# Self-Assembly of *N*,*N*′,*N*′′,*N*′′′-Tetra(pyridin-4-yl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracarboxamide with $Zn^{2+}$ or $Cd^{2+}$ Ions

**Biing-Chiau Tzeng,*[a] Yun-Mei Lu,[a] Gene-Hsiang Lee,[b] and Shie-Ming Peng[b]**

**Keywords:** Charge transfer / Luminescence / Metallomacrocycles / Self-assembly / Supramolecular chemistry

We report the design and synthesis of *N*,*N*′,*N*′′,*N*′′′-tetra(pyridin-4-yl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracarboxamide (**L**), which contains four *N*-(pyridin-4-yl)carboxamide groups as functional appendages, as well as the structural and luminescence properties of its $Zn^{2+}$ and $Cd^{2+}$ complexes. The reaction of $ZnBr_2$ with **L** forms the two-dimensional coordination polymer $[ZnBr_2(\mathbf{L})_{1/2}]_n$ (**1**). In the two-dimensional domain, the 68-membered metallomacrocycles as well as 12-membered 1,4,7,10-tetraazacyclododecane (cyclen) units propagate into two-dimensional extended structures. Interestingly, the metallomacrocycles are stacked to form one-dimensional parallelogram channels in the solid state. In addition, the reaction of $CdX_2$ (X = Br, I) with **L** forms the isomorphous, three-dimensional coordination networks $[CdX_2(\mathbf{L})]_n$ [X = Br (**2**), I (**3**)], which have tubular channels in the solid state. **L** in **1**–**3** is tetradentate and acts as a versatile connector in the construction of supramolecular coordination networks. The 34-membered metallomacrocycles and 12-membered cyclen macrocycles of **2** and **3** also propagate into three-dimensional extended structures. Unlike those of **1** and **2**, the emission maximum at around 439 nm in the iodo compound **3** can be assigned to a ligand-to-metal charge-transfer (LMCT) transition as the excited state upon photoexcitation.

## Introduction

The widespread use of the coordinative-bond approach in the construction of supramolecular coordination compounds by self-assembly is well established.[1] So far, a variety of one-, two-, and three-dimensional infinite solid-state coordination architectures[2] as well as discrete molecular structures have been isolated and structurally characterized.[1] Applications, including chemical sieving, sensing, and catalysis based on the supramolecular coordination compounds have been discovered, and some have shown really exciting and valuable progress.[3] Surprisingly, the ligands used in the assembly of materials are generally didentate, with some tridentate ones;[1,2] tetradentate ligands are relatively scarce.[4] A macrocyclic ligand with a tetraaza macrocycle seems a good candidate in this regard since macrocyclic compounds have long attracted great interest owing to their intriguing structural and spectroscopic properties as well as host–guest chemistry.[5] In addition, tetraaza macrocycles can be easily functionalized by several groups, such as alkynyl,[6] phosphanylmethyl,[7] carboxyl,[8] and pyridyl[9] on their secondary N-sites to produce some novel properties in coordination, electro- and photoluminescent, and catalytic chemistry.

We have previously reported a study of metal-containing cyclic amides based on a didentate *N*-pyridylcarboxamide ligand – *N*,*N*′-bis(4-methylpyridyl)oxalamide – where interesting solid-state frameworks featuring cyclic peptides are constructed from hydrogen bonding/π···π interactions.[10]

Organic amides have proved to be very useful in self-assembly through hydrogen bonding, and the assembled products often have relevance to biological systems. Most remarkably, cyclic oligoamides can give rise to interesting nanotube frameworks through inter-ring NH···O=C hydrogen bonding, as reported by Ghadiri et al.[11] A new *N*-pyridylcarboxamide ligand (**L**) is used here as a tetradentate ligand for a crystal-engineering study. We report the design and synthesis of *N*,*N*′,*N*′′,*N*′′′-tetra(pyridin-4-yl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracarboxamide (**L**), which contains four *N*-(pyridin-4-yl)carboxamide groups as functional appendages, as well as the structural and luminescence properties of its $Zn^{2+}$ and $Cd^{2+}$ complexes.

## Results and Discussion

Hosseini and co-workers[4c] have recently reported an interesting porphyrinic ligand with four *N*-pyridylcarboxamides as appendages for the construction of one- and two-dimensional $Cu^{2+}$-containing coordination networks as an example of supramolecular isomerism. Another new type of tetraaza macrocycle that contains four *N*-(pyridin-4-yl)-carboxamide groups as functional appendages for the construction of supramolecular coordination frameworks has also been designed and synthesized in this study. Unlike most of the literature studies, the tetradentate ligand (**L**) studied here is a rare example of a tetradentate ligand in a crystal-engineering study. A methanolic solution of $ZnBr_2$ and $CdX_2$ (X = Br, I) was carefully layered on top of a DMSO solution of **L** to give pale-yellow crystals of **1**·DMSO·4$CH_3OH$ or colorless crystals of **2**·4DMSO and **3**·4DMSO, respectively, in good yield (70–80%) within a couple of days. The compounds are all air stable and photoluminescent in the solid state.

### Description of the Crystal Structures

Complexes **1**–**3** were isolated and their molecular structures determined by an X-ray diffraction study, which confirmed the formation of coordination polymers in the solid state. The molecular structure of **1** (Figure 1, a) displays a two-dimensional coordination polymer where **L** acts as a tetradentate ligand. The cyclen macrocycle contains four *N*-pyridylcarboxamide appendages, each of which coordinates to tetrahedral $Zn^{2+}$ ions; the $Zn^{2+}$ ions coordinate to two bromides and another *N*-pyridylcarboxamide appendage. In the two-dimensional domain, the 68-membered metallomacrocycles built from four **L** and four $ZnBr_2$ units, as well as the 12-membered macrocycles of the cyclen units, propagate into two-dimensional extended structures. Interestingly, the metallomacrocycles are stacked to form one-dimensional parallelogram channels (as viewed along the *a* axis) in the solid state, as shown in Figure 1 (b); the diagonal distances of these parallelogram channels are 26.59 and 15.73 Å. In addition, doubly hydrogen-bonding interactions [N(3)–H(3A)···O(3): N(3)···O(3) = 3.041(7) Å, N(3)–H(3A)···O(3) = 159.95°; N(5)–H(5A)···O(3): N(5)···O(3) = 2.913(9) Å, N(5)–H(5A)···O(3) 167.09°] between the solvated DMSO molecules and amide groups are observed in the solid state; the channels are also filled with methanol molecules. Although **1** has a high *R* value due to the fast loss of solvated solvents, there is no doubt that the structural framework of **1** can be still corroborated by the X-ray diffraction study.

Both **2** and **3** are essentially isomorphous, therefore the molecular structure and the extended structural framework of **3** are shown in Figure 2, parts a and b, respectively, as a representative example. Unlike the two-dimensional coordination network of **1**, **2** and **3** both form three-dimensional coordination networks with octahedral $Cd^{2+}$ ions coordinating to two anionic (Br, I) and four bridging **L** ligands,

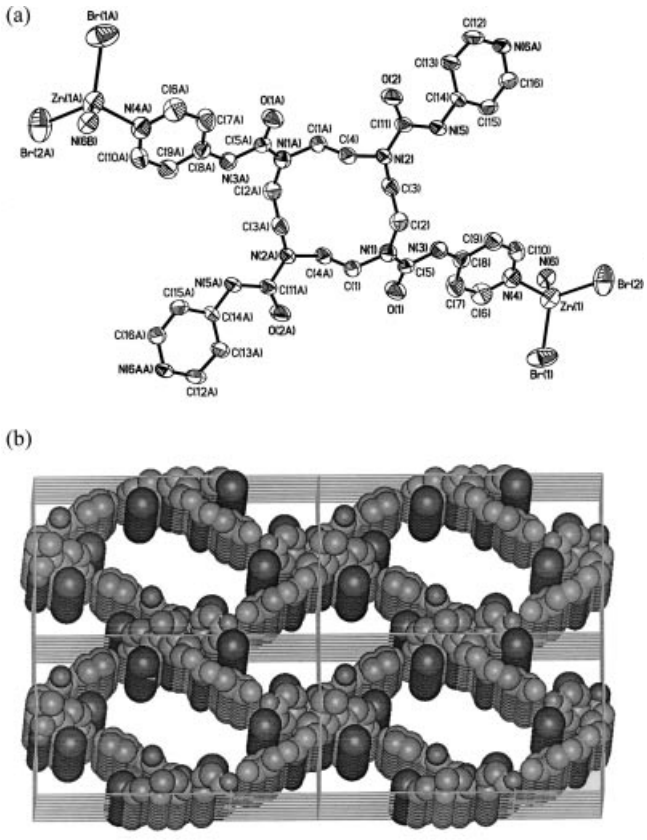

Figure 1. (a) Molecular structure of **1**·DMSO. ORTEP diagram shows 50% probability ellipsoids, and (b) its two-dimensional extended framework showing a 1-D channel structure with solvates omitted (viewing through the a axis) in the solid state.

as shown in part a of Figure 2. In more detail, the four *N*-pyridylcarboxamide appendages of the cyclen macrocycle each coordinate to octahedral $Cd^{2+}$ ions, which also coordinate to two bromides and another three N-pyridylcarboxamides. The cyclen plane is approximately perpendicular to that of the $CdN_4$ (pyridyl) unit, with two pyridyl groups (at positions 1 and 7) roughly coplanar with the cyclen plane and the other two (at positions 4 and 10) above and below the plane. This different orientation of **L** results in the formation of interesting three-dimensional coordination networks. Furthermore, the metallomacrocycles with 34-membered rings built from two $CdBr_2$ and two **L** units are packed into columns that form interesting tubular channels (viewed along the *b* axis) in the solid state, as shown in Figure 2 (b). Thus, the metallamacrocycles and cyclen macrocycles also propagate into three-dimensional extended structures. Hydrogen-bonding interactions [N(6)–H(6A)···O(4): N(6)···O(4) = 2.955(7) Å, N(6)–H(6A)···O(4) = 153.31°] between the solvated DMSO molecules and amide groups are observed in the solid state, and the channels are also filled with DMSO molecules. Upon changing the anion from $Br^-$ to $I^-$, the *trans*-$CdN_4X_2$ geometry remains unchanged, and thus the structural frameworks also retain a similar structural motif.

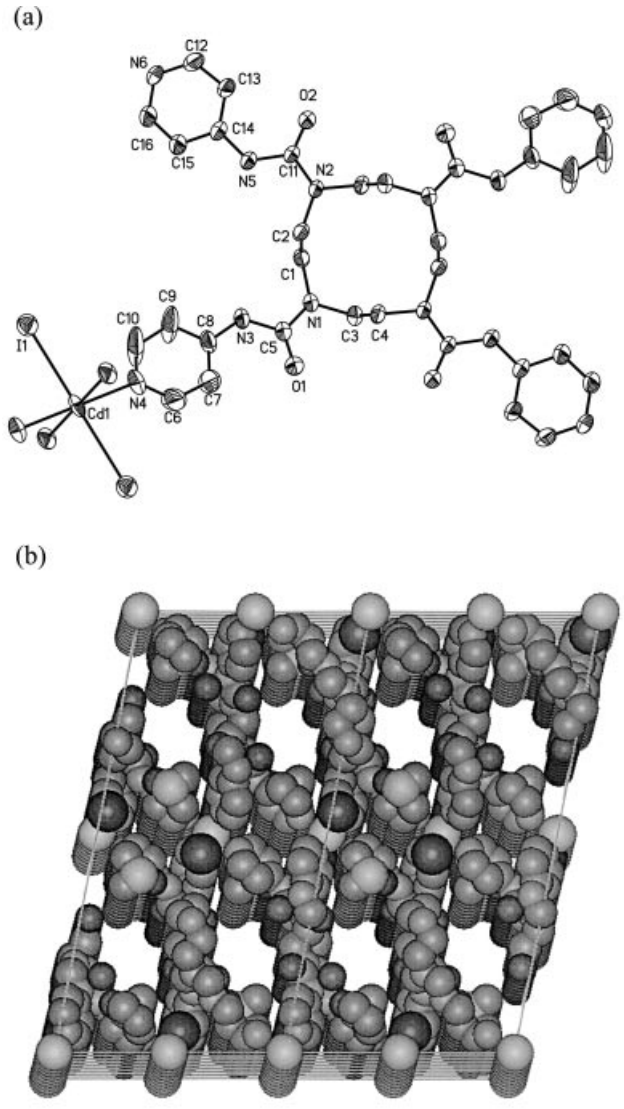

Figure 2. (a) Molecular structure of **3**. ORTEP diagram shows 30% probability ellipsoids, and (b) its three-dimensional extended framework showing a 1-D channel structure with solvates omitted (viewing through the b axis) in the solid state.

Very recently, Cao et al.[4a] reported a cyclam (1,4,8,11-tetraazacyclotetradecane)-based tetradentate ligand containing pyridylmethyl groups as appendages as well as the structural study of its two novel $Cd^{2+}$ polymeric metallomacrocyclic complexes, where the ligand adopts $\mu_2$- or $\mu_4$-coordination modes in the structural framework. Indeed, the different coordination modes that co-exist in the same structure result in the formation of interesting three-dimensional coordination networks. In this study, it is interesting to find that given the same bridging ligands (**L**) and only one coordination mode ($\mu_4$) in the system, the structural motif changes dramatically and the supramolecular complexity increases upon changing the metal ions from tetrahedral (four-coordinate) $Zn^{2+}$ to octahedral (six-coordinate) $Cd^{2+}$ ions. Unlike the structures reported by Cao et al.,[4a] which contain two coordination modes for the ligands in the same framework, the structures of **2** and **3** also form three-dimensional networks with tubular channels only due to the different orientation of the *N*-pyridylcarboxamide appendages of the cyclen moieties. In this context, **L** has been shown to be a tetradentate ligand that acts as a versatile connector in the construction of interesting supramolecular coordination networks. Unfortunately, crystals of **1**–**3** easily lose solvent, which causes the crystal lattices to collapse instantaneously and thus prevents further studies by TGA and powder XRD analysis that might allow us to gain some insight into the channel structures.

### Solid-State Emission Spectra

**L** and **1**–**3** are all luminescent in the solid state, as shown in Figure 3 (a), at room temperature. Upon photoexcitation at 325 nm, **1** shows a broad emission with a maximum at around 412 nm, whereas **L** displays a similar emission at around 403 nm. Given the high similarity between these emissions, they were tentatively assigned to an intraligand (IL) transition. The solid-state emission of **2** (Figure 3, b) at room temperature has an emission maximum at around

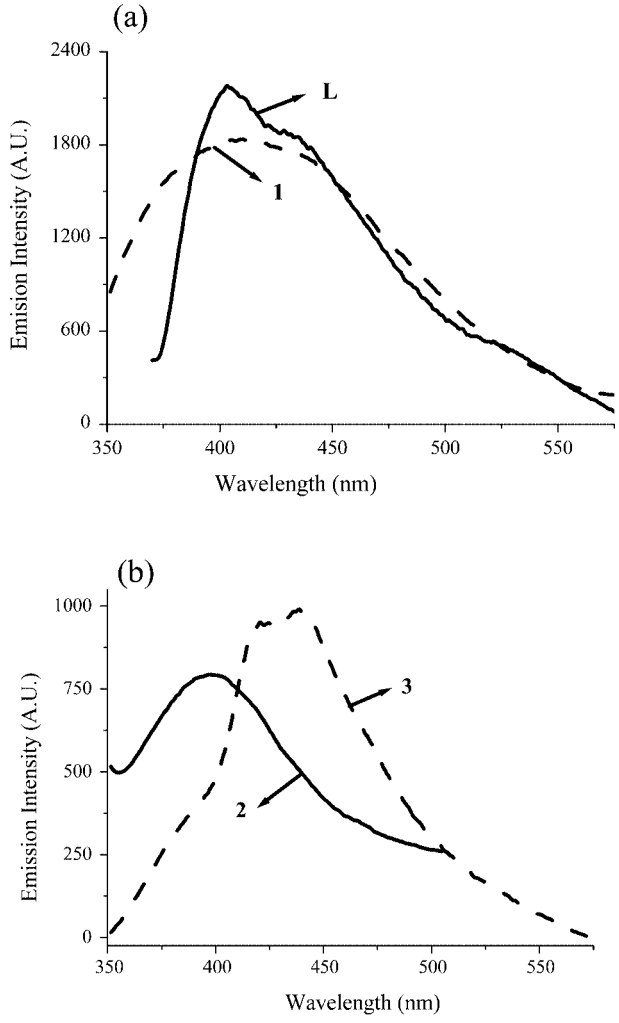

Figure 3. (a) The solid-state emission spectra of **L** and **1**, and (b) the solid-state emission spectra of **2** and **3** measured at room temperature with an excitation wavelength at 325 nm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

398 nm, which is also comparable to those of **L** and **1**. Thus, it seems reasonable that the excited state responsible for the emission for **2** is also an IL transition. Most importantly, **3** shows a solid-state emission with an emission maximum at around 439 nm, which is red-shifted with respect to those of **1** and **2**. In light of previous studies[10,12] and the red-shift in emission energy on going from the bromo to the iodo complex, this emission can tentatively be assigned to a ligand-to-metal charge-transfer (LMCT) transition, although intraligand transition mixing with LMCT cannot be excluded. Intraligand transitions as excited states are not uncommon for $Zn^{2+}$ and $Cd^{2+}$ complexes, but charge-transfer excited states are so far still rare.[13]

## Conclusion

A new type of tetraaza macrocycle (**L**) containing four *N*-pyridylcarboxamide groups as functional appendages has been designed and synthesized in this study, which is a rare example of the use of a tetradentate ligand in a crystal-engineering study. Complex **1** can be isolated as a two-dimensional coordination polymer upon reaction of $ZnBr_2$ with **L**. In the two-dimensional domain, the 68-membered metallomacrocycles built from four **L** and four $ZnBr_2$ units, as well as the 12-membered macrocycles of cyclen, propagate into two-dimensional extended structures. Interestingly, the metallomacrocycles are stacked to form one-dimensional parallelogram channels in the solid state. In addition, reaction of $CdX_2$ (X = Br, I) with **L** leads to the formation of **2** and **3**, respectively, which form isomorphous three-dimensional coordination networks with tubular channels due to the different orientation of the *N*-pyridylcarboxamide appendages of the cyclen moieties. Again, the 34-membered metallomacrocycles built from two $CdX_2$ and two **L** units, as well as the 12-membered macrocycles of the cyclen units, propagate into three-dimensional extended structures in **2** and **3**. Unlike those of **1** and **2**, the emission maximum of the iodo compound **3** at around 439 nm can be tentatively assigned to a ligand-to-metal charge-transfer transition upon photoexcitation. The channel structure, as well as the luminescence properties, of these tetraaza-macrocycle-based materials may be anticipated to hold potential for use as luminescent sensors. Moreover, the cyclen moiety acts as a versatile connector in the construction of supramolecular coordination networks, and is also capable of functioning as a receptor site for recognition events.

## Experimental Section

**General Information:** All solvents for syntheses (analytical grade), which were used without further purification, and metal salts [$ZnBr_2$, $CdX_2$ (X = Br, I)] are commercially available. *N*,*N*′,*N*″,*N*‴-Tetra(pyridin-4-yl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracarboxamide (**L**) was prepared following literature methods.[14] MS: positive-ion FAB mass spectra were recorded with a Finnigan MAT95 mass spectrometer. Steady-state emission spectra were recorded with a SPEX Fluorolog-2 spectrophotometer.

**Synthesis of *N*,*N*′,*N*″,*N*‴-Tetra(pyridin-4-yl)-1,4,7,10-tetraazacyclododecane-1,4,7,10-tetracarboxamide (L):** Isonicotinic acid (2.00 g, 16.24 mmol) was put into a 250-mL, two-necked flask with toluene (100 mL), under an atmosphere of nitrogen, and the mixture was stirred for ten minutes after addition of triethylamine (2.72 mL, 19.49 mmol). After addition of phosphorazidic acid diphenyl ester (3.15 mL, 14.62 nm) the solution was stirred for one hour; it gradually became colorless. The solution was later refluxed for three hours at 90 °C (it became yellow) and was then cooled to room temperature. 1,4,7,10-Tetraazacyclododecane (0.56 g, 3.25 mmol) dissolved in 100 mL of toluene was slowly and carefully transferred into the above two-necked flask to give a pale-yellow precipitate after stirring for two days at room temperature. The toluene was then removed under vacuum and the ligand was recrystallized from 200 mL of methanol to give a pure and white solid (0.64 g, 0.975 mmol) in 30% yield. MS (FAB): *m*/*z* (%) = 654 (35) [$M^+$]. $^1$H NMR (400 MHz, [$D_6$]DMSO, 25 °C): $\delta$ = 3.69 (s, 4 H, $CH_2$), 7.48 (d, 2 H, $NCH_2CH_2$], 8.32 (d, 2 H, $NCH_2$), 8.88 (s, 1 H, N*H*) ppm. $^{13}$C NMR (400 MHz, [$D_6$]DMSO, 25 °C): $\delta$ = 47.67,

FT-IR (KBr): $\nu_{NH}$ = 3300 and $\nu_{C=O}$ = 1681 $cm^{-1}$. $C_{32}H_{36}CdI_2N_{12}O_4$ (1018.93): calcd. C 37.72, H 3.56, N 16.50; found C 37.35, H 3.78, N 16.69.

**X-ray Crystallography:** Suitable single crystals of **1**·DMSO·4$CH_3OH$, **2**·4DMSO, and **3**·4DMSO were mounted on a glass capillary respectively, and data collection was carried out on a Bruker SMART CCD diffractometer with Mo radiation (0.71073 Å) at 295(2) K. A preliminary orientation matrix and unit cell parameters were determined from 3 runs of 15 frames each, each frame corresponding to 0.3° scan in 15 s, followed by spot integration and least-square refinement. Data were measured using an $\omega$ scan of 0.3° per frame for 20 s until a complete hemisphere had been collected. Cell parameters were retrieved using SMART[15] software and refined with SAINT[16] on all observed reflections. Data reduction was performed with the SAINT software and corrected for Lorentz and polarization effects. Absorption corrections were applied with the program SADABS.[17] The structure was solved by direct methods with the SHELX93[18] program and refined by full-matrix least-squares methods on $F^2$ with SHEXLTL–PC V 5.03.[18] All non-hydrogen atomic positions were located in difference Fourier maps and refined anisotropically. The hydrogen atoms were placed in their geometrically generated positions. Detailed data collection and refinement of the four complexes are summarized in Table 1. Selected bond lengths and angles in the structures are summarized in Table 2, and hydrogen bonds are given in Table 3, respectively.

CCDC-282733 to -282735 (for complexes **1**, **2**, and **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## COVER PICTURE

**The cover picture shows** the isomerization sequence of cobaltatricarbollides $(C_4Me_4)Co(C_3B_8H_{11})$ prepared by using convenient synthons of the $(C_4Me_4)Co$ fragment. The isomerization is associated with progressive space separation of the negatively charged carbon atoms and correlates well with the calculated relative stabilities of non-methylated analogs. Introduction of an amino substituent at the cage carbon atom dramatically reduces the rearrangement barrier and changes the pathway of the process. Details are discussed in the article by A. R. Kudinov et al. on p. 1737 ff.

# Carbon and Polymer Filaments in Nanoporous Alumina

Jörg J. Schneider*[a] and Jörg Engstler[a]

**Keywords:** Alumina / Porous templates / Nanotubes / Carbon / Nanochemistry

Nanoporous alumina membranes represent templates for the synthesis and alignment of filamentous nanostructured materials. Porous aluminium oxide (PAOX) membranes are ideal for high-temperature synthesis. They are transparent, flexible, freestanding and thermally robust. Their pore sizes can be varied over a wide range. The membrane backside seems suited for structuring processes on the nanoscale, for which it may serve as a master. After introducing the formation process of PAOX membranes, synthesis of carbon nanotubes (CNTs) with different morphologies, their electrical field emission properties, and the formation of polymeric filaments and structured polymer surfaces with the aid of PAOX are reported in this microreview.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## 1. Introduction

Nanotubes derived from various carbon sources, doped with non-carbon atoms[1] or pure inorganic tubes[2] such as $MoS_2$,[3] $WS_2$,[4] BN,[5] are intensively studied over the last years because of their unique material properties. Besides the challenge towards the synthesis of such materials, there is also the need to arrange such materials in an organized manner. One important research goal is to synthesize and organize nanomaterials in a single process step that allows for their 1D, 2D, or even 3D arrangement. A common and widely used technique for 2D structuring of nanomaterials is the template process, in which a given form acts as a structure-directing shape to organize individual building blocks in a 2D arrangement. Inorganic templates are typically solid phases; they can be crystalline or amorphous. They are stable with respect to a geometrically defined structure and usually up to higher temperatures. Zeolites are prominent examples of such template types. They enable the organization of matter in a 1D or 3D fashion. Unordered inorganic porous structures bearing multiple voids

*Jörg J. Schneider obtained his diploma and doctoral degree in chemistry at the Philipps-Universität Marburg in 1986, both in the group of Ch. Elschenbroich. After a one-year post doctoral stay in the group of K. J. Klabunde, USA, he joined the Max-Planck-Institut für Kohlenforschung, Mülheim an der Ruhr, in 1988. In 1994 he moved to the University of Essen as lecturer and Heisenberg fellow of the Deutsche Forschungsgemeinschaft. In 2000 he accepted a call as professor of inorganic chemistry at the Karl-Franzens-Universität, Graz, Austria. In 2003 he moved to his current position as professor of inorganic chemistry at the University of Technology, Darmstadt. His research interests are currently oriented towards interdisciplinary aspects of materials synthesis as well as organometallic chemistry. Examples include synthesis and properties of carbon tubes, porous materials, multinuclear metal complexes of condensed aromatics, as well as metal vapour synthesis as a synthetic tool in organometallic and materials chemistry.*

*Jörg Engstler was born in 1973. He studied chemistry at the University of Essen, Germany and obtained his diploma degree in 2000 in the field of synthesis and arrangement of carbon nanotubes. In the same year he moved to the Karl-Franzens-Universität, Graz, Austria, for pursuing his Ph.D. studies in the group of J. J. Schneider. His research activity was focussed on the synthesis and enhancement of field-emission properties of carbon nanotubes in and on porous alumina. In 2003 he received a Dr. rer nat. from the University of Essen. Since 2003, he is a post doc in the group of J. J. Schneider at TU Darmstadt, Germany. His research interests are in the area of porous nanomaterials, CVD and microscopic characterization techniques.*

**MICROREVIEWS:** This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and pores of nonuniform diameters that are randomly distributed in the material are another kind of such a template. Those materials can typically not be used for the controlled organization of matter in 2D or 3D dimensions, because their pores appear unordered.

For creating filamentous nanomaterials with functional properties, for example for optics or electronics applications, a defined 1D orientation of materials and therefore of the pore structure of the template is essential. Zeolite-based templates like MCM 41, as well as organic-based templates, for example polycarbonate membranes, are useful in this regard. However, membrane templates based on organic materials are often temperature-sensitive, and therefore high-temperature processes within the membranes often employed for the synthesis of inorganic nanostructures are impossible with these templates.

Anodic porous aluminium oxide (PAOX) is a valuable template material for high-temperature processes. It is widely used in the scientific community as a template for synthesis and organization of nanomaterials.[6] Recently Schmid has reviewed the synthesis and properties of various nanoparticle compositions in PAOX.[7] Synthesis, arrangement and properties of different rod-shaped magnetic materials in PAOX have been reviewed by Wade.[8] Our contribution presented herein is focussed on the generation, properties and 2D arrangement of CNTs and filamentous polymeric structures, both made by gas-phase processes in and on the surface of PAOX.

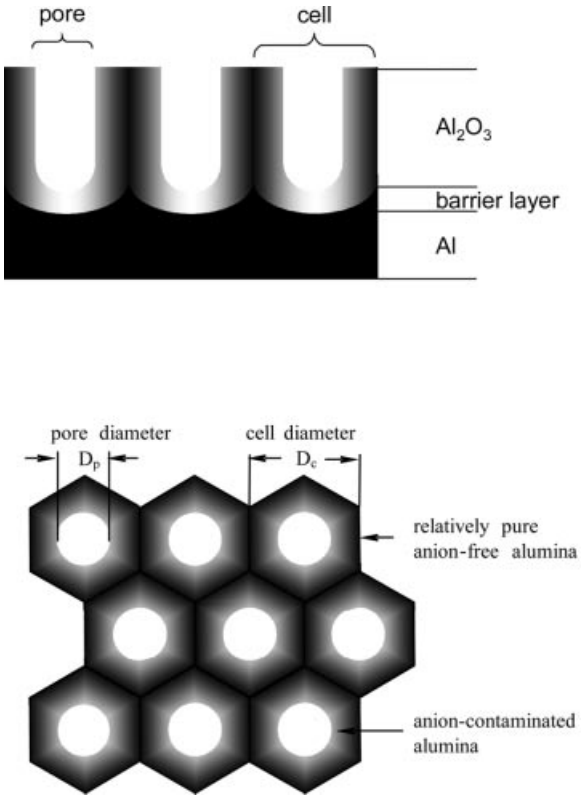

Figure 1. Schematic drawing of PAOX with idealized hexagonal ordered cells (diameter $D_c$) with a pore (diameter $D_p$) in the centre of each cell; cross-section (top), view from the top of the pore arrangement (bottom).

## 2. Nanoporous Anodic Aluminium Oxide as Template for Nanofilament Arrangement

The process of electrolytic oxidation of aluminium has a long-standing technological relevance and is commercially used for surface processing of aluminium for many decades. The pore system of alumina is formed by potentiostatic anodization, which is characterized by a constant voltage with a current change due to increased resistance in the growing oxide. The morphology of PAOX films synthesized in sulfuric acid has been investigated by Keller et al. already in 1953.[9] Early studies on the growth mechanism were performed by O'Sullivan and Wood in 1970.[10]

### *Formation and Structure of PAOX*

Figure 1 shows a schematic drawing of a PAOX membrane with a hexagonally ordered pore system.

The membrane consists of hexagonally ordered cells with one centred pore in each cell. Each cell has a unidirectional shape orthogonal to the membrane surface. The bottom of the pores is sealed by the so-called barrier layer, which connects the PAOX membrane with the aluminium metal base from which the porous membrane grows in a self-organized manner during an ongoing electrochemical oxidation process. This barrier layer is compact, however it has numerous defects due to the permanent dissolution by the electrolyte. These defects (channels, pits, voids) are the starting points for regular pore formation in latter stages of the electrochemical oxidation. Thus redissolving alumina and ongoing aluminium oxidation are competitive processes (see below). The finally resulting highly ordered PAOX membrane has a porosity of up to 10% with pore densities of up to $10^{11}$ pores per $cm^2$.[11] When a disordered growth is observed, the overall porosity can be significantly lower or higher.[12] The pore walls of the cells consist of two different types of alumina.[12] One type is a relatively pure, anion-free, dense alumina (dark grey regions in Figure 1, bottom). It builds up the hexagonal body of the cell. This material is not in direct contact with the open pore space. The inner cell region of the pores consists of a less dense alumina (light grey regions in Figure 1, bottom) contaminated with electrolyte anions ($PO_4^{3-}$ $SO_4^{2-}$, $C_2O_4^{2-}$), which forms the pore wall and therefore is in direct contact with the electrolyte during the electrochemical process. By controlled selective etching of the backside barrier layer, PAOX membranes with complete trough-hole pore morphology can be obtained.

The diameter of the pores ($D_p$) and the cells ($D_c$) of a PAOX membrane are dependent on the anodization potential applied in the electrolytic process.[6h,13] Additional experimental parameters governing the pore size are temperature and current density. The latter is influenced by the concentration and the type of electrolyte used.[11]

PAOX membrane pore diameters between ca. 5–300 nm are so far experimentally accessible. As a rule of thumb, a voltage of 1 V corresponds to a pore growth of ca.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.2 nm.[10] This value depends on anodization conditions and electrolyte concentration. Figure 2 shows examples of electron micrographs of PAOX membranes with varying pore diameters (Figure 2).

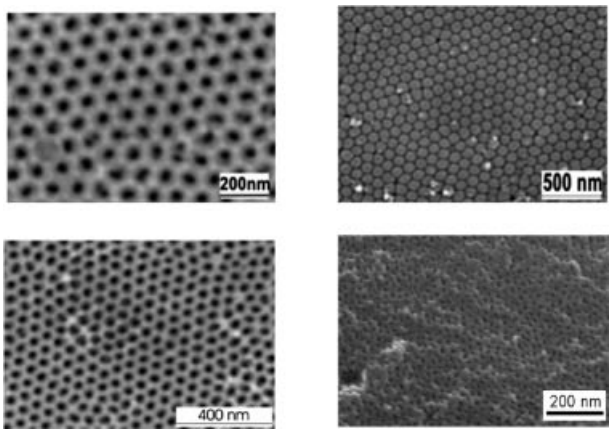

Figure 2. SEM images of freestanding PAOX membranes. From upper left to lower right: open front side of a PAOX membrane generated at 40 V, back side of a PAOX membrane generated at 40 V, open front side of a PAOX membrane generated at 25 V, open front side of a PAOX membrane generated at 8 V.

To obtain PAOX templates with different pore size regimes, different electrolytes are used. From 150 to 300 nm $H_3PO_4$, from 30 to 70 nm oxalic acid and below 20 nm $H_2SO_4$ give reproducible results with respect to pore-size diameters.[8] This electrolyte dependence of pore size distribution is mainly due to the fact that the pore diameter is affected strongly by the dissolution velocity of alumina in the electrolyte chosen. The dependence of pore size on electrolyte type is, however, complex and involves the dissociation behaviour (pH value, acid/conjugate base equilibrium) and concentration of the electrolyte (e.g. changing the electrolyte concentration changes the pH) as the foremost parameters.

The basic membrane-film-forming reaction is dissolution of the base metal according to

$$Al(s) \rightarrow Al^{3+} + 3e^-$$

$Al_2O_3$ is then formed by reaction with $O^{2-}$ ions which are generated in the acidic electrolyte medium by the reaction

$$3/2\ H_2O \rightarrow 3\ H^+ + 3/2\ O^{2-}$$

The formation process of the alumina is accompanied by a local dissolution of the formed alumina due to agitation by protons

$$1/2\ Al_2O_3(s) + 3\ H^+(aq) \rightarrow Al^{3+}(aq) + 3/2\ H_2O(l)$$

The latter reaction preferentially occurs at the bottom of the formed pores where the electrical field is highest. This reaction obviously does not play an important role during the initial formation of the compact base oxide layer lying underneath the porous layer.

During electrolyte anion incorporation into the growing membrane, the following reactions occur:[6h]

$$H_3PO_4\ (aq) \rightarrow H_2PO_4^{2-} + H^+$$

$$H_2PO_4^-\ (aq) \rightarrow HPO_4^{2-} + H^+$$

The conjugate divalent base anion $HPO_4^{2-}$ can replace $O^{2-}$ in the oxide forming reaction, thus leading to a contamination in the growing film. Therefore 6–8 wt.-% $PO_4^{3-}$ incorporation of the membranes is typically observed when phosphoric acid is used the electrolyte. Similar percentages of incorporation are observed for other electrolyte anions ($SO_4^{2-}$, $C_2O_4^{2-}$). In contrast, electrolytes which do not form protonated conjugate bases lead to contamination of free PAOX membranes (e.g. chromic acid[6h]).

The electrochemical process of controlling and downsizing the pore diameter by adjusting the anodization voltage as one of the crucial parameters works well down to pore sizes of around 15 nm in the strong electrolyte $H_2SO_4$. There is an interest in such nanoporous self-supporting template materials due to their application as nanovessels for synthesis and organization of matter on the nanoscale. In the size regime below 15 nm, quantum size effects start to become important for many materials, and a self-supporting porous template should make it possible to study anisotropic effects of such structure-confined materials. However, reports on self-supporting PAOX membranes with a pore size below ca. 15 nm are scarce. Highly unordered PAOX films deposited on glass substrates with small pore diameters (<10 nm) are known.[14–16] We have studied pore-size growth of PAOX at anodization voltages down to 8 V. Formation of a porous alumina with a pore diameter of about 10 nm results. Handling these PAOX membranes as freestanding templates, however, becomes increasingly difficult: for example, such membrane templates tend to be brittle and are mechanically fragile. In contrast, PAOX membranes with pore sizes between 20 and several 100 nm exhibit good mechanical stability. They are not very fragile and can withstand even moderate mechanical torsion, for example bending. The reason for this is their cellular structure. It is well known that if pores in a given cellular structure are hexagonally oriented, the mechanical stiffness of such a cellular arrangement decreases roughly by a factor of 50 compared to a similar compact structure.[17] This finding is based on the variation of the *E*-module which is dramatically affected when comparing a compact with a porous structure. In a first approximation, this is regardless of the individual material composition of such a structure.

Thus, the high tensile strength of the as-prepared PAOX template relative to a dense, compact alumina film of the same composition seems mainly due to its mechanical flexibility imparted by its regular open porous nature relative to the dense material of same composition.

## 3. Carbon Nanotubes and Polymer Fibres in PAOX

### 3.1 Carbon Nanotubes in PAOX

#### *CNTs Synthesized in PAOX without Catalyst*

Spatially arranged CNTs provide a promising material for applications in e.g. Li-ion batteries,[18] chemical filters,[19] capacitors,[20] cold field emitting sources[21] or tran-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sistors.[22] PAOX is ideally suited as a template for CNT synthesis by CVD, a process which typically operates above 700 °C.[23–25] The diameter of the CNTs formed inside the PAOX template pores during CVD should be the same as the PAOX pore diameter. Hence, a general feature of PAOX, its versatility to control the diameter of the CNTs, becomes apparent.

In a typical experiment, a gaseous precursor like propylene or acetylene transported by a carrier gas is decomposed within a hot-wall tube reactor in which the open membrane is inserted vertically in a flow-through geometry.[26] The pores of the membrane are then completely filled with CNTs during the CVD process. Figure 3 shows a SEM image of such a CNT/PAOX membrane composite.

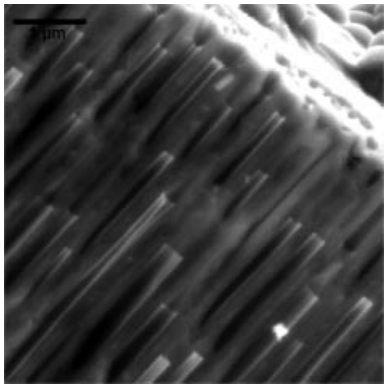

Figure 3. SEM image of a CNT/PAOX membrane composite showing a broken edge from which the CNTs protrude out of the pores of the PAOX.

Typical synthesis conditions for our CNT formation process are 900 °C, propylene flow between 1 mL and 14 mL per minute depending on the reaction time (5 min to 40 min). After the CVD process, the PAOX surface is usually covered with residual carbon materials. These can be "burned away" under controlled and mild oxidative conditions without destroying the CNTs.[26]

### *CNTs Synthesized in PAOX Loaded with Catalyst*

PAOX templates can be loaded with appropriate catalyst precursors like inorganic Fe salts prior to CNT growth, for example simply by dip filling.[27,28] Under reducing conditions, flowing $H_2$ is used for this purpose; the active catalyst can then be generated in nanoparticle form.[29] The effect of the catalyst particles on CNT growth is twofold. On the one hand, the use of catalyst particles reduce the synthesis temperature for CNT growth, on the other hand, CNT graphitization can be achieved already at lower temperatures relative to an uncatalyzed CVD process.

Impregnation of PAOX membranes with a catalyst prior to CNT synthesis leads to a CNT/PAOX composite material. The CNT/PAOX composite material can be freed from the PAOX template by dissolving it in diluted HF. The resulting carbon filaments have a fibre-like compact structure as revealed by transmission electron microscopy (TEM). At a higher magnification, a tube-in-tube morphology ("carbon nanotube bags") can be identified by TEM (Figure 4).[29,30] The smaller inner tubes display helicoidal structures and are almost densely packed within the outer "carbon nanotube bags". The compact fibre-like material therefore contains two different carbon tube morphologies of different size. The outer, larger tubes are produced by the deposition of carbonaceous precursor species derived from the molecular precursor gas source (e.g. propylene). These CNTs are formed on the inner walls of the PAOX membrane during the CVD process. Their diameter is determined by the pore dimensions of the template. In this process, the inner walls of the PAOX template are cast.

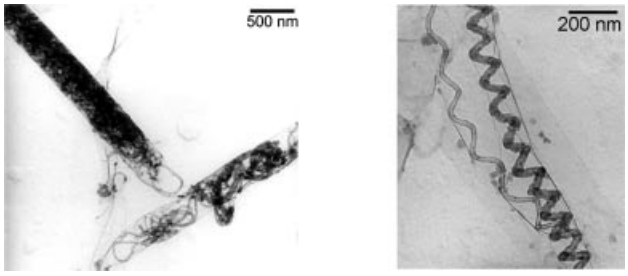

Figure 4. TEM image of "nanotube bags" freed from the PAOX template; left: the inner helicoidal CNTs are surrounded by the outer, larger CNT; right: helicoidal morphology of a single interior CNT.

The PAOX template pore walls represent a surface with high morphological roughness. This roughness is reflected in the morphology of the CNT walls, which show no ideal straight alignment but a rather high degree of dislocation of the carbon tube walls (Figure 5).

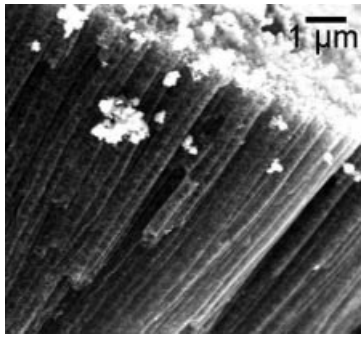

Figure 5. SEM micrograph showing PAOX-freed CNTs in typical parallel block arrangement.

The dense filling of the larger carbon tubes with the smaller helicoidal CNTs in their interior is due to a catalytic process. It is mediated by the iron particles which are derived from the catalyst precursor introduced into the PAOX by the impregnation step.[27] The diameter of the helicoidal inner CNTs is about 20 nm and corresponds well with the size of the catalyst particles which are mainly found at the end of the tubes (Figure 6).

In addition, TEM and AFM investigations[29] reveal that the diameter of the large outer CNTs is enlarged when freed from the template, relative to what is expected from the given size of the template pores in which they are formed. This fact can be understood by the only partially graphi-

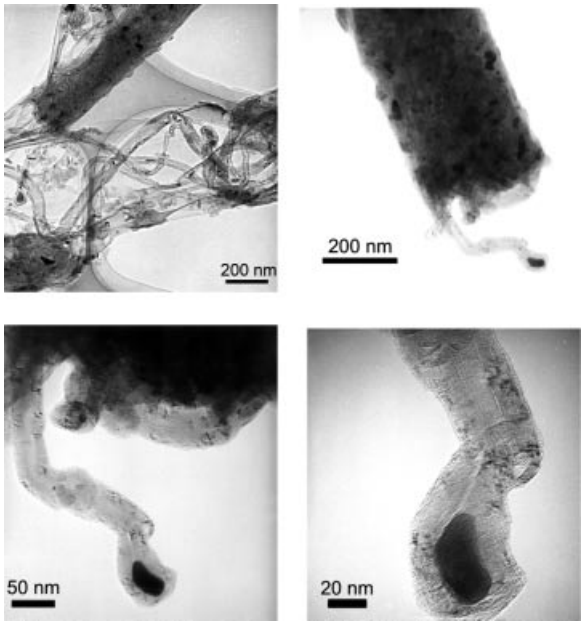

Figure 6. TEM images of CNT bags filled with small CNTs derived from catalyst impregnation. From upper left to lower right: overview of small CNTs with catalytic particles located at the end of the smaller inner tubes; different magnifications of CNT inner tubes with catalytic particles at the end of the small CNTs.

tized structure of the tube walls of the outer CNTs as it is revealed by high resolution TEM (HRTEM) investigations (Figure 7).

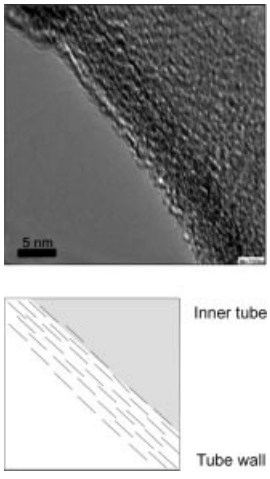

Figure 7. Top: HRTEM image of a "CNT bag" wall structure showing the partially graphitized wall structure; bottom: corresponding schematic model of the outer CNT wall structure.

The schematic model, which is in accord with the experimentally observed morphology found in the HRTEM, is shown in Figure 7. Relatively short multilayered, intermingled graphene sheets are characteristic for the CNT wall structure. This graphene sheet structure is flexible and allows the outer tubes to widen their diameter significantly when an inner pressure is exerted upon the walls. As long as the CNTs are embedded in the PAOX template, their diameter is fixed. However, when the CNTs are freed from the template, a dense filling of the CNTs may lead to a significant expansion of their diameter. This is a kind of "breathing process" which releases inner pressure from the CNT walls imposed on them by the dense filling with the small helicoidal tubes. Obviously, such a widening process can even lead to a rupture of the walls of the large CNTs and to the liberation of the entrapped small helicoidal tubes (Figure 8).

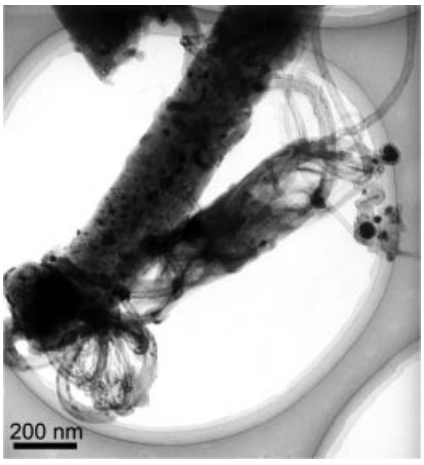

Figure 8. TEM of a compact CNT bag. After breaking the outer CNT wall, the inner CNTs swell out of their surrounding shell (bottom left).

We have studied the elastic properties of the carbon nanotube bags by AFM with the nanoindentation technique.[31–33] A Berkovitch-type indentation probe (100-nm

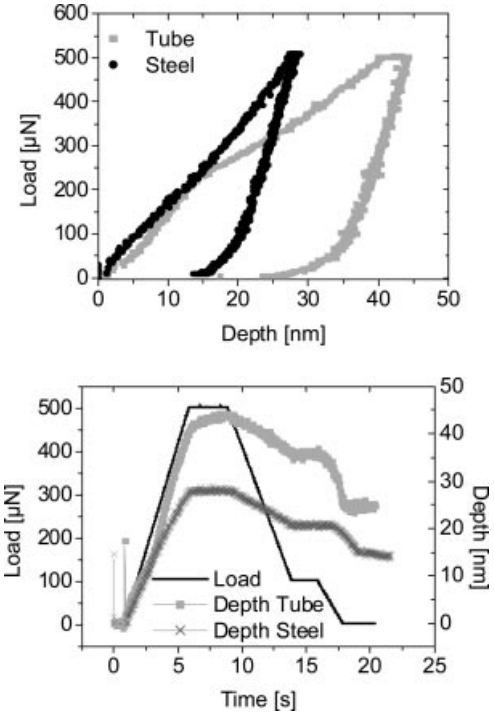

Figure 9. Nanoindentation loads (up to 500 μN) vs. indentation depth applied to a single filled carbon nanotube bag.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tip radius) was placed in the middle of a single carbon nanotube bag. Experiments were conducted with up to 500-μN loads on the tip (Figure 9, top). Up to loads of 220 μN, the indentation depth increased linearly with increasing load. In the low-load regime (up to ca. 60 μN) the CNT displayed viscoelastic behaviour with nearly no residual plastic deformation (<1 nm). When the final indentation load was increased to 500 μN, the depth of impression on the carbon nanotube bag structure increased considerably to 35 nm. However, at a load of 230 μN a sudden deviation from a linear behaviour was found (Figure 9, top).

After release of the maximum load a residual depth of impression of 27 nm remained in the material (Figure 9, bottom). Compared with the low-load regime, where a maximum load of 60 μN was applied, this dramatically different behaviour at higher loads may be attributed to a sudden rupture of the CNT wall structure. In the low-load regime, the filled CNT nanotubes show viscoelastic behaviour typically observed for soft matter (e.g. polymers), whereas high enough compression loads lead to the destruction of the outer CNTs (see Figure 8).

### *CNTs in PAOX Derived from Single-Source Precursor Molecules*

There have been several reports on the synthesis of CNTs using single-source precursors.[34] Examples for such precursors are organometallic compounds like metallocenes or coordination compounds like iron(II)phthalocyanine.[35,36] In these precursors, there exists a fixed, stoichiometrically defined metal-to-carbon ratio. Ferrocene is a prominent precursor for CNT synthesis by CVD techniques.

Figure 10 displays a typical TEM image of CNTs derived from ferrocene as the sole CNT precursor. In these experiments, the CNTs have been first synthesized and then deposited freely on a freshly cleaved mica surface. Due to the low carbon-to-iron-catalyst ratio (10:1) when employing ferrocene, the CNTs are mostly filled with iron metal.[37]

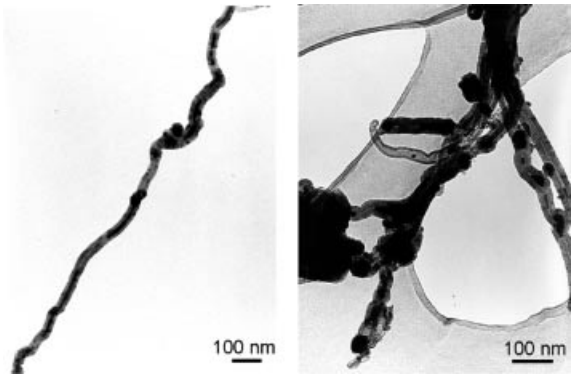

Figure 10. TEM images of CNTs synthesized via CVD of ferrocene on a native mica support at different magnifications.

When the carbon-to-iron ratio is increased by a factor of 7, CNTs with a much lower iron content are formed, and subsequently no formation of compact iron rods is observed inside the CNTs. Instead, particles are formed in the CNTs (Figure 11). An increase in the carbon-to-iron ratio was achieved by adding an additional carbon source to the ferrocene precursor.[38] We used the polycondensed aromatic hydrocarbon decacyclene $C_{36}H_{18}$ as the additional carbon source.[26,39,40]

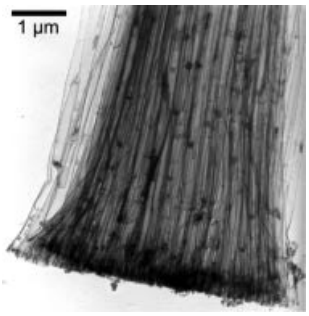

Figure 11. TEM micrograph of a CNT bundle synthesized by deposition of a mixture of decacyclene/ferrocene (70:1 at.-%) in PAOX (template removed).

Bundle-like arrangements of CNTs are found after dissolution of the PAOX template. Metal particles are distributed within these CNT bundles.

When using chromocene, $[(\eta^5\text{-}C_5H_5)_2Cr]$, a precursor with the same carbon-to-metal ratio as that in ferrocene, CNTs are formed under similar conditions (Figure 12). However, in contrast to the CNT material obtained from the ferrocene precursor, no metallic wires are formed within the tubes. The CNTs contain particles distributed alongside the CNTs, although the carbon-to-metal ratio is identical to that in ferrocene. Obviously, not only the stoichiometric carbon-to-metal ratio, but also the nature of the catalytic metal or the precursor are important for the filling of the CNTs, either with metallic rods or particles.

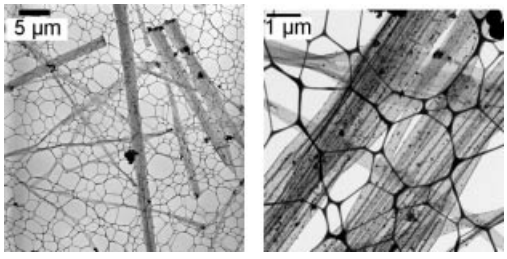

Figure 12. TEM micrographs of template-freed CNTs synthesized by deposition of chromocene in PAOX. A characteristic parallel-block arrangement of CNTs derived from PAOX is maintained (template removed).

Comparison of the results for CNT synthesis performed by the single-source strategy without a structure-directing template and those for the template-steered synthesis by using PAOX shows that the resulting CNT materials have different morphologies. CNTs prepared by the template technique display a parallel alignment of CNTs, with overall straight tube body morphology and defined tube radii. In contrast, CNTs prepared by a template-free CVD process by using a single-source strategy have a poorer straightness, a significant deviation in tube diameter and a random distribution of their metal filling.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Element-filtered TEM (EFTEM) has provided detailed information about the elemental distribution of CNT materials. In general, EFTEM enables the recording of two-dimensional distributions of chemical elements (Li to U) with a resolution down to about 1 nm. Chemical and structural heterogeneities may thus be imaged by recording elemental distributions. Applying this technique supplies an enormous amount of information relative to conventional bright-field TEM. In Figure 13, the results of such an EFTEM investigation of a single CNT synthesized by CVD by using chromocene as precursor and PAOX as template are shown.

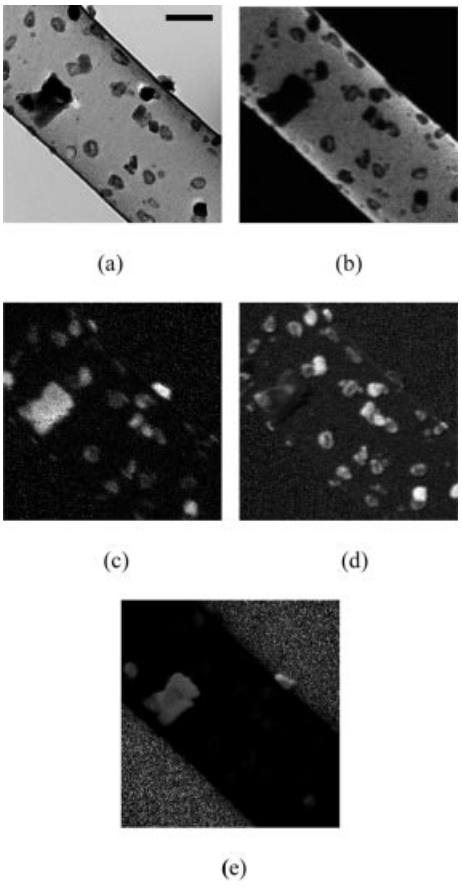

Figure 13. EFTEM investigations on a single CNT (precursor: chromocene): (a) bright-field image of a single CNT with incorporated particles; images of single-element distributions with elements displayed in lower contrast, (b) carbon, (c) oxygen, (d) chromium, (e) aluminium; (scalebar for all images: 100 nm).

The selective elemental mapping gives the spatial distribution along the CNT (Figure 13b–e). Obviously, chromium is a main constituent. Besides the elements chromium and carbon, oxygen is also present in the irregularly shaped particles, which have a diameter between 20 and 30 nm (shown in Figure 13c). Thus, the formation of chromium oxide particles seems reasonable. The formation of these oxide particles is yet unclear since the CVD process proceeds under otherwise inert conditions.

The origin of the detected alumina particles (Figure 13c,e: O and Al elemental maps) can be attributed to the incomplete dissolution process of the PAOX template during sample preparation, leaving minor amounts of residual alumina in the sample.

Similar experimental and EFTEM analytical results were obtained for the synthesis of CNTs by using metallocenes of Ni and Co as single-source precursors. In both cases, CNTs with diameters corresponding to the PAOX template were found. The CNTs again contained metal particles inside the tubes. Ultrathin samples of these CNTs, still embedded in the PAOX template, were studied by TEM (Figure 14).

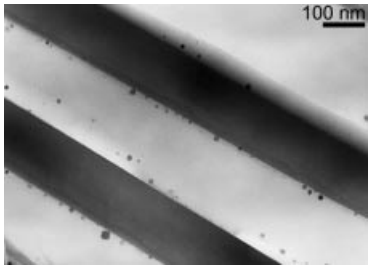

Figure 14. TEM image of an ultrathin sample of CNTs embedded in PAOX, obtained by microtoming (CVD precursor nickelocene). Dense regions which appear with a dark contrast display the PAOX template walls. Alongside the PAOX tube walls, small nickel particles are deposited. Some appear to be partly embedded in an amorphous carbon shell.

Particles with a high nickel content, which are found alongside the pore walls of the CNTs and/or the PAOX template, can be detected by EFTEM analysis of such samples. As for the chromocene case, oxygen is present, however its origin cannot be unambiguously determined, now because of the close proximity of the Ni particles to the surrounding alumina pore walls.

### *Field Emission from CNT Arrays*

An interesting electrical property of CNTs is their field-emission (FE) behaviour. Because of their small diameter, the electronic working function of CNTs is dramatically reduced. Thus, a tunnelling effect of electrons can occur, and consequently theoretical and experimental studies on the electron emission of CNTs have been in the focus of research already for more than one decade.[39,41] Multiwalled CNTs (MWCNTs) are mechanically more robust and are also less prone to electrical degradation than single-walled CNTs (SWCNTs). The emission from MWCNTs shows metal-like behaviour, as deduced from electron spectroscopic studies.[42] For MWCNTs, characteristic parameters in FE, such as the onset field for emission, current density and electrical field enhancement factors β,[43] are drastically improved[44,45] relative to other relevant FE materials like diamond tips,[46] Si[47] and GaN,[48] which were studied intensively over the past years.

For isolated, single CNTs, ten times higher field enhancing factors β are observed relative to CNT films containing bundles of unordered tubes.[49] Thus, different strategies can be followed to obtain good field-emitting devices based on SWCNTs or MWCNTs. One general strategy seeks the most perfect two-dimensional arrangement of CNTs in order to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

arrange as many emitters as possible on a substrate.[50] This assures that a huge number of high aspect ratio structures are produced and are available for FE. Another synthetic strategy arranges CNT emitters in defined areas with a high enough distance to each other, thus fulfilling the theoretical requirement that the distance between single emitters is about the height of an individual emitter to obtain long-term FE stability.[51] By realizing the latter approach, the inter-emitter field penetration due to charging and electrical degradation is significantly reduced relative to arrangements where a higher emitter density is achieved (Figure 15).

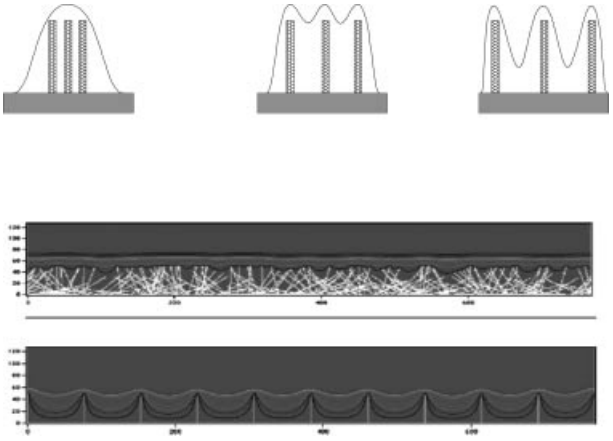

Figure 15. Schematics showing the dependence of the individual electrical field penetration of CNT emitters as a function of the emitter distance. Idealized model (top), model of a realistic CNT surface with high emitter surface coverage (bottom).

Densely populated CNT cathodes therefore have definite disadvantages in their FE behaviour at low fields due to mutual shielding effects (Figure 15).[51] Well-separated CNTs with still high enough densities per area and homogeneous FE characteristics, however, need synthesis techniques other than the former.[44] Up to this date, successful studies have been reported to optimize the FE performance for aligned CNTs.[41e,45,50,52–54] We used PAOX as a templating material for CNTs and investigated the resulting FE properties.[55] In these experiments, additional positive influences of PAOX on the FE behaviour could be detected: for example, electrical insulation of the CNT emitters due to their embedding in the dielectric matrix of PAOX seems advantageous in avoiding destructive degradation by field effects.[51] On the other hand, it has been observed that an outgrow of CNTs over the PAOX surface promotes FE properties.[56] For CNTs which are overgrowing the PAOX template structure, low onset fields for emission of 3–4 V $\mu m^{-1}$ are found. In contrast to these results, CNTs which are totally embedded in PAOX and do not surmount the surface at all, have ten times higher onset fields for FE.[55]

Our work in the area of synthesis and arrangement of CNTs for FE applications has so far focussed on metallocenes or mixtures of metallocenes with polycondensed aromatics as precursors for CNT synthesis.[29,44,57–59] Growing of CNTs by using metallocene precursors was achieved in and on the surface of PAOX membranes and led to an unordered growth on the PAOX surface. Good FE characteristics for such materials were observed when alumina particles were first deposited by CVD from a precursor [source: aluminium tris(sec-butoxide)] on the PAOX surface prior to CNT deposition by CVD (precursor: ferrocene). Then, CNT growth preferentially occurred on the deposited alumina islands (Figure 16).[44,58–60]

FE measurements on this material where performed in a diode configuration. The emission picture was obtained after sample conditioning by current processing.[58,59] Sample conditioning is a standard procedure in FE studies and is necessary because the FE effect and especially the long-term stability of the emitters are very sensitive to any surface and gaseous atmospheric impurity.[58–60] Integral FE measurements on such samples have yielded current densities up to 32 mA $cm^{-2}$ at 7.2 V $\mu m^{-1}$.[59] These values are based on a uniform emitter distribution and an emitter number density of 10000 $cm^{-2}$. This is so far a superior result compared with current values from other studies.[52–54]

Single-emitter investigations on the material revealed stable Fowler-Nordheim-like I–V curves.[58] Despite the observation of some short-term current fluctuations, the alumina-based CNT cathodes provide already reasonable long-term current stability (>18 h) as shown in Figure 17 and Figure 18.

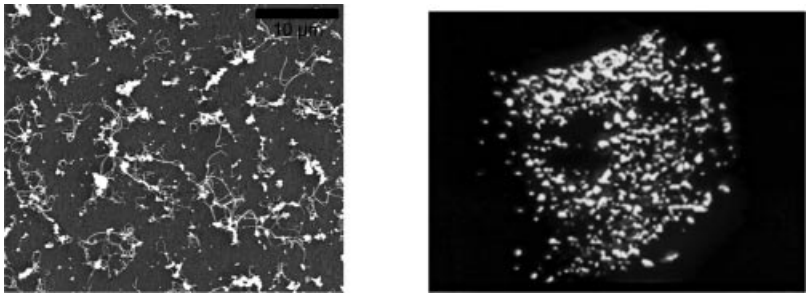

Figure 16. Typical SEM image of isolated CNTs grown on the surface of the PAOX membrane by CVD for FE investigations. The CNTs responsible for FE are linked to the surface of the PAOX by CVD deposition on predeposited alumina islands; right: emission picture of such a sample (size 28 $mm^2$) after conditioning (see text).[59]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

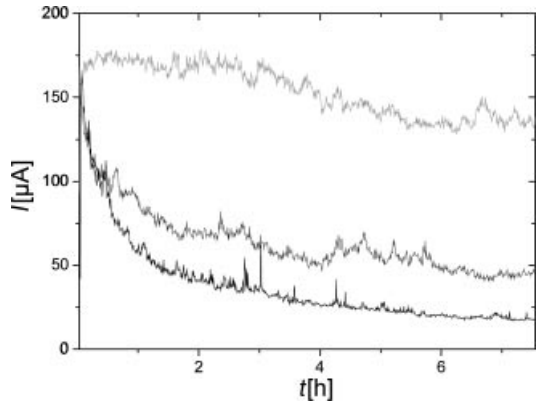

Figure 17. Long-term current stability of a 28-mm$^2$ sample on PAOX at various pressures/fields: $2\times10^{-6}$ mbar at 4.6 V µm$^{-1}$ (upper trace); $5\times10^{-5}$ mbar at 5.3 V µm$^{-1}$ (middle trace); $5\times10^{-4}$ mbar at 6.5 V µm$^{-1}$ (lower trace).[59]

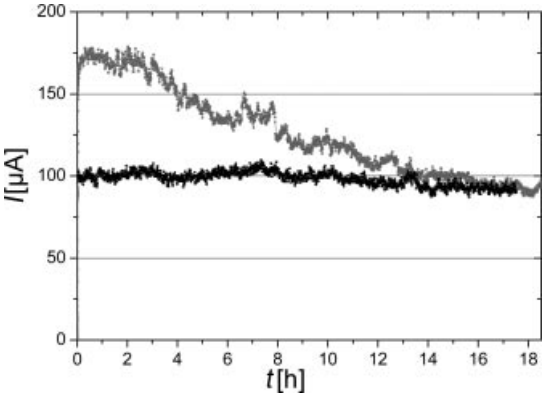

Figure 18. Comparison of the typical long-term current stability of a CNT cathode measured at $10^{-6}$ mbar at 4.6 V µm$^{-1}$ before (upper trace) and after processing (lower trace) up to 700 µA.[59]

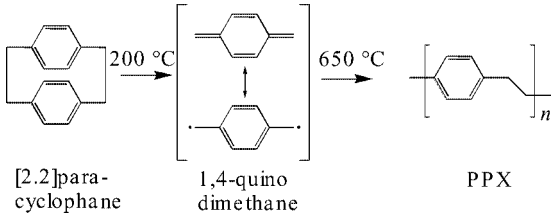
Nevertheless, developing stable CNT field emitters with high performance characteristics is an important task in this research area (long-term stability ≥ 10000 h). Furthermore, an aligned and directed growth of CNTs has to be realized in order to obtain well-separated nanotubes. Such an alignment of emitter structures is so far only realized in Spindt type configurations, which are up to now still the only industrially viable field emitter structures.

### 3.2 Polymeric Structures in and on PAOX

#### *Synthesis and Alignment of Polymeric Poly(p-xylene) (PPX) Filaments Derived from PAOX*

The first reports on the synthesis of polymer tubes and cylinders in PAOX templates appeared in the mid 1990s.[61–63] A recently explored technique uses the controlled wetting of ordered pores of PAOX to generate polymer nanotubes.[64,65] In this approach, the high-energy surface of a PAOX membrane is wetted by a low-energy organic polymer to fill the pores and mould the PAOX template structure. This results in formation of polymeric nanotubes after removal of the template. With this technique, 2D arranged polystyrene, polytetrafluoroethylene (PTFE), polymethyl methacrylate (PMMA) or palladium/polymer composite materials are accessible in filamentous form, either embedded in the template or freed from the template.[64,65] 2D confinement studies of symmetric and asymmetric block copolymers in PAOX templates have been reported recently.[66,67] Formation of polymer or block copolymer nanorods is driven by capillary forces which force the polymer[66] or copolymer melt[67] into the cylindrical nanopores of the PAOX template. These studies show that microphase separated copolymers are formed within the nanochannels of PAOX. The observed polymer structures are not only triggered by the pore size of the template but also by the specific interaction of pore wall with polymer, leading to phase-segregated copolymer rods in which for example styrene or polybutadiene forms the central core.[67,68]

Gas phase processes have been studied recently to form tube- or wire-like structures of other technically important polymers, like poly(*p*-xylene), PPX, in PAOX.[68] PPX films have very good electrical insulation and barrier properties, excellent solvent and hydrolytic resistance, biocompatibility, transparency and thermomechanical properties. PPX is formed by evaporation and vapour-phase pyrolysis of [2.2]-paracyclophanes as precursors. 1,4-Quinodimethanes are formed as intermediates, acting as monomers (Scheme 1). The in situ formed quinodimethanes polymerize spontaneously on nearly any given substrate upon vapour phase deposition at temperatures equal to or below 30 °C by formation of conformal highly adhesive PPX films.[69]



Scheme 1. Formation of PPX polymer starting from [2.2]paracyclophane precursor via intermediate 1,4-quinodimethane.

Within PAOX, PPX can be synthesized in a fibre morphology by chemical vapour deposition polymerization. Figure 19 shows a top and side view of a PPX film formed on PAOX after CVD polymerization deposition. PPX forms a closed film on top of the template, covering its surface completely.

PPX fibres are formed within the pores of the template (Figure 19). The compact PPX films on top of the template can be detached from the surface mechanically or by chemical techniques.

The ordered backside of PAOX membranes can be used for patterning a polymer such as PPX in a straightforward technique by moulding the backside when using it as a master form. This master backside with desired nanodimensions can be prepared by electrochemical oxidation of aluminium metal and detachment of the film from the metal base. This simple technique avoids complicated physical structuring processes like e-beam lithography for shaping a

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

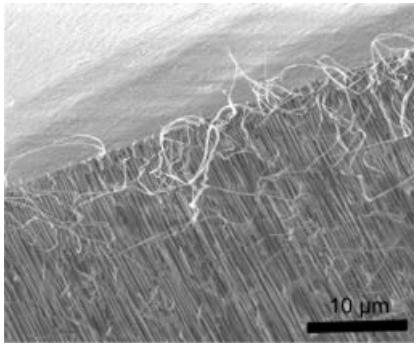


Figure 19. SEM image of a PAOX/PPX composite surface. Fibrous PPX structures protude out of the pores of the PAOX template.

master form, which can then be used in the moulding process. Instead, the self-organization process of forming the nanostructured alumina cells is used to produce the master form. The barrier layer of PAOX provides a nanostructured surface with regular hexagonally ordered concave domes (Figure 20). A replication of the backside PAOX structure with a polymer film may thus represent a straightforward way to nanostructured polymer surfaces with an inverse morphology when detached from the master.

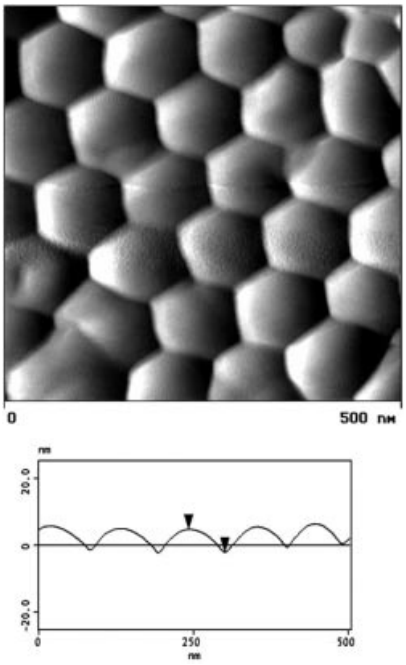

Figure 20. AFM image of a closed PAOX backside with hexagonal pore order used as master in moulding experiments with PPX; bottom: corresponding height profile.

The coating of the PAOX backside template with a thin PPX film can be done in a CVD reactor consisting of a quartz reactor tube in which a three-zone heating can be realized. A temperature gradient from 170° to 700 °C is suitable for sublimation and for initiating the in situ CVD polymerization. After CVD polymerization, the PPX film on the backside of the membrane can either be lifted off mechanically or detached chemically from the resulting PPX/PAOX composite to give a structured PPX film. This process is shown schematically in Figure 21.

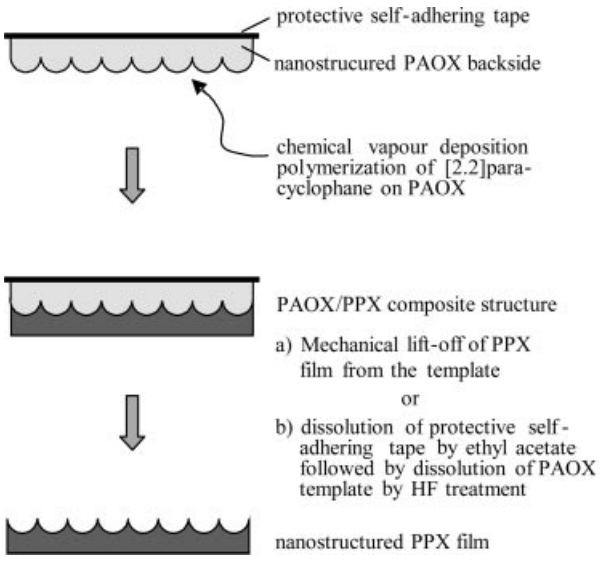

Figure 21. Schematic drawing showing the steps involved in the moulding of a PAOX backside to yield a PPX polymer as well as its detachment to obtain a freestanding nanostructured PPX film.

Figure 22 compares the appearance of a structured PPX film after mechanical lift-off with that after chemical detachment from the PAOX template. The breaking of the film by mechanical stress during the detachment results in the formation of fibrous structures. In contrast, the morphology of the structured PPX film can be retained intact over wide areas by chemical detachment from the master. The film then shows a regular concave structure, in which the small dimples mirror an almost ideal replication of the convex dome-like PAOX backside structure.

Such nanostructured surfaces may show a drastically altered wetting behaviour. Measuring the contact angle at a solid/liquid/gas interface is a very sensitive surface analytical method. It probes the outer atomic layers of a surface and enables the study of chemical as well as morphological surface changes.[70,71]

The hydrophilicity/hydrophobicity of a surface can be determined by measuring the contact angle $\Theta$ between water and the surface (Figure 23). A contact angle of 0° relates to a flat monomolecular water film on a surface of a solid. At a contact angle of 180°, a drop of water, for example, is in contact with the surface only at a single point (superhydrophobic). Between these extremes, surfaces are termed hydrophilic (<90°) or hydrophobic (>90°).

The contact angle of water on a flat PPX surface is 86° (weak hydrophilic behaviour). This compares with an angle of 14° for water on a flat glass surface (roughness ≤ 0.5 nm, piranha-solution-cleaned glass), which is classified as superhydrophilic.[72] The nanostructured PPX film (see Figure 22) which represents a rough surface, shows a drastically reduced water contact angle of only 24° compared to

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

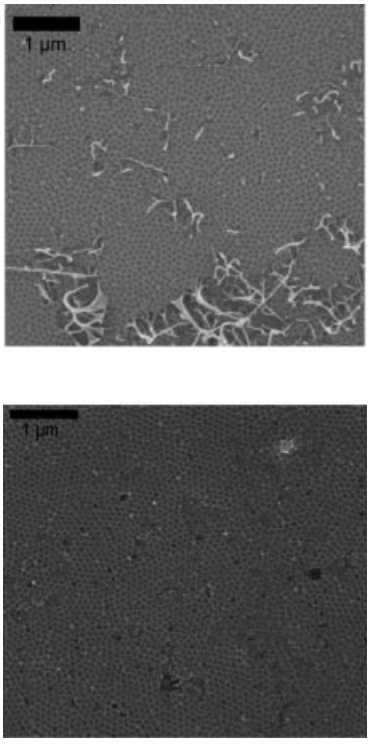

Figure 22. Top: SEM image of a PPX film obtained after deposition on the backside of a PAOX membrane. The fibrous structures result from the destruction of the PAOX film during the mechanical detachment process; bottom: SEM image of a PPX film detached chemically from the PAOX backside by HF dissolution.

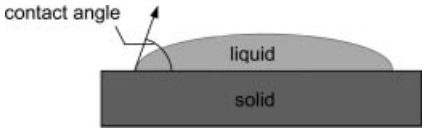

Figure 23. Definition of the contact angle $\Theta$ of a liquid on a solid surface.

a flat unstructured PPX film with a contact angle of 86°. This difference of more than 60° is caused by the structuring of the PPX surface with the regular nanopattern. A possible explanation for the reinforcement of the hydrophilicity of the structured PPX relative to the flat PPX surface can be given when considering the model developed by Wenzel, who has theoretically treated liquid wetting of small-scale rough surfaces (Figure 24).[73] A further refined model for superhydrophilic surfaces (superwetting) was developed recently by Quéré.[74]

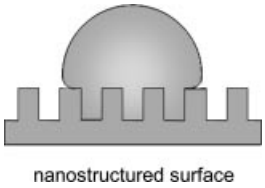

Figure 24. Schematic model of roughness filling of a nanostructured surface by water according to the Wenzel theory.[73]

In the Wenzel model, the space between the protrusions (Figure 24) is filled by a liquid (water), and the theory predicts that both hydrophilicity and hydrophobicity are reinforced by this surface roughness according to the relation:[73]

$\cos\Theta_w = r \cos\Theta_t$

Here $\Theta_w$ is the apparent angle on the rough surface (e.g. structured PPX, Figure 22), $\Theta_t$ is the contact angle of water on a smooth surface of identical chemical composition (e.g. unstructured PPX film), $r$ is a roughness factor, which is defined as the ratio of the actual surface area over the projected area.

As a result, the contact angle $\Theta$ of a surface can be tuned by its surface roughness in the hydrophilic region ($\Theta < 90°$) much in the same way as it can be done in the hydrophobic region ($\Theta > 90°$).[74,75] Thus, a structural change in the surface morphology of the polymeric PPX film is able to tailor the surface wetting of this material from weakly hydrophilic to strongly hydrophilic (Figure 25).

## 4. Conclusions

Nanoporous alumina is an extraordinary material for synthesis and alignment of nanomaterials. Its straightforward synthetic access, its availability in different sizes and shapes, and most important, its high porosity with a massive number of pores running parallel through the transparent material makes this oxidic structure a unique candidate for nanochemistry.

Consequently a wide variety of materials have been synthesized within the pore system of PAOX over the years in a number of different groups. Its high thermal and structural

stability makes PAOX also useful as template in gas-phase CVD processes.

Herein we have described the formation, alignment and FE properties of CNTs inside the pores and on the surface of PAOX. Various single-source precursors were studied and led to the formation of CNTs with and without metal filling of their interior.

In field emission, we found that PAOX has a significant influence on the emission characteristics, which is proven by the highest dc current density so far measured for CNT structures, for example. Moreover long current stabilities of up to 18 h were obtained for these materials after cathode conditioning was employed.

Polymer wires are accessible by a gas-phase route by polymerizing reactive polymer precursors inside the pores of PAOX. Besides the polymerization inside porous alumina, PAOX can be used as a mould to emboss organic polymers. PPX films with a resulting concave surface structure can be deposited on the dome-shaped backside of PAOX and afterwards securely detached from it. This leads to a nanostructured polymer surface, which shows an increased hydrophilicity relative to an unstructured flat PPX polymer film. This may be attributed to an enhanced wetting behaviour of the regular nanopatterned structure relative to a smooth unstructured PPX surface.

The future for even more synthetic as well as technological applications of porous alumina membranes is worth being explored in more detail. Research areas like catalysis, for which its mesopores can be tailored and chemically modified, have been barely touched so far.[76–78] Nanoreactors based on PAOX membranes could be an interesting extension of the already well-established microreactor technique.

Biomolecules are ideal candidates for immobilization inside the pore volume of PAOX because of the variable template pore size in the mesoporous range. Biosensor action is a possible target application that can be realized with such systems.[79] The sector of medical applications of these inorganic membranes is also under current study.[80]

[43] β is the electrical field enhancement factor of an external electrical field applied to an emitting structure. It is greatly influenced (aside from other factors) by a high aspect ratio of the emitting structure. β is a measure of the lowering of the onset field of FE which is typically between $E$ = 1–10 V μm$^{-1}$ for CNTs. β for MWCNTs can be determined from a Fowler-Nordheim plot assuming a work function of 4.6 eV for graphite.

# (Tetramethylcyclobutadiene)cobalt Complexes with Tricarbollide Ligands[‡]

**Elena V. Mutseneck,[a] Dmitry S. Perekalin,[a] Josef Holub,[b] Konstantin A. Lyssenko,[a] Pavel V. Petrovskii,[a] Bohumil Štíbr,[b] and Alexander R. Kudinov*[a]**

**Keywords:** Boron / Cobalt / Metallacarboranes / Cyclobutadiene

Reactions of the 11-vertex *nido*-tricarbollide anions [7,8,9-$C_3B_8H_{11}]^-$ (**2a**) and [7,8,10-$C_3B_8H_{11}]^-$ (**3**) with [Cb*Co-$(MeCN)_3]^+$ or [Cb*Co$(C_6H_6)]^+$ (Cb* = $C_4Me_4$) afford the expected cobaltatricarbollides 1-Cb*-1,2,3,4-$CoC_3B_8H_{11}$ (**4a**) and 1-Cb*-1,2,3,5-$CoC_3B_8H_{11}$ (**5**), respectively. A similar reaction of the amino-substituted anion [7-*t*BuNH-7,8,9-$C_3B_8H_{10}]^-$ (**2b**) is accompanied by polyhedral rearrangement even at room temperature, giving 1-Cb*-12-*t*BuNH-1,2,4,12-$CoC_3B_8H_{10}$ (**7b**). Complex **4a** rearranges to the isomeric complex **5** at 110 °C and further to 1-Cb*-1,2,4,10-$CoC_3B_8H_{11}$ (**6a**) at 160 °C. The amino-substituted derivative 1-Cb*-10-*t*BuNH-1,2,4,10-$CoC_3B_8H_{10}$ (**6b**) was obtained by isomerization of **7b** at 160 °C. The observed rearrangement sequence for Cb*$CoC_3B_8H_{11}$ correlates well with the relative stabilities of nonmethylated analogs estimated by DFT calculations. The structures of **4a** and **7b** were determined by X-ray diffraction.

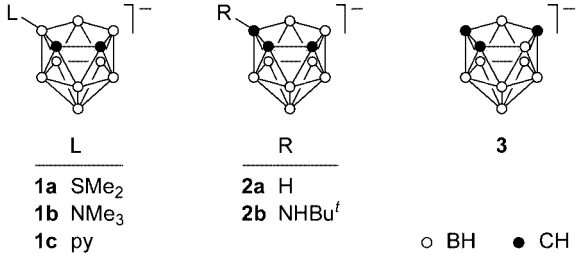
## Introduction

Recently, we have developed two methods for the preparation of (tetramethylcyclobutadiene)cobalt complexes containing cyclopentadienyl, phospholyl, and pyrrolyl ligands, Cb*Co($C_4R_4E$) (Cb* = $C_4Me_4$; E = CR, P, and N).[2,3] One method is based on the reaction of the (carbonyl)iodide complex Cb*Co$(CO)_2I$ with the corresponding anions, while another one uses the acetonitrile complex [Cb*Co-$(MeCN)_3]^+$ as a starting material. The second method is more general, allowing Cb*Co($C_4R_4E$) compounds to be synthesized in higher yields under milder conditions. The same approaches proved to be useful in metallacarborane chemistry, which was clearly demonstrated by the synthesis of Cb*Co complexes with charge-compensated dicarbollide ligands [9-L-7,8-$C_2B_9H_{10}]^-$ (**1**).[1,4] The *nido*-tricarbollide anions **2** and **3**,[5] similar to **1**, have a five-membered face and a single negative charge, which makes them analogous to $Cp^-$ in their coordinating ability. In contrast to dicarbollide derivatives, the presence of the third carbon atom hampers the prediction of the product structure owing to the ease of cluster rearrangement.[6–8] The chemistry of ferratricarbollides is well studied.[9] However, only one example of a cobalt derivative was described.[10] Herein we report the preparation of Cb*Co complexes of anions **2** and **3** and their further rearrangements.



## Results and Discussion

### Synthesis and Rearrangements of Cobaltatricarbollides

We found that the room-temperature reaction of the tricarbollide anion [7,8,9-$C_3B_8H_{11}]^-$ (**2a**) with the acetonitrile complex [Cb*Co$(MeCN)_3]^+$ in THF gives cobaltatricarbollide 1-Cb*-1,2,3,4-$CoC_3B_8H_{11}$ (**4a**)[11] (Scheme 1). The same compound was prepared by photochemical reaction of **2a** with the benzene complex [Cb*Co$(C_6H_6)]^+$ in $CH_2Cl_2$.[12] The second method is more favorable as it avoids preliminary preparation of [Cb*Co-$(MeCN)_3]^+$ by irradiation of [Cb*Co$(C_6H_6)]^+$ in MeCN.[13] As shown recently, the related iron complex 1-Cp-1,2,3,4-$FeC_3B_8H_{11}$ is formed by a similar photochemical reaction of **2a** with [CpFe$(C_6H_6)]^+$.[8] The arrangement of the carbon atoms in the cobalt and iron complexes is the same as in the starting anion **2a**. In contrast, the room-temperature reaction of **2a** with $[Cp^*RuCl]_4$ is accompanied by polyhedral rearrangement to afford 1-Cp*-1,2,3,5-$RuC_3B_8H_{11}$,[8] indicating that the ease of the process depends on the nature of the metal.

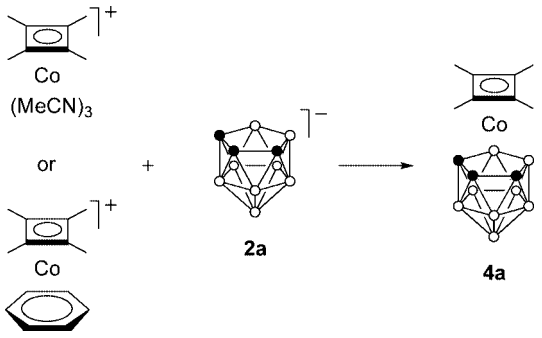
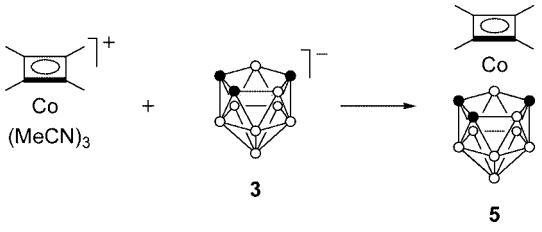


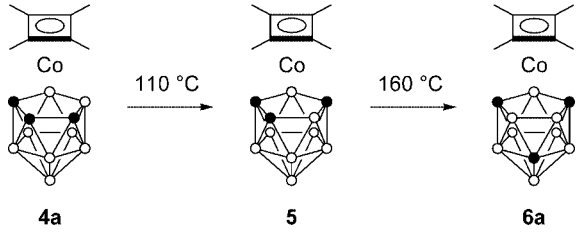
Scheme 1. Synthesis of cobaltatricarbollide **4a**.

The isomeric tricarbollide anion [7,8,10-$C_3B_8H_{11}$]$^-$ (**3**) reacts with [Cb*Co(MeCN)$_3$]$^+$ to give cobaltatricarbollide 1-Cb*-1,2,3,5-$CoC_3B_8H_{11}$ (**5**) (Scheme 2). CpFe and Cp*Ru analogs have been prepared recently by reactions of **3** with [CpFe($C_6H_6$)]$^+$ and [Cp*RuCl]$_4$.[8] No rearrangement has been observed in these reactions.



Scheme 2. Synthesis of cobaltatricarbollide **5**.

Complex **4a** rapidly rearranges into **5** in refluxing toluene (Scheme 3). Refluxing of **4a** or **5** in diglyme results in selective formation of isomer 1-Cb*-1,2,4,10-$CoC_3B_8H_{11}$ (**6a**) with mutual *m*-disposition of cage carbon atoms. The same isomerization sequence was observed earlier for the iron and ruthenium analogs.[8] This sequence is associated with progressive space separation of the CH vertices and is consistent with a diamond-square-diamond mechanism.[14]



Scheme 3. Thermal rearrangements of **4a** and **5**.

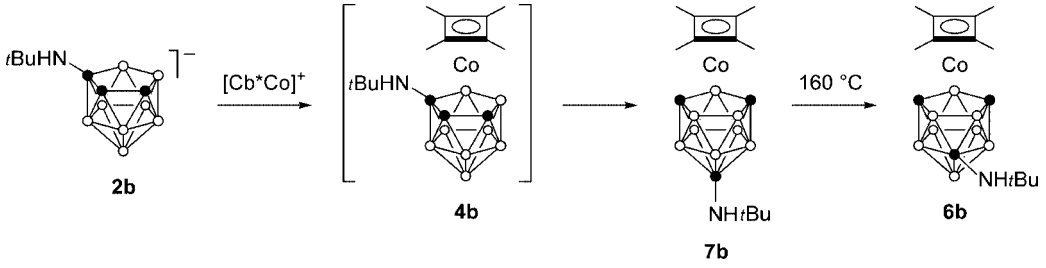
Unlike the parent anion **2a**, the room-temperature reaction of the amino-substituted derivative [7-*t*BuNH-7,8,9-$C_3B_8H_{10}$]$^-$ (**2b**) with [Cb*Co(MeCN)$_3$]$^+$ (THF) or [Cb*Co($C_6H_6$)]$^+$ ($CH_2Cl_2$, *hv*) affords the rearranged *p*-substituted complex 1-Cb*-12-*t*BuNH-1,2,4,12-$CoC_3B_8H_{10}$ (**7b**) instead of the expected isomer 1-Cb*-2-*t*BuNH-1,2,3,4-$CoC_3B_8H_{10}$ (**4b**) (Scheme 4). Interestingly, treatment of **2b** with the less reactive (carbonyl)iodide complex Cb*Co(CO)$_2$I (THF, 65 °C) also gives **7b**, in contrast to an analogous reaction with **2a**, which does not lead to any isolable complexes. This suggests the higher nucleophilicity of **2b** compared with the parent anion **2a**, in accordance with a strong donor effect of the amino group. It should be added that reactions of anion **2b** with CpFe(CO)$_2$I and [Cp*RuCl]$_4$ also afford metallatricarbollides of the same cluster configuration.[7,15] Refluxing of the *p*-substituted compound **7b** in diglyme results in the formation of *m*-isomer 1-Cb*-10-*t*BuNH-1,2,4,10-$CoC_3B_8H_{10}$ (**6b**). Analogous transformation has been observed earlier for amino-substituted ferra- and ruthenatricarbollides.[7,16]

It can be concluded that the introduction of an amino substituent dramatically reduces the rearrangement barrier of the initial complexation product **4**.[17] Moreover, the substitution changes its rearrangement direction. Nevertheless, the final product has the same polyhedral structure in both cases (cf. Scheme 3 and Scheme 4).

## X-ray Diffraction Study

Structures of the tricarbollide complexes **4a** and **7b** were confirmed by X-ray diffraction (Figure 1 and Figure 2). The Cb* ring is nearly an ideal square with a mean side length 1.453–1.457 Å, which approximates those found for the Cb*Co complexes with charge-compensated carborane ligands: 1.456 Å for Cb*Co[**1a**] and 1.452 Å for Cb*Co[**1c**].[1] The carbon atoms of the Cb* methyl groups are deviated for 0.10–0.20 Å from the ring plane away from the cobalt atom. The metal-bonding ligand planes are essentially coplanar, the dihedral angles being 1.2–2.9°.

The Co···Cb* distances in complexes **4a** (1.696 Å) and **7b** (1.703 Å) are slightly longer than that in Cb*Co(η-$C_5H_4$COMe) (1.683 Å)[3] but shorter than in Cb*Co[**1a**] (1.712 Å) and Cb*Co[**1c**] (1.711 Å),[1] suggesting that the tricarbollide ligands **2a** and [1-*t*BuNH-1,7,9-$C_3B_8H_{10}$]$^-$ are weaker donors than acetylcyclopentadienide but stronger donors than the charge-compensated dicarbollide ligands



Scheme 4. Synthesis and thermal rearrangement of **7b**.

**1a**,**c**. However, according to electrochemical data, **1a**,**c** are stronger donors than tricarbollides.[18] Apparently, the Co···Cb* distance also depends on other effects.

### DFT Calculations

Despite wide application of DFT calculations for transition-metal complexes,[19] their use in the case of metallacarboranes is rather limited.[20–24] Recently, we have shown that the calculations of ferratricarbollides $CpFeC_3B_8H_{11}$ provide reliable geometry, energy, and spectroscopic data.[8] In order to estimate the thermodynamic stability and $^{11}B$ NMR spectra of cobaltatricarbollides **4a**, **5**, and **6a**, we carried out DFT calculations (at the B3LYP/6-31G* level) for their nonmethylated analogs $(C_4H_4)CoC_3B_8H_{11}$ (**4a′**, **5′**, and **6a′**).[25]

The carbon-adjacent complex **4a′** was found to be the least thermodynamically stable, presumably because of the Coulomb repulsion of the negatively charged CH vertexes. The isomeric compounds **5′** and **6a′** are more stable than **4a′** for 17.2 and 26.2 kcal/mol, respectively. Thus, the observed rearrangement sequence **4a** → **5** → **6a** correlates with the stepwise increase of the thermodynamic stability of the isomers. Interestingly, the corresponding values for the CpFe analogs of **5′** and **6a′** are 17.0 and 25.5 kcal/mol, respectively, indicating that relative stability of isomers is mainly determined by the arrangement of the carbon atoms and is practically independent of the metal vertex.

The calculated $^{11}B$ NMR chemical shifts for **4a′**, **5′**, and **6a′** (Table 1) are in good agreement with the experimental values for **4a**, **5**, and **6a** (av. deviation 1.1 ppm), thus providing additional confirmation of their structures. The only significant deviation (about 3–5 ppm) is observed for the signal of the B12 atom, apparently because of approximation of the Cb* ligand with $C_4H_4$. Indeed, the calculation for the methylated complex **4a** decreases the deviation to 0.8 ppm. Such strong influence of the antipodal vertex on the $^{11}B$ NMR shift has been observed previously for various heteroboranes.[26]

Table 1. Calculated and experimental $^{11}B$ NMR chemical shifts of the $(C_4R_4)CoC_3B_8H_{11}$ isomers.

| Compound | $^{11}B$ NMR shifts | | | | |

## Conclusion

The methods previously used for the preparation of Cb*Co($C_4R_4E$) compounds proved to be effective for the synthesis of Cb*Co complexes with monoanionic tricarbollide ligands. Similar to iron and ruthenium analogs, these complexes undergo cluster rearrangements in relatively mild conditions. Identical isomerization sequences observed for Cb*Co, CpFe, and Cp*Ru tricarbollides suggest that relative stability of isomers is mainly determined by the arrangement of the carbon atoms and is practically independent of the metal vertex. This conclusion is also confirmed by DFT calculations for ($C_4H_4$)Co and CpFe tricarbollide isomers.

## Experimental Section

**General:** All reactions were carried out under argon in anhydrous solvents that were purified and dried using standard procedures. The isolation of products was conducted in air. Starting materials were prepared as described in the literature: Cb*Co$(CO)_2$I,[3,13] [Cb*Co$(C_6H_6)$]$PF_6$,[3,13] [Cb*Co$(MeCN)_3$]$PF_6$,[3,13] [$Me_4$N][**2a**],[5c] Tl[**2b**],[15] and [$Ph_4$P][**3**].[5c] Irradiation was conducted in a Schlenk tube using a high-pressure mercury vapor lamp with a phosphor-coated bulb (400 W). Both the tube and the lamp were placed in a vessel of an appropriate volume covered inside with aluminum foil; cooling was accomplished by running water. Column chromatography was performed on silica gel L 100/400 (0.5 × 10 cm) using $CH_2Cl_2$/petroleum ether (1:5) as an eluent. The $^1$H and $^{11}$B NMR spectra were recorded with a Bruker AMX 400 spectrometer operating at 400.13 and 128.38 MHz, respectively.

**Preparation of 1-Cb*-12-*t*BuNH-1,2,4,12-$CoC_3B_8H_{10}$ (7b). Method A [Starting from Cb*Co$(CO)_2$I]:** A mixture of Cb*Co$(CO)_2$I (100 mg, 0.29 mmol) and Tl[**2b**] (143 mg, 0.35 mmol) in THF (20 mL) was stirred under reflux for 13 h. The solvent was removed in vacuo and the residue was extracted with $CH_2Cl_2$/petroleum ether (1:1). Filtration and evaporation left a crude product, which was purified by column chromatography followed by washing with pentane (about 1 mL). Yield 90 mg (84%) of a yellow solid. $^1$H NMR ($CDCl_3$): $\delta$ = 2.28 (s, 1 H, NH), 1.52 (s, 12 H, Cb*), 1.50 (s, 2 H, CH), 1.25 (s, 9 H, *t*Bu) ppm. $^{11}$B NMR: $\delta$ = –10.4 [d (148), 2B, B5,6], –15.1 [d (170), 1B, B3], –15.5 [d (160), 2B, B9,11], –17.9 [d (156), 1B, B10], –22.3 [d (173), 2B, B7,8] ppm. $C_{15}H_{32}B_8CoN$ (371.83): calcd. C 48.45, H 8.68, B 23.26, N 3.77; found C 48.63, H 8.74, B 23.30, N 3.59.

**Method B {Starting from [Cb*Co$(C_6H_6)$]$PF_6$}:** A mixture of [Cb*Co$(C_6H_6)$]$PF_6$ (50 mg, 0.13 mmol) and Tl[**2b**] (57 mg, 0.14 mmol) in $CH_2Cl_2$/THF (15:3 mL) was irradiated with stirring for 6 h. The solvent was removed in vacuo and the residue was extracted with $CH_2Cl_2$/petroleum ether (1:1). Filtration and evaporation left a crude product, which was purified by column chromatography followed by washing with pentane (about 0.5 mL). Yield 30 mg (62%).

**Method C {Starting from [Cb*Co$(MeCN)_3$]$PF_6$}:** Tl[**2b**] (102 mg, 0.25 mmol) was added to a frozen (–196 °C) solution of [Cb*Co$(MeCN)_3$]$PF_6$ (100 mg, 0.23 mmol) in THF (5 mL). The temperature was allowed to rise to ambient and the mixture was stirred overnight. The solvent was removed in vacuo and the residue was extracted with $CH_2Cl_2$/petroleum ether (1:1). Filtration and evaporation left a crude product, which was purified by column chromatography followed by washing with pentane (about 0.5 mL). Yield 68 mg (79%).

**Preparation of 1-Cb*-1,2,3,4-$CoC_3B_8H_{11}$ (4a):** Complex **4a** was obtained in a similar manner to **7b**, using [$Me_4$N][**2a**]. Yield 41% (method B) and 35% (method C) of a yellow solid. $^1$H NMR ([$D_6$]-acetone): $\delta$ = 4.53 (s, 1 H, CH), 2.77 (s, 2 H, CH), 1.68 (s, 12 H, Cb*) ppm. $^{11}$B NMR: $\delta$ = –9.56 [d (148), 2B, B5,6], –12.72 [d (144), 1B, B10], –17.10 [d (158), 2B, B9,11], –19.03 [d (146), 1B, B12], –26.12 [d (170), 2B, B7,8] ppm. $C_{11}H_{23}B_8Co$ (300.70): calcd. C 43.93, H 7.71; found C 43.96, H 7.70.

**Preparation of 1-Cb*-1,2,3,5-$CoC_3B_8H_{11}$ (5):** Complex **5** was obtained in a similar manner to **7b**, using [$Ph_4$P][**3**]. Yield 61% (method C) of a yellow solid. $^1$H NMR ($CDCl_3$): $\delta$ = 2.50 (s, 2 H, CH), 1.91 (s, 1 H, CH), 1.60 (s, 12 H, Cb*) ppm. $^{11}$B NMR: $\delta$ = –16.59 [d (159), 4B, B7,9,10,12], –18.99 [d (161), 2B, B4,6], –24.55 [d (159), 2B, B8,11] ppm. $C_{11}H_{23}B_8Co$ (300.70): calcd. C 43.93, H 7.71; found C 44.03, H 7.84.

**Preparation of 1-Cb*-10-*t*BuNH-1,2,4,10-$CoC_3B_8H_{10}$ (6b):** A solution of **7b** (50 mg, 0.13 mmol) in diglyme (3 mL) was refluxed for 6 h. The solvent was removed in vacuo, and the residue was dissolved in petroleum ether and filtered through a short layer of silica gel (about 2 cm). Evaporation left a yellow oil which crystallized at –10 °C. Yield 33 mg (66%) of a yellow solid. $^1$H NMR ($CDCl_3$): $\delta$ = 1.70 (s, 1 H, NH), 1.60 (s, 12 H, Cb*), 1.55 (s, 2 H, CH), 1.13 (s, 9 H, *t*Bu) ppm. $^{11}$B NMR: $\delta$ = –8.4 [d (134), 2B, B5,6], –15.2 [d (156), 1B, B3], –16.0 [d (168), 2B, B9,11], –16.8 [d (190), 1B, B12], –24.7 [d (159), 2B, B7,8] ppm. $C_{15}H_{32}B_8CoN$ (371.83): calcd. C 48.45, H 8.68, B 23.26, N 3.77; found C 49.08, H 8.71, B 23.25, N 3.72.

**Preparation of 1-Cb*-1,2,4,10-$CoC_3B_8H_{11}$ (6a):** Complex **6a** was obtained in a similar manner to **6b** by refluxing a solution of **4a** or **5** (50 mg, 0.17 mmol) in diglyme (3 mL) for 13 h. Yield 35–38 mg (70–75%) of a yellow solid. $^1$H NMR ([$D_6$]acetone): $\delta$ = 2.33 (s, 1 H, CH), 1.76 (s, 2 H, CH), 1.65 (s, 12 H, Cb*) ppm. $^{11}$B NMR: $\delta$ = –10.15 [d (151), 1B, B3], –11.08 [d (155), 2B, B5,6], –17.90 [d (167), 2B, B9,11], –18.95 [d (161), 1B, B12], –23.03 [d (158), 2B, B7,8] ppm. $C_{11}H_{23}B_8Co$ (300.70): calcd. C 43.93, H 7.71, found C 44.05, H 7.82.

**Computational Details:** All calculations were performed using Gaussian 98 (revision A.7) software[27] at the B3LYP/6-31G* level. In the case of geometry optimization of **4a**, the methyl groups of the Cb* ring were fixed with ModRedundant option and treated with 3-21G* basis. The structures of the **4a**′, **5**′, and **6a**′ isomers were optimized using tightened SCF convergence criteria (SCF = Tight option). The frequency calculations were performed to confirm the global minimum and include ZPE corrections to the energy. The $^{11}$B NMR shifts were calculated using the GIAO method by subtraction of calculated isotropic shielding values from those of $B_2H_6$ (93.50 at B3LYP/6-31G*). The experimental chemical shift of $B_2H_6$ was assigned 16.6 ppm.[28]

**X-ray Crystallography:** Crystals of **4a** and **7b** suitable for X-ray diffraction were grown by slow evaporation of toluene solution under argon (**4a**) or by evaporation of petroleum ether solution in air (**7b**). The structures were solved by direct method and refined by the full-matrix least-squares against $F^2$ in anisotropic approximation for non-hydrogen atoms. All polyhedron hydrogen atoms were located from the Fourier density synthesis and refined in isotropic approximation. Crystal data and structure-refinement parameters for **4a** and **7b** are given in Table 2. All calculations were performed using the SHELXTL software.[29]

CCDC-279628 (for **4a**) and -279627 (for **7b**) contain the supplementary crystallographic data for this paper. These data can be

# Electronic Characterisation and Significant Second-Order NLO Response of 10,20-Diphenylporphyrins and Their $Zn^{II}$ Complexes Substituted in the *meso* Position with π-Delocalised Linkers Carrying Push or Pull Groups

**Tamara Morotti,[a] Maddalena Pizzotti,*[b] Renato Ugo,[b] Silvio Quici,[c] Maurizio Bruschi,[d] Patrizia Mussini,[e] and Stefania Righetto[b]**

**Keywords:** Nonlinear optics / Porphyrins / Cyclic voltammetry / UV/Vis spectroscopy

This work describes the synthesis and the electronic characterisation by electronic absorption spectroscopy, cyclic voltammetry and dipole moments of diphenyl porphyrins and their $Zn^{II}$ complexes substituted at the *meso* position by a pseudo-linear π-delocalised substituent carrying an electron-donor or an electron-withdrawing group. The second-order NLO response was investigated by the EFISH technique working with a nonresonant incident wavelength of 1.907 μm. This work confirms the ambivalent role of the polarisable porphyrin ring, which, already in the ground state, acts as a donor or acceptor depending on the nature (acceptor or donor) of the substituent in the *meso* position, as was pointed out in our previous work on tetraphenyl porphyrins substituted at the β-pyrrolic position.

The second-order NLO response has been discussed by comparing the nature of the substituent (electron donor or acceptor) and the kind of substitution (β pyrrolic or *meso*). This comparison evidenced a significant increase of the electron-donor properties of $NBu_2$ or $NMe_2$ when they are connected to the *meso* position or to the β-pyrrolic position, probably because of an auxiliary donor effect of the electron-rich porphyrin ring. When the substituent is the electron-withdrawing $NO_2$ group, the substituent position (*meso* or β pyrrolic) is influential, with the existance of a significant increase in the second order NLO response when substitution occurs at the *meso* position.

## Introduction

Over the last two decades molecular materials for nonlinear optics (NLO) have been investigated for their promising applications in optoelectronics and photonics.[1] Although most studies deal with pseudo-linear 1D organic[2] or organometallic[3] push-pull chromophores with second-order nonlinear optical response, more recent investigations have been devoted to two-dimensional push-pull chromophores based on highly π-delocalised macrocycles such as porphyrins[4–6] and phthalocyanines.[7] Porphyrins and their metal complexes appear to be advantageous, given their acceptable solubility, good thermal and chemical stability, and potential processability as layers.[8]

In addition, the architectural flexibility of porphyrins is well exemplified by the large number of structures reported in the literature, as well as by a large variety of substituents that can be attached at the *meso* or β-pyrrolic positions[5,6] of the porphyrin ring or to the axial position of a metal complex.[9]

Starting from studies carried out by Suslick and coworkers at the beginning of the 90s[4a,4b] and later by Therien and coworkers,[5a,5b] and following the theoretical approach of Marks, Ratner et al.,[10] who suggested that the presence of a π spacer between an electron-donor or acceptor group and the porphyrin ring together with the right ring substitution (β pyrrolic or *meso*) could produce chromophores with a large second-order NLO response, we recently investigated the second-order NLO response of push-pull porphyrinic chromophores with electron-donor or withdrawing groups linked, through a π spacer, to the β-pyrrolic position of the 5,10,15,20-tetraphenylporphyrin or its $Zn^{II}$ complex.[6]

Our experimental results, in agreement with the suggestion of Marks, Ratner et al.,[10] have shown that the second-order NLO response is enhanced when an electron-donor substituent is attached at the electron-rich β-pyrrolic position of the porphyrin ring. We also evidenced an ambivalent

role of the porphyrin ring (in the ground state but also in charge transfer processes), behaving as an electron donor or as an electron-rich enhancer of the donor properties of an amino group, according to the nature of the substituent in the β-pyrrolic position.

Very few studies have been devoted to the experimental investigation of the second-order NLO response of push-pull porphyrinic chromophores according to the nature of the substituents and their position on the porphyrin ring. Thus, in an effort to produce additional evidence of the ambivalent role of the porphyrin ring, we extended our investigation to the electronic characterisation and second-order NLO response of a series of 10,20-diphenylporphyrins ($H_2$DPP) and their $Zn^{II}$ complexes substituted, at the *meso* position, by electron-donor or electron-withdrawing groups connected through a π spacer.

In order to avoid resonance effects or interference resulting from fluorescent emissions, the second-order NLO response was measured by the EFISH technique working with a nonresonant 1.907 μm incident wavelength.[5a] Calculations based on density functional theory (DFT)[11] were also performed to evaluate the dipole moment of the optimised structures of the investigated porphyrinic macrocycles, using the BP86[12] functional and an all-electron valence triple-ξ basis set with polarisation functions on all atoms.[13]

## Results and Discussion

### Synthesis of Porphyrins and Their $Zn^{II}$ Complexes

The asymmetrical 10,20-diphenylporphyrins and their $Zn^{II}$ complexes investigated in this work are reported in Figure 1; the $Zn^{II}$ complexes **2** and **4** have already been synthesised by Anderson et al.[14]

The porphyrin **1** was synthesised with a modification of the synthetic route described by Anderson et al.,[14] involving a Wittig condensation of 5-formyl-10,20-diphenylporphyrin with 4-nitrobenzyltriphenylphosphonium bromide in refluxing 1,2-dichloroethane, using solid NaOH 20–40 mesh beads as the base. This reaction afforded **1** in 49%

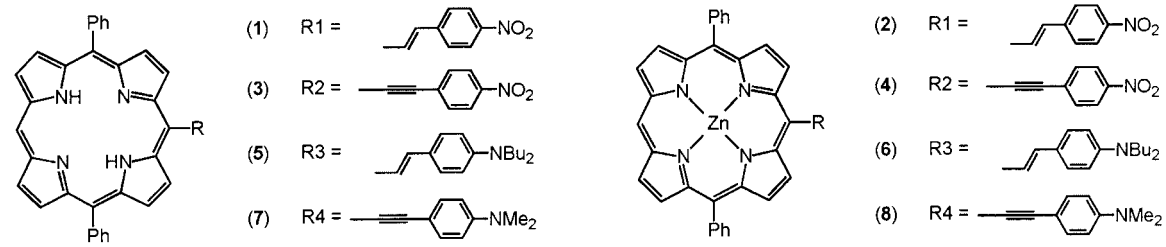

Figure 1. Asymmetrical 10,20-diphenylporphyrins and their $Zn^{II}$ complexes substituted at the *meso* position with electron-withdrawing or electron-donor groups.

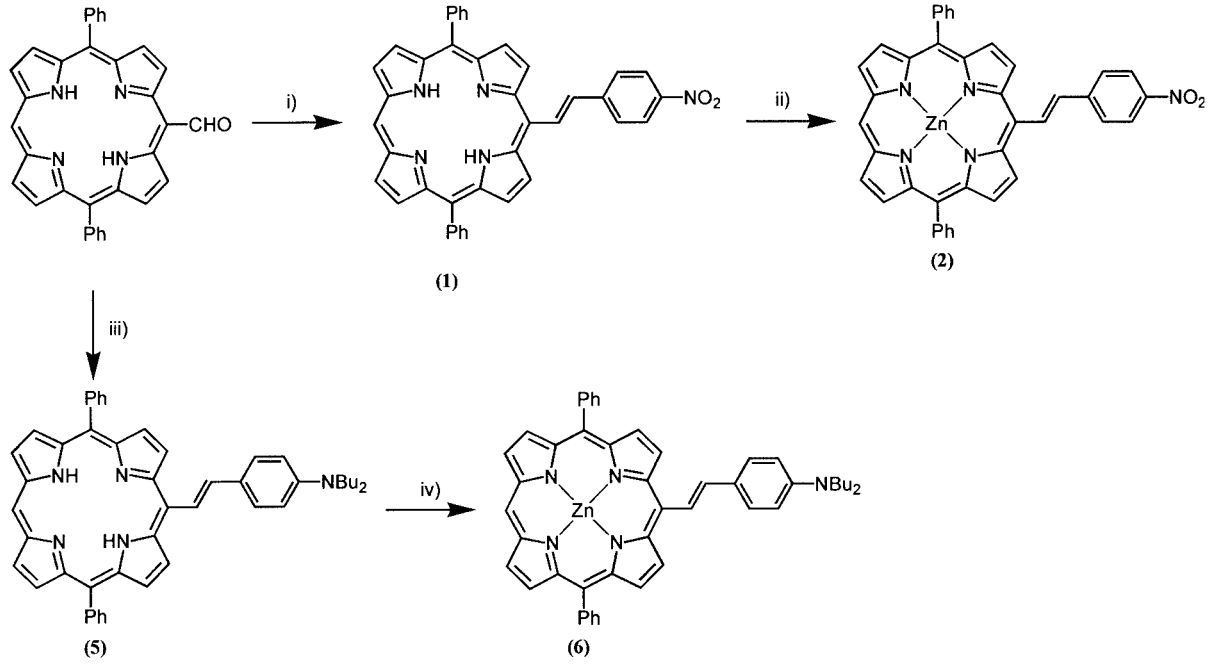

Scheme 1. i) 4-Nitrobenzyltriphenylphosphonium bromide, NaOH, $CH_2Cl_2$, reflux, 4 h; ii) $Zn(OAc)_2{\cdot}2H_2O$, $CHCl_3$/MeOH, reflux, 1 h; iii) 4-(Dibutylamino)benzyltriphenylphosphonium chloride, NaOH, $CH_2Cl_2$, room temp., 4 h; iv) $Zn(OAc)_2{\cdot}2H_2O$, $CHCl_3$/MeOH, reflux, 1 h.

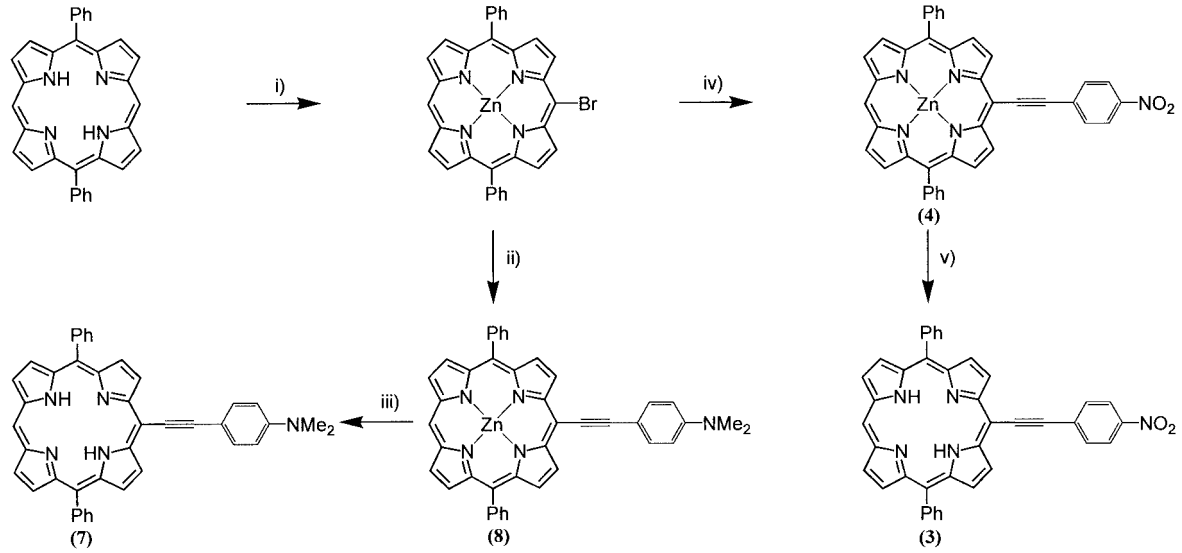

Scheme 2. i) NBS, $CHCl_3$, room temp., 30 min.; $Zn(OAc)_2{\cdot}2H_2O$, $CHCl_3$/MeOH, reflux, 1 h; ii) catalyst (see Exp. Sect.), [4-(dimethylamino)phenyl]acetylene, pyridine, toluene, 80 °C, 1.5 h; iii) TFA, $CH_2Cl_2$, 18 h; iv) catalyst (see Exp. Sect.), (4-nitrophenyl)acetylene, pyridine, toluene, 80 °C, 1 h; v) TFA, $CH_2Cl_2$, 18 h.

yield after purification by column chromatography and crystallisation from $CH_2Cl_2$/MeOH.

Analogously, Wittig condensation of 5-formyl-10,20-diphenylporphyrin with 4-(dibutylamino)benzyltriphenylphosphonium chloride afforded **5** in 59% yield after purification by column chromatography.

The corresponding $Zn^{II}$ complexes **2** and **6** were obtained in quantitative yield after refluxing **1** and **5** with $Zn^{II}$ acetate in $CH_2Cl_2$/MeOH for 1 h[15] (Scheme 1).

5-Formyl-10,20-diphenylporphyrin was prepared in 80% yield by the Vilsmaier formylation of the $Cu^{II}$ complex of 10,20-diphenylporphyrin, obtained in 83% yield by reaction of 10,20-diphenylporphyrin with $Cu^{II}$ acetate in refluxing $CHCl_3$/MeOH, followed by quantitative demetallation of the $Cu^{II}$ complex with a mixture of trifluoroacetic acid/concentrated sulfuric acid (9:1), as reported by Susumu et al.[15]

$Zn^{II}$ complexes **4** and **8** (85% and 59% yields, respectively) were synthesised, as described by Anderson et al.,[14] by the coupling reaction of the $Zn^{II}$ complex of 5-bromo-10,20-diphenylporphyrin with 4-nitrophenylacetylene and [4-(dimethylamino)phenyl]acetylene, respectively. The reaction was carried out in anhydrous toluene and pyridine at 80 °C in the presence of a $Pd^0$ catalyst, prepared in situ by the reaction, at 70 °C, of $[Pd_2(dba)_3]$ and $PPh_3$ in freshly distilled $Et_3N$ in the presence of CuI.

The free base porphyrins **3** and **7** were obtained in quantitative yields by controlled demetallation, at room temperature, of the $Zn^{II}$ complexes **4** and **8** with trifluoroacetic acid working in $CH_2Cl_2$ (Scheme 2).

### Electronic Absorption and Emission Spectra

Anderson et al.[14] have already investigated the electronic absorption and emission spectra of the $Zn^{II}$ complexes **2** and **4**, which evidence significant changes in comparison with those of the complex [Zn(DPP)]·THF of 10,20-diphenylporphyrin ($H_2$DPP). The significant red shift of both the Soret B band and the $Q_\alpha$ band at lower energy, with an increase in the intensity of this latter band suggests an electronic conjugation between the porphyrin ring and the π linker. The spectra, obtained in $CH_2Cl_2$ solution in the presence of 1% pyridine, refer to pentacoordinate species with a pyridine in the axial position.

Here we report (Table 1) and discuss the absorption and emission spectra of the $Zn^{II}$ complexes **2** and **4** in $CHCl_3$ solution, with and without pyridine addition, together with those of the corresponding porphyrins **1** and **3**.

A comparison of the absorption spectra of the porphyrins **1** and **3** with those of **2** and **4** indicates a decrease in the number of Q bands, from four to two, with the complete disappearance of the $Q_\alpha$ band at low energy (around 655–660 nm) as expected for an increase of the microsymmetry upon coordination.[6] Compounds **2** and **4**, but also **1** and **3**, still show a significant red shift of the Soret B band and of the $Q_\alpha$ band at lower energy, which increases its intensity, in comparison with that of [Zn(DPP)]·THF and $H_2$DPP (Table 1). The red shift of the Soret B band is more significant for **4** than for **2**, in agreement with the suggested[14] better π conjugation of the triple bond with the π core of the porphyrin ring.

Differently from 5,10,15,20-tetraphenylporphyrin and its $Zn^{II}$ complex substituted in the β-pyrrolic position by a similar series of π-delocalised substituents,[6] the Soret B band of porphyrins **1** and **3** and of their $Zn^{II}$ complexes **2** and **4** is quite symmetric, but with an increase of the bandwidth of the Soret B bands, which is further evidence of electronic conjugation[6] (Table 1).

Both **2** and **4** show, in the presence of pyridine, an additional small red shift of the Soret B band, and a more significant red shift of the $Q_\alpha$ band at lower energy, which is expected for the axial coordination of pyridine[9] (Table 1). The $Zn^{II}$ complex **4** is quite insoluble, suggesting

[a] $H_2$DPP = 10,20-diphenylporphyrin. [b] Values were obtained according to equation $\Delta\nu_{1/2} = f/(4.33\times10^{-9}\times\varepsilon)$ (F. L. Pilar, *Elementary Quantum Chem.*, McGraw-Hill Book Comp., **1968**) where $f$ is the oscillator strength and $\varepsilon$ is the extinction coefficient of the maximum. [c] Values obtained by irradiation at the Soret wavelength. [d] With addition of pyridine. [e] Not soluble enough for a reliable determination. [f] Highly asymmetric band. [g] Two Soret bands of relative intensities depending on the concentration. [h] In $CH_2Cl_2$ solution from ref.[14]

strong association in the solid state.[16] In accordance it becomes soluble with the addition of pyridine.

When an *E*-ethylenic linker connects a basic dibutylamino electron-donor group with the porphyrin ring as in porphyrin **5** and its $Zn^{II}$ complex **6** (Table 1), all the Q bands are notably red shifted, (notably for **5** the $Q_\alpha$ band at lower energy shifts from 630 to 747 nm), while the Soret B band is not red shifted when compared with $H_2$DPP and [ZnDPP]·THF. Both compounds **5** and **6** show a significantly asymmetric Soret B band, with the asymmetry centred at lower energy (Figure 2). Interestingly the compound with the same substituent bound to the β-pyrrolic position of the 5,10,15,20-tetraphenylporphyrin or its $Zn^{II}$ complex, shows a symmetric Soret B band.[6]

The $Zn^{II}$ complex **8** with a dimethylamino electron-donor group connected through a π-acetylenic linker to the porphyrin ring shows, in $CHCl_3$ solution even at concentrations about $10^{-6}$ M, two well-separated Soret B bands, with a relative intensity changing with the concentration (Table 1 and Figure 3, a), which is evidence of aggregation.[16]

The position of the two bands suggests that aggregation occurs via the interaction of the donor dimethylamino group of the π-delocalised substituent with the axial position of another molecule, since the Soret B band at 448 nm is typical of pentacoordination, while that at 428 nm may be because of some unassociated species. Intermolecular aggregation is also supported by the addition of traces of pyridine, which produces only one symmetric Soret B band at 451 nm (Figure 3, b) that does not shift on dilution as would be expected for an unaggregated pentacoordinate species.[9]

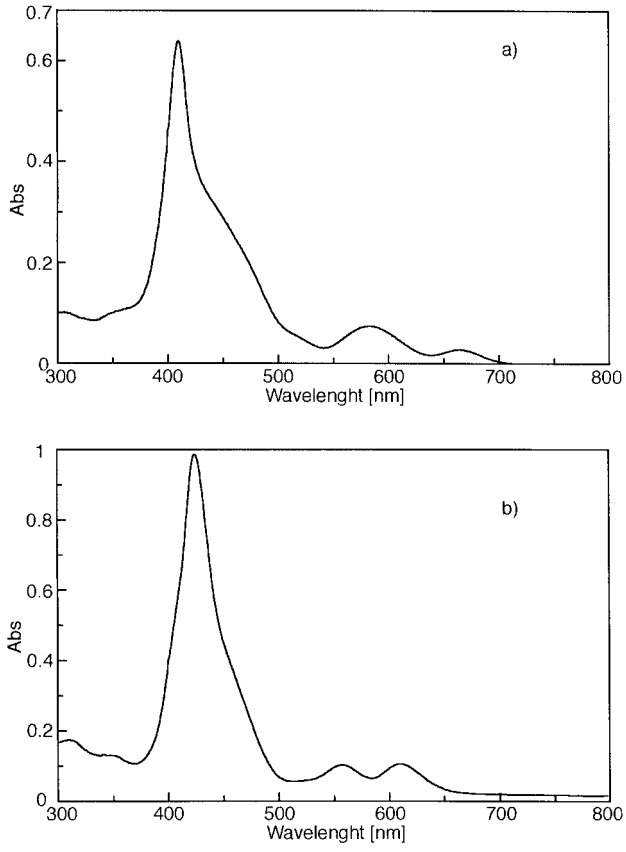

Figure 2. (a) Electronic absorption spectrum of **5** in $CHCl_3$, (b) Electronic absorption spectrum of **6** in $CHCl_3$.

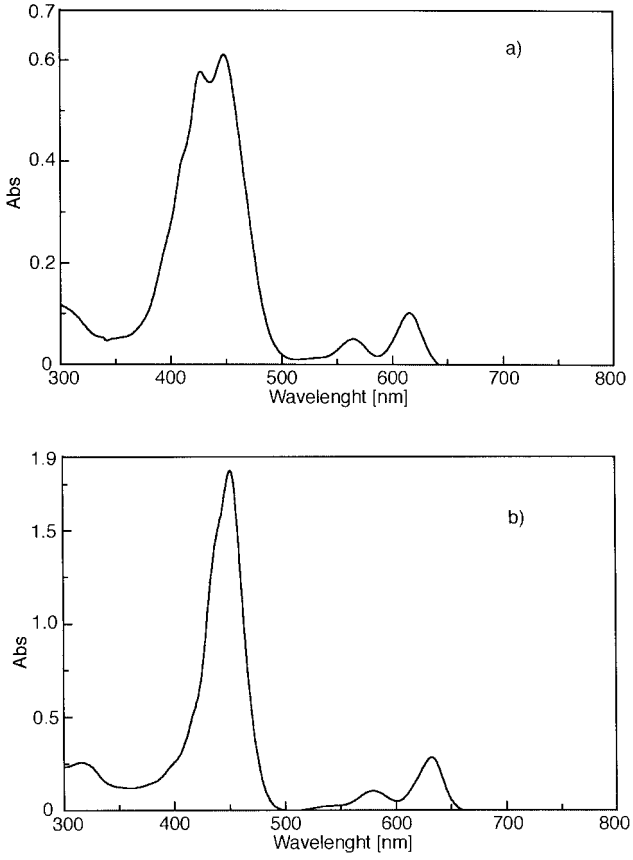

Figure 3. (a) Electronic absorption spectrum of **8** in $CHCl_3$, (b) Electronic absorption spectrum of **8** in $CHCl_3$ with the addition of pyridine.

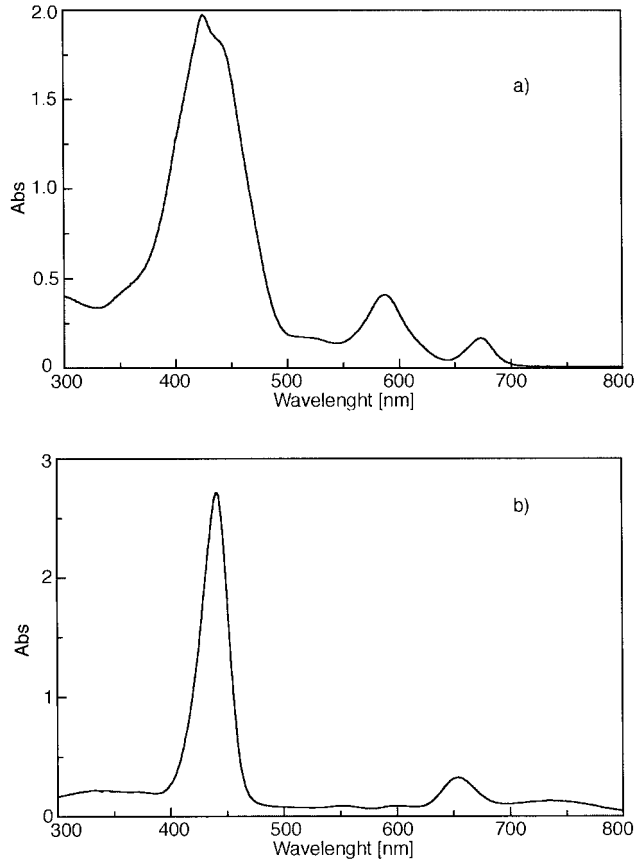

Figure 4. (a) Electronic absorption spectrum of **7** in $CHCl_3$, (b) Electronic absorption spectrum of **7** in $CHCl_3$ with the addition of trifluoroacetic acid.

Also the $Zn^{II}$ complex **6** shows a Soret B band with some asymmetry (Figure 2, b), which disappears on addition of pyridine suggesting a similar kind of aggregation. A slow aggregation process of **6** is confirmed by an $^1H$ NMR spectroscopic investigation, but working at higher concentrations (about $10^{-3}$ M). In fact, the $^1H$ NMR spectrum of **6** in $CDCl_3$ is initially the one expected for a monomeric species, but after one hour significant changes take place.

A weaker intermolecular aggregation, probably by hydrogen bonding between the NH and $NMe_2$ groups of two molecules, seems to occur for porphyrin **7**, where two poorly resolved Soret B bands are seen (Figure 4, a). On dilution two isosbestic points were evidenced, as expected for the dissociation of a dimeric species, resulting in a monomeric species only at about $10^{-6}$ M concentration.

The addition of traces of trifluoroacetic acid to a $10^{-5}$ M solution of **7** in $CHCl_3$ produced only one Soret B band (Figure 4, b) as expected for the protonation of the dimethylamino group with disruption of the hydrogen bond and therefore of the intermolecular aggregation involving the dimethylamino group of the substituent.

Interestingly compounds **1**–**3**, with a π-delocalised substituent carrying an electron-withdrawing nitro group, did not show such spectroscopic evidence for significant aggregation, for instance by π stacking,[16] at concentrations of about $10^{-4}$–$10^{-6}$ M in $CHCl_3$.

Both $H_2DPP$ and [ZnDPP]·THF, when irradiated at the Soret B band wavelength in a $CHCl_3$ solution, show two well-separated emission bands, the one at lower energy being slightly more intense. On the contrary the porphyrins **1**, **3**, **5** and **7** show only one major emission with shoulders at lower (**1**, **3**, **7**) or at higher energies (**5**). Also the $Zn^{II}$ complexes **2** and **4** in $CHCl_3$ solution show one major emission, with much weaker emission bands at lower (**4**) or higher energies (**2**). Only the $Zn^{II}$ complexes **6** and **8** show one significant emission band and two well-separated emission bands of comparable intensity (Table 1). The shift at lower energy of the emission bands of **1**–**8** compared to those of $H_2DPP$ and [ZnDPP]·THF (Table 1) is further evidence of conjugation of the π core of the porphyrin ring by the π-delocalised linker.

The $Zn^{II}$ complexes **2** and **4** in $CHCl_3$ solution show, after the addition of traces of pyridine, only one emission band shifted at lower energy, while complex **6** shows the same unshifted emission band. Only the $Zn^{II}$ complex **8** shows two well-separated emission bands as for [ZnTPP]·THF, but at much lower energy (Table 1).

In summary, we have added further evidence to the proposal of Anderson et al.[14] for a conjugation of the π core of the porphyrin ring, particularly when the π-delocalised linker carries a nitro electron-withdrawing group. In addition, when the linker carries a donor dibutyl or dimeth-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ylamino group, we found evidence of significant aggregation by intermolecular processes involving donor amino groups or hydrogen bonds.

### Voltammetric Investigation

The electronic properties of the porphyrins **1**, **3** and **5** and of their $Zn^{II}$ complexes **2**, **4** and **6** were investigated by cyclic voltammetry in $CH_2Cl_2$ solution. The relevant oxidation and reduction peak potentials are reported in Table 2. The investigation was not extended to **7** and **8**, because of the previously discussed significant aggregation in $CHCl_3$ solution, in the concentration range used for the voltammetric investigation ($10^{-3}$ to $10^{-4}$ M).

#### *Oxidation Processes*

The anodic oxidation of the porphyrins **1** and **3** and their $Zn^{II}$ complexes **2** and **4** does not take place by two monoelectronic, chemically reversible steps as such oxidation does for compounds carrying the same π-delocalised substituents in the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin or its $Zn^{II}$ complex.[6] Porphyrins **1** and **3** show a partial return peak of the first oxidation step that can clearly be perceived only by reversing the potential scan immediately after the peak and increasing the potential scan rate. This behaviour, typical of the parent compound $H_2$DPP, suggests a short-lived radical cation formed in the first oxidation step. Continuing the potential scan beyond the first oxidation peak, porphyrins **1** and **3** give a complex, ill-defined anodic pattern, with multiple maxima without a neat second oxidation step, which on the contrary was easily detected not only for 5,10,15,20-tetraphenylporphyrins carrying the same substituents in the β-pyrrolic position,[6] but also, although to a lesser extent, for the parent compound $H_2$DPP (Table 2).

The $Zn^{II}$ complex **2** shows the more usual pattern, with two subsequent neat oxidation peaks (but with the corresponding return peaks less distinguishable), while we have been unable to finely characterise the voltammetric behaviour of the $Zn^{II}$ complex **4** because of its poor solubility.

The first oxidation peak potentials of the porphyrins **1** and **3** and of the $Zn^{II}$ complex **2** are similar to those of the parent compounds $H_2$DPP and [ZnDPP]·THF or of the analogues carrying the same substituents in the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin.[6] The oxidisability sequence is the same, since in both series the *E*-double bond of the π linker seems to negligibly transmit the electron attractor effect of the nitro group, resulting in slightly higher oxidisability when compared with the case of the triple bond. This observation is an additional support to the suggested easier π conjugation of the triple bond with the π core of the porphyrin ring.[14] The complexation of **1** and **3** to $Zn^{II}$ results in the expected strong enhancement of oxidisability since the charge density on the porphyrin ring increases (negative shift of the first oxidation peak of 0.20 V for **2** compared with **1** and 0.17 V for **4** com-

Table 2. Oxidation and reduction peak potentials $E_p$/V(SCE) for porphyrins **1**, **3**, **5** and their $Zn^{II}$ complexes **2**, **4**, **6**, and four reference compounds ($CH_2Cl_2$ + 0.1 M TBAP, glassy carbon electrode, potential scan rate: 0.2 V·s$^{-1}$).

pared with **3**). This effect is only slightly lower than that found for the parent compounds $H_2$DPP and [ZnDPP]·THF and for the analogues carrying the same substituents in the β-pyrrolic position of the 5,10,15,20-tetraphenylporphyrin.[6] For porphyrins **1** and **3**, the poor chemical reversibility of the first step and the ill-defined anodic pattern beyond the first oxidation peak seems to suggest instability, introduced by the substitution at the *meso* position, of the radical cation produced by the first oxidation step. This instability after the first electron loss is not evident when porphyrin **1** is complexed to $Zn^{II}$ with increased negative charge on the porphyrin ring, since complex **2** produces a more stable radical cation (possibly because it is generated at a far less positive potential), which can evolve to the dication upon loss of a second electron.

Porphyrin **5** and its $Zn^{II}$ complex **6**, carrying a dibutylamino electron-donor group bound through an *E*-ethylene linker at the *meso* position, show a first chemically and electrochemically reversible oxidation peak at nearly the same potential as their analogues with the same substituent in the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin.[6] In this last case, the first oxidation step was assumed to be centred out of the HOMO energies of the porphyrin π core, probably at the amino functionality.[6] This assumption was justified by several experimental observations, which still hold for **5** and **6**. For instance their $\Delta E_{(ox–red)}$ parameters are 1.83 V and 1.89 V, respectively [considering half-wave potentials, defined as $(E_{p,a} + E_{p,c})/2$], which deviate significantly from the expected Kadish relationship [$\Delta E_{(ox–red)} = 2.25 \pm 0.15$ V typical of the π porphyrin core].[17] In addition, complexation is not so effective since the first oxidation peak of the $Zn^{II}$ complex **6** occurs at a potential that is only 0.070 V less positive than that of the parent porphyrin **5**.

If we assume for **5** and **6** that only the second oxidation peak is centred on the porphyrin π core, as suggested by the acceptable agreement of their potentials with the Kadish relationship (see later), and as proposed for the analogues with the same substitution in the β-pyrrolic position,[6] it seems more appropriate to discuss the oxidisability of their porphyrin core by comparing the first oxidation peak potentials of unsubstituted reference compounds $H_2$DPP (1.07 V) and [ZnDPP]·THF (0.84 V) with their second oxidation peak potentials, i.e. 0.77 V for **5** and 0.59 V for **6** (in which case the huge shift in the negative direction of the second peak results in a bielectronic peak accounting for both the first and the second oxidation steps). For the analogues substituted in the β-pyrrolic position, the second oxidation peak potentials are 1.01 V and 0.79 V, respectively.[6]

Since the second oxidation of **5** and **6** occurs at a significantly less positive potential (0.25–0.30 V) than the first oxidation of the unsubstituted reference compounds, and also those (0.20–0.24 V) of the analogues with the same substitution in the β-pyrrolic position, we can conclude that the increased oxidisability suggests a significant donor effect of the dibutylamino group together with a significant role of the position on the porphyrin ring (β pyrrolic or *meso*). Shifting the substituent from the β-pyrrolic to the *meso* position appears to enhance this donor effect.

In conclusion, if the oxidation peaks (the first for **1**, **2**, **3** and **4** and the second for **5** and **6**) can be taken as a first indication of the HOMO energy, we may conclude that its perturbation by substitution in the β-pyrrolic position or the *meso* is not so relevant when the π-delocalised substituent carries an electron-withdrawing nitro group; instead such perturbation will be quite significant, leading to destabilisation, if the substituent carries an electron-donor dibutylamino group, particularly when substitution occurs in the *meso* position.

### *Reduction Processes*

Turning to the cathodic section of the voltammetric pattern (Table 2), the porphyrins **1** and **3** appear significantly more reducible than their analogues with the same kind of substitution in the β-pyrrolic position.[6] Complexes **2** and **4**, although characterised by a lower and broader pattern of the voltammetric cathodic portion, show a first reduction peak at nearly the same potential as the corresponding porphyrins **1** and **3** (Table 2) and appear to be slightly more reducible than their analogues with the same substituent in the β-pyrrolic position.[6]

It must be noted that we cannot reliably compare the potentials of the first reduction peak of **1**–**4** with those of the reference, unsubstituted compounds $H_2$DPP and [ZnDPP]·THF. In fact the cathodic portion of the voltammetric pattern of **1**–**4** is strongly influenced by the presence of the nitro group, which, when bound to a π-delocalised aromatic system, is more reducible than an unsubstituted porphyrin core {see Table 2 with potentials at –1.26 V and –1.03 V for reference compounds $H_2$DPP and [4′-(*p*-nitrophenyl)-2,2′:6′,2′′-terpyridine], respectively}. Therefore, when we have a nitro group interacting very closely with a reducible π-delocalised system, as in our case, it is particularly hard to discriminate whether the first electron enters at the nitro group or the porphyrin core. The effect of the nitro group on the reduction of the conjugated molecule is clearly perceived since the difference $\Delta E_{(ox–red)}$ between the first oxidation and the first reduction process, which, for a strictly porphyrin ring-based redox process, should always be within $2.25 \pm 0.15$ V (Kadish relationship),[17] for porphyrins **1** and **3** is 1.96 V and 2.03 V, respectively. Interestingly, the above values of $\Delta E_{(ox–red)}$ are significantly smaller than 2.18 V and 2.10 V, in quite good agreement with the Kadish relationship, found for the analogues with the same substituents in the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin.[6] Therefore it appears that in compounds **1**–**4**, differently from their analogues with the same substituents in the β-pyrrolic position, the nitro group strongly influences the energy of the conjugated system so that we have a significant shift to less negative potentials of the first reduction peak with respect to Kadish's rule, an indication of a reduction process that does not involve just the π porphyrin core. The complexity of the first reduction step is, for instance, reflected by the observation that the first reduction peak of porphyrin **1** is bielectronic, unlike

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the classical monoelectronic first reduction peak of a nitro group bound to a π-delocalised aromatic system [see Table 2 for the properties of the first reduction peak of the reference aromatic compound 4′-(*p*-nitrophenyl)-2,2′:6′,2′′-terpyridine].

If the first reduction peak is an indication of the tendency of the whole molecule to be reduced, and therefore of the LUMO energy, we can suggest that while the shift from the β-pyrrolic to the *meso* position of π-delocalised substituents carrying a nitro group has little effect on the HOMO energy, it has a marked effect on the LUMO energy.

When the substituent carries an electron-donor dibutylamino group as in **5** and **6** or in their analogues substituted in the β-pyrrolic position,[6] the cathodic section of the voltammetric pattern is quite similar and closely resembles that of their unsubstituted reference compounds $H_2$DPP and [ZnDPP]·THF, with two neat monoelectronic reduction steps, chemically and electrochemically reversible. Considering the reduction potentials (Table 2 and ref.[6]) it appears that the displacement of the substituent carrying a dibutylamino group from the β-pyrrolic position to the *meso* one produces a less reducible system and thus has a marked effect on the LUMO energy, in agreement with the previously proposed enhancement of the electron donor effect of the dibutylamino group. The same conclusion can be applied to the reduction peaks of the $Zn^{II}$ complex **6**, which are also characterised by the expected shift to the negative direction.

The increased role of the donor amino group on the π system of the conjugated molecule is reflected, in the case of substitution at the *meso* position, by the significant deviation from Kadish's rule; for instance let us consider the second oxidation peak discussed above: $\Delta E_{(ox–red)}$ is 1.90 V for **5** and 2.05 V for its analogue with the substituent in the β-pyrrolic position, compared with the regular value of 2.34 V for the reference unsubstituted compound $H_2$DPP. For the $Zn^{II}$ complex **6** the value of $\Delta E_{(ox–red)}$ is 1.90 V, compared with 2.07 V for its analogue with the substituent in the β-pyrrolic position and 2.23 V for the unsubstituted ZnDPP.

**Dipole Moments**

Differently from 5,10,15,20-tetraphenylporphyrins and their $Zn^{II}$ complexes substituted in the β-pyrrolic position,[6] the experimental determination by the Guggenheim method[18] of the dipole moment of 10,20-diphenyl porphyrins and their $Zn^{II}$ complexes with the same substituents in the *meso* position, was not always reproducible because of insolubility or aggregation processes, the exceptions being the porphyrins **1** and **3** (Table 3). Therefore best geometries first, and then dipole moments, were theoretically calculated by an ab initio approach based on density functional theory (DFT),[11,12] using an extended basis set[13] (see Exp. Sect.).

As already suggested by the X-ray crystal structural determinations or by molecular mechanics modelling using the MM2 force field[14] our DFT calculations confirm that the aromatic ring of porphyrin $Zn^{II}$ complexes with an *E*-ethylenic linker, such as **2** or **6**, is significantly twisted. (Table 4).

Our calculated angle of twisting for **2** (53.1°) is slightly higher than that obtained in the solid state by the X-ray crystal structure determination of the analogous compound, but without the nitro group in the *para* position (44.7°).[14] In general our calculations have produced an angle of twisting of 10,20-diphenylporphyrin $Zn^{II}$ complexes with an *E*-ethylenic linker (about 52–54°) or an acetylenic linker (about 10–14.5°) (Table 4) that is higher than that calculated by the less sophisticated molecular mechanism modelling approach using the MM2 force field (about 38° for the *E*-ethylenic linker and about <0.1° for the acetylenic linker[14]).

The twisting of the porphyrin and aromatic rings calculated by our DFT approach is much less significant when the same *para*-substituted aromatic rings are bound, by the same linkers, to the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin or its $Zn^{II}$ complex, since the optimised geometries show a twisting angle of about 20–30° for an *E*-ethylenic linker (Table 4) or a much lower value for an acetylenic one.

In conclusion, we have produced additional structural evidence that the triple bond, because of the lower twisting

of the aromatic ring should, in all cases, favour a more facile electronic communication between the aromatic ring (and therefore the electron-withdrawing or electron-donor groups) and the porphyrin ring.

The porphyrins **1** and **3**, with a substituent carrying an electron-withdrawing nitro group, and their $Zn^{II}$ complexes **2** and **4** show dipole moments that are higher, and completely opposite in polarity, than those of porphyrins **5** and **7** and their $Zn^{II}$ complexes **6** and **8**, with a substituent carrying an amino electron-donor group (Table 3), as reported for porphyrins and their $Zn^{II}$ complexes with the same series of substituents in the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin or its $Zn^{II}$ complex.[6]

When there is excellent π conjugation between the porphyrin ring and the π linker, as when the linker is acetylenic, the calculated dipole moments of the compounds with a substituent carrying a nitro group are quite independent (about 8.5–8.8 D) of the position of substitution on the porphyrin ring (*meso* or β pyrrolic).[6] However, when the nitro or the dibutylamino groups are connected to the porphyrin ring by an *E*-ethylenic linker, the calculated dipole moments are slightly higher when substitution occurs in the β-pyrrolic position (8.5–8.8 D compared with 7.70–7.73 D for a substituent carrying a nitro group and 6.07–5.89 D compared with 5.33–5.16 D for a substituent carrying a dibutylamino group). The validity of our DFT calculated dipole moments is supported by the fairly good agreement between calculated values of porphyrins **1** and **3** and those measured experimentally (Table 3).

In conclusion the DFT calculations also provide evidence that for compounds **1**–**8** the π core of the porphyrin ring, already in the ground state, acts as an electron donor if the π-delocalised substituent in the *meso* position carries a nitro group, while it acts as an electron acceptor if it carries a dimethylamino or dibutylamino group. Such a trend was already observed when the same substituents were bound to the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin or its $Zn^{II}$ complex.[6]

### Determination of the Quadratic Hyperpolarisability by the EFISH Technique

The determination of the second-order NLO response was carried out by the EFISH technique[19], which allows the evaluation of the molecular quadratic hyperpolarisability, $\beta_\lambda$, from Equation (1) (see Exp. Sect.). In order to avoid resonance enhancement, we worked with an off resonance incident wavelength, $\lambda$, of 1.907 μm. When applying Equation (1) to highly π-conjugated two-dimensional molecules, such as porphyrins and phthalocyanines, the usual approach that ignores the third-order electronic contribution to $\gamma_{EFISH}$, could not be considered to be completely reliable.[4c,20] However, for asymmetrically substituted phthalocyanines, structurally related to the porphyrinic chromophores investigated in this work, and carrying an aryl ethenyl or an aryl butadienyl spacer connecting the phthalocyanine ring to a nitro group in the *para* position, the third-order electronic contribution to $\gamma_{EFISH}$ was evaluated as being much smaller than the dipolar orientational one and therefore negligible.[20] In accordance we reliably neglected the third-order electronic contribution in the determination of the quadratic hyperpolarisability $\beta_{1.907}$ from $\gamma_{EFISH}$ by Equation (1).

According to our DFT calculations, the push-pull porphyrinic chromophores investigated in this work are characterised by a dipole moment axis, parallel to the π linker axis, as in 1D pseudo-linear organometallic push-pull chromophores.[21] In this approximation $\beta_{vec}$, which is the vectorial part of the quadratic hyperpolarisability tensor, and EFISH $\beta_{1.907}$, which is the projection of $\beta_{vec}$ along the dipole moment axis, should coincide.

Since our investigation of the electronic absorption spectra provided evidence, particularly for compounds carrying a donor amino group, of aggregation processes even at low concentrations in nondonor solvents of low polarity such as $CHCl_3$, we carried out a series of EFISH measurements in $CHCl_3$ solutions of different concentrations of compound **2**, which could aggregate at relatively high concentration only by π-π stacking[16] and of compounds **5**–**8**, which could aggregate by intermolecular hydrogen bonding, or by intermolecular interaction of the amino donor group of the π-delocalised substituent with $Zn^{II}$ via the axial position of another molecule. For the $Zn^{II}$ complexes **2**, **4**, **6** and **8** the EFISH measurements were also carried out in the presence of an excess of pyridine, while for porphyrins **5** and **7** in the presence of traces of trifluoroacetic acid in order to suppress any intermolecular aggregation (Table 5).

In the presence of pyridine or trifluoroacetic acid, the product $\mu\beta_{1.907}$, obtained from $\gamma_{EFISH}$ using Equation (1), was shown not to be dependent on dilution (within the experimental error of EFISH measurements on diluted solutions) while, without these additions, a significant increase by dilution was observed as expected for an increased dissociation (Table 5). Such an effect is less relevant for the $Zn^{II}$ complex **2** confirming, as already suggested by the investigation on electronic absorption spectra, that strong aggregation occurs mainly when the π-delocalised substituent carries a donor amino group. Measurements on the $Zn^{II}$ complex **4** were done only in the presence of pyridine because of the low solubility of the complex. Interestingly the order of magnitude and the sign of the product $\mu\beta_{1.907}$ do not change upon addition of pyridine or trifluoroacetic acid (Table 5).

Since the $\mu\beta_{1.907}$ values of the porphyrins **5** and **7** and of the $Zn^{II}$ complexes **2**, **6** and **8** are dependent on dilution, it is expected that monomeric species prevail at higher dilutions (concentrations lower than $10^{-4}$ M). However, at these dilutions EFISH measurements are affected by a larger experimental error. Therefore, the values of EFISH $\beta_{1.907}$ reported in Table 3 are the mean values of many measurements carried out at concentrations about $10^{-4}$ M, thus discussions mainly concern their order of magnitude, rather than their absolute value.

The EFISH $\beta_{1.907}$ values (Table 3) of the porphyrins **1** and **3** are positive and higher than those of porphyrins carrying the same substituents in the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin[6] (about $65\times10^{-30}$ esu for **1** and **3** against $30–40\times10^{-30}$ esu, respectively).

Unexpectedly, EFISH $\beta_{1.907}$ of the $Zn^{II}$ complex **2** is negative and with a significant absolute value, while the value of EFISH $\beta_{1.907}$ of the analogous $Zn^{II}$ complex with the same substituent in the β-pyrrolic position of 5,10,15,20-tetraphenylporphyrin is positive and with a lower absolute value[6] (about $-94\times10^{-30}$ esu for **2** compared with $30\times10^{-30}$ esu for the analogous $Zn^{II}$ complex ).

Both porphyrins **5** and **7** and their $Zn^{II}$ complexes **6** and **8** show, at concentrations about $10^{-4}$ M, a positive and fairly high value of EFISH $\beta_{1.907}$ (Table 3). As suggested by the significant increase of $\mu\beta_{1.907}$ by dilution (Table 5), the value of EFISH $\beta_{1.907}$ of the monomeric species of **6**–**8** should be higher. For **5** and **6**, the value of EFISH $\beta_{1.907}$ is quite similar to that of the corresponding chromophores with the same π-delocalised substituent in the β-pyrrolic position ($64\times10^{-30}$ esu for **5** and $87.5\times10^{-30}$ esu for **6** compared with $75.7\times10^{-30}$ esu and $127.5\times10^{-30}$ esu).

In summary, with the exception of the anomaly of the sign of EFISH $\beta_{1.907}$ of **2** and **4**, the major differences between the two classes of porphyrinic chromophores carrying the same π-delocalised substituents in the β-pyrrolic[6] or *meso* positions is given by the higher absolute values of EFISH $\beta_{1.907}$ when the substituent carrying a nitro electron-withdrawing group is bound to the *meso* position. This latter result is in accordance with the proposal of Ratner, Marks et al.,[10] who suggested that second-order NLO responses should increase when π-delocalised substituents

Table 5. $\mu\beta_{1.907}$ values at different concentrations in $CHCl_3$ and in $CHCl_3$ with addition of pyridine or trifluoroacetic acid.

with electron-acceptor groups are appended to *meso* electron-deficient centres instead of β-pyrrolic electron-rich centres.

We previously suggested[6] that in porphyrinic chromophores with a π-delocalised substituent carrying a nitro group the second-order NLO response can originate mainly from a charge transfer from the occupied π orbitals of the porphyrin ring to the π*-antibonding orbitals of the π linker in accordance with a significant π conjugation between the π core of the porphyrin ring and the π linker. In this hypothesis the porphyrin ring acts as donor to the acceptor aromatic ring carrying the nitro group in the *para* position and the charge transfer takes place in the same direction as the dipole moment, in agreement with the positive value of the quadratic hyperpolarisability EFISH $\beta_{1.907}$.

For compounds **1**–**4**, our analysis of the absorption electronic spectra failed to produce clear direct evidence of such a charge transfer process. However, the voltammetric investigation not only has shown a significant effect on the LUMO energy of the porphyrin ring when conjugated with a π linker, but also revealed a more relevant effect when substitution occurs in the *meso* position, supporting a shift of the above proposed charge transfer process at lower energy, in agreement with the observed increased absolute value of EFISH $\beta_{1.907}$.

However, the anomalous negative sign of EFISH $\beta_{1.907}$ found for the $Zn^{II}$ complexes **2** and **4** cannot be explained by such a charge transfer process, given that EFISH $\beta_{1.907}$ remains positive for analogous $Zn^{II}$ complexes carrying the same π-delocalised substituents in the β-pyrrolic position.[6] At the moment only a detailed theoretical investigation, which is underway, may produce an explanation for the negative EFISH $\beta_{1.907}$ found for the $Zn^{II}$ complexes **2** and **4**, since the involvement of aggregation by π-π stacking,[16] which occurs certainly more easily in derivatives of 10,20-diphenylporphyrin than in those of 5,10,15,20-tetraphenylporphyrin, can be discarded because the second-order NLO response of **2** and **4** remains negative also in the presence of pyridine (Table 5), which prevents this kind of aggregation.

The lack of a significant decrease of EFISH $\beta_{1.907}$ when the π-delocalised substituent, carrying a strong electron-donor group, is moved from the electron-rich β-pyrrolic position to the electron deficient *meso* position does not completely fit with the proposal of Ratner, Marks et al.[10].

As for the analogues of **5** and **6** with the same π-delocalised substituent in the β-pyrrolic position,[6] we can tentatively propose that the high and positive EFISH $\beta_{1.907}$ values of chromophores **5**–**8** originate from an enhancement of the donor properties of the dibutylamino or dimethylamino group, induced by the very electron-rich π system of the porphyrin, which produces a significant depletion of the electron density on the donor group and thereby a reduction of the ground state polarisation.[22] In this view there is no involvement of the π core of the porphyrin ring in the excitation process controlling the second-order NLO response.

In agreement with this proposal, our voltammetric investigation has shown, in both classes of porphyrinic chromophores investigated by us up to now,[6] an enhanced donor effect of the dibutylamino or dimethylamino group.

## Conclusions

This and our previous investigation[6] on push-pull chromophores with electron-withdrawing groups connected to the porphyrinic ring, either in the β-pyrrolic or *meso* position by an arylethenyl or arylethynyl linker, provide clear evidence for the significant π conjugation between the porphyrin π core and the π-delocalised substituent, as a possible origin of the second-order NLO responses by a charge transfer process. Such conjugation seems to be more facile, according to the voltammetric investigation, if the π-delocalised substituent is bound to the *meso* position instead of the β-pyrrolic one. Therefore if the substitution occurs in the *meso* position, the second-order NLO response is favoured due to a more facile charge transfer and to the increased push properties of the porphyrin ring if we assume a rather simplified description of these new push-pull chromophores as pseudo 1D push-pull systems.

Accordingly, the experimental values of EFISH $\beta_{1.907}$ of chromophores **1** and **3** are comparable with those of structurally related organic push pull chromophores having, as the push group, a *para*-dimethylamino phenyl moiety, and are more significant than that having, as the push group, a ferrocenyl or of a 5,10,15,20-tetraphenylporphyrin moiety substituted in the β-pyrrolic position (Table 6).

Table 6. Quadratic hyperpolarisability $\beta_{1.907}$ of some organic and organometallic push-pull systems measured in $CHCl_3$ by the EFISH technique at an incident wavelength of 1.907 μm.

We also propose, when the substituent bound to the *meso* or β-pyrrolic position carries an electron-donor group, that the electron-rich and highly polarisable character of the porphyrin ring may be the origin of an electron screening of the ground-state polarisation, so that the electron-rich ring system weakly withdraws excessive electron density from the donor substituent through inductive effects, thereby increasing its donor properties.[22] Thus this process produces an enhancement of the second-order NLO response controlled by the $n \rightarrow \pi^*$ transition.

In accordance with this hypothesis the value of EFISH $\beta_{1.907}$ of chromophores **5**, **6** and **7**, **8** increases by complexation to $Zn^{II}$ (e.g. **6** > **5** and **8** > **7** see Table 3), which produces a higher and more polarisable electron density on the porphyrin ring as supported by the voltammetric investigation.

Since the π-electron core of the porphyrin ring is not directly involved in the excitation process controlling the second-order NLO response, it becomes irrelevant if the π-delocalised substituent is appended to an electron-rich (β-pyrrolic) or electron-deficient (*meso*) position of the porphyrin ring, as experimentally observed.

Despite the above reported agreement with a series of experimental observations, our interpretation of the electronic origin of the second-order NLO response in the series of compounds investigated in this and in our previous work,[6] does not explain the negative sign of EFISH $\beta_{1.907}$ of the $Zn^{II}$ complexes **2** and **4**.

Probably, the two-dimensional highly polarisable π system of the porphyrin core is far too complex for such a relatively simple approach based just on considerations typical of traditional 1D organic or organometallic push-pull chromophores. As already mentioned, ab initio time-dependent DFT investigations are underway in our laboratory in an effort to achieve a more profound understanding of the electronic origin of the significant second-order NLO response of these new push-pull chromophores based on the porphyrin ring.

In conclusion this and our previous work[6] have experimentally confirmed an interesting role of the porphyrin ring in push-pull chromophores, already theoretically suggested by Ratner, Marks et al.[10]

## Experimental Section

All solvents and chemicals were of reagent-grade quality, purchased commercially and used without further purification unless otherwise stated. 10,20-diphenylporphyrin[25a] was prepared according to literature methods from dipyrrylmethane.[25b] 4-Nitrobenzyltriphenylphosphonium bromide and 4-(dibutylamino)benzyltriphenylphosphonium chloride were prepared following the new procedure described in our previous work.[6] 5-Bromo-10,20-diphenylporphyrin was synthesised using the method described by Yeung et al.[5c] 4-Nitrophenyl acetylene was prepared according to Takahashi el al.[26] $^1$H NMR spectra were recorded with a Bruker AC-300 spectrometer in $CDCl_3$ as solvent; electronic absorption spectra were obtained in $CHCl_3$ with a Jasco V-530 spectrometer; emission spectra were obtained in $CHCl_3$ with a Jasco FP-777 spectrofluorimeter. Elemental analyses were carried out in the Analytical Laboratories of the Department of Inorganic, Metallorganic and Analytical Chemistry of Milan University. Dipole moments were determined in $CHCl_3$ solution, according to the Guggenheim method,[18] using a WTW-DM01 dipolemeter (dielectric constant) coupled with a Pulfrich Zeiss PR2 refractometer (refractive index).

### Cyclic Voltammetry

The cyclovoltammetric (CV) investigation was carried out using an Autolab PGSTAT 12 potentiostat/galvanostat (EcoChemie, The Netherlands) run by a PC with GPES software, correcting the ohmic drop by the positive feedback technique,[27] with a glassy carbon GC (Amel, radius 1.5 mm) as the working electrode, a platinum counter-electrode, and an aqueous saturated calomel electrode (SCE) as the operating reference electrode (the half-wave potential of the ferrocinium|ferrocene redox couple, recommended by IUPAC for inter-solvent comparison of potential scales,[28] being 0.484 V when measured in $CH_2Cl_2$, added with 0.1 M TBAP against our aqueous SCE). The working solutions were made up in dichloromethane $CH_2Cl_2$ (Merck, HPLC grade), added with 0.1 M tetrabutylammonium perchlorate TBAP (FLUKA) as the supporting electrolyte, working in a cell thermostatted at 298 K. The solutions, carefully deaerated by nitrogen bubbling, had concentrations ranging from $5 \times 10^{-4}$ to $7 \times 10^{-4}$ M (with the exception of the less soluble porphyrin complex **4**, which reaches saturation at concentrations below $3 \times 10^{-4}$ M). The optimised polishing procedure for the working GC electrode consisted of surface treatment with diamond powder (Aldrich diameter 1 μm) on a wet cloth (DP-Nap, Struers).

The electrochemical reversibility and electron number of each well-defined CV peak were checked by classical tests[29] including analysis of (a) the $I_p$ vs. $v^{1/2}$ characteristics; (b) the $E_p$ vs. $\log v$ characteristics; (c) the $(E_p - E_{p/2})$ vs. $\log v$ characteristics, and (d) the "stationary", step-like waves obtained by convolutive analysis of the original CV characteristics.

For comparison purposes, the CV characteristics of the reference compounds $H_2$DPP, [ZnDPP]·THF and 4′-(*p*-nitrophenyl)-2,2′:6′,2′′-terpyridine, recorded under the same experimental conditions, are reported in Table 2. The 4′-(*p*-nitrophenyl)-2,2′:6′,2′′-terpyridine has been included as a model for the nitro group reactivity.

### EFISH Measurements

EFISH measurements were performed in $CHCl_3$ solutions, as a function of concentration, working at 1.907 μm incident wavelengths using a Q-switched Nd:YAG laser with 60 and 20 ns pulse durations, manufactured by Atalaser. The 1.907 μm fundamental wavelength was obtained by Raman shifting of the 1.064 μm emission of the Q-switched Nd:YAG laser in a high pressure hydrogen cell (60 bar). A liquid cell with thick windows in the wedge configuration was used to obtain the Maker fringe pattern (harmonic intensity variation as a function of liquid cell translation).[19] In the EFISH experiments the incident beam was synchronised with a DC field applied to the solution containing the molecular species in order to break the centrosymmetry of the solution. The apparatus for the EFISH measurements was a prototype made by SOPRA (France).

From the concentration dependence ($10^{-3}$–$10^{-4}$ M) of the harmonic signal with respect to that of the pure solvent, the NLO response

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$\beta_\lambda$ was determined (assumed to be real as the imaginary was neglected) from the experimental value $\gamma_{EFISH}$, using Equation (1).

$$\gamma_{EFISH} = \frac{\mu\beta_\lambda(-2\omega;\omega,\omega)}{5kT} + \gamma(-2\omega;\omega,\omega,0) \quad (1)$$

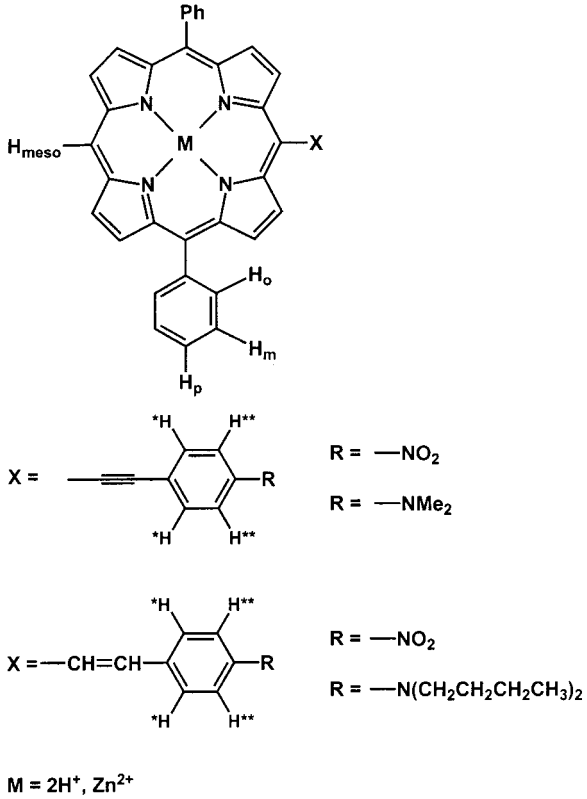
where $\gamma_{EFISH}$ is the sum of a cubic electronic contribution $\gamma(-2\omega; \omega, \omega, 0)$ and of a quadratic orientational contribution $\mu\beta_\lambda$ $(-2\omega; \omega, \omega)/5kT$; $\mu$ is the ground state dipole moment and $\beta_\lambda$ is the projection along the dipole moment direction of the vectorial component $\beta_{vec}$ of the tensorial quadratic hyperpolarisability working with the incident wavelength, $\lambda$.

**Computational Methods**

Geometry optimisation and population analysis of the compounds **1**–**8** were carried out in the framework of the density functional theory (DFT) by using the BP86 functional[12] and an all-electron valence triple-ζ basis set with polarisation functions on all atoms (TZVP).[13] Values of the dipole moments moduli and components were computed using the Turbomole suite of programs[30] in connection with the resolution of identity (RI) approximation.[31]

**Synthesis of Porphyrins**

For the numering of atoms see below.



**5-Formyl-10,20-diphenylporphyrin:** This porphyrin was prepared by the following three steps:[15]

**(a) 10,20-Diphenylporphyrinatocopper(II):** A slightly warm solution of $Cu(OAc)_2 \cdot H_2O$ (125 mg, 0.627 mmol) in MeOH (15 mL) was slowly added to a refluxing solution of 10,20-diphenylporphyrin (264 mg, 0.570 mmol) in $CHCl_3$ (60 mL). After two hours the red reaction mixture was cooled and the solvents evaporated to dryness in vacuo. The red residue was collected with MeOH, filtered and washed with MeOH to afford 248 mg (83%) of a red powder. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) = 405 (5.63), 527 (4.23), 561 (3.65) nm. $C_{32}H_{20}CuN_4$ (523.5): calcd. C 73.35, H 3.82, N 10.70; found C 72.94, H 3.78, N 10.89.

**(b) 5-Formyl-10,20-diphenylporphyrinatocopper(II):** A solution of dimethylformamide (1.1 mL, 14.2 mmol) and phosphoryl chloride (1.1 mL, 12.0 mmol) was left at room temperature and under magnetic stirring for 30 min. After this time, a solution of 10,20-diphenylporphyrinatocopper(II) (114 mg, 0.218 mmol) in 1,2-dichloroethane (50 mL) was added and the reaction mixture was stirred at 60 °C for 2 h. The dark green solution was then diluted with a saturated aqueous solution of $CH_3COONa$ (150 mL) and maintained at 60 °C whilst stirring for a further 2 h. The organic phase was separated, washed with $H_2O$ (2 × 100 mL), dried with $Na_2SO_4$ and evaporated in vacuo. Purification of the residue by column chromatography (silica gel, $CH_2Cl_2$/*n*-hexane, 7:3) afforded 96 mg (80%) of pure product. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) = 417 (5.42), 547 (3.97), 591 (4.15) nm. $C_{33}H_{20}CuN_4O$ (551.5): calcd. C 71.80, H 3.63, N 10.15; found C 72.30, H 3.76, N 10.30.

**(c) 5-Formyl-10,20-diphenylporphyrin:** A solution of 5-formyl-10,20-diphenylporphyrinatocopper(II) (251 mg, 0.455 mmol) in a mixture of $H_2SO_4$/TFA (1:10 v/v, 15 mL) was stirred for 10 min at room temperature, and then quenched by adding an excess of ice. The product was extracted with $CH_2Cl_2$ (2 × 50 mL), the organic phase was washed with aqueous NaOH (20%, 50 mL) and with $H_2O$ (2 × 50 mL), the solvent was evaporated to dryness and the residue was washed with pentane to afford 220 mg (quantitative yield) of a violet powder. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 12.62 (s, 1 H, CHO), 10.28 (s, 1 H, $H_{meso}$), 10.10 (d, $J$ = 4.98 Hz, 2 H, $H_{pyrrolic}$), 9.30 (d, $J$ = 4.44 Hz, 2 H, $H_{pyrrolic}$), 9.08 (d, $J$ = 4.98 Hz, 2 H, $H_{pyrrolic}$), 8.91 (d, $J$ = 4.44 Hz, 2 H, $H_{pyrrolic}$), 8.22 (m, 4 H, $H_o$), 7.85 (m, 6 H, $H_{m,p}$), –2.41 (s, 2 H, NH) ppm. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) = 420 (5.35), 520 (4.01), 559 (3.95), 593 (3.77), 648 (3.81) nm. $C_{33}H_{22}N_4O$ (490): calcd. C 80.82, H 4.49, N 11.43; found C 80.65, H 4.36, N 11.60.

**(1*E*)-5-[2-(4′-Nitrophenyl)ethenyl]-10,20-diphenylporphyrin (1):** A suspension of 5-formyl-10,20-diphenylporphyrin (238 mg, 0.484 mmol), 4-nitrobenzyltriphenylphosphonium bromide (670 mg, 1.407 mmol) and solid NaOH 20–40 mesh beads (400 mg, 10 mmol) in anhydrous 1,2-dichloroethane (25 mL) was refluxed, with magnetic stirring and under a nitrogen atmosphere for 4 h. After this time the solvent was evaporated to dryness, the residue was purified by column chromatography (silica gel $CH_2Cl_2$/*n*-hexane, 7:3). The product obtained from the column chromatography was first washed with MeOH and then crystallised from $CH_2Cl_2$/MeOH to give 145 mg (49%) of pure **1**. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 10.17 (s, 1 H, $H_{meso}$), 9.89 (d, $J$ = 15.87 Hz, 1 H, =CH), 9.50 (d, $J$ = 4.83 Hz, 2 H, $H_{pyrrolic}$), 9.30 (d, $J$ = 4.65 Hz, 2 H, $H_{pyrrolic}$), 8.97 (d, $J$ = 4.77 Hz, 4 H, $H_{pyrrolic}$), 8.43 (d, $J$ = 8.76 Hz, 2 H, H**), 8.24 (m, 4 H, $H_o$), 8.05 (d, $J$ = 8.76 Hz, 2 H, H*), 7.80 (m, 6 H, $H_{m,p}$), 7.42 (d, $J$ = 15.93 Hz, 1 H, CH=), –2.78 (s, 2 H, NH) ppm. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) = 422 (5.27), 518 (4.07), 564 (4.11), 594 (3.89), 655 (3.65) nm. $C_{40}H_{27}N_5O_2$ (609): calcd. C 78.82, H 4.43, N 11.49; found C 78.65, H 4.30, N 11.48.

**5-[2-(4′-Nitrophenyl)ethynyl]-10,20-diphenylporphyrin (3):** Trifluoroacetic acid (2 mL) was added in four portions to a suspension of 5-[2-(4′-nitrophenyl)ethynyl]-10,20-diphenylporphyrinatozinc(II) (**4**) (100 mg, 0.149 mmol) in $CH_2Cl_2$ (50 mL) and the reaction mixture was stirred at room temperature for 18 h. After this time, water (30 mL) was added and the mixture was carefully neutralised with a saturated aqueous solution of $NaHCO_3$. The organic phase was separated, dried with $MgSO_4$ and the solvent evaporated in vacuo

### Synthesis of $Zn^{II}$ Complexes

$Zn^{II}$ complexes **2** and **6** were synthesised following the general procedure described in the literature.[32] In a typical preparation the free porphyrin (100 mg) was dissolved in slightly warmed $CHCl_3$ (20 mL) and a solution of $Zn(OAc)_2{\cdot}2H_2O$ (free porphyrin/metal salt = 1:1.1) in MeOH (10 mL) was then added. The mixture was refluxed for 1 h, was then evaporated to dryness and the residue was collected with MeOH, filtered and washed with MeOH.

**(1*E*)-5-[2-(4′-Nitrophenyl)ethenyl]-10,20-diphenylporphyrinatozinc(II) (2):** This compound was obtained in quantitative yield as a violet powder. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 10.10 (s, 1 H, $H_{meso}$), 9.89 (d, $J$ = 16.32 Hz, 1 H, =CH), 9.56 (d, $J$ = 4.41 Hz, 2 H, $H_{pyrrolic}$), 9.35 (d, $J$ = 4.29 Hz, 2 H, $H_{pyrrolic}$), 9.04 (d, $J$ = 3.99 Hz, 4 H, $H_{pyrrolic}$), 8.43 (d, $J$ = 7.59 Hz, 2 H, H**), 8.22 (m, 4 H, $H_o$), 8.05 (d, $J$ = 7.74 Hz, 2 H, H*), 7.79 (m, 6 H, $H_{m,p}$), 7.41 (d, $J$ = 16.24 Hz, 1 H, CH=) ppm. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) 422 (5.23), 552 (4.19), 599 (4.04) nm; ($CHCl_3$ with addition of pyridine): $\lambda_{max}$ ($\log\varepsilon$) = 428 (5.05), 566 (3.72), 626 (3.89) nm. $C_{40}H_{25}N_5O_2Zn$ (672.4): calcd. C 71.39, H 3.72, N 10.41; found C 71.50, H 3.61, N 10.30.

**(1*E*)-5-[2-(4′-Dibutylaminophenyl)ethenyl]-10,20-diphenylporphyrinatozinc(II) (6):** This compound was obtained in quantitative yield as a violet powder. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 10.06 (s, 1 H, $H_{meso}$), 9.61 (d, $J$ = 4.65 Hz, 2 H, $H_{pyrrolic}$), 9.48 (d, $J$ = 15.75 Hz, 1 H, CH=), 9.28 (d, $J$ = 4.53 Hz, 2 H, $H_{pyrrolic}$), 8.99 (d, $J$ = 4.53 Hz, 4 H, $H_{pyrrolic}$), 8.96 (d, $J$ = 4.65 Hz, 2 H, $H_{pyrrolic}$), 8.21 (m, 4 H, $H_o$), 7.77 (m, 8 H, H*, $H_{m,p}$), 7.25 (d, $J$ = 15.75 Hz, 1 H, =CH), 6.82 (d, $J$ = 8.55 Hz, 2 H, H**), 3.40 (t, $J$ = 7.52 Hz, 2 H, $CH_{2Butyl}$), 1.67 (m, 2 H, $CH_{2Butyl}$), 1.43 (m, 2 H, $CH_{2Butyl}$), 1.02 (t, $J$ = 7.28 Hz, 3 H, $CH_{3Butyl}$) ppm. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) = 349 (4.35), 408 (5.26), 554 (4.27), 606 (4.32) nm; ($CHCl_3$ with addition of pyridine): $\lambda_{max}$ ($\log\varepsilon$) = 428 (5.20), 563 (4.06), 613 (4.09) nm. $C_{48}H_{43}N_5Zn$ (754.4): calcd. C 76.35, H 5.70, N 9.28; found C 75.99, H 5.68, N 9.41.

**5-[2-(4′-Nitrophenyl)ethynyl]-10,20-diphenylporphyrinatozinc(II) (4):** The catalytic solution was prepared by heating $Pd_2(dba)_3$ (9.5 mg, $9.9{\cdot}10^{-3}$ mmol), $PPh_3$ (21.8 mg, $8.3{\cdot}10^{-2}$ mmol) and CuI (7.8 mg, $4.1\times10^{-2}$ mmol) in freshly distilled $Et_3N$ (25 mL) at 70 °C for 30 min under a nitrogen atmosphere. This solution was transferred into a solution of 5-bromo-10,20-diphenylporphyrinatozinc(II) (100 mg, 0.165 mmol) and (4-nitrophenyl)acetylene (74 mg, 0.50 mmol) in anhydrous toluene (25 mL) and pyridine (0.6 mL) under a nitrogen atmosphere, and the mixture was heated at 80 °C and stirred for 1 h. After this time the solution was cooled and filtered through silica eluting with toluene and the solvent was evaporated to dryness. The residue was washed several times with small amounts of MeOH and $CHCl_3$ alternately to afford 93 mg (85%) of pure **4**. $^1$H NMR (300 MHz, $CDCl_3$ + Pyridine $d_5$): $\delta$ = 10.12 (s, 1 H, $H_{meso}$), 9.74 (d, $J$ = 4.59 Hz, 2 H, $H_{pyrrolic}$), 9.26 (d, $J$ = 4.47 Hz, 2 H, $H_{pyrrolic}$), 8.99 (d, $J$ = 4.59 Hz, 2 H, $H_{pyrrolic}$), 8.92 (d, $J$ = 4.44 Hz, 2 H, $H_{pyrrolic}$), 8.36 (d, $J$ = 7.47 Hz, 2 H, H**), 8.20 (m, 4 H, $H_o$), 8.08 (d, $J$ = 7.47 Hz, 2 H, H*), 7.75 (m, 6 H, $H_{m,p}$) ppm. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) = 439 (5.16), 560 (3.68), 608 (4.07) nm; ($CHCl_3$ with addition of pyridine): $\lambda_{max}$ ($\log\varepsilon$) = 449 (5.17), 575 (3.92), 634 (4.47) nm. $C_{40}H_{23}N_5O_2Zn$ (670.4): calcd. C 71.60, H 3.43, N 10.44; found C 71.51, H 3.48, N 10.32.

**5-[2-(4′-Dimethylaminophenyl)ethynyl]-10,20-diphenylporphyrinatozinc(II) (8):** The catalytic solution was prepared by heating a solution of $Pd_2(dba)_3$ (9.5 mg, $9.9{\cdot}10^{-3}$ mmol), $PPh_3$ (21.8 mg, $8.3{\cdot}10^{-2}$ mmol) and CuI (7.8 mg, $4.1{\cdot}10^{-2}$ mmol) in freshly distilled $Et_3N$ (25 mL) at 70 °C for 30 min under a nitrogen atmosphere. This solution was transferred into a solution of 5-bromo-10,20-diphenylporphyrinatozinc(II) (100 mg, 0.165 mmol) and [4-(dimethylamino)phenyl]acetylene (73 mg, 0.50 mmol) in anhydrous toluene (25 mL) and pyridine (0.6 mL) under a nitrogen atmosphere, and the mixture was heated at 80 °C and stirred for 1.5 h. After this time the solution was cooled, filtered through silica gel, eluted with toluene, and the solvent was evaporated to dryness. The residue was washed several times with small amounts of MeOH and $CHCl_3$ alternately to afford 65 mg (59%) of pure **8**. $^1$H NMR (300 MHz, $CDCl_3$ with addition of Pyridine $d_5$): $\delta$ = 10.05 (s, 1 H, $H_{meso}$), 9.83 (d, $J$ = 4.56 Hz, 2 H, $H_{pyrrolic}$), 9.25 (d, $J$ = 4.47 Hz, 2 H, $H_{pyrrolic}$), 8.95 (d, $J$ = 4.92 Hz, 2 H, $H_{pyrrolic}$), 8.94 (d, $J$ = 4.98 Hz, 2 H, $H_{pyrrolic}$), 8.23 (m, 4 H, $H_o$), 7.92 (d, $J$ = 8.82 Hz, 2 H, H*), 7.77 (m, 6 H, $H_{m,p}$), 6.89 (d, $J$ = 8.88 Hz, 2 H, H**), 3.11 (s, 6 H, $NCH_3$) ppm. UV/Vis ($CHCl_3$): $\lambda_{max}$ ($\log\varepsilon$) = 428 (4.97), 448 (4.98), 565 (4.02), 615 (4.24) nm; ($CHCl_3$ with addition of pyridine):

# A New and Fast Synthesis of Nanosized $LiFePO_4$ Electrode Materials

**Alvaro Caballero,[a] Manuel Cruz-Yusta,[a] Julián Morales,[a] Jesús Santos-Peña,*[a] and Enrique Rodríguez-Castellón[b]**

**Keywords:** Copper / Lithium ion batteries / Materials science / Nanostructures / Phosphates

$LiFePO_4$ has been prepared as highly crystalline nanoparticles (approx. 80 nm in diameter) of well-defined shape by heating a mixture containing lithium acetylacetonate, iron oxalate, ammonium hydrogen phosphate and oxalic acid under argon at 550 °C for 2 h. The resulting solid contains about 6 % magnetite ($Fe_3O_4$) as an impurity. Despite its small particle size, this nanomaterial exhibits relatively poor electrochemical performance in lithium cells owing to its lack of electronic conductivity. Its electrochemical response contrasts with previously reported data for nano-$LiFePO_4$ materials prepared at such low temperatures. In order to overcome its lack of conductivity, the compound was treated with a copper precursor. The copper phosphate nanocomposite thus obtained exhibits improved electrochemical performance in terms of capacity and cycling life in lithium cells. Thus Cu-$LiFePO_4$-based cells deliver capacity values close to 80 mAh g$^{-1}$ over at least 50 cycles under a C/10 regime. These values testify to the usefulness of the proposed synthetic method for preparing nanoparticulated lithium phosphate-based electrodes.

## Introduction

Recently, a new class of cathode materials based on polyanionic compounds has aroused much interest among researchers, particularly $LiFePO_4$, which is a compound with an olivine-type structure that yields a flat voltage plateau at 3.5 V during charging and a theoretical capacity of 170 mAh g$^{-1}$.[1] There have been many attempts to overcome the electronic and lithium-diffusion limitations of this electrode, which impair its electrochemical performance under high-current regimes. Some authors have obtained acceptable cycling properties by coating the particles with carbon, usually by pyrolysing organic compounds during the synthesis[2–5] or by decomposing a gaseous carbon precursor onto the phosphate at 700 °C,[6,7] whereas other authors have dispersed a metal (copper or silver[8]) in the phosphate or added a conductive organic compound such as polypyrrole.[9] The intrinsic electronic conductivity can also be increased by doping the structure with ions such as $Mg^{+2}$, $Al^{+3}$, $Ti^{+4}$ or $Nb^{+5}$, among others.[10,11]

The most common method for obtaining $LiFePO_4$ is a solid-state reaction involving the decomposition of various oxy salts. The reaction takes place at moderate temperatures, where the size of the as-formed phosphate particles is in the micron range.[12] Because lithium diffusion in the olivine structure is very slow ($10^{-18}$ cm$^2$ s$^{-1}$),[3,13] some authors have noted the importance of controlling particle size.[4,12,14,15] Thus, Prosini et al.[14] have reported that chemical lithiation of nanosized anhydrous $FePO_4$ by lithium iodide and subsequent heating under an $Ar/H_2$ atmosphere at 550 °C produces nanoparticulated $LiFePO_4$ with very good electrochemical activity; however, this procedure requires a pristine nanomaterial. Huang et al.[4] have succeeded in limiting the size of $LiFePO_4$ by introducing oxidized carbon particles as nucleating agent. The particles obtained at 700 °C were 100–200 nm in size. Recently, Hsu et al.[15] have used a method involving the calcination of a mixture of citric acid, iron oxalate, diammonium hydrogen phosphate and lithium carbonate to obtain nanometric phosphates over the temperature range 400–900 °C. Interestingly, it was necessary to decompose the oxalates and citrate at around 700 °C in order to obtain an electroactive powder; below this temperature the organic compounds are seemingly incompletely decomposed, so the carbon coating required to ensure electronic conductivity in the phosphate is not formed. Singhal et al.[7] have precipitated a precursor by using lithium oxalate, iron hydroxide and $NH_4H_2PO_4$. Heating at 350 °C and annealing between 550 and 800 °C provided $LiFePO_4$ in particles sizes over the range 5–50 nm.

In this work, we use a method that produces nanoparticulated spinels with excellent performance in lithium ion batteries. The method involves the mechanical grinding of lithium, nickel and manganese salts in the presence of a large excess of hydrated oxalic acid[16] to obtain $LiNi_xMn_{2-x}O_4$ phases. The slurry thus obtained provides a nanomaterial upon calcination at low and moderate temperatures. We

have adapted this procedure to the phosphate phases and obtained electroactive nanosized $LiFePO_4$ at 550 °C. The material was characterised by X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and transmission electron microscopy (TEM), and its electrochemical properties in lithium cells determined. The performance of the material, which was initially poorer than that of carbon-coated materials, was successfully improved by adding copper in a very low weight ratio.

## Results and Discussion

### Nanostructured Lithium Iron Phosphate

Lithium iron phosphate is typically prepared by heating a mixture of precursors above 500 °C. Iron(II) is usually protected from oxidation under an inert atmosphere during the thermal treatment. The introduction of carbon (or a carbon precursor such as glucose) into the system can produce iron or iron phosphides[11] during the thermal treatment by carbothermal reduction. The main difference of our method from other solid-state methods using related precursors is that it includes previous grinding and the use of a large excess of hydrated oxalic acid, two factors that seemingly have a significant effect on the results. Thus, they facilitate the formation of a highly homogeneous nanometric mixed oxalate precursor.[17] Also, the oxalic acid released during heating isolates the nanoparticles from one another, thereby hindering particle growth or agglomeration. In addition, water of hydration facilitates nucleation and growth of the reaction products. We checked the purity

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the obtained phases by XRD (Figure 1, a). The peaks associated with the compound matched those of the orthorhombic phase (space group *Pnmb*). Rietveld refinements, performed using the GSAS software suite,[18] yielded the following cell parameter values: $a$ = 10.298, $b$ = 5.995 and $c$ = 4.695 Å; $\alpha = \beta = \gamma = 90°$. The fitted parameters are included in Figure 1. There were also a few peaks at 30.35, 43.39 and 57.56° ($2\theta$) that could not be indexed in the olivine-type structure; such peaks could be indexed in a cubic structure with a lattice constant of 8.34 Å and are consistent with either maghemite ($\gamma$-$Fe_2O_3$) or magnetite ($Fe_3O_4$). The presence of one of these phases made the sample magnetic (as checked with a magnet stick). Based on the heating temperature used, only the magnetite phase should be stable; its content as calculated from the Rietveld refinement was found to be about 6%. The magnetite may have been formed from traces of oxygen contained in the argon flow or occluded in particle pores.[12] Other authors[6] have found that $LiFePO_4$ can yield $Fe_2O_3$ and $Li_3Fe_2(PO_4)_3$ directly during oxidation in the air at 400 °C. Interestingly, $Fe_2O_3$ has been found as an impurity in a related solid-state reaction.[15] This phase seemingly appears when no citric acid − the carbon precursor used in their preparation − is present. This phenomenon was also observed by Dokko et al.,[19] who added ascorbic acid to the reaction mixture in order to remove an amorphous layer of iron oxide that appeared at 400 °C. Based on these findings, our precursors can be deemed ineffective for obtaining carbon-rich materials, as confirmed by elemental analyses.

The TEM images provided direct evidence of crystallinity in the material. The sample consists of nanoparticles (Figure 2, a) with reasonably well-defined edges and sizes below 80 nm. Figure 2 (b) shows an HRTEM image of a crystallite exhibiting structural uniformity and a lattice spacing of 0.25 nm, which corresponds to the (311) lattice planes. Note that our particles are better defined than those formed by Chimie Douce methods[14] or a related solid-state reaction at 550 °C.[15]

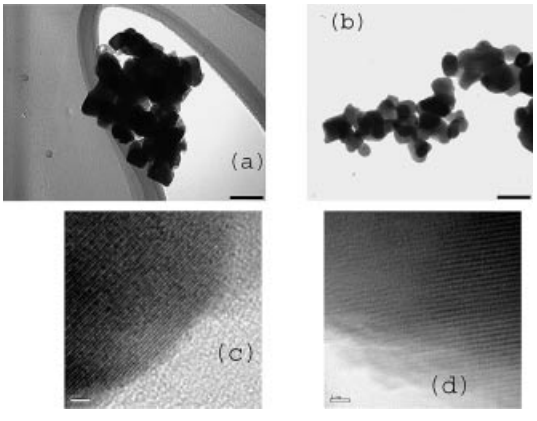

Figure 2. TEM images of (a) and (c) $LiFePO_4$; (b) and (d) Cu-$LiFePO_4$ composite. The black bar corresponds to 100 nm for the upper images and the white bar to 2 nm for the lower ones.

The oxidation states of iron and phosphorus, and the Fe/P atomic ratio, were checked by XPS. The corresponding data are shown in Table 1. The Fe/P ratio thus obtained (1.02) is consistent with the compound stoichiometry. The low intensity/background ratio of the Li 1s emission peak, which results from its low scattering coefficient towards X-rays, precluded accurate determination of its binding energy and estimation of the element content. Figure 3 (a) shows the spectrum for Fe. The shape and binding energies of the Fe 2p emission peaks are consistent with those obtained by other authors for phospholivines[20] and hinder the identification of iron oxides. Furthermore, the P 2p binding energy corresponds to the $PO_4^{3-}$ group and rules out the presence of iron phosphide,[11] a product formed when carbothermal reduction occurs during the preparation of a phospholivine. Thus, no carbothermal reaction takes place during the calcining process.

Table 1. XPS binding energies for various atoms in the $LiFePO_4$ and Cu-$LiFePO_4$ samples.

| Sample | Atom | Emission peak | Binding energy (eV) | Assignation |
|---|---|---|---|---|
| $LiFePO_4$ | Fe | $2p_{3/2}$ | 711.4 | $Fe^{2+}$ |
| | | $2p_{1/2}$ | 724.6 | |
| | P | $2p$ | 133.7 | $[PO_4]^{3-}$ |
| | O | $1s$ | 531.4 | $O^{=}$ |
| Cu-$LiFePO_4$ | Fe | $2p_{3/2}$ | 711.2 | $Fe^{2+}$ |
| | | $2p_{1/2}$ | 724.4 | |
| | P | $2p$ | 133.7 | $[PO_4]^{3-}$ |
| | O | $1s$ | 531.3 | $O^{=}$ |
| | Cu | $2p_{3/2}$ | 930.0 | $Cu^0$ |
| | | $2p_{3/2}$ | 932.9 | $Cu^{I}$–O |
| | | $2p_{3/2}$ | 934.6 | $Cu^{II}$–O |
| | | $2p_{1/2}$ | 949.8 | $Cu^0$ |
| | | $2p_{1/2}$ | 952.8 | $Cu^{I}$–O |
| | | $2p_{1/2}$ | 954.5 | $Cu^{II}$–O |

Figure 4 (a) shows selected potentiostatic charge/discharge curves for a cell made from nanosized $LiFePO_4$. A broad peak centred at 3.55 V was obtained in the first cycle. This oxidation peak corresponds to the extraction of lithium from the structure according to Equation (1).

$$LiFe^{II}PO_4 \rightarrow Li^+ + e^- + Fe^{III}PO_4 \quad (1)$$

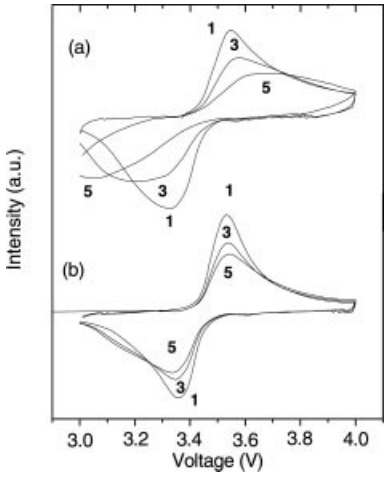

Figure 4. Voltammetric cycling of Li/$LiPF_6$(EC,DMC)/lithium iron phosphate electrodes over the 3.0–4.0 V voltage range. (a) Nanosized $LiFePO_4$, (b) Cu-$LiFePO_4$. Scan rate 5 mV/min.

The reverse reaction − the insertion of lithium into the heterosite structure − provides a broad peak at 3.33 V. The difference between both potentials, $\Delta E_p$, is 220 mV and testifies to the kinetic limitation of these electrodes due to their high resistivity.[5,8,21] The intensity of the peaks decreased in the third cycle, which suggests that the oxidation and reduction processes are much more strongly hindered; $\Delta E_p$ rose to 360 mV. In the fifth cycle, the peaks were clearly shifted from their original positions and much broader, consistent with the decreased electrochemical activity. Figure 5 (a) shows selected galvanostatic charge/discharge cycles for the nanosized $LiFePO_4$ cell. A typical flat voltage plateau close to 3.5 V was obtained during the first charge and discharge. The first capacity was 120 mAh g$^{-1}$, which, however, is 50 mAh g$^{-1}$ less than the theoretical capacity associated with the total delithiation of the phosphate. These values depart markedly from those obtained by Hsu et al.[15] for nanoparticles prepared at the same temperature, which were electrochemically inactive. Furthermore, our capacity values are higher than those found for an hydrothermally synthesised $LiFePO_4$ containing amorphous iron oxides[19] and for a nanostructured phosphate prepared by Sighal et al.[7] Note that, in the latter case, the authors used 20 wt.-% rather than 12% wt.-% carbon black to prepare the electrode mixture.

Consistent with the potentiostatic results, the capacity value was barely retained upon cycling (Figure 6) and, after five cycles, faded by 42%. This behaviour is typical of a phosphate-electrode system and illustrates the inadequate

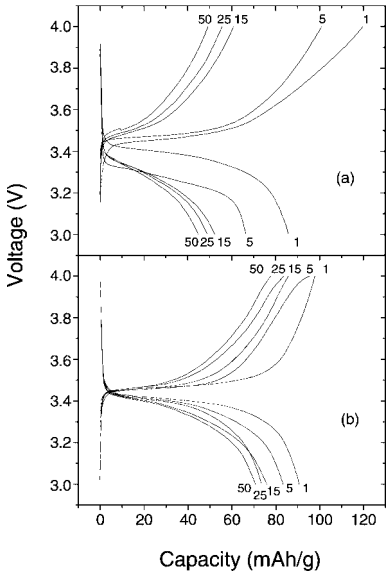

Figure 5. Galvanostatic cycles under a C/10 regime for cells with cathode based on (a) nanosized $LiFePO_4$ and (b) Cu-$LiFePO_4$.

electronic conductivity of nanoparticles. Moreover, as suggested by Yamada et al.,[12] the presence of iron oxide impurities may detract from cell performance.

### Copper-Treated Lithium Iron Phosphate

As noted earlier, the nanoparticles obtained in this work, while somewhat more electroactive than other $LiFePO_4$ nanoparticles provided by more complex methods, exhibit an electrochemical response rather different from theoretical calculations and quite poor cell performance. This is widely ascribed to the lack of a carbon or phosphide network that ensures electron conduction between particles. Based on the results of Hsu et al.,[15] the electroactivity of the nanosized phosphates is determined not only by the presence of the conductive network, but also by the particle shape, which was well defined in our case. In order to improve the electrical conductivity of the electrode, we added a metal to our original material. Like Croce et al.,[8] we chose copper for this purpose on the grounds of its low toxicity and cost; however, we used a different approach that involves formation of $Cu^0$ in situ by chemical reduction of $Cu^ICl$. The reaction of this salt with $NaBH_4$ has been confirmed to yield nanoparticulated copper[22] and proceeds according to Equation (2).

$$2\,Cu^ICl + 2\,NaBH_4 \rightarrow 2\,NaCl + B_2H_6 + 2\,Cu + H_2 \quad (2)$$

Formally, the copper thus obtained should be more effectively dispersed than submicrosized commercial copper[8] and hence increase the conductivity of the Cu-$LiFePO_4$ composite.

Rietveld refinements on the XRD patterns for the new material (Figure 1, b) confirmed that the olivine-type structure was maintained during the reaction and that the cell

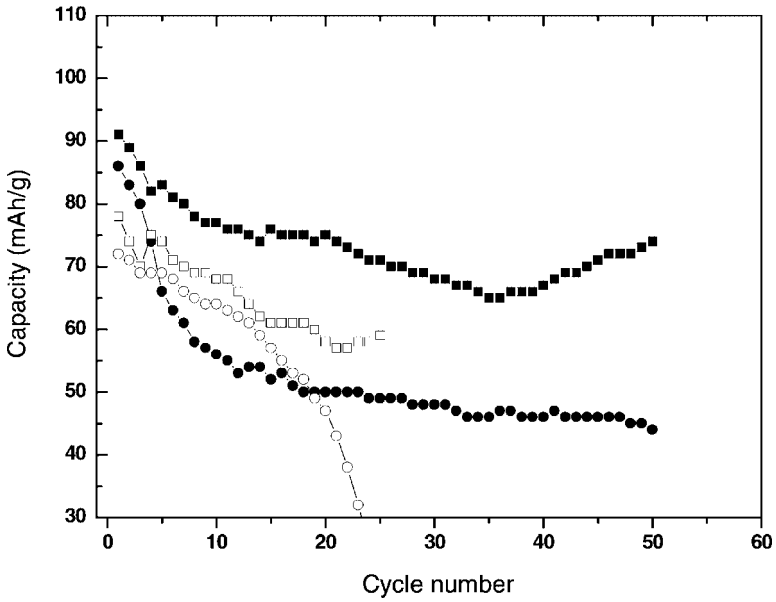

Figure 6. Variation of cell capacity as a function of the number of cycles. (●) $LiFePO_4$ under C/10, (■) Cu-$LiFePO_4$ under C/10, (○) $LiFePO_4$ under C/5 and (□) Cu-$LiFePO_4$ under C/5.

parameters were only slightly different ($a$ = 10.302, $b$ = 5.998, $c$ = 4.695, $\alpha = \beta = \gamma = 90°$). No copper was detected in the XRD pattern, although iron oxide peaks were again observed. TEM images (Figure 2, b) revealed that stirring resulted in rounder particle edges and hindered the observation of well-defined particles. The crystallographic orientation of the particles was seemingly unaffected (Figure 2, d), and the d-spacing, as calculated from the fringes, was again consistent with the value for the (311) planes. No copper could be identified from TEM images. So far, all attempts at detecting isolated or agglomerated copper particles by combining microdiffraction and energy-dispersive microanalysis have failed. The diffuse diffraction peak in Cu/Li-$FePO_4$ nanocomposites should be due to a particle microstructure degradation under the stirring conditions rather than to the diffusion of Cu atoms into the phosphate framework.

The presence of copper was confirmed from XPS measurements, which also ruled out the formation of metallic iron (by reduction of $Fe^{II}$ from the phosphate) or residual chloride. The binding-energy values obtained are listed in Table 1. The fact that the P and Fe peaks retain their positions (Figure 2, b) provides direct evidence of the stability of $LiFePO_4$ upon contact with $NaBH_4$. One unexpected finding was a complex Cu 2p profile (Figure 7) that can be resolved into the contributions of three different oxidation states ($Cu^{II}$, $Cu^{I}$ and $Cu^0$). The presence of divalent copper is also supported by the typical shake-up observed at 940 and 943 eV. These data suggest a pronounced reactivity of Cu towards oxygen as the likely result of the nanometric size of the particles. Despite the precautions exercised to minimize contact of the composite material with the air, the element was partially oxidized, at least at a surface level. The $Cu^{II}$:$Cu^{I}$:$Cu^0$ atomic ratio was found to be 2:1:1. Therefore, only 1.25% by weight of the Cu-$LiFePO_4$ mixture consists of metallic copper and the improvement in conductivity should be less than expected for total conversion (5 wt.-%). This accounts for the inability to detect copper nanoparticles by XRD or from the HRTEM images.

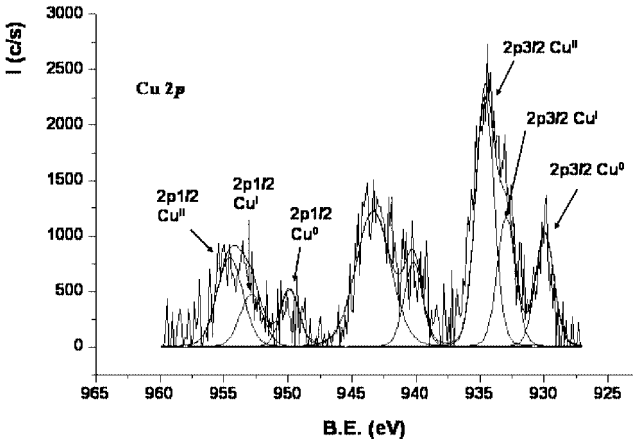

Figure 7. Cu 2p spectrum for the Cu-$LiFePO_4$ composite. Peak deconvolution is also shown.

Notwithstanding the low copper content, the favourable effect of the element on the electrochemical performance of the cell is clearly apparent. Figure 4 (b) shows the potentiostatic cycles for the cell based on the Cu-$LiFePO_4$ mixture. Now, the oxidation and reduction peaks are shaper than those for untreated $LiFePO_4$ (Figure 4, a), with this effect being stronger for the reduction peak. On further cycling, the positions of the peaks remain unchanged, even though their area decreases gradually. This suggests that electron charge-transfer is facilitated by a lower resistivity in the nanocomposite. Copper oxidation was not detected in our samples, probably because it is masked by the main reaction (the Cu potentials are 3.36–3.51 V for $Cu^{2+}$/Cu

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and $Cu^+/Cu$ vs. $Li^+/Li$, respectively). If copper is oxidised, the as-formed $Cu^I$ or $Cu^{II}$ species might dissolve into the EC/DMC solvent and poison the negative electrode. Nevertheless, this plausible inconvenience seems to be negligible as the cell performance is maintained even for bigger amounts of Cu, as reported by Croce et al.[8]

Galvanostatic cycling (Figure 5, b) also provided direct evidence of the favourable effect of copper on the electrochemical properties of the electrode. In the first charge, the compound provided a flat voltage profile and a capacity of 100 mAh g$^{-1}$; however, 10 mAh g$^{-1}$ was lost after discharge. The voltage plateau remained remarkably stable on cycling, but the plateau length decreased with cycling. The composite retained part of the capacity and voltage profiles over several cycles (Figure 6, b); thus, 70% of the original capacity was retained in the 50th cycle. In order to further check the performance of our composites we tested the electrodes under a faster regime, i.e. C/5. As shown in Figure 6, the faster cycling lowered the capacity for the first cycle. However, and once again, the copper composite showed a higher capacity retention (75% in capacity in the 25th cycle vs. 50% for the copper-free material). This means that the addition of Cu is insufficient to obtain high capacities under higher charge/discharge rates. The presence of iron oxides may be an important factor that hinders approach to the theoretical capacity values. We expect to be able to avoid the formation of this phase either by using alternative precursors or by modifying the thermal treatment.

## Conclusion

Well-crystallised nanometric $LiFePO_4$ of uniform particle size (ca. 80 nm) was synthesised at 550 °C by using a simple method involving a homogeneous mixture of iron oxalate, diammonium hydrogen phosphate, lithium acetylacetonate and excess oxalic acid plus grinding. In contrast to the typically inactive or poorly active nanomaterials provided by alternative solid-state reactions at the same temperature, our nanomaterial is electroactive in lithium batteries. The initial charge capacity of the cell, 120 mAh·g$^{-1}$, was not completely recovered during the first discharge owing to the poor electronic properties of the material – no chemical treatment such as the addition of a conductor (e.g. carbon) was performed. In order to improve the cycling efficiency, we introduced copper (hypothetically in nanosized form) thoroughly mixed with the phosphate via a chemical reaction. Although copper was partially oxidized, a small fraction (less than 1.5% by weight) sufficed to increase the reversibility of the lithium extraction/insertion process by a factor close to 2 relative to the copper-free material. The capacities delivered by the Cu-$LiFePO_4$ composite in the 50$^{th}$ cycle were close to 80 mAh·g$^{-1}$. These electrochemical properties are acceptable for a nanophosphate prepared in a fast one-step method using a moderate temperature. The electroactivity of our sample appears to be determined by two main factors, namely: the nanometric size of the particles and their well-defined shape. We are currently analysing carefully the influence of both factors on the electrochemical properties of the phosphate. The proposed method can also be used to prepare other phospholivines such as $LiMnPO_4$ and $LiCoPO_4$, the electrochemical properties of which will be reported in a future paper.

## Experimental Section

Lithium iron phosphate was obtained as follows: $FeC_2O_4{\cdot}2H_2O$ (1.80 g; Fluka), $(NH_4)_2HPO_4$ (1.32 g; Fluka), $LiC_5H_7O_2$ (1.60 g; Strem Chemicals), and $H_2C_2O_4{\cdot}2H_2O$ (8 g; Fluka) were ball-milled in a Retsch mill at 50 rpm for 30 min. The resulting slurry was supplied with 2 mL of ethanol and air-dried. The powder collected was subsequently calcined at 550 °C under argon for 2 h. We chose this moderate temperature in order to ensure adequate crystallinity in the compound and avoid sintering, which increases particle size. After cooling to room temperature, a brown solid, nanometric $LiFePO_4$, was obtained. For copper coating, the nanomaterial was immersed in a solution containing freshly prepared CuCl in methanol.[22] The Cu/$LiFePO_4$ weight ratio used was 5:95. Because this compound is readily oxidized, the process was carried out inside a glove box (Mbraun 150). After addition of several milligrams of $NaBH_4$ under continuous stirring the brown solid darkened. The solid was collected by filtration after 2 h of stirring and thoroughly washed with methanol. dried in an inert atmosphere and stored in tightly sealed glass containers under argon for transportation.

Transmission electron microscopy (TEM) images were obtained on a Jeol 2010 microscope operating at 200 keV. Samples were prepared in an ultrasonic bath, using hexane as dispersing agent and a grid covered with a carbon perforated film. X-ray diffraction patterns were recorded with a Siemens D5000 X-ray diffractometer, using Cu-$K_\alpha$ radiation and a graphite monochromator. The scan conditions for structural refinement included a 15–125° ($2\theta$) recording range, a 0.02° step size and 8 s per step. X-ray photoelectron spectra were obtained on a Physical Electronics PHI 5700 spectrometer, using non–monochromatic Mg-$K_\alpha$ radiation (300 W, 15 kV, 1253.6 eV) and a multi-channel detector. Spectra were recorded in the constant pass energy mode at 29.35 eV, using a 720 μm diameter analysis area. Binding energy (BE) values were referred to the C 1s peak (284.8 eV) from the adventitious contamination layer during data processing of the XPS spectra. Recorded spectra were always fitted using Gauss–Lorentz curves in order to more accurately determine the binding energy of the different element core levels. The error in BE was estimated to be ca. ±0.1 eV. The spectra for the C 1s and Cu 2p regions were initially recorded for 10 min. Such a short acquisition time was intended to avoid the previously reported reduction of $Cu^{2+}$ species to $Cu^+$ by the action of the X-ray excitation source as much as possible.[23] For recording of XPS spectra, the containers were opened in the air and the pellets, rapidly transferred to the preparation chamber of the XPS spectrometer. In this way, the exposure time of the sample to air was minimised.

Electrochemical measurements were carried out in CR2032 coin cells, using an electrode mixture consisting of active material, carbon black and Teflon in a weight ratio 85:12:3. The working electrode consisted of a stainless steel grid onto which approximately 3 mg of the mixture was pressed. The electrolyte used was 1 M $LiPF_6$ in 2:1 EC/DMC as solvent. Both the reference electrode and the counter-electrode consisted of a lithium disk. Potentiostatic cycles were carried out in a MacPile II (BioLogic) potentiostat under a regime of 10 mV/2 min. Galvanostatic discharges were performed

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

on a Arbin system under a regime of C/10 (i.e. one lithium mol was transferred in 10 h) or C/5 (i.e. one lithium mol was transferred in 5 h).

# Highly Symmetrical Tetranuclear Cluster Complexes Supported by *p-tert*-Butylsulfonylcalix[4]arene as a Cluster-Forming Ligand

**Takashi Kajiwara,*[a] Takanori Kobashi,[b] Reiko Shinagawa,[b] Tasuku Ito,[b] Shinya Takaishi,[a] Masahiro Yamashita,[a] and Nobuhiko Iki*[c]**

**Keywords:** Cluster compounds / Calixarenes / Magnetic properties / Ligand exchange

Square-planar tetranuclear clusters $[M_4(\mathbf{L})(AcO)_4(\mu_4\text{-}OH)]^-$ (M = $Mn^{II}$, $Co^{II}$, and $Ni^{II}$) are synthesized using tetra-anionic *p-tert*-butylsulfonylcalix[4]arene ($\mathbf{L}^{4-}$) as a cluster-forming ligand. Three complexes are crystallographically isostructural, being crystallized in the triclinic crystal system with space group $P\bar{1}$. The calix[4]arene acts as a tetrakis *fac*-tridentate ligand through four phenoxo and four sulfonyl oxygen atoms to form square arrangement of four metal ions, which are further bridged by four chelating acetate ions and one hydroxo ion in a $\mu_4$ manner to complete the hexacoordination of each metal center. Although the whole molecule of each complex is crystallographically independent, the molecule is highly symmetrical with a pseudo-four-fold axis lying on the $\mu_4$-$OH^-$ group. The tetranuclear clusters are stable enough to maintain the core structures even in highly dilute solution (≈10 μM), which was confirmed by mass spectroscopic study, however, bridging acetates were easily exchanged by other carboxylate chelates to form derivatives such as $[M_4(\mathbf{L})(BzO)_4(OH)]^-$. Metal–metal interactions were investigated by means of magnetic susceptibility, and it was revealed that both ferro- and antiferromagnetic interactions occur in the $Ni^{II}$ complex depending on the bridging angles of Ni–O–Ni.

## Introduction

Multinuclear transition-metal complexes and metal clusters have attracted much attention owing to the interesting properties and the functionalities that originate from direct and/or indirect metal–metal interactions. Recent developments of synthetic methods for metal-based assemblies have enabled construction of a variety of well-organized architectures such as helicates,[1] cages,[2] and grids,[3] and the resulting assemblies are also interesting in their possibility to be novel materials incorporating magnetic, electronic, or optical features. For example, some square-shaped [2 × 2] dot systems having reversible redox properties are considered to be candidates for quantum-dot cellular automated devices.[3d,4] Synthetic strategies to produce such metal assemblies often employ well-designed multinucleating ligand systems.[5,6] As we have demonstrated, the thiacalix[*n*]arene[6a,6b,6c,6d] and its oxidized derivatives sulfonyl- and sulfinylcalix[*n*]arenes[6e,6f,6g,6h] can act as novel metal-assembling and cluster-forming ligands. We reported in previous papers that the thiacalix[6]arene gives tetranuclear and pentanuclear cluster complexes[6c,6d] when treated with first-row transition-metal acetate involving coordination bonds with 6 phenoxo oxygen and 6 sulfur atoms. In the case of pentanuclear clusters, hexa-anionic thiacalix[6]arene in the pinched-cone conformation formed a pocket-like cavity surrounded by 12 donor atoms. The cavity had an appropriate size to include a metal-cluster core, and five metal ions with compositions of $Ni_4M$ (M = Co, Mn, or Cu) and $Co_5$ were included to form the pyramidally shaped cluster cores. Sulfonylcalix[4]arene (part a in Figure 1, $H_4\mathbf{L}$) led to octalanthanide cluster complexes ("lanthanide wheels") when it was treated with $Ln(AcO)_3 \cdot nH_2O$, in which each $\mathbf{L}^{4-}$ coordinated to one lanthanide ion as a tetradentate ligand through four phenoxo oxygen atoms,[6e] as the lanthanide ions with large ionic radii were in agreement with the cyclic donor system of $\mathbf{L}^{4-}$ to be included. However, for smaller ions such as first-row transition metals, $\mathbf{L}^{4-}$ and $H_2\mathbf{L}^{2-}$ act as a *fac*-tridentate ligand through three adjoining donor atoms, that is, two phenoxo and one sulfonyl oxygen atoms.[6f,6g] In a conic $H_{4-n}\mathbf{L}^{n-}$, eight donor atoms (four phenoxo and four axial sulfonyl oxygen atoms shown in Figure 1, b) are arranged in a flat manner where four *fac*-tridentate sites (**A**–**D**) are formed, each consisting of three donor oxygens. In the zinc(II) complex, $[Zn(H_2\mathbf{L})(tacn)]$ (tacn denotes 1,4,7-triazacyclononane), the zinc(II) ion

smoothly slides on this oxo-surface from one tridentate site to the adjoining site,[6f] and this result indicates that the four tridentate sites **A**–**D** in $\mathbf{L}^{4-}$ are equivalent and each site can bind a metal ion in a similar manner. As a result, $\mathbf{L}^{4-}$ can act as a tetranucleating ligand to give highly symmetrical square-planar clusters. Herein we report syntheses and properties of tetranuclear cluster complexes $(Me_4N)[M_4(\mathbf{L})(AcO)_4(\mu_4\text{-}OH)]$ {$M^{II}$ = $Mn^{II}$ ($Me_4N$[**1**]), $Co^{II}$ ($Me_4N$[**2**]), and $Ni^{II}$ ($Me_4N$[**3**])}, which are constructed on the basis of the cluster-forming ability of $\mathbf{L}^{4-}$.

## Results and Discussion

### Syntheses and Crystal Structures of Complexes

The reaction of $H_4\mathbf{L}$ and $Mn(AcO)_2{\cdot}4H_2O$ in a 1:5 ratio in $CHCl_3$/MeOH followed by crystallization from an EtOH/dimethylformamide (DMF) solution including $Me_4NCl$ gave colorless crystals of $Me_4N$[**1**] in 36% yield. With a similar procedure, using $Co(AcO)_2{\cdot}4H_2O$ and $Ni(AcO)_2{\cdot}4H_2O$, $Me_4N$[**2**] and $Me_4N$[**3**] were also obtained in yields of 25 and 30%. In the formation of tetranuclear clusters, the acetate ions acted as a base to remove protons from $H_4\mathbf{L}$ to give $\mathbf{L}^{4-}$ and also from $H_2O$ to give $OH^-$. To achieve the best yield, we found that the reaction ratio of the ligand and metal acetate must be 1:5 or larger.

Figure 2 shows the crystal structure of $[Mn_4(\mathbf{L})(AcO)_4(\mu_4\text{-}OH)]^-$ ($[\mathbf{1}]^-$). The complex crystallized in the triclinic crystal system and the four metal coordination sites are crystallographically independent of each other; however, the cluster is highly symmetrical and a pseudo-four-fold axis lies on the central $\mu_4$-$OH^-$ group (O13), and each metal ion is in a similar coordination environment. The conic $\mathbf{L}^{4-}$ supports the formation of the square $Mn_4$ cluster core. Four phenoxo (O3, O6, O9, and O12 in Figure 3) and four axial sulfonyl (O1, O4, O7, and O10) oxygen atoms form an almost flat surface with deviations from the ideal plane ranging from –0.132(3) to 0.220(3) Å, and $\mathbf{L}^{4-}$ acts as a tetrakis tridentate ligand through these eight oxygen atoms. Each $Mn^{II}$ ion is ligated by one sulfonyl and two phenoxo oxygens in a *fac* manner similar to that found in $[Zn(H_2\mathbf{L})(tacn)]$, with distances of $Mn\text{–}O_{phenoxo}$ = 2.1550(18)–2.248(2) Å and $Mn\text{–}O_{sulfonyl}$ = 2.150(2)–2.1832(18) Å. Four $AcO^-$ ions bridge adjoining $Mn^{II}$ ion pairs [$Mn\text{–}O_{acetate}$ = 2.097(2)–2.132(2) Å], four $Mn^{II}$ ions are further bridged by $OH^-$ in an $\mu_4$ manner [Mn–O13 = 2.2309(19)–2.3262(19) Å], and each $Mn^{II}$ ion in $[\mathbf{1}]^-$ is in an octahedral coordination. Bridging hydroxide in an $\mu_4$ manner is rather rare, and few complexes involving first-row transition-metal ions are reported in the Cambridge Crystallographic Data Base.[7] The most remarkable compounds in such a system are square-planar tetranuclear complexes constructed in the aperture of huge macrocyclic Schiff-base ligands reported by Edwards, Kruger, and McKee.[8] In our previous papers,[6d] we have demonstrated the formation of pyramidally arranged pentanuclear cluster complexes using thiacalix[6]arene, in which the basal four metal ions were also connected by $OH^-$ in the same manner. In these complexes, the valence electrons from central oxygen are insufficient to make four M–O coordination bonds, which reflects the long bond lengths found not only in $[\mathbf{1}]^-$ but also in $[\mathbf{2}]^-$ and $[\mathbf{3}]^-$ mentioned below. Hence one can conclude that the $\mu_4$-$OH^-$ system is stable only in a cluster core with the support of huge macrocyclic ligands as a template. One crystal water molecule is bound to the $\mu_4$-$OH^-$ group through hydrogen bonding [O13···O22 = 2.747(6) Å], one DMF molecule is included in the cavity of conic $\mathbf{L}^{4-}$, and one tetramethylammonium ion is included in the lattice as a countercation. $Me_4N$[**2**] and $Me_4N$[**3**] are crystallographically isostructural to $Me_4N$[**1**], showing slight differences in

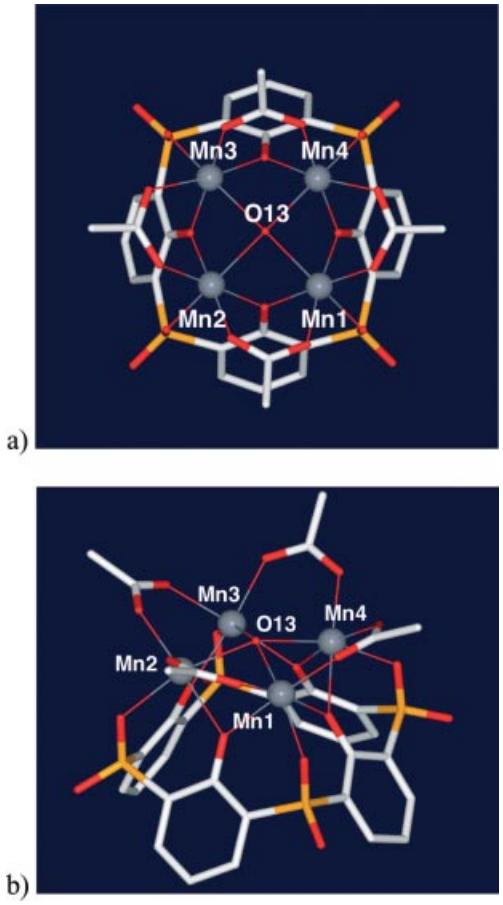

Figure 2. Crystal structure of $[\mathbf{1}]^-$. (a) Top view and (b) side view. *tert*-Butyl groups and hydrogen atoms are omitted. Each atom is depicted as follows: $Mn^{II}$ gray, S orange, O red, and C white.

coordination distances. For $[\mathbf{2}]^-$, Co–$O_{phenoxo}$ distances were found in the range of 2.042(4)–2.117(4) Å, Co–$O_{sulfonyl}$ distances in 2.102(5)–2.121(4) Å, 2.013(5)–2.042(4) Å for Co–$O_{acetate}$, and Co–O13 was found to be 2.147(5)–2.290(5) Å. Coordination angles were found to fall in the range of 84.45(17)–92.32(17)°, and the $Co^{II}$ ions are in a nearly ideal octahedral except for the slightly long bonding with the $\mu_4$-$OH^-$ group. For $[\mathbf{3}]^-$, nickel(II) ions are in a slightly elongated octahedral coordination with phenoxo and acetate oxygen atoms occupying equatorial positions [Ni–$O_{phenoxo}$ = 2.016(2)–2.072(2) and Ni–$O_{acetate}$ = 1.986(3)–2.005(3) Å] and sulfonyl and hydroxo oxygen atoms being at axial positions [Ni–$O_{sulfonyl}$ = 2.058(3)–2.079(2) and Ni–O13 = 2.142(3)–2.258(2) Å]. In $[\mathbf{3}]^-$, a residual electron peak with considerable density was found between the $\mu_4$-$OH^-$ group and a neighboring water molecule. This peak was assigned to a carbon atom and the reflection data were analyzed as a superposition of two molecules of $[Ni_4(\mathbf{L})(AcO)_4(\mu_4\text{-}OH)]^-$ ($[\mathbf{3}]^-$) and $[Ni_4(\mathbf{L})(AcO)_4(\mu_4\text{-}OMe)]^-$ ($[\mathbf{3b}]^-$) with 67% and 33% probabilities. The formation of $\mu_4$-OMe bridged complex $[\mathbf{3b}]^-$ might be due to the higher acidity of $Ni^{II}$ ion compared with $Mn^{II}$ and $Co^{II}$. The presence of $\mu_4$-OMe bridged species was also confirmed by mass spectroscopic studies (vide infra).

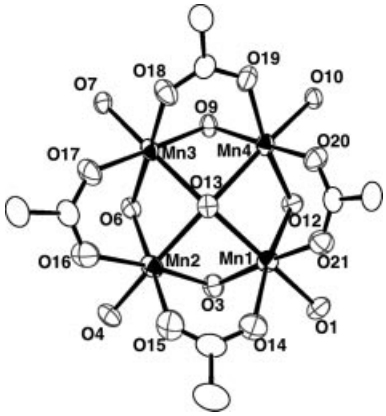

Figure 3. ORTEP diagram of tetranuclear manganese(II) core with thermal ellipsoids at 40% probability.

## Ligand Exchange Reactions

The complexes maintain the tetranuclear cluster cores in a dilute MeCN solution, which was confirmed by ESI-mass spectroscopy. For $Me_4N[\mathbf{1}]$, intense parent peaks were observed at around *m*/*z* = 1317.0, which is related to $[Mn_4(\mathbf{L})(AcO)_4(OH)]^-$ (= $[\mathbf{1}]^-$) (Figure 4, a). Similar spectra were obtained for $[\mathbf{2}]^-$, with the main peaks positioned at around *m*/*z* = 1333.0 being related to $[Co_4(\mathbf{L})(AcO)_4(OH)]^-$ (= $[\mathbf{2}]^-$) (see Figure 1Sa in the Supporting Information), and for $[\mathbf{1}]^-$ and $[\mathbf{2}]^-$ minor species were observed at around *m*/*z* = 1292.9 and *m*/*z* = 1308.9 related to $[Mn_4(\mathbf{L})(AcO)_3(\mu_4\text{-}O)(H_2O)_2]^-$ (= $[\mathbf{1}]^-$ – AcOH + $2H_2O$) and $[Co_4(\mathbf{L})(AcO)_3(\mu_4\text{-}O)(H_2O)_2]^-$ (= $[\mathbf{2}]^-$ – AcOH + $2H_2O$), respectively. For $[\mathbf{3}]^-$, the main peaks at around *m*/*z* = 1306.9 and 1331.0 related to $[Ni_4(\mathbf{L})(AcO)_3(\mu_4\text{-}O)(H_2O)_2]^-$ (= $[\mathbf{3}]^-$ – AcOH + $2H_2O$) and $[Ni_4(\mathbf{L})(AcO)_4(\mu_4\text{-}OH)]^-$ (= $[\mathbf{3}]^-$), respectively, and a minor species involving $\mu_4$-OMe $[Ni_4(\mathbf{L})(AcO)_4(\mu_4\text{-}OMe)]^-$ (= $[\mathbf{3b}]^-$) at around *m*/*z* = 1345.0 were observed (Figure 2Sa, Supporting Information). We assumed that the ligand exchange gave minor species such as $[M_4(\mathbf{L})(AcO)_3(\mu_4\text{-}O)(H_2O)_2]^-$, that is, $\mu_4$-oxo-diaqua complexes. There are other possible formulas for these species including $[M_4(\mathbf{L})(AcO)_3(\mu_4\text{-}OH)(H_2O)(OH)]^-$, $\mu_4$-hydroxo-aqua-hydroxo complexes, and this possibility was rejected by an absence of MS signals for corresponding $[Ni_4(\mathbf{L})(AcO)_3(\mu_4\text{-}OMe)(H_2O)(OH)]^-$ for $[\mathbf{3b}]^-$. The above results reveal that the tetranuclear cores in $[\mathbf{1}]^-$–$[\mathbf{3}]^-$ are stable enough to maintain their core structures even in a highly dilute coordinating solvent (≈10 μM), and moreover, formation of $[M_4(\mathbf{L})(AcO)_3(O)(H_2O)_2]^-$ species indicate that bridging acetate ions can be removed to realize a ligand exchange reaction to give some derivative complexes even in a mild condition. To confirm this, an exchange reaction of bridging acetate by benzoate was performed for all complexes. When $[\mathbf{1}]^-$ was treated with an excess of benzoic acid (1:5 molar ratio) in acetonitrile at ambient temperature, ligand exchange soon occurred to give a mixture of $[Mn_4(\mathbf{L})(AcO)_{4-n}(BzO)_n(OH)]^-$ ($n$ = 2–4) and $[Mn_4(\mathbf{L})(AcO)_{3-m}(BzO)_m(O)(H_2O)_2]^-$ ($m$ = 2–3), which was confirmed by FT-MS (Figure 4, b), and also by X-ray crystallography for $[Mn_4(\mathbf{L})(BzO)_4(OH)]^-$ (Figure 3S). Specific peaks were observed in Figure 4, b where $[Mn_4(\mathbf{L})(BzO)_4(OH)]^-$ was found to be a major component. To complete the exchange reaction, the mixed solution was evaporated once to dryness to remove AcOH, and the residue was again dissolved to the same solvent (Figure 4, c). The mass spectrum for this solution shows two main signals at around *m*/*z* = 1479.0 and 1565.0, being related to $[Mn_4(\mathbf{L})(BzO)_3(O)(H_2O)_2]^-$ and $[Mn_4(\mathbf{L})(BzO)_4(OH)]^-$, respectively, indicating that the acetate bridges were exchanged by benzoate almost quantitatively. The resulting $[Mn_4(\mathbf{L})(BzO)_4(OH)]^-$ was isolated as single crystals with the yield higher than 70%. Similar reactions for $[\mathbf{2}]^-$ and $[\mathbf{3}]^-$ also give the same result. For $[\mathbf{2}]^-$, the main signals at around *m*/*z* = 1495.0 and 1581.0 were observed for the reaction solution, which are related to $[Co_4(\mathbf{L})(BzO)_3(O)(H_2O)_2]^-$ and $[Co_4(\mathbf{L})(BzO)_4(OH)]^-$, respectively, and for $[\mathbf{3}]^-$ the main peaks at around *m*/*z* = 1493.0 and 1579.0 related to $[Ni_4(\mathbf{L})(BzO)_3(O)(H_2O)_2]^-$ and $[Ni_4(\mathbf{L})(BzO)_4(OH)]^-$ were found, indicating that $[Co_4(\mathbf{L})(BzO)_4(OH)]^-$ and $[Ni_4(\mathbf{L})(BzO)_4(OH)]^-$ should be the main products for both cases (Figure 1Sc and Figure 2Sc, respectively). For the case of $[\mathbf{3}]^-$, minor species involving $\mu_4$-OMe formulated as $[Ni_4(\mathbf{L})(BzO)_4(OMe)]^-$ at around *m*/*z* = 1593.0 were observed in Figure 3Sc. The observed ratio between $\mu_4$-OH species ($[Ni_4(\mathbf{L})(AcO)_3(O)(H_2O)_2]^-$ and $[Ni_4(\mathbf{L})(AcO)_4(OH)]^-$ for acetate-bridged complexes, and $[Ni_4(\mathbf{L})(BzO)_3(O)(H_2O)_2]^-$ and $[Ni_4(\mathbf{L})(BzO)_4(OH)]^-$ for benzoate-bridged complexes) and $\mu_4$-OMe species ($[Ni_4(\mathbf{L})(AcO)_4(OMe)]^-$ and $[Ni_4(\mathbf{L})(BzO)_4(OMe)]^-$, respectively) were estimated to be similar for acetate-bridged species (64.6:35.4) and for benzoate-bridged species (64.9:35.1), indicating that the exchange of the central $\mu_4$-OH group does not occur during

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the exchange reaction of bridging carboxylates. This result suggests that core fragmentation does not occur during this reaction.

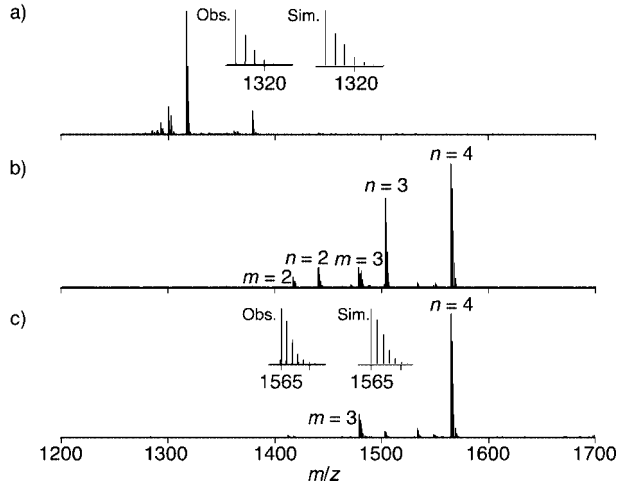

Figure 4. ESI-mass spectra of (a) complex $Me_4N$[**1**] in acetonitrile, (b) mixtures of benzoic acid and $Me_4N$[**1**] in a 5:1 ratio in acetonitrile, and (c) reaction products which were obtained by drying up the reaction solution of benzoic acid and $Me_4N$[**1**]. *n* and *m* denote the numbers of bridging benzoic groups in the species of $[M_4(\mathbf{L})(AcO)_{4-n}(BzO)_n(OH)]^-$ and $[M_4(\mathbf{L})(AcO)_{3-m}(BzO)_m(O)(H_2O)_2]^-$, respectively.

As the complexes maintain their cluster cores in the solution, electrochemical behaviors of these clusters in the same solution were preliminarily investigated by the cyclic voltammetry method at room temperature. No significant peak was observed in the range of –1.0 to +1.0 V versus $Ag/Ag^+$ for all three complexes (Figure 4S), indicating that the divalent tetranuclear complexes are rather stable under the experimental conditions.

### Magnetic Behavior

To investigate the metal–metal interactions in square-shaped clusters, dc-magnetic susceptibilities were measured in the temperature range of 2–300 K. The $\chi_M T$ versus $T$ plots for these complexes show continuous decreases of $\chi_M T$ values as the temperature is lowered (Figure 5, a). The $\chi_M T$ value at room temperature for $Me_4N$[**2**] is larger than the expected spin-only value for four isolated $S = 3/2$ spins, being due to the spin-orbit interactions, which is frequently observed for the $Co^{II}$ ion in a slightly distorted octahedron,[9] and the magnitude of the interaction was hard to analyze. For $Me_4N$[**1**] and $Me_4N$[**3**], temperature dependences of the $\chi_M T$ values were analyzed on the basis of the Hamiltonian,[9]

$$\boldsymbol{H} = -2J_1\Sigma(\boldsymbol{S}_1\cdot\boldsymbol{S}_2 + \boldsymbol{S}_2\cdot\boldsymbol{S}_3 + \boldsymbol{S}_3\cdot\boldsymbol{S}_4 + \boldsymbol{S}_4\cdot\boldsymbol{S}_1) - 2J_2\Sigma(\boldsymbol{S}_1\cdot\boldsymbol{S}_3 + \boldsymbol{S}_2\cdot\boldsymbol{S}_4)$$

where $J_1$ denotes the interaction between adjoining metal ions and $J_2$ is for the diagonal metal ions (Figure 5, b). The best-fit parameters were obtained as $J_1 = -3.0\ cm^{-1}$ and $J_2 = -4.4\ cm^{-1}$ for $Me_4N$[**1**] and $J_1 = 24.9\ cm^{-1}$ and $J_2 = -43.9\ cm^{-1}$ for $Me_4N$[**3**]. For $Ni^{II}$ ions, it is widely thought that the character of magnetic interactions clearly depends

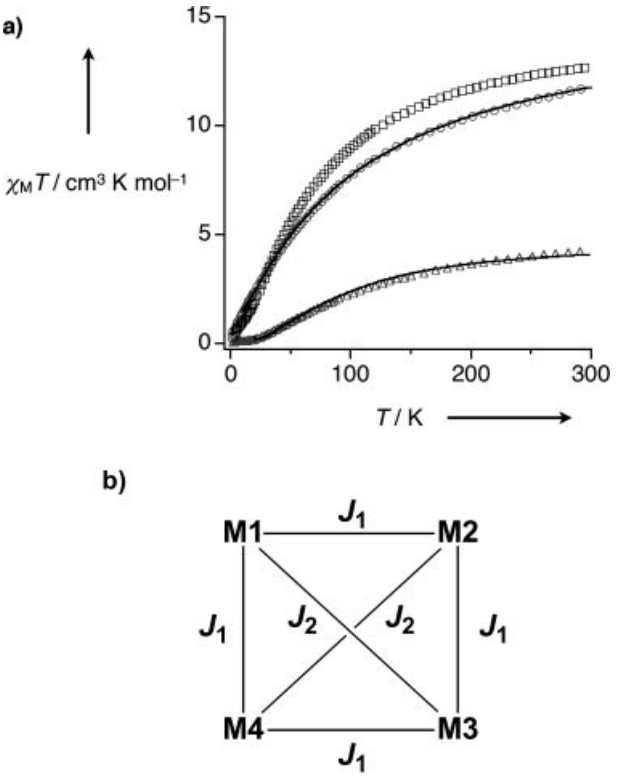

Figure 5. (a) Plots of $\chi_M T$ vs. $T$ for $Me_4N$[**1**] (circle), $Me_4N$[**2**] (square), and $Me_4N$[**3**] (triangle). The solid lines correspond to the theoretical curves for which parameters are given in the text. (b) A schematic drawing of $J_1$ and $J_2$.

on the bridging angle.[10] As two spins are located on the $e_g$ orbitals with dσ characters for $Ni^{II}$, a strict orbital orthogonality occurs and ferromagnetic interaction operates when the bridging angle is smaller than 100°, and a strong antiferromagnetic interaction occurs when the bridging angle reaches linearity. In $Me_4N$[**3**], because each adjoining $Ni^{II}$ ion is bridged by two oxygen atoms involving one phenoxo and one $\mu_4$-hydroxo oxygen atom with angles of 84.13(9)–93.18(10)°, a ferromagnetic interaction operates between two neighboring $Ni^{II}$ ions with relatively strong magnitude. However, the diagonal $Ni^{II}$ ions (two sets of Ni1/Ni3 and Ni2/Ni4) are bridged by the $\mu_4$-$OH^-$ group with angles of 144.88(12)° and 146.87(12)°, so an antiferromagnetic interaction occurs between nickel(II) ions in these two sets. In $Me_4N$[**1**], as the $Mn^{II}$ ion has dσ and dπ spins, orbital overlap through bridging oxygen atoms occurs both in adjoining $Mn^{II}$ sets and in diagonal $Mn^{II}$ sets, and this causes antiferromagnetic interactions in both pathways.

## Conclusion

In conclusion, a tetra-anionic sulfonylcalix[4]arene was used to construct three tetranuclear clusters having a highly symmetrical structure. The complexes are stable enough to maintain their structures in solution and moderate metal–metal interactions were estimated by magnetic susceptibility measurements. It is expected that $\mathbf{L}^{4-}$ generally acts as a tetranucleating ligand for other transition-metal ions, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

further studies for the development of a square-shaped tetranuclear system with reversible redox features are now in progress.

## Experimental Section

Solvents and chemicals except for acetonitrile were purchased as reagent grade and used without further purification. Acetonitrile was distilled from calcium hydride immediately prior to use in the cyclic voltammetry measurements. ESI-MS experiments were performed using a Fourier Transform Ion Cyclotron Resonance (FTICR) mass spectrometer APEX III (Bruker). The reaction solution was diluted with acetonitrile, methanol, or acetonitrile/dichloromethane (1:1 v/v) to allow the mass spectroscopic measurement, which gave the same result. Variable-temperature magnetic susceptibility measurements were made using a SQUID magnetometer MPMS 5S (Quantum Design) at 1 T for $Me_4N$[**2**], and 0.25 T and 0.5 T field for $Me_4N$[**1**] and $Me_4N$[**3**], respectively. Diamagnetic correction for each sample was determined from Pascal's constants.

**Synthesis of $Me_4N$[1] (Table 1):** $Mn(AcO)_2{\cdot}4H_2O$ (12.3 mg, 0.05 mmol) and $H_4$**L** (8.5 mg, 0.01 mmol) were mixed and refluxed in MeOH/$CHCl_3$ (1:1, v/v, 10 mL) for an hour, and the solvents evaporated to dryness. The pale brown residue was dissolved into DMF (0.5 mL), added to $Me_4NCl$ (2.2 mg, 0.02 mmol) in ethanol (2 mL), and then evaporated slowly. Colorless crystals of $Me_4N$[**1**]·3.5DMF·$H_2O$ were formed in two weeks. Crystals were filtered and dried in vacuo. Yield, 5.2 mg, 36%. $C_{53.5}H_{74.5}Mn_4N_{1.5}O_{22.5}S_4$ ($Me_4N$[**1**]·0.5DMF·$H_2O$; 1446.69): calcd. C 44.42, H 5.19, N 1.45; found C 44.25, H 5.32, N 1.46.

**Synthesis of $Me_4N$[3] (Table 3):** $Ni(AcO)_2{\cdot}4H_2O$ (12.4 mg, 0.05 mmol) and $H_4$**L** (8.5 mg, 0.01 mmol) were mixed and refluxed in MeOH/$CHCl_3$ (1:1, v/v, 10 mL) for an hour, and the solvents evaporated to dryness. The pale green residue was dissolved into DMF (0.5 mL), added to $Me_4NCl$ (2.2 mg, 0.02 mmol) in ethanol (2 mL), and then evaporated slowly. Pale green crystals of $Me_4N$·0.67[**3**]·0.33[**3b**]·3.5DMF·0.67$H_2O$ were formed in two weeks. Crystals were filtered and dried in vacuo. Yield 3.6 mg, 25%. $C_{52.33}H_{71}NNi_4O_{21.67}S_4$ ($Me_4N$·0.67[**3**]·0.33[**3b**]·0.67$H_2O$; 1423.85): calcd. C 44.14, H 5.03, N 0.98; found C 43.75, H 5.26, N 1.33.

**X-ray Crystallography:** Data for all of the compounds were collected by a Bruker SMART APEX diffractometer employing graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at low temperature (200–233 K). The data integration and reduction were undertaken with SAINT and XPREP.[11] An empirical correction determined with SADABS[12] was applied to all data. The structures were solved by the direct method using SHELXS-97[13] and refined using least-squares methods on $F^2$ with SHELXL-97.[13] Non-hydrogen atoms were modeled with anisotropic displacement parameters, and hydrogen atoms were placed by the differential Fourier syntheses and refined isotropically (Table 4).

CCDC-249858 to -249860 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Alteration in the Binding Property of a Laterally Nonsymmetric Aza Cryptand toward $Cu^{II}$, $Ag^{I}$, and $Tl^{I}$ Ions upon Derivatization with a Cyanomethyl Group

**Debdas Ray[a] and Parimal K. Bharadwaj*[a]**

**Keywords:** Cryptands / Coordination chemistry / Metal cryptate / Silver / Copper / Thallium

The laterally nonsymmetric aza cryptand $\mathbf{L_o}$ readily forms mononuclear inclusion complexes with metal ions like $Cu^{II}$, $Ni^{II}$, $Ag^{I}$, $Tl^{I}$, and so forth. However, when the secondary amines present in the three bridges are substituted by a cyanomethyl group to yield a new cryptand **L**, its metal-binding properties are drastically altered. Thus, while $\mathbf{L_o}$ binds $Ag^{I}$ at the tren end, showing $AgN_4$ coordination, in **L**, the bridgehead nitrogen atoms are pulled inside to form a two-coordinate complex of $Ag^{I}$ and none of the O or N atoms present in the three bridges are involved in coordination. This is probably the first example where the two bridgehead atoms are pulled inside to the maximum to bind the metal ion. Likewise, the $Tl^{I}$ ion shows $TlN_4$ coordination with $\mathbf{L_o}$, while in **L** it is loosely bound at the tren end, showing $TlN_3$ coordination. Upon treatment with a $Ag^{I}$ salt, the $Tl^{I}$ can be replaced almost instantaneously. On the other hand, with copper(II) tetrafluoroborate salt in moist DMF, two of the cyanide groups in **L** are converted to carboxylic acid groups and bind the metal ion from outside. The $Cu^{II}$ ion in this complex shows distorted octahedral coordination where the two O atoms from the two carboxylic acid groups and the two corresponding N atoms in the two bridges are bound equatorially. The two axial sites are occupied by the nearby bridgehead N atom and the O atom of a DMF molecule. All five complexes and the free ligands are characterized by spectroscopic and X-ray crystallographic studies.

## Introduction

Macrobicyclic cryptands[1] possess several desirable properties, such as the topology of the donor atoms, binding-site rigidity, layer effects, and so forth, that determine stability, selectivity, and properties of their complexes with metal ions. One of the important factors in the formation of metal cryptates is the cryptand conformation equilibria. For cryptands with N bridgeheads, the principal conformers arise from different orientations of the lone pairs of the electrons on the bridgehead atoms.[2] Each lone pair may be oriented into the cavity (*endo*) or away from the cavity (*exo*). Therefore, it is easy to envision a minimum of three possible conformations for the nitrogen atoms as *exo-exo*, *exo-endo*, and *endo-endo*. The cryptand $\mathbf{L_o}$ (Figure 1) has a large cavity in which two distinct binding sites are separated by a hydrophobic spacer. The tren end ($N_4$ moiety) represents[1c,3] a suitable binding site for transition as well as main-group metal ions such as $Ni^{II}$, $Cu^{II}$, $Zn^{II}$, $Pb^{II}$, $Ag^{I}$, and so forth. The $NO_3$ moiety can be expected to be effective in binding harder cations. We were interested in observing any possible alteration in the coordinating ability of the cryptand when the donor ability of the nitrogen atoms was suppressed by attaching electron-withdrawing cyanomethyl groups to them (Figure 1). Tuning the stereoelectronic factors associated with the binding site has the ultimate aim of enforcing unusual coordination mode(s) on the metal ion besides potential applications associated with metal bind-

ing.[4–6] In the present study, $Cu^{II}$, $Ag^{I}$, and $Tl^{I}$ ions are used to probe the complexing ability of the cryptands.

## Results and Discussion

The structure of $\mathbf{L_o}$ has an *endo-exo* conformation in which the distance between the bridgehead N atoms is 6.272(12) Å (Figure 2). A pseudo threefold axis passes through the bridgehead N atoms.

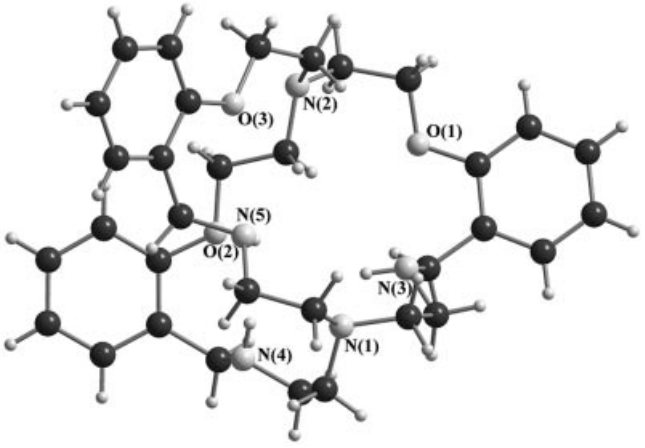

Figure 2. Perspective view of the cryptand $\mathbf{L_o}$.

For comparison, in the room-temperature structure of this cryptand,[7] the distance between the two bridgehead nitrogen atoms is 6.249(14) Å. The O···O and N···N nonbonding distances are also comparable between the two structures [$\mathbf{L_o}$ (LT) and $\mathbf{L_o}$ (RT)[7]]. Thus, temperature variation has little effect on cryptand conformation.

The asymmetric unit of **L** consists of a single strand of the cryptand and a water molecule. The nonbonding distances between two ethereal O atoms [4.72(1) Å] or two amino N atoms [4.29(1) Å] are the same because of crystallographically imposed symmetry. Therefore, in the solid state, the molecule has a threefold symmetry axis passing through the two bridgehead atoms. This cryptand has an *endo-endo* conformation in which the distance between the two bridgehead N atoms is 5.939(2) Å (Figure 3a). The shrinkage of the cryptand cavity relative to that of $\mathbf{L_o}$ may be due to a combination of delocalization of the electron density from the N atoms in the three bridges onto the cyanomethyl groups and the steric effects of these groups. The bond lengths and bond angles in the cryptand are within normal statistical errors. The $^1$H NMR spectroscopic data of **L** also indicate threefold symmetry in the molecule in $CDCl_3$. An interesting feature of this structure is the presence of a triangular planar trimeric water cluster, which shows positional disorder and can be described as two sets of triangular planar water clusters. Six cryptand molecules surround the water cluster (Figure 3b) where each water molecule shows a weak C–H···O hydrogen-bonding interaction [$d$(H···O) = 2.340(16) Å] with the nearest benzene group. The existence of aromatic C–H···O hydrogen bonds has been inferred from several theoretical[8] as well as experimental[9] studies in different organic crystal lattices.[10]

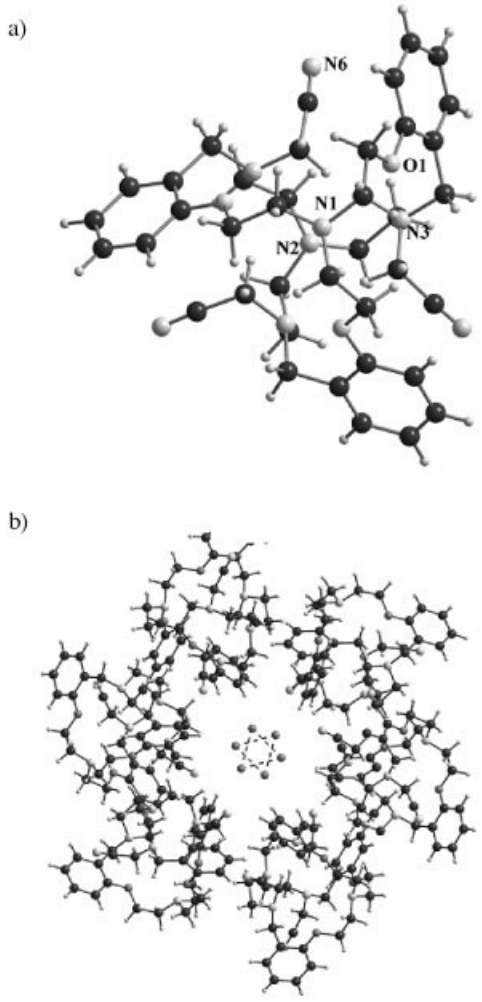

Figure 3. (a) Cryptand **L** viewed approximately along the threefold axis. (b) Packing of six **L** molecules around a cyclic water trimer. Two trimers are shown illustrating positional disorder.

The structure of complex **1** consists of an $[AgL]^+$cation and a nitrate anion. One molecule of methanol is also present in the lattice. The $Ag^{I}$ ion is bonded to four nitrogen atoms at the tren end of the cryptand and is positioned 0.71 Å above the plane described by three amino N atoms in the direction away from the bridgehead N atom (Figure 4). Thus, the coordination geometry is very distorted; all four nitrogen atoms are on one side of the metal ion. Such distorted geometry for an $Ag^{I}$ cryptate was reported[11] earlier. The bond lengths and angles involving the metal ion are similar to those found[11–13] in other Ag cryptates. The metal ion is more than 2.9(1) Å away from the ethereal oxygen atoms and so is considered to be nonbonded. The separation between the two bridgehead N atoms is found to be 5.983(7) Å, which is slightly less than the distance found in $\mathbf{L_o}$ (Table 1). The other N···N and O···O nonbonding distances do not vary appreciably upon metal binding, which means that the cryptand is mostly preorganized.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

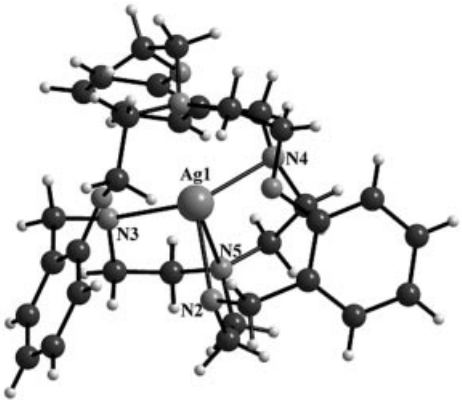

Figure 4. View of the $Ag^{I}$ ion bound at the tren end of the cavity in $\mathbf{L_o}$.

The structure of **2** shows that the $Ag^{I}$ ion is bonded inside the cavity of **L** in an unprecedented fashion (Figure 5). Here, either the electron-withdrawing groups attached to the amino groups make the lone pair unavailable for metal binding or the methylene group of the $-CH_2CN$ moiety near the aromatic group might prevent closer interaction between the amino nitrogen atom and a metal ion. However, the $Ag^{I}$ ion shows dicoordination, binding the two bridgehead N atoms at Ag–N distances of 2.325(8) and 2.388(8) Å and at an N–Ag–N angle of 167.7(10)°. Few two-coordinate $Ag^{I}$ complexes are known[14] in the literature with similar bond lengths and angles. The distance between the metal ion and any other N atoms in the three bridges is 2.82(6) Å or more, while the distance between the metal ion and an ethereal O atom is at least 2.63(5) Å; the metal ion may be considered to be semibonded to the oxygen atom. The bond lengths and bond angles of the cryptand moiety are within normal statistical errors. The two bridgehead N atoms are significantly pulled inside by the $Ag^{I}$ ion; the distance between them is 4.687(15) Å. A water dimer is also present in the lattice, which is hydrogen-bonded to the nitrate anion [O···Ow1 3.019(12) Å].

The unsubstituted cryptand $\mathbf{L_o}$ forms an inclusion complex with $Tl^{I}$ (complex **3**) in which the metal ion occupies a site at the tren end. The $Tl^{I}$ ion is in a "4+3" coordination environment with four normal[15] Tl–N bonds [2.788(8)–2.869(9) Å] and three long interactions [3.07(9)–3.14(9) Å]; the ethereal O atoms are in the cryptand side arms (Figure 6). However, the Tl–N bond lengths are at the long end of the range for Tl–N distances, and therefore are ionic in character,[15a,15b] although Tl–O bond lengths are comparable to literature values.[15f] In complex **4**, on the other hand, $Tl^{I}$ exhibits "3+5" coordination (Figure 7), which comprises three normal Tl–N bonds and five long interactions with the remaining donor atoms (Table 1). The Tl–N bond lengths are significantly increased relative to the values obtained for **3**. Hence, even though the $Tl^{I}$ ion is positioned at the tren end and bonds to the N atoms attached to the cyanomethyl groups, the bonding is weak and ionic in character. In either **3** or **4**, the metal ion is symmetrically bonded to N and O donors and the lone pair on $Tl^{I}$ does

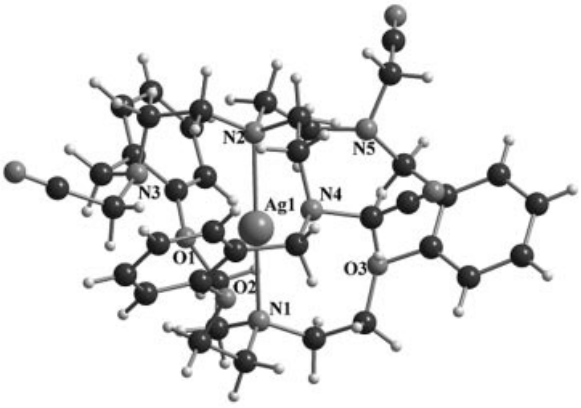

Figure 5. View of the $Ag^{I}$ ion bound to the two bridgehead N atoms in **L**. H atoms are omitted for clarity.

not seem to be stereochemically active.[16] When an equivalent amount of $AgNO_3$ is added to an acetonitrile solution of either **2** or **3**, the $Tl^{I}$ ion is quantitatively replaced by $Ag^{I}$-forming crystals of **1** or **2** overnight.

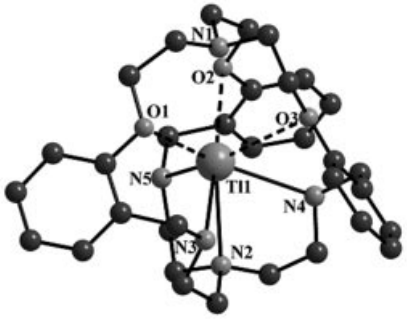

Figure 6. Perspective view of **3** showing the $Tl^{I}$ ion bound at the tren end of $\mathbf{L_o}$.

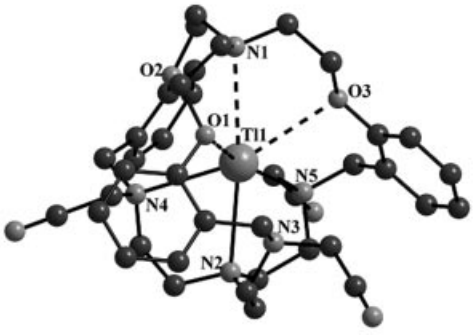

Figure 7. View of **4** showing the $Tl^{I}$ ion bound to three N atoms at the tren end of **L**.

The structure of **5** consists of discrete $[Cu(\mathbf{L}')(DMF)]^{2+}$ cations (Figure 8) and $BF_4^-$ anions. One DMF molecule is also present in the lattice. This structure reveals that two out of three cyano groups are hydrolyzed to carboxylic acid groups and bind a $Cu^{II}$ ion from outside at the tren end of the cavity. The H atoms bonded to the carboxylic acid groups could be easily found in the difference map. We speculate that $Cu^{II}$ initially binds the cryptand outside the cavity and activates the cyano group, which is then attacked by $H_2O$. Only two cyano groups are activated, as the third one is far away from the metal ion. However, the UV/Vis data for the hydrolysis of the cyano group taken at different intervals were not informative. Many metal-mediated processes of cyano group hydrolysis are known in the literature.[17] As a result of hydrolysis of the two cyano groups to carboxylic acid groups, the corresponding N atoms in the two bridges are no longer electron-deficient and bind the $Cu^{II}$ ion along with the two O atoms from the two carboxylic acid groups equatorially. The two axial sites are occupied by the nearby bridgehead N atom and the O atom of a DMF molecule, forming a distorted octahedral coordination geometry (Table 1) around the metal ion. The three N donors from the cryptand are inverted, their lone pairs being directed toward the metal ion, and the cryptand adopts an *exo-endo* conformation. The bond lengths and angles in the cryptand moiety are within normal statistical error, while those involving the metal ion (Table 1) are similar[18] to other $Cu^{II}$ cryptates.

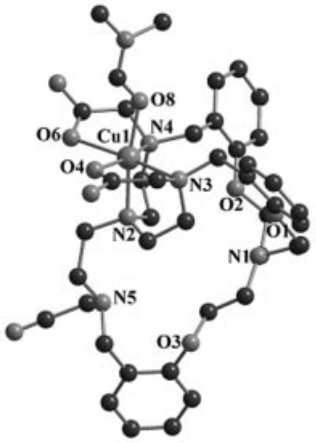

Figure 8. A view of the $Cu^{II}$ ion bound outside the cryptand cavity. Lattice DMF and H atoms bonded to C are omitted for clarity.

In the UV/Vis spectral studies, **5** shows a broad ligand-field band at 685 nm and a charge-transfer band at 325 nm, with molar extinction coefficients of 35 and 600 $cm^2 \cdot mol^{-1}$, respectively. The effective magnetic moment value ($\mu_{eff}/\mu_B$) for **3** after diamagnetic correction is found to be 2.02 at 293 K, which is consistent[19] with the discrete, mononuclear formulation of the complex. EPR spectral studies were carried out in the solid state and in DMF solution at 295 and 77 K. In the solid state at 295 K, a broad signal with $g_{av}$ = 2.09 is observed. The signal sharpens at 80 K without revealing any fine structure. In DMF solution at 80 K, an axial spectrum is obtained with $g_{\|}$ = 2.21, $g_{\perp}$ = 2.08, and $A_{\|} = 148 \times 10^{-4}$ $cm^{-1}$.

## Conclusion

We show here that, although the unsubstituted cryptand binds an $Ag^{I}$ ion inside the cavity without significant change of the cryptand conformation, it behaves very dif-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ferently when electron-withdrawing groups are attached to the amino nitrogen atoms in the three bridges. The amino nitrogen atoms lose their ability to bind $Ag^{I}$. Instead, the metal ion binds the two bridgehead N atoms, which is unprecedented. On the other hand, the $Tl^{I}$ ion forms an inclusion complex with $\mathbf{L_o}$, in which the metal ion occupies the tren end of the cavity and is ligated by all four N atoms. With **L**, $Tl^{I}$ still occupies the same end of the cavity but is loosely bound to three N atoms and can be readily replaced by $Ag^{I}$. In the case of $Cu^{II}$, two of the cyano groups are hydrolyzed to carboxylic acid groups at room temperature. This change restores the donor ability of the amino N atoms and the cryptand binds a $Cu^{II}$ ion outside the cavity in a distorted octahedral fashion. We are presently probing whether it is possible to have mixed-metal complexes with this and other related cryptands.

## Experimental Section

**Materials:** All reagent-grade chemicals were used without purification unless otherwise specified. The metal salts, bromoacetonitrile, and tris(2-aminoethyl)amine were obtained from Aldrich. Triethanolamine, salicylaldehyde, sodium borohydride, sodium hydroxide, anhydrous sodium sulfate, potassium carbonate, thionyl chloride, and solvents were received from S. D. Fine Chemicals (India). Thionyl chloride and all the solvents were freshly distilled prior to use, and all the reactions were carried out under $N_2$.

**Physical Measurements:** Spectroscopic data were collected as follows: IR (KBr disk, 400–4000 $cm^{-1}$) Perkin–Elmer Model 1320; $^1H$ NMR ([$D_6$]DMSO, TMS) JEOL JNM-LA400 FT, 400 MHz. FAB MS (positive ion, argon as the FAB gas, 6 kV, 10 mA, 10 kV accelerating voltage) JEOL SX 102/DA-6000. Magnetic susceptibility measurements were made by using a Cahn Faraday Balance with [$CoHg(SCN)_4$] as the standard and applying diamagnetic corrections as described earlier.[18] The EPR spectrum for complex **3** was recorded at X-band frequency with a BRUKER 300E automatic spectrometer at 298 and 80 K. Melting points were determined with an electrical melting point apparatus by PERFIT, India, and were uncorrected. Elemental analyses were obtained from CDRI, Lucknow.

### Synthesis

**Cryptand $\mathbf{L_o}$:** It was synthesized as reported[7] earlier. Single crystals suitable for X-ray crystallography were grown by slow concentration of an acetonitrile solution at room temperature.

**Cryptand L:** Cryptand $\mathbf{L_o}$ (1 g, 1.78 mmol) was added to a suspension of anhydrous potassium carbonate (0.86 g, 6.25 mmol) in dry acetonitrile (100 mL). The solution was stirred at 30 °C. After 30 min, bromoacetonitrile (0.42 mL, 6.25 mmol) was added to the stirred solution. The mixture was stirred at 30 °C for 24 h, and the solvent was removed completely in a rotary evaporator. The black solid that remained was shaken with water and then extracted with chloroform (3 × 50 mL). The chloroform layer, after being decolorized with activated charcoal and dried with anhydrous sodium sulfate, was concentrated completely to yield a yellowish white solid as the desired product. It was purified further by crystallization from dichloromethane to obtain colorless crystals in the form of rectangular parallelepipeds. Yield ca. 85% (1.02 g). M.p. 160 °C. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C, TMS): aliphatic: δ = 2.65 (dd, $J$ = 22.12, 5.4 Hz, 12 H), 3.18 (t, $J$ = 5.32 Hz, 6 H), 3.46 (s, 6 H), 3.52 (s, 6 H), 4.06 (t, $J$ = 5.12 Hz, 6 H); aromatic: δ = 6.78 (d, $J$ = 8.04 Hz, 3 H), 6.93 (t, $J$ = 7.32 Hz, 3 H), 7.14–7.26 (m, 6 H) ppm. FAB-MS: $m/z$ (%) = 677 $[\mathbf{L}]^+$ (100). $C_{39}H_{48}N_8O_3$ (678): calcd. C 69.21, H 7.15, N 16.56; found C 69.28, H 7.21, N 16.67.

**$[Ag(L_o)]\cdot(NO_3)\cdot CH_3OH$ (1):** Cryptand $\mathbf{L_o}$ (0.56 g, 1 mmol) in dry methanol (5 mL) was added at once to an acetonitrile solution (5 mL) of $AgNO_3$ (0.17 g, 1 mmol) at room temperature in the dark. The light brown solution formed was filtered and the filtrate stored in the dark for crystallization. Colorless X-ray quality crystals in the form of rectangular parallelepipeds appeared in about 2 d. Yield ca. 35% (0.67 g). $C_{34}H_{49}AgN_6O_7$ (761.66): calcd. C 53.61, H 6.48, N 11.034; found C 53.43, H 6.52, N 10.98.

**$[Ag(L)]\cdot(NO_3)\cdot 2H_2O$ (2):** Cryptand **L** (0.68 g, 1 mmol) in dry acetonitrile (5 mL) was added to an acetonitrile solution (5 mL) of $AgNO_3$ (0.17 g; 1 mmol) at room temperature in the dark. The light brown solution was filtered and the filtrate kept for crystallization. Colorless, X-ray-quality, square crystals appeared in 3 d. Yield ca. 55% (0.47 g). $C_{39}H_{52}AgN_9O_8$ (882.75): calcd. C 53.06, H 5.93, N 14.28; found C 52.92, H 5.90, N 14.13.

**$[Tl(L_o)](CH_3OH)(ClO_4)$ (3):** The cryptand $\mathbf{L_o}$ (0.56 g, 1 mmol) dissolved in dry methanol (5 mL) was added all at once to a $CH_3CN$ solution (3 mL) of $Tl(ClO_4)\cdot xH_2O$ (0.36 g, 1.2 mmol) at room temperature in the dark. A brown solution was obtained that was filtered, and the filtrate was stored at room temperature while the solvent evaporated. White X-ray-quality rectangular crystals of **4** appeared in about 2 d. Yield ca. 50% (0.45 g). $C_{34}H_{49}Cl_1N_5O_8Tl$ (895.62): calcd. C 45.60, H 5.51, N 7.82; found C 45.78, H 5.38, N 7.40.

**$[Tl(L)](H_2O)(ClO_4)$ (4):** Cryptand **L** (0.68 g; 1 mmol) in dry acetonitrile (5 mL) was added to an acetonitrile solution (5 mL) of $Tl(ClO_4)\cdot xH_2O$ (0.36 g, 1.2 mmol) at room temperature in the dark. The light brown solution was filtered and the filtrate kept for crystallization. Colorless, X-ray-quality, square crystals appeared in 3 d. Yield ca. 55% (0.55 g). $C_{39}H_{50}Cl_1N_8O_8Tl$ (998.70): calcd. C 46.90, H 5.05, N 11.22; found C 49.75, H 5.11, N 11.09.

**$[Cu(L')(DMF)]\cdot(BF_4)_2\cdot DMF$ (5):** Cryptand **L** (0.68 g, 1 mmol), dissolved in dry DMF (3 mL) was added all at once to a DMF solution (3 mL) of $Cu(BF_4)_2\cdot xH_2O$ (0.23 g, 1.2 mmol) at room temperature. A blue-green solution was obtained that was filtered and the filtrate was stored at room temperature while the solvent evaporated. Blue-green, X-ray-quality, rectangular crystals of **5** appeared in about 7 d. Yield ca. 50% (0.55 g). $C_{45}H_{64}CuN_8O_9(BF_4)_2$ (1098.2): calcd. C 49.21, H 5.87, N 10.20; found C 49.44, H 5.99, N 10.38.

**X-ray Structural Studies:** Single-crystal X-ray data were collected at 100 K with a Bruker SMART APEX CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The linear absorption coefficients, scattering factors for the atoms, and the anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography. Data integration and reduction were processed with the SAINT[20] software. The structure was solved by direct methods using SHELXTL and was refined on $F^2$ by full-matrix least-squares techniques using the SHELXL-97 program[21] package. All non-hydrogen atoms were refined anisotropically except C(33) of compound **1**, which was refined isotropically. All hydrogen atoms were located in successive difference Fourier maps and they were treated as riding atoms by using SHELXL default parameters. The crystal data for the structures are collected in Tables 1 and 2. CCDC-290844 to -290850 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.ac.uk/data_request/cif.

# Phosphanylborohydrides: First Assessment of the Relative Lewis Basicities of $[BH_3PPh_2]^-$, $CH_3PPh_2$, and $HPPh_2$

**Franz Dornhaus,[a] Michael Bolte,[a] Hans-Wolfram Lerner,[a] and Matthias Wagner*[a]**

**Keywords:** P Ligands / Phosphanylborohydride / Ligand design / Donor–acceptor systems / Isoelectronic analogues

The compounds $K[PPh_2]$, $HPPh_2$, $CH_3PPh_2$, $BH_3(H)PPh_2$, $BBr_3(H)PPh_2$, $BH_3(CH_3)PPh_2$, $BBr_3(CH_3)PPh_2$, $[H_2PPh_2]I$, $[CH_3(H)PPh_2]I$, $[(CH_3)_2PPh_2]I$, and $K[(BH_3)_2PPh_2]$ have been investigated by NMR spectroscopy. In addition, X-ray crystal structures have been determined for K(18-crown-6)$[PPh_2]$, $BBr_3(H)PPh_2$, $BBr_3(CH_3)PPh_2$, $[H_2PPh_2]I$, $[CH_3(H)PPh_2]I$, $[(CH_3)_2PPh_2]I$, and K(18-crown-6)$[(BH_3)_2PPh_2]$. An evaluation of coupling constants (e.g. $^1J_{PC_i}$; $C_i$ = *ipso* carbon atom of a phenyl ring) augmented by an inspection of key structural parameters (e.g. the angles $C_i$–P–$C_i'$) leads to the conclusion that dative bonds originating from ligand $[BH_3PPh_2]^-$ possess a significantly higher p character than dative bonds involving the ligands $HPPh_2$ and $CH_3PPh_2$. The $^1J_{PB}$ values obtained for $BH_3(H)PPh_2$, $BH_3(CH_3)PPh_2$, and $[(BH_3)_2PPh_2]^-$ suggest $[BH_3PPh_2]^-$ to form the strongest $[BH_3]$ adduct of all three compounds which is in agreement with the results of displacement reactions employing the couples $CH_3PPh_2$/$[(BH_3)_2PPh_2]^-$ and $[BH_3PPh_2]^-$/$BH_3(CH_3)PPh_2$.

## Introduction

Organophosphanes have been extensively studied as ligands to both main group Lewis acids and transition metals in order to unveil the factors governing the stability and reactivity of coordination complexes.[1] In the course of these studies it soon became apparent that phosphanes may not generally be viewed as simple σ donors because often an intricate interplay exists between the P → M σ interaction and an M → ligand π back-donation. The π acceptor strength of $PF_3$, for example, is comparable to that of CO, commonly regarded as the archetypical π acceptor ligand. If, on the other hand, electropositive substituents are attached to the phosphorus atom, one would expect an increase in Lewis basicity likely together with a decrease in π acidity of the respective phosphane molecule. One way to test this assumption is through replacement of alkyl groups on phosphorus by borane moieties. Using parent $[BH_3]$, we thereby arrive at a class of anionic species $[BH_3PRR']^-$ which are the heavier homologues of the better-known aminoborohydrides $[BH_3NRR']^-$.[2] Until today, phosphanylborohydrides $[BH_3PRR']^-$ have mainly been generated in situ and used as building blocks for the preparation of chiral organophosphanes.[3–6] Moreover, aiming at the synthesis of polymeric materials involving group 13 and group 15 elements, Manners and co-workers have recently employed the compound $Li[BH_3PPh_2]$ in the preparation of linear hybrid aminoborane/phosphanylborane chains.[7] The same group has also reported on the synthesis of the platinum phosphanylborohydride complexes *trans*-$[PtH(BH_3PPhR)(PEt_3)_2]$ (R = H, Ph) by the regioselective insertion of the $Pt(PEt_3)_2$ fragment into the P–H bond of $BH_3(H)_2PPh$ or $BH_3(H)PPh_2$.[8] Other examples of structurally characterised phosphanylborohydride complexes include the compounds $[(dppp)Pd(C_6F_5)(BH_3PPh_2)]$[9] and $[(C_5Me_5)Fe(CO)_2(BH_3PPh_2)]$.[10] Finally, Müller et al. have explored the complexation potential of $[BH_3P(CH_3)_2]^-$ and $[BH_3P(Ph)tBu]^-$ toward lithium and aluminium.[11]

In a 1996 paper, Fu et al. described diphenylphosphidoboratabenzene, $[(BC_5H_5)PPh_2]^-$, as anionic analogue of the ubiquitous triphenylphosphane ligand and explored its coordination chemistry.[12] Stimulated by their investigations, our group embarked on a systematic study of the ligand properties of anionic phosphanylborohydrides $[BH_3PRR']^-$ in comparison to their neutral isoelectronic and isostructural methyl analogues $CH_3PRR'$. For a start, we are focusing on compounds in which the phosphorus atom is exclusively engaged in σ bonds. Effects of π bonding will be considered at a later stage. All compounds under investigation here are based on the $PPh_2$ fragment (Figure 1). The series of derivatives starts with the $[PPh_2]^-$ ion ($K[PPh_2]$, **1**) and continues with the phosphanes $HPPh_2$ (**2**) and $H_3CPPh_2$ (**3**), followed by their complexes with the main group Lewis acids $[BH_3]$, $H^+$, and $[CH_3]^+$ (cf. **4H**, **5H**, and **6**–**8**). As we were not able to grow X-ray quality crystals of the $[BH_3]$ adducts **4H** and **5H**, the corresponding $BBr_3$ ad-

ducts **4Br** and **5Br** were structurally characterised instead. The series closes with the anionic species $K[(BH_3)_2PPh_2]$ (**9**).

Figure 1. The potassium phosphide **1**, the phosphanes **2**, **3**, and the phosphane adducts **4**–**9**.

With this selection of molecules it is possible to study systematic trends in NMR- and structural parameters (i) upon increasing the coordination number of phosphorus from two to three and four (e.g. $[PPh_2]^-$ vs. $HPPh_2$ vs. $[H_2PPh_2]^+$) and (ii) by comparing isoelectronic and isostructural species of different charge (e.g. $[(BH_3)_2PPh_2]^-$ vs. $[(CH_3)_2PPh_2]^+$). It is to be mentioned that some of the compounds under investigation here are already known in the literature (see below). However, crystal structure analyses were missing and even though selected NMR spectroscopic data have been reported, measurement conditions vary to such an extent that a re-investigation using the same solvent and (in the case of **6**–**8**) counterion was inevitable, because these can greatly influence the chemical shift values.[13]

## Results and Discussion

**Syntheses:** $K[PPh_2]$ (**1**) was prepared through deprotonation of $HPPh_2$ (**2**) with potassium metal in THF. $BH_3(H)PPh_2$ (**4H**) is accessible from $HPPh_2$ (**2**) and $B_2H_6$.[14] However, we preferred to use a calibrated solution of $BH_3$·THF in THF which is more convenient to handle. $BBr_3(H)PPh_2$ (**4Br**) was synthesised from $HPPh_2$ (**2**) and $BBr_3$ following a published procedure.[14] $BH_3(CH_3)PPh_2$ (**5H**) is formed similar to $BH_3(H)PPh_2$ (**4H**) upon treatment of $CH_3PPh_2$ (**3**) with $BH_3$·THF in THF (Manners et al. have used $BH_3$·$SMe_2$ instead[7]). An alternative route to **5H** employs $ClPPh_2$ as starting material which is first methylated with MeMgI and subsequently borylated with $NaBH_4/I_2$.[15] $BBr_3(CH_3)PPh_2$ (**5Br**) was synthesised from $CH_3PPh_2$ (**3**) and $BBr_3$ following a published procedure.[16] The phosphonium iodide salts $[H_2PPh_2]I$ (**6**) and $[CH_3(H)PPh_2]I$ (**7**) were prepared by treatment of $HPPh_2$ (**2**) and $CH_3PPh_2$ (**3**) with excess HI in toluene; for the syntheses of $[CH_3(H)PPh_2]Br$ and $[(CH_3)_2PPh_2]I$ (**8**) see refs.[17,18] The synthesis of $K[(BH_3)_2PPh_2]$ was accomplished by deprotonation of $BH_3(H)PPh_2$ (**4H**) with KH and subsequent addition of $BH_3$·THF in THF.

In the following, all compounds under investigation will be viewed as adducts between the Lewis bases $HPPh_2$ (**2**), $CH_3PPh_2$ (**3**), and $[BH_3PPh_2]^-$ with the Lewis acids $H^+$, $[BH_3]$, $BBr_3$, and $[CH_3]^+$.

**X-ray Crystallography:** Single crystals of the potassium salts **1** and **9** were obtained only after potassium complexation with 18-crown-6. The compounds K(18-crown-6)$[PPh_2]$ and K(18-crown-6)$[(BH_3)_2PPh_2]$ will be referred to as **1c** and **9c**, respectively. Selected bond lengths and angles of compounds **1c**, **4Br**, **5Br**, **6**, **7**, **8**, and **9c** are compiled in Table 1.

The potassium diphenylphosphide K(18-crown-6)$[PPh_2]$ (**1c**) crystallises from THF in the monoclinic space group $P2_1/n$ (Figure 2).

The asymmetric unit of **1c** contains two formula units and features diphenylphosphide anions in distinctly different chemical environments: The first $[PPh_2]^-$ fragment coordinates to two potassium counterions with bond lengths P(1)–K(1) and P(1)–K(1A) of 3.347(1) Å and 3.267(1) Å, respectively (sum of the ionic radius of $K^+$ and the van-der-Waals radius of phosphorus: 3.55 Å[19]). Each potassium centre is encapsulated by one crown ether ligand; in addition, a relatively short intermolecular contact is established between K(1A) and one phenyl ring [K(1A)···C(25A) = 3.518(2) Å]. The bond angles around the phosphorus atom P(1) cover the wide range from 84.0(1)° for C(21)–P(1)–K(1A) to 150.1(1)° for K(1)–P(1)–K(1A). However, the angle defined by the two phenyl *ipso*-carbon atoms and the phosphorus atom is close to the ideal tetrahedral angle of 109.5° [C(21)–P(1)–C(31) = 107.1(1)°]. A largely two-coordinate phosphorus atom is found in the second $[PPh_2]^-$ ion [shortest P(1A)···K contact: 5.918 Å]. Nevertheless, both the P–$C_i$ bond lengths ($C_i$ = *ipso* carbon atom of a phenyl ring) and the $C_i$–P–$C_i'$ bond angles of the two different $PPh_2$ fragments are almost identical within experimental error [C(21A)–P(1A)–C(31A) = 108.3(1)°; Table 1]. Two other adducts of $K[PPh_2]$ have previously been characterised, the *N*,*N*,*N*′,*N*′′,*N*′′-pentamethyldiethylenetriamine complex $\{K(pmdta)[PPh_2]\}_n$[20] and the 1,4-dioxane complex $\{K(dioxane)_2[PPh_2]\}_n$.[21] Most notably, Eaborn, Smith

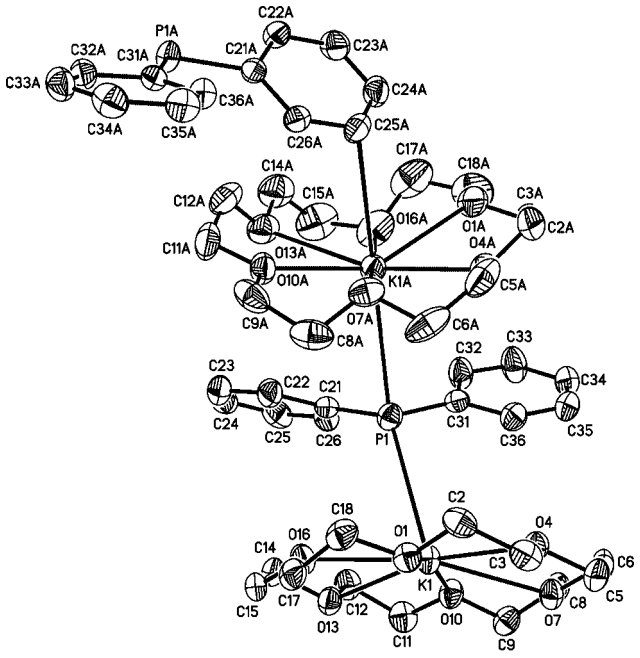

Figure 2. Molecular structure and numbering scheme of compound **1**[c]; thermal ellipsoids shown at the 50% probability level; hydrogen atoms omitted for clarity. Selected bond lengths [Å] and bond angles [°]: P(1)–C(21) = 1.815(2), P(1)–C(31) = 1.811(2), P(1A)–C(21A) = 1.817(2), P(1A)–C(31A) = 1.807(2), P(1)–K(1) = 3.347(1), P(1)–K(1A) = 3.267(1), K(1A)···C(25A) = 3.518(2); C(21)–P(1)–K(1A) = 84.0(1), K(1)–P(1)–K(1A) = 150.1(1), C(21)–P(1)–C(31) = 107.1(1), C(21A)–P(1A)–C(31A) = 108.3(1).

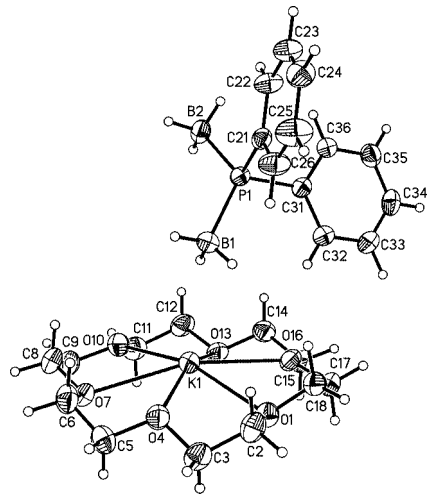

Figure 3. Molecular structure and numbering scheme of compound **9**[c]; thermal ellipsoids shown at the 50% probability level. Selected bond lengths [Å] and bond angles [°]: P(1)–B(1) = 1.930(2), P(1)–B(2) = 1.940(2), P(1)–C(21) = 1.829(2), P(1)–C(31) = 1.831(2), C(34)–K(1)$^{\#}$ = 3.372(2), K(1)–H(1A) = 2.683, K(1)···H(1B) = 3.452, K(1)–H(1C) = 3.003, B(1)···K(1) = 3.205; B(1)–P(1)–B(2) = 116.3(1), C(21)–P(1)–C(31) = 100.2(1). Symmetry transformation used to generate equivalent atoms: $x$, $-y + 1/2$, $z - 1/2$ ($^{\#}$).

et al.[22] have determined the crystal structure of solvent-free $\{K[PPh_2]\}_n$ which contains seven molecules in the asymmetric unit.

ORTEP drawings of the molecular structures of the boron–phosphorus adducts $(BBr_3)HPPh_2$ (**4Br**) and $BBr_3(CH_3)PPh_2$ (**5Br**) as well as of the phosphonium salts $[H_2PPh_2]I$ (**6**), $[CH_3(H)PPh_2]I$ (**7**), and $[(CH_3)_2PPh_2]I$ (**8**)[18,23] can be found in the Supporting Information. In all these compounds, the phosphorus atom is surrounded by four substituents. Important bond lengths and angles for comparison are listed in Table 1. In the case of **6** and **7**, the iodide ions are part of a complex network of P–H···I and Ph–H···I hydrogen bridges.

The phosphanylborohydride adduct K(18-crown-6)-$[(BH_3)_2PPh_2]$ (**9**[c]) crystallises in the monoclinic space group $P2_1/c$ (Figure 3).

Each $K^+$ ion is complexed by six oxygen atoms of a crown ether molecule and establishes two short and one significantly longer contact to the hydrogen atoms of one $[BH_3]$ fragment [K(1)–H(1A) = 2.683 Å, K(1)–H(1C) = 3.003 Å, K(1)···H(1B) = 3.452 Å]. Using Edelstein's correlation[24] of metal–boron distances as a measure of the denticity of borohydride groups, values of 1.6 ± 0.1 Å and 1.36 ± 0.06 Å are estimated for the ionic radii of bidentate and tridentate borohydride ligands, respectively. Thus, B···K distances of about 3.25 Å and 3.01 Å are to be expected for K-$\mu_2$-$BH_3R$ and K-$\mu_3$-$BH_3R$ coordination modes (ionic radius of octacoordinated $K^+$ = 1.65 Å[25]). Since the B(1)···K(1) distance in **9**[c] amounts to 3.205 Å, it may be concluded that $[(BH_3)_2PPh_2]^-$ acts as bidentate ligand toward the potassium cation which is the most common binding mode in metal borohydrides.[24] Further short contacts between the phenyl carbon atom C(34) and the neighbouring potassium ion K(1)$^{\#}$ [C(34)–K(1)$^{\#}$ = 3.372(2) Å] stabilize the molecular packing as zig-zag chains in the crystal lattice (Figure 4).

Looking at the series of compounds **1**[c], **4Br**, **5Br**, **6**, **7**, **8**, and **9**[c], it is our goal to find out whether differences in the electron-density distribution at phosphorus can be correlated to systematic trends in the key structural parameters of these molecules (cf. Table 1). To this end we are considering the P–$C_i$ bond lengths and the $C_i$–P–$C_i'$ bond angles of the $PPh_2$ fragments first. According to Bent's rule,[26] a tetracoordinate atom A directs hybrids of greater p character toward more electronegative substituents S and S′ which in turn leads to smaller S–A–S′ bond angles. In this context, lone pairs on atoms not involved in multiple bonds are in a first approximation viewed as residing in tetrahedral hybrid orbitals. Deviations from perfect $sp^3$ hybridisation that occur are in a direction that concentrates s character in the lone-pair orbitals. This effect normally becomes more pronounced as the number of unshared electron pairs about the heavy atom increases.[26]

The $K^+$-coordinated $[PPh_2]^-$ ion of **1**[c] shows a more acute $C_i$–P–$C_i'$ angle [107.1(1)°] than the free $[PPh_2]^-$ ion [108.3(1)°], however, the actual difference of 1.2(1)° is very small. One reason for this seeming violation of Bent's rule could be that the interaction of P(1) with the two potassium ions is merely electrostatic in nature and thus has no pronounced effect on the orbital composition of the phosphorus atom. In the case of the two $BBr_3$ adducts **4Br** and **5Br**,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

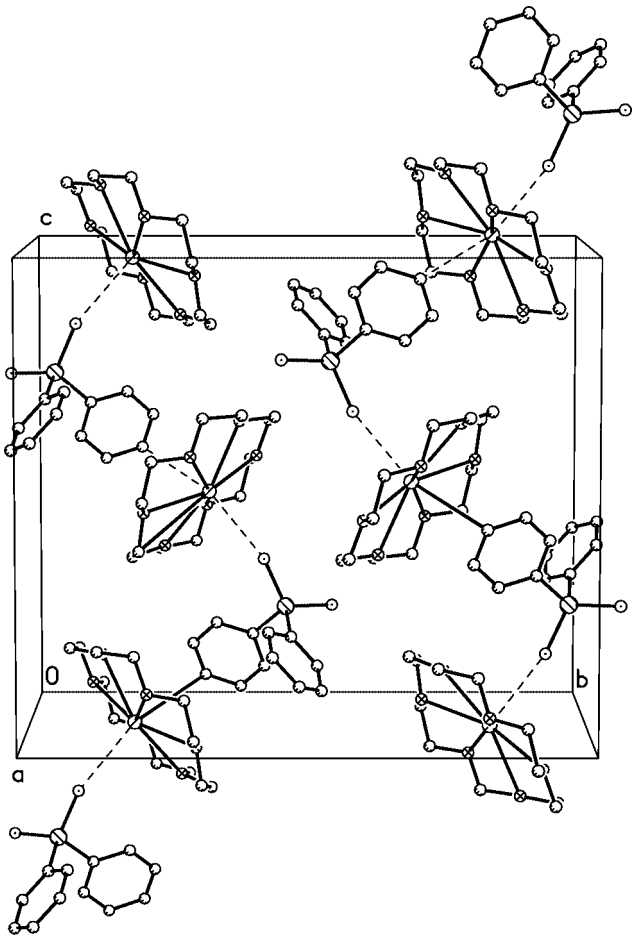

Figure 4. Crystal packing diagram of compound **9c**.

we find a significantly smaller $C_i$–P–$C_i'$ angle for the methyl derivative [**4Br**: 110.8(2)°, **5Br**: 106.5(5)°]. Given the well-known positive inductive effect of the $CH_3$ substituent, this indicates a higher p character in the P–Ph bonds of **5Br** than in those of **4Br**. Within the series **6** → **7** → **8**, only small differences between the individual $C_i$–P–$C_i'$ angles are observed, which, moreover, do not follow a systematic trend since the respective angle in the mixed compound **7** does not interpolate that of the doubly protonated molecule **6** and the doubly methylated compound **8**. By far the most pronounced deviation of $C_i$–P–$C_i'$ from the ideal tetrahedral angle is observed in the adduct K(18-crown-6)-$[(BH_3)_2PPh_2]$ (**9c**). In line with Bent's rule, the value of 100.2(1)°, as compared to 107.6(2)° in $[(CH_3)_2PPh_2]I$ (**8**), points towards a high degree of p character in the P–$C_i$ bond orbitals of **9c**. This interpretation is supported by the fact that the corresponding P–$C_i$ bond lengths are significantly elongated [cf. **9c**: 1.829(2) Å/1.831(2) Å; **8**: 1.794(3) Å]. In contrast to a priori expectations, they are even longer and the $C_i$–P–$C_i'$ angle is more acute than in the potassium phosphide **1** [1.807(2) Å to 1.817(2) Å; average value for $C_i$–P–$C_i'$: 107.7°].

**NMR Spectroscopy:** The most characteristic NMR parameters of the compounds **1**–**9** are compiled in Table 2.

For comparability and solubility reasons, all NMR spectra were run at ambient temperature (300 K). However, as $[H_2PPh_2]I$ (**6**) appeared to be largely dissociated in $CDCl_3$ solution under these conditions, the compounds **6** and **7** have also been investigated at low temperature (233 K) in order to shift the dissociation–association equilibrium to the adduct side (low-temperature data included in Table 2). In order to assess the relative degree of s and p character in the P–E bonding orbitals (E = H, C, B), we will mainly rely on the corresponding $^1J_{PE}$ coupling constants. Common wisdom has it that NMR coupling constants via a certain bond are governed by the Fermi contact term, which increases with increasing s character of the respective bond. We are aware of the fact that $^1J_{PE}$ values may change their sign upon going from one compound to another. In such cases, a correlation of $^1J_{PE}$ with the s character of the P–E bond is not possible until the signs of the coupling constants are known. We have not determined any relative sign data, however, it is firmly established in the literature that $^1J_{PB}$ coupling constants in phosphane–boranes[27] as well as $^1J_{PH}$ coupling constants[28] are generally positive. $^1J_{PC}$ coupling constants tend to be negative in three-coordinate phosphanes (cf. $PPh_3$: $^1J_{PC}$ = –12.5 Hz) and positive in compounds containing four-coordinate phosphorus centres (cf. $[PPh_4]^+$: $^1J_{PC}$ = +88.4 Hz).[28] For a detailed description

Table 2. Selected NMR parameters of compounds **1**–**9**; solvents: THF (**1**–**5Br**, **9**), $CDCl_3$ (**6**–**8**); upfield shifts are denoted by a minus sign and downfield shifts by a plus sign.

of the effect of electron lone pairs on nuclear spin–spin coupling constants, the reader is referred to the work of Gil and Philipsborn.[29]

At first, we are considering systematic changes in the NMR parameters of the three Lewis bases $HPPh_2$ (**2**), $CH_3PPh_2$ (**3**), and $[BH_3PPh_2]^-$ upon variation of the coordinated acid. Drake et al. have determined the P–H proton chemical shifts for five series of $BX_3$–P(H)RR′ adducts (R/R′ = H/H, $CD_3$/H, $CD_3$/$CD_3$, Ph/H, Ph/Ph; X = F, Cl, Br, I).[14] As a general trend within any of the five groups, the shielding of the proton on phosphorus was found to decrease in a manner parallel to the accepted order of Lewis acidity ($BF_3 < BCl_3 < BBr_3 < BI_3$). Consistently, we observe a downfield shift of the P–*H* resonance along the series $P(H)Ph_2$ (**2**; $\delta$ = 5.11) → $BH_3$–P(H)$Ph_2$ (**4H**; $\delta$ = 6.16) → $BBr_3$–P(H)$Ph_2$ (**4Br**; $\delta$ = 6.97) → $[CH_3$–P(H)$Ph_2]^+$ (**7**; $\delta$ = 9.87) → $[H$–P(H)$Ph_2]^+$ (**6**; $\delta$ = 9.91). Parallel to that, $^1J_{PH}$ becomes larger, thereby indicating an increasing degree of s character in the P–H bond. Moreover, the absolute value of the coupling constant $^1J_{PCi}$ between phosphorus and the *ipso* carbon atoms of the attached phenyl rings also increases in the same order: **2** (10.7 Hz) < **4H** (56.2 Hz) < **4Br** (65.7 Hz) < **7** (85.4 Hz) ≈ **6** (83.0 Hz). A similar trend in the $^1J_{PC}$ values of the P–$CH_3$ and the P–Ph fragments is evident within the series of methylphosphane adducts: **3** < **5H** < **5Br** < **7** < **8** (Table 2). Thus, there is obviously an increase in s character in the P–H and P–C bonding orbitals of **2** and **3** upon adduct formation. Concomitantly, an increase in the p character of the phosphorus lone pair has to be postulated as it becomes involved in dative bonding. In line with the isovalent hybridisation hypothesis,[26] the p character of the donor-acceptor bond is more pronounced when more Lewis acidic electrophiles are coordinated. Of special interest is an evaluation of the characteristic NMR parameters of the isoelectronic donors $P(CH_3)Ph_2$ (**3**) and $[P(BH_3)Ph_2]^-$ after coordination of $[BH_3]$, $H^+$, and $[CH_3]^+$, respectively. As far as the $^{31}P$–$^{13}C_i$ coupling constants are concerned, we obtain qualitatively similar results for both ligands with $^1J_{PCi}$ being consistently smaller in the $[BH_3]$ adducts as compared to the protonated or methylated derivatives {cf. $K[BH_3$–P(B$H_3$)$Ph_2]$ (**9**), H–P(B$H_3$)$Ph_2$ (**4H**), $CH_3$–P(B$H_3$)$Ph_2$ (**5H**): $^1J_{PCi}$ = 38.5 Hz, 56.2 Hz, 54.8 Hz; $BH_3$–P(C$H_3$)$Ph_2$ (**5H**), $[H$–P(C$H_3$)$Ph_2]$I (**7**), $[CH_3$–P(C$H_3$)$Ph_2]$I (**8**): $^1J_{PCi}$ = 54.8 Hz, 85.4 Hz, 87.6 Hz}.

The $^{31}P$ NMR resonances within the series $P(H)Ph_2$ (**2**), $BH_3$–P(H)$Ph_2$ (**4H**), $BBr_3$–P(H)$Ph_2$ (**4Br**), and $[CH_3$–P(H)$Ph_2]$I (**7**) possess chemical shift values of $\delta$ = –39.5 ppm, 1.7 ppm, –13.6 ppm, and –5.2 ppm, respectively (Table 2). This observation is in agreement with the known fact that in most cases quaternisation of phosphanes leads to a downfield shift of the $^{31}P$ NMR signal as the shielding effect of the lone pair is removed.[13] Deshielding is most pronounced after coordination of the isoelectronic and isosteric Lewis acids $[BH_3]$ and $[CH_3]^+$. Adduct formation of $P(H)Ph_2$ with $BBr_3$ leads to a smaller downfield shift. Within the series of $P(CH_3)Ph_2$ adducts, the following $^{31}P$ NMR shifts are observed (Table 2): **3** ($\delta$ = –26.1), **5H** ($\delta$ = 11.5), **5Br** ($\delta$ = –9.2), **8** ($\delta$ = 21.9). Thus, substitution of P–*CH*$_3$ for P–*H* results in a general deshielding of the respective $^{31}P$ nucleus. The isosteric couples **4H/7**, **5H/8**, and **8/9** deserve special attention. The $^{31}P$ NMR resonance of H–P(B$H_3$)$Ph_2$ (**4H**) is shifted by 6.9 ppm to lower field as compared to the resonance of $[H$–P(C$H_3$)$Ph_2]$I (**7**). However, this order is reversed and the absolute difference increases ($\Delta\delta$ = –10.4) in the case of $CH_3$–P(B$H_3$)$Ph_2$ (**5H**; $\delta$ = 11.5) vs. $[CH_3$–P(C$H_3$)$Ph_2]$I (**8**; $\delta$ = 21.9). Finally, the largest shift difference ($\Delta\delta$ = –33.0) is found between $K[BH_3$–P(B$H_3$)-$Ph_2]$ (**9**; $\delta$ = –11.1) and $[CH_3$–P(C$H_3$)$Ph_2]$I (**8**; $\delta$ = 21.9).

$^{11}B$ NMR spectroscopy reveals a slight downfield shift of the boron nucleus upon going from **4H** ($\delta$ = –40.0) to **5H** ($\delta$ = –37.9) and **9** ($\delta$ = –34.6). A qualitatively similar effect is observed for the couple **4Br/5Br** (Table 2).

In the second stage, we will now consider three groups of aggregates of the ligands $P(H)Ph_2$ (**2**), $P(CH_3)Ph_2$ (**3**), and $[P(BH_3)Ph_2]^-$ in which the Lewis acid is kept constant (Figure 5). Special emphasis is placed on the $^1J_{DA}$ coupling constants (D and A = donor and acceptor nuclei, respectively) because they are a property of the donor–acceptor bond in question and thus likely to provide insight into the relative base strengths of the three phosphorus donors. The proton adducts (series a, Figure 5) show similar $^1J_{PH}$ values for the $P(H)Ph_2$ and $P(CH_3)Ph_2$ ligand and a much smaller value in H–P(B$H_3$)$Ph_2$. The same is true for $^1J_{PC}$ in the $[CH_3]^+$ adducts of series b (Figure 5).

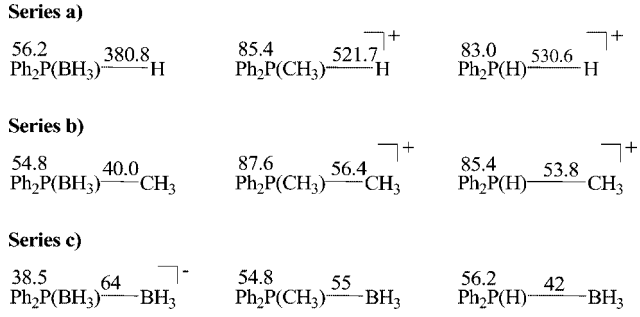

Figure 5. Systematic trends in the $^1J_{DA}$ and $^1J_{PCi}$ coupling constants along three series of $[P(BH_3)Ph_2]^-$, $P(CH_3)Ph_2$, and $P(H)Ph_2$ adducts.

Thus, compared to the neutral phosphane ligands, $[P(BH_3)Ph_2]^-$ is able to provide an electron pair of higher p character such that the charge density is more strongly polarized in the direction of the acceptor orbital. This interpretation most likely holds also for the $[BH_3]$ adducts of series c (Figure 5) even though $^{31}P$–$^{11}B$ coupling via the dative bond is now *larger* in $K[BH_3$–P(B$H_3$)$Ph_2]$ (**9**) and *smaller* in $BH_3$–P(H)$Ph_2$ (**4H**), and $BH_3$–P(C$H_3$)$Ph_2$ (**5H**). Here, the decisive factor is the rehybridisation of $[BH_3]$ as it moves from a planar $sp^2$ configuration to a tetrahedral $sp^3$ arrangement. As a consequence, we are facing two opposing trends:[14] When phosphane forms an adduct, the phosphorus orbital involved in bond formation decreases in s character. On the other hand, the stronger the donor-acceptor interaction, the more pyramidalized the coordinated borane which in turn results in more B(2s) character being diverted into the P–B bond. Despite of the fact that

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a quantitative assessment of these two competing factors is obviously difficult, an empirical correlation between the magnitude of $^1J_{PB}$ and dative bond strength became evident from several studies on [$BH_3$] adducts of selected series employing smoothly varying phosphane ligands.[14,30–32] Based on the development of $^1J_{PB}$ coupling constants along the sequence **4H** (42 Hz), **5H** (55 Hz), and **9** (64 Hz) we therefore confidently assign the highest Lewis basicity to the phosphanylborohydride ligand $[P(BH_3)Ph_2]^-$ (note that for $Li[(BH_3)_2P(CH_3)_2]$ a coupling constant $^1J_{PB}$ = 107 Hz has been published,[33] which is even larger than $^1J_{PB}$ of **9**).

To test this hypothesis, two displacement experiments have been carried out and monitored by $^{31}P$ NMR spectroscopy. First, we investigated an equimolar mixture of $K[(BH_3)_2PPh_2]$ (**9**) and $CH_3PPh_2$ (**3**) in THF. Even after prolonged storage of the NMR vessel at ambient temperature, no transfer of [$BH_3$] with formation of $K[BH_3PPh_2]$ and $BH_3(CH_3)PPh_2$ (**5H**) was observable. The result remained the same at higher temperatures. In contrast, between $BH_3(CH_3)PPh_2$ (**5H**) and $K[BH_3PPh_2]$ a reaction to $CH_3PPh_2$ (**3**) and $K[(BH_3)_2PPh_2]$ (**9**) takes place already at ambient temperature (ca. 10% conversion after 2 d). Heating of the sample to a temperature of 50 °C for 2 h leads to ca. 50% conversion.

## Conclusion

Based on NMR spectroscopy ($^1J_{PB}$ values) and displacement experiments we come to the conclusion that the phosphanylborohydride ligand $[BH_3PPh_2]^-$ possesses a higher Lewis basicity towards [$BH_3$] than its neutral isoelectronic and isostructural congener $P(CH_3)Ph_2$. Moreover, NMR spectroscopy ($^1J_{PB}$, $^1J_{PH}$, and $^1J_{PCi}$ values) and X-ray crystallography ($C_i$–P–$C_i'$ angles; $C_i$ = *ipso* carbon atom of the phenyl ring) on selected adducts of the ligands $HPPh_2$, $CH_3PPh_2$, and $[BH_3PPh_2]^-$ indicate $[BH_3PPh_2]^-$ to form dative bonds of the highest p character within this series. Consequently, $[BH_3PPh_2]^-$ is best suited to direct the charge density of its electron lone pair in the direction of the acceptor orbital of a coordinated Lewis acid.

## Experimental Section

**General Considerations:** All reactions and manipulations of air-sensitive compounds were carried out under dry nitrogen using standard Schlenk techniques. Solvents were freshly distilled under argon from sodium/benzophenone (THF, diethyl ether, toluene) or sodium-lead alloy (pentane, hexane) prior to use. NMR spectra were recorded with Bruker AMX 250 or AMX 400 spectrometers. Approximately 0.1 mL of $C_6D_6$ was added to all samples recorded in undeuterated THF (0.6 mL) to provide a lock signal. $^1H$- and $^{13}C$ NMR shifts are reported relative to tetramethylsilane and were referenced against residual solvent peaks ($C_6D_5H$: $\delta$ = 7.16, $C_6D_6$: $\delta$ = 128.06; $CHCl_3$: $\delta$ = 7.26, $CDCl_3$: $\delta$ = 77.16 ppm).[34] $^{11}B$ NMR spectra were referenced against external $BF_3{\cdot}OEt_2$. $^{31}P$ NMR spectra are reported relative to external $H_3PO_4$ (85%). Abbreviations: s = singlet, d = doublet, tr = triplet, vtr = virtual triplet, q = quartet, dq = doublet of quartets, m = multiplet, br. = broad, n.o. = signal not observed, *i* = *ipso*, *o* = *ortho*, *m* = *meta*, *p* = *para*. Elemental analyses were performed by the microanalytical laboratory of the J. W. Goethe University, Frankfurt/Main, Germany.

**Materials:** Lithium and potassium metal, $PPh_3$, $CH_3PPh_2$ (**3**), $BH_3{\cdot}THF$ solution (1 mol/ L in THF) and 18-crown-6 were purchased from Aldrich or Fluka and used as received. $HPPh_2$ (**2**) was obtained through reductive cleavage of triphenylphosphane with lithium powder in THF and subsequent hydrolysis and distillation as described by Bianco and Doronzo.[35]

**Synthesis of K[$PPh_2$] (1):** The compound was obtained through deprotonation of $HPPh_2$ (**2**; 320 mg, 1.72 mmol) with potassium metal (120 mg, 3.07 mmol) in THF (5 mL). The resulting orange solution was decanted from excess potassium and directly used for the NMR measurements. X-ray quality crystals of **1**·18-crown-6 (**1c**) were grown by gas-phase diffusion of diethyl ether into a THF solution containing K[$PPh_2$] and an equimolar amount of 18-crown-6. $^1H$ NMR (THF, 250.13 MHz): $\delta$ = 6.42 (tr, $^3J_{HH}$ = 7.2 Hz, 2 H, H-*p*), 6.73 (vtr, $^3J_{HH}$ = 7.5 Hz, 4 H, H-*m*) 7.40–7.49 (m, 4 H, H-*o*) ppm. $^{13}C\{^1H\}$ NMR (THF, 62.90 MHz): $\delta$ = 118.6 (br., C-*p*), 127.5 (d, $^3J_{PC}$ = 5.5 Hz, C-*m*), 129.2 (d, $^2J_{PC}$ = 18.6 Hz, C-*o*), 157.1 (br. d, $^1J_{PC}$ = 56.0 Hz, C-*i*) ppm. $^{31}P$ NMR (THF, 161.98 MHz): $\delta$ = –9.8 (s) ppm.

**Synthesis of $BH_3(H)PPh_2$ (4H):** To a solution of $HPPh_2$ (2.53 g, 13.5 mmol) in THF (10 mL) was added a calibrated solution (1 mol/ L) of $BH_3{\cdot}THF$ in THF (13.5 mL, 13.5 mmol) at –78 °C with stirring. After the mixture had been warmed to ambient temperature overnight, all volatiles were removed in vacuo. The resulting oily residue was purified by column-chromatography (50 g silica-gel; eluent: hexane/toluene, 1:1). After evaporation of the eluate, the resulting oil of **4H** was triturated with pentane whereupon it solidified to give a colourless waxy material. Yield: 2.29 g (85%). $^1H$ NMR (THF, 400.13 MHz): $\delta$ = 1.15 (q, $^1J_{BH}$ = 100 Hz, 3 H, $BH_3$), 6.16 (dq, $^1J_{PH}$ = 380.8 Hz, $^3J_{HH}$ = 7.1 Hz, 1 H, PH), 7.19–7.30 (m, 6 H, H-*m*,*p*), 7.51–7.65 (m, 4 H, H-*o*) ppm. $^{11}B$ NMR (THF, 128.38 MHz): $\delta$ = –40.0 (dq, $^1J_{PB}$ = 42 Hz, $^1J_{BH}$ = 100 Hz) ppm. $^{13}C\{^1H\}$ NMR (THF, 62.90 MHz): $\delta$ = 127.6 (d, $^1J_{PC}$ = 56.2 Hz, C-*i*), 129.3 (d, $^3J_{PC}$ = 10.1 Hz, C-*m*), 131.8 (d, $^4J_{PC}$ = 2.5 Hz, C-*p*) 133.3 (d, $^2J_{PC}$ = 9.3 Hz, C-*o*) ppm. $^{31}P\{^1H\}$ NMR (THF, 161.98 MHz): $\delta$ = 1.7 (m) ppm.

**Synthesis of $BBr_3(H)PPh_2$ (4Br):** The compound was synthesised from $BBr_3$ (320 mg, 1.28 mmol) and $HPPh_2$ (230 mg, 1.24 mmol) in hexane (5 mL) as described in the literature.[14] Yield: 489 mg (92%). X-ray-quality crystals were grown by gas-phase diffusion of pentane into a solution of **4Br** in toluene. Since the compound is not stable in THF for extended periods of time, NMR measurements have to be carried out immediately after sample preparation. $C_{12}H_{11}BBr_3P$ (436.72): calcd. C 33.00, H 2.54; found: C 33.15, H 2.50. $^1H$ NMR (THF, 400.13 MHz): $\delta$ = 6.97 (d, $^1J_{PH}$ = 444.4 Hz, 1 H, PH), 7.31–7.39 (m, 4 H, H-*m*), 7.43–7.48 (m, 2 H, H-*p*), 7.76–7.84 (m, 4 H, H-*o*) ppm. $^{11}B$ NMR (THF, 128.38 MHz): $\delta$ = –17.1 (d, $^1J_{PB}$ = 142 Hz) ppm. $^{13}C\{^1H\}$ NMR (THF, 100.62 MHz): $\delta$ = 121.3 (d, $^1J_{PC}$ = 65.7 Hz, C-*i*), 129.7 (d, $^3J_{PC}$ = 11.7 Hz, C-*m*), 133.4 (d, $^4J_{PC}$ = 2.8 Hz, C-*p*), 134.6 (d, $^2J_{PC}$ = 8.2 Hz, C-*o*) ppm. $^{31}P\{^1H\}$ NMR (THF, 161.98 MHz): $\delta$ = –13.6 (q, $^1J_{PB}$ = 142 Hz) ppm.

**Synthesis of $BH_3(CH_3)PPh_2$ (5H):** To a solution of $CH_3PPh_2$ (270 mg, 1.35 mmol) in THF (2 mL) was added a calibrated solution (1 mol/ L) of $BH_3{\cdot}THF$ in THF (1.3 mL, 1.3 mmol) at –78 °C with stirring. After the mixture had been warmed to ambient temperature overnight, all volatiles were removed in vacuo. **5H** was obtained in essentially quantitative yield as a colourless oil. $^1H$ NMR (THF, 250.13 MHz): $\delta$ = 1.03 (q, 3 H, $BH_3$), 1.66 (d, $^2J_{PH}$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

= 10.0 Hz, 3 H, $CH_3$), 7.18–7.31 (m, 6 H, H-*m*,*p*), 7.51–7.63 (m, 4 H, H-*o*) ppm. $^{11}B$ NMR (THF, 128.38 MHz): $\delta$ = –37.9 (dq, $^1J_{PB}$ = 55 Hz, $^1J_{BH}$ = 99 Hz) ppm. $^{13}C\{^1H\}$ NMR (THF, 62.90 MHz): $\delta$ = 11.4 (d, $^1J_{PC}$ = 40.0 Hz, $CH_3$), 129.0 (d, $^3J_{PC}$ = 9.8 Hz, C-*m*), 131.2 (d, $^4J_{PC}$ = 2.4 Hz, C-*p*), 131.9 (d, $^1J_{PC}$ = 54.8 Hz, C-*i*), 132.2 (d, $^2J_{PC}$ = 9.6 Hz, C-*o*) ppm. $^{31}P\{^1H\}$ NMR (THF, 161.98 MHz): $\delta$ = 11.5 (m) ppm.

**Synthesis of $BBr_3(CH_3)PPh_2$ (5Br):** The compound was synthesised from $CH_3PPh_2$ (235 mg, 1.17 mmol) and $BBr_3$ (302 mg, 1.21 mmol) in hexane (5 mL) following a published procedure.[16] Yield: 487 mg (90%). X-ray quality crystals were grown by gas-phase diffusion of pentane into a solution of **5Br** in toluene. $C_{13}H_{13}BBr_3P$ (450.74): calcd. C 34.64, H 2.91; found: C 34.41, H 2.79. $^1H$ NMR (THF, 400.13 MHz): $\delta$ = 2.11 (d, $^2J_{PH}$ = 11.9 Hz, 3 H, $CH_3$), 7.28–7.34 (m, 4 H, H-*m*), 7.39–7.44, (m, 2 H, H-*p*), 7.74–7.80 (m, 4 H, H-*o*) ppm. $^{11}B$ NMR (THF, 128.38 MHz): $\delta$ = –14.6 (d, $^1J_{PB}$ = 150 Hz) ppm. $^{13}C\{^1H\}$ NMR (THF, 100.62 MHz): $\delta$ = 7.1 (d, $^1J_{PC}$ = 48.7 Hz, $CH_3$), 124.2 (d, $^1J_{PC}$ = 68.2 Hz, C-*i*), 129.2 (d, $^3J_{PC}$ = 10.9 Hz, C-*m*), 132.9 (d, $^4J_{PC}$ = 2.7 Hz, C-*p*), 134.3 (d, $^2J_{PC}$ = 8.1 Hz, C-*o*) ppm. $^{31}P\{^1H\}$ NMR (THF, 161.98 MHz): $\delta$ = –9.2 (q, $^1J_{PB}$ = 150 Hz) ppm.

**Synthesis of $[H_2PPh_2]I$ (6):** For the synthesis of **6**, $HPPh_2$ (322 mg, 1.73 mmol) was treated with excess HI in toluene (3 mL) at –78 °C. Yield: 429 mg (80%). Crystals suitable for X-ray crystallography formed when a concentrated $CHCl_3$ solution of **6** was slowly cooled to –30 °C. $C_{12}H_{12}IP$ (314.09): calcd. C 45.89, H 3.85; found: C 46.16, H 3.83. $^1H$ NMR ($CDCl_3$, 250.13 MHz, 300 K): $\delta$ = 5.8 (very br., 2 H, $PH_2$), 7.41–7.56 (m, 6 H, H-*m*,*p*), 7.73–7.84 (m, 4 H, H-*o*) ppm. $^1H$ NMR ($CDCl_3$, 250.13 MHz, 233 K): $\delta$ = 7.45–7.85 (m, 6 H, H-*m*,*p*), 7.94–8.15 (m, 4 H, H-*o*), 9.91 (br. d, 2 H, $PH_2$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.90 MHz, 300 K): broad, poorly resolved signals. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.90 MHz, 233 K): 128.0 (d, $^1J_{PC}$ = 83.0 Hz, C-*i*), 129.2 (d, $^3J_{PC}$ = 13.2 Hz, C-*m*), 131.1 (d, $^2J_{PC}$ = 11.8 Hz, C-*o*), 133.4 (d, $^4J_{PC}$ = 1.6 Hz C-*p*) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 161.98 MHz, 300 K): $\delta$ = –34.2 (br. s) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 161.98 MHz, 233 K): $\delta$ = –31.0 (tr, $^1J_{PH}$ = 530.6 Hz) ppm.

**Synthesis of $[CH_3(H)PPh_2]I$ (7):** Following a published procedure,[17] $CH_3PPh_2$ (336 mg, 1.68 mmol) was treated with excess HI in toluene (3 mL) at –78 °C. Yield: 385 mg (70%). Crystals suitable for X-ray crystallography formed when a concentrated $CHCl_3$ solution of **7** was slowly cooled to –30 °C. $C_{13}H_{14}IP$ (328.11): calcd. C 47.59, H 4.30; found: C 47.82, H 4.53. $^1H$ NMR ($CDCl_3$, 250.13 MHz, 300 K): $\delta$ = 2.58 (d, $^2J_{PH}$ = 14.7 Hz, 3 H, $CH_3$), 7.51–7.61 (m, 4 H, H-*m*), 7.64–7.73 (m, 2 H, H-*p*), 7.91–8.03 (m, 4 H, H-*o*), 10.1 (d, $^1J_{PH}$ = 521.7 Hz, 1 H, PH) ppm. $^1H$ NMR ($CDCl_3$, 250.13 MHz, 233 K): $\delta$ = 2.57 (dd, $^2J_{PH}$ = 14.6 Hz, $^3J_{HH}$ = 5.7 Hz, 3 H, $CH_3$), 7.47–8.01 (m, 10 H, H-*o*/*m*/*p*), 9.87 (d, $^1J_{PH}$ = 521.7 Hz, 1 H, PH) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.90 MHz, 300 K): $\delta$ = 7.7 (d, $^1J_{PC}$ = 54.1 Hz, $CH_3$), 116.8 (d, $^1J_{PC}$ = 84.9 Hz, C-*i*), 130.3 (d, $^3J_{PC}$ = 13.2 Hz, C-*m*), 133.3 (d, $^2J_{PC}$ = 10.9 Hz, C-*o*), 135.1 (d, $^4J_{PC}$ = 3.1 Hz, C-*p*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.90 MHz, 233 K): $\delta$ = 7.1 (d, $^1J_{PC}$ = 53.8 Hz, $CH_3$), 115.9 (d, $^1J_{PC}$ = 85.4 Hz, C-*i*), 130.2 (d, $^3J_{PC}$ = 13.1 Hz, C-*m*), 133.0 (d, $^2J_{PC}$ = 10.8 Hz, C-*o*), 135.1 (br., C-*p*) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 161.98 MHz, 300 K): $\delta$ = –4.7 (s) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 161.98 MHz, 233 K): $\delta$ = –5.2 (s) ppm.

**Synthesis of $[(CH_3)_2PPh_2]I$ (8):** The compound was synthesised following a published procedure[36] via the reaction of $HPPh_2$ (204 mg, 1.10 mmol) with $ICH_3$ (217 mg, 1.53 mmol) in THF (4 mL). Yield: 353 mg (94%). Crystals suitable for X-ray crystallography formed when a concentrated $CHCl_3$ solution of **8** was slowly cooled to –30 °C. $C_{14}H_{16}IP$ (342.15): calcd. C 49.15, H 4.71; found: C 48.92, H 4.58. $^1H$ NMR ($CDCl_3$, 250.13 MHz): $\delta$ = 2.88 (d, $^2J_{PH}$ = 13.9 Hz, 3 H, $CH_3$), 7.60–7.79 (m, 6 H, H-*m*,*p*), 7.83–7.95 (m, 4 H, H-*o*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 62.90 MHz): $\delta$ = 11.4 (d, $^1J_{PC}$ = 56.4 Hz, $CH_3$), 120.5 (d, $^1J_{PC}$ = 87.6 Hz, C-*i*), 130.3 (d, $^3J_{PC}$ = 12.8 Hz, C-*m*), 132.3 (d, $^2J_{PC}$ = 10.7 Hz, C-*o*), 135.0 (d, $^4J_{PC}$ = 3.0 Hz, C-*p*) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 161.98 MHz): $\delta$ = 21.9 (s) ppm.

**Synthesis of $K[(BH_3)_2PPh_2]$ (9):** To a solution of 435 mg $K[BH_3PPh_2]$ (1.82 mmol) in THF (5 mL) was added a calibrated solution (1 mol/ L) of $BH_3$·THF (1.8 mL, 1.8 mol) at –78 °C with stirring. After 30 min, the cooling bath was removed and the reaction mixture warmed to ambient temperature with subsequent stirring for another 60 min. All volatiles were removed in vacuo and the resulting colourless solid was washed twice with pentane (2 mL). Yield: 423 mg (92%). X-ray quality crystals were grown by gas-phase diffusion of diethyl ether onto a solution containing $K[(BH_3)_2PPh_2]$ and an equimolar amount of 18-crown-6. $C_{24}H_{40}B_2KO_6P$ (516.25): calcd. C 55.84, H 7.81; found C 55.38, H 7.63. $^1H$ NMR (THF, 250.13 MHz): $\delta$ = 1.0 (q, $^1J_{BH}$ = 89 Hz, 6 H, $BH_3$), 7.00–7.10 (m, 6 H, H-*m*,*p*), 7.74–7.85 (m, 4 H, H-*o*) ppm. $^{11}B\{^1H\}$ NMR (THF, 128.38 MHz): $\delta$ = –34.6 (d, $^1J_{PB}$ = 64 Hz, $BH_3$) ppm. $^{13}C\{^1H\}$ NMR (THF, 62.90 MHz): 127.4 (d, $^3J_{PC}$ = 8.2 Hz, C-*m*), 127.9 (d, $^4J_{PC}$ = 2.0 Hz, C-*p*), 133.4 (d, $^2J_{PC}$ = 7.7 Hz, C-*o*), 140.2 (d, $^1J_{PC}$ = 38.5 Hz, C-*i*) ppm. $^{31}P$ NMR (THF, 161.98 MHz): $\delta$ = –11.1 (m) ppm.

**X-ray Structural Characterisation:** Data collections were performed on a Stoe IPDS-II two-circle diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation. Empirical absorption corrections with the MULABS option[37] in the program PLATON[38] were performed. Equivalent reflections were averaged. The structures were solved by direct methods[39] and refined with full-matrix least-squares on $F^2$ using the program SHELXL-97.[40] Hydrogen atoms bonded to carbon and boron were placed on ideal positions and refined with fixed isotropic displacement parameters using a riding model. H atoms bonded to phosphorus were refined isotropically. Details of the X-ray crystal structure analyses of **1**[c], **4Br**, **5Br**, **6**, **7**, and **9**[c] are summarised in Table 3.

CCDC-290838 (for **1**[c]), -290839 (for **4Br**), -290840 (for **5Br**), -290841 (for **6**), -290842 (for **7**), and -290843 (for **9**[c]) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): ORTEP drawings of **4Br**, **5Br**, **6**, **7**, and **8**.

# Synthesis, Structure, Electrochemistry, and Metal-Atom Dynamics of Cyclopentadienyl Ferracarboranes

**Rolfe H. Herber,*[a] Alexander R. Kudinov,[b] Piero Zanello,[c] Israel Nowik,[a] Dmitry S. Perekalin,[b] Vladimir I. Meshcheryakov,[b] Konstantin A. Lyssenko,[b] Maddalena Corsini,[c] and Serena Fedi[c]**

**Keywords:** Cyclopentadienyl ferracarboranes / Electrochemistry / X-ray diffraction / Mössbauer spectroscopy

A series of metallacarboranes, incorporating the CpFe fragment, were studied by electrochemical techniques, temperature-dependent Mössbauer effect (ME) spectroscopy, and X-ray diffraction. The compounds studied include the parent dicarbollide complex $CpFeC_2B_9H_{11}$ (**1**) and its reduced form [**1**]$^-$, the charge-compensated ferradicarbollides 1-Cp-4-L-1,2,3-$FeC_2B_9H_{10}$ [L = $SMe_2$ (**2a**), $NMe_3$ (**2b**), py (**2c**)] and their methylated analogs 1-Cp-2,3-$Me_2$-4-$SMe_2$-1,2,3-$FeC_2B_9H_8$ (**2d**) and 1-Cp*-4-$SMe_2$-1,2,3-$FeC_2B_9H_{10}$ (**2e**), the isomeric ferratricarbollides $CpFeC_3B_8H_{11}$ (**3a–c**), and the amino-substituted derivative 1-Cp-12-*t*BuNH-1,2,4,12-$FeC_3B_8H_{10}$ (**3d**). The ferradicarbollides **2a–e** were synthesized by reactions of the charge-compensated dicarbollide anions [9-L-7,8-$R_2$-7,8-$C_2B_9H_8$]$^-$ (R = H, Me) with [($C_5R_5$)-$Fe(MeCN)_3$]$^+$ cations. The structures of **1**, [$NMe_3Ph$][**1**], and **2b** were investigated by X-ray diffraction. The ME spectroscopic study elucidated the relationship between the nature of the five-membered carborane face coordinated to the metal center and the hyperfine interaction parameters of the Fe atom. Temperature-dependent recoil-free fraction studies yielded the root-mean-square-amplitude-of-vibration (rmsav) of the metal atom over a wide temperature range, which proved to be in good agreement with crystallographic $U_{i,j}$ data for **1** and **3a**,**b**. Electrochemistry shows that the isomeric ferratricarbollides **3a–c** undergo reversible oxidation to the corresponding $Fe^{III}$ derivatives at potential values higher, on average, by about 0.4 V than those of the charge-compensated complexes **2a–c** and by about 0.8 V than that of the parent ferradicarbollide [**1**]$^-$. This result indicates the strong electron-withdrawing ability of the extra carbon atom relative to that of the replaced boron atom. As a consequence of the shift of the HOMO–LUMO frontier orbitals to the high energy levels, the $Fe^{II}/Fe^{I}$ reduction becomes accessible.

## Introduction

Similar to ferrocene, the ferracarborane anion $[CpFeC_2B_9H_{11}]^-$ ([**1**]$^-$)[1] can be easily oxidized to give the neutral compound $CpFeC_2B_9H_{11}$ (**1**) which contains $Fe^{III}$. However, different charges of the $[C_2B_9H_{11}]^{2-}$ and $Cp^-$ ligands lead to significant differences in the properties of [**1**]$^-$ and $FeCp_2$. Usage of monoanionic carborane ligands of two types, [9-L-7,8-$C_2B_9H_{10}$]$^-$ and $[C_3B_8H_{11}]^-$, allows one to obtain closer analogs of ferrocene such as charge-compensated ferradicarbollides **2a–e** and ferratricarbollides **3a–d** (Scheme 1). Herein we describe the synthesis and structural, electrochemical, and Mössbauer studies of these compounds, along with a reinvestigation of key metallacarboranes **1** and [**1**]$^-$.

## Results and Discussion

### Synthesis

The charge-compensated ferradicarbollides **2a–c** were prepared by reactions of anions [9-L-7,8-$C_2B_9H_{10}$]$^-$ with the acetonitrile complex $[CpFe(MeCN)_3]^+$ (Scheme 2).[2] The starting iron complex is stable only below –40 °C,[3] and therefore its in situ generation by irradiation of $[CpFe(C_6H_6)]^+$ in a mixture of MeCN/THF and further complexation were carried out at low temperature. The analogous reaction of [9-$SMe_2$-7,8-$Me_2$-7,8-$C_2B_9H_8$]$^-$ gave the cage-methylated derivative **2d**. The ring-methylated complex **2e** was prepared by reaction of [9-$SMe_2$-7,8-$C_2B_9H_{10}$]$^-$ with $[Cp^*Fe(MeCN)_3]^+$.[4]

Ferratricarbollides **3a**[5] and **3d**[6] were recently obtained by room-temperature photochemical reaction of the tricarbollide anions [7-R-7,8,9-$C_3B_9H_{10}$]$^-$ (R = H, *t*BuNH) with $[CpFe(C_6H_6)]^+$, while compounds **3b** and **3c** were prepared by stepwise thermal rearrangement of **3a**.[5]

## Structures

The structure of ferradicarbollide **1** was studied by X-ray diffraction in 1965, but the instrumental limitations of that time resulted in approximate data only, with significant uncertainty (ca. 0.05 Å) caused by large thermal motion.[7] Low-temperature experiments allowed us to obtain highly accurate structures of **1** and its reduced form $[\mathbf{1}]^-$ (as a $[NMe_3Ph]^+$ salt) with only minor librations of the Cp rings (Figure 1 and Figure 2).[8]

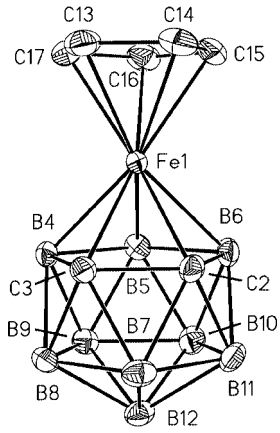

Figure 1. The molecular structure of anion $[\mathbf{1}]^-$ (thermal ellipsoids at 50% probability). Hydrogen atoms are omitted for clarity. Selected interatomic distances [Å]: Fe1–C2 2.0101(7), Fe1–C3 2.0108(7), Fe1–B4 2.0709(7), Fe1–B5 2.1090(7), Fe1–B6 2.0749(8), Fe1–C13 2.0721(7), Fe1–C14 2.0649(7), Fe1–C15 2.0514(7), Fe1–C16 2.0441(7), Fe1–C17 2.0606(7), C3–C2 1.6324(10).

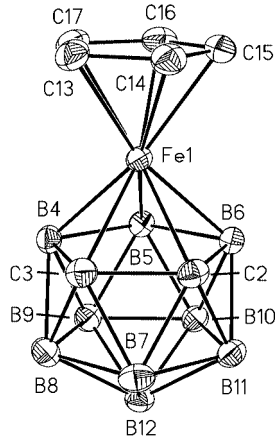

Figure 2. The molecular structure of **1** (thermal ellipsoids at 50% probability). Hydrogen atoms are omitted for clarity. Selected interatomic distances [Å]: Fe1–C16 2.0651(11), Fe1–C2 2.0716(9), Fe1–C3 2.0773(9), Fe1–C17 2.0893(11), Fe1–B6 2.0952(11), Fe1–C15 2.0961(10), Fe1–B4 2.1017(10), Fe1–B5 2.1079(11), Fe1–C13 2.1356(11), Fe1–C14 2.1399(11), C2–C3 1.6002(13).

The structure of the 18-electron anion $[\mathbf{1}]^-$ possesses a classical sandwich geometry with the Fe···$C_2B_3$ and Fe···$C_5$ distances equal to 1.437 and 1.663 Å, respectively. It is noteworthy that the latter value is very close to that in ferrocene[9] (1.660 Å), confirming a similarity of their electronic structures. The $C_2B_3$ and $C_5$ rings are nearly eclipsed (torsion angle 14°) and almost parallel (1.6°) to each other. The $C_2B_3$ face is notably nonplanar with the central B5 atom deviating from the B6–C2–C3–B4 plane by 0.061 Å away from the iron atom. Similar distortion was previously observed in structures of **3a**,**b**.[5]

The structure of the 17-electron neutral compound **1** is significantly different from anion $[\mathbf{1}]^-$. Both the Fe···$C_2B_3$ (1.487 Å) and Fe···$C_5$ (1.723 Å) distances in **1** are ca. 0.05 Å longer than those in $[\mathbf{1}]^-$. The latter distance is also longer than that in the similar 17-electron $[FeCp_2]^+$ cation (1.706 Å).[10] The $C_5$ ring is almost perfectly eclipsed with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$C_2B_3$ (torsion angle 4.5°) and inclined by 4.6° away from the cage carbon atoms. The $C_{Carb}$–$C_{Carb}$ and average $C_{Cp}$–$C_{Cp}$ distances in **1** (1.594 and 1.401 Å, respectively) are considerably shorter than those in [**1**]$^-$ (1.640 and 1.430 Å, respectively).

In order to arrive at a MO explanation for the difference between the structures of **1** and [**1**]$^-$, we carried out DFT calculations (at B3LYP/6-31G* level) of the anion [**1**]$^-$. It was found that the HOMO (Figure 3) is similar to the $e_{2g}$/$d_{x^2-y^2}$ orbital of ferrocene, with bonding for Fe···$C_2B_3$ and Fe···Cp interactions and antibonding for $C_{Cp}$–$C_{Cp}$ and $C_{Carb}$–$C_{Carb}$ interactions.[11] Accordingly, removal of one electron from this orbital leads to the lengthening of Fe···$C_2B_3$ and Fe···Cp distances and shortening of $C_{Cp}$–$C_{Cp}$ and $C_{Carb}$–$C_{Carb}$ distances.

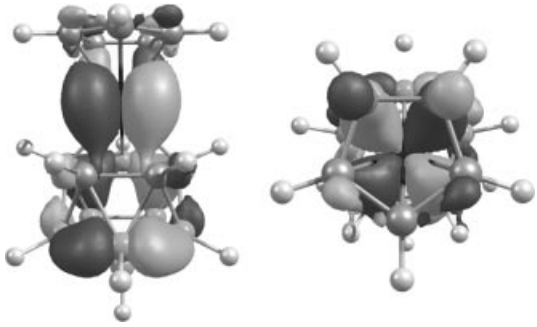

Figure 3. The plot of the HOMO of [**1**]$^-$.

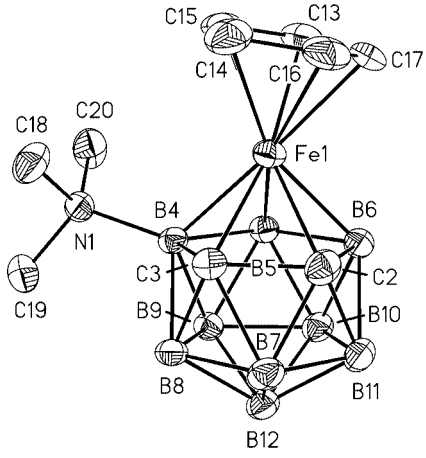

Figure 4. The molecular structure of **2b** (thermal ellipsoids at 30% probability). The second conformation of the disordered Cp ring and hydrogen atoms are omitted for clarity. Selected interatomic distances [Å]: Fe1–C2 1.995(3), Fe1–C3 2.018(3), Fe1–B4 2.108(4), Fe1–B5 2.113(3), Fe1–B6 2.072(3), Fe1–C17 2.054(9), Fe1–C16 2.079(6), Fe1–C13 2.082(7), Fe1–C14 2.091(6), Fe1–C15 2.093(5), C2–C3 1.632(5), N1–B4 1.611(4).

The structure of the charge-compensated ferradicarbollide **2b** was also confirmed by X-ray diffraction (Figure 4). In contrast to [**1**]$^-$ and **1**, the Cp ligand is disordered over two positions. The presence of the bulky $NMe_3$ substituent leads to the significantly bent sandwich geometry with a 9.7° angle between $C_5$ and $C_2B_3$ planes. The Fe···Cp and Fe···$C_2B_3$ distances (1.690 and 1.451 Å, respectively) are ca. 0.03 Å longer than those in [**1**]$^-$, probably also a result of the steric repulsion.

## Mössbauer Study

Similar to other neutral, diamagnetic ferrocenoid compounds, all of the cyclopentadienyl ferracarboranes examined in the present study, namely **1**, [$NMe_3Ph$][**1**], **2a**,**c**, and **3a**–**d**, display a ME resonance which consists of a single, well-separated doublet spectrum characterized by its isomer shift (IS), quadrupole splitting (QS), and area under the resonance curve ($A$). A representative spectrum of **3c** at 92 K is shown in Figure 5. The IS and QS values at 90 K, as well as the parameters derived from the temperature-dependent data for all of the compounds are summarized in Table 1. In the following discussion, the trends in the ME hyperfine parameters are discussed in some detail.

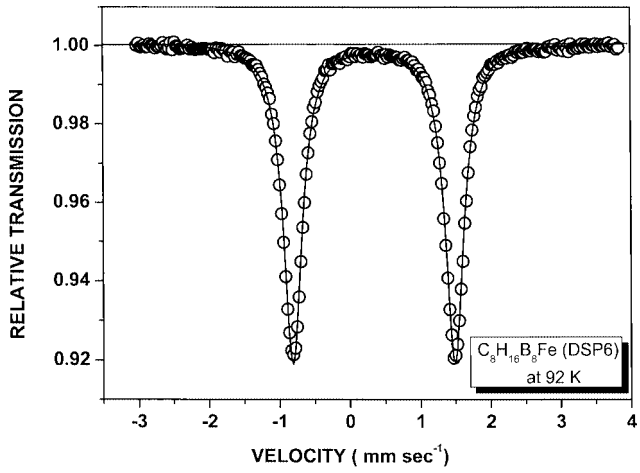

Figure 5. $^{57}$Fe Mössbauer spectrum of **3c** ("DSP-6") at 92 K. The velocity scale is with reference to the centroid of a room-temperature α-Fe spectrum which was also used for spectrometer calibration.

Table 1. $^{57}$Fe Mössbauer parameters for the compounds discussed in the text.

| | **1** | [$NMe_3Ph$][**1**] | **2a** | **2c** | **3a** | **3b** | **3c** | **3d** | Units |

### *Isomer Shift*

The IS parameters show a distinct partition into two groups: those which pertain to the ferracarboranes in which two carbon atoms of the five-membered carborane face interact with the metal atom (e.g., **3c** and **3d**), and those in which there are three carbon atoms in the pentagonal ring (e.g., **3a** and **3b**). As is evident from the electronegativity of carbon and boron and also in accordance with the results of previous DFT calculations,[5] the C atoms of the framework are more negatively charged than the B atoms. This greater electron density, which is reflected in greater shielding of the nearby iron nucleus, results in a larger IS, since it is well established that $\delta R/R$ for the 14.4 keV level of $^{57}Fe$ is negative.[12] The average difference in the IS parameter between the $B_2C_3$ and $B_3C_2$ compounds is almost 0.1 mm s$^{-1}$, a value some 30 times greater than the experimental errors in the individual measurements. An argument which further bolsters this explanation is based on the observation that other iron carboranes, in which the carborane ligand contains three carbon atoms (of which only two are located in the pentagonal ring facing the metal atom) (e.g., **3c** and **3d**), show an IS which is close to those reported for the $C_2B_3$ complexes noted earlier.

The temperature dependence of the IS, –d(IS)/d($T$), is negative for all of the compounds examined, in consonance with similar observations reported earlier for ferrocene-related complexes. For **3a**–**c**, this temperature dependence is linear within experimental error over the accessible range of temperatures, and the corresponding values are included in the data listed in Table 1. A representative data set is shown in Figure 6. For [$NMe_3Ph$][**1**], **2a**, and **3d**, the data are better approximated by two linear segments, with a minor break at $T \approx 230$ K. Again, a representative data set is included in Figure 6. For **2c**, the temperature dependence of the IS parameter shows continuous curvature, and no effort was made to separate two regions of the $T$ range in this case. As indicated in the literature,[13] the value of the –d(IS)/d($T$) parameter (in the high-temperature limit) can be used to extract an effective vibrating mass, $M_{eff}$, for the ME active atom, and the corresponding values for the cyclopentadienyl iron carboranes of the present study fall into the range of 82 ± 4 Da for the five $B_3C_2$ compounds and 102 ± 4 Da for the two $B_2C_3$ compounds. The difference between these values and the "bare atom" iron mass of 57 Da reflects the covalence of the metal–ligand interaction, and is consistent with a larger electron density of the ring in the latter than in the former compounds, as mentioned earlier.

### *Quadrupole Splitting*

The QS parameters at 90 K are included in the data summarized in Table 1. With the exception of the value for **1**, the data again fall into two groups: those with the $B_2C_3$ ring structure and those with the $B_3C_2$ configuration. At 90 K, the former have a QS ≈ 2.49 mm s$^{-1}$, while the latter have a QS ≈ 2.36 mm s$^{-1}$. However, it should be noted that the QS parameters are temperature-dependent, and (with some minor variations) show the normal decrease with increasing temperature because of the effects on the field gradient arising from thermal expansion. A typical data set showing this temperature dependence is shown in Figure 7. An exception to the earlier generalization is the data for the QS of **1**, which is smaller by about a factor of 4.6 than the values for the remainder of the carboranes reported here. This difference is readily understood in terms of the formal +3 oxidation state of the iron atom in **1** compared with the divalent state in the remainder. As has been previously noted[14] for ferrocene-related compounds, the removal of one electron from the metal atom on oxidation incurs an almost complete collapse of the QS, as has been discussed in detail in a classic paper by Collins[14] and elsewhere.[15] Typically, the change in the QS parameter on oxidation of the neutral parent compound is from 2.57 to 0.15 mm s$^{-1}$ for octamethylferrocene and the corresponding cation as $BF_4^-$ and $PF_6^-$ salts,[16] from 2.42 to 0.21 mm s$^{-1}$ for a bis-(isodicyclopentadienyl)iron complex and the cation as a $PF_6^-$ salt,[17] and from 2.41 to 0.15 mm s$^{-1}$ for ethynyloctamethylferrocene and the cation as a $PF_6^-$ salt.[18] In the case of **1**, the QS parameter at 90 K is 0.525 ± 0.003 mm s$^{-1}$, presumably due to the presence of both B and C atoms in the

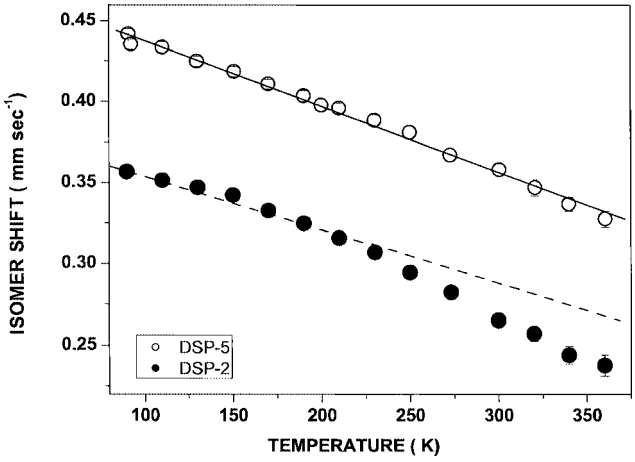

Figure 6. Temperature dependence of the isomer shift for [$NMe_3Ph$][**1**] ("DSP-2", filled circles) and **3b** ("DSP-5", open circles).

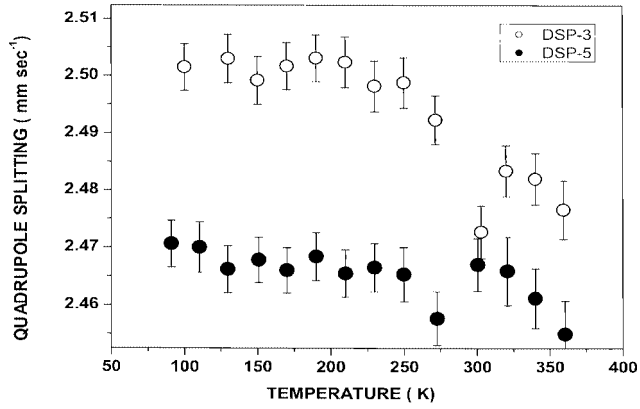

Figure 7. Temperature dependence of the quadrupole splitting for **3a** ("DSP-3") and **3b** ("DSP-5") showing the "normal" decrease with increasing temperature.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

five-membered ring facing the metal atom. This larger value permits the resolution of the two components of the ME spectrum and the detailed temperature dependence of the QS parameter. The relevant data are summarized in Figure 8 which shows that in the low-temperature region (90 to ≈250 K) the QS parameter *increases* with increasing temperature, and then decreases normally in the higher temperature range. This relatively unusual behavior is not observed for the remainder of the $Fe^{II}$ complexes as mentioned earlier.

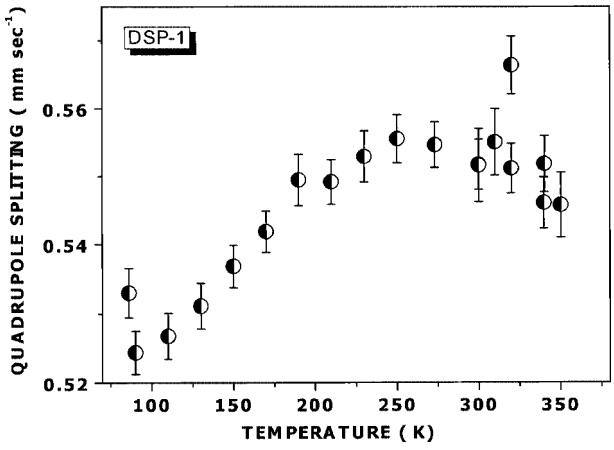

Figure 8. Temperature dependence of the quadrupole splitting for **1** ("DSP-1").

### *Recoil-Free Fraction and Vibrational Amplitude*

For an optically "thin" absorber, the area under the resonance curve scales directly with the recoil-free fraction, $f$, of the 14.4 keV gamma ray of $^{57}Fe$. Since $f = -\exp(k^2\langle x^2\rangle)$, where $k$ is the wave vector of the gamma ray and $\langle x^2\rangle$ is the mean-square-amplitude-of-vibration (msav) of the metal atom, detailed information on the temperature dependence of the area under the resonance curve can provide information on the dynamics of the iron atom in a variety of environments. To this end, the temperature dependence of the logarithm under the resonance curve, $-\mathrm{d}\ln[A(T)/A(90)]/\mathrm{d}T$, has been determined for the ferracarboranes of the present study. A representative data set is summarized graphically in Figure 9 for [$NMe_3Ph$][**1**] and **3b**. Two qualitatively different types of behavior are reflected in the data listed in Table 1. In the case of **2c** and **3b**, the data are well-represented by a linear regression over the whole temperature range. More frequently, however, as in the case of the other compounds studied, the data are better represented by two different linear functions: one at low temperatures and one at high temperatures. In the case of **3d**, the data show continuous curvature over the accessible temperature range and have not been subjected to further analysis. As has been shown previously, using the slope of $\mathrm{d}\ln[A(T)/A(90)]/\mathrm{d}T$ it is possible to calculate $\langle x_{ave}{}^2\rangle$ from the ME data and compare this to the corresponding (average) value extracted from the $U_{i,j}$ data acquired in single-crystal X-ray diffraction studies. This comparison has been performed for three of the carboranes examined in this work, and these will now be discussed in some detail.

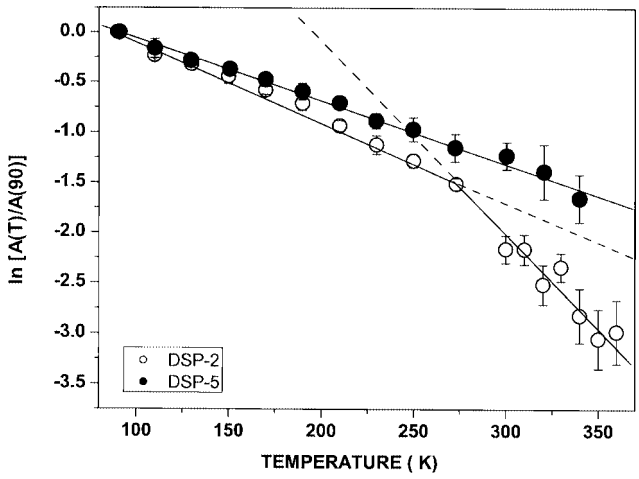

Figure 9. Temperature dependence of the logarithm of the area under the resonance curve for [$NMe_3Ph$][**1**] ("DSP-2") and **3b** ("DSP-5") showing the two types of dependencies discussed in the text.

For **1**, the ME $f$ slope is $(8.00 \pm 0.09)\cdot 10^3\ K^{-1}$ with a correlation coefficient ($R$) of 0.992 for 11 data points. From this slope, $\langle x^2_{ave}\rangle = 0.021\ Å^2$ at 120 K, while the X-ray data yield a value of 0.0229 $Å^2$ at this temperature. In addition, the early X-ray data of Zalkin et al.[7] reflected a value of 0.053 $Å^2$ at room temperature, while the present ME data at 300 K yields $\langle x^2_{ave}\rangle = 0.045\ Å^2$ which is in reasonable agreement. A similar comparison for **3a** yields a value of $\langle x^2_{ave}\rangle = 0.0192\ Å^2$ at 120 K from the X-ray data of Kudinov et al.,[5] while the present ME data show $\langle x^2_{ave}\rangle = 0.0176\ Å^2$ at the same temperature. Finally, for **3b**, $\langle x^2_{ave}\rangle$ calculated from the X-ray data at 120 K is 0.0210 $Å^2$, while that extracted from the ME data is 0.0134 $Å^2$ which is only in modest agreement. Nonetheless, it is clear from this data, that the temperature dependence of $f$ can provide a reasonable estimate of the msav of the metal atom in these compounds, and it can be used to compare the rmsav of the iron atom in different bonding environments.

The rmsav data for **3a** and **3b** at several different temperatures are summarized in Table 2, along with the corresponding data for ferrocene. This parameter is identical (within experimental error) for **3a** and ferrocene for all temperatures in the indicated range. In this context, the following correlation between the X-ray and ME data for **3a** and **3b** is significant. The corresponding rmsav data are displayed in Figure 10, which shows that this parameter is larger for **3a** than for **3b** over the whole temperature range, suggesting that the vibrational amplitude of the Fe atom in **3b** is smaller than it is for **3a**. This conclusion is in good agreement with the X-ray data at 120 K, which show that the average Fe–B bond lengths are 2.055 Å in **3b** and 2.085 Å in **3a**. Moreover, these results are also consistent with the DFT calculations which show that **3b** is 16.95 kcal $mol^{-1}$ more stable than **3a**.[5]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. The rmsav [Å] for ferrocene, **3a**, and **3b**.

| **3b** | **3a** | $FeCp_2$ | *T* [K] |
|---|---|---|---|
| 0.11 | 0.13 | 0.13 | 100 |
| 0.13 | 0.15 | 0.15 | 150 |
| 0.15 | 0.18 | 0.18 | 200 |
| 0.17 | 0.20 | 0.20 | 250 |
| 0.18 | 0.22 | 0.22 | 300 |

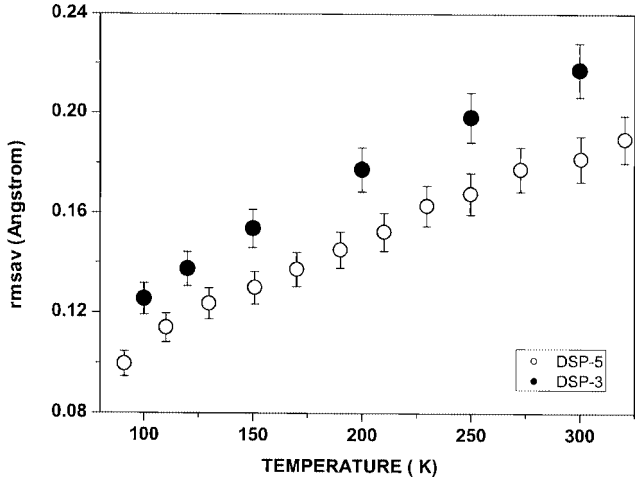

Figure 10. Temperature dependence of the rmsav of the iron atom in **3a** ("DSP-3") and **3b** ("DSP-5"). The larger vibrational amplitude is associated with the longer Fe–B bond lengths in the former than the latter compound as extracted from the 120 K X-ray data.

## Electrochemistry

The redox activity of the $Fe^{II}$ complexes shown in Scheme 1 was studied by electrochemical techniques. Before illustrating the redox aptitude of the ferratricarbollides, let us compare the classical (cyclopentadienyl)ferradicarbollide $[\mathbf{1}]^-$ with the charge-compensated analogs **2a**–**e** and bis(carboranyl) complex Fe(η-9-$SMe_2$-7,8-$C_2B_9H_{10})_2$ (**4**).

Since the $Fe^{III}$ complex **1**, in MeCN solution, undergoes reversible reduction to the corresponding $Fe^{II}$ monoanion,[20] it is not unexpected that $[\mathbf{1}]^-$, in $CH_2Cl_2$ solution, affords the complementary reversible $Fe^{II}/Fe^{III}$ oxidation. In fact, exhaustive one-electron oxidation makes the original golden-yellow solution turn wine-red, and in confirmation of the chemical reversibility of the $[\mathbf{1}]^-/\mathbf{1}$ couple also in the long timescale of macroelectrolysis, cyclic voltammetric tests show a profile quite complementary to the original profile.

Similar behavior is displayed by complexes **2a**–**e**, except that the $Fe^{II}/Fe^{III}$ oxidation occurs at markedly higher potential values, as illustrated in Table 3.

The charge compensation of the carborane ligand in 1-Cp-4-L-1,2,3,4-$Fe^{II}C_2B_9H_{10}$ makes the oxidation notably difficult with respect to the unsubstituted dicarbollyl ligand in $[\mathbf{1}]^-$, which is not only because of Coulombic effects, but in part also from the intrinsic electronic effect of the half-unit 9-L-7,8-$C_2B_9H_{10}$, as testified by the positive shift of the bis(carboranyl) derivative **4** relative to **2a**.[21] On the other hand, the methyl substitution at the carbon atoms of the carboranyl ligand in **2d** does not substantially have any effect with respect to **2a**, whereas the permethylation of the cyclopentadienyl ring in **2e** makes the oxidation significantly easier.

In order to evaluate the electronic effects played by the introduction of a third carbon atom in the framework of the classical dicarbollide dianion $[C_2B_9H_{11}]^{2-}$, Figure 11 compares the cyclic voltammetric behavior of complex **3c** with that of $[\mathbf{1}]^-$ in $CH_2Cl_2$ solution.

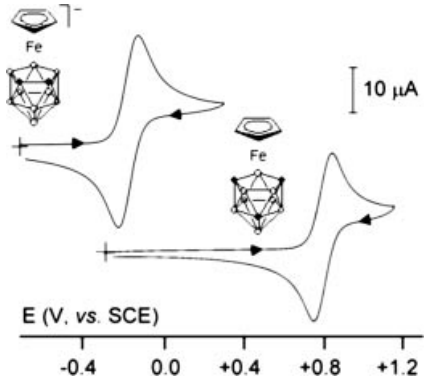

Figure 11. Cyclic voltammetric responses recorded at a platinum electrode in $CH_2Cl_2$ solutions of $[\mathbf{1}]^-$ ($1.3\cdot10^{-3}$ mol dm$^{-3}$) and **3c** ($1.2\cdot10^{-3}$ mol dm$^{-3}$); $[NBu_4][PF_6]$ (0.2 mol dm$^{-3}$) as supporting electrolyte; scan rate 0.2 V s$^{-1}$.

Similar to $[\mathbf{1}]^-$ and its charge-compensated derivatives, **3c** undergoes the reversible $Fe^{II}/Fe^{III}$ step, but the oxidation is further shifted towards positive potential values. In fact, analysis of the cyclic voltammograms with scan rates varying from 0.02 to 2.00 V s$^{-1}$ shows that (i) the current function $i_{pa}\cdot v^{-1/2}$ decreases by about 10% for each 10-fold in-

Table 3. Formal electrode potentials [V vs. SCE], peak-to-peak separations [mV], and color changes [$\lambda_{max}$ in nm] accompanying the $Fe^{II}/Fe^{III}$ oxidation of the dicarbollide complex $[\mathbf{1}]^-$ and the related charge-compensated complexes **2a**–**e** and **4** in $CH_2Cl_2$ solution.

| Complex | $E°'$ | $\Delta E_p$[a] | Original color [$\lambda_{max}$] | Color of the oxidized solution [$\lambda_{max}$] |
|---|---|---|---|---|
| $[\mathbf{1}]^-$ | –0.18 | 84 | yellow | red-wine (570) |
| **2a** | +0.47 | 72 | orange (475) | gray (594) |
| **2b** | +0.40 | 72 | orange (470) | pink-brown (580) |
| **2c** | +0.40 | 62 | red (415) | gray-green (593) |
| **2d** | +0.49 | 65 | pink-orange (470) | green (615) |
| **2e** | +0.21 | 66 | pale-orange (478) | olive-green (636; 710) |
| **4**[a] | +0.55 | 80 | pink | pink-orange |
| $FeCp_2$ | +0.39 | 80 | yellow | green (618) |

[a] Cf. with ref.[20]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

crease of the scan rate, (ii) the current ratio $i_{pc}/i_{pa}$ remains constantly equal to 1, and (iii) the peak-to-peak separation progressively increases from 84 to 154 mV. These parameters are diagnostic for a one-electron, chemically reversible, and electrochemically quasireversible process, in the short times of cyclic voltammetry.[22] Controlled-potential exhaustive oxidation ($E_w$ = +1.0 V) consumes one electron *per* molecule. The original yellow solution turns pale green, and also in this case, the cyclic voltammetric test shows a profile quite complementary to the original profile.

Figure 12 compares the spectral changes accompanying the progressive passage from $[\mathbf{1}]^-$ to **1** (top) with those from **3c** to $[\mathbf{3c}]^+$ (bottom).

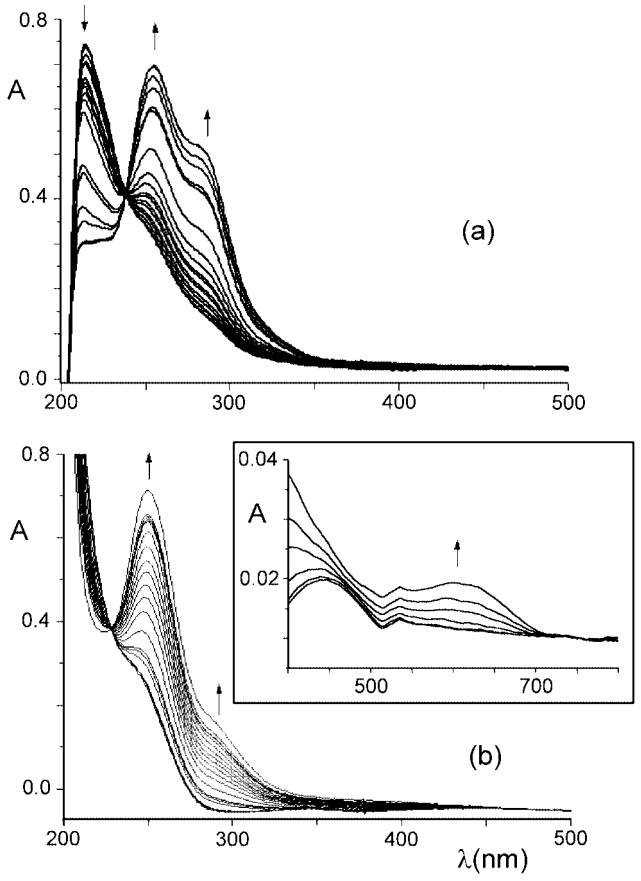

Figure 12. Spectral changes recorded in an OTTLE cell upon progressive oxidation of (a) $[\mathbf{1}]^-$ and (b) **3c**; $CH_2Cl_2$ solution with $[NBu_4][PF_6]$ (0.2 mol dm$^{-3}$) as supporting electrolyte.

In both cases, the appearance of the isosbestic point ($[\mathbf{1}]^-/\mathbf{1}$: $\lambda$ = 238 nm; $\mathbf{3c}/[\mathbf{3c}]^+$: $\lambda$ = 228 nm) further supports the chemical reversibility of the pertinent oxidation processes. The bands arising in the UV region are conceivably assigned to LMCT transitions. In agreement with the final pale-green color of the solution of $[\mathbf{3c}]^+$, a weak band also appears at $\lambda_{max}$ = 620 nm (inset of Figure 12).

A similar redox activity holds in THF solution, except that, because of the larger cathodic window of this solvent, a reduction process can also be detected, which possesses features of chemical reversibility in the cyclic voltammetric timescale (see Figure 13).

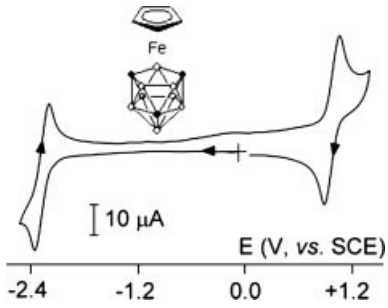

Figure 13. Cyclic voltammetric response recorded at a gold electrode in THF solution of **3c** ($1.0\cdot10^{-3}$ mol dm$^{-3}$); $[NBu_4][PF_6]$ (0.2 mol dm$^{-3}$) as supporting electrolyte; scan rate 0.2 V s$^{-1}$.

The extremely negative potential value of the process prevented the experimental measurement by controlled-potential coulometry of the number of electrons involved, but the similarity of the peak height with that of the anodic process suggests it is a one-electron process. In the first instance, we therefore assign it to the $Fe^{II}/Fe^{I}$ passage; a redox change not too unusual in organometallic chemistry,[23] but quite new in ferracarborane chemistry. The separation between the one-electron oxidation and the one-electron reduction (3.2 eV) can be roughly considered as an experimental measurement of the HOMO–LUMO separation.

Complexes **3b** and **3d** also display a chemically reversible one-electron oxidation. However, in contrast to **3c**, no reduction process is detected in THF for complex **3d**, whereas complex **3b** gives rise to an irreversible reduction. Upon exhaustive oxidation, the original orange solution of complex **3b** turns brown, and the spectroelectrochemical trend in the UV region is very similar to that illustrated for **3c**. A similar spectroelectrochemical pattern was recorded in the UV region during the golden-yellow/maroon transition from **3d** to $[\mathbf{3d}]^+$, except for a new band at 350 nm (see Supporting Information).

Finally, the one-electron oxidation of complex **3a** in $CH_2Cl_2$ solution is accompanied by chemical complica-

tions. The current ratio $i_{pc}/i_{pa}$ is lower than unity at low scan rate and progressively tends to increase with an increase of the scan rate. In fact, exhaustive one-electron oxidation leads to a presently unknown species, which reduces at $E°' = +0.34$ V. The $Fe^{II}/Fe^{I}$ reduction in THF (in such solvent the complex is stable only for short times) is also partially chemically reversible and occurs at potential values less negative than that of **3c**. In fact, a HOMO–LUMO separation of 2.5 eV can be calculated. The formal electrode potentials of the mentioned electrode processes are compiled in Table 4.

## Conclusions

The X-ray diffraction study revealed that the Fe···$C_2B_3$ and Fe···Cp distances in 17-electron ferracarborane **1** are significantly longer than those in its 18-electron congener $[\mathbf{1}]^-$, in accordance with one-electron removal from the bonding HOMO. The electrochemical investigation revealed that the $Fe^{II}$-tricarbollide complexes are more difficult to oxidize than the charge-compensated dicarbollide analogs, which in turn are more difficult to oxidize than the parent ferracarborane $[\mathbf{1}]^-$. The location of the $Fe^{II}/Fe^{III}$ couple for **3a**–**c** at highly positive potential values makes the $Fe^{II}/Fe^{I}$ reduction accessible. The fact that the redox changes of the different isomers occur at different potential values constitutes a further supporting technique in their selective recognition. Temperature-dependent $^{57}Fe$ Mössbauer effect spectroscopy (TDMES) was used to elucidate the hyperfine interaction parameters of the neutral carbollide complexes, as well as the dynamical aspects of the iron atom motion as a function of temperature. For a number of ferracarboranes studied in detail, modestly good agreement, within experimental error, was obtained for the msav extracted from single-crystal X-ray diffraction studies and TDMES.

## Experimental Section

**General Remarks:** All reactions were carried out under argon in anhydrous solvents which were purified and dried using standard procedures. The isolation of products was conducted in air. Ferracarboranes **1**, $[NMe_3Ph][\mathbf{1}]$,[20] and **3a**–**d**[5,6] were prepared as described in the literature. The solutions of sodium salts Na[9-L-7,8-$R_2$-7,8-$C_2B_9H_8$] were obtained by reaction of the corresponding carborane with NaH in THF.[24] Irradiation was conducted in a Schlenk tube using a high-pressure mercury-vapor lamp with a phosphor-coated bulb (400 W). The $^1H$- and $^{11}B$ NMR spectra were measured with a Bruker AMX-400 instrument at room temp. in [$D_6$]acetone unless otherwise stated. Materials and apparatus for electrochemistry and spectroelectrochemistry have been described elsewhere.[25] All the potential values are referred to the saturated calomel electrode (SCE).

**1-Cp-4-$SMe_2$-1,2,3-$FeC_2B_9H_{10}$ (2a):** To a solution of [$CpFe(C_6H_6)$]-$PF_6$ (344 mg, 1 mmol) in a mixture of THF (16 mL) and MeCN (4 mL) which was chilled to –78 °C, was added a solution of Na[9-$SMe_2$-7,8-$C_2B_9H_{10}$] in THF (4 mL, 1 mmol). The resulting mixture was irradiated with stirring at –60 to –40 °C within 1 h, and the solvents evaporated in vacuo. The residue was washed several times with MeOH giving red solid **2a** which was 95% pure according to $^1H$- and $^{11}B$ NMR spectroscopy. The analytically pure sample was obtained by reprecipitation using heptane from $CH_2Cl_2$. Yield 255 mg (80%). $^1H$ NMR: $\delta = 4.54$ (s, 5 H, Cp), 4.08 (br. s, 1 H, cage CH), 3.52 (br. s, 1 H, cage CH), 2.73 (s, 3 H, $SMe_2$), 2.73 (s, 3 H, $SMe_2$) ppm. $^{11}B$ NMR (*J*, Hz): $\delta = -6.04$ (d, 136, 1B), –6.04 (s, 1B, $BSMe_2$), –10.20 (d, 142, 1B), –11.30 (d, 142, 1B), –13.24 (d, 142, 1B), –17.87 (d, 138, 1B), –24.55 (d, 152, 1B), –27.11 (d, 165, 1B), –28.71 (d, 202, 1B) ppm. $C_9H_{21}B_9FeS$ (314.46): calcd. C 34.38, H 6.73, B 30.94, Fe 17.76; found C 34.32, H 6.48, B 30.80, Fe 17.44.

**1-Cp-4-$NMe_3$-1,2,3-$FeC_2B_9H_{10}$ (2b):** Compound **2b** was synthesized in a similar manner to **2a**. However, when the irradiation was finished, the reaction tube was placed into a Dewar vessel with an acetone/dry ice mixture, and the reaction mixture was additionally stirred for 24 h with gradual rising of temp. to 20 °C. Yield 32%. $^1H$ NMR: $\delta = 4.63$ (s, 5 H, Cp), 4.56 (br. s, 1 H, cage CH), 3.58 (br. s, 1 H, cage CH), 3.19 (s, 9 H, $NMe_3$) ppm. $^{11}B$ NMR (*J*, Hz): $\delta = 5.27$ (s, 1B, $BNMe_3$), –5.45 (d, 129, 1B), –10.13 (d, 130, 1B), –10.84 (d, 109, 1B), –13.31 (d, 156, 1B), –14.94 (d, 151, 1B), –24.85 (d, 152, 1B), –26.08 (d, 157, 1B), –28.30 (d, 167, 1B) ppm. $C_{10}H_{24}B_9FeN$ (311.44): calcd. C 38.57, H 7.77, N 4.50; found C 38.59, H 7.91, N 4.54.

**1-Cp-4-py-1,2,3-$FeC_2B_9H_{10}$ (2c):** To a solution of [$CpFe(C_6H_6)$]$PF_6$ (172 mg, 0.5 mmol) in a mixture of THF (3 mL) and MeCN (3 mL) which was chilled to –78 °C, was added a solution of Na[9-py-7,8-$C_2B_9H_{10}$] in THF (10 mL, 0.5 mmol). The resulting mixture was irradiated with stirring at –60 to –40 °C within 3 h, treated with MeOH (1 mL), and filtered. The filtrate was evaporated in vacuo, and the residue was eluted on a silica gel column (7 cm) with a $CH_2Cl_2$/petroleum ether (1:1) mixture. The bright-red band was collected, evaporated in vacuo, and washed several times with ether to give dark-red crystals of **2c**. Yield 60 mg (48%). $^1H$ NMR: $\delta =$ 9.00 (d, 5.6, 2 H, $C_5H_5N$), 8.46 (t, 7.6, 1 H, $C_5H_5N$), 8.00 (t, 7.2, 2 H, $C_5H_5N$), 4.72 (br. s, 1 H, cage CH), 4.15 (s, 5 H, Cp), 3.53 (br. s, 1 H, cage CH) ppm. $^{11}B$ NMR (*J*, Hz): $\delta = 2.56$ (s, 1B, Bpy), –5.68 (d, 129, 1B), –9.83 (d, 147, 1B), –11.03 (d, 158, 1B), –12.64 (d, 141, 1B), –13.72 (d, 139, 1B), –23.03 (d, 153, 1B), –25.92 (d, 151, 1B), –28.05 (d, 167, 1B) ppm. $C_{12}H_{20}B_9FeN$ (331.43): calcd. C 43.49, H 6.08, B 29.35; found C 43.49, H 6.02, B 29.08.

**1-Cp-2,3-$Me_2$-4-$SMe_2$-1,2,3-$FeC_2B_9H_8$ (2d):** Compound **2d** was prepared in a similar manner to **2a**. Yield 220 mg (64%). $^1H$ NMR: $\delta = 4.48$ (s, 5 H, Cp), 2.86 (s, 3 H, $SMe_2$), 2.60 (s, 3 H, $SMe_2$), 2.44 (s, 3 H, CMe), 2.22 (s, 3 H, CMe) ppm. $^{11}B$ NMR (*J*, Hz; $CD_2Cl_2$): $\delta = -1.65$ (s, 1B, BPy), –4.86 (d, 157, 1B), –6.20 (d, 155, 1B), –9.35 (d, 142, 1B), –12.66 (d, 138, 1B), –17.68 (d, 130, 2B), –18.55 (d, 140, 1B), –20.64 (d, 150, 1B) ppm. $C_{11}H_{26}B_9FeS$ (343.52): calcd. C 38.46, H 7.63; found C 38.39, H 7.21.

**1-Cp*-4-$SMe_2$-1,2,3-$FeC_2B_9H_{10}$ (2e):** A solution of Na[9-$SMe_2$-7,8-$C_2B_9H_{10}$] in THF (2 mL, 0.5 mmol) was added to a solution of [$Cp^*Fe(MeCN)_3$]$BF_4$ (200 mg, 0.5 mmol) in THF (10 mL) at 0 °C. The resulting mixture was stirred at this temp. for 1 h, and compound **2e** was isolated in a similar manner to **2a**. Yield 155 mg (80%). $^1H$ NMR: $\delta = 5.32$ (br. s, 1 H, cage CH), 3.58 (br. s, 1 H, cage CH), 2.59 (s, 6 H, $SMe_2$), 2.39 (s, 6 H, $SMe_2$), 2.35 (br. s, 1 H, cage CH), 1.79 (s, 15 H, Cp*) ppm. $^{11}B$ NMR (*J*, Hz): $\delta =$ –4.90 (d, 195, 1B), –6.02 (s, 1B, $BSMe_2$), –9.19 (d, 144, 1B), –12.90 (d, 130, 1B), –13.80 (d, 130, 1B), –18.18 (d, 138, 1B), –25.28 (d, 159, 1B), –27.27 (d, 176, 1B), –29.13 (d, 227, 1B) ppm.

**Mössbauer Spectroscopy:** The solid compounds were transferred to plastic sample holders and examined by standard transmission

Mössbauer effect spectroscopy (MES) using a 50 mCi $^{57}$Co/Rh source as described previously.[26] Spectrometer calibration was performed using a 10 mg cm$^{-2}$ α-Fe foil at room temp., and all isomer shifts are referred to the centroid of such a spectrum. ME data acquisition times varied from 7 to 30 h (depending on the temp.), and since one of the objectives of this research was to elucidate the temperature-dependent parameters extracted from the ME data, the thermal variation with time was continuously monitored using the Daswin program of Glaberson and Brettschneider.[27] The temp. uncertainties are estimated as ±0.1 K over the data acquisition intervals.

**Calculation Details:** All calculations were performed using Gaussian 98 package.[28] The structure of [**1**]$^-$ was optimized at B3LYP/6-31G* level in $C_s$ symmetry. The molecular orbital visualization was performed by ChemCraft software, version 1.5 (www.chemcraftprog.org).

**X-ray Crystallography:** Crystals of **1** and [$NMe_3Ph$][**1**] suitable for X-ray diffraction were grown by slow evaporation of $CH_2Cl_2$ solutions. Crystals of **2b** were grown by slow diffusion in a two-layer system, solution of the complex in [$D_6$]acetone/petroleum ether, placed in an NMR tube. X-ray diffraction experiments were carried out with a Bruker SMART 1000 CCD area detector, using graphite-monochromated Mo-$K_\alpha$ radiation at 110 K. Low temp. of the crystals was maintained with a Cryostream (Oxford Cryosystems) open-flow nitrogen gas cryostat. Reflection intensities were integrated using SAINT software,[29] and absorption correction was applied semi-empirically using SADABS program. The structures were solved by direct method and refined by the full-matrix least-squares against $F^2$ in anisotropic approximation for non-hydrogen atoms. All polyhedron hydrogen atoms were located from the Fourier density synthesis and refined in isotropic approximation. Crystal data and structure-refinement parameters for **1**, [$NMe_3Ph$][**1**], and **2b** are given in Table 5. All calculations were performed using the SHELXTL software.[30]

CCDC-291166 (for [$NMe_3Ph$][**1**]), -291167 (for **1**), and -291168 (for **2b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): Spectroelectrochemical data for transition from **3d** to [**3d**]$^+$ and the optimized coordinates from DFT calculations of [**1**]$^-$.

## Acknowledgments

We thank Prof. W. Glaberson and Dr. M. Brettschneider for the use of their Daswin program prior to publication. Financial support from the Racah Institute and the Division of General Chemistry and Material Sciences of Russian Academy of Sciences, as well as the University of Siena (PAR 2005) is also gratefully acknowledged. D. S. P. thanks INTAS for a Young Scientist Fellowship (Grant No. 04-83-3848).

# Catalytic Activity of Copper Oxide/Zinc Oxide Composites Prepared by Thermolysis of Crystallographically Defined Bimetallic Coordination Compounds

**Rainer Weiss,[a] Yanzhi Guo,[a] Sascha Vukojević,[b] Lamma Khodeir,[c] Roland Boese,[a] Ferdi Schüth,[b] Martin Muhler,[c] and Matthias Epple*[a]**

**Keywords:** Heterogeneous catalysis / Copper / Zinc / Thermochemistry / Structural chemistry

The suitability of bimetallic coordination compounds in the systems Cu/Zn/CN and Cu/Zn/CN/ethylenediamine as precursors for CuO/ZnO was explored. The kinetic and thermodynamic equilibria in these systems are discussed. The introduction of ethylenediamine led to crystalline precursor compounds, and the bimetallic coordination compounds $[Zn(en)]_2[Cu_2(CN)_6]$ and $[Zn(en)_3]_6[Cu_2(CN)_7]_2[Cu(CN)_3]\cdot 8.4H_2O$ were structurally characterised. The oxide mixtures of CuO/ZnO, prepared by mild thermolysis of the precursor compounds, were tested for their catalytic activity in the formation of methanol from synthesis gas, i.e. $CO/CO_2/H_2$. While the oxide mixtures from $Zn[Cu(CN)_3]$ were not catalytically active, the oxide mixtures derived from the crystalline compounds with ethylenediamine as the ligand had about 20–30 % of the activity of an industrial methanol catalyst. This underscores the importance of the origin of the catalyst, i.e. the dependence of its activity from the structure of its precursor.

## Introduction

Cu/ZnO is a widely used system in heterogeneous catalysis for methanol synthesis and steam reforming.[1–3] Although $Cu/ZnO/Al_2O_3$ is a more efficient catalyst, Cu/ZnO is often examined as an easier model to understand the catalytic process (note that even ZnO alone is an active catalyst in methanol synthesis[4]). Conventionally, such catalysts are prepared by thermolysis of coprecipitated carbonates or oxalates.[5] Here we report on the preparation, structural characterisation, thermolysis and catalytic activity of two bimetallic coordination compounds that contain copper and zinc within the same crystal. We showed earlier that it is possible to prepare $Zn[Cu(CN)_3]$ with two metals in the same crystal.[6] It is reasonable to assume that the oxides prepared by oxidative thermolysis occur in an intimately dispersed state, thereby enhancing the catalytic activity. Two well-defined bimetallic coordination compounds can be decomposed to intimate mixtures of CuO and ZnO. The catalytic activity of the oxides derived from these precursor compounds containing Cu–Zn–CN and Cu–Zn–CN–ethylenediamine in methanol synthesis was investigated. Therefore, a comprehensive picture ranging from the single crystal structure, through to thermolysis and on to the catalytic performance is presented here.

## Results and Discussion

### Some General Remarks about the Thermodynamic and Kinetic Equilibria in the Cu/Zn/CN Precursor System

All syntheses were typically performed by mixing aqueous solutions of the first metal with aqueous solutions of a cyanide complex of the second metal. It turned out that a number of different species are present in solution, e.g. $[Cu^{II}(H_2O)_6]^{2+}$, $[Zn^{II}(H_2O)_6]^{2+}$, $[Zn^{II}(CN)_4]^{2-}$, "$[Cu^{II}(CN)_4]^{2-}$", $[Cu^{I}(CN)_4]^{3-}$ and $[Cu^{I}(CN)_3]^{2-}$.[7] Note that "$[Cu(CN)_4]^{2-}$" is just a formal description because $Cu^{II}$ cyanide complexes are subject to an internal redox reaction resulting in $Cu^{I}$ and $(CN)_2$. In the case of the reaction of $Cu^{2+}$ with $[Zn^{II}(CN)_4]^{2-}$, the kinetic lability of the cyanocomplexes of copper and zinc had a strong influence on the products that formed. Starting with solutions of $[Zn^{II}(CN)_4]^{2-}$ and $Cu^{2+}$, the main product was $Zn^{II}[Cu^{I}(CN)_3]$, whereas $Cu^{II}[Zn^{II}(CN)_4]$ and $Zn^{II}[Zn^{II}(CN)_4]$ were only found as side products.[6]

Furthermore, in the system Cu/CN there are not only different species in solution, but also many different types of structural elements consisting of $Cu^{I}$ coordinated by $CN^-$ exist in the solid state. For instance, the unit "$[Cu(CN)_3]^{2-}$" can be either a mononuclear trigonal-planar complex, or a dinuclear complex $[Cu_2(CN)_6]^{4-}$, as in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[Cu^{II}(en)_2]_4[Cu^{I}(CN)_3]_2[Cu^{I}_2(CN)_6]\cdot 2H_2O$ (ref.[8]) or a part of an infinite three-dimensional network as in $[Zn(en)]_2[Cu_2(CN)_6]$ (**1**; see the structure below). It is essential to have the crystal structures of the precursors in this system because the crystal structure of the precursor determines the structure and morphology of the reaction products if the thermolysis is carried out at moderate temperature, i.e. not under thermodynamic equilibrium conditions.[1,9] This is of particular interest in heterogeneous catalysis where surface effects are often more important than the composition.[10,11]

The different kinetic stabilities of cyanometallate complexes are important for the preparation: In a bimetallic system which contains a kinetically stable complex, e.g. $[Fe(CN)_6]^{3-}$, and a counterion which does not form a cyanide complex itself, e.g. $Gd^{3+}$, the preparation of a bimetallic coordination compound like $Gd[Fe(CN)_6]$ is straightforward and easy.

In the pair $Cu^{I/II}$ and $Zn^{II}$, two metals are present which form kinetically unstable cyanocomplexes with comparable stability constants. The stability constant of $[Zn^{II}(CN)_4]^{2-}$ is $4\times10^{19}$ M$^{-4}$ (ref.[12]) and much smaller than that of $[Cu^{II}(CN)_4]^{2-}$ with $1\times10^{27}$ M$^{-4}$ (ref.[13]), therefore the latter compound is preferred in equilibrium. However, $Cu^{II}$ is reduced by $CN^-$ to $Cu^{I}$ upon mixing $[Zn^{II}(CN)_4]^{2-}$ and $Cu^{II}$, and the anion $[Cu^{I}(CN)_3]^{2-}$ is formed as the main copper species in solution.[6] This may serve as an example as to how the constitution of the complexes found in the solid state often cannot be predicted from the formulae of the dissolved precursor molecules, making a rational synthesis difficult.

### Bimetallic Cyanides as Precursors for CuO/ZnO for Methanol Catalysis

Mixtures of CuO and ZnO were prepared from $Zn[Cu(CN)_3]$ by oxidative thermolysis under different conditions (temperature from 200 to 500 °C). In addition, the grain size of $Zn[Cu(CN)_3]$ was adjusted by variation of the precipitation conditions as reported earlier (continuous overflow method).[6] Although the oxide mixtures (CuO and ZnO) were analytically pure (no residual cyanide compound was left after thermolysis, which was checked by IR spectroscopy and elemental analysis), the catalytic activities for methanol synthesis were practically zero in all cases. The reason for this behaviour is not known, but it is possible that the decomposition temperature was too high to preserve a sufficiently high specific surface (the BET surface area was around 5 to 10 $m^2 g^{-1}$ for these samples) and possibly some sintering had occurred.[14] On the other hand, the surface of the active copper and zinc oxide particles may have been poisoned by small amounts of cyanide that were still adsorbed under these conditions, but no longer detectable by bulk-phase techniques.

### The Precursor System Cu/Zn/CN/Ethylenediamine (en)

A better control over the precursor is possible if its crystal structure is known, yielding the coordination environment of both metals and also the unequivocal evidence that both metals are present within the same crystal. To obtain such single crystalline precursors, the solubility of the coordination compounds in the system Cu/Zn/CN had to be increased. The chelating ligand ethylenediamine, $H_2N–CH_2–CH_2–NH_2$, can substitute cyanide as a ligand.[15] It also prevents the formation of metal–cyanide–metal bonds, which lead to rapid precipitation of polymeric compounds, like the well-known Prussian Blue that contains a three-dimensional network of Fe–CN–Fe bridges or like $Zn(CN)_2$ that contains an adamantane-like network.

In the system Cu/Zn/CN/en, the formation of compounds does not only depend on the composition of the solutions. It also depends on the pH and the content of $K^+$. This was found by experiments with solutions of the formal composition "$[Cu^{II}(en)_2][Zn^{II}(CN)_4]$". From this solution, two different bimetallic compounds were obtained, just by simple modification of the conditions:

(1) From KCN and in the presence of $(NH_4)_2SO_4$ buffer (pH about 8), the compound $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) (pale green crystals) was obtained.

(2) From NaCN (not buffered; pH about 10), the compound $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) (bluish or colourless crystals) was obtained.

These structures indicate that in these systems $Zn^{2+}$ has a close affinity to ethylenediamine and that $Cu^+$ has a close affinity to cyanide. The coordination geometry around zinc and copper depends on the synthesis conditions. Chi and Fedkiw reported that $[Cu(CN)_3]^{2-}$ is the main species in the system $Cu^+/CN^-$, even if cyanide is present in excess.[16] The formation of the dinuclear anion $[Cu_2(CN)_7]^{5-}$ can be derived from joining a $[Cu(CN)_3]^{2-}$ unit with a $[Cu(CN)_4]^{3-}$ unit. The fact that both compounds are slightly coloured suggests that small amounts of $Cu^{2+}$ are also present in the crystal, possibly as substitution for $Zn^{2+}$ ($Cu^{I}$ and $Zn^{II}$ are both colourless).

Here, the structure of $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) was determined for the first time (see Figure 1, Table 1 and Table 2). Crystalline $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ contains units of $[Cu^{I}_2(CN)_6]^{4-}$ and $[Zn^{II}(en)]^{2+}$, which together form a three-dimensional network. Each zinc atom is connected to three $[Cu_2(CN)_6]^{4-}$ units by one cyanide ligand. This leads to an unusual square-pyramidal coordination of zinc where two nitrogen atoms from ethylenediamine and two nitrogen atoms from cyanide form the base of the pyramid. Copper and zinc atoms are in close vicinity in the crystal structure. The structure of $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) was reported earlier by Kappenstein et al.[17,18] and confirmed here by single-crystal structure analysis.

The infrared spectra (Figure 2) show strong similarities between the two compounds. Especially the N–H bands ($[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**): 3367/3352/3292 $cm^{-1}$; $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**): 3342/3293 $cm^{-1}$) and the C–H bands ($[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**): 2962/2924/2899 $cm^{-1}$; $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**): 2962/2934/2883 $cm^{-1}$) are almost identical whereas the C–N bands ($[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**): 2116 $cm^{-1}$;

$[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4\ H_2O$ (**2**): 2081 cm$^{-1}$) can clearly be distinguished and may be used to distinguish both compounds.

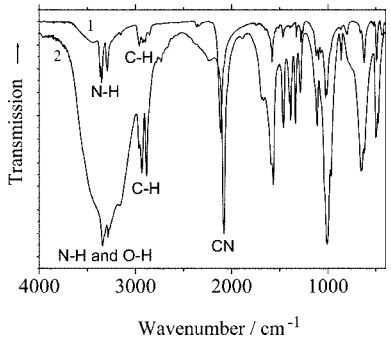

Figure 2. Infrared spectra of $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**).

### Thermolysis of 1 and 2

The thermolysis of $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) under oxygen to CuO/ZnO was followed in situ by thermogravimetry combined with infrared spectroscopic gas analysis (Figure 3 and Figure 4).

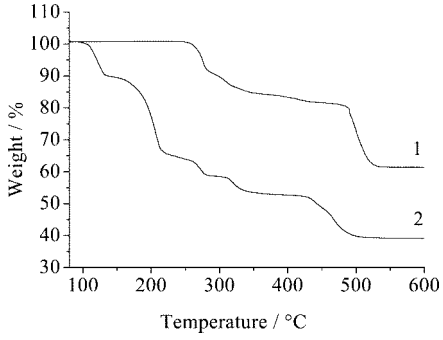

Figure 3.Thermogravimetry of **1** and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) to CuO/ZnO under a dynamic oxygen atmosphere.

The thermolysis of $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) can be divided into three parts. In a first step from 250 °C to about

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

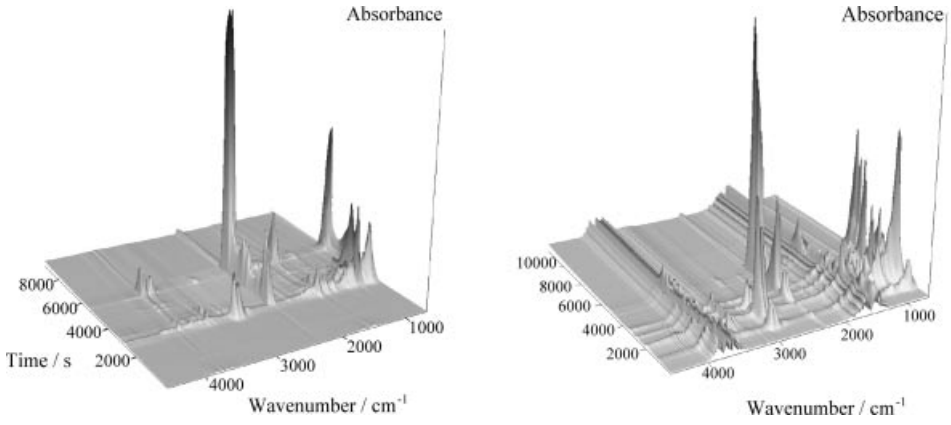

Figure 4. Time-resolved IR spectra of gases evolved from $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) (left) and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) (right) during thermolysis to CuO/ZnO.

295 °C, ethylenediamine is released without oxidation, as is visible from the C–H bands in the infrared spectrum at around 3000 cm$^{-1}$. From 295 to 490 °C the remainder of the ethylenediamine and a part of the cyanide undergo combustion as indicated by the evolution of $CO_2$ (four bands from 3740 to 3590 cm$^{-1}$ and several bands from 2560 to 2310 cm$^{-1}$) and $H_2O$. Finally, the combustion of cyanide to carbon dioxide and nitrous oxide (NO) occurs above 490 °C. The residual mass of 61.43 wt.-% corresponds well to the theoretical value of 60.25 wt.-% for a 1:1 mixture of ZnO and CuO.

The thermolysis of $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ occurs in five well-separated steps. In the first step, from 90 to 145 °C first water and then also ethylenediamine are released. Up to 240 °C, about 10 of the 18 molecules of ethylenediamine and all the crystal waters are lost. Starting around 240 °C, the reaction turns to oxidative combustion with the release of $CO_2$, first of ethylenediamine and then of cyanide. The final mass of 38.9 wt.-% corresponds well to the calculated value of 37.1 wt.-% for a 6:5 mixture of ZnO and CuO.

The morphology of the oxide mixtures, prepared by mild thermolysis of $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) in air at 300 °C for 48 h was investigated by scanning electron microscopy (Figure 5). The crystallites have a size of a few 100 nm up to a micrometer, comparable to those obtained earlier by thermolysis of $Zn[Cu(CN)_3]$.[6] High-resolution X-ray powder diffraction (synchrotron) confirmed the absence of precursors or other crystalline impurities.

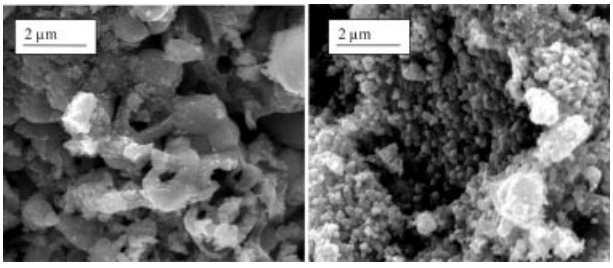

Figure 5. Scanning electron micrographs of the resulting CuO/ZnO mixtures from $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) (left) and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) (right) after annealing for 48 h at 300 °C.

### Catalytic Activity of Cu/ZnO from the Precursor System Cu/Zn/CN/Ethylenediamine (en)

The oxide samples were tested for their catalytic activity in the formation reaction of methanol from $CO/CO_2/H_2$ by two different methods. First, a 49-channel parallel flow multitubular reactor was used for rapid scanning of many samples (Table 3).[19] Note that CuO/ZnO was always reduced prior to the catalytic test in order to obtain the active catalyst Cu/ZnO. This was done in situ in the catalytic reactor. Because the absolute catalytic performance strongly depends on the specific conditions, all activities were related to an industrial benchmark catalyst (ICI Katalco 51–8) whose activity was set to 100%. This multitubular reactor permitted highly efficient parallel testing of numerous samples, including control experiments with the same sample. The oxides derived from $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4H_2O$ (**2**) showed similar activities that were much higher than the activities of the oxide mixtures from $Zn[Cu(CN)_3]$, which contained only cyanide as a ligand (see above; almost no activity). In a second experiment, both precursors were mixed with finely dispersed $Al_2O_3$ (for chromatography) as a support before the thermal decomposition to increase the specific surface. However, with this support, the catalytic activity (related to the content of CuO/ZnO in the catalyst) decreased considerably, i.e. the active surface of the catalyst could not be increased by this method.

In a single-tube reactor, the oxide mixture derived from $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) was studied more closely with regard to its reduction to Cu/ZnO, the specific copper surface area and the catalytic activity. Again, it was compared to the industrial benchmark catalyst (ICI) and also to another oxide sample derived by the conventional coprecipitation method of carbonates.[20] The content of CuO was approxi-

Table 3. Catalytic activity of CuO/ZnO samples after in situ reduction to Cu/ZnO in the multitubular reactor.

| Sample | Activity |
|---|---|
| Cu/ZnO from $Zn[Cu(CN)_3]$ | ≈ 0% |
| Cu/ZnO from $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) | 30% |
| 5 Cu/6 ZnO from $[Zn^{II}(en)_3]_6[Cu^{I}{}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4\ H_2O$ (**2**) | 29% |
| Cu/ZnO from $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) + $Al_2O_3$ | 13% |
| 5 Cu/6 ZnO from $[Zn^{II}(en)_3]_6[Cu^{I}{}_2(CN)_7]_2[Cu^{I}(CN)_3]\cdot 8.4\ H_2O$ (**2**) + $Al_2O_3$ | 9% |
| Industrial reference catalyst (ICI) | 100% |

mately 50 mol-% for these three samples. The content of CuO in the oxide derived from $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) was confirmed by the quantitative reduction (Figure 6). After reduction, the sample had a copper surface area of 2.42 $m^2 g^{-1}$ (Figure 7). Compared with the catalyst based on coprecipitated carbonate and the industrial catalyst, the sample had a smaller copper surface area, but the activity related to the copper surface area was surprisingly high (see Table 4). Note that an adsorption of nonvolatile fragments of the organic ligands on the copper surface that leads to a decrease in activity is unlikely but cannot be excluded with this compound. It was shown earlier that the Cu surface generally decreases during the catalytic process because of sintering of the Cu particles.[14]

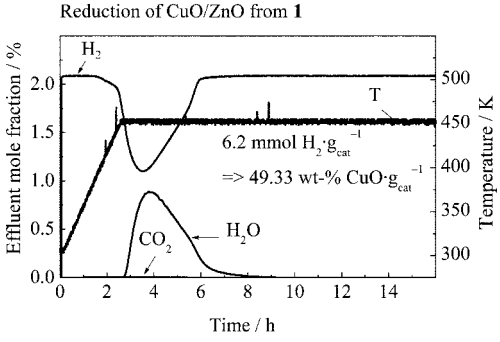

Figure 6. Reduction of CuO/ZnO from thermolysis of $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) to Cu/ZnO in the single-tube reactor.

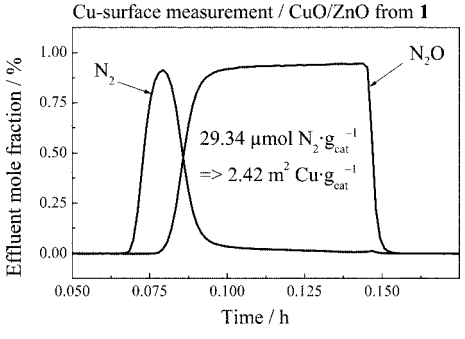

Figure 7. Measurement of the specific copper surface of Cu/ZnO prepared from the oxide derived from $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) by reaction with $N_2O$ in the single-tube reactor.

Note that the catalytic activity results obtained with the multitubular reactor cannot be directly compared with data from the single channel flow system. This is a result of the different set-ups as well as differences in the reduction process, different pressures (4.5 MPa for the parallel set-up vs. atmospheric pressure in the single-tube reactor) and slightly different feed compositions. Thus the catalytic activity of Cu/ZnO prepared from $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) measured in the single-tube reactor corresponds to 23% of the activity of the commercial ICI catalyst, which is in satisfactory agreement to the data obtained from the parallel set-up (30% of ICI). In general, the efficiency of the Cu/ZnO mixture derived from the cyanide/ethylenediamine coordination compounds is between 20 and 30% of the industrial reference catalyst.

Table 4. Catalytic activity of CuO/ZnO prepared from $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) in the single-tube reactor (reduced to Cu/ZnO) and of two reference catalysts.

| Sample | Cu surface [$m^2 g^{-1}$] | Production rate [$\mu mol\, g^{-1}{}_{cat}\, h^{-1}$] |
|---|---|---|
| Cu/ZnO from **1** | 2.42 | 92 |
| Cu/ZnO from coprecipitated carbonate | 17.0 | 115 |
| Industrial $Cu/ZnO/Al_2O_3$ catalyst (ICI) | 23.4 | 410 |

Kurtz et al. gave a linear relationship between the specific copper surface and the catalytic activity.[14] For our CuO/ZnO catalyst from $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**), only 40% of the actually observed activity would have been expected, i.e. about 40 $\mu mol\, g^{-1}{}_{cat}\, h^{-1}$. An optimised thermolysis of $[Zn^{II}(en)]_2[Cu^{I}{}_2(CN)_6]$ (**1**) with regard to a high surface area of copper oxide may lead to an even higher catalytic activity. Unfortunately, the "easy route" to increase the specific surface area by adding $Al_2O_3$, as further support, was not successful (see Table 3).

## Conclusions

By the preparation and thermolysis of bimetallic coordination compounds, which contain copper and zinc in the same crystal, it is possible to prepare active Cu/ZnO catalysts for methanol synthesis. However, if only cyanide is present as the ligand, the activity of the resulting oxide mixture is almost zero, possibly because of poisoning of the surface. The introduction of ethylenediamine as an additional ligand leads to Cu/ZnO with a catalytic activity of 20 to 30% of the industrial reference catalyst. It is important to note that the morphology (by scanning electron microscopy) and the chemical composition (CuO and ZnO) of the thermolysis products from both kinds of precursors are practically indistinguishable. This underscores the strong influence of the precursor structure on the catalytic activity of the resulting oxide,[1,2] which, despite sophisticated in situ studies,[21,22] is not yet fully understood.

## Experimental Section

For all preparations, deionised water was used.

**Preparation of $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (1):** KCN (2.6 g, 40 mmol) and $(NH_4)_2SO_4$ (2.64 g, 20 mmol) were dissolved in water (50 mL). $ZnSO_4{\cdot}7H_2O$ (2.91 g, 10 mmol) was added to this solution whilst stirring until complete dissolution occurred. A second solution of $CuSO_4{\cdot}5H_2O$ (2.53 g, 10 mmol) and ethylenediamine (1.1 mL, 20 mmol) was prepared in water (25 mL). The solutions were poured together whilst stirring and a slightly blue precipitate was obtained. Water was added to a volume of 100 mL, and the unfiltered mixture of precipitate and solution was stored in a closed flask for three days. Pale green crystals were obtained, filtered, washed with water and dried for several days at room temperature in air. Yield: 43%. $C_{10}H_{16}Cu_2N_{10}Zn_2$ (534.16) (average of four independent preparations with standard deviations): calcd. C 22.49, H 3.02, Cu 23.79, N 26.22, Zn 24.48; found C 22.16 ± 0.64, H 2.76 ± 0.34, Cu 25.06 ± 1.38, N 25.64 ± 0.86, Zn 23.70 ± 1.47. The powder diffraction pattern of $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (**1**) was simulated using the single-crystal structure data. It showed an excellent agreement with the experimental powder diffraction pattern, therefore the bulk phase has the same structure as the single crystal.

**Preparation of $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]{\cdot}8.4H_2O$ (2):** NaCN (1.96 g, 40 mmol) was dissolved in water (40 mL). CuCl (0.99 g, 10 mmol) was added to this solution whilst stirring until complete dissolution occurred. A second solution of $Zn(OAc)_2{\cdot}2H_2O$ (3.29 g, 15 mmol) and ethylenediamine (3 mL, 45 mmol) was prepared in water (35 mL). The solutions were mixed and then stored in a sealed flask for a week. Slightly bluish crystals were obtained. After addition of a small amount of ethanol, more crystals were obtained from the mother liquor. Yield: 51%. $C_{53}H_{160.8}Cu_5N_5Zn_6$ (2385.41) (average of four independent preparations with standard deviations): calcd. C 26.69, H 6.79, Cu 13.32, N 31.12, Zn 16.44; found C 26.50 ± 0.54, H 6.83 ± 0.15, Cu 12.71 ± 0.46, N 30.60 ± 0.39, Zn 16.37 ± 0.39; traces of Na were also detected (0.58 ± 0.28 from three preparations). The powder diffraction pattern of **2** was simulated using the single-crystal structure data. It showed an excellent agreement with the experimental powder diffraction pattern, therefore the bulk phase has the same structure as the single crystal.

**Preparation of CuO/ZnO from $[Zn^{II}(en)]_2[Cu^{I}_2(CN)_6]$ (1) and $[Zn^{II}(en)_3]_6[Cu^{I}_2(CN)_7]_2[Cu^{I}(CN)_3]{\cdot}8.4H_2O$ (2):** The compounds were heated in an open crucible in air at 300 °C for 24 h. The product was then ground and heated again for 24 h at 300 °C. For the carrier experiment the precursor (100 mg) was intimately ground with $Al_2O_3$ (400 mg). The thermolysis was carried out as before.

**Catalytic Measurements:** (a) High-throughput screening in the multitubular reactor: Measurements were performed with a high-throughput 49-parallel channel reactor.[19] The catalyst (100 mg diluted by 200 mg quartz per well) was placed in a sample holder consisting of a stainless-steel cartridge closed at the bottom by a stainless-steel sinter metal frit. Prior to the catalytic measurements, the catalysts were reduced with $H_2$ at 518 K following the procedure for the commercial benchmark catalyst ICI Katalco 51–8. Before measuring the catalytic activity, all samples were equilibrated for 3 h (reaction pressure 4.5 MPa, reaction temperature 518 K, analytic flow 20 mL min$^{-1}$). The reaction gas consisted of 70% $H_2$, 24% CO and 6% $CO_2$. A double GC system (HP GC 6890) equipped with a methaniser FID was used for online gas analysis. Oxo-product separation ($H_3COH$, $HCOOCH_3$, $H_3CCOOCH_3$, $H_3CCH_2OH$) was carried out on a SuppelcoWAX 0.53 mm column and CO, $CO_2$ and $CH_4$ were separated on a Carboxen 1006 column. Methanol productivities for all measured samples were compared to the productivity of the industrial benchmark catalyst ICI Katalco 51–8 [$P_{ICI}$ = 40 mmol MeOH/($g^{-1}_{cat}\,h^{-1}$) at 518 K and 4.5 MPa].

(b) Single-tube reactor: 100 mg of the sample (sieves fraction 250–355 μm) were placed in a fixed-bed glass-lined U-tube reactor. The reduction was performed under flowing diluted $H_2$ (2% $H_2$ in He) by increasing the temperature up to 448 K by 1 K min$^{-1}$ and maintaining it there for 14 h. To ensure complete reduction, the temperature was then increased to 513 K and the sample was treated with pure $H_2$. The active surface area of Cu was determined by $N_2O$ reactive frontal chromatography at 300 K as described earlier.[23] The methanol formation activity was measured at 493 K under atmospheric pressure. The feed gas consisted of 72% $H_2$, 10% CO, 4% $CO_2$ and 14% He. Gases of the highest available purity (>99.9995%) were used. The online analysis of the products was performed by a previously calibrated quadrupole mass spectrometer (Balzers GAM 422).

**Analytical Techniques:** Combined thermogravimetry-infrared spectroscopy (TG-IR) was carried out with a Netzsch STA 209 TG-DTA/DSC instrument connected to a Bruker Vertex 70 infrared system with a TGA-IR measurement cell for gas analysis. Samples were heated from 30 °C to 800 °C at a rate of 5 K min$^{-1}$ under a dynamic $O_2$ atmosphere at a flow rate of 50 mL min$^{-1}$. Infrared spectroscopy was carried out with a Bruker Vertex 70 (KBr pellets), scanning electron microscopy with an ESEM Quanta 400 instrument (FEI) on nonsputtered samples. High-resolution X-ray powder diffractometry was carried out in transmission geometry at beamline B2 at HASYLAB/DESY, Hamburg, Germany.[24]

## Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft within the scope of the Collaborative Research Center SFB 558: Metal–substrate interactions in heterogeneous catalysis. We thank HASYLAB at DESY, Hamburg, for the generous allocation of X-ray diffraction beam time.

# Coordination Chemistry and Diphenylacetylene Hydrogenation Catalysis of Planar Chiral Ferrocenylphosphane-Thioether Ligands with Cyclooctadieneiridium(I)

**Raluca Malacea,[a] Eric Manoury,*[a] Lucie Routaboul,[a] Jean-Claude Daran,[a] Rinaldo Poli,[a] John P. Dunne,[b] Adrian C. Withwood,[b] Cyril Godard,[b] and Simon B. Duckett[b]**

**Keywords:** Ferrocenylphosphane ligands / Hemilability / Hydrogenation / Iridium / Planar chirality / Thioether ligands

The reaction of the P,S ligands CpFe{1,2-$C_5H_3(PPh_2)(CH_2SR)$}, (**1-R**; R = Et, Ph, *t*Bu), with 0.5 equivalents of $[Ir(COD)Cl]_2$ (metal/ligand = 1:1) furnishes the stable mononuclear adducts [Ir(COD)Cl(**1-R**)], **2-R**, in high yields. The molecular structures of the three complexes **2-R** have been determined by single-crystal X-ray diffraction. Compounds **2-Et** and **2-Ph** have similar five-coordinate molecular structures, with an intermediate coordination geometry between a distorted trigonal-bipyramid and a distorted square-pyramid. In the solid state, the sulfur atom chirality (R group *exo*, lone pair *endo* and parallel to the Cp-Fe axis) as well as the iridium chirality (Cl atom *exo* relative to the ferrocene group) is controlled by the ligand planar chirality. In solution, only one diastereoisomer is observed in both cases, indicating that the geometries observed in the solid state are maintained in solution, or that the different species are in rapid exchange on the NMR time scale. Complex **2-*t*Bu**, on the other hand, shows a four-coordinate square-planar molecular structure with a dangling thioether moiety, probably for steric reasons. For metal/ligand ratios greater than 1, the compounds [Ir(COD){$\kappa^2$-*P:S*-(**1-R**)}]$^+$[$Ir(COD)Cl_2]^-$ (**3-R**) are obtained, resulting from the chloride abstraction by the excess iridium metal on complex **2-R**. The structure of **3-Ph** was confirmed by single-crystal X-ray diffraction. A rapid equilibration between **2-R** and **3-R** gives rise to only one set of NMR signals for each metal/ligand ratio. For the ligand **1-*t*Bu**, a similar equilibration between **2-*t*Bu** and **3-*t*Bu** is again observed, in addition to a slower equilibration with a third product, [Ir(COD)Cl](μ-**1-R**)[Ir(COD)Cl] (**4-*t*Bu**), which is proposed to contain a bridging P,S ligand spanning two Ir centres. Complex **2-Ph** reacts with $[Rh(COD)Cl]_2$ to give only the heterometallic ionic pair [Ir(COD){$\kappa^2$-*P:S*-(**1-Ph**)}][$Rh(COD)Cl_2$] without transfer of ligand **1-Ph** from Ir to Rh. Furthermore, the rhodium complex RhCl(COD)(**1-Ph**) reacts quantitatively with $[Ir(COD)Cl]_2$ at room temp. to yield **2-Ph** and $[Rh(COD)Cl]_2$, thereby illustrating the much stronger affinity of ligands **1-Ph** for iridium compared to rhodium. Finally, the complexes **2-*t*Bu** and **2-Ph** were found to be efficient catalysts for the diphenylacetylene hydrogenation, affording a mixture of monohydrogenation [both (*E*)- and (*Z*)-stilbene] and dihydrogenation (1,2-diphenylethane) products.

## Introduction

The coordination chemistry of iridium has been widely studied during the last few decades, in part because of numerous applications that have been found in various catalytic systems[1] since the pioneering work of Crabtree et al.[2] In particular, iridium has been successfully applied to asymmetric catalyses, such as olefin hydrogenation,[3–12] C=N hydrogenation,[13–21] transfer hydrogenation[22–28] and allylic substitution.[29–40] Furthermore, the largest scale industrial enantioselective catalytic process involves an iridium-based hydrogenation step in the synthesis of chiral herbicide (1*S*)-Metolachlor.[41,42] Although many catalytic systems are generated in situ by the ligand addition to the readily available chloro(cycloocta-1,5-diene)iridium dimer, a good number of ligand adducts have been isolated and crystallographically characterized. When the supporting ligand (L-L′) is bidentate, several species can be envisaged depending on the ability of the ligand to act in a monodentate or bidentate fashion, and on the competition between the donor atoms and the chloride ion for the metal center. These species correspond to five-coordinate [Ir($\kappa^2$-L-L′)(COD)Cl], four-coordinate neutral [Ir($\kappa^1$-L-L′)(COD)Cl] with a dangling L or L′ donor atom, and four-coordinate ionic [Ir($\kappa^2$-L-L′)(COD)]$^+Cl^-$. Whereas several solid-state structures are available for five-coordinate complexes[43–47] and an exam-

ple is also reported for neutral four-coordinate structure with a dangling phosphanyl ester ligand,[48] no examples are known, to the best of our knowledge, of four-coordinate ionic $[Ir(\kappa^2\text{-L-L}')(COD)]^+$ complexes with chloride as counterion (though they are known for rhodium).[49–51] Whether, for a given metal/ligand combination, the solid-state structure is maintained in solution and whether it is solvent dependent, or whether equilibria between different structures are established, has not been the subject of detailed studies to the best of our knowledge. In addition, how the ligand stereoelectronic properties may influence this structural choice is also an obscure point.

The coordination chemistry of sulfur-containing ligands,[52,53] as well as their potential in homogeneous catalysis[54,55] have recently attracted much interest, amongst other things because the sulfur atom could become asymmetric upon coordination to a metal. We have recently reported the synthesis of a family of planar-chiral P,S ligands, namely (*R*/*S*)-2-diphenylphosphanyl-[R-thiomethyl)ferrocenes (**1-R**), for instance with R = Et, *t*Bu, Ph, which proved to be very efficient in palladium-based asymmetric allylic alkylation.[56] As a first step toward the development of iridium-based catalytic systems, we wished to explore the iridium coordination chemistry of such ligands, with a particular focus on the stoichiometry, stereochemistry, potential (hemi)lability, etc. In this paper, we describe the synthesis and structure of a family of iridium complexes produced upon reaction of the racemic **1-R** (R = Et, *t*Bu, Ph) ligands with the cyclooctadieneiridium(I) moiety. We place particular emphasis on probing the relationship between the solution behaviour, the solid-state structure, and the nature of the R substituent on the ferrocenyl thioether function. New structural features and an unsuspected complex solution behaviour have been found through these investigations. Preliminary results on the catalytic diphenylacetylene hydrogenation reaction are also reported. Although the COD ligand is replaced by other ligands or substrates under most catalytic conditions (e.g. it is hydrogenated to cyclooctane under hydrogenation conditions) the structural and dynamic features observed for the pre-catalyst (i.e., the coordination stereoselectivity, the hemilability) are potentially relevant to the behaviour that one may expect under catalytic conditions.

## Results

### (a) Syntheses

Addition of the 2 equivalents of the bidentate ligands $[CpFe\{1,2\text{-}C_5H_3(PPh_2)(CH_2SR)\}]$ (**1-R**, R = Et, *t*Bu, Ph), which will be abbreviated as (P,SR), to complex $[Ir(COD)Cl]_2$ [i.e. 1 equiv. of (P,SR) to Ir] causes the splitting of the chloride-bridged dinuclear structure of the iridium precursor and formation of mononuclear products, according to the stoichiometry of Equation (1).

$$[(COD)Ir(\mu\text{-}Cl)_2Ir(COD)] + 2\ (P,SR) \longrightarrow 2\ IrCl(COD)(P,SR) \quad (1)$$

**1-R** **2-R**

The products **2-R** have been characterized by analytical and spectroscopic ($^1H$, $^{31}P$, $^{13}C$ NMR) methods. The NMR properties are shown in Table 1. These are spectra recorded on solutions obtained upon redissolving the isolated crystals, but correspond to complex equilibria between different species, as will be discussed in detail after the description of the structures. The three compounds show grossly similar physical (color, solubility) and spectroscopic properties in solution, but have different structures in the solid state. Whereas **2-Et** and **2-Ph** proved to be five-coordinate with a $\kappa^2$-*P*,*S* coordination mode for the bidentate ligand, their **2-*t*Bu** analogue is only four-coordinate, with a $\kappa^1$-*P* coordination mode and a dangling thioether functionality (see X-ray structures below).

Another remarkable feature has been observed during the crystallization of the crude product obtained from the reaction of **1-Ph** and $[Ir(COD)Cl]_2$ (2:1 ratio). Whereas crystals of **2-Ph** were obtained from dichloromethane/hexane, when the same procedure was followed for a toluene/hexane, crystals of a different compound, namely [Ir(COD)(P,SPh)][$Ir(COD)Cl_2$] (**3-Ph**) were produced. In fact, a $CDCl_3$ solution of **3-Ph** gave a $^{31}P$ resonance at 9.1 ppm, quite different from the value observed for **2-Ph** (–3.1 ppm). As will be shown later, this resonance results from an equilibrium mixture of **2-Ph** and **3-Ph**. When the synthesis was repeated for a 1:1 ratio of **1-Ph** and $[Ir(COD)Cl]_2$ (**1-Ph**/Ir = 2), the resulting orange solid displayed solution-state NMR properties in close correspondence with those of the isolated crystals of **3-Ph**. However, this solid also yielded crystals of **2-Ph** when recrystallized from dichloromethane/hexane. It seems therefore that the choice of crystallization solvent dictates the nature of the isolated product, indicating a possible equilibrium between **2-Ph** and **3-Ph** [Equation (2)]. A more detailed study of this equilibrium will be described below.

$$IrCl(COD)(P,SR) + \tfrac{1}{2}\,[Ir(COD)Cl]_2 \rightleftharpoons [Ir(COD)(P,SR)][Ir(COD)Cl_2] \quad (2)$$

**2-R** **3-R**

### (b) X-ray Structures

Views of the molecular geometries of compounds **2-Et**, **2-*t*Bu** and **2-Ph** are presented in Figure 1. It is immediately evident that the Et and Ph derivatives are five-coordinate because the S atoms are within reasonable bonding distances from the Ir centers [2.3928(17) Å and 2.3835(12) Å, respectively], whereas the *t*Bu derivative is only four-coordinate (the S···Ir distance is 5.13 Å). A comparable Ir–S bonding distances [2.3594(15) Å] has been reported for a $[(COD)Ir(P,S\textit{t}Bu)]^+$ complex containing a chiral phosphin-

[a] Chemical shifts are reported as measured, for solutions containing ca. $10^{-2}$ mol/L of the isolated crystals. [b] Overlap between COD(C*H*) and SEt ($CH_2$) resonances. [c] Overlap between COD($CH_2$) and SEt ($CH_3$) resonances. [d] Not visible (see text). [e] Overlap between the $PPh_2$ and SPh resonances. [f] Overlap between one $SCH_2$ and one $C_5H_3$ resonance.

ite–thioether donor.[57] Other significant bonding parameters are shown in Table 2 for the five-coordinate compounds and in Table 3 for the four-coordinate one. When considering the coordination sites as corresponding to the midpoints of the COD C–C double bonds, the geometry of **2-*t*Bu** corresponds quite closely to an ideal square plane, the Ir atom being only 0.0206(2) Å away from the least-squares coordination plane. The coordination geometries of compounds **2-Et** and **2-Ph**, on the other hand, may be best viewed as intermediate between a distorted trigonal-bipyramid and a distorted square-pyramid. In the distorted trigonal-bipyramidal view, the center of one C=C donor function of the COD ligand (CO2) and the S1 donor atom define the axial positions [angles of 168.1(4) and 166.703(18)°, respectively]. However, the equatorial angles deviate severely from the ideal 120° value, for instance the CT01–Ir(1)–P(1) angle in the two compounds is 153.2(4) and 156.06(2)°, respectively, whereas the P(1)–Ir(1)–Cl(1) angle is 91.33(7) and 90.03(3). In the alternative distorted square-pyramidal view, the axial ligand would be the Cl(1) ligand,

although a few of the Cl(1)–Ir–X angles [X = P(1), S(1), CO1 and CO2] are relatively close to 90°. It is interesting to note that in both **2-Et** and **2-Ph**, the Ir is located off the basal square plane by 0.363(8) Å and 0.3506(3) Å respectively, moreover the Ir is displaced toward the Cl atom. The distance from Cl to the square plane is 2.875(6) Å and 2.850(2) Å respectively. In fact, it would seem possible to view the structure as derived from that of the corresponding square planar $[Ir(COD)(P,SR)]^+$ by addition of $Cl^-$, resulting in a minimal perturbation of the square-planar geometry. Structures of five-coordinate $[IrX(COD)L_2]$ (X = any halogen) are not uncommon. They comprise examples with $L_2$ = diphosphanes[43,44] including a ferrocenyl-functionalized diphosphane,[45] diimines,[46,47] and also with L = monodentate phosphane.[58] The compounds reported here are the first such examples containing a bidentate P,S-type framework. More importantly, they illustrate the delicate

control exerted by the ligand structure on the coordination geometry. This control is unlikely to have an electronic origin, as the Et and *t*Bu substituents impart analogous electronic effects, and different from those of the Ph substituent. A steric effect appears more likely, because the *t*Bu group is more encumbering than either the Et or the Ph group and thus prevents the compound to attain the five-coordinate geometry (Figure 1).

The S coordination step is interesting from the stereochemical point of view. Coordination renders the S atom and the Ir atom asymmetric. In combination with the planar chirality of the substituted ferrocene moiety, eight possible stereoisomers, namely four diastereomeric pairs of enantiomers, can be obtained. There is, however, no indication from the NMR spectrum for the formation of more than one compound. Either the diastereoisomers have significantly different energies such that only one is present at equilibrium, or the isomerization proceeds through a low energy barrier (for instance by decoordination and recoordination through a four-coordinate square planar intermediate), or finally there may be a combination of both effects. Other observations, shown below, indicate that these compounds undergo dynamic rearrangements very rapidly. In the solid state, the compounds **2-Et** and **2-Ph** show the S atom with the same configuration relative to the ferrocene unit (R group *exo*, lone pair *endo* and parallel to the Cp–Fe axis), and the Cl ligand is located on the same side (*exo*) relative to the ferrocene group. The Ir–Cl distances of 2.5739(19) and 2.5576(12) Å compare with those in other five-coordinate [IrCl(COD)$L_2$] derivatives with chelating ligands, for instance 2.549 Å in [IrCl(COD)$L_2$] [$L_2$ = (2*R*,3*R*)-2,3-*O*-isopropylidene-1,4-bis(5*H*-dibenzophosphol-5-yl)-2,3-butanediol],[43] and 2.585(3) Å in [IrCl(COD)(dppp)].[44] However, these distances are longer relative to neutral four-coordinate complexes [e.g. 2.363(1) Å in Ir(COD)[= C($NCH_2$-*p*-Tol)$_2C_2H_2$]Cl,[59] and 2.3625(8) Å in complex **2-*t*Bu**]. A lengthening of ca. 0.2 Å accompanies this coordination number increase. This observation gives credence to the hypothesis that the Ir–Cl bond in the five-coordinate complexes is highly polarized, especially when comparing it with the insignificant change of the Ir–P distance [2.3322(15) Å and 2.3289(13) Å in five-coordinate **2-Et** and **2-Ph**, respectively; 2.3312(9) Å in four-coordinate **2-*t*Bu**] and Ir–CT distances [CT = center of the COD C=C bond; averages are 2.028(8) Å for **2-Et**, 2.032(10) Å for **2-Ph** and 2.04(4) Å for **2-*t*Bu**].

The structure of compound **3-Ph** contains discrete square-planar [Ir(COD)($\kappa^2$-P,SPh)]$^+$ and [Ir(COD)$Cl_2$]$^-$ anions. An interstitial toluene molecule completes the crystal packing. One H atom of a $CH_2$ group of the COD ligand in the cation is located at a relatively short intermolecular contact (2.759 Å) above the Ir atom in the anion, see Figure 2, a location which places it in an approximately ideal axial position. Indentification of such an interaction in solution by NMR spectroscopy was precluded by the complex redistribution equilibria (see below). However, the Ir atom in each ion sits very close to the ideal square place defined by the middle of the C=C bonds and the P,S or Cl donors, respectively [0.0158(5) Å in the cation, 0.0066(5) Å in the anion]. Structures of four-coordinate cationic complexes of type [Ir(COD)$L_2$]$^+$ are quite common in the literature with various types of bidentate $L_2$ and monodentate L ligands, including two precedents with a chelating P,S-type ligand, $Ph_2$PO(1,2-*cyclo*-$C_6H_{10}$)S*t*Bu and $Ph_2PCH_2$P(*t*Bu)$_2$S.[57,60] All these previously reported salts contain $BF_4^-$, $PF_6^-$, $SbF_6^-$, $CF_3SO_3^-$, or tetraarylborates as counterions. None contains the [Ir(COD)$Cl_2$]$^-$ anion. In fact, this quite simple anion does not appear to have previously been crystallographically characterized. This situation differs considerably from that of the rhodium congeners, for which several structure of salts of type [Rh(COD)$L_2$][Rh(COD)$Cl_2$] have been reported.[61–65]

Selected bonding parameters for compounds **3-Ph** are shown in Table 4. Both ions exhibit a relatively undistorted

square-planar geometry when considering the center of the COD C=C bonds (CT) as defining the coordination positions. The Ir–CT distances are significantly shorter in the anion [average 1.976(5) Å] than in the cation [average 2.09(4) Å], and the latter are marginally longer than in the 4- and five-coordinate neutral complexes **2-R** discussed above, attesting to the importance of back-bonding for the Ir–COD interaction. The Ir–P and Ir–S bond lengths in the cation are shorter than those in the neutral complexes, irrespective of their coordination number. This effect can be attributed to the metal ion contraction on going from the neutral to the charged system, because of an increase of

effective nuclear charge, and agrees with a predominant σ-bonding component for the Ir–P and Ir–S interactions.

### (c) NMR Spectroscopy of Compounds 2-R

Given the subtle structural difference observed for compounds **2** in the solid state depending on R, one might wonder whether the same structural dichotomy is maintained in solution. A detailed analysis of the NMR properties seems to suggest that this is the case. The $^{31}P$ resonance chemical shift is essentially identical for compounds **2-Et** and **2-Ph**, whereas it is significantly shifted downfield for **2-*t*Bu** (see Table 1), in apparent agreement with donation from the phosphorus atom to a less electron-rich metal in the latter case. This observation is the strongest indication in favor of a similar structure in the solid state and in chloroform solution for compounds **2**. Given the planar chirality of the functionalized Cp ring of the ferrocene moiety, all COD proton and carbon nuclei are magnetically inequivalent in both types of structure, although a higher degree of inequivalence could be expected for the five-coordinate structures where there is coordination-induced chirality at both the S and Ir atoms. The NMR spectra are, however, deceptively simple as only two sets of $^{13}C$ resonances are observed for both the *C*H and the *C*$H_2$ nuclei for all three compounds. For compound **2-*t*Bu**, the *C*H resonances could not be identified, even by an $^{1}H$–$^{13}C$ HMQC experiment at temperatures down to 213 K. On the other hand, these peaks were visible when the spectrum was recorded in [$D_8$]toluene solution (see Exp. Sect.). The pairs of C atoms with distinct chemical shifts are probably associated to the different coordination positions (i.e. *trans* to P and *trans* to S/Cl), whereas the asymmetry above and below the square coordination plane has a negligible effect on the chemical shift. Only for the $^{1}H$ C*H* (COD) resonances in compound **2-Et** was a slight asymmetry detected in the corresponding NMR spectra due to this asymmetry. This observation alone is not sufficient to confirm the difference in coordination geometry within the three compounds. However, the chemical shifts of the CH(COD) $^{1}H$ and $^{13}C$ resonances change significantly on going from **2-Et** and **2-Ph**. In particular, the C*H* resonances in the $^{1}H$ NMR spectrum proved to be more spread apart in **2-*t*Bu**, while one of the two *C*H resonances in the corresponding $^{13}C$ NMR spectrum is upfield shifted by ca. 15 ppm relative to the same resonance in the other two compounds. The chemical shift of the single $^{1}H$ resonance of the unsubstituted Cp ligand is also significantly different for **2-*t*Bu** relative to the other two compounds, and a slight difference is even observable for the $^{13}C$ resonance of the same group. The $^{1}H$ and $^{13}C$ resonances of the $CH_2$ group linking the S donor to the ferrocene unit, on the other hand, seem sensitive to the electronic nature of the SR group, because they are similar for the Et and *t*Bu derivatives and different for the Ph derivative. In conclusion, the overall NMR behaviour suggests that the solution structures of compounds **2** may be identical to those observed in the solid state.

### (d) Study of Solution Equilibria

Solutions obtained by mixing the complexes $[Ir(COD)Cl]_2$ and the free ligand **1-Ph** in various ratios were investigated by $^{1}H$ and $^{31}P$ NMR spectroscopy. Only one set of resonances was observed for all ratios up to **1-Ph**/Ir = 1:1, but several individual resonances of this set (notably the $^{31}P$ resonance and the $^{1}H$ resonances of the ferrocene unsubstituted Cp, of one of the substituted Cp protons, and of the two $CH_2$ protons) exhibited a continuous variation of the chemical shift as a function of the **1-Ph**/Ir ratio (see Figure 3). The COD resonances were too broad to allow their accurate monitoring. For **1-Ph**/Ir ratios greater than 1, the resonances of the free ligand **1-Ph** (mostly evident from the $^{31}P$ NMR spectrum) also appeared.

The behaviour illustrated in Figure 3 can be rationalized on the basis of Scheme 1, where rapid site exchange between the species participating in the equilibrium is required. A similar equilibrium has previously been proposed for an analogous system with the hemilabile N,O ligand 3-dimethylamino-1-(2′-pyridyl)-2-propen-1-one.[64] The resonances did not decoalesce into those of the individual species upon cooling to 213 K for a solution containing a **1-Ph**/Ir ratio of 0.6. The first ligand–metal equilibrium leading to **3-Ph** must be essentially quantitative, because the NMR signals of free **1-Ph** appear immediately after consumption of one equivalent of the ligand per Ir dimer, whereas they are not visible before this ratio is attained.

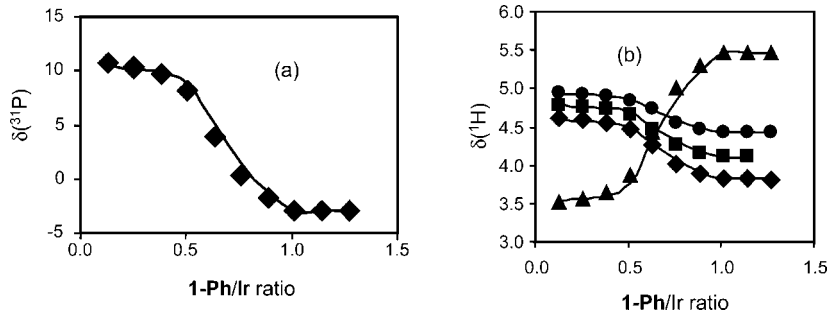

Figure 3. Dependence of the chemical shift of a few resonance for the $[Ir(COD)Cl]_2$/**1-Ph** system on the **1-Ph**/Ir ratio. (a) $^{31}P$ resonance; (b) $^{1}H$ resonances: unsubstituted Cp (5 H, diamonds); substituted Cp (1 H, circles); $CH_2$ (1 H, squares; 1 H, triangles). The solid lines are obtained by fitting the data according to Scheme 1 (see text).

$$[Ir(COD)Cl]_2 + P,SPh \longrightarrow [Ir(COD)(\kappa^2\text{-}P,SPh)]^+ [Ir(COD)Cl_2]^-$$

**1-Ph** **3-Ph**

$$[Ir(COD)(\kappa^2\text{-}P,SPh)]^+ [Ir(COD)Cl_2]^- \rightleftharpoons \tfrac{1}{2}[Ir(COD)Cl]_2 + IrCl(COD)(\kappa^2\text{-}P,SPh)$$

**3-Ph** **2-Ph**

Scheme 1.

Under the assumption of a first quantitative addition of **1-Ph** to $[Ir(COD)Cl]_2$, the individual concentrations of **2-Ph** and **3-Ph** for each measured solution were obtained from the equilibrium expression denoted in Equation (3), R = Ph, using *K* as an adjustable parameter. These concentrations were then used to calculate, for each resonance, the chemical shifts according to Equation (4) (R = Ph). Fitting to the experimental data yielded a reasonable agreement, using the same value of the equilibrium constant (0.008) for all resonances, as shown in Figure 3. The full fitting procedure and the values of $\delta$2–Ph and $\delta$3–Ph for each resonance, as obtained from the fittings, are given in the Supporting Information (for details see the footnote on the first page of this article).

$$K = \frac{[\mathbf{2\text{-}R}][Ir_2Cl_2(COD)_2]^{1/2}}{[\mathbf{3\text{-}R}]} \quad (3)$$

$$\delta_{calc} = \delta_{\mathbf{2\text{-}R}}[\mathbf{2\text{-}R}]/([\mathbf{2\text{-}R}]+[\mathbf{3\text{-}R}]) + \delta_{\mathbf{3\text{-}R}}[\mathbf{3\text{-}R}]/([\mathbf{2\text{-}R}]+[\mathbf{3\text{-}R}]) \quad (4)$$

When a sample of **1-Et** was added to $[Ir(COD)Cl]_2$ in a 1:1 molar ratio in $CDCl_3$ (i.e. a **1-Et**/Ir ratio of 0.5), a single $^{31}P$ NMR resonance was observed at $\delta$ = 10.9 ppm. The isolated complex **2-Et** (having a **1-Et**/Ir ratio of 1), on the other hand, yielded a $^{31}P$ resonance at $\delta$ –4.2 under the same conditions (see Table 1), whereas the resonance of the free ligand **1-Et** is at –20. Addition of an excess of ligand **1-Et** shifted this resonance further to $\delta$ = –4.6 ppm. We therefore presume that the solution behaviour of "Ir(COD)-Cl" in the presence of **1-Et** is the same as with the **1-Ph** ligand. A more detailed equilibrium study was not carried out in this case. In contrast, treatment of complex $[Ir(COD)Cl]_2$ with various amounts of **1-*t*Bu** in $CDCl_3$ led to the observation of two new $^{31}P$ NMR resonances. Whereas one of these (at $\delta$ = 17.5 ppm) exhibited the same chemical shift at all **1-*t*Bu**/Ir ratios, the other one shifted continuously from ca. $\delta$ = 14.6 at **1-*t*Bu**/Ir = 0.2 to ca. 15.7 at **1-*t*Bu**/Ir = 1, see Figure 4 (a). In addition, the relative intensity of these two resonances changed in favor of the second one upon increasing the **1-*t*Bu**/Ir ratio, until the first one completely disappeared at the point when **1-*t*Bu**/Ir = ca. 1, see Figure 4 (b). Further additions of the free ligand no longer moved the $\delta$ = 15.7 resonance, although, a new resonance due to the excess of free **1-*t*Bu** started to appear at $\delta$ = –20.0 ppm. This observed behaviour suggests the presence of at least three P-containing Ir complexes: two that are in rapid exchange on the NMR time scale, generating the resonance that is shifting in the $\delta$ = 14.6–15.7 ppm range, and a third one giving the $\delta$ = 17.5 ppm resonance. The latter species exchanges slowly on the NMR timescale, or not at all, with the other two. In addition, the appearance of the free **1-*t*Bu** resonance immediately after attaining the **1-*t*Bu**/Ir ratio of 1, suggested an essentially quantitative first addition of **1-*t*Bu** to $[Ir(COD)Cl]_2$ to generate **3-*t*Bu**, like for the case of the **1-Ph** addition.

It seems logical to assume, on the basis of the results shown above for the **1-Ph**/Ir system, that the shifting resonance is due to the rapidly equilibrating mixture of compounds **2-*t*Bu** and the salt $[Ir(COD)(\kappa^2\text{-}P,S\textit{t}Bu)]^+[Ir(COD)Cl_2]^-$, **3-*t*Bu** [equilibrium of Equation (2)]. The chemical shift observed at low **1-*t*Bu**/Ir ratio [Figure 4 (a), ca. $\delta$ = 14.5 ppm] is close to that observed at low **1-Ph**/Ir ratio (Figure 3, ca. $\delta$ = 11 ppm) and attributed to compound **3-Ph**. For the **1-Ph**/Ir system, addition of the free ligand leads to an upfield shift toward the resonance of five-coordinate **2-Ph** (ca. $\delta$ = –3 ppm), whereas for the **1-*t*Bu**/Ir system, addition of the free ligand leads to a downfield shift toward the resonance of four-coordinate **2-*t*Bu** (ca. $\delta$ = 15.5 ppm). This proposition is in agreement with the observed behaviour of the same system in $C_6D_6$: the lower polarity of this solvent is expected to disfavor formation of the ionic system and, indeed, the resonance does not shift significantly by

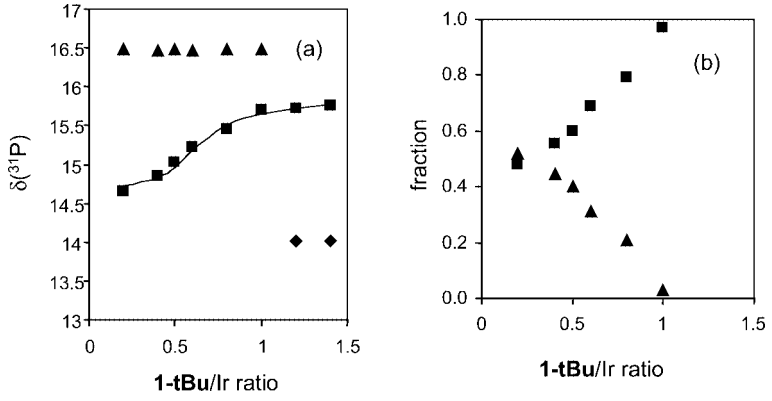

Figure 4. Chemical shift (a) and relative ratio (b) of the $^{31}P$ NMR resonances for the $[Ir(COD)Cl]_2$/1-*t*Bu system as a function of the 1-*t*Bu/Ir ratio. Squares: rapidly equilibrating mixture of 2-*t*Bu and 3-*t*Bu; triangles: 4-*t*Bu; diamonds: 1-*t*Bu. The solid line in (a) is the data fit to the model of Scheme 2 (see text).

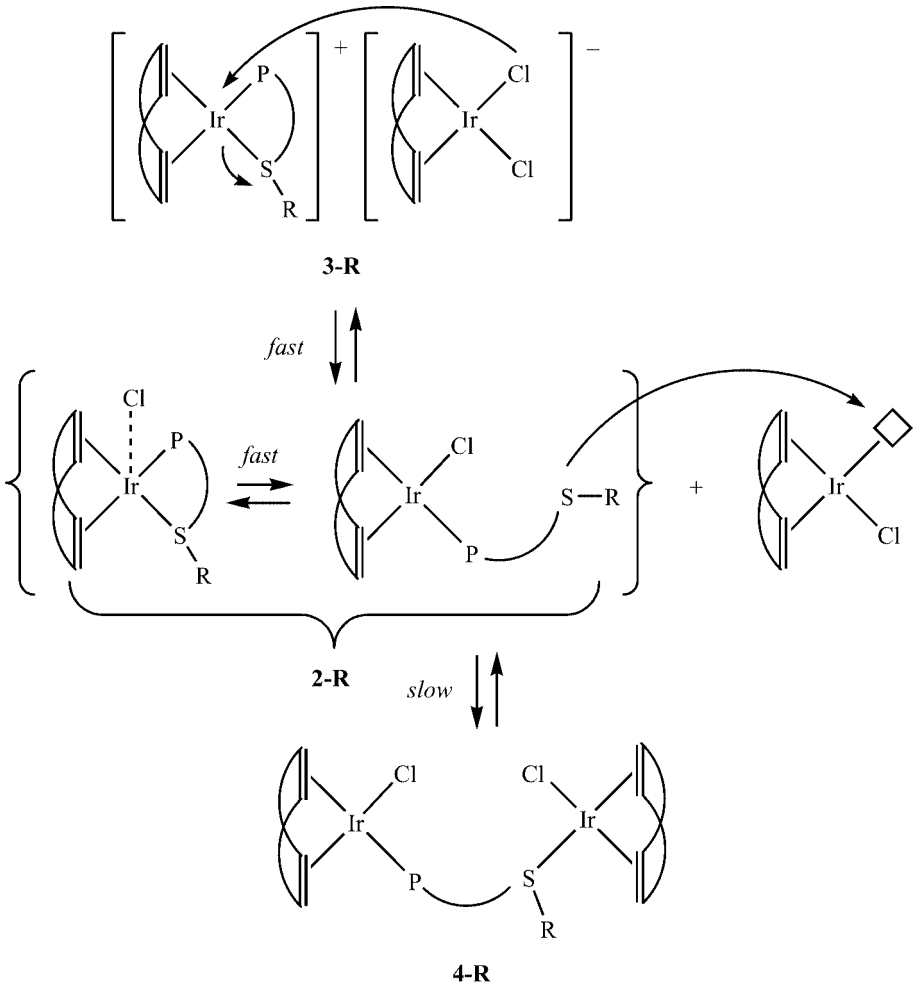

Scheme 2.

varying the **1-*t*Bu**/Ir ratio in the 0 to > 1 range ($\delta$ always in the 15.68–15.71 range).

We now need to assign the $\delta$ = 17.5 ppm resonance and to rationalize the fact that it is observed only for the **1-*t*Bu**/Ir system. The most reasonable proposal that we are able to advance involves a neutral dinuclear complex with a bridging P,S*t*Bu ligand (**4-*t*Bu**), see Scheme 2. Precedents for this type of structural arrangement exist for P,N ligands.[66,67] As the equilibrium between the five-coordinate and the four-coordinate isomers of **2-R** lies strongly in favor of the latter when R = *t*Bu, the pendant S*t*Bu arm is available to coordinate the Ir center in the unsaturated [Ir(COD)Cl] complex, which is in equilibrium with the dichloro-bridged dimer. It is rather remarkable, however, that this process is slower than the addition of the chloride anion to the same position. We presume that this is so for steric reasons. The reversible association/dissociation process of the pendant S*t*Bu arm leading from **2-*t*Bu** to **3-*t*Bu** is fast because it is intramolecular. The reason why analogous compounds **4-Ph** and **4-Et** are not observed would then be related to the preferred sulfur coordination to the same Ir center, in the five-coordinate geometry of **2-Ph** and **2-Et**.

According to this proposal, compound **4** has an identical stoichiometry to compound **3**. Therefore, the **3-*t*Bu**/**4-*t*Bu** ratio should be independent on the **1-*t*Bu**/Ir ratio. This ratio can be estimated from the extrapolated relative intensities of the $\delta$ = 14.6 and 17.5 ppmpeaks as **1-*t*Bu**/Ir → 0 (ca. 42.3:57.7), from Figure 4 (b). This number can in turn be used to estimate the individual concentrations of **2-*t*Bu** and **3-*t*Bu** at each **1-*t*Bu**/Ir ratio. At this point, the concentration of each iridium-containing species can be calculated solving the equilibrium relationship [Equation (3), R = *t*Bu], using *K* as an adjustable parameter. These concentrations were then used to calculate the $^{31}$P chemical shift according to Equation (4) (R = *t*Bu). Fitting of the simulated and experimental data yielded a reasonable agreement for an equilibrium constant of 0.036, as shown in Figure 4 (a). Thus, *K* is greater for R = *t*Bu (0.036) than for R = Ph (0.008). The release of steric pressure upon transforming the chelating P,S*t*Bu ligand into a dangling one (whereas the P,SPh ligand remains chelating in compound **2-Ph**) may provide an explanation of this difference.

### (e) Comparison with Rh Coordination Chemistry and Mixed Rh–Ir Studies

When samples of **1-R** (R = Ph, Et, *t*Bu) were treated with [Rh(COD)Cl]$_2$ in a 2:1 molar ratio, a single $^{31}$P resonance,

Table 5. $^{31}P$ resonances assigned to the products of 1:1 and 2:1 ligand **1-R** addition to $[M(COD)Cl]_2$ (solvent = $CDCl_3$).

| Complex | **1-R**/M ratio | $\delta = {}^{31}P$ ($J_{PRh}$) M = Rh | M = Ir[a] |
|---|---|---|---|
| M(COD)Cl(P,SEt) | 1:1 | **5-Et:** 25.2 (142 Hz) | **2-Et:** –4.6 |
| M(COD)Cl(P,S*t*Bu) | 1:1 | **5-*t*Bu:** 24.5 (147 Hz) | **2-*t*Bu:** 15.6 |
| M(COD)Cl(P,SPh) | 1:1 | **5-Ph:** 22.2 (143 Hz) | **2-Ph:** –2.9 |
| [M(COD)(P,SPh)][M(COD)$Cl_2$] | 1:2 | **6-Ph**: 24.0 (143 Hz) | **3-Ph**: 11.0 |

[a] Following the chemical shift analysis as a function of **1-R**/M ratio, as outlined in the text and described in detail in the Supporting Information.

split into a doublet by a rhodium coupling, was observed in each case in the NMR spectrum. This resonance is therefore assigned to a product with the stoichiometry RhCl(COD)(P,SR) (**5-R**) see Table 5. The very similar values of the chemical shifts and coupling constants, in contrast to the behaviour observed for the Ir complexes, strongly indicates the same coordination mode for the three ligands with respect to $Rh^I$.

When a sample of **1-Ph** in $CDCl_3$ was treated with $[Rh(COD)Cl]_2$ in a 1:1 molar ratio, a doublet resonance was observed at $\delta$ = 24 ppm (143 Hz) in the $^{31}P$ NMR spectrum. Both the chemical shift and the coupling constant of this resonance are very close, but not identical, to those obtained using a 2:1 ratio. Therefore, we presume that the compound formed under these conditions (**6-Ph**) has the same structure as the iridium analogue **3-Ph**, namely $[Rh(COD)(P,SPh)][Rh(COD)Cl_2]$. As for compounds **5-R**, there are two possibilities: an ionic structure $[Rh(COD)(P,SR)]^+Cl^-$, and a neutral structure with a dangling thioether function, [RhCl(COD)($\kappa^1$-P,SR)], as seen for the iridium analogue **2-*t*Bu**. In both cases, the rhodium complexes are consistently four-coordinate, in agreement with the lower propensity of $Rh^I$, relative to $Ir^I$, to give five-coordinate geometries with the involvement of the $d_z2$ orbital. A few examples of four-coordinate $[Rh(COD)L_2]^+$ complexes having $Cl^-$ as the counterion have been characterized by X-ray crystallography, namely $[Rh(COD)(bipy)_2]^+$,[49] $[Rh(COD)L_2]^+$ (L = 1,3-dimethylimidazolin-2-ylidene),[50] and a chelated version of the latter {$L_2$ = $[MeNC_3H_2N\text{-}(CH_2)_3\text{-}NC_3H_2NMe]$}.[51] However, addition of the **1-R** ligands to $[Rh(COD)Cl]_2$ in $C_6D_6$ generated soluble products whose $^{31}P$ NMR resonances [**5-Et**: 21.8 (147 Hz); **5-*t*Bu**: 23.6 (148 Hz); **5-Ph**: 21.6 (148 Hz)] turned out to be essentially identical to those recorded in $CDCl_3$. This result strongly suggests that the adducts are neutral. In conclusion, the $Ir^I$ center has a greater tendency to coordinate both the thioether function and the $Cl^-$ ion. The latter, however, is rather weakly coordinated as shown by the long Ir–Cl distances in the X-ray structures (vide supra).

Subsequent mixing experiments were carried out in order to probe the relative stability of $Rh^I$ and $Ir^I$ complexes with the coordinated P,SR ligands. The addition of $[Ir(COD)Cl]_2$ to a sample of **5-Ph** in a 1:2 molar ratio made the $^{31}P$ NMR resonance of the starting Rh complex and the P–Rh coupling disappear, yielding a new resonance (singlet) at $\delta$ = –0.25 ppm. From the observed chemical shift (cf. Table 5) and the absence of Rh coupling, we propose that the reaction leads to complex **2-Ph**, according to Equation (5). The same $^{31}P$ NMR resonance ($\delta$ = –0.21 ppm) was obtained by adding 1/2 mol of $[Ir(COD)Cl]_2$ and 1/2 mol of $[Rh(COD)Cl]_2$ simultaneously to one mol of **1-Ph**. However, complex **2-Ph** cannot be the only species in solution, because its resonance is shifted relative to that assigned to pure **2-Ph**. From the observed NMR behaviour of complex **2-Ph** in the presence of variable amounts of $[Ir(COD)Cl]_2$ (see Figure 3 and related discussion above), we can presume that the reaction mixture also contains equilibrium amounts of complex $[Ir(COD)(\kappa^2\text{-P,SPh})][Rh(COD)Cl_2]$, **3′**, obtained by transfer of the chloride ligand to the dinuclear rhodium complex as shown in Equation (6).

$$\underset{\textbf{5-Ph}}{RhCl(COD)(P,SPh)} + \tfrac{1}{2}[Ir(COD)Cl]_2 \longrightarrow \underset{\textbf{2-Ph}}{[Ir(COD)(\kappa^2\text{-P,SPh})Cl]} + \tfrac{1}{2}[Rh(COD)Cl]_2 \quad (5)$$

$$\underset{\textbf{2-Ph}}{[Ir(COD)(\kappa^2\text{-P,SPh})Cl]} + \tfrac{1}{2}[Rh(COD)Cl]_2 \rightleftharpoons \underset{\textbf{3'}}{[Ir(COD)(\kappa^2\text{-P,SPh})][Rh(COD)Cl_2]} \quad (6)$$

It is interesting to remark that the resonance observed for this mixture (ca. –0.2 ppm), which contains a P,SPh:(Rh+Ir) ratio of 0.5, is much closer to the resonance of **2-Ph** than that of a solution with the same P,SPh to metal ratio, but containing only Ir (ca. 8 ppm, see Figure 3). This observation shows that $[Ir(COD)Cl]_2$ is a stronger chloride scavenger than its rhodium analogue. Another obvious conclusion of this study is that the iridium ion forms stronger bonds with the phosphorus and sulfur atoms of the P,SPh ligand than does the rhodium ion.

### (f) Catalytic Studies

Complexes **2** were tested as catalyst for the hydrogenation of diphenylacetylene. The results are presented in Table 6. Under 30 bar of dihydrogen pressure at room temperature with 1 mol-% of precatalyst, compound **2-*t*Bu** gave a quantitative conversion after 6 h, whereas complex **2-Ph** was less active, yielding only a 59% conversion. In both cases, significant amounts of 1,2-diphenylethane were de-

Table 6. Diphenylacetylene hydrogenation in presence of complexes **2-Ph** and **2-*t*Bu**.

| Entry | Complex | Reaction time | Conversion[a,b] | Yield of *cis*-stilbene[b] | Yield of *trans*-stilbene[b] | Yield of 1,2-diphenylethane[b] |
|---|---|---|---|---|---|---|
| 1 | **2-Ph** | 6 h | 59% | 79% | 8% | 13% |
| 2 | **2-*t*Bu** | 6 h | 100% | 64% | 14% | 22% |

[a] Reaction run with 1 mmol of diphenylacetylene, 0.01 mmol of complex **2** (1 mol-%) in 2 mL $CH_2Cl_2$ at room temperature under 30 bars of dihydrogen. [b] Determined by GC.

tected by GC (alkenes/alkane ratio is 92:8 for **2-Ph** and 78:22 for **2-*t*Bu**). Compared to other hydrogenation systems for the selective transformation of alkynes into alkenes, these systems perform rather poorly.[68–75]

Furthermore, the stereoselectivity of the reaction, especially with compound **2-*t*Bu**, is also quite poor (*cis*-stilbene/*trans*-stilbene ratio is 91:9 for **2-Ph** and 82:18 for **2-*t*Bu**). The presence of (*E*)-alkenes after hydrogenation of alkynes is commonly explained by the isomerisation of (*Z*)-alkenes, which are the primary products arising from the *syn*-addition of $H_2$ to the C–C triple bonds.[76–78] In order to determine whether similar reasons are involved in our system, we carried out the reaction of *cis*-stilbene with dihydrogen in presence of complexes **2-Ph** or **2-*t*Bu** under the same conditions described in Table 6 for diphenylacetylene. Isomerisation to *trans*-stilbene as well as hydrogenation to 1,2-diphenylethane did occur, although the rate of this transformation was slower than the direct formation of these two products from diphenylacetylene. This result suggests that the isomerization and further hydrogenation processes probably occur mostly from the vinyl intermediate, before the primary *cis*-stilbene product is formed by reductive elimination. However, recoordination of the *cis*-stilbene followed by both isomerization and further hydrogenation are also possible.

## Conclusion

The use of the ferrocenyl phosphane–thioether ligands **1-R** (R = Et, Ph, *t*Bu) has allowed to reveal that the coordination geometry of chlorocyclooctadieneiridium(I) ligand adducts, both in the solid state and in solution, is delicately controlled by the nature of the R substituent, yielding five-coordinate complexes **2-R** for R = Et, Ph and a four-coordinate one for R = *t*Bu, the latter featuring a dangling thioether group. The ligand chirality controls the geometry at the sulfur and iridium atoms, producing single diastereomers.

The solid state geometries appear to be maintained in solution. However, complex equilibria between various structures are established. The chloride ligand is loosely bound to iridium in the five-coordinate complexes **2-R**, leading to its scavenging by excess metal complex and to a rapid equilibration between the complexes **2-R** and ionic $[Ir(COD)(\kappa^2\text{-P,SR})]^+[Ir(COD)Cl_2]^-$ (**3-R**). Salt-like compounds of type $[Ir(COD)(k^2\text{-L-L}')][Ir(COD)X_2]^-$ have not been structurally characterized previously for any L-L′ or X, though they are quite common for the Rh congener. Furthermore, competitive coordination reactions between rhodium and iridium for ligand **1-Ph** lead only to iridium coordination, probing the greater affinity of P,SR ligands for the heavier metal. The same solution is obtained whether the P,SR ligand is initially bonded to Rh or Ir, indicating a high lability for such systems.

Complexes **2-R** catalyse the hydrogenation of diphenylacetylene at room temperature, paving the way to the application of such complexes to other hydrogenation reactions. Our particular attention is devoted to asymmetric hydrogenation, taking advantage of the availability of the chiral ligands **1-R** in optically pure form. Further studies in this direction are currently in progress in our laboratories.

## Experimental Section

**General:** All reactions were carried out under an argon using standard Schlenk techniques. Solvents were carefully dried by conventional methods and distilled under argon before use. The (*R*/*S*)-2-diphenylphosphanyl-(R-thiomethyl)ferrocene ligands (**1-R**, R = Et, *t*Bu, Ph) were prepared according to a published procedure[56] from racemic 2-(diphenylthiophosphanylferrocenyl)methanol.[79] NMR spectra were recorded with Bruker AC200 and Bruker Avance 500 FT-NMR spectrometers. The resonances were calibrated relative to the residual solvent peaks and are reported with positive values downfield from TMS. The NMR spectra of the new compounds **2-R** (R = Et, *t*Bu, Ph) are collected in Table 1.

**Synthesis of [IrCl(COD)(P,SEt)] (2-Et):** In a Schlenk tube, under argon, ligand **1-Et** (69 mg, 0.155 mmol) was dissolved in dichloromethane (3 mL) and $[Ir(COD)Cl]_2$ (52 mg, 0.077 mmol) was added. After 1 h of stirring, the addition of pentane (10 mL) yielded a yellow precipitate, which was filtered off to give [IrCl(COD)(P,SEt)] (104 g, 86% yield). $C_{33}H_{37}ClFeIrPS$ (780.21): calcd. C 50.80, H 4.78; found C 50.64, H 5.05.

**Synthesis of IrCl(COD)(P,S*t*Bu) (2-*t*Bu):** In a Schlenk tube, under nitrogen, ligand **1-*t*Bu** (272 mg, 0.576 mmol) was dissolved in dichloromethane (3 mL) and $[Ir(COD)Cl]_2$ (193 mg, 0.288 mmol) was added. The solution was stirred for 2 h at room temperature and 10 mL of hexane was the added to form a yellow precipitate. The precipitate was filtered off under nitrogen and washed with hexane, to give [IrCl(COD)(P,S*t*Bu)] (416 mg, 89% yield). $C_{35}H_{41}ClFeIrPS{\cdot}CH_2Cl_2$ (893.13): calcd. C 48.41, H 4.85; found C 48.62, H 4.70. The presence of dichloromethane was evident from the NMR spectrum recorded on a solution of the single crystals. $^1$H NMR (500 MHz, [D$_8$]toluene: $\delta$ = 8.33 (dd, $J_{HH}$ = 10 Hz, $J_{HP}$ = 12 Hz, 2 H, Ph), 7.38 (dd, $J_{HH}$ = 10 Hz, $J_{HP}$ = 12 Hz, 2 H, Ph), 7.19 (m, 2 H, Ph), 7.17 (m, 1 H, Ph), 6.97 (m, 2 H, Ph), 6.95 (m, 1 H, Ph), 4.67 (s, sCp), 4.58 (d, $J_{HH}$ = 13 Hz, 1 H, $CH_2$), 4.24 (d, $J_{HH}$ = 13 Hz, 1 H, $CH_2$), 4.18 (s, sCp), 4.16 (s, 5 H, Cp), 4.13 (t, $J_{HH}$ = 2 Hz, sCp), 3.88 (br., COD), 2.30 (m, COD), 2.08 (m, COD), 1.65 (m, COD), 1.49 (m, COD), 1.44 (s, 9 H, *t*Bu) ppm. $^{13}$C NMR (500 MHz, [D$_8$]toluene): $\delta$ = 136.05 (d, $J_{CP}$ = 12 Hz, 2 C, Ph), 135.0 (d, $J_{CP}$ = 50 Hz, quat. Ph), 133.70 (d, $J_{CP}$ = 12 Hz, 2 C, Ph), 133.4 (d, $J_{CP}$ = 50 Hz, quat. Ph), 130.00 (d, $J_{CP}$ = 3 Hz, 1 C, Ph), 129.05 (d, Ph, $J_{CP}$ = 2 Hz, 1 C), 127.40 (d, $J_{CP}$ = 6 Hz, 2 C, Ph),

126.95 (d, $J_{CP}$ = 10 Hz, 2 C, Ph), 91.02 (d, $J_{CP}$ = 16 Hz, quat. Cp), 74.8 (d, $J_{CP}$ = 50 Hz, quat. Cp), 74.42 (d, $J_{CP}$ = 6 Hz, 1 C, sCp), 71.37 (s, Cp), 71.24 (d, $J_{CP}$ = 7.4 Hz, 1 C, sCp), 69.7 (d, $J_{CP}$ = 6.5 Hz, 1 C, sCp), 52 (COD), 43.05 [s, S-*C* ($CH_3$)]. 30.75 (COD), 32.72 (COD), 30.7 [s, S-C(*C*$H_3$)], 29.1 (s, $CH_2$) ppm. $^{31}$P NMR (500 MHz, [$D_8$]toluene): $\delta$ = 11.8 ppm.

**Synthesis of IrCl(COD)(P,SPh) (2-Ph):** In a Schlenk tube, under nitrogen, ligand **1-Ph** (240 mg, 0.488 mmol) was dissolved in dichloromethane (4 mL) and solid $[Ir(COD)Cl]_2$ (163 mg, 0.244 mmol) was subsequently added. After 10 min of stirring, a yellow precipitate was formed. Hexane (10 mL) was added to complete the precipitation and the yellow solid was filtered off to yield [IrCl(COD)(P,SPh)] (347 g, 86% yield). $C_{37}H_{37}ClFeIrPS{\cdot}CH_2Cl_2$ (913.12): calcd. C 53.66, H 4.50; found C 53.83, H 4.53.

**X-ray Crystallography:** Yellow single crystals of complexes **2-R** (R = Et, *t*Bu, Ph) were obtained by slow diffusion of light hydrocarbon vapors (pentane for Et, hexane for *t*Bu and Ph) into a $CH_2Cl_2$ solution. Diffusion of hexane vapors into a toluene solution of **2-Ph** gave yellow crystals of compound **3-Ph**. A single crystal of each compound was mounted under inert perfluoropolyether on the tip of glass fibre and cooled in the cryostream of either an Oxford-Diffraction XCALIBUR CCD diffractometer for **2-Ph**, a Stoe IPDS diffractometer for **2Et** or a Bruker SMART CCD diffractometer for **2-*t*Bu** and **3**. Data were collected using the monochromatic Mo$K_\alpha$ radiation ($\lambda$ = 0.71073). The structures were solved by direct methods (SIR97)[80] and refined by least-squares procedures on $F^2$ using SHELXL-97.[81] All H atoms attached to carbon were introduced in calculation in idealised positions and treated as riding models. As indicated by the refinement of the Flack's parameter,[82] compound **2-Et** is twinned by inversion ("racemic twin"). In compound **3** a toluene solvent molecule is statistically disordered around an inversion center. The drawing of the molecules was realised with the help of ORTEP32.[83] Crystal data and refinement parameters are shown in Table 7.

CCDC-283190 to -283193 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Procedures for fitting the equilibrium constant of Equation (1) to the experimental NMR spectroscopic data (Ir/**1-Ph** and Ir/**1-*t*Bu** systems).

# Investigations into the Reactivity of Organoelement Gallium Subhalides – Syntheses of Bifunctional Digallium Carboxylate Iodides Possessing Bridged Ga–Ga Bonds and Terminal Iodine Atoms

**Werner Uhl,*[a] Abdelhakim El-Hamdan,[a] and Klaus Peter Schindler[a]**

*Dedicated to Prof. Dr. H. Schnöckel on the occasion of his 65th birthday*

**Keywords:** Gallium / Subvalent compounds / Subhalides / Metal–metal bonds / Carboxylato ligands

The organoelement subhalide $R_2Ga_2I_2$ (**1**) [R = $C(SiMe_3)_3$] reacted with one equivalent of different lithium carboxylates $LiO_2CR$ [R = -$C_6H_5$, -4-$Me_3C$–$C_6H_4$, -4-$BrC_6H_4$, -3,5-$Me_2C_6H_3$, -$CMe_3$] by the selective replacement of only one iodine atom. Bifunctional digallium compounds were formed, in which one chelating carboxylato group bridges the Ga–Ga bonds. Thus, both gallium atoms are coordinated to one carbon atom of the tris(trimethylsilyl)methyl groups and one oxygen atom of the chelating ligand, while only one is further attached to a terminal iodine atom. This asymmetric substitution pattern results in different coordination numbers of three and four for the gallium atoms.

## Introduction

The tetrahedral cluster compounds $E_4[C(SiMe_3)_3]_4$ (E = Ga, In) are easily available by the reduction of the corresponding alkyltrichlorogallate with magnesium[1] or by the treatment of indium(I) bromide with $LiC(SiMe_3)_3$.[2] These compounds possess the gallium or indium atoms in an unusual low oxidation state of +1. Careful oxidation reactions employing the halogens or appropriate halogen donors open the facile access to organoelement subhalides, which proved to be very effective starting compounds for the generation of secondary products still containing the elements in low oxidation states. Different kinds of subhalides were obtained depending on the halogen source or the stoichiometric ratio of the starting compounds. Transfer of one bromine molecule to the tetraindium cluster gave the remarkable compound $Br_2In_4[C(SiMe_3)_3]_4$, in which the overall tetrahedral arrangement of the indium atoms is retained with some distortion.[3] The bromine atoms occupy one face of the tetrahedron and one edge of that particular face. The average oxidation state of the metal atoms is +1.5. Such a derivative could not be isolated with gallium atoms, which may be caused by the ready dissociation of the tetrahedral tetragallium cluster owing to the relatively strong steric interaction between the bulky substituents.[1] An oxidation state of +2 occurs in the compounds R(X)E–E(X)R (X = Cl, Br, I), which have E–E single bonds. They are monomeric for gallium with coordinatively unsaturated central atoms,[4,5] while $In_4X_4$ cages with all of the halogen atoms in a bridging position are formed with the larger indium atoms.[3] A further structural motif of these subhalides was observed for the compounds $I_2E_3[C(SiMe_3)_3]_3$, which contain chains of three gallium or indium atoms and iodine bridges between both terminal metal atoms.[5,6] A halogen adduct of the triindium compound with all indium atoms possessing a coordination number of four was obtained as a by-product of the cluster synthesis.[7] Organoelement subhalides that are not derived from clusters are also known in the literature.[8,9]

The organoelement subhalides of the type $X_2E_2R_2$ have been employed in several secondary reactions, which impressively showed their importance for the generation of new compounds. Treatment with two equivalents of lithium or silver acetylacetonates yielded the corresponding diacetylacetonato derivatives by the replacement of both halogen atoms and retainment of the E–E bonds.[10] The chelating ligands occupy terminal positions at each gallium or indium atom. In contrast, the bridging of the E–E bonds was observed for dicarboxylato compounds.[11] A very short E–E distance resulted in particular for the indium derivative owing to the small bite of the carboxylato group. Lithium diphenylphosphanide and the subhalide $I_2Ga_2R_2$ (**1**) gave an interesting reaction course with the formation of a gallium phosphanide possessing a $Ga_2P_2$ heterocycle.[12] Oxidation of the gallium atoms occurred and Ga–H bonds were probably formed by the reaction of radical intermediates with

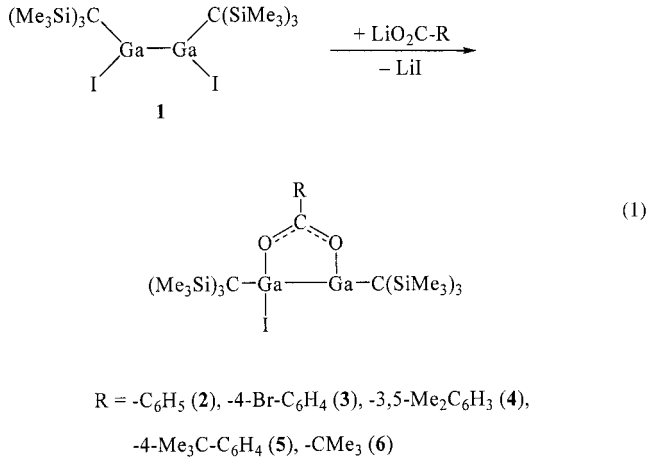
the solvent. The reduction of some subhalides substituted by aryl groups afforded products containing E–E multiple bonds.[9] Several transition metal gallium or indium compounds could be synthesized by treatment of these subhalides with transition metal carbonylate anions.[13] In general, the introduction of monodentate ligands such as alkyl or alkoxy groups proved to be rather difficult, and in most cases secondary reactions were induced with the cleavage of the E–E bonds. This instability is probably caused by the coordinative unsaturation of the central gallium or indium atoms, which favors intramolecular substituent exchange processes as the starting step for disproportionation reactions. This behavior is similar to that of the solvent-free subhalides of these elements, $E_2X_4$, which do not possess E–E bonds, but are mixed valent with the formulae $E^I[E^{III}X_4]$.[14] Therefore, we tried to synthesize digallium compounds bearing a protecting chelating group at one gallium atom, while the second one still bears its halogen atom. These bifunctional compounds are valuable starting compounds for the generation of a broad variety of secondary products.

## Results and Discussion

### Reactions of $I_2Ga_2R_2$ (1) [R = $C(SiMe_3)_3$] with Lithium Benzoates

The replacement of both iodine atoms of the subhalide $I_2Ga_2R_2$ (**1**) [R = $C(SiMe_3)_3$] by carboxylato groups resulted in reasonable yields and reaction times only when silver benzoate was employed as a starting compound,[11] while lithium benzoate gave complicated mixtures of products. However, it seems that only the exchange of the second iodine atom is relatively slow and unselective. Therefore, we did not employ the silver salts of the carboxylic acids, but treated **1** with one equivalent of the more easily available lithium carboxylates. The most selective reactions were observed when the components were mixed at a very low temperature (–90 °C). Slow warming to room temperature and stirring for a further 24–48 h gave almost quantitative formation of the pure monosubstitution products **2**–**6**, see Equation (1). Despite the high selectivity of all the reactions only compound **2** could be isolated by recrystallization in good yield (82%). In all other cases the high solubility in the noncoordinating solvents prevented the effective recrystallization and yields only between 20 and 60% were achieved. In one case (**5**), all attempts of crystallization failed and the characterization was done with the solid raw product of the reaction.

The NMR spectroscopic characterization is in complete agreement with the molecular structures of these compounds, which are schematically shown in Equation (1). The integration ratios of the resonances of the $^1$H NMR spectra clearly verify that one iodine atom of the starting compound **1** is replaced by a carboxylato ligand. Interestingly, only one resonance is observed for the trimethylsilyl groups although the molecule is unsymmetrical in the solid state with coordination numbers of three and four for the



(1)

R = -$C_6H_5$ (**2**), -4-Br-$C_6H_4$ (**3**), -3,5-$Me_2C_6H_3$ (**4**), -4-$Me_3C$-$C_6H_4$ (**5**), -$CMe_3$ (**6**)

gallium atoms. A splitting of these signals could not be detected even on cooling the solutions of **2** and **6** in toluene to –100 °C. Obviously a very fast exchange process occurs, probably including the migration of the iodine atoms. We suppose that this process is a key step in disproportionation reactions, which were discussed above in the Introduction chapter and have been observed often for similar digallium or diindium compounds bearing monodentate ligands.[15] In the case of compounds **2**–**6** the opening of the Ga–Ga bond is prevented by the chelating ligands, which bridge the Ga–Ga bond, since they act as a clamp and stabilize that particular arrangement. The $^{13}$C NMR shift of the inner carbon atoms of the tris(trimethylsilyl)methyl group is worth mentioning. Owing to the fast exchange processes only one resonance is detected for each compound showing a chemical shift of about $\delta$ = 30 ppm. This is in the characteristic range of carbon atoms attached to tricoordinate gallium. A coordination number of four causes significant high field shifts to about $\delta$ = 5 ppm.[16] Thus, although one half of the gallium atoms are coordinatively saturated, the expected average value is not detected here, instead a low coordination number is suggested by the NMR spectroscopic data.

Two compounds (**2** and **4**) were characterized by crystal structure determinations. The molecular structures are depicted in Figure 1 (a and b) and Figure 2, respectively. Both compounds contain an intact Ga–Ga bond bridged by the chelating carboxylato ligand. One gallium atom is further attached to an iodine atom, so that different coordination numbers of three (Ga2) and four (Ga1) result for the metal atoms of one molecule. Ga2 has an almost ideal planar surrounding (sum of the angles 358.5 and 357.2° for **2** and **4**, respectively), while Ga1 has a strongly distorted tetrahedral coordination sphere. The Ga–Ga bond lengths (239.9 and 240.7 pm) are quite similar to that of the starting compound **1** (240.1 pm)[4] and to the corresponding dicarboxylato derivative, in which two chelating ligands bridge the Ga–Ga bond.[11,17] However, they are shorter than the unsupported Ga–Ga bonds of tetraalkyl or tetraaryl digallium compounds (>260 pm,[18] for a review see ref.[5]). Despite the different coordination numbers the Ga–C distances differ only slightly by about 1.5 pm, the slightly longer ones belong to the coordinatively saturated gallium atoms (CN

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

= 4). Also, the Ga–O distances are in a narrow range between 198.3 and 199.6 pm. In compound **2** the Ga–O bond length to the tetracoordinate gallium atom is the slightly shorter one. The Ga–I bonds are relatively long (267.8 and 263.2 pm) compared to those of the starting compound **1** (258.7 pm)[4] or other compounds bearing terminal iodine atoms.[10,19] The Ga–Ga–C groups approach linearity at the tricoordinate gallium atoms (165.2 and 162.5°) as often observed before for dicarboxylato digallium compounds.[11,17] Smaller angles were detected at the tetracoordinate atoms (147.0 and 142.7°). The Ga–O bonds are almost ideally perpendicular to the Ga–Ga bonds (angle Ga–Ga–O about 88° on average), independent of the coordination numbers of the metal atoms. The same holds for the Ga–Ga–I moieties where a relatively small angle of 81.8° was observed for compound **2**. The five-membered heterocycles obtained by the bridging of the Ga–Ga bonds are almost ideally planar, the strongest deviation was observed in both cases for the atom O2 with a value of 8.1 and 2.1 pm, respectively, for compounds **2** and **4**. The Ga–I bonds are nearly perpendicular to these planes, and the angles between their normals and the Ga–I bonds are 11.9 and 7.7°. The distances of the iodine atoms to the second gallium atoms are long (**2**: 333.1 pm; **4**: 350.1 pm) and do not indicate a significant bonding interaction. Interestingly, a disorder occurred with compound **2**, in which the iodine atom, with an occupation factor of 16%, approaches an ideal bridging position between both gallium atoms [Ga–I 278.8(9) and 306.4(12) pm, Ga–Ga 234.3(7) pm, Figure 1, b]. This arrangement reflects excellently the transition state postulated for the fast exchange process observed in solutions of these monocarboxylato compounds (**2**–**6**). Furthermore, all inner carbon atoms of the $C(SiMe_3)_3$ groups are located in the nodal planes of the gallium p orbitals, which are oriented perpendicularly to the $Ga_2C_2O_2$ plane. This particular situation may cause the shift of the $^{13}C$ NMR resonances to a relatively low field position at about $\delta$ = 30 ppm. As discussed before these shifts are normally very characteristic of compounds possessing tricoordinate, coordinatively unsaturated gallium atoms.

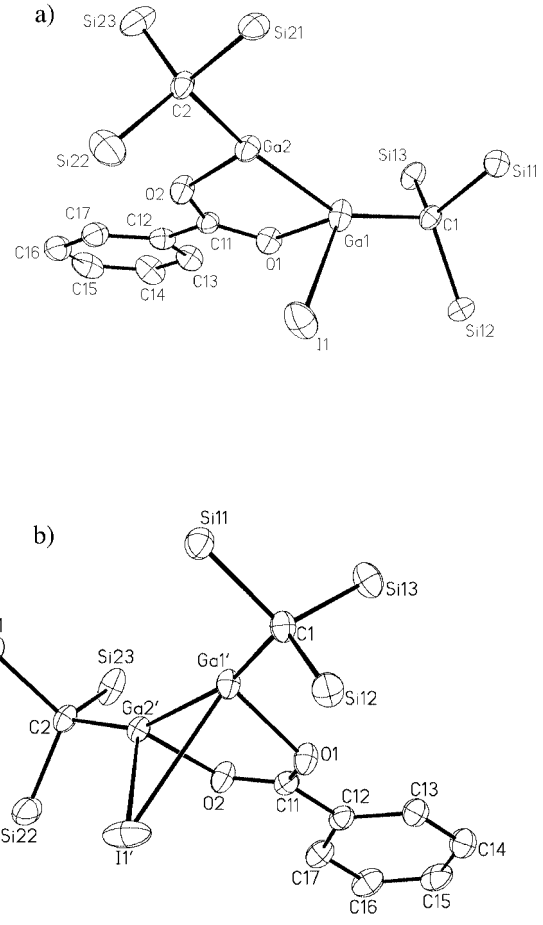


Figure 1. (a). Molecular structure and numbering scheme of compound **2**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted; of the disordered gallium and iodine atoms only those with the highest occupancy factors (0.84) were considered. Selected bond lengths [pm] and angles [°]: Ga1–Ga2 239.9(1), Ga1–C1 198.7(3), Ga2–C2 197.3(3), Ga1–O1 199.2(2), Ga2–O2 199.4(2), Ga1–I1 267.8(2), Ga1–Ga2–C2 165.2(1), Ga2–Ga1–C1 147.0(1), O1–Ga1–Ga2 87.69(7), O2–Ga2–Ga1 87.44(7), I1–Ga1–Ga2 81.81(9), I1–Ga1–O1 96.91(9). (b) Molecular structure and numbering scheme of the second individual of the disordered compound **2** possessing the lower occupation factors of the gallium and iodine atoms (16%); the thermal ellipsoids are drawn at the 40% probability level; methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted. Selected bond lengths [pm] and angles [°]: Ga1′–Ga2′ 234.3(7), Ga1′–I1′ 306(1), Ga2′–I1′ 278.8(8), Ga1′–C1 196.7(5), Ga2′–C2 198.5(7), Ga1′–Ga2′–I1′ 72.8(4), Ga2′–Ga1′–I1′ 60.3(4), Ga1′–I1′–Ga2′ 46.9(2).

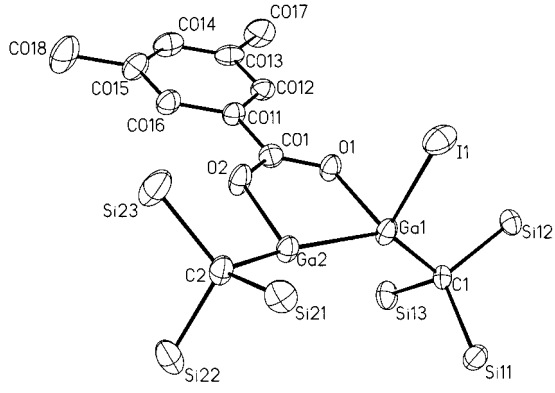

Figure 2. Molecular structure and numbering scheme of compound **4**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted. Selected bond lengths [pm] and angles [°]:Ga1–Ga2 240.67(7), Ga1–C1 198.2(4), Ga2–C2 196.7(4), Ga1–O1 199.6(3), Ga2–O2 198.3(3), Ga1–I1 263.23(7), Ga1–Ga2–C2 162.5(1), Ga2–Ga1–C1 142.7(1), O1–Ga1–Ga2 87.43(9), O2–Ga2–Ga1 87.92(9), I1–Ga1–Ga2 87.90(2), I1–Ga1–O1 97.2(1).

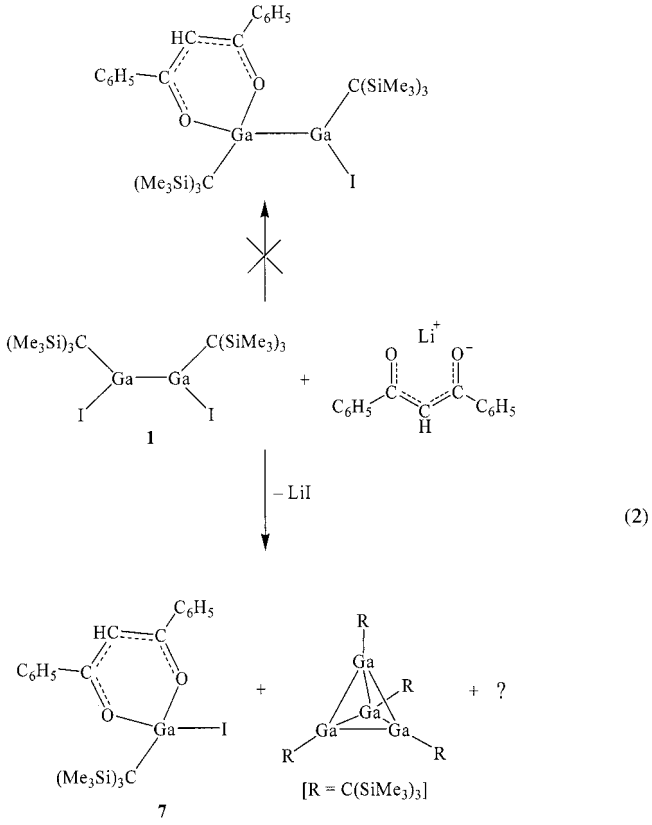
### Reaction of $I_2Ga_2R_2$ (1) [R = $C(SiMe_3)_3$] with Lithium Dibenzoylmethanide

Two equivalents of silver or lithium acetylacetonate reacted readily with the digallium(II) (**1**) or diindium(II) subhalides by the formation of the corresponding bis(acetyl-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

acetonato)dielement compounds.[10,15,20] In contrast to the bridging carboxylato ligands, the acetylacetonato groups occupy terminal positions at the E–E bonds. These compounds are thermally quite stable and decompose or melt only above 170 °C. We hoped to synthesize products analogous to **2**–**6** bearing one chelating acetylacetonato ligand along with one halogen atom by procedures similar to Equation (1).

However, the treatment of the subhalide **1** with one equivalent of lithium dibenzoylmethanide afforded a mixture of products. The three main components occur in an almost equimolar ratio and have chemical shifts in the $^1$H NMR spectrum at $\delta$ = 0.55, 0.51, and 0.23 ppm. One product could be isolated by recrystallization as a bright yellow, crystalline solid. It possesses the $C(SiMe_3)_3$ group ($\delta$ = 0.55 ppm) and the chelating ligand in a 1:1 ratio, which clearly excludes the formation of the desired mixed halogeno acetylacetonato digallium species, see Equation (2). Instead, crystal structure determination revealed a gallium(III) compound (**7**) with a $C(SiMe_3)_3$ group, an iodine atom, and a chelating ligand bonded to the central gallium atom. Thus in this case disproportionation occurred, and the saturation of the coordination sphere by a terminal chelating ligand may not be sufficient to stabilize the gallium(II) compound. Elemental gallium is not formed. The chemical shift of one resonance in the $^1$H NMR spectrum of the raw product at $\delta$ = 0.51 ppm is identical to that of the corresponding tetraalkyltetragallium(I) cluster, which has gallium atoms in an oxidation state of +1. Thus, we suppose that this cluster may be the second product of the disproportionation, however, we were unable to isolate the characteristic red crystals of that compound. Also the third main component of the reaction mixture could not be isolated in a pure form. Its constitution remains unknown. Cleavage of the Ga–Ga bond with the formation of an alkylgallium(III) iodide bearing a chelating ligand was also observed for the reaction of **1** with lithium diphenyltriazenide.[10]



The structural parameters of the molecule of **7** in the solid state (Figure 3) are as expected and do not require a detailed discussion. The gallium atom has a distorted tetrahedral coordination sphere. The Ga–I distance (254.1 pm) is shorter than that for **2** and **4** and is in the normal range for terminal Ga–I bonds.[10,19]

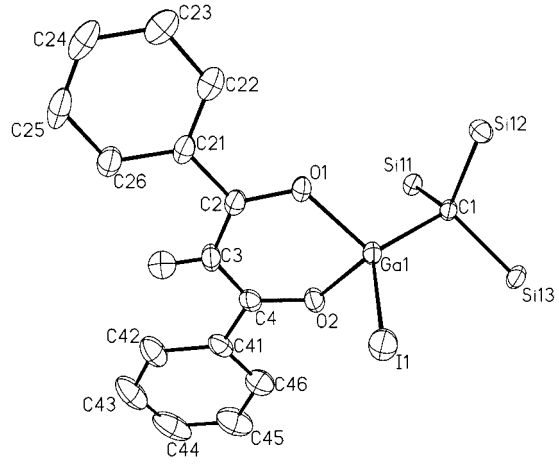


Figure 3. Molecular structure and numbering scheme of compound **7**; the thermal ellipsoids are drawn at the 40% probability level; methyl groups of $SiMe_3$ substituents and hydrogen atoms are omitted. Selected bond lengths [pm] and angles [°]: Ga1–I1 254.11(4), Ga1–C1 195.9(2), Ga1–O1 189.5(2), Ga1–O2 189.3(2), O1–Ga1–O2 95.22(8), C1–Ga1–O1 114.80(9), C1–Ga1–O2 112.64(9), C1–Ga1–I1 125.53(7), O1–Ga1–I1 101.95(6), O2–Ga1–I1 101.86(6).

## Experimental Section

**General:** All procedures were carried out under purified argon in dried solvents (toluene over Na/benzophenone; *n*-hexane and cyclopentane over $LiAlH_4$). The compound $R_2Ga_2I_2$ (**1**) was synthesized according to a literature procedure.[4] The commercially available carboxylic acids were sublimed in vacuo prior to use.

**Synthesis of $Ga_2I(\mu\text{-}O_2C\text{–}C_6H_5)R_2$ (2) [R = $C(SiMe_3)_3$]:** Freshly sublimed benzoic acid (17 mg, 0.141 mmol) was dissolved in toluene (20 mL) and treated with an equimolar quantity of a solution of *n*-butyllithium (0.145 M) in *n*-hexane (0.97 mL, 0.141 mmol) at room temperature. The mixture was heated to its boiling point for a minute. A suspension of lithium benzoate was obtained, which was cooled to –90 °C and treated with a solution of the subhalide **1** (121 mg, 0.141 mmol) in toluene (10 mL). The light yellow mixture was warmed slowly to room temperature und stirred for 48 h. After filtration all volatile components were removed in vacuo. The yellowish residue was dissolved in *n*-hexane and cooled to –70 °C. After a week an amorphous powder of the colorless product **2** was isolated. Yield: 97 mg (82%), m.p. (argon, sealed capillary) = 160 °C. $^1$H NMR ($C_6D_6$, 400 MHz, 298 K): $\delta$ = 0.46 (s, 54 H, $SiMe_3$), 7.04 (m, 3 H, *m*- and *p*-H of phenyl), 8.31 (2 H, *pseudo*-d,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*o*-H of phenyl) ppm. $^{13}$C NMR ($C_6D_6$, 100.6 MHz, 298 K): $\delta$ = 5.5 ($SiMe_3$), 30.2 (Ga–C), 128.9 (*p*-C of phenyl), 130.8 (*m*-C of phenyl), 131.0 (*i*-C of phenyl), 134.4 (*o*-C of phenyl), 178.3 ($CO_2$) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1600 (w, phenyl), 1503 [m, $\nu(CO_2)$], 1461 (vs, paraffin), 1409 [m, $\delta$(CH)], 1377 (s, paraffin), 1320 (w), 1263 (m), 1251 [m, $\delta(CH_3)$], 1177 (vw), 976 (vw), 920 (vw), 857 (vs), 788 {sh, $\rho[CH_3(Si)]$}, 719 (w, paraffin), 681 (m), 662 [m, $\nu_{as}$(SiC)], 633 (vw), 617 [vw, $\nu_s$(SiC)], 488 (w), 474 [sh, $\nu$(GaC), $\nu$(GaO)] cm$^{-1}$. $C_{27}H_{59}Ga_2IO_2Si_6$ (850.6): calcd. C 38.1, H 7.0; found C 38.5, H 7.1.

**Synthesis of $Ga_2I(\mu\text{-}O_2C\text{–}4\text{-}Br\text{–}C_6H_4)R_2$ (3) [R = $C(SiMe_3)_3$]:** 4-Bromo-benzoic acid (41 mg, 0.207 mmol) was suspended in 50 mL of *n*-hexane and treated with 1.4 mL of a 0.145 M solution of *n*-butyllithium (0.207 mmol) in *n*-hexane. The mixture was stirred at room temperature for 2 h and cooled to –90 °C. A solution of the subhalide **1** (177 mg, 0.207 mmol) in 20 mL of *n*-hexane was added. The mixture was warmed to room temperature and stirred for 4 d. LiI was separated by filtration, and the solvent was removed in vacuo. The residue was dissolved in cyclopentane and cooled to –80 °C for 4 d. The product precipitated as a colorless solid. Yield: 35 mg (18%); m.p. (argon, sealed capillary) = 135 °C. $^1$H NMR ($C_6D_6$, 300 MHz, 298 K): $\delta$ = 0.45 (s, 54 H, $SiMe_3$), 6.99 (d, 2 H, $^3J_{HH}$ = 8 Hz, *m*-H of phenyl), 7.89 (d, 2 H, $^3J_{HH}$ = 8 Hz, *o*-H of phenyl) ppm. $^{13}$C NMR ($C_6D_6$, 50 MHz, 298 K): $\delta$ = 5.4 ($SiMe_3$), 30.2 (Ga–C), 129.1 and 129.9 (*i*-C and *p*-C of phenyl), 132.1 and 132.3 (*o*-C and *p*-C of phenyl), 177.5 ($CO_2$) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1589 (m, phenyl) 1532 (m), 1505 [m, $\nu(CO_2)$], 1463 (vs, paraffin), 1407 [s, $\delta$(CH)], 1377 (s, paraffin), 1320 (w), 1263 (m), 1252 [m, $\delta(CH_3)$], 1174 (w), 1155 (vw), 1074 (w), 1012 (w), 857 (vs), 824 (w), 770 {w, $\rho[CH_3(Si)]$}, 721 (w, paraffin), 676 (w), 663 [w, $\nu_{as}$(SiC)], 634 (vw), 620 [vw, $\nu_s$(SiC)], 529 (w), 471 [vw, $\nu$(GaC), $\nu$(GaO)] cm$^{-1}$.

**Synthesis of $Ga_2I(\mu\text{-}O_2C\text{–}3,5\text{-}Me_2C_6H_3)R_2$ (4) [R = $C(SiMe_3)_3$]:** 3,5-Dimethylbenzoic acid (47 mg, 0.313 mmol) was suspended in 50 mL of toluene and treated with 2.0 mL of a 0.145 M solution of *n*-butyllithium (0.207 mmol) in *n*-hexane. The mixture was stirred at room temperature for 15 min and cooled to –90 °C. A solution of the subhalide **1** (255 mg, 0.298 mmol) in 25 mL of toluene was added. The mixture was warmed to room temperature and stirred for 24 h. All volatiles were removed in vacuo. The residue was treated with *n*-hexane and filtered. The colorless product was obtained upon cooling the filtrate to –80 °C. Yield: 147 mg (54%); colorless crystals; m.p. (argon, sealed capillary) = 187 °C. $^1$H NMR ($C_6D_6$, 300 MHz, 298 K): $\delta$ = 0.49 (s, 54 H, $SiMe_3$), 2.08 (s, 6 H, Me attached to phenyl), 6.79 (s, 1 H, *p*-H of phenyl), 8.02 (s, 2 H, *o*-H of phenyl) ppm. $^{13}$C NMR ($C_6D_6$, 50 MHz, 298 K): $\delta$ = 5.5 ($SiMe_3$), 21.1 (Me attached to phenyl), 31.9 (Ga–C), 128.3, 130.6, 136.2 and 138.6 (all phenyl), 178.7 ($CO_2$) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1652 (br, w, phenyl), 1494 [m, $\nu(CO)_2$] 1461 (vs, paraffin), 1392 [m, $\delta$(CH)], 1376 (s, paraffin), 1320 (w), 1264 (m), 1251 [m, $\delta(CH_3)$, 1152 (vw), 1077 (vw), 1040 (br, w), 856 (vs), 785 (w), 768 {w, $\rho[CH_3(Si)]$}, 722 (w, paraffin), 675 (m), 661 [m, $\nu_{as}$(SiC)], 634 (vw), 618 [vw, $\nu_s$(SiC)], 548 (w), 488 [w, $\nu$(GaC), $\nu$(GaO)] cm$^{-1}$. UV/Vis (*n*-hexane): $\lambda_{max}$ (log $\varepsilon$) = 254 (3.54), 331 (2.84) nm. $C_{29}H_{63}Ga_2IO_2Si_6$ (878.7): calcd. C 39.6, H 7.2; found C 38.5, H 7.4.

**Synthesis of $Ga_2I(\mu\text{-}O_2C\text{–}4\text{-}Me_3C\text{–}C_6H_4)R_2$ (5) [R = $C(SiMe_3)_3$]:** The procedure is similar to that for the synthesis of **4** (4-*tert*-butylbenzoic acid: 48 mg, 0.269 mmol; subhalide **1**: 230 mg, 0.269 mmol). We did not succeed in recrystallizing compound **5** from different solvents. However, the compound was formed directly in high purity, and the characterization was done with the raw product of the reaction. Owing to the unsuccessful purification by recrystallization no elemental analysis was conducted. Yield: 188 mg (77%); pale yellow amorphous solid; m.p. (argon, sealed capillary) = 97 °C. $^1$H NMR ($C_6D_6$, 200 MHz, 298 K): $\delta$ = 0.51 (s, 54 H, $SiMe_3$), 1.09 (s, 9 H, $CMe_3$), 7.16 (d, 2 H, $^3J_{HH}$ = 8 Hz, *m*-H of phenyl), 8.31 (d, 2 H, $^3J_{HH}$ = 8 Hz, *o*-H of phenyl). $^{13}$C NMR ($C_6D_6$, 50 MHz, 298 K): $\delta$ = 5.6 ($SiMe_3$), 30.1 (Ga–C), 30.9 (Me of *tert*-butyl), 35.1 ($CMe_3$), 126.2, 128.3, 131.2, and 158.2 (all phenyl), 178.3 ($CO_2$) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1606 (m), 1579 (m, phenyl), 1515 (m), 1491 [s, $\nu(CO_2)$], 1460 (vs, paraffin), 1407 [vs, $\delta$(CH)], 1377 (s, paraffin), 1263 (m), 1252 [m, $\delta(CH_3)$], 1193 (m), 1150 (w), 1107 (w), 1016 (m, br), 855 (vs), 800 (m), 786 (m), 749 {vw, $\rho[CH_3(Si)]$}, 728 (w, paraffin), 675 (m), 661 [m, $\nu_{as}$(SiC)], 637 (vw), 621 [vw, $\nu_s$(SiC)], 599 (w), 584 (vw), 541 (vw), 490 [w, $\nu$(GaC), $\nu$(GaO), $\delta(C_3C)$] cm$^{-1}$. UV/Vis (*n*-hexane): $\lambda_{max}$ (log $\varepsilon$) = 240 (3.53), 330 (2.87) nm.

**Synthesis of $Ga_2I(\mu\text{-}O_2C\text{–}CMe_3)R_2$ (6) [R = $C(SiMe_3)_3$]:** The procedure is similar to that for the synthesis of **4** (pivalic acid: 19 mg, 0.187 mmol, after addition of butyllithium stirred for 2 h at room temperature; subhalide **1**: 160 mg, 0.187 mmol). The colorless product was obtained upon cooling the filtrate to –80 °C. Yield: 77 mg (50%); colorless solid; m.p. (argon, sealed capillary) = 127 °C. $^1$H NMR ($C_6D_6$, 200 MHz, 298 K): $\delta$ = 0.42 (s, 54 H, $SiMe_3$), 1.15 (s, 9 H, $CMe_3$). $^{13}$C NMR ($C_6D_6$, 50 MHz, 298 K): $\delta$ = 5.4 ($SiMe_3$), 27.0 (Me of *tert*-butyl), 30.2 (Ga–C), 39.6 ($CMe_3$), 192.0 ($CO_2$) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1600 (m), 1502 (s), 1484 [s, $\nu(CO_2)$], 1461 (vs, paraffin), 1421 [s, $\delta$(CH)], 1378 (s, paraffin), 1364 (sh), 1293 (w), 1263 (s), 1252 [s, $\delta(CH_3)$], 1222 (m), 1169 (w), 1000 (m, br), 855 (vs), 789 (m), 752 {vw, $\rho[CH_3(Si)]$}, 721 (m, paraffin), 675 (s), 661 [s, $\nu_{as}$(SiC)], 632 (w), 618 [m, $\nu_s$(SiC), 529 (vw), 443 [w, $\nu$(GaC), $\nu$(GaO), $\delta(C_3C)$] cm$^{-1}$. UV/Vis (*n*-hexane): $\lambda_{max}$ (log $\varepsilon$) = 254 (3.60) nm. $Ga_2IO_2Si_6C_{25}H_{63}$ (830.6): calcd. Ga 16.8; found Ga 16.1.

**Reaction of $R_2Ga_2I_2$ 1 with Dibenzoylmethyllithium. Synthesis of 7:** The procedure is similar to that for the synthesis of compound **4** (dibenzoylmethane: 76 mg, 0.341 mmol, after addition of butyllithium stirred for 2 h; subhalide **1**: 292 mg, 0.341 mmol). The intensively yellow reaction mixture was filtered, toluene was removed in vacuo, and the residue was recrystallized from cyclopentane (20/–45 °C). Product **7** was precipitated as an amorphous solid. Yield: 51 mg (23%), yellow solid; m.p. (argon, sealed capillary) = 213 °C. $^1$H NMR ($C_6D_6$, 200 MHz, 298 K): $\delta$ = 0.55 (s, 27 H, $SiMe_3$), 6.80 (s, 1 H, inner H atom of the acac ligand), 7.02 (m, 6 H, *m*-H and *p*-H of phenyl), 7.84 (4 H, pseudo-d, *o*-H of phenyl) ppm. $^{13}$C NMR ($C_6D_6$, 50 MHz, 298 K): $\delta$ = 5.1 ($SiMe_3$), 31.9 (Ga–C), 96.0 (inner C of the acac ligand), 128.9, 132.5, 133.3, and 137.0 (phenyl), 186.0 (CO) ppm. IR (CsBr, paraffin): $\tilde{\nu}$ = 1590 (m, phenyl), 1523 (vs), 1478 [s, $\nu(CO_2)$], 1460 (vs, paraffin), 1377 (m, paraffin), 1364 (m), 1347 (s), 1326 (m), 1303 (m), 1263 (s), 1253 [s $\delta(CH_3)$, 1229 (m), 1173 (w), 1153 (w), 1122 (w), 1096 (w), 1064 (w), 1024 (w), 997 (w), 949 (w), 852 (vs), 772 (w) 758 {w, $\rho[CH_3(Si)]$}, 719 (m, paraffin), 677 (m, $\nu_{as}$(SiC), 643 (vw), 622 [v, $\nu_s$(SiC)], 592 (w), 544 (w), 462 [vw, $\nu$(GaC), $\nu$(GaO)] cm$^{-1}$. UV/Vis (*n*-hexane): $\lambda_{max}$ (log $\varepsilon$) = 226 (3.98), 266 (3.81), 372 (3.85) nm. $GaIO_2Si_3C_{25}H_{38}$ (651.5): calcd. C 46.1, H 5.9; found C 47.1, H 6.6.

**Crystal Structure Determinations:** Single crystals of the compounds **2**, **4**, and **7** were obtained by cooling the solutions in *n*-hexane (20/–30 °C, **2**), cyclopentane (20/–45 °C, **4**), and again cyclopentane (20/+5 °C, **7**). Crystal data and structure refinement parameters are given in Table 1.[23] The crystals of **2** enclose one molecule of *n*-hexane per formula unit of **2**. Owing to their relatively large isotropic displacement parameters the solvent carbon atoms were not

refined anisotropically. The central Ga–Ga–I group showed a disorder over two positions, see the Results and Discussion chapter for details. These atoms were refined with occupancy factors of 0.84 and 0.16. The refinement of the substituents was not affected by this disorder. The tris(trimethylsilyl)methyl group at C2 of compound **4** was disordered. Its atoms were refined with site occupation factors of 0.84 and 0.16. One molecule of cyclopentane was enclosed per formula unit of **4**. Its carbon atoms were refined only with isotropic displacement factors. Also the crystals of **7** contained one cyclopentane molecule.

# Binuclear Mixed Valence Oxovanadium(IV/V) Complexes Containing a $[OV^{IV}(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^{V}O]^{2+}$ Core: Synthesis, EPR Spectra, Molecular and Electronic Structure

**Amrita Mondal,[a] Sucharita Basak,[a] Sumana Sarkar,[a] Deepak Chopra,[b] Ranjan Das,[c] and Kajal Krishna Rajak*[a]**

**Keywords:** Vanadium / Oxovanadium complexes / Mixed valence

Binuclear mixed valence oxovanadium(IV/V) complexes of general formula $[V_2O_3L]$ containing a $[OV^{IV}(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^{V}O]^{2+}$ core have been synthesised using conformationally labile $N_4O_3$-coordinating heptadentate ligands ($H_3L$). The X-ray structure of one complex has been examined. Solution EPR spectra revealed that the unpaired electron of the complexes is delocalised between the two vanadium centres. The simulated EPR spectrum of one complex confirms this experimental observation. DFT studies have been performed using crystallographic coordinates in order to obtain further insight into the electronic structure of this type of molecule.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The chemistry of mixed valence vanadium complexes has been of considerable interest. The main interest arises from the complete or partial delocalisation of the single 3d electron of the vanadium(IV) over both vanadium centres or its complete localisation on one vanadium centre. A sizeable number of oxo-bridged binuclear mixed valence oxovanadium(IV/V) complexes have been cited in the literature[1–14] and depending on the geometry of $[V_2O_3]^{3+}$ core, the structurally characterised mixed valence binuclear complexes have been classified into several categories. For the $[V_2O_3]^{3+}$ core, containing a linear V–O–V bridge[1a,2,5,10,12,13] with the terminal oxo groups in mutual *trans* position, delocalisation is anticipated because of significant metal $d_{xy}$ orbital overlap with the $p_x$ orbital of the oxo bridge. Schulz et al.[7] reported that for the nearly *trans* V=O groups with a bent V–O–V moiety, the delocalisation of the odd electron between the two vanadium centres depends on the pi-donating ability of the equatorial ligands. Localised electronic structures have also been documented[6] for angular V–O–V moieties with *syn* or *twist* V=O groups, which probably occur due to insufficient overlap between the metal $d_{xy}$ orbitals.

Recently we have found[15] complete delocalisation of the unpaired electron between the two vanadium atoms in a mixed bridged mixed valence species containing the $[OV^{IV}(\mu\text{-}O_x)(\mu\text{-}O_{phen})V^{V}O]^{2+}$ moiety, which has an angular V–O–V group and nearly *syn* V=O groups. However the reason for the delocalisation of the odd electron is not clear. Thus, further studies of this type of system are required to allow for a better understanding of the behaviour of the unpaired electron.

In connection with our previous work,[15] herein we describe the synthesis of a series of mixed bridged mixed valence binuclear oxovanadium(IV/V) complexes incorporating $N_4O_3$-coordinating heptadentate ligands. The crystal structure of one representative case is reported. A simulated EPR spectrum is found to be similar to the EPR spectra of the complexes observed in solution at room temperature. In addition, DFT calculations have enabled us to understand qualitatively the nature of the delocalisation of the unpaired electron.

## Results and Discussion

In this paper four heptadentate ligands $H_3L^7$–$H_3L^{10}$ (general abbreviation, $H_3L$) have been used (Scheme 1).

Treatment of a solution of $VO(acac)_2$ in acetone under air with the heptadentate ligands in a 2:1 ratio afforded green coloured complexes with the general formula $[V^{IV}V^{V}O_2L]$ in good yields. The oxygen in the air is believed to act as the oxidant in this synthesis. The data for the characterisation of these binuclear mixed valence species are listed in the experimental section. All the compounds display a strong V=O stretch near 950 $cm^{-1}$in their IR spectra, and the V–O–V vibration occurs near 752 $cm^{-1}$. The green solution of the complexes absorb at ca. 1030 and ca. 660 nm

respectively. The band near 1030 nm in their UV/Vis spectra is assigned to the inter valence charge transfer transition,[15] and the absorption at 660 nm is due to ligand field excitation. The complexes exhibit an irreversible anodic response near 0.45 V vs. SCE. The stabilisation of the mixed valence oxovanadium(IV/V) binuclear species by the trianionic heptadentate ligand is reflected in the irreversible $[OV^V(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{3+}$ – $[OV^{IV}(\mu\text{-}O_x)(\mu\text{-}O_{phen})\text{-}V^VO]^{2+}$ anodic response. All the compounds are paramagnetic, and the magnetic moment value is, $\mu \approx 1.75$ BM per molecule.

## Crystal Structure

The X-ray structure of **1** has been determined, and the molecular structure is shown in Figure 1. Selected inter atomic distances and bond angles relevant to the coordination sphere are given in Table 1.

In **1** the vanadium centres are linked asymmetrically by a bridging oxygen atom, O5, and the central phenolato oxygen, O6. The V1–O5–V2 and V1–O6–V2 angles are 116.11(10)° and 91.79(7)° respectively. The geometry of each vanadium atom appears to be distorted octahedral. In the $VO_4N_2$ environment, the V=O, V–O and V–N bond lengths are as expected[15] and are in the ranges of 1.605–1.615 Å, 1.798–2.212 Å and 2.188–2.251 Å respectively. In the octahedral coordination environment, the tripodal nitrogen atom (N1 for V1 and N3 for V2) is *trans* to the O5 atom, while the terminal nitrogen atoms (N2 and N4) occupy positions *trans* to the terminal phenoxide groups (O2 and O4). The V2–O4 [1.871 (2) Å], V2–O5 [1.885 (2) Å] and V2–O6 [2.212 (2) Å] bond lengths are slightly longer than the respective V1–O2 [1.838 (2) Å], V1–O5 [1.798 (2) Å] and V1–O6 [2.140 (2) Å] bonds. The V1–N bond lengths are slightly longer than the V2–N distances, and this can be ascribed to the short V1–O2 and V1–O5 bonds.

Table 1. Selected bond lengths [Å] and angles (°) for $[V_2O_3L^7]$ $CH_2Cl_2$.

## EPR Spectra

EPR spectra of the complexes were recorded at 300 K and 77 K. Resonance parameters are shown in Table 2.

The complexes exhibit 15 nearly equally spaced lines, with isotropic structure, in dichloromethane solution (Figure 2, a). The 15 line spectrum arises from the hyperfine interaction of the unpaired electron with the two vanadium

nuclei (nuclear spin $I = 7/2$), which appear to be equivalent on the EPR timescale. The difference in the separation of the hyperfine lines at the lowest and highest fields is less than 2 gauss, suggesting that the second order shift[16] in the line position is small. We neglected this small shift, and determined the isotropic hyperfine coupling constant due to vanadium to be $49.3 \pm 0.2$ G. In the same way, neglecting the second order shift, the centre of the EPR spectrum was assumed to be the centre of the middle hyperfine line, and the $g$ value for the complex was determined to be $1.9741 \pm 0.0005$. The isotropic coupling constant and the g value are typical for binuclear complexes,[15] and the value of the isotropic hyperfine coupling constant is about half of the value observed in oxovanadium(IV) complexes.[17] This indicates that in solution at 300 K, the single unpaired electron is shared by the two vanadium nuclei. The observed line width in not same for all the hyperfine lines. The dependence of the line width on the hyperfine lines of the EPR spectrum in solution has been modelled theoretically, using a model that incorporates incomplete motional narrowing, the anisotropic $g$-tensor, and hyperfine tensor interactions.[18,19] Using the Kivelson's model[18] the line width, $\Delta H$, of a hyperfine line associated with the nuclear spin component $M_I$ is given as equation (2) in ref.[20]

Where the parameters $\alpha$, $\beta$, $\gamma$ and $\delta$ are functions of the principal values of the g-tensor, hyperfine coupling tensor, and rotational correlation time. The line width expression given in [Equation (1)] has been highly successful in explaining the variation in the widths of the EPR lines in the spectrum of vanadyl acetylacetonate in toluene,[20] and has been used to obtain the anisotropic EPR parameters from solution spectra of copper complexes.[21,22] We have assumed that Equation 1 is approximately applicable to our binuclear complex, and have simulated the EPR spectrum based on this line width expression with $M_I = -7, -6, \ldots, +6, +7$, corresponding to the two equivalent vanadium nuclei. The simulated spectrum is shown in Figure 2 (b). Here we simply note that the simulated spectrum reproduces the

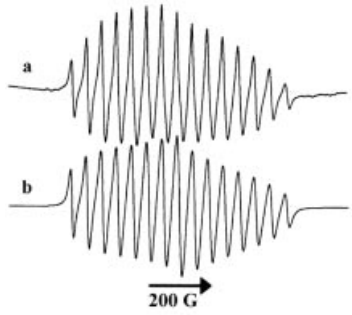

Figure 2. EPR spectra for $[V_2O_3L^7]$ (a) in DCM at 300 K. Instrument settings: microwave frequency, 9.45385 GHz; microwave power, 2.0 mW; modulation frequency, 100 kHz; modulation amplitude, ca. 1 G. (b) Simulated EPR spectrum using isotropic hyperfine coupling constant = $49.3 \pm 0.2$ G, and Kivelson's parameters $\alpha$ = 21.21 G, $\beta$ = 0.2943 G, $\gamma$ = –0.1538 and $\delta$ = 0.0007 G.

essential features of the experimental EPR spectrum of the binuclear complex at room temperature.

$$\Delta H = \alpha + \beta M_I + \gamma M_I^2 + \delta M_I^3 \quad (1)$$

The complexes display axial spectra at 77 K (Figure 3). The hyperfine structure can be attributed to the coupling of the unpaired electron to a single $^{51}$V centre ($I = 7/2$), at least on the EPR timescale.[6,8]

In frozen solution (77 K) and fluid solution (300 K) the spectral parameters are related by the following equations:[23]

$g_{av} \approx g_{iso}$

$A_{av} \approx 2A_{iso}$

From the above relationships it may be deduced that the unpaired electron is equally delocalised between the two vanadium atoms, at least on the X-band EPR timescale, and the complexes behave as class III type[5,24,25] mixed valance species at room temperature.

## DFT Study

DFT calculation have been performed on the full molecular structure using the crystallographic coordinates for $[V_2O_3L^7]$ and the previously reported $[V_2O_3L^1]$ complex[15] (ligand $H_3L^1$ is shown in Scheme 1) in order to get a better insight into the electronic structure of μ-oxo μ-phenoxo bridged binuclear oxovanadium(IV/V) complexes. The spin density, singly occupied molecular orbital (SOMO), and the lowest unoccupied molecular orbital (LUMO) plots for the complexes are shown in Figure 4, Figure 5 and Figure 6 respectively.

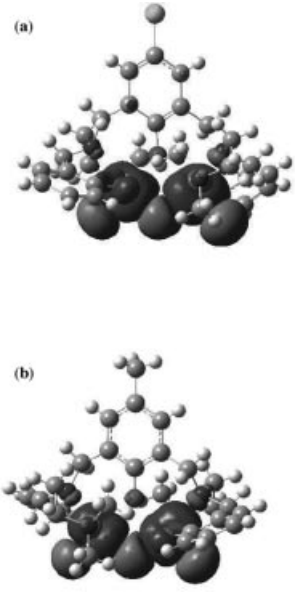

Figure 4. Spin density plots (a). $[V_2O_3L^7]$ (b). $[V_2O_3L^1]$.

The spin density population of the electron between the two vanadium atoms is 0.5700 and 0.4300 for $[V_2O_3L^7]$, and 0.5664 and 0.4336 for $[V_2O_3L^1]$. It is clear from the spin density plots (Figure 4) that the unpaired electron is delocalised between the two vanadium centres.

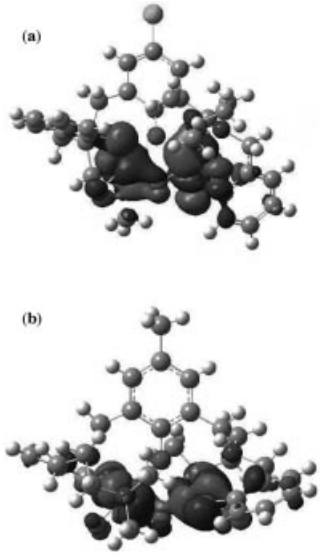

Figure 5. SOMO plots (a). $[V_2O_3L^7]$ (b). $[V_2O_3L^1]$.

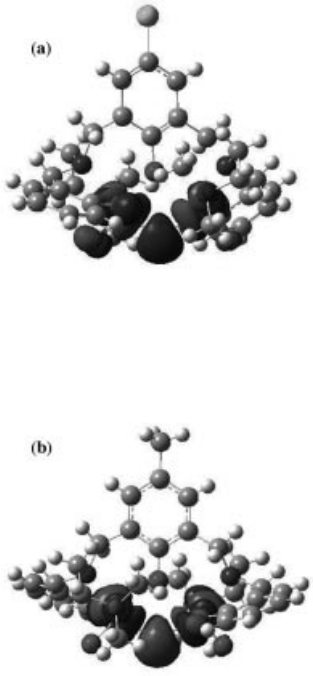

Figure 6. LUMO plots (a). $[V_2O_3L^7]$ (b). $[V_2O_3L^1]$.

It is interesting to note that the bridging oxo oxygen atom takes part in the construction of the SOMO, while the contribution of the bridging phenoxy oxygen to the SOMO is zero (Figure 5). The $p_z$ orbital of the bridging oxo oxygen atom interacts with the $d_{xz}$ orbital of the vanadium atoms asymmetrically in the $[V_2O_3L^7]$ complex, and symmetrically in the $[V_2O_3L^1]$ complex. These results are consistent with the $V–O_{oxo}–V$ bond lengths observed in these complexes. It is found from the LUMO plots that the bridging oxo oxygen (Figure 6) and the bridging phenoxy group do not in-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

teract with the metal orbital. The above results suggest that the delocalisation of the electron between the two vanadium centres takes place via a $d_{xz}$–$p_z$–$d_{xz}$ super exchange pathway in the ground state.

In summary, DFT studies reveal that in case of binuclear mixed valence oxovanadium(IV/V) complexes containing a $[OV^{IV}(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^{V}O]^{2+}$core with a bent V–O–V moiety, only the bridging oxo group is responsible for the unpaired electron delocalisation, and as such the delocalisation occurs via a $d_{xz}$–$p_z$–$d_{xz}$ super exchange pathway.

## Conclusion

Binuclear mixed valence oxovanadium(IV/V) complexes containing the $[OV^{IV}(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^{V}O]^{2+}$ moiety have been synthesised using $N_4O_3$-coordinating heptadentate ligands. In $[V_2O_3L^7]$, the V1–O5–V2 moiety is angular, and the V1–O5 and V2–O5 bond lengths are slight different [V1–O5 = 1.798(2) and V2–O5 = 1.885(2) Å]. Solution EPR spectra reveal that the unpaired electron is delocalised between the two vanadium atoms, which is attested by the simulated EPR spectrum. We have also found some important trends in the electronic structure, and hence in the behaviour of the unpaired electron, from the DFT studies. DFT calculations show that the bridging phenoxo group has no role to play in the electron delocalisation. Although the V–O–V group is angular, the delocalisation in such systems is anticipated to occur via an $d_{xz}$–$p_z$–$d_{xz}$ exchange pathway involving the oxo oxygen atom.

## Experimental Section

**Materials:** Bis(acetylacetonato)oxovanadium(IV)[26] and the ligands[27] were prepared as reported in the literature. All the starting chemicals were analytically pure and used without further purification, and the solvents were purified by standard procedures.[28]

**Physical Measurements:** UV/Vis spectra were recorded on a Perkin–Elmer LAMBDA 25 spectrophotometer, and IR spectra were measured with a Perkin–Elmer L-0100 spectrometer. Electrochemical measurements were performed (acetonitrile solution) on a CH 620A electrochemical analyzer using a platinum electrode. Tetraethylammonium perchlorate (TEAP)[29] was used as the supporting electrolyte, and the potentials are referenced to the standard calomel electrode (SCE) without junction correction. Magnetic susceptibilities were measured on a PAR-155 vibrating-sample magnetometer.

The room temperature solution EPR spectra were recorded for **1** in the following manner: the complex (ca. 10 mM in dichloromethane) was placed in a glass tube, and degassed by repeated freeze-pump-thaw cycles with a vacuum line working at a pressure of about $10^{-4}$ Torr., and then sealed off. This sealed sample was used for recording the CW-EPR spectrum at room temperature, using a home-built EPR spectrometer,[30] which was further modified.[31] Low microwave power (ca. 2 mW) and 100 kHz magnetic field modulation (ca. 1 gauss) were used to avoid distortion of the EPR lines. A proton NMR magnetometer was used to calibrate the scan range of the magnetic field. An Agilent frequency counter, model 53181A, equipped with a highly stable oven-controlled time base, was used to measure the microwave and NMR frequencies. For determining the $g$ value of the complex, a very small amount of DPPH powder ($g = 2.0037 \pm 0.0002$)[32] was attached to the outside wall of the sealed sample, and the EPR spectrum of the complex with DPPH was recorded.

The room temperature solution EPR spectra of the other complexes, and the low temperature spectra for all the complexes, were recorded on a Varian E-109C X-band spectrometer. Elemental analyses (C, H, N) were performed on a Perkin–Elmer 2400 Series II elemental analyzer.

**DFT Calculation:** DFT calculations were performed using the Gaussian-03 program.[33] The complexes were described in the unrestricted formalism using the B3LYP hybrid density function in combination with a standard 3-21 G basis set.

**Crystallographic Studies:** Single crystals of suitable quality for single-crystal X-ray diffraction studies were grown by the slow diffusion of hexane into a dichloromethane solution containing $[V_2O_3L^7]\,CH_2Cl_2$. The X-ray intensity data were measured at 293 K on a Bruker AXS SMART APEX CCD diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). The detector was placed at a distance of 6.03 cm from the crystal. A total of 606 frames were collected over a scan width of 0.3° at different settings of $\varphi$. The data were reduced with SAINTPLUS[34] and an empirical absorption correction was applied using the SADABS package.[24] Vanadium atoms were located by Direct Methods, and the rest of the non-hydrogen atoms emerged from successive Fourier syntheses. SHELXL-97[35] was used for structure solution, and for full-matrix least-squares structure refinement on $F^2$. All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were included at calculated positions. The dichloromethane solvent molecule is disordered over two positions. The disorder was modelled using the PART instruction in SHELXTL, with an initial occupancy of 0.5, which after refinement gave a final value of 0.583(5). Molecular structure plots were drawn using ORTEP.[36] Relevant crystal data are given in Table 3.

Table 3. Crystal data and structure refinement parameters for $[V_2O_3L^7]\cdot CH_2Cl_2$.

| $[V_2O_3L^7]\cdot CH_2Cl_2$ | |
|---|---|
| Formula | $C_{31}H_{40}Cl_3N_4O_6V_2$ |
| Formula weight | 772.90 |
| Crystal system | monoclinic |
| Space group | $P2_1/c$ |
| $a$ [Å] | 16.181(3) |
| $B$ [Å] | 13.986(3) |
| $c$ [Å] | 15.024(3) |
| $\beta$ [°] | 97.16(3) |
| $V$ [Å$^3$] | 3373.6(12) |
| $T$ [K] | 293(2) |
| $Z$ | 4 |
| $D_{calcd.}$ (mg·m$^{-3}$) | 1.522 |
| $\mu$ [mm$^{-1}$] | 0.841 |
| $R_1$,[a] $wR_2$[b] [$I > 2\sigma(I)$] | 0.0490, 0.1121 |

| $R_{int}$, $R_{sigma}$ | 2.65, 2.47 |
| G.O.F on $F^2$ | 1.058 |

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

CCDC-281762 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Complexes:** The complexes were prepared by the same general method. Details are given here for a representative case.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**$[V_2O_3L^7]$:** To a stirred solution of $[VO(acac)_2]$ (0.10 g, 0.37 mmol) in 20 mL acetone was added the $H_3L^7$ ligand (0.098 g, 0.19 mmol). The reaction mixture was then stirred for 2 h at ambient temperature in air, and a green precipitate separated from the solution. The solution was filtered, washed with acetone, and then dried in vacuo over fused calcium chloride. Yield: 0.116 g (90%). $C_{30}H_{38}ClN_4O_6V_2$ (687.5): calcd. C 52.36, H 5.53, N 8.15; found: C 52.61, H 5.70, N 8.31. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 1031 nm (255 $M^{-1}$ $cm^{-1}$); 640 (700). IR (KBr): $\nu$(V=O) 950, $\nu$(V–O–V) 752 $cm^{-1}$. $E_{pa}$ ($[OV^V(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{3+}/[OV^{IV}(\mu\text{-}O_x)(\mu\text{-}O_{phen})V^VO]^{2+}$): +0.56 V (irr). $\mu_{eff}$ = 1.76 BM.

**$[V_2O_3L^8]$:** Yield: 0.117 g (87%). $C_{32}H_{42}ClN_4O_6V_2$ (701.5): calcd. C 53.66, H 5.87, N 7.82; found: C 53.75, H 5.99, N 7.95. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 1036 nm (590 $M^{-1}$ $cm^{-1}$), 650 (785). IR (KBr): $\nu$(V=O) 947, $\nu$(V–O–V) 755 $cm^{-1}$. $E_{pa}$ ($[OV^V(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{3+}/[OV^{IV}(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{2+}$): +0.55 V (irr); $\mu_{eff}$ = 1.79 BM.

**$[V_2O_3L^9]$:** Yield: 0.121 g (85%). $C_{30}H_{36}Cl_3N_4O_6V_2$ (757.5): calcd. C 47.5, H 4.88, N 7.39; found: C 47.64, H 4.96, N 7.54. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 1032 nm (458 $M^{-1}$ $cm^{-1}$), 665 (1217). IR (KBr): $\nu$(V=O) 955, $\nu$(V–O–V) 745 $cm^{-1}$. $E_{pa}$ ($[OV^V(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{3+}/[OV^{IV}(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{2+}$): +0.49 V (irr); $\mu_{eff}$ = 1.75 BM.

**$[V_2O_3L^{10}]$:** Yield: 0.130 g (88%). $C_{32}H_{40}Cl_3N_4O_6V_2$ (784.5): calcd. C 48.94, H 5.09, N 7.14; found: C 49.12, H 5.21, N 7.25. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 1036 nm (590 $M^{-1}$ $cm^{-1}$), 650 (785). IR (KBr): $\nu$(V=O) 958, $\nu$(V–O–V) 748 $cm^{-1}$. $E_{pa}$ ($[OV^V(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{3+}/[OV^{IV}(\mu\text{-}O_{oxo})(\mu\text{-}O_{phen})V^VO]^{2+}$): +0.56 V (irr); $\mu_{eff}$ = 1.72 BM.

# Metal Phosphonates Based on {[(Benzimidazol-2-ylmethyl)imino]bis-(methylene)}bis(phosphonic Acid): Syntheses, Structures and Magnetic Properties of the Chain Compounds $[M\{(C_7H_5N_2)CH_2N(CH_2PO_3H)_2\}]$ (M = Mn, Fe, Co, Cu, Cd)

**Deng-Ke Cao,[a] Jing Xiao,[a] Yi-Zhi Li,[a] Juan Modesto Clemente-Juan,[b] Eugenio Coronado,[b] and Li-Min Zheng*[a]**

**Keywords:** Chain structures / Magnetic properties / N,O ligands / Organic–inorganic hybrid composites / Transition metals

Five compounds based on {[(benzimidazol-2-ylmethyl)imino-]bis(methylene)}bis(phosphonic acid) $[(C_7H_5N_2)CH_2N(CH_2PO_3H_2)_2]$, namely $[M\{(C_7H_5N_2)CH_2N(CH_2PO_3H)_2\}]$ [M = Mn (**1**), Fe (**2**), Co (**3**), Cu (**4**), Cd (**5**)] have been synthesized under hydrothermal conditions. These compounds are isostructural, crystallizing in the orthorhombic space group *Pbca*, with $a$ = 15.331(2), $b$ = 10.7150(16), and $c$ = 16.715(2) Å for **1**; $a$ = 15.320(3), $b$ = 10.477(2), and $c$ = 16.764(3) Å for **2**; $a$ = 15.207(2), $b$ = 10.4626(16), and $c$ = 16.794(3) Å for **3**; $a$ = 15.101(3), $b$ = 10.3517(17), and $c$ = 16.997(3) Å for **4**; and $a$ = 15.4679(19), $b$ = 10.8923(13), and $c$ = 16.6175(19) for **5**. Each compound shows a one-dimensional chain structure where $\{MO_3N_2\}$ trigonal bipyramids are connected by $\{CPO_3\}$ tetrahedra through corner-sharing. The chains are further connected to each other through aromatic stacking of the benzimidazole rings and extensive hydrogen bonds, forming a supramolecular 3D structure. Magnetic susceptibility studies of **1**–**4** reveal that weak antiferromagnetic interactions occur between the metal centers.

## Introduction

Increasing attention has been paid in recent years to metal phosphonate materials due to their potential applications in catalysis, nonlinear optics, magnetism, and biotechnology etc.[1] Meanwhile, the rapid development in the rational design and synthesis of coordination polymers, by using different organic ligands, has provided a variety of compounds with interesting architectures and possible functionalities.[2] The integration of the inorganic phosphonate ($CPO_3$) group and numerous rigid or flexible organic functional groups within the same composite would, therefore, be expected to result in new inorganic–organic hybrid materials with interesting structures and properties. Efforts along this line have been made where the organic moieties of the phosphonate ligand contain amino,[3] carboxylate,[4] pyridyl,[5] macrocyclic,[6] and ferrocene[7] groups etc. In this article, we report a new route to the synthesis of {[(benzimidazol-2-ylmethyl)imino]bis(methylene)}bis-(phosphonic acid) $[(C_7H_5N_2)CH_2N(CH_2PO_3H_2)_2$, bibmp$H_4$], where a benzimidazole group is incorporated into the diphosphonic acid. Five isostructural compounds based on this ligand, namely $[M\{(C_7H_5N_2)CH_2N(CH_2PO_3H)_2\}]$ [M = Mn (**1**), Fe (**2**), Co (**3**), Cu (**4**), Cd (**5**)] are obtained by hydrothermal reactions; all exhibit one-dimensional chain structures. The magnetic properties of **1**–**4** were also investigated.

## Results and Discussion

### Syntheses and Preliminary Characterization

The synthesis of bibmp$H_4$ was previously reported from 2-(2-aminomethyl)benzimidazole, phosphorus, and formaldehyde by a Mannich reaction.[8] In this paper we describe a new synthetic route to the same acid from the reaction between *N*,*N*-bis(phosphonomethyl)aminoacetic acid and 1,2-diaminobenzene (Scheme 1). The final product can be easily isolated with a much higher yield (82%) than that reported in the patent (17%).[8]

The hydrothermal reaction of bibmp$H_4$ and the appropriate metal sulfate at 140 °C for one day resulted in compounds **1**–**5**, which have identical structures even though the experimental conditions for the formation of these compounds are slightly different. A series of experiments was conducted by changing the molar ratio of the starting materials and the pH of the reaction mixture. It was found that

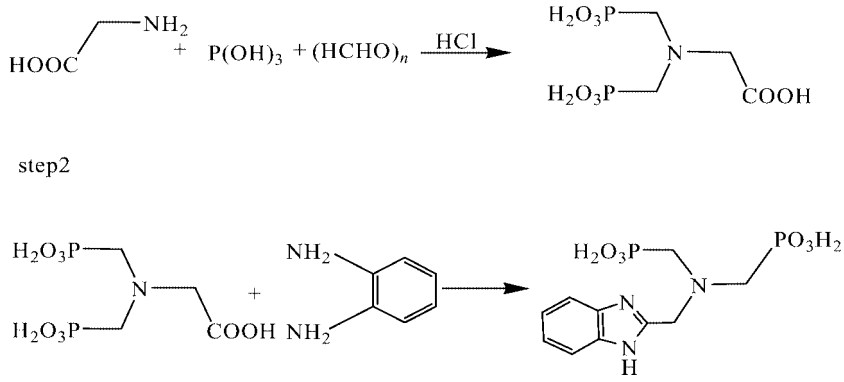

Scheme 1.

pure phases of compounds **1**, **3**, and **5** can be obtained with good yields when the molar ratio of M/ligand and the pH are 1:1 and 2.5–3.5 for **1**, 1:1 and 3.0–4.0 for **3**, and 1:1 and 2.0–4.0 for **5**, respectively. For compounds **2** and **4**, the crystallization of the products is always accompanied by the formation of brown powdery impurities when the molar ratio of M/ligand and the pH are 1:0.75–1 and 2.9–7.0 for **2** and 1:0.75–1 and 3.0–5.9 for **4**, respectively. Crystals with the best quality are formed when the pH is 7.03 for **2** and 4.90 for **4**. In preparing compound **2**, $Me_4NOH$ was used instead of NaOH to adjust the pH of the reaction mixture in order to improve the crystal quality. The same product can also be obtained with NaOH.

The IR spectra of compounds **1**–**5** are almost identical. The broad bands appearing around 3000 $cm^{-1}$ can be assigned to NH and OH stretching vibrations with the presence of extensive hydrogen bonds.[9] The sharp bands at around 1622, 1598, and 1522 $cm^{-1}$ are characteristic of the phenyl ring, and the bands near 1467 and 1455 $cm^{-1}$ are typical for ν(C=N) of the imidazole ring.[10] A series of bands between 1236 and 915 $cm^{-1}$ correspond to the the $CPO_3$ groups.[11]

### Crystal Structures of Compounds 1–5

Compounds **1**–**5** are isostructural and crystallize in the orthorhombic space group *Pbca*. Crystallographic and re-

finement details of **1**–**5** are listed in the Experimental Section, and selected bond lengths and angles are given in Table 1. Figure 1 displays the building unit of **1** with the atomic labeling scheme. The asymmetric unit of compound

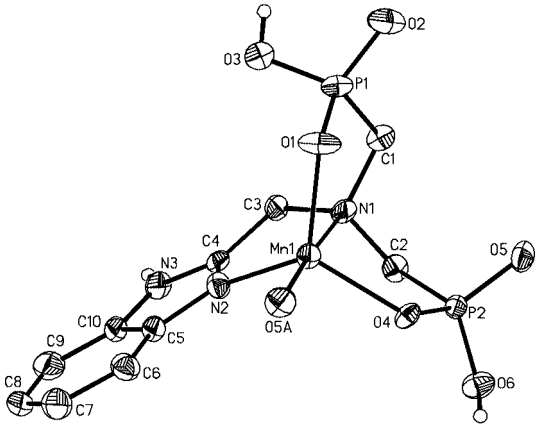

Figure 1. Asymmetric building unit of compound **1** with atomic labeling scheme (50% probability). All H atoms except H3A, H3B and H6A are omitted for clarity.

**1** contains one $Mn^{II}$ ion and one $bibmpH_2^{2-}$ ligand. The Mn1 atom has a distorted trigonal bipyramidal geometry, with the basal plane defined by the atoms O1, O4, and N2 from the same $bibmpH_2^{2-}$ ligand. The Mn1–O1, Mn1–O4, and Mn1–N2 bond lengths are 2.032(3), 2.090(3), and 2.127(4) Å, respectively, while the O1–Mn1–O4, O1–Mn1–N2, and O4–Mn1–N2 bond angles are 116.0(2)°, 114.4(2)°, and 115.7(2)°, respectively. The axial positions are occupied by the atom N1 from the same $bibmpH_2^{2-}$ ligand and O5A from the other equivalent $bibmpH_2^{2-}$ ligand. The N1–Mn1–O5A bond angle is 175.1(1)°, and the Mn1–N1 and Mn1–O5A bond lengths are 2.486(4) and 2.033(3) Å, respectively.

Each $bibmpH_2^{2-}$ behaves as a pentadentate ligand, binding through three phosphonate oxygen atoms (O1, O4, O5), one imino nitrogen atom (N1), and one benzimidazole nitrogen atom (N2). Two phosphonate oxygen atoms (O3, O6), each from a $\{CPO_3\}$ terminus, are protonated [P1–O3 = 1.580(4), P2–O6 = 1.552(3) Å]. The remaining phosphonate oxygen (O2) is pendant [P1–O2 = 1.517(4) Å]. The equivalent Mn atoms are bridged by phosphonate oxygen atoms O4 and O5 to form a zigzag chain along the *b*-axis

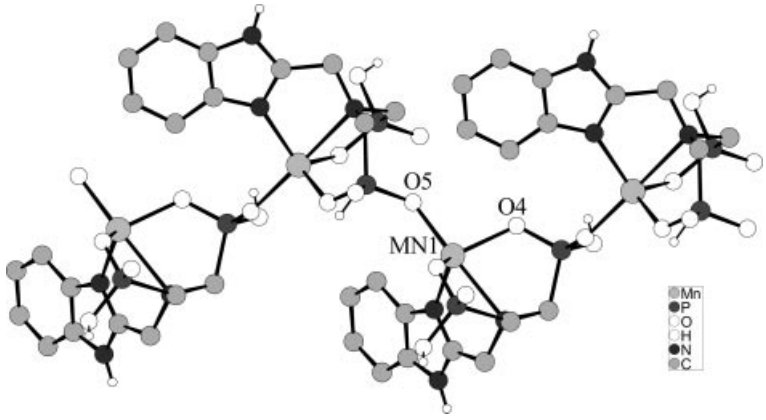

Figure 2. A fragment of chain in structure **1**. All H atoms except H3A, H3B and H6A are omitted for clarity.

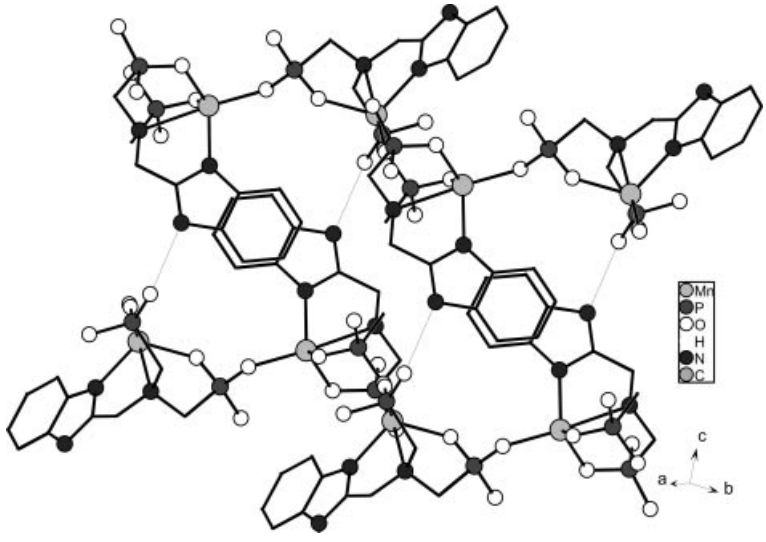

Figure 3. The inter-chain π-π stacking and N···O hydrogen bond interactions in structure **1**. All H atoms are omitted for clarity.

(Figure 2). The Mn1···Mn1A distance over the O4–P2–O5 bridge is 5.849 Å. The benzimidazole rings are arranged tilted on two sides of the chain.

Between the chains, the benzimidazole rings are approximately parallel and are π–π stacked (the average centroid–centroid distance between the two phenyl rings of the benzimidazole groups is 3.547 Å for **1**; Figure 3).[12] Hydrogen-bond interactions are found between the imidazole nitrogen atom (N3) and the phosphonate oxygen atom (O2) approximately along the *c*-axis, and among phosphonate oxygen atoms along the *a*-axis (Figures 3 and 4). The N3···O2$^{i}$, O3···O4$^{ii}$, and O6···O2$^{iii}$ distances are 2.753(6), 2.723(5), and 2.536(5) Å, respectively (symmetry codes: i: $x$, $-y + 3/2$, $z - 1/2$; ii: $x + 1/2$, $y$, $-z + 1/2$; iii: $x - 1/2$, $y$, $-z + 1/2$). Therefore, a three-dimensional network structure is built up. Figure 5 shows the packing diagram of compound **1** viewed down the *b*-axis.

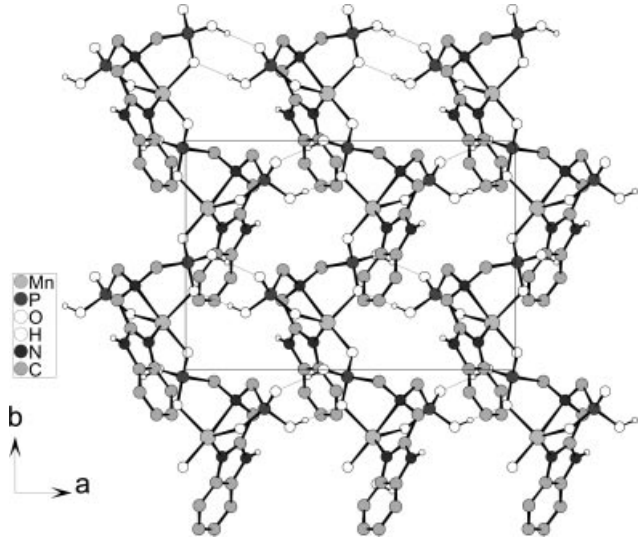

Figure 4. The inter-chain hydrogen bond interactions among the phosphonate oxygen atoms in structure **1**. All H atoms except H3A, H3B and H6A are omitted for clarity.

The structures of compounds **2**–**4** are analogous to **1** except that the $Mn^{II}$ ion in **1** is replaced by $Fe^{II}$ in **2**, $Co^{II}$ in **3**, $Cu^{II}$ in **4**, and $Cd^{II}$ in **5**. The cell volume decreases in the sequence **5** > **1** > **2** > **3** > **4**, in accordance with the decreasing sequence of the ionic radii of the corresponding metal ions.[13] Therefore, the metal atoms in **2**–**5** also have distorted trigonal bipyramidal geometries. The M–N1 distance [2.364(3) Å in **2**, 2.345(4) Å in **3**, 2.137(3) Å in **4**, and 2.551(3) Å in **5**] is significantly longer than the other M–O(N) bond lengths, although the Cu1–N1 bond length in **4** [2.137(3) Å] is much shorter. The metal atoms are bridged by O–P–O units to form infinite chains. The M···M distances across the O–P–O unit within the chain are 5.813 Å for **2**, 5.794 Å for **3**, 5.767 Å for **4**, and 5.941 Å for **5**. These chains are connected by hydrogen-bond interactions as well as π–π stacking interactions. The average centroid–centroid distances between the two phenyl rings of the benzimidazole groups are 3.482 Å for **2**, 3.470 Å for **3**, 3.490 Å for **4**, and 3.620 Å for **5**. The N3···O2$^{i}$, O3···O4$^{ii}$, and O6···O2$^{iii}$ distances are 2.757(4), 2.690(4), and 2.583(4) Å for **2**, 2.739(5), 2.699(4), and 2.570(4) Å for **3**, 2.715(3), 2.632(3), and 2.550(3) Å for **4**, and 2.805(5), 2.702(4), and 2.529(4) Å for **5**, respectively.

It could be of interest to compare the coordination capabilities of the bibmp$^{4-}$ ligand with that of *N*,*N*-bis(phosphonomethyl)aminoacetate (bpmaa$^{5-}$; Scheme 2) as both can offer up to six phosphonate oxygen atoms for coordination with the metal ions. For the bpmaa$^{5-}$ ligand, the carboxylate group has additional two oxygen donors. Thus, several transition metal/bpmada$^{5-}$ compounds have been prepared that show two- and three-dimensional structures.[14] For the bibmp$^{4-}$ ligand, only one nitrogen atom of each benzimidazole group can be used for the coordination when the reaction pH is not high enough. Besides, the benzimidazole group present in this ligand also provides a topologi-

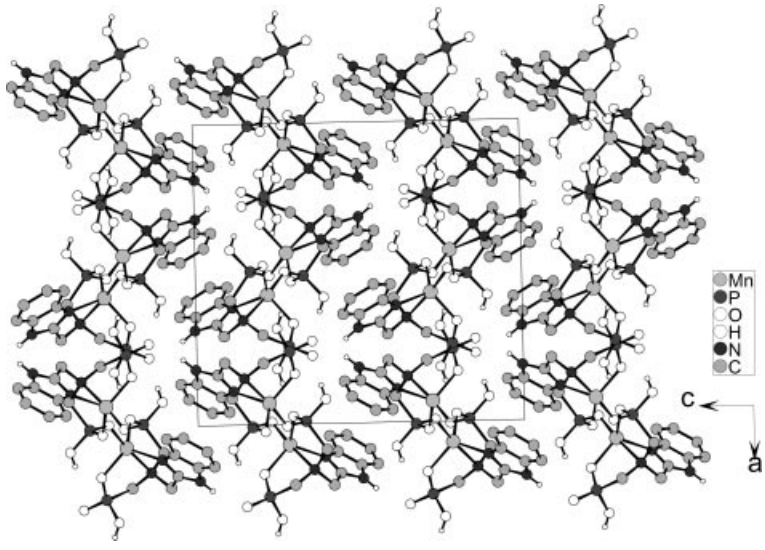

Figure 5. Packing diagram of structure **1** projected along *b*-axis. All H atoms are omitted for clarity.

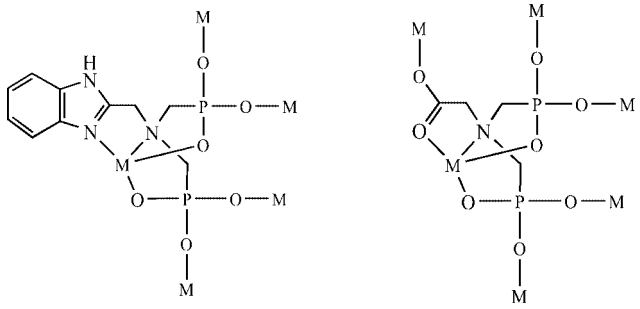
cal hydrophobic environment, possible π–π stacking interactions between the phenyl rings, and steric hindrance as well. Hence, it is not unexpected that different structures will be constructed when metal sources react with $bibmpH_4$ and $bpmaaH_5$ acids. This paper shows that metal/$bibmpH_2^{2-}$ compounds with zigzag chain structures can be obtained through hydrothermal reactions of metal sulfates and the acid $bibmpH_4$.



$bibmp^{4-}$ $bpmaa^{5-}$

Scheme 2.

## Magnetic Properties

The temperature-dependent magnetic behaviors of compounds **1**–**4** were investigated in the temperature range 1.8–300 K. The room-temperature effective magnetic moments are 6.24 $\mu_B$/Mn for **1** (expected 5.92 $\mu_B$ for $S = 5/2$), 5.12 $\mu_B$/Fe for **2** (expected 4.90 $\mu_B$ for $S = 2$), 4.57 $\mu_B$/Co for **3** (expected 3.87 $\mu_B$ for $S = 3/2$), and 1.82 $\mu_B$/Cu for **4** (expected 1.73 $\mu_B$ for $S = 1/2$). Figure 6 shows the $\chi_M$ and $\chi_M T$ vs. $T$ plots for compound **1**. The continuous decrease of $\chi_M T$ upon cooling suggests a dominant antiferromagnetic exchange coupling between the $Mn^{II}$ centers. Since structure **1** is one-dimensional and the $Mn^{II}$ ions are linked purely through O–P–O units, the susceptibility data can be analyzed by Fisher's expression for a uniform chain based on the Heisenberg Hamiltonian $H = -J\sum S_{Ai} \cdot S_{Ai+1}$, with the classical spins scaled to a real quantum spin $S = 5/2$ [Equation (1)],[15]

$$\chi_M = \frac{Ng^2\beta^2 S(S+1)}{3kT}\frac{1+u}{1-u} + N_\alpha$$

$$u = \coth\left[\frac{JS(S+1)}{kT}\right] - \left[\frac{kT}{JS(S+1)}\right] \quad (1)$$

where $J$ is the coupling constant, $N$, $g$, $\beta$ and $k$ have their usual meanings, and $N_\alpha$ accounts for both the diamagnetic and TIP contributions. A good fit, shown as the solid line in Figure 6, gives the parameters $g = 2.09$, $J = -0.075$ cm$^{-1}$, and $N_\alpha = 4.0 \times 10^{-4}$ cm$^3$ mol$^{-1}$. The value of $g$ is higher than that expected for a high-spin $Mn^{II}$ ion ($g = 2$). A higher $g$ value has also been reported for the compounds $[Mn(N_3)_2(bte)]$ [bte = 1,2-bis(1,2,4-triazol-1-ylethane)] ($g = 2.06$),[16] $[\{Mn(oda)(H_2O)\}\cdot H_2O]_n$ [oda = $O(CH_2COO)_2^{2-}$] ($g = 2.07$),[17] and $[Mn(OAc)(terpy)(\mu_{1,5}\text{-dca})]_n$ [dca = $N(CN)_2^-$, OAc = acetate, terpy = 2,2′:6′,2′′-terpyridine] ($g = 2.15$).[18]

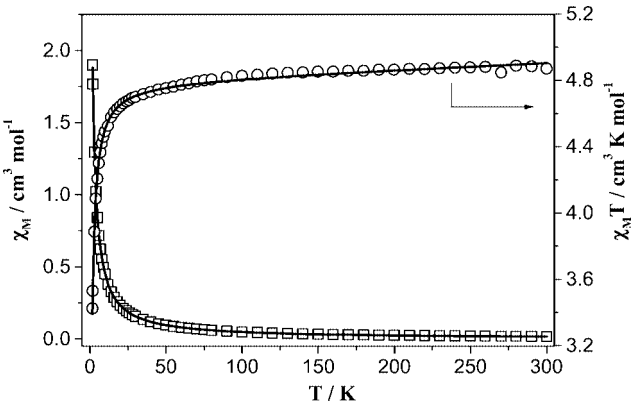


Figure 6. The $\chi_M T$ and $\chi_M$ vs. $T$ plots for **1**.

Dominant antiferromagnetic interactions are also observed in compounds **2** and **3** (Figures 7 and 8, respectively). As is well known, both $Fe^{II}$ and $Co^{II}$ ions in octahedral environments show significant single-ion anisotropies or spin-orbital couplings. When the symmetry of the molecule is lowered, the orbital contribution can be partially removed. In the present case each metal atom has a distorted trigonal-bipyramidal geometry, therefore the orbital contributions of both $Fe^{II}$ and $Co^{II}$ would be reduced. The susceptibility data were initially fitted by the Fisher formula [Equation (1)], with $S = 2$ for **2** and $S = 3/2$ for **3**, which leads to the parameters $g = 2.07$, $J = -0.33$ cm$^{-1}$, and $N_\alpha = 2.0 \times 10^{-4}$ cm$^3$ mol$^{-1}$ for **2** and $g = 2.15$, $J = -0.35$ cm$^{-1}$, and $N_\alpha = 1.7 \times 10^{-3}$ cm$^3$ mol$^{-1}$ for **3**. The $J$ value of compound **2** is comparable to that for $[NH_3(CH_2)_2NH_3][Fe\{HO_3PC(CH_3)(OH)(PO_3H)\}_2]\cdot 2H_2O$, in which the $Fe^{II}$ ions are doubly bridged by O–P–O units ($J = -0.46$ cm$^{-1}$) and the same equation was employed for the data fitting.[19] The Fisher formula, however, is a simplified model that assumes Heisenberg exchange couplings between all spins and does not take into account the single-ion anisotropy or spin-orbit coupling of either $Fe^{II}$ or $Co^{II}$ ions. A theoretical analysis considering both zero-field splitting (ZFS) and a small antiferromagnetic interaction would be a more logical approach. In order to fit the $\chi_M T$ vs. $T$ plots of compounds **2** and **3**, we calculated the magnetic susceptibility of six-membered closed rings. Due to the high-spin value we can suppose that the magnetic behavior of these closed rings is very similar to that of an infinite chain.[20] The Hamiltonian can therefore be used in its simplified axial form with an axial ZFS parameter ($D$), the antiferromagnetic exchange interaction ($J$), an axial $g$ vector, and a temperature-independent paramagnetism (TIP). The analysis of the data was performed with the full-matrix diagonalization program MAGPACK.[21] After a least-squares fitting the following parameters were found: $J = -0.1$ cm$^{-1}$, $D = 0.51$ cm$^{-1}$, $g = 2.09$, and TIP $= 3.3 \times 10^{-4}$ for the $Fe^{II}$ complex **2** and $J = -0.15$ cm$^{-1}$, $D = 7.6$ cm$^{-1}$, $g_z = 2.33$, $g_{xy} = 2.08$, and TIP $= 1.1 \times 10^{-3}$ for the $Co^{II}$ complex **3**, shown as solid lines in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figures 7 and 8, respectively. The $J$ values obtained for compounds **2** and **3** are comparable to that of compound **1**.

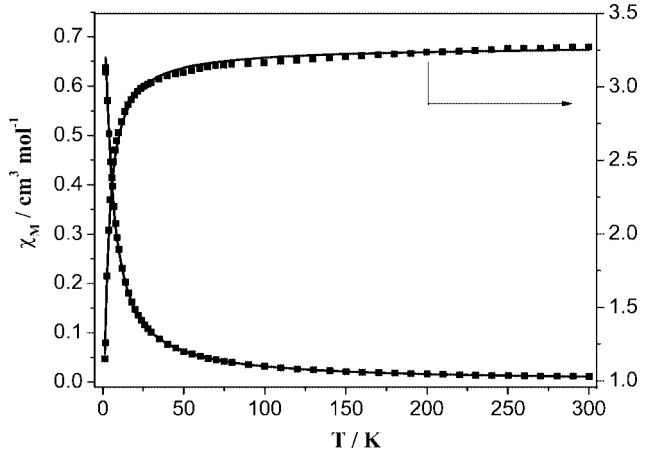

Figure 7. The $\chi_M T$ and $\chi_M$ vs. $T$ plots for **2**.

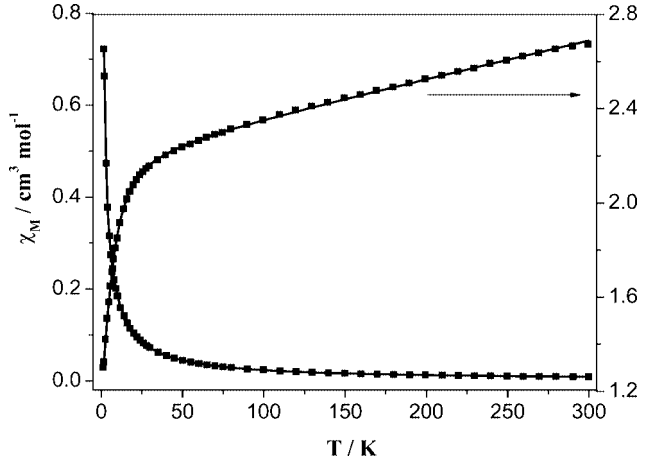

Figure 8. The $\chi_M T$ and $\chi_M$ vs. $T$ plots for **3**.

For compound **4** there is a maximum at around 3 K in the $\chi_M$ vs. $T$ plot (Figure 7), which is consistent with the antiferromagnetic nature of the magnetic interactions. Considering that compound **4** also has a chain structure with equally spaced $Cu^{II}$ ions ($S$ = 1/2), the susceptibility data can be fitted by the following equation based on the Heisenberg Hamiltonian $H = -J\sum S_{Ai} \cdot S_{Ai+1}$ [Equation (2)],[15]

$$\chi_M = \frac{Ng^2\beta^2}{kT}\frac{0.25 + 0.074975x + 0.075235x^2}{1 + 0.9931x + 0.172135x^2 + 0.757825x^3} + N_\alpha \quad (2)$$

where $x = |J|/kT$. A good fit, shown as the solid line in Figure 9, results in the parameters $g$ = 2.18, $J$ = –2.96 $cm^{-1}$, and $N_\alpha = -2.9 \times 10^{-5}$ $cm^3 mol^{-1}$. The $J$ value is smaller than those found for compounds $[\{Cu_3(di\text{-}2\text{-}pyridylamine)_3(\mu\text{-}HPO_4)(\mu\text{-}PO_4)(H_2O)\}(PF_6)(H_2O)_3]_n$ (–4.98 $cm^{-1}$)[22] and $[\{(bipy)Cu(H_2O)\}_2(\mu\text{-}P_2O_7)\cdot 7H_2O]$ ($J$ = –20 $cm^{-1}$),[23] where the $Cu^{II}$ ions are also linked by O–P–O units.

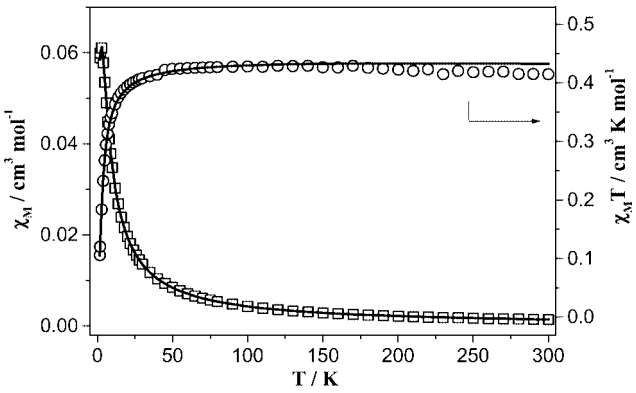

Figure 9. The $\chi_M T$ and $\chi_M$ vs. $T$ plots for **4**.

## Conclusion

Hydrothermal reactions of metal sulfates and (benzimidazol-2-ylmethyl)imino bis(methylenephosphonic acid) have resulted in five isostructural compounds with the formula $[M\{(C_7H_5N_2)CH_2N(CH_2PO_3H)_2\}]$ [M = Mn (**1**), Fe (**2**), Co (**3**), Cu (**4**), and Cd (**5**)]. Each compound shows a one-dimensional chain structure where $\{MO_3N_2\}$ trigonal bipyramids are connected by $\{CPO_3\}$ tetrahedra through corner-sharing. The benzimidazole rings are involved in both aromatic stacking and hydrogen bonds. Further work is in progress to explore new materials with other topologies based on the same phosphonate ligand.

## Experimental Section

**Materials and Methods:** *N*,*N*-Bis(phosphonomethyl)aminoacetic acid was synthesized according to the literature procedure.[14a] All other reagents were purchased as reagent-grade chemicals and used without further purification. Elemental analyses were performed with a Perkin–Elmer 240C elemental analyzer. The IR spectra were obtained as KBr disks on a VECTOR 22 spectrometer. Variable-temperature magnetic susceptibility data were obtained for microcrystalline samples using a Quantum Design MPMS-XL7 SQUID magnetometer.

**Synthesis of {[(Benzimidazol-2-ylmethyl)imino]bis(methylene)}bis(phosphonic Acid) $[(C_7H_5N_2)CH_2N(CH_2PO_3H)_2$, bibmpH$_4$]:** Bis(phosphonomethyl)imino acetic acid (5.26 g, 20 mmol) and 1,2-diaminobenzene (2.06 g, 20 mmol) were fully mixed by grinding. The mixture was transferred to an open, single-necked flask and then heated at 190 °C until no steam was produced. After cooling, 6 M hydrochloric acid (8 mL) was added to the flask. The resulting solution was refluxed at 120 °C for 2 h, and then concentrated to dryness. The blue solid was taken up in water (20 mL) and KOH was added until the solid had dissolved (pH about 5–6). After refluxing with decoloring charcoal for 30 min, the solution was filtered off. The filtrate was acidified with 6 M HCl until pH ≤ 1.0.The white precipitate was collected, washed with methanol, and dried in vacuo. Yield: 5.5 g (82%). IR (KBr): $\tilde{\nu}$ = 3153–2346 (br) $cm^{-1}$, 1625 (m), 1573 (w), 1524 (w), 1491 (w), 1460 (m), 1438 (w), 1418 (w), 1400 (m), 1383 (w), 1367 (w), 1344 (m), 1308 (m), 1285 (m), 1252 (s), 1219 (s), 1159 (s), 1134 (s), 1059 (s), 1019 (s), 992 (s), 958 (s), 926 (s), 899 (m), 887 (m), 851 (m), 828 (m), 752 (s), 727 (w), 620 (w), 572 (w), 544 (w), 496 (s), 468 (m), 456 (m), 434 (w),

411 (w). $C_{10}H_{15}N_3O_6P_2$: calcd. C 35.85, H 4.51, N 12.54; found C 35.72, H 4.82, N 12.55.

**Synthesis of [Mn{(C$_7$H$_5$N$_2$)CH$_2$N(CH$_2$PO$_3$H)$_2$}] (1):** A mixture of bibmpH$_4$ (0.15 mmol, 0.0495 g) and $MnSO_4 \cdot H_2O$ (0.15 mmol, 0.0253 g) in 8 mL of $H_2O$, adjusted to pH 2.5–3.5 with 1 M NaOH, was kept in a Teflon-lined autoclave at 140 °C for 24 h. After slow cooling to room temperature, gray-blue, block-shaped crystals were obtained as a monophasic material (according to the powder X-ray diffraction pattern). Yield: 23 mg (40%). $C_{10}H_{13}MnN_3O_6P_2$: calcd. C 30.92, H 3.35, N 10.82; found C 30.93, H 3.21, N 10.80. IR (KBr): $\tilde{\nu}$ = 3104 (m, br) cm$^{-1}$, 2939 (w), 2874 (w), 1622 (w), 1598 (w), 1522 (w), 1467 (m), 1455 (m), 1432 (m), 1387 (w), 1377 (w), 1343 (w), 1324 (w), 1309 (w), 1282 (w), 1266 (w), 1236 (m), 1181 (s), 1133 (s), 1100 (m), 1073 (s), 1035 (m), 958 (w), 941 (w), 915 (s), 852 (w), 832 (w), 754 (m), 686 (w), 651 (w), 576 (s), 505 (w), 499 (w), 472 (w), 448 (w), 408 (w).

**Synthesis of [Fe{(C$_7$H$_5$N$_2$)CH$_2$N(CH$_2$PO$_3$H)$_2$}] (2):** A mixture of bibmpH$_4$ (0.10 mmol, 0.0330 g) and $FeSO_4 \cdot 7H_2O$ (0.20 mmol, 0.0556 g) in 8 mL of $H_2O$, adjusted to pH 7.03 by adding 0.2 mmol of $Me_4NOH$, was kept in a Teflon-lined autoclave at 140 °C for 24 h. After slow cooling to room temperature, gray-green, block-shaped crystals were obtained together with a brown powder. The crystals were selected manually and were used for single-crystal structural determination and physical measurements. Yield: 16 mg (41% based on bibmpH$_4$). $C_{10}H_{13}FeN_3O_6P_2$: calcd. C 30.85, H 3.34, N 10.80; found C 30.35, H 3.56, N 10.46. IR (KBr): $\tilde{\nu}$ = 3104–2886 (m, br) cm$^{-1}$, 1623 (w), 1598 (w), 1524 (w), 1467 (m), 1456 (m), 1434 (m), 1420 (m), 1387 (w), 1377 (w), 1342 (m), 1323 (w), 1309 (w), 1281 (w), 1264 (w), 1236 (m), 1185 (s), 1140 (s), 1091 (m), 1065 (s), 1036 (s), 1021 (s), 981 (m), 968 (m), 955 (m), 941 (m), 918 (s), 898 (m), 833 (m), 778 (m), 756 (m), 704 (w), 653 (w), 577 (s), 560 (m), 509 (w), 496 (w), 470 (w), 447 (w), 420 (w).

**Synthesis of [Co{(C$_7$H$_5$N$_2$)CH$_2$N(CH$_2$PO$_3$H)$_2$}] (3):** A mixture of bibmpH$_4$ (0.15 mmol, 0.0495 g) and $CoSO_4 \cdot 7H_2O$ (0.15 mmol, 0.0422 g) in 8 mL of $H_2O$, adjusted to pH 3.0–4.0 with 1 M NaOH, was kept in a Teflon-lined autoclave at 140 °C for 24 h. After slow cooling to room temperature, magenta, block-shaped crystals were obtained as a monophasic material (according to the powder X-ray diffraction pattern). Yield: 46 mg (78%). Anal. found (calcd.) for $C_{10}H_{13}N_3O_6P_2Co$: calcd. C 30.60, H 3.32, N 10.71; found C 30.66, H 3.30, N 10.53. IR (KBr): $\tilde{\nu}$ = 3100–2887 (m, br) cm$^{-1}$, 1625 (w), 1598 (w), 1529 (w), 1469 (m), 1457 (m), 1433 (m), 1420 (w), 1388 (w), 1342 (w), 1323 (w), 1311 (w), 1282 (w), 1184 (s), 1132 (s), 1093 (m), 1067 (s), 1040 (m), 1021 (w), 982 (w), 969 (w), 918 (s), 834 (w), 781 (w), 756 (m), 714 (w), 653 (w), 578 (s), 513 (w), 499 (w), 472 (w), 448 (w), 423 (w), 408 (w).

**Synthesis of [Cu{(C$_7$H$_5$N$_2$)CH$_2$N(CH$_2$PO$_3$H)$_2$}] (4):** A mixture of bibmpH$_4$ (0.10 mmol, 0.0330 g) and $CuSO_4$ (0.13 mmol, 0.0208 g) in 8 mL of $H_2O$, adjusted to pH 4.90 with 1 M NaOH, was kept in a Teflon-lined autoclave at 140 °C for 24 h. After slow cooling to room temperature, green, block-shaped crystals were obtained together with a brown powder. The crystals were selected manually and were used for single-crystal structural determination and physical measurements. Yield: 22 mg (55% based on bibmpH$_4$). $C_{10}H_{13}CuN_3O_6P_2$: calcd. C 30.25, H 3.28, N 10.59; found C 30.34, H 3.43, N 10.62. IR (KBr): $\tilde{\nu}$ = 3121–2900 (m, br) cm$^{-1}$, 1622 (w), 1597 (w), 1529 (w), 1494 (w), 1473 (m), 1456 (m), 1434 (m), 1419 (m), 1378 (w), 1341 (w), 1320 (w), 1281 (w), 1256 (m), 1238 (s), 1193 (s), 1128 (s), 1095 (m), 1059 (m), 1035 (m), 988 (w), 961 (w), 944 (w), 918 (s), 834 (w), 784 (w), 767 (m), 757 (m), 721 (w), 653 (w), 584 (s), 560 (m), 512 (w), 499 (w), 474 (w), 447 (w), 414 (w).

**Synthesis of [Cd{(C$_7$H$_5$N$_2$)CH$_2$N(CH$_2$PO$_3$H)$_2$}] (5):** A mixture of bibmpH$_4$ (0.15 mmol, 0.0495 g) and $CdSO_4 \cdot 2.7H_2O$ (0.15 mmol, 0.0380 g) in 8 mL of $H_2O$, adjusted to pH 3.0–4.0 with 1 M NaOH, was kept in a Teflon-lined autoclave at 140 °C for 24 h. After slow cooling to room temperature, gray-blue block-shaped crystals were obtained as a monophasic material (according to the powder X-ray diffraction pattern). Yield: 37 mg (55%). Anal. found (calcd.) for $C_{10}H_{13}CdN_3O_6P_2$: calcd. C 26.93, H 2.92, N 9.43; found C 26.82, H 2.85, N 9.28. IR (KBr): $\tilde{\nu}$ = 3102 (m) cm$^{-1}$, 2939 (w), 2868 (w), 1619 (w), 1598 (w), 1521 (w), 1490 (w), 1469 (m), 1456 (m), 1432 (m), 1386 (w), 1377 (w), 1344 (w), 1325 (w), 1311 (w), 1286 (w), 1266 (w), 1238 (m), 1206 (m), 1176 (s), 1129 (s), 1097 (m), 1072 (s), 1038 (m), 979 (w), 967 (w), 955 (w), 942 (w), 913 (s), 853 (w), 830 (w), 765 (w), 754 (m), 684 (w), 649 (w), 576 (s), 502 (w), 487 (w), 460 (w), 442 (w), 410 (w).

**X-ray Crystallographic Studies:** Single crystals of dimensions $0.1 \times 0.04 \times 0.04$ mm$^3$ for **1**, $0.1 \times 0.05 \times 0.05$ mm$^3$ for **2**, $0.15 \times 0.15 \times 0.15$ mm$^3$ for **3**, $0.04 \times 0.02 \times 0.02$ mm$^3$ for **4**, and $0.1 \times 0.05 \times 0.05$ mm$^3$ for **5** were used for structural determinations on a Bruker SMART APEX CCD diffractometer using graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature. Further details can be found in Table 2. A hemisphere of

data were collected in the $\theta$ range 2.62–26.00° for **1**, 2.43–26.00° for **2**, 2.43–25.99° for **3**, 2.40–25.99° for **4**, and 2.45–26.00° for **5** using a narrow-frame method with scan widths of 0.30° in $\omega$ and an exposure time of 5 s per frame. Numbers of observed and unique [$I > 2\sigma(I)$] reflections are 13496 and 2700 ($R_{int}$ = 0.0835) for **1**, 13174 and 2634 ($R_{int}$ = 0.0585) for **2**, 13176 and 2618 ($R_{int}$ = 0.073) for **3**, 12675 and 2605 ($R_{int}$ = 0.0517) for **4**, and 14077 and 2754 ($R_{int}$ = 0.056) for **5**, respectively. The data were integrated using the Siemens SAINT program,[24] with the intensities corrected for Lorentz factors, polarization, air absorption, and absorption due to variation in the path length through the detector faceplate. Multi-scan absorption corrections were applied. The structures were solved by direct methods and refined on $F^2$ by full-matrix least-squares using SHELXTL.[25] All the non-hydrogen atoms were located from the Fourier maps, and were refined anisotropically. All H atoms were refined isotropically, with the isotropic vibration parameters related to the non-H atom to which they are bonded.

CCDC-283019 to -283023 (for **1**–**5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We thank the NNSF of China (No. 20325103), the Ministry of Education of China and the NSF of Jiangsu province (No. BK2002078) for financial supports, Mr. Yong-Jiang Liu for crystal data collections, Dr. You Song and Mr. Tian-Wei Wang for magnetic measurements.

# Binding of an Oxo-Bridged Dinuclear Iron(III) Complex $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$ to DNA and Its Recognition of Single- and Double-Stranded DNA As Determined by Electrochemical Studies

**Qing Xiang Wang,[a] Kui Jiao,*[a] Wei Sun,[a] Fang Fang Jian,[b] and Xuan Hu[a]**

**Keywords:** Oxo-bridged diiron(III) complex / Crystallography / DNA recognition / Voltammetry

An oxo-bridged dinuclear iron(III) complex, $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$, was synthesized and the molecular structure was determined by X-ray crystallography. Cyclic voltammetry shows that the complex has a cathodic peak at +0.325 V and a pair of redox peaks at +1.011 V and +0.811 V, respectively, which can be explained by an EC–C–EC mechanism. The binding property of the complex to fish-sperm DNA was investigated by electronic absorption spectrophotometry and electrochemical methods. The change in the electrochemical behavior of the complex after treatment with DNA shows that the oxo-bridged diiron(III) complex interacts with DNA mainly through electrostatic binding, while the electrochemical and chemical (EC–C) process product interacts mainly by intercalation. This result is further supported by experiments examining the influence of ionic strength. The difference in the binding modes of $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$ and its EC–C product, namely a mononuclear phen-ligated ferrous complex, to DNA implies that this strategy can be used to distinguish single-stranded (ss-) and double-stranded (ds-) DNA.

## Introduction

Studies on the interaction between DNA and small molecules are central to probing the accurate local structures of DNA,[1–5] and to understanding the natural DNA-mediated biological mechanisms.[6] The fields of applied pharmacology, novel drug design[7–8] and chemotherapy[9] also emphasize the interactions of small molecules with DNA. Among DNA-binding molecules, iron complexes with the ligands 1,10-phenanthroline (phen) or modified phen are particularly attractive because these metal complexes can effectively bind to DNA through different modes[10–13] and the iron ions and the ligands of these complexes can easily be controlled to facilitate the clear study of the DNA-binding mechanism.[14–15]

A number of studies have addressed the synthesis of a series of mononuclear iron-phen complexes and their interaction with DNA.[16–20] However, compared with the mononuclear iron complexes, the synthesis and interaction with DNA of dinuclear iron complexes have received much less attention.[21–24] Que Jr. et al.[22] have reported a dinuclear ferric complex, $Fe_2(HPTB)(OH)(NO_3)_4$ [HPTB = *N*,*N*,*N*′,*N*′′-tetrakis(2-benzimidazolylmethyl)-2-hydroxy-1,3-diaminopropane], and found that, in the presence of hydrogen peroxide or $O_2$ and a reductant, this diiron complex can promote the cleavage of plasmid DNA in a "hydrolytic fashion". This is similar to the DNA cleavage mediated by the Fe–bleomycin complex and its mimetic compounds.[23] Additionally, Xu et al.[24] have investigated the interaction of DNA with a diiron complex $Fe_2(DTPB)(\mu\text{-}O)(\mu\text{-}Ac)Cl(BF_4)_2$ [DTPB = 1,1,4,7,7-penta(2′-benzimidazol-2-ylmethyl)triazaheptane, Ac = acetate] by spectroscopic methods. In addition, the hydrolytic cleavage of the supercoiled and linear DNA by the diiron complex was supported by evidence from anaerobic reactions, free-radical quenching, high-performance liquid chromatography experiments, enzymatic manipulation, footprinting analysis, and so forth.

On the other hand, nonheme oxo-bridged dinuclear iron(III) complexes have been extensively studied because of their distinctive magnetic and spectroscopic properties.[25–26] Furthermore, the significant biological activity of these kinds of dinuclear complexes has also attracted considerable attention from researchers, as they can provide structural models for diiron sites in nonheme proteins, such as ribonucleotide reductase, which converts ribonucleotides into deoxyribonucleotides in the first step in the biosynthesis of DNA.[27–29] However, only a few crystal structures of dinuclear iron(III) complexes with phenanthroline as a terminal ligand have been reported to date.[30] Knowledge of the exact molecular structure, and electrochemical and DNA-binding properties of nonheme oxo-bridged dinuclear

iron(III) complexes will be helpful for us to understand the reaction mechanisms of these active models in cells and the body.

Herein we report the synthesis, crystal structure, and electrochemical property of a new oxo-bridged dinuclear iron(III) complex with the ligand phen, $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$. Additionally, we paid particular attention to the binding properties of this dinuclear iron(III) complex to DNA by using absorption spectroscopic and voltammetric methods. The notable phenomenon is that the dinuclear iron complex, and its EC–C mononuclear product (EC and C mean electrochemical process and chemical dissociation process, respectively), bind to DNA through different modes under the same conditions. This suggests that, on the basis of its electrochemical behavior, the complex could be an effective recognition probe for dsDNA and ssDNA. We also hope that this investigation is of value for the understanding of the biological mechanism in nonheme protein–DNA interactions and of the structure–activity relationship of nonheme oxo-bridged dinuclear iron(III) complexes in biological processes.

## Results and Discussion

### Crystal Structure of the Title Oxo-Bridged Diiron(III) Compound

The crystal structure of the title compound consists of discrete molecules in which all the atoms lie on general positions. The molecular structure of the complex is illustrated in Figure 1. The cationic complex of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ has a $C_2$ symmetry axis through the bridging O(6) atom. The two sulfate anions are present in the lattice to balance the charge. The iron atoms are surrounded by two nitrogen and four oxygen atoms to form a distorted octahedral geometry. The two parts of the dinuclear iron(III) cation complex are bridged by the O(6) atom. Three water molecues coordinate to the $Fe^{III}$ ion, with Fe–O distances of 2.004(4) Å, 2.019(4) Å, and 2.153(4) Å for Fe(1)–O(5), Fe(1)–O(7), and Fe(1)–O(8), respectively. The Fe–O–Fe linkage is nonlinear, exhibiting an angle of 163.9(4)° for Fe(1)–O(6)–Fe(1A). The Fe–μ-O(6) distance [1.7877(12) Å] is in accordance with those previously reported for $(FeL)_2O$ (1.76–1.82 Å).[31] The combination of the nonlinear bridge and the strong Fe–μ-O bonding produces an intermetallic spacing of 3.5417 Å. The bond lengths of C–N and C–C in the phenanthroline all fall within the range of the literature values,[32] and the two aromatic ring systems in each phen are coplanar within the experimental error.

### Studies on the Electrochemical Behavior of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$

The cyclic voltammetry (CV) of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ in a 0.01 M NaOAc/HOAc solution at a gold electrode was investigated, and the results are shown in Figure 2. It is found that the complex has a cathodic peak ($p_1$) at +0.325 V and a pair of redox peaks ($p_2$ and $p_2'$) at +1.011 V and +0.811 V, respectively. From Figure 2b, the formal potential ($E^{0\prime}$) of the redox peaks ($p_2$ and $p_2'$) was calculated to be +0.911 V, with the formula $E^{0\prime} = (E_{p_2}+E_{p_2'})/2$. This potential is consistent with that reported for the conversion of ferrous complexes to ferric complexes,[33] and suggests that this pair of redox peaks may be attributed to the electro-oxidation and electro-reduction of the mononuclear iron complex. The ratio of the peak height of $p_2'$ to that of $p_2$ is much smaller than that for the complex $Fe^{III/II}$-(*tris*-phen); this may result from the lack of phen coordinating to the iron atom.[34] The electron transfer number ($n$) of the irreversible reduction peak $p_1$ was calculated to be 2 according to the formula $|E_p–E_{p/2}| = 47.7/n\alpha$ (mV, 25 °C) when $\alpha$ is assumed to be 0.5,[35] ($E_p$ and $E_{p/2}$ are the peak potential and the half-peak potential, respectively, $\alpha$ the electron transfer coefficient). This indicates that the two trivalent iron atoms in the title complex have been reduced to a diferrous analog. The peak potential of $p_1$ (+0.325 V) is almost the same as the reduction potential reported for similar diiron(III) complexes.[36] According to these results, we speculate that the electrode reaction of the title diiron(III) complex may involve an EC–C–EC process, which is described in Scheme 1.

There are similar mechanisms in the literature. Walczak et al. have studied the electrochemical behavior of the oxo-bridged diiron-phen complex $[Fe_2^{III,III}O(phen)_4(H_2O)]^{4+}$ and reached the conclusion that the complex undergoes a 2e reduction to an oxo-bridged diferrous-phen complex $[Fe_2^{II,II}O(phen)_4(H_2O)_2]^{2+}$, which is unstable and quickly decomposes by a fast chemical reaction to form its mononuclear ferrous complex.[36] The electro-redox processes of the $Fe^{II/III}$ complex result in a pair of redox peaks. Chen[37] and other authors[38–39] have also studied the electrochemical behavior of oxo-bridged diiron complexes under different conditions and have obtained similar results. Namely, the electrochemical processes of these species appear as an irreversible reduction peak, corresponding to the re-

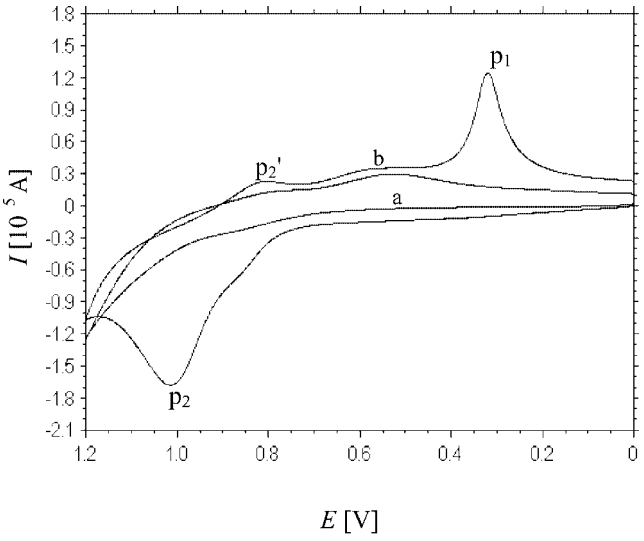

Figure 2. Cyclic voltammograms of 0.01 M NaOAc/HOAc solution, pH 6.8, without (a) and with $4.00\times10^{-4}$ M $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ (b). Rest time: 2 s. Scan rate: 100 mV/s.

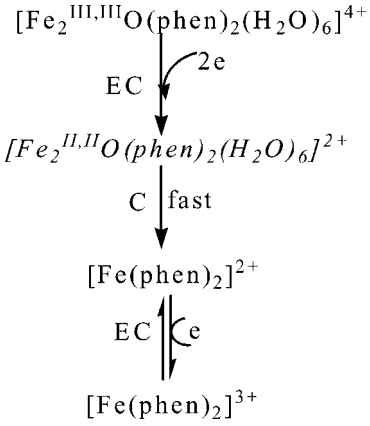

Scheme 1. Electrochemical mechanism of the complex $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$. The italic font of $[Fe_2^{II,II}O(phen)_2(H_2O)_6]^{2+}$ implies that this intermediate product is unstable.

duction of diiron(III) complex, and a pair of redox peaks with the formal potential ($E^{0\prime}$) at approximately +0.911 V, which is ascribed to the redox of the mononuclear iron(II)/(III) complex. Thus, the electrochemical behavior of the title complex reported here is very similar to those described in the conclusions in the literature.

The influence of the initial potential ($E_i$) on the cyclic voltammetric behavior of the title complex was studied to further prove the above theory involving the EC–C–EC mechanism of the diiron(III) complex. The results are shown in Figure 3. When the cyclic voltammogram was recorded in the potential range 0.400–1.200 V with an $E_i$ of 0.400 V, there were no longer any electro-redox peaks (Figure 3a), suggesting that no mononuclear iron complex was present in the solution. If $E_i$ was set to +1.000 V, and the potential was scanned in the negative direction towards 0 V and then back to +1.200 V, the reduction peak ($p_2'$) for the mononuclear ferric complex still does not appear; while at +0.325 V, there is an obvious reduction peak ($p_1$) that corresponds to the reduction of the title diiron(III) complex. There is a well-defined oxidation peak corresponding to the oxidation of the mononuclear divalent iron complex to the trivalent form (Figure 3b). If $E_i$ was set to 0 V, which is more negative than the reduction potential of the title complex, and the cyclic voltammogram ranging from 0 V to +1.200 V was recorded, all the peaks appear (Figure 3c). This experiment demonstrates that the prerequisite for the formation of the mononuclear ferrous complex is the electro-reduction of the title oxo-bridged diiron(III) complex, which is consistent with the proposed EC–C–EC mechanism.

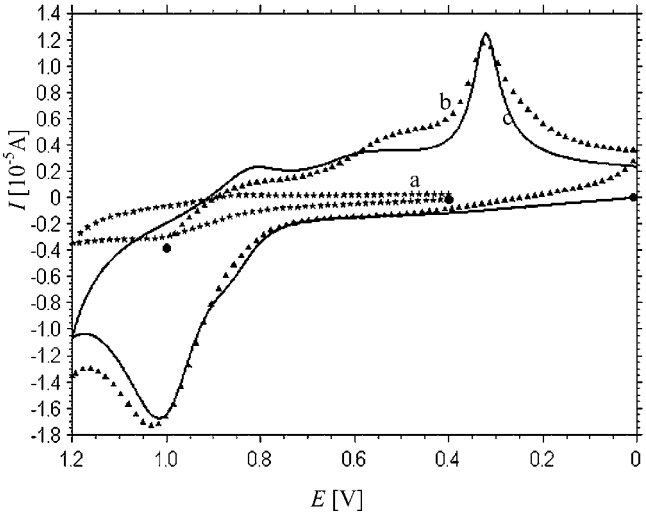

Figure 3. Dependence of the cyclic voltammograms of $4.00\times10^{-4}$ M $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ in 0.01 MNaOAc/HOAc solution (pH 6.8) on the initial scan potential ($E_i$, represented by ●). (a) $E_i$ = 0.400 V, a cyclic scan in the potential range from 0.400 to 1.200 V; (b) $E_i$ = 1.000 V, the scan from 1.000 to 0 V, followed by a positive scan from 0 to +1.200 V; (c) $E_i$ = 0 V, the scan from 0 to +1.200 V, and then scanned reversibly to 0 V. Scan rate: 100 mV/s.

In the following electrochemical studies, only the cathodic peak $p_1$ and the anodic peak $p_2$ are considered, as they represent the different species involved in the electrochemical processes and are more sensitive than the cathodic peak $p_2'$.

## Studies on the Interaction of the Iron-Phen Complex with DNA

### *UVIVis Spectroscopy*

As shown in Figure 4a, the complex has a broad absorption band and a sharp peak in the spectral region 200–320 nm, and a weak absorption band in the range 380–520 nm, which is magnified in the inset of Figure 4. From comparison with the spectral data from the paper by Que Jr. et al.[40] and with those from previously studied oxo-diiron(III) complexes,[41] it is known that the lower energy band is assigned to a phenolate-to-$Fe^{III}$ charge-transfer transition, and the higher energy band has been attributed to both phenolate- and oxo-to-$Fe^{III}$ charge-transfer transitions. While, the 300–400 nm region is featureless in Figure 4, the broad and weak absorption peak around 500 nm

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

is probably related to a small amount of phen-ligated ferrous complex, as the dinuclear unit is somewhat oxidative under the present conditions. After the addition of dsDNA to the diiron(III) complex solution, it is clearly observed that the absorption peaks in the 200–300 nm region undergo a significant decrease in molecular absorption (the hypochromism effect) and no detectable shift in wavelength (Figure 4b–c).

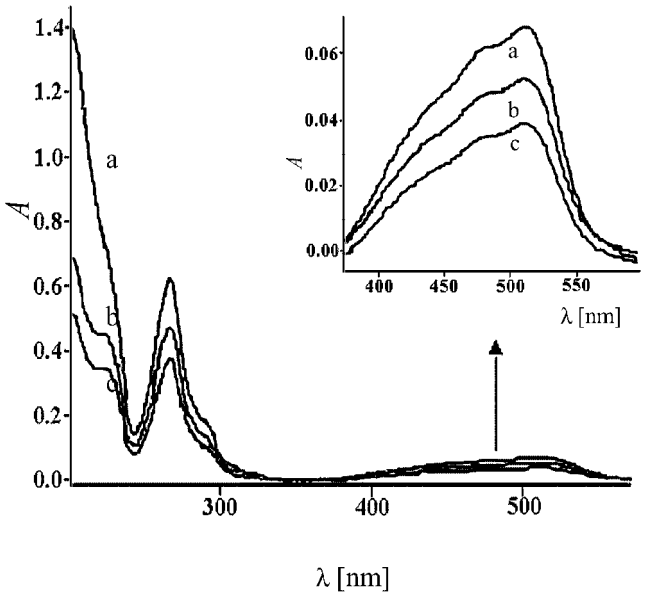

Figure 4. UV/Vis spectra of $4.00\times10^{-4}$ M $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ in the absence (a) and the presence of $3.69\times10^{-6}$ M (b) and $7.37\times10^{-6}$ M (c) DNA.

Similarly, the broad absorption band around 500 nm, ascribed to the charge transfer transition of the ferrous complex, decreases gradually and is accompanied by a weak red shift (≈2 nm) from 507.7 nm to 509.6 nm, as shown in the inset in Figure 4. In the case of 1,10-phenanthroline metal complexes, some authors have pointed out that these species interact with dsDNA mainly by the outside-binding mode,[42] while other authors suggest that the binding mode is through intercalation, which involves a stacking interaction of the aromatic chromophores with the base-pairs of the dsDNA duplex.[43] In this paper, according to the rule that when small molecules interact with dsDNA differences in binding mode are reflected by spectral changes,[44] we can speculate that the original diiron(III) complex interacts with dsDNA mainly through external electrostatic binding, while a small amount of the ferrous complex probably binds through intercalation. This rationale is plausible because the size of the ferrous complex is much smaller than that of the diiron(III) complex. This difference in binding mode will be tested by the following electrochemical experiments.

### *Electrochemical Recognition of dsDNA and ssDNA*

Figure 5 shows the cyclic voltammetric behavior of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ after reacting with dsDNA and ssDNA. From Figure 5b, it is observed that the currents of both $p_1$ and $p_2$ decrease significantly in the presence of dsDNA, which proves that both the original oxo-bridged diiron complex and its EC–C product can interact with dsDNA. Nonetheless, it is interesting that the potentials of $p_1$ and $p_2$ shift in different directions after reacting with dsDNA. Bard et al. have pointed out that the shift direction of the electrochemical potential of a small molecule, after reacting with DNA, is related to its binding mode with DNA. A positive shift of the peak potential indicates an intercalative interaction between the small molecule and DNA, and a negative shift is characteristic of an electrostatic interaction.[45] Therefore, according to this rule, we can conclude that $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ may interact with dsDNA through an electrostatic interaction, while its EC–C product interacts by intercalation. It is noticeable that when varying the pH values of the NaOAc/HOAc solution, the current difference of $p_2$ ($\Delta I_{p_2}$) and $p_1$ ($\Delta I_{p_1}$) reach maximum values at pH 6.8 and pH 5.5, respectively, after reacting with dsDNA (data not shown). Since pH 6.8 is closer to natural biological conditions, and hence can avoid the denaturing of dsDNA, which occurs at high or low acidity, a NaOAc/HOAc solution at pH 6.8 was chosen as the supporting electrolyte.

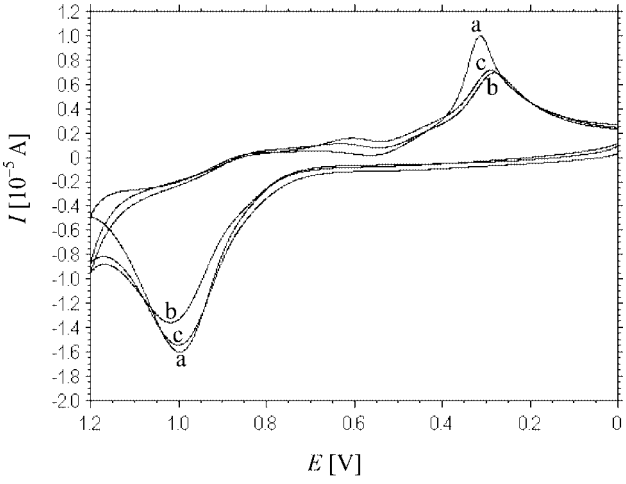

Figure 5. Cyclic voltammograms of $2.00\times10^{-4}$ M $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ in 0.01 M NaOAc/HOAc solution at pH 6.8 (a), and after the addition of $2.68\times10^{-7}$ M dsDNA (b) and $2.68\times10^{-7}$ M ssDNA (c). Rest time: 2 s, scan rate: 100 mV/s.

The change in the cyclic voltammetric behavior of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ after reacting with ssDNA confirms the above conclusions. As shown in Figure 5c, both the peak current and the peak potential of $p_1$ change relative to those in Figure 5b, illustrating that the electrostatic binding between the diiron(III) complex and ssDNA still exists. However, the inconspicuous changes in both the peak current and the peak potential of $p_2$, relative to those in Figure 5a, indicate the disappearance or weakness of the intercalation of the mononuclear ferrous complex into ssDNA. This can be ascribed to the uncoiling of the double helix structure because of the denaturing of the native DNA. According to the above experiments, we can conclude that the oxo-bridged diiron complex and the mononuclear ferrous complex bind to DNA through different modes. In other words, the diiron(III) complex can recognize

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dsDNA and ssDNA on the basis of the two steps of the electrochemical process on a gold electrode. To further confirm the above conclusions on the binding modes of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ and its mononuclear product to DNA, the influence of ionic strength on their interactions was investigated, and the results are reported in the following section.

Figure 6 shows the effect of the ionic strength ($\mu$) on the peak potential of $p_2$. The change in the ionic strength was controlled by the addition of different concentrations of KCl. In the absence of dsDNA, the shift in the anodic peak potential ($\Delta E_{p_{2,a}}$) induced by the addition of KCl is obtained by the relation $\Delta E_{p_{2,a}} = E_{p_{2,a}} - E_{p_{2,a,\mu=20}}$, where $E_{p_{2,a}}$ and $E_{p_{2,a,\mu=20}}$ represent the peak potentials of $p_2$ in the presence and absence of KCl in solution, respectively.

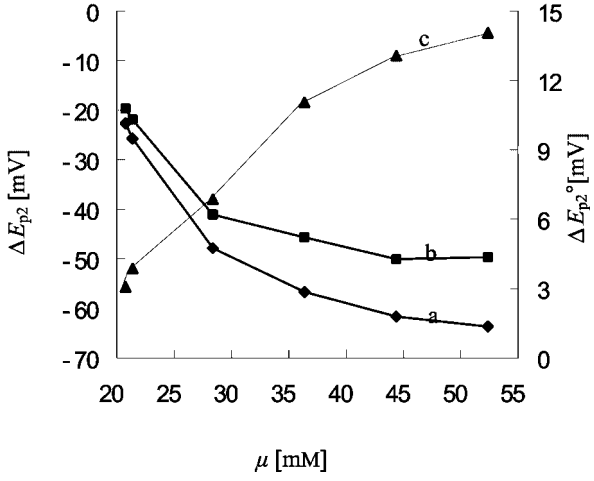

Figure 6. Effect of ionic strength ($\mu$) on the shift in the anodic peak potential ($\Delta E_{p_2}$) of the EC–C product of $4.00\times10^{-4}$ M $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$, in the absence (a) and the presence of $7.40\times10^{-6}$ M dsDNA (b). Curve (c) is the plot of $\Delta E_{p_2}°$ versus $\mu$, where $\Delta E_{p_2}° = \Delta E_{p_{2,b}} - \Delta E_{p_{2,a}}$.

The subscript "a" and "$\mu = 20$" in the formula indicate that DNA is absent from the solution and that the original ionic strength calculated for the 0.01 M NaOAc/HOAc electrolyte is 20 mM, respectively. Analogously, when DNA is present in solution, the shift in $E_{p_2}$ caused by the ionic strength is denoted as $\Delta E_{p_{2,b}}$, and its value is obtained by the formula $\Delta E_{p_{2,b}} = E_{p_{2,b}} - E_{p_{2,b,\mu=20}}$. Curve a and b in Figure 6 are the plots of $\Delta E_{p_{2,a}}$ versus $\mu$ and $\Delta E_{p_{2,b}}$ versus $\mu$, respectively. From the two curves, it is found that both $\Delta E_{p_{2,a}}$ and $\Delta E_{p_{2,b}}$ are negative on the time scale of CV measurements. Furthermore, the values of $\Delta E_{p_{2,a}}$ and $\Delta E_{p_{2,b}}$ decrease gradually with an increase in $\mu$, which suggests that, whether DNA exists in solution or not, the oxidation potential of the phen-ligated ferrous complex shifts to more negative values after the addition of KCl. Nonetheless, the values of $\Delta E_{p_2}°$ reveal the real effect of the ionic strength on the binding of $Fe(phen)_2^{2+}$ to dsDNA, and are positive on the time scale of the CV measurements and increase with an increase in $\mu$, as shown in Figure 6c. According to the literature,[46] the positive shift in $\Delta E_{p_2}°$ induced by the increase in the ionic strength demonstrates the intercalative binding mode of the mononuclear iron complex to dsDNA. This result is also consistent with the hypothesis drawn from Figure 5 with regard to the binding mode of the EC–C product to dsDNA.

However, the change in the reduction peak potential of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ ($E_{p_1}$) with an increase in the ionic strength is much more complicated. As shown in Figure 7a, the difference ($\Delta E_{p_{1,a}}$) between $E_{p_1}$ at $\mu > 20$ and that at $\mu = 20$ in the absence of dsDNA is negative and decreases with an increase in the ionic strength. This indicates that the reduction peak potential of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ also shifts negatively with an increase in the ionic strength in the absence of dsDNA. After binding to dsDNA, the plot of $\Delta E_{p_{1,b}}$ versus $\mu$ has a turning point at $\mu = 24$ mM with an increase of the ionic strength, as shown in Figure 7b. For $\mu < 24$ mM, $\Delta E_{p_{1,b}}$ decreases with an increase in $\mu$ and then increases for $\mu > 24$ mM. The plot of $\Delta E_{p_1}°$ ($\Delta E_{p_1}° = \Delta E_{p_{1,b}} - \Delta E_{p_{1,a}}$) versus $\mu$ shows the real effect of $\mu$ on the binding of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ to dsDNA and is presented in Figure 7c. The dashed line divides the plot into two regions corresponding to $\Delta E_{p_1}° < 0$ and $\Delta E_{p_1}° > 0$. This also demonstrates the change in the nature of the interaction between dsDNA and $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ from electrostatic to an intercalative mode with an increase in the ionic strength. At $\Delta E_{p_1}° = 0$, the electrostatic interaction is equal to the intercalative interaction in strength, and the corresponding value for the ionic strength ($\mu = 29$ mM) is called the critical-ionic strength (CIS).[46]

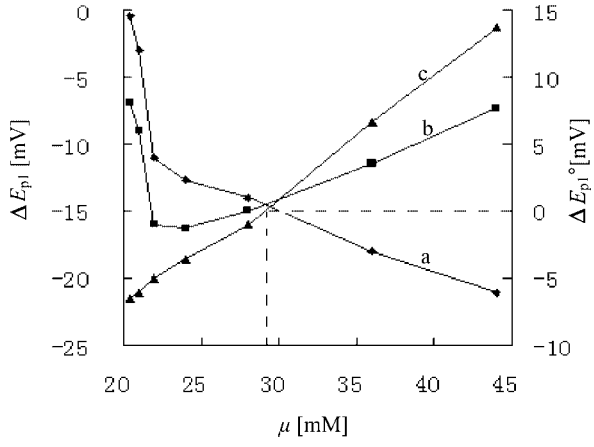

Figure 7. Effect of the ionic strength ($\mu$) on the shift in the reduction peak potential of $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$. The conditions are the same as those in Figure 6.

From electrostatic considerations, $\Delta E_{p_1}°$ should vary linearly with $\mu^{1/2}$ according to Debye–Hückel theory.[47] Figure 8 illustrates the dependence of $\Delta E_{p_1}°$ on $\mu^{1/2}$. It is observed that the plot is linear for $\mu$ up to 28 mM, with an intercept of –38 mV and a slope of 7 mV/mmol$^{1/2}$, which suggests that electrostatic interactions play a dominant role in this ionic strength range. For values of the ionic strength above 28 mM, $\Delta E_{p_1}°$ deviates from a straight line. These observations also prove the results mentioned above with regard to the change in binding mode of {[Fe(phen)-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$(H_2O)_3]_2O\}^{4+}$ to dsDNA, that is, from electrostatic binding to intercalative binding with an increase in the ionic strength. In addition, from the value of the intercept of –38 mV, a limiting ratio ($K_O'/K_R'$) from the binding constants for the oxidized ($K_O'$) and reduced ($K_R'$) forms ($\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ and $\{[Fe(phen)(H_2O)_3]_2O\}^{2+}$, respectively) can be estimated. A value of 19 is found for the ratio with the equations $\Delta E^{0\prime} = \Delta E_1^{0\prime} + B\mu^{1/2}$ (for $C_{KCl} << 1$ M)[46] and $\Delta E_1^{0\prime} = (-RT/nF)\ln(K_O'/K_R')$,[45–48] where $\Delta E_1^{0\prime}$ is the limiting difference in the formal potential at $\mu = 0$; $B$ is a constant which depends on the valences of the ions, the dielectric characteristics of the environment surrounding the ions , temperature, and the density of the solvent. This result suggests that the electrostatic interaction between the diiron(III) complex and DNA is significantly more dominant than the intercalative interaction.[45–46]

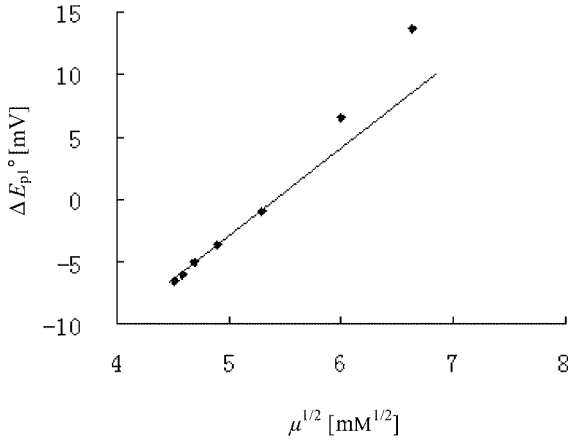

Figure 8. Dependence of $\Delta E_{p_1}$° on $\mu^{1/2}$. The conditions are the same as those in Figure 6.

The effect of the ionic strength on the difference in peak currents before and after the addition of dsDNA was also investigated. It was found that both the cathodic and anodic peak current difference ($\Delta I_{p_1}$ and $\Delta I_{p_2}$) decrease with an increase in the ionic strength, as shown in Figure 9a and Figure 9b, respectively. This suggests that the extent of the binding of both the diiron(III) complex and its EC–C product to dsDNA becomes weaker at high ionic strength.

This can be explained by the fact that the excess positively charged $K^+$ ion binds to negatively charged dsDNA phosphatediester backbone, which results in an inhibition in the binding of the cationic complex to dsDNA.[49]

The dependenc of the cyclic voltammetric behavior of the dinuclear iron(III) complex in the absence and presence of dsDNA on the scan rate ($v$) are shown in Figure 10(A) and Figure 10(B), respectively. It is found that both $I_{p_1}$ and $I_{p_2}$ vary linearly with the square root of the scan rate ($v^{1/2}$) both in the absence and presence of dsDNA, as shown in the insets of Figure 10(A) and Figure 10(B). This is as expected for a diffusion-controlled process.[50]

Furthermore, the slopes of both plots ($I_{p_1}$ versus $v^{1/2}$ and $I_{p_2}$ versus $v^{1/2}$) decrease after the addition of dsDNA, which indicates a reduction in the apparent diffusion coefficient of the complex in the presence of dsDNA.We can therefore

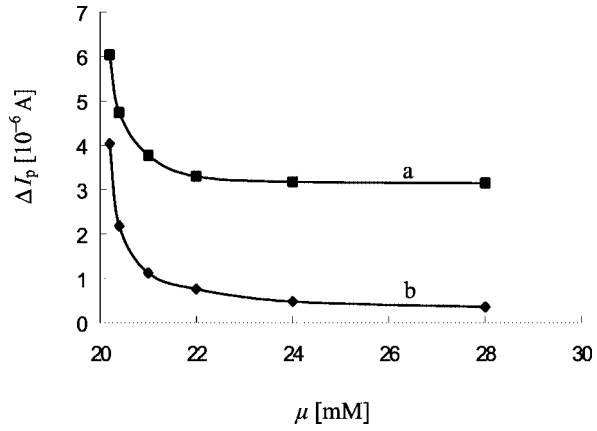

Figure 9. Influence of ionic strength ($\mu$) on $\Delta I_{p_1}$ (a) and $\Delta I_{p_2}$ (b). The conditions are the same as those in Figure 6.

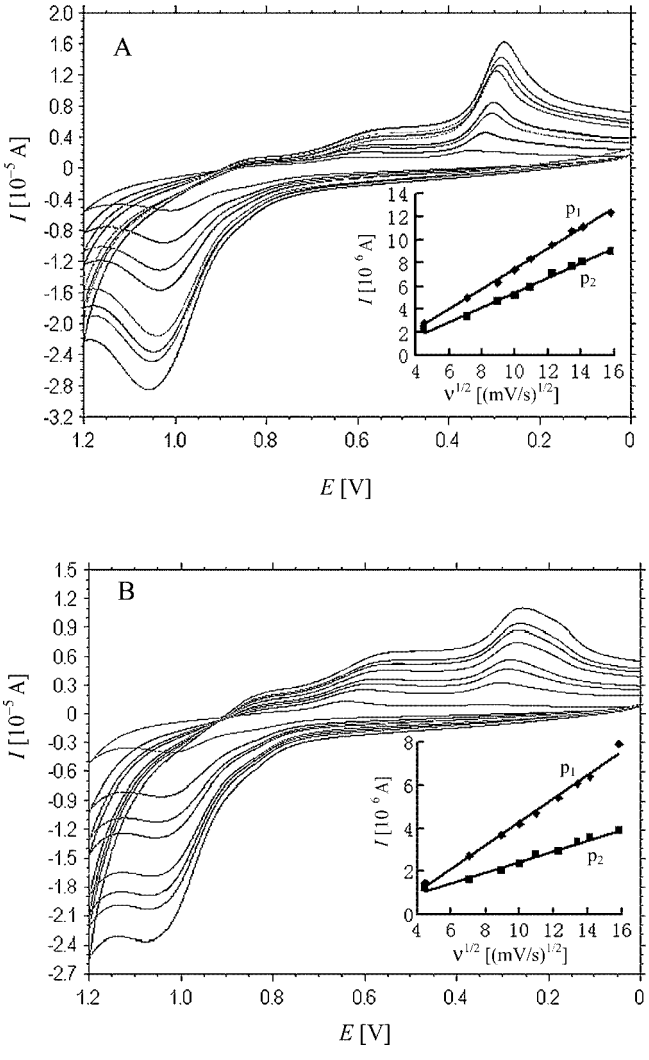

Figure 10. Dependenc of cyclic voltammetric behavior of $4.00\times10^{-4}$ M $\{[Fe(phen)(H_2O)_3]_2O\}^{4+}$ on the scan rate ($v$), in the absence (A) and the presence (B) of $7.37\times10^{-6}$ M dsDNA. Inset: plots of the peak current of $p_1$ and $p_2$ versus the square root of the scan rate ($v^{1/2}$).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

interpret the change in current upon dsDNA addition in terms of the diffusion of an equilibrium mixture of free and dsDNA-bound complex to the electrode surface.[46]

The relationship of both $\Delta I_{p_1}$ and $\Delta I_{p_2}$ to the concentration of dsDNA ($C_{DNA}$) was also studied. From Figure 11a, it can be seen that the relationship between $\Delta I_{p_1}$ and $C_{DNA}$ is linear in two $C_{DNA}$ ranges corresponding to $9.36\times10^{-7}$–$9.36\times10^{-6}$ M and $9.36\times10^{-6}$–$7.49\times10^{-5}$ M, with correlation coefficients of 0.985 and 0.998, respectively. $\Delta I_{p_2}$ becomes constant when the $C_{DNA}$ is larger than $1.87\times10^{-5}$ M (Figure 11b), which demonstrates that the intercalation between the ferrous complex and dsDNA is saturated when the concentration of dsDNA is over $1.87\times10^{-5}$ M.

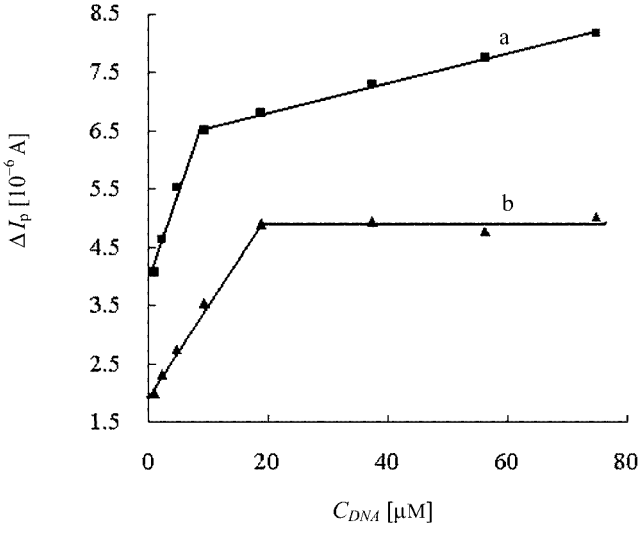

Figure 11. Plots of $\Delta I_{p_1}$ (a) and $\Delta I_{p_2}$ (b) versus the concentration of dsDNA ($C_{DNA}$).

## Conclusions

In summary, a new dinuclear iron(III) complex $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$ was synthesized and characterized by X-ray crystallography. The electrochemical behavior of the diiron(III) complex indicated an EC–C–EC mechanism at the gold electrode, and the binding mode of the diiron(III) complex and its final mononuclear product to dsDNA was studied in detail. The results indicate that $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$ interacts with dsDNA mainly through electrostatic binding, while the mononuclear EC–C product interacts mainly by intercalation. On the basis of its electrochemical behavior, the complex may be an effective recognition probe for dsDNA and ssDNA.

## Experimental Section

**Chemicals and Measurements:** Native double-stranded fish sperm DNA (dsDNA) from Beijing Baitai Biochemistry Technology Company (China) was used as received. The ratio of the absorbance at 260 and 280 nm ($A_{260}/A_{280}$) was checked to be 1.89, which indicates that the DNA was sufficiently free from protein.[51] The concentration of dsDNA (per nucleotide phosphate) was determined spectrophotometrically using the known molar-extinction coefficient value of 6600 $M^{-1}cm^{-1}$.[52] Denatured single-stranded DNA (ssDNA) was produced by heating a dsDNA solution in a water bath at 100 °C for 5–6 min, followed by rapid cooling in an ice bath.[46] The other chemical reagents used in the synthesis of the title complex were all of analytical reagent grade, purchased commercially, and used without further purification. The electrochemical and spectroscopic assays were all carried out in 0.01 M NaOAc/HOAc medium. Double-distilled water was used for preparing all the solutions. Elemental analyses were measured with a Perkin–Elmer 1400C analyzer. Voltammetry was performed with a CHI 832 electrochemical analysis system (CHI Instrument, China). A three-electrode system was used which consisted of a gold electrode ($\Phi$ = 3 mm) as the working electrode, a saturated calomel electrode (SCE) as the reference electrode, and a platinum wire as the auxiliary electrode. All the electrochemical measurements were carried out in a 10 mL electrolytic cell. UV/Vis absorption spectra were recorded on a Cary 50 probe spectrophotometer (Varian, Australia).

**Preparation and Crystallographic Study of $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$:** 1,10-phenanthroline (0.35 g, 2.0 mmol) was dissolved in ethanol (15 mL), and a 10 mL solution of iron(III) chloride hexahydrate (0.28 g, 1.0 mmol) was then added while stirring. The mixture was adjusted to a pH of 1.0 with a dilute sulfuric acid solution and sealed in a 50 mL stainless-steel reactor with Teflon liner. The reactor was heated at 100 °C for 72 h, which resulted in the formation of red crystals. C, H and N contents were determined by elemental analysis. $C_{24}H_{28}Fe_2N_4O_{15}S_2$ (788.32): calcd. C 36.53, H 3.55, N 7.10; found C 36.16, H 3.30, N 6.82.

The X-ray diffraction data for the crystal-structure determination was collected using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and $\omega$-scans with $\theta$ limits $2.04° < \theta < 27.52°$. An empirical absorption correction was carried out with the SADABS program.[53] The structure of $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$ was

Table 1. Crystal data and structure refinement for $\{[Fe(phen)(H_2O)_3]_2O\}(SO_4)_2$.

solved by direct methods and refined by least-squares on $F_{obsd.}^2$ by using the SHELXTL software package.[54] All non-H atoms were anisotropically refined. The hydrogen atoms were located by difference synthesis and refined isotropically. The final conventional $R$ indices were $R(F) = 0.0601$ and $wR(F^2) = 0.1496$ for 2391 reflections $I > 2\sigma(I)$ with weighting scheme, $w = 1/[\sigma^2(F_o^2) + (0.0905P)^2]$, where $P = (F_o^2 + 2F_c^2)/3$. The molecular graphics were plotted using SHELXTL. Atomic scattering factors and anomalous dispersion corrections were taken from the *International Tables for X-ray Crystallography*.[55] A summary of the key crystallographic information is given in Table 1. CCDC-227065 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# One Dimensional 3d–4f Heterometallic Compounds: Synthesis, Structure and Magnetic Properties

**Albert Figuerola,[a] Joan Ribas,[a] Xavier Solans,[b] Merce Font-Bardía,[b] Miguel Maestro,[c] and Carmen Diaz*[a]**

**Keywords:** Lanthanides / Chromium / Cyanide / Magnetic properties

The reaction of $Ln(NO_3)_3$·aq with $K_3[Fe(CN)_6]$ or $K_3[Co(CN)_6]$ and 2,2′:6′,2′′-terpyridine in water/methanol solution led to three one-dimensional complexes: *trans*-$[Ln(H_2O)_4(terpy)(\mu\text{-}CN)_2M(CN)_4]_n$ (Ln = $La^{3+}$ or $Sm^{3+}$; M = $Fe^{3+}$ or $Co^{3+}$). The structures of $[SmFe]_n$ (**1**), $[SmCo]_n$ (**2**) and $[LaFe]_n$ (**3**) have been solved; the complexes **1** and **2** crystallize in the monoclinic space $P2_1/c$ and are isomorphous, complex **3** crystallizes in the triclinic space $P\bar{1}$. No significant magnetic interaction was found between the samarium(III) and the iron(III) ions.

## Introduction

The design of supramolecular architectures with novel spin-carrier topologies is of current interest in the field of molecular magnetism. A successful strategy leading to heteropolymetallic systems with extended structures consists in self-assembly processes involving anionic building blocks, which contain a paramagnetic ion, and assembling complex cations with potentially free coordination sites. Cyano-bridged bimetallic systems with interesting magnetic and photomagnetic properties have been characterized.[1] Most of these systems contain two different transition-metal ions. In contrast, the lanthanide cations have not been used as much as nodes for the construction of cyano-bridged heteropolymetallic coordination networks.[2] Thus, although the research on cyano-bridged complexes has mainly focused on transition-metal ions with polycyanometallates and 4f ions, several compounds with different dimensionality have been reported.[3–19] In most cases the magnetic properties of these complexes do not seem exciting, as the coupling between the lanthanide and transition metals is very weak because of the effective shielding of the 4f electrons by the outer-shell electrons.

Important magnetic properties were found in only a few cyano-bridged rare earth transition-metal complexes. Most of the 3d–4f complexes that show long-range magnetic ordering involved the $Sm^{3+}$ ion.[3b,4b,5,13a,20] We are exploring a strategy to control the structure in the solid state that combines elements of design towards crystal engineering and the study of magnetic properties. We successfully applied this strategy in the preparation of new species starting from the mononuclear species $[M(CN)_6]^{3-}$ (M = $Fe^{3+}$, $Cr^{3+}$ and $Co^{3+}$) as building blocks, $Ln(NO_3)_3$·$xH_2O$ and different blocking ligands; a) with M = $Fe^{3+}$ or $Co^{3+}$ and dimethylformamide (DMF) as blocking ligand, working with the same conditions, we reported a family of 25 dinuclear complexes of the formula $[Ln(DMF)_4(H_2O)_3(\mu\text{-}CN)M(CN)_5]$·$nH_2O$ (with Ln = all lanthanide(III) ions except Pm and Lu) (Scheme 1, a).[4a] Structural studies of these families show that they are isomorphous; b) changes in the anionic building block modifies the structural types: using $[Cr(CN)_6]^{3-}$, $Gd(NO_3)_3$·$6H_2O$, DMF and the same conditions of reaction, a one-dimensional *cis*-$[Cr(CN)_4(\mu\text{-}CN)_2Gd(H_2O)(DMF)_4]_n$·$nH_2O$ was previously reported by the authors (Scheme 1, c).[4c] c) Changes in the terminal blocking ligand introduce new changes in the structural types: reactions involving $Ln^{3+}$ and $[Co(CN)_6]^{3-}$, $[Fe(CN)_6]^{3-}$ or $[Cr(CN)_6]^{3-}$ ions using bpy as terminal ligand instead of DMF lead to one-dimensional complexes of formula *trans*-$[M(CN)_4(\mu\text{-}CN)_2Ln(H_2O)(bpy)]_n$·$XnH_2O$ (bpy = 2,2′-bipyridine) form the late lanthanide ions (Scheme 1, b)[4e] and trinuclear complexes of the formula *trans*-$[M(CN)_4(\mu\text{-}CN)_2\text{-}\{Ln(H_2O)_4(bpy)_2\}_2][M(CN)_6]$·$8H_2O$ from the early ones (Scheme 1, d); for the one-dimensional complexes, hydrogen bonds and π–π interactions give three-dimensional networks. This work is focused on the synthesis, structures, and magnetic properties of the new one-dimensional compounds with 2,2′:6′,2′′-terpyridine (terpy) (Scheme 1, e)

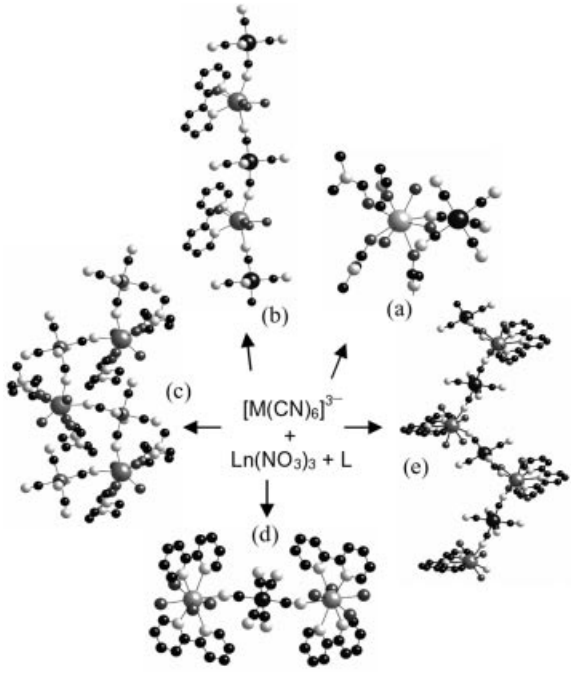
acting as blocking ligand: *trans*-[$Sm(H_2O)_4$(terpy)(μ-$CN)_2$-$Fe(CN)_4]_n$ (**1**), *trans*-[$Sm(H_2O)_4$(terpy)(μ-$CN)_2Co(CN)_4]_n$ (**2**) and *trans*-[$La(H_2O)_4$(terpy)(μ-$CN)_2$ $Fe(CN)_4]_n$ (**3**).



Scheme 1.

## Results and Discussion

### Description of the Structure of Complexes 1–3

Their crystallographic analysis revealed that complex **1** and **2** are isomorphous. Complexes **1** and **2** crystallize in the monoclinic system and complex **3** in the triclinic system. The structure of the three complexes consists of one-dimensional (1-D) chain polymer. An ORTEP view of $[SmCo]_n$ (**2**) and $[LaFe]_n$ (**3**) complexes with the atom-labeling scheme is given in Figure 1 and Figure 2, respectively. Selected bond lengths and angles for **1**–**3** are listed in Table 1. The coordination sphere around the $Ln^{3+}$ ion comprises three nitrogen atoms of the 2,2′:6′,2′′-terpyridine ligand, four oxygen atoms of four water molecules, and two nitrogen atoms of the cyanide bridges, their coordination number is nine. Six cyanide ligands surround the $M^{3+}$ (Fe, Co) ion in a distorted octahedral environment. In complex **3** the La–O and La–N distances are longer than the Sm–O and Sm–N of complexes **1** and **2** in accordance with the variation of the radius of the two-lanthanide ions. The lowest M–C distances correspond as expected to the $[Co(CN)_6]^{3-}$. In the three complexes, the chains show an alternation of $[Ln(H_2O)_4(terpy)]$ and $[M(CN)_6]$ ($M^{3+}$ = Fe, Co) fragments linked by cyanide bridges in the *trans* geometry, a schematic view of the chain of $[SmFe]_n$ (**1**) and $[LaFe]_n$ (**2**) are shown in Figure 3. In the complexes **1** and **2** the distances M–Sm ($M^{3+}$ = Co, Fe) are the same along the chain, but in complex **3** there are two different distances Fe1–La of 5.412 and Fe2–Ln of 5.446 Å. For complexes **1** and **2**, the angles Sm–M–Sm and M–Sm–M are different (176.48 and 102.32° for **1**, and 175.73 and 102.97° for **2**). For complex **3**, the angles values Fe1–La–Fe2, La–Fe1–La and La–Fe2–La are 103.69°, 179.97° and 179.98°, respectively. The chains are not in a linear configuration, the [LnMLn] trinuclear entities run along the chain in a zigzag path. An interesting feature of the conformation of the ligands around the $Sm^{3+}$ and $La^{3+}$ (complex **3**) ions is that they are chiral. As each $Sm^{3+}$ (complexes **1** and **2**) is related to the neighboring one by a glide plane, there are two enantiomeric coordination spheres in an achiral chain. In complex **3**, each $La^{3+}$ ion is related to the neighboring one by the inversion center at the $Fe^{3+}$ ion that is bridging them, there are two enantiomeric coordination spheres in the achiral trinuclear unit. For complexes **1**–**3**, the supramolecular structures are created by hydrogen bonding. Shortest inter-contacts for complexes **1** and **2** (the hydrogen atoms of coordinated water molecules were not located) are listed in the Supporting Information, Table S1 (for details see the footnote on the first page of

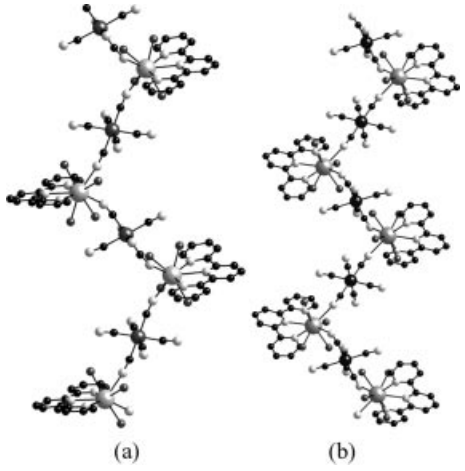

Figure 3. Schematic representation of the chains of [SmFe]$_n$ (a) and [LaFe]$_n$ (b).

this article); for complex **3**, the distances and angles corresponding to the hydrogen bonds are listed in the Supporting Information, Table S2. Complexes **1** and **2** show the same pathway of hydrogen bonds, but different than complex **3**. In complexes **1** and **2** the chains are self-assembled through hydrogen bonds in two different pathways. The O1 and O4 atoms of two coordinated water molecules to the samarium(III) ion and the two nitrogen atoms, N5 and N8 of the [M(CN)$_6$] entity, give an extensive 3D network. In Figure 4 the different ways and the atoms involved in the self-assembled structure for complex [SmFe]$_n$ (**1**), as example, are shown. In complex **3**, the O1, O2 and O3 oxygen atoms of the coordinated water molecules to the lanthanum(III) ion and three nitrogen atoms, N5, N6 and N8 of the [Fe(CN)$_6$] entity, give an extensive 3D network. In Figure 5 the different ways and the atoms involved in the self-assembled structure for complex [LaFe]$_n$ (**3**) are shown. The π–π interactions between the terpy ligands of neighboring chains are

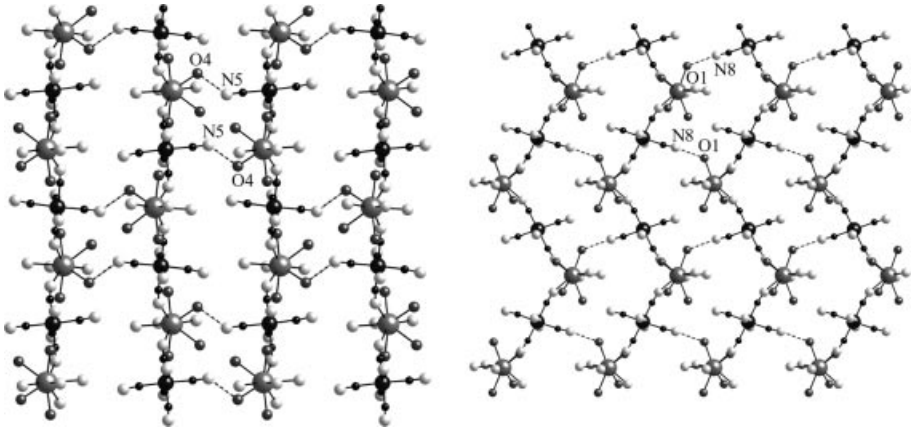

Figure 4. Schematic representation, for complex [SmFe]$_n$ (**1**), of different pathways in which the chains are self-assembled through hydrogen bonds. Complex **2** show similar self-assembly.

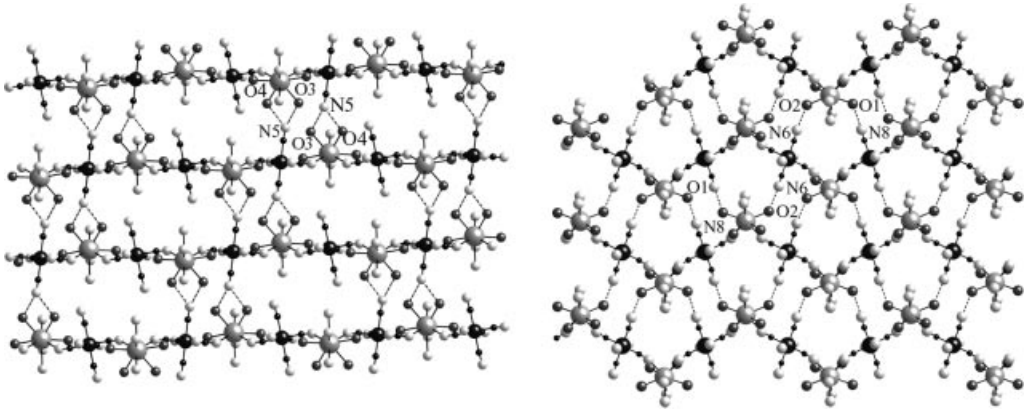

Figure 5. Schematic representation, for complex $[LaFe]_n$ (**3**), of different pathways in which the chains are self-assembled through hydrogen bonds.

very weak. Intermolecular stacking distances between centroids of the terpy rings are shown for complexes **1**–**3** in the Supporting Information, Table S3.

**Magnetic Properties:** Magnetic measurements were performed for the $[SmFe]_n$ (**1**), $[SmCo]_n$ (**2**) and $[LaFe]_n$ (**3**) complexes. The $Sm^{3+}$ and the $Fe^{3+}$ ions possess a first-order angular momentum, which prevents the use of a spin-only Hamiltonian for isotropic exchange. Not much is known about the nature of the exchange interaction of rare earth ions between themselves and with other magnetic groups, because the large orbital contribution of these ions makes a quantitative interpretation of the magnetic data of their complexes very complicated. The difficulty in having quantitative information on both these contributions has so far reduced the analysis of the magnetic properties of the anisotropic lanthanides mainly at a qualitative level, especially in molecular complexes. The most diffuse experimental approach to separate the different contributions of crystal field and exchange coupling to the magnetic properties in either heterometallic or lanthanide radical complexes involves the determination of magnetic properties of a corresponding complex where the second spin carrier is substituted by a diamagnetic analog, which gives rise to comparable ligand-field effects on the lanthanides.[21,4a,4b,4d,4e] Together with the $[SmFe]_n$ complex, we attempted to synthesize and characterize the homologous $[SmCo]_n$ and $[LaFe]_n$ complexes to use the typical empirical approach, mentioned above, to obtain insights into the nature of the $[SmFe]_n$ coupling. The approach consists of comparing its magnetic susceptibility data with the corresponding isostructural $[SmCo]_n$ compounds together with the magnetic properties of the $[LaFe]_n$ complex to take the anisotropy of the $Fe^{3+}$ ion into account. The $Co^{3+}$ and the $La^{3+}$ ions are obviously diamagnetic, and the deviation of the magnetic susceptibility of the $[SmCo]_n$ and the $[LaFe]_n$ compounds with respect to the Curie law is due entirely to the thermal population of the $Sm^{3+}$ Stark components and the anisotropy of $Fe^{3+}$, respectively. The comparison of the experimental magnetization at low temperature of the exchange-coupled system with that of the corresponding uncorrelated spin systems constitutes a further way to discriminate the sign of the coupling. Indeed if the $M$ vs. $H$ curve of the coupled system is running below the curve of the non-correlated system; an antiferromagnetic interaction within the molecular spin system is revealed, while the reverse would be true for a ferromagnetic situation.[22]

For most of the rare-earth compounds, the $\chi_M T$ value at room temperature is close to what is predicted in the free-ion approximation for the cases where only one level, $^{2S+1}L_j$, is thermally populated and second-order contributions are ignored.[23] For the complexes containing the $Sm^{3+}$ ion, the magnetic susceptibility is affected by the thermally populated excited states because of the spin-orbit coupling. The $[LaFe]_n$ complex is not isostructural with the $[SmFe]_n$ and $[SmCo]_n$ ones, but taking into account that the structural features round the $[Fe(CN)_6]$ entity are very similar in the three complexes, we can consider that the crystal field parameters around the $Fe^{3+}$ ion are analogous. So we apply the approach in order to evaluate the presence or not of magnetic interaction between the $Sm^{3+}$ and $Fe^{3+}$ ions.

***trans*-$[Sm(H_2O)_4(terpy)(\mu\text{-}CN)_2Fe(CN)_4]_n$, *trans*-$[Sm(H_2O)_4(terpy)(\mu\text{-}CN)_2Co(CN)_4]_n$ and *trans*-$[La(H_2O)_4(terpy)(\mu\text{-}CN)_2Fe(CN)_4]_n$:** The temperature dependence of the $\chi_M T$ for the three complexes is shown in Figure 6 (top). For the $[SmCo]_n$ complex, the $\chi_M T$ value at 300 K is approximately equal to 0.37 $cm^3 mol^{-1} K$. At room temperature, allowing for $\chi_M T$ = 0.05 $cm^3 mol^{-1} K$ of $Co^{3+}$ (l.s), from the TIP value for the $Co^{3+}$ ion,[24] the $\chi_M T$ value corresponding to the $Sm^{3+}$ is 0.32 $cm^3 mol^{-1} K$. At room temperature, the experimental $\chi_M T$ values found in the literature are around 0.32 $cm^3 mol^{-1} K$. These observed values are inconsistent with the theoretical value of 0.09 $cm^3 mol^{-1} K$ expected for one $Sm^{3+}$ ($^6H_{5/2}$) ion. This disagreement is ascribed to the presence of thermal populated excited states, as is well known for $Sm^{3+}$ complexes. On lowering the temperature, the $\chi_M T$ value decreases monotonically to 0.05 $cm^3 mol^{-1} K$. For the $[LaFe]_n$ complex, the $\chi_M T$ value at 300 K is approximately equal to 0.80 $cm^3 mol^{-1} K$, while it decreases with temperature to 0.53 $cm^3 mol^{-1} K$. For the $[SmFe]_n$ complex, the $\chi_M T$ value at 300 K is approximately equal to 1.14 $cm^3 mol^{-1} K$, while it decreases with temperature to 0.63 $cm^3 mol^{-1} K$. The $\chi_M T$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

value at room temperature fits nicely to the sum (1.12 $cm^3 mol^{-1} K$) of the measured values for the $Sm^{3+}$ ion (0.32 $cm^3 mol^{-1} K$) in the $[SmCo]_n$ complex and for the $Fe^{3+}$ ion (0.80 $cm^3 mol^{-1} K$) in the $[LaFe]_n$ complex. The $\Delta\chi_M T$ vs. $T$ curve is practically superimposable with the $\chi_M T$ vs. $T$ curve of the $[LaFe]_n$ complex along the whole range of temperatures indicating that no noticeable interaction is active. The experimental magnetization of $[SmFe]_n$ at 2 K (Figure 6, bottom) is superimposable with that of the uncorrelated spin system, corroborating that no exchange interaction is active.

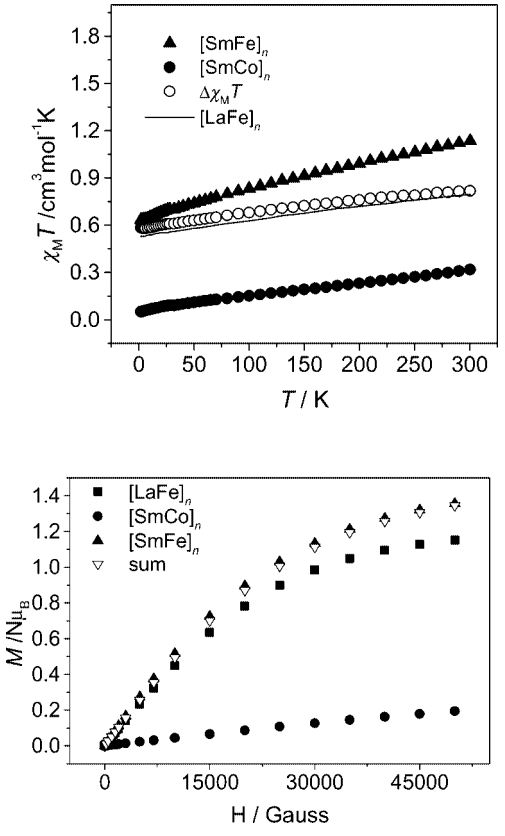

Figure 6. Top: thermal dependence at 0.1 T of $\chi_M^{[SmFe]_n}T$, $\chi_M^{[SmCo]_n}T$, $\chi_M^{[LaFe]_n}T$ and $\Delta\chi_M T = \chi_M^{[SmFe]_n}T - \chi_M^{[SmCo]_n}T$, the TIP value of the $Co^{3+}$ ion has been considered (see text). Bottom: magnetization vs. $H$ (2 K) of $M^{[SmFe]_n}$, $M^{[SmCo]_n}$, $M^{[LaFe]_n}$ and sum $M^{[LaFe]_n} + M^{[SmCo]_n}$.

## Conclusions

Three one-dimensional $[SmFe]_n$, $[SmCo]_n$ and $[LaFe]_n$ complexes, have been structurally characterized and magnetically studied. Most of the 3d–4f complexes that show long-range magnetic ordering involved the $Sm^{3+}$ ion. The replacement of $Sm^{3+}$ ion by another lanthanide ion usually gives rise to isostructural compounds that lose all three-dimensional magnetic properties. Unfortunately the magnetic interaction between the $Sm^{3+}$ and the $Fe^{3+}$ ions in the $[SmFe]_n$ complex is negligible. Trying to make magneto-structural correlations has proved impossible until now due to the complexity of the 3d–4f magnetic interactions and to the few complexes reported in the literature with similar Ln–CN–Fe core.

## Experimental Section

**Materials:** All starting materials were purchased from Aldrich and were used without further purification.

**Physical Measurements:** Magnetic measurements were carried out in the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (20 mg) with a Quantum Design SQUID MPMS-XL magnetometer working in the 2–300 K range. The magnetic field was 0.1 T. The field-dependent magnetization was measured in the applied magnetic field range 0–5 T. The diamagnetic corrections were evaluated from Pascal's constants.

**Synthesis of *trans*-$[Sm(H_2O)_4(terpy)(\mu\text{-}CN)_2Fe(CN)_4]_n$(1), and *trans*-$[La(H_2O)_4(terpy)(\mu\text{-}CN)_2Fe(CN)_4]_n$ (3):** The two $[Ln–Fe]_n$ complexes were obtained by adding a solution of $Ln(NO_3)_3{\cdot}nH_2O$ (0.2 mmol) in water (50 mL) to an equimolar solution of $K_3[Fe(CN)_6]$ in water (50 mL). To this mixture an ethanolic solution (20 mL) of 2,2′:6′,2′′-terpyridine (0.3 mmol) was added. The solution was left undisturbed, and well-formed crystals (orange for both complexes) were obtained after several days.

**Synthesis of *trans*-$[Sm(H_2O)_4(terpy)(\mu\text{-}CN)_2Co(CN)_4]_n$ (2):** The complex was obtained by the same procedure using $K_3[Co(CN)_6]$ instead of $K_3[Fe(CN)_6]$. Well-formed colourless crystals were obtained after several days.

**Complex 1:** Yield: 100 mg (75%). $C_{21}H_{19}FeN_9O_4Sm$ (667.65): calcd. C 40.70, N 16.84, H 4.19; found C 40.9, N 17.0, H 4.0.

**Complex 2:** Yield: 107 mg (80%). $C_{21}H_{19}CoN_9O_4Sm$ (670.73): calcd. C 41.44, N 17.15, H 4.04; found C 41.5, N 17.2, H 4.0.

**Complex 3:** Yields: 96 mg (73%). $C_{21}H_{18}FeLaN_9O_4$ (656.19): calcd. C 41.20, N 17.05, H 4.01; found C 41.1, N17.2, H 3.9.

**Crystallographic Studies:** Crystal data and refinement are summarized in Table 2. Prismatic crystals, (0.1 × 0.1 × 0.2 mm), (0.1 × 0.2 × 0.2 mm) and (0.1 × 0.3 × 0.3 mm) of complexes **1**, **2** and **3** were selected and mounted on a Enraf–Nonius CAD4 four-circle diffractometer for **1**, on a MAR 345 diffractometer with an image plate detector for **2**, and on a Bruker SMART-CCD area diffractometer for **3**. Unit-cell parameters were determined from automatic centering of 25 reflections ($12 < \theta < 21°$) for **1**, from 24410 reflections ($3 < \theta < 21°$) for **2**, and from 1271 frames of intensity data covering 0.3° in $\omega$ over a hemisphere of the reciprocal space by combination of three exposure sets, and refined by least-square method for **3**. Intensities were collected with graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), using $\omega/2\theta$ for **1** and **3**, and $\varphi$ scan-technique for **2**; 7269 reflections for **1**, 26881 for **2** and 8230 for **3** were measured in the range $2.43 \leq \theta \leq 29$, $2.45 \leq \theta \leq 31.55$, and $2.12 \leq \theta \leq 28.31$, respectively. For complex **2**, 7477 of which were non-equivalent by symmetry [$R_{int}(I)$ = 0.017]; 4330 reflections of **1**, 7126 reflections of **2**, and 5231 of **3** were assumed as observed applying the condition $I > 2\sigma(I)$. Lorentz polarization and absorption corrections were made.

The structures were solved by Patterson synthesis for **1** and by direct methods for **2** and **3**, using SHELXS computer program[25] and refined by full-matrix least-squares method with SHELX97 computer program,[25] using 7269 reflections for **1**, 7477 reflections for **2**, and 5231 for **3**. The function minimized was $\Sigma w||F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.0345P)^2]^{-1}$ for **1**, $w = [\sigma^2(I) + (0.0274P)^2 + 1.8065P]^{-1}$ for **2**, and $w = [\sigma^2(I) + (0.0297P)^2 + 0.8875P]^{-1}$ for **3**,

| Radiation (Mo-$K_\alpha$) [Å] | 0.71069 | 0.71073 | 0.71073 |
| $\rho_{calcd.}$ [g/cm$^3$] | 1.758 | 1.793 | 1.683 |
| $\mu_{calcd.}$ [mm$^{-1}$] | 2.925 | 3.054 | 2.232 |
| $T$ [K] | 293(2) | 293(2) | 298(2) |
| $F$[000] | 1312 | 1316 | 643 |
| $\Theta$ range for data | 2.43–29.97° | 2.45–31.55° | 2.12–28.31° |
| Total reflections | 7269 | 26881 | 8230 |
| Independent reflections ($R_{int}$) | 7269 (0.0367) | 7477 (0.0177) | 5231 (0.0169) |
| $\Theta_{max}$ [%] | 95.9 | 90.1 | 91.0 |
| Parameters refined, restraints | 313.0 | 353.0 | 328.8 |
| Final $R$ indices[a] [$I > 2\sigma(I)$] | $R_1 = 0.0341$ | $R_1 = 0.0238$ | $R_1 = 0.0256$ |
| Final $wR_2$ indices[a] | $wR_2 = 0.0706$ | $wR_2 = 0.0692$ | $wR_2 = 0.0608$ |
| Final $R$ (for all data)[a] | $R_1 = 0.0896$ | $R_1 = 0.0256$ | $R_1 = 0.0312$ |
| Final $wR_2$ (for all data)[a] | $wR_2 = 0.0830$ | $wR_2 = 0.0701$ | $wR_2 = 0.0632$ |
| Goodness-of-fit on $F^2$ | 0.897 | 1.307 | 1.012 |

[a] $R_1 = \Sigma||F_o| - |F_c||$ and $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)]/\Sigma[w(F_o^2)^2]\}^{1/2}$.

and $P = (|F_o|^2 + 2|F_c|^2)/3$, $f$, $f'$ and $f''$ were taken from International Tables of X-ray Crystallography.[26] For **1** all non-water hydrogen atoms were computed and refined, using a riding model. For complex **2**, 7 hydrogen atoms were located from a difference synthesis and 4 hydrogen atoms were computed and refined using a riding model. For complex **3**, 4 hydrogen atoms were located from a difference synthesis and refined using a riding model. For all complexes, the isotropic temperature factor for H atoms was equal to 1.2 times the equivalent temperature factor of the atom, which is linked. For complex **1**, the final $R$ (on $F$) factor was 0.034, $wR$ (on $|F|^2$) = 0.070 and goodness of fit = 0.897 for all observed reflections; for complex **2**, the final $R$ (on $F$) factor was 0.0238, $wR$ (on $|F|^2$) = 0.0692 and goodness of fit = 1.307 for all observed reflections; and for complex **3**, the final $R$ (on $F$) factor was 0.0256, $wR$ (on $|F|^2$) = 0.0608 and goodness of fit = 1.012 for all observed reflections. For complex **1**, the number of refined parameters was 313. Max. shift/esd. = 0.00, Mean shift/esd. = 0.00. Max. and min. peaks in final difference synthesis was 0.802 and –0.811 e·Å$^{-3}$, respectively. For complex **2**, the number of refined parameters was 353. Max. shift/esd. = 0.00, Mean shift/esd. = 0.00. Max. and min. peaks in final difference synthesis was 0.583 and –0.518 e·Å$^{-3}$, respectively. For complex **3**, the number of refined parameters was 328, 8 restrictions were applied. Max. shift/esd. = 0.01, Mean shift/esd. = 0.00. Max. and min. peaks in final difference synthesis was 0.590 and –0.79 e·Å$^{-3}$, respectively.

CCDC-289051 (for **1**), -289050 (for **2**) and -289049 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Additional Tables with hydrogen bonds and π–π interactions.

# A New $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ Sillén–Aurivillius Intergrowth: Synthesis and Structural Characterisation by Quantitative Transmission Electron Microscopy

**David Ávila-Brande,*[a] L. Carlos Otero-Díaz,[a,b] Ángel R. Landa-Cánovas,[c] Sara Bals,[d] and Gustaaf Van Tendeloo[d]**

**Keywords:** Sillén–Aurivillius intergrowths / Layered oxyhalide / Electron microscopy / Exit-wave reconstruction / Bismuth

The synthesis and structural characterisation of a new phase with nominal composition $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ is presented. Conventional and analytical transmission electron microscopy are used to determine the composition, unit-cell symmetry and space group of the compound, whereas a structural model is deducted by exit-wave reconstruction in the transmission electron microscope. This technique allows the microscope information limit of 1.1 Å to be reached and the (light) oxygen atoms in the presence of heavier atoms (Bi, W, Mn) to be imaged. The average structure is refined from X-ray powder diffraction data using the Rietveld method yielding an orthorhombic unit cell with lattice parameters $a$ = 5.467(4) Å, $b$ = 5.466(7) Å and $c$ = 14.159(3) Å and space group $Cm2m$, which could be described as a Sillén–Aurivillius intergrowth.

## Introduction

Bismuth-based systems have been extensively studied because of their ability to form new complex intergrowth structures with variable properties. For example, the high Tc superconducting bismuth phases[1,2] can be described as an alternation of $n$ slabs of perovskite-like layers with a double $[BiO]^+$ layer. Related to those structures, the Aurivillius phases with general composition $[Bi_2O_2][A_{n-1}B_nO_{3n+1}]$ are built up as a regular intergrowth of perovskite slabs $[A_{n-1}B_nO_{3n+1}]^{2-}$ and $[Bi_2O_2]^{2+}$ fluorite layers.[3,4] Despite the structural similarities, superconducting properties have not yet been found for the Aurivillius phases, whereas ferroelectric properties with large spontaneous polarisations[5] and high Curie temperatures[6] have been reported.

The complex oxyhalides described by Sillén[7] form another structural variant of layered compounds containing the $[Bi_2O_2]^{2+}$ structural block. These compounds are built up from single, double or triple halide ion sheets separated by $[Bi_2O_2]^{2+}$ layers.

The presence of the $[Bi_2O_2]^{2+}$ layer in the Aurivillius phases as well as in the Sillén complex oxyhalides suggests that intergrowth in these structures might yield a number of new phases. In fact, Aurivillius reported a number of intergrowths with the general sequence $[Bi_2O_2][A_{n-1}B_nO_{3n+1}]$-$[Bi_2O_2][X_m]$ in which A is a large cation (A: $Bi^{3+}$, $Pb^{2+}$, $Sr^{2+}$), B a small transition metal (B: $Nb^{5+}$, $Ta^{5+}$, $W^{6+}$, $Ti^{4+}$, $Al^{3+}$) and X a halide (Cl, Br).[8] In the above sequence, $n$ denotes the thickness of the perovskite layers in terms of $\{BO_6\}$ octahedra and $m$ the number of halide slabs.

The general formula for the simplest member ($n$ = 1 and $m$ = 1) of the Sillén–Aurivillius intergrowth can be written as $Bi_4BO_8X$ and hence B must be a pentavalent cation. However, if another lone pair cation like $Pb^{2+}$ with a lower oxidation state substituting for $Bi^{3+}$ is introduced, the B cation must be replaced by a hexavalent one like $W^{6+}$.

Aurivillius[8] was the first to synthesise the $Bi_4NbO_8Cl$ and $PbBi_3WO_8Cl$ phases. His characterisation indicated a phase mixture ($c_1$ = 14.5 Å and $c_2$ = 29.0 Å) for $Bi_4NbO_8Cl$ and a single phase for $PbBi_3WO_8Cl$ ($a \approx b$ = 5.51 Å; $c$ = 14.35 Å; space group $Cm2m$). Ackerman[9] revised these structures and assigned the orthorhombic space group $P2_1cn$ to the niobium oxychloride $Bi_4NbO_8Cl$ ($a \approx b$ = 5.49 Å and $c$ = 28.75 Å) and the tetragonal space group $P_4$ ($a = b$ = 3.84 Å; $c$ = 14.35 Å) to $PbBi_3WO_8Cl$. Recently, Kusainova et al.[10] reanalysed the structure of $Bi_4NbO_8Cl$ by using neutron diffraction powder data in the same $P2_1cn$ space group ($a$ = 5.44 Å, $b$ = 5.49 Å and $c$ = 28.81 Å). A study of the ferroelectric properties yields a $T_c$ of 765 K.

By inserting adequate transition metals in the Aurivillius block, phases with interesting electric and magnetic properties can be obtained. Manganese, for example, has attracted great attention because of the colossal magnetoresistance (CMR) observed in manganese perovskites.[11,12] In this work, we present the synthesis as well as the structural char-

acterisation of a new phase with nominal composition $Bi_4Mn_{1/3}W_{2/3}O_8Cl$.

## Results and Discussion

### Composition Analysis and Mn Oxidation State Determination

X-ray energy dispersive spectroscopy (XEDS) analyses performed on several microcrystallites yield an average composition $Bi_{3.99(2)}Mn_{0.33(1)}W_{0.70(7)}Cl_{0.62(9)}$. The measured chlorine content is lower than the nominal value, which is due to severe overlapping between the Bi–$M_\alpha$ and the Cl–$K_\alpha$ peak, making it impossible to assert the presence of chlorine using XEDS. The chlorine edge is more distinctly present in the electron energy loss spectrum (EELS) presented in Figure 1, which shows the chlorine-$L_{2,3}$ absorption edge at 200 eV and the oxygen-$K$ edge at 532 eV. The carbon-$K$ edge at 284 eV is due to the carbon coating grid of the transmission electron microscopy (TEM) specimen-supporting grid.

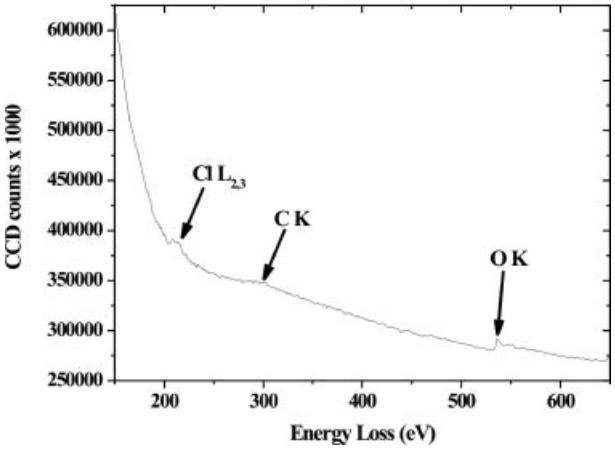

Figure 1. EEL spectrum showing the presence of the different lighter elements (Cl, O).

Figure 2 shows the magnetic susceptibility curve, with the $\chi^{-1}$ curve shown as an inset. This curve obeys the Curie–Weiss law between 50 and 300 K and $\mu_{eff}$ equals $5.20\mu_B$.

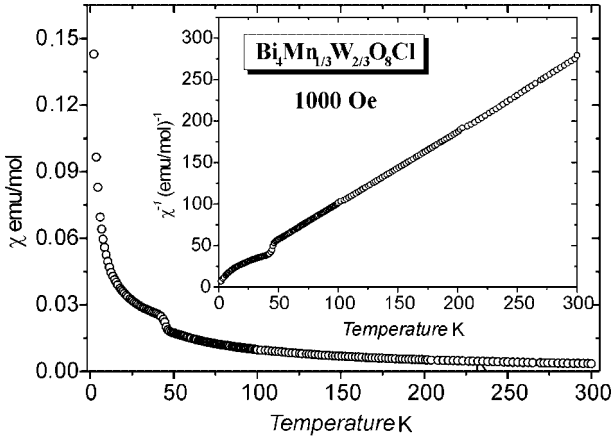

Figure 2. Curve of the magnetic susceptibility vs. temperature. The inset shows the $\chi^{-1}$ curve for the sample.

This value is slightly higher than the theoretical one ($4.90\mu_B$)[13] corresponding to a high-spin $Mn^{3+}$.

### Unit Cell and Symmetry Determination

Selected area electron diffraction (SAED) patterns of several crystals show a homogeneous sample with an either tetragonal primitive cell ($a_o = b_o = 3.8$ Å and $c_o = 14.1$ Å) or a pseudotetragonal centred one ($a \approx b = 2a_o = 5.4$ Å and $c = 14.1$ Å). In order to distinguish between the two, microdiffraction is performed following the method proposed by Morniroli and Steeds.[14] It is important to note that in Mornirolli's work, the lattice parameters for the orthorhombic system were chosen such that $c < a < b$, whereas we have chosen the setting *bca* taking into account the variation in the zone axes notation, for example, [001] changes to [010] after the application of the *bca* setting.

In the first step the crystal system is determined. The experimental [010] pattern, which displays the highest "net" symmetry, has (2mm) symmetry for the zero-order Laue zone (ZOLZ) and 2mm for the whole pattern [ZOLZ + first-order Laue zone (FOLZ)] (Figure 3, a). According to Table 7 in ref.[14] the crystal system is therefore orthorhombic. In order to determine the Bravais lattice as well as the presence of glide planes, a comparison between experimental and simulated [001] and [010] microdiffraction patterns is made (Figure 3, parts a and b). The [001] zone axis contains a "net" mirror m1 in the ZOLZ and the FOLZ reflections; the [010] pattern on the other hand exhibits two perpendicular "net" mirrors m1 and m2 in both the ZOLZ and FOLZ, but the shift between the ZOLZ and the FOLZ reflections parallel to the m2 allows identification of a C centring. According to ref.[15] this gives the extinction symbols:

C.-. for [010]

C..- for [001]

sible space groups: *Cm*2*m* and *Cc*2*m*.[15] When looking at the magnified central row of the [010] zone (Figure 3, c) it is easy to note the presence of 00*l* reflections with $l = 2n + 1$. The absence of Gjønnes–Moodie lines in those reflections indicates that they are kinematically allowed. The distinction between both can be made by analysing the reflections listed in Table 2. In *Cc*2*m* the 00*l* reflections with $l = 2n + 1$ are forbidden, whereas they are allowed in *Cm*2*m*. Figure 4 shows that 00*l* reflections with $l = 2n + 1$ are observed along the [010] and [1–10] zone axes. *Cm*2*m* is therefore identified as the correct space group for $Bi_4Mn_{1/3}W_{2/3}O_8Cl$, which is isostructural with $Bi_4Ti_{1/2}W_{1/2}O_8Cl$[16] and lattice parameters $a \approx b = 5.4$ Å and $c = 14.1$ Å.

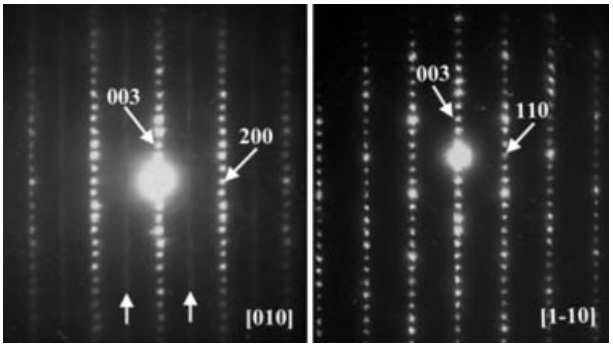

Figure 4. SAED patterns of $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ along the [010] and [1–10] zone axes.

SAED patterns along the main zone axes reveal a well-ordered phase. Only the presence of a weak streaking along [10*l*] in the [010] zone axis (Figure 4, indicated by arrows) indicates some defects or extra ordering.

## Structure Model Determination by Exit-Wave Reconstruction

Although high-resolution electron microscopy (HREM) is considered as a standard technique to image the atomic structure of materials, interpretation is not always straightforward because of aberrations of the electromagnetic lens system. The information that can be obtained by qualitative HREM is therefore limited by the Scherzer point-resolution, but for a coherent electron source (field emission gun) the information limit of the microscope reaches beyond this point-resolution. The information limit can be reached by correcting the phase changes due to the spherical aberration ($C_s$) of the objective lens. Exit-wave reconstruction uses a set of images taken from the same area but for different defocus values of the objective lens. The idea is to invert the image formation process so that lens aberrations can be eliminated and a better resolution can be obtained. A great advantage of this inversion is that the amplitude as well as the phase of the exit wave (i.e., the electron wave leaving the specimen) is reconstructed. As the light atom columns are revealed in the phase of the exit wave,[17] we are able to image the light oxygen atoms in the presence of heavy Bi, W and Mn atoms. In this manner, we directly obtain the projected coordinates, which allow us to build a structural model, assuming the *Cm*2*m* space group.

A focal series of 20 images with an equidistant focal decrease is recorded along the [1–10] zone axis using a slow-scan CCD camera. After reconstruction, using the TrueImage software, and correction for the aberrations, the complex exit wave is retrieved and split into amplitude and phase.

Figure 5 shows the phase of the reconstructed exit wave with the atom positions corresponding to the bright dots; the projected unit cell is outlined. The projected coordinates are directly determined from the phase image and the results are listed together with the ideal positions deduced for the *Cm*2*m* space group in Table 3.

The phase image clearly shows the projected octahedra $\{WO_6\}/\{MnO_6\}$ and it should be noted that also the oxygen atoms are revealed; they are indicated in Figure 5. We have fixed the W/Mn position in the origin (0,0,0) corresponding to the Wyckoff site *2a*. If we assume a model based on a Sillén–Aurivillius intergrowth, the octahedral layer from the Aurivillius block presents eight oxygens in two nonequivalent positions: four in the apex [called O(1)] and four in the equatorial plane [called O(2)]. From the reconstructed phase we can easily determine the projected positions for both, which correspond to 4c and 4d positions respectively in an ideal model.

Two types of bismuth, that is, Bi(1) and Bi(2), are present. Next to Bi(2) we can still observe smaller dots corresponding to the O(3) oxygen. Around Bi(1) we can also observe an extension of the blobs corresponding to the O(3)

| O(2) | 0.31 | 0 | *4d* | 0.22 | 0.22 | 0 |
| O(3) | 0.31 | 0.31 | *8f* | 0.22 | 0.22 | 0.31 |

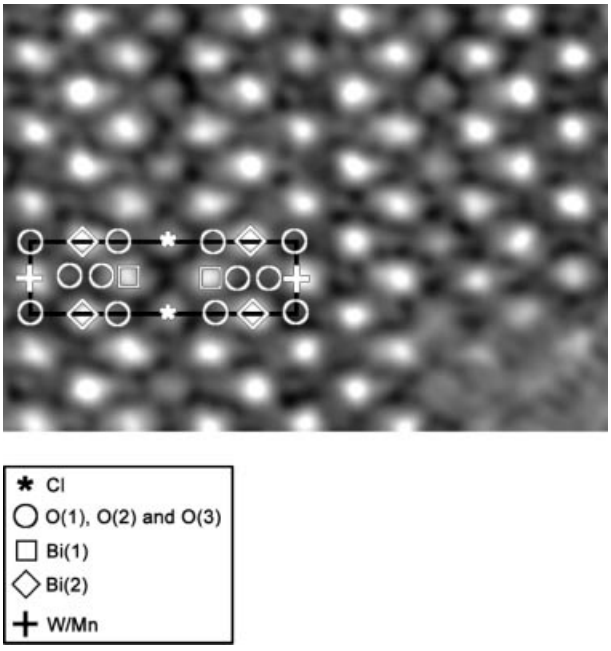

Figure 5. Phase of the reconstructed exit wave along [1–10]. The bright dots correspond to the projected position of the different atoms.

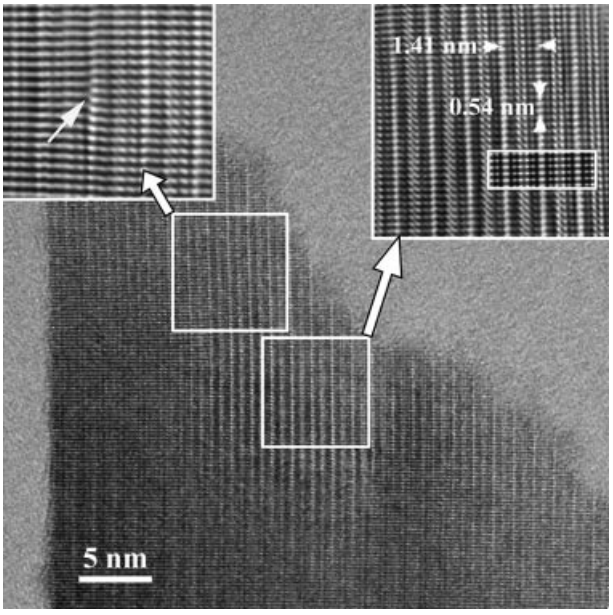

Figure 6. Experimental [010] HREM image. The upper-right enlarged area is a filtered image and shows a good match between the experimental and the simulated image ($\Delta f$ = –300 Å; $t$ = 30 Å). The filtered image on the left shows the presence of a dislocation marked by an arrow.

atoms. As the projected distance Bi(1)–O(3) is equal to 0.97 Å, which is below the information limit, it is not possible to observe Bi(1) and O(3) separately.

The measured coordinate for O(3) is only in agreement with the site symmetry *8f* for the *Cm*2*m* space group. Finally, the chlorine atom was located in a *2b* site according to the coordinates determined in the image. A more accurate fit of the projected positions of the atomic columns is being performed using statistical parameter estimation.[18]

Figure 6 displays an HREM image recorded along the [010] zone, with an enlarged (filtered) area presented as an inset on the right. This inset also shows a simulated part, which was calculated starting from the structural model obtained by exit-wave reconstruction (defocus value $\Delta f$ = –300 Å, sample thickness was 30 Å). Obviously, a good fit between the experimental image and the simulated one is found. Here, the cation positions correspond to the dark dots. The only defects observed in the HREM images are dislocations; one of them is marked with an arrow in the filtered image shown as an inset on the left.

## Average Structure: Powder X-ray Diffraction Refinement

Once the unit cell, the space group and the structural model are determined from electron microscopy data, the refinement of the average structure is carried out by X-ray powder diffraction.

The Rietveld refinement of $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ (Figure 7) is performed using the structural data obtained from the phase of the reconstructed exit wave (see Table 3). Because of the stronger X-ray scattering of $Bi^{3+}$, $Mn^{3+}$ and $W^{6+}$, the isotropic atomic displacement parameters (ADPs) of chlorine and oxygen atoms are all fixed at a reasonable value of 0.8 Å$^2$. Table 4 summarises the refined structural parameters; the $R$ factors of weighted pattern ($R_{wp}$), pattern ($R_p$) and Bragg ($R_B$) converge to 16.1%, 12.9% and 5.87% respectively. These values agree with those obtained in other Aurivillius[19,20] and Sillén–Aurivillius[8] phases. It is worth mentioning that the high B value obtained for Bi(2) in the refinement agrees with our previous work on the isostructural $Bi_4Ti_{1/2}W_{1/2}O_8Cl$ compound.[16] This high value

| | | | $R_p$ = 12.9%, $R_{wp}$ = 16.1%, $R_B$ = 5.87% | | | | | | |

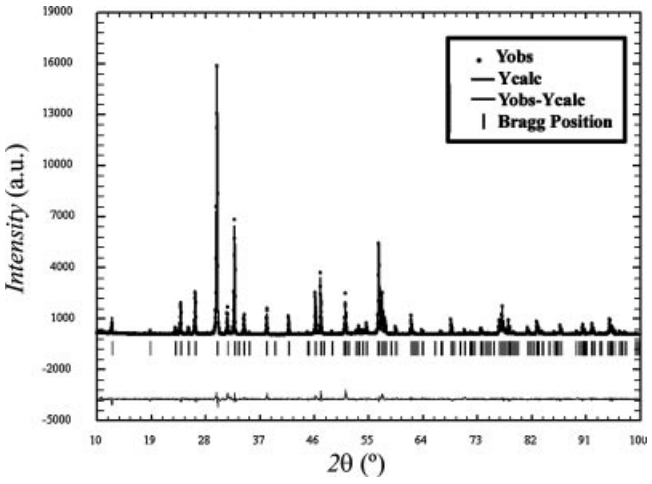

Figure 7. Experimental (circles), calculated and difference (solid lines) powder X-ray diffraction patterns of the $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ phase. Vertical bars indicate the calculated Bragg angle positions.

is due to an asymmetric surrounding around the $Bi_2O_2$ layer; Bi(1) is close to the Cl sheet whereas Bi(2) is much closer to the $\{BO_6\}$ octahedral layer and can establish short contacts to the apex oxygen atoms O(1) (see Table 4), changing its coordination from 4 to 5, as can be seen in the structural model built for the new Sillén–Aurivillius intergrowth (Figure 8, a).

Within the distorted octahedra $(W/Mn)O_6$, the W/Mn–O(1) bonds are shorter than the W/Mn–O(2) bonds. This observation can be understood in terms of the Jahn–Teller effect originated by the $Mn^{3+}$ cation replacing the $W^{6+}$. It is known that while the $W^{6+}$ cation is spherical and symmetric, the $Mn^{3+}$ cation causes a Jahn–Teller effect (compression or elongation). In this case, the presence of $Mn^{3+}$ determined by the previous magnetic susceptibility measurements confirms the Jahn–Teller effect, giving rise to an average compression of the $MnO_6$ octahedra involving a decrease of the apical bonds. This phenomenon is described in more detail in ref.[18]

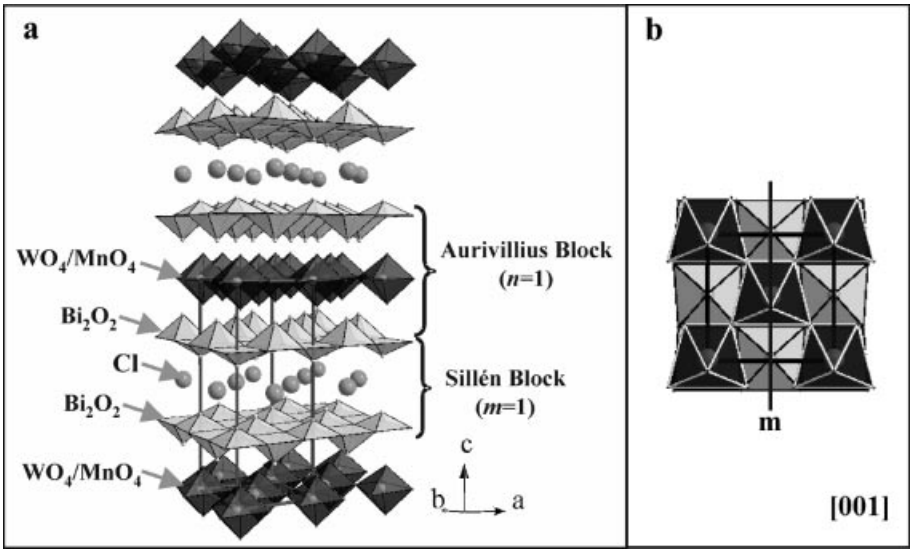

Figure 8. (a) Structure model of the Sillén–Aurivillius intergrowth $[Bi_2O_2][A_{n-1}B_nO_{3n+1}][Bi_2O_2][X_m]$ for $n$ = 1 and $m$ = 1. The stacking along $c$ shows the Aurivillius block with the octahedral sheet ($WO_4/MnO_4$) sandwiched between the square pyramidal layers ($Bi_2O_2$) and the Sillén one with a chlorine (Cl) monolayer. The unit cell is marked by a continuous line. (b) Structural projection along [001] showing in dark grey the distorted octahedra of the perovskite layer.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

These distorted polyhedra are shown in Figure 8 (b), where the structure of this new phase $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ is projected along [001], presenting the lower space group *Cm*2*m* (instead of *P*4/*mmm*) demonstrated previously by microdiffraction observations.

## Conclusions

A new phase with nominal composition $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ is synthesised. The composition and homogeneity of the sample is determined by XEDS and EELS, whereas the oxidation state of $Mn^{3+}$ is confirmed by magnetic susceptibility measurements.

The unit-cell symmetry and the space group are determined from microdiffraction and SAED experiments yielding an orthorhombic unit cell ($a \approx b$ = 5.4 Å and $c$ = 14.1 Å) with space group *Cm*2*m*. A direct structural model is retrieved from a focal series of HREM images along the [1–10] zone axis. From the phase of the reconstructed exit-wave the projected coordinates can be directly determined. This model is used as input for a Rietveld refinement of the powder X-ray diffraction data.

## Experimental Section

**Preparation of the Samples:** A polycrystalline sample with nominal composition $Bi_4Mn_{1/3}W_{2/3}O_8Cl$ was prepared by heating stoichiometric amounts of the oxides $Bi_2O_3$ (4N), $WO_3$ (4N), $Mn_2O_3$ (4N) and BiOCl (4N) at 993 K for a week in an evacuated ($P$ = $10^{-4}$ Torr) sealed silica tube. The sample was then slowly cooled to room temperature for 24 h.

**Characterisation Techniques:** Samples for transmission electron microscopy (TEM) were prepared by ultrasonic dispersion of the crystals in *n*-butanol. Drops of this dispersion were deposited on a holey carbon-coated copper grid. A JEOL 2000FX equipped with a LINK ISIS 300 analyser was used for XEDS analysis, microdiffraction and SAED. The EEL spectra were acquired using a Philips CM200 FEG TEM equipped with a Gatan Image Filter (GIF) 200. High-resolution electron microscopy (HREM) was performed using a JEOL 3000F TEM and a Philips CM30 FEG TEM, yielding an information limit of 1.1 Å. The exit wave was reconstructed from the focal series using TrueImage software.[21] HREM image simulations were performed with NCEMSS software.[22]

X-ray powder diffraction patterns were recorded with a Siemens D-501 (Cu-$K_{\alpha 1}$ radiation $\lambda$ = 1.5406 Å) over the angular range 10–100°, with a step scan of 0.04°. Rietveld full-profile refinement was done with the FULLPROF program.[23] A pseudo-Voigt function was chosen to generate the line shape of the diffraction peaks. In the final runs, the following parameters were refined: scale factor, background point to point, unit-cell parameters, asymmetry parameters, positional coordinates and isotropic thermal parameters. Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-416293.

Magnetic susceptibility measurements were performed on polycrystalline samples between 2 and 300 K, using a Quantum Design SQUID MPMS-X.

# Ten-Coordinate Neodymium(III) Complexes with Triethylenetetraaminehexaacetic Acid

**Anna Mondry*[a] and Przemysław Starynowicz[a]**

*Dedicated to our teacher and friend Professor Krystyna Bukietyńska*

**Keywords:** Chelates / Lanthanides / N ligands / Neodymium / UV/Vis spectroscopy

The crystal structures and spectroscopic (IR, Raman, UV/Vis) data for the complexes $[C(NH_2)_3]_2[Nd(HTTHA)]\cdot 3H_2O$ (**I**) and $[C(NH_2)_3]_3[Nd(TTHA)]\cdot 6H_2O$ (**II**) are presented. Crystals of **I** are triclinic, $P\bar{1}$, $a$ = 9.998(2), $b$ = 10.730(2), $c$ = 15.557(3) Å, $\alpha$ = 106.89(3)°, $\beta$ = 90.27(3)°, $\gamma$ = 93.24(3)°, $V$ = 1594.0(5) Å$^3$, $Z$ = 2, while the chiral crystals of **II** are monoclinic, $P2_1$, $a$ = 10.157(2), $b$ = 15.958(3), $c$ = 12.788(3) Å, $\beta$ = 112.68(3)°, $V$ = 1912.5(7) Å$^3$, $Z$ = 2. Both structures consist of the complex monomeric anions, guanidinium cations and water of hydration. The $Nd^{III}$ ions are ten-coordinate. The TTHA ligand coordinates to the $Nd^{III}$ ions with six of its carboxyl oxygen atoms and four nitrogen atoms. Although the coordination environments of both $Nd^{III}$ cations are essentially the same, the spectral results of both crystals reveal the influence of the degree of protonation of the ligand on the $Nd^{III}$ ion. The IR and Raman spectra allowed us to assign some important frequencies. A comparison of the electronic absorption spectra of $Nd^{III}$–TTHA complexes in solution and in single crystals of **I** and **II** allows the detection of a small elongation of the Nd–O and Nd–N bonds in these complexes as compared to the $[Nd(TTHA)]^{3-}$ moiety in the previously reported complex $Na_3[Nd(TTHA)]\cdot 2.5NaClO_4\cdot 7.617H_2O$ and indicates that the coordination geometry of the ten-coordinate neodymium complex in solution is the same as in the chiral crystal **II**. The intensities of the f–f transitions in $Nd^{III}$–TTHA solutions and of crystals **I** and **II** were analysed on the basis of the Judd–Ofelt theory.

## Introduction

The wide variety of biomedical applications of lanthanide complexes with polyamino polycarboxylic acids, including their use as contrast agents in MRI[1] and X-ray[2] diagnosis, NMR hyperfine shift-reagents[3] and bioanalytical assays,[4] is the reason for their being extensively investigated both in solution and in the solid state. The principal aim of these studies is to understand the physicochemical properties of these compounds in solution. In the case of lanthanide systems, one of the methods of choice is electron spectroscopy. Effective analysis of the spectroscopic data is, however, not a trivial task since the properties of these systems are dominated by the intraconfigurational f–f transitions, which are slightly influenced by the ligand field. Therefore, the results obtained by spectroscopic and electrochemical methods concerning the structure of complexes in aqueous solution are difficult to interpret. The situation is even more complicated in the case of lanthanide complexes with ligands characterised by a great number of functional groups, and tautomeric species of variously protonated donor groups of the ligand may be a reason that differently coordinated lanthanide species of diverse labilities coexist in solution. The lanthanide complexes with triethylenetetraaminehexaacetic acid ($H_6TTHA$), a ligand which has a sufficient number of donor atoms (six oxygen atoms and four nitrogen ones) to completely fill the first coordination sphere of the $Ln^{III}$ ion, well exemplify the problems related to lanthanide species in solution. The absence of inner-sphere water molecules for $Ln^{III}$–TTHA solutions at pH above 3 has been proved by emission spectroscopy[5,6] as well as NMR studies,[7] and was also confirmed in the crystal structures.[8–16] Previously, the coexistence of two distinct complexes of $Eu^{III}$–TTHA in solution over the entire pH range has been reported.[5,17] This is different to the $La^{III}$–TTHA system, where the $^1H$ and $^{13}C$ NMR spectra revealed the existence of only one coordination arrangement around the metal cation in solution.[5] Our results based on the optical properties of $Nd^{III}$,[8,16] $Eu^{III}$[17,18] and $Ho^{III}$[13] complexes with TTHA revealed that species differing in the number of coordinated nitrogen and oxygen atoms, namely $[Ln(N_4O_6)]^{3-}$/$[Ln(N_3O_6)]^{3-}$ and $[Ln(N_4O_5)]^{3-}$/$[Ln(N_3O_6)]^{3-}$, are present in the solution for the light and heavy lanthanide ions, respectively. Each of these species may form various stereoisomers, some of which may be op-

tically active. Circularly polarized luminescence (CPL) spectroscopy following photoselective excitation has demonstrated the presence of the optically active enantiomers in a racemic mixture for the $Eu^{III}$–TTHA system.[19]

Although many structural relationships among $Ln^{III}$–TTHA complexes in solution are still unresolved, the spectroscopic results obtained for single crystals of these complexes are very helpful in understanding the background of the various processes that may occur in solution. Since the spectral properties of lanthanide complexes with TTHA in crystals, particularly those of $Nd^{III}$–TTHA crystals,[8,16] play an important role in determining the structure of $[Nd(TTHA)]^{3-}$ solution species, it seems advisable to examine the influence of the protonation degree and the countercation on the spectral properties of these complexes. In this paper we therefore report the crystal structures and UV/Vis spectroscopic data of crystalline guanidinium salts of the monoprotonated and deprotonated $Nd^{III}$–TTHA complexes in order to compare their spectral properties with the sodium salt of the $Nd^{III}$–TTHA complex in the crystal[8] and in aqueous solution at various pH values.

## Results and Discussion

### Crystal Structures

The crystal structures of $[C(NH_2)_3]_2[Nd(HTTHA)]\cdot 3H_2O$ (crystal **I**) and $[C(NH_2)_3]_3[Nd(TTHA)]\cdot 6H_2O$ (crystal **II**) were determined and it was found that **I** is isomorphic with $[C(NH_3)_2][La(HTTHA)]\cdot 3H_2O$.[9] The crystals of both compounds are composed of complex $Nd^{III}$–TTHA anions, guanidinium cations and water of crystallisation. As the TTHA anion is hexa-negative, a proton must be present in **I** to compensate the deficiency of the positive charge caused by the $Nd^{III}$ ion and two guanidinium cations. The complex anions in both crystals are similar (Figure 1) and are composed of the TTHA residue wrapped around the neodymium cations. The metal ions are ten-coordinate, forming bonds with six carboxylic oxygen atoms and four nitrogen ones in each complex. The Nd–O and Nd–N bond lengths for **I** and **II** (Table 1) are typical and are similar to those found for the complex $Na_3[Nd(TTHA)]\cdot 2.5NaClO_4\cdot 7.617H_2O$,[8] denoted here as **Na1**. The differences between the positions of the atoms in both anions are most pronounced for the outer-sphere carboxylate oxygen atoms, which is most probably caused by different networks of hydrogen bonds. For example, the O(10) atom in **I** is involved in a short (2.67 Å) H-bond with a water molecule and a moderate bond with a guanidinium cation (O···N = 2.91 Å), whereas in **II** the O(10) atom forms three H-bonds of moderate lengths (2.87–3.08 Å) with two water molecules and a guanidinium cation. The proton that is necessary for the electric charge compensation in **I** is probably attached to O(12) as the C(17)–O(12) distance of 1.306(4) Å is about 0.05 Å longer than the other C–O bond lengths.

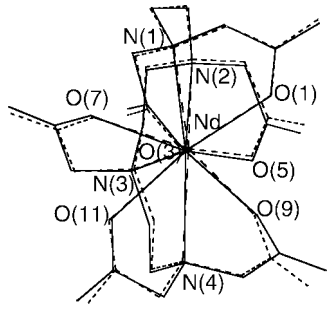

Figure 1. A view of the superimposed complex anions of **I** and **II**. The dashed lines represent **I** and the solid ones **II**. The atoms labels are given for the neodymium coordination sphere only, for the sake of clarity.

### Spectral Results

#### *IR and Raman Spectra of Crystals*

A comparison of the IR and Raman spectra of **I** and **II** with the spectra of **Na1** and $H_6TTHA$ allowed us to assign some important frequencies. These are given in Table 2. The IR bands of the three crystals **I**, **II** and **Na1**, in which the coordination environment ($N_4O_6$) around the $Nd^{III}$ ion is the same, are displayed in Figure 2 (A). The vibrations of the OH and $CH_2$ groups, as well as of the $NH_2$ group in the case of the guanidinium crystals, occur in the broad and intense IR band located in the range 2750–3750 $cm^{-1}$. Since

combinations and/or overtones transitions may also appear in this spectral region, only the ν(OH) frequency of crystal water molecules can be unequivocally assigned. The positions of the ν(OH) peaks found in the three crystals may indicate that the overall strength of the hydrogen bond between water molecules and the polyatomic anion is the weakest in the case of **Na1** (Table 2). Broad bands of the $\nu(NH_2)$ mode were found in the Raman spectra of **I** and **II**. These vibrations, which are due to the guanidinium cation, appear in the range 3200–3400 $cm^{-1}$, where a combination band of the $\delta(NH_2)$ and $\nu_{as}(COO)$ overtones also appears. The positions of the $\nu(CH_2)$ oscillations in the IR spectra agree well with those very intense found in the Raman spectra. For both guanidinium crystals a strong band of the $\delta(NH_2)$ vibration was found in the region of 1650–1700 $cm^{-1}$. The $\nu_{as}(COO)$ frequencies of the studied crystals are very similar, with the highest frequency being found for **Na1**. The presence of a protonated carboxylate group in **I**, as the long $Nd^{III}$–O(11) distance attests (Table 1), is the reason for a much broader and split band of the $\nu_s(COO)$ vibration in **I** as compared with the bands of **II** and **Na1**.

The difference, $\Delta$, between the antisymmetric and symmetric frequencies of the carboxylate groups has been suggested to be an indicator of the share of the M–O(COO) bond covalency,[20] the latter being higher when $\Delta$ increases. Accordingly, the $\Delta$ differences determined from the spectra of the three crystals were compared. Two values of $\Delta$ were found for the protonated crystal **I**. One of these differences was the highest one of all (200 $cm^{-1}$), while the second (187 $cm^{-1}$) is close to the $\Delta$ value of **Na1** (188 $cm^{-1}$). The smallest $\Delta$ was found for **II** (181 $cm^{-1}$). Comparing these $\Delta$ values with the structural data given in Table 1 one can see that they have no connection with the M–O bond lengths. A similar problem was encountered in the case of the $Nd^{III}$–N bond lengths, which may be reflected by the ν[C–$N(CH_2)$] modes. The smallest ν[C–$N(CH_2)$] frequency was found in the case of **I** (1116 $cm^{-1}$), whereas the ν(C–N) vibrations of **II** (1120 $cm^{-1}$) and **Na1** (1121 $cm^{-1}$) are similar to that of the ligand (1125 $cm^{-1}$). For both guanidinium crystals the most intense Raman bands of 1007 $cm^{-1}$ were assigned to the ν[C–$N(NH_2)$] vibrations of the guanidinium cation. All ν(C–C) frequencies of the three crystals are blue-shifted relative to the frequency of the $H_6$TTHA ligand.

Although some similarity between the IR spectra of the crystals can be seen (Figure 2, **A**), one cannot say the same about their NIR spectra. These spectra, recorded at room temperature and 4 K, are shown in Figure 2 (**B**). Apart from the oscillation bands, the electronic $^4I_{9/2} \rightarrow {}^4I_{15/2}$ transition can also be observed in this region. Recently, we have shown that the f–f transitions in this spectral region are seriously affected by coincident combination and/or overtone bands.[21,22] The present data also reveal that these

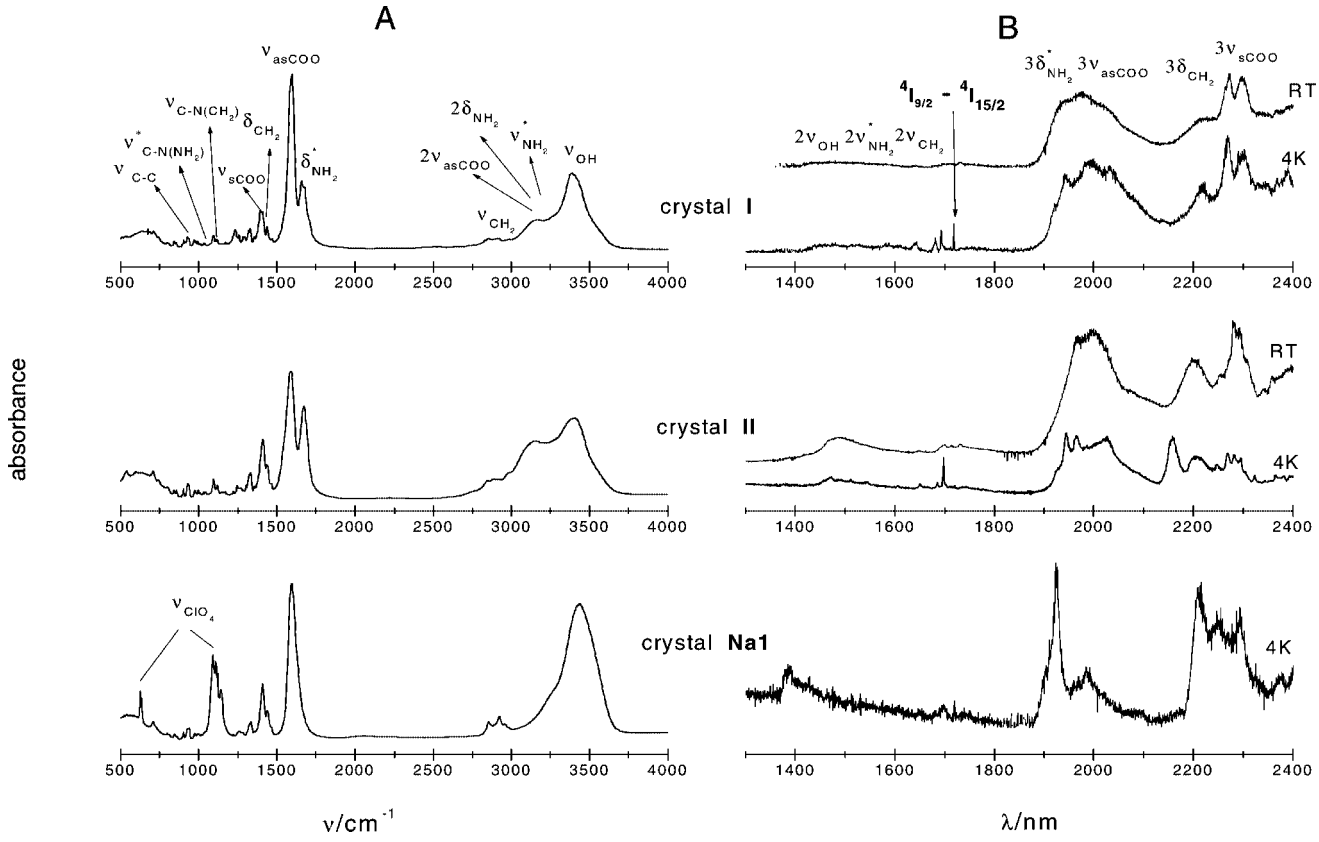

Figure 2. **A** – IR (powder crystals with KBr) and **B** – NIR (single crystals) spectra of $Nd^{III}$–TTHA complexes in **I**, **II** and **Na1**. Some identified bands are labelled, asterisks respond to bands of the guanidinium cation.

bands strongly dominate the f–f transitions of the $Nd^{III}$ ion in the NIR region and this domination is different for the three non-isomorphic crystals studied.

### *UV/Vis Spectra of the $Nd^{III}$–TTHA Complex in Solutions and in Single Crystals*

Two transitions in the $Nd^{III}$ absorption spectrum, namely $^4I_{9/2} \rightarrow {}^2P_{1/2}$ and $^4I_{9/2} \rightarrow {}^4G_{5/2}/{}^2G_{7/2}$, are particularly suitable to perform studies of equilibria changes between different species of the $Nd^{III}$–TTHA complex in solution. The peak positions in the first transition indicate splitting of the ground level in the ligand field of the $Nd^{III}$ environment, whereas the intensity of the hypersensitive $^4I_{9/2} \rightarrow {}^4G_{5/2}/{}^2G_{7/2}$ transition is influenced the most among all the f–f transitions by changes in the immediate surrounding of the $Nd^{III}$ ion.

#### *Analysis of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ Transition*

As can be seen from the equilibria variations between different species for sodium salts of $Nd^{III}$–TTHA solutions, exemplified by the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition in Figure 3, the shape and intensity of these bands do not change further when the pH of the solution exceeds 4. This observation is true for all f–f transitions in spectra of $Nd^{III}$–TTHA solutions for which the pH was adjusted with either NaOH or $[C(NH_2)_3]_2CO_3$. It can easily be seen from Figure 3 that the number of Stark components in the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ spectra of all studied solutions exceeds five, the number of optical lines predicted by group theory for a single environment of the $Nd^{III}$ ion. This means that for $Nd^{III}$–TTHA solutions at least two complexes with a different coordination arrangement around the metal ion exist over the entire pH range. At low pH, the peak maximum of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition is at 23248 $cm^{-1}$, whereas for solutions at pH above 3 it appears at 23310 $cm^{-1}$. The positions of these peaks correspond to the two different coordination cores of the lanthanide ion found in the previously studied single crystals of the $Nd^{III}$–TTHA complexes.[8,16] The neodymium entities in those crystals, which were obtained as sodium salts from the same mother liquor at pH 4.5, are $[Nd_2(N_3O_6)_2]^{6-}$ (peak maximum at 23231 $cm^{-1}$)[16] and $[Nd(N_4O_6)]^{3-}$ (peak maximum at 23302 $cm^{-1}$).[8] From the comparative studies of UV/Vis spectra of single crystals and the solution at pH 7.65 it was proved that the $[Nd(N_3O_6)]^{3-}$ and $[Nd(N_4O_6)]^{3-}$ species are present in this solution in the molar ratio of 1:4.[16] As can be seen from Figure 3, the highest concentration of the first species appears in the solution at a pH below 3, whereas the second species dominates in solution at a pH above 3.5. Hence, one could expect that crystals obtained from solutions in which one of these species prevails will contain this species. Since attempts to obtain crystals from solutions containing sodium cations at very low pH failed, the guanidinium salt solutions were used. The $^4I_{9/2} \rightarrow {}^2P_{1/2}$ spectra of crystals **I** and **II** and solutions from which they were obtained are presented in Fig-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 4. Comparing the sodium (Figure 3) and guanidinium (Figure 4) spectra of $Nd^{III}$–TTHA solutions one can see that a nine-coordinate species with a peak maximum at 23248 $cm^{-1}$ for the sodium solution and 23254 $cm^{-1}$ for the guanidinium solution prevails at a pH below 3. However, the ten-coordinate form is more favoured upon crystallisation in the presence of guanidinium cations. Although the coordination environment of the lanthanide cation is essentially the same in crystals of **I** and **II**, small differences between the bond lengths and angles bring about changes in the position of the $^2P_{1/2}$ state. It is worthwhile noting that the first two peaks in the spectrum of the chiral crystal **II** exactly match the first two peaks of the $Nd^{III}$–TTHA solution at a pH above 4.

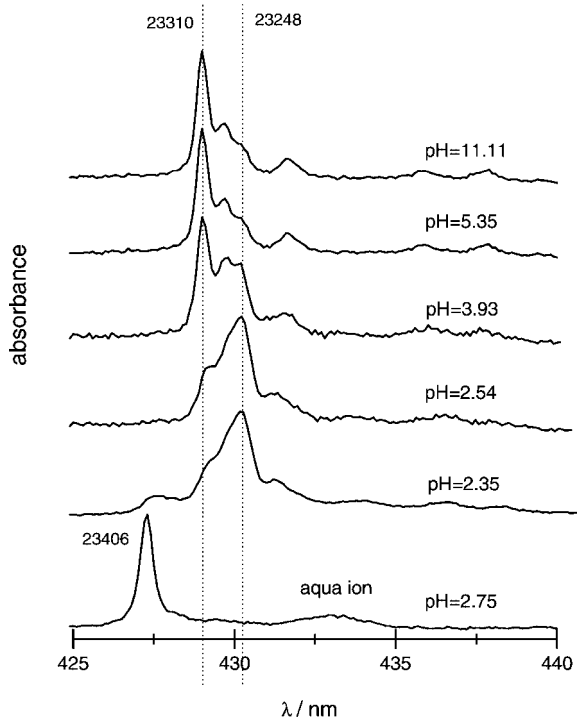

Figure 3. Absorption spectra of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition of the $Nd^{III}$–TTHA complex in solutions at different pH values adjusted by NaOH ($c_{Nd}$ = 2.219·10$^{-2}$ M, $d$ = 2 cm).

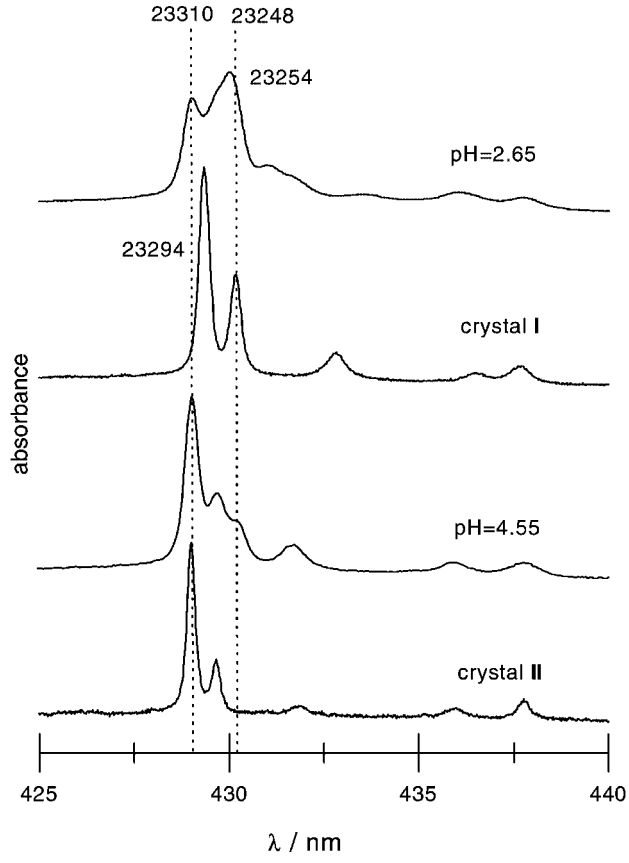

Figure 4. Absorption spectra of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition of guanidinium salts of the $Nd^{III}$–TTHA complex in solutions and in crystals obtained from these solutions (in solutions: $c_{Nd}$ = 5·10$^{-2}$ M, $d$ = 2 cm; in crystals: $c_{Nd}$ = 2.270 M, $d$ = 0.031 cm for **I** and $c_{Nd}$ = 1.898 M, $d$ = 0.059 cm for **II**).

The positions of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ peaks and the splittings of the neodymium $^4I_{9/2}$ ground state by the ligand field in the $Nd^{III}$–TTHA solutions at pH above 4 and in crystals of **Na1**,[8] **Na2**[16] (where **Na2** are crystals of $Na_{0.5}H_{5.5}[Nd_2(TTHA)_2]\cdot 7.5NaClO_4\cdot 16.83H_2O$ with the $[Nd_2(N_3O_6)_2]^{6-}$ core) as well of **I** and **II** are given in Table 3.

As it can be seen from Table 3 and Figure 4, the second intense peak in the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ spectrum of **I** has the same position as the peak that belongs to the $[Nd(N_3O_6)]^{3-}$ species. Therefore, to be sure that the peak at 23248 $cm^{-1}$ in

solution belongs to the nine-coordinate species, the solution at pH 7.8 (NaOH) was frozen. It was shown previously that only monomeric species exist in solution at this pH value.[6,23] The $^4I_{9/2} \rightarrow {}^2P_{1/2}$ spectrum of this solution, as well as of both sodium and guanidinium crystals recorded at 4 K, are displayed in Figure 5. The spectrum of the frozen solution shows a very intense peak at 23310 $cm^{-1}$ and a very weak shoulder at 23248 $cm^{-1}$, which confirms the domination of the $[Nd(N_4O_6)]^{3-}$ species over the $[Nd(N_3O_6)]^{3-}$ one and that the peak at 23248 $cm^{-1}$ in the solution indeed represents the nine-coordinate form.

The peak maxima of the deprotonated sodium (**Na1**) as well as guanidinium (**II**) crystals do not shift on cooling the samples down to 4 K, whereas the peak at 23294 $cm^{-1}$ in the spectrum of **I** at room temperature splits into two with energies of 23302 and 23293 $cm^{-1}$ at 4 K. Since in all the spectra of **I** at 4 K there are more lines than would be expected from the relevant multiplicities ($J$ + 1/2), one can assume that a phase transition occurs in **I** below room temperature. This phase transition may also be reflected in the value of the oscillator strength ($P$) determined at 4 K. The smaller decrease of $P$ in the spectra of crystal **I** than those of crystal **II** at 4 K in comparison with the respective $P$ values determined at room temperature can readily be seen from the $P_{exp}$ results given in Table 4.

It should be pointed out that for crystals of **Na1** and **II**, for which no phase transition is observed, all f–f transitions in the spectra of **Na1** at 4 K are similarly, as can be seen for the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ spectrum, broadened and red-shifted in relation to the spectra of crystal **II**. This may result from vibrational lattice and/or internal ligand modes coupled with the excited levels. This coupling is apparently much weaker for the chiral crystal.

The non-degeneracy of the $^2P_{1/2}$ level means that its shift can be used to study the nephelauxetic effect in neodymium

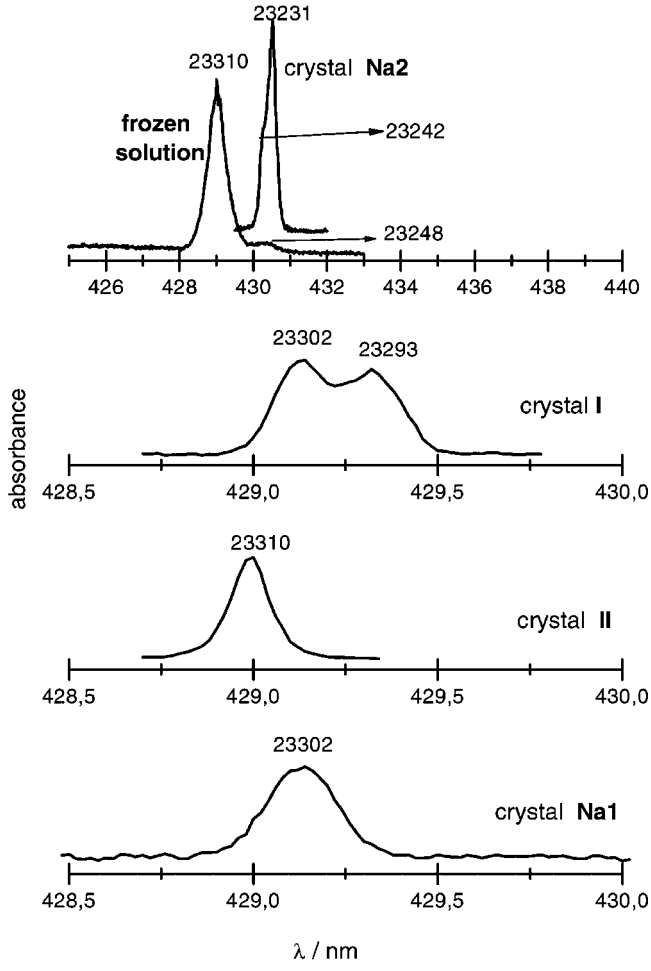

Figure 5. Absorption spectra of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition of the frozen $Nd^{III}$–TTHA solution with pH 7.8 and crystals of **I**, **II**, **Na1**[8] and **Na2**[16] at 4 K.

systems. This effect is interpreted as a covalent contribution to the bonding between the metal ion and the ligands and is connected with metal–ligand distances and coordination numbers.[24] However, a comparison of the structural data given in Table 1 with the spectroscopic data of the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition of $[Nd(N_4O_6)]^{3-}$ crystals contradicts this interpretation: of the three $[Nd(N_4O_6)]^{3-}$ crystals, the smallest $Nd^{III}$–O and $Nd^{III}$–N distances are found in the sodium crystal, but the spectral results of this crystal do not reflect this in a decrease of the $^2P_{1/2}$ energy level. The $^2P_{1/2}$ energy level shifts, however, agree well with the $\Delta$ differences between the $\nu_{as}$ and $\nu_s$ frequencies of the carboxylate groups. Therefore, our results seem to indicate that the nephelauxetic effect is caused by the change of local polarizability within the inner sphere of the metal ion.

*Analysis of the Hypersensitive Transition and f–f Intensities*

A comparison of the f–f transitions of all $Nd^{III}$–TTHA crystals as well as of the solution at pH 5.35, for which there is no difference in the spectra when the pH is adjusted with either NaOH or $[C(NH_2)_3]_2CO_3$, is shown in Figure 6. From the presented spectra, one can see a very good correspondence between the spectra of the monomeric sodium crystal **Na1** of the $[Nd(N_4O_6)]^{3-}$ complex and the solution, in spite of the fact that the presence of 20% of the $[Nd(N_3O_6)]^{3-}$ species was evidenced in the solution.[16] The remarkable similarity of the band shape and the intensities of the most intense f–f transitions between the spectra of the solution and the crystal of **Na1** is not preserved in the case of the protonated crystal **I** or in the deprotonated crystal **II**. For the latter crystal, although the shape of the f–f bands corresponds, to a considerable degree, to that of the solution, the intensity of the $^4I_{9/2} \rightarrow {}^4G_{5/2}/{}^2G_{7/2}$ transition is significantly lower. It is worthwhile stressing that the discussed crystals show low optical anisotropy, as measured by the difference of the intensities of various f–f transitions with different light polarisations and crystal orientations. The intensity results for solutions at different pH values adjusted by NaOH, as well as of crystals of **I** and **II**, are collected in Table 4. An inspection of the oscillator strengths given in this table shows that the largest differences between experimentally determined $P$ values of solutions and crystals occur for the hypersensitive transition. The oscillator strengths of the $^4I_{9/2} \rightarrow {}^4G_{5/2}/{}^2G_{7/2}$ transition of both guanidinium crystals are about two times smaller than those calculated for the solution in which the $[Nd(N_4O_6)]^{3-}$ species dominates. One might suppose that the discrepancies between the $P$ values of the solution and crystals may result from a more symmetrical arrangement of the first coordination sphere in the single crystal. However, this is not the case. In the case of the sodium crystal **Na1**, the $^4I_{9/2} \rightarrow {}^4G_{5/2}/{}^2G_{7/2}$ intensity ($P = 2076.51 \times 10^{-8}$)[8] is higher than that of the solution. Recalculation of the oscillator strengths of the most intense transitions, namely $^4I_{9/2} \rightarrow {}^4G_{5/2}/{}^2G_{7/2}$ (560–600 nm), $^4I_{9/2} \rightarrow {}^4S_{3/2}/{}^4F_{7/2}$ (720–770 nm) and $^4I_{9/2} \rightarrow {}^2H_{9/2}/{}^4F_{5/2}$ (770–830 nm), of the solution at a pH above 4.5 with the $P$ values determined for both **Na1**[8] and **Na2**[16] crystals and the percentage shares of both species reproduces well the oscillator strengths determined experimentally for the solution. This experimental fact is noteworthy, since it can be a helpful indicator of the hypersensitivity mechanism. The small decrease of metal–ligand bond lengths of the crystal **Na1** as compared with

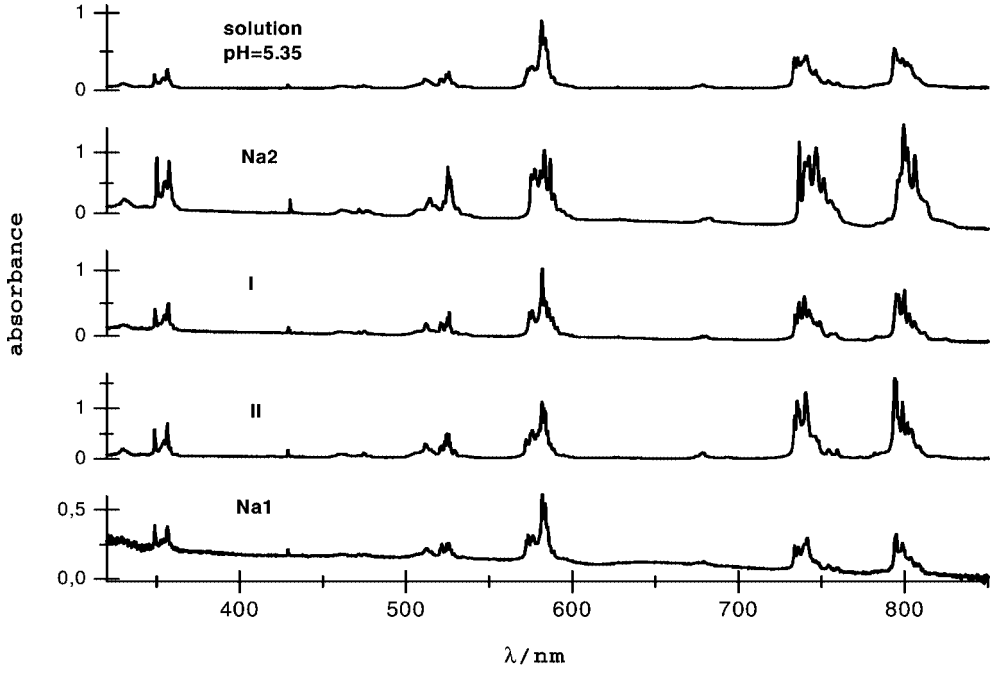

Figure 6. Absorption spectra of f–f transitions of the $Nd^{III}$–TTHA complex in solution at pH 5.35 ($c_{Nd}$ = 2.219·10$^{-2}$ M, $d$ = 2 cm) and in crystals **Na2** ($c_{Nd}$ = 1.631 M, $d$ = 0.147 cm), **I** ($c_{Nd}$ = 2.270 M, $d$ = 0.031 cm), **II** ($c_{Nd}$ = 1.898 M, $d$ = 0.059 cm) and **Na1** ($c_{Nd}$ = 1.671 M, $d$ = 0.0145 cm).

guanidinium crystals (Table 1) is probably a reason for the intensity enhancement in **Na1**. We also note that somewhat different factors affect the intensities of the hypersensitive transition and the position of the dominant peak in the $^4I_{9/2} \rightarrow {}^2P_{1/2}$ transition discussed above.

## Conclusions

Continuing our previous investigations of the structures and spectroscopic properties of complexes of TTHA with lanthanides, we have obtained crystals of two new complexes, namely $[C(NH_2)_3]_2[Nd(HTTHA)]\cdot 3H_2O$ and $[C(NH_2)_3]_3[Nd(TTHA)]\cdot 6H_2O$. The use of different countercations (guanidinium in the present compounds and sodium in our previous reports) has enabled us to observe their role in crystal formation as well as their influence on the spectroscopic properties of the investigated crystals. The complex anions $[Nd(TTHA)]^{3-}$ are monomeric and the neodymium cations are ten-coordinate in both crystals described. Although the coordination environment in both the present complexes is similar to that found in a previously published sodium salt,[8] the oscillator strengths of the hypersensitive transition differ remarkably. This may be attributed to the small differences of the Nd–O and Nd–N bond lengths, which may in turn be induced by networks of H-bonds, strong in the case of guanidinium crystals and competing with the Na–O electrostatic interactions in the case of the sodium crystal.

## Experimental Section

**Material and Sample Preparation:** A stock solution of neodymium perchlorate was prepared from $Nd_2O_3$ (99.9% Merck). The $Nd^{III}$ concentration was determined complexometrically using xylenol orange as indicator. The stock solution of $H_6TTHA$ (98% Aldrich) was prepared by half-neutralisation with NaOH. The NaOH solution was also used to adjust the pH of the investigated solutions. All measured solutions were prepared with the same ionic strength (0.5 M $NaClO_4$). Crystals of neodymium with the TTHA ligand were prepared by a slightly different method to that described by Ruloff et al.[9] The molar ratio of the applied parent substances of $Nd_2O_3$, $H_6TTHA$ and $[C(NH_2)_3]_2CO_3$ was 1:2:2. The mixture of substrates was dissolved in water and the pH of the resulting solution was 2.65. This solution was divided into two portions, one of which was basified with guanidinium carbonate to a final pH of 4.55. These solutions of pH 2.65 and 4.55 were left to crystallise and large, well-formed violet crystals of the formula $[C(NH_2)_3]_2[Nd(HTTHA)]\cdot 3H_2O$ and $[C(NH_2)_3]_3[Nd(TTHA)]\cdot 6H_2O$, denoted as **I** (pH 2.65) and **II** (pH 4.55), were obtained. The $Nd^{III}$ concentration in these crystals, determined by ICP, was 2.270 M for **I** and 1.898 M for **II**. **I**: calcd. C 29.71, H 5.20, N 17.33, Nd 17.85; found C 29.23, H 5.45, N 16.87, Nd 19.26. **II**: calcd. C 27.36, H 5.86, N 19.76, Nd 15.66; found C 27.77, H 5.75, N 19.96, Nd 17.11. The density of **I** and **II** was measured by the flotation method in $CH_3Cl$ and $CH_3Br$ and was found to be 1.70 and 1.60 g cm$^{-3}$, respectively. The refractive index, $n$, of the crystals was assumed to be 1.50 and that of the measured solutions 1.33.

**Crystal Structure Determinations of Complexes I and II:** Data for **I** and **II** were collected on a Kuma KM4 diffractometer equipped with a CCD counter. The structures were solved by Patterson methods with SHELXS-97[25] and then refined with SHELXL-97.[26] The C- and N-bonded hydrogen atoms were placed in geometrically calculated positions. All non-H atoms were refined anisotropically. The temperature factors for H-atoms were set as 1.2-times the factors of the C or N atoms to which they are bonded. For **II** the enantiomorph with the better Flack parameter [–0.019(15)] was chosen.

**Crystal Data for I:** $[C(NH_2)_3]_2[Nd(HTTHA)]\cdot 3H_2O$, $C_{20}H_{43}N_{10}NdO_{15}$, $M$ = 807.88, triclinic, $P\bar{1}$, $a$ = 9.998(2), $b$ = 10.730(2), $c$ = 15.557(3) Å, $\alpha$ = 106.89(3)°, $\beta$ = 90.27(3)°, $\gamma$ = 93.24(3)°, $V$ = 1594.0(5) Å$^3$, $Z$ = 2, $T$ = 293(2) K, $\mu$ = 1.711 mm$^{-1}$, number of reflections measured 11381, number of reflections observed [$I \geq 2\sigma(I)$] 6691, $R(F)$ = 0.0374, $R_w(F^2)$ = 0.0835.

**Crystal Data for II:** $[C(NH_2)_3]_3[Nd(TTHA)]\cdot 6H_2O$, $C_{21}H_{54}N_{13}NdO_{18}$, $M$ = 921.01, monoclinic, $P2_1$, $a$ = 10.157(2), $b$ = 15.958(3), $c$ = 12.788(3) Å, $\beta$ = 112.68(3)°, $V$ = 1912.5(7) Å$^3$, $Z$ = 2, $T$ = 293(2) K, $\mu$ = 1.445 mm$^{-1}$, number of reflections measured 5688, number of reflections observed [$I \geq 2\sigma(I)$] 4837, $R(F)$ = 0.0273, $R_w(F^2)$ = 0.0731.

CCDC-282725 (for **I**) and -282726 (for **II**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Spectroscopic Measurements and Calculations:** IR spectra of crystals and $H_6TTHA$ were recorded from KBr pellets on a Bruker FTIR IFS66 spectrometer, while FT-Raman spectra of powder samples were measured on a Bruker RFS 100/S spectrometer with a spectral resolution of 2 cm$^{-1}$. All electronic absorption spectra were recorded with a Cary 500 UV/Vis/near-IR spectrophotometer which was equipped with an Oxford CF 1204 continuous flow helium cryostat for single crystal measurements at 293 and 4 K.

The intensities of the 4f–4f transitions ($P$) and values of the $\Omega_\lambda$ parameters were calculated from the Judd–Ofelt[27,28] relation [Equation (1)]:

$$P = \chi \frac{8\pi^2 mc\sigma}{3h(2J+1)} \sum_{\lambda=2,4,6} \Omega_\lambda (f^n \psi J \| U^{(\lambda)} \| f^n \psi' J')^2 \quad (1)$$

where $P$ denotes the oscillator strength, $\chi = (n^2 + 2)^2/9n$ ($n$ is the refractive index), $J$ is the total quantum number of the ground state, $(f^n \psi J \| U^{(\lambda)} \| f^n \psi' J')$ is the reduced matrix element of the respective unit tensor operator $U^{(\lambda)}$, tabulated by Carnall et al.,[29] and $\Omega_\lambda$ is the empirical least-squares-fitted parameter.

# Synthesis of Polyamines from Ethylenediamine and Their Platinum(II) Complexes, Potential Antitumor Agents

**Mara Rubia Costa Couri,[a] Mauro Vieira de Almeida,[a] Ana Paula Soares Fontes,*[a] Joana D'Arc Souza Chaves,[a] Eloi Teixeira Cesar,[b] Ricardo José Alves,[c] Elene Cristina Pereira-Maia,[d] and Arlette Garnier-Suillerot[e]**

**Keywords:** Amines / Platinum / Antitumor agents

This work describes the synthesis and characterization of five new amine ligands and also the preparation and characterization of their respective platinum(II) complexes by reaction with $K_2PtCl_4$ in water. These ligands were obtained by treatment of different halides or epoxides with ethylenediamine. Cytotoxic activity and cellular accumulation of three complexes were investigated in a human small-cell lung carcinoma cell line and its cisplatin resistant subline. The introduction of a spacer (cycle) between the two platinum atoms leads to a significant decrease in cytotoxic activity. At equitoxic doses, the intracellular platinum concentrations found for compounds **12** and **15** were significantly higher than those found for the reference compounds, cisplatin, carboplatin, or compound **9**. This fact suggests that the formation of adducts between compounds **12** and **15** and the putative pharmacological target, DNA, is less favored. If these compounds bind more slowly to DNA, interaction with other intracellular ligands such as sulfur-containing molecules will become relevant and it may be the reason for the elevated intracellular platinum concentrations.

## Introduction

The polyamines spermidine (1,8-diamino-4-azaoctane) and spermine (1,12-diamino-4,9-diazadodecane), as well as the precursor molecule putrescine (1,4-diaminobutane), are polycation compounds that are found in significant amounts in nearly every prokaryotic and eukaryotic cell type.[1]

Many of these bases and their derivatives play key roles in a number of biological processes and possess a variety of pharmacological properties.[2] Polyamines may act as carcinogenesis promoting factors.[2,3] The connection between polyamines and cancer growth has been established by biological and molecular techniques.[4] Polyamines have been shown to accumulate in cancer tissues, and the concentration of polyamines and their derivatives increases in cancer patient fluids.[5–9] These compounds also represent an important target for chemotherapeutic intervention, since depletion of polyamines results in the disruption of a variety of functions and may, in specific cases, result in cytotoxicity.[10] Inhibitors of the polyamine pathway, therefore, have traditionally been developed as potential antitumor agents.[11]

Polyamines have multiple cellular functions that can interfere with cell growth and cell death. Therefore, their analogs can play an important role in controlling cancer. Compounds of this class can directly bind to DNA and modulate DNA–protein interactions. The production of hydrogen peroxide from polyamine catabolism might also be responsible for cell death or apoptosis.[12]

In addition to these facts, neutral ligands derived from amines have been utilized to prepare platinum(II) complexes since the discovery of the anticancer activity of cisplatin by Rosenberg et al.[13] *cis*-Diaminedichloroplatinum(II) (cisplatin, CDDP)[14] is one of the most widely used and effective oncological agents against cancers of the testicles, ovaries, bladder, head, and neck.[14–16] It is also an important adjunct for cancers of the lung, cervix, and breast.[16] However, its clinical usefulness has frequently been limited by severe side effects,[17–19] such as nephrotoxicity, ototoxicity, and neurotoxicity, and by the emergence of cancer cells resistant to cisplatin.

Tumor cells having the resistance phenotype exhibit a reduced sensitivity to cytotoxic drugs relative to sensitive cells. The molecular basis for resistance has been the subject of intensive research. Three main events are frequently observed: (i) decreased accumulation of the drug; the intracel-

lular drug concentration falls below the threshold necessary for cytotoxic activity; (ii) increased levels of sulfur-containing molecules, such as glutathione or metallothionein; these molecules could play a role in metal detoxification; and (iii) enhanced repair of DNA damage caused by cisplatin–DNA adducts.[20–22]

The need to overcome these problems, as well as to increase the antitumor activity of the platinum complexes, led to the development of structurally different compounds, which might act in different ways against the tumor cells.[23] The family of dinuclear complexes containing two monofunctional platinum spheres linked by a variable diamine chain has been extensively studied.[24] The first cytotoxic dinuclear platinum compounds described in the literature received special attention because they have shown a degree of cytotoxicity comparable to that of cisplatin in sensitive cell lines, but a significantly higher activity in acquired cisplatin-resistant cell lines.[25,26]

Since some substituted ethylenediamine platinum complexes have shown antitumor activity against a variety of cell tumors,[27,28] we sought to synthesize platinum(II) mono- and dinuclear complexes containing ethylenediamine derivatives as ligands. The novel compounds that were prepared may show a different reactivity towards DNA with the possibility of the formation of new adducts; they therefore may be active in cisplatin-resistant cell lines. In addition, compound **12** could possibly intercalate between the DNA base pairs because of its aromatic ring. Furthermore, we intended to prepare potentially active antitumor compounds in an attempt to combine the activity of the ligand to that of the metal.

## Results and Discussion

The intermediate **3** was obtained in 92% yield by the reaction of diol **2** with iodine, imidazole, and triphenylphosphane in toluene at reflux (Scheme 1). The diepoxide **8** (not isolated) was prepared by treatment of ditosylate **7** with sodium methoxide in methanol according to the procedure previously described in the literature.[29] The ligand **a** and complex **9** were prepared as described in ref.[26] The ligands **b**–**g** were prepared in satisfactory yields by treating ethylenediamine with the corresponding intermediate (halide or epoxide) in ethanol at room temperature for 24 h. In the preparation of the ligand *N*,*N*′-bis(2-aminoethyl)-2-xylylenediamine (**e**), we have also isolated the ligand *N*-(2-aminoethyl)-isoindoline (**f**). In the IR spectra, absorptions corresponding to $\nu_{N-H}$ at 3300–3100 $cm^{-1}$ can be observed for these ligands. In the $^1H$ and $^{13}C$ NMR spectra signals for the ethylenediamine moiety are observed.

The platinum(II) complexes **10**–**15** were obtained by the reaction of the corresponding ligands with potassium tetrachloroplatinate(II) in water at room temperature for 24 h, and were isolated by simple filtration (Scheme 2). Even though we have used 2 mmol of $K_2PtCl_4$ we have observed that under these reaction conditions, ligand **c** was transformed into the mononuclear platinum(II) complex **11**. For these compounds, one may observe IR spectra absorptions corresponding to $\nu_{Pt-N}$ and $\nu_{Pt-Cl}$ at 550 and 325 $cm^{-1}$, respectively, in addition to the absorptions observed for the ligand. In the $^1H$ NMR spectra there is a downfield shift for the signals corresponding to NH and $NH_2$ relative to the free ligands. The $^{195}Pt$ NMR spectra for the complexes show only one signal, and the chemical shift values are expected to be close to those of similar compounds in which the platinum is coordinated to two chlorides and two nitrogens.[30]

### Cell Growth Inhibition

The $IC_{50}$ values obtained for complexes **9**, **12**, and **15** in sensitive and resistant cells, together with the resistant factor (RF) and the intracellular platinum concentration, Ci, are shown in Table 1. For the sake of comparison, cisplatin and carboplatin data are also shown. The GLC4/CDDP subline is 6.3-fold resistant to cisplatin and 1.4- to carboplatin.

The cytotoxic activity of the compounds decreases in the order **9** > **12** > **15**. The sensitivity of the GLC4 cell line to compound **9** is comparable to that of carboplatin, and the GLC4/CDDP subline is not cross-resistant to compound **9**. The cytotoxic activity of compounds **12** and **15** is very low relative to that of the reference compounds. For **12** the RF obtained is 2.9, and for **15** the RF is 1.2 (Figure 1). In other words, the GLC4/CDDP cells are 3- and 1.2 times less sensitive than the GLC4 cells to **12** and **15**, respectively.

### Platinum Accumulation

Resistance to cisplatin has been intensively studied in tumor cells repeatedly exposed to the drug in vitro. Among the numerous mechanisms of acquired resistance to cisplatin that have been reported, decreased accumulation is frequently present in resistant cells as a result of reduced drug uptake. In a previous study, we have determined the uptake rate of cisplatin, carboplatin, and aqua-substituted cisplatin in both GLC4 and GLC4/CDDP cell lines.[31] The sensitive cell line accumulates approximately twice as much cisplatin as the resistant subline, mainly by an energy-dependent mechanism. We have postulated that the uptake of cisplatin is composed of passive diffusion of the $[Pt(NH_3)_2Cl_2]$ species, which is neutral, and of an active uptake of an aqua-substituted species, probably the $[Pt(NH_3)_2(H_2O)OH]^+$ or $[Pt(NH_3)_2(H_2O)Cl]^+$ species. For carboplatin, the rate constant for the first aquation reaction is 100-fold lower than that for cisplatin. Therefore, the concentration of aquated species will be 100 times lower. The uptake rate of carboplatin is similar in both GLC4 and GLC4/CDDP cell lines because the active uptake becomes negligible. Therefore, carboplatin enters the cells mainly by passive diffusion, which is in accordance with the low RF observed for carboplatin (Table 1).

The cytotoxic activities of compounds **12** and **15** were much lower than those exhibited by cisplatin and by com-

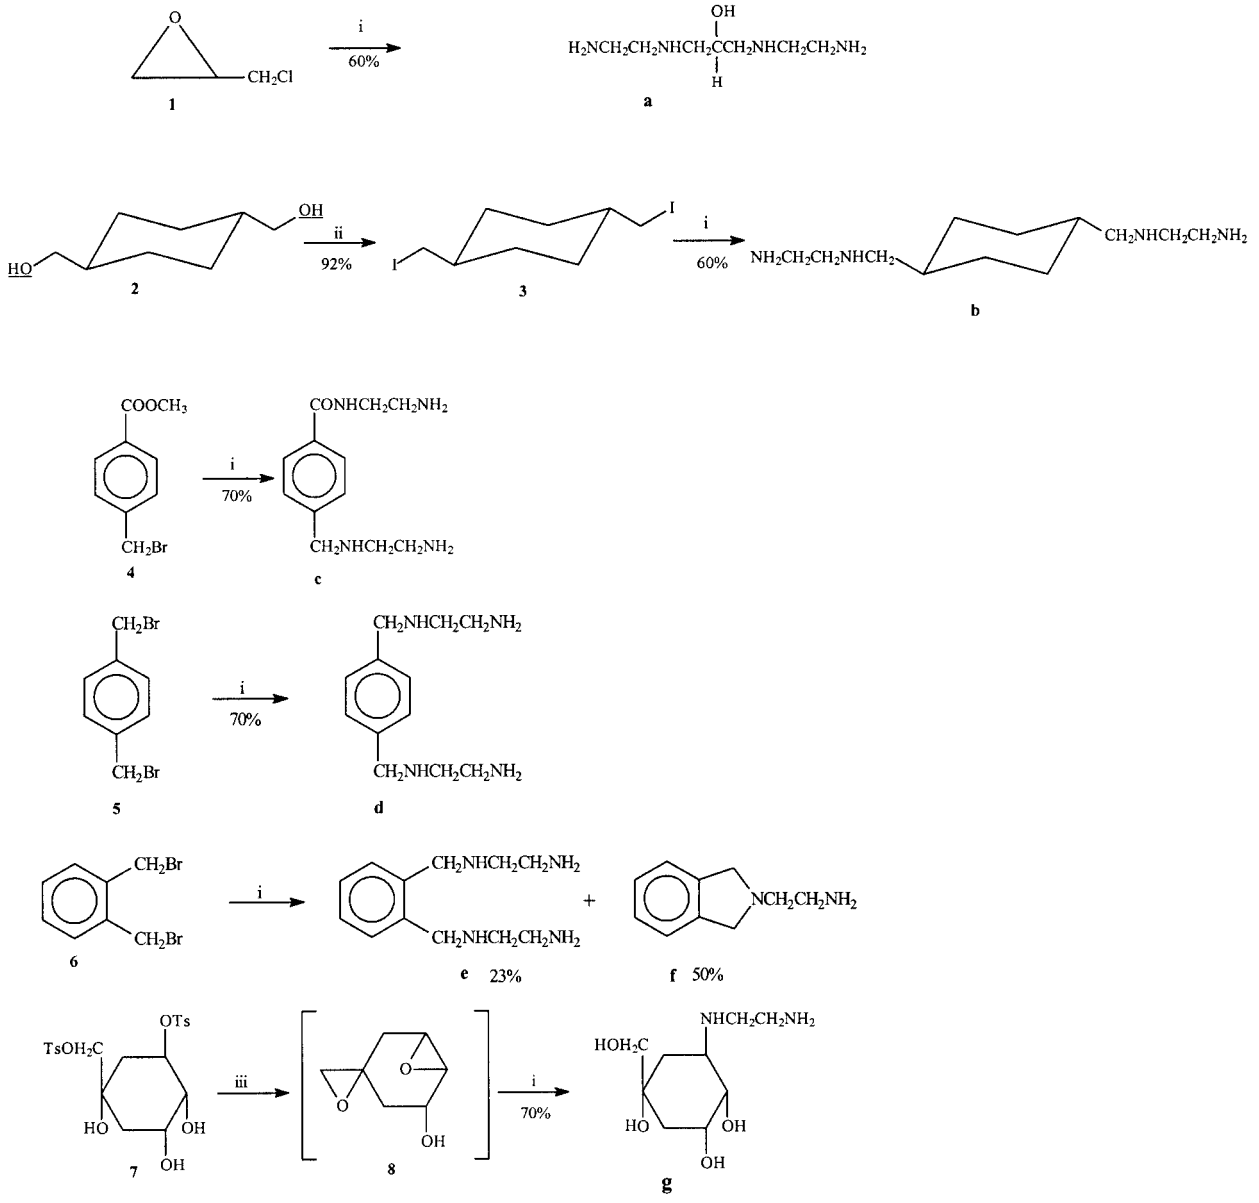

Scheme 1. Reagents and conditions: (i) $NH_2CH_2CH_2NH_2$/EtOH, reflux; (ii) $Ph_3P/I_2$/imidazole, toluene, reflux, 24 h; (iii) $MeO^-Na^+$/MeOH, room temp., 30 min.

pound **9**. These results can be explained by two possibilities: (i) the uptake of compounds **12** and **15** is very slow, thus a much higher concentration is needed to force their transport into cells (similar to the case of carboplatin when compared to cisplatin) or (ii) the interaction of the compounds with the pharmacological target, i.e. DNA, is deficient. In order to investigate whether the reason for this low activity is related to a deficient uptake, we have determined the intracellular platinum concentration after 72 h of incubation.

Let us first discuss the results obtained with the sensitive cell line. In a previous study, we found that cytotoxic activity correlates well with the intracellular drug concentration for cisplatin and carboplatin, and at $IC_{50}$, the intracellular platinum concentration was about $10 \times 10^{-17}$ mol/cell.[31] Furthermore, by studying the effect of some dinuclear platinum compounds, we also found that equitoxic platinum concentrations lead to similar intracellular platinum concentrations.[26]

Compound **9** exhibits the same behavior, for example, by incubating cells with the $IC_{50}$ dose, the intracellular concentration is approximately $10 \times 10^{-17}$ mol/cell. The ratio between the $IC_{50}$ of carboplatin and that of cisplatin is approximately 25, i.e. more carboplatin is needed to produce a cytotoxic effect because the former enters cells more slowly. Our results showed that the reason for the low cytotoxic activities of **12** and **15** was not an insufficient intracellular platinum concentration. On the contrary, the intracellular platinum concentrations found for compounds **12** and **15** were significantly higher than those found for the reference compounds, cisplatin and carboplatin, and compound **9**. For the sensitive cell line, at $IC_{50}$ values, the intracellular platinum concentrations were 14.9- and 9.3-fold higher for

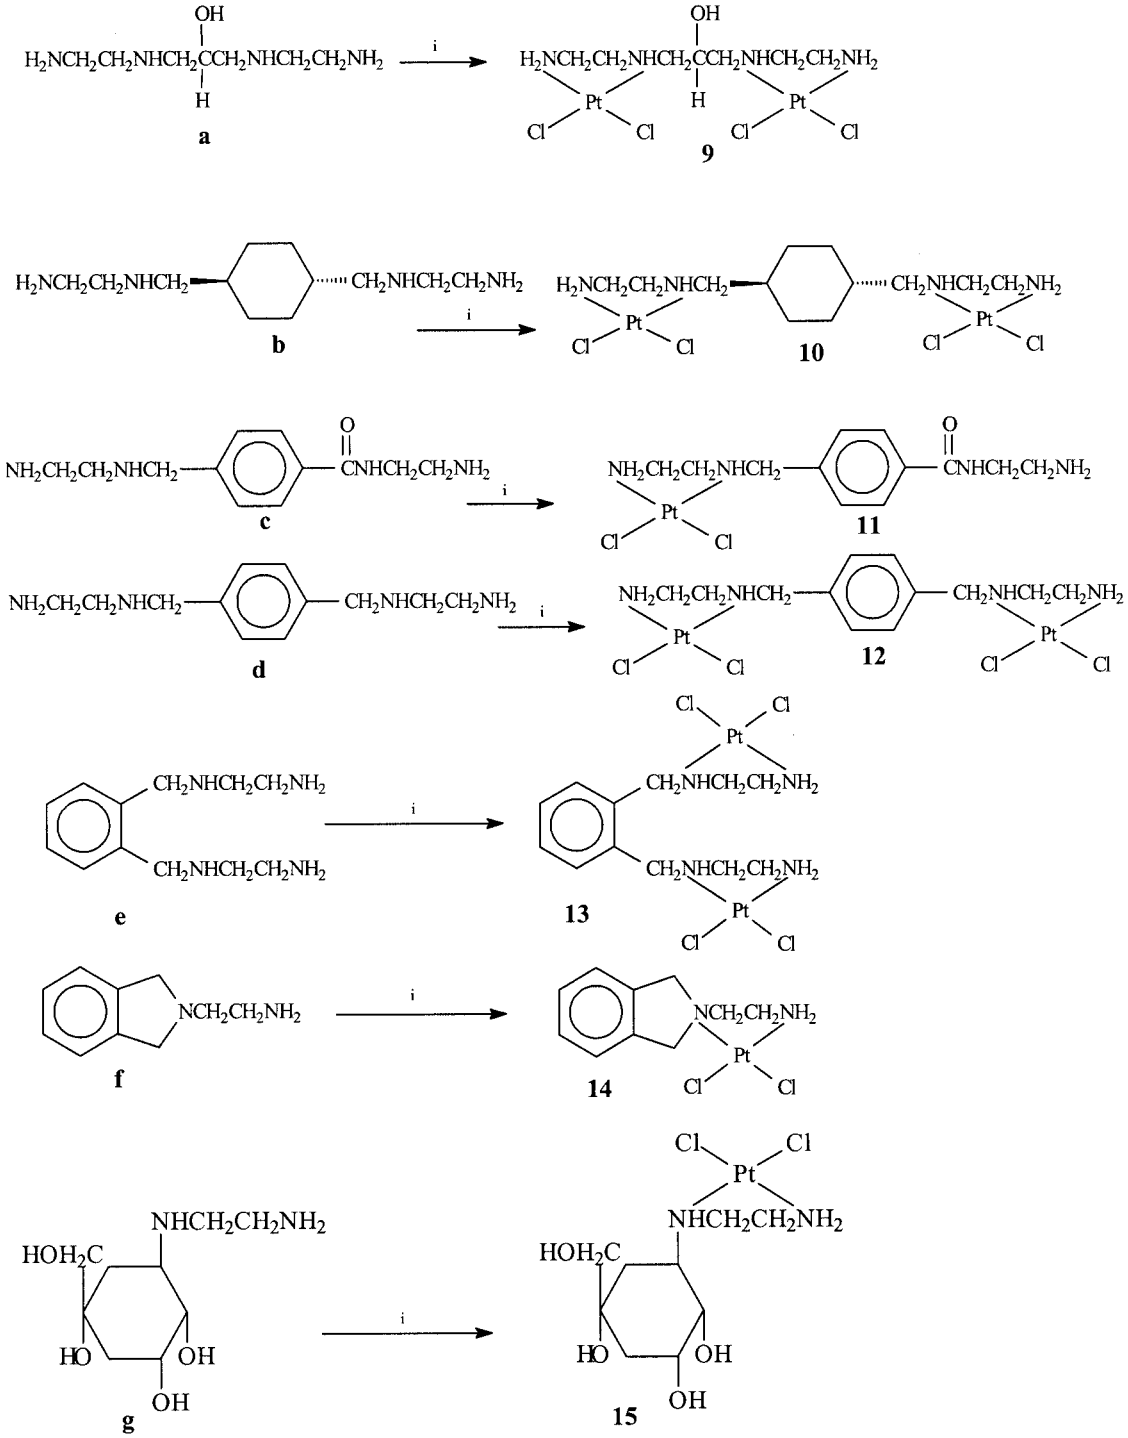

Scheme 2. Reagents and conditions: (i) $K_2PtCl_4$, $H_2O$, room temp.

compounds **12** and **15**, respectively, than that attained with cisplatin. This fact suggests that the formation of adducts between compounds **12** and **15** and the putative pharmacological target DNA is less favored. Knox et al.[32] postulated that the difference in the kinetics of the interaction with DNA is responsible for the different sensitivity of the same cell line to cisplatin and carboplatin. According to these authors, 20- to 40-fold larger doses of carboplatin were required to produce equal binding to DNA and equal cytotoxicity. In a review of structure–activity relationships of some dinuclear platinum compounds, Farrell et al.[33] reported that the cytotoxic activity of a dinuclear compound containing cyclohexane-1,4-diamine as a linker between two platinum atoms was very disappointing, probably because sterically hindered compounds bind more slowly to DNA. Assuming that equal binding to DNA would result in an equal cytotoxic effect, the fact that the intracellular concentrations found for compounds **12** and **15** are much

Table 1. $IC_{50}$, RF, and intracellular platinum concentration[a] for complexes **9**, **12**, and **15**.

| Compound | Cell Line | $IC_{50}$ [μM] | RF | $Ci \times 10^{16}$ [mol/cell] |
|---|---|---|---|---|
| DDP[b] | GLC4 | 0.40 ± 0.05 | | 0.98 ± 0.09 |
| CDDP[b] | GLC4/CDDP | 2.5 ± 0.2 | 6.3 | 1.07 ± 0.11 |
| CBDCA[b] | GLC4 | 9.9 ± 1.1 | | 0.79 ± 0.08 |
| CBDCA[b] | GLC4/CDDP | 13.5 ± 1.3 | 1.4 | 1.02 ± 0.11 |
| **9** | GLC4 | 9.9 ± 0.9 | | 0.96 ± 0.10 |
| **9** | GLC4/CDDP | 8.9 ± 0.9 | 0.9 | 1.05 ± 0.10 |
| **12** | GLC4 | 28.10 ± 2.80 | | 14.92 ± 1.50 |
| **12** | GLC4/CDDP | 81.0 ± 8.1 | 2.88 | 65.90 ± 6.70 |
| **15** | GLC4 | 84.0 ± 8.3 | | 9.28 ± 0.90 |
| **15** | GLC4/CDDP | 102.5 ± 10.3 | 1.22 | 24.10 ± 2.50 |

[a] $IC_{50}$ is the complex concentration required to inhibit 50% of cell growth. [b] ref.[31] RF value was calculated as resistant cell $IC_{50}$/sensitive cell $IC_{50}$. The values represent the mean ± SD of triplicate determinations;·Ci is the mol number of platinum per cell at $IC_{50}$ doses after 3 d.

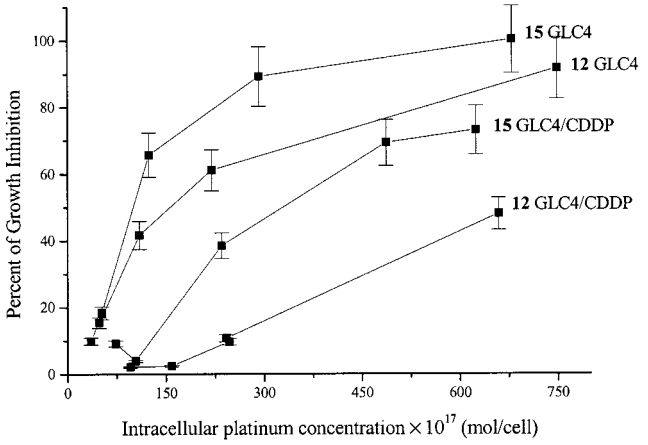

Figure 1. Growth inhibition of GLC4 and GLC4/CDDP cells as a function of the intracellular platinum concentration after 3 d of incubation with equitoxic doses of complexes **12** and **15**. The values are the mean values of two independent experiments. The platinum content was assessed by flameless atomic absorption spectroscopy.

higher than those of the reference compounds indicates that **12** and **15** bind to DNA more slowly or with a lower affinity, probably because of steric hindrance.

If these compounds bind more slowly to DNA, interaction with other intracellular ligands such as sulfur-containing molecules will become relevant and this may be the reason for the elevated intracellular platinum concentrations.

Considering **9** and **12**, these dinuclear platinum compounds are expected to form interstrand cross-links with DNA. The structural difference between them lies in the diamine linker. One can speculate that the insertion of a spacer (cycle) between the two platinum atoms engenders a steric hindrance to form DNA adducts. It is also possible that **12** only forms monoadducts with DNA.

An intriguing point to be considered is that a substantially higher intracellular platinum concentration is required to achieve a comparable cytotoxic effect in resistant cells by compounds **12** and **15** than in sensitive cells. Increased levels of sulfur-containing molecules have been found in various resistant cell lines. Hospers et al.[34] found that the GLC4/CDDP cell line possesses a significantly higher amount of sulfur-containing molecules than the GLC4 cell line, especially glutathione. Increased levels of sulfhydryl compounds are pointed as a possible mechanism for resistance. These thiols could bind to platinum and prevent it from attaining its target, DNA. If resistant cells possess higher levels of sulfur-containing compounds, one could expect to find a higher platinum concentration within resistant cells, because these compounds could bind to platinum in a detoxification mechanism. This is the case for compounds **12** and **15**. A possible explanation is that the interactions of these compounds with DNA are very slow, thus interactions of other intracellular ligands such as glutathione become determinant. They are able to accumulate in cells but are not very effective in binding to DNA and inhibiting cell growth.

In the cases of cisplatin, carboplatin, and compound **9** we have observed that the equal intracellular platinum amounts are responsible for equal cytotoxicity. Thus, the larger doses required in the case of resistant cells are necessary to force the uptake, and, once inside cells, equal platinum amounts can produce equal binding to DNA and equal cytotoxic effects. Sadowitz et al.[35] have shown that at low concentrations of cisplatin, endogenous thiols intercept cellular platinum, but this mechanism is not relevant at CDDP concentrations within the therapeutic range.

## Conclusion

This work describes the synthesis and characterization of different amine-ligand derivatives of 1,2-ethylenediamine, and also the preparation and characterization of their respective platinum(II) complexes.

Concerning the dinuclear platinum complexes, the introduction of a spacer (cycle) between the two platinum atoms leads to a significant decrease in cytotoxic activity. This finding is very important in guiding further design of dinuclear platinum compounds aimed at treating cancer.

## Experimental Section

**Reagents:** All chemicals were of reagent grade and were used without further purification.

### Starting Materials

**Compound 3:** Imidazole (2.82 g, 41.6 mmol), triphenylphosphane (10.92 g, 41.6 mmol), and iodine (10.6 g, 41.6 mmol) were added to a solution of *trans*-1,4-bis(hydroxymethyl)cyclohexane (**2**) (2.0 g, 14 mmol) in toluene (50 mL). The reaction mixture was stirred at 60 °C in an oil bath for 2 h. The solution was cooled, treated with an aqueous solution of sodium bisulfite and extracted with toluene (3 × 50 mL). The organic phases were combined and concentrated.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The crude product was purified on silica gel using *n*-hexane as the eluent to give **3** in 92% yield (4.65 g, 12.77 mmol).

**Compound 8:**[29] Methanolic sodium methoxide (25 mmol of sodium in 10 mL of methanol) was slowly added to a solution of ditosylate **7** (5 g, 10.35 mmol) in methanol (15 mL). The reaction was stirred for 30 min at room temperature, concentrated under reduced pressure and added to chloroform (10 mL). The resulting precipitate was collected and washed, and the filtrate was concentrated under reduced pressure to give **8** in quantitative yield.

### Synthesis of Ligands

**Ligand a:** This ligand was prepared by following the procedure described in ref.[26]

General procedure for the preparation of ligands **b**–**g** is shown in Scheme 1.

The corresponding halide or epoxide (10 mmol) was slowly added to a solution of ethylenediamine (6.7 mL, 100 mmol) in ethanol (20 mL) over 5 h. The reaction mixture was stirred for 12–24 h under reflux, evaporated under reduced pressure, and the residue purified on silica gel using dichloromethane/methanol as the eluent. Yields: (**b**) 1.37 g (60%), (**c**) 1.18 g (50%), (**d**) 1.56 g (70%), (**e**) 1.20 g (54%), (**f**) 0.18 g (11%), and (**g**) 1.54 g (70%)

**(b):** IR (KBr): $\tilde{\nu}_{max}$ = 2925, 2853, 1634, 1401, 1350, 1037, 772 $cm^{-1}$. $^1H$ NMR (200 MHz, $CD_3OD$): $\delta$ = 3.25 (m, 8 H, $CH_2N$), 1.38 (m, 6 H, CH, $CH_2$ cyclohexyl) ppm. $^{13}C$ NMR (50 MHz, $CD_3OD$): $\delta$ = 54.0 ($CH_2NHCH_2CH_2NH_2$), 44.7 ($NHCH_2$), 36.5 ($CH_2NH_2$), 35.4, 28.6 (cyclohexyl) ppm.

**(c):** IR (KBr): $\tilde{\nu}_{max}$ = 2933, 1646, 1543, 1506, 1313, 1160, 1108, 1019, 859, 757 $cm^{-1}$. $^1H$ NMR (200 MHz, $CD_3OD$): $\delta$ = 7.79 (d, 2 H, H-2, H-6, $J$ = 8.0 Hz), 7.55 (d, 2 H, H-3, H-5, $J$ = 8.0 Hz) ppm. $^{13}C$ NMR (50 MHz, $CD_3OD$): $\delta$ = 170.6 (C=O), 134.6, 134.0, 130.1, 128.1 (Ph), 51.0 ($CH_2Ph$), 44.0, 39.3 ($CH_2NH$), 37.4, 35.7 ($CH_2NH_2$) ppm.

**(g):** IR (KBr): $\tilde{\nu}_{max}$ = 3403, 2936, 2862, 1648, 1573, 1460, 1343, 1301, 1151, 1052, 958 $cm^{-1}$. $^1H$ NMR (200 MHz, $CD_3OD$): $\delta$ = 3.92 (m, 1 H, H-3), 3.70 (t, 1 H, H-4), 3.13 (t, 1 H, H-5), 2.64 (m, 4 H, $CH_2NH$, $CH_2NH_2$), 1.80 (m, 4 H, H-2, H-2′, H-6, H-6′) ppm. $^{13}C$ NMR (50 MHz, $CD_3OD$): $\delta$ = 76.7, 71.1, 68.5, 65.6 (C-1, C-3, C-4, C-7), 63.8, 59.8, 44.0 (C-5, $CH_2N$), 38.7, 36.7 (C-2, C-6) ppm.

### Synthesis of Complexes 9–15

**Complex 9:** Prepared following the procedure described in ref.[26]

**Complexes 10–15 (Scheme 2):** The appropriate ligand (1 mmol), dissolved in water (5 mL), was slowly added to a solution of $K_2PtCl_4$ (0.830 g, 2 mmol) in water (10 mL). After stirring for 24 h in the dark at room temperature, the solid that formed was filtered off, washed with water, and dried. In the case of complexes **14** and **15** only 1 mmol of $K_2PtCl_4$ was used. Yields: (**10**) 0.47 g (62%), (**11**) 0.25 g (50%), (**12**) 0.69 g (92%), (**13**) 0.32 g (42%), (**14**) 0.17 g (40%), (**15**) 0.364 g (75%).

**(10):** IR (KBr): $\tilde{\nu}_{max}$ = 3270, 2910, 2846, 1628, 1313, 1045, 827, 549, 326 $cm^{-1}$. $^{195}Pt$ NMR (86 MHz, [D$_6$]DMSO) (DMSO = dimethyl sulfoxide): $\delta$ = –2380 ppm. $C_{12}H_{28}N_4Pt_2Cl_4$ (760.18): calcd. C 18.95, H 3.68, N 7.37; found C 19.15, H 3.86, N 7.35.

**(11):** IR (KBr): $\tilde{\nu}_{max}$ = 3207, 3114, 2923, 2847, 1639, 1541, 1462, 1306, 1188, 1060, 1014, 861, 759, 569, 317 $cm^{-1}$. $^1H$ NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 2.83, 3.59 (m, 4 H, $CH_2NH$, $CH_2NH_2$), 4.25 (m, 4 H, $CH_2Ph$), 5.08, 6.29 (s, 3 H, NH, $NH_2$), 7.95 (m, 4 H, Ar) ppm. $^{13}C$ NMR (100 MHz, [D$_6$]DMSO): $\delta$ = 54.3–45.6 ($CH_2NH$, $CH_2NH_2$), 61.1 ($CH_2Ph$); 128.0–130.4 (Ar) ppm. $^{195}Pt$ NMR (86 MHz, [D$_6$]DMSO): $\delta$ = –2018 ppm. $C_{12}H_{20}N_4PtCl_2$ (486.21): calcd. C 28.69, H 3.98, N 11.15; found C 29.03, H 3.86, N 11.45.

**(12):** IR (KBr): $\tilde{\nu}_{max}$ = 3130, 3056, 2984, 2952, 2883, 1643, 1451, 1287, 1189, 1064, 1018, 954, 853, 759, 576, 501, 324 $cm^{-1}$. $^1H$ NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 2.53 (m, 8 H, $CH_2NH$, $CH_2NH_2$), 3.98 (s, 4 H, $CH_2Ph$), 5.30, 6.25 (s, 4 H, $NH_2$), 6.38 (s, 2 H, NH), 7.56 (m, 4 H, Ph) ppm. $^{13}C$ NMR (100 MHz, [D$_6$]DMSO): $\delta$ = 43.8, 44.7 ($CH_2NH_2$), 45.6, 46.9 ($CH_2NH$), 54.3, 54.9 ($CH_2Ph$), 130.4–136.7 (Ar) ppm. $C_{12}H_{22}N_4Pt_2Cl_4$ (754,14): calcd. C 19.10, H 2.92, N 7.43; found C 19.45, H 2.86, N 7.75.

**(13):** IR (KBr): $\tilde{\nu}_{max}$ = 3259, 3192, 3109, 2954, 2885, 2858, 1586, 1441, 1191, 1164, 1064, 762, 531, 314 $cm^{-1}$. $^1H$ NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 3.40 (m, 4 H, $CH_2NH_2$); 3.80 (m, 4 H, $CH_2NH$); 4.30 (s, 4 H, $CH_2Ph$); 5.52 (s, 4 H, $NH_2$); 5.80, 6.30 (s, 2 H, NH); 7.50 (m, 4 H, Ar) ppm.

**(14):** IR (KBr): $\tilde{\nu}_{max}$ = 3200, 3116, 2949, 1622, 1313, 1158, 1049, 978, 926, 894, 823, 749, 609, 409 $cm^{-1}$. $^1H$ NMR (400 MHz, [D$_6$]-DMSO): $\delta$ = 2.51, 2.84 (2m, 4 H, $CH_2NH_2$); 4.25, 4.45 (2d, 2 H, $CH_2N$); 4.25, 4.45, 4.87, 4.97 (4d, 4 H, $CH_2Ph$), 5.52 (s, 1 H, $NH_2$), 6.31 (s, 1 H, $NH_2$), 7.28 (m, 4 H, Ph) ppm. $^{13}C$ NMR (100 MHz, [D$_6$]DMSO): $\delta$ = 44.7 ($CH_2NH_2$), 46.2 ($NCH_2$), 64.4, 65.4 ($CH_2Ph$), 122.9–136.7 (Ar). $C_{10}H_{14}N_2PtCl_2$ (428.13): calcd. **(15):** IR (KBr): $\tilde{\nu}_{max}$ = 3415, 3269, 3197, 2958, 2928, 1140, 1034, 1018, 716, 549, 326 $cm^{-1}$. $C_9H_{20}N_2O_4PtCl_2$ (486.17): calcd. C 22.20, H 4.12, N 5.76; found C 22.15, H 3.86, N 5.75.

### Cell Lines and Cultures

The GLC4 cell line was derived from pleural effusion of a patient with small-cell lung carcinoma in the laboratory of Prof. E. G. E. de Vries (Department of Internal Medicine, University Hospital, Groningen, The Netherlands). The GLC4/CDDP was obtained in the same laboratory by continuous exposure to CDDP. No amplification of the MDR gene or expression of P-glycoprotein was found in the GLC4/CDDP subline.

The cell lines were cultured in an RPMI 1640 (Sigma Chemical Co.) medium supplemented with 10% fetal calf serum (Biomedia Co.) at 37 °C in a humidified 5% $CO_2$ atmosphere. Cultures grow exponentially from $10^5$ cells/mL to about $10^6$ cells/mL in 3 d. Cell viability was checked by Trypan blue exclusion. The cell number was determined by Coulter counter analysis. For the cytotoxicity assessment, $1 \times 10^5$ cells/mL were cultured for 72 h in the absence and the presence of various concentrations of each platinum-based compound. The sensitivity to the drug was evaluated by the drug concentration that inhibits cell growth by 50%, $IC_{50}$. A resistance

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

factor (RF) was obtained by dividing the $IC_{50}$ of resistant cells by the $IC_{50}$ of sensitive cells. The RF to cisplatin is 6.3.

Stock solutions of compounds **9**, **12**, and **15** were prepared in a mixture of water/DMSO (90:10). In the cytotoxic assays, the final concentration of DMSO was below 1.5%.

**Cellular Accumulation**

Cells were incubated with different complex concentrations for 3 d. After incubation, an aliquot was removed, washed twice with ice-cold PBS (phosphate-buffered saline), and the pellet mineralized in 65% $HNO_3$. The platinum concentration was determined by atomic absorption spectroscopy with a Varian model Zeeman 220 spectrophotometer equipped with a graphite tube atomizer and an autosampler. The heating program consisted of sequential drying (85 °C for 5 s, 95 °C for 40 s, and 95 °C for 20 s), an ashing stage (500 °C for 5.0 s followed by 15 s at 1100 °C), and atomizing at 2500 °C for 5 s.

# Reactions of $^{13}CO$ with Ethoxycarbonylcarbene-Bridged Dicobalt Carbonyl Complexes: [$\mu_2$-{Ethoxycarbonyl(methylene)}-$\mu_2$-(carbonyl)-bis(tricarbonylcobalt)(*Co–Co*)] and [Di-$\mu_2$-{ethoxycarbonyl(methylene)}-bis(tricarbonylcobalt)(*Co–Co*)]

**Eszter Fördős,[a] Neszta Ungvári,[a] Tamás Kégl,[b] and Ferenc Ungváry*[a,b]**

**Keywords:** Isotopic labeling / C–C coupling / Carbene and carbonyl ligands / Cobalt / Fluxionality

In a $CH_2Cl_2$ solution, under an atmospheric pressure of $^{13}CO$, the bridging and terminal CO ligands of the cobalt complex [$\mu_2$-{ethoxycarbonyl(methylene)}-$\mu_2$-(carbonyl)bis(tricarbonylcobalt)(*Co–Co*)] (**1**) exchange with external $^{13}CO$ at the same rate. The overall rate of CO exchange is $k_{obs}$ (10 °C) = $9.4 \times 10^{-3}$ s$^{-1}$ and $k_{obs}$ (25 °C) = $(20.1 \pm 1.2) \times 10^{-3}$ s$^{-1}$. In the presence of excess ethanol diethyl malonate (DEM), $EtO_2{}^{13}CCH_2CO_2Et$ is formed from **1** at a much smaller rate [$k_{DEM}$ (10 °C) = $0.40 \times 10^{-5}$ s$^{-1}$ and $k_{DEM}$ (25 °C) = $(1.2 \pm 0.1) \times 10^{-5}$ s$^{-1}$]. On the other hand, the complex [di-$\mu_2$-{ethoxycarbonyl(methylene)}bis(tricarbonylcobalt)(*Co–Co*)] (**2**) does not exchange its CO ligands for $^{13}CO$ at all at 10 or 25 °C. In the presence of excess ethanol, diethyl malonate with natural isotopic distribution, and $^{13}CO$, ligands containing complex **1** are formed simultaneously and at the same rate, which is $k_{obs}$ (10 °C) = $(15.2 \pm 1.1) \times 10^{-5}$ s$^{-1}$ and $k_{obs}$ (25 °C) = $(33.5 \pm 1.8) \times 10^{-5}$ s$^{-1}$. Variable temperature $^{13}C$ NMR spectra of **1** and **2** reveal fluxional behavior for both complexes.

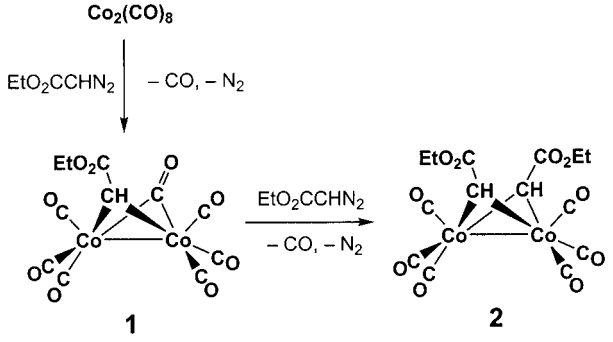
## Introduction

In the course of the past decades several dicobalt carbonyl complexes having no more than one or two carbene ligands have been prepared and the crystal structures of some representative examples determined.[1] In most of these complexes the substituted methylene- and vinylidene-type carbenes are in a bridging position between the two cobalt atoms,[2–18] while in a few recent examples *N*-heterocyclic carbene(s) are in terminal positions.[19,20]

Diverse methods of preparation have been applied to obtain dicobalt carbonyl carbene complexes. In the case of **1** and **2** (see Scheme 1) the two $\mu_2$-CO ligands in $Co_2(CO)_8$ were replaced effectively one by one by ethoxycarbonylcarbene[18] using the carbene transfer reaction[21] between ethyl diazoacetate and $Co_2(CO)_8$.

The complexes [$\mu_2$-{ethoxycarbonyl(methylene)}-$\mu_2$-(carbonyl)bis(tricarbonylcobalt)(*Co–Co*)] (**1**) and [di-$\mu_2$-{ethoxycarbonyl(methylene)}bis(tricarbonylcobalt)(*Co–Co*)] (**2**) were found to be intermediates in the octacarbonyldicobalt-catalyzed carbonylation of ethyl diazoacetate to ethyl malonic acid derivatives.[18] The key step in these carbonylation reactions is the facile coupling of carbon monoxide



Scheme 1.

with the bridging carbene ligand to form the highly reactive ethoxycarbonyl ketene,[22] which rapidly converts in the presence of a suitable scavenger to the corresponding malonic acid monoethyl ester derivative. For example, using ethanol as the scavenger results in the formation of diethyl malonate [Equations (1) and (2)].

$$\mathbf{2} + 2CO + EtOH \xrightarrow[1\ bar]{25\ °C} \mathbf{1} + EtO_2CCH_2CO_2Et \quad (1)$$

$$\mathbf{1} + 2CO + EtOH \xrightarrow[1\ bar]{25\ °C} Co_2(CO)_8 + EtO_2CCH_2CO_2Et \quad (2)$$

Applying $^{13}CO$ in the gas phase, as in Equations (1) and (2), a clear decision could be made as to whether $^{13}CO$ from the gas phase or the CO from the complexes is incorporated into the diethyl malonate product.

## Results and Discussion

The infrared spectrum of a solution of **1** in dichloromethane under an atmosphere of $^{13}CO$ changes rapidly with time. Next to the original terminal carbonyl absorptions at 2112, 2075, 2048 $cm^{-1}$, and next to the bridging carbonyl absorption at 1853 $cm^{-1}$, several new initially rapidly growing bands in the terminal ν(C≡O) range and one in the bridging ν(C=O) range appeared immediately after exposing the solution to $^{13}CO$. The well separated bridging $\nu(^{12}C{=}O)$ and $\nu(^{13}C{=}O)$ bands at 1853 and 1810 $cm^{-1}$, respectively, were suitable for quantitative analysis and to calculate the rate of $^{13}CO$ exchange. The strongly overlapping various terminal ν(C≡O) bands prevented the calculation of the concentrations of the different $^{13}CO$ containing species. However, the relative intensity values of the different totally symmetric bands of the complexes containing one, two, three, four, and five $^{13}CO$ ligands at 2112, 2107, 2101, 2096, and 2090 $cm^{-1}$, respectively, could be established. From the beginning of the reaction a parallelity of the growing amounts of complexes having $^{13}C$ in the bridging CO and the shift of the relative intensity values of the total symmetric bands is observed (see Table 1). Therefore the extent of $^{13}CO$ incorporation as calculated from the intensity of the $\nu(^{13}C{=}O)$ band reflects the overall level of $^{13}CO$ incorporation in complex **1**. Because there is no perceptible difference in the $^{13}CO$ exchange rate of the bridging and the terminal CO ligands it can be concluded that the intramolecular exchange of the different CO groups in complex **1** is much faster than the rate of $^{13}CO$ incorporation. This is in agreement with the fluxional behavior deduced from the results of the variable temperature $^{13}C$ NMR experiments of **1** in $CD_2Cl_2$ solutions. At ambient temperature we observed only one coordinated carbonyl resonance at $\delta$ = 201.85 ppm, which splits at 185 K into resonances at 195.65, 196.95, 198.16 ppm (three different terminal CO ligands), and 227.26 ppm (bridging CO) showing virtually 2:2:2:1 integral ratios.

From the data in Table 1 the overall rate of $^{13}CO$ exchange of complex **1** was calculated as $k_{obs}$ (10 °C) = $9.4 \times 10^{-3}$ $s^{-1}$. This rate is about 50% higher than that for $Co_2(CO)_8$ extrapolated at 10 °C from literature values[23] or as measured by us in order to check our technique applied in the present work. The CO-exchange reaction of $Co_2(CO)_8$ with external CO and the fluxional behavior of $Co_2(CO)_8$ have been intensively investigated in the past On the basis of X-ray structure determination it is known that $Co_2(CO)_8$ in the solid state exists exclusively in the form of a bridged isomer with two $\mu_2$-CO and six terminal CO ligands.[24] In solution this bridged isomer is in fast equilibrium with two nonbridged isomers.[25] The fast inter-conversion of the bridged and nonbridged structures makes it understandable that in the slower exchange reaction with external CO all eight CO ligands exchange at the same rate.[23] Because the rate of CO exchange was found not to depend on the CO concentrations it was concluded that the CO exchange happens by a dissociative mechanism with the involvement of a $Co_2(CO)_7$ intermediate.[23] A similar mechanism might be operating in the case of complex **1**, which involves the rate-determining formation of a coordinative unsaturated $Co_2(CO)_6(CHCO_2Et)$ intermediate that takes up CO in a fast reaction. A very fast intramolecular exchange of the bridging and terminal CO ligands distributes labeled car-

Table 1. The amount of $^{13}CO$ found in the $\mu_2$-position of $Co_2(CO)_6(\mu_2\text{-}CO)(\mu_2\text{-}CHCO_2Et)$ (**1**) (0.0224 mmol) in a $CH_2Cl_2$ solution (7.0 $cm^3$), and the observed relative intensity values of the total symmetric ν(C≡O) bands in the reaction with $CH_2Cl_2$-saturated $^{13}CO$ (99% $^{13}C$) (0.30 mmol) at 10 °C and 740 Torr total pressure at various reaction times.

bon monoxide statistically in the bridging and terminal positions.

In the presence of ethanol, the reaction of carbon monoxide with complex **1** results in the formation of $Co_2(CO)_8$ and diethyl malonate [Equation (2)]. The data in Table 2 show that complex **1** reacts three orders of magnitude slower to form diethyl malonate and $Co_2(CO)_8$ than in the $^{13}CO$-exchange reaction. Under an atmosphere of $^{13}CO$, owing to the preceding fast $^{13}CO$-exchange and the subsequent slow diethyl malonate formation, we could not decide whether complex-bound $^{13}CO$ or external $^{13}CO$ is incorporated in the $EtO_2{}^{13}CCH_2CO_2Et$ product. Performing the reaction of **1** with ethanol under an atmosphere of argon leads to reaction products of $Co_4(CO)_{12}$ and diethyl malonate [Equation (3)], as seen from the growing intensities of bands in the infrared spectra of the reaction solution with elapsing reaction time at 2065 and 2055 $cm^{-1}$ [most intensive $\nu(C{\equiv}O)$ bands of $Co_4(CO)_{12}$ in $CH_2Cl_2$] and at 1749 and 1732 $cm^{-1}$ [$\nu(C{=}O)$ bands of $EtO_2CCH_2CO_2Et$]. This result strongly suggests that the source of CO is one of the coordinated carbonyls in complex **1**.

$$\mathbf{1} + EtOH \xrightarrow[Argon]{25\ ^\circ C} \mathbf{1/2\ Co_4(CO)_{12}} + EtO_2CCH_2CO_2Et \quad (3)$$

The reaction of complex **2** with ethanol under an atmosphere of argon gave **1** and diethyl malonate [Equation (4)]. The amount of complex **1** formed in the reaction [Equation (4)] was found to be only about 70% of that expected according to the stoichiometry. A reason for this might be that the missing amount served, by decomposition, as a CO source for complex **1**.

$$\mathbf{2} + EtOH \xrightarrow[Argon]{10\ ^\circ C} \mathbf{1} + EtO_2CCH_2CO_2Et \quad (4)$$

In the absence of ethanol complex **2** and CO convert to complex **1** and the ethoxycarbonyl ketene dimer [one characteristic $\nu(C{=}O)$ band is at 1733 $cm^{-1}$] according to Equation (5).

$$\mathbf{2} + 2CO \xrightarrow[1\ bar]{10\ ^\circ C} \mathbf{1} + 1/2(EtO_2CCH{=}C{=}O)_2 \quad (5)$$

Performing the reaction in Equation (1) under an atmosphere of $^{13}CO$ results in the formation of the $^{13}C$-labeled complex **1** and diethyl malonate with a natural abundance of $^{13}C$; these compounds were simultaneously observed in the infrared spectrum of the reaction solution. Thus, the several new $\nu(^{13}C{\equiv}O)$ absorptions in the 2107–1959 $cm^{-1}$ range and the one new $\nu(^{13}C{=}O)$ absorption at 1810 $cm^{-1}$ could be assigned to complex **1**, and the new $\nu(C{=}O)$ absorptions at 1749 and 1732 $cm^{-1}$ are characteristic of $EtO_2CCH_2CO_2Et$. The observed rate of formation of complex **1** and that of diethyl malonate in Equation (1) was found to be practically the same (see Table 3). The GC-MS analysis of the reaction product confirmed the presence of diethyl malonate showing an identical mass spectrum to that of an authentic sample and the published mass spec-

Table 2. Initial rate of the overall $^{13}CO$ incorporation ($r_{in}$) and the observed rate constant ($k_{obs} = r_{in}/[\mathbf{1}]$) in the reaction of complex **1** with $^{13}CO$ at 740 Torr total pressure in $CH_2Cl_2$ solution, and the initial rate of diethyl malonate formation ($r_{DEM}$) and the observed rate constant ($k_{DEM} = r_{DEM}/[\mathbf{1}]$) in the presence of ethanol.

trum.[26] As the reaction progressed the $\nu$(C≡O) range in the infrared spectrum became very complex with the appearance of various $^{13}$CO-containing **1** products in the reaction solution. However, the $\nu$(C≡O) bands of the starting complex **2** at 2112 and 2080 cm$^{-1}$ are well recognized until the conversion according to Equation (1) is complete. This means that in contrast to complex **1** no $^{13}$CO incorporation takes place in complex **2** during the contact with external $^{13}$CO. Hence, the source of CO involved in the formation of diethyl malonate is one of the coordinated carbon monoxide ligands of complex **2**.

Complex **2** in solution shows fluxional behavior. In $CDCl_3$ at ambient temperature only one coordinated carbonyl resonance at $\delta$ = 196.63 ppm can be seen in the $^{13}$C NMR spectrum. However, in $CD_2Cl_2$ solution at 200 K this resonance splits into resonances at 195.91 and 197.84 ppm with an integral ratio of 1:2. GIAO NMR shielding calculations gave the same qualitative results (see Table 4).

Table 4. GIAO and experimental $^{13}$C chemical shifts $\delta$ [ppm] and intensity ratios (in parenthesis) of the coordinated carbonyl ligands of $Co_2(CO)_8$, $Co_2(CO)_7(CHCO_2Et)$ (**1**), and $Co_2(CO)_6(CHCO_2Et)_2$ (**2**).

| Complex | Calculated $^{13}$C chemical shifts at the B3LYP/6-31G* level of theory | Experimentally found $^{13}$C chemical shifts |
|---|---|---|
| $Co_2(CO)_8$ | 193.3, 201.3, 237.8 (1:2:1) | 182, 234 (approximately 4:1)[a] |
| **1** | 195.9, 199,7, 205.2, 234.8 (2:2:2:1) | 195.65, 196.95, 198.16, 227.26 (2:2:2:1)[b] |
| **2** | 200.5, 201.5 (1:2) | 195.91, 197.84 (1:2)[b] |

[a] See ref.[32] [b] This work.

## Conclusions

The results of experiments with complex **1** and **2** in the presence and in the absence of the reagents $^{13}$CO, CO, and ethanol suggest that the origin of the new organic carbonyl group, formed through the coupling of CO and a $\mu_2$-ethoxycarbonylcarbene ligand of the complexes, is one of the complex-bound carbonyl ligands and not an external CO.

## Experimental Section

**General Comments:** Handling of $Co_2(CO)_8$ and other carbonyl cobalt complexes was carried out in an atmosphere of dry ($P_4O_{10}$) and deoxygenated (BTS contact, room temp.) argon or carbon monoxide utilizing standard Schlenk techniques.[27] Solvents were dried and distilled under an atmosphere of argon according to standard procedures.[28] IR spectra were recorded with a Thermo Nicolet Avatar 330 FTIR spectrometer using 0.00265, 0.00765, 0.02095, or 0.05097 cm $CaF_2$ solution cells, calibrated by the interference method.[29] $^{13}$C NMR spectra were recorded with a Bruker 400 MHz spectrometer at 100 MHz using $CD_2Cl_2$ as the solvent. Chemical shifts $\delta$ are reported in ppm relative to $CH_2Cl_2$ ($\delta$ = 53.10 ppm). The GC-MS analyses were performed with an HP 5890 instrument equipped with a mass-selective detector working at 70 eV. Octacarbonyldicobalt[30] and the $\mu_2$-ethoxycarbonylcarbene complexes **1**[18] and **2**[18] were prepared by literature procedures. $^{13}$CO was obtained from Sigma–Aldrich.

**$^{13}$CO Exchange Experiment with $Co_2(CO)_8$:** The $^{13}$CO exchange reactions were performed in a magnetically stirred thermostatted glass reactor (18, 35, or 61 cm$^3$ total volume), equipped with a gas inlet and with a silicon disk port. The gas inlet was connected through a two-way stopcock to a vacuum pump and a $^{13}$CO-filled gas burette. A stainless-steel cannula connected to a 3-port T-valve was immersed close to the bottom of the reactor through the silicon disk. A Hamilton TLL syringe (2.5 cm$^3$ volume) and the IR cell (through a PTFE tube) were connected to the two other ports of the valve. Samples from the reaction mixture for IR analyses were withdrawn through the stainless steel cannula, and pumped into the IR cell continuously by using the Hamilton TLL syringe, allowing the liquid sample to return from the IR cell to the reactor through a second PTFE tube. The solvent and the solution of the reactant were added to the $^{13}$CO-filled reactor through the silicon disk using Hamilton TLL syringes. IR spectra were recorded at every minutes or less. The initial rates of $^{13}$CO exchange were calculated from the intensity values of the $\nu$($^{13}$C=O) band using the first 3 to 8 points. The $\varepsilon_M$ of the $\nu$($^{13}$C=O) band was calculated from the known $\varepsilon_M$ value of the $\nu$($^{12}$C=O) band[18,31] by multiplying it with the mass correction value $(12/13)^{-0.5}$ = 0.96077. In a typical experiment using the reactor with a 35-cm$^3$ total volume, the reactor and its connected parts were first evacuated then filled with $^{13}$CO, and $CH_2Cl_2$ (4.5 cm$^3$) was added. After stirring at 10 °C for 10 min the reaction was started by injection of $Co_2(CO)_8$ (0.064 mmol) in a precooled $CH_2Cl_2$ solution (2.5 cm$^3$). Infrared spectra were recorded from four scans after 38, 75, 114, 164, 207, 253, 297, 345 s, and so on, until $^{13}$CO enrichment of 65% had been reached. The rate constant of the overall $^{13}$CO exchange $(6.0 \pm 1.2) \times 10^{-3}$ s$^{-1}$ was calculated from the initial changes of the $Co_2(CO)_8$ concentration as obtained from the intensity values measured at 1847 cm$^{-1}$ ($\varepsilon_M$ = 938 cm$^2$/mmol), or that of $Co_2(^{13}CO)_x(CO)_{8-x}$ from the intensity values measured at 1807 cm$^{-1}$ ($\varepsilon_M$ = 902 cm$^2$/mmol) by dividing the observed initial rate by the initial $Co_2(CO)_8$ concentration.

**$^{13}$CO Exchange Experiments with Complex 1:** In a typical experiment using the reactor with an 18-cm$^3$ total volume, the reactor and its connected parts were first evacuated and then filled with $^{13}$CO (740 Torr total pressure), and then $CH_2Cl_2$ (4.5 cm$^3$) was added. After stirring at 10 °C for 10 min the reaction was started by injection of a precooled solution of complex **1** (0.0224 mmol) in $CH_2Cl_2$ (2.5 cm$^3$). Infrared spectra were recorded from four scans after 97, 150, 195, 240, 296, 341 s, and so on (see Table 1), until a $^{13}$CO enrichment of 63% had been reached in ca. 34 min. The rate constant of the overall $^{13}$CO incorporation ($9.4 \times 10^{-3}$ s$^{-1}$) was calculated from the initial changes of the concentration of complex **1**, as obtained from the intensity values measured at 1853 cm$^{-1}$ ($\varepsilon_M$ = 953 cm$^2$/mmol), or that of $Co_2(^{13}CO)_x(CO)_{7-x}(CHCO_2Et)$ from the intensity values measured at 1810 cm$^{-1}$ ($\varepsilon_M$ = 916 cm$^2$/mmol), by dividing the observed initial rate by the initial concentration of complex **1**.

At higher initial concentrations of complex **1** and at 25 °C the reactor with a volume of 35 or 61 cm$^3$ was used in order to achieve at least 50% $^{13}$CO enrichment at the end of the reaction.

**Diethyl Malonate Formation from Complex 1 and Ethanol under $^{13}$CO:** Absolute ethanol (0.029 cm$^3$, 0.496 mmol) was added to a solution of complex **1** in $CH_2Cl_2$ (7.0 cm$^3$, 0.003 mol/dm$^3$) with 62.6% $^{13}$C-enrichment, obtained in a reactor with a 61-cm$^3$ volume at 25 °C under a $^{13}$CO atmosphere in 10 min. The initial rate of diethyl malonate formation ($r_{DEM}$) was calculated from the inten-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sity values measured at 1749 $cm^{-1}$ ($\varepsilon_M$ = 579 $cm^2$/mmol, unlabeled diethyl malonate), at 1731 $cm^{-1}$ ($\varepsilon_M$ = 597 $cm^2$/mmol, 62.6% $^{13}C$-labeled and 37.4% unlabeled diethyl malonate), and at 1713 $cm^{-1}$ ($\varepsilon_M$ = 640 $cm^2$/mmol, $^{13}C$-labeled diethyl malonate) The observed rate constant ($k_{DEM}$) was obtained from the initial rate of diethyl malonate formation by dividing it with the initial concentration of complex **1**. The GC-MS analyses of the diethyl malonate product show an $M^{+\cdot}$ peak at *m*/*z* = 161, and the characteristic fragment peaks: M – 27, M – 45, and M – 72 at *m*/*z* = 134, 116, and 89, respectively.

**Diethyl Malonate Formation from Complex 1 and Ethanol under Ar:** Absolute ethanol (0.031 $cm^3$, 0.531 mmol) was added to a solution of complex **1** (0.1075 mmol) in $CH_2Cl_2$ (7.5 $cm^3$) under an atmosphere of argon at 25 °C, and the initial rate of diethyl malonate formation ($r_{DEM}$) and the observed rate constant ($k_{DEM}$) were determined as described above but using the intensity values measured at 1749 and 1732 $cm^{-1}$.

**Attempted $^{13}CO$ Exchange Experiments with Complex 2:** In a typical experiment using the reactor with a 35-$cm^3$ total volume, the reactor and its connected parts were first evacuated and then filled with $^{13}CO$ (745 Torr total pressure), and finally $CH_2Cl_2$ (4.3 $cm^3$) was added. After stirring at 10 °C for 10 min the reaction was started by injection of a precooled solution of complex **2** (0.0475 mmol) in $CH_2Cl_2$ (3.2 $cm^3$). Infrared spectra were recorded from 16 scans after 2, 10, 15, 20 min, and so on, until almost all of complex **2** was converted to complex **1** (8 h), afterwhich conversion could be followed by the gradual decrease of intensity of the characteristic bands of complex **2** at 2112 $cm^{-1}$ ($\varepsilon_M$ = 1100 $cm^2$/mmol) and 2080 $cm^{-1}$ ($\varepsilon_M$ = 3768 $cm^2$/mmol) and the increase of intensity of the characteristic $\nu$(C=O) bands of the labeled and unlabeled complex **1** at 1810 $cm^{-1}$ ($\varepsilon_M$ = 916 $cm^2$/mmol) and 1853 $cm^{-1}$ ($\varepsilon_M$ = 953 $cm^2$/mmol), respectively. At the end of the reaction 57% $^{13}CO$ enrichment of complex **1** was found based on the intensity values measured at 1853 and 1810 $cm^{-1}$. From the initial rate of the formation of complex **1** ($r_{\mathbf{2}\rightarrow\mathbf{1}} = 3.2\times10^{-7}$ mol/$dm^3$ s) the observed rate constant ($k_{\mathbf{2}\rightarrow\mathbf{1}} = 5.1\times10^{-5}\ s^{-1}$) was calculated by dividing the observed initial rate by the initial concentration of complex **2**.

**Diethyl Malonate Formation from Complex 2 and Ethanol under $^{13}CO$:** In a typical experiment the reactor (35-$cm^3$ total volume) and its connected parts were first evacuated and then filled with $^{13}CO$ until a barometric pressure of 740 Torr. $CH_2Cl_2$ (1.0 $cm^3$) and absolute ethanol (0.033 $cm^3$, 0.565 mmol) were added. After stirring at 10 °C for 10 min the reaction was started by injection of complex **2** (0.133 mmol) into a precooled $CH_2Cl_2$ solution (7.0 $cm^3$) maintaining the pressure in the reactor at 740 Torr by means of the connected gas burette. Infrared spectra were recorded from four scans after 61, 107, 164, 221, 300, 427, 530, 645, 750, 865 s, and so on, until the infrared spectrum showed no more changes in the 2200–1600 $cm^{-1}$ range (3.5 h). The rate constant for the formation of $EtO_2CCH_2CO_2Et$ was calculated from the initial changes of its concentration as obtained from the intensity values measured at 1749 $cm^{-1}$ ($\varepsilon_M$ = 579 $cm^2$/mmol) and at 1732 $cm^{-1}$ ($\varepsilon_M$ = 666 $cm^2$/mmol) by dividing the observed initial rate by the initial concentration of complex **2**. The GC-MS analyses of the diethyl malonate product show an $M^{+\cdot}$ peak at *m*/*z* = 160, and the characteristic fragment peaks: M – 27, M – 45, and M – 72 at *m*/*z* = 133, 115, and 88, respectively.

**Diethyl Malonate Formation from Complex 2 and Ethanol under Ar:** Absolute ethanol (0.033 $cm^3$, 0.565 mmol) was added to a solution of complex **2** (0.133 mmol) in $CH_2Cl_2$ (8.0 $cm^3$) under an atmosphere of argon at 10 °C, and the initial rate of diethyl malonate formation ($r_{DEM}$) and the observed rate constant ($k_{DEM}$) were determined as described above using the intensity values of diethyl malonate measured at 1749 and 1732 $cm^{-1}$.

**Variable-Temperature $^{13}C$ NMR Spectra of Complex 1 and 2:** From freshly chromatographed dichloromethane solutions of complex **1** and **2**, or from $^{13}CO$ enriched samples of complex **1** (see above), 0.25 mol/$dm^3$ solutions in $CD_2Cl_2$ were prepared by removing the dichloromethane solvent at –5 °C in vacuo (17 Torr) and dissolving the oily residue in $CD_2Cl_2$ under an atmosphere of argon. The $^{13}C$ NMR spectra were recorded at 273, 233, 200, and 185 K.

**Keywords:** Crystal engineering / Fullerenes / Metal dialkyldithiocarbamates / Magnetic properties / Photoconductivity

New complexes of fullerenes $C_{60}$ and $C_{70}$ with metal dialkyldithiocarbamates, $[M(R_2dtc)_x]\cdot[C_{60(70)}]\cdot$[Solvent], R = Et [M = $Cu^{II}$ ($C_{60}$, **1**; $C_{70}$, **2**), $Cu^{I}$ ($C_{60}$, **3**; $C_{70}$, **4**), $Ag^{I}$ ($C_{60}$, **5**), $Zn^{II}$ ($C_{60}$, **6**), $Cd^{II}$ ($C_{60}$, **7**; $C_{70}$, **8**), $Hg^{II}$ ($C_{60}$, **9**), $Mn^{II}$ ($C_{70}$, **10**)], R = Et and Me [M = $Cu^{II}$ ($C_{60}$, **11**), and $Zn^{II}$ ($C_{60}$, **12**)], and R = *n*Pr [M = $Cu^{II}$ ($C_{60}$, **13**), $Ni^{II}$ ($C_{60}$, **14**), and $Pt^{II}$ ($C_{60}$, **15**)] were obtained. $M(R_2dtc)_x$ efficiently cocrystallized with fullerene molecules as tetrahedral monomers (**6**, **12**), dimers (**1**, **7**, **11**), and tetramers (**3**, **4**). Fullerene molecules form closely packed hexagonal and square layers in **1**, **7**, and **11**, hexagonal and tetragonal 3D structures in **6** and **12**, and island motifs in **3** and **4**. Complexes **1**–**15** have a neutral ground state. However, the formation of the complexes with fullerenes changes the environment of paramagnetic $Cu^{II}$ and $Mn^{II}$. The EPR spectra of **1**, **2**, **11**, and **13** are essentially modified relative to those of pristine $Cu(R_2dtc)_2$ because of a weak coordination of $Cu^{II}$ to fullerene and a flattening of the central $(NCS_2)_2Cu$ fragments. Complex **10** shows a spectrum exhibiting features from 50 to 600 mT and manifests strong antiferromagnetic coupling of spins with a Weiss temperature of –96 K and the maximum of magnetic susceptibility at 46 K. Such magnetic behavior can be explained by the formation of $[Mn(Et_2dtc)_2]_2$ dimers in **10**. The illumination of the crystals of **1**, **2**, and **7** by white light results in up to a $10^3$ increase in photocurrent. The photoconductivity spectra have maxima at 470, 450–650, and 660 nm for **1**, **2**, and **7**, respectively. Photogeneration of free charge carriers is realized by photoexcitation of $Cu(Et_2dtc)_2$ in **1** and **2**, and by charge transfer from $Cd(Et_2dtc)_2$ to $C_{60}$ molecules in **7**. The decrease of photocurrent in **1** and **7** in a weak magnetic field with $B_0 < 0.5$ T was found.

## Introduction

Fullerenes form a wide variety of donor-acceptor complexes ranging from molecular to ionic ones[1–3] with different classes of organic and organometallic donors: aromatic hydrocarbons,[4] amines,[5–7] tetrathiafulvalenes,[6,8] porphyrins and metalloporphyrins,[9–11] porphyrazines,[12] metallocenes,[13–17] and others.[6] Great interest in fullerene complexes was evoked by their intriguing properties. Ionic compounds show ferromagnetism[5] and reversibly form σ-bonded structures.[15–17] Neutral complexes were also used as templates for the preparation of fullerene polymers.[18] They can manifest photoconductivity[19] and excited ionic states upon photoexcitation by white light.[20] The variation of a donor component allows one to affect the packing of fullerene molecules in a crystal, the charged state of fullerenes and, consequently, the properties of the resulting complexes. The search for new classes of donor molecules for the preparation of fullerene complexes can result in the design of new promising compounds. Recently, we have found that dimeric copper(II) diethyldithiocarbamate, $Cu(Et_2dtc)_2$, co-crystallizes with fullerenes to form a molecular complex, $[Cu(Et_2dtc)_2]_2\cdot C_{60}$, with a layered structure.[21] This work was extended to metal(II) dithiocarbamates with bulkier benzyl substituents (abbreviation: Bnz), namely, $Cu(Bnz_2dtc)_2$, $Ni(Bnz_2dtc)_2$, $Pd(Bnz_2dtc)_2$, and $Pt(Bnz_2dtc)_2$. They co-crystallize with $C_{60}$ to form $M(Bnz_2dtc)_2\cdot C_{60}\cdot(C_6H_5Cl)_{0.5}$ complexes.[22] In contrast to dimeric $Cu(dedtc)_2$, $M(Bnz_2dtc)_2$ are monomers with planar conformation of the central $(NCS_2)_2M$ fragment, which is charac-

teristic of $Ni^{II}$, $Pd^{II}$, and $Pt^{II}$ dithiocarbamates.[23–27] Moreover, $Pd(Bnz_2dtc)_2$ forms a multi-component ionic complex containing $C_{60}$ and bis(benzene)chromium ion-radicals: $[Cr^{I}(C_6H_6)_2^{\cdot+}]\cdot(C_{60}^{\cdot-})\cdot[Pd(Bnz_2dtc)_2]_{0.5}$. The complex demonstrates unusual low-temperature dimerization of $C_{60}^{\cdot-}$ with a relatively large hysteresis and the decrease of the dimerization temperature at a fast cooling rate.[22] Thus, metal dialkyldithiocarbamates, $M(R_2dtc)_x$, can successfully be used in the design of molecular and ionic complexes with fullerenes. It should be noted that although we have known about $M(R_2dtc)_x$ for a long time, their donor-acceptor complexes with π-acceptors are rare. To our knowledge, only some complexes of molybdenum and tungsten dialkyldithiocarbamates with tetracyanoquinodimethane were described.[28,29]

$M(R_2dtc)_x$ can easily be modified. It is possible to vary molecular structures of $M(R_2dtc)_x$ by changing "M" or the length of alkyl substituents (R). Donor properties of $M(R_2dtc)_x$ can also be varied from weak donors to strong ones[30] potentially able to ionize fullerenes. Some of $M(R_2dtc)_x$ have broad absorption in the visible range or outstanding magnetic properties [for example, $Fe^{III}(Et_2dtc)_2Cl$ is the first single-component ferromagnet with $T_c$ = 2.46 K][31] and, therefore, they can be used as light harvesting or magnetic components for the complexes.

In the present work we studied the effect of $M(R_2dtc)_x$ (depending on M and R) on composition, structure, electronic, and physical properties of their complexes with fullerenes. We used monomeric, dimeric, and tetrameric $M(R_2dtc)_x$ and varied the length of alkyl (R) substituents (Me, Et, and *n*Pr). $M(R_2dtc)_x$ were both weak and strong donors. The interaction of $C_{60}$ with the strongest donors ($Cu^{I}$, $Mn^{II}$, $Co^{II}$, and $V^{II}$ diethyldithiocarbamates) was studied in benzonitrile solution. Fifteen complexes of $C_{60}$ and $C_{70}$ with $Cu^{II}$, $Cu^{I}$, $Ag^{I}$, $Zn^{II}$, $Cd^{II}$, $Hg^{II}$, $Mn^{II}$, $Ni^{II}$, and $Pt^{II}$ dialkyldithiocarbamates were obtained and characterized in the solid state. The composition of the complexes was determined from elemental analysis and X-ray diffraction on single crystals. Crystal structures of seven complexes were solved. FTIR- and UV/Visible-NIR spectra of the complexes were studied. Magnetic properties of the complexes with $M(R_2dtc)_x$ (M = $Cu^{I}$, $Cu^{II}$, and $Mn^{II}$) were investigated by SQUID and EPR techniques. Photoconductivity of single crystals of four $C_{60}$ and $C_{70}$ complexes with $Cu(Et_2dtc)_2$ and $Cd(Et_2dtc)_2$ was studied upon illumination with white light. The comparison of the photoconductivity and the absorption spectra allows one to suggest the mechanisms of free charge carrier generation. The effect of magnetic field with $B_0 < 0.5$ T on photoconductivity was determined.

## Results and Discussion

### 1. Interaction of Fullerenes with Metal(II) Diethyldithiocarbamates in Solution

The interaction of the strongest $M(Et_2dtc)_2$ donors (M = $Cu^{I}$, $Mn^{II}$, $Co^{II}$, and $V^{II}$) with $C_{60}$ was studied in solution. $C_{60}$ and a fivefold molar excess of the corresponding $M(Et_2dtc)_x$ were dissolved in benzonitrile at 60 °C over 2 h, the solutions were cooled down, filtered off, and the spectra of the resulting solutions were measured in anaerobic conditions in the 600–1600 nm range. $Cu^{I}$, $Co^{II}$, and $V^{II}$ diethyldithiocarbamates reduce $C_{60}$ to a radical anion, and an absorption band characteristic of $C_{60}^{-}$ is manifested at 1070 nm. On the contrary, $Mn(Et_2dtc)_2$ cannot reduce $C_{60}$. These observations are in agreement with redox potentials of metal(II) dithiocarbamates. Related octahedral $M^{III}(dtc)_3^{1-/0}$ ($M^{3+}/M^{2+}$ transition) are reduced at –0.77 V for $V^{3+/2+}$, and –0.92 V for $Co^{3+/2+}$, whereas the reduction potential for $Mn^{3+/2+}$ (–0.08 V) is shifted to positive values (all vs. Ag/AgCl).[30] $C_{60}$ has the first $E^{0/-}$ potential at –0.485 V(vs. Ag/AgCl).[32]

### 2. Synthesis of Solid Complexes

The complexes obtained and the data from the elemental analysis are listed in Table 1. The ability of $M(R_2dtc)_x$ to co-crystallize with $C_{60}$ and $C_{70}$ as well as the composition of the complexes depend on the metal (M) and the length of the alkyl substituents (R). Pristine $M(R_2dtc)_2$ (R = Et, *n*Pr) have different conformations of the central $(NCS_2)_2M$ fragment. $Ni(R_2dtc)_2$ and $Pt(R_2dtc)_2$ have square planar conformation.[23–27] $Zn(R_2dtc)_2$,[33–35] $Cd(R_2dtc)_2$,[36,37] and $Fe(Et_2dtc)_2$[38] are dimers with a tetrahedral environment of $M^{II}$. $Mn(Et_2dtc)_2$ is a polymer with an octahedral environment of $Mn^{II}$.[39] $Hg(R_2dtc)_2$[40–42] and $Cu(R_2dtc)_2$[43] have both square planar or square pyramidal dimeric conformations.

$M(Et_2dtc)_2$ (M = $Cd^{II}$, $Hg^{II}$, and $Mn^{II}$) co-crystallize with fullerenes in dimeric conformation to form 1:2 [$C_{60}$/$M(R_2dtc)_2$] complexes. As this takes place, $Cd(Et_2dtc)_2$, and $Mn(Et_2dtc)_2$ precipitate $C_{60}$ and $C_{70}$ complexes from $C_6H_6$, $C_6H_5Cl$, and $C_6H_4Cl_2$ solutions in nearly a quantitative yield [a similar ability was found for $Fe(Et_2dtc)_2$]. On the contrary, square planar $Ni(Et_2dtc)_2$, and $Pt(Et_2dtc)_2$ or $Co(Et_2dtc)_2$ and $V(Et_2dtc)_2$, which reduce $C_{60}$ in solution, do not form crystals of the complexes with fullerenes.

Elongation of alkyl substituents in $M(nPr_2dtc)_2$ drastically changes their complex formation with fullerenes. $Ni(nPr_2dtc)_2$ and $Pt(nPr_2dtc)_2$ with square planar conformation form 2:1 [$C_{60}$/$M(nPr_2dtc)_2$] complexes with $C_{60}$. Similarly, among different metal(II) dibenzyldithiocarbamates only $Ni(Bnz_2dtc)_2$, $Pd(Bnz_2dtc)_2$, and $Pt(Bnz_2dtc)_2$ with the same conformation co-crystallize with $C_{60}$.[22] It is interesting to note that $Cu(R_2dtc)_2$ form 1:2, 2:1, and 1:1 [$C_{60}$:$Cu(R_2dtc)_2$] complexes independently of the R (MeEt, Et, *n*Pr, and Bnz) length. It seems possible that $Cu(R_2dtc)_2$ in the complexes with fullerenes can adopt both square planar[43,44] and square pyramidal dimeric conformations.[43]

The crystals of the complexes were obtained by the evaporation of solutions containing fullerenes and corresponding donors. We used the diffusion method to prepare the complexes with air-sensitive $M(R_2dtc)_x$ and $Cd(Et_2dtc)_2$.

[a] The composition of the complex was proved by X-ray diffraction on single crystals. [b] A smaller content of carbon relative to the calculated values may have been caused by the addition of oxygen during elemental analysis because of the high air-sensitivity of $Mn(Et_2dtc)_2$.

## 3. Crystal Structures

Main geometric parameters of $M(R_2dtc)_x$ and van der Waals (vdW) contacts in the complexes with fullerenes are listed in Table 2. Molecular structures of $M(R_2dtc)_x$ are shown in Figure 1.

The crystal structure of $[Cu(Et_2dtc)_2]_2{\cdot}C_{60}$ (**1**) has been described previously.[21]

$[Cd(Et_2dtc)_2]_2{\cdot}C_{60}$ (**7**) has a crystal structure similar to that of **1**. $Cd(Et_2dtc)_2$ and $C_{60}$ molecules are ordered at 120 K. Complex **7** has a layered structure (Figure 2, parts a and b), in which layers of closely packed $C_{60}$ molecules alternate with those composed of $Cd(Et_2dtc)_2$ dimers. Each $C_{60}$ molecule has four neighbors in the layer with the shortest interfullerene center-to-center distance of 9.99 Å along the diagonal to the *bc*-plane (Figure 2, b). This distance is close to that in pure $C_{60}$ crystals at 153 K (9.94 Å).[45] The vdW C···C contacts are 3.33–3.77 Å. Two other neighboring fullerenes are arranged in the *c*-direction with a center-to-center distance of 10.54 Å (longer than the vdW diameter of $C_{60}$ molecules of 10.18 Å). Therefore, $C_{60}$ molecules have a square arrangement in the layers.

The projection of the $Cd(Et_2dtc)_2$ layer on the $C_{60}$ one is shown in part b of Figure 2. The central $CdS_4$ fragments are arranged strictly above the $C_{60}$ spheres, whereas flexible ethyl substituents occupy available cavities in the $C_{60}$ layers. The effective packing of $Cd(Et_2dtc)_2$ and $C_{60}$ molecules in a crystal is attained due to a butterfly shape of $Cd(Et_2dtc)_2$ dimers (Figure 1), which allows them to encapsulate $C_{60}$ molecules (Figure 2, c).

The packing of $Cd(Et_2dtc)_2$ dimers in the layer has a parquet-like motif (Figure 2, b). The shortest Cd···C($C_{60}$) contacts of 3.587 and 3.592 Å are formed with two carbon atoms of the 6–6 bond of $C_{60}$. These contacts are noticeably longer than the Cu···C($C_{60}$) contacts in **1** (3.334 and 3.379 Å).[21] Co-crystallization of $Cd(Et_2dtc)_2$ with $C_{60}$ does not affect its geometry. The pristine donor has a dimeric structure with a nearly tetrahedral environment of $Cd^{II}$ with three short equatorial bonds and one short axial bond (an average length is 2.575 Å). One equatorial bond is noticeably longer than the other ones (2.812 Å).[36] The dimeric structure of $Cd(Et_2dtc)_2$ is retained in **7**. Averaged lengths of three short equatorial bonds and one short axial bond are nearly the same (2.577 Å), but the long equatorial bond is elongated to 2.877 Å. Two of four ethyl groups of $Cd(Et_2dtc)_2$ are directed towards the fullerene layer in **7** (Figure 2, c), whereas in **1** three of four ethyl groups of $Cu(Et_2dtc)_2$ are directed towards the fullerene layer.[21]

[a] The ranges for the bond lengths and angles are given for **3** and **4**. [b] The bond lengths and angles for $Zn(EtMedtc)_2$ are given for one of three crystallographically independent molecules.

$[Cu(EtMedtc)_2]_2{\cdot}C_{60}$ (**11**) is isostructural to **1**. The substitution of two of four ethyl groups by methyl ones results in the decrease of the unit cell parameters of **11** relative to those of **1** (see Table 4). $C_{60}$ and $Cu(EtMedtc)_2$ molecules are ordered. Complex **11** also has a layered structure (Figure 3, a and b) with six neighbors to each $C_{60}$ molecule. The shortest interfullerene center-to-center distances are 9.89 (four neighbors along the diagonal to the *bc*-plane) and 10.02 Å (two neighbors in the *c*-direction; Figure 3, b). For both cases the vdW C···C contacts between adjacent fullerenes of 3.28–3.41 and 3.39–3.47 Å are shorter than 3.42 Å and center-to-center distances are close to the distance in pure $C_{60}$[45] justifying the formation of closely packed hexagonal layers.

The projection of the $Cu(EtMedtc)_2$ layer on the $C_{60}$ layer is shown in Figure 3, b. The central $CuS_4$ fragments arranged above $C_{60}$ spheres allow two flexible ethyl groups to occupy cavities in the $C_{60}$ layers. $C_{60}$ forms shortened Cu···C($C_{60}$) contacts of 3.334 and 3.379 Å by two carbon atoms of one 6–6 bond (Figure 3, b). VdW S, N and H···C($C_{60}$) contacts are close to those in **1** and **7** (Table 2).

$Cu(EtMedtc)_2$ has a dimeric structure in **11** with a square pyramidal environment of $Cu^{II}$ atoms (Figure 1) with four

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

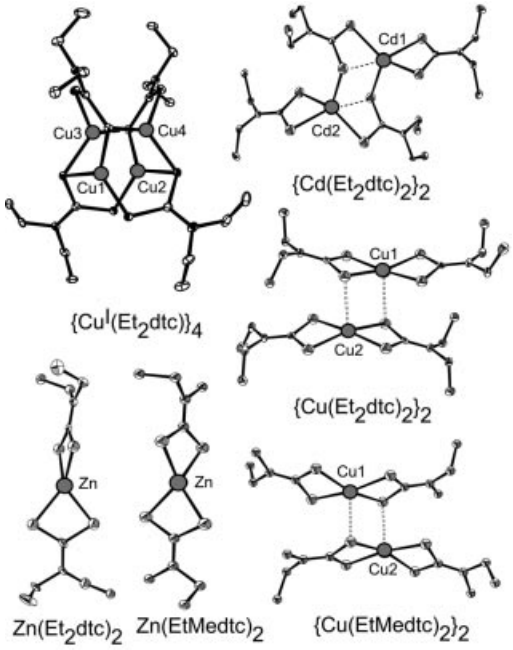

Figure 1. Molecular structures of $M(R_2dtc)_x$ in the complexes with fullerenes: $\{Cd(Et_2dtc)_2\}_2$, $\{Cu(Et_2dtc)_2\}_2$ and $\{Cu(EtMedtc)_2\}_2$ dimers; tetrahedral $Zn(Et_2dtc)_2$ and $Zn(EtMedtc)_2$ monomers and $[Cu^I(Et_2dtc)]_4$ tetramers.

short equatorial bonds (the average length is 2.325 Å) and one relatively long axial bond (2.787 Å). Both ethyl groups of $Cu(EtMedtc)_2$ are directed towards the fullerene layer.

Thus, **1**, **7**, and **11** have similar crystal structures. However, the differences in the molecular structures of $M(R_2dtc)_2$ and the length of the alkyl substituents provide their noticeable modifications. The packing motif of the fullerene layer changes from closely packed hexagonal layers in **11**, to intermediate layers in **1** (four and two neighbors with 10.02 and 10.25 Å center-to-center interfullerene distances)[21] and finally to square layers in **7**. The character of $M(R_2dtc)_2$-fullerene interactions also changes. Weakly bound $Cu(R_2dtc)_2$ dimers with relatively long axial bonds have a more planar shape of the $(NCS_2)_2M$ fragments than those in strongly bound $Cd(Et_2dtc)_2$ dimers with a short axial bond. The dihedral angles between the $NCS_2M$ planes are 160.9 and 158.6° in **1** and **11**, and only 143.8° in **7** providing shorter Cu···C($C_{60}$) distances (by about 0.3 Å) in **11** and **1** than the Cd···C($C_{60}$) distances in **7**. However, the more concave surface of the $Cd(Et_2dtc)_2$ fragments results in better conditions for the π-π interaction between the $NCS_2Cd$ planes and two adjacent $C_{60}$ hexagons (Figure 2, c) since the dihedral angle of 143.8° is close to that between adjacent $C_{60}$ hexagons (138.5°). As a result, the $NCS_2Cd$ planes and the $C_{60}$ hexagons arrange parallel to each other with the dihedral angles between them equal only to 0.8 and 8.2°. High steric complementarity is probably a reason for the ability of $Cd(Et_2dtc)_2$ to quantitatively precipitate $C_{60}$ and $C_{70}$ complexes from solutions. More planar $Cu(R_2dtc)_2$ provides worse conditions for the π-π interactions in **1** and **11** with corresponding dihedral angles of 9.8, 13.6° and 9.5, 12.6°, respectively.

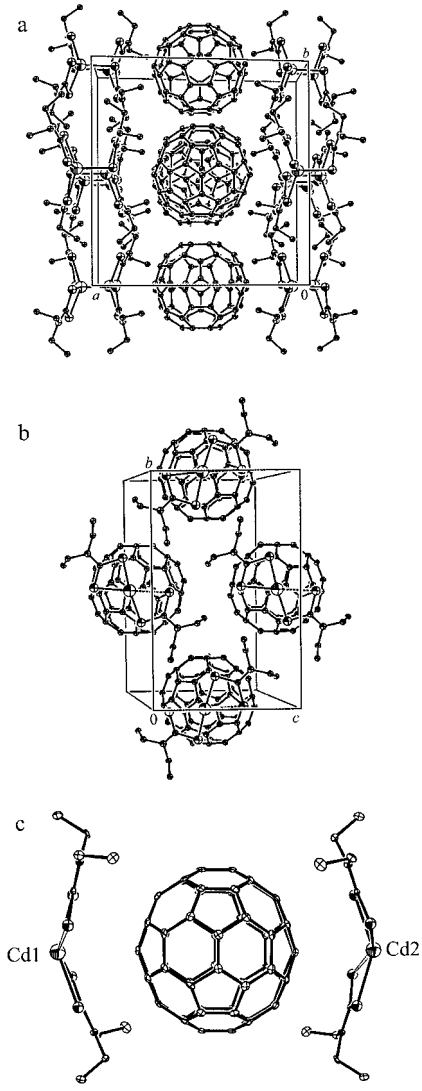

Figure 2. Crystal structure of **7**: the view of the unit cell on the *ab*-(a) and *bc*-planes (b); a mutual arrangement of concave $Cd(Et_2dtc)_2$ fragments and a spherical $C_{60}$ molecule (c).

$Zn(Et_2dtc)_2 \cdot C_{60} \cdot (C_6H_5Cl)_{0.5} \cdot (C_6H_6)_{0.5}$ (**6**) crystallizes in a triclinic lattice. $C_{60}$ and $Zn(Et_2dtc)_2$ molecules are ordered, whereas $C_6H_5Cl$ and $C_6H_6$ molecules share one position with equal occupancies and are disordered. Complex **6** has a unique cage structure with large channels along the *a*-axis accommodating $Zn(Et_2dtc)_2$ and solvent molecules. The channels are completely surrounded by the fullerene molecules, which form a hexagonal 3D framework (Figure 4). Each $C_{60}$ molecule has six neighbors. The center-to-center distances for three of them (9.74, 9.81, and 9.93 Å) are close to that distance in pure $C_{60}$,[45] whereas the other ones are larger (10.38 Å ×2 and 10.13 Å). Shortened vdW C···C contacts between the closest fullerenes are 3.250–3.360 Å.

$Zn(Et_2dtc)_2$ forms a complex with $C_{60}$ in a monomeric state with nonplanar *pseudo*-tetrahedral configuration of $Zn^{II}$ (the dihedral angle between two $NCS_2Zn$ planes being

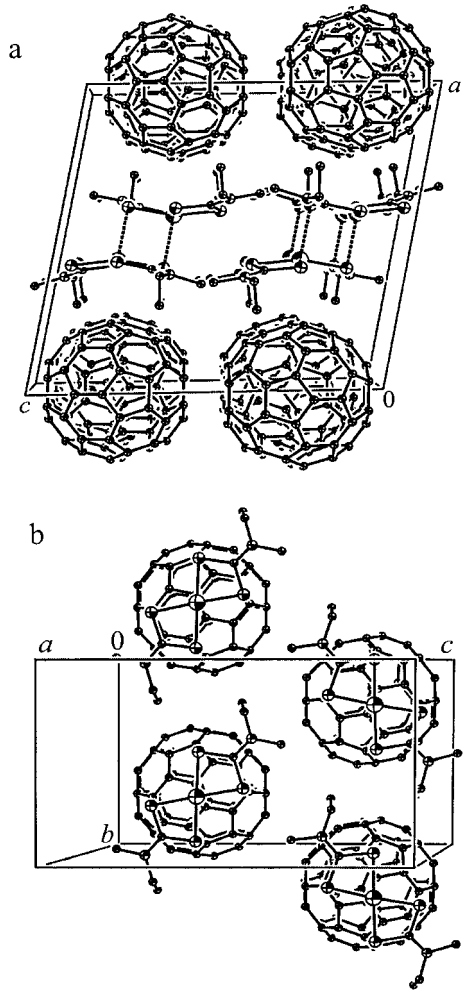

Figure 3. Crystal structure of **11**: the view of the unit cell of **11** on the *ac*- (a) and *bc*-planes (b).

91.5°) (Figure 1). This conformation is for the first time observed for $Zn(Et_2dtc)_2$. Similar geometry of the $(NCS_2)_2Zn$ fragment was reported for $Zn(Bnz_2dtc)_2$ with bulky benzyl substituents,[46] whereas pristine $Zn(R_2dtc)_2$ with R = Et, *n*Pr, *i*Pr substituents have dimeric structures.[33–35]

Because of the tetrahedral geometry, only half of each $Zn(Et_2dtc)_2$ molecule forms vdW contacts with $C_{60}$ (Table 2). The closest Zn···C($C_{60}$) distances are 3.659 and 3.822 Å. The other half of the $Zn(Et_2dtc)_2$ molecule locates above the adjacent $Zn(Et_2dtc)_2$.

The substitution of two ethyl groups by methyl ones changes the packing motif in $[Zn(EtMedtc)_2]_3 \cdot (C_{60})_2$ (**12**). In contrast to previously described complexes, both $C_{60}$ molecules are disordered at 90 K between two orientations with 66/34 and 58/42% occupancies. These orientations are linked by the rotation of the $C_{60}$ molecule by 180° about the axis passing through the centers of two oppositely located 5–6 bonds. There is also certain disorder in the positions of ethyl and methyl groups in $Zn(EtMedtc)_2$. The complex has 3D packing of fullerenes, in which each $C_{60}$ molecule has four neighbors and is located in the center of a distorted tetrahedron. This 3D packing can be split in strongly puckered $C_{60}$ layers parallel to the *ac*-plane (Figure 5). Three neighbors are seen in this plane, whereas the fourth neighbor is located in the adjacent layers. The center-to-center distances are in the 9.83–10.09 Å range (the vdW radius of $C_{60}$ is 10.18 Å) and the shortest C···C contacts lie in the 3.27–3.41 Å range. The cavities in the 3D framework are occupied by $Zn(EtMedtc)_2$ molecules. One $Zn(EtMedtc)_2$ molecule arranges parallel to the *ac*-plane and two other ones are perpendicular to this plane (Figure 5). Because of the strong puckering of fullerene layers, each $Zn(EtMedtc)_2$ molecule forms vdW contacts with four fullerene ones. The Zn···C($C_{60}$) distances of 3.66–3.94 Å are similar to those in **6**.

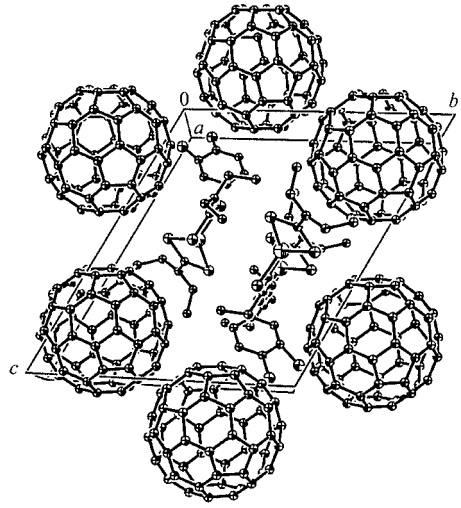

Figure 4. The view of the unit cell of **6** along the *a*-axis.

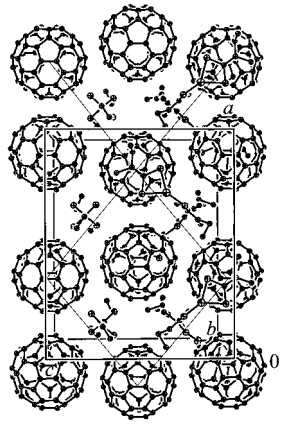

Figure 5. The view of the crystal structure of **12** on the *ac*-plane. $C_{60}$ molecules occupy two levels. Molecules belonging to one level are connected by thin lines.

$\{[Cu^I(Et_2dtc)]_4\}_5 \cdot (C_{60})_3 \cdot (C_6H_4Cl_2)_4$ (**3**) and $\{[Cu^I(Et_2dtc)]_4\}_5 \cdot (C_{70})_3 \cdot (C_6H_4Cl_2)_4$ (**4**) are isostructural and have high-symmetry cubic unit cells with parameters of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

43.7822(4) (**3**) and 44.2911(3) (**4**) Å and unusually great volumes of 83925.3(13) (**3**) and 86885.9(10) Å (**4**). Two symmetrically independent $C_{60}$ molecules are disordered. One of them is located on a twofold axis and the other molecule is on a fourfold axis. Because of the disorder, $C_{60}$ molecules have two and four orientations, respectively. $[Cu^{I}(Et_2dtc)]_4$ and solvent $C_6H_4Cl_2$ molecules are located in general positions and are ordered.

The complexes have an island motif of fullerene packing with the shortest interfullerene center-to-center distances of 13.5 Å. Loose layers can be outlined in the *bc*-plane. The main structural motif of these layers is shown in Figure 6. There are large (right in Figure 6) and small (left in Figure 6) squares consisting of five and four fullerene molecules. Each small square is surrounded by four large squares and vice versa. As this takes place, both squares have one common $C_{60}$ molecule. Small squares accommodate five $[Cu^{I}(Et_2dtc)]_4$ molecules, whereas large squares accommodate eight $[Cu^{I}(Et_2dtc)]_4$ and eight $C_6H_4Cl_2$ molecules. It is interesting that all eight $C_6H_4Cl_2$ molecules surround one $C_{60}$ molecule (Figure 6). The adjacent fullerene layers in 3D packing are arranged in such a way that large fullerene squares are located above and below small fullerene squares.

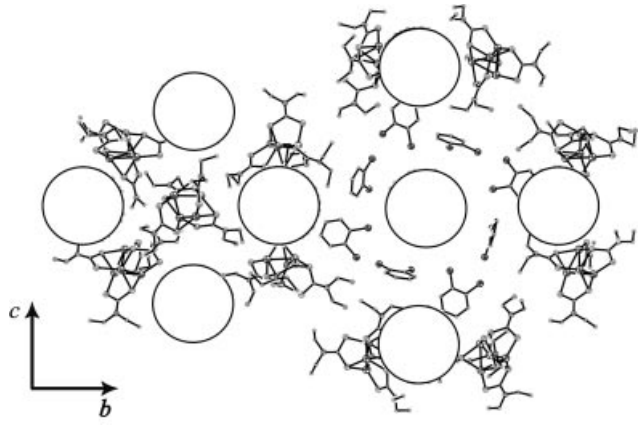

Figure 6. The view of the crystal structure of **3** on the *bc*-plane.

$[Cu^{I}(Et_2dtc)]_4$ is a tetramer containing four $Cu^{I}(Et_2dtc)$ units (Figure 1). $Cu^{I}$ atoms form a slightly distorted tetrahedron with the Cu···Cu distance of 2.5698(18)–2.6306(18) Å. Each $Cu^{I}$ atom forms three Cu–S coordination bonds of 2.245(3)–2.281(3) Å length. Therefore, the coordination number of $Cu^{I}$ is 3. Pristine $Cu^{I}(Et_2dtc)$ and $Au^{I}(Et_2dtc)$ form dimers,[47,48] and for $Ag^{I}(Et_2dtc)$ hexamers and polymers are also known.[49,50] According to the best of our knowledge, a tetrameric structure is for the first time observed for $Cu^{I}(Et_2dtc)$. Probably, the formation of complexes with $C_{60}$ and $C_{70}$ stabilizes the tetrameric structure. The Cu···C($C_{60}$) and Cu···C($C_{70}$) distances (4.80 and 4.44 Å), as well as the vdW N and S···C(fullerene) contacts (Table 2) are large enough to show low efficiency of the π-π interaction in **3** and **4**.

## 4. Magnetic Properties of the Complexes

EPR spectroscopy is a sensitive tool used to study changes in a local environment of $Cu^{II}$ atoms at the formation of fullerene complexes with $Cu(R_2dtc)_2$. Pristine $Cu(R_2dtc)_2$ with R = Et, *n*Pr possess dimeric structures with square pyramidal geometry of $Cu^{II}$ (the coordination number is 5).[43] Such geometry is characterized by the EPR spectrum shown in part a of Figure 7. $Cu(EtMedtc)_2$ has an asymmetric structure and as a result shows a more asymmetric EPR signal (Supporting Information).

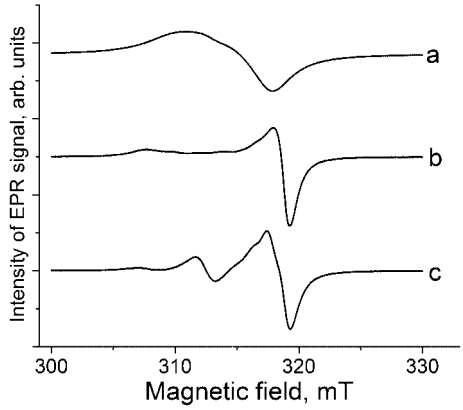

Figure 7. The EPR spectra of polycrystalline pristine $Cu(Et_2dtc)_2$ (a); **1** (b), and **2** (c) at 290 K.

The EPR signal of **1** (Figure 7, b) is noticeably different from that of pristine $Cu(Et_2dtc)_2$. According to X-ray diffraction data, $Cu(Et_2dtc)_2$ has a dimeric structure in **1** as well.[21] However, noticeable changes are observed in the environment of $Cu^{II}$. Weak axial coordination of $Cu^{II}$ to $C_{60}$ with a rather short Cu···C($C_{60}$) distance of 3.27 Å enhances the asymmetry of the environment of $Cu^{II}$. This coordination directs oppositely to the axial Cu–S bond and results in noticeable elongation of this bond from 2.844(1) in the pristine donor to 3.030(2) Å in **1**. Consequently, the central $(NCS_2)_2Cu$ fragments become more planar in **1** than in the pristine donor. Coordination of $Cu^{II}$ to $C_{60}$ is more favorable for planar conformation of $M(Et_2dtc)_2$, and most probably namely this coordination evokes the flattening of the central $(NCS_2)_2Cu$ fragments. The M···C($C_{60}$) distances (3.587, 3.334, and 3.269 Å) decrease together with the flattening of $M(Et_2dtc)_2$ fragments in the following order: **7**, **11**, and **1** (the length of axial M–S bonds are 2.599, 2.787, and 3.030 Å, respectively).

The EPR spectra of $[Cu(Et_2dtc)_2]\cdot(C_{70})_2\cdot(C_6H_5Cl)_{0.5}$ (**2**, Figure 7, c), $[Cu(EtMedtc)_2]_2\cdot C_{60}$ (**11**), and $[Cu(nPr_2dtc)_2]\cdot(C_{60})_2$ (**13**) (for spectra of **11** and **13** see supporting information) are also noticeably changed relative to those of pristine $Cu(R_2dtc)_2$. These changes are similar to those observed in the spectrum of **1** suggesting that weak coordination of $Cu^{II}$ to fullerenes and a flattening of the central $(NCS_2)_2Cu$ fragments can be realized in these complexes as well.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Magnetic susceptibilities of **1** and **2** were measured from 300 down to 1.9 K and were shown to follow the Curie–Weiss law with the small negative Weiss constants of –2.5 K (**1**) and –2.0 K (**2**), which indicate only a weak antiferromagnetic interaction between $Cu^{II}$ centers. Axial Cu–S bonds transfer the magnetic interaction in the $\{Cu(Et_2dtc)_2\}_2$ dimers and their elongation at the formation of complexes with fullerenes can weaken the antiferromagnetic interaction between $Cu^{II}$ centers.

The spectrum of $C_{60}$ and an excess of $Cu^{I}(Et_2dtc)$ in benzonitrile shows that CT is realized from donor to fullerene molecules in solution. To study CT in the solid state we measured the EPR spectra (4–290 K) and magnetic susceptibilities of $\{[Cu^{I}(Et_2dtc)]_4\}_5\cdot(C_{60})_3\cdot(C_6H_4Cl_2)_4$ (**3**) and $\{[Cu^{I}(Et_2dtc)]_4\}_5\cdot(C_{70})_3\cdot(C_6H_4Cl_2)_4$ (**4**) in the 2–300 K range. Pristine $Cu^{I}(Et_2dtc)$ is diamagnetic and EPR silent. **3** and **4** are also diamagnetic with temperature-independent diamagnetic contributions of –0.00522 and –0.00666 emu/mol$^{-1}$. Paramagnetic contributions of the Curie impurities are only 0.23 and 1.3% for **3** and **4**. According to EPR at 290 K (two narrow lines with $g_1$ = 2.0009 and $g_2$ = 2.0025 for **3** and one narrow line with $g$ = 2.0019 for **4**) these impurities originate mainly from defects.[51] Thus, in spite of the observation of CT in solution, both complexes are molecular ones in the solid state. Most probably, this is associated with the formation of $[Cu^{I}(Et_2dtc)]_4$ tetramers, whose shape is unfavorable for effective CT to fullerene molecules.

It is known that pristine $Mn^{II}(Et_2dtc)_2$ has a polymeric structure with a distorted octahedral environment of $Mn^{II}$.[39] In EPR it shows a single Lorentzian line with $g$ = 2.0115 and $\Delta H$ = 61.8 mT (Figure 8, a), which is characteristic of this environment of $Mn^{II}$.[52] The formation of $\{Mn(Et_2dtc)_2\}_2\cdot C_{70}$ (**10**) results in considerable changes in the EPR spectrum indicating noticeable modification of the local environment of $Mn^{II}$. The EPR spectrum exhibits features extending from 50 to about 500 mT (Figure 8, b). Such a spectrum is typical for dinuclear $Mn^{II}$ species[53] and previously a very similar EPR spectrum has been observed, for example, in a dinuclear $Mn^{II}$ complex bridged by chlorine atoms.[54] Magnetic susceptibility data provides evidence of a strong exchange interaction between $Mn^{II}$ centers. The magnetic moment of **10** is equal to 7.78 $\mu_B$ per formula unit at 300 K, which is close to the calculated value of 7.75 $\mu_B$ if two 5/2 spins contribute to magnetic susceptibility. $Mn^{II}$ spins interact antiferromagnetically in the 150–300 K range with a large negative Weiss constant of –96 K and magnetic susceptibility decreases below 46 K (Figure 9). Such exchange interactions between $Mn^{II}$ can be realized if $Mn(Et_2dtc)_2$ forms dimers in **10** [similar to $\{Cd(Et_2dtc)_2\}_2$ dimers in **7**]. EPR data support this conclusion. The EPR signal from $Mn(Et_2dtc)_2$ in **10** remains unchanged qualitatively down to 4 K. No EPR signals attributed to $C_{70}^{\cdot-}$ [55] were found indicating the absence of CT to fullerene molecules. Thus, $Mn(Et_2dtc)_2$ cannot ionize $C_{70}$ in the solid state. Similarly, $Mn^{II}$TPP (tetraphenylporphyrinate) ($E^{+/0}_{1/2}$ = –0.23 V vs. SCE)[56] forms only molecular complexes with fullerenes $C_{60}$ and $C_{70}$.[57]

## 5. IR- and UV/Visible-NIR Spectra of the Complexes

The IR spectra of **1**–**15** (see Supporting Information) are a superposition of those of pristine metal dithiocarbamates, fullerenes, and solvent molecules. The positions of peaks in the UV/Visible-NIR spectra of **1**–**15** and pristine donors are listed in Table 3. The absence of absorption in the NIR spectra of **1**–**15** at 1070 nm indicates neutral ground states of the complexes. Pristine $Cu(Et_2dtc)_2$ has broad absorption in the visible range with the maximum at 442 nm and a shoulder at 660 nm (Figure 10, part 1, c). This absorption retains in the spectra of the complexes with the maximum at 437 nm (**1**, Figure 10, part 1, b) and 455 nm (**2**, Figure 10, part 1, a). The bands at 341 and 263 nm (**1**) and 230 nm (**2**) were ascribed to intramolecular transitions in fullerenes.[58] The spectra of **6** (Figure 10, part 2, b) and **7** (Figure 10, part 2, a) also contain $C_{60}$ absorption bands at 263 and 340 nm and a relatively weak band at 470 nm. The latter band ascribed to intermolecular CT between neighboring $C_{60}$ molecules was also found in the spectra of fullerene films.[59] A condition necessary for the observation of this band in the solid-state spectra of the complexes is close packing of fullerene molecules in the crystal.[7,60] Since $C_{60}$ molecules are closely packed in **1**, **7**, and **6**, this band can manifest itself in their spectra. However, in the spectrum

| **15** | 266 s, 340 s | | 450 w | 650 w |

[a] The bands overlap.

of **1** it is closed by absorption of $Cu(Et_2dtc)_2$. A similar interfullerene CT band was reported for pristine $C_{70}$ at 550 nm,[59] and it can also contribute to broad absorption of **2** at 500–600 nm (Figure 10, part 1, a).

The spectrum of **7** additionally contains a broad weak band at 610 nm (Figure 10, part 2, a). Because $C_{60}$ and $Cd(Et_2dtc)_2$ do not absorb noticeably in this range, it can be attributed to intermolecular CT from $Cd(Et_2dtc)_2$ to $C_{60}$. The observation of this band is possible due to favorable π-π interaction between $Cd(Et_2dtc)_2$ and $C_{60}$ molecules (Figure 2, c). CT bands are absent in the spectra of **6** (Figure 10, part 2, b) and **1**–**5**, **8**–**12** (Supporting Information) indicating worse conditions for the π-π interaction between nonplanar $M^{II}(R_2dtc)_x$ and fullerenes. Absorption at 600–700 nm in the spectra of **1**, **2**, and **11** was attributed mainly to $Cu(R_2dtc)_2$ (a shoulder at 660 nm).

Several processes can occur at photoexcitation of **1**, **2**, and **7** in the visible range. In **1** and **2** mainly photoexcitation of $Cu^{II}(Et_2dtc)_2$ (437 and 660 nm) is realized together with a minor contribution of intermolecular CT between neighboring $C_{60}$ and $C_{70}$ molecules (470 and 550 nm, respectively), whereas in **7** intermolecular CT from $Cd(Et_2dtc)_2$ to $C_{60}$ molecules (610 nm) and between $C_{60}$ molecules (470 nm) is mainly realized.

The absorption spectra of **13** and pristine $Cu(nPr_2dtc)_2$ are shown in part 3 of Figure 10. Additionally to absorption of $Cu(nPr_2dtc)_2$ in the visible range (Figure 10, part 3, a, and Table 3), the intense band with the maximum at 900 nm (Figure 10, part 3, a) was attributed to CT from the $Cu(nPr_2dtc)_2$ to the $C_{60}$ molecules. Similar bands are observed in the spectra of **14** and **15**. Therefore, planar $M(nPr_2dtc)_2$ have better conditions for the π-π interaction with fullerenes than nonplanar $M[(Et, Me)_2dtc]_2$.

### 6. Photoconductivity in $C_{60}$ and $C_{70}$ Complexes with $Cu(Et_2dtc)_2$ and $Cd(Et_2dtc)_2$ (1, 2, 7, and 8)

According to the IR- and EPR data, **1**, **2**, **7**, and **8** are molecular complexes without CT in the ground state. The crystals of **1**, **2**, and **7** have low "dark" conductivity $\sigma \approx 10^{-10}$ to $10^{-11}$ S·cm$^{-1}$. The photoexcitation of single crystals of the complexes by white light from a 150 W halogen tube with $10^{12}$ to $10^{14}$ photons/cm$^2$·s intensity results in a 20–50-fold increase in the photocurrent in **1**, two orders of magnitude in **2**, and three orders of magnitude in **7**. These values remain unchanged under the illumination of the crystals for $10^4$ s and are completely reproducible. The crystals of **8** do not show a noticeable increase in photocurrent at photoexcitation.

Photoconductivity spectra of the complexes are shown in Figure 11. Photoconductivity has maxima at 470 nm for **1**, 450–650 nm for **2**, and about 660 nm for **7**. The comparison of the photoconductivity spectra of **1**, **2**, and **7** with their absorption spectra allows one to suppose the mechanisms of free charge carrier generation. In **1** and **2** the main contribution is given by the photoexcitation of $Cu(Et_2dtc)_2$ (440 and 660 nm) as well as interfullerene CT between neighboring $C_{60}$ or $C_{70}$ molecules (470 nm for **1** and 550 nm for **2**, Figure 11, a and b). The major contribution is given in **7** by CT from the $Cd(Et_2dtc)_2$ to the $C_{60}$ molecule (610 nm) with a small contribution of interfullerene CT between neighboring $C_{60}$ molecules (470 nm) (Figure 11, c). In spite of similar crystal structures, the mechanisms of free charge carrier generation are different in **1** and **7**. In **1** $Cu(Et_2dtc)_2$ has intense absorption in the visible range, whereas $Cd(Et_2dtc)_2$ is transparent in **7** in this range. However, steric compatibility of the $Cd(Et_2dtc)_2$ and $C_{60}$ molecules (Figure 2, c) provides better

conditions for the π-π interaction and correspondingly for intermolecular CT in **7** than in **1**. Complex **8** has no CT band in the visible range and as a result photoconductivity was not found in this complex.

Photoconductivity of **1** and **7** is sensitive to weak magnetic field (MF) with $B_0 < 0.5$ T (Figure 12). A negative MF effect on photoconductivity is because of the reaction involving triplet CT excitons and paramagnetic centers. This interaction releases charges from deep-seated traps and increases photocurrent. A collision of triplet CT-excitons with doublet paramagnetic species may lead either to spin-independent triplet scattering or quenching. During quenching a transition from the initial spin state, which is a mixture of a doublet and a quartet, to a purely doublet final state takes place:

$$^3T + {}^2R \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} {}^{2,4}({}^3T\ldots{}^2R) \xrightarrow{k_L} {}^1S + {}^2R$$

The rate constant $k_L$ of the transition from each of the six $L$-th initial spin states of an intermediate complex to a final one depends on the amplitude of the doublet compo-

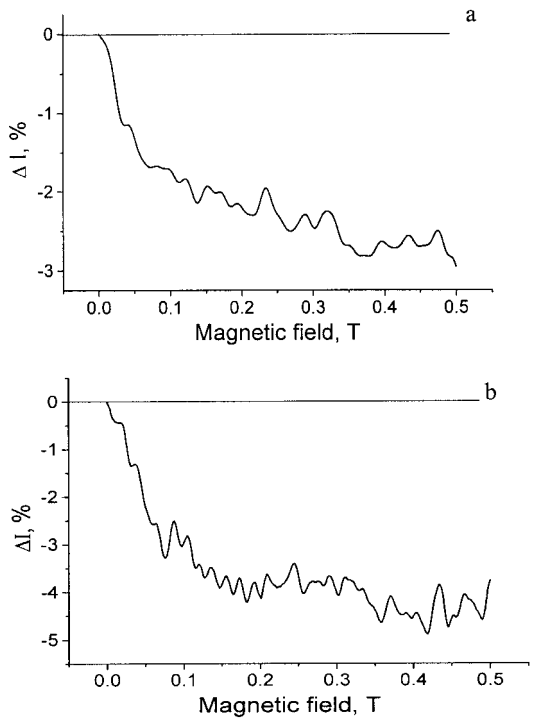

Figure 12. Magnetic field ($B_0$, $T$) dependence of photocurrent (I, %) in **1** (a) and **7** (b).

nent therein. The total rate of exciton quenching by paramagnetic impurity is:

$$Q = \frac{1}{6} k_1 \sum_{L=1}^{6} \frac{k_L}{k_{-1} - k_L},$$

where $k_1$ and $k_{-1}$ are rate constants of collision and back scattering, respectively. The value of $Q$ has a maximum, when a doublet component is uniformly distributed over all six substates, the minimum of $Q$ is attained at the complete separation of a doublet and a quartet. The quenching rate is maximal in ZMF. With the application of an external MF, the doublet component concentrates on four states and the value of $Q$ decreases together with the rate of dissociation of CT excitons and, consequently, a number of free charge carriers. A similar negative MF dependence was found in anthracene.[61]

## Conclusions

We studied the formation of the complexes between metal dialkyldithiocarbamates, $M(R_2dtc)_x$ with R = EtMe ($Cu^{II}$, $Zn^{II}$); Et ($Cu^{II}$, $Cu^{I}$, $Ag^{I}$, $Zn^{II}$, $Cd^{II}$, $Hg^{II}$, $Mn^{II}$, $Fe^{II}$, $Co^{II}$, $V^{II}$, $Ni^{II}$, and $Pt^{II}$); *n*Pr ($Cu^{II}$, $Cu^{I}$, $Zn^{II}$, $Cd^{II}$, $Ni^{II}$, and $Pt^{II}$) and fullerenes $C_{60}$ and $C_{70}$. It was shown that $M(R_2dtc)_x$ co-crystallize with fullerenes $C_{60}$ and $C_{70}$ to form complexes of different structures and compositions (**1**–**15**). Pristine $M(R_2dtc)_x$ (R = Et, *n*Pr) have a large variety of molecular structures in fullerene complexes, which can be square planar or tetrahedral monomers, strongly and weakly bound dimers and tetramers. Tetrahedral monomeric conformations for $Zn(EtMedtc)_2$ and $Zn(Et_2dtc)_2$ and tetrameric $\{Cu^{I}(Et_2dtc)\}_4$ were for the first time found for these metal dithiocarbamates.

Butterfly-shaped $[M\{(Me, Et)_2dtc\}_2]_2$ dimers (M = Cu and Cd) form layered structures in **1**, **7**, and **11**, where the packing of $C_{60}$ layers varies from a square to hexagonal one. The dimeric structure of dithiocarbamates provides a characteristic 1:2 composition of the complexes {Fullerene/$M[(Et, Me)dtc]_2$}. Complexes **8**–**10** have the same composition, and $M(R_2dtc)_2$ can have similar dimeric structures in these complexes. This supposition was justified for **10** by magnetic data. $Cd(Et_2dtc)_2$ has geometry conforming well to the spherical shape of fullerene molecules and shows high ability to nearly quantitatively precipitate $C_{60}$ and $C_{70}$ complexes from solutions. A similar ability was found for $Mn(Et_2dtc)_2$ and $Fe(Et_2dtc)_2$. Monomeric $Ni(nPr_2dtc)_2$ and $Pt(nPr_2dtc)_2$ with square planar conformation of the central $(NCS_2)_2M$ fragment form **12** and **13** with a 2:1 composition [Fullerene/$M(nPr_2dtc)_2$]. Complexes **2** and **13** have the same composition and the formation of $Cu(Et_2dtc)_2$ and $Cu(nPr_2dtc)_2$ monomers can be supposed for these complexes as well especially because pristine $Cu(R_2dtc)_2$ can adopt a square planar conformation.[43,44] However, X-ray diffraction data are needed to prove this supposition. Nonplanar tetrahedral $Zn(EtMedtc)_2$ and $Zn(Et_2dtc)_2$ provide 3D packing of fullerenes with their tetrahedral and hexahedral arrangements. Bulky $[Cu^{I}(Et_2dtc)]_4$ promotes an island motif in fullerene packing.

Using $M(Et_2dtc)_x$ with different donor ability (the strongest donors contain M = $Cu^{I}$, $Co^{II}$, $V^{II}$, and $Mn^{II}$) we found that $Cu^{I}(R_2dtc)$, $Co(R_2dtc)_2$, and $V(R_2dtc)_2$ reduce $C_{60}$ in benzonitrile. However, among these strong donors only fullerene complexes with $Mn(Et_2dtc)_2$ and $Cu^{I}(Et_2dtc)$ were obtained as crystals and no CT to fullerene molecules was found in them. The EPR spectra of paramagnetic $Cu(R_2dtc)_2$ and $Mn(Et_2dtc)_2$ noticeably change at the complex formation with fullerenes most probably due to changes in the environment of $M^{II}$. The EPR spectra of **1**, **2**, **11**, and **13** are noticeably modified relative to those of pristine $Cu(R_2dtc)_2$. Such changes can be a result of additional weak coordination of $Cu^{II}$ to $C_{60}$ and the flattening of the central $(NCS_2)_2Cu$ fragment. The changes in the EPR spectrum of $Mn(Et_2dtc)_2$ at the formation of **10** are most probably evoked by the transition from a polymeric structure of pristine $Mn(Et_2dtc)_2$ with an octahedral environment of $Mn^{II}$ to the formation in **10** of $\{Mn(Et_2dtc)_2\}_2$ dimers, in which strong antiferromagnetic exchange interaction between $Mn^{II}$ centers is possible.

The spectra of the complexes in the visible and NIR ranges indicate their neutral ground state. $Cu(R_2dtc)_2$ (**1**, **2**, **11**, and **13**) and $Ni(nPr_2dtc)_2$ (**14**) absorb in the visible range, whereas other $M(R_2dtc)_2$ are nearly transparent in this range. In addition to the bands associated with intramolecular transitions in fullerenes and $M(R_2dtc)_x$, the bands associated with intermolecular CT between neighboring fullerene molecules (at 470 nm for $C_{60}$ and at 550 nm for $C_{70}$)[59] and CT from $M(R_2dtc)_2$ to fullerene molecules are observed. The latter CT bands are observed only in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectra of **7** and the complexes with planar $M(nPr_2dtc)_2$ (**13**–**15**). The other complexes demonstrate either weak or no CT bands indicating worse conditions for the π-π interaction between fullerenes and nonplanar $M(R_2dtc)_x$. In accordance with the neutral ground state, the crystals of **1**, **2**, and **7** show low dark conductivity of $10^{-10}$ to $10^{-11}$ S·cm$^{-1}$. The illumination of the crystals by white light with $10^{12}$ to $10^{14}$ photons/cm$^2$·s intensity results in up to a $10^3$ increase in photocurrent. The photoconductivity spectra exhibit maxima at 470, 450–650, and 660 nm for **1**, **2**, and **7**, respectively. Three processes generate free charge carriers in the complexes. Photoexcitation of $Cu(Et_2dtc)_2$ contributes to photoconductivity of **1** and **2** since this donor has intense absorption in the visible range. A similar mechanism was observed in $Bz_4BTPE{\cdot}C_{60}$ {$Bz_4BTPE$: tetrabenzo[1,2-bis(4*H*-thiopyran-4-ylidene)ethane]},[62] and conjugated polymer-fullerene composites.[63] CT from donor to fullerene molecules contributes to photoconductivity of the complexes with relatively intense CT bands in the visible-NIR range: **7** and $TBPDA{\cdot}(C_{60})_2$ (*N*,*N*,*N*′,*N*′-tetrabenzyl-*p*-phenylenediamine).[19] Interfullerene CT between neighboring fullerene molecules also contributes to photoconductivity in **1** and **7** as well as in pure fullerene crystals[64] and films.[59] Common peculiarity of the $C_{60}$ complexes showing photoconductivity is a layered arrangement of fullerene and donor molecules in a crystal, which allow the movement of photogenerated carriers through the crystal. Weak MF with $B_0 < 0.5$ T differently affects photoconductivity of fullerene complexes. We found negative (**1** and **7**) and positive ($Bz_4BTPE{\cdot}C_{60}$)[64] MF dependences as well as the field dependence with sign inversion at 0.3 T [$TBPDA{\cdot}(C_{60})_2$].[19] A variety of dependences indicates that the interaction of MF with photogenerated excitons can be different in fullerene complexes depending on the donor used. The mechanisms of the effects of MF on photoconductivity involve triplet CT excitons and paramagnetic centers[61] or the population of a triplet state from a singlet one in MF.[65] Thus, fullerene complexes with $M\{Et_2dtc\}_2$ and other $M\{R_2dtc\}_x$ may be a new wide family of photoactive compounds. A study of the photophysical properties of these complexes is now in progress.

## Experimental Section

**Materials:** Sodium diethyldithiocarbamate trihydrate, [$Na(Et_2dtc){\cdot}3H_2O$], was purchased from Aldrich and recrystallized from an acetonitrile/benzene mixture. Sodium ethylmethyldithiocarbamate, Na(EtMedtc), and sodium di(*n*-propyl)dithiocarbamate, $Na(nPr_2dtc)$, were obtained by the reported procedure.[43] Carbon disulfide (3.1 mL, 0.052 mol) and sodium hydroxide (50% aqueous solution, 4 mL) were added to a stirred solution of $R_2NH$ (0.05 mol) ($R_2NH$=EtMeNH, Aldrich, and $nPr_2NH$, Wako) in ethanol (5 mL) at $T < 4$ °C (ice bath). After stirring for 4–6 h at $T <$ 4 °C Na(EtMedtc) precipitated as white crystals. $Na(nPr_2dtc)$ was obtained by the evaporation of an ethanol/water solution without heating. Pure $Na(R_2dtc)$ were obtained by recrystallization from acetonitrile/benzene mixtures (50–80% yields). Air-sensitive $M(R_2dtc)_x$ compounds (R = Et, M = Cu$^{I}$, Co$^{II}$, V$^{II}$, Fe$^{II}$, and Mn$^{II}$; R = *n*Pr, M = Cu$^{I}$) were obtained by stirring anhydrous CuCl (100 mg), $CoBr_2$ (150 mg), $VCl_2$ (100 mg), $FeBr_2$ (150 mg), and $MnI_2$ (150 mg) and $x$ [$x$ = 1 (Cu$^{I}$) or 2 (other metals)] molar equivalents of $Na(Et_2dtc)$ in 10 mL of degassed acetonitrile over 4 h in a glove box. $M(R_2dtc)_x$ were precipitated from acetonitrile as light yellow (Cu$^{I}$ and Mn$^{II}$), light pink (Fe$^{II}$), dark green-brown (Co$^{II}$), and light brown (V$^{II}$) powders together with NaCl(Br, I). The precipitates were washed with acetonitrile (3 mL) and dried. NaCl(Br, I) as well as possible admixtures of unreacted $MCl(Br, I)_x$ and $Na(Et_2dtc)$ were separated from $M(R_2dtc)_x$ at a stage of complex formation with fullerene because of their insolubility in *o*-dichlorobenzene ($C_6H_4Cl_2$). Air-stable $M(R_2dtc)_2$ (R = EtMe, M = Cu$^{II}$, and Zn$^{II}$; R = Et, M = Cu$^{II}$, Zn$^{II}$, Cd$^{II}$, Hg$^{II}$, Ag$^{I}$, Ni$^{II}$, and Pt$^{II}$; R = *n*Pr, M = Cu$^{II}$, Zn$^{II}$, Cd$^{II}$, Ni$^{II}$, and Pt$^{II}$) were obtained in aqueous solution from $CuBr_2$, $ZnCl_2$, $CdBr_2{\cdot}4H_2O$, $Hg(NO_3)_2{\cdot}H_2O$, $AgNO_3$, $NiCl_2$, $PtCl_2$, and $Na(R_2dtc)$.[43] $M(R_2dtc)_2$ were dissolved in hot chlorobenzene ($C_6H_5Cl$), filtered off from NaCl, NaBr, or $NaNO_3$ and the solvent was removed to dryness on a rotary evaporator to yield pure $M(R_2dtc)_2$ with satisfactory elemental analyses (50–80% yield). $C_{60}$ of 99.98% purity and $C_{70}$ of 99.0% purity were used from MTR Ltd. Solvents were purified under argon. $C_6H_4Cl_2$ and $C_6H_5Cl$ were distilled over $CaH_2$. Hexane and benzonitrile ($C_6H_5CN$) were distilled over Na/benzophenone. For the synthesis of air-sensitive $M(R_2dtc)_x$ (R = Et, M = Cu$^{I}$, Co$^{II}$, V$^{II}$, Fe$^{II}$, and Mn$^{II}$; R = *n*Pr, M = Cu$^{I}$) and the preparation of the fullerene complexes, solvents were degassed and stored in a MBraun 150B-G glove box with a controlled atmosphere with contents of $H_2O$ and $O_2$ of less than 1 ppm. The crystals of **3**, **4**, and **10** were stored in a glove box and were sealed in 2-mm quartz tubes for EPR and SQUID measurements under $10^{-5}$ Torr. KBr pellets for IR- and UV/Visible-NIR measurements were prepared in a glove box.

**Synthesis:** The composition of **1**–**5**, **7**–**11**, and **13**–**15** was determined from the elemental analysis (Table 1) and was justified for **1**, **3**, **4**, **6**, **7**, **11**, and **12** by X-ray diffraction on a single crystal.

The crystals of **1**, **2**, **5**, **6**, **9**, and **11**–**15** were obtained by a slow evaporation of chlorobenzene solution (15 mL) containing $C_{60}$ (25 mg, 0.0347 mmol) and two molar equivalents of $M(R_2dtc)_x$ (0.06940 mmol) over 1 week. The crystals precipitated were washed with an excess of acetone (50–80% yield). The shapes of the crystals are presented in Table 1.

The crystals of **3** and **4** were obtained under anaerobic conditions by a slow diffusion of hexane (20 mL) in $C_6H_4Cl_2$ solution (20 mL) containing $C_{60}$ (25 mg, 0.0347 mmol) (**3**) or $C_{70}$ (20 mg, 0.0238 mmol) (**4**) and a fourfold molar excess of $Cu^{I}(Et_2dtc)$ in a glass tube of 45 mL volume with a ground glass plug. After 1 month large black prisms of **3** and **4** were precipitated on the wall of the tube (up to $0.5 \times 0.5 \times 0.8$ mm$^3$ size). The solvent was decanted and the crystals were washed with hexane (50–60% yield).

$Cd(Et_2dtc)_2$, $Mn(Et_2dtc)_2$, and $Fe(Et_2dtc)_2$ nearly quantitatively precipitate $C_{60}$ and $C_{70}$ from different solvents ($C_6H_6$, $C_6H_5Cl$, and $C_6H_4Cl_2$). Because of this, the crystals of **7** and **8** were obtained by the diffusion of a benzene solution (20 mL) of $C_{60}$ (20 mg, 0.02775 mmol) (**7**) or $C_{70}$ (20 mg, 0.0238 mmol) (**8**) in $CHCl_3$ solution (20 mL) containing a twofold molar excess of $Cd(Et_2dtc)_2$. The crystals precipitated on the wall of the tube after 1 month. They were washed with acetone (70–90% yield).

The crystals of **10** were obtained similarly under anaerobic conditions by the diffusion of benzene solution (20 mL) of $C_{70}$ (20 mg, 0.0238 mmol) (**8**) into $C_6H_4Cl_2$ containing a twofold molar excess of $Mn(Et_2dtc)_2$. The crystals precipitated on the wall of the tube after 1 month. They were washed with hexane (70% yield).

The $C_{60}$ complexes with $Mn(Et_2dtc)_2$ and $Fe(Et_2dtc)_2$ were also obtained as powders by mixing $C_{60}$ (25 mg, 0.0347 mmol) and a twofold molar excess of $M(Et_2dtc)_2$ in $C_6H_4Cl_2$ (20 mL) on heating (60 °C, 2 h). The hot solution was filtered, cooled down to room temperature, and stood overnight. The solution became colorless, and a light brown polycrystalline precipitate was formed. However, in contrast to crystals of **10**, powdered samples did not show reasonable elemental analyses probably because of the high air-sensitivity of the complexes. Indeed, $Mn(Et_2dtc)_2$ and $Fe(Et_2dtc)_2$ are extremely air-sensitive and oxidize in a few seconds in air.

We tried to crystallize the $C_{60}$ complexes with $Co(Et_2dtc)_2$ and $V(Et_2dtc)_2$. $C_{60}$ (25 mg, 0.0347 mmol) and a twofold molar excess of $M(Et_2dtc)_2$ were dissolved in $C_6H_4Cl_2$ (20 mL) on stirring at 60 °C for 4 h. The hot solution was filtered, cooled down to room temperature, and filtered in a glass tube of 45 mL volume with a ground glass plug. Slow diffusion of hexane (20 mL) was carried out under anaerobic conditions. However, only black powder without crystals formed after 2 months.

**General:** UV/Visible-NIR spectra were measured with a Shimadzu-3100 spectrometer in the 240–2600 nm range. FT-IR spectra were measured in KBr pellets with a Perkin–Elmer 1000 Series spectrometer (400–7800 $cm^{-1}$). A Quantum Design MPMS-XL SQUID magnetometer was used to measure static magnetic susceptibilities of **1**–**4** and **10** from 1.9 up to 300 K. A sample holder contribution and core temperature independent diamagnetic susceptibility ($\chi_0$) were subtracted from the experimental values. The values of $\Theta$, $\chi_0$ were calculated using the appropriate formula: $\chi_M = C/(T - \Theta) + \chi_0$. EPR spectra were recorded for **1**, **2**, **11**, and **13** at room temp. and for **3**, **4**, and **10** from RT down to 4 K with a JEOL JES-TE 200 X-band ESR spectrometer equipped with a JEOL ES-CT470 cryostat. Photoconductivity of **1**, **2**, **7**, and **8** was excited using a white light halogen tube with $10^{12}$–$10^{14}$ photons/$cm^2$s intensity. To record the spectra of photoconductivity the light beam of a xenon lamp was transmitted through a high-aperture monochromator. A static magnetic field with the induction up to 1 T was generated by an electromagnet of a Radiopan SE/X 2547 ESR spectrometer.

**X-ray Crystal Structure Determination:** X-ray diffraction data for **1**, **3**, **4**, **6**, **7**, **11**, and **12** were collected with a Bruker SMART1000 CCD diffractometer installed at a rotating anode source (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å), and equipped with an Oxford Cryosystems nitrogen gas-flow apparatus. The data were collected by the rotation method with 0.3° frame-width (ω scan) and 10 s exposure time per frame. Four sets of data (600 frames in each set) were collected, nominally covering half of the reciprocal space. The data were integrated, scaled, sorted and averaged using the SMART software package.[66] The structures were solved by the direct methods using SHELXTL NT Version 5.10.[67] The structure was refined by full-matrix least-squares against $F^2$. The details of the X-ray crystal structure analysis for **1**, **3**, **4**, **6**, **7**, **11**, and **12** including CCDC numbers for the structures are given in Table 4. Non-hydrogen atoms were refined in the anisotropic approximation. Positions of hydrogen atoms were calculated geometrically. Subsequently, the positions of H-atoms were refined by the "riding" model with $U_{iso} = 1.2U_{eq}$ of the connected non-hydrogen atom or as ideal $CH_3$ groups with $U_{iso} = 1.5U_{eq}$. The supplementary crystallographic data for this paper can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): IR-data, UV/Vis-NIR spectra of pristine donors and complexes **1**–**15**, and EPR spectra of pristine Cu(EtMedtc)$_2$ and Cu($n$Pr$_2$dtc)$_2$ and complexes **11** and **13** (Tables S1 and S2, Figures S1–S7).

## Acknowledgments

The work was supported by the RFBR grants N 03-03-32699-a and 03-03-20003 BNTS-a, the Russian Science Support Foundation, Rosnauka grant 2006-RI-19.0/001/058, and partly by Grant-in-Aid Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology, Japan (152005019, 21st Century COE, and Elements Science 12CE2005). We thank Dr. E.I. Yudanova for help with the EPR investigations.

## COVER PICTURE

**The cover picture shows** a mixed metal $Mn_6Ni_{12}$ compound that results when manganese(II) and nickel(II) percursor building blocks are allowed to self-assemble. The resulting structure contains a trigonal-prismatic central framework portion made up by linking six manganese(II) coordination compound precursors with meridionally arranged labile water ligands, which are replaced here by linking carboxylate units. This framework is decorated with three self-assembled nickel(II) acetate/methoxide cubane units. The overall structure is similar to a wind turbine having a hexanuclear manganese spindle with the nickel cubanes as blades. The synthetic strategy is a promising means for obtaining high-nuclearity heterometallic assemblies with interesting magnetic properties. Details of this work are described in the Short Communication by A. K. Powell et al. on p. 1927 ff.

# Structure and Function of Xanthine Oxidoreductase

**Russ Hille***[a]

**Keywords:** Bioinorganic chemistry / Enzymes / Molybdenum / Xanthine / Oxidoreductase

An overview of the current state of our understanding of the reaction mechanism of the molybdenum-containing enzyme xanthine oxidoreductase is presented, with an emphasis on work done in the past five years. Recent studies of the biosynthesis of the pterin cofactor bound to the metal in the active site are also reviewed, as is crystallographic work that has clarified the coordination geometry of the molybdenum center. This structural work provides the context in which to understand recent mechanistic studies of the enzyme, in particular those aimed at elucidating the role of specific amino acid residues in the active site of the enzyme.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Xanthine oxidoreductase (until recently also referred to as xanthine oxidase) was first isolated from cow's milk by Dixon and Thurlow some 80 years ago,[1] and was shown to be identical to the so-called Schardinger enzyme responsible for catalyzing the oxidation of aldehydes (reducing redox-active dyes in the process) that had been described even earlier. In 1966, using an elegant $^{95}$Mo substitution protocol (and with protein from a very large eukaryote), R. C. Bray showed that the enzyme from cow's milk possessed molybdenum in its active site, and that the metal was reduced to the paramagnetic $Mo^{V}$ state in the course of reduction of substrate.[2] This work provided the first demonstration of a specific biological role for molybdenum. In the intervening years, xanthine oxidoreductase has been the subject of a great many mechanistic, structural and biophysical studies, and has come to represent the paradigm for the molybdenum-containing hydroxylases. Unlike other biological systems that hydroxylate carbon centers (including those that possess flavin, heme, non-heme iron or copper in their active sites), members of this large and phylogenetically diverse family of enzymes utilize water rather than $O_2$ as the source of the oxygen atom incorporated into product, and generate rather than consume reducing equivalents. These enzymes thus utilize a fundamentally different reaction stoichiometry than the monooxygenases. It is the catalysis of familiar chemistry in an unfamiliar way that has been the principal reason for the continued interest in the reaction mechanism of xanthine oxidoreductase and related enzymes.

The molybdenum hydroxylases constitute by far the largest of the three categories of molybdenum-containing enzymes, with more than 30 discrete members known from sources ranging from hyperthermophilic archaea to higher vertebrates.[3] Most of these enzymes catalyze the hydroxylation of (relatively activated) carbon centers of aromatic heterocycles, but some (like aldehyde oxidase and CO dehydrogenase) catalyze other types of reactions. The human genome encodes four molybdenum hydroxylases: xanthine oxidoreductase proper (expressed under normal circum-

*Russ Hille received a B.S. in Chemistry from Texas Tech University in 1974 and a Ph.D. in Biochemistry from Rice University in 1979. He did post-doctoral work at the University of Michigan in the laboratory of Vincent Massey, in affiliation with the Department of Biological Chemistry and the Michigan Society of Fellows. Afterwards, he took a faculty position in the Department of Molecular and Cellular Biochemistry at The Ohio State University, where he is now Professor. His principal research interests concern the mechanism of action of molybdenum- and flavin-containing enzymes, and biological electron transfer.*

**MICROREVIEWS:** This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stances as a $NAD^+$-reducing dehydrogenase form), and three different aldehyde oxidases [which, like the oxidase form of xanthine oxidoreductase generated under a variety of (patho)physiological conditions, reduce $O_2$ to either $O_2^{\cdot-}$ or $H_2O_2$].[4] The aldehyde oxidases appear to represent tissue-specific isozymes that are under different regulation of gene expression. This is certainly the case in higher plants, where one aldehyde oxidase isozyme oxidizes indoleacetaldehyde to the hormone indoleacetic acid, and a second the oxidation of abscissaldehyde to abscissic acid, a second plant hormone.[5] The physiological circumstances under which these two hormones are synthesized are quite distinct and genetic expression of the enzymes involved in the two biosynthetic pathways is under completely separate regulatory control. Thus, while the isolated enzymes may well exhibit considerable overlapping substrate specificity (most members of this family of enzymes exhibit rather broad substrate specificity),[6] under physiological conditions each has a specific physiological reaction for which it is responsible.

What follows is a review of our present understanding of the structure and function of xanthine oxidoreductase. Recent crystallographic studies of the enzyme have refined our understanding of the structure of the active site, particularly with regard to the coordination geometry of the molybdenum center, and this provides the structural context in which the reaction mechanism can be understood – both in the sense of the nature of the chemistry catalyzed and the roles of specific active site amino acid residues in accelerating reaction rate. Before considering these, however, we first review the current status of our understanding of the biosynthesis of the novel pterin cofactor found coordinated to the metal in the enzyme active site. Related subjects, particularly dealing with inorganic systems related to the enzymes of interest here, have been dealt with in recent reviews by other authors.[7–11]

## The Pterin Cofactor

With the exception of the extraordinary $MoFe_7$ active site of nitrogenase, molybdenum-containing enzymes all possess an organic pterin cofactor that is coordinated to the metal through an enedithiolate side chain of a third pyran ring, as shown in Figure 1.[12,13] The cofactor is in fact frequently referred to in the literature as molybdopterin, although this is somewhat confusing since: (i) the term refers to the organic component only, not to the metal complexed center; and (ii) the identical cofactor is found in tungsten-containing enzymes – the first crystal structure of an enzyme possessing this cofactor was in fact the tungsten-containing aldehyde oxidoreductase from *Pyrococcus furiosus*.[14] We will use the term pyranopterin here to avoid any possible confusion, but will occasionally use the trivial abbreviation "MPT" (for "*molybdopterin*" or "*metal-binding pterin*"[15]) when convenient. In eukaryotes the cofactor has only the phosphorylated side chain shown, but in many bacterial systems it is elaborated as the dinucleotide of guanosine, cytosine, adenosine or even inosine. As shown in Figure 2, the biosynthetic pathway for the pyranopterin cofactor can be divided into steps leading from GTP to an intermediate initially termed Precursor Z,[16,17] but more recently renamed cyclic pyranopterin monophosphate, cPMP,[18] and then on to the mature cofactor with molybdenum incorporated and (where appropriate in prokaryotes) elaborated to the dinucleotide form. The gene products required for most of the discrete steps are known; many have been crystallographically characterized and their functions are increasingly well understood, as discussed below.

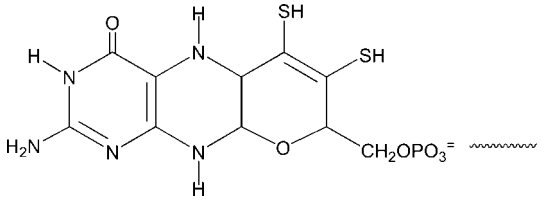

Figure 1. The structure of the pyranopterin cofactor found in molybdenum-containing enzymes. The cofactor consists of a pterin system fused to a pyran ring with a phosphorylated side-chain; molybdenum is coordinated by the dithiolene moiety of the pyran ring. As indicated in the text, the cofactor shown is that seen in eukaryotes. In prokaryotes, it is most often extended as a dinucleotide.

The intermediate cPMP is synthesized from GTP in a reaction that expands the imidazole subnucleus of the guanine moiety to a six-membered pyrazine ring using a carbon from the ribose ring of the nucleotide; the remainder of the ribose ring and α-phosphate group become incorporated into the phosphorylated four-carbon side chain destined to become the pyran ring of the mature cofactor.[19,20] The system responsible for catalyzing this reaction (in *E. coli* consisting of the MoaA and MoaC gene products) is distinct from those involved in biopterin, folate and flavin biosynthesis, and the crystal structures of MoaA[21] and MoaC[22] are each known (Table 1). MoaA is a homodimer, with a [4Fe-4S] cluster in the N-terminal domain that has only three external cysteine ligands to the irons. The missing fourth cysteine position constitutes the binding site for S-adenosylmethionine, with its α-amino and carboxyl groups coordinated to the unique iron site of the cluster in a bidentate fashion. As with other [4Fe-4S]/SAM-containing systems, it is likely that the overall reaction involves reductive cleavage of SAM by the iron-sulfur cluster to initiate a radical-based mechanism for formation of the pterin ring, and specific mechanisms have been proposed.[20,23] A second [4Fe-4S] cluster of unknown function is present in the C-terminal portion of MoaA, and like the N-terminal cluster it lacks one of the external cysteine ligands; the C-terminal [4Fe-4S] cluster lies opposite the active site from the N-terminal [4Fe-4S] cluster and may be involved in binding of GTP, or alternatively in quenching the radical-initiated reaction. The role of MoaC is at present unknown, although it is believed to form a complex with MoaA and may play a role in modulating its activity.[22]

Figure 2. The biosynthetic pathway for the pyranopterin cofactor. Starting from GTP, the key intermediates are: cyclic pyranopterin monophosphate (cPMP), the pyranopterin itself (MPT), and its adenylylated form generated in the course of molybdenum insertion (MPT-AMP).

The structure of cPMP, the product of the MoaAC reaction, was originally thought to be a dihydropterin with a keto (or enol) group at C1′ of the side chain.[19,20] More recently, however, a detailed NMR and mass spectrometric analysis has shown that the pterin ring is fully reduced in cPMP, that C1′ has a geminal diol and that the pyran ring has closed, as shown in Figure 2.[24]

Once formed by MoaAC, cPMP is next doubly sulfurated, a reaction catalyzed by MPT synthase. In *E. coli*, MPT synthase is an $\alpha_2\beta_2$ tetramer consisting of two subunits each of the MoaD (small subunit) and MoaE (large subunit) gene products. Each αβ dimer appears to be functionally independent, with the C-terminal tail of the smaller MoaD subunit inserted into an active site on its partner

MoaE subunit within the tetramer.[25] Interestingly, MoaD has strong structural similarity to ubiquitin, including a C-terminal gly–gly pair, suggesting similar modes of action. Indeed, the overall reaction of MPT synthase involves the formation of an acyl-adenylate at the C-terminus of MoaD (using ATP as the source, by analogy to the mechanism of ubiquitin), with the subsequent formation of a thiocarboxylate. The sulfur atom used to form this thiocarboxylate is delivered by the MoeB gene product, which functions as a biotin-dependent MPT synthase sulfurase and is itself homologous to the E1 family of enzymes involved in adenylylation of ubiquitin.[26] The crystal structure of a $(MoeB)_2$-$(MoaD)_2$ heterotetramer has been reported in several forms, including one in which the C-terminus of MoaD has become adenylylated.[27] For the bacterial system, no evidence has been found for the occurrence of a transiently sulfurated form of *E. coli* MoeB in the course of thiocarboxylate formation, but eukaryotic homologues of MoeB (including the human MOCS3) possess a C-terminal extension with distant homology to rhodanese, and recently it has been shown that Cys 412 of MOCS3 is converted to a persulfide upon incubation with thiosulfate (analogous to the reaction of rhodanese).[28] This persulfide presumably represents the proximal donor of sulfur to the adenylylated MoaD C-terminus, at least in eukaryotic systems. Once charged with sulfur, the synthase first makes a mono-sulfurated form of the pterin (at either C1′ or C2′ of the pterin side chain), at which point it must be recharged with a second sulfur by MoeB prior to completing formation of the dithiolene side chain of the mature pyranopterin cofactor.[29,30]

At least some organisms encode proteins that appear to serve a storage or transport function for the now mature pyranopterin cofactor. Fernandez and co-workers have characterized a protein from *Chlamydomonas rheinhardtii*, for example, that binds pyranopterin and prevents its oxidation.[31–33] The protein is a 64 kDa homotetramer which on the basis of its amino acid sequence is likely to possess a typical nucleotide-binding Rossman fold. Similar proteins exist in both bacteria and higher plants,[33] and may well prove to be widely distributed in nature.

Once the dithiolene moiety is incorporated into the pyranopterin cofactor, molybdenum must be inserted. In *E. coli*, molybdenum is taken up as molybdate by a specific ABC-type transporter system encoded by the *modABCD* operon.[34] The first component of this system is ModA,[35] which has the classic two-domain structure of a periplasmic binding protein.[36] Molybdenum is subsequently transfer-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

red to ModB, a peripheral membrane protein in the inner membrane, then internalized to the cytoplasm in an ATP-dependent reaction catalyzed by the membrane-integral ModC gene product.[34] The fourth component of this transport system, the ModD gene product, has an as-yet unidentified function. Recent crystallographic work[37–39] has demonstrated that the process by which molybdate, once in the cell cytoplasm, becomes bound to the pyranopterin cofactor is considerably more complicated than might have been suspected. In particular, solving crystal structures of two forms of the N-terminal Cnx1G domain of the Cnx1 gene product from *A. thaliana* (equivalent to MogA from *E. coli*) in complex with the mature cofactor,[39] it has been shown that the cofactor is first adenylylated to MPT-AMP by Cnx1G, and at this point is coordinated to a copper ion. The cuprated MPT-AMP is then thought to be transferred to the C-terminal Cnx1E domain of Cnx1 (equivalent to MoeA of *E. coli*), which hydrolyzes the dinucleotide in the course of replacing the copper with molybdate. The manner in which this reaction occurs is not yet understood, although the process is known to require magnesium.[39] It is interesting that Cnx1 exhibits significant homology to the mammalian protein gephyrin,[38] a cellular structural element involved in, among other things, neuroreceptor aggregation in certain cell signaling processes.

With molybdate incorporated, the cofactor is in the form seen utilized in two different types of eukaryotic molybdenum enzyme, sulfite oxidase and the assimilatory nitrate reductase, and may now be directly incorporated into the apoproteins. The structure of the center is as indicated in Figure 2, with the molybdenum having a (presumably square-pyramidal) $LMo^{VI}O_2(OH)$, with L representing the bidentate pyranopterin cofactor coordinated to the metal by its enedithiolate side chain. Insertion into apoprotein, which involves replacement of the Mo–OH ligand by a cysteine residue in the active site of the protein, likely involves additional gene products. For example, for some prokaryotic molybdenum enzymes (notably the dissimilatory nitrate reductases and the xanthine dehydrogenase from bacteria such as *R. capsulatus*), cofactor incorporation appears to involve an enzyme-specific "chaperone" protein. The *nar* operon of *E. coli* encodes a NarJ protein that is not a component of the mature protein, but whose deletion prevents proper maturation of the molybdenum center.[40] The XdhC gene product of *R. capsulatus* appears to play a similar role in the maturation of the xanthine dehydrogenase of that organism.[41]

As mentioned above, most prokaryotic enzymes utilize a dinucleotide form of the cofactor, most frequently of guanosine but occasionally of adenosine, cytosine or inosine, which must be generated prior to insertion into the apoprotein. In *E. coli*, MGD ("*M*PT *g*uanosine *d*inucleotide") is synthesized by MGD synthase, which consists of the MobA and MobB gene products.[42] The active site is found in MobA, whose crystal structure has been determined.[43] MobB appears not to be essential for the in vitro synthesis of MGD, although it seems to increase the efficiency of the process in vivo.[44] The dinucleotide form of the cofactor is now ready to be incorporated into appropriate prokaryotic apoprotein. For those enzymes that require two equivalents of the pyranopterin, however, it is not known at present whether incorporation of the second equivalent occurs before or after insertion of the first (with molybdenum attached) into the apoprotein. There is suggestive evidence that the MoeA gene product may play a specific, if as yet unidentified, role in the maturation of *bis*MPT-containing active sites (as discussed by Schwarz[18]).

Once incorporated into the polypeptide, the molybdenum center is in its functional form for those molybdenum enzymes that catalyze oxygen atom transfer reactions (e.g., sulfite oxidase, the nitrate reductases and DMSO reductase). For the molybdenum hydroxylases from both prokaryotic and eukaryotic sources, however, there is a final aspect of maturation: the replacement of one of the two Mo=O groups of the cofactor by a sulfido (Mo=S) group. This sulfuration is strictly required for activity of these enzymes – the so-called desulfo form of enzymes such as xanthine oxidoreductase have been well-characterized and are devoid of catalytic activity.[45,46] In *A. thaliana*, the sulfuration reaction is catalyzed by the ABA3 gene product,[47,48] a pyridoxal phosphate-utilizing enzyme that uses cysteine as the ultimate source of the sulfur atom incorporated into the molybdenum coordination sphere. ABA3 is a homodimer whose subunits fold into distinct N- and C-terminal domains. Pyridoxal phosphate binds to the N-terminal domain, which exhibits considerable homology to the NifS family of gene products, cysteine desulfurases that are involved in the maturation of, for example, iron-sulfur clusters.[49] The ABA3 reaction proceeds with the transient formation of a cysteine persulfide at Cys 430 of ABA3, which then transfers its terminal sulfur to the molybdenum center,[50] and there is evidence to suggest that the sulfur is transferred transiently to the C-terminal domain of ABA3. This appears not to be an essential step, however: deletion of the C-terminal domain of ABA3 compromises the effectiveness of sulfur incorporation, but does not eliminate it altogether. Interestingly, ABA3 is also able to utilize selenocysteine as substrate,[51] raising the possibility of preparing selenido forms of the hydroxylases which may have interesting catalytic properties.

## The Structure of the Active Site of Xanthine Oxidoreductase

The molybdenum hydroxylases are fairly complicated systems as enzymes go, since in addition to the molybdenum center, all members of this family possess additional redox-active centers. The typical constitution is a pair of [2Fe-2S] clusters of the spinach ferredoxin variety and, usually, FAD as well (see Figure 3 for the structure of the bovine xanthine oxidoreductase). In most enzymes, all these prosthetic groups are to be found in discrete domains within a single subunit of an $\alpha_2$ dimer, although in the *R. capsulatus* xanthine dehydrogenase the iron-sulfur centers and FAD are found in one subunit and the molybdenum

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

center in a second within an $\alpha_2\beta_2$ tetramer.[51] In the CO dehydrogenase from *O. carboxydovorans* [52] and the quinoline-2-oxidoreductase from *Pseudomonas putida*,[53] the two iron–sulfur centers, the FAD and the molybdenum center are found in separate subunits within an $\alpha_2\beta_2\gamma_2$ hexamer. It is evident from an inspection of the genes encoding these proteins from a variety of organisms that they were built up in gene duplication/fusion events over the course of evolution: not only do the protein domains fold into autonomous structural elements, but they are encoded by contiguous stretches of the gene.

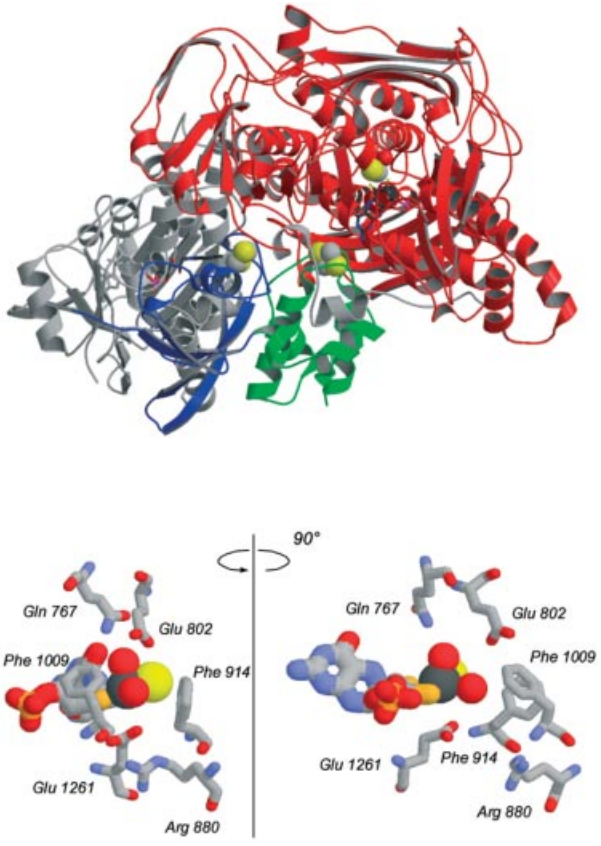

Figure 3. The structure of bovine xanthine oxidoreductase. Top, the overall domain fold of the enzyme, with (from the N-terminus): the two [2Fe–2S] domains in blue and green; the FAD domain in gray (the FAD is shown edge-on, immediately to the left of the first iron-sulfur cluster); and the molybdenum-binding portion of the protein in red. The illustration was prepared with the application MOLSCRIPT, using the structure reported by Enroth et al.[99] Bottom, two representations of the active site with specific amino acid residues discussed in the text indicated.

The first molybdenum hydroxylase to be crystallographically characterized was the aldehyde oxidoreductase from *Desulfovibrio gigas*.[54,55] Several important structural features of the enzyme were established in this work, including: the overall domain architecture of the protein (with the two [2Fe–2S] clusters of the enzyme in separate N-terminal domains and the molybdenum center at the interface of two much larger C-terminal domains); the orientation of the molybdenum center with respect to the remaining redox-active centers of the enzyme (including the hydrogen-bonding interaction between the distal amino group of the pyranopterin cofactor to one of the cysteine ligands of the nearer [2Fe–2S] cluster); the identity of specific amino acid residues in the active site likely to be involved in catalysis (including, most importantly, a highly conserved glutamate residue that was suggested to function as an active-site base[55] – see Figure 3, *bottom* for the active site of the bovine xanthine oxidoreductase); the overall square-pyramidal coordination geometry of the molybdenum coordination sphere, with an $LMoO_2(OH_{(2)})$ coordination geometry and a hydroxy/water ligand that points toward the substrate binding site; and the long channel that provides solvent access to the deeply buried active site. Unfortunately, the *D. gigas* aldehyde oxidoreductase is an example of the molybdenum hydroxylases that does not possess FAD, and the structure provided no information regarding the flavin site found in most other molybdenum hydroxylases. More importantly, the enzyme used in this initial crystallographic study was predominantly in the inactive desulfo form and lacked the catalytically essential Mo=S group. It was not possible to say which of the two Mo=O groups present in the molybdenum coordination sphere of the desulfo form (one in the apical position and the other in an equatorial position) was the one that was replaced by a sulfido group in the functional enzyme. A subsequent study of (partially) activated enzyme, obtained by treating crystals with a resulfurating agent, suggested on the basis of electron density analysis that is was the apical Mo=O that was replaced by sulfur to become Mo=S.[55] This assignment is surprising from the standpoint of the known coordination chemistry of model molybdenum complexes – inevitably, a single Mo=O group is located in the apical position within a square-pyramidal coordination sphere, opposite the vacant ligand position, owing to its strong *trans* effect. This being the case, one would have expected the equatorial position to be substituted by sulfur, not the apical one. Indeed, the magnetic circular dichroism electron of a catalytically relevant $Mo^V$ form of xanthine oxidoreductase, that giving rise to the "very rapid" EPR signal (see below), is virtually identical to that exhibited by simple model complexes known to have an apical Mo=O, indicating that the enzyme has an electronic (and presumably also physical) structure fundamentally the same as the crystallographically defined model complexes.[56]

More recently, three other enzyme crystal structures have become available that strongly indicate it is indeed the equatorial position that becomes sulfurated upon activation in the molybdenum hydroxylases. The first of these is that of the molybdenum-containing CO dehydrogenase from the aerobic *Oligotropha carboxydovorans* (as opposed to the Ni-containing enzyme from anaerobes such as *Methanosarcina thermophila* or *Rhodospirillum rubrum*[57,58]). This enzyme is an interesting variation on the theme of the molybdenum hydroxylases, with a binuclear Mo/Cu active site.[59,60] In the crystal structure,[59] the copper ion occupies a position in the equatorial plane of the molybdenum coordination sphere, connected to the molybdenum itself by a bridging

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

acid-labile sulfur that is analogous to the catalytically essential sulfur of other members of this enzyme family. Although unique among the molybdenum hydroxylases characterized to date in possessing a binuclear center, the active-site structure of CO dehydrogenase is clearly related to those of other members of this class of enzyme, and the position of the copper site suggests an equatorial Mo=S in the other enzymes. The second structure is that of the *P. putida* quinoline-2-oxidoreductase, where a careful analysis of the structure of the molybdenum center in the oxidized enzyme indicated an apical Mo=O at 1.69 Å and an equatorial Mo=S at 2.13 Å.[53] The third structure is that of a high-specific activity preparation of the (reduced) bovine oxidoreductase in complex with a potent mechanism-based inhibitor termed FYX-051.[61] This inhibitor is actually a substrate for the enzyme, but once hydroxylated becomes very tightly bound to the reduced enzyme in a classic mechanism-based mode of enzyme inhibition. In the crystal structure of this complex, it is abundantly clear that it is the equatorial position, adjacent to the bound inhibitor (which is coordinated to the molybdenum center through the newly introduced hydroxy group of the product), that has the added electron density of sulfur and not the apical position. On the basis of the present evidence, it thus seems clear that the apical position of the molybdenum centers in the molybdenum hydroxylases is an Mo=O, with an equatorial Mo=S in the oxidized from of the enzyme (or Mo–SH in the reduced form, see below).

## The Reaction Mechanism of Xanthine Oxidoreductase

The structure of the molybdenum center of xanthine oxidoreductase (Figure 3, *bottom*) provides the structural context in which to understand the reaction mechanism of the enzyme. It had been known for many years that the active site began in a $Mo^{VI}OS$ oxidation state and at the completion of the reaction was reduced by two equivalents and protonated at the Mo=S group to give a $Mo^{IV}O(SH)$.[62,63] Rather more recently it was also shown that a proximal site on the enzyme was the source the oxygen atom incorporated into product;[64] this site was regenerated with oxygen from solvent (i.e., already reduced to the level of water) at the completion of each catalytic cycle.[65] It has subsequently been demonstrated that $^{17}O$ from water exchanges into the molybdenum center rapidly under turnover conditions, and that the site labeled is strongly and anisotropically coupled to the molybdenum when in the $Mo^{V}$ valence state.[66] From a comparison with model compounds of known structure,[67] the labeled site corresponds to the equatorial Mo–OH rather than the equatorial Mo=O site. A similar conclusion has been drawn from the inability to observe a second, more weakly $^{17}O$ coupling in the "very rapid" EPR signal underneath the stronger coupling of the Mo–O-product oxygen under conditions when the molybdenum should have become labeled catalytically.[68] It is noteworthy that although initially assigned as a bound water molecule on the basis of the crystallographically determined Mo–O distance in the *D. gigas* aldehyde oxidoreductase structure, a more precise determination of this distance using X-ray absorption spectroscopy with the bovine xanthine oxidoreductase indicates that at 2.1 Å it is in fact a hydroxide ligand.[69] This is actually a fairly important mechanistic point, because a Mo–OH group deprotonated to $Mo–O^-$ is expected to be a considerably better nucleophile in initiating catalysis than would be a $Mo–OH_2$ group deprotonated to Mo–OH (see below). The protonation of the Mo=S group upon reduction of the molybdenum center in going from an $LMo^{VI}OS(OH)$ to an $LMo^{IV}O(SH)(OH)$ center is consistent with the concept of electroneutrality – that the protein environments of metal centers are designed to accommodate a specific net charge, and that changes in charge associated with reduction tend to be compensated by uptake of protons at or near the metal center. The uptake of protons by ligands to molybdenum upon reduction of the metal is in fact a property of even the simplest molybdate complexes.[70,71]

Other clues as to the chemical course of the reaction of xanthine oxidoreductases come from studies of the reaction of enzyme with the (poor) substrate 2-hydroxy-6-methylpurine. Although turnover with this substrate is some $10^3$-fold slower than with xanthine, the reaction (at least at high pH) proceeds with sequentially smaller rate constants associated with each of several steps in the catalytic sequence.[72] The result is that two reaction intermediates accumulate to an appreciable degree. The first of these has an absorption maximum (relative to oxidized enzyme) at 470 nm in the visible region, and upon *oxidation* by one equivalent is converted to a second species with an absorption maximum at 540 nm.[72] Formation of this latter species is coincident with the accumulation of the EPR-active $Mo^{V}$ state giving rise to the "very rapid" signal referred to above. This signal, so named on the basis of the kinetics of its formation and decay in the course of the reaction of enzyme with xanthine,[73,74] has long been recognized to be a fully competent catalytic intermediate. The implication of the work with the hydroxymethylpurine substrate is that the 470 nm-absorbing species must be the $Mo^{IV}$ species from which the $Mo^{V}$ species arises, and that the initial step of the reaction involves the two-electron reduction of the molybdenum center. Further, since earlier work had demonstrated that weak coupling to $^{13}C$ ($I$ = 1/2) is observed in the "very rapid" EPR signal when the sample is prepared using 8–$^{13}C$-labeled substrate,[75] the purine nucleus must be present in the EPR-active species (and hence also in its mechanistic precursor). The final mechanistically relevant observation is that the Mo–O bond of product has formed at the point of formation of the $Mo^{IV}$ species: acid quenching of the reaction mix at the point of maximum accumulation of this species followed by work-up affords the hydroxylated product of the reaction and not substrate.[72]

Under the conditions used, with 2-hydroxy-6-methylpurine as substrate and at pH 10, the entirety of the catalytic throughput passes through the "very rapid" EPR-active

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

state, and the integrated EPR intensity at maximum accumulation of the species (approximately 85% of the functional enzyme) agrees well with that expected given the observed rate constants for formation and decay of the species (1.0 and 0.1 $s^{-1}$, respectively, at 25 °C). With other substrates, and at other reaction conditions, however, the observed accumulation of this EPR-active state is significantly smaller than expected on the basis of the observed rate constants for formation and decay of the "very rapid" species.[76,77] The most likely explanation is that the reaction mechanism is bifurcated at the point of the Mo(VI)*P intermediate that precedes the "very rapid" species; oxidation by one electron yields the EPR-active species, but alternatively product may dissociate prior to oxidation of the $Mo^{IV}$ with the result that the "very rapid" species does not form. On the basis of the amount of "very rapid" signal accumulating under a variety of conditions with a wide range of substrate, it is evident that the fraction of total catalytic flux that passes through the EPR-active "very rapid" species is in fact usually quite small.

While the "very rapid" species may arise in only a relatively small fraction of turnover events, it nevertheless provides an important opportunity to understand the structure of the $Mo^{IV}$ state that precedes it, and this $Mo^{IV}$ species appears to be an obligatory catalytic intermediate. The "very rapid" EPR signal is devoid of proton superhyperfine splitting and has strong, anisotropic coupling to $^{33}S$ when enzyme is appropriately labeled, consistent with the existence of an $Mo^{V}$=S unit.[78] Strong but isotropic coupling is also observed when the sample is prepared in $^{17}O$-labeled water,[79] interpreted as evidence for a Mo–O product species. Overall, EPR work had thus early on provided strong evidence that the "very rapid" species possessed a MoOS(O-product) structure.

As indicated above, when the "very rapid" species is generated using substrate that has been labeled at $C_8$, weak superhyperfine coupling is seen in the EPR signal due to the I = 1/2 spin of the $^{13}C$ nucleus. This permits a distance from the carbon to the molybdenum to be obtained from the anisotropy of the coupling as ascertained by ENDOR spectroscopy. An initial study arrived at a short Mo–C distance – ca. 2.4 Å or shorter – which was interpreted as evidence in favor of a direct metal–carbon bond.[68] Subsequent work, however, has demonstrated convincingly that the distance is no shorter than 2.8 Å, indicating that the carbon is in the second coordination shell of the molybdenum rather than the first.[80] Further, although no proton superhyperfine is evident in the "very rapid" EPR signal, weak coupling to two sets of protons is seen using electron spin echo spectroscopy and as in the case with ENDOR distances can be estimated from the molybdenum: the results of the analysis indicate a single proton at ca. 2.4 Å and a set of two or more at ca. 6.1 Å (from the methyl group of the 2-hydroxy-6-methylpurine substrate that was used in the study).[81] With the Mo–C distance obtained from the ENDOR experiments above, it is possible to triangulate and obtain the orientation of the purine nucleus relative to the molybdenum atom. The data are consistent with binding of the (now hydroxylated) purine nucleus directly to molybdenum in an end-on fashion by the catalytically introduced hydroxy oxygen (Figure 4).

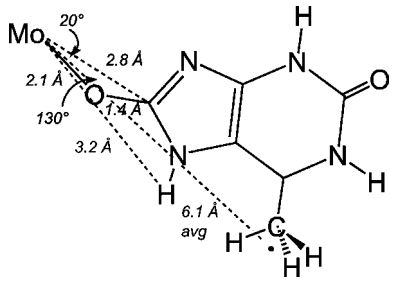

Figure 4. The structure of bound product to the molybdenum in the active site of xanthine oxidoreductase. The structure shown is for the product of the enzyme reaction with the slow substrate 2-hydroxy-6-methylpurine, which was used in the work. The Mo–C distance was obtained by ENDOR spectroscopy with 8-$^{13}C$-labeled substrate as substrate,[80] and the Mo–H distances by ESEEM spectroscopy,[81] as discussed in the text.

The above work using MCD, EPR and related methods to probe the $Mo^{V}$ state of the molybdenum center has been used to infer the structure of the preceding $Mo^{IV}$ intermediate in the catalytic sequence. Happily, with certain substrates of the enzyme this intermediate can be prepared in a stable form simply by addition of the hydroxylated product to enzyme that has been non-catalytically reduced by a reagent such as sodium dithionite. The best characterized case is that of violapterin, the product of enzyme action on the pteridine substrate lumazine (2,6-dihydroxypteridine). Addition of violapterin to reduced enzyme results in formation of a $Mo^{IV}$-containing reduced enzyme–product complex ($E_{red}$·P) that exhibits a relatively strong and broad charge-transfer transition centered at 640 nm.[82–84] This characteristic long-wavelength absorbance has been used in kinetic experiments to demonstrate that the charge-transfer complex is indeed an authentic catalytic intermediate.[83] The inhibitor FYX-051 used in the crystallographic work described above is another substrate that forms such a charge-transfer complex, and it is the $E_{red}$·P complex formed with this substrate whose structure has recently been reported.[61] In addition to establishing that the sulfido sulfur of the active form of the enzyme is in the equatorial rather than apical position, this work unambiguously shows product coordinated end-on to the molybdenum atom by the catalytically introduced hydroxy oxygen in a manner comparable to that shown in Figure 4. The position in the molybdenum coordination sphere is that occupied by the Mo–OH group of oxidized enzyme, lending further support to the conclusion that the Mo–OH represents the catalytically labile oxygen in the active site. Wedd and co-workers had in fact previously suggested that the catalytically labile oxygen could be a molybdenum-bound hydroxide.[67] The simple end-on binding of product (which formally is in the enolate tautomer at $C^7$, the site that has become hydroxylated) contrasts with other proposals where product, in the keto tautomer, binds side-on (a so-called $\eta_2$ interaction with

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the molybdenum) with partial formation of a Mo–C bond.[68] It is evident from the crystal structure that such a binding mode is sterically impossible in the active site.

The evidence thus summarized above indicates that the $Mo^{IV}$ species is formed in the first step of the catalytic sequence: the molybdenum has been reduced from $Mo^{VI}$ to $Mo^{IV}$, the O–C bond of product formed and the Mo=S of oxidized enzyme protonated to Mo–SH, all simultaneously. An important clue as to the chemical mechanism by which the $E_{red}$·P intermediate is generated comes from the pH dependence of its formation, as reflected in the kinetic parameter $k_{cat}/k_m$ from steady-state experiments (or equivalently, since the rate-limiting step for turnover is known to be in the reductive half-reaction, $k_{red}/K_d$ from rapid reaction studies following the rate of reduction of enzyme by excess xanthine as a function of substrate concentration). The pH profile for both kinetic parameters track the reaction of free enzyme with free substrate through to the formation of the $E_{red}$·P complex; it is bell-shaped with a p$K_a$ for the acid limb of 6.6 and for the alkaline limb of 7.4.[85] The latter value agrees very well with the p$K_a$ for the first ionization of substrate, indicating that enzyme acts on the neutral rather than monoanionic form of substrate. This is expected if the reaction is initiated by nucleophilic attack, since a negative charge on substrate would compromise this first step of catalysis. The former p$K_a$ has been assigned to Glu 1261 in the active site of the enzyme, the same highly conserved glutamate first seen in the crystal structure of the *D. gigas* aldehyde oxidoreductase and proposed to be the active-site base.[55] The implication is that the glutamate must be unprotonated prior to the onset of catalysis, as should be the case if its role is to abstract a proton from substrate to initiate the catalytic sequence.

The chemical mechanism for formation of the initial $E_{red}$·P complex that emerges from all of the above is one in which the reaction is initiated by base-catalyzed abstraction of a proton from the Mo–OH group by Glu 1261, followed by nucleophilic attack of the oxyanion thus generated on the $C^8$ of substrate. Concomitant hydride transfer to the Mo=S group in the equatorial plane of the molybdenum coordination sphere generates $E_{red}$·P as shown in Figure 5. Direct hydride transfer to the Mo=S in the course of the reaction is consistent with the observation of Bray and Knowles that the $C^8$–H proton of substrate is initially transferred to the molybdenum center, and only subsequently exchanges with solvent.[86] Since both pairs of electrons in the Mo=S bond belong to the sulfur in a formal valence count, conversion of Mo=S to Mo–SH with this hydride transfer brings about the formal two-electron reduction of $Mo^{VI}$ to $Mo^{IV}$. The reaction is completed by electron transfer from the molybdenum to the other redox-active centers of the enzyme and deprotonation of the $Mo^{IV}$–SH group. Displacement of bound product by hydroxide from solvent may occur prior to transfer of the first electron out of the molybdenum center or after (in which case the "very rapid" species is generated).

A reaction predicated on nucleophilic attack on the heterocycle nucleus had in fact been suggested previously be Lee and Skibo,[87] who showed that for enzyme acting on a homologous series of substituted quinazoline substrates, a linear correlation existed between $\log(k_{cat}/K_m)$ and the p$K_a$ of the quinazoline (at least for substrates having a p$K_a$ > 9). The implication was that, as with xanthine, the substrate was required to be in the neutral rather than monoanionic form for the reaction to proceed. In addition, a variety of computational studies of the reaction mechanism are fully consistent with a mechanism involving concomitant nucleophilic attack and hydride transfer.[88–91] In the earliest of these studies, Voityuk and co-workers[88] showed that the Mo–OH form of a model for the molybdenum center was considerably more stable than a Mo–$OH_2$ form, an important observation because deprotonating the latter species (to Mo–OH) is unlikely to generate a sufficiently effective base as to function catalytically, as discussed above. Subsequent work by this same group[89] examined the reaction of the model (surprisingly, starting from a Mo–$OH_2$ species rather than the more stable Mo–OH shown in their previous study) with formaldehyde, a known inhibitor of xanthine oxidoreductase. The work implicated a reaction mechanism involving hydride transfer from the substrate to the $Mo^{VI}$=S, yielding $Mo^{IV}$–SH, in the course of the nucleophilic attack on substrate. Working with a similar model for the enzyme molybdenum center, but importantly starting with a Mo–OH rather than Mo–$OH_2$ species, Ilich et al.[90] established the same two points (i.e., nucleophilic attack on substrate with concomitant hydride transfer to the Mo=S) for the reaction of the model with the bona fide enzyme substrate formamide (which is hydroxylated to carbamate). Most significantly from this study, the transition state was well-defined, permitting the unambiguous demonstration of partial negative charge on the hydrogen being transferred and indicating hydride-like character.[90] Subsequent work with the same system provided a rationale as to why substitution of a second Mo=O group for the Mo=S of functional enzyme resulted in loss of activity: the transition state for the reaction of the $MoO_2$ model was found to lie considerably earlier along the reaction coordinate than with the MoOS model and at approximately 13 kcal/mol higher in energy (corresponding to a reduction in rate of over nine orders of magnitude as compared with the sulfido form).[91] Interestingly, although calculations with a putative selenated form of the model (MoOSe) did not converge, those with a tellurated form (MoOTe) were successful and suggested that such a form of the enzyme should exhibit even greater reactivity than the naturally occurring MoOS form.[91]

Finally, it has been suggested that the initial $E_{red}$·P complex forms through a radical mechanism rather than the two-electron chemistry implicit in a mechanism involving nucleophilic attack, with rate-limiting formation of a (presumably extremely unstable) $Mo^{V}$···xanthine$^{\cdot+}$ diradical species upon direct one-electron transfer from substrate to molybdenum in the $Mo^{VI}$···xanthine Michaelis complex.[92] Were this the case, however, a linear relationship should exist between the substrate/substrate$^{\cdot+}$ one-electron reduction potential and reaction rate. Examining a homologous series

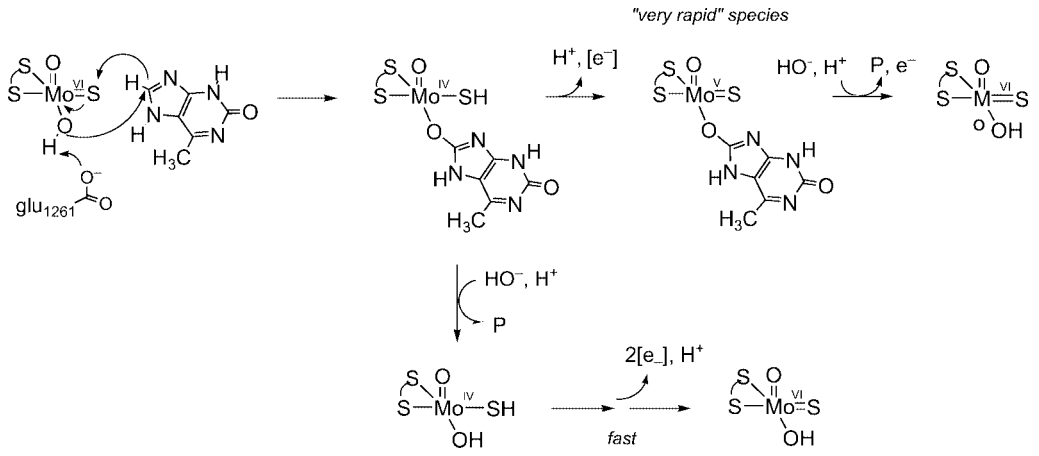

Figure 5. The reaction mechanism of xanthine oxidoreductase. The reaction involves base-assisted nucleophilic attack on the $C^8$ position of substrate, with concomitant hydride transfer to the Mo=S group of the oxidized enzyme and reduction of the molybdenum itself by two equivalents. From the initial $E_{red}$·P intermediate, the molybdenum may become oxidized (by electron transfer to the other redox-active centers of the enzyme) and deprotonated to form the species giving rise to the "very rapid" EPR signal as discussed in the text, or alternatively hydroxide may displace product from the molybdenum coordination sphere, followed by subsequent reoxidation of the molybdenum.

of purine substrates for xanthine oxidoreductase, Stockert et al. failed to observe such a relationship[93] arguing strongly against a radical-based mechanism and leaving the two-electron chemistry shown in the proposed reaction predicated on nucleophilic attack as the most likely mechanistic alternative. It is worth noting that for the molybdenum-containing aldehyde oxidases a reaction mechanism involving nucleophilic attack on the aldehyde carbonyl moiety had long been the preferred reaction mechanism for oxidation of aldehydes to carboxylic acids. It thus appears that the two principal subclasses of the molybdenum hydroxylases (those that act on aromatic heterocycles and those that act on aldehyde substrates) utilize fundamentally the same mechanism to accelerate reaction rate. This goes a long way in explaining the extremely broad and overlapping substrate specificities of the mammalian xanthine oxidoreductases and aldehyde oxidases.

## The Roles of Specific Amino Acid Residues in Catalysis

On the basis of the above, there is broad experimental support for a reaction mechanism initiated by nucleophilic attack, and in the past five years such a mechanism (Figure 5) has received general acceptance in the field. It is significant that computational studies, involving minimal structures for both the molybdenum center and substrate and not including the protein structure at all, have successfully defined the trajectory of the system across the potential energy surface that defines the reaction. This indicates that the course of the reaction is dictated by the electronic structure of the metal center itself; that is, the reactivity of the enzyme is an intrinsic property of the metal center. Having said this, it is evident that (as in all enzymes) the polypeptide (and specific amino acid residues in the active site of the enzyme in particular) is crucially involved in lowering the energies of the transition states encountered along this trajectory, in some cases enormously so. The structure of the active site of bovine xanthine oxidoreductase is shown in Figure 3, with several specific amino acid residues that are likely to play a role in catalysis indicated. Glu 1261 (in the bovine enzyme sequence) has already been referred to as the candidate active-site base that initiates nucleophilic attack on substrate. This residue is universally conserved in the molybdenum hydroxylases, both in those enzymes hydroxylating aromatic heterocycles and in the aldehyde oxidases. In addition, a second glutamate (802 in the bovine enzyme) is conserved in the heterocycle-hydroxylating enzymes, but not in those that have aldehydes as substrates. Other residues that are conserved in the heterocycle-hydroxylating enzymes, (but not always in those that act on aldehydes) include the two phenylalanine residues between which the aromatic substrate is sandwiched on binding in the active site (914 and 1009 in the bovine enzyme), Gln 767 which is within hydrogen-bonding distance of the apical Mo=O, and Arg 880, which appears to interact with the distal end of substrate opposite the $C^8$ position that becomes hydroxylated. We consider now the results of recent studies of the roles of these active-site residues in two recombinant systems that have been developed for site-directed mutagenesis studies: the bacterial xanthine dehydrogenase from *Rhodobacter capsulatus* (as expressed in *E. coli*)[94] and the rat xanthine oxidoreductase, as expressed in insect cells using the baculovirus vector.[95]

The residues that have been examined to date are the two glutamates in the active site. Leimkühler et al.[96] have mutated both Glu232 and Glu730 in the xanthine dehydrogenase from *R. capsulatus* to alanine (these residues correspond to Glu 802 and Glu1261, respectively, in the bovine enzyme). The E232A mutant exhibits considerably reduced activity, with the limiting rate of reduction of enzyme by

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

xanthine in rapid kinetic experiments decreased from 67 $s^{-1}$ for the wild-type enzyme to 5.5 $s^{-1}$ for the mutant. The $K_d$ is correspondingly affected, increasing from 34 μM to 410 μM. It is evident that the free energy associated with the interaction of this residue with substrate, ca. 3 kcal/mol, is used approximately equally to bind substrate on the one hand, and lower the activation barrier for the reaction on the other. The result is that $k_{red}/K_d$ (the effective second-order rate constant of free enzyme with free substrate in the lower [S] regime) is compromised by over two orders of magnitude in the mutant enzyme. The E730A mutant is profoundly compromised in reactivity toward substrate – no reduction of enzyme was detected in an overnight incubation with excess xanthine under anaerobic conditions (with wild-type enzyme, the reaction is complete in less than 200 ms under the conditions). Control experiments established that the mutant enzyme had only about 30% functional active sites (based on molybdenum and sulfur content), but still the absorbance change associated with reduction of the active enzyme should have been easily detected. Further, other mutants (notably E730Q and E730R) had more molybdenum and sulfur incorporated, but were similarly inactive. Conservatively, the E730A mutant has a lower limiting rate of reduction by substrate of at least $10^7$ compared to wild-type enzyme, indicating that this residue contributes at least 10 kcal/mol toward transition state stabilization in the reduction of enzyme by substrate. Clearly, this residue is essential for catalysis, consistent with its proposed role as an active base initiating the reaction. Unfortunately, it was not possible to carry out a "chemical rescue" of the E730A mutant by addition of acetate (which conceivably might have bound in the empty pocket otherwise occupied by the glutamate side chain, possibly restoring at least some activity) and an E730G mutant is not stable (S. Leimkühler, unpublished). It thus remains to be established that Glu 730 functions specifically as an active-site base in the course of the reaction.

## Resonance Roman Studies of the Molybdenum Center of Xanthine Oxidoreductase

The above site-directed mutagenesis studies illustrate how interactions between substrate and enzyme can be mapped out in the active site, and rapid reaction kinetic studies used to quantitate the extent to which the free energy associated with these interactions is used to either bind substrate (i.e. influence $K_d$) or accelerate reaction time (i.e. influence $k_{red}$). It is also possible to probe enzyme-substrate interactions using resonance Raman spectroscopy, which provides detailed information about the vibrational frequencies (and hence bond strengths) of bonds in chromophores. The method is particularly useful when applied to metalloproteins, where by virtue of resonance enhancement it is frequently possible to focus on just those bonds in the active site, ignoring those of the polypeptide in general. In the case of xanthine oxidoreductase, Kitagawa, Nishino and co-workers have examined the as-isolated, oxidized enzyme by resonance Raman spectroscopy and identified specific vibrational modes attributable to ligands to the metal, in particular the Mo=O and Mo=S stretching frequencies at 899 and 474 $cm^{-1}$, respectively.[97] Interestingly, while substitution of the Mo=S with $^{34}S$ was facile, the Mo=O group could not be exchanged with solvent $H_2{}^{18}O$ even under rather extreme reaction conditions, indicating that the apical oxo group is stable and does not readily exchange with solvent. Other vibrational modes due to the [2Fe–2S] clusters and FAD of the enzyme were assigned, but no modes attributable to the enedithiolate ligand to molybdenum could be identified.

Advantage can also be taken of the long-wavelength absorption of the $E_{red}$·P complex seen with violapterin that was discussed earlier to use resonance Raman as an active-site probe. As illustrated in Figure 6 (bottom) the (ordinary) Raman spectrum of violapterin is significantly perturbed on binding to the reduced enzyme (top).[98] Apart from the differences in band intensity, which have largely to do with the fact that only certain modes seen in the $E_{red}$·P complex are resonance-enhanced (while those of the violapterin in free solution are not), it is evident that almost every mode seen in the spectrum of violapterin is shifted in the enzyme complex to at least a small extent. The principal reason for this is that while both the free and enzyme complexed forms are monoanionic under the experimental conditions, the free violapterin has the negative charge accumulated in the $N_3$ region of the pyrimidine subnucleus, while in the enzyme complexed formal negative charge accumulates to a much greater extent at the $C^7$–O, which coordinates to the molybdenum [by analogy to the crystal structure of the $E_{red}$·(FYX-051) complex]. Two of the most prominent vibrational modes in the free violapterin monoanion, at 704 and 1286 $cm^{-1}$, are shifted modestly (to 699 and 1294 $cm^{-1}$, respectively), and the third, at 1379 $cm^{-1}$, is greatly diminished in intensity. The shifts are on the order expected for increased negative charge accumulation at the $C^7$–O upon binding the enzyme. A normal mode analysis of the $E_{red}$·P complex indicates that the bands seen at 699, 852, 1294 and 146 $cm^{-1}$ vibrations have motions that include significant ring deformation.[98] In addition, the set of modes in the 1550–1700 $cm^{-1}$ region can be assigned to a second group of vibrations that have major contributions by $C^2$=O and $C^4$=O stretching motions. It is interesting that when the sample is prepared in such a way as to label the bridging oxygen between $C^7$ of the pterin nucleus and the molybdenum that the two most isotope-sensitive modes are those seen at 1467 and 1563 $cm^{-1}$, shifting 12 and 15 $cm^{-1}$, respectively, to lower energy with the heavier isotope.[98] That both these modes lie to considerably lower energy than expected for a typical carbonyl group is consistent with the $C^7$–O bond having significant single-bond character in the enzyme-bound product.

With the mode assignments for specific experimentally observed vibrational bands that have been made to date,[98] it is possible to begin to map out the regions on the heterocycle that interact with specific amino acid residues in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

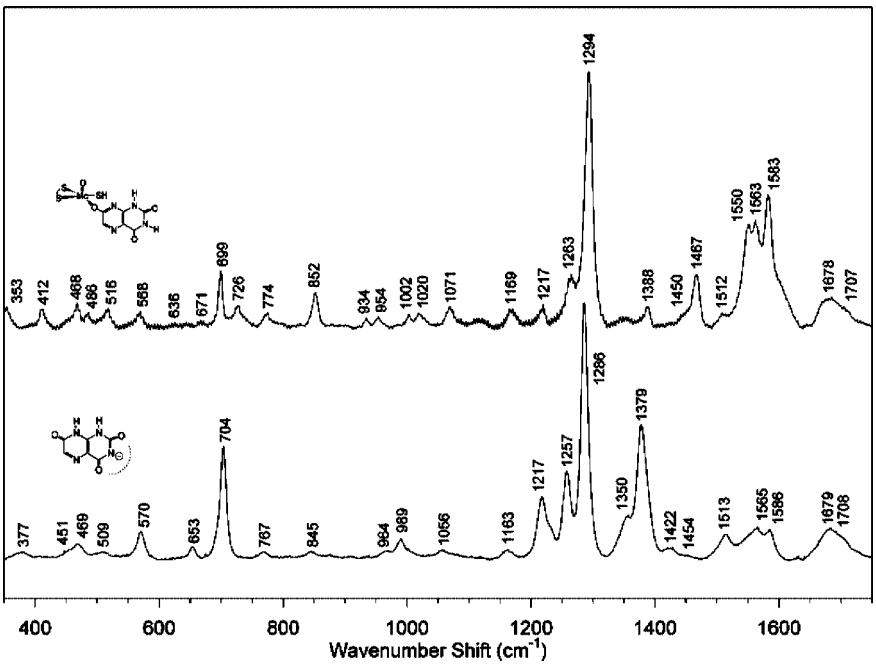

Figure 6. Resonance Raman spectra of the monoanion of violapterin (bottom) and the complex of reduced enzyme with violapterin (top). The spectra were obtained using 647-nm excitation.

active site and, importantly, quantify the amount of free energy associated with each interaction using site-directed mutagenesis. It is to be expected that work along these lines in the immediate future will provide a quantitative map of enzyme-substrate interactions, which can be correlated with changes in reactivity among the set of enzyme mutants.

## Prospectus

The crystal structures of an increasing number of members of the molybdenum hydroxylase family of enzymes have become known, and both the common and unique structural elements of these enzymes identified. There is an emerging consensus regarding the fundamental nature of carbon center hydroxylation as catalyzed by enzymes such as xanthine oxidoreductase, and the specific roles of active site amino acid residues in accelerating reaction rate at each of the several steps of this mechanism are increasingly well understood. The continued application of site-directed mutagenesis will very likely further our understanding of the catalytic process in the near future, and computational approaches in conjunction with spectroscopic methods such as resonance Raman can be expected to advance our understanding of the electronic as well as physical structures of intermediates and transition states. Finally, it can be hoped that new enzymes similar to CO dehydrogenase will be identified whose active-site structures and reaction mechanisms represent interesting variations on the theme for these enzymes that reflect the diversity of chemistry available to molybdenum in a biological context.

# The "Building-Block" Assembly of a $[Ni_{12}Mn_6]$ Aggregate

**Gang Wu,[a,d] Rodolphe Clérac,[b] Wolfgang Wernsdorfer,[c] Shilun Qiu,*[d] Christopher E. Anson,[a] Ian J. Hewitt,[a] and Annie K. Powell*[a]**

**Keywords:** Cluster compounds / Carboxylate ligands / Cooperative effects / Nickel / Manganese

Reaction of $Mn^{II}(bdoa)(H_2O)_3$ with $Ni(CH_3COO)_2{\cdot}3H_2O$ in methanol gives a heterometallic cluster, $[Ni_{12}Mn_6(bdoa)_6(O_2CMe)_{12}(\mu_3\text{-}OMe)_{12}(MeOH)_{12}]{\cdot}21MeOH$, which was structurally characterised by single-crystal X-ray diffraction and possesses three self-assembled tetranuclear nickel cubes connected by a $Mn^{II}_6(bdoa)_6(CH_3COO)_3$ subunit. The magnetic properties were studied in detail and indicate that the compound possesses a high density of spin states with small energy gaps between them.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

One of the principal synthetic challenges in the area of polynuclear metal complexes is control of molecular topology. In recent years, this has become of particular importance in the field of Single-Molecule Magnets, in which a combination of high-spin ground states and uniaxial anisotropy leads to an energy barrier to the reversal of the magnetization.[1] Heterometallic aggregates are also of particular interest in the understanding of magnetic interactions between different spin carriers.[2] For the construction of such aggregates, the "metal complex as ligand" approach has often proved to be fruitful in the designed synthesis of compounds,[3] amongst the most successful examples of which are the pre-designed metal-cyanide complexes. By careful selection of such building blocks, the fine control of target compounds with desirable architectures and magnetic properties therefore becomes a reality.[3c,3d,3f] Such a strategy has also been successfully employed in the synthesis of framework compounds constructed from secondary building units (SBUs) in which coordination-compound units are connected through rigid ligands such as 1,3,5-benzenetricarcoxylate or 4,4′-bipyridyl.[4] Using such ideas we thought it should be possible to construct a discrete molecule by choosing the correct combination of SBUs or SBU precursors. For example, a suitable metal-complex building block is one that possesses coordinated functional groups, such as carboxylate groups, which can form magnetically active bridges to other paramagnetic metal ions, and/or has exchangeable terminal ligands (e.g. $H_2O$, MeOH) that can be replaced by bridging units from other metal complexes. On the other hand, synthetic conditions can be chosen to favour known self-assembly motifs such as metal-cubane structures. Ideally, the components should be soluble in common solvents, and the desired structural motifs should be conserved during the reaction leading to a predictable final structure. Here we present the realisation of such a strategy with the synthesis, structure and magnetic properties of the large heterometallic aggregate $[Ni_{12}Mn_6(bdoa)_6(O_2CMe)_{12}(\mu_3\text{-}OMe)_{12}(MeOH)_{12}]{\cdot}21MeOH$ (**2**·21MeOH) ($bdoa^{2-}$ = benzene-1,2-dioxyacetate), which can be described in terms of a trigonal prismatic framework that corresponds to a central $\{Mn^{II}_6(bdoa)_6(\mu\text{-}O_2CMe)_3\}$ core decorated by three self-assembled $\{Ni_4(\mu_3\text{-}OMe)_4\}$ cubane units.

The complex $[Mn^{II}(bdoa)(H_2O)_3]$ (**1**) was selected as the mononuclear, metal-complex building block since, as the X-ray crystal structure[5] shows, the compound is monomeric and has a seven-coordinate metal centre, the tetradentate ligand and three aqua ligands forming a pentagonal-bipyramidal geometry (Figure 1 top). In this way, the two non-coordinated oxygen atoms of the carboxylate groups can be used to form bridges to other metal centres and the three *mer*-distributed aqua ligands can either be replaced by other bridging units, as we indeed observe in the final product, or be deprotonated to form single- or double-hydroxo bridges to other metal centres.

Reaction of complex **1** with $Ni(O_2CMe)_2{\cdot}3H_2O$ in methanol in a 1:2 molar ratio gave pale-green plate-like crystals of **2**·21MeOH in good yield after one week. The structure of **2**, viewed down the molecular threefold axis, is shown in Figure 1. The structure can be described as being built up

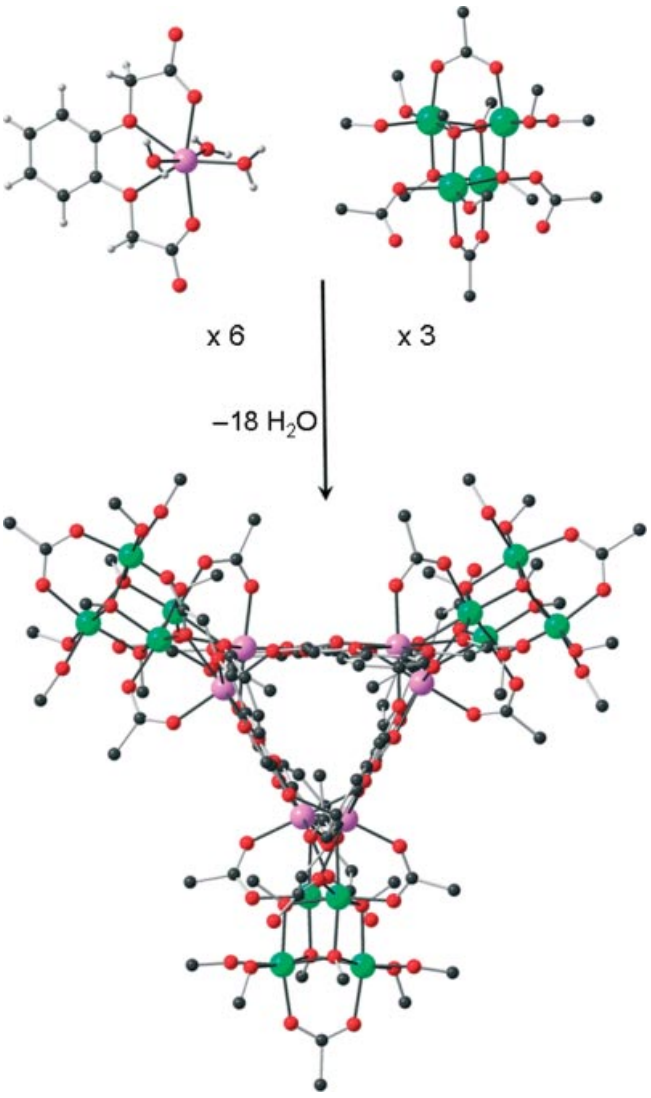

Figure 1. The self-assembly of six $Mn^{II}(bdoa)(H_2O)_3$ building blocks and three $[Ni_4(O_2CMe)_4(OMe)_4(MeOH)_4]$ cubanes to form the $[Ni_{12}Mn_6]$ cluster. The bottom picture shows the structure of **2**, viewed down the molecular threefold axis.

round a central, slightly twisted, trigonal-prismatic $\{Mn_6(bdoa)_6(\mu\text{-}O_2CMe)_3\}$ core, and the triangular faces correspond to two trinuclear units in which each Mn(bdoa) centre is bridged, through an outer, non-chelating $bdoa^{2-}$ carboxylate oxygen atom, to the next manganese atom in a cyclic fashion. The resulting $\{Mn_3(bdoa)_3\}$ triangles are linked by three *anti-anti*-bridging acetate ligands to form the prism, which has an idealised $D_3$ (32) molecular symmetry. The pentagonal-bipyramidal coordination geometry of the $Mn^{II}$ centres in precursor **1** (Figure 1, top) has been preserved during the self-assembly process. As hoped, the three *mer* terminal water ligands have been substituted and replaced by oxygen atoms from two acetate ligands and one carboxylate oxygen atom from another precursor unit. In the structure of **2**, each of the three acetate ligands that link the triangles together is incorporated into and is thus also structurally part of each of the $[Ni_4(O_2CMe)_4(OMe)_4(MeOH)_4]$ cubane structures. They are oriented such that their methyl groups point towards the centre of the core and bridge the two $Ni^{II}$ centres of one face of the cubane in a *syn*,*syn* coordination mode. Another acetate ligand bridges across the opposite face of the cubane in the same fashion and the remaining two acetates provide further links between the cubane and the Mn core. The $\mu_3$-methoxy ligands bridge three Ni centres rather unsymmetrically, and for each ligand, the three Ni–O–Ni angles fall in the ranges 89.3–91.5°, 96.3–97.5° and 99.6–101.8°; the smallest angle refers to an acetate-bridged Ni···Ni edge. All Ni centres are six coordinate, and the coordination spheres of the outer Ni centres are completed by two further methanol ligands on each centre. Conceptually, compound **2** is the combination of three neutral $Ni^{II}$ cubanes and six neutral $Mn^{II}$ precursors, which results in a neutral molecular framework.

Figure 2 shows the attachment of the cubanes onto the $Mn_6$ core in detail. As well as the links involving ligand oxygen atoms mentioned above, in which each Mn···Ni linkage involves a pair of oxygen bridges with Mn–O–Ni angles in the range 96.5–99.0°, further stabilisation of the overall structure is provided by rather strong hydrogen bonds between the methanol ligands on the cubanes and the carboxylate oxygen atom of the $Mn_6$ core unit. Complex **2** can be likened to a wind-turbine and the three $Ni_4(OMe)_4$ cubanes correspond to the blades attached to the $Mn_6(bdoa)_6(\mu\text{-}O_2CMe)_3$ core that acts as the spindle (Figure 1 bottom).

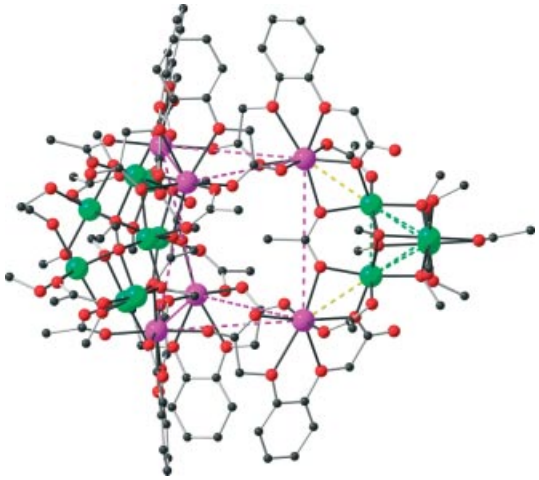

Figure 2. The linkage of the $Ni_4Mn_2$ units to the $\{Mn_6(bdoa)_6(O_2CMe)_3\}$ core in **2**; the magnetic interaction pathways are highlighted by dashed lines and the triangular prismatic framework in pink.

Metal-cubane complexes, which have four metal ions and four $\mu_3$-bridging atoms alternately aligned at the vertices of the cube, often have high-spin ground states because of the orthogonality of the magnetic orbitals. The Ni–O–Ni angles and Ni–Ni distances of the $Ni_4(OMe)_4$ portions in complex **2** are very similar to those in previous examples in which all the $Ni^{II}$ couple ferromagnetically to give an $S_T = 4$ spin ground state.[6] To the best of our knowledge, **2** is the first cluster compound that contains more than one such tetranuclear Ni cubane complex in which the cubane units are

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

well-separated but linked through a magnetically active structure. The magnetic properties of **2** were therefore investigated.

The temperature dependence of the magnetic susceptibility of **2**·21$CH_3OH$ was measured between 1.8 and 300 K at H = 1000 Oe (Figure 3). The $\chi T$ value at room temperature is 42.3 $cm^3 K mol^{-1}$, which is in very good agreement with the spin-only value of twelve $S = 1$ $Ni^{II}$ and six $S = 5/2$ $Mn^{II}$ metal ions (42.25 $cm^3 K mol^{-1}$ with $g = 2$). Upon decreasing the temperature, the slight increase followed by a decrease in the $\chi T$ product reveals the presence of competing magnetic interactions. The maximum value of 44.6 $cm^3$ K $mol^{-1}$ for $\chi T$, reached at ca. 12 K, suggests, at a first glance, that **2** has a large-spin ground state. Below 12 K, the $\chi T$ product significantly decreases rapidly, probably as a result of zero-field splitting of the ground state or antiferromagnetic intra-/intercluster interactions.

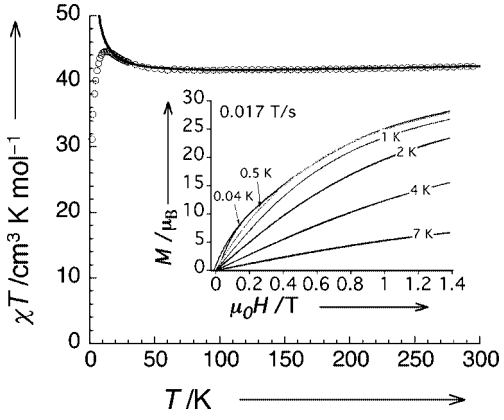

Figure 3. Plot of $\chi T$ vs. $T$ for **2** measured at 1000 Oe. The solid line is the best fit using the model described in the text. Inset: $M$ vs. $H$ data for **2** between 0.04 and 7 K at a sweep field rate of 0.017 T/s.

Unfortunately, the large number of magnetic centres and the presence of multiple magnetic exchange pathways preclude a determination of the individual exchange parameters in **2**. Nevertheless, by considering previously reported magneto–structural analyses of different bridging modes in the literature, two qualitative approaches can be carried out in order to analyse the magnetic properties. The strongest magnetic couplings are most likely located in a $Ni_4Mn_2$ unit (Figure 2) that contains two types of magnetic interactions: $Ni^{II}$–$Ni^{II}$ ($J_{Ni–Ni}$) and $Ni^{II}$–$Mn^{II}$ ($J_{Ni–Mn}$). Since all of the previously reported $Ni_4O_4$ cubane complexes were found to possess an $S_T = 4$ spin ground state with intracubane ferromagnetic Ni–Ni interactions,[6] we can predict that in the $Ni_4Mn_2$ units, $J_{Ni–Ni}$ couplings are also likely to be ferromagnetic. We are not aware of any previous case of $J_{Ni–Mn}$ mediated by a double alkoxo- and a *syn-syn* carboxylate bridge, although there are two reports on weakly ferromagnetic $Ni^{II}$–$Mn^{III}$ interactions through two alkoxo bridges.[7] In **2**, three such $Ni_4Mn_2$ units are linked in a triangular arrangement through *anti-anti* carboxylate bridges between $Mn^{II}$ ions ($J_{Mn–Mn}$) that are known to be very weakly antiferromagnetic.[8]

On the basis of this analysis, two possibilities can be considered, depending on the magnitude of these interactions. Firstly, these interactions could be strong enough to stabilise a well-defined ground state at 12 K, which corresponds to a $\chi T$ value of 44.6 $cm^3 K mol^{-1}$. In this case, the resulting overall ground state ($S_T$) of **2** is obtained by considering an antiferromagnetically coupled triangle of $Ni_4Mn_2$ units. In other words, $S_T$ corresponds to the spin ground state of one $Ni_4Mn_2$ unit. In order to reproduce the experimental $\chi T$ value at low temperature, the only possibility is to have ferromagnetic $J_{Ni–Mn}$ couplings, which leads to an $S_T = 9$ $Ni_4Mn_2$ unit and thus $S_T = 9$ for the cluster **2** as a whole, giving a theoretical $\chi T$ value of 45 $cm^3 K mol^{-1}$ (with $g = 2$). Nevertheless, a second hypothesis can be proposed. From the increase in the $\chi T$ product, it is clear that the ferromagnetic interactions are dominant, but the other exchanges could be very weak and only experimentally observable below 12 K with the decrease in the $\chi T$ product. In this case, the magnetic behaviour of **2** should be described at a first approximation by the magnetism of three isolated $Ni_4$ cubanes in addition to the Curie contributions from the six Mn metal ions. By using an isotropic Heisenberg model and the same $J_{Ni–Ni}$ value between the Ni spins,[9] the magnetic susceptibility was perfectly reproduced down to 15 K[10] and leads to $J_{Ni–Ni}/k_B = +0.99(1)$ K and $g = 2.19(1)$ (solid line Figure 3). Hence, both hypotheses might be relevant even if the usually weak antiferromagnetic $J_{Mn–Mn}$ interactions are in favour of the second one. $M$ vs. $H$ measurements were performed on powdered crystalline samples in fields of up to 7 T at 1.8 K. Even at 7 T, the magnetization is not completely saturated, and reaches 42 $\mu_B$. This value is much larger than expected for a well-defined $S_T = 9$ spin ground state. On the other hand, this result is not surprising as a high-nuclearity complex such as **2**, particularly one in which many of the magnetic interactions are likely to be weak, as would be the case for our second hypothesis, vide supra, is likely to possess a high density of spin states with small energy gaps. So low-lying excited states, including those of greater $S$ value (for example, an $S = 27$ spin state where the spins of the three $Ni_4Mn_2$ units are aligned parallel), can be populated under an applied field.[11]

Since some $Ni_4$ cubane complexes have either been found to be or suspected to be SMMs,[6c,6d] magnetization measurements were made on **2** at low temperatures by using a microSQUID. Measurements performed at different angles of the applied field with respect to the molecule showed no significant differences. A typical measurement at several temperatures is presented in the inset of Figure 3. Only very small hysteresis effects were observed below 0.3 K in the rather featureless magnetization curves. However, for a cluster with $S_T = 9$ as the ground state, a sharp step in the magnetization at $H = 0$ should be observed at very low temperature (0.04 K). The absence of such a step thus confirms the second hypothesis given above and suggests that, at 0.04 K, **2** possesses a small spin ground state. Moreover, the absence of significant anisotropy in the $M$ vs. $H$ data is indicative of rather low anisotropy within the cluster.

In summary, a new building block, $Mn^{II}(bdoa)(H_2O)_3$, has been successfully incorporated into the framework of a new heterometallic cluster, [$Ni_{12}Mn_6(bdoa)_6(O_2CMe)_{12}(\mu_3$-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$OMe)_{12}(MeOH)_{12}]\cdot 21MeOH$, which suggests that $Mn^{II}(bdoa)(H_2O)_3$ is a useful precursor for the construction of heterometallic assembles in a rational manner and thus is a potential candidate for the synthesis of new SMMs. A further attractive feature of this strategy is that it should be possible to decorate the $M_6(bdoa)_6(O_2CMe)_3$ frame with different metal cube units, allowing us to probe the effect on magnetic interactions between metal cubes with high-spin ground states and different transition-metal ions. Attempts to synthesize new heterometallic compounds with this precursor are underway.

## Experimental Section

Reaction of **1** (prepared following a reported method[5a]) (0.2 mmol) and $Ni(OAc)_2\cdot 3H_2O$ (0.4 mmol) in wet methanol (15 mL) gave a light-green solution, which was filtered and layered with diethyl ether (10 mL). Green plates of **2** were collected in high yield (100 mg, 70%) by filtration after 1 week. $C_{128}H_{248}Mn_6Ni_{12}O_{104}$ (4486.44): calcd. C 34.25, H 5.53; found: C 33.89, H 5.21.

**Crystal Structural Data for 2:** $C_{129}H_{252}Mn_6Ni_{12}O_{105}$, $F_W$ = 4517.47 g mol$^{-1}$; monoclinic, $P2_1/c$, $a$ = 20.4004(11), $b$ = 20.0722(9), $c$ = 48.307(3) Å, $\beta$ = 94.067(5)°, $U$ = 19730.9(18) Å$^3$, $Z$ = 4, $T$ = 150 K, $\rho_{calcd.}$ = 1.521 Mg m$^{-3}$, $\rho$(Mo-$K_\alpha$) = 1.582 mm$^{-1}$, $F$(000) = 9408; pale-green plate 0.21 × 0.17 × 0.03 mm, Stoe IPDS-II area detector diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation; 98171 data measured and corrected for absorption, 33821 unique. $R_{int}$ = 0.1378, $2\theta_{max}$ = 50°, $wR_2$ = 0.2248, $S$ = 0.966 (all data), $R_1$ = 0.0942 [13949 reflections with $I \geq 2\sigma(I)$], 2166 parameters, residual electron density +0.72/–0.61 e Å$^{-3}$; structure solution (direct methods) and full-matrix least-squares refinement with SHELXTL;[12] anisotropic refinement for all non-H atoms in the cluster and one lattice methanol, C and O of remaining methanol groups isotropic, hydrogen atoms in calculated position except for OH of coordinated methanol groups. Most of the lattice methanol groups were disordered; solvent-accessible voids remained in the structure, and the data were corrected using the *squeeze* option in PLATON,[13] which indicated the presence of an additional lattice methanol per cluster.

CCDC-295080 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): MicroSQUID data is available.

# Rational Design and Control of the Dimensions of Channels in Three-Dimensional, Porous Metal-Organic Frameworks Constructed with Predesigned Hexagonal Layers and Pillars

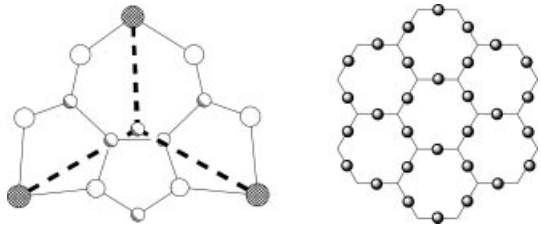
**Cui-Jin Li,[a] Sheng Hu,[a] Wei Li,[b] Chi-Keung Lam,[a] Yan-Zhen Zheng,[a] and Ming-Liang Tong*[a]**

**Keywords:** Cobalt / Microporous / MOFs / Imidazole-4,5-dicarboxylate / Pillar / Magnetism

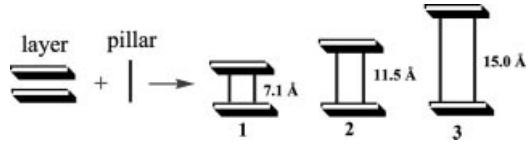
New three-dimensional, microporous metal-organic frameworks exhibiting reversible water adsorption, constructed from hexagonal $[Co_3(imda)_2]$ layers and *N*,*N*′-pillars, in which the dimensions of the channels are rationally adjustable by varying the lengths of pillars, have been designed, hydrothermally synthesized, and characterized.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

Pillared metal-organic framework (MOF) structures, analogous to natural clays and zeolites, are potentially important for applications in adsorption, separation and catalysis.[1,2] Although many attempts have been made to prepare functionalized pillared materials through cross-linking metal-phosphate, metal-phosphonate, or metal-sulfonate layers,[1a] these structures are built upon closed-window layers and pillars.[1,2] Contrasting the metal-phosphate, -phosphonate or -sulfonate systems, we have, with the aid of crystal engineering, been recently investigating rational synthetic strategies towards designed assembly of microporous MOFs constructed from the cationic layers with "open windows" and anionic linear dicarboxylates as pillars.[3] The advantage of this synthetic method promises not only to produce a wide variety of porous MOF materials with controlled channel sizes but also to mediate their chemical behavior by the decoration of diverse functional groups as part of the pillars. Recently, imidazole-4,5-dicarboxylic acid ($imdaH_3$) has been used as a versatile ligand to construct some intriguing porous MOFs, such as the molecular square[4a] and cube[4b,4c] in $Na_2[Co_4(imda)_4(2,2'\text{-bpy})]$ and $[Ni_8(imdaH)_{12}]^{8-}$, respectively. Among the coordination modes of the $imda^{3-}$ ligand in the reported complexes, the most remarkable one is the triangular arrangement of the three metal ions around $imda^{3-}$ (Scheme 1), which implies that it can be employed as a module in the construction of hexagonal layers by sharing the corners of the trigonal subunit $[M_3(imda)_2]$. In this communication, we report a strategy for pillaring the hexagonal $[M_3(imda)_2]$ layers into three 3D, porous MOF solids with controlled channel sizes (Scheme 2): $[Co_3(imda)_2(pyz)_3]\cdot 8H_2O$ (**1**), $[Co_3(imda)_2(4,4'\text{-bpy})_3]\cdot 4,4'\text{-bpy}\cdot 8H_2O$ (**2**), and $[Co_3(imda)_2(2,5\text{-bptz})_3]\cdot 2,5\text{-bptz}\cdot 9H_2O$ (**3**) [pyz = pyrazine, 4,4′-bpy = 4,4′-bipyridine, 2,5-bptz = 2,5-bis(pyrid-4-yl)-1,3,4-thiadiazole].



Scheme 1. Predesigned hexagonal layer constructed from the 3-connected 4,5-imda ligand.



Scheme 2. A strategy for design and control of the channels in **1**–**3**.

## Results and Discussion

Hydrothermal reactions of $CoCl_2\cdot 6H_2O$, $imdaH_3$, NaOH, and different *N*,*N*′-pillars (pyz, 4,4′-bpy, or 2,5-bptz) in a mol ratio of 1.5:1:3:1.5 generate crystals of **1**–**3**.

Single-crystal X-ray analysis has revealed that **1** crystallizes in the hexagonal space group *P6/mmm*. The $Co^{II}$ ions occupy Wyckoff position 3(*f*) with site symmetry *mmm*. Notably, the ideal molecular symmetries of the pyz ligand ($D_{2h}$) and the imda trianion ($C_{2v}$) are retained in the crystal structure, but the imda trianion exhibits a threefold disorder about the $\bar{6}$-axis (Figure S1). The $Co^{II}$ ions are located in two different distorted octahedral coordination environments, $[CoO_2N_4]$ or $[CoO_4N_2]$ (Figure 1a). The coordination sphere is formed by four N atoms (two from pyz and two from imidazolate) and two carboxylato O atoms, or by two pyridyl N atoms and four carboxylato O atoms [Co–$N_{imda}$ = 1.955(13), Co–$N_{bpy}$ = 2.162(12), Co–O = 2.193(15) Å]. Each imda ligand bridges three Co atoms [Co···Co separations of 6.091(4) Å] to generate neutral and essentially planar $[Co_3(imda)_2]$ layers with (6,3) topology (Figure 2a). For simplicity, one of three possible orientations of $imda^{3-}$ is considered. Each 2D layer consists of two types of hexagonal 24-membered rings: $Co_6$(imidazolato)$_6$ and $Co_6$(carboxylato)$_6$. Interestingly, each $Co_6$(imidazolato)$_6$ ring is surrounded by six $Co_6$(carboxylato)$_6$ rings, while each $Co_6$(carboxylato)$_6$ ring is alternately surrounded by three $Co_6$(imidazolato)$_6$ rings and three $Co_6$(carboxylato)$_6$ rings. A sixfold axis lies across each cavity of the hexagonal layer. It is noteworthy that the hexagonal $[Co_3(imda)_2]$ layers are ideally stacked in an AAA fashion along the *c*-axis and are further pillared by pyz spacers into a non-interpenetrated 3D microporous MOF structure with the effective channel size of 4.7 × 4.7 Å estimated from the van der Waals radii for carbon (1.70 Å), hydrogen (1.20 Å),

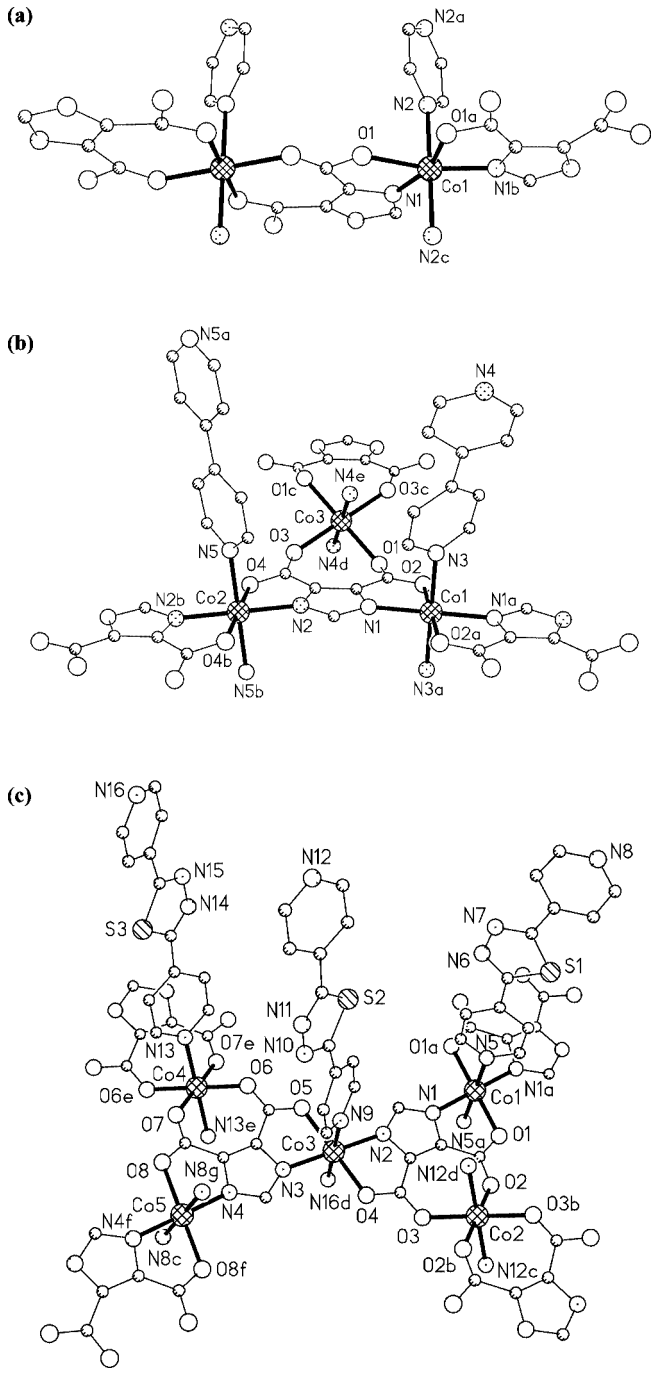

Figure 1. Coordination geometries of the $Co^{2+}$ ions in **1** (a), **2** (b), and **3** (c).

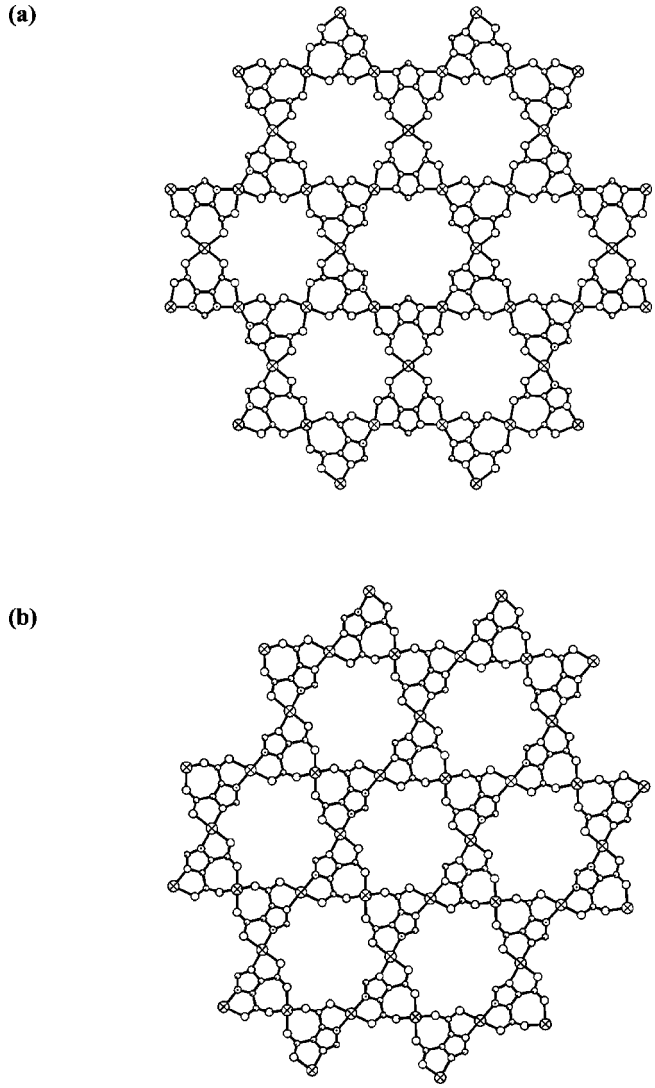

Figure 2. 2D hexagonal layers in **1** (a), and **2** or **3** (b).

nitrogen (1.55 Å), and oxygen (1.40 Å) (Figure S2 and Figure 3a). The disordered guest water molecules are located within these channels. An analysis with PLATON[5] suggested that the channels occupy 39.1% of the crystal volume. The network topology can be simplified by considering just the cobalt atoms (represented by a square-planar node) and the tri-connected imda ligands (represented by a triangular node); the bidentate pyz ligands can be represented simply as links between the cobalt nodes. The resulting net, shown in Figure 3b, is a rare 3D (3,4)-connected net with triangular and square-planar nodes in the ratio 2:3. A topological analysis of this net was performed with OLEX.[6] The long topological (O'Keeffe) vertex symbol is $6_2.6_2.6_2.6_2.12_2$ for the Co node and $6_2.6_2.6_2$ for the imda node, giving the short vertex symbol $(6^3)_2(6^4.8.10)_3$. The net is different to other previously identified (3,4)-connected networks.[7]

The porous MOF structures of **2** and **3** are similar to that of **1**. Both of them are built of neutral hexagonal $[Co_3(imda)_2]$ layers and longer 4,4′-bpy or 2,5-bptz pillars. The asymmetric unit of **2** contains one and a half 4,4′-bpy ligand, one $imda^{3-}$ ion, and three independent $Co^{II}$ ions lying at inversion centers (Figure 1b). Both Co1 and Co2 atoms are similarly in a distorted octahedral $[CoO_2N_4]$ environment, in which the coordination sphere for Co1 or Co2 is formed by two pyridyl N atoms, two imidazolate N atoms, and two carboxylate O atoms [Co–$N_{imda}$ = 2.046(3)–2.048(4), Co–$N_{bpy}$ = 2.172(4)–2.206(3), Co–O = 2.106(3)–2.119(3) Å], while the coordination sphere for Co3 is formed by two pyridyl N atoms and four carboxylato O atoms [Co–N = 2.157(3), Co–O = 2.063(3)–2.066(3) Å]. Each imda ligand bridges three Co atoms with Co···Co separations of 5.7704(5)–6.2939(4) Å. For **3**, the asymmetric unit of the host MOF contains five unique $Co^{II}$ atoms, four (Co1, Co2, Co4, and Co5) of which lie across inversion centers and the other one (Co3) on a general position, two imda ligands which lie on general positions, and three unique 2,5-bptz ligands (Figure 1c). The adjacent intralayer Co···Co distances separated by the imda ligands are 5.8168(9)–6.3064(9) Å.

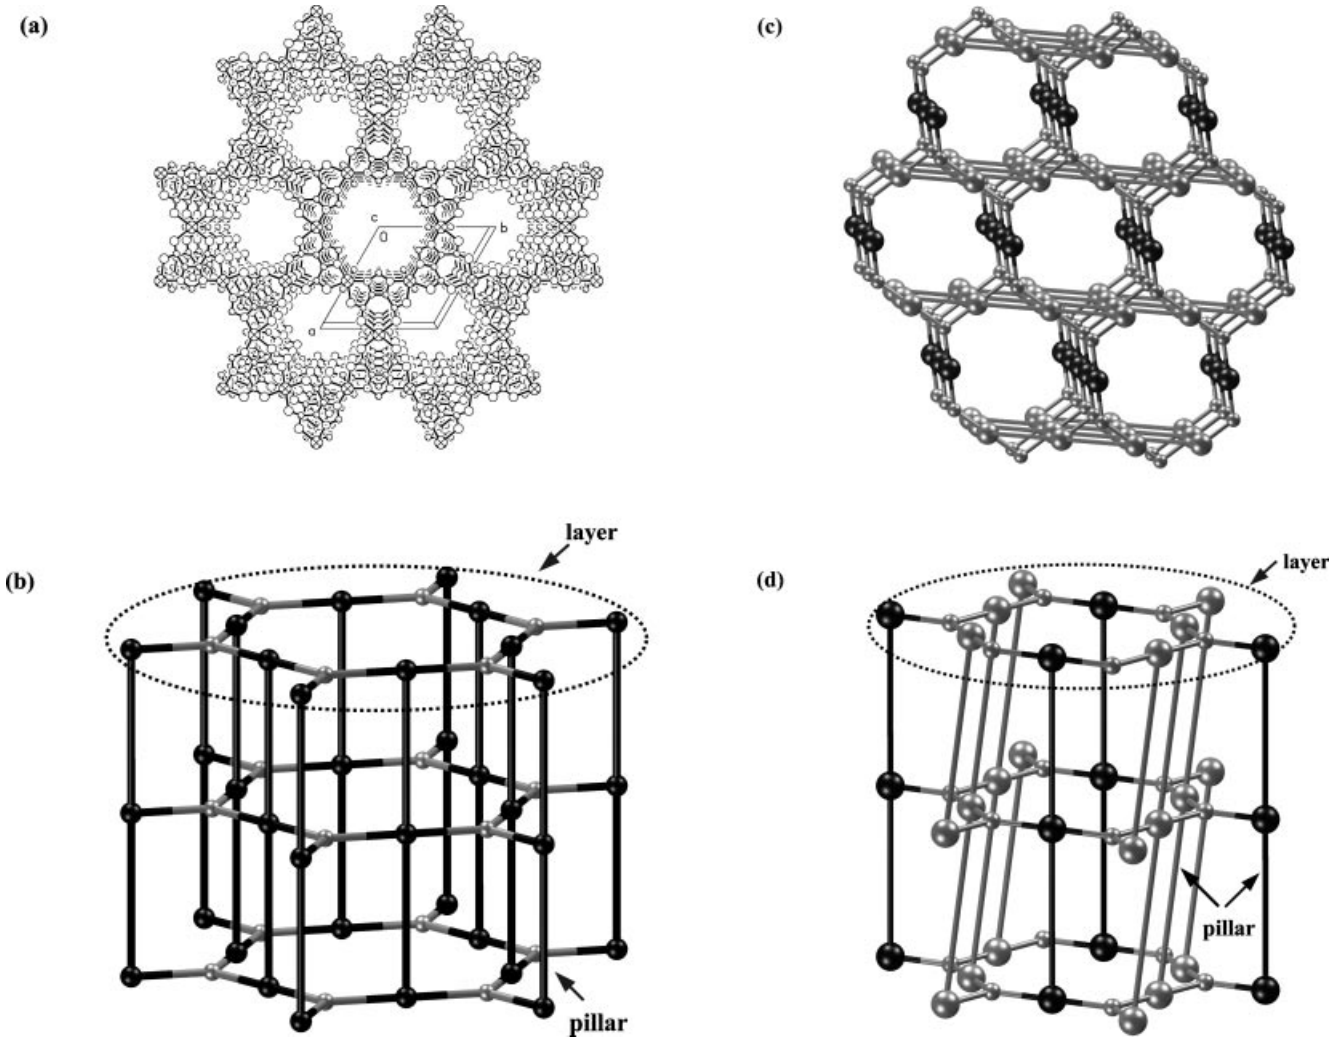

Figure 3. (a) The pillared 3D MOF in **1**. (b) Topological connectivity in **1**. (c) Topological net of the pillared 3D MOF in **2** or **3**. (d) Topological connectivity in **2** or **3**. The big dark grey or black spheres represent cobalt atoms, while the small grey spheres represent the centers of mass of imda ligands. The *N*,*N*′-pillar ligands are represented by interlayer bold lines.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In contrast to that in **1**, each 2D hexagonal layer in **2** or **3** consists of only hexagonal $Co_6$(imidazolato)$_2$(carboxylato)$_4$ 24-membered rings (Figure 2b). Adjacent hexagonal layers are stacked in a ABAB fashion and are further pillared by 4,4′-bpy or 2,5-bptz spacers into a non-interpenetrated 3D microporous MOF structure with the effective channel sizes of 4.2×6.2 Å and 4.7×6.5 Å for **2** and **3**, respectively. It should be noted that the network topology of **2** and **3** are identical, but different from that of **1** though the three 3D MOF structures are 3D (3,4)-connected nets with triangular and square-planar nodes in the ratio 2:3. In **1**, all the Co nodes are the same. But in **2** and **3**, only two-thirds of the Co nodes are equivalent (for **2**: Co1 and Co3; for **3**: Co1, Co2, Co4 and Co5). The difference between the two types of nodes can be seen in Figure 3c, d. The long topological (O'Keeffe) vertex symbol is $6_2.6_2.6.6.12_2.12_2$ and $6.6.6.6.10_2$ for the two kinds of Co nodes, and $6.6.6_2$ for the imda node, giving the short vertex symbol $(6^3)_2(6^4.8^2)_2$-$(6^4.10^2)$. An analysis with PLATON[5] suggested that the channels occupy 38.8% and 44.6% of the crystal volume for **2** and **3**, respectively. The guest 4,4′-bpy/2,5-bptz and water molecules are located within these channels. The calculated crystal densities (in the absence of guests) of 1.172 g cm$^{-3}$ and 1.09 g cm$^{-3}$ are comparable to those found for some porous MOF materials with low density.[8]

To examine the thermal stability of these porous networks, thermal gravimetric (TG) analyses and powder X-ray diffraction (XRD) measurements were carried out. The thermal decomposition behaviors of **1**, **2**, and **3** are much alike. For **1**, the first weight loss of 15.7% from 20 to 180 °C is in accordance with the loss of eight lattice water molecules per $Co_3$ (calculated: 16.6%), while the release of the pyz and imda components occurs at ca. 250 °C and 360 °C in two separate steps (Figure S4) to yield the residue $Co_3O_4$ at ca. 410 °C (found: 28.6%; calculated: 27.8%). The TG curve of **2** indicate the release of all lattice water molecules before 106 °C (found: 11.3%; calc: 11.5%). At 265 °C, the solvated 4,4′-bpy and coordinated ligands start to be released (Figure 4). No chemical decomposition was observed between 106 and 265 °C. The TG curves of the dehydrated and rehydrated samples of **2** show that it exhibits reversible water adsorption. Powder XRD patterns of **2** and dehydrated samples of **2** are nearly identical, indicating that the initial framework is retained after the lattice water molecules are removed by heating at 180 °C under vacuum for 8 h. For **3**, the first weight loss of 9.9% from 20 to 120 °C is in accordance with the loss of nine lattice water molecules per Co3 (calculated: 10.1%). No chemical decomposition was observed between 120 and 350 °C (Figure S6). Similar reversible dehydration and rehydration are also found for **1** and **3** (Figures S4–6).

The temperature-dependent magnetic susceptibility, $\chi_M$, of **1**, **2**, and **3** were measured in a 5.0-kOe field (Figure S7). At room temperature, $\chi_M T$ is 8.30, 8.29, and 7.20 cm$^3$ mol$^{-1}$ K per $Co_3$ unit for **1**, **2**, and **3**, respectively, which is significantly higher than the spin-only value (5.63 cm$^3$ mol$^{-1}$ K) expected for three uncoupled $Co^{II}$ ions ($S$ = 3/2), indicating that the orbital contribution is incompletely quenched. Upon cooling, the $\chi_M T$ gradually decreases owing to the contribution of single-ion behavior of high-spin $Co^{II}$ ions and also to antiferromagnetic exchange between the Co centers. The $\chi_M(T)$ in the high-temperature region (30–280 K) can be fit into the Curie–Weiss equation with $C$ = 9.77 cm$^3$ mol$^{-1}$ K and $\theta$ = –53.99 K for **1**, $C$ = 9.69 cm$^3$ mol$^{-1}$ K, and $\theta$ = –46.24 K for **2** and $C$ = 8.48 cm$^3$ mol$^{-1}$ K and $\theta$ = –58.94 K for **3**; these values agree well with those expected for high-spin $Co^{II}$ ions in octahedral sites.[9a] The negative sign of $\theta$ and the decrease of $\chi T$ point to the existence of antiferromagnetic exchange interactions. Spin-orbit coupling most certainly also contributes to this decay.[9a–9c] Detailed magnetic studies and other functions of this porous family are under way.

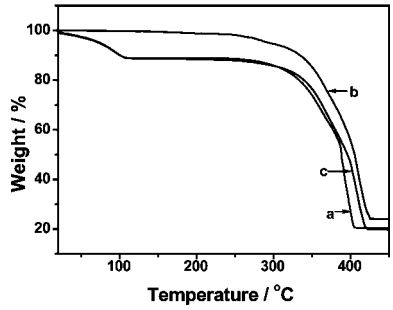

Figure 4. TG data for **2**: (a) as-synthesized sample, (b) dehydrated sample at 180 °C, (c) re-hydrated sample.

In conclusion, we present a new strategy for the generation of novel 3D porous metal-organic framework solids that exhibit reversible water adsorption with predesigned hexagonal [$Co_3$(imda)$_2$] layers and length-controllable $N,N'$-spacers as pillars. They may be good candidates for porous materials owing to their high thermal stability and reversible guest exchange.

## Experimental Section

**X-ray Crystallographic Study:** Diffraction intensities of **1**, **2**, and **3** were collected with a Bruker Apex CCD area-detector diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). Absorption corrections were applied by using the multiscan program SADABS.[10] The structures were solved with direct methods and refined with a full-matrix least-squares technique with the SHELXTL program package.[11]

Crystal and structure-refinement parameters. Compound **1**: $C_{22}H_{30}Co_3N_{10}O_{16}$, $M$ = 867.35, hexagonal, space group *P6/mmm* (No. 191), $a$ = 12.183(1), $c$ = 7.092(1) Å, $V$ = 911.6(2) Å$^3$, $Z$ = 1, $T$ = 123(2) K, $F$(000) = 441, $D_c$ = 1.580 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 1.427 mm$^{-1}$; $R_1$ = 0.0847, $wR_2$ = 0.1687 and GOF = 1.159 for 61 parameters, 307 reflections with $|F_o| \geq 4\sigma(F_o)$. Compound **2**: $C_{50}H_{50}Co_3N_{12}O_{16}$, $M$ = 1251.81, triclinic, space group $P\bar{1}$ (No. 2), $a$ = 11.448(1), $b$ = 11.541(1), $c$ = 11.766(1) Å, $\alpha$ = 65.370(1), $\beta$ = 80.540(1) $\gamma$ = 72.759(1)°, $V$ = 1348.2(2) Å$^3$, $Z$ = 1, $T$ = 123(2) K, $F$(000) = 663, $D_c$ = 1.542 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 0.993 mm$^{-1}$; $R_1$ = 0.0580, $wR_2$ = 0.1552 and GOF = 1.036 for 412 parameters, 4147 reflections with $|F_o| \geq 4\sigma(F_o)$. Compound **3**: $C_{58}H_{52}Co_3N_{20}O_{17}S_4$, $M$ = 1606.23, triclinic, space group $P\bar{1}$ (No. 2), $a$ = 11.791(1), $b$ = 17.050(2), $c$ = 20.795(2) Å, $\alpha$ = 104.726(2), $\beta$ = 106.360(2), $\gamma$ = 103.481(2)°, $V$ = 3664.6(7) Å$^3$, $Z$ = 2, $T$ = 123(2) K, $F$(000) = 1642,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$D_c$ = 1.456 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 0.862 mm$^{-1}$; $R_1$ = 0.0834, $wR_2$ = 0.2467 and GOF = 1.029 for 955 parameters, 7210 reflections with $|F_o| \geq 4\sigma(F_o)$. The PLATON SQUEEZE procedure[12] was also used to treat regions of disordered solvent in **2** which could not be sensibly modeled in terms of atomic sites. Their contribution to the diffraction pattern was removed and modified $F_o^2$ written to a new HKL file. The number of electrons thus located, 160.1 per unit cell, is included in the formula, formula weight, calculated density, $\mu$, and $F$(000). This residual electron density was assigned to eight water molecules and a 4,4′-bpy [8 × 10 ($H_2O$) + 1 × 82 (4,4′-bpy) = 162e]. However, the disordered solvents in **1** and **3** could not be subtracted from the corresponding diffraction patterns by the squeeze/bypass procedure because of their disordered host MOF structures.

CCDC-289570 (**1**), CCDC-284833 (**2**) and CCDC-284834 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): X-ray crystallographic files of **1**–**3** (CIF), synthesis, packing plots, TG curves, simulated and experimental powder XRD data, temperature- and field-dependent magnetic susceptibility of **1**–**3**.

## Acknowledgments

# Mesoporous Aluminium Organophosphonates Functionalized with Chiral L-Proline Groups in the Pore

Xin Shi,[a] Jie Yang,[a] and Qihua Yang*[a]

**Keywords:** Chiral / Mesoporous compounds / Aluminium organophosphonates

Mesoporous aluminium organophosphonates with chiral L-proline groups in the pore were synthesized for the first time through surfactant-assisted one-pot co-condensation of $Al(OsBu)_3$ with a mixture of 1-phosphonomethylproline (*S*)-$H_2PO_3CH_2NC_4H_7COOH$ ($H_3PMP$) and phosphoric acid ($H_3PO_4$) [$H_3PMP/(H_3PMP + H_3PO_4)$ = 50, 75, 100 mol-%] under basic conditions in the presence of cetyltrimethylammonium bromide.

## Introduction

Recently, the interest in the design and fabrication of organic-inorganic materials with high surface area and hierarchically ordered porous structure is growing because of their potential applications in the fields of optics, electronics, membranes, catalysis, biology and etc.[1,2] The periodic mesoporous organosilicas (PMOs) with organic bridging groups in the framework were regarded as one of the recent breakthroughs in the fields of hybrid organic-inorganic mesoporous materials.[3,4] Compared with the silica-based materials, metal organophosphonates are more promising in respect of their unique properties, such as proton conductivity, nonlinear optical effects, electron transfer, topochemical reactivity, and photochromism.[5–7] Inspired by the success of PMOs, a pure mesostructured aluminium organophosphonate (AOPs) containing internal methylene groups was first reported by Kimura in 2003.[8] To the best of our knowledge, only limited types of organic groups (alkyl, alkylene and phenyl) were incorporated in the mesoporous metal organophosphonates,[8–12] however, mesoporous AOPs functionalized with chiral organic groups have not been reported so far.

Amino acids are the principal building blocks of proteins and enzymes. Among them, L-proline is one of the cyclic aliphatic amino acids that is a major component of the protein collagen. Also, L-proline is an efficient catalyst for the asymmetric catalysis and chiral selector for the chiral separation.[13,14] The combination of the mesoporous AOPs with L-proline will be interesting in view of the enzyme adsorption, chiral synthesis etc. Here, we report for the first time the synthesis of mesoporous AOPs containing chiral L-proline groups in the pore by a one-pot synthetic method.

## Results and Discussion

Mesoporous AOPs with different amounts of L-proline were synthesized through the "atrane route" previously reported for the synthesis of aluminium phosphonates and diphosphonates with slight modification.[11] During the synthesis, the pre-hydrolysis of aluminium species is essential for the formation of pure mesoporous AOPs, otherwise pure mesoporous AOPs cannot be obtained. The mesoporous AOPs with different amounts of L-proline in the pore are designated as MAOP-*n*, while *n* (= 50, 75, 100) is the mol-% value of $H_3PMP/(H_3PMP + H_3PO_4)$ in the initial mixture.

The powder XRD patterns of all as-synthesized MAOPs-*n* display a single broad diffraction peak at low diffraction angle, suggesting that these hybrid materials have a "worm-like" mesoporous structure (Figure 1). The TEM images of as-synthesized MAOPs-*n* clearly show the "worm-like" pore arrangement throughout the materials, which is consistent with the XRD results (Figure 2). It is noteworthy to mention that the mesoporous structure could be formed even for MAOP-100, synthesized from 100 mol-% of $H_3PMP$. With the amounts of organophosphonic acid, $H_3PMP$, in the initial mixture increasing, the intensity of the diffraction peak decreased. The XRD patterns of MAOPs-*n* remain almost the same before and after the surfactant extraction, showing that the mesoporous structure of MAOPs-*n* is stable enough to survive during the surfactant removal process. Additionally, the diffraction peaks shift toward lower 2θ angles after removal of the surfactant, which is in agreement with the results of previous reports on mesoporous ALPOs.[11,15,16] All surfactant-extracted MAOP-*n* solids present typical type IV isotherms with H2

hysteresis loop according to IUPAC classification, characteristic of the mesoporous material with "ink-bottle" pores (see Supporting Information). The BET surface area, the pore volume, and the pore diameter of MAOP-100 are lower than those of MAOP-50 and MAOP-75. The results of XRD and $N_2$ sorption isotherms imply that the mesoporous structure of MAOPs-*n* are disturbed by the incorporation of L-proline groups in the materials. This can be explained by the fact that it is difficult for the monophosphonic acid to construct the mesoporous framework[11] and the steric hindrance resulting from the large L-proline group.

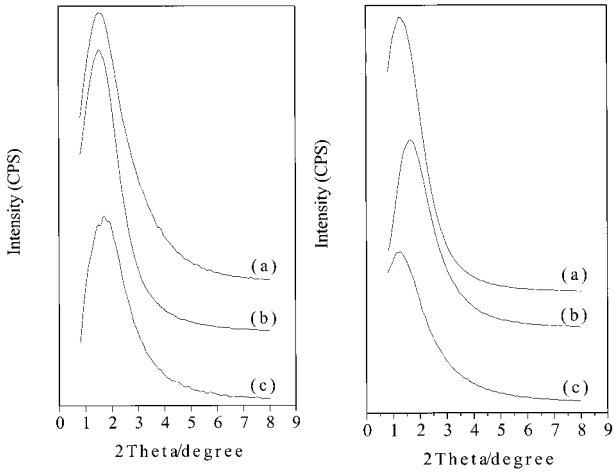

Figure 1. Powder X-ray diffraction patterns of (left) as-synthesized and (right) surfactant-extracted MAOPs-*n*: (a) MAOP-50; (b) MAOP-75; (c) MAOP-100.

The ratio of Al/P for the mesoporous aluminium phosphates varies in the range of 1.0 to 5.5 depending on the synthetic conditions.[17] The ratio of Al/P for MAOPs-*n* is about 3, which is higher than the ideal stoichiometric value of 1 (Table 1). This fact shows that the extra aluminium species participate in the formation of the mesoporous framework. During the synthesis, the reaction rate between the aluminium species and $H_3PMP$ is retarded because of the steric restriction derived from the L-proline group. Also, before the addition of $H_3PMP/H_3PO_4$, the aluminium precursor was allowed to pre-hydrolyze. As a result, the interaction of the hydrolyzed aluminium species with $H_3PMP$ and the condensation between the hydrolyzed aluminium species occurred simultaneously. The excess aluminium species that could be incorporated in the mesoporous framework of MAOPs-*n* in a controllable way can act as a stabilizer in the pore wall to stabilize the mesoporous framework of MAOPs-*n*.

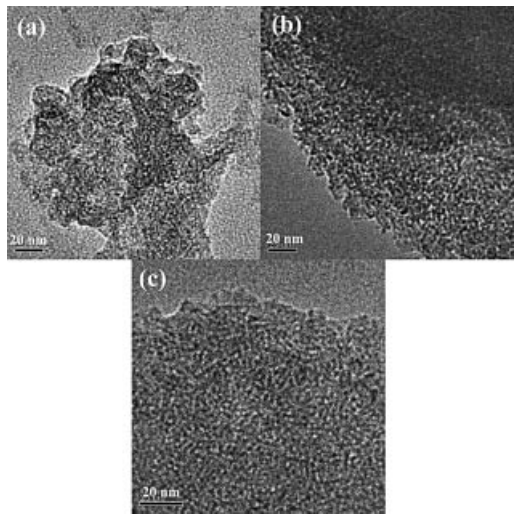

Figure 2. TEM images of as-synthesized MAOPs-*n*: (a) MAOP-50; (b) MAOP-75; (c) MAOP-100.

$^{31}P$ MAS NMR spectra of the surfactant-extracted MAOPs-*n* show that the organophosphonate groups are actually incorporated in the materials (Figure 3). MAOP-100 displays a broad peak centered at δ = 2 ppm with a shoulder at δ = 6 ppm, which could be assigned to P atoms of $RPO_3^{2-}$ and $RPO_3H^-$, respectively. The presence of $RPO_3H^-$ in MAOP-100 is also supported by the FT-IR. The stretching vibration of the P–OH band was clearly observed at 950 $cm^{-1}$ (see Supporting Information). A broad signal centered at δ = –12 ppm was observed in $^{31}P$ MAS NMR spectra of MAOP-50 and MAOP-75. After deconvolution by computer simulation, the broad peak was divided into two singals. The signal at δ = –12 ppm is attributed to the inorganic phosphorus species according to ref.[18], while the singal at δ = 2 ppm is derived from the organic phosphorus species, $RPO_3^{2-}$. From the ratio of $P_{inorg}/P_{org}$ (calculated from the peak area, Table 1), we could see that only 10 and 22 mol-% of $H_3PMP$ could be incorporated in MAOP-50 and MAOP-75, respectively. This is probably due to the severe steric hindrance of $H_3PMP$.

$^{13}C$ MAS NMR spectrum of MAOP-100 also confirms that L-proline groups have been incorporated in the material (Figure 4). The signals at δ = 174 and 179 ppm are associated with the C atoms of $CO_2H$ and $CO^{2-}$, respectively. The resonance at $\delta$ = 72 ppm can be assigned to the C atom of

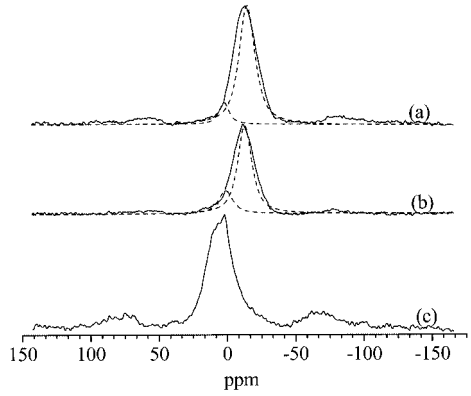

Figure 3. $^{31}$P MAS NMR spectra of surfactant-extracted MAOPs-*n*: (a) MAOP-50; (b) MAOP-75; (c) MAOP-100.

the CH group connected with the carboxy group, while the signal at $\delta$ = 56 ppm is attributed to the C atom of $CH_2$ group connected with the phosphonic group. The signals related to the $CH_2$ group of the pyrrolidine ring are observed at $\delta$ = 23, 29 and 59 ppm. The $^{13}$C MAS NMR spectrum shows that organophosphonic acid, $H_3PMP$, retains its integrity in the mesoporous solid. In addition, the peak at $\delta \approx 15$ ppm, associated with the C atom of the terminal $CH_3$ group of the surfactant CTAB, cannot be observed in the spectrum, which illuminates that the surfactant is almost completely removed using the extraction method.

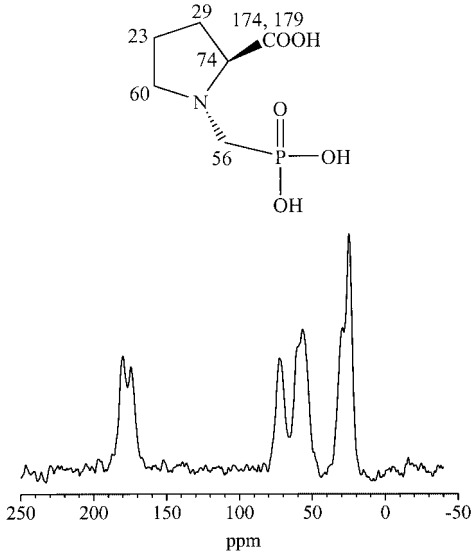

Figure 4. $^{13}$C MAS NMR spectra of surfactant-extracted MAOP-100.

The $^{27}$Al MAS NMR spectra of surfactant-extracted MAOPs-*n* give information of the aluminium coordination environment (see Supporting Information). Two signals at $\delta$ = 0 and 50 ppm are observed in the spectra of MAOP-50 and MAOP-75, which could be assigned to octahedral and tetrahedral Al centers, respectively. The peak at $\delta$ = 0 ppm is dominant, showing that almost all aluminium species are six-coordinate. Only a six-coordinate Al species is observed for MAOP-100. This may be due to the large influence of the charge balance of MAOPs-*n* on the coordination environment of the Al species. The different charges between $H_3PO_4$ and $H_3PMP$ may be the main reason for the different aluminium coordination environments in MAOPs-*n*.

The chirality of L-proline in the solid product was analyzed by CD spectroscopy (see Supporting Information). A positive Cotton effect was observed for MAOP-100, which is consistent with that of $H_3PMP$. From the CD results, we can draw the conclusion that L-proline groups retain their chirality during the synthesis and subsequent surfactant-removing process.

## Conclusion

In summary, mesoporous AOPs with different amounts of chiral L-proline groups in the pore were synthesized for the first time through the surfactant-templated method. The existence of extra aluminium species in the mesoporous framework (formed through "pre-hydrolysis" of the aluminium precursor) plays an important role in stabilizing the mesoporous structure of the materials. The integrity and chirality of L-proline were retained in the mesoporous AOPs. The successful synthesis of mesoporous AOPs containing chiral molecules may provide a new method for the design and synthesis of chiral solid materials.

## Experimental Section

**MAOP-*n* Materials:** In a typical synthesis, Al(O*s*Bu)$_3$ (0.985 g, 4 mmol) was added dropwise to a solution of triethanolamine (2.389 g, 16 mmol) at 160 °C. After cooling to 120 °C, cetyltrimethylammonium bromide (0.364 g, 1 mmol) was added to the above mixture. The solution was further cooled to 70 °C and distilled water (20 mL) was added. The mixture was stirred for a few minutes to "pre-hydrolyze" the aluminium precursor (this "pre-hydrolysis" process for the aluminium precursor is essential, otherwise pure mesoporous AOPs cannot be obtained). An aqueous solution (20 mL) containing a mixture (6 mmol) of phosphoric acid and 1-phosphonomethylproline [(*S*)-$H_2PO_3CH_2NC_4H_7COOH$, $H_3PMP$] was added to above mixture under vigorous stirring. The mixture was kept at 70 °C for 30 min. After filtration, the resulting white powder was dried under vacuum at 60 °C. The surfactant was extracted using an acetic acid/ethanol solution (1 g of powder in 130 mL of ethanol containing 16 mL of acetic acid) at room temperature.

**Supporting Information** (see footnote on the first page of this article): $N_2$ sorption isotherms, FT-IR spectra, and $^{27}$Al MAS NMR specra of MAOPs-*n*; CD spectrum of MAOP-100.

# A Zig-Zag [$Mn^{II}_4$] Cluster from a Novel Bis(β-diketonate) Ligand

**Guillem Aromí,*[a] Patrick Gamez,[b] Christophe Boldron,[b] Huub Kooijman,[c] Anthony L. Spek,[c] and Jan Reedijk[b]**

**Keywords:** Ligand design / O ligands / NMR spectroscopy / Magnetism / Mn

A new ligand, $H_5L3$, has been synthesized featuring seven linearly arranged oxygen donors in form of two 1,3-diketone and three phenol groups. The X-ray structure of $H_5L3$ unveils a rare case where one of the diketones is in the enolic form and the other one in the bis(carbonyl) form. This structure is shown by $^1H$ NMR to persist in solution. Reaction of $H_5L3$ with $Mn(AcO)_2$ in pyridine leads to the novel tetranuclear cluster $[Mn_4(H_2L3)_2(OAc)_2(py)_5]$ (**1**), which displays an unusual core in form of a zig-zag chain. Bulk magnetic measurements revealed the existence of weak antiferromagnetic coupling within the molecule. Numerical fits to a model described by the Hamiltonian $H = -2J_1(S_1S_2 + S_3S_4) - 2J_2(S_2S_3)$ yield coupling constants of $J_1 = -2.23\ cm^{-1}$, $J_2 = -0.85\ cm^{-1}$ and $g = 2.08$.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

The preparation of molecular cluster complexes of interacting transition-metal ions is useful to areas as important and diverse as molecular magnetism,[1,2] homogeneous catalysis[3] or bioinorganic chemistry.[4,5] A very successful approach for accessing such species has been the assembly of metal ions by means of small bridging ligands, such as carboxylates, where growth into infinite arrays is often prevented by additional terminal ligands.[6,7] Such a method has been sometimes termed "serendipitous approach" since it does not allow prediction of the structure of the final species.[8] An alternative strategy has been the design and preparation of complicated multidentate ligands favoring the assembly of metal ions into aggregates with topologies that may be anticipated from the structure of these ligands. This second course of action has led to the production of a large amount of polynuclear edifices displaying sophisticated shapes and architectures, such as helicates,[9] grids,[10] cylinders,[11] catenates,[12] and many more. Of these molecular species, only a minority have the metal ions disposed in close proximity so as to show cooperative effects resulting from strong magnetic-exchange interactions[13] or metal–metal bonding.[14] We have been interested in preparing new ligands incorporating various β-diketone units and other donor groups in a linear fashion ($H_3L1$ and $H_4L2$ in Scheme 1),[15,16] aimed at forming molecular strings of metal ions in close proximity. Maximum occupancy of their coordination pockets would result in tetranuclear clusters in form of $[M_4]$ chains[17] for $H_3L1$ and aligned $[M_2]_2$ dimers of dimers for $H_4L2$. Reactions of the latter with $M(OAc)_2$ salts have resulted invariably in the formation of complexes of the type $[M_2(H_2L2)_2(S)_n]$ ($n$ = 2 or 4; S = solvent; M = Mn, Ni, Co, Cu).[16] Similar dinuclear compounds have been obtained with $H_3L1$.[18] However, in the absence of a coordinating solvent, molecules exhibiting higher occupancy, $[Co_3(HL1)_3]$ and $[Mn_3(HL1)_3]$, were characterized, which represented a new asymmetric topology within the context of coordination helicates.[19] Inspired by these early results, we have now designed and synthesized a new ligand displaying as many as six adjacent coordination pockets ($H_5L3$, Scheme 1). Reaction of $H_5L3$ with $Mn^{II}$ produces a very rare magnetically exchanged tetranuclear complex featuring an $[Mn_4O_6]$ core in form of a zig-zag chain.

The new ligand $H_5L3$ {2-hydroxy-1,3-bis[3-(2-hydroxyphenyl)-3-oxopropionyl]benzene} was prepared from the methoxide derivative $H_4L4$ (Scheme 1).[20] The latter is also a new molecule not described in the literature and constitutes a bis(β-diketone) with potentially interesting coordination chemistry. The NMR spectra ($^1H$ and $^{13}C$) of $H_5L3$ (Figure 1) do not reflect the symmetry presumed for this molecule in Scheme 1. The crystal structure of the compound (Figure 1),[21] obtained following its recrystallization from MeOH, threw light into the solution structure responsible of its $^1H$ NMR pattern, allowing its assignment, with help of a COSY spectrum (see Supporting Information). In fact, the molecule of $H_5L3$ crystallizes with one of its 1,3-diketone groups in its enolic form and the other one in the bis(carbonyl) form, constituting a very rare example where

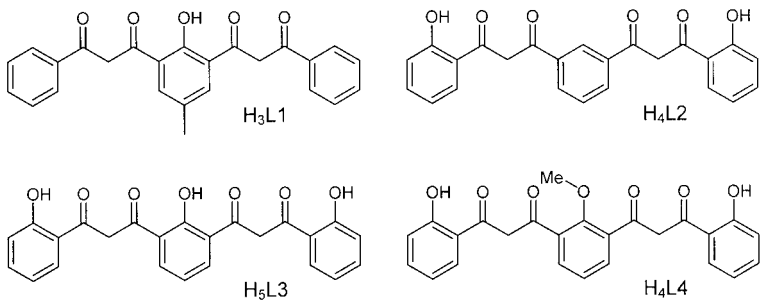

Scheme 1.

both forms are present simultaneously in one molecule. The only such previous example featured by the Cambridge data base is a cyclic polyketide lactone where the strain of the macrocycle is forcing the formation of the mixed tautomer.[22] In $H_5L3$, the simultaneous occurrence of both forms may be favored by the formation of five intramolecular [O–H···O] hydrogen bonds, which are all part of π-delocalized systems. The structural parameters within these delocalized systems follow indeed the criteria of resonance-assisted hydrogen bonding (RAHB).[23] According to this theory, intramolecular hydrogen bonds within β-diketone enols are reinforced by the existence of π-delocalization within the heterodienic O=C–C–C=O–H chain, translating into abnormally short O···O distances. The same phenomenon occurs, although less pronounced, within 2-hydroxybenzoketones, such as these present in $H_5L3$, and this trend is clearly observed on the crystal structure of the molecule. RAHB predicts a good correlation between *d*(O···O) and the $^1$H NMR chemical shift of the proton concerned by the H-bond, and this criterion was used to assign this class of protons in $H_5L3$ (Figure 1).

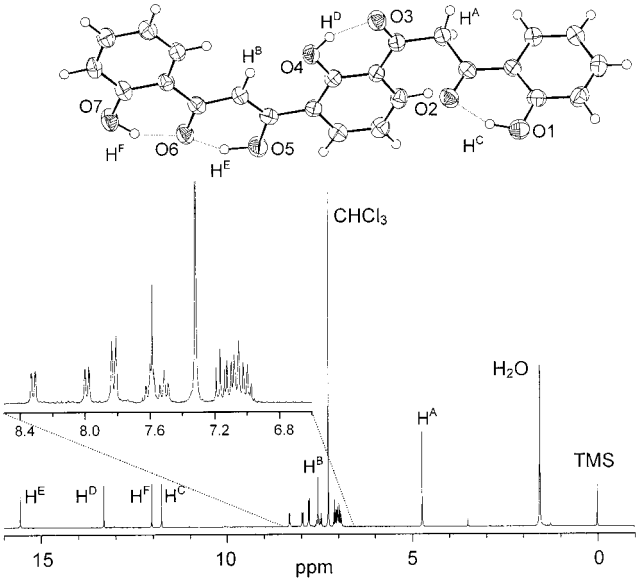

Figure 1. Top: ORTEP representation at the 50% probability level of the ligand $H_5L3$. Only the oxygen atoms are labeled. Intramolecular hydrogen bonds are shown as dashed lines. H-bond [O–H···O] distances [Å]: 2.578(2) (O1,O2), 2.533(2) (O3,O4), 2.488(2) (O5,O6), 2.536(2) (O6,O7). Bottom: 300 MHz $^1$H NMR spectrum of $H_5L3$ in $CDCl_3$ reflecting the symmetry of the solid state. The assignment of the non-aromatic protons is shown (see text for details). Full assignments are given in the Supporting Information.

The reaction of $H_5L3$ with 2 equiv. of $Mn(OAc)_2{\cdot}H_2O$ in pyridine affords a dark orange solution that produces orange crystals upon layering with $Et_2O$. This product was identified by single-crystal X-ray diffraction to be $[Mn_4(H_2L3)_2(OAc)_2(py)_5]$ (**1**).[24] The structure of **1** (Figures 2 and 3)[21] reveals a linear tetranuclear array of $Mn^{II}$, assembled by the action of two triply deprotonated $\mu_4$-$(H_2L3)^{3-}$ ligands located face-to-face, through four adjacent chelating units per side constituted by the five central oxygen donors of each ligand. All chelating units form six-membered rings. The peripheral ones, formed by the 1,3-diketonate units, deviate significantly from planarity [Cremer and Pople puckering amplitude in the range 0.0756(13)–0.2321(15) Å],[25] although not as much as the central ones, involving the phenoxide moiety [puckering amplitudes in the range 0.3804(15)–0.8351(16) Å]. The latter can be described as in a distorted boat, twist-boat or screw-boat conformation. The ionizable protons remaining on each $(H_2L3)^{3-}$ moiety are those of the peripheral neutral phenol groups and are involved in internal hydrogen bonds, as seen with the free ligand. Interestingly, each chelating pocket binds a metal ion disposed in *cis* configuration with respect to its counterpart from the other ligand. This is presumably because the ionic radius of $Mn^{II}$ is too large to accommodate the four metal ions in a linear array with the chelating units disposed equatorially (i.e. *trans*). The result is an $[Mn(\mu\text{-}O)_2Mn(\mu\text{-}O)_2Mn(\mu\text{-}O)_2Mn]$ chain with a very unusual "zig-zag" shape. In complex **1**, each peripheral pair of metal ions is further bridged by one μ-$OAc^-$ ligand, while pyridine ligands complete the six- (Mn1, Mn2 and Mn4) or seven-donor (Mn3) coordination spheres present in this system. Thus, the external $Mn_2$ pairs are bridged by one *syn*,*syn*-OAc and two alkoxide-type μ-O donors, while the central $Mn_2$ is linked by just two phenoxide-type bridges. The bond lengths around the metal ions range from 2.066(1) to 2.488(2) Å, within the limits expected for $Mn^{II}$ ions (ranges for each type of bond are listed in the caption of Figure 2). The average nearest and second-nearest neighbor Mn···Mn separations are 3.378 and 5.826 Å, respectively.

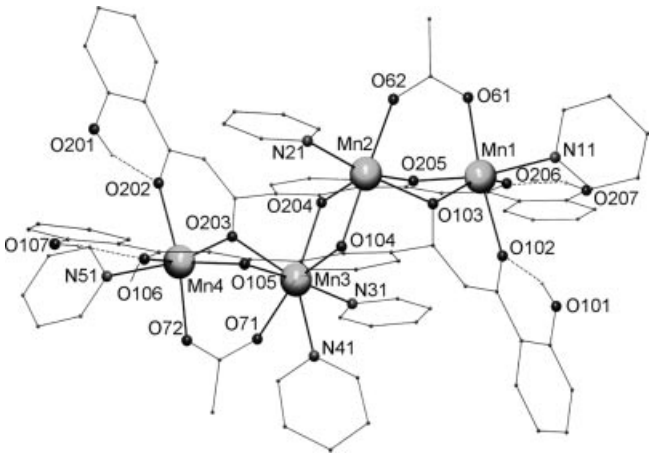

Figure 2. Labeled Pov-ray representation of $[Mn_4(H_2L3)_2(AcO)_2(py)_5]$ (**1**). Only hydroxy H-atoms are shown. Intramolecular hydrogen bonds are shown as dashed lines. Ranges of selected interatomic distances [Å] and angles [°]: Mn–O 2.0661(14) to 2.4031(14), Mn–N 2.2660(18) to 2.488(2), Mn1···Mn2 3.2876(6), Mn2···Mn3 3.4950(7), Mn3···Mn4 3.3502(6), Mn2···Mn4 5.7526(9), Mn3···Mn1 5.8984(9), Mn1···Mn4 8.8046, Mn1–Mn2–Mn3 120.80(2), Mn2–Mn3–Mn4 114.35(2), O107–H···O106 2.513(2), O207–H···O206 2.500(2), O101–H···O102 2.501(2), O201–H···O202 2.495(2).

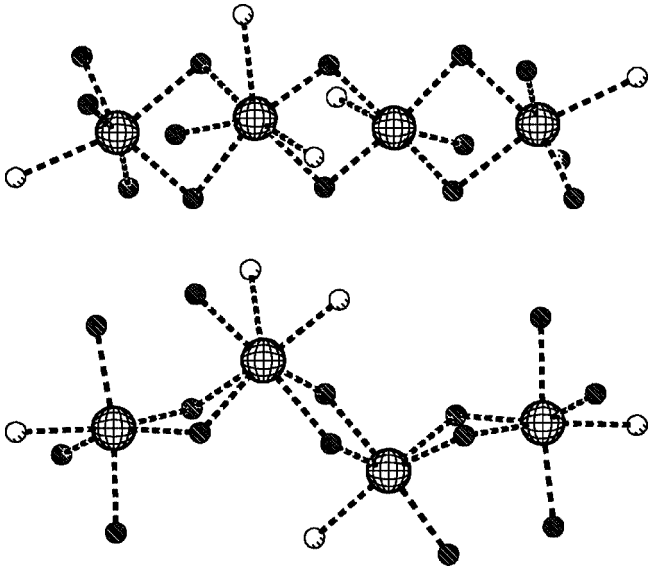

Figure 3. Platon representation of the core of $[Mn_4(H_2L3)_2(AcO)_2(py)_5]$ (**1**) emphasizing two different views. Code for atoms: large, Mn; small hatched, O; shaded, N.

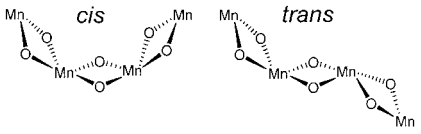
Tetranuclear manganese clusters are interesting from the magnetic point of view,[26] or as synthetic models of the dioxygen-evolving complex of photosystem II.[27] Of the dozens of examples existing in the literature only three types consist of linear arrays of fused $[Mn_2(\mu\text{-}O)_2]$ moieties as in **1**; the $[Mn_4^{IV}O_6(bpy)_6]^{4+}$ cation,[28,29] the $[Mn_2^{III}Mn_2^{II}(Me\text{-}hmp)_6Cl_4]$ cluster [Me-hmpH = 2-(hydroxymethyl)-6-methylpyridine],[30] and the cations $[Mn_4^{II}L_6]^{2+}$ [HL = a (2-hydroxyphenyl)bipyridine or -phenanthroline ligand].[31,32] All of these display a *cis* conformation with respect to the central $[Mn_2O_2]$ unit (Scheme 2), while complex **1** is the first example of the *trans* form as forced presumably by the structure of the $(H_2L3)^{3-}$ ligand.



Scheme 2.

The magnetic exchange within complex **1** was examined by means of variable-temperature (2–300 K) bulk-magnetization measurements under a constant magnetic field of 0.3 T. The results are given in Figure 4 in form of a $\chi_M T$ vs. $T$ plot. The product $\chi_M T$ at 300 K is 18.43 $cm^3 \cdot K \cdot mol^{-1}$ (quite near to the value of 17.5 $cm^3 \cdot K \cdot mol^{-1}$ for four independent high-spin $Mn^{II}$ centers with $g = 2$), and it decreases slowly and then more rapidly near 70 K to reach a value of 1.22 $cm^3 \cdot K \cdot mol^{-1}$ at 2 K. This indicates the presence of dominant antiferromagnetic interactions within the cluster. A fit of the experimental data was obtained through a matrix diagonalization procedure using the program CLUMAG,[33] by considering the Heisenberg spin Hamiltonian $H = -2J_1(S_1S_2 + S_3S_4) - 2J_2(S_2S_3)$, where $S_i$ is the spin angular momentum operator of $Mn_i$ ($S_i = 5/2$) and the interaction between the metal ions of both external $Mn_2$ pairs was assumed to be equal (see inset in Figure 4). Good fits were obtained for two sets of solutions. One was reached for values $J_1 = -1.37$ $cm^{-1}$, $J_2 = +0.77$ $cm^{-1}$ and $g = 2.06$, which leads to a total spin ground state of $S_T = 0$. Since $J_1 > J_2$, a very similar behavior is expected if $J_2$ were instead negative but with comparable absolute value. This turns out to be the case if the fit is performed by restricting both coupling constants to be antiferromagnetic, yielding the parameters $J_1 = -2.23$ $cm^{-1}$, $J_2 = -0.85$ $cm^{-1}$ and $g = 2.08$. The latter fit is preferred since it yields a smaller error factor $R$ ($R = \Sigma[\chi_M T_{exp} - \chi_M T_{calc}]^2/\Sigma[\chi_M T_{exp}]^2$) than the first fit ($R = 7.73 \cdot 10^{-5}$ vs. $1.62 \cdot 10^{-4}$). The value of $g$ is similar in both cases; however, it must be taken with caution, since this parameter is the most affected by errors in the molecular weight used for treatment of the magnetic data. The bridging arrangement found within the $Mn_{1-2}$ and $Mn_{3-4}$ pairs (see above) is very uncommon for $Mn^{II}$ ions; however, the few reports showing preliminary magnetic studies on systems containing this moiety suggest weak antiferromagnetic coupling as found in **1**.[34,35] The central $[Mn_2O_2]$ unit on the other hand, is bridged by two phenoxide-type ligands. Such a type of link between divalent Mn centers has been reported to lead to both, ferro-[31,36–39] and antiferromagnetic interactions.[40–43] The actual magnetic behaviour depends strongly on the efficiency of the overlap between $d_{x^2-y^2}$ orbitals of the metal ions through the phenoxide O-donors, which is considered the main pathway to antiferromagnetism. In **1**, the latter is expected to be much reduced, given the weakening of antiferromagnetic pathways that might be caused by the severe distortion in the coordination geometry shown by the metal ions. The coupling appears thus antiferromagnetic and very weak in any case, as for all previous analogous cases.

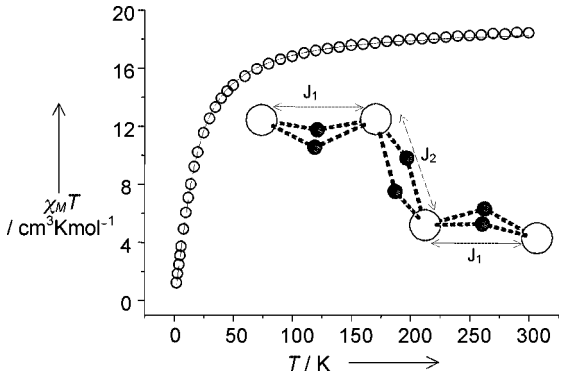

Figure 4. Plot of $\chi_M T$ vs. $T$ per mol of $[Mn_4(H_2L3)_2(AcO)_2(py)_5]$ (**1**). The solid line is a fit to the experimental data (see text for details). The inset shows the model and spin coupling scheme used for the fitting procedure.

The preparation of $H_5L3$ and its association with $Mn^{II}$ ions have demonstrated that rigid ligands with linearly disposed O-donors do provide access to metallic coordination chains with interesting magnetic properties, difficult to obtain otherwise. The preparation of **1** offers a very promising prospect in this direction. We are currently exploring the coordination chemistry of this new ligand with other metals and in the presence of other small co-ligands.

**Supporting Information** (see footnote on the first page of this article): This material includes the description of the preparation of ligands $H_5L3$ and $H_4L4$, full $^1H$ NMR characterization of the ligands and the COSY diagram of $H_5L3$.

[21] Crystals of $H_5L3$ and **1** were measured with a Nonius KappaCCD diffractometer on a rotating anode ($\theta_{max}$ = 25.3°, $T$ = 150 K, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, no absorption correction). The structures were solved with direct methods and refined on $F^2$ (SHELXL-97). Pertinent data for $H_5L3$: $C_{24}H_{18}O_7$, yellow block-shaped crystal (0.10×0.25×0.35 mm), orthorhombic, space group *Pbcn* (no. 60) with $a$ = 13.9229(15), $b$ = 8.5263(12), $c$ = 32.190(5) Å, $V$ = 3821.3(9) Å$^3$, $Z$ = 8, 18194 reflections measured, 3410 independent, $R_{int}$ = 0.1106, $R_\sigma$ = 0.0664. The structure was solved with SHELXS-86. All hydrogen atoms could be located on a difference Fourier map and their coordinates were refined. Refinement of 334 parameters converged at a final $wR_2$ value of 0.1254, $R_1$ = 0.0468 [for 2302 reflections with $I > 2\sigma(I)$], $S$ = 1.044, $-0.22 < \Delta\rho < 0.20$ e·Å$^{-3}$. Pertinent data for **1**: $C_{77}H_{61}Mn_4N_5O_{18}$+solvent (vide infra), pale orange blockshaped crystal (0.05×0.18×0.35 mm), triclinic, space group $P\bar{1}$ (no. 2) with $a$ = 10.8441(10), $b$ = 18.591(2), $c$ = 20.904(3) Å, $\alpha$ = 85.172(15), $\beta$ = 77.893(15), $\gamma$ = 87.872(15)°, $V$ = 4105.1(9) Å$^3$, $Z$ = 2, 83947 reflections measured, 14832 independent, $R_{int}$ = 0.0443, $R_\sigma$ = 0.0330. The structure was solved with SHELXL-97. Electron density in a cavity with a volume of 896 Å$^3$, filled with a disordered mixture of $Et_2O$ and pyridine, was taken into account in the refinement with PLATON/SQUEEZE. A total number of 321 electrons per unit cell were found. Where relevant, data cited above are given without disordered solvent contribution. The coordinated pyridine molecule containing N11 is disordered and is described with a two-site disorder model. The hydroxy hydrogen atoms could be located on a difference Fourier map and their coordinates were refined. All other hydrogen atoms were included with calculated positions and riding on their carrier atoms. Refinement of 967 parameters converged at a final $wR_2$ value of 0.1203, $R_1$ = 0.0407 [for 11825 reflections with $I > 2\sigma(I)$], $S$ = 1.074, $-0.44 < \Delta\rho < 0.59$ e·Å$^{-3}$. # pH-Specific Synthesis and Structural and Spectroscopic Characterization of a Complex between $Co^{II}$ and *N*,*N*-Bis(phosphonomethyl)glycine: Cobalt–Phosphonate Interactions in the Solid State and in Solution

**Anca Mateescu,[a] Catherine P. Raptopoulou,[b] Aris Terzis,[b] Vassilis Tangoulis,[c] and Athanasios Salifoglou*[d]**

**Keywords:** Cobalt / Magnetic properties / Materials science / Phosphonates / Structural speciation

The presence of cobalt in biological systems has been associated with a variety of regulatory roles as an inorganic cofactor. Its involvement in (bio)chemical processes, where it contributes to the integrity of the physiology of humans, underscores its ability to promote (bio)chemistry with molecular targets of variable mass and biological properties. Given the fact that organic phosphonates are widespread substrates/ligands in biological fluids, we sought to investigate the relevant chemistry with $Co^{II}$. With the organophosphonate ligand *N*,*N*-bis(phosphonomethyl)glycine ($H_5$NTA2P) as the main metal ion binder, aqueous reactions with $Co^{II}$ were examined, ultimately leading to the isolation of the complex $[Co(C_4H_9O_8NP_2)(H_2O)_2]\cdot 2H_2O$ (**1**) at pH 1.5. This complex was characterized analytically, spectroscopically (FT-IR, UV/Vis, EPR), magnetically, and by cyclic voltammetry. X-ray crystallography shows that **1** is a compound with a molecular type of lattice. The complex consists of a mononuclear, octahedral $Co^{II}$ center coordinated by oxygen atoms belonging to the terminal phosphonate and carboxylate groups of $H_3NTA2P^{2-}$, the ligand nitrogen, and two bound water molecules. It should be emphasized that similar structural features have been observed in other metal organophosphonate lattices of materials with potential catalytic and chemical reactivity. The magnetic and EPR data for **1** suggest the presence of a high-spin octahedral $Co^{II}$, with a ground state of an effective spin $S = 1/2$. The solution UV/Vis and EPR spectra suggest retention of the integrity of **1**, which is consistent with the magnetization measurements in the solid state. Collectively, the data suggest a soluble $Co^{II}$–organodiphosphonate species, not unlike those expected in bio-fluids containing the specific ligand or ligands structurally akin to $H_3NTA2P^{2-}$.The biological relevance of **1** to species in biofluids and the structural association with $Co^{II}$–organophosphonate materials is discussed.

## Introduction

Cobalt has been known to be present in biological systems for a long time. Its involvement in biomolecular activity is intimately linked to its entry in molecular targets like $B_{12}$ coenzyme and vitamin $B_{12}$ and its potential as an inorganic cofactor to influence biological processes.[1–4] To this end, cobalt has been found in metallohydrolases like methionine aminopeptidase,[5] nitrile hydratases,[6] ribonucleotide reductase, glutamate mutase, and others.[7] Beyond that, an absence or excess of cobalt has been linked to pathological aberrations in human physiology. In particular, vitamin B12 deficiency has been linked to pernicious anemia,[8] while overexposure to the metal has been associated with toxic effects linked to heart disease and excessive formation of red corpuscles.[9,10]

Understanding the role of cobalt in those biological systems entails a deep understanding of its (bio)chemical interactions with low as well as high molecular mass biomolecules in the requisite fluids.[2,3,6,7] These interactions reflect the potential binding of cobalt to organic substrates/ligands of variable structure and function in physiological or aberrant processes thereof. The binary and ternary species of cobalt thus formed participate in complex equilibria, the delineation of which is essential in defining soluble bioavailable species that actively participate in bioprocesses. At the low mass end of the spectrum of molecular targets are molecules like organic acids, amino acids, small peptides, and other molecules that possess variable structural features, prominent among which are the carboxylate and phosphonate groups.[11] Phosphonate groups are known to participate in key phosphorylation events that influence the (bio)chemical activity, signal transduction, enzyme inhibition, neuroactivity, plant-growth regulation, antibiotic, and herbicidal activity of both small and large molecules.[11,12]

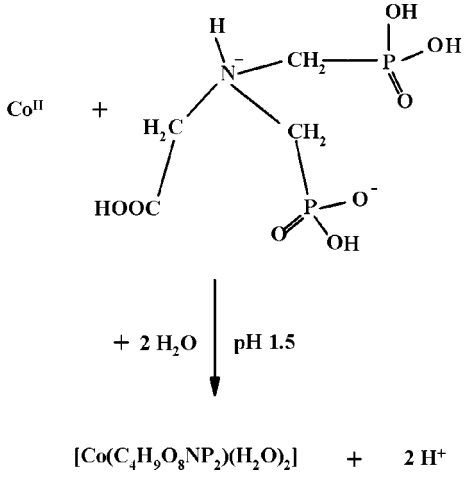
Organophosphonates are a particularly interesting family of organic targets in the biochemistry of metal ions and the chemistry of materials.[13] Such materials have been known for some time for their versatility in coordination and variability in nuclearity.[14] Both these properties are intimately associated with variable dimensionality[15] materials and layered metal organophosphonates[16] and also with a diverse reactivity that is linked to catalysis, intercalation chemistry, optical properties of novel materials, and others.[17,18]

The significance of metal organophosphonate chemistry in the fields of research mentioned above necessitates the extensive perusal of the relevant chemistry with $Co^{II}$, many aspects of which[19] have yet to be discovered. Bearing in mind that the structural features of potential metal ion binders, like organophosphonates, dictate the chemistry of interactions with the metal ion under investigation and most likely influence any arising physical and/or biological properties, we have launched research efforts targeting the reactivity of one such class of diphosphonic ligands toward $Co^{II}$. Herein, we report on the synthesis, isolation, spectroscopic and structural characterization, and cyclic voltammetric, magnetic, and EPR studies of a new species between $Co^{II}$ and the carboxydiphosphonate ligand *N*,*N*-bis(phosphonomethyl)glycine ($H_5NTA2P$).

## Results and Discussion

### Synthesis

The synthesis of complex **1** was carried out in aqueous solutions containing $Co^{II}$ and *N*,*N*-bis(phosphonomethyl)-glycine. The overall reaction leading to compound **1** is depicted schematically below.



The metal-to-ligand stoichiometry employed was 1:1, with a pH of 1.5. Slow diffusion of ethanol into the reaction mixture led to the precipitation of well-formed pink prismatic crystals. Elemental analysis of the crystalline material was consistent with the formulation $[Co(C_4H_9O_8NP_2)(H_2O)_2]\cdot 2H_2O$ for complex **1**. The yield of the reaction was approximately 60%.

The isolated crystalline material **1** appears to be stable in the solid state for long periods of time, with no discernible deterioration. Complex **1** is soluble in water and insoluble in alcohols ($CH_3OH$, *i*PrOH), acetonitrile, and DMSO.

### X-ray Crystal Structure of $[Co(C_4H_9O_8NP_2)(H_2O)_2]\cdot 2H_2O$ (1)

The X-ray crystal structure of **1** reveals the presence of a molecular lattice. The compound crystallizes in the monoclinic system $P2_1$. Crystallographic details are given in the Experimental Section. The ORTEP diagram of **1** is shown in Figure 1, and selected interatomic distances and bond angles for **1** are listed in Table 1. The structure consists of a mononuclear core unit containing an octahedral $Co^{II}$ ion. The coordination sphere of $Co^{II}$ is formulated by an oxygen–nitrogen donor atom environment created by the two main participant ligands, namely bis(phosphonomethyl)glycinate [$(^{-}HO_3PCH_2)_2NCH_2COOH$ = $H_3NTA2P^{2-}$] and water. More specifically, each $H_3NTA2P^{2-}$ ligand, employing both phosphonate groups as well as the carboxylic terminal oxygen, coordinates to the metal ion through its singly deprotonated phosphonates, with the carboxylic acid anchor staying in its protonated form. In addition, two water molecules are coordinated to the $Co^{II}$ ion. Both they as well as the $H_3NTA2P^{2-}$ ligand fulfill the coordination requirements of the octahedral sphere around $Co^{II}$. A closer look at the octahedron shows that one of the water molecules along with the two phosphonate oxygens and the terminal carboxylate of the $H_3NTA2P^{2-}$ ligand form the equatorial plane of the octahedral metal ion. The second bound water molecule along with the nitrogen of the $H_3NTA2P^{2-}$ ligand bound to $Co^{II}$ occupy the axial positions in the octahedron. In view of the above description and the available structural data, the mononuclear $Co^{II}$ ion resides in a distorted octahedron.

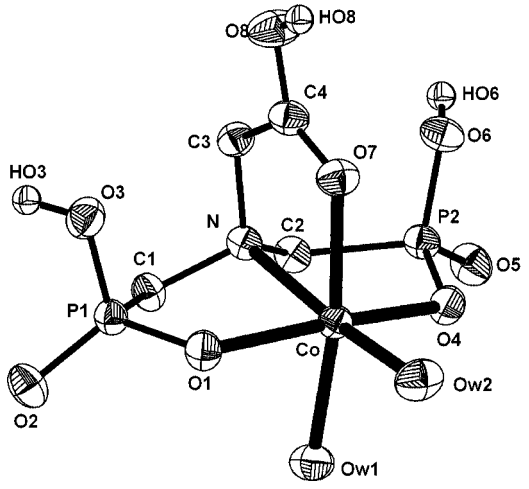


Figure 1. The molecular structure of the $Co(C_4H_9O_8NP_2)(H_2O)_2$ unit, with the atom labeling scheme in **1**. Thermal ellipsoids represent 50% probability surfaces.

The Co–O distances in **1** are similar to those observed in other mononuclear octahedral $Co^{II}$ sites, among which are

those in $[Co(C_2H_8O_6NP_2)_2(H_2O)_2]$ [2.067(2)–2.132(2) Å] (**2**),[20] $(NH_4)_4[Co(C_6H_5O_7)_2]$ [2.051(2)–2.157(2) Å] (**3**),[21] $[Co\{COOCH_2CH(OH)COO\}]\cdot 3H_2O$ [2.067(3)–2.136(3) Å] (**4**),[22] the phosphonate derivatives $[Co(NH_3CH_2PO_3)_2(H_2O)_2]_n\cdot nH_2O$ [2.104(4)–2.121(4) Å] (**5**),[23] $[Co\{HO_3PC(CH_3)(OH)PO_3H\}_2(H_2O)_2][NH_2(C_2H_5)_2]_2$ [2.064(2)–2.179(2) Å] (**6**),[24] and $[Co(OPMe_3)_3(H_2O)_2]I_2\cdot[Co(OPMe_3)_3(H_2O)_3]I_2$ [1.87(6)–2.18(4) Å for the octahedral site].[25]

The Co–O distances in the equatorial plane of the octahedron are of similar length [2.100(2)–2.141(2) Å], despite the variable nature of the anchor terminals in the two different ligand components in the coordination sphere of $Co^{II}$ and the fact that they all utilize their oxygens as terminal anchors to the metal ion. In contrast to the equatorial distances, the corresponding axial Co–L bonds reflect more radically varying lengths, with the Co–N distance being about 0.1 Å longer than the equatorial ones, while the Co–$O_w$ distance is about 0.1 Å shorter than the equatorial ones. It is not unlikely that such bond-length variations might be due to Jahn–Teller distortions, which are usually encountered in high-spin $Co^{II}$ octahedral species.

The angles within the equatorial plane defined by O(1), O(4), $O_w(1)$, and O(7) are in the range 82.68(8)–97.58(8)°, with the average being very close to the ideal octahedral angle of 90°. A similar yet wider angle variation is observed between the axial donor atoms N and $O_w(2)$ and those in the equatorial plane [range: 78.47(7)–95.99(8)°]. The aforementioned sets of angles are similar to those observed in **2**–**6** and in the complexes $[Cu\{HO_3PC(CH_3)(OH)PO_3H\}_2(H_2O)_2]^{2-}$ [84.7(2)–95.3(2)° and 87.8(2)–92.2(2)°, respectively][24] and $[Zn\{HO_3PC(CH_3)(OH)PO_3H\}_2(H_2O)_2]^{2-}$ [84.98(6)–95.02(6)° and 88.65(6)–91.37(6)°, respectively].[26]

The $H_3NTA2P^{2-}$ ligand in **1** binds to the central metal ion through all of its available anchors each in a unidentate coordination mode. This is in contrast to the bidentate mode of coordination that the $H_3IDA2P^-$ ligand employs in its binding to the same metal ion in $[Co(C_2H_8O_6NP_2)_2(H_2O)_2]$. The latter observation is exemplified through the binding of the two phosphonate anchors to two different $Co^{II}$ ions. Moreover, the four $H_3IDA2P^-$ molecules surrounding the central metal ion are also coordinated to four other $Co^{II}$ ions as a consequence of the presence of the second phosphonate group in each molecule. In this sense, occupancy of the coordination sites in contiguous octahedral $Co^{II}$ ions extends to infinity, thus affording the molecular lattice in **2**.

Another interesting attribute of the $H_3NTA2P^{2-}$ ligand's participation in the coordination sphere of $Co^{II}$ is the presence of a nonprotonated central imino moiety in the ligand.

Table 2. Hydrogen bonds in $[Co(C_4H_9O_8NP_2)(H_2O)_2]\cdot 2H_2O$ (**1**).

As a result, the overall charge of the $H_3NTA2P^{2-}$ ligand coordinated to $Co^{II}$ is 2–, which means that the overall charge for complex **1** is zero. Again, this behavior contrasts with that which has been previously observed for $H_3IDA2P^-$ bound to $Co^{II}$ in complex **2**. There, the central imino moiety of the bound ligand is protonated, thus yielding an overall charge of 1– for the ligand and a zero charge for the complex.

Hydrogen-bonding interactions are present in the crystal structure of **1** (Table 2). These interactions involve the coordinated water molecules, the phosphonate oxygen and hydroxy moieties on the $H_3NTA2P^{2-}$ ligand, and the solvent water molecules. These hydrogen-bonding interactions (Figures 2, parts a and b) generate an extensive network, which very likely contributes to the overall stability of the crystal lattice in **1** (see Discussion).

### Electronic Spectroscopy

The UV/Vis spectrum of **1** was recorded in water at the autogenous pH (Figure 3). The spectrum shows a shoulder-like band at around $\lambda_{max}$ = 550 nm ($\varepsilon \approx 6.8$), ultimately reaching a well-formed major peak at $\lambda_{max}$ = 517 nm (10), with ensuing, subtly discernible, shoulders at around 473 (4) and 462 nm (7.6). A distant band rising into the UV region appears at 222 nm (122.7). The absorption features are likely due to d–d transitions, which are typical for a $Co^{II}$ $d^7$ octahedral species.[27] The multiply structured band around 517 nm can be tentatively attributed to the $^4T_{1g} \rightarrow {}^4T_{1g}(P)$ transition. The observed multiple structure is in line with literature reports that invoke an admixture of spin-forbidden transitions to doublet states derived from $^2G$ and $^2H$, spin-orbit coupling, and vibrational or low-symmetry components to account for the complexity of the spectrum.[28] No further assignments can be made in the absence of detailed specific studies. The spectrum of **1** in water is different from that of $Co^{II}_{aq}$,[29] thus indicating that the coordination sphere of $Co^{II}$ in **1** is likely to be retained in solution.

### FT-IR Spectroscopy

The FT-IR spectrum of complex **1** in KBr shows strong absorptions for the various vibrationally active groups. Antisymmetric as well as symmetric vibrations for the carboxylate group of the coordinated $H_3NTA2P^{2-}$ ligand dominate the spectrum. Specifically, the antisymmetric stretching vibrations, $\nu_{as}(COO^-)$, are present for the carboxylate carbonyls at around 1664 $cm^{-1}$, with the symmetric vibrations, $\nu_s(COO^-)$, for the same group appearing in the range 1461–1408 $cm^{-1}$. The frequencies of the observed carbonyl vibrations are shifted to lower values in comparison to the corresponding vibrations in the free $H_5NTA2P$ acid. The difference between the symmetric and antisymmetric stretches, $\Delta[\nu_{as}(COO^-) - \nu_s(COO^-)]$, is greater than 200 $cm^{-1}$, which indicates that the carboxylate group of the $H_3NTA2P^{2-}$ ligand is either free or coordinated to the metal ion in a monodentate fashion.[30] This was further confirmed by the X-ray crystal structure of **1**.

Vibrations for the $PO_3$ groups were observed for the antisymmetric stretching vibrations, $\nu_{as}(PO_3)$, between 1060 and 986 $cm^{-1}$. Symmetric stretching vibrations, $\nu_s(PO_3)$, were observed in the range 967–906 $cm^{-1}$. The frequencies for the aforementioned stretches appear to be shifted to lower values compared to those of free $H_5NTA2P$ acid, thereby indicating changes in the vibrational status of the ligand upon binding to the $Co^{II}$ ion.[31,32] The aforementioned tentative assignments are also in line with previous data reported for iminophosphonate-containing complexes of various metals.[33]

### Cyclic Voltammetry

The cyclic voltammetric behavior of complex **1** was studied in aqueous solution at the autogenous pH, in the presence of $KNO_3$ as a supporting electrolyte. The cyclic voltammogram shows an irreversible oxidation wave at $E_{1/2}$ = 1.18 V vs. Ag/AgCl, corresponding to the $Co^{II}/Co^{III}$ redox couple and a quasi-reversible wave ($\Delta E$ = 105 mV,

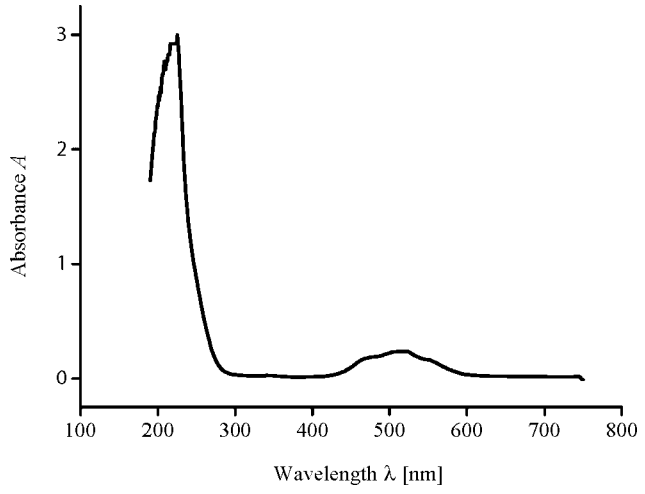

Figure 3. UV/Visible spectrum of **1** in water.

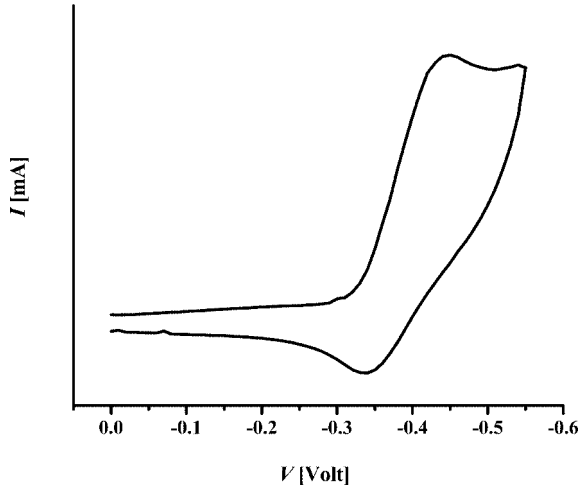

Figure 4. Cyclic voltammogram of **1** in water.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$0 < i_{pa}/i_{pc} < 1$, $i_{pc}/\{(v)^{1/2}C\}$ variable) at $E_{1/2}$ = –0.40 V vs. Ag/AgCl corresponding to the $Co^{II}/Co^{I}$ redox couple (Figure 4). The observed $E_{1/2}$ value for the reduction wave is comparable to, albeit lower than, the one reported for other $Co^{II}$–organophosphonate species. Attempts to pursue the isolation of the one-electron-reduced product of the title complex **1** are currently ongoing.

## Magnetic-Susceptibility Studies

### *Magnetic Susceptibility*

Magnetic-susceptibility measurements were carried out at different magnetic fields and in the temperature range 2.3–300 K. Figure 5 shows the $\chi_M T$ vs. $T$ susceptibility data at 0.1 T, where the solid line represents the fit according to the following general Hamiltonian [Equation (1)]

$$H = D\left[S_z^2 - \frac{1}{3}S(S+1)\right] + E(S_x^2 - S_y^2) + g\mu_B H \cdot S \quad (1)$$

where all the parameters have their usual definitions, and $S$ = 3/2.

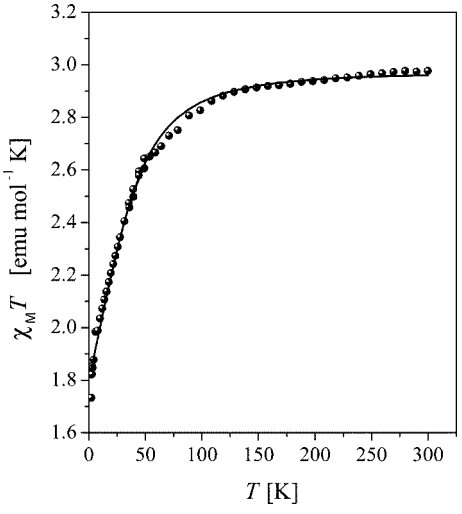

Figure 5. Temperature dependence of the magnetic susceptibility of **1**, in the form of $\chi_M T$ [emu mol$^{-1}$ K] vs. $T$ [K], in the temperature range 2.3–300 K using an external magnetic field of 0.1 T. The solid line represents the fitting results (see text).

The $\chi_M T$ values decrease smoothly from 2.98 emu mol$^{-1}$ K at 300 K to 2.82 emu mol$^{-1}$ K at 98 K and then more steeply to a value of 1.73 emu mol$^{-1}$ K at 2.3 K. The high-temperature value of $\chi_M T$ is higher than 1.875 emu mol$^{-1}$ K, the value that would be expected for a $Co^{II}$ system with $S$ = 3/2. This behavior is consistent with the presence of a significant orbital contribution to the anisotropic nature of the $Co^{II}$ system investigated. The fitting model employed for the susceptibility data is shown in Equation (1). The model takes into account both the axial and rhombic parts of the distortion of the crystal field ($D$, $E$), and an isotropic $g$ value, with the fitting results yielding the following parameters: $D$ = 41.1 cm$^{-1}$ and $g$ = 2.53. The theoretical curve is shown as a solid line in the same figure. It must be pointed out that the signs of $D$ and $E$ cannot be resolved from the magnetic measurements, while introduction of an axial symmetry to $g$ ($g_\perp$, $g_\parallel$) leads to no improvement of the fit. The large value of $D$ is in accordance with an octahedral $Co^{II}$, where the ground-state doublet is well-isolated from the excited ones.[34]

## Magnetization Studies

The magnetization data for **1** in the form of an $M/N\mu_B$ vs. $H$ plot are shown in Figure 6 for two different temperatures and in the field range 0–6 T. The dotted lines represent the theoretical magnetization curves for a system having a ground state with an effective spin, $S$, of 1/2 and an effective $g$ value equal to 4.697. The ground state of the free high-spin $Co^{II}$ ion in an octahedral environment is $^4F$, but the orbital degeneracy is removed in an octahedral crystal field, yielding one $^4A$ and two $^4T$ levels, with the lowest-lying state being a $^4T_{1g}$. The degeneracy of the $^4T_{1g}$ level is removed through the action of axial and rhombic distortions of the crystal field as well as through spin-orbit coupling. The overall effect of low-symmetry crystal-field components and spin-orbit coupling produces six Kramers doublets and results in a doublet ground state. Since the same doublet energy level remains lowest in energy for all values of the applied field strength, and the energy difference between the two lowest lying doublets is relatively large with respect to the thermal energy present at low temperatures (<30 K), the $Co^{II}$ system may be described as having a ground state with an effective spin of $S$ = 1/2.

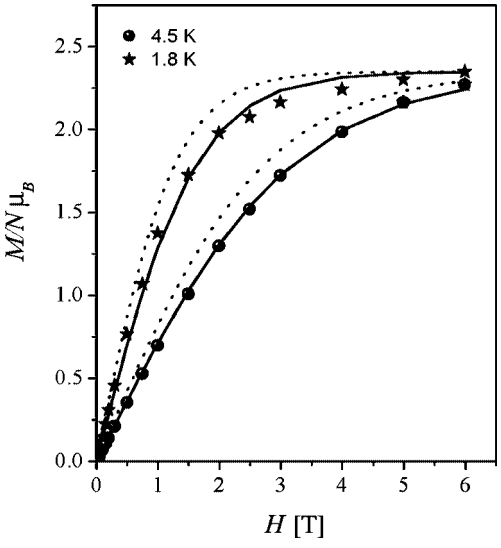

Figure 6. Magnetization of **1**, in the form of $M/N\mu_B$ vs. $H$ [T], at different temperatures and in the field range 0-6 T. The dotted lines represent the theoretical Brillouin functions for an isolated $S$ = 1/2 system with a $g_{eff}$ = 4.697, while the solid lines represent a mean field correction ($zJ$ = –1.5 cm$^{-1}$) taking into account the complex intermolecular interactions.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The discrepancy between the theoretical and the experimental curves is mainly due to the fact that a complex hydrogen-bonding network exists, which introduces intermolecular interactions that are important in the low-temperature regime.

A different magnetic model was used to fit the magnetization data according to the following modified Hamiltonian:

$$H = g\mu_B H \cdot S_z - zJ\langle S_z\rangle S_z \quad (2)$$

where the magnetic field is assumed to be along the $z$ direction and the $g$-tensor is taken to be isotropic. $\langle S_z\rangle$ is given by the Boltzmann distribution law

$$\langle S_z\rangle = \frac{\sum_{M_s=-S}^{S} M_s \exp[-E(S,M_s)/kT]}{\sum_{M_s=-S}^{S} \exp[-E(S,M_s)/kT]} = \frac{\sum_{M_s=-S}^{S} M_s \exp\left[1 - M_s\left(g\mu_n H - zJ\langle S_z\rangle\right)/kT\right]}{\sum_{M_s=-S}^{S} \exp\left[1 - M_s\left(g\mu_n H - zJ\langle S_z\rangle\right)/kT\right]} \quad (3)$$

According to Equations (2) and (3) the magnetization formula becomes [Equation (4)]

$$M = -Ng\mu_B\langle S_z\rangle \quad (4)$$

with the negative sign originating from the negative charge of the electron.

An excellent agreement between the experimental modified and theoretical curves (solid lines) was obtained for the following fitting parameters: $zJ = -1.5$ cm$^{-1}$, $g_{eff} = 4.7$.

## EPR Spectroscopy

X-Band EPR measurements were carried out in powder samples as well as in frozen solutions of **1** in water and are shown in Figures 7 and 8, respectively. As a consequence of the fast spin-lattice relaxation time of high-spin $Co^{II}$, signals were observed only below 70 K. For the powder spectra, a strong signal appears at low fields and a small broad one at $g = 2.30$ at temperatures below 23 K. In an attempt to comprehend the observed behavior, a simulation[34] was carried out in order to derive the effective $g$ values riding on a Hamiltonian formalism [Equation (5)]

$$H = g_z\mu_B H_z S_z + g_x\mu_B H_x S_x + g_y\mu_B H_y S_y \quad (5)$$

with an effective spin of 1/2 and an anisotropic $g$-tensor. The results are shown in Figure 9. An isotropic magnetic-field domain line-width was used in both cases (lw = 35 G for the powder and 75 G for the frozen solution), with the broadness of the spectra revealing $g$-strain effects. Gaussian distributions of the $g$-principal values were used and the results were $\sigma g_x = \sigma g_z = 0.78$, $\sigma g_y = 0.23$ for the powder, and $\sigma g_x = \sigma g_y = \sigma g_z = 0.78$ for the frozen solution. The principal $g$ values for the powder spectrum are $g_x = 4.92(1)$, $g_y = 2.28(1)$, $g_z = 6.33(1)$ ($g_{eff} = 4.51$) and for the frozen solution $g_x = 4.20(1)$, $g_y = 2.35(1)$, $g_z = 5.33(1)$ ($g_{eff} = 3.96$).

The dominant broadening effect emerges when the $g$-strain is converted into $B$-strain through the equation $\Delta B = -(h\nu/\mu_B)\cdot(\Delta g/g^2)$, where the parameters have their usual meaning. Thus, the largest and smallest $g$ values of the powder and solution spectra have field widths that differ by an order of magnitude, thereby rationalizing the broad high-field features of the spectrum.

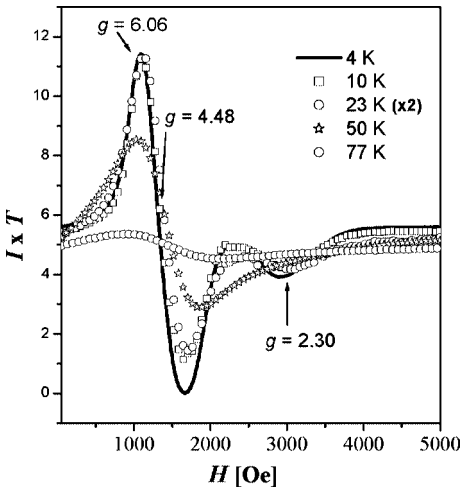

Figure 7. Temperature dependence of the powder X-Band EPR spectrum (the intensity is multiplied by the temperature) of **1** in the field range 0–5000 Oe.

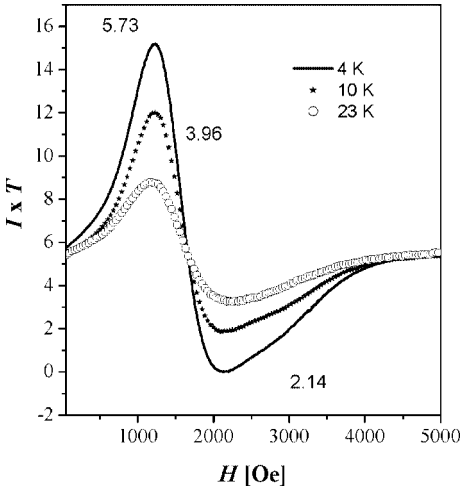

Figure 8. Temperature dependence of the water solution X-Band EPR spectrum (the intensity is multiplied by the temperature) in the field range 0–5000 Oe.

A very important feature of the $Co^{II}$ ion is the value of the effective $g$ parameter, $g_{eff}$, extracted from the EPR measurements, as a result of which interesting comments can be made. To this end, one important issue, not sufficiently discussed in the literature, pertains to an octahedron in a high-spin $Co^{II}$ system with a small tetragonal or trigonal distortion, whereby additional terms are added in the ground-state doublet. Provided that these terms are small compared with the spin-orbit coupling of the ground-state doublet, they may be written in the form [Equation (6)]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

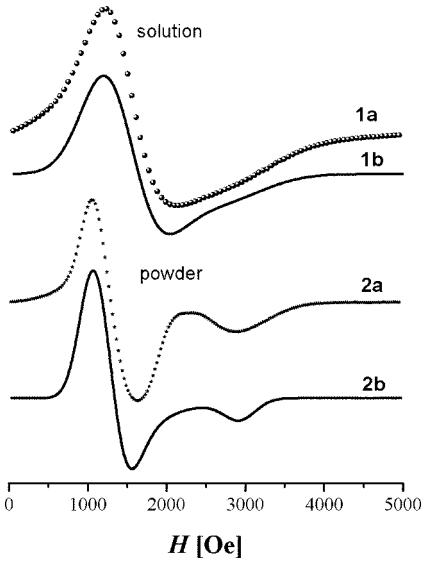

Figure 9. Simulations of the solution (1a) and powder (2a) EPR spectrum are shown as solid lines (1b) and (2b), respectively. The derived g values and the distribution widths of the g principal values in each case are given in the text.

$$\left|J=\frac{1}{2},J_z=\pm\frac{1}{2}\right\rangle+a\left|\frac{3}{2},\pm\frac{1}{2}\right\rangle+b\left|\frac{5}{2},\pm\frac{1}{2}\right\rangle \quad (6)$$

where $a$, and even more so $b$, are small compared to unity. According to Abragam and Bleaney,[35] and by neglecting terms of order $a^2$ and $b^2$, the expressions for the $g$ parameters of the $Co^{II}$ system are [Equations (7)]

$$g_{\parallel}=\frac{5}{3}g_s-\frac{2}{3}g_l+\left(\frac{4\sqrt{5}a}{3}\right)(2g_s-g_l)$$
$$g_{\perp}=\frac{5}{3}g_s-\frac{2}{3}g_l-\left(\frac{2\sqrt{5}a}{3}\right)(2g_s-g_l) \quad (7)$$

where $g_s = 2.0$ and $g_l = -3/2$.

The dependence of the $g$ parameters on the $a$ parameter of Equation (6) is shown in Figure 10. From Equations (7) and Figure 10, it is clear that the value of $g_{eff} = (g_{\parallel} + 2g_{\perp})/3 \approx (5g_s - 2g_l)/3 \approx 4.33$. Therefore, an isotropic $g$ value of $g_{\parallel} = g_{\perp} = 4.33$ corresponds to $a = 0$ (the energy difference between the ground-state doublet and the excited one is very large), whereas for an admixture of other terms the value of $g_{eff}$ increases accordingly (Figure 10).

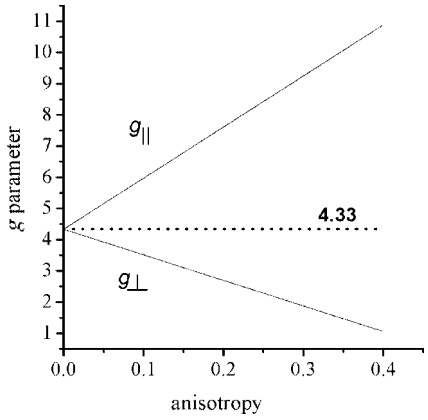

Figure 10. Anisotropy dependence of the $g$ parameters ($g_{\parallel}$ and $g_{\perp}$) of a high-spin $Co^{II}$ octahedron resulting from a small tetragonal or trigonal distortion.

Another issue emerges from the fact that weak intermolecular interactions (hydrogen bonding) between $Co^{II}$ ions can influence the value of $g_{eff}$, and this can be resolved only if EPR measurements are carried out in both powder and solution samples.

The magnetic and EPR parameters of different high-spin $Co^{II}$ complexes are shown in Table 3.[36] Based on the collective data and the aforementioned comments, several interesting conclusions can be drawn. First of all, it seems that for values of $g_{eff}$ above 4.33 (in the EPR spectra of powder samples), the intermolecular interactions contribute significantly to the magnetic behavior of the system. In the case of $[Co(C_4H_8NO_3)_2(H_2O)_2]$,[36a] a weak exchange interaction transmitted through hydrogen bonds is proposed between neighboring $Co^{II}$ centers in the exchange limit $0.25 < |J| < 1.2\ cm^{-1}$. To this end, the Brillouin function of an isolated $S = 1/2$ system could reproduce the magnetization curves, leading to the conclusion that its contribution is small. For all the other cases ($g_{eff} < 4.33$) no significant

[a] $g_{eff}$ $[(g_x + g_y + g_z)/3]$ is derived from the EPR measurements performed in powder (p) or solution (s) samples. [b] $g_{eff}$ is derived by simulation of the magnetization data at different temperatures using the Brillouin function for an isolated $S = 1/2$ system, or Equation (4) in the case of intermolecular interactions. [c] Fitting parameters ($D$, $E$, $g$) obtained from Equation (1) for the fit of the susceptibility data. [d] The simulation was carried out using the magnetization data from ref.[21]. [e] This complex is a dimer in the solid state. We only used the solution spectrum of the complex, since it dissociates into monomers in solution.[36b]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

intermolecular interactions are observed. The significance of the aforementioned point is also exemplified in the small $g_{eff}$ value of the frozen-solution spectrum, where the hydrogen-bonding system breaks apart and no longer exists. Secondly, the $g_{eff}$ value derived from the magnetization data is not equal to the value obtained from EPR measurements due to the fact that, in the magnetization data, there is also some contribution from intermolecular interactions, a fact amply emphasized and alluded to in the magnetization study of this work.

### Linking the Aqueous Chemistry of the Binary $Co^{II}$–$H_5NTA2P$ System to the Organophosphonate Structural Features

In a simple and pH-specific manner, the employment of the binary system $Co^{II}$-($H_5NTA2P$) led to the isolation of a clean product **1** in crystalline form. The idea was to initially explore the reactivity of the aforementioned system at low pH. The $H_5NTA2P$ ligand projects important features that emerge due to its structure containing both carboxylic and phosphonic moieties (see below). Under such conditions, addition of ethanol contributed to the isolation of $[Co(C_4H_9O_8NP_2)(H_2O)_2]\cdot 2H_2O$ (**1**) at pH 1.5. The nature of **1** is that of a molecular type of lattice comprised of mononuclear units linked together through water molecules of crystallization and an extensive network of hydrogen bonds.

The carboxydiphosphonate ligand anchored onto the octahedral $Co^{II}$ site reveals a coordination mode that reflects employment of all potential anchor sites in $H_5NTA2P$. Variable modes of phosphonate coordination have previously been observed in a plethora of metal organophosphonate complexes containing the phosphonate ligand termini in varying deprotonation states.[37] In the present case, the coordinated $H_5NTA2P$ ligand loses two of its protons from the two terminal phosphonate groups, rendering each one of them singly deprotonated. As a result, the remaining carboxylic acid moiety remains protonated and, as such, it is anchored to the metal site. The double deprotonation of the $H_5NTA2P$ ligand yields an overall charge of zero for the assembled mononuclear complex, affording the previously mentioned molecular type of lattice in **1**.

The nitrogen center plays a prominent role in the coordination of the $H_5NTA2P$ ligand around $Co^{II}$. A strong interaction with the metal center brings it to a distance of 2.229(2) Å from $Co^{II}$. Thus, the tetradentate ligand imparts significant stability upon the resulting species. Due to the fact that the ligand itself employs four potential anchoring sites to bind the metal ion, the octahedral coordination environment is left with two unoccupied sites, which are occupied by water molecules from the reaction medium.

As a consequence of the molecular chemistry between the $H_5NTA2P$ and $Co^{II}$, discrete moieties evolve as mixed carboxylate-phosphonate species in aqueous media. This is in contrast to the intermolecular chemistry previously observed between another diphosphonate ligand, namely iminodiphosphonic acid (IDA2P), and $Co^{II}$.[36b] There, the ligand promotes an intermolecular linkage of nearby $Co^{II}$ centers, affording a molecular lattice with distinct structural features, at low pH.

The magnetic susceptibility and magnetization measurements on complex **1** support the presence of a high-spin octahedral $Co^{II}$ species having a ground state with an effective spin of 1/2. EPR measurements in the solid state and in aqueous solution corroborate the magnetization data, suggesting the existence of a high-spin $Co^{II}$ complex in solution. Such a complex would very likely include the ligand octahedral environment provided by $H_3NTA2P^{2-}$ and the two water molecules.[37] To this end, both UV/Vis and EPR data suggest a species with a formulation not unlike that of the title complex $[Co(C_4H_9O_8NP_2)(H_2O)_2]^0$. A similar behavior has previously been observed for $[Co(C_2H_8O_6NP_2)_2(H_2O)_2]$.[20]

To the extent that the title complex is an aqueous species of $Co^{II}$, it appears that the aqueous distribution of species arising from the binary system $Co^{II}$–$H_5NTA2P$ encompasses such components emerging at low pH. That, in turn, hints at the existence of other species that might participate in the requisite speciation at higher pH values. This contention is potentially exemplified by the nature of the $H_5NTA2P$ ligand, with its mixed composition eliciting variable chemical coordination events around $Co^{II}$ with equally variable protonation states. Furthermore, $H_5NTA2P$ is a ligand that can be viewed as a derivative of the nitrilotriacetic acid ligand $(HOOCCH_2)_3N$ ($H_3NTA$), with the two terminal carboxylates replaced by phosphonates. Solution as well as synthetic studies have been carried out for dicarboxylic acids,[38,39] aminoalkylphosphonates, and IDA-derived phosphonate ligands, like *N*-(phosphonomethyl)glycine,[40] in the presence of various metal ions.[41,42] These studies suggest that these ligands bind metal ions like $Co^{II}$ efficiently to form soluble complexes.[12a] Despite the fact that analogous studies with $(H_2O_3PCH_2)_2NCH_2COOH$ and $Co^{II}$ have not been carried out, it would not be unreasonable to suggest that a similar chemistry may be unfolding in this system too. In this sense, solution investigations would be helpful in revealing the nature of the interaction as well as the properties of the arising species as a function of pH and molecular stoichiometry. Such studies are under way in our laboratory.

Given that solubility is a prerequisite for bioavailability of species eliciting interactions at the cellular level, the structural and molecular composition of complex **1** suggest that significant features of $Co^{II}$ might be associated with interactions with biological targets. The distinct nature of $H_5NTA2P$ allows both phosphorylated and carboxylic sidechains of abutting biomolecular sites to interact concurrently with $Co^{II}$, thus giving rise to soluble species. Even though studies of soluble bioavailable $Co^{II}$–carboxyphosphonate species have yet to be performed, they could provide significant insight into the nature and properties of binary or ternary $Co^{II}$–ligand species of potential biological value to variable activity pathways in human physiology. Along these lines, the value of $E_{1/2}$ (–0.40 V) observed in the cyclic voltammogram of **1** for $Co^{II}/Co^{I}$ is an indicator

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the physicochemical properties bestowed on $Co^{II}$ upon coordination by $H_5NTA2P$ and tuned into in the biologically relevant redox potential range.

### Potential Formation of Organophosphonate-Containing Materials

The nature and properties of organophosphonate substrates have drawn keen interest in the search for new materials containing a variety of metals. Numerous approaches and synthetic methodologies have been employed in the quest for metal-organophosphonate materials with varying structures. The search for new materials has targeted diverse applications, extending from electronics to catalysis. To that end, organophosphonic acid substrates like $H_2O_3PCH_2CH_2$-COOH, or diphosphonic acids[43] like $H_2O_3PRPO_3H_2$, have been employed with different R groups [$C_6H_4$, $(CH_2)_n$],[44] joining the phosphonate moieties, that influence the structural features of the derived material significantly (compare [$Co(C_4H_9O_8NP_2)(H_2O)_2$]·$2H_2O$ (**1**) with [$Zn_2\{O_2CCH_2NH$-$(CH_2PO_3)_2\}$]).[45,46] Such features include lattice parameters, shape, size, and dimensionality, all of which affect the applied chemistry in selective and specific low molecular mass (alcohol, amine, etc.) transformation processes.

One such key factor that influences the nature of the lattice formed in a solid-state material is hydrogen bonding. This dominates the lattice structure of **1** and involves the coordinated and solvent water molecules as well as the protonated phosphonate and carboxylate moieties. The extensive network of hydrogen bonds can be simplified if one attempts to assemble it step by step. Specifically, the mononuclear species of **1** are hydrogen bonded through O6–HO6···O1 (1 + *x*, *y*, *z*) and Ow1–Hw1B···O5 (–1 + *x*, *y*, *z*) interactions to form polymeric chains that extend in a direction parallel to the crystallographic *a* axis. These chains are further hydrogen bonded through an Ow2–Hw2B···O2 (*x*, *y*, –1 + *z*) interaction to form a two-dimensional network lying parallel to the crystallographic *ac* plane. As shown in Figure 2 (a), the layered structure thus formed contains vacancies between the mononuclear species. Furthermore, the involvement of the remaining protonated phosphonate and carboxylate moieties in hydrogen-bonding interactions [O3–HO3···O5 (1 – *x*, –0.5 + *y*, 1 – *z*) and O8–HO8···O4 (1 – *x*, –0.5 + *y*, –*z*)] leads to the extended 3D lattice structure of **1**. As shown in Figure 2 (b), tubular channels are formed down the crystallographic *a* axis, where the lattice water molecules are encapsulated. Ostensibly, hydrogen-bonding interactions between the encapsulated lattice water molecules and the protonated phosphonate and carboxylate groups of the ligand, as well as the coordinated water molecules, are responsible for the stabilization of the encapsulated solvent molecules.

The nature of the metal ion is another key factor in metal organophosphonate materials. To this end, phosphonate-containing pillared layered structures have been synthesized from vanadium, such as the material [(VO)$(H_2O)$-$\{O_3PCH_2NH(C_2H_4)_2NHCH_2PO_3\}$],[46,47a] while manganese- and cobalt-containing materials such as [$M\{O_3PCH_2NH(C_2H_4)_2NHCH_2PO_3\}$]·$H_2O$ (M = $Mn^{II}$, $Co^{II}$) have also been isolated.[47b] Numerous such materials have emerged in the past few years, with key representatives including the compounds [$Co\{(CH_3COO)_2NCH_2PO_3\}$-$(H_2O)_5$]·$H_2O$,[48] [$Co(C_2H_8O_6NP_2)_2(H_2O)_2$],[20] [$Co_2(O_3$-$PC_6H_4PO_3)(H_2O)_2$],[49] and [$Co_2(O_3PC_6H_4OC_6H_4PO_3)$]·$2H_2O$,[50] amongst others. Collectively, the physical and chemical properties of $Co^{II}$–organophosphonate materials signify the decisive role of features upon which rests the design of future compounds with specific attributes for potential selective applications. To this end, examination of the herein described binary $Co^{II}$-$H_5NTA2P$ system under conditions far removed from a room-temperature environment (e.g. hydrothermal conditions) could, in principle, result in a material with distinct physical and chemical characteristics not necessarily similar to those observed in the title species **1**. This approach could prove to be effective in affording diverse species that could potentially participate in the aqueous binary speciation scheme and possess physicochemical characteristics associated with applications alluded to above in other cobalt-containing materials.

## Conclusions

The mixed carboxydiphosphonate complex of $Co^{II}$, reflected in the structural formulation of [$Co(C_4H_9O_8NP_2)$-$(H_2O)_2$]$^0$ (**1**), contains basic structural features of species that might arise as a result of the interaction of $Co^{II}$ with adjacent carboxy and phosphorylated sites on low molecular mass biotargets in biological fluids. Complex **1**, in fact, constitutes proof of a species arising from speciation of binary systems containing $Co^{II}$ and simple phosphonate ligands.[40] In the absence of solution speciation studies on the specific $Co^{II}$-$H_5NTA2P$ system, the synthetic efforts of this work prove the existence of discrete species with characteristic structural and chemical properties both in the solid state as well as in solution. Spectroscopic studies combined with cyclic voltammetric, magnetic, and EPR data in the solid state and in solution support the experimental observations and formulate the speciation signature of the investigated binary system, and hint at the existence of other, as yet elusive, species arising in a pH-dependent fashion across the pH physiological range under both room temperature and hydrothermal conditions. Albeit low, the pH at which the assembly of the investigated species was pursued gives clues to the physicochemical properties of soluble species that might become bioavailable in the presence of suitable molecular targets at the cellular level. The investigation of such interactions and in-depth research of related materials and their potential applications are currently being pursued in our laboratory.

## Experimental Section

**Materials and Methods:** All experiments were carried out in the open air at room temperature. Nanopure-quality water was used

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for all reactions. $Co(NO_3)_2 \cdot 6H_2O$ and *N*,*N*-bis(phosphonomethyl)-glycine ($H_5NTA2P$) were purchased from Aldrich.

**Physical Measurements:** FT-IR measurements were taken with a Perkin–Elmer 1760X FT-infrared spectrometer. UV/Vis spectra were recorded with a Hitachi U-2001 spectrophotometer in the range 200–1000 nm. The EPR spectra of complex **1** in the solid state and in aqueous solution were recorded with a Bruker ER 200D-SRC X-band spectrometer, equipped with an Oxford ESR 9 cryostat. The powder spectra were recorded at 9.4261 GHz in the temperature range 4–77 K. The solution spectra were recorded at 9.3979 GHz in the temperature range 4–23 K. Magnetic susceptibility data were collected on powdered samples of **1** with a Quantum Design SQUID susceptometer in the temperature range 2.3–300 K, under various applied magnetic fields. Magnetization measurements were carried out at three different temperatures in the field range 0–6 T. Fitting procedures for the acquired experimental data were applied through the use of Fortran programming routines relating to the Hamiltonians employed and the basic parameters *D*, *E*, and *g*.[20,21,36b] Elemental analyses were performed by Quantitative Technologies, Inc. Electrochemical measurements were carried out with a Uniscan Instruments Ltd. model PG580 potensiostat-galvanostat. The entire system was under computer control and supported by the appropriate computer software (Ui Chem. Version 1.08RD) running on Windows. The electrochemical cell used had platinum (disk) working and auxiliary (wire) electrodes; an Ag/AgCl electrode was used as reference electrode. The water used in the electrochemical measurements was of nanopure quality. $KNO_3$ was used as supporting electrolyte. Normal concentrations used were 1–6 mM in electroanalyte and 0.1 M in supporting electrolyte. Purified argon was used to purge the solutions prior to the electrochemical measurements.

**Preparation of $[Co(C_4H_9O_8NP_2)(H_2O)_2]\cdot 2H_2O$ (1):** $Co(NO_3)_2 \cdot 6H_2O$ (0.17 g, 0.58 mmol) and *N*,*N*-bis(phosphonomethyl)glycine ($H_5NTA2P$; 0.16 g, 0.59 mmol) were dissolved in nanopure water. The pH of the resulting solution was 1.5. This reaction mixture was stirred at room temperature for 10–15 min. Subsequently, the reaction flask was cooled to 4 °C in the presence of ethanol. A couple of weeks later pink prismatic crystals grew out of the solution. The crystalline material was collected by filtration, and was dried under vacuum. Yield: 0.14 g (≈ 61%). $C_4H_{17}CoNO_{12}P_2$ (392.06): calcd. C 12.24, H 4.34, N 3.57; found C 12.53, H 4.45, N 3.54.

**X-ray Crystal Structure Determination of 1:** X-ray quality crystals of compound **1** were grown from aqueous solution. A single crystal with dimensions $0.12 \times 0.40 \times 0.60$ mm$^3$ was mounted on a Crystal Logic dual-goniometer diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source. Unit-cell dimensions for **1** were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11 < 2\theta < 23°$. Intensity data were measured by the $\theta$–$2\theta$ scans technique. Throughout data collection, three standard reflections were monitored every 97 reflections, and showed less than 2% variation and no decay. Lorentz, polarization, and psi-scan absorption corrections were applied by using Crystal Logic software. Further experimental crystallographic details for **1**: $2\theta_{max} = 50°$; scan speed: 4.0° min$^{-1}$; scan range: $2.25 + \alpha_1\alpha_2$ separation; number of reflections collected/unique/used: 2670/2474 ($R_{int}$ = 0.0198)/2474; 249 parameters refined; $F(000)$ = 402; $(\Delta/\sigma)_{max}$ = 0.015; $(\Delta\rho)_{max}/(\Delta\rho)_{min}$ = 0.341/–0.227 e Å$^{-3}$; GOF = 1.049; $R/R_w$ (for all data), 0.0226/0.0611.

The structure of complex **1** (Table 4) was solved by direct methods using SHELXS-86,[51] and refined by full-matrix least-squares techniques on $F^2$ with SHELXL-97.[52] All non-H atoms in the structure of **1** were refined anisotropically. All H atoms in the structure of **1** were located by difference maps and were refined isotropically.

Table 4. Summary of crystal, intensity collection, and refinement data for $[Co(C_4H_9O_8NP_2)(H_2O)_2]\cdot 2H_2O$ (**1**).

# In Search of Binary Hybrid Systems in Manganese Chemistry: The Synthesis, Spectroscopic and Structural Characterization, and Magnetic Properties of a New Species in the Aqueous $Mn^{II}$-Quinic System

**Melita Menelaou,[a] Catherine P. Raptopoulou,[b] Aris Terzis,[b] Vassilis Tangoulis,[c] and Athanasios Salifoglou*[a]**

**Keywords:** Manganese / Structural speciation / $Mn^{II}$–quinate interactions / Magnetic properties / Hybrid materials

Manganese is a metal with diverse (bio)chemical reactivity in aqueous media in the presence of biologically relevant ligands. Key to that reactivity is the existence of soluble and bioavailable forms of $Mn^{II}$ across the physiological range of pH. To probe the interactions arising between $Mn^{II}$ and the low-molecular-mass ligand D-(–)-quinic acid, research efforts were targeted at the synthetic aqueous chemistry in the requisite binary system. The pH-specific synthetic reaction of $Mn^{II}$ with D-(–)-quinic acid led to the isolation of the new species $[Mn_2(C_7H_{11}O_6)_4]_n \cdot nH_2O$ (**1**). Complex **1** was characterized by elemental analysis, spectroscopic techniques (EPR, FTIR), thermal and magnetic studies, and X-ray crystallography. The molecular lattice of **1** reveals the presence of dimeric units of $Mn^{II}$ centers, with the quinate ligands coordinated to the metal ions through variable binding modes, indicating the diversity of chemical reactivity in the system. The octahedral $Mn^{II}$ centers in the molecular assembly of **1** serve as chemical prototypes of the forms of interactions that most likely develop in biologically relevant fluids, similar to those encountered in plant exudates and plant cellular structures. Concurrently, the physicochemical features of **1** (from the 3D hydrogen-bonding network to the magnetic susceptibility properties and EPR spectral results) exemplify the key features that constitute the rudiments of $Mn^{II}$-organic hybrid lattices of specific functions and (bio)chemical reactivity patterns. The collective properties of **1** are discussed in the context of their occurrence in natural binary $Mn^{II}$-influenced systems and advanced metal-hybrid materials of potential applications.

## Introduction

Manganese is an element of considerable occurrence in the earth's lithosphere. It is found in minerals as well as biological systems. In the biotic systems, manganese is an essential element[1] and is involved in the active sites of metalloenzymes, key to the integrity of cellular processes.[2] Among those are catalases,[3] the mitochondrial superoxide dismutase (SOD) and pyruvate carboxylase, the glial-specific enzyme glutamine synthetase, and others.[4] Albeit controversial, the role of manganese in cellular processes in the brain has been the subject of considerable research, given that the specific metal in its ionic forms can cross the blood brain barrier and behave as a neurotoxin.[5] As a result, manganese ions and their chemical reactivity have been associated with physiological aberrations in humans, including manganism and a number of other neurological impairments such as Parkinson's disease. Outstanding, on the other hand, is the participation of manganese in the oxygen-evolving complex of photosystem II (PSII), with the manganese playing an important role as an inorganic cofactor of catalytic importance.[6]

Metal ions in biological systems are mobilized efficiently through interactions with organic substrates, that is, ligands capable of coordinating them and solubilizing them in biological fluids. These ligands include both low- and high-molecular-mass cellular targets. Manganese, as $Mn^{II}$ and/or $Mn^{III}$, aptly coordinates to such ligands and enters further ternary interactions with biological molecules. One such low-molecular-mass molecule is D-(–)-quinic acid, 1α,3α,4α,5β-tetrahydroxy-1-cyclohexane carboxylic acid. It is a molecule that is found widely in plants where it is a precursor to shikimic acid.[7] The latter molecule is involved in the synthesis of essential amino acids. Hence, the presence of quinic acid appears to be vital to cellular physiology,[7a,8] with the organic acid capable of binding metal ions in biological fluids. Among the metal-ion nutrients targeted by such ligands are $Fe^{II,III}$, $Mn^{II}$, $Zn^{II}$, $Cu^{II}$, and others. In exemplifying its chemical reactivity towards $Mn^{II}$, quinic acid contains three very important features that render it

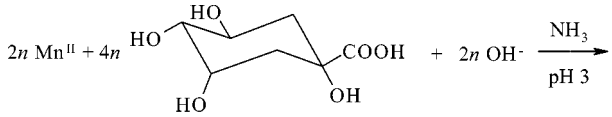
an efficient metal-ion binder. It contains (a) a carboxylate moiety known to promote binding, (b) alcohol moieties, one of which is in an α position to the carboxylate group, and (c) three alcohol groups relevant to polyol functionalities. In all cases, coordination to a metal ion like $Mn^{II}$ promotes solubilization and contributes to $Mn^{II}$ bioavailability, leading to metallo(bio)chemical interactions characterizing the role of the specific metal ion in cellular environments like those of a plant.

On the basis of these views, the exploration of the aqueous chemistry of $Mn^{II}$ with α-hydroxycarboxylate binders, like D-(–)-quinic acid, is expected to (a) shed light on the structural speciation of that aqueous binary system and (b) provide chemical clues on the interaction of that metal ion with a biologically important substrate, the reactivity of which plays an important role in cellular biosynthetic pathways. The paucity of related $Mn^{II}$-quinic acid derivative species prompted us to look into the pH-specific synthetic chemistry of that binary system. To this end, we herein report on (a) the synthesis and spectroscopic properties of a new $Mn^{II}$-quinate species $[Mn_2(C_7H_{11}O_6)_4]_n{\cdot}nH_2O$ (**1**) and (b) the relevance of the physicochemical properties of **1** in the development of interactions of $Mn^{II}$ with biologically relevant targets and the assembly of lattices illustrating the solid-state features of multimodal quinate-containing $Mn^{II}$ materials.

## Results and Discussion

### Synthesis

A simple procedure was employed for the synthesis of **1**. A facile reaction between $Mn^{II}$ and quinic acid in aqueous media occurred at pH 3. The pH was adjusted to 3 by addition of aqueous ammonia. The stoichiometric reaction that led to the formation of compound **1** is shown by Reaction 1.



D-(-)-quinic acid

$$[Mn_2(C_7H_{11}O_6)_4]_n \cdot n\,H_2O \quad + \quad 2n\,H_2O \qquad \text{(Reaction1)}$$

The derived hybrid $Mn^{II}$-quinate material was easily retrieved in pure crystalline form upon standing of the reaction mixture at room temperature and allowing for slow evaporation over a period of 24 to 36 hours. Elemental analysis of the isolated colorless crystalline product indicated the molecular formulation $[Mn_2(C_7H_{11}O_6)_4]{\cdot}H_2O$. Further evaluation of the crystalline product by FTIR spectroscopy confirmed the presence of quinate bound to $Mn^{II}$, consistent with the proposed formulation. Finally, X-ray crystallography confirmed the analytical and spectroscopic results by rendering the molecular formulation of the crystalline product as $[Mn_2(C_7H_{11}O_6)_4]_n{\cdot}nH_2O$ (**1**). In a synthetic effort making use of various bases, the same reaction mixture of $Mn^{II}$ and quinic acid reacted in the presence of NaOH and KOH to a final pH value of 3, finally affording a crystalline solid. That solid proved to be complex **1** by virtue of its identical FTIR spectrum with that of the title compound beyond the elemental analysis results. Attempts to synthesize a congener $Mn^{III}$-quinate species in aqueous solutions under identical conditions to Reaction 1 [using $M^{III}(acetate)_3$ and quinic acid with a molecular ratio 1:2 in the presence of ammonia] consistently led to the isolation of a $Mn^{II}$ species, which was shown to be **1** by spectroscopic and crystallographic methods. Other reaction conditions leading to $Mn^{III}$ species of quinate are currently being investigated.

Compound **1** is insoluble in water. It is also insoluble in organic solvents like methanol, acetonitrile, chlorinated solvents ($CHCl_3$, $CH_2Cl_2$), toluene, and DMF. Complex **1** is stable in the crystalline form in the air at room temperature for long periods of time.

### Description of the Crystal Structure

Compound **1** emerges from a molecular type of crystal lattice. The ORTEP diagram for complex **1** is shown in Figure 1. Selected bond lengths and angles for **1** are given in Table 1. Complex **1** crystallizes in the monoclinic space group $P2_1$ with two molecules per unit cell. In complex **1**, there are two distinct types of $Mn^{II}$ ions, with each residing in a variable-nature coordination environment. In the first type of $Mn^{II}$ ions, reflected in the $Mn1^{II}$ assembly, one quinate ligand coordinates to the metal ion through the carboxylate and alcohol oxygens O1 and O3, respectively. These two moieties bind to $Mn^{II}$ through the formation of a five-membered metallacyclic ring, rendering the arising species quite stable. The second carboxylate oxygen atom, O2, of that quinate ligand coordinates to a neighboring Mn1′ ion [(′): 1 + *x*, *y*, *z*] leading to the *syn-anti* bridging mode of the carboxylate moiety depicted as mode I in Scheme 1. The interatomic distance between the so bridged $Mn^{II}$ ions (Mn1 and Mn1′) is evidently equal to the length of the *a* crystallographic axis [5.813(3) Å]. This type of bridging is responsible for the formation of chains of Mn1 assemblies along the *a* axis (Figure 2). A second quinate ligand entering the coordination sphere of the Mn1 ion employs a similar coordination mode by using one of the carboxylate and the alcohol oxygen atoms to anchor to Mn1 (O11 and O13, respectively). The second terminal oxygen, O12, of the carboxylate group, however, does not participate in the coordination of an adjacent manganese ion as was the case with the first quinate ligand. Thus, the carboxylate group of the second quinate ligand adopts the monodentate coordination mode depicted as mode II in Scheme 1. The remaining two coordination sites around Mn1 are taken up by the oxygen terminals O21′′ [(′′): 2 – *x*, –0.5 + *y*, 1 – *z*] and O2′′′ [(′′′): –1 + *x*, *y*, *z*] of the quinate ligands belonging to two abutting $Mn^{II}$ ions in the lattice

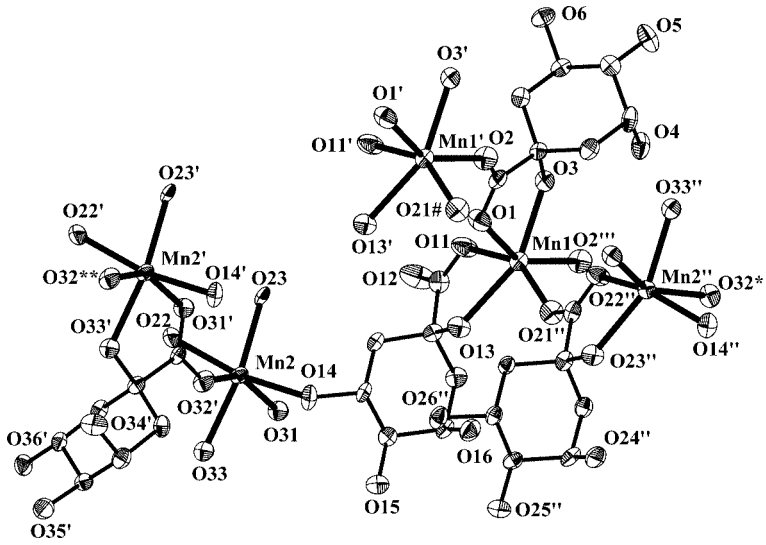

Figure 1. The molecular structure of $[Mn_2(C_7H_{11}O_6)_4]_n \cdot nH_2O$ (**1**) with the atom labeling scheme (50% thermal probability ellipsoids). Symmetry operations shown: (′): 1 + *x*, *y*, *z*; (′′): 2 – *x*, –0.5 + *y*, 1 – *z*; (′′′): –1 + *x*, *y*, *z*; (*): 1 – *x*, –0.5 + *y*, 1 – *z*; (**): 2 + *x*, *y*, *z*; (#): 3 – *x*, –0.5 + *y*, 1 – *z*.

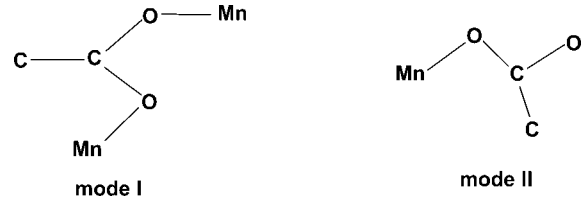
{Mn2′′ [(′′): 2 – *x*, –0.5 + *y*, 1 – *z*] and Mn1′′′ [(′′′): –1 + *x*, *y*, *z*], respectively}. Collectively, the assembly of the aforementioned quinate ligands render the Mn1 ion six-coordinate with distorted octahedral geometry. In this octahedron, the terminal oxygens O1, O11, O21′′, and O2′′′ define the equatorial plane, while the two remaining oxygens O3 and O13 occupy the axial positions.

A different type of coordination sphere is formulated around a second distinct manganese ion in the lattice. In particular, four coordination sites are taken up by two quinate ligands, both of which bind the manganese ion Mn2 through the carboxylate and alcohol oxygen terminals.



Scheme 1.

These oxygen anchors are O31, O33 and O22, O23 for the corresponding carboxylate and alcohol oxygen terminals. One coordination site is occupied by the oxygen terminal

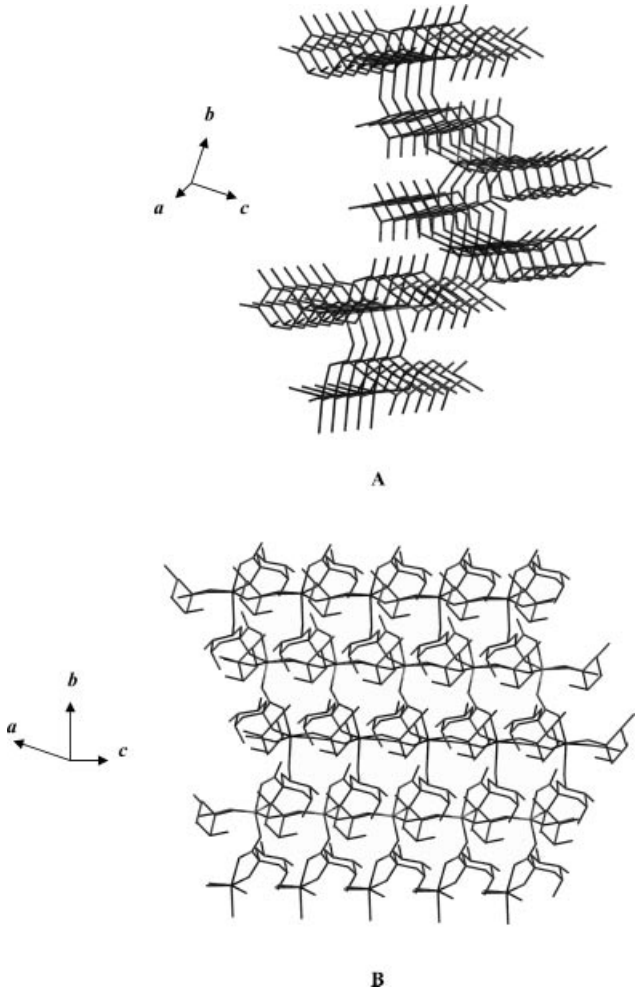

Figure 2. **A**: Packing diagram showing the chains of the Mn1 and Mn2 assemblies in **1** along the *a* axis. **B**: Layer diagram showing the bridging between Mn1 and Mn2 assemblies of **1** along the *a* axis forming the 2D polymeric structure.

O32′ [(′): 1 + *x*, *y*, *z*] of the carboxylate group of an abutting quinate ligand attached to a nearby manganese ion Mn2′ [(′): 1 + *x*, *y*, *z*], leading to a Mn2···Mn2′ separation equal to 5.813(3) Å, which is the length of the *a* axis. As a result, polymeric chains of the Mn2 assemblies are formed which are parallel to the crystallographic *a* axis. The last coordination site is occupied by the oxygen atom of one of the three alcohol moieties borne by the quinate ligand, namely O14, which is anchored to the first discrete Mn1 site discussed earlier. Overall, the coordination number of the Mn2 site is six, and the arising environment is distorted octahedral. The oxygen terminals O22, O32′, O31, and O14 formulate the equatorial composition of the octahedron, whereas the alcohol oxygen atoms O23 and O33 fulfil the axial requirements of the Mn2 environment.

The four crystallographically independent quinate ligands are divided into two groups according to their coordination mode around the two $Mn^{II}$ ions. The first group contains three members which anchor to $Mn^{II}$ through the carboxylate and alcohol oxygen atoms (O1, O3, O22, O23, O31, O33). In particular, the first member of the group binds to Mn1, while the two remaining members bind to Mn2 assemblies. The second carboxylate oxygen atom in all three quinate ligands is attached to a neighboring $Mn^{II}$ ion in a *syn*,*anti* binding mode. More specifically, O1, O2 and O31, O32 bridge $Mn^{II}$ ions belonging to Mn1 and Mn2 assemblies, respectively, and are responsible for the formation of the Mn1 and Mn2 polymeric chains along the *a* axis, while O21, O22 bridge Mn1 and Mn2′′ [Mn1···Mn2′′ 5.758(3) Å] and are responsible for the linkage of the chains. The second group contains one quinate ligand, which is anchored to Mn1 through O11 and O13, in the same way as the quinate ligands of the first group. In this case, however, the carboxylate moiety is coordinated to the metal ion in an $\eta^1$ fashion, and the alcohol oxygen O14 is used as a bridge to Mn2. Thus, that particular quinate ligand is used as an extended bridge between the chains of the two $Mn^{II}$ assemblies yielding an 8.065(11) Å separation between Mn1 and Mn2. In conclusion, the multifunctional nature of the crystallographically distinct quinate ligands and the way they extend into the coordination sphere of $Mn^{II}$ ions, promoting various coordination modes, are responsible for the formation of the 2D polymeric structure of compound **1** (Figure 2). This structure becomes even more complicated when hydrogen-bonding interactions are taken into consideration for the assembly of the requisite network.

Variable coordination modes of carboxylate-bearing organic ligands were previously observed in the coordination sphere of other divalent metal ions like $Cd^{II}$ and $Pb^{II}$. Representative examples of such complexes include $Cu^{I}(OOCCH_3)$,[9] and the physiological ligand citrate-containing complexes $[Cd(C_6H_6O_7)(H_2O)]_n$ (**2**),[10] $[Cd_3(C_6H_5O_7)_2(H_2O)_5]\cdot H_2O$ (**3**) and $(NH_4)[Cd(C_6H_5O_7)(H_2O)]\cdot H_2O$ (**4**), and $[Pb(C_6H_6O_7)]_n\cdot nH_2O$ (**5**).[11]

The Mn–O bond lengths for **1** are in the range from 2.067(4) to 2.324(4) Å, very similar to corresponding distances in complexes $(NH_4)_4[Mn^{II}(C_6H_5O_7)_2]$ (**6**),[12] $Mn^{II}(C_4H_4O_5)\cdot 3H_2O$ [2.111(2)–2.220(2) Å],[13] $Mn^{II}(C_7H_3NO_5)(H_2O)_2$ [2.124(3)–2.262(1) Å],[14] $Mn^{II}(C_2H_3O_3)_2\cdot 2H_2O$ [2.124(3)–2.225(3) Å],[15] $[Mn^{II}(XDK)(NO_3)(CH_3OH)_4(H_2O)_2](NO_3)$ [2.116(2)–2.345(2) Å][16] [$H_2XDK$ = *m*-xylenediamine bis(Kemp's triacid imide)] and $[Mn^{II}(bpca)_2\{Mn^{II}(hfac)_2\}_2]$ [2.113(3)–2.190(2) Å],[17] [Hbpca = bis(2-pyridylcarbonyl)amine; Hhfac = hexafluoroacetylacetone], where oxygen-containing octahedral coordination is the predominant feature of the structure around the $Mn^{II}$ ion. Also worth noting is the case of the polymeric material $[Mn^{II}(H_2O)_6][Mn^{II}(C_6H_5O_7)(H_2O)]_2\cdot 2H_2O$.[18] In this compound, the observed Mn–O distances between the tridentate citrate and $Mn^{II}$ range from 2.123(2) to 2.224(2) Å and compare favorably with those seen in **1**. The octahedral $Mn^{II}$ ion in **1** corresponds to other octahedral divalent metal ions like $Zn^{II}$,[19] $Cu^{II}$,[20] and $Ni^{II}$[21] in analogous octahedral species bearing citrates. The M–O distances observed in those complexes are in agreement with those seen in **1** and range from 2.052(2) to 2.164(2) Å ($Zn^{II}$) and 2.021(3) to 2.072(3) Å ($Ni^{II}$), while a wider range due to Jahn–Teller distortions is observed in the copper analog [1.969(3)–2.341(3) Å]. Equally comparable are the M–O distances oc-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

curring in the congener quinate complexes $[Zn(C_7H_{11}O_6)_2]$,[22] $[Cd(C_7H_{11}O_6)_2]\cdot H_2O$, $[Cu(C_7H_{10}O_6)(H_2O)]_2(H_2O)_2$,[23] $\{[Cu(NO_3)(C_7H_{11}O_6)(H_2O)]\cdot 2H_2O\}_n$, $\{[CuCl(C_7H_{11}O_6)(H_2O)]\cdot H_2O\}_n$,[24] $[Pt(C_6H_{14}N_2)(C_7H_{10}O_6)]$,[25] and the trinuclear $(NH_4)_2\{[V(O)_2]_2[V(O)](\mu\text{-}C_7H_{10}O_6)_2\}\cdot H_2O$.[26]

Overall, the quinate ligand plays the role of an efficient metal-ion chelator, employing all possible types of anchors available in its structure and effectively formulating the coordination environment around $Mn^{II}$.

Hydrogen-bonding interactions are a dominant feature of the crystal structure of **1**. Specifically in **1**, the alcohol and carboxylate moieties of the quinate ligands along with the lattice water molecules participate in an extensive network of intra- and intermolecular hydrogen bonds (Table 2), which very likely contributes to the stability of the crystal lattice.

Table 2. Hydrogen bonds in **1**.

| Interaction | D···A [Å] | H···A [Å] | D–H···A [°] | Symmetry operation |
|---|---|---|---|---|

## FTIR Spectroscopy

The FTIR spectrum of **1** exhibits strong absorptions for the carbonyl groups of the carboxylate groups in both the antisymmetric and symmetric vibration regions. The antisymmetric stretching vibrations $\nu_{as}(COO^-)$ appear in the range 1639–1607 $cm^{-1}$, whereas the symmetric stretches $\nu_s(COO^-)$ appear in the range 1451–1380 $cm^{-1}$. The frequencies for the carbonyl stretches in **1** are shifted to lower values relative to those of the free quinic acid. Hence, they indicate a change in the vibrational status of the quinate anion upon coordination to the metal ion. The difference between the symmetric and antisymmetric stretches, $\Delta[\nu_{as}(COO^-) - \nu_s(COO^-)]$, is greater than 200 $cm^{-1}$, indicating that the carboxylate groups of the quinate ligand are either free or coordinated to the metal ion in a monodentate fashion.[9b,27] The latter contention is further confirmed by the X-ray crystal structure of **1**. Similar trends in the frequencies for the carboxylate carbonyl groups have also been observed in the FTIR spectra of other metal-quinate complexes as well as α-hydroxycarboxylate complexes with metal ions.[28]

## Thermal Studies

The thermal decomposition of the title complex was studied by TGA-DSC under an atmosphere of oxygen. $[Mn_2(C_7H_{11}O_6)_4]_n\cdot nH_2O$ (**1**) is thermally stable up to 190 °C. From that point on, an initial process emerges that involves dehydration of **1**, with the release of water between 190 and 210 °C signifying an endothermic process. A fairly clear plateau is reached at 210 °C, suggesting that the arising anhydrous species is thermally stable. The observed weight loss, attributed to the release of the water content, amounts to 4.8%, a value very close to the calculated value of 5.1% based on the molecular formula of the title complex **1**.

Two additional steps are observed in the thermal decomposition of complex **1**. No clear plateaus are reached in these stages, suggesting that the derived products are unstable and decompose further. The total weight loss of 83%, due to the decomposition of the title complex, is reached at 450 °C with no further loss up to 1000 °C. This value is in agreement with the calculated weight loss of 83%, derived upon the proposition that the final product at 1000 °C is $Mn_3O_4$. The DSC profile of the complex exhibits clear features that correspond to the TGA diagram. Collectively, the rather small number of observed TGA and DSC peaks likely reflects simple mechanisms of decomposition pathways for the title complex.

## Magnetic Susceptibility

The temperature dependence of $\chi_M$ and $\chi_M T$ ($\chi_M$ being the magnetic susceptibility for two $Mn^{II}$ ions) for complex **1** is shown in Figure 3. The $\chi_M T$ value is 8.5 emu $mol^{-1}$ K at 300 K (close to the value expected for two isolated $Mn^{II}$ ions). From 300 K down to 50 K there is a smooth decrease of the $\chi_M T$ value (Figure 3, A), while from 50 K down to 2 K there is a more pronounced decline of the $\chi_M T$ ultimately reaching the value of 1.5 emu $mol^{-1}$ K. In the inset of Figure 3 (A), the maximum of the $\chi_M$ data is shown at 3.5 K. The shape of these curves is characteristic of the occurrence of weak antiferromagnetic interactions between the $Mn^{II}$ centers. Taking into account the 2D character of **1**, the susceptibility data were fitted through the following approaches:

(a) The first one was based on the expansion series[29] of Lines for a $S = 5/2$ antiferromagnetic quadratic layer, riding on the exchange Hamiltonian $\boldsymbol{H} = \sum_{nn} \boldsymbol{J}\boldsymbol{S}_i\cdot\boldsymbol{S}_j$, where $\sum_{nn}$ runs over all pairs of nearest-neighbor spins $i$ and $j$ [Equation (1)], in which $\theta = kT/|J|S(S+1)$ $C_1 = 4$, $C_2 = 1.448$, $C_3 = 0.228$, $C_4 = 0.262$, $C_5 = 0.119$, $C_6 = 0.017$, and $N$, $g$, and $\beta$ have their usual meanings.

$$\frac{Ng^2\beta^2}{\chi|J|} = 3\theta + \left(\sum \frac{C_n}{\theta^{n-1}}\right) \quad (1)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

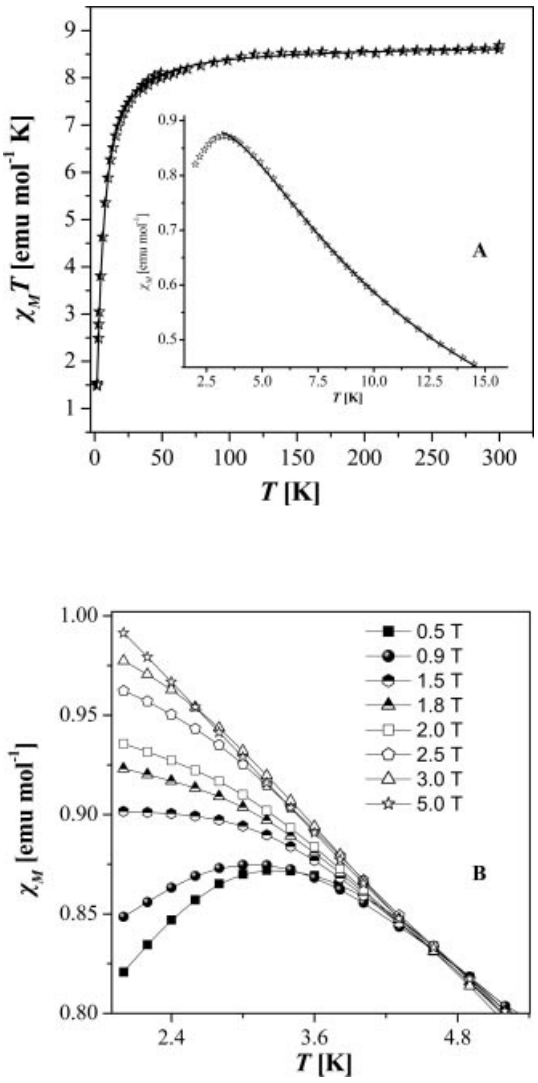

Figure 3. **A**: Temperature dependence of the susceptibility data at 0.6 T, in the form of $\chi_M T$ vs. $T$ (solid stars). In the inset, the temperature dependence of the susceptibility data is shown at 0.6 T, in the form of $\chi_M$ vs. $T$ near the maximum. The solid line represents the best fit according to the model discussed in the magnetic susceptibility section. **B**: Temperature dependence of the susceptibility data at different external fields in the range 0.5–5 T. The solid line represents the best fit according to the model discussed in the text.

The best fit is given by the superexchange parameters $J$ = –0.28 cm$^{-1}$ and $g$ = 1.98. In this hypothesis, a quadratic character of the layer has been assumed, that is, only one $J$ value. In fact, in complex **1** there are two $J$ values because there are two chemically distinct pathways: The first coupling pathway involves pairs of abutting Mn$^{II}$ ions, with the intervening linker emanating from a specific Mn$^{II}$ ion and traversing through the α-hydroxycarboxylate moiety, the quinate cyclic backbone, and the terminal alcohol anchor, ultimately binding the abutting Mn$^{II}$ ion. The second coupling pathway involves adjacent Mn$^{II}$ ions with the shorter spacer linker being the α-hydroxycarboxylate moiety. The two distinct pathways in the *ab* plane are explicitly portrayed in Figure 4, with the appropriate schematic and the associated $J$ ($J_1$ and $J_2$) coupling constants. As indicated earlier, both cases give a weak antiferromagnetic coupling, which we can assume to be similar for the fit.

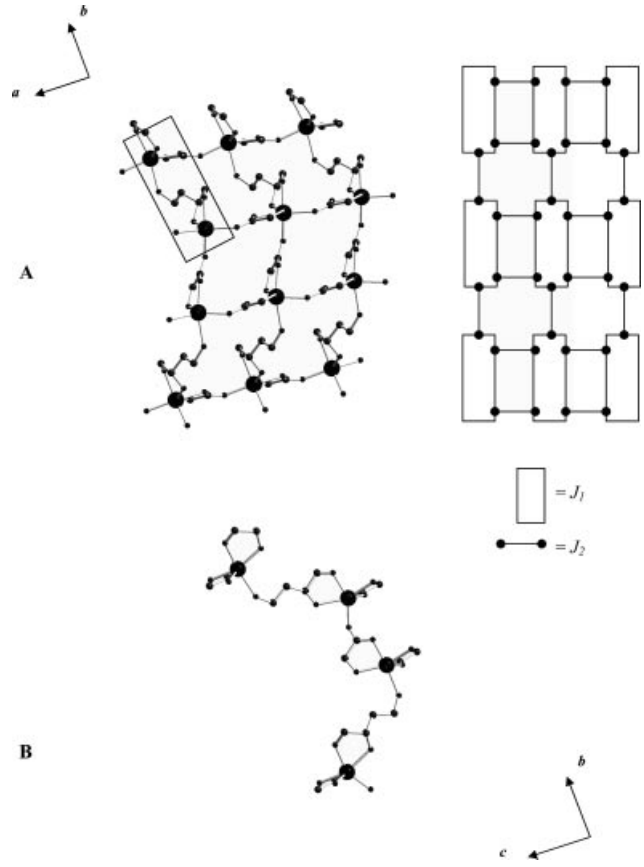

Figure 4. Different views (**A** and **B**) of the magnetic pathways of the system in **1**.

(b) The second one involved the analytical expression, derived by Curely, for an infinite 2D square lattice composed of classical spins ($S$ = 5/2) isotropically coupled and based on the exchange Hamiltonian $\boldsymbol{H} = \sum_{nn} \boldsymbol{J S_i \cdot S_j}$, where $\sum_{nn}$ runs over all pairs of nearest-neighbor spins $i$ and $j$ (Heisenberg couplings), see Equation (2).[30]

$$\chi = \frac{\left[Ng^2\beta^2 S(S+1)(1+u)^2\right]}{\left[3kT(1-u)^2\right]} \quad (2)$$

Here, $N$ is Avogadro's number, $\beta$ is Bohr's magneton, $k$ is Boltzmann's constant, and $u$ is the well-known Langevin function, see Equation (3).

$$u = L\left(\frac{JS(S+1)}{kT}\right) = \coth\left(\frac{JS(S+1)}{kT}\right) - \frac{kT}{JS(S+1)} \quad (3)$$

The best fit leads to $J$ = –0.2 cm$^{-1}$ and $g$ = 1.98 (Figure 3, part A, solid line). The $J$ values obtained through the Lines

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

or Curely expressions are very similar: –0.28 and –0.2 $cm^{-1}$, respectively. Taking into consideration the fact that the Curely formula is more accurate and is valid down to 0 K (the Lines formula is only valid up to the maximum of $\chi_M$, approximately), the value of –0.2 $cm^{-1}$ seems to be the most accurate estimate for complex **1**.

(c) Another possible magnetic model could also be considered. Such a model takes into account the fact that the only significant and maybe measurable interaction is the one through the α-hydroxycarboxylate ligand, thus reflecting a potential 1D character for **1**. For that reason, the susceptibility data were fitted to the following Equation (4),

$$\chi_M = \frac{Ng^2\beta^2}{kT}\frac{\left(A+Bx^2\right)}{\left(1+Cx+Dx^3\right)} \quad (4)$$

which is based on Weng's numerical approach,[31] and the coefficients have been generated by Hatfield et al.[32] for a $S = 5/2$ antiferromagnetic linear chain, where $x = |J|/kT$, $A = 2.9167$, $B = 208.04$, $C = 15.543$, $D = 2707.2$, and $N$, $g$, and $\beta$ have their usual meanings. The best fit is given by the parameters $J = -0.2\ cm^{-1}$ and $g = 2.0$, and it is equally good, indicating that the couplings are weak. The distinction between a 2D and 1D magnetic model is quite difficult to address solely through the fitting of the susceptibility data. In order to investigate and confirm the 2D magnetic character of the system, a different experimental approach was employed and it is explained later.

The comparison of $\chi_M$ (note that here the quantity actually measured is the ratio between the magnetization and the applied magnetic field) versus $T$ curves at different magnetic fields from 0.5 to 5.0 T applied fields (Figure 3, B) provides additional information. At the lower field, a clear sign of a transition to an antiferromagnetic state is observed with a maximum at 3.5 K. The critical temperature, taken as the maximum of the $T\mathrm{d}\chi/\mathrm{d}T$ versus $T$ curve, was estimated to occur at 2.0 K.[33] On the other hand, no maximum is observed at 5 T, thus indicating that the transition is suppressed at this field. Interestingly, ZFC/FC curves measured at 50 G (not shown) did not reveal any divergence, thus indicating that no hysteretic phenomenon is active below the ordering temperature.

Isothermal magnetization curves at $T = 2$–5 K in the applied field 0–5 T are shown in Figure 5 (A). The curves for the increasing and decreasing fields are identical. The magnetization at 5 T reaches 8.4 and 6.8 $\mu_B$ at $T = 2$ and 5 K, respectively, values which are smaller than the expected saturation value of 10 $\mu_B$ (two isolated $Mn^{II}$ ions) for the molecule of **1**. The sigmoidal shape of the $M(H)$ dependence is shown in Figure 5 (B), where a pronounced peak appears in the $\mathrm{d}M(H)/\mathrm{d}H$ curve that disappears at temperatures higher than 5 K.[34] This shape reveals the metamagnetic-like behavioral characteristic for systems in which the magnetocrystalline anisotropy is superimposed on the exchange couplings. Similar features have been recently observed for $Cu^{II}$–$W^{V}$ coordination polymers with 2D structures.[35] The shape of the $T = 2$ K curve suggests that the effective anisotropy field ($H_A$) is less than the exchange field ($H_E$), in contrast to the case of metamagnets, where $H_A \geq H_E$ and an immediate *spin-flip* transition to the saturated ferromagnetic state occurs. When the anisotropy field is of moderate intensity, the magnetization process proceeds through the *spin-flop* transition connected with reorientation of the antiferromagnetically coupled spins to the configuration perpendicular to the field. The threshold field for the spin-flop transition in the polycrystalline sample is 0.3 T, whereas the inflection point of the $\mathrm{d}M(H)/\mathrm{d}H$ curve (Figure 5, B) occurs at $H_{SF} = 2.1$ T. At $T = 5$ K, the $M(H)$ curve hardly shows any transition, most probably because of the change of the $H_A/H_E$ ratio.[36]

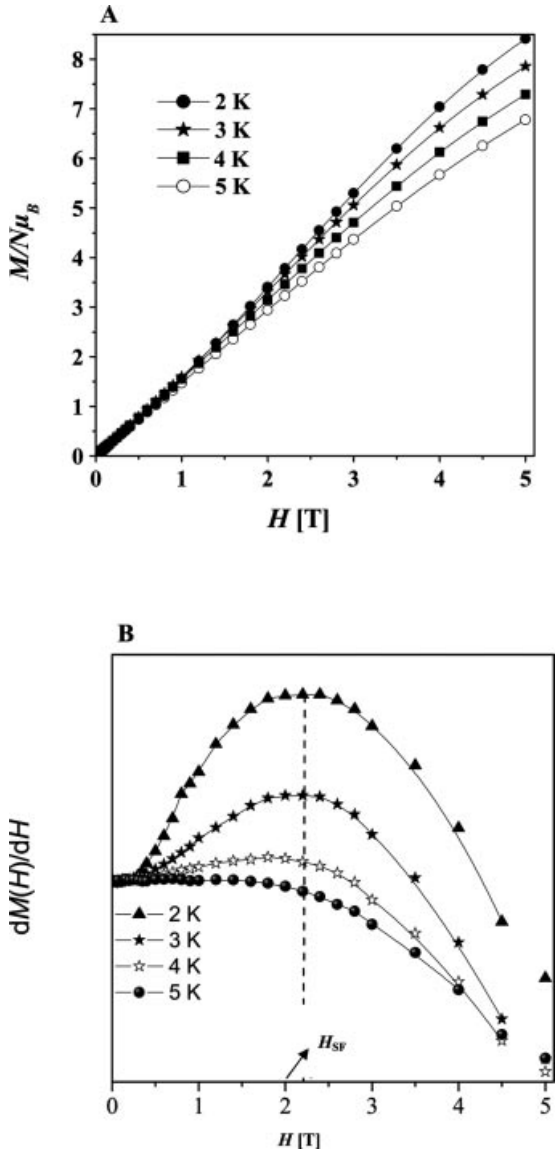

Figure 5. **A**: Magnetization curves at different temperatures in the field range 0–5 T. **B**: Field dependence of the magnetization derivatives in order to reveal their sigmoidal character (see text for details).

### EPR Spectroscopy

The EPR spectrum of complex **1** measured on a polycrystalline powder at room temperature shows an isotropic signal centered at $g = 2.00$, with a line width of 380 G. The spectra measured at variable temperatures are practically identical, but the line width of the signal increases upon lowering of the temperature (at 4 K it is 650 G). Since the EPR signal does not vanish at low temperatures, proof for antiferromagnetic ordering below the temperature of the transition, the possible magnetic ordering, needs further measurements at a lower temperature (about 2 K, see earlier).

### The Binary $Mn^{II}$-Quinate System in Aqueous Media

The synthesis of $[Mn_2(C_7H_{11}O_6)_4]_n{\cdot}nH_2O$ (**1**) through a facile reaction of $MnCl_2$ with quinic acid at pH 3, demonstrates the strong affinity of D-(–)-quinic acid for the divalent metal ion $Mn^{II}$. Albeit low, the pH of the reaction solution was sufficient to promote the reaction to completion and to afford the crystalline product in a pure form in a few hours. The physicochemical characterization of the derived material reflected the physical and chemical properties of **1** and revealed a considerable number of structural details linked to the reactivity of the binary system investigated. Specifically, the points worth noting are the following:

(a) *the retention of the protonation of the α-hydroxy group in the quinate ligand*. It appears that in the presence of $Mn^{II}$, the alcohol group adjacent to the carboxylic acid moiety retains its proton, following binding of the quinate group to the metal ion. Protonation of the alcohol group in the α position to the carboxylate group has also been observed in the case of the congener α-hydroxycarboxylic acid, citric acid, upon binding of the latter to $Mn^{II}$.[12]

(b) *employment of the terminal alcohol moieties in the coordination of the quinate ligand to an adjacently located $Mn^{II}$ ion*. In that respect, the organic moiety extends its coordination to two distinct manganese ions by (1) employing different anchors to bind them, (2) satisfying the coordination requirements of both $Mn^{II}$ ions, (3) preserving the protonation state of the alcohol group(s) upon binding to the metal ions, and (4) retaining the overall (de)protonation state of the carboxylate ligand bound to the manganese ion(s) to –1.

(c) *the variable mode of binding of the quinate carboxylate group to the $Mn^{II}$ ions*. Here, there exist two coordination modes, one of which is the conventional mode and is often observed in the case of other metal ions bound to carboxylate-containing substrates. The second one is a characteristic coordination-binding motif (Scheme 1). In this sense, the two $Mn^{II}$ ions to which the carboxylate group spans lie in the *syn-anti* conformation. This distinct mode of coordination has been observed for other metal ions bound to carboxylate-bearing molecules.[37] The two manganese ions lie in the same plane with carboxylate oxygen atoms and the abutting carbon atoms (the atoms, C1, C2, O1, O2, of the quinate backbone, Mn1, and Mn1′ are coplanar with the largest standard deviation 0.18 Å for O2).

The aforementioned structural features define the physical formulation of complex **1** and reflect the chemical reactivity, due to which the title species arose out of the reaction mixture and crystallized out of solution. The distinct modes of binding of the quinate ligand to the $Mn^{II}$ ions led inevitably to the formulation of a dimeric assembly $Mn_2(C_7H_{11}O_6)_4$ in **1**. The latter moiety is the repeat unit of the polymeric compound **1**. To this end, species **1** is a polymer similar to the one in the previously reported polymeric manganese complex $[Mn^{II}(H_2O)_6][Mn^{II}(C_6H_5O_7)(H_2O)]_2{\cdot}2H_2O$. Despite the obvious differences between the fundamental ligands bound to the $Mn^{II}$ in the two different complexes, (a) the underlying variability in the coordination mode of the two ligands to $Mn^{II}$ and (b) the resulting geometric features with the associated total variable charges, signify the diversity of the chemical reactivity of the $Mn^{II}$ ions towards α-hydroxycarboxylate ligands differing in their structure. In this case, the structural differences in the organic ligands reflect commensurate structural differences in the metal complexes in the two polymeric species. Such profoundly different chemical reactivity and structural variability may reflect analogously variable chemical reactivity at the biological level, where the two organic ligands constitute key molecular targets of essential biosynthetic pathways linked to cellular integrity and survival in bacteria and plants.

Further structural characteristics inherent to the lattice of **1** include the involvement of water molecules in the assembly. To that end, solvent water molecules of crystallization participate in the establishment of extensive hydrogen-bonding interactions throughout the lattice of **1**.

### $Mn^{II}$ Aqueous Speciation in Plants and Plant Fluids

Manganese is widely found in various structures and compartments in plants (e.g., older leaves, the plant stem, etc.),[38,39] contributing to their physiology.[40] Given that any influence of cellular biochemical processes entail bioavailable and thus soluble forms of manganese ions, $Mn^{II}$ bound to quinic acid presents a distinct form of an essential ion promoting binary and ternary interactions in biological fluids. Akin to this notion is the fact that solubility of $Mn^{II}$ increases at low pH, that is, under conditions employed in this work.[41] It is through such interactions that (bio)chemical reactivity arises, similar to the one linked to enzymes in the shikimate pathway in plants.[42] Of the variety of species that might form in solution, compound **1**, albeit insoluble itself, illustrates multimodal interactions of quinic acid with $Mn^{II}$ at low pH. In this sense, the dinuclear core species in **1**, is only one of the various forms potentially arising in the aqueous milieu. Undoubtedly, a solution speciation study would help delineate the nature and properties of species forming as a function of pH and metal-ligand stoichiometry.

Furthermore, the chemical reactivity of the binary system studied here exemplifies one more aspect of the chemis-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

try unfolding at the biological level, that is, the ability of the cell to seek and identify micronutrients influencing its physiology. In that respect, aqueous $Mn^{II}$-quinate species at low pH provide a first glimpse of the chemistry promoted by bacterial organisms to (a) internalize, and/or (b) metabolize organic substrates in the presence of $Mn^{II}$, and/or (c) bind substrates in the presence of toxic metal ions (e.g., $Cd^{II}$), thus inhibiting their metabolic processing.[43,44] Such chemistries could arise from the needs of a plant under variable environmental adversities (e.g., nutritional deficiencies, extreme changes in soil pH, accumulation of toxic metals and substrates, etc.).[45]

### $Mn^{II}$-Containing Lattices in $Mn^{II}$-Organic Hybrid Materials

The lattice in **1** indicates the diversity of structural motifs generated by a single polydentate ligand: D-(–)-quinic acid gives rise to distinct $Mn^{II}$ sites, binding to it through the hydroxy carboxylate groups on one hand and the triol moieties on the other. The 1D wires strewn along the *a* axis formulate a 2D lattice with gaps in between the $Mn^{II}$-quinate strings that potentially allow for variable chemical reactivity in the intervening space (Figure 2). In those strings, the octahedrality of $Mn^{II}$ sites is a feature previously observed in $[Zn(C_7H_{11}O_6)_2]$, but not in $[Cd(C_7H_{11}O_6)_2]\cdot H_2O$, where a monocapped trigonal prismatic arrangement of quinates around $Cd^{II}$ dictates a different lattice. Equally interesting is $[Cu(C_7H_{10}O_6)(H_2O)]_2(H_2O)_2$, where the lattice is dictated by the square pyramidal geometry around $Cu^{II}$. Even more complex appears to be the 3D $Mn^{II}$–citrate lattices of various species, like $[NaMn(C_6H_5O_7)]$ and $[Ca_2Mn(C_6H_5O_7)_2(H_2O)_4]_n$.[46] This plethora of lattice types involving variable structure ligands bearing similarity to quinic acid, project an equally diverse type of hybrid materials still eluding isolation and characterization under speciation conditions in binary and even ternary systems.

## Conclusions

Collectively, the work on the binary $Mn^{II}$-quinic system of **1** (a) projects a clear view of the complexity of the speciation in aqueous media and the diversity of interactions developing in plant fluids, (b) sheds light on specific structural features of the related solid-state lattices that could be useful in designing new $Mn^{II}$-organic hybrid materials, and (c) defines the challenges of the future in the bioinorganic chemistry of quinic acid.

## Experimental Section

**Materials and Methods:** All manipulations were carried out in the open air. $MnCl_2\cdot 4H_2O$ was purchased from Merck and D-(–)-quinic acid from Fluka. Nanopure-quality water was used for all reactions.

**Physical Measurements:** FTIR measurements were recorded with a 1760X FT-Infra Red spectrometer from Perkin–Elmer, using KBr pellets. A ThermoFinnigan Flash EA 1112 CHNS elemental analyzer was used for the simultaneous determination of carbon, hydrogen, and nitrogen (%). The analyzer was based on the dynamic flash combustion of the sample (at 1800 °C) followed by reduction, trapping, complete GC separation and detection of the products. The instrument was fully automated and controlled by PC using the Eager 300 dedicated software and was capable of handling solid, liquid or gaseous substances.

A TA Instruments thermal analyzer, model Q 600, system was used to run the simultaneous TGA-DSC experiments. The employed heating rate was 10 °C min$^{-1}$. The instrument mass precision was 0.1 μg. Sample (about 20 mg) was placed in an open alumina sample pan for each experiment. High purity helium and air (80:20 in $N_2/O_2$) were used at a constant flow rate of 100 mL min$^{-1}$, depending on the conditions required for running the experiment(s). During the experiments, the sample weight loss and rate of weight loss were recorded continuously under dynamic conditions, as a function of time or temp., in the range 30–1000 °C. Prior to activating the heating routine program, the entire system was purged with the appropriate gas for 10 min, at a rate 400 mL min$^{-1}$, to ensure that the desired environment was established.

The EPR spectra of complex **1** in the solid state and in aqueous solutions were recorded with a Bruker ER 200D-SRC X-band spectrometer, equipped with an Oxford ESR 9 cryostat at 9.174 GHz, 10 dB, and at 4 K. Magnetic susceptibility data were collected using powdered samples of **1** with a Quantum Design SQUID susceptometer in the 2–300 K temp. range, under various applied magnetic fields. Magnetization measurements were carried out at three different temp. in the field range 0.5–5 T.

**Synthesis of $[Mn_2(C_7H_{11}O_6)_4]_n\cdot nH_2O$ (1):** $MnCl_2\cdot 4H_2O$ (0.50 g, 2.5 mmol) and D-(–)-quinic acid (0.97 g, 5.0 mmol) were placed in a round-bottomed flask (25 mL) and dissolved in water (5 mL). The reaction mixture was then stirred at room temp. until both reactants were completely dissolved. Subsequently, the pH of the clear solution was adjusted to 3 with aqueous ammonia. The resulting reaction mixture was allowed to stand at room temp. for slow evaporation. A few hours later, colorless crystalline material appeared on the bottom of the flask. The crystalline product was isolated by filtration and dried in vacuo. Yield 0.56 g (50%). **1**, $[Mn_2(C_7H_{11}O_6)_4]_n\cdot nH_2O$, $C_{28}H_{46}Mn_2O_{25}$ (892.52): calcd. C 37.64, H 5.15; found C 37.39, H 5.09.

**X-ray Crystal Structure Determination:** X-ray quality crystals of compound **1** (Table 3) were grown from reaction mixtures upon slow evaporation. A single crystal with dimensions $0.50\times0.30\times0.20$ mm (**1**) was mounted on a $P2_1$ Nicolet diffractometer using graphite monochromated Cu-$K_\alpha$ radiation. Unit cell dimensions for **1** were determined and refined by using the angular settings of 25 automatically centered reflections in the range $22 < 2\theta < 54°$. Relevant crystallographic data appear in Table 3. Intensity data were measured by using a $\theta$-$2\theta$ scan. Three standard reflections were monitored every 97 reflections, over the course of data collection. They showed less than 3% variation and no decay. Lorentz, polarization, and psi-scan absorption corrections were applied using Crystal Logic software. Further crystallographic details for **1**: $2\theta_{max} = 118°$; scan speed 3.0° min$^{-1}$; scan range $2.45 + \alpha_1\alpha_2$ separation; reflections collected/unique/used, 4667/4467[$R_{int}$ = 0.0372]/4467; 620 parameters refined; $[\Delta/\sigma]_{max}$ = 0.018; Flack parameter = 0.023(5); $[\Delta\rho]_{max}/[\Delta\rho]_{min}$ = 0.312/–0.639 e Å$^{-3}$; $R/R_w$ (for all data) = 0.0506/0.1140. The structure of compound **1** was solved by direct methods using SHELXS-86[47] and refined by full-matrix least-squares techniques on $F^2$ by using SHELXL-97.[48] All the non-hydrogen atoms were refined aniso-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tropically. The methylene hydrogen atoms of the quinate ligand were introduced at calculated positions as riding on bonded atoms. The remainder of the hydrogen atoms were located by difference Fourier maps and were refined isotropically.

Table 3. Summary of crystal, intensity collection, and refinement data for $[Mn_2(C_7H_{11}O_6)_4]_n{\cdot}nH_2O$ (**1**).

# Direct Epimetallation of π-Bonded Organic Substrates with Titanium(II) Isopropoxide: Intermediacy of Biradical, Oligomeric Titanium(II) Reagents[‡]

John J. Eisch,*[a] John N. Gitua,[a] and David C. Doetschman[a][b]

**Keywords:** Titanium(II) / EPR determination of biradicals / Titanium(II) isopropoxide trimer / Epititanation / Nonstereochemical $Ti^{II}$ additions

Extensive EPR experiments show that a titanium-containing molecular triplet state is formed in solution by the reaction of two equivalents of butyllithium with one equivalent of titanium(IV) isopropoxide. At higher concentrations this product, titanium(II) isopropoxide, admixed with two equivalents of lithium isopropoxide, is accompanied by the formation of a variety of nontitanium-containing side products. The powder EPR spectrum of the molecular triplet state in frozen solution is consistent with an asymmetric molecular chain of three Ti centers on which the unpaired electron centers are three metal atoms apart. Dilution experiments show that at lower concentrations, where the nontitanium-containing side products have dissipated, the intensity of the molecular triplet spectrum varies approximately linearly with concentration. Thus there is no evidence that the observed triplet molecule is one component in a series of concentration-dependent oligomerization steps. The bulky isopropoxy substituents and the coordination of the isopropoxide anions from the LiO*i*Pr present appear to prevent closure of the $Ti_3$ centers into an equilateral triangular diamagnetic structure. This steric hindrance, operative at the terminal diisopropoxytitanium centers and preventing closure to a ring, seems not to be observed with $TiCl_2$·2THF, which is diamagnetic and may thus be expected to exist as an equilateral triangular cluster of three units of $TiCl_2$·2THF, a structural model currently under further investigation. The smaller steric demand of the chloro and THF units would seem to permit octahedral coordination about each Ti center in such an equilateral trigonal array of $Ti_3$ atoms. Chemical reactions carried out individually with diphenylacetylene, *cis*-stilbene or *cis*-stilbene oxide and titanium(II) diisopropoxide provide stoichiometric and stereochemical evidence that the attacking titanium(II) reagent is in fact the trimeric biradical. The role of the lithium isopropoxide byproduct in fostering the course of the previously reported SET reactions of titanium(II) isopropoxide and in determining the detailed structure of the open-chain Ti trimer biradical has been explicated.

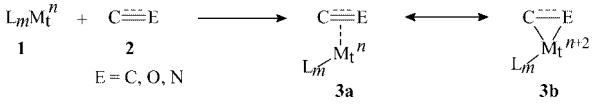
## Introduction

The complexation of subvalent transition-metal reagents ($L_mM_t^n$, **1**) with various C=C, C≡C, C=O, or C=N linkages (as in **2**) has led to adducts **3** that may be considered as π complexes **3a**, where the metal has undergone little change in oxidation number ($M_t^n$). On the other hand, the metal center can have released significant electron density to the π*-orbital of the organic substrate with the formation of three-membered metallocycles **3b**, and the metal may thereby have a higher oxidation number ($M_t^{n+2}$) [Equation (1)]. To determine which of the resonance structures **3a** and **3b** is the better single structure of adduct **3**, it is necessary to perform individual evaluations of the structural parameters of adduct **3**, if isolated, or of its observed chemical reactions.[2–4]



(1)

The process involved in the formation of adduct **3** has been termed epimetallation, because the metal reagent **1** is added with the rupture of a π-bond.[2] If reagent **1** is generated in a separate step and then added to **2**, this process may be termed direct epimetallation (Scheme 1, path a). More recently, however, we have found that a precursor dialkyl derivative of higher oxidation number, $R_2M_t^{n+2}L_m$ (**4**), can itself transfer the $L_mM_t^n$ unit to the unsaturated substrate **2** with concomitant loss of the R groups (Scheme 1, path b). This latter process has accordingly been termed transfer-epimetallation.[5a, 6]

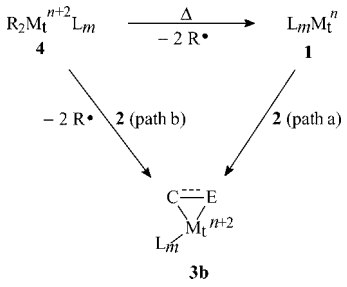
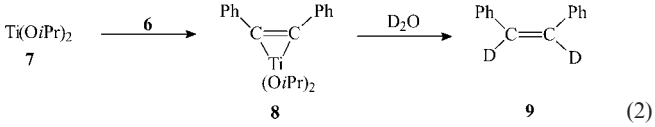


Scheme 1.

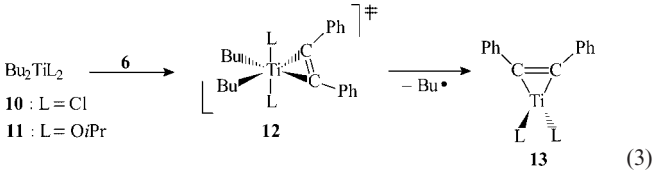
It is noteworthy to observe that the epititanation of ethylene by titanium(II) diisopropoxide (**7**) is widely thought to lead to 1,1-diisopropoxy-1-titanacyclopropane, postulated as the key intermediate in the Kulinkovich cyclopropanol synthesis.[5]

A most unusual and unexpected observation made in comparing such epimetallations with titanium reagents is that the direct epititanations with preformed $TiL_2$ (L = Cl, O*i*Pr)$_2$ are much slower than transfer-epititanations with $Bu_2TiL_2$.[2,5] For example, preformed $TiCl_2$ (**5**) in THF can achieve no epititanation of diphenylacetylene (**6**) whatsoever at 25 °C; similarly, Ti(O*i*Pr)$_2$ (**7**) in THF reacts with **6** over 24 h to provide only 31% of the epititanation product **9**, presumed to stem from adduct **8**, which was detected through $D_2O$ cleavage as **9** [Equation (2)]. In considering this low reactivity of $TiCl_2$ or Ti(O*i*Pr)$_2$ in direct epititanations, it is still noteworthy that some moderate activity is shown by Ti(O*i*Pr)$_2$ at 25 °C, while $TiCl_2$ is completely unreactive. As will be observed later in this study, this distinct difference in the chemical reactivity of Ti(O*i*Pr)$_2$ vs. $TiCl_2$ is also reflected in their respective EPR activity.



(2)

In sharp contrast, however, when either $Bu_2TiCl_2$ (**10**) or $Bu_2Ti(OiPr)_2$ (**11**) was generated in THF at –78 °C and 0.9 equiv. of diphenylacetylene (**6**) was then added, subsequent warming to 25 °C and treatment with $D_2O$ gave a 91–99% yield of *cis*-[$D_{1,2}$]stilbene (**9**). This outcome clearly demonstrates that **10** or **11** achieves a rapid epititanation of **6** at or below 25 °C. The facility of such transfer-epititanation has been rationalized by the formation of an octahedral transition state **12** with **6**, in which the new, incipient C–Ti bonds of the epititanated product are formed as the butyl–titanium bonds are thereby predisposed to homolytic cleavage [Equation (3)].



(3)

A most likely reason for the greater epititanation activity of $Bu_2TiL_2$ (**10** or **11**) over that of $TiL_2$ (**5** or **7**) may well be the more associated character of $TiL_2$. In the solid state, it should be noted that the $TiCl_2$ crystal lattice consists of layers of an infinite plane of Ti atoms flanked on both sides by infinite planes of chlorine atoms. It is understandable that considerable activation energy would be required to generate monomeric $TiL_2$ units, even from a far less associated form of these titanium(II) salts. As produced from 2 equiv. of butyllithium with 1 equiv. of $TiCl_4$ or Ti(O*i*Pr)$_4$, the resulting $TiL_2$ remains admixed with 2 equiv. of either LiCl or Li(O*i*Pr)$_2$. The separation of pure $TiCl_2$ or Ti(O*i*Pr)$_2$, free of Li salts, for analytical or molecular weight measurements, is a difficult task. We have been able to isolate and analyze successfully $TiCl_2$·2THF, free of LiCl, but we have been uniformly unsuccessful in separating Ti(O*i*Pr)$_2$ from LiO*i*Pr, since both components are freely soluble in pure THF or in hexane.

Hindered from determining the degree of association of pure Ti(O*i*Pr)$_2$ (**7**) in solution, we have availed ourselves of another interesting physical property of **7**. In contrast with the diamagnetic character of $TiCl_2$ (**5**) in THF over a range of temperatures below 25 °C, we have found that Ti(O*i*Pr)$_2$ with its byproduct LiO*i*Pr in heptane/toluene solution is pronouncedly paramagnetic and displays an EPR triplet signal characteristic of a biradical. The detailed study of such an EPR spectrum now permits us to estimate the degree of association of such Ti(O*i*Pr)$_2$ units.[7] Extrapolating from data on alkali metal complexes of $TiCl_2$, such as $Na_2Ti_3Cl_8$, we now suggest a possible similarity in the association of $TiCl_2$ units in THF.

## Results and Discussion

### The EPR Investigation of the 1:2 Mixture of Titanium(II) Diisopropoxide (7) and Lithium Isopropoxide in 1:1 Solutions of Heptane/Toluene

The initial CW EPR investigation of diluted samples of such mixtures, where the concentration of **7**, formally considered as the monomer, was successively 20.0, 7.0, 2.0, and 0.7 mM, revealed a broad, strong line at $g$ = 1.944, a sharp line at $g$ = 1.964, and a complex set of lines around $g$ = 1.98. Subsequent examination of this flash-frozen sample at 80 K gave a spectrum with a central set of features between 3100 and 3800 Gauss (microwave frequency, $\nu$ = 9.36947 GHz) and a weak feature at 1690 Gauss (microwave frequency, $\nu$ = 9.36583 GHz). The experiment was repeated with the spin-echo technique at 25 K, which confirmed the CW EPR results. In both cases, the central region appeared to comprise weak wing features at 3150 and 3750 Gauss, shoulders at 3125 and 3575 Gauss, and a peak at 3460 Gauss, relative to $\nu$ = 9.4181 GHz. After refinements in sample preparation had been made, the 3150 and 3575-Gauss features were eliminated. Please note the $g$-value representation of the central region of the spectrum as presented in Figure 1, as the derivative of EPR absorption with respect to the field. An integral (absorption vs.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

field) of the EPR spectrum in this region is shown in Figure 2. The low-field part of the EPR spectrum is shown in Figure 3.

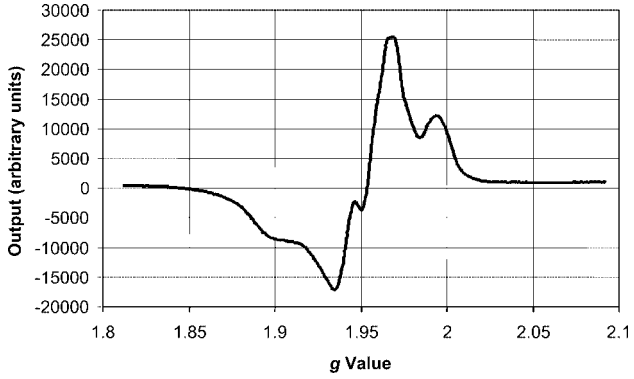


Figure 1. CW EPR derivative spectrum of a 0.7 mM frozen 1:1 hexane/toluene solution of titanium isopropoxide at 50 K as a function of $g$ value in the $g$ = 2 region.

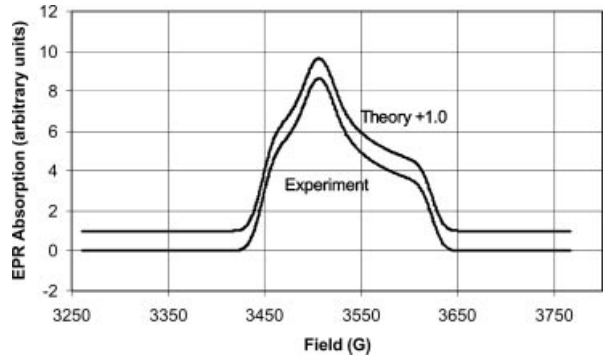

Figure 2. CW EPR absorption spectrum of a 0.7 mM frozen 1:1 hexane/toluene solution of titanium isopropoxide at 50 K, experiment and theory at microwave frequency 9.54971 GHz. (The normal derivative output of the EPR spectrometer has been numerically integrated.).

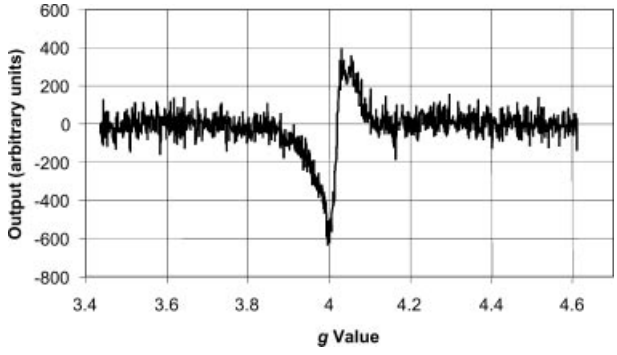

Figure 3. CW EPR derivative spectrum of a 0.7 mM frozen 1:1 hexane/toluene solution of titanium isopropoxide at 50 K as a function of $g$ value in the $g$ = 4 region.

Dilution experiments were done in order to try to understand the relationships between the several features observed in the CW EPR solution spectrum (not shown) and to consider the possibility that various oligomers of titanium(II) isopropoxide were being observed. Four sets of dilution experiments at nominal monomeric titanium(II) isopropoxide concentrations of 20.0, 7.0, 2.0, and 0.7 mM were done with successively greater refinements in the procedures. The sharp line at $g$ = 1.964 observed at 20.0 and 7.0 mM was largely eliminated with this improved procedure. The complex set of weak lines around $g$ = 1.98 initially observed at all concentrations except 0.7 mM was eliminated by means of the improved technique at all concentrations except 20.0 mM. The intensity of the triplet signal varies approximately in a linear dependence with the concentration, once the complex at $g$ = 1.98 disappears upon dilution.

## Analysis of the Observed EPR Spectra of Titanium Diisopropoxide (7)

The central part of the frozen solution spectrum, shown in integral form in Figure 2, is characteristic of a powder pattern of a molecular triplet state. The so-called half-field feature shown in the frozen solution spectrum of Figure 3 is located at a field consistent with a weakly allowed $\Delta m_s = \pm 2$ transition between the levels of a triplet state under the influence of the dipole–dipole interaction of the unpaired triplet-state electrons.[8] The parameters determined with the following triplet-state spin Hamiltonian [Equation ()] are given in Table 1.

$$\mathbf{H} = H\cdot g\cdot S + DS_z^2 + E(S_x^2 - S_y^2) \quad (4)$$

Table 1. Spin Hamiltonian parameters obtained from a least-squares fit of the parameters in Equation (4) to the titanium diisopropoxide frozen solution in Figure 2. (The standard deviations $\sigma$ in the parameters are also presented. The absolute signs of $D$ and $E$ are unknown but their relative signs are opposite.).

| | Value | $\sigma$ |
|---|---|---|
| $D$ ($10^{-4}$ cm$^{-1}$ $hc$) | ±81.7 | 1.8 |
| $E$ ($10^{-4}$ cm$^{-1}$ $hc$) | ∓23.1 | 0.2 |
| $g_{xx}$ | 1.9293 | 0.0002 |
| $g_{yy}$ | 1.9449 | 0.0002 |
| $g_{zz}$ | 1.9304 | 0.0002 |
| $\Delta H$ (Gauss) | 18.7 | 0.5 |

The $g$ value (1.944) of the broad strong line in the solution spectrum (not shown) is the same as that of the triplet molecule. Thus the solution spectrum is believed to be the motionally averaged spectrum of the powder pattern of the triplet molecule observed at lower temperatures (See Figure 2). The relatively smaller $g$-shift of the complexes giving the variable set of lines at $g$ = 1.98 suggests that these are radicals free of a Ti center. In the most highly refined dilution spectra it appears that the only highly concentration-dependent spectrum is that of the non-Ti-containing complex. It would appear that the triplet spectrum associated with Ti at $g$ = 1.944 is present at all concentrations and its spectrum does not change appreciably with concentration. Its intensity scales approximately with concentration, once the complex at $g$ = 1.98 disappears upon dilution.

Ignoring the $E$ value for the moment, the $D$ value alone corresponds to the dipolar interaction of two point-electron spins on titanium atoms at a distance of 0.668 nm.[9] Since

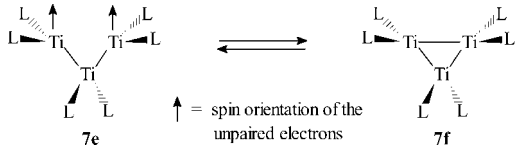
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

this Ti–Ti separation is more than twice the titanium atom separation in the $[Ti_3]$ cluster found in $Na_2Ti_3Cl_8$, the unpaired electrons are clearly not on the same Ti center or unlikely even on adjacent Ti centers. The nonzero $E$ value rules out a symmetric trigonal (equilateral) array, such as the $[Ti_3]$ cluster[10] for which $E = 0$ by symmetry.

Quantitative estimates of the triplet component(s) present in samples with 0.7, 2.0, 7.0, and 20.0 mM Ti content gave an average of $0.28 \pm 0.14$ triplet spins per Ti atom. Although within one standard deviation such a value is not consistent with triplet spins on the same Ti atom (1.0) or on adjacent Ti atoms (0.50). However, this value is in agreement with three Ti atoms per triplet molecule (0.33). Of course, this value is also consistent with four (0.25), five (0.20), six (0.17), or seven (0.14) Ti atoms per triplet molecule. This outcome supports the conclusion that a determination of the number of Ti atoms per triple molecule, measured with a precision typical of such experiments, cannot by itself be expected to determine the specific number of Ti atoms per Ti cluster.

### Comparison of the EPR Data for Titanium(II) Diisopropoxide (7) with Various Structural Models

A continuum of titanium(II) isopropoxide oligomers come under consideration (**7a**–**7d**, arrow = relative orientation of electron spin). From the $D$ and $E$ values, monomer **7a** and diamagnetic trimer **7d** can be excluded from further consideration. From the $D$ values alone the Ti–Ti distance in **7b** (0.2996 nm) is too short, and even a linear trimer of **7c** ($\theta = 180°$) falls short (0.599 nm) of the calculated experimental value of 0.668 nm (see Figure 4). The linear tetramer of **7** would lead to a $D$ value of 0.8988; however, the substantial value of $E$ is not predicted by a range of models reproducing the value of $D$, including one with parallel $p$-type orbitals simulated by point spins on terminal Ti atoms, a model with a twist angle between the terminal Ti $p$-type orbitals, and a model with in-plane $p$-type point spins and a Ti–Ti–Ti bond angle $\theta = 105°$. This failure in prediction suggests that there may also be one-center dipole–dipole contributions from different orbitals for different spin contributions or spin-orbit contributions to the zero-field parameters of Equation (4). The $D$ value and the nonzero $E$ value suggest a structure differing fundamentally in two respects from that of the $[Ti_3]^{6+}$ cluster found by Hinz et al. in $Na_2Ti_3Cl_8$ at low temperatures.[10] The $D$ value suggests a greater average triplet electron separation than the ≤0.2996 nm value in the $[Ti_3]^{6+}$ cluster. The nonzero $E$ value rules out a symmetric trigonal structure, such as was found for the $[Ti_3]^{6+}$ cluster, for which $E = 0$ by symmetry. Thus, with all factors considered, the structural model most in accord with the EPR data would appear to be **7c**, where $\theta$ approaches 180°, and the individual Ti–Ti bonds are lengthened to greater than 0.2996 nm by the steric repulsion of the isopropoxy groups attached to adjacent titanium centers (**7e**, L = O*i*Pr) (See Figure 4). The same steric bulk of the isopropoxy groups would weaken any coordination of THF units to Ti centers, as well as hindering spin-pairing and closure to the symmetrical $[Ti_3]$ cluster **7f** [Equation (5)].



**7e** **7f** (5)

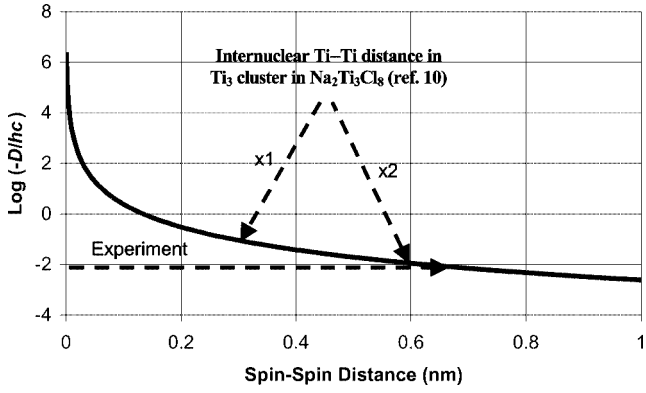


Figure 4. Logarithmic plot of the $D$ values as a function of point-spin–point-spin distance, according to a simple dipole-dipole model placing the spins on terminal Ti atoms. On this plot, the experimentally measured value of $D$ is indicated in relation to multiples of the Ti–Ti internuclear distance in the $Ti_3$ cluster reported by Hinz and co-workers.[10]

The tendency of divalent titanium centers to form trimeric Ti clusters, as in the solid state of $Na_2Ti_3Cl_8$[10] and as here in solutions of $Ti(OiPr)_2$ (**7**), encourages us to suggest that diamagnetic $TiCl_2$·2THF (**5**·2THF) may exist in solution as the cyclic symmetrical structure **7f**, (L = Cl), in which each Ti center, because of the smaller, electronegative chlorine ligand, could further accommodate two THF ligands and thereby attain octahedral coordination. The possible existence of cyclic and open-chain trimeric clusters of **7e** and **7f** (L = Cl) will be probed by EPR measurements of $TiCl_2$·2THF conducted at higher temperatures.[11]

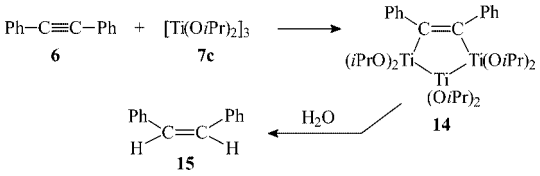
### Structure of Titanium(II) Diisopropoxide (7) Implied by Its Chemical Reactions

In both $[Ti(OiPr)_2]_3$ and $[TiCl_2$·2THF$]_3$, it is readily apparent that the monomeric $TiL_2$ unit, necessary for the epi-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

titanation of unsaturated organic ligands [Equation (1)], would require considerable activation energy to be liberated from its trimer, and thus such direct epititanations [Equation (1)] would understandably be slower than transfer-epititanations [Equation (3)].

Moreover, certain reactions of $Ti(OiPr)_2$ (**7**) with organic substrates, as reported in this study, follow pathways consistent with the participation mainly of the trimeric biradical **7c**. For example, with 1 equiv. of diphenylacetylene (**6**) and 2 equiv. of **7**, the addition reaction leading to *cis*-stilbene (**15**) upon hydrolysis proceeded to the extent of 30% at 25 °C. When a similar reaction mixture was heated at reflux, the reaction went only to an extent of 74%, despite the presence of an excess of **7**. Now, if the 2 equiv. of **7** is actually present as trimer **7c**, then the 0.67 equiv. of **7c** could react with only 0.67 equiv. of **6**, close to the observed 0.74 equiv. of **6** consumed. Thus, we conclude that the addition reaction to **6** should be described as involving mostly attack by **7c** [Equation (6)] to form **14**. Hydrolysis would then yield **15** or with $D_2O$, 1,2-dideuterio-*cis*-stilbene (**9**), as is observed.

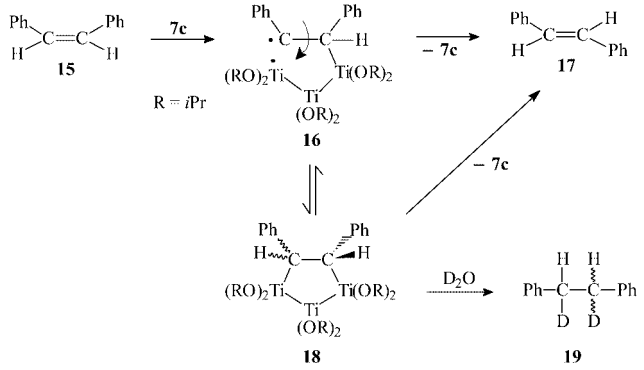


(6)

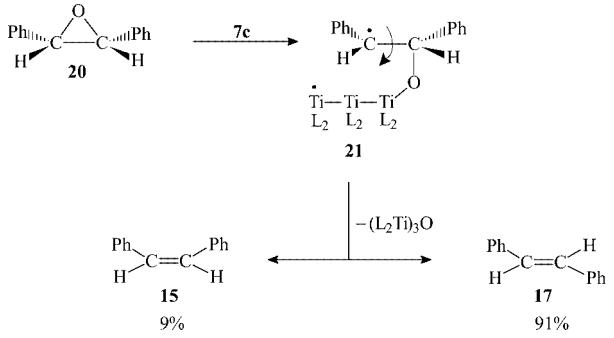
Two other reactions giving evidence for the participation of biradical **7c** directly are those involving *cis*-stilbene (**15**) itself and *cis*-stilbene oxide (**20**). Regardless of how long and at what temperature the reaction proceeded and whether **7** contained LiO*i*Pr or not, the main reaction of a 1:2 equiv. ratio of **15** and **7**, as revealed by hydrolysis, was isomerization to *trans*-stilbene (**17**), rather than addition to form **18** (detected as deuteriolysis product **19**). Workup with $D_2O$ produced 1,2-dideuteriobibenzyl (**19**), consistent with its formation from organotitanium precursor **18**. Again, we suggest that the 0.67 equiv. of trimer **7c** is operative, as shown in Scheme 2. The *trans*-stilbene could be formed directly from **16** by reeliminating **7c** or from **18** by stepwise Ti–C bond homolysis. In the conversion of **16** into **17**, the greater thermodynamic stability of **17** over **15** (about 91:9) should favor the formation of the *trans* isomer.

In a similar manner, the deoxygenation of *cis*-stilbene oxide (**20**) by **7** to give the thermodynamic mixture of *trans*- and *cis*-stilbenes (**17** and **15**) in a 91:9 ratio is consistent with the stepwise attack of biradical **7c** on **20** to form an acyclic biradical intermediate **21**. Biradical **21** could exist sufficiently long to permit rotation about the C–C bond before the second Ti–C bond undergoes induced homolysis and thereby produces the thermodynamic mixture of **15** and **17** (Scheme 3).

The first indication that the isopropoxy ligand exerts an activating effect on titanium(II), over that observed with the chloro ligand, was the faster direct epimetallating action of the $Ti(OiPr)_2/2LiOiPr$ system on diphenylacetylene (**6**) over



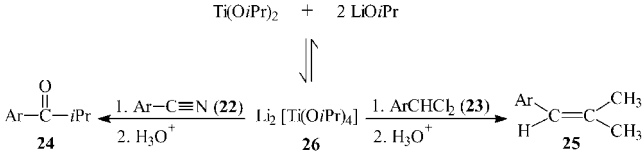
Scheme 2.



Scheme 3.

that of the similar $TiCl_2/2LiCl$ reagent (**5**) on **6** [Equation (2) and related text]. The greater reactivity of **7** over **5** has been ascribed to the electron-withdrawal effect of the isopropoxy groups already bonded in **7**, as well as any isopropoxy anions (from the LiO*i*Pr) that may also coordinate with the $Ti(OiPr)_2$ with the formation of complex titanium(II) anions, such as $[Ti(OiPr)_4]^{2-}$.[12]

A final previously studied reaction of **7** that clearly involves the participation of radical intermediates in SET (Single Electron Transfer) processes and implicates the byproduct LiO*i*Pr as an essential coreactant, is the reaction of **7** with aromatic nitriles (**22**) or geminal dichlorides (**23**), as shown in Scheme 4. The hydrolysis products, **24** and **25** respectively, had individually resulted from a reductive isopropylation. Since $Ti(OiPr)_2$ containing *no LiOiPr byproduct* (only LiCl) was *unable* to bring about such a reaction, the necessary SET reagent was proposed to be **26**, a complex of LiO*i*Pr with the supposed monomer $Ti(OiPr)_2$.[12]

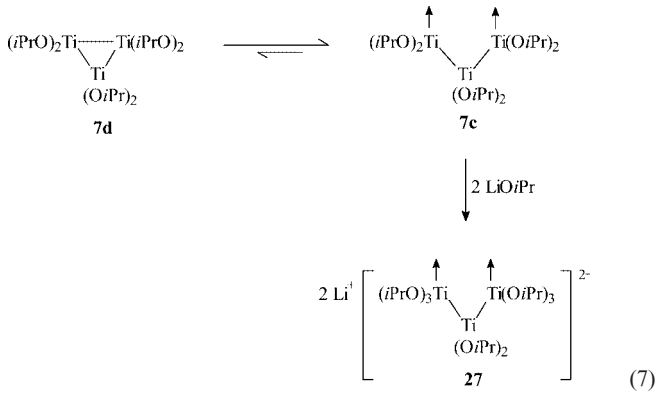


Scheme 4.

With the new structural insight into the nature of **7** offered by the present study, we would now propose that trimeric **7c** or **7d** undergoes coordination with one or more equivalents of LiO*i*Pr to form anionic coordination com-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plex(es), such as **27** [Equation (7)]. The coordination of the LiO*i*Pr with adjacent Ti atoms in **7d** or terminal Ti atoms in **7c** would tend to force the Ti trimer into the open-chain dianionic biradical **27**. Therefore, we can deduce from this chemical evidence that a mixture of **7** and LiO*i*Pr most likely exists in solution as one or more coordination complexes of the type depicted in **27**.



(7)

A corollary deduction of these considerations is that highly pure titanium(II) diisopropoxide, absolutely free of coordinating anions, such as from LiO*i*Pr or LiCl, and perhaps even free of coordinating solvents such as THF, might well exist at lower temperatures as the diamagnetic trimer **7d**. This possibility is currently under investigation.[11]

## Conclusions

In summary, the EPR experiments show that a Ti-containing molecular triplet state is formed in solution from the reaction of 2 equiv. of butyllithium with 1 equiv. of titanium(IV) isopropoxide. At high concentrations this product, titanium(II) isopropoxide, admixed with 2 equiv. of lithium isopropoxide, is accompanied by the formation of a variety of non-Ti-containing side products. The powder EPR spectrum of the molecular triplet state in frozen solution is consistent with an asymmetric molecule or chain of three Ti centers on which the unpaired electron centers are most probably three centers apart. Dilution experiments show that at lower concentrations, where the non-Ti-containing side products have dissipated, the molecular triplet spectrum intensity varies approximately linearly with concentration. Thus there is no evidence that the observed triplet molecule is one component in a series of concentration-dependent oligomerization steps. Coordination of this open-chain, three-titanium cluster with the lithium isopropoxide byproduct would, for steric reasons, tend to keep such anions in their open-chain biradical form. This steric hindrance for the terminal diisopropoxytitanium centers closing to a ring seems not to be observed with $TiCl_2$·2THF, which is diamagnetic and may thus exist as an equilateral triangular cluster of three units of $TiCl_2$·2THF. The smaller steric demand of the chloro and THF units may permit octahedral coordination about each Ti center in such a trigonal array of $Ti_3$ atoms.

Finally, chemical reactions carried out individually with diphenylacetylene, *cis*-stilbene, or *cis*-stilbene oxide and titanium(II) isopropoxide provide stoichiometric and stereochemical evidence that the attacking titanium(II) reagent is in fact the trimeric biradical **7c**, rather than some monomeric form of titanium(II) isopropoxide. The previously reported SET reductive isopropylation of aromatic nitriles and geminal dichlorides is reinterpreted in light of this new evidence on the structure of titanium(II) isopropoxide, and the essential role of lithium isopropoxide in shaping the detailed structure of the trimeric titanium biradical is explicated.

## Experimental Section

### Starting Materials, Reaction Conditions, and Instrumentation

The starting $TiCl_4$ and Ti(O*i*Pr)$_4$ employed were of 98% or greater purity as commercially available, and the *n*-butyllithium used was as a 1.60-M solution in hexane. All reactions, transfers, and separations were carried out under a positive pressure of anhydrous, oxygen-free argon. All solvents, mainly tetrahydrofuran, heptane, and toluene, employed with these air- and moisture-sensitive reagents were dried and distilled from a mixture of sodium metal and benzophenone ketyl prior to use.[13] The $^1$H- and $^{13}$C NMR spectra were recorded with a Bruker spectrometer, model EM-360, with tetramethylsilane ($Me_4Si$) as the internal standard. The chemical shifts reported are expressed on the $\delta$-scale in parts per million (ppm) from the $Me_4Si$ reference signal.

The electron paramagnetic spectra (EPR) measurements were performed with a Bruker EPR spectrometer, model ESP580 X-band, equipped with a split-ring ER4AA9 resonator and were detected with 100-kHz field modulation and phase-sensitive detection. Temperatures below room temperature were achieved with an Oxford Instruments CF935 cryostat and an ITC502 temperature controller. Two types of EPR experiments were performed on solutions of the divalent titanium derivatives in THF, heptane, or 1:1 (v/v) heptane/toluene mixtures: (1) CW EPR scans of various widths (200–1000 Gauss) were performed at room temperature (20–25 °C), mainly about fields corresponding to $g = 2$, and similar CW EPR experiments were performed with solutions flash-frozen at 50 K or 80 K; and then (2) a Hahn-echo detected, pulsed EPR spectrum was acquired at 20 K. Quantitative estimates of the concentrations of paramagnetic components present in the samples were obtained by comparison with the spectrum of a freshly prepared 1.032-mM standard solution of 1,1-diphenyl-2-picrylhydrazyl.

**Preparation of Titanium(II) Isopropoxide (7, containing LiO*i*Pr):** In a typical procedure on a 10-mmol scale, a solution of titanium(IV) isopropoxide (1.28 g, 10 mmol) in THF (40 mL) and cooled to –78 °C was slowly treated with *n*-butyllithium (12.5 mL, 1.6 M) in hexane (20 mmol) in an argon atmosphere. Stirring the light-brown mixture for 2 h at this temperature and then warming to 25 °C over 10 h gave a black, completely soluble mixture of titanium(II) diisopropoxide (**7**) containing lithium isopropoxide (2 equiv.). This THF solution measured directly gave a strong EPR signal (cf. Results) and was employed for reactions with diphenylacetylene (**6**), with *cis*-stilbene (**15**) and with *cis*-stilbene oxide (**20**).[12]

Upon removal of all volatiles from THF solutions of **7** and redissolving the residue in heptane or 1:1 mixtures of heptane and toluene (v/v), black complete solutions of the 1:2 mixtures of **7** and LiO*i*Pr resulted. For EPR studies, solutions of **7** in a 1:1 heptane/

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

toluene mixture were prepared individually at concentrations of 20.0, 7.0, 2.0, and 0.7 mM. That the THF had been completely removed was indicated by $^1$H NMR spectra of these hydrocarbon solutions of **7**, which showed no $^1$H triplets of THF at $\delta$ = 3.72 and 1.84 ppm. Instead, only broad $^1$H signals of the isopropoxy group were evident at around 4.0 and 1.2 ppm. These hydrocarbon solutions also displayed strong EPR signals.

**Preparation of Titanium(II) Diisopropoxide (7, free of LiO*i*Pr):** To a stirred solution of titanium(IV) chloride (1.89 g, 10 mmol) in THF (40 mL), prepared and maintained under an argon atmosphere at –78 °C, in order to avoid cleavage of the THF ring by the $TiCl_4$, was added slowly with stirring *n*BuLi (2 equiv.) in hexane (12.5 mL, 1.6 M, 20 mmol), and the resulting mixture was stirred for 30 min. The di-*n*-butyltitanium(IV) dichloride thereby formed was then treated with isopropyl alcohol (2 equiv., 1.20 g, 20 mmol), also at –78 °C. The resulting mixture was warmed to 25 °C over 10 h, and the dark brown suspension of the proposed titanium(IV) dichloride diisopropoxide was cooled again to –78 °C. Finally, a further aliquot of *n*BuLi (2 equiv.) was added. A subsequent warming of this last reaction product gave a black solution of titanium(II) diisopropoxide from which the white LiCl slowly precipitated. Concentration and cooling of the solution permitted about 1.6 g (94%) of the LiCl to be removed. Thus the yield of titanium(II) seems to have been almost quantitative.[12]

The careful examination of such titanium(II) diisopropoxide solutions, which contain little LiO*i*Pr or LiCl, will have to await further refinements in mixing the reactants and filtering the solutions to remove suspected paramagnetic particles in suspension. It will be of great interest to learn whether solutions of absolutely pure titanium(II) diisopropoxide show any EPR activity. Such information will be valuable in determining what the role of LiO*i*Pr in influencing the triplet character of trimeric clusters of $[Ti(OiPr)_2]_3$, commingled with LiO*i*Pr.

**Preparation of Titanium(II) Chloride (5):** In a procedure analogous to the foregoing, a stirred solution of titanium(IV) chloride (1.89 g, 10 mmol) in THF (40 mL) was treated at –78 °C under argon with *n*-butyllithium (20 mmol) in hexane. Further stirring at –78 °C and warming to 25 °C yielded a gray-black suspension of titanium(II) chloride (**5**) and lithium chloride as a 1:2 mixture. The resulting black solution of **5** with suspended LiCl showed no EPR signal, either at 25 °C or at lower temperatures.

As already has been published,[14] titanium(II) chloride (**5**) can be isolated free of LiCl from the suspension in THF by removing the THF and all volatiles under reduced pressure in argon. The residue is then slurried with toluene, and the suspension is filtered to remove all the LiCl. The filtrate is concentrated and chilled, in order to deposit black crystals, whose analysis corresponds to a 1:2 ratio of Ti/Cl and a Ti analysis agreeing with the empirical formula of $TiCl_2$·THF (**5**). Solutions of **5** in toluene again showed no EPR signal either at room temperature or at 80 K.

**Reactions of Titanium(II) Isopropoxide with *cis*-Stilbene (15)**

(1) The reaction of **15** (5.0 mmol, 0.89 mL) with **7** (10 mmol, containing LiO*i*Pr) in THF (30 mL) for 24 h gave a product (880 mg) after hydrolytic workup with aqueous HCl (6 N) and extraction of the organic products into ethyl ether, drying of the ether with $Na_2SO_4$, and removal of volatiles by rotary evaporation. Analysis of the product by $^1$H NMR spectroscopy showed the presence of 35% of *trans*-stilbene (**17**), 25% of bibenzyl, and 40% of the starting **15**.

(2) A reaction identical to that given above, except that **7** did not contain any LiO*i*Pr, produced a somewhat greater amount of isomerization of *cis*-stilbene: 50% of *trans*-stilbene (**17**), 15% of bibenzyl, and 35% of the starting **15**.

(3) A reaction identical to run (1), except that a 3-h reflux period was included, yielded 64% of *trans*-stilbene (**17**), 27% of bibenzyl, and 9% of the starting **15**.

(4) One-half of the reaction mixture in run (3) was worked up with $D_2O$ (min. 98%). The *cis*- and *trans*-stilbenes were found to contain no deuterium, but the bibenzyl was found to be 1,2-dideuteriated (PhCHD-CHDPh, **19**).

**Diphenylacetylene (6)**

(1) A solution of **6** (5.0 mmol, 890 mg) and **7** (10 mmol, containing LiO*i*Pr) in THF (40 mL) was heated at reflux for 12 h and then subjected to the usual hydrolytic workup. Flash column chromatography of the product by using a 60:1 (v/v) hexane/THF mixture showed the presence of 74% of *cis*-stilbene (**15**), 5% of bibenzyl, 1% of hexaphenylbenzene, and 20% of the starting **6**.

(2) A reaction mixture identical with the foregoing was stirred for 24 h at 25 °C. Hydrolysis and a similar $^1$H NMR analysis revealed the presence of only 30% of *cis*-stilbene (**15**) and 5% of bibenzyl, the rest being unreacted **6**. A deuteriolytic workup produced exclusively *cis*-1,2-dideuterio-*cis*-stilbene (**9**, with deuterons at the vinyl carbons).

(3) A reaction mixture treated as in run (2), except that **7** did not contain any LiO*i*Pr, gave again 31% of **15** and 4% of bibenzyl, essentially in the same product ratio as in section (2).

***cis*-Stilbene Oxide (20):** A mixture of **20** (5.0 mmol) and **7** (10 mmol) in THF (30 mL) was allowed to react for 12 h at 25 °C. Hydrolytic workup and $^1$H NMR analysis of the flash-chromatography eluate obtained with a 60:1 (v/v) mixture of hexane/THF showed the presence of 91% of *trans*-stilbene (**17**) and 9% of its *cis* isomer (**15**).

## Acknowledgments

The authors are grateful to the Boulder Scientific Company, Mead, Colorado, for the general support of their research with transition-metal alkyls and to the Alexander von Humboldt Foundation for a Senior Scientist Award to the first-cited author, renewed in 2005 for studies in the laboratory of Professor W. A. Herrmann, Institute of Inorganic Chemistry, Technische Universität München, Munich, Germany.
Furthermore, they thank the Regional Facility for Pulsed EPR and Photochemistry at Binghamton University, established with National Science Foundation support (CHE9512274), for its services in performing the EPR experiments.

# Study of Thermodynamic and Kinetic Stability of Transition Metal and Lanthanide Complexes of DTPA Analogues with a Phosphorus Acid Pendant Arm

**Jan Kotek,*[a,c] Ferenc K. Kálmán,[b] Petr Hermann,[a] Ernő Brücher,[b] Koen Binnemans,[c] and Ivan Lukeš[a]**

**Keywords:** Phosphonate complexes / Phosphinate complexes / MRI contrast agents / Kinetics / Thermodynamics

The thermodynamic and kinetic stabilities of the complexes of phosphonate and phenylphosphinate analogues of $H_5$dtpa with selected transition- and lanthanide-metal ions are presented. Both phosphorus-containing ligands form thermodynamically very stable complexes, with stability constants comparable with or even higher than those reported for the parent $H_5$dtpa. However, the kinetic inertness of their gadolinium(III) complexes against acid- and metal-assisted decomplexations is surprisingly much lower. The half-life times of gadolinium(III) complexes of the new ligands in the presence of excess of concurrent metal ions [copper(II) or europium(III)] are about 2–3 orders of magnitude shorter compared to $H_5$dtpa and its amide derivatives. The behaviour can probably be attributed to steric strain in the new complexes, to the high affinity of phosphonate ligand for proton, and/or to easy formation of binuclear complexes, which act as intermediates in the complex dissociation.

## Introduction

Multidentate ligands and their complexes are frequently used in medicine. Gadolinium(III) complexes of octadentate ligands having the ninth coordination site occupied with a water molecule are utilized as contrast agents (CA) in magnetic resonance imaging (MRI).[1–3] As such toxic-metal-containing contrast agents have to be administered in relatively high doses, the gadolinium(III) ion must be encapsulated in stable complexes. These must survive with no decomplexation in body fluids containing many concurrent ligands (amino acids, phosphate anion, peptides etc.) and metal ions (e.g. $Ca^{2+}$, $Zn^{2+}$, $Cu^{2+}$). Ligands whose complexes fulfil such stability requirements are mostly derivatives of two prototype ligands (Scheme 1) – macrocyclic 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid ($H_4$dota) and acyclic diethylenetriaminepentaacetic acid ($H_5$dtpa, 1,4,7-triazaheptane-1,1,4,7,7-pentaacetic acid). In vivo stability of the complexes may be estimated from thermodynamic and kinetic properties. The thermodynamic stability of metal complexes of $H_5$dtpa and $H_4$dota (expressed as stability constants) is very high. Ligands derived from the linear ligand $H_5$dtpa are in general much cheaper and more easily available than derivatives of the macrocyclic $H_4$dota. However, the resistance of complexes of macrocyclic ligands against decomplexation in body fluids (measured e.g. as acid- or metal-assisted dissociations) is usually much higher.[4,5]

According to theory, the water molecule which saturates the coordination sphere of the central $Gd^{3+}$ ion should be bound in the complex for an optimal residence time before exchange with bulk water. The residence time should lay in the range of 20–30 ns for MRI contrast agents used at magnetic fields applied in commercial tomographs, and in addition, the molecular tumbling of the CA should be as slow as possible.[1–3,6] However, the complexes of $H_4$dota and $H_5$dtpa themselves are far from such optimum.[7] In the search for better MRI contrast agents, sterically crowded ligands were developed as the enhanced steric strain around metal-binding site increases the exchange rate of coordinated water molecule. The steric strain was usually reached by introduction of one extra methylene group into the backbone (propylene group instead of ethylene bridge) or in one of the pendant arms (i.e. with propionate pendant instead of acetate),[8–11] or by substitution of ligand backbone by alkyl/aryl group.[12,13] The complexes formed with these new ligands are thermodynamically usually slightly less stable than those of $H_4$dota and $H_5$dtpa.[9,10,14,15] Unfortunately, no detailed kinetic studies are available in the literature for these complexes.

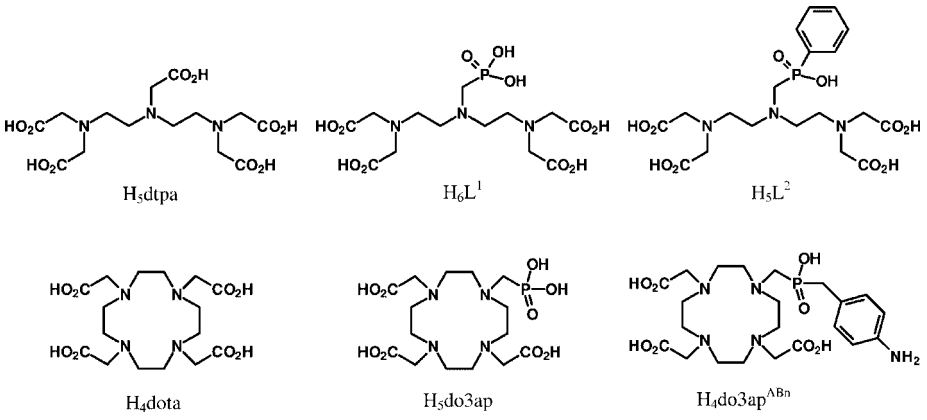

Scheme 1. Structural formulas of the ligands mentioned in the text.

To contribute to this field, we prepared several analogues of $H_4$dota and $H_5$dtpa having a bulkier phosphorus acid pendant moiety instead of the carboxylate group. The corresponding lanthanide(III) complexes of the linear ligands $H_6L^1$ and $H_5L^2$ (Scheme 1) have been studied by NMR and relaxometry.[16] It was shown, that the water-exchange rate is much higher for the complexes with phosphorus-containing ligands than what was reported for the complexes of $H_5$dtpa and its amides. Noticeable acceleration of water exchange was observed also for macrocyclic ligands with one phosphorus-based pendant arm (e.g. $H_5$do3ap or $H_4$do3ap$^{ABn}$, Scheme 1) comparing to $H_4$dota.[17,18] Furthermore, the relatively easy substitution on the phosphorus atom offers the possibility to attach the complex to a macromolecular carrier,[19–21] or to bind it non-covalently to plasma proteins (e.g. by hydrophobic interactions).[16] Here we report on the thermodynamic and kinetic stability studies of the complexes of two linear ligands – phosphonate and phenylphosphinate derivatives $H_6L^1$ and $H_5L^2$, respectively (Scheme 1) – with selected divalent transition and trivalent lanthanide metal ions.

## Results and Discussion

### Crystal Structure of $H_6L^1 \cdot HCl \cdot 1.5H_2O$

In the crystal structure, a molecule of the ligand is present in the charged sevenfold-protonated form $(H_7L^1)^+$ (Figure 1). All the nitrogen atoms of the backbone are protonated together with one oxygen atom of the phosphonate moiety (O1) and three carboxylate oxygen atoms (O111, O211 and O311). The geometry around the phosphorus atom is tetrahedral, with noticeably longer P–O bond to the protonated oxygen O1 comparing to others (Table 1). One chloride anion serves as counterion. Additionally, two water molecules were found in the structure, but one of them (O2W) is best refined with a half-occupancy. Molecules of the ligand are connected by short hydrogen bonds (2.45–

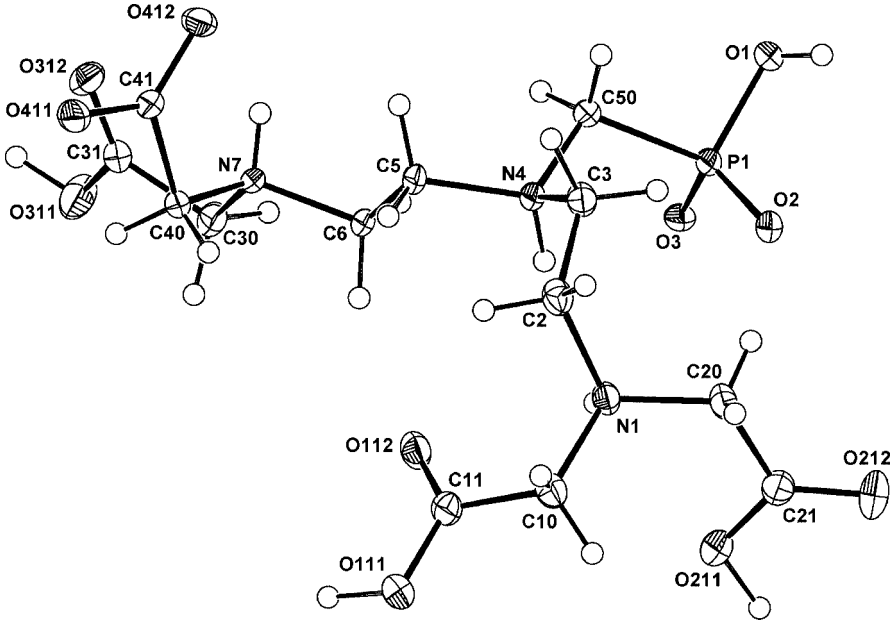

Figure 1. Molecular structure of $(H_7L^1)^+$ with atom numbering scheme.

2.65 Å) between protonated and unprotonated oxygen atoms of acetate and phosphonate moieties. Furthermore, the protonated amino groups are also involved in rather strong (2.64–2.77 Å) hydrogen binding to oxygen atoms of neighbouring ligand molecules. Additionally, the solvate water molecules and chloride anion bind each other (3.04–3.20 Å), and also the water molecule O1W has a short contact to protonated carboxylate oxygen atom O311 (Table S1).

## Equilibrium Studies

The protonation and complexation equilibrium were studied by conventional potentiometry. Table 2 lists the protonation constants of concerned ligands together with those of $H_5$dtpa. Distribution diagrams of $H_6L^1$ and $H_5L^2$ are shown in Figure S1 (supporting information; for supp. inf. see also the footnote on the first page of this article. As polydentate aminocarboxylic acids can form relatively strong complexes with alkali metal ions, the potentiometric studies were performed using tetramethylammonium chloride (TMAC) as a background electrolyte. Indeed, the determined values of the highest protonation constants are systematically higher than those reported previously,[16] which were obtained by NMR and are lower as a consequence of sodium(I)-induced deprotonation (Table 2). A similar trend was observed also for $H_5$dtpa, where constant $\log\beta_1$ determined with NaCl as the supporting electrolyte is about one order of magnitude lower (9.45[22]) than that measured in TMAC (10.41,[22] Table 2). Accordingly to NMR-assigned sites of protonations[16] and well-known protonation Scheme of $H_5$dtpa itself,[23] the first and second protonations take place on the nitrogen atoms of the ligand backbone. In the case of the phosphonate ligand $H_6L^1$, the third protonation ($pK_A$ = 7.57) corresponds to the protonation of the phosphonate moiety. Other protonations have $pK_A$'s values close to each other and correspond to the carboxylate pendants. Deprotonation of the singly protonated phosphonate ligand $(HL^1)^{5-}$ occurs at very high pH ($pK_A$ = 11.82) comparing to the phosphinate derivative and $H_5$dtpa ($pK_A$'s 10.28 and 10.41, respectively), as a result of spreading of high electron density of fully deprotonated phosphonate (charge 2–) to the neighbouring nitrogen atom. This trend is usually observed for analogous aminocarboxylic/phosphorus acid derivatives.[24] The potentiometric data of the ligand/metal mixtures were best fitted according to a model employing the formation of 1:1 and 1:2 ligand-to-metal complexes in various protonation states. The resulting stability constants of the complexes are compiled in Tables 3, 4, 5 and 6. In the case of 1:1 complexes with the transition-metal ions $Cu^{2+}$ and $Zn^{2+}$, all nitrogen atoms of the ligands are probably coordinated to the metal ion, and no free metal ions are present in the mixtures above pH ≈ 2.7. As usual, the coordination number of transition metal ions is 6, and the hapticity of the ligands studied is higher (8), the coordination sphere of the central metal ion is closed by two or three oxygen atoms of the pendant arms and some pendants remain uncoordinated (and can bind another metal ion in binuclear complexes, see below). The protonation of the $[M(L^1)]^{4-}$ species takes place on the phosphonate pendant moiety, which is probably coordinated (corresponding $pK_A$ slightly dropped comparing to the free ligand, 6.86 and 7.24 vs. 7.57, respectively). Other protonations takes place on oxygen atoms of the uncoordinated carboxylates ($pK_A$'s in range 1.37–3.97). Contrary, protonation of calcium(II) complexes takes place on the nitrogen atoms, as the corresponding $pK_A$'s are noticeably higher than that of acetates in the free ligands. In a twofold excess of the metal ion, complexes of $M_2L$ stoichiometry are formed. They loose additional two protons with increasing pH, forming bis(hydroxo) species. Because the corresponding dissociation constants are similar for both stepwise deprotonations [9.39 and 7.74 for copper(II) and 8.81 and 8.86 for zinc(II) complexes, respectively], these deprotonations occur almost simultaneously. The stability constant of the dinuclear species is lower, but still comparable to that of iminodiacetic acid, so the coordination of each

metal ion to these ligands is probably analogous. Therefore, one can suggest that both metal ions in the dinuclear complexes are coordinated separately by the opposite $H_2$ida-like sides of ligands and behave almost independently. The stabilities of these dinuclear complexes with transition-metal ions are comparable in the cases of $H_6L^1$ and $H_5$dtpa, but corresponding complexes of the phosphinate ligand are much less stable. However, stability of calcium(II) dinuclear complexes is comparable in all the cases (Table 6). Representative distribution diagrams of copper(II)/ligand systems are shown in Figures S2 and S3 (see Supporting Information).

Lanthanide(III) ions are usually fully encapsulated in eight coordinating atoms of $H_5$dtpa-like ligands. This coordination mode was also proved in the case of these phosphorus-containing ligands.[16] Therefore, protonations of their complexes occurs on non-coordinated oxygen atoms of the coordinated pendant moieties. In the case of the phosphonic ligand, first $pK_A$'s are in range 5.70–6.48, which corresponds to the deprotonation of the coordinated

phosphonate arm. Second protonations occur with $pK_A$'s in the range 2.3–3.2, comparable to that reported for complexes of $H_5$dtpa (1.9–2.6) and take place on carboxylate moieties. The phosphonate ligand forms relatively stable dinuclear complexes, which is probably a consequence of the high charge of the deprotonated phosphonate and its ability to bridge coordination polyhedrons (Table 6). Contrary, dinuclear complexes of the phenylphosphinate ligand and $H_5$dtpa itself are much less stable and were detected only in few cases due to a precipitation of metal hydroxides, which occurred in the other systems.

Representative distribution diagrams of gadolinium(III)/ligand systems are shown in Figure 2 and Figure 3. In the 1:1 mixtures, the $Gd^{3+}$ ion is fully encapsulated to the complexes above pH 3. Comparing the distributions simulated for twofold excess of the metal ion, the phosphonate ligand binds second $Gd^{3+}$ ion much better than the phosphinate, as a result of the higher negative charge of the ligand and the better possibility of the phosphonate to serve as a bridging group in the binuclear complexes (see parts B in Figures 2 and 3). Relatively high concentration of the free $Gd^{3+}$ ion in Figure 3 (B) at high pH values is not reasonable, and it is a result of the conditions used for the simulation. In

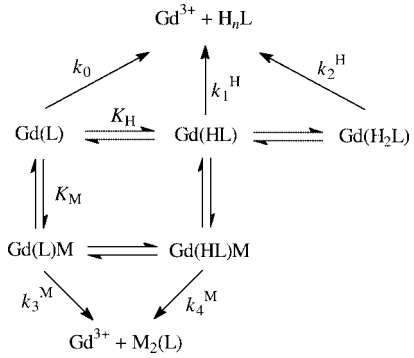
the real titration of $H_5L^2/Ln^{3+}$ systems, only 1.5-fold excess of hydrolyzable $Ln^{3+}$ ions was used and, therefore, the concentration of the free metal ions was suppressed.

Comparison of the determined stability constants of phosphorus acid derivatives with those found for $H_5$dtpa and $H_2$ida shows differences. The stability constants in $H_2$ida series follow the expected trend and increase from lanthanum(III) to lutetium(III). For $H_5$dtpa, the values increase from $La^{III}$ to $Eu^{III}$ and then are similar to the end of lanthanide series. For the phosphorus acid derivatives, the highest values were found for $Eu^{III}$ and $Gd^{III}$, and then decrease to $Lu^{III}$ and $Y^{III}$. These results indicate that size of the coordination cavity of $H_5$dtpa and its phosphorus acid derivatives is optimal for ions in the middle of lanthanide series. In contrast to the $H_5$dtpa, in the new ligands the phosphorus groups are too large and the ligands form bigger cavity which do not fit to the heavy lanthanides(III) or yttrium(III).

## Dissociation Kinetics

In preliminary experiments, the gadolinium(III) complexes with the new ligands were found to be much less stable against proton- and metal-assisted dissociations, comparing to the gadolinium(III) complex of $H_5$dtpa[26] and its mono- and bis-amides.[27,28] Therefore, the kinetic data had to be acquired by a stopped-flow technique. Dissociation reactions were performed in high excess (10–70×) of the concurrent metal ion ($Cu^{2+}$ or $Eu^{3+}$), ensuring pseudo-first-order reaction conditions, and in buffered solutions (pH in range 3.5–5.7). The dependences of the observed pseudo-first-order rate constants on the acidity of the solutions are shown in Figure 4, together with the best fits of the experimental data (for discussion of fittings see below).

For decomplexation of the gadolinium(III) complexes of $H_5$dtpa-like ligands, the general reaction Scheme is usually accepted,[26] where proton and metal-assisted pathways are taking place as shown in Scheme 2.



Scheme 2. Reaction mechanism of the dissociation of gadolinium(III) complexes of $H_5$dtpa-like ligands (charges are omitted for clarity).

Rearrangement of the corresponding rate law gives dependence of pseudo-first order constant $k_{obsd.}$ on proton and concurrent metal ion concentrations as given in Equation (1), similarly as it was evaluated for the fitting of dissociation kinetics of the $[Gd(dtpa)]^{2-}$ complex.[26] Here, the constants $K_H$ and $K_M$ are the protonation constant of the gadolinium(III) complex [Gd(HL)] and the stability constant for the mixed dinuclear gadolinium(III)-attacking metal-ion complex [Gd(L)M], respectively. The protonation and stability constants of $[Gd(H_2L)]$ and [Gd(HL)M] can be omitted from the denominator as the concentration of these complexes is negligible (the values of the corresponding constants are low).

$$k_{obsd.} = \frac{k_0 + k_1^H[H^+] + k_2^H[H^+]^2 + k_3^M[M^{n+}] + k_4^M[H^+][M^{n+}]}{1 + K_H[H^+] + K_M[M^{n+}]} \quad (1)$$

As $k_1^H$ and $k_2^H$ are independent of the nature of concurrent metal ion, the dissociation kinetics for copper(II) and europium(III) systems with the same starting gadolinium(III) complex were fitted simultaneously keeping these parameters identical in both cases. The results of these fittings are

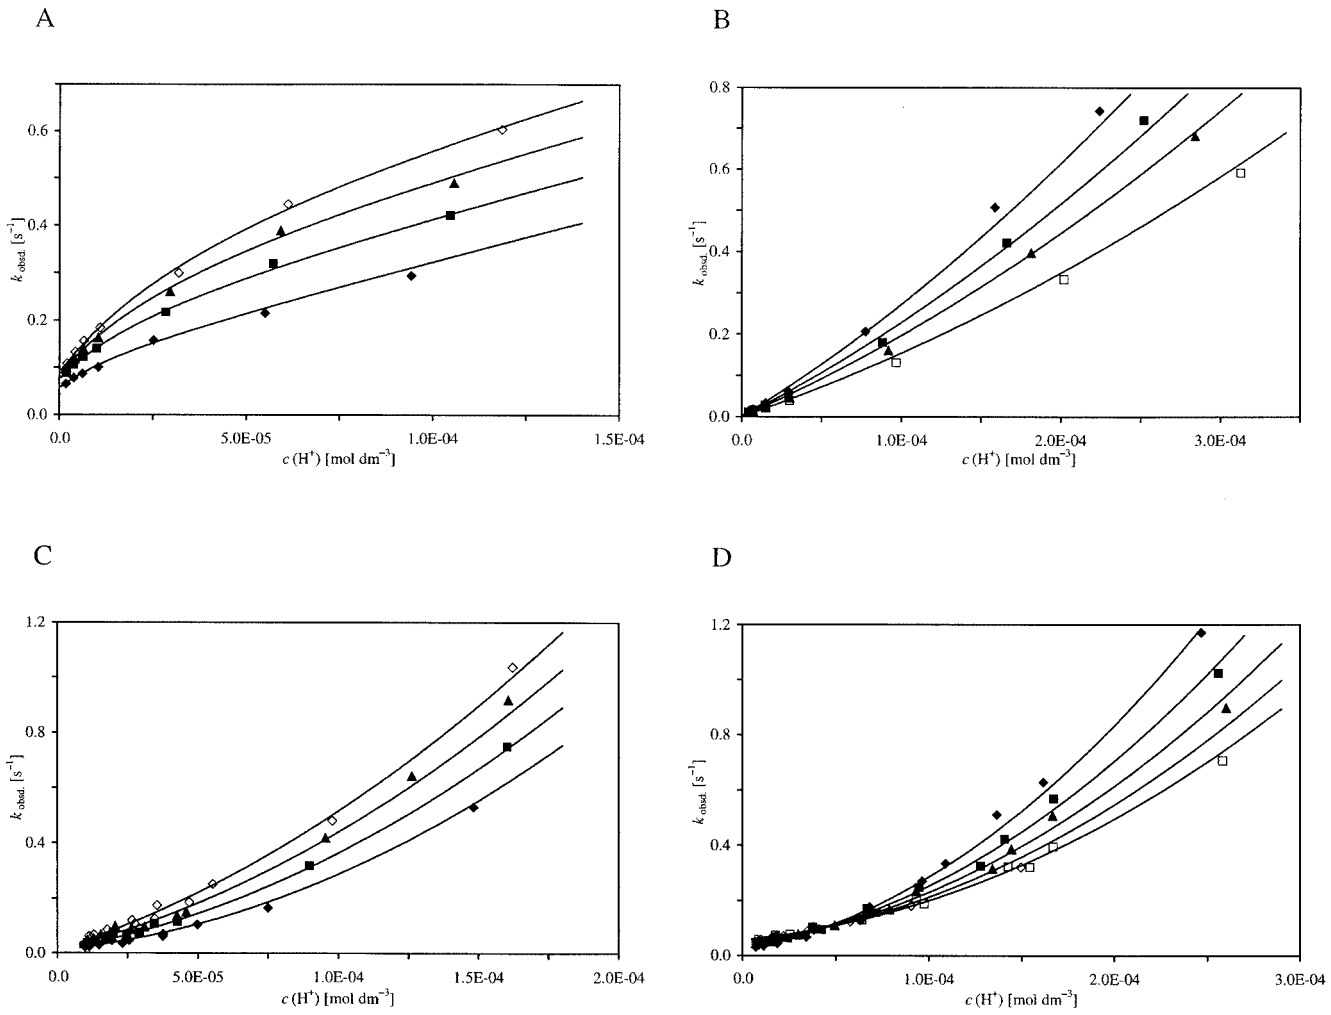

Figure 4. Dependence of pseudo-first-order rate constant $k_{obsd.}$ on proton and metal ion concentrations. Excess of the concurrent metal ion: 10×: full diamond; 20×: full square; 30×: full triangle; 40×: open diamond; 50×: open square; (A) $[Gd(L^1)]^{3-}/Cu^{2+}$ system, (B) $[Gd(L^1)]^{3-}/Eu^{3+}$ system, (C) $[Gd(L^2)]^{2-}/Cu^{2+}$ system, (D) $[Gd(L^2)]^{2-}/Eu^{3+}$ system.

compiled in Table 7 and the representative fits of the pH-dependence of the first-order rate constants $k_{obsd.}$ are shown in Figure 4.

As the pH region where dissociations were studied is much lower (3.5–5.7) than the p$K_A$ of the $[Gd(HL^1)]^{2-}$ complex (6.5, Table 4), one can suggest that the singly protonated complex species $[Gd(HL^1)]^{2-}$ is the major species in the reacting solution (Figure 2). Therefore, the calculated constant $K_H$ corresponds to the second protonation of the complex species. This hypothesis can be supported by the relatively low value of this constant (the corresponding p$K_A$ is 3.7, Table 7).

In the case of the copper(II)-assisted dissociation of the $[Gd(L^1)]^{3-}$ complex (Figure 4, A), the most complicated rate

Table 7. Rate and equilibrium constants characterizing the dissociation reactions between the complexes $[Gd(L^1)]^{3-}$, $[Gd(L^2)]^{2-}$ and $[Gd(dtpa)]^{2-}$, and $Cu^{2+}$ and $Eu^{3+}$ ions (25 °C, 1.0 M KCl).

law was found. The best fits were obtained according to Equation (2) which is formally derived from Equation (1) when the term $K_M[Cu^{2+}]$ in the denominator is neglected, as can be because the $K_M$ value is low, comparing to the value of the protonation constant $K_H$. The reaction rate increases with both proton and copper(II) concentrations, and a saturation-like shape of $k_{obsd.}$ dependences (Figure 4, A) reveals a formation of the protonated complex, which slightly slow down the dissociation reaction as the $Cu^{2+}$ ion cannot easily attack the less negatively charged protonated complex $[Gd(H_2L^1)]^-$ in comparison with $[Gd(HL^1)]^{2-}$.

$$k_{obsd.} = \frac{k_1^H[H^+] + k_2^H[H^+]^2 + k_3^{Cu}[Cu^{2+}] + k_4^{Cu}[H^+][Cu^{2+}]}{1 + K_H[H^+]} \quad (2)$$

However, in the europium(III)-promoted dissociation of $[Gd(L^1)]^{3-}$ complex, only proton-assisted pathways were found, as the observed rate constant $k_{obsd.}$ can be extrapolated to zero at zero proton concentration. Furthermore, the increase in the $Eu^{3+}$ concentration dropped the value of $k_{obsd.}$ (Figure 4, B), which is an evidence for the formation of a dinuclear complex. This complex is kinetically relatively stable, and its structure should be analogous to the dinuclear $[Gd_2(L^1)]$ species (Figure 2, B). The presence of the highly charged metal ions bound on opposite sides of the complex prevents the attack by an additional proton. Therefore, the data were best fitted according to Equation (3).

$$k_{obsd.} = \frac{k_1^H[H^+] + k_2^H[H^+]^2}{1 + K_{Eu}[Eu^{3+}]} \quad (3)$$

The copper(II)-assisted dissociation of the $[Gd(L^2)]^{2-}$ complex can be best fitted by Equation (4), which can be derived from Equation (1) by neglecting of the stabilization of the gadolinium(III) complex by the protonated and dinuclear species formation [i.e. $1 >> K_H[H^+] + K_M[Cu^{2+}]$ in the denominator of Equation (1)], as the stability of the dinuclear complex with $Cu^{2+}$ is even lower for the phosphinate derivative $H_5L^2$ comparing to phosphonate ligand $H_6L^1$ and also because of the lower protonation constants of the $[Gd(L^2)]^{2-}$ complex the term $K_H[H^+]$ is of a low importance. The representative data are given together with the best fits in Figure 4 (C).

$$k_{obsd.} = k_1^H[H^+] + k_2^H[H^+]^2 + k_4^{Cu}[H^+][Cu^{2+}] \quad (4)$$

In the case of the europium(III)-assisted dissociation of the $[Gd(L^2)]^{2-}$ complex, the crossing region in $k_{obsd.}$ dependences on the proton concentration was found at $[H^+]$ of about $5 \cdot 10^{-5}$ M (pH ≈ 4.3, Figure 4, D). At higher proton concentrations, the increase in $Eu^{3+}$ concentration slows down the reaction rate, contrary, at low proton concentrations, the reaction accelerates with increasing $Eu^{3+}$ concentration. Similar behaviour was reported for the $Eu^{3+}$-promoted dissociation of the $[Gd(dtpa)]^{2-}$ complex.[26] The non-zero reaction rate at the zero proton concentration is an evidence for the proton-independent term in the rate law. Therefore, the best fits were obtained using Equation (5).

$$k_{obsd.} = \frac{k_1^H[H^+] + k_2^H[H^+]^2 + k_3^{Eu}[Eu^{3+}]}{1 + K_{Eu}[Eu^{3+}]} \quad (5)$$

Spontaneous dissociation of diprotonated complex $[Gd(H_2L^1)]^-$ and the monoprotonated complexes $[Gd(HL^2)]^-$ is about three orders in magnitude faster than in the case of $[Gd(Hdtpa)]^-$ complex (Table 7). Further protonation causes noticeable increase in the reaction rate of about four orders in all the cases.

To compare the kinetic inertness of the complex species with the new ligands and that with $H_5$dtpa, we calculated half-life times of all the complex species under various conditions (Table 8).

Table 8. Comparison of half-life times of the complexes $[Gd(L^1)]^{3-}$, $[Gd(L^2)]^{2-}$ and $[Gd(dtpa)]^{2-}$ in various reaction media (25 °C, $I$ = 1.0 M KCl).

| Conditions | Half-life times [s] $[Gd(L^1)]^{3-}$ | $[Gd(L^2)]^{2-}$ | $[Gd(dtpa)]^{2-}$ |
|---|---|---|---|
| | pH = 4.0 | | |
| without metal ions | 2.5 | 2.2 | 680 |
| 0.001 M $Cu^{2+}$ | 1.9 | 1.9 | 360 |
| 0.001 M $Eu^{3+}$ | 2.6 | 2.3 | 690 |
| 0.01 M $Cu^{2+}$ | 0.6 | 0.8 | 77 |
| 0.01 M $Eu^{3+}$ | 3.3 | 2.5 | 780 |
| | pH = 5.0 | | |
| without metal ions | 21 | 40 | $4.5 \cdot 10^4$ |
| 0.001 M $Cu^{2+}$ | 9.5 | 31 | 740 |
| 0.001 M $Eu^{3+}$ | 22 | 37 | $4.3 \cdot 10^4$ |
| 0.01 M $Cu^{2+}$ | 1.6 | 9.7 | 84 |
| 0.01 M $Eu^{3+}$ | 31 | 21 | $3.4 \cdot 10^4$ |
| | pH = 6.0 | | |
| without metal ions | 210 | 440 | $1.0 \cdot 10^6$ |
| 0.001 M $Cu^{2+}$ | 19 | 330 | 750 |
| 0.001 M $Eu^{3+}$ | 220 | 190 | $5.8 \cdot 10^5$ |
| 0.01 M $Cu^{2+}$ | 2.0 | 99 | 84 |
| 0.01 M $Eu^{3+}$ | 310 | 35 | $1.4 \cdot 10^5$ |

In general, the stability of the complexes of new phosphorus-containing ligands is much lower comparing to that of $[Gd(dtpa)]^{2-}$. Increase in copper(II) concentration speed-up the dissociation reaction in all the cases, bud especially, for $[Gd(dtpa)]^{2-}$ complex in neutral solutions, where is the half-life time comparable to that calculated for $[Gd(L^2)]^{2-}$. It is a consequence of a spontaneous dissociation of dinuclear [Gd(dtpa)Cu] complex. In the case of $[Gd(L^2)]^{2-}$, the lower basicity of the donor groups results in lower ability of binuclear complex formation (see also the values of stability constants of dinuclear species, Table 6) and therefore, to worse formation of such reactive intermediate. For europium(III)-promoted dissociations, the stabilization of [Gd(L)] complexes with increasing $Eu^{3+}$ concentration was found in all the cases at low pH. It is the result of formation of [Gd(L)Eu] complexes, which cannot be easily attacked by

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

proton and their own dissociation is slower comparing to proton-assisted pathway. Increasing the pH, half-life times slightly drop with increasing $Eu^{3+}$ concentration for $[Gd(dtpa)]^{2-}$ and $[Gd(L^2)]^{2-}$ complexes, as result of their spontaneous dissociation. However, in the case of $[Gd(L^1)Eu]$, there was no evidence for such process and therefore, half-life times still increase.

For the $H_5$dtpa and its various amide derivatives, all the gadolinium(III) complexes have similar kinetic stability comparing to each other.[26–28] Surprisingly, we found that the gadolinium(III) complexes with $H_5$dtpa-analogues derived on the central nitrogen atom by the phosphorus acid pendant arm are much less kinetically stable with the half-life times about two to three orders of magnitude shorter. This can probably be attributed to a steric strain in the new complexes, which coordination sphere is not so compact and which can be attacked by a proton or by an additional metal ion. Furthermore, the complex of phosphonate ligand can easily be protonated due to the high basicity of the pendant arm. Also, it can easily form dinuclear complexes, which are the intermediates in the dissociation mechanism. Anyway, the rate constants for complexes of both ligands with phosphorus pendant arm are comparable, so the stereochemistry of both the complexes and the intermediates is probably similar. It should be noticed that assistance of proton or the metal ions in the decomplexation is much more pronounced for $H_5$dtpa complex itself. The results obtained here correspond very well with *trans*-chelation experiments between the gadolinium(III) complexes and $Zn^{2+}$ followed by $^1H$ relaxation measurements ($Gd^{3+}$ complex/$Zn^{2+}$ = 1:1, pH 7, phosphate buffer, 37 °C).[16] The experiments gave the same relative kinetic inertness of the complexes $[Gd(dtpa)]^{2-} >> [Gd(L^1)]^{3-} \approx [Gd(L^2)]^{2-}$. On the other hand, a difference in kinetic inertness (pH 2, 25 °C) of the gadolinium(III) complexes of $H_4$dota and its monophosphonate analog $H_5$do3ap are much smaller; the $[Gd(do3ap)]^{2-}$ complex decomposes about one order of magnitude faster ($\tau_{1/2}$ = 7.9 h) than the $[Gd(dota)]^-$ complex ($\tau_{1/2}$ = 95.5 h).[29]

## Conclusions

The study of thermodynamic and kinetic stabilities of the complexes of phosphonate and phenylphosphinate analogues of $H_5$dtpa (derived by phosphorus functionality on the central nitrogen atom) with selected transition and lanthanide metal ions is presented. Both phosphorus-containing ligands form thermodynamically very stable complexes, with stability constants comparable or even higher than those reported for parent $H_5$dtpa. However, the kinetic stability of their gadolinium(III) complexes against acid- and metal-assisted decomplexations is surprisingly much lower. The half-life times of the gadolinium(III) complexes of the new ligands in the presence of an excess of the concurrent metal ions [copper(II) or europium(III)] are shorter by about 2–3 orders of magnitude comparing to those of $H_5$dtpa and its amidic derivatives. This can probably be attributed to the steric strain in the new complexes, to a high affinity of the phosphonate ligand for protons and/or to the easy formation of binuclear complexes, which acts as the intermediates in the dissociation mechanism. The data presented here show that lanthanide(III) complexes of this class of ligands are less suitable for medicinal use due to the rather low kinetic inertness.

## Experimental Section

**Materials:** The ligands used in this work were prepared according to reported procedures.[16] Metal salts were of analytical grade and were used as obtained from commercial sources or after recrystallization from water. The deionized water (Milli-Q, Millipore, 20 kΩ) was used for physico-chemical experiments. Materials (analytical grade) for preparation of the buffer solutions were obtained from commercial sources.

### Equilibrium Studies

The stock solution of hydrochloric acid (ca. 0.03 mol·dm$^{-3}$) was prepared from 35% aqueous solution (quality "puriss.", Fluka). Commercial $NMe_4Cl$ (99%, Fluka) was recrystallized from boiling *i*PrOH and the solid salt was dried with $P_2O_5$ in vacuo to constant weight (this dried form of the salt is extremely hygroscopic).[29] Carbonate-free $NMe_4OH$ solution (ca. 0.2 mol·dm$^{-3}$) was prepared from $NMe_4Cl$ using ion exchanger Dowex 1 in the $OH^-$ form (elution with carbonate-free water, under argon). The hydroxide solution was standardized against potassium hydrogen phthalate and the HCl solution against the ca. 0.2 mol·dm$^{-3}$ $NMe_4OH$ solution.

The ligand stock solutions ($c \approx 0.02$ mol·dm$^{-3}$) were prepared by dissolution of a weighted amount of the solid hydrochloride salts of ligands ($H_6L^1$·HCl·2$H_2O$ and $H_5L^2$·2HCl·$H_2O$, respectively) in an appropriate amount of deionized water. The exact content of hydrochloric acid was determined gravimetrically as AgCl. Concentrations of the ligands were calculated from potentiometrical data during the determination of the protonation constants using the OPIUM program package.[30] The exact concentrations of metal chlorides stock solutions were determined by titrations with standardized solution of $Na_2H_2$edta.

Titrations were carried out in a vessel thermostatted at 25 ± 0.1 °C, at an ionic strength $I(NMe_4Cl)$ = 0.1 mol·dm$^{-3}$ and in the presence of extra HCl in the $-\log[H^+]$ range 1.5–12.0 (except of titrations in presence of excess of hydrolyzing metal ions, which were finished at $-\log[H^+]$ of about 9.5) using a PHM 240 pH meter, 2-mL ABU 900 automatic piston burette and a GK 2401B combined electrode (Radiometer). The initial volume of the measured solution was about 5 cm$^3$ and concentrations of ligands were about 0.004 mol·dm$^{-3}$. For determination of the stability constants of metal complexes, the mixtures with one or 1.5–2 equivalents of metal ions were used. Titration of each system in each M:L ratio was carried out at least three times and each titration consisted of about 40 data points. An inert atmosphere was ensured by constant flow of dinitrogen saturated with the water vapour by passing through 0.1 mol·dm$^{-3}$ solution of $NMe_4Cl$. The concentration protonation constants $\beta_h$ are defined by the equation

$$\beta_h = [H_hL]/([H]^h[L])$$

As dissociation constant $K_{A,h}$ is commonly defined by

$$K_{A,h} = ([H][H_{h-1}L])/[H_hL],$$

it is evident, that $pK_{A,h} = \log\beta_h - \log\beta_{h-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The concentration stability constants $\beta_{hlm}$ are defined by the equation

$\beta_{hlm} = [H_hL_lM_m]/([H]^h[L]^l[M]^m)$,

and dissociation constant $K_{A,hlm}$ can be defined similarly to the case of free ligand as

$K_{A,hlm} = ([H][H_{h-1}L_lM_m])/[H_hL_lM_m]$.

Analogously, $pK_{A,hlm} = \log\beta_{hlm} - \log\beta_{h-1lm}$.

The constants (and their standard deviations) were calculated with the OPIUM program package.[30] This program minimizes the criterion of the generalized least-squares method using the calibration function

$E = E_0 + S\times\log[H^+] + j_1\times[H^+] + j_2\times K_w/[H^+]$

where the additive term $E_0$ contains the standard potentials of the electrodes used and contributions of inert ions to the liquid-junction potential, $S$ corresponds to the Nernstian slope, the value of which should be close to the theoretical value of $RT/zF\{\log(e)\}$ = 59.159 mV. It was reported in the literature that for a glass electrode this value can oscillate at about 99.7% of the theoretical value.[31] The terms $j_1\times[H^+]$ and $j_2\times K_w/[H^+] = j_2\times[OH^-]$ are contributions of $H^+$ and $OH^-$ ions to the liquid-junction potential. By simple view on the calibration function, it is clear, that they cause a deviation from a linear dependence of $E$ on $[H^+]$ and are significant only in strong acidic and strong alkaline solutions. The calibration parameters were determined from titration of standard HCl with standard $NMe_4OH$ before and immediately after the titration of ligand or ligand-metal system. Thus, two sets of calibration parameters for each titration were used for the calculations of the constants. The water ion product $pK_w$ = 13.81 and the stability constants of hydroxo metal complexes were taken from the literature.[25,32]

**Kinetic Studies**

The stock solutions of ligands of the concentration of about 0.05 mol·dm$^{-3}$ were prepared by dissolution of a weighted amount of solid hydrochloride salts ($H_6L^1$·HCl·2$H_2O$ and $H_5L^2$·2HCl·$H_2O$, respectively) in appropriate amounts of double-distilled water. Exact content of ligands was determined by addition of a defined excess of $EuCl_3$ and re-titration with a standardized solution of $Na_2H_2$edta (xylenol orange indicator, pH 5.8–6.0, urotropine buffer). The concentrations of lanthanide(III) chlorides stock solutions were determined by titrations with standardized solution of $Na_2H_2$edta. From the solutions, the gadolinium(III) complexes [$c$ = 0.2 mmol·dm$^{-3}$ for copper(II)-exchange reaction and 2 mmol·dm$^{-3}$ for europium(III)-exchange reaction, respectively] of each ligand were prepared. Constant ionic strength of potassium chloride (1 mol·dm$^{-3}$) and buffers [0.02 mol·dm$^{-3}$ boric acid in 0.08 mol·dm$^{-3}$ mannitol for the copper(II)-exchange reaction and 0.02 mol·dm$^{-3}$ *N*-methylpiperazine for the europium(III)-exchange reaction] were used to adjust the pH in the range 3.5–5.7. Large excesses of copper(II) (10–50×) and europium(III) (10–70×) chlorides were employed to assure pseudo-first order conditions of the exchange reactions. All metal-assisted dissociation kinetics experiments were followed spectrophotometrically on a stopped-flow apparatus (Applied Photophisics DX-17MV) at 25 °C at 300 nm [copper(II)-promoted decomplexations], 250 nm [europium(III)-exchange on Gd–$H_6L^1$ system] and 290 nm [europium(III)-exchange on Gd–$H_5L^2$ system]. The rate constants $k_{obsd.}$ were determined by fitting of the time-dependence of the absorbance with $A_t = (A_\infty - A_0)e^{-kt} + A_0$ and were reproducible within ±5% in the independent runs. The values of the rate constants used for the fittings were the averages from at least two independent runs using a firmware.

**X-ray Measurement**

A single crystal of $H_6L^1$·HCl·1.5$H_2O$ suitable for a diffraction experiment was prepared by slow evaporation of a saturated aqueous solution at room temperature. The colourless block-like crystal was mounted on a glass fibre by silicone fat. Diffraction data were collected using graphite-monochromated Mo-$K_\alpha$ radiation with an Enraf–Nonius KappaCCD diffractometer at 150(1) K [Cryostream Cooler (Oxford Cryosystem)] and analyzed using the HKL DENZO program package (ref.[33]). Cell parameters were determined from all data by the same program package.[33] The structure was solved by direct methods (SIR 97[34]) and refined by full-matrix least-squares techniques (SHELXL97[35]). The used scattering factors for neutral atoms were included in the SHELXL97 program. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were localized in the difference map of electronic density and refined isotropically. The pertinent crystallographic data are presented in Table 9. CCDC-287906 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Titanium Complexes of Dialkanolamine Ligands: Synthesis and Structure

**Kirill V. Zaitsev,[a] Sergey S. Karlov,*[a] Anastasia A. Selina,[a] Yu. F. Oprunenko,[a] Andrei V. Churakov,[b] Bernhard Neumüller,[c] Judith A. K. Howard,[d] and Galina S. Zaitseva[a]**

**Keywords:** Titanium / Alkoxides / Pentacoordination / Hexacoordination / Dialkanolamine complexes

Synthesis of the title compounds, viz. $[RN(CH_2CH_2O)(CHR^1CR^2R^3O)]Ti(OiPr)_2$ (**13**–**15**) and $[RN(CH_2CH_2O)(CHR^1CR^2R^3O)]_2Ti$ (**18**–**28**), by the reaction of one or two equivalents of the corresponding dialkanolamines $RN(CH_2CH_2OH)(CHR^1CR^2R^3OH)$ (**1**–**12**) with $Ti(OiPr)_4$ is reported. Other routes to $[RN(CH_2CH_2O)(CHR^1CR^2R^3O)]_2Ti$, such as the reaction of $Ti(CH_2Ph)_4$ with dialkanolamine and the reaction of $TiCl_4(THF)_2$ with dialkanolamine/$Et_3N$ were also tested. Dimeric titanocane **16**, $[PhCH_2N(CH_2CH_2O)_2Ti(OMe)_2]_2$, was obtained from the reaction of one equivalent of dialkanolamine **3** with $CpTi(OMe)_3$. $PhCH_2N(CH_2CH_2O)_2Ti(OMenth)_2$ (**17**) was prepared from the transalkoxylation reaction of **15** with two equivalents of menthol. The composition and structures of all novel compounds were established by $^1H$ and $^{13}C$ NMR spectroscopy as well as elemental analysis data. The possible solution structure features of **13**–**28** are discussed. The single-crystal X-ray diffraction study of titanocane **16** clearly indicates a dimeric structure for this compound in the solid state. According to X-ray data, compounds $[PhCH_2N(CH_2CH_2O)_2]_2Ti$ (**19**), $[MeN(CH_2CH_2O)(CH_2CHPhO)]_2Ti$ (**20**), $[MeN(CH_2CH_2O)(CH_2CPh_2O)]_2Ti$ (**23**), *erythro*-$[MeN(CH_2CH_2O)(CHPhCHPhO)]_2Ti$ (**24**), *threo*-$[MeN(CH_2CH_2O)(CHPhCHPhO)]_2Ti$ (**25**), and $\{MeN(CH_2CH_2O)[CH(CH_2)_4CHO]\}_2Ti$ (**27**) possess a monomeric structure with a hexacoordinate titanium atom in the solid state. Among them complexes **19**, **20**, **23**, **25**, and **27** are characterized by a *cis* disposition of the nitrogen atoms in the coordination environment of the Ti atom, while nitrogen atoms in **24** occupy *trans* positions.

## Introduction

Alkoxy- or aroxytitanium derivatives have attracted the attention of researchers during the last five decades because of their possible application as catalysts in various organic reactions,[1–8] as well as precursors for titanium sol-gel chemistry[9] and metal-organic chemical vapor deposition (MOCVD) processes.[10] Among these species, the compounds with different trialkanolamines, titanatranes, $N(CR^1R^4CR^2R^3O)_3TiX$, with different substituents at the carbon atoms of the atrane skeleton, have been investigated to a considerable extent because of their rich structural features and catalytic activities including polymerization reactions of alkenes (see key references and references cited therein).[11–19] At the same time the closely related derivatives of dialkanolamines, titanocanes, $RN(CR^1R^4CR^2R^3O)_2Ti(X)X'$, are less studied.[20–26] However, this class of compounds could be more promising for investigations because of their greater chemical and structural flexibility. In addition, some cyclic titanium alkoxides with transannular interactions were recently found to be good catalysts in olefin polymerization reactions.[27–33]

As a part of our program to investigate the structure and chemical behavior of metal complexes containing di- and trialkanolamine ligands,[34–43] we present the study of reactions of dialkanolamines **1**–**12** with $Ti(OiPr)_4$. In the case of the reaction of $RN(CH_2CH_2OH)_2$ with $Ti(OiPr)_4$ (1:1 ratio) novel titanocanes **13**–**15** formed (R = Ph, Me, $PhCH_2$). The dimer $[PhCH_2N(CH_2CH_2O)_2Ti(OMe)_2]_2$ (**16**), was obtained from the reaction of dialkanolamine **3** with $CpTi(OMe)_3$. The reaction of **15** with two equivalents of menthol led to $PhCH_2N(CH_2CH_2O)_2Ti(OMenth)_2$ (**17**). 1,1′-Spirobititanocanes **18**–**28** of type $[RN(CH_2CH_2O)(CHR^1CR^2R^3O)]_2Ti$ were prepared from the reaction of two equivalents of the corresponding dialkanolamines with $Ti(OiPr)_4$. The solid state and solution structures of prepared compounds are discussed on the basis of X-ray diffraction and NMR spectroscopic data. Once this work had been finished the report of Carpentier and coworkers was published where the synthesis and structural investigations of several closely related titanocanes and 1,1′-spirobititanocanes were reported.[44]

## Results and Discussion

Dialkanolamines **1**–**12** were involved in this study. The compounds **8**–**12** were obtained from the reaction of the corresponding alkene oxides with *N*-methylethanolamine in high yields (Scheme 1). The reaction with indene oxide was previously reported, but the structure of product **12** was not discussed.[45] Compound **7** was previously prepared by another method.[46] Compounds **8**–**11** are novel.

The reactions proceeded regiospecifically, only one expected product formed in the reactions with but-1-ene oxide, 1,1-diphenylethylene oxide, and indene oxide. Only one diastereomer formed in the reactions with *cis*- and *trans*-stilbene oxides, as well as cyclopentene and cyclohexene oxides.

**Titanocanes:** According to the literature, the most suitable approach to the dialkoxy complexes of titanium with chelate ligands is the transalkoxylation reaction of $Ti(OAlk)_4$ with the free ligand containing two OH groups. This method was used in the case of the closely related ligands $RN(CH_2\text{-}o\text{-}ArOH)_2$, where *o*-Ar is a benzene ring with different alkyl (methyl or *tert*-butyl) substituents and R is $CH_2CH_2NMe_2$.[27] When R is *n*Pr, the presence of an alkyl group in the other *ortho* position to the OH group of such ligands is required for the formation of bis(isopropoxide) complexes, otherwise the formation of bishomoleptic substances $[RN(CH_2\text{-}o\text{-}ArO)_2]_2Ti$ has been found.[27] Analogous results were found for other structurally close bis(phenols). The treatment of $Ti(OAlk)_4$ (Alk = *i*Pr, Me) with one equivalent of the bis(phenol), $CH_2[(3\text{-}t\text{Bu-}5\text{-}MeC_6H_2)\text{-}2\text{-}OH]_2$, gave monomeric complexes with a tetracoordinate Ti atom (NMR spectroscopic data), $CH_2[(3\text{-}t\text{Bu-}5\text{-}MeC_6H_2)\text{-}2\text{-}O]_2Ti(OAlk)_2$.[30] Reacting the thio-bis(phenol), $S[(3\text{-}t\text{Bu-}5\text{-}MeC_6H_2)\text{-}2\text{-}OH]_2$, with $Ti(OiPr)_4$ resulted in the dimeric $[S[(3\text{-}t\text{Bu-}5\text{-}MeC_6H_2)\text{-}2\text{-}O]_2Ti(OiPr)_2]_2$ (X-ray data) where dimerization ensues from the interaction of the oxygen atom of the isopropoxy group of one monomeric unit with the Ti atom of the other.[31] The diisopropoxy titanium complexes based on diamino-dialkoxide ligands, $[\text{-}CH_2N(Me)CH_2C(CF_3)_2OH]_2$ and $CH_2[CH_2N(Me)CH_2C(CF_3)_2OH]_2$, were also recently prepared by Carpentier and coworkers by the transalkoxylation reaction of $Ti(OiPr)_4$.[32]

To the best of our knowledge, the reactions of dialkanolamines with $Ti(OiPr)_4$ have only been published in a series of works by Kemmitt et al. and very recently in the report of Lavanant et al.[20–23,44] Kemmitt et al. noted that the reaction of two equivalents of dialkanolamine **2** with $Ti(OiPr)_4$ gave the bishomoleptic complex $[MeN(CH_2\text{-}CH_2O)_2]_2Ti$ (**29**). This transformation was supposed to proceed through a very reactive and unstable $MeN(CH_2\text{-}CH_2O)_2Ti(OiPr)_2$ but this suggestion was not confirmed by any analytical methods.[20] Increasing the amount of $Ti(OiPr)_4$ in the reaction mixture led to the unexpected $[Ti_2\{\mu_2\text{-}(OCH_2CH_2)_2NMe\}(\mu_2\text{-}OiPr)(OiPr)_5]$.[21] The analogous species, $Ti_2(OCH_2CH_2NMe)_2(OtBu)_6$, was prepared by the reaction of $Ti(OtBu)_4$ with **2**.[22] The treatment of $Ti(OiPr)_4$ with one equivalent of **2** in the presence of one equivalent of different diols led to dimeric titanium aminoalkoxydiolates, $[MeN(CH_2CH_2O)_2Ti(O\text{-}A\text{-}O)]_2$ (O-A-O = $OCMe_2CMe_2O$, $OCEt_2CEt_2O$, $OCMe_2CH_2CMe_2O$, $OCMe_2CH_2CHMeO$). Dimerization in latter complexes is realized by the interaction of the oxygen atom of one dialkanolamine "arm" of one monomeric unit with the Ti atom of the other.[23] Lavanant et al. have found that the reaction of one equivalent of $PhCH_2N(CH_2CMe_2OH)_2$ with $Ti(OiPr)_4$ gave the complex $PhCH_2N(CH_2CMe_2O)_2Ti(OiPr)_2$, which is monomeric in the solid state and in solution ($[D_8]$toluene).[44]

We have found that dialkanolamines **1**–**3** reacted readily with an equimolar amount of $Ti(OiPr)_4$ at room temperature in chloroform or toluene solution to give the corresponding titanocanes **13**–**15** in high yields (Scheme 2). We also tested two other reactions that may lead to the titanocanes, where X = X′. However, both reactions did not result in the desired products (Scheme 2). $CpSn\text{-}nBu_3$, one of the possible by-products in the reaction of $Cp_2TiCl_2$ with $MeN(CH_2CH_2OSn\text{-}nBu_3)_2$, was detected by NMR spectroscopy.

Our efforts to prepare titanocane with different substituents X and X′ by the transalkoxylation reaction of dialkanolamine **3** with $(MeO)_3TiCp$ failed. Only the dimer **16** was obtained. In contrast, Kim et al. synthesized $RN(CH_2CH_2O)_2Ti(Cl)Cp^*$ by the reaction of $Cl_3TiCp^*$ (where $Cp^*$ = pentamethylcyclopentadienyl) with $RN(CH_2CH_2OH)_2$ (R = Me, *n*Bu).[25] We believe that the difference in the behavior of $(MeO)_3TiCp$ and $Cl_3TiCp^*$ (the rupture of Ti–Cp bond and the stability of Ti–$Cp^*$ bond in the course of the reaction) is because of the different properties of these bonds.

The possibility of alkoxy groups exchanging at the titanium atom was confirmed by the formation of complex **17** in the reaction of diisopropoxy derivative **15** with L-(–)-menthol (Scheme 2).

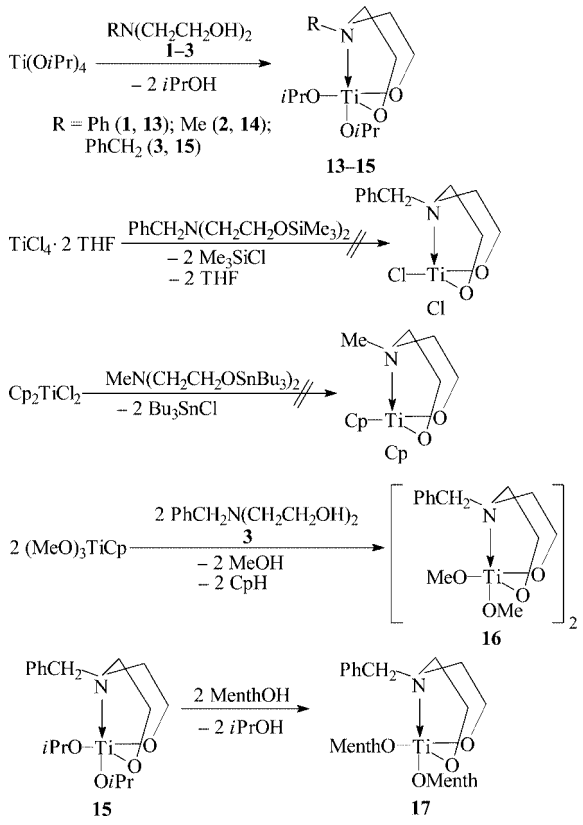

Scheme 2.

One of the most important questions in the chemistry of titanium is the coordination state of the Ti atom both in the solid state and in solutions. In our opinion the type of coordination environment around the titanium atoms is very important because of the potential ability of these compounds to catalyze different organic reactions where the stereochemistry of the catalytic center is significant.[3–8] Titanocanes prepared by us may possess monomeric structures with pentacoordinate titanium atoms or dimeric structures with hexacoordinate titanium atoms. There are two possibilities for dimerization: through the dialkanolamine moiety or through the alkoxy groups. According to the literature, most of the titanocanes prepared to date, $[MeN(CH_2CH_2O)_2Ti(O\text{-}A\text{-}O)]_2$ (O-A-O = $OCMe_2CMe_2O$, $OCEt_2CEt_2O$, $OCMe_2CH_2CMe_2O$, $OCMe_2CH_2CH$-MeO),[23] are dimeric in the solid state. The dimerization is realized by the additional contact of the oxygen atom of one diethanolamine "arm". In $CDCl_3$ solutions two compounds are also dimeric at room temperature (O-A-O = $OCMe_2CMe_2O$, $OCEt_2CEt_2O$) while two others are monomeric (O-A-O = $OCMe_2CH_2CMe_2O$, $OCMe_2CH_2CH$-MeO).[23] $PhCH_2N(CH_2CMe_2O)_2Ti(OiPr)_2$ is monomeric in the solid state and in solution (toluene-$d_8$).[44] As cited above, the closely related derivatives, $n$PrN{$CH_2$[3,5-bis($t$Bu)-$C_6H_2$]-2-O}$_2$Ti(O$i$Pr)$_2$ and $n$PrN{$CH_2$[3,5-bis(Me)-$C_6H_2$]-2-O}$_2$Ti(O$i$Pr)$_2$, are monomeric both in the solid state and in solution ($C_6D_6$).[27]

Among five dialkoxytitanocanes prepared by us only one compound **16**, the titanocane with two methoxy groups at the titanium atom, gave crystals suitable for an X-ray diffraction study. The molecular structure of **16** is shown in Figure 1. Table 1 lists selected geometrical parameters for **16**. The molecule of **16** represents a centrosymmetric complex with a $Ti_2O_2$ lozenge. The dimer results from $\mu_2$-bridging by one methoxy group of one monomeric unit. The diethanolamine ligands in each dimer are bound meridionally to each titanium atom. Of interest, all previously studied alkoxytitanocanes except $PhCH_2N(CH_2CMe_2O)_2Ti(OiPr)_2$ are also dimeric, but the dimerization results from $\mu_2$-bridging by one alkoxy "arm" of the diethanolamine ligand.[23,44] The coordination polyhedron of the Ti atoms in compound **16** represents a distorted octahedral geometry with the N(1) atom and O(4) atom (nonbridging methoxy group) in a *trans* orientation. The Ti(1)–N(1) distance in **16** [2.355(2) Å] is close to that previously found for $[MeN(CH_2CH_2O)_2$-Ti(O-A-O)]$_2$ [2.351(4)–2.431(4) Å].[23] The longest Ti–O distances in **16** [Ti(1)–O(3A) 2.024(1); Ti(1)–O(3) 2.066(1) Å] correspond to the bonds of titanium with both bridging methoxy groups, as expected. All five-membered rings of the ocane skeletons in **16** adopt an envelope-like conformation, all carbon atoms in the α positions to the N atom occupy "flap" sites, while the C-β atoms form the base of these envelope planes.

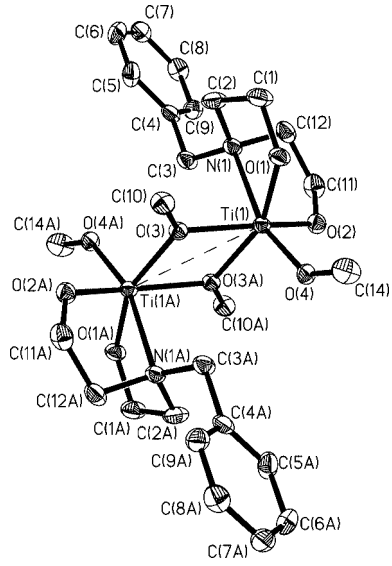

Figure 1. Molecular structure of **16**. Hydrogen atoms and solvate dichloromethane molecules are omitted for clarity.

Table 1. Selected bond lengths [Å] and angles [°] for **16**.

| | | | |
|---|---|---|---|

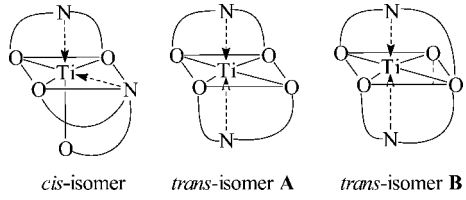
| Ti(1)–N(1) | 2.355(2) | | |

$^1$H and $^{13}$C NMR spectroscopic data ($CDCl_3$ solution, room temperature) of **16** are in agreement with the centrosymmetric dimeric solid-state structure. In the $^1$H NMR spectrum of **16** there are two singlets of methoxy groups.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The signals of the methylene protons of one ocane skeleton appear as a set of multiplets resulting from the nonequivalence of all protons. Separate $^{13}C$ NMR signals were found for each carbon of the diethanolamine ligand in **16**. On the contrary, two other titanocanes with the benzyl group at the nitrogen atom (**15** and **17**) are monomeric in $CDCl_3$ solution at room temperature. This conclusion is based on the presence of one signal of the $OCH_2$ group and one signal of the $NCH_2$ group for the C atoms of the ocane skeleton of these compounds. Thus, these species (**15** and **17**) possess monomeric structures with trigonal-bipyramidal coordination environments of the titanium atom. These compounds may undergo exchange processes in solution (the exchange between equatorial and axial alkoxy groups).[44] Thus, the drastic difference in $^1H$ NMR spectra of **15** (OCH protons of the isoproxy group represent one broad singlet) and **17** (OCH protons of two menthoxy groups represent two spaced multiplets), to our opinion, resulted from the different dynamic behavior of these compounds in solution. While isopropoxy groups in **15** undergo fast position exchange around the Ti atom, more bulky menthoxy groups in **17** resulted in the rigid structure of the molecule. It should be noted that previously prepared $PhCH_2N(CH_2CMe_2O)_2Ti(OiPr)_2$ demonstrated the same trends in the NMR spectra as compound **15**.[44] The authors concluded that a monomeric structure of $PhCH_2N(CH_2CMe_2O)_2Ti(OiPr)_2$ occurs. This conclusion was also supported by variable temperature NMR spectroscopy.[44] The structure of diisopropoxytitanocane **14** is close to that of **15** according to the NMR spectroscopic data. In the $^{13}C$ spectrum of **13** the broadening of each signal is observed, probably because of possible monomer-dimer interconversion in this compound. Thus we can conclude that the steric bulkiness of alkoxy ligands in titanocanes is the determining factor that governs the coordination number in titanocanes.

**Spirobititanocanes:** Only two spirobititanocanes were reported by the beginning of our investigation, one of them is $[MeN(CH_2CH_2O)_2]_2Ti$ (**29**).[20] Very recently the synthesis of $[PhCH_2N(CH_2CMe_2O)_2]_2Ti$ from the reaction of $Ti(OiPr)_4$ with two equivalents of corresponding dialkanolamine was reported.[44] For synthesis of **29** the treatment of two equivalents of dialkanolamine **2** with $Ti(OiPr)_4$ or freshly prepared α-titanic acid was used. The structure of **29** was confirmed by X-ray diffraction, this species is monomeric in the solid state. The coordination polyhedron of the Ti atom represents a distorted octahedral geometry with two nitrogen atoms in a *cis* orientation (Scheme 3).[20] We have very recently found an analogous situation in spirobigermocanes. Both $[PhN(CH_2CH_2O)_2]_2Ge$ and $[MeN(CH_2CH_2O)(CH_2CHPhO)]_2Ge$ possess the structure of the *cis* isomer.[34] The bishomoleptic titanium derivative, $\{S[(3\text{-}tBu\text{-}5\text{-}MeC_6H_2)\text{-}2\text{-}O]_2\}_2Ti$, has an analogous structure.[47] Lavanant et al. supposed that the monomeric structure is present in solution for $[PhCH_2N(CH_2CMe_2O)_2]_2Ti$.[44]



Scheme 3.

The closely related spiro-bishomoleptic or spiro-bisheteroleptic complexes of titanium were prepared by Tshuva et al. by the reaction of $nPrN(CH_2\text{-}o\text{-}ArOH)_2$ or $RN(CH_2\text{-}o\text{-}Ar'OH)_2$ (R = *n*Pr or $CH_2CH_2NMe_2$) with $Ti(OiPr)_4$ lead-

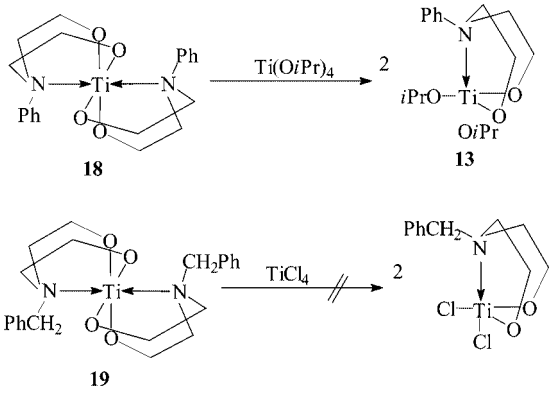
ing to [*n*PrN(CH$_2$-*o*-ArO)$_2$]$_2$Ti or [*n*PrN(CH$_2$-*o*-ArO)$_2$]Ti[(O-*o*-Ar′-CH$_2$)$_2$NR], respectively.[27] Three complexes were studied by X-ray diffraction and showed the structure of *trans*-isomer **A** (Scheme 3). The authors noted that the bulky substituents in the Ar groups prevent the formation of spiro-bishomoleptic species and the reaction stops at the titanocanes.[27] An analogous result in Zr chemistry has been found by Mountford and coworkers.[33] A very interesting result was found by Lavanant et al. for Zr derivatives of two dialkanolamines: [PhCH$_2$N(CH$_2$CMe$_2$O)$_2$]$_2$Zr and [PhCH$_2$N(CH$_2$C-*p*-Tol$_2$O)$_2$]$_2$Zr.[44] According to the NMR spectroscopic data both spirobizirconocanes are monomeric in solution while the X-ray diffraction study of [PhCH$_2$N(CH$_2$CMe$_2$O)$_2$]$_2$Zr showed the dimeric structure of this compound in the solid state resulting from the rupture of three of the four Zr–N bonds into two monomeric units.[44] Thus, one can conclude that the structure of the ligand is the main factor governing the coordination environment around the metal atom in spirobiocanes.

In order to clarify the structure of the ligand influence we explored the synthesis and structures of the number of novel spirobititanocanes. The compounds **18**–**28** were obtained in high yields from the reaction of Ti(O*i*Pr)$_4$ with two equivalents of corresponding dialkanolamines **1**, **3**–**12** at reflux in toluene (Scheme 4). Compound **19** was also prepared in 33% yield from the treatment of TiCl$_4$·(THF)$_2$ with **3** in the presence of Et$_3$N or in quantitative yield from the reaction of Ti(CH$_2$Ph)$_4$ with two equivalents of **3** (Scheme 4). The latter approach was also used for the synthesis of **23**.

We also tried to prepare spiro-bisheteroleptic ocanes (Scheme 5), but in all of the studied cases equimolar mixtures of spiro-bishomoleptic ocanes were obtained (NMR spectroscopic data). This result contradicts that previously found for bis(aminophenol)-type ligands, where the bisheteroleptic species are stable.[27] We suppose that, on the one hand, the symmetric bis(ocanes) are more thermodynamically stable in the case of dialkanolamine type ligands. On the other hand, the unsymmetric bis(ocanes) are probably formed in the course of the reactions, but because of their higher flexibility in comparison with that for phenolic species[27] a mixture of symmetric compounds forms through a metathetical process.

One dialkanolamine ligand in spirobititanocane **18** can easily be exchanged by the treatment with equimolar amounts of Ti(O*i*Pr)$_4$ (Scheme 6). The reaction of **19** with one equivalent of TiCl$_4$ resulted in a mixture of unidentified products (Scheme 6).



Scheme 6.

According to the NMR spectroscopic data, spirobititanocane **19** possesses a monomeric structure in solution ($CDCl_3$) and exists as one isomer (Scheme 3). It should be noted that in the *trans* and *cis* isomers of **19** the two dialkanolamine groups are equivalent. Thus, in theory it is impossible to define what kind of isomer exists in $CDCl_3$ solution, but we can conclude that only one isomer is present under these conditions. We believe that spirobititanocane **18** is also monomeric in solution, but the broadening of

signals was found for its NMR spectra (like in closely related titanocane **13**). This indicates the presence of dynamic processes in solution of **18**, such as Berry pseudorotation, *cis-trans* isomerization and/or N–Ti bond dissociation. Although different sets of signals should be present in the $^{13}C$ NMR spectra of the *trans* and *cis* isomers for compound **20**–**28**, it is very difficult to determine unambiguously the type of isomer in this case because of the presence of several diastereomers of these compounds in solution resulting from the asymmetric carbon atoms. However, the importance of the synthesis of compounds with asymmetric car-

bon atoms is connected with the usefulness of these derivatives in catalytic processes.

The structures of six spirobititanocanes **19**, **20**, **23**, **24**, **25**, **27** were studied by X-ray diffraction. The monomeric nature of all the studied species with a hexacoordinate titanium center was confirmed. The coordination polyhedron of the titanium atom in these compounds represents a distorted octahedron. The molecular structures of **19** (one independent molecule), **20**, **23**, **24**, **25**, and **27** are shown in Figure 2, Figure 3, Figure 4, Figure 5, Figure 6, and Figure 7, respectively. Table 2 and Table 3 list selected geometrical parameters for these compounds.

structure is considered to be *trans*-isomer **B** (Scheme 3). To the best of our knowledge, compound **24** is the first example of such a structure; however, a similar *trans* disposition of the nitrogen atoms in $TiO_4N_2$ was previously found.[48]

The Ti–N distances in **19**, **20**, **23**, **24**, **25**, and **27** vary over the range 2.310(2)–2.471(3) Å, the shortest distance being found in compound **24** (*trans* disposition of N atoms). These values are close to that previously found for **29** [2.422(2) Å].[20] The substitution of hydrogen atoms (**19**, **29**) of the ocane skeleton for phenyl groups (**20**, **23**, **24**, **25**) shortens the Ti–N bond, while the substitution with alkyl groups (**27**) slightly elongates this distance. In general, the Ti–N distances in phenolic compounds [*n*PrN($CH_2$-*o*-ArO)$_2$]-Ti[(O-*o*-Ar′$CH_2$)$_2$NR] [2.248(2)–2.308(4) Å][27] are shorter than those in **19**, **20**, **23**, **24**, **25**, **27**, and **29** based on dialkanolamine-type ligands. This difference is probably explained by the higher polarity of the Ti–O bonds in phenolic species, which leads to depletion of electron density at the titanium center. A similar tendency was found for Ti–O bonds in hexacoordinate compounds discussed above. In general, the shorter Ti–N bonds in the molecules correspond to longer Ti–O bonds. This tendency is also supported by the fact that Ti–O bonds in the only X-ray studied monomeric tetraalkoxy titanium derivative with a tetracoordinate Ti atom [1.752(2)–1.825(2) Å][49] are considerably shorter than those in the hexacoordinate compounds.

All five-membered unsubstituted rings of the ocane skeletons in **19**, **20**, **23**, **24**, **25**, and **27** adopt an "envelope"-like conformation, all carbon atoms in the α positions to the N atom occupy "flap" sites. In the case of substituted rings their conformation may be treated as an "envelope" with α-C atoms in "flap" sites (**20**, **23**, and **25**) or a "twist" (**24** and **27**).

## Conclusion

We have found that tetraisopropoxytitanium or cyclopentadienyltrimethoxytitanium react with one equivalent of dialkanolamines **1**–**3** leading to the formation of the corresponding dialkoxytitanocanes **13**–**16**. The substitution reaction of diisopropoxy derivative **15** with L-(–)-menthol easily occurs to give dimenthoxytitanocane **17**. The nature of the alkoxy substituent at the Ti atom strongly affects the structure and dynamic behavior of **13**–**17** in solution. The reaction of Ti(O*i*Pr)$_4$ with two equivalents of dialkanolamines **1**, **3**–**12** led to the corresponding spirobititanocanes **18**–**28** with a hexacoordinate Ti atom. The structure of latter compounds is governed by the nature of the ligands: depending on the substituents in the ocane skeleton the nitrogen atoms occupy *cis* or *trans* positions around the Ti atom. Spirobititanocane **18** is easily converted into the corresponding titanocane **13** by its reaction with one equivalent of Ti(O*i*Pr)$_4$. The reaction of titanocanes **14** and **15** with the different dialkanolamines (**1**, **3** and **2**, **8**, respectively) did not give the expected bisheteroleptic compounds but resulted in a mixture of bishomoleptic titanocanes **18** and **29**, **19** and **29** and **19** and **29**, **19** and **24**, respectively.

## Experimental Section

**General Remarks:** All manipulations were performed under a dry, oxygen-free argon atmosphere using standard Schlenk techniques. Solvents were dried by standard methods and distilled prior to use. PhN($CH_2CH_2OH$)$_2$ (**1**), MeNH$CH_2CH_2OH$ (Aldrich) and (1*R*,2*S*,5*R*)-menthol (Acros) were used as supplied. HN($SiMe_3$)$_2$ (Aldrich), Ti(O*i*Pr)$_4$ (Aldrich), and $TiCl_4$ (Aldrich) were distilled before use. CpTi(OMe)$_3$,[50] $TiCl_4$(THF)$_2$,[51] Ti($CH_2Ph$)$_4$,[52] MeN($CH_2CH_2OH$)$_2$ (**2**),[53] PhC$H_2$N($CH_2CH_2OH$)$_2$ (**3**),[54] MeN($CH_2CH_2OH$)$CH_2$CH(Ph)OH (**4a**) and MeN($CH_2CH_2OH$)-CH(Ph)$CH_2OH$ (**4b**) as a mixture 9:1,[34] MeN($CH_2CH_2OH$)-$CH_2$CH(Me)OH (**5**),[55] and MeN($CH_2CH_2OH$)$CH_2$CH(Et)OH (**6**)[55] were prepared according to the literature. $^{13}C\{^1H\}$ NMR spectrum for **5**: $\delta$ = 20.17 (Me), 42.42 (MeN), 59.21, 59.73 (2 $NCH_2$ groups), 63.65, 65.52 ($OCH_2$ and OCH groups) ppm. $^{13}C\{^1H\}$ NMR spectrum for **6**: $\delta$ = 9.86 ($CH_2CH_3$), 27.71 ($CH_2CH_3$), 42.48 ($NCH_3$), 59.30, 59.75 ($NCH_2$), 63.77, 68.91 (OCH and $OCH_2$) ppm. PhC$H_2$N($CH_2CH_2OSiMe_3$)$_2$[43] and MeN($CH_2$-$CH_2$OSn-*n*Bu$_3$)$_2$[38] were prepared according to the method reported previously. PhC$H_2$N($CH_2CH_2OSiMe_3$)$_2$: B.p. = 126–129 °C (0.7 Torr). NMR spectra: $^1H$ NMR: $\delta$ = 0.07 (s, 18 H, $SiMe_3$), 2.67 (t, 4 H, $NCH_2$), 3.61 (t, 4 H, $OCH_2$), 3.69 (s, 4 H, PhC$H_2$N), 7.18–7.32 (m, 5 H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = –0.54 ($SiMe_3$), 56.66 ($NCH_2$), 60.07 ($OCH_2$), 61.17 (PhC$H_2$), 126.83, 128.13, 128.78, 139.83 (aromatic carbons) ppm. MeN($CH_2CH_2OSn$-*n*Bu$_3$)$_2$: NMR spectra: $^1H$ NMR: $\delta$ = 0.95–0.82 (m, 18 H, $CH_2CH_3$), 1.14–0.98 (m, 12 H, $CH_2CH_3$), 1.33–1.26 (m, 12 H, $SnCH_2CH_2$), 1.57–1.49 (m, 12 H, $SnCH_2$), 2.24 (s, 3 H, $NCH_3$), 2.47 (t, 4 H, $NCH_2$), 3.74 (t, 4 H, $OCH_2$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 13.61 ($CH_2CH_3$), 14.55 ($CH_2CH_3$), 27.16 ($SnCH_2CH_2$), 27.95 ($SnCH_2$), 43.83 ($NCH_3$), 62.65 ($NCH_2$), 64.04 ($OCH_2$) ppm.

A solution of *n*-butyllithium in hexane was obtained and analyzed by the Gilman double-titration method.[56] $CDCl_3$ was obtained from Deutero GmbH and dried with $P_4O_{10}$. $^1H$ NMR (300 MHz) and $^{13}C$ NMR (75 MHz) spectra were recorded with a Bruker–Evance spectrometer (in $CDCl_3$ at 295 K unless otherwise stated). Chemical shifts in the $^1H$ and $^{13}C$ NMR spectra are given in ppm relative to internal $Me_4Si$. Elemental analyses were carried out by the Microanalytical Laboratory of the Chemistry Department of the Moscow State University.

**MeN($CH_2CH_2OH$)$CH_2$C(Ph)$_2$OH (7):** A mixture of *N*-methylethanolamine (1.15 g, 15 mmol) and 2,2-diphenyloxyrane (3.00 g, 15 mmol) was heated at 90 °C for 35 h. The resulting dense yellow oil was crystallized from the mixture diethyl ether/hexane (1:1) at –20 °C to give **7** as a white crystalline solid [3.14 g, 77%; 109–110 °C (110–111 °C[46])]. NMR spectra: $^1H$ NMR: $\delta$ = 2.12 (s, 3 H, $NCH_3$), 2.61 (t, 2 H, $NCH_2$), 3.36 (s, 2 H, $NCH_2$), 3.56 (t, 2 H, $OCH_2$), 7.16–7.20, 7.26–7.31, 7.46–7.49 (3 m, 10 H, 2 $C_6H_5$) ppm, the signal from the OH groups was not observed. $^{13}C\{^1H\}$ NMR: $\delta$ = 44.15 ($NCH_3$), 59.86, 61.27, 67.76 (2 $NCH_2$ and $OCH_2$ groups), 75.60 [C($C_6H_5$)$_2$], 125.79, 126.73, 128.15, 146.55 ($C_6H_5$) ppm.

***erythro*-MeN($CH_2CH_2OH$)CH(Ph)CH(Ph)OH (8):** A mixture of *N*-methylethanolamine (2.0 mL, 25 mmol) and *trans*-stilbene oxide (4.91 g, 25 mmol) was heated at 130 °C for 22 h. The resulting dense orange oil was crystallized from the mixture of diethyl ether/hexane (1:1) at –20 °C to give **8** as a light yellow crystalline solid (6.20 g, 91%; 90–91 °C). NMR spectra: $^1H$ NMR: $\delta$ = 1.98 (br. s, 2 H, 2 OH), 2.13 (s, 3 H, $NCH_3$), 2.38–2.51 (m, 2 H, $NCH_2$), 3.30–3.40 (m, 2 H, $OCH_2$), 3.71 (d, 1 H, NCH), 5.22 (d, 1 H, OCH), 7.23–7.37 (m, 10 H, 2 $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 37.36 ($NCH_3$), 56.78 ($NCH_2$), 57.97 ($OCH_2$), 72.98 (NCH), 74.63 (OCH), 126.58, 127.89, 127.92, 128.30, 129.51, 134.85, 142.19 ($C_6H_5$).

**MeN(CH$_2$CH$_2$OH)CH(C$_3$H$_6$)CHOH (10):** A mixture of *N*-methylethanolamine (2.95 g, 40 mmol) and cyclopentene oxide (3.36 g, 40 mmol) was stirred at 85 °C for 20 h. The distillation of the reaction mixture gave **10** as a viscous light-yellow liquid [5.29 g, 91%; 105–106 °C (0.2 Torr)]. NMR spectra: $^1$H NMR: $\delta$ = 1.93–1.35 (m, 6 H, cyclopentane 3$CH_2$), 2.25 (s, 3 H, $NCH_3$), 2.59 (m, 2 H, $NCH_2$), 2.74–2.81 (m, 1 H, NCH), 3.52–3.65 (m, 2 H, $OCH_2$), 3.76 (br. s, 2 H, OH), 3.99–4.06 (m, 1 H, OCH) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 20.72, 24.39, 33.15 (cyclopentane carbons $CH_2$), 38.64 ($NCH_3$), 56.20 ($NCH_2$), 58.57 ($OCH_2$), 73.34 (NCH), 74.41 (OCH) ppm. $C_8H_{17}NO_2$ (159.23): calcd. C 60.35, H 10.76, N 8.80; found C 59.98, H 10.63, N 9.20.

**MeN(CH$_2$CH$_2$OH)CH(C$_4$H$_8$)CHOH (11):** A mixture of *N*-methylethanolamine (13.2 mL, 0.165 mol) and cyclohexene oxide (15.2 mL, 0.15 mol) was heated at 100 °C for 48 h. The distillation of the reaction mixture gave **11** as a viscous colorless liquid [22.89 g, 88%; 105–107 °C (0.2 Torr)]. NMR spectra: $^1$H NMR: $\delta$ = 0.99–1.24, 1.59–1.69, 1.96–2.03 (3 m, 8 H, cyclohexane, 4 $CH_2$), 2.19 (s, 3 H, $NCH_3$), 2.14–2.22, 2.36–2.44, 2.58–2.67, 3.27–3.35, 3.48–3.59 (5 m, 6 H, $NCH_2$, $OCH_2$, NCH, OCH), 3.75 (br. s, 2 H, 2 OH) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 21.82, 24.12, 25.20, 33.38 (cyclohexane carbons $CH_2$), 36.68 ($NCH_3$), 54.98 ($NCH_2$), 59.42 ($OCH_2$), 69.25, 69.42 (NCH, OCH) ppm. $C_9H_{19}NO_2$ (173.25): calcd. C 62.39, H 11.05, N 8.08; found C 61.99, H 11.07, N 8.42.

**MeN(CH$_2$CH$_2$OH)CH(C$_6$H$_4$CH$_2$)CHOH (12):** Analogously to **8** (except only diethyl ether was used for recrystallization), dialkanolamine **12** was obtained from *N*-methylethanolamine (2.30 g, 30 mmol) and indene oxide (3.96 g, 30 mmol) as a light-yellow crystalline solid (5.82 g, 94%; 75–76 °C). NMR spectra: $^1$H NMR: $\delta$ = 2.44 (s, 3 H, $NCH_3$), 2.82–2.95, 3.26–3.34 [2 m, 2 H, C$H_2$C(OH) H], 2.88–2.95 (m, 2 H, $NCH_2$), 3.19 (br. s, 2 H, 2 OH), 3.66–3.79 (m, 2 H, $OCH_2$), 4.29 (d, 1 H, NCH), 4.66 (q, 1 H, OCH), 7.23–7.35 (m, 4 H, aromatic protons) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 37.34 ($CHCH_2$), 39.68 ($NCH_3$), 55.87 ($NCH_2$), 58.44 (NCH), 73.75 ($OCH_2$), 113.46 (OCH), 125.06, 125.08, 126.79, 127.94, 140.00, 140.10 (aromatic carbons) ppm.

**PhN(CH$_2$CH$_2$O)$_2$Ti(O*i*Pr)$_2$ (13):** A mixture of alkanolamine **1** (2.00 g, 11.0 mmol), Ti(O*i*Pr)$_4$ (3.14 g, 11.0 mmol), and chloroform (20 mL) was refluxed for 8 h, and all volatiles were removed under reduced pressure. Hexane (20 mL) was added to a yellow, waxy solid. The solution was filtered and the solvent removed under reduced pressure to give **13** as a yellow solid (3.05 g, 80%). NMR spectra: $^1$H NMR: $\delta$ = 1.19 (br. s, 12 H, $CH_3$), 3.47 (br. s, 4 H, $NCH_2$), 4.30–4.90 (br. m, 6 H, $OCH_2$, OCH), 6.53–6.70, 7.07–7.19 (2 m, 5 H, $C_6H_5$) ppm. $^{13}$C{$^1$H} NMR (323 K): $\delta$ = 26.24 ($CH_3$), 55.21 (broad, $NCH_2$), 73.22 (broad, $OCH_2$), 77.44 (OCH), 113.38, 116.58, 130.05, 149.41 (broad, $C_6H_5$) ppm. Satisfactory results for the elemental analyses were unobtainable because of the presence of traces of **18**.

**MeN(CH$_2$CH$_2$O)$_2$Ti(O*i*Pr)$_2$ (14):** A mixture of alkanolamine **2** (2.14 g, 18.0 mmol), Ti(O*i*Pr)$_4$ (5.11 g, 18.0 mmol), and chloroform (20 mL) was refluxed for 7 h, all volatiles were removed under reduced pressure. The residue was dissolved in hexane (20 mL), the solution was filtered and stored at –30 °C for 18 h to give an oil under a supernatant solution. The solvent was removed through a cannula and **14** was obtained as a colorless oil (4.53 g, 89%). NMR spectra: $^1$H NMR: $\delta$ = 1.07 (d, 12 H, CHC$H_3$), 2.48 (s, 3 H, $NCH_3$), 2.80 (br. s, 4 H, $NCH_2$), 4.20 (br. s, 4 H, $OCH_2$), 4.48 (br. s, 2 H, OCH) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 25.70 (CHC$H_3$), 44.38 ($NCH_3$), 59.50 ($NCH_2$), 69.20 ($OCH_2$), 76.30 (OCH) ppm. Satisfactory results for the elemental analyses were unobtainable because of the presence of traces of **29**.

**PhCH$_2$N(CH$_2$CH$_2$O)$_2$Ti(O*i*Pr)$_2$ (15):** The procedure was the same as for **14** except that Ti(O*i*Pr)$_4$ (3.70 g, 13.0 mmol) was treated with alkanolamine **3** (2.50 g, 13.0 mmol) in toluene. The compound **15** was obtained as a white oil (4.30 g, 92%). NMR spectra: $^1$H NMR: $\delta$ = 1.26 (d, 12 H, CH$CH_3$), 2.93 (br. s, 4 H, $NCH_2$), 4.19 (s, 2 H, $PhCH_2$), 4.39 (br. s, 4 H, $OCH_2$), 4.66 (br. s, 2 H, OCH), 7.23–7.34 (m, 5 H, $C_6H_5$) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 26.11 (CH$CH_3$), 54.21 ($NCH_2$), 58.01 ($PhCH_2$), 69.43 ($OCH_2$), 76.53 (OCH), 128.01, 128.30, 131.01, 133.74 ($C_6H_5$) ppm. $C_{17}H_{29}NO_4Ti$ (359.28): calcd. C 56.51, H 7.98, N 3.72; found C 56.83, H 8.14, N, 3.90.

**Reaction of PhCH$_2$N(CH$_2$CH$_2$OSiMe$_3$)$_2$ with TiCl$_4$(THF)$_2$:** $PhCH_2N(CH_2CH_2OSiMe_3)_2$ (0.95 g, 2.8 mmol) was added dropwise to a suspension of $TiCl_4(THF)_2$ (0.94 g, 2.8 mmol) in toluene (15 mL). The reaction mixture was refluxed for 14 h, and then filtered off to give a yellow solid, which was insoluble in the usual organic solvents. According to NMR spectroscopic data in $(CD_3)_2$-SO, a mixture of unidentified compounds formed.

**Reaction of MeN(CH$_2$CH$_2$OSn-*n*Bu$_3$)$_2$ with Cp$_2$TiCl$_2$:** $MeN(CH_2CH_2OSn\text{-}nBu_3)_2$ (2.35 g, 3.4 mmol) was added dropwise to a solution of $Cp_2TiCl_2$ (0.60 g, 2.4 mmol) in $CHCl_3$ (65 mL). The reaction mixture was stirred for 10 h, then all volatiles were removed under reduced pressure. According to NMR spectroscopic data of the residue a mixture of CpSn-*n*Bu$_3$ with unidentified compounds formed.

**[PhCH$_2$N(CH$_2$CH$_2$O)$_2$Ti(OMe)$_2$]$_2$ (16):** A solution of alkanolamine **3** (0.71 g, 3.6 mmol) in THF (10 mL) was added dropwise at –50 °C to a solution of $CpTi(OMe)_3$ (0.75 g, 3.6 mmol) in THF (20 mL). The mixture was warmed to room temperature and stirred overnight. The solid that formed was filtered off and recrystallized from the mixture of dichloromethane/heptane (1:1) to give **16** as white microcrystals (0.84 g, 77%). NMR spectra: $^1$H NMR: $\delta$ = 2.85–2.90, 3.05–3.10 (2 br. m, 4 H, $NCH_2$), 4.17, 4.22 (2 s, 6 H, $OCH_3$), 4.43 (br. s, 2 H, $PhCH_2$), 4.28–4.36, 4.57–4.63 (2 br. m, 4 H, $OCH_2$), 7.25–7.36 (m, 5 H, $C_6H_5$) ppm. $^{13}$C{$^1$H} NMR: $\delta$ = 54.22 ($NCH_2$), 55.70 ($PhCH_2$), 60.46, 64.74 ($OCH_3$), 68.82 ($OCH_2$), 127.88, 128.22, 131.47, 134.01 ($C_6H_5$) ppm. Satisfactory results for the elemental analyses were unobtainable because of the presence of traces of **19**.

**PhCH$_2$N(CH$_2$CH$_2$O)$_2$Ti(OMenth)$_2$ (17):** L-(–)-Menthol (1.56 g, 10 mmol) was added to a stirred solution of the compound **15** (1.80 g, 5.0 mmol) in chloroform (30 mL) at room temperature. The reaction mixture was refluxed for 6 h, all volatiles were removed under reduced pressure. Hexane (20 mL) was added to the white oil. The mixture was stored at –30 °C for several days. The solid that formed was filtered off to give **17** as a white powder (2.64 g, 96%). NMR spectra: $^1$H NMR: $\delta$ = 0.76 (d, 3 H, $CH_3$), 0.82 (br.

d, 6 H, $CH_3$), 0.85–0.95 (m, 13 H, $CH_3$, $CH_2$), 1.01–1.18 (m, 4 H, $CH_2$), 1.38 (br. s, 2 H, CH), 1.50–1.62 (br. m, 4 H, $CH_2$), 2.07–2.12, 2.17–2.22 (2 br. m, 2 H, CH), 2.33–2.48 (br. m, 2 H, CH), 2.84, 3.00 (2 br. s, 4 H, $NCH_2$), 3.83–3.90, 4.05–4.14 (2 m, 2 H, OCH), 4.16 (br. s, 2 H, $PhCH_2$), 4.33, 4.46 (2 br. s, 4 H, $OCH_2$), 7.26–7.37 (m, 5 H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 15.78, 21.20, 22.25 ($CH_3$), 22.70 ($CH_2$), 25.45, 31.65 (CH), 34.63, 46.51 ($CH_2$), 50.98 (CH), 54.22 (broad, $NCH_2$), 57.84 ($PhCH_2$), 69.37 ($OCH_2$), 84.14, 85.01 (OCH), 128.05, 128.36, 131.10, 133.89 ($C_6H_5$) ppm. Satisfactory results for the elemental analyses were unobtainable because of the presence of traces of **19**.

**[PhN(CH$_2$CH$_2$O)$_2$]$_2$Ti (18):** A mixture of alkanolamine **1** (0.83 g, 4.6 mmol), Ti(O*i*Pr)$_4$ (0.65 g, 2.3 mmol), and toluene (15 mL) was refluxed for 13 h, and all volatiles were removed under reduced pressure. The residue was recrystallized from toluene to give **18** as a yellow solid (0.77 g, 82%). NMR spectra: $^1H$ NMR: $\delta$ = 3.41 (br. s, 8 H, $NCH_2$), 4.17 (br. s, 8 H, $OCH_2$), 6.58–6.70, 7.13–7.26 (m, 10 H, $C_6H_5$) ppm $^{13}C\{^1H\}$ NMR: $\delta$ = 56.71 (broad, $NCH_2$), 73.52 (broad, $OCH_2$), 112.01, 116.02, 130.46, 148.16 ($C_6H_5$) ppm. $C_{20}H_{26}N_2O_4Ti$ (406.30): calcd. C 59.12, H 6.45, Ti 11.79; found C 59.46, H 6.44, Ti 11.51.

**[PhCH$_2$N(CH$_2$CH$_2$O)$_2$]$_2$Ti (19). Method 1:** The procedure was the same as that for **18** except that Ti(O*i*Pr)$_4$ (0.94 g, 3.3 mmol) was treated with alkanolamine **3** (1.29 g, 6.6 mmol). The compound was obtained as white microcrystals (1.22 g, 85%). NMR spectra: $^1H$ NMR: $\delta$ = 3.00 (t, 8 H, $NCH_2$), 4.11 (s, 4 H, $PhCH_2$), 4.49 (t, 8 H, $OCH_2$), 7.27–7.38 (m, 10 H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 53.48 (broad, $NCH_2$), 56.73 ($PhCH_2$), 70.22 ($OCH_2$), 127.92, 128.29, 130.99, 133.90 ($C_6H_5$) ppm. $C_{22}H_{30}N_2O_4Ti$ (434.38): calcd. C 60.83, H 6.96, N 6.45; found C 61.01, H 7.10, N 6.59.

**Method 2:** A solution of alkanolamine **3** (1.10 g, 5.6 mmol) and triethylamine (1.15 g, 11.4 mmol) in THF (30 mL) was added dropwise at –50 °C to a suspension of $TiCl_4(THF)_2$ (0.94 g, 2.8 mmol) in THF (20 mL). The mixture was stirred for 1 h at the same temperature, and was then warmed to room temperature overnight. All volatiles were evaporated under reduced pressure. A white solid was extracted with hot benzene (3 × 20 mL). The solvent was removed under reduced pressure, and the residue was recrystallized from toluene to give **19** as white microcrystals (0.4 g, 33%).

**Method 3:** A solution of alkanolamine **3** (0.70 g, 3.6 mmol) in toluene (5 mL) was added dropwise to a solution of Ti($CH_2Ph$)$_4$ (0.75 g, 1.8 mmol) in toluene (40 mL) at (–40 °C). The reaction mixture was slowly warmed to room temperature and then refluxed for 1 h. The resulting solution was concentrated under vacuum, to give **20** as a white solid (0.78 g, 100%).

**[MeN(CH$_2$CH$_2$O)(CH$_2$CHPhO)]$_2$Ti (20):** The procedure was the same as that for **18** except that Ti(O*i*Pr)$_4$ (0.77 g, 2.7 mmol) was treated with a mixture of (**4a** and **4b**) (9:1) (1.05 g, 5.4 mmol). The compound **20** was obtained as colorless microcrystals, a mixture of diastereomers. NMR spectra: $^1H$ NMR: $\delta$ = 2.61, 2.64, 2.66 (3 s, 6 H, $NCH_3$), 2.72–2.85, 2.98–3.25, 3.37–3.54 (3 m, 8 H, $NCH_2$), 4.26–4.31, 4.57–4.66 (2 m, 4 H, $OCH_2$), 5.63–5.70, 5.75–5.81 (2 m, 2 H, OCH), 7.13–7.47 (m, 10 H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 42.15, 42.72, 44.18 ($NCH_3$), 56.23, 59.49 ($NCH_2$), 69.43 (broad, $OCH_2$), 80.67, 80.78 (OCH), 124.33, 124.86, 125.55, 126.18, 126.35, 126.93, 127.32, 128.04, 128.24, 143.73, 143.85, 144.18 ($C_6H_5$) ppm, the signals of several carbons were not found, the signals of solvated toluene are not described. $C_{22}H_{30}N_2O_4Ti$*$PhCH_3$ (526.51): calcd. C 66.16, H 7.27, N 5.32; found C 66.06, H 7.01, N 4.89.

**[MeN(CH$_2$CH$_2$O)(CH$_2$CHMeO)]$_2$Ti (21):** The procedure was the same as for **18** except that the mixture of alkanolamine **5** (2.40 g, 18.0 mmol) and Ti(O*i*Pr)$_4$ (2.56 g, 9.0 mmol) was refluxed for 15 h in toluene (15 mL). The compound **21** was obtained as a colorless oil (2.67 g, 96%), a mixture of diastereomers. NMR spectra: $^1H$ NMR: $\delta$ = 1.00, 1.02, 1.11 (3 d, 6 H, CH*C*H$_3$), 2.41, 2.43, 2.45 (3 s, 6 H, $NCH_3$), 2.48–2.53, 2.60–2.81, 3.00–3.24 (3 br. m, 8 H, $NCH_2$), 4.00–4.09, 4.46–4.51 (2 m, 4 H, $OCH_2$), 4.70 (br. s, 2 H, OCH) ppm. $^{13}C\{^1H\}$ NMR (323 K): $\delta$ = 20.90, 21.05, 21.22 (CH*C*H$_3$), 43.42, 44.27, 44.51 ($NCH_3$), 58.92, 59.70, 59.91 ($NCH_2$), 69.57, 69.51 ($OCH_2$), 74.89, 75.04 (OCH) ppm, the signals of several carbons were not found. $C_{12}H_{26}N_2O_4Ti$ (310.21): calcd. C 46.46, H 8.45, N 9.03; found C 46.20, H 8.56, N 8.94.

**[MeN(CH$_2$CH$_2$O)(CH$_2$CHEtO)]$_2$Ti (22):** The procedure was the same as for **18** except that alkanolamine **6** (2.97 g, 20 mmol) was treated with Ti(O*i*Pr)$_4$ (2.87 g, 10 mmol) in toluene (15 mL). Compound **22** was obtained as a colorless oil (3.18 g, 94%), a mixture of diastereomers. NMR spectra: $^1H$, $\delta$ = 0.78–0.81 (m, 6 H, $CH_2CH_3$), 1.30 (br. s, 4 H, $CH_2CH_3$), 2.42 (br. s, 6 H, $NCH_3$), 2.45–2.55, 2.76–2.85, 3.15–3.39 (3 br. m, 8 H, $NCH_2$), 4.07, 4.48 (2 br. s, 6 H, $OCH_2$, OCH); $^{13}C\{^1H\}$, $\delta$ = 9.08 (broad, $CH_2CH_3$), 27.67 (broad, $CH_2CH_3$), 41.93, 43.71 ($NCH_3$), 59.22, 60.35 ($NCH_2$), 68.25 (broad, $OCH_2$), 79.64 (broad, OCH), the signals of several carbons were not found. $C_{14}H_{30}N_2O_4Ti$ (338.27): calcd. C 49.71, H 8.94, N 8.28; found C 49.29, H 8.73, N 8.09.

**[MeN(CH$_2$CH$_2$O)(CH$_2$CPh$_2$O)]$_2$Ti (23). Method 1:** The procedure was the same as for **18** except that alkanolamine **7** (0.97 g, 3.6 mmol) was treated with Ti(O*i*Pr)$_4$ (0.51 g, 1.8 mmol) in chloroform (10 mL). Compound **23** was obtained as white microcrystals (0.70 g, 90%). NMR spectra: $^1H$ NMR: $\delta$ = 2.42 (br. s, 6 H, $NCH_3$), 2.84, 2.97 (2 br. s, 4 H, N*C*H$_2$), 3.85, 3.98 (2 d, 4 H, N*C*H$_2$CPh$_2$), 4.35 (br. s, 4 H, $OCH_2$), 7.10–7.30, 7.50–7.56 (2 m, 20 H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 44.79 ($NCH_3$), 61.45 ($NCH_2$), 70.41 ($OCH_2$), 88.75 (O*C*Ph$_2$), 125.46, 125.51, 126.08, 126.14, 127.98, 128.01, 149.68 ($C_6H_5$) ppm, the signals of several carbons were not found. $C_{34}H_{38}N_2O_4Ti$ (586.54): calcd. C 69.62, H 6.53, Ti 8.16; found C 69.86, H 6.64, Ti 8.17.

**Method 2:** Alkanolamine **7** (1.14 g,4.2 mmol) was added to a solution of titanium tetrabenzyl (0.87 g, 2.1 mmol) in toluene (50 mL) at (–40 °C). The reaction mixture was slowly warmed to room temperature and then refluxed for 1 h. The resulting colorless solution was concentrated under vacuum, to give **23** as a white solid (1.23 g, 100%). Crystals, suitable for X-ray analysis, were obtained by recrystallization from the mixture of dichloromethane/*n*-hexane.

***erythro*-[MeN(CH$_2$CH$_2$O)(CHPhCHPhO)]$_2$Ti (24):** The procedure was the same as that for **13** except that alkanolamine **8** (2.17 g, 8.0 mmol) was treated with Ti(O*i*Pr)$_4$ (1.14 g, 4.0 mmol) in chloroform (20 mL). Compound **24** was obtained as colorless microcrystals (1.97 g, 84%), a mixture of diastereomers. NMR spectra: $^1H$ NMR: $\delta$ = 2.57 (br. s, 6 H, $NCH_3$), 2.96–3.38 (br. m, 4 H, $NCH_2$), 4.15–4.32 (br. m, 4 H, $OCH_2$), 4.50–4.59 (br. m, 2 H, NCH), 6.10–6.15, 6.26–6.45 (br. m, 2 H, OCH), 7.05–7.34 (m, 20 H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 42.29, 42.36, 45.82 ($NCH_3$), 60.63 (broad, $NCH_2$), 69.72, 70.46 71.48, 71.52 ($OCH_2$, NCHPh), 86.51 (broad, OCHPh), 125.90, 126.22, 126.43, 126.90, 127.11, 127.27, 127.45, 127.68, 127.84, 131.21, 142.11, 142.77 ($C_6H_5$) ppm, the signals of several carbons were not found. $C_{34}H_{38}N_2O_4Ti$ (586.54): calcd. C 69.62, H 6.53, Ti 8.16; found C 70.55, H 6.83, N 4.55.

***threo*-[MeN(CH$_2$CH$_2$O)(CHPhCHPhO)]$_2$Ti (25):** The procedure was the same as that for **13** except that the mixture of alkanolamine **9** (2.00 g, 7.4 mmol),Ti(O*i*Pr)$_4$ (1.05 g, 3.7 mmol) and chloroform (20 mL) was refluxed for 16 h. The compound **25** was recrystallized from the mixture of dichloromethane/heptane (4:1) and isolated as colorless microcrystals (1.52 g, 96%), a mixture of diastereomers.

ene (10 mL). The mixture was refluxed for 2 h, and all volatiles were removed under reduced pressure. According to NMR spectroscopic data, a mixture of **19** and **29**[20] was formed.

**Reaction of 15 with Alkanolamine 2:** Alkanolamine **2** (0.46 g, 2.5 mmol) was added to a solution of **15** (0.91 g, 2.5 mmol) in chloroform (15 mL). The mixture was refluxed for 3 h, and all volatiles were removed under reduced pressure. According to NMR spectroscopic data, a mixture of **19** and **29**[20] was formed.

**Reaction of 15 with Alkanolamine 8:** Alkanolamine **8** (1.32 g, 4.9 mmol) was added to a solution of compound **15** (1.75 g, 4.9 mmol) in toluene (10 mL). The mixture was refluxed for 2 h, and all volatiles were removed under reduced pressure. Ether (20 mL) was added to the residue, the precipitate was filtered off to give **19** as a white powder (1.02 g). According to NMR spectroscopic data, the mother liquor contained a mixture of **19** and **24**.

**Reaction of 18 with Ti(O*i*Pr)$_4$:** Ti(O*i*Pr)$_4$ (0.52 g, 1.8 mmol) was added dropwise to a solution of compound **18** (0.74 g, 1.8 mmol) in chloroform (20 mL), and the reaction mixture was refluxed for 5 h. After cooling to room temperature, all volatiles were removed under reduced pressure. Hexane (10 mL) was added to the yellow oil. The solution was filtered, and the solvent was removed under reduced pressure to give **13** as a yellow solid (1.22 g, 97%).

**Reaction of 19 with TiCl$_4$:** TiCl$_4$ (0.44 g, 2.3 mmol) was added at –78 °C to a suspension of **19** (1.00 g, 2.3 mmol) in toluene (15 mL) and the mixture was stirred for 2 h at the same temperature. A yellow solid formed. The reaction mixture was warmed to room temperature, and all volatiles were removed under reduced pressure. The formed yellow solid was insoluble in the usual organic solvents. According to NMR spectroscopic data in $(CD_3)_2SO$, a mixture of unidentified compounds formed.

**X-ray Crystallographic Study:** Crystal data, data collection, structure solution, and refinement parameters for compounds **16**, **19**, **20**, **23**, **24**, **25**, and **27** are given in Table 4. Experimental data were collected using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods[57] and refined by full-matrix least-squares based on $F^2$ with anisotropic thermal parameters for all non-hydrogen atoms.[58] In the structures **16**, **20**, and **25**, all hydrogen atoms were found from diff. Fourier syntheses and refined isotropically. As for **19**, **23**, **24**, and **27** all hydrogen atoms were placed in calculated positions and refined using a riding model. The structure **25** contains disordered $CH_2Cl_2$ molecules lying on a crystallographic twofold axis; **24** contains disordered toluene molecules lying on a crystallographic inversion center. In **19**, one of the two independent molecules possesses disordered -$CH_2CH_2$- skeleton fragments with an occupancy ratio of 0.71/0.29.

CCDC-292591 to -292597 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Rare Earth Benzotriazolates: Coordination Polymers Incorporating Decomposition Products from Ammonia to 1,2-Diaminobenzene in $^1_\infty[Ln(Btz)_3(BtzH)]$ (Ln = Ce, Pr), $^1_\infty[Ln(Btz)_3\{Ph(NH_2)_2\}]$ (Ln = Nd, Tb, Yb), and $^1_\infty[Ho_2(Btz)_6(BtzH)(NH_3)]$[‡]

**Klaus Müller-Buschbaum,*[a] and Yassin Mokaddem[a]**

**Keywords:** Solvent-free synthesis / Lanthanides / Benzotriazolate / Crystal structure / X-ray diffraction

The solvent-free melt reactions of benzotriazole (BtzH, $C_6H_4N_2NH$) with rare earth metals result in three different types of benzotriazolate coordination polymers. Early 4f metals yield $^1_\infty[Ln(Btz)_3(BtzH)]$ [Ln = Ce (**1**), Pr (**2**)], from neodymium to ytterbium the type $^1_\infty[Ln(Btz)_3\{Ph(NH_2)_2\}]$ is observed [Ln = Nd (**3**), Tb (**4**), Yb (**5**)], whereas the late 4f metal Ho gives $^1_\infty[Ho_2(Btz)_6(BtzH)(NH_3)]$ (**6**). Depending on the reaction conditions and the respective rare earth element, ligand fragments originating from decomposition products are incorporated in the coordination polymers. Compounds **1**–**3** and **6** were obtained as single crystals and their crystal structures determined by single-crystal X-ray analysis, whilst **4** and **5** were obtained as powders. X-ray powder diffraction shows the isotypic character of polymers **3**, **4**, and **5**. The benzotriazolates contain trivalent lanthanide ions with complete nitrogen coordination. Decomposition of the ligand accompanies the formation of the coordination polymers. X-ray analysis was combined with thermal analysis and mass spectrometry to investigate the influence of reaction temperatures on ligand decomposition. Ln-benzotriazolates exhibit aspects of materials science such as luminescence {$^5D_4 \rightarrow {}^7F_J$, $J$ = 4–6 for $^1_\infty[Tb(Btz)_3\{Ph(NH_2)_2\}]$ (**4**)} without quenching by concentration.

## Introduction

Nearly all syntheses in coordination chemistry, including rare earth chemistry, are carried out in solution, mostly in classical solvents such as THF, toluene, DME etc.[1–7] These syntheses are used to form a range of complexes, from the first cyclopentadienyl complexes[8] and metallocenes[9] to the oxo and amido complexes of today.[1–7] In contrast solvent-free syntheses by high-temperature reactions have been successfully utilized to obtain organic amides of the rare earth elements over the past seven years.[10–20] It has been shown that novel coordination chemistry is possible without classical solvent procedures. The products obtained from the extreme conditions of melt reactions are unique and exhibit interesting features such as the formation of homoleptic compounds[10–16] and coordination polymers,[10,16,17,19,20] whereas for syntheses in solvents, ligand criteria such as multi-chelating[21–27] are necessary to obtain homoleptic complexes. The reactivity of rare earth metals has proven to be high enough so that they can directly react with amine melts without the need for multi-chelation or high steric congestion. We have systematically developed this kind of solvent-free synthesis including the crystallization of products under the reaction conditions.[9,12–17,19,20] Independent from the synthesis, a systematic approach that involves the amine ligand leads from ammonia to unsubstituted and substituted 1-N heterocycles such as pyrrole[28–32] and carbazole,[16,20] to 2-N ligands such as imidazole[33] and pyrazole,[11,12,17,19] and to ring systems that contain three or more nitrogen atoms per ring. The tendency to release $N_2$ upon heating N-heterocycles increases as the number of N atoms they contain increases. It becomes exothermic for triazoles, whereas tetrazoles tend to become explosive.[34] Accordingly, high-temperature chemistry with these ligands is a synthetic challenge. 1*H*-Benzotriazole (BtzH) marks the first step in our approach as it is thermally more stable than one-ring 3-N ligands. Nonetheless, our results (**1**–**6**) already illustrate the influence of thermal decomposition on this chemistry. To the best of our knowledge no benzotriazolates of the rare earth elements have been previously known.

## Results and Discussion

The solvent-free ampoule reactions of cerium, praseodymium, neodymium, terbium, holmium, and ytterbium with 1*H*-benzotriazole were carried out in the amine melt. The reactions with cerium and praseodymium yield single crystals of $^1_\infty[Ln(Btz)_3(BtzH)]$ (**1**, **2**) [Equation (1)], whereas

 InterScience © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

reactions with neodymium, terbium, holmium, and ytterbium metal result in compounds that contain additional ligands, 1,2-diaminobenzene and ammonia. Two different types are observed depending on the metal, $^1_\infty$[Ln(Btz)$_3${Ph(NH$_2$)$_2$}] for Ln = Nd (**3**), Tb (**4**), and Yb (**5**) [Equation (2)], and $^1_\infty$[Ln$_2$(Btz)$_6$(BtzH)(NH$_3$)] for Ln = Ho (**6**) [Equation (3)].

$$\text{Ln} + 4\ \text{H–Btz} \xrightarrow{\Delta T} {}^1_\infty[\text{Ln(Btz)}_3\text{(BtzH)}] + \text{H}_2 \quad (1)$$

$$\text{Ln} + 4\ \text{H–Btz} \xrightarrow{\Delta T} {}^1_\infty[\text{Ln(Btz)}_3\{\text{Ph(NH}_2)_2\}] + \tfrac{1}{2}\ \text{N}_2 \quad (2)$$

$$2\ \text{Ln} + 8\ \text{H–Btz} \xrightarrow{\Delta T} {}^1_\infty[\text{Ln}_2\text{(Btz)}_6\text{(BtzH)(NH}_3)] + \text{N}_2 + \text{H}_2 + \text{C}_6\text{H}_6 \quad (3)$$

Of the decomposition products of 1*H*-benzotriazole, both 1,2-diaminobenzene and ammonia are incorporated into the products and in the coordination spheres of the metal atoms, whilst the neutral molecules $N_2$, $H_2$, and benzene are not. Consequently, **6** was formed at the highest reaction temperatures used as Ho is the metal with the highest melting point in **1**–**6**. In order to illuminate this decomposition influence, we investigated the thermal behavior of 1*H*-benzotriazole and of the products of the syntheses.[35,36] It can be concluded that rare earth metals promote and induce the decomposition of BtzH by a redox reaction. With compound **5** a red phase is reproducibly formed in a ratio of 4:1, which probably contains $Yb^{II}$ though this has not yet been confirmed as we have not succeeded in crystallizing it. In order to crystallize the products from Equation (2), solvothermal reaction and crystallization from pyrrole were carried out for **3**, whereas the melt synthesis results in powders to microcrystalline products as for **4** and **5**.

The thermal decomposition of each type of lanthanide benzotriazolates was investigated by simultaneous DTA/TG[37] on the bulk as well as on single crystalline materials of **1**, **3**, and **6**. This analysis provides additional information with regard to the completeness of the reactions, the possible phase impurities, and the decomposition path of the product of the melt reactions and the ligand used. We have already shown the value of this method for the comprehension of comparable melt reactions with 2,2-(pyridyl)benzimidazole, 2,2′-dipyridylamine, as well as with pyrazole.[10,14,38,39]

The DTA/TG versus temperature diagrams of the rare earth benzotriazolates presented here show an ensemble of endothermic as well as exothermic signals in the heat flow and are accompanied by several steps of mass losses, which end in the decomposition of the coordination polymers. Investigations of the bulk materials show additional signals that can be identified with excess ligand (BtzH: m.p. 98 °C, b.p. 204 °C, measured 95 °C, 205 °C). The diagram of the single crystalline material is free of these signals and exhibits the thermal processes of the products only (see Figure 1).

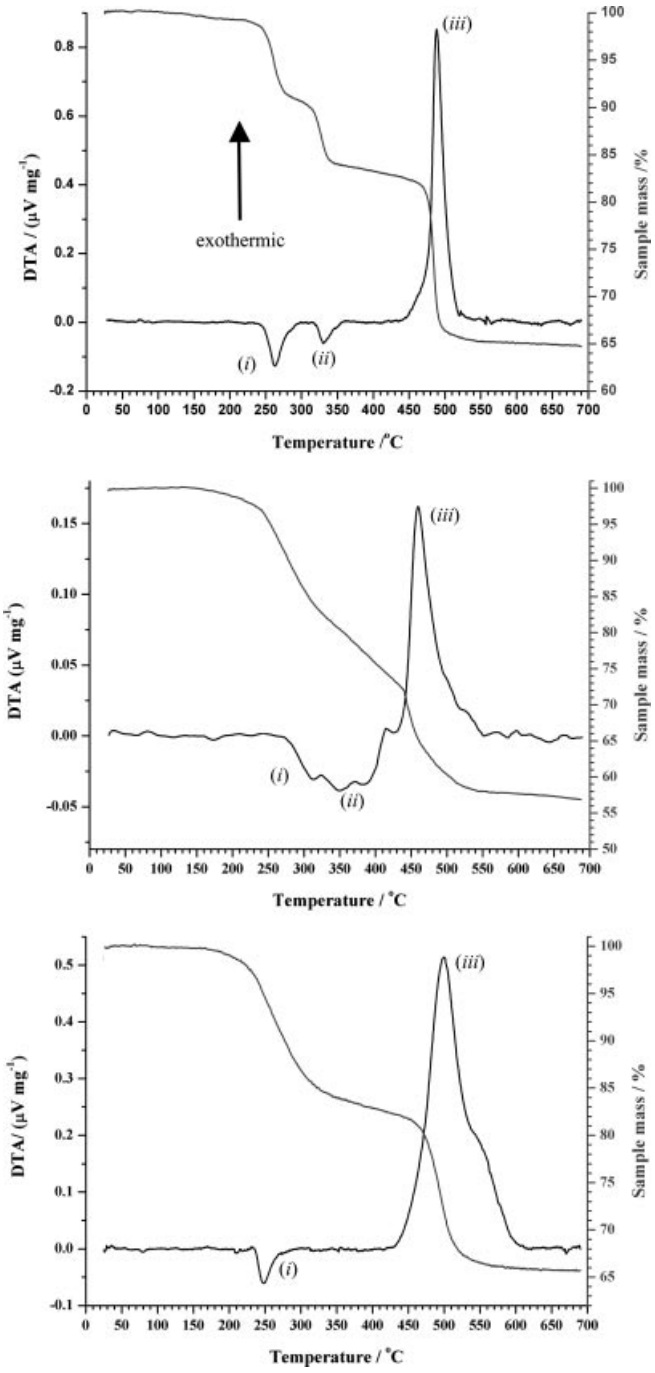

Figure 1. The thermal decompositions of $^1_\infty$[Ce(Btz)$_3$(BtzH)] (**1**, top), $^1_\infty$[Nd(Btz)$_3$(BtzH)] (**3**, middle) and $^1_\infty$[Ho$_2$(Btz)$_6$(BtzH)(NH$_3$)] (**6**, bottom), which were purified by sublimation. The compounds were investigated by simultaneous DTA/TG in the temperature range 20–700 °C. The release of amine ligands is observed first and is endothermic, whereas the decomposition of the amido backbone of the polymers is exothermic releasing $N_2$.

$^1_\infty$[Ce(Btz)$_3$(BtzH)] (**1**) releases coordinating benzotriazole in two endothermic steps at 250 °C and 320 °C [signals (*i*) and (*ii*)], which adds up to the mass loss of one equivalent of BtzH per formula (calculated 19%, observed 18%) and thus all coordinating BtzH. A strong exothermic peak [signal (*iii*)] follows at 470 °C, indicating decomposition of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

homoleptic polymer [Ce(Btz)$_3$] with the release of $N_2$. Furthermore, Ph(NH$_2$)$_2$, its decomposition products, and $NH_3$ can be observed in the mass spectrum.

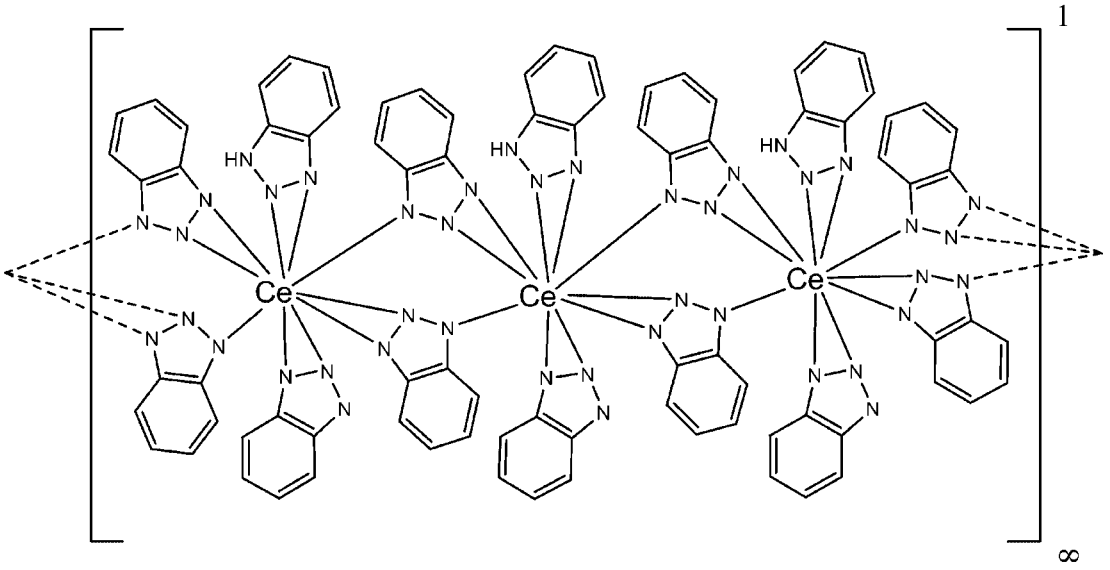
Because of the different chemical formulas of $^1_\infty$[Nd(Btz)$_3${Ph(NH$_2$)$_2$}] (**3**) and **1**, differences in their simultaneous DTA/TG/MS **1** can be seen. Compound **3** shows a multistep decomposition with endothermic and exothermic signals but also three mass loss steps. At 270 °C [signal (*i*)], the release of coordinated Ph(NH$_2$)$_2$ begins [Ph(NH$_2$)$_2$: calculated 17.8%, observed 18%] before the polymer [Nd(Btz)$_3$] decomposes without a stable temperature plateau [310 °C: at least two steps, endothermic signal group (*ii*); 440 °C: exothermic step (*iii*)]. Prior to the exothermic release of $N_2$, Ph(NH$_2$)$_2$ as well as $NH_3$ are formed again from the coordinating Btz$^-$ anions.

$^1_\infty$[Ho$_2$(Btz)$_6$(BtzH)(NH$_3$)] (**6**) exhibits only two thermal decomposition steps. The first step at 240 °C [signal (*i*)] is, again, endothermic and can be identified with the release of the coordinated equivalent of BtzH and $NH_3$ (calculated 13.8%, observed 15.5%). Signal (*ii*) at 450 °C represents decomposition of [Ho(Btz)$_3$] accompanied by the release of the same products as for **1** and **3** (observed 17%).

It can thus be deduced that none of the coordination polymers melts congruently, that additional coordinating amine ligands in **1**–**6** are released prior to amide anions, and that the release of amide groups results in overall decomposition of the polymers. A general formula for a homoleptic decomposition intermediate is assumed to be [Ln(Btz)$_3$], though investigation of **3** shows that it is questionable to isolate these polymers for all lanthanide ions. Thermal stabilities of these coordination polymers are high, up to 450 °C for **5**. The exothermic release of $N_2$ is delayed to higher temperatures for **1**–**6** than for the free ligand.

Each of the far-infrared as well as Raman spectra of **1**–**6** show bands that cannot be identified with the ligand and thus represent the ν(Ln–N) and δ(N–Ln–N) stretching modes {$^1_\infty$[Ce(Btz)$_3$(BtzH)] (**1**) FarIR: 244, 200, 183, 169, Raman 123 cm$^{-1}$; $^1_\infty$[Pr(Btz)$_3$(BtzH)] (**2**) FarIR: 250, 195, 179, 171, Raman: 120 cm$^{-1}$; $^1_\infty$[Nd(Btz)$_3$(Ph(NH$_2$)$_2$)] (**3**) FarIR: 249, 195, 178, 147, Raman 150, 124 cm$^{-1}$; $^1_\infty$[Tb(Btz)$_3$(Ph(NH$_2$)$_2$)] (**4**) FarIR: 247, 193, 175, 146, Raman: 150 sh, 125 cm$^{-1}$; $^1_\infty$[Yb$_2$(Btz)$_6$(BtzH)(NH$_3$)] (**5**) FarIR: 254, 214, 173, 144 cm$^{-1}$; $^1_\infty$[Ho$_2$(Btz)$_6$(BtzH)(NH$_3$)] (**6**) FarIR: 249, 230, 210, 191, 176, 158, 146, Raman 122 cm$^{-1}$}. These bands match well with other Ln–N containing compounds like rare earth porphyrin complexes,[40] dipyridyl amides,[10,15,38] pyridylbenzimidazolates,[10,13,14] and carbazolates[10,16,20] with regard to the coordination spheres, valences, and ionic radii. Ligand lattice stretching modes are reflected by rather broad bands (FarIR: 423, 286 cm$^{-1}$). The MIR and Raman spectra additionally present vibrational bands of the benzotriazolate, diaminobenzene, and ammonia ligands, which are shifted by about ten wavenumbers relative to those of the free ligand, or show band splitting as a result of coordination to the metal centers and thus weakening of the C–N and C–C bonds. The ν(N–H) vibrational bands[41] of the amine ligands are also observed [**1**, **2**: BtzH: 3430 and 3422 cm$^{-1}$, respectively; **3**, **4**, **5**: Ph(NH$_2$)$_2$: 3360 and 3339, 3362 and 3333, 3363 and 3342 cm$^{-1}$, respectively; **6**: BtzH and $NH_3$: 3390 and 3367 cm$^{-1}$, respectively] and are confirmed by the MIR spectrum of the free ligands.[34] Furthermore, **3** shows a strong and broad band at 1975 cm$^{-1}$ in the Raman spectrum according to the luminescence $^4I_{11/2}\rightarrow{}^4I_{9/2}$ for Nd$^{III}$[42] resulting from the frequency of the Nd-YAG laser of the IR-/Raman spectrometer.

The crystal structures of **1**–**6** consist of structurally related one-dimensional coordination polymers. Benzotriazolate ligands connect the metal centers and are thus vital for the formation of the strands. The coordination spheres of the 4f ions contain N atoms only of both amido and amino character. No π coordination is observed. As the



Scheme 1. μ-η$^2$;η$^1$- and η$^2$ coordination of the benzotriazolate and 1*H*-benzotriazole ligands in the coordination polymer $^1_\infty$[Ce(Btz)$_3$(BtzH)] (**1**). Pr$^{III}$ exhibits an identical coordination in **2**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structure analyses of **1** and **2** show, four $Btz^-$ anions link a cerium or praseodymium center with two adjacent metal cations in a $\mu$-$\eta^2$;$\eta^1$ manner such that two nitrogen atoms of one ligand coordinate to one metal ion and the third to the next metal center (see Scheme 1). Another $Btz^-$ anion and the coordinated BtzH molecule do not participate in the polymer backbone and are coordinated to a single cerium atom in an $\eta^2$ fashion; a hydrogen bond between the two noncoordinating N atoms is present. The $\eta^2$ coordination shows a slight asymmetry of 5–10 pm in the corresponding Ln–N distances of **1** and **2**. Despite an octahedral arrangement of ligands the C.N. is ten for each Ce/Pr. Figure 2 depicts a part of the polymeric structure of $^1_\infty$[Ln(Btz)$_3$(BtzH)] [Ln = Ce (**1**) and Pr (**2**)] and Figure 3 the unit cell of the crystal structure.

The backbone of polymer **3** is identical to that of **1**, the difference stems from coordinated 1,2-diaminobenzene ligands that replace the benzotriazole molecules (see Scheme 2). The diaminobenzene ligands coordinate in a $\eta^1$;$\eta^1$ manner, with no hydrogen bond to the noncoordinating N atom of the third benzotriazolate equivalent. Replacement of the BtzH ligand in **1** and **2** with a Ph(NH$_2$)$_2$ ligand neither changes the C.N. nor the coordination polyhedron for **3**–**5**. Figure 4 displays part of the polymeric structure of $^1_\infty$[Nd(Btz)$_3${Ph(NH$_2$)$_2$}] (**3**) and Figure 5 the unit cell of the crystal structure.

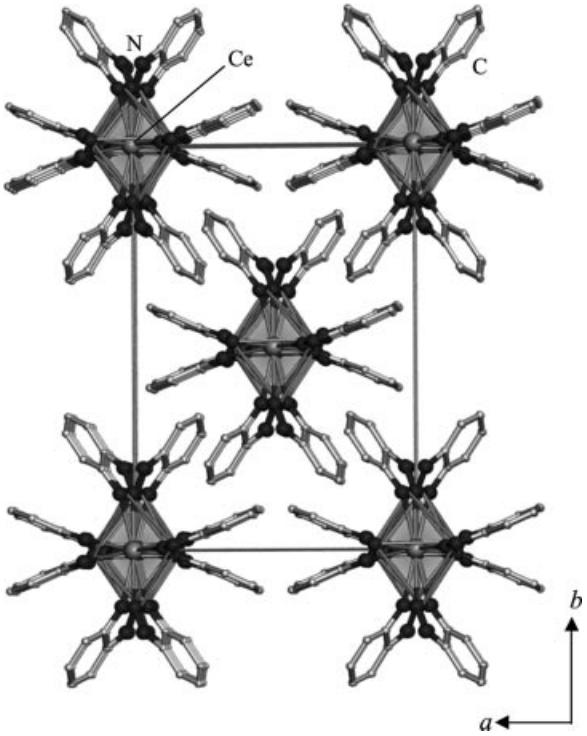


Figure 3. The crystal structure of $^1_\infty$[Ce(Btz)$_3$(BtzH)] (**1**) with a view along the chain direction [001]. N–N connection lines mark only the coordination polyhedra and not bonds.

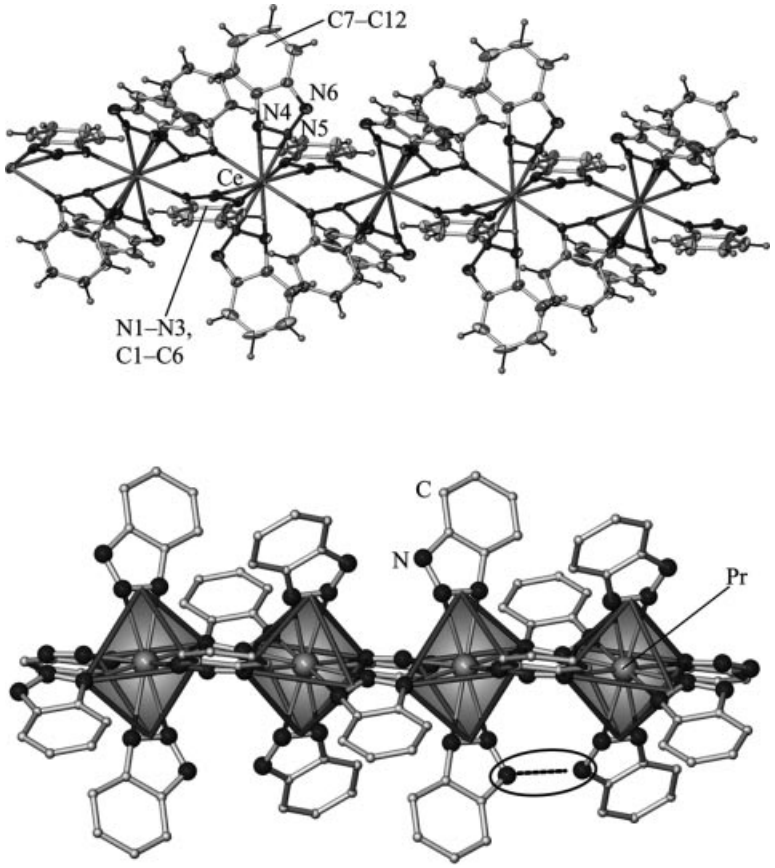

Figure 2. Section of the polymeric structure of $^1_\infty$[Ln(Btz)$_3$(BtzH)], Ln = Ce (**1**, top) and Pr (**2**, bottom). The hydrogen bond between the terminal $Btz^-$ and BtzH ligands is represented by a dotted line. In this, and the following Figures, the thermal ellipsoids are scaled to a probability density level of the atoms of 50%. N–N connection lines mark only the coordination polyhedra and do not represent bonds. Metal atoms are depicted by large mid grey balls, nitrogen atoms by dark grey balls, and carbon atoms by small light grey balls.

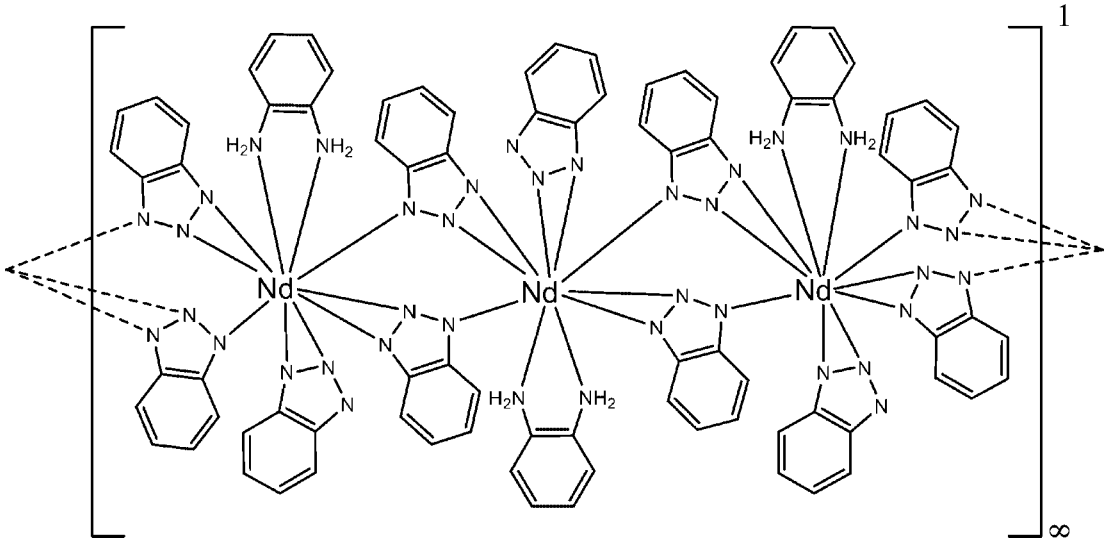

Scheme 2. μ-$\eta^2$;$\eta^1$- and $\eta^1$;$\eta^1$ coordination of the benzotriazolate and 1,2-diaminobenzene ligands in the coordination polymer $^1_\infty$[Nd(Btz)$_3${Ph(NH$_2$)$_2$}] (**3**). $Tb^{III}$ and $Yb^{III}$ exhibit identical polymers in **4** and **5**.

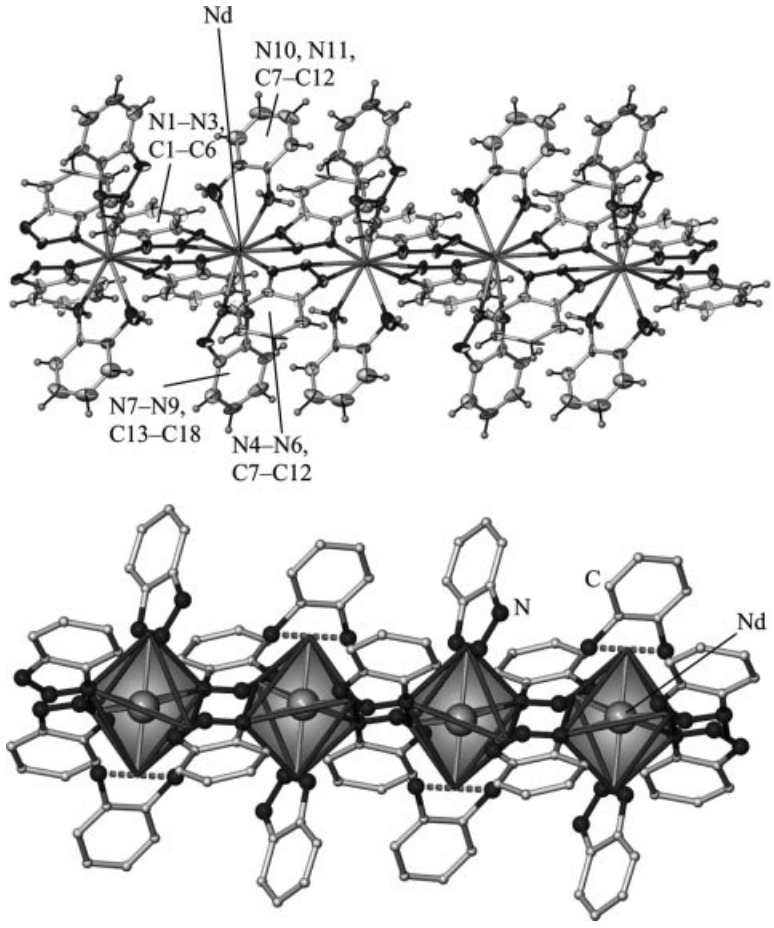

Figure 4. Section of the polymeric structure of $^1_\infty$[Nd(Btz)$_3${Ph(NH$_2$)$_2$}] (**3**) displaying thermal ellipsoids (top) and coordination polyhedra (bottom).

Polymer **6** differs from **1** and **3** in its backbone and additional ligands. The holmium ions are arranged in a triangular fashion that resembles a ladder-like structure (see Figure 6). No Ho–Ho bonds are observed in the triangles as benzotriazolate ligands again link the metal centers to build up a polymeric strand (see Scheme 3). Benzotriazole and ammonia molecules complete the coordination spheres of Ho. In contrast to **1**–**5**, the holmium polymer **6** exhibits

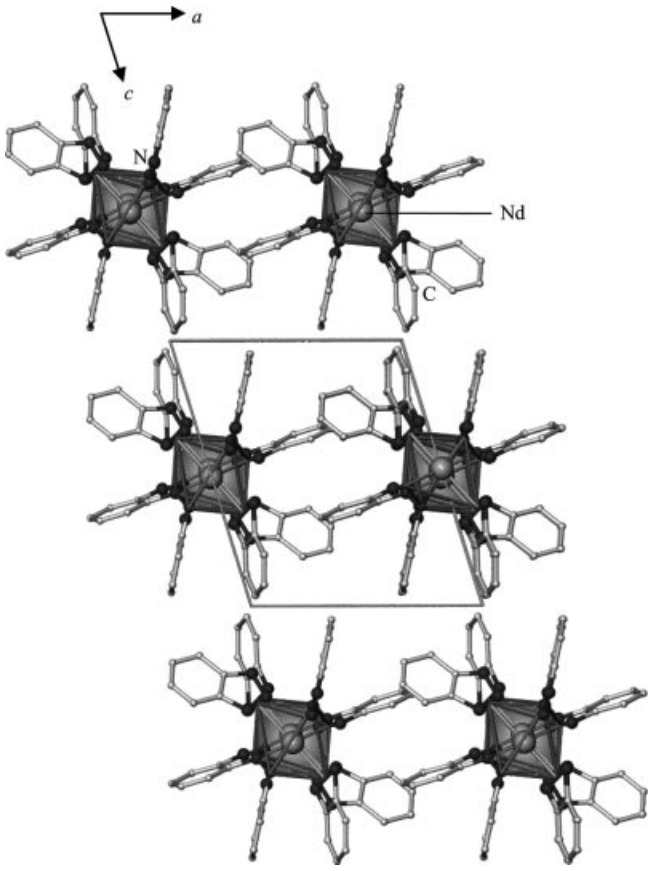

Figure 5. The crystal structure of $^{1}_{\infty}$[Nd(Btz)$_3${Ph(NH$_2$)$_2$}] (**3**) with a view along the chain direction [010]. The relation between the structures of the types $^{1}_{\infty}$[Ln(Btz)$_3${Ph(NH$_2$)$_2$}], Ln = Nd (**3**), Tb (**4**), Yb (**5**), and $^{1}_{\infty}$[Ln(Btz)$_3$(BtzH)], Ln = Ce (**1**), Pr (**2**), is evident.

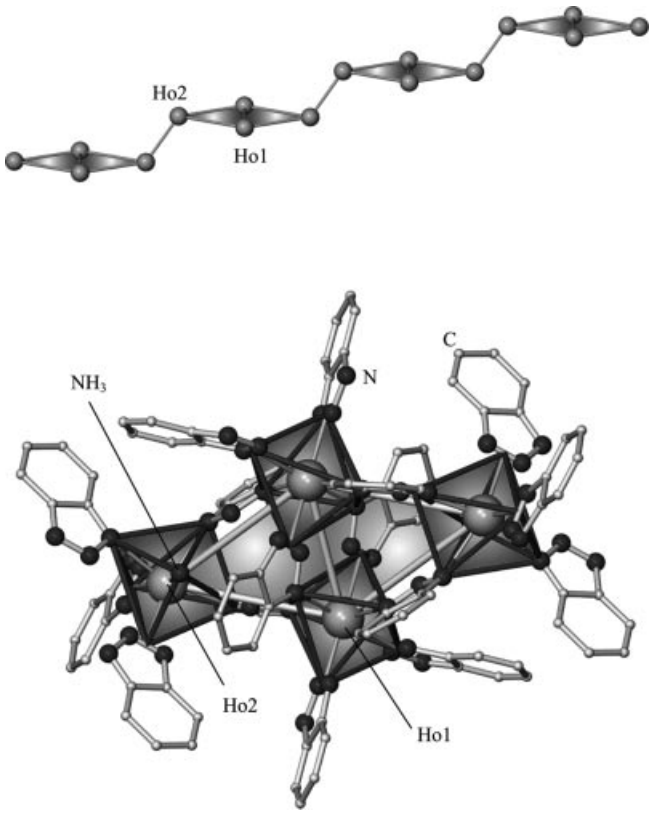

Figure 6. The arrangement of Ho atoms in **6** (top). Triangular units are combined to di-triangles with a common edge and form a ladder-like arrangement with no Ln–Ln bonds. The depiction at the bottom displays the ligands linking the metals to form double triangles. No triangular arrangement is observed for **1**–**5**.

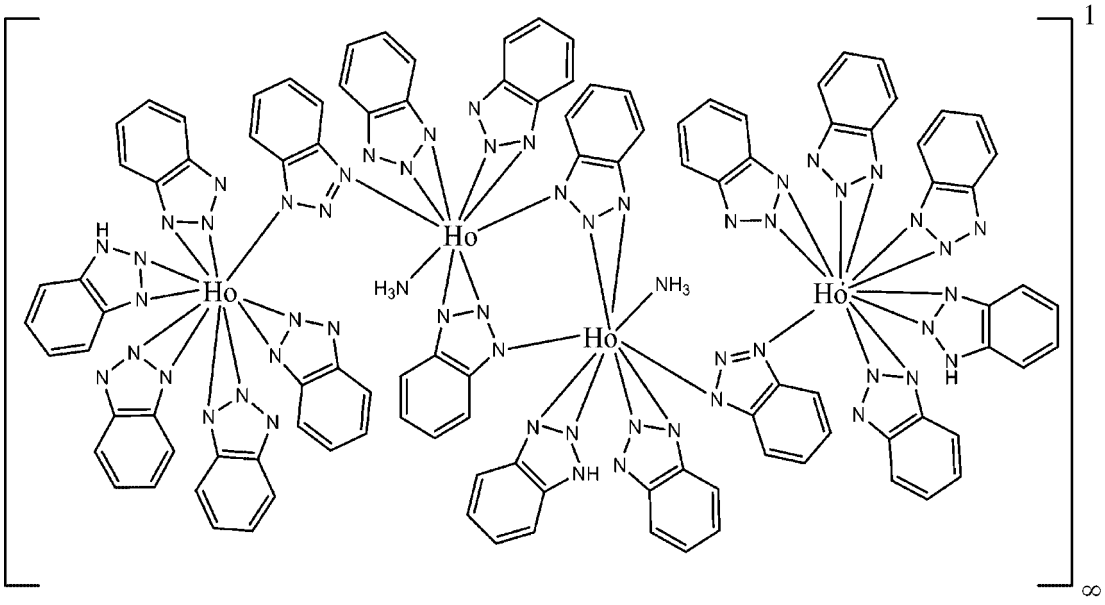

Scheme 3. μ-$\eta^2$:$\eta^1$-, $\eta^2$- and $\eta^1$:$\eta^1$ coordination of the benzotriazolate and 1*H*-benzotriazole ligands as well as the $\eta^1$ coordination of ammonia in polymeric $^{1}_{\infty}$[Ho$_2$(Btz)$_6$(BtzH)(NH$_3$)] (**6**).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a C.N. of 9 with two different holmium ions. Ho1 is surrounded by four μ-$\eta^2$;$\eta^1$ $Btz^-$ ligands, one $\eta^1$;$\eta^1$ coordinated BtzH molecule, and one μ-($\eta^1$;$\eta^1$) $Btz^-$ anion that is linked to Ho2. Ho2 is also coordinated by four μ-$\eta^2$;$\eta^1$ $Btz^-$ ligands, one μ-($\eta^1$;$\eta^1$) $Btz^-$ anion that is linked to Ho1, and one $\eta^1$-coordinated $NH_3$ molecule. Thus, one of the benzotriazolate ligands does not coordinate with its center nitrogen atom to any Ho atom. Two of the $\eta^2$-coordinated $Btz^-$ anions show a strong asymmetry of >25 pm in their Ho–N distances, so that this coordination mode can also be referred to as μ-$\eta^1$;$\eta^1$;$\eta^1$. Figure 7 displays part of the polymeric structure of $^1_\infty[Ho_2(Btz)_6(BtzH)(NH_3)]$ (**6**) and Figure 8 the unit cell of the crystal structure.

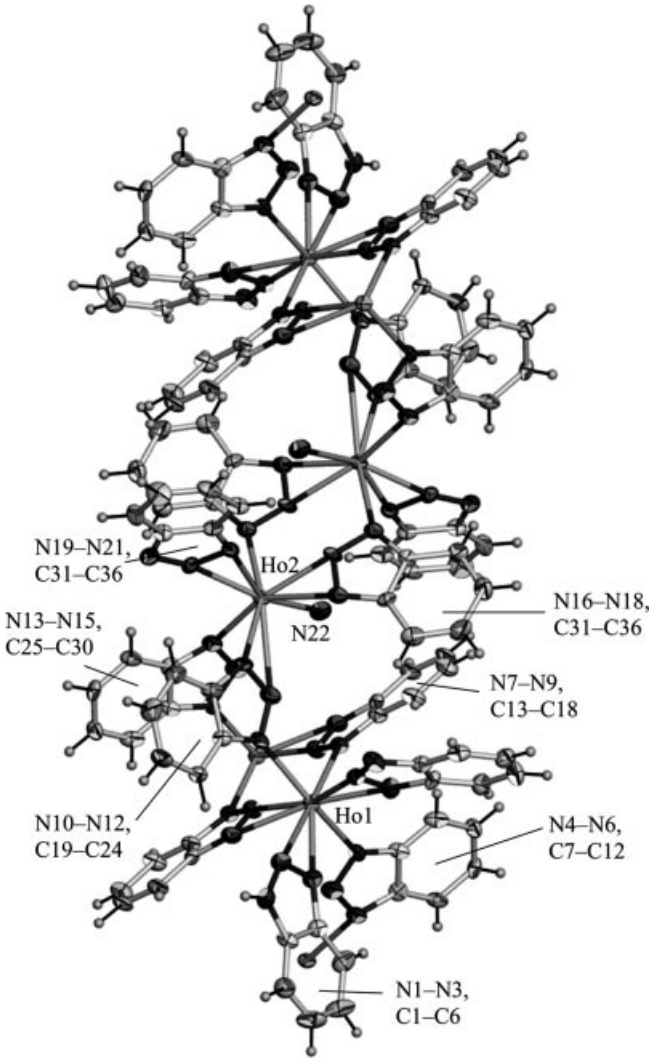

Figure 7. Part of the polymeric structure of $^1_\infty[Ho_2(Btz)_6(BtzH)(NH_3)]$ (**6**) displaying thermal ellipsoids (top) and coordination polyhedra (bottom).

The contraction of the radii of the lanthanide ions[43] influences both the C.N. as well as the Ln–N distances and is observed throughout the course of the products. In general, the C.N.s are high also for lanthanides, which mainly derives from the $\eta^1$;$\eta^1$ mode of the coordinated neighboring N atoms of the ligands. All rare earth ions are trivalent in

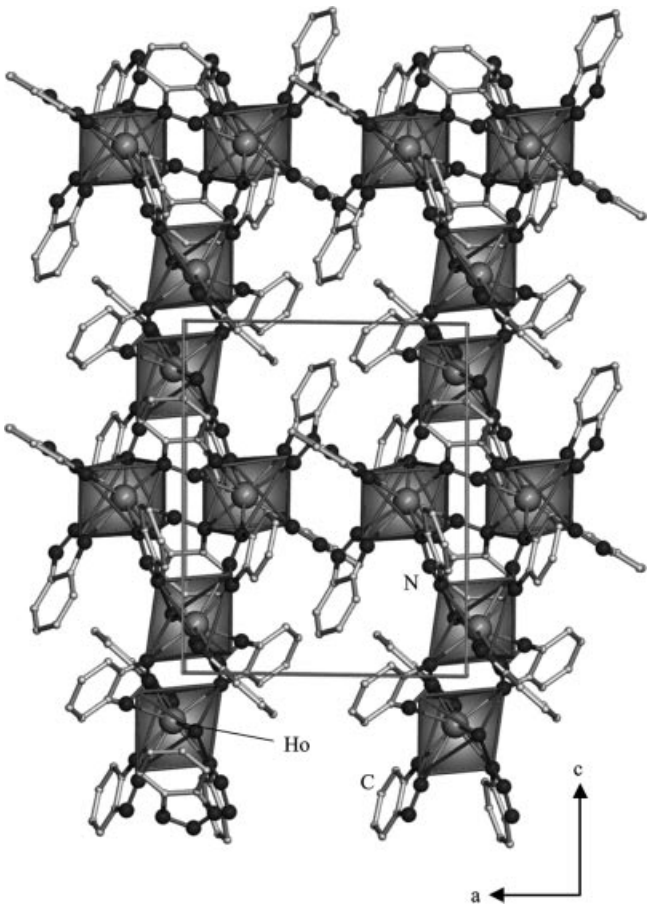

Figure 8. The crystal structure of $^1_\infty[Ho_2(Btz)_6(BtzH)(NH_3)]$ (**6**) with a view on the chains along [010].

**1**–**6**. The Ln–N distances range from 232.6(9)–253(1) pm for Ho–N amide and amine distances, to 248(2)–264(2) pm for Nd, through to 251.6(9)–265.0(9) pm for Ce. These distances match well with those of other trivalent lanthanide amido and amino complexes in which the metal ions are linked such as dipyridylamides $[Ln_2(Dpa)_6]$, $Dpa^-$ = $(C_5H_4N)_2N^-$, with 236–255 pm for $Ho^{III}$, 244–268 pm for $Nd^{III}$, and 247–273 pm for $Ce^{III}$.[38] For a detailed selection of interatomic distances and angles see Table 1. Deviations of the coordination polyhedron from a regular octahedron are less than five degrees for all metal ions.

Powder diffraction of $^1_\infty[Tb(Btz)_3\{Ph(NH_2)_2\}]$ (**4**) and $^1_\infty[Yb(Btz)_3\{Ph(NH_2)_2\}]$ (**5**) shows that the compounds crystallize in a manner isotypic to that of $^1_\infty[Nd(Btz)_3\{Ph(NH_2)_2\}]$ (**3**). Thus, the description of the crystal structure in the space group $P\bar{1}$ is analogous to that of **3**. According to the larger ionic radius of $Nd^{III}$ than those of $Tb^{III}$ and $Yb^{III}$,[43] the unit cells of **4** and **5** are smaller than that of **3** {**3**: 1314.2(2), **4**: 1258.2(3), **5**: 1232(1) [$\times 10^6$ pm$^3$]}.

$^1_\infty[Tb(Btz)_3\{Ph(NH_2)_2\}]$ (**4**) exhibits a strong green emission when exposed to UV light. The luminescence can be identified with the emission processes of the $Tb^{3+}$ ions $^5D_4 \rightarrow {}^7F_4$ at 590 nm, $^5D_4 \rightarrow {}^7F_5$ at 545 nm, and $^5D_4 \rightarrow {}^7F_6$ at 490 nm.[44,45] Though **4** contains 100% Tb and is not a doped compound, no quenching of the luminescence by

concentration is observed. The emission spectrum of **4**, and the absorption spectra of **4** (room temperature and 120 K) and 1*H*-benzotriazole (room temperature) can be seen in Figure 9. A comparison of the absorption spectra of the free ligand with that of polymer **4** shows excitation of the ligand into the Soret band in the UV region. Benzotriazole and its derivatives are commercially used as UV absorbers.[46,47] We assume an energy transfer from the ligand to the metal ions as the luminescence is present independent of whether the excited states of Tb or the ligand are populated; additionally both absorption maxima of $^1_\infty$[Tb(Btz)$_3${Ph(NH$_2$)$_2$}] (**4**) at 310 and 205 nm cannot be identified with $Tb^{III}$ absorptions. We chose 310 nm as the excitation wavelength for the emission spectrum of **4**. Furthermore, an energy back-transfer from the metal centers to the ligand is possible, which would lead to quenching. Presently, we cannot explain why no quenching by concentration is observed. High resolution excitation spectra of **4** as well as of BtzH, emission efficiency, and decay time measurements are planned to further investigate the luminescence properties of $^1_\infty$[Tb(Btz)$_3${Ph(NH$_2$)$_2$}].

## Conclusions

The formation of **1**–**6** shows that triazolates can also be utilized for high-temperature oxidations of rare earth metals with amines. Though the release of $N_2$ from BtzH is exothermic, coordination polymers of the 4f elements can be obtained below the decomposition temperature. Depending on the temperature and lanthanide, three chemically different polymers can be obtained. With the largest lanthanide ions and the lowest melt temperatures, $^1_\infty$[Ln(Btz)$_3$(BtzH)] is formed up to praseodymium. $^1_\infty$[Ln(Btz)$_3${Ph(NH$_2$)$_2$}] is formed from neodymium to ytterbium. $^1_\infty$[Ln$_2$(Btz)$_6$(BtzH)(NH$_3$)] has so far been isolated for holmium only, and at the highest reaction temperatures investigated. Compounds **1**–**6** are the first triazolates of the lanthanides. Partial decomposition of the benzotriazole ligands accompanies the syntheses and yields 1,2-diaminobenzene as well as ammonia, which are both incorporated in the coordination polymers of the heavier 4f elements. Thermal analyses of **1**, **3**, and **6** lead to the assumption that homoleptic polymers [Ln(Btz)$_3$] are formed upon release of the coordinated amine ligands, though these polymers could not be isolated as single crystalline material so far. The coordination polymers also exhibit aspects of materials science such as a green luminescence {$^5D_4 \rightarrow {}^7F_J$, $J$ = 4–6 for $^1_\infty$[Tb(Btz)$_3${Ph(NH$_2$)$_2$}] (**4**)} without quenching by concentration, and an energy transfer from the ligand to the $Tb^{3+}$ ions.

## Experimental Section

All reactions were carried out under argon using a dry box and standard Schlenk and ampoule techniques because of the air- and moisture-sensitivity of **1**–**6**. The lanthanide metals (ChemPur, STREM, 99.9%) and 1*H*-benzotriazole (ACROS, 99%) were used

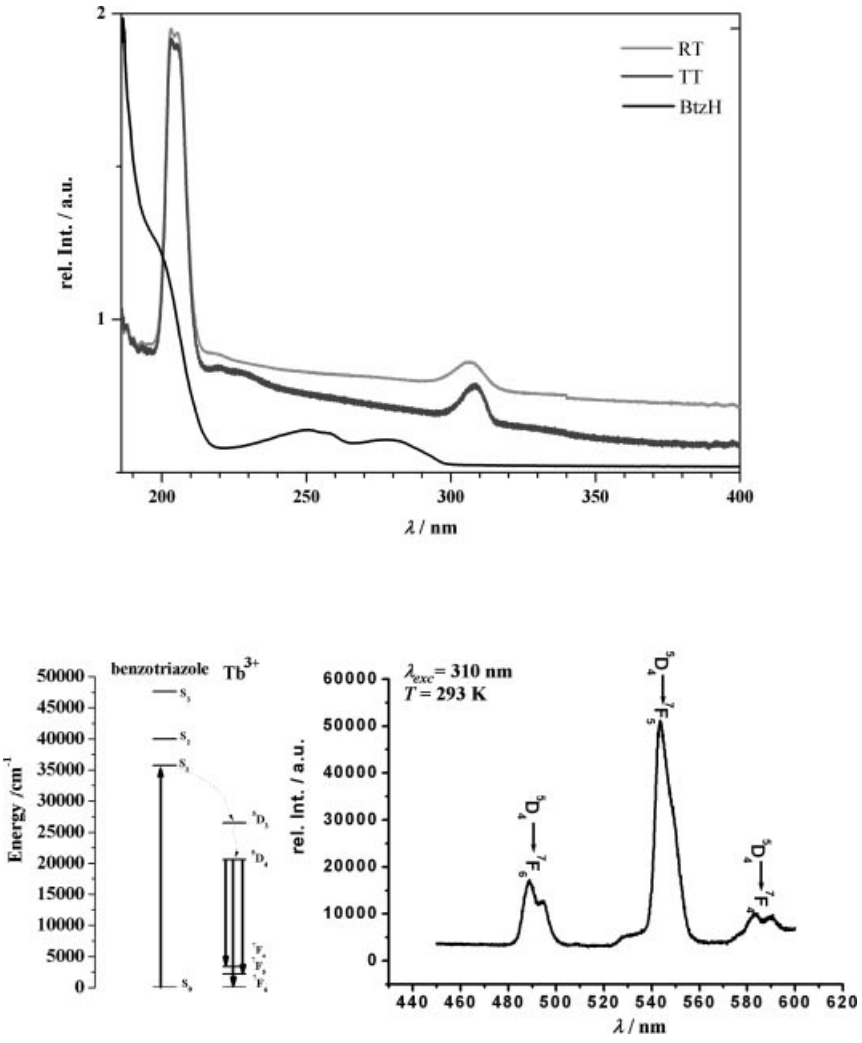

Figure 9. The absorption spectra of $^{1}_{\infty}$[Tb(Btz)$_3${Ph(NH$_2$)$_2$}] (**4**) at 293 and 120 K and that of 1*H*-benzotriazole at 293 K (top), and the emission spectrum of **4** with an excitation wavelength of $\lambda$ = 310 nm (bottom).

as purchased. Mercury (Fluka, 99.9%) was used for activation of the metals. The IR spectra were recorded with a BRUKER FTIR-IS66V-S spectrometer, the Raman spectra with a BRUKER FRA 106-S spectrometer. For MIR investigations KBr pellets and for FIR measurements PE pellets were used under vacuum. The absorption spectroscopy was carried out at 293 and 120 K with a VARIAN Carey 05E (BRUKER) spectrometer on samples sealed under argon between $CaF_2$ windows. Emission spectroscopy was carried out with a SPEX-Flurolog DM3000F fluorescence spectrometer (JOBIN YVON GmbH) on samples sealed under vacuum in quartz tubes. The thermal decompositions of **1**, **3**, and **6** were studied using simultaneous DTA/TG (NETZSCH STA-409) on samples that were previously purified of excess BtzH and pyrrole by evaporation (16.1 mg of the Ce product **1**, 18.5 mg of the Nd product **3**, and 12.0 mg of the Ho product **6**). The samples were heated from 20–700 °C at a heating rate of 10 °C/min in a constant Ar flow of 60 mL/ min.

**$^{1}_{\infty}$[Ce(Btz)$_3$(BtzH)] (1):** Cerium metal (70 mg, $0.5\times10^{-3}$ mol), the amine 1*H*-benzotriazole (BtzH, $C_6H_4N_2NH$; 179 mg, $1.5\times10^{-3}$ mol), and Hg (20 mg) were sealed in an evacuated DURAN glass ampoule. The reaction mixture was heated over 5 h to 100 °C and over another 80 h to 140 °C. The temperature was held constant for 48 h. The melt was cooled down to 90 °C over 150 h and then to room temperature over 14 h. Except for a slight excess of Ce metal and BtzH, the reaction reached completion to give highly reflective colorless crystals of **1** (0.2–0.3 mm in size). Yield: 275 mg (91%). MIR: 3430 (m), 3343 (m), 3260 (m), 3076 (m), 1577 (m), 1502 (m), 1483 (m), 1444 (m), 1388 (w), 1280 (s), 1259 (m), 1208 (m), 1188 (s), 1143 (s), 1084 (m), 991 (m), 937 (m), 914 (s), 781 (vs), 753 (vssh), 744 (vs), 694 (m), 633 (s) cm$^{-1}$. **X-ray Crystal Structure Determination:** The data collections for single-crystal X-ray determinations of **1**, **2**, **3**, and **6** were carried out with an IPDS-II diffractometer (STOE). Structure solutions: SHELXS-86;[48] structure refinements: SHELXL-97.[49] Integrity of symmetry and geometry: PLATON.[50] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in calculated positions and assigned to an isotropic displacement parameter of 1.2× the size of the isotropic displacement parameter of the referring carbon atom. The crystal of **3** used for data collection shows another small crystalline individual that grows on the surface (RECIPE).[51] The two individuals were separated (TWIN)[52] and refined individually.

The powder samples of compounds **4** and **5** were investigated in sealed capillaries with a Huber Image Foil Guniner Camera 670 diffractometer with a focused single crystal germanium monochromator (Mo-$K_{\alpha1}$ radiation, $\lambda$ = 0.709300 Å for **4** and Cu-$K_{\alpha1}$ radiation, $\lambda$ = 1.540598 Å for **5**). Because **4** and **5** decline in their grade of crystallinity upon grinding, samples of both compounds could be made only roughly homogeneous and were investigated in 0.3 mm capillaries, though this led to a higher background due to absorption phenomena of the rare earth atoms. The diffraction patterns of the terbium (**4**) and the ytterbium (**5**) compounds were compared with simulated diffractograms of **1**, **2**, **3**, and **6** and reveal that **3**, **4**, and **5** crystallize isotypically, whereas the powder patterns of **1**, **2**, and **6** are completely different. The cell constants of **4** were refined on 23 reflections, and the best possible resolution leads to a triclinic unit cell without unindexed lines and an average $\delta(2\theta)$ of 0.020° [$T$ = 293(2) K, $a$ = 1019.0(14) pm, $b$ = 1061.3(21), $c$ = 1248.1(21) pm, $\alpha$ = 72.27(13), $\beta$ = 84.12(14), $\gamma$ = 78.43(13)°, $V$ = 1258.3(24)$\times10^6$ pm$^3$]. The cell constants of **5** were refined on 20 reflections with the best possible resolution without unindexed lines and an average $\delta(2\theta)$ of 0.044° [$T$ = 293(2) K, $a$ = 1008.7(9) pm, $b$ = 1068.7(10), $c$ = 1214.6(11) pm, $V$ = 1232.2(12) $10^6$ pm$^3$].[53]

**Crystallographic Data for $CeC_{24}H_{17}N_{12}$ (1):** monoclinic, $C2/c$, $Z$ = 4, $T$ = 170(1) K, $a$ = 1385.2(3), $b$ = 1789.7(4), $c$ = 1071.5(3) pm, $\beta$ = 115.90(3)°, $V$ = 2389.7(5)·$10^6$ pm$^3$, $\mu$ = 19.5 $cm^{-1}$, Mo-$K_\alpha$, 4.56 ≤ 2 $\theta$ ≤ 59.30°, –6 ≤ $h$ ≤ 18, –24 ≤ $k$ ≤ 24, –12 ≤ $l$ ≤ 13, $F$(000) = 1212, $R_1$ = 0.0827 for 1523 reflections [$I > 2\sigma(I)$], $R_1$ = 0.1313 and $wR_2$ = 0.1670 for all 2333 unique reflections, GOOF on $F_2$ = 1.008.

# Syntheses, Crystal Structures, and Characterizations of a Series of New Layered Lanthanide Carboxylate-Phosphonates

Si-Fu Tang,[a] Jun-Ling Song,[a] and Jiang-Gao Mao*[a]

**Keywords:** Lanthanides / Phosphonate / Luminescence

Hydrothermal reactions of different lanthanide(III) salts with $(H_2O_3PCH_2)_2NCH_2COOH$ ($H_5L^1$) led to two new layered lanthanide(III) carboxylate-diphosphonates, namely La($H_2L^1$)($H_2O$)$_2$·$H_2O$ (**1**) and La($H_2L^1$)($H_2O$) (**2**). The structure of compound **1** features a layered architecture in which the nine-coordinate $La^{3+}$ ions are bridged by phosphonate groups of the ligands. The carboxylate group of the phosphonate ligand remains protonated and is involved in the interlayer hydrogen bonding. Compound **2** features a double layer structure in which the $La^{3+}$ ion is eight-coordinated and the carboxylate group of the ligand is chelated to a $La^{3+}$ ion in a bidentate fashion. Hydrothermal reactions of lanthanide(III) salts with 4-HOOC–$C_6H_4$–$CH_2N(CH_2PO_3H_2)_2$ ($H_5L^2$) afforded three new compounds, namely, La($H_4L^2$)($H_3L^2$)-($H_2O$)·2$H_2O$ (**3**), Er($H_3L^2$)($H_4L^2$) (**4**), and Er($HL^3$)($H_2L^3$)($H_2O$) (**5**) [$H_2L^3$ = $H_2O_3PCH_2N(CHO)(CH_2–C_6H_4–COOH)$]. $H_2L^3$ was formed by the in situ oxidation of one P–C bond of the $H_5L^2$ ligand. Compound **3** features a (002) lanthanum(III) phosphonate layer in which the seven-coordinate $La^{3+}$ ions are bridged by diphosphonate moieties of the ligands. The carboxylate group remains protonated and is involved in the interlayer hydrogen bonding. The structure of compound **4** contains a 1D chain along the *a* axis in which each pair of $ErO_6$ octahedra is bridged by a pair of phosphonate groups. These 1D chains are further interconnected by hydrogen bonds between noncoordinated phosphonate oxygen atoms into a (002) layer with the phenyl carboxylate groups hanging on the interlayer space. The structure of compound **5** is also layered. The interconnection of $Er^{3+}$ ions by bidentate and tetradentate bridging phosphonate groups resulted in a (002) inorganic layer with the organic groups orientated to the interlayer space. Luminescence properties of compounds **4** and **5** have also been studied.

## Introduction

During the past two decades, a lot of research attention has been devoted to the chemistry of metal phosphonates for their potential applications in the areas of catalysis, ion exchange, proton conductivity, intercalation chemistry, photochemistry, and materials chemistry.[1] Most metal phosphonates exhibit a variety of open framework architectures such as layered and microporous structures. The use of bifunctional or multifunctional anionic units, such as diphosphonates, aminophosphonates, or phosphonocarboxylates, has been found to be an effective method to prepare new materials with microporous or open framework structures.[2–5] Results from ours and other groups indicate that amino-carboxylic-phosphonic acids are good ligands for building inorganic–organic hybrid open frameworks.[6] Reports on lanthanide phosphonates are rather limited and a number of them are based on X-ray powder diffraction.[7–11,13–16] Low solubility and poor crystallinity are two big obstacles for the structural studies for these lanthanide(III) compounds. The elucidation of the structures of lanthanide phosphonates is very important, as these compounds may exhibit useful luminescent properties in both visible and near IR regions.[12] A series of lanthanide diphosphonates with a 3D pillared-layer structure were isolated by the Ferey group.[13] Several lanthanide phosphonates with a crown ether or calixarene moiety have been reported by Clearfield, Bligh, Lukes, and Lin et al.[8a,14] Their structures normally feature a chelating mononuclear unit or a layer architecture. A series of one-dimensional lanthanide diphosphonates containing a hydroxy group were also reported.[15] Results from our group indicate that introducing a second ligand such as 5-sulfoisophthalic acid ($H_3BTS$) or oxalate acid, whose lanthanide compounds have good solubility and very good crystallinity, into the lanthanide–phosphonate system can lead to novel luminescent lanthanide phosphonate hybrids.[16] Another useful alternative method is the use of a phosphonic acid to which the carboxylate group or amino acid moiety is directly attached. So far, research on this aspect is scarce. Only a few 2D or 3D lanthanide phosphonates with additional carboxylate group or amino acid moiety have been prepared.[17] We have initiated a research project to systematically study the influence of counteranion, pH value, the ionic size of the lanthanide(III)

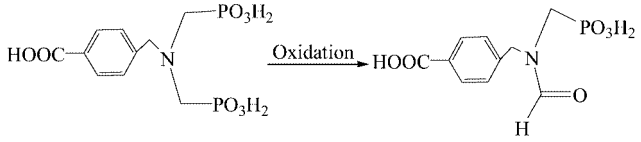
ion and the substituent on the structures, and luminescence properties of lanthanide amino-carboxylate-phosphonates formed. Two carboxylate-phosphonic acids, $H_5L^1$ [$H_5L^1$ = $(H_2O_3PCH_2)_2NCH_2COOH$] and $H_5L^2$ [$H_5L^2$ = 4-HOOC–$C_6H_4$–$CH_2N(CH_2PO_3H_2)_2$], in which the carboxylate group is well separated from the diphosphonate moiety were selected. Hydrothermal reactions of the lanthanide(III) salts with the above two phosphonic acids afforded five new compounds, namely, $La(H_2L^1)(H_2O)_2{\cdot}H_2O$ (**1**), $La(H_2L^1)(H_2O)$ (**2**), $La(H_4L^2)(H_3L^2)(H_2O){\cdot}2H_2O$ (**3**), $Er(H_3L^2)(H_4L^2)$ (**4**), and $Er(HL^3)(H_2L^3)(H_2O)$ (**5**) [$H_3L^3$ = $H_2O_3PCH_2N(CHO)(CH_2–C_6H_4–COOH)$]. $H_3L^3$ resulted from the in situ oxidation of one P–C bond of the $H_5L^2$ ligand during the reaction (Scheme 1). Herein we report their syntheses, crystal structures, and luminescent properties.



$H_5L^2$ $H_3L^3$

## Results and Discussion

Hydrothermal reactions of different lanthanide(III) salts with $(H_2O_3PCH_2)_2NCH_2COOH$ ($H_5L^1$) at two different temperatures lead to two new layered lanthanide(III) carboxylate-diphosphonates, namely $La(H_2L^1)(H_2O)_2{\cdot}H_2O$ (**1**) and $La(H_2L^1)(H_2O)$ (**2**). The higher temperature used for the synthesis resulted in compound **2** with fewer water molecules. Hydrothermal reactions of lanthanide(III) salts with 4-HOOC–$C_6H_4$–$CH_2N(CH_2PO_3H_2)_2$ ($H_5L^2$) afforded three new compounds, namely, $La(H_4L^2)(H_3L^2)(H_2O){\cdot}2H_2O$ (**3**), $Er(H_3L^2)(H_4L^2)$ (**4**), and $Er(HL^3)(H_2L^3)(H_2O)$ (**5**) [$H_2L^3$ = $H_2O_3PCH_2N(CHO)(CH_2–C_6H_4–COOH)$]. The higher number of water molecules present in the lanthanum(III) compound are probably due to the higher coordination number for the $La^{3+}$ ion than that for the $Er^{3+}$ ion. $H_2L^3$ was formed by the in situ oxidation of one P–C bond of the $H_5L^2$ ligand by oxidizing nitrate anion. Hence the counteranion, the temperature, and the ionic size of the lanthanide(III) ion have a strong effect on lanthanide phosphonates formed.

Compound **1** features a layered structure. The $La^{III}$ ion is nine-coordinate by seven phosphonate oxygen atoms from five $\{H_2L^1\}^{3-}$ anions and two aqua ligands (Figure 1). The La–O distances are in the range 2.4453(19)–2.888(2) Å, which is comparable to those reported for other $La^{III}$ phosphonates.[16] The $H_2L^1$ anion is septadentate; it chelates bidentately with one $La^{3+}$ ion by using a phosphonate group and another $La^{III}$ ion by using two oxygen atoms from two phosphonate groups, and also bridges with three other $La^{III}$ ions. Two phosphonate oxygen atoms [O(11) and O(12)] are bidentate metal linkers. The carboxylate group of the ligand remains protonated and noncoordinated; so does its amine group. The protonation of the amine group in a phosphonate ligand is well known, as amino-phosphonic acid usually exists as a zwitterion in which a proton of the phosphonate group is transferred to the basic amine group.[1,5]

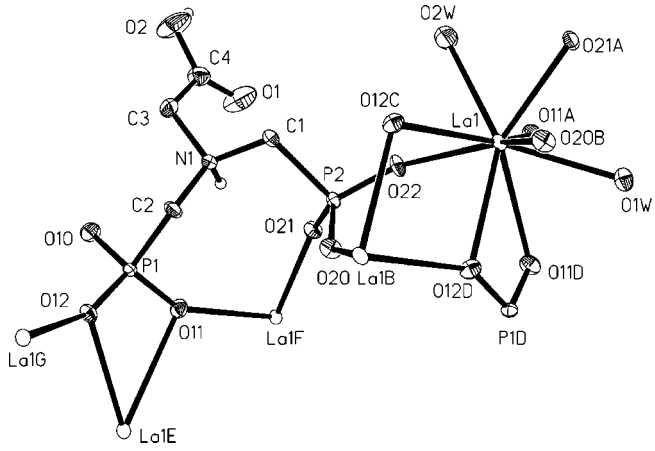

Figure 1. ORTEP representation of the selected unit of compound **1**. The thermal ellipsoids are drawn at 50% probability. The lattice water molecules have been omitted for clarity. Symmetry codes for generated atoms: A) $x$, $-y + 1/2$, $-z - 1/2$; B) $-x + 2$, $-y + 1$, $-z + 1$; C) $x$, $-y + 3/2$, $-z - 1/2$; D) $-x + 2$, $-y - 1/2$, $-z + 3/2$; E) $-x + 2$, $y + 1/2$, $-z + 3/2$; F) $x$, $-y + 1/2$, $z + 1/2$; G) $x$, $-y + 3/2$, $z + 1/2$.

The interconnection of the $La^{3+}$ ions by bridging phosphonate ligands resulted in (100) inorganic layers with the carboxylate moieties orientating toward the interlayer space (Figure 2). The interlayer distance is about 12.0 Å. Neighboring layers are held together by hydrogen bonds among carboxylate oxygens, noncoordinated phosphonate oxygen [O(10)], aqua ligand O(2w), and lattice water [O(3w)] (Table 1).

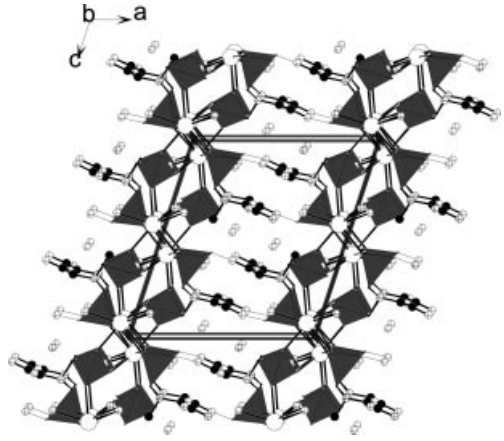

Figure 2. View of the structure of compound **1** down the *b* axis. The phosphonate tetrahedra are shaded in medium gray. La, C, N, and O atoms are drawn as open, black, octand, and crossed circles, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Compound **2** has a different layered structure. The asymmetric unit of **2** consists of one unique $La^{3+}$ ion, one $\{H_2L^1\}^{3-}$ anion, and an aqua ligand (Figure 3). The $La^{3+}$ ion is eight-coordinate by five phosphonate oxygen atoms from five phosphonate groups of four $\{H_2L^1\}^{3-}$ anions, two carboxylate oxygens of another phosphonate ligand, and an aqua ligand. The La–O distances are in the range 2.360(9)–2.728(8) Å, which is comparable to those in compound **1** and other lanthanum(III) phosphonates.[16] The coordinating mode of the phosphonate anion is different from that in compound **1**. The singly protonated phosphonate group (P1) is bidentate and connects with two $La^{3+}$ ions. The fully deprotonated phosphonate group (P2) is tridentate and is bridged to three $La^{3+}$ ions. Unlike that in compound **1**, the carboxylate group of the phosphonate ligand in compound **2** is deprotonated and forms a four-member chelating ring [La(1)–O(2)–C(4)–O(1)] (Figure 3). The amine group is protonated as in compound **1**.

The interconnection of $La^{3+}$ ions by phosphonate ligands led to a (010) double layer (Figure 4). The thicknes of the double layer is about 9.0 Å. Neighboring 2D layers

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are held together by weak hydrogen bonds among the amine group, aqua ligand, and noncoordination phosphonate oxygen, as well as a weak van der Waals force (Table 1, Figure 4).

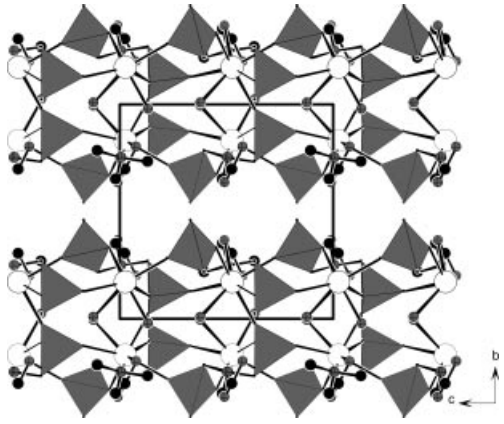

Figure 4. View of the structure of compound **2** down the *a* axis. The phosphonate tetrahedra are shaded in medium gray. La, C, N, and O atoms are drawn as open, black, octand, and crossed circles, respectively.

Compound **3** also features a layered structure. The asymmetric unit of **3** consists of one $La^{3+}$ ion, one $\{H_4L^2\}^-$ anion, one $\{H_3L^2\}^{2-}$ dianion, an aqua ligand, and two lattice water molecules (Figure 5). The $La^{3+}$ ion is seven-coordinate by six phosphonate oxygen atoms from five phosphonate ligands and an aqua ligand. The La–O distances are in the range 2.409(5)–2.632(7) Å, which is comparable to those in compounds **1** and **2**. The $\{H_4L^2\}^-$ anion composed of P(1) and P(2) is bidentate and bridges with two $La^{3+}$ ions; each phosphonate group is singly protonated, as are the amine group and the carboxylate group. The $\{H_3L^2\}^{2-}$ anion composed of P(3) and P(4) is tetradentate; it forms an eight-member chelating ring with a $La^{3+}$ ion, and also bridges with two other $La^{3+}$ ions. Only one phosphonate group is singly protonated; the amine group and the carboxylate group are also protonated.

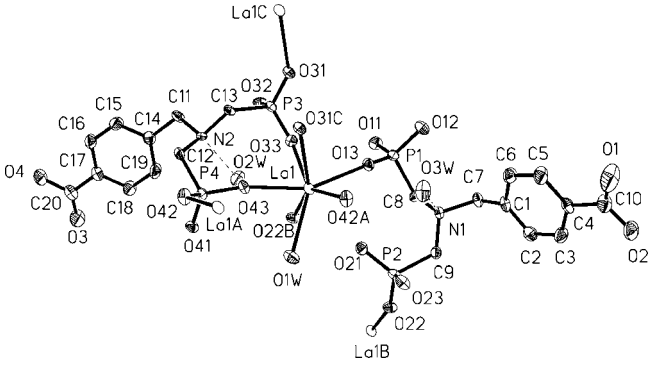

Figure 5. ORTEP representation of the selected unit of compound **3**. The thermal ellipsoids are drawn at 50% probability. Hydrogen bonds are drawn as dashed lines. Symmetry codes for the generated atoms: A: $-x + 2, -y + 1, -z + 1$; B) $-x + 2, -y + 2, -z + 1$; C) $-x + 1, -y + 1, -z + 1$.

Adjacent $La^{3+}$ ions are bridged by the above two types of phosphonate anions into a (002) lanthanide phosphonate layer with $-C_6H_4-$COOH moieties hanging on both sides of the layer (Figure 6). Extensive intralayer and interlayer hydrogen bonds further crosslink these layers into a 3D supramolecular network (Figure 6, Table 1). The lattice water molecules are located at the voids of the structure and are involved in hydrogen bonding (Figure 6, Table 1). The interlayer distance of about 16.8 Å is significantly larger than that in compound **1**, which is due to the introduction of the additional phenyl group into the phosphonate ligand.

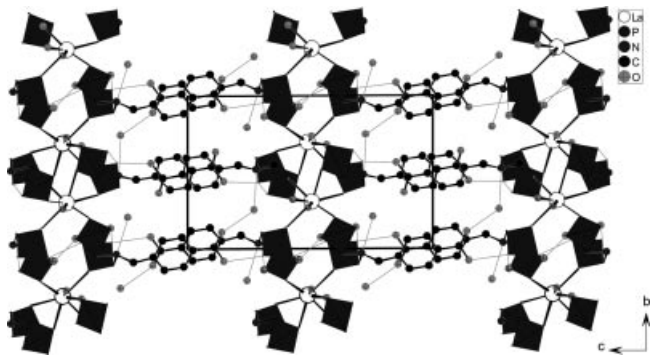

Figure 6. View of the structure of compound **3** down the *a* axis. The phosphonate tetrahedra are shaded in grey. La, N, C, and O atoms are represented by open, dark grey, black, and light grey circles, respectively. Hydrogen bonds are drawn as dashed lines.

The structure of $Er(H_3L^2)(H_4L^2)$ (**4**) features a 3D supramolecular network based on 1D erbium(III) phosphonate chains. The asymmetric unit of **4** is composed of one $Er^{3+}$ ion, one $(H_3L^2)^{2-}$ dianion, and one $(H_4L^2)^-$ anion. The $Er^{3+}$ ion is octahedrally coordinated by six phosphonate oxygens from six different phosphonate ligands (Figure 7). The Er–O distances [2.280(2)–2.331(2) Å] are comparable to those found in the other erbium(III) phosphonate.[16] The coordination modes for the $(H_3L^2)^{2-}$ dianion and $(H_4L^2)^-$ anion are similar. One phosphonate group is monodentate whereas the other is bidentate. The amine group and the carboxylate group for both types of anion are singly protonated. The main difference between the two phosphonate anions are that both phosphonate groups are singly protonated for the $(H_4L^2)^-$ anion [O(31) and O(41)] whereas only one phosphonate group is singly protonated for the $(H_3L^2)^{2-}$ dianion [O(21)].

Each pair of $Er^{3+}$ ions is bridged by a pair of phosphonate groups to form a 1D chain along the *a* axis. Such chains are further interconnected by strong hydrogen bonds between noncoordinated phosphonate oxygens into a (002) layer. These hydrogen bonds are O(21)···O(22) 2.558(6) Å (symmetry code: $1 - x, 3 - y, 1 - z$) and O(31)···O(32) 2.681(6) Å (symmetry code: $-x, 1 - y, 1 - z$). The $-CH_2-C_6H_4-$COOH groups of the phosphonate ligands are hanging on the interlayer space (Figure 8). Intrachain hydrogen bonds are also formed between the amine group and noncoordinated phosphonate oxygens, and between two noncoordinated phosphonate oxygens (Table 1). The interlayer distance is about 14.3 Å, which is shorter than that of compound **3**. These 2D layers are further interlinked by hydro-

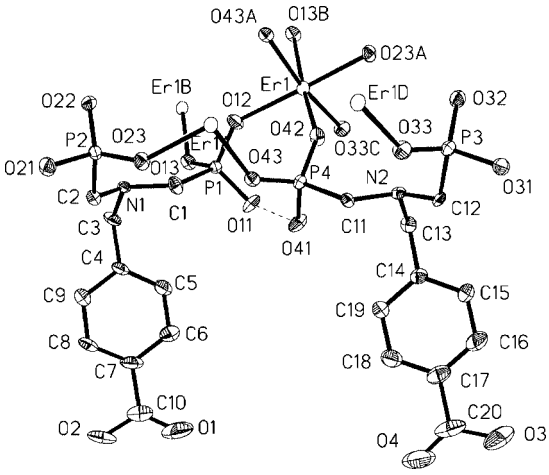

Figure 7. ORTEP representation of the selected unit of compound **4**. The thermal ellipsoids are drawn at 50% probability. Hydrogen bonds are drawn as dashed lines. Symmetry codes for the generated atoms: A) 1 + *x*, *y*, *z*; B) 2 – *x*, 1 – *y*, 1 – *z*; C) 2 – *x*, 2 – *y*, 1 – *z*; D) –1 + *x*, *y*, *z*.

gen bonds between carboxylate oxygen and noncoordinated phosphonate oxygen [O(3)···O(11) 2.624(8) Å, symmetry code: 1 – *x*, 1 – *y*, –*z*].

When erbium(III) nitrate was used instead of erbium(III) chloride, compound **5** was isolated. $H_5L^2$ was also oxidized by the nitrate anion to a new ligand, $H_3L^3$ (Scheme 1). Such in situ oxidation of the P–C bond has also been observed during the hydrothermal reactions of cobalt(II) nitrate with $H_5L$.[2,18] The asymmetric unit of **5** consists of one erbium(III) ion, a $\{H_2L^3\}^-$ anion, a $\{HL^3\}^{2-}$ dianion, and an aqua ligand (Figure 9). The erbium(III) ion is seven-coordinate by six phosphonate oxygens from five phosphonate ligands and an aqua ligand. The Er–O distances range from 2.214(6) to 2.438(6) Å, which is comparable to those in compound **4**. The $\{HL^3\}^{2-}$ dianion is tetradentate; it forms a chelating ring with an erbium(III) ion [Er(1)–O(21)–P(2)–O(22)] and also bridges with two other erbium(III) ions [Er(1b) and Er(1c)]. The phosphonate group is fully deprotonated whereas the amine group remains protonated. The $\{H_2L^3\}^-$ anion is bidentate and bridges with two erbium(III)

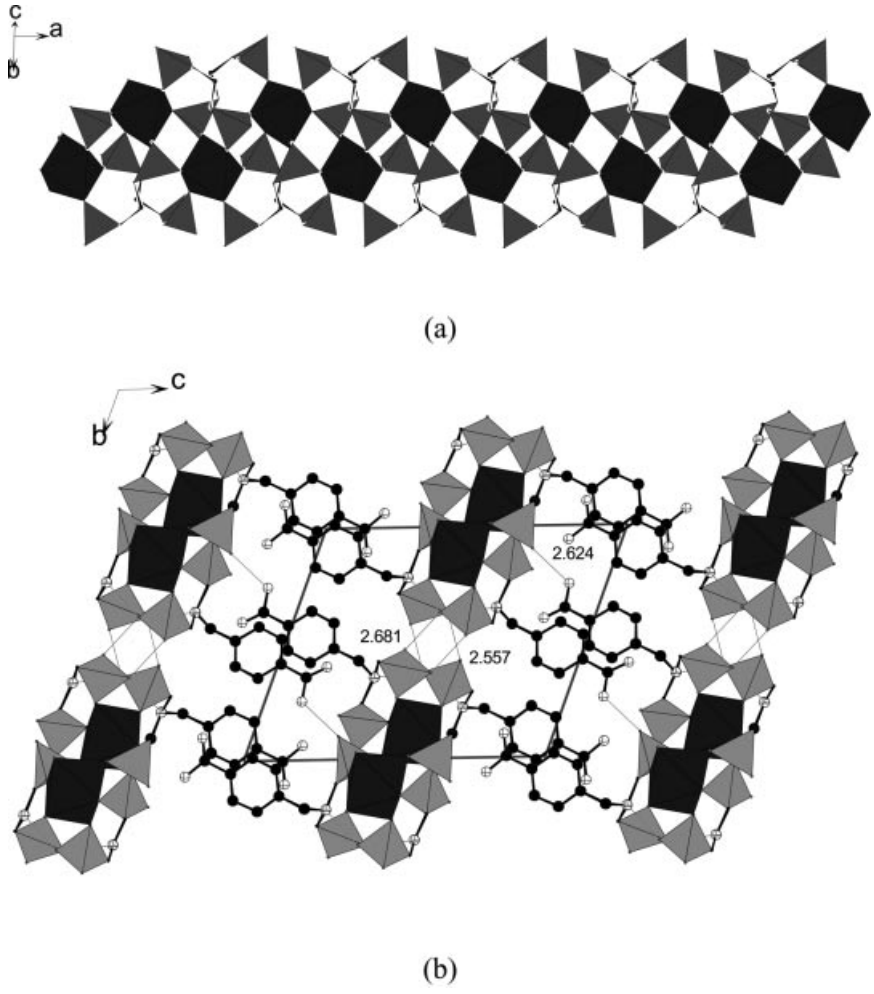

Figure 8. An erbium(III) phosphonate inorganic chain along the *a* axis (a) and view of the structure of compound **4** down the *a* axis (b). The $ErO_6$ octahedra and phosphonate tetrahedra are shaded in dark gray and medium gray, respectively. N, C, and O atoms are represented by octand, black, and crossed circles, respectively.

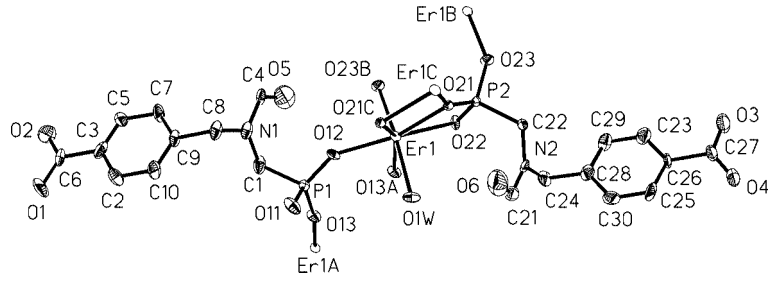

Figure 9. ORTEP representation of the selected unit of compound **5**. The thermal ellipsoids are drawn at 50% probability. Symmetry codes for the generated atoms: A) $-x, -y + 2, -z + 1$; B) $-x - 1, -y + 1, -z + 1$; C) $-x, -y + 1, -z + 1$.

ions using two oxygen atoms [O(12) and O(13)]. The third phosphonate oxygen and the amine group are protonated and noncoordinated. The carboxylate groups in both types of anions are noncoordinated.

The $Er^{3+}$ ions in compound **5** are bridged by phosphonate groups of ligands into a (002) inorganic layer (Figure 10). Within the layer, $Er_2O_2$ rings and $Er(-O-P-O-)_2Er$ rings can be found. Neighboring 2D layers are further interlinked by hydrogen bonds between carboxylate groups. These hydrogen bonds are O(1)···O(4) 2.614(13) Å and O(2)···O(3) 2.585(13) Å (symmetry codes are the same for both bonds: $1 + x$, $1 + y$, $-1 + z$). The interlayer distance of about 21.6 Å is the largest among five compounds, because the carboxylate groups in other compounds are directly hydrogen bonded to a neighboring inorganic layer, whereas the interlayer hydrogen bonding in compound **5** is between two hanging organic groups (head to head).

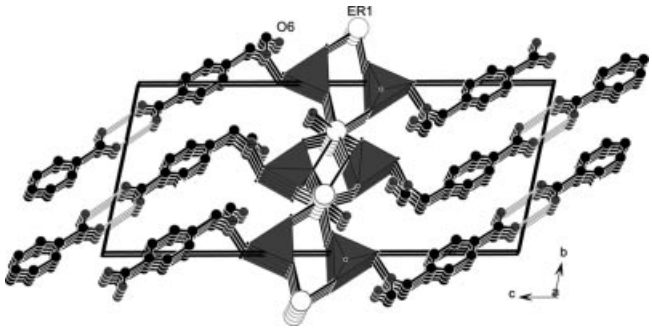

Figure 10. View of the structure of compound **5** down the *a* axis. The phosphonate tetrahedra are shaded in medium gray. Er, C, N, and O atoms are drawn as open, black, octand, and crossed circles, respectively. Hydrogen bonds are shown as dashed lines.

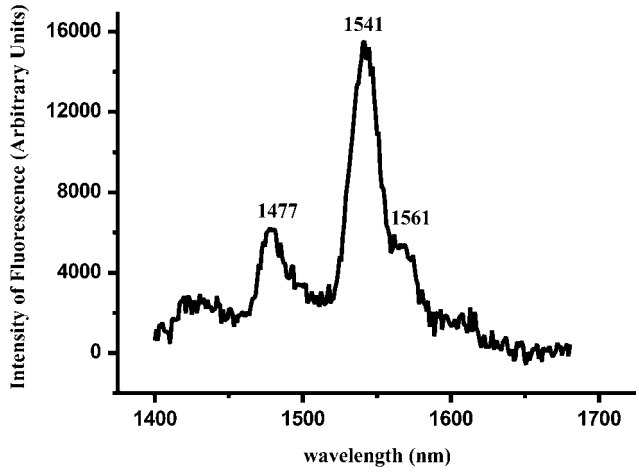
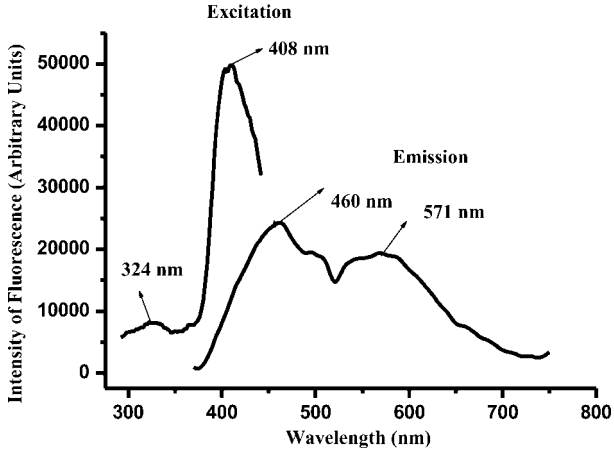
Based on X-ray powder diffraction studies, compounds **2**–**5** are prepared as single phases. The measured patterns are in good agreement with those simulated from single-crystal structures (see Supporting Information).

The solid-state luminescent properties of compounds **4** and **5** were investigated at room temperature. The emission spectrum of compound **4** shows three strong near IR emission bands at 1477, 1541, and 1561 nm under 520 nm excitation (Figure 11a), all of which can be attributed to the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition for the $Er^{3+}$ ion.[16] The splitting of the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition into several sub-bands is due to the low symmetry of the coordination geometry around the $Er^{3+}$ ion ($C_1$). The luminescence properties of compound **5** are very interesting. Under emission of 330 nm, the excitation spectrum of compound **5** displays one weak



(a)



(b)

Figure 11. Luminescence spectra for compounds **4** (a) and **5** (b) at room temperature.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

absorption peak at 324 nm and a very strong absorption peak at 408 nm. Surprisingly, compound **5** shows no near IR emission band under our experimental conditions. Under excitation of 408 nm, the emission spectrum of compound **5** exhibits a very broad band with two maximum intensity peaks at 460 and 571 nm (Figure 11b), which may be assigned to the intraligand π–π* fluorescence. The absence of near IR emission is probably due to the quenching effect of the luminescent state by high-frequency vibrating water molecules.[16a]

TGA curves for compounds **2**–**5** are shown in Figure 12. TGA curves of compound **2** indicate one main step of weight loss. The weight loss between 260 and 620 °C corresponds to the release of water molecules and the combustion of the phosphonate ligand. The weight loss is about 20.5%. There is small weight loss starting from 800 °C, which can be attributed to the further decomposition of the compound. The total weight loss at 1000 °C is 24.4%. The residue was not characterized. Compound **3** shows no obvious weight loss before 135 °C. The weight loss in the temperature range of 135–270 °C corresponds to the release of two lattice water molecules and an aqua ligand. The observed weight loss of 6.8% is close to the calculated value (6.2%). Then the compound decomposes continuously up to 1000 °C, which corresponds to the combustion of organic groups. The total weight loss at 1000 °C is 48.6% and the residue was not characterized. Compound **4** is stable up to 355 °C. Then it exhibits a sharp weight loss between 355 and 575 °C with a weight loss of 23.8%. The total weight at 1000 °C is 34.3% and the final residue was not characterized. TGA curves for compound **5** display two main steps of weight losses. There is no obvious weight loss before 280 °C. The weight loss in the range of 280–340 °C corresponds to the release of an aqua ligand and the decomposition of the two carboxylate groups of two phosphonate ligands. The observed weight loss of 13.4% is slightly smaller than the calculated one (14.5%). The second weight loss covers a temperature range from 340 to 650 °C, which corresponds to further combustion of the phosphonate ligands. The total weight loss at 1000 °C is 34.3% and the final residue was not characterized.

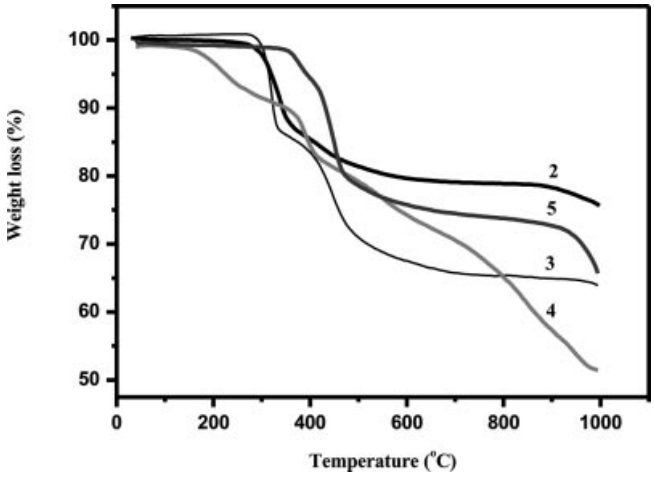


Figure 12. TGA curves for **2** (thick line, black), **3** (thin line, black), **4** (light grey line), and **5** (medium grey line).

## Conclusion

In summary, the hydrothermal syntheses, crystal structures, and luminescent properties of five new lanthanide(III) phosphonates with layered structures have been described. Results from this and previous work indicate that we can greatly improve the solubility and crystallinity of lanthanide phosphonates by attaching amino acid moiety to the phosphonic acid or introducing a second ligand such as oxalate or carboxylate-sulfonate. The counteranion used plays an important role. It affects the acidity of the solution and the extent of deprotonation of phosphonate ligands, as well as the coordination mode a phosphonate ligand adopts. Oxidizing anions such as nitrate groups may also trigger the in situ oxidation of P–C bonds. Furthermore, the so-called "lanthanide contraction" is also important. Heavy lanthanide ions usually have smaller coordination numbers than the light ones, which may result in different coordination modes for the phosphonate ligands. However, more systematic studies are still needed to further understand the chemistry of lanthanide phosphonates.

## Experimental Section

**Materials and Methods:** $(H_2O_3PCH_2)_2NCH_2CO_2H$ ($H_5L^1$) and 4-$HO_2C$–$C_6H_4$–$CH_2N(CH_2PO_3H_2)_2$ ($H_5L^2$) were prepared by a Mannich-type reaction according to the procedures described previously.[6] All other chemicals were obtained from commercial sources and used without further purification. Elemental analyses were performed on a Vario EL III elemental analyzer. Thermogravimetric analyses were carried out on a NETZSCH STA 449C unit at a heating rate of 15 °C/min under nitrogen. IR spectra were recorded with a Magna 750 FTIR spectrometer photometer as KBr pellets in the range 4000–400 $cm^{-1}$. Photoluminescence analyses were performed on an Edinburgh FLS920 fluorescence spectrometer. X-ray powder diffraction patterns (Cu-$K_\alpha$) were collected in a sealed glass capillary on a XPERT-MPD $\theta$–$2\theta$ diffractometer.

**Preparation of $La(H_2L^1)(H_2O)_2{\cdot}H_2O$ (1):** A mixture of $LaCl_3{\cdot}6H_2O$ (176.7 mg, 0.5 mmol), $H_5L^1$ (131.6 mg, 0.5 mmol), and 2-hydroxypyridine (95.1 mg, 1.0 mmol) in 10 mL of distilled water was sealed into an autoclave equipped with a Teflon liner (25 mL) and then heated at 120 °C for 4 days. The initial pH value of the resultant solution was 3.0. Colorless plate-shaped crystals of **1** were collected. Yield: 11.3 mg (5%, based on La). Based on the X-ray powder diffraction study, the majority of impurity was powder of compound **2**. Efforts to prepare a single-phase product of compound **1** were unsuccessful.

**Preparation of $La(H_2L^1)(H_2O)$ (2):** A mixture of $La(OH)_3$ (189.9 mg, 1.0 mmol) and $H_5L^1$ (263.1 mg, 1.0 mmol) in 10 mL of distilled water was sealed into a bomb equipped with a Teflon liner (25 mL) and then heated at 150 °C for 4 days. The initial and final pH values of the resultant solution were 3.5 and 2.5, respectively. Colorless plate-shaped crystals of **2** were collected. Yield: 250 mg (60%, based on La). IR (KBr): $\tilde{\nu}$ = 3359 m, 3139 m, 1607 m, 1448 w, 1407 s, 1371 m, 1305 w, 1214 m, 1164 m, 1083 vs, 1008 m, 974 w, 949 w, 844 w, 768 w, 720 m, 587 w, 496 w, 468 w, 447 w $cm^{-1}$.

$C_4H_{10}LaNO_9P_2$ (416.98): calcd. C 11.52, H 2.42, N 3.36; found C 11.60, H 2.54, N 3.28.

**Preparation of $La(H_4L^2)(H_3L^2)(H_2O)\cdot 2H_2O$ (3):** A mixture of $La(OH)_3$ (56.98 mg, 0.3 mmol) and $H_5L^2$ (169.6 mg, 0.5 mmol) in 10 mL of distilled water was sealed into a bomb equipped with a Teflon liner (25 mL) and then heated at 145 °C for 4 days. The initial and final pH values of the resultant solution were 4.5 and 2.5, respectively. Colorless plate-shaped crystals of **3** were collected. Yield: 121.6 mg (56%, based on $H_5L^2$). IR (KBr): $\tilde{\nu}$ = 3480 m, 3387 m, 3219 m, 3020 w, 3010 w, 2614 w, 1697 s, 1642 m, 1460 w, 1403 m, 1321 w, 1274 w, 1163 m, 1115 vs, 991 m, 931 m, 825 w, 761 m, 644 w, 560 m, 535 m, 484 w, 451 w $cm^{-1}$. $C_{20}H_{33}LaN_2O_{19}P_4$ (868.27): calcd. C 27.65, H 3.83, N 3.23; found C 27.70, H 3.92, N 3.18.

**Preparation of $Er(H_3L^2)(H_4L^2)$ (4):** A mixture of $ErCl_3\cdot 6H_2O$ (95.4 mg, 0.25 mmol) and $H_5L^2$ (84.8 mg, 0.25 mmol) in 10 mL of distilled water was sealed into an autoclave equipped with a Teflon liner (25 mL) and heated at 145 °C for 5 days. The initial and final pH values of the resultant solution were 3.5 and 2.0, respectively. Pink brick-shaped crystals of **4** were collected. Yield: 147 mg (70%, based on Er). IR (KBr): $\tilde{\nu}$ = 3494 m, 3114 m, 2674 w, 2557 w, 1705 s, 1401 m, 1318 m, 1206 m, 1113 vs, 1020 m, 994 m, 951 m, 908 w, 879 w, 820 w, 808 w, 763 m, 719 m, 681 w, 637 w, 582 m, 515 w, 493 w, 465 w, 413 w $cm^{-1}$. $C_{20}H_{26}ErN_2O_{16}P_4$ (841.57): calcd. C 28.54, H 3.11, N 3.33; found C 28.50, H 3.17, N 3.39.

**Synthesis of $Er(HL^3)(H_2L^3)(H_2O)$ (5):** A mixture of $Er(NO_3)_3\cdot 6H_2O$ (230.70 mg, 0.5 mmol), $H_5L^2$ (169.6 mg, 0.5 mmol), and 2-hydroxypyridine (95.10 mg, 1.0 mmol) in 10 mL of distilled water was sealed into a bomb equipped with a Teflon liner (25 mL) and then heated at 120 °C for 4 days. The initial and final pH values of the resultant solution were 3.0 and 2.5, respectively. Light yellow brick-shaped crystals of **5** were collected. Yield: 91 mg (25%, based on Er). IR (KBr): $\tilde{\nu}$ = 3494 m, 3116 m, 2674 w, 2557 w, 1686 s, 1611 m, 1579 w, 1511 w, 1453 m, 1430 m, 1324 m, 1296 m, 1239 m, 1175 w, 1104 vs, 1025 m, 994 m, 951 m, 908 w, 879 w, 820 w, 791 w, 763 m, 719 w, 681 w, 641 w, 575 m, 506 w, 493 w, 465 w, 414 w $cm^{-1}$. $C_{20}H_{23}ErN_2O_{13}P_2$ (728.60): calcd. C 29.59, H 3.18, N 7.51; found C 30.08, H 3.26, N 7.46.

**Single-Crystal Structure Determination:** Data collections for compounds **1**–**5** were performed with a Rigaku Mercury CCD diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Intensity data were collected by the narrow frame method at 293 K. The data sets were corrected for Lorentz and polarization factors as well as for absorption by the multiscan technique.[18] All five structures were solved by the direct methods and refined by full-matrix least-squares fitting on $F^2$ by SHELX-97.[19] All non-hydrogen atoms were refined with anisotropic thermal parameters, except for C(1), C(4), and O(11) in compound **2**, and C(21) in compound **5**, which were refined isotropically. The lattice water molecule in compound **1** was disordered over two orientations [O(3w) and O(3w′)], with an interatomic distance of 0.932 Å. Each orientation was refined with 50% occupancy. Hydrogen atoms attached to carbon atoms, amine groups, and phosphonate groups were located at geometrically calculated positions and refined with isotropic thermal parameters. The protonation for the amine groups as well as phosphonate groups was based on P–O distances and charge balance. Hydrogen atoms for water molecules were not included in refinements.

**Crystal Data for 1:** $C_4H_{14}LaNO_{11}P_2$ (453.01), monoclinic, space group $P2_1/c$, $T$ = 293(2) K, $a$ = 12.675, $b$ = 7.300, $c$ = 14.212 Å, $\beta$ = 108.125(2)°, $V$ = 1249.6 $Å^3$, $Z$ = 4, $d_{calcd}$ = 2.408 $Mg/m^3$, $F(000)$ = 880, $\mu$(Mo-$K_\alpha$) = 3.730 $mm^{-1}$, 9815 reflections collected, 3093 unique ($R_{int}$ = 0.0307). $R_1$ = 0.0236, $wR_2$ = 0.0612 [$I > 2\sigma(I)$], $R_1$ = 0.0263 and $wR_2$ = 0.0627 (all data) and final Gof = 1.056.

**Crystal Data for 2:** $C_4H_{10}LaNO_9P_2$ (416.98), orthorhombic, space group $Pca2_1$, $T$ = 293(2) K, $a$ = 9.9649(13), $b$ = 10.5833(15), $c$ = 10.5288(15) Å, $V$ = 1110.4(3) $Å^3$, $Z$ = 4, $d_{calcd}$ = 2.494 $Mg/m^3$, $F(000)$ = 800, $\mu$(Mo-$K_\alpha$) = 4.173 $mm^{-1}$, 8258 reflections collected, 2418 unique ($R_{int}$ = 0.0891). $R_1$ = 0.0644, $wR_2$ = 0.1039 [$I > 2\sigma(I)$], $R_1$ = 0.0793 and $wR_2$ = 0.1113 (all data) and final Gof = 1.142.

**Crystal Data for 3:** $C_{20}H_{33}LaN_2O_{19}P_4$ (868.27), triclinic, space group $P\bar{1}$, $T$ = 293(2) K, $a$ = 8.246(17), $b$ = 10.58(2), $c$ = 16.79(3) Å, $\alpha$ = 90.34(3), $\beta$ = 90.21(4), $\gamma$ = 93.52(3)°, $V$ = 1461(5) $Å^3$, $Z$ = 2, $d_{calcd}$ = 1.973 $Mg/m^3$, $F(000)$ = 872, $\mu$(Mo-$K_\alpha$) = 1.772 $mm^{-1}$, 11453 reflections collected, 6609 unique ($R_{int}$ = 0.0456). $R_1$ = 0.0542, $wR_2$ = 0.1036 [$I > 2\sigma(I)$], $R_1$ = 0.0722 and $wR_2$ = 0.1143 (all data) and final Gof = 1.088.

**Crystal Data for 4:** $C_{20}H_{26}ErN_2O_{16}P_4$ (841.57), triclinic, space group $P\bar{1}$, $T$ = 293(2) K, $a$ = 7.9178(7), $b$ = 12.5608(5), $c$ = 15.3008(7) Å, $\alpha$ = 110.453(7), $\beta$ = 90.296(12), $\gamma$ = 90.586(13)°, $V$ = 1425.66(15) $Å^3$, $Z$ = 2, $d_{calcd}$ = 1.960 $Mg/m^3$, $F(000)$ = 832, $\mu$(Mo-$K_\alpha$) = 3.247 $mm^{-1}$, 11127 reflections collected, 6439 unique ($R_{int}$ = 0.0456). $R_1$ = 0.0528, $wR_2$ = 0.0984 [$I > 2\sigma(I)$], $R_1$ = 0.0684 and $wR_2$ = 0.1072 (all data) and final Gof = 1.107.

**Crystal Data for 5:** $C_{20}H_{23}ErN_2O_{13}P_2$ (728.60), triclinic, space group $P\bar{1}$, $T$ = 293(2) K, $a$ = 5.752(4), $b$ = 9.382(5), $c$ = 22.050(15) Å, $\alpha$ = 101.507(16), $\beta$ = 92.62(2), $\gamma$ = 98.155(19)°, $V$ = 1151.0(12) $Å^3$, $Z$ = 2, $d_{calcd}$ = 1.715 $Mg/m^3$, $F(000)$ = 718, $\mu$(Mo-$K_\alpha$) = 3.839 $mm^{-1}$, 3176 reflections collected, 2217 unique ($R_{int}$ = 0.0277). $R_1$ = 0.0440, $wR_2$ = 0.1207 [$I > 2\sigma(I)$], $R_1$ = 0.0469 and $wR_2$ = 0.1239 (all data) and final Gof = 1.033.

CCDC-295013 to -295017 (for **1**–**5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis, Characterization, and NO Release Study of the *cis*- and *trans*-$[Ru(Bpy)_2(SO_3)(NO)]^+$ Complexes

**Francisco O. N. Silva,[a] Sérgio X. B. Araújo,[a] Alda K. M. Holanda,[a] Emerson Meyer,[a] Francisco A. M. Sales,[a] Izaura C. N. Diógenes,[a] Idalina M. M. Carvalho,[a] Ícaro S. Moreira,*[a] and Luiz G. F. Lopes*[a]**

**Keywords:** Ruthenium / Nitrogen oxides / Bioinorganic chemistry / Drug design

Aiming at the development of novel NO donors, the synthesis and reactivity of the *trans*-$[Ru(bpy)_2(SO_3)(NO)](PF_6)$ and *cis*-$[Ru(bpy)_2(L)(NO)](PF_6)_n$ complexes (L = imidazole, isonicotinamide, or sulfite ions) were investigated. The complexes were characterized and the NO release capabilities were evaluated. The rate constant for NO dissociation for the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex is $k = 2.0 \cdot 10^{-3}$ s$^{-1}$. The *cis* and *trans*- $[Ru(bpy)_2(SO_3)(NO)]^+$ complexes showed promising physical-chemical properties towards nitric oxide generation, and great stability towards hydroxide attack in the 2.0–9.0 pH range. The reduction potential of the $\{RuNO\}^{6/7}$ process of the *cis* and *trans*-$[Ru(bpy)_2(SO_3)NO]^+$ complexes ($E_{1/2}$ = –0.14 and –0.34 V vs. Ag/AgCl) is appropriated for reduction in vivo by biological reducing agents, with consequent NO release.

## Introduction

Nitric oxide (NO) has a critical role in physiological and pathophysiological processes in the cardiovascular system.[1–3] NO insufficiency limits NO-mediated signal transduction of normal or protective physiological processes. Dysfunction of the normally protective endothelium is found in several cardiovascular diseases, including hypertension, coronary heart disease, and arterial thrombotic disorders.[4] The endothelial dysfunction leads to nitric oxide (NO) deficiency, which has been implicated in the underlying pathobiology of many of these disorders.[5] Exogenously administered NO donors have provided the basis for a broad field of pharmacotherapeutics in cardiovascular medicine. Pharmacological compounds that release NO have been useful tools for evaluating the pivotal role of NO in cardiovascular physiology and therapeutics. NO donors are pharmacologically active substances that spontaneously release or are metabolized to NO or its redox partners. For example in cases of emergency hypertension or heart attacks, NO needs to be administered due to its vasodilator effect. Sodium nitroprusside, $Na_2[Fe(CN)_5NO]\cdot 2H_2O$, is part of a class of compounds that release NO spontaneously and is the unique NO metal complex used clinically.[6] Problems associated with the use of $Na_2[Fe(CN)_5NO]\cdot 2H_2O$ include susceptibility to photolysis and oxidative breakdown through the action of the immune system, both of which lead to the release of cyanide.[7] There are also Ru-edta complexes that can control the levels of circulating NO such as K[Ru(Hedta)Cl] that exists in equilibrium with its aqua species.[8] This aqua species has been shown to be useful in some conditions such as septic shock (also for diabetes, arthritis, inflammation, and epilepsy) where excessive production of NO can be a problem. This can lead to arteries responding poorly to vasoconstrictor drugs during treatment.[9]

Many drugs have direct vasoactive effects and have been used to treat ischemic heart disease, heart failure, and hypertension for many years. Nevertheless, undesirable effects such as the short therapeutic half-life, adverse hemodynamic effects, and drug tolerance limit the use of most of them.[5] To overcome these limitations, the development of novel NO donors are of great interest. The literature[10–12] has pointed out that it is possible to modulate the NO reduction potential by coordination to transition metals and by the π character of the spectator ligands. Hence, the correct establishment of the NO reduction potential in a specific compound is an important requirement for its use as a metallodrug.[10] With this purpose in mind, we have investigated the synthesis and reactivity of the *trans*-$[Ru(bpy)_2(SO_3)(NO)](PF_6)$ and *cis*-$[Ru(bpy)_2(L)(NO)](PF_6)_n$ complexes, where L = imidazole (imN), isonicotinamide (isn), or sulfite ions ($SO_3^{2-}$), and bpy = 2,2′-bipyridine. The complexes were characterized in order to infer the correct composition and coordination modes of the ligands, and to evaluate their NO release capabilities.

## Results and Discussion

The electronic spectra of the *cis*-$[Ru(bpy)_2L(NO_2)]^{+/-}$ nitro complexes (L = imN, isn, $SO_3^{2-}$) are dominated by intense (bpy)π*←dπ(Ru) MLCT bands (around 410 nm) and by the bpy intraligand bands, which are characteristic of the $Ru^{II}$-bipyridine complexes.[13,14] The bands observed in the 320–326 nm range for the *cis*-$[Ru(bpy)_2L(NO)]^{n+}$ and *trans*-$[Ru(bpy)_2(SO_3)(NO)]^+$ nitrosyl complexes (Table 1) are attributed to the (bpy)π*←dπ(Ru) MLCT transition. These bands are shifted to a higher energy range when compared with the spectra of the corresponding nitro complexes. This effect can be explained by the strong $(NO^+)$π*←dπ(Ru) backbonding interaction, which causes a large stabilization of the molecular orbitals that have a high contribution of the metal dπ levels. Unfortunately, the $(NO^+)$π*←dπ(Ru) transitions were not detected in the spectra probably because of superposition with those of (bpy)π*←dπ(Ru) transitions. These bands are expected to appear in the higher energy region of the spectra because of the stabilization of the dπ levels by the (bpy)π*←dπ(Ru) backbonding interaction. In fact, the $(NO^+)$π*←dπ(Ru) transition is observed in the range of 420–480 nm for $[Ru(NH_3)_4(NO)X]^{n+}$ complexes (X = $OH^-$, $Cl^-$, $Br^-$, and $I^-$), with a very weak intensity ($\varepsilon < 50$ $mol^{-1}\cdot cm^{-1}\cdot L$).[15,16] The intense bands observed at about 290 nm are assigned to the π*←π (bpy) transition, which commonly appears in the spectra of bis(2,2′-bipyridine)ruthenium(II) complexes.[17]

Table 1. Electronic spectra data for the nitro and nitrosyl-bis(2,2′-bipyridine)ruthenium(II) complexes, in 0.10 M $CF_3CO_2Na$ aqueous solution.

| Complexes | (bpy)π*←dπ(Ru) MLCT, $\lambda$ [nm] ($\varepsilon$, $mol^{-1}$ L·$cm^{-1}$) |
|---|---|
| *cis*-$[Ru(bpy)_2(imN)(NO_2)]^+$ | 412 ($7.30\cdot10^3$) |
| *cis*-$[Ru(bpy)_2(isn)(NO_2)]^+$ | 408 ($9.04\cdot10^3$) |
| *cis*-$[Ru(bpy)_2(SO_3)(NO_2)]^-$ | 405 ($1.02\cdot10^3$) |
| *cis*-$[Ru(bpy)_2(imN)(NO)]^{3+}$ | 325 sh ($8.92 \times 10^3$) |
| *cis*-$[Ru(bpy)_2(isn)(NO)]^{3+}$ | 321 sh ($1.11\cdot10^4$) |
| *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ | 326 ($8.27\cdot10^3$) |
| *trans*-$[Ru(bpy)_2(SO_3)(NO)]^+$ | 320 sh ($3.08\cdot10^4$) |

The electronic spectra of the nitrosyl complexes were observed to be pH dependent. As the pH of the solutions containing these complexes is increased, new intense bands with a maximum in the 400–450 nm range are observed. These bands can be assigned to the (bpy)π*←dπ(Ru) MLCT transition of the nitro species formed according to the chemical equilibrium displayed in Reaction (1).[18–20] Similar behavior was observed in the spectra of the *trans*-$[Ru(NH_3)_4(L)(NO)]^{3+}$ complexes.[21]

The pH vs. absorbance plots for all nitrosyl complexes showed only one inflection (Figure 1), indicating a unique equilibrium assigned to the $[NO]^+ \rightleftharpoons [NO_2]^-$ interconversion, with both species present in equal concentrations at pH = 1.45 for L = isn, pH = 5.54 for L = imN, and pH = 10.32 for L = $SO_3^{2-}$. The calculated $K_{eq}$ equilibrium constants are displayed in Table 2 together with $\nu(NO^+)$ and $E_{1/2}\{RuNO\}^{6/7}$ values for correlation purposes. The electrophilic character of coordinated nitrosyl has been associated with the ν(NO) frequency.[22] The ν(NO) values reflect the electron density at the nitrogen atom of the nitrosyl group, which is the target for the nucleophilic attack. The literature has established that complexes with ν(NO) greater than 1860 $cm^{-1}$ are reactive $OH^-$.[16] It has also been observed that the equilibrium constant [Reaction (1)] is greater as the ν(NO) frequency is more positive. Therefore, the $K_{eq}$ values might also reflect the electrophilic character of the nitrosyl complex involved in the chemical equilibrium.

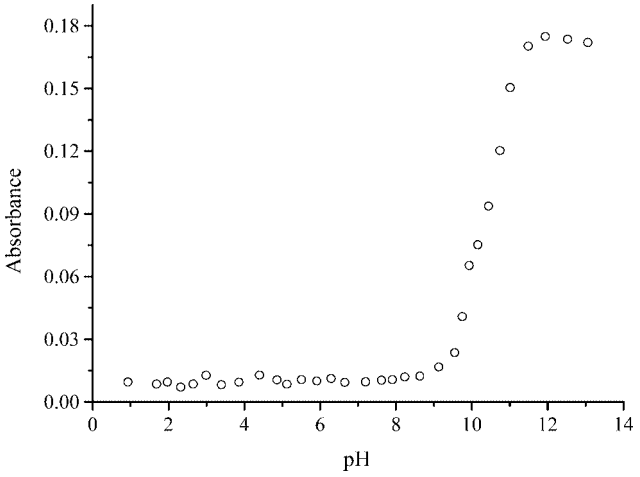

Figure 1. Spectrophotometric titration of $[Ru(bpy)_2(SO_3)(NO)]^+$ complex, $\lambda_{max}$ = 410 nm; $\mu$ = 1.0 M $CF_3CO_2Na$ aqueous solution.

Table 2. Values of $K_{eq}$ for the equilibrium (*1*), $\nu(NO^+)$, and $E_{1/2}\{RuNO\}^{6/7}$ for the $[Ru(bpy)_2(L)(NO)]^{n+}$ complexes, pH = 2.0; *pH = 1.0.

| Complexes | $K_{eq}$ | $\nu(NO^+)$ [$cm^{-1}$] | $E_{1/2}$, $\{RuNO\}^{6/7}$ [V] |
|---|---|---|---|
| *cis*-$[Ru(bpy)_2(isn)(NO)](PF_6)_3$ | $1.80\cdot10^{25}$ | 1948 | +0.34* |
| *cis*-$[Ru(bpy)_2(imN)(NO)](PF_6)_3$ | $1.42\cdot10^{16}$ | 1944 | +0.20 |
| *cis*-$[Ru(bpy)_2(SO_3)(NO)](PF_6)$ | $1.74\cdot10^{7}$ | 1911 | –0.14 |
| *trans*-$[Ru(bpy)_2(SO_3)(NO)](PF_6)$ | $6.42\cdot10^{3}$ | 1881 | –0.34 |

From the data presented in Table 2, the proportionality between the $K_{eq}$, $\nu(NO^+)$, and $E_{1/2}$ parameters is clearly observed. Compounds in which the $NO^+$ character is favored [larger $\nu(NO^+)$] present large $K_{eq}$ values in the whole series. In fact, the greater the electron deficiency of the NO moiety resulting from the π-acid character of the $[Ru(bpy)_2L]^{2+}$ group, the larger will be the driving force for reaction of

$$[Ru(bpy)_2(L)(NO)]^n_{(aq)} + 2\ OH^-_{(aq)} \overset{K_{eq}}{\rightleftharpoons} [Ru(bpy)_2(L)(NO_2)]^{(n-2)}_{(aq)} + H_2O_{(aq)} \quad (1)$$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the coordinated $NO^+$ with $OH^-$ in Reaction (1). The $E_{1/2}$ values are in accordance with the $\nu(NO^+)$ and $K_{eq}$ data, and reflect well the influence of electronic effects on the reactivity of the nitrosyl metal complexes. In addition, a good linear correlation between $E_{1/2}$ $\{RuNO\}^{6/7}$ and $\nu(NO^+)$ is observed for the series of nitrosyl complexes. From Figure 2, it is observed that the lower redox potential of the $\{RuNO\}^{6/7}$ redox couple gives also a lower $\nu(NO^+)$, which is in agreement with the decrease seen in the electronic density of the $NO^+$ group because of the higher π-acceptor character of the L ligand.

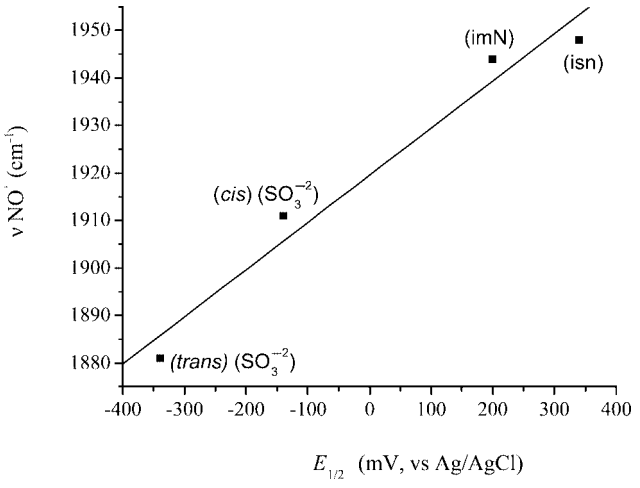

Figure 2. $\nu(NO^+)$ vs. $E_{1/2}$ $\{RuNO\}^{6/7}$ plot for the $[Ru(bpy)_2(L)NO]^{n+}$ complexes.

Generally, when a good σ-donor ligand is coordinated to nitrosyl-metal complexes in the *trans* position in relation to the $NO^+$ moiety, an increase of the $NO^+\leftarrow M$ backbonding interaction occurs and the $\nu(NO^+)$ stretching shifts to a lower frequency in the infrared (IR) spectrum. Conversely, the electron-withdrawing capability of π-acid ligands reduces the $NO^+\leftarrow M$ backbonding interaction causing an opposite effect on the $\nu(NO^+)$.[23] It should be noted that the $\nu(NO^+)$ peak of free NO is located at 1876 $cm^{-1}$, but in the metal complexes it is very sensitive to the binding properties and oxidation states of the metal ion. The literature reports that the $\nu(NO^+)$ frequencies for *cis*-$[Ru^{II}(bpy)_2(NO)L]$ complexes (L = $N_3^-$, $Cl^-$, $NO_2^-$, $NH_3$, py, $CH_3CN$) have been observed in the 1923–1970 $cm^{-1}$ range.[17] For $[Ru^{II}(NH_3)_5(NO)]^{3+}$[24] and *trans*-$[Ru^{II}(NH_3)_4(NO)L]$[25] complexes [L = imidazole, L-histidine, py, isonicotinamide, pyrazine, $P(OEt)_3$], $\nu(NO^+)$ values lie in the 1909–1941 $cm^{-1}$ range, whereas for L = $SO_3^{2-}$, the ν(NO) value is 1871 $cm^{-1}$. In the case of *trans*-$[Ru^{II}(py)_4(NO)L]$[26] complexes, for L = $Cl^-$ and $Br^-$, $\nu(NO^+)$ = 1910 and 1901 $cm^{-1}$, respectively, but for L = $OH^-$, $\nu(NO^+)$ = 1860 $cm^{-1}$. Also, $\nu(NO^+)$ = 1860 $cm^{-1}$ is observed for the *trans*-$[RuCl([15]aneN_4)NO]^{2+}$ complex.[27] In such examples, the ruthenium center has been considered as mainly $Ru^{II}$, thus giving a predominantly $NO^+$ character to the nitrosyl ligand.

On the basis of these discussions, the very intense peaks observed in the IR spectra of the nitrosyl complexes at 1948, 1944, 1911, and 1882 $cm^{-1}$ for the *cis*-$[Ru(bpy)_2(isn)(NO)](PF_6)_3$, *cis*-$[Ru(bpy)_2(imN)(NO)](PF_6)_3$, *cis*-$[Ru(bpy)_2(SO_3)(NO)](PF_6)$, and *trans*-$[Ru(bpy)_2(SO_3)(NO)](PF_6)$ complexes, respectively, are assigned to $\nu(NO^+)$. The most relevant features in the IR spectra of the nitro complexes are the strong absorptions at 1340 and 1280 $cm^{-1}$ attributed respectively to the symmetric and asymmetric $\nu(NO_2)$ stretching modes of the coordinated nitro ligand.[28] It is important to point out that the infrared spectrum for the product isolated from Reaction (1) for L = $SO_3^{2-}$ at pH 12.0 does not show the ν(NO) frequency value, characteristic of the $NO^+$ form. Instead of the band at 1911 $cm^{-1}$, this spectrum presented bands at 1321 and 1271 $cm^{-1}$, which are associated with the asymmetric and symmetric stretching mode of the nitro ligand ($NO_2$). This result supports the proposed equilibrium suggested by Reaction (1), in agreement with that reported in the literature.[21,23]

To better characterize the nitrosyl complexes, their $^1H$ NMR, 2D COSY, and HMQC spectra were acquired. Figure 3 illustrates the HMQC spectrum for the *cis*-$[Ru(bpy)_2(imN)(NO)]^{3+}$ complex. The presence of all signals of the N-heterocyclic ring suggests that the imN and isn ligands are coordinated to the metal center through the nitrogen atom.[10] The appearance of 16 signals for the hydrogen atoms of the two bipyridine molecules suggests that all hydrogen atoms are nondiamagnetically equivalent,[29,30] strongly indicating the *cis* configuration for the $[Ru(bpy)_2(isn)(NO)]^{3+}$, $[Ru(bpy)_2(imN)(NO)]^{3+}$, and $[Ru(bpy)_2(SO_3)(NO)]^+$ complexes. On the other hand, the $^1H$ NMR spectrum of the *trans*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex shows only four signals at $\delta$ = 8.85 ppm (d; $H_6$, $H_{11}$), $\delta$ = 8.57 ppm (d; $H_3$, $H_8$), $\delta$ = 8.40 ppm (t; $H_5$, $H_{10}$), and $\delta$ = 7.87 ppm (t; $H_4$, $H_9$), which is characteristic of the *trans* configuration of the bipyridine ligands.[31]

The cyclic voltammograms (Figure 4) of the nitro complexes show only one reversible redox process. The data are summarized in Table 3.

Because of the π-acceptor character of the imidazole, isonicotinamide, and nitro moieties, all values of $E_{1/2}$ for the $Ru^{III/II}$ redox couple are more positive than that for the $[Ru(bpy)_2Cl_2]$ complex in aqueous solution.[32]

The electrochemical studies of the nitrosyl complexes were performed by using cyclic voltammetry and square wave voltammetry techniques. Figure 5 presents the cyclic voltammogram of the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex in an aqueous medium, at pH = 7.0. The electrochemical data for all complexes are illustrated in Table 2.

By applying a negative scan potential to the working electrode, starting from +0.90 V, only one reversible electrochemical process characteristic of the $\{RuNO\}^{6/7}$ redox couple was observed (Figure 5, dotted line). With a positive scan potential, a second electrochemical process is observed at 0.72, 0.70, and 0.62 V for L = isn, imN, and $SO_3^{2-}$, respectively. This process is strongly dependent on the $NO^{+/0}$ redox couple, as can be observed in Figure 5 (solid line), and is assigned to the $Ru^{III/II}$ redox process of the $[Ru(bpy)_2(L)(H_2O)]^{2+}$ complexes, which are generated by NO dissociation from the $[Ru(bpy)_2(L)(NO)]^{n+}$ nitrosyl compounds. These results suggest the existence of a chemi-

Table 3. $E_{1/2}$ values for the $Ru^{III/II}$ redox couple in $[Ru(bpy)_2L^1L^2]^{+/2+}$ complex ions.

| $L^1$, $L^2$ | $E_{1/2}$ [V] |
|---|---|
| isn, $NO_2^-$ | +0.97 |
| imN, $NO_2^-$ | +0.75 |
| $SO_3^{2-}$, $NO_2^-$ | +0.45 |
| $SO_3^{2-}$, $H_2O$ | +0.38 |

cal reaction that precedes the oxidation of the metal center in the aqua complexes. A reasonable interpretation of the electrochemical results is proposed in Reactions (2), (3), and (4).

$$[Ru^{II}(bpy)_2(L)(NO^+)]^{3+} + e^- \underset{}{\overset{-0.14}{\rightleftharpoons}} [Ru^{II}(bpy)_2(L)(NO^0)]^{2+} \quad (2)$$

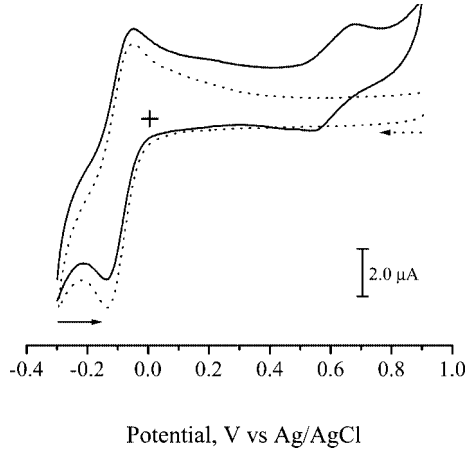

Figure 5. Cyclic voltammograms at 0.10 $Vs^{-1}$ of the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex in 0.10 M $CF_3CO_2Na$ aqueous solution, pH 7.0, scan starting at –0.3 V (solid line) and at 0.9 V (dotted line). + → $i$ = 0.0 μA and $E$ = 0.0 V.

$$[Ru(bpy)_2(L)(NO^0)]^{2+} + H_2O \xrightarrow{k_{NO}} [Ru(bpy)_2(L)(H_2O)]^{2+} + NO^0 \quad (3)$$

$$[Ru^{II}(bpy)_2(L)(H_2O)]^{2+} \underset{}{\overset{+0.62}{\rightleftharpoons}} [Ru^{III}(bpy)_2(L)(H_2O)]^{3+} + e^- \quad (4)$$

The chemical scheme of the reaction proposed in Reaction (3) is corroborated by the redox process observed in the 0.72–0.62 V range, which is characteristic of the aqua complex, illustrated in Figure 5 (solid line).

Aiming to reinforce this assignment, the square wave voltammograms for the *cis*-$[Ru(bpy)_2(L)(NO)]^{n+}$ complexes were acquired by a change in the time polarization of the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

working electrode, at –0.30 V. For all nitrosyl complex series, it was observed that the peak current related to the $Ru^{III/II}$ redox process increases with an increase in time polarization. Figure 6 illustrates the electrochemical behavior of the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex.

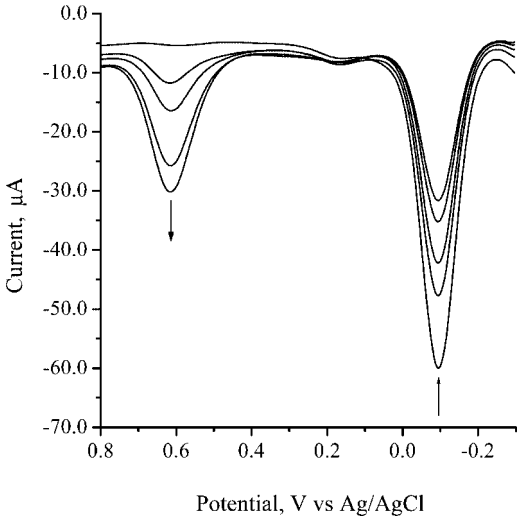

Figure 6. Square wave voltammogram at 0.10 $Vs^{-1}$ of the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex in 0.10 M $CF_3CO_2Na$ aqueous solution, pH 7.0, scans starting at –0.30 V.

The proposed scheme for the reaction is also supported by the electronic and FTIR spectra obtained for the $[Ru(bpy)_2(L)(NO)]^{3+}$ complexes acquired after the electrolysis experiments in which the potential was controlled at –0.30 V. Upon reduction, the electronic spectrum showed the two MLCT bands characteristic of the $[Ru(bpy)_2(L)(H_2O)]^{2+}$ complexes.[32] Furthermore, the IR spectra of all the reduced species, in the solid state, do not present the characteristic $\nu(NO^+)$ band. The rate constant of the NO dissociation, determined by the chronoamperometric method, was $k_{NO} = 2.0 \cdot 10^{-3} \cdot s^{-1}$ for $L = SO_3^{2-}$.

Preliminary photochemical studies of the nitrosyl complexes presented here were performed by irradiation at 355 nm wavelength. The electronic spectra changes observed during the photolysis of the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex in aqueous solution are presented in Figure 7.

From Figure 6, the appearance of the LMCT band at 450 nm is clearly observed, typical of the *cis*-$[Ru(bpy)_2(SO_3)(OH)]$ generated after the release of NO, in accordance with Scheme 1.[33]

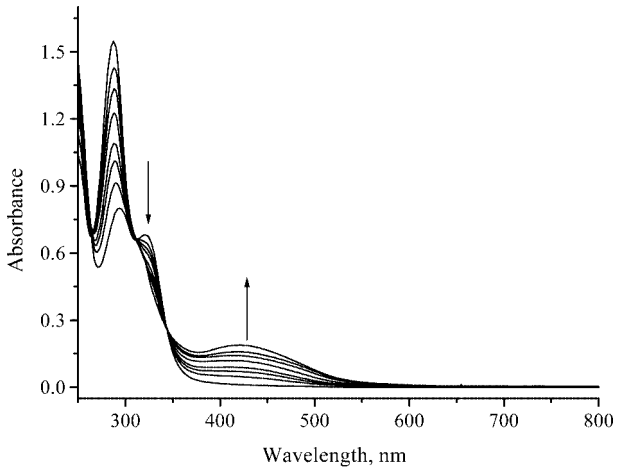

Figure 7. Spectral changes observed during the photolysis of the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex in $CF_3CO_2Na$ aqueous solution, pH 7.0 at 355 nm.

The calculated quantum yield for photochemical NO release from the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ complex was $0.10 \pm 0.01$. A similar photochemical behavior is found for the other complexes as reported in the literature.[34,35]

In addition, the photolysis of the *cis*-$[Ru(bpy)_2(SO_3)(NO)](PF_6)$ complex dispersed in solid KBr was performed and monitored by IR spectroscopy. The successively acquired IR spectra show the decrease in the intensity of the $\nu(NO^+)$ peak at 1915 $cm^{-1}$, which corroborates the proposed photochemical reaction (Scheme 1). The same behav-

ior has been observed for several nitrosyl ruthenium complexes.[25,27,35]

The *cis*- and *trans*-$[Ru(bpy)_2(SO_3)(NO)]^+$ nitrosyl complexes are also reduced by biological reducing agents, such as cysteine, with subsequent NO release. The signal recorded by the NO sensor was observed when a reaction with cysteine was initiated (Figure 8), which indicated the presence of free NO. These results, along with other biological experiments, are currently under investigation and will be reported in a further publication.

## Conclusion

The properties of the *cis* and *trans*- $[Ru(bpy)_2(SO_3)(NO)]^+$ species reported here suggest the considerable advantages provided by these complexes because of their nitric oxide generation, when compared with other NO donors reported in the literature.[36–38] For instance, the *trans*-$[Ru(NH_3)_4P(OEt)_3(NO)]^{3+}$ complex is considered a promising compound that enhances neuronal firing in mice hippocampal slices.[39] Unfortunately, this complex is chemically modified by hydroxide attack on the $NO^+$ moiety, resulting in dissociation of nitrite ions in physiological conditions.[39] Since the *cis* and *trans*- $[Ru(bpy)_2(SO_3)(NO)]^+$ complexes are inert to hydroxide attack in the 2.0–9.0 pH range, and the reduction potential of the $\{RuNO\}^{6/7}$ redox process for the *cis*-$[Ru(bpy)_2(SO_3)(NO)]^+$ species ($E_{1/2}$ = –0.14 V vs. Ag/AgCl) is close to that of the *trans*-$[Ru(NH_3)_4P(OEt)_3(NO)]^{3+}$ complex,[38] the sulfite complex is potentially a better NO donor in vivo.

## Experimental Section

**Chemicals and Reagents:** Ultrahigh purity water from a Millipore system was used throughout the experiments. $RuCl_3{\cdot}xH_2O$, imidazole, isonicotinamide, cysteine, and sodium sulfite were purchased from Aldrich and used without further purification. $[Ru(bpy)_2Cl_2]$ and *trans*-$[Ru(NH_3)_4(SO_2)Cl]Cl$ were prepared according to the literature procedures.[13,14,40]

**Synthesis of the Complexes:** The $[Ru(bpy)_2(SO_3)(H_2O)]$ complex was prepared by dissolving *trans*-$[Ru(NH_3)_4(SO_2)Cl]Cl$ (0.080 g, 0.26 mmol) in water (5.0 mL) under argon. 2,2′-Bipyridine (0.082 g, 0.52 mmol) was then added, and the mixture was stirred for 2 h. The solution volume was reduced under vacuum to approximately 2 mL. Addition of ethanol (10 mL) resulted in the precipitation of the product as a black solid. The precipitation of the product was induced by the addition of ethanol (10 mL). Yield (0.107 g) >80%. $C_{20}H_{16}N_4O_4RuS$ (511.38): calcd. C 46.92, H 3.52, S 6.25; found C 46.83, H 3.50, N 6.21.

The $[Ru(bpy)_2(L)(NO_2)](PF_6)_n$ complexes were prepared by following a standard procedure in all series. In a typical procedure, the reactions were performed by mixing a sample of $[Ru(bpy)_2Cl_2]$ (0.200 g, 0.41 mmol) and L (0.49 mmol; L = imidazole, isonicotinamide, sodium sulfide) in a 1:1 ethanol/water solution (20 mL). The mixtures were kept under reflux for 1 h. To these solutions, $NaNO_2$ (0.034 g, 0.49 mmol) was added and the mixtures were then allowed to react for 2 h, under reflux. The resulting solutions were concentrated by rotary evaporation until reduction of the volume to approximately 10 mL has been achieved. The solids were precipitated by the addition of saturated aqueous $NH_4PF_6$ solution (2 mL). Yields (0.209 g, 0.126 g, and 0.195 g for L = imidazole, isonicotinamide and sulfite, respectively) >75%. $C_{23}H_{19}F_6N_7O_2PRu$ (672.36): calcd. C 41.05, H 2.82, N 14.58; found C 41.23, H 2.79, N 14.38. $C_{26}H_{22}F_6N_7O_3PRu$ (726.46): calcd. C 42.94, H 3.02, N 13.49; found C 42.65, H 2.98, N 13.32. $C_{20}H_{16}N_5NaO_5Ru$ (562.38): calcd. C 42.67, H 2.85, N 12.45; found C 42.37, H 2.78, N 12.19.

The $[Ru(bpy)_2L(NO)](PF_6)_n$ complexes (L = imidazole, isonicotinamide, sulfite) were prepared by dissolving the $[Ru(bpy)_2L(NO_2)](PF_6)_n$ complexes (0.2 mmol) in methanol (15 mL) under an argon atmosphere. To this mixture, concentrated trifluoroacetic acid solution (2 mL) was added to promote the conversion of $NO_2$ to $NO^+$.[28] The reaction was monitored by HPLC by following the decrease of the peak at *Rt* = 6.78 min of the nitro complex at the expense of the increase of the peak at *Rt* = 3.93 min of the nitrosyl complex. After 2 h, no changes in the heights of the peaks were observed, indicating that the reaction is close to the saturation kinetics point. The solvent was then concentrated in a rotary evaporator to near 8 mL, and the solid was precipitated by the addition of ammonium hexafluorophosphate (1.0 g), collected by filtration and stored under vacuum. Yields (0.151 g, 0.160 g, and 0.107 g for L = imidazole, isonicotinamide, and sulfite, respectively) >80%. $C_{23}H_{23}F_{18}N_7O_3P_3Ru$ (982.36): calcd. C 28.15, H 2.36, N 9.99; found C 28.23, H 2.29, N 9.68. $C_{26}H_{22}F_{18}N_7O_2P_3Ru$ (1000.42): calcd. C 31.18, H 2.19, N 9.80; found C 31.09, H 2.12, N 9.75. $C_{20}H_{16}F_6N_5OPRuS$ (619.98): calcd. C 35.90, H 2.39, N 10.47; found C 35.81, H 2.31, N 10.32.

**Determination of the Equilibrium Constant:** The literature reports of the study of some similar chemical systems that exhibit the $NO_2^- \rightleftharpoons NO^+$ equilibrium.[23,41] The determination of the equilibrium constant $K_{eq}$ for Reaction (1) was carried out using the spectrophotometric method (absorbance measurements were performed at 410 nm). The total ionic strength was kept at 1.0 M with $CF_3CO_2Na$, according to similar studies reported for the $Fe^{II}$ [42] and $Ru^{II}$ [28] systems.

**Determination of the Rate Constant for the NO Dissociation:** The rate constant for the NO dissociation in the $[Ru(bpy)_2(SO_3)(NO)](PF_6)$ complex was determined by the chronoamperometric method, according to the procedure reported in the literature.[43]

**Quantum Yield:** Quantum yield was determined from initial spectral changes and was plotted vs. reaction percentage and extrapolated back to 0% reaction to minimize inner filter effects. The reported quantum yield is the average of, at least, three independent experiments.

**Apparatus:** Electrochemical experiments were performed with an electrochemical analyzer BAS 100W from Bioanalytical Systems at 25.0 ± 0.2 °C. These were generally performed on millimolar solutions of the complexes in 0.10 M $CF_3CO_2Na$ (pH = 7.0) aqueous solution by using a conventional three-electrode glass cell with a glassy carbon (ca. 0.13 $cm^2$ of geometrical area) and Pt foil as the working and auxiliary electrodes, respectively. The electrochemical experiments were performed at room temperature. The reversibility of the electrochemical processes was checked by the linearity of the peak height for the reduction process as a function of the square root of the scan rate, and the separation between the anodic (Ea) and cathodic potential peaks in the range of 50–80 mV at 25 °C.[44] NO release was measured with an ISONOP NO meter from World Precision Instruments that directly detects NO concentration by an amperometric technique.

The chromatographic analyses were performed with a Shimadzu liquid chromatograph equipped with a model LC-10AD pump and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

an SPD-M10A UV/Visible photodiode-array detector with a CBM-10AD interface. An ODS column (250 mm × 4.6 mm id., 5 μm particles; from Altech) was used with an isocratic elution with 20:80 acetonitrile/water containing 0.1% $CF_3CO_2H$, pH = 3.7. The chromatograms were taken at a constant flow rate of 1.0 mL·min$^{-1}$. Samples for analyses were dissolved in the mobile phase and 5 μL of volumes were injected.

Elemental analyses were performed with a Perkin–Elmer CHN 2400 analyzer. Electronic spectra were acquired with a HP-8453 diode-array spectrophotometer. NMR spectra were obtained with a Bruker AVANCE DPX 500 spectrometer in $D_2O$ and $CD_3COCD_3$. IR spectra were obtained in KBr pellets with a Shimadzu IR Prestige-21 spectrophotometer.

Monochromatic irradiation at 355 nm was carried out using an Oriel 200-Watt universal arc lamp source in model 68805. The irradiation wavelength was selected with an Oriel interference filter for photolysis at the appropriate wavelength. The interference filter had an average band pass of 10 nm and the collimated beam intensities ranged from $4{\cdot}10^{-8}$ to $1{\cdot}10^{-9}$ einstein$^{-1}$·cm$^{-2}$ as determined by ferrioxalate actinometry. The progress of the photoreactions was monitored spectrophotometrically with an HP-8453 diode-array spectrophotometer.

# Coordination Mode of the Zinc(II) and Cadmium(II) Cations with *N*-(Diisopropoxyphosphoryl)thiobenzamide

**Felix D. Sokolov,[a] Damir A. Safin,*[a] Nail G. Zabirov,[a] Vasiliy V. Brusko,[a] Bulat I. Khairutdinov,[a] Dmitry B. Krivolapov,[b] and Igor A. Litvinov[b]**

**Keywords:** Chelates / Coordination modes / Crystal structures / (Thioacylamido)phosphates / Zinc(II) / Cadmium(II) complexes

Reaction of the potassium salt of *N*-(diisopropoxyphosphoryl)thiobenzamide ($i$PrO)$_2$P(O)NHC(S)C$_6$H$_5$ (**HL**) with Zn$^{II}$ and Cd$^{II}$ cations in aqueous EtOH leads to three different complexes: [Zn(L-*O*,*S*)$_2$] (**1**), [Cd$_2$(L-*O*,*S*)$_4$] (**2**) and [Cd(HL-*O*)$_2$(L-*O*,*S*)$_2$] (**3**). The structures of these compounds were investigated by single-crystal X-ray diffraction analysis, EI-MS and ES-MS, IR, $^1$H, $^{13}$C and $^{31}$P NMR spectroscopy and microanalysis. The zinc(II) atom in complex **1** is in a distorted tetrahedral ZnO$_2$S$_2$ environment formed by the C=S sulfur atoms and the P=O oxygen atoms of two deprotonated ligands. The cadmium(II) complex **2** is centrosymmetric and consists of dimeric species. Two [Cd(L-*O*,*S*)$_2$] moieties are connected by two bridging [S–Cd–S] units through the sulfur atoms of the ligand C=S groups. Complex **2** has a distorted trigonal-bipyramidal Cd(O$^{ax}$)$_2$(S$^{eq}$)$_3$ core. Complex **3** has a tetragonal-bipyramidal environment, Cd(O$^{ax}$)$_2$(O$^{eq}$)$_2$(S$^{eq}$)$_2$, and two neutral ligand molecules are coordinated in the axial positions through the oxygen atoms of the P=O groups. The base of the bipyramid is formed by two anionic ligands in a typical 1,5-O,S coordination mode. The ligands are in a *trans* configuration.

## Introduction

Amidophosphates of the type RC(X)NHP(Y)R′$_2$ (X, Y = O or S; R = Alk, Ar, ArNH, AlkNH, Alk$_2$N; R′ = OAlk, OAr, Ar) are attractive because of their ability to form stable chelates with d- and f-metal cations. These complexes possess antivirus[1] and anticancer activity,[2] and show nonlinear optical properties.[3] They can be used as components of ion-selective electrodes,[4–7] or as extragents and masking reagents in analytical chemistry.[8,9]

An application as structural blocks for the synthesis of supramolecular coordination compounds has excited a new wave of interest in the coordination chemistry of amidophosphates[10,11] and their nearest analogues such as 1,3-dichalcogenimidodiphosphinates R$_2$P(X)NHP(Y)R′$_2$[12] or carbamoylphosphane oxide R$_2$P(O)CH$_2$C(X)R′.[13] Polynuclear complexes of the type M$_n$L$_n$ (M = Co$^{II}$, Ni$^{II}$, Pd$^{II}$, Ag$^{I}$, Zn$^{II}$, Cd$^{II}$, Hg$^{II}$) of bis(bipodal) amidothiophosphates with the general formula [($i$PrO)$_2$P(S)NHC(S)NH]$_2$Z [Z = (CH$_2$)$_2$O(CH$_2$)$_2$, (CH$_2$)$_2$O(CH$_2$)$_2$O(CH$_2$)$_2$, (CH$_2$)$_2$, (CH$_2$)$_7$] have been investigated.[14,15] It was established that the cadmium(II) complex with bipodal amidophosphate, where Z = (CH$_2$)$_2$,[15] represents a macrocyclic dimer ($n$ = 2) containing two Cd$^{II}$ cations in a distorted tetrahedral CdS$_4$ environment.

The structure of Zn$^{II}$ and Cd$^{II}$ complexes with the general formula M[L-*S*,*S*′]$_2$ {L = [H$_2$NC(S)NP(S)(C$_6$H$_5$)$_2$]$^-$, M = Zn$^{II}$;[16] L = [C$_6$H$_5$NHC(S)NP(S)(O$i$Pr)$_2$]$^-$, M = Zn$^{II}$ or Cd$^{II}$;[17] L = [C$_6$H$_5$C(S)NP(S)(O$i$Pr)$_2$]$^-$, M = Zn$^{II}$[17] and Cd$^{II}$[18]} has been investigated by IR and NMR spectroscopy[16–18] and X-ray analysis.[16] It was established that, in all cases, there is chelate formation in which the metal cation has a distorted tetrahedral MS$_4$ environment.

In contrast to dithio derivatives, the Zn$^{II}$ and Cd$^{II}$ complexes with *N*-acylamidophosphates RC(X)NHP(Y)R′$_2$, containing both donor atoms of sulfur and oxygen (X ≠ Y), were not studied earlier. The substitution of two sulfur atoms in the central ion coordination sphere by oxygen atoms lowers the degree of stabilisation of π interactions. This leads to an increase in the coordination numbers of the Zn$^{II}$ and Cd$^{II}$ cation from 4 to 5 and 6, respectively. For example, it is known that Cd$^{II}$ complexes with R$_2$P(X)-NHP(Y)R′$_2$ (X = S, Y = O or X = Y = O) exhibit dinuclear structures in which the imidodiphosphinate anions act simultaneously as didentate ligands and as bridging units through the oxygen atoms of the P=O groups.[12]

The present work was carried out with the aim of appraising the influence of the cation (M$^{II}$ = Zn$^{II}$ and Cd$^{II}$) on the formation of either mono- or dinuclear complexes with the amidophosphate ligand ($i$PrO)$_2$P(O)NHC(S)C$_6$H$_5$ (**HL**).

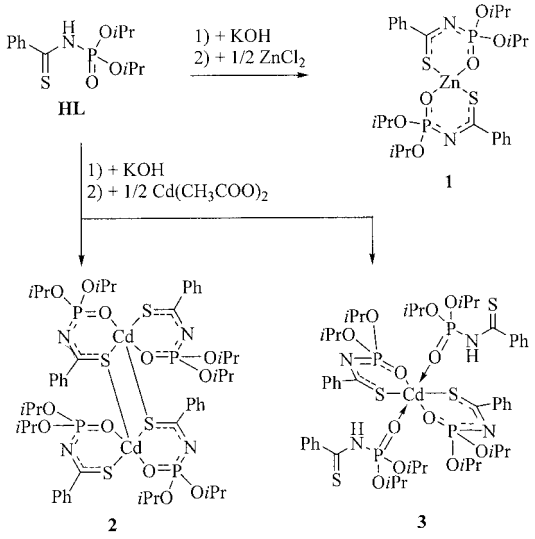
## Results and Discussion

### Synthesis

The ligand **HL** was prepared by reaction of thiobenzamide $C_6H_5C(S)NH_2$ with diisopropyl chlorophosphate $(iPrO)_2P(O)Cl$.

Complexes of **HL** with $Zn^{II}$ and $Cd^{II}$ cations (**1**–**3**) were prepared by the following procedure: the ligand was converted into the potassium salt **KL**, followed by reaction with salts of the corresponding metals. The compounds obtained are crystalline solids that are soluble in most polar solvents. Reaction of the salt **KL** with $ZnCl_2$ in aqueous EtOH leads only to the formation of the complex $[ZnL_2]$ (**1**). Reaction with $Cd(CH_3COO)_2$ leads to the formation of two complexes: $[Cd_2L_4]$ (**2**) and $[Cd(HL)_2L_2]$ (**3**) (Scheme 1). Complex **3** was separated from the mixture by extraction with *n*-hexane.



Scheme 1.

It has been shown that in the crystal form all listed complexes have various coordination environments at the metal atoms. The IR and NMR spectroscopic data confirm that in $CDCl_3$ and $CCl_4$ solutions and in all three cases the dominating forms are $[ML_2]$ chelates with a tetrahedral $MO_2S_2$ core.

### IR and NMR Spectroscopy

The IR spectrum of **1** in Nujol is similar to the spectrum of **2**. The absorption bands of the P=O group of the anionic forms **L** in complexes **1** and **2** are shifted by approximately 70 $cm^{-1}$ to low frequencies relative to the band of the parent ligand **HL**. This confirms their participation in chelate formation. The signal for the NH proton is absent in the IR spectra of complexes **1** and **2**.

The main difference involves the absorption bands of the SCN group.[19,20] In the spectrum of a suspension of **1** in Nujol there is an intense absorption band at 1528 $cm^{-1}$, whereas in **2** the participation of sulfur atoms in dimer formation results in the occurrence of three intense absorption bands in the given area: 1536, 1576 and 1584 $cm^{-1}$. In a $CCl_4$ solution of complex **2** the bands merge into one with a maximum of 1536 $cm^{-1}$, which suggests the dissociation of the dimeric molecules.

The IR spectrum of **3** contains two bands for different phosphorus groups. Along with the above band corresponding to the **L** form, a strong P=O band is observed at 1240 $cm^{-1}$ because of the bound neutral molecules of **HL**. Its frequency also decreases relative to that of the band of the free ligand; however, the shift is 12 $cm^{-1}$. The absorption band for the NH group at 3176 $cm^{-1}$ also indicates the presence of **HL** molecules in complex **3**.

The $^{31}P\{^1H\}$ NMR signals of complexes **1** and **2** appear at $\delta$ = 5.7 and 3.0 ppm, respectively, and a down-field shift, relative to that of the free ligand **HL** ($\delta$ = –5.6 ppm), is observed. Full width at half peak maximum is in the range 1.0–5.0 Hz.

The $^1H$ NMR spectra contain a single set of signals for the $(iPrO)_2P(O)$ and $C_6H_5$ protons. The *o*-phenyl proton signals in complexes **1** and **2** are shifted down-field. The signal for the NHP(O) group proton is absent in $^1H$ NMR spectra. This confirms the presence of the **HL** anionic form in the structures of complexes **1** and **2**.

The formation of dimeric structures in solution would lead to doubling or to exchange broadening of the signals in the NMR spectra. Distinction between the trailer and bridging ligand forms should be shown in the NMR spectra for $^{13}C$ and $^{31}P$ nuclei. Experimental evidence has shown that in both complexes **1** and **2** the $^{13}C$ and $^{31}P$ NMR spectra indicate that there is no doubling or exchange broadening of the signals for carbon and phosphorus atoms. Thus, the NMR spectroscopic data confirm that in $CDCl_3$ solution complexes **1** and **2** are exclusively in the monomeric form.

There are two singlet signals at $\delta$ = –6.0 and 3.7 ppm, which have identical integrated intensities, in the $^{31}P\{^1H\}$ NMR spectrum of complex **3**. The signal at $\delta$ = –6.0 ppm is in the region that is characteristic for neutral *N*-phosphorylated thioamides and thioureas, whereas the second signal corresponds to the amidophosphate environment in complexes of *N*-acylamidophosphate anions.

The $^1H$ NMR spectrum contains a double set of equal-intensity signals for the $(iPrO)_2P(O)$ and $C_6H_5$ protons. The spectrum of complex **3** basically represents the sum of the spectra of ligand **HL** and complex **2** (Figure 1). The assignment of the $^1H$ NMR spectrum of compound **3** is executed by comparing the spectrum of **3** with those of **HL** and complex **2**. For a more exact reference of OCH proton signals of complex **3**, the spectrum of a mixture of **3** and **HL** was run at a molar ratio of 3:1. The increase in intensities of the low-field OCH group signal and the signal for the high-field *o*-$C_6H_5$ protons, concerning the neutral **HL** form, confirms the reference made by comparison of the spectra.

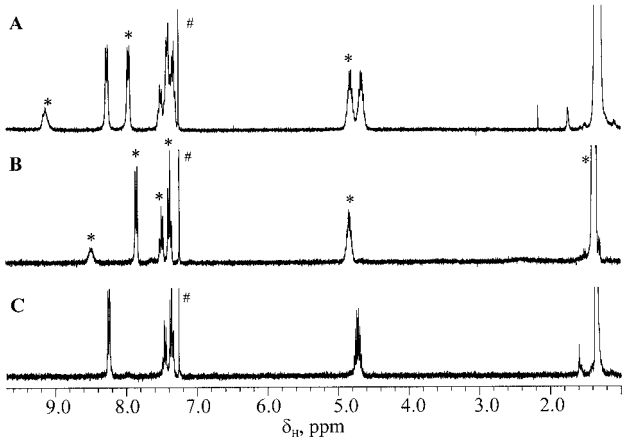

Figure 1. $^1H$ NMR spectra of complexes **3** (A), **2** (C) and **HL** (B). Signals of **HL** (free and in the structure of **3**) are marked * and a signal for the solvent #.

## EI and ES Mass Spectrometry

The electron impact mass spectrum (EI-MS) of **1** contains the $[ZnL_2]^+$ structure molecular ion peak. The molecular ions of **2** $[Cd_2L_4]^+$ and **3** $[Cd(HL)_2L_2]^+$ are unstable under the measurement conditions, and the heaviest molecular ion observed in the spectra of **2** and **3** corresponds to the neutral $[CdL_2]^+$ complex core.

ES-MS experiments (electrospray method) on complexes **1** and **2** show peaks for the molecular ions $[ML_2 + Na]^+$ and $[ML_2 + K]^+$. The cations $[ML_2 + H]^+$, on the contrary, are unstable. This is, apparently, connected to the separating of the **HL** molecule.

The ES-MS data of **2** (Figure 2) shows propensity to dimer formation. The intensity of the $[Cd_2L_3]^+$ peak in the electrospray spectrum of complex **2** is 38% and is maximal in a number of the investigated compounds. The $[Cd_2L_4 + Na]^+$ peak has an intensity of 0.8%.

The molecular ion peak of **3** is absent. Its electrospray spectrum contains all ions characteristic of the $[CdL_2]$ complex core: $[CdL_2 + H]^+$ (low intensity), $[CdL_2 + Na]^+$, $[CdL_2 + K]^+$, $[Cd_2L_3]^+$.

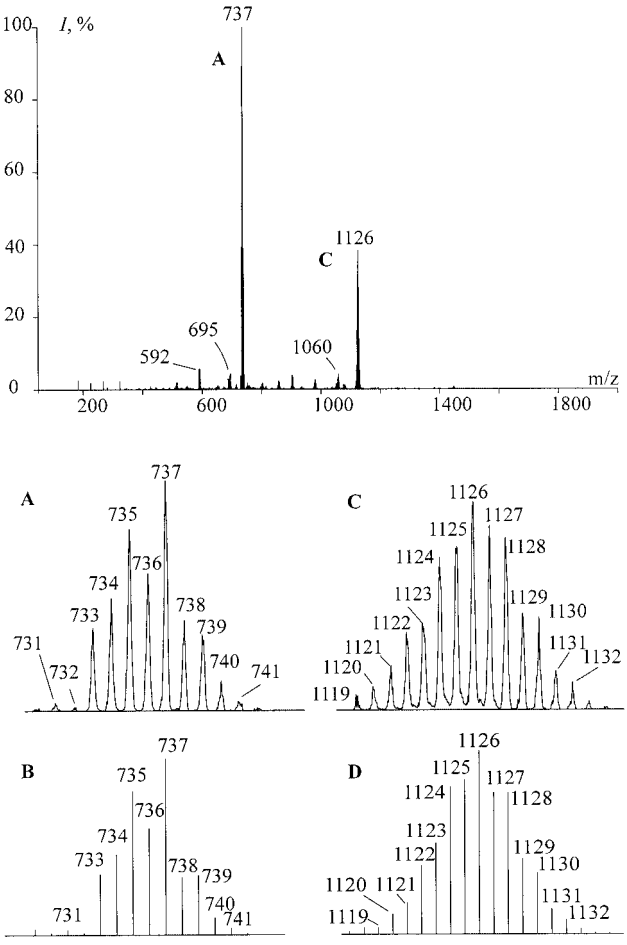

Figure 2. ES-MS spectra of complex **2**. Peak **A** is observed for the $[CdL_2 + Na]^+$ cation, pattern **B** is calculated for $C_{26}H_{38}CdN_2NaO_6P_2S_2$, peak **C** is observed for the $[Cd_2L_3]^+$ cation and pattern **D** is calculated for $C_{39}H_{57}Cd_2N_3O_9P_3S_3$.

## Crystal Structure of 1

According to the X-ray data, complex **1** is a spirocyclic chelate with a distorted tetrahedral $ZnO_2S_2$ core (Figure 3).

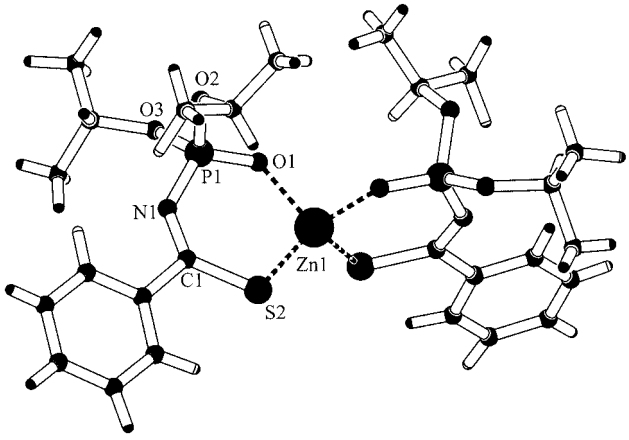

Figure 3. Molecular structure of complex **1**.

Table 1. Selected bond lengths [Å], and bond and torsion angles [°] for complex **1**.[a]

| | | | |
|---|---|---|---|
| Bond lengths | | | |

Similarly to those of the [$Co^{II}L_2$] complex with the same ligand, investigated by us earlier,[21] the six-membered chelate rings are practically flat. The phosphorus atoms usually have a tetrahedral configuration in such compounds. Selected values of bond lengths, bond and torsion angles are given in Table 1.

### Crystal Structure of 2

The X-ray data show that in a crystal form complex **2** is a centrosymmetric dimer. In contrast to the imidodiphosphinate complexes, the bond does not occur through the oxygen atoms of the P=O[12] groups, but through the sulfur atoms of the C=S groups of the deprotonated ligand **HL**. Complex **2** contains two types of ligand anions – tridentate bridging and didentate terminal (Figure 4).

The $Cd^{II}$ cations are in a distorted trigonal-bipyramidal environment ($CdO_2S_3$). The axial positions are occupied by the oxygen atoms of the P=O groups, and the sulfur atoms lie in its base. The $Cd_2S_4$ moiety is flat in the molecule of **2** (Table 2). Predictably, coordination bonds with the sulfur atoms of terminal ligands Cd01–S2A are, essentially, more than 0.16 Å shorter than with the bridging sulfur atoms Cd01–S2B. The lengths of the Cd–O bonds in the $Cd^{II}$ cation's coordination sphere are practically equivalent, but the bond with the oxygen atom of the bridging ligand, Cd01–O1B, deviates from the normal to the $Cd_2S_4$ plane (O1A–Cd01–O1B 155°), while the Cd01–O1A bond is practically perpendicular to the $Cd_2S_4$ plane. The S2B–Cd01–S2B_a angle in the $Cd_2S_4$ plane is more than 50° sharper than S2A–Cd01–S2B.

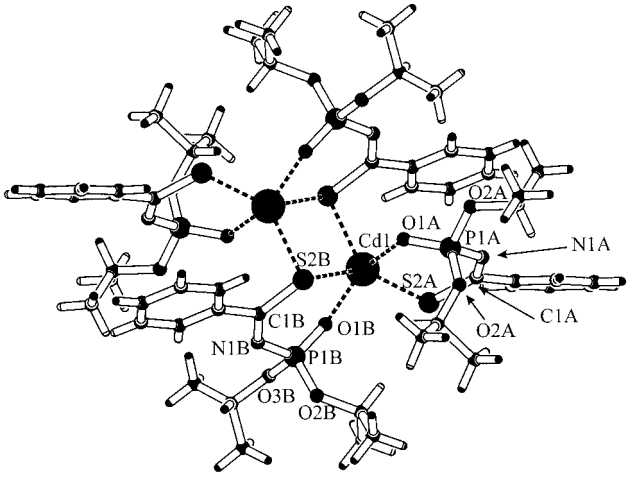

Figure 4. Molecular structure of complex **2**.

The lengths of the bonds in the S–C–*N*–P–O backbone confirm the distinction in negative charge delocalisation mechanisms in bridging and terminal ligands. It is known that three tautomeric forms, A, B and C, contribute to the distribution of electronic density in six-membered chelates of (thioacylamido)phosphates (Scheme 2).

Table 2. Selected bond lengths [Å], and bond and torsion angles [°] for complex **2**.[a]

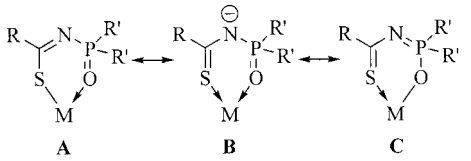

Scheme 2.

Displacement of electronic density on the sulfur atom in bridging ligands leads to the shortening of the C–N and P=O bonds and also to the lengthening of the P–N and C=S bonds because of the prevalence of the tautomeric form A. The P=O bond in these ligands is even shorter than in the free ligand molecule.[19] In the cases with terminal ligands, the contribution of forms B and C which leads to average bonds lengths in the cycle, is shown to a greater degree.

The dimer formation leads to a significant lengthening of the Cd–S bonds in six-membered chelate cycles of the bridging ligands. Therefore, these bonds are the longest in a number of compounds investigated by us, their lengths exceeding even those of the bridging Cd–S bonds connecting [$CdL_2$] moieties in the structure of the dimer.

## Crystal Structure of 3

According to the Cambridge Crystallographic Database, there are no structural analogues of complex **3** that involve *N*-acylamidophosphates or related chelators such as imidodiphosphinates and β-dicarbonyl compounds and Group IIB cations. The nearest analogue of complex **3** is described for $iBu_2NC(S)NHC(O)C_6H_5$ (**HQ**). The complex has the structure [Cd(HQ-*S*)(Q-*O*,*S*)$_2$] (**4**).[22] As in complex **2**, the $Cd^{II}$ cation in complex **4** is in a distorted trigonal-bipyramidal $Cd(O^{ax})_2(S^{eq})_3$ environment.

The molecule of complex **3** in a crystal is located in a special position at the symmetry centre. The coordination geometry of the $Cd^{II}$ atom is tetragonal bipyramidal ($D_{2h}$) (Figure 5). Isostructural complexes of $Co^{II}$ and $Ni^{II}$ with **HL** exist and have been synthesised by us previously.[21]

The equatorial positions of the bipyramid are occupied by two *N*-phosphorylthiobenzamide anions, bonded through sulfur atoms and oxygen atoms of the phosphoryl groups. The six-membered Cd–O–P–*N*–C–S cycle has a half-chair conformation; the O–P–*N*–C–S backbone is flat (Table 3). The ligands are in a *trans* configuration. A negative charge delocalisation in the S–C–*N*–P–O moiety also takes place in this case. This leads to the contraction of the C–N and P–N bonds and also to the lengthening of the C=S bonds, but the P=O bond lengths decrease by 0.013 Å relative to that of the free ligand **HL**. As in complex **2**, this observation results from a significant preference of the form A (Scheme 2).

Neutral ligand molecules are coordinated in the axial positions through the oxygen atoms of the phosphoryl groups. The conformation of the neutral molecules and the lengths of C–N and P–N bonds in a crystal are practically identical to those of free *N*-phosphorylthiobenzamide **HL**. Some lengthening of the P=O and C=S bonds is observed, which results from the displacement of electronic density in the S–C–*N*–P–O moiety on the oxygen atom of the phosphoryl group.

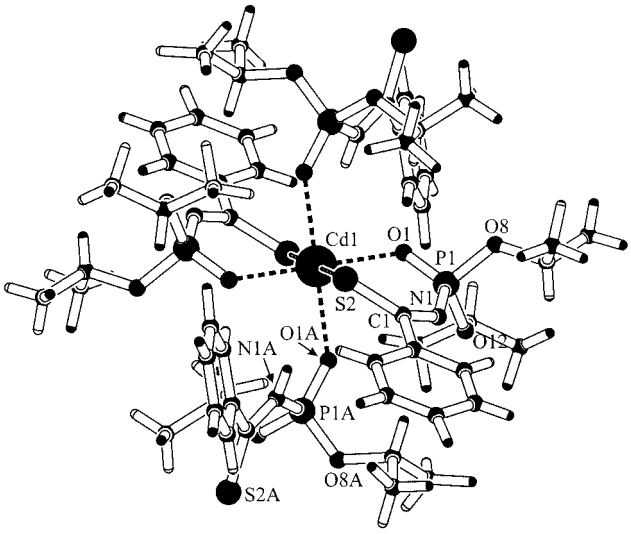

Figure 5. Molecular structure of complex **3**.

Table 3. Selected bond lengths [Å], and bond and torsion angles [°] for complex **3**.[a]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

There are two intramolecular NH···S bonds between the neutral and anionic ligands in the crystal of complex **3**. The hydrogen bond parameters are as follows: N(1A)–H(1A)···S(2) (*–x*, *–y*, *–z*), *d*(N–H) 0.81(3) Å, *d*(H···S) 2.72(3) Å, *d*(N···S) 3.499(3) Å, ∠(N–H···S) 164(2)°.

## Conclusion

Comparison of the data of complex compounds of cadmium(II), known from the literature, with acylureas and imidodiphosphinates shows that the cadmium(II) cation in the structure of the complex $CdO_2S_2$ core exhibits properties of a "universal" Lewis acid. Its coordination environment can be expanded because of interaction with both "soft" and "hard" bases. Differences in modes of interaction are apparently related to the distribution of electronic density in the ligand molecules.

These features of complexes with a $CdO_2S_2$ core can be used in the future for the creation of new types of building blocks for polynuclear metal-containing macrocyclic compounds. We have recently reported the synthesis of close structural analogues of the ligand **HL** that contain crown ether moieties and their complexes with $Ni^{II}$ and $Cu^{I}$.[11,23–25] The cavities of the macrocycles in the given structures remain free and are capable of participating in secondary coordination. We suppose that the combination of the $CdO_2S_2$ core and crown ether in the molecule will allow one to synthesise compounds that are able to bind cations, by the crown ether moiety, and anions and neutral molecules, by the electrophilic $CdO_2S_2$ core. Such kinds of compounds are of interest as agents for molecular recognition and membrane transport.

## Experimental Section

**Physical Measurements:** Infrared spectra (Nujol) were recorded with a Specord M-80 spectrometer in the range 400–3600 $cm^{-1}$. NMR spectra were obtained on a Varian Unity-300 NMR spectrometer at 25 °C. $^1H$, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectra were recorded at 299.948, 121.420 and 75.429 MHz, respectively. Chemical shifts are reported with reference to $SiMe_4$ ($^1H$ and $^{13}C\{^1H\}$) and $H_3PO_4$ ($^{31}P\{^1H\}$). Electron ionisation mass spectra were measured on a TRACE MS Finnigan MAT instrument. The ionisation energy was 70 eV. The substance was injected directly into the ion source at 150 °C. Heating was carried out in a programmed mode from 35–200 °C at a rate of 35 °C/min. Electrospray ionisation mass spectra were measured with a Thermo Finnigan LCQ mass spectrometer on a $10^{-6}$ M solution in a $CHCl_3/CH_3OH$ mixture (1:1 v/v). The speed of a sample submission was 3 μL/min. The ionisation energy was 4.1 kV. The capillary temperature was 210 °C. Elemental analyses were performed on a Perkin–Elmer 2400 CHN microanalyser.

**Synthesis of $(i\mathrm{PrO})_2\mathrm{P(O)NHC(S)C_6H_5}$ (HL):** *N*-Diisopropoxyphosphorylthiobenzamide was prepared according to previously described methods.[26] M.p. 134 °C. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.34 (d, $^3J_{H,H}$ = 5.9 Hz, 6 H, $CH_3$), 1.38 (d, $^3J_{H,H}$ = 6.2 Hz, 6 H, $CH_3$), 4.83 (d. sept, $^3J_{POCH}$ = $^3J_{H,H}$ = 6.1 Hz, 2 H, OCH), 8.49 [s, 1 H, NHP(O)], 7.37–7.42 (m, 2 H, *m*-H, $C_6H_5$), 7.49–7.54 (m, 1 H, *p*-H, $C_6H_5$), 7.85–7.88 (m, 2 H, *o*-H, $C_6H_5$), 8.49 (s, 1 H, NH) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = –5.6 ppm. IR: $\tilde{\nu}$ = 3104 (NH), 1500 (S=C–N), 1012 (POC), 1252 (P=O) $cm^{-1}$.

**Synthesis of $[ZnL_2]$ (1):** A suspension of **HL** (1.505 g, 5 mmol) in aqueous ethanol (20 mL) was mixed with an ethanol solution of potassium hydroxide (0.28 g, 5 mmol). An aqueous (20 mL) solution of $ZnCl_2$ (0.381 g, 2.8 mmol) was added dropwise under vigorous stirring to the resulting potassium salt. The mixture was stirred at room temperature for a further 3 h and left overnight. The resulting complex was extracted with dichloromethane, washed with water and dried with anhydrous $MgSO_4$. The solvent was then removed in vacuo. A colourless precipitate was isolated from dichloromethane by *n*-hexane. Yield (based on the metal salt): 0.865 g (52%). M.p. 92 °C. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.34 (d, $^3J_{H,H}$ = 5.9 Hz, 12 H, $CH_3$), 1.35 (d, $^3J_{H,H}$ = 5.8 Hz, 12 H, $CH_3$), 4.72 (d. sept, $^3J_{POCH}$ = 7.6 Hz, $^3J_{H,H}$ = 6.2 Hz, 4 H, OCH), 7.35–7.40 (m, 4 H, *m*-H, $C_6H_5$), 7.45–7.50 (m, 2 H, *p*-H, $C_6H_5$), 8.26–8.29 (m, 4 H, *o*-H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): 24.5 ($CH_3$), 73.5 (OCH), 128.4 (*o*-C, $C_6H_5$), 129.3 (*m*-C, $C_6H_5$), 132.6 (*p*-C, $C_6H_5$), 143.8 (*ipso*-C, $C_6H_5$), 195.2 (C=S) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): 5.7 ppm. IR: $\tilde{\nu}$ = 1528 (SCN), 996 (POC), 1152 (P=O) $cm^{-1}$. EI-MS: *m*/*z* (%) = 664 (8) $[M]^+$, 301 (8) $[HL]^+$. ES-MS (positive ion): *m*/*z* (%) = 687 (100) $[M + Na]^+$, 703 (10) $[M + K]^+$, 1032 (1) $[M_2L_3]^+$, 1353 $[M_2L_4 + Na]^+$. $C_{26}H_{38}N_2O_6P_2S_2Zn$ (666.05): calcd. C 46.87, H 5.77, N 4.18; found C 46.88, H 5.75, N 4.19.

**Synthesis of $[Cd_2L_4]$ (2) and $[Cd(HL)_2L_2]$ (3):** A suspension of **HL** (1.806 g, 6 mmol) in aqueous ethanol (20 mL) was mixed with an ethanol solution of potassium hydroxide (0.336 g, 6 mmol). An aqueous (20 mL) solution of $Cd(CH_3COO)_2{\cdot}2H_2O$ (0.798 g, 3 mmol) was added dropwise to the resulting potassium salt under vigorous stirring. The mixture was stirred at room temperature for a further 3 h and left overnight. The resulting complex was extracted with dichloromethane, washed with water and dried with anhydrous $MgSO_4$. The solvent was then removed in vacuo. The residue was extracted by *n*-hexane. A hexane insoluble deposit was recrystallised from a dichloromethane/*n*-hexane mixture, and complex **2** was isolated. Complex **2** was obtained as colourless crystals. Yield (based on the metal salt): 0.918 g (43%). M.p. 102 °C. $^1H$ NMR ($CDCl_3$): 1.40 (d, $^3J_{H,H}$ = 6.4 Hz, 24 H, $CH_3$), 4.82 (d. sept, $^3J_{POCH}$ = 7.5 Hz, $^3J_{H,H}$ = 6.4 Hz, 4 H, OCH), 7.34–7.39 (m, 4 H, *m*-H, $C_6H_5$), 7.44–7.49 (m, 2 H, *p*-H, $C_6H_5$), 8.23–8.26 (m, 4 H, *o*-H, $C_6H_5$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): 24.5 ($CH_3$), 73.2 (OCH), 128.4 (*o*-C, $C_6H_5$), 129.5 (*m*-C, $C_6H_5$), 132.4 (*p*-C, $C_6H_5$), 144.3 (*ipso*-C, $C_6H_5$), 193.9 (C=S) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): 3.0 ppm. IR: $\tilde{\nu}$ = 1536, 1576, 1584 (SCN), 1015 (POC), 1184 (P=O) $cm^{-1}$. EI-MS: *m*/*z* (%) = 714 (34) $[ML_2]^+$, 301 (15) $[HL]^+$. ES-MS (positive ion): *m*/*z* (%) = 715 (2) $[ML_2 + H]^+$, 737 (100) $[ML_2 + Na]^+$, 753 (2) $[ML_2 + K]^+$, 1126 (38) $[M_2L_3]^+$, 1449 (0.8) $[M_2L_4 + Na]^+$. $C_{52}H_{76}Cd_2N_4O_{12}P_4S_4$ (1424.12): calcd. C 43.80, H 5.34, N 3.97; found C 43.81, H 5.33, N 3.98.

At the solvent-removal stage (hexane soluble), product **3** was isolated. Complex **3** was obtained as yellow crystals. Yield (based on the metal salt): 0.355 g (18%). M.p. 94 °C. $^1H$ NMR ($CDCl_3$): 1.29 (d, $^3J_{H,H}$ = 6.1 Hz, 36 H, $CH_3$, L + HL), 1.35 (d, $^3J_{H,H}$ = 6.1 Hz, 12 H, $CH_3$, L), 4.67 (d. sept, $^3J_{POCH}$ = $^3J_{H,H}$ = 6.2 Hz, 4 H, OCH, L), 4.82 (d. sept, $^3J_{POCH}$ = $^3J_{H,H}$ = 6.4 Hz, 4 H, OCH, HL), 7.47–7.74 (m, 12 H, *m*-H + *p*-H, $C_6H_5$, L + HL), 7.95–7.98 (m, 4 H, *o*-H, $C_6H_5$, HL), 8.26–8.28 (m, 4 H, *o*-H, $C_6H_5$, L), 9.15 [s, 2 H, NHP(O)] ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): –6.0 (HL), 3.7 (L) ppm. IR: $\tilde{\nu}$ = 1536 (SCN), 1013 (POC), 1168 (L, P=O), 1240 (HL, P=O) $cm^{-1}$. EI-MS: *m*/*z* (%) = 714 (29) $[M – 2HL]^+$, 301 (73) $[HL]^+$. ES-MS (positive ion): *m*/*z* (%) = 715 (2) $[ML_2 + H]^+$, 737 (100) $[ML_2 +$

**Crystal Structure Determination and Refinement:** The X-ray diffraction data for the crystals of **1**–**3** were collected on a CAD4 Enraf–Nonius automatic diffractometer using graphite-monochromated Mo-$K_\alpha$ (0.71073 Å) and Cu-$K_\alpha$ (1.54184 Å) radiation. The crystal data, data collection and the refinement are given in Table 4. The stability of the crystals and the experimental conditions were checked every 2 h using three control reflections, while the orientation was monitored every 200 reflections by centring two standards. No significant decay was observed. An empirical absorption correction based on *ψ*-scans was applied. The structure was solved by direct methods using the SIR[27] program and refined by the full-matrix least-squares using the SHELXS-97[28] program. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms for compounds **1** and **3** were located from a subsequent difference map and refined isotropically in the final cycles. The hydrogen atoms for compound **2** were included in calculated positions with thermal parameters 30% larger than the atom to which they were attached. All calculations were performed on a PC using the WinGX[29] program. Cell parameters, data collection and data reduction were performed on an Alpha Station 200 computer using the MolEN[30] program. All figures were made using the program PLATON.[31]

CCDC-286427, CCDC-286426 and CCDC-286425 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Diamagnetic versus Paramagnetic Structure of SPS-Type Pincer-Based $Co^{I}$, $Rh^{I}$, and $Ir^{I}$ Complexes

**Marjolaine Doux,[a] Pascal Le Floch,[a] and Yves Jean*[a]**

**Keywords:** Group 9 / Density functional calculations / P ligands / S ligands / QM/MM

The lowest singlet and triplet states of SPS-type pincer-based [M(SPS)($PPh_3$)] complexes (M = Co, Rh, and Ir) were studied by means of DFT/B3PW91 calculations on the model complexes in which the nine phenyl substituents were replaced by H atoms. Although the Rh and Ir compounds were found to be diamagnetic with a square-planar geometry, the yet unknown Co complex was predicted to be paramagnetic ($\Delta E_{S/T}$ = –22.4 kcal·mol$^{-1}$) with two unpaired electrons localized on the metal center. Three minima were actually located on the triplet potential energy surface that differ by the arrangement of the ligands (nearly tetrahedral or butterfly geometries), two of them being close in energy ($\Delta E$ = 2.5 kcal·mol$^{-1}$). Finally, the paramagnetism of the Co complex was confirmed by calculations on the real complex at the B3PW91//ONIOM(B3PW91:UFF) level of theory ($\Delta E_{S/T}$ = –29.6 kcal·mol$^{-1}$).

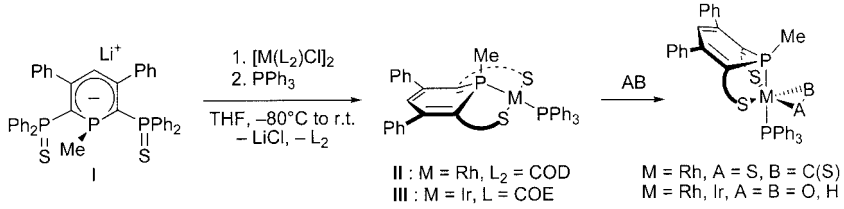
## Introduction

Since the pioneering work of Shaw in 1976,[1] the development of pincer-based ligands has been flourishing and many of these polydentate systems have found numerous applications in coordination chemistry, homogeneous and heterogeneous catalysis.[2–4] Whereas the first studies focussed on PCP-based systems, it rapidly appeared that the introduction of heteroatoms (N, O, P, S) either as central or ancillary ligands could be used to finely tune the electronic properties of the corresponding complexes.[5–7] However, the use of oxygen and sulfur as ancillary ligands remains limited compared to their nitrogen (amine, amide, imine), phosphorus (phosphane, phosphite, phosphaalkene), or carbon (NHC) counterparts. Sulfur-based systems are of great interest as they can be used to modelize enzyme active sites.[8] Sulfur ligands can be found either as thioethers,[9–12] thiolates,[13,14] sulfoxides,[15] or phosphanyl sulfides.[16–19]

Recently, we described the synthesis and the coordination chemistry of the anionic SPS-based pincer ligand **I**, which features two ancillary P=S ligands and a phosphorus atom as the central binding site (Scheme 1).[20] In a series of papers we showed that these ligands can accommodate various metal fragments in different oxidation states ($Re^{I}$, $Mn^{I}$, $Rh^{I}$, $Rh^{II}$, $Rh^{III}$, $Ir^{I}$, $Ir^{III}$, $Ni^{II}$, $Pd^{II}$, $Pt^{II}$, $Au^{I}$, $Cu^{I}$).[21–24] Some of these complexes have found applications in catalysis,[25] photochemistry[21] and activation of small molecules.[26–28] Among these complexes, the 16 VE square-planar $Rh^{I}$ complex [Rh(SPS)($PPh_3$)] (**II**) proved to be particularly reactive towards small molecules such as CO, $SO_2$, $O_2$, $CS_2$, and $H_2$ and the corresponding $Rh^{III}$ complexes, [Rh($\eta^2$-$O_2$)(SPS)($PPh_3$)], [Rh($\eta^2$-$CS_2$)(SPS)($PPh_3$)], and [Rh$(H)_2$(SPS)($PPh_3$)], or $Rh^{I}$ complexes, [Rh($\eta^1$-CO)(SPS)($PPh_3$)] and [Rh($\eta^1$-$SO_2$)(SPS)($PPh_3$)], were isolated and structurally characterized in most cases



Scheme 1.

(Scheme 1).[23,28] Later it was found that the iridium counterpart of **II**, the [Ir(SPS)($PPh_3$)] complex **III**, could also activate $O_2$ and $H_2$.[27,28] Moreover, the attack of the small molecule proved to be stereospecific and only led to a single isomer (the attack occurring *syn* to the P–Me moiety). This

planar discrimination has been studied in the case of $O_2$,[27] CO,[26] and $H_2$.[28]

We now wish to report on a theoretical study of the cobalt complex [Co(SPS)($PPh_3$)], analog of **II** and **III**. In order to shed some light on the electronic structure of these SPS-based complexes, examination of the singlet and triplet states of this yet unknown cobalt complex is presented herein and a comparison is drawn with its Rh and Ir analogs.

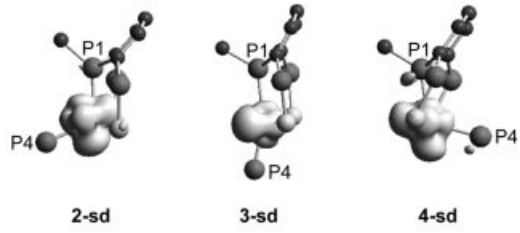

Figure 2. Total spin density (**sd**) surfaces computed for the triplet state of the cobalt complexes **2**, **3**, and **4**. Hydrogen atoms are omitted for clarity.

## Results and Discussion

The geometry of the [Co(SPS)($PH_3$)] model complex was first optimized in the singlet state without any symmetry constraint. The optimized structure (**1**, Figure 1) came out to be nearly of $C_s$ symmetry with an almost perfect square-planar (SP) arrangement around the metal center (S1–Co–S2 = 178.4° and P1–Co–P4 = 177.8°), a geometry usual for a diamagnetic complex of the $d^8$-[$ML_4$] type.

The optimization of the triplet state led to three minima of $C_s$ symmetry (**2**, **3**, and **4**, Figure 1), which differ by the arrangement of the ligands around the metal center. A pseudotetrahedral (*Td*) geometry was found for **2** ($^3A'$) with S1–Co–S2 and P1–Co–P4 angles of 128.3 and 113.1°, respectively. The two other minima can be described as butterfly structures: in **3** ($^3A''$) there is a large P1–Co–P4 angle (164.2°) and a smaller S1–Co–S2 angle (124.2°), while the reverse is true for **4** ($^3A'$) (111.5 and 169.3°, respectively). Such a change in the geometry in going from the singlet to the triplet state is consistent with qualitative molecular orbital arguments: moving away from the square-planar geometry towards tetrahedral or butterfly structures reduces the energy gap between the frontier MOs of $d^8$-[$ML_4$] complexes,[29] a trend which is favorable for the triplet state. The total spin density (**sd**) surface is pictured in Figure 2 and, for each complex, it was found to be mainly developed on the metal center with a Mulliken spin density of 1.970, 1.993, and 1.857 for **2**, **3**, and **4**, respectively.

From an energetic point of view, complex **2** was found to be more stable than **3** and **4** by 2.5 and 12.9 kcal·mol$^{-1}$, respectively. Interestingly, all these triplet-state structures are lower in energy than the singlet-state **1**, as $\Delta E_{S/T}$ = –22.4 kcal·mol$^{-1}$ between **1** (singlet state) and **2** (lowest triplet state) (Figure 1). Note that **2** and **3**, which differ by their symmetry ($^3A'$ and $^3A''$) and their geometry [nearly tetrahedral (**2**) and butterfly-type with a wide P1–Co–P4 angle (**3**)], are predicted to be competitive in energy ($\Delta E$ = 2.5 kcal·mol$^{-1}$). It is remarkable that large changes in the metal–ligand bond angles induce rather small energy changes on the triplet potential energy surface. Note, however, that relative energies and even orderings can depend critically on the amount of HF exchange included in the functional. The energy separation of the four structures was therefore tested by single-point ab initio calculations at the MP2 level. The same energy ordering is found: **2** (0.0) < **3** (+4.1) < **4** (+14.1) < **1** (+34.5) (in kcal·mol$^{-1}$), the main change being an increase of the singlet–triplet energy separation (34.5 instead of 22.4 kcal·mol$^{-1}$ at the B3PW91 level). These values are large enough to conclude unambiguously that the model complex [Co(SPS)($PH_3$)] is paramagnetic. The energy ordering of the three triplet-state structures can be qualitatively traced to two factors: (i) the energy required to distort the complex in its singlet state from the equilibrium square-planar geometry to the actual geometry in the triplet-state structure. This distortion energy (in kcal·mol$^{-1}$) increases in the order **3** (14.0) < **2** (19.8) < **4** (23.7) (restricted B3PW91 calculations); (ii) the energy gap

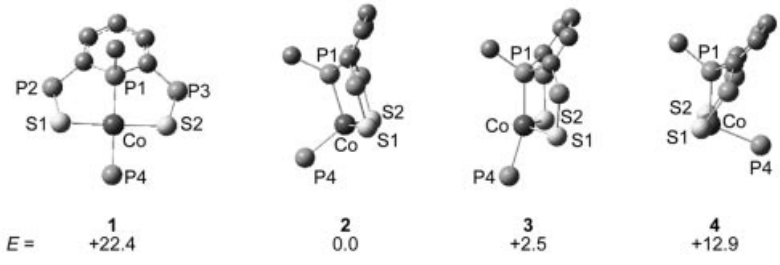

Figure 1. Optimized geometries for the [Co(SPS)($PH_3$)] complex in its singlet (**1**) and triplet (**2**, **3**, and **4**) states. Hydrogen atoms are omitted for clarity. *E*: relative energies (at the B3PW91 level) are given in kcal·mol$^{-1}$. Selected geometrical parameters (bond lengths in Å and bond angles in °): **1**: Co–S 2.292, Co–P1 2.175, Co–P4 2.203; S1–Co–S2 178.4, P1–Co–P4 177.8. **2**: Co–S 2.455, Co–P1 2.324, Co–P4 2.288; S1–Co–S2 128.3, P1–Co–P4 113.1. **3**: Co–S 2.513, Co–P1 2.317, Co–P4 2.308; S1–Co–S2 124.2, P1–Co–P4 164.2. **4**: Co–S 2.568, Co–P1 2.286, Co–P4 2.340; S1–Co–S2 169.3, P1–Co–P4 111.5.

between the two singly occupied MOs in the triplet state (a small value favoring a low-lying triplet state), which increases in the order **2** (10.7) < **3** (23.8) < **4** (29.5). Therefore structure **4** appears to be the least favorable, while the two factors work in opposite direction for structures **2** and **3**, which were actually found to be close in energy.

For the sake of comparison, similar calculations were performed on the rhodium and iridium analogs, the energetic results and the main geometrical parameters being reported in Table 1. A nearly square-planar geometry was found for the singlet state[26,27] and three minima were located for the triplet state. Their geometries are close to that pictured in Figure 1 for the cobalt complex and two of them (**2** and **3**) are still found to be close in energy. However, the singlet state is now located well below the lowest triplet state, by 19.0 and 26.2 kcal·mol$^{-1}$ for M = Rh and Ir, respectively (Table 1). The electronic ground state of the Rh and Ir complexes is thus found to be diamagnetic, in agreement with NMR spectroscopic data.[23,27] Therefore, the trend for the first-row transition metals to form high-spin complexes is large enough to induce a change of the magnetic properties in this family of SPS-based complexes.

Table 1. Relative energies (given in kcal·mol$^{-1}$) at the B3PW91 level of the lowest square-planar (SP) singlet state (**1**) and triplet states [**2** (pseudo-*Td*), **3** (butterfly-1), and **4** (butterfly-2)] of the [M(SPS)(PH$_3$)] model complexes (M = Co, Rh, and Ir).[a]

| | **1** (SP) $^1$A′ | **2** (pseudo-*Td*) $^3$A′ | **3** (butterfly-1) $^3$A′′ | **4** (butterfly-2) $^3$A′ |
|---|---|---|---|---|
| Co | +22.4 | 0.0 | +2.5 | +12.9 |
| Rh | 0.0 | +19.0 | +19.9 | +27.8 |
| Ir | 0.0 | +26.7 | +26.2 | +39.7 |

[a] Selected geometrical parameters (bond lengths in Å and bond angles in °) for Rh and Ir complexes: **Rh(1)**: Rh–S 2.401, Rh–P1 2.259, Rh–P4 2.303; S1–Rh–S2 173.9, P1–Rh–P4 174.3. **Rh(2)**: Rh–S 2.551 (av.), Rh–P1 2.335, Rh–P4 2.304; S1–Rh–S2 138.1, P1–Rh–P4 106.6. **Rh(3)**: Rh–S 2.568, Rh–P1 2.358, Rh–P4 2.369; S1–Rh–S2 111.3, P1–Rh–P4 170.4. **Rh(4)**: Rh–S 2.642, Rh–P1 2.309, Rh–P4 2.332; S1–Rh–S2 168.3, P1–Rh–P4 103.2. **Ir(1)**: Ir–S 2.380, Ir–P1 2.274, Ir–P4 2.272; S1–Ir–S2 172.7, P1–Ir–P4 171.4. **Ir(2)**: Ir–S 2.461, Ir–P1 2.275, Ir–P4 2.240; S1–Ir–S2 128.6, P1–Ir–P4 106.5. **Ir(3)**: Ir–S 2.509, Ir–P1 2.304, Ir–P4 2.300; S1–Ir–S2 106.0, P1–Ir–P4 166.5. **Ir(4)**: Ir–S 2.453, Ir–P1 2.266, Ir–P4 2.284; S1–Ir–S2 163.1, P1–Ir–P4 107.6.

Finally, optimizations of both the singlet and triplet states were performed at the ONIOM(B3PW91:UFF) level of calculation on the real complex (**rc**) [Co(SPS)(PPh$_3$)] bearing nine phenyl substituents. The square-planar singlet state (**1-rc**) and the two lowest structures optimized for the triplet state (**2-rc** and **3-rc**) are pictured in Figure 3.[30] Complex **2-rc** is a slightly distorted tetrahedral complex with S1–Co–S2 and P1–Co–P4 angles of 119.8 and 112.2°, respectively, and **3-rc** adopts a butterfly-type structure with S1–Co–S2 and P1–Co–P4 angles of 103.2 and 150.9°, respectively. From an energetic point of view, complex **2-rc** was found to be more stable than **3-rc** by 6.2 kcal·mol$^{-1}$, the two triplet-state structures being lower in energy than the singlet-state **1-rc** ($\Delta E_{S/T}$ = –20.3 kcal·mol$^{-1}$ between **2-rc** and **1-rc**). Finally, the influence of a QM treatment of the phenyl ligands was tested by single-point calculations at the B3PW91//ONIOM(B3PW91:UFF) level (Figure 3). A triplet ground state was still found, with **2-rc** and **3-rc** very close in energy (only 0.4 kcal·mol$^{-1}$ in favor of **3-rc**) and significantly more stable than the square-planar singlet-state **1-rc** ($\Delta E_{S/T}$ = –29.6 kcal·mol$^{-1}$ between **3-rc** and **1-rc**). Both from the geometrical and energetic points of view, the results of these calculations on the real complex are similar to those from the study of the model complex (Figure 1).

## Conclusion

According to DFT calculations, there is a change in the nature of the electronic ground state when Rh or Ir is replaced by Co in the family of SPS-based pincer-based [M(SPS)(PH$_3$)] model complexes. While Rh and Ir compounds are found to be diamagnetic, a triplet ground state is predicted for the yet unknown cobalt complex, a conclusion confirmed by calculations on the real complex [Co(SPS)(PPh$_3$)] with nine phenyl substituents. This change in the electronic ground state in going from (Rh, Ir) to Co is likely to result in a different chemical behavior of the Co complex compared to its rhodium or iridium analogs. This

result has prompted us to synthesize this interesting Co derivative and to study its reactivity towards small molecules.

## Computational Details

Calculations on the model complexes (quoted as [M(SPS)($PH_3$)] with M = Co, Rh, and Ir), in which the phenyl groups were replaced by H atoms, were performed with the GAUSSIAN 03 series of programs.[31] Density functional theory (DFT)[32,33] was applied with the B3PW91 functional.[34] A quasirelativistic effective core potential operator was used to represent the 10 innermost electrons of the cobalt atom, the 28 innermost electrons of the rhodium atom, and the 60 innermost electrons of the iridium atom.[35] The basis set for the metal atom was that associated with the pseudopotential, with a standard double-ζ LANL2DZ contraction[35] completed by a set of polarization *f* functions.[36] Geometry optimizations were performed with the 6-31+G* basis for phosphorus and sulfur atoms, 6-31G* for the carbon atoms, and 6-31G for hydrogen atoms[37–40] (basis set A) and the minimum energy structures were characterized by vibration frequency calculations. Finally, the energies were recomputed by single-point calculations on the optimized structures using the same basis set for the metal center and the 6-31+G* basis set for all the other atoms (basis set B). Note that the changes in relative energies were found to be lower than 0.7 kcal·$mol^{-1}$ in going from basis set A to basis set B. The restricted singlet-state wave function was reoptimized in the Co complex **1**, as an RHF → UHF instability was detected (single-point calculation on the geometry optimized at the restricted level). The geometry of the real complex (**rc**) [Co(SPS)($PPh_3$)] with nine phenyl substituents was optimized and characterized by vibration frequency calculations by means of QM/MM calculations at the ONIOM(B3PW91:UFF) level with the phenyl substituents in the MM part.[41] The QM part was treated at the DFT/B3PW91 level with the basis set A (see above) and the UFF force field was used for the MM part.[42] Finally, DFT-B3PW91 single-point calculations were performed on the optimized structures [B3PW91//ONIOM(B3PW91:UFF) calculations] using the 6-31G basis set for the phenyl substituents and the basis set A for the other atoms.

**Supporting Information** (see footnote on the first page of this article): Optimized geometry and frequencies of **1**–**4**, **1-rc**, **2-rc**, **3-rc**, **Rh(1)**, **Rh(2)**, **Rh(3)**, **Rh(4)**, **Ir(1)**, **Ir(2)**, **Ir(3)**, and **Ir(4)**.

# Multielectron Storage and Photo-Induced Electron Transfer in Oligonuclear Complexes Containing Ruthenium(II) Terpyridine and Ferrocene Building Blocks

**Katja Heinze,*[a] Klaus Hempel,[a] and Manuela Beckmann[a]**

**Keywords:** Electron transfer / Heterometallic complexes / Luminescence / Metallocenes / Ruthenium

The heteroleptic complex $[(HOOC\text{-}tpy)Ru(tpy\text{-}NH_2)](PF_6)_2$ (tpy = 2,2′;6′,2′′-terpyridine) has been incorporated into a multicomponent system with ferrocene moieties attached on either the N-terminal end or the C-terminal end and on both ends of the ruthenium complex. Electrochemical studies reveal almost noninteracting subunits in the oligonuclear systems, whereas ground-state and excited-state optical properties are shown to strongly depend on the site of ferrocene attachment. Interpretation of the experimental results is supported by DFT calculations.

## Introduction

Design and synthesis of multicomponent systems such as polynuclear metal complexes incorporating electroactive and/or photoactive moieties, especially ruthenium polypyridine complexes,[1–11] is of great current interest for fundamental studies of energy and electron transfer and photoinduced charge separation modelling natural photosynthesis[12] as well as in terms of potential applications in molecular wires and devices, photocatalysis, energy conversion and information storage.[13–17] Most of these topics rely fundamentally on vectorial energy or electron transfer that requires asymmetric multicomponent systems. This requirement has been elegantly met by the design of metallostars and metallodendrimers.[18,19]

Natural proteins represent an archetype for directional multicomponent systems with a well-defined sequence of building blocks. Biological peptides and proteins already provide interesting functions such as molecular recognition and catalysis,[20,21] while artificial amino acid building blocks expand the diversity of peptides and proteins. Combining metal-containing electroactive and photoactive units in peptide-like structures should merge the advantages of both worlds: the amide linkage provides directionality and the introduction of metal complexes provides functionality.[22–31]

In this contribution the synthesis of a bis(terpyridine) ruthenium complex with amino and carboxylato substituents and its conjugates with ferrocene units attached on the N or C terminus as well as on both ends is reported. The influence of the site of ferrocene attachment on ground- and excited-state properties of the multicomponent systems is investigated.

## Results and Discussion

### Design and Synthetic Strategy

The assembly of ruthenium and ferrocene building blocks is based on a modular approach using peptide chemistry.[22–24,32] The key building block is the heteroleptic complex $\mathbf{2}(PF_6)_2$ with a bis(terpyridine) ruthenium(II) core. This asymmetrical complex can be functionalised on either the C-terminal or the N-terminal end giving access to asymmetric multinuclear complexes with a well-defined sequence of building blocks.

Two synthetic challenges have to be met for the success of the synthetic strategy: (i) the selective formation of the heteroleptic complex $\mathbf{2}(PF_6)_2$ and (ii) the activation of the unreactive amino group of the positively charged complex for amide formation. The synthetic approach to $\mathbf{2}(PF_6)_2$ is outlined in Scheme 1.

The terpyridine ligands tpy-COOEt and tpy-$NH_2$ were prepared using Stille coupling reactions according to literature procedures.[33–35] To selectively obtain the heteroleptic complex $\mathbf{1}(PF_6)_2$ the ester-substituted terpyridine ligand is coordinated to ruthenium trichloride[34] before the amino-substituted terpyridine is attached using microwave irradiation (Scheme 1). This optimised procedure results in a negligible amount of homoleptic complexes and $\mathbf{1}(PF_6)_2$ was isolated in 85% yield. In the $^1H$ NMR spectrum of $\mathbf{1}(PF_6)_2$ characteristic singlet signals for the protons $H^2$ and $H^{2'}$ are observed at $\delta$ = 9.15 and $\delta$ = 7.96, respectively, while the

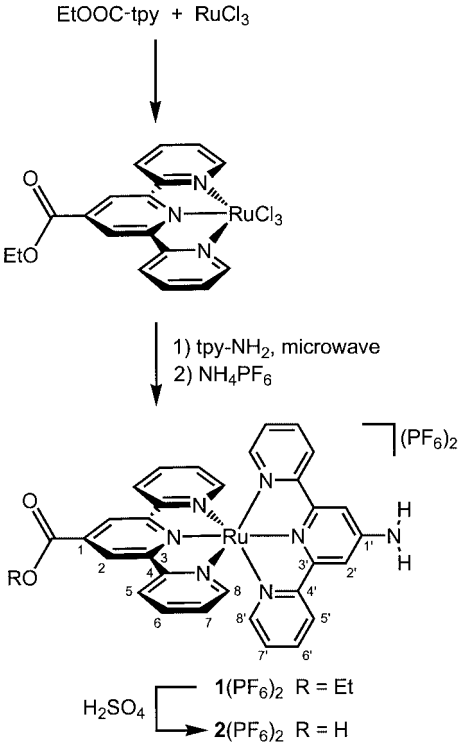

Scheme 1.

amine protons resonate at $\delta$ = 6.00 and the aliphatic protons of the ethyl group at $\delta$ = 4.64 and $\delta$ = 1.57 with expected intensity ratios (for full assignment see Table 1). The assignment of $^{13}$C NMR signals is summarised in the Exp. Sect. (Table 5). The FAB mass spectra establish the composition of $\mathbf{1}^{2+}$ showing signals for $[\mathbf{1} + H,PF_6]^+$ and $[\mathbf{1}]^+$ at $m/z$ = 801 and $m/z$ = 655, respectively. In the IR spectrum of $\mathbf{1}(PF_6)_2$ characteristic absorption bands are observed for the substituents and the hexafluorophosphate counterions (Table 2; Supporting Information, see footnote on the first page of this article).

Table 2. Characteristic IR spectroscopic data [$\tilde{\nu}$/cm$^{-1}$] of complexes $\mathbf{1}(PF_6)_2$–$\mathbf{5}(PF_6)_2$.

| | $\mathbf{1}(PF_6)_2$ | $\mathbf{2}(PF_6)_2$ | $\mathbf{3}(PF_6)_2$ | $\mathbf{4}(PF_6)_2$ | $\mathbf{5}(PF_6)_2$ |
|---|---|---|---|---|---|
| CO (ester/acid) | 1723 | 1719 | – | – | 1721 |
| Amide I | – | – | 1622 | 1668, 1619 | 1674 |
| Amide II | – | – | 1551 | 1574, 1560 | 1577 |
| $NH_2$ (def.) | 1636 | 1634 | 1634 | – | – |
| PF | 838 | 838 | 841 | 839 | 841 |

Hydrolysis of the ester moiety of $\mathbf{1}(PF_6)_2$ to the corresponding acid was unsuccessful with a catalytic amount of hydrochloric acid at room temperature and under microwave heating, while under more forcing conditions (20% sulfuric acid, reflux) the acid $\mathbf{2}(PF_6)_2$ was isolated in 74% yield (Scheme 1). The successful synthesis of $\mathbf{2}(PF_6)_2$ was confirmed by NMR and IR spectroscopy (Tables 1, 2 and 5) as well as mass spectrometry (see Exp. Sect.).

Single crystals have been obtained from an aqueous acidic solution of $\mathbf{2}(PF_6)_2$. The mixed salt $\mathbf{2}(PF_6)(F)$ crystallises in the triclinic space group $P\bar{1}$ with two independent cationic molecules in the asymmetric unit (Figure 1). The cations and anions are embedded in strands of solvent water (about 4–5 per ruthenium centre) held together by

hydrogen bonds and involving both the acid and amine groups of the cations. Selected bond lengths and angles of the independent complex molecules (Table 3) show that both cations exhibit similar primary coordination geometries. However, the two cations display different secondary coordination spheres. The amine group of one cation is hydrogen-bonded to a hexafluorophosphate counterion while the amine group of the other cation is hydrogen-bonded to solvent water (Figure 1).

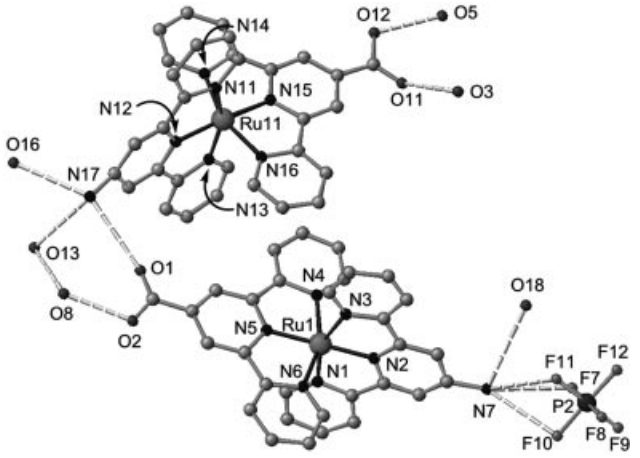

Figure 1. Two independent complex cations of $\mathbf{2}(PF_6)(F)$ and their partial secondary coordination sphere (O3, O5, O8, O13, O16 and O18 denote solvent water).

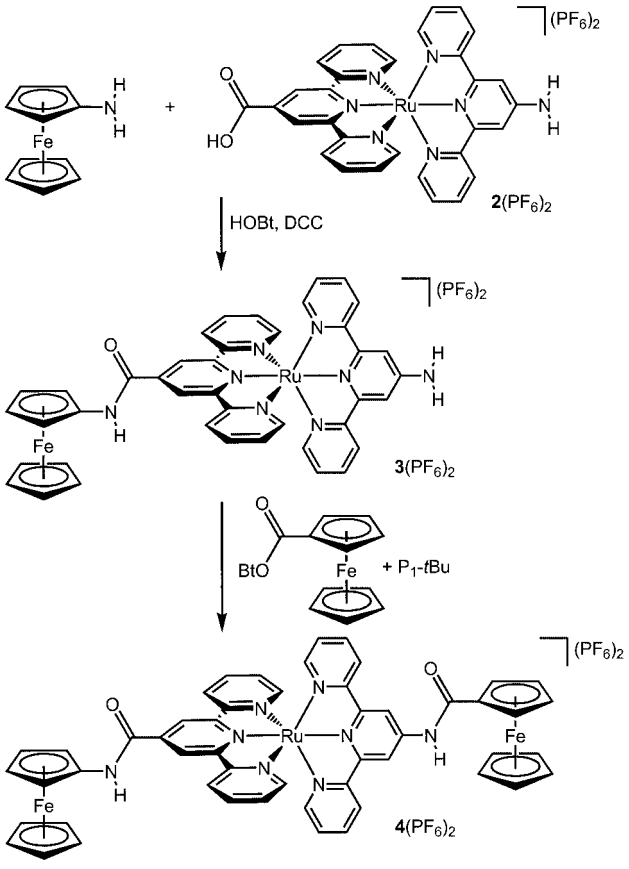
The acid group of $\mathbf{2}(PF_6)_2$ is activated by 1-hydroxybenzotriazole (HOBt) in the presence of 1,3-dicyclohexylcarbodiimide (DCC). Subsequent reaction with aminoferrocene[22] gives the C-terminal-substituted ferrocene conjugate $\mathbf{3}(PF_6)_2$ (Scheme 2). Under these conditions the less reactive aromatic amino group of $\mathbf{2}(PF_6)_2$ remains intact, thus the use of protective groups can be avoided.



Scheme 2.

Under more forcing conditions employing the organic-soluble, nonionic Schwesinger phosphazene base $P_1$-*t*Bu[36–38] the amino groups of $\mathbf{1}(PF_6)_2$ and $\mathbf{3}(PF_6)_2$ form peptide bonds with ferrocenoyl benzotriazol ester Fc-CO-OBt[39] to give the N-terminal-substituted ferrocene conjugate $\mathbf{5}(PF_6)_2$ and the bis-ferrocene bisamide $\mathbf{4}(PF_6)_2$, respec-

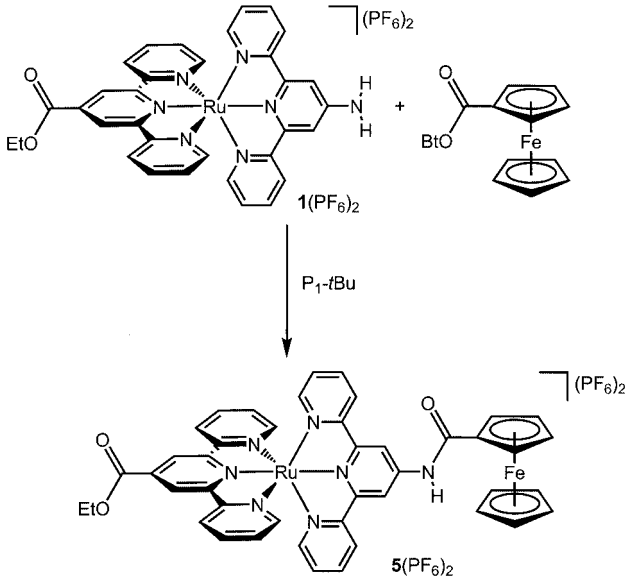
tively (Scheme 2 and Scheme 3). All ferrocene conjugates, **3**$(PF_6)_2$, **4**$(PF_6)_2$ and **5**$(PF_6)_2$, were fully characterised by NMR and IR spectroscopy (see Tables 1, 2, 5 and Supporting Information) as well as mass spectrometry and elemental analyses (see Exp. Sect.).



Scheme 3.

The amide protons of **3**$(PF_6)_2$, **4**$(PF_6)_2$ and **5**$(PF_6)_2$ resonate at low field around $\delta$ = 9.0–9.4 ppm. The signals of the cyclopentadienyl protons are found between $\delta$ = 4.2 and 5.2 ppm with typical chemical shifts of N- and C-substituted ferrocenes.[22,24,39] Amide formation at the N terminus of the terpyridine complex results in a downfield shift of the terpyridine proton signal $H^{2'}$ by 1.3 ppm, confirming the activation of the amino group.

## Acid/Base Equilibria of 2$(PF_6)_2$

Solubility and reactivity of **2**$(PF_6)_2$ strongly depends on the pH of the solution. Thus **2**$(PF_6)_2$ was investigated in aqueous solution at different pH values. The corresponding UV/Vis spectra are shown in Figure 2 and Figure 3. As can be deduced from the spectra, three different species exist in aqueous solution, which are assigned different protonated forms of $\mathbf{2}^{2+}$ namely $[\mathbf{2} - H]^+$, $[\mathbf{2}]^{2+}$ and $[\mathbf{2} + H]^{3+}$ (Scheme 4) with absorption maxima of the MLCT transitions at 494, 498 and 486 nm, respectively. Isosbestic points are observed in the spectra of $[\mathbf{2} - H]^+$ and $[\mathbf{2}]^{2+}$ at 494 and 531 nm (Figure 2) and in the spectra of $[\mathbf{2}]^{2+}$ and $[\mathbf{2} + H]^{3+}$ at 491 and 533 nm (Figure 3). The monocationic deprotonated carboxylate complex $[\mathbf{2} - H]^+$ exists at pH > 4 (up to pH ≈ 12 in aqueous solution) and the ammonium trication $[\mathbf{2} + H]^{3+}$ at pH < 0 (concentrated sulfuric acid), while the dication $[\mathbf{2}]^{2+}$ dominates in the intermediate pH range. The p$K_a$ values for the two protonation steps are p$K_{a1}$ = 2.69(8) and p$K_{a2}$ < 0, showing that $[\mathbf{2}]^{2+}$ is a stronger acid than benzoic acid and a weaker base than aniline.

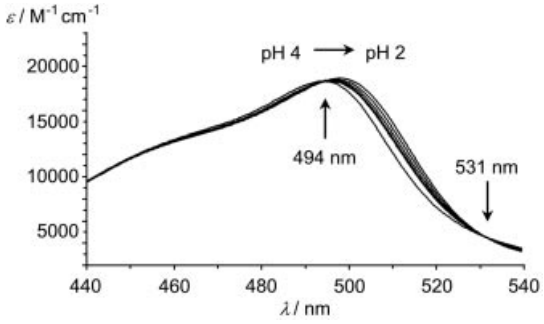


Figure 2. Absorption spectra of **2**$(PF_6)_2$ measured between pH 4 and pH 2.

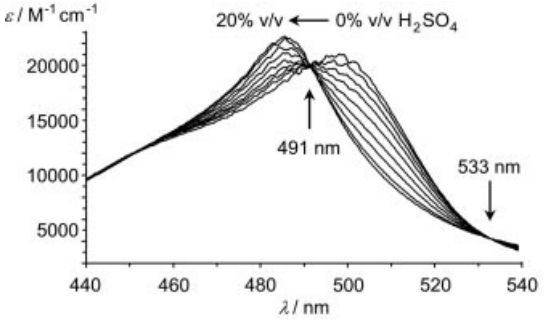

Figure 3. Absorption spectra of **2**$(PF_6)_2$ during titration with conc. sulfuric acid.

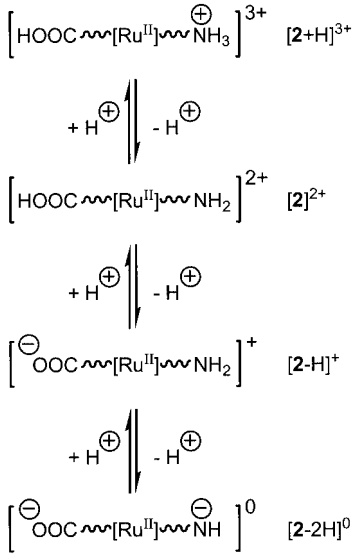

Scheme 4.

The strong base $P_1$-*t*Bu activates the amino groups in the ruthenium complexes **1**$(PF_6)_2$ and **3**$(PF_6)_2$ (see above). This can also be monitored in the UV/Vis spectra of **2**$(PF_6)_2$ during titration with $P_1$-*t*Bu in $CH_3CN$ (Figure 4). The acid group of $[\mathbf{2}]^{2+}$ is deprotonated first to give $[\mathbf{2} - H]^+$ (Figure 4 top, $\lambda_{max}$ = 491 nm; isosbestic points at 351, 474, 489 and 523 nm) and upon further addition of $P_1$-*t*Bu the amino group is deprotonated to give the neutral complex $[\mathbf{2} - 2H]^0$ with an absorption maximum at $\lambda_{max}$ = 493 nm (Figure 4 bottom, isosbestic points at 342, 423 and 515 nm).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

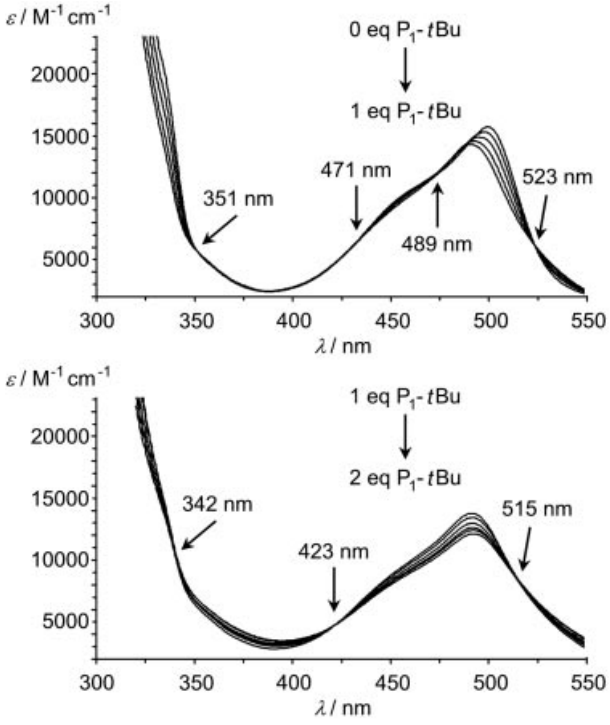

Figure 4. Absorption spectra of $\mathbf{2}(PF_6)_2$ during titration with $P_1$-*t*Bu in $CH_3CN$ from $[\mathbf{2}]^{2+}$ to $[\mathbf{2} - H]^+$ (top) and from $[\mathbf{2} - H]^+$ to $[\mathbf{2} - 2H]^0$ (bottom).

For both $[\mathbf{2} + H]^{3+}$ and $[\mathbf{2} - H]^+$ the low-energy $^1$MLCT absorption (involving the tpy-COOH and the tpy-$COO^-$ ligands, respectively; see below) is shifted to higher energy as compared to $[\mathbf{2}]^{2+}$. Protonation of the amino group renders the tpy-$NH_3^+$ ligand a weaker σ donor, thus decreasing the electron density at the metal centre and lowering the occupied metal-based orbitals.[12,40] Deprotonation of the COOH group of $[\mathbf{2}]^{2+}$ shifts the unoccupied orbitals of the tpy-$COO^-$ ligand to higher energies. Further deprotonation (of the $NH_2$ group) renders the tpy-$NH^-$ ligand a better donor, increasing the energy of the occupied ruthenium orbitals and thus shifting the $^1$MLCT absorption to lower energy. These simple molecular orbital arguments explain the experimentally observed relative positions of the absorption maxima of $[\mathbf{2} + H]^{3+}$, $[\mathbf{2}]^{2+}$, $[\mathbf{2} - H]^+$ and $[\mathbf{2} - 2H]^0$.

The proton NMR spectrum of $[\mathbf{2}]^{2+}$ (precipitated from solutions of pH 2) shows a singlet at $\delta = 6.03$ for the amine substituent with an intensity corresponding to two protons (Figure 5). At lower pH the amino group of $[\mathbf{2}]^{2+}$ is protonated to give $[\mathbf{2} + H]^{3+}$, which does not display any signal for the nitrogen-bonded hydrogen nuclei because of fast proton exchange. Raising the pH to 7 (presence of $[\mathbf{2} - H]^+$) results in downfield shifts of the $^1$H NMR signals of the amino group and the protons $H^2$ and $H^{2'}$ (Figure 5). Thus the NMR spectra confirm that the amine group is protonated only at pH < 2. On the other hand the IR spectrum of $[\mathbf{2}]^{2+}$ in dilute solution shows a signal at 1732 $cm^{-1}$, characteristic for a COOH group (see Supporting Information).

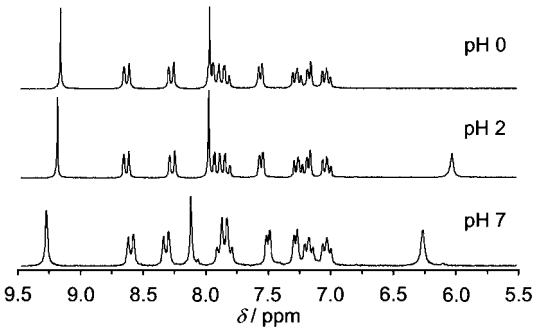

Figure 5. NMR spectra of $\mathbf{2}(PF_6)_2$ at pH 0, 2 and 7.

Thus the NMR and IR spectra provide evidence that $[\mathbf{2}]^{2+}$ does not form a zwitterion in solution in contrast to aliphatic amino acids with basic amino groups. This finding is easily explained by the very low basicity of the aromatic amino group of $[\mathbf{2}]^{2+}$.

### Electrochemistry, Absorption and Emission Spectra

Optical and electrochemical data of $\mathbf{1}(PF_6)_2$–$\mathbf{5}(PF_6)_2$ are collected in Table 4. For all complexes a ruthenium-centred oxidation is observed around 1.1 V versus SCE and two ligand-centred reductions are found around –1.2 V and –1.5 V (irr.). The ferrocene conjugates $\mathbf{3}(PF_6)_2$ and $\mathbf{5}(PF_6)_2$ undergo additional oxidations at 0.37 and 0.64 V, respectively, while $\mathbf{4}(PF_6)_2$ shows two further oxidation waves at 0.37 and 0.66 V corresponding to the two differently substituted ferrocene moieties in the oligonuclear species (Figure 6).

All compounds display two intense $^1$MLCT bands centred around 460–500 nm with a tail on the low-energy side extending as far as 650 nm and corresponding to spin-forbidden $^3$MLCT transitions around 550–600 nm, which become partially allowed because of spin-orbit coupling (Table 4, Figure 7). The $^1$MLCT bands undergo a slight bathochromic shift with increasing solvent polarity from acetonitrile to DMSO (Table 4).

For $\mathbf{3}(PF_6)_2$–$\mathbf{5}(PF_6)_2$, distinct transitions that could be assigned to ferrocene → terpyridine transitions have not been observed on the low-energy side of the absorption bands as found in, for example, $[Ru(tpy\text{-}Fc)_2](PF_6)_2$[42] or [(Fc-tpy)Ru(tpy-FcFc-tpy)Ru(tpy-Fc)]$(PF_6)_4$.[43] However, the extinction coefficients of the MLCT bands of $\mathbf{4}(PF_6)_2$ and $\mathbf{5}(PF_6)_2$ are significantly higher than those of $\mathbf{1}(PF_6)_2$–$\mathbf{3}(PF_6)_2$. The difference spectra "$\mathbf{4}(PF_6)_2 - \mathbf{3}(PF_6)_2$" and "$\mathbf{5}(PF_6)_2 - \mathbf{1}(PF_6)_2$" (Supporting Information) reveal an additional band around $\lambda_{max} \approx 493$ nm with $\varepsilon \approx 7000$ $M^{-1}cm^{-1}$, which could be assigned to a d(Fe) → π*(tpy-NHR′) transition originating from the C-substituted (the N-terminal) ferrocene to the electron-deficient aromatic tpy system.[22,42,43] Thus the $^1$MLCT region contains contributions arising from electron injection from the ruthenium centre and from the ferrocene [in the case of $\mathbf{4}(PF_6)_2$ and $\mathbf{5}(PF_6)_2$] into the differently substituted terpyridine ligands (see below).

[a] Species obtained by precipitating from solutions of pH 2. [b] In acetonitrile. [c] These waves are no more reversible as oxidation to a highly charged species (+4, +5) results in precipitation of the complexes on the electrode. [d] In acetone. [e] In DMSO. [f] The extinction coefficients $\varepsilon$ are the experimentally observed values at the fitted band maxima. [g] Excitation at low-energy $^1$MLCT absorption maximum. [h] Luminescence quantum yield (±15%), using fluorescein in ethanol as standard. [i] Determined by fitting the emission data to Meyers equation.[44]

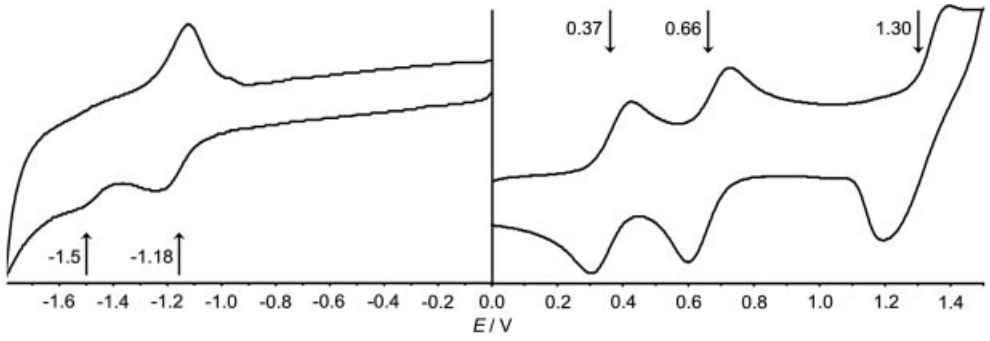

Figure 6. Cyclic voltammogram of $\mathbf{4}(PF_6)_2$ in $CH_3CN/nBu_4NPF_6$.

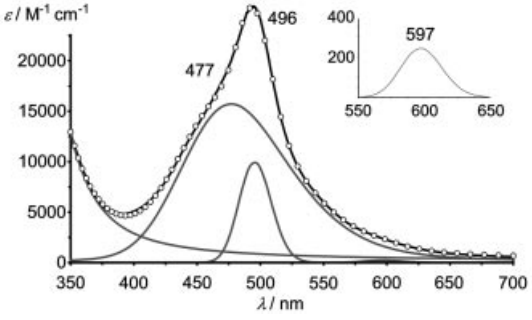

Figure 7. Absorption spectrum of $\mathbf{4}(PF_6)_2$ in $CH_3CN$ and calculated band profiles (the open circles represent the sum of the calculated profiles[41]). The inset shows an expansion of the $^3$MLCT region (fitted band profile).

All complexes are luminescent in argon-saturated acetone at room temperature ($\lambda_{max} \approx$ 700–800 nm; Table 4), although intensity is very weak for $\mathbf{3}(PF_6)_2$ and $\mathbf{4}(PF_6)_2$ ($\Phi < 0.1\times10^{-4}$). Deactivation of the emitting state ($^3$MLCT) in the parent complex $[Ru(tpy)_2]^{2+}$ occurs through a $^3$MC(Ru) state.[1,12] In complexes $\mathbf{1}(PF_6)_2$–$\mathbf{5}(PF_6)_2$ the $^3$MC(Ru) state is shifted to higher energy because of the stronger averaged ligand field raising the energy of the $e_g$ (Ru) orbitals and increasing the $^3$MLCT–$^3$MC(Ru) energy gap.[1,12]

The emission spectra of $\mathbf{1}(PF_6)_2$, $\mathbf{2}(PF_6)_2$ and $\mathbf{5}(PF_6)_2$ could be fitted to the Meyers equation[44] with $E_{0'-0}$ around 1.9 eV (Figure 8). The emission properties of $\mathbf{2}(PF_6)_2$ strongly depend on the pH with higher luminescence quantum yield ($\Phi = 2.1\times10^{-4}$ in water) between pH > 4 and pH < 10 (corresponding to the presence of $[\mathbf{2} - H]^+$, see above) and weak emission at either lower or higher pH ($\Phi = 0.6\times10^{-4}$ in water; see Supporting Information).

For $\mathbf{1}(PF_6)_2$ and $\mathbf{2}(PF_6)_2$ emission gains intensity with increasing excitation wavelength ($\lambda_{exc}$ = 500–650 nm), while for $\mathbf{5}(PF_6)_2$ the reverse is observed (see Supporting Infor-

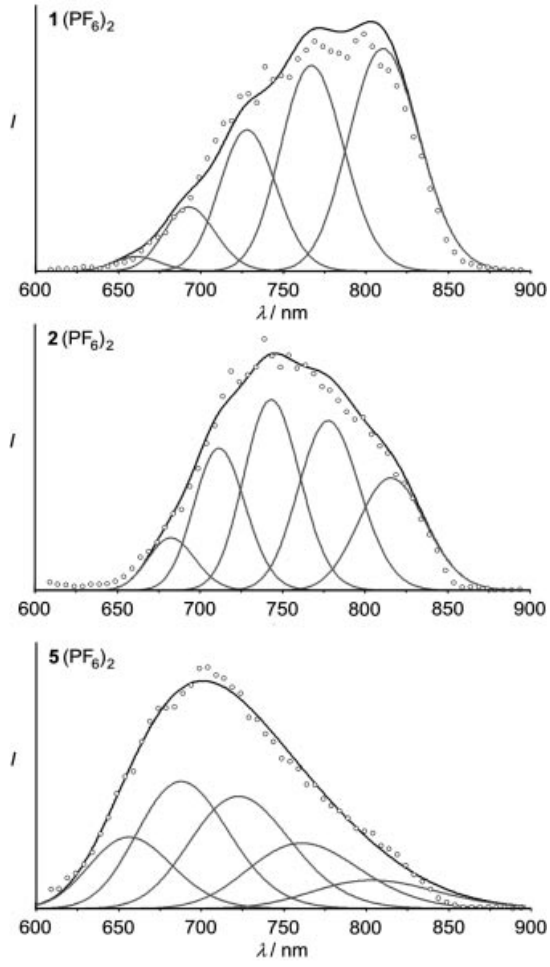

Figure 8. Emission spectra of **1**$(PF_6)_2$, **2**$(PF_6)_2$ and **5**$(PF_6)_2$ (○) in acetone at room temperature and spectral fitting according to Meyers equation.[44]

mation). The C-terminal ferrocene conjugates **3**$(PF_6)_2$ and **4**$(PF_6)_2$ show a much weaker luminescence than their ester analogues **1**$(PF_6)_2$ and **5**$(PF_6)_2$, respectively (Table 4).[45]

### DFT Calculations

All complex cations $\mathbf{1}^{2+}$–$\mathbf{5}^{2+}$ were studied using the B3LYP/LanL2DZ functional. The energy-minimised structure of $\mathbf{5}^{2+}$ shown in Figure 9 as an example shows the expected pseudo-octahedral geometry around the ruthenium centre. The geometric results of the calculation for $\mathbf{2}^{2+}$ reproduce the experimental data of **2**$(PF_6)$(F) sufficiently well (Table 3).

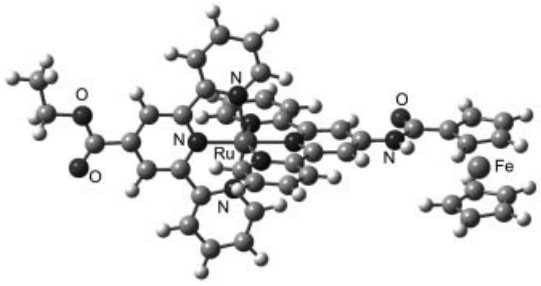

Figure 9. Energy-minimised structure of $\mathbf{5}^{2+}$.

The frontier orbital region of the complex cations consists of closely spaced molecular orbitals (Figure 10). The lowest unoccupied molecular orbitals are π* orbitals of the terpyridine ligands with the LUMO level lying 0.2–0.3 eV below the next highest virtual orbital. Throughout the series the LUMO is localised on the C-terminal terpyridine (tpy-COR). The "$t_{2g}$" manifold of the ruthenium centre provides the high-lying occupied orbitals. For the ferrocene conjugates $\mathbf{3}^{2+}$–$\mathbf{5}^{2+}$ molecular orbitals composed of iron and cyclopentadienyl moieties are inserted in between (Figure 10). The C-terminal ferrocene orbitals d(Fe) + π*(Cp-NHR′′) are found at higher energies than the N-terminal ferrocene orbitals d(Fe) + π*(Cp-COR′′′), as expected from the respective oxidation potentials (Table 4).

The $^1$MLCT transitions arise from $t_{2g}$ (Ru) → π*(tpy) excitations. The low-energy transition (≈500 nm) can be assigned to involve the C-terminal terpyridine tpy-COR, while the next highest transitions (≈480 nm) can be assigned to involve mixtures of both terpyridine ligands tpy-NHR′ and tpy-COR. Low-energy d(Fe) → π*(tpy-NHR′) transitions were observed experimentally for **4**$(PF_6)_2$ and **5**$(PF_6)_2$ around 493 nm with significant intensity (Supporting Information).

A schematic energy level diagram (Figure 11) shows the typical ruthenium $^1$MLCT and $^3$MLCT states. The numerical values are estimates using experimental data obtained under different conditions, thus some caution in their interpretation is advisable. The UV/Vis spectroscopic data

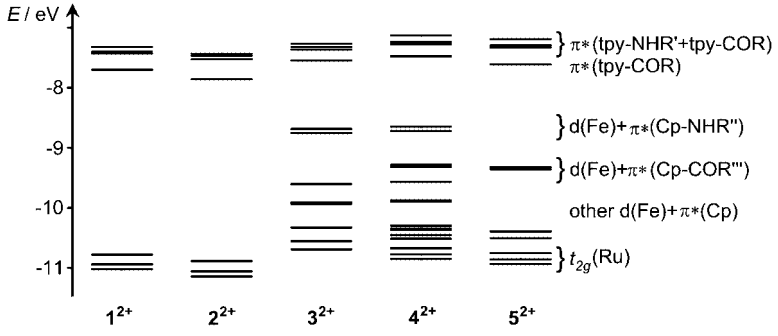

Figure 10. Partial molecular orbital diagrams for $\mathbf{1}^{2+}$–$\mathbf{5}^{2+}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

provide estimates for the energies of the Franck–Condon excited $^1$MLCT states around 2.5 eV. The emission data indicate that the energy level of the emitting $^3$MLCT state has an energy around 1.9 eV,[44] which fits to the Franck-Condon excited $^3$MLCT state (not shown in Figure 11), estimated to be around 2.1–2.2 eV (Table 4).

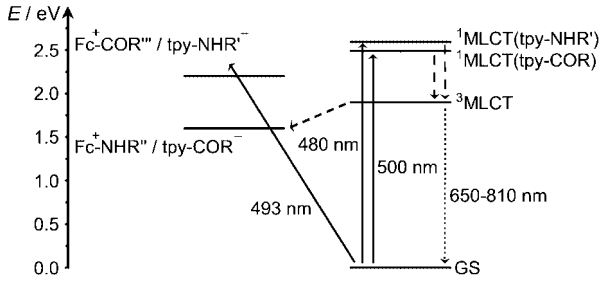

Figure 11. Schematic Jablonski-type energy level diagram (solid lines: excitation; dashed lines: intersystem crossing and electron transfer; dotted line: emission).

Excitation of **1**$(PF_6)_2$ or **2**$(PF_6)_2$ with $\lambda_{exc}$ = 480–500 nm will populate the $^1$MLCT states that undergo intersystem crossing to the emitting $^3$MLCT state while excitation of **1**$(PF_6)_2$ or **2**$(PF_6)_2$ with $\lambda_{exc} > 500$ nm will also directly populate the $^3$MLCT state leading to the experimentally observed increase of the emission intensity (see above; Supporting Information).

For **3**$(PF_6)_2$–**5**$(PF_6)_2$ states arising from the presence of the ferrocene moieties are depicted on the left side of Figure 11. The Franck–Condon excited state d(Fe) → π*(tpy-NHR′) could be observed for **4**$(PF_6)_2$ and **5**$(PF_6)_2$ in the UV/Vis difference spectra around 493 nm (see above and Supporting Information). The ferrocene oxidation potentials and ligand reduction potentials of **3**$(PF_6)_2$–**5**$(PF_6)_2$ (Table 4) allow approximation of the energies of the charge separated states [$Fc^+$-COR′′′/tpy-NHR′$^-$] and [$Fc^+$-NHR′′/tpy-$COR^-$] by 2.2 and 1.6 eV. The former level lies above and the latter below the emitting $^3$MLCT state of the ruthenium core. For **3**$(PF_6)_2$ and **4**$(PF_6)_2$ with a C-terminal ferrocene photoinduced electron transfer is exergonic by 0.3 eV while for **5**$(PF_6)_2$ containing an N-terminal ferrocene photoinduced electron transfer would be endergonic by 0.3 eV. Thus reductive electron transfer from ferrocene to ruthenium is conceivable for **3**$(PF_6)_2$ and **4**$(PF_6)_2$ but not for **5**$(PF_6)_2$, accounting for the experimentally observed luminescence quenching (Table 4).

In contrast to **1**$(PF_6)_2$ and **2**$(PF_6)_2$, direct population of the $^3$MLCT state of **5**$(PF_6)_2$ is hampered because of the population of the d(Fe) → π*(tpy-NHR′) state leading to the experimentally observed decrease in emission intensity at $\lambda_{exc} > 500$ nm (see above and Supporting Information).

The low-lying ferrocene triplet state (not shown in the diagram) has been estimated at an energy between 1.1 and 1.8 eV,[1] that is, in the same energy range as the $^3$MLCT and charge-separated states. Thus energy transfer might also be an additional channel for radiationless excited-state decay.[46–50] Further photophysical investigations including low-temperature emission spectroscopy, lifetime measurements and transient absorption spectroscopy as well as DFT calculations on excited states are currently underway.

## Conclusion

The amino-substituted acid **2**$(PF_6)_2$ and its ester **1**$(PF_6)_2$ have been synthesised and characterised. Complex $\mathbf{2}^{2+}$ undergoes several protonation and deprotonation steps, which have been observed by UV/Vis and emission spectroscopy as well as NMR spectroscopy. Amide formation of **1**$(PF_6)_2$ or **2**$(PF_6)_2$ with ferrocene derivatives was successful in spite of the low reactivity of the aromatic amino group. Ferrocenes have been attached on either side or on both sides of the bis(terpyridine) ruthenium(II) core [**3**$(PF_6)_2$–**5**$(PF_6)_2$].

The ground-state electronic situation of these multinuclear species has been investigated by electronic spectroscopy and cyclic voltammetry, while preliminary emission studies gave insight into the excited-state properties. The ground-state properties of the bis(terpyridine) ruthenium(II) moiety are only slightly modified by the presence of the ferrocenes. The exception is an additional charge-transfer band observed in the absorption spectra of **4**$(PF_6)_2$ and **5**$(PF_6)_2$ but not in the spectra of **3**$(PF_6)_2$. This transition is associated with N-terminal bound ferrocenes and has been assigned d(Fe) → π*(tpy-NHR′) charge transfer character.

The excited-state behaviour of the ferrocene conjugates is strongly dependent on the site of ferrocene attachment: **5**$(PF_6)_2$ with an N-terminal bound ferrocene is luminescent with an inverse correlation to the excitation wavelength as compared to the ferrocene-free **1**$(PF_6)_2$. This behaviour arises from the presence of d(Fe) → π*(tpy-NHR′) charge-transfer bands. Complexes **3**$(PF_6)_2$ and **4**$(PF_6)_2$ with C-terminal bound ferrocenes are much less luminescent. This finding is explained on the assumption that electron transfer from the ferrocene to the ruthenium centre efficiently quenches the $^3$MLCT state of ruthenium.

Thus the optical ground-state properties of the bis(ferrocene) conjugate **4**$(PF_6)_2$ resemble those of the N-terminal conjugate **5**$(PF_6)_2$, while its excited-state properties are analogous to those of the C-terminal conjugate **3**$(PF_6)_2$.

To expand the scope of this design strategy we currently build larger arrays from ruthenium and ferrocene amino acids as well as chiral α-amino acids[22–24] using peptide chemistry for application in electron storage devices, molecular wires, photosensitisers and molecular sensors.

## Experimental Section

**General Methods:** Unless otherwise noted, starting materials were obtained from commercial suppliers and used without further purification. The terpyridine ligands tpy-COOEt[33] and tpy-$NH_2$[34,35] as well as the ferrocene derivatives[22,39] were synthesised according to literature procedures.

NMR spectra were recorded with a Bruker Avance DPX 200 at 200.15 MHz ($^1$H) and 50.323 MHz ($^{13}$C); chemical shifts ($\delta$) in ppm with respect to residual solvent peaks as internal standards:

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CD_3CN$ ($^1H$: $\delta$ = 1.93; $^{13}C$: $\delta$ = 1.3 ppm). IR spectra were recorded with a BioRad Excalibur FTS 3000 spectrometer using $CaF_2$ cells or CsI disks. UV/Vis/NIR spectra were recorded with a Perkin–Elmer Lambda 19, 0.2-cm cells (Hellma, suprasil). Cyclic voltammetry was performed using a glassy carbon electrode, a platinum electrode and a SCE electrode, $10^{-3}$ M in 0.1 M $n$Bu$_4$NPF$_6$/$CH_3CN$; potentials are given relative to that of SCE. Mass spectra were recorded with a Finnigan MAT 8400 spectrometer. Emission spectra were recorded with a Varian Cary Eclipse Fluorescence Spectrometer, slit widths 5 nm, in argon-saturated solution. Quantum yields were determined by comparing the areas under the emission spectra recorded for optically matched solutions of the samples and the fluorescein reference ($\Phi$ = 0.79 in ethanol). Elemental analyses were performed by the microanalytical laboratory of the Organic Chemistry Department, University of Heidelberg. Microwave-assisted reactions were performed in a domestic microwave oven operating at a frequency of 2450 MHz and maximum power of 700 W in 20-mL test tubes (Rotilabo).

**Computational Method:** Density functional calculations were carried out with the Gaussian03/DFT[51] series of programs. The B3LYP formulation of density functional theory was used employing the LanL2DZ basis set.[51] All structures were characterised as minima by frequency analysis ($N_{imag}$ = 0) except **3**$^{2+}$, which shows one imaginary frequency for Cp rotation (–10.4 cm$^{-1}$).

**X-ray Crystallography:** Data were collected with an Enraf–Nonius Kappa CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. The data were processed using the standard Nonius software.[52] All calculations were performed using the SHELXT PLUS software package. Structures were solved using direct or Patterson methods with the SHELXS-97 program and refined with the SHELXL-97 program.[53] Graphical handling of the structural data during refinement was performed using XMPA[54] and WinRay.[55] Atomic coordinates and anisotropic thermal parameters were refined by full-matrix least-squares calculations on $F^2$.

Crystal dimensions 0.1 × 0.02 × 0.02 mm; triclinic crystal system; space group $P\bar{1}$; $a$ = 8.6940(17), $b$ = 21.412(4), $c$ = 21.588(4) Å; $\alpha$ = 94.86(3); $\beta$ = 96.52(3); $\gamma$ = 101.01(3)°; $V$ = 3895.9(13) Å$^3$; $\rho_{calcd.}$ = 1.474 g cm$^{-3}$; $2\theta_{max}$ = 50.1°; $\omega$-scans; $T$ = 200 K; measured reflections 21949; independent reflections 13619; observed reflections 6146 [$I > 2\sigma(I)$]; Lorentz and polarisation correction; $\mu$ = 0.530 mm$^{-1}$; $R_1$ = 0.102 [$I > 2\sigma(I)$]; $wR_2$ = 0.271 [$I > 2\sigma(I)$]; residual electron density 0.915 e Å$^{-3}$.

Because of the large amount of solvent water present in the crystal of **2**(PF$_6$)(F) causing diffuse reflection data and the rather poor data/parameter ratio, carbon atoms, solvent water, some counterions and hydrogen atoms have been refined isotropically.

CCDC-280162 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of 1(PF$_6$)$_2$:** (EtOOC-tpy)RuCl$_3$[33–35] (200 mg, 0.39 mmol) and tpy-NH$_2$ (97 mg, 0.39 mmol) were finely suspended in dry ethanol (15 mL) with the aid of an ultrasonic bath. The test tube was closed and heated in the microwave oven for 5 × 1 min at the lowest operating power (80 W). The solution was filtered through a small pad of Celite, washed with water, and $NH_4PF_6$ (191 mg, 1.17 mmol) dissolved in 1 mL water was added. After cooling for 12 h to 4 °C the red product was collected by filtration, washed with water and dried in vacuo. Yield 85% (312 mg, 0.33 mmol). MS (FAB): $m/z$ (%) = 801 (11) [M + H,PF$_6$]$^+$, 655 (55) [M$^+$]. $C_{33}H_{27}F_{12}N_7O_2P_2Ru$ (944.6): calcd. C 41.96, H 2.88, N 10.38; found C 42.09, H 3.15, N 10.22. $^{13}C$ NMR data see Table 5.

**Synthesis of 2(PF$_6$)$_2$:** **1**(PF$_6$)$_2$ (250 mg, 0.27 mmol) was dissolved in 20% sulfuric acid (50 mL) and heated under reflux for 2 h. After cooling to room temperature and adjusting the pH to 2 with $NaOH_{aq}$, $NH_4PF_6$ (132 mg, 0.81 mmol) dissolved in 1 mL water was added and the product precipitated. The red product was collected by filtration, washed with water and dried. Yield 74% (185 mg, 0.20 mmol). MS (FAB): $m/z$ (%) = 772 (60) [M, PF$_6$]$^+$, 626 (100) [M$^+$ – H]. $C_{31}H_{23}F_{12}N_7O_2P_2Ru$ (916.6): calcd. C 40.62, H 2.53, N 10.70; found C 40.63, H 3.20, N 10.65. $^{13}C$ NMR data see Table 5.

**Synthesis of 3(PF$_6$)$_2$:** **2**(PF$_6$)$_2$ (150 mg, 0.16 mmol) was activated with HOBt (34 mg, 0.25 mmol) and DCC (52 mg, 0.25 mmol) in acetonitrile (25 mL) for 2.5 h. A solution of aminoferrocene (51 mg, 0.25 mmol) and *N*-ethylmorpholine (0.1 mL) in acetonitrile (5 mL) was added and the reaction mixture was stirred at room temperature for 2.5 h. The solvent was removed in vacuo, the residue was dissolved in dichloromethane and the product was

precipitated by adding diethyl ether. Recrystallisation from hot ethanol and precipitating with $NH_4PF_6$ (78 mg, 0.48 mmol) dissolved in 1 mL water gave the pure product. Yield 88% (150 mg, 0.14 mmol). MS (FAB): *m*/*z* (%) = 810 (40) [$M^+$ – H]. $C_{41}H_{32}F_{12}FeN_8OP_2Ru{\cdot}2H_2O$ (1099.6·$2H_2O$): calcd. C 43.36, H 3.20, N 9.87; found C 43.44, H 3.61, N 10.07. $^{13}C$ NMR data see Table 5.

**Synthesis of 4(PF$_6$)$_2$:** **3**$(PF_6)_2$ (100 mg, 0.09 mmol), ferrocenoyl benzotriazol ester Fc-COOBt (38 mg, 0.11 mmol) and phosphazene base $P_1$-*t*Bu (43 mg, 0.18 mmol) were dissolved in acetonitrile (15 mL) and stirred at room temperature for 16 h. The solvent was removed in vacuo, the residue was dissolved in dichloromethane and the product was precipitated by adding diethyl ether. Recrystallisation from hot ethanol and precipitating with $NH_4PF_6$ (44 mg, 0.27 mmol) dissolved in 1 mL water gave the pure product. Yield 89% (110 mg, 0.08 mmol). MS (FAB): *m*/*z* (%) = 1167 (92) [M, $PF_6$]$^+$, 1021 (100) [$M^+$ – H]. $C_{52}H_{40}F_{12}Fe_2N_8O_2P_2Ru{\cdot}5H_2O$ (1311.6·$5H_2O$): calcd. C 44.56, H 3.60, N 7.99; found C 44.40, H 3.60, N 8.11. $^{13}C$ NMR data see Table 5.

**Synthesis of 5(PF$_6$)$_2$:** **2**$(PF_6)_2$ (100 mg, 0.11 mmol), ferrocenoyl benzotriazol ester Fc-COOBt (37 mg, 0.11 mmol) and phosphazene base $P_1$-*t*Bu (53 mg, 0.22 mmol) were dissolved in acetonitrile (15 mL) and stirred at room temperature for 16 h. The solvent was removed in vacuo, the residue was dissolved in dichloromethane and the product was precipitated by adding diethyl ether. Recrystallisation from hot ethanol and precipitating with $NH_4PF_6$ (54 mg, 0.33 mmol) dissolved in 1 mL water gave the pure product. Yield 91% (115 mg, 0.10 mmol). MS (FAB): *m*/*z* (%) = 1113 (50) [M + H, $PF_6$]$^+$, 866 (100) [$M^+$ – H]. $C_{44}H_{35}F_{12}FeN_7O_3P_2Ru{\cdot}H_2O$ (1156.6·$H_2O$): calcd. C 44.99, H 3.17, N 8.35; found C 44.96, H 3.52, N 8.68. $^{13}C$ NMR data see Table 5.

**Supporting Information Available** (for details see the footnote on the first page of this article): Absorption spectra of **1**$(PF_6)_2$–**5**$(PF_6)_2$ in $CH_3CN$, difference spectrum "**3**$(PF_6)_2$ – **1**$(PF_6)_2$", difference spectrum "**4**$(PF_6)_2$ – **3**$(PF_6)_2$", difference spectrum "**5**$(PF_6)_2$ – **1**$(PF_6)_2$", IR spectra of **1**$(PF_6)_2$, **2**$(PF_6)_2$ and **5**$(PF_6)_2$ in $CH_3CN$, emission spectra of **3**$(PF_6)_2$ and **4**$(PF_6)_2$ with excitation at $\lambda_{max}$ in acetone at room temperature, emission spectra of **2**$(PF_6)_2$ at different pH in water (excitation wavelength 497 nm) at room temperature, pH profile of the emission of **2**$(PF_6)_2$ (excitation wavelength 497 nm, monitored at $\lambda$ = 719 nm), emission spectra of **1**$(PF_6)_2$, **2**$(PF_6)_2$ and **5**$(PF_6)_2$ with different excitation wavelengths in acetone at room temperature, excitation profiles of **1**$(PF_6)_2$, **2**$(PF_6)_2$ and **5**$(PF_6)_2$ in acetone at room temperature, Cartesian coordinates of DFT calculated geometries of **1**$^{2+}$–**5**$^{2+}$, molecular orbital energies (eV) of selected orbitals of **1**$^{2+}$–**5**$^{2+}$, absorption spectrum of **2**$(PF_6)_2$ in $CH_3CN$ in the range 250–800 nm.

# On the Staudinger Reaction of $SP(N_3)_3$ with $PPh_3$ and $(Me_3Si)_2N–(Me_3Si)N–PPh_2$

**Nadine Götz,[a] Sebastian Herler,[a] Peter Mayer,[a] Axel Schulz,*[a] Alexander Villinger,[a] and Jan J. Weigand[a][‡]**

**Keywords:** Azides / PN rings / Phosphazenes / Staudinger reaction

The Staudinger reactions of $SP(N_3)_3$ (**1**) with 1, 2 and 3 equiv. of triphenylphosphane $PPh_3$ and $(TMS)_2N–(TMS)N–PPh_2$ (**2**) have been investigated (TMS = $Me_3Si$). Reaction with $PPh_3$ yields the single and double Staudinger products $SP(N_3)_2NPPh_3$ (**3**) and $SP(N_3)(NPPh_3)_2$ (**4**), but not the triple, while the reaction with **2** results only in the formation of the single Staudinger product $SP(N_3)_2NPPh_2[N(TMS)N(TMS)]_2$ (**5**). Compound **5** is air- and moisture-sensitive but stable under argon over a long period in the solid state and in common organic solvents. Although there are covalently bound azide groups in **3**, **4** and **5**, these Staudinger products are neither shock- nor heat-sensitive in contrast to **1**. Furthermore **3**, **4** and **5** are easily prepared in bulk (yield > 95 %), and unlimitedly stable when cooled and stored in the dark. Compound **5** is thermally stable up to over 150 °C while **3** and **4** are stable only up to 96 °C. However, when a solution of **5** is heated, a new surprising eight-membered ring (**6**) is formed in an intermolecular $TMS–N_3$ elimination reaction. The structure and bonding is discussed on the basis of experimental X-ray data and theoretical B3LYP calculations (thermodynamics, energy landscape and charge distribution).

## Introduction

As early as 1919, Staudinger and Meyer investigated the reaction of triphenylphosphane and phenylazide in diethyl ether.[1] Ever since, this reaction has been known as the Staudinger reaction and describes an oxidation of phosphorus(III) to phosphorus(V) compounds, which is accompanied by a linkage of a P (phosphane) and a N (azide) atom of two different molecules upon $N_2$ release. With respect to the azide and phosphorus(III) compounds, the Staudinger reaction is very flexible. Hence, a great diversity of iminophosphanes and their applications are well known.[2–6] Phosphorus(V) nitrogen species represent a well-established group of compounds that is still growing. Of special interest are PN compounds that can be used as interesting reagents in organic synthesis.[7]

Recently, we reported on the reaction of 2,4,6-triazido-1,3,5-triazine with triphenylphosphane resulting in the formation of different triphenylphosphanimino-azido- or tetrazolo[1,3,5]triazines, depending on the stoichiometry of the azide and phosphane component (1:1, 1:2, 1:3).[8] Because the azido group in 2,4,6-triazido-1,3,5-triazine is attached to a C atom adjacent to an annular nitrogen, it can spontaneously cyclise to give a tetrazole.

Lately, the chemistry of hydrazinophosphanes of the type $(TMS)_2N–(TMS)N–PR_2$ (R = Ph, Cl; TMS = $Me_3Si$) has attracted considerable interest.[9] Experimentally and theoretically the intramolecular $GaCl_3$-assisted TMS–Cl elimination in $(TMS)_2N–N(TMS)–PCl_2$ has been studied, resulting in the first binary triazadiphosphole.[10]

We found it of interest to investigate the Staudinger reaction of hydrazinophosphanes with phosphorus azides. Table 1 displays a compilation of neutral phosphorus azides. However, only a few neutral singly, doubly or multiply substituted phosphorus azides are known that have been structurally characterised (Table 1). More structural data of phosphorus azides are needed to gain further insight into the relationship between bonding and stability.

In this study we demonstrate that the final products of the reaction of highly explosive $SP(N_3)_3$ (**1**) with $PPh_3$ and *N*,*N*′,*N*′-[tris(trimethyl)silyl]hydrazinodiphenylphosphane $[(TMS)_2N–(TMS)N–PPh_2]$ (**2**), as well as their distribution, strongly depend on the reaction conditions, stoichiometry and temperature (Figure 1). Depending on the temperature, different products are formed, which can be isolated and characterised.

## Results and Discussion

### Reaction of $SP(N_3)_3$ with $PPh_3$

By addition of 1 equiv. of triphenylphosphane to a solution of **1** in ether at ambient temperature, initially a yellow-green intermediate is formed, thought to be due to the formation of R–NNN–$P(C_6H_5)_3$ [R = $SP(N_3)_2$]. This adduct has only a fleeting existence and decomposes by giving off $N_2$, resulting in the formation of a monophosphaniminodiazide species, $SP(N_3)_2(NPPh_3)$ (**3**) (Figure 1), as illustrated by $^{31}$P NMR experiments; two duplets with the same intensity are detected at $\delta$ = 50.3 ppm [S*P*$(N_3)_2$NP$Ph_3$] and 16.8 ppm [SP$(N_3)_2$N*P*$Ph_3$] ($^2J_{PP}$ = 22.6 Hz). By addition of a second equiv. of triphenylphosphane, again $N_2$ release was observed. $^{31}$P NMR spectroscopic data suggest the exclusive formation of only one species (Table 2): a triplet at $\delta$ = 42.4 ppm [t, S*P*$(N_3)$$(NPPh_3)_2$] and a duplet at 7.5 ppm [d, SP$(N_3)$(N*P*$Ph_3)_2$] are observed as expected for the double Staudinger product, $SP(N_3)(NPPh_3)_2$ (**4**) ($^2J_{PP}$ = 7.6 Hz). Addition of a third equiv. of $PPh_3$ results in no further reaction, as shown by $^{31}$P NMR experiments. Also heating under reflux condition of this reaction mixture does not support the release of a third molecule $N_2$ and finally the formation of the triple Staudinger product [$SP(NPPh_3)_3$, Figure 1].

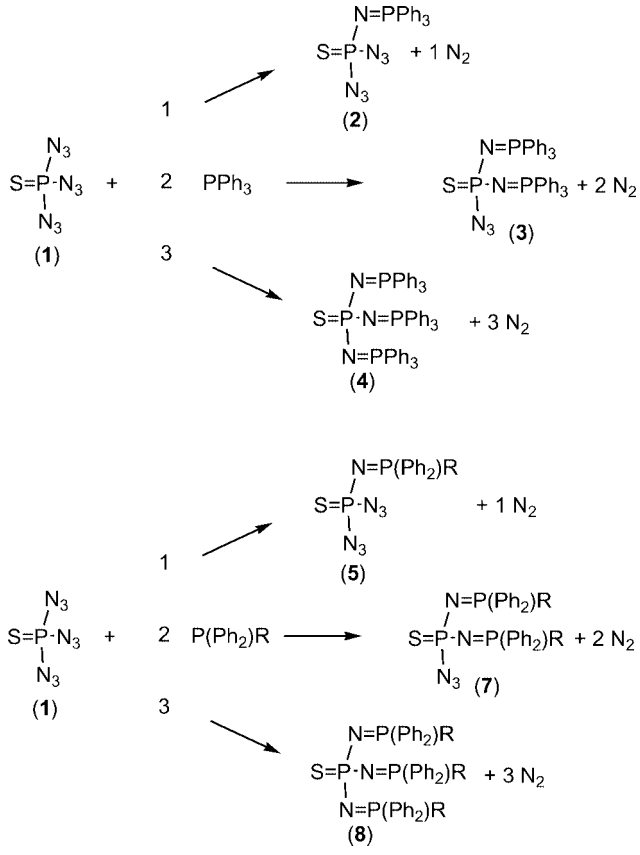

Figure 1. Top: Staudinger reaction of thiophosphoryl azide, $SP(N_3)_3$, with triphenylphosphane; bottom: Staudinger reaction of thiophosphoryl azide and *N*,*N*′,*N*′-[tris(trimethyl)silyl]hydrazinodiphenylphosphane, $(TMS)_2N$–(TMS)N–$PPh_2$ (**2**) [R = N(TMS)–$N(TMS)_2$].

### Reaction of $SP(N_3)_3$ with $Ph_2P–N(TMS)N(TMS)_2$ (TMS = $Me_3Si$)

Similar to the reaction with $PPh_3$, 1 equiv. of $Ph_2P–N(TMS)N(TMS)_2$ reacts spontaneously with $SP(N_3)_3$ in an ether/acetonitrile mixture at ambient temperature to give the single Staudinger product $SP(N_3)_2NPPh_2[N(TMS)-N(TMS)]_2$ (**5**). As expected, two duplets, at $\delta$ = 46.6 ppm $\{SP(N_3)_2N–PPh_2[N(TMS)N(TMS)_2]\}$ and 26.5 ppm $\{SP(N_3)_2NPPh_2[N(TMS)N(TMS)_2]\}$ ($^2J_{PP}$ = 34.3 Hz), are observed in the $^{31}P$ NMR experiment ($^{31}P$ MAS: 30.7 and 51.0 ppm). The presence of two remaining azide groups in the single Staudinger product (Figure 1) was also deduced from Raman and IR spectroscopy. Bands at 2153 and 2129 $cm^{-1}$ assigned to the characteristic asymmetric stretching vibration of the azide group in combination with the molecular peak (mass spectrometry) supported this assumption. Crystals (colourless plates) of sufficient quality for X-ray structure determination were obtained from a colourless ether/$CH_3CN$ solution of **5** after stepwise removal of solvent at –10 °C.

In contrast to the Staudinger reaction with $PPh_3$, addition of another equivalent of **2** to **5** leads to no further substitution in solution, even upon long heating.[11] However, when this reaction mixture was slowly cooled, two different types of crystals were obtained within two weeks: colourless plates and needles. X-ray investigations of crystals of both types revealed a surprising eight-membered ring, **6**, for the colourless needles and again the single Staudinger product **5** for the plates.

The exothermic formation ($\Delta_{calc}E$ = –8.8 kcal/mol, see computational details) of an eight-membered $P_4N_4$ ring starting from **5** seems to be quite interesting, as two intermolecular TMS–$N_3$ elimination steps (corresponding to two condensation steps) are required (Figure 2).

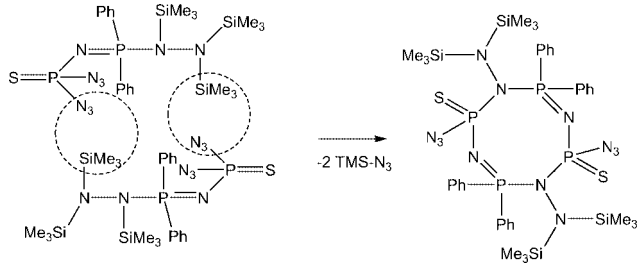

Figure 2. Formation of **6** by two intermolecular TMS–$N_3$ elimination steps (TMS = $Me_3Si$).

The single Staudinger product **5** is air- and moisture-sensitive but stable under argon over a long period in the solid state and in common organic solvents (e.g. benzene, $CH_2Cl_2$, diethyl ether etc.). Although there are two azide groups, **5** is neither shock- nor heat-sensitive, is easily prepared in bulk (yield > 95%) and infinitely stable when stored in a sealed tube and kept cool at 5 °C in the dark. Compound **5** is thermally stable up to over 150 °C while **3** and **4** are stable only up to 96 °C. At these temperatures decomposition starts, accompanied by a slow release of nitrogen (MS experiments).

### X-ray Structure Elucidation of 5 and Bonding

Compound **5** crystallises in the monoclinic space group $P2_1/c$ with four molecules in the unit cell. The perspective view of **5** is depicted in Figure 3 and selected bond lengths and angles are given in Table 3.

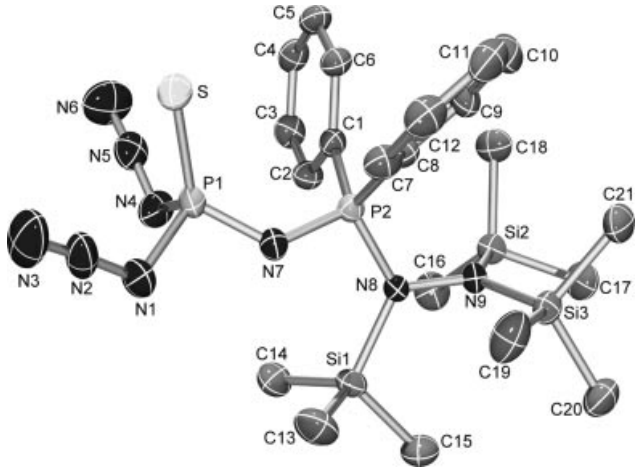

Figure 3. ORTEP drawing of the molecular structure of **5** in the crystal. Thermal ellipsoids with 50% probability at 200 K (hydrogen atoms omitted for clarity).

Table 3. X-ray analysis of **5**: selected bond lengths [Å] and angles [°].

Both $P^V$ atoms in **5** sit in a slightly distorted tetrahedral environment (angles around the P atoms between 99 and 112°) with the two azide groups at P1 in a *cis* position to the sulfur atom. Interestingly, two further isomers are possible with respect to the two azide groups: (i) only one azide group in a *trans* position, and (ii) both azide groups in a *trans* position to the sulfur atom. In agreement with the experiment, the close inspection of the conformational space of **5** revealed the experimentally observed *cis*/*cis* isomer to be the global minimum. The potential energy surface (PES) with respect to the rotation about all P–N bonds is very flat (see Supporting Information). The energy difference between the rotamers is smaller than 8 kcal/mol. The largest energy gap was found for the *cis*/*trans* isomers, whereas a *trans*/*trans* arrangement of both azide groups does not represent a minimum on the PES of **5**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As shown on numerous occasions,[12] both covalently bound azide groups display a *trans*-bent configuration (regarding the P atom) with a N–N–N bond angle of 175.2(3) (N1–N2–N3) and 174.0(3)° (N4–N5–N6). The P1–N7–P2 angle is rather large at 129.1(1)° compared to the N9–N8–P2 angle at 117.4°(1). Another interesting feature of this structure is the almost planar environment of both hydrazine nitrogen atoms (<Si3–N9–Si2–N8 = 173.1, <N9–N8–Si1–P2 = 177.1°; all N–N–X angles are between 117 and 121°, X = P, Si; Table 3), however both planes are almost perpendicular to each other. Hence, as displayed by NBO analysis,[13] the lone pair on both nitrogen atoms is localised in a pure p-type atomic orbital. Both lone pairs are also perpendicular to each other.[9]

Three different types of P–N bond lengths are found: (i) the longest between P1 and the N atoms of the azide groups with 1.713(3) Å, (ii) 1.662(1) Å for the P2–N8 bond (N atom of the hydrazine group) and (iii) the smallest with 1.583(2) and 1.586(2) Å for the two P–N bonds of the dicoordinated imino N atom connecting the two P atoms. These P–N distances are substantially shorter than the sum of the covalent radii [$d_{cov}$(N–P) = 1.8, $d_{cov}$(N=P) = 1.6 Å],[14,15] which indicates partial double bond character, especially for the P1–N7 and P2–N7 bonds. A typical P–N bond with π character is found in R–P=N–R′ species with P–N distances between 1.495(4) Å (R = Cl, R′ = aryl)[16] and 1.619(2) Å [R = $t$Bu$_2$P, R′ = N(SiMe$_3$)$_2$].[17] According to NBO analysis, all P–N bonds are highly polarised (25–27% P, 73–75% N) and almost ideally covalent between the adjacent N–N and P–S bonds (P: 48%, S: 52%).

Figure 4 shows the energetically preferred Lewis representation (from NBO analysis) along with the calculated partial charges of **5**, indicating a highly ionic molecular system.[18] Both four-coordinate P atoms formally obey the octet rule by forming only four single bonds. A positive formal charge is found on both P atoms and a negative on the dicoordinated N atom and the S atom. The experimentally found short P–N (between P1–N7 and P2–N7, Table 3) and P–S bonds possess double bond character, which can be explained by intramolecular donor–acceptor interactions (hyperconjugation, noncovalent effects) along the P1(S)–N7–P2 moiety (Figure 3). As shown by NBO analysis (see below), these interactions describe a highly delocalised π system including the lone pairs of the dicoordinated N atom (N7) and the S atom but *not* the tricoordinated N atom (N8).[19]

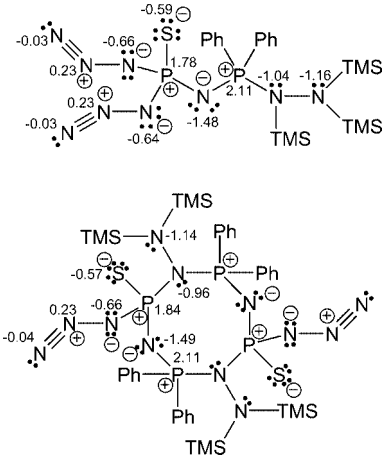

Figure 4. Lewis representations of **5** (top) and **6** (bottom) along with NPA partial charges (TMS = Me$_3$Si).

### X-ray Structure Elucidation of 6 and Bonding

SP(N$_3$)[NP(Ph)$_2$NN(TMS)$_2$]$_2$ (**6**) crystallises in the monoclinic space group $P2_1/n$ with four molecules in the unit cell (Figure 5, Table 4). The eight-membered $P_4N_4$ ring adopts a chair conformation with all four N atoms being in one plane as well as all four P atoms. An inversion centre is found right in the middle of the $P_4N_4$ ring. Interestingly, all N and P ring atoms of each of the monomeric fragments lie within a plane (e.g. N1–P1–N2–P2 = 3.6°). These two N–P–N–P planes are distorted by about 104°, forming the eight-membered $P_4N_4$ chair. As two tri- and dicoordinated nitrogen atoms form the $P_4N_4$ ring, **6** cannot be regarded to be a phosphazene, but a tetrazatetraphosphocine with two formal double and two single P–N bonds. Traditional bonding descriptions for cyclic PN rings have involved N(2p)–P(3d) overlap,[20] both in and perpendicular to the plane of the PN ring. However, this model is not consistent with the fact that phosphorus makes little or no use of its 3d orbitals (see above).[18,21] In accord with this, NBO analysis localises only single bonds (Figure 4) within the ring, again obeying the octet rule for all involved elements. However, according to the X-ray analysis, two smaller P–N bond lengths [π PN: $d$(N1–P2) = 1.573(3), $d$(N1–P2) = 1.586(3) Å] and two longer P–N distances [σ PN: $d$(N2–P1) = 1.703(2), $d$(N2–P2) = 1.707(2) Å] are experimentally observed. Both types of P–N bond lengths are a little bit shorter than the sum of the covalent radii for a single [$d_{cov}$(N–P) = 1.8 Å] and a double bond [$d_{cov}$(N=P) = 1.6 Å],[22,23] indicating a certain degree of multiple bond

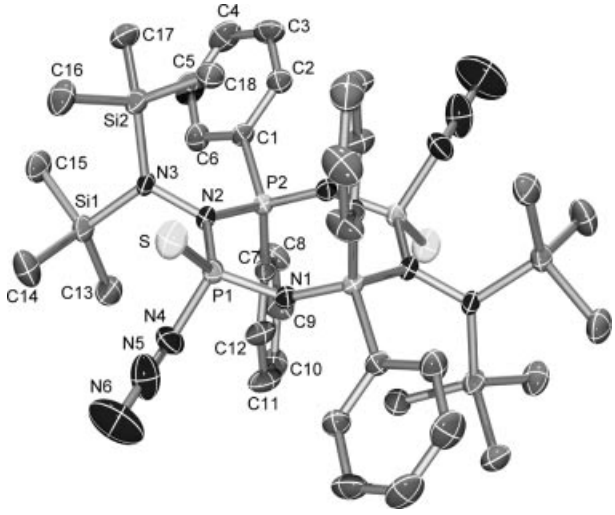

Figure 5. ORTEP drawing of the molecular structure of **6** in the crystal. Thermal ellipsoids with 50% probability at 200 K (hydrogen atoms omitted for clarity).

character due to intramolecular donor–acceptor interactions. For comparison, the P–NNN distance with 1.738(3) Å represents a typical single bond.

Table 4. X-ray analysis of **6**: selected bond lengths [Å] and angles [°].

| | | | |
|---|---|---|---|
| S–P1 | 1.932(1) | P2–C1 | 1.805(3) |
| P1–N1 | 1.586(3) | P2–C7 | 1.810(3) |
| P1–N2 | 1.703(2) | N2–N3 | 1.462(3) |
| P1–N4 | 1.738(3) | N2–P2 | 1.707(2) |
| P2–N1 | 1.573(3) | N4–N5 | 1.113(5) |
| P2–N2 | 1.707(2) | N5–N6 | 1.193(7) |
| N1–P1–N2 | 104.9(1) | N1–P2–N2 | 108.9(1) |
| N1–P1–N4 | 103.1(1) | N1–P2–C1 | 108.5(1) |
| N2–P1–N4 | 99.6(1) | N2–P2–C1 | 108.4(1) |
| N1–P1–S | 122.1(1) | N1–P2–C7 | 114.8(1) |
| N2–P1–S | 115.35(9) | N2–P2–C7 | 110.3(1) |
| N4–P1–S | 108.9(1) | C1–P2–C7 | 105.6(1) |

NBO analysis of **6** gives an almost identical picture compared to **5** (Figure 4) with respect to the type and magnitude of intramolecular donor–acceptor interactions, charge distribution and bond properties. Upon ring closure the partial charges of all atoms hardly change. The same holds for polarisation effects (similar PN and SP bond polarisation, see above) and the intramolecular donor–acceptor interactions describing the π system along the P–N moieties.[19,20] Only a close inspection of these interactions utilising the NBO partitioning scheme clearly indicates a highly delocalised π system along the P1(S)–N1–P2 moiety, which includes the lone pairs of both the S and the dicoordinated N atoms but not the azide group and the tricoordinated N atoms. These noncovalent effects represent typical $n(X) \rightarrow \sigma^*(Y–Z)$ hyperconjugative interactions ($n$ = sp$^{\lambda}$- or p-type lone pair; X = S, N1; Y = P1, P2; Z = C1, C7, S, N1, N2, N4) and explain the partial double bond character of the P1–S, P1–N1 and N1–P2 bonds (Figure 4 and Figure 5).[19,20]

To summarise, the molecular and electronic structure of **6** strongly resembles the molecular structure of **5**: (i) a staggered conformation with two perpendicular planes was also found for the hydrazine groups (dihedral angle: <P2–N2–N3–Si2 = –90.1°), (ii) both nitrogen atoms of the hydrazine group are in an almost planar environment [Σ<(N2) = 359.98°, Σ<(N3) = 358.9°][9] and (iii) the azide groups are slightly *trans*-bent with an N–N–N angle of 171.7(5)°, which is in accordance with the structures of other covalent phosphorus azides.[24] Because of inversion symmetry, both azide groups adopt a *trans* position to each other. It is interesting to note that the longest chain composed of only pnictogen atoms in **6** consists of eleven pnictogens (eight N and three P atoms) compared to eight in compound **5** (six N and two P atoms). Moreover, **6** represents a rare example of a structurally characterised phosphorus azide involving a binary PN ring (Table 1).

## Summary and Conclusions

Two different Staudinger reactions of thiophosphoryl triazide have been investigated: (i) with triphenylphosphane, $PPh_3$, and, (ii) with *N*,*N*′,*N*′-[tris(trimethyl)silyl]hydrazinediphenylphosphane, $(Me_3Si)_2N–(Me_3Si)N–PPh_2$ (**2**). While the reactions with $PPh_3$ utilising 1:1, 1:2 and 1:3 stoichiometries yield the single and double but not the triple Staudinger product, only the single Staudinger product was observed when $(Me_3Si)_2N–(Me_3Si)N–PPh_2$ was reacted. Even upon heating no further reaction of the remaining two azide groups with an excess of $(Me_3Si)_2N–(Me_3Si)N–PPh_2$ was detected. However, heating results in a partial intermolecular trimethylsilylazide elimination, which is combined with two condensation steps, yielding an eight-membered $P_4N_4$ ring (**6**). All four isolated Staudinger products represent new substituted phosphorus azides, are neither heat- nor shock-sensitive and, except for **6**, all can be prepared in large quantities (with yields >95%). Moreover, only a few neutral singly, doubly or multiply substituted phosphorus azides are known that have been structurally characterised (Table 1). Hence, the X-ray data of compound **5** and **6** may fill this gap.

## Experimental Section

***Caution:*** Although compounds **2**–**5** are kinetically stable compounds, they are nonetheless energetic materials and appropriate safety precautions should be taken, especially when these compounds are prepared on a larger scale. In the case of $SP(N_3)_3$ (**1**), special care has to be taken because of the extreme risk of explosion. Never handle this compound neat.

**General Remarks:** Solvents were freshly distilled, dried and stored under nitrogen. NMR: JEOL Eclipse 400 and 270 ($^1$H, $^{13}$C chemical shifts refer to $\delta_{TMS}$ = 0.00; $^{31}$P to $\delta_{H_3PO_4(85\%)}$ = 0.00). IR: Nicolet 520 FTIR (as KBr pellets or in Nujol mulls between KBr windows). Raman: Perkin–Elmer Spectrum 2000R NIR FT equipped with a Nd:YAG laser (1064 nm). CHN analyses: Analysator Elementar Vario EL. MS: Jeol MStation JMS 700. Melting points are uncorrected (Büchi B540). Thiophosphoryl triazide[30] and *N*,*N*′,*N*′-[tris(trimethyl)silyl]hydrazinediphenylphosphane[9] were prepared according to the procedures given in the literature.

**Synthesis of 5:** A solution of freshly prepared $SP(N_3)_3$ (0.242 g, 1.28 mmol) in acetonitrile (25 mL) was added to a solution of $Ph_2PN(TMS)N(TMS)_2$ (0.55 g, 1.28 mmol) in diethyl ether (50 mL) over a period of 1 h at ambient temperature. An immediate release of gas was observed. After the $N_2$ release stopped (about 2 h) the solvent was removed in vacuo and a white solid (**5**) was obtained. Complex **5** was purified by recrystallisation from an ether/acetonitrile mixture. $SP(N_3)_2[NP(Ph)_2N(TMS)N(TMS)_2]$ (**5**) (593.86) yield: 714 mg (94%) colourless crystals, m.p. 153 °C (decomposition). IR (KBr): $\tilde{\nu}$ = 3051 w, 2960 w, 2109 vs, 1588 w, 1482 w, 1436 s, 1260 vs, 1219 vs, 1177 s, 1111 vs, 1026 m, 996 m, 803 m, 777 m, 745 m, 718 s, 690 s, 675 m, 586 w, 529 s, 505 w cm$^{-1}$. Raman (200 mW, 25 °C, 100 scans): 3178 (4), 3146 (5), 3066 (100), 3052 (56), 2993 (18), 2958 (23), 2907 (84), 2255(2), 2153 (10), 2129 (7), 1591 (58), 1576 (21), 1442 (5), 1411 (6), 1316 (3), 1288 (17), 1267 (4), 1256 (4), 1184 (13), 1168 (9), 1107 (25), 1031 (40), 1002 (82), 935 (2), 858 (5), 762 (5), 728 (6), 692 (18), 650 (39), 619 (19), 598 (3), 569 (10), 542 (39), 523 (6), 506 (18), 381 (14), 345 (13), 314 (14), 296 (13), 270 (40), 239 (29), 191 (21), 168 (21), 139 (22) cm$^{-1}$. $^1$H NMR (109 MHz, $C_6D_6$, 25 °C): $\delta$ = 0.01 (s, 18 H, $N[Si(CH_3)_3]$-$N[Si(CH_3)_3]_2$), 0.37 (s, 9 H, $N[Si(CH_3)_3]N[Si(CH_3)_3]_2$), 7.5–8.0 (m, 10 H, $C_6H_5$) ppm. $^{13}$C NMR (68 MHz, $CDCl_3$, 25 °C): $\delta$ = 3.90 (s,

**Supporting Information** (see footnote on the first page of this article): Experimental details for the synthesis of **3**, **4** and **6**, and computational details.

**X-ray Analyses of 5 and 6:** Crystals of sufficient quality for X-ray structure determination were mounted on a glass fibre and the X-ray crystallographic data collected on a Nonius Kappa CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Selected bond lengths and angles are available in Table 3 and Table 4. All structures were solved by direct methods (structure solution program: SIR97[25] for **5** and **6**) and refined by full-matrix least-squares methods with SHELXL-97.[26] Hydrogen atoms were included at geometrically idealised positions and were not refined; the non-hydrogen atoms were refined anisotropically.

**Crystallographic Data for 5:** $C_{21}H_{37}N_9P_2SSi_3$, *fw* = 593.87, monoclinic, $P2_1/c$, $a$ = 9.0514(1), $b$ = 18.2759(3), $c$ = 18.7805(3) Å, $\alpha$ = 90.0, $\beta$ = 96.4276(8), $\gamma$ = 90.0°, $V$ = 3087.19(8) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.278 g/cm$^3$, $\mu$ = 0.353 mm$^{-1}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å, $T$ = 200 K, 36065 reflections collected, 6983 independent reflections, $R_{int}$ = 0.092, 5381 observed reflections, $R_1$ = 0.0469, $wR_2$ = 0.1308.

**Crystallographic Data for 6:** $C_{36}H_{56}N_{12}P_4S_2Si_4$, *fw* = 957.29, monoclinic, $P2_1/n$, $a$ = 11.6491(3), $b$ = 13.8277(4), $c$ = 15.1723(5) Å, $\alpha$ = 90.0, $\beta$ = 95.776(1), $\gamma$ = 90.0°, $V$ = 2431.5(1) Å$^3$, $Z$ = 2, $\rho_{calcd.}$ = 1.308 g/cm$^3$, $\mu$ = 0.381 mm$^{-1}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å, $T$ = 200 K, 5520 reflections collected, 28073 independent reflections, $R_{int}$ = 0.080, 3880 observed reflections, $R_1$ = 0.0558, $wR_2$ = 0.1364.

CCDC-283470 (for **5**) and -283471 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** The structural data of all considered species were calculated using the hybrid density functional theory (B3LYP) with the program package Gaussian 98.[27] For all elements a standard 6-31G(d,p) basis set was used. Comparison with experimental data shows differences in bond lengths no larger than 0.01–0.02 Å.[12a] As frequency analyses were not possible because of the large size of all species at the B3LYP level, PM3 optimised structures (stationary points) were characterised by a frequency analysis displaying only positive frequencies. NBO analyses[13a,28] were carried out to investigate the bonding in all molecules at the SCF level utilising the optimised B3LYP/6-31G(d,p) geometry and RHF orbitals. Also, NBO population analysis for **5** and **6** was carried out with the structure fixed at the position determined from X-ray analysis of **5** and **6** to investigate the bonding and hybridisation in this experimentally observed species. The computed geometrical parameters for all molecules, relative energies, details of the NBO analyses and absolute energies are given as Supporting Information. The computed frequencies can be obtained from the authors. It should be emphasised that the computation was carried out for a single, isolated (gas-phase) molecule. There may well be significant differences among gas-phase, solution and solid-state data.

## Acknowledgments

A.S. thanks Prof. Dr. T. M. Klapötke (LMU München) for his generous support and advice. We also wish to thank the Leibniz Rechenzentrum for the generous allocation of CPU time. This research was supported by the DFG SCHU 1170/4-1.

# Syntheses and Fluxional Processes of Diphenyl(2-thienyl)phosphane Derivatives of Triosmium Clusters

Nitsa K. Kiriakidou Kazemifar,[a] Marc J. Stchedroff,[a] M. Abdul Mottalib,[a][‡] Simona Selva,[b] Magda Monari,[b] and Ebbe Nordlander*[a]

**Keywords:** Cluster / Thienylphosphane / Fluxionality / Hydrodesulfurisation

Thermal treatment of $[Os_3(CO)_{12}]$ with diphenyl(2-thienyl)-phosphane, $Ph_2P(C_4H_3S)$, results in the formation of $[Os_3(CO)_{12-x}\{Ph_2P(C_4H_3S)\}_x]$ (x = 1–3, **1**–**3**), but no C–H bond activation was observed. Reaction of $[H_2Os_3(CO)_{10}]$ with diphenyl(2-thienyl)phosphane at ambient temperature affords $[HOs_3(\mu\text{-}H)(CO)_{10}\{Ph_2P(C_4H_3S)\}]$ (**4**), but when the same reaction is repeated at elevated temperatures, the cyclometallated species $[(\mu\text{-}H)Os_3(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$ (**5**) and $[(\mu\text{-}H)Os_3(CO)_8\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{Ph_2P(C_4H_3S)\}]$ (**6**) are formed. In addition, two more products, tentatively assigned as $[(\mu\text{-}H)Os_3(CO)_6\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{\mu\text{-}Ph_2P(C_4H_3S)\}\{Ph_2P(C_4H_3S)\}]$ (**7**) and $[(\mu\text{-}H)Os_3(CO)_7\{\mu\text{-}Ph_2P(C_4H_2S)\}\{\mu\text{-}Ph_2P(C_4H_3S)\}\{Ph_2P(C_4H_3S)\}]$ (**8**) are obtained. The dynamic behaviours of **2**, **5** and **6** have been studied by variable-temperature (VT) $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy. The VT $^{31}P\{^1H\}$ NMR spectra of $[Os_3(CO)_{10}\{Ph_2P(C_4H_3S)\}_2]$ (**2**) demonstrate that a mixture of two isomers, which are in rapid exchange at room temperature, is present and that the less common *cis-trans* isomer, whose structure has been determined by X-ray crystallography, is favoured for this cluster. The VT $^1H$ NMR spectra of **5** indicate the presence of two isomers which are proposed to arise from an oscillation of the $\sigma,\eta^2$-vinyl group of the thienyl moiety between two metal atoms. A similar fluxional process is proposed to occur in **6** and the assignment of the room-temperature structure(s) of this cluster was confirmed by $^1H$-$^{187}Os$ 2D HMQC spectroscopy. In addition to **2**, the solid-state structures of **3**, **5** and **6** have been determined by X-ray crystallography.

## Introduction

More strict laws concerning sulfur-containing emissions have intensified the interest in hydrodesulfurisation (HDS) processes. As a consequence, studies of adsorption and activation of organosulfur compounds onto metal surfaces is a rapidly developing area. The objectives of this research are the understanding of the nature of the active HDS catalysts, the binding modes and the activation of sulfur-containing molecules – in particular thiophenes – at the active catalyst sites, and the improvement of the efficiency of the catalysts.[1–6] Organometallic complexes,[3–5] including transition-metal clusters,[7] have been used as models for HDS catalysts because mechanistic information easily can be extracted by spectroscopic and analytical studies of discrete molecular complexes.

One of the very first reports of the interaction of thiophene with organometallic compounds described the desulfurisation of the heterocycle by a metal cluster, $[Fe_3(CO)_{12}]$.[8,9] Rauchfuss and co-workers[10] demonstrated shortly after, that thiaferroles are easily converted into the corresponding ferroles on heating and thereby established that insertion of an iron atom into a C–S bond clearly activates the heterocycle towards desulfurisation [Scheme 1(a)]. Similarly, the reaction of $[Ru_3(CO)_{12}]$ with thiophene proceeds through C–S bond cleavage, producing the sulfur-free ferrole-type compound $[Ru_2(\mu\text{-}C_4H_4)(CO)_6]$ and the tetranuclear cluster $[Ru_4(\mu_3\text{-}S)(\mu\text{-}C_4H_4)(CO)_{11}]$;[11] this is the first reported example of desulfurisation of a thiophene in which both the extruded sulfur and the hydrocarbon residue remain coordinated within the same complex [Scheme 1(b)]. More recently, Angelici and co-workers[12] have demonstrated $[Re_2(CO)_{10}]$-promoted C–S bond cleavage in benzothiophenes.

Despite the above-mentioned examples of C–S bond activation, C–H bond activation predominates over other types of oxidative addition in reactions of thiophenes with $[M_3(CO)_{12}]$ (M = Ru, Os) and their derivatives.[7] Thus, the carbonyltriosmium clusters $[Os_3(CO)_{12}]$ and $[Os_3(CO)_{10}(MeCN)_2]$ react with thiophene and thiophene derivatives through C–H bond cleavage in preference to C–S bond cleavage to afford the *endo*- and *exo*-thienyl isomers of

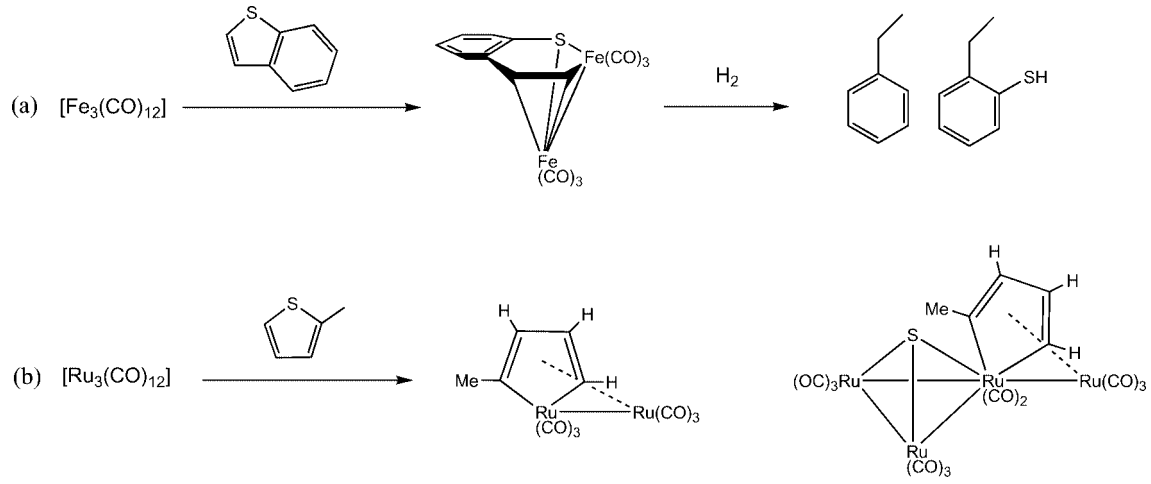
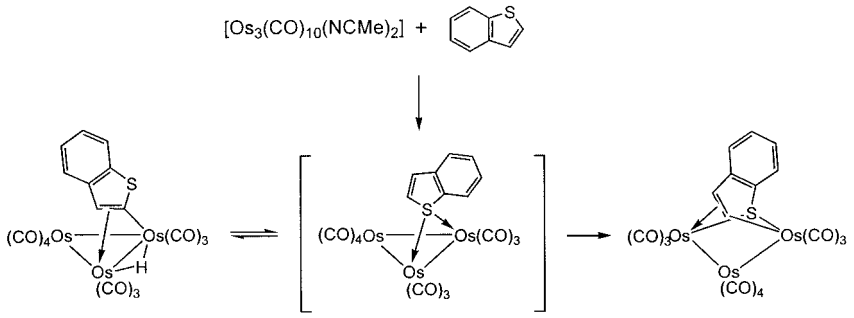


Scheme 1. Examples of desulfurisation of benzothiophene and 2-methylthiophene by carbonyl transition-metal clusters (see text and references cited therein).



Scheme 2. Room-temperature C–S bond cleavage effected by a carbonyltriosmium cluster (cf. ref.[17]).

$[Os_3(\mu\text{-}H)(CO)_9(\mu\text{-}C_4H_2S)]$, which are in rapid equilibrium at room temperature.[13–15] Similar results have been observed for 2-methylthiophene, 2,2′-bithiophene and 2,2′:5′,2′′-terthiophene.[16] The first room-temperature C–S bond cleavage of a (benzo)thiophene coordinated to a metallic cluster was reported by Arce et al.[17] In chloroform at room temperature the cluster $[Os_3(\mu\text{-}H)(CO)_{10}(\mu\text{-}C_8H_5S)]$, which contains a $\mu\text{-}\eta^2$-benzothienyl ligand, undergoes C(vinyl)–S bond cleavage to yield the cluster $[Os_3(CO)_{10}(\mu\text{-}C_8H_6S)]$, which contains an open benzothiophene ligand coordinated to an open $Os_3$ unit through a μ-S atom and a $\mu\text{-}\eta^2$-vinyl group (Scheme 2).

Despite the above-mentioned examples of thiophene coordination and activation, thiophene remains a relatively poor ligand for low-valent metal complexes, and thienylphosphanes [e.g. diphenyl(2-thienyl)phosphane] have therefore been used to bring the heterocycle into the coordination sphere of transition-metal clusters through the phosphane moiety of the ligand.[18–20] Treatment of diphenyl(2-thienyl)phosphane with $[Ru_3(CO)_{12}]$ has led to the incorporation of the thiophene ring into tri- and tetraruthenium clusters by cyclometallation and C–P bond cleavage of the ligand.[20] Here we report the reactions of $[Os_3(CO)_{12}]$ and $[H_2Os_3(CO)_{10}]$ with diphenyl(2-thienyl)phosphane, $Ph_2P(C_4H_3S)$, which have been undertaken in an effort to achieve C–P and C–S bond cleavage of the ligand.

## Results and Discussion

### Thermal Treatment of $[Os_3(CO)_{12}]$ with $Ph_2P(C_4H_3S)$

Reaction of $[Os_3(CO)_{12}]$ with diphenyl(2-thienyl)phosphane, $Ph_2P(C_4H_3S)$, in refluxing toluene yielded, after separation by thin layer chromatography, three yellow, substituted compounds, which were identified as $[Os_3(CO)_{11}\{PPh_2(C_4H_3S)\}]$ (**1**) (23%), $[Os_3(CO)_{10}\{PPh_2(C_4H_3S)\}_2]$ (**2**) (44%), and $[Os_3(CO)_9\{PPh_2(C_4H_3S)\}_3]$ (**3**) (8%) on the basis of their IR spectra. They are analogous with those of known mono-, bis-, and tris(phosphane)-substituted triosmium clusters.[21–24] The FAB mass spectra of all three compounds are also in complete agreement with the proposed formulas.

The $^1H$ NMR spectra of **1**–**3** display only aromatic resonances. No hydrido signals could be detected, indicating that *ortho*-metallation had not taken place. The room-temperature $^{31}P\{^1H\}$ NMR spectra show a singlet at $\delta$ = –16.2 ppm for **1**, a signal at $\delta$ = –17.3 (br.) ppm and doublet at $\delta$ = –32.7 ($J_{P-P}$ = 6.4 Hz) ppm for **2** (vide infra), and a singlet at $\delta$ = –17.2 ppm for **3**. The $^{31}P\{^1H\}$ spectra of both **1** and **3** remain unchanged when the temperature is decreased to –60 °C. This is consistent with the presence of one isomer of both **1** and **3**, in which the phosphane ligand(s) adopt equatorial positions with respect to the clus-

ter. However, the low-temperature $^{31}P\{^1H\}$ NMR spectrum of **2** indicates the presence of more than one isomer. The two most reasonable isomers are the *cis-trans* and *trans-trans* isomers (*cis* or *trans* with respect to the Os–Os vector) shown in Figure 1, which have previously been detected for related $[Os_3(CO)_{10}(phosphane)_2]$ clusters.[25,26] The $^{31}P\{^1H\}$ NMR spectrum at –60 °C (Figure 1) reveals that the predominant form is the *cis-trans* isomer with non-equivalent phosphorus nuclei, represented by two singlets at $\delta$ = –18.12 and –21.97 ppm.

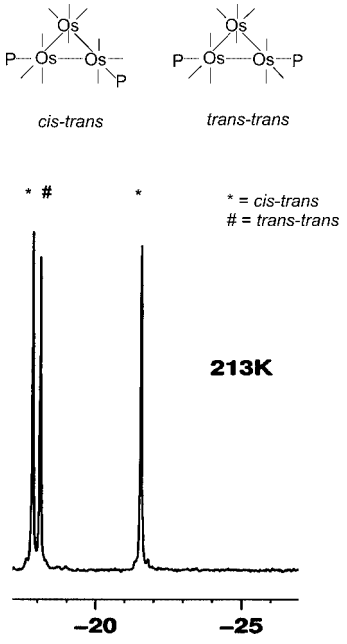

Figure 1. $^{31}P\{^1H\}$ NMR spectrum ($CD_2Cl_2$, 300 MHz) of $[Os_3(CO)_{10}(Ph_2PC_4H_3S)_2]$ (**2**) at –60 °C. The appearance of two equally intense singlets ($\delta$ = –18.12 and –21.97 ppm) is consistent with the *cis-trans* isomer and the third singlet ($\delta$ = –18.26 ppm) is attributed to the *trans-trans* isomer.

Until recently, only the *trans-trans* form of an $[Os_3(CO)_{10}(phosphane)_2]$ cluster had been verified crystallographically. Leong and Liu[27] have reported the first crystallographic confirmation of a *cis-trans* structure, that of *cis-trans*-$[Os_3(CO)_{10}(PPh_3)_2]$, which can be crystallised in both isomeric forms. We were able to grow yellow crystals of compound **2** by slow concentration of a dichloromethane/*n*-hexane solution at 4 °C, and these crystals were somewhat surprisingly found to contain only the *cis-trans* isomer. The molecular structure of **2** is shown in Figure 2; selected bond lengths and angles are listed in Table 1.

The molecule consists of a triangle of osmium atoms with ten carbonyl ligands, four bonded to Os(3) and three to each of Os(1) and Os(2). Two diphenyl(2-thienyl)phosphane ligands occupy equatorial coordination sites on Os(1) and Os(2), respectively. The average Os–Os distance [2.901(1) Å] is slightly longer than that found in the parent cluster, $[Os_3(CO)_{12}]$ [$Os–Os_{ave}$ = 2.877(3) Å].[28] In agreement with previous studies indicating that the presence of a tertiary phosphane ligand tends to lengthen the *cis*-Os–Os bond in $[Os_3(CO)_{11}(phosphane)]$ clusters,[29,30] some

lengthening of the Os(1)–Os(2) and Os(2)–Os(3) interactions in *cis* position is observed [2.910(1) and 2.907(1) Å, respectively, vs. Os(1)–Os(3) 2.886(1) Å]. This trend confirms the similar lengthening of the two Os–Os distances in *cis* position in the *cis-trans* form of the cluster $[Os_3(CO)_{10}(PPh_3)_2]$.[27] On the other hand, in *trans-trans* structures of $[Os_3(CO)_{10}(phosphane)_2]$ [phosphane = $PPh_3$, $PPh(OMe)_2$, $P(OMe)_3$] there is no change of Os–Os bond lengths that can be related to the presence of two phosphane ligands.[31] The Os(1)–P(1) (2.343 Å) and Os(2)–P(2) [2.333(2) Å] distances are normal and close to those reported for $[Os_3(CO)_{10}(PPh_3)_2]$.[27] (*cis-trans* and *trans-trans* forms) and the phosphane-substituted compounds mentioned above. The phosphorus atoms are slightly displaced out of the $Os_3$ plane [P(1) +0.102(1) and P(2) +0.292(1) Å]. This structure

determination and the above-mentioned low-temperature NMR measurements indicate that the *cis-trans* isomer of **2** is the thermodynamically favoured compound, as has previously been found by Deeming and co-workers for related clusters.[25,26]

Compound **3** crystallises with two independent molecules, which are conformational isomers (vide infra), in the asymmetric unit. The molecular structure of **3** is similar to that of previously characterised trisubstituted complexes of the general formula $[M_3(CO)_9(phosphane)_3]$ [M = Os, Ru and phosphane = $PMe_2(CH_2Ph)$, $PMe_2Ph$, $PPh(OMe)_2$, $P(OEt)_3$, $P(OCH_2CF_3)_3$ and $PPh_3$].[31] The molecular structure of one of the two crystallographically independent molecules of **3** is shown in Figure 3; selected bond lengths and angles are listed in Table 2. The cluster consists of a triangular $Os_3$ core with nine terminal carbonyl ligands. Three diphenyl(2-thienyl) ligands, each one coordinated to an osmium atom, occupy equatorial sites in such a way as to minimize steric interactions. The Os–Os distances average 2.894 Å, which is slightly longer than that found for $[Os_3(CO)_{12}]$ (vide supra), and the Os–P distances are comparable to those observed in compound **2**. It is worth noting that the introduction of the three diphenyl(2-thienyl)-phosphane ligands results in a significant twisting of the $Os(CO)_3(Ph_2PC_4H_3S)$ units with respect to the $Os_3$ plane. This distortion towards $D_3$ symmetry, which presumably occurs to minimize the steric interaction of the large phosphane ligands and may be rationalised in terms of more effective ligand packing, has been observed previously for related mono-, di- and tri-substituted complexes.[29,31,32] The usual arrangement of the phosphane substituents, with one lying below the metal plane and the other two lying above, is found in both of the conformationally distinct molecules that are present in the asymmetric unit. However, these conformational isomers differ in the orientations of the phosphane substituents. In the isomer shown in Figure 3, the two substituents on the same side of the metal plane are one phenyl and one thienyl ring for all three phosphane ligands, and the sulfur atom points towards the inner part of the phosphane cone. In the other isomer, one phosphane ligand is rotated so that its thienyl group occupies the "other" side of the $Os_3$ plane.

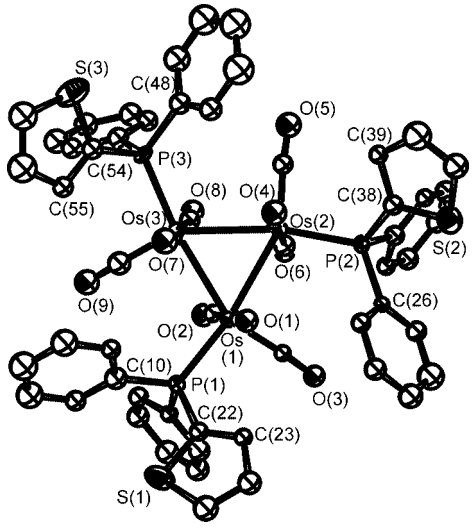

Figure 3. Molecular structure of one of the two crystallographically independent molecules of $[Os_3(CO)_9(Ph_2PC_4H_3S)_3]$ (**3**) (thermal ellipsoids at 30% probability). The carbon atoms of the carbonyl ligands bear the same numbering as the oxygen atoms. Hydrogen atoms have been omitted for clarity.

### Room-Temperature Reaction of $[H_2Os_3(CO)_{10}]$ with $(Ph_2PC_4H_3S)$

A colour change from purple to yellow was observed immediately upon mixing 1 equiv. of diphenyl(2-thienyl)phosphane with $[H_2Os_3(CO)_{10}]$ in dichloromethane at room temperature. Comparison of the IR and NMR spectra of the product to the known $[H_2Os_3(CO)_{10}(L)]$ clusters,[32]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

indicated that the product is $[HOs_3(\mu\text{-}H)(CO)_{10}\{Ph_2P(C_4H_3S)\}]$ (**4**), which was isolated in 26% yield after TLC purification. The room-temperature $^1H$ NMR spectrum shows a broad hydrido signal ($\delta \approx -15$ ppm) due to rapid exchange of the two hydrido ligands, but at –35 °C the exchange is frozen out and two distinct resonances are observed in the hydrido region – one for the terminal hydrido ligand at $\delta = -10.2$ ppm and one for the bridging hydrido ligand at $\delta = -19.7$ ppm. The $^{31}P\{^1H\}$ NMR spectrum displays one singlet at $\delta = -16.7$ ppm. On the basis of these NMR spectra we propose that the phosphane ligand in **4** is situated *trans* to the Os–Os bond and *cis* to the bridging hydrido ligand, which is reported as the thermodynamically most favourable of the isomers of $[HOs_3(\mu\text{-}H)(CO)_{10}(phosphane)]$ that have been identified.[33,34] Earlier investigations have shown that four more isomers have been detected from the reaction between $[H_2Os_3(CO)_{10}]$ and phosphanes.[35] In contrast to those results, we did not observe any additional isomers, even at –75 °C. This lack of observation of isomers may be related to the relative bulk of the ligand, making the other possible isomers sterically unfavourable. An alternative explanation is that the populations of (transient) isomers were too low to be observed.

### Thermal Treatment of $[H_2Os_3(CO)_{10}]$ with $Ph_2P(C_4H_3S)$

Reaction of an excess of diphenyl(2-thienyl)phosphane with $[H_2Os_3(CO)_{10}]$ in refluxing toluene for 3 h gives a colour change from initial purple colour to yellow, then to dark green and ultimately to brown. Separation by TLC led to the isolation of three products.

The first product was isolated in 21% yield. Although IR spectra of isostructural Os and Ru clusters are not always comparable, the product was identified as the cyclometallated cluster $[(\mu\text{-}H)Os_3(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$ (**5**) on the basis of the similarity of its IR spectrum to that of the known cluster $[Ru_3(\mu\text{-}H)(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$.[20] Mass spectrometric and microanalytical data were found to be consistent with the proposed formula. The $^1H$ NMR spectrum displays a doublet at $\delta = -18.0$ ppm confirming the presence of a bridging hydrido ligand, which couples to one phosphorus atom ($J_{P-H} = 13.2$ Hz). In the phenyl region, two *ortho* signals are observed, corresponding to two isomers. This is similar to that previously observed for $[Ru_3(\mu\text{-}H)(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$.[20] Unlike the ruthenium analogue, where the *ortho*-protons are fluxional at 20 °C and only become static on the NMR timescale at –20 °C, the *ortho*-protons of **5** were not fluxional at ambient temperature. The $^{31}P\{^1H\}$ NMR spectrum of **5** at 27 °C displays a singlet at $\delta = -3.3$ ($^1J_{P-Os} = 147$ Hz) ppm, with a small change of shift to $\delta = -5.3$ ppm at –80 °C. The small $^1J_{P-Os}$ coupling of 147 Hz is in agreement with axial coordination of the phosphorus atom with respect to the plane of the metal triangle. Typical equatorial $^1J_{P-Os}$ couplings are of the order of 185–225 Hz while axial couplings are much smaller as the metal–phosphane bond is no longer aligned with the electron density of the metal triangle.[36–39]

It was possible to grow crystals suitable for X-ray diffraction for cluster **5**, and single-crystal diffraction studies were undertaken in order to confirm the structure. The molecular structure of **5** is shown in Figure 4; selected bond lengths and angles are listed in Table 3. $[Os_3(\mu\text{-}H)(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$ (**5**) crystallises with two independent slightly different conformers in the asymmetric unit and is isostructural with $[(\mu\text{-}H)Ru_3(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$.[20] Compound **5** consists of an irregular triangle of osmium atoms, each of which is coordinated by three carbonyl ligands. A triply bridging diphenyl(2-thienyl)phosphane ligand and a bridging hydrido ligand complete the coordination sphere of the cluster. The $\mu_3\text{-}Ph_2P(C_4H_2S)$ ligand, which acts as a five-electron donor, is coordinated through the phosphorus atom in axial position to Os(1) and through the *ortho*-metallated thienyl ring to Os(3) with a C(11)–Os(3) σ-bond [Os(3)–C(11) 2.10(1) and 2.09(1) Å in molecule A and B] and to Os(2) with an $\eta^2(\pi)$-interaction between C(10)–C(11) and Os(2) [Os(2)–C(10) 2.34(1) and 2.36(1) Å, Os(2)–C(11) 2.35(1) and 2.32(1) Å in A and B, respectively]. This $\sigma,\eta^2$-vinyl-type interaction is not unprecedented; it has, for example, been observed in $[(\mu\text{-}H)Ru_3(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$[20] and $[(\mu\text{-}H)Ru_3(CO)_9\{\mu_3\text{-}Ph_2P(C_8H_4S)\}]$ ($C_8H_4S$ = benzothienyl),[40] $[Os_3(\mu\text{-}H)(CO)_9(\mu\text{-}Ph_2PCH{=}CH)]$,[34] $[Os_3(\mu\text{-}H)(CO)_9\{\mu_3\text{-}PMePh(C_6H_4)\}]$[41] as well as in the closely related $[Os_3(\mu\text{-}H)(MeSC_4H_2S)(CO)_9]$,[42] in which the $Ph_2P$ unit in **5** is substituted by an SMe group. The $C_4H_2S$ ring is tilted with respect to the $Os_3$ plane [dihedral angle between the $Os_3$ and $C_4H_2S$ planes 129.2(3) and 128.5(5)° for A and B, respectively] as has previously been noticed for the triruthenium analogue $[(\mu\text{-}H)Ru_3(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$[20] and $[Os_3(\mu\text{-}H)(MeSC_4H_2S)(CO)_9]$.[42] This tilt of the thienyl ring, which has been found also for the *ortho*-metallated phenyl ring in $[Os_3(\mu\text{-}H)(CO)_9\{\mu_3\text{-}PMePh(C_6H_4)\}]$,[41] takes place in order

to favour the $\eta^2$-interaction. The hydrido ligand which, as expected, is bridging the longest edge of the cluster, was located directly in the electron-density map. In both molecules, the hydrido ligand is on the same side of the $Os_3$ plane as the $\mu_3$-$Ph_2P(C_4H_2S)$ ligand [ca. 0.4 Å above the metal plane]. The Os–P bond lengths [Os(3)–P(1) 2.350(3) and 2.344(3) Å in A and B, respectively] are similar to those found in the cyclometallated compounds [$Os_3$(μ-H)(CO)$_9$-{μ-$Ph_2P$(CH=CH)}][34] [2.361(4) Å] and [$Os_3$(μ-H)(CO)$_9$-{$\mu_3$-PMePh($C_6H_4$)}][41] [2.342(6) Å].

The second product, which was isolated in 34% yield, was identified as [(μ-H)$Os_3$(CO)$_8${$\mu_3$-$Ph_2P(C_4H_2S)$}{$Ph_2P$-($C_4H_3S$)}] (**6**). The IR spectrum of **6** is similar to that of [(μ-H)$Ru_3$(CO)$_8${$\mu_3$-$Ph_2P(C_8H_4S)$}{$Ph_2P(C_8H_5S)$}][40] and mass spectrometric and microanalytical data are consistent with the proposed formula. The variable-temperature $^1$H and $^{31}$P{$^1$H} NMR spectra of **6** demonstrate that this complex is highly fluxional. The $^{31}$P{$^1$H} NMR spectrum of **6** at 20 °C shows two doublets at $\delta$ = –0.63 and –1.48 ($J_{P-P}$ = 16.6 Hz) ppm (Figure 5). This is supported by the bridging hydrido signal ($\delta$ = –17.4 ppm), appearing as a doublet of doublets due to the coupling to two non-equivalent phosphorus ligands. At –100 °C, the spectrum freezes out to show two distinct isomers in both the $^{31}$P{$^1$H} and $^1$H NMR spectra, although the $^1$H spectrum had to be acquired at 600 MHz before the shift differences could be clearly discerned (Figure 5). The limiting $^{31}$P{$^1$H} spectrum (–100 °C) shows two pairs of doublets centred at $\delta \approx$ 1.2 ppm, while the signal in the hydrido region of the $^1$H spectrum is shifted upfield and split into two doublets of doublets. It is possible that the two isomers that are observed in solution are related by the relative location of the terminal phosphane ligand with respect to the hydrido ligand. This is supported by the observed differences in the phosphane–hydrido couplings. We believe that this may be explained in terms of an oscillation of the thienyl group identical to that observed for **5** (vide supra) except that, unlike **5**, the isomers of **6** (Figure 6) are observable by NMR due to the presence of the terminally coordinated phosphane ligand, which renders the two hydrido positions non-equivalent.

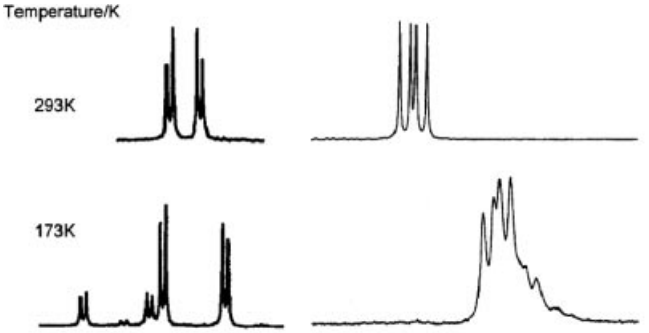

Figure 5. $^{31}$P{$^1$H} and $^1$H NMR spectra of [(μ-H)$Os_3$(CO)$_8${$\mu_3$-$Ph_2P(C_4H_2S)$}{$Ph_2P(C_4H_3S)$}] (**6**) at 293 K and 173 K. The low-temperature $^1$H NMR spectrum ($CD_2Cl_2$, 600 MHz) shows the very small shift differences between the two isomers.

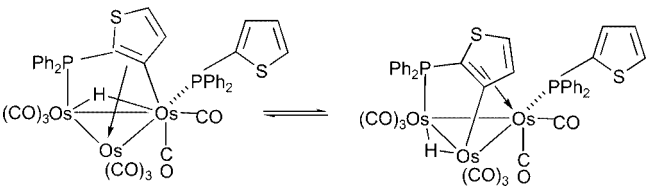

Figure 6. Proposed structures of the two isomers of **6**.

The assignment of the room-temperature structure could be confirmed by the acquisition of a $^{187}$Os NMR spectrum by inverse methods.[38] The presence of a P–P coupling

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

makes it potentially more difficult to extract the $^1J_{Os-P}$ values directly from a $^{31}P\{^1H\}$ spectrum. The $^1H$-$^{187}Os$ 2D HMQC spectrum at –100 °C (Figure 7) shows two shifts ($\delta$ = –13965 and –13230 ppm), corresponding to two osmium centres directly bonded to the bridging hydrido ligands, and it is possible to extract the two $^1J_{Os-P}$ couplings of 147 Hz and 211 Hz from the HMQC spectrum. The first coupling constant corresponds to that observed for **5** (147 Hz) and the coupling constant of 211 Hz is similar to other known $^1J_{Os-P}$ values for terminal phosphane ligands.[39] The fact that the $^1J_{Os-P}$ values for the axial phosphane ligands in **5** and **6** are identical is surprising (and may be coincidental), but it is indicative of the low level of electronic communication between the metal centres in the clusters.

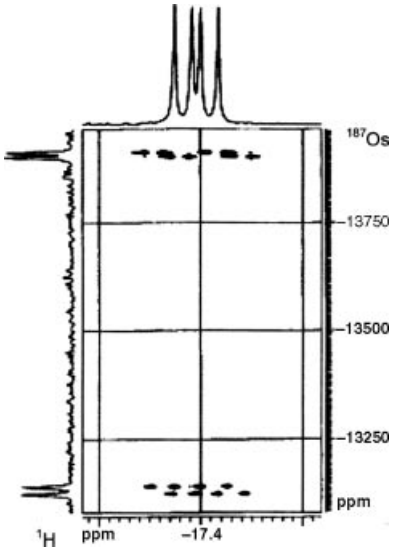

Figure 7. 2D $^1H$-$^{187}Os$ HMQC spectrum of **6** which clearly demonstrates the two different $^{187}Os$-$^{31}P$ couplings for each of the hydrido-bridged osmium centres (cf. Figure 5).

It was possible to grow crystals suitable for X-ray diffraction for cluster **6**, and a single-crystal diffraction study was undertaken in order to confirm its structure and investigate whether isomers could be detected also in the solid state. The structure of $[Os_3(\mu\text{-}H)(CO)_8\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{Ph_2P(C_4H_3S)\}]$ (**6**) is shown in Figure 8; selected bond lengths and angles are listed in Table 4.

As expected, the structure is similar to that of $[(\mu\text{-}H)Ru_3(CO)_8\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{Ph_2P(C_4H_3S)\}]$[20] and of $[(\mu\text{-}H)Ru_3(CO)_8\{\mu_3\text{-}Ph_2P(C_8H_4S)\}\{Ph_2P(C_8H_5S)\}]$.[40] It is also closely related to $[Ru_3(\mu\text{-}H)(CO)_8\{\mu_3\text{-}Ph_2P(CH{=}CH)\}\{Ph_2P(CH{=}CH_2)\}]$[43] and differs from **5** only in the substitution of one carbonyl ligand by one terminal thienylphosphane ligand. The cluster consists of a scalene triangle of Os atoms [Os(1)–Os(2) 3.014, Os(1)–Os(3) 2.863 Å, Os(2)–Os(3) 2.780(1) Å] bound to eight terminal carbonyl ligands, a terminal $Ph_2PC_4H_3S$ ligand, a $\mu_3$-$Ph_2PC_4H_2S$ and a $\mu_2$-bridging hydrido ligand. The $\mu_3$-$Ph_2PC_4H_2S$ ligand behaves as a five-electron donor and interacts with all three metal atoms in the same fashion as observed in **5**. The σ- and $\eta^2$-interactions of the *ortho*-metallated thienyl ring [Os(2)–C(22) 2.10(1), Os(3)–C(21) 2.32(1) and Os(3)–C(22) 2.33(1) Å] are very similar to those found in **5** and unaffected by the presence of the terminal phosphane ligand. The C(21)–C(22) distance [1.45(1) Å] in the bridging thienyl ring is identical to the equivalent interaction in **5** and similar to the analogous bonds in $[(\mu\text{-}H)Ru_3(CO)_8\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{Ph_2P(C_4H_3S)\}]$[20] [1.425(5) Å]. The terminal diphenyl(2-thienyl)phosphane ligand is coordinated in an equatorial position, but the phosphorus atom is displaced out of the metal plane [P(2) +1.034(2) Å] on the same side of the $\mu_3$-$Ph_2PC_4H_2S$ ligand. The two Os–P interactions [Os(1)–P(1)

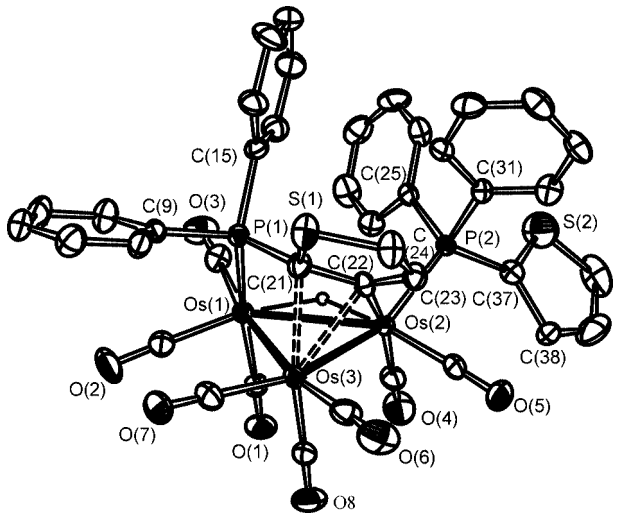

Figure 8. Molecular structure of $[(\mu\text{-}H)Os_3(CO)_8\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{Ph_2P(C_4H_3S)\}]$ (**6**) (thermal ellipsoids at 30% probability). The carbon atoms of the carbonyl ligands bear the same numbering as the oxygen atoms. All hydrogen atoms except the hydrido ligand have been omitted for clarity.

Table 4. Selected bond lengths [Å] and angles [°] for $[(\mu\text{-}H)Os_3(CO)_8\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{Ph_2P(C_4H_3S)\}]$ (**6**).

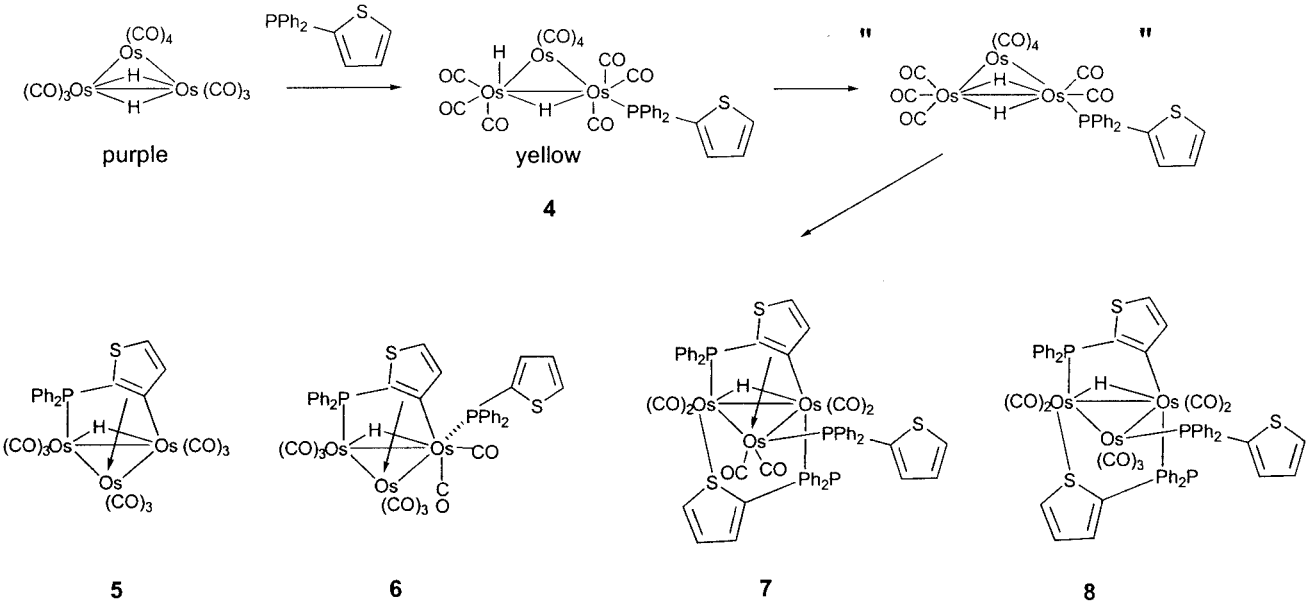

Scheme 3. Possible reaction scheme for the reaction between $[H_2Os_3(CO)_{10}]$ and $Ph_2P(C_4H_3S)$ in toluene.

2.360(2) and Os(2)–P(2) 2.325(3) Å] are not equivalent; the Os–P(axial) distance is longer than the Os–P(equatorial) but very similar to the corresponding distance in **5**. The bridging hydrido ligand has been directly located along the Os(1)–Os(2) edge which is, as usual, the longest Os–Os interaction.

The third product, compound **7**, was isolated in 5% yield. The mass spectrometric analysis suggests the stoichiometric formula $[Os_3(CO)_6\{Ph_2P(C_4H_3S)\}_3]$ for this product, and microanalytical data are consistent with the proposed formula. The $^1H$ NMR spectrum displays a signal in the (bridging) hydrido region ($\delta$ = –16.67 ppm) indicating that an *ortho*-metallation has taken place. The hydrido signal appears as a triplet (overlapping doublet of doublets), indicating coupling to two non-equivalent phosphorus atoms. Three signals are observed in the $^{31}P\{^1H\}$ NMR spectrum, confirming the presence of three non-equivalent phosphorus atoms; a multiplet at $\delta$ = 4.50 ppm, a doublet at $\delta$ = –1.65 ($J_{P-P}$ = 16 Hz) ppm and a multiplet at $\delta$ = –5.98 ppm. On the basis of these data, we propose the molecular formula $[(\mu\text{-H})Os_3(CO)_6\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{\mu_2\text{-}Ph_2P(C_4H_3S)\}\{Ph_2P(C_4H_3S)\}]$ (cf. Scheme 3) for compound **7**, containing three diphenyl(2-thienyl) ligands coordinated in three different coordination modes; a $\mu_3$-fashion, a $\mu$-(P,S) fashion and a terminal fashion. The $\mu$-(P,S) coordination mode has been detected for a diphenyl(2-benzothienyl)phosphane derivative of $[Os_3(CO)_{12}]$[44] as well as in thienylphosphane derivatives of $[Rh_6(CO)_{16}]$.[45]

The fourth product, compound **8**, was isolated in 3% yield. The mass spectrum of this compound indicates that it has one more carbonyl ligand than compound **7**. The $^1H$ NMR spectrum displays, in addition to signals of aromatic hydrogen atoms, a triplet (overlapping doublet of doublets) at $\delta$ = –17.05 ppm, thus confirming the presence of a single bridging hydrido ligand. In the $^{31}P\{^1H\}$ NMR spectrum, three non-equivalent phosphorus resonances are observed at $\delta$ = –3.19 (m), –5.30 (d) and –9.15 (m) ppm. These data suggest that this complex and compound **7** are structurally similar except for one carbonyl ligand. Therefore, we propose the molecular formula $[(\mu\text{-H})Os_3(CO)_7\{\mu\text{-}Ph_2P(C_4H_2S)\}\{\mu\text{-}Ph_2P(C_4H_3S)\}\{Ph_2P(C_4H_3S)\}]$ for compound **8**, containing the $\mu$-$Ph_2P(C_4H_2S)$ ligand bonded through P and a $\sigma$-interaction to the osmium triangle, but lacking an $\eta^2$-interaction with an osmium atom (cf. Scheme 3).

Several colour changes were observed during the reaction of diphenyl(2-thienyl)phosphane with $[H_2Os_3(CO)_{10}]$, indicating that the reaction proceeds via a number of intermediates. A possible reaction scheme is shown in Scheme 3. Addition of the ligand to the cluster results in an immediate colour change from purple to yellow and formation of $[HOs_3(\mu\text{-H})(CO)_{10}\{Ph_2P(C_4H_3S)\}]$ (**4**) (indicated by IR spectroscopy). Cluster **4** then reacts further, possibly undergoing a loss of one CO ligand and forming an unsaturated intermediate cluster which is likely to be $[H_2Os_3(CO)_9\{Ph_2P(C_4H_3S)\}]$. It has previously been observed, that heating solutions of compounds of the type $[H_2Os_3(CO)_{10}(L)]$ (L = tertiary phosphane), leads to a loss of one carbonyl ligand giving $[H_2Os_3(CO)_9(L)]$.[33,46] $[H_2Os_3(CO)_9\{Ph_2P(C_4H_3S)\}]$ then presumably undergoes further decarbonylation ultimately giving rise to the four products isolated.

## Conclusion

In conclusion, the introduction of diphenyl(2-thienyl)phosphane into the coordination sphere of triosmium clusters by direct thermal substitution of carbonyl ligands or room-temperature reaction with the unsaturated cluster $[H_2Os_3(CO)_{10}]$ is facile. In all cases surveyed in this study, the ligand initially coordinates as a monodentate phos-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phane, but further activation/metallation of the ligand is possible at elevated temperatures, although the osmium clusters are considerably less reactive than their ruthenium analogues.[20]

## Experimental Section

**General Remarks:** The clusters $[Os_3(CO)_{12}]$[47] and $[Os_3(\mu\text{-}H)_2(CO)_{10}]$[48–50] and the ligand diphenyl(2-thienyl)phosphane[20] were synthesised by published methods. Solvents were dried by standard methods prior to use. TLC was performed on commercial plates precoated with Merck Kieselgel 60 to 0.5 mm thickness. NMR spectra were acquired with Bruker DRX300 WB, DRX500 and DRX600 spectrometers. Gradient-selected $^{187}$Os 2D HMQC experiments were carried out with a Bruker DMX600 equipped with an XYZ 10A gradient amplifier ($z$-gradient strength 0.05 T m$^{-1}$). Details regarding the experimental setup and acquisition parameters for the $^{187}$Os 2D HMQC experiments are listed in the Supporting Information (see footnote on the first page of this article). IR spectra were acquired with a Nicolet Avatar FT-IR spectrometer and FAB-MS (3-nitrobenzyl alcohol matrix) data with a JEOL SX-102 mass spectrometer.

**Direct Thermal Reaction of $[Os_3(CO)_{12}]$ and Diphenyl(2-thienyl)-phosphane in Toluene:** A solution of $[Os_3(CO)_{12}]$ (300 mg, 0.33 mmol) and diphenyl(2-thienyl)phosphane (98 mg, 0.37 mmol) in toluene (40 mL) was refluxed under nitrogen for 2.5 h. The solvent was removed under reduced pressure. Preparative TLC of the residue, using dichloromethane/*n*-hexane (3:7, v/v) as eluent gave four compounds, in order of decreasing $R_f$: $[Os_3(CO)_{12}]$ (pale yellow, trace), $[Os_3(CO)_{11}\{Ph_2P(C_4H_3S)\}]$ (**1**, intense yellow, 96 mg, 23%), $[Os_3(CO)_{10}\{Ph_2P(C_4H_3S)\}_2]$ (**2**, intense yellow, 203 mg, 44%), $[Os_3(CO)_9\{Ph_2P(C_4H_3S)\}_3]$ (**3**, orange, 42 mg, 8%).

**1:** $C_{27}H_{13}O_{11}Os_3PS$ (1147.12): calcd. C 28.27, H 1.14, P 2.76; found C 28.19, H 1.33, P 2.76. FAB-MS: *m*/*z* = 1148 [M$^+$], [M$^+$ – *n* CO, *n* = 1–11]. **2:** $C_{42}H_{26}O_{10}Os_3P_2S_2$ (1387.42): calcd. C 36.36, H 1.89, P 4.46; found C 36.33, H 1.62, P 4.94. FAB-MS: *m*/*z* = 1388 [M$^+$], [M$^+$ – *n* CO, *n* = 1–10]. IR ($CH_2Cl_2$): $\tilde{\nu}_{co}$ = 2086 w, 2070 s, 2031 s, 1999 s, 1970 w, 1956 w cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.82–7.17 (m, 26 H, arom.) ppm. $^{31}$P NMR (300 MHz, $CD_2Cl_2$, –60 °C): $\delta$ = –18.12 (s, 1 P, terminal), –18.26 (s, 2 P, terminal), –21.97 (s, 1 P, terminal) ppm.

**3:** $C_{57}H_{39}O_9Os_3P_3S_3$ (1627.72): calcd. C 42.06, H 2.42, P 5.71: found C 42.48, H 2.85, P 5.23. FAB-MS: *m*/*z* = 1628 [M$^+$], 1600 [M$^+$ – CO]. IR ($CH_2Cl_2$): $\tilde{\nu}_{co}$ = 2068 sh, 2034 sh, 2013 w, 1998 m, 1975 m, 1945 w cm$^{-1}$. $^1$H NMR (500 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.6–7.12 (m, 39 H, arom.) ppm. $^{31}$P NMR (500 MHz, $CDCl_3$, 25 °C): $\delta$ = –17.2 (s, 3 P, terminal) ppm.

**Room-Temperature Reaction of $[H_2Os_3(CO)_{10}]$ with Diphenyl(2-thienyl)phosphane in $CH_2Cl_2$:** Diphenyl(2-thienyl)phosphane (2 equiv., 95 mg, 0.36 mmol) was added to $[H_2Os_3(CO)_{10}]$ (1 equiv., 150 mg, 0.18 mmol) in freshly distilled dichloromethane (30 mL) at room temperature under nitrogen. Within 5 min, the solution turned from purple to yellow and the IR spectrum indicated that no starting material had remained unreacted. The solution was concentrated and absorbed onto TLC plates using dichloromethane/*n*-hexane (3:7, v/v) as eluent. Two bands were recovered, in order of decreasing $R_f$: $[HOs_3(\mu\text{-}H)(CO)_{10}\{Ph_2P(C_4H_3S)\}]$ (**4**, 34 mg, 26%, yellow), uncharacterised product (5 mg, 4%, red).

**4:** $C_{26}H_{15}O_{10}Os_3PS$ (1121.12): calcd. C 27.85, H 1.35, P 2.76; found C 28.86, H 1.38, P 2.72. FAB-MS: *m*/*z* = 1120 [M$^+$], [M$^+$ – *n* CO, *n* = 1–10]. IR ($CH_2Cl_2$): $\tilde{\nu}_{co}$ = 2106 s, 2090 m, 2086 m, 2068 s, 2052 s, 2025 s, 1984 m, 1972 m, 1933 sh cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.79–7.27 (m, 13 H, arom.), –10 to –20 (br. s, 2 H, hydrido) ppm. $^1$H NMR (300 MHz, $CDCl_3$, –45 °C): $\delta$ = 7.8–7.3 (m, 13 H, arom.), –10.12 (d, $J_{H,H}$ = 3.3 Hz, 1 H, terminal hydrido), –19.72 (dd, $J_{H,H}$ = 3.3 Hz, $J_{P,H}$ = 11 Hz, 1 H, bridging hydrido) ppm. $^{31}$P NMR (300 MHz, $CDCl_3$, –45 °C): $\delta$ = –16.7 (s, 1 P, terminal phosphane) ppm.

**Thermal Reaction of $[H_2Os_3(CO)_{10}]$ with Diphenyl(2-thienyl)phosphane in Toluene:** A solution of $[H_2Os_3(CO)_{10}]$ (150 mg, 0.18 mmol) and ($Ph_2PC_4H_3S$) (95 mg, 0.36 mmol) in toluene (30 mL) was refluxed under nitrogen for 3 h. During the reaction the colour changed from purple to yellow, to green, and finally to brown. The products were separated by TLC using dichloromethane/*n*-hexane (2:3, v/v) as eluent. Five bands were recovered, in order of decreasing $R_f$: $[H_2Os_3(CO)_{10}]$ (purple, trace), $[(\mu\text{-}H)Os_3(CO)_9\{\mu_3\text{-}Ph_2P(C_4H_2S)\}]$ (**5**, intense yellow, 99 mg, 21%), $[(\mu\text{-}H)Os_3(CO)_8\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{Ph_2P(C_4H_3S)\}]$ (**6**, intense yellow, 197 mg, 34%), $[(\mu\text{-}H)Os_3(CO)_6\{\mu_3\text{-}Ph_2P(C_4H_2S)\}\{\mu\text{-}Ph_2P(C_4H_3S)\}\{Ph_2P(C_4H_3S)\}]$ (**7**, yellow, 32 mg, 5%), $[(\mu\text{-}H)Os_3(CO)_7\{\mu\text{-}Ph_2P(C_4H_2S)\}\{\mu\text{-}Ph_2P(C_4H_3S)\}\{Ph_2P(C_4H_3S)\}]$ (**8**, intense yellow, 22 mg, 3%).

**5:** $C_{25}H_{13}O_9Os_3PS$ (1091.1). FAB-MS: *m*/*z* = 1092 [M$^+$], [M$^+$ – *n* CO, *n* = 1–9]. IR ($CH_2Cl_2$): $\tilde{\nu}_{co}$ = 2088 s, 2060 s, 2034 s, 2019 s, 1989 s, 1974 w, 1965 m cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.93–7.07 (m, 12 H, arom.), –18.0 (d, $J_{H,P}$ = 13.2 Hz, 1 H, bridging hydrido) ppm. $^{31}$P NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = –3.27 (s, $J_{Os,P}$ = 147 Hz, 1 P, axial phosphorus) ppm.

**6:** $C_{40}H_{26}O_8Os_3P_2S_2$ (1331.4): calcd. C 36.09, H 1.97, P 4.65; found C 36.09, H 1.97, P 4.56. FAB-MS: *m*/*z* = 1332 [M$^+$], [M$^+$ – *n* CO, *n* = 1–8]. IR ($CH_2Cl_2$): $\tilde{\nu}_{co}$ = 2074 s, 2032 s, 2015 s, 1993 sh, 1981 m, 1967 m, 1957 m, 1945 sh cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.86–6.35 (m, 25 H, arom.), –17.4 (dd, $J_{H,P}$ = 15.4 Hz, $J_{H,P}$ = 11 Hz, 1 H, bridging hydrido) ppm. $^{31}$P NMR (300 MHz, $CD_2Cl_2$, 27 °C): $\delta$ = –0.70 (d, $J_{P,P}$ = 16.7 Hz, 1 P), –1.22 (d, $J_{P,P}$ = 16.7 Hz, 1 P) ppm. $^{31}$P NMR (300 MHz, $CD_2Cl_2$, –90 °C): $\delta$ = 1.27 (d, $J_{P,P}$ = 16.8 Hz, 1 P), –0.36 (d, $J_{P,P}$ = 16.8 Hz, 1 P), –0.69 (d, $J_{P,P}$ = 16.5 Hz, 1 P), –2.13 (d, $J_{P,P}$ = 16.4 Hz, 1 P) ppm. $^1$H-$^{187}$Os 2D HMQC NMR (600 MHz, $CD_2Cl_2$, –100 °C): $\delta$ = –13965 ($^1J_{Os,P}$ = 147 Hz), –13230 ($^1J_{Os,P}$ = 211 Hz) ppm.

**7:** $C_{54}H_{39}O_6Os_3P_3S_3$ (1543.69). FAB-MS: *m*/*z* = 1544 [M$^+$], 1516 [M$^+$ – CO], 1488 [M$^+$ – 2 CO], 1460 [M$^+$ – 3 CO]. IR ($CH_2Cl_2$): $\tilde{\nu}_{co}$ = 2068 w, 2058 w, 2025 sh, 2015 m, 1985 s, 1961 sh, 1929 sh cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.85–6.65 (m, 38 H, arom.), –16.67 [t, $J_{H,P}$ = 11 Hz, 1 H, bridging hydrido] ppm. $^{31}$P NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 4.50 (m, 1 P), –1.65 (d, $J$ = 16.18 Hz, 1 P), –5.98 (m, 1 P) ppm.

**8:** $C_{55}H_{39}O_7Os_3P_3S_3$ (1571.7). FAB-MS: *m*/*z* = 1572 [M$^+$], 1544 [M$^+$ – CO]. IR ($CH_2Cl_2$): $\tilde{\nu}_{co}$ = 2061 m, 2040 vs, 2002 s, 1988 m, 1968 w, 1944 m cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 7.85–6.20 (m, 38 H, arom.), –17.05 [t (dd), $J_{H,P}$ = 14.7 Hz, $J_{H,P}$ = 13.2 Hz, 1 H, bridging hydrido] ppm. $^1$H NMR (300 MHz, $CD_2Cl_2$, –50 °C, hydrido region): $\delta$ = –17.16 (t, $J$ = 13.5 Hz, 12.9 Hz, 1 H) ppm. $^{31}$P NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = –3.19 (m), –5.30 (d, $J$ = 17.1 Hz), –9.15 (m) ppm. $^{31}$P NMR (300 MHz, $CD_2Cl_2$, –35 °C): $\delta$ = –0.58 (d, $J$ = 9.95 Hz, 1 P), –9.5 (2, 1 P), –11.15 (s, 1 P) ppm.

**X-ray Crystallographic Study:** Crystals of **2**, **3**, **5** and **6** were obtained by slow concentration of dichloromethane/*n*-hexane solu-

tions at 4 °C. Crystal data and other experimental details for all structures are reported in Table 5. The diffraction experiments were carried out with an Enraf–Nonius CAD4 diffractometer at room temperature, using graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The unit cells were determined by a least-squares fitting procedure using 25 randomly selected strong reflections. The diffracted intensities were corrected for Lorentz and polarisation effects. An empirical absorption correction was applied using the azimuthal scan method.[51] The positions of the metal atoms were determined by direct methods (SIR-97[52]) and all non-hydrogen atoms were located from Fourier difference syntheses. In compounds **5** and **6**, the bridging hydrido ligands were also located in the Fourier map. The phenyl and thienyl H atoms were added in calculated positions ($d_{C-H}$ 0.93 Å). The final refinement on $F^2$ proceeded by full-matrix least-squares calculations (SHELXL97[53]) using anisotropic thermal parameters for all non-hydrogen atoms in **2**, **5** and **6**, whereas in **3** only the Os, P and S atoms were treated anisotropically. The asymmetric units of **3** and **5** contain two independent molecules, and the latter contains also one-half of a disordered *n*-hexane solvent molecule, which is related to the other half by an inversion centre. The 2-thienyl rings [bound to P(4) and P(5), respectively] of one of the molecules present in the asymmetric unit of **3** showed disorder due to a 180° rotation around the P–C axis, and therefore the sulfur and α-carbon atoms of the rings were refined for the two orientations. The refined occupancy factors of S(4) and S(5) in the second conformer of the molecule (Figure S3, Supporting Information) were 52 and 66%, respectively. The phenyl and thienyl H atoms were assigned isotropic thermal parameters 1.2 times $U_{eq}$ of the carrier carbon atoms. The relatively low quality of the diffraction data for compound **3** was due to the fact that good quality crystals could not be obtained despite repeated crystallisations by different techniques. CCDC-203202 (**2**), -203203 (**3**), -203204 (**5**) and -203205 (**6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

This research was supported by grants to E. N. from the Swedish Research Council (VR) and the European Union (TMR network Metal Clusters in Catalysis and Organic Synthesis, MECATSYN). We would like to thank Dr. Jason D. King for his helpful comments on the variable-temperature NMR spectra, and Prof. Silvio Aime and Dr. Karl-Erik Bergquist for the use of NMR spectrometers. M. M. and S. S. thank the University of Bologna and MIUR (Cofin2003) for financial support.

**Keywords:** Silver / MOFs / Cyclohexanehexacarboxylate / Water tape / Ag···Ag interactions / Supramolecular chemistry

Two new silver polycarboxylate coordination polymers, $[Ag_3(H_3L)(H_2O)_2]_n \cdot 2nH_2O$ (**1**) and $[Ag_6L(NH_3)(H_2O)_3]_n \cdot nH_2O$ (**2**), have been obtained from the reaction of $[Ag(NH_3)_2](OH)$ (freshly synthesized from $Ag_2O$ and aqueous ammonia) with *cis*,*cis*,*cis*,*cis*,*cis*,*cis*-1,2,3,4,5,6-cyclohexanehexacarboxylic acid ($H_6L$) by control of the molar ratio of starting materials. The X-ray crystal structure analysis reveals that both of them crystallize in the triclinic space group $P\bar{1}$ with $a$ = 6.375(4), $b$ = 9.505(6), $c$ = 15.097(8) Å, $\alpha$ = 93.249(14), $\beta$ = 100.364(15), $\gamma$ = 96.453(15)°, $V$ = 891.4(9) Å$^3$, $Z$ = 2 for **1**, and $a$ = 8.0380(7), $b$ = 10.1220(9), $c$ = 13.8458(12) Å, $\alpha$ = 76.3450(10), $\beta$ = 80.9370(10), $\gamma$ = 68.7230(10)°, $V$ = 1016.83(15) Å$^3$, $Z$ = 2 for **2**. Complex **1** features a three-dimensional (3D) metal-organic framework (MOF) with one-dimensional (1D) rectangular channels surrounded by carboxylato-supported Ag–Ag dimers, Ag–Ag chains, and half deprotonated $[H_3L]^{3-}$ ligands. Each $[H_3L]^{3-}$ ligand connects eight $Ag^I$ atoms. The weakly coordinated water ligands and lattice water molecules are located at the channels and form interesting 1D hydrogen-bonded T4(2)8(2) water tapes with cyclic $R_8^6(16)$ $(H_2O)_8$ and $R_4^4(8)$ $(H_2O)_4$ units. Complex **2** is also a 3D MOF structure constructed by two types of Ag–Ag chains with Ag8 cluster units and linear Ag4 units, respectively, and fully deprotonated $L^{6-}$ ligands. The silver(I) atoms in **2** exhibit linear, T-shaped, Y-shaped, and tetrahedral coordination geometries. Each $L^{6-}$ ligand connects thirteen $Ag^I$ atoms. The intrachain robust argentophilic interactions play a vital role in the formation of the structure.

## Introduction

The design and synthesis of metal-organic frameworks (MOFs) are of great interest because of their intriguing structural topologies and novel properties for potential applications.[1–3] In the past few decades, the development of supramolecular assembled chemistry has allowed the possibility to rationally design and prepare supramolecular architectures through noncovalent interactions, in which it is crucial to meet both geometric as well as energetic considerations.[4] Recent advances in this field have led to many periodic MOFs formed through the deliberate selection of functionalized organic ligands and coordination geometries of transition-metal ions.[5] A successful strategy in building such networks is to employ appropriate bridging ligands that can bind metal ions in different modes and provide a possible way to achieve more robust MOF structures.[6] Moreover, the recent development of self-assembled supramolecular chemistry has made it possible to rationally design and synthesize MOFs depending on the ligand geometry and coordination propensity of the metal ion, which has been proved by the reports of a large number of silver MOFs.[7]

Silver(I) ion principally exhibits linear, trigonal, and tetrahedral coordination and has high affinity for hard donor atoms such as nitrogen or oxygen atoms and soft donor atoms such as sulfur atoms, being a favorable and fashionable building block for MOFs.[8] Furthermore, silver ion is apt to form short Ag···Ag contacts as well as ligand unsupported interactions, which have been proved to be two of the most important factors contributing to the formation of such complexes and special properties.[9–11] Previous works[12,13] have proved rigid benzene-multicarboxylic acids, such as 1,4-benzenedicarboxylic acid, 1,3,5-benzenetricarboxylic acid, and 1,2,4,5-benzenetetracarboxylic acid, are a good choice for the construction of MOFs owing to their versatile coordination modes. However, although many benzene multicarboxylate-bridged MOFs have been reported, those on a silver(I) ion are relatively rare, probably because of their low solubility, which makes structural analyses difficult.[14–16] Compared with benzene multicarboxylic acid, cyclohexane multicarboxylic acid not only has advantages over the former such as having rich coordination modes, being the hydrogen-bond donors and acceptors as well as possessing potential high symmetries, but also

has more conformations and flexibility, which remain largely unexplored for constructing 3D MOFs. Cyclohexanedicarboxylates and cyclohexanetricarboxylates are therefore regarded as excellent candidates for the construction of multidimensional MOFs.[17] Although one could anticipate that 1,2,3,4,5,6-cyclohexanehexacarboxylic acid ($H_6L$) will be applied as a more flexible ligand than cyclohexanedicarboxylates and cyclohexanetricarboxylates in the construction of functional MOFs (Scheme 1), its coordination chemistry has not been explored until now. Herein, we report the creation of two interesting silver(I) complexes with robust argentophilic interactions by the self-assembled reaction of *cis*,*cis*,*cis*,*cis*,*cis*-1,2,3,4,5,6-cyclohexanehexacarboxylic acid ($H_6L$) with freshly synthesized $[Ag(NH_3)_2](OH)$, $[Ag_3(H_3L)(H_2O)_2]_n{\cdot}2nH_2O$ (**1**), and $[Ag_6L(NH_3)(H_2O)_3]_n{\cdot}nH_2O$ (**2**). Complex **1** is a 3D MOF with 1D rectangular channels surrounded by carboxylato-supported Ag–Ag dimers, Ag–Ag chains and half deprotonated $\mu_8$-$[H_3L]^{3-}$ bridges, and water molecules in the channels forming interesting hydrogen-bonded water tapes of eight- and four-membered rings; while **2** is a 3D MOF constructed with two types of Ag–Ag chains with Ag8 cluster units and linear Ag4 units, respectively, and fully deprotonated $\mu_{13}$-$L^{6-}$ bridges.

## Results and Discussion

### Synthesis and Characterization

As is well known, the reactions of silver(I) ion with multicarboxylates in aqueous solution often result in the formation of insoluble 'silver salts', presumably because of the fast coordination of the carboxylates to silver ion to form polymer structures. Mak and co-workers pioneered the generation of polymeric structures in silver(I)-carboxylate-like complexes by using various zwitterionic betaine ligands.[18] Smith and co-workers[19] obtained a series of Ag–multicarboxylate complexes by using ammoniacal conditions to enhance the solubility of the silver carboxylates. Michaelides and co-workers[14b] reported a novel succinatodisilver(I) complex that was synthesized by gel permeation. Hence, properly tuning the reaction conditions may result in the formation of appropriate crystalline products for X-ray structural analysis. Considering this, we tried reactions of freshly synthesized $[Ag(NH_3)_2](OH)$ and the $H_6L$ ligand in various molar ratios [Equations (1), (2), and (3)].

$$Ag_2O + 4NH_3 + 2H_2O = 2[Ag(NH_3)_2](OH) \quad (1)$$

$$3n[Ag(NH_3)_2](OH) + nH_6L + nH_2O = [Ag_3(H_3L)(H_2O)_2]_n{\cdot}2nH_2O + 6nNH_3 \quad (2)$$

$$6n[Ag(NH_3)_2](OH) + nH_6L = [Ag_6L(NH_3)(H_2O)_3]_n{\cdot}nH_2O + 2nH_2O + 11nNH_3 \quad (3)$$

We first selected the molar ratio of $[Ag(NH_3)_2](OH)/H_6L$ = 3:1, resulting in the formation of complex **1**, which possesses a 3D microporous MOF structure filled with water molecules. As anticipated, only half of the carboxylate groups are deprotonated and the others form intra- or intermolecular hydrogen-bond interactions with the deprotonated ones, which may be attributed to the *cis* conformation of the ligand. The carboxylate groups lie alternately on the axial position and on the equatorial position, which is useful for the formation of intramolecular hydrogen-bonded interactions.

As the self-assembly of the frameworks is greatly influenced by factors such as the solvent system,[3a,20a] the template,[16] the pH value of the solution,[20b,20c] and the steric requirement of the counterion,[21] some changes in the reaction conditions may result in significantly different final reaction products. The successful isolation of **1**, in which not all the carboxylate groups are deprotonated, prompted us to extend our study to change the molar ratio of $[Ag(NH_3)_2](OH)/H_6L$. As expected, when the molar ratio of $[Ag(NH_3)_2](OH)/H_6L$ was increased to 6:1, all the carboxylate groups were deprotonated and then complex **2** was obtained. Furthermore, we attempted to change the silver(I) salts and solvents such as MeOH or EtOH, and raise the pH values in order to prepare different silver MOFs. However, the same product as **2** was obtained, although the yields were somewhat different or precipitates were obtained when treated by other silver(I) salts at higher pH values, suggesting that the proper pH value and molar ratio of the reactants play a vital role in the formation of the products. It should be noted that, in our recently synthesized 3D MOFs $[M_3(trans\text{-}L)(H_2O)_6]_n$ (M = $Co^{2+}$, $Mn^{2+}$, and $Fe^{2+}$; $[trans\text{-}L]^{6-}$ = *trans*,*trans*,*trans*,*trans*,*trans*-1,2,3,4,5,6-cyclohexanehexacarboxylate),[22] the fully deprotonated $L^{6-}$ ligand changed its *cis* conformation to *trans* conformation under hydrothermal conditions, while in **1** and **2**, the half and fully deprotonated L ligands keep their *cis*,*cis*,*cis*,*cis*,*cis* conformation, which may be ascribed to the cooperative effect of the intraligand hydrogen-bonding interaction and the metal coordination.

### Crystal Structure

X-ray crystallography has established that **1** is a 3D MOF structure with 1D rectangular channels along the *a*

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

axis. As illustrated in part (a) of Figure 1, each asymmetric unit in **1** contains three crystallographically unique silver(I) atoms, one $[H_3L]^{3-}$ ligand, two coordinated water molecules, and two lattice water molecules, all of which lie on general positions. The selected bond lengths and angles are listed in Table 1. Noticeably, the three deprotonated carboxylate groups of each $[H_3L]^{3-}$ ligand are located at the equatorial positions and the rest at the axial positions, in agreement with the IR spectrum, where the absorption peak is at around 1720 $cm^{-1}$ for the protonated carboxylic groups. Ag1 is coordinated in a greatly irregular geometry, by three oxygen atoms from three $[H_3L]^{3-}$ ligands [Ag1–O = 2.256(4)–2.584(4) Å, O–Ag1–O = 82.5(2)–162.4(2)°], an aqua ligand [Ag1–O1w = 2.457(5) Å, O–Ag1–O1w = 80.0(2)–116.1(2)°], as well as a Ag···Ag contact [2.916(1) Å]. The Ag1–Ag1*a* distance is significantly shorter than the van der Waals contact distance 3.40 Å,[23a] is comparable to the Ag···Ag separation (2.89 Å) in metallic silver, and twice the covalent radius of silver (1.455 Å for four-coordinate silver),[24] which provides supporting evidence for the significance of argentophilicity.[25] Similar Ag···Ag distances were found in silver benzenesulfonate (2.915 Å)[23b] and in the

succinatodisilver complex (2.938 and 3.104 Å).[14b] Ag2 adopts a slightly distorted Y-shaped geometry, coordinated by two oxygen atoms from two $[H_3L]^{3-}$ ligands [Ag2–O = 2.187(4) and 2.191(4) Å, O–Ag2–O = 153.8(2)°] and a weakly coordinated aqua ligand [Ag2–O2w = 2.632(6) Å, O–Ag2–O2w = 74.5(2) and 130.2(2)°] as well as two Ag···Ag contacts [2.916(1) and 3.162(1) Å]. Similarly, Ag3 also has a distorted Y-shaped geometry, surrounded by three oxygen atoms from three $[H_3L]^{3-}$ ligands [Ag3–O = 2.235(4)–2.542(5) Å, O–Ag3–O = 85.0(2)–142.3(2)°] as well as by two Ag···Ag contacts [3.162(1) and 3.329(2) Å]. Each $[H_3L]^{3-}$ ligand connects eight $Ag^{I}$ atoms through one protonated carboxylic group and three deprotonated carboxylato groups with $\mu_2$:$\eta^1$:$\eta^1$, $\mu_2$:$\eta^1$:$\eta^1$, and $\mu_3$:$\eta^2$:$\eta^1$ coordination modes, respectively (Figure 1, b). Two of the three protonated carboxylic groups of each $[H_3L]^{3-}$ ligand donate two strong intraligand hydrogen bonds to the deprotonated carboxylato groups, further stabilizing their *cis* conformation [O8···O9 = 2.564(6) Å, O8–H8O···O9 = 164(9)°; O12···O1 = 2.582(6) Å, O12–H12O···O1 = 160(9)°]. Moreover, there are rich intermolecular hydrogen-bond interactions between the protonated or deprotonated carboxylate groups with water molecules (Table 2). Two types of cluster units of Ag···Ag interactions exist: the carboxylato-supported Ag1···Ag1 dimer and the 1D carboxylato-supported Ag2···Ag3···Ag3···Ag2 chain unit (Figure 2, a and b). The distances of Ag2···Ag2*a*, Ag2···Ag3*a*, and Ag3···Ag3*d* are 2.916(1), 3.162(1), and 3.329(2) Å, respectively. Such robust Ag···Ag interactions make the silver(I) atoms form a silver chain running along the *a* axis direction supported by the $\mu_2$- and $\mu_3$-carboxylate bridges. These dimeric motifs and 1D Ag···Ag chains are connected by the $[H_3L]^{3-}$ ligands into an open MOF having a rectangular channel along the *a* axis direction (Figure 2, c). Water molecules are located at these channels and form 1D hydrogen-bonded water tapes[26] (Figure 3, a, b). There are cyclic $R_8^6(16)$ $(H_2O)_8$ and $R_4^4(8)$ $(H_2O)_4$ units with two water molecules shared between the adjacent circles, leading to a T4(2)8(2) water tape. The water tapes further donate hydrogen bonds to the deprotonated carboxylate groups of the host [O···O 2.738(7)–3.161(8) Å] (Table 2). Each water molecule is tetrahedrally surrounded by four hydrogen bonds or three hydrogen bonds and one Ag–$H_2O$ coordination bond (Figure 3, b). Other interesting water chains and tapes have been observed in MOF structures of $[(H_2O)_2\subset\{Ni(Hsglu)(H_2O)_2\}]\cdot H_2O$ [Hsglu = *N*-(2-hydroxybenzyl)-l-glutamic acid],[27a] apdo·$4H_2O$ (apdo = *trans*-4,4′-azopyridine dioxine),[27b] [Co(tartarate)(2,2′-bipy)·$5H_2O$],[27c] [Cu(DPA)$(CO_3)$]·$3H_2O$ (DPA = 2,2′-dipyridylamine),[27d] [Fe(2,2′-bipy)$_2$$(CN)_2$]·

$2.5H_2O$,[27e] and $[Co_2(ptc)(py)_2(H_2O)_4]\cdot 4H_2O$ (ptc = pyrazine-2,3,5,6-tetracarboxylate).[27f]

Complex **2** is also a 3D MOF structure with more complicated Ag···Ag interactions. As illustrated in Figure 4 (a), each asymmetric unit in **2** contains one formula unit, and therefore there are six crystallographically unique silver(I) atoms, one $L^{6-}$ ligand, one ammonia ligand, three aqua ligands, and one lattice water molecule, all of which lie in general positions. Compared with **1**, all the carboxylate groups are deprotonated, which is in agreement with the IR spectrum with no absorption peak around 1720 $cm^{-1}$. Ag1 and Ag3 have similar greatly distorted tetrahedral coordination geometries. They are coordinated by three carboxylato oxygen atoms from two $L^{6-}$ ligands [Ag1–O = 2.213(3)–2.587(3) Å, O–Ag1–O = 75.6(1)–134.0(1)°; Ag3–O = 2.229(3)–2.400(3) Å, O–Ag3–O = 79.0(1)–139.1(1)°] and an aqua ligand [Ag1–O1w = 2.340(4) Å, O–Ag1–O1w = 93.2(1)–132.8(1)°; Ag3–O3w = 2.340(4) Å, O–Ag3–O3w = 93.9(1)–126.7(1)°] as well as surrounded by two Ag···Ag contacts [3.0938(6) and 3.3396(8) Å for Ag1 and 2.9040(6) and 3.1645(6) Å for Ag3]. Ag2 is coordinated in a Y-shaped coordination geometry by two carboxylato oxygen atoms from different $L^{6-}$ ligands [Ag2–O = 2.196(3) and 2.335(3) Å; O–Ag2–O = 136.0(1)°] and an aqua molecule [Ag2–O2w = 2.320(4), O–Ag2–O2w = 87.7(1) and 135.3(1)°] as well as two relatively weak Ag···Ag contacts

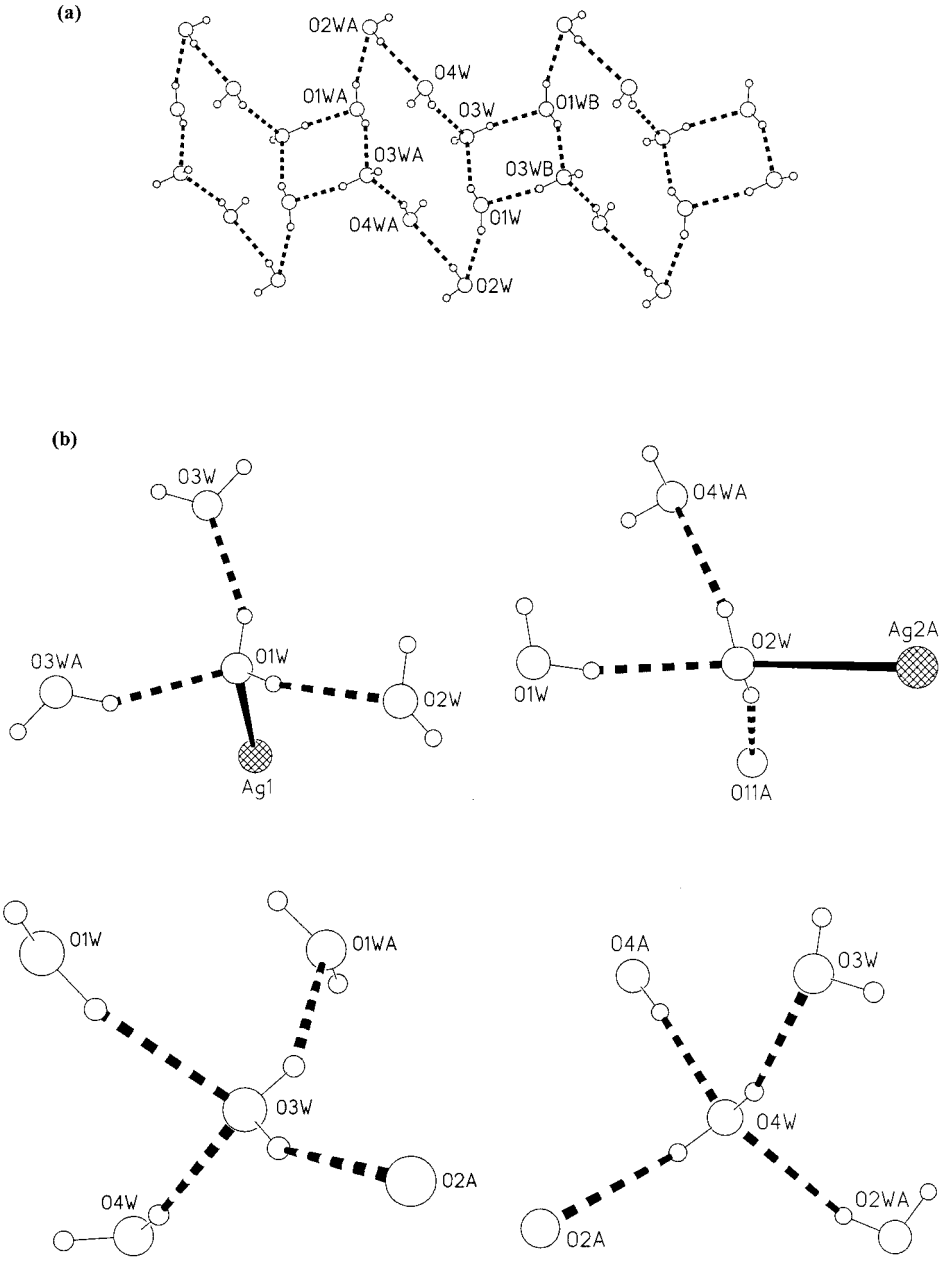

Figure 3. Perspective views showing 1D water tape (a) and the hydrogen-bonding modes of each water molecule (b) in **1**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[Ag2···Ag1*b* = 3.0938(6) Å, Ag2···Ag2*d* = 3.336(1) Å]. Ag4 and Ag6 have similar slightly distorted T-shaped coordination geometries. Ag4 is coordinated by three carboxylato oxygen atoms from three $L^{6-}$ ligands [Ag4–O = 2.166(3), 2.204(3), and 2.502(3) Å, O–Ag4–O = 97.7(1), 100.6(1), and 161.7(1)°], while Ag6 is coordinated by two carboxylato oxygen atoms from two $L^{6-}$ ligands and an ammonia ligand [Ag6–O/N = 2.125(4), 2.135(3), and 2.528(3) Å, O/N–Ag6–O = 93.5(1), 94.9(1), and 170.1(2)°]. Moreover, Ag4 and Ag6 are further surrounded by four and three Ag···Ag contacts, respectively [Ag···Ag = 2.9438(6)–3.3159(6) Å for Ag4 and 2.9438(6)–3.2021(8) Å for Ag6]. Ag5 adopts a nearly linear geometry, coordinated by two oxygen atoms from different $L^{6-}$ ligands [Ag5–O = 2.176(3) and 2.193(3) Å, O–Ag5–O = 166.5(1)°]. Interestingly, Ag5 is surrounded by five strong or weak Ag···Ag contacts [Ag···Ag = 2.9040(6)–3.3159(6) Å]. Most of these Ag···Ag interactions are slightly longer than that found in ternary silver-hexamethylenetetramine-carboxylato compounds (2.8154–2.9144 Å).[9b] Each $L^{6-}$ ligand connects 13 silver atoms (Figure 4, b) to generate a complicated 3D MOF structure.

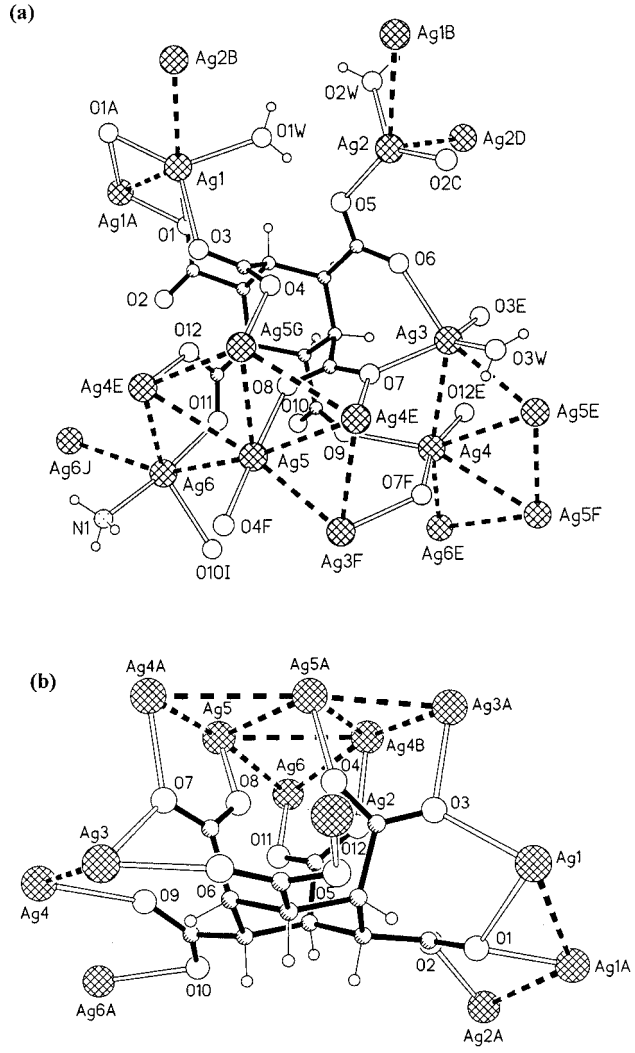

Figure 4. Perspective views showing the coordination environment of silver atoms (a) and the bridging mode of the $L^{6-}$ ligand (b) in **2**.

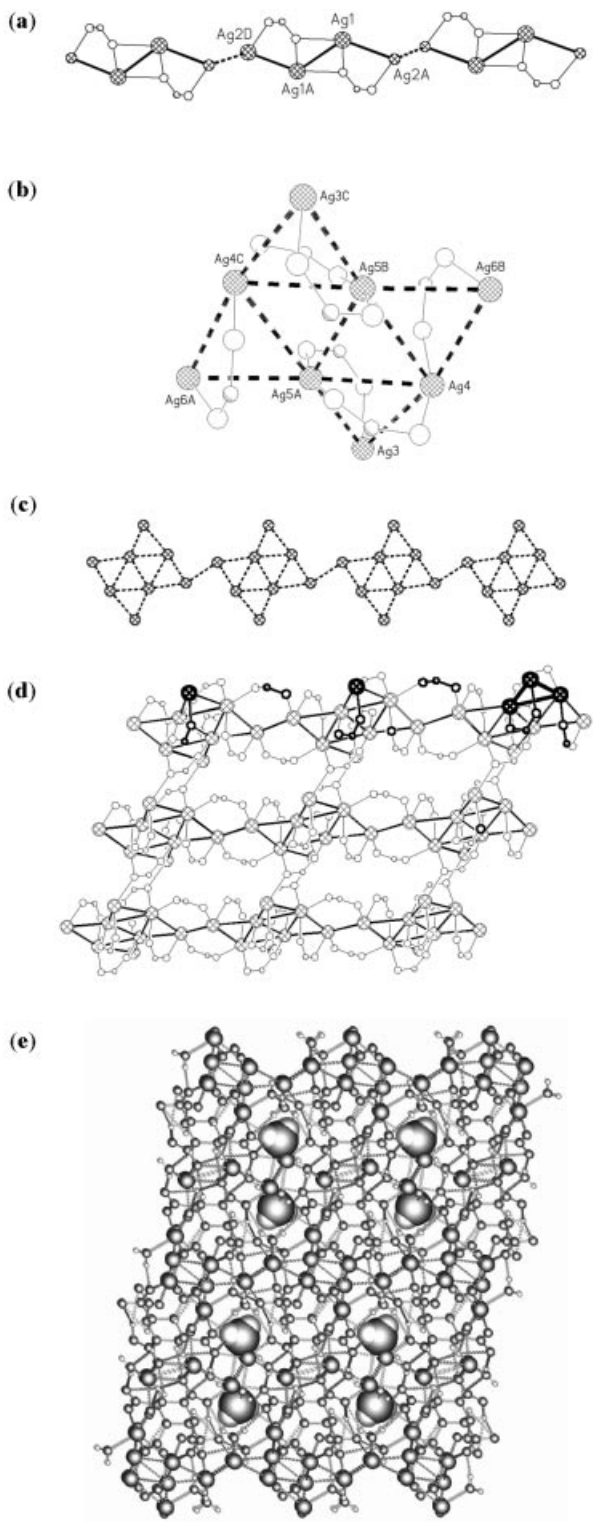

Figure 5. (a) The 1D silver chain constructed from Ag1 and Ag2 atoms by Ag···Ag interactions, (b) the $Ag_8$ cluster aggregated by Ag···Ag interactions, (c) the 1D silver chain constructed by $Ag_8$ clusters, (d) the 2D silver layer formed by the 1D silver chains and carboxylates along the *c* axis, and (e) the 3D MOF along the *b* axis direction in **2**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The Ag···Ag interactions in **2** are much more complicated and interesting than in compound **1**. As shown in Figure 5, the six crystallographically independent silver(I) atoms can be divided into two groups. Ag1 and Ag2 are connected by Ag···Ag interactions to generate 1D $\mu_3$-carboxylato-supported ···Ag1···Ag1···Ag2···Ag2··· silver(I) chains running along the *b* axis (Figure 5, a), while Ag3, Ag4, Ag5, and Ag6 are aggregated by complicated $\mu_2$-carboxylato-supported Ag···Ag interactions into 1D Ag···Ag tapes with a Ag8 cluster unit with six edge-sharing triangles (Figure 5b, c, d). Two of the six triangles constructed by Ag4, Ag4*a*, Ag5, and Ag5*a* are coplanar but others are somewhat out of the plane. The dihedral angles between this plane and the plane made of Ag3, Ag4, and Ag5*a* as well as the plane of Ag5, Ag6, and Ag4*a* by edge-sharing are 7.8 and 13.0°. Interestingly, the 1D Ag···Ag tapes are further connected by carboxylates into 2D layers along the *bc* plane (Figure 5, c), which are further extended by adjacent ···Ag1···Ag1···Ag2···Ag2··· silver(I) chains into a 3D MOF structure (Figure 5e). The lattice water molecules are located at the cavities of **2** and form rich hydrogen-bonding interactions with the MOF host [O4w···O4*a* = 3.039(5) Å, O4w–H4wa···O4*a* = 144(6)°; O4w···O5*a* = 2.970(6) Å, O4w–H4wb···O5*a* = 133(5)°; O4w···O10*g* = 2.650(5) Å, O4w–H4wb···O10*g* = 167(6)°; O1w···O4w = 2.772(5) Å, O1w–H1wa···O4w = 166(5)°; O2w···O4w = 2.811(6) Å, O2w–H2wb···O4w = 165(8)°].

### Thermogravimetric Analysis

In order to examine the thermal stabilities of the porous networks, we carried out thermogravimetric (TG) analyses and measurement of the XPRD patterns to confirm the purity of the two complexes (Figure 6). Samples of the complexes were heated to 600 °C with exposure to air. The TGA curve (Figure 7) of **1** shows that the first weight loss of 5.1% between 20 and 68 °C corresponds to a loss of the included water molecules (calculated: 4.9%), while the second weight loss of 2.4% between 68 and 93 °C is in accordance with the loss of one coordinated water molecule per unit cell (calculated: 2.5%), and the succeeding weight loss of 2.8% corresponds to another coordinated water molecule between 93 and 175 °C (calculated: 2.5%). Complex **1** began to decompose at 190 °C to yield the residue $Ag_2O$ at about 450 °C (found: 43.4%; calculated: 46.9%). The TGA curve of **2** shows that the first weight loss of 4.5% between 50 and 110 °C corresponds to the gradual loss of one included molecule, one coordinated water, and one coordinated ammonia molecule or two coordinated water molecules per unit cell (calculated: 4.8%), while the remaining water molecules were completely removed at 225 °C. Complex **2** began to decompose at 230 °C to yield the residue $Ag_2O$ at about 455 °C (found: 61.3%; calculated: 64.5%). Powder XRD patterns (Figure S2 in the Supporting Information) of the dehydrated samples of **1** and **2** indicate that removal of the guest molecules causes a significant structural change of crystalline to amorphous to the framework of **1** and **2**.

## Conclusion

Two new silver(I) compounds incorporating *cis*,*cis*,*cis*,*cis*,-*cis*,*cis*-1,2,3,4,5,6-cyclohexanehexacarboxylic acid ($H_6L$) have been successfully obtained, by controlling the molar ratio of the self-assembled reactions, and crystallographically characterized. Rich Ag···Ag interactions and versatile coordination modes of the half or fully deprotonated ligands ($[H_3L]^{3-}$ or $L^{6-}$) lead to two interesting microporous MOFs. Our work is the first to reveal that the $H_6L$ ligand is characteristic of multifunctional coordination sites and pH-dependent coordination fashions and has a much more important effect on the structures of MOFs.

## Experimental Section

**General Remarks:** The reagents and solvents employed were commercially available and used as received without further purification. The C, H, and N microanalyses were carried out with an Elementar Vario-EL CHNS elemental analyzer. The IR spectra were recorded from KBr pellets in the range 4000–400 $cm^{-1}$ with a Bio-Rad FTS-7 spectrometer. Powder X-ray diffraction (PXRD) intensities for **1** and **2** were measured at 293 K on a Rigaku D/max-IIIA diffractometer (Cu-$K_\alpha$, $\lambda$ = 1.54056 Å). The crushed single-crystalline powder samples were prepared by crushing the crystals and scanned from 5 to 60° with a step of 0.1°/s.

| $R$ indices (all data) | $R_1$ = 0.0494, $wR_2$ = 0.1165 | $R_1$ = 0.0315, $wR_2$ = 0.0618 |
| Largest diff. peak and hole [e/Å$^3$] | 2.803/–1.661 | 0.820/–0.751 |

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

**Synthesis of 1:** Excess aqueous $NH_3$ solution was dropped slowly into a suspension of $Ag_2O$ (0.087 g, 0.375 mmol) in MeCN/$H_2O$ (30 mL, v/v = 2:1) with magnetic stirring for 15 min. Then the powder of the ligand *cis*,*cis*,*cis*,*cis*,*cis*-1,2,3,4,5,6-cyclohexanehexacarboxylic acid (0.092 g, 0.25 mmol) was slowly added to the former solution and stirred for 30 min after being dissolved. The resultant solution was allowed to slowly diffuse in darkness at room temperature for several weeks to give colorless needle-like crystals. The crystals were isolated by deionized water and dried in air (yield 0.112 g, about 60% based on Ag). $C_{12}H_{17}Ag_3O_{16}$ (740.87): calcd. C 19.45, H 2.31; found C 19.69, H 2.34. IR (KBr) (400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3430 m, 2903 w, 2563 w, 1916 vw, 1717 vs, 1557 vs, 1460 vs, 1385 vs, 1316 s, 1240 s, 1206 s, 1160 m, 1028 m, 994 m, 894 m, 803 m, 760 m 687 m, 618 w, 495 w cm$^{-1}$.

**Synthesis of 2:** Complex **2** was prepared as described for **1** by only changing the molar ratio of $Ag_2O$ to $H_6L$ ligand from 1.5:1 to 3:1. Colorless prism-like crystals were isolated by deionized water and dried in air (yield 0.135 g, about 80% based on Ag). $C_{12}H_{17}Ag_6NO_{16}$ (1078.49): calcd. C 13.36, H 1.59, N 1.30; found C 13.47, H 1.58, N 1.22. IR (KBr) (400–4000 cm$^{-1}$): $\tilde{\nu}$ = 3354 m, 3320 m, 3259 m, 3181 m, 1545 vs, 1386 vs, 1319 s, 1203 m, 1166 m, 1032 w, 994 w, 916 w, 844 m, 767 m, 692 m, 591 m, 523 w cm$^{-1}$.

**X-ray Crystallographic Study:** Single crystals of complexes **1** and **2** with approximate dimensions 0.21×0.20×0.14 mm$^3$ (**1**) and 0.20×0.30×0.26 mm$^3$ (**2**) were used for X-ray diffraction analyses. The crystals were mounted on the end of a thin glass fiber using an inert epoxy gel. Data collection of **1** and **2** was performed with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) with a Bruker Apex CCD diffractometer at 123(2) K. The raw data frames were integrated with SAINT$^+$, which also applied corrections for Lorentz and polarization effects. Absorption corrections were applied by using the multiscan program SADABS.[28] The structures were solved by direct methods, and all non-hydrogen atoms were refined anisotropically by least-squares on $F^2$ using the SHELXTL program.[29] Hydrogen atoms on organic ligands were generated by the riding mode (C–H bond length: 0.98 Å); the water, hydroxy, and ammonia hydrogen atoms were located from difference maps, and refined with nominal geometric restraints [O–H 0.85(1), N–H 0.90 Å]. Selected bond lengths and bond angles are listed in Table 1. A summary of the crystal data is given in Table 3.

CCDC-291579 (for **1**) and -291580 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): The supporting information contains the IR spectra for compounds **1** and **2**, and the powder XRD of the dehydrated samples of **1** and **2**.

# Single-Electron Oxidation of Tungsten Acetylide Complexes $[(\eta^5\text{-}C_5H_5)(CO)(NO)W\text{–}C{\equiv}C\text{–}R]Li$

**Junes Ipaktschi*[a] and Frank Munz[a]**

**Keywords:** Tungsten / Alkyne ligands / Oxidation / Bridging ligands / Metal–metal interactions

The reaction of a tungsten acetylide complex $[(\eta^5\text{-}C_5H_5)(CO)(NO)W\text{–}C{\equiv}C\text{–}R]Li$ (**1**) [**1a**, R = $C_6H_5$; **1b**, R = $C(CH_3)_3$; **1c**, R = $Si(CH_3)_3$] with one equivalent of ferrocenium tetrafluoroborate $[Cp_2Fe][BF_4]$, acting as a one-electron oxidant in THF at –50 °C, leads to the bimetallic tungsten–alkynyl complexes $[(\eta^5\text{-}C_5H_5)(NO)W\text{–}C{\equiv}C\text{–}R]_2$ (**9**) [**9a**, R = $C_6H_5$; **9b**, R = $C(CH_3)_3$; **9c**, R = $Si(CH_3)_3$] as pale-orange crystals. The crystal structure of complex **9a** is reported.

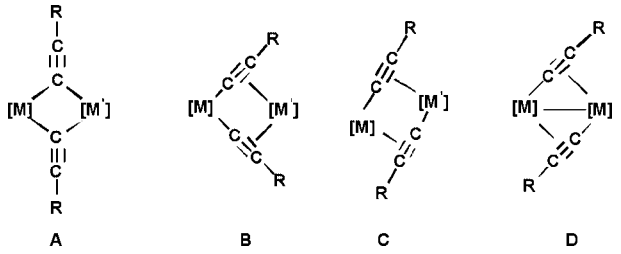
## Introduction

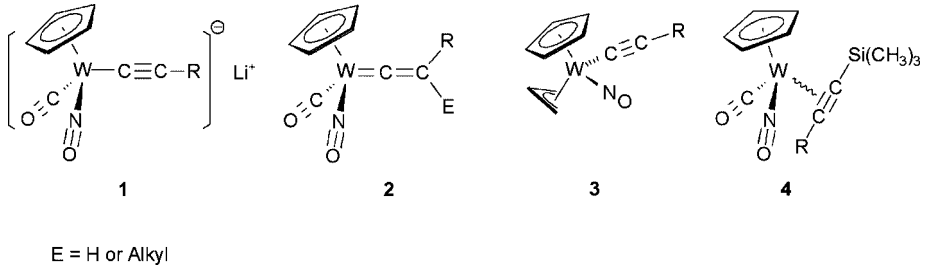
The chemistry of transition-metal acetylides M–C≡C–R and $\eta^2$-acetylene complexes has been the subject of much attention in the past years.[1] The nature of the metal–carbon bond in these systems and the possibility of conversion of alkynyl complexes to other organometallic derivatives, such as $\eta^1$-vinylidene complexes, are the subject of many investigations.[2] Furthermore, the fascinating properties of some alkynyl complexes in the field of materials science as possible nonlinear optical or luminescent materials as well as polymeric compounds have attracted much interest in recent years.[3]

As a strong σ-donor, the alkynyl group has a strong tendency to bind terminally to a main-group-metal- or transition-metal center. In the presence of a second metal atom, an alkynyl group can act either as a σ-donor to both metals (structure **A**, Scheme 1), or preferably as a σ-donor to one metal and a π-donor to the other metal center (structures **B** or **C**), depending on the nature of the metal and the ligands.[4,5] In this paper we describe the formation of binuclear σ,π-acetylide bridged complexes of type **D**, a structure analogous to **C** and additionally containing a tungsten–tungsten σ-bond.[6]



Scheme 1.

In a series of publications we have described the richly faceted chemistry of the σ-acetylide complexes $[(\eta^5\text{-}C_5H_5)(CO)(NO)W\text{–}C{\equiv}C\text{–}R]Li$ (**1**).[7] The preferred reacti-



Scheme 2.

vity mode of these $\eta^1$-acetylide complexes is the addition of "hard" electrophiles $E^+$, such as a proton or alkylating reagents e.g. methyl triflate, to the β-carbon atom, which generates the corresponding $\eta^1$-vinylidene complexes **2**.[7g]

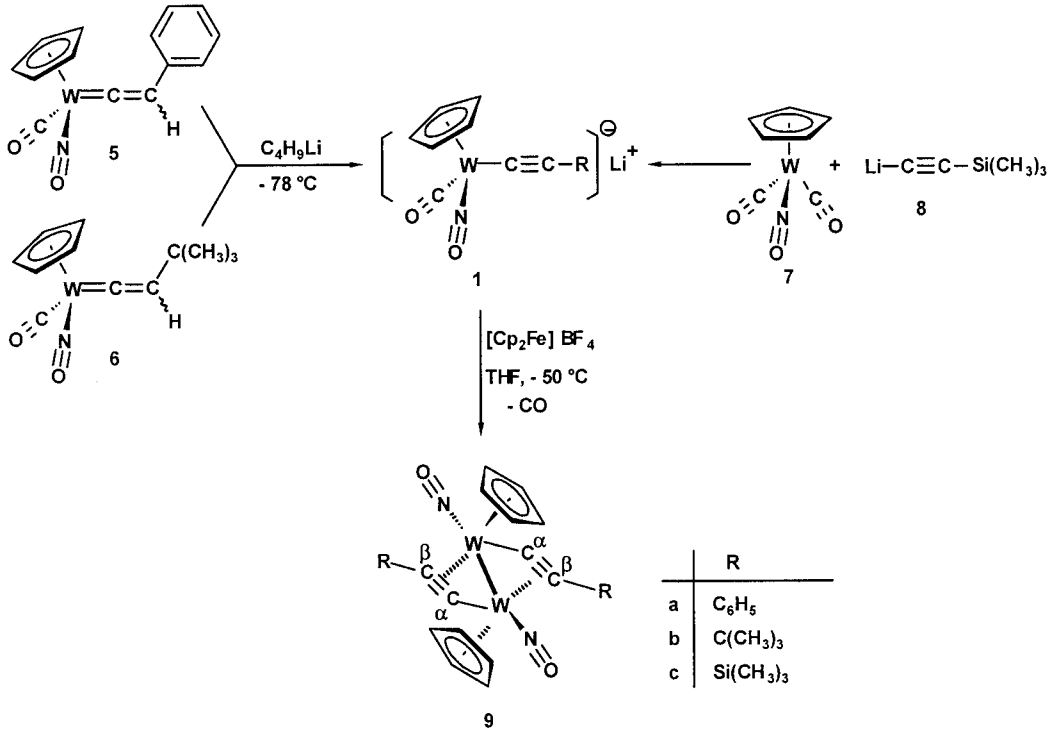
The addition of "soft" electrophiles, such as allyl iodide, furnishes complex **3**[7f] by allylation of the metal center, and $\eta^2$-acetylene complexes such as **4** are formed by reaction with trimethylsilylchloride (Scheme 2).[7g] The single-electron oxidation of this tungsten σ-acetylide complex by ferrocenium tetrafluoroborate $[Cp_2Fe][BF_4]$ is the subject of the present study.

## Results and Discussion

The reactants $[(\eta^5\text{-}C_5H_5)(CO)(NO)W\text{–}C{\equiv}C\text{–}R]Li$ [**1a**, R = $C_6H_5$; **1b**, R = $C(CH_3)_3$; **1c**, R = $Si(CH_3)_3$] were prepared as described previously,[7] either by the deprotonation of $\eta^1$-vinylidene complexes **5** and **6**, or alternatively by the reaction of lithium $\eta^1$-acetylide **8** with the tungsten–carbonyl complex **7**. Reaction of an emerald-green solution of **1** in THF at –50 °C with 1 equiv. of $[Cp_2Fe][BF_4]$, was monitored by IR spectroscopy. After 2 h the typical $\tilde{\nu}$(CO) band for the acetylide **1** (≈1870 $cm^{-1}$) disappeared while a new band characteristic for the C≡C group, in the range 1820–1852 $cm^{-1}$, appeared. Workup of the dark-red solution resulted, after purification through chromatography, in the formation of binuclear complexes **9a**–**c** as orange crystals in 25–54% yield (Scheme 3). The complexes **9a**–**c** are sparingly soluble in $CHCl_3$ and $CH_2Cl_2$ and can be stored under inert gas at –20 °C.

The unequivocal characterization of complexes **9a**–**c** was achieved by means of elemental analysis and by standard spectroscopic techniques. The structure of the products is further confirmed by the result of the single-crystal structure analysis of complex **9a**. In the IR spectrum, the signal for the $\tilde{\nu}$(C≡C) stretch of **9c** at 1820 $cm^{-1}$ and similar IR bands for complexes **9a** (1847 $cm^{-1}$) and **9b** (1852 $cm^{-1}$) are in accordance with the related absorptions of the zirconocene complexes $[(RCp)_2Zr]_2(\mu\text{-}C{\equiv}C\text{–}R)_2$[5a,5c] (1770–1820 $cm^{-1}$) and the bimetallic tungsten–iron complexes $\{[(\eta^5\text{-}C_5H_5)\text{-}\mu\text{-}(CO)(NO)W][(\eta^5\text{-}C_5H_5)(CO)Fe\text{–}C{\equiv}C\text{–}R]\}$ (1861–1908 $cm^{-1}$).[8] The decrease in the $\tilde{\nu}$(C≡C) stretching frequency of **9c** is a result of the strong electron back-donation $Si{\leftarrow}C_\pi$.[9] Additionally, the IR spectra of complexes **9a**–**c** show for the nitrosyl ligand, as expected, a strong and broad signal in the 1553–1560 $cm^{-1}$ region. At ambient temperature, the $^1H$- and $^{13}C$ NMR spectra of complexes **9b** and **9c** show two singlets for both the Cp ligand and for the methyl groups, in the ratio 6:1 and 5:1 for **9b** and **9c**, respectively, indicating the presence of two isomers. Besides these signals, the most informative absorptions in the $^{13}C$ NMR spectra are the signals for the α-carbon atoms at $\delta$ = 167.7 ppm (**9b**) and 197.9 ppm (**9c**) and for the β-carbon atoms at $\delta$ = 124.4 ppm (**9b**) and 108.1 ppm (**9c**), which are characteristic for the π-bridging acetylide ligand.[8] Because of the β-effect of the $(CH_3)_3Si$ group in complex **9c**, the singlet of the α-carbon atom appears at lower-field. We believe that the minor signals of the Cp ligands and methyl groups present in the NMR spectra can be attributed to a stereoisomer of **9b** and **9c**, with (*Z*)-orientation of the cyclopentadienyl rings.[8]

Contrary to complexes **9b** and **9c**, the $^1H$ NMR spectrum of complex **9a** shows at room temperature, for the cyclopentadienyl ligand, one singlet at $\delta$ = 5.71 ppm, and in the $^{13}C$ NMR spectrum, a broad signal with low intensity at $\delta$ = 98.3 ppm. Signals for the acetylide carbon atoms were not detectable. Low-temperature $^{13}C$ NMR spectroscopy of this



Scheme 3.

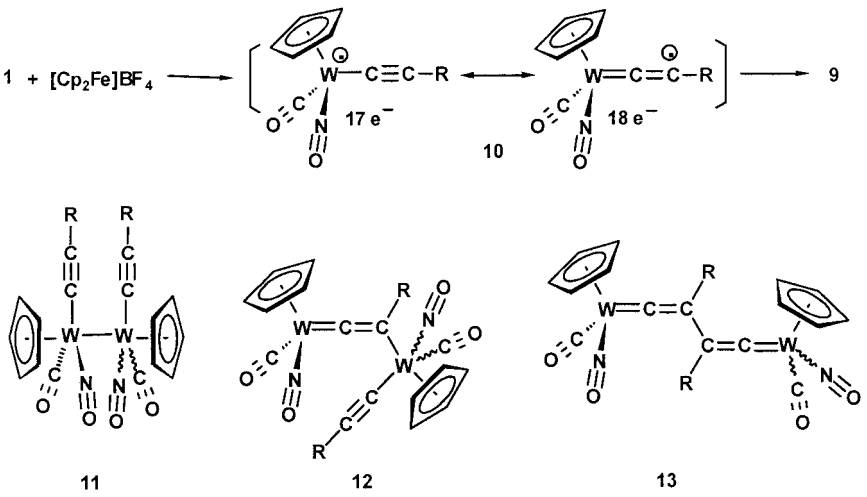

Scheme 4.

complex in $CD_2Cl_2$ at –40 °C revealed sharp singlets for the Cp-carbon atoms ($\delta$ = 98.0 ppm), the α-carbon atom ($\delta$ = 177.3 ppm), and the β-carbon atom ($\delta$ = 112.2 ppm). Additionally, a small signal appeared at $\delta$ = 97.5 ppm, and was attributed to the Cp ligand of a second minor stereoisomer. Increasing the temperature to 90 °C ([$D_2$]-1,1,2,2-tetrachloroethane) also resulted in the sharpening and increased relative intensity of the Cp signal, as well as in the emergence of a signal for the β-carbon atom.[10] The observed dynamic features of complex **9a** are not yet fully understood. One possible explanation would be an (*E*/*Z*) isomerization at the metal center by the reversible opening of the tungsten–tungsten bond.

## Mechanistic Considerations

As expected, the single-electron oxidation of the 18-electron tungsten–alkynyl complex **1** generates the reactive species **10**, which can be represented by resonance structures of a 17-electron metal-centered radical and an 18-electron carbon-centered radical (Scheme 4). As a result of metal-centered reactivity, the 17-electron radical dimerizes to form **11**, which has a metal–metal bond. Subsequent elimination of carbon monoxide leads to the binuclear 18-electron complexes **9a**–**c** with bridged σ,π-acetylide ligands. Products such as **12** and **13**, which could be formed by an alternative path through dimerization of radical **10**, could not be detected.[11,12]

## Molecular Structure of 9a

The structure of **9a** is further supported by single-crystal X-ray diffraction analysis. Single crystals were obtained by slow diffusion of *n*-pentane into a dichloromethane solution of **9a** at –20 °C. The crystal parameters, data collection parameters, and conditions for structure refinement are summarized in Table 1. Selected bond lengths and angles are given in Table 2. The ORTEP drawing with atomic numbering scheme is provided in Figure 1. Complex **9a** crystallizes in a $C_{2h}$-symmetric molecular structure with a planar arrangement of the atoms W(1)–C(6)–W(1$^{\#}$)–C(6$^{\#}$), which have a dihedral angle of 0° and an angle of 163.4° for W(1)–

## Experimental Section

**General Procedures:** All operations were carried out under argon. All solvents were purified by standard techniques. Literature methods were used to prepare **5**, **6**,[7g] **7**,[16] and [$Cp_2Fe$][$BF_4$].[17] NMR spectra were recorded with a Bruker AM 400 spectrometer. $^1$H NMR spectra were measured at 400 MHz, $^{13}$C NMR spectra were measured at 100 MHz. Proton and carbon-13 chemical shifts are relative to TMS. IR spectra were recorded with a Bruker FT-IR IFS 85. Microanalyses were done with a Carlo–Erba 1104 elemental analyzer.

**Preparation of [(η$^5$-$C_5H_5$)(NO)W–C≡C–$C_6H_5$]$_2$ (9a):** *n*BuLi (1 mmol) in hexane was added to a solution of [(η$^5$-$C_5H_5$)(CO)(NO)W=C=CH($C_6H_5$)] (**5**) (409 mg, 1 mmol) in THF (30 mL) at –78 °C. The resulting emerald-green solution was stirred for 15 min and then warmed up to –50 °C. [$Cp_2Fe$][$BF_4$] (273 mg, 1 mmol) was added in small portions to the solution over 30 min and stirred for 2 h. The color of the solution changed from green to dark red. After removing the solvent under reduced pressure at low temperature (–10 °C), the crude product was extracted several times with pentane to remove ferrocene. Chromatography of the residue on silica gel with pentane/diethyl ether (1:1), followed by crystallization from $CH_2Cl_2$ layered with pentane, gave 130 mg (39%) of complex **9a** as orange crystals [m.p. 252 °C (dec.)]. $C_{26}H_{20}N_2O_2W_2$ (760.16): calcd. C 41.08, H 2.65, N 3.68; found C 41.09, H 2.23, N 3.84. $^1$H NMR (400 MHz, $CDCl_3$, r.t.): δ = 7.90–7.83 (m, 4 H, Ph), 7.53–7.38 (m, 6 H, Ph), 5.71 (s, 10 H, Cp) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, r.t.): δ = 131.9, 131.4, 128.98, 128.5 (4s, Ph), 111.7 (s, $C_β$), 98.3 (br. s, Cp) ppm. IR (KBr): ṽ = 1847 (C≡C), 1553 (NO) cm$^{-1}$. MS (70 eV): *m*/*z* = 760 [M$^+$, $^{184}$W]. HRMS: calcd. for $C_{26}H_{20}N_2O_2{}^{182}W_2$ [M$^+$] 756.0489; found 756.0474.

**Preparation of [(η$^5$-$C_5H_5$)(NO)W–C≡C–C($CH_3$)$_3$]$_2$ (9b):** The reaction was carried out as described for **9a** by using [(η$^5$-$C_5H_5$)(CO)(NO)W=C=CH{$C(CH_3)_3$}] (**6**) (389 mg, 1 mmol) instead of **5**. Chromatography followed by crystallization yielded 90 mg (25%) of the product as orange crystals [m.p. 245 °C (dec.)]. $C_{22}H_{28}N_2O_2W_2$ (720.18): calcd. C 36.69, H 3.91, N 3.88; found C 36.45, H 3.59, N 3.30. $^1$H NMR (400 MHz, $CDCl_3$, r.t.): δ = 5.69, 5.65 (2 s, 6:1, 10 H, Cp), 1.58 and 1.54 (2 s, 6:1, 18 H, $CH_3$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, r.t.): δ = 167.7 (s, $C_α$), 124.5 [t, $^2J$($^{183}$W–$^{13}$C) = 29.6 Hz] and 123.9 (s) (2 $C_β$), 97.0 and 96.1 (2 s, 2 Cp), 37.9 and 37.5 [2 s, *C*($CH_3$)$_3$], 33.2 and 32.7 (2 s, $CH_3$) ppm. IR (KBr): ṽ = 1852 (C≡C), 1560 (NO) cm$^{-1}$. MS (70 eV): *m*/*z* = 720 [M$^+$, $^{184}$W]. HRMS: calcd. for $C_{22}H_{28}N_2O_2{}^{182}W_2$ [M$^+$] 716.1115; found 716.1107.

**Preparation of [(η$^5$-$C_5H_5$)(NO)W–C≡C–Si($CH_3$)$_3$]$_2$ (9c):** *n*BuLi (1.2 mmol) in hexane was added to a solution of ethinyltrimethylsilane (0.167 mL, 1.2 mmol) in THF (15 mL) at –78 °C. The resulting green solution of the tungsten acetylide [(η$^5$-$C_5H_5$)(NO)(CO)W–C≡C–Si($CH_3$)$_3$]Li (**1c**) was transferred dropwise to a precooled (–30 °C) solution of [(η$^5$-$C_5H_5$)(CO)$_2$(NO)W] (**7**) (335 mg, 1 mmol) in THF (15 mL) and stirred for 3 h. The green solution was treated, as above, with [$Cp_2Fe$][$BF_4$] (273 mg, 1 mmol). Removal of the solvent followed by recrystallization yielded 208 mg (54%) of complex **9c** as orange crystals [m.p. 243 °C (dec.)]. $C_{20}H_{28}N_2O_2Si_2W_2$ (752.33): calcd. C 31.93, H 3.75, N 3.72; found C 31.64, H 3.40, N 3.85. $^1$H NMR (400 MHz, $CDCl_3$, r.t.): δ = 5.69 and 5.64 (2 s, 5:1, 10 H, Cp), 0.46 and 0.44 (2 s, 5:1, 18 H, $CH_3$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, r.t.): δ = 197.9 (s, $C_α$), 108.1 (s, $C_β$), 97.2 and 96.2 (2 s, Cp), 1.6 and 1.2 (2 s, $CH_3$) ppm. IR (KBr): ṽ = 1820 (C≡C), 1560 (NO) cm$^{-1}$. MS (70 eV): *m*/*z* = 752 [M$^+$, $^{184}$W]. HRMS: calcd. for $C_{20}H_{28}N_2O_2Si_2{}^{182}W_2$ [M$^+$] 748.0653; found 748.0643.

CCDC-602108 contains the supplementary crystallographic data for compound **9a**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# An Experimental and Density Functional Study of the Interaction of $Cu^{II}$ Complexes of Diethylenetriamine (Dien) with Pyridine, Nicotinic Acid, and Nicotinamide: The Crystal Structure of [Cu(dien)(nicotinamide)$(NO_3)_2$]

**Panagiotis A. Papanikolaou,[a] Panagiotis C. Christidis,[b] Aikaterini Th. Chaviara,[a] Christos A. Bolos,*[a] and Athanassios C. Tsipis*[c]**

**Keywords:** Copper / Density functional calculations / N ligands / Thermal analysis

The reaction of pyridine (py), nicotinamide (nica), nicotinic acid (nic), and its nicotinate anion ($nic^-$) with [Cu(dien)$X_2$] (dien = diethylenetriamine; X = $Br^-$, $NO_3^-$) in a 1:1 molar ratio affords the new compounds [Cu(dien)(py)$(NO_3)_2$], [Cu(dien)(nica)$(NO_3)_2$], [Cu(dien)($nic^-$)$(NO_3)(H_2O)$]·$H_2O$, [Cu(dien)($nic^-$)(Br)$(H_2O)$]·$2H_2O$, and [Cu(dien)$(NO_3)$($nic^-$)(Guo)]·$5H_2O$. These compounds were characterized by elemental analysis, and their molecular structures were determined by spectroscopic methods (infrared and electronic spectra), magnetic susceptibility, and molar conductivity measurements, and further corroborated by geometry optimization using electronic structure calculation methods at the B3LYP/6-31G(d,p) level of theory. The structural, bonding and electronic properties of the complexes are adequately described by B3LYP computational techniques. According to the experimental data, the complexes can be characterized in the solid state as mononuclear, with a distorted octahedral stereochemistry. The distorted octahedral stereochemistry adopted by the complexes was further confirmed by the X-ray structure analysis of [Cu(dien)(nica)$(NO_3)_2$], which consists of a six-coordinate Cu atom in a distorted octahedral environment constructed from four N atoms (three from dien and one from nica) and two O atoms from the loosely associated $NO_3^-$ counteranions, with the former occupying the equatorial square plane of the octahedron and the latter the axial positions, Cu–O bond lengths being rather long (2.373 and 2.858 Å, respectively). Some substitution reactions have also been studied and are discussed in light of the electronic structure of the complexes computed at the B3LYP/6-31G(d,p) level.

## Introduction

Nicotinamide (nica) and nicotinic acid (nic) are two of most extensively studied pyridine derivatives. The former is a component of the vitamin B complex and of the vital coenzyme NAD (nicotinamide adenine dinucleotide),[1] and is a typical N-donor ligand system in crystal engineering.[2] Furthermore, early administration of nicotinamide has been reported to impair learning and memory in mice.[3] The medicinal chemistry of nicotinamide in the treatment of ischemia and reperfusion has also developed rapidly in the past few years. Nicotinic acid has a wide-ranging ability to reduce lipid levels, but its clinical uses are restricted due to its various side-effects. Nicotinic acid and nicotinamide form niacin, a water-soluble vitamin that reduces VLDL cholesterol and increases HDL cholesterol (the so-called "good" cholesterol).[4] Moreover, coordination compounds of nicotinic acid, nicotinamide, and their derivatives are known to have antiviral or antibacterial activity,[5,6] and they also selectively affect tumor tissues.[7]

Preliminary toxicity and anticancer results of diethylenetriamine (dien)–$Cu^{II}$ mixed-ligand complexes with nicotinic acid (nic) and nicotinamide (nica) ligands encouraged us to thoroughly study such complexes. In effect, what we want to address here is the synthesis and the structural, bonding, electronic, and spectroscopic properties of a number of new compounds resulting from interaction of [Cu(dien)$X_2$] (X = $Br^-$, $NO_3^-$) with pyridine (py), nicotinic acid, and nicotinamide. The electronic structure and bonding of the new complexes was inferred from electronic structure calculation methods at the DFT level.

## Results and Discussion

### Synthesis

The synthetic procedures used to prepare the new complexes can be divided into two categories: the first method is based on the reaction of [Cu(dien)$(NO_3)_2$] with nicotinic acid (nic), nicotinamide (nica), or pyridine (py), while the second one involves the reaction of deprotonated nic ($nic^-$)

with [Cu(dien)$(NO_3)_2$] (**1**) or [Cu(dien)$Br_2$] (**2**). Both syntheses were performed in methanol using a 1:1 molar ratio of the reactants. The new $Cu^{II}$ complexes, formulated as [Cu(dien)(py)$(NO_3)_2$] (**3**), [Cu(dien)(nica)$(NO_3)_2$] (**4**), [Cu(dien)($nic^-$)$(NO_3)(H_2O)$]·$H_2O$ (**5**), [Cu(dien)($nic^-$)(Br)-$(H_2O)$]·$2H_2O$ (**6**), and [Cu(dien)$(NO_3)$($nic^-$)(Guo)]·$5H_2O$ (**7**), are paramagnetic, as expected from the $d^9$ electron configuration of the $Cu^{II}$ central atom, blue in color, and stable in air. They are soluble in water and other coordinating solvents such as DMF and DMSO, slightly soluble in alcohols, but insoluble in common organic solvents.

## Spectroscopy

The salient structural features of the new complexes were determined by spectroscopic methods (infrared and electronic spectra), while details of the structures were obtained by the X-ray structural investigation of a representative complex, namely [Cu(dien)(nica)$(NO_3)_2$] (**4**). In the IR spectra of the precursor complexes [Cu(dien)$(NO_3)_2$] (**1**) and [Cu(dien)$Br_2$] (**2**) the absorption bands at around 3270 and 3233 $cm^{-1}$ are attributed to the antisymmetric and symmetric stretching vibration of the primary and secondary amino group of dien, respectively, thus confirming the tridentate coordination bonding mode of the ligand.[9] In the IR spectrum of [Cu(dien)(py)$(NO_3)_2$] (**3**), the ν(C=N) stretching vibration at 1608 $cm^{-1}$ is shifted towards lower frequencies with respect to that of the free pyridine (1622 $cm^{-1}$), thereby indicating coordination of the pyridine through the endocyclic nitrogen atom. The same also holds true for the rest of the complexes involving the nic and $nic^-$ ligands. In contrast, upon coordination of the nica ligand the absorption band at 1593 $cm^{-1}$ is shifted slightly towards higher frequencies (1603 $cm^{-1}$), in line with previous observations.[10] The new bands at around 520–535 $cm^{-1}$ due to ν(Cu–N) stretching vibrations[11] confirm the N-coordination of py and its derivatives through the endocyclic nitrogen atom. In addition, the experimental ν(C=O) stretching vibration of the free nicotinamide ligand appearing at 1681 $cm^{-1}$ is slightly shifted to higher frequencies (1693 $cm^{-1}$) upon coordination to the metal center in [Cu(dien)(nica)$(NO_3)_2$] (**4**), in line with previous studies.[12–14] In the IR spectrum of nicotinic acid the ν(C=O) stretching vibration absorbing at 1709 $cm^{-1}$[15,16] is shifted to lower frequencies (1661–1668 $cm^{-1}$) upon coordination, regardless of the deprotonation of the ligand. Moreover, the IR spectra of [Cu(dien)-$(NO_3)$($nic^-$)]·$2H_2O$ (**5**) [Cu(dien)(Br)($nic^-$)]·$3H_2O$ (**6**), and [Cu(dien)$(NO_3)$($nic^-$)(Guo)]·$5H_2O$ (**7**) show that the $nic^-$ ligand is not coordinated through the N atom of the pyridine ring. The two IR absorption bands at 1760 and 1745 $cm^{-1}$, combined with a very intense and broad band at around 1380 $cm^{-1}$, are indicative of the unidentate coordination mode of the nitrate anions with copper(II). Finally, the very weak band at 324 $cm^{-1}$ should be attributed to the ν(Cu–Br) stretching vibration of **6**.[11] The presence of water in all hydrated complexes, either as ligands or as lattice water, as well as the large number of hydrogen bonds, was indicated by the appearance of broad bands at 3414 and 3476 $cm^{-1}$, respectively. The former can be attributed to hydrogen bonds and the latter to the existence of water either in the lattice or as a ligand. The presence of water was further corroborated by thermal DTA analysis (vide infra).

The UV/Vis electronic spectra of the complexes in aqueous $10^{-3}$ M solutions show a band in the visible region at 608–623 nm (Figure 1), which can be attributed to crystal-field d–d electronic transitions (probably $3d_{x^2-y^2} \leftarrow 3d_{z^2}$). This band is characteristic for $Cu^{II}$ complexes with a distorted square-pyramidal geometry.

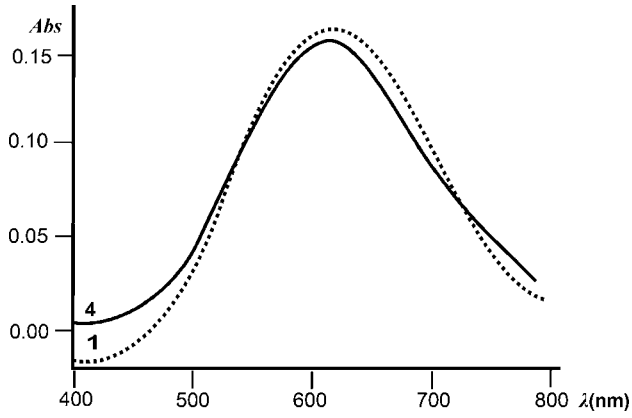

Figure 1. Electronic spectra of [Cu(dien)$(NO_3)_2$] (**1**) and [Cu(dien)-(nica)$(NO_3)_2$] (**4**) in aqueous solution.

In the UV region of the spectra of the "free" py, nic, $nic^-$, and nica ligands the absorption bands and shoulders occur around 240–260 nm ($\log\varepsilon$ = 3.63–3.90), which can be attributed to intraligand π* ← π electronic transitions due to the conjugated C=N, C=C, and C=O groups of the pyridine-ring-containing ligands. These bands are shifted either to lower or higher frequencies, depending on the coordination mode of the ligand. The band at 204–214 nm could be assigned to σ* ← σ type transitions of the free dien molecule, which is not shifted upon coordination.

In the solid state (Nujol mulls), all $Cu^{II}$ complexes show the crystal-field band at around 560–580 nm. Such bands are typical for octahedral $Cu^{II}$ complexes. Therefore, it is obvious that the different structures adopted by the complexes in aqueous and methanol solutions and in the solid state may be due to the dissociation of the compounds in solution.[17]

## Conductivity and Magnetic Measurements

The molar conductivity values, $\Lambda_\mu$, for the complexes, which vary between 159–423 and 77–213 μS $cm^{-1}$ for $10^{-3}$ M aqueous and methanol solutions, respectively, strongly suggest the ionic nature of the complexes. Specifically, in aqueous solutions, the zwitterionic complexes [Cu(dien)($nic^-$)-$(NO_3)(H_2O)$]·$H_2O$ (**5**), [Cu(dien)($nic^-$)(Br)$(H_2O)$]·$2H_2O$ (**6**), and [Cu(dien)$(NO_3)$($nic^-$)(Guo)]·$5H_2O$ (**7**) are 1:1 electrolytes[18] that dissociate according to the following general scheme:

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[Cu(dien)(X)(nic^-)(H_2O)] \rightleftharpoons [Cu(dien)(nic^-)]^+ + X^-$ (X = $NO_3^-$, $Br^-$)

$[Cu(dien)(py)(NO_3)_2]$ (**3**) and $[Cu(dien)(nica)(NO_3)_2]$ (**4**) are 2:1 electrolytes in aqueous solutions, with two dissociating nitrate anions. In methanol solution, complexes **3**–**7** are 1:1 electrolytes. Taken together, the above data lead to the conclusion that the complexes dissociate to a lesser degree in methanol solution.

The $\mu_{eff}$ values for the $Cu^{II}$ complexes were found in the range 1.72–1.93 $\mu_B$, consistent with their mononuclear structures.

### Thermal Analysis

The thermal behavior of selected $Cu^{II}$ complexes was studied by TG/DTG/DTA thermal analysis in the temperature range 40–1000 °C. The intermediates were confirmed from the mass-loss calculations. Generally, the thermal decomposition of the complexes proceeds in 4–6 stages, which depend on the nature of the ligands involved. For example, the thermal behavior of **4** (Figure 2) is characterized by four decomposition stages. The first one (200–281 °C) corresponds to the removal of the dien and nica ligands, while during the next two stages, which are non-distinct (281–519 and 519–865 °C), the successive decomposition of two nitrate ions to a nitrite moiety takes place; the calculated and found values for this process are almost identical. During the fourth step (865–973 °C), the elimination of an oxygen molecule, derived from the decomposition of two nitrate ions to the corresponding nitrito moiety, occurs. The elimination of $O_2$ at such a high temperature should be due to its strong binding with Cu as a $CuO_2$ fragment. The last step corresponds to the formation of metallic copper as a residue, as proved by IR spectroscopy and its quantitative analysis.

The thermal analysis of **5** (Figure 3) starts with the dehydration of the molecule, which takes place in a single mass-loss step corresponding to 9.2% (calcd. 9.3%), up to 123 °C, due to the endothermic elimination of lattice and coordinated water molecules. A total weight loss of 58.00% occurs in the temperature range 212–327 °C, presumably due to the loss of $nic^-$ and dien ligands (calcd. 58.22%). The third step (665–964 °C) involves loss of the nitrate anion, while the residue remaining at temperatures higher than 964 °C is metallic copper, as evidenced by the mass loss (calcd. 16.45; found 16.80%) and the IR spectroscopic data.

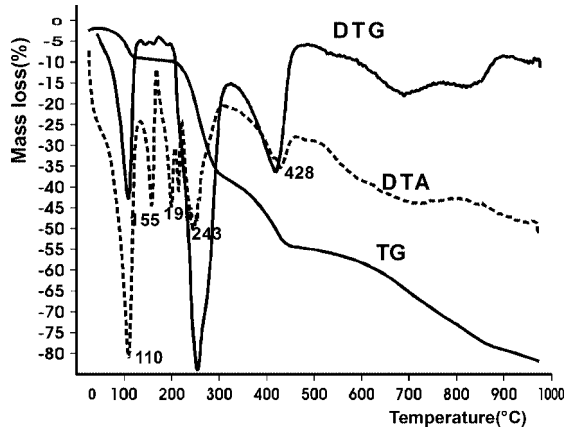

Figure 3. Thermal analysis diagram of $[Cu(dien)(nic^-)(NO_3)(H_2O)]\cdot H_2O$ (**5**).

Complex **6** partly dehydrates up to 110 °C in a single mass-loss process that corresponds to the endothermic elimination of two lattice water molecules, for which the theoretical and experimental mass loss are almost the same (Figure 4). The removal of the nicotinate anion takes place in the temperature range 216–300 °C in a second endothermic mass-loss procedure (28.75% found, 29.36% theoretical), as was proposed by Yeh et al.[19] The Br atom is removed between 300 and 432 °C (18.75% found, 19.37% calcd.), while the liberation of the dien molecule takes place at 432–848 °C (24.38% found, 24.97% calcd.). The elimi-

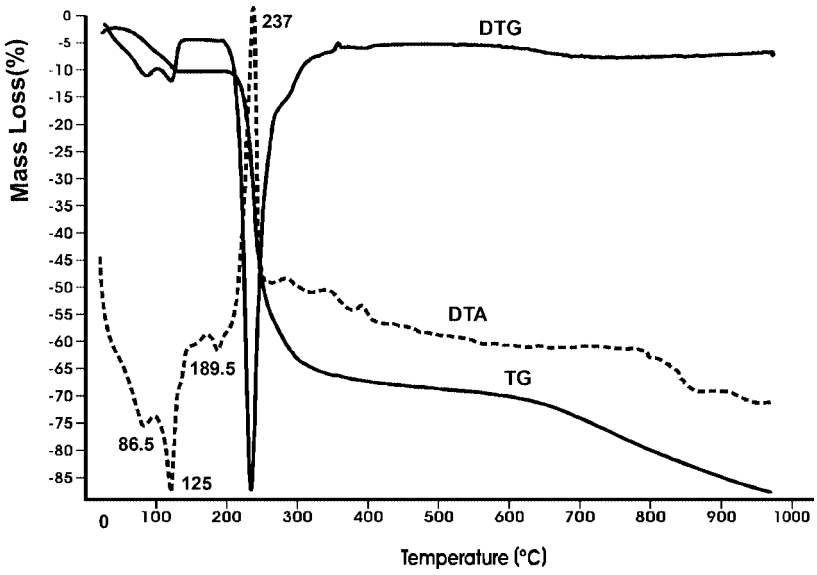

Figure 4. Thermal analysis diagram of [Cu(dien)(nic$^-$)(Br)($H_2O$)]·2$H_2O$ (**6**).

nation of the coordinated water at a higher temperature (848–964 °C) is tentatively proposed. The solid residue of the procedure above 964 °C corresponds to metallic copper.

### Crystal Structure of [Cu(dien)(nica)($NO_3$)$_2$] (4)

The molecular structure of **4** is shown in Figure 5, while bond lengths and angles along with the established hydrogen bonds are given in Table 1. The coordination polyhedron around the $Cu^{II}$ central atom is a distorted octahedron (4 + 1 + 1) with three of the equatorial positions occupied by the three nitrogen atoms of the dien ligand and the fourth position occupied by the nitrogen atom of the pyridine ring. The two axial positions of the coordination polyhedron are occupied by oxygen atoms from each of the two $NO_3^-$ anions at considerably different distances from the copper atom [Cu1–O2 = 2.373(2) and Cu1–O5 = 2.858(3) Å]. The conformation of the dien ligand is as expected.[21–23] The Cu–N distances range from 1.998(3) to 2.015(3) Å, while both the $N^p$–Cu–$N^s$ valence angles ($N^p$ from primary and $N^s$ from secondary amino groups) are smaller than 90° [84.1(1)° and 84.3(1)°]. Moreover, the $N^p$–Cu–$N^p$ angle is much smaller than 180° [163.7(1)°], which indicates a slight strain in the coordinated dien ligand. The reported observation that the Cu–$N^s$ distance is significantly shorter than the Cu–$N^p$ distances[22,24] seems to be generally valid only when referred to the mean Cu–$N^p$ distance [compare, for example, the Cu–N(dien) distances reported previously[8,25]]. The Cu–N(pyridine) distance of 2.036(3) Å deviates only slightly from the mean Cu–N(dien) distance [2.005(5) Å]. The four equatorial nitrogen atoms of the copper coordination polyhedron lie almost on a plane (rms deviation of the fitted atoms of 0.06 Å), forming an angle of 58.9(1)° to the plane of the pyridine ring. The copper atom deviates significantly from the above equatorial plane by 0.150(2) Å towards the axial O(2) atom with the shorter Cu–O bond. The established geometry of the pyridine ring is as expected, with the C–C bond lengths lying in the range 1.375(5)–1.391(5) Å and the C–N bond lengths lying in the range 1.333(4)–1.339(4) Å. The two nitrato groups also have a normal geometry, with the N6–O and N7–O bond lengths ranging from 1.226(4) to 1.258(4) Å and 1.217(4) to 1.246(4) Å, respectively.

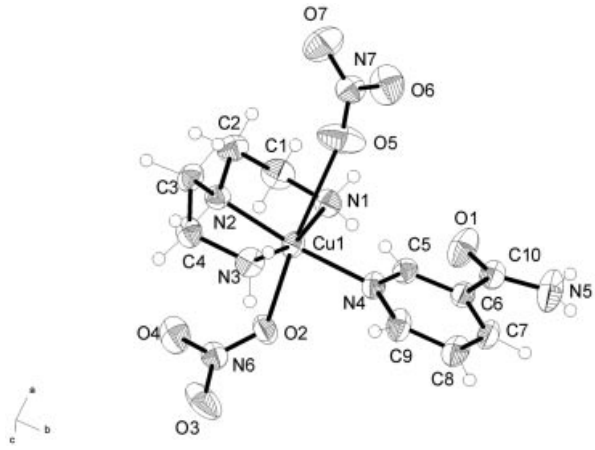

Figure 5. DIAMOND[20] plot of the molecular structure of [Cu(dien)(nica)($NO_3$)$_2$] (**4**), with the labeling scheme of the non-H atoms. Displacement ellipsoids are shown at the 30% probability level.

Hydrogen bonding plays a predominant role in the stabilization of the structure. As can be seen from Table 1, both the $N^p$ atoms of the dien ligand and the N atom of the amide group donate exclusively to oxygen atoms of $NO_3$ groups of neighboring molecules, while the $N^s$ atom of the dien ligand donates to the oxygen atom of the amide group of another molecule.

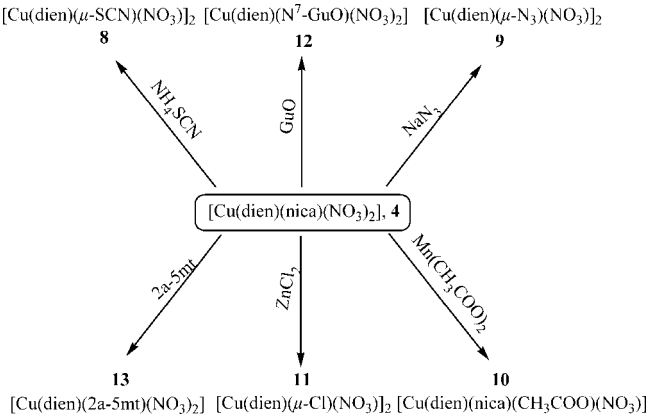
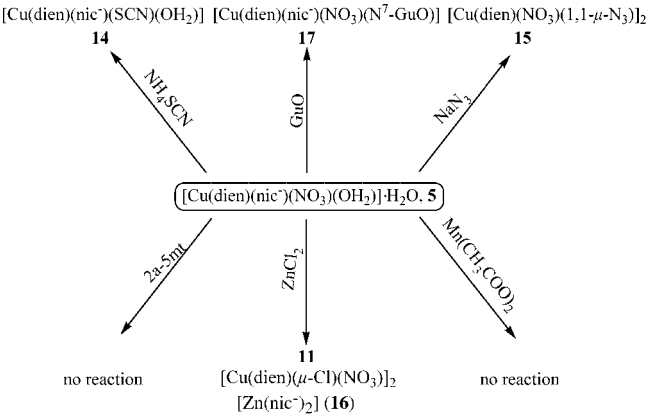


Scheme 1. Reactivity of [Cu(dien)(nica)$(NO_3)_2$] (**4**) towards nucleophiles.



Scheme 2. Reactivity of complex **5** towards nucleophiles.

### Reactivity of [Cu(dien)(nica)$(NO_3)_2$] (4) and [Cu(dien)$(NO_3)$(nic$^-$)$(OH_2)$]·$H_2O$ (5)

We selected [Cu(dien)(nica)$(NO_3)_2$] and the zwitterionic complex [Cu(dien)$(NO_3)$(nic$^-$)$(OH_2)$]·$2H_2O$ to exploit their chemical reactivity towards nucleophiles. In particular, the zwitterionic form is expected to exhibit interesting reactivity due to the different electronic, steric, and nucleophilicity factors of the coordinated dien, $NO_3$, $H_2O$, nic$^-$, and nica ligands. The reactivity studies were performed using the reaction of a water/methanol solution of the precursor complex with various nucleophiles, such as $SCN^-$, $N_3^-$, $Cl^-$, $CH_3COO^-$, guanosine (GuO), and 2-amino-5-methylthiazole (2a-5mt) in a 1:1 molar ratio. All the reactions of complexes **4** and **5** studied are depicted schematically in Schemes 1 and 2, respectively.

The reaction products were identified by elemental analysis, spectroscopic measurements (IR and UV/Vis spectra), and magnetic and molar conductivity measurements, and the results compared with the experimental data available.[26] All reaction products are blue crystalline solids that are very soluble in water and in coordinating solvents, and slightly soluble in alcohols. The compounds are monomers or dimers and their magnetic moments are as expected for the $d^9$ electron configuration of $Cu^{II}$.

The reaction of **4** with $NH_4SCN$ or $NaN_3$ leads to the nucleophilic substitution of the nica and one of the $NO_3^-$ ligands to afford the dinuclear complexes [Cu(dien)(μ-SCN)$(NO_3)_2$] (**8**) and [Cu(dien)(μ-$N_3$)$(NO_3)_2$] (**9**), which are bridged by the ambidentate $SCN^-$ and $N_3^-$ ligands, respectively. In the IR spectra of **8** and **9** the bands related with the nicotinamide ligand disappear, while the new bands absorbing at 2073 and 2049 $cm^{-1}$ are characteristic of the coordinated thiocyanate and azide ligands, respectively. The dinuclear nature of **8** and **9** was further confirmed by their molar conductivity values of 240–250 μS $cm^{-1}$ in water solutions, which are indicative of the 1:2 electrolytic character of the complexes due to the dissociation of the $NO_3^-$ counterion. The UV/Vis spectroscopic data of **8** and **9** in the solid state are characteristic of $Cu^{II}$ complexes with octahedral stereochemistry.[26]

The reaction of **4** with $Mn(CH_3COO)_2·4H_2O$ leads to the substitution of one nitrate ion by an acetato group to yield [Cu(dien)(nica)$(CH_3COO)(NO_3)$] (**10**). This was confirmed by the IR spectrum of **10**, where the nitrato peak at 1749 $cm^{-1}$ has disappeared and a new band at 1604 $cm^{-1}$, characteristic of the acetate ligand, has appeared. The acetate ligand binds in a $\kappa O$ fashion.[27]

The analytical and spectroscopic data of the crystals isolated from the reaction mixture resulting from the reaction of **4** with $ZnCl_2$ correspond to the dinuclear $Cu^{II}$ complex formulated as [Cu(dien)(μ-Cl)]$_2$·[$NO_3$]$_2$ (**11**), which contains

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bridging chloride ligands.[28] The reaction of **4** with Guo or 2a-5mt leads to the formation of the adducts [Cu(dien)($N^7$-Guo)($NO_3$)$_2$] (**12**) and [Cu(dien)(2a-5mt)($NO_3$)$_2$] (**13**) by replacement of the coordinated nica ligand with the respective nucleophile. The IR spectra of **12** and **13** show the presence of characteristic bands for guanosine and 2-amino-5-methylthiazole, which are indicative of their coordination with copper(II), while the UV/Vis spectra suggest an octahedral geometry of the complexes. The molecular structure of **12** has been determined previously by X-ray crystallography.[29]

The reaction of the zwitterionic complex **5** with $NH_4SCN$ yields blue needles of the mixed-ligand complex [Cu(dien)(NCS)($nic^-$)($H_2O$)] (**14**) by substitution of the nitrate ion by the thiocyanato ligand. The substitution reaction was monitored by the disappearance of the two bands at 1745 and 1380 $cm^{-1}$ due to the stretching vibration of the nitrato ligands, and the appearance of the strong and sharp band at 2072 $cm^{-1}$ due to the isothiocyanato ligand coordinated as a terminal ligand through its hard N-end.[30] The bands due to $nic^-$ remain almost unchanged.

The reaction of **5** with $NaN_3$ leads to the replacement of both the $nic^-$ ligand and the coordinated $H_2O$ molecule by the azido ligand, which bridges the two $Cu^{II}$ centers in an asymmetric end-on fashion to afford the dinuclear complex [Cu(dien)($NO_3$)(1,1-μ-$N_3$)]$_2$ (**15**). The end-on bridging mode of the $N_3^-$ group was proved by the presence of one intense band at 2049 $cm^{-1}$.

The reaction of **5** with $ZnCl_2$ leads to the dissociation of the complex and the formation of two new complexes: one of them, which is blue, corresponds to the dinuclear complex **11**.[28] Specifically, the IR spectrum of **11** is dominated by the absence of peaks for the $nic^-$ ligand, while the bands at 344 and 388 $cm^{-1}$ confirm the bridging mode of the chloro ligand. Moreover, the molar conductivity value (238 μS $cm^{-1}$) in water substantiates the 1:2 electrolytic nature of **11**. The second complex is a white solid that corresponds to Zn(nicotinate)$_2$ (**16**), where the Zn center is coordinated by two bidentate chelating carboxylato groups of the nicotinate anions.

Finally, the reaction of **5** with guanosine leads to the formation of the adduct [Cu(dien)($nic^-$)($NO_3$)($N^7$-Guo)] (**17**) by replacement of the coordinated $H_2O$ ligand. The IR spectrum of **17** shows the presence of both $nic^-$ and Guo bands, which are indicative of their coordination with the copper(II) center, while the UV/Vis spectra suggest an octahedral stereochemistry for the $CuN_5O$ chromophore. The reactions of complexes **4** and **5** with guanosine clearly mirror their ability to react with DNA components in the cell nucleus, which, in turn, could open up a new pathway for their further biological studies. Despite many attempts, the reactions of **5** with Mn($OOCCH_3$)$_2$·4$H_2O$ or 2-amino-5-methylthiazole were unsuccessful.

## Computational Studies Using DFT

### Equilibrium Geometries, Electronic Structure, and Bonding Mechanism of [Cu(dien)(nic)] and [Cu(dien)(nica)] Complexes

In an attempt to understand some marked structural features of the complexes under investigation, we performed electronic-structure calculations based on density functional theory at the B3LYP/6-31G(d,p) level. We started the calculations with the various possible forms of nicotinic acid that exist in aqueous solutions. These species, along with their p$K$ values,[31] are shown in Scheme 3.

The equilibrium geometries of the various forms of nicotinic acid (**A**, **B**, and **C**) and that of a deprotonated form of **A** at the heterocyclic N-atom (**A′**), computed at the B3LYP/6-31G(d,p) level, are given in Figure 6. No significant structural differences can be observed in the pyridine ring of the various forms of nicotinic acid. However, there are some changes in the structural parameters of the carboxylic group. For instance, the C–$COO^-$ bond lengthens and the OCO bond angle decreases upon going from **B** to **C**, following the trend **B** > **A** > **A′** > **C**.

The vibrational frequencies obtained from our calculations are in line with those obtained from a previous theoretical study by Sala et al.[32] The β(COO) in-plane pyridinic ring deformation appears at 629, 631, and 625 $cm^{-1}$ for **A′**, **B**, and **C**, respectively, and the ν(C=O) stretching vibration appears at 1855 and 1796 $cm^{-1}$ for **A′** and **B**, respectively.

The various forms of nicotinic acid are expected to act as ambidentate ligands that coordinate to a metal center either through the carboxylato O- or heterocyclic N-donor atoms. This is clearly illustrated by their frontier molecular orbitals (FMOs; Figure 7).

In both **A** and **A′** the two occupied FMOs (HOMO and HOMO–1), which are involved in the formation of a coor-

dination bond with the Cu$^{II}$ central atom, have significant contributions from p-AOs of the carboxylato O-donor atoms. However, the HOMO–1 has a significant contribution from a p-AO of the heterocyclic N-donor atom only in **A′**. In the latter, the unoccupied FMO (LUMO) has significant contributions from p-AOs located on the carboxylato O- or heterocyclic N-donor atoms, which could be involved in a π-back-bonding interaction with the central

$Cu^{II}$ atom. The HOMO and LUMO eigenvalues, along with selected electronic properties of the various nicotinic acid forms, are compiled in Table 2.

The proton affinities (PA) of the various forms of nicotinic acid calculated at the B3LYP/6-31G(d,p) level are also given in Table 2. Based upon the PA values, it is expected that the σ-donor ability of **C** and **B** through either the N- or O-donor atoms should be higher than that of **A** or **A′**.

The various forms of nicotinic acid can coordinate to copper(II) either through their endocyclic N-donor atom or through their carboxylato O-donor atoms to form a series of [Cu(dien)(nic)] complexes. The equilibrium geometries of the complexes computed at the B3LYP/6-31G(d,p) level are given in Figure 8 along with selected structural parameters.

All complexes adopt a distorted square-planar geometry. In [Cu(dien)(A′)] (**1A′**) the plane of **A′**, which is coordinated to $Cu^{II}$ through its N-donor atom, is twisted almost 60° out of the coordination plane (Figure 8a). The same also holds true for the complex [Cu(dien)(C)] (**1C**), with **C** coordinated to copper(II) through its N-donor atom (Figure 8c). On the other hand, the torsion angle between the two planes is estimated to be diminished to around 25° in [Cu(dien)(B)] (**1B**) and [Cu(dien)(C′)] (**1C′**; Figures 8b and 8d, respectively), where ligands **B** and **C′** are coordinated to copper(II) through their carboxylato O-donor atoms. The three Cu–N coordination bonds formed between $Cu^{II}$ and the dien ligand are longer in **1B** than in **1A**, **1C**, and **1C′**. The length of the Cu–N coordination bond formed between nicotinic acid and $Cu^{II}$ decreases slightly upon going from

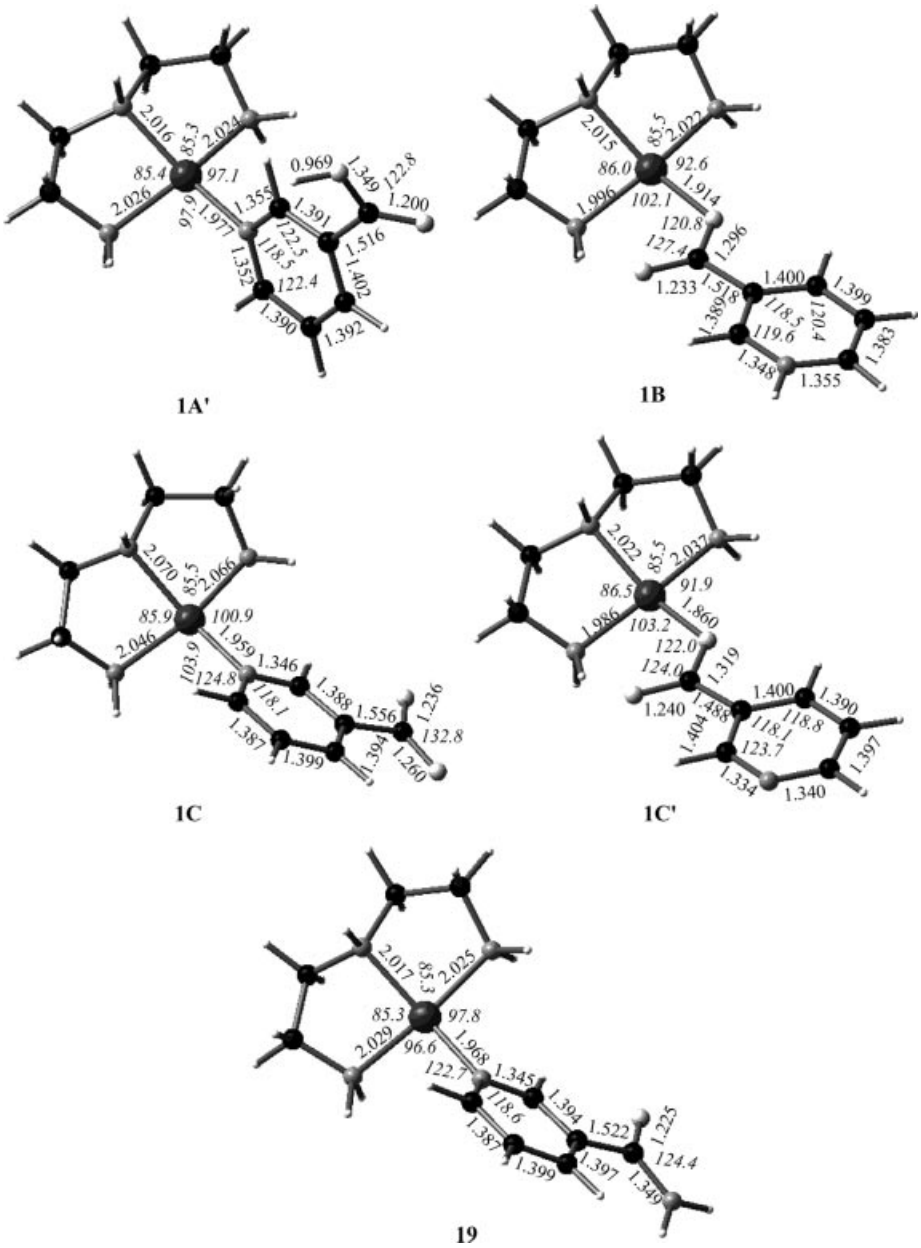

Figure 8. Equilibrium geometries of the [Cu(dien)(nic)] and [Cu(dien)(nica)] complexes computed at the B3LYP/6-31G(d,p) level of theory.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**1A** to **1B**. No significant changes in the structural parameters of the various nicotinic acid species could be observed upon coordination to $Cu^{II}$.

Selected energetic and electronic properties of the [Cu(dien)(nic)] and [Cu(dien)(nica)] complexes computed at the B3LYP/6-31G(d,p) level of theory are summarized in Table 3.

According to the natural bond orbital (NBO) analysis the $Cu^{II}$ center acquires a positive natural charge of about 1.20–1.38 |e|. Based upon the natural electron configurations, the electron density is transferred from the N-donor atoms of the dien and nicotinic acid ligands to the 4s- and 3d-AOs of $Cu^{II}$ (Table 2). Note that the natural electron configuration on the $Cu^{II}$ central atom does not vary significantly upon going from **1A′** to **1C**. Interestingly, there is an increase in natural atomic charges of the N-donor atom of the nicotinic acid ligand in **1A′** and **1C** upon coordination to the $Cu^{II}$ center, which could be attributed to a π-backbonding interaction between the 3d lone pair AOs of the $Cu^{II}$ center and the vacant LUMO of **A′** or **C** (Figure 5). On the other hand, the same also holds true for **1B**, where an increase of the natural atomic charge on the O-donor atom of the nicotinic acid ligand is observed upon coordination. In all [Cu(dien)(nic)] complexes the spin density is mainly localized on the $Cu^{II}$ and the N-donor atoms of the dien and nicotinic acid ligands, while in **1C** it is delocalized over the nicotinic acid ring and mainly on one of the carboxylate O donor atoms (Figure 8).

The equilibrium geometry of [Cu(dien)(nica)] (**18**), computed at the B3LYP/6-31G(d,p) level, is also given in Figure 8. The complex adopts a distorted square-planar geometry with the nicotinamide ligand being twisted almost 60° out of the coordination plane. The calculated structural parameters of **18** are in line with those obtained from the X-ray structural analysis for $[Cu(dien)(nica)(NO_3)_2]$ (**4**). No significant structural changes in nicotinamide could be observed upon coordination to $Cu^{II}$.

According to the NBO analysis the $Cu^{II}$ center acquires a positive natural atomic charge of about 1.37 |e|. The natural electron configurations illustrate that the electron density is transferred from the N-donor atoms of the dien and nicotinamide ligands to the 4s- and 3d-AOs of $Cu^{II}$ (Table 3). Also, there is an increase in the natural atomic charge of the N-donor atom upon coordination of the nicotinamide ligand to the $Cu^{II}$ center in **18**, which could be attributed to a π-backbonding interaction between the 3d lone pair AOs of $Cu^{II}$ and the LUMO of the nica ligand (Figure 7). Finally, the bond dissociation energy (BDE) of the nica ligand is predicted to be 67.2 kcal mol$^{-1}$ at the B3LYP/6-31G(d,p) level.

### Vibrational and Electronic Spectra of [Cu(dien)(nic)] and [Cu(dien)(nica)] Complexes

The unscaled vibrational frequencies in the vibrational spectra of the [Cu(dien)(nic)] and [Cu(dien)(nica)] complexes, calculated at the B3LYP/6-31G(d,p) level, appear within the range 3450–3530 $cm^{-1}$. The ν(C=O) stretching vibration for **A′**, **B**, and **C** appears at 1855, 1796, and 1591 $cm^{-1}$ respectively. Upon coordination to $Cu^{II}$ this vibration is red-shifted for **1A′**, **1C**, and **1C′**, appearing at 1876, 1688, and 1681 $cm^{-1}$ respectively, while it is blue-shifted for **1B**, appearing at 1731 $cm^{-1}$. The N-coordination of nicotinic acid species is reflected in the calculated unscaled in-plane pyridinic ring deformation, $\delta_{py}$, which is red-shifted in **1A′** and **1C** relative to the corresponding uncoordinated nicotinic acid species **A′** and **C**, appearing at 673 and 668 $cm^{-1}$, respectively. In contrast, it remains almost unaffected in **1B** and **1C′**, appearing at 635 and 633 $cm^{-1}$ respectively. Moreover, the N-coordination of the nicotinamide is also reflected in the calculated in-plane pyridinic

Table 4. Principal electronic transitions, wavelengths (λ), and oscillator strengths (*f*) for [Cu(dien)(nic)] (**1B**) and [Cu(dien)(nica)] (**18**) computed at the B3LYP/6-31G(d,p) level.

ring deformation, $\delta_{py}$, vibrational frequency, which in **18** appears at 801 and 672 $cm^{-1}$, while in uncoordinated nicotinamide it appears at 782 and 642 $cm^{-1}$, respectively.

TD-DFT calculations at the B3LYP/6-31G(d,p) level were performed in order to evaluate the properties of the excited states of [Cu(dien)(nic)] and [Cu(dien)(nica)] complexes. The principal singlet–singlet electronic transitions, excitation energies, and oscillator strengths, along with assignments, for **1B** and **18** are compiled in Table 4.

The computed electronic transitions for **1B** and **18** at 608 and 604 nm, respectively, are in excellent agreement with the experimental values. This broad and very intense band for 1B arises from the HOMO–2 → SOMO electronic transition (Figure 9). However, because of the highly delocalized MOs involved and the high mixing of the excited configurations due to the low symmetry of the complexes, it could not be assigned to one of the well-known LL, MLCT, LMCT, or d → d transitions. On the other hand, for **18** this band arises from a HOMO–1 → SOMO (Figure 9) electronic transition and can be classified as an intraligand (LL) transition.

The calculated electronic transitions at 249 and 256 nm for nic and nica, respectively, are in excellent agreement with the experimental values. These bands arise from π → π* and σ → π* type transitions for nic and nica, respectively (Figure 9). Upon coordination of the latter to $Cu^{II}$ these bands are blue-shifted, appearing at 235 and 204 nm for **1B** and **18**, respectively.

## Conclusions

We have reported the synthesis, structural characterization, and DFT study of the novel mixed-ligand $Cu^{II}$ complexes formed upon reaction of [Cu(dien)$X_2$] (dien = diethylenetriamine; X = $Br^-$, $NO_3^-$) with pyridine (py), nicotinamide (nica), nicotinic acid (nic), and nicotinate anion ($nic^-$) in a 1:1 molar ratio. The salient structural features of the new complexes were determined by spectroscopic measurements (infrared and electronic spectra), while details of the structures were obtained by an X-ray structural investigation of the [Cu(dien)(nica)$(NO_3)_2$] complex. Conductivity measurements revealed the electrolytic nature of the complexes, while magnetic measurements are compatible with the $d^9$ electron configuration of the $Cu^{II}$ centers. Moreover, DFT/B3LYP calculations of the structural, bonding, and electronic properties of the complexes corroborate the experimental evidence for the coordination of nicotinic acid preferably through the pyridine N-donor atom. Finally, the chemical reactivity of the $Cu^{II}$ complexes towards a variety nucleophiles has been studied experimentally and discussed in relation with the electronic structure of the complexes computed at the DFT level.

## Experimental Section

**Materials and Instrumentation:** All chemicals were purchased from Aldrich, EDH Chemicals and Merck, as reagent grade, and were used as received. C, H, and N were analyzed with a Perkin–Elmer 240B elemental analyser. IR spectra were recorded with a Perkin–Elmer Spectrum One spectrophotometer in the 400–4000 $cm^{-1}$ region using KBr pellets and in the 200–400 $cm^{-1}$ region using polyethylene disks. Electronic spectra were recorded with a Hitachi U-2001 spectrophotometer in the 200–1100 nm region, using 10-mm Teflon-stoppered quartz cells. Molar conductivities were measured with a WTW conductivity bridge and a calibrated dip-type cell. Magnetic susceptibilities on powdered samples were measured at room temperature using a Johnson–Matthey balance. Diamagnetic corrections were estimated from Pascal constants. The TG/DTA curves were obtained in a dynamic nitrogen atmosphere with a Setaram SETSYS-1200 thermal analyzer at a heating rate of 5 °C $min^{-1}$ in a platinum crucible, in the temperature range 40–950 °C, with a sample mass of about 10 mg.

**Synthesis of the Complexes:** The starting material [Cu(dien)-$(NO_3)_2$] (**1**) was prepared according to a literature procedure,[9] while [Cu(dien)$Br_2$] (**2**) was prepared by the direct reaction of dien and $CuBr_2$.

**[Cu(dien)(py)$(NO_3)_2$] (3):** Pyridine (0.16 mL) was added dropwise to a suspension of**1** (0.581 g,2 mmol) in of methanol (20 mL). After stirring for 4 h, the solution was filtered to remove any impurities. Diethyl ether (10 mL) was then added to the filtrate, which was left at low temperature (5 °C) overnight. The dark-blue solid formed was isolated by filtration, washed with diethyl ether, and dried in air. Yield: 0.144 g (19%). $C_9H_{18}CuN_6O_6$ (369.82): calcd. C 29.23, H 4.91, N 22.72; found C 29.11, H 4.89, N 22.63. IR (KBr disk): $\nu_a$(N–H) 3266 vs, $\nu_s$(N–H) 3238 vs, $\nu_{sec}$(N–H) 3196 vs, ν(C=N) 1608 s, ν(Cu–N) 523 m, ν(Cu–O) 456 m $cm^{-1}$. UV/Vis ($H_2O$): $\lambda$ (log $\varepsilon$) = 616 nm (1.91), 263 sh, 256 sh, 249 (3.73), 243 sh. $\Lambda\mu$ ($H_2O$) = 247 μS $cm^{-1}$. $\mu_{eff}$ = 1.93 BM. M.p. 247 °C (dec.).

**[Cu(dien)(nica)$(NO_3)_2$] (4):** Complex **1** (1.456 g, 5 mmol) was dissolved in $H_2O$ (2 mL) and further diluted with MeOH (10 mL). Nicotinamide (0.623 g, 5 mmol) in MeOH (15 mL) was added to this solution, with a concomitant darkening of the color. After the addition of diethyl ether (10 mL), the solution was left at low temperature (5 °C). After 14 h at this temperature, the dark-blue crystals formed were isolated by filtration, washed with diethyl ether, and dried at room temperature. Yield: 1.89 g (92%). $C_{10}H_{19}CuN_7O_7$ (412.85): calcd. C 29.09, H 4.64, N 23.75; found C 29.06, H 4.56, N 23.68. IR (KBr disk): $\nu_a$(N–H) 3273 vs, $\nu_s$(N–H) 3244 s, $\nu_{sec}$(N–H) 3156 s-br, ν(C=O) 1693 vs, ν(C=N) 1603 s, ν(Cu–N) 537 m, ν(Cu–O) 461 m $cm^{-1}$. UV/Vis ($H_2O$): $\lambda$ (log $\varepsilon$) = 612 nm (1.87), 269 sh, 254 (3.72). $\Lambda\mu$ ($H_2O$) = 206 μS $cm^{-1}$. $\mu_{eff}$ = 1.82 BM. M.p. 193–195 °C.

**[Cu(dien)($nic^-$)$(NO_3)(H_2O)$]·$H_2O$ (5):** A solution of nicotinic acid (0.62 g,5 mmol) in methanol (10 mL) was added to an aqueous solution of NaOH (0.2 g in 2 mL) with vigorous stirring. This solution of sodium nicotinate was added to a solution of **1** (1.45 g, 5 mmol) in $H_2O$/MeOH (1 mL/10 mL). The final solution was left overnight at room temperature. The blue needles formed were isolated by filtration, washed with diethyl ether, and dried at room temperature. Yield: 0.81 g (42%). $C_{10}H_{21}CuN_5O_7$ (386.85): calcd. C 31.05, H 5.47, N 18.10; found C 31.02, H 5.43, N 18.02. IR (KBr disk): $\nu_a$(N–H) 3270 vs, $\nu_s$(N–H) 3204 vs, $\nu_{sec}$(N–H) 3163 vs, ν(C=O) 1668 s, ν(C=N) 1591 vs, ν(Cu–N) 527 s, ν(Cu–O) 449 m $cm^{-1}$. UV/Vis ($H_2O$): $\lambda$ (log $\varepsilon$) = 618 nm (1.62), 269 sh, 262 sh, 255(3.84). $\Lambda\mu$ ($H_2O$) = 164 μS $cm^{-1}$. $\mu_{eff}$ = 1.76 BM. M.p. 141 °C (dec.).

**[Cu(dien)($nic^-$)(Br)$(H_2O)$]·$2H_2O$ (6):** A solution of nicotinic acid (0.262 g, 2.5 mmol) in methanol (10 mL) was added to an aqueous solution of NaOH (0.2 g in 2 mL) with vigorous stirring. This solu-

tion of sodium nicotinate was added to a solution of **2** (0.82 g, 2.5 mmol) in $H_2O$/MeOH (2 mL/10 mL). The final solution was stirred to give a blue solid, which was isolated by filtration, washed with diethyl ether, and dried at room temperature. Yield: 0.44 g (40%). $C_{10}H_{23}BrCuN_4O_5$ (422.76): calcd. C 28.41, H 5.48, N 13.25; found C 28.48, H 5.49, N 13.28. IR (KBr disk): $\nu_a$(N–H) 3271 s, $\nu_s$(N–H) 3203 s, $\nu_{sec}$(N–H) 3163 m, $\nu$(C=O) 1667 m, $\nu$(C=N) 1591 s, $\nu$(Cu–N) 525 m, $\nu$(Cu–O) 448 m $cm^{-1}$. UV/Vis ($H_2O$): $\lambda$ ($\log\varepsilon$) = 608 (1.93), 269 sh, 262 sh, 255 (3.77), 214 sh. $\Lambda\mu$ ($H_2O$) = 173 $\mu S\,cm^{-1}$. $\mu_{eff}$ = 1.80 BM. M.p. 131–133 °C.

**[Cu(dien)($NO_3$)(nic$^-$)($N^7$-Guo)]·5$H_2O$ (7):** A solution of sodium nicotinate (5 mmol) in $H_2O$/EtOH (1 mL/10 mL) was added dropwise to a water/methanol (1 mL/10 mL) solution of **1** (1.453 g, 5 mmol) and the mixture stirred continuously for 5 min. After the addition of guanosine (Guo) (1.516 g, 5 mmol) in small quantities and ethanol (80 mL), the new suspension was further stirred for 12 h so as to allow complete reaction of Guo, after which the blue-purple solid formed was isolated by filtration, washed with diethyl ether, and dried at room temperature. Yield: 3.55 g (98%). $C_{20}H_{40}CuN_{10}O_{15}$ (724.14): calcd. C 33.17, H 5.57, N 19.34; found C 33.52, H 5.66, N 19.71. IR (KBr disk): $\nu_a$(N–H) 3270 vs,br, $\nu_s$(N–H) 3226 vs-br, $\nu_{sec}$(N–H) 3165 vs, $\nu$(C=O) 1680 s, $\nu$(C=N)1591 s, $\nu$(Cu–N) 527 m, $\nu$(Cu–O) 449 w $cm^{-1}$. UV/Vis ($H_2O$): $\lambda$ ($\log\varepsilon$) = 612 (1.86), 269 sh, 253 (4.24). $\Lambda\mu$ ($H_2O$) = 159 $\mu S\,cm^{-1}$. $\mu_{eff}$ = 1.83 BM. M.p. 108–110 °C.

**Computational Details:** The structural, electronic, and energetic properties of all compounds were computed with Becke's three-parameter hybrid functional[33] combined with the Lee–Yang–Parr correlation functional,[34] abbreviated as B3LYP, using the 6-31G(d,p) basis set. In all computations no constraints were imposed on the geometry. Full geometry optimization was performed for each structure using Schlegel's analytical gradient method[35] and the attainment of the energy minimum was verified by calculating the vibrational frequencies that result in absence of imaginary eigenvalues. All calculations were performed using the GAUSSIAN03 suite of programs.[36]

**X-ray Crystallographic Study:** Crystal data, data collection, and refinement details for [Cu(dien)(nica)($NO_3$)$_2$] are given in Table 5. Cell parameters were calculated by least-squares refinement of the setting angles of 21 reflections and their equivalents ($13.60° < 2\theta < 22.20°$). Intensities were collected using graphite-monochromated Mo-$K_\alpha$ radiation and a scintillation counter.[37] Three standard reflections monitored every 120 min showed no significant deterioration. They were used to scale the intensities, which were further corrected for Lorentz and polarization effects,[38] as well as for absorption (empirical $\psi$-scan method).[39] Most calculations were performed with the WinGX system of programs.[40] The structure was solved by direct methods and subsequent difference Fourier syntheses with the SHELXS-97 program[41] and refined with the SHELXL-97 program.[42] Some of the geometrical calculations were performed with the PLATON program.[43] All the non-hydrogen atoms were refined anisotropically. The hydrogen atoms could be located on the difference Fourier map, and in the final refinement step their positions were varied freely but their displacement parameters were constrained to 1.2 $U_{eq}$ of the corresponding values of the atoms to which they are bonded. CCDC-264390 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

## COVER PICTURE

**The cover picture shows** how the treatment of the oxide molecular model [{TiCp*($\mu$-O)}$_3$($\mu_3$-CMe)] (Cp* = $\eta^5$-$C_5Me_5$) with alkaline earth metal amide and alkyl compounds produces the deprotonation of the $\mu_3$-ethylidyne fragment to give $\mu_3$-$CCH_2^-$, $\mu_3$-$CHCH^-$ or $\mu_3$-$CCH^{2-}$ carbanions. Simultaneously, the alkaline earth cation is incorporated through the oxygen atoms to build new cage structures. Details of this chemistry are described by M. Mena et al. on p. 2137ff.

# σ-Silane Ruthenium Complexes: The Crucial Role of Secondary Interactions

**Sébastien Lachaize[a] and Sylviane Sabo-Etienne*[a]**

**Keywords:** σ-Complexes / Ruthenium / Silanes / Hydrides / Coordination modes / Intramolecular interactions / Oxidative addition / Hypervalent compounds

The bonding coordination mode of various silanes to ruthenium complexes is discussed on the basis of a detailed analysis of NMR, IR, X-ray and DFT data. It is now more and more obvious that a continuum exists between the two extreme situations, i.e. formation of a σ-silane complex or Si–H bond breaking leading to oxidative addition. Within this continuum, secondary interactions involving Si and H play a significant role, in particular for the stabilization of unusual structures or as intermediates in exchange processes. Here, we highlight the criteria allowing the best description of the different bonding modes.

## Introduction

A σ-complex is defined by the coordination of an H–E (E = H, Si, B, C...) bond to a metal center, a three center-two electron bond. "True" σ-complexes display no intramolecular interaction as the one found in the related family of agostic complexes. σ-complexes are now well recognized, and their properties have been reviewed in an excellent monograph by G. Kubas.[1] A parallel is often made with the Chatt–Dewar and Duncanson model, thus involving two components, σ-donation and back-donation (see Figure 1). Among the four main classes of σ-complexes (σ-dihydrogen,[1–3] σ-silane,[1,4–6] σ-borane[1,7] and σ-alcane[1,8,9]) σ-dihydrogen complexes are the most numerous and also the most documented. One of the main reasons is that two identical atoms are involved in the σ-coordination, whereas the situation is much more complex for the other cases. The substituents on the E atom have a tremendous impact, as steric and electronic effects can tune the σ-coordination. We will see in this review that in silane chemistry, the situation is quite complex, in particular as a result of the hyperval-

*Sylviane Sabo-Etienne was born in France in 1956. She received her "Doctorat d'Etat" from the Université Paul Sabatier, Toulouse, in 1984, under the supervision of the late Professor Danièle Gervais, in the field of heterobimetallic complexes. In 1985, she moved to the Université de Bretagne Occidentale in Brest, to work as "Chargée de Recherche" in Prof. Hervé des Abbayes' group in the field of carbonylation. After a year working with Prof. Maurice Brookhart (Chapel Hill, USA) as a NSF-CNRS research associate, on acrylate dimerization, she returned to Toulouse to the Laboratoire de Chimie de Coordination to work in collaboration with Dr. Bruno Chaudret on polyhydride chemistry. She was promoted to the position of "Directrice de Recherche" in 1997. Her research interests deal with various aspects of coordination chemistry, organometallic chemistry and catalysis with some emphasis on the chemistry of σ-complexes. Silane and borane activation, role of secondary interactions, catalytic studies in the field of hydrogenation and C–X bond breaking and formation (X = B, C, Si, S, CN...), hydrogen transfer and C–H activation, assembly of novel functional groups, are present research topics.*

*Sébastien Lachaize was born in France in 1976. After graduating from the Ecole Normale Supérieure, Lyon, in 2001, he moved to Toulouse in the group of Dr. Bruno Chaudret at the Laboratoire de Chimie de Coordination. He received his PhD from the Université Paul Sabatier, Toulouse, in 2004 under the supervision of Dr Sylviane Sabo-Etienne working on σ H–E (E = H, Si and B) bond activation by ruthenium complexes. After one year as a postdoctoral fellow in Rochester, NY, USA, working with Prof. William D. Jones on C–CN bond activation, he came back to Toulouse in September 2005. He is currently a "Attaché Temporaire d'Enseignement et de Recherche" at the Institut National des Sciences Appliquées. His current research interests concern the synthesis of metallic nanoparticles using an organometallic route, with special focus on fundamental aspects of the nucleation-growth mechanism, control of the nanoparticle physical properties, and development of new applications.*

**MICROREVIEWS:** This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ence properties of silicon.[10] It is first interesting to compare the coordination of a dihydrogen and of a silane ligand to a metal center. The silane ligand imposes a dissymmetry in the coordination mode, due to the difference in size and electronegativity of the two elements. The Si–H bond is more basic than the H–H bond, and thus is a better σ-donor. Moreover, the Si–H bond is also a better π acceptor, as the σ*(Si–H) orbital is lower in energy than the σ*(H–H) orbital (dissociation energy for the Si–H bond in the range 350–430 kJ·mol$^{-1}$ vs. 435 kJ·mol$^{-1}$ for $H_2$). When a competition between σ-dihydrogen or σ-silane coordination exists, σ-silane coordination is thus favoured. By comparison to the dihydrogen complexes, the σ-silanes are generally more advanced in the process of oxidative addition, thanks again to a better back donation. For this reason, it is often difficult to discriminate a σ-silane coordination from a hydrido(silyl) formulation.[11] σ-Silane complexes exist for a wide variety of metals, but this review will focus on ruthenium complexes, a metal of choice to act as catalyst precursor for several processes such as hydrosilylation, dehydrosilylative coupling of alkenes, and dehydrogenative polymerisation.[12,13] Moreover, polyhydride ruthenium complexes offer to analyze a wide range of situations. Indeed, a hydrogen atom can be coordinated to the metal as a classical hydride, involved in a σ-coordination (σ-dihydrogen or σ-silane), or in a secondary interaction with a silicon atom. We will in particular highlight the role of additional interactions in the coordination sphere of a metal, as they play a major role for the stabilization of silane complexes and are involved in most of the exchange processes that are often present in these highly dynamic systems.[14]

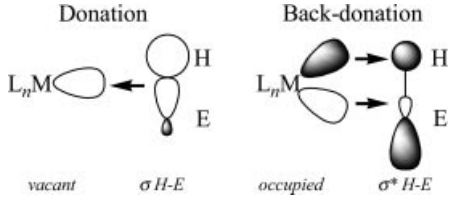

Figure 1. Bonding interactions in a σ-complex.

However, before presenting the different complexes, we would like to give some essential and fairly general features to illustrate the main issues in relation with the degree of activation of the Si–H bond. Between the two extreme situations, formation of a σ-silane complex or Si–H bond breaking and formation of a hydrido(silyl) complex, the Si–H bond activation can be viewed as a continuum (Figure 2). As a consequence, it is extremely difficult to establish the boundaries between the extremes, especially when other hydrogen atoms are present in the coordination sphere of the metal. In such a case, thanks to the tendency of Si to be hypervalent, additional interactions can be established. We have introduced the term *SISHA* to shorten the rather long quotation: *S*econdary *I*nteraction between a *S*ilicon and a *H*ydrogen *A*tom.[14] These interactions play an important role both in the stabilization of unusual geometries and in the exchange processes occurring in polyhydride species. At this point, it is important to remember the preference of ruthenium for oxidation state (II) vs. (IV) and that polyhydride ruthenium chemistry is dominated by σ-ligand coordination.

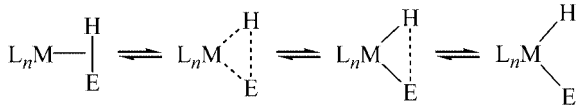

Figure 2. E–H bond activation: a continuum between the σ-complex and the product of oxidative addition.

Multinuclear NMR studies are particularly useful and give key information on the exchange processes and the activation of the Si–H bond. $^1$H chemical shift values are not a very useful parameter, as those for classical hydrides and hydrogen atoms involved in a σ-bond fall in the same range. A similar situation is found for $^{29}$Si chemical shift values of the corresponding silane or silyl complexes. Coupling constant values have been extensively used in particular to discriminate the two extremes, σ-silane complex and oxidative addition product. However, as we will detail below (see *primary silane* section) cautious must be taken in particular for values between 20 and 50 Hz, depending on the substituents on the silicon and in presence of fast exchange processes, which is unfortunately the case for many systems. Activation of the Si–H bond can also be monitored by IR. It is easy to follow the addition of a silane to a transition-metal complex by checking the disappearance of the stretching Si–H bond in the free silane (around 2100–2150 cm$^{-1}$). It is much more difficult to identify the corresponding band in a σ-silane complex (around 1000 cm$^{-1}$) due to extensive mixing of vibrational motions and overlap with some bands of other ligands. However, in many cases, a broad and rather intense band can be observed in the range 1650–1800 cm$^{-1}$, identified as an antisymmetric stretch of the activated Ru–H bond, with H still coordinated to Si. X-ray analysis and DFT calculations are very informative for the identification of σ-bonds and secondary interactions. It is worth noting that X-ray data are now more and more reliable for hydrogen location.[15] Low temperature and high quality measurements are of course required, and comparison with DFT data is very useful. Key parameters, as we will see below, are not only the Si–H distances, but also the Ru–Si distances. The Ru–Si distance within a series of compounds diminishes as the activation of the Si–H bond increases. For Si–H distances of typically 1.7–1.8 Å, σ-bond coordination can be reasonably proposed. The situation becomes more controversial for values around 1.9–2.0 Å. Higher values up to 2.4 Å are typically the range indicating a significant interaction between a hydrogen and a silicon, values still much shorter than the sum of the van der Waals radii, 3.4 Å. The nature of the silicon substituents is highly important. For electron-withdrawing substituents, the tendency of Si to be hypervalent is favored as a result of a σ*(Si–R) orbital lower in energy. The IHI (interligand hypervalent interaction) analysis developed by Nikonov is nothing more than the direct consequence of this well-known hypervalence property applied to hydrido(silyl) complexes.[16]

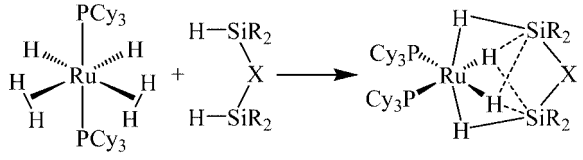
Through some selected examples, we will see the need to combine these various techniques to draw the best view of the bonding nature of a silane. Two main classes of compounds will be examined in details. The first section deals with a series of complexes resulting from the activation of disilane compounds, whereas in a second part we will examine the reactivity of ruthenium complexes with monosilane compounds, either primary or secondary silanes.

### Disilane Coordination

In view of the fascinating chemistry displayed by the bis(dihydrogen) ruthenium complex $RuH_2(H_2)_2(PCy_3)_2$ (**1**),[17] we were interested to isolate an analogous complex but incorporating two other σ-ligands, silane in place of dihydrogen. This was achieved by using disilane compounds. The chelating effect allowed for the stabilization but was not the determinant factor, as we will detail below. The series of general formula $[RuH_2\{(\eta^2\text{-}HSiMe_2)_2X\}(PCy_3)_2]$ [the spacer X between the two Si atoms contains two or three atoms, X = $C_6H_4$, $(CH_2)_n$, $OSiMe_2O$] was isolated and fully characterized (Scheme 1).[18] The most relevant data from multinuclear NMR experiments (see Table 1, compounds **2**–**5**) were the following: (i) one triplet near –8 ppm for the σ-Si–H protons and an AA′XX′ resonance near –12 ppm for the two classical hydrides. Coalescence of the two signals was observed at high temperature and an exchange barrier of roughly 65 kJ·mol$^{-1}$ was determined. Deuterium incorporation was equally observed on the two hydride sites implying a rather easy exchange process between the two types of hydrogen atoms. (ii) The $^{29}Si\{^{31}P\}$ INEPT spectra showed a doublet with $J_{SiH}$ values in the range 65–82 Hz, representing a significant reduction from the values for the free disilane (Δ = 106 to 125 Hz) in agreement with a stretching of the Si–H bond as a result of σ-coordination.



**1**

Scheme 1. Synthesis of the bis(silane) complexes of general formula $[RuH_2\{(\eta^2\text{-}HSiMe_2)_2X\}(PCy_3)_2]$.

The complexes were characterized by X-ray diffraction, and the measurements at low temperature allowed a very good location of the hydrogen atoms, ascertained by DFT calculations (see below and Table 2). They display the same overall structure, a distorted octahedral with two *cis* phosphane groups (P–Ru–P angle close to 108°) and the disilane ligand bonded to the ruthenium through two σ-Si–H bonds in a *trans* position. Activation of the Si–H bond is illustrated by a significant lengthening compared to the free silane. For example for $[RuH_2\{(\eta^2\text{-}HSiMe_2)_2(C_6H_4)\}(PCy_3)_2]$ (**2**) the two σ-Si–H bond lengths are 1.84(2) Å as determined by X-ray diffraction and 1.848 Å by DFT calculations at the B3LYP level, whereas the Ru–Si distances are close to 2.42 Å by X-ray diffraction or DFT calculations (Table 2, Figure 3). After obtaining the first X-ray structure,[19] we were quite surprised by the *cis* position of the bulky phosphane groups. In fact, no matter the nature of the disilane $[HMe_2Si(X)SiMe_2H$ with X = $C_6H_4$, $(CH_2)_2$, $OSiMe_2O]$ or the phosphane ($PCy_3$, $PPh_3$) coordinated, the same overall geometry was obtained (Table 2).[18] We noted that the distances between the classical hydrides and the silicon atoms were close to 2.2 Å, much shorter than the sum of the van der Waals radii (3.4 Å for hydrogen and silicon). Detailed DFT studies by means of two hybrid functionals B3LYP and B3PW91 gave important information on the coordination mode of the disilane ligand to the ruthenium. Three isomers were characterized on the singlet potential energy surface. As an example, we will concentrate on the three isomeric structures of $[RuH_2\{(\eta^2\text{-}HSiH_2)_2(C_6H_4)\}(PH_3)_2]$. The most stable isomer **A** has a geometry closely resembling that found by X-ray diffraction for **2** (Figure 3). The disilane is symmetrically coordinated to the ruthenium with the two σ-hydrogen atoms almost *trans* to each over (the H–Ru–H angle is 172°). The two Si–H distances of 1.848 Å are identical to the values found by X-ray diffraction. More interesting, the classical hydrides are turned toward the silicon atoms, imposing a *cis* position for the phosphane groups. The distances between the silicon atoms and the hydrides are 2.25 Å, indicative of weak attractive interactions again in excellent agreement with X-ray data. It is worth noting that location of hydrogen atoms in the coordination sphere of a metal has been always subject to debate. Very recently, we have published X-ray and neutron data for the bis(dihydrogen) complex $RuH_2(H_2)_2(PCyp_3)_2$ incorporating two tricyclopentylphosphane li-

[a] All the calculations were carried out at the B3LYP level of theory, except for compounds **2**, **6** (B3PW91) and **20** (BP86), by using the following model compounds: **2** $RuH_2[(\eta^2\text{-}HSiH_2)_2(C_6H_4)](PH_3)_2$, **3a** $RuH_2[(\eta^2\text{-}HSiH_2)_2(CH_2)_2](PH_3)_2$, **5** $RuH_2[(\eta^2\text{-}HSiH_2)_2(OSiH_2O)](PH_3)_2$, **6** $RuH_2[(\eta^2\text{-}HSiMe_2)_2NH](PCy_3)_2$, **13** $RuH_2(\eta^2\text{-}HSiH_3)(\eta^2\text{-}H_2)(PH_3)_2$, **15** $RuH_2\{\eta^4\text{-}HSiH_2(CH{=}CHMe)\}(PH_3)_2$, **18** $RuH(\eta^2\text{-}HSiMe_3)\{(\eta^3\text{-}C_6H_8)PH_2\}(PH_3)$, **19** $RuH(\eta^2\text{-}HSiMe_2Cl)\{(\eta^3\text{-}C_6H_8)PH_2\}(PH_3)$, **20** $Cp^*RuCl(\eta^2\text{-}HSiClMe_2)(P\mathit{i}Pr_3)$, **22** $Ru_2H_4(\mu\text{-}SiH_4)(PH_3)_4$, **23** $Ru_2H_2(\mu\text{-}H_2Si(OMe)_2)]_3(PH_3)_2$. [b] Data for one isomer.

gands.[15] Additional comparison with DFT values shows that X-ray data are more and more reliable for hydride location, when of course, high quality measurements can be obtained at low temperature. Isomer **B** was optimized as a minimum lying 32 kJ·mol$^{-1}$ above **A**. Isomer **B** has no symmetry whatsoever, and the two Si–H bonds are now very different: one is *trans* to a phosphane whereas the second one is *trans* to a hydride. One more striking difference with isomer **A** is that all the distances between the hydrides and the silicon atoms exceed the sum of the van der Waals radii (3.52 and 3.58 Å). A similar situation is found in isomer **C** with distances between the hydrides and the silicon atoms of 3.42 Å. Isomer **C** is characterized by a *trans* position of the phosphane groups, with the two Si–H bonds being *trans* to a hydride. Thus, **C** displaying an analogous geometry to the bis(dihydrogen) complex **1**, with in particular *trans* phosphane groups and two σ-ligands *trans* to the hydrides, is not the most stable isomer and is in fact 45 kJ·mol$^{-1}$ above **A**. Similar observations were found when using various disilanes with at least two atoms bridging the two Si. Thus, these close H···Si contacts are a stabilizing feature of the overall structure: we call them *SISHA* interactions (*S*econdary *I*nteraction between a *S*ilicon and a *H*ydrogen *A*tom). These SISHA interactions energetically compensate not only the hindered *cis* position of the bulky phosphane groups, but also the disfavored *trans* position of the σ-bonds (back-donation competition).

In the specific case of only one atom between the two Si, as for example in the case of disiloxane or disilazane, the situation is different as a result of a steric constraint upon coordination of the disilane ligand. Indeed, we have recently characterized both by X-ray diffraction and DFT calculations the disilazane complex $[RuH_2\{(\eta^2\text{-}HSiMe_2)_2NH\}(PCy_3)_2]$ (**6**).[20] For the first time the choice of the functional for DFT calculations in silane ruthenium chemistry turned to be crucial. Major differences were observed with the use of B3LYP by comparison to the X-ray data, whereas a very good match was obtained with B3PW91 (Figure 4). The two phosphane groups in **6** are still in a *cis* disposition but the disilazane ligand has now the two Si–H bonds also in a *cis* disposition, similarly to the case of isomer **B** described above. In **2** by X-ray diffraction or **A** by DFT calculations, the four Si···H distances between the hydrides and the silicon atoms were close to 2.2 Å, whereas in **6** they lie between 2.1 and 3.7 Å by X-ray diffraction and 2.2 to 3.9 Å by DFT calculations. It is now interesting to compare the NMR properties of the two complexes. At room temperature, as already pointed out, the $^1$H NMR spectrum of **2** displays two signals for the two types of hydrogen atoms. Coalescence is observed at much higher temperature. In contrast, in the case of **6**, only one signal is observed at room temperature, whereas decoalescence is achieved at low temperature. The exchange process is thus easier in the case of **6**. In-depth NMR and theoretical studies of the mechanism of the exchange process were undertaken on $[RuH_2\{(\eta^2\text{-}HSiMe_2)_2(C_2H_4)\}(PCy_3)_2]$ (**3a**), a complex very similar to **2** as shown by X-ray, NMR and DFT data.[14] The free energy of activation for exchange is 72 kJ·mol$^{-1}$ at 376 K, and the entropy of activation is close to zero, indicative of an intramolecular process. A complete

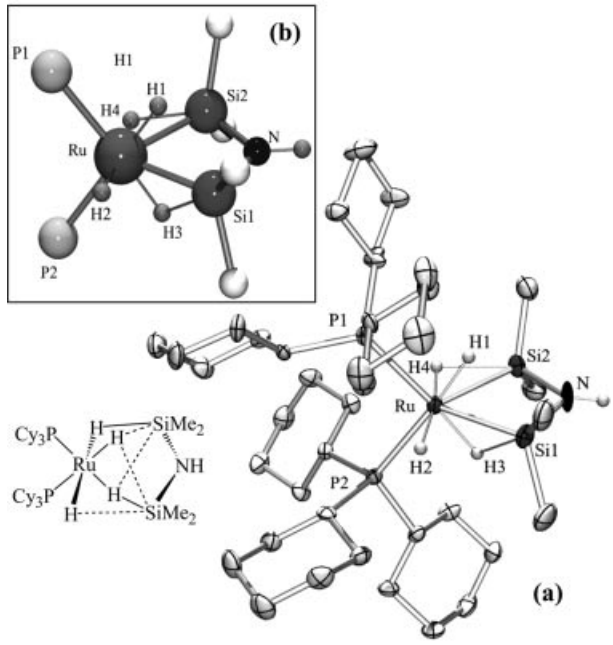

Figure 4. (a) X-ray crystal structure of $[RuH_2\{(\eta^2\text{-}HSiMe_2)_2NH\}(PCy_3)_2]$ (**6**). (b) DFT/B3PW91-optimized geometry of $[RuH_2\{(\eta^2\text{-}HSiMe_2)_2NH\}(PCy_3)_2]$.

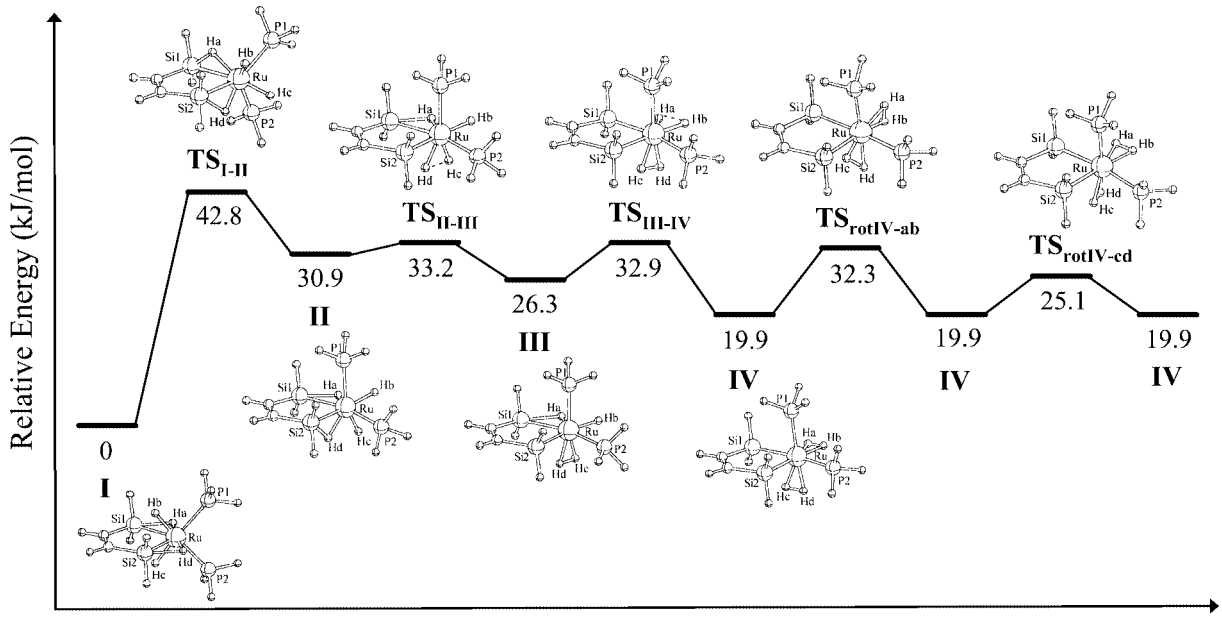

Figure 5. A picture of the intermediates and the transition states involved in the exchange process between the hydrides and the Si–H hydrogen atoms within the model complex $[RuH_2\{(\eta^2\text{-}HSiH_2)_2(C_2H_2)\}(PH_3)_2]$ at the DFT/B3LYP level.

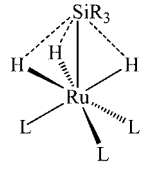
picture of the exchange process deriving from DFT calculations is drawn in Figure 5. Isomer **I** $[RuH_2\{(\eta^2\text{-}HSiH_2)_2(C_2H_2)\}(PH_3)_2]$ was also used as a model complex for **3a**. Exchange of all the different hydrogen atoms can be achieved through the intermediacy of new σ-dihydrogen complexes. Indeed conversion of isomer **I** to the asymmetric isomer **II** in which the SISHA interactions have been broken is the first step. It is then easy to break a Si–H bond. Two hydrogen atoms are now close enough to form a new σ-ligand as in isomer **III**. A similar process with the second Si–H bond leads to isomer **IV** with two dihydrogen ligands. Exchange can now occur via rotation of the dihydrogen ligands and reversal of the isomerisation process. All the transition states connecting the different isomers have been calculated. $\mathbf{TS_{I-II}}$ is the most energetically demanding step. The overall barrier is 42.8 kJ·mol$^{-1}$. In summary, breaking of the SISHA interactions is responsible for the most energetically demanding step in the exchange process.

## Monosilane Coordination

### *Primary Silanes*

A wide variety of monosilanes of the type $HSiR_3$ (R = alkyl, aryl, alkoxy or halogen) reacts with dihydride ruthenium complexes to form the corresponding silane complexes stabilized by various interactions between the hydrides and the silicon atom (see Figure 6).[21–25] Depending on the activation degree of the Si–H bond, they can be interpreted as σ-silane or silyl hydride complexes, namely $RuH_2(\sigma\text{-}HSiR_3)L_2L'$ or $RuH_3(SiR_3)L_2L'$, respectively (L, L′ = $PR_3$, CO, σ-$H_2$). The NMR spectroscopic data are very similar for most of the complexes, as can be seen from Table 1. In the case of $RuH_3(SiCl_2Me)(PPh_3)_3$ (**10**) for example,[21] the $^1$H NMR spectrum exhibits only one hydride resonance at –9.76 ppm with the characteristic AA′A′′XX′X′′ coupling pattern of $MH_3(SiX_3)(PR_3)_3$ complexes arising from the sum of three phosphorus–hydrogen coupling constants, $|^2J_{HPtrans} + 2\ ^2J_{HPcis}|$. The $^1H\{^{31}P\}$ NMR spectrum gives a singlet with $^{29}$Si satellites ($J_{SiH}$ = 39.7 Hz) in agreement with a possible σ-silane bonding mode and/or Si···H interactions. The $^{31}P\{^1H\}$ NMR spectrum shows only a singlet at $\delta$ = 38.31 ppm, suggesting that the three phosphorus are equivalent on the NMR time scale. This is confirmed by the $^{29}Si\{^1H\}$ DEPT NMR spectrum that exhibits a quadruplet centered at $\delta$ = 36.4 ppm ($^2J_{SiP}$ = 12.8 Hz). No decoalescence of the hydride or phosphorus signals was observed even at low temperature, indicative of a fast exchange process in this unsymmetrical compound.



L = phosphane, CO, σ-$H_2$
R = alkyl, aryl, alkoxy, amino or halogen

Figure 6. Schematic representation of a series of complexes of general formula $RuH_3(SiR_3)L_2L'$.

In the case of symmetrical complexes ($C_3$ axis), the equivalency of the hydrides prevents any further interpretation regarding the bonding mode. This situation leads to some disagreement on whether or not the $SiPyr_3$ group is rotating in $RuH_3(SiPyr_3)(PPh_3)_3$ (**11**) for example (Pyr = pyrrolyl). Hübler et al. proposed a bonding scheme that allows a facile rotation when considering the contribution represented in Figure 7 (b) to be preponderant.[23] On the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

contrary, Nikonov pleads an electron-density transfer from the σ(M–H) bonding orbitals into the σ*(Si–N) antibonding orbitals to be the main contribution, thus leading to a rigid structure (Figure 6 and Figure 7, a).[26] However, Nikonov uses a DFT study reported by Hübler et al. to support his argumentation, but this was actually a MP2 study of an osmium analogue, which is certainly not transposable to the ruthenium case. It is thus difficult to make conclusions on the basis of these experimental and computational data. In the case of the $SiMe_3$ group, Berry et al. observed no dynamic process in $RuH_3(SiMe_3)(PMe_3)_3$ (**12a**) on the NMR time scale (only a slight broadening of the Ru–H resonances at 190 K).[27] In these symmetrical compounds, the presence of a Ru-$\eta^2$-H–Si bond (or one strong Si···H interaction) could have led to decoalescence of the hydride signal. However, due to the limited range in temperatures, one cannot conclude on whether the activation energy for the formation/breaking of such interactions would be very low or very high.

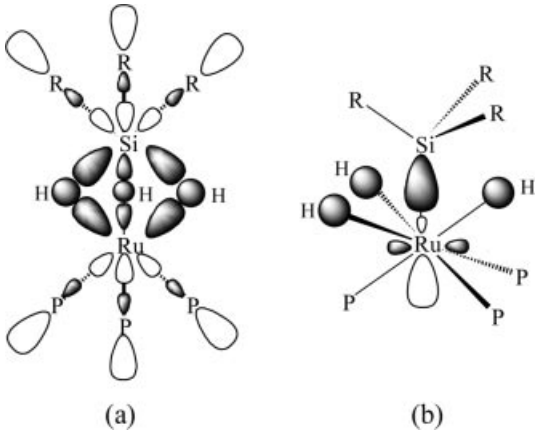


Figure 7. Orbital representation of Ru–H···Si bonding adapted from ref.[19,21]

The fluxionality observed at the NMR time scale for $RuH_3(SiMeCl_2)(PPh_3)_3$,[21] (**10**) but also for $RuH_2(\eta^2\text{-}HSiPh_3)(\eta^2\text{-}H_2)(PCy_3)_2$ (**13**),[28] $RuH_2(\eta^2\text{-}HSiMe_2Cl)(\eta^2\text{-}H_2)(PCy_3)_2$ (**14**),[29] and $RuH_3(SiMe_2CH_2SiMe_3)(PMe_3)_3$ (**12c**),[22] is consistent with exchange processes characterized by low activation energy barriers. In **10** and **12c**, the silane ligand is bearing different substituents (a situation not depicted in Figure 7, a). The presence of different R substituents should affect more or less the balance between the three Si···H interactions in the contribution shown in Figure 7 (a). In **13** and **14**, one phosphane is now replaced by a dihydrogen ligand. It is thus expected a reinforcement of hydride inequivalency. Again, one cannot conclude when no decoalescence of the hydride resonance is observed. NMR spectroscopy can still provide $J_{SiH}$ coupling constants but they are mean values. The interpretation of the raw values has to be done cautiously since the typical ranges for which the Si–H bonds were considered to be either fully activated ($< 20$ Hz) or just partially elongated (20–70 Hz) have been recently reconsidered.[22,30] The free silane $^1J_{SiH}$ substituent-dependency clearly illustrates the problem. Values vary from 190 Hz in $HSiMe_3$ to 370.6 Hz in $HSiCl_3$ due in part to an increase in the s character in the Si–H bond (Bent's rule). This naturally applies to the $J_{SiH}$ coupling in a complex, more precisely to its two contributions of opposite signs, $^1J_{SiH}$ and $^2J_{SiH}$. The measured $J_{SiH}$ value corresponds to the sum $|^1J_{SiH} + {}^2J_{SiH}|$. In the series of $CpRu(SiR_3)(PR'_3)_2$ complexes, Lemke et al. have shown that an increase in the electron-withdrawing character of the $SiR_3$ group leads to stronger Ru–Si bonds as monitored by the increase of the $|^2J_{SiP}|$ values.[31] For hydrido(silyl) or σ-silane species with different $SiR_3$ groups, but considering a similar activation of the Si–H bond, the $|^1J_{SiH}|$ values should increase as a function of the R substituent, with the highest value for the more electronegative group. As an example, coordination of $HSiR_3$ to a metal center leading to 80% activation of the Si–H bond would result to a $|^1J_{SiH}|$ value of 74 Hz for R = Cl and 38 Hz for R = Me. Assuming that the $|^2J_{SiH}|$ values will follow the same trend as the $|^2J_{SiP}|$ values in silyl complexes, the magnitude of the apparent $J_{SiH}$ coupling may not necessarily reflect the silane bonding and its modifications. For example, the apparent $J_{SiH}$ values of 39.7 Hz in $RuH_3(SiMeCl_2)(PPh_3)_3$ (**10**) and 47.4 Hz in $RuH_3(SiPyr_3)(PPh_3)_3$ (**11**) do not necessarily indicate the presence of a σ-silane bond. However, in order to define a trend for the $J_{SiH}$ coupling constants in silane ruthenium complexes, one can start with the coupling constant of 105 Hz measured in the allylsilane complex $RuH_2[\eta^4\text{-}HSiMe_2(CH{=}CHMe)](PCy_3)_2$ (**15**) to give an idea of the upper limit corresponding to an agostic Si–H interaction.[32] We can then consider the *fac* and *mer* isomers of $RuCl(CH_2SiHMe_2)(PMe_3)_3$ described by Berry et al. that reflect a further point on the oxidative addition process (still close to the agostic interaction type).[33] They respectively exhibit $J_{SiH}$ values of 75 and 77.5 Hz associated to Si–H distances of 1.664 Å in the *fac* isomer and 1.557 Å in the *mer* one, in agreement with only slightly elongated Si–H bonds. The next step can be represented by the bis(σ-silane) complexes described in the previous section with coupling constants around 70 Hz. Below that value, it is recommended to interpret the $J_{SiH}$ values with caution, especially when the silicon atom has electron-withdrawing substituents. More information could be now gained thanks to recent improvements in DFT calculations, which allow calculations of $J_{SiH}$ values.[34] Generally, a negative value is the sign of a direct Si–H interaction as $^1J_{SiH}$ are negative due to the negative magnetogyric value of silicon.[35]

Decoalescence of the hydride signal in a polyhydride system is rarely observed. The $^1H$ NMR spectrum of $RuH_2\{(\eta^2\text{-}HSiPh_2)O(SiHPh_2)\}(PPh_3)_3$ (**9a**) at 203 K, a complex with a dangling Si–H ligand, shows two broad multiplets at –8.97 ppm and –9.40 ppm ($^2J_{HP\,trans}$ = 50 Hz and $^2J_{HP\,cis}$ = 25 Hz) in a 2:1 ratio.[14] At this temperature, the $^{31}P\{^1H\}$ NMR spectrum displays a triplet at $\delta$ = 42.62 and a doublet at $\delta$ = 38.49 with $J_{PP}$ of 23 Hz. The $^{29}Si$-$^1H$ COSY spectrum acquired at 203 K shows a signal corresponding to the dangling Si–H bond ($\delta$ –21.4) and another one ($\delta$ = 11.7 ppm) correlated to the hydride high-field resonance at $\delta$ –8.97 ppm attributed to an ($\eta^2$-Si–H) hydrogen.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The fast exchange at room temperature is associated to a $J_{SiH}$ mean value of 35 Hz. Due to line broadening, no $J_{SiH}$ value could be measured at low temperature. According to the above discussion about coupling constants, a definitive assignment between the two formulations, dihydride σ-silane or trihydride silyl with one strong Si···H interaction, is difficult. An X-ray structure of $RuH_2\{(\eta^2\text{-}HSiPh_2)\text{-}O(Si(OH)Ph_2)\}(PPh_3)_3$ (**9b**), resulting from hydrolysis of the dangling Si–H bond of **9a** was obtained. The structure is similar to those described for other $RuH_3(SiR_3)L_3$. The ruthenium is surrounded by the three phosphane groups in a tripodal position with P–Ru–P angles of 103° (av.) and Si–Ru–P angles of 115° (av.). However, one Si–Ru–P angle is 119°, indicating a dissymmetric geometry. The hydrogen atoms were located in the vicinity of the ruthenium at 1.6 Å (av.). The distances between the silicon and the three hydrides are 1.97(5), 2.03(5) and 2.07(5) Å. They are in agreement with an elongated σ-Si–H bond and two SISHA interactions (unfortunately, we have no DFT data for comparison). The Ru–Si distance is 2.356(2) Å, thus at the lower limit of the Ru–Si distances observed in other silane ruthenium complexes. We note that steric hindrance between the phosphane groups and the $OSi(OH)Ph_2$ group may have influenced the bonding. As a matter of fact, there is no decoalescence of the hydride resonance for $RuH_3(SiMe_2CH_2SiMe_3)(PMe_3)_3$ (**12c**) in which the phosphane groups are rather small.[22] In this series of complexes, X-ray data show that the Ru–Si bond lengths range from 2.2760(4) Å in $RuH_3(SiCl_2Me)(PPh_3)_3$ to 2.385(2) Å in $RuH_2(\eta^2\text{-}HSiPh_3)(\eta^2\text{-}H_2)(PCy_3)_2$ (see Table 2). They overlap the distances reported for silyl and σ-silane species and they are mainly in the lower limit region (taking into account the nature of the silicon substituents). In fact, the process of Si–H bond activation can be described similarly to the one proposed for C–H bond activation. Once the proton/metal interaction is established, the Si–M distance decreases while the M–H and Si–H distances stay almost unchanged (until a certain point).[6,36] The main difference comes from the silicon hypervalence that may favor Si···H interactions, keeping the atoms close together in a *cis* position. Lin has discussed this point in a previous review on the structural and bonding characteristics in transition metal–silane complexes.[5] Consequently, a long Ru–Si distance is consistent with an early stage in the activation, i.e. a σ-silane bonding mode, while it remains difficult to conclude for a short one, which appears to be the case in this series. When comparing the Ru–Si distances obtained for this family to the ones measured in the bis(σ-silane) complexes, we deduce that the latter represents an earlier stage in the Si–H bond activation process. This is confirmed by the shorter σ-Si–H bond lengths and the weaker SISHA interactions (longer Si···H distances). For the complexes we are considering here, the SISHA interactions are dedicated to only one silicon atom. This certainly results in a better stabilization of the activated silane and consequently highlights a tight relationship between the Si–H bond activation level and the SISHA interaction strength. The Si–H bond oxidative addition process is better seen as a continuum in energy. SISHA interactions help to equilibrate the electronic density transfers between the ruthenium, the hydrides and the silicon.

The X-ray structure analysis of $RuH_2(\eta^2\text{-}HSiPh_3)(\eta^2\text{-}H_2)(PCy_3)_2$ (**13**) done at 160 K exhibits an elongated σ-Si–H bond [1.72(3) Å] and one strong SISHA interaction [1.843(3) Å]. The remaining hydride is at 2.40(4) Å. This can be related to the nature of the *trans* ligands ($PCy_3$ and $\sigma\text{-}H_2$) and the steric hindrance as much as the electronic effects can be invoked. The Ru–Si distance [2.385(2) Å] is the longest reported for that series, consistent with a rather early stage in the Si–H bond activation process and one main SISHA interaction. A $J_{SiH}$ value of 18 Hz was recently determined. Considering that five hydrogen atoms are in fast exchange, this observed value is in agreement with the presence of a σ-silane. However the overall geometry was not predictable by NMR spectroscopy, but was confirmed by DFT/B3LYP calculations on the model $RuH_2(\eta^2\text{-}HSiH_3)(\eta^2\text{-}H_2)(PH_3)_2$.[25] The ground state structure shows two SISHA interactions (2.071 and 2.116 Å) and an elongated σ-Si–H (1.946 Å) that is less than 0.2 Å shorter. This short difference is in agreement with the high fluxionality observed by NMR spectroscopy. An analogous study performed on the model $RuH_2(\eta^2\text{-}HSiMe_2Cl)(\eta^2\text{-}H_2)(PH_3)_2$ gives the same results. The location of Cl with respect to the hydrides influences the positioning of the σ-Si–H bond but does not change the energy that much ($\Delta E$ = 4.8 kJ/mol between isomers A and B) (see Figure 8 and Table 3). The closest Si···H contact is not in a position *trans* to Cl, as would be predicted for a hydrido(silyl) formulation by using the Nikonov model of interaction, IHI. All the observations are consistent with a σ-bonding mode of the silane.

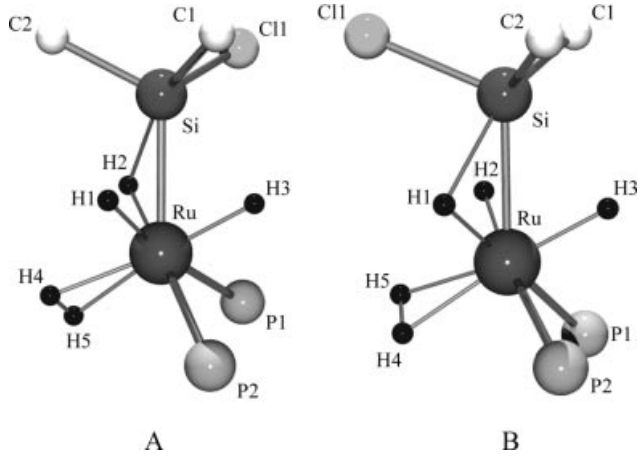

Figure 8. The two DFT/B3LYP-optimized isomeric structures of $RuH_2(\eta^2\text{-}HSiMe_2Cl)(\eta^2\text{-}H_2)(PH_3)_2$.

We undertook a detailed investigation on the complexes $RuH(\eta^2\text{-}HSiR_3)\{(\eta^3\text{-}C_6H_8)PCy_2\}(PCy_3)$ ($SiR_3$ = $SiEt_3$, $SiMe_2Et$ and $SiMe_2Cl$). In this series, the situation is different because there is no hydride exchange at room temperature, as the result of the presence of two different phosphane groups.[29,37,38] In $RuH(\eta^2\text{-}HSiMe_2Cl)\{(\eta^3\text{-}C_6H_8)PCy_2\}(PCy_3)$ (**19**) for example, the two hydrides resonate at –9.06 ppm (br. t) and –11.98 ppm (dd) and an AB pattern

(83.9 and 68.8 ppm, $J_{PP}$ = 18.6 Hz) is observed in the $^{31}P\{^1H\}$ spectrum. A 1D HMQC $^{29}Si\text{-}^1H\{^{31}P\}$ experiment shows two doublets in the high-field region with $J_{SiH}$ values of 37.3 and 24.1 Hz (see Figure 9). The coupling of H1 and H2 with silicon are different by more than 10 Hz, but are surprisingly almost the same in the two analogous complexes **17** and **18** with $HSiEt_3$ and $HSiMe_2Et$, respectively (see Table 1). A rather significant change on the Si–H bond activation was expected at least between $HSiMe_2Cl$ and $HSiMe_2Et$ because of the chloride substituent. This point comforts the idea that a direct interpretation of the $J_{SiH}$ value is not appropriate to the description of the bonding mode of the silane. The X-ray structures of the latter two species have been obtained. A partial disorder on the Si substituents could not be solved and the hydrides could only be detected for **19** (see Figure 10). The Si–H distances of 1.91(2) Å (1.891 by DFT calculations) and 1.99(2) Å (2.076 by DFT calculations) can be assigned to an $\eta^2$-Si–H and a SISHA interaction, respectively. Even if the values overlap when taking into account the standard deviations, they seem to be in agreement with the corresponding coupling constants. The Ru–Si bond lengths in **18** [2.418(1) Å] and **19** [2.353(2) Å] are clearly different, in agreement with the higher electronegativity of the more tightly bound $SiMe_2Cl$ group. The Ru–Si distances mirror the stability of the silane bonding. As a matter of fact, **19** is stable under an atmospheric pressure of ethylene in toluene, whereas **18** leads to C–Si coupling product and formation of $RuH(\eta^2\text{-}C_2H_4)\{(\eta^3\text{-}C_6H_8)PCy_2\}(PCy_3)$.[37] Compound reactivity is certainly an interesting criterion to differentiate the bonding in this series of silanes. However, what does this shorter Ru–Si bond really mean? The Ru–Si interaction can be strong both in a silyl and in a σ-silane species and increased by the hypervalence tendency of Si. The Ru–Si bond can be shorter thanks to an additional contribution: a bonding overlap between an occupied d(Ru) orbital and empty σ*(Si–R) orbitals. Such a bonding contribution, favored by chloro substituents, has already been used by Lemke et al. to describe a large series of silyl ruthenium complexes.[31] When no d(Ru) orbital is "available", one can consider that the σ(Ru–H) orbital can play the same role. As we have already explained, SISHA interactions help back-donation of electronic density from Ru to Si via the hydrides. This has also been extensively studied by Nikonov et al. but mainly in the particular case of Cl substituents.[16] In summary, the interpretation of the similarities and differences

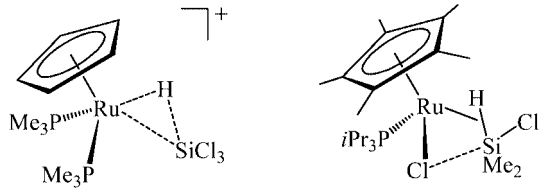
between **18** and **19** is tricky and requires more information. We will publish in due course a full experimental and theoretical study on that series, focusing particularly on the bonding nature of the silane as a function of the chloride number.

It is worth to note that SISHA interactions are not limited to chloride-containing silanes as they clearly appear in most of the examples presented above. But Cl seems to favor secondary interactions as illustrated by the work of Nikonov et al. Cp*RuCl($\eta^2$-HSiMe$_2$Cl)(P*i*Pr$_3$) (**20**) is defined as a σ-silane complex on the basis of experimental and theoretical data (see Figure 11 and Table 1, Table 2).[35] Its X-ray structure exhibits an unusual interaction between the Cl ligand and the silicon atom [$d_{Cl\cdots Si}$ = 3.014(1) Å and the sum of the van der Waals radii is 3.81 Å]. This is well reproduced by DFT calculations on the model CpRuCl($\eta^2$-HSiMe$_2$Cl)(PMe$_3$). The ground state corresponds to the X-ray structure, i.e. the chloride substituent on the silicon is almost "*trans*" to the chloride [Cl–Si···Cl = 165.61(3)°]. The rotamer with a methyl group in "*trans*" is 10.5 kJ/mol less stable and the Si···Cl distance is elongated by about 0.2 Å. This confirms the stabilizing role played by the chloride as it is more electron-withdrawing than the methyl group. A small elongation of the Si–R bond "*trans*" to the secondary interaction is always reported, in agreement with the implication of the σ*(Si–R). In this example, the Si–H bond is absolutely not in the same plane as the Cl substituent which is the case in several silyl hydrido complexes with IHI described by Nikonov et al. Here, the compound is a "real" σ-silane complex. In the absence of any other hydride, further stabilization can only be gained by the formation of a secondary interaction between Si and Ru–Cl. Such an interaction is maximized for a Ru–Cl not orientated *trans* to Si–H. As discussed above, a similar situation has been observed when considering the RuH$_2$($\eta^2$-HSiMe$_2$Cl)($\eta^2$-H$_2$)(PH$_3$)$_2$ rotamers.



**21** **20**

Figure 11. Schematic view of Cp*RuCl($\eta^2$-HSiMe$_2$Cl)(P*i*Pr$_3$) (**20**) and [CpRu($\eta^2$-HSiCl$_3$)(PMe$_3$)$_2$]$^+$ (**21**).

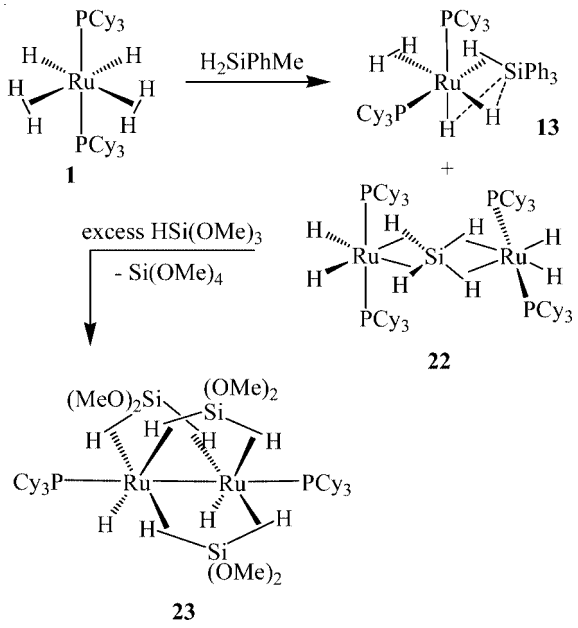
Lemke et al. reported the full characterization of the cationic complex [CpRu($\eta^2$-HSiCl$_3$)(PMe$_3$)$_2$]$^+$ (**21**) formed by protonation of the silyl complex CpRu(SiCl$_3$)(PMe$_3$)$_2$.[39] Compound **21** was formulated as a σ-silane species on the basis of X-ray diffraction and NMR spectroscopic data (see Figure 11). The silane ligand was characterized by a Si–H bond length of 1.77(5) Å in the typical range for σ-silane ligands. The $J_{SiH}$ value of 48 Hz is also in the range expected for a σ-coordination. However, comparison with the corresponding value for the free silane HSiCl$_3$ (370 Hz) denotes a very strong reduction in the Si–H interaction. NMR spectroscopic data also indicate some fluxionality of the silane with respect to its orientation with the two phosphane ligands. The authors associate their data to a σ-silane arrested in its oxidative addition to the ruthenium center indicative of a latter stage of such a process. The geometry can be described as a "three- or four-legged piano stool" depending on how the HSiCl$_3$ ligand is considered. This appears to be in agreement with the measured Si–H distance, only if we analyze this strong interaction to be the consequence of the silicon hypervalence enhanced by the chloro substituents. This is a perfect example to highlight the crucial role of silicon hypervalency on silane bonding.

### *Secondary Silane*

The next step in our silane studies was to examine the reactivity of the bis(dihydrogen) complex **1** with dihydrogenosilanes. We mentioned in the introduction the complexity of silane activation toward σ-coordination as compared to dihydrogen activation. Steric and electronic effects of the Si substituents can tune the σ-coordination as well as the hypervalence properties of the silicon. But one can also face redistribution reactions. Indeed, by adding dihydrogenosilanes to **1**, several silanes were generated in situ. For example, when starting with H$_2$SiMePh, HSiMe$_2$Ph and HSiMePh$_2$ were formed and remained in solution whereas formation of SiH$_4$ and HSiPh$_3$ resulted in their coordination to a metal fragment to produce the corresponding complexes [Ru$_2$H$_4$(μ-$\eta^2$:$\eta^2$:$\eta^2$-SiH$_4$)(PCy$_3$)$_4$] (**22**) and [RuH$_2$($\eta^2$-H$_2$)($\eta^2$-HSiPh$_3$)(PCy$_3$)$_2$] (**13**) (Scheme 2).[40,41] Compound **22** is a unique example of a SiH$_4$ ligand in a bridging position. It is coordinated to two Ru through four σ-Si–H bonds. Each σ-bond [$d_{Si-H}$ = 1.69(3) Å and 1.73(3) Å by X-ray diffraction and 1.685 Å by DFT calculations] is the result of a σ-donation to an empty d orbital of one ruthenium and backbonding from the occupied d orbital of *the other* ruthenium into the σ*(Si–H) antibonding orbital. Interestingly, **22** is characterized by a fast exchange process as the eight hydrogen atoms (four hydrides and four involved in the σ-Si–H bonds) gave a nonet in the $^{29}$Si INEPT spectrum with an average $J_{SiH}$ value of 36 Hz. The $^1$H NMR spectrum displayed one signal in the hydride region at room temperature, but decoalescence into two signals of equal intensity was obtained at 203 K characterized by a low barrier of 36 kJ·mol$^{-1}$. Another redistribution process was observed by adding an excess of HSi(OMe)$_3$ to **22** (Scheme 2). Formation of Si(OMe)$_4$ and of a new dinuclear complex [Ru$_2$H$_2$(μ–$\eta^2$:$\eta^2$-H$_2$Si(OMe)$_2$)$_3$(PCy$_3$)$_2$] (**23**) was obtained. Compound **23** represents a very interesting case, illustrating the difficulty in assigning a defined structure in such highly delocalized species. Again eight hydrogen atoms in fast exchange are detected by multinuclear NMR studies with an average $J_{SiH}$ value of 22 Hz. Location of the hydrides was not possible by X-ray diffraction and the proposed formulation was deduced in particular from DFT studies (see Figure 12) and correlated to NMR spectroscopic data. In the model complex [Ru$_2$H$_2$(μ-H$_2$Si(OMe)$_2$)$_3$(PH$_3$)$_2$], one bridging H$_2$Si(OMe)$_2$ ligand is symmetrically coordinated to the two Ru with rather long Ru–

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Si distances (2.551 Å) and short Si–H distances (1.653 Å) whereas the two other ligands are dissymetrically bonded to the ruthenium but with shorter Ru–Si distances (2.40 and 2.49 Å) and longer Si–H distances (1.74 and 1.76 Å). The Wiberg bond indices obtained from a natural bond orbital analysis are also in agreement with a different level of activation within the three ligands.



Scheme 2. Redistribution at silicon.

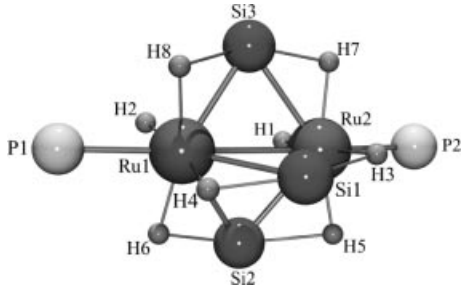


Figure 12. DFT/B3LYP-optimized structure of $[Ru_2H_2(\mu\text{-}H_2Si(OMe)_2)_3(PH_3)_2]$.

An elegant study concerning the synthesis of dinuclear silane ruthenium complexes was reported by Suzuki et al.[42] The mono(silane) complex $[Cp^*Ru(\mu\text{-}H)]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}H_2Si\textit{t}Bu_2)$ (**24**) was obtained by reacting $H_2Si\textit{t}Bu_2$ with the ruthenium tetrahydride complex $Cp^*Ru(\mu\text{-}H)_4Cp^*Ru$ (see Scheme 3). The fluxionality observed by NMR at room temperature for the two types of hydrogen was blocked at 153 K resulting in the formation of two signals. The signal at –6.15 ppm displaying a coupling constant of 75 Hz was thus assigned to the σ-ligands, whereas the signal at –16.63 ppm was assigned to the bridging hydrides. The broad adsorption in the IR spectrum at 1790 $cm^{-1}$ (confirmed by deuterium labeling) was also in agreement with σ-silane coordination. Reaction of (**24**) with CO yields a mixture of two new σ-complexes $[Cp^*Ru(CO)]_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}H_2Si\textit{t}Bu_2)$ (**25a**) and $[Cp^*Ru(CO)]_2(\mu\text{-}\eta^2\text{-}HSi\textit{t}Bu_2)H$ (**25b**). The X-ray structure of **25a** shows long Ru–Si bonds [2.447(1) Å and 2.457(1) Å] and two Si–H bond lengths of 1.77(3) Å and 1.75(3) Å in agreement with two σ-Si–H bonds. (**25a**) is in equilibrium in solution with **25b**. When compound **24** was treated with $H_3SiPh$ or $H_2SiEt_2$ the corresponding mixed-bridge complexes were obtained, $[Cp^*Ru]_2(\mu\text{-}\eta^2\text{-}HSi\textit{t}Bu_2)(\mu\text{-}\eta^2\text{-}HSiPhH)(\mu\text{-}H)H$ (**26a**) and $[Cp^*Ru]_2(\mu\text{-}\eta^2\text{-}HSi\textit{t}Bu_2)(\mu\text{-}\eta^2\text{-}HSiEtH)(\mu\text{-}H)H$ (**26b**), respectively. Again the σ-Si–H bonds are characterized by long Ru–Si bond lengths.

## Conclusions

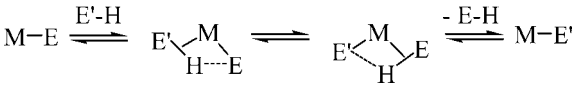
Much work has been published in the area of catalytic silane activation by metal complexes as a wide variety of valuable substrates can be produced. No matter the catalytic process in consideration, one of the main important goal remains selectivity control. This can be achieved by a knowledge of the different key steps occurring in a catalytic cycle. Silane activation by the metal complex is one of these key steps. Throughout all the examples we have considered, it is clear that it is difficult to control this activation process. A continuum exists between the two extremes leading either to σ-silane coordination or oxidative addition. There is no doubt that the tendency of silicon to be hypervalent favors such a continuum, by creating secondary interactions as described above (SISHA interactions).

None of the useful criteria i.e. $J_{SiH}$, IR bands, $d_{Si-H}$ and $d_{Ru-Si}$ by X-ray diffraction or DFT calculations, can be used *alone* to evaluate the degree of silane activation. In particular, it appears that the interpretation of $J_{SiH}$ values can be difficult, especially for systems including electron-withdrawing substituents and showing fluxional behavior.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The lower limit of 20 Hz used by several authors (including us) should now be set up to 65 Hz for a secure criterion of a σ-Si–H bond. Observation of a broad and intense IR band in the range 1650–1800 $cm^{-1}$ remains a good indication of σ-coordination. When X-ray data involving hydrogen atoms can be supported by DFT calculations, one can considered that a $d_{Si–H}$ value around 1.7–1.8 Å will support the formation of a σ-silane complex. Moreover, silicon-hydrogen distances around 1.9–2.4 Å should alert the researchers of the presence of secondary interactions. The Ru–Si bond strength depends significantly on the silicon-attached substituents, but a short bond length will be consistent with an advanced oxidative addition process.

We have shown that σ-Si–H bonds and SISHA interactions play a major role in alkyl and chloro silane catalytic activation.[29,32,38,43] Moreover, in 2002 we proposed a σ-bond metathesis mechanism which offers alternatives that are distinct from the standard σ-bond metathesis mechanisms and the oxidative addition pathways.[14,44] Successive formation of σ-bonds and secondary interactions (see Scheme 4) allow operating at constant oxidation state whereas oxidative addition/reductive elimination mechanisms change oxidation states by two units. More work is needed both at the stoichiometric and catalytic level to examine the relevance of these types of bonding (σ-Si–H bonds and SISHA interactions) in various catalytic systems with the main goal to achieve better selectivity.



Scheme 4. Functionalization assisted by σ-ligand substitutions and secondary interactions.

# Dithiolato-Bridged [$MRu_2$] (M = Rh, Ir, Ru) Triangular 50e$^-$ Cluster Complexes Synthesized by Complete Metal Framework Reconstruction

**Norikiyo Nakagawa,[a] Masaki Murata,[a] Manabu Sugimoto,[b] and Hiroshi Nishihara*[a]**

**Keywords:** Metal framework reconstruction / Electron excess / X-ray crystallographic analysis / Three-centers-four-electrons bond

A method for synthesizing triangular dithiolene-bridged trinuclear cluster complexes [{LM($S_2C_6H_4$)}$Ru_2$(CO)$_4$($S_2C_6H_4$)] [M = Rh, L = ($\eta^5$-$C_5Me_5$); M = Ir, L = ($\eta^5$-$C_5Me_5$); M = Ru, L = ($\eta^6$-$C_6Me_6$)] by complete reconstruction of the metal framework was developed. The complexes thus obtained have 50 electrons around the metal atoms, indicating 3c4e$^-$ bonds; their molecular structures were determined by X-ray diffraction analyses and theoretical calculations.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

There have been various reports about syntheses of transition-metal cluster complexes and their unique properties, and the finding of a new metal–metal bond formation reaction and a new metal–metal bond character can lead to the creation of valuable metal cluster materials with novel chemical functions (including catalytic reactivity) and with novel optical, magnetic, and electronic properties.[1] We have recently reported the synthesis of a triangular trinuclear heterometal cluster complex [{($\eta^6$-$C_6Me_6$)Ru($S_2C_6H_4$)}$Co_2$(CO)$_5$] (**3**), a rare example containing a planar metalladithiolene ring.[2] The number of the electrons around the trimetal framework in **3** is 48, adjusted to make three metal–metal single bonds in a triangle. We report here the unique reactivity of **3** and [{($\eta^6$-*p*-cymene)Ru($S_2C_6H_4$)}$Co_2$(CO)$_5$] (**4**) [*p*-cymene = *p*-($Me_2CH$)-$C_6H_4$Me], with mononuclear complexes [($\eta^5$-$C_5Me_5$)Rh($S_2C_6H_4$)] (**1**) and [($\eta^5$-$C_5Me_5$)Ir($S_2C_6H_4$)] (**2**) to give new triangular cluster complexes composed of other metals. These reactions show the first complete reconstruction of the trimetal framework caused by successive metal–metal bond scission and formation reactions. The obtained complexes [{($\eta^5$-$C_5Me_5$)Rh($S_2C_6H_4$)}$Ru_2$(CO)$_4$($S_2C_6H_4$)] (**5**), [{($\eta^5$-$C_5Me_5$)Ir($S_2C_6H_4$)}$Ru_2$(CO)$_4$($S_2C_6H_4$)] (**6**), and [{($\eta^6$-$C_6Me_6$)Ru($S_2C_6H_4$)}$Ru_2$(CO)$_4$($S_2C_6H_4$)] (**7**) have triangular metal frameworks with 50 electrons around the trimetal framework, indicating that they belong to electron-rich compounds. Their unusual metal–metal bond properties were clarified by X-ray crystallography and molecular orbital calculations.

The reactions of the cluster complexes **3** and **4** with the mononuclear complexes **1** and **2** are summarized in Scheme 1 and Table 1. Scheme 1 shows the formation of the cluster complexes by transmetallation; products **5**–**7** were synthesized from another cluster complex consisting of completely different transition metals. There have been reports on syntheses of cluster complexes by transmetallation,[1d] but the syntheses of cluster complexes by complete metal framework reconstruction is new. A mixture of **1** and **3** in a 1:1 molar ratio was refluxed in 1,4-dioxane to afford a red compound **5** in 41% yield based on the Ru cluster **3** (Entry 1). Product **5** seems to be generated from 1 equiv. of **1** and 2 equiv. of **3**; when the same reaction of **1** and **3** was performed in a 1:2 molar ratio, the same product **5** formed, however in a lower yield (24%). Similarly, the reaction of **2** with **3** gave the red compound **6** in 10% yield as a major product and a trace amount of **7** (Entry 2). The same cluster complexes **5** and **6** were obtained when **4** was used instead of **3**, but in relatively low yields (Entries 3 and 4). The trinuclear complexes **5**–**7** did not appear to be air- or moisture-sensitive either in the crystalline state or in solution, irrespective of their unusual electronic configuration (vide infra). In these reactions, a black powder precipitated which contained Co, but unfortunately it could not be characterized because of the insolubility in common solvents.

The molecular structures of **5**, **6**, and **7** were determined by single-crystal X-ray diffraction analysis, and an ORTEP drawing of **5** is shown in Figure 1.[3] The metal frameworks of **5**–**7** are those of isosceles triangles, and the bond lengths and angles of **5**–**7** are similar to each other (Figure 1; Figures S1 and S2, Supporting Information). There are two benzenedithiolato ligands in **5**; one of them bridges two Ru atoms, and the other one bridges Rh and Ru atoms. The dihedral angle of the SRuS plane vs. the SCCS plane in the

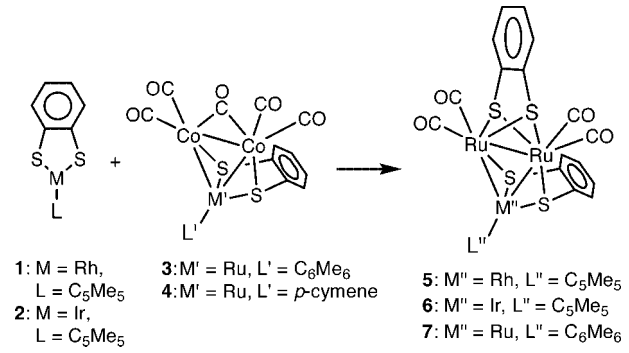

Scheme 1. Reactions of the mononuclear complexes **1** and **2** with the trinuclear cluster complexes **3** and **4**.

Table 1. Reactions of **1** and **2** with **3** and **4**.

| Entry | Starting compounds | Products | Yield |
|---|---|---|---|
| 1 | **1** + **3** | **5** | 41% |
| 2 | **2** + **4** | **6** (major) and **7** (minor) | 10% (for **6**) |
| 3 | **1** + **3** | **5** | 28% |
| 4 | **2** + **4** | **6** | 4% |

ruthenadithiolene in **5**, which bridges two Ru atoms, is 48.5°, indicating that the planarity of the metalladithiolene is lost; in contrast, the dihedral angle in the rhodiadithiolene, which bridges Rh and Ru atoms, is 15.5°, indicating that the planarity and thus the quasi-aromaticity of the metalladithiolene ring are not totally lost after coordination of S to Ru. The maintenance of the planarity of the metalladithiolene ring with the coordination of S to other metal atoms is rare but is found in some cases like **3**, [{($\eta^5$-$C_5Me_5$)Rh($S_2C_6H_4$)}$Co_2(CO)_5$] (**8**), and [{($\eta^5$-$C_5Me_5$)Ir($S_2C_6H_4$)}$Co_2(CO)_5$] (**9**), the structures of which are similar to each other.[2] As mentioned above, an intriguing difference in the electronic structure of the trinuclear complexes between the starting materials **3** or **4** and the products **5**–**7** is the number of electrons around the three metal atoms; in **3** or **4** this number is 48, satisfying the 18-electron rule at each metal atom for three metal–metal single bonds in a triangle, which is common in transition-metal cluster complexes containing three metals in a triangular arrangement,[4,5] whereas in **5**–**7** this number is 50. We have previously reported that the molecular structure of **3** as determined by X-ray crystallography is actually consistent with the existence of three metal–metal single bonds (Figure 2, closed form **A**).[2] In contrast, the existence of two excess electrons around the trimetal framework in **5**–**7** suggests that some of the metal–metal bonds should be weaker than a single bond. Most trinuclear 50e⁻ complexes are known to have linear or bent metal frameworks with two direct metal–metal single bonds (Figure 2, open form **B**),[6] while some triangular cluster complexes exist that have more than 48 electrons around their metal frameworks and longer metal–metal bonds than the usual single metal bonds (Figure 2, closed form **C**).[7] Compounds **5**–**7** are new examples of 50e⁻ closed triangle complexes for which the Ru–Ru distance is 2.7648(4) Å, which is nearly equal to a single Ru–Ru bond in other complexes.[8] The average Rh–Ru distance is 3.019 Å, which is apparently longer than a single bond.

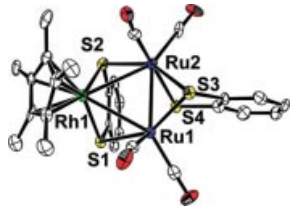

Figure 1. ORTEP drawing of **5** with 50% probability; hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Rh1–Ru1 3.0062(4), Rh1–Ru2 3.0308(4), Ru1–Ru2 2.7648(4), Rh1–S1 2.2910(8), Rh1–S2 2.2968(8), Ru1–S1 2.3838(8), Ru1–S3 2.3862(9), Ru1–S4 2.4531(9), Ru2–S2 2.3832(9), Ru2–S3 2.3693(9), Ru2–S4 2.4555(9); Ru1–Rh1–Ru2 54.511(9), Rh1–Ru1–Ru2 63.198(9), Rh1–Ru2–Ru1 62.29(1).

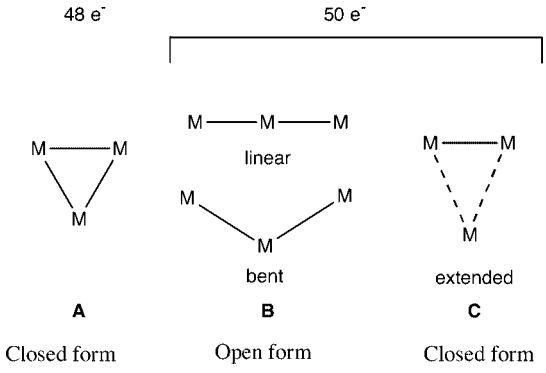

Figure 2. The metal frameworks of a trinuclear 48e⁻ cluster complex and trinuclear 50e⁻ cluster complexes.

To clarify the metal–metal bond characters in these 50e⁻ triangle complexes, theoretical calculations were carried out for **5** using the DFT(B3LYP) method based on the molecular structures determined by X-ray crystallography. The HOMO of **5**, is drawn in Figure 3, together with the frontier orbitals of the molecular fragments, ($\eta^5$-$C_5Me_5$)-Rh($S_2C_6H_4$) and $Ru_2(S_2C_6H_4)(CO)_4$. The result shows that the HOMO of the Rh fragment is primarily the Rh $d_{z^2}$ orbital directing the midpoint of the Ru–Ru bond, and the LUMO of the $Ru_2$ fragment is the Ru–Ru π-bonding orbital primarily made up of $d_{z^2}$ orbitals of two Ru atoms. The HOMO of **5** is a bonding orbital among three metal atoms that includes π-electron donation from the HOMO of the $Ru_2$ fragment to the LUMO of the Rh fragment. Therefore, the trimetal framework is composed of one Ru–Ru single bond and one coordination bond from $Ru_2$ to Rh, and thus the trimetal bonding character in **5** is a three-centers-four-electrons (3c4e⁻) bond. This finding is consistent with the longer Ru–Rh distances than that observed for a regular Ru–Rh single bond. Compounds **6** and **7** can be elucidated to have similar 3c4e⁻ characteristics according to their similarity in structure and in the bond length distribution to **5**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

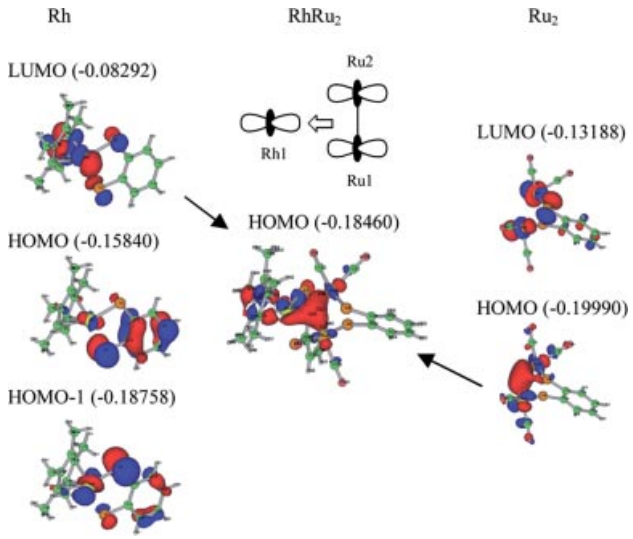

Figure 3. HOMO of **5** and frontier orbitals of the $Ru_2$ fragment and the Rh fragment calculated by the DFT(B3LYP) method. The core electrons of Ru and Rh have been replaced with the effective core potential, and their valence orbitals are described with the LANL2DZ basis set. To the other atoms, the all-electron 6-31G basis set was applied. Energy values of the orbitals in eV are given in the parentheses. The HOMO of **5** was composed of the interaction of an Ru–Ru π-bonding orbital (HOMO of the $Ru_2$ fragment) and an Rh orbital (LUMO of the Rh fragment).

UV/Vis/NIR spectra of **5** and **6** show no absorption peak around 900 nm, whereas **3**, **8**, and **9** have peaks attributable to the excitation from the HOMO to the LUMO.[2] This result indicates that the energy gaps between the HOMO and the LUMO in 50e⁻ trinuclear cluster complexes **5**–**7** are larger than those in 48e⁻ trinuclear cluster complexes **3**, **4**, **8**, and **9** because the metal–metal bonds in **5**–**7** are weaker than those in **3**, **4**, **8**, and **9**. Cyclic voltammetry of **5**–**7** in $Bu_4NClO_4$ in $CH_2Cl_2$ showed an irreversible reduction peak at –1.79 V vs. ferrocenium/ferrocene, while metalladithiolene cluster complexes **3**, **4**, **8**, and **9** underwent reversible 1e⁻ reduction.[2] This result indicates that the metal frameworks of **5**–**7** would be corrupted when electrons are added to the LUMO, the antibonding orbital of metal atoms.

Contrary to the reactions of **1** (Rh) or **2** (Ir) with **3** ($RuCo_2$) or **4** ($RuCo_2$), a mixture of **1** (Rh) and **9** ($IrCo_2$) in a 1:1 molar ratio was refluxed in 1,4-dioxane to give a 1:1 mixture of **8** ($RhCo_2$) and **9** ($IrCo_2$). The same result was obtained by the reaction of **2** (Ir) with **8** ($RhCo_2$). The differences in reactivity of the cluster complexes were thought to be due to the leaving ability of the ligands; neutral $\eta^6$ ligands, $C_6Me_6$ and *p*-cymene, on Ru cluster complexes **3** and **4**, have a higher leaving ability than $C_5Me_5$, an anionic $\eta^5$ ligand on Rh cluster complex **8** and Ir cluster complex **9**.

In summary, we have found a novel synthetic method for cluster complexes involving complete reconstruction of the trimetal framework. The cluster complexes obtained have 50 electrons around the trimetal framework, which is explained by a 3c4e⁻ bond character supported by bond lengths and theoretical calculation of molecular orbitals.

**Supporting Information** (see the footnote on the first page of this article): Synthesis, characterization of **8**, **9**, and **10**, $^1H$ and $^{13}C$ NMR spectra and UV/Vis/NIR spectra of **8** and **9**, X-ray crystallography of **9** and **10**, DFT calculation results for **8**, and a cyclic voltammogram of **8**.

# A Coordination Polymer Containing Inorganic Buckybowl Analogues

Tao Wu,[a] Miao Chen,[a] and Dan Li*[a]

**Keywords:** Inorganic buckybowl analogues / Tetrazoles / Sharpless' cycloaddition / Copper / Coordination polymers

Two photoluminescent coordination polymers, $\{[Cu_{10}(\mu_3\text{-Mtta})_3(\mu_4\text{-Mtta})_7]\cdot 2H_2O\}_n$ (**1**), containing 2-D wavy motifs with inorganic buckybowl analogues, and $[Cu_5(\mu_3\text{-Mtta})_2(\mu_4\text{-Mtta})_3(NH_3)_2]_n$ (**2**, Mtta = 5-methyl tetrazolate), were obtained by the control of solvents and auxiliary complexing agent. The ligand Mtta is a likely candidate for the construction of metal-organic, fullerene-like molecules. The luminescent properties of **1** and **2** are discussed.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

As a bridge between the fullerene family and flat aromatic compounds, buckybowls, curved-surface fragments of fullerenes, were found a few years ago, and only a few examples are available to date.[1] Great attention has been paid to the coordination chemistry of transition-metal buckybowl complexes because of their intriguing curvatures and reactivity.[2] On the other hand, substantial effort has recently been directed towards studies of metal-containing, inorganic, fullerene-like molecules that comprise five- and six-membered rings mapping onto the surface of the $C_{60}$ analogue.[3] The design and construction of inorganic, fullerene-like molecules, even of their fragments, are still a great challenge for inorganic chemists because of the difficulty to control the formation of the curvature. The five-membered ring tetrazole is possibly a potential candidate for constructing fullerene-like fragments. In our continuing research of designing novel coordination networks,[4] herein we report the synthesis and the structural characterization of a supramolecular network containing inorganic buckybowl analogs, and of another 2D polymeric network for comparison, by using Sharpless' cycloaddition reactions of nitriles and azides.[5]

## Results and Discussion

Reactions of $Cu(NO_3)_2$, $NaN_3$, and $CH_3CN$ with 2, 2′-bipyridine/$H_2O$ or toluene/$NH_3\cdot H_2O$ (v/v, 2:1) gave two complexes $\{[Cu_{10}(\mu_3\text{-Mtta})_3(\mu_4\text{-Mtta})_7]\cdot 2H_2O\}_n$ (**1**) or $[Cu_5(\mu_3\text{-Mtta})_2(\mu_4\text{-Mtta})_3(NH_3)_2]_n$ (**2**), respectively, (Mtta = 5-methyltetrazolate). Interestingly, 2, 2′-bipiridine does not appear in **1**. The influence of bipyridine on the self-assembly of the complex is obvious because **1** cannot be synthesized in the absence of bipyridine.

X-ray single-crystal analyses of **1** and **2** confirm the formation of 5-methyl tetrazolate. Complex **1** is composed of guest water molecules and a 3D neutral microporous framework based on copper(I) and the ligand Mtta, with a space group of *C*2/*m* (Figure 1a, and Figures S1 and S2 in the Supporting Information). The elliptic cavities along the *c* axis in the 3D framework of **1** are constructed by stacking two different kinds of 2D layers (Part A and Part B, Figure 1b and Figure 1c, respectively) in the alternative mode ABAB. Approximately 18.3% of the crystal volume can be occupied by free water molecules, with a volume of ca. 958.6 Å$^3$ in each cell unit.[6]

In Part A (Figure 1b), each $Cu^I$ center adopts a distorted tetrahedral geometry. The copper atoms bound to the tetradentate Mtta ligands show significant out-of-plane displacements with respect to the "best plane" of the heterocycle (in the range +0.1328 to +1.6078 Å). Markedly, the out-of-plane displacements result in the formation of a buckybowl analogue that possesses 26 inorganic core atoms of $Cu_6(Mtta)_4$ with four five-membered rings and five six-membered rings (Figure 2a). In the buckybowl analogue, each $N_4C$ ring of Mtta is surrounded by six-membered $N_4Cu_2$ rings. Adjacent buckybowl analogues facing the opposite direction in an alternating convex and concave fashion are linked by Cu–N coordination bonds to form a wavy ribbon along the *b* direction (Figure 2b). Adjacent ribbons are fused by the Cu–N bonds into a 2D wavy layer (Figure 1b, Figure S3). The ligand Mtta possesses a $\mu_4$-$\eta^1{:}\eta^1{:}\eta^1{:}\eta^1$ coordination mode which is rare in tetrazolate derivatives.[7] Because of the tetrahedral coordination sphere of the $Cu^I$ ions, the nonplanar, six-membered rings formed are folded along the Cu···Cu axis by about 131–170°. The existence of carbon atoms that cannot be coordi-

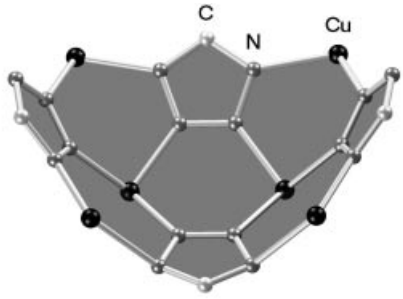
nated and the steric hindrance of methyl groups most likely prevents the assembly from developing a larger fullerene-like fragment.



(a)

(b)

Figure 2. View of the buckybowl composed of $Cu_6(Mtta)_4$ with four five-membered rings and five six-membered rings. (b) 1D wavy ribbon constructed by alternating convex and concave buckybowls.

In Part B, the copper(I) centers adopt two types of coordination geometries: the trigonal planar copper(I) center that binds three nitrogen atoms from three different ligands, and the distorted tetrahedral copper(I) center that binds four nitrogen atoms from four different ligands. The Mtta ligand bridges the copper atom through $\mu_3$ and $\mu_4$ bridging modes (in the ratio 1:1) to form a 2D double-layer plane with an approximately rectangular cavity (Figure 1c). All Mtta ligands located above and below the double-layer plane occupy the fourth coordination site of the copper atoms of Part A and form Cu–N bonds to construct the final 3D framework (Figure S2).

In **2**, there are four crystallographically unique copper atoms, which adopt trigonal and tetrahedral geometries (Figures S4 and S5). The Mtta ligand bridges the copper atom through $\mu_3$ and $\mu_4$ bridging modes (in the ratio 2:3) to form a 2D double-layer plane with rectangular cavities as shown in Figure 3. The coordination geometry around the rectangular cavities is identical to that of our previously reported 3D network $[Cu(\mu_4\text{-Mtta})]_n$[4c] shown in Figure S6 (top). The $NH_3$ molecules most likely act as a "molecular scissor" to cut the 3D network of $[Cu(\mu_4\text{-Mtta})]_n$ along the *b* axis to form the 2D layer and to occupy the vacancy of the $Cu^I$ center.

The tetrazolate group in Part B of **1** and **2**, which bears a $\mu_3$ bridging mode, does not allow for the formation of a buckybowl. It seems that the $\mu_4$-$\eta^1$:$\eta^1$:$\eta^1$:$\eta^1$ coordination mode is crucial for the construction of an arched surface.

Both **1** and **2** in the solid state show strong photoluminescence at room temperature with emission maxima at 469 nm and 497 nm, respectively (Figure 4). In comparison

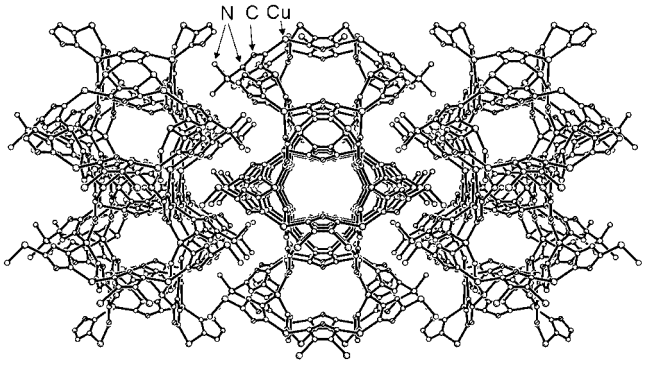

Figure 3. 2D double-layer plane with rectangular cavitivies in complex **2**.

with the photoluminescence of $Cu^I$ azolate,[8] the possibility of an MLCT [Cu→Mtta] excited state in the two complexes may be suggested. The similar emission spectra of these two complexes imply that the properties of the excited state are related only to the local coordination geometry. This explains the red shift of the bands in the spectrum of complex **2** relative to that of complex **1**, since the d* energy level in trigonal planar $Cu^I$ is higher than that in tetrahedral $Cu^I$.

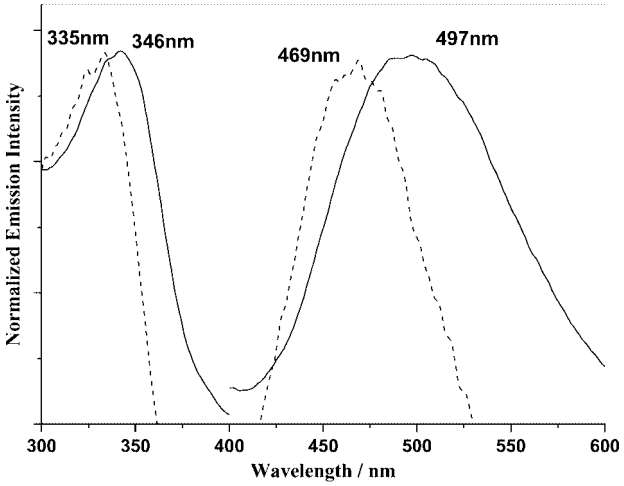

Figure 4. Solid-state excitation (left) and emission (right) spectra of complex **1** (dashed line) and **2** (solid line) at room temperature.

The TG curve of **1** shows a weight loss of 2.28% (calcd. 2.39%) from 45–230 °C that corresponds to the release of lattice water (Figure S7). After a stable platform, complex **1** begins to decompose at 298 °C and finally sublime at 415 °C. The observed weight loss that corresponds to $NH_3$ (5.15%) in complex **2** is in good agreement with the calculated value from 202–229 °C. A very stable platform from 229–276 °C is observed, which increases the possibility of the solid transformation from **2** to $[Cu(\mu_4\text{-Mtta})]_n$, and this is followed by an abrupt decline (approximately 100%). Unfortunately, the XPRD pattern of the solid prepared by heating complex **2** at 250 °C under argon for 0.5 h is different from the simulated pattern of $[Cu(\mu_4\text{-Mtta})]_n$ (Figure S8), which implies that the solid transformation from **2** to $[Cu(\mu_4\text{-Mtta})]_n$ was unsuccessful.

## Conclusions

In summary, we obtained a 3D coordination network containing inorganic buckybowl analogues. The ligand Mtta with a $\mu_4$-$\eta^1$:$\eta^1$:$\eta^1$:$\eta^1$ coordination mode is most likely a good candidate for the construction of inorganic, fullerene-like molecules. Furthermore, the $N_5$ ring may be an optimal component, demonstrating the great potential for the synthesis of other half shells, nano-sized molecules, and full-shell structural motifs. This work provides a new avenue for designing and constructing an inorganic, fullerene-like molecule.

## Experimental Section

**Preparation of Complex 1:** A mixture of $Cu(NO_3)_2{\cdot}3H_2O$ (0.241 g, 1.0 mmol), $NaN_3$ (0.065 g, 1.0 mmol), 2, 2′-bipyridine (0.156 g, 1.0 mmol), and acetonitrile (5.0 mL) was stirred for 10 min in air, and then transferred and sealed in a 15-mL Teflon-lined reactor. The reactor was heated in an oven to 140 °C for 72 h and then cooled to room temperature at a rate of 5 °C $h^{-1}$. The pale-yellow block crystal was attained in a reasonable yield (35.5%, 0.053 g) based on $Cu(NO_3)_2{\cdot}3H_2O$. $C_{20}H_{34}Cu_{10}N_{40}O_2$ (1502.27): calcd. H 2.28, C 15.99, N 37.29; found H 2.31, C15.90, N 37.34. IR data (KBr): 2921 (m), 1634 (m), 1499 (s), 1384 (s), 1135 (m), 1045 (m), 698 (w) $cm^{-1}$.

**Preparation of Complex 2:** A mixture of $Cu(NO_3)_2{\cdot}3H_2O$ (0.241 g, 1.0 mmol), $NaN_3$ (0.065 g, 1.0 mmol), acetonitrile (5.0 mL), and aqueous ammonia (25%, 5.0 mL) was stirred for 10 min in air, and then transferred and sealed in a 15-mL Teflon-lined reactor. The reactor was heated in an oven to 140 °C for 50 h and then cooled to room temperature at a rate of 5 °C $h^{-1}$. The colorless, bar crystal was attained in a reasonable yield (46.3%, 0.036 g) based on $Cu(NO_3)_2{\cdot}3H_2O$. $C_{10}H_{21}Cu_5N_{22}$ (767.19): calcd. H 2.76, C 15.66, N 40.17; found H 2.72, C15.71, N 40.60. IR data (KBr): 3419 (s), 2921 (m), 1646 (m), 1482 (s), 1372 (s), 1123 (s), 1083 (m), 702 (w) $cm^{-1}$.

**X-ray Crystallographic Study:** Data collections of **1** and **2** were performed on a Bruker Smart Apex CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), using frames of 0.3° oscillation ($2\theta \leq 56°$). The structures were solved with direct methods and refined with the full-matrix least-squares technique with the SHELXTL programs. Anisotropic thermal parameters were applied to all non-hydrogen atoms. The hydrogen atoms were generated geometrically (C–H = 0.960 Å). The crystallographic calculations were conducted with the SHELXL-97 programs.[9] Crystal data for **1**: $C_{20}H_{34}Cu_{10}N_{40}O_2$, monoclinic, space group *C*2/*m* (no. 12), *Mr* = 1502.27, *a* = 21.5327(12) Å, *b* = 16.4443(9) Å, *c* = 14.8195(8) Å, $\beta$ = 92.5190(10)°, *V* = 5242.4(5) $Å^3$, *Z* = 4, $D_c$ = 1.903 g $cm^{-3}$, $\mu$ = 4.036 $mm^{-1}$, *F*(000) = 2960, *T* = 298(2) K, 16576 reflections measured, 6175 unique ($R_{int}$ = 0.0268), final $R_1$ = 0.0553, $wR_2$ = 0.1483, *S* = 1.083 for all data. Crystal data for **2**: $C_{10}H_{21}Cu_5N_{22}$, monoclinic, space group *C*2/*m* (no. 12), *Mr* = 767.19, *a* = 11.5328(6) Å, *b* = 30.1639(17) Å, *c* = 8.8471(5) Å, $\beta$ = 130.2320(10)°, *V* = 2349.6(2) $Å^3$, *Z* = 4, $D_c$ = 2.169 g $cm^{-3}$, $\mu$ = 4.504 $mm^{-1}$, *F*(000) = 1520, *T* = 298(2) K, 7343 reflections measured, 2762 unique ($R_{int}$ = 0.0185), final $R_1$ = 0.0294, $wR_2$ = 0.0791, *S* = 1.108 for all data. CCDC-279776 and CCDC-279777 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Titanium–Alkaline Earth Molecular Oxides as Supports for Carbanions Derived from $\mu_3$-Ethylidyne Groups

**Avelino Martín,[a] Miguel Mena,*[a] María del Carmen Morales-Varela,[a] and Cristina Santamaría[a]**

*Dedicated to Professor Victor Riera on the occasion of his 70th birthday*

**Keywords:** Alkaline earth metals / Alkylidyne complexes / Carbanions / O ligands / Titanium

Treatment of the $\mu_3$-ethylidyne complex [{TiCp*($\mu$-O)}$_3$($\mu_3$-CMe)] (**1**) (Cp* = $\eta^5$-$C_5Me_5$) with the alkaline earth amides [M{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (M = Mg, Ca, Sr) promotes the deprotonation of the alkylidyne moiety $\mu_3$-CMe and leads to the oxoheterometallocubane derivatives [{(thf)$_x$(Me$_3$Si)$_2$NM}-($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}] [M = Mg, *x* = 0 (**2a**); Ca, *x* = 1 (**3**); Sr, *x* = 1 (**4**)]. In the case of the magnesium amide, complex **2a** is obtained together with the isomer [{(Me$_3$Si)$_2$NMg}-($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-$\eta^2$-CHCH)}] (**2b**). The addition of pentamethylcyclopentadiene ($C_5Me_5H$) or triphenylmethanol ($Ph_3COH$) to these compounds causes the displacement of the amide fragment to give the heterometallocubanes [RM($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-$C_2H_2$)}] [R = $C_5Me_5$, M = Ca (**5**), Sr (**6**); R = $Ph_3CO$, M = Mg (**7a**,**b**), Ca (**8**), Sr (**9**)]. This substitution can also be performed on **3** and **4** by treatment with the starting complex **1**, which gives the corner-shared double cubanes [M{($\mu_3$-O)$_3$(Ti$_3$Cp*$_3$)($\mu_3$-CCH$_2$)}$_2$] [M = Ca (**11**), Sr (**12**)]. Complexes **2a**,**b** do not react with **1**, and heating of this mixture affords the edge-linked double cubane [Mg($\mu_4$-O)-($\mu_3$-O)$_2${Ti$_3$Cp*$_3$($\mu_3$-CCH)}]$_2$ (**10**). The combination of the barium reagents [Ba(CH$_2$Ph)$_2$] or [Ba{N(SiMe$_3$)$_2$}$_2$] with **1** leads to the corner-shared double cubane [Ba{($\mu_3$-O)$_3$(Ti$_3$Cp*$_3$)($\mu_3$-CCH$_2$)}$_2$] (**13**). The molecular structures of **3** and **10** have been established by single-crystal X-ray analysis.

## Introduction

The alkylidyne groups of the complexes [{TiCp*($\mu$-O)}$_3$-($\mu_3$-CR)] (Cp* = $\eta^5$-$C_5Me_5$; R = H, Me)[1] have revealed a surprising and unprecedented reactivity[2] that allows us to form an understanding between molecular and surface chemistry.[3] Both discrete systems may provide relevant information about the mechanisms and the presence of intermediate species on catalytic surfaces even though the reaction conditions are different.

Ethylidyne, in particular, is a well-known hydrocarbon fragment in the dehydrogenation of ethylene on metallic surfaces and its transformation has been actively investigated.[4] However, at present, detailed studies concerning the titanium surface reactivity are scarce and evidence for the formation of ethylidyne has only recently appeared during the decomposition of ethylene on carbon–modified titanium surfaces.[5] Nevertheless, complete dissociation to produce carbon and hydrogen takes place when a clean titanium surface interacts with ethylene.[5] However, the pathways for ethylidyne dehydrogenation to $C_2H_2$, $C_2H$ or carbonaceous species and possible hydrogen exchange have not been well established.

In our molecular approach to the interaction of hydrocarbons with a surface, we have shown that $\mu_3$-ethylidyne groups supported on a $Ti_3O_3$ core can be sequentially hydrogenated (ethylidene, ethyl, and ethane) upon reaction with amines (see Scheme 1).[2d] The dehydrogenation of the $\mu_3$-ethylidyne ligand has also been observed during the incorporation of ketones into the complex [{TiCp*($\mu$-O)}$_3$-($\mu_3$-CMe)] (**1**) by an insertion of the carbonyl groups into a Ti–H bond of the hydridovinylidene intermediate [{TiCp*($\mu$-O)}$_3$($\mu$-CCH$_2$)(H)] formed in situ.[2b] Recently, we have also shown how the incorporation of alkali metal cations into the organometallic titanium oxide **1** takes place with proton abstraction from the alkylidyne and formation of the species [M($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}] (M = Li, Na, K, Rb, Cs).[6]

Herein we discuss the evolution of the ethylidyne fragment when the molecular model [{TiCp*($\mu$-O)}$_3$($\mu_3$-CMe)] (**1**) tries to incorporate alkaline-earth derivatives.

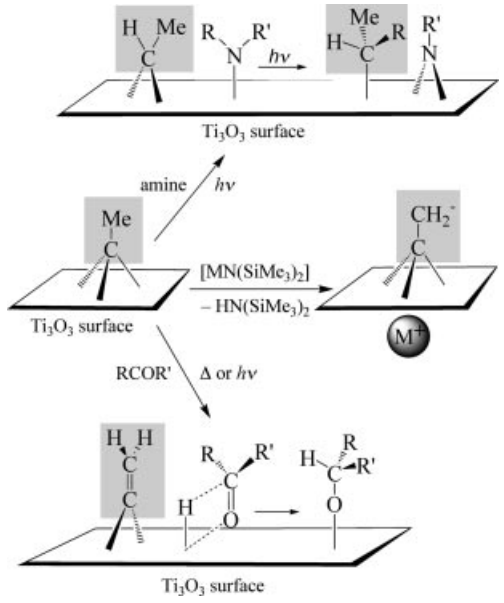
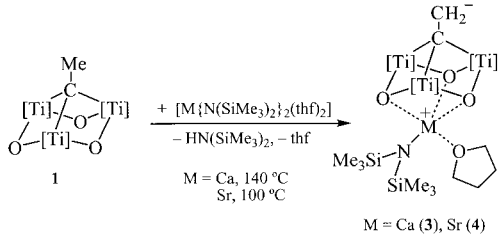


Scheme 1. Chemical reactivity of the $\mu_3$-ethylidyne group on the $Ti_3O_3$ core with amines, alkali metal amides, and ketones.

## Results and Discussion

We began our study with the reaction between the beryllium amide $Be[N(SiMe_3)_2]_2$ and $[\{TiCp^*(\mu\text{-}O)\}_3(\mu_3\text{-}CMe)]$ (**1**), but we did not observe any reaction, even when heating the mixture to over 200 °C. However, the thermal treatment of **1** with $[M\{N(SiMe_3)_2\}_2(thf)_2]$ (M = Ca, Sr) in a 1:1 ratio, in hexane or toluene, leads to the oxoheterometallocubanes $[\{(thf)(Me_3Si)_2NM\}(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}CCH_2)\}]$ [M = Ca (**3**), Sr (**4**)] in high yields (Scheme 2). The isolated compounds **3** and **4** proved to be stable under argon at room temperature and sufficiently soluble in most common solvents (toluene, hexane, dichloromethane...).



Scheme 2. Reactivity of **1** with calcium and strontium bis(trimethylsilyl)amides. [Ti] = $Ti(\eta^5\text{-}C_5Me_5)$.

The NMR spectra of these species in $[D_6]$benzene show the equivalence of the $\eta^5\text{-}C_5Me_5$ groups, with only one signal in the $^1H$ NMR [$\delta$ = 1.99 (**3**) and 2.00 ppm (**4**)] and two in the $^{13}C\{^1H\}$ NMR spectra [$\delta$ = 11.7 (**3**) and 11.6 ppm (**4**) for $C_5\mathit{Me}_5$ and $\delta$ = 117.9 (**3**) and 117.5 ppm (**4**) for $\mathit{C}_5Me_5$]. The NMR spectra also display resonances due to the $\mu_3\text{-}CCH_2^-$ group, as a singlet at $\delta$ = 2.82 (**3**) and 2.72 ppm (**4**) in the $^1H$ NMR spectra and a triplet at $\delta$ = 82.3 (**3**) and 81.2 ppm (**4**) [$J_{C,H}$ = 149 Hz (av.)], attributed to the $C_\beta$ resonance, in the $^{13}C$ NMR spectra. Furthermore, the apical $\mu_3$-carbon appears as a singlet at $\delta$ = 380.1 (**3**) and 377.3 ppm (**4**), which is shifted to high field with respect to complex **1** [$\delta(\mu_3\text{-}\mathit{C}Me)$ = 401.7 ppm].[1a] These data are in agreement with the rotation of the organometallic ligand around the alkaline-earth metal center, analogously to the situation found in other similar compounds,[7] and with removal of the proton of the starting $\mu_3$-ethylidyne group. The molecular structure of these derivatives was confirmed by an X-ray single crystal structure analysis of **3** (see Figure 1). Selected bond lengths and angles for **3** are included in Table 1.

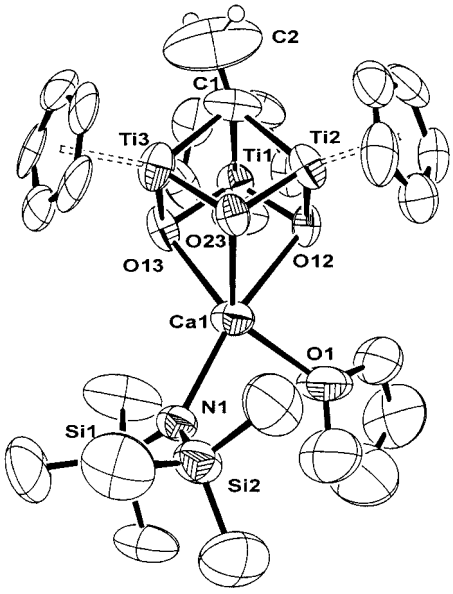


Figure 1. Molecular structure of **3** in the crystal. Hydrogen atoms and the methyl groups of the rings have been omitted for clarity.

Table 1. Selected bond lengths and angles for complex **3**.

The crystal structure of compound **3** reveals a cubic core where the $[CaN(SiMe_3)_2(thf)]$ moiety occupies the free vertex of the incomplete cube-type complex **1**, being linked through the three oxygen atoms. The calcium atom adopts a distorted trigonal bipyramid geometry constituted by the three oxygen atoms of the organometallic oxide, the oxygen of the tetrahydrofuran molecule and the nitrogen atom of the bis(trimethylsilyl)amide ligand, in a similar way to that found for the calcium atom of the previously reported compound $[\{(thf)(Me_3Si)_2NCa\}(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}C)\}]$.[8] The axial positions of this bipyramid in complex **3** are occupied by the N(1) and O(12) atoms.

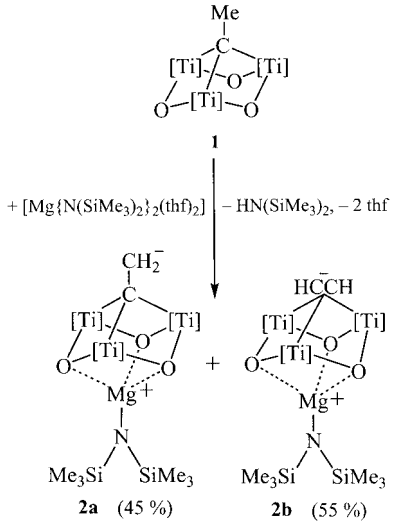
The $[CaN(SiMe_3)_2(thf)]$ fragment presents similar bond lengths and angles to other calcium complexes containing

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

this unit.[9] Also, the distances from calcium to the oxygen atoms of the organometallic oxide are in the range 2.421(8)–2.488(8) Å, and the longest is that corresponding to the *trans* position to the bis(trimethylsilyl)amide ligand. Both the amide and the tetrahydrofuran fragments are located in an alternate position with respect to the pentamethylcyclopentadienyl rings to minimize the steric repulsion.

The incorporation of the alkaline earth atom into the organometallic ligand **1** does not produce significant variations in the $[CTi_3O_3]$ core, although it leads to a significant shortening of the C(1)–C(2) length, from 1.514(7) Å[1] in **1** to 1.23(2) Å in **3**. At the same time the C(1)–C(2) bond, which is perpendicular to the plane formed by the three titanium atoms in **1**, now forms an angle of 64.1(1)°.[10] This arrangement contrasts with that found for the complex $[(thf)_2Cs(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}CCH_2)\}]$, where the spatial disposition of the deprotonated ethylidyne is also perpendicular and the carbon–carbon distance is 1.528(11) Å.[6]

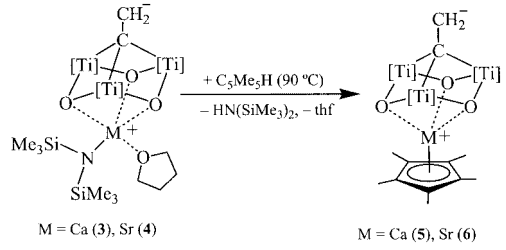
Interestingly, the reaction of **1** with the magnesium amide $[Mg\{N(SiMe_3)_2\}_2(thf)_2]$, in hexane at 180 °C, takes place with deprotonation of the $\mu_3$-ethylidyne group and formation of two compounds, **2a** and **2b**, in approximately a 45:55 ratio (Scheme 3). Both species co-crystallize as red crystals that are soluble in the usual solvents (toluene, hexane...) and are highly air-sensitive. Attempts to separate these compounds were unsuccessful.



Scheme 3. Reaction of **1** with magnesium bis(trimethylsilyl)amide. [Ti] = Ti($\eta^5$-$C_5Me_5$).

Compounds **2a** and **2b** were characterized by standard analytical and spectroscopic techniques. The most notable features in the $^1H$ and $^{13}C$ NMR spectra of $[\{(Me_3Si)_2NMg\}(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}CCH_2)\}]$ (**2a**) are the resonances for the $\mu_3$-$CCH_2^-$ group. The $^1H$ NMR spectrum displays a singlet at $\delta$ = 2.95 ppm and the $^{13}C$ NMR spectrum reveals a triplet at $\delta$ = 85.1 ppm ($J_{C,H}$ = 151 Hz), assigned to the β-carbon atom, and the α-carbon atom resonance at $\delta$ = 384.3 ppm, similar to the values found for the calcium (**3**) and strontium (**4**) derivatives. $[\{(Me_3Si)_2NMg\}(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}\eta^2\text{-}CHCH)\}]$ (**2b**) exhibits a singlet at $\delta$ = 6.55 ppm in the $^1H$ NMR spectrum and a doublet of doublets at $\delta$ = 206.2 ppm ($J_{C,H}$ = 156, $^2J_{C,H}$ = 5.1 Hz) in the $^{13}C$ NMR spectrum for the $\mu_3$-$\eta^2$-$CHCH^-$ group. Furthermore, the presence of single signals at $\delta$ = 1.86 ppm for the methyl group, $\delta$ = 119.9 ppm for the ring carbons, and $\delta$ = 12.5 ppm for the methyl carbons of the Cp* ligands in these spectra suggest a dynamic behavior for compound **2b**. An analogous situation has been reported[11] for the complex $[Rh_3Cp^*_3(\mu_3\text{-}\eta^2\text{-}C_2H_2)(\mu_3\text{-}S)]^{2+}$, where the authors suggest that the cavity constructed by the three Cp* ligands and the metal atoms is big enough to allow the movement of the hydrocarbon ligand $\mu_3$-$\eta^2$-CHCH.

The reaction of **2**–**4** with protic reagents such as pentamethylcyclopentadiene ($C_5Me_5H$) and the alcohol $Ph_3COH$ led to the metathesis of the amide group in a regioselective way, although, surprisingly, the $\mu_3$-ethylidyne group was not regenerated. $C_5Me_5H$ reacts with complexes **3** and **4** at about 90 °C to give the derivatives $[Cp^*M(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}CCH_2)\}]$ [M = Ca (**5**), Sr (**6**); see Scheme 4]. However, it does not react with the magnesium complexes **2a** and **2b**, probably due to the steric hindrance and low acidity of the pentamethylcyclopentadiene. Compounds **5** and **6** were isolated as brown solids in good yields and characterized by standard analytical and spectroscopic techniques.



Scheme 4. Reactivity of **3** and **4** with pentamethylcyclopentadiene. [Ti] = Ti($\eta^5$-$C_5Me_5$).

The NMR spectroscopic data are consistent with the structure shown in Scheme 4, thus confirming the existence of the Cp* group at the coordination sphere of the alkaline-earth elements and revealing the presence of the fragment $\mu_3$-$CCH_2^-$ [$\delta(CCH_2)$ = 2.64 (**5**) and 2.55 ppm (**6**) (s); $\delta(CCH_2)$ = 82.5 (**5**) and 81.3 ppm (**6**) (t, $J_{C,H} \approx$ 150 Hz); $\delta(CCH_2)$ = 378.2 (**5**) and 375.6 ppm (**6**)].

The reactions of the alcohol $Ph_3COH$ with complexes **2**–**4** were carried out in NMR tubes in [$D_6$]benzene as solvent at room temperature (see Experimental Section). In all cases the elimination of the amide group as free amine was detected and the complexes $[(Ph_3COMg)(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}C_2H_2)\}]$ (**7a**,**b**) and $[(Ph_3COM)(\mu_3\text{-}O)_3\{Ti_3Cp^*_3(\mu_3\text{-}CCH_2)\}]$ [M = Ca (**8**) and Sr (**9**)] characterized.

Once the displacement of the amide group by several reagents had been established, we wondered what would happen if compounds **2**–**4** were treated with the starting complex **1** as organometallic tridentate ligand. The oxometallocubanes **2a**,**b** did not react with **1** at room temperature. However, when the solution was heated for several days at

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

about 200 °C and then slowly cooled, an insoluble microcrystalline red solid **10** was isolated in high yield. Curiously, the same result was obtained when complexes **2a**,**b** were heated at that temperature in the absence of **1** (see Scheme 5). Furthermore, compound **10** also resulted from the combination of equimolecular amounts of **1** and the dialkylmagnesiums $[MgR_2(thf)_2]$ (R = $CH_2Ph$, $CMe_3$). Solid **10** proved to be stable under argon at room temperature and insoluble in most common solvents (toluene, hexane, THF...). The new complex was characterized by elemental analysis, IR spectroscopy, and by single-crystal X-ray diffraction.
