable because the resultant structure is devoid of any bridge between the two taci-frames. Formation of an amidine moiety together with *N*-methylation must again be interpreted in terms of a Cannizzaro type hydride shift. The lack of observation of a bridge is, however, a clear sign that the hydride shift already occurs after the first condensation step (bridge formation would require a double attack of the nucleophile to two adjacent imino groups, see Scheme 1). At present, it is still not clear why the hydride shift already occurs here at an earlier stage. Either electronic properties (reduced nucleophilicity of the aniline nitrogen) or steric reasons (increased repulsion due to the larger aromatic substituent) may account for this behaviour.

The reaction of the hexaimine complex with cyanide is special because $CN^-$ cannot undergo multiple binding to adjacent $H_2C{=}N(R)$–Co groups. In a nonaqueous medium, the reaction of $CN^-$ with an imine would simply generate a Co–$N(R)^-$–$CH_2$–CN moiety. Such a product could then become protonated to give Co–N(R)H–$CH_2$–CN. It would, however, remain in equilibrium with the initial components.[37] In an aqueous environment, $CN^-$ binding and hydrolysis may occur simultaneously as competing processes. It is possible to control the reaction in such a way that one imino group reacts with $OH^-$ reforming the deprotonated, coordinated amine, whereas at the same time, an adjacent imino group reacts with $CN^-$ (Scheme 7). The nitrile-carbon atom can now react as an electrophilic centre,[26,38] being able to accept the adjacent, negative nitrogen donor. In organic chemistry, the reaction of a nitrile RCN with an amine to give a corresponding amidine is only known for nitriles which are activated either by a strongly electron-withdrawing substituent R or by coordination of a Lewis acid.[39] The situation is different in coordination chemistry in which the generation of a metal-bound amidine by an intramolecular reaction between a deprotonated, coordinated amine and a nitrilo group has been documented with a few examples.[37,40]

Owing to the reversible addition of $CN^-$ to the imine, successful formation of $[Co(L^e)]^{3+}$ requires a well balanced ratio of the two reaction rates. This ratio can be influenced by varying either the $CN^-$ or the $OH^-$ concentration. We obtained reasonable yields of the mono-bridged species in aqueous solution around pH 10–12. Even at this relatively moderate $OH^-$ concentration, complete hydrolysis of the hexaimine represents a significant side reaction as indicated by the isolation of considerable amounts of $[Co(taci)_2]^{3+}$ from the reaction mixture. Further lowering of the pH should, however, be avoided, due to possible HCN formation. We have not yet succeeded in the isolation of any doubly bridged product and it appears that the formation of a second bridge would occur at a significantly lower rate. Since the reaction of a coordinated imine with $CN^-$ is reversible, all of the remaining imino groups are hydrolysed and the final product was found to be devoid of any *N*-methylidene-imino groups. The reaction of $[Co\text{-hmi-}(taci)_2]^{3+}$ with $CN^-$ in aqueous media thus represents a promising route for connecting two taci-rings by one N–C–C–N bridge. However, we have not yet established whether reduction of the amidine to the amine and de-metallation can be readily achieved. Similar to the reaction of $[Co^{III}\text{-hmi-}(taci)_2]^{3+}$ with aniline and with nitromethane, the hexaamine coordination appears to be retained in $[Co(L^e)]^{3+}$,

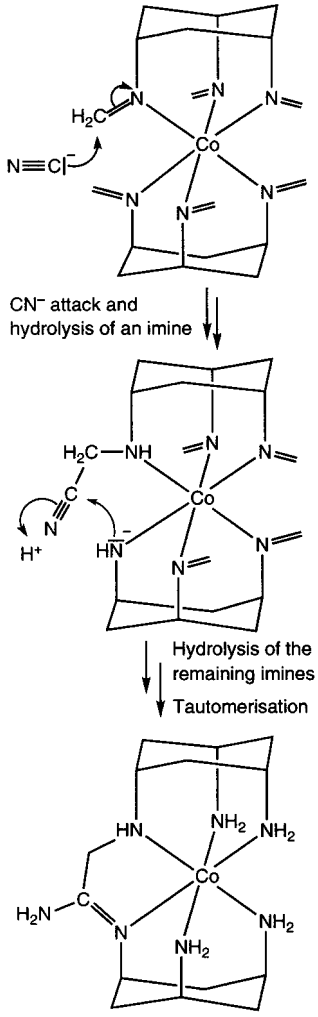

Scheme 7. Proposed mechanism for the formation of $[Co(L^e)]^{3+}$.[14] The non-coordinating OH-groups are omitted for clarity.

although molecular mechanics calculation indicated some distortion from regular octahedral geometry. $[Co(L^e)]^{3+}$ is the only example in this study in which the coupling reaction does not result in formation of a methylamino group. Clearly a hydride shift from the Co–N(R)$^-$–$CH_2$–CN methylene group to an adjacent imino group is not possible.

In conclusion, our study has fully confirmed that the successful capping reaction observed for $[Co(en)_3]^{3+}$ cannot be applied to (hexaamine)Co$^{III}$ complexes with rigid cyclic amine ligands. Sargeson proposed that the lack of observation of the capping process in such systems is a consequence of the slow exchange rate of the amine protons.[10] Such an assumption is plausible because condensation with the aldehyde and addition of the capping reagent can be performed in a single reaction with N–H deprotonation as the first step. In our investigation, we have used the hexamethylideneimine derivative as a starting material and it has thus become evident that other factors must be responsible for the different behaviour of the cyclic ligands. We attribute the slow rate or indeed the failure to observe bridge formation to be mainly due to steric constraints. The molecular mechanics calculations provided unambiguous evidence that in general, bridging of two taci moieties by means of two nitrogen donors of the hexaamine coordination implies a significant increase of strain and that this strain increases with an increasing number of bridges.

## Experimental Section

**Physical Measurements and Analyses:** $^1H$ and $^{13}C$ NMR spectra were recorded in $D_2O$ at 306 K with a Bruker Avance DRX 500 spectrometer at frequencies of 500.13 MHz and 125.9 MHz, respectively. Chemical shifts (in ppm) are given relative to [$D_4$]sodium (trimethylsilyl)propionate (0 ppm) as the internal standard. The pD values of the NMR samples were adjusted with NaOD and DCl and were determined as described previously.[41] Multiplicities are abbreviated as follows: s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet. The gradient-selected (gs) $^1H$-$^1H$ COSY, gs $^1H$-$^{13}C$ COSY and gs $^1H$-$^{13}C$ HMBQ experiments were performed as described in the literature.[42] $CH_3$, $CH_2$ and CH carbon atoms were assigned using $^{13}C$ DEPT experiments.[17] IR spectra were recorded on a Perkin-Elmer 883 IR spectrometer (KBr wafer) and UV/Vis spectra were measured on a Uvikon 940 spectrometer at 25 ± 1 °C. FAB$^+$ mass spectra were recorded on a VG ZAB VSEQ instrument. The samples were measured as aqueous solutions using a glycerol matrix. Cyclic voltammetry was performed at ambient temperature (23 ± 2 °C) on a BAS C2 cell equipped with an Hg or Au electrode, a platinum counter electrode and an Ag/AgCl reference electrode with a BAS 100B/W potentiostat. The measurements were performed in an aqueous borax buffer (pH 9) with 1-mM sample concentrations and NaCl (1 M) as a supporting electrolyte. p$K_a$ values were determined by potentiometric titrations as described previously[41] (25.0 °C, 0.10 M KCl) and evaluated using a fixed value of 13.78 for p$K_w$. C, H and N analyses were performed by H. Feuerhake (Universität des Saarlandes).

**Materials:** $Et_3N$, $CH_3CN$, aniline, aqueous $NH_3$ (≈ 25%), KCN and trisodium citrate dihydrate were commercially available products from Fluka. $CH_3CN$ was dried with $P_4O_{10}$. Aniline was freshly distilled prior to use. $CF_3SO_3H$ (>98%) was purchased from Lancaster Synthesis and stored under $N_2$. $[Co(taci)_2](NO_3)_3{\cdot}2H_2O$[31] and its hexamethylideneimino (hmi) derivative [Co-hmi-(taci)$_2$]-$Cl_3{\cdot}6H_2O$[9] were prepared according to published procedures. Dowex 50 W-X2 cation-exchange resin (100–200 mesh, $H^+$ form) was obtained from Fluka. SP-Sephadex C-25 cation exchange resin (200 mesh, from Pharmacia Biotech) was converted into the $Na^+$ form by elution with NaCl (2 M) prior to use and sufficient rinsing with $H_2O$ until the eluent was free of chloride (checked with $AgNO_3$).

**[Co-hmi-(taci)$_2$](CF$_3$SO$_3$)$_3$·2H$_2$O:** [Co-hmi-(taci)$_2$]$Cl_3{\cdot}6H_2O$ (500 mg, 0.71 mmol) was dissolved in $CF_3SO_3H$ (20 mL). The clear yellow solution was heated to 80 °C and a stream of dry $N_2$ was passed through the mixture for 3 h. The clear, dark yellow solution was cooled to room temperature and was then cautiously poured into $Et_2O$ (750 mL). A solid precipitated which was removed by filtration, washed six times carefully with $Et_2O$ (portions of 100 mL) and dried in air. Yield: 636 mg (92%) of a pale yellow solid. $C_{21}H_{34}CoF_9N_6O_{17}S_3$ (968.6): calcd. C 26.04, H 3.54, N 8.68; found C 26.22, H 3.34, N 8.71. IR (KBr): $\tilde{\nu}$ = 1618 (s) cm$^{-1}$. $^1H$ NMR ($D_2O$, pD < 1): $\delta$ = 4.07 (t, $J$ = 3.0 Hz, 6 H), 4.62 (t, $J$ = 3.0 Hz, 6 H), 7.91 (d, $J$ = 7.5 Hz, 6 H), 8.13 (d, $J$ = 7.5 Hz, 6 H) ppm. $^{13}C\{^1H\}$ NMR ($D_2O$, pD < 1): $\delta$ = 68.5 (CH), 76.7 (CH), 122.6 (q, $J_{C,F}$ = 317 Hz), 187.2 (C) ppm.

**Reaction of [Co-hmi-(taci)$_2$](CF$_3$SO$_3$)$_3$·2H$_2$O with NH$_3$:** [Co-hmi-(taci)$_2$](CF$_3$SO$_3$)$_3$·2H$_2$O (1.0 g, 1.03 mmol) was dissolved in dry

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CH_3CN$ (100 mL). To the yellow solution was rapidly added concentrated aqueous $NH_3$ (10 mL). An immediate colour change to dark green was noted and the reaction mixture turned to a reddish brown within a few minutes. A brownish solid finally precipitated. The suspension was stirred for 24 h at room temperature giving a bright red solution together with a yellow solid. The entire mixture was poured into a solution of aqueous $H_2SO_4$ (30 g of conc. $H_2SO_4$ dissolved in 600 mL of $H_2O$). The solution was further diluted with $H_2O$ to a total volume of 1 L (pH ≈ 1) and adsorbed on Dowex 50. The column was washed with $H_2O$ until the eluent was neutral and then elution with aqueous HCl (0.5 M) was carried out. Further elution with HCl (3 M) yielded a red fraction which was evaporated to dryness and redissolved in $H_2O$ (100 mL). Traces of acid were neutralised by adding small portions of NaOH (1 M). The solution was then adsorbed on Sephadex. Elution with trisodium citrate (0.2 M) resulted in the separation of three bands: A pink fast moving minor fraction (F1) followed by a major red fraction (F2) and a slower moving badly resolved third fraction (F3). The yellow front part of F3 was identified as $[Co(taci)_2]^{3+}$ by $^1H$ and $^{13}C$ NMR spectroscopy. According to NMR and MS measurements, the purple coloured tailing part of F3 was a mixture of several components which could be neither separated nor identified. Each fraction was desalted on Dowex 50, (elution with 0.5 M HCl and 3 M HCl). The products which were obtained in the 3-M HCl fractions were evaporated under reduced pressure and dried in air.

**Analytical Data of Fraction F1 {$[Co(H_2L^b)]Cl_5$}:**[14] Yield: 5 mg of pink brittle flakes. $^1H$ NMR ($D_2O$, pD = 0.2): $\delta$ = 2.83 (s, 6 H), 3.36 (m, 2 H), 3.39 (t, $J$ = 5 Hz, 2 H), 3.71 and 3.98 (AB-system, $J$ = 12 Hz, 4 H), 4.11 (t, $J$ = 4 Hz, 2 H), 4.33 (m, 2 H), 4.66 (m,4 H), 8.53 (s, 2 H) ppm. $^{13}C\{^1H\}$ NMR ($D_2O$, pD = 1): $\delta$ = 35.7 ($CH_3$), 60.0 (CH), 61.0 ($CH_2$), 62.2 (CH), 62.9 (CH), 63.2 (CH), 64.9 (CH), 76.4 (CH), 174.1 (CH) ppm. MS-FAB$^+$ $m/z$ (%) = 518 (36) $[Co(H_{-1}L^b)]^+$,[15] 554 (6) $[Co(L^b)Cl]^+$. UV/Vis: $\lambda_{max}$ = 525 nm (12 M HCl), $\lambda_{max}$ = 517 nm (pH = 12).

**Analytical Data of Fraction F2 {$[Co(HL^a)]Cl_4\cdot H_2O$}:**[14] Yield: 283 mg (0.45 mmol, 44%) of a deep red solid. $C_{15}H_{36}CoCl_4N_7O_7$ (627.2): calcd. C 28.72, H 5.79, N 15.63; found C 28.84, H 5.83, N 15.70. IR (KBr): $\tilde{\nu}$ = 1628 (s) cm$^{-1}$. $^1H$ NMR ($D_2O$, pD = 1): $\delta$ = 2.55 (t, $J$ = 3.5 Hz, 1 H), 2.82 (s, 3 H), 3.04 (t, $J$ = 3.5 Hz, 1 H), 3.28 (m, 1 H), 3.32 (m,1 H), 3.58 (m, 1 H), 3.60 (t, $J$ = 3.5 Hz, 1 H), 3.84 and 3.96 (AB-system, $J$ = 11.5 Hz, 2 H), 4.04 (m, 1 H), 4.13 (t, $J$ = 3.5 Hz, 1 H), 4.22 (t, $J$ = 3.5 Hz, 1 H), 4.23 (t, $J$ = 3.5 Hz, 1 H), 4.71 (m, obscured by HDO, $\delta$ taken from $^1H$ $^1H$-COSY, 1 H) 4.75 (m, obscured by HDO, $\delta$ taken from $^1H$ $^1H$-COSY, 1 H), 8.15 (s, 1 H) ppm. $^{13}C\{^1H\}$ NMR ($D_2O$, pD = 1): $\delta$ = 33.2 ($CH_3$), 52.0 (CH), 52.1 (CH), 54.8 (CH), 57.9 (CH), 59.7 (CH), 61.4 ($CH_2$), 62.2 (CH), 62.7 (CH), 64.1 (CH), 65.8 (CH), 65.9 (CH), 66.7 (CH), 75.7 (CH), 172.8 (CH); (pD = 8): 40.2, 52.5, 53.2, 60.5, 61.7, 65.1, 65.5, 66.0, 66.85, 66.94, 67.3, 68.1, 68.3, 80.0, 170 ppm. MS-FAB$^+$ $m/z$ (%): 465 (100) $[Co(H_{-1}L^a)]^+$, 501 (13) $[Co(L^a)Cl]^+$. UV/Vis (12 M HCl): $\lambda_{max}$ = 383 nm ($\varepsilon$ = 289 M$^{-1}$cm$^{-1}$), $\lambda_{max}$ = 513 nm ($\varepsilon$ = 120 M$^{-1}$cm$^{-1}$); (NaOH, pH = 12) $\lambda_{max}$ = 386 nm ($\varepsilon$ = 170 M$^{-1}$cm$^{-1}$), $\lambda_{max}$ = 508 nm ($\varepsilon$ = 90 M$^{-1}$cm$^{-1}$). Crystals of composition $[Co(HL^a)][ZnBr_4]_2\cdot 5H_2O$ suitable for X-ray analysis were grown by slow diffusion of EtOH into an acidified (HBr) aqueous solution of $[Co(HL^a)]Cl_4$ saturated with $ZnBr_2$ at 4 °C.

**Reaction of [Co-hmi-(taci)$_2$](CF$_3$SO$_3$)$_3\cdot 2H_2O$ with Aniline:** Aniline (3.3 mL, 36 mmol) and [Co-hmi-(taci)$_2$](CF$_3$SO$_3$)$_3\cdot 2H_2O$ (520 mg, 0.54 mmol) were dissolved in dry $CH_3CN$ (150 mL). $NEt_3$ (6.6 mL, 47 mmol) was added to the resultant light yellow solution which caused an immediate colour change to dark green. The mixture was stirred for 30 min at room temperature and then poured into aqueous $H_2SO_4$ (18 g of $H_2SO_4$ in 400 mL of $H_2O$). The reddish orange solution was further diluted with $H_2O$ to a total volume of 1 L and sorbed on Dowex 50. The column was eluted with aqueous HCl (0.5 M and 4 M). The 4-M HCl fraction was evaporated to dryness and the residue redissolved in $H_2O$ (50 mL). NaOH (1.5 M) was added carefully in small portions until the pH reached a value of 11 (checked using a glass electrode). During this addition, the colour changed to violet and precipitation of a solid was observed. The suspension was stirred at room temperature for 24 h, acidified with dilute HCl to pH 7 and sorbed onto Sephadex. Elution with $Na_2SO_4$ (0.28 M) resulted in the separation of three bands: a very small fast moving light red band which was discarded, a yellow band of $[Co(taci)_2]^{3+}$, and a strong red band of $[Co(L^c)(L^d)]^{3+}$. The last red fraction was desalted on Dowex 50, evaporated to dryness and dried in vacuo. Yield: 177 mg (0.26 mmol, 49%) of red $[Co(L^c)(L^d)]Cl_3\cdot 2H_2O$.[14] $C_{20}H_{41}CoCl_3N_7O_8$ (672.9): calcd. C 35.70, H 6.14, N 14.57; found C 35.94; H 5.77; N 14.54. IR (KBr): $\tilde{\nu}$ = 1658 (s) cm$^{-1}$. $^1H$ NMR ($D_2O$): $\delta$ = 2.60 (s, 3 H), 2.69 (t, $J$ = 3.5 Hz, 1 H), 2.72 (t, $J$ = 3.5 Hz, 1 H), 2.83 (t, $J$ = 3.5 Hz, 1 H), 2.95 (t, $J$ = 3.5 Hz, 1 H), 2.96 (t, $J$ = 3.5 Hz, 1 H), 3.84 (t, $J$ = 3.5 Hz, 1 H), 4.07 (t, $J$ = 3.5 Hz, 1 H), 4.13 (t, $J$ = 3.5 Hz, 1 H), 4.16 (t, $J$ = 3.5 Hz, 1 H), 4.21 (m, 2 H), 4.32 (t, $J$ = 3.5 Hz, 1 H), 7.29 (m, 3 H), 7.47 (m, 2 H), 8.74 (s, 1 H) ppm. $^{13}C\{^1H\}$ NMR ($D_2O$): $\delta$ = 44.3 ($CH_3$), 52.3 (CH), 52.4 (CH), 52.8 (CH), 53.5 (CH), 55.5 (CH), 61.6 (CH), 65.3 (CH), 65.6 (CH), 65.8 (CH), 66.7 (CH), 67.6 (CH), 68.9 (CH), 120.7 ($CH_{arom}$), 128.1 ($CH_{arom}$), 132.5 ($CH_{arom}$), 141.0 ($C_{arom}$), 162.6 (CH) ppm. MS-FAB$^+$ $m/z$ (%): 529 (97) $[H_{-1}\{Co(L^c)(L^d)\}]^+$, 565 (9) $[Co(L^c)(L^d)]Cl^+$. UV/Vis ($H_2O$): $\lambda_{max}$ = 368 nm ($\varepsilon$ = 147 M$^{-1}$cm$^{-1}$), $\lambda_{max}$ = 510 nm ($\varepsilon$ = 44 M$^{-1}$cm$^{-1}$).

**Reaction of [Co-hmi-(taci)$_2$]Cl$_3\cdot 6H_2O$ with KCN: Caution!** KCN and HCN are strong poisons. All manipulations must be performed in a well ventilated fume hood. HCN must be destroyed by passing any evolving gas through an NaOCl solution. A solution of KCN (250 mg, 3.84 mmol) in $H_2O$ (250 mL) was added to a solution of [Co-hmi-(taci)$_2$]Cl$_3\cdot 6H_2O$ (1.05 g, 1.50 mmol) in $H_2O$ (250 mL). The first 50 mL of the KCN solution were added dropwise whereas the remaining 200 mL were added in one portion. The solution, which by this time showed a red colour, was stirred at room temperature for 30 min and then poured into aqueous sulfuric acid (15 g of conc. $H_2SO_4$ in 500 mL of $H_2O$). **Caution!** Formation of HCN. The solution was further diluted with $H_2O$ until a pH of 2 was reached and was then sorbed on Dowex 50. The resin was eluted with $H_2O$ and with aqueous HCl (0.5 M). Further elution with HCl (3 M) gave a major broad band with a yellow front ($[Co(taci)_2]^{3+}$) and a red tail. The red portion was collected. However, complete separation from the yellow part was not possible. The resultant solution was evaporated to dryness, redissolved in 250 mL of $H_2O$ and sorbed on Sephadex. Elution with trisodium citrate (0.2 M) gave four bands: a fast moving, very weak pink band which was discarded, a yellow band of $[Co(taci)_2]^{3+}$, a major red band and a violet band. NMR measurements showed that the violet band consisted of several unidentified $Co^{III}$ complexes. The red and the yellow bands again showed some overlap and could not be separated completely. The entire red fraction was collected, desalted on Dowex 50 and the solvents evaporated to dryness. Remaining traces of $[Co(taci)_2]^{3+}$ could be removed by crystallisation: The solid was dissolved in $H_2O$ (5 mL). $ZnBr_2$ (500 mg, dissolved in 4 mL of $H_2O$) and HBr (5 mL 48% in $H_2O$) were added and the solution was allowed to stand at 4 °C for 12 h. $[Co(taci)_2]^{3+}$ precipitated quantitatively as the $[ZnBr_4]^{2-}$ salt which was removed by filtration. The remaining red solution was then sorbed again on Dowex 50. The column was washed with $H_2O$ and eluted with aqueous HCl (0.5 M and 1.0 M). Further elution with HCl (3 M) gave a red solu-

**X-ray Diffraction Analysis:**[43] Diffraction data of $[Co(HL^a)][ZnBr_4]_2 \cdot 5H_2O$ were collected at room temperature on a Siemens CCD Platform using monochromated Mo-$K_\alpha$ radiation and a crystal of dimensions 0.24 × 0.16 × 0.14 mm (Table 3). 21887 reflections were collected in the range 1.49° < $\theta$ < 23.24°. An empirical absorption correction was performed (SADABS). Of a total of 5572 unique reflections 3217 were observed with 2σ($I$). The structure was solved by direct methods and refined using full-matrix least-squares calculations on $F^2$.[44] One of the two counter-anions (Zn2) proved to be disordered and was modelled using a superposition of three discrete positions with occupancies of 50%, 38% and 12%. The Zn2 centre was located on two split positions (Zn2a and Zn2b) with a Zn2a–Zn2b separation of 0.753 Å. Both of these positions had an occupancy of 50%. The four Br$^-$ ligands (Br21–Br24) which are bound to Zn2a could be unambiguously located. They were also refined with occupancies of 50%. The Zn2a–Br distances and Br–Zn2a–Br angles are as expected. For each of the four Br$^-$ ligands bound to Zn2b, a major (Br31–Br34, 38%) and a minor (Br41–Br44, 12%) position was assigned. The major component refined well again but the minor component, which corresponds to a relatively small amount of electron density, was rather poorly defined (Zn2b–Br distances: 2.12–2.64 Å, mean value: 2.37 Å, and Br–Zn2b–Br angles of 89–133°, mean value: 108.5 °). Five additional peaks (O1S–O5S) were interpreted as $H_2O$ molecules. The distances O1···O3S···O4S···O5S and O4···O2S fall between 2.7–2.8 Å which is the range expected for normal O–H···O hydrogen bonds. The O4S···O6 distance of 2.50 Å is rather short and indicative of a strong hydrogen bond. This is consistent with the high acidity of the coordinated hydroxy group (see Characterisation of $[Co(L^a)]^{3+}$ in the Results section above). O2S was found to be distributed over two positions with an O2Sa···O2Sb separation of 0.98 Å and occupancy factors of 60 and 40%. O1S and O5S were located in proximity to the disordered $[Zn2Br_4]^{2-}$ counterion and some of the corresponding O···Br separations were considerably shorter than the sum of the van der Waals radii. A split model was again used for O5S with occupancies of 20% for O5Sa (which is in conflict with Br24) and 80% for O5Sb. O1S was found to be in conflict with Br43. Since Br43 itself has an occupancy of only 12%, the occupancy of O1S was set to 88%. Although the remaining 12% of this $H_2O$ molecule could not be located, a search for free voids[45] clearly indicated that sufficient empty space would be available for accommodation of this $H_2O$ molecule within the Zn2bBr41–Br44 variant of the structure. Anisotropic displacement parameters were refined for all nonhydrogen atomic positions except for the two split positions of the disordered $H_2O$ oxygen O5S. Hydrogen atoms of the complex cation were placed in calculated sites (riding model) and isotropic displacement parameters were used which were fixed at 1.5 × $U_{eq}$ of the pivot atom of hydroxy, amino, and methyl groups and 1.2 × $U_{eq}$ for all other C atoms. Owing to the isolation from an acidic medium (HBr), the meaningful hydrogen bonding scheme and based on charge balance considerations, N5 and O6 were both considered as being protonated. A total of 495 parameters were used in the final refinement, yielding a residual electron density with a minimum and a maximum of –0.58 and +1.07 e Å$^{-3}$. Puckering parameters of the two cyclohexane rings were calculated using the computer program PLATON.[45]

Table 3. Crystallographic data for $[Co(HL^a)][ZnBr_4]_2 \cdot 5H_2O$ and $[Co(taci)_2][NO_3]_3 \cdot 2H_2O$.

Diffraction data of $[Co(taci)_2](NO_3)_3 \cdot 2H_2O$ were collected at 25(2) °C on a Stoe Stadi 4 diffractometer using monochromated Mo-$K_\alpha$ radiation and a crystal of dimensions 0.20 × 0.15 × 0.15 mm. Of a total of 3975 reflections which were collected in the range 2.28° < $\theta$ < 25.00°, 2066 were unique and 1742 were observed with $I > 2\sigma(I)$. An empirical absorption correction was applied to the data. The structure was solved by direct methods and was refined using full-matrix least-squares calculations on $F^2$ (259 parameters).[44] All non-hydrogen atoms were refined in the anisotropic mode. The hydrogen atoms (including $H_2O$) were all located in a difference Fourier map and were refined using variable isotropic displacement parameters. One of the $NO_3^-$ counterions was found to be slightly disordered. Its nitrogen atomic position (N5) was located on a two fold rotational axis and each of the oxygen atoms were equally distributed over two positions. The minimum and maximum in the final residual electron density map were –0.21 and +0.29 e Å$^{-3}$.

**Molecular Modelling:** The commercially available program MOMEC97 was used for the calculations.[46,47] Since the structures of the complexes investigated in this paper contain a variety of fragments which were not considered in MOMEC97, additional parameters had to be added to the force field. These parameters were derived from a total of 30 related structures with their geometries obtained from the Cambridge Structural Data Base (see Scheme S1, and Table S1 in the Supporting Information). The required parameters were estimated and systematically varied until the calculated bond lengths could reproduce the experimental values within ± 0.02 Å and the bond angles within ± 5°. This additional data set is listed in Table 4. In the course of geometry optimisation, it became obvious that three of the already supplied parameters (CI–NI bond-stretch, CI–NI–CT valence angle and **–NI–CT–** torsion angle) also had to be adjusted slightly in order to get better consistency during the parametrisation procedure. In all calculations, the N=C–N portion of the amidine moieties was modelled

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

using the atom types NI–CI–NT. The structures were refined using the geometry optimization procedure with the full-matrix Newton Rapson algorithm. Convergence was reached in all calculations. As exemplified in Table 1 for $[Co(HL^a)]^{4+}$, the new parameter set allowed accurate reproduction of the structural parameters.

Table 4. New MOMEC force-field parameters.[a]

[a] For atom-type labels, see ref.[46] [b] 1 dyn = $10^{-5}$ N. [c] ** = any atom.

**Supporting Information** (see footnote on the first page of this article): Comments on the parametrisation procedure. Table S1 and Scheme S1: Structures (CCDC) considered for parametrisation. Table S2: Strain energies for the isomers **1**–**3** of $[Co(H_{-2}L^b)]^+$ and $[Co(\kappa^6\text{-}N_6\text{-}L^b)]^{3+}$.

## Acknowledgments

We thank Dr. Irmgard Buder, Prof. Dr. Frank Endres and Prof. Dr. G. Schwitzgebel (Saarbrücken) for the cyclovoltammetric measurements, Dr. Norbert Okon and Dr. Gilber Lauer (both Heidelberg) for help with the parametrisation of the force field and Dr. Walter Amrein (ETH Zürich) for the measurements of the FAB-mass spectra. Single crystals of $[Co(taci)_2](NO_3)_3{\cdot}2H_2O$ were prepared by Jochen Huppert (Saarbrücken). The crystal structure analyses of $[Co(HL^a)][ZnBr_4]_2{\cdot}5H_2O$ and $[Co(taci)_2](NO_3)_3{\cdot}2H_2O$ were performed by Dr. Fabio Zürcher (ETH Zürich), Stefan Steinhauser and Dr. Volker Huch (both from Saarbrücken). We thank Dr. Peter Osvath (Melbourne) and Prof. Johann Jauch (Saarbrücken) for valuable advice. Financial support by the Studienstiftung des deutschen Volkes for D. K. is gratefully acknowledged.

(3,5-diamino-2,4,6-trihydroxycyclohexyl)amino]ethanimidamide.

[15] The multi-peak signal in the range of $515 \leq m/z \leq 520$ was interpreted in terms of a superposition of $[Co^{III}(H_{-4}L^b)]^+$ (5%), $[Co^{II}(H_{-3}L^b)]^+$ (8%), $[Co^{III}(H_{-2}L^b)]^+$ (19%), $[Co^{II}(H_{-1}L^b)]^+$ (55%) and $[Co^{I}(L^b)]^+$ (13%). This assignment was established by least-squares calculations $R^2$ = min, with $R = \Sigma|I_{calc}-I_{obs}|/\Sigma I_{obs} = 0.016$ for all possible isotopomers. The different types of ions postulated for the interpretation of this signal are in line with well established processes observed in a glycerol matrix under FAB conditions, where the bombarding of the matrix with fast atoms results in the generation of organic radicals which can either abstract $H_2$ from the NH–$CH_3$ single bond (generation of a corresponding imine) or reduce the central metal cation (generation of $Co^{II}$ and $Co^{I}$).[16]

[19] In the reference complex $[Co^{III}(cis\text{-tach})(H_{-1}taci\text{-}\kappa^3\text{-}N^1,O^2,N^3)]^{2+}$ (Supporting Information, Scheme S1b, structure O8), the resonance of the carbon atom attached to the coordinated oxygen donor was observed at $\delta$ = 87 ppm.[20] For $[Co(L^a)]^{3+}$ and $[Co(L^b)]^{3+}$, this value is somewhat lower apparently due to a $\gamma$ effect caused by the non-hydrogen substituents attached to the neighbouring nitrogen donors. The 2D NMR experiments confirmed our proposition that it is the high-frequency cyclohexane-carbon atom at $\delta$ = 76–80 ppm which is directly bonded to the coordinated oxygen donor.

[29] For $[Co(taci)_2]^{3+}$, the calculated Co–N bond length is 1.97 Å, whereas the value obtained from X-ray diffraction analysis is 1.99 Å.[30] Similarly, the Co–N6 distance in $[Co(HL^a)]^{4+}$ was calculated as 1.97 Å instead of 2.02 Å as observed in the crystal structure (Table 1). The slight underestimation of long Co–N distances might be due to the use of a harmonic potential for the $Co^{III}$–N bond, see: P. Comba, A. F. Sickmüller, *Angew. Chem. Int. Ed. Engl.* **1997**, *36*, 2006.

[30] The crystal structure of $[Co(taci)_2](NO_3)_3{\cdot}2H_2O$ was determined several years ago.[31] Because of the moderate quality of the data, we decided to determine this structure again. Consequently we now possess a data set of significantly higher accuracy. The Co–N bond lengths changed from 1.991(6) Å–2.009(5) Å (mean value: 2.000 Å)[31] to 1.9854(18) Å–2.0057(18) Å (mean value 1.994 Å).

# A Theoretical Study on Structures, Bonding Energies and Aromaticity of Two New Series of Dinuclear Phosphametallocenes: ($\eta^5$-$P_5$)MM′($\eta^5$-$P_5$) and ($\eta^5$-$C_5H_5$)MM′($\eta^5$-$P_5$) (M, M′ = Zn, Cd)

**Zi-Zhong Liu,[a,b,c] Wei Quan Tian,*[a] Ji-Kang Feng,*[a,c] Gang Zhang,[a] Wei-Qi Li,[a] Yan-Hong Cui,[a] and Chia-Chung Sun[a]**

**Keywords:** Dinuclear phosphametallocenes / Structures / Bonding energies / Aromaticity / Density functional theory

The equilibrium geometries, the energies, the harmonic vibrational frequencies, and the nucleus independent chemical shifts (NICSs) of the ground state of ($\eta^5$-$P_5$)MM′($\eta^5$-$P_5$) and ($\eta^5$-$C_5H_5$)MM′($\eta^5$-$P_5$) (M, M′ = Zn, Cd) are calculated by the hybrid density functional method B3LYP with LANL2DZ basis sets. The analysis of energy and harmonic frequencies on the equilibrium geometries of both series dinuclear deca- and pentaphosphametallocenes shows that all the minima with singlet electronic state have an staggered ($9° \leq D_{(E-M-M-E')} \leq 36°$) conformation except for the eclipsed $CpCd_2(P_5)$ ($C_{5v}$), and all the $D_{5h}$ and the $D_{5d}$ symmetric conformations are transition states while the energy differences between the most stable minimum and the transition states are very small ($\leq$ 0.1 kcal/mol), thus, the rotation of the $P_5$ ring about M–M bond in all complexes is almost free. The analysis of the NBO, the Laplacian of the electron density, the electrostatic interaction energy, the bonding energy decomposition, and the molecular orbital correlation diagrams for the two series complexes reveals that the properties of all the dinuclear phosphametallocenes investigated are similar to that of the dizinc metallocenes. The M–M (or M–M′) bond in the dinuclear phosphametallocenes is a weak σ covalent bond, and the magnitude of bonding energy of the M–M (or M–M′) bond correlates with the energy difference between the energy of HOMO in M($\eta^5$-$P_5$) (or MCp) ($^2A$, $C_{5v}$) fragment and the energy of HOMO-2 in [MM′($\eta^5$-$P_5$)$_2$] ($^1A$, $D_5$, or $D_{5h}$) [or ($\eta^5$-$P_5$)MM′Cp ($^1A$, $C_5$, or $C_{5v}$)] (M, M′ = Zn, Cd). The strength of the M–M (or M–M′) bond plays a decisive role on the stability of the dinuclear phosphametallocenes. However, the M–($\eta^5$-$P_5$) (or M–Cp) bonding mainly is ionic. Among the different dinuclear phosphametallocenes with the same ligands, the bonding energies of the M–M (or M–M′) bond and of the M–($\eta^5$-$P_5$) (or M–Cp) bond decrease as M varying from Zn to Cd. Among the different phosphametallocenes with the same metals, the bonding energies of the M–M (or M–M′) bond and the M–ligand bond increase with ligand varying from the ($\eta^5$-$P_5$) to the Cp. The negative NICSs indicate that all dinuclear phosphametallocenes have aromaticity. The various dissected bond NICS contributions reveal that the NICS contributions of the metal–ligand bond, the metal–metal bond, and the metal lone pair electrons to the overall aromaticity in the Zn-containing dinuclear phosphametallocenes are different from their counterpart contributions in the Cd-containing dinuclear phosphametallocenes, such difference causes that the overall NICSs of the Zn-containing dinuclear phosphametallocenes are more negative than that of the Cd-containing dinuclear phosphametallocenes.

## 1. Introduction

The successful synthesis of the linear organometallic molecule, decamethyldizincocene, [$Zn_2$($\eta^5$-Cp*)$_2$] (Cp* = $C_5Me_5$) by Resa and co-workers recently,[1,2] has provided inorganic chemists with their first example of a stable organometallic compound with a homonuclear metal Zn–Zn bond, and has been considered as a new frontier of the dinuclear metallocenes study.[3] One motivation of the present study is stimulated by the new synthesis routes[4,5] and theoretical studies on the structures, the bond interactions,[2] and the vibrational signatures of the Zn–Zn stretching mode in the novel molecule.[6] The analogous dinuclear metallocenes, such as $CpCu_2Cp$ and $CpNi_2Cp$,[7] [$M_2$($\eta^5$-$Cp^X$)$_2$] (M = Zn and Cd, $Cp^X$ = $C_5Me_5$ and $C_5H_5$),[8] and the dinuclear cyclopentadienylcobalt carbonyls[9] were investigated. The homodinuclear metallocenes, [$M_2$-($\eta^5$-Cp)$_2$] (M = Be, Mg, and Ca),[10] and the heterodinuclear metallocenes, CpE–MCp (E = B, Al, Ga; M = Li, Na, K),[11] and Cp–Zn–Cd–Cp[12] were studied as well. These studies are fascinating and encourage our further explorations of analogous homodinuclear and heterodinuclear phosphametallocenes.

Since the first synthesis of pentamethylpentaphosphaferrocene by Scherer et al.[13] and pentaphosphacyclopentadi-

enide anion ($P_5^-$) by Baudler and co-workers,[14,15] the structure of pentaphosphametallocene and the aromaticity of polyphosphaphospholes and $P_5^-$ have attracted much attention from the chemistry community by the fact that metallocene and analogous organometallic compounds have been found in many applications, e.g. synthetic reagents, catalysts of polymerization and hydrogenation of olefin, and building blocks for new materials.[16–32] Experimental and computational studies suggested that the pentaphospholyl anion, $P_5^-$, is aromatic, as cyclopentadienyl anion, $Cp^-$.[16–21,33,35] Recent synthesis and X-ray structural analysis of the homoleptic sandwich complex with pentaphospholyl anion ligands, $[Ti(\eta^5\text{-}P_5)_2]^{2-}$,[34] gave a new impetus to the versatile chemistry of phosphametallocenes. The structure, bonding and aromaticity of the decaphosphametallocenes $[Ti(\eta^5\text{-}P_5)_2]^{2-}$ were theoretically reported by Lein et al.[35] and our group,[33] respectively. $[Ti(\eta^5\text{-}P_5)_2]^{2-}$ is aromatic with stronger aromaticity.[33] However, it has not been investigated, to the best of our knowledge, on the stabilities, electronic structures and aromaticity of the homodinuclear phosphametallocenes: $[M_2(\eta^5\text{-}P_5)_2]$ and $(\eta^5\text{-}C_5H_5)\text{-}M_2(\eta^5\text{-}P_5)$, (M = Zn, Cd), and the heterodinuclear phosphametallocenes: $(\eta^5\text{-}P_5)MM'(\eta^5\text{-}P_5)$ and $(\eta^5\text{-}C_5H_5)\text{-}MM'(\eta^5\text{-}P_5)$ (M, M′ = Zn, Cd).

To better understand the bonding nature of the M–M (or M–M′) and of the M–$(\eta^5\text{-}P_5)$ in titled molecules, it is necessary to investigate the geometric and electronic structures and binding energies of a series of complexes. The purpose of this paper is to exhibit the features of structures, the bonding energies and the aromaticity of the homodinuclear and the heterodinuclear phosphametallocenes within density functional theory (DFT). Meanwhile, the qualitative analysis of the molecular orbital correlation diagram and the Laplacian of the electron density $[\nabla^2\rho(r)]$ of the atom in molecule (AIM)[36–38] are performed to characterize the bonding features of the interaction and to provide insights into the influences of metals and ligands on the bonding character and aromaticity in both series of complexes.

## 2. Computational Methods

The DFT geometry optimizations at B3LYP/gen [P: 6-311+G(2d), C, H: 6-311+G(d,p), Zn, Cd: LANL2DZ] level of theory are carried out on several symmetrical conformations [eclipsed ($D_{5h}$ or $C_{5v}$), staggered ($D_{5d}$, $D_5$ and $C_5$)] of the homodinuclear with homo-ligands, the heterodinuclear with homo-ligands, the homodinuclear with hetero-ligands and the heterodinuclear with hetero-ligands sandwich-like complexes with pentaphospholyl ligands and Cp ligand: $(\eta^5\text{-}P_5)M_2(\eta^5\text{-}P_5)$, $(\eta^5\text{-}P_5)MM'(\eta^5\text{-}P_5)$, $(\eta^5\text{-}C_5H_5)\text{-}M_2(\eta^5\text{-}P_5)$ and $(\eta^5\text{-}C_5H_5)MM'(\eta^5\text{-}P_5)$ (M, M′ = Zn, Cd), respectively (as shown in Figure 1). In order to check our computational reliability and to compare the differences between $[M_2(\eta^5\text{-}P_5)_2]$ and $[M_2(\eta^5\text{-}Cp)_2]$ (M = Zn, Cd), we optimized the dinuclear metallocene $[M_2(\eta^5\text{-}Cp)_2]$ ($D_{5h}$, $D_{5d}$, $D_5$) reported by Xie et al.[8] The vibrational frequencies were calculated and the DFT wavefunction instabilities were checked at the same level of theory. The nature of all the stationary points on the potential energy surface (PES) are verified with the vibrational frequency calculations in which Hessian (the second order derivatives of total energy with respect to nuclear coordinates on PES) are calculated. If all eigenvalues in Hessian are positive for a stationary point, this stationary point is a minimum on the PES. One or more negative eigenvalues of a stationary point indicates a saddle point on PES. The natural bond orbital (NBO)[39] analyses are performed to gain insight into the bonding pattern of these complexes. The bond lengths, the natural atomic charges, the vibrational frequencies, the Wiberg bond index (WBI) in Natural Atomic Orbital (NAO), and the Laplacian of the electron density $\nabla^2\rho(r)$ of the constituent atoms of the complexes under investigation are calculated. The nucleus-independent chemical shift (NICS), as an index of aromaticity, at different positions in every structure are predicted with GIAO-B3LYP//B3LYP/gen [P: 6-311+G(2d), C, H: 6-311+G(d,p), Zn,Cd: LANL2DZ]. The NICS(0) is computed at the ring center, the NICS(1) is computed at 1 Å above the ring center, and the NICS(–1) is computed at 1 Å beneath the ring center. All of the NICS dissections of various bonds and cores are computed by NBO3.1.[39,40] All the calculations were carried out with the Gaussian03 program package.[39] The molecular orbitals (MOs) of the complexes are plotted with MOLDEN 4.0.[40]

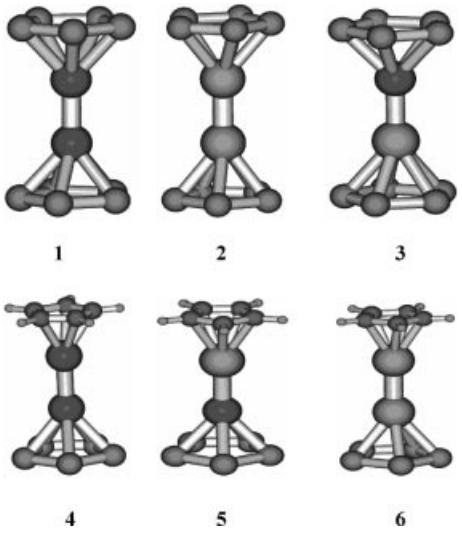

Figure 1. Molecular structures. 1 $(\eta^5\text{-}P_5)Zn_2(\eta^5\text{-}P_5)$, 2 $(\eta^5\text{-}P_5)\text{-}Cd_2(\eta^5\text{-}P_5)$, 3 $(\eta^5\text{-}P_5)ZnCd(\eta^5\text{-}P_5)$, 4 $CpZn_2(\eta^5\text{-}P_5)$, 5 $CpCd_2(\eta^5\text{-}P_5)$, 6 $CpCdZn(\eta^5\text{-}P_5)$.

## 3. Results and Discussions

### 3.1 Geometric Structures

Table 1 and Table 2 list the bond lengths, the WBI in NAO, the natural atomic charge (NAC) $q|e|$, the staggered angle ($D_{(E\text{–}M\text{–}M\text{–}E')}$) between the two $P_5$ (or Cp) rings, and the Laplacian of the electron density $\nabla^2\rho(r)$ between the M

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms and between the M atom and the ligand ring for the homodinuclear phosphametallocenes, $[M_2(\eta^5\text{-}P_5)_2]$ and $(\eta^5\text{-}C_5H_5)M_2(\eta^5\text{-}P_5)$ (M = Zn and Cd) and the heterodinuclear phosphametallocenes, $(\eta^5\text{-}P_5)MM'(\eta^5\text{-}P_5)$ and $(\eta^5\text{-}C_5H_5)MM'(\eta^5\text{-}P_5)$ (M, M′ = Zn, Cd).

All the minima of the dinuclear phosphametallocenes with singlet electronic state, including the homodinuclear phosphametallocenes, $[M_2(\eta^5\text{-}P_5)_2]$ and $(\eta^5\text{-}C_5H_5)M_2(\eta^5\text{-}P_5)$ (M = Zn and Cd) and the heterodinuclear phosphametallocenes, $(\eta^5\text{-}P_5)MM'(\eta^5\text{-}P_5)$ and $(\eta^5\text{-}C_5H_5)MM'(\eta^5\text{-}P_5)$ (M, M′ = Zn, Cd), have an staggered ($9° \leq D_{(E\text{–}M\text{–}M\text{–}E')} \leq 36°$) conformation except for the eclipsed $CpCd_2(P_5)$ ($C_{5v}$, $D_{(E\text{–}M\text{–}M\text{–}E')} = 0°$). All the $D_{5h}$ and $D_{5d}$ symmetric conformations are transition states while the energy differences between the minima and the transition states are very small ($\leq 0.1$ kcal/mol). This is in agreement with the energy differences (0.01 kcal/mol) between the minima in $D_{5d}$ symmetry and the transition states in $D_{5h}$ symmetry in CpZnZnCp,[8] CpNiNiCp,[8] and $[M_2(\eta^5\text{-}Cp)_2]$ (M = Be, Mg, Ca).[10] These results indicate that the rotation of $P_5$ ring about the M–M bond in all complexes is almost free. It suggests that the $[M_2(\eta^5\text{-}P_5)_2]$ (M = Zn, Cd) may be similar to CpMMCp (M = Zn, Cd).

As shown in the Table 1, the Zn–Zn bond lengths in our predictions, 2.487, 2.476, and 2.466 Å in $[Zn_2(\eta^5\text{-}P_5)_2]$, $[CpZn_2(\eta^5\text{-}P_5)]$, and $CpZn_2Cp$, respectively, are close to

Table 1. Bond lengths, natural atomic charge, WBI in NAO, staggered angle, electrostatic interaction energies ($V_{Ep\text{–}M_2^{2+}(M)}$) and the Laplacian of the electron density $\nabla^2\rho(r)$ between M atoms and between M atom and ligand ring for the local minima of $(\eta^5\text{-}P_5)M_2(\eta^5\text{-}P_5)$, $CpM_2(\eta^5\text{-}P_5)$ and $CpM_2Cp$ (M = Zn and Cd) predicted at B3LYP/Gen [P: 6-311+G(2d), C, H: 6-311+G(d,p), Zn,Cd: LANL2DZ] level.

each other, and decrease with the ligand varying from $P_5$ to Cp. The change of the Cd–Cd bond length in $[Cd_2(\eta^5\text{-}P_5)_2]$, $CpCd_2(\eta^5\text{-}P_5)$, and $CpCd_2Cp$ is analogous to that of the Zn–Zn bond length in three Zn-containing complexes, while the Cd–Cd bond length is longer than Zn–Zn in their counterparts. The Zn–($\eta^5$-$P_5$) (2.126 Å) distance in $[Zn_2(\eta^5\text{-}P_5)_2]$ is longer than the Zn–Cp (2.067 Å) distance in $CpZn_2Cp$, and the Cd ligand distance is analogous to the Zn ligand distance. The M–($\eta^5$-$P_5$) distance in $[M_2(\eta^5\text{-}P_5)_2]$ is shorter than the M–Cp distance in $[CpM_2(\eta^5\text{-}P_5)]$ (M = Zn and Cd). However, the Zn ligand distance is shorter than the Cd ligand distance. This indicates that the interaction between the M atom and the $\eta^5$-$P_5$ rings is similar to that between the M atom and the Cp rings, while the interaction in the former is slightly smaller than that in the latter, and the interaction between the Zn atoms and the ligand rings is stronger than that between the Cd atoms and the ligand rings. The interaction trends between the M atom and the ligand rings is completely in the same trends as the electrostatic interaction energies between Ep and $M^+$ as $V_{Ep-M^+}$ listed in Table 1, in which the electrostatic interaction between the M atom and the $\eta^5$-$P_5$ rings is similar to that between the M atom and the Cp rings, but the electrostatic interaction in the former is slightly smaller than that in the latter, and the electrostatic interaction between the Zn atoms and the ligand rings is stronger than that between the Cd atom and the ligand rings. The analyses of the WBI and the $\nabla^2\rho(r)$[36–39,42] between M atoms, and between M atoms and the ligand rings, indicate that the M–M bond is predominantly weakly covalent, and the M–($\eta^5$-$P_5$) bonding is mainly of ionic, and the bond strengths of the M–M bond in the two series complexes are very close.

As shown in Table 2, in the heterodinuclear phosphametallocenes, the magnitudes of bond length, the WBI and the$\nabla^2\rho(r)$ between Zn and Cd, and between M and Ligands, reveal that the Zn–Cd bond is a weak covalent, and the M–Ligand bond is main ionic, too. The electrostatic interaction between the M atom and the $\eta^5$-$P_5$ rings is slightly weaker than the interaction between the M atom and Cp ring, while the covalent interaction in the former is stronger than that in the latter.

Comparing the $r_{P-P}$ in the homodinuclear or the heterodinuclear phosphametallocenes with that in the $\eta^5$-$P_5^-$($D_{5h}$) ion, in which all P–P bonds are equal, we can find that the $r_{P-P}$ in the former is longer than that in the latter. According to the fact that the bond lengths of $r_{P-P}$ lie between the single P–P (≥ 2.21 Å) and the double P=P (≤ 2.02 Å) bonds,[21,34] and the calculated adjacent P–P WBI in all molecules from the NBO analyses is in the range of 1.3–1.4, which is between the standard values of single-bond (1.0) and double-bond (2.0), we can infer that the building block $P_5$ in all $[M_2(\eta^5\text{-}P_5)_2]$ complexes has conjugated P–P bonds, and all molecules have aromaticity according to the P–P bond lengths.

### 3.2 Dissociation Energies

On the basis of the NBO charge and the sign of the $\nabla^2\rho(r)$ in the complexes, in which the $M_2$ unit (or M) and the ($\eta^5$-$P_5$) building block have nearly +2 |e| (or +1 |e|) and –1 |e| charges, respectively, and the $\nabla^2\rho(r) > 0$, the interaction between M and the ($\eta^5$-$P_5$) is mainly ionic. In order to compare their stabilities, eight dissociation pathways are proposed, and their dissociation energies are calculated for each pathway as shown in Table 3 and Table 4.

The pathways (1) and (4) involve breaking of the M–M and the M–M′ (M,M′ = Zn, Cd) bond. From Table 3 and Table 4, according to the magnitude of the dissociation energies of the M–M (M = Zn, Cd) bond, except for that of the Cd–Cd bond in $[Cd_2(\eta^5\text{-}P_5)_2]$, the dissociation energies of the M–M (or M–M′) (M = Zn, Cd) bond in the complexes and in the $CpM_2Cp$ ($D_5$ or $D_{5h}$) are very close, especially, that of the Zn–Zn bond. These results indicate that the stability of three complexes is analogous to $CpZn_2Cp$ which was successfully synthesized by Resa et al.,[1] that

Table 3. Dissociation energies for ($\eta^5$-$P_5$)$M_2$($\eta^5$-$P_5$), $CpM_2$($\eta^5$-$P_5$) and $CpM_2Cp$ (M = Zn, Cd) at 3LYP/Gen level of theory.[a]

| (6) $[(Ep)_2ZnCd] \xrightarrow{\Delta E_6} ZnCd^{2+} + 2\ Ep^-$ | 329.0 | | 410.9 | | 469.9 | |

[a] All $EpZnCd^+$ have $C_{5v}$ symmetry and $^2A$ electronic state, all EpM (M = Zn and Cd) have $C_{5v}$ symmetry and $^2A_1$ electronic state; all Ep and Cp have $D_{5h}$ symmetry and $^1A_{1g}$ electronic state; $ZnCd^{2+}$ has $^1S_g$ electronic state.

they can be synthesized. However, the dissociation energy of the M–M (M = Zn, Cd) bond in the homodinuclear phosphametallocenes or of the M–M′ (M, M′ = Zn, Cd) bond in heterodinuclear phosphametallocenes increases with the number of Cp ligands, i.e. $[M_2(P_5)_2] < CpM_2(P_5) < CpM_2Cp$, and $(P_5)ZnCd(P_5) < CpCdZn(P_5) < CpZnCdCp$, though their energy differences are very small, only about 1.6–2.5kcal/mol in homodinuclear phosphametallocenes, and bout 1.6–14.1 kcal/mol in heterodinuclear phosphametallocenes. Comparison the dissociation energy of the dinuclear phosphametallocenes with that of the counterpart metallocenes indicates that the M–M (M = Zn, Cd) bond and the M–M′ (M, M′ = Zn, Cd) bond in phosphametallocenes are slightly weaker than that in the counterpart metallocenes. Comparison of the dissociation energy of the Zn–Zn bond in the dizinc phosphametallocenes with that of the Cd–Cd bond in the dicadmium phosphametallocenes reveals that the Zn–Zn bond is stronger than the Cd–Cd bond. Thus the dizinc phosphametallocenes are more stable than the dicadmium phosphametallocenes. These results are consistent with the $WBI_{M-M}$ analysis that the M–M (M = Zn, Cd) bond in phosphametallocenes is less stable than that in metallocenes which is a weak covalent bond.

Pathway (2) or (5) in Table 3 and Table 4 involves the breaking of the metal–ligand bonds in two-step dissection, while pathway (3) or (6) involves the breaking of the two metal–ligand bonds in one-step dissection. As shown in Table 3 and Table 4, the first and the second dissociation energies of the metal–ligand bonds in pathway (2) [or pathway (5)] are not equal. The first dissociation energy ($E_{21}$) is much smaller than the second one ($E_{22}$). This indicates that the first group metal–ligand bonds are easier to break while the second group metal–ligand bonds are more stable after the first step dissection. $\Delta E_{21}$, $\Delta E_{22}$, and 1/2 $\Delta E_3$ in Table 3 (or $\Delta E_{51}$, $\Delta E_{52}$ and 1/2 $\Delta E_6$ in Table 4) giving the first, the second and the average dissociation energy of the $M_2^{2+}$ ($^1S_{gg}$) with $P_5^-$ ($^1A_1$, $D_{5h}$) in the dinuclear phosphametallocenes are very large, thus indicating that the bonding of $M_2^{2+}$ with $P_5^-$ is very strong in those systems.

Comparing the first, the second and the average dissociation energy of the metal–$P_5$ bonds in the dinuclear phosphametallocenes with those of the metal–Cp bonds in the dinuclear metallocenes, it can be inferred that the interaction between $M_2^{2+}$ and $P_5^-$ is close to (and slightly weaker than) that between $M_2^{2+}$ and $Cp^-$. Furthermore, this interaction is consistent with the electrostatic interaction, in which the $V_{Ep-M^+}$ between the M cation and the $P_5$ anion in the dinuclear phosphametallocenes is close to that between the M cation and the Cp anion in the dinuclear metallocenes, though the magnitude in the former is slightly smaller. However, this is opposite to the conclusion of the WBI analysis between the metal and the ligand ($P_5$ or Cp), in which the WBI between the M cation and the $P_5$ anion in the dinuclear phosphametallocenes is larger than that between the M cation and the Cp anion in the dinuclear metallocenes. It further illustrates that the electrostatic interaction between the metal and the ligand ($P_5$ or Cp) in the dinuclear phosphametallocenes dominates the overall interactions.

Comparison of the dissociation energy of the Zn–$P_5$ bonds in $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) with that of the Cd–$P_5$ bonds in $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$), and comparison of the dissociation energy of the Zn–$P_5$ bonds with that of Cd–$P_5$ bonds in $[ZnCd(\eta^5\text{-}P_5)_2]$ ($C_5$) show that the dissociation energy of the Zn–$P_5$ bonds is larger than that of the Cd–$P_5$ bonds. The analysis of electrostatic interactions (the $V_{Ep-M^+}$ listed in Table 3 and Table 4) also supports this observation.

Comparison of the dissociation energy of the M–M (or M–M′; M, M′ = Zn, Cd) bond with that of the M–($\eta^5$-$P_5$) bonds in the dinuclear phosphametallocenes, in which the magnitude of the former from 45 to 64 kcal/mol is much smaller than that of the latter from 105 to 316 kcal/mol, reveals that the strength of the M–M bond is much weaker than that of the M–($\eta^5$-$P_5$) bond. Therefore, the stability of the dinuclear phosphametallocenes mainly depend on the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

magnitude of the M–M bond strength, i.e. the strength of the M–M bonding plays a more dominant role to the stability of the dinuclear phosphametallocenes.

### 3.3 Electronic Structures

Analyses of the WBI, the $\nabla^2\rho(r)$ and the dissociation energy of the M–M (or M–M′) and the M–($\eta^5$-$P_5$) in the dinuclear phosphametallocenes reveal that the M–M (or M–M′) bond is covalent and the interaction between M and ligands is mainly ionic. In order to gain insight into the covalent nature of the M–M (or M–M′) bond and to explore the reason for the stabilities of the dinuclear phosphametallocenes, a correlation diagram between the M($\eta^5$-$P_5$) fragments is depicted in Figure 2, in which several most relevant MOs in M($\eta^5$-$P_5$) and [$M_2$($\eta^5$-$P_5$)$_2$] (M = Zn, Cd) are plotted.

As shown in Figure 2, the frontier MOs for the M($\eta^5$-$P_5$) fragment are singly occupied HOMO [5a, an antibonding combination of the π-($\eta^5$-$P_5$) orbital in $P_5^-$($D_{5h}$) and the *n*s orbital in the M atom] and a pair of degenerate MOs. However, the frontier MOs for the [$M_2$($\eta^5$-$P_5$)$_2$] (M = Zn, Cd) are two degenerate nonbonding doubly occupied HOMO and HOMO-1 and a doubly occupied HOMO-2 ($5a_1$, a M–M bonding MO). The bonding MO of the M–M bond with σ symmetry mostly forms from the weak interaction of the singly occupied HOMOs of two M($\eta^5$-$P_5$) fragments [partly

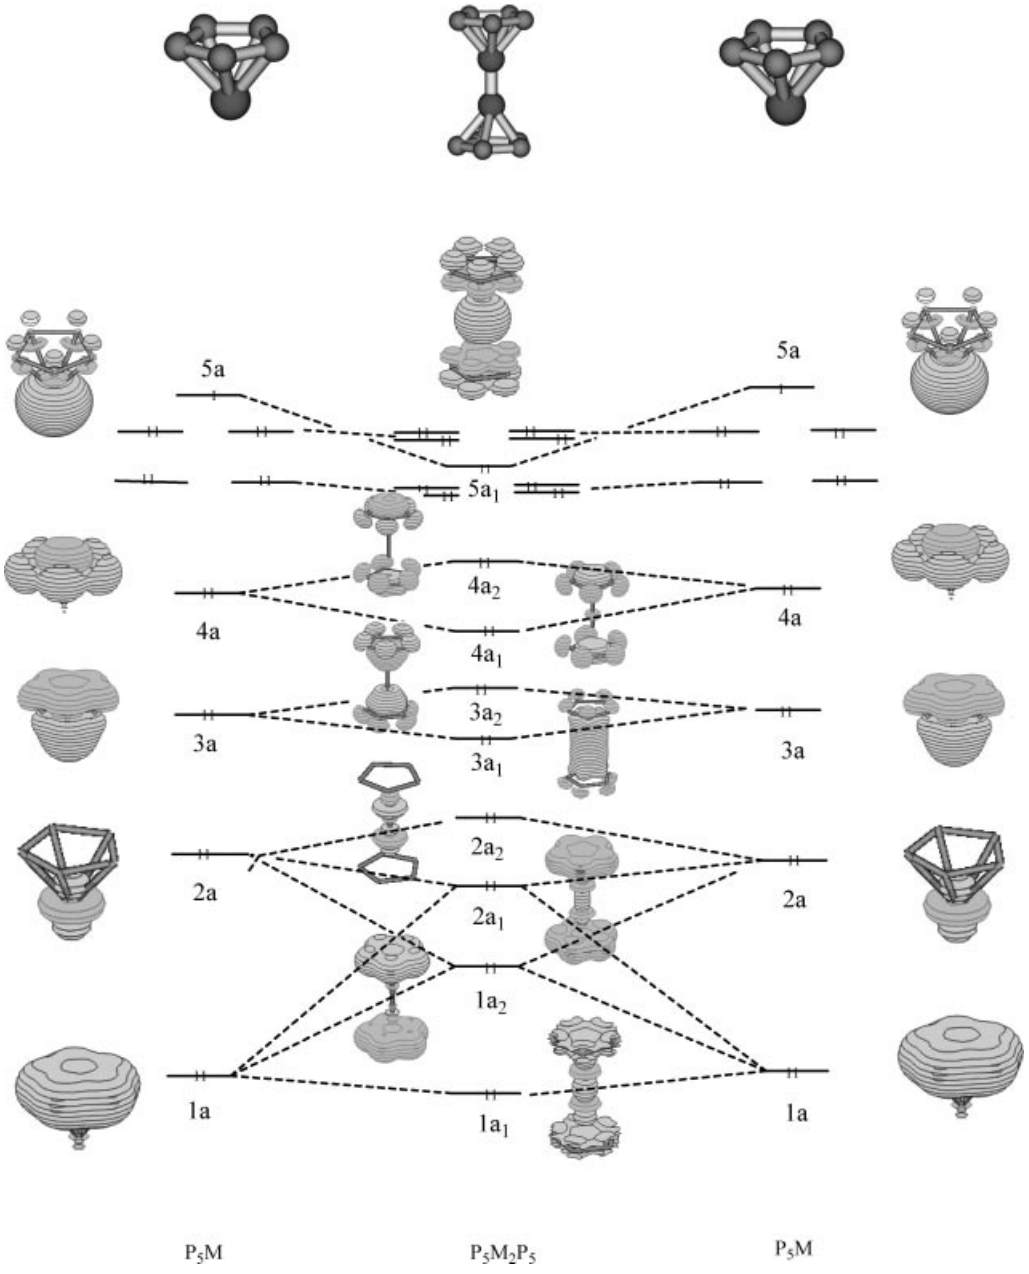

Figure 2. Orbital correlation diagram between the fragments M($\eta^5$-$P_5$) in ($\eta^5$-$P_5$)$M_2$($\eta^5$-$P_5$) and showing the most relevant orbital plots of the fragments M($\eta^5$-$P_5$) and the correlative molecular orbital plots of ($\eta^5$-$P_5$)$M_2$($\eta^5$-$P_5$) (M = Zn, Cd).

Table 5. Correlative occupied orbital energy differences between the HOMO (5a) in *Ep*M Fragments and the HOMO–2 ($5a_1$) in [$M_2(\eta^5$-$P_5)_2$] {or $CpM_2Cp$, [$MM'(\eta^5$-$P_5)_2$], Cp $MM'(\eta^5$-$P_5)$ and CpMM′Cp (M, M′ = Zn, Cd)}.

| Energy difference | $[Zn_2(P_5)_2]$ | $P_5Cd_2P_5$ | $P_5ZnCdP_5$ | $CpZn_2P_5$ | $CpCd_2P_5$ | $CpCdZnP_5$ | $CpZn_2Cp$ | $CpCd_2Cp$ |
|---|---|---|---|---|---|---|---|---|
| $\Delta E_{5a-5a_1}$ (cal/mol) | 55.3 | 52.4 | 53.8 | 59.4 | 55.0 | 55.9 | 59.1 | 54.9 |

coming from the interactions of the double occupied 3a, 2a and 1a of the two M($\eta^5$-$P_5$) fragments and resulting in $3a_1$, $2a_1$, and $1a_1$ MOs as shown in Figure 2, but these weak bonding interactions are counteracted by their antibonding interactions]. Meanwhile, Figure 2 shows that the stabilities of the dinuclear phosphametallocenes correlates with the M–M bond strength, i.e. the magnitude of the MO energy difference ($\Delta E_{5a-5a_1}$) between the singly occupied HOMOs of M($\eta^5$-$P_5$) fragments and the HOMO–2($5a_1$) representing the M–M bonding orbital in the dinuclear phosphametallocenes correlates with stability of the dinuclear phosphametallocenes. The orbital energy differences ($\Delta E_{5a-5a_1}$) of the phosphametallocenes are listed in Table 5. For comparison, the results of the similar calculations for the $CpM_2Cp$ ($D_5$ or $D_{5h}$) (M = Zn, Cd) are listed in Table 3 as well.

As shown in Figure 2 and Table 5, the magnitudes of the orbital energy differences ($\Delta E_{5a-5a_1}$) for the dinuclear phosphametallocenes are very close, and they are slightly smaller than that of the $CpM_2Cp$ ($D_5$ or $D_{5h}$). The energy differences among them are small, for example, the $\Delta E_{5a-5a_1}$ difference between [$Zn_2(\eta^5$-$P_5)_2$] ($D_5$) and $CpZn_2Cp$ ($D_5$) is about 3.8 kcal/mol, and that between [$Cd_2(\eta^5$-$P_5)_2$] ($D_5$) and $CpCd_2Cp$ ($D_{5h}$) is only about 2.5 kcal/mol. The magnitude of the orbital energy difference in [$Zn_2(\eta^5$-$P_5)_2$] ($D_5$) is bigger than that in [$Cd_2(\eta^5$-$P_5)_2$] ($D_5$), and such energy difference in $P_5ZnCdP_5$ ($C_5$)lies between those of [$Zn_2(\eta^5$-$P_5)_2$] ($D_5$) and [$Cd_2(\eta^5$-$P_5)_2$] ($D_5$). On the basis of the magnitude of the $\Delta E_{5a-5a_1}$, the order of the stabilities of the dinuclear phosphametallocenes and the dinuclear $CpM_2Cp$ ($D_5$ or $D_{5h}$) is that: $CpZn_2P_5$ ($C_5$) ≈ $CpZn_2Cp$ ($D_5$) > $CpCdZnP_5$ ($C_5$) ≈ [$Zn_2(P_5)_2$]($D_5$) ≈ $CpCd_2P_5$ ($C_{5v}$) ≈ $CpCd_2Cp$ ($D_{5h}$) > $P_5ZnCdP_5$ ($C_5$) ≈ $P_5Cd_2P_5$ ($D_5$).

Comparison of the $\Delta E_{5a-5a_1}$ ($52.4 \le \Delta E_{5a-5a_1} \le 59.4$ kcal/mol) and the change trends with those of the dissociation energy of the M–M (or M–M′, M, M′ = Zn, Cd) bond ($44.6 \le \Delta E \le 55.4$ kcal/mol) as calculated from equations (1) and (5) (listed in Table 3 and Table 4) reveals that the magnitudes and the change trends of the $\Delta E_{5a-5a_1}$ and the dissociation energy of the M–M are very similar. Therefore, the stability of the dinuclear phosphametallocenes correlates with the magnitude of the $\Delta E_{5a-5a_1}$.

The plots of the $3a_1$ and $3a_2$ MO electron density distribution in [$M_2(\eta^5$-$P_5)_2$], derived from the interaction of the unoccupied antibonding $e_u$ of the $M_2^{2+}$ with the doubly occupied 3a, the π bond of $(\eta^5$-$P_5)^-$, shows that there is small amount of orbital overlap between the $M_2^{2+}$ and the $(\eta^5$-$P_5)^-$, thus the covalent interaction between the $M_2^{2+}$ and the ($\eta^5$-$P_5$) plays a secondary role in the stability of [$M_2(\eta^5$-$P_5)_2$], while the electrostatic interaction plays the dominant role. This conclusion is consistent with that the interaction between the $M_2^{2+}$ and the ($\eta^5$-$P_5$) is ionic basing on the analysis of the Laplacian of the electron density.

In addition, the ring currents of the electrons of $4a_1$, $4a_2$, $3a_1$, $3a_2$, $2a_1$, $1a_1$, and $1a_2$ in [$M_2(\eta^5$-$P_5)_2$] as shown in Figure 2 indicate that the dinuclear phosphametallocenes have aromaticity.

## 4. Aromaticity

The dinuclear phosphametallocenes have equivalent P–P bonds and the charge of the $P_5$ ring is close to –1 |e| as listed in Tables 1 and 2, which satisfy the geometric criterion of aromaticity and the $(4n+2)\pi$ Hückel's rule.[43] As shown in Figure 2, there are $\sigma$ ring current[44,45] in the $1a_2$, $1a_1$, $2a_1$, $4a_1$, and $4a_2$ MOs and π ring current in the $3a_1$ and $3a_2$ MOs in $P_5M_2P_5$ ($D_5$)(M = Zn, Cd). These results indicate that the $P_5$ rings in the dinuclear phosphametallocenes have aromaticity, and is worthy of further studying on the degree of aromaticity of the complexes.

The NICSs of the optimized structures of the dinuclear phosphametallocenes at the ring center [NICS(0)], at 1 Å above [NICS(1)] and beneath [NICS(–1)] the ring center are computed with GIAO–B3LYP/Gen method. All of the NICSs are listed in Table 6 and Table 7.

NICS has the negative value of the magnetic shielding. It is a simple and efficient aromaticity probe proposed by Schleyer et al.,[46–48] and one of the effective measures of aromaticity recommended by Katritzky et al.[45] This concept has been applied to both organic[46,48] and inorganic compounds,[17,47] transition metal complexes.[49,50] Aromaticity, antiaromaticity, and multiple fold aromaticity,[51] presented in molecules that possess more than one independent

Table 6. Total NICSs (in ppm) for ($\eta^5$-$P_5$)$M_2$($\eta^5$-$P_5$), $CpM_2$($\eta^5$-$P_5$) and $CpM_2Cp$ (M = Zn, Cd) at GIAO–B3LYP/Gen level of theory.

delocalized bonding system, either σ-type or π-type, have also been found in the all–metal systems[52,53] and the sandwich–like complexes.[33,38,43,54–57] Recently, we extended NICS to $P_5^-$ and $[Ti(P_5)_2]^{2-}$,[33] and dinuclear metallocene $[CpZn_2Cp]$.[58] Negative NICSs denote aromaticity, positive NICSs denote antiaromaticity, and zero NICS means non-aromaticity. The magnitude of NICSs indicates the degree of aromaticitiy or antiaromaticity.[46,47] According to the dissected NICS analysis on π-aromaticity and antiaromaticity, NICS(1) values (i.e. at 1 Å above) was recommended as better measures of π aromaticity than NICS(0) for benzene (i.e. at the ring centers).[59]

As shown in Table 6 and Table 7, NICS(0), NICS(1) and NICS(–1) in all the dinuclear phosphametallocenes and $CpM_2Cp$ ($D_5$ or $D_{5h}$) (M = Zn, Cd) being negative indicates that they are aromatic. However, the differences of NICSs at the same position in different systems reveal that their magnitude of local aromaticity is different. First, the magnitude of NICS(0) in $[M_2(\eta^5\text{-}P_5)_2](D_5)$ is less negative than that in the building block $P_5^-$ ($D_{5h}$) ion, while NICS(1) and NICS(–1) in $[Zn_2(\eta^5\text{-}P_5)_2](D_5)$ are more negative than those of counterpart in the building block $P_5^-$ ($D_{5h}$) ion. These are consistent with elongation of the calculated P–P bond lengths. The present calculation predict that the mono-facially coordinated cyclo-$P_5$ in dinuclear phosphametallocenes undergoes significant ring expansion leading to "loosening of P–P bond " as observed experimentally and calculated theoretically by Malar.[19,32] The consequent loss of local aromaticity in the central cyclo-$P_5$ indicates that a significant π-electron density can be further transferred from the ring towards the $M_2^{2+}$ unit, such that the positive charge of the $M_2^{2+}$ unit becomes small and the negative charge of cyclo-$P_5^-$ decreases as listed in Table 1 and Table 2. Second, in both the dinuclear phosphametallocenes and $CpM_2Cp$ ($D_5$ or $D_{5h}$) (M = Zn, Cd), the magnitude of NICSs in all Zn–($\eta^5$-$P_5$) (or Zn–Cp) ring plane is more negative than that in all Cd($\eta^5$-$P_5$) (or Cd–Cp) ring plane, and the magnitude of NICSs in the former (Zn) is more negative than that in the $P_5^-$ ($D_{5h}$)[or $C_5H_5^-$ ($D_{5h}$)] ion. Finally, the magnitude of NICSs in $[M_2(\eta^5\text{-}P_5)_2](D_5)$ is more negative than those in counterpart $CpM_2Cp$ ($D_5$ or $D_{5h}$). This may be because that the NICSs in the building block $P_5^-$ ($D_{5h}$) ion are more negative than those in the building block $C_5H_5^-$ ($D_{5h}$) ion as listed in Table 6 so that the magnitude of NICSs in $[M_2(\eta^5\text{-}P_5)_2]$ ($D_5$) is more negative than those in counterpart $CpM_2Cp$ ($D_5$ or $D_{5h}$).

We dissected the total NICS values of $P_5^-$ ring in $P_5^-$ ($D_{5h}$), $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) and $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$) into different P–P bond contributions (σ and π), the M–M bond contribution, the lone pair electrons contributions of P atom and M atom, and the M–($\eta^5$-$P_5$) bonding contribution are shown in Figures 3, 4 and 5.

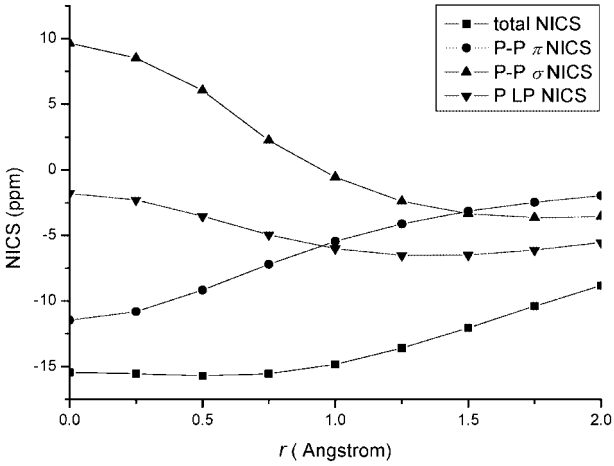

Figure 3. Plot of the NICS contributions of various bonds and total NICS distribution at the center of $P_5^-$($D_{5h}$) ring up to 2.0 Å above at GIAO-B3LYP/+G(2d).

As shown in Figures 3, 4 and 5, although there is a minimum in curves of total NICS distributions of the outer of cyclo- $P_5$ plane for $P_5^-$ ($D_{5h}$), $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$), and $[Cd_2(\eta^5\text{-}P_5)_2]$ ($C_5$), the magnitude of NICS and the position got the minimum is not complete same, NICS(0.5) = –15.7 ppm for $P_5^-$ ($D_{5h}$), NICS(0.75) = –15.9 ppm for $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$), NICS(0.75) = –13.9 ppm for $[Cd_2(\eta^5\text{-}P_5)_2]$ ($C_5$). This result reveals that the maximal π-electron ring current of the cyclo- $P_5$ plane in $[M_2(\eta^5\text{-}P_5)_2]$ is shifted from ring center to outer of plane corresponding to $P_5^-$ ($D_{5h}$). It confirms that there is indeed the expansion of the π-electron density in dinuclear phosphametallocenes again. Therefore, we suggest that the most negative NICS($r$) ($r$ may be not equal to 1 Å) should be one of criterion of π aromaticity, too.[33,57]

Comparison of the NICS contributions of various bonds and total NICS distribution in the out-of $P_5^-$ ($D_{5h}$) plane (as shown in Figure 3) with that in out-of $P_5$ ring plane of $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) [as shown in Figure 4 (a)] indicates that both magnitudes and distributions of total NICS are very similar. Although the NICS contribution of the Zn–Zn bond in $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) is positive, and that of Zn–($\eta^5$-$P_5$) bonding contribution is negative, and the negative contribution slight preponderates the positive contribution, both magnitude and distribution of total NICS in two contributions are very close while the other bond contributions are very close in two contributions. However, the analogous

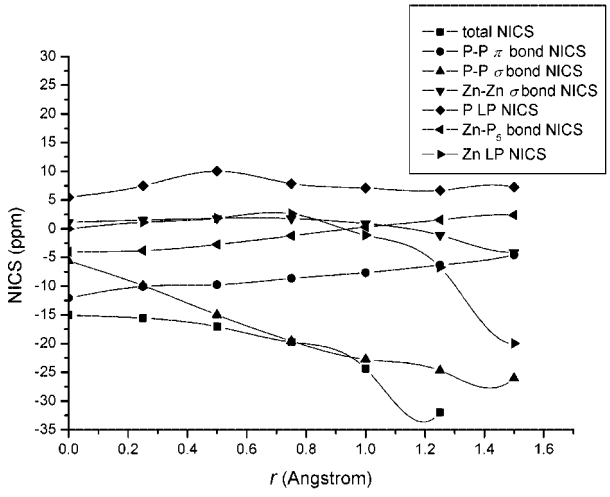
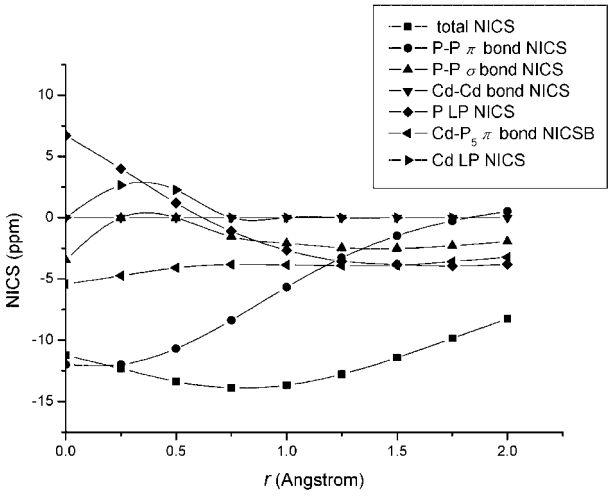
(a)

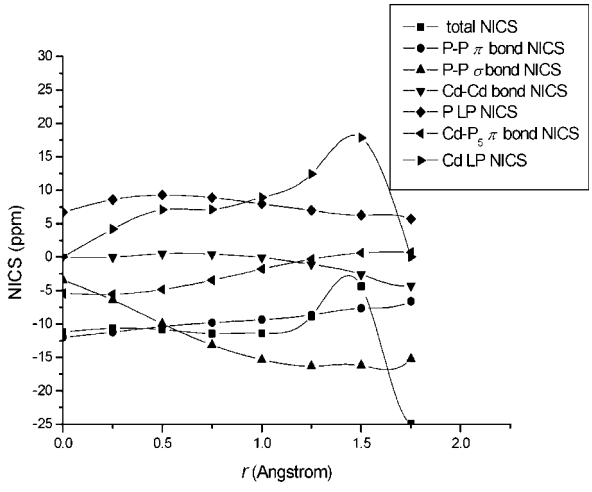


(b)

Figure 4. Plot of the NICS contributions of various bonds and total NICS distribution at the center of $P_5^-$ ring up to 2.0 Å above in $P_5Zn_2P_5$ ($D_5$) at GIAO-B3LYP/Gen (a) out-of-plane (b) in-plane.



(a)



(b)

Figure 5. Plot of the NICS contributions of various bonds and total NICS distribution at the center of $P_5^-$ ring up to 2.0 Å above in $P_5Cd_2P_5$ ($D_5$) at GIAO-B3LYP/Gen (a) out-of-plane (b) in-plane.

comparison of NICS of out-of $P_5^-$ ($D_{5h}$) ion plane (as shown in Figure 3) with that of out-of $P_5$ ring plane of $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$) [as shown in Figure 5 (a)] reveals that the sum of the positive NICS contribution of the lone pair (LP) electron of Cd atom and of the P–P σ bond preponderates the negative NICS contribution of Cd–($\eta^5$-$P_5$) bonding while the other bonding NICS contributions are very close. So that the magnitude of total NICS of the out-of $P_5$ ring plane in $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$) is not as negative as that of $P_5^-$ ($D_{5h}$) ion. As for the NICSs of the other dinuclear phosphametallocenes, the magnitude and distribution of total NICS is analogous to that in $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) and $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$). Therefore, the NICSs of the dizinc phosphametallocenes is slightly more negative than that of $P_5^-$ ($D_{5h}$) ion except for NICS(0), but the NICSs of the dicadmium phosphametallocenes is less negative than that of $P_5^-$ ($D_{5h}$) ion.

As for the reason that NICS(–1) of the dizinc phosphametallocenes is much more negative than that of the dicadmium phosphametallocenes, as shown in Figure 4 (b) and Figure 5 (b), the curve of total NICS distribution of inner side of the $P_5$ ring plane in $[M_2(\eta^5\text{-}P_5)_2]$ ($D_5$) [M = Zn, Cd] drops off with the distance to the $M_2^{2+}$ unit, but the curve of total NICS distribution in $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) is much steeper than that in $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$), so that the distribution curves of NICS contributions of in-$P_5$-ring

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plane for the Zn–Zn bond, the LP of Zn, and the P–P σ bond in $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) is much steeper than that of the Cd–Cd bond, the LP of Cd, and the P–P σ bond in $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$). Therefore, the magnitude of total NICS of inner side of the $P_5$ ring plane in $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) is much more negative than that in $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$) at the same position, the NICS(–1) of $[Zn_2(\eta^5\text{-}P_5)_2]$ ($D_5$) is much more negative than that of $[Cd_2(\eta^5\text{-}P_5)_2]$ ($D_5$). The NICS(–1) of other dinuclear phosphametallocenes has similar phenomena.

## 5. Conclusions

The analysis of energy and the harmonic frequencies on the equilibrium geometries of both series of dinuclear phosphametallocenes, $[MM'(\eta^5\text{-}P_5)_2]$ and $(\eta^5\text{-}P_5)MM'Cp$ (M, M′ = Zn, Cd), shows that all the minima of the dinuclear phosphametallocenes with singlet electronic state have an staggered ($9° \leq D_{(E\text{–}M\text{–}M\text{–}E')} \leq 36°$) conformation except for the eclipsed $CpCd_2(P_5)$ ($C_{5v}$, $D_{(E\text{–}M\text{–}M\text{–}E')} = 0°$), and all the $D_{5h}$ and the $D_{5d}$ symmetric conformations are transition states while the energy differences between the most stable minimum and the transition states are very small ($\leq 0.1$ kcal/mol). The rotation of $P_5$ ring about the M–M bond in all complexes is almost free.

The analyses of the NBO, the Laplacian of the electron density, the electrostatic interaction energy, the bonding energy decomposition, and the MO correlation diagrams for the two series complexes reveal that the properties of all the dinuclear phosphametallocenes are similar to that of the dizinc metallocenes. The M–M (or M–M′) bond in the dinuclear phosphametallocenes is a weak σ covalent bond, and the magnitude of bonding energy of the M–M (or M–M′) bond correlates with the energy difference between the energy of HOMO in $M(\eta^5\text{-}P_5)$ [or MCp] ($^2A$, $C_{5v}$) fragment and the energy of HOMO–2 in $[MM'(\eta^5\text{-}P_5)_2]$ ($^1A$, $D_5$, or $D_{5h}$) [or $(\eta^5\text{-}P_5)MM'Cp$ ($^1A$, $C_5$ or $C_{5v}$)] (M, M′ = Zn, Cd). The M–M (or M–M′) bond strength plays a dominant role in the stability of the dinuclear phosphametallocenes. On the other hand, the M–($\eta^5$-$P_5$) [or M–Cp] bonding is mainly ionic. Among the different dinuclear phosphametallocenes with the same ligands, the bonding energies of the M–M (or M–M′) bond and the M–($\eta^5$-$P_5$) (or M–Cp) bonds decrease as M varying from Zn to Cd. However, among the different dinuclear phosphametallocenes with the same metal, the bonding energies of the M–M (or M–M′) bond and the M–ligand bonds increase as ligand varying from ($\eta^5$-$P_5$) to Cp.

The negative NICSs indicate that all dinuclear phosphametallocenes have aromaticity. The various dissected bond NICS contributions reveal that the NICS contributions of the metal–ligand bond, the metal–metal bond and the metal lone pair electrons to the overall aromaticity in the Zn-containing dinuclear phosphametallocenes are different from their counterpart contributions in the Cd-containing dinuclear phosphametallocenes, such difference causes that the overall NICSs of the Zn-containing dinuclear phosphametallocenes are more negative than that of the Cd-containing dinuclear phosphametallocenes.

[42] At present, some scientists differentiate the type of chemical bonds using the Laplacian of the electron density of the bond critical points (BCPs). For ionic bonds, hydrogen bonds, and van der Waals interactions, the Laplacian of the electron density $\nabla^2\rho(r)$ is positive, while the $\nabla^2\rho(r_{Ep-M})$ is negative for covalent bond. We think that the $\nabla^2\rho(r_{Ep-M})$ near to zero indicates both ionic bond and covalent bond.

# Water-Soluble $Sal_2en$- and Reduced $Sal_2en$-Type Ligands: Study of Their $Cu^{II}$ and $Ni^{II}$ Complexes in the Solid State and in Solution

**Isabel Correia,[a] Agnes Dornyei,[b] Tamás Jakusch,[c] Fernando Avecilla,[d] Tamás Kiss,*[b,c] and João Costa Pessoa*[a]**

**Keywords:** Copper(II) / Nickel(II) / Reduced Schiff bases / Speciation / Crystal structure

The $Cu^{II}$ and $Ni^{II}$ complexes of the Schiff base $pyr_2en$ [*N*,*N*′-ethylenebis(pyridoxyliminato)] and reduced Schiff bases $Rpyr_2en$ [*N*,*N*′-ethylenebis(pyridoxylaminato)] and $R(SO_3$–sal$)_2en$ ($SO_3$–sal = salicylaldehyde-5-sulfonate) were prepared and characterized by elemental analysis, IR, UV/Vis, and EPR spectroscopy. The structure of $Ni(pyr_2en)\cdot 3H_2O$ was determined by single-crystal X-ray diffraction. The $pyr_2en^{2-}$ ligand is coordinated through two phenolate-O and imine-N atoms, in a distorted square-planar geometry. The complexation of $Cu^{II}$ and $Ni^{II}$ with $Rpyr_2en$ in aqueous solution is studied by pH-potentiometry, UV/Vis spectroscopy, as well as by EPR spectroscopy for the $Cu^{II}$ system, and $^1H$ NMR spectroscopy for the $Ni^{II}$ system. Complex formation constants were determined and binding modes proposed. While for the $Cu^{II}$ system all complexes present a 1:1 stoichiometry with different protonation states, for the $Ni^{II}$ system the 2:1 (L/M) complexes become important in the basic pH range at a higher ligand excess.

## Introduction

The application of Green Chemistry principles in organic transformations has attracted increased attention in the development of transition metal catalysts. $Sal_2en$-type ligands derived from *o*-hydroxyaldehydes and diamines are one of the most important ligand systems in asymmetric, homogeneous, and heterogeneous catalysis and in stereoselective synthesis.[1–5] Their transition metal complexes can be used in a large variety of applications, namely asymmetric ring opening of epoxides,[4] cyclopropanation,[6] and enantioselective epoxidation of olefins.[7] Their versatility and selectivity in chemical reactions is partly due to the ability of $sal_2en$-type ligands to complex a variety of transition metals in several oxidation states. They normally form square-pyramidal or octahedral complexes in which the four donor atoms coordinate in an almost planar fashion. Numerous $sal_2en$-type ligands have been synthesized and investigated, but most of them show low solubility in aqueous solution, which can be overcome by changing the diamine precursor and/or the ring substituents on the aldehyde.

In solution, Schiff base (SB) ligands have the disadvantage of the hydrolysis of the C=N bond, particularly in water-containing solvents. Reduction of the SB to give an amine may present interesting advantages. The reduced SBs (hereafter designated by $sal_2an$) are not so prone to hydrolysis and are more flexible and unrestrained to remain planar when coordinated to a metal center. Several $sal_2an$ complexes have been synthesized and characterized, namely with $Cu^{II}$,[8–10] $Co^{II}$,[8] $Ni^{II}$,[11] $VO^{IV}$,[12,13] $Fe^{III}$,[14] and $Zn^{II}$.[15] In the $Ni^{II}$ and $Co^{II}$ complexes the ligand coordinates in a slightly distorted square-planar geometry, and these complexes have shown the ability to interact with oxygen:[9,11] when dissolved in organic solvents these complexes can undergo oxidative dehydrogenation,[9,11] i.e. in the presence of $O_2$ one of the C–N bonds may be oxidized to an imine-type bond. This process has not been observed in most of the $Cu^{II}$ complexes, which are stable in organic solutions exposed to air.

One of the guidelines in Green Chemistry research is the elimination of hazardous solvents in reaction media. As mentioned above, $sal_2en$ complexes are frequently used as catalysts for several applications. As most $sal_2en$ complexes are not water soluble one of our objectives is the synthesis of water-soluble ligands and complexes.

In a previous work[12] we reported the preparation and characterization of the Schiff base *N*,*N*′-ethylenebis(pyridoxyliminato) ($pyr_2en$) and its reduced derivative *N*,*N*′-ethylenebis(pyridoxylaminato) ($Rpyr_2en$). Their $V^{IV}O$ and $V^{V}O_2$ complexes were characterized in the solid state and in

solution. The molecular structure of two dioxovanadium(V) complexes with this reduced SB evidenced the tetradentate binding mode and the flexibility of the Rpyr$_2$en when coordinated to the metal ion. The solution studies showed that Rpyr$_2$en forms much more stable complexes with $V^{IV}$ and $V^{V}$ than the corresponding Schiff base pyr$_2$en, and that the SB has a much higher tendency to hydrolyze in aqueous solution. This is reflected in the proton displacement constants ($K$*), characteristic for the formation equilibrium: $H_6L + V^{IV}O^{2+} \leftrightarrows [V^{IV}OLH_2]^{2+} + 4H^+$; the log$K$* values are –14.1 and –5.63 for pyr$_2$en and Rpyr$_2$en, respectively.[12] Similar results were obtained for (SO$_3$–sal)$_2$en and R(SO$_3$–sal)$_2$en with their vanadium complexes.[16]

In this work we report on the preparation of several new moderately water-soluble $Cu^{II}$ and $Ni^{II}$ complexes (the ligands and formula names are shown in Scheme 1), one of them characterized by single-crystal X-ray diffraction. We also report on the solution study of the reduced SB Rpyr$_2$en with $Cu^{II}$ and $Ni^{II}$ by pH-potentiometry, visible absorption (Vis), EPR ($Cu^{II}$), and $^1$H NMR ($Ni^{II}$) spectroscopy.

## Results and Discussion

### Synthesis and Characterization of the Solid Compounds

Sal$_2$en-type ligands were prepared by the condensation of ethylenediamine with the aldehyde derivative. Reduction with NaBH$_4$ yielded the reduced SB.[12,16] From solutions containing $Ni^{II}$ and Rpyr$_2$en, orange crystals of the SB complex Ni(pyr$_2$en)·3H$_2$O were obtained. This implies that the two amine bonds underwent dehydrogenation. The solid-state characterization of all complexes was done by taking into account that this process might also have occurred with the other metal complexes. For the Rpyr$_2$en complexes the characterization (elemental analysis, IR, and UV/Vis spectroscopy) is consistent with a formulation of M(Rpyr$_2$en) (M = $Ni^{II}$ or $Cu^{II}$). Complex K$_2${Ni[R(SO$_3$–sal)$_2$en]}, although it was characterized and is included here, is not stable; its color changes from grey, immediately after the synthesis, to soft pink, and after a week to brown. The ESI mass spectrum, measured for solutions of the pink solid, confirms the presence of the reduced Schiff base showing important peaks that can be assigned to [NiL + 2K + 1]$^+$ ($m/z$ = 565) and [NiL + 3K]$^+$ ($m/z$ = 603).

### X-ray Diffraction Studies

#### *Ni(pyr$_2$en)·3H$_2$O (1)*

Figure 1 includes an ORTEP representation of the molecular structure of Ni(pyr$_2$en)·3H$_2$O (**1**), and Table 1 shows selected bond lengths and angles. The molecule is neutral with both pyridinic nitrogens deprotonated, and the ligand coordinates the Ni atom through two phenolate oxygen ($O_{phenolate}$) and two imine nitrogen ($N_{imine}$) atoms. The geometry around the metal ion is distorted square planar, and there are three water molecules in the asymmetric unit (not shown). The planar arrangement Ni(ONNO) is slightly distorted due to the *cis*/*trans* angles, which are not 90° and 180°. The *cis* and *trans* angles are 84.2 and 94.8°, and 178.4 and 178.5°, respectively. The ligand forms a set of chelate rings of (6+5+6)-members, and the highest deviation from planarity is found in the ring defined by Ni(1)–N(1)–C(2)–C(1)–N(2), which has an rms value of 0.1074(75) Å (the others are less than 0.05 Å). It is noteworthy that the torsion angle between the N(1)–C(2)–C(1)–N(2) atoms is only 29.24(1.71)°, lower than those previously observed in this type of complexes.[17] The pyridoxal rings are planar, with rms values of 0.0172(63) and 0.0127(58) Å.

The Ni–O and Ni–N bond lengths are similar and in the usual range found for $Ni^{II}$–sal$_2$en-type complexes.[11,18–21] The C–O distances are also typical for this type of ligands,[9,11,19–21] and the C=N bonds show double bond character with distances of ca. 1.3 Å. After coordination to

Table 1. Selected bond lengths [Å] and angles [°] for complex $Ni(pyr_2en)\cdot 3H_2O$ (**1**).

| Bond lengths [Å] | | Bond angles [°] | |
|---|---|---|---|
| Ni(1)–O(3) | 1.838(5) | O(3)–Ni(1)–O(4) | 84.2(3) |
| Ni(1)–O(4) | 1.842(5) | O(3)–Ni(1)–N(1) | 94.4(3) |
| Ni(1)–N(1) | 1.849(7) | O(4)–Ni(1)–N(1) | 178.5(3) |
| Ni(1)–N(2) | 1.821(7) | O(3)–Ni(1)–N(2) | 178.4(3) |
| O(3)–C(5) | 1.310(10) | O(4)–Ni(1)–N(2) | 94.8(3) |
| O(4)–C(12) | 1.328(9) | N(1)–Ni(1)–N(2) | 86.7(3) |
| N(2)–C(1) | 1.455(12) | | |
| N(2)–C(10) | 1.308(11) | | |
| N(1)–C(2) | 1.451(12) | | |
| N(1)–C(3) | 1.262(10) | | |

the metal ion the ligand does not undergo a significant change in the $C–O_{phenolic}$ and $C–N_{imine}$ bond lengths: the C–O bonds decrease by 0.034 Å and the C=N bonds increase by 0.035 Å.[12] In the complex the $HO–(CH_2)–$ groups of the pyridoxal rings are perpendicular to the apparent molecular plane, in an *anti* position to each other. This results in a three-dimensional crystalline structure connected by H bonds. ESI-1 shows the crystalline packing and emphasizes the intermolecular bonds. The molecular planes are approximately parallel, but overlaid in an alternate manner; this is probably because of the *anti* position of the hydroxy groups. The distance between neighboring Ni atoms is between 6.381 and 8.268 Å.

### Infrared Spectroscopy

Table 2 contains selected IR bands of the complexes. The assignment was based on data from refs.[22–25] and by comparison with the spectra of the ligands.[12] All complexes present broad bands in the 2400–3600 $cm^{-1}$ range, which correspond to the stretching vibration (symmetric and antisymmetric) of the $CH_2O–H$ groups of the pyridoxal rings (for the $Rpyr_2en$ complexes) and to the water molecules. The weak $\nu$(N–H) band that emerged from the broad band at 3286 $cm^{-1}$ in $Rpyr_2en$[12] appears in the complexes at lower wavenumbers, in agreement with the coordination through the $N_{amine}$ groups. The $\nu(C–O)_{phenolate}$ band appears in the normal range for these types of complexes.[23,26] The strong $\nu$(C=N) band of complex $Cu(pyr_2en)$ is assigned to the band at 1635 $cm^{-1}$, at a higher wavenumber than the ligand (1626 $cm^{-1}$),[12] and no such band is seen in the IR spectrum of $Cu(Rpyr_2en)$. Similarly, while the $\nu$(C=N) band of $Ni(pyr_2en)$ appears at ca. 1620 $cm^{-1}$, no band is seen in the IR spectrum of $Ni(Rpyr_2en)$, which might be assigned to this vibration. Complex $Ni[(SO_3–sal)_2en]$ presents a very

strong band at 1609 $cm^{-1}$ assigned to $\nu$(C=N). This band is absent in the corresponding reduced SB complex Ni[R($SO_3$–sal)$_2$en], which presents bands at 1593 and 1639 $cm^{-1}$, assigned to aromatic =C–H and C=C stretching vibrations.

### UV/Vis Absorption Spectroscopy

The UV/Vis spectra were recorded over the 250–900 nm range in DMSO or water. The results are summarized in Table 2. Some of the intense bands at low wavelengths ($\lambda <$ 400 nm) are assigned to charge transfer (CT), imine π-π* (when appropriate), and intramolecular transitions in the aromatic rings. In the visible range ($\lambda >$ 420 nm) the bands are predominantly due to d-d transitions. The copper complexes **2**–**4** have one well-defined broad d-d band at $\lambda_{max}$ = 550–650 nm, and stronger bands at ca. $\lambda$ = 380–420 nm from the $Cu^{II} \rightarrow$ phenolate (π*) transitions [and also imine π-π* in the case of Cu(pyr$_2$en)], which is in agreement with that expected for tetrahedrally distorted square-planar complexes of the $CuO_2N_2$ type.[27,28] The $Ni^{II}$ complexes **5**–**8** have low intensity broad bands in the 400–550 nm range, assigned to transitions from the four low-lying d orbitals to the σ antibonding $d_{x^2-y^2}$ orbital. At higher energies ($\lambda <$ 400 nm) a group of high intensity bands appears, and in the case of Ni(pyr$_2$en) and Ni[($SO_3$–sal)$_2$en] relatively intense bands from the imine π-π* transition also show up. The UV/Vis data of the complexes in DMSO are in agreement with that expected for $Ni^{II}$ and $Cu^{II}$ complexes with square-planar geometries.[9,10,27] The relatively high $\varepsilon$ values of the d-d bands of the Ni complexes suggest some borrowing of intensity from CT bands and/or a significant distortion of the coordination geometry.

### EPR Spectroscopy

The EPR spectra of the $Cu^{II}$ complexes were measured in "frozen" ($T \approx$ 77 K) solutions of an adequate solvent. The spectrum of Cu(pyr$_2$en) in DMSO showed a broad band centered at $g$ = 1.995 without hyperfine structure. This is probably because of molecular aggregation during the freezing process. No signal was detected at $g$ = 4.

The EPR spectrum of Cu(Rpyr$_2$en) was measured in water and DMSO at 77 K. Both show well-resolved hyperfine structure and suggest axial symmetry. The spin Hamiltonian parameters were obtained by computer simulation of the experimental spectra using a program from Rockenbauer and Korecz.[29] Among other factors, the $g_\parallel$ and $A_\parallel$ values depend on the nature of the donor atoms and can be used to confirm the binding mode. The parameters (DMSO: $g_\perp$ = 2.047, $A_\perp = 22.2\times10^{-4}$ $cm^{-1}$, $g_\parallel$ = 2.233, $A_\parallel = 197.3\times10^{-4}$ $cm^{-1}$; $H_2O$: $g_\perp$ = 2.052, $A_\perp = 38.4\times10^{-4}$ $cm^{-1}$, $g_\parallel$ = 2.237, $A_\parallel = 193.5\times10^{-4}$ $cm^{-1}$) fit well with that expected for a $N_2O_2$ binding mode.[30] On the other hand, the $g_\parallel/A_\parallel$ ratio of 113 in DMSO and 116 in $H_2O$ indicates a square-planar coordination environment.[30] In the spectrum of Cu(Rpyr$_2$en), dissolved in water, superhyperfine structure is observed in the perpendicular region of the spectrum, arising from the interaction of the $Cu^{II}$ unpaired electron with the two nitrogen donor atoms of the ligand, which results in a five line splitting ($A_N = 10.5\times10^{-4}$ $cm^{-1}$).

In the EPR spectrum of Cu[R($SO_3$–sal)$_2$en], dissolved in $H_2O$, more than one species is present. Observation of the low-field range and comparison with the EPR spectrum of $[Cu(OH_2)_6]^{2+}$ in the same solvent, shows that part of the ligand was removed from the coordination sphere of the metal ion upon dissolution and that some free $Cu^{2+}$ is present in solution (see ESI-2). Since the simulation of such $Cu^{II}$ spectra with more than one species is difficult, only an estimate of the parameters for the complex was obtained: $g_\parallel$ = 2.25 and $A_\parallel = 189\times10^{-4}$ $cm^{-1}$. The $g_\parallel/A_\parallel$ ratio (119) also indicates a square-planar geometry for this complex.[30] These parameters are similar to those obtained for other $Cu^{II}$–sal$_2$an complexes, which present square-planar geometry and a $N_2O_2$ coordination mode.[8]

### Study of the Oxidative Dehydrogenation Process of Ni(Rpyr$_2$en)

Some $Ni^{II}$ complexes with the sal$_2$an-type ligands are able to react with dissolved $O_2$.[9,11] In solutions of organic solvents the complexes undergo oxidative dehydrogenation, and one of the two C–N bonds dehydrogenates yielding a C=N bond. Further dehydrogenation of the second C–N bond has not been previously observed.[9,11] Since crystals of Ni(pyr$_2$en) (**1**) were obtained from the filtrate solution of the Ni(Rpyr$_2$en) synthesis, we might expect that in the present system the dehydrogenation is complete. To further investigate the process, complex Ni(Rpyr$_2$en) was dissolved in DMSO and air was bubbled through the stirred solution over a period of three days; the initial pink solution slowly became orange. Another identical solution was saturated with $N_2$; it also became progressively orange but at a much slower rate. The process was monitored by UV/Vis spectroscopy and Figure 2 shows the spectra recorded for both solutions. Initially there is an isosbestic point at ca. 510 nm, indicating the transformation of the reduced SB complex into another species, but it is quite clear that the final product is not Ni(pyr$_2$en) (its spectrum is included in the figure for comparison). The spectrum of the final product obtained in solution has similar features to those reported for $Ni^{II}$ complexes of half dehydrogenated complexes:[9,11] two new bands develop at 390 and 460 nm.

$^1$H NMR spectra of complexes Ni(Rpyr$_2$en) and Ni(pyr$_2$en) were measured in $(CD_3)_2SO$. The spectrum of Ni(pyr$_2$en) did not change over 24 hours, and all peaks could be easily assigned (see Experimental Section), while after 24 hours the spectrum of Ni(Rpyr$_2$en) showed features corresponding to two compounds [half dehydrogenated complex and Ni(Rpyr$_2$en)], indicating that the complex suffered partial dehydrogenation at only one of its amine bonds.

## Speciation Studies

The acid-base behavior of $pyr_2$en, R$pyr_2$en, and R($SO_3$–sal)$_2$en and their complexation with $V^{IV}$ and $V^{V}$ were previously reported.[12,16] The study of the $Cu^{II}$– and $Ni^{II}$–R$pyr_2$en systems by pH-potentiometry, Vis, EPR (for the $Cu^{II}$ system), and $^1$H NMR (for the $Ni^{II}$ system) spectroscopy is now presented.

### *$Cu^{II}$–R$pyr_2$en*

The pH-metric titration curves were measured between pH 2 and 11.3, and the best equilibrium model that fitted the experimental data corresponds to a model similar to that obtained for the $V^{IV}O$ system.[12] The stability constants are listed in Table 3 and a species distribution diagram is depicted in Figure 3 (a).

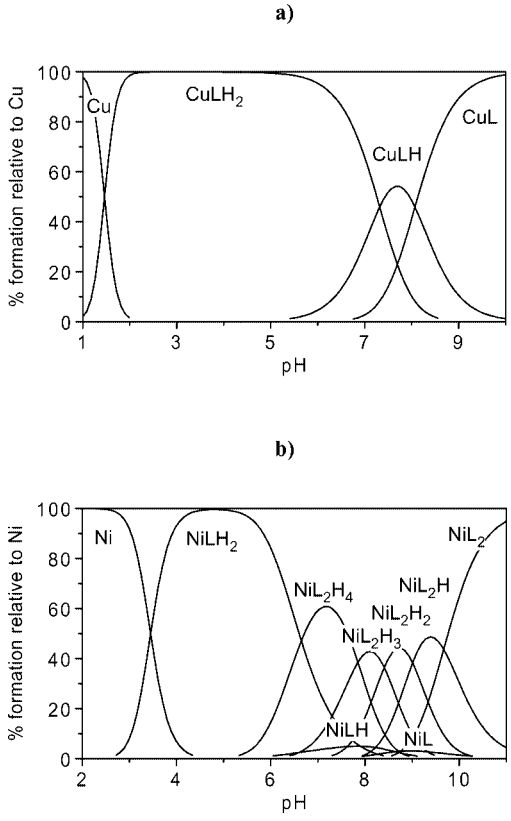

Figure 3. Species distribution diagram for the complexes formed in the (a) $Cu^{II}$–R$pyr_2$en system for solutions containing $C_{Cu}$ = 2.0 mmol dm$^{-3}$ and a L/M ratio of 2; (b) $Ni^{II}$–R$pyr_2$en system for solutions containing $C_{Ni}$ = 3.0 mmol dm$^{-3}$ and a L/M ratio of 4.

Analysis of the potentiometric data with the PSEQUAD program[31] shows the presence of only 1:1 complexes in solution over the whole pH range, in various protonation states. In the pH range 1–10 stoichiometries $[CuLH_2]^{2+}$, $[CuLH]^{+}$, and [CuL] are formed, with the deprotonations taking place at the N-pyridine atoms of the pyridoxal rings.

Table 3. Protonation and formation constants for the $M_pL_qH_r$ species formed in the $Cu^{II}$- and $Ni^{II}$-R$pyr_2$en systems, calculated from the pH-potentiometric and spectrophotometric data (EPR and UV/Vis) with the PSEQUAD program.[31]

The stability of the complexes is high, and even at pH 2 the amount of $[Cu(OH_2)_6]^{2+}$ is very small.

The Vis spectra for this system as the pH is varied (Figure 4) consists of a broad band (of d-d origin) with a maximum around 625 nm ($\varepsilon \approx 200$ mol dm$^{-3}$ cm$^{-1}$ at pH = 6.0). Deprotonation of the pyridine nitrogen atoms causes significant changes in the UV/Vis spectra: the d-d transition shifts to a higher energy as the pH is increased and the shoulder at ca. 420 nm (ascribed to phenolate → $Cu^{II}$ CT transition) shows a bathochromic effect with increasing pH. These shifts demonstrate that the pyridoxal ring forms a connected electron system and thus deprotonation of the pyridine-NH groups will influence the donor properties of the phenolate oxygen atoms.

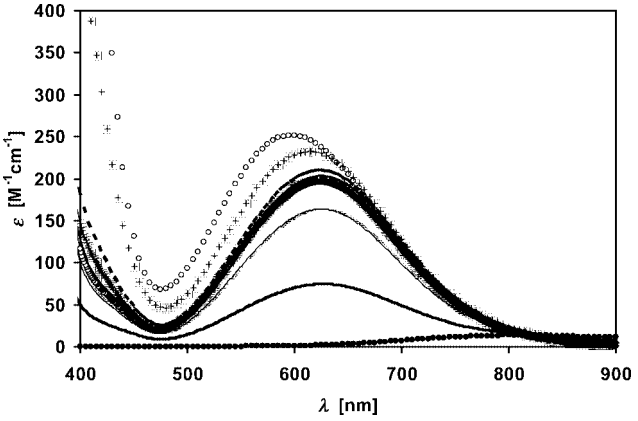

Figure 4. Visible spectra of aqueous solutions containing $Cu^{II}$ and $Rpyr_2en$, with $C_{Cu}$ = 5 mmol dm$^{-3}$ and a L/M ratio of 1 at several pH values. Below pH 2 the solutions were individually prepared and the $[H^+]$ was determined from a calibration curve (see Exp. Sect.). $[Cu(OH_2)_6]^{2+}$ (···), pH = 1.29 (——), 1.60 (——), 6.64 (---), 7.71 (+++), 10.56 (○). The superimposed spectra correspond to pH values in the pH range 2.2–6.0.

EPR spectra of samples containing $C_{Cu}$ = 5 mM and a L/M ratio of 1.1 at several pH values were measured at room temperature and 77 K. The parameters are collected in Table 4, and Figure 5 shows a few of the spectra obtained at room temperature. The frozen solution spectra (data not shown) show axial symmetry with resolved hyperfine structure, supporting the tetradentate binding of the ligand. For pH > 3 the spin Hamiltonian parameters do not show significant variation, confirming that the coordination mode for complexes $CuLH_2$, CuLH, and CuL is the same ($N_2O_2$),[30] that the deprotonation processes $[CuLH_2]^{2+} \rightarrow [CuLH]^+ \rightarrow [CuL]$ involve only the $NH^+_{pyridinic}$ groups of the ligand (these are not involved in the coordination), and that the coordination geometry is square planar.

It is clear from the speciation (Figure 3, a) and spectroscopic data (Figures 4 and 5) that for pH < 2 a significant amount of $Cu^{II}$ is already complexed by the ligand, and that the relevant data for calculation of the $\log\beta_{112}$ value occurs at pH ≤ 2. The visible absorption and room temperature EPR spectra were used to confirm the calculated stability constant obtained for $[CuLH_2]^{2+}$ and the proposed speciation model. The molar fraction of each species, obtained from both the EPR and visible absorption data for

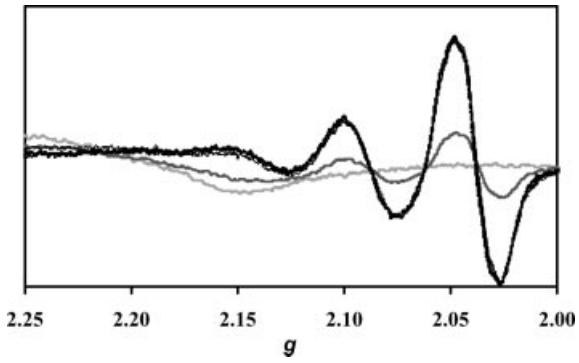

Figure 5. EPR X-band spectra (room temperature) of solutions containing $Cu^{II}$ and $Rpyr_2en$ with $C_{Cu}$ = 5 mmol dm$^{-3}$ and a L/M ratio of 1.1 at several pH values. $[Cu(OH_2)_6]^{2+}$ (light gray) and pH = 1.3 (dark gray). The superimposed black lines correspond to spectra measured at pH 1.6, 2.19 and 6.0.

pH ≤ 2 were introduced into the PSEQUAD program,[31] and a $\log\beta_{112}$ value of 35.64 ± 0.12 was refined for $CuLH_2$. On the other hand, from the pH-potentiometry data a $\log\beta_{112}$ = 35.01 ± 0.01 was obtained from data in the pH range 1.7–11, but varying the $\log\beta_{112}$ in the range 35.0–35.7 hardly affects the fitting parameter of the PSEQUAD program when using only the pH-metric data. The difference may be due to (i) the ionic strength, which was not exactly constant in the spectroscopic experiments at pH ≤ 2 and (ii) the higher error associated with the pH-metric data used in the pH range 1.7–2.0. The $\log\beta_{112}$ presented in Table 3 is the average of both values and the corresponding S.D. value reflects the different calculated values.

It should be emphasized that in complexes with the $sal_2an$ ligands, once each of the $N_{amine}$ atoms coordinates they become a stereogenic centers and *R* and *S* configurations become possible. Therefore, for each of the stoichiometries $MLH_2$, MLH, and ML at least three diastereoisomers are possible. These diastereoisomers are schematically represented by the configuration of the coordinated amine i.e. (*R*,*R*), (*S*,*S*), (*S*,*R*), or (*R*,*S*). Only for the MLH stoichiometry does the complex represented by (*S*,*R*) differ from (*R*,*S*). As found by DFT calculations for the $V^{IV}O$– and $V^{V}O_2$–$Rpyr_2en$ complexes,[12] the energies of the (*S*,*R*) and (*R*,*S*) diastereoisomers do not differ much from (*R*,*R*) or (*S*,*S*) (for this pair they are the same), and we predict that in solution all of them should form. With the techniques used

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in this work it is not possible to distinguish between these different diastereoisomers.

Pyridoxamine (pyrN) is a vitamin $B_6$ analog and $Rpyr_2en$ can be seen as two pyridoxamine molecules linked by an ethylene bridge. The acid-base behavior and complexation of pyrN with $Cu^{II}$ and $Ni^{II}$ has been reported[32] and the data ($I$ = 0.15 M $NaNO_3$, 37 °C) is included in Table 3 for comparison. PyrN forms complexes with $Cu^{II}$ with the stoichiometry 1:1 and 2:1 (L/M) in various protonation states. The stability of the complexes formed in both ligand systems can be compared based on the constants ($\log K^*$) for the displacement of four protons: $H_6L + Cu^{2+} \leftrightarrows CuLH_2 + 4H^+$ (for $Rpyr_2en$), and $2H_3L + Cu^{2+} \leftrightarrows CuL_2H_2 + 4H^+$ (for pyrN). The $\log K^*$ values are –3.3 and –11.6, respectively. As expected, because of the chelate effect, the stability of the $Rpyr_2en$-$Cu^{II}$ complexes is much higher than that of the corresponding pyridoxamine complexes.

### *$Ni^{II}$–$Rpyr_2en$*

In equimolar solutions slow processes take place at pH > 8, and precipitation of a pink complex occurs. However, for solutions with L/M ratios greater than 1 the pH-metric titration curves could be measured up to 11.7. The model that best fitted the experimental data was obtained considering the formation of 1:1 and 2:1 complexes. Without bis complexes the fitting parameter of PSEQUAD was ca. five times higher. The stability constants obtained are listed in Table 3, and Figure 3b depicts a species distribution diagram.

As is usually the case for $Ni^{II}$ complexes the large zero-field splitting precluded the observation of any X-band resonances.[33] Although samples were measured by EPR spectroscopy, we were not able to obtain any EPR spectra. Moreover, $^1H$ NMR titrations carried out in $D_2O$ with L/M ratios of 1 and 4 confirmed that the $Ni^{II}$ complexes are paramagnetic. In fact, in solutions with a L/M ratio of 1, no $^1H$ NMR peaks were observed for pH > 3, where only metal bound ligand is present, while for pH < 3 only the peaks from the noncomplexed ligand are seen. In solutions with a L/M ratio of 4 only the free ligand peaks were observed, and for pH > 3 their areas decrease (when compared with the peak of the internal reference).

Spectroscopic data for solutions of complexes Cu($Rpyr_2en$) or Ni($Rpyr_2en$) in DMSO are consistent with a square-planar coordination of the $Rpyr_2en$ ligand. In water the spectroscopic data of Ni($Rpyr_2en$) is consistent with an octahedral geometry involving the donor set: $O_{phen}$, $N_{amine}$,$N_{amine}$,$O_{phen}$,$O_w$,$O_w$ ($O_{phen}$ = phenolate-$O^-$ donor atom, $N_{amine}$ = amine-N donor atom, $O_w$ = water-O atom).

In aqueous solutions containing $Ni^{II}$ and $Rpyr_2en$ the situation is more complex. To confirm the pH-metric results and the presence of the bis complexes, spectrophotometric measurements were carried out with L/M ratios of 1 and 4. Upon changing the pH the spectra show a continuous change, indicating that the speciation is much more complex than that for the $Cu^{II}$ system. Below pH 3 (Figure 6, a) the spectra present two d-d bands in the wavelength range shown, with maxima at ca. 725 and 395 nm, which can be assigned to the $[Ni(H_2O)_6]^{2+}$ transitions $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$, respectively.[34] As the pH is increased stronger bands progressively build up. At pH 5.0, where species $NiLH_2$ is ca. 100% formed, the $\lambda_{max}$ are at 620 and 430 nm, and the latter transition [$^3T_{1g}(P) \leftarrow {}^3A_{2g}$, using the notation for an octahedral symmetry] overlapping the $O_{phen}$–Ni CT band tailing in from the UV region. Spectra were also measured for pH > 3 in the near IR range (see Supporting Information, Figure SI-7 in ESI-3), which show the presence of a broad band at ca. 995 nm ($\varepsilon$ = 18 mol dm$^{-3}$ cm$^{-1}$ at pH = 6.7), confirming the octahedral geometry of the complexes. This band, assigned to $^3T_{2g} \leftarrow {}^3A_{2g}$, gives a measure of the ligand field and shifts to higher energies between pH 3 and 6, confirming the increase in the field strength as the ligand replaces water in the $Ni^{II}$ coordination sphere. For solutions with a L/M ratio of 4 (Figure 6, b), the spectral features are the same as for L/M = 1 up to pH ca. 6, but above this pH the changes in the Vis spectra, upon increasing the pH, differ. With solutions containing L/M ratios of 4 no precipitation is observed below pH ca. 9.5, but at higher pH values a slight increase in the baseline suggests the presence of a small amount of precipitate. In the pH range 7.0–8.7, and for solutions with L/M = 4 (Figure 6, b), the spectra roughly intersect at 425 and 475 nm (not exactly isosbestic points) indicating the presence of two main types of species in equilibrium (between 1:1 and 2:1 complexes). Overall the Vis spectra confirm the species distribution diagram shown in Figure 3 (b).

ESI mass spectra were also measured to confirm the presence of the 2:1 (L/M) species. For aqueous solutions containing L/M = 1, $C_{Ni} \approx 1$ mM and pH = 5.3 several species were found in solution: $m/z$ = 363.5 $[L + 1]^+$, 419.3 $[NiL + 1]^+$, 455.0 $[NiL + 2H_2O]^+$, 781.0 $[NiL_2 + 1]^+$. For solutions containing L/M = 4, $C_{Ni} \approx 1$ mM and pH = 7.1: $m/z$ = 363.1 $[L + 1]^+$, 385.1 $[L + Na]^+$, 419.1 $[NiL + 1]^+$, 780.9 $[NiL_2 + 1]^+$. Although $NiL_2$ is found in both solutions, the intensity ratio of the MS peaks $NiL/NiL_2$ is 10:5 in the L/M = 1 solutions and 3.5:10 in the L/M = 4 solutions, showing the much higher importance of the bis complexes in solutions containing an excess of ligand.

$NiLH_2$ is the dominant species in the pH range 4–6 (see Figure 3). Its coordination geometry corresponds to a $O_{phen}$,$N_{amine}$,$N_{amine}$,$O_{phen}$,$O_w$,$O_w$ donor set, where the pyridine-N atoms are protonated. For pH > 5.5 the species $NiL_2H_4$, $NiL_2H_3$, $NiL_2H_2$, $NiL_2H$, and $NiL_2$ successively form up to a pH ca. 10.

For 2:1 complexes with tridentate ligands containing an $O_{phen}$, $N_{imine}$ or $N_{hydrazone}$, and $N_{amine}$ donor set binding modes corresponding to what is shown schematically as **I** have been characterized in the solid state by X-ray diffraction.[35–37] While in these compounds a significant part of each of the two ligands [($O_{phen}$ and $N_{imine}$ or $N_{hydrazone}$)] is constrained to be planar, the $Rpyr_2en$ ligand is much more flexible, and to the best of our knowledge this study is the first example of Ni–$sal_2en$- or Ni–$sal_2an$-type complexes reported showing the formation of bis complexes.

The intensity of the phenolate–$Ni^{II}$ CT band increases over the pH range ca. 5.3 to ca. 8.5. This suggests an in-

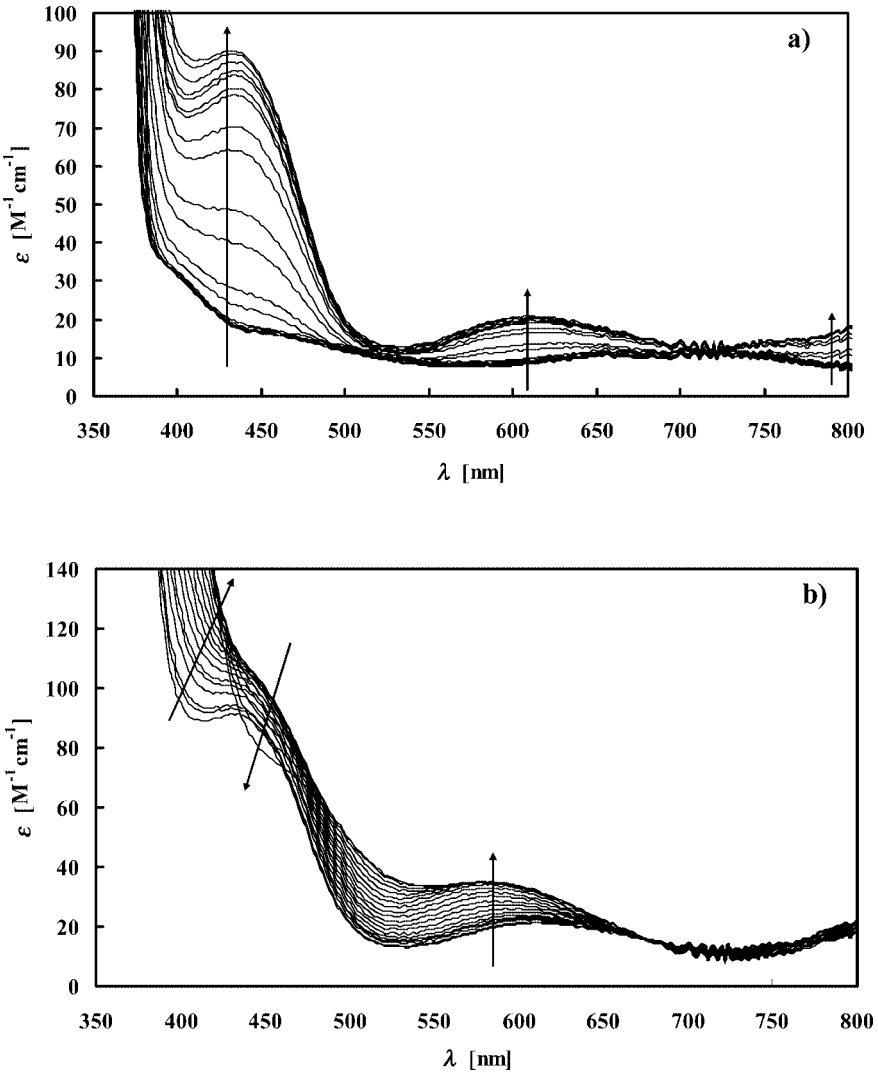

Figure 6. Visible spectra of aqueous solutions containing $Ni^{II}$ and $Rpyr_2en$, with $C_{Ni}$ = 2 mmol dm$^{-3}$ and L/M = 4 between (a) pH 2.10–5.02 and (b) pH 5.02–9.11. Arrows indicate increasing pH. Signal perturbations in the range 690–750 nm are due to instrumental noise.

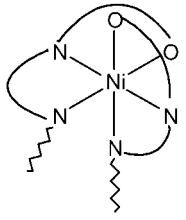

**I**

crease in the number of phenolate donor atoms in the $Ni^{II}$ coordination sphere upon the successive formation of $NiLH_2 \rightarrow NiL_2H_4 \rightarrow NiL_2H_3$. For pH > 8.7 the CT band remains approximately unchanged up to ca. 11.7, while the absorption over the wavelength range 450–800 nm increases until pH 10.3, and then decreases up to 11.7 (see Supporting Information, Figure SI-5 in ESI-3). However, the structure of the 2:1 Ni–$Rpyr_2en$ complexes in water is not easily anticipated. Formation of 2:1 complexes possibly involves displacement of one donor atom of the first ligand and the tridentate coordination of the second ligand. Binding modes such as **I** are a reasonable hypothesis, but the increase in intensity of the $O_{phen}$–Ni CT band may be indicative of the coordination of at least a third $O_{phen}$-donor atom.

The ratio $\log(K_{MLH_2}/K_{ML_2H_4}) = 0.55$ indicates a favorable interaction between the side chains in the bis complexes. These may be stabilized by intramolecular H bonds formed between groups of the coordinated ligands. In fact, the $Rpyr_2en$ ligand is quite flexible and contains several groups that may be involved in H bond formation: e.g. the pyridine-N atom (either as $N_{pyridine}$ or $NH^+_{pyridine}$), the –$(CH_2)$–OH groups of pyridoxal, or the phenolic-O atoms ($O_{phen}$ or $OH_{phen}$). Many possible binding modes and types of H bonds can be envisaged but discussing these further would be mainly speculation, as the techniques used do not help in this regard.

A comparison with pyridoxamine, which forms complexes of 1:1 and 2:1 L/M stoichiometry with $Ni^{II}$, can be

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

done based on the $\log K^*$ for the same equilibrium, as in the case of $Cu^{II}$ (see above); the $\log K^* = -10.08$ for $Rpyr_2en$ and –15.99 for pyrN[32] shows the higher stability of the $Rpyr_2en$ complexes, and also the lower stability of the $Ni^{II}$–$Rpyr_2en$ complexes when compared with those of $Cu^{II}$–$Rpyr_2en$.

## Conclusions

The coordination of the $sal_2en$- and $sal_2an$-type ligands $pyr_2en$, $Rpyr_2en$, and $R(SO_3–sal)_2en$ to $Cu^{II}$ and $Ni^{II}$ was investigated. These ligands form stable and moderately water-soluble complexes with $Cu^{II}$ and $Ni^{II}$. From solutions containing $Ni^{II}$ and $Rpyr_2en$, crystals of the SB complex $Ni(pyr_2en)$ were obtained, resulting from oxidative dehydrogenation of the two amine bonds, probably by molecular oxygen. The solution and solid-state characterization of the metal complexes showed that this process did not occur with the other complexes. Time-dependent visible absorption spectroscopic studies in aqueous solution with $Ni(Rpyr_2en)$ indicated that the dehydrogenation process, facilitated by molecular $O_2$, stops after oxidation of one amine bond. On standing for longer periods $Ni(pyr_2en)$ was obtained but only in the solid state.

The complexation of $Rpyr_2en$ with $Cu^{II}$ and $Ni^{II}$ could be studied by pH-potentiometry and spectroscopic techniques in aqueous solutions. In the $Cu^{II}$–$Rpyr_2en$ system very stable 1:1 complexes form, and at pH ca. 2 these correspond to ca. 95% of the total $Cu^{II}$. Characterization of the solid complex obtained indicates a square-planar coordination geometry involving the two $O_{phenolate}$ and two $N_{amine}$ as donor atoms. In the $Ni^{II}$–$Rpyr_2en$ system, when an excess of ligand is used bis complexes are formed in aqueous solution at pH > 6, avoiding the precipitation of the neutral NiL complex. The proton displacement constants ($K^*$) of the process $H_6L + M^{2+} \leftrightarrows ML{H_2}^{2+} + 4H^+$ are as follows: $K^*(CuLH_2^{2+}) = -3.27$; $K^*(V^{IV}OLH_2^{2+}) = -5.63$,[12] $K^*(NiLH_2^{2+}) = -10.08$, $K^*(ZnLH_2^{2+}) = -11.38$,[38] i.e. the stability order is $Cu^{II} > V^{IV}O > Ni^{II} > Zn^{II}$.

We should emphasize several aspects of the ligands studied in this work (or ligands obtained using the same aldehyde precursors and other diamines), which may have considerable advantages for e.g. catalytic applications using less toxic solvents, namely their higher solubility in aqueous and alcoholic solutions, when compared with most $sal_2en$-type ligands reported so far, because of the presence of hydrophilic groups in the aromatic rings. Moreover, the lower susceptibility to hydrolysis of the reduced $sal_2an$ derivatives, when compared with the corresponding SB, and the higher stability of $V^{IV}O$, $V^V$,[12] $Cu^{II}$, and $Ni^{II}$ complexes formed with the $sal_2an$-type ligands, may be important for both improving reaction yields and catalyst recovery. Finally, the higher flexibility of the $sal_2an$-type ligands and the fact that the coordinated $N_{amine}$ atoms are stereogenic centers may also prove useful for asymmetric synthesis if suitable diamine and/or aldehyde precursors are chosen. In the particular case of $Rpyr_2en$, with ligands containing $N_{pyridinic}$ atoms, the possibility of the various protonation states for the pyridinic nitrogens, which do not participate in coordination to the metal ions, allowing the formation of neutral and cationic complexes with the same coordination mode, may also help in tuning the redox characteristics of the complexes formed.

## Experimental Section

The synthesis of $pyr_2en$, $Rpyr_2en$, and $R(SO_3–sal)_2en$ was previously reported.[12,16]

### Synthesis of Complexes

**Crystals of $Ni(pyr_2en)\cdot 3H_2O$ (1):** From the filtrate solution of the reaction mixture used in the preparation of complex **6** orange crystals suitable for X-ray diffraction studies were obtained after six weeks.

**$Cu(pyr_2en)$ (2):** The Schiff base $pyr_2en$ (0.05 g, 0.2 mmol) was dissolved in water (25 mL) and the pH was adjusted to 7 by addition of KOH (3 M). Cupric acetate (0.03 g, 0.1 mmol) was added and the mixture was heated to 50 °C for an hour. A dark pink solid precipitated, which was collected by filtration and washed with water, ethanol, and diethyl ether, and dried under vacuum. Yield: 0.063 g, 68%. $C_{18}H_{20}N_4O_4Cu\cdot 2.3H_2O$ (461.36) {$[Cu(pyr_2en)]\cdot 2.3H_2O$}: calcd. C 46.86, H 5.37, N 12.14; found C 46.9, H 5.5, N 12.0.

**$Cu(Rpyr_2en)$ (3):** The procedure was similar to the one used for **2**. A blue solid was obtained. Yield: 0.043 g, 45%. $C_{18}H_{24}N_4O_4Cu\cdot 2.7H_2O$ (472.60) {$[Cu(Rpyr_2en)]\cdot 2.7H_2O$}: calcd. C 45.75, H 6.27, N 11.86; found C 45.8, H 6.3, N 11.7.

**$Cu\{R(SO_3–sal)_2en\}$ (4):** The procedure was similar to the one used for complex **2**. A green solid was obtained. Yield: 0.053 g, 50.0%. $C_{16}H_{18}N_2O_8S_2Cu\cdot 2H_2O$ (531.03), {$[Cu\{R(SO_3–sal)_2en\}]\cdot 2H_2O$}: calcd. C 36.26, H 4.18, N 5.29, S 12.10; found C 36.2, H 4.5, N 5.1, S 12.5.

**$Ni(pyr_2en)$ (5):** $Pyr_2en$ (0.5 g, 1.4 mmol) was dissolved in methanol (25 mL) containing a few drops of a KOH solution. $Ni(CH_3COO)_2\cdot 4H_2O$ (0.35 g, 1.4 mmol) dissolved in methanol/water (1:1, 25 mL) was slowly added and the mixture became orange. The pH was adjusted to 7 by the addition of methanolic HCl. An orange solid precipitated and was collected by filtration and washed with water, methanol, and diethyl ether, and dried under vacuum. Yield: 0.53 g, 85%. $C_{18}H_{20}N_4O_4Ni\cdot 1.7H_2O$ (445.70) {$[Ni(pyr_2en)]\cdot 1.7H_2O$}: calcd. C 48.51, H 5.29, N 12.57; found C 48.5, H 5.6, N 12.3. $^1H$ NMR [300 MHz, $(CD_3)_2SO$, 297 K]: $\delta$ = 8.23 (s, 2 H, CH=N), 7.47 (s, 2 H, $CH_{arom}$), 4.50 (s, 4 H, $CH_2CH_2$), 3.56 (s, 4 H, $CH_2OH$) and 2.51 (s, 6 H, $CH_3$) ppm. ESI-MS ($H_2O$): $m/z$ = 415.2 $[M + 1]^+$.

**$Ni(Rpyr_2en)$ (6):** The procedure was similar to the one used for **5**. A pink complex was obtained. Yield: 0.47 g, 72%. $C_{18}H_{24}N_4O_4Ni\cdot 2.4H_2O$ (462.34), {$[Ni(Rpyr_2en)]\cdot 2.4H_2O$}: calcd. C 46.76, H 6.28, N 12.12; found C 47.0, H 6.8, N 11.8. $^1H$ NMR [300 MHz, $(CD_3)_2SO$, 297 K]: $\delta$ = 6.97 (s, 2 H, $CH_{arom}$), 4.92 (s, 4 H, $CH_2OH$), 4.24 (s, 4 H, $CH_2NH$), 3.40 (s, 4 H, $CH_2$ $CH_2$), 2.75 (s, 6 H, $CH_3$) ppm. ESI-MS ($H_2O$): $m/z$ = 419.2 $[M + 1]^+$.

**$Ni[(SO_3–sal)_2en]$ (7):** The procedure was similar to the one used for the preparation of **5**. An orange solid was obtained. Yield: 0.35 g, 82%. $C_{16}H_{12}N_2O_8S_2NiK_2\cdot 3.8H_2O$ (629.75) {$K_2\{Ni[(SO_3–sal)_2en]\cdot 3.8H_2O$} calcd. C 30.52, H 3.14, N 4.45, S 10.18; found C 30.7, H 2.5, N 5.2, S 8.7. $^1H$ NMR [300 MHz, $D_2O$, 297 K]: $\delta$ = 7.97 (s, 2

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

H, CH=N), 7.74 (s, 2 H, $CH_{arom}$), 7.55 (d, 2 H, $CH_{arom}$), 6.87 (d, 2 H, $CH_{arom}$), 3.45 (s, 4 H, $CH_2CH_2$).

**Ni[R(SO$_3$–sal)$_2$en] (8):** The procedure was similar to the one used for the preparation of **5**. Since there was no precipitation at pH 7 the solution was evaporated to dryness. Methanol was added to the residue, which did not dissolve everything. The solid was filtered, washed with methanol and diethyl ether, and dried under vacuum. After a few hours the grey solid obtained turned soft pink and after a week brown. Yield: 0.52 g, 62.0%. $C_{16}H_{16}N_2O_8S_2NiK_2{\cdot}8.5H_2O$ (718.45) {$K_2${Ni[R(SO$_3$–sal)$_2$en]·8.5H$_2$O} calcd. C 26.75, H 4.63, N 3.90, S 8.92; found C 27.1, H 4.0, N 4.0, S 7.2. ESI-MS ($H_2O$): $m/z$ = 565.0 $[M + 2K + 1]^+$ and 603.0 $[M + 3K]^+$.

**Physical and Spectroscopic Studies:** Infrared spectra were recorded with a BioRad FTS 3000 MX FTIR spectrometer. UV/Visible spectra were recorded either with a Hitachi U-2000, a Perkin–Elmer Lambda 9 UV/Vis/NIR, or an HP 8452A diode array spectrophotometer. The EPR spectra were recorded with a Bruker ESP 300E X-band spectrometer. $^1$H NMR spectra were recorded with a Varian Unity 300 spectrometer at probe temperature.

**X-ray Crystal Structure Determination:** Three-dimensional X-ray data were collected with a Bruker SMART 1000 CCD diffractometer by the $\varphi$-$\omega$ scan method. Data was collected at room temperature. Reflections were measured from a hemisphere of data collected from frames each covering 0.3° in $\omega$. Of the 12502 reflections measured, all of which were corrected for Lorentz and polarization effects, and for absorption by semi-empirical methods based on symmetry-equivalent and repeated reflections, 1941 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. Because of the crystal nature (possibly pseudo-merohedrally twined emulating a metrically orthorhombic cell) and diffraction capabilities, some discrepant reflections were suppressed. Complex scattering factors were taken from the program package SHELXTL.[39] The structures were solved by direct methods and refined by full-matrix least-squares methods on $F^2$. The hydrogen atoms were included in calculated positions and refined by using a riding model, except the hydrogen atoms from the water molecules. Hydrogen atoms H(11W) and H(21W) of one water molecule were located from a difference electron density map and fixed to 0.97 Å from the corresponding heteroatom. Hydrogen atoms of the other two water molecules were left to refine freely. Refinement converged with allowance for thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron densities are: –0.586 and 0.758 e Å$^{-3}$. Crystal data and details on data collection and refinement are summarized in Table 5.

Table 5. Crystal data collection and refinement.

CCDC-287242 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Solution Studies:** All solutions were manipulated in an inert atmosphere (high purity nitrogen or purified argon). The stock solution of $Cu^{II}$ was prepared and standardized as described earlier.[40] The $Ni^{II}$ stock solution was prepared by dissolving $NiCl_2$ of puriss quality in HCl solution. The $Ni^{II}$ content was determined by complexometry with EDTA, and the free acid content was measured pH-metrically. The ionic strength was adjusted to 0.2 mol dm$^{-3}$ with KCl. For pH-potentiometric measurements the temperature was 25.0 ± 0.1 °C, and for Vis spectra 25.0 ± 0.3 °C with circulating water.

**pH Measurements**

**Spectroscopic Measurements:** For the preparation of the solutions and pH calibrations we used a special glass vessel with a double wall, with entries for the combined electrode (Radiometer "Red Rod" pHC2015–8), thermometer, nitrogen, and reagents (e.g. base). A computerized system developed locally was used to control the titration conditions for pH calibrations. The emf measurements were performed with a Denver Model 15 pH meter.

**pH-Potentiometric Titrations:** Stability constants were determined from pH-metric titrations of 25 mL samples. The ligand concentrations were in the range 0.001–0.004 mol dm$^{-3}$ and the metal ion to ligand molar ratio was varied from 1 to 4 (up to 10 for the Ni–Rpyr$_2$en system). Titrations were normally made from pH 2.0 up to 11.7, but some titration curves started at 1.7, with a KOH solution of known concentration (ca. 0.2 mol dm$^{-3}$) under a purified argon atmosphere. The reproducibility of titration points included in the evaluation was within 0.005 pH units over the whole pH range. For the $Cu^{II}$– and $Ni^{II}$–Rpyr$_2$en systems 5 and 7 titration curves were measured, respectively.

The pH was measured with an Orion 710A precision digital pH meter equipped with an Orion Ross 8103BN type combined glass electrode, calibrated for hydrogen ion concentration as described earlier.[41] The ionic product of water was p$K_w$ = 13.76. The concentration stability constants $\beta_{pqr} = [M_pL_qH_r]/[M]^p[L]^q[H]^r$ were calculated with the aid of the PSEQUAD computer program.[31] When referring to stoichiometries of complexes present in solution the normal $M_pL_qH_r$ notation is used, where L = Rpyr$_2$en$^{2-}$.

**Spectroscopic Measurements:** Visible absorption spectra were measured using cells with 0.1, 1, or 3 cm path lengths. The spectral range covered was normally 300–900 nm, and in some cases 350–1100 nm. For the $Cu^{II}$–Rpyr$_2$en system the EPR (at 77 K) and Vis spectra were recorded varying the pH and using a ligand to metal ratio of approximately 1 and $C_{Cu} \approx 5$ mmol dm$^{-3}$. To obtain data for the low pH range individual samples containing the same metal ion concentration and L/M ratio were also prepared by adding different amounts of HCl. A calibration curve ($E_{measured}$ versus p[H$^+$]) was measured to determine the system response to the [H$^+$] of the samples. The standards were prepared by mixing various accurately

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

known volumes of HCl of known concentration (ca. 0.1 mol dm$^{-3}$) with water. The Vis ($300 < \lambda < 900$ nm) and room temperature EPR spectra of these samples were recorded and used for the determination of the speciation model at low pH, namely the $\log\beta$ of $CuLH_2$ with the PSEQUAD program.[31]

For the $Ni^{2+}$–$Rpyr_2en$ system the spectral range covered was 190–820 nm (for the quantitative evaluation only the 390–820 nm range was used). The absorption spectra were recorded at L/M ratios of 1 and 4 (the total concentrations of the $Ni^{II}$ [$C_M$] were 0.004 and 0.002 mol dm$^{-3}$, respectively). All other experimental conditions were as described for the pH-potentiometric titrations. For the solutions with a L/M ratio of 1 ($C_{Ni}$ = 0.004 mol dm$^{-3}$) precipitation of a pink compound occurred at pH ca. 8.3; this was not observed for solutions with L/M ratios of 4. With the latter solutions, the increasing absorbance of the baseline above pH ca. 9.2 suggested the presence of small amounts of precipitate. In order to confirm the octahedral geometry of the complexes Vis spectra with a L/M ratio of 1 and $C_{Ni}$ = 0.003 mol dm$^{-3}$ were measured at several pH values (3.0–7.7) in the 350–1100 nm range.

In the absence of ethylene glycol a relatively broad background was present in most of the frozen solution EPR spectra; therefore most spectra were run with solutions containing 5% of ethylene glycol.

For the $^1$H NMR measurements, solutions containing $Ni^{II}$ and $Rpyr_2en$ with a L/M ratio of 1 (5 mmol dm$^{-3}$) and 4 (16:4 mmol dm$^{-3}$) were prepared in $D_2O$ (DSS, sodium 3-trimethylsilyl-[$D_4$]propionate, as internal reference), and the pD was adjusted with DCl or $CO_2$ free KOD, using a Crison micropH 2002 instrument fitted with a combined Mettler Toledo U402-M3 S7/200 microelectrode. The microelectrode was previously calibrated with standard buffered aqueous solutions and –log[$D^+$] was measured directly in the NMR tubes. The final values of pD were determined from pD = pH* + 0.40, where pH* corresponds to the reading from the pH meter previously calibrated with two aqueous buffers at pH 4 and 7.

Mass spectrometer experiments were performed with a LCQ Duo (Finnigan, San Jose, CA, USA) ion trap mass spectrometer equipped with an electrospray ion source, operated in the positive mode and maintained at 4.5 kV. The temperature of the heated capillary was set to 200 °C. The flow rate of the electrospray solution was 5 μL min$^{-1}$. Other parameters, including capillary voltage, lens, and octapole voltages and sheath gas flow rate were optimized for maximum abundance of the ions of interest.

The ESI mass spectra measurements were done with solutions of nickel complexes **5**–**8** ($1 \times 10^{-4}$ mol dm$^{-3}$) and of solutions containing $Ni^{II}$ and $Rpyr_2en$ with a L/M ratio of 1 (1 mmol dm$^{-3}$) and 4 (4:1 mmol dm$^{-3}$). All solutions were prepared with deionized water.

**Supporting Information** (see also the footnote on the first page of this article): **ESI-1** Crystalline packing in complex Ni(pyr$_2$en)·3H$_2$O (**1**). **ESI-2** EPR spectra of complex Cu[R-(SO$_3$–sal)$_2$en] (**4**) and $[Cu(OH_2)_6]^{2+}$ in $H_2O$. **ESI-3** Visible spectra for the $Ni^{II}$–$Rpyr_2en$ system with L/M = 1 and 4.

# Study on the Photochromism of Ni–Al Layered Double Hydroxides Containing Nitrate Anions

**Min Wei,[a] Xiangyu Xu,[a] Xinrui Wang,[a] Feng Li,[a] Hui Zhang,[a] Yanluo Lu,[a] Min Pu,[a] David G. Evans,[a] and Xue Duan*[a]**

**Keywords:** Layered compounds / Photochromism / Host–guest systems

The photochromism of nitrate-containing nickel–aluminum layered double hydroxides (NiAl-$NO_3$-LDHs) has been studied. Powder X-ray diffraction (PXRD), FTIR, UV/Vis, XPS, ESR, EXAFS, and elemental analysis were used to investigate the structure, composition, and photochromic behavior of NiAl-$NO_3$-LDHs. A possible photochromic mechanism in NiAl-$NO_3$-LDHs has been proposed.

## Introduction

Layered double hydroxides (LDHs) consist of metal brucite type layers – $Mg(OH)_2$ sheets where octahedra of $Mg^{2+}$ ions, sixfold coordinated to $OH^-$, share edges to form two-dimensional infinite sheets. LDHs constitute a vast family of compounds of general formula $[M^{II}_{1-x}M^{III}_x(OH)_2]A^{y-}_{x/y}\cdot nH_2O$, where $x$ typically varies between 0.20 and 0.33. They are stacks of positively charged, partially substituted brucite-like layers that are spaced by exchangeable $A^{y-}$ anions and water molecules.[1,2] LDHs are attractive materials for various fields of application such as catalysis,[3] optical materials,[4,5] biomimetic catalysis,[6,7] separation science,[8,9] medical science,[10,11] and electrochemistry.[12,13]

Recently, research on photochromic materials has received much attention because of the potential use of these materials in photonic applications. Practical applications are also well established, for example, in optical transmission.[14] Photochromism is also widely utilized from the molecular level up to complete devices; representative examples are molecular switching of host–guest aggregates,[15,16] sol–gel thin films,[17] and pigment–protein complexes involved in proton pumping.[18] However, there are very few reports of LDHs being used as candidates for photochromic materials. It has been reported that a sulfonated spiropyran dye (SP-$SO_3^-$) intercalated in Mg–Al, Zn–Al, and Li–Al LDHs exhibited photochromism due to interlayer reversible photoisomerization between SP-$SO_3^-$ and photoinduced merocyanine.[19,20]

Although photochromism resulting from the properties of the interlayer organic guest has been observed in LDH composites, the mechanism related to the host–guest interaction has not been reported. In this paper, we report for the first time photochromism in a NiAl-$NO_3$-LDH. PXRD, FTIR, UV/Vis, ESR, XPS, EXAFS, and elemental analysis were used to investigate the photochromic behavior, and its possible mechanism has also been proposed.

## Results and Discussion

### The Crystalline Structure and Chemical Composition of NiAl-$NO_3$-LDHs

Figure 1 shows the PXRD pattern for NiAl-$NO_3$-LDHs. A typical PXRD pattern was found for NiAl-$NO_3$-LDHs prepared by a hydrothermal method (a profile similar to those observed in hydrotalcite-like compounds): sharp and symmetric peaks related to 00$l$ reflections and broad and less symmetric peaks related to 0$kl$ reflections (Figure 1). The peaks were indexed in a hexagonal cell with rhombohedral symmetry, where $c$ = 26.79 Å and $a$ = 3.00 Å. The $d_{003}$ parameter, which corresponds to an interlayer distance of 8.93 Å, is typical for hydrotalcite-like materials containing nitrate anions.[2]

On the basis of elemental analysis, the chemical composition of this particular NiAl-$NO_3$-LDH (Ni/Al = 2) was found to be $[Ni_{0.643}Al_{0.357}(OH)_2](NO_3^-)_{0.357}\cdot 0.7H_2O$ (calcd. H 2.92, Al 8.29, N 4.30, Ni 32.62; found H 3.01, Al 8.15, N 4.23, Ni 33.49).

Figure 2A shows the Ni $K$-edge $k^1\chi(k)$ spectrum and Fourier transform magnitude of the powdered NiAl-$NO_3$-LDH, while Figure 2B displays the experimental (solid) and fitted (dotted) EXAFS curves with $k^1$-weight for Ni–O coordination in the powdered NiAl-$NO_3$-LDH. The fitting parameters are listed in Table 1 [$Ni(OH)_2$ was used as a reference sample]. Data analysis suggests a Ni–O distance of 2.04 Å and a Ni–O coordination number ($CN_{Ni-O}$) of six

for the NiAl-$NO_3$-LDH, which corresponds well to the data reported by Scheidegger et al.[21] This reveals that the first coordination shell of Ni comprises six oxygen atoms at 2.04 Å, indicating that $Ni^{II}$ is coordinated in an octahedral environment.

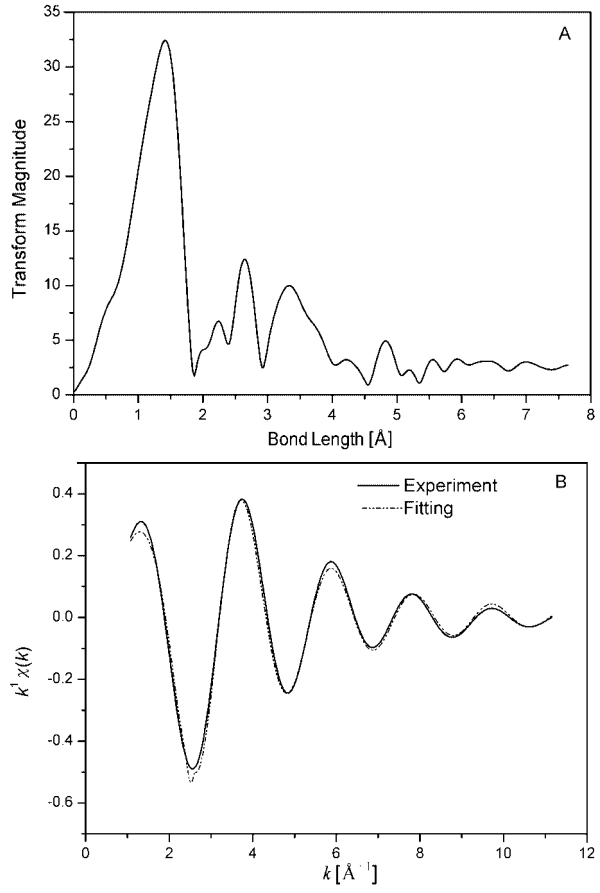

Figure 2. (A) Ni *K*-edge $k^1\chi(k)$ spectrum and Fourier transform magnitude of powdered NiAl-$NO_3$-LDH. (B) Experimental (solid line) and fitted (dotted line) EXAFS curves with $k^1$-weight for Ni–O coordination in powdered NiAl-$NO_3$-LDH.

Table 1. Local coordination parameters around Ni in powdered NiAl-$NO_3$-LDH.

| Sample | $CN_{Ni-O}$ | $R_{Ni-O}$ [Å] | $\sigma^2_{Ni-O}$ [Å]$^2$ |
|---|---|---|---|
| $Ni(OH)_2$ | 6.0 | 2.05 | 0.002 |
| NiAl-$NO_3$-LDH | 6.0 | 2.04 | 0.003 |

### Photochromism in NiAl-$NO_3$-LDHs

Photochromism in NiAl-$NO_3$-LDHs has been observed for the first time in this work. Figure 3c shows the UV/Vis absorption spectra of NiAl-$NO_3$-LDH both before and after UV irradiation. For the as-synthesized NiAl-$NO_3$-LDH sample before UV irradiation, two absorption peaks (at ca. 376 and 652 nm) were observed, which were assigned to the (d–d) spin-allowed electronic transitions expected for a $Ni^{2+}$ ion in an octahedral crystal field.[22] Upon irradiation of NiAl-$NO_3$-LDH with UV light, the green samples rapidly turned black. Furthermore, there was a remarkable enhancement of absorption in the wavelength range 300–650 nm (Figure 3c). No change in color could be observed, even when the black-colored NiAl-$NO_3$-LDH was kept at room temperature for a week. However, upon heating to 70 °C for 2 h, the color returned to green. The UV/Vis absorption spectrum also recovered its original profile (dotted line shown in Figure 3c, almost coincident with the initial spectrum), demonstrating the reversibility of the photochromism. Moreover, both the reversibility and reproducibility of the photochromism were investigated. The inset in Figure 3 displays the UV absorbance of this material at 500 nm, before and after ten irradiation cycles, indicating a rather high reversibility and reproducibility.

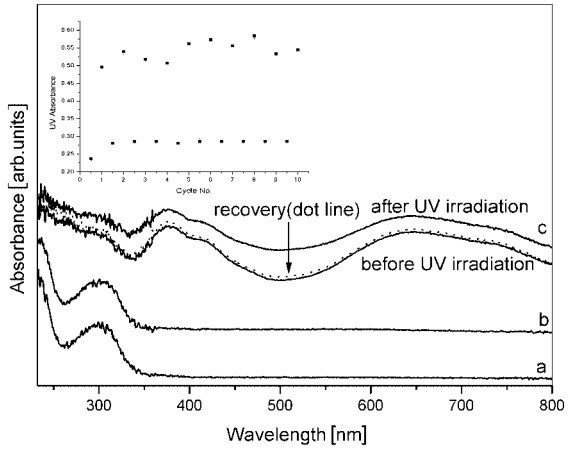

Figure 3. UV/Vis absorption spectra of (a) MgAl-$NO_3$-LDH, (b) ZnAl-$NO_3$-LDH and (c) NiAl-$NO_3$-LDH, before and after UV irradiation [absorption curves of before and after UV irradiation for (a) and (b) are coincident]. Inset: the relationship between the UV absorbance of NiAl-$NO_3$-LDH at 500 nm (before and after irradiation) and cycle number.

### The Photochromic Mechanism in NiAl-$NO_3$-LDHs

#### *Influence of Nickel Ions*

In order to study the effect of the nickel ions of the host layers on photochromic behavior, MgAl-$NO_3$-LDH and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ZnAl-$NO_3$-LDH were prepared as samples for comparison. All three samples exhibit a PXRD pattern characteristic of LDH-like materials, and the interlayer distance of the three intercalates is about 0.88 nm, indicating well-defined LDHs containing nitrate anions.

Figure 3 displays the UV/Vis absorption spectra of the three samples, both before and after UV irradiation. No obvious change could be observed in the spectra of MgAl- and ZnAl-$NO_3$-LDHs after UV-light irradiation (Figure 3a and Figure 3b, respectively). This observation is in agreement with their invariable white color, and in contrast with the photochromic behavior that was observed in the case of NiAl-$NO_3$-LDH, as described above. This indicates that the nickel ions in the host layer play an important role in the photochromic behavior. This is possibly related to the octahedral coordination environment of the nickel ion.

### *Influence of Aging Conditions*

Figure 1 and Figure 4 display the PXRD patterns of NiAl-$NO_3$-LDHs with different aging times and aging temperatures, respectively. All nine samples exhibit a PXRD pattern characteristic of LDH-like materials, with an interlayer distance of approximately 0.89 nm. It can be seen from Figure 1 and Figure 4 that the reflection intensity of the LDHs becomes stronger with an increase in the aging time or aging temperature. The indexing parameters are listed in Table 2. It should be noted that there is a decrease in the half-peak-width parameter, and an increase in the crystallite size in the *c* direction, upon increasing aging time or temperature. This is an indication that the stacking sequences of the LDHs become more ordered and higher crystallinity is obtained with increasing aging time or temperature.

Figure 5A and Figure 6A show the UV/Vis absorption spectra of powdered NiAl-$NO_3$-LDHs with different aging times and temperatures, respectively, both before and after UV irradiation. On irradiation the samples prepared with a 6 h aging time, or at 70 °C aging temperature, show the most remarkable enhancement of absorption in the wavelength range 300–650 nm. They are also accompanied by

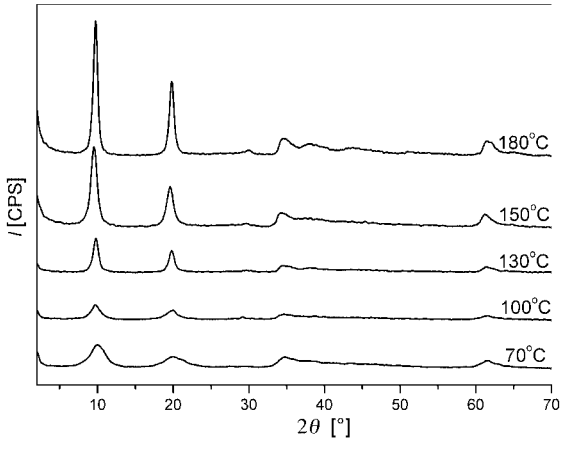

Figure 4. Powder XRD patterns of NiAl-$NO_3$-LDH aged for 24 h at different aging temperatures.

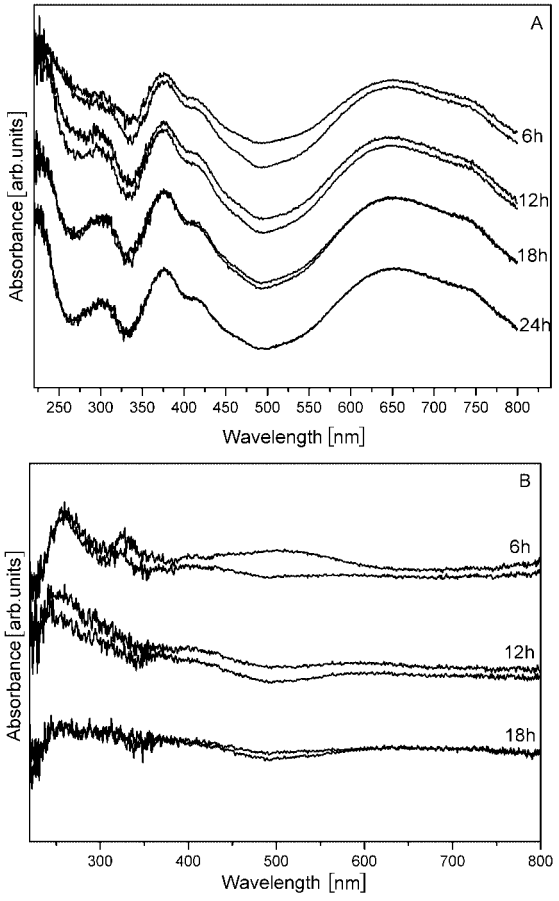

Figure 5. (A) UV/Vis absorption spectra of NiAl-$NO_3$-LDHs with different aging times at 180 °C, before and after UV irradiation. (B) Background correction for the absorption spectra of the NiAl-$NO_3$-LDHs from (A) before and after UV irradiation.

Table 2. Lattice parameters of NiAl-$NO_3$-LDHs prepared under different conditions.

| Parameters | Samples with different aging temperatures | | | | | Samples with different aging times | | | |
|---|---|---|---|---|---|---|---|---|---|
| | 70 °C | 100 °C | 130 °C | 150 °C | 180 °C | 6 h | 12 h | 18 h | 24 h |
| $d_{003}$ [nm] | 0.879 | 0.904 | 0.927 | 0.903 | 0.906 | 0.893 | 0.900 | 0.912 | 0.906 |
| half-peak width of the 003 reflection [°] | 1.810 | 1.270 | 0.933 | 0.808 | 0.515 | 0.866 | 0.613 | 0.583 | 0.515 |
| $d_{110}$ [nm] | 0.151 | 0.151 | 0.151 | 0.151 | 0.151 | 0.150 | 0.151 | 0.152 | 0.151 |
| lattice parameter *a* [nm][a] | 0.302 | 0.302 | 0.302 | 0.302 | 0.302 | 0.300 | 0.302 | 0.304 | 0.302 |
| lattice parameter *c* [nm][b] | 2.637 | 2.712 | 2.781 | 2.709 | 2.718 | 2.679 | 2.700 | 2.736 | 2.718 |
| crystallite size in *c* direction [nm][c] | 4.361 | 6.215 | 8.458 | 9.768 | 15.32 | 9.115 | 12.88 | 13.54 | 15.32 |

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the most obvious change in sample color, which indicates the most significant photochromism. Moreover, the enhancement of the absorption in the range 300–650 nm decreased upon increasing aging time or temperature. As the aging time was increased to 24 h, or the aging temperature was increased to 180 °C, no change could be observed in either the absorption spectra or the sample color following UV-light irradiation, which implied the absence of photochromic behavior. On the basis of the PXRD characterization above, it can be concluded that the ordered stacking sequences and the crystallinity of NiAl-$NO_3$-LDH have a marked influence on its photochromism. Moreover, the effect of the wavelength of the excitation light has been studied, and it was found that UV light with a wavelength below 376 nm could cause photochromism in the material.

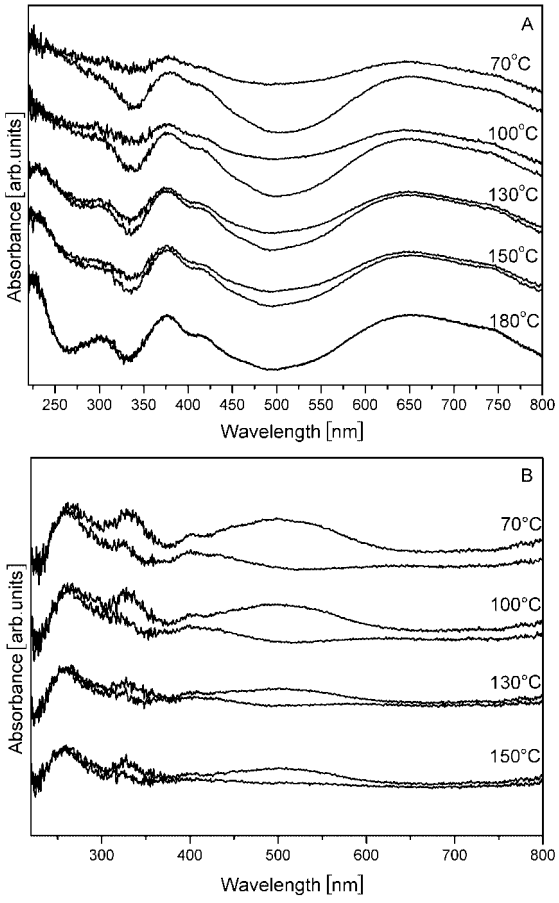

Figure 6. (A) UV/Vis absorption spectra of NiAl-$NO_3$-LDHs with different aging temperatures and aged for 24 h, before and after UV irradiation. (B) Background correction for the absorption spectra of the NiAl-$NO_3$-LDHs from (A) before and after UV irradiation.

In order to gain direct insight into photochromism in NiAl-$NO_3$-LDH, the NiAl-$NO_3$-LDH samples which were nonphotochromic (aging time 24 h and aging temperature 180 °C) were used as the baseline reference for further analysis of the UV/Vis spectra. Background correction was performed by subtracting the absorption spectrum of the nonphotochromic sample from the photochromic NiAl-$NO_3$-LDH samples, both before and after UV irradiation. The results are shown in Figure 5B and Figure 6B. Comparing the UV/Vis absorption spectra before and after UV irradiation, it can be seen that there is an obvious peak at approximately 500 nm. This indicates that there might be some specific structural unit, with Ni in an octahedrally coordinated environment, which results in photochromism in NiAl-$NO_3$-LDH. As the aging time or temperature increases, the stacking sequences of the LDHs become more ordered, leading to the loss of the specific structural unit and thus to the loss of photochromic behavior.

### *Influence of Host–Guest Interactions*

In order to study the influence of host–guest interactions, two samples of NiAl-$CO_3$-LDH were prepared: one by the ion-exchange method from a NiAl-$NO_3$-LDH precursor and the other by direct coprecipitation. Both samples exhibit a PXRD pattern characteristic of LDH-like materials, with an interlayer distance of approximately 0.76 nm, indicating well-defined LDHs containing carbonate anions. Figure 7 displays a comparison of the FTIR spectra of the two NiAl-$CO_3$-LDH samples. Both show the strong, sharp band at approximately 1363 $cm^{-1}$ due to the absorption of interlayer carbonate anions. However, it can be seen that a peak at approximately 1384 $cm^{-1}$ was observed in the sample prepared by ion-exchange (Figure 7a), which indicates the presence of a small amount of nitrate anions.

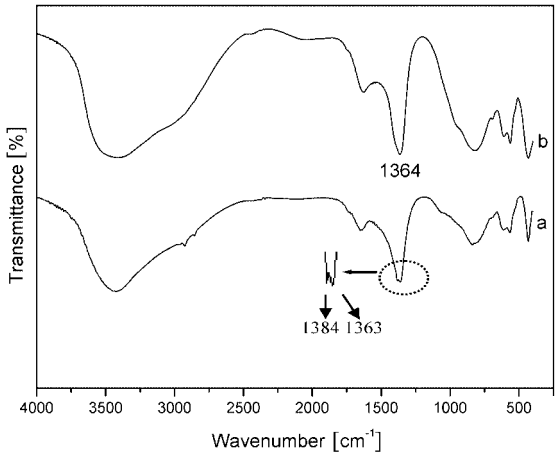

Figure 7. FTIR spectra of NiAl-$CO_3$-LDHs prepared by (a) ion exchange and (b) coprecipitation.

On the basis of elemental analysis, the chemical composition of the NiAl-$CO_3$-LDH that was prepared by coprecipitation was found to be $[Ni_{0.656}Al_{0.344}(OH)_2](CO_3^{2-})_{0.172}\cdot 0.8H_2O$ (calcd. C 2.06, H 3.37, Al 8.70, Ni 36.27; found C 2.12, H 3.31, Al 8.73, Ni 36.19). However, the chemical composition of the NiAl-$CO_3$-LDH that was prepared by the ion-exchange method from a NiAl-$NO_3$-LDH precursor was found to be $[Ni_{0.647}Al_{0.353}(OH)_2](CO_3^{2-})_{0.151}(NO_3^{-})_{0.051}\cdot 0.7H_2O$ (calcd. C 1.70, H 3.19, Al 8.95, N 0.67, Ni 35.83; found C 1.62, H 3.13, Al 8.86, N 0.71, Ni 35.76). It can be seen that the sample prepared by coprecipitation was a pure $CO_3^{2-}$ LDH, while the other one, prepared by ion-exchange from a NiAl-$NO_3$-LDH precursor, contained both $CO_3^{2-}$ and a little unexchangeable $NO_3^{-}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figure 8a and b show the UV/Vis absorption spectra of the two powdered NiAl-$CO_3$-LDH samples before and after UV irradiation. It was found that almost no change in the absorption spectrum, after UV-light irradiation, could be observed for the NiAl-$CO_3$-LDH prepared by coprecipitation (Figure 8b), which means that photochromism is not an intrinsic property of NiAl-$CO_3$-LDHs. However, in the case of the sample prepared by ion exchange, a considerable enhancement in the 300–650 nm range (Figure 8a) was observed after UV irradiation. This is an indication that the interaction between $Ni^{2+}$ and co-intercalated nitrate anions is indispensable for the photochromism in NiAl-$CO_3$-LDHs prepared by ion exchange. This is possibly related to the remaining nitrate anions that interact strongly with $Ni^{2+}$ ions in NiAl-$NO_3$-LDHs through chemical bonding and thus cannot be exchanged by $CO_3^{2-}$.

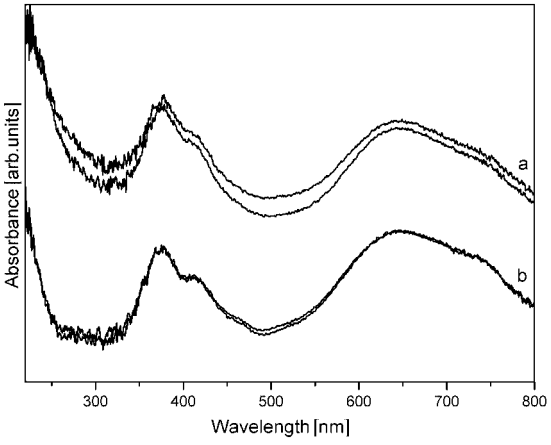

Figure 8. UV/Vis absorption spectra of powdered NiAl-$CO_3$-LDHs, both before and after UV irradiation, prepared by (a) ion exchange and (b) coprecipitation.

### *XPS Data*

In order to confirm whether the photochromic behavior of NiAl-$NO_3$-LDHs is related to the redox of $Ni^{2+}$, XPS was used to determine the chemical environment of Ni, N, and O before and after UV irradiation. The XPS Ni2$p_{3/2}$, N1s, and O1s core level spectra of NiAl-$NO_3$-LDHs, before and after UV irradiation, are shown in Figure 9. The binding energy (BE) value of the main Ni2$p_{3/2}$ peak, at around 856.4/856.5 eV, is assigned to the $Ni^{2+}$ ion by comparison with the known BE value for Ni2$p_{3/2}$ photoelectrons in $Ni(OH)_2$ (855.6–856.6 eV).[23] The XPS N1s peak at around 406.6/406.7 eV is attributed to $N^{5+}$ from the nitrate anions, and the XPS O1s peak at around 531.9/531.8 eV is due to $O^{2-}$ from the nitrate anions. As no remarkable change in the values of the BE can be observed after UV irradiation, it is reasonable to deduce that the oxidation states of Ni, N, and O in NiAl-$NO_3$-LDHs do not change, and hence a mechanism based on the redox of $Ni^{2+}$ can be excluded.

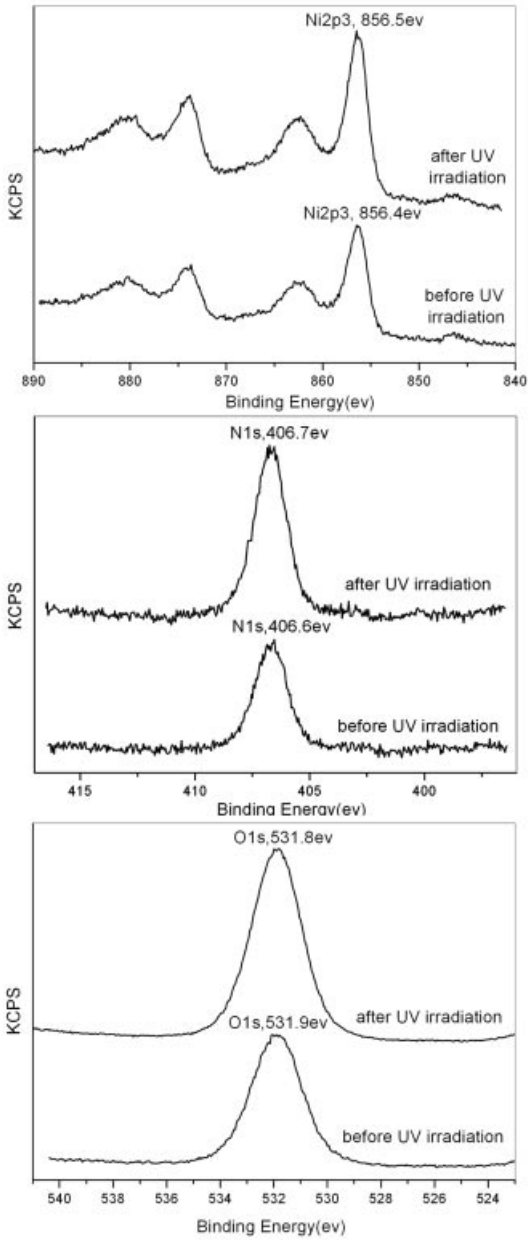

Figure 9. XPS spectra of Ni2$p_{3/2}$, N1s, and O1s for NiAl-$NO_3$-LDHs before and after UV irradiation.

### *ESR Data*

ESR was used to study the coordination environment of $Ni^{2+}$ in NiAl-$NO_3$-LDHs to obtain a further understanding of the photochromic mechanism. It has been reported that $Ni^{2+}$ ions in $Ni(OH)_2$ are ESR silent at room temperature, most probably because of the regular octahedral crystal field.[22] Figure 10 displays the ESR spectra of powdered NiAl-$NO_3$-LDH before and after UV irradiation, as well as that of NiAl-$CO_3$-LDH prepared by coprecipitation, as a reference sample. It can be seen from Figure 10a that NiAl-$CO_3$-LDH is ESR silent at room temperature and at liquid nitrogen temperature, because of its Ni–OH regular octahedral crystal field. However, in the case of NiAl-$NO_3$-LDH, distinct signals with $g$ = 2.163 (Figure 10b) and $g$ = 2.643

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(Figure 10c) were observed for the sample before and after UV irradiation, respectively. These can be attributed to $Ni^{2+}$ ions ($3d^8$ electronic configuration) in a strongly distorted octahedral crystal field.[22] The difference in the *g* values indicates that the distortion in the octahedral crystal field for NiAl-$NO_3$-LDH is not completely the same before and after UV irradiation.

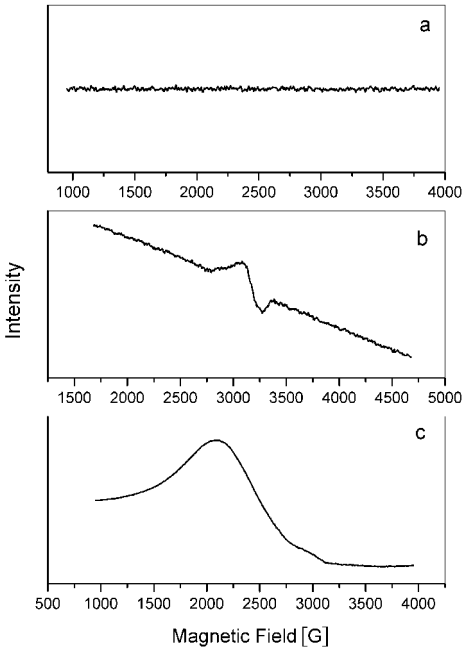

Figure 10. ESR spectra of powdered NiAl-$CO_3$-LDH prepared by coprecipitation (a), and NiAl-$NO_3$-LDHs before irradiation (b) and after irradiation (c).

On the basis of the discussion above, it can be concluded that the host–guest interaction between $Ni^{2+}$ and the nitrate anions, and thus the presence of the specific octahedral crystal field of the $Ni^{2+}$, leads to photochromism in NiAl-$NO_3$-LDHs. Single-crystal structure analysis of CaAl-$NO_3$/$CO_3$/$SO_4$/Cl-LDHs has revealed that $Ca^{2+}$ ions are sevenfold coordinated by O atoms. A water molecule, a carbonate anion, or a nitrate anion occupies the seventh coordination site of three of the four $Ca^{2+}$ ions contained in the main layer.[24–27] Moreover, Steven et al. reported that, in the layered material $Ni_2(OH)_3NO_3$, the nitrate anion was located in the interlayer region and was coordinated through one oxygen atom directly to the matrix $Ni^{2+}$ cation.[28] In the current study, taking into account the confirmation by EXAFS data that $Ni^{2+}$ ions are sixfold coordinated (Table 1), the evidence from ESR data that $Ni^{2+}$ ions exist in a distorted octahedral crystal field, and the presence of unexchangeable $NO_3^-$, it can be concluded that there are specific units of octahedral structure in which $Ni^{2+}$ is coordinated by five hydroxy groups and one nitrate anion through the O atom in NiAl-$NO_3$-LDH, as shown in Figure 11. The influence of water cannot be excluded completely, and there is the possibility that a hydrogen-bonding system exists between the host hydroxy and nitrate anions, and water molecules, and thus water has a secondary influence on the photochromism of NiAl-$NO_3$-LDH (as shown in Figure 11). Further studies on the effects of water, as well as theoretical calculations, are under investigation at our laboratory.

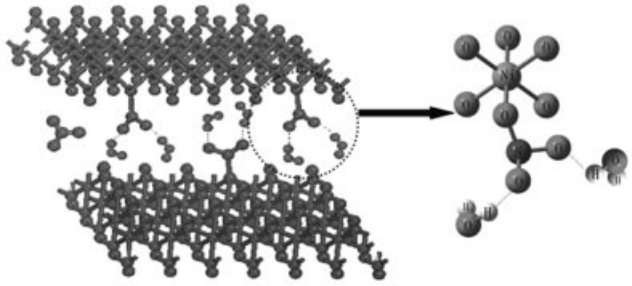

Figure 11. Schematic representation of the structure of NiAl-$NO_3$-LDH.

The electronic configuration of $Ni^{2+}$ ions in the ground state is $3d^8$ ($t_{2g}^6e_g^2$). As shown in Figure 12a, the octahedral crystal field of the $Ni^{2+}$ ions is generated by the coordinated O atom of the nitrate anion, and is somewhat distorted with a *g* value of 2.163, derived from ESR spectroscopy data. Under UV-light irradiation, the electronic configuration of the $Ni^{2+}$ ions in the excited state is $3d^8$ ($t_{2g}^5e_g^3$), which speaks in favor of the Jahn–Teller effect, and thus leads to a more strongly distorted octahedral crystal field (Figure 12b). The latter structure is quite stable at room temperature and cannot revert spontaneously. In comparison with the sample before UV irradiation, it demonstrates changes in the UV/Vis absorption spectrum (especially the strong absorption enhancement in at a wavelength of 500 nm) and in the *g* value determined by ESR spectroscopy (from 2.163 to 2.634). Upon heating, the radiation-induced structure recovers its original state, and the color changes from black to green. Because the distorted octahedral structure [$Ni(OH)_5NO_3$] was a metastable state thermodynamically, it reverted to the stable regular octahedral unit [$Ni(OH)_6$] by substitution of the $NO_3^-$ by an $OH^-$ group upon increasing aging time or temperature during the preparation process. As a result, the specific octahedral crystal field of the $Ni^{2+}$ ion, coordinated by a nitrate anion, leads to photochromism in NiAl-$NO_3$-LDHs.

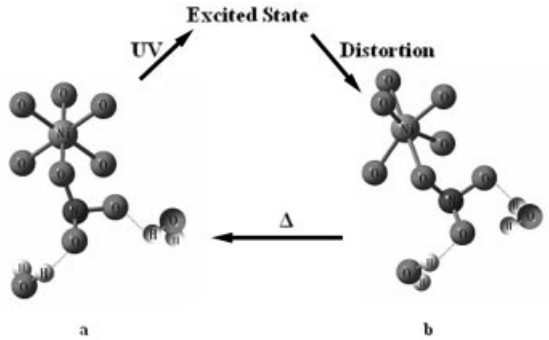

Figure 12. Photochromic mechanism in NiAl-$NO_3$-LDH: (a) structure before UV irradiation and (b) structure after UV irradiation.

## Conclusions

Photochromism in NiAl-$NO_3$-LDHs has been studied in this work. The crystalline structure and chemical composition of NiAl-$NO_3$-LDHs have been characterized on the basis of the results of PXRD, FTIR, EXAFS, and elemental analysis. The studies on the influence of aging conditions indicate that the host–guest interaction between the nickel ion in the host layer and the interlayer $NO_3^-$ plays an important role in its photochromic behavior. Taking into account the confirmation by EXAFS data that the $Ni^{2+}$ ions are sixfold coordinated, the ESR spectroscopy data that indicates that $Ni^{2+}$ is ESR active in NiAl-$NO_3$-LDHs, the confirmation of the presence of some unexchangeable $NO_3^-$, and the exclusion of the redox of $Ni^{2+}$, it can be concluded that there is a specific unit of distorted octahedral structure. This unit consists of a $Ni^{2+}$ ion, which is coordinated by O atoms from five hydroxy groups and one nitrate anion, and results in photochromism in NiAl-$NO_3$-LDHs.

## Experimental Section

**Preparation of NiAl-$NO_3$-LDH:** NiAl-$NO_3$-LDH was synthesized by a hydrothermal method.[29] Typically, an aqueous solution of NaOH (24 g, 0.6 mol) in deionized water (40 mL) was added dropwise to a vigorously stirred, freshly prepared solution containing $Ni(NO_3)_2{\cdot}6H_2O$ (58.156 g, 0.2 mol) and $Al(NO_3)_3{\cdot}9H_2O$ (37.513 g, 0.1 mol) ($Ni^{2+}/Al^{3+}$ = 2) in deionized water (100 mL) under a nitrogen atmosphere at room temperature. The final pH was approximately 6. The suspension was transferred to a Teflon-lined autoclave and heated at 70, 100, 130, 150, or 180 °C for a specific time. The solid precipitate was collected by filtration through a membrane filter under suction, washed thoroughly with water, and dried at 70 °C for 18 h.

**Preparation of MgAl-$NO_3$-LDH and ZnAl-$NO_3$-LDH:** MgAl-$NO_3$-LDH and ZnAl-$NO_3$-LDH, which were used as comparison samples, were synthesized by a hydrothermal method. MgAl-$NO_3$-LDH was synthesized by a procedure similar to that described previously.[30] A solution of $Mg(NO_3)_2{\cdot}6H_2O$ (32.0 g, 0.125 mol) and $Al(NO_3)_3{\cdot}9H_2O$ (11.7 g, 0.062 mol) in deionized water (200 mL) was added dropwise over 2 h to a solution of NaOH (12.5 g, 0.310 mol) and $NaNO_3$ (18.2 g, 0.210 mol) in water (250 mL). The mixture was transferred to a Teflon-lined autoclave and heated at 70 °C for 24 h. The precipitate was separated by centrifugation, washed with water, and dried at 70 °C for 18 h. ZnAl-$NO_3$-LDH was obtained by a similar method.

**Preparation of NiAl-$CO_3$-LDH:** NiAl-$CO_3$-LDH was prepared by both coprecipitation and ion exchange. The sample prepared by the coprecipitation method was synthesized according to a literature procedure.[31] In the case of the NiAl-$CO_3$-LDH sample obtained by ion exchange, the precursor NiAl-$NO_3$-LDH was synthesized first by the procedure described above. Subsequently, a solution of $Na_2CO_3$ in deionized water (50 mL) was added to a suspension of NiAl-$NO_3$-LDH in water (50 mL), and the mixture was then heated to 70 °C for 24 h. The product was washed extensively with deionized water, centrifuged, and dried at 70 °C for 18 h.

### Characterization Techniques

PXRD patterns were obtained by using a Shimadzu XRD-6000 diffractometer under the following conditions: Cu-$K_\alpha$ radiation ($\lambda$ = 1.542 Å, $2\theta$ = 2–70°), 40 kV, 30 mA. Infrared spectra of samples were recorded by using a Bruker Vector 22 FTIR spectrometer. Specimens were prepared as KBr pellets. Elemental analysis of the metal content was performed with an ICPS-7500 inductively coupled plasma optical-emission spectrometer. C, H, and N elemental analysis was carried out with an Elementar Vario elemental analyzer. The ESR spectra were recorded at room temperature with a Bruker ESP300 spectrometer. A standard 100 MHz field modulation and a 5–10 G modulation width were used. XPS was recorded with a VG Scientific ESCALab220i-XL (VG Scientific Ltd., UK) spectrometer.

The EXAFS spectrum around the Ni *K*-adsorption edge was obtained by using the beamline 4W1B of the Beijing Synchrotron Radiation Facility (BSRF). The NiAl-$NO_3$-LDH nanoparticles were homogeneously smeared on Scotch adhesive tape. More than eight layers were folded to reach the optimum absorption thickness. The X-ray absorption spectrum of the Ni *K*-edge of NiAl-$NO_3$-LDH was collected at ambient temperature in the transmission mode. The storage ring was operated at 2.2 GeV with a typical current of 50 mA. Fixed-exit Si(111) flat double crystals were used as a monochromator. The incident and transmission X-ray intensities were detected by using ion chambers installed in front of and behind the sample. The X-ray energy was calibrated by using the Ni *K*-absorption edge (8348 eV). The absorption spectrum was collected from 200 eV below the absorption threshold to over 700 eV above the threshold.

EXAFS data reduction was performed by using WinXAS 97 1.1 and following standard procedures. The first maximum of the first derivative of the absorption edge was chosen as the energy threshold. The pre-edge absorption background was fitted and subtracted by using a linear function. A derivative method was used to derive the EXAFS signal and remove the post-edge absorption background. EXAFS functions were normalized by using the absorption-edge jump and were Fourier-transformed to *R* space with $k^1$-weight in the range 1.1–11.3 Å. Fourier filters were used in the range 0.3–1.8 Å. Theoretical scattering paths for the fit were calculated by using the structures of α-$Ni(OH)_2$. To reduce the number of adjustable parameters, the amplitude reduction factor, $S_0^2$, was fixed at 1.1. The $R_{Ni–O}$ values are estimated to be accurate to 0.02 Å, and the $\Delta E_0$ and $CN_{Ni–O}$ values are estimated to be accurate to 20%. The accuracy estimates are based on the results of theoretical fits to the spectra of the reference compounds of known structure.

**Study of the Photochromic Properties of LDHs:** UV irradiation was carried out by using a 500-W xenon lamp. Absorption spectra were recorded by using a UV/Vis spectrophotometer (Shimadzu UV-2501 PC).

# Synthesis, Electrochemical and Electrogenerated Chemiluminescence Studies of Ruthenium(II) Bis(2,2′-bipyridyl){2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole} Complexes

**Roberto Gobetto,*[a] Giuseppe Caputo,[b] Claudio Garino,[a] Simona Ghiani,[a] Carlo Nervi,[a] Luca Salassa,[a,c] Edward Rosenberg,*[c] J. B. Alexander Ross,[c] Guido Viscardi,[d] Gianmario Martra,[b] Ivana Miletto,[d] and Marco Milanesio[e]**

**Keywords:** Electrochemistry / Luminescence / Ruthenium / ECL / Bioinorganic chemistry

A series of photoactive complexes of [$Ru^{II}$bis(bipyridyl){2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole}]$(PF_6)_2$ (X = N–$CH_3$, **1**; S, **2**; or O, **3**) have been synthesized and fully characterized by proton and $^{13}C$ NMR spectroscopy and UV/Vis spectroscopy. The X-ray structure of **1** is also reported. The electrochemical behavior and the photophysical properties of **1**–**3** have been investigated. Cyclic voltammetry (CV) reveals the presence of three consecutive one-electron reduction processes and a single one-electron oxidation process that are chemically and electrochemically reversible. In all cases, electrogenerated chemiluminescence (ECL) has been observed in the presence of the co-reactant tri-*n*-propylamine (TPA). An analogue of **1** has been synthesized, [$Ru^{II}$bis(bipyridyl){2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole}]$(PF_6)_2$ [X = $N(CH_2)_5CO_2H$, **4**], it has been coupled with bovine serum albumin (BSA), and its photophysical properties investigated.

## Introduction

Luminescent techniques are among the fastest-growing analytical tools in life science and analytical chemistry.[1] These techniques are useful because they couple high sensitivity and selectivity with automated monitoring. Furthermore, many parameters can be detected: luminescence intensity, quantum yield, lifetime, luminescence polarization, quenching efficiency, and radiative and nonradiative energy transfer.

In recent years, metal–ligand complexes (MLCs) have gained paramount importance in luminescence spectroscopy because of their wide range of absorption and emission wavelengths and their long decay times, which range from 100 ns to 10 μs.[1] Careful selection of metal and ligand can result in properties that are helpful for specific applications; for example, absorption wavelengths between 460 and 700 nm can be obtained using osmium and ruthenium in MLCs. Also, ruthenium complexes have been used as lifetime-based optical sensors for pH,[2,3] potassium,[4] chloride,[5] and carbon dioxide detection.[6] In addition, ruthenium complexes have been developed as luminescent probes for immunoassays.[7–10] Furthermore, the rotation of proteins and other macromolecules can be studied by a combination of polarized emission and time-resolved measurements in the microsecond range. Lastly, the use of ruthenium complexes in place of ethidium bromide in DNA analysis has also been reported.[11] In this application, the probe's luminescence increases when it intercalates into double-stranded DNA. Thus, the spectral and temporal resolution of MLC-based excited-state microscopy can result in increased resolution and probe selectivity for biological applications.

Our focus is the development of novel electrogenerated chemiluminescence (ECL) devices suitable for the detection of different biological analytes of clinical and environmental interest. To this end, we report the synthesis, characterization, redox behavior, and photophysical properties of the series of complexes [$Ru^{II}$bis(bipyridyl){2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole}]$(PF_6)_2$ (X = N–$CH_3$, **1**; S, **2**; or O, **3**). The use of [2-(4-methylpyridin-2-yl)-1*H*-benzoimidazole] (X = NH) as a free ligand offers the opportunity to introduce a substituent in the 1*H* position suitable for bioconjugation using standard synthetic organic techniques. As an example of a biological application, we also

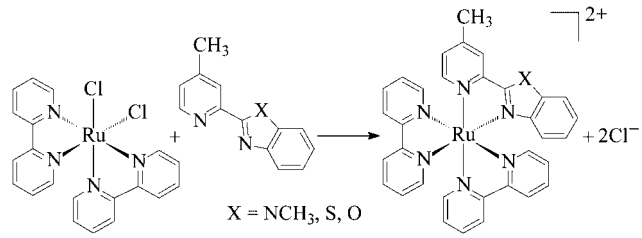
report the synthesis of an analogue of **1** in which the methyl group is substituted by 1-hexanoic acid and the resulting complex, **4**, is bioconjugated to bovine serum albumin (BSA) through an amidic bond. Photophysical investigations show efficient luminescence and ECL properties for all the derivatives. The synthesis of **2** and **3** also allows us to evaluate how the electronic and photophysical properties of the metal complex are affected by subtle alterations in the bidentate heterocyclic ligand.



Scheme 1.

## Results and Discussion

Following our synthesis of novel metal complexes of ruthenium and osmium with potentially useful fluorescence properties,[12,13] we investigated the reactivity of $Ru(bpy)_2Cl_2$ with bidentate ligands of formula 2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole (X = N–$CH_3$, S, or O). The choice of this unsymmetrical bidentate ligand, which has a single, easily modifiable site in the case of the benzimidazole ligand, avoids the formation of unwanted isomeric species, which are often difficult to separate from the desired product.

The reaction of $Ru(bpy)_2Cl_2$ with 2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole (X = N–$CH_3$, S, or O) in refluxing ethylene glycol gives a single orange crystalline product in good yield for all the ligands that have been identified as **1**, **2**, and **3** respectively (Scheme 1). The products have been recrystallized as $PF_6^-$ salts and in the case of **1**, analyzed by single-crystal X-ray diffraction.

### Crystal Structure of [$Ru^{II}$bis(bipyridyl){2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole}]$(PF_6)_2$ (X = N–$CH_3$, 1)

The crystal structure of **1** is illustrated in Figure 1, crystallographic data are given in Table 5, and selected distances and angles are given in Table 1. The asymmetric unit of the complex is arranged in the $P2_1/c$ space group. Two $PF_6^-$ anions assure the electrical neutrality of the structure. As already observed in related structures,[13,14] the $PF_6^-$ moieties are rather mobile, as evidenced by their large equivalent atomic displacement parameters (ADP), ranging from 0.090(1) for F(2) to 0.149(2) for F(5). Also the atoms belonging to the bpy and 2-pyridyl-benzimidazole ligands show large ADP values. The magnitudes of the ADP increase with increasing distance from the ruthenium atom, as expected. For example, the 6 N atoms, N(1)–N(6), bonded to Ru show ADP values in the range 0.044(1)–0.048(1), whereas C(33), the atom furthest away from the Ru atom, has an ADP value of 0.114(3).

The geometry around the Ru atom is a fairly regular octahedron with five-membered chelate rings having bite

[a] Numbers in parentheses are estimated standard deviations.

angles of 78.8(2)°, and the angles between the chelate rings are divided into the usual two groups of 85.9–88.5(2)° and 95.6–99.1(2)° (Table 1). This geometry is very similar to the closely related complex $[Ru(bpy)_2(bbbpyH_2)](ClO_4)_2$ [$bbbpyH_2$ = 2,2′-bis(benzimidazol-2-yl)-4,4′-bipyridine][15] and to bis(bipyridyl) complexes in general.[16,17] Similarly, the Ru–N bipyridyl bond lengths [2.050–2.078(4) Å] and the benzimidazole bond length [Ru–N(6) = 2.060(4) Å] are very similar to Ru–N bonds in the related complexes.[16,17] The N(6)–C(32) and N(6)–C(26) bond lengths of 1.399(6) and 1.335(5) Å are also similar to the previously reported Ru-benzimidazole complex [1.39(1) and 1.35(1) Å] as are the other N–C bonds within the bipyridyl rings.[15] Although it is dangerous to draw conclusions about relative bond strengths from metal–ligand bond lengths alone, it would seem from these data that the benzimidazole ring has donor properties similar to those of the pyridinyl ligands and that these properties are relatively insensitive to substitution of a methyl group in the 3-position of the ring.

In the solid state, the cationic and anionic moieties are vertically stacked in layers (Figure 2), and are stabilized by ionic interactions between anions and cations and by weak C–H···F interactions (dotted lines in Figure 2). The layers are connected by $PF_6^-$ ions to form a low-density structure – 1.570 $Mg/m^3$ is small for a Ru-containing compound – with channels containing two acetonitrile molecules in half-occupancy. The acetonitrile positions are represented in Figure 2 by circles located in the acetonitrile centers of mass. The acetonitrile molecules are only weakly bound to the cation–anion couple by weak CH···F and CH···N interactions, depicted by broken lines in Figure 3. The geometric features of the C(36)–H···F and C–H···N(8) interactions that are shorter than 3.0 Å are reported in Table 2. The contact distances are large, being just within twice the standard deviation of the sum of the van der Waals radii ($vdW_N + vdW_H$ = 2.75 Å, $vdW_F + vdW_H$ = 2.64 Å) except in the case of the C(36)–H(36B)···F8 contact. Because of the long contact distances, the acetonitrile moiety can be accommodated by optimizing the contact angles, which range from 124(1)° to 154(1)°. The acetonitrile moieties thus have considerable freedom of movement and, in fact, they are disordered in the crystal structure and can be successfully refined only by imposing a 1/2 population of the N(8), C(1), and C(2) atoms.

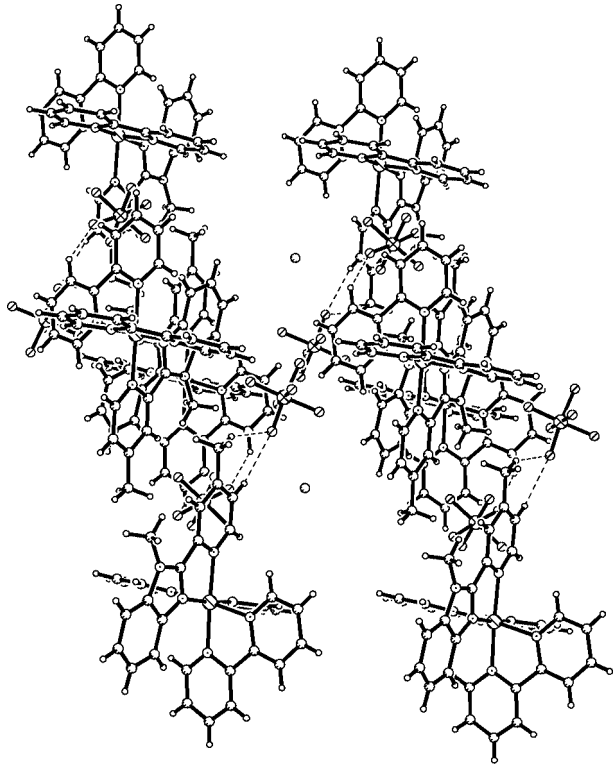

Figure 2. Crystal packing of compound **1**, showing the channels between the layers formed by the $[Ru(bpy)_2(LegN)](PF_6)_2$ ionic couples. Acetonitrile positions are indicated by their center of mass.

## NMR Spectroscopy

The $^1H$ NMR spectrum (Figure 4, top) of **1** recorded in acetone is entirely consistent with the structure found in the solid state, showing 22 proton resonances in the aromatic region from 7.10 to 8.82 ppm and one at $\delta$ = 5.94 ppm. Sixteen signals belong to protons of the two-bpy moieties and the other seven are assigned to the 2-(4-methylpyridin-

| C(36)–H(36B)···F(6) | 133(1) |
| C(36)–H(36C)···F(2) | 2.82(2) |
| C(36)–H(36C)···F(2) | 124(1) |

[a] Numbers in parentheses are estimated standard deviations.

2-yl)-benzimidazole ligand. Furthermore, two other signals are observed at $\delta$ = 4.5 and 2.5 ppm, assigned to methyl groups of the benzimidazole and pyridine rings, respectively.

As for **1**, the spectra of **2** and **3** also show 23 proton resonances in the aromatic range and a signal at 2.6 ppm because of the 4-pyridine methyl group. The $^{13}C$ spectra of complexes **1**–**3** are also consistent with the proposed structures (see Figure 4, bottom for **1**).

### Electrochemistry

The cyclic voltammetric (CV) response in acetonitrile at a glassy carbon (GC) electrode for each of the Ru derivatives shows three sequential ligand-centered one-electron reductions (Figure 5, top) and a single metal-centered one-electron oxidation (Figure 5, bottom). The electrochemical behavior described is similar to that of the well-known $Ru(bpy)_3Cl_2$ and related complexes.[18] In the particular case of $Ru(bpy)_3Cl_2$, however, the chlorine ions undergo an additional irreversible oxidation in acetonitrile solutions.[19] We do not observe this particular oxidation process in the CV of complexes **1**–**3**, as the counterion is $PF_6^-$. The redox processes are chemically and electrochemically reversible, with $i_p^a/i_p^c \approx 1$ and $|E_p^c - E_p^a| \approx 60$–70 mV at scan rates ranging from 0.050 to 1.000 V/s. The half-wave redox potentials evaluated as a mean of the cyclic voltammetric anodic and cathodic peaks, as well as the peak-to-peak separations, are reported in Table 3. In the case of **1**, the processes centered at $E_{1/2}(+2/+3)$ = +0.732, $E_{1/2}(+2/+1)$ = –1.782, $E_{1/2}(+1/0)$ = –1.982, and $E_{1/2}(0/-1)$ = –2.215 V versus $Fc/Fc^+$ are shifted towards more negative values of about 0.2 V when compared with the corresponding values of **2** and **3**. This is in line with the better σ-donor electronic properties of the ligand containing nitrogen. In addition, the closely related mononuclear and dinuclear $Ru(bpy)_2$ complexes of the free ligand 2,2′-bis(benzimidazol-2yl)-4,4′-bipyridine have similar oxidation and reduction potentials.[15,20] The oxidation of $[Ru(bpy)_3]^{2+}$ is at the somewhat more positive potential [$E_{1/2}(+2/+3)$ = +0.881 vs. $Fc/Fc^+$] in acetonitrile, indicating that the benzimidazole ring is a slightly better donor than bipyridyl. On the contrary, reductions of compounds **2** and **3** occur at less negative potentials. The diffusion coefficient of **1** ($D_1$) relative to that

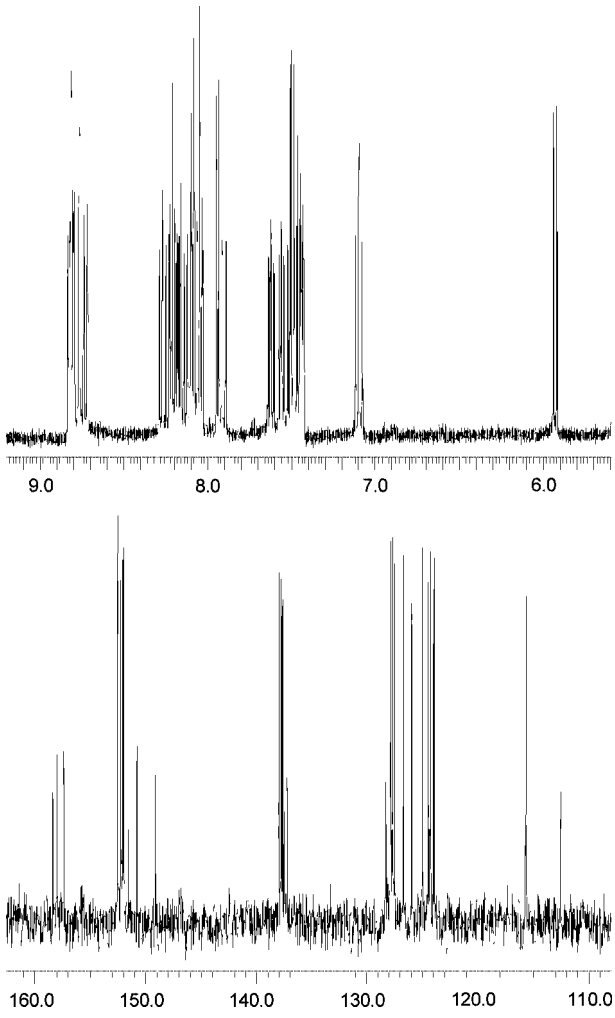

Figure 4. $^{1}H$ NMR expansion of the aromatic region and $^{13}C$ NMR of **1** at 400 MHz in acetone.

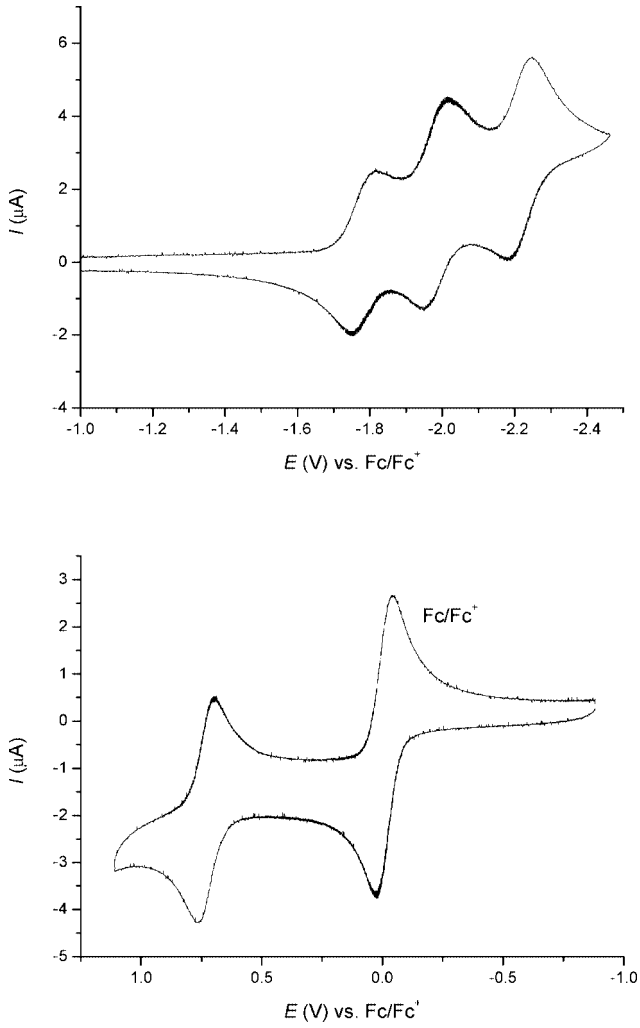

Figure 5. Top: cyclic voltammogram (reduction only) of a 1 mM solution of **1** in MeCN at a GC electrode, scan rate of 0.100 V/s. Bottom: cyclic voltammogram (oxidation only) of an equimolar (1 mM) solution of **1** and ferrocene in MeCN at a GC electrode, scan rate of 0.100 V/s.

of ferrocene ($D_{Fc}$) can be evaluated to be $D_{\mathbf{1}}/D_{Fc} = 0.588$ through the Nicholson–Shain equation[21] by means of the ratio between the anodic peak current of ferrocene and that of **1** (Figure 5, bottom) because the one-electron oxidation processes are Nernstian. Exactly the same value is obtained[22] by the Stoke–Einstein equation[23] using the crystallographic molecular volumes of **1** and ferrocene:[24]

$D_{\mathbf{1}}/D_{Fc} = (V_{Fc}/V_{\mathbf{1}})^{1/3} = (203.08\ Å^3/1001.5\ Å^3) \approx 0.587$

### Absorption Spectra and Photoluminescence

UV/Vis absorption spectra of **1**–**3** are characterized by several ligand-based transitions in the UV with metal-to-ligand charge transfer (MLCT) bands in the visible region. In $CH_3CN$ solution, the complexes display four absorption bands, three in the range of 250–400 nm attributable to the π-to-π* transitions of the bipyridine and heterocyclic rings and one in the 450–460 nm range assigned to a MLCT transition. The MLCT absorption bands display a maximum at 460 nm for **1** and at 450 nm for **2** and **3**. Their luminescent behavior has been investigated by acquiring emission spectra and by evaluating the molar extinction coefficient for absorption and the quantum yields of the emission after irradiation at $\lambda_{max}$ for the MLCT transition (Table 4).

Table 3. Redox potentials (V vs. $Fc/Fc^+$) and peak-to-peak separation in parenthesis (mV) at a scan rate of 0.1 V/s in acetonitrile for the reference $Ru(bpy)_3Cl_2$ and complexes **1**–**3**.

| $E_{1/2}$ | $Ru(bpy)_3Cl_2$ | **1** | **2** | **3** |
|---|---|---|---|---|

nescence lifetimes of the metal complexes, determined by time-correlated single-photon counting as described in Methods, were single exponential decays (see Table 4).

### Electrogenerated Chemiluminescence

Electrochemiluminescence (ECL) involves the production of reactive intermediates at the electrode surface from stable precursors. These intermediates can react in various ways to form excited states that emit light at or near the electrode surfaces. ECL has useful commercial applications in clinical analyses (e.g. immunoassays, DNA probes) using $Ru(bpy)_3^{2+}$ and a co-reactant to generate the signal. The co-reactant is generally defined as a species that, after electrochemical oxidation or reduction, produces intermediates that can react with other compounds in the solution and that are able to produce excited states. We used the well-known tri-*n*-propylamine (TPA) as co-reactant. Details of the mechanism by which TPA acts[26] are found in the excellent ECL review by Richter.[27] Compounds **1**–**3** show stable reversible electrochemistry, and therefore are promising ECL luminophores.

Solutions containing only the Ru complex or only the co-reactant do not give an ECL signal. The intense ECL signals resulting from the oxidation of TPA in aqueous solutions of all three complexes were acquired simultaneously with the CV in the potential range between 0 and +1.5 V, at a scan rate of 50 mV/s. The ECL efficiencies, $\Phi_{ECL}$, in water were estimated using the following equation:[28,29]

$$\Phi_{ECL} = \Phi°_{ECL}(IQ°/I°Q)$$

where $\Phi°_{ECL}$ is the ECL efficiency of the standard $Ru(bpy)_3Cl_2$ under the same conditions, $I$ and $I°$ are the integrated ECL intensities of the luminophore under investigation, and the standard, and $Q$ and $Q°$ are the charges passed (in coulombs) for the luminophore and the standard, respectively. In experiments performed with the co-reactant, the absolute ECL quantum efficiency for the reference system $Ru(bpy)_3Cl_2$/TPA is unknown, so relative efficiencies are reported taking its $\Phi°_{ECL} = 1$. The $\Phi_{ECL}$ values in Table 4 are a mean of the first three sequential measurements and are subject to an error of about ±10%. It has been reported that adsorption phenomena could influence the ECL emission.[30,31] Moreover, the MLCT states, and hence the luminescence properties, are sensitive to the nature of the environment and to the solvation shell.[32] Typical ECL responses are sketched in Figure 6.

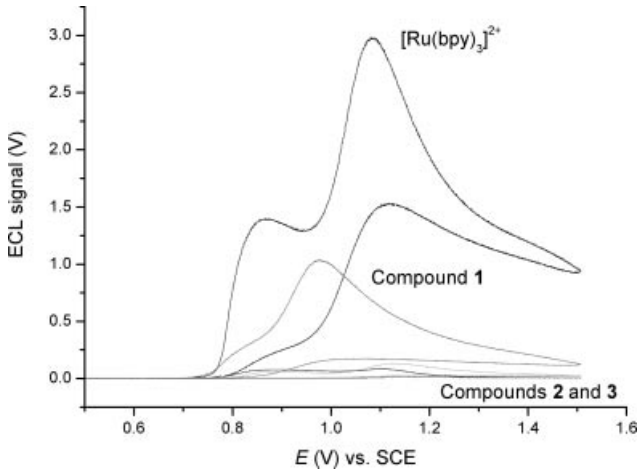

Figure 6. Electrochemiluminescence (ECL) of complexes **1**–**3** in the presence of tri-*n*-propylamine (TPA) in water borate buffer at pH = 8.5.

The presence of dissolved oxygen in water (acquired primarily from ambient air) is undesirable, as this often results in quenching of the luminophore. However, at the high TPA concentrations used in this work (20 mM), the influence of dissolved oxygen on the emission of the $Ru(bpy)_3^{2+}$/TPA system is negligible, provided the source of oxygen is air only.[33] For these reasons we performed all measurements in air.

Despite the limitations described above, it is worth noting that the $\Phi_{ECL}$ for **1** is almost an order of magnitude greater than either **2** or **3**. This is undoubtedly due to the lower oxidation potential of **1** relative to **2** and **3**. It is generally accepted that the primary mechanisms for producing ECL with $Ru(bpy)_3^{2+}$ in the presence of the co-reactant TPA are: (1) oxidation of $Ru(bpy)_3^{1+}$, produced by reduction of $Ru(bpy)_3^{2+}$ by $TPA^{\cdot}$ (this species results from ejection of a proton from the relatively long-lived $TPA^{\cdot+}$), which gives rise to an excited state $Ru(bpy)_3^{2+}$; and (2) reduction of electrochemically generated $Ru(bpy)_3^{3+}$ by $TPA^{\cdot}$ to give the same excited state $Ru(bpy)_3^{2+}$.[26] In the ECL spectrum reported in Figure 6, the first peak is due to the effect of the oxidation of TPA at the electrode, whereas the latter is relative to the oxidation of $Ru(bpy)_3^{2+}$.[26] In the case of **1**, its lower oxidation potential relative to **2** and **3** would contribute to both of these mechanisms. The better donor properties of the benzimidazole ligand are not only due to electronegativity considerations, but also to the expected greater contribution of the resonance structure (shown in Scheme 2) as a result of more efficient π overlap.

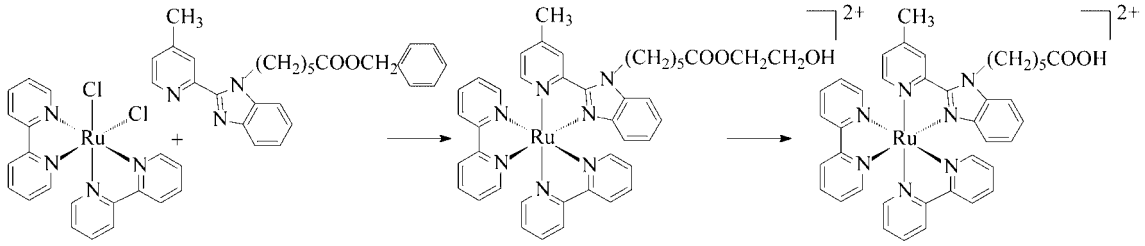

Scheme 3.

## Bioconjugation

Although the ECL efficiency of **1** is only about one-third that of $Ru(bpy)_3^{2+}$, its luminescent properties are sufficient to take advantage of the fact that the 2-(4-methylpyridin-2-yl)-benzo-X-azole (X = NH) ligand can be readily and regioselectively modified at the NH group with a linker suitable for bioconjugation. Thus, by reacting $Ru(bpy)_2Cl_2$ with the benzyl ester in ethylene glycol, an intermediate 1-hexanoic acid glycol ester analogue of **1** is obtained, which on acid hydrolysis yields the corresponding hexanoic acid complex **4** in good yield (Scheme 3).

This complex was characterized by one- and two-dimensional $^1H$ NMR and $^{13}C$ NMR spectroscopy. Complex **4** has virtually the same absorption spectrum as **1**, showing absorption maxima at 250, 290, 330, and 458 nm and emission band at 630 nm.

The reaction of **4** with *N*-hydroxysuccinimide (NHS) in the presence of dicyclohexylcarbodiimide (DCC) in anhydrous DMF gives the activated succinimide ester **4-NHS** (Scheme 4),[34] suitable for bioconjugation with BSA. The primary structures of BSA, a 67-kDa acidic protein with prolate ellipsoidal shape, and its human homologue, HSA,[35] are well established.[36] Among the 582 amino acids that form BSA, 59 lysines and one N-terminal residue are potentially available for the coupling. In nondenaturing conditions (i.e. low temperature, physiological pH, and low concentration of organic co-solvent), 30–40 lysines are believed to be accessible to coupling reagents.[37] The reaction was monitored by HPLC, and the unstable activated ester **4-NHS** was immediately incubated with BSA in borate buffer (pH = 8.5, ratio dye:protein = 10:1). The resulting **4**-BSA conjugate was purified by gel exclusion chromatography on a Sephadex G-25 M prepacked column with detection at 460 nm. The **4**-BSA conjugate showed an absorption spectrum virtually identical to that of **4** except for increased absorbance at 280 nm because of the protein (Figure 7). Irradiation of the **4**-BSA conjugate at 460 nm gave an emission at 630 nm, identical to that of **4** and very similar to that of **1** (Figure 8). It must be noted that, besides the similarity in shape, the photoluminescent signal of the solution of **4** alone and **4-BSA** equimolar in fluorophore (determined on the basis of the dye-to-protein ratio reported below) exhibited almost the same intensity, indicating that **4** maintains its $\Phi_{em}$ when linked to the protein. The dye-to-protein ratio of the **4**-BSA conjugate and the whole protein concentration were estimated by measuring the absorbance of **4-BSA** at 460 nm ($\varepsilon_{460}$ = 12200 $M^{-1}$/cm)[38,39] and by the Bradford method,[40] respectively. The molar dye-to-protein conjugation ratio of **4-BSA** was 1.2.

## Conclusions

We report a new series of ruthenium complexes based on the ligand system 2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole (X = N–$CH_3$, S, or O). The benzimidazole complex **1** exhibits the highest quantum yield for luminescence and also the highest ECL efficiency based on its superior donor properties. The X-ray crystal structure of **1** is reported. The photophysical and ECL properties of the series correlate well with their electrochemical properties, and this observation for a homologous series such as **1**–**3** lends support to the idea that such correlations should be general. This study shows also that the ECL emission of **1** in aqueous solutions with the co-reactant TPA is 0.35 times that of the reference compound $Ru(bpy)_3Cl_2$, still reasonably efficient for use as a biological marker. Furthermore, the protocol presented here for bioconjugation is particularly valuable because it provides a simple pathway that can be generalized for linking **4** to small peptides for selective conjugation to proteins and protein receptor sites. The carboxylic acid group in **4** can also be easily modified to target other functionalities besides primary amines.

Further studies are currently in progress for the synthesis of ruthenium derivatives bioconjugated to monoclonal antibodies to serve as novel photoluminescent and electrochemiluminescent probes for diagnostics at very low concentration.

## Experimental Section

**Materials:** Ruthenium(III) chloride hydrate was purchased from Lancaster and used as received. 2,2′-Bipyridine, obtained from Aldrich, was purified by crystallization from hexane and dried under vacuum over $P_2O_5$.[41] *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ was prepared according to the literature methods.[42] The intermediate 6-bromohexanoic acid benzyl ester[43] and the ligands 2-(4-methylpyridin-2-yl)benzo[*d*]-X-azole (X = N–$CH_3$, S, or O) and 2-(4-methylpyridin-2-yl)-1*H*-benzoimidazole[44,45] were prepared according to published procedures. Tetrabutylammonium hexafluorophosphate ($TBAPF_6$) was obtained as previously reported.[12] Acetonitrile was distilled from calcium hydride just before use. Triple-distilled water was used routinely. BSA was purchased from Fluka and used as received. Prepacked PD-10 columns Sephadex™ G-25 M were purchased from Amersham Biosciences. All other reagents and solvents, obtained from commercial suppliers, were of reagent grade and were used as received without any further purification. All the reactions involving the metal complexes were carried out in argon by standard Schlenk techniques.

**Physical Methods:** NMR spectra were recorded with a JEOL EX 400 spectrometer ($B_0$ = 9.8 T, $^1H$ operating frequency 399.78 MHz) with chemical shifts referenced to residual protons in the solvent ([$D_6$]acetone). Absorption spectra were measured at room temperature, using a DR LANGE CADAS 200 spectrophotometer, and emission spectra were measured with a Perkin Elmer LS 55 spectrofluorimeter.

Luminescence lifetimes were performed under magic angle polarization conditions by time-correlated single-photon counting[1] using excitation with picosecond pulses of 455-nm light at a repetition rate of 500 kHz generated by a Ti:Sapphire laser system (Verdi V10, Mira 900, and pulse picker from Coherent, Inc., Santa Clara, CA. Second harmonic generation was provided by a 5-050 system from Inrad, Northvale, NJ). The sample was maintained at 20 °C in an automated sample chamber (FLASC 1000 from Quantum Northwest, Spokane, WA). The emission was collected using a bandpass of 20 nm. The data were collected into 2048 channels (1 ns/channel) to 40000 counts in the peak channel. Because the excitation pulse is essentially a delta function at this time resolution, the decays were fit directly without reconvolution as sums of exponentials using Origin 7 (Northampton, MA 01060, USA). IR spectra were recorded with a V22 Bruker FTIR spectrophotometer with a resolution of 2 $cm^{-1}$ and an accumulation of 64 scans.

**Electrochemistry:** Electrochemistry was performed either with an EG&G PAR 273 electrochemical analyzer or with an AMEL potentiostat model 7050 connected to a PC. All experiments employed a standard three-electrode cell; the reference electrode was a 3 M KCl calomel electrode, the auxiliary electrode a platinum wire, and the working electrode a glassy carbon (GC) with a diameter of 1 mm (CV in acetonitrile) or 2 mm (ECL experiments in water). Positive feedback *iR* compensation was applied routinely. Measurements were carried out either in water or acetonitrile. The supporting electrolytes were 0.1 M phosphate buffer and tetrabutylammonium hexafluorophosphate ($TBAPF_6$), in water and acetonitrile, respectively.

Experiments in acetonitrile were carried out in argon. We used ferrocene (Fc) as an internal standard, and potentials are reported relative to the Fc(0/+1) redox couple [measured $E_{1/2}$(0/+1) = 0.384 V in MeCN, with a peak-to-peak separation of 65 mV]. The aqueous measurements were carried out in air, and the potentials reported relative to the 3 M KCl Calomel Electrode. The ECL along with the cyclic voltammetric (CV) signals (scan rate of 50 mV/s) were measured simultaneously with the AMEL 7050 combined with a photomultiplier tube (PMT, Hamamatsu H9306-03) installed under the electrochemical cell. A home-built power supply (±15 V) regulates the amplification of the PMT, which is directly proportional to the logarithm of the output (between 0 and 10 V). A dark cage, equipped with electrical connection for WE, RE, CE, stirring and inert gas inlet, was built around the electrochemical cell and the PMT, resulting in a background current at the maximum PMT amplification of about 18 ± 12 mV. The measurements were made at half-amplification, where the signal output is attenuated about 200 times with respect to the maximum of the amplifi-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cation. The concentration of the solutions employed were: TPA 20 mM, $Ru(bpy)_2LX$ $1.0\times10^{-6}$ M, supporting electrolyte 0.1 M.

**X-ray Structure Determination:** The crystal structure of **1** was solved by single-crystal X-ray diffraction analysis. Suitable crystals were obtained by slow evaporation of an acetonitrile–ethanol solution. Diffraction data were collected at room temperature on a Bruker SMART-APEX CCD[46] area detector diffractometer, using graphite monochromated Mo-$K_\alpha$ = 0.71073 Å radiation. Absorption correction was performed using SADABS.[47] The structure was solved by direct methods (SIR97)[48] and refined by full-matrix least-squares (SHELX97).[49] All hydrogen atoms were generated in their calculated positions with the XP[50] software and refined as riding atoms. All non-hydrogen atoms, except C1, C2, and N8 belonging to the acetonitrile molecule, were refined employing anisotropic ADP parameters. Two restraints on the C1–C2 and on the C2–N8 distances were used because of the disorder of the acetonitrile moiety. Crystallographic data and details of data collections and refinements are given in Table 5.

[a] The empirical formula has nonintegral values because of the half-populated $CH_3CN$ moiety.

CCDC-288567 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Complexes**

**[Ru(bpy)$_2${1-methyl-2-(4-methylpyridin-2-yl)-1*H*-benzo[*d*]imidazole}](PF$_6$)$_2$ (X = N–CH$_3$, 1):** $[Ru(bpy)_2Cl_2]\cdot2H_2O$ (0.200 g, $3.84\times10^{-4}$ mol) and 1-methyl-2-(4-methylpyridin-2-yl)-1*H*-benzo[*d*]imidazole (0.128 g, $5.73\times10^{-4}$ mol) were refluxed in ethylene glycol (50 mL) for 4 h. After cooling to room temperature, water (20 mL) and an aqueous $NH_4PF_6$ solution (1.0 g/10 mL) were added and the resulting precipitate was collected. The crude product was recrystallized from acetonitrile/ethanol. The sample was dried under vacuum for several hours before elemental analysis. Yield: 0.286 g (80.4%).

$C_{34}H_{29}F_{12}N_7P_2Ru$ (926.65): calcd. (from **1** without crystallization solvent) C 44.07, H 3.15, N 10.58; found C 43.80, H 3.65, N 9.59. $^1$H NMR (400 MHz, [D$_6$]acetone): $\delta$ = 8.82 (m, 3 H), 8.77 (s, 1 H), 8.73 (d, 1 H, $J$ = 8.05 Hz), 8.28 (t of d, 1 H, $J_1$ = 7.87, $J_2$ = 1.46 Hz), 8.16 (m, 5 H), 8.05 (t, 2 H, $J_1$ = 6.04 Hz), 7.95 (d, 1 H, $J$ = 8.86 Hz), 7.91 (d, 1 H, $J$ = 8.54 Hz), 7.63 (m, 1 H), 7.57 (m, 1 H), 7.48 (m, 4 H), 7.10 (t, 1 H, $J$ = 7.81 Hz), 5.94 (d, 1 H, $J$ = 8.42 Hz), 4.59 (s, 3 H), 2.63 (s, 3 H) ppm. $^{13}$C NMR (100 MHz, [D$_6$]acetone): $\delta$ = 159.92, 159.54, 158.96, 158.92, 154.06, 154.03, 153.77, 153.61, 153.53, 153.09, 152.30, 150.65, 142.24, 139.50, 139.32, 139.18, 139.00, 138.78, 129.85, 129.43, 129.36, 129.22, 129.04, 128.22, 127.50, 126.53, 126.01, 125.85, 125.78, 125.48, 117.19, 114.02, 34.62, 22.00 ppm.

**[Ru(bpy)$_2${2-(4-methylpyridin-2-yl)benzo[*d*]thiazole}](PF$_6$)$_2$ (X = S, 2):** $[Ru(bpy)_2Cl_2]\cdot2H_2O$ (0.200 g, $3.84\times10^{-4}$ mol) and 2-(4-methylpyridin-2-yl)benzo[*d*]thiazole (0.130 g, $5.74\times10^{-4}$ mol) were refluxed in ethylene glycol (50 mL) for 4 h. After cooling to room temperature, water (20 mL) and an aqueous $NH_4PF_6$ solution (1.0 g/10 mL) were added and the resulting precipitate was collected. The crude product was washed with water and dried with diethyl ether. Yield: 0.298 g (83.5%). $C_{33}H_{26}F_{12}N_6P_2RuS$ (929.67): calcd. C 42.63, H 2.82, N 9.04; found C 43.47, H 2.93, N 8.77. Deviation of the C% value from the calculated one indicates the presence of some impurity, probably because of the presence of reaction solvent. $^1$H NMR (400 MHz, [D$_6$]acetone): $\delta$ = 8.86 (m, 3 H), 8.76 (d, 1 H, $J$ = 8.05 Hz), 8.67 (s, 1 H), 8.36 (d, 1 H, $J$ = 7.81 Hz), 8.26 (m, 5 H), 8.15 (t of d, 1 H, $J_1$ = 8.05, $J_2$ = 1.46 Hz), 8.06 (d, 1 H, $J$ = 4.88 Hz), 8.01 (d, 1 H, $J$ = 5.61 Hz), 7.91 (d, 1 H, $J$ = 5.74 Hz), 7.68 (m, 1 H), 7.63 (m, 1 H), 7.55 (m, 4 H), 7.34 (m, 1 H), 6.48 (d, 1 H, $J$ = 8.54 Hz), 2.62 (s, 3 H) ppm. $^{13}$C NMR (100 MHz, [D$_6$]acetone): $\delta$ = 168.85, 159.69, 159.34, 158.89, 158.82, 154.68, 154.59, 153.97, 153.68, 153.58, 153.18, 152.91, 140.06, 139.94, 139.72, 139.64, 135.86, 131.16, 130.28, 129.85, 129.68, 129.64, 129.62, 129.55, 129.13, 126.19, 126.14, 126.00, 125.79, 121.40, 21.70 ppm.

**[Ru(bpy)$_2${2-(4-methylpyridin-2-yl)benzo[*d*]oxazole}](PF$_6$)$_2$ (X = O, 3):** $[Ru(bpy)_2Cl_2]\cdot2H_2O$ (0.200 g, $3.84\times10^{-4}$ mol) and 2-(4-methylpyridin-2-yl)benzo[*d*]oxazole (0.120 g, $5.71\times10^{-4}$ mol) were refluxed in ethylene glycol (50 mL) for 4 h. After cooling to room temperature, water (20 mL) and an aqueous $NH_4PF_6$ solution (1.0 g/10 mL) were added and the resulting precipitate was collected. The crude product was washed with water and dried with diethyl ether. Yield: 0.275 g (78.4%). $C_{33}H_{26}F_{12}N_6OP_2Ru$ (913.61): calcd. C 43.38, H 2.87, N 9.20; found C 43.84, H 3.04, N 9.04. $^1$H NMR (400 MHz, [D$_6$]acetone): $\delta$ = 8.84 (m, 3 H), 8.76 (d, 1 H, $J$ = 8.18 Hz), 8.53 (s, 1 H), 8.46 (d, 1 H, $J$ = 5.61 Hz), 8.30 (m, 2 H), 8.20 (m, 4 H), 8.08 (d, 1 H, $J$ = 5.61 Hz), 7.98 (s, 1 H), 7.96 (d, 1 H, $J$ = 3.17 Hz), 7.60 (m, 6 H), 7.34 (t, 1 H, $J$ = 7.87 Hz), 6.12 (d, 1 H, $J$ = 8.18 Hz), 2.66 (s, 1 H) ppm. $^{13}$C NMR (100 MHz, [D$_6$]-acetone): $\delta$ = 165.62, 160.03, 159.62, 158.84, 154.80, 154.49, 154.32, 154.17, 153.86, 153.21, 153.08, 146.94, 140.46, 140.06, 139.66, 132.06, 130.44, 129.75, 129.51, 129.43, 129.16, 128.90, 128.55, 126.11, 125.94, 125.85, 125.63, 118.36, 114.54, 21.82 ppm.

**Benzyl 6-[2-(4-Methylpyridin-2-yl)benzoimidazol-1-yl]hexanoate:** Freshly sublimated potassium *tert*-butoxide (0.63 g, $5.6\times10^{-3}$ mol) was added to a 50-mL three-neck round-bottom flask containing a solution of 2-(4-methylpyridin-2-yl)-1*H*-benzoimidazole (1 g, $4.80\times10^{-3}$ mol) in anhydrous dimethylformamide (10 mL) at room temperature in argon. After 15 min of mechanical stirring a solu-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion of 6-bromohexanoic acid benzyl ester (4.6 g, 0.016 mol) in dimethylformamide (2.5 mL) was added drop by drop. After 15 h of heating at 45 °C, the mixture was cooled and deionized water (20 mL) added. The mixture was extracted with ethyl acetate, and the organic layers were dried with anhydrous sodium sulfate, evaporated under vacuum, and purified chromatographically over silica gel with linear gradients using hexane/ethyl acetate mixture as eluent, 95:5 to 70:30. A slightly yellow oil was obtained with a yield of 75% (1.49 g). $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 8.82 (m, 3 H), 8.77 (s, 1 H), 8.50 (d, 1 H, $J$ = 5.00 Hz), 8.23 (s, 1 H), 7.73 (d, 1 H, $J$ = 7.20 Hz), 7.43 (d, 1 H, $J$ = 7.20 Hz), 7.32 (m, 7 H), 7.15 (d, 1 H, $J$ = 5.00 Hz), 5.06 (s, 2 H), 4.80 (t, 2 H, $J$ = 7.57 Hz), 2.43 (s, 3 H), 2.31 (t, 2 H, $J$ = 7.57 Hz), 1.89 (m, 2 H, $J$ = 7.57 Hz), 1.68 (m, 2 H, $J$ = 7.57 Hz), 1.38 (m, 2 H, $J$ = 7.57 Hz) ppm. $^{13}$C NMR (100 MHz, $CD_2Cl_2$): $\delta$ = 173.31, 150.82, 150.23, 148.63, 148.30, 143.00, 136.97, 136.64, 128.68, 128.28, 125.45, 124.90, 123.17, 122.40, 120.02, 110.39, 66.14, 45.38, 34.20, 29.83, 26.43, 24.65, 21.08 ppm.

**[Ru(bpy)$_2${6-[2-(4-methylpyridin-2-yl)benzo[*d*]imidazol-1-yl]hexanoic acid}](PF$_6$)$_2$ (4):** [Ru(bpy)$_2$Cl$_2$]·2H$_2$O (0.200 g, $3.84\times10^{-4}$ mol) and benzyl 6-{2-(4-methylpyridin-2-yl)benzo[*d*]imidazol-1-yl}hexanoate (0.185 g, $5.74\times10^{-4}$ mol) were dissolved in ethylene glycol (50 mL). The mixture was degassed with argon for 15 min and then refluxed for 4 h. After cooling at room temperature, water (20 mL) and an aqueous solution of $NH_4PF_6$ (1.0 g/10 mL) were added. The precipitate was then collected, washed with water (10 mL) and dried with $Et_2O$. 0.304 g of [Ru(bpy)$_2${2-(4-methylpyridin-2-yl)-benzo-X-azole}](PF$_6$)$_2$ [X = N(CH$_2$)$_5$CO$_2$CH$_2$CH$_2$OH] was obtained (yield 74%). The complex was dissolved in methanol (80 mL) containing 10% KOH and then stirred for 15 h at room temperature. After acidification at pH ≈ 2–3 with $H_2SO_4$, the methanol was removed at reduced pressure, and the acidic solution was extracted with dichloromethane. All the organic fractions were collected, dehydrated with $Na_2SO_4$, and the solvent was removed at reduced pressure. Yield: 0.250 g (86%). $^1$H NMR (400 MHz, [D$_6$]-acetone): $\delta$ = 8.82 (m, 3 H), 8.72 (d, 1 H, $J$ = 8.05 Hz), 8.58 (s, 1 H), 8.27 (t, 1 H, $J$ = 8.05 Hz), 8.19 (m, 3 H), 8.09 (m, 3 H), 8.04 (d, 1 H, $J$ = 5.37 Hz), 7.96 (m, 2 H), 7.63 (t, 1 H, $J$ = 6.35 Hz), 7.52 (m, 4 H), 7.44 (d, 1 H, $J$ = 5.61 Hz), 7.11 (t, 1 H, $J$ = 7.81 Hz), 5.96 (d, 1 H, $J$ = 8.42 Hz), 5.08 (t, 1 H, $J$ = 7.14 Hz), 2.63 (s, 3 H) 2.26 (d, 2 H, $J$ = 7.20 Hz), 2.13 (m, 2 H), 1.65 (m, 2 H), 1.52 (m, 2 H) ppm. $^{13}$C NMR (400 MHz, [D$_6$]acetone): $\delta$ = 175.21, 159.86, 159.44, 158.94, 158.91, 153.92, 153.88, 153.49, 153.42, 152.52, 152.22, 150.24, 142.27, 139.54, 139.36, 139.25, 139.06, 138.48, 129.92, 129.46, 129.41, 129.31, 129.04, 127.90, 127.72, 126.73, 126.05, 125.93, 125.81, 125.52, 117.34, 114.25, 47.14, 34.55, 31.39, 27.35, 25.84, 22.11 ppm.

**Conjugation of 6-{2-(4-Methylpyridin-2-yl)-1*H*-benzo[*d*]imidazol-1-yl}hexanoic Acid with BSA:** Complex **4** ($1.34\times10^{-5}$ mol), dicyclohexylcarbodiimide (DCC) ($2.68\times10^{-5}$ mol) and *N*-hydroxy succinimide (NHS) ($2.68\times10^{-5}$ mol) were added to anhydrous DMF (5 mL). The mixture was stirred for 5 h at 70 °C over a silicon oil bath. The total conversion to **4-NHS** was assessed by HPLC using an RP $C_{18}$ column with an acetonitrile/water gradient and UV/Vis detection, and the **4-NHS** was used immediately. *N*-Hydroxysuccinimide ester of **4** (56 μL, $1.50\times10^{-7}$ mol) was added to BSA ($1.50\times10^{-8}$ mol) in sodium borate buffer (1 mL, pH 8.5) giving a 10-fold molar excess. After stirring for 2 h at room temperature, *N*-hydroxysuccinimide ester of **4** (56 μL) was added, and the reaction continued for another 2 h. The reaction mixture was then passed over a PD10-type prepacked chromatographic column containing Sephadex G-25 M and was eluted with sodium borate (pH 8.5). One-milliliter fractions were collected and detection was performed at 460 nm. The absorbance and fluorescence spectra of the fractions collected (1–8 mL) showed absorption maxima at 250, 290, 330, and 460 nm with an emission at 630 nm upon irradiation at 460 nm.

**Supporting Information Available** (see also the footnote on the first page of this article): IR spectra of complexes **1**–**4**.

## Acknowledgments

We acknowledge financial support of this work by Regione Piemonte and European Commission DG-XII (IFCA Project, contract number G5RD-CT2002-00723). G.V. and I.M. were supported by the University of Torino and are particularly grateful to Compagnia di San Paolo (Torino) and Fondazione della Cassa di Risparmio di Torino (Italy), for the supply of laboratory equipment. We are indebted to Prof. G. Civera (Politecnico di Torino, Italy) for building a power supply that regulates the amplification of the PMT, and to Prof. D. Viterbo and Dr. G. Croce (Università del Piemonte Orientale, Italy) for useful discussions and assistance during X-ray diffraction analysis. J.B.A.R. gratefully acknowledges support by NSF MCB-0517644 and by NIH COBRE RR-15583.

# Synthesis, Structure, and Magnetic Properties of Hydroxo-Bridged Vanadium Oxalate $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$

Sihai Yang,[a] Guobao Li,*[a] Shujian Tian,[a] Fuhui Liao,[a] and Jianhua Lin[a]

**Keywords:** Vanadium / Bridging ligands / Magnetic properties / Dimers / Oxalates

The reaction of $V_2O_5$ with $H_2C_2O_4{\cdot}2H_2O$ in the presence of $H_3BO_3$ under hydrothermal conditions has afforded $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ (**1**), which crystallizes in the triclinic system, space group $P\bar{1}$ with $a$ = 5.2405(10) Å, $b$ = 5.7340(11) Å, $c$ = 7.1778(14) Å, $\alpha$ = 76.44(3)°, $\beta$ = 69.37(3)°, $\gamma$ = 75.37(3)°. The vanadium atoms in **1** form dimers by sharing edges consisting of μ-OH groups, and these dimers are connected further by oxalate ligands to form chains. The magnetic susceptibility data of **1** fit excellently with the Heisenberg dimer model in the temperature interval 2–300 K. Compound **1** is antiferromagnetic with a $J$ value of –29.6 $cm^{-1}$.

## Introduction

The oxalate ion $C_2O_4^{2-}$ shows a large variety of structural characteristics. It can act as a monodentate,[1] bidentate,[2] tridentate,[3] or tetradentate[4] donor ligand and can form chains,[5] layers,[6] or three-dimensional networks with metal centers.[7] In the presence of water molecules directly linked to the metal ions or weakly bonded to the framework,[5,8] abundant structural architectures in one-, two-, or three dimensions can be formed.[9] Moreover, the oxalate ion can mediate strong spin coupling between paramagnetic centers separated by more than 5 Å.[10] Thus, homo- and heterometallic systems involving oxalate ions (ox) as bridging ligands have been studied intensively in the search for new molecular-based magnets.[11–13] Because of the variable oxidation states of vanadium ($V^{III}$, $V^{IV}$, and $V^{V}$) and the coordination geometries of vanadium oxide polyhedra (tetrahedral, square pyramidal, trigonal bipyramidal, and octahedral),[14] many compounds containing both vanadium atoms and oxalate ions have been reported,[10,15–17] with different linkages between the vanadium atoms and the oxalate ions as shown in Figure 1, which result in different magnetic properties.[10,16,18–21] Recently, a new bonding mode for vanadium atoms and oxalate ions (Figure 1i) has been found in the compound $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ (**1**). The synthesis, structure and magnetic properties of **1** are reported below.

## Results and Discussion

### Synthesis

The synthesis of compound **1** was performed in an aqueous solution of $H_3BO_3$ under hydrothermal conditions. Some experimental parameters, including the $V_2O_5/H_2C_2O_4$ molar ratio, were varied, but the resulting products remained the same. Finally, a $V_2O_5/H_2C_2O_4$ ratio of 1:14 was used. The formation of **1** was found to be sensitive to the presence of $H_3BO_3$. Compound **1** did not form when no $H_3BO_3$ was added to the mixture of $V_2O_5$, $H_2C_2O_4{\cdot}2H_2O$, and water. Although crystals of **1** formed from an aqueous solution, their solubility in pure water was low.

### Crystal Structure

$V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ is centrosymmetric in the triclinic system with the space group $P\bar{1}$, the center of inversion lies along the C–C bond of the bridging oxalato moiety, or on the common edge of two adjacent $VO_6$ octahedra. The asymmetric unit of **1** corresponds to half of the molecular formula, including one vanadium(IV) atom, half an oxalate ligand, one water molecule, one oxygen atom, and two half μ-OH groups. As shown in Figure 2, the vanadium(IV) atom binds to two oxygen atoms from one oxalate ligand, one oxygen atom from a water molecule, two oxygen atoms from the μ-OH groups, and one terminal oxo oxygen atom to form a distorted octahedron, a very common geometry in vanadium(IV) compounds.[10,16,18–21]

The $VO_6$ octahedra of **1** link together by sharing a common edge consisting of two μ-OH groups to form $V_2O_{10}$ dimers; this type of link is rare in vanadium oxalate compounds. The typical ways to link oxalate ligands with $VX_6$ (X = O, Cl, F, and/or N) octahedra are shown in Figure 1.

The $V_2O_{10}$ dimers are further linked by oxalate ligands to form chains (Figure 1i). The oxygen atoms of the μ-OH groups (O4) in one chain form hydrogen bonds with the oxygen atoms (O3) from the oxalate ions in the neighboring chain, which connects the chains into layers (Figure 3a). The water molecules coordinated to the vanadium atoms in one layer form two hydrogen bonds with the oxygen atoms

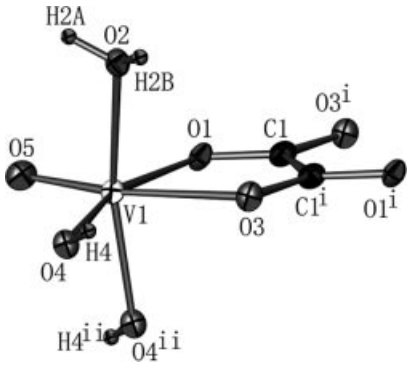

Figure 2. ORTEP drawing (at 30% probability) of the coordination environment of the vanadium atoms in $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$. Symmetry codes: i) $1 - x, 1 - y, -z$; ii) $-x, 1 - y, 1 - z$.

of the μ-OH groups (O4) and the terminal oxo oxygen atoms (O5) in neighboring layers (Figure 3b). This results in the formation of a three dimensional net structure for **1**.

### Vibrational Spectroscopy

The Fourier transform infrared (FTIR) spectrum of **1** exhibits two broad peaks centered at 3272 and 3041 $cm^{-1}$, mainly attributed to the symmetric and asymmetric stretching modes of water molecules and hydroxy groups. The signal for the bending mode of water expected at around 1600 $cm^{-1}$ is overlapped by the intense oxalate band. The antisymmetric stretching mode of the oxalate ion appears at 1650 $cm^{-1}$. The peaks at 1355 $cm^{-1}$ and 1311 $cm^{-1}$ correspond to the symmetric stretching modes of the oxalate ion. The peak at around 979 $cm^{-1}$ is assigned to the bending mode of the μ-OH group. The strong bands observed at around 771 and 731 $cm^{-1}$ correspond to the in-plane deformation mode of the oxalate ion.

### Thermal Stability

Thermogravimetric analysis shows that compound **1** is stable up to 200 °C and then undergoes decomposition to form a mixture of products with a maximum weight loss of

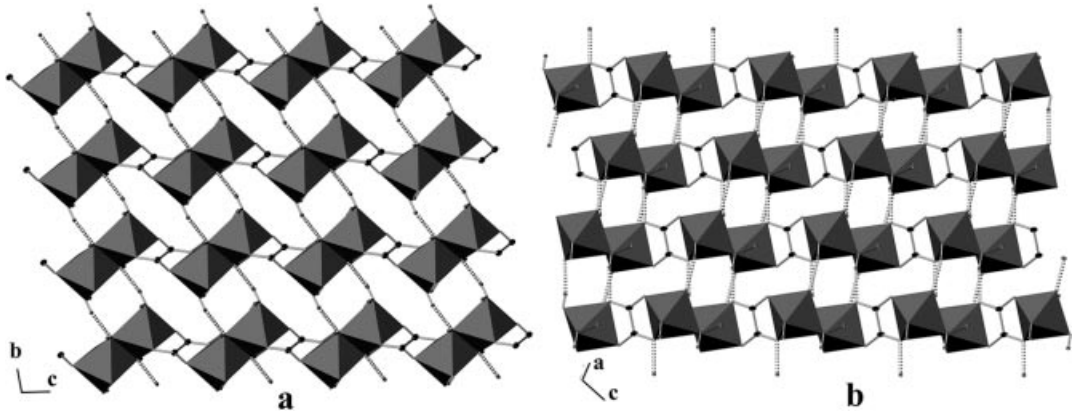

Figure 3. Packed structure of $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$, showing hydrogen bonding.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

40.0%. The mixture is then slowly oxidized to $V_2O_5$ with a total weight loss of 37.8% (calcd. 37.7%), as confirmed by X-ray diffraction data.

### Magnetochemical Investigations

The magnetic properties of $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ are depicted in Figure 4. A near-perfect fit with the Heisenberg dimer model is attainable with the parameters listed in Table 3. A susceptibility maximum occurs near 50 K, and the compound exhibits Curie–Weiss paramagnetism at high temperatures. The compound is thus strongly antiferromagnetic with a $J$ value of about –30 $cm^{-1}$, which is comparable to values for copper hydroxo-bridged dimers with antiferromagnetic coupling[22,23] and is larger than those for the (oxo)vanadium(IV) ($d^1$) oxalate-bridged dimers listed in Table 3. In fact, when oxalate bridging is considered, $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ can be seen to consist of alternating-exchange Heisenberg chains with $S = 1/2$.[24–26] In this case, two exchange constants $J$ and $\alpha J$ should be considered in order to understand the magnetic properties. However, the value of $\alpha$ is so small that the interaction represented by $\alpha J$ may be neglected (see Table 3). Therefore, the magnetic data fit very well with the dimeric model.

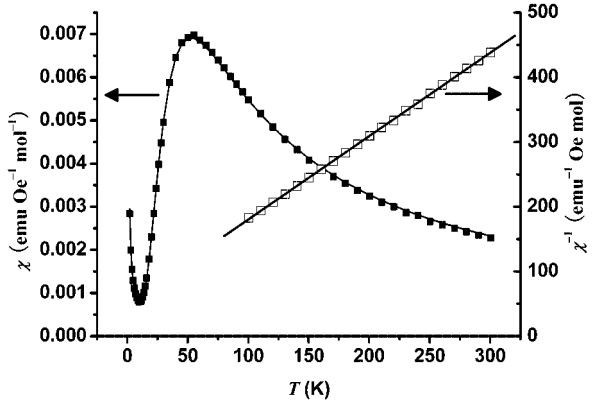

Figure 4. Thermal variation of the molar magnetic susceptibility and the reciprocal magnetic susceptibility for $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$; the solid line represents the best fit obtained with the parameters reported in the text.

## Conclusions

The use of oxalate, with the help of $H_3BO_3$, has led to the preparation of $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ from $V_2O_5$. The $V_2O_{10}$ dimer connected by a common edge found in this compound induces a stronger antiferromagnetic coupling than the oxalato-bridged (oxo)vanadium(IV) dimer.[27]

## Experimental Section

**Materials and Analyses:** All reagents were of analytical grade and were used as obtained from commercial sources without further purification. IR spectra were recorded in the 400–4000 $cm^{-1}$ range with a Magna-IR 750 FTIR spectrometer. Elemental analyses were carried out on an Elementar Vario EL III microanalyzer. TG analysis was performed with a heating rate of 10 °C $min^{-1}$ using a Dupont 1090 instrument.

**Preparation of $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ (1):** A mixture of $V_2O_5$ (1.00 g, 5.50 mmol), $H_2C_2O_4{\cdot}2H_2O$ (10.0 g, 79.4 mmol), $H_3BO_3$ (10.0 g, 162 mmol), and deionized $H_2O$ (15 mL, 0.83 mol) with a mol ratio of about 1.0:14:29:151 was placed in a 50-mL Teflon-lined stainless steel autoclave, and the autoclave was sealed, heated to 155 °C under autogenous pressure for 20 d, and then cooled to room temperature at a rate of 5 °C/h. The pH values of the system before and after synthesis are about 2 and 1, respectively. The blue crystalline product was filtered, washed with hot distilled water, and dried at ambient temperature to give about 1.44 g of complex

[b] These values were obtained by fitting the data using Heisenberg alternating chain model with Equation (2) and all others are for the Heisenberg dimer model with Equation (1).

**1** (yield 90% based on $V_2O_5$). Complex **1** is stable and insoluble in water and most organic solvents. $V_2O_2(OH)_2(C_2O_4)(H_2O)_2$ (291.94): calcd. C 8.22, H 2.05; found: C 8.32, H 2.13.

**Crystallographic Studies:** Intensity data were collected on a Rigaku AFC6S diffractometer with graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation by using the $\omega$-$2\theta$ scan method at room temperature. The structure was solved with direct methods and refined on $F^2$ with full-matrix least-squares methods using SHELXS-97 and SHELXL-97 programs, respectively.[28] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were added in the riding model and refined isotropically with O–H = 0.82 Å. The crystallographic data are summarized in Table 1, and the selected bond lengths are listed in Table 2. CCDC-294737 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Measurements:** Magnetic data of polycrystalline samples ($H$ = 5000 Oe) were recorded on 47.90 mg of **1** in the 2–300 K temperature range with a Quantum Design MPMS-5S SQUID Spectrometer. Correction for the sample holder was applied. The data were fitted to the Heisenberg dimer model for two $S$ = 1/2 spins [Equation (1)] whilst taking into account the presence of monomeric paramagnetic impurities (second term) and temperature-independent magnetism (third term) [where $\chi$ is the magnetic susceptibility, $N_A$ the Avogadro constant, $k_B$ the Boltzmann constant, $\mu_B$ the Bohr magneton, $T$ the temperature, $g$ the $g$ factor, $J$ the exchange constant, $\rho$ the ratio of the paramagnetic impurities, *tip* is the temperature-independent contribution]. The best-fit parameters are given in Table 3.

$$\chi = (1-\rho)\frac{N_A g^2 \mu_B^2}{k_B T}\frac{2\exp\left(\frac{2J}{k_B T}\right)}{1+3\exp\left(\frac{2J}{k_B T}\right)} + \rho\frac{N_A g^2 \mu_B^2}{2k_B T} + tip \qquad (1)$$

The data were also fitted to the Heisenberg alternating chain model with $S$ = 1/2 using the following Equation (2), where the first term describes the Heisenberg alternating chain model, $x = |J|/k_B T$, $J$ is the exchange integral between a spin and its right neighbor, $\alpha J$ the exchange integral between a spin and its left neighbor, the values for $A(\alpha)$, $B(\alpha)$, $C(\alpha)$, $D(\alpha)$, $E(\alpha)$, and $F(\alpha)$ can be found in ref.[25] The fit was good, and the best-fit parameters are listed in Table 3.

$$\chi = (1-\rho)\frac{N_A g^2 \mu_B^2}{k_B T}\frac{A(\alpha)+[B(\alpha)]x+[C(\alpha)]x^2}{1+[D(\alpha)x+[E(\alpha)]x^2+[F(\alpha)]x^3]} + \rho\frac{N_A g^2 \mu_B^2}{2k_B T} + tip \qquad (2)$$

**Keywords:** Water-soluble catalysts / Sulfonated phosphanes / Arene complexes / Ruthenium(II) / Hydrogen transfer

New half-sandwich ruthenium(II) complexes [$RuCl_2$($\eta^6$-arene)(TPPMS)] [$\eta^6$-arene = *p*-cymene (**1a**), benzene (**1b**)] and [RuCl($\eta^6$-arene)$(TPPMS)_2$][Cl] [$\eta^6$-arene = *p*-cymene (**2a**), benzene (**2b**)] containing the water-soluble (*meta*-sulfonatophenyl)diphenylphosphane potassium salt (TPPMS) have been synthesised. The X-ray analysis for complex **1a** revealed that, in the solid state, complex anions are held together in the crystal lattice by weak electrostatic interactions with potassium cations leading to a linear chain structure. The extent of the association in solution depends on the solvent and the determination of the size of the particles in THF can be accomplished using Multiangle Light Scattering (MALS). The new complexes proved to be excellent catalysts for transfer hydrogenation of ketones and the hydrophilic properties of the TPPMS ligand allow the catalyst recovery. The hydride derivative [RuClH($\eta^6$-*p*-cymene)(TPPMS)] (**4**) has also been shown to be an efficient catalyst for these processes. Moreover, when **1a** was used as catalyst, complex **4** was observed as the main product after the catalysis, supporting the implication of hydride species in transfer hydrogenation catalysis.

## Introduction

Over the last decades, aqueous organometallic chemistry has become a priority research area. This interest has arisen from the advantages of replacing organic solvents with water and from the attention directed to the aqueous-biphasic technology in catalysis which allows the separation of the products from the catalyst and subsequent catalyst recovery and recycling.[1]

One of the most common approaches to obtain water-soluble organometallic compounds is the use of ligands with hydrophilic properties. The phosphane ligands containing sulfonated groups are among the most widely used ligands for this purpose.

In particular, complexes containing the sodium or potassium salt of (*meta*-sulfonatophenyl)diphenylphosphane (TPPMS) have been used as catalysts in a number of processes.[2] Thus, palladium complexes with TPPMS act as catalysts in cross coupling reactions[3] and cationic iridium(I) complexes show a moderate catalytic activity in hydrogenation reactions.[4] Ruthenium complexes containing the TPPMS ligand[5] have been widely used in two phase and aqueous hydrogenation reactions.[6] Thus the preformed complexes [RuClH(CO)$(TPPMS)_3$],[7] [$Ru(CO)_3$-$(TPPMS)_2$],[8] [$RuH_2(CO)(TPPMS)_3$][8] and [RuH(CO)-(NCMe)$(TPPMS)_3$][9] have shown catalytic activity for the hydrogenation of olefins. Furthermore, ruthenium complexes with *N*-donor ligands [$RuHCl(L)_2(TPPMS)_2$] (L = 1,2,3,4-tetrahydroquinoline, aniline) catalyse the hydrogenation of quinoline and benzothiophene[10] and the complexes [$RuCl_3(TPPMS)_2(NO)$][11] and [$RuCl_2(TPPMS)_2]_2$[12] show catalytic activity in the hydrogenation of carbon dioxide and hydrogencarbonate.

Aqueous transfer hydrogenation has been less developed and, in spite of the recent studies in aqueous transfer hydrogenation,[13] the only ruthenium-TPPMS complex reported as a catalyst for these reactions[14] has been [$RuCl_2$-$(TPPMS)_2$].[15] In addition, to the best of our knowledge, the only isolated half-sandwich ruthenium(II) complexes

bearing the TPPMS ligand[16] are the complexes [RuCl($\eta^5$-$C_5H_5$)(TPPMS)$_2$][17] and [RuCl($\eta^5$-$C_5H_5$)(TPPMS)$_2$]-[$SnCl_3$][18] and no catalytic studies have been carried out.

Due to the lack of half-sandwich ruthenium(II) complexes containing the water-soluble ligand TPPMS and our interest in the catalytic activity of new half-sandwich ruthenium(II) complexes[19] and their reactivity in coupling-coupling reactions,[20] we have considered the synthesis of $\eta^6$-arene complexes and in this paper we report the synthesis and catalytic activity of new water-soluble half-sandwich ruthenium(II) complexes with the ligand TPPMS on the transfer hydrogenation of ketones.

## Results and Discussion

### Synthesis of Half-Sandwich Ruthenium(II) Complexes Containing the TPPMS Ligand

#### *a) Synthesis of [$RuCl_2$($\eta^6$-arene)(TPPMS)] [$\eta^6$-arene = p-cymene (1a), benzene (1b)]*

The reaction of two equiv. of the potassium salt of (*meta*-sulfonatophenyl)diphenylphosphane (TPPMS) with the dinuclear complex [RuCl(μ-Cl)($\eta^6$-arene)]$_2$ ($\eta^6$-arene = *p*-cymene, benzene) in methanol at room temperature gives the complexes [$RuCl_2$($\eta^6$-arene)(TPPMS)] [$\eta^6$-arene = *p*-cymene (**1a**), benzene (**1b**)] which can be isolated as air-stable orange solids in yields of 95% (**1a**) and 68%[21] (**1b**) (Scheme 1).

Complexes **1a** and **b** are soluble in water and in common organic solvents such as alcohols, acetone, chloroform, dichloromethane, acetonitrile and dimethylsulfoxide but insoluble in diethyl ether and hexane. The complexes have an ionic character due to the potassium sulfonate group of the TPPMS ligand as shown in the conductivity measurements (see Exp. Sect.).

Spectroscopic data (IR as well as $^1$H, $^{13}$C{$^1$H} and $^{31}$P{$^1$H} NMR) support the proposed formulation (see Exp. Sect. for details). In particular, the following must be noted: i) The IR spectra (KBr) show the characteristic strong $\nu(SO_3)$ absorption for the TPPMS ligand at 1200 (**1a**) and 1198 (**1b**) cm$^{-1}$; ii) a singlet resonance can be observed at 26.1 (**1a**) and 29.6 (**1b**) ppm in the $^{31}$P{$^1$H} NMR spectra; iii) the $^1$H NMR spectra show a high field doublet at 8.37 ($^3J_{H,P}$ = 10.2 Hz) (**1a**) and 8.28 ($^3J_{H,P}$ = 11.1 Hz) (**1b**) corresponding to the hydrogen atom in an *ortho* position with respect to the phosphorus atom and to the sulfonato group ($H_o$).

Slow diffusion of diethyl ether into a solution of **1a** in methanol resulted in crystals suitable for X-ray diffraction studies. In this ruthenium derivative, the asymmetric unit consists of two anionic complexes which are held together in the crystal lattice by electrostatic interactions with potassium cations. An ORTEP type representation is shown in Figure 1. Selected bonding data are collected in the caption.

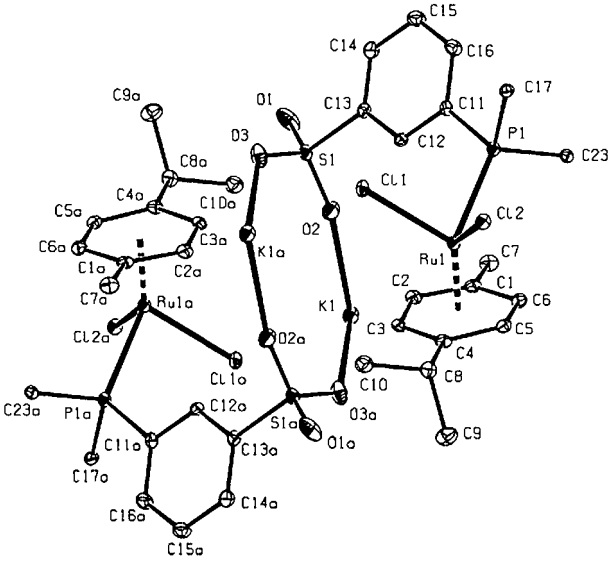

Figure 1. Molecular structure and atom labelling scheme for complex **1a**. Nonhydrogen atoms are represented by their 20% probability ellipsoids. Hydrogen atoms and phenyl rings ($Ph_2P$) have been omitted for clarity. Selected bond lengths [Å]: Ru(1)–C* 1.7061(3), Ru(1)–P(1) 2.3656(11), Ru(1)–Cl(1) 2.4046(10), Ru(1)–Cl(2) 2.4227(10), O(2)–K(1) 2.573(4). Selected bond angles [°]: C*–Ru(1)–P(1) 132.38 (3), C*–Ru(1)–Cl(1) 125.49(3), C*–Ru(1)–Cl(2) 123.46(3), Cl(1)–Ru(1)–P(1) 84.64(4), Cl(2)–Ru(1)–P(1) 88.54(4), Cl(1)–Ru(1)–Cl(2) 88.81 (4). C* means the centroid of C(1), C(2), C(3), C(4), C(5) and C(6) atoms.

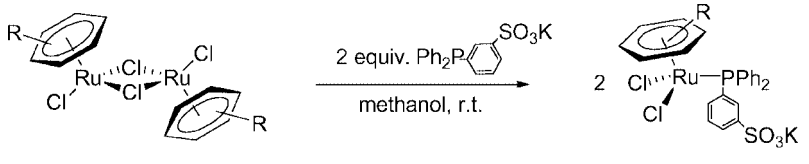
The ruthenium atom, which exhibits a pseudo-octahedral three-legged piano stool geometry, is bonded to the phosphorus atom of the TPPMS ligand, to two chlorine atoms and $\eta^6$- to the *p*-cymene ring. An important feature of this crystal structure is that the complex in the solid state consists of linear chains (Figure 2) generated by the crystal periodicity along the *a* axis. These chains are generated by



Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

electrostatic interactions between the anionic complexes and the potassium atoms. Thus, three ruthenium complexes surround each potassium atom leading to a pentacoordinate environment provided by two chlorine atoms of one anionic moiety, a chlorine and an oxygen from a second and an oxygen atom from a third unit (Figure 3).

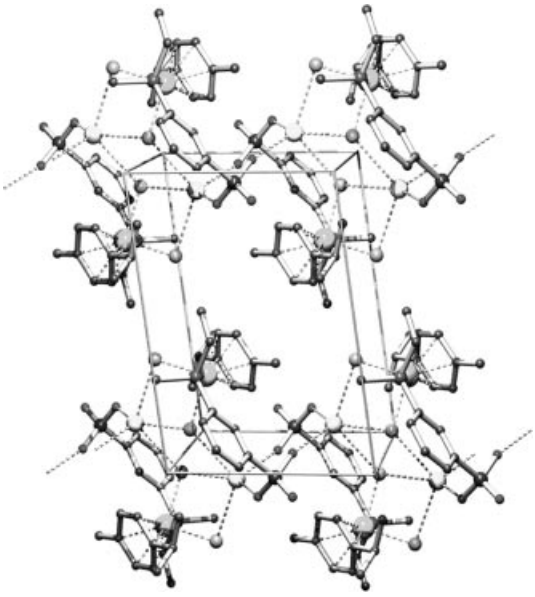


Figure 2. Layer structure for complex **1a**. Hydrogen atoms and phenyl rings have been omitted for clarity.

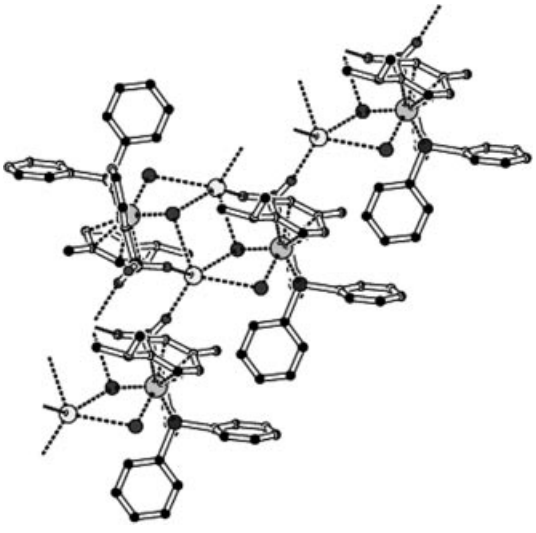

Figure 3. Potassium environment in the chain structure of **1a**. Hydrogen atoms have been omitted for clarity.

In addition, this complex shows different NMR spectroscopic behaviour depending on the solvent. In polar solvents such as $CD_3OD$ or $D_2O$ the NMR spectra show sharp signals while in $CD_2Cl_2$, $CDCl_3$ or $[D_8]$THF very broad signals may be observed. This prompted us to explore whether the chains are retained in solution leading to aggregates, the size of which being dependent on the solvent. In order to find the particle size in solution, the radius of gyration of the complex in THF solution has been measured using a detector of multiangle light scattering (MALS) coupled to size exclusion chromatographic equipment. The MALS spectrophotometer measures the excess Rayleigh ratio of the light scattered by the solute molecules in solution at different scattering angles. Thus, it enables the determination of the molecular dimensions, in terms of the radius of gyration, from the angular dependence of the scattered light (see Exp. Sect.). The mean square of the radius of gyration, $<s^2>$, is a very convenient quantity for expressing the molecular dimensions because it can be directly obtained from light scattering data and its definition is applicable to macromolecules of any shape.

When MALS is used as a second detector in size exclusion chromatography (SEC), together with a concentration dependent detector such as a differential refractive index interferometer (RI), the radius of gyration for each individual slice across the whole chromatogram of the sample can be determined. Thus, the SEC-MALS technique allows the analysis of the distribution of the radius of gyration with elution volume.[22]

The chromatograms obtained from different injections are reproducible and there were no adsorption problems in the columns. Figure 4 depicts the signal of the differential refractive index detector (RI) (which is sensitive to the sample concentration) and the light scattering signals, determined with the MALS spectrophotometer, at different values of the scattering angle $\theta$. The dependence of the intensity of the signal on the angle is evident and the scattering is therefore anisotropic. Thus the size of the molecules, i.e. the radius of gyration, can be determined for each slice of the chromatogram.[22] These values of the radii of gyration for the different slices are shown in Figure 5. The signal of the light scattering detector at 90° is superimposed. As can be seen in this figure, if we do not take into account the values determined for the head and tail of the chromatogram, the precision of which is lower, the monodispersity of the radius of gyration values is impressive. Both the appearance of the chromatogram, a very neat and defined peak, and the uniformity of the radius of gyration obtained through the slices of the chromatogram support the stability of the aggregates in THF. This stability is enough to bear the high pressures used in the chromatography. The average value for the root mean squared radius of gyration calculated for the sample is $<s^2>^{1/2} = 25 \pm 5$ nm. A water-soluble organometallic polymer which retains the polymeric structure in solution has been recently reported.[23]

### *b) Synthesis of [RuCl(η⁶-arene)(TPPMS)₂][Cl] [η⁶-arene = p-cymene (2a), benzene (2b)]*

Addition of an aqueous solution of TPPMS to a solution of [RuCl(μ-Cl)(η⁶-arene)]$_2$ (η⁶-arene = *p*-cymene, benzene) in toluene affords, after five minutes at room temperature, the disubstituted complexes [RuCl(η⁶-arene)(TPPMS)$_2$][Cl] [η⁶-arene = *p*-cymene (**2a**), benzene (**2b**)] isolated from the aqueous phase as yellow solids in yields of 94% (**2a**) and 90% (**2b**) (Scheme 2).

Complexes **2a** and **b** are soluble in water, alcohols and dichloromethane but insoluble in diethyl ether. Elemental analyses agree with the proposed stoichiometry for each.[24] Conductivity measurements for these complexes were not very useful since the observed values are strongly dependent on the solvent (112–166 $\Omega^{-1}cm^2mol^{-1}$ in water, 66–80 $\Omega^{-1}cm^2mol^{-1}$ in acetone). The reason can be found in ionic associations between the ions which are important for these types of electrolytes and which increase when the dielectric constant of the solvent decreases.[25]

The most remarkable features of complexes **2a** and **2b** are: i) the ν(SO$_3$) absorption for the TPPMS ligand at 1197 cm$^{-1}$ (**2a**) and 1198 cm$^{-1}$ (**2b**) in the IR spectra (KBr); ii) the $^{31}P\{^1H\}$ NMR spectra show a singlet signal at $\delta$ = 22.5 (**2a**) and 22.8 ppm (**2b**) and iii) the high field signal at 8.39 (**2a**) and 8.24 ppm (**2b**) corresponding to the two H$_o$ hydrogen atoms of the TPPMS ligand which appears as a broad unresolved signal for these complexes.

Metathesis of the halide with $KPF_6$ in complex **2a** allows the synthesis of [RuCl(η⁶-*p*-cymene)(TPPMS)$_2$][PF$_6$] (**2a′**) which shows almost the same spectroscopic data as the former complex **2a**, except for the signals due to the $PF_6^-$ group in the IR and in the $^{31}P\{^1H\}$ NMR spectra.

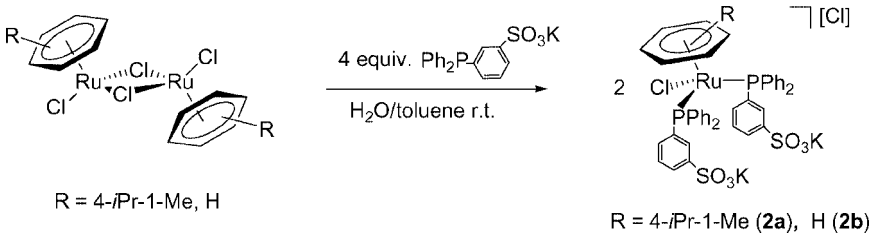
It is worth noting that **1a** and **b** as well as **2a** and **b** have been synthesised under very mild conditions in comparison with the recently reported analogous complexes with the tris(*meta*-sulfonatophenyl)phosphane trisodium salt (TPPTS) ligand, namely [RuCl$_2$(η⁶-*p*-cymene)(TPPTS)][26] and [RuCl(η⁶-benzene)(TPPTS)$_2$][Cl][27] which require reflux temperatures (methanol and water, respectively).

## Reactivity of the Complex [RuCl$_2$(η⁶-*p*-cymene)(TPPMS)] (1a)

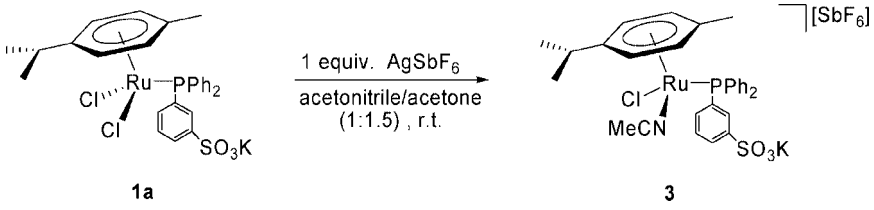
### *a) Synthesis of the Complex [RuCl(η⁶-p-cymene)(NCMe)-(TPPMS)][SbF₆] (3)*

Treatment of complex **1a** with an appropriate chloride abstractor easily generates the non-isolated unsaturated species [RuCl(η⁶-*p*-cymene)(TPPMS)]$^+$ which can be identified by means of its reactivity. Thus, the reaction of complex **1a** with $AgSbF_6$ in the presence of acetonitrile gives rise to the adduct [RuCl(η⁶-*p*-cymene)(NCMe)-(TPPMS)][SbF$_6$] (**3**) in a moderate yield (58%) (Scheme 3).

Complex **3** can be isolated as an air-stable yellow solid which is soluble in water, methanol, acetonitrile and acetone but insoluble in diethyl ether and hexane. It has been analytically and spectroscopically characterised. The spectroscopic data agree with the proposed stoichiometry (see the Exp. Sect. for details). Thus, the IR spectrum shows a strong band at 1199 cm$^{-1}$ for the sulfonato group and one at 660 cm$^{-1}$ for the $SbF_6^-$ anion. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet resonance at $\delta$ = 35.1 ppm. The expected signals for the methyl group of the acetonitrile ligand appear at $\delta$ = 2.12 ppm in the $^1H$ NMR spectrum and at $\delta$ = 3.4 ppm in the $^{13}C\{^1H\}$ NMR spectrum.



Scheme 2.



Scheme 3.

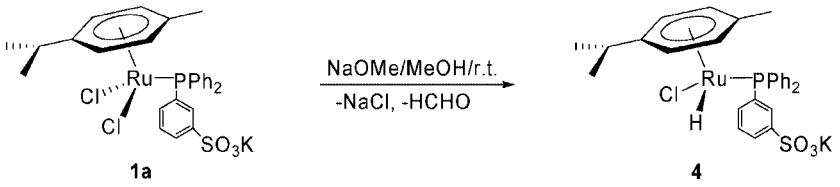

Scheme 4.

### *b) Synthesis of [RuClH(η⁶-p-cymene)(TPPMS)] (4)*

One of the most efficient synthetic methods for transition metal hydrides is that using sodium alkoxides bearing β hydrogen atoms as hydrogen transfer agents.[28] Thus, the reaction of [$RuCl_2$(η⁶-*p*-cymene)(TPPMS)] (**1a**) with NaOMe in methanol yields the hydride derivative [RuClH(η⁶-*p*-cymene)(TPPMS)] (**4**) which can be isolated as a yellow solid in 63% yield after work-up (Scheme 4).

IR and NMR spectroscopic data of **4** are in accordance with the proposed formulation (see Exp. Sect. for details). Significantly, i) the IR spectrum of **4** shows the ν(RuH) absorption at 1954 $cm^{-1}$ and the ν($SO_3$) absorption at 1196 $cm^{-1}$; ii) the $^{31}P\{^1H\}$ spectrum displays a singlet resonances at $\delta$ = 55.0 ppm and iii) the $^1H$ NMR spectrum shows a high-field doublet resonance ($\delta$ = –7.45 ppm, $^2J_{H,P}$ = 53.0 Hz) due to the hydride ligand. This value is in agreement with that reported by Bennett for the analogous complex [RuClH($C_6Me_6$)($PPh_3$)].[29]

## Catalytic Transfer Hydrogenation of Ketones

In recent years, transition metal catalysed transfer hydrogenation reactions between alcohols and ketones have become an efficient and clean alternative to the hydrogenation of carbonyl groups as illustrated by useful applications recently reported.[30] Also, ruthenium(II) complexes have been widely applied as efficient catalysts in these processes.[31] However, as in most of the homogeneous processes, the main problem stems from the difficulty in separating the products from the catalysts and in the recycling of expensive noble metals. The use of catalysts with hydrophilic properties can be a clean alternative for these processes since a simple extraction with water easily enables catalyst recovery.

This prompted us to explore the catalytic activity of the water-soluble complexes **1a** and **b** and **2a** and **b** in the reaction of transfer hydrogenation. The transfer hydrogenation of cyclohexanone by propan-2-ol was used as a model reaction. For comparative purposes, the activity of the derivative [RuCl(η⁵-$C_9H_7$)($TPPMS)_2$] is also reported.[32] Thus, in a typical experiment, KOH was added to an *i*PrOH solution of the ruthenium catalyst precursor (0.2 mol-%) and the ketone at 82 °C and the reaction was monitored by gas chromatography. In order to optimise the reaction, the following parameters were investigated: i) concentration: the best results were obtained with concentrated solutions (0.5 or 1 M). This result allows the reduction of the volume of *i*PrOH used in the catalysis in contrast with the conditions reported for other catalysts, where the best conditions are 0.1 or 0.2 M.[31] ii) base: KOH was the preferred option. Again, in our system, the amount of base could be drastically reduced (1.2 mol-%) compared with the usual conditions reported for this reaction (2–4 mol-%); iii) temperature: the activity of the catalyst decreases with temperature and almost no reactivity was observed at room temperature.

On the basis of our results, we conclude that the best conditions for the catalysis with these systems are as follow: 0.5 M cyclohexanone, 0.2 mol-% catalyst and 1.2 mol-% KOH in a total volume of 10 mL of *i*PrOH

Table 1 shows the results obtained with the different complexes in the reduction of cyclohexanone under the optimised reaction conditions. Although all the complexes studied have been shown to be active catalysts for the reduction of cyclohexanone to cyclohexanol, the arene complexes **1a** and **b**, and **2a** and **b** are much more efficient than the indenyl complex [RuCl(η⁵-$C_9H_7$)($TPPMS)_2$].

Table 1. Transfer hydrogenation of cyclohexanone.[a]

| Complex | *t* (min) | Conv. (%) | *TOF* ($h^{-1}$) |
|---|---|---|---|
| [$RuCl_2$(η⁶-*p*-cymene)(TPPMS)] (**1a**) | 15 | > 99 | 1994 |
| [$RuCl_2$(η⁶-benzene)(TPPMS)] (**1b**) | 10 | > 99 | 2982 |
| [RuCl(η⁶-*p*-cymene)($TPPMS)_2$][Cl] (**2a**) | 45 | > 99 | 663 |
| [RuCl(η⁶-benzene)($TPPMS)_2$][Cl] (**2b**) | 30 | > 99 | 1000 |
| [RuCl(η⁵-$C_9H_7$)($TPPMS)_2$] | 270 | 63 | 70 |

[a] 0.2 mol-% catalyst, 0.5 M cyclohexanone, 10 mL *i*PrOH and 0.06 mmol KOH.

Complexes **1a** and **b** are very efficient catalysts leading to quantitative conversions in very short times. Therefore, the activity of complex **1a** as catalyst in the reduction of a variety of ketones to the corresponding alcohols was explored. Table 2 summarises the results obtained.

For all ketones, quantitative conversions were obtained. The observed TOF decrease appreciably when open-chain ketones with bulkier substituents were used (entries 5 and 7 vs. 4 and 6) indicating that steric requirements are important. Finally, aliphatic ketones are easier to reduce than aromatic ketones as shown for phenyl methyl ketone (entry 3).

Unfortunately, the activity of the catalyst decreases drastically when using water as a solvent or in biphasic conditions. The possibility of chloride dissociation in aqueous solutions, which would explain this behaviour, can be ruled out since the NMR spectra of complexes **1a** and **1b** were recorded in both $D_2O$ and $CD_3OD$ and no significance differences were detected. In addition, the conductivity measurements do not indicate chloride dissociation.

Although the diminished catalytic activity of **1a** in the presence of water prevents further studies on transfer hy-

drogenation with these complexes, the hydrophilic character of the complexes allows catalyst recovery. Thus, once the catalytic process has finished, the solvents can be evaporated under vacuum and diethyl ether and water added. The catalyst can be then easily recovered by extracting the mixture with water while the alcohol remains in the organic phase. Evaporation of the water under vacuum leads to a brown solid which can be reused for a further catalytic cycle. Figure 6 shows the results for three consecutive catalytic cycles.

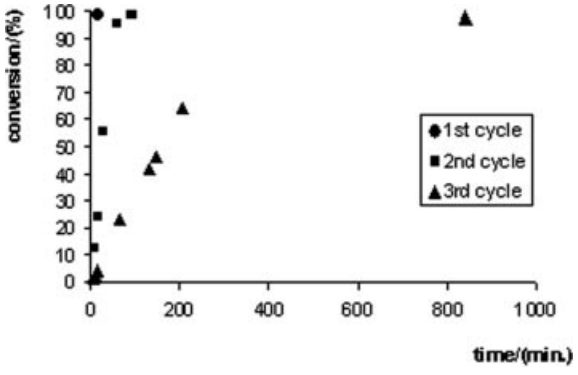

Figure 6. Transfer hydrogenation of cyclohexanone in three consecutive catalytic cycles.

The $^{31}P\{^1H\}$ and $^1H$ NMR spectra of the sample recovered after the catalysis show the presence of the hydride complex **4**, along with some other species. This observation agrees with the proposed hydride active species as a catalysts in the transfer hydrogenations reactions.[33] We have also tested the isolated hydride **4** as a catalyst. The reaction was complete within 40 minutes when a 1:1 ratio of KOH to catalyst was added. When the reaction was carried out without base, the catalytic activity decreased with time showing that a minimum amount of base is required, probably to promote the hydrogen transfer and/or the regeneration of the catalyst during the catalytic cycle.

## Conclusions

In summary, we have reported the mild synthetic conditions of new water-soluble half-sandwich ruthenium(II) complexes and a preliminary study of their reactivity. The structure of complex **1a** has been determined X-ray diffraction studies showing a linear chain structure which is retained in nonpolar solvents. The radius of gyration calculated for the sample in a THF solution of $<s^2>^{1/2}$ = 25 ± 5 nm supports this assertion.

The derivatives **1a** and **b** as well as **2a**, **2b** and **4** allow fast transfer hydrogenation of ketones at low catalyst and base loading with TOF values of up to 3000 $h^{-1}$. Furthermore, the catalyst can be recycled due to the hydrophilic properties of the TPPMS ligand. The implication of hydride species in transfer hydrogenation catalysis can be assessed by the presence of the hydride derivative [RuClH(η⁶-*p*-cymene)(TPPMS)] (**4**) in the reaction mixture after the catalytic reactions.

## Experimental Section

**General Procedures:** All manipulations were performed under an atmosphere of dry nitrogen using vacuum-line and standard Schlenk techniques. All reagents were obtained from commercial suppliers and used without further purification. Solvents were dried by standard methods and distilled under nitrogen before use. The compounds [RuCl(μ-Cl)(η⁶-*p*-cymene)]$_2$,[34] [RuCl(μ-Cl)(η⁶-benzene)]$_2$[34] and (*meta*-sulfonatophenyl)diphenylphosphane potassium salt (TPPMS)[35] were prepared by previously reported methods. Infrared spectra were recorded on a Perkin–Elmer FTIR Paragon 1000 spectrometer. The conductivities were measured at room temperature in ca. $5 \times 10^{-4}$ mol $dm^{-3}$ solutions with a Jenway PCM3 conductimeter. The C, H and N analyses were carried out with a Perkin–Elmer 240-B microanalyser. NMR spectra were recorded on Bruker AC300 and 300DPX instruments at 300 MHz ($^1H$), 121.5 MHz ($^{31}P$) or 75.4 MHz ($^{13}C$) using $SiMe_4$ or 85% $H_3PO_4$ as standards. DEPT experiments were carried out for all the compounds. Coupling constants *J* are given in Hertz. Abbreviations used: br, broad signal; d, doublet; dd, double doublet; m, multiplet; sept, septuplet; s, singlet. Gas chromatographic measurements were made on Hewlett–Packard HP6890 instrument using a Supelco Beta-Dex 120 (30 m, 0.25 mm) column. The instability of complex **4** prevented us from obtaining any satisfactory analyses.

**Synthesis of [$RuCl_2$(η⁶-*p*-cymene)(TPPMS)] (1a):** To a solution of the dimer [RuCl(μ-Cl)(η⁶-*p*-cymene)]$_2$ (100 mg, 0.16 mmol) in methanol (15 mL) was added the (*m*-sulfonatophenyl)diphenylphosphane potassium salt (TPPMS) (103 mg, 0.32 mmol) and the reaction mixture was stirred for 30 min at room temperature. The solvents were removed under vacuum and the residue was washed with diethyl ether (2 × 10 mL) and dried under vacuum to afford

complex **1a** as an orange solid. Yield: 201 mg (95%). IR (KBr): $\tilde{\nu}$ ($SO_3$) = 1200 $cm^{-1}$. Conductivity (water): 159 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300 MHz, $CD_3OD$, 20 °C): $\delta$ = 8.37 (d, $^3J_{H,P}$ = 10.2 Hz, 1 H, $H_o$), 7.78 (m, 5 H, TPPMS), 7.40 (m, 8 H, TPPMS), 5.33 (d, $^3J_{H,H}$ = 6.0 Hz, 2 H, CH of *p*-cymene), 5.20 (d, $^3J_{H,H}$ = 6.0 Hz, 2 H, CH of *p*-cymene), 2.63 [sept, $^3J_{H,H}$ = 6.8 Hz, 1 H, C*H*($CH_3$)$_2$], 1.87 (s, 3 H, $CH_3$), 1.06 [d, $^3J_{H,H}$ = 6.8 Hz, 6 H, CH(C*H*$_3$)$_2$] ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_3OD$, 20 °C): $\delta$ = 143.3–126.0 (TPPMS), 108.5 (d, $^2J_{C,P}$ = 2.4 Hz, C of *p*-cymene), 95.4 (s, C of *p*-cymene), 87.7 (d, $^2J_{C,P}$ = 3.8 Hz, CH of *p*-cymene), 85.8 (d, $^2J_{C,P}$ = 4.9 Hz, CH of *p*-cymene), 28.8 [s, *C*H($CH_3$)$_2$], 19.4 [s, CH(*C*H$_3$)$_2$], 15.2 (s, $CH_3$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_3OD$, 25 °C): $\delta$ = 26.1 (s) ppm. $C_{28}H_{28}Cl_2KO_3PRuS$ (686.60): calcd. C 48.98, H 4.11; found C 48.90, H 4.13.

**Synthesis of [$RuCl_2$(η⁶-benzene)(TPPMS)] (1b):** To a solution of TPPMS (160 mg, 0.40 mmol) in methanol (100 mL) was added the dimer [RuCl(μ-Cl)(η⁶-benzene)]$_2$ (100 mg, 0.20 mmol) and the reaction mixture was stirred for 2 h at room temperature. The solution was then filtered through kieselguhr and concentrated under vacuum to a volume of approx. 1 mL. Addition of diethyl ether afforded an orange precipitate. The solvents were decanted and the solid residue was washed with diethyl ether (2 × 10 mL) and dried under vacuum to afford complex **1b** as an orange solid. Yield: 170 mg (68%). Conductivity (water): 160 $\Omega^{-1}$ $cm^2mol^{-1}$. IR (KBr): $\tilde{\nu}$ ($SO_3$) = 1198 $cm^{-1}$. $^1H$ NMR (300 MHz, $CD_3OD$, 20 °C): $\delta$ = 8.28 (d, $^3J_{H,P}$ = 11.1 Hz, 1 H, $H_o$), 7.90 (br. s, 1 H, TPPMS), 7.72–7.65 (m, 4 H, TPPMS), 7.50–7.30 (m, 8 H, TPPMS), 5.52 (s, 6 H, CH of $C_6H_6$) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_3OD$, 20 °C): $\delta$ = 137.3–126.7 (m, TPPMS), 90.6 (d, $^2J_{C,P}$ = 3.7 Hz, CH of $C_6H_6$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_3OD$, 20 °C): $\delta$ = 29.6 (s) ppm.

**Syntheses of [RuCl(η⁶-arene)(TPPMS)$_2$][Cl]·2$H_2O$ (2a) and (2b):** A solution of TPPMS (206 mg, 0.64 mmol) in water (20 mL) was added dropwise to a solution of the respective dimer [RuCl(μ-Cl)(η⁶-*p*-cymene)]$_2$ (100 mg, 0.16 mmol) or [RuCl(μ-Cl)(η⁶-benzene)]$_2$ (80 mg, 0.16 mmol) in toluene (5 mL) and the reaction mixture was stirred for 5 min at room temperature. Then the aqueous layer was separated, filtered through kieselguhr and the solvent was removed under vacuum. The residue was washed with diethyl ether (2 × 10 mL) and dried under vacuum to afford the complexes **2a** or **2b** as yellow solids. **2a**: Yield: 330 mg (94%). IR (KBr): $\tilde{\nu}$ ($SO_3$) = 1197 $cm^{-1}$. Conductivity (water): 176 $\Omega^{-1}$ $cm^2$ $mol^{-1}$. $^1H$ NMR (300 MHz, $CD_3OD$, 20 °C): $\delta$ = 8.39 (br. s, 2 H, $H_o$), 7.87 (d, $J_{H,H}$ = 7.7 Hz, 2 H,TPPMS), 7.49–7.17 (m, 24 H, TPPMS), 5.76 (d, $^3J_{H,H}$ = 6.4 Hz, 2 H, CH of *p*-cymene), 5.51 (d, $^3J_{H,H}$ = 6.4 Hz, 2 H, CH of *p*-cymene), 2.87 [sept, $^3J_{H,H}$ = 6.9 Hz, 1 H, C*H*($CH_3$)$_2$], 1.21 [d, $^3J_{H,H}$ = 6.9 Hz, 6 H, CH(C*H*$_3$)$_2$], 1.00 (s, 3 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_3OD$, 20 °C): $\delta$ = 144.5–125.5 (TPPMS), 109.4 (s, C of *p*-cymene), 99.8 (s, C of *p*-cymene), 97.0 (s, CH of *p*-cymene), 88.7 (d, $J_{C,P}$ = 4.5 Hz, CH of *p*-cymene), 30.4 [s, *C*H($CH_3$)$_2$], 20.0 [s, CH(*C*H$_3$)$_2$], 13.6 (s, $CH_3$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_3OD$, 20 °C): $\delta$ = 22.5 (s) ppm. $C_{46}H_{46}Cl_2K_2O_8P_2RuS_2$ (1067.08): calcd. C 50.09, H, 4.20; found C 49.03, H 4.20. **2b**: Yield: 340 mg (90%). IR (KBr): $\tilde{\nu}$ ($SO_3$) = 1198 $cm^{-1}$. Conductivity (water): 200 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300 MHz, $CD_3OD$, 20 °C): $\delta$ = 8.24 (br. s, 1 H, TPPMS), 7.91 (br. s, 1 H, TPPMS), 7.16 (m, 26 H, TPPMS), 5.67 (s, 6 H, CH of $C_6H_6$) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_3OD$, 20 °C): $\delta$ = 143.9–128.4 (TPPMS), 96.6 (s, CH of $C_6H_6$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_3OD$, 20 °C): $\delta$ = 22.8 (s) ppm. $C_{42}H_{38}Cl_2K_2O_8P_2RuS_2$ (1010.97): calcd. C 48.18, H 3.66; found C 48.20, H 3.03.

**Synthesis of [RuCl(η⁶-*p*-cymene)(NCMe)(TPPMS)][$SbF_6$] (3):** To a solution of [$RuCl_2$(η⁶-*p*-cymene)(TPPMS)] (**1a**) (100 mg, 0.15 mmol) in a mixture acetonitrile (20 mL) and acetone (50 mL) was added $AgSbF_6$ (50 mg, 0.15 mmol) and the reaction mixture was stirred for 14 h at room temperature in the absence of light. The solution was then filtered through kieselguhr and concentrated under vacuum to a volume of approx. 1 mL. Addition of diethyl ether afforded a yellow precipitate. The solvents were decanted and the solid residue was washed with diethyl ether (2 × 10 mL) and dried under reduced pressure to afford complex **3**. Yield: 80 mg (58%). IR (KBr): $\tilde{\nu}$ ($SO_3$) = 1199, $\tilde{\nu}$ ($SbF_6$) = 660 $cm^{-1}$. Conductivity (acetonitrile): 92 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300 MHz, $CD_3OD$, 20 °C): $\delta$ = 8.19 (d, $^3J_{H,P}$ = 12.2 Hz, 1 H, $H_o$), 7.95 (m, 1 H, TPPMS), 7.62–7.46 (m, 12 H, TPPMS), 6.05 (d, $^3J_{H,H}$ = 6.2 Hz, 1 H, CH of *p*-cymene), 5.56 (d, $^3J_{H,H}$ = 6.2 Hz, 1 H, CH of *p*-cymene), 5.53 (d, $^3J_{H,H}$ = 6.3 Hz, 1 H, CH of *p*-cymene), 5.21 (d, $^3J_{H,H}$ = 6.0 Hz, 1 H, CH of *p*-cymene), 2.72 [sept, $^3J_{H,H}$ = 6.8 Hz, 1 H, C*H*($CH_3$)$_2$], 2.12 (m, 3 H, NCC*H*$_3$), 1.87 (s, 3 H, $CH_3$), 1.23 [d, $^3J_{H,H}$ = 6.8 Hz, 3 H, CH(C*H*$_3$)$_2$], 1.19 [d, $^3J_{H,H}$ = 7.1 Hz, 3 H, CH(C*H*$_3$)$_2$] ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 135.3–128.4 (TPPMS and N*C*$CH_3$), 114.6 (s, C of *p*-cymene), 103.1 (s, C of *p*-cymene), 93.7 (s, CH of *p*-cymene), 89.0 (s, CH of *p*-cymene), 88.7 (s, CH of *p*-cymene), 31.3 [s, CH(*C*H$_3$)$_2$], 22.8 [s, CH(*C*H$_3$)$_2$], 21.0 [s, *C*H($CH_3$)$_2$], 18.0 (s, $CH_3$), 3.4 (s, NC*C*H$_3$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_3OD$, 20 °C): $\delta$ = 35.1 (s) ppm. $C_{30}H_{31}ClF_6KNO_3PRuSSb$ (927.98): calcd. C 38.83, H 3.37, N 1.51; found C 38.39, H 3.63, N 1.36. MS (FAB+): *m*/*z* = 614 [$M^+$–K–NCMe], 576 [$M^+$–Cl –K–$NCCH_3$], 271 [$M^+$+2–NCMe –TPPMS].

**Synthesis of [RuClH(η⁶-*p*-cymene)(TPPMS)] (4):** A solution of complex **1a** (100 mg, 0.15 mmol) in methanol (5 mL) was added dropwise to a solution of NaOMe (4 mg, 0.17 mmol) in methanol (5 mL) and the reaction mixture was stirred at room temperature for 1 h. The solvent was removed and the solid residue was extracted with dichloromethane and the resultant solution filtered through kieselguhr and concentrated under vacuum to a volume of approx. 1 mL. Addition of diethyl ether afforded a yellow precipitate. The solvents were decanted and the solid residue was washed with diethyl ether (4 × 10 mL) and dried under reduced pressure to afford complex **4**. Yield: 45 mg (46%). IR (KBr): $\tilde{\nu}$ (Ru–H) = 1954, $\tilde{\nu}$ ($SO_3$) = 1199 $cm^{-1}$. Conductivity (methanol): 87 $\Omega^{-1}cm^2mol^{-1}$. $^1H$ NMR (300 MHz, $CD_3OD$, 20 °C): $\delta$ = 8.34–7.36 (m, 14 H, TPPMS), 5.68 (d, $^3J_{H,H}$ = 6.4 Hz, 1 H, CH of *p*-cymene), 5.20 (d, $^3J_{H,H}$ = 6.4 Hz, 1 H, CH of *p*-cymene), 4.97 (dd, $^3J_{H,H}$ = 6.4 and 5.6 Hz, 1 H, CH of *p*-cymene), 4.25 (d, $^3J_{H,H}$ = 5.6 Hz, 1 H, CH of *p*-cymene), 2.16 [m, 1 H, C*H*($CH_3$)$_2$], 1.99 (s, 3 H, $CH_3$), 1.12 [d, $^3J_{H,H}$ = 6.8 Hz, 3 H, CH(C*H*$_3$)$_2$], 1.06 [d, $^3J_{H,H}$ = 6.8 Hz, 3 H, CH(C*H*$_3$)$_2$], –7.45 (d, $^2J_{H,P}$ = 53.0 Hz, 1 H, Ru–H) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $CD_3OD$, 20 °C): $\delta$ = 144.0–125.2 (m, TPPMS), 104.6 (s, 2 × C of *p*-cymene), 91.4 (s, CH of *p*-cymene), 91.3 (s, CH of *p*-cymene), 79.3 (s, CH of *p*-cymene), 79.2 (s, CH of *p*-cymene), 30.5 [s, *C*H($CH_3$)$_2$], 22.6 [s, CH(*C*H$_3$)$_2$], 21.3 [s, CH(*C*H$_3$)$_2$], 17.0 (s, $CH_3$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_3OD$, 20 °C): $\delta$ = 55.0 (s) ppm.

**Synthesis of [RuCl(η⁶-*p*-cymene)(TPPMS)$_2$][$PF_6$]·2$H_2O$ (2a′):** To a solution of complex **2a** (50 mg, 0.05 mmol) in methanol (5 mL) was added $KPF_6$ (11 mg, 0.06 mmol). The mixture was stirred for 30 min at room temperature and was then evaporated to dryness. The residue was extracted with dichloromethane and concentrated under vacuum to a volume of approx. 1 mL. Addition of diethyl ether afforded a yellow precipitate. The solvents were decanted and the solid residue was washed with diethyl ether (2 × 10 mL) and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dried under vacuum to afford complex **2a′**. IR (KBr): $\tilde{\nu}$ ($PF_6^-$) = 844 $cm^{-1}$.

**Transfer Hydrogenation of Ketones – General Procedure:** The samples were typically prepared as follows: the ketone (5 mmol), ruthenium catalyst precursor (0.01 mmol, 0.2 mol-% of Ru) and propan-2-ol (9.25 mL) were introduced into a Schlenk tube fitted with a condenser and heated at 82 °C for 15 min in an inert atmosphere. KOH was then added (0.75 mL of a 0.08 M solution in propan-2-ol, 1.2 mol-%) and the reaction monitored by gas chromatography. The corresponding alcohol and acetone were the only products detected in all cases. The identity of the alcohols was assessed by comparison with commercially available (Aldrich Chemical Co. or Acros Organics) pure samples.

**X-ray Crystal Structure Determination of Complex 1a:** Crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of diethyl ether into a saturated solution of the complex in methanol. The most relevant crystal and refinement data are collected in Table 3. A light-orange prismatic single crystal was mounted on a glass fibre and transferred to a Bruker SMART 6 K CCD area-detector three-circle diffractometer (Cu-$K_\alpha$ radiation, $\lambda$ = 1.5418 Å).[36] X-ray data were collected at 100(2) K with a combination of three runs at different $\varphi$ and $2\theta$ angles. The data were collected using 0.3° wide $\omega$ scans with a crystal-to-detector distance of 4.0 cm. The substantial redundancy in data allowed empirical absorption corrections (SADABS)[37] to be applied using multiple measurements of symmetry-equivalent reflections (ratio of minimum to maximum apparent transmission = 0.602305). A total number of 8520 reflections were collected, with 4401 independent reflections ($R_{int}$ = 0.0316). The raw intensity data frames were integrated with the SAINT program[38] which also applied corrections for Lorentz and polarisation effects.

Table 3. Crystal data and structure refinement for **1a**.

| | **1a** |
|---|---|
| Chemical formula | $C_{28}H_{28}Cl_2KO_3PRuS$ |
| *F*w | 686.60 |
| *T* [K] | 100(2) |
| Wavelength [Å] | 1.5418 |
| Crystal system | triclinic |
| Space group | $P\bar{1}$ |
| *a* [Å] | 9.1813(2) |
| *b* [Å] | 12.1763(2) |
| *c* [Å] | 12.5166(2) |
| *α* [°] | 94.1940(10) |
| *β* [°] | 96.1750(10) |
| *γ* [°] | 94.8240(10) |
| *V* [Å$^3$] | 1381.46(4) |
| *Z* | 2 |
| $\rho_{calcd.}$ [g $cm^{-3}$] | 1.651 |
| $\mu$ [$mm^{-1}$] | 9.219 |
| *F*(000) | 696 |
| Crystal size [mm] | 0.12 × 0.09 × 0.104 |
| $\theta$ range [°] | 3.56 to 66.73 |
| Index ranges | $-9 \le h \le 10$; $-14 \le k \le 13$; $-13 \le l \le 14$ |
| No. of reflections collected | 8520 |
| No. of unique reflections | 4401 [$R_{int}$ = 0.0316] |
| Completeness to $\theta_{max.}$ | 90.1% |
| No. of parameters/restraints | 337/0 |
| Goodness-of-fit on $F^2$ | 1.034 |
| $R_1$[a] [$I > 2\sigma(I)$]; $wR_2$[a] [$I > 2\sigma(I)$] | 0.0400; 0.1011 |
| $R_1$(all data); $wR_2$(all data) | 0.0497; 0.1078 |
| Largest diff peak and hole [e Å$^{-3}$] | 1.295 and –0.510 |

[a] $R_1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

CCDC-290177 (for **1a**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

The software package WINGX was used for space group determination, structure solution and refinement.[39] The space group determination was based on a check of the Laue symmetry and systematic absences and ascertained from the structure solution. The structure was solved by Patterson interpretation and phase expansion using DIRDIF,[40] completed with difference Fourier syntheses and refined with full-matrix least-squares using SHELXL-97.[41] Weighted *R* factors ($R_w$) and all goodness of fit *S* are based on $F^2$. Conventional *R* factors (*R*) are based on *F*. All nonhydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were geometrically located and their coordinates were refined as riding on their parent atoms. The function minimised was $[\Sigma w(F_o^2 - F_c^2)/\Sigma w(F_o^2)]^{1/2}$ where $w = 1/[\sigma^2(F_o^2) + (0.0921P)^2 + 0.0000P]$ with $\sigma^2(F_o^2)$ from counting statistics and $P = [\max(F_o^2, 0) + 2F_c^2]/3$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[42] Geometrical calculations were made with PARST.[43] Plots were made with PLATON.[44]

**Radius of Gyration Measurements:** Size exclusion chromatography (SEC) measurements were carried out using a Waters Associates instrument coupled with an Optilab interferometric differential refractive index detector (RI) and a multiangle light scattering (MALS) DAWN DSP-F laser photometer detector both from the Wyatt Technology Corp. The photometer was calibrated with spectrometric grade toluene (Scharlau) and the normalisation of its detectors in THF was performed with low molecular weight standard samples of polystyrene. The same polystyrene standard was used to determine the interdetector volume. Two columns PLgel mixed B (Polymer Laboratories) in series completed the setup and THF freshly distilled from sodium and benzophenone, filtered through a 0.2 μm Fluoropore membrane (Millipore) and degassed, was used as eluent. The flow rate was 1.0 mL $min^{-1}$ and the temperature 25 °C.

The basic light-scattering equation at the small concentrations used in the size exclusion chromatography is[45] given by Equation (1).

$$\frac{K_c}{\Delta R_\theta} = \frac{1}{M}\left(1 + \frac{16\pi^2}{3\lambda^2} < s^2 > \sin^2\left(\frac{\theta}{2}\right) + \cdots\right) \quad (1)$$

where $R_\theta$ is the excess Rayleigh ratio of the light scattered by the solute molecules in a solution, *c* is the concentration of the solution, $\lambda$ is the wavelength of the incident light in the medium, $\theta$ is the scattering angle, $<s^2>$ the mean squared radius of gyration and *K* is an optical constant.

The parentheses of Equation (1) contain the terms of the particle form factor which takes into account the interferences among light scattered at different angles for large molecules. At $\theta = 0$ the interferences vanish and the following expression can be written (Equation 2).

$$\frac{\Delta R_{\theta=0}}{\Delta R_\theta} = 1 + \frac{16\pi^2}{3\lambda^2} < s^2 > \sin^2\left(\frac{\theta}{2}\right) + \cdots \quad (2)$$

Thus the angular dependence of the scattered light enables the measurement of radius of gyration provided that the size of the par-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ticles is large enough compare with the wavelength and that the normalisation constants for the different detectors have been determined.[22,45]

# Coordination and Reduction of HMPA in the Lithiation of (*S*)-*N*-(α-Methylbenzyl)allylamine: Crystal Structures of {(*S*)-α-[PhC(H)$CH_3$](C$H_2$CH=C$H_2$)NLi·HMPA}$_2$ and [(Me$_2$N)$_2$POLi]$_6$

**Philip C. Andrews,*[a] Magdaline Minopoulos,[a] and Evan G. Roberston[a]**

**Keywords:** Lithium / Chiral metal amides

Monolithiation of the chiral amine (*S*)-*N*-(α-methylbenzyl)allylamine, in the presence of the strong Lewis donor solvent hexamethylphoshoramide (HMPA), results in pale yellow crystals which have been crystallographically analysed revealing the structure of the complex to be an asymmetric *cisoid* dimer {(*S*)-α-[PhC(H)$CH_3$](C$H_2$CH=C$H_2$)NLi·HMPA}$_2$. Variable-temperature NMR studies show this complex can undergo a thermally induced rearrangement to a 1-azaallyl complex at ca. 90 °C. Attempted dilithiation of the chiral amine at the N and vinylic C centres with *n*BuLi and HMPA results in competitive reduction of HMPA to give crystals of the lithium dimethylamidophosphite, structurally authenticated as the hexamer [(Me$_2$N)$_2$POLi]$_6$, in which the Li cation is bonded preferentially to the O centre and not P. The effect is a reduction in the oxidation state of the P centre from (V) to (III), which is supported by ab initio calculations showing the crystal structure to represent the most thermodynamically stable of the possible isomers.

## Introduction

Chiral lithium amides derived from α-methylbenzylamine are invaluable reagents in the formation of β-amino acids and β-lactams from their selective conjugate addition reaction with unsaturated β-amino esters and amides.[1] In particular, the use of lithium (*S*)-*N*-(α-methylbenzyl)allylamide, as developed by Davies and co-workers, has proved highly effective because of the ease by which deprotection of the conjugate addition product can be achieved by simple application of Wilkinson's catalyst in removing the allyl group.[1,2] Our recent endeavours in probing the causes of high selectivity have focused on establishing the structural chemistry and unexpected anion transformations which occur when the common chiral amines derived from α-methylbenzylamine are treated with *n*BuM (M = Li, Na, K) in the presence of Lewis bases. A variance in the metal, solvents and/or Lewis donors can promote dramatic and unexpected structural changes such as azaallyl and enamide formation.[3,4] In this regard, we have previously shown that the complex formed on reaction of (*S*)-*N*-(α-methylbenzyl)allylamine (= *S*-*N*-α-mba) with *n*BuNa in the presence of tmeda undergoes a 1,3-sigmatropic shift, converting from the expected allylamide to the 1-azaallylic complex, {[(*S*)-α-(PhC(H)$CH_3$N⁻⁻C(H)⁻⁻$CHCH_3$)]Na·tmeda}$_2$,[5] Figure 1, and because our numerous attempts at crystallising analogous lithium complexes with a variety of Lewis donors resulted only in a series of impure oils, we were unable to confirm definitively whether a similar transformation was, or could be, occurring with lithium (*S*)-*N*-(α-methylbenzyl)-allylamide.

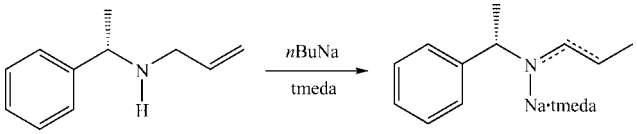

Figure 1. The 1-azaallyl structure of {[(*S*)-α-(PhC(H)$CH_3$N⁻⁻C(H)⁻⁻$CHCH_3$)]Na·tmeda}$_2$ derived from sodiation of (*S*)-*N*-(α-methylbenzyl)allylamine.

This lack of success in obtaining definitive structural information from the monolithiation reactions led us to subsequently examine and describe the cyclic structures of the homo- and hetero-bimetallic complexes, which result from a second deprotonation of lithium (*S*)-*N*-(α-methylbenzyl)-allylamide at the terminal vinylic site by Li, Na and K organyls.[6] The synthesis and reactions of the dilithiated complex have been described previously by Yus who used *t*BuLi to force metallation at the terminal vinylic proton,[7] though we have since noted that despite the proximity of the relative p$K_a$ values of the terminal vinylic protons (44) and Bu*H* (50) that the dilithiated product will also form using only *n*BuLi in toluene, albeit slowly and in low yield.[6] Recent detailed structural and ab initio studies by Williard and co-workers on related *N*-silylallylamines have highlighted the importance of using ethereal solvents to increase the kinetic reactivity of the terminal vinylic protons towards *n*BuLi, and their influence in determining a *cis* stereochemi-

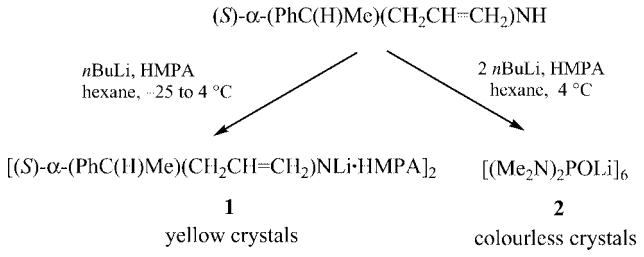
cal outcome for the dilithiated complex, even when the solvents are used in catalytic amounts.[8,9]

Because structural information is crucial in establishing and understanding the causes of stereo- and regioselectivies, and observed enantioselectivities, we have re-examined both the mono- and dilithiation reactions of *n*BuLi with *S*-*N*-α-mba in the presence of HMPA, and now report the crystal structure of the formerly elusive $[(S)$-α-$(PhC(H)CH_3)$-$(CH_2CH{=}CH_2)NLi{\cdot}HMPA]_2$ complex (**1**), Figure 2, and the unexpected reduction of HMPA in the attempted dilithiation reaction to give the hexameric lithium dimethylamidophosphite, $[(Me_2N)_2POLi]_6$ (**2**), Figure 3, as the only isolated crystalline product.

## Results and Discussion

The synthesis of **1** and **2** are shown in Scheme 1. While all other standard aprotic Lewis bases produced only oils on their addition to lithium (*S*)-*N*-(α-methylbenzyl)allylamide we found that with HMPA a yellow powder could be forced to precipitate by rapid cooling. This precipitate, which is often accompanied by an orange oil, can be readily redissolved and, with slow cooling and storage at 4 °C, produces fine yellow needles. These crystals were analysed by single-crystal X-ray diffraction and revealed the solid-state structure to be unusual on two counts: the dimer itself is asymmetric, comprised of two independent lithium amide monomers, and adopts an atypical *cisoid* arrangement of the allyl and benzyl groups relative to the planar $(NLi)_2$ ring, in what is generally considered an energetically less favourable arrangement for such dimers.[10] The few other crystallographically characterised lithium amide dimers complexed by HMPA all display a symmetrical *trans* arrangement of the amido moieties relative to the central $(NLi)_2$ ring.[11–15] The structure of **1** is shown in Figure 2.



Scheme 1. Synthesis of compounds **1** and **2**.

Importantly, and in contrast to the sodium analogue, the allylic nature of the chiral amide is retained [N(1)–C(9) 1.466(4), C(9)–C(10) 1.494(5), C(10)–C(11) 1.311(5) Å] supporting the structural assumptions made in its application in conjugate addition reactions. Though one of the allyl groups is slightly disordered, mainly at the terminal vinylic carbon, they are clearly oriented differently relative to the Li centres, and both appear on the same side of the $Li_2N_2$ plane. This inequivalency is evident from an analysis of the bonding environment of the Li centres with the closest Li to allylic C($H_2$) distances being 2.707 Å for Li(2)–C(9) and 2.871 Å for Li(1)–C(20), both of which are within the range for agostic bonding.

NMR studies in $C_6D_6$ indicate that the solution-state structure is consistent with that observed for the monomeric unit in the solid state. In comparison to the free amine, the NC$H_2$CH protons are diastereotopic ($\delta$ = 3.91 and 3.66 ppm) and because these are the same protons that are involved in the agostic interactions observed in the solid-state structure of **1**, it suggests that these interactions with the lithium centre are retained in solution. Variable-temperature studies in $C_7D_8$, in the range –60 °C to 90 °C, revealed an interesting transformation. At lower temperatures only a broadening of the peaks occurs. However, upon heating to 80 °C, followed by sustained heating at 90 °C for 10 min, the complex undergoes significant rearrangement to the 1-azaallyl isomer, as observed in $\{[(S)$-α-$(PhC(H)CH_3N{\cdots}C(H){\cdots}CHCH_3)]Na{\cdot}tmeda\}_2$. This is most clearly indicated by a decrease in the multiplet for –C$H$=C$H_2$ at $\delta$ = 6.23 ppm, which is mirrored by the emergence of a new multiplet for this proton at $\delta$ = 3.81 ppm. The two dd of dd for NC$H_2$ at $\delta$ = 3.77 and 3.54 ppm decrease with the concomitant emergence of a doublet (N···C$H$···C) at $\delta$ = 6.77 ppm. The new Me group appears as a doublet at $\delta$ = 1.83 ppm with a coincident diminution of signals for the =C$H_2$ protons at $\delta$ = 5.09 and 4.96 ppm. The overall transformation at this temperature was ca. 75% complete. As we observed for related 2-azaallyl formation in group-1 (α-methylbenzyl)benzylamides, the effect of using sodium is to induce anion changes which require thermal promotion for Li.[4]

HMPA, despite its acknowledged carcinogenicity, is still a ubiquitous, highly useful and remarkably versatile ligand in organolithium chemistry. In the vast majority of cases it behaves simply as a highly polar solvent and/or a strongly coordinating Lewis base; however, it has been observed, through chemical trapping reactions, to undergo decomposition on addition of *n*BuLi, MeLi or with NaH at elevated temperatures.[16,17] We now present unequivocal structural evidence of this decomposition and the nature of the lithiated species.

The addition of one equiv. of HMPA to promote the second lithiation of (*S*)-*N*-(α-methylbenzyl)allylamine at the terminal vinylic proton resulted only in isolation of large colourless crystals, which were identified by single-crystal X-ray diffraction to be $[(Me_2N)_2POLi]_6$ (**2**). The structure is shown in Figure 3 and indicates that the asymmetric unit comprises three Li atoms and three dimethylamidophospite units with the hexameric inner core resembling two stacked trimers. While analogous stacked trimer-type structures have been previously reported for lithium imides,[18] enolates[19] and alkoxides (e.g. $[PhOLi{\cdot}thf]_6$),[20,21] the structure of the monomeric unit of **2**, $(Me_2N)_2POLi$, is unique.

The loss of $Me_2N^-$, believed to occur through electron transfer from RLi to HMPA with elimination of RH,[16] is accompanied by reduction of the P centre from oxidation state (V) to (III). This stands in contrast to previous assumptions that the lithium dimethylphosphite could still be viewed as a $P^V$ compound and formulated as $(Me_2N)_2P$-

(=O)Li, assuming a covalent P–Li bond. The preference for the $Li^+$ cation to bond with the O atom has previously been observed in related lithiated $P^V$ phosphane oxide complexes derived from deprotonation of alkyl[22] and amino substituents,[23,24] and though these may be functionally related to **2** there is no $P^{III}$ centre formed and the P–O bonds retain most of their double bond character. A close analysis of the structure adopted by **2** reveals an interesting bonding arrangement within the unique lithiated dimethylamidophosphite moiety, and a comparison is given with the datively bound intact HMPA molecule in **1** in Figure 4.

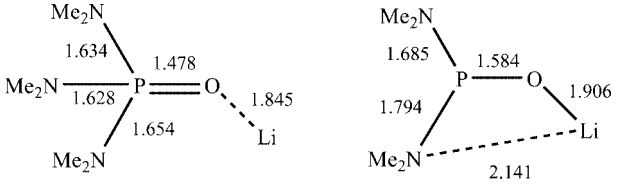

Figure 4. Comparison of the bonding arrangements for coordinated HMPA and the structurally determined dimethylamidophosphite anion in **1** and **2**, respectively. Bond lengths in Å.

There are two differing N–P bond lengths, with the longest found for the N, which datively bonds with a nearby Li cation [range 2.14(4) to 2.16(9) Å]; elongation presumably resulting from removal of the lone-pair electrons from any contribution to the N–P bond itself. This affects the bonding angles around the two N centres which differ substantially, with the longer datively bound N displaying the more acute C–*N*–P angles. Each O is bound to three Li atoms and, as is typical of stacked trimers, show a range of short, medium and longer bonds [e.g. O(3)–Li(1), 1.906(4); O(3)–Li(2), 1.970(3); O(3)–Li(3), 1.996(3) Å].

To further probe the nature of the amidophosphite intermediate ab initio calculations were performed using the Gaussian03 suite of programs.[25] Figure 5 shows structures obtained at the MP2/6-311G(d,p) level, while relative energies are reported in Table 1. Structure **2a** shows the tetrahedral complex previously proposed as the reaction intermediate.[16,17] This structure is not a potential energy minimum – it can be obtained only by constraining the angle Li–P–O. When this angle is allowed to optimize, **2a** undergoes a rearrangement to the form **2a′** which is 100 kJ·mol$^{-1}$ more stable. It is clear that **2a** is not a viable structure. Structures **2b** and **2c** are a further 50 kJ·mol$^{-1}$ more stable than **2a′**. Structures **2b** and **2c** both show pyramidal bonding at the phosphorus, with the Li atom preferring to be associated with the oxygen (and nitrogen) atoms. The structure **2c** consistent with the X-ray data is preferred over **2b** by just 1.6 kJ·mol$^{-1}$ at the MP2/6-311G(d,p) level and by a larger margin of 14.6 kJ·mol$^{-1}$ at the B3LYP/6-311+G(d,p) level. The N atom interacting with the Li also has its N–P bond lengthened relative to the other N atom in **2c**, as is evident in the crystal structure.

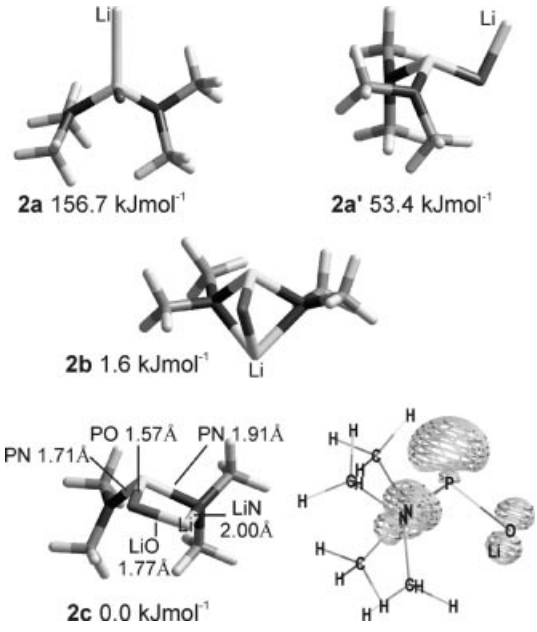

Figure 5. Li···OP[N(CH$_3$)$_2$]$_2$ structures computed at MP2/6-311G(d,p) level, together with their relative energies and HOMO of **2c**.

Calculated Mulliken charges on the P atom, at the MP2 level are given in Table 1. There is a large and significant difference between the charge of 1.8 e found in $Li^+$[OP[N(CH$_3$)$_2$]$_3$], and the charges of around 1.0 e found in structures **2a**–**2c**. This strongly suggests that the phosphorus atom in these forms has been reduced to $P^{III}$. The HOMO orbital for **2c** plotted in Figure 5 has the character of a "lone pair" on the phosphorus, consistent with this conclusion.

The first step in aggregation has also been investigated by computing dimeric structures based on **2b** and **2c**. These are shown in Figure 6. In the dimer structures, the energetic preference for **2c** is further increased: 7.6 kJ·mol$^{-1}$ at the MP2/6-311G(d,p)//MP2/6-31G(d,p) level and 45 kJ·mol$^{-1}$ at the B3LYP/6-311+G(d,p) level (Table 2). This is presumably due to the formation of slightly stronger, shorter LiO bonds – see Figure 6. In regard to larger aggregates, the lithium and oxygen atoms of **2c** are more accessible steri-

Table 1. Calculated Mulliken charges on the P atom, and relative energies of alternative LiOP[N(CH$_3$)$_2$]$_2$ structures at the MP2/6-311G(d,p) level.

Thus, while the results of Williard[9] indicate that the presence of thf produces a particular structural dimer, which facilitates deprotonation of the terminal vinylic group, it seems from our results that HMPA is preferentially cleaved, and that this most likely occurs at a greater rate than deprotonation can occur. One reason for this, which may support Williard's findings, is that the HMPA molecule is just too bulky to promote close interaction of the vinylic group and lithium base in the particular mixed aggregate structure required for deprotonation.

## Experimental Section

Compound manipulations were carried out under strict inert atmosphere and dry conditions using a vacuum/argon line Schlenk techniques and a high purity argon gas recirculating dry box. Prior to use, solvents were dried by reflux over Na/K alloy and stored over molecular sieves (4 Å). (*S*)-*N*-(α-methylbenzyl)allylamine was prepared by a literature procedure.[7] *n*BuLi was purchased from Aldrich (2.5 M solution in heptane). NMR spectra were obtained on Bruker DRX-400 spectrometer with chemical shifts referenced to the appropriate deuterated solvent. Elemental analyses were carried out by CMAS, Australia.

**Synthesis of $[(S)$-α-$(PhC(H)CH_3)(CH_2CH{=}CH_2)NLi{\cdot}HMPA]_2$ (1):** A solution of *n*BuLi (2 mL, 2.5 M in heptane, 5 mmol) was added dropwise to a stirring solution of *S*-*N*-α-mba (0.81 g, 5 mmol) in hexane (≈ 25 mL) at room temperature. The solution was stirred for 30 min, during which time the colour changed from clear to pale yellow. The solution was then cooled to 0 °C. HMPA (0.87 mL, 5 mmol) was then added dropwise. The resulting cloudy solution was stirred and warmed to room temperature, changing to a clear yellow colour. The solution was cooled rapidly to –25 °C resulting in the precipitation of a yellow solid. The mixture was gently heated in order to dissolve the precipitate and cooled slowly to room temperature before being stored at 4 °C. This resulted in the formation of needle-like crystals. The pale yellow crystals of **1** were filtered, washed with cold hexane and dried under vacuum. Yield 1.28 g, 74%. M.p. 84–86 °C. $^1$H NMR (300 MHz, $C_6D_6$, 30 °C): $\delta$ = 7.86 (d, $^1J$ = 6.9 Hz, 2 H, *ortho*-H), 7.38 (t, $^1J$ = 7.2 Hz, 2 H, *meta*-H), 7.24 (t, $^1J$ = 7.2 Hz, 1 H, *para*-H), 6.43 (m, 1 H, $CH_2CH{=}CH_2$), 5.28 (dd, $^1J$ = 3.0 Hz, $^2J$ = 17.1 Hz, 1 H, $CH_2CH{=}CH_2^a$), 5.14 (dd, $^1J$ = 3.0 Hz, $^2J$ = 9.9 Hz, 1 H, $CH_2CH{=}CH_2^b$), 4.44 [q, $^1J$ = 6.7 Hz, $^2J$ = 13.2 Hz, 1 H, PhC(*H*)-$CH_3$], 3.90 (dd, $^1J$ = 5.7 Hz, $^2J$ = 13.3 Hz, 1 H, $CH_2^aCH{=}CH_2$), 3.66 (dd, $^1J$ = 7.5 Hz, $^2J$ = 13.2 Hz, 1 H, $CH_2^bCH{=}CH_2$), 2.38 (d, $^1J$ = 3.03 Hz, 18 H, $PO[N(CH_3)_2]_3$), 1.81 [d, $^1J$ = 6.0 Hz, 3 H, $PhC(H)CH_3$] ppm. $^{13}$C NMR (300 MHz, $C_6D_6$, 30 °C): $\delta$ = 156.4 ($CH_2CH{=}CH_2$), 146.3 ($CH_2CH{=}CH_2$), 129.3 (*o*-C), 128.7 (*m*-C), 125.8 (*p*-C), 111.8 (*ipso*-C), 65.7 [$PhCH)CH_3$], 59.4 ($CH_2CH{=}CH_2$) 37.6 ($PO[N(CH_3)_2]_3$), 29.2 [$PhC(H)CH_3$] ppm. $C_{34}H_{64}LiN_4OP$ (582.8): calcd. C 59.0, H 9.3, N 16.2; found C 58.9, H 9.4, N 16.0.

**Synthesis of $\{(Me_2N)_2P{=}OLi\}_6$ (2):** A solution of *n*BuLi (4 mL, 2.5 M in heptane, 10 mmol) was added dropwise to a stirred solution of S-*N*-α-mba (0.81 g, 5 mmol) in hexane (≈ 25 mL) at room temperature. The solution changed to a yellow colour and was further stirred for 1 hour. It was then cooled to 0 °C and HMPA (0.87 mL, 5 mmol) was added slowly. The solution became cloudy and dark yellow in colour, and warming to room temperature resulted in a dark orange oil falling out of solution. The emulsion was homogenised and filtered, and the mother liquor subsequently reduced by 50%. The solution was stored at 4 °C overnight resulting in the precipitation of colourless block crystals of **2**. Yield (0.23 g, 32%). M.p. 187–189 °C (dec.) $^1$H NMR (300 MHz, $C_6D_6$, 30 °C): $\delta$ = 2.60 (d, $^1J$ = 8.8 Hz, 12 H, $PO[N(CH_3)_2]_2$) ppm. $^{13}$C NMR (300 MHz, $C_6D_6$, 30 °C): $\delta$ = 38.5 (d, $^1J$ = 19.8 Hz, 4 C, $PO[N(CH_3)_2]_2$) ppm. $C_4H_9LiN_2OP$ (142): calcd: C 33.8, H 8.5, N 19.7; found C 33.9, H 8.4, N 19.6.

**Crystallography:** Single crystals of **1** and **2** were coated in oil under argon in a dry box, mounted on a fibre and data collected with an Enraf Nonius KappaCCD at 123 K with Mo-$K_a$ radiation ($\lambda$ = 0.71073 Å). The structure was solved by direct methods (SHELXS 97)[26] and refined by full-matrix least-squares on $F^2$. All H were placed in calculated positions (C–H 0.95 Å) and included in the final least-squares refinement. All other atoms were located and refined anisotropically.

CCDC-297298 and -297299 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Dicopper(II) Complexes with the Enantiomers of a Bidentate Chiral Reduced Schiff Base: Inclusion of Chlorinated Solvents and Chiral Recognition of 1,2-Dichloroethane Rotamers in the Crystal Lattice

**Vamsee Krishna Muppidi[a] and Samudranil Pal*[a]**

**Keywords:** Dicopper(II) complexes / Chiral reduced Schiff Bases / Crystal structures / Chlorinated solvents / Enantioselective inclusion

Bisphenoxo-bridged dicopper(II) complexes $[Cu_2L^n{}_2Cl_2]$ {**1** ($n$ = 1) and **2** ($n$ = 2)} with the N,O-donor reduced Schiff bases *N*-(2-hydroxybenzyl)-(*R*)-α-methylbenzylamine ($HL^1$) and *N*-(2-hydroxybenzyl)-(*S*)-α-methylbenzylamine ($HL^2$) have been synthesised and characterised. In both **1** and **2**, the bidentate chiral ligands coordinate the metal centres through the secondary amine N atom and the bridging phenolate O atom. The chloride ion occupies the fourth coordination site and completes a slightly distorted square-planar $NO_2Cl$ environment around each copper(II) centre. Magnetic susceptibility measurements in the solid state suggest a strong antiferromagnetic interaction between the metal centres in both complexes. Both **1** and **2** readily form 1:1 host-guest compounds with chlorinated solvents such as $CH_2Cl_2$, $CHCl_3$ and $Cl(CH_2)_2Cl$. All the host-guest compounds crystallise in noncentrosymmetric space groups. **1**·$CH_2Cl_2$ and **2**·$CH_2Cl_2$ crystallise in the $P2_1$ space group while **1**·$CHCl_3$, **2**·$CHCl_3$, **1**·$Cl(CH_2)_2Cl$ and **2**·$Cl(CH_2)_2Cl$ crystallise in the $P2_12_12_1$ space group. In these inclusion crystals, the C–H···Cl interactions between the guest and the host molecules are primarily responsible for enclatheration of the chloroalkane molecules. In the case of $CH_2Cl_2$, one of its Cl atoms acts as the acceptor. On the other hand, for $CHCl_3$ and $Cl(CH_2)_2Cl$, the metal coordinated Cl atom of the host complex acts as the acceptor. The structures of **1**·(*P*)-$Cl(CH_2)_2Cl$ and **2**·(*M*)-$Cl(CH_2)_2Cl$ provide rare examples for chiral recognition of the right handed (*P*) and the left handed (*M*) gauche forms of $Cl(CH_2)_2Cl$ in molecular assemblies.

## Introduction

Materials generated by noncentrosymmetric organisation of molecules in the crystalline state are of current interest because of their potential applications in a variety of research areas such as enantioselective separation, asymmetric catalysis, drug delivery, non-linear optical effects and ferro-, pyro- and piezoelectricity.[1,2] The general strategy for noncentrosymmetric organisation in the crystal lattice is insertion of chirality in the molecule.[3] Synthesis and structures of some coordination complexes with chiral Schiff bases and their nonlinear optical properties have been reported recently.[4] Compared to the Schiff bases the reduced Schiff bases with the $–CH_2–NH–$ backbone are considered to be conformationally more flexible. In coordination complexes with reduced Schiff bases, the increased acidity of the N–H fragment resulting from metal coordination is also expected to facilitate its participation in intermolecular hydrogen bonding interactions.[5] Introduction of chirality to such metal coordinated reduced Schiff bases often leads to novel metal–organic frameworks through intermolecular noncovalent interactions.[5,6] Complexes of this type have shown the potential for applications in DNA cleavage activity and asymmetric catalysis.[6e,f] Recently we have reported two mononuclear square-pyramidal copper(II) complexes of the general formula $[Cu(L^nNO_2)_2(H_2O)]$ with the N,O-donor chiral reduced Schiff bases *N*-(2-hydroxy-5-nitrobenzyl)-(*R*)-α-methylbenzylamine {(*R*)-2(OH)-5-$(NO_2)$-$C_6H_3CH_2NHCH(CH_3)C_6H_5$, $HL^1NO_2$} and *N*-(2-hydroxy-5-nitrobenzyl)-(*S*)-α-methylbenzylamine {(*S*)-2(OH)-5-$(NO_2)$-$C_6H_3CH_2NHCH(CH_3)C_6H_5$, $HL^2NO_2$}. The complexes crystallise in the noncentrosymmetric space group *C*2 with $Cl(CH_2)_2Cl$ molecules as the guests. The crystal packing of these 1:1 inclusion compounds revealed intermolecular hydrogen-bonding-assisted, perfectly polar alignment of both host and guest molecules as well as enantioselective confinement of the chiral rotamers of $Cl(CH_2)_2Cl$.[7] In the present work, we report the synthesis and characterisation of the enantiomeric pair of bisphenoxo-bridged dicopper(II) complexes $[Cu_2L^1{}_2Cl_2]$ (**1**) and $[Cu_2L^2{}_2Cl_2]$ (**2**) with $HL^n$, the unsubstituted analogues of $HL^nNO_2$. Both **1** and **2** are found to be very good hosts to confine chloroalkanes [$CH_2Cl_2$, $CHCl_3$ and $Cl(CH_2)_2Cl$] and to isolate the enantiopure chiral rotamers of $Cl(CH_2)_2Cl$ in the noncentrosymmetric crystal lattice through intermolecular C–H···Cl interactions.

(HL$^n$)

## Results and Discussion

### Synthesis and Some Properties

The chiral reduced Schiff bases *N*-(2-hydroxybenzyl)-(*R*)-α-methylbenzylamine (HL$^1$) and *N*-(2-hydroxybenzyl)-(*S*)-α-methylbenzylamine (HL$^2$) were synthesised in about 75% yield by condensation of salicylaldehyde with the corresponding α-methylbenzylamine (*R* or *S*) in methanol followed by reduction with $NaBH_4$.[5,7] The elemental analysis and the spectroscopic data (IR and $^1$H NMR) for HL$^1$ and HL$^2$ are very similar and consistent with the expected molecular formula and structure. The reactions of these reduced Schiff bases (HL$^n$) with $CuCl_2{\cdot}2H_2O$ (1:1 mol ratio) in methanol provided the dark brown complexes **1** ($n$ = 1) and **2** ($n$ = 2) in about 60% yield. The elemental analysis data for **1** and **2** are consistent with the empirical formula CuL$^n$Cl. In solutions, the complexes are electrically nonconducting in nature. Thus in each complex the metal ions are in the +2 oxidation state and the chloride ions are coordinated to the metal centres.

The IR spectra of **1** and **2** are very similar. A sharp band observed at 3245 cm$^{-1}$ is assigned to the secondary amine N–H group of the ligands. Several weak bands are observed in the range 2800–3050 cm$^{-1}$. These are possibly due to the aromatic and aliphatic C–H stretches. The absence of any band near 3400 cm$^{-1}$ indicates the deprotonation of the phenolic OH of the bidentate ligands in both complexes. Thus, it is very likely that in each complex the metal ions are coordinated to the bridging phenoxo groups and the secondary amine N atoms of the two ligands. The remaining fourth coordination site of each metal ion is occupied by the chloride ion. X-ray structures (vide infra) confirm this type of coordination of the metal ions by the deprotonated reduced Schiff bases and the chloride ions in **1** and **2**.

The electronic spectral features of both complexes in chloroform solutions are essentially identical. A weak absorption observed near 650 nm is followed by three strong absorptions in the range 430–268 nm. The absorption at 650 nm is assigned to the d-d transition. The occurrence of this weak absorption in this region is consistent with square-based coordination geometry around the metal centre.[8] The intense absorptions at higher energy are most likely from the ligand-to-metal charge transfer and intraligand transitions.

### Magnetic Properties

Room temperature (300 K) magnetic moments of **1** and **2** in the powder phase are 1.10 and 1.11 $\mu_B$, respectively. These values suggest a strong antiferromagnetic spin coupling between the metal centres in each of the two complexes. In similar bisphenoxo-bridged dicopper(II) complexes, strong to very strong antiferromagnetic spin coupling is very common. The magnitude of the coupling constant $J$ varies from –145 to –429 cm$^{-1}$ in this type of species.[9,10] To quantify the extent of antiferromagnetic spin coupling in the present complexes we have collected the magnetic susceptibility data of **1** in the temperature range 300–18 K at a fixed magnetic field of 5 kG. On cooling the magnetic moment gradually decreases and reaches a value of 0.20 $\mu_B$ at 18 K. The nature of the curve obtained by plotting the $\mu_{eff}$ against $T$ is typical for two antiferromagnetically coupled copper(II) centres (Figure 1). The data were analysed using the Bleany–Bowers expression[11] for $\chi_M$ versus $T$ derived from the isotropic spin-exchange Hamiltonian $H = -2JS_1{\cdot}S_2$, where $S_1 = S_2 = 1/2$. The best least-squares fit[12] was obtained with $g$ = 1.93(2), $J$ = –307(2) cm$^{-1}$, $p$ (paramagnetic impurity with $S$ = 1/2) = 0.5% and TIP (temperature independent paramagnetism) = $1.2\times10^{-4}$ emu mol$^{-1}$ (Figure 1).

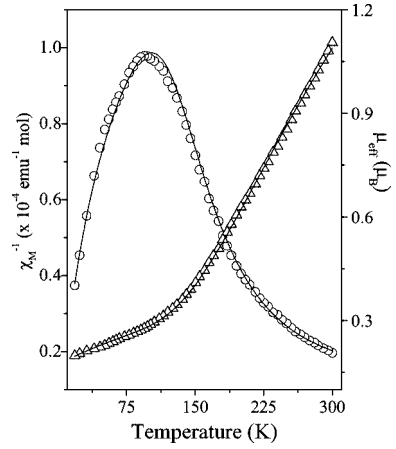

Figure 1. Temperature dependence of the inverse molar magnetic susceptibilities (O) and the effective magnetic moments (Δ) of $[Cu_2L^1{}_2Cl_2]$ (**1**); the solid lines were generated from the best least-squares fit parameters given in the text.

### Molecular Structures of 1 and 2

X-ray structures of very few bisphenoxo-bridged dicopper(II) complexes of formula $[Cu_2L_2X_2]$ (L = monoanionic bridging N,O-donor ligand and X = halide) are known.[10] All these complexes are with achiral Schiff bases and they crystallise in centrosymmetric space groups with the monomeric unit in the asymmetric unit. The $Cu_2O_2$ core is perfectly planar as the crystallographic inversion centre sits at the centre of the dimeric structure. For the same reason the X–Cu···Cu–X torsion angles are exactly 180° indicating a perfect trans orientation of the metal coordinated halides. In contrast, the host-guest compounds of both **1** and **2** crystallise in noncentrosymmetric space groups as they contain chiral ligands. In each case, the asymmetric unit contains a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complete dimeric complex molecule. Representative molecular structures of **1** and **2** are depicted in Figure 2 and the bond parameters associated with the metal ions for all the structures are listed in Table 1. The $NO_2Cl$ coordination sphere around each metal centre is constituted by the secondary amine N atom, two bridging phenoxo groups and the chloride ion. The metal to coordinating atom bond lengths are essentially identical in all the structures and they are comparable with the values reported for copper(II) species having the same coordinating atoms.[7,9,10] In the N,O-donor reduced Schiff bases, $HL^1$ and $HL^2$, the chiral C centre has the absolute configuration *R* or rectus and *S* or sinister, respectively. After complexation with the metal ion the N atom of the deprotonated monoanionic ligand becomes chiral. In **1**, the absolute configuration of the N centre is found to be *S* while in **2**, it is found to be *R*. Thus the generation of the new chiral centre is heterogeneous in both cases. As expected, the structures of **1** and **2** are mirror images of each other (Figure 2). In all the structures, the geometrical parameters for the $Cu_2N_2O_2Cl_2$ fragment are very similar. The $NO_2Cl$ coordination sphere around each metal centre is not exactly square planar. The Cl atoms deviate significantly from the $NO_2$ plane. The deviation of Cl2 [1.198(8)–1.385(5) Å] is noticeably larger than that of Cl1 [0.674(9)–0.876(7) Å] (Figure 2). There is a relatively marginal deviation of the metal centre (0.05–0.09 Å for Cu1 and 0.15–0.21 Å for Cu2) from the $NO_2$ plane. The $Cu_2O_2$ core is also not planar in any of the structures; it is folded along the O···O line. The fold angles are in the range 18.61(9)–21.02(13)°. However, the solid angles (358.34–359.99°) indicate that the bridging phenoxide O atoms have essentially no pyramidal character. The Cu–O–Cu bridge angles and the Cu···Cu distances are in the ranges 100.01(12)–103.17(12)° and 3.0198(8)–3.0280(8) Å, respectively. Unlike the previously known structures of analogous dicopper(II) complexes,[10] the metal coordinated chlorides are not trans orientated in the present structures (Figure 2). Here the Cl1–Cu1···Cu2–Cl2 torsion angles are in the range 105–112°. Although the $Cu_2N_2O_2Cl_2$ fragments are very similar in all the structures, the overall molecular conformations of the dicopper(II) complexes differ to some extent in the adducts of $CH_2Cl_2$ compared to the very similar conformations in the adducts of $CHCl_3$ and $Cl(CH_2)_2Cl$. The difference arises primarily from the variation in the orientation of the phenyl ring of the α-methylbenzylamine fragment of the chiral bidentate ligands. The overlay diagrams of the dicopper(II) complex molecules **1** and **2** in all the inclusion compounds are shown in Figure 3.

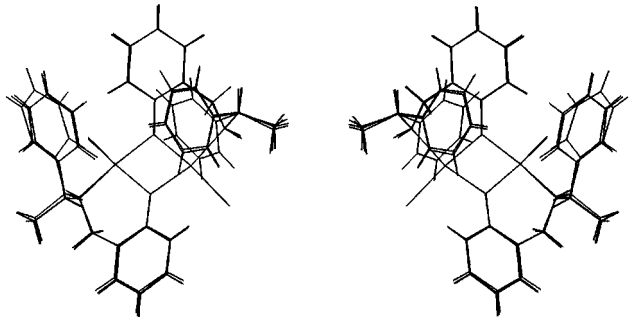

Figure 3. Overlay diagrams of (a) the molecules of $[Cu_2L^1{}_2Cl_2]$ (**1**) and (b) the molecules of $[Cu_2L^2{}_2Cl_2]$ (**2**) in the host-guest crystals with $CH_2Cl_2$, $CHCl_3$ and $Cl(CH_2)_2Cl$.

## Host-Guest Interactions

Attempts to grow single crystals of both **1** and **2** revealed that the host lattices formed by these enantiomeric complexes have considerable structural adaptability to accommodate a range of chlorinated solvents such as $CH_2Cl_2$, $CHCl_3$ and $Cl(CH_2)_2Cl$. In all the cases, 1:1 host-guest crystals have been isolated. The host-guest crystals involving $CH_2Cl_2$ crystallise in the monoclinic $P2_1$ space group while the other host-guest crystals involving $CHCl_3$ and $Cl(CH_2)_2Cl$ crystallise in the orthorhombic $P2_12_12_1$ space group. Both space groups are noncentrosymmetric. In each case, the asymmetric unit contains one dicopper(II) complex molecule and one chloroalkane molecule. Recently, there have been several reports on the propensity of the Cl atom of C–Cl and M–Cl moieties to act as an acceptor in intermolecular hydrogen bonding interactions.[13] The crystal structures described here provide examples for both C–H···Cl–C and C–H···Cl–Cu hydrogen bonding interactions involving the host and guest molecules. The geometrical parameters associated with the observed C–H···Cl interactions are listed in Table 2.

Table 2. Geometrical parameters for intermolecular hydrogen bonds.

| Compound | D···A | $d_{(D\cdots A)}$ [Å] | D–H···A [°] |
|---|---|---|---|
| **1**·$CH_2Cl_2$ | C(11)···Cl(3) | 3.444(7) | 132 |
| | C(22)···Cl(4) | 3.726(4) | 161 |
| **2**·$CH_2Cl_2$ | C(11)···Cl(3) | 3.451(8) | 134 |
| | C(22)···Cl(4) | 3.724(4) | 161 |
| **1**·$CHCl_3$ | C(31)···Cl(2) | 3.450(11) | 153 |
| **2**·$CHCl_3$ | C(31)···Cl(2) | 3.446(10) | 152 |
| **1**·(*P*)-$Cl(CH_2)_2Cl$ | C(31)···Cl(2) | 3.695(13) | 137 |
| **2**·(*M*)-$Cl(CH_2)_2Cl$ | C(31)···Cl(2) | 3.678(14) | 134 |

In both **1**·$CH_2Cl_2$ and **2**·$CH_2Cl_2$, the C–H groups from the phenyl ring of the α-methylbenzylamine fragment (C11–H) of one ligand and the methylene group (C22–H) of the other ligand participate in the C–H···Cl interactions with the Cl atoms (Cl3 and Cl4) of the two adjacent $CH_2Cl_2$ molecules. As a result a one-dimensional arrangement of hydrogen bonded alternating dicopper(II) complexes and $CH_2Cl_2$ molecules is formed. These chains propagate along the *b* axis and there is a mirror-image relationship between the chains formed by **1**·$CH_2Cl_2$ and **2**·$CH_2Cl_2$ (Figure 4).

In the case of **1**·$CHCl_3$ and **2**·$CHCl_3$, one of the metal coordinated Cl atoms acts as the acceptor in the C–H···Cl interaction involving the C–H group of the $CHCl_3$ molecule. These C–H···Cl connected host-guest units, **1**·$CHCl_3$ and **2**·$CHCl_3$, are mirror images of each other (Figure 5). There is no other noncovalent interaction between these discrete host-guest units to form extended networks in the crystal lattice.

The same type of C–H···Cl interaction as observed in **1**·$CHCl_3$ and **2**·$CHCl_3$ is present in the cases of **1**·Cl-

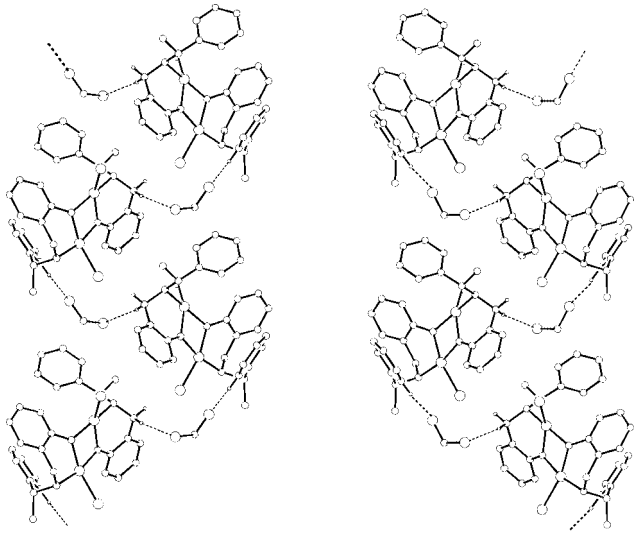

Figure 4. One-dimensional assemblies of (a) $[Cu_2L^1{}_2Cl_2]\cdot CH_2Cl_2$ (**1**·$CH_2Cl_2$) and (b) $[Cu_2L^2{}_2Cl_2]\cdot CH_2Cl_2$ (**2**·$CH_2Cl_2$) in the crystal lattice along the *b* axis through C–H···Cl–C interactions; except for the hydrogen atoms of the methylene groups that are involved in intermolecular interactions, all other hydrogen atoms are omitted for clarity.

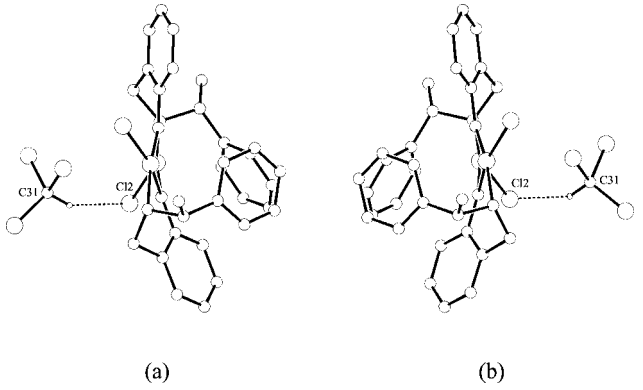

Figure 5. The discrete C–H···Cl–Cu connected (a) $[Cu_2L^1{}_2Cl_2]\cdot CHCl_3$ (**1**·$CHCl_3$) and (b) $[Cu_2L^2{}_2Cl_2]\cdot CHCl_3$ (**2**·$CHCl_3$) units; hydrogen atoms of **1** and **2** are omitted for clarity.

$(CH_2)_2Cl$ and **2**·$Cl(CH_2)_2Cl$. One of the metal coordinated Cl atoms and the C–H group of one of the two methylene groups of $Cl(CH_2)_2Cl$ participate in the C–H···Cl interaction. Here as well, no other noncovalent interactions are observed and the crystal lattice contains the discrete C–H···Cl connected host-guest units. Reports on the isolation of the gauche form of $Cl(CH_2)_2Cl$ are very rare.[7,14] In each of the two present structures, the guest $Cl(CH_2)_2Cl$ molecule is in the chiral gauche form. The Cl–C–C–Cl torsion angles are 58(6)° and 50(7)° in **1**·$Cl(CH_2)_2Cl$ and **2**·$Cl(CH_2)_2Cl$, respectively. The right-handed or *P* form of the enantiomer is stabilised in the host lattice formed by **1** while the left-handed or *M* form of the enantiomer exists in the host lattice formed by **2** (Figure 6). Thus the chiral host complexes **1** and **2** produce the appropriate crystal lattices for enantioselective confinement of the chiral *P* and *M* forms of the $Cl(CH_2)_2Cl$ rotamers, respectively.

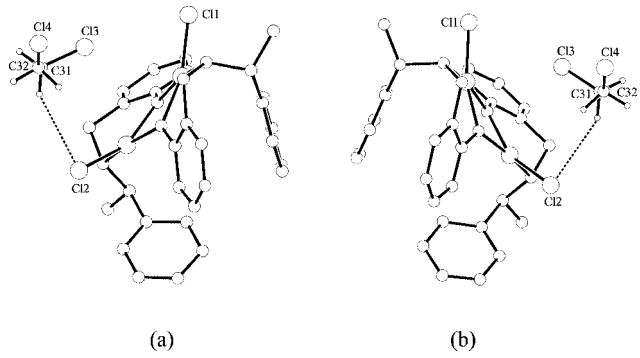

Figure 6. The discrete C–H···Cl–Cu connected (a) $[Cu_2L^1{}_2Cl_2]\cdot(P)$-$Cl(CH_2)_2Cl$ {**1**·(*P*)- $Cl(CH_2)_2Cl$} and (b) $[Cu_2L^2{}_2Cl_2]\cdot(M)$-$Cl(CH_2)_2$-Cl {**2**·(*M*)-$Cl(CH_2)_2Cl$} units; hydrogen atoms of only the $Cl(CH_2)_2Cl$ molecules are shown.

## Conclusions

An enantiomeric pair of bisphenoxo-bridged dicopper(II) complexes, $[Cu_2L^1{}_2Cl_2]$ (**1**) and $[Cu_2L^2{}_2Cl_2]$ (**2**), with the N,O-donor reduced Schiff bases *N*-(2-hydroxybenzyl)-(*R*)-α-methylbenzylamine ($HL^1$) and *N*-(2-hydroxybenzyl)-(*S*)-α-methylbenzylamine ($HL^2$) have been synthesised and characterised. In each complex, a strong antiferromagnetic spin coupling is operative between the metal centres. Crystallisation efforts revealed that both complexes are excellent hosts for small chloroalkane molecules such as $CH_2Cl_2$, $CHCl_3$ and $Cl(CH_2)_2Cl$. In all the cases, 1:1 host-guest compounds are formed which crystallise in the noncentrosymmetric space groups. The asymmetric unit of each structure contains a dicopper(II) complex molecule and a guest molecule. The molecular structures of **1** and **2** are mirror images of each other. The $NO_2Cl$ coordination sphere around each metal centre is distorted from square-planar geometry mainly because of the deviation of the Cl atom from the $NO_2$ plane. The previously known analogous dicopper(II) complexes are all centrosymmetric and the metal coordinated Cl atoms are trans oriented. In contrast, **1** and **2** are noncentrosymmetric and the Cl atoms are in between the trans and cis orientations. The guest molecules are held in the crystal lattice by intermolecular C–H···Cl interactions. In these interactions, the Cl atom of $CH_2Cl_2$ acts as the acceptor while for both $CHCl_3$ and $Cl(CH_2)_2Cl$ the metal coordinated Cl atom acts as the acceptor. Self-assembly of **1**·$CH_2Cl_2$ and **2**·$CH_2Cl_2$ leads to one-dimensional ordering in the crystal lattice. On the other hand, the crystal lattice contains discrete host-guest units when $CHCl_3$ or $Cl(CH_2)_2Cl$ is the guest. Finally, the rare enantioselective trapping of the chiral rotamers (*P*)-$Cl(CH_2)_2Cl$ and (*M*)-$Cl(CH_2)_2Cl$ has been realised in the host lattices formed by **1** and **2**, respectively.

## Experimental Section

**Materials:** The chiral reduced Schiff bases ($HL^1$ and $HL^2$) have been synthesised from salicylaldehyde, *R*- or *S*-α-methylbenzylamine and $NaBH_4$ by following the procedure reported previously.[5,7] All other chemicals and solvents were of analytical grade available commercially and were used as received.

**Physical Measurements:** Microanalytical (C, H, N) data were obtained with a Thermo Finnigon Flash EA1112 series elemental analyser. Infrared spectra were collected by using KBr pellets with a Jasco-5300 FT-IR spectrophotometer. A Shimadzu 3101-PC UV/Vis/NIR spectrophotometer was used to record the electronic spectra. Solution electrical conductivities were measured with a Digisun DI-909 conductivity meter. The variable temperature (18–300 K) magnetic susceptibility measurements on powdered samples of **1** were performed using the Faraday technique with a setup comprising a George Associates Lewis coil force magnetometer, a CAHN microbalance and an Air Products closed-cycle helium cryostat. $Hg[Co(NCS)_4]$ was used as the standard. Diamagnetic corrections calculated from Pascal's constants[15] were used to obtain the molar paramagnetic susceptibilities.

**Synthesis of the Complexes**

**$[Cu_2L^1{}_2Cl_2]$ (1):** A methanol solution (10 mL) of $CuCl_2{\cdot}2H_2O$ (170 mg, 1.0 mmol) was added to a methanol solution (20 mL) of $HL^1$ (227 mg, 1.0 mmol). The mixture was stirred at room temperature in air for 1 h. The brown solid that separated was collected by filtration, washed with cold methanol (10 mL) and finally dried in air. Yield obtained was 390 mg (60%). $C_{30}H_{32}Cl_2Cu_2N_2O_2$ (650.6): calcd. C 55.38, H 4.96, N 4.31; found C 55.45, H 5.02, N 4.20. Electronic spectroscopic data in $CHCl_3$: $\lambda_{max}$ (ε) = 650 sh (345), 430 (3670), 336 sh (2520), 268 nm (12140).

**$[Cu_2L^2{}_2Cl_2]$ (2):** This complex was synthesised in 62% yield from $HL^2$ and $CuCl_2{\cdot}2H_2O$ (1:1 mol ratio) by following the same procedure as described for **1**. It was isolated as a brown solid. $C_{30}H_{32}Cl_2Cu_2N_2O_2$ (650.6): calcd. C 55.38, H 4.96, N 4.31; found C 55.24, H 4.92, N 4.26. Electronic spectroscopic data in $CHCl_3$: 650 sh (353), 430 (3800), 336 sh (2790), 268 (12530).

**X-ray Crystallography:** X-ray quality crystals of the host-guest species **1**·$CH_2Cl_2$, **2**·$CH_2Cl_2$, **1**·$CHCl_3$, **2**·$CHCl_3$, **1**·$Cl(CH_2)_2Cl$ and **2**·$Cl(CH_2)_2Cl$ were grown by slow evaporation of the solutions of **1** and **2** in the corresponding solvents in air at room temperature (298 K). Unit cell parameters and the intensity data for all the crystals were collected with a Bruker-Nonius SMART APEX CCD single crystal diffractometer, equipped with a graphite monochromator and a Mo-*K*a fine-focus sealed tube ($\lambda$ = 0.71073 Å) operated at 2.0 kW. The detector was placed at a distance of 6.0 cm from the crystal. Data were collected at 298 K with a scan width of 0.3° in $\omega$ and an exposure time of 15 s/frame. The SMART software was used for data acquisition and the SAINT-Plus software was used for data extraction.[16] The absorption corrections were performed with the help of the SADABS programme.[17] The structures were solved by direct methods and refined on $F^2$ by full-matrix least-squares procedures. In each structure, all the non-hydrogen atoms were refined using anisotropic thermal parameters. For all the structures, the hydrogen atoms of the metal coordinated secondary amine N atoms were located in the difference Fourier maps and refined isotropically. The rest of the hydrogen atoms in each structure were included in the structure factor calculation at idealised positions by using a riding model, but not refined. The SHELX-97 programmes[18] of the WinGX package[19] were used for structure solution and refinement. The ORTEX6a[20] and Platon packages[21] were used for molecular graphics. Selected crystal and refinement data are listed in Table 3.

CCDC-600238 to -600243 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Financial support for this work was provided by the Council of Scientific and Industrial Research (CSIR), New Delhi [Grant No. 01(1880)/03/EMR-II]. V. K. M. thanks the CSIR for a research fellowship. Our sincere thanks go to Prof. A. R. Chakravarty for providing the cryomagnetic data. X-ray crystallographic studies were performed at the National Single Crystal Diffractometer Facility, School of Chemistry, University of Hyderabad (funded by the Department of Science and Technology, New Delhi). We thank the University Grants Commission, New Delhi for the facilities provided under the UPE and CAS programmes.

# Reactions of Aminobis(phenolate)-Supported Dioxidotungsten(VI) and Dioxidomolybdenum(VI) Complexes

**Ari Lehtonen*[a] and Reijo Sillanpää[b]**

**Keywords:** Molybdenum / Tungsten / Oxido ligands / N,O ligands / Halides

The dioxidotungsten(VI) and -molybdenum(VI) complexes $[WO_2(O_2NO^{Me})]$ (**1**), $[MoO_2(O_2NO^{Me})]$ (**2**) and $[\{MoO_2(O_2N^{Me})\}_2]$ (**3**) [$O_2NO^{Me}$ methoxyethylamino-*N*,*N*-bis(2-methylene-4,6-dimethylphenolate) dianion, $O_2N^{Me}$ = methylamino-*N*,*N*-bis(2-methylene-4,6-dimethylphenolate) dianion] can react with chloride sources ($Me_3SiCl$, $SOCl_2$) to form resultant monooxido dichloro compounds $[WOCl_2(O_2NO^{Me})]$ (**4**), $[MoOCl_2(O_2NO^{Me})]$ (**5**) and $[MoOCl_2(O_2N^{Me})]$ (**6**), respectively. The reaction of tungsten complex yields of the mixture of *cis*-**4** and *trans*-**4**, which can be separated and characterized. The reactions of analogous molybdenum complexes with $Me_3SiCl$ yield *trans* isomers of **5** and **6** as individual products. Reaction of dioxidotungsten complex **1** with isopropyl isocyanate was found to produce a tungsten(VI) complex $[W(O_2NO^{Me})(N\text{-}i\text{Pr})(L)]$ (**7**) (L = *N*,*N*′-diisopropylureate) with a terminal imido group and a bidentate ureate ligand.

## Introduction

The research on early transition metal complexes with chelating aryloxide ligands is mostly motivated by their relevance in organometallic and catalytic chemistry.[1,2] For example, various oxidomolybdenum and oxidotungsten compounds with diverse aryloxide ligands have attracted considerable attention as they can catalyze scientifically and industrially interesting olefin metathesis reactions.[3] In particular, oxidotungsten complexes with various numbers of aryloxide and chloride ligands can form active catalysts when treated with alkylating aluminium or tin cocatalysts.[4] The chloride ligands seems to enhance the activity of these catalyst systems, as they allow the alkylation and formation of catalytically active carbene complexes.[3] The standard procedure for these oxidotungsten(VI) phenoxides comprises a straightforward reaction of $WOCl_4$ with a stoichiometric amount of phenolic ligand precursor in an appropriate solvent. On the other hand, reports on molybdenum complexes $[MoO(OAr)_{4-n}Cl_n]$ are very scarce in comparison with their tungsten congeners, which is most probably due to the poor stability of the starting material $MoOCl_4$. Some monooxidomolybdenum aryloxides, e.g. $[MoOCl_2(OAr)_2]$ (Ar = 2,6-*i*Pr$_2$C$_6$H$_3$) have been prepared from a commercially available precursor, $MoO_2Cl_2$ and parent phenols ArOH.[5] However, these preparations are rather delicate and they require sophisticated inert atmosphere techniques, while moisture and acidic impurities have to be rigorously excluded from the reaction medium.

Various cyclopentadienyl derivatives of dioxidotungsten(VI) and -molybdenum(VI) can be converted into the corresponding monooxido dichloro species using HCl as a chloride source.[6] This reaction proceeds probably via a stepwise addition of two HCl molecules across one of the M=O bonds, which yields one molecule of water as a by-product. Other efficient chlorination reagents are $Me_3SiCl$ and $PCl_5$, which can initially react with proton sources, e.g. traces of water or alcohols, to generate the necessary amount of HCl for the reaction. Group 6 metallocenes $Cp_2MO$ (M = Cr, Mo, W) were reported to undergo a direct silylation of M=O group with $Me_3SiCl$ to yield $Cp_2MCl_2$ complexes.[7] Silylation of benzene-1,2-dithiolate (bdt) complex $[WO_2(bdt)_2]^{2-}$ leads to the formation of anionic chloro monooxido complex $[WO(bdt)_2Cl]^-$.[8] Molybdenum(VI) complex $[MoO_2(Sap)(EtOH)]$ (Sap = *N*-salicylidene-2-aminophenolate dianion) has been reported to react with $SOCl_2$ to yield the dichloro complex *trans*- $[MoO(Sap)Cl_2]$.[9] In this reaction, the active species are proposed to be $SOCl^+$ or $Cl^-$. Previously, we have prepared series of new dioxidomolybdenum(VI) and -tungsten(VI) complexes with dianionic aminobis(phenolato) ligands and studied their use as catalysts in oxotransfer reactions and ROMP of norbornene.[10] For example, $[WO_2(O_2NO^{Me})]$ (**1**), $[MoO_2(O_2NO^{Me})]$ (**2**) and $[\{MoO_2(O_2N^{Me})\}_2]$ (**3**) [$O_2NO^{Me}$-methoxyethylamino-*N*,*N*-bis(2-methylene-4,6-dimethylphenolate) dianion, $O_2N^{Me}$ = methylamino-*N*,*N*-bis(2-methyl-

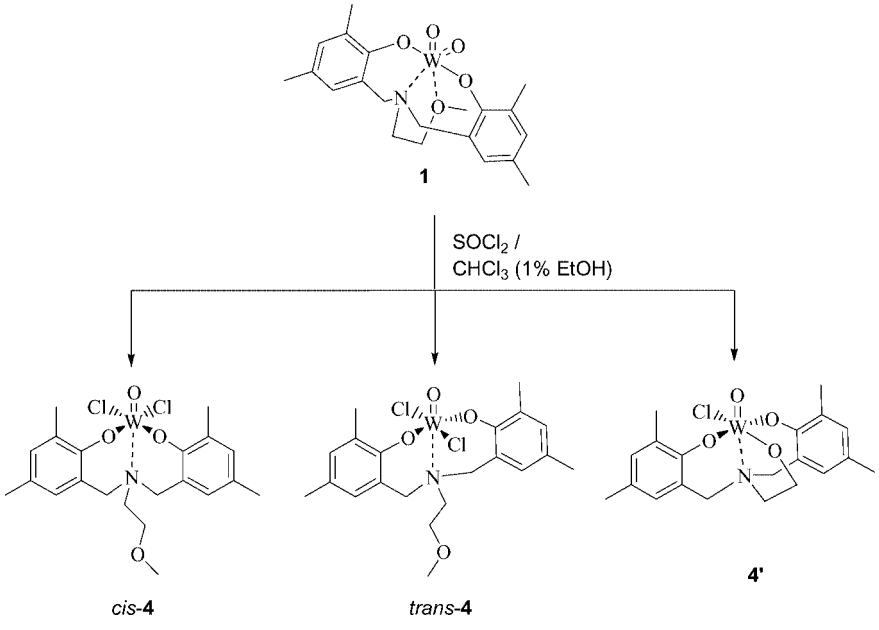
ene-4,6-dimethylphenolate) dianion] have been synthesized and structurally characterized.[10b,10c] We supposed that these air-stable dioxido compounds may also provide useful entries to the new monooxido-dichloro-tungsten(VI) and -molybdenum(VI) complexes, which would resemble well-known metathesis catalyst precursors. In present study we demonstrate a chloride-for-oxide substitution as a simple route to prepare dichloro oxidotungsten(VI) and oxidomolybdenum(VI) complexes with aminobis(phenolate) ligands. In addition, the reaction of tungsten complex **1** with isopropyl isocyanate is studied.

## Results and Discussions

### Chloride-for-Oxide Substitution of Dioxidotungsten(VI) Complex 1

In order to prepare aminobis(phenolate)-supported dichloro monooxido complex of tungsten(VI), we treated dioxidotungsten complex **1** with various potential chloride sources, i.e. HCl, $SOCl_2$, $Me_3Cl$ and $PCl_5$. The stirred mixtures in various solvents ($CHCl_3$, THF, PhMe) were allowed to react with an excess of chlorinating reagents to obtain intense red solutions.[11] The reaction mixtures that formed were then heated to the reflux temperature while the reactions were monitored by TLC. As a result, complex **1** reacted smoothly to produce the mixtures of three distinct products (Scheme 1).

Dark red mixtures were separated by column chromatography to get two intense red solids and one yellow product as a minor component. The IR spectra of red solids presented strong absorption bands at ca. 950 $cm^{-1}$ instead of characteristic doublet (939 and 899 $cm^{-1}$) for $WO_2^{2+}$ moiety in complex **1**.[10c] NMR spectra of red solids were closely similar to those found for isomers of a related compound $[WOCl_2(O_2N^{Me})]$,[12] thus they were identified as *cis* and *trans* isomers of expected dichloro monooxido complex **4**. The third component in the reaction mixtures was a bright yellow complex **4′**, which was formed as trace amounts in all separate experiments. Spectroscopic studies of **4′** suggested some changes in the original aminobis(phenolate) ligand. Compound **4′** was finally identified by X-ray crystallography (see below) to be a mononuclear, monooxido chloro complex, in which the degraded aminobis(phenolato) ligand has coordinated as a tetradentate trianion. When the reaction parameters were optimized, it was found that the highest total conversion could be obtained when the starting compound **1** is dissolved in commercial chloroform with 1% of EtOH stabilizer and subsequently treated with excess of $SOCl_2$. Under these conditions, the reaction yielded a *trans* isomer of **4** as a major component. Although various amounts of both isomers were formed in all of these experiments, any selective reaction conditions for the preparation of *cis*-**4** could not be found.[13] As $SOCl_2$ reacts readily with EtOH to produce HCl, we can assume that the actual reaction is an addition of two HCl molecules across one of the W=O bonds, like reported by Legzdins[6a] and Schrock.[6b] Formation of the *trans* isomer as an eventual result of studied chloride-for-oxide substitution appears reasonable, seeing that two newly introduced chloride ligands replace one terminal oxido group and one neutral oxygen donor, which are at *trans* positions. Conversely, the development of the *cis* isomer is not so obvious, as it results in the substantial rearrangement of the aminobis(phenolate) ligand. Besides, the *cis* isomer appears to be thermodynamically less favourable, as it tends to isomerize in solutions. However, our attempts to isomerize quantitatively *cis*-**4** to *trans*-**4** by heating a sample in a xylene solution at reflux temperature failed, leading mainly to the decomposition of initial complex. Interestingly, the only isolable de-



Scheme 1. Reaction of $[WO_2(O_2NO^{Me})]$ with $SOCl_2$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

composition product was abovementioned **4′**. The formation of this complex is appealing, as the emergence of the atrane-type ligand[14] requires a breaking of the ether C–O bond upon formation of the metal alkoxide bond. Such an ether cleavage as this is a well-known transformation in organic synthesis, and it can be catalyzed by various Lewis and Brönstedt acids.[15] For example; $WCl_6$ can catalyze acylative cleavage of ether C–O bonds, while the reaction is supposed to proceed via a metal alkoxide intermediate.[16] Similar demethylation of the methoxy group upon coordination is earlier observed in the reaction of $TaCl_5$ with *p-tert*-butylcalix[4]arene dimethyl ether.[17] Correspondingly, we can assume that in present experiments, the ether functionality of the ligand side-arm reacts with the metal centre leading to the formation of W–O bond associated with evolution of $CH_3Cl$.

### Chloride-for-Oxide Substitution of Dioxidomolybdenum(VI) Complexes 2 and 3

The reactions of the monomeric molybdenum complex **2** and the dimeric complex **3** with selected chlorinating agents in various solvents were conducted identically as described for tungsten complex **1** (see above). To our discontent, when chloride sources $SOCl_2$ or $PCl_5$ were added to the stirred solutions of dioxidomolybdenum(VI) complexes in $CHCl_3$, the vigorous reactions yielded predominantly to the swift decomposition of starting complexes, whereas only minor amounts of chlorinated products **5** or **6** could be isolated. However, the silylation of Mo=O moiety with $Me_3SiCl$ in toluene proved a convenient procedure for the chloride-for-oxide substitution of these reactive molybdenum complexes. The reaction of complex **2** with $Me_3SiCl$ in a toluene suspension at room temperature led to the formation of dark blue solution, from which the dichloro monooxido complex **5** was obtained in a high yield (Scheme 2).

The IR spectrum of dark purple solid indicated the absence of initial $MoO_2^{2+}$ moiety, whereas the NMR spectra of complex were practically identical to those of *trans*-**4**. Consequently, this isolable reaction product was identified as the *trans* isomer of the expected dichloro derivative. The reaction of **2** appeared to yield also a minor amount of *cis* isomer (according to TLC and $^1H$ NMR analyses), but it could not be isolated, probably due to its tendency to isomerize during processing. The reaction of practically insoluble **3** in a toluene suspension led correspondingly to the intense blue solution, from which the complex **6** was obtained in practically quantitative yield as a dark blue solid. This solid has closely analogous IR and NMR spectra to **2** and tungsten complexes *trans*-[$WOCl_2(O_2N^{Me})$],[12] therefore it was identified as *trans*-[$MoOCl_2(O_2N^{Me})$]. The suspected structure was also verified by X-ray crystallography (see below).

### Reaction of Dioxidotungsten(VI) Complex with Isopropyl Isocyanate

Some transition metal oxido compounds are known to react with alkyl and aryl isocyanates to produce corresponding metal imido complexes.[18,19] In our experiment, dioxidotungsten complex **1** was treated with an excess of isopropyl isocyanate in toluene and the reaction mixture was heated for 120 min at 100 °C in a screw cap vial. As a result, the reaction mixture turned red while complex **1** dissolved. This red solution was subsequently cooled to the room temperature to obtain complex **7** as orange-red crystals. Somehow, identical reaction involving molybdenum complex **2** did not yield any isolable products. IR spectrum of complex **7** presented a strong absorption band at 1634 $cm^{-1}$, which can be assigned as a C=O stretch. X-ray crystal structure analysis verified that the product contains one imido group and one diisopropylureate ligand. The ureate ligand is supposedly formed via bis-imido intermediate, which reacts further with the additional molecule of isocyanate (Scheme 3).[18,20]

Legzdins et al. have studied analogous reactivity of dioxidotungsten complex $Cp^*WO_2(CH_2SiMe_3)$ with *p*-tolyl isocyanate, and reported that the use of hexanes as a reaction medium yields mono- and bis(imido) complexes, whereas the reaction in toluene solution affords an imido ureate complex.[18a] In our experiments, the reaction was conducted in a toluene solution, while the tungsten precursor dissolved slowly upon reaction. Thus, the stoichiometry of starting materials was unfeasible to control and the reaction yielded the ultimate ureate complex without any isolable intermediates. Complex **7** is stable in air as crystalline solid, but it decomposes in organic solvents, therefore adequate NMR spectroscopic data were not obtained.

## Structural Studies

X-ray structure determinations were carried out for complexes *trans*-**4**, **4′**, **6** and **7**. In t*rans*-**4** the tungsten(VI) cation has adopted a distorted octahedral coordination geometry, whereas the aminobis(phenolate) ligand is coordinated as a tridentate $O_2N$ donor (Figure 1). Two chloro ligands are in *trans* orientation. General structural parameters, e. g. W–O and W–Cl distances along with O–W–O and Cl–W–Cl angles, are of the same magnitude as usually found in $[WOCl_2(OAr)_2]$ complexes.[4,21] Consequently, the overall structure of *trans*-**4** is essentially similar to that found in related complexes with methylamino-*N*,*N*-bis(2-methylene-4,6-dialkylphenolate) ligands.[12] Complex **4′** forms monomeric molecules in which the aminobis(phenolate)ethanolate group has coordinated as a tetradentate trianionic ligand through three oxygen donors and one nitrogen donor (Figure 2). The nitrogen donor is located t*rans* to the terminal oxido group, while the chloro ligand is sited *trans* to the alkoxide oxygen. In the solid-state structure of **4′**, the $W–O_{aryloxide}$ bond lengths are 1.896(5) and 1.918(5) Å, whereas the $W–O_{alkoxide}$ bond is 1.909(4) Å. The bonding parameters between the metal centre and the aminobis(phenolato)ethanolato ligand is rather expected, although the W–O bond lengths are slightly longer and W–N distances are slightly shorter than in comparable oxidotungsten(VI) complexes with tridentate aminobis(phenolates). In general, the solid-state structure of **4′** resembles those found in oxidotungsten(VI) complexes with tripodal aminotris(phenolate)s.[22]

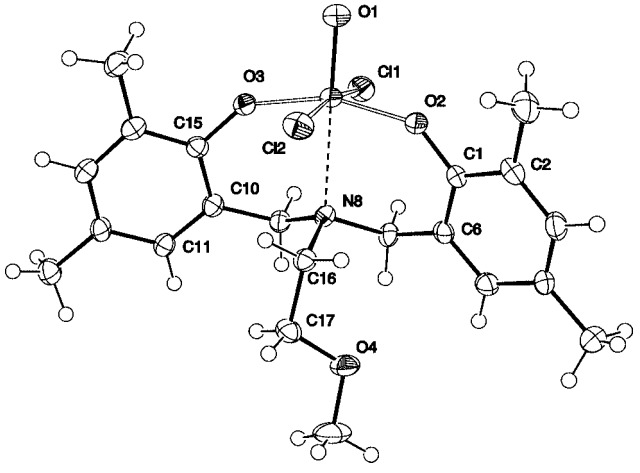

Figure 1. Molecular structure of *trans*-**4**. Thermal ellipsoids have been drawn at 30% probability level.

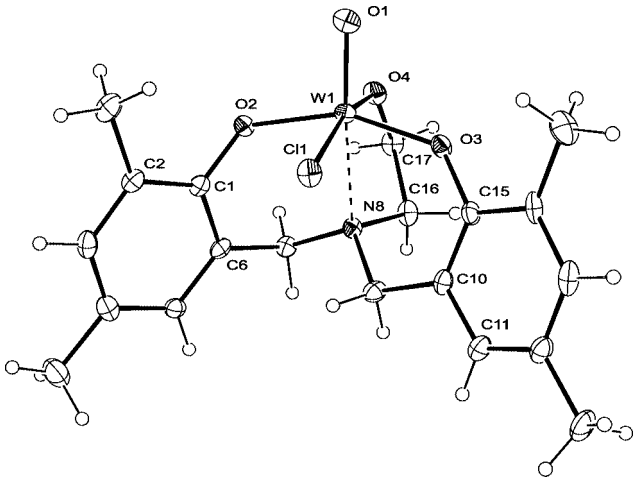

Figure 2. Molecular structure of **4′**. Thermal ellipsoids have been drawn at 30% probability level.

The coordination sphere around the metal centre in the molybdenum complex **6** (Figure 3.) is very similar to that in *trans*-**4** and other related tungsten complexes. Essentially, complex **6** is isostructural with the equivalent tungsten compound $[WOCl_2(O_2N^{Me})]$.[12] Only small structural differences are found between these two complexes, e.g. the M=O and M–N bond lengths are 1.672(4) and 2.536(4) for the Mo complex, whereas corresponding distances for the tungsten analogue are 1.696(5) Å and 2.512(5) Å, respectively.

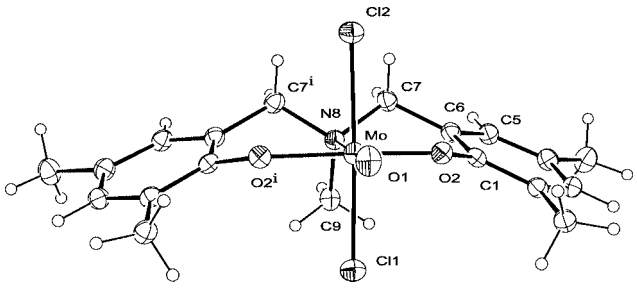

Figure 3. Molecular structure of **6**. Thermal ellipsoids have been drawn at 30% probability level.

In complex **7** the metal centre is surrounded by two phenoxides oxygen atoms, one neutral nitrogen donor, one imido group and two amido nitrogen donors (Figure 4.). The phenoxides oxygen atoms of aminobis(phenolato) ligand have arranged in a *cis* fashion [the O–W–O angle is 107.51(19)°], while the neutral amino nitrogen has located

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*trans* to the imido nitrogen atom. Amido nitrogen atoms of the ureate group are in *cis* positions by necessity [the N–W–N angle is 63.4(2) °]. The $W{=}N_{imido}$ and two $W{-}N_{ureate}$ distances [1.723(6), 1.926(4) and 1.939(5) Å, respectively] are slightly shorter than found in related high-valent metal complexes derived from aromatic isocyanates.[18]

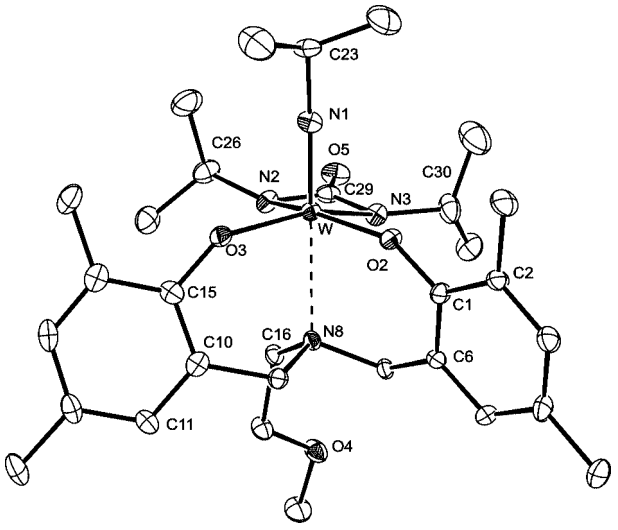

Figure 4. Molecular structure of **7**. Hydrogen atoms are omitted for clarity. Thermal ellipsoids have been drawn at 30% probability level. Selected bond lengths [Å] and angles [°]: W–N1, 1.723(6); W–N2, 2.062(5); W–N3, 2.063(5); W–O2, 1.926(4); W–O3, 1.939(5); W–N(3), 2.064(5); W–N8, 2.458(5); W–N1–C23, 172.0(5); N2–W–N3, 63.4(2); O2–W–O3, 107.51(19); N1–W–N8, 170.2(2).

## Conclusions

In summary, we have shown that aminobis(phenolate)-supported dioxidotungsten(VI) and -molybdenum(VI) complex can be used as starting materials for new dichloro monooxido complexes. The chloride-for-oxide substitution can be easily carried out using $SOCl_2$ or $Me_3SiCl$ as chloride sources. Particularly, the chlorination of molybdenum complexes can be easily carried out in synthetically useful yields. Resulting oxidometal(VI) complexes carry primarily a *trans* dichloro functionality. These complexes resemble potential metathesis catalyst precursors; therefore their use in catalytic applications will be probed in future. The aminobis(phenolate)-supported dioxidotungsten(VI) can also react with isopropyl isocyanate to generate corresponding imido ureate complex.

## Experimental Section

Starting complexes **1**, **2** and **3** were prepared according published procedures.[10b,10c] Other chemicals were from commercial sources and were used as purchased. Solvents were of HPLC grade. All syntheses and manipulations were performed under ambient laboratory atmosphere if not otherwise stated. $^1H$ and $^{13}C$ NMR spectra (500 MHz) were recorded at 20 °C using Bruker AV 500 spectrometer in $CDCl_3$ solutions and were referenced internally to $SiMe_4$. IR spectra were recorded as Nujol mulls using a Mattson Galaxy FTIR spectrometer. Elemental analyses were obtained using a Perkin–Elmer CHNS Analyzer 2400. Crystalline samples were dried in vacuo at 40 °C for 4 h prior to elemental analyses.

**Chloride-for-Oxide Substitutions of 1:** Complex **1** (110 mg, 0.20 mmol) was mixed with $CHCl_3$ (10 mL, stabilized with 1% of EtOH) and subsequently treated with $SOCl_2$ (0.10 mL, 1.4 mmol). The reaction mixture was then heated at reflux temperature under dynamic $N_2$ atmosphere for two hours while the reaction was monitored by TLC (toluene as an eluent). As a result, complex **1** reacted completely to produce a mixture of two red products and one yellow product. The dark red mixture was separated by silica column chromatography using toluene as an eluent to get *trans* and *cis* isomers, in that order, of dichloro complex **4** as intense red solids. The third component in the reaction mixture was a bright yellow complex **4′**.

***cis*-4:** Yield: 8 mg (7%). $C_{21}H_{27}Cl_2NO_4W$ ($M$ = 612.19 g mol$^{-1}$): calcd. C 41.20, H 4.45, N 2.29; found C 40.80, H 4.27, N 2.11. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.13 (s, 2 H, Ar), 6.91 (s, 2 H, Ar), 3.75–3.78 (overlapping d + s, 6 H, $CH_2$), 3.36 (s, 3 H, $OCH_3$), 2.95 (s, 2 H, $CH_2$), 2.50 (s, 6 H, $ArCH_3$), 2.47 (s, 6 H, $ArCH_3$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 155.91, 135.83, 131.16, 129.46, 128.24, 127.42, 68.23, 58.81, 57.90, 56.98, 20.80, 16.00 ppm. [a] Values in parentheses for reflections with $I > 2.0\sigma(I)$: $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$. $wR_2 = \{\Sigma[w(F_o^2-F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ and $w = 1/[\sigma^2(F_o^2)+(aP)^2+bP]$, where $P = (2F_c^2+F_o^2)/3$.

58.92, 56.45, 50.53, 21.33, 16.43 ppm. IR (Nujol): ṽ = 1306 (w), 1239 (s), 1219 (s), 1171 (vs), 1117 (s), 1090 (m), 959 (vs), 882 (vs), 873 (m), 746 (s), 731 (m), 681 (w), 661 (m), 598 (m), 574 (m) cm$^{-1}$.

**6:** Yield: 1.325 g (92%). $C_{19}H_{23}Cl_2MoNO_3$ ($M$ = 480.22 g mol$^{-1}$): calcd. C 47.52, H 4.83, N 2.92; found C 47.81, H 5.05, N 2.78. $^1$H NMR ($CDCl_3$): $\delta$ = 7.11 (s, 2 H, Ar), 6.94 (s, 2 H, Ar), 4.86 (d, $J$ = 13.0 Hz, 2 H,Ar-$CH_2$), 3.08 (d, $J$ = 13.0 Hz, 2 H,Ar-$CH_2$), 2.56 (s, Ar$CH_3$, 6 H), 2.48 (s, 6 H,Ar$CH_3$) 1.86 (s, 3 H,N–$CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 160.78, 138.95, 131.03, 129.56, 129.20, 128.25, 62.80, 46.83, 21.23, 16.43 ppm. IR (Nujol): ṽ = 1300 (m), 1240 (s), 1223 (s), 1157 (s), 1132 (m), 1082 (vs, br), 955 (vs), 937 (m), 866 (vs), 844 (m), 748 (w), 696 (w), 666 (w), 600 (m), 573 (w) cm$^{-1}$.

**Reaction of 1 with Isopropyl Isocyanate:** Complex **1** (110 mg, 0.20 mmol) was mixed with toluene (3.0 mL) in a screw cap vial and subsequently treated with isopropyl isocyanate (0.10 mL, 1.0 mmol). The reaction mixture was then heated at 110 °C for 16 hours. The red solution formed was cooled to the room temperature and hexane (3.0 mL) was added to enhance the crystallization. The solution was then kept at –18 °C overnight, after that the orange-red crystals (85 mg, 60%) were separated by decantation and washed by hexane. Crystals were stable in air for several days, but they decompose quickly upon dissolution.

Table 2. Selected bond lengths [Å] and angles [°] for *trans*-**4**, **4′** and **6**.

| | *trans*-**4** | **4′**[a] | **6** |
|---|---|---|---|
| M–O1 | 1.693(3) | 1.714(5) | 1.672(4) |

[a] Parameters for the W1-centered molecule. [b] O3 corresponds to O2$^i$, where $i = x, -y+1/2, z$.

**7**: Yield: 54 mg (37%). $C_{31}H_{48}N_4O_4W$ ($M$ = 724.58 g mol$^{-1}$): C 51.39, H 6.68, N 7.73; found C 50.99, H 6.35, N 7.59. IR: ṽ = 1634 (vs, br), 1283 (vs), 1245 (vs), 1221 (vs), 1159 (s), 1113 (s), 1094 (m), 1055 (m), 1038 (w), 988 (m), 961 (m), 932 (m), 860 (s), 855 (vs), 783 (m), 750 (m), 733 (m), 690 (w), 598 (m), 556 (m), 422 (w) cm$^{-1}$.

**X-ray Crystallography:** Crystals of *trans*-**4** and **4′**, suitable for X-ray measurements were grown at 4 °C from acetonitrile. Crystals of **6** were obtained from concentrated toluene solution at room temperature. Crystals of **7** precipitated from the reaction mixture at –18 °C. Crystal data for the compounds *trans*-**4**, **4′**, **6** and **7** along with other experimental details are summarized in Table 1. Single-crystal data collections, reduction, and subsequent calculations were performed essentially as described in our earlier papers.[12,22] Figures were drawn with *Ortep-3 for Windows*[23] (Table 2).

CCDC-601925, -601926, -601927 and -601928 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[11] Chloride-for-oxide substitution of the dioxidotungsten(VI) complex **1** was carried out using HCl, $SOCl_2$, $Me_3Cl$ and $PCl_5$ as chloride sources in various solvents ($CHCl_3$, THF, PhMe). Isolated yields of *cis*-**4**, *trans*-**4** and **4′** from each experiment are reported in the Supporting Information.
[12] A. Lehtonen, R. Sillanpää, *Inorg. Chem.* **2004**, *43*, 6501–6506.
[13] Dichloro complex **4** was prepared also by a direct reaction of $WOCl_4$ with ligand precursor $H_2O_2NO^{Me}$. This reaction was repeated in toluene and THF solutions at reflux temperature. Consequently, it was appreciated, that the use of THF afforded *cis*-**4** as an only isolable product, although the yield was moderate low (35%), whereas the reaction in toluene lead to the isomeric mixture. Again, these reactions produced also small amounts of yellow **4′**.

# Tricarbonylchlororhenium(I) Carboxaldimine Derivatives: Synthesis, Structure, and NMR Characterization of *Z* and *E* Isomers

**Claudio Garino,[a] Simona Ghiani,[a] Roberto Gobetto,[a] Carlo Nervi,*[a] Luca Salassa,[a] Gianluca Croce,[b] Marco Milanesio,[b] Edward Rosenberg,*[c] and J. B. Alexander Ross[c]**

**Keywords:** *E*/*Z* isomerization / Density functional calculations / N ligands / Rhenium

The ligand *N*-(2-pyridylmethyl)anthracene-9-carboxaldimine (**1**) has been synthesized and characterized by NMR spectroscopic techniques. The experimental procedure leads selectively to the *E* isomer, which has been studied by a combined theoretical (Density Functional Theory) and 2D NOESY NMR spectroscopic approach. The trifluoroacetic acid promotes the *E* to Z isomerization of **1**. The process has been investigated by NMR spectroscopy and computationally for the neutral ligand **1**. DFT methods calculate that the *E* isomer is 2.2 kcal/mol more stable than the *Z* isomer, whereas the reverse situation is observed for the protonated species, where the *Z* isomer is 4.5 kcal/mol more stable than the *E* isomer. Transition state calculations for the interconversion of the neutral and protonated *E* species into their corresponding *Z* isomers show that the energy barriers are 27.6 and 20.3 kcal/mol for the neutral and protonated species, respectively. The reaction with pentacarbonylchlororhenium leads, in the absence and in the presence of trifluoroacetic acid, to the synthesis of the corresponding tricarbonylchlororhenium isomer complexes **Re-*E*-1** and **Re-*Z*-1**, respectively. Compounds **Re-*E*-1** and **Re-*Z*-1** were characterized by 1D and 2D NMR spectroscopy in solution, and their crystal structures were determined. Their photophysical and electrochemical properties are also reported.

## Introduction

The electrochemical, photophysical, and photochemical properties of α,α′-diimino ligands have made their coordination chemistry with transition metals, in particular with ruthenium, one of the most relevant in recent decades.[1–4] $Re(CO)_3X$ (where X = halogen) derivatives bearing α,α′-diimine ligands have been studied for their effectiveness in the electrocatalytic reduction of $CO_2$[5,6] and for their photo-induced electron and energy transfer properties.[7,8] The nitrogen atoms contained in these ligands are most commonly part of heterocyclic rings like pyridine, pyrimidine, and pyrazine. In comparison, less attention has been devoted to the investigation of similar Schiff base ligands, such as carboxaldimines, in which at least one nitrogen atom is not part of an aromatic ring. Rhenium derivatives with 2,2′-azobispyridine,[9–11] pyridinylmethylene amino derivatives,[8,12] and the $Re(CO)_3$ mediated Schiff base formation from the in situ reaction between pyridinecarbaldehyde and $NH_2$-containing biomolecules[13] have been studied. This class of compounds is of great interest because of their close relationship with their better-known counterparts, mentioned above. Furthermore, the imine functional group has become important in the synthesis of therapeutic agents, for example the third generation of the class of antibiotics known as cephalosporins,[14] and in the modeling of metal biosites in proteins and enzymes.[15] They have also attracted interest in asymmetric homogeneous and heterogeneous catalysis,[16] and in the synthesis of chiral heterocycles.[17] Their photophysical properties have also been studied theoretically by means of DFT calculations.[18,19] Because of the lower energy of the π* states, in metal complexes containing Schiff base ligands, their adsorption and emission MLCT bands show a red shift when compared with the MLCT transitions of the corresponding bipyridyl derivatives. This red shift can be explained in terms of a distortion of the excited states (π-π* and n-π*) that are localized on the C=N double bond and that contribute significantly to the composition of the LUMO,[20–22] especially in the case of carboxaldimines.[12] In general, imine–metal complexes are relatively unstable towards hydrolysis, particularly in the case of ruthenium and osmium.[23] Bulky ligands could be employed in the synthesis of more stable metal complexes with the aim of limiting or blocking such hydrolysis. Also, the acid-catalyzed *E*/*Z* isomerization is well known and several attempts towards understanding its mechanism have been made.[14] Yet, in some cases the de-

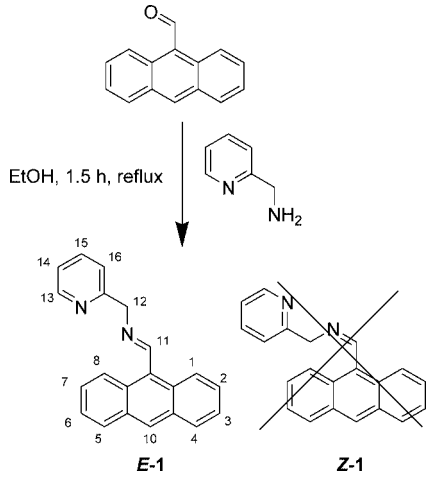
tails of the isomerization mechanism itself remain unclear. In this contribution we report the coordination of tricarbonylchlororhenium to the new organic ligand *N*-(2-pyridylmethyl)anthracene-9-carboxaldimine (**1**) in its *Z* and *E* isomeric forms, which leads to the synthesis of rather stable complexes.

## Results and Discussion

### *Z* and *E* Isomers of the Ligand 1

The ligand *N*-(2-pyridylmethyl)anthracene-9-carboxaldimine (**1**), was synthesized in refluxing ethanol by the condensation of 2-(aminomethyl)pyridine with anthracene-9-carboxaldehyde (Scheme 1).



Scheme 1.

The imine **1** can exist in the *E* or *Z* isomeric forms. The presence/absence of bulky groups is generally accepted as the main reason for the preferential formation of one isomer over the other. However, to the best of our knowledge, a complete understanding of the process is not available to date. It is interesting to note that the procedure shown in Scheme 1 yields the isomer ***E*-1**, exclusively (see below). In the DFT-optimized structures of *E* and *Z* isomers, obtained using Jaguar[24] at the B3LYP/6-311++G** level, the two planes defined by the C=N imine and the anthracene moieties are perpendicular to each other. This situation is commonly found whenever an imine carries bulky groups.[25,26] From the DFT calculations it turns out that these geometries have a plane of symmetry, and that the *Z* isomer is only 0.8 kcal/mol more stable than the *E* form. The difference in energy is very small and much lower than the expected accuracy of the DFT method (about 2 kcal/mol).[27] The DFT calculations were repeated by using Gaussian 03[28] for the conformations resulting from 10° rotations around the imine bond. The highest energy conformation was noted at 90°, and the calculated value of 53 kcal/mol for the C=N rotational barrier appears to be fairly high. A similar value (56 kcal/mol) has been obtained for the rotational pathway of the *E*/*Z* isomerization in methyleneimine.[29] Attempts to gain thermal corrections based on harmonic frequencies from these symmetric structures of ***E*-1** and ***Z*-1** failed because of the oscillations of the computed energies. The difficulty in getting stable frequency calculations, and the fact that we get more than one imaginary frequency, suggested that these symmetric forms are only at a local rather than a global energy minimum (saddle point). In order to overcome these local minima of energies, we started from slightly distorted structures and excluded the use of symmetry during the optimization process. The geometries of *E* and *Z* isomers corresponding to the global minima, found by DFT optimizations with Jaguar at the same level, namely B3LYP/6-311++G**, are shown in Figure 1. The frequency calculations performed on these optimized asymmetric structures reveal that the *E* form is more stable than the *Z* form by 2.2 kcal/mol. Thus, better thermodynamic agreement with the experimental observations is obtained, although the difference in energy is still comparable with the accuracy of the DFT method. The calculated structures of *E* and *Z* have very different intramolecular H–H distances (see Table 1), which are doubled in the case of the asymmetric ones because the two geminal H(12) and the two H(1) and H(8) hydrogen atoms are not equivalent. However, whatever the real dynamic structures are, both the symmetrical (local minimum) and nonsymmetrical (global minimum) structures of *Z* have H(11)–H(12) distances that are larger than those of the *E* isomers. This peculiarity is revealed experimentally by the phase-sensitive NOESY spectrum, in which an evident cross-peak system from the dipolar interaction between the lone H(11) and the two H(12) hydrogen atoms is clear evidence of the presence of the ***E*-1** isomer. Proton NMR resonances have been assigned by conventional 1D, 2D COSY, and NOESY spectra (see Supporting Information), and are summarized in Table 2. Moreover, variable temperature experiments performed on ***E*-1** in the range 220–300 K do not produce any changes in the NMR spectra, revealing that *Z* and *E* isomers are not easily interconverted. Having obtained both the optimized structures, we have performed a search for the transition state (TS) associated with the isomerization of neutral ***E*-1** to ***Z*-1**. The optimized TS structure is provided in Figure 2 (a). The calculated structure of the TS shows that the bond angle C=N–C is linear, clearly indicating that the isomerization of the neutral species proceeds via an in-plane lateral shift process. The calculated free energy of the TS relative to the reactant, i.e. the energetic barrier for isomerization of neutral ***E*-1** to ***Z*-1** is moderately high (27.6 kcal/mol), but much lower than the energetic barrier associated with the pure C=N rotation. Similar values were calculated for the in-plane lateral shift process of methyleneimine (32.5 kcal/mol) and dicyandiamide (29 kcal/mol).[29,30]

However, when a slight molar excess of $CF_3COOH$ is added to a $CD_2Cl_2$ solution of ***E*-1**, the resonances of H(11) and H(12) shift from 9.63 and 5.23 to 10.34 and 5.94 ppm, and then rapidly convert into two new resonances at 11.40 and 4.80 ppm, respectively. The conversion does not occur significantly when only a catalytic amount of acid is used, at least not over short periods. This new species does not

show the above-mentioned NOESY cross peak signal (see Supporting Information). The overall process is therefore explained as (a) instantaneous protonation of ***E*-1**, (***E*-1H$^+$**) and (b) relatively fast conversion into the protonated ***Z*-1** form (***Z*-1H$^+$**). Thus ***E*-1** is easily converted into ***Z*-1** by adding trifluoroacetic acid. The trend in the proton resonance sequences on going from ***E*-1** to ***E*-1H$^+$**, and finally to the ***Z*-1H$^+$** form is more difficult to interpret. As mentioned, for H(11) and H(12) the experimental sequences are 9.63 to 10.34 to 11.40 ppm and 5.23 to 5.94 to 4.80 ppm, respectively. We optimized the geometries of ***E*-1**, ***E*-1H$^+$** and ***Z*-1H$^+$**, and the corresponding calculated $^1$H NMR chemical shift sequences of H(11) and H(12) are 10.18 to 10.45 to 10.51 ppm and 5.51 to 5.59 to 4.81 ppm, respectively. Although quantum mechanical calculations of $^1$H NMR chemical shifts are subject to significant errors,[31–33] especially whenever hydrogen bonds are involved, the same experimental trend is reproduced. More importantly, a frequency calculation gives a Gibbs free energy value for ***Z*-1H$^+$** that is 4.5 kcal/mol lower than that of the corresponding ***E*-1H$^+$**. This small but significant inversion of energy gives further support to the outlined interpretation, and it is in agreement with the experimental observation, which

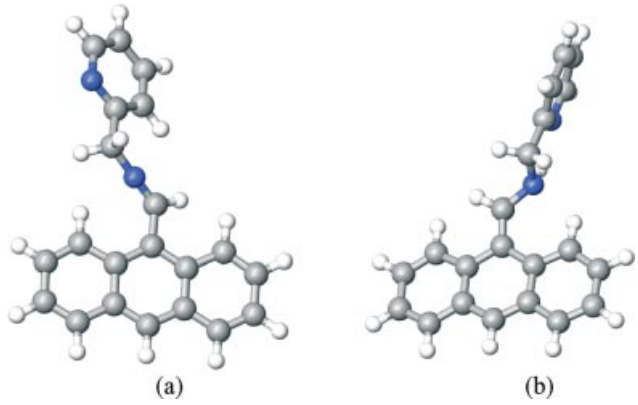

Figure 2. Transition State (TS) optimized structures for the isomerization processes ***E*-1** to ***Z*-1** (a) and ***E*-1H$^+$** to ***Z*-1H$^+$** (b).

shows that the ratio between the integrated $^1$H NMR resonances H(12) of ***E*-1H$^+$** and ***Z*-1H$^+$**, namely the signals centered at $\delta$ = 5.94 and 4.80 ppm, respectively, are 1:16 (see Supporting Information). This corresponds to a Gibbs free energy difference of 1.6 kcal/mol between the two isomers at 298 K, in reasonable agreement with the calculated value. Computational searches for the TS for the isomerization process ***E*-1H$^+$** to ***Z*-1H$^+$** leads to the structure shown in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figure 2 (b). The calculated free energy of the TS relative to the reactant ***E*-1H$^+$** is evaluated to be 20.3 kcal/mol. As one could expect, in both the neutral and protonated TSs, the dihedral angle that defines the rotation around the C=N double bond, $D_{C=N}$, is roughly midway between the values observed for the *Z* and *E* isomers. However, it is interesting to note that the protonated TS has a $D_{C=N}$ value closer to that of the *Z* isomer. The $D_{C=N}$ values for ***E*-1H$^+$**, ***Z*-1H$^+$**, and for the corresponding TS are 178.3, 12.0, and 111.5°, respectively, whereas the $D_{C=N}$ values for ***E*-1**, ***Z*-1**, and for the corresponding neutral TS are 179.3, 0.8, and 89.4°, respectively. The neutral and protonated TSs have a HC=N–$CH_2$ bond angle of 177.7 and 114.9°, and only one imaginary frequency of 274i and 325i cm$^{-1}$, respectively. Therefore, these first-order saddle points are real transition states. The vibrational mode of the neutral TS is associated with the reaction coordinate that involves major motion of the nitrogen atom (in-plane lateral shift), whereas the vibrational mode of the protonated TS is associated with the reaction coordinate that involves major motion of the hydrogen atoms HC=N and NH. Therefore, the protonation has two effects: the first is evident and it is to alter the geometry of the transition state and to significantly decrease its energy for the isomerization process, whereas the second effect is less certain, but most likely makes the *Z* isomer thermodynamically more stable than the *E* isomer. This could also explain why the isomerization is not observed with only a small, catalytic amount of acid. Finally, it should be pointed out that whereas the DFT calculations apparently reproduce the ground-state structures very well, the energies of the transition states are presumably overemphasized.

**Rhenium Complexes of 1**

The reaction of $Re(CO)_5Cl$ with ***E*-1** in refluxing toluene, under an Ar atmosphere, produces the corresponding complex (***E*-1**)$Re(CO)_3Cl$ (**Re-*E*-1**). When carrying out the same reaction in the presence of an approximately half molar quantity of $CF_3COOH$, we obtained a mixture of **Re-*E*-1** and (***Z*-1**)$Re(CO)_3Cl$, hereafter called **Re-*Z*-1**. The latter compound was obtained only in small amounts. Remarkably, **Re-*E*-1** and **Re-*Z*-1** have different solubilities in benzene, and can be separated by a simple extraction. The two rhenium-imino derivatives **Re-*E*-1** and **Re-*Z*-1** have been fully characterized with several spectroscopic techniques. In particular, the $^1$H NMR spectrum of **Re-*E*-1** in $CD_2Cl_2$ shows three resonances at $\delta$ = 9.63, 6.23, and 5.60 ppm, assigned to H(11) and to the two diastereotopic $CH_2$ protons H(12a) and H(12b), respectively, whereas in the case of **Re-*Z*-1** the corresponding signals are observed at $\delta$ = 9.99, 5.12, and 4.76 ppm.

More interestingly, the NOESY experiment on **Re-*E*-1** reveals the presence of a dipolar interaction between H(11) and the two H(12) protons, which is absent in the case of **Re-*Z*-1** (see Supporting Information). Determination of the X-ray structures of the two isomers **Re-*E*-1** and **Re-*Z*-1** confirms the retention of the ligand conformation on coordination to the metal center (Figure 3). The isomerization does not take place after the metal complex formation, since the NMR spectra of **Re-*E*-1** and **Re-*Z*-1** in $CD_2Cl_2$ solutions before and after the addition of a molar amount of $CF_3COOH$ are identical, most likely because the coordination of the metal does not allow the protonation of the ligand, which then freezes the isomerization process.

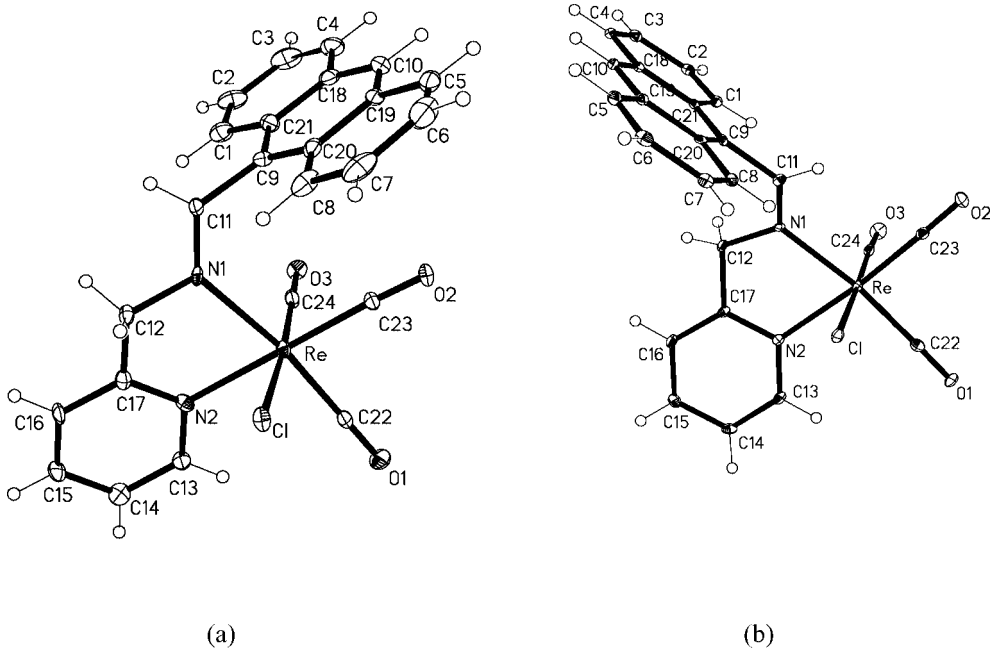

Figure 3. Molecular structures of **Re-*E*-1** (a) and **Re-*Z*-1** (b), showing the adopted labeling scheme, with displacement ellipsoids drawn at the 20% probability. A solvated benzene molecule in **Re-*Z*-1** is not shown for the sake of clarity.

### Crystal Structure Analysis

The structures of **Re-*E*-1** and **Re-*Z*-1** isomers are illustrated in Figure 3 and the crystallographic data are given in Table 5. **Re-*E*-1** is arranged in the $P2_1$ chiral space group, while **Re-*Z*-1** is arranged in the centrosymmetric $P\bar{1}$ space group. The *E* isomer was therefore obtained chirally pure, while the *Z* isomer is a racemate of the two possible enantiomers. Compound **Re-*Z*-1** crystallizes with one benzene molecule of solvation.

The *E*/*Z* isomerization of the N(1)–C(11) double bond causes significant rearrangements of the overall shape and of the crystal packing of the two complexes. The selected geometric parameters for the two isomers, and the differences and significances with respect to esd's, are reported in Table 3. The larger differences between the two isomers (Δ values larger than 8) are due to the location and the orientation of the anthracene moiety with respect to the metal core of the complex. Also the pyridine group orientation, defined by the Cl–Re–N(2)–C(17) torsion angle, with Δ = 16.5, is rather different in the two isomers. Conversely, the planarity of the anthracene and of the pyridine groups are similar in the two isomers: 0.035(6) and 0.003(5) Å in **Re-*E*-1** and 0,020(3) and 0.003(2) Å in the **Re-*Z*-1** isomer, respectively. As a result of the above mentioned differences, the anthracene group in **Re-*E*-1** is bent towards the C(23)–O(2) and C(23)–O(4) carbonyl groups, the resulting contact distances being rather short (reported with respect to anthracene center of mass, $A_{CM}$ in Table 3), while in **Re-*Z*-1** the anthracene group is located in the external part of the complex, far away from the metal core and the carbonyl groups. The C(11)–H(11) bond shows an opposite behavior, pointing towards carbonyl groups in **Re-*Z*-1** and towards the anthracene moiety of the adjacent molecule in **Re-*E*-1**. This opposite behavior has a dramatic effect on the crystal packing features of the two isomers. In fact, in **Re-*Z*-1** the crystal packing (see Figure 4, b) is clearly driven by the π-π stacking between parallel anthracene moieties, as indicated by the similar distances observed between the anthracene centers of mass (3.694 Å) and between planes containing adjacent anthracene moieties (3.743 Å). On the contrary, in **Re-*E*-1** the anthracene groups once again lie on parallel planes, with a distances between planes of 3.422 Å, much smaller than the distances between the centers of mass (7.823 Å), thus avoiding the π-π stacking.

In **Re-*E*-1** the anthracene moiety is too close to the metal center to allow the π-π stacking observed in **Re-*Z*-1** and the molecules are helicoidally packed, obeying to the $2_1$ screw axis. Finally, CH···OC and CH···Cl interactions are also present.

The *E*/*Z* isomerization also affects the coordination geometry of the Re atom, as indicated by the Δ values highlighted in bold character in Table 3. The differences mostly occur with the Cl ligand (Δ values larger than 2 esd.). Smaller differences, close to the detection limit ($1 < \Delta < 2$ in Table 3) involve the C(24)–O(3) distance and the N(2) atom of the pyridine ligand.

Table 3. Selected geometric parameters for **Re-*E*-1** and **Re-*Z*-1** (distances in Å and angles in °) and relevance of difference with respect to esd's (Δ), calculated as Δ = {esd.[value(**Re-*E*-1**), value(**Re-*Z*-1**)]}/{esd.[value(**Re-*E*-1**)] + esd.[value(**Re-*Z*-1**)]}. Values differing by a significant value (Δ > 1) are highlighted in **bold**.

### Electronic Absorption and Emission Spectra

The electronic absorption spectrum of ***E*-1** in $CH_3CN$ solution shows an intense absorption peak at 251 nm ($\varepsilon$ = 64800 $M^{-1}$) and three bands at 351, 369, and 387 nm, which probably correspond to the $\pi\rightarrow\pi^*$ and $n\rightarrow\pi^*$ transitions. Excitation at 370 nm in $CH_3CN$ produces an intense emission peak at 440 nm. These absorption and emission peaks are very similar to those of pure anthracene.[34] Rhenium complexes **Re-*E*-1** and **Re-*Z*-1** have identical absorption (bands at 354, 371, and 389 nm) and emission spectra, which in turn are very similar to that of the free ligand ***E*-1**. However, **Re-*E*-1** and **Re-*Z*-1** show a weaker emission centered at 441 nm (Figure 5). We did not observe a metal-centered MLCT emission band. $Re(bpy)(CO)_3Cl$ and analogous imino derivatives[8,12,35] usually have MLCT absorptions in the range 340–430 nm. Time-Dependent DFT calculations (TDDFT) help to understand these data. The geometries of ***E*-1**, **Re-*E*-1**, and **Re-*Z*-1** were optimized in the singlet ground state in the gas phase. The HOMO and LUMO of ***E*-1** are mostly localized on the anthracene unit, only slightly involving the C=N double bond. The spectroscopic properties were calculated employing the combined TDDFT/CPCM computational approach, which is currently considered to be the most appropriate method for the treatment of the solvent effects on the excited-state energies of transition-metal complexes.[36,37] A number of singlet excited states of ***E*-1**, **Re-*E*-1**, and **Re-*Z*-1** in acetonitrile were calculated and are reported in Table 4. The absorption of ***E*-1** with the highest oscillator strength (393 nm) is mainly from a HOMO→LUMO transition. In the case of **Re-*E*-1** and **Re-*Z*-1**, the absorptions calculated at 420 and 424 nm are still largely HOMO→LUMO transitions, and therefore labeled as ligand-centered transitions, with a modest contribution from the metal ion. This supports the absence of charge transfer states observed in the absorption and emission spectra of the free ligands and metal complexes. Furthermore, there is a very small effect of the rhenium atom on the fluorescence lifetime. In fact, the average lifetime is 11.5 ns for the ligand and 11.3 ns for the complexes.

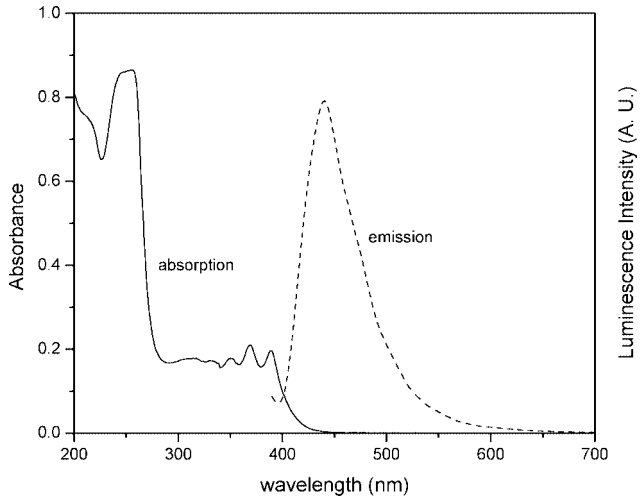

Figure 5. Absorption and emission spectra (excitation at 370 nm) of **Re-*E*-1** in $CH_3CN$.

Table 4. Energies (in nm) and oscillator strengths (*f*) of the first calculated singlet excited states for ***E*-1**, **Re-*E*-1**, and **Re-*Z*-1** in acetonitrile.

### Electrochemistry

The electrochemical behavior of the rhenium complexes **Re-*E*-1** and **Re-*Z*-1** has been investigated by cyclic voltammetry (CV) and square wave voltammetry (SWV) in $CH_2Cl_2$ solutions using glassy carbon as a working electrode, under an Ar atmosphere. The CV response of **Re-*E*-1**, identical to that of **Re-*Z*-1**, exhibits a 1e chemically irreversible reduction at $E_p$ = –1.89 V vs. $Fc/Fc^+$, and a multi-electron chemically irreversible oxidation at $E_p$ = +1.11 V vs. $Fc/Fc^+$. Our attempts to slow down the chemical complications by lowering the temperature were unsuccessful. CV performed as low as –80 °C and at a scan rate between 0.05 and 5 V/s did not freeze the homogeneous chemical reactions and the redox processes remained chemically irreversible.

## Experimental Section

**(*E*)-*N*-(Methyl-2-pyridyl)antracen-9-carboxaldimine (*E*-1):** Anthracene-9-carboxaldehyde (1.00 g, 4.85 mmol) was dissolved in absolute ethanol (250 mL) and the solution was degassed for 10 min under argon. 2-(Aminomethyl)pyridine (0.524 g, 4.85 mmol) was added and the solution was refluxed for 1.5 h. After evaporation of the solvent, the yellow solid was washed with hexane (20–25 mL) and recrystallized from ethanol (yield 75%, 1.078 g). $^1$H NMR [400 MHz, $(CD_3)_2CO$, 25 °C]: $\delta$ = 9.75 (s, 1 H), 8.75 [d, $^3J_{H,H}$ = 7.7 Hz, 2 H], 8.65 (s, 1 H), 8.61 (d, $^3J_{H,H}$ = 4.2 Hz, 1 H), 8.11 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H), 7.78 (t, $^3J_{H,H}$ = 7.7 Hz, 1 H), 7.60 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H), 7.53 (m, 4 H), 7.28 (t, $^3J_{H,H}$ = 6.4 Hz, 1 H), 5.25 (s, 2 H) ppm. $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 9.63 (t, $^3J_{H,H}$ = 1.3 Hz, 1 H, 11-H), 8.61 (m, 2 H, 1-H and 8-H), 8.59 (m, 1 H, 13-H), 8.53 (s, 1 H, 10-H), 8.06 (dd, $^3J_{H,H}$ = 7.9 and 1.9 Hz, 2 H, 4-H and 5-H), 7.72 (t, $^3J_{H,H}$ = 7.7 and 1.9 Hz, 1 H, 15-H), 7.52 (m, 5 H, 16-H, 2-H, 3-H, 6-H, 7-H), 7.23 (dd, $^3J_{H,H}$ = 5.0 and 1.1 Hz, 1 H, 14-H), 5.23 (d, $^3J_{H,H}$ = 1.3 Hz, 2 H, 12-H) ppm. $^{13}$C NMR [100 MHz, $(CD_3)_2CO$, 25 °C]: $\delta$ = 162.34, 159.69, 149.51, 136.72, 131.60, 130.27, 129.59, 128.99, 128.56, 126.80, 125.54, 125.40, 122.54, 122.24, 68.15 ppm. $^{13}$C NMR (100 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 162.46, 159.54, 149.70, 136.92, 131.63, 130.37, 129.77, 129.11, 128.52, 126.98, 125.62, 125.27, 122.75, 122.39, 68.68 ppm. Electronic spectrum in $CH_3CN$: absorption, $\lambda_{max}$ = 251, 351, 369, 387 nm, emission, $\lambda_{max}$ = 440 nm.

**(*Z*)-*N*-(2-Pyridylmethyl)antracen-9-carboxaldimine (*Z*-1):** The *Z* isomer was obtained from the irradiation for 3 h at 365 nm, 50 W, of a $CH_2Cl_2$ solution of the *E* isomer containing an equimolar amount of $CF_3COOH$. The conversion occured without any side reaction. $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C) of the protonated species: $\delta$ = 11.40 (s, 1 H), 9.02 (dd, $^3J_{H,H}$ = 9.0 and 0.8 Hz, 2 H), 8.82 (s, 1 H), 8.80 (dd, $^3J_{H,H}$ = 5.9 and 1.3 Hz, 1 H), 8.58 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H), 8.19 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H) 8.12 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H), 8.06 (t, $^3J_{H,H}$ = 5.9 Hz, 1 H), 7.75 (dd, $^3J_{H,H}$ = 9.0 and 1.5 Hz, 2 H), 7.60 (dd, $^3J_{H,H}$ = 8.6 and 1.0 Hz, 2 H), 4.80 (s, 2 H) ppm. $^{13}$C NMR (100 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 195.24, 147.77, 146.13, 143.11, 137.68, 133.15, 131.10, 130.15, 129.85, 129.68, 128.13, 126.02, 123.29, 40.94 ppm.

**Re(*E*-1)(CO)$_3$Cl (Re-*E*-1):** $Re(CO)_5Cl$ (300 mg) was refluxed in toluene (50 mL) for 2 h with a 10% excess of ***E*-1** (270 mg) under argon. The solution was then cooled before the yellow product was filtered and washed with toluene and hexane. Finally, the solid was dried in vacuo (yield 78%, 390 mg). $^1$H NMR [400 MHz, $(CD_3)_2CO$, 25 °C]: $\delta$ = 9.96 (s, 1 H), 8.87 (d, $^3J_{H,H}$ = 5.4 Hz, 1 H), 8.77 (s, 1 H), 8.15 (m, 4 H), 98.04 (d, $^3J_{H,H}$ = 8.5 Hz, 1 H), 7.91 (d, $^3J_{H,H}$ = 7.8 Hz, 1 H), 7.53 (m, 5 H), 6.29 (d, $^3J_{H,H}$ = 18.3 Hz, 1 H), 6.06 (d, $^3J_{H,H}$ = 18.6 Hz, 1 H) ppm. $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 9.63 (s, 1 H), 8.82 (d, $^3J_{H,H}$ = 5.3 Hz, 1 H), 8.70 (s, 1 H), 8.13 (m, 2 H), 8.06 (d, $^3J_{H,H}$ = 8.5 Hz, 1 H), 8.00 (t, $^3J_{H,H}$ = 7.9 Hz, 1 H), 7.81 (m, 1 H), 7.65 (m, 2 H), 7.56 (m, 3 H), 7.38 (t, $^3J_{H,H}$ = 6.5 Hz, 1 H), 6.23 (d, $^3J_{H,H}$ = 18.2 Hz, 1 H), 5.60 (d, $^3J_{H,H}$ = 18.2 Hz, 1 H) ppm. $^{13}$C NMR [100 MHz, $(CD_3)_2CO$, 25 °C]: $\delta$ = 198.11, 194.40, 191.62, 175.53, 160.38, 152.34, 139.66, 131.43, 131.21, 129.87, 128.84, 128.75, 128.24, 126.74, 126.60, 125.90, 125.78, 125.34, 124.57, 122.14, 69.12 ppm. IR (powder-ATR): $\tilde{\nu}$ = 2025, 1922, 1897 cm$^{-1}$. $^{13}$C NMR (100 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 198.11, 194.40, 191.62, 174.71, 163.26, 159.13, 152.95, 139.57, 131.50, 131.29, 130.48, 129.41, 129.16, 128.31, 127.54, 127.29, 126.38, 125.55, 124.88, 124.75, 121.89, 69.78 ppm. Electronic spectrum in $CH_3CN$: absorption, $\lambda_{max}$ = 255, 317, 335, 354, 372, 391 nm, emission, $\lambda_{max}$ = 440 nm.

**Re(*Z*-1)(CO)$_3$Cl (Re-*Z*-1):** The complex was obtained as a side product during a modified synthesis of **Re-*E*-1**. $Re(CO)_5Cl$ (200 mg) was stirred in toluene (50 mL) with a 10% excess of ***E*-1** (180 mg) under argon. $CF_3COOH$ (30 μL) was added, and the solution was refluxed for 4 h. After cooling at room temperature, a yellow precipitate of **Re-*E*-1** and a red solution containing a mixture of **Re-*E*-1** and **Re-*Z*-1** were obtained. The solution was filtered, and the solvent evaporated. The solid was treated with benzene, which only dissolved **Re-*Z*-1**. Finally, the solvent was evaporated and the solid dried in vacuo (yield 15%, 50 mg). $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 9.99 (t, $^3J_{H,H}$ = 2.3 Hz, 1 H), 8.89 (d, $^3J_{H,H}$ = 5.3 Hz, 1 H), 8.72 (s, 1 H), 8.22 (d, $^3J_{H,H}$ = 8.4 Hz, 1 H), 8.16 (m, 2 H), 7.83 (d, $^3J_{H,H}$ = 8.4 Hz, 1 H), 7.75 (t, $^3J_{H,H}$ = 7.9 and 1.6 Hz, 1 H), 7.61 (m, 4 H), 7.33 (t, $^3J_{H,H}$ = 6.7 Hz, 1 H), 7.01 (d, $^3J_{H,H}$ = 7.9 Hz, 1 H), 5.12 (dd, $^3J_{H,H}$ = 19.0 and 2.5 Hz, 1 H), 4.76 (dd, $^3J_{H,H}$ = 19.0 and 2.5 Hz, 1 H) ppm. IR (powder-ATR): $\tilde{\nu}$ = 2024, 1921, 1896 cm$^{-1}$. Electronic spectrum in $CH_3CN$: absorption, $\lambda_{max}$ = 255, 303, 335, 354, 372, 391 nm, emission, $\lambda_{max}$ = 440 nm.

**Physical Methods:** The NMR spectra were recorded with a JEOL EX 400 spectrometer ($B_0$ = 9.8 T) with chemical shifts referenced to residual protons in the solvent ($CD_2Cl_2$). COSY and NOESY experiments were acquired using standard procedures. IR spectra were recorded as powder-ATR using a Thermo-Nicolet 670 FT-IR spectrophotometer with a resolution of 1 cm$^{-1}$ and an accumulation of 64 scans. Absorption spectra were measured at room temperature, in $CH_2Cl_2$, using a Hitachi U-3210 double-beam spectrophotometer, and emission spectra were measured with a SLM 4800 spectrofluorimeter. Luminescence lifetimes were performed under magic-angle polarization conditions by time-correlated single-photon counting using excitation with picosecond pulses of 370 nm light at a repetition rate of 500 kHz generated by a Ti:Sapphire laser system (Verdi V10, Mira 900, and pulse picker from Coherent, Inc., Santa Clara, CA. Second harmonic generation was provided by a 5–050 system from Inrad, Northvale, NJ). The sample was maintained at 20 °C in an automated sample chamber (FLASC 1000 from Quantum Northwest, Spokane, WA). The emission was collected using a bandpass of 20 nm. The data were collected into 2048 channels (0.25 ns/channel) to 40,000 counts in the peak channel. Because the excitation pulse is essentially a delta function at this time resolution, the decays were fitted directly without reconvolution as sums of exponentials using Origin 7 (Northampton, MA 01060, USA).

**X-ray Structure Determinations:** Single crystal diffraction data were collected at 100 K, using an Oxford Cryostream low temperature

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

device, on an Oxford Xcalibur CCD area detector diffractometer, using graphite monochromatic Mo-$K_\alpha$ ($\lambda$ = 0.71069 Å) radiation. Data reduction and absorption corrections were performed using CrysAlis RED 1.171.26 (Oxford Diffraction). The structure was solved by direct methods using SIR2004[38] and refined by full-matrix least-squares using SHELX-97.[39] All hydrogen atoms were located in the electron density map and then refined using isotropic displacement parameters.

The Crystallographic Information File (CIF) has been deposited with deposition number CCDC-298650 for the **Re-*E*-1** structure and CCDC-298651 for the **Re-*Z*-1** structure. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Details of data collections and refinements are given in Table 5.

**Electrochemistry:** Dichloromethane was distilled over calcium hydride just before use. Tetrabutylammonium hexafluorophosphate ($Bu_4NPF_6$) was obtained from a metathesis reaction between $KPF_6$ (Fluka) and tetrabutylammonium iodide (Aldrich), recrystallized three times from 95% ethanol and dried in a vacuum oven at 110 °C overnight. The electrochemistry was performed in a three-electrode cell using a potentiostat AMEL 7050 and an EG&G PAR 273 electrochemical analyzer, both connected to a PC. The reference electrode was a 3 M KCl Calomel Electrode, the auxiliary electrode a platinum wire, and the working electrode a glassy carbon (GC). Positive feedback *iR* compensation was applied routinely. All measurements were carried out under Ar in anhydrous deoxygenated solvents. We used ferrocene (Fc) as the internal standard, and potentials are reported against the Fc(0/+1) redox couple, which under our conditions is $E°$(0/+1) = 0.595 V.

**DFT Calculations:** The DFT method with Becke's[40] three-parameter hybrid functional and Lee–Yang–Parr's[41] gradient corrected correlation functional was used. The calculations have been made with the Gaussian 03 (G03)[28] and Jaguar[24] programs. The Stuttgart–Dresden (SDD) ECP[42] was used for the Re atom and the 6-311++G** basis set for all other atoms. Calculations of the absolute magnetic shielding $\sigma$ were performed at the B3LYP/6-311++G** level using either G03 or Jaguar. The $\sigma$ absolute values were converted into proton chemical shifts $\delta$, relative to the magnetic shielding of tetramethylsilane computed with the same basis set (31.9793, H and 184.1441, C for G03; 31.9821, H and 184.0820, C for Jaguar). The nature of transition states was confirmed by performing a harmonic vibrational frequencies calculation and a normal-mode analysis. Vibrational frequencies and Gibbs free energy calculations were performed at 298.15 K and 1 atm. Time-dependent density functional theory[43,44] (TDDFT) combined with the conductor-like polarizable continuum model[45–47] (CPCM) method with acetonitrile as solvent has been used to calculate the excited-state energies by means of G03.

**Supporting Information** (see also the footnote on the first page of this article): $^1$H, $^1$H-$^1$H COSY and $^1$H-$^1$H NOESY NMR spectra of ***E*-1**, **Re-*E*-1**, and **Re-*Z*-1** in $CD_2Cl_2$, and the $^1$H NMR spectra of **1** before, after, and during its *E* to *Z* isomerization by means of $CF_3COOH$ in $CD_2Cl_2$.

# Preparation, Characterization, and Aquation Kinetics of Pyridine *N*-Oxide Complexes of Chromium(III)

**Mirjana Kotowski,[a][‡] Radovan Marcec,[a][†] Vjera Butkovic,[a] Andreja Bakac,*[b] and Matko Orhanovic[a]**

**Keywords:** Pyridine oxide / Chromium / Kinetics / Mechanism / Aquation

A series of $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ ions (pyO = pyridine *N*-oxide, X = H, 3-$CH_3$, 4-$CH_3$, 4-$OCH_3$, 4-$NO_2$) were prepared by the reduction of the corresponding pyridine *N*-oxide adducts of diperoxochromium(VI) species with acidic ferrous perchlorate. The $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ complexes undergo aquation to yield $Cr(H_2O)_6^{3+}$ and X-pyO according to the rate law $k_{obs} = k_o + k_{-1}[H^+]^{-1}$. The values of the rate constants extrapolated to 298 K at 1.0 M ionic strength are: $k_0 = 2.80\times10^{-6}\,s^{-1}$, $k_{-1} = 1.86\times10^{-8}\,M\,s^{-1}$ (X = 4-$NO_2$); $7.80\times10^{-8}$, $6.27\times10^{-10}$ (H); $4.80\times10^{-8}$, $3.20\times10^{-10}$ (3-$CH_3$); $3.05\times10^{-8}$, $1.60\times10^{-10}$ (4-$CH_3$); and $2.37\times10^{-9}$, $4.76\times10^{-11}$ (4-$OCH_3$). The reaction of the 4-$OCH_3$ complex exhibits two additional terms in the rate law, $k_1[H^+] + k_{-2}[H^+]^{-2}$. The binding of 4-$OCH_3$–pyO to chromium is suggested to take place through the methoxy group. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Pyridine *N*-oxides (X-pyO) are important reagents in thermal[1,2] and photochemical[3–5] oxidations. Often, although not always,[6] such reactions involve oxygen-atom transfer[7–9] with pyridine *N*-oxide playing a role of either oxygen-atom donor[2,7–12] or a promoter of oxygen transfer from active donors to the substrate.[13–16] Metal catalysis is frequently involved[17] in such processes, which makes mechanistic studies of transition-metal complexes of pyridine *N*-oxides an important area of investigation.

A large number of complexes with an array of metal ions have been prepared and characterized structurally, spectroscopically, electrochemically, and chemically. There are, however, few reports available on the kinetics and mechanisms of the reactions of such complexes,[18–20] especially in aqueous solutions.[21,22] Several pentaamminecobalt(III) ions, $(NH_3)_5Co(X\text{-}pyO)^{3+}$ have been prepared[21,22] and found to be reasonably stable at room temperature, provided there are no cyano substituents on the pyridine ring, in which case facile hydrolysis to a bound amide takes place.[21] The reduction of the parent $(H_2O)_5Co(pyO)^{3+}$ by chromium(II) is believed to take place by an inner-sphere mechanism whereby $Cr_{aq}^{2+}$ attacks at the coordinated pyO oxygen,[21] although the expected product, $(H_2O)_5Cr(pyO)^{3+}$, was not observed, possibly because of its decomposition on ion-exchange resin. In the reduction of $(NH_3)_5Co(X\text{-}pyO)^{3+}$ by 2-hydroxy-2-propyl radicals, $^{\cdot}C(CH_3)_2OH$, the initial site of attack was shown to be at the aromatic ring of the coordinated X-pyO.[23]

These studies have now been extended to a series of chromium complexes, $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ (X = H, 3-$CH_3$, 4-$CH_3$, 4-$OCH_3$, 4-$NO_2$). In this first report, we focus on the preparation and spectral and kinetic characterization of these complexes. Prior to this work, only the parent ion, $(H_2O)_5Cr(pyO)^{3+}$, was known.[24] It was generated by thermal equilibration of $Cr(H_2O)_6^{3+}$ with an excess of pyO in slightly acidic aqueous solutions at elevated temperatures, followed by ion exchange. In the present work, our previously published procedure for the preparation of pyridine chromium complexes[22] was applied to pyridine *N*-oxide analogues. This method represents a great advantage over the thermal equilibration method because it yields exclusively the mono-substituted products.

## Results

The method used to prepare the complexes in Table 1 is based on the chemistry that we have developed earlier for the pyridine complexes.[22] By analogy to that work, the blue paste-like material generated from $CrO_3$, X-pyO and $H_2O_2$ is assigned the formula $CrO(O_2)_2(X\text{-}pyO)$. Reduction with $Fe_{aq}^{2+}$ produces the desired $(H_2O)_5Cr(X\text{-}pyO)^{3+}$, Equation (1).

The chemical composition of the complexes was confirmed by chromium and ligand analysis after the complex had been allowed to aquate. In every case, the [Cr]/[X-pyO]

[a] In 1.0 M aqueous $HClO_4$. [b] This work. [c] Ref. [25]. [d] Ref. [24].

$$CrO(O_2)_2(X\text{-}pyO) + 7Fe_{aq}^{2+} + 10H^+ \rightarrow (H_2O)_5Cr(X\text{-}pyO)^{3+} + 7Fe_{aq}^{3+} \quad (1)$$

ratio was found to be $1.00 \pm 0.02$. As expected, the behavior of the complexes on the cation-exchange resin was consistent with a 3+ charge.

The UV/Visible spectroscopic data are summarized in Table 1. The spectrum of the unsubstituted material (X = H) agrees well with the literature data for a complex obtained by anation of $Cr(H_2O)_6^{3+}$ with pyO followed by ion-exchange to remove $Cr(H_2O)_6^{3+}$ and *cis*- and *trans*-$(H_2O)_4Cr(pyO)_2^{3+}$.[24]

The kinetics of aquation of $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ complexes were studied as a function of acidity and temperature at 1.0 M ionic strength. As illustrated in Figure 1 for $(H_2O)_5Cr(pyO)^{3+}$, the spectra exhibit clean isosbestic points as expected if the stoichiometry remains unchanged throughout the reaction, and no long-lived intermediates are involved.

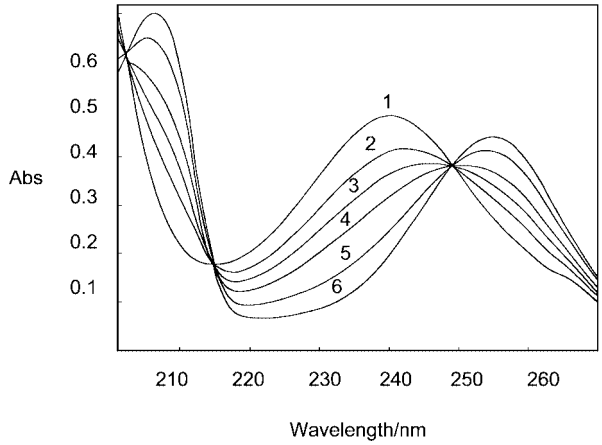

Figure 1. Spectral changes accompanying the aquation of $4.16\cdot10^{-5}$ M $(H_2O)_5Cr(pyO)^{3+}$ in 0.020 M $HClO_4$ at 1.0 M ionic strength and 90 °C. Spectrum **1** was obtained on a fresh sample at 25 °C before the onset of the reaction. Spectra **2** through **6** were measured at time 0 (arbitrary), 8, 18, 45.5, and 1250 minutes.

The standard treatment of the exponential kinetic traces yielded first-order rate constants $k_{obs}$ which decreased with an increase in $[H^+]$ according to the expression in Equation (2) for all the complexes except for $(H_2O)_5Cr(4\text{-}OCH_3\text{–}pyO)^{3+}$, which exhibited a more complex behavior, see below.

$$k_{obs} = k_o + k_{-1}\,[H^+]^{-1};\ X = H,\ 3\text{-}CH_3,\ 4\text{-}CH_3,\ 4\text{-}NO_2 \quad (2)$$

The adherence to Equation (2) is shown for X = 3-$CH_3$ in Figure 2. The plot of $k_{obs}$ against $1/[H^+]$ at several temperatures is linear yielding $k_0$ as an intercept and $k_{-1}$ as a slope. Data for the remaining complexes (X = H, 4-$CH_3$, and 4-$NO_2$) are presented in the supporting information (Figures S1–S3; for supporting information see also the footnote on the first page of this article). The kinetic data are summarized in Table 2.

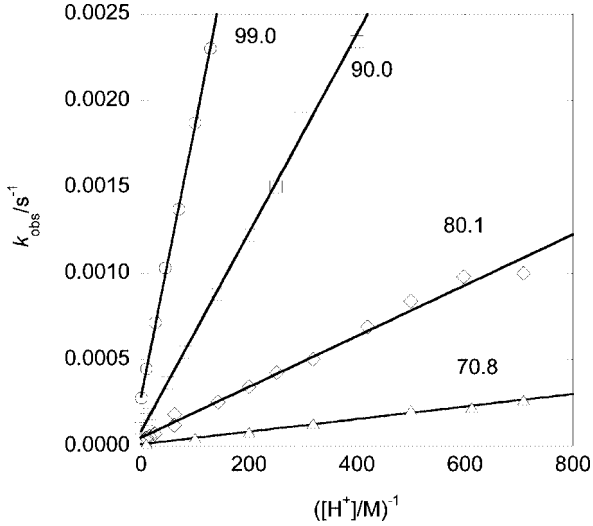

Figure 2. Plot of $k_{obs}$ vs. $1/[H^+]$ for the aquation of $(H_2O)_5Cr(3\text{-}CH_3\text{–}pyO)^{3+}$ at 99.0 °C (circles), 90.0° (squares), 80.1° (diamonds), and 70.8° (triangles).

The activation parameters, also shown in Table 2, were obtained by fitting simultaneously all the individual acid-dependent rate constants $k_{obs}$ for a given complex to the Eyring expression, Equation (3), where $k_B$ and $h$ are the Boltzman and Planck constants, respectively, $T$ is the absolute temperature, and $i = 0$ and $-1$. The fit of the data to Equation (3) for $(H_2O)_5Cr(3\text{-}CH_3\text{–}pyO)^{3+}$ is shown in Figure 3, and for the rest of the complexes in Figures S4–S7 in the supporting information.

The plots of $k_{obs}$ vs. $1/[H^+]$ for the 4-methoxy complex, Figure 4, exhibited deviations from Equation (2) at both the

[a] Ionic strength: 1.0 M ($HClO_4 + NaClO_4$). Units: $\Delta H^{\ddagger}$ in kJ $mol^{-1}$, $\Delta S^{\ddagger}$ in J $mol^{-1}$ $K^{-1}$. [b] Obtained as intercept of $k_{obs}$ vs. 1/[$H^+$] plots, as in Figure 2. [c] Obtained as a slope of $k_{obs}$ vs. 1/[$H^+$] plots, as in Figure 2. [d] Additional data in 1.0 M $HClO_4$: $1.36\times10^{-3}$ $s^{-1}$ (80 °C), $8.43\times10^{-4}$ (75 °C), $9.10\times10^{-5}$ (55 °C). [e] Calculated from the activation parameters. [f] At >5 mM [$H^+$], a term directly proportional to [$H^+$] also contributes, $\Delta H_1^{\ddagger} = 104\pm43$ kJ $mol^{-1}$, $\Delta S_1^{\ddagger} = -48\pm115$ J $mol^{-1}$ $K^{-1}$.

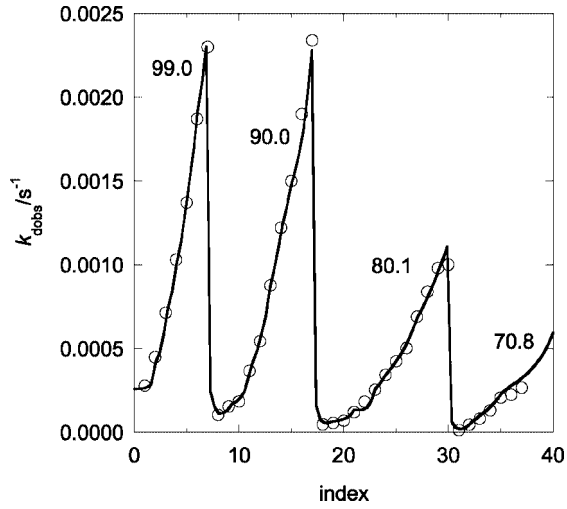

Figure 3. Fit of the data for the aquation of $(H_2O)_5Cr(3\text{-}CH_3\text{–}pyO)^{3+}$ to Equation 3 with use of the program Kaleidagraph 3.6. Index numbers on the $x$ axis identify each unique point at a given acidity and temperature. Temperature (in °C) for each data set is indicated.

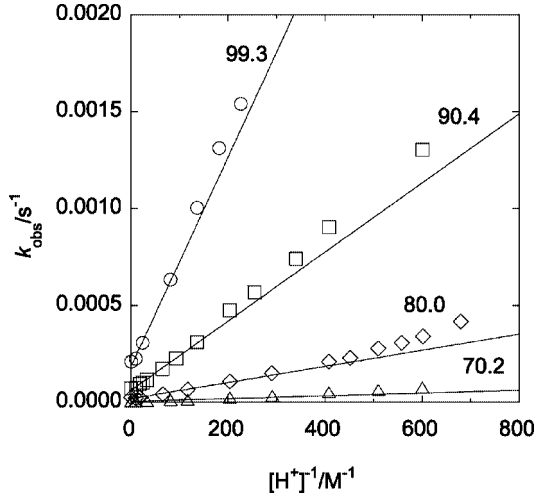

Figure 4. Plot of $k_{obs}$ vs. 1/[$H^+$] for the aquation of $(H_2O)_5Cr(4\text{-}OCH_3\text{–}pyO)^{3+}$ at 1.0 M ionic strength.

$$k_{obs} = \frac{k_B T}{h}\sum_i [H^+]^i (e^{-\Delta H_i^{\ddagger}/RT} e^{\Delta S_i^{\ddagger}/R}) \quad (3)$$

high and low ends of [$H^+$], and required two additional terms in the rate law, Equation (4), which is analogous to that reported for the azido complex, $(H_2O)_5CrN_3^{2+}$.[26]

The attempted fit of all the data to the multi-term Eyring expression of Equation (3) with $i$ = 1, 0, –1, and –2 failed to converge, presumably because the contribution from the $k_{-2}$ term was small and thus subject to large error under all of the conditions. The activation parameters in Table 2 were obtained by fitting only the data at >5 mM [$H^+$] to a 3-term variant of Equation (3), i.e., $i$ = 1, 0, and –1. The rather

$$k_{obs} = k_1[H^+] + k_o + k_{-1}[H^+]^{-1} + k_{-2}[H^+]^{-2};\ X = 4\text{-}OCH_3 \quad (4)$$

large errors, especially for the less prominent terms, were to be expected for a complex fit and a large number of parameters.

To ascertain that the $k_1$ term is real and not a result of misinterpreted deviations from a simpler rate law, several experiments were conducted at higher acid concentrations at 4.0 M ionic strength where $k_1$ and $k_0$ terms should dominate. The results are shown in Figure 5, which clearly confirms the expectations. The rate constants at 99.0 °C are $k_0$ = $2.20(\pm0.14)\times10^{-4}$ $s^{-1}$ and $k_1$ = $1.16(\pm0.07)\times10^{-4}$ $M^{-1}$ $s^{-1}$. The corresponding values extracted from the more complex

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

set of data at 1.0 M ionic strength are $k_0 = 1.52(\pm 0.11) \times 10^{-4}$ $s^{-1}$ and $k_1 = 5.6(\pm 1.9) \times 10^{-5}$ $M^{-1}$ $s^{-1}$.

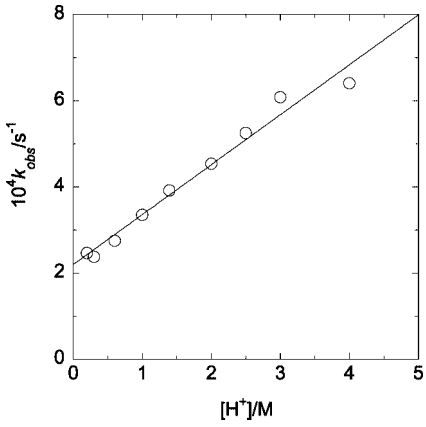

Figure 5. Plot of $k_{obs}$ vs. $[H^+]$ for the aquation of $(H_2O)_5Cr(4\text{-}OCH_3\text{–}pyO)^{3+}$ at 4.0 M ionic strength and 99 °C.

## Discussion

**UV/Vis Spectra:** The ligand-field transitions for all the pyridine *N*-oxide complexes studied (Table 1) are red-shifted relative to the corresponding pyridine complexes,[22] consistent with the greater ligand-field strength of the pyridines.

With the exception of the 4-$OCH_3$ derivative, the positions of the UV bands for $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ ions are considerably different from those of the free ligands. As an example, $(H_2O)_5Cr(4\text{-}CH_3\text{–}pyO)^{3+}$ in 1 M $H^+$ exhibits a maximum at 246 nm ($\varepsilon = 1.35 \times 10^4$ $M^{-1}$ $cm^{-1}$). Under the same conditions, the free ligand has maxima at 254 nm ($\varepsilon = 2.7 \times 10^3$) and 226 nm ($\varepsilon = 8.3 \times 10^3$). In neutral solutions, these maxima shift to 256 nm ($\varepsilon = 1.40 \times 10^4$) and 206 nm ($1.9 \times 10^4$). Similar spectral differences between the free and Cr-bound pyridine *N*-oxides are observed for the rest of the materials in Table 1. Only the spectrum of $(H_2O)_5Cr(4\text{-}OCH_3\text{–}pyO)^{3+}$ ($\lambda_{max} = 262$ nm, $\varepsilon = 1.50 \times 10^4$ $M^{-1}$ $cm^{-1}$) is almost identical to that of the free ligand in $H_2O$. This observation suggests that the binding of 4-$OCH_3$–pyO to chromium perhaps takes place at the methoxy oxygen, whereas the rest of the complexes utilize the pyridine oxide oxygen. We rationalize this assignment by noting that coordination via the methoxy group should affect the intraligand charge-transfer transitions to a lesser extent than coordination via the *N*-oxo group, or the protonation of the *N*-oxo group. Additional arguments in favor of the unique binding mode in $(H_2O)_5Cr(4\text{-}OCH_3\text{–}pyO)^{3+}$ will be presented shortly.

**Kinetics of Aquation of $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ (X = H, 3-$CH_3$, 4-$CH_3$, 4-$NO_2$):** The two-term rate law of Equation (2) is common to all the complexes with the exception of the 4-methoxy derivative which exhibits two additional terms, $k_1[H^+]$ and $k_{-2}[H^+]^{-2}$, Equation (4). The rate law of Equation (2) is typical for the aquation of pentaaquachromium(III) complexes, including those of the closely related $(H_2O)_5Cr(X\text{-}py)^{3+}$ ions. A reasonable mechanism features parallel reactions of the pentaaqua complex and its conjugate base, Equations (5), (6) and (7) leading to the rate law in Equation (8). In the limit $K_a << [H^+]$, Equation (8) reduces to the observed form, Equation (2), where $k_{-1} = k_{-1}'K_a$.

$$(H_2O)_5Cr(4\text{-}X\text{-}pyO)^{3+} \rightleftharpoons (H_2O)_4(OH)Cr(4\text{-}X\text{-}pyO)^{2+} + H^+ \; K_a \quad (5)$$

$$(H_2O)_5Cr(4\text{-}X\text{-}pyO)^{3+} \xrightarrow{H_2O} Cr(H_2O)_6^{3+} + 4\text{-}X\text{-}pyO \; k_0 \quad (6)$$

$$(H_2O)_4(OH)Cr(4\text{-}X\text{-}pyO)^{2-} \xrightarrow{H_2O} (H_2O)_5CrOH^{2+} + 4\text{-}X\text{-}pyO \; k_{-1}' \quad (7)$$

$$k_{obs} = \frac{k_0[H^+] + k_{-1}'K_a}{K_a + [H^+]} \quad (8)$$

The acidity constants for the pyridine oxide complexes have not been determined, but the excellent fit of the data to Equation (2) throughout the acid range studied places a limit $K_a << 10^{-3}$ M for all the complexes in the temperature range examined.

The activation enthalpies are large for both pathways for all the complexes. Activation entropies are moderately negative for the $k_0$ path, and moderately positive for the $k_{-1}$ path. The only exception seems to be the parent pyO complex, for which $\Delta S_{-1}^{\ddagger}$ is close to zero ($-1.6 \pm 10$ $J\,mol^{-1}\,K^{-1}$). These results are consistent with a strong associative component in the $k_0$ path, as is often the case with aqua $Cr^{III}$ complexes, including the water substitution in $Cr(H_2O)_6^{3+}$.[27] The $k_{-1}$ path is a composite, which makes the mechanistic assignment of the kinetic step more difficult to make. Still, given that the $\Delta S^0$ component (associated with the $K_a$) will be positive, and the overall $\Delta S_{-1}^{\ddagger}$ is only on the order of 20–40 $J\,mol^{-1}\,K^{-1}$, one can all but rule out a strong dissociative contribution to $k_{-1}$. The data are consistent with an interchange mechanism in either dissociative or associative regime.

**The Case of $(H_2O)_5Cr(4\text{-}OCH_3\text{-}pyO)^{3+}$:** As already mentioned, the aquation of aqua and amine complexes of chromium(III) often follows the general rate law of Equation (2). The direct dependence on $[H^+]$, on the other hand, has been observed only for those complexes that have a ligand with an open basic site, i.e. anions such as $F^-$, $N_3^-$, $SO_4^{2-}$, $CN^-$, or $CH_3COO^-$.[28–32] This path is not expected to operate for $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ complexes; the basicity of X-pyO oxygen is greatly reduced upon coordination to Cr, and the probability of protonation is minimal. The complexes having X = H, 3-$CH_3$, 4-$CH_3$, and 4-$NO_2$ follow this prediction and do not feature a $k_1[H^+]$ term. The 4-$OCH_3$ de-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rivative, on the other hand, has a pronounced $k_1[H^+]$ term which would be difficult to explain for a complex having a Cr–oxopyridine bond, Cr–Opy(4-$OCH_3$). If, however, the ligand is coordinated through the methoxy group, as in Cr–$O(CH_3)$pyO, then the protonation at the exposed pyO oxygen becomes more likely. We suggest that bonding through the methoxy group indeed takes place and is responsible for the unique behavior of the 4-$OCH_3$–py complex. The UV spectrum discussed earlier supports this assignment. Even though the basicity of the methoxy oxygen should be greatly diminished in the chromium complex as compared to the free base, the protonation can still take place at the high end of $[H^+]$ used in this work. The proposed isomer, $(H_2O)_5Cr–O(CH_3)pyO^{3+}$, should not be considered an unusual species in that related alcohol complexes of $Cr^{III}$, such as $(H_2O)_{6-n}Cr[O(H)CH_3]_n^{3+}$, are well known and quite stable.[33]

The positive $\Delta S_0^{\ddagger}$ value for $(H_2O)_5Cr(4\text{-}OCH_3\text{–}pyO)^{3+}$, $43 \pm 29\ J\,mol^{-1}\,K^{-1}$, seems outstanding, and may suggest a mechanistic deviation from the associative interchange assigned to the rest of the complexes in Table 2. The large error bars for all the entropy values in Table 2, however, make such a conclusion uncertain. We also note that an unexplained positive $\Delta S_0^{\ddagger}$ term was observed in the aquation of $(H_2O)_5Cr(3\text{-}CH_3\text{–}py)^{3+}$,[22] which does not appear outstanding in any other respect.

The $k_{-2}$ path was observed only for $(H_2O)_5Cr(4\text{-}CH_3O\text{–}pyO)^{3+}$, implying a greater acidity of the coordinated waters for this complex. This is a surprising observation and contrary to what one might expect on the basis of the strong electron donation from the 4-methoxy group and the greater basicity of 4-$CH_3O$–pyO[34] compared to other pyridine oxides in this work. It is not clear whether the different binding mode to $Cr^{III}$ would cause the observed shift in the $pK_a$.

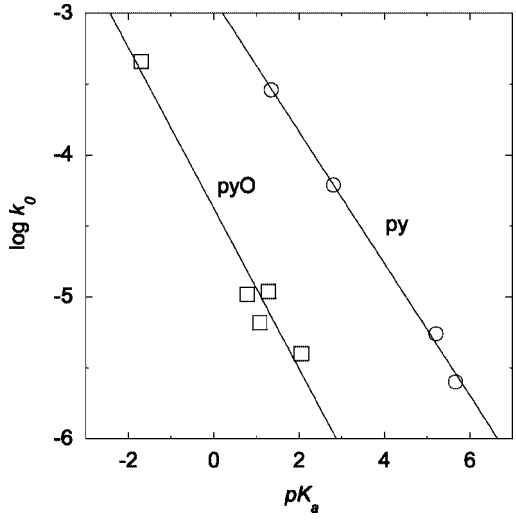

Figure 6. Plot of $\log k_0$ vs. $pK_a$ of the free ligands for the aquation of $Cr(H_2O)_5^{3+}$ complexes of pyridines (py, circles) and pyridine *N*-oxides (pyO, squares) at 70 °C. The substituents on pyO, in the order of increasing $pK_a$, are 4-$NO_2$, H, 3-$CH_3$, 4-$CH_3$, and 4-$OCH_3$. In the pyridine series, the order is 3-CN, 3-Cl, H, 3-$CH_3$. Data are from Table 2 and references [22], [23] and [34].

**Comparison with Pyridine Complexes:** Figure 6 shows a plot of the logarithms of the first-order rate constants $k_0$ against the $pK_a$ of the protonated ligands for complexes of $Cr^{III}$ with pyridines and pyridine *N*-oxides at 70 °C. The correlation was not sought for $k_{-1}$, which is a composite of rate and acid dissociation constants.

Both sets of rate constants in Figure 6 are linearly related to the ligand $pK_a$, a measure of σ electron donation. In both cases, the greater thermodynamic affinity for the proton results in a kinetically more inert chromium complex, i.e. the greater the $pK_a$ the slower the aquation. When the two series are compared to each other, however, then the $pK_a$ argument breaks down; the less basic pyridine *N*-oxides bind to the chromium more strongly, at least in the kinetic sense. One obvious source of the apparent anomalous inertness of pyridine *N*-oxide complexes is the greater ability of pyridine *N*-oxides to engage in π-bonding with the metal.

## Experimental Section

**Preparation of Complexes. $(H_2O)_5Cr(pyO)^{3+}$:** To a stirred, ice-cold aqueous solution (2 mL) of 1 M pyridine oxide (PyO) and 1 M $CrO_3$ was added dropwise cold 30% $H_2O_2$ (2 mol-equiv.). The resulting blue paste was immediately treated with a solution containing 7.5 mol-equiv. of ferrous perchlorate and 11 mol-equiv. of $HClO_4$. The green product solution was loaded onto a column of Dowex 50W-X8 cation-exchange resin. Iron(III) ions were eluted with 0.1 M NaSCN in 1 M $HClO_4$. The column was rinsed with 1 M $HClO_4$ to remove the remaining NaSCN. Chromium(III) species were eluted with 3 M $HClO_4$ and collected in several fractions. The blue $Cr(H_2O)_6^{3+}$ was eluted first, followed by the green $(H_2O)_5Cr(pyO)^{3+}$. The middle fraction of this complex was used for all the kinetics and spectral measurements. The same procedure was used to prepare the ring-substituted complexes $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ (X = 3-$CH_3$, 4-$CH_3$, 4-$CH_3O$ and 4-$NO_2$), except that in the case of $(H_2O)_5Cr(4\text{-}NO_2\text{–}pyO)^{3+}$, the solvent water in the initial step was replaced by a 1:1 $H_2O$/dioxane mixture to increase the solubility of the ligand.

**Materials:** Pyridine *N*-oxides (pyO, 3-$CH_3$–pyO, 4-$CH_3$–pyO, and 4-$NO_2$–pyO) were purchased from Fluka and recrystallized twice from ethanol. 4-$CH_3O$–pyO was prepared by refluxing 28 g 4-$NO_2$–pyO (Fluka) and 28 g $K_2CO_3$ in 200 mL of methanol for 8 hours.[35] The product was recrystallized twice from heptane. Solutions of iron(II) perchlorate were prepared by zinc amalgam reduction of the $Fe^{III}$ salt. Sodium perchlorate was prepared from perchloric acid and sodium carbonate. The solid was recrystallized three times from doubly distilled water. Other chemicals were purchased at the highest purity available and used as received.

**Analyses:** The chromium content of $(H_2O)_5Cr(X\text{-}pyO)^{3+}$ was determined spectrophotometrically after oxidizing the chromium to chromate ($\varepsilon_{372} = 4.82 \cdot 10^3\ M^{-1}\,cm^{-1}$)[36] with alkaline hydrogen peroxide. The concentration of the appropriate pyridine *N*-oxides generated by hydrolysis of the complex in 0.10 M $HClO_4$ for ≥ 10 half-lives was determined spectrophotometrically.

**Kinetic Measurements:** The aquation of all the complexes was monitored spectrophotometrically at a wavelength, typically close to $\lambda_{max}$ for the free ligand, where the difference in molar absorptivities for reactants and products was at a maximum. The initial concentration of all the complexes was in the range 3–30 μM. In most cases, the change in absorbance was monitored continuously inside

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a thermostatted cell compartment of a Cary 17 spectrophotometer. In some experiments, especially those at ≥ 90 °C, the samples were sealed in glass ampoules and immersed into thermostatted (±0.05 °C) oil. At the desired times, an ampoule was removed, and the reaction quenched in either ice-cold water or liquid nitrogen. The sample was brought to room temperature to record the absorbance. The rate constants and activation parameters were obtained by fitting the data to appropriate equations with the program Kaleidagraph 3.6.

# Design, Crystal Growth, Characterization, and Second-Order Nonlinear Optical Properties of Two New Three-Dimensional Coordination Polymers Containing Selenocyanate Ligands

**Sheng-Li Li,[a,b] Jie-Ying Wu,[a] Yu-Peng Tian,*[a,c,d] Hai Ming,[b] Pei Wang,[b] Min-Hua Jiang,[c] and Hoong-Kun Fun[e]**

**Keywords:** Self-assembly / Coordination polymer / Crystal growth / Nonlinear optical properties

Two new second-order nonlinear optical coordination polymers, zinc cadmium tetraselenocyanate ($[ZnCd(SeCN)_4]_n$, **1**) and cadmium mercury tetraselenocyanate ($[CdHg(SeCN)_4]_n$, **2**), have been synthesized by reactions of self-assembly. Their structural, optical, and physicochemical properties were characterized by X-ray diffraction, infrared and Raman spectroscopy, electronic spectra, and thermal analyses. Structure analyses reveal that they belong to the tetragonal system $I\bar{4}$ space group. The cell dimensions for **1**: $a$ = 11.3420(1), $b$ = 11.3420(1), $c$ = 4.6326(1) Å, $V$ = 595.94(1) Å$^3$, $Z$ = 2, $D_c$ = 3.331 g·cm$^{-3}$, $R_1$ = 0.0411, $wR_2$ = 0.1058; for **2**: $a$ = 11.6579(7), $b$ = 11.6579(7), $c$ = 4.5109(4) Å, $V$ = 613.06(8) Å$^3$, $Z$ = 2, $D_c$ = 3.970 g·cm$^{-3}$, $R_1$ = 0.0432, $wR_2$ = 0.1031. The structural features of **1** and **2** are Cd–Se=C=N–Zn and Hg–Se=C=N–Cd bridges, respectively, which lead to the formation of an infinite three-dimensional (3D) network. Consistent with their polar structures, compounds **1** and **2** exhibit powder second harmonic generation (SHG) responses much stronger than urea, indicating quite a promising application potential as useful nonlinear optical (NLO) materials.

## Introduction

It is well known that the rapidly developing area of research on supramolecular architectures has provided implications for the rational design of functional materials[1,2] and a number of the assemblies are predominantly controlled by the coordination preferences of the transition metal and the ligand building blocks.[3,4] Recent developments in the specific, efficient syntheses by self-assembly processes of coordination complexes have afforded a variety of unusual topologies such as molecular helicates, grids, ladders, rings, and boxes.[5,6] Self-assembly of polynuclear structure has received considerable attention from researchers in areas ranging from chemistry to solid-state physics and biology.[7] Some complexes are of interest not only for their unusual structures and the simple synthetic methods used to prepare them, but also because they allow the preparation of polynuclear complexes in which several potentially interesting metal centers are designed to link in a well-defined spatial array. The use of metal complexes to function as molecular devices is one of the major interests in coordination chemistry.

There has been considerable interest in the synthesis of new materials with optical nonlinearities because of their potential use in device applications in telecommunications, optical computing, optical storage, and optical information processing. However, organic systems can suffer from problems such as volatility, low thermal stability, and mechanical weakness. The low-energy d–d transitions present in nearly all organometallic compounds, normally observed in the visible light region, will limit the usefulness of these materials. On the other hand, the inorganic ligands such as the ambidentate thiocyanate ($SCN^-$) and the selenocyanate ($SeCN^-$) ligand, can govern the nonlinearities for the metal complexes from the viewpoint of molecular design.[8] In particular, the group IIB divalent $d^{10}$ ions, $Zn^{2+}$, $Cd^{2+}$, and $Hg^{2+}$ complexes, have attracted our interest for their unique characteristics of pale color and high thermal stability.[9]

As a result of the unsymmetrical nature of complexes, optical activity can occur as specific physical effects such as nonlinear optical (NLO) response.[10] The incorporation of the strong conjugation ligands, such as the asymmetric selenocyanate (SeCN) groups in the title polymers with a three-dimensional (3D) network, can introduce strong electronic asymmetry and electron delocalization in the whole unsym-

metrical structure, resulting in large second-order microscopic and macroscopic nonlinearity. Considering this, attention has been paid to the following facts: (1) The large nonlinear optical response comes with a big conjugation system, which is able to provide sufficient electronic channels for the photoelectric process. (2) The electronic nature of the metal center has an influential effect on the nonlinear optical interactions. In particular, the d orbital of the transition metal can become a component of the π conjugation system, thus extending the electronic interactions; (3) Reducing the molecular symmetry can help the formation of a noncentrosymmetric space group. Then, specific crystallization techniques are taken into account to form a proper crystal lattice, in which the good microscopic NLO response can be collected rather than eliminated; (4) Making use of the coordination bond or forming the polymeric complex to connect molecules and sequentially control the alignment of molecules in the crystal, the interaction for the bulk NLO response could be accumulated.

As far as we know, the preparation of selenocyanate-containing metal–inorganic compounds along with their characterization have been reported, but the NLO properties of the selenocyanate-containing polymers have scarcely been described hitherto. Referring to the title NLO polymers, we have systemically carried out research[11] not only on the preparation, crystal growth, physicochemical, and nonlinear optical properties of the complexes, but also on the design and structure–property relationship, which is original and different from other related reports.[12] In the crystal growth process, we used a one-step building-block approach capable of forming a chemically stable system, which enabled us to grow the high-quality and transparent polymeric single crystals, in contrast to the complicated approach used before resulting in mixtures of small molecular compounds or perhaps even monomers. In this context, the building-block approach of self-assembly for the synthesis of coordination polymers illustrates both the importance of metal-ion geometry and the effect that the ligand backbone can have on network construction. This article deals with two novel 3D coordination polymers, $[ZnCd(SeCN)_4]_n$ (**1**) and $[CdHg(SeCN)_4]_n$ (**2**), and their preparation, crystal growth, structures, and NLO properties are described.

## Results and Discussion

### Single-Crystal Growth

The chalcogenocyanate ion, $SeCN^-$, is a linear triatomic pseudohalide and a highly versatile ambidentate ligand with a polarizable π system. It can coordinate to transition-metal ions through either the hard nitrogen or the soft selenium atom, or both, giving rise to linkage isomers or polymers.

The crystal growth processes of **1** and **2** were carried out in one step by self-assembling in aqueous solutions containing cadmium chloride, potassium selenocyanate, and zinc chloride (for **1**) or mercury chloride (for **2**). Preparations were accomplished by two continuous reactions, where M = Zn or Hg:

$$4\ KSeCN + MCl_2 = K_2M(SeCN)_4 + 2\ KCl$$

$$K_2M(SeCN)_4 + CdCl_2 = MCd(SeCN)_4 + 2\ KCl$$

We have obtained good single crystals from RMS and the experiments showed that the success of growing large and high-quality single crystals with low defect density was highly dependent on the purity of the starting materials. Several foreign metallic cations, such as $Al^{3+}$, $Fe^{3+}$, $Co^{2+}$, $Ni^{2+}$, $Cu^{2+}$ and so forth, would badly influence the quality of the crystals, especially their transparency. Meanwhile, the crystal growth processes of the two polymers were affected by the pH value of RMS. We optimized the pH values of **1** and **2** solutions at 3.5–5.0 to get well-developed and transparent single crystals. As potassium selenocyanate (KSeCN) easily decomposes in air, the entire crystallization process was performed in a desiccator in vacuo. Moreover, the experiments indicated that the colors of **1** and **2** solutions easily turn slightly red or gray when the precipitates form as byproducts at a relatively high temperature, although the crystals show no decomposition and hygroscopic effect at atmospheric pressure and room temperature.

### IR and Raman Spectra

Figure 1 and Figure 2 show the IR transmission spectra of **1** and **2** crystals. The assignments of the main characteristic IR band frequencies observed for KSeCN,[13] $Cd(SeCN)_4Zn$,[12a] **1**, and **2** are listed in Table 1. It is known that in IR spectra of the metal (M) complexes containing monodentate SeCN ligands, $\nu_{CN}$ often lies higher than 2085 $cm^{-1}$, $\nu_{CSe}$ lies at about 700–620 $cm^{-1}$ (N–M bonding) or 550–500 $cm^{-1}$ (Se–M bonding), and $\delta_{SeCN}$ lies near 425 $cm^{-1}$ (N–M bonding) or 370 $cm^{-1}$ (Se–M bonding).[14] From Table 1, one can see the sharp increase in frequencies of $\nu_{CN}$ stretching and $\nu_{CSe}$ stretching and the decrease in frequencies of $\delta_{SeCN}$ bending in **1** and **2** compared with the corresponding bands in the free selenocyanate radical of KSeCN. This can be explained by the electron transport model.[15] In **1** and **2** crystals, the SeCN group is a good

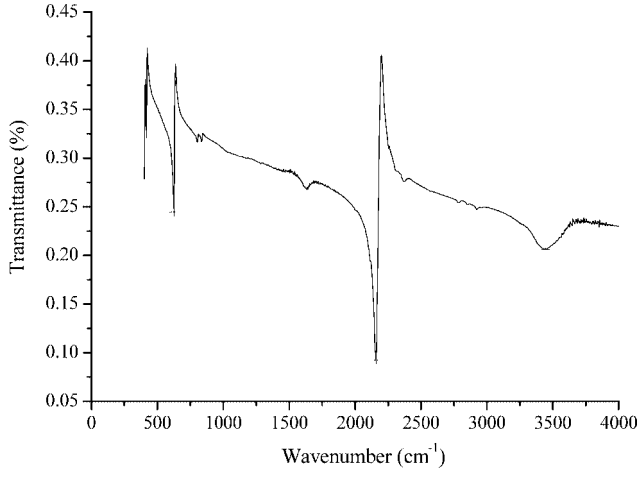

Figure 1. IR transmission spectra of **1** crystal.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

electron supplier, whereas $Zn^{2+}$, $Cd^{2+}$, and $Hg^{2+}$ are all strong electron acceptors. The electron transformation from $SeCN^-$ to $Zn^{2+}$, $Cd^{2+}$, and $Hg^{2+}$ ions makes the wavenumbers of CN and CSe stretching vibrations increase significantly and that of SeCN bending vibrations decrease. This confirms the presence of M–N and M–Se bands in their structures.

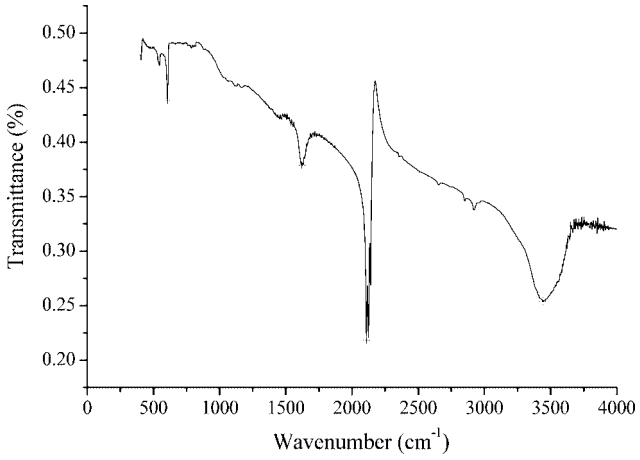

Figure 2. IR transmission spectra of **2** crystal.

Table 1. Assignments of the main characteristic IR band frequencies [$cm^{-1}$] observed for KSeCN,[13] $Cd(SeCN)_4Zn$,[12a] **1**, and **2**.

| | KSeCN | $Cd(SeCN)_4Zn$ | **1**, $[ZnCd(SeCN)_4]_n$ | **2**, $[CdHg(SeCN)_4]_n$ |
|---|---|---|---|---|
| $\nu_{CN}$ | 2070 | 2154 | 2158 | 2140 |
| $\nu_{CSe}$ | 558 | 628 | 625 | 606 |
| $\delta_{NCSe}$ | 424, 416 | 420, 406 | 417, 403 | 407, 393 |

The Raman spectra (Figure 3 and Figure 4) of $AB(SeCN)_4$ (A = Zn, B = Cd for **1**; A = Cd, B = Hg for **2**), recorded at room temperature in the frequency range from 50 to 2500 $cm^{-1}$, consist of four frequency regions (below 100 $cm^{-1}$, lattice vibration modes; 100–300 $cm^{-1}$, vibration bands of A and B centers; 300–1200 $cm^{-1}$, NCSe internal vibration modes; and 2100–2200 $cm^{-1}$, CN stretching vibration modes). According to the vibrational spectra,[16] the Raman peaks can be assigned as $\nu_1$ [a doubly degenerate $B(SeCN)_4$ bending vibration mode], $\nu_2$ [a doubly degenerate $A(NCSe)_4$ bending vibration mode], $\nu_3$ (a SeCN bending vibration mode), $\nu_4$ (a doubly degenerate SeCN bending vibration mode), $\nu_5$ (a CSe stretching vibration mode), and $\nu_6$ (a CN stretching vibration mode). The Raman peaks ($\nu_1$ and $\nu_2$) are split on the low-wavenumber side owing to the distortion of the $B(SeCN)_4$ and $A(NCSe)_4$ tetrahedra in $AB(SeCN)_4$ crystals. The observed bands along with their vibrational assignments are summarized in Table 2.

Table 2. Assignments of the main characteristic Raman vibrational spectra data [$cm^{-1}$] observed for **1** and **2**.

| Assignment[a] | **1**, $[ZnCd(SeCN)_4]_n$ | **2**, $[CdHg(SeCN)_4]_n$ |
|---|---|---|
| $\delta_{SeBSe}$ | 141, 158, 184 | 138, 159 |
| $\delta_{NAN}$ | 254 | 253 |
| $\delta_{SeCN}$ | 402, 418 | 394, 407 |
| $\nu_{CSe}$ | 631 | 612 |
| $2\delta_{SeCN}$ | 804, 838 | 792, 818 |
| $\nu_{CN}$ | 2114, 2155, 2172 | 2135, 2153 |

[a] A stands for Zn in **1** and for Cd in **2**; B stands for Cd in **1** and for Hg in **2**.

## UV/Vis Spectra

Linear absorption spectra of **1** and **2** powders, resolved in dimethyl formamide (DMF), were determined with a 1-cm path and a concentration of $1\times10^{-5}$ mol·$dm^{-3}$. The spectra show a distinctly strong absorption band at about 270 nm for **1** and 266 nm for **2**. Additionally, the solid-state electronic spectra show an intense band at approximately 263 nm for **1**, and 268 and 311 nm for **2**. These bands may be assigned to the metal-mediated ligand $\pi\rightarrow\pi^*$ charge transition of the polymeric metal–selenocyanate system. Such a transition is believed to be the origin of the NLO response.[8a]

### Thermal Stability and Solubility

Thermogravimetric analyses (TGA) of **1** and **2** were performed on the single-crystal samples. The TGA curves of the two complexes exhibited that **1** was stable up to its decomposition temperature of 345.5 °C without showing any melting process and **2** did not melt until the decomposition temperature of 278.2 °C, indicating the high stability of each polymeric structure. Furthermore, in water, **1** is stable at atmospheric pressure and 65 °C for several days without decomposition and hydrolysis, while **2** decomposes and hydrolyzes if it is kept at over 45 °C for several hours.

Because of the poor solubility of **1** and **2** in common solvents, no considerably large single crystal can be grown. The experiments show that the crystals exhibit relatively high solubilities in a mixture of water and acetone (v/v = 1:3); while acetone is very volatile, they can be easily recrystallized and purified by this mixed solvent.

### Description of the Structures

Some valuable experiences have been accumulated that enhance the possibility of obtaining the optimal crystallization. Single crystals obtained have low $R$ values: polymer **1**, $R_1 = 0.0411$ and $wR_2 = 0.1058$; and polymer **2**, $R_1 = 0.0432$ and $wR_2 = 0.1031$. The latter final $R$ indices [$I > 2\sigma(I)$] and the crystal size $0.26 \times 0.22 \times 0.14$ mm of **2** are superior to those in the related article.[12b] The crystal structures of **1** and **2** are shown in Figure 5 and Figure 6 and their molecule stackings are shown in Figure 7 and Figure 8, respectively. Crystallographic data and structure refinements for **1** and **2** are summarized in Table 3 and selected bond lengths [Å] and angles [°] are shown in Table 4.

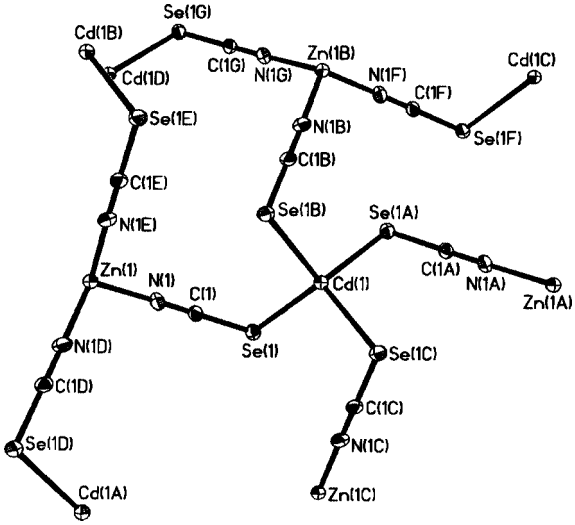

Figure 5. Crystal structure with the atom-numbering scheme of **1**.

Crystals **1** and **2** consist of two kinds of slightly flattened coordinate tetrahedrons with a local symmetry of $D_{2d}$: for **1** one is $ZnN_4$ and the other is $CdSe_4$ and for **2** one is $CdN_4$ and the other is $HgSe_4$. The central atoms, Zn and Cd in **1**

or Hg and Cd in **2**, are located at the center of the fourfold inversion axis. From Table 4, one can see that all the Se–C–N bond angles in the two crystals are very close to 180°, that is, the SeCN group is almost perfectly linear. Therefore, the bond parameters of **1** and **2** are quite similar and it is not strange that both of them belong to the tetragonal system $I\bar{4}$ space group. Furthermore, the most striking features of the structures are the Cd–Se=C=N–Zn bridges and Hg–Se=C=N–Cd bridges, which effectively lead to the formation of an infinite three-dimensional (3D) network in a zigzag way. The coordination modes in the structures can be rationalized in terms of the hard–soft acid–base (HSAB) concept.[17]

The structural characteristics of **1** and **2** account for quite high physicochemical stability. They both possess high thermal stability and do not show hygroscopic or decomposition effects at room temperature to a great extent because of the presence of this strong polymeric structure. The asymmetric arrangements of Se and N atoms around the metal atom give rise to asymmetrical metal coordination and highly asymmetric electronic distribution about the metal atom. The extended π conjugation system within the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

3D network structure, with the high polarizabilities of both the metal and the ligand, can induce desirable physical properties such as NLO effects.[8a,18]

### X-ray Powder Diffraction

The X-ray powder diffraction (XRPD) patterns and diffraction indices of **1** and **2** are shown in Figure 9 and Figure 10, respectively. The tetragonal unit-cell parameters calculated by the TREOR program[19] according to the values of $2\theta$ in the XRPD patterns are $a$ = 11.3352, $c$ = 4.5709 Å, $V$ = 587.30 Å$^3$ for **1**, and $a$ = 11.6450, $c$ = 4.2155 Å, $V$ = 571.65 Å$^3$ for **2**, which agree well with the results determined by the Siemens SMART CCD area detector diffractometer mentioned above.

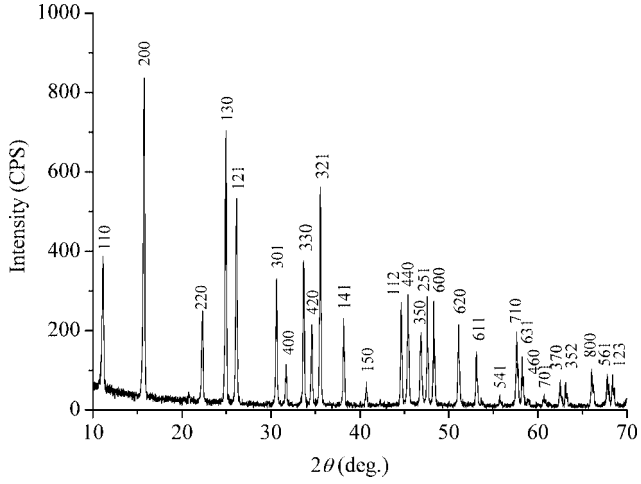

Figure 9. XRPD pattern and diffraction indices of **1** crystal.

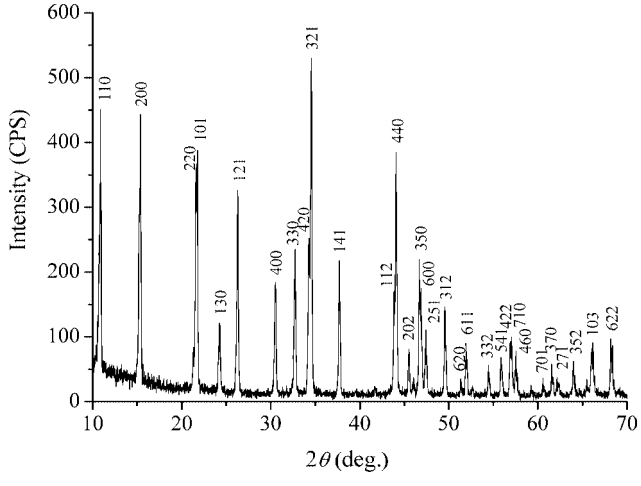

Figure 10. XRPD pattern and diffraction indices of **2** crystal.

### Optical Properties

As for the feature of unsymmetrical structure, NLO activity can occur as specific physical effects. Complexes **1** and **2**, with the noncentrosymmetric space group $I\bar{4}$, were expected to give rise to efficient SHG effects for NLO application. Preliminary experimental results confirmed this and showed they both displayed strong powder SHG efficiencies. The SHG intensity was determined by the powder technique of Kurtz and Perry,[20] in which the second harmonic output was generated by irradiating powder samples of randomly oriented crystallites. The incident radiation came from a Q-switched and mode-locked Nd:YAG laser, and the results indicate that the power SHG efficiency of **1** is superior to that of **2**. The 532 nm second harmonic intensities of **1** and **2** powders were estimated as about 45 and 25 times that of NLO urea powders by direct frequency doubling of a laser diode at 1064 nm at room temperature. We assume that the high nonlinearity of the two crystals is attributed to two structural factors. One is the conjugated charge-moving bridges (Cd–Se=C=N–Zn for **1** and Hg–Se=C=N–Cd for **2**) that connect all the distorted tetrahedrons together, and the other is the effective sum of the microscopic hyperpolarizabilities originating from the parallel molecular stacking in the direction of the fourfold inversion axis. The second harmonic responses of **1** and **2** evidently resulted from the polar arrangement of all the bridging $SeCN^-$ groups, as the utilization of the asymmetric ligands can introduce electronic asymmetry, which is essential for a SHG response.[21] Considering their high thermal stability and tolerance to hydrolysis, both **1** and **2** are considered as quite promising SHG materials. Now we are managing to improving the SHG output efficiency along with exploring better crystal growth conditions.

## Conclusions

The present study shows that a rational design utilizing suitable ligands and metal ions has prepared new supramolecular polymers with nonlinear optical property. The synthetic approach is based on self-assembly of the functional components into well-defined crystalline materials, which allows important structure–property relationships to be established. The title crystals possess better stability and do not show any decomposition and hygroscopic effects at room temperature, but the pH value sensitivity in solution and the physicochemical change at high temperature show the difficulties of single-crystal growth. X-ray diffraction investigations reveal that they crystallize in the same noncentrosymmetric space group, $I\bar{4}$. The high degree of polarizability of the chosen metal and the ambidentate ligand $SeCN^-$, together with the three-dimensional (3D) network structures, provide the crystals with a large interaction force between molecules, which in turn induces large macroscopic NLO properties. The SHG intensities of **1** and **2** were observed to be much stronger than that of urea powders because of the presence of distorted $AN_4$ (A = Zn or Cd) and $BSe_4$ (B = Cd or Hg) tetrahedra in the 3D structure. In summary, being 3D coordination polymers, **1** and **2** have emerged as two promising candidate materials for generation of blue-violet light using a diode laser and this, their high SHG efficiency, excellent optical transparency, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

high thermal stability make them attractive for device applications. Further studies on related properties are currently under way.

## Experimental Section

**General:** Potassium selenocyanate (KSeCN) was prepared by the method given in the literature.[22] All other starting materials were analytical reagent grade (Purity ≥ 98.0%) and used as purchased, and all the synthetic and growth processes were carried out in aqueous solutions. Elemental analyses were performed with a Perkin–Elmer 240 instrument. IR spectra were recorded with a Nicolet FTIR 170SX instrument (KBr discs) in the 4000–400 $cm^{-1}$ region. The far-IR spectra (500–100 $cm^{-1}$) were recorded in Nujol mulls between polyethylene sheets. UV/Vis spectra were recorded with a UV-265 spectrophotometer. TGA analyses were recorded with a Perkin–Elmer Pris-1 DMDA-V1 analyzer in nitrogen at a heating rate of 5 °C $min^{-1}$. The second-order nonlinear optical tests were carried out by the powder second harmonic generation (SHG) method.[20]

Room-temperature Raman spectra of the two crystal powders were measured on a LABRAM microscopic Raman spectrometer with a slit width of 100 nm, using a 100 mW argon ion laser at 514.53 nm with a power density of 5 mW·μ$m^{-2}$ at the sample. The Raman spectra with a resolution of 0.15 $cm^{-1}$ and a wavelength precision of 0.5 $cm^{-1}$ in a wavenumber range from 50 to 2500 $cm^{-1}$ were collected.

The XRPD patterns of the **1** and **2** crystals were registered with a Rigaku D/Max-γA diffractometer, operated at 40 KV and 40 mA, using a Cu target tube and a graphite monochromator. Fixed scatter and divergence slits of 1° and a 0.15-mm receiving slit were used. The intensity data were recorded by continuous scan in a $2\theta/\theta$ mode from 10° to 70° with a step size of 0.02° and a scan speed of 4°$min^{-1}$.

**Syntheses**

**$[ZnCd(SeCN)_4]_n$ (1):** Cadmium chloride ($CdCl_2$) (0.03 mol, 5.50 g) was dissolved in deionized water (30 mL) at room temperature. This solution was added slowly to a colorless solution (50 mL) containing zinc chloride ($ZnCl_2$) (0.03 mol, 4.09 g) and potassium selenocyanate (KSeCN) (0.12 mol, 17.29 g). The stoichiometric mixture was stirred for 1 h and then filtered. The resulting filtrate was kept standing and evaporated slowly in a desiccator in vacuo over calcium chloride. Two weeks later, the colorless and transparent tetrahedral-shaped single crystals were obtained. Yield 12.98 g (72.4%). $ZnCd(SeCN)_4$ (597.69): calcd. C 8.03, N 9.36; found C 8.07, N 9.39.

**$[CdHg(SeCN)_4]_n$ (2):** This complex was prepared in an analogous way to that of **1**. Cadmium chloride ($CdCl_2$) (0.03 mol, 5.50 g) was dissolved in solution and then added slowly into a colorless solution containing mercury chloride ($HgCl_2$) (0.03 mol, 8.14 g) and potassium selenocyanate (KSeCN) (0.12 mol, 17.29 g) with stirring. After 1 h the stoichiometric mixture was filtered and evaporated slowly in a desiccator in vacuo. Twenty days later, the silvery gray and transparent tetrahedral-shaped single crystals were obtained. Yield 14.85 g (67.5%). $CdHg(SeCN)_4$ (732.91): calcd. C 6.55, N 7.64; found C 6.59, N 7.67.

**Crystallographic Structure Determination:** High optical quality **1** and **2** single crystals suitable for X-ray diffraction analyses were grown from their reaction mother solutions (RMS) by the solvent-evaporation method and then separated and dried, respectively. A single crystal of polymer **1** or **2** with suitable dimensions was mounted on a glass fiber and data collections were performed using a Siemens SMART CCD area detector diffractometer with Mo-$K_\alpha$ radiation with $\omega$-scan mode ($\lambda$ = 0.71073 Å). The structures were solved with direct methods using the program SHELXTL[23] and refined anisotropically with SHELXTL using the full-matrix least-squares procedure.

CCDC-207921 (for **1**) and -207922 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## COVER PICTURE

**The cover picture shows** a chiral catalyst heterogenized into confined nanospaces of porous materials. The site-isolation of catalytic sites easily prevents the formation of inactive multinuclear species, consequently increasing the stability and turnover numbers of catalysts. In addition to this enhanced stability, increased enantioselectivity was also found upon immobilization in the confined spaces, due to the confinement effect originating from the interaction of catalyst/substrate with pore surfaces. Details of this chemistry are described in the Microreview by C. E. Song et al. on p. 2927 ff.

# Chiral Organometallic Catalysts in Confined Nanospaces: Significantly Enhanced Enantioselectivity and Stability

**Choong Eui Song,*[a] Dong Hyun Kim,[a] and Doo Seoung Choi[a]**

**Keywords:** Asymmetric catalysis / Supported catalysts / Mesoporous materials / Zeolite analogs / Nanostructures

This microreview presents some selected representative examples which demonstrate that significant improvement in the catalytic performance (increase in catalytic activity, stability and chemo- and enantioselectivity) of organometallic chiral catalysts as well as their recycling ability can be achieved by heterogenizing them in the confined spaces of porous or layered support materials. The positive effects of immobilization on the catalytic efficiencies are discussed in terms of the confinement effect and site-isolation effect, etc., with the aim of understanding the extent to which such effects lead to positive changes in the catalytic properties.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

For economic, environmental and social reasons, the trend towards the application of optically pure compounds is undoubtedly increasing. Among the various methods which can be used to selectively produce single enantiomer, asymmetric catalysis is the most attractive method from the atom-economic point of view.[1,2] Over the last thirty years, numerous catalytic reactions allowing the enantioselective formation of C–H, C–C, C–O, C–N and other bonds have been discovered. A number of homogeneous organometallic chiral catalysts have gained wide acceptance in terms of their efficiency and selectivity, and some of them are even

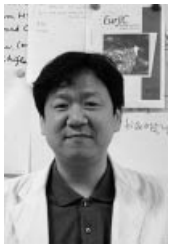
*Choong Eui Song has been a Professor at Sungkyunkwan University since 2004. He received his B.S. in 1980 from Chungang University and obtained a Diploma (1985) and a Ph.D. (1988) at RWTH Aachen in Germany. After completing his Ph.D. he worked as a Principal Research Scientist at the Korea Institute of Science and Technology (KIST). In 2001 he was appointed as head of the national research laboratory for Green Chirotechnology in Korea. In 2004 he moved to his current position and in 2006 he was appointed as a director at the Research Institute of Advanced Nanomaterials and Institute of Basic Science in Sungkyunkwan University. His research interests focus on asymmetric catalysis, ionic liquid chemistry and nanochemistry. He received an academic award from the KIST (2000) and the Scientist of the Month Award from the Ministry of Science and Technology in Korea.*

*Dong Hyun Kim was born in 1978 in Seoul, Korea. He received his B.S. degree in 2005 from Korea University. He is currently a MS student with Professor Song at the same university, focusing on heterogeneous asymmetric catalysis and chiral sensors.*



*Doo Seoung Choi was born in 1965 in Seoul, Korea. He worked in the field of process development for Chong-Kun Dang pharmaceutical company in Korea from 1993 to 2001 and then he moved to C-TRI Co. Ltd. in Korea, where he worked in the R&D team investigating ionic liquids as a team manager for three years. He is currently a PhD student with Professor Song at the same university, focusing on heterogeneous asymmetric catalysis. During summer 2005, as a visiting fellow, he worked at the laboratory of Professor Benjamin List in the Max Planck-Institute (Muellheim), Germany.*

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

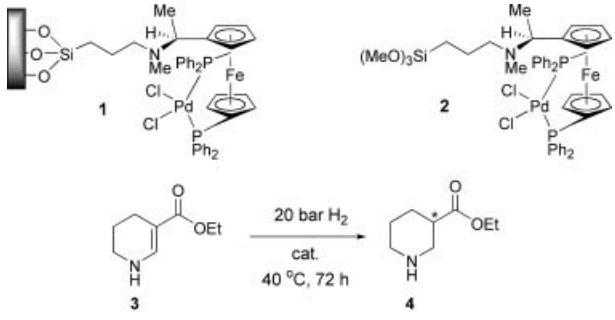
used on an industrial scale.[3–5] However, in spite of the huge amount of work devoted to this subject in both the academic and industrial fields, the contribution of asymmetric catalysis to the overall production of chiral chemicals is much lower than originally expected. One of the major drawbacks of homogeneous catalysis is the need to separate the relatively expensive chiral catalysts from the reaction mixture at the end of the process. The possible contamination of the product with metal catalysts also severely restricts their use in industry. In order to overcome these drawbacks, a great deal of effort has been made to develop effective heterogenized catalyst systems, mainly, by immobilizing homogeneous chiral catalyst on solid supports by: (i) covalent bonding, (ii) adsorption or ion-pair formation, (iii) encapsulation, or (iv) entrapment, etc.[6–8] In any case of heterogenization method, the support materials need to be thermally, chemically, and mechanically stable during the reaction process. Moreover, the structure of the support needs to be such that the active sites are well dispersed on its surface and easily accessible. Generally, this requires the support to have a reasonably high surface area (typically $>100\ m^2\,g^{-1}$) and an appropriate pore size (i.e. >20 Å), in order to allow for the easy diffusion of the reactants to the active sites.[9] Thus, inorganic supports[10] such as mesoporous silica and clay, have been extensively used for the immobilization of catalysts because of their large surface area, chemical and physical stability, and tunable pore or layer structure. One obvious benefit of supported catalysts is the easy separation of the relatively expensive chiral catalysts from the reaction mixture at the end of the process. In addition, catalysts immobilized on porous or layered materials have sometimes been found to exhibit much better catalytic performances than their homogeneous analogues due to geometrical constraints imposed by the pores or layers.[11–13]

The instability of homogeneous catalysts is often due to the formation of inactive multinuclear species. However, the colocalization of the catalytic sites can easily be prevented by immobilizing the catalysts in confined spaces, i.e., by the site-isolation of the catalytic sites,[14–16] consequently increasing the stability and turnover numbers of the catalyst. In this respect, mesoporous-type materials appear to be more attractive, due to their regular structures and tunable pore diameters. In addition to this enhanced stability, increased activity and selectivity were also observed upon immobilization in the confined space, due to the confinement effect originating from the weak interactions (hydrogen bond, van der Waals force, adsorption, etc.) between catalyst/substrate and pore surfaces. The polar or acidic pore surface can participate in the catalysis cooperatively, e.g., by stabilizing a charged transition state and thereby increasing the reaction rate.[17–19] In addition, because this weak interactions between catalyst/substrate and pore surfaces is about the same level as the energy difference between the two transition states corresponding to the (*R*) product and the (*S*) product, the enantioselectivity can also be very sensitively (positively or negatively) altered.[11] Enantioselectivity can be, thus, increased or decreased, or even reversed. Therefore, the enantioselectivity could be improved by careful tuning the confinement effect based on the molecular designing of the pore/surface and the immobilized catalysts according to the requirements of chiral reactions.[11–13] In this microreview, some selected examples will be given which can nicely demonstrate that a significant improvement in the stereoselectivity of the organometallic catalyst may be achieved by heterogenizing it into the confined nanospaces of porous or layered materials. Also, the effects positively influencing the catalytic efficiencies of the supported catalysts are discussed in terms of the confinement effect and site-isolation effect, etc., with the aim of understanding how such effects lead to positive changes in the catalytic properties.

## Selected Examples

### Asymmetric Hydrogenation

Several striking examples of the positive control effected by nanopores have been provided by the research group of Thomas and Johnson.[20–24] The Pd catalyst **1** supported on the mesoporous channels of MCM-41 affected the hydrogenation of ethyl 1,4,5,6-tetrahydronicotinate (**3**) to afford nipecotic acid ethyl ester (**4**) in 17% *ee*, whereas the use of the soluble version **2** resulted in a racemic mixture (Scheme 1). This enhanced chiral induction was explained in terms of the confinement effect of the ordered mesopore of MCM-41, which confine the substrate and ligand of the catalysts.[21]

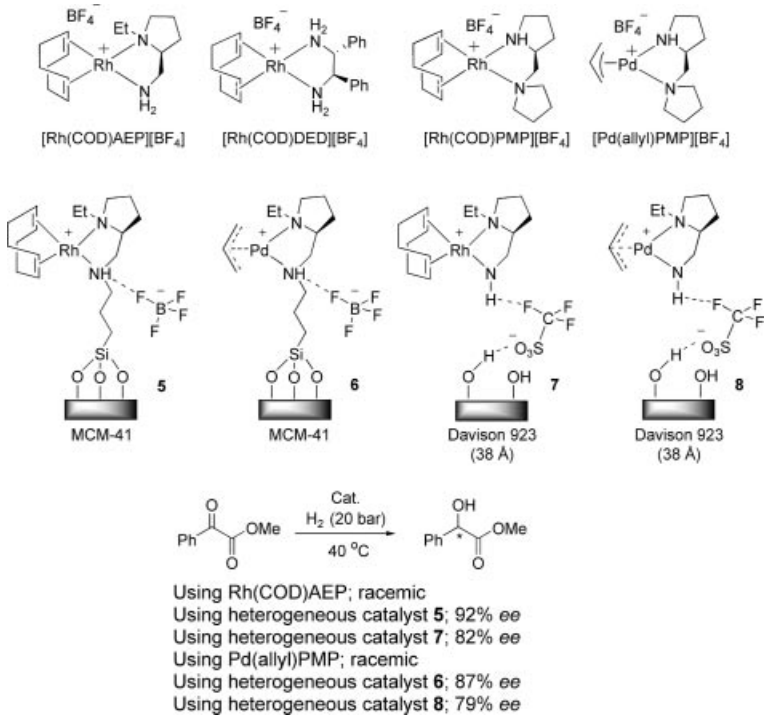


Using homogeneous catalyst **2**: racemic, TON = 98
Using heterogeneous catalyst **1**: 17% *ee*, TON = 291

Scheme 1.

The same research group[23] incorporated (*S*)-2-aminomethyl-1-ethylpyrrolidine (AEP) or (1*R*,2*R*)-1,2-diphenylethylenediamine (DED) into the concave surface of MCM-41 (pore diameter 30 Å) and to the convex surface of nonporous silica (Carbosil). Catalytic reactions were carried out using heterogeneous Rh and Pd catalysts for the asymmetric hydrogenation of (*E*)-α-phenylcinnamic acid and methyl benzoyl formate. Compared to the corresponding homogeneous catalyst or silica-supported catalyst, a significant enhancement of the *ee* value was observed for the MCM-41-supported catalyst (with the concave surface). For example, surprisingly, the Rh(COD)- and Pd(allyl)

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

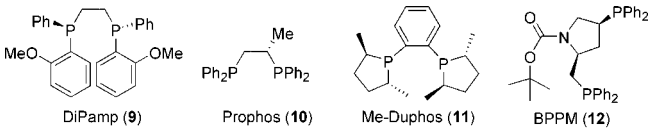
complex of AEP anchored on MCM-41, **5** and **6**, gave 92 and 87% *ee*, respectively, in the hydrogenation of methyl benzoyl formate, while the homogeneous catalysts gave a racemic product (Scheme 2). This increase in the *ee* values was attributed to the restricted access of the reactant to the active site generated by the concavity of the pore. Soon after, the same group[24] also anchored [Rh(COD)(*S*)-PMP][$CF_3SO_3$], [Pd(allyl)(*S*)-1-(2-PMP)] [$CF_3SO_3$], [Rh(COD)(*S*)-AEP] [$CF_3SO_3$] and [Rh(COD) (1*R*,2*R*)-DED][$CF_3SO_3$] noncovalently through N–H···F hydrogen bonding with the triflate ion, $CF_3SO_3^-$ to the inner surface of a set of silicas with narrowed pore-size distributions (38, 60, and 250 Å). The catalytic performances of the heterogeneous catalysts were tested in the asymmetric hydrogenation of methyl benzoyl formate to produce methyl mandelate. The supported catalysts generally exhibited remarkably higher *ee* values than their homogeneous counterparts. Notably, the heterogeneous catalysts **7** and **8** gave up to 82 and 79% *ee*, respectively, while their two homogeneous counterparts, $[Rh(COD)AEP]^+$ and $[Rh(COD)DED]^+$, did not display any significant *ee* (Scheme 2). The increase of the *ee* values of the supported catalysts was observed in a manner that logically reflects the declining influence of spatial constraint in proceeding from the 38-Å- to the 60-Å- to the 250-Å-pore-diameter silica. A similar enhancement of enantioselectivity in the hydrogenation of (*E*)-α-phenylcinnamic acid affording 2,3-diphenylpropanoic acid was also observed by heterogenizing [Rh(COD)(*S*)-AEP][$CF_3SO_3$] and [Rh(COD)(1*R*,2*R*)-DED][$CF_3SO_3$] noncovalently through H bonding of the triflate ion, $CF_3SO_3^-$ to the silanol groups of inner surface of MCM-41.[25]

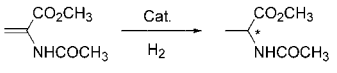
The above examples provided by the research group of Thomas and Johnson strongly suggest that the conventional heterogenization approach, i.e., heterogenizing those catalysts designed for homogeneous processes, may not necessarily be the best solution for the development of efficient heterogenized chiral catalyst systems when it comes to immobilizing catalysts in the confined spaces of porous or layered support materials. Moreover, the above-mentioned results also suggest that the heterogenization of catalysts in confined spaces may provide a new paradigm for the development of highly efficient chiral catalysts.

## Other Examples

Augustine et al.[26] immobilized various Rh complexes of well-known chiral bis(phosphane) ligands, such as DiPamp (**9**), Prophos (**10**), Me-DuPhos (**11**), and BPPM (**12**) onto heteropolyacid-modified inorganic supports, e.g., montmorillonite K, alumina. Somewhat surprisingly, both reaction rates and enantioselectivities significantly increased upon subsequent reuse of the recovered immobilized catalysts. After 9$^{th}$ reuse, DiPamp-rhodium supported on a PTA-alumina gave rise to a 97% *ee* vs. 76% *ee* for the homogeneous complex during the hydrogenation of methyl 2-acetamidoacrylate (**13**) (Scheme 3). Rege et al. also observed that the noncovalent immobilization of [(*R*,*R*)-Me-(DuPHOS)Rh(COD)]OTf afforded by interaction of triflate counterion with surface silanol groups of MCM-41 resulted in 99% *ee* in the hydrogenation of **13**, compared to 87% *ee* with the homogeneous Rh complex of **11** (Scheme 3).[27]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 





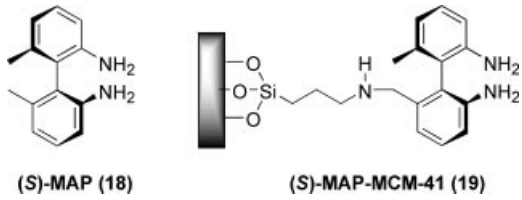
13

Using homogeneous catalyst **9**; 76% *ee*, TOF($min^{-1}$) = 0.25
Using PTA-alumina supported **9**; 97% *ee*, TOF($min^{-1}$) = 1.29
Using homogeneous catalyst **11**; 87% *ee* (in hexane)
Using MCM-41 supported **11**; 99% *ee* (in hexane)

Scheme 3.

Corma et al.[28–31] immobilized a number of proline derivatives on silica and modified USY zeolite (pore diameter 12–30 Å) (e.g. **15a** and **15b** in Scheme 4), and used them for the hydrogenation of various (*Z*)-*N*-acylcinnamic acid derivatives such as **16a** and **16b**. For all of the substrates tested using these catalysts, the enantioselectivity was higher with the zeolite-supported complex **15a** than with either the silica-supported **15b** or unsupported complex **14**, suggesting that the steric constraints of the support play an important role, especially in the case of zeolite where the reaction must take place in the confined spaces of the supermicropores. This is the first example in which the steric constraints of support (in this case, zeolite) was found to have positive effect on enantioselectivity.[28,29]

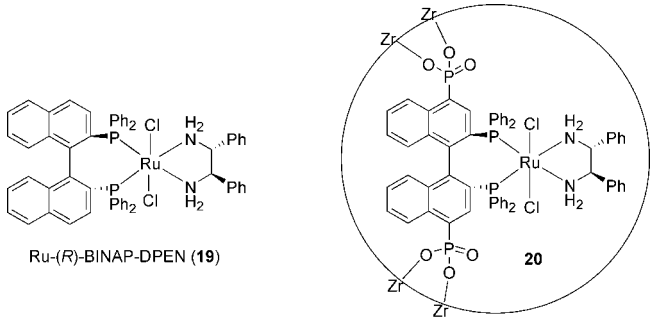
Pérez et al. also reported that the enantioselectivity of the supported complex was significantly increased compared with that obtained with the homogeneous one.[32] (*S*)-MAB-Ru anchored onto MCM-41 (**19**-Ru) catalyze the asymmetric hydrogenation of itaconic acid and α-acetamidocinnamic acid to yield the (*R*) product with 100% yield and 97% *ee*, while the homogeneous one, (*S*)-MAB-Ru (**18**-Ru), gave only moderate *ee* values (80 and 69.8%, respectively) (Scheme 5). The authors hypothesized that the interaction of the ligands with the pendant hydroxy groups present on the pores of MCM-41 may increase the rigidity of the overall catalytic structure. This, in turn, would restrict the rotation of the transition state and favor formation of nearly pure stereoisomers. In addition, the reaction yield remained at 100% while the enantioselectivity decreased only slightly, from 97 to 94%, after three runs.



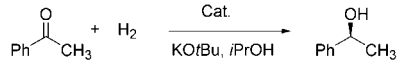
**(*S*)-MAP (18)** **(*S*)-MAP-MCM-41 (19)**

Scheme 5.

In an effort to rationally design functional hybrid solids based on organic linkers and metal nodes, Hu et al.[33] designed and synthesized novel chiral porous zirconium phosphonates containing Ru-BINAP-DPEN moieties **20**. The synthesized chiral porous hybrid solid catalyzed the asymmetric hydrogenation of unfunctionalized aromatic ketones with remarkably higher activity and enantioselectivity (up to 99.2% *ee*) than the parent homogeneous counterpart Ru-BINAP-DPEN system **19**. For example, acetophenone was hydrogenated to 1-phenylethanol with complete conversion and 96.3% *ee* in 2-propanol with 0.1 mol% loading of the solid catalyst **20**. This level of enantioselectivity is significantly higher than that observed for the parent homogeneous catalyst **19** which typically gives ca. 80% *ee* for the



Ru-(*R*)-BINAP-DPEN (**19**) **20**



Using the homogeneous catalyst **19**: ~80% *ee*
Using the solid catalyst **20**: 96.3% *ee*

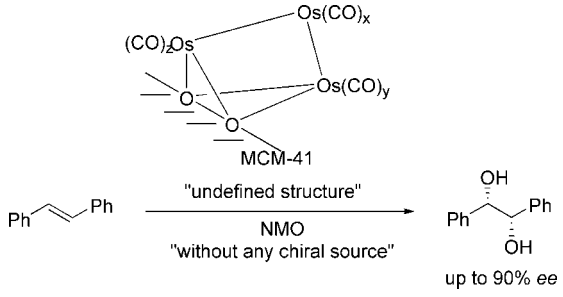
same reaction (Scheme 6). A similar method has also been used to synthesize other chiral, porous hybrid ruthenium solids.[34] In the heterogeneous asymmetric hydrogenation of β-keto esters, an *ee* value of up to 95% was achieved.

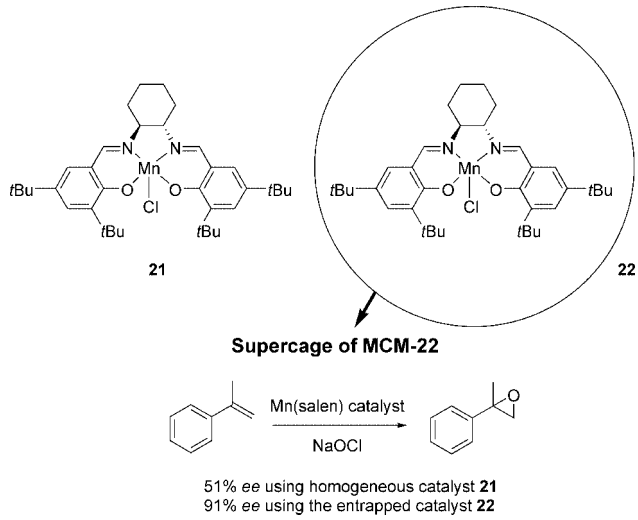
### Asymmetric Oxidation

An extremely exciting example was very recently provided by Caps et al.,[35] which demonstrates that the heterogenization of catalysts in confined spaces can be used not only to improve the stereoselectivity but also to generate a new chiral species in situ from achiral catalyst precursors. The heterogenization of the achiral cluster, $Os_3(CO)_{12}$, on the internal space of MCM-41 using simple chemical vapor deposition (CVD) gave a superior enantioselectivity towards the (*S*,*S*) configuration of the 1,2-diphenyl-1,2-ethanediol in the dihydroxylation of *trans*-stilbene using *N*-methylmorpholine *N*-oxide (NMO) as an oxidant without adding any chiral ligand. This surprising effect was even more pronounced when surface Al sites were introduced into the silicate [90% *ee* for (*S*,*S*)-isomer] (Scheme 7). This 90% *ee* towards the (*S*,*S*) configuration is much higher than that reported using a homogeneous $OsO_4$/NMO/acetone/water system containing a chiral ligand (78%).[36] One possible reason for this chiral induction might be the "spontaneous symmetry breaking"[37–39] of achiral $Os_3(CO)_{12}$ during CVD on the MCM-41 or related surfaces, resulting in a new surface-chiral catalytic species. However, unfortunately, many attempts by us to reproduce this highly interesting result have been failed yet.



Scheme 7.

A significant enhancement of the enantioselectivity as a result of the confinement effect was also observed in the epoxidation of α-methylstyrene with hypochlorite.[40] Jacobsen's Mn(salen) complex encapsulated in the spacious supercages of MCM-22 (**22**) showed significantly better enantioselectivity than the homogeneous catalyst **21** under the same conditions, i.e., 91.3% *ee* vs. 51% *ee* (Scheme 8). Moreover, the encapsulated complex was three times more active than the homogeneous counterpart **21**, which is also attributed to site-isolation, i.e., to the suppressed formation of dimeric and other oligomeric Mn oxo complexes due to geometric constraints.



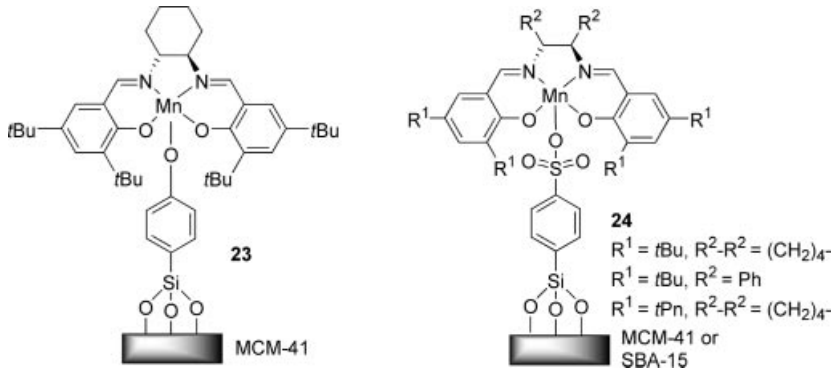
Scheme 8.

Li et al. also observed that the immobilization of the chiral Mn(salen) complex through the complexation of manganese by the oxygen atoms of the phenoxyl groups grafted on the surface of MCM-41 leads to a markedly higher *ee* value than that observed for the free complex in the asymmetric epoxidation of simple olefins.[41] For example, in the epoxidation of α-methylstyrene in $CH_2Cl_2$ with NaOCl as the oxidant, the enantiomeric excess is notably increased from 56% for the homogeneous catalyst to 72% for the heterogeneous Mn(salen)/MCM-41 catalyst (**23**). Soon after, the same group also reported that chiral manganese(salen) catalysts axially immobilized in nanopores by Ph sulfonic groups (**24**) also resulted in remarkably higher *ee* values (up to 95%) for the asymmetric epoxidation of unfunctionalized olefins (Scheme 9).[42,43]

Similar results were observed with other salen-M complexes anchored on porous supports.[44–46] Kim et al.[44] reported that, for the asymmetric epoxidation of α-methylstyrene, the *ee* value increased from 51% to 59% after the immobilization of Mn(salen) on the siliceous MCM-41 by multi-step grafting. Kureshy et al.[45] also reported that montmorillonite clay supported dicationic Mn(salen) exhibited similar or even higher *ee* values for the epoxidation of 2,2-dimethyl-6-nitrochromene, indene, and styrene than the corresponding homogeneous catalysts. It has also been reported that, for the enantioselective epoxidation of β-methylstyrene, the *ee* value increased from 54% to 73% after the immobilization of Cr(salen) through axial $NH_2$ complexation.[46]

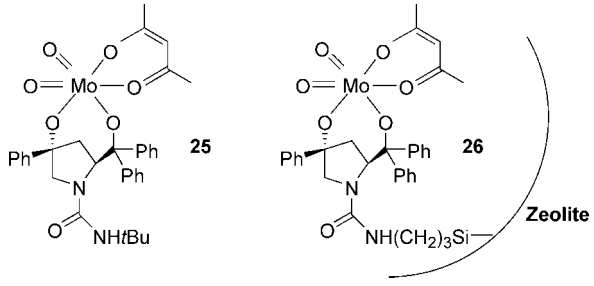
Another good example of the confinement effect in heterogenized catalysts on porous supports was provided by Corma et al. The use of $Mo^{VI}$ complexes of chiral ligands derived from (2*S*,4*R*)-4-hydroxyproline, heterogenized onto a modified USY zeolite by covalent bonding,[47] in the epoxidation of geraniol and nerol with TBHP as the oxygen source resulted in much higher enantioselectivities (47% *ee* for geraniol and 64% *ee* for nerol) than those (up to 27.6% *ee* for geraniol and up to 10.4% *ee* for nerol) obtained with the homogeneous counterpart **25**. This enhanced enantio-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 9.

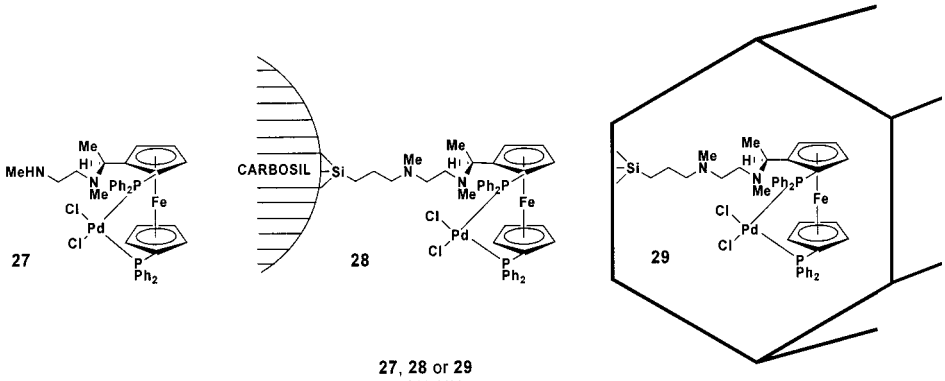
selectivity can also be ascribed to the additional steric constraints imposed by the zeolite pores. The lifetime of the heterogenized catalyst was also examined by the repeated use of the catalyst **26** which showed similar rates and yields of epoxide, even after five runs (Scheme 10). The enhanced stability of the heterogenized complex was ascribed to the stronger coordination of the dihydroxy ligand to Mo than that of the acetylacetonate or hydroxy group present on the substrate, *tert*-butyl alcohol or hydroperoxide. The site-isolated catalyst molecules on the mesopores could also avoid being deactivated by dimerization and oligomerization of the Mo species.



Scheme 10.

## Asymmetric C–X and C–C Bond-Forming Reactions

A good example of the confinement effect dramatically improving the performance of chiral catalysts for C–X bond-forming reactions was described by Thomas et al.[48] In the case of the allylic amination of cinnamyl acetate, catalyst **29**, immobilized on the inner walls of mesoporous MCM-41, exhibited superior catalytic properties than catalyst **28** anchored on Carbosil (a nonporous, high-area silica) and than homogeneous catalyst **27**. The MCM-41-immobilized catalyst **29** showed a degree of regioselectivity for the desirable branched product (51%) and extremely high enantioselectivity (>99% *ee*), whereas the Carbosil-immo-



| Catalyst | Conversion (%) | Straight chain (%) | Branched (%) | %*ee* |
|---|---|---|---|---|
| **27** | 76 | >99 | - | - |
| **28** | 98 | 98 | 2 | 43 |
| **29** | >99 | 49 | 51 | >99 |

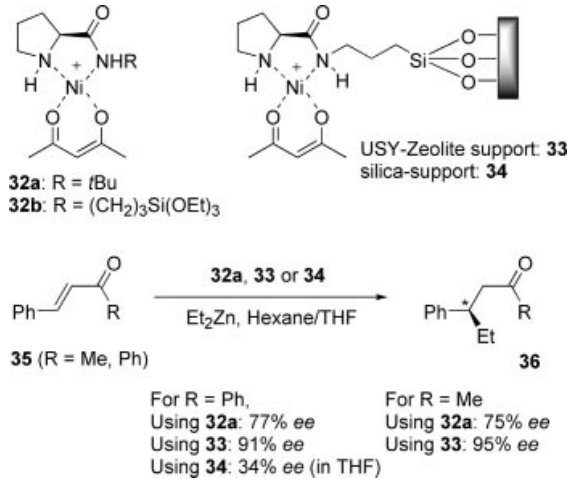
Scheme 11.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bilized catalysts **28** afforded the branched product in only 2% yield and with 43% *ee*. In the case of the homogeneous catalyst **27**, the reaction produced solely the straight chain product (Scheme 11). Although the regioselectivity of **29** is still not very high, the careful design of active centers and the control of pore size of supports will probably lead to more unexpected selectivities.

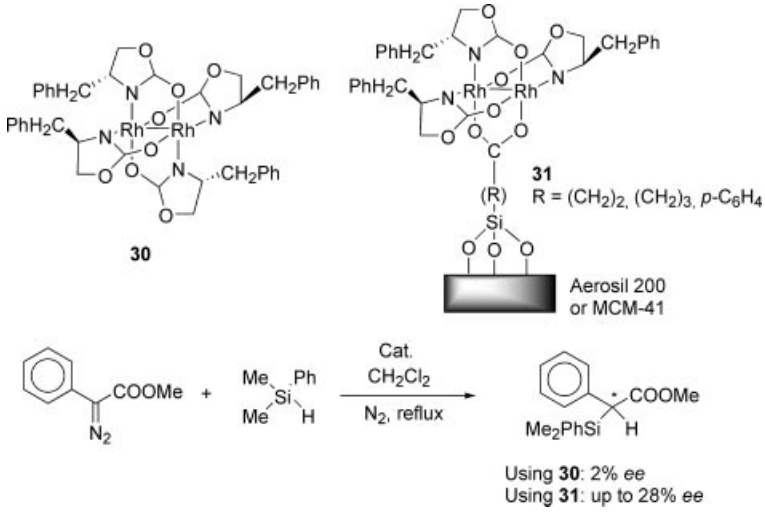
Also in the Si–H insertion reactions of dimethylphenylsilane with methylphenyldiazoacetate, a significant improvement in enantioselectivity was observed by immobilizing the chiral dirhodium complexes on Aerosil 200.[49,50] This immobilized catalyst, $SiO_2$–$(CH_2)_2COO$–$Rh_2[(4S)\text{-BNOX}]_3$ (**31**), showed a more than 10-fold increase in enantioselectivity (up to 28% *ee*), while the homogeneous analogue $Rh_2[(4R)\text{-BNOX}]_4$ (**30**) gave nearly racemic product (Scheme 12). In contrast to the catalysts immobilized on Aerosil 200 having an average pore size of 50 nm, none of the catalysts immobilized inside the pores of MCM-41 showed any activity. It is possible that there is not enough space inside the pores of MCM-41 for the reaction to take place. This result is reasonable, considering that the average pore diameter (19 Å) of MCM-41 is only slightly larger than the catalyst size (between 19 and 13 Å). A transition state requiring a space-demanding conformation of the catalyst might, therefore, be impossible under these circumstances.

Sanchez and co-workers[51] anchored the Ni complex of the L-proline amide **32b** on USY zeolites or silica by covalent bonding. Although the use of the insoluble catalysts **33** and **34** caused the conjugate addition of $ZnEt_2$ to the enones **35** to take place more slowly, the *ee* values of the resulting saturated ketones **36** were much higher for the zeolite-supported Ni complex **33** (91 and 95% *ee*, for R = Ph and Me, respectively) than its homogeneous counterpart **32a** (77 and 75% *ee*, for R = Ph and Me, respectively) or the silica-supported analogue **34** (34% *ee*, R = Ph) (Scheme 13). The steric constraint imposed by the zeolite pore was thought to contribute to the enhanced enantioselectivities that were observed. Sanchez et al. also attached a series of chiral amines covalently to modified USY zeolite and MCM-41 zeolite supports, and evaluated the ability of the obtained chiral base catalysts confined in porous hosts to improve stereoselectivity in conjugate additions of nucleophiles to enones.[52] It was found that the reaction rate was enhanced, and the catalysts showed higher selectivity than the free amines.



Scheme 13.

Chiral bis(oxazoline)copper complexes are known to be highly effective enantioselective, homogeneous catalysts for many C–C and C–X bond -forming reactions, such as Diels–Alder, aldol, Michael, ene, amination and aziridination reactions. It has also been reported that chiral bis(oxazoline)copper complexes constrained within the confined spaces of porous materials exhibited substantially higher enantioselectivity than the homogeneous catalyst.[53–56] For example, Wan et al. immobilized the Ph-substituted bis(oxazoline)copper(II) complex in zeolite Y for the hetero-Diels–Alder reaction of (ethyl *E*)-pentenoate (**39**) with ethyl vinyl ether, affording the dihydropyran **40** (Scheme 14).[53] The enantioselectivity (41%) of the solid catalyst **38** was significantly higher than that obtained with



Scheme 12.

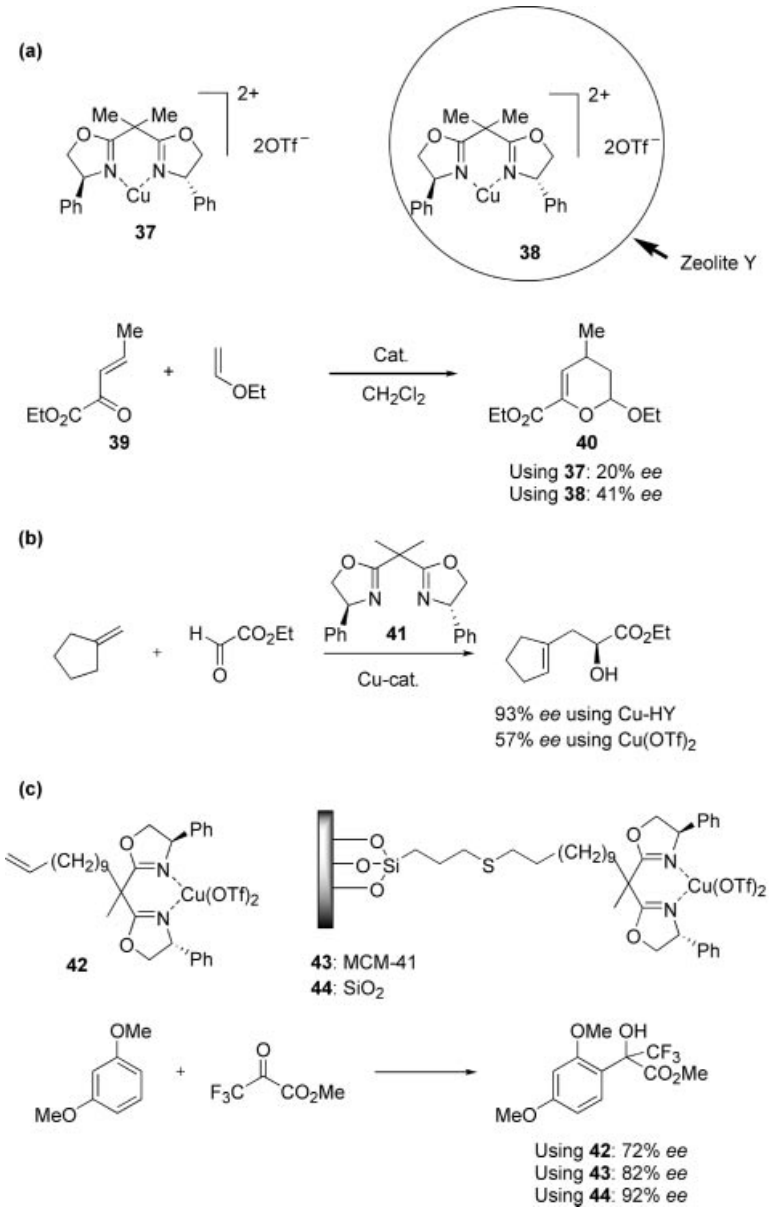

Scheme 14. Selected examples of chiral bis(oxazoline)copper complexes constrained within confined spaces and their use in catalytic reactions.

the homogeneous catalyst **37** (20% *ee*) (Scheme 14a). Very interestingly, the configuration of the (2*S*,4*R*) product obtained from the heterogeneous reaction is opposite to the (2*R*,4*S*) product obtained from the homogeneous reaction. As described in the introduction section, this reversed enantioselectivity could also be attributed to the confinement effect of the porous supports.

The heterogeneous catalyst obtained by impregnating $Cu^{II}$ ion in zeolite Y and subsequent modification with the bisoxazoline ligand **41**[54] also exhibited the superior enantioselectivity (93% *ee*) compared to the homogeneous catalyst (57% *ee*) for the reaction of methylenecyclopentane with ethyl glyoxylate (Scheme 14, b). The same authors observed a similar enhancement of the *ee* value in the aziridination reaction which result from the confinement effect of the zeolite pores.[55]

Corma et al. covalently anchored the chiral bis(oxazoline)copper(II) onto silica and MCM-41 and tested its catalytic ability in the Friedel–Crafts hydroxyalkylation of 1,3-dimethoxybenzene with 3,3,3-trifluoropyruvate.[56] The activity and enantioselectivity of the two heterogeneous catalysts were higher than those of the homogeneous analogue (Scheme 14, c).

## Conclusions

This microreview presents some selected representative examples which demonstrate that not only facile catalyst recycling but also a significant improvement in the catalytic performances (activity, stability and enantioselectivity) of the organometallic chiral catalysts can be achieved by hetero-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

genizing them in the confined spaces of porous or layered support materials. Surprisingly, in some cases, even non-enantioselective catalysts showed significant asymmetric induction when they were anchored into confined nanospaces.[21,23,24,35,48] These results suggest that the conventional approaches, i.e. (i) designing chiral catalysts for homogeneous conditions and (ii) heterogenizing those catalysts well-designed for homogeneous processes, may not necessarily be the best solution for the development of efficient chiral catalyst systems. In conclusion, the heterogenization of catalysts in confined spaces will provide a new paradigm for the development of a highly efficient chiral catalyst in future.

# Formation of Unexpected Selenium-Rich Compounds by Selenation of the Very Bulky $(PhMe_2Si)_3CLi$: *s*-Tetraselenane, a Novel Polyseleno Heterocycle

**Thomas M. Klapötke,[a] Burkhard Krumm,*[a] Kurt Polborn,[a][‡] and Matthias Scherr[a][‡]**

**Keywords:** Bulky substituents / DFT calculations / Selenium / Structure elucidation

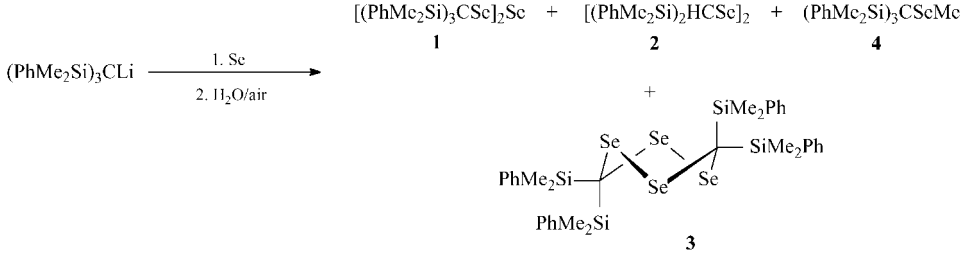
The reaction of the highly crowded trisilylmethyllithium compound $(PhMe_2Si)_3CLi$ with elemental selenium resulted in a variety of products, among them the triselane $[(PhMe_2Si)_3CSe]_2Se$, the unexpected diselane $[(PhMe_2Si)_2HCSe]_2$ and the novel heterocycle $[(PhMe_2Si)_2CSeSe]_2$. The constitution of the latter could be elucidated from the NMR spectroscopic data and was confirmed by the crystal structure which displays the $C_2Se_4$ cycle in the twist form. Calculations were performed for the chair and twist conformers of the heterocycles $[(H_3Si)_2CXX]_2$ (X = O, S, Se, Te, Po).

## Introduction

The stabilization of low-coordinated main-group compounds is possible with extremely bulky substituents and has been reviewed recently in detail.[1] Chalcogen compounds containing the tris(trimethylsilyl)methyl group, $(Me_3Si)_3C$, have been prepared (sulfur,[2] selenium,[3–5] and tellurium[3,6]). The introduction of such sterically demanding substituents at the heavier chalcogen elements has been a part of our research for the recent time, because they have been useful to stabilize or detect rather reactive species or intermediates in tellurium(II),[7] and selenium(II) azide chemistry.[8] The tris[dimethyl(phenyl)silyl]methyl group, $(PhMe_2Si)_3C$, is expected to have some increased shielding properties compared to the permethylated substituent. The tellurolate $(PhMe_2Si)_3CTeLi$ and the corresponding ditellane, tellurenyl iodide and azide were isolated and characterized by us very recently. In this communication we would like to present our study of the reactivity of $(PhMe_2Si)_3CLi$ towards selenium.

## Results and Discussion

The alkyllithium reagent $(PhMe_2Si)_3CLi$, generated as described,[7] was treated with elemental selenium to give the selenolate $(PhMe_2Si)_3CSeLi$ in a straightforward manner according to $^{77}Se$ NMR spectroscopy (in THF: $\delta$ = –63.3 ppm). The product mixture, which was obtained after hydrolysis and oxidation (exposure to air) of the selenolate, was surprisingly complex and, according to $^{77}Se$ NMR spectroscopy, consisted of several selenium-containing species. From this mixture the four main components could be separated, isolated and identified [Equation (1)].



(1)

No evidence was found for the formation of the diselane $(PhMe_2Si)_3CSeSeC(SiMe_2Ph)_3$, which is usually formed as the main product by oxidation of selenolates RSeLi or selenols RSeH; the corresponding ditellane is also the main product in the oxidation of $(PhMe_2Si)_3CTeLi$.[7] Here, the triselane $(PhMe_2Si)_3CSeSeSeC(SiMe_2Ph)_3$ (**1**) is the main

product, which can be explained by the bulkiness of the substituent, to stabilize selanes with increased chain lengths in the case of smaller chalcogens. The triselane **1** was separated from the mixture because of its lower solubility in diethyl ether. The remaining mixture was subjected to column chromatography and resulted finally in the isolation and identification of two further selanes, the diselane $(PhMe_2Si)_2HCSeSeCH(SiMe_2Ph)_2$ (**2**) and the heterocycle $[(PhMe_2Si)_2CSeSe]_2$ (**3**). The formation and existence of **2** demonstrates that three dimethyl(phenyl)silyl groups attached to the carbon atom are too bulky for a corresponding diselane, but two dimethyl(phenyl)silyl groups, in the bis[dimethyl(phenyl)silyl]methyl group which is slightly less bulky, form a stable diselane **2**. The formation of the novel heterocycle **3**, a tetrasilyl-substituted *s*-tetraselenane, cannot be explained with certainty. Probably due to similar reasons as observed with **2**, one silyl group was eliminated and maybe a radical $(PhMe_2Si)_2CSeSe$, for which we have no evidence, dimerized to give the stable six-membered $C_2Se_4$ heterocycle **3**. The fourth main component of this reaction

was identified as the mixed monoselane $(PhMe_2Si)_3CSeMe$ (**4**). The formation of **4** can be explained by the always incomplete lithiation of $(PhMe_2Si)_2CH$ with methyllithium. Upon addition of selenium, immediate formation of MeSeLi occurs which can combine with tris[dimethyl(phenyl)silyl]methyl groups to give **4**. The monoselane **4** is already detected by $^{77}Se$ NMR in the THF solution of $(PhMe_2Si)_3CSeLi$ in amounts of ca 3–5% as the only other selenium-containing product.

The triselane **1** displays two resonances in the $^{77}Se$ NMR spectrum at $\delta$ = 666 ppm for the central selenium atom, and 552 ppm for the two terminal selenium atoms. The coupling constant $^1J(^{77}Se\text{-}^{77}Se)$ = 20.7 Hz is in the typical range found for other dialkyltriselanes.[9] The diselane **2**, as well as the symmetric *s*-tetraselenane **3**, exhibit single resonances at $\delta$ = 391 ppm and $\delta$ = 456 ppm, respectively. The resonance of the monoselane **4** is found at relatively high field at $\delta$ = 135 ppm, displaying a quartet due to coupling with methyl hydrogen atoms.

The crystal structure of the triselane **1** is shown in Figure 1 and gives an impression of the rather extreme bulkiness of the tris[dimethyl(phenyl)silyl]methyl substituent which allows the stabilization of this triselane (Figure 1a). In general, triselanes show a high propensity to eliminate red selenium at higher temperatures or already in solution at lower temperatures to form the corresponding diselanes.[10,11] The characteristic features of the triselane chain consist of the typical V-shaped unit (Figure 1b) with an angle of 109.90(7)° and an Se–Se bond length of 2.340(1) Å, forming a torsion angle Se2(*i*)–Se1–Se2–C1 of –101.6(3)°, parameters which are comparable to the structures of other undisturbed dialkyl triselanes.[10,12]

The structure of the novel *s*-tetraselenane **3**, shown in Figure 2 also can be regarded a cyclic bis(diselane), adopting a twist-boat conformation. The analoguous sulfur heterocycle, an *s*-tetrathiane, is fairly well known and also crystal structures exist. Whereas the bis(pentamethylene) derivative displays a chair configuration of the heterocycle,[13] the tetramethyl derivative, "duplodithioacetone", adopts the twist-boat conformation.[14] The Se–Se [2.3120(6)/2.3085(6) Å] and C–Se bond lengths [1.993(4)–2.001(4) Å] of **3** are in the same range as found in the structures of

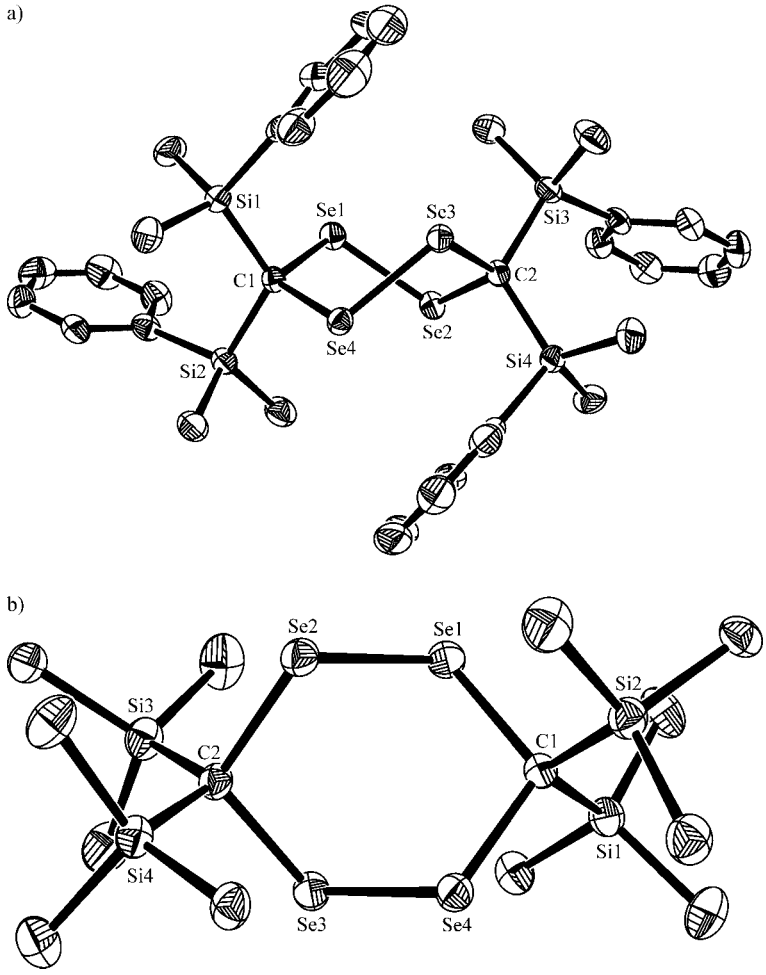

Figure 2. Different views (a) and (b) of the molecular structure of **3** with thermal ellipsoids of 30% probability. acyclic aliphatic and aromatic diselanes.[4,15] Figure 2a nicely shows the twisted six-membered heterocycle encumbered by two bis[dimethyl(phenyl)silyl]methylene moieties. In Figure 2b a view onto the heterocycle is given with all phenyl groups omitted for clarity.

The NMR spectra of **3** indicate a restricted rotation of the methyl groups, visible for the corresponding resonances in the $^{1}H$ and $^{13}C$ NMR spectra. At 25 °C two broadened resonances are observed for the methyl groups in the $^{1}H$ and $^{13}C$ NMR spectra, respectively. In the $^{1}H$ NMR spectrum coalescence is observed at 32 °C, whereas in the $^{13}C$ NMR spectrum at 47 °C both resonances coalesce. The resonance of the $CSi_2Se_2$ carbon atom remains unaffected. The variable-temperature $^{77}Se$ NMR spectrum of **3** shows only the temperature dependency of the resonance, i.e. spanning from $\delta$ = 462 ppm at 60 °C over $\delta$ = 456 ppm at 25 °C to $\delta$ = 443 ppm at –60 °C (all in $CDCl_3$). No additional resonances were detected within this temperature range, which then could indicate a change of the conformation of the heterocycle.

The experimentally observed twist conformation of **3** was subject of calculations for the sulfur analogue *s*-tetrathiane, where a molecular mechanics (MM) and an NMR study already predicted the twist conformer to be favored over the chair conformer by 0.7 kcal mol$^{-1}$.[16] In order to confirm the early MM study we now decided to compute the full series of O, S, Se, Te and Po heterocycles using hybrid density functional theory (DFT) at the B3LYP level. The model compounds, which were included in the computation were the chair and twist conformers of the heterocycles $[(H_3Si)_2CXX]_2$ (X = O, S, Se, Te, Po) (Table S1, Figure S1 in Supporting Information). The structures of all ten species were fully optimized and the vibrational frequencies calculated at the B3LYP/SDD level of theory. All ten entities represent stable minima on their potential energy surface. Whereas according to our calculations for the oxygen and sulfur compounds the chair conformers are favored by 5.8 and 0.4 kcal mol$^{-1}$ (nicely in agreement with our X-ray structure for the selenium heterocycle), the twist conformers of the Se, Te and Po heterocycles represent the lower energy species, although the energy differences are again relatively small: $\Delta E$(chair–twist) = +1.9 (Se), +3.1 (Te), +3.3 (Po) kcal mol$^{-1}$. It seems that the relative stability of the twist over the chair conformer increases with the heteroatoms (O → Po) descending within group 16 (Figure 3). For oxygen the chair is favored, for sulfur the chair and twist conformer are essentially identical in their energy, whereas for the heavier congeners Se, Te and Po the twist structure is favored over the chair conformer.

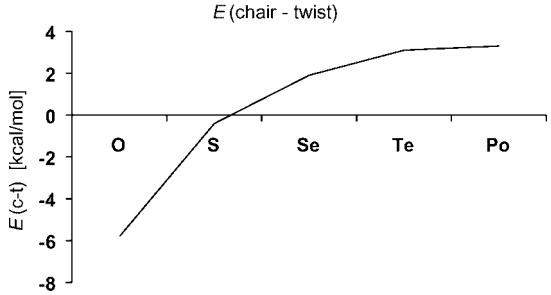

Figure 3. Relative stabilities of the chair and twist conformers of $[(H_3Si)_2CXX]_2$ (X = O, S, Se, Te, Po).

The existence of a claimed tetratellurium analogue, *s*-tetratellurane $(CH_2Te_2)_2$,[17] remains highly questionable in our opinion, due to the poor spectroscopic data. Substituted *s*-tetratellurane derivatives may possibly be prepared in the future, if one considers the relatively high stability of the corresponding sulfur and selenium heterocycles, and as well taking the calculations into account.

## Experimental Section

**General:** All manipulations of air- and moisture-sensitive materials were performed under dry argon using flame-dried glass vessels and Schlenk techniques. The compounds $PhMe_2SiCl$,[18] and $(PhMe_2Si)_3CH$[19] were prepared according the literature, elemental selenium and methyllithium (1.6 M in $Et_2O$) (Aldrich) was used as received. Solvents were dried by standard methods and freshly distilled prior to use. NMR spectra were recorded with a JEOL Eclipse 400 instrument in $CDCl_3$ at 25 °C, and chemical shifts are with respect to $Me_4Si$ ($^{1}H$: 400.2 MHz; $^{13}C$: 100.6 MHz; $^{29}Si$: 79.5 MHz) and $Me_2Se$ ($^{77}Se$: 76.3 MHz). Raman spectra were recorded with a Perkin–Elmer 2000 NIR FT spectrometer fitted with an Nd-YAG laser (1064 nm, 100 mW, 25 °C), and only 100% peak and Se–Se stretching frequency listed. Mass spectrometric data were obtained with a JEOL MStation JMS spectrometer. Elemental analyses: Analytical service LMU. Melting points were determined in capillaries using a Büchi B540 instrument.

**Lithiation and Selenation of $(PhMe_2Si)_3CH$:** Into a solution of $(PhMe_2Si)_3CH$ (6.0 g, 14.3 mmol, sublimed at 90 °C/10$^{-3}$ mbar) in 75 mL of THF was added methyllithium (10 mL, 16 mmol) in diethyl ether (1.6 M) at 25 °C within 1 h. This mixture was stirred at ambient temperature for an additional 1 h and then heated to 60 °C for 3 h. After cooling to ambient temperature, selenium (1.2 g, 15.2 mmol) was added in one portion and the mixture stirred for 1 h. The selenium reacted immediately and darkening of the solution occurred. This mixture was stirred at ambient temperature, now upon contact with air, for 3 d. All volatile materials were removed in vacuo, and the resulting dark orange residue was treated with 50 mL $Et_2O$, and 30 mL water was slowly added at 25 °C. Additionally, 20 mL of 10% HCl was added carefully at 0 °C and the mixture stirred for 2 h. The extracted dark red diethyl ether phases were separated and dried. The solvent was removed in vacuo, and the brown-red solid residue was treated again with small amounts of cold diethyl ether. The insoluble solid was washed repeatedly. This material was only poorly soluble in $Et_2O$ and was shown to be pure triselane $(PhMe_2Si)_3CSeSeSeC(SiMe_2Ph)_3$ (**1**) (600 mg, ca. 8% yield). The remaining diethyl ether soluble fraction, a highly viscous red-brown oil, still containing considerable amounts of the triselane **1**, was subjected to column chromatography. The eluent was an *n*-hexane/chloroform mixture (10:1). The first fraction was the monoselane **4**, the second fraction contained a mixture of the diselane **2** and the *s*-tetraselenane **3**. The last fraction, containing a mixture of further other selenium-containing species that could not be separated, was discarded. The mixture consisting of **2** and **3**, could be separated by their different solubilities in diethyl ether. By repeated extraction of the mixture, the diselane **2** could be separated because of its slightly higher solubility in diethyl ether than that of the *s*-tetraselenane **3**.

# Metal Directed Assemblies of a Dipeptide: Formation of β-Pleated Sheets

Nilotpal Barooah,[a] Rupam J. Sarma,[a] and Jubaraj B. Baruah*[a]

**Keywords:** Hydrogen bonding / Self-assembly / Dipeptide / β-Sheets / Coordination polymer

The crystal structure of *N*-phthaloylglycylglycine and its complexes with copper(II) and zinc(II) are studied. The *N*-phthaloylglycylglycinato copper(II) complex has a polymeric structure formed by bridging carboxylates. The corresponding *N*-phthaloylglycylglycinato zinc(II) complex is monomeric. Both the metal complexes have self-assembled hydrogen-bonded structures in which dipeptide ligand adopt β-pleated conformations.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Directed assembly of molecules through noncovalent interactions and metal coordination is a fundamental process in nature.[1] Self-organization and molecular recognition of biomolecules[1e] using peptides are rationalized by taking into account a host of weak interactions[2] that include hydrogen bonding, aromatic π interactions, and hydrophobic interactions. The ability of peptides to adopt various secondary structures has been a subject of extensive study,[3] and in this regard the effects of metal ions in stabilizing particular conformations of peptides have immense importance.[4] The β-sheet assembly of peptide chains is particularly important in case of globular proteins and various template-directed strategies to assemble natural or non-natural peptides and synthetic peptide analogs into similar assemblies have been investigated.[5] Coordination of the peptide to a particular metal ion predominantly governs the local structure of the active site in metalloenzymes.[6] Even though attempts have been made to rationalize the interaction of metal ions with peptides,[7] the structural elucidation of such assemblies with regard to tuning the secondary interactions in the peptide[5b,8] is scarce. Given this background, we report the solid-state structures of the *N*-protected dipeptide derived from glycylglycine, and subsequently rationalize the effect of metal-ion templating on the self-assembly of this dipeptide.

Condensation of glycylglycine with phthalic anhydride under hydrothermal conditions and subsequent recrystallization from aqueous ethanol afforded the *N*-protected dipeptide, *N*-phthaloylglycylglycine (**L**) as colorless needles. The introduction of the phthaloyl group was expected to stabilize the two-dimensional assembly of the molecules in the solid state through intermolecular aromatic interactions.[9] These π interactions can be complementary in nature to the intermolecular N–H···O interactions observed in case of amides, which have a dominating effect on the self-assembly process.[10] Crystal structure shows that the self-assembly of the dipeptide **L** in the solid state is governed by intermolecular hydrogen-bonding interactions; the molecule adopts a puckered conformation as shown in Figure 1. The amide N–H is involved in the formation of hydrogen bonds with the carbonyl oxygen atom of the phthalimide unit ($d_{N2\cdots O4}$ 3.04 Å; ∠ D–H···A 156.0°), which extends along crystallographic *a* axis. Moreover, the amide carbonyl is strongly hydrogen-bonded to the oxygen atom of the carboxylic acid group ($d_{O1\cdots O3}$ 2.59 Å; ∠ D–H···A 165.1°) as shown in Figure 1. Thus, intermolecular hydrogen-bonding interactions in **L** leads to the formation of two-dimensional sheets, wherein the individual molecules adopt folded conformations; however, the structure does not correspond to β-pleated sheet structure. The torsion angle for rotation about the C–N bond ($\varphi$) is 70.9° while the corresponding angle for the C–C bond rotation ($\psi$) is 19.9°. The important hydrogen bond angles and bond lengths of **L** in the hydrogen-bonded assembly are listed in Table 1. It is important to note that the interplanar distance between the phthalimide groups of **L** is ca. 3.34 Å, which could indicate the presence of weak aromatic π interactions.

The templating effect of $Cu^{II}$ and $Zn^{II}$ ions, two of the biologically important metal ions, on the self-assembly of the dipeptide **L** has been studied by preparing the corresponding $Cu_2L_4(H_2O)_4{\cdot}2H_2O$ and $ZnL_2(H_2O)_4$ complexes. Reaction of **L** with copper acetate mono hydrate results in the formation of the complex **1** which possess the molecular formula $CuL_2(H_2O)_2{\cdot}2H_2O$. The crystal structure of **1** shows that each of the copper center is coordinated to **L** through the oxygen atoms of the carboxylate group; the coordinated water molecules are *trans* to each other in a nearly square-planar geometry with Cu1···O1 and Cu1···O6 bond lengths of 1.9471(10) and 1.9445(13) Å, respectively. The carbonyl oxygen of another adjacent glycinato unit leads to a weak Cu1···O2 ($d_{Cu1\cdots O2}$ 2.650 Å) coordination,

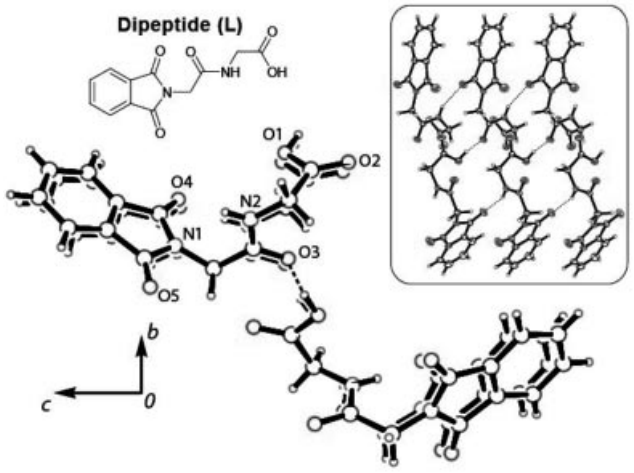

Figure 1. 2D Molecular sheets arising from intermolecular hydrogen bonding in **L**; (Inset) The hydrogen-bonded molecular sheets viewed parallel to *bc* plane.

Table 1. Hydrogen-bonding geometry (distances and angles) in *N*-phthaloylglycylglycine (**L**).

| D–H···A | $d_{D–H}$ [Å] | $d_{H···A}$ [Å] | $d_{D···A}$ [Å] | ∠ D–H···A[°] |
|---|---|---|---|---|
| N2–H···O4$^{\#[a]}$ | 0.85 | 2.24 | 3.044 | 157.03 |
| O1–H···O3$^{\#\#}$ | 0.89 | 1.71 | 2.593 | 164.82 |

[a] Symmetry transformations used to generate atoms: $^{\#}$ $x-1$, $y$, $z$, $^{\#\#}$ $-x+3/2$, $y+1/2$, $-z+1/2$.

which gives the $Cu^{II}$ center axially distorted octahedral geometry as shown in Figure 2 (a). The unusual bridging mode of the carboxylate group in this coordination motif leads to a one-dimensional coordination network of $Cu^{II}$ ions along crystallographic *b* axis with $Cu^{II}\cdots Cu^{II}$ distance of 4.71 Å. The two O1···Cu1···O6 and O1···Cu1···O2 bond angles are 93.40° and 86.85°, respectively. The distorted octahedral geometry (Figure 2, b) of the $Cu^{II}$ center in complex **1** is also obvious from its ESR spectra. At room temperature, the ESR spectrum of the solid complex **1** shows a strong signal with center field at 3177.6 G ($g$ = 2.124), which is an indication for the axially distorted octahedral geometry around the $Cu^{II}$ center. It may be pointed out here that metal-directed self-assembled systems also give rise to porous metal-organic frameworks as well as coordination polymers.[11]

In the case of complex **1**, the water molecules included inside the lattice probably underlines the importance of water in stabilizing the β-sheets,[2] formed by the dipeptide units connected to the $Cu^{II}$ center. We have found that the ligand organization in this complex is governed by weak hydrogen-bonding interactions between the amide groups of the dipeptide and the interstitial water molecules. In this complex, intermolecular hydrogen bonding between the amide N–H groups and the amide carbonyl groups ($d_{N1···O3}$ 2.94 Å; ∠ D–H···A 157.8°) is complemented by weak C–H···O interaction involving C4–H as donor and O3 as acceptor ($d_{C4···O3}$ 3.05 Å). This weak C–H···O interaction is well within the range reported elsewhere.[2b] These two weak interactions assemble the *N*-phthaloylglycylglycinato ligands leading to a parallel β-pleated sheet conformation as shown in the Figure 2 (a). The torsion angle for rotation about the C–N bond ($\varphi$) is –135.3°, while the corresponding angle for the C–C bond rotation ($\psi$) is 169.2° which is within the limit of β-sheet structure.[3a–3b] This corresponds to a *trans* conformation about the C–C bond.[3b] The hydrogen-bond donor···acceptor distances and angles of complex **1** are listed in Table 2.

Table 2. Hydrogen bonding geometry (distances and angles) in complex **1**[a].

| D–H···A | $d_{D–H}$ [Å] | $d_{H···A}$ [Å] | $d_{D···A}$ [Å] | ∠ D–H···A[°] |
|---|---|---|---|---|
| N1–H···O3$^{\#[b]}$ | 0.79 | 2.18 | 2.944 | 162.3 |
| O6–H···O7$^{\#\#}$ | 0.81 | 1.89 | 2.668 | 158.5 |
| O6–H···O2 | 0.81 | 1.88 | 2.650 | 157.7 |
| O7–H···O2+$^{\#\#\#}$ | 0.74 | 2.11 | 2.851 | 170.5 |

[a] O6 is from coordinated water; O7 is from interstitial water. [b] Symmetry transformations used to generate atoms: $^{\#}$ $x$, $y+1$, $z$; $^{\#\#}$ $x-1$, $y+1$, $z+1$, $^{\#\#\#}$ $-x+1$, $y$, $-z+3/2$.

In a similar way, the $Zn^{II}$ complex $ZnL_2(H_2O)_4$ (**2**) was synthesized and structurally characterized. Each $Zn^{II}$ ion is coordinated to two monodentate carboxylic groups of **L** and four water molecules; which results in an octahedral

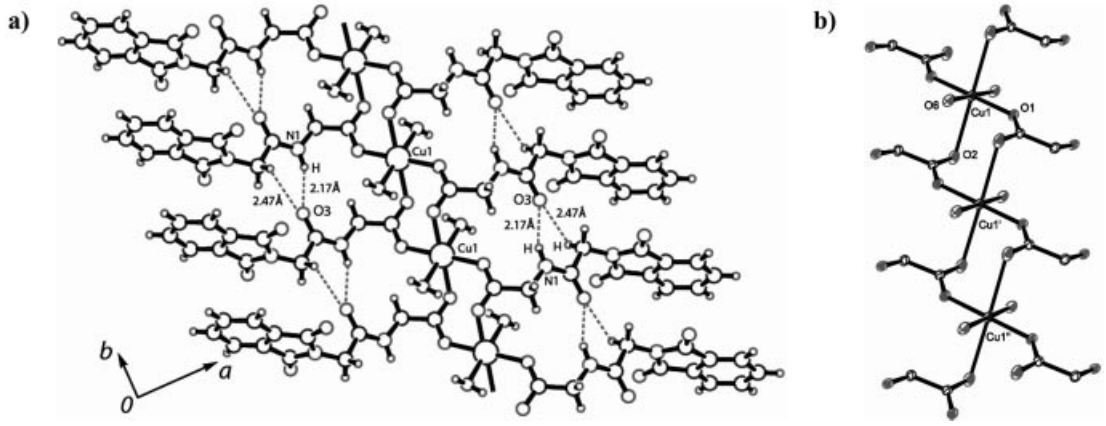

Figure 2. (a) Structure of the hydrogen-bonded sheets in complex **1** (interstitial water molecules are excluded for clarity); (b) Coordination environment of $Cu^{II}$ centers in the complex (thermal ellipsoids drawn to 30% probability).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coordination environment around each $Zn^{II}$ center as shown in Figure 3. The Zn1···O1, Zn1···O6 and Zn1···O7 bond lengths are 2.0921(15), 2.0586(16), 2.1429(16) Å, respectively. The crystal structure of **2** also reveals that the *N*-phthaloyl-protected dipeptide residues assemble through intermolecular N1–H···O3 hydrogen bonds ($d_{N1\cdots O3}$ 3.04 Å; ∠ D–H···A 157.8°) along with weak C4–H···O3 interactions ($d_{C4\cdots O3}$ 3.11 Å). These two weak interactions lead to the formation of parallel β-pleated sheets as shown in Figure 3.

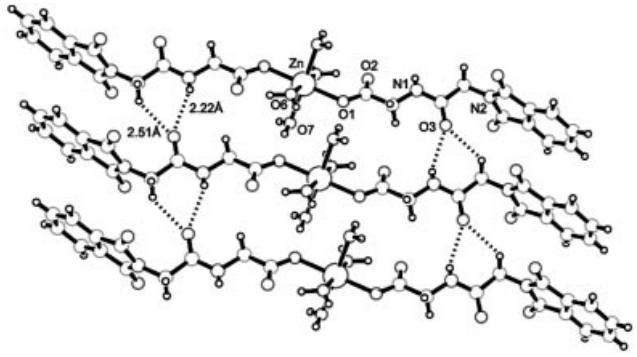

Figure 3. Ligand organization around the $Zn^{II}$ centers of the complex **2**.

It is noteworthy that in both the structures of complexes **1** and **2**, the presence of coordinated water as well as the interstitial water molecules (in case of **1**) is crucial in stabilizing the self-assembled β-pleated sheets. The hydrogen bond lengths and bond angles that are involved in the formation in complex **2** are listed in Table 3. The torsion angle for rotation about the C–N bond ($\varphi$) in this case is –153.6° and for the C–C bond rotation ($\psi$) is 165.7°, which are similar to those in the complex **1** and is indicative of β-pleated sheets.[2b]

Table 3. Hydrogen bonding geometry (distances and angles) in complex **2**.

| D–H···A | $d_{D-H}$ [Å] | $d_{H\cdots A}$ [Å] | $d_{D\cdots A}$ [Å] | ∠ D–H···A[°] |
|---|---|---|---|---|
| N1–H···O3 [$x$, $y+1$, $z$] | 0.86 | 2.23 | 3.044 | 157.8 |
| O6–H···O2 | 1.03 | 1.65 | 2.652 | 159.7 |
| O7–H···O1 [$x$, $y+1$, $z$] | 0.80 | 1.88 | 2.672 | 170.4 |

The presence of two interstitial water molecules per formula unit in complex **1** has a structural role to play, as they hold the hydrogen-bonded dipeptide β-sheets (Figure 4, a) through intermolecular O7–H···O2 ($d_{O7\cdots O2}$ 2.85 Å; ∠ D–H···A 170.5°) and O7–H···O5 ($d_{O7\cdots O5}$ 2.99 Å; ∠ D–H···A 165.7°) interactions. Furthermore, each interstitial water molecule is bound to a coordinated water molecule through intermolecular O6–H···O7 ($d_{O6\cdots O7}$ 2.66 Å; ∠ D–H···A 158.5°) hydrogen bonds. The presence two interstitial water molecules in the lattice is reflected in the thermogram of the compound, which shows 8.9% weight loss in the temperature range 75–120 °C corresponding to loss of three water molecules (theoretical weight loss 8.2%) corresponding to interstitial and coordinated water molecules. In the case of **2**, the coordinated water molecules are involved in intramolecular O6–H···O7 ($d_{O6\cdots O7}$ 2.91 Å; ∠ D–H···A 149.9°) and intermolecular O7–H···O4 ($d_{O7\cdots O4}$ 3.02 Å; ∠ D–H···A 150.2°) hydrogen-bonding interactions. These interactions stabilize the formation of individual β-pleated sheets in **1** and **2** as shown in Figure 4, parts a and b, respectively. Thermogravimetric analysis of complex **2** (please refer to supporting information, for supporting information see also the footnote on the first page of this article) shows that the four-coordinated water molecules are lost between 70–135 °C, which corresponding to about 9.3% weight loss (theoretically calculated weight loss for such process corresponds to 10.9%).

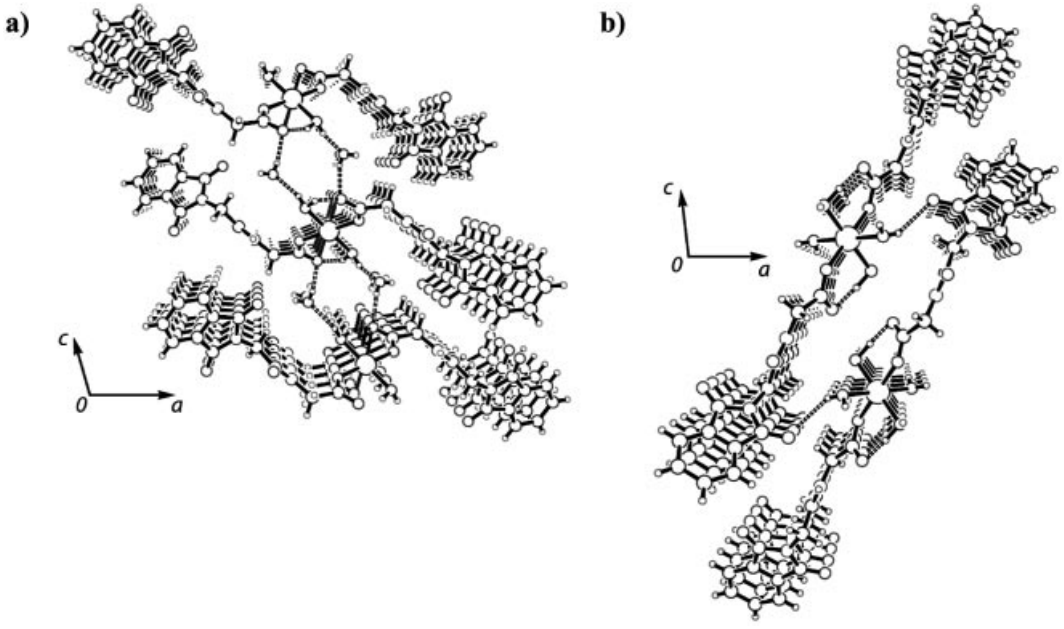

Figure 4. (a) Packing pattern of **1** (viewed along *b* axis); (b) packing pattern of **2** (viewed along *b* axis).

Thus, we have structurally characterized the solid-state assemblies of *N*-phthaloylglycylglycine that are formed through intermolecular hydrogen bonding, and shown that the self-assembly of this molecule can be tuned to adopt a β-sheet conformation by introduction of metal ions, in this case $Cu^{II}$ and $Zn^{II}$. It is found that the parallel β-pleated sheet assembly of the dipeptide leads to a one-dimensional $Cu^{II}$ carboxylate coordination polymer through carboxylate bridging in a different manner over conventional paddle-wheel-type of structures.[12] Currently, we are studying the different motifs that are crucial in the metal template assembly of similar dipeptides and higher analogs.

## Experimental Section

The X-ray diffraction data were collected at room temperature with a Bruker 3-circle diffractometer (Bruker Nonius SMART APEX 2) equipped with CCD area detectors, and using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) from 60W microfocus Siemens Microsource with glass polycapillary optics. X-ray diffraction data for all the crystals were collected with Bruker SMART software. This software was also used for indexing and determining the unit cell parameters. The structures were solved by direct methods and refined by full-matrix least-squares against $F^2$ for all data using SHELXTL software.[14] All non-H atoms were refined by full-matrix least-squares in the anisotropic approximation and the hydrogen atoms attached to these atoms were treated as "riding" in calculated positions in the case of complex **2**; with **L** and complex **1** the hydrogen atoms were located on the difference Fourier maps. In all cases, the hydrogen atoms attached to polar atoms such as O and N were located on the difference Fourier maps and refined in the final structure in isotropic approximation.

CCDC-297186 (for **1**), -297187 (for **2**) and -299730 (for **L**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Glycylglycine, phthalic anhydride, copper(II) acetate dihydrate and zinc(II) acetate dihydrate were procured from Fluka and used as received. The NMR spectra were recorded with a Varian 400 MHz spectrophotometer at room temperature while the FT-IR spectra were recorded with Nicolet Impact–410 spectrometer using OMNIC software.

**Synthesis of *N*-Phthaloylglycylglycine (L):** A finely ground mixture of phthalic anhydride (0.444 g, 3 mmol) and glycylglycine (0.396 g, 3 mmol) was heated to approximately 175 °C in a 50-mL round-bottomed flask. The molten mixture was cooled to room temperature, and the resulting solid was purified by recrystallization from ethanol/water (1:9, v/v) mixture to obtain the product. Yield: 0.30 g (39%). IR (KBr): $\tilde{\nu}$ = 3363 (s), 2935 (br. s), 2873 (br. s), 2597 (s), 1737 (s), 1701 (s), 1621 (s), 1543 (s), 1419 (s), 1393 (s), 1332 (w), 1230 (s), 1107 (w), 953 (s), 728 (w) $cm^{-1}$. $^1H$ NMR ([$D_6$]DMSO): $\delta$ = 12.8 (br. s, 1 $H_{-COOH}$), 8.5 (s, 1 $H_{-NH}$), 7.8 (m, 4 H), 4.2 (s, 2 H), 3.7 (d, $J$ = 5.6 Hz, 2 H) ppm. $^{13}C$ NMR ([$D_6$]DMSO): $\delta$ = 176.1,172.7, 171.7, 139.9, 137.1, 128.5, 46.2, 45.7 ppm.

**Synthesis of Complex 1:** A solution of copper(II) acetate dihydrate (0.100 g, 0.5 mmol) in ethanol (20 mL) was added dropwise to a homogeneous stirred solution of **L** (0.263 g, 1 mmol) in ethanol/water (20 mL, 1:9, v/v) at room temperature. Light blue precipitate had started appearing within 15 minutes of addition of the ligand. The solution was stirred for another two hours, and the resulting precipitate was filtered and washed with ethanol. The precipitate was redissolved in 20 mL of distilled water, concentrated to 10 mL, and left undisturbed. After three days light blue needle-like crystals of the product were collected by filtration and dried in air. Yield for the crystalline product: 0.067 g (20% based on Cu). IR (KBr): $\tilde{\nu}$ = 3590 (s), 3309 (s) 3094 (br. s), 1772 (w), 1726 (s), 1658 (s), 1562 (s), 1409 (s), 1322 (w), 1265 (w), 1122 (w), 958 (s), 758 (s), 723 (s) $cm^{-1}$.

**Synthesis of Complex 2:** A solution of zinc(II) acetate dihydrate (0.110 g, 0.5 mmol) in 20 mL ethanol was added dropwise to a homogeneous stirred solution of **L** (0.263 g, 1 mmol) in ethanol/water (20 mL, 1:1, v/v) at room temperature. Off-white precipitate had started appearing within 15 minutes of addition. The solution was stirred for another two hours, and the resulting precipitate was filtered and washed with ethanol. The precipitate was redissolved in 20 mL of distilled water, concentrated to 10 mL and left undisturbed. After five days light colorless plate-like crystals of the product were collected by filtration and dried in air. Yield for the crystalline product: 0.078 g (23% based on Zn). IR (KBr): $\tilde{\nu}$ = 3534 (s), 3319 (s) 3075 (br. s), 1770 (w), 1722 (s), 1650 (s), 1551 (s), 1411 (s), 1311 (w), 1246 (w), 1116 (w), 955 (s), 755 (s), 715 (s) $cm^{-1}$. $^1H$ NMR ([$D_6$]DMSO): $\delta$ = 8.3 (s, 1 $H_{-NH}$), 7.8 (m, 4 H), 4.2 (s, 2 H), 3.6 (d, $J$ = 4.4 Hz, 2 H) ppm.

**Supporting Information** (see also the footnote on the first page of this article) is available for selected crystallographic data, FT-IR spectra of the dipeptide and complex **1**, the ESR spectrum of **1** and $^1H$ HOMOCOSY spectra of complex **2**.

# Synthesis of Ionic Liquid Functionalized SBA-15 Mesoporous Materials as Heterogeneous Catalyst toward Knoevenagel Condensation under Solvent-Free Conditions

**Yong Liu,[a] Jiajian Peng,[a] Shangru Zhai,[b] Jiayun Li,[a] Jianjiang Mao,[a] Meijiang Li,[a] Huayu Qiu,*[a] and Guoqiao Lai*[a]**

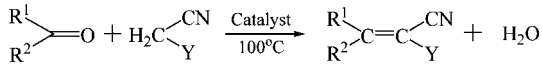
**Keywords:** Mesoporous materials / Heterogeneous catalysis / Ionic liquids

1-Methyl-3-propylimidazolium chloride (MPImCl) and 1-propylpyridinium chloride (PPyCl) ionic liquid functionalized SBA-15 mesoporous materials were synthesized and used as heterogeneous catalysts in Knoevenagel reactions with excellent yields and reusability.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The Knoevenagel condensation, one of the most important preparation methods of substituted alkenes, is widely employed to synthesize intermediates of fine chemicals (Scheme 1). Compared to traditional homogeneous catalysts including organic bases (primary, secondary, tertiary amines), $ZnCl_2$, LiCl, and cetyltrimethylammonium bromide (CTAB),[1] solid-based heterogeneous catalysts are more desirable for their advantages in separation and reusability. In recent years, resins, zeolites, hydrotalcites etc. have been applied to this reaction as heterogeneous catalysts,[2] among which organo-functionalized mesoporous silicas are specially studied due to their unique properties such as high surface area, uniform pore structure and controllable surface properties.[3] Recently, synthesis and catalysis activities of different structured mesoporous materials functionalized by amino/diamino groups have been reported.[4]



Scheme 1.

Ionic liquids, known as novel environmental benign media, have attracted great interest in the last two decades[5] since they can serve not only as favorable solvents for catalysis but also as green catalysts themselves in many reactions such as cycloaddition, Biginelli reaction, nitration, Beckmann rearrangement[6] and Knoevenagel condensation as well.[7] However, in some cases ionic liquids are miscible with some products or reactants, leaving separation and reuse of catalyst still a problem. Thus, immobilization of ionic liquids on solid-based materials is of particular interest. Recently, several groups reported the successful synthesis of silica-based ionic liquids,[8] while reports on ordered ionic liquids functionalized mesoporous materials are still quite rare.[9] Herein, we report the synthesis of MPImCl and ionic liquid functionalized SBA-15 mesoporous material and its catalytic activity toward Knoevenagel condensation under solvent-free conditions. The resulting hetergeneous catalyst could be easily recovered with high catalytic activity remaining after 10 cycles.

## Results and Discussion

1-Methyl-3-[(triethoxysilyl)propyl]imidazolium chloride (MTESPImCl) and 1-[(triethoxysilyl)propyl]pyridinium chloride (TESPPyCl) were prepared by the reaction of 1-methylimidazole or pyridine with (3-chloropropyl)triethoxysilane, different from the literature[8a] not only because the reactants were cheaper but also the corresponding pyridine species could be obatined. The XRD patterns of the MPImCl-SBA materials obtained with different MTESPImCl amounts are given in Figure 1. When the MTESPImCl content in the initial mixture was 5%, one intense diffraction peak together with two weak ones could been seen (Figure 1, b), corresponding to the (100), (110), and (200) planes of highly ordered SBA-15 structured mesoporous materials, respectively. As the MTESPImCl content increased to 10%, the (110) and (200) peaks disappeared (Fig-

ure 1, c), indicating the decrease of pore regularity. With a further increase of the MTESPImCl content to 15%, no characteristic peaks of SBA-15 mesoporous materials could be seen. It is noteworthy that when the pre-hydrolysis time of tetraethyl orthosilicate (TEOS) was prolonged to 4 h, the order of pore structure (MTESPImCl content 10%) was greatly improved (Figure 1, a). Similar phenomena have been reported in the synthesis of sulfonic acid and aminopropyl functionalized SBA-15 mesoporous materials under acid conditions[4c,10] and could be explained by the following reasons: On one hand, MTESPImCl can perturb the self-assembly of surfactant micelles and silica precursors; on the other hand, the cationic part of MTESPImCl probably interacts with ethoxy groups of TEOS, thus inhibiting its hydrolysis and condensation. Therefore, prolonging the pre-hydrolysis time of TEOS can prevent MTESPImCl from disturbing the mesophase. XRD results of PPy-SBA materials also proved that orderd structures could be obtained with TEOS pre-hydrolyzed for 4 h (Figure 2).

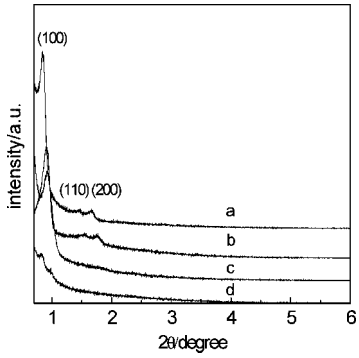

Figure 1. XRD patterns of MPImCl-SBA materials with different MTESPImCl contents and different TEOS pre-hydrolyze times.

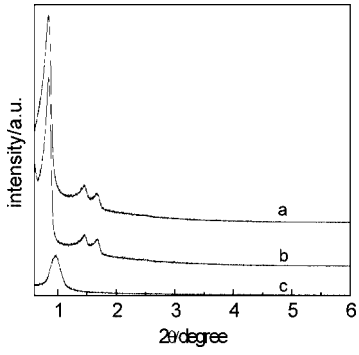

Figure 2. XRD patterns of PPyCl-SBA materials with different TESPPyCl contents with TEOS prehydrolyzed for 4 h; a: 5%, b: 10%, c: 15%.

$N_2$ adsorption-desorption was carried out to supply further information about the physical properties of the ionic liquid functionalized SBA-15 materials. As shown in Table 1, surface areas, pore volumes and pore diameters of the products all decreased as the ionic liquid content increased from 0 to 15%, which could be attributed to the increasing distribution of ionic liquid moieties in the interior mesopore surfaces. PPy-SBA materials were found to display higher surface areas and larger pore diameters compared with MPImCl counterparts, and longer pre-hydrolysis time was found helpful to improve the structures of products, which was in agreement with XRD results. Elemental analysis was used to obtain accurate amounts of the ionic liquid attached to the mesopores. As summarized in Table 1, loading amounts of PPy-SBA and MPImCl-SBA were comparable and increased with the increase of the ionic liquid contents in the initial mixture. The effect of pre-hydrolysis time on the loading amounts was negligible. Solid-state $^{29}Si$ NMR spectroscopy and thermogravimetric analysis (TGA) were also used to characterize the ionic liquid functionalized mesoporous materials and the results well agree with that of the elemental analysis.

Table 1. $N_2$ adsorption-desorption and elemental analysis results of ionic liquid functionalized SBA-15 materials.

[a] TEOS pre-hydrolysis time 40 min. [b] TEOS pre-hydrolysis time 4 h.

In view of the increasing emphasis on the adoption of clean manufacturing processes and environmentally benign technologies, clean, solvent-free and highly efficient catalytic technologies for the chemical production are highly desirable, so we carried out the Koevenagel condensation of various aldehydes with malononitrile/ethyl cyanoacetate at 100 °C under solvent-free conditions. 10% MPImCl-SBA and 10% PPy-SBA were used as catalysts, respectively, and the optimal amount of catalyst was determined to be 0.8 mol-% based on the reaction of benzaldehyde with malononitrile (Table 2, Entries 1–3). As illustrated in Table 2 (Entries 4, 6, 13, 15), the catalytic activities of PPy-SBA were slightly lower than those of MPImCl-SBA; thus, MPImCl-SBA was slected as catalyst for the other reactions. As shown in Entries 7–10, reactions of malononitrile with all tested aldehydes were complete in 3.5 h with excellent yields (not lower than 87%), which was not lower (if not higher) compared with those in traditional homogeneous systems.[1,2] The influence of substituents in the aromatic ring was negligible, indicating the high catalysis activity of the MPImCl-SBA materials. In the case of ethyl cyanoacetate, however, the yields decreased even if the reaction time was prolonged to 6 h (Entries 9–15). Besides, aldehydes with electron-donating groups (Entries 11, 14, 15) showed lower yields compared with the others. The reusability of the MPImCl-SBA materials was examined by the reaction of benzaldehyde with malononitrile. As shown in Entry 20, a yield as high as 86.1% was obtained in the 10th cycle.

[a] MPImCl-SBA as catalyst. [b] PpyCl-SBA as catalyst. [c] MPImCl-SBA in the 10th cycle.

In summary, ionic liquid functionalized SBA-15 mesoporous materials were synthesized and gave high yields and good reusability in Koevenagel condensations. These materials might be used not only as heterogeneous catalysts in reactions such as cycloaddition and Biginelli reactions but also as support for transition metals (work in this direction is in progress and will be reported soon).

## Experimental Section

In a typical procedure to synthesize MPImCl-SBA materials, 4.378 g of P123 ($EO_{20}PO_{70}EO_{20}$) was dissolved in 115 g of $H_2O$ to which 25 g of HCl was added. After 10.17 mL (0.045 mol) of TEOS was added and pre-hydrolyzed for 40 min, 1.535 g (0.005) of MTESPImCl was added. The mixture was stirred at 40 °C for 24 h and then transferred into a Teflon-lined stainless steel autoclave and kept at 100 °C for 24 h. The precipitate was filtered, subsequently washed with distilled water and EtOH, and dried at 60 °C in air. The template was removed by refluxing the as-synthesized material in EtOH for 24 h. The Knoevenagel condensation was carried out at 100 °C under solvent-free conditions. In a typical procedure, 1.82 g (0.025 mol) of malononitrile, 2.41 g (0.023 mol) of benzaldehyde and 0.22 g (0.2 mmol MPImCl) of 10% MPImCl-SBA were mixed and allowed to react for an appropriate time. The products were purified by column chromatography and the catalyst was filtered, washed with $CH_2Cl_2$, and collected for reusability test.

X-ray powder diffraction (XRD) data were acquired with a Rigaku D/max 2500V/PC diffractometer with Cu-$K_\alpha$ radiation. $N_2$ adsorption and desorption isotherms were measured with a Quantacrome Autosorb-1 system at 77 K. Surface areas were calculated according to the BET method with relative pressures in the range 0.2–0.3, and pore volumes were taken at the $P/P_0$ = 0.9923 single point. Pore diameters were determined from absorption branches according to the Barrett–Joyner–Halenda (BJH) method. Loading amounts of ionic liquids were caculated from the nitrogen contents performed with an Elementar Vario EC III CHNOS element analyzer.

# Bonding Trends in Lewis Acid Adducts of $S_4N_4$ – X-ray Structure of $TeCl_4 \cdot S_4N_4$

**Jari Konu,[a] Tom Bajorek,[a] Risto S. Laitinen,*[a] Tristram Chivers,[b] Reijo J. Suontamo,[c] and Markku Ahlgrén[d]**

**Keywords:** Lewis acid adducts of $S_4N_4$ / Tellurium tetrachloride / DFT calculations / Vibrational spectroscopy / X-ray crystallography

Tetrasulfur tetranitride and tellurium tetrachloride react in dichloromethane to form a 1:1 adduct $TeCl_4 \cdot S_4N_4$ (**1**). The crystal structure of **1** shows that $TeCl_4$ is bonded to the $S_4N_4$ ring through a Te–N linkage. As a consequence, the transannular S···S bonds in $S_4N_4$ are broken and the molecule assumes an open, monocyclic conformation. The Te–N bond of 2.16(1) Å is slightly longer than the single bond. The S–N bonds span a range of 1.55(1)–1.67(1) Å. The adduct **1** was also characterized by mass spectrometry and Raman spectroscopy. The bonding and spectroscopic properties of **1** are compared by DFT calculations at the B3PW91/(RLC ECP) level of theory with those of $BF_3 \cdot S_4N_4$ (**2**), $SO_3 \cdot S_4N_4$ (**3**), $AsF_5 \cdot S_4N_4$ (**4**), $SbCl_5 \cdot S_4N_4$ (**5**) for which experimental structural information is available. The structural and bonding trends in $TeF_4 \cdot S_4N_4$ (**6**), $TeBr_4 \cdot S_4N_4$ (**7**), and $SeX_4 \cdot S_4N_4$ [X = F (**8**), Cl (**9**), Br (**10**)] are also discussed.

## Introduction

Tetrasulfur tetranitride is known to react in inert solvents with a wide variety of Lewis acids and a number of 1:1 adducts have been structurally characterized. The crystal structures are known for $BF_3 \cdot S_4N_4$,[1] $SO_3 \cdot S_4N_4$,[2] $AsF_5 \cdot S_4N_4$,[3] $SbCl_5 \cdot S_4N_4$,[4–6] $FeCl_3 \cdot S_4N_4$,[7,8] $TaCl_5 \cdot S_4N_4$,[9] and $TiCl_4 \cdot S_4N_4$.[10] The complexes $SnCl_4 \cdot 2S_4N_4$[11] and $TiCl_4 \cdot 2S_4N_4$[10] exemplify structurally characterized adducts with a 1:2 stoichiometry. However, the number of other known tellurium tetrahalide adducts containing a Te–N bond is sparse. Gieren et al.[12] have reported the crystal structure of $TeF_4(NNCHCHCH)_2$ and Massa et al.[13] have determined that of $[Te_6N_8(TeCl_4)_4] \cdot 4THF$.

The preparation of $TeCl_4 \cdot S_4N_4$ (**1**) by the reactions of $S_4N_4$ with $TeCl_4$ in various solvents,[14–16] or $S(NSO)_2$ with $TeCl_4$ in $CH_2Cl_2$[17] has been reported. The compound, however, was identified only by elemental analysis and IR spectroscopy. While Paul et al.[14] concluded on the basis of conductance measurements that in the solid state **1** has an ionic structure, Alange et al.[15] inferred $TeCl_4 \cdot S_4N_4$ to be a covalent coordination complex by comparing the IR spectrum of the adduct with those of the structurally characterized analogues $BF_3 \cdot S_4N_4$ and $SbCl_5 \cdot S_4N_4$. Ginn et al.[16] used **1** to produce a platinum complex containing the $^{15}N$-labelled $TeSN_2$ ligand, but they did not provide structural details of $TeCl_4 \cdot S_4N_4$.

In this paper, we describe the structural and vibrational characterization of **1** and demonstrate that the compound represents one further example of a tellurium tetrahalide bonded to nitrogen. DFT MO calculations have been utilized to compare the trends in the molecular structures, bonding, stabilities, and spectroscopic properties of **1**, $BF_3 \cdot S_4N_4$ (**2**), $SO_3 \cdot S_4N_4$ (**3**), $AsF_5 \cdot S_4N_4$ (**4**), and $SbCl_5 \cdot S_4N_4$ (**5**) for which there is experimental information available, and to evaluate the corresponding properties in $TeF_4 \cdot S_4N_4$ (**6**), $TeBr_4 \cdot S_4N_4$ (**7**), and $SeX_4 \cdot S_4N_4$ [X = F (**8**), Cl (**9**), Br (**10**)]. $S_4N_4H^+$ (**11**) is included in this study for comparison.[18]

## Results and Discussion

### Synthesis and Spectroscopic Characterization of $TeCl_4 \cdot S_4N_4$ (1)

$TeCl_4 \cdot S_4N_4$ was produced by the reaction of $S_4N_4$ with $TeCl_4$ in $CH_2Cl_2$ as orange powder in ca. 76% yield. The EI mass spectrum of the product shows $TeS_4N_4^+$ ($m/z$ = 314) as the fragment with highest mass. Although the mass spectrum shows no evidence of the molecular ion, the fragmentation pattern indicates the correct composition for $TeCl_4 \cdot S_4N_4$. The observed and calculated isotopic distributions were in good agreement for all fragments.

The $^{14}N$ NMR spectrum of the reaction solution from which the orange precipitate was removed by filtration

shows one resonance at $\delta$ = –256 ppm, but we did not observe the $^{125}$Te resonance. The single resonance in the $^{14}$N NMR spectrum is assigned to $S_4N_4$.[20] The compound **1** is expected to give rise to one resonance in the $^{125}$Te NMR spectrum and three resonances with the intensity ratio of 1:2:1 in the $^{14}$N NMR spectrum. Conductance measurements[14] imply that **1** has a different structure in solution than that observed in the solid state. The NMR spectroscopic data and the insolubility of the product give further support for this conclusion.

Raman spectra were recorded for both the orange powder and the red crystals that were used for the X-ray structure determination. The adduct $TeCl_4{\cdot}S_4N_4$ belongs to the point group $C_s$ and, therefore, all 33 fundamental vibrations are Raman active. The observed and calculated B3PW91/(RLC ECP) fundamental vibrations together with the main contributions to their potential energy distributions are given in Table 1, and the observed and calculated spectra are shown in Figure 1. The calculated values yield a good agreement with the observed wavenumbers and Raman activities (the DFT calculations are discussed in more detail below).[21] The four observed Raman lines in the region 672–1045 cm$^{-1}$ are mainly due to $\nu_{S-N}$ stretching modes. The $\nu_{Te-Cl}$ stretching is the main contributor to the line at 265 cm$^{-1}$ and also appears to be the major vibrational mode of the strongest Raman line at 296 cm$^{-1}$ together with a torsion mode. The remainder of the Raman lines are predominantly torsional vibrations with the exception of the lines at 138 and 149 cm$^{-1}$ for which the $\delta_{ClTeCl}$ bending mode is also a significant contributor.

## Crystal Structure of $TeCl_4{\cdot}S_4N_4$ (1)

The crystal structure of $TeCl_4{\cdot}S_4N_4$ (**1**) with the atomic numbering scheme is shown in Figure 2(d), and the selected bond parameters are compared with those for related $S_4N_4$ adducts in Table 2. The molecule consists of an opened mo-

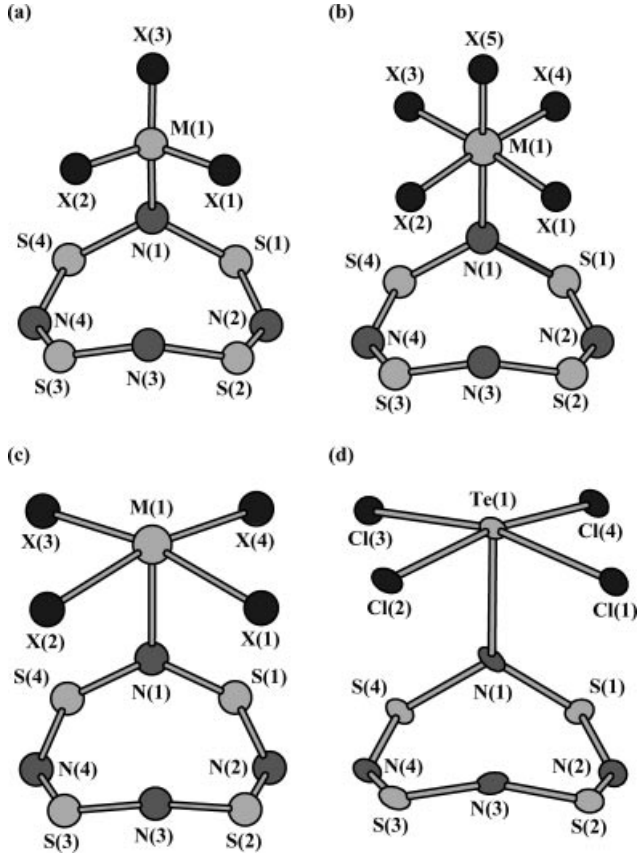

Figure 2. The B3PW91/(RLC ECP)-optimized geometries of (a) $BF_3{\cdot}S_4N_4$ (**2**) and $SO_3{\cdot}S_4N_4$ (**4**), (b) $AsF_5{\cdot}S_4N_4$ (**4**) and $SbCl_5{\cdot}S_4N_4$ (**6**), (c) $TeX_4{\cdot}S_4N_4$ [X = F (**6**), Cl (**1**), Br (**7**)] and $SeX_4{\cdot}S_4N_4$ [X = F (**8**), Cl (**9**), Br (**10**)]. (d) The X-ray structure of $TeCl_4{\cdot}S_4N_4$ (**1**). The thermal ellipsoids have been drawn at 50% probability level. The numbering of the atoms in all adducts is indicated in the figures.

nocyclic $S_4N_4$ ring in boat conformation that is bonded to $TeCl_4$ through one nitrogen atom. The S–N bond lengths [range 1.55(1)–1.67(1) Å] and the S–N–S bond angles (range 110.2–140.7°) in **1** are in good agreement with those reported for other adducts of $S_4N_4$ (Table 2).[1–9] The S(2)–S(4) and S(1)–S(3) distances [4.09(1) and 4.125(1) Å] across the ring are significantly longer than the corresponding distances in $S_4N_4$ [2.595(1) and 2.590(1) Å][26] indicating the expected loss of transannular S···S interaction.

The Te–N bond length of 2.16(1) Å in $TeCl_4{\cdot}S_4N_4$ is significantly longer than the single bond length[27] and ca. 0.12 Å longer than the $Cl_4Te$–N bond length in $[Te_6N_8(TeCl_4)_4]{\cdot}4THF$.[12] The Te–Cl bonds [2.464(3)–2.504(4) Å] are similar to the bond length of 2.516(4) Å in $[Te_6N_8(TeCl_4)_4]{\cdot}4THF$.[13] The shortest intermolecular Te···Cl contacts in $TeCl_4{\cdot}S_4N_4$ are 3.37(1) and 3.44(2) Å and are typical for secondary bonding interactions involving tellurium {for instance, the shortest intermolecular Te···Cl contact in $[Cl_2Te(\mu\text{-}NtBu)_2TeCl_2]_3$ is 3.107(1) Å[30]}. These contacts and a weak intermolecular S···N interaction link the molecules into a three-dimensional network (see Figure 3).

### A DFT Study of Selected Lewis Acid Adducts of $S_4N_4$

The B3PW91/(RLC ECP)-optimized geometries of $TeCl_4{\cdot}S_4N_4$, $BF_3{\cdot}S_4N_4$, $SO_3{\cdot}S_4N_4$, $AsF_5{\cdot}S_4N_4$, $SbCl_5{\cdot}S_4N_4$, and $S_4N_4H^+$ are shown in Table 2 and compared to experimental information from crystal structure determinations. Whereas the optimized bond lengths show a slight overestimation, it can be seen that the calculated bond angles are close to the experimental values. The RMS deviation between the calculated and observed bond lengths is only 0.034 Å and that of the bond angles is 2°. The optimized geometries of all adducts exhibit local minima with molecular symmetry $C_s$. The geometries are slightly distorted from the ideal in the crystal structures due to packing effects in the lattices. The optimized bond parameters of $TeF_4{\cdot}S_4N_4$, $TeBr_4{\cdot}S_4N_4$, and $SeX_4{\cdot}S_4N_4$ (X = F, Cl, Br) are shown in Table 3 and exhibit features similar to those species for which experimental information is available (c.f. Table 2).

The $S_4N_4$ ring in all adducts shows similar structural features irrespective of the identity of the Lewis acid (see Figure 2). The transannular S···S interactions of the free $S_4N_4$ cage are absent and, in each adduct, the molecule exhibits a monocyclic ring in the boat conformation.[31]

The B3PW91/(RLC ECP) natural atomic charges and Mayer–Mulliken bond orders of the adducts **1**–**10** are shown in Table 4. With the exception of values involving N(1), the atomic charges and bond orders within the $S_4N_4$ ring are virtually independent of the Lewis acid. While the bond orders of N(1)–S(1) and N(1)–S(4) bonds are close to unity, those of other S–N bonds are significantly higher. This might indicate delocalization of π-electron density, but the high bond orders and consequently short S–N bond lengths have also been discussed in terms of electrostatic reinforcement of the bonds.[32–36]

The bond orders of the M(1)–N(1) bond and the natural atomic charges of M(1) and N(1) expectedly show variation

[a] This work. [b] The calculations have been carried out at the B3PW91/(RLC ECP) level of theory. [c] Ref.[1] [d] Ref.[2] [e] Ref.[3] [f] Ref.[6] [g] Ref.[19]

with respect to the identity of $MX_n$, and therefore play a role in the stabilities of the adducts.

The calculated energies of formation of the different Lewis acid adducts of $S_4N_4$ are listed in Table 5 (see Supporting Information for zero-point energy-corrected total energies of the relevant molecular species). While the formation of each adduct is an energetically favorable process, the energy changes span a wide range of values from almost energy-neutral formation of $SeBr_4{\cdot}S_4N_4$ to a very strongly exothermic reaction yielding $AsF_5{\cdot}S_4N_4$. There are two qualitative trends that affect the energy of formation, as shown in Figure 4. On one hand, the energy of formation becomes less negative with increasing M(1)–N(1) bond order. On the other hand, the energy of formation becomes more negative with increasing difference of charges between the M(1) and N(1) atoms. It can be concluded that the most stable adducts have the largest ionic contribution and the smallest covalent contribution in their M(1)–N(1) bonds.

## Vibrational Spectroscopy

As discussed above, the calculated fundamental vibrations and Raman activities of $TeCl_4{\cdot}S_4N_4$ yield a good agreement with the observed Raman spectrum and provide the definite identification of the orange bulk powder that is obtained from the direct reaction of $S_4N_4$ and $TeCl_4$ (see Table 1). The Raman spectrum of the red crystals that were obtained as a side product in the reaction of $(Me_3SiNSN)_2S$ and $TeCl_4$ was virtually identical with that recorded for the orange powder.

The observed IR spectra of $BF_3{\cdot}S_4N_4$,[37] $SO_3{\cdot}S_4N_4$,[2] $AsF_5{\cdot}S_4N_4$,[38] $SbCl_5{\cdot}S_4N_4$,[15] $SeCl_4{\cdot}S_4N_4$,[15] and $TeF_4{\cdot}S_4N_4$[15] are also in good agreement with the calculated B3PW91/(RLC ECP) wavenumbers and intensities, as shown in the Supporting Information. This good agreement between the calculated and observed parameters also enables the prediction of both IR and Raman spectra of

$SeF_4{\cdot}S_4N_4$, $SeBr_4{\cdot}S_4N_4$, and $TeBr_4{\cdot}S_4N_4$ for which no experimental information is available (see Supporting Information).

## Conclusions

The X-ray structure of $TeCl_4{\cdot}S_4N_4$ reveals features similar to those reported for other 1:1 adducts of $S_4N_4$ with Lewis acids. The coordination of a nitrogen centre to the acid results in loss of the transannular S···S interactions in $S_4N_4$ ring, which adopts a boat conformation. DFT calculations for a series of 1:1 adducts reveal that the π electron density in the ring is delocalized. Consequently, all S–N bond lengths lie between those of single and double bonds. The B3PW91/(RLC ECP) Mayer–Mulliken bond orders support this conclusion. The bond parameters, natural atomic charges, and bond orders within the $S_4N_4$ ring are rather insensitive to the chemical identity of the Lewis acid, the most notable exceptions being the charge on the nitrogen atom that is bonded to the acid molecule.

The B3PW91/(RLC ECP) energies of formation of the adducts from their component molecules vary significantly. The formation of $AsF_5{\cdot}S_4N_4$ is most exothermic and that of $SeBr_4{\cdot}S_4N_4$ is almost thermoneutral. The DFT calculations qualitatively show that the relative stabilities of the adducts with respect to their components depend on the ionic character of the M–N bond.

The fundamental vibrations calculated at the B3PW91/(RLC ECP) level of theory show good agreement with the experimental IR and Raman vibrations and their intensities. The calculations indicate that vibrational spectroscopy can be used to identify the species formed upon adduct formation and that this level of theory is sufficient to predict the vibrational spectra of the adducts that are still unknown.

## Experimental Section

**General Procedures:** All reactions and manipulations of air- and moisture-sensitive reagents were carried out under argon passed through $P_4O_{10}$. The reagents $SCl_2$, $SO_2Cl_2$ and $TeCl_4$ (Aldrich) were used without further purification. $[(Me_3Si)_2N]_2S$ was prepared from $(Me_3Si)_2NH$ by utilizing the method of Wolmershäuser et al.[39] and purified by distillation. $S_4N_4$ was produced by the reaction of $[(Me_3Si)_2N]_2S$ with a mixture of $SCl_2$ and $SO_2Cl_2$.[40] Dichloromethane was dried by distillation over $P_4O_{10}$ under nitrogen prior to use.

**Spectroscopic Methods and Vibrational Analysis:** The $^{14}N$ and $^{125}Te$ NMR spectra were recorded in dichloromethane with a Bruker DPX 400 spectrometer operating at 28.909 and 126.240 MHz, respectively. The spectral widths were 14.49 and 95.24 kHz, yielding

[a] The energy changes are based on total energies of the molecular species incorporating the zero-point-energy corrections.

the respective resolutions of 7.08 and 1.45 Hz/data point. The pulse widths were 12.0 μs for $^{14}N$ and 6.67 μs for $^{125}Te$, corresponding to nuclear tip angles of 44 and 30°, respectively. All spectra were recorded unlocked. The $^{14}N$ NMR chemical shifts are reported relative to $CH_3NO_2$ and $^{125}Te$ NMR spectra were referenced externally to a saturated solution of $H_6TeO_6$. The MS-EI mass spectrum was recorded with a Micromass Quattro II spectrometer at 70 eV of electron energy. Raman spectra were recorded for solid samples at room temperature with a Bruker IFS-66 spectrometer equipped with a FRA-16 Raman unit and Nd:YAG laser (power 110 mW; 8–64 scans; spectral resolution ±1 cm$^{-1}$; Blackmann–Harris four-term apodization, no white light correction, 180 ° scattering geometry).

**Preparation of $TeCl_4{\cdot}S_4N_4$ (1):** $S_4N_4$ (0.092 g, 0.5 mmol) was dissolved in dichloromethane (10 mL) and added to a suspension of $TeCl_4$ (0.135 g, 0.5 mmol) in dichloromethane (10 mL) at –80 °C. The reaction mixture was stirred overnight and warmed slowly to room temperature to give a yellow solution and an orange, insoluble precipitate of **1** (0.174 g, 76%). This precipitate was used for vibrational and mass spectroscopic characterization of the product. The NMR spectrum was recorded from the yellow solution obtained after filtration. $^{14}N$ NMR ($CH_2Cl_2$, 25 °C): $\delta$ = –256 ($S_4N_4$) ppm. MS: *m*/*z* (%) = 46 (100) [$SN^+$], 78 (18) [$S_2N^+$], 92 (26) [$S_2N_2^+$], 130 (77) [$Te^+$], 138 (18) [$S_3N_3^+$], 144 (7) [$TeN^+$], 165 (72) [$TeCl^+$], 176 (25) [$TeSN^+$], 184 (5) [$S_4N_4^+$], 200 (52) [$TeCl_2^+$], 211 (22) [$TeClSN^+$], 235 (38) [$TeCl_3^+$], 246 (28) [$TeCl_2SN^+$], 257 (67) [$TeClS_2N_2^+$], 292 (19) [$TeCl_2S_2N_2^+$], 314 (5) [$TeS_4N_4^+$]. All fragments show expected isotopic distributions. The *m*/*z* and intensities in the list above refer to the fragments containing the $^{130}Te$ isotope.

**X-ray Crystallography:** A small number of red, moisture-sensitive crystals of $TeCl_4{\cdot}S_4N_4$ (**1**) were obtained by the reaction of $(Me_3SiNSN)_2S$ with $TeCl_4$ in $CH_2Cl_2$.[41] *FW* = 453.68 g/mol, monoclinic, space group *Cc*, *a* = 12.998(2), *b* = 11.914(2), *c* = 7.214(1) Å, $\beta$ = 101.65(1)°; *V* = 1080.5(3) Å$^3$; *Z* = 4, $D_c$ = 2.789 g cm$^{-3}$; *F*(000) = 848; $\mu$(Mo-$K_\alpha$) = 4.471 mm$^{-1}$, *T* = 120 K, crystal dimensions 0.2 × 0.1 × 0.1 mm$^3$. Reflections (2890 total, 1610 unique, $\theta$ range 3.42–26.00°, $R_{int}$ = 0.0369) were collected on Nonius Kappa CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The intensity data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied to the net intensities. The structure was solved by direct meth-

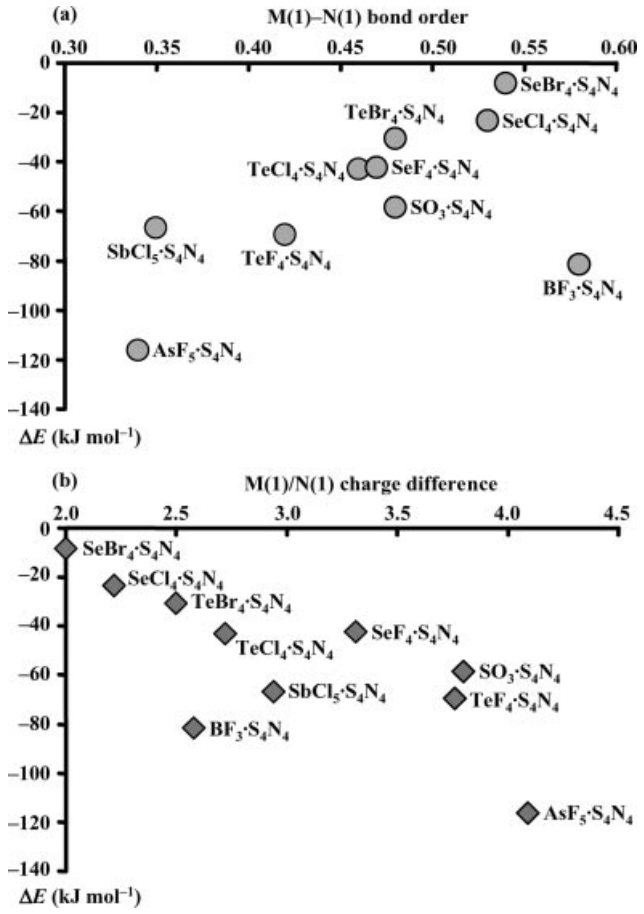

Figure 4. The dependence of the B3PW91/(RLC ECP) energy of formation of adducts **1**–**10** on (a) M(1)–N(1) bond order and (b) difference of atomic charges of M(1) and N(1) (see Table 4).

ods using SHELXS-97[43] and refined using SHELXL-97.[44] The scattering factors for the neutral atoms were those incorporated with the programs. The final $R_1 = 0.0515$ [$I > 2\sigma(I)$] and $wR_2 = 0.1242$ (all data) [$R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]1/2$, $w = [\sigma^2(F_o^2) + (0.0700P)^2 + 10.00P]^{-1}$ where $P = \{\max(F_o^2,0) + 2F_c^2\}/3$]. Maximum and minimum values in the final difference Fourier synthesis are 2.342 and –1.629 e·Å$^{-3}$.

Further details of the crystal-structure investigation of **1** can be obtained free of charge from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, Fax: +49-7247-808-666, E-mail: crysdata@fiz-karlsruhe.de, http://www.fiz-karlsruhe.de (under "Products and Services") on quoting the depository number CSD-416253.

**Computational Details:** The molecular orbital calculations of $TeCl_4{\cdot}S_4N_4$ (**1**), $BF_3{\cdot}S_4N_4$ (**2**), $SO_3{\cdot}S_4N_4$ (**3**), $AsF_5{\cdot}S_4N_4$ (**4**), $SbCl_5{\cdot}S_4N_4$ (**5**), $TeF_4{\cdot}S_4N_4$ (**6**), $TeBr_4{\cdot}S_4N_4$ (**7**), and $SeX_4{\cdot}S_4N_4$ [X = F (**8**), Cl (**9**), Br (**10**)] were carried out at the DFT level of theory involving Becke's three parameter hybrid functionals with the Perdew/Wang 91 correlation (B3PW91)[45–51] and using the Stuttgart relativistic large core effective core potential approximation (RLC ECP)[52–54] by augmenting the double-zeta quality basis sets of the valence orbitals by two polarization functions for all atoms except for hydrogen for which a standard Pople-type 6-31G* basis was used, as implemented in Gaussian 98 and Gaussian 03. Complete geometry optimizations were performed for each adduct. Fundamental vibrations were calculated to establish the nature of the stationary points and to enable the assignment of the Raman spectra. The calculated wavenumbers and zero-point-energy corrections (ZPE) were scaled by 0.993 to eliminate the systematic errors.[55] The calculations were mainly performed with the GAUSSIAN 03 (Rev. B.04) program package.[56] The wavefunction files for NBO 5.0,[57] however, were calculated with the GAUSSIAN 98 (Rev. A.9) package.[58]

[41] We have recently observed that $S_4N_4$ is one product in the reaction of $(Me_3SiNSN)_2S$ with $TeCl_4$.[42] It reacts with unreacted $TeCl_4$ and forms a small amount of well-formed red crystals of $TeCl_4{\cdot}S_4N_4$ that were suitable for the X-ray structure determination. While the direct reaction between $S_4N_4$ and $TeCl_4$ yields an orange powder that could be shown by vibrational analysis and mass spectroscopy to be $TeCl_4{\cdot}S_4N_4$, we were unable to obtain single crystals from this direct reaction.

# Energetic Nitrate, Perchlorate, Azide and Azolate Salts of Hexamethylenetetramine

**Hong Xue,[a] Haixiang Gao,[a] Brendan Twamley,[a] and Jean'ne M. Shreeve*[a]**

**Keywords:** Hexamethylenetetrammonium salts / Energetic materials / Quaternization / Heats of formation

Hexamethylenetetrammonium salts, composed of energetic anions 3,5-dinitropyrazolate, 4,5-dinitroimidazolate, 3,5-dinitro-1,2,4-triazolate, 5-nitrotetrazolate, perchlorate, nitrate and azide, were synthesized and characterized. The structure of *N*-methyl-hexamethylenetetrammonium 3,5-dinitro-1,2,4-triazolate (**6**) was confirmed by X-ray analysis. The standard enthalpies of formation for the new salts were calculated by using the computationally feasible DFT(B3LYP) and MP2 methods in conjunction with an empirical approach based on the densities of the salts. The calculated values range from $\Delta H_f^\circ$ = –30.6 (**7**) to +468.8 kJ·mol$^{-1}$ (**10**) where the experimental densities > 1.35 g cm$^{-3}$.

## Introduction

In recent years, the synthesis of energetic heterocyclic compounds has attracted considerable interest,[1–7] especially the syntheses of new members of heterocyclic-based energetic, low-melting salts.[8,9] Energetic materials that are salt-based often possess advantages over non-ionic molecules because these salts tend to exhibit lower vapor pressure and higher densities than their atomically similar non-ionic analogues. The cation is generally a bulky organic species with low symmetry. Nitrogen-containing heterocyclic-based salts predominate. The anion most frequently is inorganic, such as nitrate,[8,9,10g] perchlorate,[8,9,10e] dinitramide,[8,9c,10] azide[10g] and tetraazidoborate anion.[11] However, reports are already available that describe analogous salts with organic anions, such as α-cyano-4-hydroxycinnamate, anthraquinone-2-sulfonate,[12] salicylate and lactate,[13] imidazolate and triazolate and tetrazolate.[9e,14,15] Some metal salts composed of organic anions, such as lithium 4,5-dicyano-1,2,3-triazolate, were reported as electrolytes.[16] Alkali metal salts of 5,5′-azotetrazolate[17] and transition-metal salts of 5-nitro-2,4-dihydro-3*H*-1,2,4-triazol-3-one[18] were also synthesized as energetic compounds.

Hexamethylenetetramine is an interesting raw material which is useful in the production of antibacterial agents, adhesives, coatings, dye fixatives, anticorrosive agents as well as powerful explosives, e.g., 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX), 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX) and pentaerythrol tetranitrate (PETN).[19] The mechanisms of nitration of hexamethylenetetramine were also studied in detail.[20] The preparation of certain salts of hexamethylenetetramine has long been known, including both inorganic salts, such as chloride, sulfate, phosphate, and organic salts, such as formate, methanesulfonate, *p*-toluenesulfonate and many others.[21] The literature data of energetic hexamethylenetetramine dinitrate (HEXADI) and related compounds were given recently.[22] The syntheses and crystal structures of various energetic urotropinium salts with azide, nitrate, dinitramide and azotetrazolate counterions are also reported,[23] but no energetic characterization was cited. Our main interest in this work is to investigate the syntheses and thermal properties of hexamethylenetetrammonium salts containing both energetic inorganic and organic anions, such as nitrate, perchlorate, and azide, and 3,5-dinitropyrazolate, 4,5-dinitroimidazolate, 3,5-dinitro-1,2,4-triazolate, and 5-nitrotetrazolate, respectively. The calculated heats of formation of these compounds based on DFT(B3LYP) and MP2 methods in conjunction with an empirical approach based on densities of salts are also presented.[10h]

## Results and Discussion

Hexamethylenetetrammonium salts with nitrate, azide, dinitramide and azotetrazolate counterions have been prepared either from hexamethylenetetramine and nitric acid or the metathesis reaction from the corresponding iodide (or sulfate) with $AgN_3$, $[AgNCCH_3][N(NO_2)_2]$, or barium azotetrazolate.[23] It was found that 4,5-dinitroimidazole and 5-nitrotetrazole, which are strong NH acids ($pK_a$ = –0.8 for 5-nitrotetrazole)[24] with electron-withdrawing nitro substituents on the ring, can be readily quaternized with azoles to form energetic azolium-azolate salts.[9e] Here we synthesized several new hexamethylenetetrammonium salts

Y = 3,5-dinitro-1,2,4-triazolate, $NO_3$, $ClO_4$, F

Scheme 1. Syntheses of energetic hexamethylenetetrammonium salts.

based on energetic azolate anions (3,5-dinitropyrazolate, 4,5-dinitroimidazolate, 3,5-dinitro-1,2,4-triazolate and 5-nitrotetrazolate) and inorganic anions (nitrate, perchlorate and azide). Typical examples for preparation of such salts are given in Scheme 1. It was found that 3,5-dinitropyrazole, 4,5-dinitroimidazole, 3,5-dinitro-1,2,4-triazole and 5-nitrotetrazole can readily quaternize hexamethylenetetramine in methanol. The salts were formed in nearly quantitative yields and in high purity (**1**–**4**). However, although excess 4,5-dinitroimidazole (or 5-nitrotetrazole) was heated with hexamethylenetetramine, it was not possible to react more than one mol of either azole. This is in contrast with the diammonium salt which resulted when excess nitric acid was employed.[22]

*N*-(Methyl)hexamethylenetetrammonium iodide (**5**) was prepared in quantitative yield from hexamethylenetetramine and $CH_3I$ with chloroform as solvent based on a modified literature method.[23] Initially, the synthesis of *N*-(methyl)-hexamethylenetetrammonium 3,5-dinitro-1,2,4-triazolate was attempted by metathesis reactions of the corresponding iodide salt with sodium 3,5-dinitro-1,2,4-triazolate.[25] However, the reaction did not work well. Although silver 3,5-dinitro-1,2,4-triazolate[26] was water-insoluble, it had good solubility in acetonitrile. Therefore, metathesis of the quaternary iodide **5** with silver 3,5-dinitro-1,2,4-triazolate with $CH_3CN$ as solvent led to the formation of the new quaternary salt **6** in nearly quantitative yield and in high purity. The quaternary salts **7**–**9** were also obtained in high yield using a similar method as **6**, from compound **5** and $AgNO_3$, $AgClO_4$ and AgF with water as solvent. *N*-(Methyl)hexamethylenetetrammonium azide (**10**) was obtained from compound **9** and $Si(CH_3)_3N_3$ in methanol as solvent in high purity and in quantitative yield.[27]

The structure of compound **6** was determined by single-crystal X-ray diffraction, and the asymmetric unit is shown in Figure 1. This consists of two independent ion pairs.

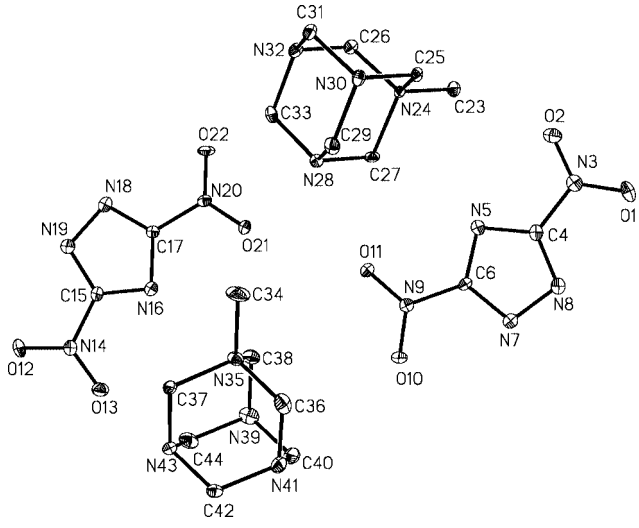

Figure 1. Thermal ellipsoid plot (30%) of the asymmetric unit of compound **6**. Hydrogen atoms omitted for clarity.

The most distinctive feature of this structure is the angle of the $NO_2$ groups to the triazolate anion which vary widely (O1–N3–O2, 2.7°; O10–N9–O11, 7.8°; O12–N14–O13, 7.5°; O21–N20–O22, 14°). These dinitrotriazolate anions pack in offset stacks parallel to the *b* axis, with an inter anion spacing of 3.11 Å (see supporting information). A summary of the crystal data for compound **6** is given in Table 1.

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

Comparison of the melting points of compounds **1**–**4**, and **6**, **7**, **8**, **10** (Table 2), clearly illustrates the influence of different anions, e.g., the melting point for compound **4** (m.p. 166 °C), which has 5-nitrotetrazolate as anion, is considerably lower than that of 3,5-dinitropyrazolate, 4,5-dinitroimidazolate and 3,5-dinitro-1,2,4-triazolate as anions in **1** (m.p. 180 °C), **2** (m.p. 183 °C) and **3** (m.p. 177 °C), respectively. The melting point for compound **6** (m.p. 170 °C), which has 3,5-dinitro-1,2,4-triazolate as anion, is lower or higher than that of nitrate, perchlorate or azide as anions, which melts at 194 °C, 200 °C, and 165 °C, respectively. It is also can be seen that compounds **3** and **6** have the same anion (3,5-dinitro-1,2,4-triazolate), for **6**, which has a *N*-methyl group on the cation ring, its melting point and decomposition temperature (**6**, $T_d$ = 202 °C) are lower and higher than that of compound **3** ($T_d$ = 182 °C), respectively.

Density, oxygen coefficient, and enthalpy of formation are important characteristics of energetic compounds, and are governed by their molecular structures. Increasing the number of nitrogen atoms in a heterocycle results in a considerable gain in the heat of formation.[5] Density, oxygen coefficients, nitrogen content and the calculated heats of formation for the energetic salts are listed in Table 2. Densities for all of the compounds exceed 1.35 g cm$^{-3}$, and compound **3** has the highest density (1.72 g cm$^{-3}$). The oxygen coefficient (*α*), which is defined as $\alpha = c/(2a + b/2)$ for the molecular formula $C_aH_bO_cN_d$, is calculated by a literature method.[28a] Incorporation of a nitro group can substantially improve the oxygen balance of the corresponding compounds, and eventually results in higher exothermicities

Table 2. Phase transition, decomposition temperatures, densities, oxygen coefficient (*α*), nitrogen content (N), and thermochemical results for synthesized salts.

of the combustion and detonation processes. The oxygen coefficient values of C,H,O,N-containing energetic compounds belong to the classes of fuels ($\alpha < 0.4$), explosives ($0.4 \le \alpha \le 1.0$), and oxidants ($\alpha > 1.0$).[28b] The oxygen coefficients for the new salts are between 0.10–0.18 (Table 2), which fall at < 0.4 among the majority of the known energetic compounds.[28b] The calculated nitrogen contents for the new salts are between 22–50% (Table 2).

The standard molar enthalpy of formation ($\Delta_f H_m°$) for the salts **3**, **4**, **6**–**8**, **10** were calculated by the following Born–Haber energy cycles (Scheme 2). Calculations were made with the Gaussian03 (Revision D.01) suite of programs.[29] The geometric optimization of the structures and frequency calculations were performed at (DFT)[30,31]/B3LYP[32] level of theory using the 6-31+G** basis set. Single-point energies were calculated at the MP2/6-311++G** level.[33,34] According to the previous studies, the computed harmonic vibrational frequencies were scaled uniformly by a factor of 0.96 to take into account the systematic overestimation of these frequencies in the B3LYP/6-31+G** calculations.[35] Based on this data, the heats of formation of the anions and cations were calculated and combined with the lattice energy of the salts to give the heats of formation of the salts. Because the most efficient computational procedure for finding accurate heats of formation is based on isodesmic (bond type conserving) reactions,[36] in the present case, the reactions used to calculate the heat of formation of both cations and anions are given in Scheme 3.

The heat of formation of 3,5-dinitrotriazole was calculated by averaging its actual resonance hybrids shown in Equations (5) and (6) in Scheme 3. The lattice potential energy $\Delta H_L$ for $M_pX_q$ was calculated using the relationship provided by Jenkins (equation **A**),[37] where $n_M$ and $n_X$ depend on the nature of the ions $M_p^+$ and $Xq^-$, respectively, and is equal to

$$\Delta H_L = U_{POT} + [p(n_M/2 - 2) + q(n_X/2 - 2)]RT \quad \textbf{(A)}$$

with $n$ = 3 for monatomic ions, 5 for linear polyatomic ions, and 6 for nonlinear polyatomic ions.

The equation for lattice potential energy $U_{POT}$ (equation **B**) has the form

$$U_{POT}\ [kJ{\cdot}mol^{-1}] = \gamma\ (\rho_m/M_m)^{1/3} + \delta \qquad (\mathbf{B})$$

where $\rho_m$ [g cm$^{-3}$] is the density, $M_m$ is the chemical formula mass of the ionic material [g or Mg]; the coefficients $\gamma$ [kJ·mol$^{-1}$ cm] and $\delta$ [kJ·mol$^{-1}$] are equal to 8375.6 and –178.8, respectively. Comparison of the data for compounds **3** and **4** reveals that $\Delta_f H_m°$ for **4** (+435.3 kJ·mol$^{-1}$), which has 5-nitrotetrazolate as the anion, is considerably higher than that for the 3,5-dinitro-1,2,4-triazolate anion and **3** (+268.7 kJ·mol$^{-1}$). From the $\Delta_f H_m°$ values for **6**, **7**, **8**, **10** it can be seen that for the same cation, the heat of formation of the compound with azide as anion, is considerably higher than those of corresponding compounds with 3,5-dinitro-1,2,4-triazolate, perchlorate or nitrate as anions, which varies as **10** (azide) > **6** (3,5-dinitro-1,2,4-triazolate) > **8** (perchlorate) > **7** (nitrate) (+468.8, +250.7, +14.5, –30.6 kJ·mol$^{-1}$), respectively.

In conclusion, we have synthesized new hexamethylenetetrammonium salts composed of the energetic anions 3,5-dinitropyrazolate, 4,5-dinitroimidazolate, 3,5-dinitro-1,2,4-triazolate, 5-nitrotetrazolate, perchlorate, nitrate and azide. Most of the new salts exhibit valuable physical properties, including relatively high densities (>1.35 g cm$^{-3}$) and high positive heats of formation.

## Experimental Section

**Caution:** Although we have not experienced any problems in handling these compounds, based on the high positive heats of formation, all materials should be handled with extreme care.

**General Methods:** $^1$H and $^{13}$C NMR spectra were recorded with a 300-MHz nuclear magnetic resonance spectrometer operating at 300.13, and 75.48 MHz, respectively. Chemical shifts were reported relative to $Me_4Si$. The melting and decomposition points were recorded with a differential scanning calorimeter and a thermogravimetric analyzer at a scan rate of 10 °C min$^{-1}$, respectively. IR spectra were recorded using KBr pellets for solids. Densities of solid salts were measured at room temperature using a Micromeritics Accupyc 1330 gas pycnometer. Elemental analyses were measured with a CE-440 elemental analyzer.

3,5-Dinitropyrazole,[42] 4,5-dinitroimidazole,[43] 3,5-dinitro-1,2,4-triazolate[25] 5-nitrotetrazole[44] and silver 3,5-dinitro-1,2,4-triazolate[26] were synthesized according to literature procedures.

**X-ray Crystallographic Studies:** Crystals of compound **6** were removed from the flask and covered with a layer of hydrocarbon oil. A suitable crystal was selected, attached to a glass fiber and placed in the low-temperature nitrogen stream.[38] Data for **6** were collected at 87(2) K with a Bruker/Siemens SMART APEX instrument (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) equipped with a Cryocool NeverIce low-temperature device. Data were measured using $\omega$ scans of 0.3° per frame for 60 s, and a full sphere of data was collected. A total of 2400 frames were collected with a final resolution of 0.83 Å. The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved using SMART[39] software and refined using SAINTPlus[40] on all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPlus software. Absorption corrections were applied using SADABS.[41a] The structure was solved by direct methods and refined by least-squares method on $F^2$ using the SHELXTL program package.[41b] The structure was solved in the space group $P21/n$ (#14) by analysis of systematic absences. All non-hydrogen atoms were refined anisotropically. No decomposition was observed during data collection.

CCDC-294742 (for **6**) contains the complete set of crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Ball and stick packing diagrams of **6** and a table with hydrogen bonds for **6**.

**Hexamethylenetetrammonium 3,5-Dinitropyrazolate (1):** A dry, nitrogen-filled Schlenk glass tube was charged with hexamethylenetetramine (0.140 g, 1.0 mmol), dry methanol (5 mL), and 3,5-dinitropyrazole (0.158 g, 1.0 mmol). The mixture was stirred 10 h at room temperature. The solvent was removed under vacuum overnight to leave a white solid **1**: 97% yield (0.29 g), m.p. 180 °C. IR (KBr): $\tilde{\nu}$ = 3151, 2949, 2899, 2253, 1540, 1487, 1438, 1346, 1315, 1262, 1224, 1161, 1066, 1016, 982, 871, 823, 748, 686, 662 cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 4.82 (s, 12 H), 7.29 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 157.24, 99.16, 72.17 ppm. $C_9H_{14}N_8O_4{\cdot}0.5H_2O$ (307.11): calcd. C 35.18, H 4.88, N 36.48; found C 35.52, H 4.52, N 36.89.

**Hexamethylenetetrammonium 4,5-Dinitroimidazolate (2):** A dry, nitrogen-filled Schlenk glass tube was charged with hexamethylenetetramine (0.140 g, 1.0 mmol), dry methanol (5 mL), and 4,5-dinitroimidazole (0.158 g, 1.0 mmol). The mixture was stirred for 10 h at room temperature. The solvent was taken off under vacuum overnight to give a yellow solid **2**: 97% yield (0.29 g), m.p. 183 °C. IR (KBr): $\tilde{\nu}$ = 3106, 2937, 2777, 2555, 2485, 1760, 1535, 1506, 1462, 1351, 1311, 1261, 1219, 1184, 1098, 1063, 985, 817, 751, 659 cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 4.83 (s, 12 H), 6.96 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 141.69, 140.77, 72.70 ppm. $C_9H_{14}N_8O_4$ (298.11): calcd. C 36.24, H 4.73, N 37.57; found C 35.88, H 4.56, N 37.11.

**Hexamethylenetetrammonium 3,5-Dinitro-1,2,4-triazolate (3):** Compound **3** was prepared by a similar procedure as above, from hexamethylenetetramine (0.140 g, 1.0 mmol) and 3,5-dinitro-1,2,4-triazole (0.159 g, 1.0 mmol) to form a white solid in 98% yield, m.p. 177 °C. IR (KBr): $\tilde{\nu}$ = 3092, 2967, 2679, 2390, 1549, 1489, 1384, 1350, 1285, 1265, 1206, 1101, 1010, 977, 840, 815, 748, 650 cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 4.84 (s, 12 H) ppm. $^{13}$C NMR ([D$_6$]-DMSO): $\delta$ = 163.75, 72.07 ppm. $C_8H_{13}N_9O_4$ (299.11): calcd. C 32.11, H 4.38, N 42.13; found C 31.79, H 4.17, N 41.88.

**Hexamethylenetetrammonium 5-Nitrotetrazolate (4):** Compound **4** was prepared by a similar procedure as above, from hexamethylenetetramine (0.140 g, 1.0 mmol) and 5-nitrotetrazole (0.115 g, 1.0 mmol) to form a white solid in 98% yield, m.p. 166 °C. IR (KBr): $\tilde{\nu}$ = 2953, 2813, 2771, 2548, 2410, 2133, 1541, 1466, 1413, 1364, 1314, 1267, 1216, 1143, 1011, 818, 745, 654 cm$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 4.84 (s, 12 H) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 170.27, 72.57 ppm. $C_7H_{13}N_9O_2{\cdot}H_2O$ (273.12): calcd. C 30.77, H 5.49, N 46.15; found C 30.99, H 4.66, N 46.68.

***N*-Methylhexamethylenetetrammonium Iodide (5):** Compound **5** was prepared by a minor modification of the previous synthesis,[23] from hexamethylenetetramine and $CH_3I$ at room temperature, using chloroform as solvent to give a white solid **5** in quantitative yield: m.p. 202 °C. IR (KBr): $\tilde{\nu}$ = 2955, 1736, 1462, 1431, 1382, 1312, 1253, 1150, 1043, 1018, 993, 958, 816, 712, 648 cm$^{-1}$. $^1$H NMR

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

([$D_6$]DMSO): $\delta$ = 2.49 (s, 3 H), 4.41–4.62 (q, $^2J$ = 12.0 Hz, 6 H), 5.09 (s, 6 H) ppm. $^{13}$C NMR ([$D_6$]DMSO): $\delta$ = 80.81, 71.22, 43.70 ppm.

**General Procedure for the Preparation of Salts from 5**

***N*-Methylhexamethylenetetrammonium 3,5-Dinitro-1,2,4-triazolate (6):** To a magnetically stirred solution of **5** (0.282 g, 1.0 mmol) in $CH_3CN$ (5 mL) was added silver 3,5-dinitro-1,2,4-triazolate (0.266 g, 1.0 mmol). After 2 h at room temperature, silver iodide was removed by filtration. The filtrate was dried in vacuo to give a yellow solid (0.30 g, 96% yield), m.p. 170 °C. IR (KBr): $\tilde{\nu}$ = 2960, 2713, 2434, 2139, 1535, 1483, 1463, 1375, 1335, 1244, 1150, 1097, 1039, 1015, 990, 956, 823, 648 cm$^{-1}$. $^1$H NMR ([$D_6$]DMSO): $\delta$ = 2.47 (s, 3 H), 4.40–4.64 (q, $^2J$ = 12.0 Hz, 6 H), 5.04 (s, 6 H) ppm. $^{13}$C NMR ([$D_6$]DMSO): $\delta$ = 164.43, 80.93, 71.27, 43.76 ppm. $C_9H_{15}N_9O_4$ (313.12): calcd. C 34.51, H 4.83, N 40.24; found C 34.53, H 4.58, N 40.14.

***N*-Methylhexamethylenetetrammonium Nitrate (7):** Compound **7** was prepared by a similar procedure as compound **6**, from **5** (0.282 g, 1.0 mmol) and silver nitrate (0.170 g, 1.0 mmol) using $H_2O$ as solvent to form a white solid in 98% yield, m.p. 194 °C. IR (KBr): $\tilde{\nu}$ = 2959, 2712, 2152, 2059, 1742, 1634, 1470, 1376, 1246, 1145,1043, 993, 957, 817, 785, 713, 650 cm$^{-1}$. $^1$H NMR ([$D_6$]-DMSO): $\delta$ = 2.47 (s, 3 H), 4.40–4.64 (q, $^2J$ = 12.0 Hz, 6 H), 5.05 (s, 6 H) ppm. $^{13}$C NMR ([$D_6$]DMSO): $\delta$ = 80.88, 71.24, 43.70 ppm. $C_7H_{15}N_5O_3$ (217.12): calcd. C 38.70, H 6.96, N 32.24; found C 38.22, H 6.85, N 32.10.

***N*-Methylhexamethylenetetrammonium Perchlorate (8):** Compound **8** was prepared by a similar procedure as compound **6**, from **5** (0.282 g, 1.0 mmol) and silver perchlorate (0.208 g, 1.0 mmol) using $H_2O$ as solvent to give a white solid in 98% yield, m.p. 200 °C. IR (KBr): $\tilde{\nu}$ = 3012, 2972, 2453, 2178, 1634, 1469, 1381, 1267, 1247, 1147, 1086, 992, 952, 821, 785, 650, 619 cm$^{-1}$. $^1$H NMR ($D_2O$): $\delta$ = 2.65 (s, 3 H), 4.55–4.75 (q, $^2J$ = 12.0 Hz, 6 H), 5.09 (s, 6 H) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 81.00, 70.95, 44.11 ppm. $C_7H_{15}N_4ClO_4$ (254.08): calcd. C 33.01, H 5.94, N 22.00; found C 33.10, H 5.98, N 21.88.

***N*-Methylhexamethylenetetrammonium Fluoride (9):** Compound **9** was prepared by a similar procedure as compound **6**, from **5** (0.282 g, 1.0 mmol) and silver fluoride (0.127 g, 1.0 mmol) using $H_2O$ as solvent to form a white solid in 98% yield, m.p. 68 °C. IR (KBr): $\tilde{\nu}$ = 3397, 2958, 1666, 1457, 1389, 1246, 1148, 1011, 959, 933, 816, 648 cm$^{-1}$. $^1$H NMR ($D_2O$): $\delta$ = 2.65 (s, 3 H), 4.55–4.75 (q, $^2J$ = 12.0 Hz, 6 H), 5.08 (s, 6 H) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 80.98, 70.93, 44.08 ppm. $^{19}$F NMR ($D_2O$): $\delta$ = –122.35 (s, 1F) ppm. $C_7H_{15}N_4F{\cdot}0.8H_2O$ (188.53): calcd. C 44.58, H 8.82, N 29.72; found C 44.60, H 8.88, N 30.03.

***N*-Methylhexamethylenetetrammonium Azide (10):** Compound **10** was prepared by a modified literature method,[23,27] from **9** (0.174 g, 1.0 mmol) and $(CH_3)_3SiN_3$ (0.173 g, 1.5 mmol) using dry methanol as solvent, stirred at room temperature for 5 h to leave a white solid in quantitative yield, m.p. 165 °C. IR (KBr): $\tilde{\nu}$ = 3443, 3282, 2956, 2890, 2446, 2293, 2030, 1627, 1460, 1386, 1315, 1248, 1147, 1043, 993, 956, 817, 713, 648 cm$^{-1}$. $^1$H NMR ($D_2O$): $\delta$ = 2.66 (s, 3 H), 4.56–4.76 (q, $^2J$ = 12.0 Hz, 6 H), 5.10 (s, 6 H) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 81.00, 70.95, 44.09 ppm.

## Acknowledgments

The authors gratefully acknowledge the support of AFOSR (F49620-03-1-0209), NSF (CHE0315275), and ONR (N00014-02-1-0600). We appreciate the high quality assistance of Drs. Gary Knerr and Alex Blumenfeld for mass spectra and NMR analyses, respectively. We are grateful to Drs. Jerry A. Boatz and Gregory W. Drake for many helpful discussions. The Bruker (Siemens) SMART APEX diffraction facility was established at the University of Idaho with the assistance of the NSF-EPSCoR program and the M. J. Murdock Charitable Trust, Vancouver, WA.

# Ligand Variations in [ReX(diimine)(CO)$_3$] Complexes: Effects on Photocatalytic $CO_2$ Reduction

**Philipp Kurz,[a][‡] Benjamin Probst,[a] Bernhard Spingler,[a] and Roger Alberto*[a]**

**Keywords:** Photocatalysis / $CO_2$ reduction / Rhenium / Technetium / Diimine ligands

Two series of complexes [MX(diimine)(CO)$_3$] (M = Tc, Re) have been prepared, fully characterised and investigated for their ability to act as photocatalysts for the reduction of $CO_2$ to CO. One series consists of complexes with different aromatic diimine ligands while keeping X = Br$^-$ constant. The second series describes complexes with diimine = 2,2-bipyridine and variations in the anionic ligand X$^-$. Although numerous complexes of this type have been prepared and investigated before, a systematic study of their photocatalytic activity has not yet been carried out. Electrochemical and spectroscopic characterisation of these complexes has been performed with the objective of better understanding their respective activity in the photocatalytic $CO_2$ reduction. Despite various modifications, catalytic activity is retained for all compounds exhibiting fluorescence, including [$^{99}$TcCl(bipy)(CO)$_3$], whereas nonfluorescing compounds did not convert $CO_2$ to CO. The correlation of catalytic activity and spectroscopic or electrochemical properties such as absorption or emission wavelengths, redox potentials or Stern–Volmer constants for the reductive quenching of the excited complexes is difficult. Nevertheless, the study emphasises the possibility to obtain [ReX(CO)$_3$(diimine)] complexes with a wide range of physicochemical properties by ligand variations and the great potential of compounds of this class of complexes as inorganic photosensitisers.

## Introduction

The development of a system for the conversion of solar energy into a chemical fuel is one of the most demanding challenges chemists face today. The choice of the photosensitiser performing the initial step of light absorption is of key importance. Complexes of the type [Ru(diimine)$_3$]$^{2+}$ have been most thoroughly studied in this respect.[1–4] Among further possible candidates, rhenium tricarbonyl diimine complexes [ReX(diimine)(CO)$_3$] have also attracted broad interest.[5–14] The complex [ReCl(phen)(CO)$_3$] was one of the first rhenium(I) carbonyl compounds ever synthesised.[15] Detailed studies have unveiled the remarkable photochemical properties of [ReCl(phen)(CO)$_3$] and related compounds such as [ReX(bipy)(CO)$_3$] (X = Cl$^-$ **1**, X = Br$^-$ **2**).[5,9,16,17] The excited state generated by visible light absorption at 450 to 500 nm has been identified as a metal to ligand charge transfer (MLCT) state, with the photoelectron ejected from a metal-centred π-d into a vacant ligand-centred π* orbital with up to μsec lifetimes. On the basis of the Rehm-Weller approximation[18] the photoexcited molecules are powerful oxidising agents with potentials of +500 to +1200 mV (vs. Ag/AgCl).[6] Thermodynamically, [ReX(diimine)(CO)$_3$] complexes can therefore oxidise very poor electron donors, even $H_2O$, in their excited states, which makes them very interesting compounds for light-energy conversion.

In a marked contrast to the large number of physicochemical investigations, there are only a few examples of light-driven reactions with these complexes as photosensitisers. Most prominent is a system for the photochemical reduction of $CO_2$ developed in Strasbourg over 20 years ago. Hawecker et al. found that **1** and **2** are both able to act as photosensitiser and reduction catalysts for the two-electron conversion of $CO_2$ to CO transferring reduction equivalents from poor reducing agents like triethanolamine (TEOA, $\Delta E°_{1/2}$ = +0.8 V) (Scheme 1).[10,19] In this "Strasbourg system", the energetically uphill, two-electron reduction process is achieved using the energy of absorbed

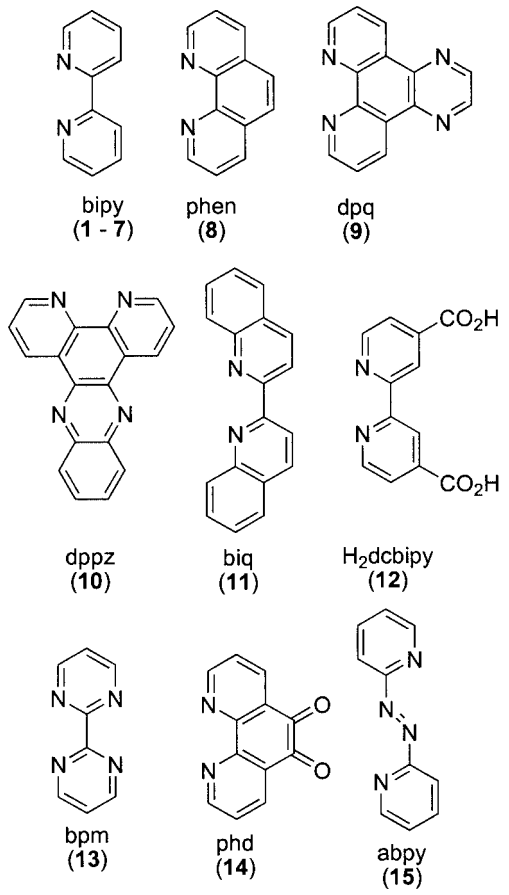
visible light. From the initial experiments on, the mechanism of this unprecedented reaction has been of great interest.[8,10,20,21] Many experiments have been carried out with the original catalysts **1** or **2**, but studies of the catalytic performance with variations in the anion $X^-$ or the diimine ligand N∩N are rare.[13,20]

We present in this study the synthesis and characterisation of two series of [ReX(diimine)(CO)$_3$] complexes and an investigation of the respective ligand effects on the photocatalytic activities. In a first series of complexes [ReX(bipy)(CO)$_3$] (**4**–**7**), also including the Tc(I) analogue [TcCl(bipy)(CO)$_3$] **3**, the bipy ligand is kept constant and X is varied. In a second series of [ReBr(diimine)(CO)$_3$] (**8**–**15**), the $Br^-$ ligand is kept constant but the diimine ligand is altered. The selected diimine ligands are depicted in Scheme 2. The detailed study of these series of complexes showed that the influence of both diimine and terminal $X^-$ ligands on physicochemical and catalytic properties is large. Nevertheless, catalytic activity is retained in most cases.



Scheme 2. Diimine ligands used for the synthesis of [ReBr(diimine)(CO)$_3$] complexes with the numbering of the corresponding complexes in brackets: 2,2′-bipyridine (bipy) (**1**–**7**); 1,10-phenanthroline (phen) (**8**); dipyrido[3,2-*f*:2′,3′-*h*]quinoxaline (dpq) (**9**); dipyrido[3,2-*a*:2′,3′-*c*]phenazine (dppz) (**10**); 2,2′-biquinoline (biq) (**11**); 2,2′-bipyridine-4,4′-dicarboxylic acid ($H_2$dcbipy) (**12**); 2,2′-bipyrimidine (bpm) (**13**); 1,10-phenanthroline-5,6-dione (phd) (**14**); 2,2′-azobispyridine (abpy) (**15**).

## Results and Discussion

**Synthesis and Characterisation:** The complexes [ReBr(CO)$_5$] and $(NEt_4)_2$[ReBr$_3$(CO)$_3$] are convenient starting materials from which [ReBr(diimine)(CO)$_3$] complexes are directly afforded with the diimine ligands shown in Scheme 2. The Tc(I) complex **3** was prepared similarly from $(NEt_4)_2$[TcCl$_3$(CO)$_3$]. For the synthesis of the [ReX(bipy)(CO)$_3$] series, [Re(bipy)(CO)$_3$(sol)]$^+$ was prepared as an intermediate by halide precipitation and in a consecutive step the ligands X = $OH_2$ (**4**), $SCN^-$ (**5**) or $CN^-$ (**6**) were introduced. Treatment of **4** with only half an equivalent of cyanide gave the dinuclear complex **7** in which two Re centres are linked by a cyanide bridge with a Re–Re distance of 5.4 Å.[22]

**Structures:** All complexes depict an octahedral ligand arrangement with a facial tricarbonyl moiety, a bidentate diimine ligand and an anion X. The structure of the Tc surro-

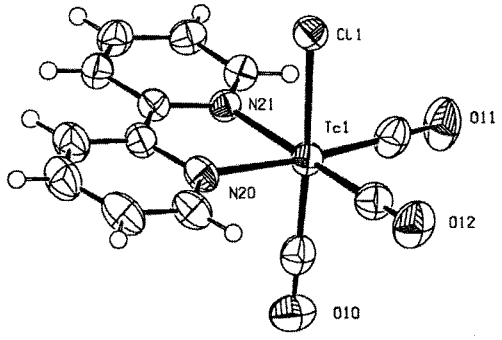


Figure 1. ORTEP drawing of one of the two independent molecules of [TcCl(bipy)(CO)$_3$] (**3**).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gate **3** of the original photocatalyst **1** is shown in Figure 1 and complex **10** with the most extended ligand dppz in Figure 2. In all cases the two equatorial carbonyl ligands, the rhenium centre and aromatic rings of the diimine ligand are in a nearly ideal planar arrangement. Bond lengths and angles around the metal centres (see data deposited in The Cambridge Crystallographic Centre) are similar for all structures and comparable to those in closely related compounds.[23–25]

For the biquinoline (biq) complex **11** the usual planar arrangement of metal centre, diimine ligand and equatorial CO's was not observed. The aromatic rings of biq are displaced from the otherwise favoured $Re(CO)_2$- plane by 23 and 12°, respectively, due to steric strain between the hydrogen atoms of the outer aromatic rings and the equatorial carbonyl ligands (Figure 3). Similar biq complexes show comparable structural features.[26] The different twist angles for the two quinoline rings seem to be an effect of crystal packing since only six $^1H$ NMR signals are observed, indicating equivalence for the biq rings on the NMR timescale in solution.

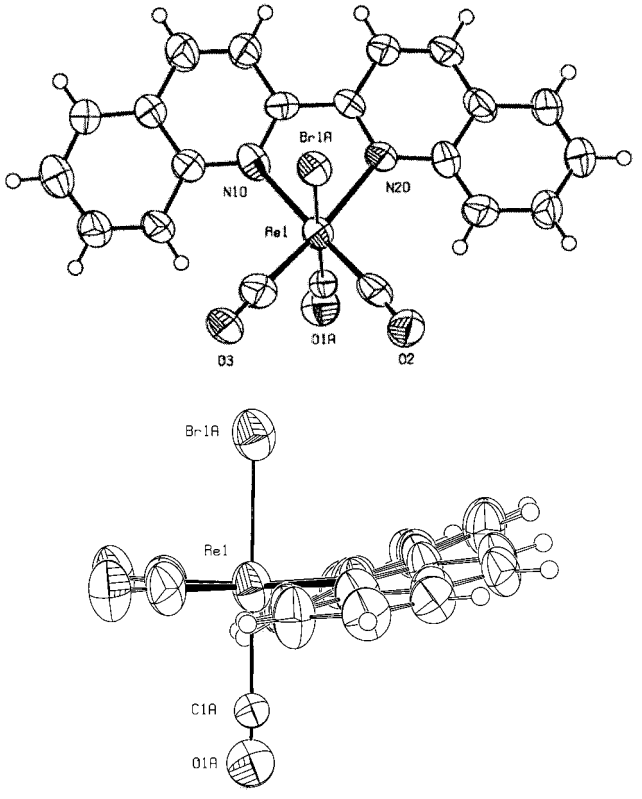

Figure 3. ORTEP drawings of a top and side view of **11**.

**Spectroscopic Properties:** Table 1 summarises analytical data obtained for the [ReX(bipy)$(CO)_3$] series of complexes. Variation of ligand $X^{(-)}$ causes clear effects, but a correlation between $X^{(-)}$ and the spectroscopic or electronic data of the corresponding complexes is not readily obvious. The exchange of $Br^-$ for water results in the formation of the cationic complex **4**. As a consequence of its charge, complex **4** has the series' lowest reduction potential and its light absorption shifts towards higher energy, as it is more difficult to excite an electron. The π- backbonding is reduced in **4** and the IR vibrations $\nu_{CO}$ shift to higher wavenumbers. The mono-cation **7** fits in this series with respect to the $\nu_{CO}$ frequencies, however, $E_{1/2}$ is larger than for example **5**. Considering $\nu_{CO}$, the thiocyanate complex **5** appears to be about as low in electron density as **4**, yet its visible absorption is shifted the most towards lower energies. The lowest carbonyl vibration frequency of the series is observed for the cyano complex **6**. This indicates high electron density on $Re^I$, but is in contrast to the low wavelength of visible light absorption found for **6**.

[a] In DMF solution. [b] KBr pellets. [c] In DMF solution containing 0.1 M $NBu_4PF_6$.

Much larger differences in spectroscopic properties are observed when the diimine ligand is altered (Table 2). The carbonyl stretching frequencies vary by only about ±5 $cm^{-1}$ for all the complexes, thus, the electron density on $Re^I$ does not seem to be as greatly affected as in the case of the [ReX(bipy)$(CO)_3$] series. The differences in the spectroscopic properties stem from the decreased energy of the diimine's LUMO when going to larger aromatic systems or heteroatom substitution.[1,16] The shift in $\lambda_{max}$ towards smaller energies causes a larger part of the absorption to be in the visible spectrum for complexes like **10**, **11** or **15** (Figure 4). While all other compounds are orange yellow solids, **11** and **15** are deep red and dark blue-green, respectively. For **11**, this might be explained by the effect of the unusual coordination geometry on the electronics of the molecule. In the case of **15**, the exceptionally low-lying, par-

ticularly stabilised LUMO of this ligand has already been reported to cause the unusual absorption properties of abpy- complexes.[27]

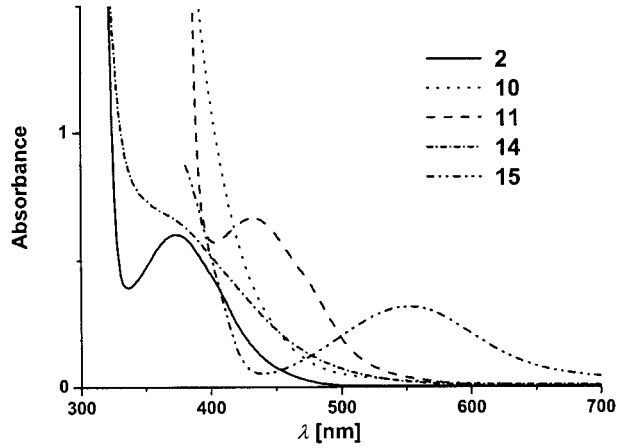

Figure 4. Absorption spectra for different [ReBr(diimine)(CO)$_3$] complexes in DMF (all solutions 0.2 mM).

According to Table 2, not all of the complexes exhibit room temperature fluorescence in DMF when irradiated with light between 350 and 450 nm (Figure 5). The emission maxima are between 520 and 585 nm for **2**, **8**, **9**, **10** and **12**, but **11**, **13**, **14** and **15** do not fluoresce. This behaviour is rationalised in **11** and **15** by the small energy gap between ground and excited states as indicated by the high values of $\lambda_{max}$. Accordingly, radiationless decay to the ground state will be fast in accordance with the energy gap law.[18] Other reasons must account for the absence of fluorescence in **13** and **14** as the energy gap is similar to the structurally related complexes **2** and **8**, respectively. The emission of the dppz complex **10** is observed at much lower wavelengths (520 nm) than that of all other fluorescing complexes of this study. Because of the special nature of the dppz ligand, both diimine and phenazine centred excited states are theoretically possible,[28] resulting in the observation of MLCT or LC emissions, respectively. It was found in a recent study of closely related complexes of [Re(CO)$_3$Cl] with 11-substituted dppz that the ligand-centred emission dominates for two 11-X-dppz complexes of rhenium tricarbonyl,[25] thus explaining the unusual emission behaviour observed for **10**.

**Electrochemistry:** Reversible, one-electron reduction is observed for all complexes except **12**. This process has been assigned to a ligand-centred reduction resulting in the formation of what is best described as a rhenium(I) organic radical anion species [ReX(CO)$_3$(diimine$^{-}$)].[11] In agreement with the spectroscopic properties, the exchange of the ligand X influences the reduction potential $E_{1/2,red}$ of the complexes far less than the variation of the diimine ligand (Table 1 and Table 2).

Factors changing $E_{1/2,red}$ are the overall charge of the complex and the size of the aromatic system of the diimine. In the [ReX(CO)$_3$bipy] series, cationic **4** is the one most easily reduced. Similarly, the reduction of the cationic dinuclear cyano complex **7** is more facile compared to, for example, the neutral complex **6**. It is furthermore easier to place an additional electron into the LUMO of a large aromatic ligand, as seen for the [ReBr(CO)$_3$(diimine)] series for which the reduction potential of the complexes increases with the size of the diimine ligand.

Remarkable redox behaviour was found for **14** and **15**. Complex **15** shows a very high reduction potential of $E_{1/2,red}$ = +50 mV as the additional electron is localised in its unusual LUMO at the azo-bridge.[29] The electrochemistry of **14**, its molecular structure shown in Figure 6, is special since the phd ligand is formally an *ortho*-benzoquinone system. The first reduction already occurs at –15 mV and generates a strongly stabilised semiquinone radical. The diolate is formed at –755 mV in a second reversible step. Increasing concentrations of $H_2O$ shift the second reduction to higher potentials, as direct two-electron reduction to the diol is known to occur in the presence of protons (Figure 7).[30] The phd complex **15** thus offers the possibility of a reversible storage of two electrons within a range of accessible potentials, which is unique within this series of rhenium diimine complexes.

| **12** | 20.5 | –1250 | 540 |

**Reductive Fluorescence Quenching:** The original work on the "Strasbourg system" suggested that the primary events of reaction are photoexitation of the complex followed by the reaction of the thexi- state with the electron donor.[8,10,21] It was therefore of interest how the synthetic modifications of the catalyst influence the ability of the excited complexes to react with the standard electron donor TEOA.

$$I_0/I = 1 + k_{q\ \tau}\,[Q] = 1 + K_{SV}\,[Q]$$

Fluorescence quenching is a good way to probe the reactions of the excited state with electron donors. For all fluorescing complexes, Stern–Volmer kinetics are observed for the reductive quenching by TEOA in DMF solutions. According to the Stern–Volmer equation, constants $K_{SV}$ can be determined from plots of $(I_0/I) - 1$ versus quencher concentration (Figure 8).[18]

Table 3 summarises the determined $K_{SV}$ values, which are indicators for the "success rate" of forming the reduced complex after photoexcitation in the presence of a quencher. The variations of diimine or $X^-$ cause $K_{SV}$ to vary by a factor of up to five. To explain this result, measurements of the excited state lifetimes $\tau$ would be necessary to estimate differences in the bimolecular quenching reaction rate $k_q$. It is known that the $k_q$ of this reaction can vary by at least up to a factor of 2.5 for a series of much more closely related [ReX(CO)$_3$bipy] compounds.[13] Unfortunately, we did not have access to an instrument for fluorescence decay measurements.

A number of experiments were carried out to probe the possibility of finding a different solvent/donor combination for which reductive fluorescence quenching is observed. Fluorescence quenching of **2** by either TEOA or TEA is also found in acetonitrile or acetonitrile/water solutions, but the $K_{SV}$ values found in these systems are smaller than in DMF by a factor of 2 and 5, respectively. The use of ternary amines as sacrificial electron donors restricts the reactions to alkaline conditions. This is a particular disadvantage for the goal of shifting the reactivity from $CO_2$ to $H_2O$ reduction, as $H_2O$ reduction is thermodynamically more difficult under basic or neutral conditions. Therefore other, nonbasic electron donors with irreversible oxidation between +0.5 and +1 V and solubility in DMF, MeCN or $H_2O$ were studied. Well-suited candidates are oxalic acid, vitamin C, cystamine or EDTA.[31] None of these donors caused any quenching of [ReX(diimine)(CO)$_3$] fluorescence in solution, although all meet the requirements of a thermodynamically accessible, irreversible oxidation.[31]

**Photochemical $CO_2$ Reductions:** Experiments to study the photocatalytic activity of these complexes in the Strasbourg system were carried out under conditions similar to the reported set-up.[10] Only CO with no detectable quantities of $H_2$ was found in the headspace of the reaction solutions.

The time course of produced CO per mol of catalyst for the [ReX(bipy)(CO)$_3$] series and the technetium homologue **3** are shown in Figure 9. All complexes of this series are active catalysts, though at very different rates (Table 4). It is most interesting to note that after a significant change of the metal centre — from rhenium to technetium — catalytic

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

activity was retained. The thiocyanato complex **5** is a better catalyst than the original complexes **1** and **2** as it combines a rate as fast as **1**, but with improved long-term stability, as the turnover rate for **5** does not change over the first 2 h. The reason for this enhanced stability might be the suppression of the formation of the catalytically inefficient formato complex [Re(HCOO)(bipy)(CO)$_3$][10] as an undesired side product in reactions catalysed by **1** or **2**. The complexes of the larger diimines (**8**, **9** and **10**) are all active photocatalysts but at smaller rates than **2** (Table 4). No CO or any other gaseous products were detected for reactions using **11**, **13**, **14** or **15**. Thus, there is a strict correlation between the detection of room temperature fluorescence and catalytic activity: all fluorescing complexes are active catalysts for photocatalytic $CO_2$ reduction while the others are not.

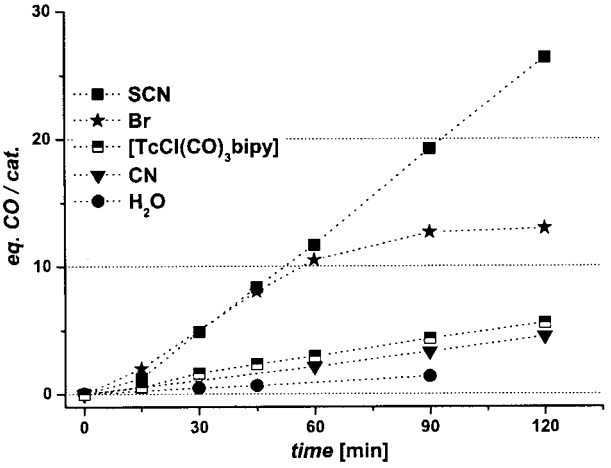

Figure 9. Formation of CO. Reactions with different [ReX(bipy)(CO)$_3$] and [TcCl(bipy)(CO)$_3$(bipy)] complexes.

Table 4. Formation of CO for reactions of photocatalysts of the [ReX(CO)$_3$(bipy)] series and [TcCl(bipy)(CO)$_3$].

| Catalyst | CO after 30 min. [equiv./cat.] | CO after 120 min. [equiv./cat.] |
|---|---|---|

| **6** | 1.1[a] | 4.5 |
| **7** | 0.6[a] | 2.6 |
| **8** | 4.8 | 11.5 |
| **9** | 0.5 | 1.1 |
| **12** | 2.2 | 7.7 |

[a] Extrapolated values.

In agreement with the fluorescence quenching experiments described earlier, the same experiments with different donors such as cystamine or vitamin C in DMF gave no CO. Furthermore, it has been claimed in the literature that the system would switch from $CO_2$ to $H_2O$ reduction if the reaction was carried out in a THF/water mixture instead of DMF.[32] We tried to reproduce this result multiple times with our catalysts but no product at all, neither $H_2$ nor CO, was detected in a THF/water (4:1) mixture. On the other hand, about half the rate of CO production was observed with **2** in DMF/10% water.

These results support the original catalytic mechanism proposed by the Strasbourg group.[10] The well-established initial step is the absorption of a visible-light photon by the catalyst [Re$^{I}$X(diimine)(CO)$_3$] and subsequent MLCT to form the excited state [Re$^{II}$X(diimine$^{-}$)(CO)$_3$]. This step occurs for all complexes discussed here but for **11**, **13**, **14** and **15** nonradiative relaxation pathways to the ground state are most probably so fast that no consecutive reactions can occur, as the absence of fluorescence for these compounds indicates. Hence, they are inactive as Strasbourg catalysts regardless of their electro- or photochemical properties.

According to our results, there is no evidence to support a carboxylate-bridged rhenium dimer as a key intermediate, as proposed in a recent study,[14] as this is in disagreement with the pronounced influence observed for the terminal ligands in the [ReX(bipy)(CO)$_3$] series. Also, the different compounds act both as photoactive and catalytic centres for the reduction of $CO_2$, but none show any reactivity to reduce water, as has been claimed before.[32]

## Conclusions

We were able to show in this study that the [ReX(bipy)(CO)$_3$] catalysts could easily be modified for the Strasbourg system. The catalytic activity for photocatalytic reduction of $CO_2$ is retained in most cases or even enhanced, even though spectroscopic and electrochemical properties of the complexes are substantially altered. There are, however, limitations to the degree to which the diimine ligand can be varied. For a group of [ReBr(CO)$_3$(diimine)] compounds, catalytic activity is lost together with the ability of these complexes to fluoresce, indicating that a sufficiently long excited state life-time is of course a key prerequisite for photoreactivity. While many of the rhenium complexes are able to catalyse the two-electron photoreduction of $CO_2$, none show any reactivity for the reduction of the much more important substrate $H_2O$. Nevertheless, the unusual reactivity of [ReX(CO)$_3$(diimine)] compounds, observed once more in this study, justifies the idea that they should be considered as promising alternatives to the [Ru(diimine)$_3$]$^{2+}$ class of compounds.

## Experimental Section

**General:** All chemicals were of reagent grade and used without further purification. Water was doubly distilled before use. Synthetic reactions were carried out under $N_2$ using standard Schlenk techniques. Abbreviations of the diimine ligands are according to Scheme 2. The complexes [ReBr(CO)$_5$],[33] (NEt$_4$)$_2$[ReBr$_3$(CO)$_3$][34] and (NEt$_4$)$_2$[TcCl$_3$(CO)$_3$],[35] [ReCl(bipy)(CO)$_3$][36] (**1**), [ReBr(bipy)(CO)$_3$][36] (**2**), [ReBr(phen)(CO)$_3$][37] (**8**), [ReBr(biq)(CO)$_3$][38] (**11**) as well as the ligands abpy,[39] dpq,[40] dppz[41] and phd[42] were synthesised according to published procedures. Preparations of the complexes **4**,[43] **5**,[44] **6**,[45] **7**,[45] **13**[37] and **15**[46] have been reported before in the literature but for this study these compounds were ob-

tained via the different, in most cases more facile, routes described below.

***Caution!*** $^{99}$Tc is a weak $\beta$-emitter with a half-life of $2.12 \cdot 10^5$ years. Although radiation from small amounts of material is absorbed completely by the walls of the glassware, reactions should only be carried out in specially equipped laboratories and under well-ventilated hoods.

**[$^{99}$TcCl(bipy)(CO)$_3$] (3):** $(NEt_4)_2[^{99}TcCl_3(CO)_3]$ (33 mg, 0.06 mmol) was stirred in $H_2O$ (5 mL) for 2 h, bipy (15.5 mg, 0.1 mmol) was added, dissolved in a mixture of EtOH (1 mL) and $H_2O$ (2 mL). After 30 min a yellow precipitate started to form, which was filtered off after a reaction time of 12 h, washed with diethyl ether and dried in vacuo. Yield: 18 mg (80%). IR (KBr): $\tilde{\nu}_{CO}$ = 2031 (s), 1944 (s), 1920(s); $\tilde{\nu}_{bipy}$ = 1601 (m), 1469(m), 1441 (m), 771 (m) cm$^{-1}$. $^1$H NMR ([D$_4$]MeOH): $\delta$ = 9.03 (br., 2 H), 8.63 (d, 2 H), 8.28 (m, 2 H), 7.75 (m, 2 H) ppm. $^{99}$Tc NMR ([D$_4$]MeOH): $\delta$ = –1094.0 (s) ppm.

**[Re(H$_2$O)(bipy)(CO)$_3$](OTf) (4):** Complex **2** (150 mg, 0.3 mmol) was dissolved in acetone (15 mL) and AgOTf (76.1 mg, 1 equiv.) in acetone (5 mL) was added. The mixture was heated to 70 °C for 2 h. AgBr was filtered off and the solvent was removed in vacuo. The yellow residue was suspended in water (20 mL) and stirred at room temperature for 3 h. Insoluble parts were filtered off and the yellow solution was lyophilised to obtain the yellow, slightly hygroscopic product. Yield: 105 mg (60%). $\lambda_{max}$ (DMF): 350 nm (sh, $\varepsilon$ = 4000), 553 nm ($\varepsilon$ = 1500). IR (KBr): $\tilde{\nu}_{CO}$ = 2036 (s), 1918 (s); $\tilde{\nu}_{bipy}$ = 1604 (m), 1475 (m), 1447 (m), 771 (m); $\tilde{\nu}_{OTf}$ = 1291 (m), 1230 (m), 1179 (m) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 426.87 [(M – H$_2$O)$^+$]. $^1$H NMR ([D$_4$]MeOH): $\delta$ = 9.17 (m, 2 H), 8.70 (m, 2 H), 8.39 (m, 2 H), 7.82 (m, 2 H) ppm. $^{13}$C NMR ([D$_4$]MeOH): $\delta$ = 155.3, 142.9, 129.7, 125.8 ppm. $C_{14}H_{10}F_3N_2O_7ReS_1$ (593.51): calcd. C 28.33, H 1.70, N 4.72; found C 28.99, H 1.79, N 5.08.

**[Re(SCN)(bipy)(CO)$_3$] (5):** **2** (50.6 mg, 0.1 mmol) was dissolved in acetone (5 mL) and AgOTf (17.1 mg, 1 equiv.) in acetone (2 mL) was added. The mixture was heated to 70 °C for 2 h. AgBr was filtered off and the solvent removed in vacuo. The residue was stirred MeOH (10 mL) for 1 h. KSCN (20 mg, 2 equiv.), dissolved in $H_2O$ (2 mL), was added and the mixture heated to 70 °C for 4 h to obtain a clear yellow solution. The product precipitated after 1 d at 4 °C. The yellow compound was filtered off, washed with cold $H_2O$, MeOH and ether and dried in vacuo. Yield: 30 mg (60%). $\lambda_{max}$ (DMF): 376 nm ($\varepsilon$ = 2500). $\lambda_{em}$ (DMF): 580 nm. IR (KBr): $\tilde{\nu}_{SCN}$ = 2093 (s); $\tilde{\nu}_{CO}$ = 2020 (s), 1928 (s), 1914 (s); $\tilde{\nu}_{bipy}$ = 1602 (m), 1471(m), 1444 (m), 765 (m) cm$^{-1}$. ESI-MS (acetone): *m*/*z* (%) = 426.87 [(M – SCN)$^+$]. $^1$H NMR ([D$_6$]acetone): $\delta$ = 9.15 (m, 2 H), 8.77 (m, 2 H), 8.42 (m, 2 H), 7.86 (m, 2 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 154.4, 141.6, 129.1, 125.3 ppm.

**[Re(CN)(bipy)(CO)$_3$] (6):** $(NEt_4)_2[ReBr_3(CO)_3]$ (100 mg, 0.13 mmol) was dissolved in $H_2O$ (5 mL) and $AgNO_3$ (66.2 mg, 3 equiv.) in $H_2O$ (3 mL) was added. The solution was stirred at room temperature for 30 min before AgBr was removed by filtration. Bipy (20.3 mg, 1 equiv.), dissolved in EtOH (2 mL) was added. HPLC analysis confirmed the quantitative formation of $[Re(H_2O)(bipy)(CO)_3]^+$ after 12 h. The addition of KCN (25.4 mg, 3 equiv.) and 20 h of stirring at 100 °C, resulted in the quantitative conversion to **6**, as detected by HPLC. The solvent was removed in vacuo and the product was obtained by extraction of the residue with three 5-mL portions of THF. Yield: 45 mg (75%). $\lambda_{max}$ (DMF): 354 nm ($\varepsilon$ = 2300). $\lambda_{em}$ (DMF): 540 nm. IR (KBr): $\tilde{\nu}_{CN}$ = 2117 (w); $\tilde{\nu}_{CO}$ = 2006 (s), 1878 (s); $\tilde{\nu}_{bipy}$ = 1603 (m), 1473 (m), 1445 (m), 775 (m) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 453.60 [M$^+$]. $^1$H NMR ([D$_6$]acetone): $\delta$ = 9.07 (d, 2 H), 8.21 (d, 2 H), 8.07 (m, 2 H), 7.54 (m, 2 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 154.4, 140.8, 128.8, 125.1 ppm.

**[{Re(bipy)(CO)$_3$}$_2$(μ-CN)](ClO$_4$) (7):** $(NEt_4)_2[ReBr_3(CO)_3]$ (100 mg, 0.13 mmol) was dissolved in $H_2O$ (10 mL) and $AgClO_4$ (80.8 mg, 3 equiv.) was added. AgBr was removed after 30 min by filtration. Bipy (20.3 mg, 1 equiv.), dissolved in EtOH (5 mL) was added. After 20 h at room temperature $[Re(bipy)(CO)_3(H_2O)]^+$ formed quantitatively, and KCN (4.2 mg, 0.5 equiv.) in $H_2O$ (2 mL) was added. After 2 h at 100 °C, a yellow precipitate started to form which was filtered off after 20 h, washed with $H_2O$ and diethyl ether and dried in vacuo. Yield: 28 mg (45%). $\lambda_{max}$ (DMF): 363 nm ($\varepsilon$ = 2000). $\lambda_{em}$ (DMF): 535 nm. IR (KBr): $\tilde{\nu}_{CN}$ = 2151 (w); $\tilde{\nu}_{CO}$ = 2025 (s), 1910 (s), 1896 (s); $\tilde{\nu}_{bipy}$ = 1605 (m), 1473 (m), 1446 (m), 771 (m); $\tilde{\nu}_{ClO4}$ = 1121 (m) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 879.53 [M$^+$]. $^1$H NMR ([D$_6$]acetone): $\delta$ = 8.83 (br., 4 H), 8.00 (br., 4 H), 7.60 (br., 4 H), 7.41 (br., 4 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 154.3, 154.1, 142.2, 141.8, 129.0 (2C), 125.9, 125.7 ppm.

**[ReBr(dpq)(CO)$_3$] (9):** A procedure similar to the published method for the preparation of [ReBr(phen)(CO)$_3$] was applied.[37] A suspension was prepared consisting of $[ReBr(CO)_5]$ (50 mg, 0.12 mmol) and dpq (28.5 mg, 1 equiv.) in petroleum ether (10 mL, boiling range 100–130 °C). The suspension was heated to 100 °C for 2 h to obtain the product as a yellow precipitate. The powder was filtered off, washed with portions of petroleum ether and diethyl ether and then dried in vacuo to obtain the product as a yellow powder. Yield: 70 mg (quantitative). $\lambda_{max}$ (DMF): 400 nm (sh, $\varepsilon$ = 2500). $\lambda_{em}$ (DMF): 585 nm. IR (KBr): $\tilde{\nu}_{CO}$ = 2025 (s), 1948 (s), 1902 (s); $\tilde{\nu}_{dpq}$ = 1402 (m), 1384 (m), 820 (w), 729(w), 631 (w) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 530.40 [M – Br + CO]$^+$, 502.80 [M – Br]$^+$. $^1$H NMR ([D$_6$]acetone): $\delta$ = 9.96 (m, 2 H), 9.82 (m, 2 H), 9.38 (s, 2 H), 8.45 (m, 2 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 155.8, 147.8, 136.5, 128.3 ppm. $C_{17}H_8BrN_4O_3Re$ (582.39): calcd. C 35.06, H 1.38, N 9.62; found C 35.38, H 1.53, N 9.69.

**[ReBr(dppz)(CO)$_3$] (10):** The same procedure as for $[ReBr(dpq)(CO)_3]$ was applied, using $[ReBr(CO)_5]$ (50 mg, 0.12 mmol) and dppz (33.8 mg, 1 equiv.), to obtain the complex as an orange powder. Yield: 50 mg (65%). $\lambda_{max}$ (DMF): 400 nm (sh, $\varepsilon$ = 5000). $\lambda_{em}$ (DMF): 520 nm. IR (KBr): $\tilde{\nu}_{CO}$ = 2018 (s), 1918 (s), 1890 (s); $\tilde{\nu}_{dppz}$ = 1493 (m), 1418 (m), 1384 (m), 1360 (m), 822 (w), 773 (w), 729 (w) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 580.53 [M – Br + CO]$^+$, 553.00 [M – Br]$^+$. $^1$H NMR ($CDCl_3$): $\delta$ = 10.04 (m, 2 H), 9.88 (m, 2 H), 8.47 (m, 2 H), 8.08 (m, 2 H), 7.26 (m, 2 H) ppm. $C_{21}H_{10}BrN_4O_3Re$ (632.45): calcd. C 39.88, H 1.59, N 8.86; found C 39.53, H 1.77, N 8.58.

**(NEt$_4$)[ReBr(Hdcbipy)(CO)$_3$] (12):** $(NEt_4)_2[ReBr_3(CO)_3]$ (154 mg, 0.2 mmol) was dissolved in $H_2O$ (15 mL) and $H_2$dcbipy (53.7 mg, 1.1 equiv.) was added as a solid. The pH of the solution was raised to pH ca. 6–7 by the careful addition of 10 mM NaOH. The mixture was stirred for 2 d at room temperature and some yellow precipitate formed, which was filtered off. The filtrate was lyophilised, triturated three times with $CH_2Cl_2$ (5 mL) to remove $NEt_4Br$ and then dried in vacuo. Yield: 75 mg (50%). $\lambda_{max}$ (DMF): 360 nm (sh, $\varepsilon$ = 3000). $\lambda_{em}$ (DMF): 540 nm. IR (KBr): $\tilde{\nu}_{CO}$ = 2024 (s), 1896 (s); $\tilde{\nu}_{dcbipy}$ = 1719 (w), 1619 (m), 1551 (w), 1366 (m), 1289 (m), 1071 (w), 766 (m), 682 (m) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 468.40 [(M – Br – COOH – H)$^-$]. $^1$H NMR ($D_2O$/NaOH): $\delta$ = 9.02 (m, 2 H), 8.65 (s, 2 H), 7.81 (m, 2 H) ppm. $^{13}$C NMR ($D_2O$/NaOH): $\delta$ = 151.6, 124.2, 120.7 ppm.

**[ReBr(bpm)(CO)$_3$] (13):** $(NEt_4)_2[ReBr_3(CO)_3]$ (385 mg, 0.5 mmol) was dissolved in $H_2O$ (20 mL) and bpm (87 mg, 1.1 equiv.), dissolved in EtOH (2 mL) was added. The mixture was stirred for 2 d at room temperature, after which a fine orange precipitate had

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

formed. The solid was filtered off, washed with $H_2O$, cold EtOH and ether, and dried in vacuo. Yield: 210 mg (80%). $\lambda_{max}$ (DMF): 383 nm ($\varepsilon$ = 2500). IR (KBr): $\tilde{\nu}_{CO}$ = 2030 (s), 1931 (s), 1906 (s); $\tilde{\nu}_{bpm}$ = 1575 (m), 1547 (w), 1407 (s), 834 (w), 755 (w) cm$^{-1}$. ESI-MS ([D$_6$]acetone/MeOH): *m*/*z* (%) = 508.00 [M$^+$]. $^1$H NMR ([D$_6$]-acetone): $\delta$ = 9.41 (dd, 2 H), 9.35 (dd, 2 H), 7.98 (dd, 2 H). $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 162.0, 161.4, 125.6 ppm. $C_{11}H_6BrN_4O_3Re$ (508.30): calcd. C 25.99, H 1.19, N 11.02; found C 26.24, H 1.05, N 10.87.

**[ReBr(phd)(CO)$_3$] (14):** The same procedure as for [ReBr(bpm)-(CO)$_3$] was applied, using $(NEt_4)_2[ReBr_3(CO)_3]$ (500 mg, 0.65 mmol) and phd (163 mg, 1.2 equiv.) to isolate the orange complex. Yield: 350 mg (95%). $\lambda_{max}$ (DMF): 375 nm (sh, $\varepsilon$ = 3000). IR (KBr): $\tilde{\nu}_{CO}$ = 2033 (s), 1943 (s), 1885 (s); $\tilde{\nu}_{phd}$ = 1703 (m), 1573 (w), 1427 (m), 1298 (w), 1026 (w), 828 (w), 727 (w) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 512.73 [(M – Br + MeOH)$^+$], 480.73 [(M – Br)$^+$]. $^1$H NMR ([D$_6$]acetone): $\delta$ = 9.34 (dd, 2 H), 8.81 (dd, 2 H), 8.05 (dd, 2 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 158.0, 139.0, 129.8 ppm. $C_{15}H_6BrN_2O_5Re$ (560.33): calcd. C 32.15, H 1.08, N 5.00; found C 32.37, H 1.12, N 5.08.

**[ReBr(abpy)(CO)$_3$] (15):** The same procedure as for [ReBr(bpm)(CO)$_3$] was applied, using $(NEt_4)_2[ReBr_3(CO)_3]$ (76 mg, 0.1 mmol) and abpy (27 mg, 1.5 equiv.) to isolate the violet-blue compound. Yield: 50 mg (95%). $\lambda_{max}$ (DMF): 361 nm ($\varepsilon$ = 5000), 553 nm ($\varepsilon$ = 1500). IR (KBr): $\tilde{\nu}_{CO}$ = 2020 (s), 1924 (s), 1900 (s); $\tilde{\nu}_{abpy}$ = 1465 (w), 1433 (m), 1370 (w), 797 (m) cm$^{-1}$. ESI-MS (MeOH): *m*/*z* (%) = 454.67 [M – Br]$^+$. $^1$H NMR ([D$_6$]acetone): $\delta$ = 9.33 (m, 1 H), 8.96 (m, 1 H), 8.87 (m, 1 H), 8.57 (td 1 H), 8.20 (br., 2 H), 8.00 (br., 1 H), 7.85 (br., 1 H) ppm. $^{13}$C NMR ([D$_6$]-acetone): $\delta$ = 152.7, 149.7, 142.7, 140.3, 131.4, 130.9, 129.5, 115.7 ppm. $C_{13}H_8BrN_4O_3Re$ (534.34): calcd. C 29.22, H 1.51, N 10.49; found C 29.61, H 1.43, N 10.56.

**Physical Measurements:** UV/Vis spectra were measured with a Cary 50 spectrometer with solution samples in 1-cm quartz cells. If necessary, cells with silicon septa lids were used to keep samples under an inert gas atmosphere during measurements. Fluorescence measurements were performed with a Perkin–Elmer LS50B fluorescence spectrometer with argon purged solution samples in 1-cm cells. IR spectra were recorded with a Bio-Rad FTS-45 spectrometer with samples in compressed KBr pellets. $^1$H NMR spectra were recorded with Varian Mercury and Varian Gemini-2000 spectrometers ($^1$H at 199.97 MHz and 300.08 MHz, respectively) and $^{13}$C NMR spectra were recorded with Varian Gemini-2000 and Bruker DRX500 spectrometers ($^{13}$C at 75.47 MHz and 125.81 MHz, respectively). The chemical shifts are reported relative to residual solvent protons as a reference. $^{99}$Tc NMR spectra were recorded with a Varian Gemini-2000 spectrometer ($^{99}$Tc resonance 67.40 MHz), referenced to $[^{99}TcO_4]^-$. Electrospray ionisation mass spectra (ESI-MS) were recorded with a Merck–Hitachi M-8000 spectrometer, reported are the values of the $^{187}$Re isotope. Elemental analyses were performed with a Leco CHNS-932 elemental analyser. It was found that cyano- and thiocyanato compounds analysed by this instrument often show elemental analyses differing greatly from the expected calculated percentages. This analytical problem was also observed for commercial, analytical grade chemicals like NaCN, $K_3[Fe(CN)_6]$ or CuSCN. Electrochemical measurements were carried out in DMF containing 0.1 M TBA $PF_6$ as conducting electrolyte. A Metrohm 757 VA Computrace electrochemical analyser was used with a standard three-electrode setup of glassy carbon working and auxiliary electrodes and a Ag/AgCl reference electrode. All potentials are given vs. Ag/AgCl (NHE: +221 mV). Gas chromatograms were recorded with a Varian CP-3800 gas chromatograph with helium as the carrier gas. The permanent gases CO, $N_2$, $O_2$ and $H_2$ were separated by a 3 m × 2 mm column packed with Varian molecular sieves 13X. The gases were detected using a thermal conductivity detector (Varian). Calibrations were performed by the injection of known quantities of pure gases.

**Photochemical Carbon Dioxide Reductions:** Reactions catalysed by [Re(CO)$_3$(diimine)X] complexes were tested in 50 mL septum capped Schlenk tubes. Exact volumes were determined gravimetrically. 10 mL of a solution containing TEOA (1 M) and the catalyst (1 mM) in DMF were prepared, wrapped in black foil and degassed using a $CO_2$-purged Schlenk-line. The mixture was equilibrated under 1.5 bar $CO_2$ pressure for 15 min and then transferred to a dark room for illumination. The light source was a Leica Pradovit S AF slide projector equipped with a 250-W Osram Xenophot HLX lamp. The light was filtered by a 400-nm cut-off filter (Schott GG 400) before reaching the sample at 40 cm distance from the projector. Light intensities illuminating the sample were determined by a TES 1332A luxmeter to be 46.000 lux. 100-μL gas samples were

drawn from the headspace above the solution and injected into the GC-TCD gas analyser.

**X-ray Diffraction Studies:** Suitable crystals were covered with Paratone N oil, mounted on top of a glass fibre and immediately transferred to a Stoe IPDS diffractometer. Data was collected at 183(2) K using graphite-monochromated Mo radiation (0.71073 Å). Data was corrected for Lorentz and polarisation effects as well as for absorption. Structures were solved with direct methods using SHELXS-97[47] or SIR97[48] and were refined by full-matrix least-squares methods on $F^2$ with SHELXL-97.[49] ORTEP plots were generated by the PLATON software package[50] and are drawn at 50% probability. The crystal data and refinement parameters of the presented structures are summarised in Table 5.

CCDC-299061 to -299065 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Centre via www.ccdc.cam.ac.uk/datarequest/cif.

## Acknowledgments

We would like to thank Prof. Jon Dilworth and his group for the possibility to carry out initial $CO_2$ reduction experiments at the Inorganic Chemistry Laboratory of the University of Oxford, Great Britain. H. C. Starck, Berlin, Germany, generously donated rhenium metal to support our research.

# A Cationic (N-Heterocyclic carbene)silver Complex as Catalyst for Bulk Ring-Opening Polymerization of L-Lactides

**Manoja K. Samantaray,[a] Vimal Katiyar,[b] Dipankar Roy,[a] Keliang Pang,[c] Hemant Nanavati,[b] Raji Stephen,[a] Raghavan B. Sunoj,*[a] and Prasenjit Ghosh*[a]**

**Keywords:** Carbenes / DFT studies / Functionalized NHC / Ring-opening polymerization (ROP) / Organometallic catalysis / Silver

Synthetic, theoretical, and catalysis studies of a cationic functionalized N-heterocyclic carbene complex of silver, namely [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$-Ag]$^+$Cl$^-$ (**1b**), is reported. Specifically, **1b** was synthesized by the reaction of 1-isopropyl-3-(*N*-phenylacetamido)imidazolium chloride (**1a**) with $Ag_2O$ in 64 % yield; **1a** was synthesized by the alkylation reaction of 1-isopropylimidazole with *N*-phenyl chloroacetamide in 90 % yield. The molecular structure of **1b** was determined by X-ray diffraction studies and was found to be active for polymerization of L-lactide at elevated temperatures under solvent-free melt conditions to give polylactide of moderate molecular weight with narrow molecular weight distribution. Density functional theory studies of the cationic species **2b**, derived from NHC silver complex **1b**, were employed to obtain an understanding of the structure, bonding, and electronic features of the molecule. Bonding in complex **2b** has been probed with the help of charge decomposition analysis (CDA), the atoms in molecules (AIM) approach as well as natural bond orbital (NBO) methods. The Ag–NHC bond has been found to be more covalent with NHC acting as an effective σ-donor. The π-back-bonding from the metal atom to the ligand was found to be negligible. It has been noticed that the imidazole rings remain nearly orthogonal with respect to each other, in contrast to the experimental geometry. Intramolecular hydrogen bonds as well as Ag···O interaction involving the carbonyl oxygen atoms have been identified as additional stabilizing factors contributing towards the lower energy conformer of **2b** compared to the corresponding planar geometry.

## Introduction

Ever since the first successful isolation of a stable singlet carbene by Arduengo,[1] there has been phenomenal growth in the field of N-heterocyclic carbene (NHC) chemistry.[2] As a consequence, the N-heterocyclic carbenes have found wide-spread application in chemical catalysis with new catalysts being discovered recently.[3] The growth in NHC chemistry has made a profound impact, particularly in the field of organometallic catalysis, with the NHC-based catalysts exhibiting superior performance over the traditional catalysts in many important transformations. For example, it is now a well-established fact that Grubbs' second-generation ROMP catalyst bearing NHC exhibits better efficiency over the original phosphane-based ruthenium catalyst, $(PCy_3)_2(Cl)_2Ru{=}CHPh$.[4–6] Not surprisingly, the trendy NHCs are fast replacing the phosphanes and are gradually emerging as the designer's choice of ligand in organometallic catalysis. Remarkably, the NHC transition metal complexes have exhibited catalytic activities for a truly impressive range of reactions covering the C–C coupling reaction,[7,8] olefin metathesis,[9] hydrogenation,[10,11] hydroformylation,[12] hydrosilylation,[13] CO/ethylene copolymerization,[14] and hydroboration[15] reactions to name a few. In addition to the newly found successes in organometallic catalysis, the NHCs have shown promise in organocatalysis as potent nucleophilic organic catalysts and are increasingly gaining popularity and acceptance in such roles. Recently, there have been several reports of organocatalysis by NHCs particularly in transesterification reactions[16] and in ring-opening lactide polymerization reactions.[17–19] Both the in-situ generated carbenes as well as the isolable stable singlet N-heterocyclic carbenes have been directly employed in these organocatalysis reactions.

The mainstay of N-heterocyclic carbene chemistry has been its silver complexes, which played an important role in the development of the field of NHCs.[20] The interest in NHC silver complexes is primarily due to it being an effec-

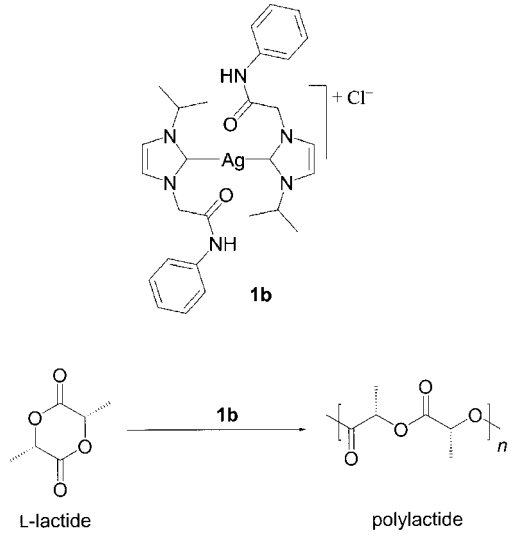
tive transmetallating agent, a property which is being extensively used for synthesizing other desired transition metal complexes. Lin[21] provided a commonly employed methodology for synthesizing the NHC silver complexes using $Ag_2O$, which represents by far the most popular route to these complexes. As an outcome of all the efforts toward designing new N-heterocyclic carbene systems, many silver complexes were synthesized and structurally characterized.[22–25] A notable feature of the silver complexes is their structural diversity in the solid state. For example, an NHC ligand with a sterically demanding mesityl substituent gave a neutral (NHC)AgCl-type complex with a 1:1 ligand/metal ratio, whereas the less bulky variant of the same ligand bearing a methyl substituent gave a cationic $(NHC)_2$-$Ag^+$-type complex with a 2:1 ligand/metal ratio.[26]

Interestingly, apart from its exclusive use in transmetallation reactions, a few reports of the utility of NHC silver complexes in chemical catalysis have appeared lately. For instance, there have been reports of the NHC silver complexes exhibiting catalytic activity in ethyl diazoacetate (EDA) assisted carbene transfer reactions,[27] in transesterification reactions, and in ring-opening lactide polymerization reactions.[28] Thus, for the NHC silver complexes, the focus of research is gradually shifting from being solely used in transmetallation reactions to its applications in chemical catalysis, which has opened up a new frontier of research. As the catalytic applications of NHC silver complexes are relatively less explored, we became interested in investigating the catalytic properties of these complexes.

NHCs are often compared with the tertiary phosphane ligands because of their good σ-donating ability.[29] However, a closer scrutiny based on both theoretical[30–34] and experimental[35,36] results revealed that the NHCs are more strongly σ-donating than the phosphanes.[37] Another notable difference between the two is that the NHCs are generally easier to synthesize but harder to metallate while the reverse is true for phosphanes. In general, the success of NHCs can be attributed partly to their ease of synthetic accessibility and partly to the observed improved air, moisture,[38] and thermal stabilities[39] of the so-called NHC catalysts. The issue of improved stabilities of NHC metal complexes may be related to the nature of the metal–carbene (NHC) bond in these complexes and this requires a detailed theoretical study to gain a better understanding of these complexes. Alongside our main aim of designing new NHC silver complexes for applications in chemical catalysis, we became interested in carrying out a detailed theoretical analysis of our NHC silver complexes in order to gain insight into their reactivity pattern and catalytic potential. In this regard, we have recently communicated a detailed synthetic and theoretical study of a newly designed neutral monomeric NHC silver complex, [1-isopropyl-3-(2-*tert*-butyl-2-oxoethyl)imidazol-2-ylidene]AgCl.[40] In addition to the theoretical understanding, our interest is in the testing of these new NHC silver complexes for catalysis, particularly with regard to ring-opening polymerization (ROP) of L-lactides. Because of ecological reasons, the ROP of L-lactides is of current research interest. The polylactide polymers (PLAs), not only are biodegradable but they can also be generated from renewable resources (i.e. the L- and D-lactide monomers) by a corn fermentation process or from agricultural starch wastes.[41] Because of their good mechanical properties and biocompatibility, the PLAs have found wide utility in medical and pharmaceutical applications.[42,43] As the sequence of stereocenters in the polymer chain has a direct bearing on its mechanical properties, the ring-opening polymerization of cyclic lactides thus enjoys inherent advantage over α-olefin polymerizations that need intricate ligand design for control of polymer tacticity.

Herein, we report the synthesis and structural characterization of a silver complex, namely [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (**1b**), of a new functionalized N-heterocyclic carbene ligand along with a theoretical study. Furthermore, in this contribution we disclose that **1b** effectively catalyzes ring-opening polymerization of L-lactides (Scheme 1) at elevated temperatures under solvent-free melt conditions to give a polylactide polymer of moderate molecular weight with narrow molecular weight distribution.



Scheme 1.

## Results and Discussion

Despite the phenomenal successes of NHCs and NHC metal complexes in chemical catalysis, the NHC silver complexes have so far shown only limited utility as catalysts. Recently, there was a report of NHC silver complexes catalyzing a carbene transfer reaction from ethyl diazoacetate to cyclohexane.[27] On another occasion, Waymouth and Hedrick reported NHC silver complexes as novel carbene delivery agents for ring-opening polymerization of L-lactides and for transesterification reactions.[28] These promising applications of NHC silver complexes in chemical catalysis have opened up a new frontier of research. As this area still remains largely unexplored, we became interested in designing novel N-heterocyclic carbene silver complexes

and testing their catalytic utility in ring-opening polymerization of L-lactides.

### Synthesis of [{1-Isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (1b)

The N-heterocyclic carbene ligand precursor, 1-isopropyl-3-(*N*-phenylacetamido)imidazolium chloride (**1a**), was synthesized by the alkylation reaction of 1-isopropylimidazole with *N*-phenyl chloroacetamide in refluxing toluene in 90% yield (Scheme 2). Recently, Burgess[44] synthesized similar *N*-acetamidoimidazolium chloride derivatives, synthesized by analogous alkylation procedures, for preparing theNHC silver and palladium complexes. The NMR analysis of 1-isopropyl-3-(*N*-phenylacetamido)imidazolium chloride (**1a**) showed that the diagnostic imidazolium (NC*H*N) resonance appeared downfield-shifted at $\delta$ = 9.97 ppm in the $^1$H NMR spectrum and at $\delta$ = 137.7 ppm in the $^{13}$C NMR spectrum. As expected, the amide proton (CON*H*) resonance appeared downfield-shifted at $\delta$ = 11.37 ppm in the $^1$H NMR spectrum, while the amide carbon (*C*ONH) resonance appeared at $\delta$ = 163.0 ppm in the $^{13}$C NMR spectrum. The C–O stretching frequency of the amide group (CONH) appeared at 1697 cm$^{-1}$ in the IR spectrum.

The silver complex, [{1-isopropyl-3-(*N*-phenylacetamido)-imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (**1b**), was prepared by the reaction of 1-isopropyl-3-(*N*-phenylacetamido)imidazolium chloride (**1a**) with $Ag_2O$ in $CH_2Cl_2$ at room temperature in 64% yield (Scheme 2). Consistent with the formation of the silver complex, the (NC*H*N) resonance of the starting material was conspicuously absent at $\delta$ = 9.97 ppm in the $^1$H NMR spectrum, while a new peak at $\delta$ = 179.5 ppm, corresponding to the silver-bound carbene (N*C*N) resonance, was observed in the $^{13}$C NMR spectrum. The (*C*ONH) resonance appeared at $\delta$ = 165.0 ppm in the $^{13}$C NMR spectrum. The carbonyl peak ($\nu_{CO}$) of the amide moiety (CONH) appeared at 1694 cm$^{-1}$ in the IR spectrum. The electrospray mass analysis gave a 100% abundance peak at *m*/*z* = 593 corresponding to the cationic [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$ fragment.

The molecular structure of [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (**1b**) was determined by X-ray diffraction (Figure 1). In the complex, two [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}] ligands are found to be bound to the metal center. It is noteworthy that for a related NHC ligand, 1-isopropyl-3-(2-*tert*-butyl-2-oxoethyl)imidazolin-2-ylidene, a neutral monomeric complex [1-isopropyl-3-(2-*tert*-butyl-2-oxoethyl)-imidazolin-2-ylidene]AgCl[40] bearing a 1:1 ligand/metal ratio was obtained under analogous reaction conditions unlike the cationic 2:1 ligand/metal ratio observed in the present case. Köhler et al.[45] have recently demonstrated that for the same ligand both the cationic 2:1 NHC/metal complex and the neutral 1:1 NHC/metal complex could be isolated upon changing the polarity of the reaction medium. For example, the reaction in THF gave a neutral 1:1 NHC/metal complex of the type [(saturated NHC)AgCl] while the same in highly polar water gave a 2:1 NHC/metal complex of the type [(saturated NHC)$_2$Ag]$^+$BF$_4^-$.

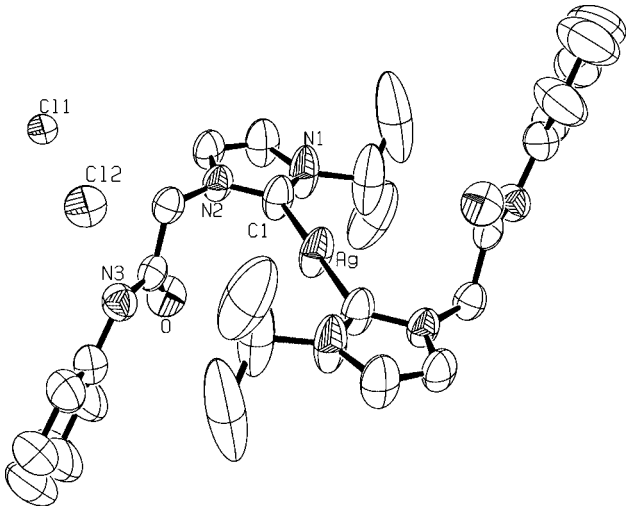

Figure 1. ORTEP of **1b**. The Cl$^-$ ion is disordered with Cl1 having 1/3 occupancy and Cl2 having 2/3 occupancy. Selected bond lengths [Å] and angles [°]: Ag–C(1) 2.085(3), N(1)–C(1) 1.350(4), N(1)–C(2) 1.379(4), C(1)–Ag–C(1) 180.000(1), N(2)–C(1)–N(1) 104.0(2), N(2)–C(1)–Ag 124.7(2), N(1)–C(1)–Ag 131.3(2).

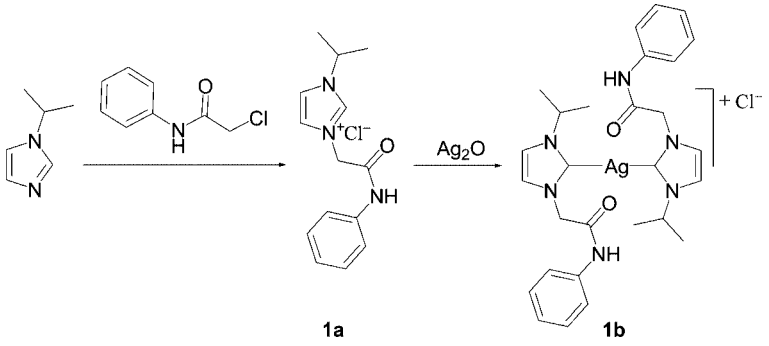
Another notable feature of the **1b** structure is that the two imidazolyl rings surrounding the silver atom are coplanar. The isopropyl and the *N*-phenylacetamide substituents on the imidazole rings are at a *trans* disposition to each other presumably for steric reasons. The coordination geometry around the silver atom is linear [$\angle C_{carb}$–Ag–$C_{carb}$ angle is 180.0(1)°] and is consistent with the preferred linear



Scheme 2.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

geometry exhibited by two-coordinate $Ag^I$ complexes having $d^{10}$ configuration.[46] The chloride anion is disordered in the structure with Cl2 having 2/3 occupancy while Cl1 has 1/3 occupancy. The Ag–$C_{carb}$ bond length of 2.085(3) Å more closely resembles a single bond, being slightly shorter than the sum of the covalent radii of silver and carbon (2.111 Å)[47] and also falls well within the observed range of Ag–$C_{carb}$ bond lengths of other analogous complexes (Table 1). Furthermore, the ∠(N–$C_{carb}$–N) angle of 104.0(2)° in **1b** is consistent with that observed for other analogous complexes (Table 1).

Table 1. Selected metrical data for some [(*N*-$R^1$-*N*′-$R^2$-imidazol-2-ylidene)$_2$Ag]$^+$-type complexes.

| Complexes | *d*($C_{carb}$–Ag)/ [Å] | ∠(N–$C_{carb}$–N)/ [°] | ∠($C_{carb}$–Ag–$C_{carb}$)/ [°] | Ref. |
|---|---|---|---|---|
|  | 2.117(5)<br>2.106(6) | 103.6(5)<br>103.5(5) | 176.8(2) | [24] |
|  | 2.092(10)<br>2.088(11) | 103.9(9)<br>105.0(9) | 179.5(4) | [26] |
|  | 2.069(5)<br>2.074(5) | 102.7(4) | 175.90(19) | [77] |
|  | 2.096(6)[a]<br>2.084(5)[b] | 105.3(6)[a]<br>104.6(5)[b] | 180.0(4)[a]<br>180.0[b] | [78] |

[a] Counter anion is $AgCl_2^-$. [b] Counter anion is $AgBr_2^-$.

Important is the comparison of the structure of **1b** with a related [(saturated NHC)$_2$Ag]$^+$ counterpart. For example, in an analogous saturated NHC silver complex, bis[(4*R*,5*S*)-4,5-diallyl-1,3-bis(2,4,6-trimethylphenyl)-4,5-dihydro-3*H*-imidazolin-2-ylidene]silver(I) tetrafluoroborate,[45] the ∠(N–$C_{carb}$–N) angle of 109.0(4)° is larger than the corresponding value of 104.0(2)° observed in the case of **1b** and this is presumably due to the differences in their respective N-heterocyclic ring geometries. The Ag–$C_{carb}$ bond lengths [2.082(4) and 2.087(4) Å] in bis[(4*R*,5*S*)-4,5-diallyl-1,3-bis(2,4,6-trimethylphenyl)-4,5-dihydro-3*H*-imidazolin-2-ylidene]silver(I) tetrafluoroborate, however, compare well with the corresponding values of 2.085(3) Å observed in complex **1b**.

## Density Funtional Theory Studies

Electronic structure calculations using the density functional theory were performed on the [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$ cationic complex (**2b**) in order to gain further insights into structure and bonding. We used the B3LYP/SDD,6-31G* level of theory. Two major conformers differing in energy by about 2.66 kcal/mol were identified.[48] In the lower energy conformer the imidazole rings were found to remain nearly orthogonal to each other. In an earlier study by Frenking and co-workers on a series of unfunctionalized (NHC)$_2$Ag$^+$ complexes, the energy difference between such conformers was reported to be of the order of 5 kcal/mol with only a negligible barrier to interconversion.[33] A close inspection of the optimized structure with that obtained through X-ray crystallography revealed interesting facts. In the experimental structure, where the imidazole rings are coplanar, it appears that there is an obvious intermolecular hydrogen bonding interaction involving olefinic hydrogen atoms (C8–C10) from the imidazole unit with that of the carbonyl O atom from the functional side-arm of the neighboring NHC silver molecule.[49] Furthermore, additional intramolecular stabilization interactions were noticed in the nonplanar conformer rather than in the planar one (vide infra).

In general, agreement between computed and experimental geometrical parameters was found to be quite good (Table 2). Calculated structural parameters for the unbound carbene, in its singlet ground state, are indicated in Figure 2. It can be seen that the bond lengths in the imidazole ring do not undergo any major change, except for the ∠(N–$C_{carb}$–N) angle, which shows a modest widening by about 1.8°. Since NHCs are known to act as efficient σ-donors through the carbenic carbon atom, one can expect only a minimal geometric distortion as predicted by the computed geometries in Figure 2.

The σ-donation increases the electron deficiency on the $C_{carb}$ atom and thus facilitates a better N→$C_{carb}$ π-donation. We have found an effective delocalization of the nitrogen lone pair electrons into the adjacent C–N bond with the help of natural bond orbital (NBO) analysis. Such delocalizations are responsible for shorter C–N distances in complex **2b** compared to that of the unbound carbene.[50] The computed natural population on C7 (and C42) revealed that the pπ atomic orbital is substantially more populated (1.14 e) in the complex **2b** than in the unbound singlet ground state (0.83 e).[51] The NPA charges on the imidazole nitrogen atoms were found to be increasingly positive upon complexation while the charges on the $C_{carb}$ atoms remain unchanged. Similar observations on related systems have been made earlier and independently by Frenking[31] and Scherer.[32]

In order to gain better insight into the nature of the chemical bonding we carried out charge decomposition analysis (CDA) using the B3LYP wave function. CDA has been known to be a useful tool in analyzing the extent of back-bonding in organometallic systems.[52] The CDA results in **2b** show a significant $C_{carb}$→Ag σ-donation (*d* =

[a] The calculated structure does not include chloride ions and thus refers to the cationic complex **2b**. The atom numbering is therefore different from that in the cif file. For optimized coordinates, please refer to the Supporting Information.

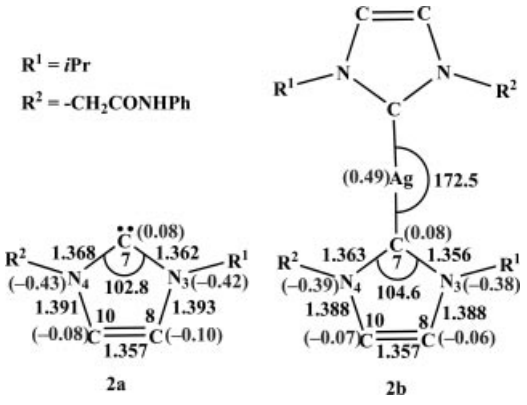

Figure 2. Calculated key structural parameters of free carbene **2a** and the complex **2b**. NPA charges are given in parentheses.

0.656) and a very negligible $C_{carb}$←Ag back-donation ($b$ = 0.053). A $d/b$ ratio of 11.4 and 12.4 between Ag and the two NHC ligands evidently underscores the ability of NHC to function as an effective σ-donor ligand (see Table S3, Supporting Information). The structural parameters as well as population analysis presented in the previous sections are in concurrence with the CDA result that the back-bonding in **2b** is not very significant.

Analysis of the topological features of electron density offers valuable information pertaining to the nature of chemical bonding in molecules. Bader's theory of "Atoms In Molecules" (AIM) has widely been applied to examine interesting bonding situations.[53] Topological properties such as the density at the bond critical point ($\rho_{bc}$), Laplacian of electron density ($\nabla^2\rho_{bc}$) as well as the total energy density ($H$) are analyzed. A covalent interaction is characterized by a negative value for $\nabla^2\rho_{bc}$ as well as $H < 0$. The value of $H$ is widely accepted as a better descriptor in determining the nature of interaction than the $\nabla^2\rho_{bc}$ value.[54] Inspection of computed topological features in the present system, as given in Table 3, reveals that the $C_{carb}$–Ag bond is covalent. For **2b**, values of Laplacian $\nabla^2\rho_{bc}$ as well as total energy density $H_{bc}$ for the $C_{carb}$–Ag bonds were found to be –0.07 and –4.5 au, respectively. These values suggest that the $C_{carb}$–Ag bond is more covalent than ionic. Further, the computed NPA charges on Ag (+0.49) and $C_{carb}$ (+0.08) are consistent with this observation (Figure 2). All other bonds such as C–N and C=C of the imidazole ring were found to be more covalent, as expected. Another noticeable feature emerging from the AIM analysis pertains to the π-bonds in the imidazole rings. The characteristic ellipticity associated with π-bonds is clearly reflected in the computed $\varepsilon$ values that are found to be as high as 0.4 for the C=C bonds. The $C_{carb}$–Ag bond exhibits the lowest value for ellipticity, again indicating lack of π-bonding interactions. Interestingly, the $\varepsilon$ values for the N3–C8 and N4–C10 (also N38–C43 and N39–C45) bonds suggest a moderate π-character, presumably arising due to an N→$C_{carb}$ π-donation into the carbene π-type orbital.

Table 3. Summary of the AIM analysis performed on **2b** at the AIM//B3LYP/SDD,6-31G* level of theory.[a]

| Bond | $\rho_{bc}$ [e·Å$^{-3}$] | $\nabla^2\rho_{bc}$ [e·Å$^{-5}$] | $\varepsilon$ | $H_{bc}$ |

[a] See Figure 3 for atom numbers.

As mentioned earlier, the geometry of the lowest energy conformer has a nearly orthogonal disposition of the imidazole rings. In the optimized geometry, there are two interesting intramolecular hydrogen bonds, rendering additional stabilization as shown in Figure 3. The first one is between the hydrogen atom of the tethered isopropyl group of one imidazole ring with the carbonyl group of the other imidazole ring (2.91 Å, $\rho$ = 0.003). The second hydrogen bond-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing interaction is between the methylene hydrogen atom and the carbonyl group attached to another imidazole ring (2.49 Å, $\rho$ = 0.008). These intramolecular interactions were identified correctly by the AIM calculations, where the densities at the bond critical points ($\rho_{bc}$) were found to fall within the hydrogen bonding range.[55] There are also additional interactions between the carbonyl oxygen atoms from both imidazole rings and the silver atom (3.26 Å, $\rho$ = 0.01). These interactions together could be responsible for the near orthogonal orientations of the imidazole rings in the gas-phase-optimized geometry.

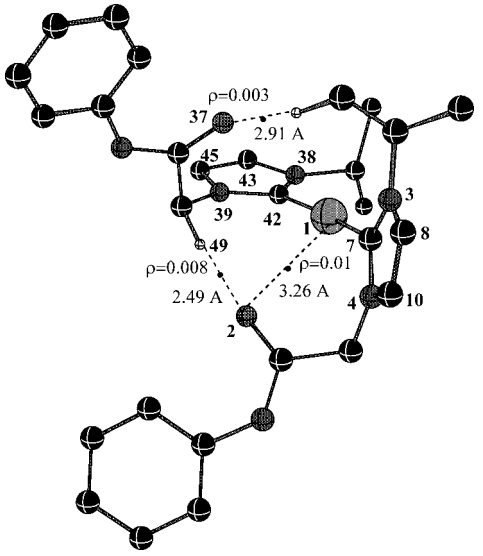

Figure 3. The B3LYP/SDD,6-31G* optimized geometry of **2b** showing weak intramolecular interactions and the corresponding densities at the bond critical points ($\rho_{bc}$) computed using the AIM theory (only selected hydrogen atoms are shown for clarity).

## Polymerization Studies

The silver complex [{1-isopropyl-3-(*N*-phenylacetamido)-imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (**1b**) was found to be an active catalyst for ring-opening polymerization of L-lactides carried out at elevated temperatures under melt conditions in the absence of any solvent.[56] For example, a typical run involved heating of L-lactide and [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (**1b**) in a sealed vessel under vacuum at designated temperatures for stipulated periods of time. Under these conditions the reaction mixture would form a monomer melt in which the polymerization would occur. The variation of the [M]/[C] ratio (M = monomer, C = catalyst) at 160 °C showed that the maximum molecular weight ($M_w$ = 12.2·10$^3$, Entry 2, Table 4) was obtained at a 100:1 monomer/catalyst ratio. The observed polydispersity index (PDI) was in the range 1.22–1.47. Consistent with the observed molecular weight distributions, the time dependence studies (Entries 2 and 7–9, Table 4) showed no correlation of the observed molecular weight with time thereby ruling out the possibility of a true living polymerization process. The temperature dependence study carried out in the range 100–180 °C[57] (Entries 2 and 10–13, Table 4) showed that the molecular weight of the polymer decreased with an increase in temperature, with the highest molecular weight observed at 100 °C (13.5·10$^3$, Entry 10, Table 4). The decrease in molecular weight with the increase in temperature may be caused by thermal depolymerization as well as an enhanced transesterification reaction occurring at elevated temperatures. In this regard, Liao et al.[56a] and Albertsson and Varma[42] have recently reported a similar decrease in polymer molecular weight with temperature, arising from thermal depolymerization and accelerated transesterification reactions.

Table 4. Melt polymerization of L-lactide by **1b**.

| Entry | L-Lactide/**1b** | Temp. [°C] | Time [h] | $M_w$ | $M_w/M_n$ | Conv. [%] |
|---|---|---|---|---|---|---|
| 1 | 50 | 160 | 4 | 8.1·10$^3$ | 1.37 | 90 |
| 2 | 100 | 160 | 4 | 12.2·10$^3$ | 1.40 | 98 |
| 3 | 250 | 160 | 4 | 9.2·10$^3$ | 1.41 | 78 |
| 4 | 500 | 160 | 4 | 6.6·10$^3$ | 1.28 | 46 |
| 5 | 750 | 160 | 4 | 5.3·10$^3$ | 1.23 | 35 |
| 6 | 1000 | 160 | 4 | 4.9·10$^3$ | 1.22 | 36 |
| 7 | 100 | 160 | 3 | 11.0·10$^3$ | 1.41 | 79 |
| 8 | 100 | 160 | 1.5 | 11.4·10$^3$ | 1.47 | 78 |
| 9 | 100 | 160 | 0.5 | 10.6·10$^3$ | 1.29 | 65 |
| 10 | 100 | 100 | 4 | 13.5·10$^3$ | 1.27 | 84 |
| 11 | 100 | 120 | 4 | 11.9·10$^3$ | 1.46 | 81 |
| 12 | 100 | 140 | 4 | 11.2·10$^3$ | 1.36 | 91 |
| 13 | 100 | 180 | 4 | 8.3·10$^3$ | 1.35 | 94 |

In order to gain insight into the nature of the active species in the catalytic cycle, the thermal stability of [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (**1b**) was studied by a thermogravimetric analysis (TGA) experiment (Figure 4). Compound **1b** was found to be stable up to 180 °C above which drastic mass loss started to occur presumably caused by the generation of the carbene. Consistent with the TGA results, the attempts to trap the in-situ generated carbene from the thermal decomposition of **1b** with $CS_2$, carried out at a much lower temperature (60 °C), proved to be unsuccessful.[58]

In this regard, it is worth mentioning that Waymouth and Hedrick[28] have recently proposed a mechanism invoking in-situ generation of carbene from similar NHC silver complexes for the ring-opening polymerization of L-lactides. However, for sterically demanding NHC silver precatalysts that were thermally sufficiently stable and did not dissociate to generate carbenes at the polymerization temperature, the possibility of the silver complexes directly mediating the polymerization was also suggested to exist. A similar possibility of silver directly participating in the polymerization also exists in the case of **1b** and is in agreement with the TGA experiment that showed the complex did not undergo significant mass loss below 180 °C while the polymerizations were carried out at a lower temperature range (100–180 °C). Such direct metal-mediated polymerization would lead to the capping of polymer chain ends with NHC fragments (Scheme 3) and indeed, the characteristic resonances of the NHC moieties could be seen in both the $^1$H NMR and $^{13}$C NMR spectra of the polymer.[59] The MALDI spectrometric analysis of the polymer also confirms the presence of NHC chain end groups.[60] In this re-

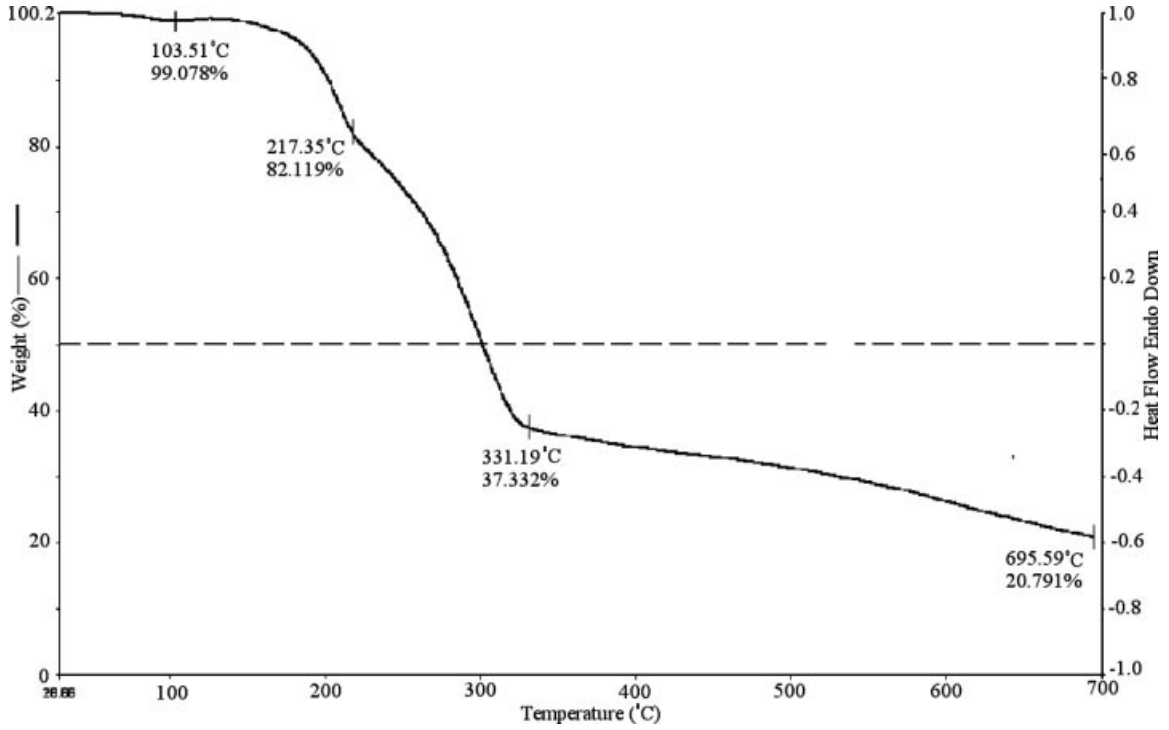

Figure 4. Thermogravimetric analysis of **1b** as a function of temperature.

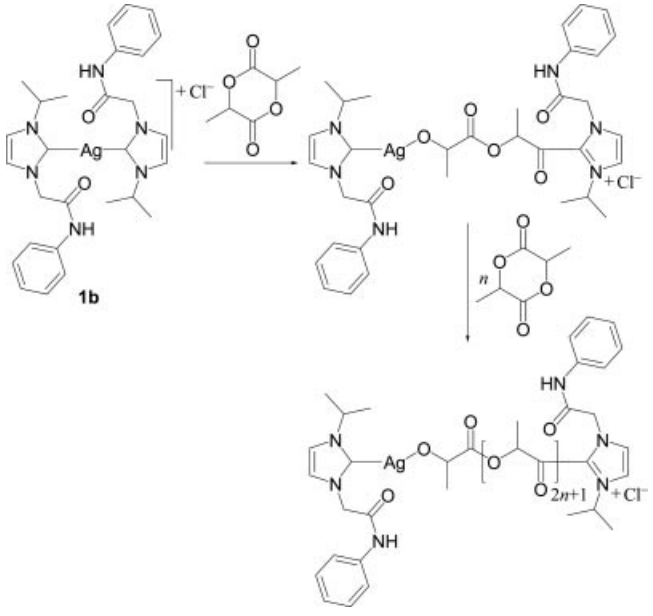
gard it is worth mentioning that a $(NHC)Y^{III}$ complex has been recently reported to exhibit metal-mediated coordination insertion polymerization of lactides.[61] However, the other possibility that minute amounts of carbene, generated during the thermal decomposition of **1b**, are responsible for the polymerization also cannot be ruled out completely. Currently, detailed mechanistic studies are underway to establish the identity of the active species responsible for the catalysis.



Scheme 3.

## Conclusions

In summary, a new functionalized N-heterocyclic carbene ligand precursor, 1-isopropyl-3-(*N*-phenylacetamido)-imidazolium chloride (**1a**), was synthesized by the alkylation of 1-iso-proplyimidazole with *N*-phenyl chloroacetamide. The silver complex, $[\{1\text{-isopropyl-3-(}N\text{-phenylacetamido)imidazol-2-ylidene}\}_2Ag]^+Cl^-$ (**1b**), was synthesized by treatment of **1a** with $Ag_2O$. Complex **1b** has been structurally characterized by X-ray diffraction studies and was found to effectively initiate polymerization of L-lactide at higher temperatures under solvent-free melt conditions producing polylactide polymers with a narrow molecular weight distribution. Density functional theory studies and post-wave function analysis were able to establish that the functionalized NHC was acting as an effective σ-donor. Weak intramolecular stabilizing interactions were identified as responsible factors in contributing to the perpendicular dispositions of the imidazole rings, compared to the coplanar arrangement as revealed by the X-ray crystallographic study.

## Experimental Section

**General Procedures:** All manipulations were carried out using a combination of a glovebox and standard Schlenk techniques. Solvents were purified and degassed by standard procedures. $Ag_2O$ was purchased from SD-Fine Chemicals (India) and used without any further purification. L-Lactide was purchased from Sigma Aldrich (Germany) and was subjected to polymerization without further purification. L-Lactide was stored at 4 °C as supplied, to avoid the formation of lactyl lactate. *N*-Phenyl chloroacetamide[62] and 1-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

isopropylimidazole[63] were synthesized according to literature procedures. $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Varian 400 MHz NMR spectrometer. $^1H$ NMR peaks were labeled as singlet (s), doublet (d), triplet (t), and septet (sept). Infrared spectra were recorded with a Perkin–Elmer Spectrum One FT-IR spectrometer. Mass spectrometry measurements were carried out with a Micromass Q-Tof spectrometer. The thermal analysis was performed in $N_2$ (flow rate: 10 mL/min) with a heating rate of 10 °C/min using a Perkin–Elmer Pyris thermal analyzer. X-ray diffraction data were collected with a Bruker P4 diffractometer equipped with a SMART CCD detector, and crystal data collection and refinement parameters are summarized in Table 5. The structures were solved by direct methods and standard difference map techniques, and were refined by full-matrix least-squares procedures on $F^2$ with SHELXTL (Version 6.10). CCDC-297479 (for compound **1b**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. The polymer molecular weights were determined using a Waters GPC (Waters 2414 RI Detector) with PL-gel, a 5 μ-mixed-D (2×300 mm) column, with polystyrene standards in chloroform, and a covered molecular weight range of 140 to $4{\cdot}10^5$. The MALDI-TOF MS measurements were performed with a Voyager-DE STR Biospectrometry Workstation mass spectrometer. A 19 kV accelerating voltage was used with pulsed ion extraction (PIE). The positive ions were detected using the reflection mode (20 kV). A nitrogen laser (337 nm, 1 ns pulse width operating at 4 Hz) was used to produce laser desorption and 50 shots were scanned per spectra. The instrument was calibrated with four standards [Des-Arg 1, Bradykinn and Angiotensin-1, and ACTH (1-17)] by means of linear calibration. The sample was prepared with an α-cyanohydroxy cinnamic acid (CHC) matrix (10 mg /mL). A 1 μL analyte solution (10 mg/mL) was deposited onto the sample plate (stainless steel) and allowed to air-dry. Subsequently, a 1 μL matrix solution (50:50 v/v, CHC/acetonitrile) was added to the analyte.

**Synthesis of 1-Isopropyl-3-(*N*-phenylacetamido)imidazolium Chloride (1a):** *N*-Phenyl chloroacetamide (2.01 g, 11.8 mmol) and 1-isopropylimidazole (1.30 g, 11.8 mmol) were added to toluene (ca. 10 mL) and heated at 140 °C for 12 h during which a brown precipitate was formed. The precipitate was collected by filtration and washed with hot hexane (ca. 8 mL) and dried under vacuum to give the product as a brown crystalline solid (2.98 g, 90%). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta$ = 11.37 (s, 1 H, N*H*), 9.97 (s, 1 H, NC*H*N), 7.71 (d, $^3J_{H,H}$ = 7 Hz, 2 H, *o*-$C_6H_5$), 7.59 (s, 1 H, NC*H*CHN), 7.28 (s, 1 H, NCHC*H*N), 7.22 (t, $^3J_{H,H}$ = 7 Hz, 2 H, *m*-$C_6H_5$), 7.03 (t, $^3J_{H,H}$ = 7 Hz, 1 H, *p*-$C_6H_5$), 5.60 (s, 2 H, C$H_2$), 4.63 [sept, $^3J_{H,H}$ = 6 Hz, 1 H, C*H*$(CH_3)_2$], 1.52 [d, $^3J_{H,H}$ = 7 Hz, 6 H, CH(C$H_3$)$_2$] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 100 MHz, 25 °C): $\delta$ = 163.0 (*C*O), 137.7 (N*C*N), 135.8 (*ipso*-$C_6H_5$), 128.4 (*o*-$C_6H_5$), 124.0 (N*C*HCHN), 123.7 (NCH*C*HN), 119.8 (*p*-$C_6H_5$), 118.9 (*m*-$C_6H_5$), 52.9 (*C*$H_2$), 51.9 [*C*$(CH_3)_2$], 22.6 [C(*C*$H_3$)$_2$] ppm. IR (KBr pellet): $\tilde{\nu}$ = 1697 (s) ($\nu_{CO}$) cm$^{-1}$. LRMS (ES): *m*/*z* (%) = 244 (100) [NHC ligand]$^+$. HRMS (ES): calcd. for [NHC ligand]$^+$ 244.1450, found 244.1455.

**Synthesis of [{1-Isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$Cl$^-$ (1b):** The reaction was carried out under exclusion of light. A mixture of **1a** (1.81 g, 6.47 mmol) and $Ag_2O$ (0.748 g, 3.23 mmol) in dichloromethane (ca. 25 mL) was stirred at room temperature for 4 h. The reaction mixture was filtered and the solvent was removed under vacuum to give the product as a light yellow solid (1.30 g, 64%). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta$ = 11 (br., 1 H, N*H*), 7.78 (d, $^3J_{H,H}$ = 8 Hz, 2 H, *o*-$C_6H_5$), 7.29 (s, 1 H, NC*H*CHN), 7.20 (t, $^3J_{H,H}$ = 8 Hz, 2 H, *m*-$C_6H_5$), 7.02 (t, $^3J_{H,H}$ = 8 Hz, 1 H, *p*-$C_6H_5$), 6.99 (s, 1 H, NCHC*H*N), 5.27 (s, 2 H, C$H_2$), 4.60 [sept, $^3J_{H,H}$ = 7 Hz, 1 H, C*H*$(CH_3)_2$], 1.42 [d, $^3J_{H,H}$ = 7 Hz, 6 H, CH(C$H_3$)$_2$] ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 100 MHz, 25 °C): $\delta$ = 179.5 (N*C*N), 165.0 (*C*O), 138.0 (*ipso*-$C_6H_5$), 128.1 (*o*-$C_6H_5$), 123.5 (N*C*HCHN), 122.6 (NCH*C*HN), 119.5 (*p*-$C_6H_5$), 116.4 (*m*-$C_6H_5$), 54.4 [*C*$(CH_3)_2$], 53.5 (*C*$H_2$), 23.2 [C(*C*$H_3$)$_2$] ppm. IR (KBr pellet): $\tilde{\nu}$ = 1694 (s) ($\nu_{CO}$) cm$^{-1}$. LRMS (ES): *m*/*z* (%) = 593 (100) [(NHC ligand)$_2$Ag]$^+$.

**Computational Methods:** The density functional theory calculations were performed on the [{1-isopropyl-3-(*N*-phenylacetamido)imidazol-2-ylidene}$_2$Ag]$^+$ cationic complex (**2b**) using the Gaussian98 suite of quantum chemical programs.[64] The Becke three-parameter exchange functional in conjunction with the Lee–Yang–Parr correlation functional (B3LYP) was employed in this study.[65,66] The Stuttgart-Dresden effective core potential (ECP), representing 19 core electrons, along with valence basis sets (SDD) was used for the silver atom.[67] All other atoms were treated with the 6-31G(d) basis set.[68] We will be designating the level of theory hereafter as B3LYP/SDD,6-31G*. Inspection of the metal–ligand donor–acceptor interactions was carried out using charge decomposition analysis (CDA).[69] CDA is a valuable tool for analyzing the interactions between molecular fragments in a quantitative fashion, with an emphasis on the electron donation.[70] The CDA calculations were performed with the program AOMIX using the B3LYP/SDD,6-31G* wave function.[71] Natural bond orbital analysis was performed using the NBO3.1 program as implemented in the Gaussian98 package.[72] Second-order perturbation energy analysis, natural charges,[73] and bond orders[74] for **2b** were calculated using the B3LYP wave function. The nature of the chemical bonding was further explored with Bader's "Atoms in Molecules" approach[75] using the AIM2000 program.[76]

**Polymerization Experiments:** Typical polymerization experiment: L-Lactide (1.01 g, 7.01 mmol) and **1b** (0.044 g, 0.070 mmol) were charged in an ampoule inside a glove box. The ampoule was taken out and put under vacuum at 50 °C for 15 min, after which the ampoule was sealed under vacuum and heated at 160 °C for 4 h. Under these conditions, the reaction mixture turned into a monomer melt in which polymerization occurred. Subsequently, the molten reactive polymer mixture was cooled by submerging the se-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

aled ampoule into liquid nitrogen to stop the polymerization. The conversion of L-lactide monomer was determined using the size exclusion chromatography method. The analyses were performed on the crude reaction mixture, no precipitation was executed to avoid fractionation of the sample so as not to influence the results.

**Supporting Information** (see footnote on the first page of this article): Polymer characterization data, B3LYP-optimized coordinates for NPA data, and list of NBO delocalizations for **2b**.

## Acknowledgments

We thank the Department of Science and Technology (Grant No. SR/S1/IC-25/2003) for financial support of this research. M. K. S. and D. R. thank CSIR, New Delhi for research fellowships. Computational facilities from the IIT Bombay computer center are gratefully acknowledged.

[38] Charette recently reported an air- and moisture-stable (NHC) $Ag^{I}$ complex that could be stored on a bench without any precautions for over 4 months, see ref.[23]
[39] For example, Faller and Crabtree recently reported two such remarkable catalysts namely (i) an air- and thermally stable Pd catalyst (see ref.[39a]) for the Heck olefination reaction with activated aryl chlorides and (ii) an air- and moisture-stable Ir catalyst for an efficient transfer hydrogenation reaction involving ketones. The Ir catalysts could even survive column chromatography, with which they were purified (see ref.[11]): a) S. Gründemann, M. Albrecht, J. A. Loch, J. W. Faller, R. H. [48] It was noticed that during geometry optimization, the initial guess geometry with coplanar imidazole rings goes out of plane and ends up with the nonplanar structure. The coplanar structure is obtained as a result of a constrained optimization with the N3–C7–C42–N38 angle fixed.

[56] For ring-opening polymerization of L-lactides under similar solvent-free monomer melt conditions, see: a) X. Wang, K. Liao, D. Quan, Q. Wu, *Macromolecules* **2005**, *38*, 4611–4617; b) A. J. Nijenhuis, D. W. Grijpma, A. J. Pennings, *Macromolecules* **1992**, *25*, 6419–6424.

[57] The bulk polymerization temperatures were chosen to be higher than the melting point of the lactide monomer (96 °C).

[58] Because of the low boiling point of $CS_2$ (46 °C) these carbene trapping experiments could not be carried out at a high temperature (> 180 °C) where the carbene generation was supposed to take place according to the thermal gravimetric analysis results.

[59] It is noteworthy that the NHC end-groups were seen in the $^1H$ NMR and $^{13}C\{^1H\}$ NMR spectra of the polymer when analyzed directly from the melt as well as after dissolving in a minimum of dichloromethane and precipitating with hexane whereas no NHC resonances were observed when the precipitation of the polymer was done with methanol. See Figures S2 and S3 in the Supporting Information.

[60] A series of sodium (23 Da) cationized peaks of the polymers bearing NHC end groups can be recognized in the MALDI spectrum. See Figure S4 in Supporting Information. The mass ($M_C$) of the sodium cationized peak of the polymer bearing the (NHC)Ag (350 Da) and NHC (243 Da) end groups is given by $M_C = 72x + 350 + 243 + 23$ where $x$ = number of repeat unit (72Da).

# Molecular and Electronic Structures of Homoleptic Nickel and Cobalt Complexes with Non-Innocent Bulky Diimine Ligands Derived from Fluorinated 1,4-Diaza-1,3-butadiene (DAD) and Bis(arylimino)acenaphthene (BIAN)

**Marat M. Khusniyarov,[a] Klaus Harms,[a] Olaf Burghaus,[a] and Jörg Sundermeyer*[a]**

*Dedicated to Professor Hansgeorg Schnöckel on the occasion of his 65th birthday*

**Keywords:** EPR spectroscopy / Magnetochemistry / Non-innocent ligands / Nickel / Cobalt / X-ray diffraction

The diimine complexes with bulky fluorinated *N*-substituents $[Ni^{II}(^{F}DAD)_2]$ **1** and $[Co^{II}(^{F}DAD)_2]$ **2** [$^{F}$DAD = *N*,*N*′-bis-(pentafluorophenyl)-2,3-dimethyl-1,4-diaza-1,3-butadiene] as well as diimine complexes with extended π system $[Ni^{II}(^{F}BIAN)_2]$ **3** and $[Co^{I}(^{F}BIAN)_3]$ **4** ($^{F}$BIAN = bis[*N*-{3,5-bis(trifluoromethyl)phenyl}imino]acenaphthene) were synthesized. Compound **4** represents the first complex with three bis(imino)acenaphthene ligands synthesized so far. The molecular structures of the complexes **1**–**4** were determined by X-ray crystallography at 193 K. Complexes **1**, **2** and **3** comprise the divalent metal ions with pairs of radical monoanionic ligands, whereas **4** is best described as a cobalt(I) complex with two neutral $(^{F}BIAN)^0$ and one $(^{F}BIAN)^{1-}$ ligand in the radical monoanionic form. The electronic structures of the paramagnetic cobalt complexes **2** and **4** were investigated by SQUID measurements and X-band EPR spectroscopy. Both complexes possess a doublet ground state, with electron density located mostly in the metal d-orbitals. The doublet–quartet energy gap for **4** was established to be 159 $cm^{-1}$.

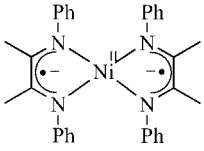
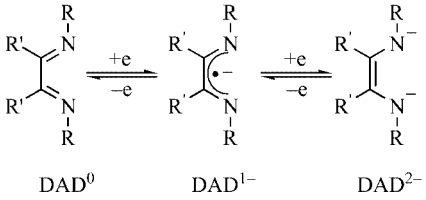
## Introduction

Homoleptic complexes of substituted 1,4-**di**aza-1,3-buta-**d**iene (DAD) with late transition metals $[M(DAD)_2]$ are well know since the first publication of Balch and Holm in early 1966.[1] They synthesized the extremely oxygen-sensitive complex $[Ni\{Ph\text{-}DAD(Me)\}_2]$ and proposed the electronic structure as a $Ni^{II}$ center with two radical monoanionic $(DAD)^{1-}$ ligands.



Nowadays, it is clearly established that the $(DAD)^0$ ligand possessing a low-lying antibonding π* orbital is able to accept one or two electrons giving open-shell monoanion $(DAD)^{1-}$ or closed-shell dianion $(DAD)^{2-}$, respectively. Thus, DAD along with related *o*-phenylenediamido ligands belong to the classical *N*,*N*′-coordinating non-innocent ligands.[2]

R'-DAD(R) :



$DAD^0$ $DAD^{1-}$ $DAD^{2-}$

The class of $[M(DAD)_2]$ complexes was expanded by the groups of tom Dieck (M = Fe,[3] Ni[4]) and von Walther (M = Fe,[5] Co,[5,6] Ni[7]). Later, several $[Ni(DAD)_2]$ complexes were characterized by single-crystal X-ray analysis.[8,9] In contradiction to the electronic model given by Balch and Holm all these complexes were formulated as zero-valent metal species with pairs of closed-shell $(DAD)^0$ ligands. At the same time closely related complexes derived from *o*-phenylenediamine $[Ni^{II}(sbqdi)_2]$[10] [sbqdi – **s**emi**b**enzo-**q**uinone**di**iminato(1–)] and diaminomaleonitrile $[Ni^{II}(sdisn)_2]$[11] [sdisn – **s**emi**di**imino**s**ucci**n**o**n**itrilo(1–)] are well known to consist of a divalent metal and a pair of monoanionic radical ligands.

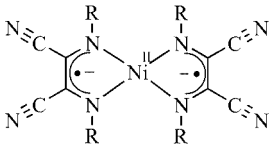
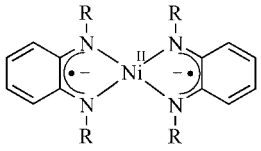
$[Ni(DAD)_2]$



$[Ni(sdisn)_2]$



$[Ni(sbqdi)_2]$

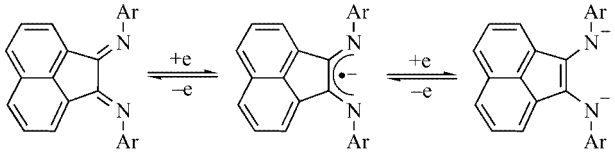
Throughout this paper we carefully distinguish between formal[12] and spectroscopic (or physical)[13] oxidation states. The formal oxidation state of a metal ion in a given coordination compound is a non-measurable, physically meaningless, usually integral number that is derived by heterolytic removal of all ligands in their closed-shell electron configuration, whereas the spectroscopic oxidation state is derived from the actual electron configuration of the metal ion in a given ligand regime.

Complexes of late transition metals with redox active non-innocent ligands[2] are of particular interest with regard to their electronic structures. Since late transition metals can exist in several oxidation states, ambiguity of oxidation state determination may arise with transition metals coordinated to non-innocent ligands. Often spectroscopic (or physical) oxidation state of the non-innocent ligand can be elegantly determined using a high-quality single-crystal X-ray analysis, as different oxidation states of the ligand reveal different characteristic bond lengths.[14]

Following our studies on complexes of late transition metals containing non-innocent ligands[15] we report here the first structurally characterized $[Co(DAD)_2]$ complex along with its Ni analogue. Both molecular and electronic structures of them are being investigated by X-ray analysis, EPR spectroscopy, and variable-temperature magnetic susceptibility measurements.

Similar to DAD **b**is(aryl**i**mino)**ac**e**n**aphthene (BIAN)[16] owing to its non-innocent nature is known to form complexes in different ligand oxidation states.

Ar-BIAN:



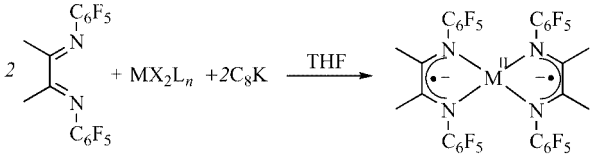
$BIAN^0$ $BIAN^{1-}$ $BIAN^{2-}$

Very recently, Fedushkin et al.[17] reported the first homoleptic complexes of the type $[M^{II}(BIAN)_2]$ (M = Mg, Ca). The molecular structure of $[Ca^{II}(dip\text{-}BIAN)_2]$ (dip = 2,6-diisopropylphenyl) was established and monoanionic nature of both ligands along with conventional oxidation state for calcium were established. To the best of our knowledge homoleptic complexes of the type $[M(BIAN)_2]$ with transition metals have been not isolated and structurally characterized so far. Therefore, the class of homoleptic DAD complexes has been further expanded by us to corresponding BIAN complexes. Molecular structures of BIAN complexes of nickel and cobalt are reported. The electronic structure of the paramagnetic cobalt complex is investigated in detail by means of EPR spectroscopy and variable-temperature magnetic susceptibility measurements.

## Results and Discussion

### Synthesis and Characterization of DAD Complexes

In order to synthesize complexes **1** and **2** we employed a variation of the well-known in situ reduction method.[7,8] Complexes **1** and **2** were obtained in moderate to high yields by complexation of anhydrous metal salts with two equivalents of the ligand in the presence of two equivalents of $C_8K$ as a reducing agent. The target complexes are oxygen and moisture sensitive and should be handled and stored under strictly anaerobic conditions.



M = Ni, X = Br, L = DME, $n$ = 1 $[Ni^{II}(^{F}DAD)_2]$ **1**

M = Co, X = Cl, $n$ = 0 $[Co^{II}(^{F}DAD)_2]$ **2**

At room temperature complex **1** is diamagnetic in solution and shows three sharp multiplets in the $^{19}F$ NMR spectrum in the expected region –150 to –164 ppm vs. $CFCl_3$. It is interesting to note significant changes in the $^1H$ NMR spectrum accompanying the complexation. While in the free ligand the methyl group is observed at $\delta$ = 2.24 ppm, it is slightly broadened ($W_{1/2}$ = 6 Hz) and strongly high-field shifted in the complex and observed at $\delta$ = –1.98 ppm. The same observation was made by tom Dieck et al. for a series of $[Ni(DAD)_2]$ complexes.[8] We ascribe this unusual shift to residual paramagnetism of **1** derived from a low-lying triplet state populated at room temperature. The signal at $\delta$ = –1.98 ppm in the $^1H$ NMR spectrum of **1** is virtually temperature-independent, it is only slightly low-field shifted to –1.79 ppm by cooling the sample from 300 to 243 K.

Although a distorted tetrahedral environment of $Ni^{II}$ (vide infra) results in high-spin complex ($S_{Ni}$ = 1), the two radical ligands seem to couple antiferromagnetically with the metal giving ultimately a diamagnetic complex. Quenching of inherent paramagnetism of $Ni^{II}$ in a distorted tetrahedral arrangement of two chelating radical ligands has recently been reported by Wieghardt et al.[18] EPR spectroscopy applied to **1** gave evidence for its diamagnetism. Complex **1** was X-band EPR silent in solution/frozen solution at temperatures 4–300 K.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Complex **2** is paramagnetic both in solid state and in solution, the effective magnetic moment, $\mu_{eff}$ = 3.26 ($\mu_B$), was measured for the solid at room temperature. This value is close to the spin state $S$ = 3/2, further investigation of the electronic structure of **2** is given below.

### Crystal Structures of DAD Complexes

The molecular structure of **1** consists of two *N*,*N*′-chelating $^F$DAD ligands coordinated to the metal center (Figure 1). Two $^F$DAD ligands form a dihedral angle 55.28(9)° reflecting a twisted tetrahedral geometry at the metal center. The complex shows $C_2$ symmetry having twofold symmetry axis defined by Ni atom and the centroids of the diimine C–C bonds. Two metallacycles NiNCCN do not show any bend along NN′ axis, which would be the characteristic feature for doubly reduced DAD ligands.[19] In contrast they are essentially planar with maximum deviation of 0.031(2) Å from the best-fit planes defined by $E_1$ (Ni1N1C1C1′N1′) and $E_2$ (Ni1N2C3C3′N2′). The sum of angles at each nitrogen atom is close to 360° typical for planar $sp^2$-hybridized N-centers. Since the bond lengths in two diimines are the same within ±0.012 Å (3σ), two ligands have an identical oxidation state.

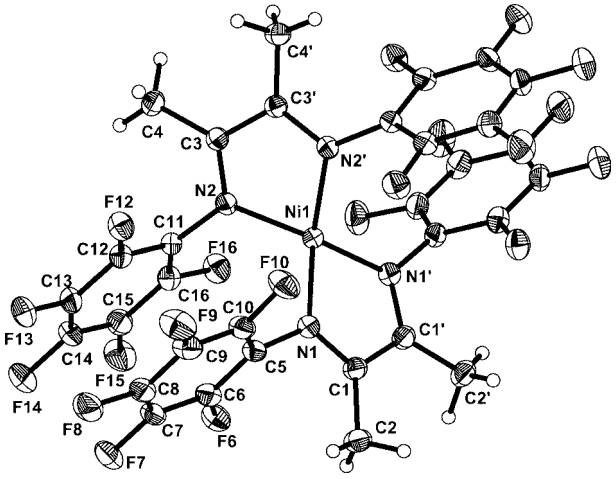


Figure 1. Molecular structure of **1**, thermal ellipsoids are drawn at 30% probability level.

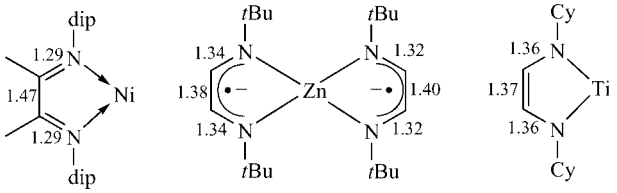
The oxidation state of the ligands and consequently of the metal can be unambiguously assigned on the basis of the bond lengths analysis. In comparison of C–C and C–N bond lengths of diimine moieties in **1** (Table 1) with corresponding bond lengths in complexes, whose structures were determined accurately (Scheme 1), it is evident that both ligands in **1** are radical monoanions ($^F$DAD)$^{1-}$. The C–N bond length, on average 1.344(3) Å, along with the C–C bond of NCCN backbone, on average 1.413(5) Å, are in good agreement with the presence of an open-shell ($^F$DAD)$^{1-}$.[20] Since the complex possesses no extra charge, the physical (or spectroscopic)[13] oxidation state of Ni is +II ($d^8$ electronic configuration).



Scheme 1. Characteristic bond lengths for DAD ligand in different oxidation states: $(DAD)^0$ in $[Ni^{II}\{dip\text{-}DAD(Me)\}(CH_2SiMe_3)_2]$[38] (left), $(DAD)^{1-}$ in $[Zn^{II}\{t\text{Bu-}DAD(H)\}_2]$[20] (middle), and $(DAD)^{2-}$ in $[Ti^{IV}\{Cy\text{-}DAD(H)\}Cl_2(THF)_2]$[39] (right).

The molecular structures of several homoleptic complexes $[Ni(DAD)_2]$ were reported previously.[8,9] All of them were formulated as $Ni^0$ complexes containing a pair of closed-shell $(DAD)^0$ ligands. Taking into account the bond lengths of diimine moieties found in these complexes we suggest reformulation of their electronic structures. For example, the structure of $[Ni\{dmp\text{-}DAD(H)\}_2]$[8b] (dmp = 2,6-dimethylphenyl) reveals C–N bonds on av. 1.341(2) Å and C–C bonds of NCCN backbone on av. 1.374(2) Å. The bond length pattern observed in the former is in better agreement with the presence of the open-shell $(DAD)^{1-}$ rather than the closed-shell $(DAD)^0$. Having analyzed molecular structures of a series of reported $[Ni(DAD)_2]$ complexes we suggest new electronic structures for the following complexes: $[Ni^{II}\{Cy\text{-}DAD(H)\}^{1-}_2]$,[8a] $[Ni^{II}\{dmp\text{-}DAD(H)\}^{1-}_2]$,[8b] $[Ni^{II}\{t\text{Bu-}DAD(H)\}^{1-}_2]$,[9a] $[Ni^{II}\{dip\text{-}DAD(H)\}^{1-}_2]$.[9b]

Almost all related homoleptic *o*-phenylenediamine-derived complexes $[Ni^{II}(sbqdi)_2]$[10a,21] and the diaminomaleonitrile-derived $[Ni^{II}(sdisn)_2]$[11a] show strictly square-planar geometry, whereas **1** as well as $[Ni(DAD)_2]$ structurally characterized previously reveal twisted tetrahedral geometry. The dihedral angle formed by two diimine moieties varies from 44.5° in $[Ni\{dmp\text{-}DAD(H)\}_2]$[8b] to 88.95° in $[Ni\{t\text{Bu-}DAD(H)\}_2]$.[9a] The large deviation from a square-planar geometry observed in $[Ni(DAD)_2]$ complexes can be rationalized by steric repulsion of bulky *N*-substituents. In

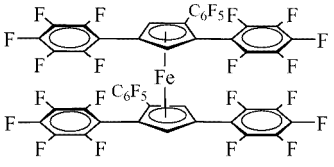
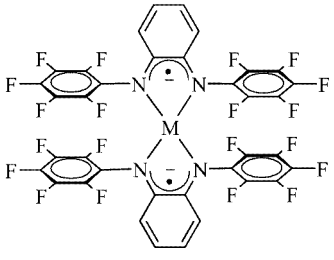
contrast, a series of $[Ni^{II}(sbqdi)_2]$ and $[Ni^{II}(sdisn)_2]$ complexes with small N–H substituents do not show any deviation from square-planar geometry, whereas $[Ni^{II}(sbqdi)_2]$ having bulky $C_6F_5$ groups attached to four nitrogen atoms does show tetrahedral distortion: the two planar ligands form dihedral angle of 53.7(1)°.[22]

The strong distortion from planarity in **1** is caused by interaction between the bulky $C_6F_5$ groups engaged in intramolecular $C_6F_5$–$C_6F_5$ stacking. The phenyl rings form dihedral angles in the range of 65.7(1)–67.3(1)° with corresponding diimine NCCN planes and are pairwise close to coplanar with an interplanar angle of 2.9(1)°. The smaller distance between $C_6F_5$ centroid and the least-squares plane of adjacent $C_6F_5$ ring is 3.23 Å. If we assume that complex **1** adopts a square-planar geometry without significant changes in bond lengths and angles, a simple geometrical consideration predicts that the coplanar $C_6F_5$ rings would be forced to a face-to-face distance of approximately 2.9 Å. Recently, by DFT calculations Lorenzo et al.[23] have shown that energy minimum for the gas-phase dimer $(C_6F_6)_2$ in face-to-face configuration is reached when the interplanar distance $C_6F_6$–$C_6F_6$ is 3.31–3.37 Å. Assuming that the energy minima for the pair $C_6F_5$–$C_6F_5$ in **1** and the calculated pair $C_6F_6$–$C_6F_6$ are reached at the close distances we expect strong repulsion between two pairs of $C_6F_5$ rings in the hypothetical square-planar complex **1**.

A tetrahedral distortion of the complex and synchronous rotation of the phenyl rings provide a relaxation of repulsive interaction and sufficient increase of the $C_6F_5$–$C_6F_5$ distances. The molecular structure of **1** reveals a slipped arrangement of two pairs of $C_6F_5$ rings. The interplanar $C_6F_5$–$C_6F_5$ distance found at 3.23 Å is in good agreement with distances 3.23 and 3.32 Å between $C_6F_5$ rings engaged in intramolecular stacking in the sandwich complex bis[$\eta^5$-1,2,4-tris(pentafluorophenyl)cyclopentadienyl]iron(II)[24] and with distances 3.20–3.28 Å in the series of complexes $[M(^{F}sbqdi)_2]$ [M = Co, Ni, Pd, Cu, $^{F}$sbqdi – radical anion derived from doubly deprotonated *N*,*N*′-bis(pentafluorophenyl)-*o*-phenylenediamine].[22]





In conclusion, the twisted tetrahedral geometry of **1** is determined by repulsion forces between the two pairs of perfluorinated rings, which is a typical feature of four-coordinate $Ni^{II}$ complexes with bulky ligands.

Although the synthesis of one homoleptic cobalt complex [Co{Ph-DAD(Ph)}$_2$] was reported earlier[5,6] up to now no structural information about $[Co(DAD)_2]$ complexes is available. The molecular structure of $[Co^{II}(^{F}DAD)_2]$ (**2**), which is isomorphous with **1**, is shown in Figure 2. The cobalt atom is located in a twisted tetrahedral environment of two chelating $^{F}$DAD ligands, nearly planar diimine moieties form a dihedral angle of 58.0(2)°. The molecule is symmetrical having a $C_2$-axis defined by the cobalt atom and the centroids of the diimine C–C bonds. The five-membered metallacycles formed are essentially planar: the maximum deviation from the best-fit plane is 0.027(4) Å for both rings. The bond lengths and angles within the two $^{F}$DAD moieties are the same within 3σ.

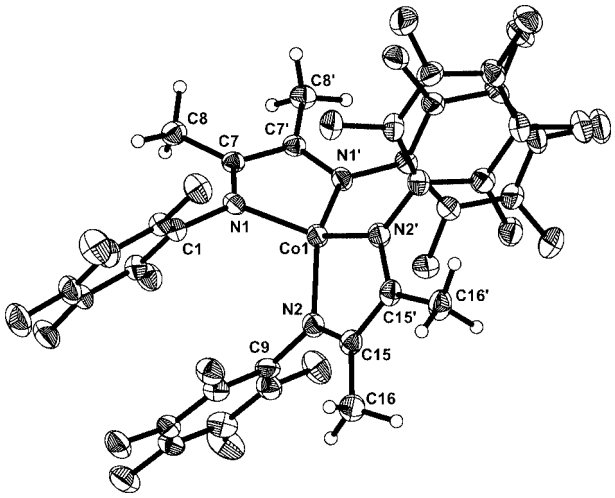


Figure 2. Molecular structure of **2** showing distorted tetrahedral geometry around the metal center; thermal ellipsoids are drawn at 30% probability level.

By comparison of the bond length pattern of the NCCN moieties in **2** with that of **1** it is found that $^{F}$DAD ligands in both complexes are nearly similar. In complex **2** the C–N bond lengths on av. 1.355(5) Å along with the C–C bonds of the NCCN backbone on av. 1.410(8) Å are in good agreement with the presence of two radical monoanions $(^{F}DAD)^{1-}$. Taking into account that the complex is not charged we assign the cobalt oxidation state to be +II ($d^7$ electronic configuration).

Slight C–N bond lengthening of 0.011 Å along with negligibly small C–C bond shortening of 0.003 Å in NCCN backbone of **2** compared to **1** are ascribed to slightly higher population of π* orbitals of the ligands in **2**. Nearly coplanar $C_6F_5$ rings with a dihedral angle of 3.9(2)° display an interplanar distance close to that observed in **1**: the smaller distance between $C_6F_5$-centroid and the least-squares plane of adjacent $C_6F_5$ ring is 3.27 Å. Close interplanar distances $C_6F_5$–$C_6F_5$ observed for **1** and **2** confirm that the geometry of both complexes is governed by intramolecular $C_6F_5$–$C_6F_5$ interactions.

## Synthesis and Characterization of BIAN Complexes

Complexes **3** and **4** were prepared by ligand reduction with $C_8K$ in the presence of the metal salts as described before for $^F$DAD complexes. Surprisingly, the reaction of 2 equiv. of the ligand with 1 equiv. of $CoCl_2$ gave neutral [Co($^F$BIAN)$_3$] but not the expected [Co($^F$BIAN)$_2$]. Subsequent reaction of $CoCl_2$ with 3 equiv. of $^F$BIAN led to the formation of the same [Co($^F$BIAN)$_3$] with improved yield. Both complexes are sensitive towards oxygen and water. Strict anaerobic conditions should be applied during working with the extremely sensitive [Co($^F$BIAN)$_3$].

[Ni$^{II}$($^F$BIAN)$_2$] shows sharp signals in $^1$H and $^{19}$F NMR spectra demonstrating its diamagnetism, whereas **4** is clearly paramagnetic. The $\mu_{eff}$ measured for solid **4** at room temperature is found to be 3.80 $\mu_B$, which is consistent with three unpaired electrons per molecular unit and spin state $S = 3/2$. By means of NMR and X-band EPR spectroscopy we did not detect any equilibrium between **3** and free $^F$BIAN with a hypothetical octahedral nickel analogue of **4**. Complex **3** was EPR silent in solution/frozen solution in the temperature range 4–300 K.

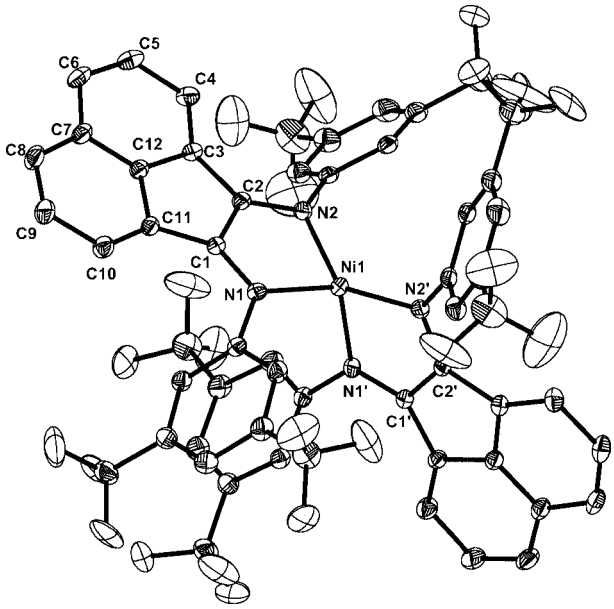

Figure 3. Molecular structure of **3**: disordered fluorine atoms are shown as semitransparent ellipsoids, hydrogen atoms are omitted for clarity, thermal ellipsoids are drawn at 30% probability level.

## Crystal Structures of BIAN Complexes

The molecular structure of **3** consists of two planar chelating $^F$BIAN ligands attached to the nickel atom (Figure 3). Similar to **1** and **2** the two $^F$BIAN ligands in **3** form a distorted tetrahedral $NiN_4$ ligand environment. The dihedral angle formed by two diimine chelates is found to be 83.66(8)°.

It is interesting to note that the two almost orthogonal diimine ligands do not form a regular tetrahedron. Instead, one ligand seems to be turned around the axis through Ni, perpendicular to the plane of the other diimine. For visualization of this unusual geometry the first coordination sphere of **3** is depicted in Figure 4. Consequently, local symmetry is missing completely in **3**. In contrast, complexes **1**, **2**, and all structurally characterized [Ni(DAD)$_2$] complexes with diverse sterically demanding *N*-substituents,[8,9] as well as [Ca(dip-BIAN)$_2$] with bulky *N*-dip groups[17] all form distorted tetrahedra with pseudo $C_2/D_2$ symmetry. The distorted tetrahedral geometry of **3** can be ascribed to intermolecular arene–arene interactions observed in the crystal structure. The acenaphthene rings involved in π stacking are parallel with respect to each other and show an interplanar distance of 3.533 Å (see Figure S1 in the supporting information).

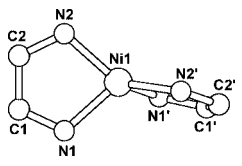

Figure 4. Ligands arrangement in **3**: a view exactly perpendicular to the plane defined by Ni1N1C1C2N2 (paper plane).

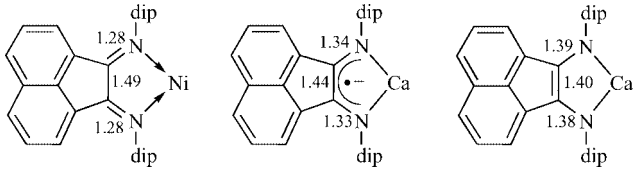
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Oxidation state of the ligands can be unambiguously assigned by a bond lengths analysis. Typical bond lengths of bis(arylimino)acenaphthene ligand in different oxidation states are represented in Scheme 2. As the naphthalene system does not show distinct changes in bond lengths only C–N and C–C bond lengths of diimine moieties are given for the ligand in different oxidation states. In complex **3** the diimine C–N bond length is found to be on average 1.339(2) Å and the diimine bridging C–C bond is 1.427(3) Å long. After having compared the bond length pattern observed in **3** with those of known structures we assign both diimines in **3** to be in monoanionic radical form (Scheme 2). This implies that the oxidation state of Ni is +II and the electronic configuration of the metal is $d^8$.



Scheme 2. Characteristic bond lengths for BIAN ligand in different oxidation states: $(BIAN)^0$ in $[Ni^{II}(dip\text{-}BIAN)Br_2]_2$[40] (left), $(BIAN)^{1-}$ in $[Ca^{II}(dip\text{-}BIAN)_2]$[17] (middle), and $(BIAN)^{2-}$ in $[Ca^{II}(dip\text{-}BIAN)(THF)_3]$[41] (right).

The *N*-phenyl rings in **3** form dihedral angles 57.9(1) and 49.9(1)° with the corresponding diimine moieties, hence the influence of these rings on the π system of $^F$BIAN is negligible. The observed dihedral angles along with deviation of N–C(phenyl) bonds from the diimine planes can be readily ascribed to intramolecular interactions between sterically demanding substituted phenyl rings. The only structurally characterized complex of the type $[M(BIAN)_2]$ was reported very recently by Fedushkin et al.[17] The crystal structure of paramagnetic $[Ca^{II}(dip\text{-}BIAN)_2]$ reveals a dihedral angle of 28° between the diimine moieties and does not show any π stacking between the diimine moieties in the crystal lattice.

The molecular structure of cobalt complex **4** is represented in Figure 5. It consists of three(!) sterically demanding $^F$BIAN ligands attached to the metal center. While complexes containing three less demanding DAD ligands are known,[25] to the best of our knowledge complexes containing three BIAN ligands are unknown so far.

The cobalt ion in **4** has a slightly distorted octahedral environment. Three diimine ligands show considerable planarity and planes of them are almost perpendicular to each other, as expected for a perfect octahedron. Taking into account that synthesis of complex **4** is performed under strong reducing conditions we disagree with its description as $Co^{III}$ with three $(^FBIAN)^{1-}$ ligands. The oxidation state of the metal is assumed to be +II or lower. Analysis of bond lengths of diimines shows non-equivalence of the three ligands. Two $^F$BIAN ligands are crystallographically identical (Table 1, form **I**), whereas the third one (form **II**) reveals a distinctly differing bond pattern. The bond length pattern observed in **II** closely resembles that in complex **3**. The diimine C–N bond on av. 1.331(3) Å and diimine C–C bond of 1.442(5) Å in **II** [1.339(2) and 1.427(3) Å, respectively, in complex **3**] are in agreement with the formulation of **II** as a radical monoanion. On the other hand, C–N bonds in **I** are significantly shorter, on av. 1.303(4) Å, the diimine C–C bond is significantly longer [1.474(4) Å] compared to **II** indicating neutral diimine character. Comparison of bond lengths in **I** with those of previously characterized complexes confirms that **I** is best described as neutral ligand. Hence complex **4** contains one diimine in form of the radical monoanion and two neutral diimine ligands. This implies that the oxidation state of the cobalt atom in **4** is best described as +I with $d^8$ electronic configuration and correct description of **4** is $[Co^I(^FBIAN)^0{}_2(^FBIAN)^{1-}]$.

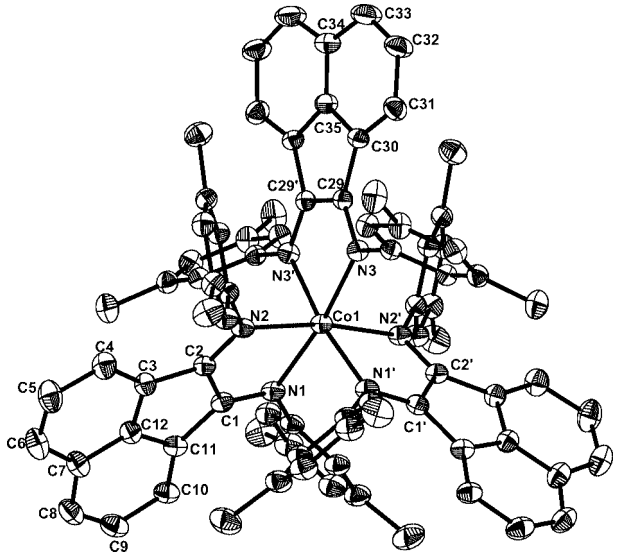


Figure 5. Molecular structure of **4**: hydrogen and disordered fluorine atoms are omitted for clarity, thermal ellipsoids are drawn at 30% probability level.

As expected the Co–N distances were found to be much longer in **4** compared to **2**. This is due to the increase of effective ionic radius $Co^{II}\rightarrow Co^I$ and to a change of coordination number from four in complex **2** to six in complex **4**. It can be noted that in complex **4** the distances Co–N in monoanionic $(^FBIAN)^{1-}$ at 2.125(2) Å are slightly shorter then those in closed-shell $(^FBIAN)^0$ at av. 2.132(2) Å. We refer this difference to the additional attraction between monoanionic $(^FBIAN)^{1-}$ and positive charged metal, which is lacking in the case of the neutral $(^FBIAN)^0$. The observed Co–N bond lengths are close to that reported for $[Co(bpy)_3]Cl$ at av. 2.11(2) Å.[26]

## Magnetochemistry and EPR Spectroscopy

The electronic structures of the paramagnetic complexes **2** and **4** were further investigated by variable-temperature magnetic susceptibility measurements and X-band EPR spectroscopy.

The temperature dependence of the effective magnetic moment ($\mu_{eff}$) of **2** is shown in Figure 6. The magnetic mo-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ment decreases gradually from 3.26 $\mu_B$ at 300 K to 2.36 $\mu_B$ at 5 K. From the crystal structure we have established that **2** contains $Co^{II}$ ion ($d^7$) and two radical anionic ligands. Therefore **2** represents a three-center odd-electron system. The value of $\mu_{eff}$ at low temperatures is in agreement with a doublet ground state ($S$ = 1/2). The first excited quartet state ($S$ = 3/2) becomes populated with increasing temperature.

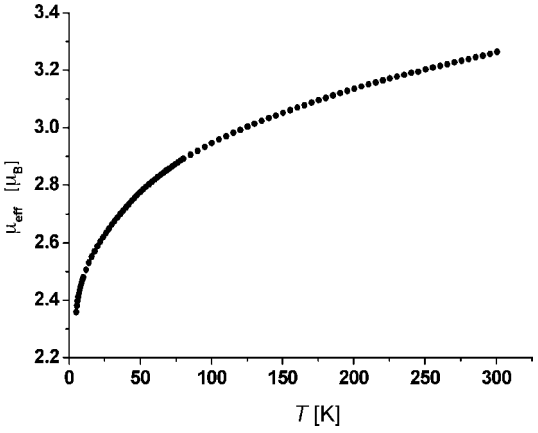

Figure 6. Temperature dependence of the effective magnetic moment of **2**.

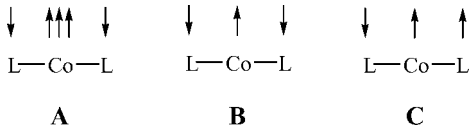
The spin state of cobalt is not inherently clear because of the twisted coordination geometry around the metal center of **2**. Most cobalt(II) complexes are high-spin compounds ($S_{Co}$ = 3/2) in tetrahedral, but low-spin ($S_{Co}$ = 1/2) in planar environment. The molecular structure of **2** showing the dihedral angle of 58.0(2)° between the two diimines moieties takes an intermediate position between the tetrahedral and the planar geometries. The doublet ground state can be achieved by combination of the high-spin cobalt ion with the two radical ligands both coupled antiferromagnetically with the metal (Scheme 3, **A**). Another possibility to achieve the ground state doublet is to let the low-spin cobalt ion couple with two organic radicals, where two more types of electronic structures are to be considered. Two organic radicals couple in ferromagnetic fashion with each other but in antiferromagnetic fashion with the metal (**B**) yielding required $S$ = 1/2. Or the two ligand spins couple antiferromagnetically with each other so that the metal spin is aligned ferromagnetically to one of the ligand spin but antiferromagnetically to the other one resulting in the doublet ground state (**C**).



Scheme 3. Ground state spin models for **2**.

In recent publications by Wieghardt et al.[10] it was shown that related planar complexes $[M^{II}(sbqdi)_2]$ (M = Ni, Pd, Pt) containing radical ligands reveal strong antiferromagnetic coupling between two remote ligands. The ligands interact strongly with each other via an efficient superexchange mechanism that is mediated by a back-bonding interaction to the central metal. Such a superexchange interaction between two remote radicals is efficient only for certain geometries of the complexes. Very recently Ye et al.[27] showed, that if the geometry of such complexes deviates significantly from planarity, the interaction between two remote radical ligands becomes significantly weaker. Therefore, the spin state of **2** is likely to be of type **A** or **B**, with dominating antiferromagnetic interactions between the cobalt and radical ligand, but unlikely **C**, with dominating antiferromagnetic coupling between two radical ligands.

For fitting the experimental data we tentatively used the following Hamiltonian, see Equation (1).

$$\mathbf{H} = -J_{ab}(\mathbf{S_{Co}}\cdot\mathbf{S_1} + \mathbf{S_{Co}}\cdot\mathbf{S_2}) - J_{aa}(\mathbf{S_1}\cdot\mathbf{S_2}) + \beta[(\mathbf{S_1} + \mathbf{S_2})\cdot\mathbf{g_R} + \mathbf{S_{Co}}\cdot\mathbf{g_{Co}}]\cdot H \quad (1)$$

Here the first term is the Heisenberg term accounting for the isotropic exchange interaction between the metal and the radical ligands with $J_{ab}$, the second term relates to the isotropic exchange between two radical ligands with $J_{aa}$, and the third one is the Zeeman perturbation term. For the spin model **A** $S_{Co}$ = 3/2 and for the model **B** $S_{Co}$ = 1/2. The $\mathbf{g_{Co}}$ and $\mathbf{g_R}$ were assumed to be isotropic with $g_{Co}$ and $g_R$ principal values, for radical ligands $S_1 = S_2$ = 1/2. Unfortunately, we were not able to obtain a reasonable fit to the experimental data for both low- and high-spin cobalt complex models. The introduction of the intermolecular interactions and paramagnetic impurities did not improve the fit significantly. A more accurate model considering the local anisotropy and/or anisotropic interactions is therefore needed.

In spite of the unsuccessful simulations of magnetic susceptibility data, the ground state of **2** can be determined by EPR spectroscopy at cryogenic temperatures. Indeed, if we reject **C** because of geometrical reasons, then **A** and **B** would give apparently different EPR spectra at low temperatures. Model **A** would give the EPR signal typical for cobalt(II) complexes, whereas **B** would give a spectrum of an organic radical.

The X-band EPR spectrum of **2** measured in a frozen solution at 20 K is shown in Figure 7. The large anisotropy of the $g$ tensor and the hyperfine splitting of $^{59}Co$ ($I$ = 7/2) indicate that the unpaired electron is located mostly on the metal d-orbitals and not on the ligands. Therefore the model **A** with high-spin $Co^{II}$ is the most plausible description of this system. The EPR spectrum of **2** has been successfully simulated by using the orthorhombic $g$ tensor: $g_1$ = 4.296, $g_2$ = 1.676, $g_3$ = 1.625, with $^{59}Co$ hyperfine coupling constants: $A_1$ = 197, $A_2$ = 52, $A_3$ = 56 G. Furthermore, the line width dependence was introduced as shown in Equation (2), where $m_I$ is the nuclear spin ($m_I$ = –7/2, ..., +7/2 for $^{59}Co$ nucleus); $\alpha_i$, $\beta_i$, $\gamma_i$ are orientation-dependent ($i = x, y, z$) line width parameters.

$$\Delta B(m_I) = \sum_{i=1}^{3} \alpha_i + \beta_i m_I + \gamma_i m_I^2 \quad (2)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

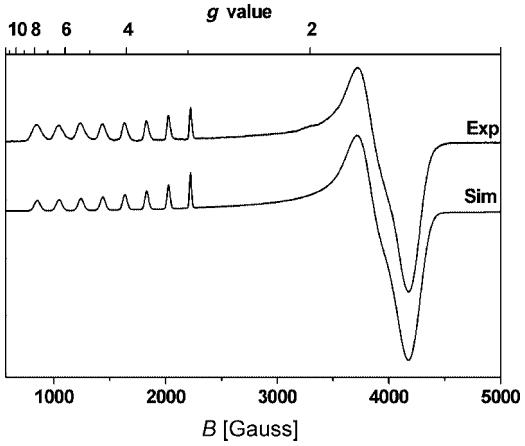


Figure 7. X-band EPR spectrum of **2**. Conditions: THF/toluene ca. 1:1 at 20 K; frequency 9.2265 GHz; power 5.0 μW; modulation amplitude 10 G. The fit parameters are given in the text.

The temperature dependence of $\mu_{eff}$ of **4** is shown in Figure 8. The magnetic moment measured at 300 K is 3.80 $\mu_B$ indicates the presence of three unpaired electrons ($S$ = 3/2). With decreasing temperature $\mu_{eff}$ gradually decreases to the value of 2.07 $\mu_B$ at 10 K followed by a steep descent to 1.79 $\mu_B$ at 1.8 K. This behavior is explainable by the presence of the high-spin $Co^I$ ($d^8$, $S_{Co}$ = 1, pseudooctahedral environment) and a radical ligand ($S_R$ = 1/2) coupled in antiferromagnetic fashion. Thus, the ground state of **4** is a doublet with an excited quartet populated at higher temperatures. The abrupt decreasing of the magnetic moment at temperatures below 10 K can be ascribed to the intermolecular antiferromagnetic interactions in the solid.

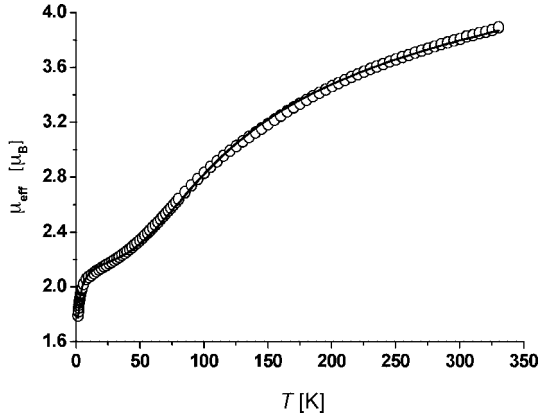

Figure 8. Temperature dependence of the effective magnetic moment of **4**, the fit parameters are given in the text.

To fit the experimental data we used the following Hamiltonian, see Equation (3), where the first term is the Heisenberg term related to the isotropic exchange interaction ($J$) between two magnetic centers and the second term is the Zeeman perturbation, nonequivalence of **g** tensors is supposed.

$$\mathbf{H} = -J\mathbf{S_{Co}}\cdot\mathbf{S_R} + \beta(\mathbf{S_{Co}}\cdot\mathbf{g_{Co}} + \mathbf{S_R}\cdot\mathbf{g_R})\cdot H \quad (3)$$

Assuming tensors $\mathbf{g_{Co}}$ and $\mathbf{g_R}$ to be isotropic with $g_{Co}$ and $g_R$ principal values and taking $S_{Co}$ = 1, $S_R$ = 1/2 the equation for magnetic susceptibility can then be derived, Equation (4).[28]

$$\chi = \frac{N\beta^2}{4kT}\frac{g_{1/2}^2 + 10g_{3/2}^2\exp(3J/2kT)}{1+2\exp(3J/2kT)} \quad (4)$$

Here $g_{1/2}$ and $g_{3/2}$ factors correspond to each of the spin states, they are related to the local $g$ factors through Equation (5).

$$g_{1/2} = (4g_{Co} - g_R)/3 \qquad g_{3/2} = (2g_{Co} + g_R)/3 \quad (5)$$

By adding temperature-independent paramagnetism (*TIP*) into Equation (4) it was possible to obtain a good fit for magnetic susceptibility for the temperature range 10–330 K. To fit the data on the whole temperature range we modified Equation (4) according to the molecular field approximation for weak intermolecular interactions, Equation (6).[29] Here $z$ is the number of the nearest neighbors around a given magnetic molecule in the crystal lattice and $J'$ is the interaction parameter, the $g$ factor in Equation (6) was taken as equal to 2.

$$\chi' = \frac{\chi}{1-(2zJ'/Ng^2\beta^2)\chi} + TIP \quad (6)$$

The best fit using Equation (6) was obtained with the following parameters: $g_R$ = 2.00 (fixed), $g_{Co}$ = 2.37, $J$ = –106.0 $cm^{-1}$, $zJ'$ = –0.78 $cm^{-1}$, $TIP = 1.23\times10^{-3}$ $cm^3\,mol^{-1}$. The accuracy of the fit used is very good showing $R^2$ = 0.99924. Hence, the ground state doublet is separated from the excited quartet by $-3J/2$ = 159 $cm^{-1}$. Week intermolecular antiferromagnetic interactions are present in the polycrystalline sample of **4**, as indicated by negative value of $zJ'$ = –0.78 $cm^{-1}$. Abrupt decreasing of $\mu_{eff}$ of **4** at low temperatures may be governed by zero-field splitting effect as well, this supposition was not examined.

The X-band EPR spectrum of **4** measured in frozen solution at 4 K is shown in Figure 9. It is evident that more than one paramagnetic species is present. We propose two compounds to exist in the frozen solution. The first one is a cobalt complex with a large anisotropy of the $g$ tensor (**Tet**): a well resolved octet centered at $g \approx 3.8$ and a less resolved signal at $g \approx 1.9$. The second species is a cobalt complex as well, but with a higher symmetric arrangement at the metal (**Oct**), its signal is partly hidden by those of **Tet** and centered at $g \approx 2.3$. Because **4** is extremely sensitive towards both oxygen and moisture, the EPR experiment was repeated several times with freshly prepared solutions. All samples measured gave nearly identical spectra. It was concluded that the two cobalt species observed originate not from decomposition of **4**, but from partially dissociation.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

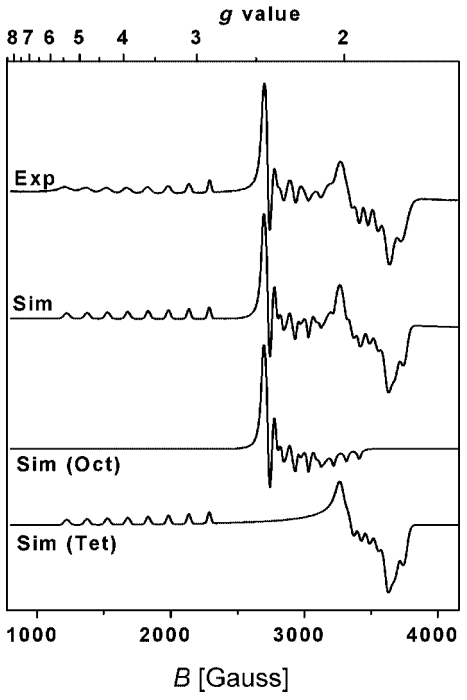

Figure 9. X-band EPR spectrum of **4**. Conditions: THF/toluene ca. 1:1 at 4 K; frequency 9.2278 GHz; power 1.3 μW; modulation amplitude 10 G. The fit parameters are given in the text.

Thus the distorted octahedral complex **4** partially dissociates in solution (toluene/THF ≈ 1:1) into the neutral species [Co($^{F}$BIAN)$_2$], which has very likely distorted tetrahedral geometry, and the free ligand $^{F}$BIAN. Assuming that this dissociation takes place we can readily assign the signals in the EPR spectrum. Species **Tet** is expected to be [Co($^{F}$BIAN)$_2$], whereas **Oct** is apparently **4**. The EPR spectrum is therefore best explained by the superposition of two orthorhombic signals. The spectrum has been successfully simulated by using the following parameters: for **Oct** $g_1$ = 2.363, $g_2$ = 2.243, $g_3$ = 2.143, hyperfine coupling constants ($^{59}$Co) $A_1$ = 17, $A_2$ = 58, $A_3$ = 96 G; for **Tet** $g_1$ = 3.756, $g_2$ = 1.874, $g_3$ = 1.895, hyperfine structure ($^{59}$Co) $A_1$ = 153, $A_2$ = 65, $A_3$ = 38 G. For **Tet** showing the large anisotropy the line width dependence was included in the simulation. On warming, the signal of **Oct** disappears much faster than that of **Tet**. At 100 K only the poorly resolved signal of **Tet** is observed. This indicates that the relaxation time for **Oct** compared to **Tet** is small.

### Electronic Spectra

Electronic spectra of the complexes **1**–**4** in chloroform and in *n*-hexane solutions were recorded at room temperature in the range 200–1100 nm. Spectra of DAD complexes **1** and **2** consist of a strong band in the ultra-violet ($\varepsilon > 10^4$ dm$^3$·mol$^{-1}$·cm$^{-1}$) and weaker two (**1**) or four bands (**2**) in the visible region. The UV absorption can be assigned to intra-ligand (IL) transition, since the free ligand absorbs in the similar region. The long-wavelength bands in visible, determining the intensive color of the complexes presumably are charge-transfer (CT) transitions. Solvent dependence and high intensity renders them easily distinguishable from solvent-independent and low-intensity d–d transitions. The two bands in the visible region are characteristic of [Ni(DAD)$_2$] complexes, as was observed by tom Dieck for a series of such complexes.[8]

UV/Vis spectra of BIAN complexes **3**–**4** are dominated by intense IL electronic transitions (329–332 nm, $\varepsilon > 10^4$ dm$^3$·mol$^{-1}$·cm$^{-1}$), and three transitions in visible/NIR. The latter are supposed to be CT transitions relying on their relative high intensities ($\varepsilon$ = 8–10·10$^3$ and 5–12·10$^3$ dm$^3$·mol$^{-1}$·cm$^{-1}$ for **3** and **4**, respectively) and solvatochromism. High-energy absorption maxima in visible at 512 and 519 nm for **3** and **4**, respectively, are indicative of the presence of a radical anion (BIAN)$^{1-}$. Several complexes reported recently by Fedushkin[30] containing the radical (BIAN)$^{1-}$ all show absorption maximum/maxima in the region 420–530 nm.

We refrain from discussing the more specific assignment of electronic absorptions of **1**–**4** in visible/NIR as sufficient confidence may only be achieved in combination with high-quality excited-state TD-DFT calculations.

## Conclusions

We have synthesized new complexes of nickel and cobalt containing the non-innocent highly π acidic diimine ligands $^{F}$DAD and $^{F}$BIAN with bulky fluorinated *N*-substituents. The oxidation states of the ligands and subsequently of the metals were determined by single-crystal X-ray analysis at low temperatures. The electronic structure of [Ni$^{II}$($^{F}$DAD)$_2$] as well as electronic structures of [Ni(DAD)$_2$] complexes previously characterized by X-ray analysis were shown to be consistent with a divalent nickel d$^8$ ion and a pair of radical monoanionic ligands. The unique [Co$^{I}$($^{F}$BIAN)$_3$] comprises a cobalt(I) ion, two neutral ($^{F}$BIAN)$^0$ ligands and one radical monoanion ($^{F}$BIAN)$^{1-}$. Both [Co$^{II}$($^{F}$DAD)$_2$] and [Co$^{I}$($^{F}$BIAN)$_3$] possess a doublet ground state with electron density located mostly in the metal d-orbitals as was concluded from magnetic susceptibility measurements and the X-band EPR spectroscopy.

## Experimental Section

The ligand $C_6F_5$-DAD(Me) (= $^{F}$DAD) can be prepared by a known procedure in low yield.[31] Here we describe an alternative method of its preparation with much higher yield (vide infra). Anhydrous metal salts $NiCl_2$·DME,[32] $NiBr_2$·DME[32] as well as [3,5-$(CF_3)_2$-$C_6H_3$]-BIAN[33] (= $^{F}$BIAN) and $C_8K$[34] were prepared according to the known procedures. Anhydrous $CoCl_2$ was obtained by refluxing of $CoCl_2$·$n$H$_2$O with $SOCl_2$ for several hours followed by removing the volatiles under reduced pressure at 90 °C. Syntheses of all complexes were performed under a dry argon atmosphere using standard Schlenk techniques and dried solvents.

**Physical Measurements:** Mass spectra were obtained on a Finnigan MAT 95S mass spectrometer (70 eV, EI). IR spectra were obtained in Nujol mull using a Nicolet 510 FT-IR. UV/Vis spectra were measured on a Shimadzu UV-1601PC instrument in absolute

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CHCl_3$ and *n*-hexane at concentrations $10^{-4}$ to $10^{-5}$ M. NMR spectra were recorded at room temperature on a Bruker ARX 200 spectrometer at 200.13 MHz for $^1H$ and 188.29 MHz for $^{19}F$. $^1H$ NMR spectra are referenced (in ppm) to residual proton signals of $CDCl_3$ ($\delta$ = 7.26 ppm) and $C_6D_6$ ($\delta$ = 7.15 ppm). $^{19}F$ NMR spectra were referenced to external standard $CFCl_3$. Abbreviations used are the following: s = singlet, d = doublet, t = triplet, pst = pseudo-triplet, m = multiplet. EPR spectra were recorded in the X-band on a Bruker System ESP 300. The magnetic susceptibility measurements were performed on a powder samples using a Quantum Design MPMS2 SQUID magnetometer with an applied field of 1 T. Experimental susceptibility data were corrected for the underlying diamagnetism using Pascal's constants.

**X-ray Crystallographic Data Collection and Refinement of the Structures:** Single crystals of **1**–**4** were coated with inert oil, picked up with a glass fiber and mounted in the nitrogen cold stream of the STOE IPDS2 (**1**, **3**, **4**) or STOE IPDS diffractometer (**2**). Intensity data were collected at 193 K using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.17073 Å). Data collection was performed by hemisphere runs taking frames at 1.0° in $\omega$. Final cell constants were obtained from a least-squares fit of a subset of several thousand strong reflections. Intensity data of **1** and **3** were corrected using indexed crystal faces, the data of **4** using the semiempirical correction routine MulScanAbs.[35] For **2** an absorption correction did not improve the quality of the data and was not applied. There was disordered solvent (toluene) present in the crystal structures of **1**, **2**, and **4**. In the crystal structures of **3** and **4** the $CF_3$ groups are disordered: two positions for each fluorine atom with different occupancies were found. All structures have been solved by the direct methods in SHELXS-97[36] (**1**, **3**, **4**) or SIR92[37] (**2**) and refined using the full-matrix least-squares refinement procedure of SHELXL97,[36] all non-hydrogen atoms anisotropically; H atoms have been located and isotropically refined (**1**, **3**) or have been placed at calculated positions and have been refined using a riding model with $U_{iso}(H) = 1.2U_{eq}(C)$ (**2**, **4**). Crystallographic data of the compounds are listed in Table 2.

CCDC-290299 to -290302 contain the complete crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of $C_6F_5$-DAD(Me) (1a):** To 2,3,4,5,6-pentafluoroaniline (9.15 g, 0.050 mol) dissolved in dry MeOH (15 mL), 2,3-butanedione (3.2 mL, 0.038 mol), *p*-toluenesulfonic acid (ca. 0.2 g), and trimethyl orthoformate (10.0 mL, 0.097 mol) were added. After stirring for 1 day at room temperature the pale yellow precipitate was filtered, washed with cold MeOH and dried in vacuo. Yield: 5.19 g (50%). $^1H$ NMR (200.13 MHz, $CDCl_3$, 300 K): $\delta$ = 2.24 (t, $J$ = 1.2 Hz, 6H, $CH_3$) ppm. $^{19}F$ NMR (188.29 MHz, $CDCl_3$, 300 K): $\delta$ = –151.3 (d, $^3J_{F,F}$ = 20 Hz, 4F, $Ar_{ortho}$), –161.3 (t, $^3J_{F,F}$ = 21 Hz, 2F, $Ar_{para}$), –162.9 (pst, $^3J_{F,F}$ = 20 Hz, 4F, $Ar_{meta}$) ppm.

**Syntheses of Complexes. [$Ni^{II}${$C_6F_5$-DAD(Me)}$_2$] (1):** $NiBr_2$·DME (371 mg, 1.20 mmol), $C_8K$ (341 mg, 2.52 mmol) and **1a** (1000 mg, 2.40 mmol) were placed in a Schlenk flask and THF (50 mL) was added. The reaction mixture was stirred overnight at room temperature. The mixture was filtered via Celite and THF was removed in vacuo giving a purple powder. The raw product was repeatedly extracted with boiling toluene (50 mL) from a glass frit until almost colorless solution. After the toluene extract was stored for a night at –30 °C, dark-purple crystals were collected by decantation of the solvent. The crystals were washed with cold *n*-hexane (2 × 5 mL) and dried in vacuo. Yield: 660 mg (62%). Single crystals of **1** suitable for X-ray crystallography were obtained from a THF/toluene mixture (1:2) by cooling. M.p. 200–203 °C. $C_{32}H_{12}F_{20}N_4Ni$ (891.13): calcd. C 43.13, H 1.36, N 6.29; found C 43.66, H 1.85, N 5.96. MS (EI): *m/z* = 889 [M–H$^+$], 474 [M–(DAD)$^+$], 416 [(DAD)$^+$]. $^1H$ NMR (200.13 MHz, $CDCl_3$, 300 K): $\delta$ = –1.98 ppm (s, 12H, $CH_3$) ppm. $^{19}F$ NMR (188.29 MHz, $CDCl_3$, 300 K): $\delta$ = –150.2 (m, 8F, $Ar_{ortho}$), –160.1 (t, $^3J_{F,F}$ = 21 Hz, 4F, $Ar_{para}$), –164.0 (m, 8F, $Ar_{meta}$) ppm. IR (Nujol): $\tilde{\nu}$ = 1630 (w), 1508 (s), 1408 (s), 1308 (w), 1260 (w), 1196 (m), 1146 (w), 1117 (m), 1033 (s), 987 (s), 928 (m), 798 (w), 732 (m), 696 (w), 644 (w), 598 (w), 558 (w), 466

(w) $cm^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon_{max}$/$dm^3 \cdot mol^{-1} \cdot cm^{-1}$) = 756 sh (3200), 524 (8000), ≈ 292 (15200) nm.

**[$Co^{II}${$C_6F_5$-DAD(Me)}$_2$] (2):** $CoCl_2$ (156 mg, 1.20 mmol), $C_8K$ (341 mg, 2.52 mmol) and **1a** (1000 mg, 2.40 mmol) were placed in a Schlenk flask and THF (40 mL) was added. The reaction mixture was stirred overnight at room temperature. The mixture was filtered and THF was removed in vacuo giving a brown powder. The raw product was extracted with *n*-hexane (65 mL), concentrated in vacuo and washed with cold benzene (5 mL). Yield: 431 mg (40%). Brown single crystals of **2** suitable for X-ray crystallography were obtained from a THF/toluene mixture (3:1) by cooling. M.p. 194–196 °C. $C_{32}H_{12}CoF_{20}N_4$ (891.38): calcd. C 43.12, H 1.36, N 6.29; found C 42.92, H 1.69, N 5.91. MS (EI): *m*/*z* = 890 [M–$H^+$], 475 [M–(DAD)$^+$], 416 [(DAD)$^+$]. IR (Nujol): $\tilde{\nu}$ = 1632 (w), 1514 (s), 1504 (s), 1402 (m), 1308 (w), 1197 (m), 1142 (w), 1119 (m), 1030 (s), 987 (s), 929 (m), 797 (w), 683 (m), 640 (w), 597 (w) $cm^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon_{max}$/$dm^3 \cdot mol^{-1} \cdot cm^{-1}$) = 697 (1200), 529 (3100), 470 (5400), 429 (5200), 335 (11600) nm.

**[$Ni^{II}$({3,5-$(CF_3)_2C_6H_3$}-BIAN)$_2$] (3):** $NiCl_2$·DME (610 mg, 1.00 mmol), $C_8K$ (143 mg, 1.06 mmol) and $^F$BIAN (111 mg, 0.51 mmol) were placed in a Schlenk flask and THF (30 mL) was added. The reaction mixture was stirred overnight at room temperature. The resulting dark-blue suspension was concentrated under reduced pressure. The raw product was extracted with toluene (40 mL). After toluene was removed, a dark-blue fine crystalline material was obtained, which was washed with MeCN and dried in vacuo. Yield: 518 mg (81%). Single crystals of **3** suitable for X-ray crystallography were obtained from a saturated *n*-hexane solution by cooling. M.p. 321–323 °C. $C_{56}H_{24}F_{24}N_4Ni$ (1267.47): calcd. C 53.07, H 1.91, N 4.42; found C 52.53, H 2.01, N 4.41. MS (EI): *m*/*z* = 1266 [$M^+$], 1247 [M–$F^+$], 662 [M–(BIAN)$^+$]. $^1$H NMR (200.13 MHz, $C_6D_6$, 300 K): $\delta$ = 8.98 (s, 4H, $H_{Ph}$), 7.97 (m, 4H, $H_{Ph}$, $H_{naph}$), 7.10 (d, $^3J_{H,H}$ = 7.2 Hz, 2H, $H_{naph}$), 6.41 (pst, $^3J_{H,H}$ = 7.7 Hz, 2H, $H_{naph}$) ppm. $^{19}$F NMR (188.29 MHz, $C_6D_6$, 300 K): $\delta$ = –63.0 (s, 12F, $CF_3$) ppm. IR (Nujol): $\tilde{\nu}$ = 1776 (w), 1600 (m), 1510 (w), 1418 (w), 1275 (s), 1243 (w), 1127 (s), 1091 (s), 1014 (s), 974 (m), 884 (m), 850 (m), 812 (m), 761 (m), 700 (m), 678 (m), 544 (w), 496 (w) $cm^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon_{max}$/$dm^3 \cdot mol^{-1} \cdot cm^{-1}$) = 874 (8300), 600 (12200), 512 (10300), ≈ 332 (32700) nm.

**[$Co^{I}$({[3,5-$(CF_3)_2C_6H_3$]-BIAN}$_3$] (4):** $CoCl_2$ (43 mg, 0.33 mmol), $C_8K$ (95 mg, 0.70 mmol) and $^F$BIAN (604 mg, 1.00 mmol) were placed in a Schlenk flask and THF (15 mL) was added. The reaction mixture was stirred overnight at room temperature. THF was removed in vacuo and the raw product was extracted with toluene (50 mL). Toluene solution was concentrated to 25 mL, *n*-hexane (25 mL) was added and the resulting solution was stored for a night at –30 °C. Solution was decanted, dark-purple crystals were washed with *n*-hexane and dried in vacuo. Yield: 283 mg (46%). Single crystals of **4** suitable for X-ray crystallography were obtained from a toluene/*n*-hexane mixture by cooling. M.p. 275–278 °C. $C_{84}H_{36}CoF_{36}N_6$ (1872.13): calcd. C 53.89, H 1.94, N 4.49; found C 53.44, H 1.96, N 4.47. MS (EI): *m*/*z* = 1267 [M–(BIAN)$^+$], 1248 [M–(BIAN)–$F^+$], 663 [M–2(BIAN)$^+$]. IR (Nujol): $\tilde{\nu}$ = 1600 (w), 1278 (s), 1261 (m), 1242 (m), 1175 (s), 1140 (s), 1102 (m), 1035 (m), 1019 (m), 972 (m), 892 (m), 856 (m), 846 (m), 822 (w), 795 (w), 770 (m), 723 (m), 705 (w), 683 (m), 668 (m), 616 (w), 576 (w), 533 (m), 513 (m), 481 (m) $cm^{-1}$. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\varepsilon_{max}$/$dm^3 \cdot mol^{-1} \cdot cm^{-1}$) = 735 (5000), 519 sh (12100), ≈ 329 (41300) nm.

# Synthesis, Complexation and Spectrofluorometric Studies of a New $NS_3$ Anthracene-Containing Macrocyclic Ligand

**Abel Tamayo,[a] Lluis Escriche,*[a] Jaume Casabó,[a] Berta Covelo,[b] and Carlos Lodeiro*[b]**

**Keywords:** PET Systems / N,S ligands / Macrocycles / Fluorescence / Palladium

A new fluorescent device for detecting protons and metal ions, 11-(9-anthracenylmethyl)-1,4,7-trithia-11-azacyclotetradecane (**L**), has been synthesised. In addition, the photophysical properties of both the free and protonated species have been examined by absorption and fluorescence titrations of dichloromethane solutions of **L** with methanesulfonic acid. The coordinating properties of **L** toward $Pd^{II}$, $Zn^{II}$, $Ni^{II}$ and $Co^{II}$ have been studied both in solution and in the solid state. Different behaviours have been observed in the absorption and fluorescence titrations of **L** with the above-mentioned transition-metal ions. To evaluate whether these differences were due to the existence of equilibria between protonated and complexed species, such titrations have been repeated in the presence of an equivalent amount of acid. The structure of the $[Pd(\mathbf{L})](BF_4)_2$ complex has been solved by X-ray crystallography.

## Introduction

The design of new fluorescence chemosensors capable of signalling the presence of metal ions is a subject of particular interest for chemists.[1] These systems usually consist of a fluorescent moiety (signalling unit), covalently connected to a binding site (receptor unit).[2] The more specific the interaction between the receptor unit and the analyte, the greater the selectivity of the chemosensor. Many fluorescence chemosensors have macrocycles as receptor units, as the coordinating properties of macrocycles have been shown to be more effective than those of the analogous acyclic ligands. Most of these chemosensors are made up of polyoxa,[3] polyaza[4] and oxa-azamacrocycles,[5] which have been used for the detection of alkali and *hard* metal ions. However, less attention has been paid to the study of thiamacrocycle-containing chemosensors, which could be useful for detecting *soft* transition-metal ions.[6] On the other hand, the stronger the effects of the ion on the properties of the fluorophore, the greater the sensitivity of the chemosensor. Aliphatic amines closely bonded to anthracene moieties are known to be involved in electron transfer quenching, which facilitates the signalling of the presence of metal ions in amine-containing systems.[7] Taking these considerations into account, we here report the synthesis of a new fluorescence device 11-(9-anthracenylmethyl)-1,4,7-trithia-11-azacyclotetradecane (**L**), which consists of an azathiamacrocycle connected by its aliphatic amine to an anthracene moiety. Protonation and coordination properties towards $Pd^{II}$, $Zn^{II}$, $Ni^{II}$ and $Co^{II}$ have also been studied, with the crystallographic data of the $[Pd(\mathbf{L})](BF_4)_2$ complex analysed as well.

## Results and Discussion

### Synthesis of Ligands

Scheme 1 shows the two methods used to synthesise the anthracene-containing macrocycle **L**. The first method (pathway A in Scheme 1) is based on using macrocycle **2** as a precursor of **L**. Compound **2** was obtained by cyclisation of 2,2′-thiobis(ethanethiol) with the dichloride precursor **1**, following a procedure similar to that described by Buter and Kellogg for the synthesis of sulfur-containing macrocycles. This method is based on the simultaneous reaction between aliphatic α,ω-dithiols and α,ω-dihalides, using DMF as a solvent and $Cs_2CO_3$ as a base.[8] In our case, CsOH was used instead of $Cs_2CO_3$, as the carbonate ions react with **1** to produce 3-(3-chloropropyl)-[1,3]oxazin-2-one.[9] This modification allowed us to obtain **2** in 62% of the yield. The preparation of **2** was previously reported in the literature using other methods.[10] Those methods avoid the reaction between the carbonate ions and the dihalide **1** by using protection–deprotection strategies, which increase the number of synthetic steps and decrease the final yields. The last step in synthetic procedure A is the functionalisation of **2** with an anthracene derivative. This was performed by a reaction of **2** with 9-(chloromethyl)anthracene in the presence of KI, as we have recently shown that iodide

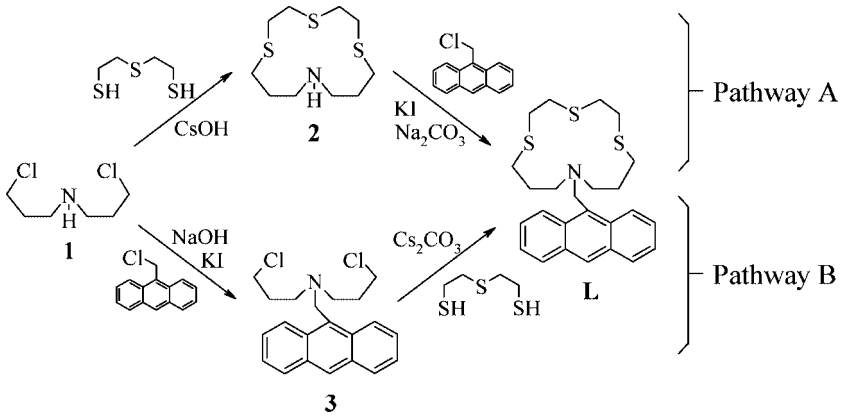

Scheme 1.

ions can be used as catalysts for the nucleophilic substitution reactions of 9-(chloromethyl)anthracene and secondary aliphatic amines.[11] The overall yield of pathway A was 45%.

The second method for the synthesis of **L** (pathway B in Scheme 1) is based on the functionalisation of the dichloride precursor **1**, prior its use in the cyclisation reaction with 2,2′-thiobis(ethanethiol). Although the cyclisation conditions of pathway B are very close to those optimised for the synthesis of sulfur-containing macrocycles,[8] as $Cs_2CO_3$ could be used as a base,[12] the overall yield of this second pathway (38%) was not significantly different from that found in pathway A.

### Complexation of L

The reaction of equimolar amounts of **L** and $Pd(BF_4)_2 \cdot 4CH_3CN$ in acetonitrile yielded a light brown solution. The addition of diethyl ether to this solution led to the precipitation of a crystalline product, whose elemental analysis is consistent with the formula $Pd(\mathbf{L})(H_2O)_2(BF_4)_2$. Its IR spectrum confirmed the presence of **L**, tetrafluoroborate ions and water molecules, as well as the absence of acetonitrile, as no signal was observed between 2250 and 2350 $cm^{-1}$. This compound behaves as a 2:1 electrolyte in acetonitrile solution, which indicates that the tetrafluoroborate anions are not coordinated with the metal ions. The $^1H$ NMR spectrum of this complex in acetonitrile solution shows a complex pattern in the aliphatic region, as most of the signals become multiplets because of the nonequivalence of the hydrogen atoms. However, its $^{13}C\{^1H\}$NMR spectrum shows the same number of signals as that of the free ligand, which indicates that although the two protons bonded to each carbon atom are magnetically nonequivalent, each pair of carbon atoms is chemically equivalent. On the other hand, those carbons directly bonded to a donor atom of **L** show downfield displacement compared with those of the free ligand, which suggests that the $Pd^{II}$ ion is coordinated to all four donor atoms of **L**. This fact, together with the ESI-MS and electronic spectra of this complex, points to the presence of the $[Pd(\mathbf{L})]^{2+}$ unit, which was confirmed by X-ray analysis of the pale brown crystals obtained by slow diffusion of hexane into a dichloromethane solution of $[Pd(\mathbf{L})](BF_4)_2 \cdot 2H_2O$. It is important to note that although the elemental analysis, as well as the IR spectrum of this complex, indicates the presence of water molecules, these are not present in the crystal lattice of the complex. Therefore, they were probably lost during the crystallisation process.

The crystal structure of this complex consists of discrete $[Pd(\mathbf{L})]^{2+}$ cations and tetrafluoroborate anions. A displacement ellipsoid representation of the cation complex and a list of selected bond lengths and angles are given in Figure 1. The metal coordination geometry is square-planar with the N2, S6, S9, S12 and Pd atoms on a plane. The largest deviation from this plane is 0.0941 Å for the S9 atom. The Pd–N distance [2.133(2) Å] is slightly larger than that of the analogous $Pd^{II}$ complex without the pendant arm.[10b] The Pd–S bond lengths [2.2718(9), 2.306(3) and

2.3221(9) Å] are similar to those found for other $Pd^{II}$ complexes of thioether-containing macrocycles.[10b,13] In this structure, **L** adopts a conformation in which all carbon atoms of the macrocyclic unit lie below the plane defined by the four heteroatoms, whereas the whole anthracene moiety lies over this plane. As expected, the anthracene unit is essentially planar. In fact, the largest deviation from the least-squares plane calculated using all 14 aromatic atoms is 0.126 Å for the C29 atom. A ring of the anthracene moiety is located over the $Pd^{II}$ ion. The distance between the centroid of such a ring [Cg(1): C25–C26–C27–C28–C29–C30] and the metal ion is 3.635 Å, whereas the angle between the normal of the ring and the Cg(1)···Pd vector is 41.26°. These considerations may suggest a weak intramolecular cation···π interaction.[14] On the other hand, nonclassical C–H···F hydrogen bonds lead to the formation of a 2D supramolecular network along the crystallographic *ab* plane (Figure 2).
