Scheme 5. Thermal treatment of complexes **2a**,**b** and reaction of **1** with dialkylmagnesiums. [Ti] = Ti($\eta^5$-$C_5Me_5$).

The molecular structure of **10** is shown in Figure 2, while selected bond lengths and angles are included in Table 2. The crystallographic study of **10** revealed the presence of two $[MgO_3Ti_3C_2]$ cores directly linked by two Mg–O bonds to form a central planar rhombic $Mg_2O_2$ moiety. The alkaline-earth atoms are located in the vacant vertex of the preorganized organometallic oxide **1** and present a tetracoordinate environment. The pentamethylcyclopentadienyl rings of the cubes adopt an alternate configuration to minimize steric hindrance. The disposition of the core in complex **10** is similar to that reported for $[Li(\mu_4\text{-}O)(\mu_3\text{-}O)_2\{Ti_3Cp^*_3(\mu_3\text{-}C)\}]_2$,[12] and confirms the ability of **1** to encapsulate magnesium atoms.

The magnesium···magnesium distance [2.765(4) Å] is shorter than those found in the literature for other complexes containing $Mg_2O_2$ units,[13] and even shorter than the sum of the Van der Waals radii (3.40 Å).[14] This shortening could be due to the geometry of the molecule itself and the steric hindrance of the ligands around the magnesium

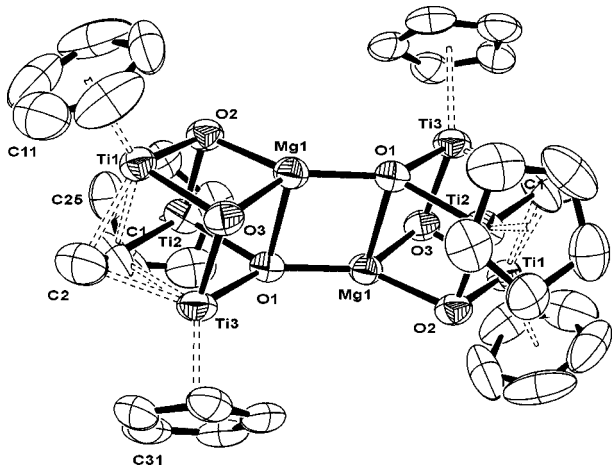

Figure 2. Molecular structure of **10**. The methyl groups of the Cp* rings and hydrogen atoms have been omitted for clarity.

Table 2. Selected bond lengths and angles for complex **10**.

[a] Intercube.

atoms, giving rhombic and not square arrangements. The distance between the magnesium atom and the closer oxygen atom of the other cube Mg(1)–O(1) [1.929(4) Å] is similar to those to O(2) and O(3) of the same cube, while the distance with respect to O(1) of the same cube [2.149(4) Å] is clearly longer and allows us to describe the environment of each magnesium atom as a trigonal pyramid instead of tetrahedral. The sum of the angles in the base of that pyramid is 359.8(2)°.

Complex **10** presents narrower Ti–O–Ti and O–Ti–O angles (10° and 16.5° respectively) and Ti–O distances up to 0.28 Å longer than those found in **1**. However, the Ti···Ti

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

distances stay in the same range [2.819(1) Å in **1** and an average value of 2.830(2) Å in **10**].

The main feature of the solid-state structure of complex **10** is undoubtedly the relative disposition of the hydrocarbyl unit that is formed as a result of the double deprotonation of the $\mu_3$-$CCH_3$ group with respect to the $Ti_3O_3$ surface (see Figure 3). The C(1)–C(2) bond length of 1.297(12) Å is similar to that found in compound **3** but now the Ti–C(1) lengths are quite different, with values ranging from 1.956(7) Å for Ti(2)–C(1) to 2.147(7) Å for Ti(1)–C(1). This means that C(1) is no longer equidistant to the three titanium atoms, being closer to Ti(2). Simultaneously, C(2) shows shorter distances to the titanium atoms [Ti(1)–C(2) = 2.094(9) and Ti(3)–C(2) = 2.239(10) Å] than those found in complex **3**.[15] All this leads to the fact that the C(1)–C(2) line forms an angle of only 20.5° with respect to the plane constituted by the three titanium atoms. The different dispositions of the C(1)–C(2) bond with respect to the $Ti_3$ plane in complexes **1**, **3**, and **10** are represented in Scheme 6.

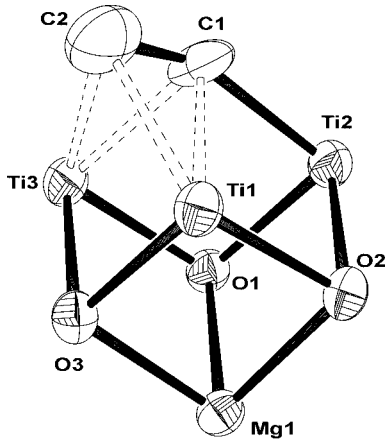

Figure 3. View of the $[MgO_3Ti_3C_2]$ core in complex **10**.

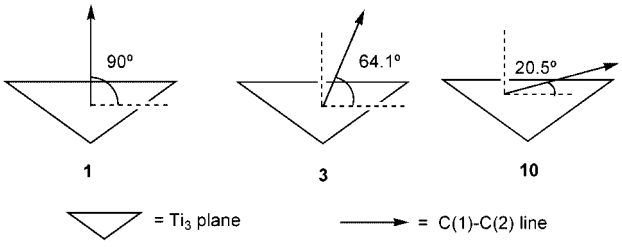
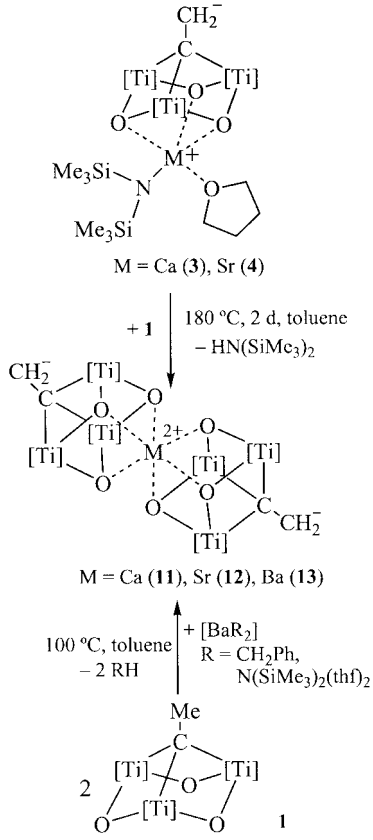


Scheme 6. Disposition of the C(1)–C(2) bond with respect to the $Ti_3$ plane in **1**, **3**, and **10**.

Complexes **1**, **3**, and **10** present an organic ligand supported on an organometallic oxide containing titanium atoms in their higher oxidation state. The electronic deficiency of the titanium centers of **3** and **10** can be alleviated, at least partially, by the donation of electron density from the respective carbanions $\mu_3$-$CCH_2^-$ and $\mu$-$CCH^{2-}$, which bends the C(1)–C(2) bond towards the titanium atoms.

In the case of the calcium and strontium complexes, the addition of **1** to toluene solutions of **3** or **4** and heating to 180 °C for several days afforded the corner-shared double cubane compounds $[M\{(\mu_3\text{-}O)_3Ti_3Cp^*_3(\mu_3\text{-}CCH_2)\}_2]$ [M = Ca (**11**), Sr (**12**)] as dark-red, microcrystalline solids that are insoluble in the usual solvents (toluene, hexane, tetrahydrofuran,...). The IR spectra, elemental analysis, and an X-ray diffraction study of **11** confirmed the structures proposed in Scheme 7.



Scheme 7. Formation of calcium, strontium, and barium oxoheterometallodicubanes.

Repeated attempts to obtain crystals of complex **11** failed and only once did we succeed in performing an X-ray diffraction study. The crystals were obtained from a toluene solution at –20 °C, but unfortunately their quality was very poor and the results[16] prevent us from making a detailed discussion of the structure. However, it can be established that **11** shows a double cube $[C_2Ti_6O_6Ca]$ core with the calcium atom located at the shared vertex of a distorted octahedral environment formed by the oxygen atoms of both preorganized ligands (Figure 4) in a similar way to other already reported double cube complexes.[8]

The analogous barium complex $[Ba\{(\mu_3\text{-}O)_3Ti_3Cp^*_3(\mu_3\text{-}CCH_2)\}_2]$ (**13**) can be obtained by treatment of $[BaR_2]$ [R = $N(SiMe_3)_2$, $CH_2Ph$] with the $\mu_3$-ethylidyne complex **1** (see Scheme 7). Both reactions occur with formation of the complex, after heating [R = $N(SiMe_3)_2$, 100 °C, 2 days; R = $CH_2Ph$, 90 °C, one night], to give a red microcrystalline insoluble solid in 77–87% yield. The new complex was characterized by elemental analysis and IR spectroscopy.

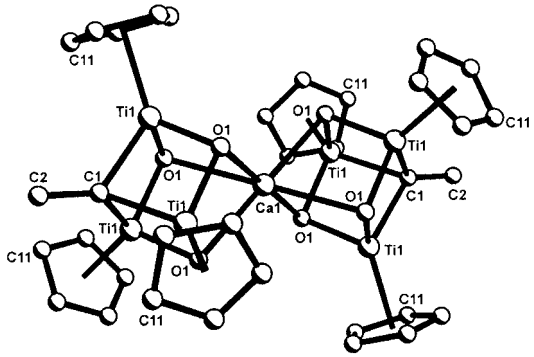

Figure 4. Molecular structure of compound **11**.

## Conclusions

This work is part of an ongoing effort to study the peculiar chemical behavior exhibited by the $\mu_3$-ethylidyne complex [{TiCp*(μ-O)}$_3$($\mu_3$-CMe)] (**1**). Treatment of this molecular model with alkaline-earth metal amides and alkyls produces the deprotonation of the $\mu_3$-ethylidyne fragment to give $\mu_3$-$CCH_2^-$, $\mu_3$-$CHCH^-$, or $\mu_3$-$CCH^{2-}$ carbanions. The interaction of these fragments with the titanium atoms increases with a higher charge of the carbanion. Simultaneously, the alkaline-earth cation is incorporated through the oxygen atoms to build new cage structures.

## Experimental Section

**General Remarks:** All manipulations of the described compounds were carried out with exclusion of air and moisture using Schlenk-line or glovebox techniques. Solvents were carefully dried with the appropriate drying agents and distilled prior to use.

[{TiCp*(μ-O)}$_3$($\mu_3$-CMe)] (**1**) was synthesized according to the published procedure.[1] [$MgR_2(thf)_2$] (R = $CH_2Ph$,[17] $CMe_3$[18]), [$Ba(CH_2Ph)_2$],[19] and [M{$N(SiMe_3)_2$}$_2$(thf)$_2$], (M = Mg,[20] Ca,[21] Sr,[21] Ba[21]) were prepared following the literature methods. Pentamethylcyclopentadiene was purchased from Aldrich and $Ph_3COH$ from Fluka and sublimed before use.

Elemental analyses (C, H, N) were performed with a Heraeus CHN-O-RAPID and/or Perkin–Elmer 2400-Serie II C, H, N, S/O. IR spectra were obtained in KBr pellets with a FT-IR Perkin–Elmer SPECTRUM 2000 spectrophotometer. NMR spectra were recorded on Varian NMR System spectrometers: Gemini-200, Unity-300, or Mercury-VX. Trace amounts of protonated solvents were used as references, and chemical shifts are reported relative to TMS. Thermal reactions were carried out in a Roth autoclave model III (300 mL), with heater model 30S (20–300 °C) and temperature regulator model DR 500.

**Preparation of [{$(Me_3Si)_2NMg$}($\mu_3$-O)$_3${$Ti_3Cp^*_3$($\mu_3$-$C_2H_2$)}] (2a,b):** A 100-mL Carius tube was charged with [{TiCp*(μ-O)}$_3$($\mu_3$-CMe)] (**1**; 0.30 g, 0.48 mmol), [Mg{$N(SiMe_3)_2$}$_2$(thf)$_2$] (0.24 g, 0.48 mmol), and hexane (30 mL) and then sealed under vacuum. This solution was heated in an autoclave at 180 °C for one day. The Carius tube was opened in a glovebox and the solution concentrated and cooled to –40 °C to give a clean mixture of products which contained complexes **2a** and **2b** in approximately a 45:55 ratio (yield: 0.32 g, 82%). IR (KBr): $\tilde{\nu}$ = 2945 $cm^{-1}$ (s), 2911 (vs), 2859 (s), 1492 (w), 1433 (m), 1377 (s), 1242 (s), 1180 (w), 997 (vs), 931 (w), 888 (s), 843 (s), 829 (s), 752 (m), 669 (m), 543 (s), 576 (s), 513 (m), 476 (m), 429 (m). $C_{38}H_{65}MgNO_3Si_2Ti_3$ (807.91): calcd. C 56.48, H 8.11, N 1.73; found C 56.12, H 8.37, N 1.38.

**2a:** $^1$H NMR (300 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 0.46 [s, 18 H, N(Si$Me_3$)$_2$], 1.91 (s, 45 H, $C_5Me_5$), 2.95 (s, 2 H, $\mu_3$-$CCH_2$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 7.4 [N(Si$Me_3$)$_2$], 12.1 ($C_5Me_5$), 85.1 ($\mu_3$-$CCH_2$), 120.0 ($C_5Me_5$), 384.3 ($\mu_3$-$CCH_2$) ppm.

**2b:** $^1$H NMR (300 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 0.45 [s, 18 H, N(Si$Me_3$)$_2$], 1.86 (s, 45 H, $C_5Me_5$), 6.55 (s, 2 H, $\mu_3$-$\eta^2$-*H*C*C*H) ppm. $^{13}$C{$^1$H} NMR (75 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 7.2 [N(Si$Me_3$)$_2$], 12.5 ($C_5Me_5$), 119.9 ($C_5Me_5$), 206.2 ($\mu_3$-$\eta^2$-H*C*CH) ppm.

**Preparation of [{(thf)$(Me_3Si)_2NM$}($\mu_3$-O)$_3${$Ti_3Cp^*_3$($\mu_3$-$CCH_2$)}] [M = Ca (3), Sr (4)]:** The preparation of **3** or **4** was performed in a similar fashion to **2**. Complex **1** (0.4 g, 0.64 mmol) was treated with [Ca{$N(SiMe_3)_2$}$_2$(thf)$_2$] (0.32 g, 0.64 mmol) or [Sr{$N(SiMe_3)_2$}$_2$(thf)$_2$] (0.33 g, 0.64 mmol) in hexane (50 mL) at 140 °C for 4 d to afford **3** as red crystals (0.51 g, 88%) or at 100 °C for two days to give **4** as a bright red solid (0.50 g, 83%).

**3:** $^1$H NMR (300 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 0.37 [s, 18 H, N(Si$Me_3$)$_2$], 1.41 [m, 4 H, O($CH_2CH_2$)$_2$], 1.99 (s, 45 H, $C_5Me_5$), 2.82 (s, 2 H, $\mu_3$-$CCH_2$), 3.87 [m, 4 H, O($CH_2CH_2$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 6.2 [N(Si$Me_3$)$_2$], 11.7 ($C_5Me_5$), 25.5 [O($CH_2CH_2$)$_2$], 69.6 [O($CH_2CH_2$)$_2$], 82.3 ($\mu_3$-$CCH_2$), 117.9 ($C_5Me_5$), 380.1 ($\mu_3$-$CCH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 2955 $cm^{-1}$ (s), 2908 (vs), 2857 (s), 1493 (w), 1437 (m), 1377 (s), 1254 (s), 1179 (m), 1055 (vs), 1031 (vs), 931 (m) 879 (s), 820 (vs),762 (w), 618 (s), 584 (s), 520 (m), 415 (s). $C_{42}H_{73}CaNO_4Si_2Ti_3$ (895.82): calcd. C 56.31, H 8.21, N 1.56; found C 56.17, H 8.58, N 1.18.

**4:** $^1$H NMR (300 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 0.35 [s, 18 H, N(Si$Me_3$)$_2$], 1.37 [m, 4 H, O($CH_2CH_2$)$_2$], 2.00 (s, 45 H, $C_5Me_5$), 2.72 (s, 2 H, $\mu_3$-$CCH_2$), 3.62 [m, 4 H, O($CH_2CH_2$)$_2$] ppm. $^{13}$C{$^1$H} NMR (75 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 5.8 [N(Si$Me_3$)$_2$], 11.6 ($C_5Me_5$), 25.3 [O($CH_2CH_2$)$_2$], 69.4 [O($CH_2CH_2$)$_2$], 81.2 ($\mu_3$-$CCH_2$), 117.5 ($C_5Me_5$), 377.3 ($\mu_3$-$CCH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 2911 $cm^{-1}$ (vs), 2858 (s), 1493 (w), 1435 (s), 1376 (s), 1244 (s), 1178 (w), 1077 (vs), 1033 (s), 932 (m), 879 (s), 819 (vs), 758 (s), 645 (s), 623 (s), 584 (s), 391 (s). $C_{42}H_{73}NO_4Si_2SrTi_3$ (943.34): calcd. C 53.47, H 7.80, N 1.48; found C 53.22, H 7.75, N 1.43.

**Preparation of [Cp*Ca($\mu_3$-O)$_3${$Ti_3Cp^*_3$($\mu_3$-$CCH_2$)}] (5):** Pentamethylcyclopentadiene (53 μL, 0.34 mmol) was added to a solution of **3** (0.30 g, 0.33 mmol) in hexane (40 mL) and the reaction mixture was heated at 90 °C for 6 h to afford a dark-red solution. The solvent was removed in vacuo and the product was isolated in a 75% yield (0.20 g). $^1$H NMR (300 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 1.90 (s, 45 H, Ti$C_5Me_5$), 2.22 (s, 15 H, Ca$C_5Me_5$) 2.64 (s, 2 H, $\mu_3$-$CCH_2$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 11.4 (Ti$C_5Me_5$), 11.4 (Ca$C_5Me_5$), 114.0 (Ca$C_5Me_5$), 118.1 (Ti$C_5Me_5$), 82.5 ($\mu_3$-$CCH_2$), 378.2 ($\mu_3$-$CCH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 2962 $cm^{-1}$ (m), 2910 (s) 2857 (m), 1495 (w), 1438 (m), 1377 (m), 1088 (m), 1022 (m), 791 (vs), 675 (s), 617 (m), 579 (m), 420 (m). $C_{42}H_{62}CaO_3Ti_3$ (798.64): calcd. C 63.16, H 7.82; found C 63.09, H 8.11.

**Preparation of [Cp*Sr($\mu_3$-O)$_3${$Ti_3Cp^*_3$($\mu_3$-$CCH_2$)}] (6):** Complex **4** (0.30 g, 0.32 mmol) was dissolved in toluene (40 mL) in a 100-mL Carius tube fitted with a Young valve and pentamethylcyclopentadiene (50 μL, 0.32 mmol) was added. The reaction mixture was heated at 90 °C for 6 h. After that, the solution was filtered and the solvent was removed to yield **6** (0.20 g, 74% yield). $^1$H NMR (300 MHz, [$D_6$]benzene, 20 °C, TMS): $\delta$ = 1.90 (s, 45 H, Ti$C_5Me_5$),

**Reaction of [{(Me$_3$Si)$_2$NMg}($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-C$_2$H$_2$)}] (2a,b) with Ph$_3$COH:** Complexes **2a**,**b** (22 mg, 0.027 mmol) and $Ph_3COH$ (ca. 7 mg, 0.027 mmol) were dissolved in [D$_6$]benzene (1.0 mL). The mixture reaction was transferred to a 5-mm NMR tube and once **2a**,**b** had been consumed at room temperature, the solvent and most of the amine formed, [NH(SiMe$_3$)$_2$], were removed under vacuum. The solid was then dissolved in [D$_6$]benzene and the solution was checked by $^1$H and $^{13}$C NMR spectroscopy allowed us to characterize the products as [($Ph_3COMg$)($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-C$_2$H$_2$)}] (**7a**,**b**).

**7a:** $^1$H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 1.87 (s, 45 H, $C_5Me_5$), 2.82 (s, 2 H, $\mu_3$-$CCH_2$), 6.9–7.5 (m, $OCPh_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 11.8 ($C_5Me_5$), 83.7 ($\mu_3$-$CCH_2$), 120.0 ($C_5Me_5$), 125.0–155.0 ($OCPh_3$), 379.1 ($\mu_3$-$CCH_2$) ppm.

**7b:** $^1$H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 1.80 (s, 45 H, $C_5Me_5$), 6.18 (s, 2 H, $\mu_3$-$\eta^2$-$CHCH$), 6.9–7.5 (m, $OCPh_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 12.2 ($C_5Me_5$), 120.2 ($C_5Me_5$), 125.0–150.0 ($OCPh_3$), 200.8 ($\mu_3$-$\eta^2$-$CHCH$) ppm.

**Reaction of [{(thf)(Me$_3$Si)$_2$NCa}($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}] (3) with Ph$_3$COH:** In a similar fashion to **7**, complex **3** (21 mg, 0.023 mmol) and $Ph_3COH$ (ca. 6 mg, 0.023 mmol) were dissolved in [D$_6$]benzene (1.0 mL). After thirty minutes at room temperature, the solvent and most of the amine formed were removed under vacuum and the solid was dissolved in [D$_6$]benzene. The NMR spectra allowed us to characterize the product as [($Ph_3COCa$)($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}] (**8**). $^1$H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 1.98 (s, 45 H, $C_5Me_5$), 2.80 (s, 2 H, $\mu_3$-$CCH_2$), 6.9–7.7 (m, $OCPh_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 12.0 ($C_5Me_5$), 81.3 ($\mu_3$-$CCH_2$), 117.8 ($C_5Me_5$), 125.0–155.0 ($OCPh_3$), 378.6 ($\mu_3$-$CCH_2$) ppm.

**Reaction of [{(thf)(Me$_3$Si)$_2$NSr}($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}] (4) with Ph$_3$COH:** The preparation was similar to that for **8**, but with **4** (22 mg, 0.023 mmol) and $Ph_3COH$ (ca. 6 mg, 0.023 mmol) in [D$_6$]benzene (1.0 mL). The NMR spectra of the resulting solution allowed us to characterize the product as [($Ph_3COSr$)($\mu_3$-O)$_3${Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}] (**9**). $^1$H NMR (300 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 2.03 (s, 45 H, $C_5Me_5$), 2.78 (s, 2 H, $\mu_3$-$CCH_2$), 6.9–7.7 (m, $OCPh_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, [D$_6$]benzene, 20 °C, TMS): $\delta$ = 11.6 ($C_5Me_5$), 80.5 ($\mu_3$-$CCH_2$), 82.6 ($OCPh_3$), 117.0 ($C_5Me_5$), 125.0–155.0 ($OCPh_3$), 377.7 ($\mu_3$-$CCH_2$) ppm.

**Preparation of [Mg($\mu_4$-O)($\mu_3$-O)$_2${Ti$_3$Cp*$_3$($\mu_3$-CCH)}]$_2$ (10). Method A:** [{TiCp*($\mu$-O)}$_3$($\mu_3$-CMe)] (**1**; 0.20 g, 0.32 mmol), [Mg{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (0.16 g, 0.32 mmol), and hexane (30 mL) were placed in a 100-mL Carius tube. The pressure of the argon atmosphere was reduced and the reaction mixture was heated at 200 °C for four days. Slow crystallization of the solution at room temperature afforded **10** as red crystals suitable for an X-ray diffraction analysis. The isolated compound was obtained in 82% (0.17 g) yield.

**Method B:** Complex **1** (0.20 g, 0.32 mmol) and [Mg(CH$_2$Ph)$_2$(thf)$_2$] (0.112 g, 0.32 mmol) or [Mg(CMe$_3$)$_2$(thf)$_2$] (0.091 g, 0.32 mmol) were placed in a 100-mL Carius tube fitted with a Young valve and dissolved in toluene (30 mL). The mixture was heated at 90 °C for two days. The reddish solution was filtered, concentrated until 15 mL, and, finally, cooled to –40 °C to give a dark-red microcrystalline solid with a yield of 77% (0.16 g) from [Mg(CH$_2$Ph)$_2$(thf)$_2$] and 82% (0.17 g) from [Mg(CMe$_3$)$_2$(thf)$_2$]. IR (KBr): $\tilde{\nu}$ = 2906 cm$^{-1}$ (vs), 2855 (s), 1489 (w), 1437 (s), 1373 (s), 1023 (m), 793 (m), 645 (vs), 534 (s), 492 (s), 454 (m), 403 (m). $C_{64}H_{92}Mg_2O_6Ti_6$ (1293.3): calcd. C 59.44, H 7.17; found C 59.29, H 7.52.

**Preparation of [Ca{($\mu_3$-O)$_3$Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}$_2$] (11):** Compound **11** was prepared by heating **3** (0.15 g, 0.17 mmol) and **1** (0.104 g, 0.17 mmol) in toluene (20 mL) at 180 °C for two days. The Carius tube was opened in a glovebox and the solution was concentrated and cooled (–20 °C) to yield **11** as a dark-red, microcrystalline solid (0.19 g, 88%). IR (KBr): $\tilde{\nu}$ = 2907 cm$^{-1}$ (vs), 2857 (s), 1492 (w), 1437 (m), 1375 (s), 1023 (m), 793 (m, br), 615 (vs), 518 (m), 472 (w), 418 (s), 387 (s). $C_{64}H_{94}CaO_6Ti_6$ (1286.8): calcd. C 59.74, H 7.36; found C 60.03, H 7.52.

**Preparation of [Sr{($\mu_3$-O)$_3$Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}$_2$] (12):** Similarly to the preparation of **11**, **4** (0.15 g, 0.16 mmol) and **1** (99 mg, 0.16 mmol) were heated in toluene (20 mL) at 180 °C for two days to afford **12** as a red, microcrystalline solid (0.16 g, 75%). IR (KBr): $\tilde{\nu}$ = 2908 cm$^{-1}$ (vs), 2857 (s), 1493 (w), 1435 (m), 1375 (s), 1023 (m), 793 (vs), 664 (m), 615 (vs), 528 (m), 416 (m), 389 (m). $C_{64}H_{94}O_6SrTi_6$ (1334.29): calcd. C 57.61, H 7.10; found C 57.70, H 7.20.

**Preparation of [Ba{($\mu_3$-O)$_3$Ti$_3$Cp*$_3$($\mu_3$-CCH$_2$)}$_2$] (13):** The thermal treatment of a mixture of **1** and $BaR_2$ [R = N(SiMe$_3$)$_2$, $CH_2Ph$] led to the formation of compound **13**. Thus, a solution of **1** (0.40 g, 0.64 mmol) and [Ba{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (0.183 g, 0.32 mmol) in toluene (40 mL), in a 100-mL Carius tube sealed under vacuum by flame, was heated in an autoclave at 100 °C for 2 d. When using [Ba(CH$_2$Ph)$_2$] (0.077 g, 0.24 mmol) and **1** (0.30 g, 0.48 mmol), the solution was heated at 90 °C for one night. After that, the Carius tube was opened in a glovebox and the solution concentrated and cooled to –40 °C to yield a dark-red, microcrystalline solid, which was identified as **13**, in a yield of 86% (0.38 g) for the reaction with [Ba{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] and 78% (0.26 g) with [Ba(CH$_2$Ph)$_2$]. IR (KBr): $\tilde{\nu}$ = 2911 cm$^{-1}$ (vs), 2858 (s), 1493 (w), 1436 (s), 1377 (s), 1103 (m), 1023 (m), 795 (vs), 668 (m), 616 (s), 543 (m), 486 (w), 394 (m). $C_{64}H_{94}BaO_6Ti_6$ (1384.0): calcd. C 55.54, H 6.85; found C 55.02, H 6.97.

**X-ray Structure Determinations of 3 and 10:** Crystals of **3** were grown from a hexane solution at –20 °C. Crystals of **10** were grown as described in the Experimental Section using Method A. Crystals were mounted in a glass capillary in a random orientation and transferred to an Enraf–Nonius CAD4 diffractometer for characterization and data collection at room temperature. Table 3 provides a summary of the crystal data, data collection, and refinement parameters for both complexes.

Intensity measurements were performed by $\omega$–$2\theta$ scans in the range $3° < 2\theta < 46°$ for **3**. Of the 15341 measured reflections, 7387 were independent; $R_1$ = 0.083 and $wR_2$ = 0.219 [for 2706 reflections with $F > 4\sigma(F)$]. The values of $R_1$ and $wR_2$ are defined as: $R_1 = \Sigma||F_o| - |F_c||/[\Sigma|F_o|]$; $wR_2 = \{[\Sigma w(F_o^2 - F_c^2)^2] / [\Sigma w(F_o^2)^2]\}^{1/2}$.

Intensity measurements were performed by $\omega$–$2\theta$ scans in the range $3.6° < 2\theta < 46°$ for **10**. Of the 4721 measured reflections, 4472 were independent; $R_1$ = 0.074 and $wR_2$ = 0.198 [for 3174 reflections with $F > 4\sigma(F)$].

The structures were solved, using the WINGX package,[22] by direct (**3**) and Patterson (**10**) methods (SHELXS-97)[23] and refined by least-squares against $F^2$ (SHELXL-97).[23] Complex **3** crys-

tallized with half a molecule of hexane. All non-hydrogen atoms of **3** were refined anisotropically, except those of the solvent, and the hydrogen atoms positioned geometrically and refined by using a riding model in the last cycles of refinement.

Compound **10** showed disorder in the pentamethylcyclopentadienyl linked to Ti(1) and also in C(2). Both disorders were treated conventionally by using the PART command of the SHELXL[23] program and allowing free refinement of the occupancy factors with the FVAR command. The final values were 70% of occupancy for C(2) and 53% for the C(11)–C(20) ring. All non-hydrogen atoms, except those of the disordered pentamethylcyclopentadienyl fragment, were refined anisotropically. All the hydrogen atoms were positioned geometrically and refined by using a riding model in the last cycles of refinement.

CCDC-296004 (for **3**) and -296005 (for **10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Syntheses, Spectroscopic Studies, and Crystal Structures of Chiral [Rh(aminocarboxylato)($\eta^4$-cod)] and Chiral [Rh(amino alcohol)($\eta^4$-cod)]-(acetate) Complexes with an Example of a Spontaneous Resolution of a Racemic Mixture into Homochiral Helix-Enantiomers

**Mohammed Enamullah,*[a] Aisha Sharmin,[a] Miki Hasegawa,[b] Toshihiko Hoshi,[b] Anne-Christine Chamayou,[c] and Christoph Janiak*[c]**

**Keywords:** Rhodium(I) / Amino acids / Chirality / Spontaneous resolution / Helix

The dimeric complex acetato($\eta^4$-cycloocta-1,5-diene)rhodium(I), [Rh($O_2$CMe)($\eta^4$-cod)]$_2$ (cod = cycloocta-1,5-diene), reacts with amino acids [HAA = L-alanine, (*S*)-2-amino-2-phenylacetic acid (L-phenylglycine), *N*-methylglycine, and *N*-phenylglycine] and with the amino alcohol (*S*)-2-amino-2-phenylethanol to afford the aminocarboxylato($\eta^4$-cycloocta-1,5-diene)rhodium(I) complexes [Rh(AA)($\eta^4$-cod)] (AA = deprotonated amino acid = aminocarboxylato ligand) and [(*S*)-2-amino-2-phenylethanol]($\eta^4$-cycloocta-1,5-diene)-rhodium(I) acetate, [Rh{(*S*)-HOCH$_2$–CH(Ph)-NH$_2$}($\eta^4$-cod)]-($O_2$CMe) (**V**). The complexes are characterized by IR, UV/Vis, $^1$H/$^{13}$C NMR and mass spectroscopy. The achiral *N*-phenylglycine ligand gives a chiral *N*-phenylglycinato complex [Rh($O_2$C–CH$_2$–NHPh)($\eta^4$-cod)] (**IV**) with the amine nitrogen atom becoming the stereogenic center upon metal coordination. Complex **IV** crystallizes in the tetragonal, chiral space group $P4_3$ and the crystal structure reveals twofold spontaneous resolution of a racemic mixture into homochiral helix-enantiomers. The investigated crystal contained only one type of helix, namely (left-handed or *M*-) $4_3$-helical chains. This is traced first to an intermolecular N–H···O hydrogen bonding from the stereogenic amino group to a neighboring unligated carboxyl oxygen atom that connects only molecules of the same (*R*)-configuration into (left-handed or *M*-) $4_3$-helical chains. This intrachain homochirality is supplemented, secondly, by the interlocking of adjacent chains with their corrugated van der Waals surface to allow for an interchain transmission of the sense of helicity, building the single crystal from the same homochiral helix-enantiomer. The enantiomeric amino alcohol complex **V** crystallizes in the monoclinic, noncentrosymmetric (Sohncke) space group $P2_1$.

## Introduction

Syntheses and reactivities of metal complexes with amino acids or peptides are of considerable interest and some of them show potential applications as chiral catalysts.[1] Singh first reported the syntheses of [Rh(AA)($CO)_2$][2a,2b] and [Rh(AA)(CO)($L)_2$] (AA = deprotonated amino acid = aminocarboxylato ligand; L = $PPh_3$ or $AsPh_3$) complexes.[2c,2d] Later, Marko synthesized the [Rh(AA)($CO)_2$] complexes starting from the dimeric [Rh($O_2$CR)($\eta^4$-cod)]$_2$ by synthesis of the intermediate [Rh(AA)($\eta^4$-cod)] complexes (cod = cycloocta-1,5-diene).[3] Accordingly, Beck has reported the syntheses and crystal structures of the [Rh(AA)(CO)(L)] (L = $PPh_3$, $AsPh_3$)[4a] and [Rh(L-aziridin-2-carboxylato)($CO)_2$][4b] complexes and efforts to synthesize the analogous Ru$^{II}$-aminocarboxylato complexes containing the bidentate 2,7-dimethylocta-2,6-dien-1,8-diyl ligand.[4c] Molybdocene and titanocene compounds of the formulae [$Cp_2$Mo$^{IV}$($\kappa N$,$\kappa O$-AA)]$^+$Cl$^-$,[5] [$Cp_2$Mo$^{IV}$($\kappa N$,$\kappa O$-AA)]$^+$-$PF_6^-$,[6] [$Cp_2$Ti$^{IV}$($\kappa O$-AA)$_2$]$^{2+}$,[7,8] and the isoelectronic half-sandwich molybdenum compounds [CpMo$^{II}$($CO)_2$($\kappa N$,$\kappa O$-AA)][9] and [CpMo$^{II}$(NO)(*I*){$\kappa N$,$\kappa O$-L-$H_2$NCH(*t*Bu)-COO}][10] have been prepared and structurally elucidated (Cp = $\eta^5$-$C_5H_5$, $\eta^5$-cyclopentadienyl). However, no detailed studies on the syntheses, spectroscopy, and crystal structures of Rh($\eta^4$-cod) complexes containing chiral amino acid/amino alcohol or *N*-amino acids have been reported so far. It is envisioned that these coligands will exercise strong influences on the stereochemistry as well as the stability and reactivity of the Rh complexes and their uses as catalysts for the enantioselective hydrogenation of olefins, unsaturated carboxylates, amidocinnamic acids, and their ester derivatives.

Recently, we attempted to synthesize and characterize the Rh($\eta^4$-cod/diphos/triphos) complexes containing chiral amino acids and amino alcohols as coligands[11] and to study their catalytic behaviors in an asymmetric hydrogenation reaction. Here, we report the syntheses and spectroscopic studies of the complexes [Rh(AA)($\eta^4$-cod)] {AA = L-alaninato (**I**), (*S*)-2-amino-2-phenylacetato (**II**), *N*-methylglycinato (**III**), *N*-phenylglycinato (**IV**)} and [Rh{(*S*)-$HOCH_2$–CH(Ph)-$NH_2$}($\eta^4$-cod)]($O_2CMe$) (**V**) as well as the crystal structures of **IV** and **V**.

## Results and Discussion

Reaction of dimeric [Rh($O_2CMe$)($\eta^4$-cod)]$_2$ (cod = 1,5-cyclooctadiene) with amino acids in toluene/MeOH yields the monomeric complexes [Rh(AA)($\eta^4$-cod)] (AA = deprotonated amino acid = aminocarboxylato) (**I**–**IV** in Scheme 1). Reaction of [Rh($O_2CMe$)($\eta^4$-cod)]$_2$ with the amino alcohol (*S*)-2-amino-2-phenylethanol gives the complex [Rh{(*S*)-$HOCH_2$–CH(Ph)-$NH_2$}($\eta^4$-cod)]($O_2CMe$) (**V** in Scheme 1).

UV/Vis absorption spectra of complexes **I**–**IV**, measured in toluene at 25 °C, are identical with each other and different from those of the dimeric [Rh($O_2CMe$)($\eta^4$-cod)]$_2$ and [RhCl($\eta^4$-cod)]$_2$ complexes and different from those of the amino alcohol compound **V** (see Figure S1, Table S1 in the Supporting Information).[12]

In the infrared spectrum the aminocarboxylato complexes **I**–**IV** show a strong carbonyl band ($\nu CO_2$, asymmetric) around 1620 cm$^{-1}$, which is typical for the *N*,*O*-coordination of the aminocarboxylato ligand to $Rh^I$, as is the shifting and splitting of the $\nu NH_{asy}/\nu NH_{sy}$ stretching vibrations.[2–4,11] Absence of the νO–H stretching band (which is usually observed as a strong broad band at about 3450 cm$^{-1}$ for the free carboxylic group of the amino acid) in **I**–**IV** indicates acid deprotonation and bond formation between $Rh^I$ and $^-$O–C(O). The vibrational results strongly suggest that the amino acidato ligand is bound to Rh by its nitrogen and oxygen atoms as a *N*,*O*-chelate, as depicted in Scheme 1.[2–4,11] In contrast to these findings, van Koten synthesized the [Rh(L-alaninato)($\eta^4$-cod)]$_2$ complex starting from [Rh{$C_6H_3(CH_2NMe_2)_2$-*o*,*o*′-C,N}($\eta^4$-cod)] and described it as an *O*,*O*-coordinated carboxylato-bridged dimer.[14]

FAB-MS spectra are dominated by ions containing the species $M_2$, $M_2$ – AA = M + Rh(cod), M + $AAH_2$, M + H, M – $CO_2$, and Rh(cod) (M = molecule, AA = aminocarboxylato) for the aminocarboxylato complexes [Rh(AA)($\eta^4$-cod)] (**I**–**IV**). The appearance of dinuclear species may be due to intermolecular hydrogen bonding as evidenced by the crystal structure of **IV** (see below).

The rhodium-coordinated 1,5-cyclooctadiene ligand shows three proton NMR signals corresponding to the *exo*- and *endo*-methylene proton and to the methine proton.[11,15,16] The $CH_2cod_{exo}$ signal appears as doublet–doublet, while $CH_2cod_{endo}$ and CHcod exhibit a multiplet. In **V** the methylene protons of the chiral amino alcohol ligand are diastereotopic and couple differently to the vicinal

Scheme 2. Hydrolysis of complexes **I**–**V** from NMR studies.

methine proton, thereby showing two sets of doublet of doublets at 3.63 ppm and 3.71 ppm.[13] Similarly in **I** and **II** the amino protons of the chiral amino carboxylate ligands are diastereotopic and appear as two multiplets that are more than 0.7 ppm apart. $^{13}C$ NMR spectra of complexes **I**–**IV** show a singlet at about 30 ppm for *C*$H_2$cod and broad peaks at 72–80 ppm for *C*Hcod in [$D_6$]DMSO.[11,15,16] Complex **V** *shows two peaks* of equal intensity around 30 ppm for *C*$H_2$cod, indicating the nonequivalency of the carbon atoms at either side of the chiral amino alcohol ligand. In contrast to the related chiral complexes **I** and **II**, the nonequivalency of the *C*$H_2$cod carbon atoms may be enhanced in **V** by the acetate anion coordination through N–H···O hydrogen bonding (see structural analysis below).

Upon addition of acid (as 5% DCl/$D_2O$ in $CD_3CN$) the $^1H$ and $^{13}C$ NMR spectra indicate that complexes **I**–**V** are readily hydrolyzed with dissociation of the amino carboxylate or amino alcohol ligand to form the dimeric chloro complex [RhCl($\eta^4$-cod)]$_2$ and the free amino acid or amino alcohol (Scheme 2).[11]

Complexes **IV** and **V** could be crystallized and subjected to single-crystal X-ray diffraction studies. The single-crystal X-ray analysis proved the suggested *N*,*O*-chelate formation of the aminocarboxylato or amino alcohol ligand to the rhodium atom of the Rh($\eta^4$-cod) fragment (Figure 1 and Figure 2). Related Rh($\eta^4$-cod) complexes with a five-membered Rh-*N*,*O*-chelate ligand are structurally elucidated with 8-hydroxyquinolinato,[17] tryptophan benzyl ester,[18] 4-methylpyridinium 2-pyridylcarbonylmethylide,[19] 1-(2′-pyridyl)-3-(dimethylamino)-2-propenone,[20] imidazole-4,5-carboxylato,[21] orotato,[22] and 3-oxo-1-(pyridin-2-yl)-prop-1-en-1-olato.[16a] The five-membered *N*,*O*-chelate ring with rhodium is planar within (largest deviation) ±0.16 Å in **IV** and ±0.28 Å in **V**. Selected distances and angles are compared in Table 1. Both complexes are highly similar in their relevant bonding parameters. The Rh–O distance to the carboxylate oxygen in **IV** and to the alcohol oxygen in **V** is identical.

The achiral (prochiral) *N*-phenylglycine ligand acquires a stereogenic center at the nitrogen atom upon metal coordination. Initially this metal–ligand coordination will give a racemic mixture of (*R*)- and (*S*)-configured complexes. The chiral *N*-phenylglycinato complex [Rh($O_2C$–$CH_2$–NHPh)($\eta^4$-cod)] (**IV**) crystallizes in the tetragonal, chiral space group $P4_3$[23,24] with spontaneous resolution within the single crystal. The homochirality results from the solid-state packing in that N–H···O hydrogen bonding from the stereogenic amino group to a neighboring unligated car-

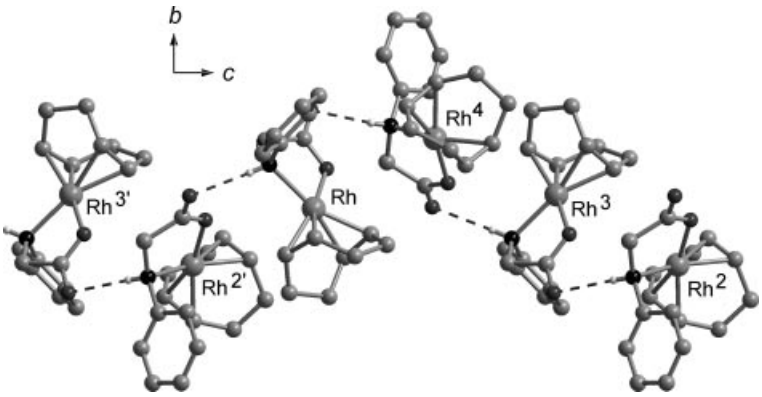

Figure 3. $4_3$-Helical chain in **IV** along *c*. Hydrogen-bonding interaction (dashed line) as D–H, H···A, D···A, D–H···A [Å (°)]: N–H···O2$^{2'}$ 0.73(4), 2.19(4), 2.925(5), 176(5); symmetry transformations: 2 = 2 – *y*, *x*, 0.75 + *z*; 2′ = 2 – *y*, *x*, –0.25 + *z*; 3 = 2 – *x*, 2 – *y*, 0.5 + *z*; 3′ = 2 – *x*, 2 – *y*, –0.5 + *z*; 4 = *y*, 2 – *x*, 0.25 + *z*.

boxyl oxygen atom (Figure 3 and Figure 4) connects and assembles only molecules of the same configuration [here (*R*), see Figure 1 and Figure 3] into a (left-handed or *M*-) $4_3$-helical chain (in the crystal investigated) along *c* (Figure 3 and Figure 4).

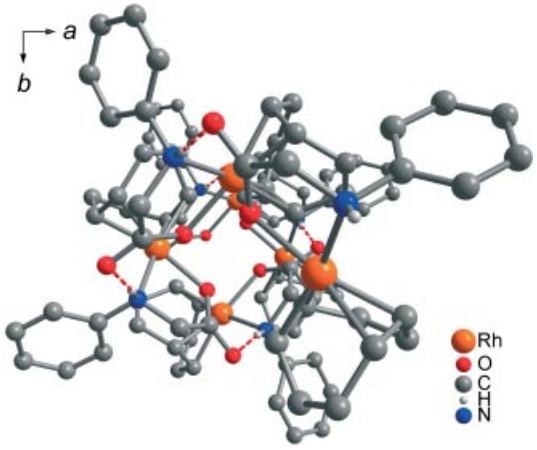

Figure 4. Left-handed $4_3$-helical chain in **IV** viewed along the chain direction.

Yet, most homochiral helices that are formed from achiral ligands and even from racemic mixtures of chiral building blocks almost always lead to racemic mixtures of *P*- and *M*- (right- and left-handed) helices.[25–30] Of interest are structures that spontaneously resolve to contain only one type of helix (within a crystal), that is a single, homochiral helix-enantiomer that requires a sufficient homochiral helicating element in the molecular building block, for example, the ligand. This is typically a stereogenic center of an enantiomerically pure ligand in combination with strong interhelix supramolecular interactions. However, in the structure of **IV** there are no classical hydrogen-bonding interactions between neighboring chains. The exterior of the chains is covered by CH bonds (Figure 4). Also, there are no noteworthy reasonable π–π stacking or C–H···π interactions seen in **IV** (or **V**) [that is, for π–π with centroid–centroid distances <6.0 Å, a dihedral angle between the ring planes <10° and an angle between the centroid vector Cg(I)···Cg(J) and the normal to the plane *I* <60°; for C–H···π, H···Cg < 3.0 Å and an angle between the vector H···Cg(J) and the normal to the plane *J* <30°].[31,32] In **IV** the shortest perpendicular distance of H on a phenyl ring plane is 3.3 Å, about 0.4–0.5 Å longer than seen in typical C–H···π interactions.[33]

The investigated crystal of **IV** contained only one type of helix, namely (left-handed or *M*-) $4_3$-helical chains, thereby representing a case of spontaneous resolution of a racemic mixture into homochiral helix-enantiomers. To account for this fact we invoke an interlocking of adjacent chains with their corrugated van der Waals surface in order to transmit the sense of helicity upon crystallization (Figure 5). The overall ensemble of the crystals in a batch of **IV** can be expected to be racemic, that is, to contain crystals of space groups $P4_3$ and $P4_1$ with left- and right-handed helices based on (*R*)- and (*S*)-configured metal–ligand complexes, respectively, in equal amounts.

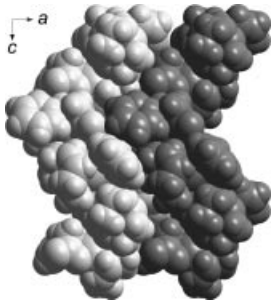

Figure 5. The interlocking of two neighboring left-handed (*M*-) $4_3$-helical chains in **IV** based on the corrugated van der Waals surface without any strong supramolecular interactions; space-filling representation of the chains, which are differentiated by light and dark gray shading.

Spontaneous resolution of achiral or of racemic chiral molecular materials within the single crystal, that is, crystallization in noncentrosymmetric (polar) space groups, can be dictated by supramolecular solid-state packing interactions. This phenomenon has been observed by us in the crystallization of *achiral* hydrotris(pyrazolyl)boratothallium(I) (in $P2_1$),[34,35] dihydrobis(1,2,4-triazolyl)boratothalli-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

um(I)[35] and -potassium (in $P2_12_12_1$),[36] hydrotris(indazolyl)boratothallium(I) (in $C2$),[35,37] and hydrotris(1,2,4-triazolyl)boratosilver(I) (in polar $Pna2_1$).[38] The spontaneous resolution of a *racemic chiral* material within a noncentrosymmetric space group was seen in the crystallization of $[Ag^+(NH_3)_2](BINOLAT^-)(BINOL)(EtOH)$ (in $P1$).[39] The crystallization of a racemic chiral material within a noncentrosymmetric polar space group was encountered in the crystallization of $[\Lambda/\Delta\text{-}Fe^3(DABP)_3]^{2+}[\Delta/\Lambda\text{-}Fe^2(DABP)_3\subset \Lambda/\Delta\text{-}Fe^1(DABP)_3(nitrophenolate)_6]^{2-}$ (in $P3_1c$).[40] The spontaneous resolution of *rac*-2,3-dihydro-2,3-dipyridylbenzo[*e*]indole with $Cd(ClO_4)_2\cdot 6H_2O$ is a recent example of symmetry breaking through supramolecular interactions and solvent, where in the presence of either 2-butanol or ethanol crystals of the opposite enantiomers were favored (crystallizing in the enantiomorphous space groups $P6_122$ and $P6_522$).[41] Particularly intriguing is the formation of a homochiral (helical) polymer from achiral components through spontaneous enantiomer resolution. A homochiral helix winding together with homochiral crystallization was reported for the adduct of 5-(9-anthracenyl)pyrimidine with $Cd(NO_3)_2\cdot H_2O\cdot EtOH$. The chirality arises from a pyrimidine-$Cd^{2+}$ helical array and is preserved in each crystal by homochiral interstrand water–nitrate hydrogen bonding. All the crystals are of the same chirality as a result of single-colony homochiral crystal growth (homochiral crystallization).[42] The achiral building blocks in $^{\infty}_1\{[Ni(PhCOO)_2(4,4'\text{-bipy})]\cdot 2MeOH\}$ gave rise to a $4_1$- or $4_3$-helical polymer with homochirality in the crystal. Different crystals contain statistically either *P*- or *M*-helices.[43] Homochiral right-handed (*P*-) $6_1$ helices of $Cd\{B(OMe)_4\}$ are found in $^{\infty}_3\{[Cd(tcm)\{B(OMe)_4\}]\cdot x MeOH\}$ with neighboring helices connected by the tricyanomethanide (tcm) ion.[44] Compound $^{\infty}_1\{[Mn(hfac)_2\{ferrocenyl\ bis(nitronyl\ nitroxide)\}]\cdot CH_2Cl_2\}$ spontaneously resolves in enantiomorphous crystals with either Λ- or Δ-configuration at Mn and an additional six sources of chirality within the *P*- or *M*-helices, respectively (hfac = hexafluoroacetylacetonate).[45] Variation of the proton content with $KOH/HCl_{aq}$ allows for a reversible interconversion between the achiral molecular square of $[Cu(HL)(H_2O)_{0.5}]_4(ClO_4)_4$ (high pH) and a spontaneously resolved homochiral double-chain motif of $^{\infty}_1\{[H_3O]_2[Cu_3(L)_2Cl](ClO_4)_2(Cl)\}$ (low pH) {$H_2L$ = 1,5-diazacyclooctane-1,5-bis(3-propionic acid)}.[46]

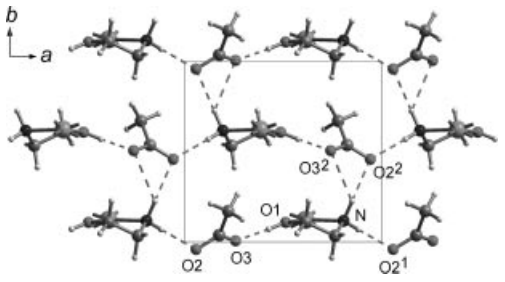

Figure 6. Two-dimensional hydrogen-bonded network in **V**. Phenyl groups and cod ligands are not shown for clarity but only indicated as broken-off bonds. For details of the hydrogen bonds see caption to Figure 2.

The enantiomeric amino alcohol complex **V** crystallizes in the monoclinic, noncentrosymmetric (Sohncke) space group $P2_1$.[23,24] Hydrogen-bonding interactions between the amino and hydroxy donor groups in the metal complex to the acetate anion acceptors link the building blocks into supramolecular two-dimensional nets co-planar to the *ab* plane (Figure 6). Along *c* the nets are separated by the phenyl groups and cod ligands without meaningful π–π-stacking or C–H···π interactions (see above).

## Conclusions

Aminocarboxylato($\eta^4$-cycloocta-1,5-diene)rhodium(I) complexes [Rh(AA)($\eta^4$-cod)] could be easily prepared from dimeric $[Rh(O_2CMe)(\eta^4\text{-cod})]_2$ with amino acids in toluene/MeOH. The compounds [Rh(AA)($\eta^4$-cod)] (AA = deprotonated amino acid = aminocarboxylato) were found to be monomeric. Solid-state structures of $[Rh(O_2C\text{–}CH_2\text{–}NHPh)(\eta^4\text{-cod})]$ (**IV**) and $[Rh\{(S)\text{-}HOCH_2\text{–}CH(Ph)\text{–}NH_2\}(\eta^4\text{-cod})](O_2CMe)$ (**V**) reveal strong intermolecular N–H···O hydrogen-bonding interactions to assemble the molecular units into 1D chains (**IV**) or 2D nets (**V**). In **IV** the achiral (prochiral) *N*-phenylglycine ligand acquires a stereogenic center at nitrogen upon complexation and the racemic compound undergoes spontaneous resolution upon crystallization. Supramolecular N–H···O and van der Waals interactions are responsible for collecting only one enantiomer along fourfold screw axes of the same handedness within a single crystal. This could be called a twofold spontaneous resolution in two homochiral building units, namely the molecular complex and the fourfold helix.

## Experimental Section

All reactions were carried out under dry nitrogen using Schlenk techniques. Solvents used were highly purified and distilled: toluene and benzene over Na metal; petroleum ether (PE) (boiling range 40–60 °C) over $CaH_2$; methanol and ethanol over CaO under nitrogen. The starting complex $[Rh(O_2CMe)(\eta^4\text{-cod})]_2$ was synthesized from $[RhCl(\eta^4\text{-cod})]_2$[47] according to the literature.[3a] UV/Vis spectra were obtained with a Shimadzu UV 3150 spectrophotometer in toluene at 25 °C. IR spectra were recorded as KBr disks with a Bruker IFS 66 FTIR Spectrometer at ambient temperature. NMR spectra were run on a Bruker AC DPX 200 spectrometer operating at 200 MHz ($^1$H) and a JEOL AC 500 at 500 MHz ($^1$H), 125 MHz ($^{13}$C) at 25 °C. NMR grade solvents [$D_6$]DMSO, $CD_3OD$, $CD_3CN$, and $DCl/D_2O$ solution (20% v/v) were used as internal standard and deoxygenated prior to use. $^1$H and $^{13}$C NMR chemical shifts are expressed in ppm relative to $SiMe_4$ ($\delta$ = 0 ppm). FAB-MS (positive mode): Finnigan MAT 8230 with data system SS 300, matrix: *m*-nitrobenzyl alcohol (NBA). EI- and CI-MS: Thermo-Finnigan TSQ 700, with $NH_3$ as ionization gas for CI.

**(L-Alaninato)($\eta^4$-cycloocta-1,5-diene)rhodium(I), {Rh[(*S*)-$O_2C$–CHMe–$NH_2$]($\eta^4$-cod)} (I):** L-Alanine (166 mg, 1.86 mmol) was dissolved in methanol (5 mL) and this solution was poured into a solution of $[Rh(O_2CMe)(\eta^4\text{-cod})]_2$ (503 mg, 0.93 mmol) in toluene (20 mL). Stirring the solution for 10–12 h at room temperature led to the formation of a yellow precipitate. After the solvent was evap-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

orated in vacuo, toluene/MeOH (4:1, v/v) (10 mL) was added to the dried precipitate and evaporated again. This procedure was repeated three times. Finally, the precipitate was dried in vacuo (0.1–0.2 mbar) at 40 °C to give a yellow powder (yield 417 mg, 75%). $^1$H NMR (200 MHz, $CD_3OD$): $\delta$ = 1.45 (d, $J$ = 7.0 Hz, 3 H, C$H_3$), 1.88 (dd, $J$ = 8.2 Hz, 4 H, C$H_2$cod$_{exo}$), 2.46 (m, 4 H, C$H_2$cod$_{endo}$), 3.43 (q, $J$ = 7.0 Hz, 1 H, C$H$), 4.13 (m, 4 H, C$H$cod) ppm. $^1$H NMR (500 MHz, [D$_6$]DMSO): $\delta$ = 1.20 (d, $J$ = 7.0 Hz, 3 H, C$H_3$), 1.72 (dd, $J$ = 8.0 Hz, 4 H, C$H_2$cod$_{exo}$), 2.32 (m, 4 H, C$H_2$cod$_{endo}$), 3.09 (q, $J$ = 7.0 Hz, H, C$H$), 3.68 (m, 1 H, N$H$), 3.92 (m, 4 H, C$H$cod), 4.31 (m, 1 H, N$H$) ppm. $^1$H NMR (500 MHz, $CD_3CN$ + 5% DCl/$D_2O$): $\delta$ = 1.50 (d, $J$ = 8 Hz, 3 H, C$H_3$), 1.77 (dd, $J$ = 8.5 Hz, 4 H, C$H_2$cod$_{exo}$), 2.36 (m, 4 H, C$H_2$cod$_{endo}$), 4.02 (q, $J$ = 8.5 Hz, 1 H, C$H$), 4.22 (m, 4 H, C$H$cod) ppm. $^{13}$C NMR (125 MHz, [D$_6$]DMSO): $\delta$ = 20.4 (s, $C$H$_3$), 30.1 (s, $C$H$_2$cod), 52.5 (s, $C$H), 72.1, 79.6 (br., $C$Hcod), 183.2 (s, $CO_2$) ppm. $^{13}$C NMR (125 MHz, $CD_3CN$ + 5% DCl/$D_2O$): $\delta$ = 15.1 (s, $C$H$_3$), 30.2 (s, $C$H$_2$cod), 48.5 (s, $C$H), 80.3 (d, $J_{C,Rh}$ = 13 Hz, $C$Hcod), 171.1 (s, $CO_2$) ppm. **X-ray Crystallography:** *Data Collection:* Bruker AXS with CCD area-detector, temperature 203(2) K, Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), graphite monochromator, $\omega$-scans, data collection and cell refinement with SMART,[48] data reduction with SAINT,[48] experimental absorption correction with SADABS.[49] *Structure Analysis and Refinement:* The structure was solved by direct methods (SHELXS-97);[50] refinement was done by full-matrix least-squares on $F^2$ using the SHELXL-97 program suite.[50] For **IV** structure refinement has also been attempted in the enantiomorphic space group $P4_1$ but this gave a Flack parameter of 1 with the message "absolute structure probably wrong – invert and repeat refinement". All non-hydrogen positions were found and refined with anisotropic temperature factors. Hydrogen atoms on oxygen (–OH) and nitrogen (–NH–Ph, –NH$_2$) were found and refined with $U_{eq}$(H) = 1.2$U_{eq}$(N) in **IV** and freely in **V**. Hydrogen atoms on C (phenyl, CH, CH$_2$, and CH$_3$) were calculated with appropriate riding models (AFIX 43, 13, 23, and 33, respectively) and $U_{eq}$(H) = 1.2$U_{eq}$(C) (CH, CH$_2$) or $U_{eq}$(H) = 1.5$U_{eq}$(C) (CH$_3$). Details of the X-ray structure determinations and refinements are provided in Table 2. Graphics were drawn with DIAMOND (Version 3.0e).[51] Computations on the supramolecular interactions were carried out with PLATON for Windows.[52]

CCDC-297844 (for **IV**) and -297845 (for **V**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (for details see the footnote on the first page of this article): UV/Vis spectra and data.

Table 2. Crystal data and structure refinement for **IV** and **V**.

| Compound | **IV** | **V** |
|---|---|---|
| Empirical formula | $C_{16}H_{20}NO_2Rh$ | $C_{18}H_{26}NO_3Rh$ |
| $M$ [g mol$^{-1}$] | 361.24 | 407.31 |
| Crystal size [mm] | 0.42 × 0.10 × 0.09 | 0.40 × 0.27 × 0.16 |

## Acknowledgments

We thank the Alexander von Humboldt Foundation (AvH), Bonn, and the Matsumae International Foundation (MIF), Tokyo, for offering a post-doctoral fellowship to M.E. Our sincere thanks go to Dr. Inayoshi for collecting the mass spectra at the Department of Chemistry, College of Science and Engineering, Aoyama Gekuin University, Tokyo. We acknowledge the financial support under the JU projects, Department of Chemistry, Jahangirnagar University, Bangladesh, by the Deutsche Forschungsgemeinschaft through grant JA-466/14-1, and the Fonds der Chemischen Industrie.

# Photoinduced Processes in a Dendritic Zn Porphyrin Structure with a Free-Base Porphyrin Core

**Lucia Flamigni,*[a] Anna Maria Talarico,[a] Barbara Ventura,[a] Chloé Sooambar,[b] and Nathalie Solladié*[b]**

**Keywords:** Dendrimers / Energy transfer / Luminescence / Porphyrinoids / Supramolecular chemistry

The photophysical characterization of a nonameric porphyrin assembly made up of a central free-base and eight peripheral zinc porphyrins connected by flexible nucleosidic linkers, and the identification of the photoinduced processes taking place in the array, is reported. Both singlet–singlet and triplet–triplet energy transfer from the peripheral zinc porphyrins to the free-base porphyrin core is detected. The kinetic parameters of singlet–singlet energy transfer are interpreted by assuming the existence of several nonequilibrated conformations in the array due to the flexibility of the linkages. A fast quenching of the donor beyond the time detection limit of the instrument is also hypothesized and assigned to strong interactions between the zinc chromophores in close contact which can give self-quenching phenomena. For the zinc porphyrin triplet excited state, a triplet–triplet annihilation is detected at moderate photon flux as a consequence of multi-excitation of the same array. Drastic reduction of the photon flux allows us to determine the triplet energy transfer rate from zinc porphyrin to free-base porphyrin, which is the final recipient of the energy collected by the array. The decay of the triplet state of the core free-base porphyrin is prolonged with respect to the model, indicating a shielding effect of the peripheral groups. Complexation experiments with monodentate and didentate bases have been performed in order to gain insight into the spatial arrangement of the zinc porphyrin chromophores and the proposed mechanism of self-quenching. Association of didentate bases increases the rigidity of the multi-porphyrin structure and improves the energy collection ability.

## Introduction

Natural photosynthesis is triggered by the absorption of photons by a light-harvesting antenna system with a large absorption cross-section, followed by a rapid and efficient transfer of excitation energy to the reaction center. To mimic the natural processes, artificial light-harvesting antennae require a great number of chromophore units that are well organized in space and able to transfer the absorbed energy to one specific site with high efficiency. Porphyrins are ideal candidates for the construction of light-harvesting arrays and, in the past decade, many artificial multi-porphyrin systems have been developed, such as linear or linear-branched arrays,[1–5] rings,[6–8] windmills,[9] dendrimers,[10,11] and other assemblies.[12,13] Among these, dendritic frameworks appear to be the most promising arrays as they allow site-specific placement of the dye molecules in a three-dimensional hyperbranched treelike fashion, and a good choice of the chromophoric units permit the conveyance of the collected energy toward the central core.

Many dendritic arrays with a variety of linkers have been developed recently.[10,13] We present here a study of the photoinduced processes in a dendritic nonameric porphyrin assembly (Scheme 1) made up of a central free-base porphyrin and eight peripheral zinc porphyrins connected in pairs to the core by a flexible nucleosidic linker whose synthesis has been reported recently.[14] The structure can be considered a further step in the elaboration of porphyrin-based antennas with respect to a pentaporphyrin previously reported by our groups.[15] The eight peripheral zinc porphyrin chromophores can absorb light extensively over the full visible spectrum and the energy stored can be conveyed to the central free-base porphyrin. The study of convenient model compounds, Zn and FBS (Scheme 1), can help in the elucidation of the fundamental steps occurring upon light absorption in the nonaporphyrin FB-$Zn_8$, whose photophysical behavior could be strongly influenced by the existence of different conformations due to the flexible linkers. Steady-state and time-resolved spectroscopic methods are used to quantify the energy-transfer processes.

## Results and Discussion

### Absorption Spectroscopy

Scheme 1 shows the structures of the nonaporphyrin FB-$Zn_8$ and of the molecules used as models of the periphery

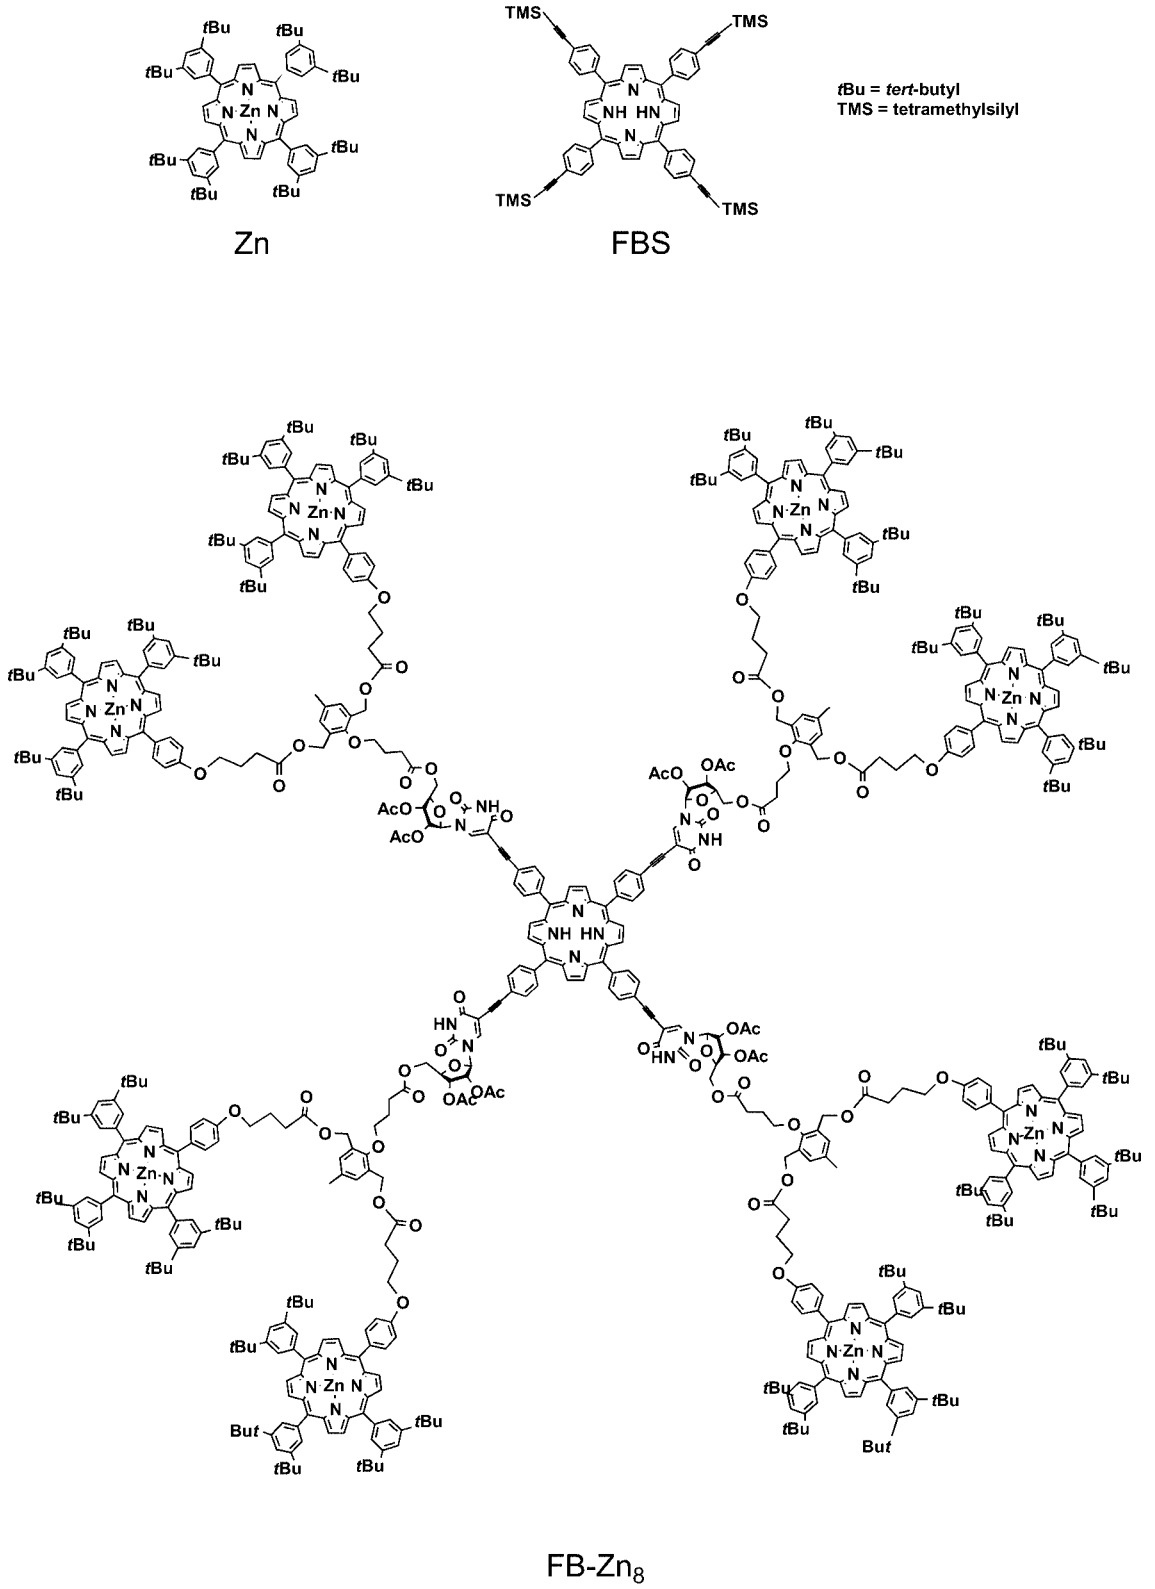

Scheme 1. The component models Zn and FBS and the nonaporphyrin FB-$Zn_8$.

and the core units, Zn and FBS, respectively. The absorption spectrum of FB-$Zn_8$ in toluene is in good agreement with the superposition of the model components, as can be seen in Figure 1, where the absorption spectra of the models are reported with the sum of the nine components and the experimental absorption spectrum of the nonaporphyrin FB-$Zn_8$. In addition to the usual broadening of the Soret band, which is typical of covalently bound porphyrinic ar-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rays, a 2–3-nm shift to lower energies can be detected in the maximum wavelength of both the Soret and Q bands with respect to the simple superposition of the components. A long, weak tail extending up to 700 nm can be detected in the array compared to the superposition of components, which can be taken as an indication of some interaction between the porphyrinic chromophores. Nonetheless, this interaction is modest and the single chromophores in the array can be considered to retain essentially their own spectroscopic properties (see below).

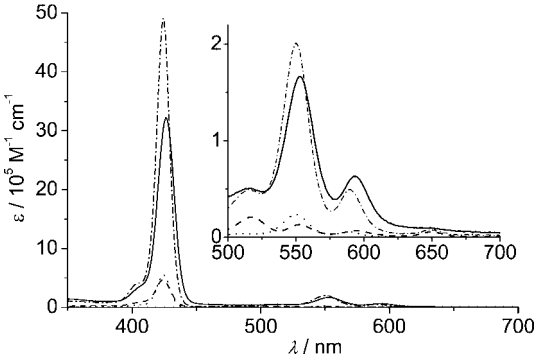

Figure 1. Molar absorption coefficients of the models Zn (dot) and FBS (dash), and of FB-$Zn_8$ (solid) in toluene solution. The sum of the molar absorption coefficients of the nine components is also reported (dash-dot).

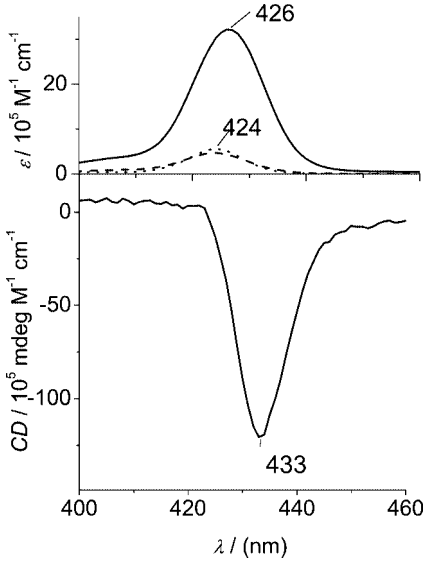

Figure 2. UV (upper panel) and CD (lower panel) spectra of FB-$Zn_8$ (solid) in toluene solutions. In the upper panel the absorption spectra of components Zn (dot) and FBS (dash) are also reported.

FB-$Zn_8$ displays optical activity − the CD spectrum is reported in Figure 2, lower panel, with the absorption spectra of the two models Zn and FBS and the array shown in the upper panel. In the spectrum the positive band is almost absent, whereas a strong, negative band can be detected. Its origin could be assigned to exciton interactions between the porphyrin chromophores, similarly to what was recently reported and discussed in detail for a similar porphyrin pentamer;[15a] however, we cannot exclude a CD effect induced on the porphyrin by the chiral nucleosidic linkers.

## Luminescence

The Zn singlet excited state at 295 K in toluene has a lifetime of 2.2 ns and an emission quantum yield of 0.08,[16] whereas the lifetime of FBS under the same conditions is 9.5 ns and the emission quantum yield is 0.18. The energy levels of the lowest singlet excited state of the models, derived from the maximum of the emission band at 77 K, are 2.08 eV for $^1$Zn and 1.92 eV for $^1$FBS (Table 1), which means that a photoinduced energy transfer from the peripheral Zn to the core FBS would spontaneously occur with a $\Delta G^0$ value of –0.16. Phosphorescence from porphyrin components could be detected in the near-IR region at 77 K in glassy media.[17] From the maximum of the phosphorescence bands, the energy levels of the triplet can be derived for $^3$Zn (1.6 eV) and for $^3$FBS (1.48; Table 1). An energy transfer could also occur spontaneously in this case from the triplet excited state localized on the zinc porphyrin to the free-base central unit with a $\Delta G^0$ of –0.12 eV.

The luminescence spectrum of FB-$Zn_8$ in toluene upon excitation at 550 nm is reported in Figure 3 together with the superposition of the emission spectra of the individual components (Zn and FBS) in toluene, for absorbance corresponding to the same number of photons absorbed by the units in the array. The band positions of the units in the

array are essentially unaltered with respect to the models, thereby confirming that the components retain their own spectroscopic properties. A partial quenching of the zinc porphyrin component ($\lambda_{max}$ = 600 nm) to about 20% can be detected, ($\Phi_{fl}$ = 0.015) but no corresponding sensitization of the free-base component ($\lambda_{max}$ at 651 nm and 720 nm) appears. This observation could be explained by a self-quenching of the zinc porphyrin donors that does not lead to a sensitization of the free-base acceptor and/or to a change in the emissive properties of the free-base core compared to the model FBS. In order to establish whether the present system displays some form of light energy collection and transfer properties, the experiments described below were carried out.

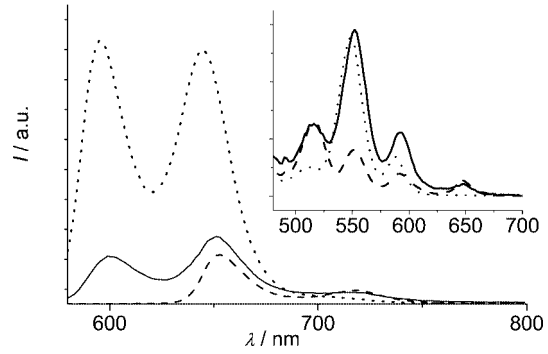

Figure 3. Emission spectra at 295 K of the models Zn (dot), FBS (dash), and of FB-$Zn_8$ (solid) in toluene solution upon excitation at 550 nm. The concentrations are adjusted to provide the same absorbance of the models and of the corresponding unit in FB-$Zn_8$. The inset shows the excitation spectrum registered at $\lambda_{em}$ = 720 nm for the models and the array.

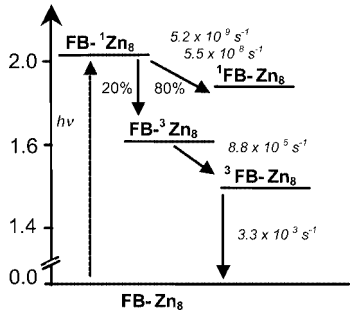
The emission quantum yield of the porphyrin core in the array was determined by selective excitation of the free-base porphyrin unit at 650 nm and turned out to be reduced ($\Phi_{fl} \approx 0.10$[18] with respect to $\Phi_{fl}$ = 0.18 in the model FBS). This perturbation could be the result of interaction of the porphyrin core with some peripheral Zn porphyrin that is in close contact because of the flexibility of the linker. At short distances, low lying charge-transfer states could play a role, leading to a static quenching of the free-base porphyrin. The long absorption tail detected in the nonamer (see above) up to 700 nm could confirm the presence of such an interaction generating low-lying states that are able to quench the free-base porphyrin luminescence. Support in favor of an energy transfer in the array comes from the excitation spectrum detected at $\lambda_{em}$ = 720 nm, where only the free-base porphyrin core emits (inset of Figure 3). From this spectrum, which is displayed with the excitation spectra of the components, the contribution of the zinc porphyrin unit at 550 nm to the emission of the free base at 720 nm is quite evident, and confirms that an energy transfer from the peripheral components to the core is actually taking place. The fact that there is no evidence of this transfer from the steady-state luminescence experiment as a sensitization of the free-base porphyrin unit (Figure 3) could be ascribed to a decreased emission yield of the energy acceptor free-base unit from $\Phi_{fl}$ = 0.18 to 0.10, as reported above.

The spectroscopic data from Table 1 allow us to draw a schematic energy-level diagram for FB-$Zn_8$ (Scheme 2), from which both a singlet-to-singlet (FB-$^1Zn_8 \rightarrow {}^1$FB-$Zn_8$) and a triplet-to-triplet (FB-$^3Zn_8 \rightarrow {}^3$FB-$Zn_8$) energy transfer appear feasible.



Scheme 2. Schematic energy-level diagram and photoinduced processes in FB-$Zn_8$. The percentage of units following different reaction paths is reported.

## Singlet–Singlet Energy Transfer

The mechanism of singlet–singlet energy transfer between porphyrins is generally of the Förster type,[19] with a mechanism involving a dipole–dipole interaction. For this mechanism it is possible to calculate the rate, $k^F_{en}$, as a function of the donor–acceptor distance, $d_{DA}$, with some accuracy as the emission quantum yield, $\Phi$, and the lifetime, $\tau$, of the donor Zn, the overlap integral, $J^F$, and the refractive index of toluene, $n$, are known; see Equation (1).[19]

$$k^F_{en} = \frac{8.8 \times 10^{-25} \cdot \kappa^2 \cdot \Phi}{n^4 \cdot \tau \cdot {d_{DA}}^6} \cdot J^F \quad (1)$$

$J^F$ is calculated from the experimental emission and absorption spectra to be $5.47 \times 10^{-14}$ cm$^3$ M$^{-1}$ and $\kappa^2$, the orientation factor, is taken as 2/3 since the partners can be assumed to randomly approach each other because of the long, flexible linker. On the basis of these parameters and of the data in Table 1, a critical transfer distance, $R_c$, which is the distance at which the energy transfer rate equals the intrinsic deactivation rate of the donor, of about 28 Å can be calculated. In view of the approximations involved in the present determinations, we can assume that for a fully extended linkage, corresponding to a center-to-center distance of about 34 Å, essentially no quenching of the donor can occur.[20] Due to the flexibility of the linkages, a large number of conformations are expected, characterized by distances varying between a few angstroms, for conformations corresponding to a highly bent linkage, and a maximum distance of 34 Å. The time decay of the luminescence of the zinc porphyrin detected at 600 nm in FB-$Zn_8$ in toluene (Figure 4) is in perfect agreement with this picture as it displays a multi-exponential decay. This is typical of the luminescence decay of Zn porphyrin donors in either flexible or rigid dendritic multiporphyrin arrays for light har-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vesting and is due to the existence of several donor–acceptor couples with different distances and orientations.[21] A three exponential fitting of the zinc porphyrin luminescence decay gives satisfactory results, with *average* calculated lifetimes of 0.175, 0.990, and 2.2 ns with relative weights of 50%, 30%, and 20% respectively. Whereas most of the emission is fitted by lifetimes shorter than that of the reference model Zn, indicating an important quenching, a residual 20% (under our experimental conditions) displays the same lifetime (2.2 ns) as the model. This could be due to the fraction of conformers with donor–acceptor distances corresponding to the fully extended array (34 Å), which are not liable to quenching, although the contribution of zinc porphyrin impurities cannot be excluded. The time profile of the luminescence detected at 720 nm, a wavelength typical of the free-base acceptor, is also shown in Figure 4. Although rather weak, it comes, in fact, from one of the nine chromophores − the luminescence-time evolution in FB-$Zn_8$ shows a clear rise in the luminescence at early times on the same time scale as the fast decay of the zinc porphyrin donor at 600 nm. A fitting of the formation and decay signal would be meaningless due to the poor signal-to-noise ratio and the multi-exponential nature of the kinetics. The detected formation at 720 nm can be assigned to sensitization of the free-base porphyrin units by the Zn porphyrin moieties. The subsequent time evolution detected at 720 nm can be considered a superposition of the tail of the zinc porphyrin moiety ($\lambda_{max}$ = 600 nm; lifetime: 2.2 ns) and the decay of the free-base unit emissions ($\lambda_{max}$ = 720 nm; lifetime: 9 ns).

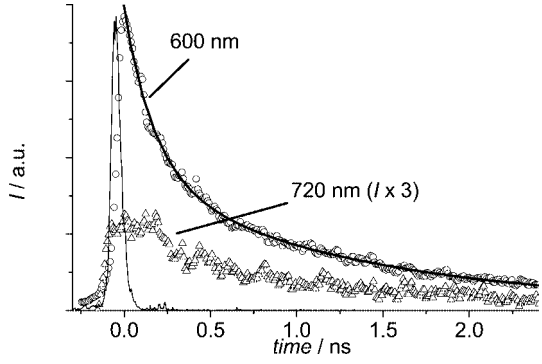


Figure 4. Time-resolved luminescence of FB-$Zn_8$ in toluene solution after excitation at 532 nm. Decay at 600 nm (circle) is shown with the tri-exponential fitting with lifetimes of 175 ps, 990 and 2.2 ns. The time profile of the luminescence at 720 nm is also reported (triangle) with the exciting flash profile.

It is interesting to compare the steady-state luminescence results with the time-resolved data. The emission quantum yield, $\Phi_{fl}$, is related to the lifetime of a species by the equation $\Phi_{fl} = \tau k_r$, where $\tau$ is the lifetime and $k_r$ is the radiative rate constant. In case of more than one lifetimes of the species, as in the present case, where a multi-exponential decay of the luminescence is present, the equation becomes $\Phi_{fl} = \Sigma(f_i\tau_i k_r)$, where $f_i$ is the fraction of component corresponding to the lifetime $\tau_i$. Assuming that $k_r$ of the zinc porphyrin singlet excited state in FB-$Zn_8$ is identical to that of the model Zn ($k_r = \Phi_{fl}/\tau$; $k_r = 3.6\times10^7\ s^{-1}$) the fluorescence quantum yield can be calculated from the following equation: $\Phi_f = k_r\times(f_1\tau_1 + f_2\tau_2 + f_3\tau_3)$, where the index 1, 2, and 3 is relative to the average conformations displaying the three different lifetimes. The result of this calculation is $\Phi_f = 0.03$, which is different from the experimental value ($\Phi_f = 0.015$; Table 1). This discrepancy, which is much higher than the experimental uncertainty, could be accounted for by: (i) the radiative rate constant of the zinc porphyrin moiety in the nonaporphyrin is different than the one of the model, and/or (ii) there is some faster quenching, which escapes the time resolution of the experimental set-up (20 ps) and can therefore be considered a "static quenching". This would be detectable by steady-state techniques, which integrate a signal over time, but *not* by time-resolved methods with time resolution exceeding the timescale of the process. In the latter case, the correct fraction, $f_i$, of each component for the calculation of $\Phi_f$ should be scaled to take into account the component which gives "static" quenching and which is missed by our apparatus.

The luminescence properties at 295 K and 77 K are summarized in Table 1.

### Triplet–Triplet Energy Transfer

Porphyrin triplets exhibit strong and well-characterized triplet absorption spectra and lifetimes in the hundreds of microseconds range in fluid, oxygen-free solutions. They can be conveniently monitored by laser flash photolysis with nanosecond/microsecond resolution. The transient change in the absorption spectra due to the triplet excited states of the models FBS and Zn are reported in Figures 5 and 6, respectively, with one inset (a) showing the lifetime in oxygen-free and the other (b) in air-equilibrated toluene solutions at 295 K. To prevent triplet–triplet second-order competitive reactions, which are a very common phenomenon for long-lived triplet excited states, the lifetime of the species in air-free solutions was measured at extremely low excitation energy (≤0.2 mJ per pulse) in order to provide a low concentration of excited species and a good single exponential decay of the excited triplet [insets (a) of Figures 5 and 6]. The triplets are quenched by oxygen and their lifetime in air-saturated solutions is greatly decreased [see Table 2, insets (b) of Figures 5, and 6]. Since the concentration of $O_2$ in air-equilibrated toluene solutions is $1.8\times10^{-3}$ M,[22] a reaction rate with oxygen in toluene of the order of $1–1.5\times10^9\ M^{-1}s^{-1}$ can be derived for Zn and FBS, in agreement with previous reports.[23]

In FB-$Zn_8$, once the triplet state of the zinc porphyrin unit is formed, a triplet energy transfer to the core free-base porphyrin can be envisaged. Energy transfer between triplet states occurs generally by a Dexter (electron-exchange) mechanism.[24] This type of mechanism involves the synchronized transfer of two electrons, one from the LUMO of the donor to the LUMO of the acceptor and the other from the HOMO of the acceptor to the HOMO of the donor. It requires either a direct physical contact (through

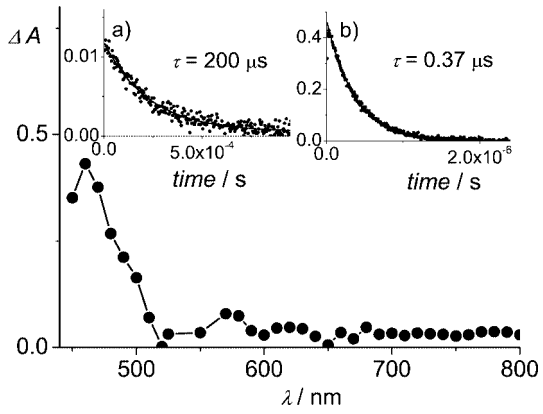

Figure 5. Transient absorbance changes of FBS ($A$ = 0.13) following laser excitation at 532 nm (5 mJ per pulse) in toluene solutions. Inset a) shows the decay in oxygen-free (0.2 mJ per pulse) and inset b) the decay in air-saturated solution (5 mJ per pulse).

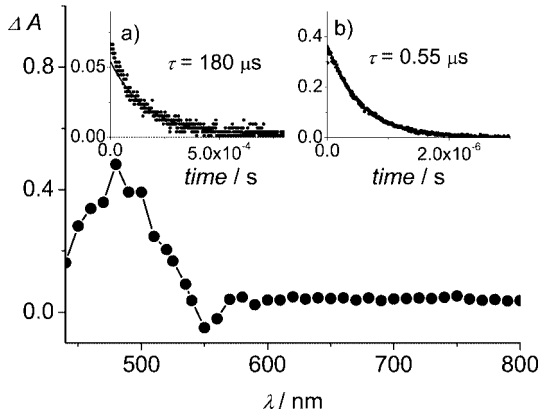

Figure 6. Transient absorbance changes of Zn ($A$ = 0.12) following laser excitation at 532 nm (5 mJ per pulse) in toluene solutions. Inset a) shows the decay in oxygen-free (0.125 mJ per pulse) and inset b) the decay in air-saturated solution (5 mJ per pulse).

Table 2. Transient absorbance data at 295 K in toluene.

| | State | $\tau$ [μs][a] | $\tau$ [μs][b] | $\Phi_T$[c] |
|---|---|---|---|---|
| Zn | $^3$PZn | 250 | 0.50 | 1 |
| FBS | $^3$FBS | 200 | 0.37 | 1 |
| FB-Zn$_8$ | FB-$^3$Zn$_8$ | 1.1 | n.d. | 0.2 |
| | $^3$FB-Zn$_8$ | 300 | n.d. | ca. 1[d] |

[a] Lifetime in air-free toluene, low laser energy (see text). [b] Lifetime in air-saturated toluene. [c] Triplet formation quantum yields, relative to the models and calculated on the basis of the photons absorbed by the unit in the array. [d] Poor signal to noise ratio, the determination is subject to an error of the order of 30%.

space), or the intermediacy of a linkage (through bond), between the reacting partners. Without entering into detail, in the case of through-bond transfer the rate depends on the type of bond and its length. For alkane chains and large distances, as in the present case, the through-bond energy transfer rate is slow and is expected to occur on the microsecond timescale; it is therefore able to compete with the deactivation rate of the Zn porphyrin triplet in air-free solutions.

A nanosecond flash photolysis experiment on the nona FB-Zn$_8$ in air-free solution allowed us to detect an end-of-pulse spectrum mostly ascribable to the zinc porphyrin triplet state (Figure 7). The yield of formation of this state calculated with respect to the model Zn in the wavelength range out of the ground-state absorbance (650–700 nm) is about 20%, which is in good agreement with the fraction of unquenched singlet derived by luminescence time-resolved determinations (see above). This clearly indicates that the triplet states are produced only by the unquenched singlet excited states of the zinc porphyrin donor via an intersystem-crossing step. The end-of-pulse spectrum of FB-Zn$_8$ evolves rapidly, with a slight shift of the maximum from 490 to 480 nm, and after a few microseconds it reaches a value that is stable on the microsecond timescale (Figure 7). The exponential decay rate of the fast decay was found to depend on the laser intensity, as shown in inset (a) of Figure 7. This can be understood by considering that excitation of a $3\times10^{-6}$ M solution with several millijoules at 532 nm is able to produce multiple excitation of porphyrins (mostly of the zinc porphyrin units, which absorb 85% of the incident photons) within the same array.[25] Multiple excitation in an array that has a very high *local* concentration of zinc porphyrins would cause a fast intramolecular triplet–triplet reaction and lead to a rapid self-quenching of the zinc porphyrin triplet. The experimental first-order reaction rate would therefore be due to the contribution of two different processes: the intramolecular triplet–triplet annihilation, which is dependent on the square of the laser energy, and the energy-transfer process, which is independent of it. The rate at different incident laser conditions was measured and a plot of rate versus laser intensity was extrapolated to zero energy [inset (a) of Figure 7] in order to derive the decay rate of FB-$^3$Zn$_8$ in the absence of multi-photonic excitation. Under these conditions, the first-order decay rate of FB-$^3$Zn$_8$ was $8.8\times10^5$ s$^{-1}$ and was assigned to an energy-transfer process from the triplet localized on the zinc porphyrin moiety (FB-$^3$Zn$_8$) to the triplet localized on the free-base central unit ($^3$FB-Zn$_8$).[26] The latter species, which can be identified from the spectrum after 3 μs in Figure 7, decays exponentially with a lifetime of 300 μs [inset (b) of Figure 7]. The lifetime of the triplet porphyrin core in $^3$FB-Zn$_8$ is longer than that determined for the model FBS under the same conditions (ca. 200 μs), very likely because of a sort of shielding effect of the periphery components toward traces of oxygen or quenching contaminants in the solution. A similar protecting effect of the periphery on the triplet excited state of a core chromophore was previously found for a similar pentaporphyrin[15] and has also been reported for a fullerene-based dendrimeric structure.[27]

Scheme 2 shows the rate constants of the intramolecular processes; the decay of the excited state localized on the zinc porphyrin chromophore, FB-$^1$Zn$_8$, is assigned to different processes depending on the type of conformation: the 20% extended conformation decays mainly to the triplet state

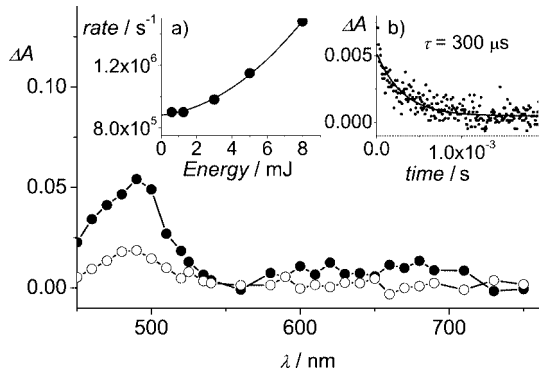

Figure 7. Transient absorbance changes of FB-$Zn_8$ ($A$ = 0.17) following laser excitation at 532 nm (5 mJ per pulse) in toluene solutions; end-of-pulse spectra (filled circle) and 3 μs after the end of the pulse (open circle). Inset a) shows the rate constant dependence of the fast decay (see text) from the laser intensity and inset b) shows the decay of the 3-μs species, assigned to $^3$FB-$Zn_8$, in oxygen-free solutions.

FB-$^3Zn_8$, whereas the other conformations with lower donor–acceptor distances decay by energy transfer to $^1$FB-$Zn_8$ with average rates of $5.2\times10^9$ and $5.5\times10^8$ $s^{-1}$, corresponding respectively to average lifetimes of 175 and 990 ps.

## Complexation

Zinc porphyrins are know to axially bind pyridine or pyridyl residues with association constants of the order of $10^4$ $M^{-1}$. These constants have been found to increase dramatically up to around $10^6$ to $10^8$ $M^{-1}$ when multiple bonds can contribute to the formation of the complex.[28,29]

We have undertaken this type of experiment with both monodentate pyridine (Pyr) and didentate 4,4′-bipyridine (Bipy) in order to gain information about the spatial arrangement and the interactions between the zinc porphyrin chromophores in FB-$Zn_8$. As a reference, the same experiments were performed with Zn. Our aim was to derive the association constants by spectrophotometric and spectrofluorimetric methods and to monitor the effect of FB-$Zn_8$ complexation on CD spectroscopy, in order to gain some insight into the system. The association constants were derived by a nonlinear treatment previously developed for the analysis of absorption and emission signals at a selected wavelength (see Exp. Sect. for details).[29]

The results for the absorption of Zn ($1.7\times10^{-6}$ M) upon titration with increasing amounts of Pyr are reported in Figure 8, together with the emission spectra of the same solutions upon excitation at 428 nm, which is the isosbestic point between the complexed and uncomplexed forms. The insets show the nonlinear fittings to the experimental data, and the derived association constants are summarized in Table 3. The same type of experiment was also performed with Bipy as a titration agent, and the results are illustrated in Figure 9. The plots of the signals at the selected wavelengths (inset) allow us to derive the association constants (Table 3). The behavior with the two different titration agents is essentially the same for Zn: in both cases the absorption of the porphyrin Soret band shifts from 424 to 431 nm (7 nm), with a clear isosbestic at 428 nm typical of the formation of a 1:1 complex.[30] In principle, the didentate Bipy could complex two Zn molecules to form a 2:1 (Zn/Bipy) complex, which should be favored at low concentrations of Bipy. Nonetheless, in the present experimental conditions we were unable to detect the 2:1 complex, which is reported to display a red shift of only about 4 nm with respect to the Zn porphyrin band, i.e. a band maximum at lower wavelengths with respect to the 1:1 complex.[30] The low association constant and the use of a large excess of Bipy are very likely to be unfavorable for the formation of the 2:1 complex.

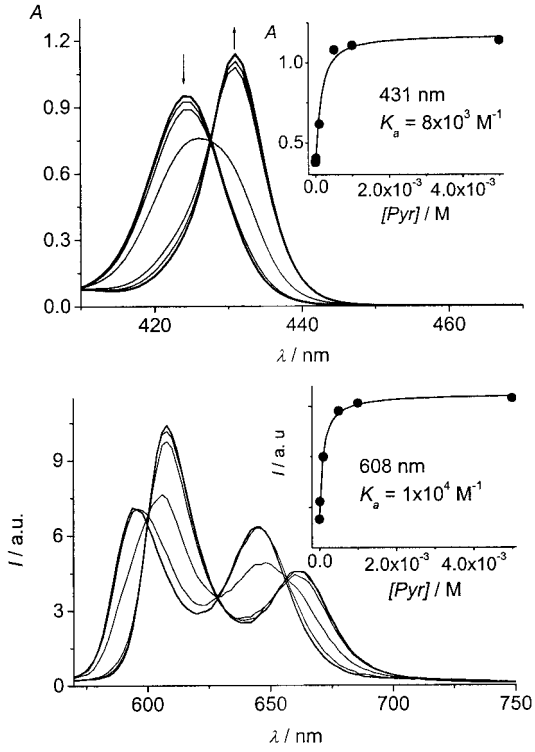

Figure 8. Zn ($1.7\times10^{-6}$ M) in toluene solution upon titration with increasing amounts of Pyr. The upper panel shows the change of absorbance in the Soret band region and the inset shows the data points at 431 nm, fitted according to Equation (2). In the lower panel the change in emission intensity is shown and in the inset the data points at 608 nm, fitted to Equation (2), are reported.

Table 3. Association constants $K_a$ [$M^{-1}$] of the model Zn and of FB-$Zn_8$ with pyridine and bipyridine.

| | Pyr | | | Bipy | | |
|---|---|---|---|---|---|---|
| | Abs | Em | Average | Abs | Em | Average |
| Zn | $8\times10^3$ | $1\times10^4$ | $9\times10^3$ | $9\times10^3$ | $1.4\times10^4$ | $1.2\times10^4$ |
| FB-$Zn_8$ | $6\times10^3$ | $6\times10^3$ | $6\times10^3$ | – | – | – |

In the case of titration of a solution of FB-$Zn_8$ ($2.6\times10^{-7}$ M), the results obtained with Pyr and Bipy are rather different. The effects on the absorption and emission properties upon titration with the monodentate Pyr are shown in Figure 10. The absorption titration data do not differ appreciably from that of the model Zn − the shift in

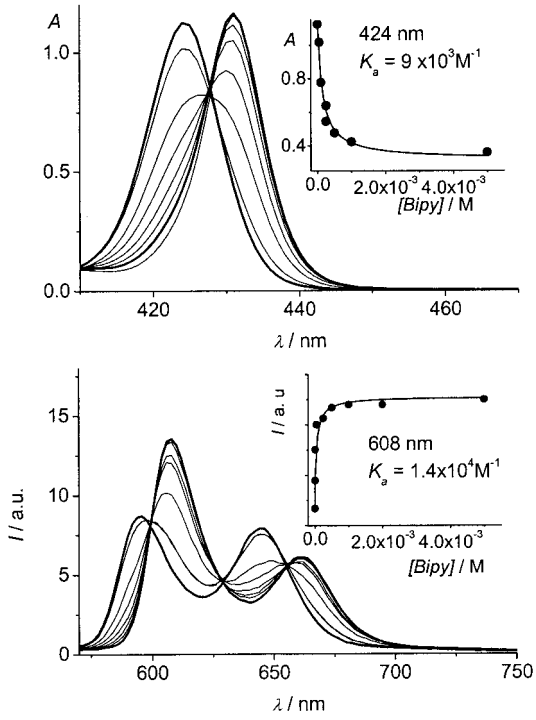

Figure 9. Zn ($1.7\times10^{-6}$ M) in toluene solution upon titration with increasing amounts of Bipy. The upper panel shows the change of absorbance in the Soret band region and the inset shows the data points at 424 nm, fitted according to Equation (2). In the lower panel the change in emission intensity is shown and in the inset the data points at 608 nm, fitted to Equation (2), are reported.

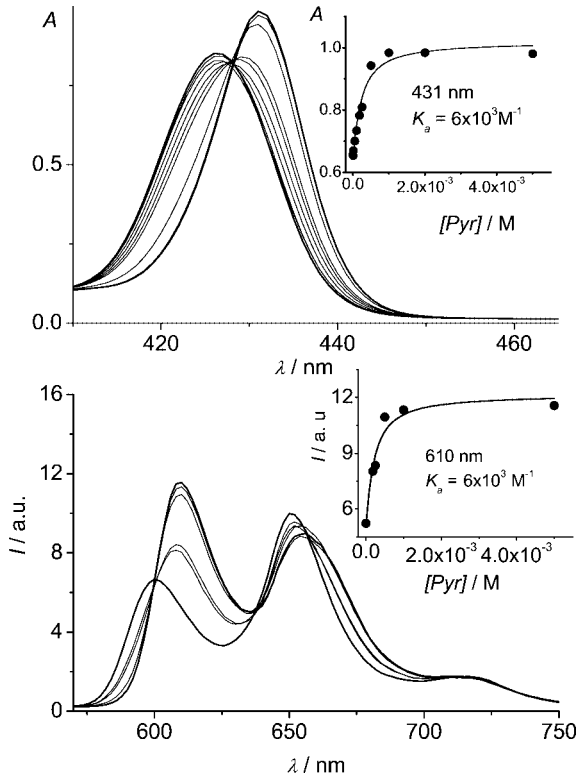

Figure 10. FB-$Zn_8$ ($2.6\times10^{-7}$ M) in toluene solution upon titration with increasing amounts of Pyr. The upper panel shows the change of absorbance in the Soret band region and the inset shows the data points at 431 nm, fitted according to Equation (2). In the lower panel the change in the emission intensity is shown and in the inset the data points at 610 nm, fitted to Equation (2), are reported.

the Soret band of the zinc porphyrin unit upon complexation is from 426 to 431 nm, with a single isosbestic point at 428 nm. The emission data, making allowance for the bands of the free-base unit in FB-$Zn_8$, do not appear different from the titration results of the model Zn in the region 570–640 nm, where only the zinc porphyrin chromophore emits. The derived association constant is slightly lower than that determined for the model Zn, and this is perhaps related to the less accessible Zn porphyrin units in the nona structure compared to simple Zn.

The results of titration of FB-$Zn_8$ with the didentate Bipy are more interesting. Absorption data show that in this case there is no isosbestic point (see Figure 11), but from the initial spectrum of the free nonaporphyrin ($\lambda_{max}$ = 426 nm) a rather complicated evolution can be detected. This shows an initial decrease of the band at 426 nm with a shift to 429 nm in the concentration range from $5\times10^{-7}$ to $5\times10^{-6}$ M, followed by an increase of the band at 429 nm, which reaches a maximum for a Bipy concentration of $10^{-4}$ M, and a final evolution for concentrations above $5\times10^{-3}$ M to the absorption with maximum at 431 nm typical of the 1:1 complex spectrum, in analogy to the model system. An absorption maximum around 429 nm is typical of the 2:1 (Zn/Bipy) complex spectrum, but the exact position of the maximum and the extinction coefficient of the species could change slightly depending on the geometry and conformations of the complex. Similar data have recently been reported by Hunter and Ballester.[31] In one of the cases studied − a calixa-tetraporphyrin titrated by didentate DABCO − they detected a similar behavior in the middle part of the titration by absorption spectroscopy. That behavior was assigned, and confirmed by $^1$H NMR spectroscopy, to the formation of a 2:1 complex (Zn/DABCO) with different conformations and geometries. Whereas in Hunter and Ballester's case the presence of different conformations was mainly ascribed to the possibility of formation of intra- or intermolecular complexes, in the present experiment the possibility of forming different 2:1 complexes depends on the relative positions of the porphyrins involved, i.e. whether they are on the same branch or on different branches. We also expect that, due to the high flexibility of the system, the geometry of the complexes could be extremely variable.

The situation is obviously rather complex, and we can only derive from the present data the information that an intermediate group of slightly different 2:1 complexes is formed prior to the formation of a 1:1 complex, which is favored in conditions of high concentration of Bipy. The determination of one or more association constants for this system is far too complex and beyond the purposes of the present work.

Due to the absence of a clear isosbestic point in the absorption experiment it was not possible to perform a neat luminescence titration experiment, as done in the previous

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

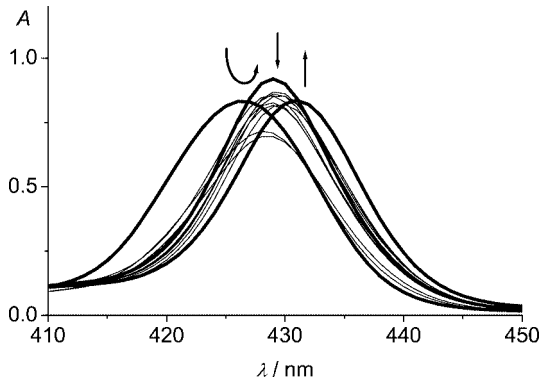

Figure 11. FB-$Zn_8$ ($2.6\times10^{-7}$ M) in toluene solution upon titration with increasing amounts of Bipy (range $5\times10^{-7}$^$5\times10^{-2}$ M).

cases. It was, however, possible to select some concentrations of titrant and to compare the luminescence of the complex to the luminescence of FB-$Zn_8$ alone, upon excitation at the iso-absorbing wavelength for the couple of solutions. The data are reported in Figure 12 and seem to indicate that an increase of the luminescence of the zinc porphyrin at 610 nm *and* of the free-base moiety around 715 nm occurs in FB-$Zn_8$ upon increasing the complexation degree. In fact, comparing the results of Figure 12 with those of Figure 9, which shows data for the model Zn and Bipy, the band at 610 nm, due to the complexed zinc porphyrin component, appears to be higher in the system FB-$Zn_8$ plus Bipy than in the model complex Zn plus Bipy (2.4 vs. 1.6). This finding, which is ascribable to a disruption of the interaction between zinc porphyrin chromophores by Bipy, *could* make available more excitation energy of the zinc porphyrin donor for the energy-transfer process. This type of behavior does not seem to take place for the system FB-$Zn_8$ plus Pyr (see Figure 10); the difference in the two systems could very likely be due to the larger dimensions and to the didentate binding by Bipy.

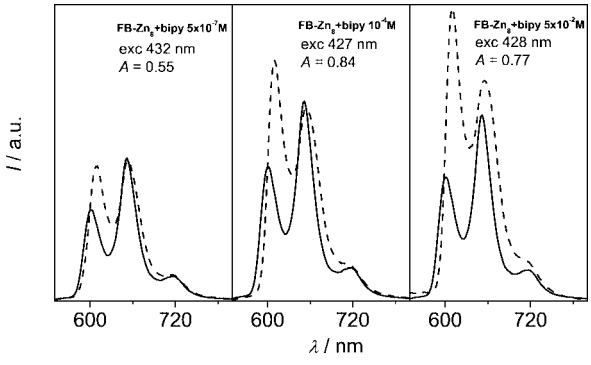

Figure 12. Luminescence spectra of FB-$Zn_8$ ($2.6\times10^{-7}$ M) in toluene solutions upon different Bipy additions compared to the luminescence of FB-$Zn_8$ alone. The excitation wavelength corresponds to the isoabsorbing wavelength for each pair of solutions (see text for details).

What is worth noting is the effect that complexation by both Pyr and Bipy has on the CD signal, as shown in Figure 13. It can be seen that complexation is effective in decreasing the optical activity. The CD signal is, however, not fully cancelled by complexation, as can be seen in the upper panel of Figure 13, where about 40% of the original signal remains at concentrations of Pyr corresponding to complexation of the zinc porphyrin units of 95%.[32] Similar results are obtained for the titration with Bipy (lower panel of Figure 13). These data indicate that a nearly complete association of the array with Pyr and Bipy (the completeness of the complexation reaction in the Bipy case can be derived from the invariance of the absorption spectra upon further addition of Bipy) can decrease most of the CD activity but not completely suppress it. Complexation can certainly interfere with exciton coupling by changing the geometry and/or the distance between interacting porphyrins but can also increase the rigidity and influence the geometry of the structure affecting the CD activity induced by chiral nucleosidic linkers. So this does not help to provide a clear identification of the origin of the observed CD effect.

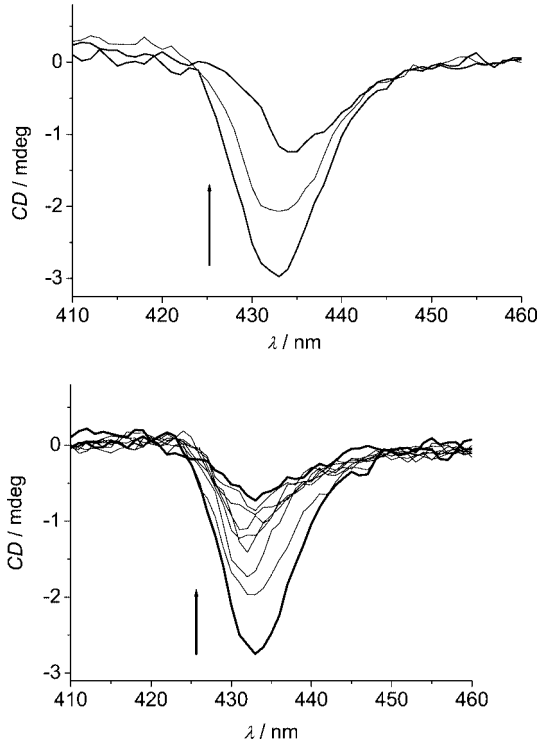

Figure 13. CD spectra of FB-$Zn_8$ in toluene solutions upon Pyr (upper panel; [Pyr] range 0–$10^{-3}$ M) and Bipy complexation (lower panel; [Bipy] range 0–$5\times10^{-2}$ M.

## Conclusions

A full spectroscopic characterization of FB-$Zn_8$ and of the photoinduced processes in this nonaporphyrin have been performed; singlet–singlet and triplet–triplet energy-transfer processes have been detected and their kinetic parameters derived. Complexation experiments withy monodentate Pyr and didentate Bipy have been performed and the association constants have been derived; furthermore, the effect of complexation on the luminescence and on the optical activity have been monitored.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Light absorption of this nonaporphyrin structure appears rather promising for possible applications in solar-energy conversion devices; the molar absorption coefficient has, in fact, extremely high values throughout the visible region with a maximum on the Soret band higher than 3000000 $M^{-1}cm^{-1}$. Nonetheless, its performance with respect to the ability to convey the collected light energy to the focal free-base porphyrin seems to be less satisfactory, and transfer to the core free-base porphyrin is not complete in spite of the fact that the quenching of the donor is, for most of the conformations, rather fast. The fact that the absorbed energy is not completely conveyed to the core energy acceptor and/or is not released by the latter as emitted light could be due to interactions between the chromophores, which can come into close contact because of the flexibility of the linkers and bring about self-quenching phenomena. Disruption of the interactions by using some coordinating component to separate the chromophores appears to be a promising strategy to try to overcome/reduce the undesired interactions with a consequent increase of the energy available for the transfer to the core free-base porphyrin acceptor.

## Experimental Section

The synthesis of the nonaporphyrin has been reported elsewhere.[15]

**Spectroscopic and Photophysical Determinations:** The solvent used was spectroscopic grade toluene (C. Erba). Absorption spectra were recorded with a Perkin–Elmer Lambda 9 spectrophotometer and emission spectra, uncorrected if not otherwise specified, were recorded with a Spex Fluorolog II spectrofluorimeter equipped with a Hamamatsu R928 photomultiplier. Relative luminescence intensities were evaluated from the area (on an energy scale) of the luminescence spectra corrected for the photomultiplier response. Luminescence quantum yields, $\Phi$, for the components were obtained with reference to a standard, namely (1,5,10,15-tetra-*tert*-butylphenyl)porphyrinatozinc(II), in toluene with $\Phi = 0.08$.[16] Experiments at 77 K made use of quartz capillary tubes immersed in liquid nitrogen contained in a home-made quartz dewar. Circular dichroism spectra were obtained with a Jasco J-710 dichrograph.

Titration experiments for the determination of the association constants were performed using a constant concentration of porphyrins and variable concentrations of Pyr or Bipy. In titration experiments excitation was performed at the isosbestic point of the complexed and uncomplexed porphyrin spectra. Equation (2) was used to derive the association constant, $K_a$, where $K_a$ is $1/K_d$, *Obs* is any observable (i.e. absorbance or emission intensity), $S_0$ is the constant concentration of FB-$Zn_8$, $X$ is the variable concentration of the complexing agent, $\Delta Obs$ is the maximum variation of the observable under examination and $Obs_0$ is its value at zero concentration of titration agent.[28,29]

$$Obs = Obs_0 + \frac{\Delta Obs}{2S_0}\cdot\{K_d + X + S_0 - [(K_d + X + S_0)^2 - 4XS_0]^{1/2}\} \quad (2)$$

Fluorescence lifetimes in the nanosecond range were detected by an IBH Time-Correlated Single Photon Counting apparatus with excitation at 337 nm. Luminescence lifetimes shorter than one nanosecond were determined by an apparatus based on a Nd:YAG laser (Continuum PY62-10) with a 35-ps pulse duration (532 nm, 1 mJ per pulse) and a Streak Camera (Hamamtsu C1587 equipped with M1952). The luminescence signals from 1000 laser shots were averaged and the time profile was measured from the streak image in a wavelength range of about 20 nm around the selected wavelength. The fitting of the luminescence decays was performed by standard iterative nonlinear programs taking into consideration the instrumental response.[33a] Transient absorbance in the nanosecond range made use of a laser flash photolysis apparatus based on a Nd:YAG laser (JK Lasers) delivering 532-nm pulses of 18 ns. Absorbance of the solutions at the exciting wavelength was about 0.2 and the energy used was 5 mJ per pulse for the determination of the spectra and less than 0.2 mJ per pulse for the triplet lifetime determination, in order to prevent undesired second-order T-T annihilation reactions. Relative triplet yields were calculated with respect to the photons absorbed only by the unit of interest, calculated on the basis of the photon partition in the array, and were determined by comparing the transient absorbance in the region 600–650 nm with that of Zn for FB-$^3Zn_8$ and at 680–700 nm with that of FBS for $^3$FB-$Zn_8$. Experiments on triplets were conducted in homemade, 10-mm optical path cuvettes, bubbled with argon for 5 min, if not otherwise specified. Further details on the experimental setup can be found elsewhere.[33b,33c]

Computation of the integral overlap and of the rate of the energy-transfer processes according to the Förster mechanism was performed with Matlab 5.2.[34]

Estimated errors are 20% for quantum yields, 30% for association constants, and 10% for lifetimes; the working temperature, if not otherwise specified, was 295 ± 2 K. The error in lifetime determinations is increased in case of multi-exponential fitting to 20%.

# Kinetic and Thermodynamic Aspects of the CT and T-Shaped Adduct Formation Between 1,3-Dimethylimidazoline-2-thione (or -2-selone) and Halogens

M. Carla Aragoni,[a] Massimiliano Arca,[a] Francesco A. Devillanova,*[a] Patrizio Grimaldi,*[b] Francesco Isaia,[a] Francesco Lelj,*[b] and Vito Lippolis[a]

**Keywords:** Density functional calculations / Donor–acceptor systems / Hypervalent compounds / Selenium / Sulfur

The reactions between L=E donors [L: 1,3-dimethylimidazolyl framework; E: S (**1**), Se (**2**)] and halogens $X_2$ (X: Cl, Br, I) to form either "T-shaped" hypervalent chalcogen (TY) or linear charge-transfer-type adducts (CT) have been studied in the density functional theory (DFT) context by considering both thermodynamic and kinetic aspects. Apart from the case of the adducts between sulfur donors and diiodine, hypervalent compounds are calculated to be always more stable than CT ones in the gas phase, in agreement with the experimental results based on spectroscopic and structural determinations. NBO and FMO analyses suggest explanations for this. Reaction mechanism studies reveal that CT adducts are always the first products of the reactions and no transition states connecting the reactants directly to TY adducts have been found. The present calculations indicate that, at least for **1** and **2**, TY adducts are obtained from CT adducts and not directly from the reactants.

## Introduction

The reactions between chalcogenone donors (L=E; L: organic framework; E: S, Se) and $X_2$ halogen molecules (X: Cl, Br, I) continue to attract a great deal of interest in the scientific community due to their implication in numerous and different fields of research, which span from synthetic and supramolecular aspects to biological, materials, and industrial chemistry.[1–10] In particular, in the last ten years we have reported[4] the isolation of several classes of compounds from the reactions of thio- and selenoketone donors with halogens. In fact, besides charge transfer (CT) and T-shaped (TY) adducts, which bear linear E–X–X and X–E–X groups, respectively, donor oxidation products with chalcogen–halogen terminal bonds (L–E–X), linear two-coordinate halogen (I) atoms with chalcogen ligands ([LE–X–EL]$^+$), and dications containing a chalcogen–chalcogen single bond ([$(LE)_2$]$^{2+}$) represent some of the most common types of products characterised by X-ray crystallography. In many cases, a very small change in the chemical environment of the donor or the experimental conditions is enough to produce each of the above-mentioned products.[8] Therefore, an important goal in this field is the complete understanding of all possible pathways that allow for the interconversion between the various species in equilibrium.

The first general qualitative criterion that can be used to foresee the formation of CT or TY adducts was based on the electronegativity values of the halogen and the chalcogen: the formation of TY adducts prevails if the electronegativity value of the halogen is higher than that of the chalcogen atom, while CT adducts prevail if the reverse is true.[2] However, a more general attempt to explain the formation of the various types of compounds obtainable by reacting L=E donors with halogens has been made by Husebye and co-workers,[3] who proposed a chemical scheme according to which the [LEX]$^+$ cation plays a central role in determining the different pathways of the reactions and the nature of the final products. This cation might originate from either the CT adduct or from the TY adduct by heterolytic cleavage of the X–X or E–X bond, respectively.

Recently, the central role of the cation [LEX]$^+$ in the formation of the various products has been tested on a series of different L=E donors on the basis of DFT calculations.[4h] In particular, the NBO charge distribution calculated for the hypothetical cationic species allowed the prediction of the preferential formation of CT or TY adducts when X is Br or I. In addition, a criterion was proposed to draw-up an order of ability to form the dicationic species ([L–E–E–L]$^{2+}$) for the considered L=E donors. This criterion suggested imidazoline-2-thione to be the top-ranking sulfur donor in the ability to form these dications, as sub-

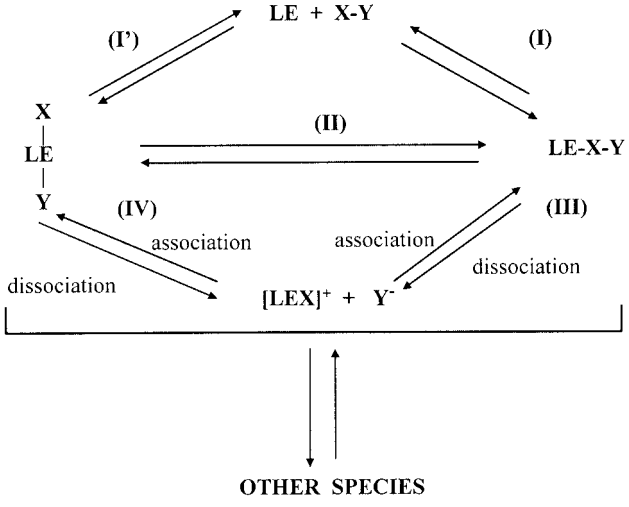
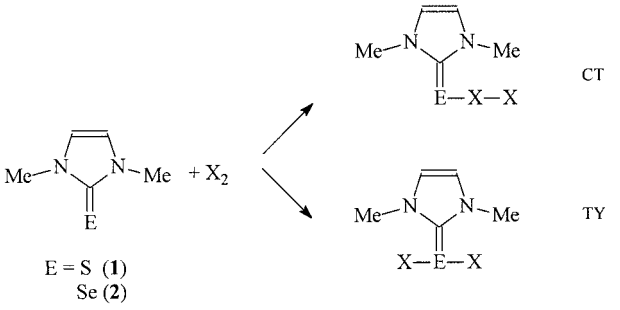
sequently observed experimentally.[7] On the basis of these encouraging results, we decided to use DFT calculations in order to achieve further insight into the origin of the relative stability of the various products and to explore the possibility of interconversion among the various species in solution. In fact, this seemed very important in order to clarify the whole reaction mechanism and test the hypothesis of Husebye from a computational point of view. A first problem to clarify was whether it is always necessary to hypothesize the formation of the $[LEX]^+$ cation as an intermediate or whether there are other accessible reaction pathways that lead to formation of the final products.

The most general reactivity scheme of L=E donors with halogens or inter-halogens in forming CT and TY adducts is depicted in Scheme 1.



Scheme 1. General scheme for the reactivity of LE donors with halogen (X equal to Y) and interhalogen molecules (X not equal to Y), involving only the CT and TY adducts and the $[LEX^+]$ cation.

In the present study we discuss the mechanistic aspects with respect to non-ionic species also, addressing our attention to the kinetic and thermodynamic aspects of the formation of CT and TY adducts (pathways I′ and I of Figure 1) by direct attack of an $X_2$ molecule (X: Cl, Br or I) on 1,3-dimethylimidazoline-2-thione (**1**) and -2-selone (**2**) (see Scheme 2), and on the possible interconversion between these adducts (pathway II).



Scheme 2. The two donors and the two possible products (CT and TY adducts) of the interaction between the imidazoline donors and $X_2$.

## Computational Methods and Search Techniques for Transition States

DFT and MP2[11] calculations were performed on an Alpha workstation using the Gaussian 98 (rev. A7 and A11) program and the implemented version of the NBO (natural bond orbital) analysis program.[12,13] The geometries of the adducts were fully optimised at the DFT level. In our previous DFT calculations on the TY adducts,[4h,4j] we used the hybrid B3LYP functional,[14] the Schafer, Horn and Ahlrichs[15] basis sets for C, H, N, O, S and Se, and the LANL2DZ basis sets together with effective core potentials (ECP)[16] for halogen atoms. The geometries of the CT and TY halogen adducts of 1,3-dimethylimidazoline-2-thione (**1**) and 1,3-dimethylimidazoline-2-selone (**2**) were therefore optimised at the same level of theory. In order to evaluate the influence of the model on the optimisations, CT and TY $Br_2$ adducts of **1** and **2** were also optimised at the MP2 and DFT with an asymptotic corrected hybrid functional[17] level with the Schafer, Huber and Ahlrichs basis sets.[18] $Br_2$ adducts were been chosen because it is possible to use a basis set without pseudo-potentials and because of the intermediate position of Br between Cl and I. In both cases the results showed no significant differences with respect to those obtained with the other model. The transition states of the reactions between **1** and **2** and halogens $X_2$ (X: I, Br, Cl) were localised by the NEPR (negative eigenvalues progressive reduction) technique.[19]

Since it has been observed[20] that the DFT approach can give incorrect indications about the structures and energies of transition states of closed-shell interacting fragments, we have also performed some MP2 calculations on the potential energy surface (PES) of selected reactants (**1** and $Br_2$) towards the CT isomer. The relative stabilities of the CT and TY adducts in the gas phase were analysed according to the NBO method.[13] NBO analysis is based on a method for optimally transforming a given wavefunction into its

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

localised form, corresponding to the one-centre (lone pair) or two-centre (bond) functions. Delocalisation effects appear as weak departures from this idealised localised picture. The energetic importance of these effects can be estimated according to a second-order perturbation theory approach. Since these delocalisation effects lead to loss of occupancy from the localised NBO (σ, π or lone pair) of the idealised Lewis structure into the empty non-Lewis, antibonding (σ* or π*) and Rydberg (R*) orbitals, and thus to departures from the idealised Lewis structure description, they are referred to as "delocalisation" corrections to the zeroth-order Lewis structure. For each donor NBO (*i*) and acceptor NBO (*j*), the stabilisation energy ($\Delta E_{ij}$) associated with delocalisation $i \rightarrow j$ is estimated as $\Delta E_{ij} = q_i \cdot [F(i,j)^2]/(\varepsilon_j - \varepsilon_i)$, where $q_i$ is the donor orbital occupancy, $\varepsilon_j$ and $\varepsilon_i$ are the diagonal elements (orbital energies) and F(*i*,*j*) is the off-diagonal NBO Fock matrix element (see ref.[13] for a detailed discussion).

## Results and Discussion

### Relative Stability of Isomers: Optimisations, NBO and FMO Analysis

Table 1 reports some relevant optimised geometrical parameters together with available experimental data of the CT and TY adducts of **1** and **2**. The agreement is very good and, furthermore, it is worthy to note that for TY adducts the method is able to account for the small deviations of the angle X–E–X from 180°, as observed for **2**·$I_2$ and other related adducts.[4h–4k,8,9] Analysis of $\nabla\rho^2$[22] suggests an explanation for this deviation (see Figure 1). According to the $\nabla\rho^2$ values there is a charge accumulation near the chalcogen on the outer side of the adduct that bends the two halogen atoms towards the molecular ring. DFT calculations indicate that hypervalent compounds for both **1** and **2** are thermodynamically favoured with respect to the CT isomers in all but the case of **1**·$I_2$ (see Table 2). The energy difference between CT and TY adducts decreases as the halogen atomic number increases and the chalcogen one reduces.

Table 2. Calculated stability [kcal mol$^{-1}$] of the CT with respect to the TY isomers (taken as 0.0) for **1** and **2**.

| | **1** | **2** |
|---|---|---|
| $Cl_2$ | 11.5 | 21.3 |
| $Br_2$ | 2.1 | 10.6 |
| $I_2$ | –3.7 | 3.5 |

In the cases of **1**·$Cl_2$, **2**·$Cl_2$, and **2**·$Br_2$ the TY adduct formation is clearly preferred, whereas in the cases of **1**·$Br_2$, **1**·$I_2$ and **2**·$I_2$ the energy differences between the two types of adducts are so small (<4 kcal mol$^{-1}$) that the experimental trend in the stability of the possible isomers can be modified by environmental effects. However, it should be remembered that no CT adducts between thioketonic donors and $Br_2$ or TY adducts with $I_2$ have been characterised so far. This relative order of stability does not change when using different approximations both in basis set and in the level of approximations.

Figure 2 reports the HOMO–1 and HOMO energies of **1** and **2** and the LUMO energies of the $X_2$ molecules. As can be seen, the HOMO energy of **1** is lower than the LUMO energy of $I_2$ only in the case of the couple **1**/$I_2$, and only in this case is the CT adduct thermodynamically favoured with respect to the TY one. It is also interesting to observe that there is a linear relationship between the NBO charges on the chalcogen atom E of the TY adducts and the frontier molecular orbital $(HOMO–1)_{LE}$ – $(LUMO)_{X_2}$ energy difference (see Figure 3).

In fact, Figure 2 shows that $(HOMO–1)_{LE}$ – $(LUMO)_{X_2}$ is lower than the $(HOMO)_{LE}$ – $(LUMO)_{X_2}$ energy difference in all cases, the exception being the case of **1**·$I_2$. Moreover, the HOMO–1 is mainly a p orbital on the chalcogen, whereas the HOMO has a non-negligible delocalisation on the imidazoline ring. This makes the interaction of dihalogen LUMOs with $(HOMO–1)_{LE}$ more relevant than the interaction with $(HOMO)_{LE}$.

Table 1. Relevant geometrical parameters of the optimised geometries of CT and TY adducts of **1** and **2** (X: halogen, E: chalcogen; distances in angstroms and angles in degrees). The structural data available for related compounds are reported in parentheses.

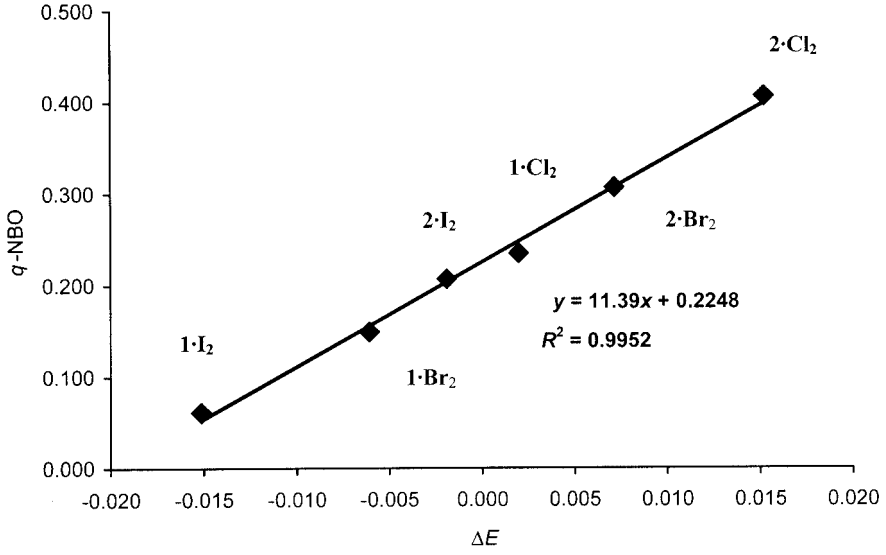

Figure 3. NBO net charges on the chalcogen (E) atoms of the TY adducts between **1** and **2** with the halogen $X_2$ as a function of the energy difference between $(HOMO–1)_{LE}$ and $(LUMO)_{X_2}$.

To gain a deeper insight into the relative stability of TY and CT adducts, an NBO energetic analysis was performed on all the compounds at the B3LYP/(SV-LanL2DZ) level by assigning the electrons in order to obtain two closed-shell fragments: a halide anion, $X^-$, and the remaining $[LEX]^+$ cation. The interaction of $X^-$ either with the chalcogen atom or with the halogen atom of the $[LEX]^+$ cation formally accounts for the formation of the TY and CT adducts, respectively. We must stress, however, that this scheme does not suggest any underlying reaction mechanism but is simply a useful approach that allows us to compare the origin of the stability in the two isomers (CT and TY) with respect to the same reference fragments.

The NBO energetic analysis (see Table 3) and the particular choice of the interacting fragments allow us not only to quantify the energy contribution of the charge transfer from the halide anion to the cation (column e in Table 3) but also to account for the contributions of the polarisation effects within the $[LEX]^+$ fragment. As an example, the NBO orbitals that contribute most to the relative stabilities of the TY adduct **1**·$Br_2$ are depicted in Figure 4.

For all the adducts examined the excitation processes within the $[LEX]^+$ cation involve two-centre localised bond orbitals (σ) and a one-centre valence lone pair (lp) orbital as donors and higher energy empty orbitals (σ*, π* and R*) that can behave as acceptors and, subsequently, as donors. In the interaction between the two fragments, two of the numerous delocalisation contributions are found to be the most relevant ones (see Table 3 and Figure 4). The first of these is due to an intramolecular polarisation effect and involves the reorganisation of the electronic structure of the cation due to the presence of the anion. This reorganisation can be described by two intra-cation charge-transfer processes, one from a carbon–chalcogen bonding orbital to a carbon–nitrogen antibonding orbital, which occurs through two intermediate orbitals: a carbon–chalcogen antibonding and a carbon Rydberg orbital (see columns a–c of Table 3), and the other involving a relatively small back-donation

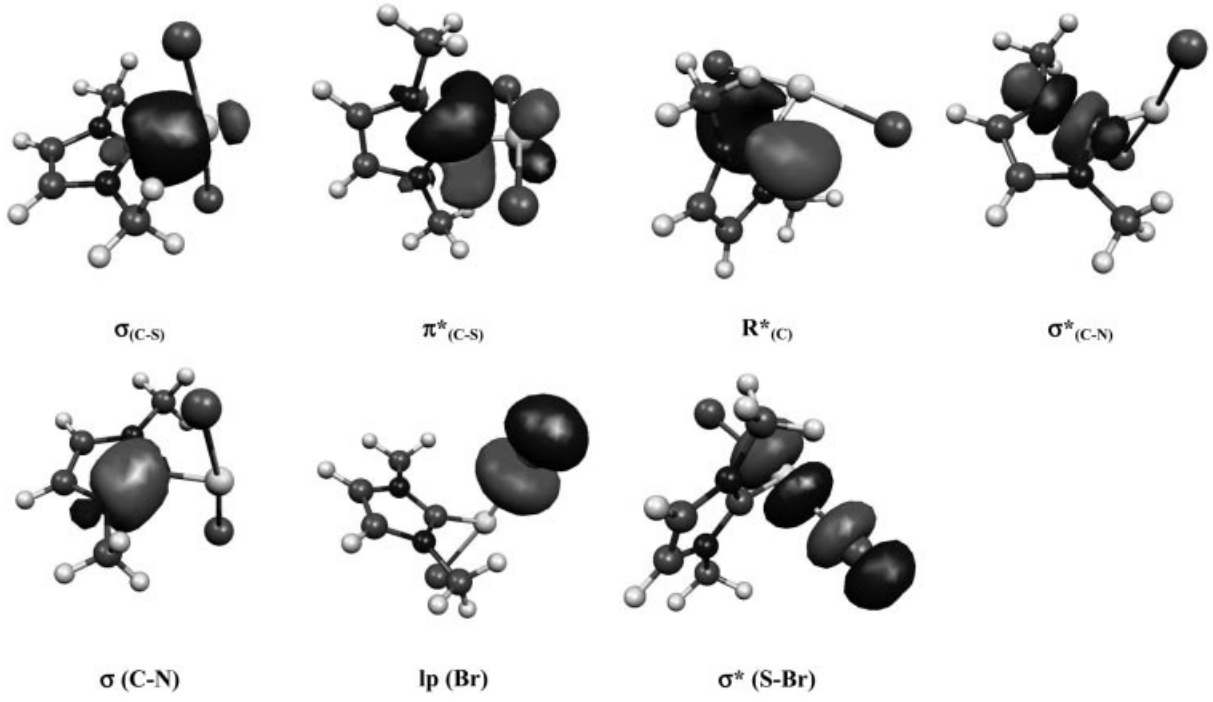

Figure 4. NBO localised orbitals calculated for **1**·$Br_2$ involved in the polarisation effects (see Table 3).

from carbon–nitrogen bonding orbitals to carbon–chalcogen antibonding orbitals (see column d of Table 3). The second is an inter-fragment process that involves the two $[LEX]^+$ and $X^-$ fragments. It is a strong charge-transfer from the halide anion lone pair to the halogen–chalcogen σ* orbital.

The sum of the energy stabilisation contributions (Table 3) gives, approximately, the relative stability for every pair of isomers. As can be deduced from this table, the different weight of each contribution determines the energy differences between the CT and TY compounds (see Table 2). In particular, the total polarisation effect contribution in the cation is bigger for the latter compounds, whereas the interfragment charge-transfer prevails in the former.

This approach also allows us to analyse the different behaviour shown by sulfur and selenium derivatives. The NBO analysis shows that the smaller energy difference between **1**·$Cl_2$ adducts (11.5 kcal mol$^{-1}$) with respect to **2**·$Cl_2$ ones (21.3 kcal mol$^{-1}$) is due to a greater stabilisation energy of the charge transfer in the case of the chlorine anion lone pair towards the antibonding S–Cl NBO orbital of the CT adduct. The growing importance of this charge transfer in the selenium CT adducts is the main factor responsible for the smaller energy difference for bromine and iodine compounds with respect to chlorine ones.

## Reaction Mechanism

### *Path I*

Scanning the PES for the motion of $X_2$ toward **1** and **2** allowed the identification of putative transition states, although their refinement did not give definite stationary structures in any case. Therefore a deeper investigation was performed in the case of the motion of $Br_2$ toward **1** using different approximations both in the Hamiltonian and in the basis set. DFT with an asymptotic corrected hybrid functional[17] and a post Hartree–Fock perturbative MP2 approach were used. The MP2 approach was used since long-range dispersive interactions need at least a bi-excited configuration contribution. In all cases the Schafer, Horn and Ahlrichs pVDZ[18] basis sets with polarisation functions on all atoms were used in order to better describe polarisation effects. All the models used showed the same Morse-like shape for the total energy, which can be fitted with the Morse function $y = D^*[1 - e^{-\beta(x-x_0)}]^2$ with the following parameters: $\beta$ = 1.3133, $x_0$ = 2.7180 Å and $D$ = 13.5461 kcal mol$^{-1}$ (see Figure 5), thereby excluding the existence of a transition state between reactants and CT adducts. Indeed, the Morse function, starting from a distance $x = x_0 - \beta\ln 2$, always has a negative value of the second derivative with a stationary point at $x = \infty$. This is the reason why, in our opinion, approximately localised putative transition states did not converge to definite transition states but were taken apart to very large distances during the optimisations.

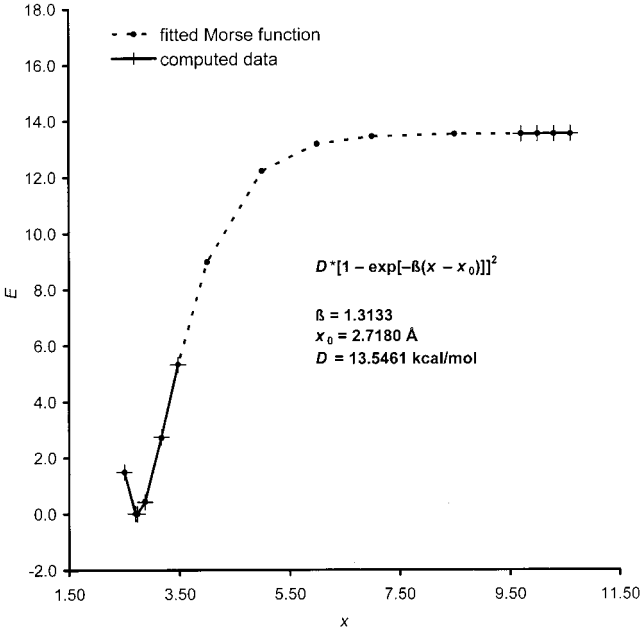

Figure 5. Computed data (in MP2 approximation) and fitted Morse function for the motion of $Br_2$ toward **1**. (energy in kcal mol$^{-1}$ and $x$ in angstroms).

Furthermore, the study of $\nabla^2\rho$[21] allowed us to describe the possible interaction of the two fragments due to electron density. As matter of fact, the $\nabla^2\rho$ (see Figure 6) shows a definite accumulation of the density in an sp shape in front of the chalcogen and a toroidal hole around the π C=E bond in the case of **1**. This can explain the fact that at large distances the interaction is between the "density hole " on the halogen and the charge concentration on the chalcogen, whereas at shorter distances the interaction is on the toroidal hole around the chalcogen and with a spherical charge concentration to even shorter distance in the CT adduct.

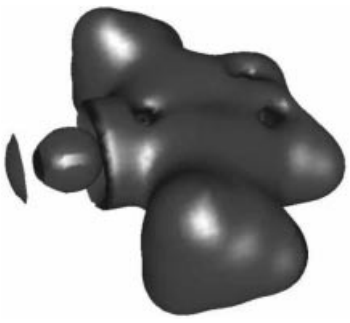

Figure 6. $\nabla^2\rho$ computed for **1** using MP2 density showing a charge concentration in front of the chalcogen atom and a depletion with cylindrical symmetry around the same atom.

### *Path I′ and II*

The six transition states leading to the six TY adducts in the reactions between **1** and **2** with halogens $X_2$ (X: Cl, Br, I) were successfully identified by applying the NEPR technique and confirmed by calculations of the second derivative matrix of the energy with respect to the coordinates. Only one negative eigenvalue was found for each of them, thus confirming the nature of the transition state for the computed structures.

To further confirm the assignment of the transition states to a given reaction path we used the intrinsic reaction coordinate (IRC) approach.[22] This approach allows the connection of each saddle-point to a given reactant/product couple. Indeed, the IRC approach confirmed that the six transition states (of the kind reported in Figure 7) link TY adducts to CT ones but, surprisingly, not to the (LE + $X_2$) reactants. Any further attempt to find a different transition state connecting TY adducts and LE and $X_2$ failed because we always found the same transition state that connected TY and CT adducts. As a consequence of these findings, step I′ of Scheme 1 should be excluded as a possible pathway leading to the TY adduct. Some relevant structural parameters of each optimised transition state are reported in Table 4.

Interestingly, all the six transition states leading to the TY from the CT adducts (see Figure 6) show the halogen molecule occupying the axial and equatorial position of a hypothetical trigonal bipyramid centred on the chalcogen atom. Figure 8 shows the snapshot sequence of the interconversion leading from the CT to the TY adduct through the axial–equatorial transition state. The energy barrier to overcome, with respect to the CT adduct, is in the range 25–40 kcal mol$^{-1}$. In order to evaluate the direct interconversion between the CT and TY adducts (pathway II) of the general Scheme 1 and the paths III and IV

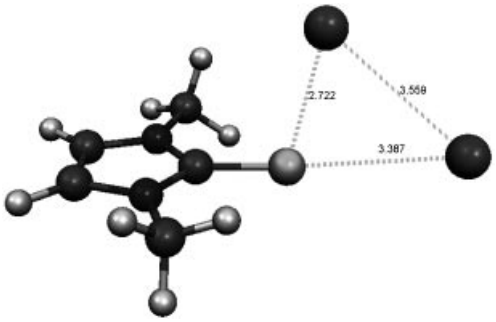

Figure 7. Transition state leading from the CT to the TY adduct in **1**·$I_2$.

Table 4. Relevant geometrical parameters of transition states of TY adducts (distances in angstoms, angles in degreees; X:halogen; E: chalcogen).

| | $E–X_{eq}$ | $E–X_{ax}$ | X–X | X–E–X | $X_{ax}$–E–C–N |
|---|---|---|---|---|---|
| **1**·$Cl_2$ | 2.6 | 2.4 | 3.7 | 97.6 | 81.1 |
| **1**·$Br_2$ | 3.4 | 2.7 | 3.7 | 74.7 | 69.2 |
| **1**·$I_2$ | 3.4 | 2.9 | 4.0 | 76.9 | 71.7 |
| **2**·$Cl_2$ | 3.3 | 2.5 | 4.1 | 89.3 | 111.5 |
| **2**·$Br_2$ | 3.4 | 2.9 | 3.3 | 61.8 | 107.2 |
| **2**·$I_2$ | 3.5 | 3.0 | 3.9 | 72.3 | 64.3 |

through association and dissociation processes, we evaluated the difference between the energy of the transition state leading to the TY from the CT adducts and the energies of the $LEX^+$ and $X^-$ products, which should be lower than the transition state energy of paths III and IV. Our calculation showed that the energies of the $LEX^+$ and $X^-$ ions at infinite distance is of the order of 300 kcal mol$^{-1}$, thus excluding III and IV as possible paths, at least in the gas phase. However, in solvents of high dielectric constant or in the presence of "acid" molecules that can accept the $X^-$ ion (e.g. free $X_2$ molecules), III and IV might compete with the path II. Thus, on the basis of these results it seems very likely that, in the case examined in the present study, the initial product of the interaction between **1** and **2** and $X_2$ is always a linear charge-transfer adduct. In the case of **1** and $I_2$, the CT adduct is the final product of the reaction, otherwise the CT adduct can evolve to the thermodynamically more stable TY adduct. So, although we can't rule out the Husebye hypothesis in polar media, we have shown that a monomolecular process can give rise to the formation of the TY adduct.

## Conclusions

In order to get a deeper insight into the reactions between L=E [L: 1,3-dimethylimidazolyl framework; E: S (**1**), Se (**2**)] and halogens $X_2$ (X: Cl, Br, I), twelve adducts (six of the CT type and six of the TY type) have been theoretically investigated. DFT calculations indicate that, except for the case of **1** and $I_2$, hypervalent adducts (TY) are generally more stable than the linear (CT) ones. Nevertheless, the CT compounds always play an important role in the process as

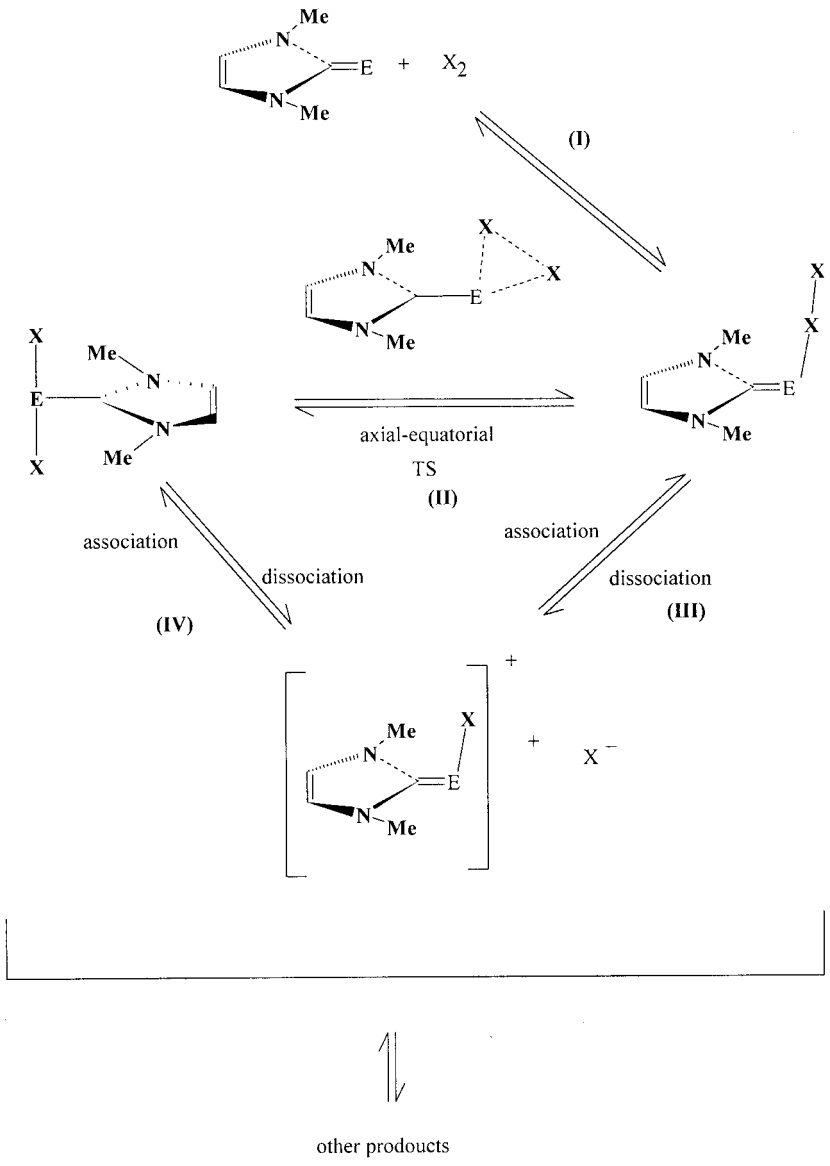

Scheme 3. Reactivity scheme proposed in the present study.

they are always the first product of the reaction from which the TY isomers can be formed through an axial–equatorial transition state.

This study suggests that the supposed formation of the cation $[LEX]^+$ is not always necessary to explain the formation of the TY adducts since the direct interconversion path of the CT to the TY adducts is accessible. In conclusion, on the basis of our calculations we propose the reaction mechanism reported in Scheme 3.

# Synthesis, Characterisation and Molecular Hyperpolarisabilities of Pseudo-Octahedral Hydrido(nitrile)iron(II) Complexes for Nonlinear Optics: X-ray Structure of $[Fe(H)(dppe)_2(4\text{-}NCC_6H_4NO_2)][PF_6]\cdot CH_2Cl_2$

**Maria Paula Robalo,*[a,b] António P. S. Teixeira,[b,c] Maria Helena Garcia,[b,d] M. Fátima Minas da Piedade,[b,d] M. Teresa Duarte,[b] Alberto Romão Dias,[b] Jochen Campo,[e] Wim Wenseleers,*[e] and Etienne Goovaerts[e]**

**Keywords:** Hydride ligands / Iron / Nonlinear optics / Hyperpolarizability / Hyper-Rayleigh scattering

A series of ionic pseudo-octahedral *trans*-hydrido(nitrile)-iron(II) complexes with the general formula $[Fe(H)(dppe)_2(4\text{-}NCR)][PF_6]$ [dppe = 1,2-bis(diphenylphosphanyl)ethane; R = acceptor-substituted conjugated ligand] have been synthesised by chloride abstraction from the starting compound *trans*-$[FeHCl(dppe)_2]$ and fully characterised. First hyperpolarisabilities ($\beta$) have been determined by hyper-Rayleigh scattering (HRS) at the fundamental wavelength of 1072 nm and the high near-resonant values obtained (up to $1130\times10^{-30}$ esu) are interpreted in terms of the two-level model (TLM) and are correlated with IR and NMR spectroscopic data. Wavelength-dependent HRS has been performed in the 1072–1580 nm range for two of the compounds, namely $[Fe(H)(dppe)_2\{4\text{-}NC(CH)(CH)C_6H_4NO_2\}][PF_6]$ and $[Fe(H)(dppe)_2\{4\text{-}NCC_6H_4(CH)(CH)C_6H_4NO_2\}][PF_6]$. These results clearly show the two-photon resonance but also the shortcomings of the TLM when it comes to deriving reliable static $\beta$ values. A structural study of the compound $[Fe(H)(dppe)_2(4\text{-}NCC_6H_4NO_2)][PF_6]$ by X-ray diffraction shows that it crystallises in the centrosymmetric monoclinic space group $P2_1/n$, with four molecules in the unit cell and a pairwise antiparallel alignment of the dipoles.

## Introduction

Organometallic molecules have been extensively studied in the search for new materials with enhanced second-order nonlinear optical (NLO) properties.[1–7] Because of their large first hyperpolarisabilities ($\beta$), fast response times and architectural flexibility, they have many potential applications in photonic devices such as frequency doublers, photonic switches and electro-optic modulators.[8] Many studies have focused on organic and organometallic molecules composed of a highly polarisable π-conjugated backbone with an electron-donor (D) and an -acceptor (A) group attached to opposite ends. In this way a so called asymmetric "push-pull" or D-π-A system is created, which can be used to obtain a macroscopically non-centrosymmetric medium with a large second-order nonlinear susceptibility.[3] In the search for better donor and acceptor groups, it appeared that an organometallic moiety could serve as a very efficient alternative electron-donor group to the traditional, purely organic, push-pull system.[1,2,5–7,9] In these systems, the characteristic charge transfer from metal to ligand (MLCT) could be the origin of a large charge separation over the long conjugated ligand, which can be tuned to optimise the molecular nonlinear optical properties. We have previously reported hyper-Rayleigh scattering (HRS) results for such a systematically varied series of ionic organometallic complexes, consisting of a transition metal centre coordinated by an $\eta^5$-monocyclopentadienyl ring, a bidentate phosphane ligand and a conjugated nitrile ligand.[10–12] By comparing complexes with electron-donor and -acceptor substituted ligands we found that the ruthenium and especially the iron fragments could be used as very efficient electron-donor groups.

In order to further enhance the NLO response new structural changes are now implemented. First of all, the donor fragment is modified by replacing the $\eta^5$-monocyclopentadienyl ring by a second bidentate phosphane ligand [1,2-bis(diphenylphosphanyl)ethane, $Ph_2P(CH_2)_2PPh_2$, dppe] and a hydride, which leads to a pseudo-octahedral coordi-

nation at the transition metal. This coordination creates new possibilities for fine-tuning the molecular structure since an extra ligand can be bound to the metal *trans* to the conjugated ligand. Because of the pseudo-octahedral coordination it also becomes possible to use these complexes as a building block for highly branched macromolecules or metallodendrimers,[13,14] which have promising applications in nonlinear optics. A series of pseudo-octahedral ruthenium acetylide compounds[15] exhibits even higher $\beta$ values[16] than the analogous cyclopentadienyl compounds studied before,[17] although they are about equally resonant. Therefore, in this work, the favourable iron centre is combined with the pseudo-octahedral surrounding and with a nitrile linkage in order to obtain very high hyperpolarisabilities together with extensive molecular versatility. Apart from the improvement of the metallic electron donor, we have also looked for a more efficient acceptor by introducing a second nitro group at the conjugated backbone. Finally, the conjugated backbone itself, which connects the electron-acceptor and -donor groups, is also varied in both length and structure to further optimise the hyperpolarisability.

## Results and Discussion

### Preparation of the Pseudo-Octahedral Iron(II) Dppe Derivatives

The complexes of general formula $[Fe(H)(dppe)_2(4\text{-}NCR)][PF_6]$ were prepared following a general procedure that involves chloride abstraction from the starting compound *trans*-$[FeHCl(dppe)_2]$ by $TlPF_6$, in the presence of a slight excess of the corresponding nitrile chromophores (see Scheme 1). The reactions were carried out in $CH_2Cl_2$ or THF by stirring at room temperature for several hours. After work-up, the compounds were obtained in moderate to high yields (37–71%).

### Characterisation of the New Complexes $[Fe(H)(dppe)_2(4\text{-}NCR)][PF_6]$

All of the *trans*-hydrido(nitrile)iron(II) complexes were obtained as deep-red or purple crystals with the exception of $[Fe(H)(dppe)_2\{2,4\text{-}NCC_6H_3(NO_2)_2\}][PF_6]$ (**4**), which is dark green. They are fairly air stable in the solid state towards oxidation, but less stable in solution. They are soluble in polar solvents and insoluble in less polar and apolar organic solvents. The complexes were characterised by a combination of IR and $^1H$, $^{13}C$ and $^{31}P$ NMR spectroscopy, and elemental analysis.

The solid-state IR spectra (KBr pellets) of complexes **1**–**6** present a large number of bands due to the presence of the various co-ligands. They exhibit strong ν(NC) bands in the range 2138–2185 $cm^{-1}$ (see Table 1) at lower wavenumbers than those observed for the corresponding uncoordinated nitriles. Thus, on coordination of the nitrile to the metal fragment, the NC stretching band shifts by 33 to 101 $cm^{-1}$ to lower frequency. This weakening of the NC bond is consistent with a π back-donation interaction $d_\pi(Fe)$–$\pi^*(NC)$, which makes the metal group a more effective donor. This shift is found to be much higher in the present complexes than in the cyclopentadienyl compounds,[10] where shifts of up to 35 $cm^{-1}$ were obtained. The π back-donation is enhanced by the interaction between the electron-donating metal moiety and the electron-accepting nitro group through the conjugated chain, as desired for a large first hyperpolarisability. In agreement with this in-

[a] At 1064 nm. [b] In methanol.[10] [c] KBr pellets, some bands are very weak. [d] $CD_2Cl_2$, room temperature. [e] $(CD_3)_2CO$, room temperature. [f] $CDCl_3$, room temperature; * H adjacent to NC group.

terpretation, the shifts are dependent on the number of nitro groups present at the nitrile ligand and on the distance between the NC and $NO_2$ groups. Thus, the highest shift is found for **4** due to the presence of two strongly electron-withdrawing nitro groups separated by only a short, well-conjugated link from the donor group. The trend in the values indicates that removal of electron density from the nitrile linkage becomes less marked on chain lengthening. For the dinitro derivatives (compounds **5** and **6**), the position of the ν(NC) absorption seems to be independent of the type of conjugated bridge between the aromatic rings. The ν(Fe–H) bands are very weak, with high frequencies in the range 1853–1896 cm$^{-1}$, consistent with a strongly bound hydride *trans* to an aromatic nitrile.[18,19]

The $^1$H NMR spectra of the compounds were obtained in $CD_2Cl_2$ solutions. The chemical shifts of the dppe protons are within the range of other octahedral iron(II) complexes with coordinated nitriles and are almost constant in all compounds synthesised. The hydride is observed upfield of the TMS signal ($\delta$ = –14.6 to –18.8 ppm) (see Table 1) as a quintuplet due to coupling with the phosphorus atoms of the dppe units, thus showing that all phosphorus atoms are equivalent, in an equatorial position, with a *trans* orientation between the hydride and the nitrile ligands. The position of the hydride signal is affected by the nitrile ligand and it also seems to be dependent on the distance between the NC and $NO_2$ groups, with short distances changing the signal to less-negative chemical shifts. This observation is consistent with a hydride ligand coordinated *trans* to a good π-acceptor like the nitrile ligands, as reported before.[20] Upon coordination of the nitrile ligand, the chemical shifts of the aromatic *ortho* protons (relative to the nitrile group) can be used to assess the electron-donating capabilities of the metal centre (see, for instance, refs.[11,12,21]) and have been shown to be correlated with high molecular hyperpolarisabilities $\beta$. An upfield shift of the *ortho* protons, corresponding to a stronger shielding effect, indeed indicates a back-donation from the metal centre to the nitrile ligand and suggests a more efficient donor and/or a stronger acceptor group. For the present complexes all the *ortho* protons or the $H_\beta$ (in compound **2**) are shielded, with upfield shifts between 0.43 and 2.78 ppm, with the highest shift found for the *ortho* proton of complex **4**. These shifts are much higher than those measured in our previous studies of the cyclopentadienyl compounds (0.05–1.2 ppm),[11,12,21] which makes the high $\beta$ values obtained comprehensible (see Table 1).

The compounds were also characterised by $^{13}$C NMR spectroscopy in [D$_2$]dichloromethane. The deviations in the chemical shifts of the carbon atoms are small and in agreement with the data observed in the $^1$H NMR spectra. The $^{31}P\{^1H\}$ NMR spectra of these compounds show a single sharp signal in the range $\delta$ = 81–84 ppm, attributed to the phosphorus atoms of the dppe ligand, which confirms that all the complexes adopt an exclusively *trans* configuration in solution. These data are also consistent with the expected deshielding effect upon coordination of the phosphane, since free dppe shows a singlet at $\delta$ = –12.1 ppm in the same solvent.

### X-ray Structural Determination of $[Fe(H)(dppe)_2(4\text{-}NCC_6H_4NO_2)][PF_6]$ (1)

Recrystallisation of compound $[Fe(H)(dppe)_2(4\text{-}NCC_6H_4NO_2)][PF_6]$ (**1**) by slow diffusion of diethyl ether into a dichloromethane solution gave crystals suitable for X-ray diffraction studies. The crystals belong to the monoclinic system (space group $P2_1/n$), with four molecules in the unit cell. The structural studies confirm the presence of $\mathbf{1}^+$ cations, hexafluorophosphate anions and a crystallisation solvent molecule of dichloromethane. The molecular structure of the cation is shown in Figure 1 (obtained with ORTEP-3[22]), along with the atom-numbering scheme. Selected bond lengths and angles are given in Table 2.

Complex **1** presents a distorted octahedral coordination geometry with the atoms coordinated to Fe displaying bond angles close to 90° (see Table 2). The X-ray structure confirms the *trans* position of the nitrile and hydride ligands, which define a vertical axis, with the two bidentate phos-

phane ligands occupying the equatorial plane. The four phosphorus atoms (P1–P4) are roughly coplanar, with an average atomic displacement of 0.1407(6) Å with the Fe atom lying within the plane.

The investigation of the Fe–N and Fe–H bond lengths is of particular interest as they can often indicate the presence of a d-p π overlap in the Fe–N bond. The hydride could be located and reasonably isotropically refined with an Fe–H bond length of 1.45(5) Å, which is in the lower range of the values observed in similar compounds, as can be seen in Table 3 (hydride structures in refs.[18–20,23,24]). The Fe–N bond length [1.880(5) Å] is slightly shorter than those observed in these compounds, while the N≡C bond length [1.162(7) Å] is relatively longer (see Table 3). These observations, as well as the Fe(1)–N(1)–C(1) and N(1)–C(1)–C(2) bonding angles of 174.2(5)° and 175.4(7)°, respectively, confirm the existence of Fe→N π back-donation. The distances and angles within the benzonitrile group, in particular the absence of any obvious bond-length alternation, are consistent with the retention of aromaticity. The nitro group is slightly twisted relative to the aromatic ring plane, characterised by $C_{ar}$–$C_{ar}$–N–O torsion angles of around 10°.

The dppe chelate ring is not planar but exhibits an envelope conformation, i.e. the atoms Fe, P1, P2 and C(231) are essentially coplanar while atom C(131), the "flap" atom of the envelope, lies more than 0.73 Å away from this plane. The same applies to the other phosphane. The non-planarity of this conformation diminishes the contacts between the chelate phenyl groups and the nitrile ligand.

The compound displays a pseudo-fourfold rotation axis through H–Fe–N, relating the P atoms, which is almost perpendicular to the equatorial plane [87.6(5)°]. This equivalency of the P atoms agrees with the NMR spectroscopic data of the compounds, which show a quintuplet for the H ligand in their $^1H$ NMR spectra and a singlet for the four P atoms in their $^{31}P\{^1H\}$ NMR spectra. These results show that these molecules maintain in the solid state the general structure found in solution.

In the crystal packing, the molecules of compound **1** form pseudo-dimers with an antiparallel alignment due to a $C_{ar}$–H···$O(1)_{nitrile}$ hydrogen-bond interaction [D–A = 2.58(2) Å], thus cancelling their NLO responses in the crystalline state (Figure 2, a). Each constituent of this dimer is part of a chain in which the molecules are aligned due to the other $C_{ar}$–H···$O(2)_{nitrile}$ hydrogen-bond interaction [D–A = 2.58(2) Å] and also through the $PF_6$ anion, with C–H···F interactions [C123–H···F5 = 2.67(2), C7–H···F2 = 2.51(2), C212–H···F2 = 2.30(2), C246–H···F4 = 2.54(2), C226–H···F4 = 2.58(2), C341–H···F1 = 2.50(2) Å], which arrange the molecules in a straight line (along a). Overall, as can be seen in Figure 2 (b), the crystal structure is formed by alternating chains of molecules aligned in opposite directions. It can also be seen that, in each chain, the

$PF_6$ anion occupies the "open space" to form an anion channel along *c*.

The second-order NLO response of compound **1** is cancelled in the solid state because of the pairwise antiparallel alignment of the chromophores, which results in a centrosymmetric structure. It has been shown previously that it is possible to overcome this problem of antiparallel alignment of neighbouring dipolar molecules by appropriate design of the molecular shape, in particular by introducing a spacer group between the successive chromophores.[25,26] In this approach, the Coulomb interaction becomes equally favourable for the parallel alignment as for the antiparallel alignment of the chromophores. The actual crystal structure formed is then determined by more subtle factors, such as chirality, hydrogen bonding and steric (van der Waals) interactions. These considerations are the subject of a previous paper,[25] where we have shown that this strategy works for complexes of very similar size and dipole moment. In fact, an ideal crystal structure with perfectly aligned chromophores was obtained for two cyclopentadienylruthenium and -iron complexes with chiral coligands;[25,27] in both cases the analogous complex with an achiral coligand crystallised centrosymmetrically. While the condition of proper spacing along the dipolar axis was met accurately in those Cp complexes,[25] this spacing was hard to control. In view of these design strategies, the new complexes studied here, besides the obvious possibility to replace the dppe co-ligands with chiral phosphanes, have the additional advantage of an available valence *trans* to the nitrile ligand due to their pseudo-octahedral geometry. This should allow a better control of the spacing (adapted to the length of the dipolar chromophore) and thus enable optimisation of the microscopic and macroscopic NLO properties.

## UV/Visible Studies

The electronic spectra of the compounds and of the uncoordinated nitrile ligands were recorded for $10^{-4}$ to $10^{-5}$ M chloroform solutions (Figure 3) in order to identify the M–L charge transfer and π–π* absorption bands expected in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

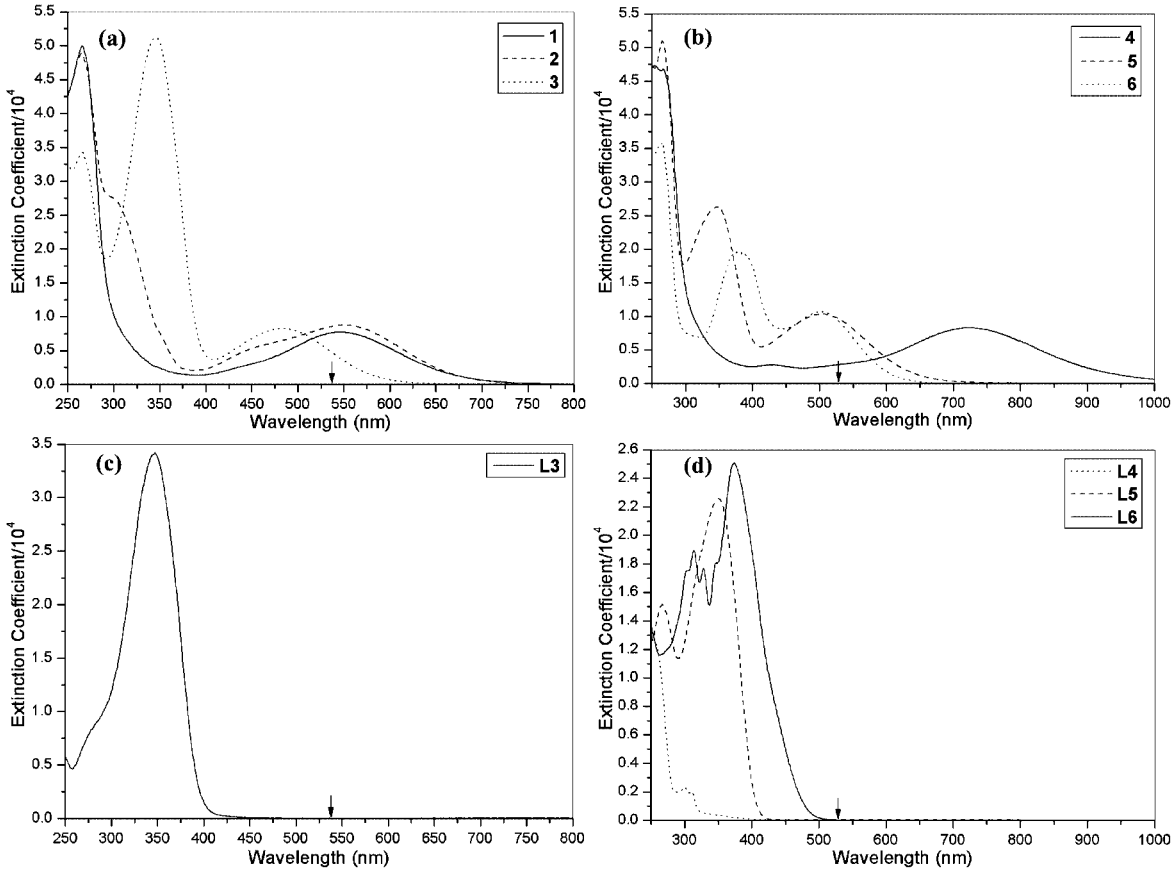

Figure 3. Optical absorption spectra of the compounds of Table 1: The nitro complexes (a) with an associated free ligand (c) and the dinitro complexes (b) with the free ligands (d). The downward arrow indicates the second harmonic wavelength of 536 nm at which most of the HRS measurements were performed.

these complexes. Additionally, a study of one of the compounds in other solvents was carried out to examine the solvatochromic effect.

The absorption bands in the 253–376 nm range are associated with the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions in the nitrile ligands, since they are also observed in this region for the corresponding free nitriles. Transitions at longer wavelengths (500–725 nm) are due to M–L charge transfer involving the $Fe^{II}$ centre and the nitro-substituted aromatic nitrile and are explained by π back-donation involving $d_\pi(Fe)$–$\pi^*(NC)$ orbitals (see Table 1). Dinitro substitution of the aromatic nitrile, going from **1** to **4**, results in a red-shift of 177 nm for the MLCT band. Chain lengthening leads to different behaviours for the absorption bands in the spectra: while the short wavelength absorption band, associated with the π–π* transition of the conjugated nitrile ligand (250–375 nm range), displays a red-shift with increasing chain length, as would be expected, a reverse effect was observed for the lowest energy band. In fact, going from **1** to **3** (or from **4** to **5**) we can observe a blue-shift and a slight enhancement of the MLCT band. Such a blue-shift has been observed before for CT transitions in organic[28,29] and organometallic[30] strong push-pull systems, for which a lower energy charge-transfer transition is obtained when the donor and acceptor groups are well-coupled through a shorter conjugated path.

Sizable solvent-induced shifts of absorption maxima (solvatochromism) are a measure of the CT character of the transition (large change in dipole moment $\Delta\mu$), and therefore have been used as an indication of appreciable quadratic molecular hyperpolarisabilities $\beta$.[27] It was therefore of interest to assess the solvatochromic response of the MLCT band for the complexes and $[Fe(H)(dppe)_2(4\text{-}NCC_6H_4NO_2)][PF_6]$ (**1**) was studied in solvents of different polarity (chloroform, acetone and DMSO). A positive solvatochromic shift of 21 nm across the range of these solvents was observed, with the lowest energy transition found in the polar solvent DMSO. This identifies this band as a CT transition and shows that the dipole moment increases upon excitation, consistent with a charge transfer from the metallic donor to the acceptor side of the complex.

## Hyper-Rayleigh Scattering Measurements

The experimental resonant hyperpolarisabilities obtained by hyper-Rayleigh scattering (HRS) at 1072 nm for the series of compounds studied in this work and the chemical structures of the acceptor-substituted ligands are summarised in Table 1. In general, high $\beta$ values are obtained for the complexes. HRS measurements were also performed on the free acceptor-substituted nitrile ligands, which exhibit

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

very low hyperpolarisabilities, in contrast to the corresponding push-pull systems.

To interpret the nearly resonant $\beta$ values of the complexes in terms of electronic properties it is useful to consider the two-level model (TLM), which is based on the assumption that only one excited state [i.e. the charge transfer (CT) state] contributes to the $\beta$ value. Assuming that the difference between the dipole moment in the ground and excited state, $\Delta\mu$, and the transition dipole, $\mu_{eg}$, are parallel to each other (along the $z$-axis), the $\beta$ tensor only has a diagonal zzz-component and can be written as[3,31,32]

$$\beta_{zzz}(-2\omega;\omega,\omega) = \frac{3e^2 f_{osc}\Delta\mu}{2\hbar m\omega_{eg}^3}\cdot\frac{\omega_{eg}^4}{(\omega_{eg}^2-\omega^2)(\omega_{eg}^2-4\omega^2)}$$

where $f_{osc}$ is the oscillator strength of the CT transition and $\omega_{eg}$ its frequency. The expression consists of a static value, $\beta_0$, multiplied by a wavelength-dependent resonance factor.

Because this model does not take into account the line broadening of the transition, it cannot be used to describe the dispersion of $\beta$ close to resonance. Hence, because most of the compounds studied in this work have a $\lambda_{max}$ value close to the second harmonic wavelength of 536 nm, the model is not suitable to calculate static $\beta$ values. To study the wavelength dependence of $\beta$ in the NIR, and eventually derive a more reliable estimate of the static value $\beta_0$, two of the compounds (**2** and **3**) were studied in the 1072–1580 nm range. These wavelength-dependent HRS data are presented in Figure 4, where a pronounced resonant enhancement associated with the low-energy charge-transfer transition can be seen in both cases.

The TLM curves based on the most resonant (1072 nm) and the least resonant $\beta$ value (1540 nm, shown for **2** only) are also plotted in Figure 4. For compound **3**, which is not extremely resonant, the TLM curve going through the 1072 nm value appears to give quite a good description of the dispersion of $\beta$, and the obtained static value of $115\times10^{-30}$ esu seems adequate. In fact, this curve is (coincidentally) overlapping with the one based on the 1580 nm

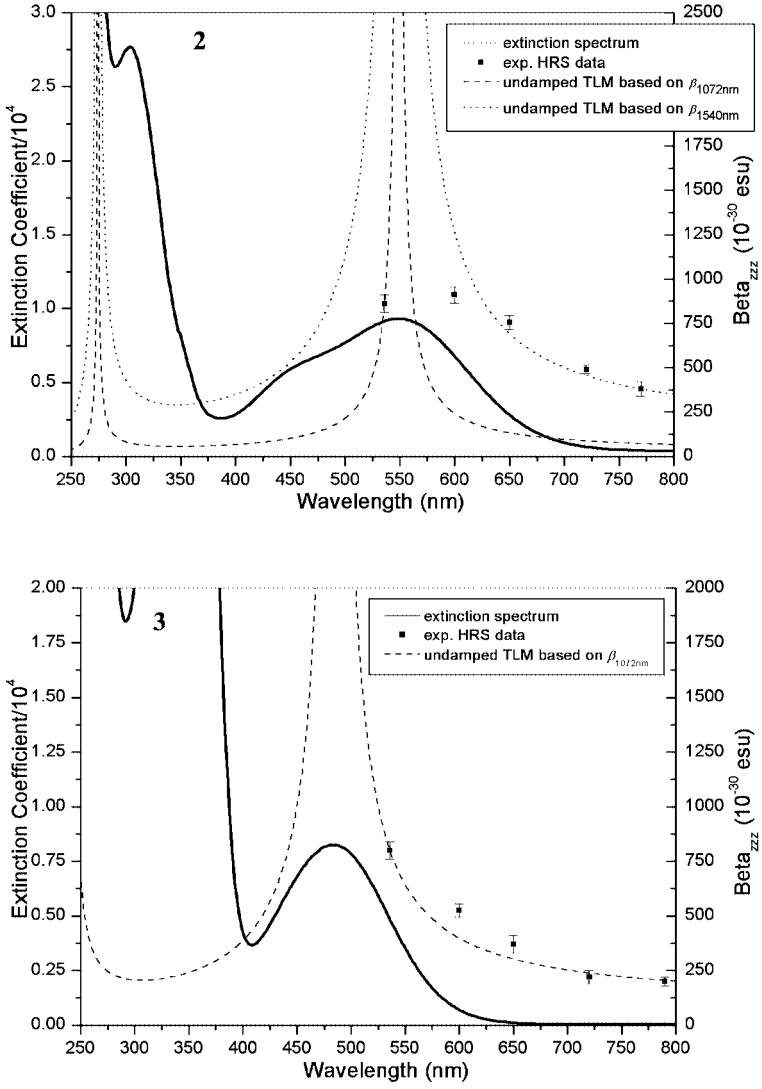

Figure 4. Wavelength-dependent HRS data for complexes **2** (top) and **3** (bottom) together with their extinction spectra. The two-level model (TLM) curves based on the most and least resonant $\beta$ values are also shown (overlapping for **3**). For a clear view of the two-photon resonance, the experimental hyperpolarisabilities and the TLM curves are displayed at the frequency-doubled wavelength.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

value, which leads to practically the same $\beta_0$ value ($113 \times 10^{-30}$ esu). Compound **2**, on the other hand, is closer to resonance and it is clearly seen that the undamped TLM is totally inadequate to derive the static value from $\beta$ at 1072 nm. The dispersion is very poorly modelled and a far too low $\beta_0$ would be obtained using only this resonant value. However, using only the least resonant $\beta$ (at 1540 nm) shows that the TLM gives a good description of the long wavelength tail of the dispersion curve and yields a more reliable static $\beta_0$ ($163 \times 10^{-30}$ esu). So, this wavelength-dependent HRS study clearly shows that the TLM cannot be used to calculate $\beta_0$ from strongly resonant hyperpolarisabilities and therefore, in the following discussion, we will use the TLM for only qualitative comparisons between the different structural variations. One way to improve on this model is to introduce an ad hoc damping factor, $\Gamma$, into the expression of $\beta$ but, unfortunately, some additional complications arise in this procedure. Firstly, it is not clear whether such a damping factor (i.e. a homogeneous line-broadening) can also be used to properly describe the actual linewidth, which is largely due to inhomogeneous broadening and vibronic coupling, and secondly, there is a possible red-shift between the absorption and the $\beta$ maximum, as reported by Wang et al.[33] Therefore, more extended wavelength-dependent HRS measurements are needed to decide between different possible models.[31,34–37]

The first structural variation which will be discussed is the replacement of the $\eta^5$-monocyclopentadienyl ring at the organometallic donor fragment by a second bidentate phosphane (dppe) ligand to create a pseudo-octahedral surrounding of the iron moiety. Comparing **1** with **7** and **2** with **8** (see Table 1) we can see that in both cases the introduction of the second dppe ligand results in a red-shift of the CT band and an increase of the extinction coefficient, $\varepsilon_{max}$, which results in an increase of the resonant $\beta$ value, in agreement with the two-level model. From IR measurements a significant shift to lower $\nu$(N≡C) values was observed upon coordination ($\Delta\nu_{NC} = -56\ cm^{-1}$ for **1** and $-43\ cm^{-1}$ for **2**; see Table 1). This points to a stronger π back-donation and hence a higher donor efficiency in the pseudo-octahedral cases **1** and **2** as compared to the analogous cyclopentadienyl compounds **7** and **8**, where a shift of only –35 and $-15\ cm^{-1}$ was found, respectively.[12] This is indeed supported by the higher static value of $163 \times 10^{-30}$ esu obtained for the pseudo-octahedral compound **2** than the $\beta_0$ of $112 \times 10^{-30}$ esu for the analogous cyclopentadienyl complex **8**.[12] So, in conclusion, based on the spectroscopic measurements and the increase of the static $\beta$ value it appears that the pseudo-octahedral surrounding yields a more efficient electron donor.

A second strategy we used to optimise the push-pull system was to also increase the strength of the electron-withdrawing moiety by introducing an extra nitro group at the *ortho* position of the last phenyl ring of the conjugated backbone. Comparing compounds **1** and **4** and **3** and **5** we can see that in both cases the introduction of the second nitro group results in a shift of the CT band to higher wavelengths and an increase of the extinction coefficient. It appears that introducing the second nitro group results in a more efficient electron-withdrawing moiety, thereby lowering the energy of the CT transition. The energy shift makes the longer compound **5** more resonant than compound **3**, while for the shorter compound **4**, the shift is much more drastic and results in a CT band in the NIR, beyond resonance. However, compound **4** has a remarkably high $\beta$ value, taking into account that it is farther from resonance, so it probably has a higher static value $\beta_0$ than compound **1**.

The smaller red-shift observed for the longer compounds (**3** and **5**) can be understood by considering that the second nitro group was introduced on the second phenyl ring, farther from the donor metal fragment, leading to a less effective D–A interaction through the π back-donation effect.

The third degree of freedom which can be used to optimise the molecular $\beta$ value is the structure and length of the conjugated backbone connecting the electron donor and acceptor. It is well known that $\beta$ increases sharply with conjugation length, therefore we extended the conjugated backbone of both the nitro (**1**, **2** and **3**) and the dinitro compounds (**4** and **5**). A very surprising result is that, for both forms, the CT band shifts to higher energy for the longer compounds. As we mentioned previously, this can be explained by a better interaction of the donor with the acceptor through the shorter conjugated path, leading to a very low energy CT transition. However, the longer compound **2** yields a larger $\beta$ than the shorter one **1**, which in this case is compatible with the difference in extinction coefficients, $\varepsilon_{max}$. This trend is continued for the even longer compound **3**. Indeed, comparing compounds **2** and **3** we see that although compound **3** is much less resonant and has about the same extinction coefficient, it still has a comparable $\beta$ value to compound **2**. This points to a large static $\beta$ value for compound **3** as a consequence of a large dipole moment difference, according to the two-level model. In the case of the dinitro compounds the difference between the $\beta$ values of the shorter compound **4** and the longer one **5** can be explained in terms of resonant enhancement and difference between extinction coefficients.

Finally, the structural change of introducing one hydrazone spacer (–C=N–NH) between the two phenyl rings forming the backbone on going from compound **5** to **6** seems to have virtually no effect on the $\beta$ values; $\nu$(N≡C), $\delta_{^1H_{hydride}}$ and $\delta_{^{31}P_{dppe}}$ (see Table 1) also remain unchanged, and only $\nu$(Fe–H) is slightly higher. Neither the spectral position of the CT band nor the extinction coefficient is modified significantly so it seems that the D–A interaction is barely changed by this last modification.

In conclusion, a series of hydrido(nitrile)iron(II) complexes have been synthesised that show improved molecular NLO properties, which we ascribe to an improved donor character of the pseudo-octahedral organometallic moiety. The NLO push-pull system was further improved by increasing the conjugation length and by double nitro substitution to form a better electron-accepting moiety. Wavelength-dependent HRS measurements, performed for the first time on organometallic NLO chromophores, show the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

effect of two-photon resonance enhancement and demonstrate that for highly resonant cases the TLM is inadequate and therefore wavelength-dependent measurements are needed to model the dispersion of $\beta$. The X-ray structure of $[Fe(H)(dppe)_2(4\text{-}NCC_6H_4NO_2)][PF_6]$ (**1**) showed that the NLO response is cancelled at the macroscopic level for this compound by a pairwise antiparallel orientation of the complexes. However, the pseudo-octahedral coordination appears to be very suitable for a more systematic implementation of the previously demonstrated[25,27] design strategies (replacement of dppe by chiral phosphanes and inclusion of appropriate spacing groups along the dipolar axis) to promote a favourable non-centrosymmetric crystal structure.

## Experimental Section

**General Procedures:** All preparations were carried out under vacuum or nitrogen using standard Schlenk techniques. The solvents were dried before use following published methods.[38] The starting material $[FeHCl(dppe)_2]$ was synthesised according to a published method.[39] The aromatic nitrile ligands 4-nitrobenzonitrile and 2,4-dinitrobenzonitrile were purchased from Sigma–Aldrich and used as received. Ligands (*E*)-4-[2-(4-nitrophenyl)ethenyl]benzonitrile,[40] (*E*)-3-(4-nitrophenyl)acrylonitrile,[41] 4-[*N*-(2,4-dinitrophenyl)hydrazonomethyl]benzonitrile[42] and (*E*)-4-[2-(2,4-dinitrophenyl)ethenyl]benzonitrile[43] were prepared following the literature procedures.

IR spectra were recorded for KBr pellets on a Perkin–Elmer Paragon 1000 PC FT-IR or a Bio-Rad Excalibur FTS 3000MX spectrophotometer; only the significant bands are cited. $^1H$, $^{13}C$ and $^{31}P$ NMR spectra were recorded for $[D_2]$dichloromethane solutions with a Varian Unity 300 spectrometer at probe temperature, using $SiMe_4$ as internal reference ($^1H$ and $^{13}C$ NMR chemical shifts) and 85% $H_3PO_4$ as external reference for $^{31}P$ NMR chemical shifts. Spectral assignments follow the numbering scheme given in Scheme 1. The UV/Vis spectra were recorded with a Shimadzu 1603 spectrophotometer for $10^{-4}$ or $10^{-5}$ M solutions in several solvents. Elemental analyses were performed at the Laboratório de Análises of the Instituto Superior Técnico, using a Fisons Instruments EA1108 system, with data acquisition, integration and handling performed with a PC and the software package Eager-200 (Carlo Erba Instruments). Melting points were measured with a Leica Galen III melting point apparatus and are not corrected.

**General Procedure for the Synthesis of the Pseudo-Octahedral Iron(II) Derivatives:** A slight excess of the nitrile chromophore (1.1–1.2 equiv.) and $TlPF_6$ (1.1–1.2 equiv.) were added to a solution of $[Fe(H)(Cl)(dppe)_2]$ (0.68–1.01 mmol) in dichloromethane (THF for compound **1**). The mixture was then stirred at room temperature for 2–4 h (18 h for compounds **1** and **6**). A colour change was observed with simultaneous precipitation of thallium chloride. After filtration, the solvents were evaporated under vacuum to dryness and the residues were washed several times with diethyl ether to remove the excess of nitrile. Recrystallisation from dichloromethane/diethyl ether afforded powder or crystalline samples of the pure compounds.

**$[Fe(H)(dppe)_2(4\text{-}NCC_6H_4NO_2)][PF_6]$ (1):** Yield: 97 mg (37%), purple crystals; m.p. 132.7–134.2 °C. **Crystal Structure of 1:** $C_{59}H_{53}F_6FeN_2O_2P_5 \cdot CH_2Cl_2$, $M$ = 1231.66, $\mu$ = 4.774 $mm^{-1}$, $\rho$ = 1410 $mg\,m^{-3}$, monoclinic, $P2_1/n$, $Z$ = 4, $a$ = 12.48(1), $b$ = 35.599(9), $c$ = 13.243(9) Å, $\beta$ = 99.49(2)°, $V$ = 5803(6) $Å^3$, from 23 reflections (16.7° < 2$\theta$ < 18.9°). Cell dimensions and intensities were measured at 293(2) K with an Enraf–Nonius TURBOCAD4 diffractometer (Cu rotating anode, $\lambda$ = 1.54180 Å). As a general procedure, the intensity of three standard reflections was measured periodically every 5 h. This procedure did not reveal any appreciable decay. Using the CAD4 software, data were corrected for Lorentz and polarisation effects and empirically for absorption (from $\Psi$-scan measurements). Data were collected in the range 3.6° < $\theta$ < 67° (–13 < $h$ < 14, 0 < $k$ < 42, 0 < $l$ < 15); 10579 measured reflections, 10140 of which were considered as observed [$|F_o|^2 > 3\sigma(|F_o|^2)$]; $R_{int}$ = 0.0503 for equivalent reflections. The structure was solved by direct methods using SIR97[44] and refined with SHELXL[45] in the WINGX[46] program package. Full-matrix least-squares refinement based on $F^2$ gave final values $R$ = 0.0729, $wR_2$ = 0.1397 for 923 variables and 10140 contributing reflections. The position of the Fe atom was obtained from a three-dimensional Patterson synthesis, while all the other non-hydrogen atoms were located in subsequent difference Fourier maps. The hydrogen atoms were inserted in calculated positions and refined isotropically as riding on the parent carbon atom. The final difference electron density map showed a maximum of 0.558 and a minimum of –0.695 e $Å^{-3}$.

CCDC-286415 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Hyper-Rayleigh Scattering Measurements:** First hyperpolarisabilities were determined by means of the hyper-Rayleigh scattering (HRS) technique.[47,48] The measurements were performed in a new HRS setup based on an optical parametrical amplifier (OPA) pumped by a Ti:sapphire regenerative amplifier (pulse width: 2 ps, repetition rate: 1.5 kHz, average power: ca. 30 mW). The different fundamental wavelengths used (1072, 1200, 1300, 1440, 1540 and 1580 nm) were obtained by tuning the signal beam of the OPA, and were chosen carefully to avoid vibrational absorption bands of chloroform. To prevent dielectric breakdown and self-focusing, the pulses were focused onto the sample with cylindrical lenses. The scattered second harmonic light was collected at 90° and detected with a combination of a spectrograph and an intensified charge coupled device (ICCD) with red-sensitive photocathode. The ICCD provides nanosecond-gated parallel detection of a small (ca. 23 nm) spectral area around the harmonic wavelength. The outer regions of this range was used to correct the HRS signal for multi-photon fluorescence, as described before.[4,10] A large photoluminescence background was only observed for one of the free ligands (**L3**, see Table 1), for which the luminescence signal, integrated over the central region of 6 nm, was about equal to the actual HRS signal. HRS measurements were performed in a rectangular fused silica cell containing a dilute solution of the compound in chloroform. Concentrations used were of the order of $10^{-6}$–$10^{-4}$ M for the complexes and $10^{-3}$–$10^{-4}$ M for the free ligands. With these concentrations the absorption of the second harmonic wavelength was kept well below 10%, so that an accurate correction for this effect could be carried out. The absorption measurements where performed with a Varian Cary 5 absorption spectrometer. All hyperpolarisabilities were determined by internal reference relative to chloroform,[48] as described before.[4,10] Within the assumption of only one significant diagonal $\beta$ tensor component along the $z$-axis (i.e. the conjugated backbone of the molecule), $\beta_{zzz}$ values can be calculated by measuring the HRS signal for a dilute solution with known concentration of the chromophores and from pure chloroform. The $\beta$ value of $0.49 \times 10^{-30}$ esu for chloroform, determined with the EFISHG technique at 1064 nm,[49] was used as internal reference. The dispersion of the reference value in the explored 1072–1580 nm range was neglected. An upper limit of 5% to this effect was estimated using the TLM expression with the maximum of the longest wavelength absorption band of chloroform (143 nm)[50] taken as $\lambda_{eg}$.

# Synthesis and Characterization of Ternary $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) Nanocages

Xin Liang,[a] Xun Wang,*[a] Leyu Wang,[a] Ruoxue Yan,[a] Qing Peng,[a] and Yadong Li[a]

**Keywords:** Nanostructures / Lanthanides

In this paper, a new class of $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) inorganic nanocages that has been discovered will be presented. A facile template-free synthetic route was developed for one step, high yield, and large scale synthesis of ternary $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) nanocages. On the basis of our studies, these nanocages are thermodynamically stable forms of this group of $NH_4Ln_2F_7$ compounds. The tendency of $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) to form these new-type nanostructures is believed to have a close relationship with their inherent layered structures, similar to that of inorganic fullerene-like nanoparticles. This new type of nanocage can be easily doped with other lanthanide ions, which may endow these nanocages with novel properties.

## Introduction

In recent years, novel nano-sized morphologies of inorganic materials have become a new focus of research as they may offer new opportunities for application in various areas of nanotechnology, such as optical, biology, and catalysis, etc. Among these different morphologies, hollow nanostructures, as competitive building blocks for future nanodevices, attract considerable interest due to their high surface area and low-density characteristics as well as their other shape-dependent properties.[1–7] Great effort has been focused on the fabrication of different kinds of hollow nanostructures for this is a crucial step in the research and application of hollow nanostructures. Tenne and co-workers successfully synthesized a series of transition metal sulfide fullerene-like hollow nanostructures, such as $MoS_2$, $WS_2$, and $ReS_2$.[8–11] Many other hollow nanostructures (e.g., $TiO_2$, $SnO_2$, CdTe) have been prepared by using layer-by-layer self-assembly, sonochemical deposition, chemical-bath deposition, and other template-dependent methods.[12–19] On the basis of the colloidal chemical template-free hydrothermal method, binary lanthanide fluoride and hydroxide fullerene-like hollow spheres have been synthesized.[20] However, to the best of our knowledge, there are few reports concerning a colloidal chemistry-based template-free one-step synthesis of hollow nanostructures with small diameters for ternary (quaternary) lanthanide fluoride compounds. As is well known, MF-$LnF_3$ is a big family of compounds including many useful materials, such as $KY_3F_{10}$ and $NaYF_4$, which have great potential as biological labels,[21] in solid lasers, and display panels.[22] The tendency of $NH_4Ln_2F_7$ to form these new types of nanostructures is believed to have a close relationship with their inherent layered structures, similar to inorganic fullerene-like nanoparticles. The synthesis of hollow spheres of such complex compounds has great importance and is worthy of thoughtful research.

Herein we report a facile water/ethanol solvothermal synthetic method for one-step, high-yield preparation of a novel family of ternary $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) nanocages under a temperature of 180 °C. The tendency of $NH_4Ln_2F_7$ to form these new types of nanostructures is believed to have a close relationship with their inherent layered structures, similar to inorganic fullerene-like nanoparticles. Since the structures of such materials have great similarity, especially for the KF-$LnF_3$ and $NH_4F$-$LnF_3$ systems, synthesis of other MF-$LnF_3$ hollow nanostructures should be possible and have great significance.

## Results and Discussion

$NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) crystallized in a cubic structure. The XRD pattern of $NH_4Y_2F_7$ shown in part a of Figure 1 can be indexed as arising from the pure cubic phase (JCPDS 43-0842) with lattice constant $a$ = 13.4 Å. Similar XRD patterns of a cubic phase were also observed from $NH_4Ho_2F_7$ (JCPDS 43-0842) to $NH_4Lu_2F_7$ (JCPDS 43-0842). The peak positions and relative intensities in those samples were almost identical to those observed in $NH_4Y_2F_7$, which indicated that this class of compounds shares a similar crystal structure. By careful observation a tiny difference can be found in the $2\theta$ values of

the XRD peaks, which gradually increase on going from $NH_4Ho_2F_7$ to $NH_4Lu_2F_7$, indicating the gradual shrinkage of crystal structures according to the atomic number. The diffraction patterns for $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) group compounds reveal an internal consistency associated with structural isotypes. The work of Krishnan Rajeshwar and Etalo A. Secco et al., showed that the structure of $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) can be visualized as layers of $LnF_6$ octahedron (built up by mutual sharing of corners and edges) with interleaving layers of $NH_4$ groups,[23] which is somewhat similar to that of inorganic fullerene-like nanoparticles.

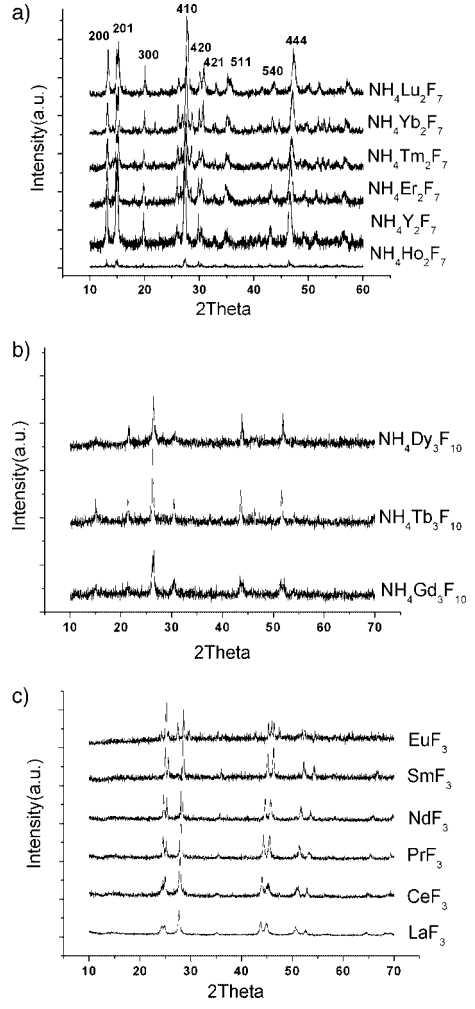

Figure 1. XRD patterns of (a) $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu); (b) $NH_4Ln_3F_{10}$ (Ln = Gd, Dy, Tb); (c) $LnF_3$ (Ln = La–Eu).

On the basis of our former work, we realized that for families of lanthanide compounds that share a similar composition, such as $LnF_3$[24] and $LnPO_4$,[25] both the crystal structures and physical properties may vary gradually on ascending the series as a result of the lanthanide contraction. For our system, the ionic radii of lanthanide elements were found to be greatly responsible for the phase formation. For all the lanthanide members, the resulting products derived under the same synthetic conditions were of different structure. The variation in the structure is believed to be caused by the contraction of ionic radii of $Ln^{3+}$ (Table 1). The members from Lu to Ho, ionic radius 0.85–0.89 Å, formed $NH_4Ln_2F_7$ compounds; the members from La to Dy, whose ionic radii range 1.06–0.91 Å, adopt other crystal structures that are different from the layered structures of $NH_4Ln_2F_7$. The XRD patterns of other lanthanide categories from La–Dy can be seen in Figure 1 (parts b, c). For the larger lanthanide ions (Ln = La, Ce, Nd, Pr, Sm, Eu), $LnF_3$ structures were obtained (Ln = La–Sm, the resulting products are pure hexagonal structures; Ln = Eu, a mixture of hexagonal and orthorhombic structures were found). For the intermediate-sized lanthanide ions (Ln = Gd, Tb, Dy) $NH_4Ln_3F_{10}$ was formed.[26]

The morphology and microstructural details can be observed from the TEM, HRTEM observations. The typical low-magnification images of the as-prepared $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) nanocages (here Y, Ho, and Tm have been chosen as examples) are shown in Figure 2. The hollow interior features of $NH_4Ln_2F_7$ nanocages were confirmed by the TEM observations. It can be seen from Figure 2 (a–c) that nearly all the nanoparticles in the images are of hollow interiors and the nanoparticles are uniform with an average size of 20–30 nm. Careful TEM observations were also carried out on both the $LnF_3$ (Ln = La–Eu) and $NH_4Ln_3F_{10}$ (Ln = Gd–Dy) series (TEM images are found in the supporting information). However, only a few hollow-sphere-type structures were found. This morphology difference between $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu), $LnF_3$ (Ln = La–Eu), and $NH_4Ln_3F_{10}$ (Ln = Gd–Dy) indicates that the formation of the hollow interior forms is unique to the $NH_4Ln_2F_7$ series and it also excludes the possibility that the nanocages were formed by the Marangoni effect. That is where the concentrated solutes diffuse out into the droplet-vapor interface leaving the pure solvent behind in the center of the nanoparticle. At this point the solvent evaporates leaving the polycrystalline material to deposit on the outer circumference and leaving a hollow core in the center. According to this assumption, nanocages

would form in other lanthanide categories from La to Dy, because of the similar environments in the growth procedure.

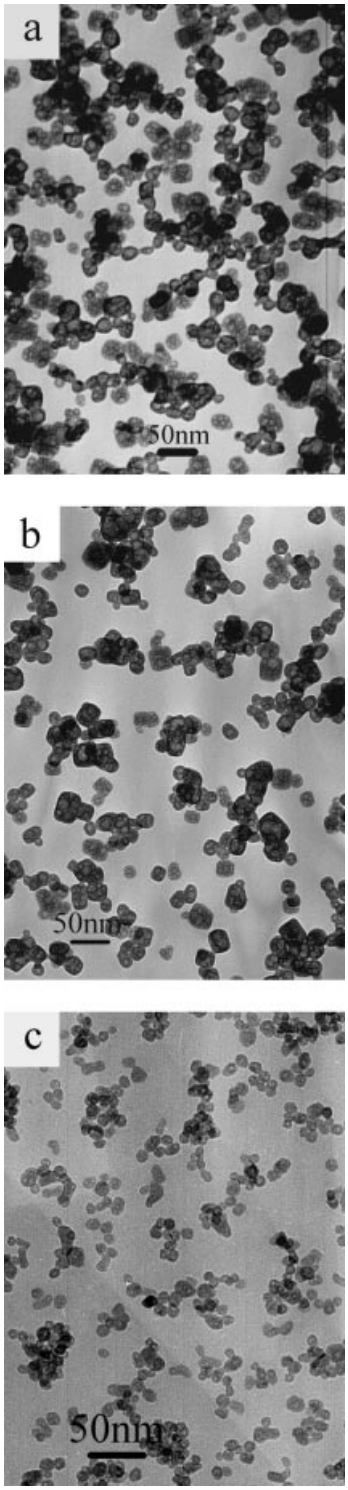

Figure 2. TEM images of (a) $NH_4Y_2F_7$ nanocages; (b) $NH_4Tm_2F_7$ nanocages; (c) the Tem images of $NH_4Ho_2F_7$ nanocages.

HRTEM characterization (Figure 3, a–f) provides us with further insight into the structural details of $NH_4Ln_2F_7$ nanocages. It can be seen from the HRTEM images that most of the nanoparticles usually had a hollow interior, which proved the formation of hollow sphere nanostructures under current experimental conditions. The distance between the inner and outer layers was calculated to be approximately 0.32 nm for $NH_4Y_2F_7$ nanocages, corresponding to the crystal plane of (410), and the other categories show a close value of about 0.32 nm, indicating a similar formation mode under adopted conditions. Though the crystal lattices were somewhat distorted compared with the typical onion-like lattices of fullerene-like nanoparticles, the lattice striations displayed a nearly close-caged configuration with high crystallinity. The electronic diffraction of the selected area (insert in Figure 3, a), where the diffractive dots of single crystal can be clearly seen, further confirmed the single crystal features of the nanocages. It is interesting to note that the inner spaces are usually quite different in shape, including all kinds of irregular polygons, indicating that the growth of these structures might be rather sensitive to fluctuations from the outer environment. Nevertheless, the nanoparticles with hollow interiors can be easily obtained under designed synthetic conditions, and from the TEM images we can see that almost all of the final products are hollow nanostructures. The HRTEM observations confirmed that the formation of the nanocages may have a close relationship with the inherent layered structure of $NH_4Ln_2F_7$.

The thermal gravimetric analysis was carried out to study the thermal stability of these nanocages. $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) decomposes at high temperature. The TGA curves for $NH_4Ln_2F_7$ (Ln = Y, Ho, Tm) powders are shown in Figure 4. From the TGA curves, two weight-loss steps can be observed. The first step is from room temperature to 250 °C, in which, the mild weight loss may be caused by desorption of water and other solvents such as ethanol on the $NH_4Ln_2F_7$ surface. The main weight loss occurs in the temperature range from 250 to 360 °C. In this step, $NH_4Ln_2F_7$ converted to $LnF_3$. The experimental weight loss is about 11.10 wt.-% for $NH_4Y_2F_7$, 7.35 wt.-% for $NH_4Ho_2F_7$, and 6.84 wt.-% for $NH_4Tm_2F_7$, respectively, which agrees well with the theoretical weight loss of the decomposition of $NH_4Ln_2F_7$ to $LnF_3$ (11.25 wt.-% for $NH_4Y_2F_7$, 7.69 wt.-% for $NH_4Ho_2F_7$, and 7.57 wt.-% for $NH_4Tm_2F_7$). The chemical reaction that occurs in the process of this main weight loss can be expressed as follows:

$$NH_4Ln_2F_7 \rightarrow LnF_3 + NH_3 \uparrow + HF \uparrow$$

The decomposition temperature of these three samples is quite similar. It is about 356 °C for $NH_4Y_2F_7$, 352 °C for $NH_4Ho_2F_7$, and 361 °C for $NH_4Tm_2F_7$.

$NH_4Y_2F_7$ samples were annealed at 200 and 400 °C for 3 h to investigate this conversion process. XRD confirmed that the sample annealed at 200 °C remained as $NH_4Y_2F_7$; in contrast the sample annealed at 400 °C converted to $YF_3$ completely. TEM images of the samples derived at different annealing temperatures are shown in Figure 5 from which we can see that most of the $NH_4Y_2F_7$ nanoparticles remain intact with hollow interiors and have no apparent aggregation after being annealed at 200 °C for 3 h, in contrast to the nanoparticles annealed at 400 °C that have aggregated

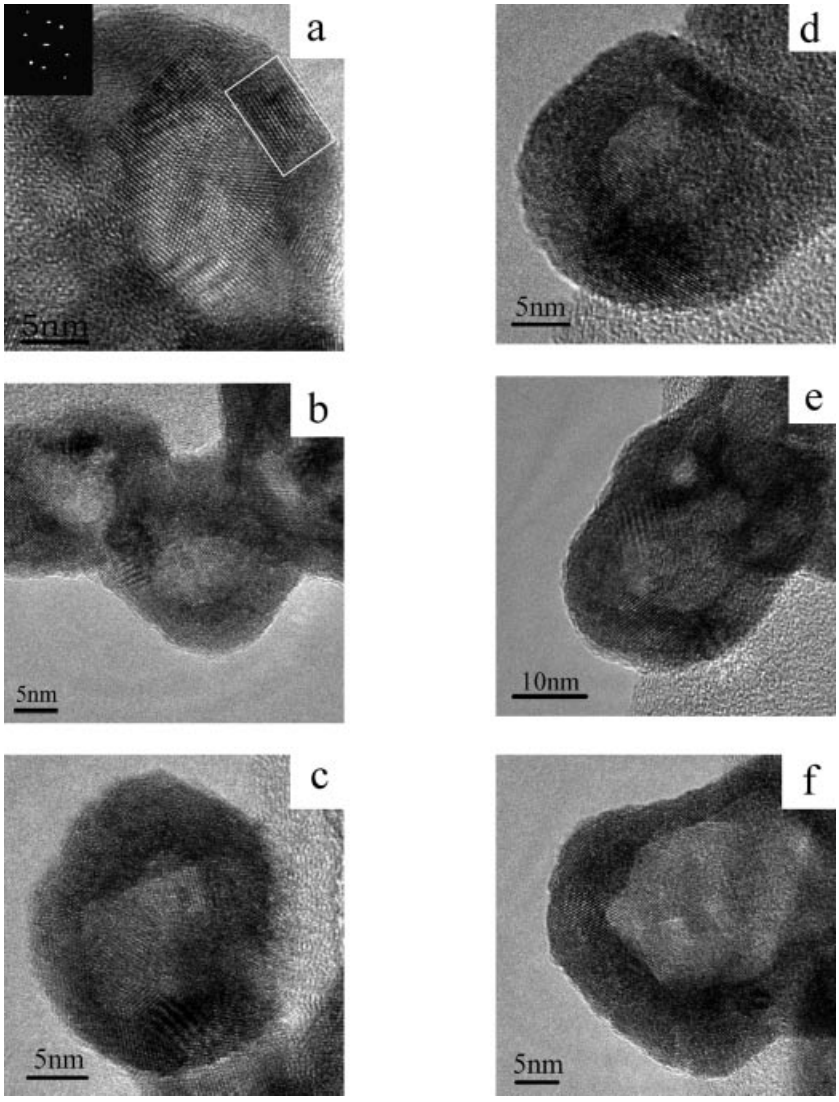

Figure 3. HRTEM image of (a) an individual $NH_4Y_2F_7$ nanocage with diameter about 22 nm, the inset is an EDS analysis of the selected area; (b) three conterminous $NH_4Y_2F_7$ nanocages; (c) an individual $NH_4Y_2F_7$ nanocage with diameter ca. 20 nm; (d) an individual globular $NH_4Tm_2F_7$ nanocage; (e) an individual $NH_4Yb_2F_7$ nanocage; (f) $NH_4Ho_2F_7$ nanocage.

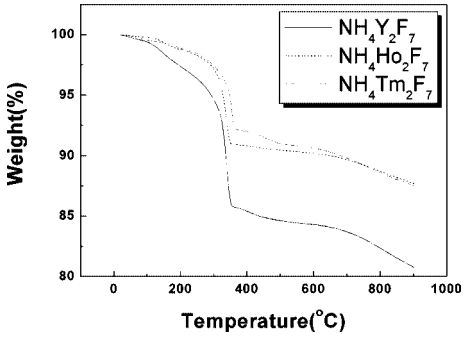

Figure 4. TGA curves of $NH_4Ln_2F_7$ (Ln = Y, Ho, Tm).

to a large extent with no remaining nanocages. These results show that the nanocages can be maintained at the relatively high temperature of 200 °C before the composition of $NH_4Y_2F_7$ and the hollow interior forms collapse as $NH_4Y_2F_7$ converts to $YF_3$ at higher temperature. As the literature has reported, the structure of $NH_4Y_2F_7$ can be visualized as layers of $YF_6$ octahedron with interleaving layers of $NH_4$ groups and the hydrogen bonding effect of $NH_4^+$ is a critical factor responsible for the stability of ammonium fluorometallates.[27–28] The layered structure of $NH_4Y_2F_7$ would collapse if the interleaving layers of $NH_4$ groups were lost. So it is believed that ammonium loss in the process of conversion of $NH_4Y_2F_7$ to $YF_3$ is an important factor in the collapse of the nanocages. These phenomena show that the inner structure of $NH_4Y_2F_7$ is very important for the stability of these hollow interior forms.

$Y^{3+}$, $Ho^{3+}$, $Er^{3+}$, $Tm^{3+}$, $Yb^{3+}$, and $Lu^{3+}$ can crystallize in homogeneous phase $NH_4Ln_2F_7$ and their ionic radii are similar, thus making it convenient to dope $NH_4Ln_2F_7$ nanocages with these lanthanide ions, which may then endow this class of nanocage with novel properties. The most frequently used up-conversion ion $Er^{3+}$ and the sensitizer ion

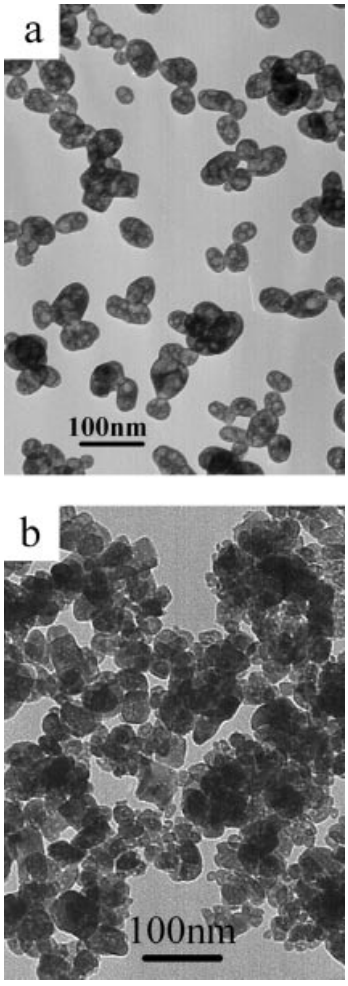

Figure 5. TEM images of samples annealed at (a) 200 °C; (b) 400 °C.

$Yb^{3+}$ were co-doped into $NH_4Y_2F_7$ to denote the feasibility of doping lanthanide ions into $NH_4Ln_2F_7$. Doped samples were prepared by the same synthetic procedure, except for adding 5% (total molar ration) $YbCl_3$ and $ErCl_3$ in $YCl_3$ in the first stage. The up-conversion fluorescence property of the final product was measured by a 980-nm IR laser. The up-conversion emission of doped $NH_4Y_2F_7$ sample is weak due to the quenching effect of ammonium. After being annealed at 500 °C for 3 h, the $NH_4Y_2F_7$ can convert into

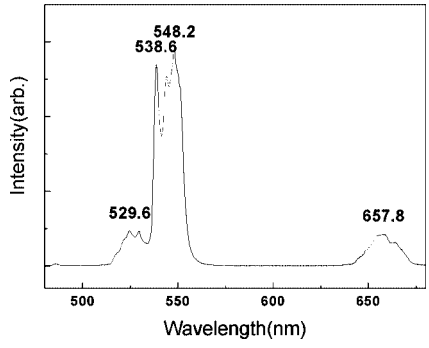

Figure 6. UC emission spectra of $YF_3$ ($Er^{3+}$, $Yb^{3+}$).

$YF_3$ (revealed by the XRD analysis). It can be seen that the up-conversion emission is stronger and can be observed by the naked eye. The UC spectrum exhibits the characteristic peaks of an $Er^{3+}$- and $Yb^{3+}$-doped $YF_3$ system (Figure 6). This consequence proves the successful doping of $Er^{3+}$/$Yb^{3+}$ into $NH_4Y_2F_7$.

## Conclusion

In this work, a novel class of ammonium lanthanide fluoride nanocage was successfully synthesized. The tendency of $NH_4Ln_2F_7$ to form nanocages is believed to have a close relationship with their inner structure. Our study presents the first example of ternary nanocages to the best of our knowledge. We believe that this method could be expanded to the synthesis of other rare-earth hollow nanostructures, especially the MF-$LnF_3$ categories, and thus brings new opportunities to these fast expanding research fields.

## Experimental Section

In a general preparation, EDTA chelated with $Ln^{3+}$ to form a clear solution at pH 2–3 by adding diluted HCl and $NH_3{\cdot}H_2O$ solution. And then $NH_4F$, which was dissolved into water/ethanol mixed solvents, was added. The mixture was transferred to an autoclave and was treated at 180 °C for 20 h under solvothermal conditions. The autoclave was then cooled to room temperature. The precipitate was then filtered, washed with water to remove ions possibly remnant in the final products, and dried at 80 °C in air. Following the above procedures, $NH_4Ln_2F_7$ (Ln = Y, Ho, Er, Tm, Yb, Lu) nanocages with high yield (90%) could be obtained.

$NH_4^+$ and EDTA are found to be responsible for the phase formation of $NH_4Y_2F_7$. To investigate the influence of $NH_4^+$, EDTA was dissolved with NaOH instead of $NH_3{\cdot}H_2O$, and then $NaYF_4$ was prepared and no hollow-sphere structures were found in the samples. This result confirms that it is easy to induce other cations to take the place of ammonium in the products. The concentration of EDTA greatly affects the phase purity of $NH_4Y_2F_7$. Keeping the amount of $Y^{3+}$ (0.2 mmol) unchanged, when the amount of EDTA is less than 0.2 g, the resulting products are mixtures of flakes and hollow-spheres. When the amount of EDTA is more than 1.0 g, the nanocages were elongated to an irregular form. Similar phenomena have been observed on the samples of other $NH_4Ln_2F_7$ (Ln = Ho, Er, Tm, Yb, Lu). When the amount of EDTA is kept at 0.2–1.0 g, regular nanocages can be easily obtained on a large scale.

The obtained sample was characterized by a Bruker D8-Advance X-ray powder diffractometer with Cu-$K_a$ radiation ($\lambda$ = 1.5418 Å). The size and morphology of the IF nanoparticles were determined at 200 kV by a Hitachi H-800 transmission electron microscope (TEM) and a JEOL JEM-2010F high-resolution transmission electron microscope. Fluorescent spectra were recorded with a Hitachi F-4500 Fluorescence Spectrophotometer. Up-conversion fluorescent spectra were obtained with the LS-50B fluorescence spectrophotometer (Perkin–Elmer Corp., Forster City, CA) with an external 0–800 mW adjustable laser (980 nm, Beijing Hi-Tech Optoelectronic Co., China) as the excitation source, instead of the Xenon source in the spectrophotometer, and with an optic fiber accessory. The thermal decomposition behavior of the $NH_4Ln_2F_7$ (Ln = Y, Ho, Tm) samples was studied by thermogravimetric analysis (TGA) with a TGA2050 thermal analysis device (American TA Corpora-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion). TGA determination was carried out in nitrogen at a heating rate of 20 °C/min in a range of room temperature to 900 °C.

**Supporting Information** (for details see the footnote on the first page of this article): XRD patterns of samples that were annealed at 200 °C and 400 °C, respectively, and the TEM images of $CeF_3$, $SmF_3$, and $NH_4Tb_3F_{10}$.

# Hydrogen Bonding and Proton Transfer to the Trihydride Complex [Cp*$MoH_3$(dppe)]: IR, NMR, and Theoretical Investigations

**Natalia V. Belkova,[a] Pavel O. Revin,[a] Maria Besora,[b] Miguel Baya,[c] Lina M. Epstein,[a] Agustí Lledós,*[b] Rinaldo Poli,*[c] Elena S. Shubina,*[a] and Evgenii V. Vorontsov[a]**

**Keywords:** Dihydrogen bonding / Hydride ligands / Molybdenum / Proton-transfer mechanism / DFT calculations

The interaction between [Cp*$MoH_3$(dppe)] (dppe = $Ph_2PCH_2CH_2PPh_2$) and a variety of proton donors has been investigated by a combination of experiments and DFT calculations. Weak proton donors [2-monofluoroethanol (MFE) and trifluoroethanol (TFE)] allow the determination of basicity factor ($E_j$ = 1.42 ± 0.02) and thermodynamic parameters for the hydrogen bond formation ($\Delta H_{HB}$ = –4.9 ± 0.2 and –6.1 ± 0.3 kcal mol$^{-1}$; $\Delta S_{HB}$ = –15.7 ± 0.7 and –20.4 ± 1 cal mol$^{-1}$ K$^{-1}$ for MFE and TFE, respectively). For TFE, a stable low-temperature proton-transfer equilibrium (220–240 K) with the cationic classical tetrahydrido derivative [Cp*$MoH_4$(dppe)]$^+$ could be investigated independently by UV/Vis ($\Delta H°_{PT}$ = –2.8 ± 0.4 kcal mol$^{-1}$ and $\Delta S°_{PT}$ = –15 ± 2 cal mol$^{-1}$ K$^{-1}$) and $^1$H NMR ($\Delta H°_{PT}$ = –2.7 ± 0.5 kcal mol$^{-1}$ and $\Delta S°_{PT}$ = –11 ± 2 cal mol$^{-1}$ K$^{-1}$) spectroscopy. Upon warming, however, the tetrahydride evolves by dihydrogen loss and formation of a hydride-free diamagnetic product. Stronger proton donors [hexafluoroisopropanol (HFIP), *p*-nitrophenol (PNP), perfluoro-*tert*-butyl alcohol (PFTB), and $HBF_4$·$OEt_2$] lead to more extensive proton transfer at lower donor/Mo ratios. A 1:1 proton-transfer stoichiometry is indicated independently by a titration experiment with UV/Vis monitoring for the [Cp*$MoH_3$(dppe)]–PNP reaction, and by a stopped-flow kinetics investigation for the [Cp*$MoH_3$(dppe)]–HFIP reaction. For all proton-transfer processes investigated, the classical tetrahydrido cation forms directly, without the observation of a nonclassical intermediate. DFT calculations have been carried out on the interaction between TFE and HFIP and the model compound [CpMo$H_3$(dpe)] (dpe = $H_2PCH_2CH_2PH_2$) both in the gas phase and in $CH_2Cl_2$ solvent with the polarizable continuum model and, to a more limited extent, on the full [Cp*$MoH_3$(dppe)] system. A detailed comparison of the observed and calculated frequency shifts for the M–H vibrations is presented. The calculations have explored the relative energy and geometry of various configurations involving either a hydride ligand or the metal as the principal proton-accepting site. They have also probed two principal proton-transfer pathways, leading to the unobserved nonclassical intermediate and to the observed classical product. From these studies, it appears that a nonclassical intermediate may be obtained by a kinetically controlled proton transfer to a hydride site, followed by an intramolecular rearrangement through a very low energy barrier. However, a competitive low-energy pathway for direct proton transfer at the metal site is also revealed by the calculations.

## Introduction

Proton-transfer processes to and from transition-metal centers and hydride ligand sites continue to attract considerable research interest because of their fundamental importance for catalysis and in biochemistry.[1,2] The kinetic preference for hydride versus metal protonation is now quite firmly established,[3–9] though exceptions have recently been reported from studies carried out in our laboratories.[10,11] The proton transfer occurs via intermediates, for which characteristic spectroscopic signatures have been established, that contain hydrogen bonds between the proton donor and the proton acceptor (the metal center or a hydride ligand) (see Scheme 1).[12,13] The term "nonclassical hydrogen bonding" has been coined to address these interactions, while H-bonding specifically involving a hydride ligand has also been termed "dihydrogen bonding".[14] The relationship between the preferred thermodynamic site of hydrogen bonding (i.e., the relative energy of species **I** and **IV**) and the kinetic site of proton transfer (i.e., the relative energy barrier leading to species **II** and **V**) is of interest to us. We have recently presented combined experimental and theoretical results showing that the preferred hydrogen-

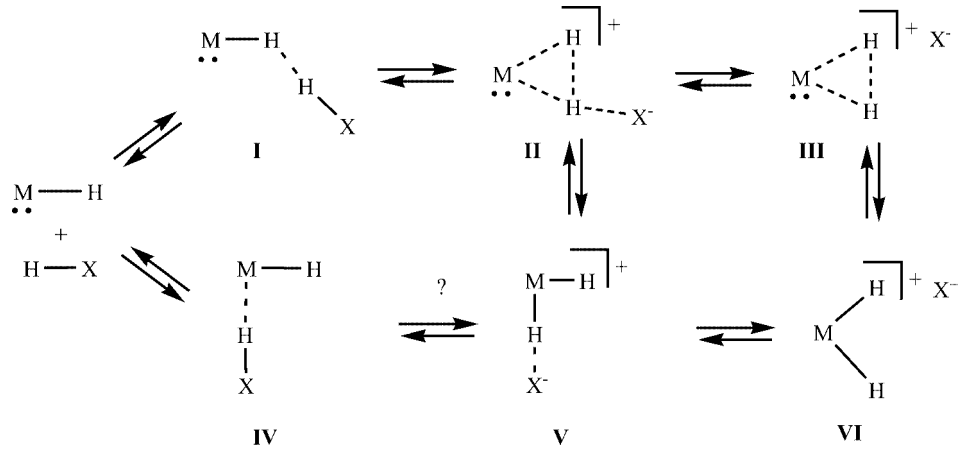
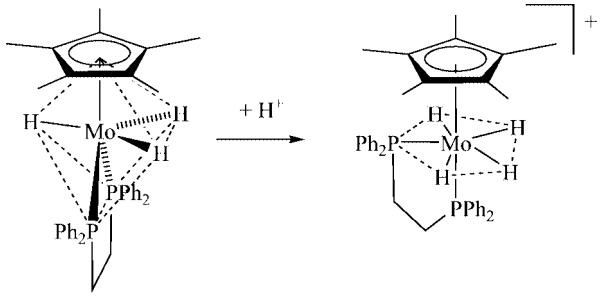


Scheme 1.

bonding site for compound [Cp*Fe(dppe)H], that is, the hydride site, corresponds to the site of preferred proton transfer.[15] In parallel work, some of us have studied the mechanism of the hydride protonation, analyzing the influence of medium polarity and concentration effects, both experimentally and theoretically.[16–18] We have demonstrated the involvement of ion pairs formed by cationic dihydrogen complexes and the anionic conjugate basis of the proton donor. In these studies the stabilizing role of the solvent and the homoconjugate anions [A···H···A]$^-$ in the protonation process has also been recognized.

In order to determine the general relationship between the thermodynamics of hydrogen bonding to various possible sites and the energy barrier leading from each of these sites to proton transfer, a greater number of case studies is necessary, especially for polyhydride complexes where the hydride ligands occupy inequivalent positions so that it is also possible in principle to discriminate between different hydride sites. For this reason, we have selected compound [Cp*Mo(dppe)H$_3$], which was synthesized in one of our laboratories a few years ago.[19] In this system there are four basic potential sites (the metal and the three hydride ligands) able to establish hydrogen bonds with a proton donor. Moreover, several isomers could result from the proton-transfer process. The X-ray structure of the trihydride compound was of sufficient quality to locate the hydride ligands and showed that they occupy two different sites, as shown in Scheme 2.[20] The geometry is best described as an ideal trigonal prism if the Cp* ligand is considered to occupy a single position in correspondence to its ring centroid. However, the compound is highly fluxional and a single hydride resonance, which is split into a binomial triplet by the two equivalent P nuclei, remained sharp down to 183 K.[19]

Protonation studies have previously been carried out only with $HBF_4$, leading to the formal product of metal protonation, the classical tetrahydride complex [Cp*MoH$_4$(dppe)]$^+$.[19] However, this product is unstable and easily loses $H_2$. It could be isolated upon low-temperature protonation in ether, where it precipitates. An X-ray structure was not obtained for the Mo complex, but the



Scheme 2.

analogous W derivative displays a pseudopentagonal bipyramidal structure. As the two metal complexes show analogous NMR properties, the same structure is also assumed to be adopted by the Mo complex and is illustrated in Scheme 2. Both Mo and W cationic tetrahydride complexes are fluxional at room temperature, showing only one hydride resonance and one phosphorus resonance, but the P resonance decoalesces at low temperature, whereas the hydride resonance does not. The protonation of [Cp*Mo(dppe)H$_3$] in MeCN or the dissolution of [Cp*MoH$_4$(dppe)]$^+$ in MeCN gives a variety of products resulting from the substitution of $H_2$ with MeCN. The tungsten compound is stable under these conditions.[19]

Preliminary studies of the hydrogen bonding and proton transfer to the Cp*M(dppe)H$_3$ (M = Mo, W) compounds with weaker proton donors has been recently communicated.[21] We present here a full report of our investigation on the Mo compound, whereas further details concerning the W system, including a comparison of the two metal complexes, will be reported in a forthcoming paper.[22]

## Results

### Experimental Studies

Two solvents – THF or $CH_2Cl_2$ – were used for spectroscopic studies. Their relatively high polarity ($\varepsilon$ = 7.3 for THF and 8.9 for $CH_2Cl_2$) helps maintain the ionic proton-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

transfer products in solution. However, THF has itself pronounced proton-acceptor properties and competes with the hydride complex for hydrogen bonding to the proton donor. Therefore, much higher proton donor concentrations are needed in order to observe similar spectral changes to those in $CH_2Cl_2$.[23] Unfortunately, compound [Cp*Mo(dppe)$H_3$] slowly decomposes at room temperature in dichloromethane, probably by attack of the solvent C atom by the hydride ligand. The stability of the trihydride complex in $CH_2Cl_2$ is greatly enhanced at low temperatures, with no visible change occurring at 200 K for at least 3 h. Thus IR and UV/Vis studies were carried out either in THF or in $CH_2Cl_2$ at low temperatures, or in $CH_2Cl_2$ at higher temperatures within a short timescale relative to the decomposition reaction. The NMR studies were carried out at low temperatures in $CD_2Cl_2$. In all cases, the extent of decomposition was carefully monitored to insure the significance of the results. The proton donors used in this study were 2-monofluoroethanol (MFE), 2,2,2-trifluoroethanol (TFE), hexafluoroisopropanol (HFIP), perfluoro-*tert*-butyl alcohol (PFTB), and *p*-nitrophenol (PNP).

### *Analysis of the $\nu_{OH}$ Region in the IR Spectra*

The interaction between [Cp*Mo(dppe)$H_3$] and proton donors was first studied by IR in the $\nu_{OH}$ range by using MFE and TFE in $CH_2Cl_2$. The observed decrease of the intensity (A) of the $\nu_{OH(free)}$ band and the appearance of a low-frequency shifted broad $\nu_{OH}$ band for the hydrogen-bonded OH group is unquestionable evidence for the formation of hydrogen bonds between the alcohol OH proton and the transition-metal hydride complex, although it does not establish the nature of the hydrogen-bonding site. The $\Delta\nu_{OH}$ band shift [$\Delta\nu_{OH} = \nu_{OH(free)} - \nu_{OH(bonded)}$] increased with the strength of the proton donors (see Figure 1 and Table 1).

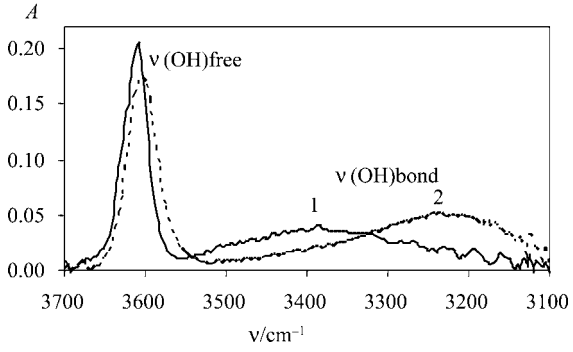


Figure 1. IR spectra in the $\nu(R_FO–H)$ stretching region of MFE (1) or TFE (2) in $CH_2Cl_2$ in the presence of [Cp*Mo(dppe)$H_3$].

The hydrogen bond enthalpies, $\Delta H_{HB}$, were obtained by two independent methods (see Table 1). The first one is based on the empirical correlation outlined in Equation (1), originally established for classical H bonds and later extended to hydrogen bonds to metal centers and to hydride ligands as proton acceptors.[12,13] The van't Hoff method uses the integrated IR intensities for the free alcohol absorption band in the presence or absence of the hydride complex as a function of temperature. It has the advantage of also yielding the reaction entropy. There is quite good agreement between the reaction enthalpies obtained from the two methods. It should be noted that the computed values for the interaction with TFE (see later) are in good agreement with these experimental results.

$$-\Delta H_{HB} = \frac{18\Delta\nu}{\Delta\nu + 720} \quad (1)$$

### *Analysis of the $\nu_{MH}$ Region in the IR Spectra*

The IR analysis in the $\nu_{MH}$ stretching vibration range was carried out with the goal of learning about the nature of the preferred hydrogen-bonding site. Previous studies on monohydride complexes have demonstrated that the interaction with a hydride ligand has the effect of shifting the M–H stretching vibration to lower frequencies, whereas the opposite effect is associated to an interaction with the metal site or other ligands.[12,13] For polyhydride compounds, however, the situation may not be so simple, as each vibrational normal mode results from the combination of more M–H bond stretching vibrations, each of which may be affected by hydrogen bonding in a different way. A previous combined experimental and theoretical study on the dihydride complex $Ru(PP_3)H_2$ [$PP_3 = P(CH_2CH_2PPh_2)_3$][23] was simplified by the fact that the two M–H bonds, being *trans* to ligands that exert a very different *trans* effect, do not mix extensively with each other, thus each of the two bands is composed of an essentially pure stretching vibration of a single M–H bond. The study of hydrogen bonding implicating the $Cp_2NbH_3$ complex,[18] having $C_{2v}$ symmetry and one $\nu_{MH}$ vibrational band resulting from the overlap of $2a_1 + b_1$ vibrations,[24] revealed the formation of dihydrogen-bonded complexes leading to band splitting with a low-frequency shift for the hydrogen-bonded $\nu_{MH}$ band. Although hydrogen bonding for other polyhydride compounds has been investigated,[11] no detailed analysis of the normal modes and how these are affected by hydrogen bonding have been reported. We intend to carry out such

Table 1. Parameters of the dihydrogen bonding between [Cp*Mo(dppe)$H_3$] and MFE or TFE, and basicity factors.

an analysis here for the [Cp*Mo(dppe)H$_3$] complex, by a combination of experimental and computational methods.

The trihydride complex displays wide $\nu_{MH}$ bands of complex shape with the maxima at 1772 cm$^{-1}$ in $CH_2Cl_2$ and at 1785 cm$^{-1}$ in THF. Deconvolution of the spectrum in $CH_2Cl_2$, after subtraction of overtones because of the phenyl groups, yields two overlapping bands at 1821 and 1772 cm$^{-1}$ ($\Delta\nu_{1/2}$ = 57 and 54 cm$^{-1}$, correspondingly) (see Figure 2). A third, much weaker band is found at 1904 cm$^{-1}$ ($\Delta\nu_{1/2}$ = 41 cm$^{-1}$). However, its parameters are less reliable because of the low intensity and superposition with one of the phenyl overtones. Therefore, it will not be used later for the comparison with the theoretical data on $\nu_{MH}$ in hydrogen-bonded complexes. The intensities of the $\nu_{MH}$ bands increase as the temperature is decreased. The extinction coefficient of the strongest band increases from 49.0 to 60.3 L mol$^{-1}$ cm$^{-1}$ upon cooling from 290 to 200 K in THF.

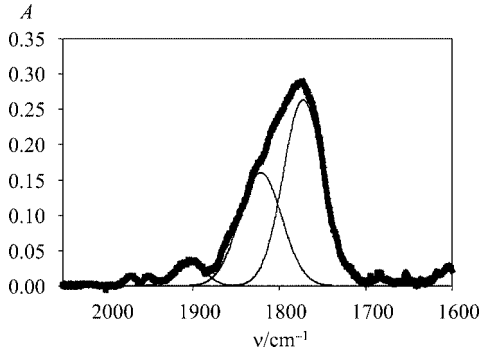

Figure 2. IR spectrum in the ν(Mo–H) stretching region of [Cp*Mo(dppe)H$_3$] (0.030 M) in $CH_2Cl_2$, after subtraction of the phenyl overtones, showing the band decomposition.

Upon interaction between the [Cp*Mo(dppe)H$_3$] complex and MFE at 200 K in $CH_2Cl_2$ the $\nu_{MH}$ band becomes wider and shifts to lower frequencies by about 5 cm$^{-1}$. A band decomposition analysis carried out after the subtraction of both dppe and MFE spectra shows that the two major bands become wider and appear at different positions: 1822 and 1769 cm$^{-1}$ ($\Delta\nu_{1/2}$ = 73 and 60 cm$^{-1}$, $\Delta\nu$ = +1 and –3 cm$^{-1}$, respectively). These changes can be attributed to the effect of hydrogen bonding on the $MoH_3$ moiety. The experiments in THF, as expected, necessitated the use of the stronger proton donors at higher concentrations in order to observe similar changes. For instance, using just a 10-fold excess of TFE, the only observed change was a small low-frequency band shift and intensity decrease upon increasing the temperature, just like in the absence of alcohol, without a shape change. This change is reversible up to 270 K, demonstrating that no proton transfer occurs with this alcohol in THF up to 270 K (cf. proton transfer in $CH_2Cl_2$ later). A deeper analysis of the M–H stretching vibrations in the absence and presence of proton donors will be carried out below in the light of the theoretical data.

### *NMR and IR Studies of Proton Transfer*

As stated in the Introduction, the molybdenum trihydride complex can be protonated by $HBF_4$·$Et_2O$ to give the tetrahydride complex [Cp*Mo(dppe)H$_4$]$^+$.[19] New $^1$H NMR investigations carried out at low temperatures (200–250 K) in $CD_2Cl_2$ using either $HBF_4$·$Et_2O$ or TFE show a direct transformation, without the detection of any intermediate (notably nonclassical species). With the weaker proton donor TFE, an equilibrium between the starting [Cp*Mo(dppe)H$_3$] complex and the protonated product is established and a large excess is needed to achieve a high degree of proton transfer.

Well-established, free, and hydrogen-bonded complexes exchange rapidly on the NMR timescale, yielding only one resonance. Typically, the effect of hydrogen bonding on chemical shifts is small, especially in the case of polyhydrides, where the effect is averaged over the various hydride ligands. The [Cp*Mo(dppe)H$_4$]$^+$ complex on one side, and the rapidly equilibrating mixture of the free trihydride complex and the hydrogen-bonded adduct [Cp*Mo(dppe)H$_3$···HOR$_F$] on the other side, give rise to triplet resonances at about $\delta$ –3.7 ($J_{HP}$ = 37.4 Hz) and –6.0 ($J_{HP}$ = 48.0 Hz) in the $^1$H NMR spectrum at low temperatures (190–210 K). The positions of these peaks change significantly with the temperature, moving to about –3.5 and –5.7 at 300 K. The chemical shift difference between these resonances decreases steadily from 2.32 ppm at 200 K to 2.22 ppm at 300 K. On the other hand, neither chemical shift, at a given temperature, seems highly dependent on the nature of the proton donor (TFE, HFIP, or $HBF_4$) or on its concentration. Furthermore, the $J_{HP}$ values remain practically unchanged over the entire temperature range. Therefore, the chemical shift changes are probably unrelated to variations in hydrogen-bonding equilibria. The relative amounts of the two species are also afforded by a parallel monitoring of the $^{31}$P{$^1$H} NMR spectrum (resonance at –75.0 ppm and –92.8 ppm, respectively). As for the case of the $^1$H NMR resonances, the $^{31}$P{$^1$H} NMR chemical shifts do not depend on the nature and concentration of the proton donor.

The establishment of hydrogen bonding is more clearly evidenced from the change of longitudinal relaxation time ($T_1$) for the trihydride resonance (see Table 2). As expected, this parameter decreases upon addition of proton donors, in proportion to the strength of the donor.[2,13] It is also significant that the temperature corresponding to $T_{1min}$ increases slightly upon protonation from 220 to 230 K. This phenomenon signals a decreased correlation time ($\tau_C$), that is, a slower tumbling motion, for the protonated species, in agreement with its expected larger size. Thus, slightly higher temperatures are needed to again raise $\tau_C$ to the conditions required for the most efficient longitudinal relaxation ($w_0^2\tau_C^2 \approx 1$). The $T_{1min}$ of the tetrahydride product is smaller relative to the parent complex, but not in the range expected for dihydrogen complexes.[25] This decrease is expected, as the dipolar relaxation implicates four hydride ligands instead of three. Note, however, that the tetrahydride resonance $T_1$ value is also sensitive, like that of the parent trihydride, to the nature of the proton donor used. A possible interpretation of this difference is a stronger hydrogen bonding between one or

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

more hydride ligands with the stronger conjugate base $CF_3CH_2O^-$, thereby increasing the average H···H distances.

Table 2. Longitudinal relaxation time $T_{1min}$ (ms) for [Cp*Mo(dppe)$H_3$] in $CD_2Cl_2$ solution under different conditions.[a]

| | $T_{min}$ [K] | [Cp*Mo(dppe)$H_3$] | [Cp*Mo(dppe)$H_4$]$^+$ |
|---|---|---|---|
| Free | 220 | 302 | |
| +$HBF_4$ (1 equiv.) | 230[b] | 274 | 174 |
| +TFE (6 equiv.) | 230[b] | 295 | 191 |

[a] At 400 MHz. [b] The resonances of both complexes have a minimum $T_1$ at the same temperature.

The complex [Cp*Mo(dppe)$H_4$]$^+$ was also characterized by means of IR spectroscopy (see Figure 3). After the addition of 1.1 equiv. of $HBF_4$, new bands appeared in the spectrum at 1818, 1839, and 1920 cm$^{-1}$ (see spectrum b). Formation of bands at higher frequency upon protonation is spectroscopic evidence for the formation of a cationic classical product. Treating [Cp*Mo(dppe)$H_3$] with 7 equiv. of HFIP in THF at 200 K did not lead to significant proton transfer, only a minor decrease of the initial 1785 cm$^{-1}$ band observed after the subtraction of the HFIP spectrum (see spectrum c).

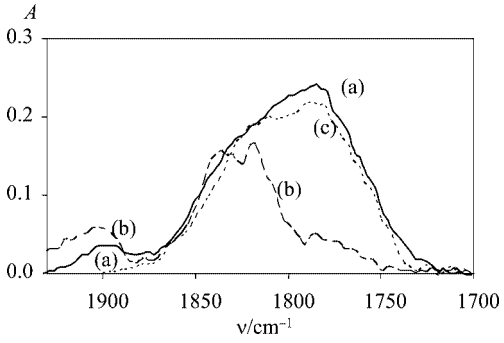

Figure 3. IR spectra in the ν(Mo–H) stretching region of [Cp*Mo(dppe)$H_3$] (0.084 M) in THF at 200 K. (a) Without proton donor. (b) With HBF4 (1.1 equiv.). (c) With HFIP (7 equiv.) after subtraction of the HFIP spectrum.

The protonation process was studied more extensively with a wider range of fluorinated alcohols of different strength in dichloromethane by variable temperature IR. An equilibrium between the hydrogen-bonded system and the tetrahydride complex was observed, which shifts toward the protonation product for stronger alcohols and higher alcohol/Mo ratios. For PFTB, the complete disappearance of the trihydride occurs in the presence of a twofold excess at 200 K. The addition of 2 equiv. of TFE leads to only 20% conversion, while a 10-fold excess is required to consume nearly all the hydride precursor (see Figure 4). For the case of the weakest fluorinated alcohol MFE, a 50-fold excess leads only to a moderate decrease of the MoH band intensity. The proton transfer with TFE at variable temperatures has given kinetic information (see later). Above 250 K, a slow evolution of the spectroscopic properties was observed, indicating instability for the tetrahydride product (see below). A quantitative measurement of the equilibrium position in a wide temperature range was not possible by IR spectroscopy because of the complex shape of the spectra, further complicated by the temperature dependence of the extinction coefficients. The thermodynamic parameters of this equilibrium were obtained from UV and NMR investigations as shown below.

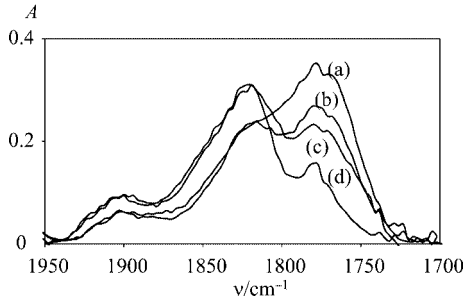

Figure 4. IR spectra in the ν(Mo–H) stretching region of [Cp*Mo(dppe)$H_3$] (0.037 M) in $CH_2Cl_2$ at 200 K. (a) Without TFE. (b) With TFE (2 equiv.). (c) With TFE (5 equiv.). (d) With TFE (10 equiv.).

### *Establishment of the Proton-Transfer Stoichiometry*

The equilibrium resulting from the interaction between [Cp*Mo(dppe)$H_3$] and *p*-nitrophenol (PNP; $P_i$ = 1.27) was investigated by UV/Vis spectroscopy. This was rendered possible by the sensitivity of the proton donor chromophore to hydrogen bonding and proton transfer,[26] making it possible to probe the nature of the species in equilibrium. However, quantitative information on the concentration of each species was not accessible. Spectra were recorded for $CH_2Cl_2$ solutions of PNP (0.001 M) in the presence of [Cp*Mo(dppe)$H_3$] at different ratios from 1:0.1 to 1:2, in the 200–250 K temperature range, where the observed spectral changes were fully reversible. The spectra show wide overlapping bands of both the phenol in its various forms and the hydride complexes (both free and dihydrogen bonded). The absence of free phenolate is signaled by the absence of a band at 430 nm. A deconvolution analysis yields three bands with maxima at 312, 351, and 395 nm. The first two bands are assigned to free PNP and to the dihydrogen-bonded complex [Cp*(dppe)$MoH_3$]···$HOC_6H_4NO_2$. Note that the 351 nm band is red-shifted not only relative to free PNP ($\Delta\lambda$ = 39 nm), but also to the related iron complex [Cp*(dppe)FeH]···$HOC_6H_4NO_2$ (340 nm, $\Delta\lambda$ = 11 nm),[27] signaling a stronger hydrogen bonding. This is consistent with the higher basicity factor of [Cp*Mo(dppe)$H_3$] (Table 1) versus that of [Cp*Fe(dppe)H] (1.35–1.38).[27] The band at 395 nm is attributed to a hydrogen-bonded phenolate ion, [Cp*(dppe)$MoH_4$]$^+$···[OAr]$^-$, because this is blue-shifted from the free phenolate band by 35 nm. Notably, this band is red-shifted in comparison to the corresponding band previously attributed to [Cp*(dppe)Fe($H_2$)]$^+$···[ArOHOAr]$^-$.[15] The assignment of this absorption to the 1:1 hydrogen-bonded ion pair, rather than to a species containing a homoconjugated pair [ArOHOAr]$^-$, was confirmed by the titration experiment (see Figure 5). Therefore, the proton-accepting strength of the Cp*(dppe)-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$MoH_3$ complex is sufficiently high to abstract a proton from a single molecule of PNP.

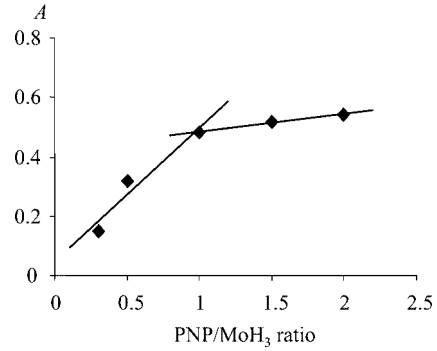

Figure 5. Intensity changes at 390 nm vs. the PNP/Mo ratio.

The stoichiometry was also probed with a weaker proton donor, that is HFIP ($P_i$ = 1.05), by way of a kinetics approach, as HFIP and the species derived from its protonation do not contain chromophores allowing their direct detection. The reaction was studied in toluene at 293 K under pseudo-first-order conditions with HFIP/$MoH_3$ ratios in the 20–80 range, using the stopped-flow technique. The proton-transfer step required a few seconds to reach equilibrium. On a much longer timescale, a slower decomposition reaction occurred, as indicated by NMR monitoring (see below). The time evolution of the spectra could be properly fitted on the basis of a first-order decay, giving an observed rate constant that turned out to be independent of the alcohol concentration (see Figure 6). The average value for $k_{1\,obs}$ is $10.1 \pm 0.2$ s$^{-1}$. This result is consistent with the involvement of a single HFIP molecule in the rate-determining step (Scheme 3), because the hydrogen-bonding pre-equilibrium is heavily shifted to the adduct under these conditions [see Equation (2)]. Therefore, as $K_{HB}$[HA] >> 1, the expression simplifies to $k_{obs} = (k_1 + k_{-1})$. In the previously published kinetics study of the [Cp*Fe(dppe)H] + HFIP system, on the other hand, a first-order dependence on [HFIP] was observed under the same ($K_{HB}$[HA] >> 1) conditions. This difference is again consistent with the higher proton-accepting ability of [Cp*Mo(dppe)$H_3$] versus [Cp*Fe(dppe)H].

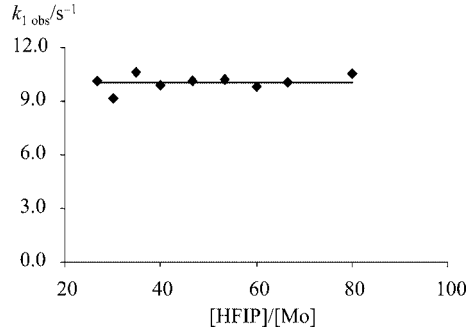

Figure 6. Pseudo-first-order rate constants ($k_{1\,obs}$) for the proton transfer from HFIP to [Cp*Mo(dppe)$H_3$].

$$k_{obs} = \frac{k_1 K_{HB}[HA]}{1+K_{HB}[HA]} + k_{-1} \quad (2)$$

### *Thermodynamics of the Proton-Transfer Equilibrium*

The equilibrium of proton transfer to [Cp*Mo(dppe)$H_3$] was investigated by UV/Vis and $^{31}$P NMR spectroscopy in the 200–240 K temperature range using TFE as proton donors. The results of the UV/Vis study using TFE are shown in Figure 7. The spectra of the initial trihydride (a) and final tetrahydride (b) complexes have very different extinction coefficients at the $\lambda_{max}$ of the trihydride species (400 nm): 2128 and 245, respectively. The UV/Vis properties of the dihydrogen-bonded complexes are essentially indistinguishable from those of the free hydride complex: the UV/Vis spectra of [Cp*Mo(dppe)$H_3$] (0.02 M) in the presence of 15 equiv. MFE do not differ significantly from those of pure trihydride. The same phenomenon was observed earlier for iron hydride.[15] Upon addition of TFE at 200 K, 54% of the complex converts to the tetrahydride, leading to an absorption decrease. The intensity of the band increases upon heating, showing that the equilibrium shifts towards the initial complex. These changes are perfectly reversible in the 200–240 K range.

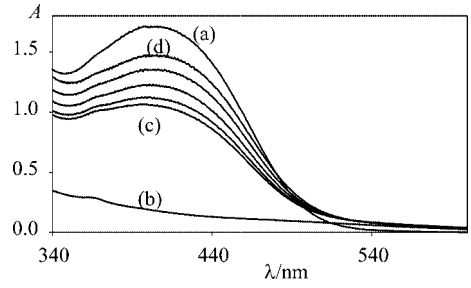

Figure 7. UV/Vis study of the interaction between [Cp*Mo(dppe)$H_3$] and TFE (4 equiv.) in $CH_2Cl_2$. (a) Initial complex $c$ = 0.02 M. (b) Tetrahydride $c$ = 0.02 M. (c) $T$ = 200 K. (d) $T$ = 240 K. The other intermediate spectra were recorded at each 10 K step.

The temperature reversibility enabled the determination of the equilibrium constant for the formation of [Cp*Mo(dppe)$H_4$]$^+$$OCH_2CF_3^-$. It was assumed that the equilibrium involves only one TFE molecule, as experimentally verified for the PNP and HFIP systems (see above, Scheme 3). Taking into account the above-determined hydrogen-bond formation constant $K_{HB}$, the analysis of the data of Figure 7 led to the calculation of the proton-trans-

$$Cp^*Mo(dppe)H_3 + R_FOH \rightleftharpoons Cp^*Mo(dppe)H_3\cdots HOR_F \qquad K_{HB}$$

$$Cp^*Mo(dppe)H_3\cdots HOR_F \rightleftharpoons [Cp^*Mo(dppe)H_4]^+\cdots OR_F^- \qquad K_{PT} = k_1/k_{-1}$$

Scheme 3.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fer equilibrium constant $K_{PT}$ at each temperature. A van't Hoff analysis of these $K_{PT}$ constants yields $\Delta H°_{PT} = -2.8 \pm 0.4$ kcal mol$^{-1}$ and $\Delta S°_{PT} = -15 \pm 2$ cal mol$^{-1}$ K$^{-1}$ for the proton-transfer process.

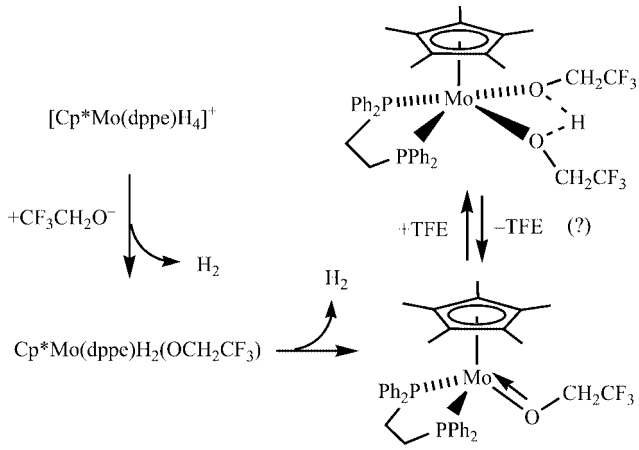
The proton-transfer equilibrium constants were also obtained by $^1$H NMR spectroscopy. Like for the UV/Vis investigation, the NMR technique only provides information on the sum of the concentrations of rapidly equilibrating free trihydride and its hydrogen-bonded adduct. Knowledge of the $K_{HB}$ allowed the calculation of the individual concentrations, from which the $K_{PT}$ constants could be calculated at each temperature. The van't Hoff analysis yields $\Delta H°_{PT} = -2.7 \pm 0.5$ kcal mol$^{-1}$ and $\Delta S°_{PT} = -11 \pm 2$ cal mol$^{-1}$ K$^{-1}$. These values are identical to those established from the low-temperature UV/Vis data within experimental error.

### *Decomposition of the Proton-Transfer Product: Hydrogen Evolution*

NMR monitoring of the [Cp*Mo(dppe)H$_3$]–TFE interaction at high temperatures (>280 K) revealed further irreversible evolution. The hydride resonances of the starting trihydride and the protonated tetrahydride complexes disappeared completely within 2 h at room temperature. No new hydride resonance appeared in the spectrum. On the other hand, the formation of a new diamagnetic product was indicated by the replacement of the Cp* resonances ($\delta$ = 1.69 for the trihydride and 1.83 for the tetrahydride complexes) with a new one at $\delta$ = 1.58 in the $^1$H NMR and by the appearance of a resonance at $\delta$ –69.5 in the $^{31}$P{$^1$H} NMR spectrum. This indicates the selective formation of a single, hydride-free diamagnetic product. This evolution is accompanied by the appearance of a new sharp resonance at $\delta$ = 4.61 in the $^1$H NMR spectrum, which is characteristic of free $H_2$. All this evidence points to reductive elimination of two $H_2$ molecules from the tetrahydride complex [Cp*MoH$_4$(dppe)]$^+$, the product being stabilized by coordination of the trifluoroethoxide anion.

Stable 16-electron compounds of type [(C$_5$R$_5$)MoL$_2$X] (the X ligand has π-donating properties) have previously been reported, for example [CpMo(CO)$_2${As(*t*Bu)$_2$}],[28] [Cp*Mo(PMe$_3$)(PHPh$_2$)(PPh$_2$)],[29] [Cp*Mo(dppe)Cl],[30] and [CpMo(PMe$_3$)$_2$(OH)].[30,31] These precedents suggest that the [Cp*Mo(dppe)(OCH$_2$CF$_3$)] molecule may be stable. Interestingly, compounds [CpMo(PMe$_3$)$_2$(OH)] and [Cp*Mo(dppe)Cl] have two unpaired electrons, whereas our observed $H_2$ elimination product is diamagnetic like compound [Cp*Mo(PMe$_3$)(PHPh$_2$)(PPh$_2$)].[29] It is also possible, however, that one additional TFE molecule adds to the system to afford an 18-electron adduct, which could even be further stabilized by intramolecular hydrogen bonding (see Scheme 4).

The $^1$H NMR spectrum does not remove this ambiguity, because only one $\delta_{CH_2}$ resonance for TFE is observed, at the same position as in free TFE ($\delta \approx 3.9$). It is not split or shifted by the deprotonation process, possibly because of a rapid exchange between the free alcohol and its conjugate anion. The absence of a new resonance for a coordinated TFE molecule represents only negative evidence, because



Scheme 4.

fast exchange could also average the resonances of free TFE/$CF_3CH_2O^-$ with that of any coordinated TFE. Neither does the OH resonance give any useful information, as it also remains unsplit under all conditions because of rapid exchange processes. In addition, the position of this resonance is highly temperature- and concentration-dependent, even before any dihydrogen evolution from [Cp*MoH$_4$(dppe)]$^+$ takes place. All our attempts to isolate the final product in the crystalline state have failed. The spin states' dichotomy for complex [Cp*Mo(dppe)(OCH$_2$CF$_3$)], as well as the thermodynamics of further TFE coordination, has been investigated by DFT calculations (vide infra).

## Computational Studies

The interaction of [Cp*Mo(dppe)H$_3$] with fluorinated alcohols has been studied theoretically by using the model complex [CpMo(dpe)H$_3$] (dpe = H$_2$PCH$_2$CH$_2$PH$_2$) and TFE and HFIP as proton donors, both in gas phase and in dichloromethane. Test calculations for the real complex have also been performed. The computational study was carried out with several objectives in mind: (i) explore the thermodynamics of hydrogen bonding at different sites; (ii) investigate the effect of hydrogen bonding at different sites on the vibrational modes of the $MoH_3$ moiety; (iii) investigate the stability of the protonation products and the possible involvement of nonclassical intermediates during the proton-transfer process; (iv) determine the protonation pathway; and (v) rationalize the further evolution of the protonation product.

### *The Free Trihydride Complex*

The optimization of the free [CpMo(dpe)H$_3$] model system gave a geometry that is in close correspondence with that observed experimentally[19,20] for the full [Cp*Mo(dppe)H$_3$] system. For the purpose of the present discussion, the most important parameters are those related to the $MoH_3$ moiety (see Figure 8). Taking the plane that contains the two P atoms and the center of the Cp as a reference, the three H ligands are disposed asymmetrically,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

two (H1 and H2) on one side and one (H3) on the other side. The unique H3 atom shows the longest distance to the Mo center (1.724 Å). The other two hydrides seem to occupy approximately symmetric positions relative to the Mo–H vector to the unique H ligand (H3–Mo–H1 = 132°, H3–Mo–H2 = 129°), but they in fact show quite different Mo–H distances. One distance (to H2) is similar to that of the unique hydride (1.717 Å), whereas the other one is much shorter (1.682 Å). This asymmetry parallels a slight asymmetry in the Cp*Mo(dppe) moiety (the two CNT–Mo–P angles are different at 131.1 and 143.1°) and its origin is not clear. The three hydride ligands have quite different Mulliken charges: –0.017, –0.003, and –0.053 for H1, H2, and H3, respectively. Thus H3 is clearly the most hydridic site. The distance between H1 and H2 (1.753 Å) indicates that they do not directly interact with each other, because it is longer than the longest separation between hydrogen atoms in what have been described as "stretched dihydrogen ligands" {e.g., 1.49 Å in $[OsH_5(PMe_2Ph)_3]^+$}.[32] In addition, a theoretical analysis of another stretched dihydrogen complex {i.e., $[Os(H\cdots H)(NH_2CH_2CH_2NH_2)_2(HCO_2)]^+$ with a distance of 1.428 Å} indicates no critical point connecting the two atoms.[33]

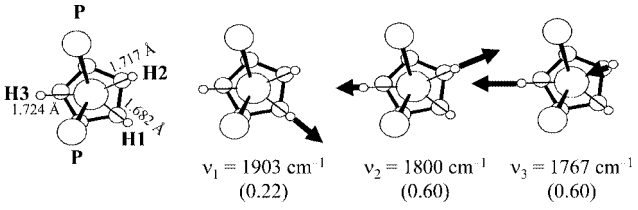


Figure 8. ORTEP view of the DFT optimized [CpMo(dpe)H$_3$] molecule. The Cp- and P-bonded H atoms and ethylene backbone have been omitted for clarity. The M–H normal modes are represented with their respected computed frequency and intensity ($10^4$ L mol$^{-1}$ cm$^{-2}$) in parentheses.

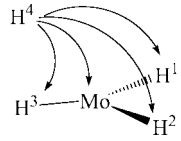
The analysis of the M–H normal modes in the free complex, also represented in Figure 8, will serve as a basis for discussion of the changes induced by hydrogen bonding. A comparison between the experimental spectrum for compound [Cp*Mo(dppe)H$_3$] and the computed one for the [CpMo(dpe)H$_3$] model shows a rather good agreement, both in terms of the frequencies and the relative intensities. As shown in Figure 8, the higher-energy normal mode ($\nu_1$) is essentially a pure stretching vibration of the hydride ligand H1, which shows the shortest (and therefore strongest) bond. The other two vibrations are relatively close to each other in frequency and are a mixture of the other two M–H bond vibrations, the higher-frequency one ($\nu_2$) being an in-phase combination with the major contribution from the shorter bond to H2, and the lower-frequency one ($\nu_3$) being an out-of-phase combination with the major contribution from the longer bond to H3.

### *Hydrogen-Bonded Adducts with TFE: Structures and Vibrational Modes*

[CpMo(dpe)H$_3$] has four potential hydrogen-bonding sites: the three hydrides and the metal (Scheme 5).



Scheme 5.

To account for all the possible hydrogen-bonded minima we optimized the adduct between TFE and the [CpMo(dpe)H$_3$] starting from the different regions around the metal. In this way five stable hydrogen-bonded structures were obtained, as shown in Figure 9. Table 3 shows the rel-

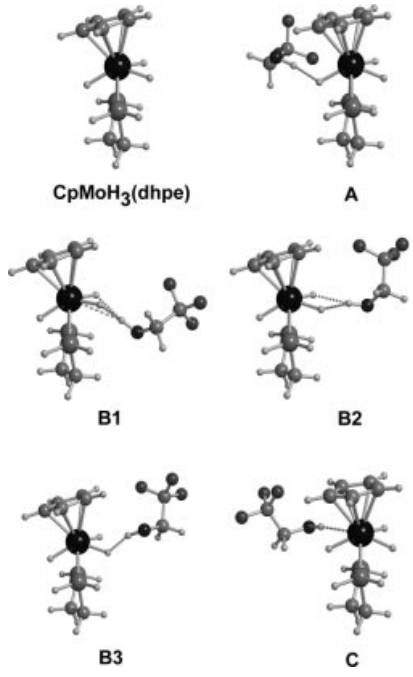


Figure 9. Optimized geometries of [CpMo(dpe)H$_3$] and the [CpMo(dpe)H$_3$···TFE] hydrogen-bonded adducts **A**–**C**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

evant optimized geometrical parameters. The computed frequencies and the normal modes for the M–H stretching vibrations are depicted in Figure 10.

The adducts can be classified depending on the proton-acceptor site. System **A** is the only one where TFE interacts with the unique hydride ligand H3. In systems **B** (**B1**–**B3**) the interaction occurs at one or both of the other two hydride ligands, H1 and H2, that occupy pseudoequivalent positions. Systems **B2** and **B3** are topologically related, as they exhibit the same Mo–H···H–O moiety. They differ in the relative orientation of the proton donor molecule, which places the C–H bond in front of the second hydride in **B3** and in the opposite direction in **B2**. In system **B1** the alcohol molecule is placed with the same relative orientation as in **B2** but farther from the Cp ring. Both in **B1** and **B2** the proton is closer to H2, but also interacts with H1. Thus, these geometries may be better described as containing a "bifurcated hydrogen bond", similar to that described for the $Cp_2NbH_3{\cdot}HOR_F$ adducts.[18] In addition, the distance of the proton from the metal center in system **B1** is also relatively short. In **B3** the proton interacts only with H2, with H2···H–O and Mo···H–O angles of 160.3° and 170.4°, respectively. Finally, system **C** is the only one where the most important interaction appears to involve the metal center, as indicated by the shortest Mo···H distance and the almost linear Mo···H–O bond. The metal–proton interaction is accompanied by a relatively long H···H3 interaction (2.104 Å). This initial description of the hydrogen-bonded adducts, based on the structural data, will be reinforced by the analysis of the changes in the vibrational frequencies and atomic charges of the $MoH_3$ moiety on going from the free complex to the TFE adduct.

The evolution of the Mulliken charges on the hydride atoms and on the Mo atom upon going from the free complex to the TFE adducts also provides useful information. The relevant charges are collected in Table 4. The O–H bond is lengthened in all complexes, in comparison to free TFE (0.965 Å). The magnitude of this elongation is variable

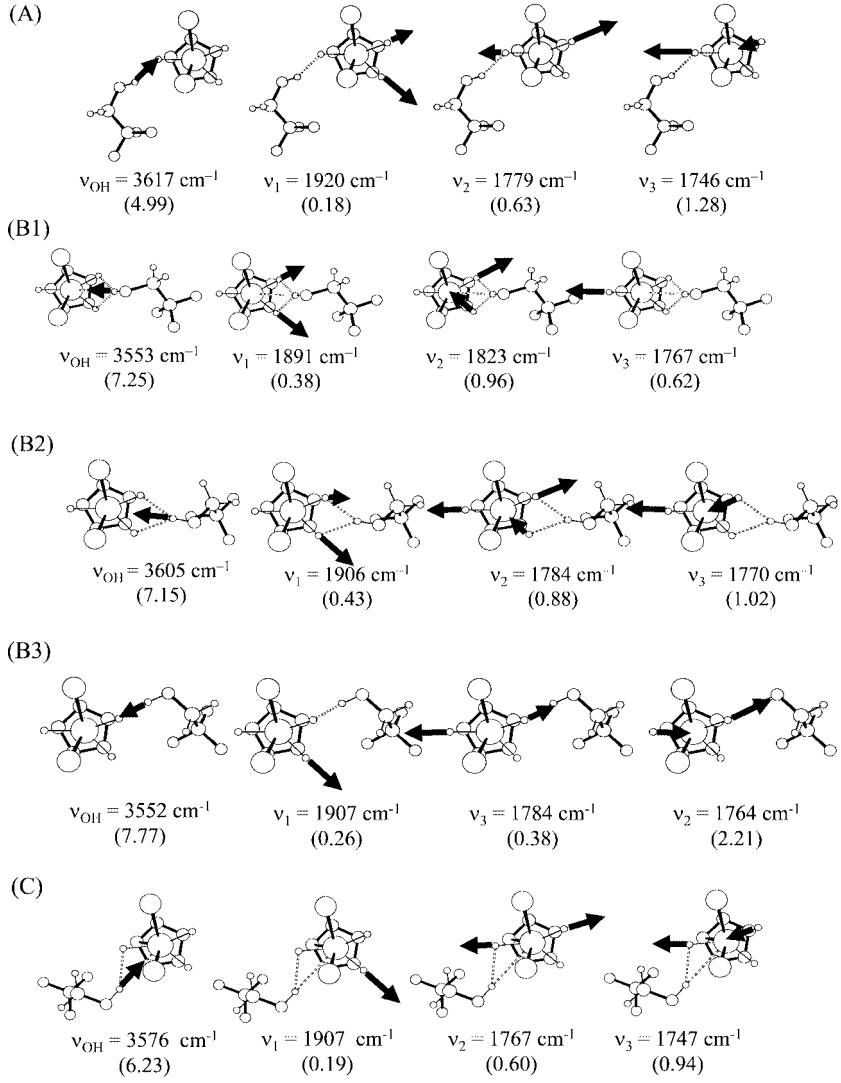

Figure 10. ORTEP view of the DFT optimized [CpMo(dpe)$H_3$···TFE] adducts, showing selected bonding parameters and a representation of the normal modes with the computed frequency and intensity ($A$ = $10^4$ L mol$^{-1}$ cm$^{-2}$) in parentheses. The P-bonded H atoms and ethylene backbone have been omitted for clarity.

but is always rather large (0.012–0.015 Å). The positive charge of the proton increases by 0.027–0.047 units. In system **A** TFE interacts only with the unique hydride ligand (H3). The negative charge of H3 increases from –0.053 to –0.128 ($\Delta q$ = –0.075), whereas the charges of H1 and H2 remain essentially unchanged and that of Mo slightly decreases ($\Delta q$ = +0.009). The Mo–H3 bond is significantly elongated ($\Delta r_{M-H}$ = +0.010 Å), whereas the Mo–H1 and Mo–H2 bonds are less affected (slight contraction for the former and slight elongation for the latter). The composition of the three M–H vibrational modes (Figure 10) remains close to that observed in the free trihydride (Figure 8). The $\nu_1$ mode is blue-shifted by +17 cm$^{-1}$, in agreement with the slight contraction of the Mo–H1 bond; the $\nu_2$ mode does not shift significantly (the major contribution is from Mo–H2, which maintains essentially the same distance); and the $\nu_3$ mode is strongly red-shifted ($\Delta\nu_3$ = –21 cm$^{-1}$), correlating with the weakening of the Mo–H3 bond by the hydrogen bond.

Table 4. Computed Mulliken charges for selected atoms in the [CpMo(dpe)H$_3$] complex and its TFE adducts.[a]

| | H(TFE) | Mo | H1 | H2 | H3 |
|---|---|---|---|---|---|

| TFE | 0.326 | | | | |
| **A** | 0.353 | –0.307 | –0.015 | –0.001 | –0.128 |
| **B1** | 0.373 | –0.367 | –0.017 | –0.076 | –0.047 |
| **B2** | 0.368 | –0.310 | –0.046 | –0.088 | –0.051 |
| **B3** | 0.364 | –0.296 | –0.020 | –0.123 | –0.049 |
| **C** | 0.373 | –0.422 | –0.010 | 0.002 | –0.072 |

[a] For the location of H1, H2, and H3, see Figure 8.

The H1 and H2 hydrides are involved in the hydrogen bond in systems **B1**–**B3**. For system **B3**, the major observed effects of hydrogen bonding are a significant lengthening of the Mo–H2 bond (+0.019 Å), a slight shortening of Mo–H3 (–0.007 Å), a dramatic increase for the H2 negative charge (–0.120), and a slight decrease for that of Mo (+0.020). Therefore, these charge and bond length changes confirm the description of this adduct as involving a dihydrogen bond to H2. The $\nu_1$ vibration is very weakly influenced by the dihydrogen bonding ($\Delta\nu_1$ = +4 cm$^{-1}$), whereas $\nu_2$ and $\nu_3$ are dramatically affected (Figure 10). In fact, hydrogen bonding with H2 weakens the Mo–H2 bond to such a point that the $\nu_2$ mode (to which the Mo–H2 vibration contributes the most) now appears at a *lower* frequency than $\nu_3$ ($\Delta\nu_2$ = –36 cm$^{-1}$). Conversely, $\nu_3$ is shifted to a higher frequency ($\Delta\nu_3$ = +17 cm$^{-1}$), in agreement with the Mo–H3 bond shortening, and the band intensity is decreased by a factor of two. An additional contribution to the red-shift of $\nu_2$ and to the blue-shift of $\nu_3$ may be associated with the modified mixing: in-phase for $\nu_2$ and out-of-phase for $\nu_3$, that is, the opposite of the situation in the free trihydride.

For system **B2**, the negative charge increases significantly, relative to the free trihydride complex, on both H1 ($\Delta q$ = –0.029) and especially H2 ($\Delta q$ = –0.085), correlating well with the H···H distances (longer for H1, 1.944 Å; shorter for H2, 1.799 Å). The charge slightly decreases on Mo ($\Delta q$ = +0.006). The trends of the H···H distances and hydride charges agree with the evolution of the Mo–H bond lengths: both Mo–H1 and Mo–H2 are lengthened (by +0.002 and +0.008 Å, respectively), whereas Mo–H3 is shortened (–0.004 Å) (Table 3). The O–H vector bisects the H1MoH2 angle, with an essentially coplanar MoH1H2···HO fragment. System **B2**, therefore, appears to be best described as having a bifurcated hydrogen bond with H1 and H2. This situation reflects onto the vibrational modes as follows. The $\nu_1$ mode appears at a slightly higher frequency (+3 cm$^{-1}$), which is unexpected because the Mo–H1 bond is slightly lengthened by the hydrogen bond. The $\nu_2$ mode exhibits a moderate low-frequency shift (–16 cm$^{-1}$; a compromise between the Mo–H2 bond weakening and the Mo–H3 bond strengthening), whereas the $\nu_3$ mode correspondingly shows a moderate high-frequency shift (+3 cm$^{-1}$) for the same reasons.

For system **B1**, on the other hand, the charge on H1 remains unchanged, whereas it increases significantly on H2 (–0.073) *and also on the Mo atom* (–0.051), suggesting that the metal center also participates directly in the hydrogen bonding. The O–H···Mo distance is 0.1 Å shorter in **B1** than in **B2**. A folding of the O–H vector along the H1H2 axis by 141.2° toward the metal, in the opposite direction from the Cp ring, signals an interaction that forces the proton donor to approach the metal center. These changes suggest the description of adduct **B1** as featuring a bifurcated hydrogen bond to H2 and Mo. Note that, whereas the H···H distances would suggest that hydrogen bonding with H2 is stronger in **B1** than in **B2** (1.779 Å vs. 1.799 Å), the Mo–H2 distance shortens (–0.004 Å), rather than lengthens, in **B1**. In addition, the charge on H2 increases to a smaller extent in **B1** than in **B2**. These perturbations may be caused by the Mo···HO interaction and suggest that conclusions about the hydrogen bond nature in a complicated polyatomic system should not be based solely on the H···H distances. The low-frequency shift for $\nu_1$ (–12 cm$^{-1}$) correlates with the lengthening of the Mo–H1 bond and the strong high-frequency shift for $\nu_2$ (+23 cm$^{-1}$) correlates with the Mo–H2 bond compression, whereas there is no clear correlation with the H···H distances. Note that system **B1** exhibits mixing of the Mo–H1 and Mo–H2 vibrations in $\nu_1$ and $\nu_2$, whereas $\nu_3$ is an essentially pure Mo–H3 vibration. The latter experiences no shift relative to the free trihydride compound, consistent with the invariance of the Mo–H3 bond length.

Finally, system **C** shows a dramatic increase of the metal negative charge ($\Delta q$ = –0.106), whereas the charge on H3 increases only slightly ($\Delta q$ = –0.019). Together with the structural features discussed above, these charge variations suggest that the bonding in this adduct is dominated by the metal site, and is unique amongst all the optimized adducts **A**–**C** in this respect. It is interesting to observe that not only is the Mo–H3 bond elongated in this adduct (+0.007), but the Mo–H2 bond is also (+0.008 Å), whereas the Mo–H1 bond is slightly shortened. There is no obvious explanation for this phenomenon. The evolution of the normal modes

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

is again in line with the observed changes of Mo–H bond lengths: $\nu_1$ shows a small high-frequency shift (+4 $cm^{-1}$), whereas $\nu_2$ and $\nu_3$ exhibit large low-frequency shifts (–33 and –20 $cm^{-1}$, respectively).

### *Hydrogen-Bonded Adducts with TFE: Relative Stability*

The relative stability of these systems was estimated in different ways (see Table 5). Comparing the energy changes associated to the hydrogen bond formation, the stronger interactions are those involving the two equivalent hydride ligands. Structures **B** show the most exothermic hydrogen bond. This behavior can be traced back to the establishment of two dihydrogen bonds in **B1** and **B2** or only one strong dihydrogen bond in **B3**.[18] Although the primary interaction is shorter in system **B3**, the relative stability of the three systems is not too different. A fast exchange of the ROH molecule between the three **B** sites can be expected from the structural features and low energy differences found between the three isomers. The interactions at the unique hydride site (**A**) and at the metal site (**C**) have similar energies, around 2 kcal $mol^{-1}$ less exothermic than for the **B** structures. A fast exchange between the **A** and **C** sites can be also expected. The gas-phase complexation energies span a range between 9 and 12 kcal $mol^{-1}$, similar to those calculated for the same kind of interactions in other transition-metal hydride systems,[15,17,18] and notably higher than the experimental enthalpies. Previous results concerning hydrogen bonding in transition-metal systems showed that the Basis Set Superposition Error (BSSE) can be very important in this type of system.[18] BSSE-corrected bonding energies have been calculated, showing that the BSSE accounts for 40–50% of the interaction energy. However, after correction all the adducts are still stable, with interaction energies between 5 and 8 kcal $mol^{-1}$. It is worth mentioning that a negative and significant interaction energy remains at the metal site after the BSSE correction, in contrast with what we have found in a recent study of the hydrogen bonding to the [Cp*Fe(dppe)H].[15] This result demonstrates the basicity of the molybdenum center in this compound and points towards competition between the hydride and the metal sites for the proton.

Table 5. Calculated parameters of the hydrogen bonding between [CpMo(dpe)$H_3$] and TFE.

| | A | B1 | B2 | B3 | C |
|---|---|---|---|---|---|
| $\Delta E$ [kcal $mol^{-1}$] | –9.6 | –11.3 | –11.2 | –11.5 | –10.4 |
| $\Delta E$(BSSE)[a] [kcal $mol^{-1}$] | –5.1 | –7.9 | –7.8 | –5.9 | –5.9 |
| $\Delta H$(BSSE)[b] [kcal $mol^{-1}$] | –3.5 | –6.0 | –6.1 | –5.9 | –4.3 |
| $\nu$(OH) [$cm^{-1}$] | 3617 | 3553 | 3605 | 3552 | 3576 |
| $A$ ($10^{-4}$) [L $mol^{-1}$ $cm^{-2}$] | (4.99) | (7.25) | (7.15) | (7.77) | (6.23) |
| $\Delta H(\Delta\nu)$[c] [kcal $mol^{-1}$] | –4.3 | –5.2 | –4.5 | –5.2 | –4.9 |
| $\Delta H(\Delta A)$[d] [kcal $mol^{-1}$] | –4.7 | –5.8 | –6.0 | –6.3 | –5.5 |
| $\Delta G(CH_2Cl_2)$[e] [kcal $mol^{-1}$] | –1.6 | –3.1 | –3.2 | –3.4 | –2.8 |

[a] Complexation energy corrected by the basis set superposition error. [b] Complexation enthalpy, taking the BSSE-corrected energy. [c] Application of Equation (1),[34] using the computed $\Delta\nu$(OH). [d] Application of Equation (3),[35] using the computed intensities $A$. [e] Complexation free energy in dichloromethane.

The calculated enthalpies, taking the BSSE-corrected energies, are slightly decreased, but the ordering **B** > **C** > **A** is preserved. The interaction enthalpy was also estimated on the basis of Iogansen's empirical relationships [Equation (1)[34] and Equation (3)[35]] using the computed $\nu$(OH) stretching vibration frequencies or $\nu$(OH) band intensities $A$, which are also reported in Table 5. Remarkably, the $\Delta H$ computed in the different ways are very similar. Indeed, the highest values obtained (about 6 kcal $mol^{-1}$) are close to the experimental hydrogen-bond enthalpies. The $\nu$(OH) bands are found at lower frequency {$\Delta\nu$(OH) = 227–292 $cm^{-1}$}, and with a dramatically increased intensity [from $0.38\times10^4$ L $mol^{-1}$ $cm^{-2}$ in free TFE to (4.99–7.77)$\times10^4$ L $mol^{-1}$ $cm^{-2}$ in the H-bonded adducts], in good agreement with the experimental observations. Both correlations work well for medium-strength hydrogen bonds of organic bases and appear to be successfully applicable also to organometallic complexes.[12,13] Note that Equation (3) is considered as universal (valid for different types of H complexes in solution or in the gas phase) and more precise.

$$\Delta H = 2.9\Delta A^{1/2} = 2.9(A^{1/2}_{\text{bonded}} - A^{1/2}_{\text{free}}) \quad (3)$$

PCM calculations give the solvation free energy of a species, and its partition into enthalpic and entropic parts is not possible.[36] From the $\Delta G_{solv}$ of free [CpMo(dpe)$H_3$], free TFE, and their adduct, it is possible to get a rough estimation of the $\Delta G$ of the hydrogen-bond formation in solution, which does not take into account the internal contributions to the entropy. The $\Delta G$ obtained in this way for adducts **A**–**C** in $CH_2Cl_2$ are collected in Table 5. Although the $\Delta G(CH_2Cl_2)$ are less exothermic than the $\Delta H$ in gas phase, for all the adducts $\Delta G(CH_2Cl_2)$ is negative, pointing out the stability of the hydrogen-bonded species in solution. Moreover, the ordering **B** > **C** > **A** is maintained.

### *Protonation Products*

The calculations on the protonation product, the system having the $[CpMo(dpe)H_4]^+$ stoichiometry, reveal the existence of two stable local minima for the classical tetrahydride complex and another two for a dihydrogen–dihydride tautomer, $[CpMo(dpe)(H_2)H_2]^+$. They can be envisaged as the products of the proton transfer to the different proton-acceptor sites revealed by the hydrogen-bonded adducts. The optimized structures are shown in Figure 11. Relevant geometrical parameters are available as Supporting Information.

The most stable isomer is the tetrahydride **TETRA1**. This structure presents a rather symmetrical arrangement, with two hydrides at each side of the plane defined by the two phosphorus atoms and the center of the Cp ring. The tetrahydride nature of this complex is evident from the H···H distances, the shortest one being 1.799 Å. There are two sets of Mo–H distances, longer (1.708 and 1.706 Å) for the two most distant hydrides, and shorter (1.671 and 1.674 Å) for the closest ones. The geometry of **TETRA1** agrees with the experimental structure of $[Cp^*WH_4(dppe)]^+$ and its description as a distorted pseudopentagonal bipyramid (see Scheme 2).[19] The four H ligands are practically in the same

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

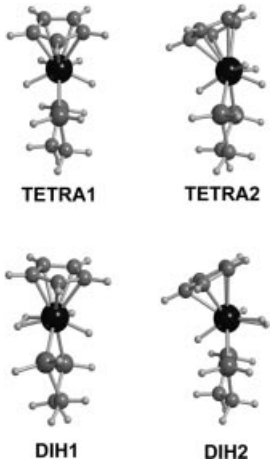

Figure 11. Views of the optimized geometries for isomeric structures having the [CpMo(dpe)H$_4$]$^+$ stoichiometry.

plane (the fourth H is only 0.010 Å away) and one P atom is only 0.035 Å away from the least-squares $H_4$ plane. The five angles between adjacent bonds in the pseudopentagonal plane are relatively similar and close to that expected for the equatorial ligands in a pentagonal bipyramid (72°). **TETRA1** can be considered the product of proton transfer to the metal site, although it may also result from the oxidative addition of a coordinated dihydrogen ligand. Both possibilities will be considered in the next two sections.

The second tetrahydride minimum, **TETRA2**, has three hydrides on one side of the P–Cp$_{centroid}$–P plane and one on the opposite side. The Mo–H distances for the three hydrides on the same side are 1.666, 1.710, and 1.668 Å, the longest one being that to the central hydride. The shortest H···H distance is 1.602 Å (H1···H2), in agreement with the tetrahydride nature of this isomer. The Mo–H distance of the unique hydride H3 is 1.691 Å. **TETRA2** could be regarded as the protonation product at the metal site close to hydrides H1 and H2. **TETRA2** is considerably less stable than **TETRA1**, lying 8.0 kcal mol$^{-1}$ higher.

Two dihydrogen–dihydride structures have been characterized as local minima (**DIH1** and **DIH2**). Their geometries are comparable to that of the parent complex [CpMo(dpe)H$_3$], but with a $\eta^2$-H$_2$ ligand in place of a hydride. **DIH1** is the most stable dihydrogen–dihydride isomer, only 3.7 kcal mol$^{-1}$ above **TETRA1**. The presence of a dihydrogen ligand in the coordination sphere of the metal is apparent from the H–H distance of 0.896 Å between the adjacent H3 and H4 atoms. This structure is reached by protonation of the unique hydride H3 in the initial trihydride. The second dihydrogen–dihydride isomer (**DIH2**) is attained by proton transfer to the H1 or H2 ligands. The H–H distance in the dihydrogen ligand (0.851 Å) is shorter than in **DIH1**, indicating a weaker metal–H$_2$ interaction. In agreement with this, **DIH2** is less stable than **DIH1**, 5.1 kcal mol$^{-1}$ above **TETRA1**.

We have also considered the relative stability of the four [CpMo(dpe)H$_4$]$^+$ isomers in dichloromethane. There is little change on going from the gas phase to the $CH_2Cl_2$ medium. The tetrahydride **TETRA1** remains the most stable species in $CH_2Cl_2$, with **TETRA2**, **DIH1**, and **DIH2** being placed 6.6, 3.3, and 5.0 kcal mol$^{-1}$ above **TETRA1**.

To assess how the chosen model affects the results, we have studied the protonation products in the full system, performing full QM calculations on the actual [Cp*Mo(dppe)H$_4$]$^+$ complex. The four stable structures found for the model [CpMo(dpe)H$_4$]$^+$ system have also been located in the full system, with very similar arrangements of the $MoH_4$ unit to the model systems. A general view of the optimized geometries is shown in the Supporting Information. As can be appreciated in Table S1, the structural changes induced by the modeling of the real ligands are minor.

The relative energies of the different isomers of the full system are comparable to those of the model system. The tetrahydride **TETRA1** is still the most stable species, with **TETRA2**, **DIH1**, and **DIH2** placed 7.0, 4.4, and 6.6 kcal mol$^{-1}$ above **TETRA1**. Thus, the calculations indicate that the classical tetrahydride product **TETRA1** is strongly favored relative to all possible dihydrogen structures. This result agrees with the experiment, as the tetrahydride is the only observed protonation product. The presence of dihydrogen–dihydride species at low relative energies suggests that they may be intermediates along the proton-transfer pathway.

The simplifications introduced in the modeling of the system have very little influence in the relative energies of the protonation products. To further check the differences between the model and the full systems we have computed the gas phase proton affinity (PA), that is the energy change associated to Equation (4)

$$([Mo]\text{-}H_3) + H^+ \rightarrow ([Mo]\text{-}H_4)^+ \quad (4)$$

where [Mo] stands for CpMo(dpe) or Cp*Mo(dppe) and **TETRA1** has been considered the protonation product. The model system presents a slightly lower proton affinity (249.9 kcal mol$^{-1}$) than the full system (271.0 kcal mol$^{-1}$), but the difference amounts to only 8%. As all four protonated structures have very similar relative energies in the full and model systems, we can conclude that all the proton-acceptor sites of the $MoH_3$ unit are a little more basic in the full system than in the model one.

### *Proton-Transfer Reaction Profiles with HFIP*

We have also carried out a study of the [CpMoH$_3$(dpe)·HFIP] adduct, analogous to that illustrated above for the [CpMoH$_3$(dpe)·TFE] adduct. The results are not detailed for the sake of brevity, but the main outcome is that five hydrogen-bonded structures comparable to the **A**–**C** ones reported for TFE (Figure 9) have been located, which will be correspondingly labeled **A′**, **B1′**, **B2′**, **B3′**, and **C′**. They follow the same stability ordering **B′** > **C′** > **A′**, with slightly increased interaction energies, caused by the stronger acidity of HFIP compared with TFE. For instance, the $\Delta H$(BSSE) are –3.9, –6.3, –5.7, –6.8, and –4.4 kcal mol$^{-1}$ for the HFIP adducts **A′**, **B1′**, **B2′**, **B3′**, and **C′**, respectively.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

When one imagines the reaction trajectory leading to proton transfer, it can be predicted that system **C′** may lead to the classical tetrahydride complex directly, whereas systems **A′**–**B′** could yield dihydrogen intermediates. The most stable protonation product (**TETRA1**) formally arises from proton transfer to **C′**, whereas the most stable dihydrogen complex (**DIH1**) may be viewed as formally arising from proton transfer from **A′** to the H3 hydride site. For this reason we have studied both proton-transfer pathways. In addition, the close vicinity of the protonation sites in the **A′** and **C′** structures will allow a study of the direct competition for the proton between a hydride and the metal sites and a discussion of whether a direct proton transfer to the metal is possible in this case.

Starting from the hydrogen-bonded adducts **C′** and **A′**, the final products of the proton transfer should be the ion pairs made up by the **TETRA1** (metal site protonation) or **DIH1** (hydride site protonation) cations and the $[(CF_3)_2HCO]^-$ (**[X]**$^-$) anion. However, whereas the optimization of the **TETRA1·[X]** ion pair was successful, attempts to optimize the **DIH1·[X]** ion pair failed. Several optimizations starting from different input geometries were tried but led systematically to the same initial hydrogen-bonded adduct. The optimized geometries of hydrogen-bonded complexes and the ion pair are available in the Supporting Information.

As no stable dihydrogen–conjugate base ion pair was found, we have not pursued the proton-transfer pathway at the hydride site. We have further explored the protonation at the metal. Initially the gas-phase reaction profile leading from **C′** to **TETRA1·[X]** has been investigated by using the O–H distance of the HFIP donor as the pivot parameter along the reaction coordinate, all other geometrical parameters being optimized. Then, the maximum of this curve has been used as the starting point to locate the transition state, which practically coincides with this maximum. The profile in the dichloromethane solvent was obtained from single-point calculations on each point of the gas-phase profile with the solvent PCM. The energy of the starting hydrogen-bonded adduct **C′** was taken as the zero of energy. The energetic profiles are depicted in Figure 12.

The gas-phase energy barrier to form the ion pair at the metal site is 24.7 kcal mol$^{-1}$. The $CH_2Cl_2$ solvent slightly favors the kinetics of the proton transfer, decreasing the energy barrier to 22.8 kcal mol$^{-1}$. In the transition state the O–H bond is completely broken (O–H = 1.581 Å) and the Mo–H bond is almost formed (Mo–H = 1.795 Å). The distance between the proton that is being transferred and the contiguous H3 hydride (1.795 Å) is too long to consider the formation of a dihydrogen ligand. Thus, even in this crowded system there is a pathway for protonating the metal, without involvement of the hydride ligands.

There is experimental evidence that the participation of a second molecule of the proton donor might be crucial for the proton transfer to transition-metal hydride by means of the so-called homoconjugate pairing effect.[8,16,27] In our previous theoretical studies, the second proton donor molecule was used to locate the gas-phase minima of the proton-

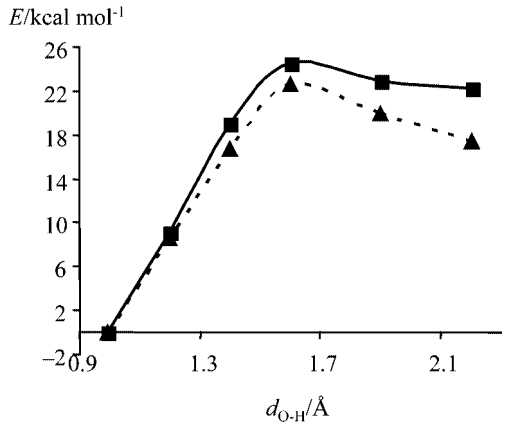

Figure 12. Potential energy curves for the proton transfer from HFIP to the Mo trihydride at the metal site. Plain curve and squares: in the gas phase; dashed line and triangles: in dichloromethane solution. The O–H length of the transferring proton has been taken as the reaction coordinate.

ated species.[15,17,18] Thus, we have also studied the proton transfer to complex $[CpMo(dpe)H_3]$ with two HFIP molecules.[15,27] The final products of the proton transfer are the ion pairs made up by the **TETRA1** or **DIH1** cations and the $[(CF_3)_2HCO\cdots HOCH(CF_3)_2]^-$ (**[XHX]**$^-$) homoconjugate anion. With the inclusion of the second AH molecule, both ion pairs give stable local minima and it is possible to study the proton-transfer process both at the metal and hydride sites. The corresponding starting points are the hydrogen-bonded adducts **C′·HFIP** and **A′·HFIP**, with a second HFIP molecule joined by a O···H hydrogen bond to the first HFIP molecule. The optimized geometries are available in the Supporting Information.

The thermodynamic viability of the proton transfer involving a second alcohol molecule [Equation (5)] is very different from the situation shown above for a single HFIP molecule. Now the reaction is clearly exothermic, by –5.2 kcal mol$^{-1}$ for the **C′**+HFIP/**TETRA1·[XHX]** couple and –3.2 kcal mol$^{-1}$ for the **A′**+HFIP/**DIH1·[XHX]** one. $\Delta G(CH_2Cl_2)$ values, although considerably decreased (–1.6 and –0.7 kcal mol$^{-1}$ for **TETRA1** and **DIH1**, respectively), suggest the thermodynamic feasibility of the reaction in dichloromethane and indicate that the equilibrium is displaced toward the right. The presence of a strong hydrogen bond in the homoconjugated pair has a substantial impact on the overall reaction energy.

$$[CpMoH_3(dpe)\cdots HOCH(CF_3)_2] + (CF_3)_2CHOH \rightarrow [CpMo(dpe)\text{“}H_4\text{”}]^+\cdot[(CF_3)_2CHO\cdots H\cdots O\text{–}CH(CF_3)_2]^- \quad (5)$$

Both reaction profiles, leading from **A′·HFIP** to **DIH1·[XHX]** and from **C′·HFIP** to **TETRA1·[XHX]**, have been investigated, both in the gas phase and in dichloromethane solvent, taking the O–H distance of the transferring proton as the reaction coordinate. The energy of the starting hydrogen-bonded adduct was taken as the zero of energy in each case. The energetic profiles are depicted in Figure 13.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

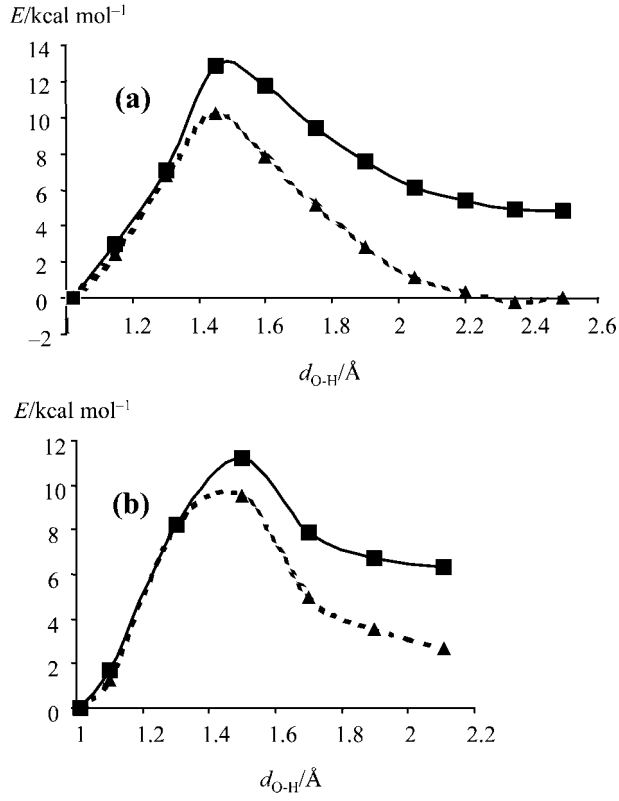

Figure 13. Potential energy curves for the proton transfer from two HFIP molecules to the Mo trihydride: (a) at the metal site; (b) at the hydride site. Plain curves and squares: in the gas phase; dashed lines and triangles: in dichloromethane solution. The O–H length of the transferring proton has been taken as the reaction coordinate.

The gas-phase barriers to form the ion pair at the hydride and the metal site are 11.2 and 12.9 kcal mol$^{-1}$, respectively. As already found with one HFIP molecule, the $CH_2Cl_2$ solvent favors the kinetics of the proton transfer, decreasing the energy barriers to 9.4 and 10.2 kcal mol$^{-1}$, respectively. The ion pairs resulting from the protonation at the hydride ([**DIH1**]$^+$·[**XHX**]$^-$) and metal site ([**TETRA1**]$^+$·[**XHX**]$^-$) are found to be 6.3 and 4.8 kcal mol$^{-1}$, respectively, above the hydrogen-bonded complexes in the gas phase, and 2.7 above and 0.3 kcal mol$^{-1}$ below, in dichloromethane. The solvent also favors the thermodynamics of the proton transfer, stabilizing the charged species to a greater extent than the initial neutral hydrogen-bonded ones. The role played by the homoconjugate pairing in the proton-transfer process can be appreciated following the evolution of the two O–H distances of the HFIP dimer throughout the protonation process. In the hydrogen-bonded initial species **A′·HFIP** and **C′·HFIP** there is a normal hydrogen bond between the oxygen atom of the first HFIP molecule and the proton of the second one. The O···O and O···H distances are 2.718 and 1.761 Å in **A′·HFIP** and 2.703 and 1.745 Å in **C′·HFIP**. The O–H bond of the second HFIP molecule is only slightly lengthened by the hydrogen bond interaction (O–H = 0.980 and 0.981 Å in **A′·HFIP** and **C′·HFIP**, respectively; the O–H distance in free HFIP is 0.968 Å). The presence of a strong [A···H···A]$^-$ hydrogen bond in the anion of the ion pair can be inferred from the shortening of the O···O distance (2.439 and 2.396 Å in [**DIH1**]$^+$·[**XHX**]$^-$ and [**TETRA1**]$^+$·[**XHX**]$^-$, respectively). The O··H distances (1.359 and 1.241 Å) and O–H–O angles (178.5 and 178.1°) also agree with a proton shared by two [**X**]$^-$ units. The acidity of the coordinated dihydrogen makes the homoconjugate anion interact more strongly with the H of the dihydrogen than with that of the tetrahydride (M–H···O distances of 2.467 and 2.493 Å in [**DIH1**]$^+$·[**XHX**]$^-$ and [**TETRA1**]$^+$·[**XHX**]$^-$, respectively). In opposition, the O···H···O interaction in the homoconjugate anion is stronger in [**TETRA1**]$^+$···[**XHX**]$^-$ than in [**DIH1**]$^+$···[**AHA**]$^-$, according to both O···O and O···H distances.

### *Dihydrogen–Dihydride → Tetrahydride Interconversion in the Ion Pair*

To solve the dichotomy between easy protonation at the hydride site and no detection of dihydrogen intermediates, we have studied the interconversion from the [**DIH1**]$^+$···[**XHX**]$^-$ to the [**TETRA1**]$^+$···[**XHX**]$^-$ ion pair. As in previous studies of dihydrogen → dihydride interconversions,[37] we have chosen the H–H distance as a reaction coordinate for the H–H bond breaking. This distance varies from 0.884 Å in the dihydrogen structure to 1.812 Å in the tetrahydride. For each fixed value of the reaction coordinate all the other geometrical parameters, including those of the homoconjugate anion, were optimized. The profiles in dichloromethane solvent were obtained from single-point calculations on each point of the gas-phase profiles with the solvent PCM. The energy of the dihydrogen ion pair was taken as the zero of energy. The energetic profiles in gas phase and $CH_2Cl_2$ are depicted in Figure 14.

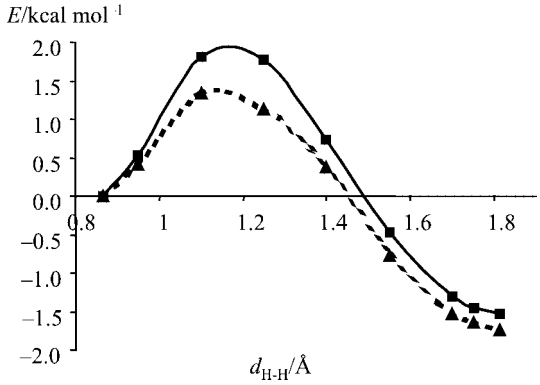

Figure 14. Potential energy curve for the interconversion from the ([**DIH1**]$^+$·[**XHX**]$^-$) to the ([**TETRA1**]$^+$·[**XHX**]$^-$) ion pairs. Plain curves and squares: in the gas phase; dashed lines and triangles: in dichloromethane solution. The H–H length of the coordinated dihydrogen has been taken as the reaction coordinate.

The calculations illustrate that the dihydrogen–dihydride → tetrahydride rearrangement in the ion pairs easily takes place. The energy barrier is only 1.8 kcal mol$^{-1}$ in gas phase and 1.3 kcal mol$^{-1}$ in $CH_2Cl_2$. The homoconjugate anion

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

does not appreciably change its position along the interconversion, as proved by the evolution of the H···O distance (from 1.359 Å in the dihydrogen structure to 1.241 Å in the tetrahydride). The process is exoergic, ending up in a tetrahydride ion pair 1.5 kcal mol$^{-1}$ more stable than the initial dihydrogen in the gas phase (–1.7 kcal mol$^{-1}$ in $CH_2Cl_2$). The solvent influence in this process is very small because it does not involve a charge change.

### *Dihydrogen Evolution*

We have theoretically studied the successive elimination of two $H_2$ molecules in the model [CpMo(dpe)$H_3$]–TFE system. The results are graphically assembled in Figure 15 and discussed only briefly here. More details can be found in the Supporting Information. The significant difference between the results in the gas phase and in $CH_2Cl_2$ can be attributed to the solvation of the free TFE molecules (note that the gap is about twice greater when both molecules have been consumed, relative to the intermediate situations where only one has been consumed). The results show that the first $H_2$ elimination, affording the [CpMo(dpe)-$H_2$($OR_F$)] intermediate (unobserved for the real system), is less favorable than the process leading to loss of two $H_2$ molecules. Note also that the $H_2$ elimination process will further benefit from an entropic drive. Furthermore, the subsequent addition of a second alcohol molecule, to afford the 18-electron adduct, results in a significant stabilization. At least part of this stabilization may be attributed to the intramolecular hydrogen bond. Thus, the calculations point to the identity of the final product as a solvated species. It is also of interest to mention that the 16-electron [CpMo-(dpe)($OR_F$)] intermediate prefers to adopt a singlet ground state (the triplet is higher in energy by 6.5 and 7.3 kcal mol$^{-1}$ in the gas phase and in solution, respectively). On the other hand, a parallel calculation on [CpMo($PMe_3$)$_2$(OH)] shows that the triplet is 2.3 kcal mol$^{-1}$ lower than the singlet, in agreement with the experimental observation or paramagnetism for this molecule.[30,31]

## Discussion

It has been shown in previous spectroscopic[14,38] and theoretical[15,17,39] studies of monohydride compounds that the MH···HX interaction weakens the MH bond (low-frequency shift for the M–H stretching vibration), whereas the HM···HX interaction strengthens it (high-frequency shift). The present contribution reports the first detailed analysis of the effect of hydrogen bonding on the M–H stretching vibrations for a polyhydride compound where the individual M–H stretching components are heavily mixed into the normal modes. The first outcome of this investigation is that the variation of the vibrational frequencies can be predicted, in most cases, by extension of the previously established trends for monohydride complexes:[12,13] normal modes whose main contribution is from M–H vibrations where the hydride is directly implicated in hydrogen bonds as a proton acceptor experience a low-frequency shift. Conversely, normal modes whose main contribution is from M–H vibrations where the hydride is not directly implicated in hydrogen bonds (either the metal center or other hydride ligands act as the proton-acceptor site) experience a low-frequency shift. However, the contribution of various M–H stretching vibrations, some of which may be proton acceptors in hydrogen bonds while others may not, in the normal modes calls for a more detailed and in-depth analysis.

Secondly, the existence, in the present case, of additional interactions with other neighboring proton-accepting sites may be the major cause of the complicated changes found, for example the changes of certain Mo–H bond lengths that are found to be opposite to expectations based on H···H distances (e.g., shortening of Mo–H2 in **B1**, lengthening of Mo–H2 in **C**). An interaction involving exclusively the metal center, without involvement of at least secondary interactions with hydride ligands, does not occur for this compound. It can be easily imagined, by extrapolation, that a direct hydrogen bond with a metal site may be difficult in general, if not impossible, when the system has a relatively

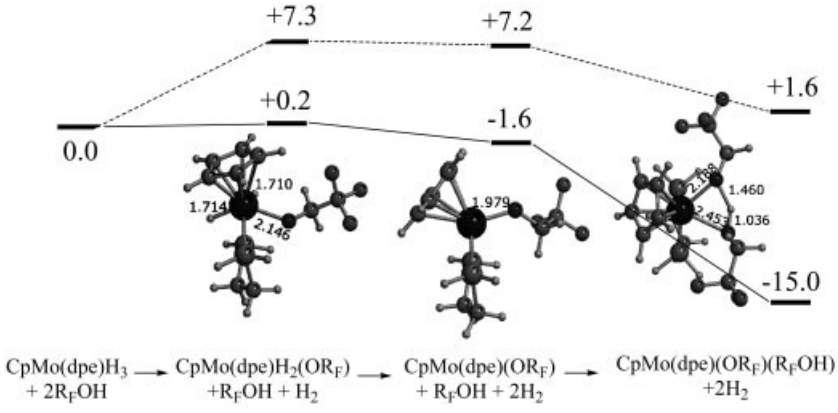

Figure 15. Computed energy profile (solid lines: gas phase; dashed lines: $CH_2Cl_2$ solution) in kcal mol$^{-1}$ for the $H_2$ elimination from complex [CpMo(dpe)$H_3$] ($R_F$OH = TFE). Full details are reported in the Supporting Information.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

crowded coordination sphere and especially when more than one hydride ligand is present. Also, the same circumstances may favor the establishment of simultaneous interactions with more than one hydride ligand.

The computational study allows rather good reproduction of the experimentally determined hydrogen bond enthalpy for the [Cp*Mo(dppe)$H_3$]·TFE interaction by use of the [CpMo(dpe)$H_3$] model system. The calculations also indicate that the most stable hydrogen-bonded adducts between [CpMo(dpe)$H_3$] and TFE are complexes **B**, where the proton donor approaches the complex from the side of the molecule containing hydrides H1 and H2. Structure **B3**, which yields the lowest energy minimum, is also the model structure that best reproduces the experimentally observed frequency shifts: the $\nu_2$ band experiences a large low-frequency shift and appears 3 $cm^{-1}$ lower than $\nu_3$ mode in free trihydride, whereas the $\nu_3$ band experiences a large high-frequency shift, ending up near the position of the $\nu_2$ mode in free trihydride (compare Figure 8 and Figure 10). The composition of the normal modes is in agreement with this interpretation (the low-frequency band in **B3** has the major component from the Mo–H2 vibration, whereas the low-frequency band in the free trihydride is mostly a Mo–H3 vibration). The other structural models of the hydrogen-bonded adduct (**A**, **B1**, **B2**, and **C**) yield calculated normal mode frequency patterns in greater discrepancy with the experiment. In conclusion, it seems that the proton donor approaches the complex from the side of the molecule containing the hydrides H1 and H2, and establishes a hydrogen bond with the hydride H2.

One interesting issue for proton-transfer reactions to hydride molecules is the number of proton donor molecules that are involved in proton transfer. Although the involvement of only one molecule should be sufficient in principle, it has been shown in several cases that the protonation product contains the homoconjugate anion, therefore implicating two proton donor molecules in the reaction stoichiometry.[8,16,17] It was also shown by kinetics investigations that a second proton donor molecule is necessary to trigger proton transfer from fluorinated alcohols to the hydride complex [Cp*Fe(dppe)H].[15,27] On the other hand, when the stronger acid $CF_3COOH$ was used with the same hydride system, even a single acid molecule was sufficient to transfer the proton. Theoretical calculations have also shown that the involvement of a second proton donor (HX) molecule strengthens hydrogen bonding of the first HA molecule with the proton acceptor in the MH···HX···HX adduct.

The basicity of the hydride ligand of Cp*$MoH_3$(dppe) ($E_j = 1.42 \pm 0.02$) is higher than that of trihydride complexes studied previously [compare with $E_j$ of 0.93 for $Cp_2NbH_3$[18] and 0.94 for Cp*$RuH_3(PCy_3)$][40] and is among the highest reported in the literature.[13] Consequently, it can be protonated by such a weak acid as TFE. Two separate experiments on the proton-transfer process indicate that complex Cp*$MoH_3$(dppe) is able to accept a proton from a *single* molecule of proton donor, at least from donors as weak as HFIP. The UV/Vis study of the Cp*$MoH_3$(dppe)–PNP ($P_i = 1.27$) interaction shows a breakpoint at a 1:1 ratio and a visible band consistent with the formation of the [Cp*(dppe)$MoH_4$]$^+$···[OAr]$^-$ ion pair. On the other hand, the kinetic study of the Cp*$MoH_3$(dppe)–HFIP ($P_i = 1.05$) interaction illustrates the need for only one HFIP molecule to reach the transition state for proton transfer. This situation markedly differs from that previously established for the protonation of the less basic hydride ligand in complex [Cp*Fe(dppe)H] ($E_j = 1.35 \pm 0.02$), where a second molecule is necessary.[27] Interestingly, the formation of hydrogen-bonded ion pairs is not only evident from the UV/Vis study of the Cp*$MoH_3$(dppe)–PNP system, but also from the $^1$H NMR spectroscopic data through the different $T_1$ values obtained for the TFE and $HBF_4$ protonation products (Table 2), although the latter result cannot distinguish between the simple ($X^-$) and the homoconjugate ($XHX^-$) anion.

The low-temperature NMR study does not show any evidence for the formation of a dihydrogen intermediate, whereas the low-temperature IR study suggests that the preferred hydrogen-bonding pathway involves the hydride ligand. Thus, an intermediate dihydrogen complex along the proton-transfer pathway may be expected. The computational investigation suggests that, both in gas phase and in dichloromethane, the tetrahydride ion pair resulting from the protonation at the metal site is more stable than the dihydrogen–dihydride ion pair arising from the hydride protonation, in agreement with the experiment. Both proton-transfer pathways leading to hydride and metal protonation show low barriers, in agreement with the experimental evidence of a very fast process. However, these values are rather similar (9.4 and 10.2 kcal mol$^{-1}$ for proton transfer from the HFIP dimer in $CH_2Cl_2$), indicating that in this molybdenum trihydride there is no clear kinetic preference for the protonation at the hydride site. This theoretical result contrasts with the commonly admitted kinetic preference for the protonation at the hydride site, and with a recent theoretical study of the protonation of CpFe(dpe)H with two HFIP molecules.[15]

If the nonclassical intermediate indeed forms during the proton-transfer process, its activation barrier to the rearrangement leading to the classical tetrahydride product must be very low. Indeed, a very low barrier for the rearrangement of the model compounds ([**DIH1**]$^+$···[**XHX**]$^-$ to [**TETRA1**]$^+$···[**XHX**]$^-$ where HX = HFIP) is shown by the calculations. Note that this rearrangement does not necessitate any ion pair dissociation, as the anion does not appreciably change its position along the interconversion.

To summarize, the tetrahydride product can originate either from the direct protonation at the metal site or from the fast isomerization of the dihydrogen intermediate and the available experimental and theoretical results do not allow us to clearly distinguish these two possibilities. The involvement of a transient dihydrogen species in the formation of trihydride by protonation of a transition-metal dihydride has been reported in a mechanistic study of the protonation of $Cp_2MH_2$ (M = Mo, W) by an excess of anhydrous HCl.[41]

## Conclusions

The unambiguous determination of the hydrogen-bonding site for a polyhydride compound by NMR and IR spectroscopic techniques is not an easy task. The high fluxionality of polyhydride complexes on the NMR timescale renders the application of this method less straightforward, while the use of vibrational spectroscopy is complicated by the normal mode structure and weak intensity of the M–H stretching bands. The theoretical analysis of the vibrational modes, which was performed here for the first time for a transition-metal polyhydride compound in the absence and presence of hydrogen bonding, shows a different behavior for each M–H vibrational normal mode. Nevertheless, the evolution of the vibrational frequencies follows in most cases the trends previously established for monohydride complexes: a low-frequency shift for modes that primarily involve the M–H vibrations where the H ligand is implicated in the hydrogen bond and a high-frequency shift for modes that primarily involve M–H vibrations where the H ligand is not implicated in the hydrogen bond (hydrogen bonding to other hydride ligands or to the metal atom). According to the calculations the most stable hydrogen-bonded adducts are those where the proton donor approaches the $Cp^*MoH_3(dppe)$ complex from the side of the molecule containing the hydrides H1 and H2. Of these, the one giving good agreement with the experimental IR observations features a hydrogen bond with H2.

Dihydrogen bond formation precedes the proton transfer to form the cationic tetrahydride $[Cp^*(dppe)MoH_4]^+$ complex, stabilized by hydrogen bonding to the proton donor conjugate base. This is reversible at low temperatures (below 250 K) when using *p*-nitrophenol or TFE. The precursor $Cp^*(dppe)MoH_3$ complex is sufficiently basic to accept the proton from a single molecule of these two proton donors.

The experiments do not show any direct evidence for the formation of a dihydrogen intermediate, whereas the preferred hydrogen-bonding pathway, according to the computational study, appears to involve the hydride ligand. The intermediacy of a dihydrogen complex along the proton-transfer pathway is possible, as suggested by the computations. However, the calculated low barrier for its isomerization into the classical tetrahydride complex would rationalize our inability to observe it experimentally.

## Experimental Section

**General:** All manipulations were carried out under argon by standard Schlenk techniques. The $[Cp^*Mo(dppe)H_3]$ hydride was synthesized according to the literature.[19] All solvents used ($CH_2Cl_2$, THF, toluene) were dried using appropriate agents and freshly distilled prior to use.

**IR and UV/Vis Investigations:** IR measurements were performed on "Specord M82" and Infralum FTIR-81 (Lumex) spectrometers using $CaF_2$ cells (0.12 cm path length). In order to limit the significance of self-association phenomena, a concentration of the proton donor between 0.005 and 0.01 M was used for the ν(OH) measurements. The UV measurements were performed on Specord M-40 and Varian Cary 5 spectrophotometers. Low-temperature IR and UV measurements were carried out by use of a cryostat (Carl Zeiss Jena) in the 200–290 K temperature range. The accuracy of the temperature adjustment was ±0.5 K. The reagents were mixed at low temperature and the cold mixtures were subsequently transferred into the precooled cryostat.

**NMR Investigations:** NMR studies were carried out in standard 5-mm NMR tubes containing solutions of the complexes in $CD_2Cl_2$. $^1H$ and $^{31}P$ NMR spectroscopic data were collected with a Bruker AMX 400 spectrometer operating at 400.13 and 161.98 MHz, respectively. The conventional inversion-recovery-pulse method (180-τ-90) was used to determine the variable-temperature longitudinal relaxation time $T_1$. Low-temperature experiments were carried out in the 180–260 K temperature range using a TV-3000 Bruker temperature control unit. The accuracy and stability of temperature was ±1 K. All mixings between the alcohols and the hydride complexes were performed at low temperature.

**Stopped-Flow Investigations:** The stopped-flow kinetic runs were carried out at 293 K with a Bio-Logic SF20 apparatus coupled to a J&M TIDAS MMS-UV/Vis diode-array UV/Vis spectrophotometer using a cuvette with a 0.15-cm pathlength. The data were collected within the first 10 s, yielding reproducible results. Data analyses were carried out by using the SPECFIT3 global analysis package of programs.[42] At least three runs were averaged to yield the reported results.

**Computational Details:** Calculations were performed with the Gaussian98[43] package at the DFT/B3LYP level.[44–46] Effective core potentials (ECP) were used to represent the innermost electrons of the molybdenum atom as well as the electron core of phosphorus atoms.[47,48] The basis set for the Mo and P atoms was that associated with the pseudopotential,[47,48] with a standard double-ζ LANL2DZ contraction,[43] supplemented in the case of P with a set of d-polarization functions.[49] The carbon and hydrogen atoms of the transition-metal complexes that are not bonded to the metal atom, together with the atoms of proton donor molecules (C, F, H) that are not involved in hydrogen bonds, were described with a 6-31G basis set.[50] The carbon and hydrogen atoms directly bonded to the metal and the proton donor molecules' hydrogen and oxygen atoms involved in hydrogen bonding were described with a 6-31G(d,p) set of basis functions.[51] Geometry optimizations were carried out without symmetry restrictions and the resulting structures were characterized as minima by the real value of all 3N-6 vibrational frequencies. Solvent effects were taken into account by means of polarized continuum model (PCM) calculations,[52,53] using standard options.[43] The solvation free energies were computed in dichloromethane ($\varepsilon = 8.93$) at the gas-phase optimized geometries. The gas-phase complexation energies were corrected from the BSSE according to the counterpoise method of Boys and Bernardi.[54]

**Supporting Information** (for details see the footnote on the first page of this article): Table of optimized geometrical parameters for $[CpMo(dpe)H_3]$ and $[CpMo(dpe)H_4]^+$ complexes, views of optimized $[Cp^*Mo(dppe)H_3]$, $[Cp^*Mo(dppe)H_4]^+$, a variety of dihydrogen-bonded adducts, and a description of computational results on the $H_2$ elimination process from $[CpMo(dpe)H_4]^+$ (7 pages).

# Azide–Tetrazole Ring-Chain Isomerism in Polyazido-1,3,5-triazines, Triazido-*s*-heptazine, and Diazidotetrazines

**Anton Hammerl,[a] Thomas M. Klapötke,*[a] and Reginaldo Rocha[b]**

**Keywords:** ab initio calculations / Nitrogen heterocycles / Azides / Nitrogen

The azide–tetrazole isomerism in several polyazido-1,3,5-triazines, triazido-*sym*-heptazine, and some diazido-1,2,4,5-tetrazines was investigated by ab initio quantum chemical methods in order to determine whether the polyazides are suitable starting materials for the synthesis of the isomeric tetrazoles. The effects of solvation in $CCl_4$, DMSO and water on this isomerism were included using the self consistent reaction field (SCRF) method. The effect of amino- and nitro-substituents on the azide–tetrazole isomerism was also examined. In the gas phase all investigated polyazidoheterocycles do not cyclize to form tetrazoles. An electron-donating amino group favors the ring closure to tetrazoles, whereas an electron-withdrawing nitro group favors the azides. Solvation in polar solvents favors the formation of a tetrazole ring system due to higher charge separation in the tetrazole ring system, but for all polyazido-1,3,5-triazines, including triazido-*s*-heptazine, the effects of solvation are not strong enough to shift the equilibrium to the tetrazole side, which explains why several attempts to detect these compounds have failed. The monotetetrazoles of diazidotetrazine and bis(azido)azo-1,2,4,5-tetrazine and the ditetrazole of bis(azido)hydrazo-1,2,4,5-tetrazine are the minimum energy species in DMSO and water. Thus we predict that the diazidoazo- and hydrazotetrazines will readily cyclize to the tetrazoles in polar solvents.

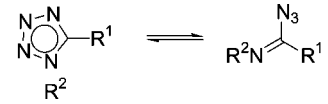
## Introduction

In recent years nitrogen-rich azidoheterocycles have been investigated as potential high energy density materials[1] and as precursors for carbon nitrides. Their clean and thermodynamically favorable decomposition, where only $N_2$ is released, makes them good precursors for nitrogen rich carbon nitrides, whose application is not only governed by texture and size of the particles,[2] but also by the relative nitrogen content. Nitrogen-rich carbon nitrides with the bulk formulas $C_3N_4$ and $C_3N_5$ have been prepared from cyanuric azide[3] as well as bis(azido)-1,2,4,5-tetrazine[4] and nitrides with the formulas $C_2N_3$ and $C_3N_5$ have been prepared from tetra(azido)azo-1,3,5-triazine.[5] Unfortunately, all described polyazides are very sensitive toward shock and friction and are classified as primary explosives. This makes the handling of these substances, especially in the amounts needed for commercial purposes, very difficult. The isomeric tetrazoles,[6] which are formed by an 1,5-dipolar cyclization[7] of the polyazides, are potential replacements for the hazardous polyazides. Even though we know of no precise data comparing the sensitivity of an azide to its isomeric tetrazole, the aromatic tetrazoles are, in general, less sensitive toward shock or friction than covalent azides. The nature of $R^1$ and $R^2$ determines whether the azide or the tetrazole isomer is dominant or whether both compounds are in equilibrium.[8] The open-ring azidoimine form is favored by electron-withdrawing groups and the tetrazole form is favored in the presence of electron-donating groups.[9] A wide series of fluoroalkyl-substituted imidoazyl azides is known that do not form a tetrazole.[10]



A key prerequisite for this cyclization is a *cis* orientation of the imino lone pair and the azide group. Therefore, electron-rich imidoazyl azides without the required conformation do not cyclize easily to the tetrazoles. Higher temperatures may help to overcome the activation barrier for tetrazole formation,[11] but higher temperatures generally favor the azide form.[12,13]

A decrease of solvent polarity shifts the equilibrium towards the azide form.[14] In the gas phase the reaction from the tetrazoles to the azides is exothermic.[15] Other reports indicate that the ring opening of the tetrazoles in the solid phase is endothermic.[16–18]

In this investigation we address several points regarding the azide–tetrazole isomerism of the polyazidoheterocycles shown in Figure 1. Earlier investigations of the azide–tetrazole isomerism of cyanuric azide showed that the azide groups of cyanuric azide do not cyclize to form tetrazoles, but that the reaction of cyanuric acid with $PPh_3$ leads to triphenylphosphanimino compounds where an azide group is in equilibrium with the ring-closed tetrazole in solution and a tetrazole is formed upon precipitation.[19,20] While no tetrazole formed from a polyazido-1,3,5-triazine has yet been detected, the mono- and ditetrazoles of diazido-1,2,4,5-tetrazine were synthesized only very recently.[21] In order to better understand the effects of electron-donating and electron-withdrawing groups on the azide–tetrazole equilibrium of cyanuric azide, we replaced one azide group with an amino and a nitro group, respectively. We also investigated the recently synthesized azo- and hydrazo-bridged dimers[5,22] of bis(azido)-1,3,5-triazine as well as triazido-*s*-heptazine.[23] The same calculations were also performed for several polyazido-1,2,4,5-tetrazines: bis(azido)-tetrazine[4] and the yet unknown azo- and hydrazo- bridged dimers of azidotetrazine.

The differences in electronic energy in the gas phase were used to determine the favored side of the equilibrium in the gas phase. In order to understand the favorization of the azides at higher temperatures, the entropies of the involved species were compared.

The Mulliken charges of the molecules were analyzed to understand the effect of different solvent polarities. Three different continuum environments with the characteristics of $CCl_4$, DMSO, and water were calculated using the polarized continuum model to explore the influence of increasing

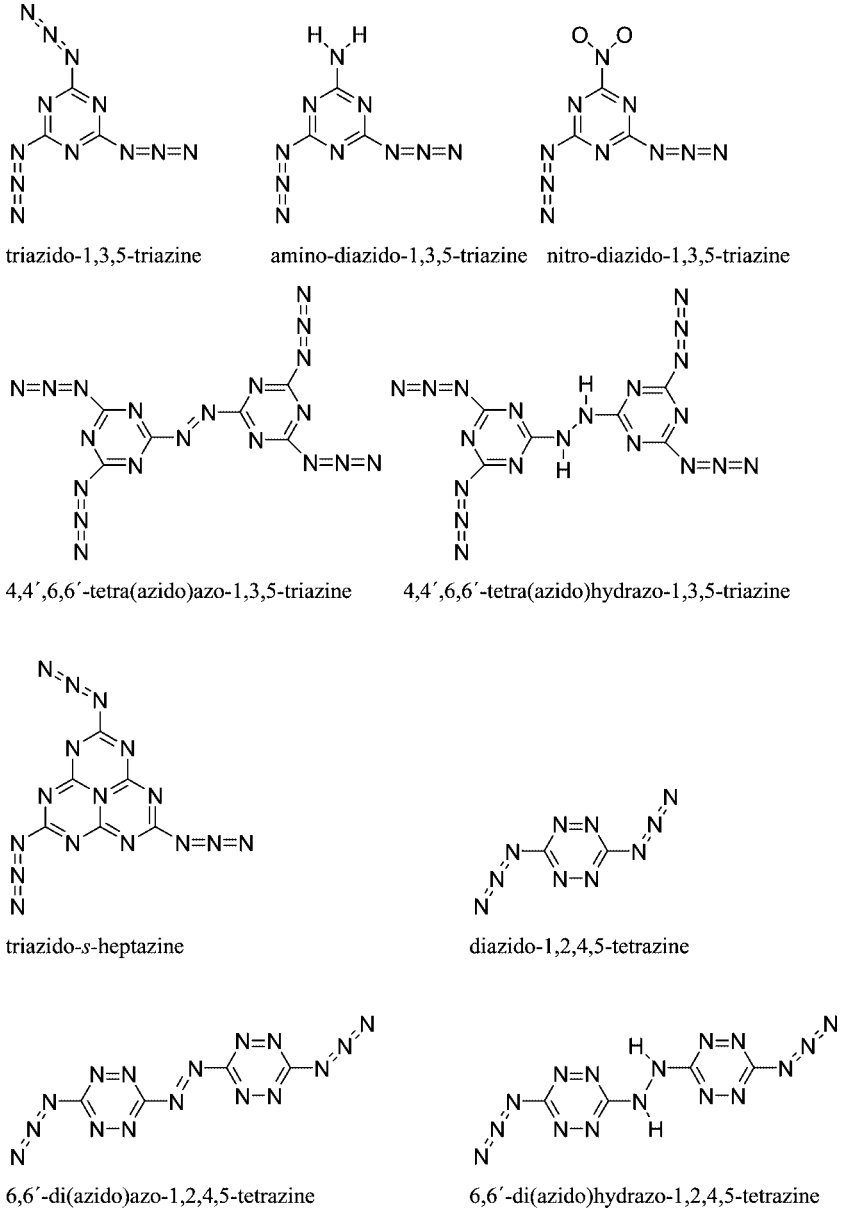

Figure 1. Investigated polyazidoheterocycles.

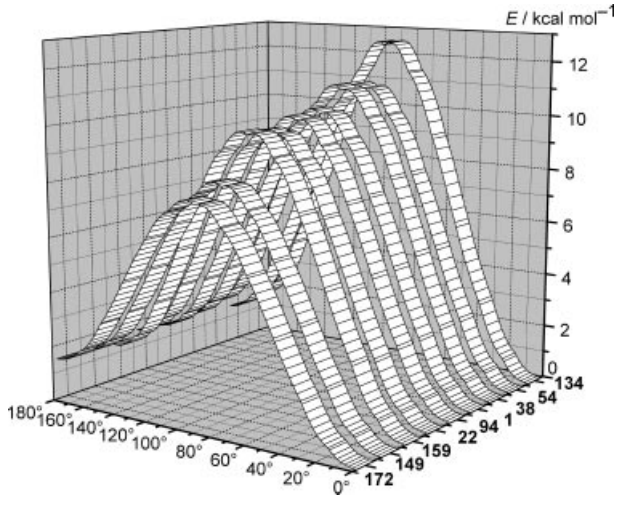
the dielectric permittivity on the potential energy of the investigated compounds.

## Results and Discussion

The azide groups of the discussed compounds can rotate along the C–N σ bond. Scheme 1 shows the energy profile of the rotation of an azide group around the C–N single bond determined by single point energy calculations in 15° intervals. The azide groups prefer a planar configuration with a slight energy difference between the two possible planar configurations. The rotation profiles of the azo-bridged compounds show a slightly higher activation energy for a 180° rotation than for the hydrazo-bridged dimers.



Scheme 1. Energy profile for the rotation of an azide group around the $N_\alpha$–$C_{aryl}$ σ bond at the MP2 level. Single point energy calculations were performed at 15° intervals.

The minimum energy conformations for cyanuric azide and triazido-*s*-heptazine are the $C_{3h}$ isomers **1** and **134**. The global minima **22** and **38** of amino- and nitro-1,3,5-triazine are derived from this structure by replacing one azide group with the respective substituent. The minimum energy structures **54** and **94** of the azo- and hydrazo-bridged dimers of bis(azido)-1,3,5-triazine are dimers of **1**. The global minimum for bis(azido)tetrazine is the $C_{2h}$ conformer **149**. The global minima **159** and **172** of the azo- and hydrazo-bridged dimers of azidotetrazine also have a *trans* alignment of the azido groups.

### Triazido-1,3,5-triazine (Cyanuric Azide)

Structures for all planar isomers and their possible intermediates for all three cyclization steps of cyanuric azide were calculated (Scheme 1). The calculated bonding parameters of **1** (see Supporting Information) are in good agreement with structural data.[19] The $N_\beta$–$N_\gamma$ and bonding distances of the azide unit and the carbon–nitrogen bond of the azide unit are longer than in the X-ray structure.

Two series of rotamers are formed based on the successive cyclization of the isomers **1** and **9**. The minimum energy reaction path (Scheme 2) is formed by cyclization of the $C_{3h}$ isomer **1**, the less symmetric isomer **9** is about 0.5 kcal mol$^{-1}$ higher in energy.

The energy difference calculated at the CCSD(T) level of theory are in good agreement with previously calculated values at the B3LYP level of theory (Table 1).[20] The MP2 energy differences are higher than the CCSD(T) values and increase for isomers with more tetrazole rings. The energy differences between the MP2 and CCSD(T) values are bigger for the transition states than for the ground states. At the CCSD(T) level, isomer **3** with one tetrazole ring system is 11.1 kcal mol$^{-1}$ higher in energy than the triazide **1**, the ditetrazole **6** is 7.9 kcal mol$^{-1}$ higher in energy than **3** and the tritetrazole **8** is 9.7 kcal mol$^{-1}$ higher in energy than the ditetrazole **6**. The formation of the first tetrazole ring system has a CCSD(T) activation energy of 23.8 kcal mol$^{-1}$, the second cyclization requires an activation energy of 21.0 kcal mol$^{-1}$ and the third cyclization requires an activation energy of 22.4 kcal mol$^{-1}$ based on the respective azides. This shows that the formation of the first tetrazole ring system requires the most energy and consecutive ring formations are slightly easier.

The entropies slightly favor the azides over the ring-closed isomers. The entropy decreases with an increasing amount for every ring closure, in agreement with the loss of degrees of freedom upon cyclization. According to the equation $\Delta G = \Delta H - T\Delta S$ a temperature increase would therefore shift the equilibrium from the tetrazole to the azide in the long run. The slight entropy difference allow the use of heat to overcome the activation barrier for the formation of a tetrazole, but at higher temperatures the entropy favors the azides.

The sum of the positive and negative Mulliken charges is higher for the azide than for the tetrazole compounds (see Supporting Information). The individual charges of the atoms are higher in the tetrazoles. The positive charge is spread over more atoms in the azides. In the tetrazoles generally only the carbon atoms retain positive charges while in the azides the azide $N_\beta$ atom is also positively charged. The charge in the tetrazoles is concentrated in the five-membered aromatic ring system, while in the azides the $N_\alpha$ and $N_\beta$ atoms also retain a significant charge. The higher individual charges in the tetrazoles can be stabilized by more polar solvents, thus shifting the azide–tetrazole equilibrium to the tetrazole side. This explains the experimentally observed shift to the azide compounds with a decreasing solvent polarity, which was observed for example for thiazole[3,2-*d*]tetrazole[15] and diazidotetrazine.[21]

The PCM calculations for $CCl_4$, DMSO, and water also indicate that more polar solvents favor the tetrazoles. The ground states are influenced more by solvation than the ground states. Solvation in $CCl_4$ favors the monotetrazole **3** by 3.9 kcal mol$^{-1}$, the ditetrazole **6** by 6.5 kcal mol$^{-1}$ and the tritetrazole **8** by 8.1 kcal mol$^{-1}$. The activation energy for the first cyclization is only slightly favored by 0.6 kcal mol$^{-1}$, the activation energy for the second cyclization is favored by 3.7 kcal mol$^{-1}$ and the activation energy for the third cyclization is favored by 6.0 kcal mol$^{-1}$ over the

gas phase. The solvation in the more polar solvents water and DMSO also favors the tetrazoles. The differences between water and DMSO solvation are less than 0.4 kcal mol$^{-1}$, therefore only water solvatization is discussed here. In water the monotetrazole **3** is favored by 7.4 kcal mol$^{-1}$, the ditetrazole **6** by 12.2 kcal mol$^{-1}$ and the tritetrazole **8** by 15.5 kcal mol$^{-1}$ over the gas phase. The activation energy for the first cyclization is only slightly favored by 1.2 kcal mol$^{-1}$, the activation energy for the second cyclization is favored by 6.6 kcal mol$^{-1}$ and the activation energy for the third cyclization is favored by 11.1 kcal mol$^{-1}$ over the gas phase. While solvation in water favors the tritetrazole **8** to a great extent, it is still 22.7 kcal mol$^{-1}$ higher in energy than **1** and has not yet been detected experimentally.[20,21] Thus cyanuric azide is not a suitable starting material for the synthesis of its tetrazole isomers.

### Amino- and Nitro-diazido-1,3,5-triazine

One azide substituent of cyanuric azide was replaced by the electron-donating amino group and the electron-withdrawing nitro group. As before, all possible planar conformations of the azide groups were considered (see Scheme 2 and Scheme 3).

Both diazides have three planar isomers whose successive cyclization leads to the isomers shown in Scheme 4 and Scheme 5. The minimum energy reaction paths (Scheme 6 and Scheme 7) are formed by cyclization of the isomers **22** and **38**, which are derived from **1**. Isomers **30** and **31** as well as **40** and **41**, which are derived from **9**, have similar energies but their cyclization leads to tetrazoles with higher energies (Tables 2, 3). Interestingly, the amino compound first closes the tetrazole ring next to the amino group whereas

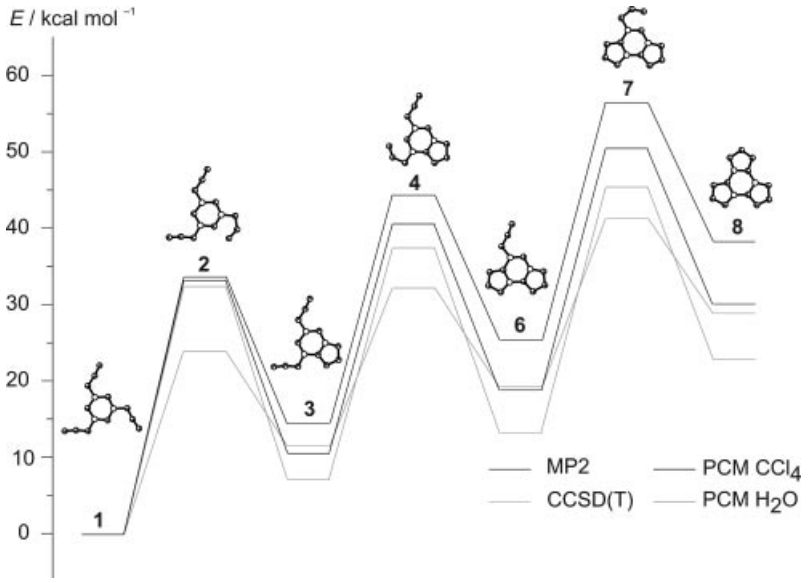
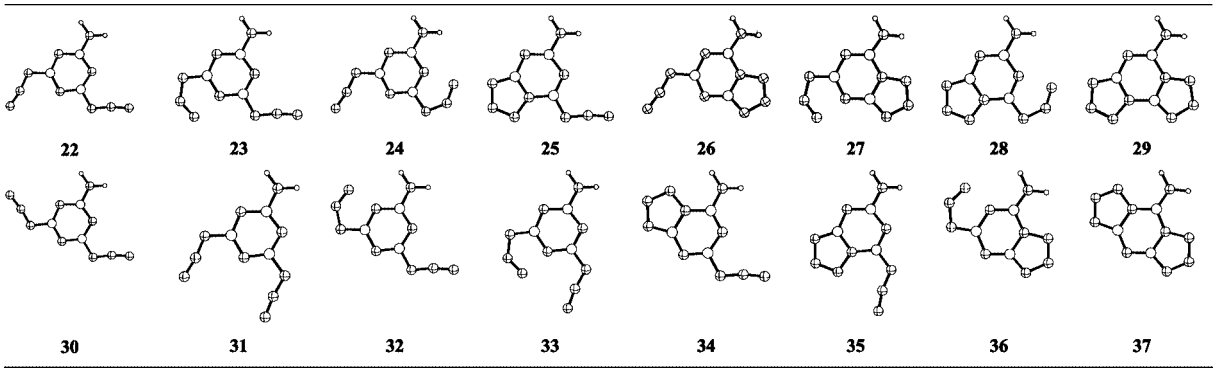
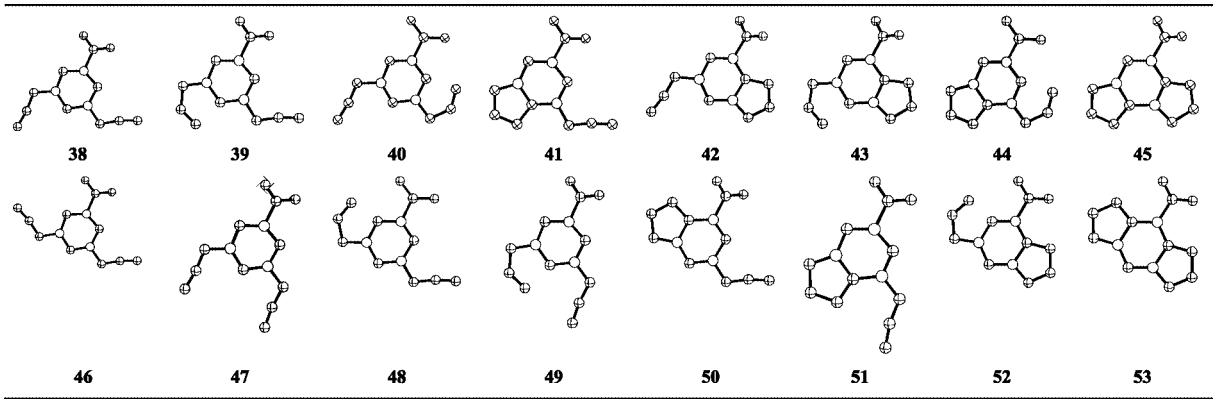


Scheme 3. Reaction profile for the ring closures in triazido-1,3,5-triazine.



Scheme 4. Calculated amino-diazido-1,3,5-triazine isomers, all isomers have $C_1$ symmetry.



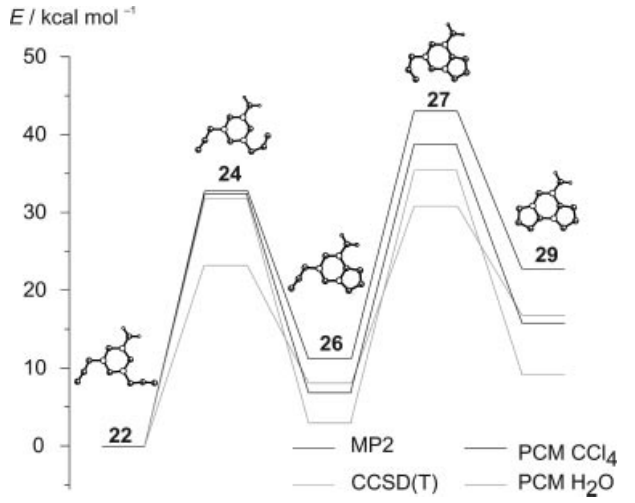
Scheme 5. Calculated diazido-nitro-1,3,5-triazine isomers, isomers have $C_1$ symmetry.

the nitro compound prefers to close the tetrazole ring farther away from the nitro group.

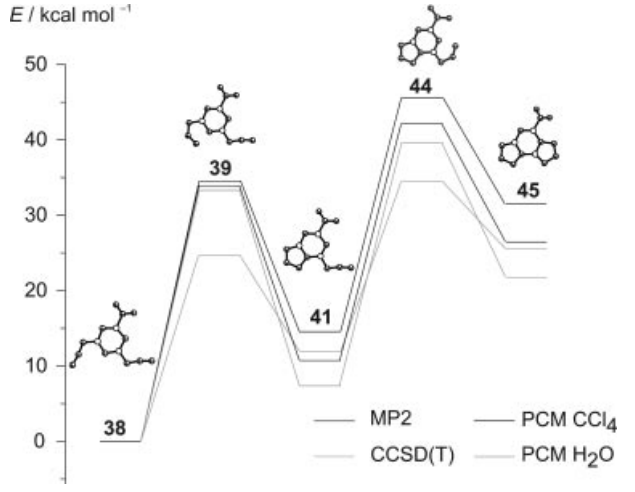
At the CCSD(T) level the amino derivative **26** with one tetrazole ring is 8.1 kcal mol$^{-1}$ higher in energy than the azide **22** and the ditetrazole **29** is 8.5 kcal mol$^{-1}$ higher in energy than the monotetrazole **26**. The activation energy for the cyclization of the amino compound **22** is 23.2 kcal mol$^{-1}$ and the activation energy for the second cyclization is 22.7 kcal mol$^{-1}$. The nitro derivative **41** with one tetrazole group is 11.8 kcal mol$^{-1}$ higher in energy than the azide **38** and the ditetrazole **45** is 13.8 kcal mol$^{-1}$ higher in energy than the monotetrazole **41**. The activation energy for the cyclization of the nitro compound **41** is 24.6 kcal mol$^{-1}$ and the activation energy for the second cyclization is

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

22.6 kcal mol$^{-1}$. As mentioned above for cyanuric azide, the MP2 energy differences for both compounds are larger and increase with the number of tetrazole rings.



Scheme 6. Reaction profile for the ring closures in 2-amino-4,6-diazido-1,3,5-triazine.



Scheme 7. Reaction profile for the ring closures in 4,6-diazido-2-nitro-1,3,5-triazine.

The formation of a tetrazole system leads to an entropy decrease for both amino- and nitro derivatives.

As observed for cyanuric azide, the sum of the positive and negative Mulliken charges is higher for the azide than for the tetrazole compounds (see Supporting Information) for both the amido and nitro derivatives, but the tetrazoles have higher individual charges. Similar to cyanuric azide, the ground states are influenced more by solvation in $CCl_4$, DMSO and water than the transition states.

Solvation of the amino derivatives in $CCl_4$ favors the monotetrazole **26** by 1.2 kcal mol$^{-1}$ and the ditetrazole **29** by 7.0 kcal mol$^{-1}$ over the gas phase. The activation energy for the first cyclization is only slightly favored by 0.9 kcal mol$^{-1}$ and the activation energy for the second cyclization is favored by 4.2 kcal mol$^{-1}$ over the gas phase. For the nitro derivatives solvation in $CCl_4$ decreases the energy difference to the diazide **1** by 3.6 kcal mol$^{-1}$ for the monotetrazole **39** and by 4.9 kcal mol$^{-1}$ for the ditetrazole **29** over the gas phase. The activation energies are lowered by 0.5 kcal mol$^{-1}$ for the first cyclization and by 3.3 kcal mol$^{-1}$ for the second cyclization compared to the gas phase. As observed for cyanuric azide, the effects of solvation in DMSO and water are similar. The amino-monotetrazole **26** is favored by 8.1 kcal mol$^{-1}$ and the ditetrazole **29** by 13.4 kcal mol$^{-1}$ over the gas phase. The activation energy for the first cyclization is lowered by 1.9 kcal mol$^{-1}$ and the activation energy for the second cyclization by 7.6 kcal mol$^{-1}$ over the gas phase. The nitro derivatives show a similar picture. Here the monotetrazole **41** is favored by 7 kcal mol$^{-1}$ and the ditetrazole 45 by 9.5 kcal mol$^{-1}$ in aqueous solution. The activation energies are lowered by 0.9 kcal mol$^{-1}$ for the first cyclization and by 6.0 kcal mol$^{-1}$ for the second cyclization.

In comparison to cyanuric azide, where the ditetrazole **16** is 19 kcal mol$^{-1}$ higher in energy than the respective diazide **1**, the aminoditetrazole **29** is 16.6 kcal mol$^{-1}$ higher in energy than the diazide **22** and the nitroditetrazole **45** is 25.6 kcal mol$^{-1}$ higher in energy than the diazide **38** [CCDS(T) values]. This shows that substitution with an electron-donating group favors the tetrazole whereas substitution with an electron-withdrawing group favors the azide.

Table 2. Calculated energy differences between different amino-diazido-1,3,5-triazine isomers. The gas phase calculations include zero point energy corrections. The PCM values represent the differences in free energy of the various species.

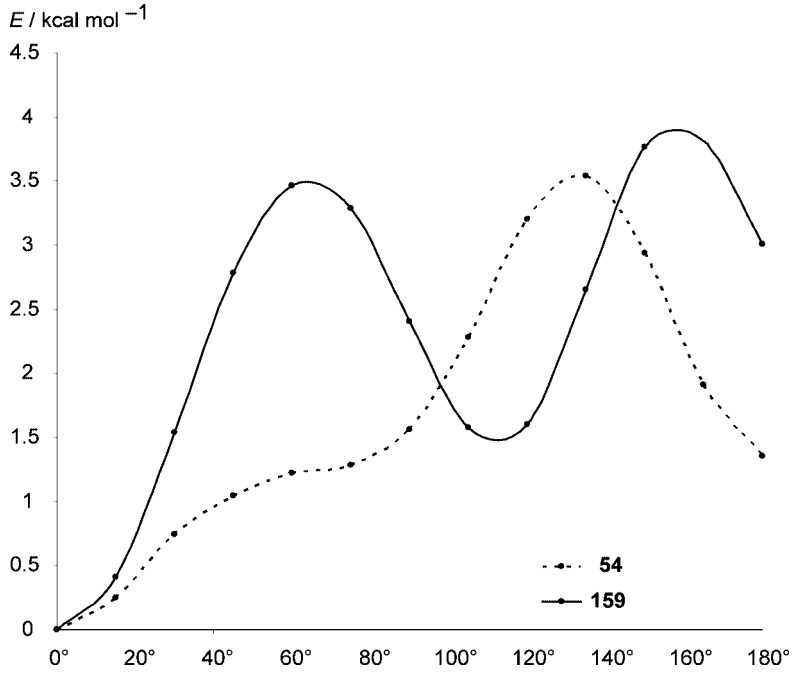
The activation energies for the first (23.8 kcal mol$^{-1}$ for cyanuric azide, 23.8 kcal mol$^{-1}$ for the amino derivative and 24.6 kcal mol$^{-1}$ for the nitro derivative) and second cyclization (21.0 kcal mol$^{-1}$ for cynuric azide, 22.7 kcal mol$^{-1}$ for the amino derivative and 22.6 kcal mol$^{-1}$ for the nitro derivative) are barely influenced by the substitution.

### 4,4′,6,6′-Tetra(azido)azo-1,3,5-triazine and 4,4′,6,6′-Tetra(azido)hydrazo-1,3,5-triazine

Here the size of the molecules prevented MP2 calculations due to computational cost. The good agreement between the B3LYP and CCSD(T) energy differences for cyanuric azide shows that these compounds could be investigated with density functional theory. Scheme 8, Scheme 9, and Scheme 10 show the rotation profiles around the C–N and N–N single bonds of the hydrazo-bridged **74** and the C–N bond of the azo-bridged dimer **54** with the minimum energy bonding angle set to zero. As expected, the C–N rotation barrier in the azo-bridged dimer is higher due to a partial double bond. The rotation around the N–N single bond in the hydrazo-bridged **94** is sterically hindered.

As there are too many possible routes for cyclization, not all possible isomers for the cyclization were calculated. Instead all possible tetraazides and tetratetrazoles were calculated. Then the isomers on the cyclization route linking the lowest energy tetraazide to the lowest energy tetratetrazole were calculated.

Two conformers of the azo-bridged tetraazide have already been found in the same crystal structure and yet another in a second crystal structure.[22] This confirms that the energy differences between the different tetraazide con-



Scheme 8. Energy profile for the rotation of **54** and **159** around the $N_{hydrazo}$–$C_{aryl}$ σ bond with the minimum energy bonding angle set to zero at the MP2 level. Single point energy calculations were performed at 15° intervals.

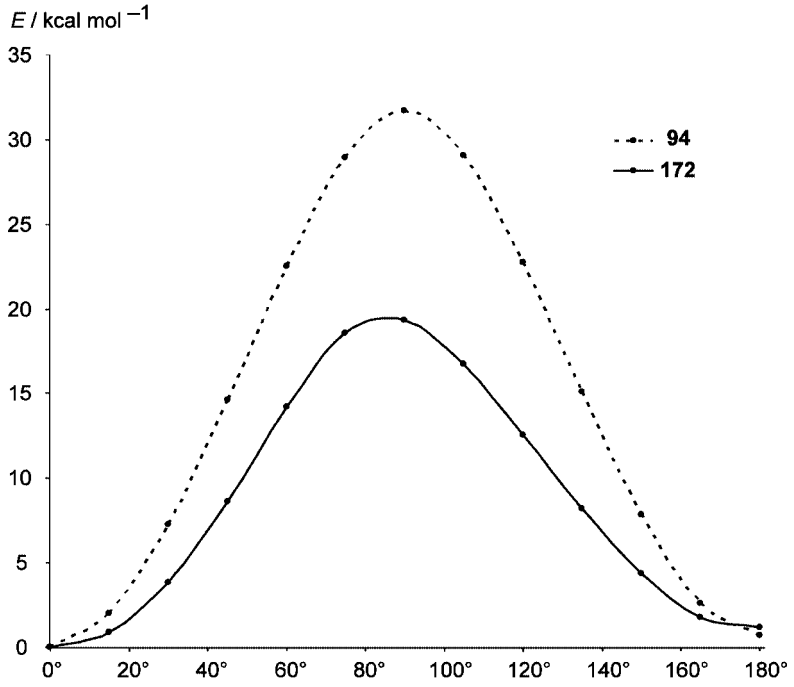
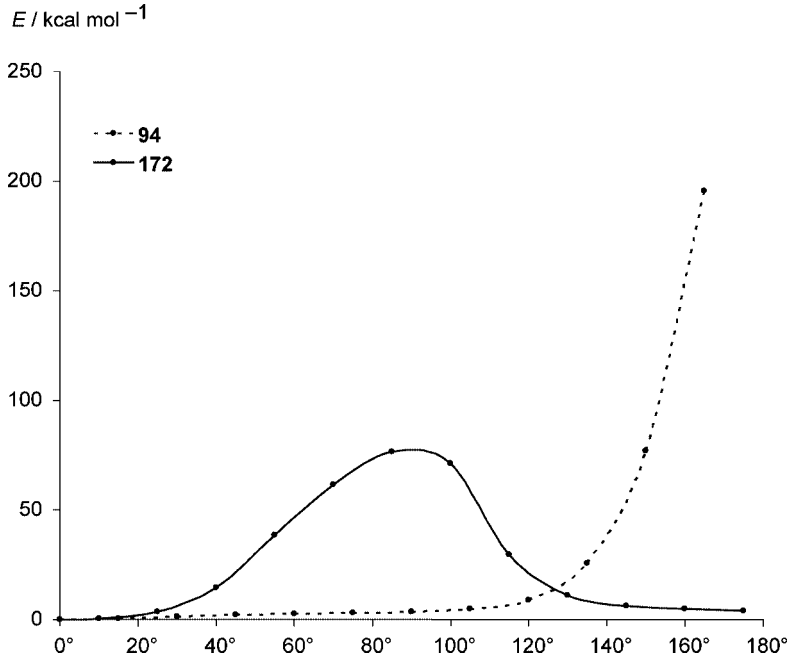


Scheme 9. Energy profile for the rotation of **94** and **172** around the $N_{hydrazo}$–$C_{aryl}$ σ bond with the minimum energy bonding angle set to zero at the MP2 level. Single point energy calculations were performed at 15° intervals.



Scheme 10. Energy profile for the rotation of **94** and **159** around the $N_{hydrazo}$–$C_{aryl}$ σ bond with the minimum energy bonding angle set to zero at the MP2 level. Single point energy calculations were performed at 15° intervals.

formers are only slight. For the azo-bridged dimers we find differences of only 1.3 kcal mol$^{-1}$ between isomers **54**–**63**. Interestingly, the highest energy conformer **56** was found in a crystal structure together with conformer **55**. This is probably due to a better space filling in the crystal in the presence of both isomers. While isomer **54** does not have the lowest energy in the gas phase, it is the lowest energy isomer in solution and its cyclization product **88** is the lowest energy tetratetrazole. The tetratetrazoles have higher energy differences of up to 25.7 kcal mol$^{-1}$. Therefore, a cyclization route linking **54** to **88** was calculated. The hydrazo-bridged dimers **94**–**103** are also only separated by 1.5 kcal mol$^{-1}$ in energy. Here the lowest energy tetraazide **94** was also found in the crystal structure[22] and no other conformers have yet been observed. The cyclization route linking **94** to the lowest energy tetratetrazole **128** was calculated. Similar to the

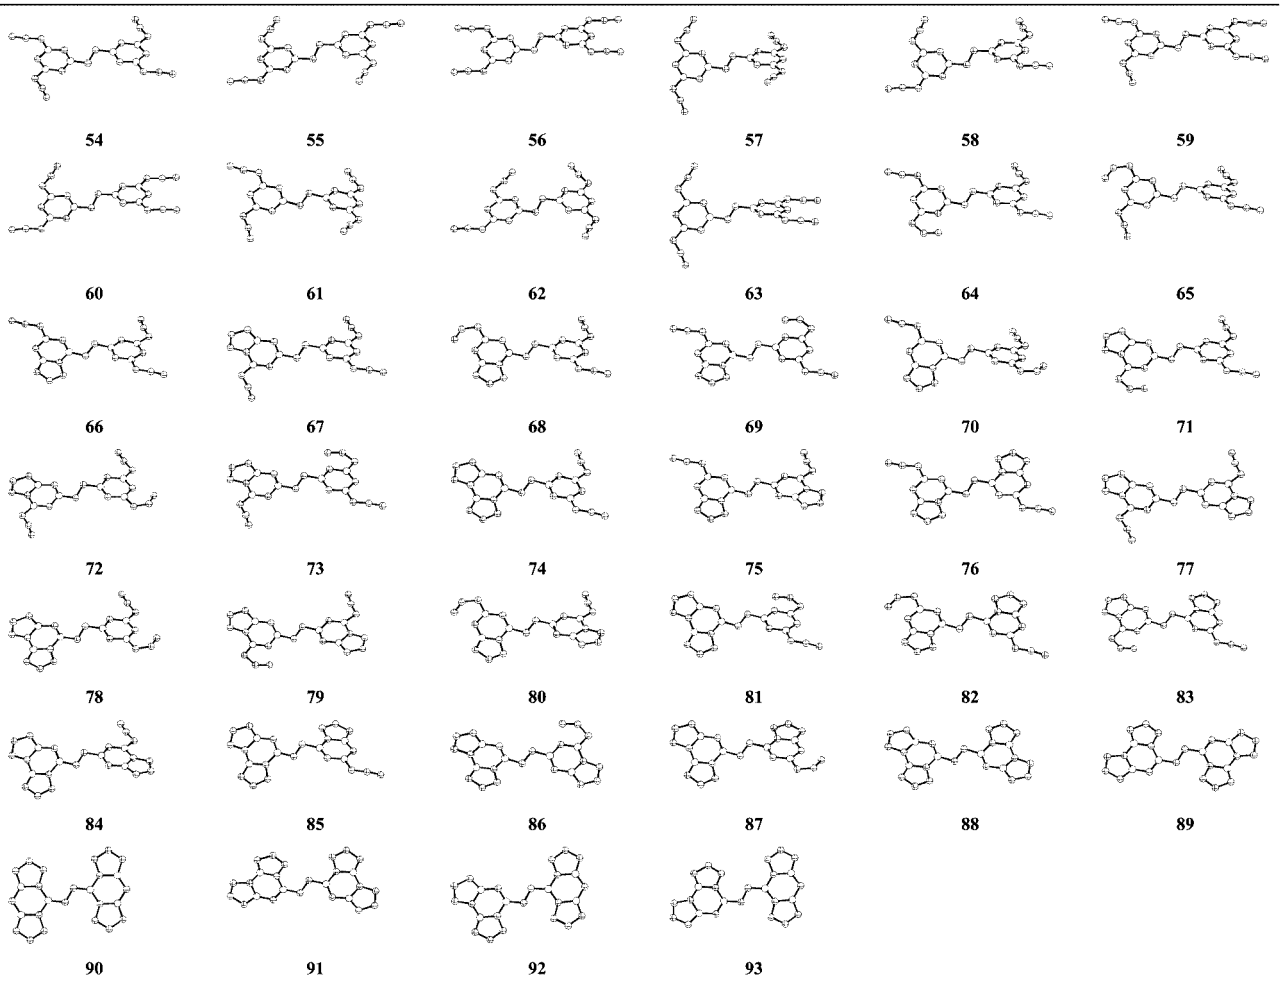
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

azo compounds the tetratetrazole isomers **128**–**133** have energy differences up to 27.0 kcal mol$^{-1}$. The lowest energy azo- and hydrazo-bridged tetraazides **54** and **94** and tetratetrazoles **88** and **128** have the same conformation of the azide groups and are, like the minimum energy amino- and nitro-diazido-1,3,5-triazines, derived from the minimum energy triazido-1,3,5-triazine **1**. The calculated bonding parameters of **55**, **56**, **57**, and **94** are in good agreement with the structural data.[22] The $N_\beta$-$N_\gamma$ bond of the azide units is slightly longer than in the X-ray structures (see Supporting Information).

Scheme 11 and Scheme 12 show that the azo- and hydrazo-bridged dimers first cyclize both azide groups belonging to one triazine ring and then the azide groups of the second triazine unit.

The azo-bridged monotetrazole **67** is 11.2 kcal mol$^{-1}$ higher in energy than the tetraazide **54**, the ditetrazole **74** 20.8 kcal mol$^{-1}$, the tritetrazole **84** 32.5 kcal mol$^{-1}$ and the tetratetrazole **88** 44.3 kcal mol$^{-1}$, which translates to energy differences of 9.6 kcal mol$^{-1}$ between the monotetrazole **67** and the ditetrazole **74**, 11.7 kcal mol$^{-1}$ between the ditetrazole **74** and the tritetrazole **84** and 11.8 kcal mol$^{-1}$ between the tritetrazole **84** and the tetratetrazole **88** (Scheme 13, Table 4). The ditetrazoles **75**–**77** with tetrazole rings at different triazine rings are about 3 kcal mol$^{-1}$ less favored than **74**, where both tetrazole rings are bonded to the same triazine ring. The activation energies for the cyclizations are 23.5 kcal mol$^{-1}$, 21.4 kcal mol$^{-1}$, 23.9 kcal mol$^{-1}$ and 22.5 kcal mol$^{-1}$. The third cyclization transition state **79**, which links ditratrazole **77** with tritetrazole **84**, is 0.6 kcal mol$^{-1}$ lower than **78**, but the ditetrazole **77** is 1.7 kcal mol$^{-1}$ higher in energy than ditetrazole **74**. The cyclization therefore should lead to ditetrazole **77**, which then requires a slightly higher activation energy to cyclize to tritetrazole **84**.

The hydrazo-bridged compounds have slightly lower energy differences than the azo-bridged compound to the tetraazide **94** for the mono- and ditetrazoles, while the tri- and tetratetrazoles have similar energies (Scheme 14, Table 5). The monotetrazole **106** is 10.7 kcal mol$^{-1}$ higher in energy, the ditetrazole **114** 20.5 kcal mol$^{-1}$, the tritetrazole **124** 33.0 kcal mol$^{-1}$ and the tetratetrazole **128** 44.3 kcal mol$^{-1}$. This translates to energy differences of 9.8 kcal mol$^{-1}$ between one and two tetrazole rings, 12.5 kcal mol$^{-1}$ between two and three tetrazole rings and 11.3 kcal mol$^{-1}$ between three and four tetrazole rings. The ditetrazoles **115**–**117**



Scheme 11. Calculated isomers of 4,4′,6,6′-tetra(azido)azo-1,3,5-triazine.

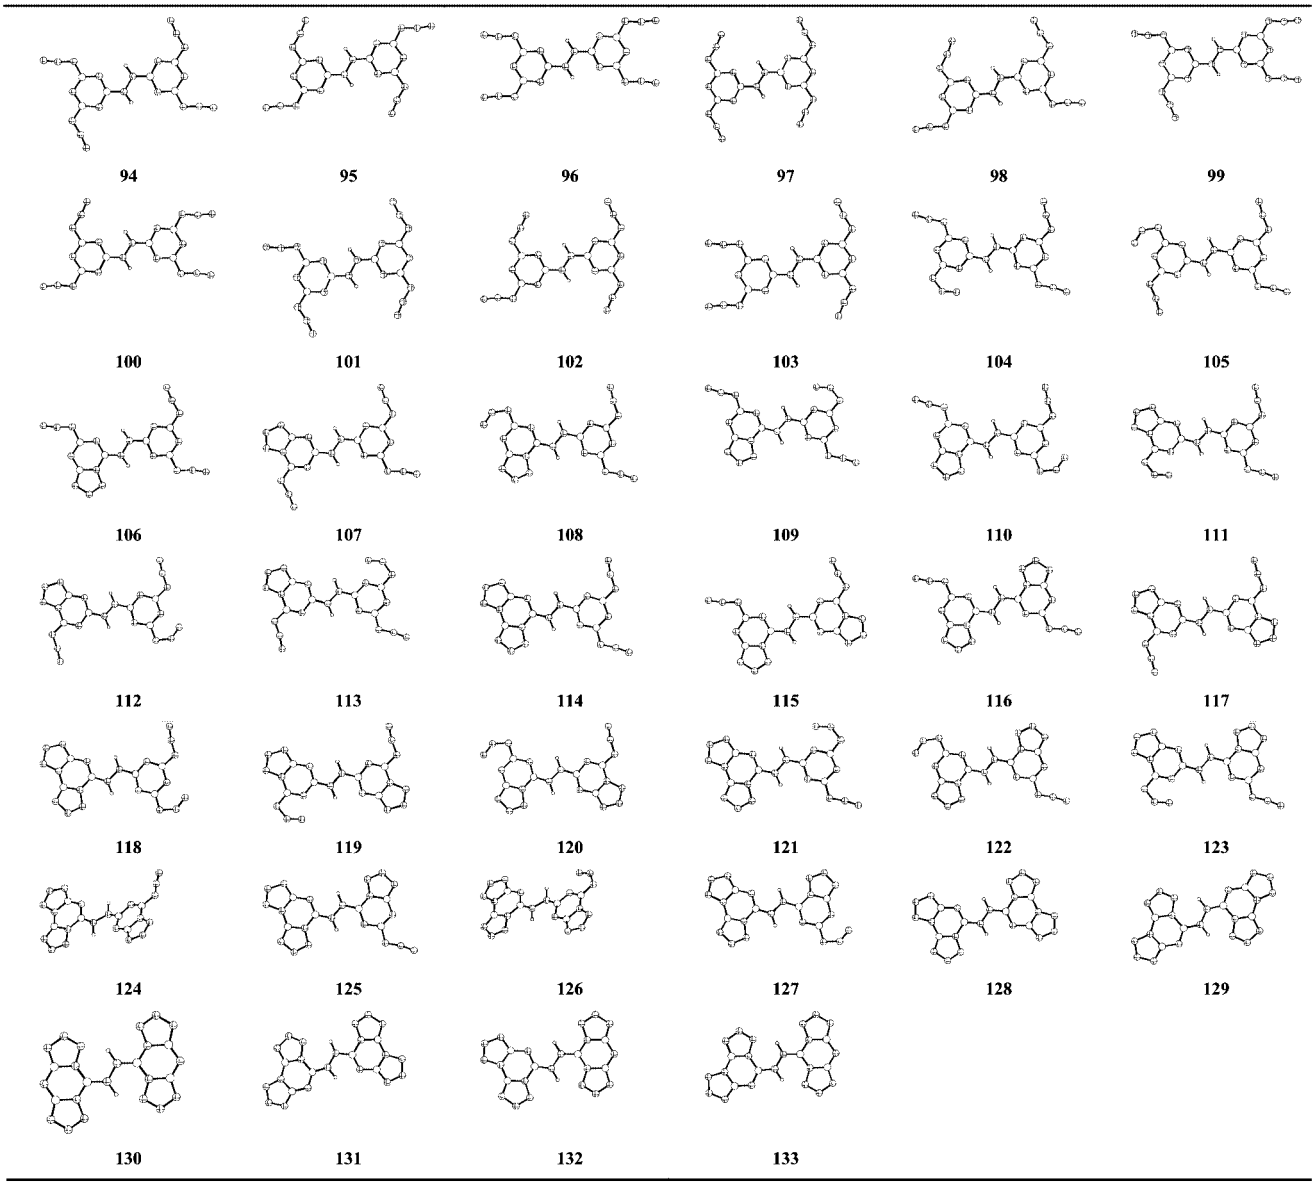

Scheme 12. Calculated isomers of 4,4′,6,6′-tetra(azido)hydrazo-1,3,5-triazine.

with tetrazole rings at both triazine rings are about 2.5 kcal mol$^{-1}$ less favored than **114**, where both tetrazole rings are bonded to the same triazine ring. The activation energies for the cyclizations are 23.4 kcal mol$^{-1}$, 22.3 kcal mol$^{-1}$, 23.0 kcal mol$^{-1}$, and 22.5 kcal mol$^{-1}$. Transition state **105** for the first cyclization, which links the tetraazide **94** with the monotetrazole **107**, is 0.7 kcal mol$^{-1}$ lower than **104**, but the montetrazole **107** is 0.8 kcal mol$^{-1}$ higher in energy than the monotetrazole **106**. The kinetic product **107** also requires a higher activation energy for a second cyclization, therefore the minimum energy cyclization route includes transition state **104** and monotetrazole **106**. As observed for all previous compounds, successive cyclization leads to a successive decrease of the entropy for both azo and hydrazo compounds. The sum of the positive and negative Mulliken charges is higher for the azides than for the tetrazole compounds (see Supporting Information) for both the azo- and hydrazo compounds, but the tetrazoles have higher individual charges.

Solvatization in $CCl_4$, DMSO and water has a higher influence on the ground states than on the transition states. Solvation in $CCl_4$ of the azo compound favors the monotetrazole **67** by 3.5 kcal mol$^{-1}$, the ditetrazole **74** by 5.2 kcal mol$^{-1}$, the tritetrazole **84** by 8.8 kcal mol$^{-1}$ and the tetratetrazole **88** by 10.6 kcal mol$^{-1}$ over the gas phase. The activation energy for the first cyclization is only slightly favored by 0.2 kcal mol$^{-1}$, the second cyclization is favored by 2.8 kcal mol$^{-1}$, the third cyclization by 5.5 kcal mol$^{-1}$ and the final cyclization by 8.1 kcal mol$^{-1}$ over the gas phase. The hydrazo compounds are favored by 3.1 kcal mol$^{-1}$ for the monotetrazole **106**, by 5.8 kcal mol$^{-1}$ for the ditetrazole **114**, by 10.3 kcal mol$^{-1}$ for the tritetrazole **124**, and by

11.1 kcal mol$^{-1}$ for the tetratetrazole **128** by solvation in $CCl_4$. The activation energy for the first cyclization is slightly increased by 0.2 kcal mol$^{-1}$ while the activation energy for the second, third and fourth cyclization are favored by 2.9 kcal mol$^{-1}$, 6.0 kcal mol$^{-1}$, and 10.0 kcal mol$^{-1}$.

The difference between solvation in water and DMSO is more pronounced compared to the previous compounds, probably due to different displacement of solvent molecules. Still, the energy differences between DMSO and water solvation are within 1 kcal mol$^{-1}$. The azo-bridged mono- **67**, di- **74**, tri- **84**, and tetratetrazoles 88 are favored by 6.6, 9.4, 16.3, and 19.9 kcal mol$^{-1}$ over the gas phase and the activation energy for the first, second, third, and fourth cyclization by 0.8, 5.3, 10.3, and 15.5 kcal mol$^{-1}$. Solvation of the hydrazo compounds in water leads to an even higher stabilization of the tetrazoles. The hydrazo-bridged mono- **106**, di- **114**, tri- **124**, and tetratetrazoles **128** are stabilized by 6.7, 11.2, 20.4, and 24.6 kcal mol$^{-1}$ over the gas phase. The activation energy for the first, second, third, and fourth cyclizations are favored by 1.4, 6.3, 12.4, and 20.4 kcal mol$^{-1}$ by solvation in water.

As a consequence, both 4,4′,6,6′-tetra(azido)azo-1,3,5-triazine and 4,4′,6,6′-tetra(azido)hydrazo-1,3,5-triazine do not form tetrazoles in gas phase or in solution. Solvation in polar solvents favors the tetrazoles, even more for the

hydrazo compounds than the for the azo compounds. The solvation effect is not sufficient so that the detection of the tetrazoles in solution was not observed.[21]

### Triazido-*s*-heptazine

Triazido-*s*-heptazine behaves similarly to triazido-1,3,5-triazine. Two azide rotamers cyclize to different tetrazoles. To save computer time, we only calculated the ground states and the transition states linking the lowest ground states (Scheme 15).

The minimum energy $C_{3h}$ isomer **139** is similar to the minimum energy cyanuric azide isomer **1**. The bonding parameters are in agreement with X-ray structural data,[23] with the same longer azide $N_\beta$–$N_\gamma$ bond found for all previous compounds (Scheme 16, Table 6).

The reaction profile for the cyclization of the triazidoheptazine **139** is similar to the reaction profile of triazidotriazine **1**. The energy differences between the triazide **134** and monotetrazole **136**, the ditetrazole **139** and the tritetrazole **141** are 12.6, 23.8, and 34.9 kcal mol$^{-1}$. The ditetrazole **139** is therefore 11.2 kcal mol$^{-1}$ higher in energy

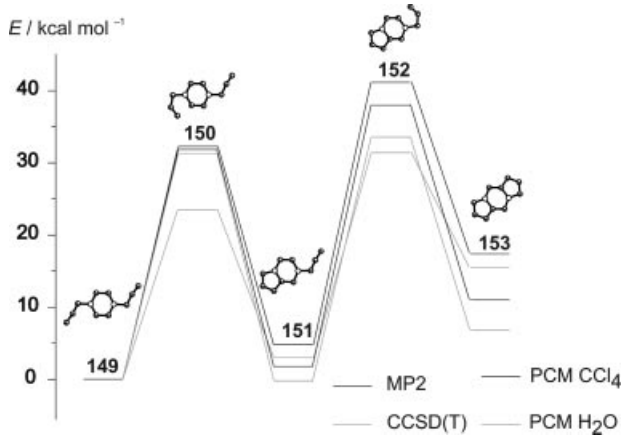
than the monotetrazole **136** and the tritetrazole **141** 11.1 kcal mol$^{-1}$ higher than the ditetrazole **139**. The activation energies for the first, second and third cyclization are 23.5, 22.8, and 22.7 kcal mol$^{-1}$. The formation of the tetrazole rings is accompanied by a decrease of the entropy and a decrease of the sum of the positive and negative Mulliken charges. The tetrazoles have higher individual positive charges. Similar to cyanuric azide, the ground states are more influenced by solvation in $CCl_4$, DMSO, and water than the ground states.

Solvation in $CCl_4$ favors the monotetrazole **136** by 3.3 kcal mol$^{-1}$ and the ditetrazole **139** by 6.2 kcal mol$^{-1}$ and the tritetrazole **141** by 8.8 kcal mol$^{-1}$ over the gas phase. The activation energy for the first cyclization is only slightly favored by 0.4 kcal mol$^{-1}$ and the activation energy for the second and third cyclization are favored by 3.0 kcal mol$^{-1}$ and 5.7 kcal mol$^{-1}$ over the gas phase. The optimization of the solvation of **142** and **143** in DMSO and $CCl_4$ did not converge. Solvation in water and DMSO is only different by maximally 1 kcal mol$^{-1}$. Solvation lead to a favorization of 6.7 kcal mol$^{-1}$ for the monotetrazole **136**, of 12.4 kcal mol$^{-1}$ for the ditetrazole **139** and of 17.8 kcal mol$^{-1}$ for the tritetrazole **141** over the gas phase. The activation energies for the cyclization are favored by 0.4, 6.4, and 11.8 kcal mol$^{-1}$ for the first, second and third cyclization. Compared to triazido-1,3,5-triazine, triazido-*s*-heptazine is even less likely to form a tetrazole and it is therefore not surprising that the attempt to form a tetrazole isomer from triazido-*s*-heptazine have not been successful.[21]

### Diazidotetrazine

The rotation barriers of the azide unit around the C–N bonds of diazidotetrazine are slightly lower than those of the azido-1,3,5-triazines (see Scheme 1). Cyclization of diazidotetrazine in a *trans* **149** and a *cis* **154** conformation was investigated (Scheme 17). In the crystal structure only *trans* **149** was found.[4] Its bonding parameters are in agreement with the calculation. As observed for the triazines, the azide $N_\beta$–$N_\gamma$ bond is shorter in the X-ray structure (see Supporting Information).

The *trans* and *cis* diazides **149** and **154** as well as the *trans* and *cis* monotetrazoles **151** and **156** are only separated at most 0.5 kcal mol$^{-1}$ at the MP2 level and even less at the CCSD(T) level of theory (Scheme 18). The B3LYP values in Table 7 show the same tendency. Similar to the results for the triazines, the MP2 energy differences between azide and tetrazoles are larger. The *cis* ditetrazole **158** has an energy that is 5.2 kcal mol$^{-1}$ higher than that of the *trans* ditetrazole **153** at the CCSD(T) level of theory. Therefore, the minimum energy cyclization path connects the *trans* diazide **149** with the *trans* ditetrazole **153**. The difference between the ditetrazole **153** and the monotetrazole **151** is with 12.6 kcal mol$^{-1}$ much larger than the difference of 2.9 kcal mol$^{-1}$ between diazide and monotetrazole. The cyclization of an azide group belonging to one of the previously mentioned 1,3,5-triazine derivatives resulted in relatively constant energy differences of 9 to 12 kcal mol$^{-1}$ per tetrazole ring. Therefore the cyclization of an azide group, especially the first cyclization, is favored for the tetrazine ring system compared to the triazine ring system. The activation energies for the first and second cyclization are 23.6 and 28.6 kcal mol$^{-1}$. For comparison, the monotetrazoles of pyridazine diazides and triazides are favoured by about 3 kcal mol$^{-1}$ over the all-azide and all-tetrazole isomers



Scheme 18. Reaction profile for the ring closures in diazidotetrazine.

with activation energies of about 20 kcal mol$^{-1}$ for one cyclization.[24]

The formation of the tetrazole rings is accompanied by a decrease of the entropy and a decrease of the sum of the positive and negative Mulliken charges. Again the tetrazoles have higher individual positive charges. Solvation has a bigger effect on the ground states than on the transition states. In $CCl_4$ the monotetrazole **151** is favored by 2.7 kcal mol$^{-1}$ and the ditetrazole **153** by 6.3 kcal mol$^{-1}$, while the first and second transition states are favored by 0.1 and 3.3 kcal mol$^{-1}$. As before, the results of DMSO and water are similar. Solvation in water leads to a stabilization of the monotetrazole **151** by 4.9 kcal mol$^{-1}$ and of 10.4 kcal mol$^{-1}$ for the ditetrazole **153**. The activation energies for the first and second cyclization are lowered by 0.1 and 6.7 kcal mol$^{-1}$. After solvation in water, the monotetrazole **151** is 0.2 kcal mol$^{-1}$ lower in energy than the diazide **149**.

Very recently an equilibrium of diazidotetrazine with its monotetrazole in DMSO was observed with NMR spectroscopy.[21] Heating to 80 °C overcame the activation barrier and a ditetrazole was observed. The authors indicate that the ditetrazole **158** was formed. $^{13}C$ NMR spectroscopic data are not sufficient for this prediction. According to the energies caculated for the ditetrazole isomers **153** and **158**, we believe that ditetrazole **153** is formed in this reaction. For better identification of the diazide **149**, the monotetrazole **151** and the ditetrazole **153**, we included the calculated MP2 vibrational spectra in Figure 2 for easier assignment and positive identification of the respective isomers.

### 6,6′-Bis(azido)-azo-1,2,4,5-tetrazine and 6,6′-Bis(azido)-hydrazo-1,2,4,5-tetrazine

For comparison with the polyazidoazo- and hydrazo-1,3,5-triazines we also calculated the yet unknown bis(azido)azo- and bis(azido)hydrazo-1,2,4,5-tetrazines. In order to keep the computational costs low, all calculation were performed at the B3LYP level only. The rotation profiles along the C–N bond of the azo and hydrazo group are given in Scheme 11 and Scheme 12 and the rotation profile around the N–N bond of the hydrazo group in Scheme 13.

Both the azo- and hydrazotetrazines have the same *cis* and *trans* alignments of the azide groups found in bis(azido)-tetrazine. The hydrazo compound also has a third conformation due to the conformation of the hydrazo-hydrogen atoms.

The *trans* orientation of the azide groups is the lowest energy conformation of the azo- and hydrazo compounds, but the energy differences are negligible for the diazides and only very slight for the mono- and ditetrazoles. The azo-bridged monotetrazole **161** is 4.1 kcal mol$^{-1}$ higher than the diazide **159** and the ditetrazole **163** 9.2 kcal mol$^{-1}$ (Scheme 19, Table 8). The activation energies for the first

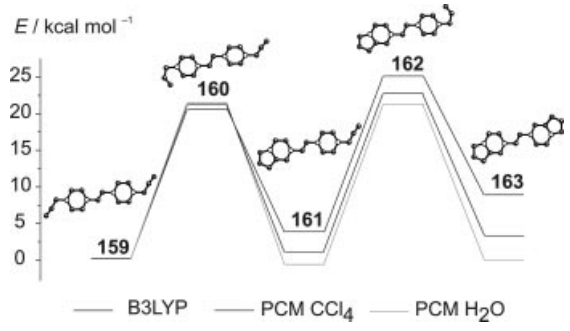
and second cyclization are 21.0 and 16.2 kcal mol$^{-1}$. The hydrazo-bridged monotetrazole **174** is only 1.9 kcal mol$^{-1}$ higher than the diazide **172** and the ditetrazole **176** 4.6 kcal mol$^{-1}$ (Scheme 20, Table 9). The activation energies for the first and second cyclization of the hydrazo-bridged compound are 22.2 and 19.9 kcal mol$^{-1}$. As observed before, the formation of the tetrazole rings is accompanied by a decrease of the entropy and a decrease of the sum of the positive and negative Mulliken charges with have higher individual charges for the tetrazoles.

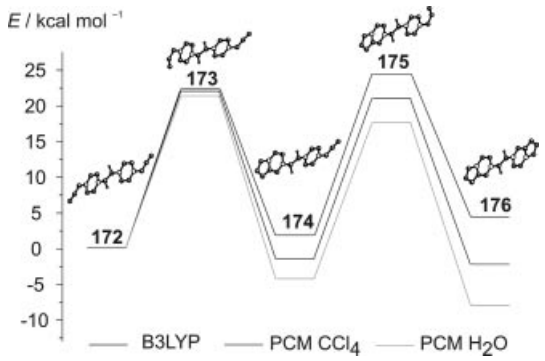
Solvation also leads to a stabilization of the tetrazoles. In $CCl_4$ the azo-bridged monotetrazole **160** is favored by 2.4 kcal mol$^{-1}$ and the ditetrazole **163** by 9.1 kcal mol$^{-1}$. The activation energy for the first cyclization is increased by 0.3 kcal mol$^{-1}$ and the activation energy for the second cyclization is decreased by 2.4 kcal mol$^{-1}$. The hydrazo-bridged monotetrazole **174** is favored by 3.3 kcal mol$^{-1}$ and the ditetrazole **174** by 6.9 kcal mol$^{-1}$ in $CCl_4$. The activation energy for the first cyclization of the hydrazoazide is not influenced by $CCl_4$ and the activation energy for the second cyclization is lowered by 3.6 kcal mol$^{-1}$. DMSO and water solvation give similar energy differences. The energy difference to the diazide **159** for the azo-bridged tetrazole is lowered by 4.4 kcal mol$^{-1}$ and for the ditetrazole **163** by 9.1 kcal mol$^{-1}$ (Scheme 21). The activation energies for the first cyclization is increased by 0.6 kcal mol$^{-1}$ and the activation energy for the second cyclization is decreased by 3.8 kcal mol$^{-1}$. The solvation in water has a larger effect on the hydrazo-bridged compounds. Here the monotetrazole **174** is stabilized by 6.1 kcal mol$^{-1}$ and the ditetrazole **176** is stabilized by 12.5 kcal mol$^{-1}$ (Scheme 22). The activation energies for the first and second cyclization are lowered by 0.6 and 6.9 kcal mol$^{-1}$, respectively.



Scheme 21. Reaction profile for the ring closures in bis(azido)azo-1,2,4,5-tetrazine.

In absolute terms, the azo-bridged monotetrazole **161** is favored over the diazide **159** in the investigated solvents and the azo-bridged ditetrazole is only 0.1 kcal mol$^{-1}$ above the diazide in aqueous solution. The hydrazo-bridged mono-**174** and ditetrazoles **176** are even more favored over the diazides in solution. The diazide **176** is the lowest energy diazo-bridged compound in all solvents and is favored by 7.9 kcal mol$^{-1}$ over the diazide in aqueous solution.

For better experimental assignment, the calculated B3LYP vibrational spectra of the azo- and hydrazo-bridged



Scheme 22. Reaction profile for the ring closures in bis(azido)-hydrazo-1,2,4,5-tetrazine.

diazides, azidotetrazoles, and ditetrazoles are shown in Figure 3 and Figure 4.

## Conclusions

The formation of a tetrazole ring requires a planar arrangement of the azide group. Both for polyazido-1,3,5-triazines and bis(azido)-1,2,4,5-tetrazines several planar orientations of the azide group are possible. The rotation barrier of the azide group is around 10 kcal mol$^{-1}$ and the energy differences between the different planar conformers of the polyazides are slight. The ring closed polytetrazoles show larger energy differences. The minimum energy conformers derive from the $C_{3h}$ isomer of triazido-1,3,5-triazine and from *trans* bis(azido)tetrazine.

The ring closure of an azide to a tetrazole in the 1,3,5-triazine systems increases the electronic energy by 9–12 kcal mol$^{-1}$ per tetrazole ring, the activation energy for a tetrazole ring formation is around 20 kcal mol$^{-1}$. The electronic energy of the tetrazines increases by 2–5 kcal mol$^{-1}$ for the first tetrazole ring and by another 3–10 kcal mol$^{-1}$ for the second tetrazole ring. It was shown that the electron-donating amino group lowers the energy of a tetrazole ring relative to the azide by about 3 kcal mol$^{-1}$ and the electron-withdrawing nitro group increases the relative energy of a tetrazole ring by about 6 kcal mol$^{-1}$ relative to the azide. The entropy of the investigated compounds decreases slightly with every tetrazole ring closure due to the loss of degrees of freedom. Thus it is possible to overcome the activation barrier for the formation of some tetrazoles, e.g. diazidotetrazine, by heating, but at higher temperatures the azides are generally favored.

Taking into account solvent effects using a continuum of an uniform dielectric, the energy differences between the tetrazoles and the azides are lowered for both the polyazido-1,3,5-triazines and -tetrazines. This is explained by higher charges of individual atoms in the tetrazoles compared to the azides. Polar solvents stabilize these charges compared to the gas phase and lower the energy difference to the azides. The effect is smaller for the apolar $CCl_4$ with about 3 kcal mol$^{-1}$ per tetrazole unit and larger for the more polar solvents DMSO and water with about 6 kcal mol$^{-1}$

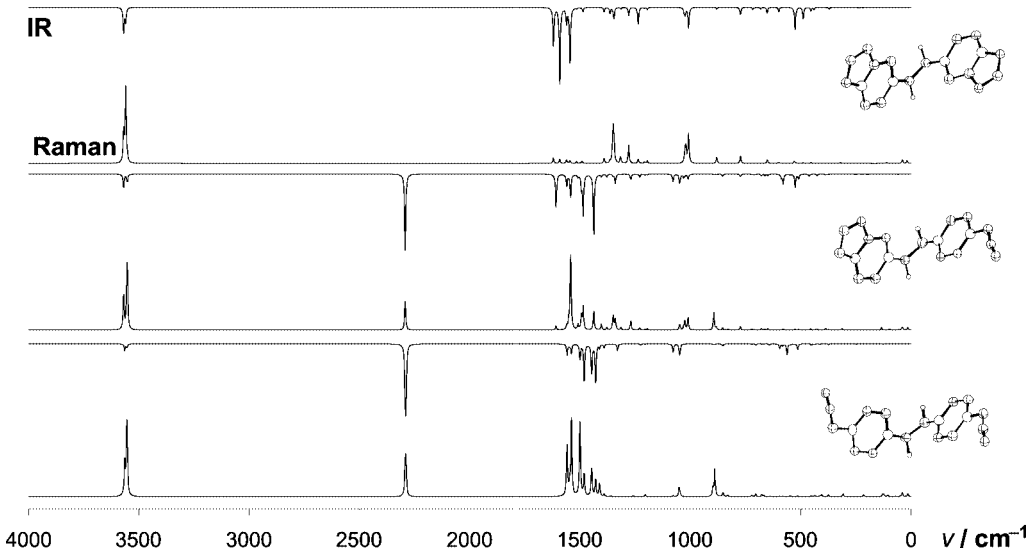

Figure 4. Vibrational spectra of bis(azido)hydrazo-1,2,4,5-tetrazine isomers.

per tetrazole unit. Solvation in DMSO has about the same effect as solvation in water. We conclude that solvation can change the equilibrium for the tetrazines. For the 1,3,5-triazines the energy differences are too large for the effects of the solvation to allow the formation of a tetrazole. For practical consequences two other effects have to be taken into account: hydrogen bonds to solvents like water which are not included in our treatment and the lattice energy of the respective azide and tetrazole species. Depending on lattice energy and therefore solubility, it is possible that both the ditetrazoles and the diazides of tetrazines can be isolated, while the energy differences of the 1,3,5-triazines suggest that the tetrazoles derivatives cannot be prepared from the corresponding azides. Solvation in DMSO and water makes the monotetrazoles **151** and **161** the minimum energy species for the bis(azido)-1,2,4,5-tetrazine and the bis(azido)azo-1,2,4,5-tetrazine system. The ditetrazole **176** is the minimum energy species in the bis(azido)hydrazo-1,2,4,5-tetrazine system.

The calculated data explain the experimental detection of the mono- and ditetrazole derivatives of diazidotetrazine. As the data supplied by the authors do not confirm the conformation of the ditetrazine, we believe that isomer **153**, which is 8.3 kcal mol$^{-1}$ lower in energy, is formed in the reaction in contrast to the reported isomer **158**.

## Computational Methods

The geometries of the triazido-1,3,5-triazine, aminodiazido-1,3,5-triazine, diazidonitro-1,3,5-triazine, and diazidotetrazine compounds were optimized at the MP2 level (full active orbital space) within the symmetry constraints stated in the respective Tables using a cc-pVDZ basis set.[25] Due to computational cost all other compounds were optimized on the B3LYP level of theory with the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

same basis set. Comparison of the B3LYP energies from reference[20] for cyanuric azide and of values obtained for the diazidotetrazine isomers at the B3LYP/aug-cc-pVTZ level of theory shows good agreement with the energies obtained at the CCSD(T) level. The vibrational frequencies, which were computed at the optimized structures, show true minima on the potential energy surface with no imaginary frequencies for all azides and tetrazoles. The located transition states are of the first order, the Cartesian displacement coordinates of the imaginary frequency mode correspond to the ring opening of a tetrazole to an azide. For further validation single-point CCSD(T) calculations using a cc-pVDZ basis set were performed using the full orbital space for the triazido-1,3,5-triazine, aminodiazido-1,3,5-triazine, diazidonitro-1,3,5-triazine, and diazidotetrazine compounds. A Mulliken analysis was used for the charge discussion. For the discussion of solvent-induced changes, the solvent effects were introduced within the self-consistent reaction field (SCRF) formalism by means of the polarized continuum model (PCM) of Tomasi et al.[26] as implemented in GAUSSIAN 03. This method models the solvent as a continuum of uniform dielectric and therefore does not take into account explicit solvent–solute interactions such as hydrogen bonding. Three different continuum environments with the characteristics of $CCl_4$, DMSO and water were employed to explore the influence of an increasing dielectric permittivity on the potential energy of the investigated compounds. While the isomers of cyanuric azide, triazido-*s*-heptazine and diazidotetrazine were optimized within the PCM model, for all other compounds single point calculations were used due to computational cost. Coupled cluster single point calculations, for which the MP2 geometries were used, were performed with the MOLPRO program package,[27] all other calculations were performed with Gaussian03.[28]

# Comparative Sol–Hydro(Solvo)thermal Synthesis of $TiO_2$ Nanocrystals

Xianfeng Yang,[a] Hiromi Konishi,[b] Huifang Xu,[c] and Mingmei Wu*[a]

**Keywords:** Crystal growth / Nanostructures / Self-assembly / Solvothermal synthesis / Titanium

Three small inorganic compounds [acetic acid ($CH_3COOH$), nitric acid ($HNO_3$), and hydrochloric acid (HCl)] and five small organic compounds [*n*-butyl alcohol ($CH_3CH_2CH_2CH_2OH$), 1,2-propanediol ($CH_2OHCHOHCH_3$), propane-1,3-dicarboxylic acid ($HOOCCH_2COOH$), butane-1,4-dicarboxylic acid ($HOOCCH_2CH_2COOH$), and ethylenediamine ($H_2NCH_2CH_2NH_2$)] with different donors ($Cl^-$, $NO_3^-$, OH, $COO^-$, and $NH_2$) are used respectively and comparatively in different reaction media for tailoring the sol–hydrothermal synthesis of $TiO_2$ nanocrystals at a specific reaction temperature and/or for different reaction times. Both anatase and rutile with a variety of nanostructures such as nanocubes, nanorods, nanoneedles, and their self-assembled nanospheres are selectively grown. Well-defined and crystalline anatase nanocrystals with a narrow size distribution are prepared in the presence of *n*-butyl alcohol. With the use of HCl, nanoneedles and their assembled nanospheres of phase-pure rutile are obtained under much less drastic conditions, even at 100 °C and for only two hours. The effects of the reaction media, synthesis temperatures, and aging times on the structures and shapes of the products are investigated in detail by powder X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM).

## Introduction

Titanium dioxide has great potential in pigments, sensors, dielectric ceramics, as a catalyst supporter, and in solar cells as it exhibits outstanding ability for deodorization, air purification, and sterilization by strong photocatalysis.[1–10] Its performance depends to a large extent on its physical and chemical nature, which are related to its crystal structure, grain (crystal) size, morphology, and even surface structure.[11] Therefore, there is considerable interest in the controlled preparation of $TiO_2$ with a specific nanostructure.[12–24]

Many chemical routes have been developed to synthesize titania nanoparticles, typically gas condensation and wet chemistry.[25–32] In the former, it is not easy to control grain size and crystal shape; in addition, there are some limitations such as low output, complex equipment, and high cost. In contrast, it is much easier to control and modify the growth by adopting appropriate organic ligands in wet chemical processing such as sol–gel and hydrothermal synthesis.

The sol–gel approach provides a feasible route to prepare nanosized particles by using organic ligands to confine the growth. However, the high-temperature calcination may lead to aggregation into larger particles, phase transformation, and unavoidable evaporation of organic molecules. More attention has been paid to hydrothermal synthesis because of its much milder and friendly reaction conditions in a tightly closed vessel, and it shows advantages over sol–gel processes in most aspects.[30,31]

Multidispersed nanocrystals are generally produced because of the heterogeneous nature of the reaction and Ostwald ripening during hydrothermal aging. Therefore, the use of an organic solvent as a reaction medium[16,32] and of organic surfactants as ligands to confine the growth has raised great interest.[21,22] It has been reported that rutile nanofibers and poorly crystalline, multidispersed anatase nanoparticles can be prepared using alcohols as solvents.[33] In the first part of this manuscript, we will use *n*-butyl alcohol instead of water as a nonaqueous reaction medium and titanium *n*-butoxide (TNB) as a titanium precursor to prepare monodispersed anatase $TiO_2$ nanocubes.

Besides the use of organic surfactants with long alkyl chains, some smaller organic acids and amines with oxygen and nitrogen as donors have also been employed to modify the growth of titania in aqueous or nonaqueous solvents.[17,34] For example, Sugimoto and co-workers have investigated organic amines for the shape-controlled synthesis of $TiO_2$ nanoparticles by employing titanium isopropoxide as a titanium source[29] while Jiang and co-workers have investigated carboxylic acids for the size-controlled synthesis of $TiO_2$ by employing inorganic metatitanic acid as a

titanium source.[35] The use of diols in an autoclave synthesis of nanosized $TiO_2$ crystals has also been reported in several papers.[36,37] Herein we compare the use of organic diamines, diacids, and diols as additives on the growth of $TiO_2$ nanocrystals in a sol–hydrothermal approach.

As with the use of organic molecules, inorganic acidic aqueous solutions have been extensively used in the past few decades to precipitate $TiO_2$ nanocrystals. Besides our previous work, the influence of some small inorganic acids such as HCl on the growth of products has been investigated in detail.[30,38,39] Recently, the growth process of $TiO_2$ nanocrystals is receiving more and more interests.[40–42] However, to the best of our knowledge there are no reports about the evolution of one-dimensional rutile nanostructures with hydrothermal growth and aging. Such a growth and aging process of pure-phase rutile nanocrystals is investigated here in detail based on our previous work.[30]

## Results and Discussion

### The Use of Pure Water as Solvent

TNB is very reactive towards nucleophilic reagents and its hydrolysis occurs very easily in water. However, its hydrolysis can be modified and the growth of the resultant $TiO_2$ controlled by organic alcohols, acids, and even amines. A comparable experiment was performed without adding any additive or co-solvent to investigate the effect of alcohol, acid, and amine on the crystallization of $TiO_2$. The powder XRD pattern shown in part a of Figure 1 reveals that $TiO_2$ particles from "pure hydrothermal treatment" of TNB crystallize in phase-pure tetragonal anatase (JCPDS card no. 84-1286) in the space group $I4_1/amd$ (no. 141) with unit cell dimensions $a$ = 0.3782 and $c$ = 0.9502 nm. The TEM image in Figure 1 (b) demonstrates that most of the particles range from 10 to 20 nm in size and are finely dispersed. The crystal sizes calculated from the 101 and 200 diffractions using Scherrer's equation are 15.7 and 12.2 nm, respectively. The ratio of $D_{101}/D_{200}$ is about 1.30, which indicates some anisotropic growth. A few aggregates and much larger particles can be clearly observed, which is probably due to the easy hydrolysis of TNB, precipitation of amorphous titania particles, and heterogeneous reactions. In order to obtain more uniform titania nanocrystals, organic solvents such as *n*-butyl alcohol were used as solvents and/or chelating ligands to inhibit hydrolysis and manipulate the growth of $TiO_2$.

### The Use of Organic Compounds

#### *n-Butyl Alcohol as Solvent*

Recently, highly crystalline anatase nanoparticles have been synthesized by the reaction of titanium tetraisopropoxide with common ketones and aldehydes as oxygen-supplying agents under solvothermal conditions.[32] In our present work, highly crystalline and monodispersed anatase nanocrystals are obtained in *n*-butyl alcohol. TNB is dissolved in *n*-butyl alcohol to form a transparent sol. This homogeneous sol can be used in a solvothermal reaction to prepare uniform $TiO_2$ nanocrystals. During the synthesis, the etherification of *n*-butyl alcohol in the system would occur and slowly generate water, which could play a role as an oxygen donor in the hydrolysis of TNB to form titania.[33]

The powder XRD pattern (Figure 2, a2) indicates the product is phase-pure anatase. The calculated crystallite

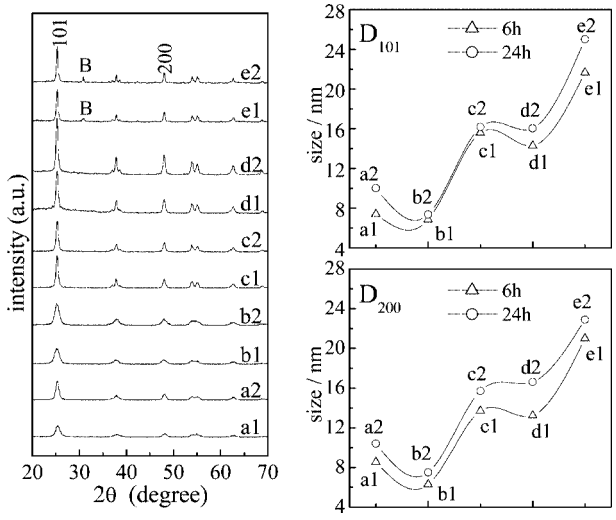

Figure 2. XRD patterns (left panel) of $TiO_2$ powders derived from several different media at 220 °C after 6.0 h (a1–e1) and 24 h (a2–e2), and a comparison of the corresponding calculated particle sizes by fitting the FWHM of (101) (top-right panel) and (200) (bottom-right panel) peaks: (a) *n*-butyl alcohol, (b) 1,2-propanediol, (c) propanedicarboxylic acid, (d) butanedicarboxylic acid, (e) ethylenediamine. B means Brookite.

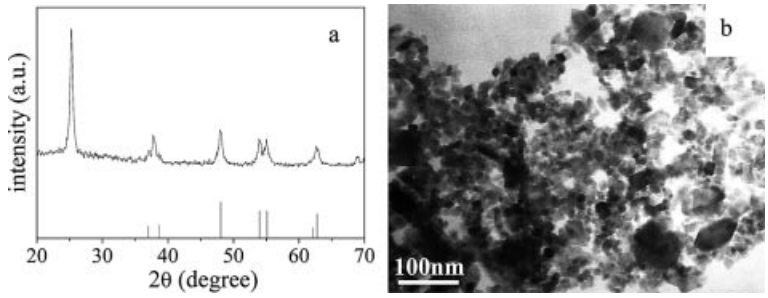

Figure 1. (a) Powder XRD pattern of the nanocrystalline titania product generated in "pure water" at 220 °C for 24 h (top), and pattern with vertical bars (bottom) derived from the JCPDS card (no. 84-1286) of anatase $TiO_2$. (b) TEM image of the product.

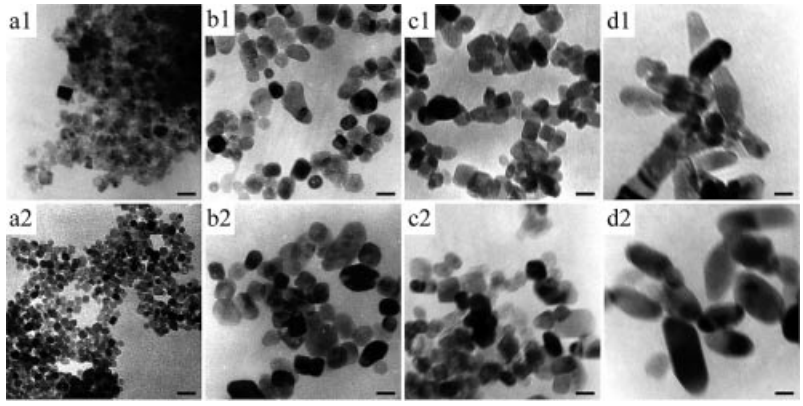

Figure 3. TEM images of nanocrystalline $TiO_2$ samples obtained under various sol–hydrothermal conditions: (a) *n*-butyl alcohol, (b) propanedicarboxylic acid, (c) butanedicarboxylic acid, (d) ethylenediamine. Scale bar: 20 nm.

sizes are 10.0 ($D_{101}$) and 10.4 nm ($D_{200}$), which imply an isotropic growth of $TiO_2$ nanocrystals. Besides the crystal sizes, the particle sizes of $TiO_2$, as displayed in Figure 3 (a2), are smaller than those in Figure 1 (b), further confirming that the use of *n*-butyl alcohol can confine the growth of titanium dioxide. Besides acting as an oxygen donor, *n*-butyl alcohol is also the by-product of the hydrolysis of TNB, therefore the use of *n*-butyl alcohol as a solvent would significantly retard the hydrolysis, polycondensation, and eventual crystallization and growth. More significantly, monodispersed nanocubes of highly crystalline anatase crystals are obtained from such a solvothermal growth in *n*-butyl alcohol.

### *An Organic Diol*

In order to compare the effect of a monoalchol and diol on the growth of $TiO_2$, 1,2-propanediol was used as an additive. A homogeneous sol of the precursor was formed by mixing TNB and 1,2-propanediol with magnetic stirring before performing the reaction. The product was indexed to be anatase, with crystallite sizes of 7.4 ($D_{101}$) and 7.5 nm ($D_{200}$; Figure 2, b2), which also indicate an isotropic growth as compared to that obtained with *n*-butyl alcohol. However, 1,2-propanediol inhibits the growth of $TiO_2$ more, probably due to its stronger chelating ability because of its didentate structure.

### *Organic Diacids*

A carboxyl group could serve as a donor to coordinate titanium atom in aqueous solution,[35] and organic acids can serve as ligands to limit the hydrolysis of TNB. Thus, a homogeneous hydrosol was produced as a hydrothermal reaction precursor for the formation of uniform titania nanoparticles. Herein, propanedicarboxylic acid and butanedicarboxylic acid were chosen as additives in the reaction media to modify the hydrothermal growth of $TiO_2$. The products were identified from their powder XRD patterns to be anatase (parts c2 and d2 in Figure 2). Highly dispersed nanoparticles, as shown in Figure 3 (see b2 and c2), are clearly obtained. Although organic diacids could be used as ligands to complex titanium atoms and might confine the growth of $TiO_2$ crystals, in our present work the calculated crystal sizes ($D_{101}$ = 16.2, $D_{200}$ = 15.7 nm and $D_{101}$ = 16.2, $D_{200}$ = 16.6 nm for propanedicarboxylic acid and butanedicarboxylic acid, respectively) are a little larger than those from a "pure hydrothermal reaction", and are much larger than those from alcohols (Figure 2, right panel). Thus, the ability of these diacids to confine the growth is greatly reduced. This can be attributed to the presence of $H_3O^+$ ions[30,31] and esterification of the acid with *n*-butyl alcohol, which is the by-product of the hydrolysis of TNB. In this way, the chelating ability of the acid is greatly reduced.

### *A Diamine*

The titanium dioxide product from the reaction with the addition of ethylenediamine is anatase with a trace of brookite (Figure 2, e2). The existence of brookite might result from the weakly basic nature of the amine.[43]

The crystal sizes of the product are related to both nucleation and growth: a greater number of nuclei generally result in a smaller crystal size. The isoelectronic point (IEP) of titania is around pH 6. In either basic or acidic medium, the solubility of titania is greater than that in both alcohol and water, which means that the number of nucleation sites in either a basic or acidic medium is less than that in alcohol. Therefore, the sizes of crystals grown in either acidic or basic medium should be larger than those grown in alcohol or water. In addition, it has been well established that both organic amines and acids can catalyze the growth of titania particles.[13,30] The crystal sizes, as shown in Figure 2 (e2), are larger than those from alcohol (parts a2 and b2 in Figure 2).

Figure 3 (d2) reveals that the use of ethylenediamine can significantly promote an anisotropic growth of $TiO_2$ nanocrystals and, consequently, $TiO_2$ nanorods are obtained. The anisotropic growth of anatase is attributed to its stronger adsorption of ethylenediamine onto the crystal faces parallel to the *c*-axis than the others.[29] This organic diamine is a strong ligand for some transition metals such as zinc, copper, and nickel, and is widely used in coordination chemistry.[44] However, the capping ability of nitrogen

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms − the electron donors in amines − with titanium is relatively weaker than the oxygen atoms in carboxyl moieties or hydroxide ions. Therefore, the particle sizes of the final products obtained from the aqueous solution of ethylenediamine are significantly larger than those from the organic media mentioned above (Figure 2).

### Reaction Times

In order to further investigate the growth behavior of $TiO_2$ in various reaction media in the presence of organic alcohol, acid, or amine, the reaction time was shortened to six hours. The powder XRD and TEM images in Figures 2 and 3, respectively, confirm similar growth features to those observed after 24 h, and it can also be observed that the crystal sizes of $TiO_2$ from the amine medium are the largest and those from the alcohol medium are the smallest. However, some titania particles are not well crystallized after a crystallization time of only 6.0 h, as observed in Figure 3 (a1).

Well-crystallized anatase particles can be observed after only a short time either in butanediacarboxylic acid or in propanedicarboxylic acid. Anatase crystals exhibit very similar growth behavior in these two organic acids. The TEM images and calculated crystal sizes indicate a similar isotropic growth behavior of $TiO_2$ nanocrystals in the presence of these organic acids, which have similar structures except for the length of their alkyl chain.

The resultant crystal sizes are dependent on a cooperative effect of hydrolysis, nucleation, growth, and aging. Beside the growth, the other fundamental significance for studying the size and shape control of the nanocrystals lies in the understanding of their nucleation. Facile hydrolysis, such as in "pure water", might yield larger amount of nuclei and reduce crystal sizes, especially without aging, although it could also shorten the time to reach the nucleation and growth step, which might increase the crystal sizes. Therefore, the role of the nucleation and its effect on the crystal sizes is quite complicated and generally poorly understood due to a lack of reliable experimental data.[45] Here, for example, the growth of anatase crystals in alcohol, particularly in the diol, is obviously inhibited, whereas in amine it is considerably accelerated (Figure 2, right panel). In summary, the ability to retard the growth of anatase follows the trend 1,2-propanediol > *n*-butyl alcohol > water > butane(or propane)dicarboxylic acid > ethylenediamine, with the donor sequence OH, $COO^-$, $NH_2$. Based on these experimental results, we are convinced that the growth step generally plays a crucial role during the hydrothermal reaction.[17] Therefore, in order to obtain optimal nanostructured materials, it is quite important to adopt appropriate organic molecule to modify the growth behavior.[45,46]

### The Use of Inorganic Acids: A Typical Growth and Aging of Rutile in Hydrochloric Acid

In our previous work we investigated the effects of inorganic acids on the growth of $TiO_2$ and found that pure-phase anatase, a mixture of anatase and rutile, and pure-phase rutile were obtained in acetic acid, nitric acid, and hydrochloric acid, respectively.[30] It has also been reported that pure rutile can be grown in nitric acid.[47] However, upon changing the TNB and nitric acid concentrations from those in the literature,[30,47] no rutile phase appeared, and phase-pure anatase was formed instead. This suggests that the growth of $TiO_2$ in nitric acid is very complicated. The anatase products formed as nanograins and rutile as nanorods (Figure 4, right panel, parts b and c).

We have previously reported the synthesis of rutile nanocrystals at temperatures above 200 °C by using TNB as a starting material in sol–hydrothermal reactions. A low-temperature preparation of rutile nanorods was also achieved at around 100 °C by using either titanium tetrachloride or trichloride as titanium source.[33,40] However, titanium chlorides release large amounts of heat, which prevents the homogeneous precipitation of $TiO_2$ particles because of the vigorously exothermic reaction, when titanium chloride is dissolved in water.[15,30]

According to the above experimental results with inorganic media (Figure 4), it can be concluded that phase-pure rutile nanorods can be formed in HCl. Therefore, HCl solution was selected as a representative inorganic medium to examine the growth of rutile at a much lower temperature. We used a modified sol–hydrothermal growth to prepare

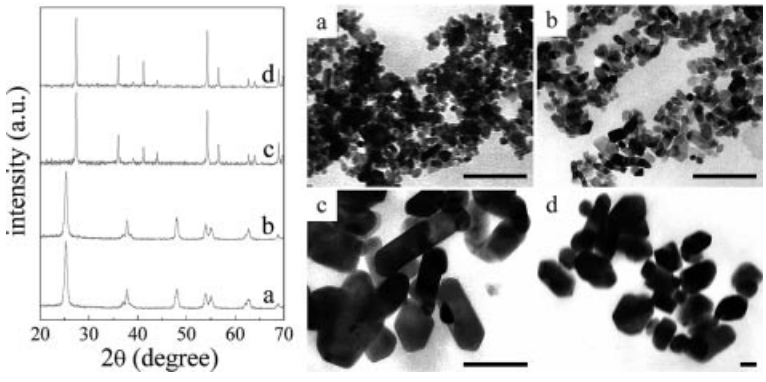

Figure 4. XRD patterns and TEM images of titania samples generated from various solutions at 220 °C: (a) HOAc, (b) $HNO_3$, and (c) HCl for 24 h; (d) HCl for 7 d. Scale bar: 100 nm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rutile nanoneedles with a much higher aspect ratio at 100 and 140 °C, respectively. As indicated in Figure 5 (a1), rutile was obtained as the exclusive product at 100 °C after only two hours. The nanoparticles of rutile prepared at this point are highly aggregated into nanospheres consisting of very thin nanorods (Figure 6, a1 and inset). Their radial assembly in a good geometrical match to create the spherical nanostructure could significantly reduce the total free energy. These spherical structures are present for about 10 h at 100 °C and are then destroyed by further hydrothermal reaction (Figure 6, a4). The calculated crystalline sizes of rutile prepared at 100 °C after two hours are about 2.1 and 5.5 nm for the 110 and 101 diffractions, respectively. With an increase of reaction time, the crystal sizes assigned to $D_{110}$ tend to increase progressively. However, the crystal sizes calculated from the 101 diffraction tend to increase only up to 10 h and decrease a little thereafter (Figure 5, middle).

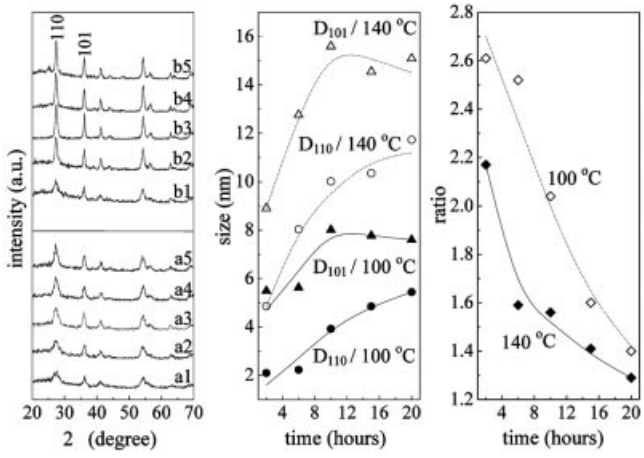

Figure 5. XRD patterns (left panel) of the products formed with HCl at 100 °C (a1–a5) and 140 °C (b1–b5) after 2.0 h (a1, b1), 6.0 h (a2, b2), 10 h (a3, b3), 15 h (a4, b4), and 20 h (a5, b5). Crystallite sizes (middle panel) calculated by fitting the FWHM of the (110) and (101) peaks. $D_{101}/D_{110}$ ratios (right panel).

Phase-pure rutile can also be obtained at 140 °C (Figure 5, b1) and a similar hydrothermal growth behavior to that at 100 °C is observed (Figure 5, middle). These rutile particles synthesized at 140 °C also self-aggregate into microspheres up to 10 h (Figure 6, b1–b3). However, the aggregated microspheres self-disperse after a longer hydrothermal aging such as for 15 h (Figure 6, b4). This might be due to a much higher activation energy for self-aggregation for the formation of larger nanorods. The typical product obtained at 140 °C after 10 h consists of well-defined nanoneedles, as clearly illustrated in Figure 7 (a), in which the sample for TEM observation has been highly and strongly ultrasonically dispersed. The anisotropic growth of rutile nanoneedles into self-assembled sub-microspheres can clearly be observed in the low-magnification TEM image (Figure 7, b). The lattice spacing of 0.32 nm perpendicular to the longitudinal direction in the high-magnification TEM image implies a <001> growth direction (Figure 7, c). The favorable growth along the *c*-axis in the early stages is due to the internal structure, as we described previously.[30] The growth velocity at the initial stage either in the radial or longitudinal direction is much faster than that at 100 °C due to kinetic factors. This type of quick growth feature during the initial stage has been well documented by Peng for semiconductors.[45] With further aging after 10 h, the radial growth tends to be slower and the longitudinal growth also tends to be retarded. The maximum value

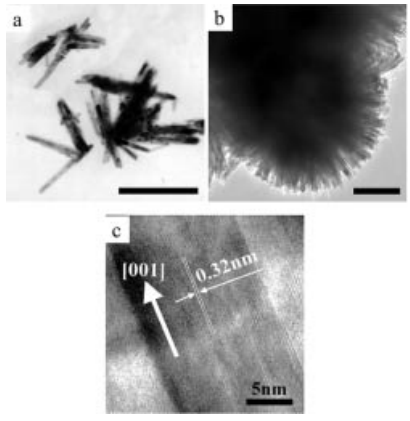

Figure 7. TEM images of ultrasonically dispersed rutile nanoneedles (a), a self-assembled sphere (b), and a high-resolution TEM image of a specific nanoneedle (c). Scale bar: 200 nm.

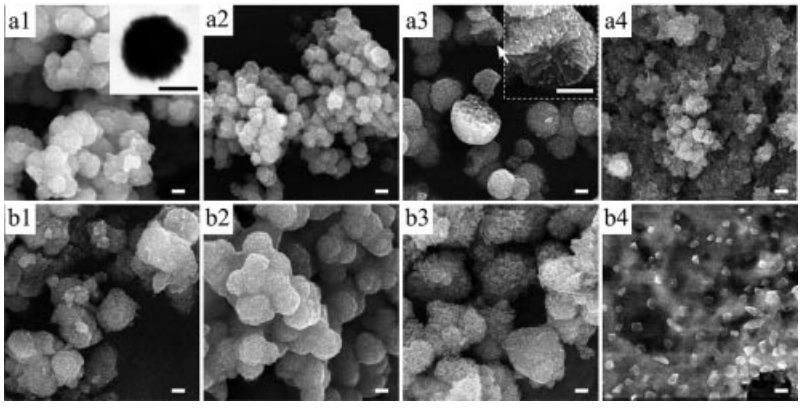

Figure 6. Electron microscopy images of the products obtained with HCl at 100 °C (a1–a4) and 140 °C (b1–b4) after 2.0 h (a1, b1), 6.0 h (a2, b2), 10 h (a3, b3), and 15 h (a4, b4). The inset in a3 is the magnified sphere indicated by the white arrow. Scale bar: 200 nm.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of $D_{101}$ at 10 h and the slow decrease of $D_{101}$ after 10 h (Figure 5, middle) reveals an obvious 1D/2D ripening during hydrothermal aging, as described previously for CdSe nanorods.[45]

The ratio of $D_{101}/D_{110}$ indicates that the aspect ratio drops noticeably with hydrothermal reactions longer than two hours in our present work. We did not observe the 1D and 3D growth stage described previously by Peng for the growth of CdSe nanocrystals[45] when our reaction is shorter than two hours (Figure 5, right panel). However, both the short and long axes increase when the reaction time is shorter than 10 h at either 100 °C or 140 °C (Figure 5, middle). Thus, the reaction at times shorter than 10 h can be referred to as a three-dimensional growth stage. After 10 h, the short axis keeps growing while the long axis becomes shorter. There is therefore a noticeable net growth and net dissolution along the short and long axes, respectively, along with a 1D/2D ripening. This produces nanorods with smaller aspect ratios, and granular particles are produced if allowed enough reaction time. A significant experimental result in our present work is that the aspect ratio at 100 °C is greater than that at 140 °C, as shown in Figure 5 (right). This means that the higher reaction temperature accelerates the 1D/2D ripening, especially for longer reaction times. For example, many more and larger granular crystals are noticeable at 220 °C after one day, and even more so after seven days (Figure 4, c, d, right).

## Conclusions

A variety of sol–hydro(solvo)thermal syntheses of anatase and rutile nanocrystals have been comparatively described that use small inorganic and organic compounds as additives at various reaction temperatures for different aging times. Instead of water, alcohol as a solvent in the sol–hydrothermal synthesis can result in a confined growth of well-crystalline and uniform anatase nanocubes. Except for HCl medium, phase-pure anatase can be formed in an organic alcohol, an organic diamine, an organic diacid, and acetic and nitric acids. The use of a diamine promotes the anisotropic growth of anatase nanocrystals, while the use of a diacid cannot do this efficiently because of its stronger capping ability. Rutile nanospheres self-assembled from rutile nanorods are obtained through a facile sol–hydrothermal growth route in HCl medium. More significantly, a 3D growth and 1D/2D ripening mechanism of rutile nanocrystals are revealed. It is proposed that prolonging the reaction time and increasing the reaction temperature will lead to the formation of larger rutile crystals but will reduce the aspect ratios of one-dimensional rutile nanocrystals.

## Experimental Section

**Preparation:** Titanium salts such as titanium chloride ($TiCl_3$ or $TiCl_4$),[40,42] titanium sulfate $Ti(SO_4)_2$,[48,49] and titanium alkoxide $[Ti(OR)_4]$[30,41] in solution are often used as titanium sources to synthesize $TiO_2$ nanoparticles. The hydrolysis of $Ti(OR)_4$ is relatively mild as compared with inorganic salts and is easy to control. Therefore, tetrabutyl titanate was employed here as the titanium source. In the present work, besides $H_2O$ and *n*-butyl alcohol as "pure solvents", the others were used as aqueous 2.0 M solutions of acetic acid, nitric acid, hydrochloric acid, 1,3-propanedicarboxylic acid, 1,4-butanedicarboxylic acid, 1,2-propanediol, and ethylenediamine. Titanium *n*-butoxide $[Ti(OC_4H_9)_4$, TNB] was added dropwise to one of the pure organic solvents or one of the concentrated inorganic acids/amine under magnetic stirring to form a clear sol. Then, distilled water was added dropwise to the sol while stirring to prepare a reagent with a fixed concentration of diol, acid, amine, and titanium (2.0 M). Subsequently, the homogeneous hydrosol was transferred into a Teflon-lined stainless-steel vessel, which was tightly closed instantly for sol–hydrothermal reaction under an autogenous pressure at 220 °C for one day, unless otherwise mentioned. The vessel was then taken out from the oven and cooled to ambient temperature. The white product was filtered, washed with distilled water, and dried in a desiccator at ambient temperature.

**Characterization:** Products were characterized by powder X-ray diffraction using Cu-$K_\alpha$ radiation ($\lambda$ = 0.15045 nm) and a graphite monochromator on a RIGAKUD/MAX 2200 VPC diffractometer operating at 40 kV and 30 mA. Crystallite sizes of $TiO_2$ particles were calculated using Scherrer's equation from the FWHM (full-width at half-maximum) of the anatase (101 and 200) and rutile (110 and 101) diffractions, respectively. Electron microscopy observations were carried out with a JSM-6330F Field Emission scanning electron microscope at 15 kV or JEM-100CX and JEM-2010 transmission electron microscopes at 100 kV and 200 kV, respectively. The samples for TEM examination were prepared by depositing an ultrasonically dispersed suspension of $TiO_2$ powder from a water/alcohol mixture onto a carbon-coated copper grid.

# A Systematic Exploration of Nickel(II)/Acetate/Di-2-pyridyl Ketone Chemistry: Neutral and Cationic Tetranuclear Clusters, and a Novel Mononuclear Complex

**Constantinos G. Efthymiou,[a] Catherine P. Raptopoulou,[b] Aris Terzis,[b] Roman Boča,*[c] Maria Korabic,[d] Jerzy Mrozinski,*[d] Spyros P. Perlepes,*[a] and Evangelos G. Bakalbassis*[e]**

**Keywords:** Acetate ligands / Di-2-pyridyl ketone / Magnetic properties / Nickel(II) cubanes / Nickel(II) defect dicubanes / X-ray diffraction

The further use of di-2-pyridyl ketone [$(2\text{-py})_2CO$] in nickel(II) acetate chemistry has been investigated. Various synthetic procedures have led to the synthesis of complexes $[Ni_4(O_2CMe)_2\{(2\text{-py})_2C(OH)O\}_4(H_2O)_2](ClO_4)_2$ (**1**), $[Ni(O_2CMe)\{(2\text{-py})_2C(OH)_2\}\{(2\text{-py})_2CO\}](ClO_4)\cdot H_2O$ (**2**·$H_2O$), $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)\cdot 2H_2O\cdot 2EtOH$ (**3**·$2H_2O$·2EtOH), $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]\cdot 2MeCN$ (**4**·2MeCN), and $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](O_2CMe)\cdot 6H_2O\cdot MeCN$ (**5**·$6H_2O$·MeCN). The $Ni^{II}$-mediated hydrolysis of $(2\text{-py})_2CO$ to give the coordinated molecule $(2\text{-py})_2C(OH)_2$ or the monoanion $(2\text{-py})_2C(OH)O^-$ involves nucleophilic attack by $H_2O$ on the carbonyl group. The $Ni^{II}$ ion in **2**·$H_2O$ is coordinated by one monodentate acetate, one *N*,*N*′,*O*-tridentate chelating $(2\text{-py})_2C(OH)_2$ molecule, and one *N*,*N*′-bidentate chelating $(2\text{-py})_2CO$ ligand. The tetranuclear cluster cation of **1** has a cubane $\{Ni_4(\mu_3\text{-}OR)_4\}^{4+}$ core with $Ni^{II}$ ions and deprotonated oxygen atoms occupying alternate vertices. The $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4]^+$ cations present in the complexes **3**·$2H_2O$·2EtOH and **5**·$6H_2O$·MeCN have almost identical cubane structures that are different from the structure of the cation of **1**. The four metal ions in the centrosymmetric molecules of **4**·2MeCN are located at four vertices of a defect dicubane (with two missing vertices) and are bridged by six oxygen atoms. Characteristic IR bands are discussed in terms of the known structures of **1**–**5**. The magnetic data for the $Ni^{II}$ cubane **1** has been modeled with two *J* values, and shows that the coupling consists of two ferromagnetically coupled pairs that are antiferromagnetically coupled to give a diamagnetic ground state. The magnetic properties of **4** have been modeled with three *J* values, and reveal competing antiferromagnetic and ferromagnetic coupling between the four $Ni^{II}$ ions.

## Introduction

The last 15 years have witnessed explosive growth in interest in the polynuclear complexes (clusters) of 3d-metals at intermediate oxidation states with primarily oxygen- and/or nitrogen-based ligation.[1] This has been mainly due to their relevance to two fields, bioinorganic chemistry[2] and molecular magnetic materials. For the latter field, the discovery that individual polynuclear molecules can function as nanoscale magnets was a significant development.[3,4] Such molecules have since been named single-molecule magnets (SMMs). Although Mn clusters at various oxidation levels have to date proven to be the most fruitful source of SMMs, complexes displaying SMM behavior are known for several other 3d-metals (e.g., $V^{III}$, $Fe^{II}$, $Fe^{III}$, $Co^{II}$, $Ni^{II}$)[5] with various *S* values, both integer and half-integer. The future health of the field of 3d-metal clusters, and the chances of discovering high-spin molecules (molecules with a large *S*) and/or identifying new SMMs will benefit from the development of new synthetic routes for polynuclear complexes.

With the points mentioned above in mind, and in the context of "serendipitous assembly",[1b] our group[6] and others[7] have been exploring "ligand blend" reactions involving (i) the monoanion, $(2\text{-py})_2C(OH)O^-$, or the dianion, $(2\text{-py})_2CO_2^{2-}$, of the *gem*-diol form (derivative) of di-2-pyridyl ketone, $(2\text{-py})_2CO$, and carboxylates; and (ii) the monoanion, $(2\text{-py})_2C(OR)O^-$, of the hemiacetal form of $(2\text{-py})_2CO$ and carboxylates, with the belief that they might

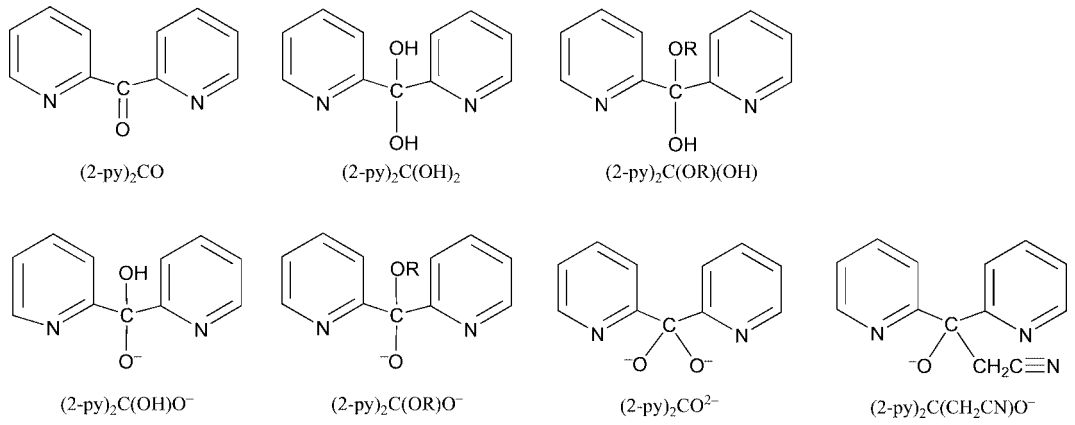

Figure 1. The formulae of the ligands discussed in the text; note that $(2\text{-py})_2C(OH)_2$, $(2\text{-py})_2C(OR)(OH)$, and all four anions do not exist as free species but exist only in their respective metal complexes.

foster the formation of discrete polynuclear metal systems. The formulae of these ligands are shown in Figure 1. The reactions of $(2\text{-py})_2CO$ with 3d-metal ions have been well studied over the years.[6–9] There is a chemical characteristic of $(2\text{-py})_2CO$ that makes this molecule a special ligand, this is its carbonyl group. Water and alcohols (ROH) have been shown to add to the carbonyl group upon coordination of the carbonyl oxygen atom and/or the 2-pyridyl rings forming the ligands $(2\text{-py})_2C(OH)_2$ [the *gem*-diol form of $(2\text{-py})_2CO$] and $(2\text{-py})_2C(OR)(OH)$ [the hemiacetal form of $(2\text{-py})_2CO$], respectively. The neutral ligands $(2\text{-py})_2C(OH)_2$ and $(2\text{-py})_2C(OR)(OH)$ coordinate to the metal centers as *N*,*N*′,*O* chelates, with the M–O bond often being weak; therefore, both neutral ligands do not hold much interest from the viewpoint of cluster formation.[8] Completely different and much more interesting (for cluster chemistry) coordination modes are seen when the ligands $(2\text{-py})_2C(OH)_2$ and $(2\text{-py})_2C(OR)(OH)$ are deprotonated. Upon deprotonation, the latter becomes monoanionic, while the former can function either as mono- or dianionic. The presence of deprotonated hydroxy group(s) leads to a great coordinative flexibility, because of the well-known ability of the negatively charged oxygen atom to bridge two or three metal ions. The monoanionic forms usually bridge two ($\mu_2$) or three ($\mu_3$) metal ions, while the dianionic form can bridge as many as five metal sites ($\mu_5$). The immense structural diversity displayed by the complexes reported stems in part from the ability of $(2\text{-py})_2CO_2^{2-}$, $(2\text{-py})_2C(OH)O^-$, and $(2\text{-py})_2C(OR)O^-$ to exhibit no less than ten distinct coordination modes.[8] Carboxylates ($R'CO_2^-$) are employed for two reasons in the "ligand blends". Firstly, they are able to deprotonate the hydroxy group(s) under mild conditions (the use of external hydroxides often perplexes the reactions). Secondly, they are flexible ligands, a consequence of their ability to adopt a number of different ligation modes, both terminal and bridging as well as both bidentate and tridentate, giving an extraordinary structural versatility in the mixed-ligand systems. Thus, the $(2\text{-py})_2CO_2^{2-}/R'CO_2^-$, $(2\text{-py})_2C(OH)O^-/R'CO_2^-$, and $(2\text{-py})_2C(OR)O^-/R'CO_2^-$ "blends" (R = Me, Et; R′ = Me, $CF_3$, Ph), without (binary "blends") or with (ternary "blends") additional inorganic ligands [$NO_3^-$, $N_3^-$, $SCN^-$, $N(CN)_2^-$] have led to a variety of Mn, Fe, Co, Ni, and Cu clusters with nuclearities ranging from 3 to 14[8] and with interesting magnetic properties, including single-molecule magnetism.[6b]

Restricting further discussion to nickel(II) chemistry, the investigation of the binary $(2\text{-py})_2CO_2^{2-}$, $(2\text{-py})_2C(OH)O^-$, or $(2\text{-py})_2C(OR)O^-/MeCO_2^-$ "blend" has up to now led to clusters $[Ni_9(OH)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$,[6f] $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$,[7a] and $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]$.[7b] We suspected that our,[6f] Tong's and Chen's,[7a] and Brown's and Krebs'[7b] groups had merely scratched the surface of this binary reaction system and we, thus, decided to perform a systematic synthetic study of the $Ni^{II}/MeCO_2^-/(2\text{-py})_2CO$ reaction system. Here we discuss the syntheses, structures, and IR spectra of the resulting products; the magnetic properties of two representative clusters will also be described and analyzed. The discovery of single-molecule magnetism in high-spin $Ni^{II}$ cubane clusters[10] revived the interest in such compounds.

## Results and Discussion

### Synthesis

As stated above, we were interested in extending the very small family of $Ni^{II}/MeCO_2^-/(2\text{-py})_2CO$-based ligand complexes[6f,7a,7b] *without* the introduction of additional anionic inorganic ligands (binary "blends"). The chemical and structural identity of the products from the $Ni(O_2CMe)_2\cdot 4H_2O/(2\text{-py})CO$ reaction system depends on the solvent used, the presence/absence of counterions (this synthetic parameter is related to the choice of the solvent), the ligand–to-metal reaction ratio and the $OH^-$ concentration. Our general route for the isolation of heteroleptic $(2\text{-py})_2CO_2^{2-}$, $(2\text{-py})_2C(OH)O^-$, or $(2\text{-py})_2C(OR)O^-/MeCO_2^-$ $Ni^{II}$ clusters was to treat an excess of nickel(II) acetate with $(2\text{-py})_2CO$; we shall describe our efforts in terms of the solvent. Obviously "$(2\text{-py})_2C(OH)_2$" and "$(2\text{-py})_2C(OR)(OH)$" can be fully/partially deprotonated by the basic acetate groups and polynuclear $Ni^{II}/(2\text{-py})_2CO_2^{2-}$, $(2\text{-py})_2C(OH)O^-$, or $(2\text{-py})_2C(OR)O^-/MeCO_2^-$ complexes may result

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$4\ Ni(O_2CMe)_2{\cdot}4H_2O + 4\ (2\text{-py})_2CO + 2\ NaClO_4 \xrightarrow{H_2O} \underset{\mathbf{1}}{[Ni_4(O_2CMe)_2\{(2\text{-py})_2C(OH)O\}_4(H_2O)_2](ClO_4)_2} + 2\ NaO_2CMe + 4\ MeCO_2H + 10\ H_2O \quad (1)$$

from the reactions as long as the $MeCO_2^-$-to-$(2\text{-py})_2CO$ ratio is high enough to leave an amount of nonprotonated acetate in the reaction mixture, given the fact that the anionic forms of $(2\text{-py})_2CO$ and the acetate can adopt a variety of terminal and bridging modes.

Complexes **1** and **2** were prepared from aqueous reaction mixtures. The preparation of compound **1** can be achieved by the reaction of $Ni(O_2CMe)_2{\cdot}4H_2O$ with $(2\text{-py})_2CO$ according to the balanced Equation (1). One feature of the chemical Equation (1) deserves a comment.

This is the "wrong" stoichiometry, i.e. $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO$ = 1.5:1, employed for the preparation of **1** (see Exp. Sect.) compared with that required by Equation (1) [1:1]. The "incorrect" reaction ratio is because of our desire to avoid the formation of the mononuclear complexes **2** and $[Ni\{(2\text{-py})_2C(OH)O\}\{(2\text{-py})_2C(OH)_2\}]_2[Ni\{(2\text{-py})_2C(OH)O\}_2](ClO_4)_2{\cdot}7H_2O$[11] that contain a 1:2 $Ni^{II}/(2\text{-py})_2CO$-based ligand ratio (vide infra). If we assume that the simplified chemical equilibrium represented by Equation (2) takes place (this is only one of the possible chemical equilibria), then the presence of an excess of nickel(II) acetate shifts the equilibrium to the right.

$$2\ [Ni(O_2CMe)\{(2\text{-py})_2C(OH)_2\}\{(2\text{-py})_2CO\}]^+ + 2\ Ni(O_2CMe)_2 + 4\ H_2O \rightleftharpoons [Ni_4(O_2CMe)_2\{(2\text{-py})_2C(OH)O\}_4(H_2O)_2]^{2+} + 4\ MeCO_2H \quad (2)$$

Having obtained and identified complex **1**, the next question addressed was whether, and in what manner, changes to the $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO$ ratio might affect the product identity. In particular, we wondered whether it might be possible to prepare mononuclear complexes containing the ligand $(2\text{-py})_2C(OH)_2$ [the neutral *gem*-diol form of $(2\text{-py})_2CO$, Figure 1] and/or clusters containing the dianion $(2\text{-py})_2CO_2^{2-}$ [Figure 1] that are different from $[Ni_9(OH)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$ previously reported.[6f] We were successful with the first goal but unsuccessful with the second.

The 1:2 reaction between $Ni(O_2CMe)_2{\cdot}4H_2O$ and $(2\text{-py})_2CO$ in $H_2O$ in the presence of an excess of $NaClO_4$ gave a mauve solution. Slow solvent evaporation at room temperature yielded crystals that were obviously a mixture of two products. Microscopic examination showed both brown-red prisms and mauve needles to be present in a visual ratio of roughly 3:1. The unit cell dimensions of hand-picked prisms and needles did not correspond to known compounds. Since repeated crystallizations from $H_2O$ or $H_2O/Me_2CO$ could not yield a sample free of the needles for elemental analysis, full data sets were collected for both compounds and the structures solved. The extreme differences in color and in crystal shape were fortuitous and allowed easy manual separation of the two materials. The prisms proved to be $[Ni(O_2CMe)\{(2\text{-py})_2C(OH)_2\}\{(2\text{-py})_2CO\}](ClO_4)$ (**2**) as its mono(water) solvate, while the needles were shown to be $[Ni\{(2\text{-py})_2C(OH)O\}\{(2\text{-py})_2C(OH)_2\}]_2[Ni\{(2\text{-py})_2C(OH)O\}_2](ClO_4)_2{\cdot}7H_2O$ consisting of two chemically similar cations, one neutral complex molecule, two perchlorate anions, and water solvate molecules.[11] The latter compound will not be further discussed because it will be incorporated into a full paper dealing with all the acetate-free complexes that have been isolated from the $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO$ and $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/ClO_4^-$ reaction mixtures. The formation of **2** as an individual species can be summarized in the balanced Equation (3). With the identity of **2** established, we subsequently tried to devise a route to pure material. Complex **2** has a $Ni^{II}/ClO_4^-$ ratio of 1:1, whereas the acetate-free complex has a $Ni^{II}/ClO_4^-$ ratio of 3:2, i.e. 1.5:1. Thus, attempts to obtain pure **2** were made by further lowering the $Ni^{II}/ClO_4^-$ ratio.

$$Ni(O_2CMe)_2{\cdot}4H_2O + 2\ (2\text{-py})_2CO + NaClO_4 \xrightarrow{H_2O} \underset{\mathbf{2}}{[Ni(O_2CMe)\{(2\text{-py})_2C(OH)_2\}\{(2\text{-py})_2CO\}](ClO_4)} + NaO_2CMe + 3\ H_2O \quad (3)$$

Somewhat to our disappointment, the use of $Ni^{II}/ClO_4^-$ ratios of 1:2 or even of 1:3 again gave mixtures of **2** and $[Ni\{(2\text{-py})_2C(OH)O\}\{(2\text{-py})_2C(OH)_2\}]_2[Ni\{(2\text{-py})_2C(OH)O\}_2](ClO_4)_2{\cdot}7H_2O$. It is likely that the reaction solution contains a complicated mixture of several mononuclear species in equilibrium, with factors such as relative solubility, lattice energy, crystallization kinetics − amongst others − determining the identity of the isolated products.

The incorporation of a coordinated ligand molecule in its ketone form [$(2\text{-py})_2CO$] (Figure 1) in **2** was unexpected, given the fact that the complex was isolated from $H_2O$.[8] One possible reason for the presence of the $(2\text{-py})_2CO$ ligand is the satisfaction of the requirements of the crystal lattice. Another reason could be the combined tendencies of the acetate ion to coordinate (and not to act as a counterion) in the presence of $ClO_4^-$ ions and of the $Ni^{II}$ ion to adopt the octahedral stereochemistry; the monodentate acetate coordination (vide infra) "forces" the second neutral organic molecule to behave as a bidentate ligand; the bidentate chelating mode is much more common for $(2\text{-py})_2CO$ than for $(2\text{-py})_2C(OH)_2$.

The 3:1:1 or 2 $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/NaClO_4$ reaction mixtures in $H_2O$ were also investigated due to our desire to doubly deprotonate the *gem*-diol form of $(2\text{-py})_2CO$ [as a consequence of the high $MeCO_2^-/(2\text{-py})_2C(OH)_2$ ratio] and to prepare complexes of $(2\text{-py})_2CO_2^{2-}$. However, such efforts were in vain. Complex **1** was again

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

isolated even employing a $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO$ ratio of 4:1, emphasizing the fact that $H_2O$ is not the appropriate solvent for the isolation of metal complexes of $(2\text{-py})_2CO_2^{2-}$.[6b,e,f,g,12]

The access to **1** and **2** from $H_2O$ suggested that the reaction system might be capable of extension to other solvents. The 1:1 or 2:1 $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO$ reaction mixtures in EtOH gave green crystals upon layering with $Et_2O$. The unit cell dimensions of a hand-picked crystal confirmed this product to be the known complex $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]{\cdot}4EtOH$,[7b] on the basis of comparison with those of the authentic sample. We were rather surprised to see that this complex could not be easily isolated without the addition of $Et_2O$, e.g. upon slow solvent evaporation at room temperature. We suspected that a cationic species was present in solution and we thus reasoned that adding $ClO_4^-$ ions might give a cationic cluster. Not only did the addition of $ClO_4^-$ confirm our suspicion about the importance of the counterion in determining the reaction product but it also yielded a tetranuclear cluster with a topology (cubane) different from that of the neutral complex $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]{\cdot}4EtOH$[7b] (defective double cubane). The formation of the tetranuclear cluster $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$ (**3**), which was crystallized upon lowering the temperature of the EtOH reaction solution can be summarized in the balanced Equation (4).

$$4\ Ni(O_2CMe)_2{\cdot}4H_2O + 4\ (2\text{-py})_2CO + NaClO_4 \xrightarrow{EtOH}$$

$$[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4) + NaO_2CMe + 4\ MeCO_2H + 12\ H_2O \quad (4)$$

**3**

The "wrong" $Ni^{II}/(2\text{-py})_2CO/ClO_4^-$ ratio employed for the preparation of **3** (4:4:2, see Exp. Sect.) compared to that required by Equation (1) [4:4:1] did not prove detrimental to the formation of the complex. With the identity of **3** established, the "correct" stoichiometry was employed and led to the pure compound in high yield. The employment of EtOH as the solvent might imply the presence of the monoanion of the hemiacetal form of di-2-pyridyl ketone, i.e. $(2\text{-py})_2C(OEt)O^-$ (Figure 1) in the complex. However, only $(2\text{-py})_2C(OH)O^-$ ligands are present in complex **3**. It is difficult to rationalize this result; suffice it to say that the moisture present in solution (from the solvent and the starting materials) is responsible for the formation of the $(2\text{-py})_2C(OH)O^-$ ligands and that complex **3** is the thermodynamically stable product from the $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/NaClO_4$ reaction system in nonabsolute EtOH. It should be mentioned at this point that although the incorporation of $(2\text{-py})_2C(OMe)OH/(2\text{-py})_2C(OMe)O^-$ ligands in solid metal complexes isolated from MeOH is common,[8,9d,e,f,g,i,k,l,13] the participation of $(2\text{-py})_2C(OEt)OH/(2\text{-py})_2C(OEt)O^-$ ions in the coordination spheres of metal ions is rare[7b,9k] inspite of the plethora of reactions performed in EtOH.

The last reaction solvent investigated was *MeCN*. Previous synthetic studies on the $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/NaClO_4$ reaction system in $MeCN/H_2O$ ($H_2O$ is necessary to keep the produced $NaO_2CMe$ soluble) had led to the isolation of the cationic cubane cluster $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$.[7a] We wondered whether a neutral cluster could be formed in the absence of $ClO_4^-$ ions. The 1:1 reaction between $Ni(O_2CMe)_2{\cdot}4H_2O$ and $(2\text{-py})_2CO$ in MeCN under reflux gave complex $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]$ (**4**) in high yield according to the balanced Equation (5). We were happy to see (vide infra) that the structural motif in **4** (double defective cubane) is different from that in the cationic cluster isolated from the same solvent (cubane).[7a]

$$4\ Ni(O_2CMe)_2{\cdot}4H_2O + 4\ (2\text{-py})_2CO \xrightarrow[\Delta]{MeCN}$$

$$[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4] + 4\ MeCO_2H + 12\ H_2O \quad (5)$$

**4**

The 2:1 and 3:1 reactions of $Ni(O_2CMe)_2{\cdot}4H_2O$ with $(2\text{-py})_2CO$ in MeCN under reflux gave a mixture of green crystals and green powder. The extreme difference in crystallinity was fortuitous and allowed ready manual separation of the two materials. The crystals were shown to be the known complex $[Ni_9(OH)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$[6f] by determination of the unit cell dimensions. The double deprotonation of the *gem*-diol form of di-2-pyridyl ketone is a consequence of the high $MeCO_2^-$ (base) to "$(2\text{-py})_2C(OH)_2$" ratio (4:1 or 6:1) used in the reactions. The green powder is certainly $Ni(O_2CMe)_2{\cdot}4H_2O$ (that was not initially dissolved), a conclusion consistent with IR data.

A last synthetic parameter that was studied was the $OH^-$ concentration. Although it is well known that the use of external hydroxides often perplexes the reactions of metal ions with $(2\text{-py})_2CO$, we tried to prepare clusters containing $(2\text{-py})_2CO_2^{2-}$ ligands under conditions that favor formation of neutral or anionic complexes; for the latter purpose we employed bulky noncoordinating countercations, e.g. $NnBu_4^+$, $BPh_4^+$, and $PPh_4^+$. Synthetic studies of hundreds of $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/OH^-$ or $Ni(O_2CMe)_2{\cdot}4H_2O/(2\text{-py})_2CO/OH^-/Z^+$ ($Z^+$ = countercation) reaction systems in various solvents repeatedly led to amorphous or microcrystalline materials with poor analytical results. We were luckier when we employed a solvent mixture comprising EtOH and MeCN, and $LiOH{\cdot}H_2O$ as the base under reflux. Using a rather unusual crystallization process we isolated single crystals of complex $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](O_2CMe)$ (**5**). However, we were unlucky at the same time because (i) the complex does not contain $(2\text{-py})_2CO_2^{2-}$ and (ii) the molecular structure of the cation is similar to that present in complex **3**. The formation of **5** can be summarized in the balanced Equation (6). The isolation of **5** that contains an acetate counterion was surprising and, needless to say, unexpected. Ethanol is necessary in the solvent mixture to keep $LiOH{\cdot}H_2O$ soluble, while treatment of the obtained residue (obtained after solvent evaporation under reduced pressure) with MeCN allows removal of the produced, insoluble

$LiO_2CMe$ and dissolution of the cluster, which is subsequently crystallized pure upon storage of the resulting solution at 5 °C.

$$4\ Ni(O_2CMe)_2{\cdot}4H_2O + 4\ (2\text{-py})_2CO + 4\ LiOH{\cdot}H_2O \xrightarrow{EtOH/MeCN\ (3:1\ v/v)} [Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](O_2CMe) + 4\ LiO_2CMe + 20\ H_2O \quad (6)$$

**5**

## Description of Structures

### *[Ni(O$_2$CMe){(2-py)$_2$C(OH)$_2$}{(2-py)$_2$CO}](ClO$_4$)·H$_2$O (2·H$_2$O)*

A partially labeled plot of the mononuclear cation $[Ni(O_2CMe)\{(2\text{-py})_2C(OH)_2\}\{(2\text{-py})_2CO\}]^+$ present in compound **2**·$H_2O$ is shown in Figure 2. Selected bond lengths and angles are listed in Table 1. The structure consists of the above mentioned mononuclear cation, one $ClO_4^-$ anion, and one $H_2O$ solvate molecule.

Table 1. Selected bond lengths [Å] and angles [°] for [Ni(O$_2$CMe)-{(2-py)$_2$C(OH)$_2$}{(2-py)$_2$CO}](ClO$_4$)·H$_2$O (**2**·H$_2$O).

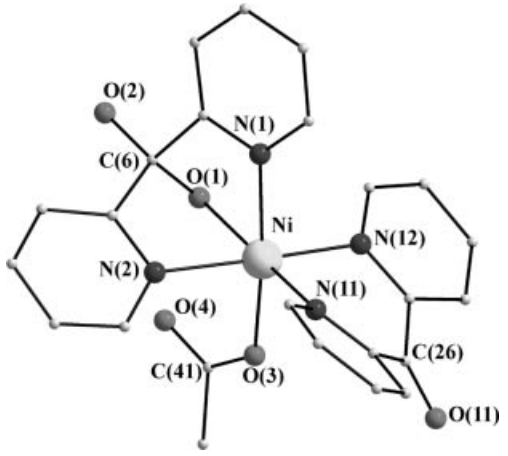

Figure 2. Partially labeled ORTEP plot of the mononuclear cation present in complex **2**·$H_2O$.

The $Ni^{II}$ atom is coordinated by one monodentate acetate, one tridentate chelating $(2\text{-py})_2C(OH)_2$ molecule, and one bidentate chelating $(2\text{-py})_2CO$ ligand. The ligated atoms of the latter are the 2-pyridyl nitrogen atoms (Figure 3), while the *gem*-diol ligand adopts the coordination mode $\eta^1{:}\eta^1{:}\eta^1$, see also Figure 3. The two oxygen atoms [O(1), O(3)] are in *cis* positions. The Ni–N and Ni–O bond lengths agree well with values expected for high-spin $Ni^{II}$ in octahedral environments.[7a,b,10] The distortion from a perfect octahedral geometry is primarily a consequence of the presence of three different ligands in the coordination sphere of $Ni^{II}$. The short length of the C(26)–O(11) bond [1.218(5) Å, compared with the C(6)–O(1, 2) bond lengths of 1.387(4) and 1.417(5) Å] reflects the ketone character of this group. There is one strong intramolecular hydrogen bond with the coordinated hydroxy oxygen of $(2\text{-py})_2C(OH)_2$ as the donor and the uncoordinated acetate oxygen

as the acceptor; its dimensions are: O(1)···O(4) 2.525 Å, H(O1)···O(4) 1.688 Å, and O(1)–H(O1)···O(4) 168.7°. The crystal structure is stabilized by a hydrogen bond in which the uncoordinated hydroxy oxygen of the *gem*-diol ligand acts as the donor and one of the perchlorate oxygen atoms as the acceptor; the corresponding dimensions are O(2)···O(7) [$-x$, $y - 1/2$, $-z + 1$] 2.700 Å, H(O2)···O(7) 1.828 Å, and O(2)–H(O2)···O(7) 161.8°.

Compound **2**·$H_2O$ is the first example of a metal complex in which the ketone [$(2\text{-py})_2CO$] and the *gem*-diol [$(2\text{-py})_2C(OH)_2$] forms of di-2-pyridyl ketone co-exist as ligands.

### *[$Ni_4(O_2CMe)_2\{(2\text{-py})_2C(OH)O\}_4(H_2O)_2$](ClO$_4$)$_2$ (1), [$Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4$](ClO$_4$)·2H$_2$O·2EtOH (3·2H$_2$O·2EtOH), and [$Ni_4(O_2CMe)_3\{(2\text{-py})_2$-$C(OH)O\}_4$]($O_2$CMe)·6H$_2$O·MeCN (5·6H$_2$O·MeCN)*

Partially labeled plots of the tetranuclear cations present in compounds **1**, **3**·2$H_2O$·2EtOH, and **5**·6$H_2O$·MeCN are shown in Figure 4, Figure 5, and Figure 6, respectively. Tables 2, 3, 4, 5, and 6 show selected interatomic distances plus angles and hydrogen bonding data for complexes **1** and **5**·6$H_2O$·MeCN.

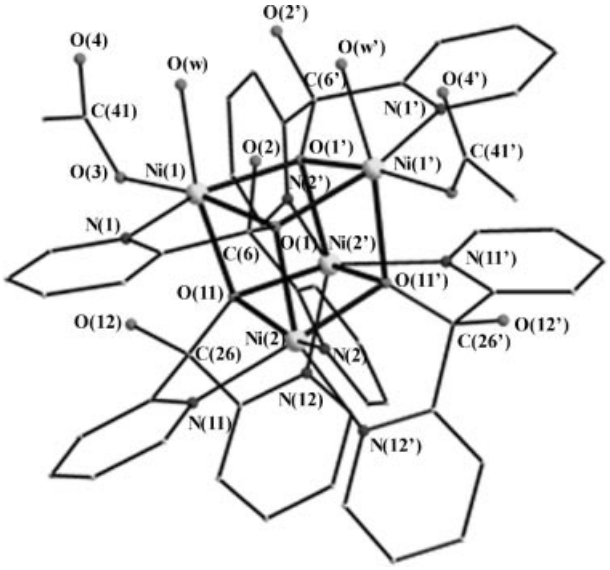

Figure 4. Partially labeled ORTEP plot of the tetranuclear cation present in complex **1**. Primed and unprimed atoms are related by the crystallographic twofold axis.

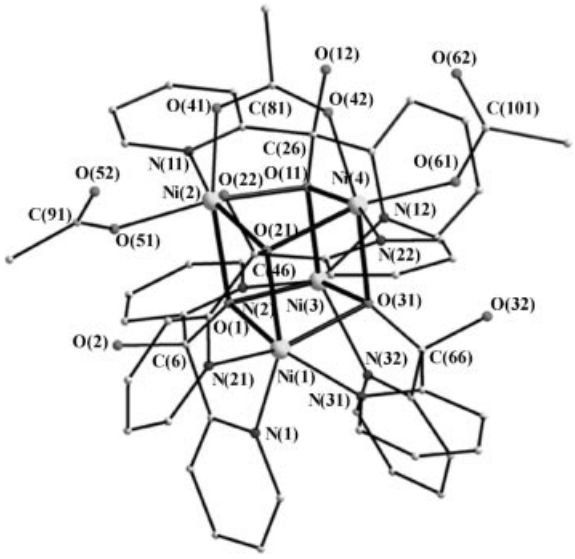

Figure 5. Partially labeled ORTEP plot of the tetranuclear cation present in complex **3**·2$H_2O$·2EtOH. The cubane core is outlined in bold.

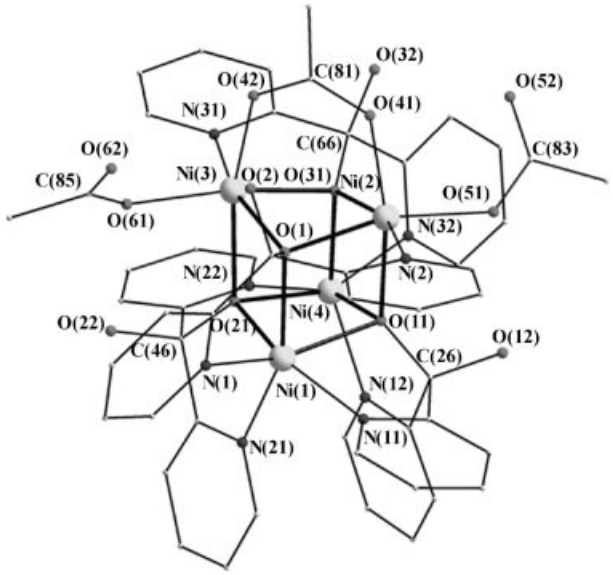

Figure 6. Partially labeled ORTEP plot of the tetranuclear cation present in complex **5**·6$H_2O$·MeCN. The cubane core is outlined in bold.

Complex **1** crystallizes in monoclinic space group *C*2/*c*. Its structure consists of tetranuclear [$Ni_4(O_2CMe)_2\{(2\text{-py})_2$-$C(OH)O\}_4(H_2O)_2$]$^{2+}$ cations and well-separated $ClO_4^-$ counterions; the latter will not be further discussed. The tetranuclear cluster cation of **1** lies on a crystallographic twofold axis and has a cubane $\{Ni_4(\mu_3\text{-}OR)_4\}^{4+}$ core with $Ni^{II}$ and oxygen atoms occupying alternate vertices. In addition to three $\mu_3$-oxygen atoms, each of the metal ions Ni(1) and Ni(1′) is coordinated to one pyridyl N atom, to one aquo ligand, and to one O atom from a monodentate acetate ligand, whereas each of Ni(2) and Ni(2′) is coordinated to three pyridyl N atoms belonging to different $(2\text{-py})_2C(OH)O^-$ ligands. Thus, an octahedral coordination environment is created about each metal center; the chromophores are Ni(1, 1′)$O_5N$ and Ni(2, 2′)$O_3N_3$. One octahedral face of each $Ni^{II}$ atom is occupied by the three alkoxide-type oxygen atoms and the other contains the remaining donor atoms.

One oxygen atom [O(2), O(2′), O(12), O(12′)] of each $(2\text{-py})_2C(OH)O^-$ ligand remains protonated and unbound to the metal ions. The resultant monoanion functions as a $\eta^1{:}\eta^3{:}\eta^1{:}\mu_3$ ligand (Figure 3). This ligation mode is common for $(2\text{-py})_2C(OH)O^-$.[8]

There are two types of Ni–O (alkoxide-type) bonds for each metal ion: one bond is rather short at an average dis-

[a] A = acceptor; D = donor. [b] These oxygen atoms belong to the acetate counterion.

values for the corresponding bond lengths of other tetranuclear cubane $Ni^{II}$clusters.[6a,7a,10,14]

There is an amount of hydrogen bonding in **1** (Table 3). The donors are the aqua ligands and the hydroxy groups of all the $(2\text{-py})_2C(OH)O^-$ ligands. A notable feature here is that both uncoordinated and coordinated oxygen atoms of the terminal acetate ligands participate in intracubane hydrogen bonds; of interest is also the fact that the hydroxy oxygen atom O(2) acts both as a donor and an acceptor.

The cation $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4]^+$ present in complex **3**·$2H_2O$·2EtOH also has a cubane structure (Figure 5), with the $\eta^1{:}\eta^3{:}\eta^1\mu_3$ $(2\text{-py})_2C(OH)O^-$ ligands (Figure 3) supplying the O atoms at the alternate sites of the heterocubane. However, its structure is different from the structure of the cation present in **1**. There are no solvate ligands and a third acetate is present. Two acetates are coordinated to each of Ni(2) and Ni(4). The third acetate acts as an 1,3-bridge ($\eta^1{:}\eta^1{:}\mu_2$) between Ni(2) and Ni(4); thus, one face of the cube is capped by the $\mu_2$-bridging acetate which lies across the face diagonally. The metal centers that are bridged by the acetate ion have the shortest metal–metal distance [Ni(2)···Ni(4) 2.970(2) Å]. There are two distinct nickel sites in **3**·$2H_2O$.2EtOH. Two [Ni(1), Ni(3)] have an $O_3N_3$ coordination sphere, while for the other two [Ni(2),Ni(4)] the coordination environment is $O_5N$. Three Ni–O (alkoxide-type) distances are realized for Ni(1), Ni(2), and Ni(4). One bond is short with an average of 2.035(6) Å, one bond is relatively long with an average distance of 2.156(7) Å, while the third bond is of intermediate strength [average Ni–O distance of 2.089(7) Å]. For Ni(3) one bond is rather short to a distance of 2.045(7) Å, whereas the two other bonds are longer [2.106(6), 2.100(7) Å]. As in **1**, the $\{Ni_4O_4\}$ cube deviates from the ideal geometry. Since all the hydrogen atoms of this complex were not located by difference maps, we can not comment on the hydrogen bonds.

The molecular structure of the cation $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4]^+$ present in complex **5**·$6H_2O$·MeCN (Figure 6) is almost identical to that of the tetranuclear cation with the same formula in complex **3**·$2H_2O$·2EtOH. Clearly, the replacement of the $ClO_4^-$ counterion by the $MeCO_2^-$ counterion and the change of the lattice solvate molecules have very little structural effect. The crystal structure is stabilized by a series of strong or relatively strong hydrogen bonds with water solvate molecules as donors.

The molecular structure of the cations $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4]^+$ of complexes **3**·$2H_2O$·2EtOH and **5**·$6H_2O$·MeCN is very similar to that of the same cation present in complex $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)\cdot 8\cdot 25H_2O$.[7a]

Complexes **1**, **3**·$2H_2O$·2EtOH and **5**·$6H_2O$·MeCN join a family of polynuclear $Ni^{II}$ complexes with $(2\text{-py})_2CO$-based ligands, which currently comprises 12 clusters. The eight previously characterized clusters (solvate molecules are not indicated) are $[Ni_9(OH)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$,[6f] $[Ni_9(N_3)_2(O_2CMe)_8\{(2\text{-py})_2CO_2\}_4]$,[6f] $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$,[7a] $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]$,[7b] $[Ni_4\{(2\text{-py})_2C(OH)O\}_2\{(2\text{-py})_2C(OEt)O\}_2(CH_3CONHO)_2]Cl_2$,[7b] where $CH_3CONHO^-$ is the acetohydroxamate(–1) ion, $[Ni_4\{N(CN)_2\}_2(O_2CMe)_2\{(2\text{-py})_2C(OH)O\}_4]$,[6a] $\{K[Ni_6(CO_3)(N_3)_6(O_2CMe)_3\{(2\text{-py})_2C(CH_2CN)O\}_3]\}_2[K_2(H_2O)_2]$,[15] where $(2\text{-py})_2C(CH_2CN)O^-$ is the monoanion of a ligand generated in situ by the reaction of MeCN and $(2\text{-py})_2CO$ in the presence of *tert*-butoxide, $[Ni_4(N_3)_4\{(2\text{-py})_2C(OH)O\}_4]$,[9h] and $[Ni_4(N_3)_2\{(2\text{-py})_2C(OH)O\}_2\{(2\text{-py})_2C(OMe)O\}_2(H_2O)_2](ClO_4)_2$.[9i] From the tetranuclear clusters in the above list, only complexes $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$,[7a] $[Ni_4\{N(CN)_2\}_2(O_2CMe)_2\{(2\text{-py})_2C(OH)O\}_4]$,[6a] and the clusters **1**, **3**·$2H_2O$·2EtOH, **5**·$6H_2O$·MeCN reported in this work have a cubane structure.

[a] A = acceptor; D = donor. [b] Intramolecular hydrogen bonds.

Complex **4**·2MeCN crystallizes in monoclinic space group $P2_1/n$. Its structure consists of centrosymmetric tetranuclear $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)_2O\}_4]$ molecules and lattice MeCN molecules; the latter will not be further discussed. The four $Ni^{II}$ ions are located at four vertices of a defect dicubane (two cubanes sharing one face and each missing one vertex, Figure 8) and bridged by means of O atoms from the $(2\text{-py})_2C(OH)O^-$ ligands and two $\eta^2{:}\mu_2$ acetate ions (Figure 9). Peripheral ligation is provided by two O atoms of two monodentate ($\eta^1$, Figure 9) acetates and the N atoms of the eight 2-pyridyl rings. Atoms O(11)/O(11′) of two $(2\text{-py})_2C(OH)O^-$ ligands are triply bridging with distances to $Ni^{II}$ ions of 2.039(3), 2.091(3), and 2.157(3) Å. Atoms O(1)/O(1′) of the last two $(2\text{-py})_2C(OH)O^-$ ligands are doubly bridging forming one strong bond to Ni(2)/Ni(2′) [2.023(3) Å] and one weaker bond to Ni(1)/Ni(1′) [2.108(3) Å]. The bridging Ni–$O_{acetate}$ distances [2.061(3), 2.101(3) Å] are slightly asymmetric. The Ni–O bond lengths for the bridging acetate oxygen are longer than the Ni(2)–O(5) distance [2.025(3) Å] exhibited by the terminal acetate. One O atom of each $(2\text{-py})_2C(OH)O^-$ ligand remains protonated and unbound to the metal ions. Therefore, two $(2\text{-py})_2C(OH)O^-$ ligands adopt the $\eta^1{:}\eta^3{:}\eta^1{:}\mu_3$ coordination mode and the other two bind with the $\eta^1{:}\eta^2{:}\eta^1{:}\mu_2$ mode. Ni(1) and Ni(2) are also bridged by the O(3) atom of the $\eta^2{:}\mu_2$ acetate ligand. In the centrosymmetric tetramer two types of octahedrally coordinated $Ni^{II}$ ions can be distinguished, Ni(1) and Ni(2). The two chromophores are Ni(1)($O_{alkoxo}$)$_3$($O_{acetate}$)$N_2$ and Ni(2)($O_{alkoxo}$)$_2$($O_{acetate}$)$_2N_2$.

Complex **4** is the 13th member in the above-mentioned family of structurally characterized $Ni^{II}$ clusters with $(2\text{-py})_2CO$-based ligands.[6a,f,7a,b,9h,i,15] Within this family, complexes **4**, $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]$ (as the tetraethanol solvate),[7b] $[Ni_4\{(2\text{-py})_2C(OH)O\}_2\{(2\text{-py})_2C(OEt)O\}_2(CH_3CONHO)_2]Cl_2$,[7b] $[Ni_4(N_3)_4\{(2\text{-py})_2C(OH)O\}_4]$,[9h] and $[Ni_4(N_3)_2\{(2\text{-py})_2C(OH)O\}_2\{(2\text{-py})_2C(OMe)O\}_2(H_2O)_2](ClO_4)_2$[9i] have a defect dicubane structural motif. Complex **4** has a remarkable structural similarity with compound $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]\cdot 4EtOH$;[7b] only the crystal packing of this cluster differs.

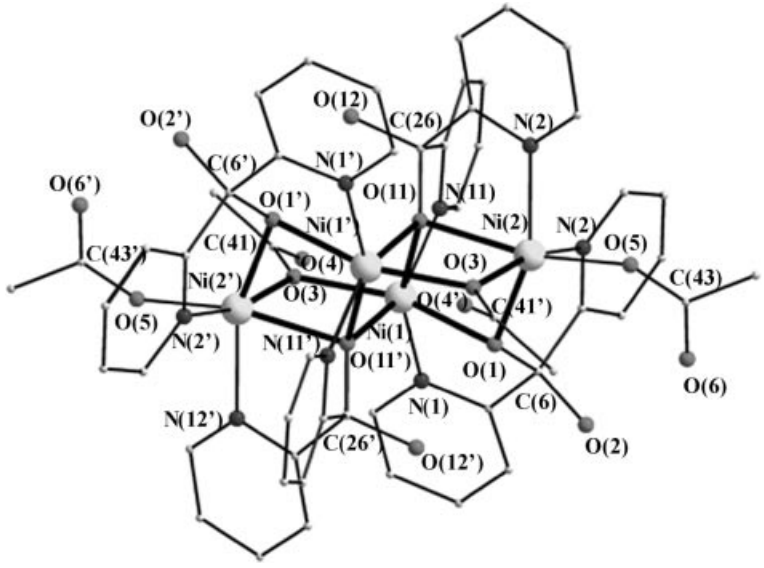

Figure 7. Partially labeled ORTEP plot of the tetranuclear molecule present in complex **4**·2MeCN. Primed and unprimed atoms are related by the crystallographic inversion center. The defect dicubane core has been highlighted.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

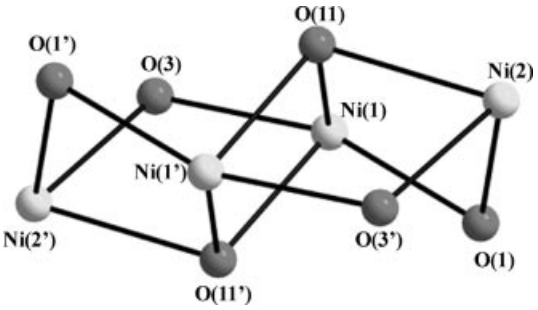

Figure 8. Labeled plot of the defect dicubane core present in complex **4**·2MeCN. Atoms O(3) and O(3′) originate from the $\eta^2$:$\mu_2$ acetates, while atoms O(1), O(1′), O(11), and O(11′) are the deprotonated oxygens of the $(2\text{-py})_2C(OH)O^-$ ligands.

Figure 9. The crystallographically established coordination modes of the acetate ligands present in complex **4**·2MeCN.

Tetranuclear $Ni^{II}$ clusters with the defect dicubane unit have been reported,[7b,9h,i,16] but these are significantly less than the $Ni^{II}$ cubanes.

## IR Spectra

The prepared complexes exhibit medium to strong intensity bands in the 3605–3150 $cm^{-1}$ region, assignable to ν(OH) vibrations of the $(2\text{-py})_2C(OH)_2$, $(2\text{-py})_2C(OH)O^-$, $H_2O$, and EtOH ligands/lattice molecules.[6a,9a] The broadness and relatively low frequencies of these bands are both indicative of hydrogen bonding.

The spectrum of **2**·$H_2O$ exhibits a strong band at 1686 $cm^{-1}$, assigned to ν(C=O) and suggesting that a certain amount of the organic ligand is present in its ketone form. This mode is situated at the same wavenumber (1684 $cm^{-1}$) in the spectrum of free $(2\text{-py})_2CO$, confirming the nonparticipation of the ketone group in the coordination in this complex. The spectra of **1** and **3**–**5** do not exhibit bands in the region expected for ν(C=O) vibrations, with the nearest IR absorptions at ca. 1600 $cm^{-1}$ assigned as a 2-pyridyl stretching mode raised from 1582 $cm^{-1}$ on coordination, as observed earlier[17] upon complex formation involving hydration of di-2-pyridyl ketone.[17]

Several bands appear in the 1600–1400 $cm^{-1}$ range in the spectra of the complexes. Contributions from the $MeCO_2^-$ $\nu_{as}(CO_2)$ and $\nu_s(CO_2)$ modes would be expected in this region, but overlap with the stretching vibrations of the 2-pyridyl rings and $\delta(CH_3)$ renders assignments tentative and application of the spectroscopic criterion of Deacon and Phillips[18] extremely difficult.

The IR spectra of **1**–**3** exhibit medium or strong bands at ca. 1100 and 620 $cm^{-1}$, because of the $\nu_3(F_2)$ and $\nu_4(F_2)$ modes of the uncoordinated $T_d$ $ClO_4^-$, respectively.[19] The $\nu_3(F_2)$ band is broadened and split, indicating the crystallographically established (at least for **1** and **2**) involvement of the $ClO_4^-$ ion in hydrogen bonding.[20]

## Magnetic Studies

Solid-state dc magnetic susceptibility measurements were performed on polycrystalline samples of the representative complexes **1** and **4**, under a constant field of 0.5 T in the temperature range of 1.9 to 300 K.

The exchange coupling of four $S = 1$ centers results in $n = 3^4 = 81$ molecular magnetic states that are split into 3 singlets ($S = 0$), 6 triplets ($S = 1$), 6 quintets ($S = 2$), 3 septets ($S = 3$), and 1 nonet ($S = 4$). Depending upon the actual topology, these states can be degenerate (the case of a perfect tetrahedron with a single exchange coupling constant) or the degeneracy can be partially removed.

The structural parameters of **1** suggest a lower symmetry than $T_d$. The magnetic analyses were carried out using a 2-*J* model and assuming that the tetranuclear structure results from the association of two planar, doubly-bridged dimeric units as shown in Figure 10. The intradimer interaction (noted $J_1$) is between Ni(1) and Ni(1′) on the one hand and between Ni(2) and Ni(2′) on the other hand, while the interdimer one is noted $J_2$. The spin Hamiltonian for such a model, reflecting the $S_4$ symmetry, is given by Equation (7).

$$\hat{H}(\mathbf{S}_4) = -J_1(\vec{S}_1\cdot\vec{S}_{1'} + \vec{S}_2\cdot\vec{S}_{2'}) - J_2(\vec{S}_1\cdot\vec{S}_2 + \vec{S}_1\cdot\vec{S}_{2'} + \vec{S}_{1'}\cdot\vec{S}_2 + \vec{S}_{1'}\cdot\vec{S}_{2'}) + \mu_B B g_{iso}(\vec{S}_1 + \vec{S}_{1'} + \vec{S}_2 + \vec{S}_{2'}) \quad (7)$$

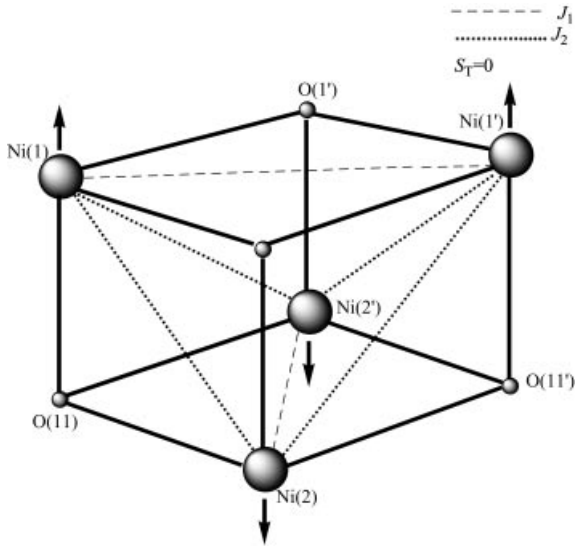

Figure 10. Core representation of the cation of **1** showing the coupling scheme used in the magnetic model and the relative orientation of the $Ni^{II}$ spins in the ground state. The numbering scheme from Figure 4 has been used.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The Hamiltonian matrix in the basis set of coupled kets $|S_1S_{1'}S_{11'}S_2S_{2'}S_{22'}SM\rangle$ is already diagonal, so that the energy levels are given[21] by a simple formula [Equation (8)], where the last, constant term can be omitted.

$$\varepsilon_{B=0}(S) = \left\langle S_{11'}S_{22'}SM \left| \hat{H}(S_4) \right| S_{11'}S_{22'}SM \right\rangle = -(J_2/2)[S(S+1) - S_{11'}(S_{11'}+1) - S_{22'}(S_{22'}+1)] - (J_1/2)[S_{11'}(S_{11'}+1) + S_{22'}(S_{22'}+1)] + (J_1/2)[S_1(S_1+1) + S_{1'}(S_{1'}+1) + S_2(S_2+1) + S_{2'}(S_{2'}+1)] \quad (8)$$

The addition of the Zeeman term results in the formula given by Equation (9), where a single, isotropic $g_{iso}$-factor common to all magnetic centers occurs.

$$\varepsilon_B(S,M) = \varepsilon_{B=0}(S) + \mu_B g_{iso} MB \quad (9)$$

The identification of the van Vleck coefficients is now an easy task, so that one can applythe van Vleck equation (with a vanishing second-order term) to end up with an analytical formula [Equation (10)] for the mean magnetic susceptibility, where the physical constants in the reduced Curie constant $C_0 = N_A\mu_0\mu_B^2/k$ adopt their usual meaning.

$$\overline{\chi}_{mol} = C_0 \frac{g_{iso}^2}{T} \frac{\sum_S \sum_{M=-S}^{+S} M^2 \exp[-\varepsilon_{B=0}(S)/kT]}{\sum_S \exp[-\varepsilon_{B=0}(S)/kT]} \quad (10)$$

Figure 11 shows plots of the experimental data for **1** in the form of $\mu_{eff}$ (effective magnetic moment) per complex, $\chi_{mol}$ and $\chi_{mol}^{-1}$ vs. $T$, respectively. The value of $\mu_{eff}$ at 300 K is 6.13 $\mu_B$ per complex. As the temperature is lowered, $\mu_{eff}$ experiences a slight increase, reaching a maximum value of 6.57 $\mu_B$ at 30 K, followed by a much sharper decline at lower temperatures, 2.48 $\mu_B$ at 1.9 K. The best fit parameters ($R$ = 0.055) are found to be $J_1$ = 13.7 cm$^{-1}$, $J_2$ = –1.4 cm$^{-1}$, and $g_{iso}$ = 2.14. Since the fit with $J$ constants is sufficient, there is no need to add $D$ to the model, risking an overparameterization. The experimental data show that complex **1** can be described as two ferromagnetically coupled $Ni_2$ pairs that, in turn, are coupled antiferromagnetically. The zero-field energy levels of **1** are shown in the inset of Figure 11. One can observe that the width of the energy band is less than $\Delta\varepsilon$ <100 cm$^{-1}$. This means that at ambient temperature a Curie law holds true owing to a uniform population of all energy levels. Upon cooling down, some "magnetically less productive states" (singlets, triplets, quintets) are depopulated and, thus, the overall "magnetic productivity" is raised; under the term "magnetic productivity" we mean the contribution of the state $g^2M^2\exp[\varepsilon_B = {}_0(S)/kT]$ to the susceptibility function and/or the effective magnetic moment. This point explains the maximum of $\mu_{eff}$ at 30 K. However, the ground state is $S$ = 0, because of the antiferromagnetic coupling between the two dimeric units. Consequently, the magnetic susceptibility exhibits a turning point on cooling (at 5.0 K), below which it drops to zero. Low-temperature data bring no evidence for the presence of a paramagnetic impurity in **1**. It can not be excluded that the zero-field splitting of the $S \geq 1$ states occurs, as the $D$ values (the axial zero-field splitting parameter), ranging between $D/k$ = –10 and +10 K, are typical for mononuclear $Ni^{II}$ complexes on departure from the octahedral geometry.[22] The involvement of the local anisotropy through the axial zero-field splitting parameter led to a rather slight improvement of the data-fit ($R$ = 0.0082) with magnetic parameters $J_1$ = 11.7 cm$^{-1}$, $J_2$ = –1.3 cm$^{-1}$, $g_{iso}$ = 2.16, and $D_{Ni}$ = –2.8 cm$^{-1}$. The obtained $D_{Ni}$ parameter lies at the limit of its detection from the susceptibility data; moreover, it has been obtained by assuming all the $D$ tensors are collinear, the negligible $g$-tensor anisotropy, and neglect of the pair-interaction $D_{Ni–Ni}$ parameters (the asymmetric exchange) that are inconsistent approximations.[22]

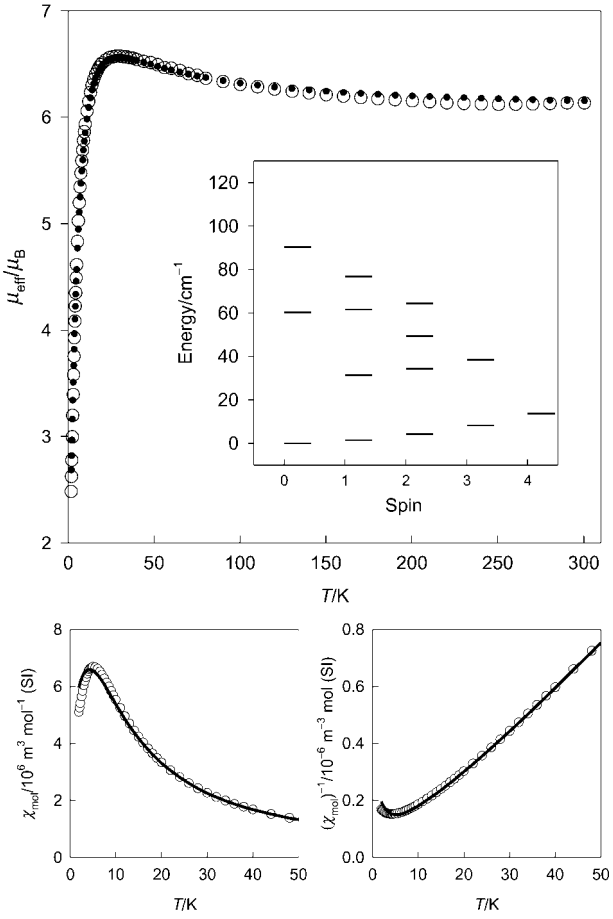

Figure 11. Plots of experimental (open circles) $\mu_{eff}$ (left), $\chi_{mol}$ (right up) and $\chi_{mol}^{-1}$ (right bottom) vs. $T$ per molecule of **1**. The filled circles and the solid lines are the fits to the experimental data (see text for details). Inset: calculated energy levels for individual total spins.

The lowest temperature data (below 5 K) can suffer from eventual saturation effects; when the magnetization approaches saturation, the apparent susceptibility $\chi = \mu_0 M/B$ decreases substantially [the true differential susceptibility, $\tilde{\chi} = \mu_0(\partial M/\partial B)$, as measured by the alternating-current susceptometer, then drops to zero]. Finally, some molecular field correction, accounting for the weak intercluster inter-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

actions can contribute to the low-temperature data. All of these effects are assumed to be of secondary importance and they do not alter the main conclusion for **1**, i.e. that the intradimer coupling is of ferromagnetic nature, whereas the interdimer interaction is antiferromagnetic.

It should be mentioned at this point that the most important parameter in the magnetostructural correlation of tetranuclear nickel(II) clusters possessing the $\{Ni_4(\mu_3\text{-}OR)_4\}^{4+}$ cubane core has been reported[6a,10c,14e–h,14k–14n] to be the average Ni–O–Ni angle of a cubane face. A ferromagnetic exchange interaction is observed for Ni–O–Ni angles lower than ca. 99° and the $J$ value increases as the angle decreases. On the other hand, Ni–O–Ni angles in the vicinity of, and larger than, 99° lead to an antiferromagnetic interaction and the $|J|$ value increases as the angle increases. Accordingly, a linear correlation between $J$ and the Ni–O–Ni angle has been reported.[14e] The $J_1$ and $J_2$ values for **1** are in line with the previous studies mentioned above. The mean Ni–O–Ni angle for the pairs described by $J_1$ is 96.6°, thus the coupling is predicted to be ferromagnetic, and indeed, it is ($J_1$ = 13.7 cm$^{-1}$). The value of the ferromagnetic parameter $J_1$ matches satisfactorily the linear dependence reported.[14e,h,l] The mean Ni–O–Ni value of 100.0° for the remaining four faces of the cube justifies the weak antiferromagnetic value of $J_2$ (–1.4 cm$^{-1}$).

Magnetically, the closest precedents of complex **1** are the cubanes $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4)$[7a] and $[Ni_4(O_2CCMe_3)_4(Mq)_4]$ (Mq = 1,8-hydroxyquinaldinate);[14n] their behavior was interpreted on the basis of two pairs of ferromagnetically coupled dimers that couple antiferromagnetically to give a diamagnetic ground state.

Variable-temperature magnetic data for complex **4** are presented in Figure 12. As the temperature is lowered, $\mu_{eff}$ experiences a very slight increase from $\mu_{eff}$ = 5.71 $\mu_B$ at 300 K (it practically has a constant value), reaching a broad maximum of $\mu_{eff}$ = 5.79 $\mu_B$ at 90 K, followed by a much sharper decline at lower temperatures, down to $\mu_{eff}$ = 1.33 $\mu_B$ at 1.9 K. Considering the cluster topology and core connectivity, the magnetic data were analyzed with the spin Hamiltonian given in Equation (11) [the spin numbering follows the Ni$^{II}$ ions in Figure 8],

$$\hat{H} = -J_1(\vec{S}_1 \cdot \vec{S}_{1'}) - J_2(\vec{S}_1 \cdot \vec{S}_{2'} + \vec{S}_{1'} \cdot \vec{S}_2) - J_3(\vec{S}_1 \cdot \vec{S}_2 + \vec{S}_{1'} \cdot \vec{S}_{2'}) + \mu_B B g_{iso}(\vec{S}_1 + \vec{S}_{1'} + \vec{S}_2 + \vec{S}_{2'}) \quad (11)$$

where $J_1$ is assigned to the Ni(1)···Ni(1′) interaction of the central pair, $J_2$ to the Ni(1)···Ni(2′) [Ni(1′)···Ni(2)] interaction, and $J_3$ to the Ni(1)···Ni(2) [Ni(1′)···Ni(2′)] exchange interaction. The above Hamiltonian cannot be taken to a diagonal form so that we are left with the diagonalization of its matrix elements and a numerical finding of the van Vleck coefficients that enter the formula for the magnetic susceptibility.[23] The best-fit parameters ($R$ = 0.030) are: $J_1$ = –5.0 cm$^{-1}$, $J_2$ = –4.8 cm$^{-1}$, $J_3$ = 15.3 cm$^{-1}$ with $g$ = 2.00. The involvement of the local anisotropy through the axial zero-field splitting parameter $D_{Ni}$ led only to a slight improvement of the data-fit ($R$ = 0.018) with magnetic parameters $J_1$ = –5.3 cm$^{-1}$, $J_2$ = –4.6 cm$^{-1}$, $J_3$ = 15.7 cm$^{-1}$, $g$ = 2.00, and $D_{Ni}$ = –2.0 cm$^{-1}$.

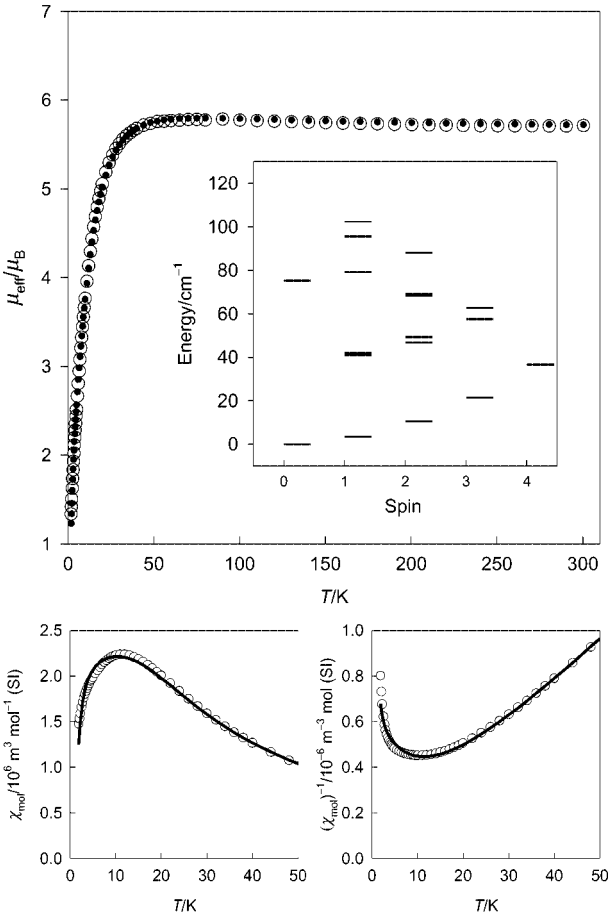

Figure 12. Plots of experimental (open circles) $\mu_{eff}$ (left), $\chi_{mol}$ (right up) and $\chi_{mol}^{-1}$ (right bottom) vs. $T$ per molecule of **4**. The filled circles and the solid lines are the fits to the experimental data (see text for details). Inset: calculated energy levels for individual total spins.

The calculated zero-field, total spin energy levels of complex **4** are shown in the inset of Figure 12. Approaching room temperature, all the levels are equally populated, so that we end up with Curie law behavior. On cooling, however, some magnetically less productive states are depopulated and, thus, the overall magnetic productivity rises. This explains the shallow maximum of $\mu_{eff}$ at about 90 K. Upon further cooling below 40 K, the $S$ = 4, $S$ = 3, $S$ = 2, and $S$ = 1 states are gradually depopulated and, therefore, the effective magnetic moment drops to zero. Because of the $S$ = 0 ground state, a turning point exists at 11 K in the $\chi_{mol}$ vs. $T$ curve upon cooling.

The signs of the $J$ values are in line with the already mentioned magnetostructural correlation for nickel(II) clusters. The double oxygen bridge [Ni(1)–O(1)–Ni(2) and Ni(1)–O(11)–Ni(2)], which mediates the positive $J_3$ exchange interaction, has angles of 96.8 and 94.8° that are known to lead to ferromagnetic interactions.[16a] The other two weak antiferromagnetic exchange interactions of –5.0 ($J_1$) and –4.8 ($J_2$) are associated with angles in the range

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

100.6–103.7°; such angles are expected to lead to weak antiferromagnetic interactions.[24] In the three previously characterized[16a,16b] tetranuclear defect dicubane $Ni^{II}$ clusters *possessing exclusively oxygen monoatomic bridges*, ferromagnetic exchange interactions have been observed leading to a $S = 4$ ground state. However, in the present case of **4**, competing ferromagnetic and antiferromagnetic interactions are observed as a result of the two different types of Ni–O–Ni angle values, those at 94.8 and 96.8°, and those between 100.6 and 103.7°. This result further emphasizes the sensitivity of both ferromagnetic and antiferromagnetic exchange interactions with respect to the Ni–O–Ni angles.

## Conclusions and Perspectives

The further use of di-2-pyridyl ketone in nickel(II) acetate chemistry has provided access to five new complexes, four tetranuclear and one mononuclear. The structure of **2** is novel in the coordination chemistry of di-2-pyridyl ketone, because this complex constitutes the first example of any metal, in which both the ketone and the *gem*-diol forms coexist as ligands. Complexes **1** and **3**–**5** are valuable additions to the chemistry of tetranuclear $Ni^{II}$ clusters; with their structural characterization, and bearing in mind the relevant literature,[7a,7b] the cubane and the defect dicubane topologies can now be considered as general structural motifs in $Ni^{II}/MeCO_2^-/(2\text{-py})_2CO$ chemistry. For two clusters (**1**, **4**) under investigation we have derived the exchange couplings between $Ni^{II}$ ions. In both cases, the coupling is mediated by the μ-oxygen bridges and one can draw some correlations between the coupling sign and the Ni–O–Ni angles; as has been shown previously, there is a clear trend with ferromagnetic coupling observed for small Ni–O–Ni angles and antiferromagnetic couplings at higher angles. Although **1** and **4** have been found to possess an $S = 0$ ground state, the bridging modes of $(2\text{-py})_2C(OH)O^-$ nevertheless suggest possibilities for other $Ni_x$ species that might exist (e.g. clusters containing $SO_4^{2-}$ instead of $MeCO_2^-$) and that may have high-spin ground states.

Analogues of compounds **1** and **3**–**5** with pivalates or benzoates are not known, at least to date, and it is currently not evident whether the preparation and stability of such cubanes are dependent on the particular nature of the carboxylate ligand. The two terminal acetates present in the structures of **1** and **3**–**5** and the aqua ligands in **1** could have future utility as sites for facile incorporation of other monodentate ligands by metathesis or as a means to access higher-nuclearity species by using bis(monodentate) bridging aromatic heterocycles or α,ω-dicarboxylates. Work is in progress to clarify these matters.

## Experimental Section

**Materials and Physical Measurements:** All manipulations were performed under aerobic conditions using materials and solvents (Merck, Aldrich) as received. Elemental analyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Service using an EA 108 Carlo Erba analyzer. IR spectra (4000–450 $cm^{-1}$) were recorded with a Perkin–Elmer PC 16 FT-IR spectrometer with samples prepared as KBr pellets. Magnetic susceptibility measurements in the 1.9–300 K range under a field of 0.5 T were performed with a Quantum Design SQUID-based MPMSXL-5-type magnetometer. The magnetometer was calibrated with a palladium rod sample (Materials Research Corporation, measured purity 99.9985%). The measurements were carried out on polycrystalline samples. Data were corrected for diamagnetic contributions using Pascal's constants; the temperature-independent paramagnetism of the $Ni^{II}$ ion was considered to be $Na = 2.5 \cdot 10^{-9}\ m^3\ mol^{-1}$ (SI units).

**CAUTION**: Although no such tendency was observed during the present work, perchlorate salts are potentially explosive and should be handled with care and in small quantities.

**$[Ni_4(O_2CMe)_2\{(2\text{-py})_2C(OH)O\}_4(H_2O)_2](ClO_4)_2$ (1):** A solution of $(2\text{-py})_2CO$ (0.100 g, 0.54 mmol) in $H_2O$ (3 mL) was added to an aqueous solution (6 mL) of $Ni(O_2CMe)_2 \cdot 4H_2O$ (0.200 g, 0.80 mmol) and $NaClO_4$ (0.099 g, 0.81 mmol). The resulting green solution was stirred for about 10 min and was then allowed to slowly concentrate by solvent evaporation at room temperature for a period of 8–10 d. Well-formed green needles appeared that were collected by filtration, washed with $Me_2CO$ (2 × 3 mL) and dried in air. Yield (based on the ligand): 0.121 g (64%). $C_{48}H_{46}Cl_2N_8Ni_4O_{22}$ (1392.67): calcd. C 41.39, H 3.34, N 8.05; found C 41.60, H 3.40, N 7.89. Crystals of the product were also obtained by layering the initial aqueous reaction solution with a double volume of $Me_2CO$ (18 mL). IR data (KBr pellet): $\tilde{\nu}$ = 3420 $cm^{-1}$ (s, broad), 3051 (w), 2923 (w), 1604 (s), 1576 (s), 1470 (sh), 1430 (s), 1342 (w), 1290 (w), 1260 (w), 1220 (m), 1122 (s), 1082 (s), 1048 (m), 1022 (sh), 960 (m), 904 (w), 806 (w), 782 (sh), 768 (m), 682 (m), 626 (m), 598 (w), 516 (w), 470 (w) $cm^{-1}$.

**$[Ni(O_2CMe)\{(2\text{-py})_2C(OH)_2\}\{(2\text{-py})_2CO\}](ClO_4) \cdot H_2O$ ($2 \cdot H_2O$):** An aqueous, green solution (5 mL) containing $Ni(O_2CMe)_2 \cdot 4H_2O$ (0.062 g, 0.25 mmol) and $NaClO_4$ (0.061 g, 0.50 mmol) were slowly added to a solution of $(2\text{-py})_2CO$ (0.092 g, 0.50 mmol) in $H_2O$ (2.5 mL). A noticeable color change from green to mauve occurred. The resulting mauve solution was stirred for about 10 min and was then allowed to slowly concentrate by solvent evaporation at room temperature for a period of 5–7 d. An approximately 3:1 mixture of brown-red and mauve crystals formed. The crystals were carefully collected by filtration. The two products were readily separable manually, and the brown-red and mauve crystals proved by single-crystal X-ray crystallography to be complexes $2 \cdot H_2O$ and $[Ni\{(2\text{-py})_2C(OH)O\}\{(2\text{-py})_2C(OH)_2\}]_2[Ni\{(2\text{-py})_2C(OH)O\}_2](ClO_4)_2 \cdot 7H_2O$,[11] respectively. Yields for $2 \cdot H_2O$ (based on $Ni^{II}$) as high as 0.085 g (55%) were obtained. A batch of brown-red crystals was used for analyses and IR spectroscopy. $C_{24}H_{23}ClN_4NiO_{10}$ (621.62): calcd. C 46.40, H 3.74, N 9.02; found C 46.51, H 3.60, N 8.86. IR data (KBr pellet): $\tilde{\nu}$ = 3604 $cm^{-1}$ (m), 3476 (m, broad), 3352 (m, broad), 3082 (w), 3005 (w), 2910 (w), 1686 (s), 1650 (m), 1602 (s), 1574 (m), 1464 (sh), 1442 (s), 1430 (sh), 1318 (s), 1288 (m), 1272 (w), 1232 (m), 1168 (m), 1156 (m), 1104 (s, broad), 1088 (s), 1062 (sh), 1022 (m), 944 (m), 914 (m), 828 (m), 806 (m), 778 (sh), 760 (s), 690 (m), 668 (s), 644 (sh), 624 (s), 576 (m), 512 (w) $cm^{-1}$.

**$[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](ClO_4) \cdot 2H_2O \cdot 2EtOH$ ($3 \cdot 2H_2O \cdot 2EtOH$):** A solution of $(2\text{-py})_2CO$ (0.092 g, 0.50 mmol) in EtOH (10 mL) was added dropwise to a slurry of $NaClO_4$ (0.031 g, 0.25 mmol) in the same solvent (15 mL). The obtained slurry was added to a green solution of $Ni(O_2CMe)_2 \cdot 4H_2O$ (0.124 g,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.50 mmol) in EtOH (20 mL). Solid $NaClO_4$ soon dissolved. The resulting solution was stirred for 45 min at room temperature and allowed to stand undisturbed in a closed flask for 2 d. Well-formed green crystals appeared, which were collected by filtration, washed with ice-cold EtOH (1 mL) and $Et_2O$ (2 × 3 mL) and dried in vacuo with silica gel. Yield (based on $Ni^{II}$): 0.120 g (71%). The dried solid analyzed as EtOH-free **3**·2$H_2O$. $C_{50}H_{49}ClN_8Ni_4O_{20}$ (1352.36): calcd. C 44.40, H 3.66, N 8.29; found C 44.51, H 3.49, N 8.25. The obtained crystals were good diffractors of X-rays, as long as they were kept in contact with the mother liquor to prevent EtOH loss. IR data for the dried sample (KBr pellet): $\tilde{\nu}$ = 3425 $cm^{-1}$ (m, broad), 3085 (w, broad), 3017 (w), 2928 (w), 1590 (s, broad), 1443 (sh), 1430 (s), 1341 (w), 1296 (w), 1263 (w), 1218 (m), 1162 (sh), 1082 (s, broad), 1050 (sh), 1012 (sh), 958 (m), 804 (w), 760 (m, broad), 680 (m), 618 (m), 543 (w), 500 (w), 465 (w) $cm^{-1}$.

**$[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]$·2MeCN (4·2MeCN):** An almost colorless solution of $(2\text{-py})_2CO$ (0.100 g, 0.54 mmol) in MeCN (10 mL) was added dropwise to a pale green slurry of $Ni(O_2CMe)_2$·4$H_2O$ (0.135 g, 0.54 mmol) in the same solvent (15 mL). The color of the reaction mixture did not change. The mixture was refluxed for 1 h and 45 min, a small quantity of undissolved green material removed by filtration and the filtrate layered with $Et_2O$ (50 mL). Slow mixing gave X-ray quality green crystals of the product. The crystals were collected by filtration, washed with ice-cold MeCN (1 mL) and $Et_2O$ (2 × 2 mL), and dried in vacuo with silica gel. Yield (based on $Ni^{II}$): 0.128 g (74%). The dried solid analyzed satisfactorily as MeCN-free **4**. $C_{52}H_{48}O_{16}N_8Ni_4$ (1275.92): calcd. C 48.95, H 3.80, N 8.78; found C 48.99, H 3.67, N 8.86. Crystals of the same product could also be isolated, by allowing the initial MeCN solution to slowly evaporate at room temperature. The crystals of **4**·2MeCN were found to lose solvent rapidly, and they were kept in the mother liquor until a suitable crystal had been found for X-ray crystallography. IR data for the dried sample (KBr pellet): $\tilde{\nu}$ = 3418 $cm^{-1}$ (m, broad), 3072 (m), 3025 (w), 2983 (w), 2806 (m, broad), 1638 (sh), 1602 (s), 1574 (s), 1454 (sh), 1438 (sh), 1412 (s), 1370 (m), 1306 (s), 1262 (w), 1210 (s), 1154 (m), 1120 (sh), 1098 (s), 1066 (s), 1046 (sh), 1020 (s), 958 (m), 926 (w), 900 (w), 806 (m), 782 (sh), 764 (s), 684 (s), 656 (s), 640 (sh), 602 (m), 536 (sh), 508 (m), 478 (m) $cm^{-1}$.

**$[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](O_2CMe)$·6$H_2O$·MeCN (5·6$H_2O$·MeCN):** EtOH (15 mL) and MeCN (5 mL) were added to a solid mixture containing $Ni(O_2CMe)_2$·4$H_2O$ (0.124 g, 0.50 mmol), $(2\text{-py})_2CO$ (0.092 g, 0.50 mmol), and LiOH·$H_2O$ (0.021 g, 0.50 mmol). Most of the quantities of the solids dissolved upon reflux for 30 min and a cloudy green "solution" was obtained. This was filtered and the solvents were then evaporated under reduced pressure at 35 °C. The obtained residue was dissolved in MeCN (8 mL), filtered and the closed reaction flask containing the filtrate was stored in the refrigerator (ca. 5 °C) for a period of one month. X-ray quality green needles formed, which were collected by filtration, washed with $Et_2O$ (3 mL), and dried in air. Yield (based on $Ni^{II}$): 0.080 g (46%). The air-dried solid analyzed satisfactorily as MeCN-free **5**·6$H_2O$. $C_{52}H_{60}O_{22}N_8Ni_4$ (1384.04): calcd. C 45.12, H 4.38, N 8.10; found C 44.91, H 4.41, N 8.02. The crystals of the

product were found to lose MeCN readily, and they were maintained in the mother liquor for X-ray crystallography. IR data for the analytically pure sample (KBr pellet): $\tilde{\nu}$ = 3406 $cm^{-1}$ (m, broad), 3149 (w, broad), 3065 (w, broad), 2925 (w), 2851 (w), 1625 (sh), 1573 (s, broad), 1429 (s, broad), 1402 (m), 1335 (w), 1293 (w), 1215 (m), 1160 (w), 1120 (w), 1080 (m), 1049 (sh), 957 (w), 795 (sh), 770 (m), 675 (m), 660 (sh), 604 (w), 516 (w), 462 (w) $cm^{-1}$.

**X-ray Crystallographic Studies:** Crystals of **1**, **3**·2$H_2O$·2EtOH, **4**·2MeCN, and **5**·6$H_2O$·MeCN were mounted in capillaries filled with drops of mother liquor, while crystals of **2**·$H_2O$ were stable and mounted in air. Diffraction measurements for **1**, **3**·2$H_2O$·2EtOH, **4**·2MeCN, and **5**·6$H_2O$·MeCN were made on a Crystal Logic Dual Goniometer diffractometer using graphite–monochromated $M_o$-$K_\alpha$ radiation. The X-ray data set for **2**·$H_2O$ was collected with a $P2_1$ Nicolet diffractometer upgraded by Crystal Logic using graphite–monochromated Cu-$K_\alpha$ radiation. Complete crystal data and parameters for data collection and refinement are listed in Table 9 and Table 10. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the ranges 11° < 2$\theta$ < 23° (for **1**, **3**·2$H_2O$·2EtOH, **4**·2MeCN, and **5**·6$H_2O$·MeCN) and 22° < 2$\theta$ < 54° (for **2**·$H_2O$). Intensity data were recorded using the $\theta$-2$\theta$ scan method. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization, and $\Psi$-scan absorption (for **2**·$H_2O$, **3**·2$H_2O$·2EtOH, and **4**·2MeCN) were applied using the Crystal Logic software package. The structures were solved by direct methods using SHELXS-86[25a] and refined by full-matrix least-squares techniques on $F^2$ with SHELXL-97.[25b] For complexes **2**·$H_2O$ and **3**·2$H_2O$·2EtOH, the reflections to parameters ratio is relatively low. For the former a full data set was collected for a quarter of the sphere of reflections to 2$\theta$ = 135° (for Cu radiation). When the structure was solved it proved to belong to the noncentrosymmetric monoclinic space group $P2_1$. The collection of additional data was continued for a second quarter of the reflections sphere only until 2$\theta$ = 95°, because the complex is mononuclear and its structural characterization was valuable mainly in terms of our synthetic efforts. For the latter the data collection was stopped at 2$\theta$ = 45° (for Mo radiation), because the molecular structure of the cation present in **3**·2$H_2O$·2EtOH is almost identical to that of the cation with the same formula in complex **5**·6$H_2O$·MeCN, for which a full data set to 2$\theta$ = 50° had already been collected. For all the structures the ordered non-hydrogen atoms were refined anisotropically. In the case of **1**, the chlorine atoms and one of the perchlorate oxygen atoms were found to be disordered and refined anisotropically over two positions with occupation factors fixed at 0.50. Three of the perchlorate oxygen atoms of **2**·$H_2O$ were found to be disordered and refined in two orientations with occupation factors summing one. In the structure of **3**·2$H_2O$·2EtOH the solvate molecules were refined isotropically, while the methyl group of one of the acetate ligands was found to be disordered and refined isotropically over two positions with occupation factors summing one. The non-hydrogen atoms of the MeCN solvate molecules of **4**·2MeCN were refined isotropically. For **1**, **2**·$H_2O$, **4**·2MeCN, and **5**·6$H_2O$·MeCN, all hydrogen atoms were located by difference maps and were refined isotropically, ex-

Table 10. Crystal data and structure refinement for $[Ni_4(O_2CMe)_4\{(2\text{-py})_2C(OH)O\}_4]$·2MeCN (**4**·2MeCN) and $[Ni_4(O_2CMe)_3\{(2\text{-py})_2C(OH)O\}_4](O_2CMe)$·6$H_2O$·MeCN (**5**·6$H_2O$·MeCN).

cept those of the acetate ligands which were introduced at calculated positions as riding on bonded atoms; no hydrogen atoms for the water solvate molecule of **2**·$H_2O$ were included in the refinement. All hydrogen atoms of **3**·2$H_2O$·2EtOH were introduced at calculated positions as riding on their respective bonded atoms. CCDC-278891, -278892, -278893, -278894, and CCDC-278895 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Note Added in Proof** (March 22, 2006): After this paper had been submitted, the single-crystal X-ray structure of complex **1** was published. The complex was prepared in MeOH under reflux; however, no magnetic studies for this cluster were reported (Y.-M. Li, J.-J. Zhang, R.-B. Fu, S.-C. Xiang, T.-L. Sheng, D.-Q. Yuan, X.-H. Huang, X.-T. Wu, *Polyhedron*, DOI: 10.1016/j.poly.2005.11.002).

## Acknowledgments

S. P. # Syntheses, Structures and Characterisation of Two $Cu^{II}$ Polymers with 8-Connected Topologies Based on Highly Connected SBUs

**Jian Zhang,[a] Yao Kang,[a] Jie Zhang,[a] Zhao-Ji Li,[a] Ye-Yan Qin,[a] and Yuan-Gen Yao*[a]**

**Keywords:** Coordination polymers / Copper / Hydrothermal synthesis / Magnetic properties / N ligands

Two hydrothermally synthesised 3D metal-coordination polymers, namely [Cu(isonicotinate)(nicotinate)]$_n$ (**1**), with an 8-connected CsCl topology, and [$Cu_2$($\mu_3$-OH)(isonicotinate)$_2$-(BDC)$_{0.5}$]$_n$ (**2**), with an unusual 8-connected $3^5.4^{11}.5^8.6^4$ topology, demonstrate that highly connected SBUs can be employed in the construction of complicated frameworks. The temperature-dependent magnetic susceptibilities for the two complexes were also determined.

## Introduction

Recent studies on inorganic/organic hybrid materials, especially in the area of metal–ligand coordination framework polymers, have enriched crystal engineering and have provided a wide range of inorganic networks in the solid state.[1] A large number of the lowly connected network topologies depicted by Wells[2] are commonly found in framework materials such as zeolites and in coordination polymers.[3] However, highly connected topologies are still a major challenge to chemists because the construction of such systems is severely hampered by the available number of coordination sites at the metal centres and the steric demand of the organic ligands. Yaghi et al. have developed a SBU (secondary building unit) strategy to direct the assembly of metal–organic frameworks (MOFs), which has been widely used for understanding and predicting structural topologies.[4] Most recently, Champness et al. have successfully obtained a series of highly connected topologies by selecting high coordinate lanthanide metals and flexible 4,4′-bipyridine-*N*,*N*′-dioxide ligands.[5] Although a large number of crystalline materials constructed from SBUs and linkers have been reported, the construction of highly connected topologies based on highly connected SBUs are extremely rare.[6] Compared with complexes with d- or f-block metal nodes, complexes with metal cluster nodes generally have weak metal–metal interactions and some interesting physical properties, such as luminescence and magnetism. We report here two novel polymers, namely [Cu(isonicotinate)(nicotinate)]$_n$ (**1**) and [$Cu_2$($\mu_3$-OH)(isonicotinate)$_2$(BDC)$_{0.5}$]$_n$ (**2**; BDC = 1,3-benzenedicarboxylate), which exhibit 8-connected CsCl and non-CsCl topologies, respectively.

## Results and Discussion

### X-ray Crystal Structure of [Cu(isonicotinate)(nicotinate)]$_n$ (1)

The single-crystal X-ray structure of complex **1** reveals that it adopts a 3D structure consisting of dimetallic clusters bridged by both nicotinate and isonicotinate ligands. Each $Cu^{II}$ cation exhibits a distorted trigonal-bipyramidal geometry with an $N_2O_3$ coordination sphere from three nicotinate ligands and two isonicotinate ligands (Figure 1 and Table 1). Nicotinate acts as a $\mu_3$-ligand with its carboxylate group bridging two Cu atoms that are separated by 4.330 Å. As shown in Figure 2 (a), the nicotinate ligands bridge the dinuclear copper clusters to form a 2D sheet parallel to the *bc* plane. The isonicotinate ligand bridges the Cu centres through one O donor and one N donor to form a zigzag chain in a head-to-tail manner. These chains are also linked by the carboxylate group of nicotinate ligands to form another 2D sheet almost parallel to the *ab* plane (Figure 2, b). In other words, each dinuclear copper cluster binds to four nicotinate ligands and four isonicotinate ligands simultaneously.

According to the concept of SBUs, this structure can be reduced to a schematic that rationalizes the structure as the assembly of $[Cu_2(CO_2)_2O_2N_4]$ SBUs, as shown in Figure 2 (c). Each SBU has eight vertices to eight adjacent SBUs. By treating the SBU as a single node and connecting the nodes according to the connectivity defined by nicotinate and isonicotinate ligands, a CsCl-like 3D network sustained by 8-connected nodes is formed, as illustrated in Figure 3. Although there is only one type of node in this net, there are two different links, identified by two different node–node distances (8.351 and 10.774 Å). The isonicotinate ligand defines the longer node–node distance and connects the nodes into a (4,4) 2D net, while the nicotinate ligand defines the shorter node–node distance and connects the nodes into another (4,4) 2D net parallel to the *bc* plane. These two types of nets intersect at an angle of 75.65° to generate the distorted CsCl net. To the best of our knowledge, this is the first transition metal complex with this unusual CsCl topology.

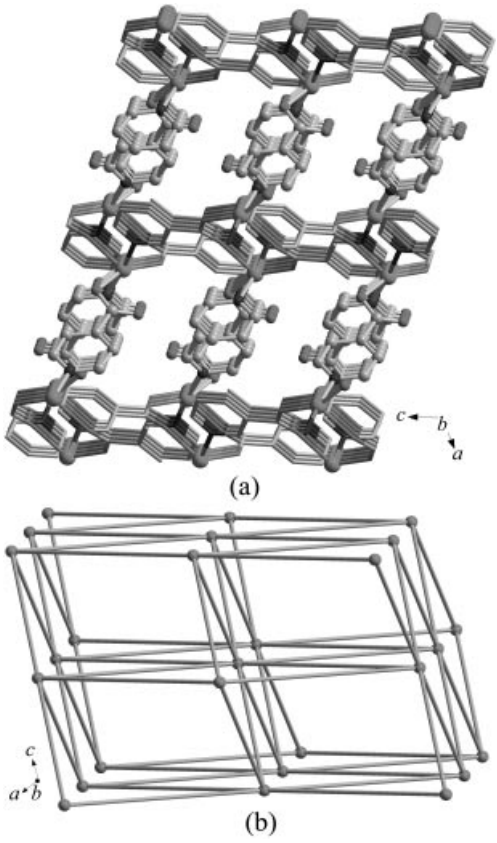

Figure 3. (a) The 3D packing structure of **1**; (b) schematic representation of the distorted CsCl net in complex **1**.

### X-ray Crystal Structure of $[Cu_2(\mu_3\text{-OH})(isonicotinate)_2(BDC)_{0.5}]_n$ (2)

The single-crystal X-ray diffraction study showed that complex **2** consists of tetranuclear $Cu^{II}$ clusters linked by isonicotinate and the BDC ligand. As shown in Figure 4, the tetranuclear cluster contains two independent Cu centres: one Cu centre (Cu1) has a distorted trigonal-bipy-

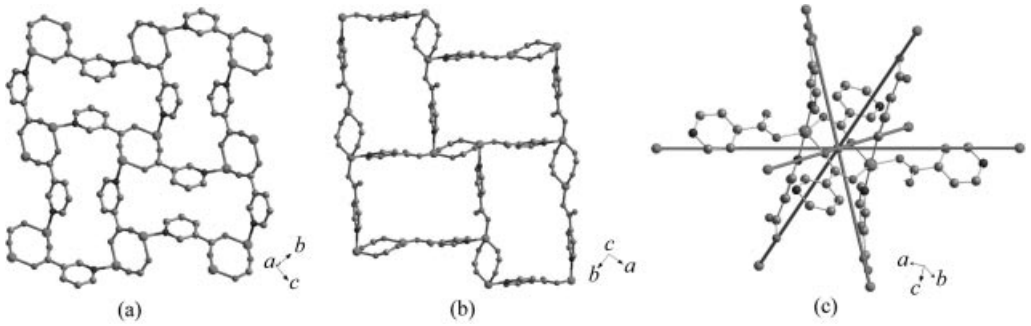

Figure 2. (a) View of the 2D (4,4) net constructed from dimetallic clusters and nicotinate ligands; (b) view of the 2D (4,4) net constructed from dimetallic clusters and isonicotinate ligands; (c) view of the 8-connected SBU in complex **1**, illustrating the connections to eight neighbours.

ramidal geometry and is bound by one BDC ligand, three different isonicotinate ligands and one hydroxide ion, whereas the other Cu centre (Cu2) has a distorted square-pyramidal geometry and is bound by one BDC ligand, two independent isonicotinate ligands and two hydroxide ions. A pair of $CuO_4N$ square-pyramidal polyhedra share an edge with each other and a corner with two $CuO_4N$ trigonal-bipyramidal polyhedra through two $\mu_3$-hydroxy groups (Figure 5, e). The centre of inversion is situated in the middle of the two $\mu_3$-hydroxy groups. The four copper ions, which lie on a plane, form an approximate parallelogram. Two $\mu_3$-hydroxy groups bridge four Cu centres with an adjacent Cu···Cu separation in the range of 3.006 to 3.342 Å.

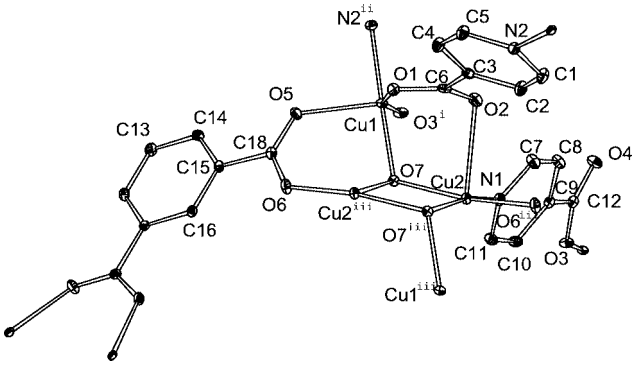

Figure 4. An ORTEP drawing of the molecular structure of complex **2**. For definition of i, ii and iii see footnote b in Table 1.

The asymmetric unit of **2** also contains two independent isonicotinate ligands, each of which has different coordination modes: one isonicotinate ligand acts as a $\mu_3$-bridge and links the tetranuclear clusters to form a 2D sheet parallel to *bc* plane (Figure 5, a), while the other isonicotinate ligand binds through one O donor and one N donor to bridge the tetranuclear clusters and form a 1D double-chain (Figure 5, b). At the same time, the BDC ligand acts as a $\mu_4$-bridge and links the tetranuclear clusters to form a 1D zigzag chain (Figure 5, c). In other words, each tetranuclear copper cluster binds to two BDC ligands and eight isonicotinate ligands simultaneously (Figure 5, d).

Four Cu polyhedra and four carboxylate carbon atoms represent a 10-connected inorganic SBU, as illustrated in Figure 5 (e). Although ten bridging ligands ligate each SBU, each SBU is connected to only eight nearest neighbours because two pairs of isonicotinate ligands form "double bridges". By treating the SBU as a single node and connecting the nodes according to the connectivity defined by the BDC and isonicotinate ligands (the double bridge being considered as one connection), a non-CsCl 3D network sustained by 8-connected nodes is then formed, as illustrated in Figure 6. This net is clearly different from other reported network topologies containing 8-connected nodes[5,6c] and adopts an unprecedented $3^5.4^{11}.5^8.6^4$ topology.[9] The asymmetric unit of **2** contains one BDC ligand and two independent isonicotinate ligands such that three different node–node distances (9.726, 10.362 and 10.940 Å) can be iden-

tified. Each node, which is located at the symmetrical centre, links six neighbours in one plane, and the angles between the adjacent nodes are 54.251°, 65.904° and 59.845°, respectively.

The structure of **2** is completely different from the CsCl net and the other two previously known non-CsCl eight-connected nets. As shown in Figure 7, the parallel (4,4) nets of all nets are cross-linked by zigzag chains, although the detailed connection modes are different: in CsCl, the zigzag chain in the inter-layer region bridges the diagonal of a single window in the (4,4) net (Figure 7, a), in the $3^3 4^{15} 5^8 6^2$ topological net the zigzag chains bridge the edges of one (4,4) net and the diagonal of the next (Figure 7, b),[5b] and in the third net the zigzag chains bridge the diagonal of two neighbouring windows (Figure 7, c),[6c] whereas in **2** the zigzag chain is out of a plane and bridges two zigzag chains in two (4,4) nets, which, moreover, are alternately arranged on the two sides of the (4,4) net.

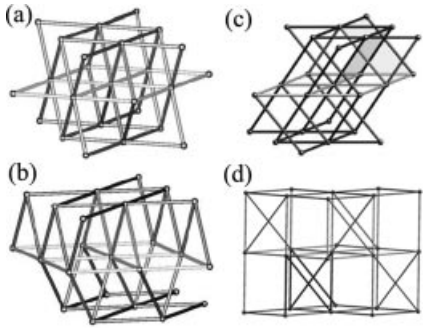

Figure 7. Difference between the four eight-connected nets: (a) CsCl-type net; (b) the $3^3 4^{15} 5^8 6^2$ topological net; (c) the self-penetrating eight-connected net; (d) the $3^5.4^{11}.5^8.6^4$ topology in complex **2**.

## Magnetic Properties

The variable-temperature magnetic susceptibility of **1** was measured in the temperature range from 300 to 2 K (Figure 8), at a magnetic field strength of 5000 G. The $\chi_m T$ value at room temperature is 0.42 $cm^3 K mol^{-1}$, which is slightly bigger than the value of 0.375 $cm^3 K mol^{-1}$ expected for a noncoupled $Cu^{II}$ ion with $g = 2$. Upon cooling, the $\chi_m T$ product decreases smoothly, thus indicating that a predominantly antiferromagnetic interaction exists in **1**. The $1/\chi_m$ vs. $T$ (Curie) plot is linear. Fitting this curve to the Curie–Weiss law gives a Curie constant, $C$, of 0.454 $cm^3 K mol^{-1}$ and a Weiss constant, $\theta$, of –18.13 K, which is a further indication of the weak antiferromagnetic interactions in **1**. According to the crystal structure of **1**, it can be assumed that the superexchange interactions between $Cu^{II}$ ions through the bridging carboxylate groups are weak, which may lead to such a magnetic behaviour.

The Cu···Cu distance in **2**, which is much shorter than that in **1**, implies a weak Cu···Cu interaction. The variable-temperature magnetic susceptibility measurements of a powdered sample of complex **2** were performed in the temperature range 300–2 K. The magnetic behaviour of complex **2** is shown in Figure 9 in the form of $\chi_M T$ and $\chi_M^{-1}$ vs. $T$ plots. The $\chi_M T$ value at room temperature is 1.50 $cm^3 K mol^{-1}$ per tetramer, which is consistent with the spin-only value for four uncoupled $S = 1/2$ centres with $g = 2$. Upon cooling, $\chi_M T$ decreases rapidly down to about 40 K, showing a dominant antiferromagnetic interaction between paramagnetic $Cu^{II}$ ions. A Curie–Weiss fitting above 50 K give a Weiss constant of –90 K; this large negative value demonstrates a strong antiferromagnetic coupling. The pathway of antiferromagnetic interactions may be between the adjacent copper centres (Cu···Cu = 3.006 to 3.342 Å) bridged by a $\mu_3$-hydroxy group. The decrease of $\chi_M T$ is less pronounced between 40 and 20 K, tending to a small plateau at a value (ca. 0.7 $cm^3 K mol^{-1}$) close to that expected for two uncoupled electrons resulting from an antiferromagnetically coupled tetranuclear $Cu^{II}$ compound. Below 20 K, a rapid decrease appears due to further intra- and inter-tetramer antiferromagnetic interactions.

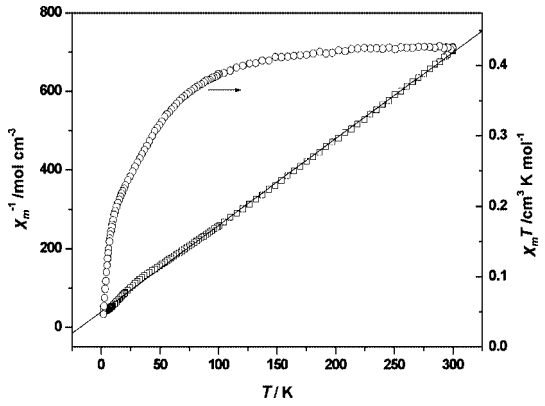

Figure 8. Plots of the temperature dependence (from 300 to 2 K) of $\chi_m T$ and $\chi_m^{-1}$ for **1**.

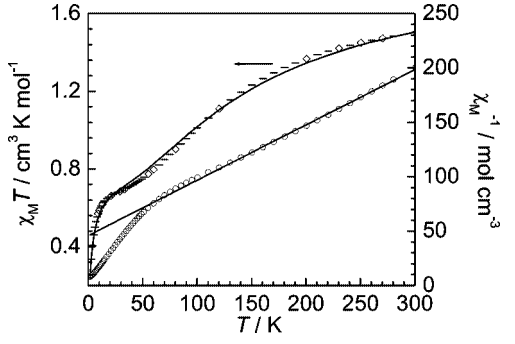

Figure 9. Plots of the temperature dependence (from 300 to 2 K) of $\chi_m T$ and $\chi_m^{-1}$ for **2**.

Considering the butterfly arrangement of the $Cu^{II}$ ions in **2**, the experimental magnetic susceptibility data were analysed with the modified analytical expression derived by combining the tetramer model with $S = 1/2 \cdot [H = -J_1(S_1 + S_2)\cdot(S_3 + S_4) - J_2 S_3 \cdot S_4]$ by Murugavel[10] and inter-tetramer interactions ($J$) under the molecular-field approximation.[11] The best fitting for the experimental data gives $J_1 = -56.7\ cm^{-1}$, $J_2 = -114.9\ cm^{-1}$, $g = 2.25$ and $zj' =$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$-3.38\ cm^{-1}$. The agreement factor $R = \Sigma[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2/\Sigma(\chi_M T)_{obs}^2$ is $3.93 \times 10^{-4}$.

## Conclusion

In summary, two 8-connected nets of a CsCl-type and an unusual $3^5.4^{11}.5^8.6^4$ topology have been structural characterised. The size of the SBUs increases from dinuclear to tetranuclear and their connections also increase from eight-connected to ten-connected. We have confirmed that SBUs can adopt highly connected nodes that can be employed for the construction of highly connected frameworks.

## Experimental Section

**General Remarks:** All the syntheses were performed in Teflon-lined stainless-steel autoclaves under autogenous pressure. Reagents were purchased commercially and were used without further purification. Elemental C,N,H analyses were performed on an EA1110 CHNS-0 CE elemental analyzer. IR (KBr pellet) spectra were recorded with a Nicolet Magna 750FT-IR spectrometer. Variable-temperature magnetic susceptibilities in the temperature range 2–300 K were performed with a model CF-1 superconducting extracting sample magnetometer with the powdered sample kept in the capsule for weighing. All data were corrected for diamagnetism of the ligands estimated from Pascal's constants.

**$[Cu(isonicotinate)(nicotinate)]_n$ (1):** An aqueous mixture (15 mL) containing $CuNO_3{\cdot}3H_2O$ (0.24 g, 1 mmol), isonicotinic acid (0.123 g, 1 mmol) and nicotinic acid (0.123 g, 1 mmol) was placed in a Parr Teflon-lined stainless-steel bomb, which was sealed and placed in a programmable furnace. The temperature was raised to 160 °C over 4 h and held at that temperature for 60 h, then cooled over 60 h to 80 °C and finally cooled down to room temperature over 12 h. The resulting rectangular blue crystals were collected (0.1 g, 32.49% yield). This compound is stable in air and is insoluble in water and common organic solvents. $C_{12}H_8CuN_2O_4$ (307.74): calcd. C 46.91, H 2.63, N 9.12; found C 47.05, H 2.66, N 8.98. IR (solid KBr pellet): $\tilde{\nu}$ = 3434 (w), 3119 (s), 1651 (w), 1629 (vs), 1398 (vs), 1385 (s), 693 (w), 613 (w) $cm^{-1}$.

**$[Cu_2(\mu_3\text{-}OH)(isonicotinate)_2(BDC)_{0.5}]_n$ (2):** A mixture containing $Cu(OH)_2{\cdot}CuCO_3$ (0.44 g, 2 mmol), 1,3-benzenedicarboxylic acid (0.1 g, 0.6 mmol), isonicotinic acid (0.123 g, 1 mmol) and distilled water (10 mL) was placed in a Teflon-lined stainless-steel bomb, which was sealed and placed in a programmable furnace. The temperature was raised to 160 °C over 4 h and held at that temperature for 60 h, then cooled over 60 h to 80 °C and finally cooled down to room temperature over 12 h. The blue prismatic crystals were collected (0.1 g, 64% yield). This complex is stable in air and is insoluble in water and common organic solvents. $C_{16}H_{11}Cu_2N_2O_7$ (470.35): calcd. C 40.95, H 2.36, N 5.97; found C 41.05, H 2.66, N 5.98. IR (solid KBr pellet): $\tilde{\nu}$ = 3314 (w), 3108 (s), 1614 (s), 1559 (m), 1401 (vs), 1087 (m), 751 (m), 728 (m) $cm^{-1}$.

**X-ray Crystallographic Study:** X-ray intensities of complexes **1** and **2** were collected on a Siemens Smart CCD diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) at 293(2) K. Empirical absorption corrections were applied to the data using the SADABS program.[7] The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXTL-97 program.[8] All of the non-hydrogen atoms were refined anisotropically. The H atoms bonded to C atoms were positioned geometrically and refined using a riding model. Crystallographic data and other pertinent information for **1** and **2** are summarised in Table 2. Selected bond lengths and angles are listed in Table 1.

# Reactivity of Polyiodides Towards 1,3-Bis(4-pyridyl)propane (bpp): A New CuI Cluster Polycatenane Framework and a Novel 2D AgI Cluster Motif

**Yunyin Niu,[a] Yinglin Song,[b] Ning Zhang,[a] Hongwei Hou*[a] Deji Che,[a] Yaoting Fan,[a] Yu Zhu,[a] and Chunying Duan[c]**

**Keywords:** Clusters / Copper / Iodine / Lead / Organic–inorganic hybrid composites / Silver

The solution-phase reactions of metal iodides or iodine with 1,3-bis(4-pyridyl)propane (bpp) yields four new organic–inorganic hybrid frameworks, namely $[(CuI)_4(bpp)_4]_n$ (**1**), $[(AgI)_6(bpp)]_n$ (**2**), $[PbI_2(bpp)]_n$ (**3**), and $[I_3(bppH)]$ (**4**), each of which adopts a different structural motif. For example, complex **1** is a 2D "open" coordination polymeric cluster consisting of a $CuI_2Cu$ rhomboid cluster core coordinated by *anti-anti* and *anti-gauche* bpp interactions to produce an interpenetrating 2D (4,4) polycatenane net; **2** is a novel bpp inclusion compound with a unique 2D polymeric hexagonal prism-shaped $[Ag_6I_6]_n$ cluster motif; compound **3** is also a 2D "open" supramolecular cluster made from $[PbI_2]_n$ "ribbons" and bpp bridges; compound **4** is a triiodide made up of organic $[bppH]^+$ cations and a $I_3^-$ anion chain. The clusters **1**–**3** obtained from the reaction between polyiodide complexes and an organic ligand suggest that this simple synthetic approach is likely to be applicable to the construction of polymeric clusters. The third-order NLO effects of **1** were studied by Z-scan techniques. The polymeric cluster exhibits good nonlinearities and the effective third-order NLO refractive index ($n_2$) value is $2.56\times10^{-12}$ esu which is comparable to those of most cluster monomers and polymers.

## Introduction

The construction of supramolecular polymeric networks has been of great interest in recent years, not only due to their intriguing architectures and topologies[1] but also for their potential properties as functional solid materials in catalysis,[2] optics,[3] and magnetism.[4] In addition to the main driving forces of metal–ligand coordination and hydrogen bonding, weak interactions and other subtle factors such as molecular entanglement[5] and halogen–halogen interactions[6] can also have a dramatic effect on the assembly of extended porous topologies. Polycatenation can be regarded as regularly repeated infinite versions of the closed molecular loops via a topological Hopf link − the whole catenated array has a higher dimensionality than the component motifs for a possible combination of interlocking or interweaving covalent, mechanical, and coordination bonds.[5c,7] Since no genuine example of an organic polycatenane has been characterized, a number of metal-based molecular rings have been used as building blocks for the construction of polycatenanes. According to Fujita,[8] transition-metal-directed self-assembly is a designable and highly efficient catenane synthesis pathway, and the configuration of the bridging ligands plays an important role in the self-assembly of metal-based catenanes.

Polyiodides are well-known for their ability to form a vast diversity of extended networks with unique conducting and optical properties.[9] Studies have shown that their structures and macroscopic physical properties can be understood through the level of halogen–halogen interactions between three fundamental building blocks: the Lewis acid acceptor $I_2$, and the Lewis base donors $I^-$ or $I_3^-$, and "guest" building blocks (e.g. metal iodides). These building blocks can be catenated easily and a large variety of polyiodides can be synthesized. The synthesis methods can be described simply as the addition of iodine to an iodide in an appropriate reaction medium, such as $I_3^-$: $I_2(s) + I^-(aq) \rightarrow I_3^-(aq)$. Recently, the reaction between monovalent metal halides MI ($M = Cu^+$, $Ag^+$) and $I^-$ attracted our attention because the solubility of MI increases in mixed solvents (such as $THF/H_2O$ and $CH_3CN/H_2O$) upon addition of excess KI. This increase in solubility may be a consequence of the formation of a metal diiodide anion: $MI(s) + I^- \rightarrow MI_2^-$. More importantly, the active intermediate $MI_2^-$ ion is a good iodine source for cluster construction, and its self-assembly reaction with rigid and flexible bispyridyl ligands is an effective route for the preparation of novel polymeric complexes containing iodine clusters. The systematic incorporation of a metal iodide and organic spacer-based molecular rings within polymeric cluster networks allows for the

modulation of their structural and physical properties. With this method we have previously obtained a 2D "open" polymer $[AgI(bpe)]_n$ [bpe = 1,2-bis(4-pyridyl)ethane][10] and a unique 1D coordination polymeric cluster $\{[AgI(inh)]_6(KI)\}_n$ with hexagonal cluster units centered by $\mu_6$-I.[11]

Herein we use bpp as a bridging ligand due to its networking ability[12] and its variable configurations (*anti-anti*, *anti-gauche*, and *gauche-gauche*; Figure 1), and report the formation of four bpp-based compounds by self-assembly with polyiodide species (Scheme 1): **1**–**3** are cluster compounds and **4** is a triiodide. The good nonlinear optical effects of cluster **1** are also presented.

## Results and Discussion

### Preparation of Compounds

As far as the use of insoluble inorganic metal salts in coordination chemistry is concerned, their solubility is a crucial question to the related preparation procedure. Several strategies have been employed to circumvent this practical problem. Firstly, the use of an appropriate solvent. For example, THF is a superior solvent to dissolve $HgI_2$ as the solubility of $HgI_2$ in THF is about 20 times better than that in ethanol. More than ten $HgI_2$ coordination polymers have been obtained with the method.[13] The second procedure is solid-state reaction at low temperature. When an insoluble salt such as CuI or AgI is mixed and ground with $Bu_4NBr$ (or $Et_4NBr$) and $MoS_4^{2-}$, the mixture reacts easily at room temperature or low temperature to give a soluble product in organic solvents. About six polymeric clusters with novel motifs have been synthesized with the method.[14] The third method involves finding a soluble precursor complex. When the concentration of $X^-$ (X = $Cl^-$, $Br^-$, and $I^-$) increases to a certain level, the solubility of MX increases due to the formation of polyhalide anion complexes $MX_2^-$. This method has been used unintentionally by the addition of NaI, KI, HI, $Bu_4NI$, or $Ph_4PI$,[15] and moreover, we found a small quantity of water is helpful for accelerating the dissolution. Many insoluble metal iodides such as CuI, AgI, $PbI_2$, $HgI_2$, etc. can be dissolved efficiently by this method, and several interesting metal–iodine clusters have been found.[10,11] In this contribution, complex **1** was prepared as light-yellow crystals by the addition of a DMF solution of bpp to a THF/$H_2O$ solution of CuI in excess KI. The product is insoluble in common organic solvents and stable in air.

Compound **2** was obtained by a similar procedure to that of **1**, except that the mixed solvent THF/$CH_3CN$/$H_2O$ was used; the use of a single solvent (such as THF or $CH_3CN$) never gave a perfect crystal. Complex **2** was only obtained when the solvent evaporation was conducted in the dark and the solution was nearly dry.

For **3**, the dissolution of $PbI_2$ may obey the following well-known equation: $PbI_2 + 2KI \rightarrow K_2(PbI_4)$. Slow evaporation of the solution gives **3** as a colorless crystal. Compound **3** is also the first example of a $PbI_2$ coordination polymer obtained by the polyiodide reaction.

Compound **4** was obtained without a metal polyiodide. The formation of $I_3^-$ shows its special stability in $CH_3OH$/$H_2O$.[9a] The N-protonation of bpp may be a result of protonation by the mixed solvents.

### Crystal Structure of $[(CuI)_4(bpp)_4]_n$ (1)

In the structure of $[(CuI)_4(bpp)_4]_n$ (**1**), $Cu^I$ adopts a distorted $CuI_2N_2$ tetrahedral coordination sphere and binds two pyridines from bpp and two bridging iodide counterions (Figure 2). Both the bridging iodides are also bound to another symmetry-related $Cu^I$ center to form a $Cu(\mu_2\text{-}I)_2Cu$ rhombohedron. A similar unit is also present in dissociated dimeric molecules[16a,16b] and its self-assembly products with multitopic ligands.[16c–16j] Due to the flexibility of both the Cu–I–Cu and I–Cu–I angles, this $CuI_2Cu$ rhomboid unit can adapt to a given coordination geometry produced by the ligands.[16b] In **1**, these metallic $CuI_2Cu$ subunits connect alternately two couples of didentate bpp ligands to form a one-dimensional double-bridged polymeric chain which propagates along the *a* or *b* crystallographic direction. The doubly bridging iodides lie above and below the planes of the chain rings. An interesting feature of **1** is the parallelity of the $CuI_2Cu$ metallacycles. All these cycles retain a plane perpendicular to the double-bridge surfaces, which shows that the bpp ligands have no evident impact on the $CuI_2Cu$ configuration. On the other hand, the flexible

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trimethylene spacer decreases the rigidity of the chain to cater for the parallelity of the $CuI_2Cu$ rings. From this point of view, cluster **1** is a typical example of metal-directed self-assembly.

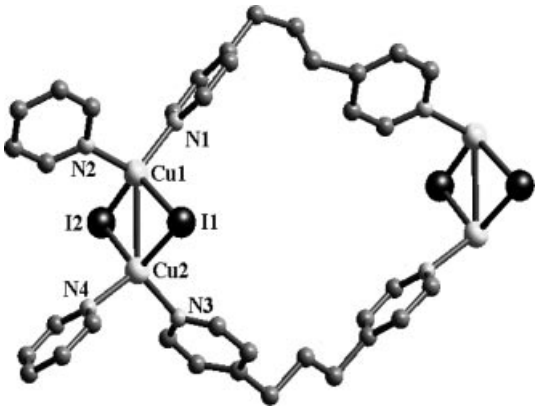

Figure 2. The elliptic molecular ring with approximate dimensions of $12.56 \times 10.79$ Å$^2$ in **1**.

Another noteworthy aspect of this structure is the existence of the interweaving linkages. In the doubly bridged chains, two such subunits and two bpp ligands with distinct conformations (*anti-anti* and *anti-gauche*) form an elliptic molecular ring with approximate dimensions of $12.56 \times 10.79$ Å$^2$. As mentioned above, there are two groups of equivalent chains extended along the *a* and *b* axes, respectively. Each closed elliptic circuit is penetrated by the same loop from another chain at the loosest point with a Hopf link (Figure 3, top), leaving no residual space for solvent inclusion. These two groups of interweaving chains display 2D "open" vertical interpenetration (Figure 3, bottom) to give a uniform (4,4) net containing square intermolecular boxes with approximate dimensions of $12.56 \times 12.56$ Å$^2$. The catenated coordination rings indicate an ideal separation between the ligands in each molecular ring, whereas catenation does not take place if the elliptical rings possess no voids in their cavities due to the possible excessive flexibility or the entanglement of the ligands. Compound **1** also emphasizes that optimized ligand conformations are essential for the self-assembly of catenanes.[8] Thus, this net is clearly different from other reported network topologies containing $CuI_2Cu$ rhomboids[16g,16h] and represents the first uniform net of [2]-catenane nodes.

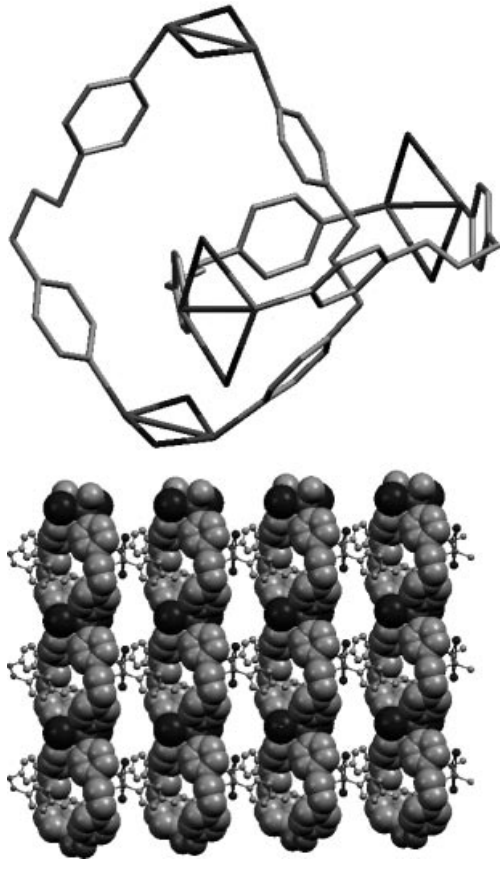

Figure 3. Solid-state structure of **1**. Top: The catenation of two individual $[(CuI)_2(bpp)_2]_n$ chains showing the Hopf links. Bottom: View along the *c*-direction the infinite interlocking 2D (4,4) lattice in **1** showing [2]-catenane nodes. The two individual polymeric chains are perpendicular to each other and are shown in capped-stick and space-filling representations, respectively.

### Crystal Structure of $[(AgI)_6(bpp)]_n$ (2)

The X-ray single-crystal structural analysis showed that compound **2** crystallizes in the monoclinic system with space group *C*2/*c*. A portion of the cluster is shown in Figure 4. The structure of **2** is made up of isolated bpp units and the infinite polymeric cluster $[(AgI)_6]_n$.

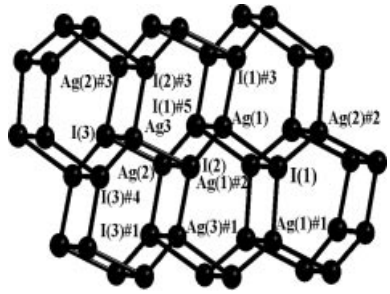

Figure 4. View of the two-dimensional $[AgI]_{6n}$ double layer in $[(AgI)_6(bpp)]_n$ (**2**).

In the polymeric structure, each silver atom is covalently bonded to three iodines at 2.77–2.87 Å in the same layer (Figure 4). The bond angles are in the range 102–114°. The iodine and silver atoms can therefore form six-membered rings but don't link up to form flat sheets. A fourth strong Ag–I covalent force with distances of 2.88–2.97 Å holds the layers together. This interaction prevents the layers from slipping over each other, which is different from the graphite lattice structure. The cluster can also be seen as a double layer (6,3) net motif composed of an edge-sharing $Ag_6I_6$ hexagonal prism-shaped cell. A section of the double layer of **2** is shown in Figure 5. There have been a series of polymeric metal(I) halide clusters reported;[17] comparing the crystallographic data available for different classes of silver

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

iodide clusters in the Cambridge Structural Database (CSD) and search results from the Chemical Abstracts database with SciFinder Scholar®, we see that compound **2** is the first example of a 2D bilayer AgI cluster motif.

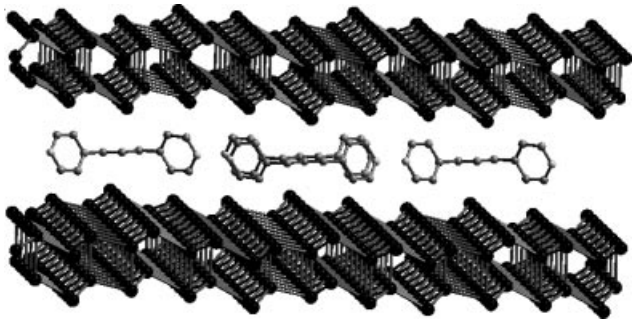

Figure 5. View showing the alternating $[AgI]_{6n}$ bilayer and bpp layer in **2**.

There is a closely related example for **2**, namely the triazine-based coordination polymer $[Cu_2I_2(tri)]_n$ (tri = triazine).[17b] In $[Cu_2I_2(tri)]_n$, the $[CuI]_n$ layer is also an undulating hexagonal net, with each six-membered ring adopting a boat conformation, but the fourth position of the tetrahedral copper center is occupied by a triazine nitrogen and triazine ligands link $[CuI]_n$ layers to give alternating copper(I) iodide and triazine layers. Because of the existence of bridging triazine layers, the longer distances between neighboring $[CuI]_n$ monolayers (minimum Cu–I distance is 6.2–7.1 Å) eliminate the possible Cu···I interlayer interactions. In **2**, the uncoordinated bpp is more like a cluster cutter and isolates the $[AgI]_n$ double layer unit from the metal polyiodide phase. The $[AgI]_n$ double layers are much more regular than $[CuI]_n$ in $[Cu_2I_2(tri)]_n$, so this structure can be considered to be a novel topological type for monovalent $M^I$ halide polymeric clusters.

### Crystal Structure of $[PbI_2(bpp)]_n$ (3)

An ORTEP drawing with the atom-numbering scheme of **3** is shown in Figure 6. The geometry around the lead atom is a distorted octahedron involving the nitrogen atom from pyridyl donors and the iodine atoms. Around the lead the four Pb–I distances range from 3.15 to 3.31 Å and the Ag–N distance is 2.64 Å. Each Pb also has a supramolecular interaction with a nitrogen atom from another bpp at a distance of 2.80 Å. The polymeric structure is comprised of $[PbI_2]_n$ "staircase clusters" and bpp bridges. The bpp ligands link cluster ribbons to form a 2D "open" motif spreading out in the *ab* plane. The bpp molecules stack along the *a*-axis with a stacking distance of 4.54 Å (to the neighboring equivalent pyridyl ring), forming a two-column structure between the $[PbI_2]_n$ ribbons. Each bpp ligand adopts an *anti-anti* configuration and the two pyridyl rings have a dihedral angle of 58.6°. The nearest Pb–Pb distance along the *a*-axis is equal to the repetition distance of bpp. The 2D sheets stack along the *c*-direction in an ABAB pattern, with the equivalent interlayer Pb–Pb separation distance being 11.92 Å. These 2D sheets are similar to those observed in $[PbX_2(4,4'\text{-bipy})]_n$,[18a] $[PbI_2(C_{12}H_{10}N_4)]_{2n}\cdot 0.5n(C_{12}H_{10}N_4)$,[18b] and $[PbI_2(L)]_n$ [L = *N*,*N*′-bis(3-pyridylmethyl)-1,4-biphenylenedimethyleneimine].[18c]

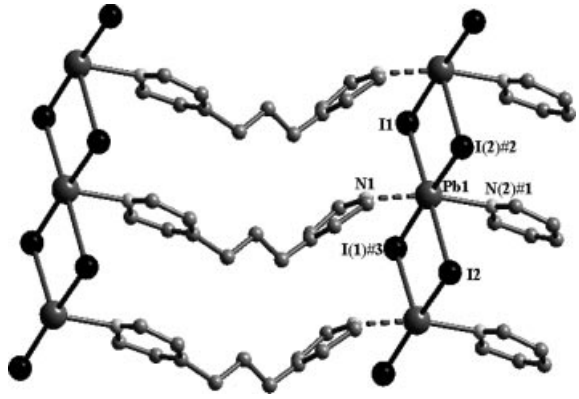

Figure 6. The 2D sheet structure of **3** formed by association of $[PbI_2]_n$ "staircase clusters" through supramolecular Pb···N interactions.

### Crystal Structure of $[I_3(bppH)]$ (4)

The structure of **4** is made up of organic $[bppH]^+$ cations and $I_3^-$ anion chains (Figure 7). The crystal packing is dominated by noncovalent donor–acceptor interactions involving both N–H···N (2.66 Å) hydrogen bonding between $bppH^+$ cations and I···I interactions between $I_3^-$ anions. The triiodide ion is nearly linear (I2–I1–I3 = 178.12°) and asymmetric, and has *d*(I–I) distances of 2.901 and 2.921 Å. The triiodide ions are stacked in zigzag patterns with weak $I_3^-\cdots I_3^-$ interactions (3.69 Å). It is believed that the large linear deformation of the $I_3^-$ ion is a result of the different environments in the solid state. Packing effects and electrostatic interactions may be considered to explain the induced asymmetry of $I_3^-$ here.[9a] In **4**, all these interactions are considerably shorter than the sums of the van der Waals contact distances for the atoms involved (N: 1.55–1.61 Å; I: 1.98–2.00 Å).[19] The *anti-anti* configuration of bpp is also retained.

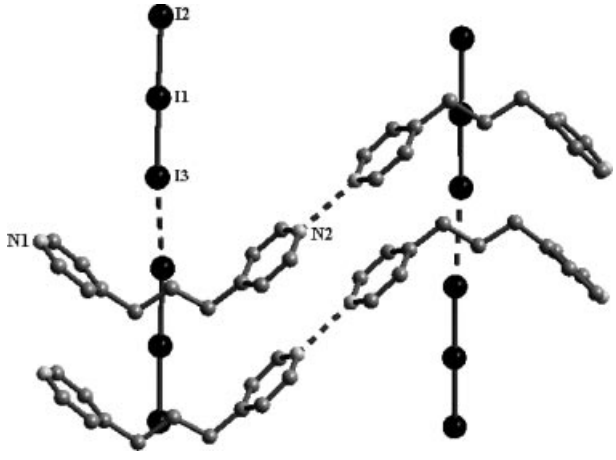

Figure 7. Crystal structure of polyiodide **4**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

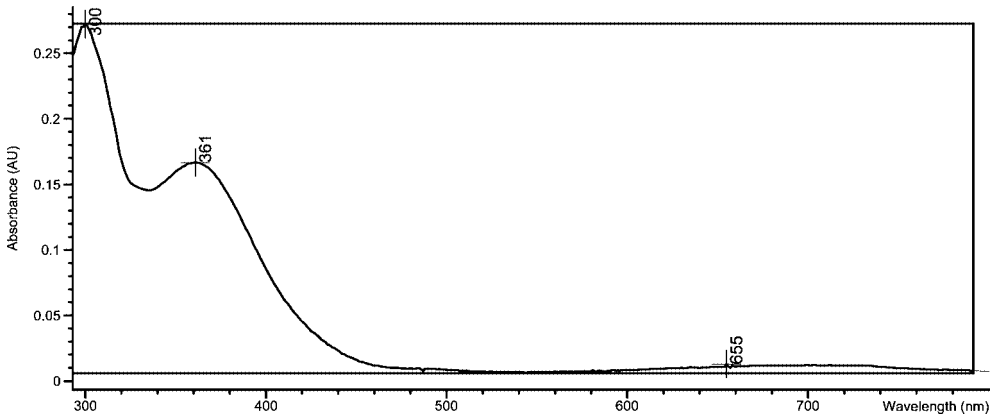

Figure 8. UV/Vis spectra of compound **1**.

### *Third-Order NLO Properties of 1*

#### *UV/Vis Spectra of 1*

In the ground state UV/Vis spectra (Figure 8) of **1**, two strong absorption peaks at 300 and 361 nm in the near ultraviolet (UV) wavelength range are attributed to the charge-transfer excitation between $Cu^+$ and $I^-$ ions of the cluster segment, perhaps the HOMO (mostly iodide in character) to LUMO (mostly metal) cluster-centered transition suggested by ab initio calculations.[20] In the visible region, there is a weak linear absorption at 655 nm assigned to d-d ligand field (LF) transition.[21]

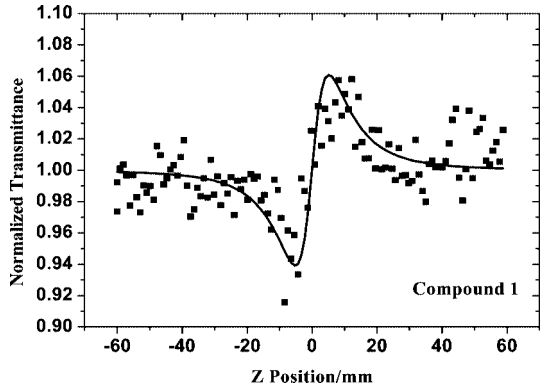

Figure 9. *Z*-scan measurement of the cluster **1** in $1.28\times10^{-4}$ M DMF solution.

#### *Nonlinear Effects of 1*

A preliminary study of the third-order NLO properties of **1** was carried out by the *Z*-scan method in a $1.28\times10^{-4}$ M DMF solution. The compound exhibits strong nonlinear optical behavior at 532 nm and the nonlinear optical properties are dominated by nonlinear refraction. The *Z*-scan data of the compound are given in Figure 9. The filled boxes are the experimental data measured under an open aperture. The nonlinear refractive components of the compound were assessed by dividing the normalized *Z*-scan data obtained in an open-aperture configuration. An effective third-order nonlinear refractive index, $n_2$, can be derived from the difference between normalized transmittance values at valley and peak positions ($\Delta T_{V-P}$) by using Equation (1), where $\Delta T_{V-P}$ is the difference between normalized transmittance values at valley and peak positions, $\alpha_0$ is the linear coefficient, $L$ is the sample thickness, $I$ is the peak irradiation intensity at focus, and $\lambda$ is the wavelength of the laser. The effective third-order NLO refractive index was calculated to be $2.56\times10^{-12}$ esu. The data show that the cluster has a positive sign for refractive nonlinearity, and the valley–peak pattern of the normalized transmitted curve obtained in the closed-aperture configuration shows the characteristic self-focusing behavior of propagating light in the sample.

$$n_2^{eff} = \frac{\lambda\alpha_0}{0.812\pi I\left(1-e^{-\alpha_0 L}\right)}\Delta T_{V-P} \quad (1)$$

Although this value of $n_2$ was obtained with a dilute solution of **1**, it is better than many best known third-order materials in neat solid form, such as $SiO_2$ ($2\times10^{-20}$ $m^2W^{-1}$) and CdS ($2.5\times10^{-18}$ $m^2W^{-1}$),[22] $SrLaGa_3O_7$ ($11.1\times10^{-20}$ $m^2W^{-1}$) and $Ca_2Ga_2SiO_7$ ($6.5\times10^{-20}$ $m^2W^{-1}$).[23] In particular, the $n_2$ value is also comparable to that of some clusters, including monomers, oligomers, and polymers in solution, such as the nest-shaped cluster $[MoOS_3Cu_3I(py)_5]$ ($3.0\times10^{-17}$ $m^2W^{-1}$),[24] the hexagonal prism cluster $[W_2S_8Ag_4(AsPh_3)_4]$ ($5.9\times10^{-17}$ $m^2W^{-1}$),[25] and the 2D microporous cluster $[MoS_4Cu_6I_4(py)_4]_n$ ($2.5\times10^{-17}$ $m^2W^{-1}$).[26] We speculate that the NLO properties of **1** are enhanced, in part, by the planar skeleton and the $Cu^I$–bpp molecular rings in the cluster. The heavy-atom effects of the planar "open" structures in **1** may allow better spin–orbital couplings, and thus intersystem crossing at the excited states.[27] In addition, the use of heavy atoms such as Cu and I may introduce more sublevels into the energy hierarchy and provide more allowed electronic transitions for the initial excited state in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**1**. The increased numbers of allowed electronic transitions probably enhance the nonlinear optics. On the other hand, these planar clusters have higher symmetry than other clusters. This higher symmetry, as in the phthalocyanine systems,[28] may decrease the probability of ground-state electronic transitions and gives a smaller absorption cross-section, $\sigma_g$, and a larger $\sigma_e/\sigma_g$ ($K_\alpha$) ratio. Our recent results have also shown that sometimes the metal core and peripheral ligands may have a complimentary effect on the strength of the NLO properties.[29] This presentation is the first report on the coordination chemistry of metallic polyiodides where the systematic incorporation of metal iodide and organic ligand-based molecular rings into polymeric cluster networks allows for the fine modulation of their structural and optical properties. In addition, although the concentration of coordination polymeric clusters in solution is apparently limited by their poor solubility, larger nonlinear index values may be expected if higher concentrations are attained.

## Conclusions

The metal halides CuI, AgI, and $PbI_2$ form three different polymeric networks with bpp depending upon the coordination geometry of the metals and the reaction condition. In **2** bpp isn't coordinated to the Ag atoms, presumably due to the additional structural rigidity and stability of the 2D $(AgI)_n$ polymer sheet. The use of mixed organic solvents (THF/$CH_3CN$/$H_2O$) shows that the formation of **2** is also sensitive to the experimental conditions.[12d,12e] The choice of bpp as ligand is of great importance in determining the cluster skeleton (0D $[Cu_2I_2]$ for **1**, 1D $[PbI_2]_n$ for **3**, and 2D $[(AgI)_6]_n$ for **2**) and the final topology of the supramolecular arrays.

In summary, we have prepared and characterized the first uniform polycatenane (4,4) net with good NLO properties. The current work shows that this metallic polyiodides approach, which incorporates a metal-organic molecular ring or altering cluster skeletons into polymeric species, is perhaps a promising research direction in the search for better NLO materials. Further systematic investigation will focus on the influence of assembly conditions on the diversity of cluster networks and the design and construction of better NLO materials like the planar "open" coordination polymeric cluster **1**. Studies are under way to extend this facile method to other metal polyiodide anions, and to further probe their structure/properties relationship.

## Experimental Section

**Genaral:** 1,3-Bis(4-pyridyl)propane (bpp) was obtained from Aldrich. Other chemicals were obtained from commercial sources and used as received. All solvents were pre-dried with activated molecular sieves and refluxed over the appropriate drying agents under argon. The IR spectrum was recorded with a Shimazu IR435 spectrometer as KBr disk (4000–400 $cm^{-1}$). UV/Vis spectra of **1** were measured with a HP 8453 ultraviolet-visible spectrophotometer. The C, H, and N microanalyses were performed with a Perkin–Elmer 240C instrument.

**Preparation of $[(CuI)_4(bpp)_4]_n$ (1):** A DMF solution of bpp (19.8 mg, 0.1 mmol) was added to a stirring colorless solution of CuI (19 mg, 0.1 mmol) dissolved in 10 mL of THF/$H_2O$ (volume ratio of 1:5) in the presence of excess KI (99.6 mg, 0.6 mmol). The solution was then filtered and slowly evaporated in a vial at room temperature. Light-yellow crystals of **1** suitable for X-ray analysis were obtained after several days in about 22% yield. $C_{52}H_{56}Cu_4I_4N_8$ (1554.8): calcd. C 40.17, H 3.63, N 7.21; found C 40.36, H 3.70, N 7.20. IR (KBr): $\tilde{\nu}$ = 1608(vs), 1423 (s), 1218 (m), 809 (m) $cm^{-1}$. UV/Vis (DMF): $\lambda_{max}$ ($\log\varepsilon$) = 300.0 nm (3.327), 361.0 (3.115), 655.0 (2.004).

**Preparation of $[(AgI)_6(bpp)]_n$ (2):** Compound **2** was obtained by a similar reaction procedure from bpp, AgI, and KI (molar ratio = 1:1:6) in THF/$CH_3CN$/$H_2O$ at room temperature. Upon slow evaporation in the dark, colorless needles of **2** were harvested in 47% yield when the solution was nearly dry. $C_{13}H_{14}Ag_6I_6N_2$ (1606.9): calcd. C 9.74, H 0.88, N 1.75; found C 9.56, H 0.76, N 1.24. IR (KBr): $\tilde{\nu}$ = 3428 (sh), 3139 (sh), 2983 (w), 1710 (w), 1620 (s), 1400 (s), 1177 (w), 814 (w), 619 (w), 545 (w) $cm^{-1}$.

**Preparation of $[PbI_2(bpp)]_n$ (3):** Compound **3** was obtained by a similar reaction procedure from bpp, $PbI_2$, and KI (molar ratio = 1:1:2) in DMF/$H_2O$ at room temperature. A colorless polymer **3** was harvested in 25% yield after 1 month. $C_{13}H_{14}I_2N_2Pb$ (659.25): calcd. C 23.64, H 2.14, N 4.24; found C 23.56, H 2.20, N 4.24. IR (KBr): $\tilde{\nu}$ = 2940 (w), 1606 (s), 1425 (w), 1221 (w), 1010 (m), 815 (m), 514 (w) $cm^{-1}$.

**Preparation of $[I_3(bppH)]$ (4):** Compound **4** was obtained by a similar reaction procedure from bpp, $I_2$, and KI (molar ratio = 1:1:2) in $CH_3OH$/$H_2O$ at room temperature. Needle-shaped, dark-red crystals of **4** were obtained in 32% yield after 1 d. $C_{13}H_{15}I_3N_2$ (579.97): calcd. C 26.92, H 2.61, N 4.83; found C 26.86, H 2.56, N

4.75. IR (KBr): $\tilde{\nu}$ = 3029 (w), 2922 (w), 1616 (s), 1501 (w), 1406 (w), 1351 (w), 1223 (w), 1029 (m), 816 (m), 618 (w), 552 (w), 442 (w) $cm^{-1}$.

**Nonlinear Optical Measurements:** The optical measurements were performed with linearly polarized 8-ns pulses at 532 nm generated from a frequency-doubled Q-switched Nd:YAG laser. This wavelength is of paramount practical importance in the field of optical limiting as well as the design and fabrication of resonance cavities of lasers. The spatial profiles of the pulses were nearly Gaussian after a spatial filter was employed. A DMF solution of compound **1** was placed in a 1-mm-thick quartz cell for optical limiting measurements. Crystalline samples of **1** are stable toward oxygen, moisture, and laser light. The laser pulse was focused into the cells containing the non-linear medium with a 250-mm focal length lens. The laser beam was divided into two beams. One was used to monitor the incident laser energy meter and the other was focused onto the sample cell. The input and the output energies of the beams were measured with an energy meter (Laser Precision Rjp-735), which were linked to a computer by an IEEE interface.[30,31] The experimental data were collected utilizing a single shot at a rate of 1 pulse per minute to avoid the influence of thermal effects.

**X-ray Crystallography:** Crystallographic data for the title compounds were collected using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) on a Rigaku RAXIS-IV image plate area detector. The data were corrected for Lorentz and polarization factors and for absorption by using empirical scan data. The structure was solved with the SHELX program,[32] and refined by full-matrix least-squares methods based on $F^2$, with anisotropic thermal parameters for the non-hydrogen atoms. The hydrogen atoms were located theoretically and not refined. Selected bond lengths and bond angles for **1** (Table 1), **2** (Table 2), and **3** and **4** (Table 3) are given below. Crystal data are summarized in detail in Table 4.

CCDC-252911 (for **1**), -287706 (for **2**), -287707 (for **3**), and -287708 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# (Diphosphane monosulfide)platinum(II) Complexes for Hydroformylation Reactions: Their Catalytic Activity and a High-Pressure NMR Mechanistic Study

**Antonio Lofù,[a] Piero Mastrorilli,*[a] Cosimo F. Nobile,[a] Gian P. Suranna,[a] Piero Frediani,[b] and Jonathan Iggo[c]**

**Keywords:** Heteroditopic ligands / Hydroformylation / NMR spectroscopy / P,S ligands / Platinum

The neutral complexes of formula [$\kappa^2P,S$-(dppmS)Pt($CH_3$)(Cl)] (**1**), [$\kappa^2P,S$-(dppeS)Pt($CH_3$)(Cl)] (**2**) and [$\kappa^2P,S$-(dpppS)Pt($CH_3$)(Cl)] (**3**) [dppmS = $Ph_2PCH_2P(S)Ph_2$; dppeS = $Ph_2P(CH_2)_2P(S)Ph_2$; dpppS = $Ph_2P(CH_2)_3P(S)Ph_2$] are active catalyst precursors for the hydroformylation of 1-octene in methyl isobutyl ketone. The order of reactivity found is **3** > **2** > **1**. Surprisingly, the cationic complexes [$\kappa^2P,S$-(dppeS)Pt($CH_3$)($CH_3CN$)]$BF_4$ (**4a**) and [{$\kappa P,\mu$-$\kappa S$-(dppeS)Pt($CH_3$)}$_2$][$BF_4$]$_2$ (**5**) are less active than the analogous neutral complex **2**. High-pressure NMR studies revealed that, at 20 °C under 1 to 50 bar of syngas, and in the presence of $SnCl_2$, both **2** and **4a** react immediately to form the same acetyl complex (**8**). However, in the absence of $SnCl_2$, the methyl carbonyl complex [$\kappa^2P,S$-(dppeS)Pt($CH_3$)(CO)]$^+$ (**9**), which is formed from **4a** and CO, does not undergo insertion to give the acetyl complex, even under 50 bar of syngas. Thus, the role of $SnCl_2$ is not only to create a vacant site for CO coordination and to lower the energy barrier for the hydrogenolysis, but also to assist migration of the alkyl group in the CO insertion step. High-pressure NMR studies of the working reaction solution, under steady-state conditions, found no evidence for intermediates in which the phosphane sulfide group shows hemilabile behaviour during catalysis.

## Introduction

Hydroformylation of alkenes is one of the most important catalytic reactions in industry, which runs plant processes with Co- or Rh-based catalysts.[1] On the other hand, there is an increasing interest in platinum-catalysed olefin hydroformylation, mainly devoted to the optimisation of chemo- and regioselectivity of the reaction and the synthesis of linear aldehydes.[2]

Since Parshall's pioneering work using $PtCl_2$ in the ionic liquid [$(NEt_4)SnCl_3$],[3] many catalytic systems,[4–7] including some specifically suited to enantioselective catalysis,[8–15] have been developed. A common feature of all these systems is the use of $SnCl_2$ in combination with the $Pt^{II}$ salt or complex. Several mechanistic studies on the catalytic cycle[16–19] and on the role of the $SnCl_2$[20,21] have appeared, and these have concluded that the $SnCl_2$ generates trichlorostannate species by reaction with chloroplatinum(II) catalyst precursors and promotes the hydrogenolysis of the Pt–acetyl intermediate. The use of chelating diphosphanes brings about considerable activity enhancement, especially in the case of dppb,[22] and Scrivanti et al. have performed a mechanistic study intended to explain why the seven-membered metallacycle is the most efficient.[23]

Heteroditopic ligands are chelating compounds endowed with different chemical functionalities capable of coordinating to a metal centre. The very different *trans* effects produced by the dissimilar donor atoms in these ligands offer the potential to introduce widely different activity and selectivity at selected coordination sites in metal complexes and has resulted in such ligands receiving increasing attention in the field of organometallic chemistry and catalysis.[24] Interest in P^S heteroditopic ligands[25–31] is driven by the ability of sulfur to coordinate strongly to soft metal centres.[32,33] In the framework of our studies into the coordination chemistry of heteroditopic ligands,[34,35] we recently became interested in the monosulfides of diphosphane ligands (P^PS)[36] and have studied the synthesis and reactivity of neutral and cationic methyl complexes of platinum(II) with the P^PS heteroditopic ligands dppmS and dppeS.[37]

The heteroditopic behaviour of the diphosphane monosulfide (P^PS) ligands has recently been exploited in Rh- and Ir-catalysed methanol carbonylation.[38,39] Considerably less attention has been paid to the use of Pt complexes

of heteroditopic ligands as catalysts for olefin hydroformylation.[7,40,41] Here we report our results using both neutral and cationic methylplatinum complexes of diphosphane monosulfide ligands in combination with $SnCl_2$ as catalysts for the hydroformylation of 1-octene. In particular, we have focused our interest on the roles of the heteroditopic ligand and the cocatalyst, and on the effects of chelating ring size in/on the catalytic reaction. The study has been complemented by high-pressure NMR experiments aimed at gaining insights into the reaction mechanism.

## Results and Discussion

### Synthesis

The neutral and cationic methylplatinum(II) complexes of diphosphane monosulfides used in this study are depicted in Figure 1. Neutral complexes of general formula [$\kappa^2$*P*,*S*-(P^PS)Pt($CH_3$)Cl] [P^PS: $Ph_2PCH_2P(S)Ph_2$, dppmS (**1**); $Ph_2P(CH_2)_2P(S)Ph_2$, dppeS (**2**); $Ph_2P(CH_2)_3P(S)Ph_2$, dpppS, (**3**)] were synthesised by reaction of [(cod)Pt($CH_3$)(Cl)] (cod = 1,5-cyclooctadiene) with one equivalent of the relevant ligand.[37] Reaction of **2** with silver tetrafluoroborate in MeCN affords the cationic complex [$\kappa^2$*P*,*S*-(dppeS)Pt($CH_3$)($CH_3CN$)][$BF_4$] (**4a**), in which the chloride is replaced with acetonitrile. The cationic dimer [{$\kappa$*P*,$\mu$-$\kappa$*S*-(dppeS)Pt($CH_3$)}$_2$][$BF_4$]$_2$ (**5**), in which the sulfur atoms bridge the two platinum atoms, is obtained quantitatively on heating solid **4a** at 363 K under vacuum, as described previously.[37] Reaction of [(cod)Pt($CH_3$)(Cl)] with two equivalents of dpppS affords [*trans*-($\kappa$*P*-dpppS)$_2$Pt($CH_3$)(Cl)] (**6**) in high yield, in which the two dpppS ligands are coordinated through the phosphorus atoms only.

### Hydroformylations

Preformed complexes **1**–**6** were used as catalyst precursors for the hydroformylation of 1-octene (Scheme 1) in the presence of five equivalents of $SnCl_2 \cdot 2H_2O$ as cocatalyst, in methyl isobutyl ketone as solvent (Table 1). Alternatively, catalysts were formed in situ from [(cod)Pt($CH_3$)Cl] or [(cod)$PtCl_2$] and the appropriate ligand (this experimental procedure has been validated; compare entries 4 and 7 with entries 3 and 6 of Table 1). The progress of the reaction was monitored by gas consumption. The reaction times of all catalytic tests were kept below 4 h in order to minimise the formation of side products deriving from aldol condensation between formed aldehydes and between aldehyde and solvent. In all tests, the amount of condensation products was less than 10%, while the regioselectivity towards normal aldehyde ranged from 79 to 91%.

[a] Reaction conditions: olefin (1-octene: 5.8 mmol), olefin/Pt/Sn = 100:1:5; $T$ = 353 K, $P(CO) = P(H_2)$ = 25 bar; solvent: methyl isobutyl ketone (5.8 mL). The reaction times are those required to reach the stated conversions. [b] Selectivity: *n*-nonanal/total aldehydes. [c] TOF: Turn over frequency as (mol aldehydes)(mol Pt)$^{-1}$(time)$^{-1}$. [d] Pt/$SnCl_2$ = 1:1. [e] Reaction performed in the absence of $SnCl_2$.

### Effect of Ring Size

In agreement with previous reports on the effect of chelate ring size in diphosphaneplatinum(II)-based catalytic systems,[42] we found a pronounced increase in both activity and selectivity as the ring size is increased. Thus, **1** (five-membered platinacycle) affords incomplete substrate conversion after 4 h, and 25% yield in nonanals (Table 1, entry 1), whereas with **2** (six-membered platinacycle) we observed complete conversion after 3.5 h with a 56% yield in nonanals (entry 3). Complete conversion after 1.25 h and 60% yield in aldehydes (Table 1, entry 6) was observed with **3**, thereby clearly demonstrating the beneficial effects of a larger metallacycle. This effect has previously been reported and ascribed to a lowering in the activation energy for the hydrogenolysis step.[22,23]

### Effect of the Heteroditopic Ligand

The performance of catalyst systems incorporating heteroditopic P^PS ligands is comparable with that of analogous systems containing P^P ligands that give equally sized platinacycles, although the P^P complexes were found to be more stable under hydroformylation conditions, no Pt black being observed in the products at the end of the reaction, in contrast to the P^PS-containing systems.[43] Thus, using catalysts formed in situ from [(cod)Pt($CH_3$)Cl] and the appropriate ligand the P^PS ligands give slightly more regio- and chemoselective catalyst systems (compare entries 1 and 2, 4 and 5, and 7 and 8 of Table 1), although the P^P ligands show comparable or greater activity. Replacement of a diphosphane by a diphosphane monosulfide ligand on the catalyst precursor will reduce the electronic density at the metal centre, which should favour Markovnikoff-type hydride attack on the olefin to give the linear Pt–alkyl intermediate and account for the observed increase in the *n*:*iso* ratio. The diminished electron density on Pt might also be expected to retard hydrogenolysis thereby lowering the activity of the catalyst, and this is indeed observed.

### Effect of Ligand/Metal Ratio

We have also investigated the effect of the ligand/metal ratio using both P^PS and P^P ligands. Thus, with [*trans*-(κ*P*-dpppS)$_2$Pt($CH_3$)Cl] (**6**) as the catalyst precursor the reaction gave the highest chemoselectivity towards hydroformylation products (70% aldehydes), the remainder being octane and internal octenes, with the highest regioselectivity towards *n*-nonanal (91%). However, the catalytic activity was lower, with conversion of 76% in 4 h (Table 1, entry 9) compared to that obtained using a ligand/metal ratio of 1 (Table 1, entry 6). A similar behaviour was observed for the P^P system using a mixture of [(cod)Pt($CH_3$)Cl] and 1,4-bis(diphenylphosphanyl)butane (dppb) as catalyst precursor (Table 1, entries 8 and 10). Once again, activity is lower and selectivity to linear product higher. This is not surprising as the 2:1 ligand to metal ratio may lead to the blocking of coordination sites, thereby reducing the activity,[5,42] and increase the steric hindrance at the metal, thus improving the regioselectivity.[5,44]

### Role of $SnCl_2$

Given that cationic $Pt^{II}$ species are normally invoked in the catalytic cycle, and the role of the $SnCl_2$ is widely believed to be the generation of such cationic species by abstraction of $Cl^-$ to form $SnCl_3^-$, we tested the mono- and dinuclear cationic complexes **4a** and **5** in the catalysis and were surprised to find that these complexes gave much lower activity and productivity than **2** (27% and 32% yield of nonanals after 3.5 h for **4a** and **5**, respectively, see en-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tries 14 and 15 of Table 1) even though $SnCl_2$ was present in the reactions. The similar catalytic activities exhibited by **4a** and **5** suggest the formation of the same active species from these cationic precursors, i.e. MeCN is not retained at Pt and does not interfere in the catalysis. In the absence of $SnCl_2$ cocatalyst (Table 1, entry 16) **4a** is almost inactive. Thus, independent of the charge on the $Pt^{II}$ precursor, the addition of $SnCl_2$ is necessary to trigger the hydroformylation,[5,15] and the formation of $SnCl_3^-$ (which is possible starting from **2** but not from **4a** or **5** since chloride is not available in the latter systems) further increases the reaction rate.

Interestingly, using [(cod)$PtCl_2$] as the platinum source (and 5 equiv. of $SnCl_2$) affords catalyst systems that are less chemo- and regioselective than those using [(cod)Pt-($CH_3$)Cl], from which only one equivalent of $SnCl_3^-$ can be obtained by halide abstraction, as the Pt source (compare entries 4 and 11 and 5 and 13 of Table 1). However, using equimolar amounts of Sn and Pt (Table 1, entry 12) and [(cod)$PtCl_2$] as the Pt source affords higher chemo-and regioselectivities, similar to those obtained using **2** with a Sn/Pt molar ratio of 5:1. This seems to indicate a detrimental effect of a Sn/Pt molar ratio higher than 1 when using [(cod)$PtCl_2$] as the Pt source.

### Summary of the Catalytic Results

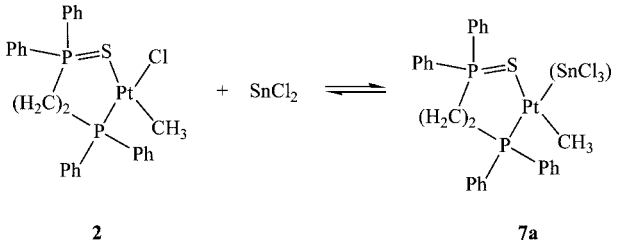
The use of heteroditopic P^PS ligands in Pt/Sn olefin hydroformylation systems affords catalysts that compare favourably with analogous systems that use P^P ligands. No significant variation in regioselectivity was observed using cationic vs. neutral complexes as catalyst precursors, thus indicating that regioselectivity is established in a $Pt^{II}$ intermediate that is identical for both cationic and neutral catalyst precursors. For both P^P and P^PS systems, activity is related to ring size, with seven-membered rings giving the most active systems. The correlation of activity with ring size is consistent with a chelating structure being maintained in the rate-determining steps of the catalysis, although it has been suggested that the dppb may, alternatively, form oligomeric/polymeric metal species.[23] The presence of $SnCl_2$ is essential to the generation of effective catalyst systems from both neutral and cationic precursors, thus indicating that the role of $SnCl_2$ is more than simply the generation of an active site at Pt by removal of $Cl^-$. However, the presence of excess $SnCl_3^-$ is detrimental to the catalysis under our conditions.

### High-Pressure NMR Study

A high-pressure NMR study of the reaction was performed using both a HP-NMR bubble column reactor developed in Liverpool[45] and conventional sapphire tubes with the aim of gaining additional insight into the mechanistic differences responsible for the reactivities of the neutral (**2**) and cationic (**4a**) complexes. Except where otherwise stated, [$D_6$]acetone was used as solvent for this study since the catalytic reaction is known to proceed smoothly in ketonic solvents.

### HP-NMR Behaviour of the Catalyst Precursors 2 and 4a

Compound **2** is poorly soluble in acetone. However, upon addition of $SnCl_2$ (Sn/Pt = 5:1), rapid dissolution of the solids occurred, accompanied by a colour change from pale straw yellow to dark orange, indicating the formation of a new species (**7a**; Scheme 2), which we propose to be the $SnCl_2$ adduct of **2**. Thus, the $^1H$ NMR spectrum of **7a** (Table 2, entry 2) shows a resonance at $\delta_H$ = 0.43 ppm, which can be assigned to a methyl group directly bound to Pt. The $^{31}P\{^1H\}$ NMR spectrum of **7a** shows resonances at similar chemical shifts to those of **2** in $CD_2Cl_2$. However, the $^3J_{P,P}$, $^2J_{P,Pt}$ and $^1J_{P,Pt}$ coupling constants are significantly different from those of **2**, clearly indicating the formation of a new methylplatinum complex. The chemical shifts and coupling constants (Table 2, entry 2) indicate that the methyl group remains *trans* to the phosphane sulfide donor. Thus, Tóth et al. have reported a $^1J_{P,Pt}$ value of 1628–1836 Hz for $CH_2PPh_2$ *trans* to methyl in the structurally similar diphosphane complexes [(BDPP)Pt($CH_3$)(L)] (L = Cl, $SnCl_3$),[18] to be compared with $^1J_{P,Pt}$ = 3869 Hz in **7a**. We can suggest at least three possibilities for the group occupying the fourth coordination site at Pt in **7a**: i) acetone, in which case $SnCl_3^-$ is present as the counterion; ii) $SnCl_3^-$ directly bonded to platinum; or iii) Pt-bound $SnCl_2$. We can discount the latter hypothesis since, in an otherwise identical experiment but using one equivalent of $SnCl_2$, complex **7a** was again obtained in high yield.



**2** **7a**

Scheme 2.

In an attempt to differentiate the remaining possibilities we measured the $^{31}P\{^1H\}$NMR spectrum of **4a** in [$D_6$]acetone since we believed that acetone would displace the coordinated MeCN to give [Pt(dppeS)($CH_3$)(acetone)]$^+$, the cation of the first hypothesis, as a result of mass action. In this experiment, in addition to the resonances of **4a** and its dimer **5**,[37] two new resonances were observed in the $^{31}P\{^1H\}$NMR spectrum at chemical shifts, and with coupling constants, different to those of **2** + $SnCl_2$ reported above (compare entries 2 and 3 in Table 2). We assign these resonances to the new complex [Pt(dppeS)($CH_3$)(acetone)]$^+$ (**4b**). The larger value of $^1J_{P,Pt}$ (5003 Hz in **4b** vs. 4606 Hz in **2**) confirms the displacement of the acetonitrile by acetone, a ligand with a weaker *trans* influence. These observations allow us to exclude **4b** or **5** as the complex **7a** and

[a] At 353 K; n.d. = not determinable.

support the hypothesis of $SnCl_3^-$ directly bonded to platinum. Moreover, the reduction of $^1J_{P,Pt}$, from 4606 Hz in **2** to 3869 Hz in **7a** is consistent with displacement of chloride by $SnCl_3^-$, a ligand with a stronger *trans* influence. However, the $^{119}Sn\{^1H\}$ spectrum of **7a** shows no resonance in the region $\delta$ = –300 to +300 ppm over the temperature range 298–213 K, which suggests that the $SnCl_3^-$ ligand is involved in a fluxional process.[46] Support for this hypothesis is the marked broadness of the $^{31}P\{^1H\}$ signal of the P *trans* to this site ($\Delta\nu_{1/2}$ = 110 Hz, $T$ = 290 K).

Finally, reaction of an acetone solution of **4a** (comprising **4a**, **4b** and **5**) with $SnCl_2$ gives a bright yellow solution of a new complex (**7b**) quantitatively (by $^{31}P\{^1H\}$ NMR spectroscopy; Table 2, entry 7). The NMR spectroscopic data for **7b** are similar to those of **7a** with the exception of $^1J_{P,Pt}$, which increases from 3869 Hz in **7a** to 4036 Hz in **7b**, thus indicating that **7a** and **7b** have a similar overall structure but a different ligand, of similar *trans* influence, occupying the fourth coordination site at Pt. Since $Cl^-$ is not present in acetone solutions of **4a**, thereby precluding the formation of $SnCl_3^-$, we suggest this ligand is $SnCl_2$,[47] i.e. **7a** is the adduct formed between [Pt(dppeS)($CH_3$)Cl] (**2**) and $SnCl_2$, and **7b** its cationic analogue [Pt(dppeS)($CH_3$)($SnCl_2$)]$^+$. Again, no clear $^{119}$Sn NMR resonance could be observed in the case of **7b**, presumably due to fluxionality, as confirmed by the broadness of the $^{31}P\{^1H\}$ NMR signals.

Both **7a** and **7b** react under 50 bar of syngas at 290 K to give **8** (quantitatively by $^{31}P\{^1H\}$ NMR spectroscopy), which is an acyl complex derived from CO insertion into the Pt–$CH_3$ bond (Table 2, entries 5 and 8). In a separate experiment, **7a** was treated with $^{13}$CO (4.5 bar) at 290 K in a sapphire tube. After pressurizing with $^{13}$CO, the dark-orange colour of **7a** progressively lightened as $^{13}$CO diffused into solution to become straw yellow after about 20 min, when $^{31}P\{^1H\}$ NMR spectroscopy confirmed the formation of **8**. The $^1$H NMR spectrum (Table 2, entry 4) shows the disappearance of the Pt–C$H_3$ signal of **7a** to be replaced by a sharp doublet at $\delta$ = 1.77 ppm attributable to the methyl group of the acyl moiety ($^2J_{C,H}$ = 5 Hz).[48] In agreement with this assignment, the $^{13}C\{^1H\}$ NMR spectrum of this sample shows a sharp singlet at $\delta_C$ = 224 ppm flanked by platinum satellites, as expected for a Pt–$^{13}$C(O)$CH_3$ group. The magnitude of the $^1J_{P,Pt}$ coupling constant (4001 Hz) is not consistent with the acetyl group occupying the site *trans* to P, for which Tóth has reported a value of about 1400 Hz for the analogous diphosphane complexes [(BDPP)Pt(COMe)L]$^{n+}$ (L = Cl, $n$ = 0;L = CO, $n$ = 1). Therefore, we propose that the acetyl group is *trans* to the sulfur donor,[18] a disposition also observed in related dppeS–Rh complexes.[38]

The identity of the ligand occupying the fourth coordination site on Pt is more difficult to establish. The value of $^1J_{P,Pt}$ in **8** is significantly smaller than that observed in **4b** (5003 Hz), which seems to exclude acetone. No signal attributable to a Pt–CO group is observed in the $^{13}C\{^1H\}$ NMR spectrum, coupling between phosphorus and $^{13}$CO is not observed, and the $^{31}$P NMR chemical shift and coupling constants are unchanged on purging the solution with nitrogen,[49] observations that exclude both tightly bound and labile CO as the ligand at the fourth site on Pt. Starting from **4a**, $SnCl_3^-$ cannot be present, which therefore excludes $SnCl_3^-$. However, an identical $^{31}P\{^1H\}$ NMR spectrum is obtained starting from **2** and one equivalent of $SnCl_2$, when $SnCl_2$ is presumably reacted (Figure 2). Thus we cannot assign with certainty the ligand occupying the fourth site on Pt in **8**. This contrasts with the analogous P^P acylplatinum(II) system[18,19] in which the fourth coordination site is occupied by CO even at low pressure.

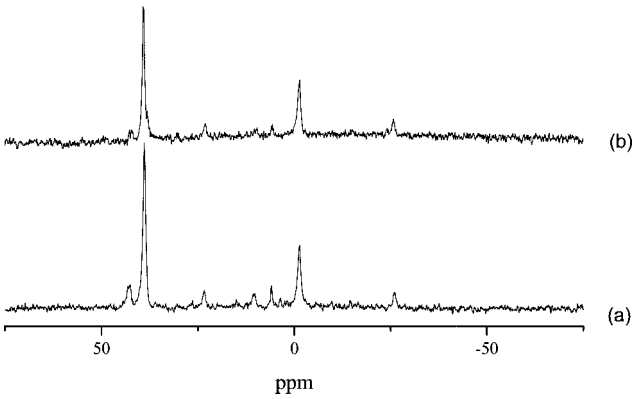

Figure 2. $^{31}P\{^{1}H\}$ HP-NMR spectra of the acyl complex **8** obtained from **2** (a) or **4a** (b) (entries 5 and 8 of Table 2 respectively).

The ready formation of the acetyl complex **8** from the reaction of either **2** or **4a** with CO in the presence of $SnCl_2$ (Scheme 3) contrasts with our previous report of the formation of $[Pt(dppeS)(CH_3)(CO)][BF_4]$ (**9**), which is inert to methyl migration in $CH_2Cl_2$, in the absence of $SnCl_2$.[37] We have confirmed this result for **4a** in acetone (Scheme 4), which gives **9** even under 6.7 bar of $^{13}CO$ or 50 bar of syngas (Table 2, entries 9 and 10). The dependence of the CO insertion reaction on $SnCl_2$ for P^PS ligand complexes contrasts with the situation for $Pt^{II}$ complexes of diphosphane[18,19,50] or P^N ligands,[24] for which no such requirement is reported. The reluctance of CO to insert into the Pt–alkyl bond in the absence of $SnCl_2$ provides a ready explanation for the initially surprising inactivity of the cationic complex **4a** in olefin hydroformylation in the absence of a co-catalyst (entry 6 of Table 1).

## HP-NMR Behaviour of the Working Catalyst

The understanding of the chemistry of the catalyst precursors outlined above provides a firm basis for an HP-NMR study of the working catalyst. Figure 3 shows the $^{31}P\{^{1}H\}$ HP-NMR spectra, recorded in our bubble column reactor at 353 K and 50 bar of syngas, of solutions prepared from either **2** or **4a** (0.010 M), $SnCl_2$ (5 equiv.) and 1-octene (100 equiv.). The spectra of both solutions show resonances of the same two species (**10** and **11**). The similarity of the $^{31}P\{^{1}H\}$ NMR spectroscopic data of **10** and **8** (Table 2, entries 4 and 11) allow us to formulate **10** as the acyl complex $[Pt(dppeS)\{C(O)(C_8H_{17})\}(L)]^{n+}$, in which an octyl chain derived from octene is present, as required by the catalysis. The close similarity of $^{1}J_{P,Pt}$ in **8** and **10** is consistent with the same L in both complexes. The identity of **11** ($\delta_P$ = 9.0, $\delta_{PS}$ = 40.6 ppm; $^{1}J_{P,Pt}$ = 4001 Hz) is less certain. The significant difference in the $^{31}P\{^{1}H\}$ NMR spectra of **10** and **11** is not consistent with **11** also being an acyl complex, with **10** and **11** being the acyls derived from the *n*- and *iso*-alkyl intermediates. The similarity in the $^{31}P\{^{1}H\}$ NMR spectroscopic data of **11** with those of the methyl complexes **7a** and **7b** suggests **11** as the octyl intermediate $[Pt(dppeS)(C_8H_{17})(L)]^{n+}$ (Scheme 5). The resonances of **10** and **11** were not observed in an analogous experiment using **4a** as the catalyst precursor in the absence of $SnCl_2$, consistent with **10** and **11** being intimately associated with the working catalyst (the lack of reactivity in the absence of $SnCl_2$ is discussed above). Furthermore we changed the reacting gas from $CO/H_2$ to $H_2$ (50 bar), in order to convert the working catalyst into a hydride species, but we observed only the slow disappearance of the resonances of both **10** and **11**. Furthermore, no high-field signals, ascribable to hydrides, were observed in the $^{1}H$ HP-NMR spectrum, consistent with our attribution of these complexes to the nonanoyl- and octylplatinum(II) resting states.

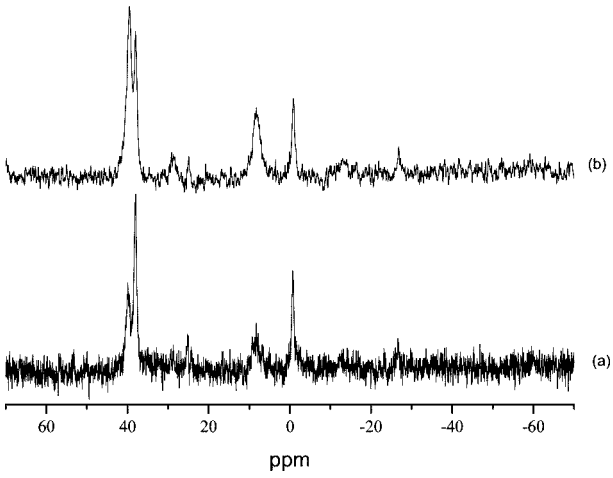

Figure 3. In situ $^{31}P\{^{1}H\}$ HP-NMR spectra showing the steady state of catalytic reactions using **2** (a) or **4a** (b).

The observation of both resting states is consistent with both CO insertion and hydrogenolysis being slow in this catalytic system, since the use of a bubble column reactor allows us to eliminate artifacts resulting from poor gas delivery to the reaction.

## Conclusions

Complexes **1**, **2** and **3** in the presence of $SnCl_2$ are active catalyst precursors for the hydroformylation of 1-octene with yields ranging from 25 to 60% and regioselectivity in linear aldehyde higher than 79%. The reactivity is dependent on the ring size of the platinacycle, with the seven-membered ring being the most active. Tin halides have been shown to fulfil three essential roles in the Pt/diphosphane monosulfide/$SnCl_2$ catalysed hydroformylation of higher alkenes: (i) removal of halide from the platinum centre as $SnCl_3^-$, which can then (ii) function as a labile ligand, and (iii) for diphosphane-monosulfide-based catalyst systems, tin(II) chloride plays an essential additional role in activating the alkyl complex for the CO insertion step, presumably by coordination to the CO oxygen. The observation of both the alkyl and acyl intermediates in solutions of the working catalyst, and in the absence of the gas delivery problems that are often encountered in sapphire NMR tubes, indicates that, at least for the diphosphane monosulfide studied here, there are two slow steps in the reaction. It is interesting to note that tin halides appear to play a role in accelerating *both* slow steps.

## Experimental Section

All reactions (at least two replicates) were carried out under nitrogen using standard Schlenk techniques. Methyl isobutyl ketone was refluxed with a little $KMnO_4$, washed with aq. $NaHCO_3$, dried over $CaCl_2$ and purified by passing through a small column of activated alumina and freshly distilled prior to use. 1-Octene was purchased from Acros and purified by percolation through a short plug of neutral alumina prior to use.

$SnCl_2{\cdot}2H_2O$ was purchased from Carlo–Erba and used as received. The ligand dpppS was prepared by adapting the procedure published for dppmS or dppeS.[36] Complexes **1**, **2**, **3**, **4a** and **5** were synthesised as described.[37] Anhydrous $SnCl_2$ for the mechanistic study was purchased from Aldrich. $CDCl_3$ was purchased from Aldrich and [$D_6$]acetone from Cambridge.

C,H,S elemental analyses were carried out with a Eurovector CHNS-O Elemental Analyser. IR spectra were recorded with a Bruker Vector 22 instrument. Chromatographic analyses were carried out on Hewlett–Packard 6890 instruments using a 19091Z-236 HP-1 methylsiloxane capillary column (60.0 m × 250 μm × 1.00 μm) or a HP 19091J-413 HP-5 phenylmethyl siloxane column (30.0 m × 320 μm × 0.25 μm; injector temperature: 553 K; FID temperature: 553 K; carrier: nitrogen). GCMS data (EI = 70 eV) were acquired with an HP 6890 instrument using an HP 19091S-433 HP-5MS 5% phenylmethylsiloxane column (30.0 m × 250 μm × 0.25 μm) coupled with an HP 5973 mass spectrometer (injector temperature: 553 K; carrier: helium; 70 eV). $^1H$, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$ and $^{119}Sn\{^1H\}$ NMR spectra were recorded with a Bruker Avance 400 MHz. HPNMR spectra were recorded with a Bruker AM200SWB spectrometer using a home built HP-NMR bubble column reactor.

**Synthesis of [κ²*P,S*-(dpppS)Pt(CH₃)Cl] (3):** A solution containing an equimolar amount of dpppS (129 mg) in $CH_2Cl_2$ (10 mL) was added dropwise over about 2 h to a solution of [(cod)Pt($CH_3$)Cl] (102.6 mg, 0.290 mmol) in $CH_2Cl_2$ (5 mL) and the mixture stirred vigorously at room temperature overnight. The solvent was then evaporated to about one fifth of the volume and addition of diethyl ether caused the precipitation of a pale-yellow powder. Filtration followed by washing with diethyl ether (3 × 5 mL) and drying under vacuo afforded **3** in high yield (180 mg, 90%). M.p. 493 K (dec.). $C_{28}H_{29}ClP_2PtS$ (690.07): calcd. C 48.73, H 4.24, S 4.65; found C 48.43, H 4.38, S 4.32. IR (KBr): $\tilde{\nu}$ = 3051 $cm^{-1}$ (m), 2882 (m), 1481 (m), 1435 (vs), 1136 (vs), 927 (s), 834 (s), 743 (vs), 690 (vs), 582 (s, P=S, str.), 518 (s), 275 (m, Pt–Cl). LC-MS: exact mass calcd. for $C_{28}H_{29}ClP_2PtS$: 689.08 amu; APCI; found 724.7 $[M + Cl]^-$. $^1H$ NMR (400 MHz, $CDCl_3$, 298 K): $\delta$ = 0.79 [dd, $^3J_{H,P}$ = 3.2, $^4J_{H,PS}$ = 1.2, $^3J_{Pt,H}$ = 74 Hz, 3 H, $CH_3$], 1.76–1.97 (m, 2 H, $CH_2$), 2.91–3.00 (m, 2 H, $CH_2$), 3.04–3.14 (m, $CH_2$), 7.35–7.50 (m, 6 H, $H_{arom.}$), 7.50–8.09 (m, 14 H, $H_{arom.}$) ppm. $^{13}C\{^1H\}$ NMR (101 MHz, $CDCl_3$, 298 K): $\delta$ = –3.4 (d, $^2J_{P,C}$ = 6, $^1J_{Pt,C}$ = 640 Hz, $CH_3$), 18.3 (s, $CH_2$) 24.6 (d, $J_{P,C}$ = 40 Hz, *C*$H_2$P), 28.9 (m, *C*$H_2$PS), 128.1–133.3 ($C_{arom.}$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 298 K): $\delta$ = 4.3 (s, $^1J_{P,Pt}$ = 4565 Hz, $PPh_2$), 37.3 (s, $^2J_{Pt,PS}$ = 49 Hz, $Ph_2PS$) ppm. $^{195}Pt\{^1H\}$NMR (86 MHz, $CDCl_3$, 298 K): $\delta$ = –4337.5 ppm (dd, $^1J_{Pt,P}$ = 4565, $^2J_{Pt,PS}$ = 49 Hz) ppm.

**Synthesis of [*trans*-(κ*P*-dpppS)₂Pt(CH₃)Cl] (6):** A solution of two equivalents of dpppS (139 mg, 0.312 mmol) in $CH_2Cl_2$ (10 mL) was added dropwise over about 2 h to a solution of [(cod)Pt($CH_3$)Cl] (55.43 mg, 0.156 mmol) in $CH_2Cl_2$ (10 mL) and the mixture stirred vigorously at room temperature overnight. The solvent was then evaporated to about one fifth of the volume and addition of diethyl ether caused the precipitation of a white powder. Filtration followed by washing with diethyl ether (3 × 5 mL) and drying under vacuo afforded **6** in high yield (159 mg, 90%). M.p. 508 K (dec.). $C_{55}H_{55}ClP_4PtS_2$ (1134.6): calcd. C 58.22, H 4.89, S 5.65; found C 58.37, H 4.92, S 5.61. IR (KBr): $\tilde{\nu}$ = 3052 $cm^{-1}$ (m), 2935 (m), 1480 (m), 1435 (vs), 1102 (vs), 953 (s), 803 (m), 749 (s), 691 (vs), 610 (s, free P=S), 493 (s), 276 (m, Pt–Cl). LC-MS: exact mass calcd. for $C_{55}H_{55}ClP_4PtS_2$: 1133.20 amu; APCI; found 1097.2 $[M - Cl]^+$. $^1H$ NMR (400 MHz, $CDCl_3$, 298 K): $\delta$ = –0.10 (t, $^3J_{H,P}$ = 4, $^2J_{H,Pt}$ = 73 Hz, 3 H, $CH_3$), 2.03–2.17 (m, 4 H, $CH_2$), 2.68–2.84 (m, 8 H, $2CH_2$), $\delta$ = 7.29–7.85 (m, 40 H, $H_{arom}$) ppm. $^{13}C\{^1H\}$ NMR

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(101 MHz, $CDCl_3$, 298 K): $\delta$ = –12.8 (t, $^2J_{C,P}$ = 6, $^1J_{C,Pt}$ = 659 Hz, $CH_3$), 18.2 (s, $CH_2$), 26.7 (m *C*$H_2$–P), 33.5 (m, *C*$H_2$P*S*), 128.2–133.7 ($C_{arom}$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 298 K): $\delta$ = 41.9 (s, $Ph_2PS$), 21.5 (s, $^1J_{P,Pt}$ = 3050 Hz, $Ph_2P$) ppm. $^{195}Pt\{^1H\}$ NMR (86 MHz, $CDCl_3$, 298 K): $\delta$ = –4578.4 ppm (t, $^1J_{Pt,P}$ = 3059 Hz) ppm.

**Hydroformylation Experiments:** In a typical experiment using preformed catalysts, a solution of the platinum complex (0.058 mmol), 1-octene (5.8 mmol) and $SnCl_2{\cdot}2H_2O$ (0.29 mmol) in 5.8 mL of methyl isobutyl ketone was transferred under nitrogen into a 50-mL stainless steel autoclave. The reaction vessel was pressurised to 50 bar total pressure ($CO/H_2$ = 1:1) and the magnetically stirred mixture was heated to 353 K in a thermostated apparatus. The reaction was monitored by following the drop in pressure.

For the "in situ" procedure, the ligand, dissolved when possible in about 1.5 mL of methyl isobutyl ketone, was added to a solution of the platinum precursor in about 1.5 mL of methyl isobutyl ketone and the mixture was kept under vigorous stirring for 30 min. After this time $SnCl_2{\cdot}2H_2O$, 1-octene and methyl isobutyl ketone (up to 5.8 mL of solvent) were added to the solution. The pressure was monitored throughout the reaction. After cooling and venting of the gas, the pale-yellow solution was immediately analysed by GLC. Conversion of 1-octene and yield of aldehydes were calculated using dodecane as internal standard.

**HP-NMR Experiments:** In a typical experiment, a solution of 0.058 mmol of the desired Pt complex, together with the specified amounts of $SnCl_2$ and 1-octene (Table 2) in $[D_6]$acetone (6 mL) were injected into the HP-NMR bubble column reactor against a counter stream of $N_2$, CO or syngas, as appropriate. The reactor was sealed, pressurised, and heated to the desired temperature (Table 2), upon which the $^{31}P\{^1H\}$ NMR spectrum of the sample was recorded.

## Acknowledgments

We thank Dr. G. Ciccarella for LC/MS measurements. The Italian MURST (PRIN 2004 project, prot. 2004030719) and COSTD30 (fellowship for STSM to A. L.) are gratefully acknowledged for financial support.

# Luminescence Modulation of a Terbium Complex with Anions and Its Application as a Reagent

Dengqing Zhang,[a] Mei Shi,[a] Zhiqiang Liu,[a] Fuyou Li,*[a] Tao Yi,[a] and Chunhui Huang*[a]

**Keywords:** Luminescence modulations / Fluoride anions / Terbium complexes

A terbium complex $Tb(PMIP)_3(PhCN)$, namely tris(1-phenyl-3-methyl-4-isobutyl-5-pyrazolone)-terbium-(pyrazino[2,3-*f*][1,10]phenanthroline-2,3-dicarbonitrile), was synthesized as a reagent for anions. Compared with $Tb(PMIP)_3(H_2O)_2$, the fluorescent quantum yield of $Tb(PMIP)_3(PhCN)$ was reduced because the triplet energy level of PhCN (20920 $cm^{-1}$) is a little higher than that of $^5D_4$ of $Tb^{3+}$ (20400 $cm^{-1}$) and lower than that of PMIP (23000 $cm^{-1}$). This resulted in a back-energy transfer from $Tb^{3+}$ to PhCN. Interestingly, the photoluminescent properties of $Tb(PMIP)_3(PhCN)$ drastically depend on the nature of the anions added into the solution. When apropos equivalents of fluoride (or acetate) anions were added into the $CH_3CN$ solution of $Tb(PMIP)_3(PhCN)$, the replacement of PhCN with fluoride (or acetate) anions took place and the above back-energy transfer was prohibited, which resulted in a fluorescence enhancement of the terbium complex. After excessive equivalents of fluoride (or acetate) anions were added, the replacement of PMIP with fluoride (or acetate) anions prohibited the ligand PMIP sensitized energy transfer of the terbium complex, resulting in the fluorescence quenching of the system. However, in the aqueous solution, the terbium complex shows a remarkable selectivity of fluoride anions over the other anions. As a reagent, its sensitivity is about $10^{-8}$ mol·$L^{-1}$ for the fluoride anions.

## Introduction

Anion recognition and sensing are of current interest because of their importance in biological, environmental, and chemical systems.[1–4] The construction of anion chemosensors is essentially composed of two units, the binding site and the signaling subunit, which may be covalently linked (binding site-signaling submit approach)[5–8] or not (displacement approach).[9] The interaction with the anion and the change in color or fluorescence are in principle reversible. However, development of fluorescent reagents has emerged as a research area of significant importance.[1,10,11] In these systems, anion signaling using fluorescence or color changes can also be observed using irreversible reactions.[12] The underlying idea of these irreversible systems is to take advantage of the selective reactivity that certain anions may display. Hence, the use of an anion-induced reagent system usually has high selectivity and also an accumulative effect is directly related with the anion concentration. Fluoride, the smallest anion, has unique biological and chemical properties, and its recognition and detection are of growing interest because it is associated with dental care[13] and the treatment of osteoporosis.[14] As a result, there is a need to develop new sensitive methods for fluoride detection. Most of the emerging detection methods have focused on the specific Lewis acid-base interaction, such as the strong affinity of a boron atom towards the fluoride anion,[15–19] or the designed hydrogen bonding with the fluoride anion.[20,21] These binding events have been converted into an electrochemical[22] or fluorescent change,[23–26] or more directly, colorimetric change seen by the naked eye.[27,28] However, the reported fluorescent reagents for fluoride anions is quite limited.[29–31]

In the past decade, the synthesis, characterization, and application of luminescent lanthanide complexes have been the focus of much attention.[32–35] On the basis of the unique photophysical properties of lanthanide cations (long luminescence lifetime and very sharp emission band),[36,37] lanthanide complexes as luminescent materials were paid particular attention in the immunoassay[38] and organic light-emitting diode (OLED).[39–42] Recently, some luminescent lanthanide complexes have been used as a chemosensor for anions.[43–50] For example, Ziessel et al. reported that several lanthanide complexes were engineered from a ligand consisting of a single P=O fragment and two methylene linked bipyridine subunits for nitrate anion detection.[49,50] It is well known that fluoride anions bind tightly with lanthanide ions, and some work has reported on the influence of fluoride anions on the luminescence property of crown-based lanthanide complexes by exchanging coordinated water with fluoride anions.[51,52] In this paper, a new terbium complex $Tb(PMIP)_3(PhCN)$ (see Scheme 1) was designed and synthesized as a reagent for detecting anions by another mechanism. Here, PMIP and PhCN stand for

the anion of 4-isobutyl-3-methyl-1-phenyl-5-pyrazolone and pyrazino[2,3-*f*][1,10]phenanthroline-2,3-dicarbonitrile, respectively. The photophysical studies of $Tb(PMIP)_3(PhCN)$ showed that the luminescent properties of this complex could be modulated upon addition of the different anions.

## Results and Discussion

### Structure Characterization of $Gd(PMIP)_3(H_2O)_2$·$Gd(PMIP)_3(C_2H_5OH)(H_2O)$ (A)

The structure of the gadolinium complex **A** was characterized by X-ray crystallography. An ORTEP diagram for the asymmetric unit is shown in Figure 1. Details of the crystal data and data collection parameters for **A** are given in Table 1. It can be seen form Figure 1 that a common repeating unit exists for the two molecules of $Gd(PMIP)_3(H_2O)_2$ and $Gd(PMIP)_3(C_2H_5OH)(H_2O)$. In $Gd(PMIP)_3(H_2O)_2$, the geometry around the central ions can be described as a distorted bicapped-trigonal prism where the trigonal prism is composed of six oxygen atoms (O9, O10, O12, O13, O15, O16). Among them, O9 and O10 are from one β-diketone, O12 and O13 are from the other two β-diketones, and O15 and O16 are from two water molecules. Another two oxygen atoms (O11, O14) cap the two quadrilateral faces O9–O10–O12–O16 and O9–O15–O13–O16, respectively. The average Gd–O distance is 2.42 Å [2.31(2)–2.53(3)], which is a little smaller than the sum of the radii of $Gd^{3+}$ (1.05 Å, eight coordinated) and $O^{2-}$ (1.42 Å). Furthermore, the structure of $Gd(PMIP)_3(C_2H_5OH)(H_2O)$ is the same as that of $Gd(PMIP)_3(H_2O)_2$ except for an ethanol molecule occurring in place of the water molecule, the coordination geometry is that of distorted a bicapped-trigo-

nal prism, as illustrated in Figure 1. Moreover, an independent $C_2H_5OH$ solvent molecule exists in the unit cell.

### UV/Vis Spectra

UV/Vis absorption spectra of the ligands (PMIP and PhCN) and $Tb(PMIP)_3(PhCN)$ in $CH_3CN$ solution are shown in Figure 2. The maximum absorption band of PMIP at 263 nm is attributed to a singlet-singlet π-π* enol absorption of the β-diketonate. The ligand PhCN has two absorption bands at 264 and 306 nm, which are attributed to n-π* and singlet-singlet π-π* absorption, respectively. Compared with the spectrum of PMIP, the absorption maximum of $Tb(PMIP)_3(PhCN)$ is red-shifted by 5 nm, which is agreement with the enlargement of the conjugated structure of ligands after coordinating to the terbium ion. It can be seen from Figure 2 that the spectral shape of $Tb(PMIP)_3(PhCN)$ in $CH_3CN$ is similar to that of PMIP, indicating that the coordination of the terbium ion does not significantly influence the singlet-state energy of PMIP. The molar absorption coefficients ($\varepsilon$) of PMIP, PhCN, and $Tb(PMIP)_3(PhCN)$ are calculated as $2.55\times10^4$, $6.11\times10^4$, and $9.61\times10^4$ $L\cdot mol^{-1}\cdot cm^{-1}$, respectively, revealing that the two ligands and the terbium complex have a strong ability to absorb light.

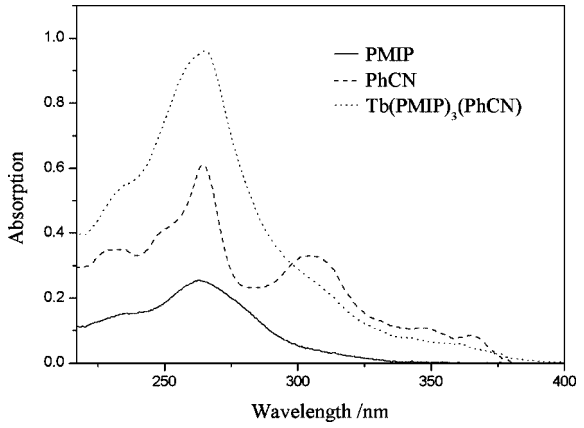

Figure 2. UV/Vis spectra of PMIP, PhCN, and $Tb(PMIP)_3(PhCN)$ in $CH_3CN$ ($1.0\times10^{-5}$ $mol\cdot L^{-1}$).

### Fluorescence Characteristics

The fluorescence spectrum of $Tb(PMIP)_3(PhCN)$ in $CH_3CN$ solution (see Figure 3) shows characteristic emission bands of $Tb^{3+}$ ($\lambda_{ex}$ = 280 nm) centered at 489, 544, 584, and 612 nm resulting from the deactivation of the $^5D_4$ excited state to the corresponding ground state $^7F_J$ ($J$ = 6, 5, 4, 3) of the $Tb^{3+}$ ion. The strongest emission is centered around 544 nm and corresponds to the hypersensitive transition of $^5D_4\rightarrow{}^7F_5$. The excitation spectrum of $Tb(PMIP)_3$-(PhCN) overlays the absorption wavelength range of PMIP well, indicating that the emission of $Tb(PMIP)_3(PhCN)$ originates mainly from the energy absorbed by PMIP. We also investigated the emission spectrum of $Tb(PMIP)_3$-(PhCN) in the different solvents, such as $CHCl_3$, DMF, and DMSO, the similarity of the emission patterns in these solvents suggests that there are no solvent-dependent structural changes.

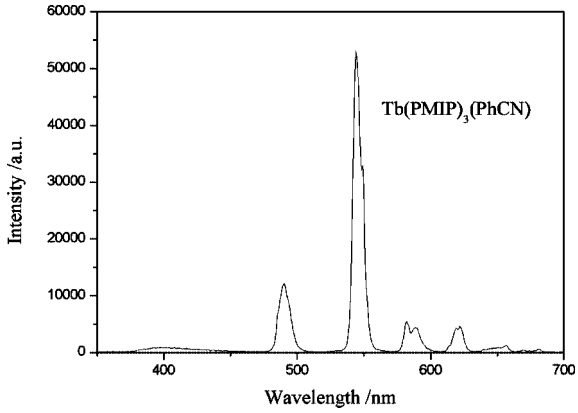

Figure 3. The luminescence spectrum of $Tb(PMIP)_3(PhCN)$ at 298 K in $CH_3CN$.

### Phosphorescence Spectra

Since the first excited energy level of the $Gd^{3+}$ ion ($^6P_{7/2}$) is high, the energy absorbed by the ligand in the $Gd^{3+}$ complex usually cannot be transferred to the $Gd^{3+}$ ion. Therefore the phosphorescence emission from the $Gd^{3+}$ complex can be considered as ligand-localized phosphorescence emission, and then the energy level of $^3$π-π* of the ligand can be deduced. At room temperature, the phosphorescent emission spectrum of the $Gd^{3+}$ complex is very weak, however at a lower temperature (77 K), the ligand-localized phosphorescent spectrum can be observed. Herein, the gadolinium complexes $Gd(NO_3)_3(PhCN)$ and **A** were synthesized for triplet-energy level measurements. The phosphorescent spectra of **A** and $Gd(NO_3)_3(PhCN)$ at 77 K are shown in Figure 4. The emission bands of **A** and $Gd(NO_3)_3(PhCN)$ peak at 464 nm (21552 $cm^{-1}$) and 502 nm (19920 $cm^{-1}$), respectively. By referring to the lower wavelength emission edges of the corresponding phosphorescent

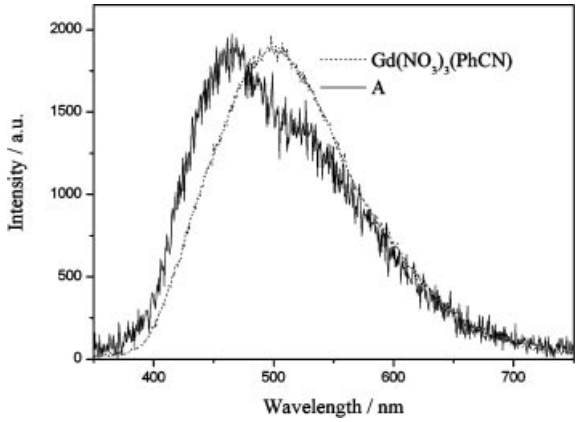

Figure 4. Phosphorescent spectra of **A** and $Gd(NO_3)_3(PhCN)$ at 77 K.

spectra, the energies of zero-phonon transition of the triplet states ($^3\pi\pi^*$) at about 435 nm (23000 $cm^{-1}$) and 478 nm (20920 $cm^{-1}$) were obtained for PMIP and PhCN, respectively.

### Photophysical Properties of the Terbium Complexes

By using Rhodamine 6G in ethanol ($1\times10^{-6}$ mol·$L^{-1}$, $\varphi_{ref}$ = 0.92) as a reference, the overall luminescence quantum yields ($\varphi_{overall}$) of $Tb(PMIP)_3(PhCN)$ and $Tb(PMIP)_3(H_2O)_2$ in $CH_3CN$ were measured to be 0.15% and 2.97% according to the well-known method.[53] The luminescence lifetimes ($\tau$) were also investigated for $Tb(PMIP)_3(PhCN)$ and $Tb(PMIP)_3(H_2O)_2$ in $CH_3CN$. The measured luminescent decay can be described by monoexponential kinetics, and the luminescence lifetimes of $Tb(PMIP)_3(PhCN)$ and $Tb(PMIP)_3(H_2O)_2$ are 95.5 and 341.1 μs, respectively.

In order to understand the influence of the ligand modification on the photophysical property of $Tb(PMIP)_3(PhCN)$, the efficiency of energy transfer ($\varphi_{transfer}$) from the ligand to $Tb^{3+}$ and the probability of the terbium emission ($\varphi_{Ln}$) were investigated for $Tb(PMIP)_3(PhCN)$ and $Tb(PMIP)_3(H_2O)_2$ on the basis of the method developed by Selvin et al.[54] The overall quantum yield ($\varphi_{overall}$) can be defined as Equation (1).

$$\varphi_{overall} = \varphi_{transfer}\varphi_{Ln} \quad (1)$$

When a lanthanide complex is mixed with an acceptor of known quantum yield and very short fluorescence lifetime (ns), the efficiency of energy transfer between them ($\varphi_{ET}$) and the probability of lanthanide emission ($\varphi_{Ln}$) are calculated from both the fluorescence decay lifetime and intensity measurements, see Equation(2) and (3).

$$\varphi_{ET} = 1 - (\tau_{da}/\tau_d) \quad (2)$$

$$\varphi_{Ln} = \varphi_a(I_{da}/I_{ad})/(1/\varphi_{ET} - 1) = \varphi_a I_{da}(\tau_d - \tau_{ad})/(I_{ad}\tau_{ad}) \quad (3)$$

Here $\tau_{ad}$ and $\tau_d$ are the excited state lifetime of the lanthanide complex in the presence and absence of the acceptor, respectively; $\varphi_a$ is the fluorescence quantum yield of the acceptor; $I_{da}$ is the integral area under the residual lanthanide emission in the presence of the acceptor; and $I_{ad}$ is the integral area of the fluorescent emission part of the acceptor.

Here, Rhodamine 6G was used as the acceptor in ethanol ($\varphi_a$ = 0.92 and $\tau < 10$ ns). For example, in a mixture solution consisting of $Tb(PMIP)_3(PhCN)$ (10 μM) and Rhodamine 6G (1.25 μM), the emission lifetime of the $Tb^{III}$ complex ($\lambda_{em}$ = 544 nm) decreased from 95.5 to 80.0 μs, indicating that 16.2% of the energy was transferred from $Tb(PMIP)_3(PhCN)$ to Rhodamine 6G. From these measurements and Equation (3), the probability of $Tb^{3+}$ emission ($\varphi_{Ln}$) in $Tb(PMIP)_3(PhCN)$ was determined to be 1.1% (Table 2). In combination with the overall quantum yield ($\varphi_{overall}$) of $Tb(PMIP)_3(PhCN)$, the efficiency of energy transfer ($\varphi_{transfer}$) from the ligand to $Tb^{3+}$ was calculated to be 14.2% (see Table 2) according to Equation (1). Similarly, the efficiency of energy transfer ($\varphi_{transfer}$) of 56.3% and the probability of $Tb^{3+}$ emission ($\varphi_{Ln}$) of 5.3% were obtained for $Tb(PMIP)_3(H_2O)_2$.

With $\varphi_{Ln}$ and $\tau_d$ determined in acetonitrile, radiative and nonradiative decay rates of the $Tb^{III}$ complex were calculated from Equation (4).

$$k_{rad} = \varphi_{Ln}/\tau_d k_{nr} = (1 - \varphi_{Ln})/\tau_d \quad (4)$$

Taking 1.1% of $\varphi_{Ln}$ and 95.5 μs of $\tau_d$ into account, the radiative and norradiative decay rates of $Tb(PMIP)_3(PhCN)$ were calculated as 111 and $1.04\times10^4$ $s^{-1}$, respectively (see Table 2). Similarly, the radiative and nonradiative decay rates of $Tb(PMIP)_3(H_2O)_2$ were determined as 151 and $2.71\times10^3$ $s^{-1}$ (see Table 2), respectively.

To elucidate the energy transfer process of the terbium complex, the energy levels of the relevant electronic states should be estimated. By referring to their wavelengths at the UV/Vis absorbance edges, the singlet-energy levels of PMIP and PhCN were estimated to be 32260 $cm^{-1}$ (310 nm) and 29410 $cm^{-1}$ (340 nm), respectively. In combination with the triplet-energy levels of PMIP and PhCN, the schematic energy level diagram and the energy transfer process are shown in Figure 5.

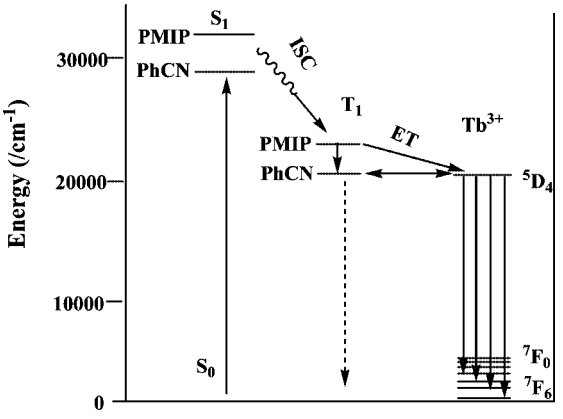

Figure 5. Schematic energy level diagram and the energy transfer process in the system of $Tb(PMIP)_3(PhCN)$. $S_1$: the first excited singlet state, $T_1$: the first excited triplet state.

Generally, the sensitization pathway in luminescent terbium complexes consists of the excitation of the ligands from the ground state to their excited singlet states, and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

subsequently through the intersystem crossing of the ligands to their triplet states, following the energy transfer from the triplet state of the ligand to the central ion. In this process the 4f electrons of the $Tb^{3+}$ ion are excited to the $^5D_J$ manifold ion from the ground state, finally the $Tb^{3+}$ ion emits when the 4f electrons undergo a transition from the excited state of $^5D_4$ to the ground state.[55,56] We noticed that the energy gaps $\Delta E$ ($^1\pi\pi^*$-$^3\pi\pi^*$) between the $^1\pi\pi^*$ and $^3\pi\pi^*$ levels are 9260 and 8490 $cm^{-1}$ for PMIP and PhCN, respectively (see Figure 5). According to Reinhoudt's empirical rule that the intersystem crossing process will be effective when $\Delta E$ ($^1\pi\pi^*$-$^3\pi\pi^*$) is at least 5000 $cm^{-1}$,[57] the intersystem crossing processes are effective for PMIP and PhCN. On the other hand, the triplet-energy level of PMIP ($\approx$23000 $cm^{-1}$) is higher than that of $^5D_4$ (20400 $cm^{-1}$) for $Tb^{3+}$, and their energy gap $\Delta E$ ($^3\pi\pi^*$-$^5D_4$) between the ligand- and metal-centered level is 2600 $cm^{-1}$. According to Latva's empirical rule,[58] an optimal ligand-to-metal transfer process for $Tb^{III}$ is when $\Delta E$ ($^3\pi\pi^*$-$^5D_0$) $> 2000$ $cm^{-1}$. It can be concluded that the transfer process is also effective from PMIP to $Tb^{3+}$ and that PMIP is suitable as a sensitizer for $Tb^{III}$. On the contrary, the $^3\pi\pi^*$ state (ca. 20920 $cm^{-1}$) of PhCN is so close to $^5D_4$ (20400 $cm^{-1}$) of $Tb^{3+}$, giving $\Delta E$ ($^3\pi\pi^*$-$^5D_0$) = 520 $cm^{-1}$, which is too low to prevent the back-energy transfer from the $Tb^{3+}$ excited state to the triplet state of PhCN. Moreover, the triplet energy level of PhCN is lower than that of PMIP, and the energy transfer from PMIP to PhCN may occur. Therefore, it is not difficult to understand the fact that $Tb(PMIP)_3(PhCN)$ exhibits a lower fluorescence quantum yield ($\varphi_{overall}$) (0.15%) compared to that (2.97%) of $Tb(PMIP)_3(H_2O)$.

### Fluorescence Modulation of the Complex with Anions

The fluorescence modulation of $Tb(PMIP)_3(PhCN)$ with anions was investigated by the fluorescence titration experiments in $CH_3CN$. Figure 6 shows the titration curves of the spectral parameters of $Tb(PMIP)_3(PhCN)$ against the [anion]/[$Tb(PMIP)_3(PhCN)$] ratio in acetonitrile. Interestingly, a different fluorescent modulation of $Tb(PMIP)_3$-(PhCN) was observed upon addition of the different anions. For example, a slight variation of the luminescent properties of $Tb(PMIP)_3(PhCN)$ was observed upon addition of other anions such as $ClO_4^-$, $NO_3^-$, or $NO_2^-$. When one equivalent of $Cl^-$, $Br^-$, or $I^-$ was added, the fluorescent intensity of $Tb(PMIP)_3(PhCN)$ reached the maximum (see Figure 6), and then it was almost unchanged with further addition of $Cl^-$, $Br^-$, or $I^-$. Similarly, Mahajan et al. reported that the luminescence intensity of tris(β-diketonate) europium ($\lambda_{em}$ = 611 nm) was enhanced twofold when three equivalents of $Cl^-$ were added.[47] Generally, the coordination number of the $Tb^{III}$ complexes in solution is nine.[59] The coordination number of $Tb^{3+}$ in $Tb(PMIP)_3(PhCN)$ is eight, implying that the complex can bond one anion to form a coordination of nine, hence, the increasing fluorescent emission was observed upon addition of one equivalent of the anions. Because of their weak bonding ability to the terbium ion, $Cl^-$, $Br^-$, and $I^-$ had difficultly in displacing the ligands PhCN and PMIP, which was confirmed by the fact that there was no obvious change in the luminescent emission of $Tb(PMIP)_3(PhCN)$ with further addition of $Cl^-$, $Br^-$, or $I^-$ (see Figure 6).

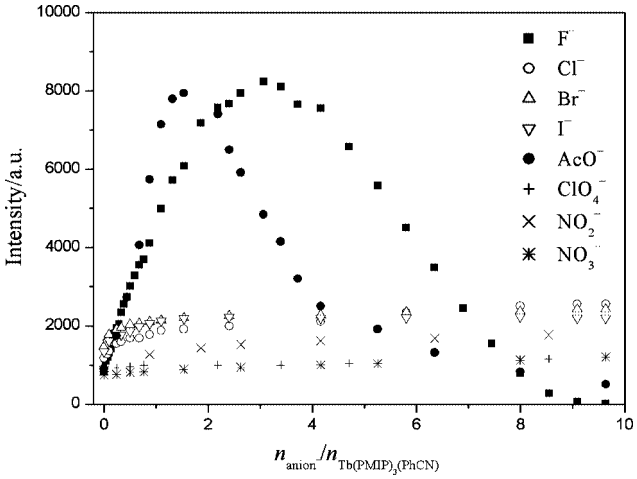

Figure 6. Fluorescent titrations of $Tb(PMIP)_3(PhCN)$ ($1.0\times10^{-5}$ mol·$L^{-1}$) in $CH_3CN$ upon addition of $F^-$, $Cl^-$, $Br^-$, $I^-$, $ClO_4^-$, $NO_3^-$, $NO_2^-$, and $AcO^-$.

It is well known that the lanthanide complex receptor prefers smaller (harder) $F^-$ (or $AcO^-$) to larger (softer) $Cl^-$, $Br^-$, or $I^-$. In fact, a special fluorescent modulation of $Tb(PMIP)_3(PhCN)$ was observed upon addition of fluoride and acetate anions. For example, Figure 7 shows fluorescent spectral changes of $Tb(PMIP)_3(PhCN)$ in $CH_3CN$ solution (10 μM) upon addition of tetra-*n*-butylammonium fluoride ($Bu_4NF$). Upon addition of the fluoride anion, the characteristic terbium emission ($\lambda_{ex}$ = 280 nm) greatly increased along with an increase of the emission intensity of PhCN centred at 400 nm (see Figure 7, a). When $Bu_4NF$ reached about three equivalents of $Tb(PMIP)_3(PhCN)$ (see Figure 7, a), this change became saturated with a fluorescent quantum yield of 1.05%. Under these conditions, the efficiency of energy transfer ($\varphi_{transfer}$) and the probability of $Tb^{3+}$ emission ($\varphi_{Ln}$) for this mixture were measured to be 28.4% and 3.7%, respectively (see Table 2). It can be seen from Table 2 that the mixture exhibited a higher energy transfer efficiency ($\varphi_{transfer}$) and larger probability of $Tb^{3+}$ emission compared with $Tb(PMIP)_3(PhCN)$. Because of its strong bonding ability, the fluoride anions were able to substitute one solvent molecule and one PhCN molecule that were weakly coordinated to $Tb^{III}$ in the complex, and so $Tb^{III}$ reached a coordination number of nine, revealing that the back-energy transfer from $^5D_4$ of $Tb^{3+}$ and the triplet state of PMIP to the triplet state of PhCN was restrained (see Figure 5); consequently, both the probability of $Tb^{3+}$ emission ($\varphi_{Ln}$) and the fluorescent quantum yield of the mixture were improved. However, further addition of a large excess of $Bu_4NF$ caused a decrease of the characteristic fluorescent emission of $Tb^{3+}$, and the emission was quenched completely when nine equivalents of $Bu_4NF$ were added (see Figure 7b). These changes can be interpreted as the follow-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing: upon addition of more fluoride anions, PMIP ligands were completely replaced by fluoride anions, resulting in the breakage of the ligand-sensitized energy transfer from PMIP to $Tb^{3+}$, consequently reducing the fluorescent quantum yield of the complex. Compared with the fluoride anion, the acetate anion exhibited a similar modulation behavior for the fluorescent emission of the terbium complex (see Figure 6). From the above results, we can see that the addition of fluoride and acetate anions affects the quantum yield of $Tb^{3+}$ emission and modulates the energy transfer path, which finally results in the modulation of the overall emission quantum yield.

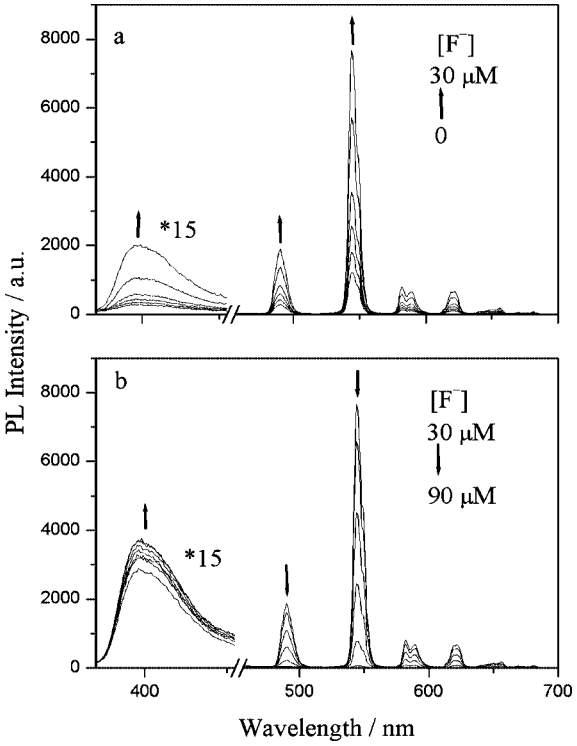

Figure 7. Fluorescent titrations of $Tb(PMIP)_3(PhCN)$ ($1.0\times10^{-5}$ mol·L$^{-1}$) upon addition of $Bu_4NF$.

However, when $Tb(PMIP)_3(PhCN)$ was dissolved in the mixture of $CH_3CN/H_2O$ (9:1 v/v), only a decrease in fluorescent emission of the complex was observed upon addition of fluoride and acetate anions. Under these conditions, the coordinating water molecules can compete with PhCN fragments and gradually remove them from the first coordination sphere of $Tb^{3+}$, then back-energy transfer from the $Tb^{3+}$ excited state to the triplet state of PhCN was broken. In fact, the complex exhibited more intense fluorescent emission ($\varphi$ = 0.62%) in $CH_3CN/H_2O$ (9:1 v/v). When further fluoride anions were added, PMIP was replaced by fluoride anions, resulting in the breakage of the ligand-sensitized energy transfer from PMIP to $Tb^{3+}$ (see Figure 5), and then the fluorescence of $Tb^{3+}$ was quenched. However, fluorescent quenching to different degrees was observed for $Tb(PMIP)_3(PhCN)$ upon addition of the different anions (see Figure 8). Consequently, the complex showed a remarkable selectivity of fluoride anions over the other anions, which may be explained by the small size, the high surface charge density of the fluoride anion and its strong affinity to $Tb^{3+}$.[60] Even in this situation, the solution is very clear and transparent, the observable sensitivity is about $10^{-8}$ mol·L$^{-1}$ of fluoride anions.

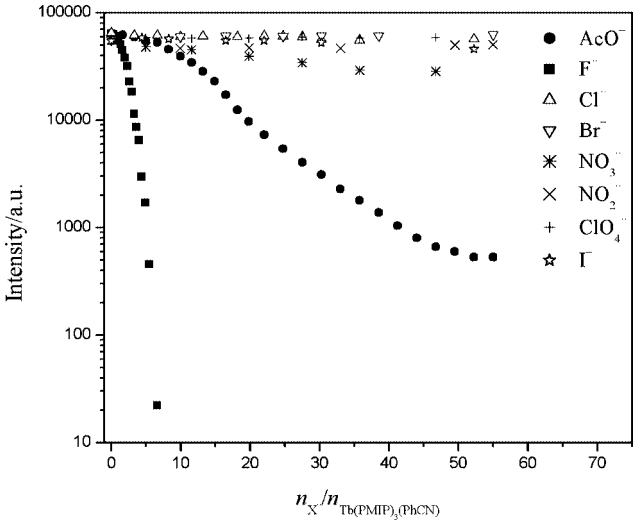

Figure 8. Fluorescent titrations of $Tb(PMIP)_3(PhCN)$ ($1.0\times10^{-5}$ mol·L$^{-1}$) in $CH_3CN/H_2O$ (9:1 v/v) upon addition of $F^-$, $Cl^-$, $Br^-$, $I^-$, $ClO_4^-$, $NO_3^-$, $NO_2^-$, and $AcO^-$.

## Conclusions

In summary, we have designed and synthesized a novel lanthanide-based luminescent reagent $Tb(PMIP)_3(PhCN)$ for anions. By using $Tb^{3+}$ as the fluorophore, $Tb(PMIP)_3$-(PhCN) displays high selective fluorescent modulation on the fluoride and acetate anions in acetonitrile. The large fluorescent enhancement at first and then fluorescence quenching were observed for the terbium complex upon addition of fluoride and acetate anions. However, in aqueous solution, $Tb(PMIP)_3(PhCN)$ shows a unique fluorescent quenching upon addition of fluoride, indicating its remarkable selectivity for fluoride anions over the other anions. At the same time, the reason for the fluorescence modulation with the anions was described. This system is particularly useful relative to other molecules because it allows detection of traces of fluoride and acetate anions by luminescence monitoring at a terbium center.

## Experimental Section

**General:** Diaminomaleonitrile and tetrabutylammonium fluoride trihydrate were obtained from Acros. $TbCl_3\cdot6H_2O$, $Gd(NO_3)_3\cdot6H_2O$, and 1-phenyl-3-methyl-4-isobutyl-5-pyrazolone were purchased from Shanghai Sinopharm Chemical Reagent Co. Ltd., Phenanthroline-5,6-dione was synthesized according to the literature.[61] The complexes $Tb(PMIP)_3(H_2O)_2$ and $Gd(PMIP)_3(H_2O)_2\cdot Gd(PMIP)_3(C_2H_5OH)(H_2O)$ (**A**) were synthesized according to a similar method reported previously[62] and characterized by elemental analyses. Moreover, the structure of the complex **A** was characterized by X-ray crystallography. UV/Visible absorption

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectra were recorded with a UV 2550 spectrophotometer of Shimadzu. The element analyses were performed with Vario EL III O-Element analyzer. $^1$HNMR spectra were recorded with a Mercury Plus 400NB NMR spectrometer. The luminescence and phosphorescence spectra were measured with an Edinburgh LFS920 fluorescence spectrophotometer and LP-920 laser flash photolysis spectrophotometer, respectively. For the phosphorescence measurements, the fourth harmonic 266 nm of the pulsed GCR-4 Nd:YAG Laser (Spectra-Physics, USA) with 30 Hz repetition rate and 6 ns pulse width was used as the excitation source, and the experiments were completed at 77 K in ethanol/methanol (1:1 v/v). Fluorescence lifetimes were recorded with a single photon counting spectrometer from Edinburgh LFS920 fluorescence spectrophotometer with microsecond pulse lamp as the excitation source. The data were analyzed by an iterative convolution of the luminescence decay profile with the instrument response function using a software package provided by Edinburgh Instruments.

**Synthesis of Pyrazino[2,3-*f*][1,10]phenanthroline-2,3-dicarbonitrile (PhCN):** PhCN was synthesized according to a similar method reported previously.[63] 2,3-Diaminomaleonitrile (6.0 mmol) was added to a solution consisting of 1,10-phenanthroline-5,6-dione (1.0 g, 4.8 mmol) and absolute ethanol (30 mL) in a 50 mL flask. The reaction mixture was refluxed for 3 h and then cooled to room temperature. The solution was concentrated to ca. 10 mL with a rotary evaporator and the solid product was filtered. After recrystallization from ethanol twice, the desired pale yellow powder (1.0 g) was obtained with a yield of 74%. $^1$HNMR (400 MHz, $CDCl_3$): $\delta$ = 7.93 (q, 2 H), 9.4–9.46 (d, 2 H), 9.46–9.52 (d, 2 H) ppm. $C_{16}H_6N_6$(282.26): calcd. C 68.08, H 2.14, N 29.77; found C 68.00, H 2.10, N 30.02.

**Synthesis of Tb(PMIP)$_3$(PhCN) and Gd(NO$_3$)$_3$(PhCN):** The complexes Tb(PMIP)$_3$(PhCN) and Gd(NO$_3$)$_3$(PhCN) were synthesized according to a previous literature procedure.[64]

**Tb(PMIP)$_3$(PhCN):** Ethanol (10 mL), 4-isobutyl-3-methyl-1-phenyl-5-pyrazolone (3.0 mmol), and triethylamine (3 mmol) were added to a 25 mL side-arm flask. The mixture was stirred for 10 minutes, and then PhCN and $TbCl_3{\cdot}6H_2O$ (1.0 mmol) were added to the flask. The reaction mixture was refluxed for 3 h whilst stirring, and then cooled to room temperature. The solvent was removed under reduced pressure and the residue was washed with water. The crude product was then recrystallized from an ethanol/water mixture (8:2 v/v) to afford the desired product (1.42 g) with a yield of 80%. $C_{58}H_{51}N_{12}O_6Tb$ (1771.03): calcd. C 59.49, H 4.39, N 14.35; found C 59.30, H 4.41, N 14.19.

**Gd(NO$_3$)$_3$(PhCN):** $Gd(NO_3)_3{\cdot}6H_2O$ (0.25 mmol) was added dropwise whilst stirring to an ethanol solution (10 mL) containing PhCN (0.25 mmol), and then the reaction mixture was refluxed for 4 h. The resulting solution was filtered and a white powder was obtained by recrystallization from an ethanol solution, 117 mg, yield 75%. $C_{16}H_6N_9O_9Gd$ (625.52): calcd. C 30.72, H 0.97, N 20.15; found C 30.65, H 0.91, N 20.10.

**Crystallography:** The crystal of complex **A** was mounted on a glass fiber and transferred to a Bruker SMART CCD area detector. Crystallographic measurements were carried out using a Bruker Apex II CCD diffractometer, $\sigma$ scans, graphite-monochromated Mo-$K_a$ radiation ($\lambda$ = 0.71073 Å) under room temperature. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ values using the program SHELXS-97.[65] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were calculated in ideal geometries. For the full-matrix least-squares refinements [$I > 2\sigma(I)$], the unweighted and weighted agreement factors of $R_1 = \Sigma(F_o - F_c)/\Sigma F_o$ and $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{1/2}$ were used. The crystal data and details of the structure determinations are summarized in Table 1.

CCDC-288368 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Fluorescence Modulation:** Fluorescence modulations were carried out in the following manner: the solution of Tb(PMIP)$_3$(PhCN) in a 1.0 cm quartz cuvette was titrated with the concentrated solutions of tetrabutylammonium salts of different anions (X = $F^-$, $Cl^-$, $Br^-$, $I^-$, $ClO_4^-$, $NO_3^-$, $NO_2^-$, and $AcO^-$) by a micro sample injector. In order to account for the dilution effect, the volume of these concentrated solutions was negligible. The concentration of Tb(PMIP)$_3$(PhCN) in all experiments was $1.0 \times 10^{-5}$ mol·L$^{-1}$.

# Oxidorhenium(V) Complexes of a Family of Bipyridine-Like Ligands Including Pyridyltriazines and Pyrazinyltriazine: Oxygen-Atom Transfer, Metal Redox and Correlations

**Samir Das[a] and Animesh Chakravorty*[a,b]**

**Keywords:** N ligands / Oxido ligands / Nitrogen heterocycles / Reduction potentials / Rhenium

The title ligands (general abbreviation L) are bipyridine (bpy), its dimethyl (mbpy) and diphenyl (pbpy) derivatives, phenanthroline (phen), 5,6-diphenyl-3-(2-pyridyl)-1,2,4-triazine (ppyt) and its dimethyl (mpyt) and pyrazinyl (ppzt) analogues. The concerned oxido complexes are $[ReOCl_3(L)]$, $[ReOBr_3(ppyt)]$ and $[ReOBr_3(ppzt)]$. The chloro and bromo complexes of ppyt and ppzt were prepared by reacting these ligands with $[ReOX_3(AsPh_3)_2]$ (X = Cl, Br). The X-ray structures of $[ReOCl_3(ppyt)]$ and $[ReOCl_3(ppzt)]$ reveal that the $ReCl_3$ fragment is meridionally disposed and that the L ligand is *N*,*N*-coordinated such that the pyridine/pyrazine nitrogen lies *trans* to the oxido oxygen atom. The Re–O lengths [1.656(10)/1.625(9) Å] correspond to approximate triple bonding. The rate of oxygen-atom transfer from $[ReOX_3(L)]$ to triphenylphosphane in solution follows second-order kinetics and is associated with a large and negative entropy of activation (approx. $-30\ cal\,K^{-1}\,mol^{-1}$). The initial attack is believed to involve the phosphane lone pair and Re≡O $\pi^*$-orbitals. Electron withdrawal from the $Re^{V}O$ moiety by varying X or L facilitates oxygen-atom transfer. Thus, the rates follow the orders Br < Cl; mbpy < bpy < phen < pbpy << mpyt < ppyt < ppzt. The reduction potential of the quasireversible $Re^{VI}O/Re^{V}O$ couple displays similar trends and the logarithmic rate constant of oxygen-atom transfer is found to correlate linearly with the reduction potential.

## Introduction

The oxygen-atom transfer ability of the oxidorhenium(V) moiety $Re^{V}O$ has been known for a long time,[1,2] and the nature and scope of the process have attracted significant recent attention.[3–9] In this laboratory we have been concerned[10] with the design and reactivity of $Re^{V}O$ complexes incorporating *N*,*N*-chelation by pyridyl ligands where the second nitrogen site belongs either to an acyclic function, such as an imine[11–13] or azo[13–16] group, or to a heterocyclic moiety. The scope of the latter alternative is potentially wide because of the many interesting variations possible in the form of aza-aromatic ligands.

Although a beginning in this direction was recently made with pyridylazole ligands,[17,18] the logical starting point would be the familiar didentate pyridyl aza-aromatic, viz. bipyridine (bpy). This has prompted us to examine the $Re^{V}O$ chemistry of bpy and certain bpy-like ligands including pyridyltriazine and pyrazinyltriazine. Very little is currently known about rhenium binding by the latter two ligands (vide infra).

The oxygen-atom transfer potency of the family of $Re^{V}O$ complexes is estimated using triphenylphosphane as a model oxophile. The systematics in the rate of oxygen-atom transfer, which spans nearly two orders of magnitude, are scrutinized in terms of electron withdrawal and metal reduction potential.

## Results and Discussion

### The $Re^{V}O$ Family

The ligand family used here consists of **1**–**4**, each member being abbreviated as shown below. The family spans three distinct types of bpy modifications: simple substitution (as in **1**), augmented conjugation (as in **2**) and incorporation of nitrogen hetero atoms (as in **3** and **4**).

The nine oxido complexes (Table 1) of **1**–**4** are of coordination type **5**, abbreviated as $[ReOX_3(L)]$, where X = Cl or Br.

The complexes of **1** and **2** (X = Cl) were conveniently synthesised as yellow solids following a method previously used for bpy.[19] The pink chelates $[ReOCl_3(L)]$ (L = **3** and **4**) were prepared by the 1:1 reaction of $[ReOCl_3(AsPh_3)_2]$ with L in benzene at room temperature. The use of the arsane precursor is crucial for optimum yield. When $[ReOCl_3(PPh_3)_2]$ is employed the initially formed oxido com-

plex reacts with the liberated phosphane (vide infra), which affects the yield and purity of the product.

The use of $[ReOBr_3(AsPh_3)_2]$ in place of the chloro precursor gives the bromo system $[ReOBr_3(L)]$ for L = ppyt and ppzt. Attempted synthesis of the iodo analogue from $[ReOI_3(AsPh_3)_2]$ furnished only unstable products. However, in the presence of $ArNH_2$ in the reaction mixture the imido system $[Re(NAr)I_3(L)]$ could be isolated, which is a possible intermediate in the formation of the $Re^{V}O$ analogue.[20]

Selected spectroscopic data for $[ReOX_3(L)]$ are collected in the Experimental Section. The species uniformly display an Re≡O stretch near 1000 $cm^{-1}$ and two absorption bands in the visible region around 500 and 750 nm, which are of diagnostic value in rate studies (vide infra). The complexes are diamagnetic ($5d^2$) and show well-resolved $^1H$ NMR spectra, which have been assigned.

Of the complexes listed in Table 1, $[ReOCl_3(bpy)]$[19,21] and $[ReOCl_3(phen)]$[22] have been reported before. The analytical[23] and coordination[24,25] chemistry of ppyt complexes has been well-documented, but the only reported rhenium complex is $[Re(CO)_3Cl(ppyt)]$,[26] which has recently been structurally characterised in this laboratory.[20] There is no report of rhenium complexes of mpyt and ppzt, which have otherwise been only sparsely studied as ligands.[25,27]

## Structure

The X-ray structures of $[ReOCl_3(ppyt)]$ (**5e**) and $[ReOCl_3(ppzt)]$ (**5h**) were determined. Molecular views are shown in Figures 1 and 2, respectively, and selected bond parameters are listed in Table 2. In the distorted octahedral $ReOCl_3N_2$ coordination sphere the chloride ligands are meridionally disposed. In both molecules the coordinated nitrogen of the triazine ring is N2 and not N4, as also observed in copper[24b] and ruthenium[27] chelates of ppyt/ppzt. The coordinated pyridine nitrogen in **5e** and pyrazine nitrogen in **5h** lie *trans* to the oxido ligand. In both cases the chloride ligands and the triazine N2 atom define a good equatorial plane (mean deviation: 0.03 Å) from which the Re atom is displaced by 0.32 (**5e**) and 0.37 Å (**5h**) towards the oxygen atom. The chelate ring in both cases is satisfactorily planar (mean deviation of about 0.06 Å). The two heterocyclic rings deviate significantly from coplanarity, the dihedral angles being 6.9° (**5e**) and 13.3° (**5h**).

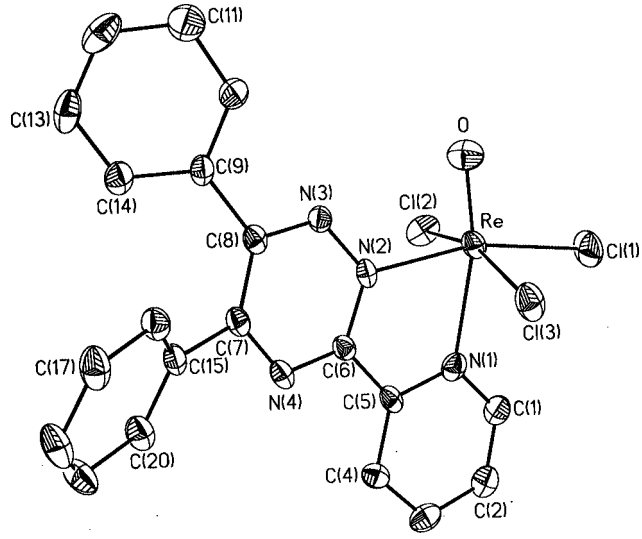

Figure 1. Molecular view and atom labelling scheme for $[ReOCl_3(ppyt)]$ (**5e**). All non-hydrogen atoms are represented by 30% thermal probability ellipsoids. Hydrogen atoms have been omitted for clarity.

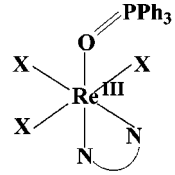
Table 2. Selected bond length [Å] and angles [°] for **5e** and **5h**.

| | **5e** | **5h** |
|---|---|---|
| Re–O | 1.656(10) | 1.625(9) |
| Re–N(1) | 2.262(11) | 2.296(8) |
| Re–N(2) | 2.104(9) | 2.124(7) |
| Re–Cl(1) | 2.313(4) | 2.318(3) |
| Re–Cl(2) | 2.332(3) | 2.345(3) |
| Re–Cl(3) | 2.363(3) | 2.363(3) |
| N(2)–N(3) | 1.327(13) | 1.330(10) |
| O–Re–N(2) | 90.5(4) | 90.9(3) |
| N(2)–Re–N(1) | 73.1(4) | 71.9(3) |
| N(2)–Re–Cl(1) | 164.4(3) | 162.1(2) |
| O–Re–Cl(2) | 99.3(4) | 100.3(3) |
| O–Re–Cl(3) | 97.8(4) | 99.5(3) |
| N(2)–Re–Cl(3) | 85.8(3) | 87.4(2) |
| Cl(1)–Re–Cl(3) | 88.77(14) | 87.53(13) |
| O–Re–N(1) | 163.5(4) | 162.9(3) |
| O–Re–Cl(1) | 104.8(4) | 106.8(3) |
| N(1)–Re–Cl(1) | 91.6(3) | 90.3(2) |
| N(2)–Re–Cl(2) | 91.4(3) | 92.1(2) |
| N(1)–Re–Cl(3) | 80.2(3) | 79.9(2) |
| Cl(2)–Re–Cl(3) | 162.76(14) | 160.17(11) |

The Re–O length, which corresponds to approximate triple bonding,[28] is somewhat longer in **5e** [1.656(10) Å] than in **5h** [1.625(9) Å]. The Re–N1 bond lying *trans* to Re≡O is longer than the Re–N2 bond by around 0.17 Å. Significantly, the shorter Re–O bond in **5h** is associated with a longer Re–N1 bond. The structure of the bpy complex of type **5**, viz. [ReOBr$_3$(bpy)], is known.[29] Here, the Re–O distance is significantly longer [1.689(8) Å] than those in **5e** and **5h**.

### Oxygen-Atom Transfer

The [ReOX$_3$(L)] (X = Cl, Br) complexes are uniformly reactive towards triphenylphosphane in solution, furnishing a violet solution from which paramagnetic phosphane oxide complexes of type [Re$^{III}$(OPPh$_3$)X$_3$(L)] have been isolated. Characterisation data for two representative species are set out in the Experimental Section. The observed room-temperature magnetic moments (1.5–1.7 $\mu_B$) are much lower than the idealised spin-only value for the $t_{2g}^4$ configuration due to strong orbital coupling, as is common for trivalent rhenium. As expected, the $^1$H NMR spectra of the complexes are paramagnetically shifted.[14,17,19,30]



**6**

Although no direct structural characterisation was possible due to lack of single crystals, our previous work[11–18,31] on related systems strongly supports the gross geometry of the phosphane oxide complexes to be **6**.

The rate of the reaction of Equation (1) was determined spectrophotometrically in dichloromethane solution.

$$Re^{V}OX_3(L) + PPh_3 \xrightarrow{k} Re^{III}(OPPh_3)X_3(L) \quad (1)$$

Selected rate data are listed in Tables 1 and 3. A representative time-evolution spectrum characterised by isosbestic points is shown in Figure 3. Under pseudo-first-order con-

[a] Initial concentrations of [ReOCl$_3$(ppyt)] and [ReOCl$_3$(ppzt)] are $5.43 \times 10^{-5}$ M and $4.65 \times 10^{-5}$ M, respectively. [b] Least-squares deviations are given in parentheses.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ditions (excess $PPh_3$), the rate is proportional to the concentration of the oxido complex, and the observed rate constant, $k_{obs}$, is proportional to the concentration of $PPh_3$. The reaction is thus second order in nature, see Equation (2).

$$\text{rate} = k_{obs}[ReOX_3(L)] = k[ReOX_3(L)][PPh_3] \quad (2)$$

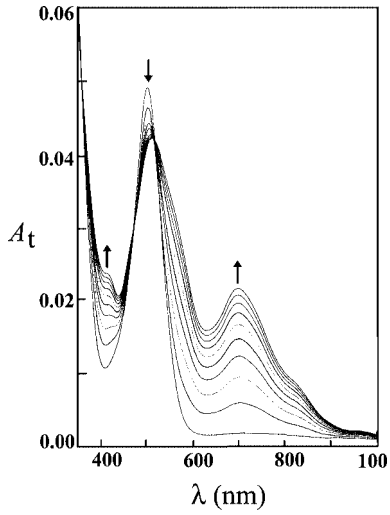

Figure 3. Time evolution spectra for the reaction of $[ReOCl_3(ppyt)]$ and $PPh_3$ in dichloromethane solution at 303 K ($A_t$ is absorbance).

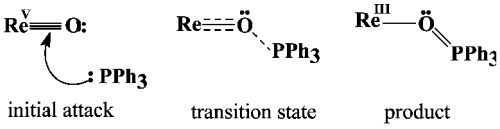
Rates for all the complexes were determined at 303 K (Table 1), although in the cases of $[ReOCl_3(ppyt)]$ (**5e**) and $[ReOCl_3(ppzt)]$ (**5h**) variable-temperature studies were also made (Table 3). In both cases the rate constant, $k$, was found to obey the Eyring equation. The activation parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are as follows: 11.66(0.26) kcal mol$^{-1}$ and –27.48(0.88) cal K$^{-1}$ mol$^{-1}$ for **5e** and 9.94(0.28) kcal mol$^{-1}$ and –31.95(0.95) cal K$^{-1}$ mol$^{-1}$ for **5h**. The large and negative entropy of activation implies close association of $[ReOX_3(L)]$ and $PPh_3$ in the transition state, as in the model **7**,[10,17] where initial attack involves the phosphane lone pair and Re≡O π*-orbitals.



**7**

### Electron Withdrawal, Rate and Reduction Potential

The observed trend of reactivity is qualitatively consistent with the reaction model. Electron withdrawal from the $Re^{V}O$ moiety due to variation of X or due to modification of L is expected to favour the initial nucleophilic attack and thereby facilitate oxygen-atom transfer. This is systematically observed. We note that $[ReOCl_3(ppyt/ppzt)]$ is nearly twice as reactive as $[ReOBr_3(ppyt/ppzt)]$, in line with the higher electronegativity of Cl. Again, the rate trend $[ReOCl_3(mbpy)] < [ReOCl_3(bpy)] < [ReOCl_3(pbpy)]$ correctly reflects the electron-withdrawal power of the substituent (Me < H < Ph). The $[ReOCl_3(phen)]$ complex fits between the bpy and pbpy species. An increase in the number of nitrogen hetero atoms is a very effective instrument for achieving electron withdrawal.[32] Accordingly, the rate of oxygen-atom transfer in the case of $[ReOCl_3(ppzt)]$ is 2.5 and 25 times faster than that for $[ReOCl_3(ppyt)]$ and $[ReOCl_3(pbpy)]$, respectively (Table 1).

While electron withdrawal from the $Re^{V}O$ moiety by ligand variation facilities oxygen-atom transfer, it is also expected to make metal oxidation more difficult. Fortunately, the $[ReOX_3(L)]$ complexes are uniformly electroactive in acetonitrile solution, exhibiting a quasi-reversible one-electron oxidative response near 1.5 V vs. SCE assigned to the $Re^{VI}O/Re^{V}O$ couple. Representative voltammograms are shown in Figure 4 and reduction potential data are listed in Table 1.

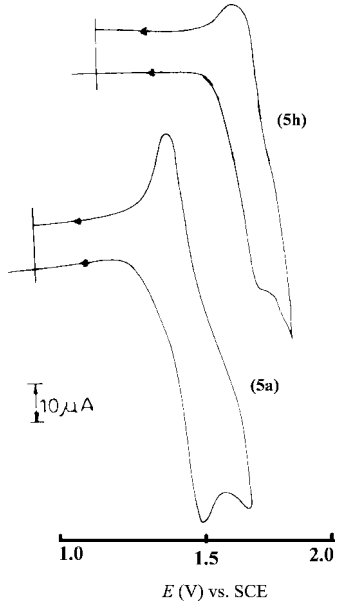


Figure 4. Cyclic voltammograms of $[ReOCl_3(bpy)]$ (**5a**) and $[ReOCl_3(ppzt)]$ (**5h**) in acetonitrile solution at platinum working electrode (scan rate: 100 mV s$^{-1}$).

The data of Table 1 reveal that the rate of oxygen-atom transfer rapidly increases with $E_{1/2}$ of the $Re^{VI}O/Re^{V}O$ couple. Indeed, there is a satisfactory linear correlation (correlation constant 0.99) between the logarithmic rate constant and the reduction potential (Figure 5). All the complexes except **5g** lie virtually on the least-squares line itself. The slope of the line is about 16. Evidently, a single linear equation of this type cannot encompass all $Re^{V}O$ complexes but it is gratifying to note that within a group where the L ligands belong to the same type (two six-membered N-heterocycles connected by a single bond) a simple correlation does exist.

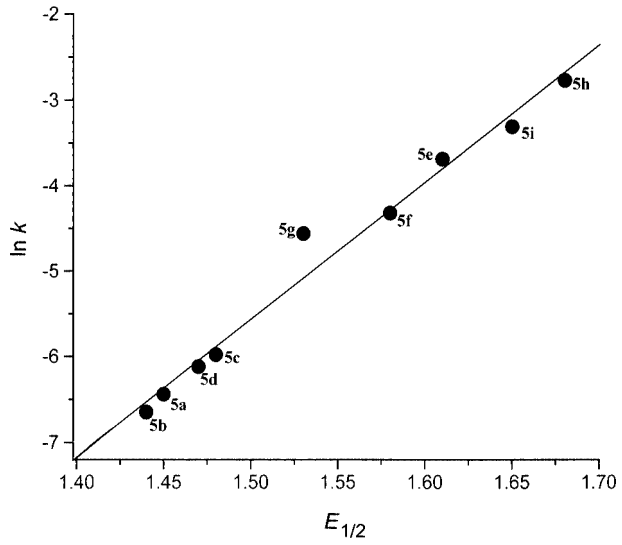

Figure 5. Plot of logarithmic rate constant vs. $Re^{VI}O/Re^{V}O$ reduction potential at 303 K.

## Conclusion

In our search for reactive $Re^{V}O$ complexes of *N*,*N*-chelating heterocyclic ligands (L) the rhenium chemistry of the pyridyl- and pyrazinyltriazine heterocycles ppyt, mpyt and ppzt has been developed in the form of the complexes [$ReOX_3$(L)] (X = Cl, Br), two of which have been structurally characterised.

These undergo strongly associative oxygen-atom transfer to $PPh_3$ ($\Delta S^{\ddagger} \approx -30$ cal $K^{-1}$ $mol^{-1}$). The rate of transfer has also been determined for other [$ReOCl_3$(L)] complexes (L = bpy, mbpy, pbpy and phen). The oxygen-atom transfer rates span nearly two orders of magnitude for the whole family examined here.

Consistent with the proposed reaction model based on nucleophilic attack of the $PPh_3$ lone pair on π*(Re≡O) orbitals, the transfer rate increases systematically with increasing electron withdrawal from $Re^{V}O$ due to variation of X (Cl > Br) or L (ppzt > ppyt > mpyt >> pbpy > phen > bpy > mbpy).

A second molecular parameter also responsive to electron withdrawal is the voltammetric $Re^{VI}O/Re^{V}O$ reduction potential, which shows the same trends as above. Indeed, the logarithmic rate of transfer correlates linearly with the $Re^{VI}O/Re^{V}O$ reduction potential within the present family of [$ReOX_3$(L)] complexes.

## Experimental Section

**Materials:** The complexes [$ReOX_3(AsPh_3)_2$][33] and [$ReOCl_3(Me_2S)(OPPh_3)$][19] and the triazine ligands[25,27] were prepared by reported methods. The purification and drying of dichloromethane and acetonitrile for spectral and electrochemical work was done as before.[34] Tetrahydrofuran and benzene ware dried using standard methods. All other chemicals and solvent were of reagent grade and were used as received.

**Physical Measurements:** UV/Vis spectral measurements were carried out with a Shimadzu UVPC 1601 spectrometer fitted with thermostatted cell compartments. $^1$H NMR spectra were recorded with a Bruker FT 300 MHz spectrometer. The atom numbering scheme used in $^1$H NMR is the same as in crystallography. Electrochemical measurements were performed under nitrogen with a CH 620A electrochemical analyzer, using a platinum working electrode. The supporting electrolyte was tetraethylammonium perchlorate (TEAP), and potentials are referred to the standard calomel electrode (SCE). Room-temperature magnetic susceptibilities of powders were measured with a model 155 PAR vibrating sample magnetometer. Microanalyses (C,H,N) were performed using a Perkin–Elmer 2400 series II elemental analyzer. Mass spectra were measured with Q-TOF mass spectrometer.

**Synthesis of Complexes:** The complex [$ReOCl_3$(bpy)] (**5a**) was synthesised from [$ReOCl_3(Me_2S)(OPPh_3)$] and bpy by a reported procedure.[19] We found the procedure to be suitable for synthesis of **5b**–**5d** as well with some modifications. Details are given below for [$ReOCl_3$(phen)] (**5d**).

**[$ReOCl_3$(phen)] (5d):** A suspension of [$ReOCl_3(Me_2S)(OPPh_3)$] (84 mg, 0.13 mmol) and phen (30 mg, 0.15 mmol) in 10 mL of tetrahydrofuran was stirred for 5 h. Filtration and washing with diethyl ether (5 × 5 mL) gave 43 mg (0.09 mmol, 68%) of yellowish **5d** in pure form. $C_{12}H_8Cl_3N_2ORe$ (488.78): calcd. C 29.49, H 1.64, N 5.73; found C 29.40, H 1.69, N 5.78. UV/Vis ($CH_2Cl_2$ solution: $\lambda_{max}$ (ε) = 270 nm (56500 $M^{-1}cm^{-1}$), 410 (4150), 456 (5690), 795 (160). IR (KBr): $\tilde{\nu}$ = 989 $cm^{-1}$ ($\nu_{Re=O}$). $^1$H NMR (300 MHz, $CDCl_3$, 298 K): δ = 10.03 (d, *J* = 5.20 Hz, H1), 9.31 (d, *J* = 8.10 Hz, H7), 8.98 (d, *J* = 5.01 Hz, H3), 8.62 (t, *J* = 7.62 Hz, H2), 8.60 (d, *J* = 7.98 Hz, H9), 8.55 (d, *J* = 5.32 Hz, H12), 8.52 (d, *J* = 5.30 Hz, H11), 8.30 (t, *J* = 8.02 Hz, H8) ppm.

**[$ReOCl_3$(mbpy)] (5b):** Yield: 44 mg (69%.) $C_{12}H_{12}Cl_3N_2ORe$ (492.81): calcd. C 29.25, H 2.45, N 5.68 found C 29.30, H 2.40, N 5.60. UV/Vis ($CH_2Cl_2$ solution): $\lambda_{max}$ (ε) = 299 (47400), 458 (7670), 795 (225). IR (KBr): $\tilde{\nu}$ = 984 $cm^{-1}$ ($\nu_{Re=O}$). $^1$H NMR (300 MHz, [$D_6$]DMSO, 298 K): δ = 8.92 (s, H4), 8.55 (s, H10), 8.40 (d, *J* = 5.85 Hz, H1), 8.10 (d, *J* = 6.06 Hz, H7), 7.48 (d, *J* = 6.03 Hz, H2), 7.40 (d, *J* = 5.79 Hz, H8), 4.70 (s, 3 H, 3-Me), 3.65 (s, 3 H, 9-Me) ppm.

**[$ReOCl_3$(pbpy)] (5c):** Yield: 52 mg (65%). $C_{22}H_{16}Cl_3N_2ORe$ (616.96): calcd. C 42.79, H 2.59, N 4.53; found C 42.70, H 2.53, N 4.58. UV/Vis ($CH_2Cl_2$ solution): $\lambda_{max}$ (ε) = 326 nm (50000 $M^{-1}cm^{-1}$), 465 (13100), 774 (253). IR (KBr): $\tilde{\nu}$ = 987 $cm^{-1}$ ($\nu_{Re=O}$). $^1$H NMR (300 MHz, $CDCl_3$, 298 K): δ = 9.08 (s, H4), 8.60 (d, *J* = 8.10 Hz, H1), 8.55 (d, *J* = 8.16 Hz, H2), 8.00–7.50 (m, 13 H, H3, H8, H10, 2Ph) ppm.

**The Complexes 5e–5i:** These complexes were prepared in 75–85% yield by the same general procedure based on the reaction of [$ReOX_3(AsPh_3)_2$] with L in benzene at room temperature. Details are given here for a representative case.

**[$ReOCl_3$(ppyt)] (5e):** The ligand ppyt (34 mg, 0.11 mmol) was added to a suspension of [$ReOCl_3(AsPh_3)_2$] (100 mg, 0.11 mmol) in 25 mL of benzene. The resulting mixture was stirred for 1 h at room temperature to produce a pink solution. The solvent was then removed under reduced pressure. The solid mass thus obtained was repeatedly washed with *n*-hexane to remove the liberated $AsPh_3$. The solid was then dissolved in 5 mL of dichloromethane and subjected to chromatography on a silica gel column (10 × 1 cm, 60–120 mesh) prepared in toluene. The pink complex was eluted with pure dichloromethane. Solvent removal from the eluate under reduced pressure afforded [$ReOCl_3$(ppyt)] in pure form, which was dried under vacuo over fused calcium chloride. Yield: 53 mg (78%). $C_{20}H_{14}Cl_3N_4ORe$ (618.93): calcd. C 38.81, H 2.28, N 9.05; found C 38.87, H 2.21, N

**[ReOCl$_3$(ppzt)] (5h):** Yield: 57 mg (83%). $C_{19}H_{13}Cl_3N_5ORe$ (619.92): calcd. C 36.81, H 2.11, N 11.30; found C 36.86, H 2.17, N 11.35. UV/Vis ($CH_2Cl_2$ solution): $\lambda_{max}$ ($\varepsilon$) = 310 nm (36400 $M^{-1}cm^{-1}$), 523 (13800), 737 (540). IR (KBr): $\tilde{\nu}$ = 1004 $cm^{-1}$ ($\nu_{Re\equiv O}$). $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 9.95 (s, H3), 8.85 (d, $J$ = 6.00 Hz, H2), 7.95 (d, $J$ = 4.20 Hz, 2 H, H9, H13), 7.88 (d, $J$ = 7.20 Hz, H1), 7.74 (d, $J$ = 7.80 Hz, 2 H, H15, H19), 7.65 (t, $J$ = 6.90 Hz, 2 H, H10, H12), 7.54 (t, $J$ = 10.80 Hz, 2 H, H16, H18), 7.45 (t, $J$ = 7.80 Hz, H11), 7.45 (t, $J$ = 7.80 Hz, H17) ppm.

**[ReOBr$_3$(ppzt)] (5i):** Yield: 64 mg (85%). $C_{19}H_{13}Br_3N_5ORe$ (753.27): calcd. C 30.30, H 1.74, N 9.30; found C 30.25, H 1.70, N 9.24. UV/Vis ($CH_2Cl_2$ solution): $\lambda_{max}$ ($\varepsilon$) = 310 nm (35100 $M^{-1}cm^{-1}$), 531 (10600), 739 (850). IR (KBr): $\tilde{\nu}$ = 999 $cm^{-1}$ ($\nu_{Re\equiv O}$). $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 9.75 (s, H3), 8.81 (d, $J$ = 4.76 Hz, H2), 8.60 (d, $J$ = 4.88 Hz, H1), 7.74 (d, $J$ = 7.59 Hz, 2 H, H9, H13), 7.66 (d, $J$ = 6.42 Hz, 2 H, H15, H19), 7.56 (t, $J$ = 7.80 Hz, 2 H, H10, H12), 7.52 (t, $J$ = 6.42 Hz, 2 H, H16, H18), 7.48 (t, $J$ = 5.90 Hz, H11), 7.46 (t, $J$ = 7.44 Hz, H17) ppm.

**Complexes [Re(OPPh$_3$)Cl$_3$(L)]:** These were prepared in 75–80% yield by the same general procedure based on the reaction of [ReOX$_3$(L)] with triphenylphosphane in benzene at room temperature. Details are given below for a representative case and data for a second compound prepared analogously follow.

**[Re(OPPh$_3$)Cl$_3$(ppyt)]:** $PPh_3$ (68 mg, 0.28 mmol) was added to a solution of [ReOCl$_3$(ppyt)] (80 mg, 0.13 mmol) in 25 mL of dichloromethane. The resulting solution was magnetically stirred for 4 h at room temperature and during this time the colour of the solution changed from pink to violet. It was then subjected to chromatography on a silica gel column. Excess $PPh_3$ was eluted with benzene. A violet band was eluted with a benzene/acetonitrile (25:2) mixture. The solvent was removed under reduced pressure and the violet complex so obtained was dried under vacuo over fused calcium chloride. Yield: 90 mg (75%). $C_{38}H_{29}Cl_3N_4OPRe$ (881.22): calcd. C 51.80, H 3.32, N 6.35; found C 51.72, H 3.39, N 6.30. UV/Vis ($CH_2Cl_2$ solution): $\lambda_{max}$ ($\varepsilon$) = 289 nm (31300 $M^{-1}cm^{-1}$), 532 (8700), 701 (5150). IR (KBr): $\tilde{\nu}$ = 1119 $cm^{-1}$ ($\nu_{O=P}$). $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 25.99 (t, $J$ = 9.00 Hz, H2), 10.19 (t, $J$ = 7.50 Hz, H12), 9.58 (d, $J$ = 8.40 Hz, 2 H, H16, H20), 9.50 (t, $J$ = 7.50 Hz, 2 H, H11, H13), 8.22 (d, $J$ = 7.80 Hz, H1), 8.10 (d, $J$ = 8.10 Hz, 2 H, H10, H14), 7.73 (t, $J$ = 7.20 Hz, H18), 7.17 [d, $J$ = 7.20 Hz, 6 H, $o$-H($PPh_3$)], 6.77 [t, $J$ = 7.50 Hz, 3 H, $p$-H($PPh_3$)], 5.06 (t, $J$ = 7.50 Hz, 2 H, H17, H19), 4.00 [t, $J$ = 7.80 Hz, 6 H, $m$-H($PPh_3$)], 2.79 (d, $J$ = 4.80 Hz, H4), –17.01 (t, $J$ = 9.00 Hz, H3) ppm. $E_{1/2}$ ($Re^{IV}/Re^{III}$ couple): 0.33 V ($\Delta E_p$ = 70 mV). $\mu$ (in powder): 1.51 $\mu_B$ (298 K). Q-TOF-MS: $m/z$ 881.30.

**[Re(OPPh$_3$)Br$_3$(ppzt)]:** Yield: 104 mg (79%). $C_{37}H_{28}Br_3N_5OPRe$ (1015.56): calcd. C 43.76, H 2.78, N 6.96; found C 43.70, H 2.73, N 6.83. UV/Vis ($CH_2Cl_2$ solution): $\lambda_{max}$ ($\varepsilon$) = 300 nm (32900 $M^{-1}cm^{-1}$), 525 (8400), 665 (5900). IR (KBr): $\tilde{\nu}$ = 1121 $cm^{-1}$ ($\nu_{O=P}$). $^1H$ NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 42.83 (d, $J$ = 7.11 Hz, H1), 21.98 (s, H3), 8.78 (t, $J$ = 7.62 Hz, 2 H, H10, H12), 8.62 (d, $J$ = 7.08 Hz, 2 H, H9, H13), 7.93 (t, $J$ = 6.87 Hz, H11), 7.68 (d, $J$ = 7.89 Hz, H2), 7.41 [d, $J$ = 6.72 Hz, 6 H, $o$-H($PPh_3$)], 6.96 [t, $J$ = 6.96 Hz, 3 H, $p$-H ($PPh_3$)], 6.27 (t, $J$ = 6.36 Hz, H17), 6.13 [t, $J$ = 8.03 Hz, 6 H, $m$-H($PPh_3$)], 5.67 (t, $J$ = 7.44 Hz, 2 H, H16, H18), 4.61 (d, $J$ = 7.74 Hz, 2 H, H15, H19) ppm. $E_{1/2}$ ($Re^{IV}/Re^{III}$ couple): 0.58 V ($\Delta E_p$ = 90 mV). $\mu$ (in powder): 1.67 $\mu_B$ (298 K). Q-TOF-MS: $m/z$ 1015.34.

**Rate Measurement:** The representative case of the reaction of [ReOCl$_3$(ppyt)] with $PPh_3$ will be described. A known excess of $PPh_3$ was added to a solution of [ReOCl$_3$(ppyt)] ($5.43 \times 10^{-5}$ M) in dichloromethane at the desired temperature, and the thermostatted reaction was followed spectrophotometrically (quartz cell; path length: 1 cm) by measuring the absorbance ($A_\alpha$) of the peak at 710 nm as a function of time ($t$). The absorbance ($A_\alpha$) at the end of the reaction (24 h) was also measured. Values of $k_{obs}$ and $k$ were obtained from the slopes of the linear plots of $-[\ln(A_\alpha - A_t)]$ vs. $t$ and $k_{obs}$ vs. [$PPh_3$] respectively. The activation enthalpy and entropy parameters were determined from the linear plot of $-\ln(kh/k_BT)$ vs. $T^{-1}$ using the Eyring equation, see Equation (3).

$$k = (k_BT/h)\exp(-\Delta H^{\ddagger}/RT)\exp(\Delta S^{\ddagger}/R) \quad (3)$$

**Crystal Structure Determination:** Single crystals of the complexes [ReOCl$_3$(ppyt)] (**5e**) and [ReOCl$_3$(ppzt)] (**5h**) were grown by slow diffusion of hexane into dichloromethane solutions of the respective compounds. Data were collected on a Nicolet R3m/V four-circle diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) by the $\omega$-scan technique in the range $3° \leq 2\theta < 50°$. All data were corrected for Lorentz-polarisation and absorption.[35] The metal atoms were located from Patterson maps and the rest of the non-hydrogen atoms emerged from successive Fourier syntheses. The structures were then refined by a full-matrix least-squares procedure on $F^2$. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were included in calculated positions. Calculations were performed using the SHELXTL™ V 5.03 program package.[36]

**Data for 5e:** $C_{20}H_{14}Cl_3N_4ORe$, monoclinic, $P2_1/n$, $a$ = 8.920(2), $b$ = 15.021(3), $c$ = 15.558(3) Å, $\beta$ = 92.05(3)°, $V$ = 2083.2(3) Å$^3$, $Z$ = 4, 3111 unique reflections ($R_{int}$ = 0.0000). Final residuals $R_1$ = 0.0556 and $wR_2$ = 0.1405 [$I > 2\sigma(I)$].

**Data for 5h:** $C_{19}H_{13}Cl_3N_5ORe$, monoclinic, $P2_1/c$, $a$ = 9.274(2), $b$ = 16.418(3), $c$ = 13.732(3) Å, $\beta$ = 98.70(3)°, $V$ = 2066.8(7) Å$^3$, $Z$ = 4, 3617 unique reflections ($R_{int}$ = 0.0648). Final residuals $R_1$ = 0.0472 and $wR_2$ = 0.1154 [$I > 2\sigma(I)$].

# Relationship Between the Nearest-Neighbor Exchange Coupling Constants and the Number of Exchange Interactions in the Cyano-Bridged $MnMo_6(CN)_{18}$ Cluster: Density Functional Theory Calculations

**Yi-Quan Zhang*[a] and Cheng-Lin Luo[a]**

**Keywords:** Molecular magnetism / Density functional calculations / Broken symmetry / Cyano-bridged clusters / Single-molecule studies

A theoretical density functional study of the relationship between the nearest-neighbor MnMo constants and the number of exchange interactions in the cyano-bridged $K[(Me_3tacn)_6MnMo_6(CN)_{18}](ClO_4)_3$ cluster is presented. Two approaches (the first approach consisted of evaluating the exchange coupling constant $J_{ij}$ between two paramagnetic metal centers *i* and *j* in the hexanuclear molecule by calculating the energy differences between the highest and broken-symmetry spin states of a model molecule in which metal atoms except for *i* and *j* are substituted by diamagnetic $Y^{III}$ cations, and the second is to calculate the different spin-state energies of hexanuclear complexes and use the Heisenberg Hamiltonian to obtain the exchange coupling constants between different metal centers) show that the antiferromagnetic coupling interactions between nearest neighbors weaken with the increase of the number of exchange interactions. The various $\theta$ angles have an influence on the interactions between the nearest-neighbor MoMn but do not change the trend between $J_{12}$ and the number of exchange interactions. Moreover, Kahn's qualitative theory succeeded in being applied to interpret the trend.

## Introduction

In recent years, the synthesis and study of single-molecule magnets with high total spin that can be used to store potential data have received much attention.[1–14] In these single-molecule magnets, much attention is focused on developing cyano-bridged cluster systems, for which the parameters S and D are more readily adjusted by substitution of various metal ions.[5–14] Long and coworkers found that the absolute nearest-neighbor constants *J* always diminish as the number of exchange interactions increases for a series of cyano-bridged $Mn^{II}$–$Cr^{III}$,[5,6] $Mn^{III}$–$Cr^{III}$,[7–9] $Mo^{III}$–$Ni^{II}$,[10] and $Cr^{III}$–$Ni^{II}$ [11,12] complexes. It was demonstrated that the interactions between the nearest-neighbor $Mn^{III}$ and $Cr^{III}$ decrease with the increase of the number of exchange interactions when we investigated the magnetism of the cyano-bridged $\{Cr[CNMn(salen)(H_2O)]_6\}^{3+}$ [7,8] cluster and the linear trinuclear $[(5\text{-Brsalen})_2(H_2O)_2Mn_2Cr(CN)_6]$[9] cluster.[13] For the cyano-bridged single-molecule cluster $K[(Me_3tacn)_6MnMo_6(CN)_{18}](ClO_4)_3$,[14] which has a substantial increase in the nearest-neighbor MnMo interactions compared to those of the above MnCr complexes, we want to know whether the above trend also exists. and whether the MoMnMo angle has an influence on the interactions between the nearest neighbors. Kahn's qualitative theory[15,16] was used to interpret the relationship. Finally, we will discuss the relationship between the calculated spin-density populations on $Mn^{II}$ or $Mo^{III}$ and the number of exchange interactions.

## Computational Methodology

### Description of the Complexes and Models

In calculations, we used model $\mathbf{A^6}$ $[(Me_3tacn)_6MnMo_6(CN)_{18}]^{2+}$, which is a polynuclear cluster in which six $[(Me_3tacn)Mo(CN)_3]$ units surround a central $Mn^{II}$ ion (see Figure 1) and was directly taken from complex $K[(Me_3tacn)_6MnMo_6(CN)_{18}](ClO_4)_3$[14] and not optimized. The bridges are of the Mo–CN–Mn type and, therefore, the Mn atom with an $N_6$ coordination sphere is in a high-spin configuration. Models $\mathbf{A^1}$, $\mathbf{A^2}$, $\mathbf{A^3}$, $\mathbf{A^4}$, and $\mathbf{A^5}$ (the superscript numbers denote the number of exchange interactions) (see Figure 2) were used to investigate the relationship between the nearest-neighbor exchange coupling constants $J_{12}$ and the number of exchange interactions. To investigate the relationship between $J_{12}$ and the $\theta$ angle (we use $\theta$ to represent the MoMnMo angle), we obtained three different structures that all include two of the exchange interactions $\mathbf{A^2}$, $\mathbf{A^{2'}}$, and $\mathbf{A^{2''}}$ (see Figure 3). The $\theta$ angles for $\mathbf{A^2}$, $\mathbf{A^{2'}}$, and $\mathbf{A^{2''}}$ are 86.38°, 113.33°, and 154.92°, respectively. All the mod-

els were directly taken from model **A**$^{6}$, and not optimized because small changes to the experimental structures could result in significant deviations for the coupling constants. To easily perceive the topology of the metal framework, we used sticks for the carbons of the tacn ligands and the terminal CN ligands in Figure 1, Figure 2, and Figure 3.

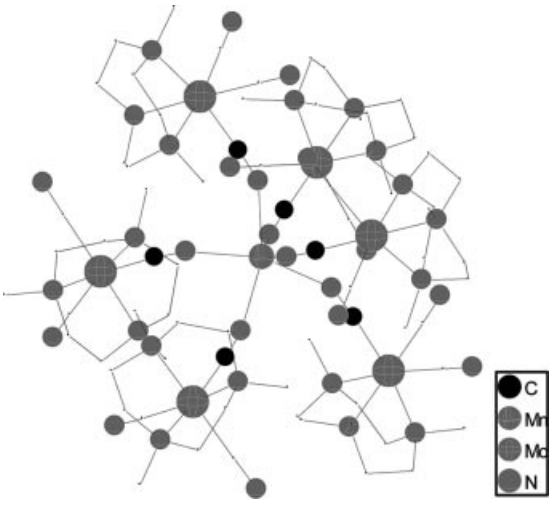

Figure 1. Structure of model **A**$^{6}$ ($MnMo_6$).

**Calculation on Exchange Coupling Constant**

There are two different approaches to calculating the exchange coupling constants for the polynuclear complexes.[17–19] In all calculations, the spin-orbit coupling is not considered, so the magnetic anisotropy does not need to be considered. The first approach consisted of evaluating the exchange coupling constant $J_{ij}$ between two paramagnetic metal centers $i$ and $j$ in the hexanuclear molecule by calculating the energy difference between the highest and broken-symmetry spin states of a model molecule in which metal atoms except for $i$ and $j$ are substituted by diamagnetic $Y^{III}$ cations. This approach was used to calculate the exchange coupling interactions of hexanuclear complexes in many papers and proved to give good results compared to the experimental ones.[17–20] The second approach is to calculate the different spin-state energies of hexanuclear complexes and use the Heisenberg Hamiltonian to obtain the exchange coupling constants between different metal centers.[17–21] It is a more rigorous approach in evaluating $J$ for polynuclear complexes than the first one. How to use these two approaches will be interpreted thoroughly below.

For the first approach, the magnetic interactions between $Mn^{II}$ and $Mo^{III}$ metal ions were studied on the basis of density functional theory (DFT) coupled with the broken-symmetry approach (BS).[22–24] The exchange coupling constants $J$ were evaluated by calculating the energy difference

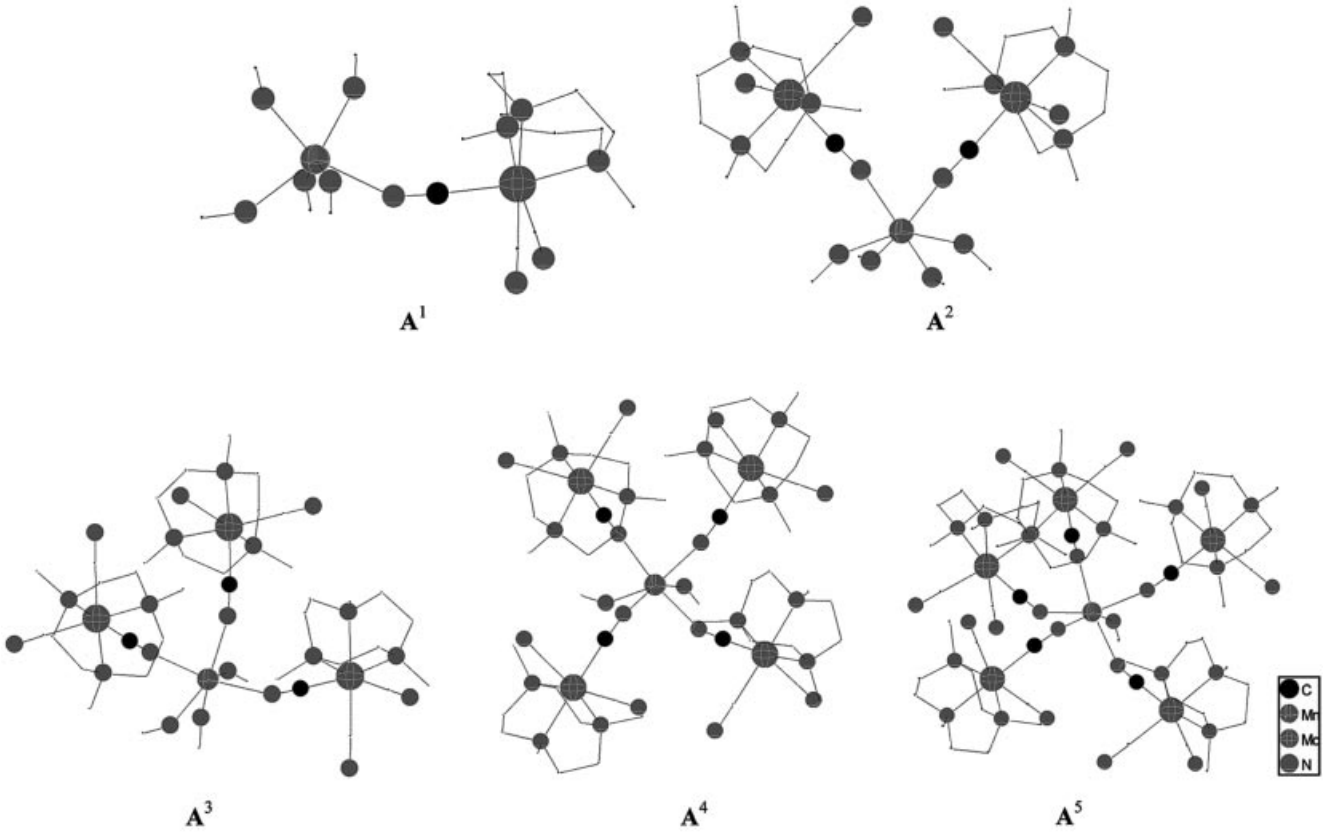

Figure 2. Structure of models **A**$^{1}$ (MnMo), **A**$^{2}$ ($MnMo_2$), **A**$^{3}$ ($MnMo_3$), **A**$^{4}$ ($MnMo_4$), and **A**$^{5}$ ($MnMo_5$).

between the high-spin state ($E_{HS}$) and the broken-symmetry state ($E_{BS}$). Assume the spin Hamiltonian is defined as Equation (1).

$$\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2 \quad (1)$$

If the spin-projected approach is used, the equation proposed by Noodleman[22–24] to extract the $J$ value for a binuclear transition-metal complex is thus Equation (2).

$$J = \frac{E_{BS} - E_{HS}}{4S_1S_2} \quad (2)$$

while with the nonprojected approach:[25]

$$2J = \frac{E_{BS} - E_{HS}}{2S_1S_2 + S_2} \quad (3)$$

where $S_1$ and $S_2$ are the total spins of two interacting paramagnetic centers and $S_1 > S_2$ is assumed for heterodinuclear complexes.

However, Equation (3) corresponds strictly to the limit of complete overlap between the magnetic orbitals and such a hypothesis is not sustained,[26] although it can give good $J$ results compared to the experimental ones.[25,27,28]

For all models, where $S_1$ = 5/2 for $Mn^{II}$ and $S_2$ = 3/2 for $Mo^{III}$, from Equation (2) we get Equation (4).

$$J = (E_{BS} - E_{HS})/15 \quad (4)$$

The second approach is more rigorous. If one neglects the spin-orbit coupling effects, the Hamiltonian for a general extended structure is indicated in Equation (5).

$$\hat{H} = \sum_{i>j} -2J_{ij}\hat{S}_i\hat{S}_j \quad (5)$$

where $\hat{S}_i$ and $\hat{S}_j$ are the spin operators of the different paramagnetic centers. The $J_{ij}$ values are the coupling constants between all the paramagnetic centers. In our paper, we only consider the exchange interactions between nearest neighbors. This fact together with the presence of additional symmetry elements in the structure normally result in a reduced set of $J_{ij}$ values.

When using single-determinant methods such as DFT, the calculated energies are related to the diagonal matrix elements of the Heisenberg Hamiltonian. An alternative way to describe the system is by considering an Ising Hamiltonian as a special case of a Heisenberg Hamiltonian in which only the diagonal terms are kept. Thus, we can consider that the wave functions obtained with the single-determinant methods are eigenfunctions of an Ising Hamiltonian that is formulated with the same $J$ values as the original Heisenberg Hamiltonian because their diagonal terms are identical. For that reason, the $J$ values obtained with single-determinant methods are directly comparable to those obtained from experimental data.[19] So we can use the single-dominant method DFT to obtain the $J$ values from calculating the energy differences between two spin-states. A thorough description of this approach can be found in refs.[17–19,21]

For **A²**, which includes three magnetic centers, the magnetic coupling constants $J_{12}$ between each nearest-neighbor $Mo^{III}$–$Mn^{II}$ pair are the same for the symmetry of the complete structure. Moreover, we only need the nearest-neighbor coupling constant. So, the $J_{12}$ can be extracted by

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

calculating the energies of two spin-states: **1** with $S = 1/2$, and **2** with $S = 11/2$, which are shown in Figure 4. The equation to extract $J_{12}$ is thus Equation (6).

$$J_{12} = (E_1 - E_2)/35 \quad (6)$$

Figure 4. Two spin states: **1** with $S = 1/2$ (left), **2** with $S = 11/2$ (right) for model $\mathbf{A^2}$.

To obtain all the nearest-neighbor constants $J_{12}$ for the modeled structures $\mathbf{A^3}$, $\mathbf{A^4}$, $\mathbf{A^5}$, and $\mathbf{A^6}$, we also only need to calculate the energy of two spin-states for each model. Two spin-states for each model are as follows: **1** with $S = 1/2$ and **2** with $S = 11/2$ for $\mathbf{A^2}$, **1** with $S = 2$ and **2** with $S = 14/2$ for $\mathbf{A^3}$, **1** with $S = 7/2$ and **2** with $S = 17/2$ for $\mathbf{A^4}$, **1** with $S = 5$ and **2** with $S = 10$ for $\mathbf{A^5}$, and **1** with $S = 13/2$ and **2** with $S = 23/2$ for $\mathbf{A^6}$. For all these **1** states, only the spins on $Mn^{II}$ are flipped. The equations to extract $J_{12}$ values for all of the models are as follows:
For model $\mathbf{A^3}$, Equation (7) is thus:

$$J_{12} = (E_1 - E_2)/50 \quad (7)$$

For model $\mathbf{A^4}$, Equation (8) is thus:

$$J_{12} = (E_1 - E_2)/65 \quad (8)$$

For model $\mathbf{A^5}$, Equation (9) is thus:

$$J_{12} = (E_1 - E_2)/80 \quad (9)$$

For model $\mathbf{A^6}$, Equation (10) is thus:

$$J_{12} = (E_1 - E_2)/95 \quad (10)$$

DFT calculations have been performed using the Amsterdam Density Functional (ADF, version 2004.01[29–31]) package for four models. Illas et al.[32] showed the strong dependence of the calculated $J$ with respect to the exchange-correlation functionals chosen. Several exchange-correlation functionals will be used to evaluate $J$. In the calculations of $J$ using ADF, the local density approximation (LDA) made use of the Vosko, Wilk, and Nusair[33] (VWN) local correlation functional. A series of generalized gradient approximation (GGA): Perdew-Wang 1991 (PW91),[34] Perdew-Burke-Ernzerhof (PBE),[35] and the recently developed OPTX-Perdew (Operdew)[36,37] and OPTX-Perdew–Burke–Ernzerhof (OPBE)[35–37] functionals were examined. Basis set TZV2P [a basis set of triple-ζ quality[38] supplemented with two p orbitals ("polarization functions")] was applied for all of the metals (Mo, Mn) and basis set DZP (a basis set of double-ζ quality[38] supplemented with one polarization function) for the other atoms (C, N, and H). The inner core shells of C(1s), N(1s), Mn(1s, 2s, 2p), Y(1s, 2s, 2p, 3s, 3p), and Mo(1s, 2s, 2p, 3s, 3p) were treated by the frozen core approximation. The accuracy parameter (accint) for the numerical integration grid was set to 4.0 for all of the complexes. The convergence standard of the system energy was set to be smaller than $10^{-6}$ eV, reaching a precision required for the evaluation of $J$.

## Results and Discussion

### Relationship Between $J$ and the Number of Exchange Interactions

The relationship between the nearest-neighbor exchange coupling constants $J_{12}$ and the number of exchange interactions is shown in Figure 5. Two approaches show that the absolute $J_{12}$ values decrease with the increase of the number of exchange interactions. The second approach gives better results than the first one for $\mathbf{A^2}$, $\mathbf{A^{2'}}$, and $\mathbf{A^{2''}}$. However, the two approaches give similar results for $\mathbf{A^3}$, $\mathbf{A^4}$, $\mathbf{A^5}$, and $\mathbf{A^6}$. This is because the decrease of the absolute $J_{12}$ values with the increase of the number of exchange interactions will reduce the differences between the results using the two approaches. Moreover, this is of conceptual importance, as the

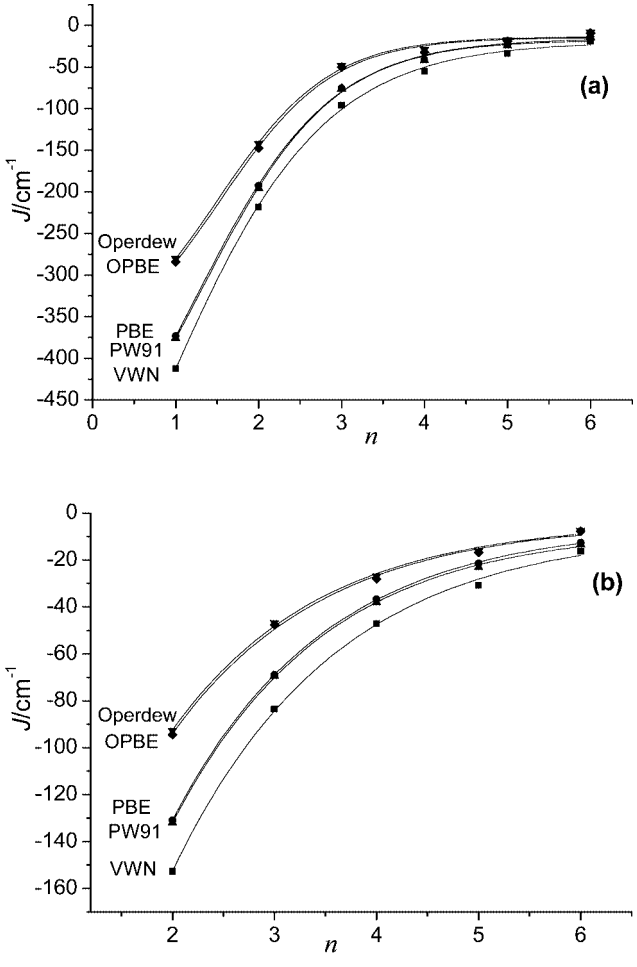

Figure 5. Relationship between the nearest-neighbor interaction constant $J_{12}$ ($cm^{-1}$) and the number of exchange interactions $n$ with several functionals [VWN (■), PW91 (●), PBE (▲), Operdew (▼), and OPBE (♦)] for the models of complex **I**. | | second | –16.3 | –12.6 | –13.5 | –7.4 | –7.7 | |

changes in $J_{12}$ values with the number of Mo atoms has to do with the fact that one new $t_{2g}$ orbital is incorporated in the exchange interaction for the first three Mo atoms, then the addition of new atoms does not introduce new orbital interactions, as reflected in the small slopes between $n = 3$ and $n = 6$. From Figure 5, the consistent behavior between the calculated $J_{12}$ values and the experimental value becomes better in the sequence: LDA (VWN), GGA (PW91, PBE), GGA (Operdew, OPBE), which was also found in our previous paper,[13] and the differences between the calculated $J_{12}$ values using the two approaches decrease with the increase of the number of exchange interactions for all of the functionals. From Table 1, the calculated $J_{12}$ values of model **A**$^{6}$, which is the most similar to the complete structure using two approaches with Operdew and OPBE functionals, have good agreement with the experimental result.[14]

The nearest-neighbor exchange coupling constants $J_{12}$ calculated using different functionals with two approaches for models **A**$^{2}$, **A**$^{2'}$, and **A**$^{2''}$ are shown in Table 1 where the absolute $J_{12}$ values calculated using two approaches with all the functionals all decrease with the increase of the $\theta$ angle. From Table 1, we also found that the increase of the $J_{12}$ values from **A**$^{2}$ to **A**$^{2'}$ is very small but large from **A**$^{2'}$ to **A**$^{2''}$. However, all the $J_{12}$ values of models **A**$^{2}$, **A**$^{2'}$, and **A**$^{2''}$ are between those of **A**$^{1}$ and **A**$^{3}$ and thus, the different $\theta$ angles do not change the trend between $J_{12}$ and the number of exchange interactions.

### Qualitative Analysis of the Exchange Interaction

According to Kahn's theory,[15,16] the exchange coupling constant $J$ is expressed in Equation (11) ($\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2$).

$$J_{ab} \approx K_{ab} - S_{ab}(\Delta^2 - \delta^2)^{1/2} \quad (11)$$

The positive term $K_{ab}$ represents the ferromagnetic contribution $J_F$, favoring parallel alignment of the spins and a triplet ground state, while the negative term $-S_{ab}(\Delta^2 - \delta^2)^{1/2}$ is the antiferromagnetic contribution $J_{AF}$, favoring antiparallel alignment of the spins and a singlet ground state. $S_{ab}$ is the overlap integrals between **a** and **b**. $\delta$ is the initial energy gap between the magnetic orbitals, and $\Delta$ the energy gap between the molecular orbitals derived from them. When several electrons are present on each center, $n_A$ on one side, $n_B$ on the other, $J$ can be described by the sum of the different "orbital pathways" $J_{ab}$, defined as above for pairs of orbitals **a** and **b** located on each site, weighted by the number of electrons [Equation (12)].

$$J = \sum_{a,b} J_{ab}/n_A n_B \quad (12)$$

Some authors[39,40] have recently shown that magnetic orbitals **a** and **b** are well represented by the localized orbitals of the broken-symmetry solution (they call them BS-OMSO[41]). There are 15 different contributions to the exchange coupling constant in each $Mo^{III}$–$Mn^{II}$ pair; the inappropriate orientation of some of the magnetic orbitals involved allows us to discard most of them. The ferromagnetic contributions are not considered because the antiferromagnetic coupling interactions for all the complexes are dominant. Moreover, as usual, the changes in the $J_{AF}$ term are more important and these contributions usually control the magnetostructural correlations, especially for those whose intramolecular interactions are antiferromagnetic. Hence, we only consider the changes in the $J_{AF}$ term. Among the important antiferromagnetic contributions, the most relevant ones are those involving two $t_{2g}$ orbitals ($d_{xy}$ and $d_{xz}$) of the $Mo^{III}$, which are directed toward the bridging ligands because of the good overlap with the appropriate $t_{2g}$ orbitals ($d_{xy}$ and $d_{xz}$) of the $Mn^{II}$. The mean overlap integral $S_{ij}$ between the four orbitals of the $Mo^{III}$ and $Mn^{II}$ can be expressed as Equation (13).

$$S_{ij} = 1/4(d_{xy}d_{xy} + d_{xy}d_{xz} + d_{xz}d_{xy} + d_{xz}d_{xz}) \quad (13)$$

Figure 6 gives the relationship between $J_{12}$ and $S_{ij}$ obtained using Equation (13) and the PW91 functional with the increase of the number of the exchange interaction. The absolute $J_{12}$ values decrease with the decrease of the $S_{ij}$ in accordance with Kahn's qualitative theory. Therefore, we can conclude that the increase of the number of exchange interactions will decrease the overlap integral $S_{ij}$ and lead to the decrease of the absolute $J_{12}$ values. This conclusion can be verified by investigating the relationship between $J_{12}$ and the spin-density populations on $Mo^{III}$ and $Mn^{II}$ with the increase of the number of exchange interactions. Because the spin-density populations on several $Mo^{II}$ are al-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

most the same, we only use the spin-density population on one $Mo^{III}$. The spin-density populations on $Mo^{III}$ and $Mn^{II}$ were obtained with Mulliken Population Analysis[42] calculated using the PW91 functional in the ADF2004.01 package in the high-spin (HS) states. The relationship is shown in Figure 7 where the spin populations on $Mo^{III}$ and $Mn^{II}$ increase with the decrease of the absolute $J_{12}$. From Kahn's theory, the increase of the spin populations on $Mo^{III}$ and $Mn^{II}$ will decrease the $S_{ij}$ and then lead to the decrease of the absolute $J_{12}$. Moreover, we also found that the various spin populations on $Mn^{II}$ were much smaller than those on $Mo^{III}$. These results were calculated using the first approach. The second approach also gives the same trend between $J_{12}$ and the spin-density populations on $Mo^{III}$ and $Mn^{II}$ in the high-spin states.

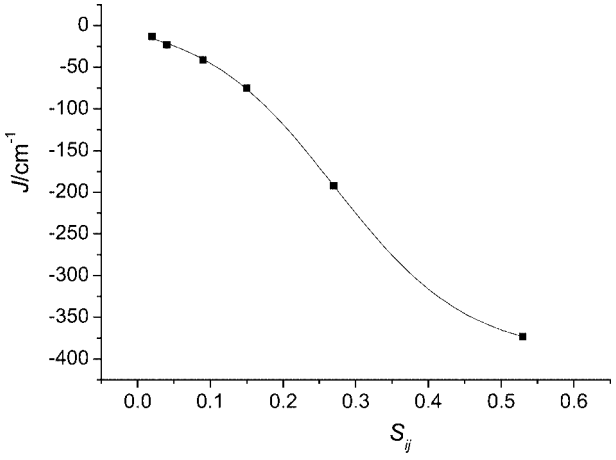

Figure 6. Relationship between the nearest-neighbor interaction constant $J_{12}$ ($cm^{-1}$) and the mean overlap integral $S_{ij}$ with the increase of the number of exchange interactions using the PW91 functional.

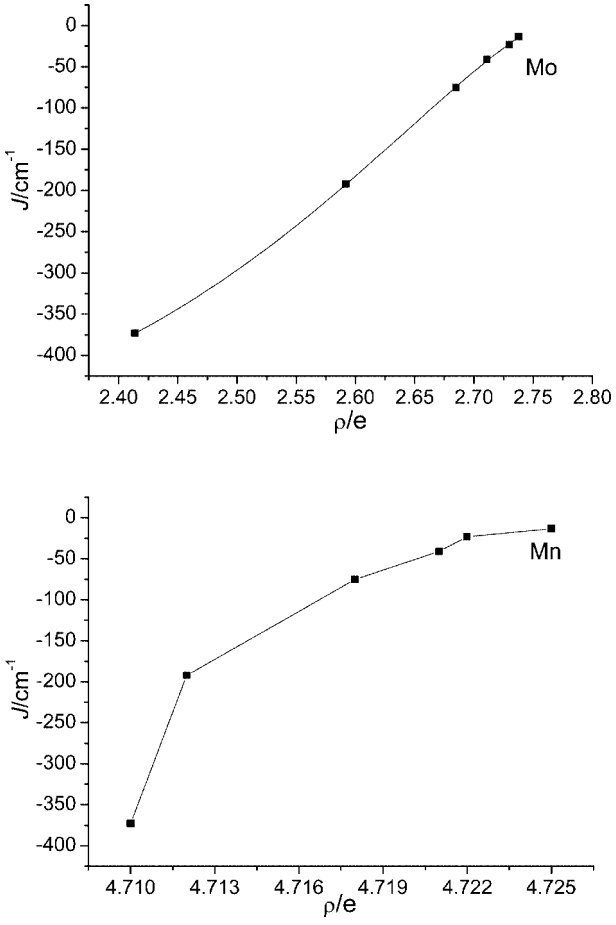

Figure 7. Relationship between the nearest-neighbor interaction constant $J_{12}$ ($cm^{-1}$) and the spin-density populations $\rho$ on $Mo^{III}$ (top) and $Mn^{II}$ (bottom) in the high-spin states with the PW91 functional using the first approach.

## Conclusions

Two approaches were used to investigate the magnetic coupling interactions between the nearest-neighbor $Mo^{III}$ and $Mn^{II}$. From our calculations, both approaches show that the antiferromagnetic interactions between nearest-neighbors decrease with the increase of the number of exchange interactions for our studied $Mo^{III}$–$Mn^{II}$ system. The trend is rationalized by using Kahn's theory through the overlap integral $S_{ij}$ and the spin-density populations on $Mo^{III}$ and $Mn^{II}$ in the HS states successfully. The absolute $J_{12}$ values calculated using two approaches with all the functionals all decrease with the increase of the $\theta$ angle, and the decrease of the absolute $J_{12}$ values from $\mathbf{A^2}$ to $\mathbf{A^{2'}}$ is very small but large from $\mathbf{A^{2'}}$ to $\mathbf{A^{2''}}$. However, all the $J_{12}$ values of models $\mathbf{A^2}$, $\mathbf{A^{2'}}$, and $\mathbf{A^{2''}}$ are between those of $\mathbf{A^1}$ and $\mathbf{A^3}$ and, thus, the different $\theta$ angles do not change the trend between $J_{12}$ and the number of exchange interactions.

# Reactivity of the Inversely Polarised Arsaalkenes R–As=C(NMe$_2$)$_2$ {R = [($\eta^5$-C$_5$Me$_5$)(CO)$_2$Fe], *t*BuC(O)} Towards Vinylidene Complexes [$\eta^5$-(C$_5$H$_5$)(CO)(NO)W=C=C(H)R] (R = Ph, *t*Bu)

**Lothar Weber,*[a] Philipp Bayer,[a] Gabriel Noveski,[a] Hans-Georg Stammler,[a] and Beate Neumann[a]**

**Keywords:** Arsaalkenes / Heteroallene ligands / Vinylidene complexes / Tungsten

The reaction of the vinylidene complexes [(C$_5$H$_5$)(CO)(NO)W=C=C(H)R] (**10a**: R = *t*Bu; **10b**: R = Ph) with the arsaalkene *t*BuC(O)–As=C(NMe$_2$)$_2$ (**11**) afforded the novel $\eta^2$-1-arsaallene complexes [$\eta^2$-{*t*BuC(O)–As=C=C(H)R}W(CO)(NO)C$_5$H$_5$] (**13**: R = *t*Bu; **15**: R = Ph). Similarly, treatment of **10a** with the ferrioarsaalkene [(C$_5$Me$_5$)(CO)$_2$Fe–As=C(NMe$_2$)$_2$] (**12**) led to the formation of [$\eta^2$-{[(C$_5$Me$_5$)(CO)$_2$Fe]–As=C=C(H)*t*Bu}W(CO)(NO)(C$_5$H$_5$)] (**14**), whereas combination of **12** and **10b** yielded the carbene complex [(C$_5$H$_5$)(CO)(NO)W=C(NMe$_2$)C(Ph)=C(H)NMe$_2$] (**16**) in high yield instead of the anticipated arsaallene complex. The novel compounds **13**, **14**, **15** and **16** were characterised by elemental analyses and by means of spectroscopy (IR, $^1$H, $^{13}$C NMR). Moreover, the molecular structures of **14** and **15** were elucidated by X-ray diffraction analyses.

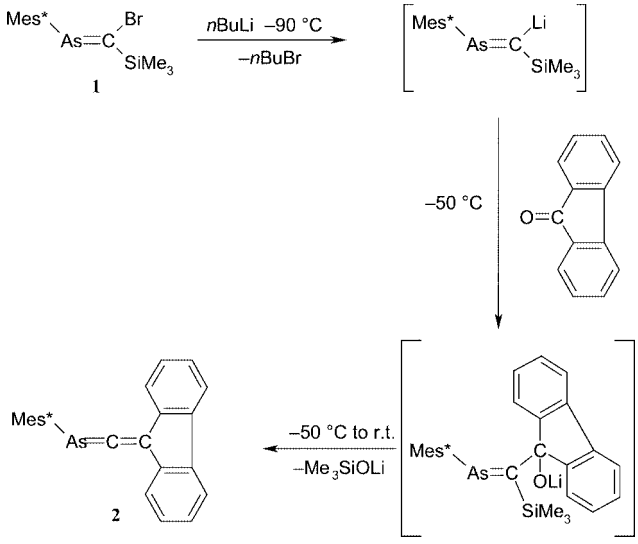
## Introduction

A considerable number of heteroallenes showing cumulated P=C and C=X bond systems[1] (X = CR$_2$,[2] NR,[2b,3] O,[2a,2d,4] PR[5]) have been described in the literature. Only those having bulky substituents at the phosphorus atom could be isolated and fully characterised. In some cases coordination to transition-metal complex fragments provides additional stability to such heterocumulenes.

In contrast to this, the chemistry of heterocumulenes with $\lambda^3$,$\sigma^2$-arsenic atoms is only poorly developed. The first stable arsaallene **2** has been synthesised from arsaalkene **1** and fluorenone in an organolithium-mediated condensation (Scheme 1).[6]



Scheme 1. Synthesis of arsaallene **2**.

The first and only arsaphosphaallene Mes*P=C=AsMes* (**5**) was synthesised from the reaction of phosphaalkene Mes*P=CBr$_2$ (**3a**) (Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_2$) with *n*-butyllithium followed by the addition of Mes*AsF$_2$ to give intermediate **4a**. Treatment of the latter with *n*-butyllithium and LiF elimination led to the heterocumulene[7] (Scheme 2). Similarly, the stable 1,3-diarsaallene **6** was synthesised from Mes*As=CBr$_2$ (**3b**) and Mes*AsF$_2$[8] (Scheme 2).

During the course of our studies on inversely polarised arsaalkenes of the type R–As=C(NMe$_2$)$_2$ we disclosed their properties to act as nucleophilic arsanediyl transfer reagents. Reaction of phosphavinylidene complexes [(C$_5$H$_5$)(CO)$_2$M=P=C(SiMe$_3$)$_2$] (M = Mo, W) with [Cp*(CO)$_2$Fe–As=C(NMe$_2$)$_2$], *t*BuC(O)–As=C(NMe$_2$)$_2$ or MesC(O)–As=C(NMe$_2$)$_2$ [Mes = 2,4,6-(CH$_3$)$_3$C$_6$H$_2$] afforded complexes **7** featuring novel $\eta^3$-2-phospha-1-arsaallyl ligands[9] (Scheme 3).

Employment of the less bulky arsaalkene 4-EtC$_6$H$_4$–As=C(NMe$_2$)$_2$ gave rise to the formation of complexes **8** and **9** depending upon the stoichiometry of the reaction[9b,9c] (Scheme 4).

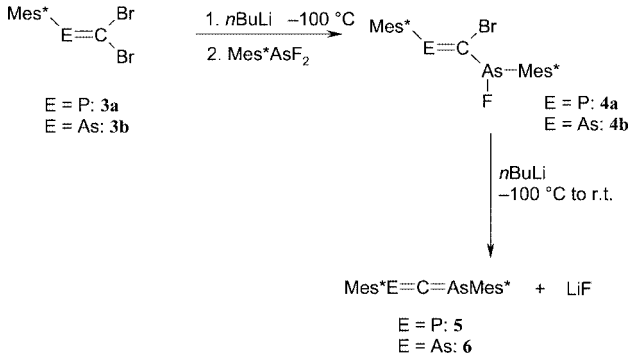
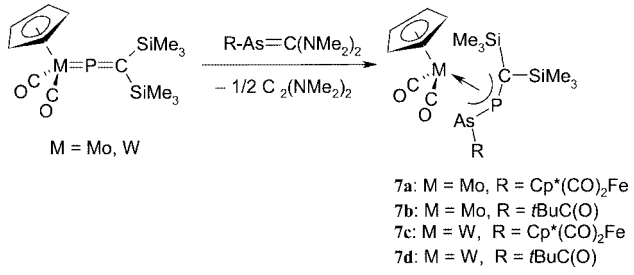


Scheme 2. Synthesis of heteroallenes **5** and **6**.



Scheme 3. Formation of 2-phospha-1-arsaallyl complexes **7a**–**d**.

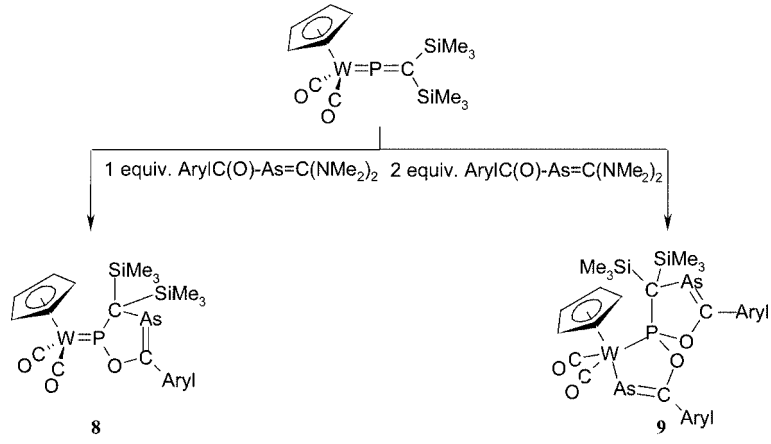
In order to explore the scope and limitations of inversely polarised arsaalkenes to formally act as a source for arsanediyl species, we extended our investigations from phosphavinylidene to the related vinylidene complexes.

## Results and Discussion

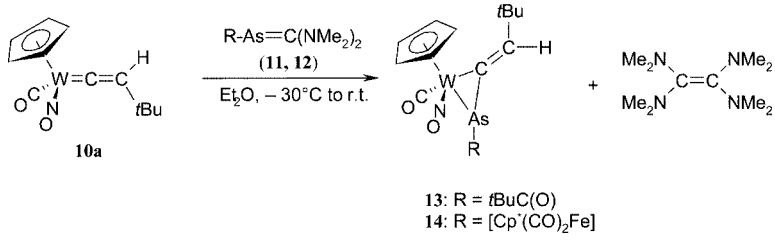
Treatment of complex [Cp(CO)(NO)W=C=C(H)*t*Bu] (**10a**)[10] with an equimolar amount of arsaalkenes R–As=C(NMe$_2$)$_2$ {**11**: R = *t*BuC(O);[9b] **12**: R = [Cp*(CO)$_2$-Fe][11]} in diethyl ether solution in the range of –30 °C to 20 °C afforded the crystalline $\eta^2$-1-arsaallene complexes **13** (50% yield) and **14** (73% yield), respectively. Purification of the products was effected by column chromatography on Florisil with diethyl ether (for **13**) or pentane (for **14**) as eluents. In case of product **14**, two isomers could be distinguished by NMR spectroscopy (Scheme 5).

The air- and moisture-sensitive complexes are well soluble in saturated hydrocarbons, ethereal and aromatic solvents. Tetrakis(dimethylamino)ethene was formed as a by-product. After removal of solvent from the reaction mixture, a few drops of the alkene were distilled off and identified by comparison of the $^1$H and $^{13}$C NMR spectra with those of an authentic sample.

In the $^1$H NMR spectrum of **13**, singlets at $\delta$ = 1.24, 1.25, 4.81 and 7.86 ppm were assigned to the protons of the two different *tert*-butyl groups, the Cp ligand and the exocyclic methylene group, respectively. These data and the absence of resonances because of the C(NMe$_2$)$_2$ fragment indicate the combination of the vinylidene unit of **10a** and the arsanediyl group of **11** to the novel ligand in product **13**. In the precursor molecule **10a** the protons of the $C_5H_5$ ring are much more deshielded ($\delta$ = 5.81, 5.83 ppm), whereas the signal of the hydrogen atom at the vinylidene unit was observed at significantly higher field ($\delta$ = 5.69,



Scheme 4. Synthesis of complexes **8** and **9** (Aryl = 4-Et$C_6H_4$).



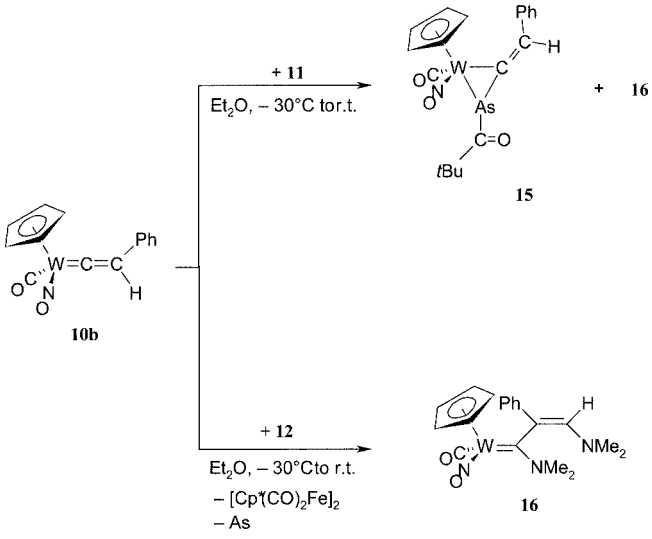
Scheme 5. Formation of the 1-arsaallene complexes **13**, **14**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

5.73 ppm). In the $^{13}C\{^1H\}$ NMR spectrum of **13**, singlets at $\delta$ = 174.8 and 158.3 ppm were assigned to the carbon atoms in β and α positions, respectively, of the arsaallene ligand. In **10a** these carbon atoms give rise to resonances at $\delta$ = 139.5, 140.0 and 338.4, 338.7 ppm. In the unsupported arsaallene **2**, singlets at $\delta$ = 255.8 and 129.1 ppm are due to the α- and β-C atoms, respectively, of the heteroallenic skeleton. The strong high-field shift of the α-C signal in going from **10a** to **13** points to the $\eta^2$-ligation of the As=C bond to the metal atom. The $^{13}C$ NMR signals of the terminal CO ligand and the acylic carbonyl group were observed at $\delta$ = 216.7 and 227.5 ppm, respectively. The significant low-field shift of the resonance of the CO ligand compared to precursor **10a** ($\delta$ = 210.8, 211.8 ppm) points to an improved donor capacity of the heteroallene ligand over the vinylidene system. This is also evident from the $\nu$(CO) bands in the IR spectrum of **13** ($\tilde{\nu}$ = 1982 $cm^{-1}$) and **10a** ($\tilde{\nu}$ = 2002 $cm^{-1}$).

Singlets in the $^1H$ NMR spectrum of the ferrioarsaallene complex **14** at $\delta$ = 1.35, 1.41; 1.51, 1.59; 5.08, 5.33 and 8.01, 8.03 ppm are readily assigned to the *tert*-butyl, methyl, cyclopentadienyl and vinylic protons, respectively, of two isomers. In the $^{13}C\{^1H\}$ NMR spectrum of **14**, the signals of the α-C atoms appeared as singlets at $\delta$ = 175.7 and 178.8 ppm with $^{13}C$-$^{183}W$ coupling constants of 109 and 118 Hz. Singlets at $\delta$ = 156.08 and 156.14 ppm were assigned to the carbon atoms in β-position. Carbonyl resonances at $\delta$ = 219.3 and 219.9 ppm are due to the W–CO unit whereas singlets at $\delta$ = 216.1, 216.9, 217.1 and 217.7 are due to the carbonyliron moieties.

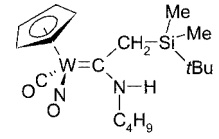
An analogous treatment of vinylidene complex **10b** with pivaloylarsaalkene **11** afforded the thermolabile complex **15** as orange crystals in 29% yield (Scheme 6).



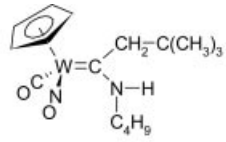
Scheme 6. Reaction of **10b** with arsaalkenes **11** and **12**.

In sharp contrast to this, reaction of **10b** with ferrioarsaalkene **12** did not lead to the expected arsaallene system. Instead, carbene complex **16** was isolated as red crystals in 69% yield. Elemental arsenic and complex $[Cp^*Fe(CO)_2]_2$ were obtained in 82% yield. According to the NMR spectra, product **15** was generated as one single isomer. Singlets in the $^1H$ NMR spectrum of **15** at $\delta$ = 1.24, 4.72 and 8.69 ppm are attributed to the hydrogen atoms at the *tert*-butyl group, the $C_5H_5$ ring and the vinylic unit, respectively. The carbon atoms of the arsaallene in α- and β-positions give rise to singlets at $\delta$ = 183.3 and 144.7 ppm, respectively. The resonances of the carbonyl ligand and the acylic CO group were observed as singlets at $\delta$ = 221.9 and 223.0 ppm, respectively. In comparison to precursor **10b** [$\tilde{\nu}$(CO) = 2010; $\tilde{\nu}$(NO) = 1654 $cm^{-1}$], the bands of the corresponding vibrations in **15** are bathochromically shifted [$\tilde{\nu}$(CO) = 1960; $\tilde{\nu}$(NO) = 1634 $cm^{-1}$].

The $^{13}C\{^1H\}$ NMR spectrum of **16** displays a singlet at $\delta$ = 260.8 ppm for the carbene carbon atom. This chemical shift is in good agreement with the corresponding signals of the aminocarbene complexes **17** ($\delta$ = 259.3; 259.7 ppm) or **18** ($\delta$ = 262.0 ppm).[12]



**17**



**18**

The methyl groups of the $Me_2N$ unit attached to the carbene centre are chemically and magnetically not equivalent giving rise to singlets at $\delta$ = 3.33 and 3.73 ppm in the $^1H$ NMR spectrum and $\delta$ = 44.4 and 49.3 ppm in the $^{13}C\{^1H\}$ NMR spectrum of **16**. Singlets at $\delta$ = 2.92 ppm in the $^1H$ NMR spectrum and $\delta$ = 42.6 ppm in the $^{13}C\{^1H\}$ spectrum are assigned to the $Me_2N$ group at the γ-carbon atom. The signal of the hydrogen atom at the C=C double bond was observed as a singlet at $\delta$ = 5.65 ppm. $^{13}C$ NMR singlets at $\delta$ = 140.6 and 118.8 ppm are due to the carbon atoms β-C and γ-C, respectively, of this double bond. A $^{13}C$ NMR singlet at $\delta$ = 233.2 ppm is attributed to the carbonyl ligand. This resonance is markedly low-field shifted in comparison to those of precursor **10b** and complex **15**, which reflects the pronounced donor capacity of the aminocarbene ligand. Accordingly, the $\nu$(CO) band in the IR spectrum of **16** is registered at $\tilde{\nu}$ = 1899 $cm^{-1}$, whereas the band for the nitrosyl stretching vibration appears at $\tilde{\nu}$ = 1768 $cm^{-1}$ and is hypsochromically shifted relative to those of **10b** [$\tilde{\nu}$(NO) = 1654 $cm^{-1}$] and **15** [$\tilde{\nu}$(NO) = 1634 $cm^{-1}$].

### X-ray Structural Investigations

Single crystals of **14** suitable for X-ray diffraction analysis were grown from diethyl ether at –30 °C.

The analysis (Figure 1, Table 1) displays a molecule with a distorted piano-stool geometry [As(1)–W(1)–C(6) =

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

67.8(1)°, C(6)–W(1)–N(1) = 93.2(2)°, N(1)–W(1)–C(7) = 92.7(1)°], with the nearly linear carbonyl and nitrosyl ligands [W(1)–C(6)–O(2) = 174.4(3)°, W(1)–N(1)–O(1) = 174.3(3)°]. The most interesting part of the molecule is the 1-arsaallene ligand, which is unsymmetrically linked to the metal atom in an $\eta^2$-fashion by bonds W(1)–As(1) [2.7145(3) Å] and W(1)–C(7) [2.165(3) Å]. The latter bond is significantly shorter than the W(1)–C distances of the [$C_5H_5W$] part of the molecule [2.353(3)–2.390(3) Å].

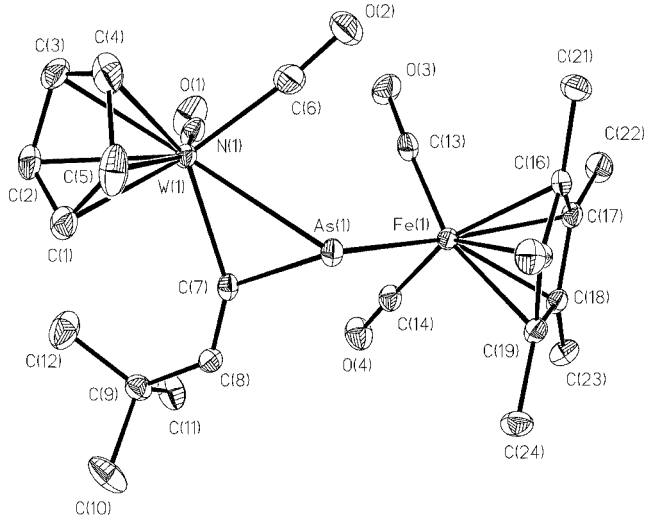


Figure 1. Molecular structure of **14** in the crystal. Selected bond lengths [Å] and angles [°]: W(1)–C(6) 2.004(4), W(1)–N(1) 1.809(3), W(1)–C(7) 2.165(3), W(1)–As(1) 2.7145(3), W(1)–C(1-5) 2.353(3)–2.390(3), As(1)–C(7) 1.911(3), As(1)–Fe(1) 2.4416(5), C(7)–C(8) 1.348(4); W(1)–C(6)–O(2) 174.4(3), W(1)–N(1)–O(1) 174.3(3), W(1)–C(7)–As(1) 52.4(1), W(1)–C(7)–C(8) 147.8(2), C(7)–W(1)–As(1) 44.4(1), C(7)–W(1)–N(1) 92.7(1), N(1)–W(1)–C(6) 93.2(1), C(6)–W(1)–As(1) 67.8(1), W(1)–As(1)–Fe(1) 119.5(2), W(1)–As(1)–C(7) 52.4(1), As(1)–C(7)–C(8) 129.0(2), Fe(1)–As(1)–C(7) 112.9(1).

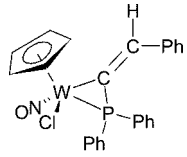
The bond length W(1)–C(7) is comparable to that in complex **19** [2.178(7) Å][13] but much smaller than in the ($\eta^3$-2-phospha-1-arsaallyl)tungsten complex **7d** [2.439(2) Å].[9b]



**19**

Thus, the situation of a π-complex involving the W-atom and As=C double bond is not reflected satisfactorily by the structural data of **14**. Moreover, inspection of W=C bond lengths in a series of (carbene)tungsten complexes [1.859(4)–2.23(2) Å][14] reveals some WC multiple bonding in our new complex. The separation W(1)–As(1) [2.7145(3) Å] is similar to the endocyclic bonds W(2)–As(1) [2.697(5) Å] and W(2)–As(2) [2.696(4) Å] determined in the diarsene complex **20**, whereas the exocyclic contacts W(1)–As(1) [2.638(5) Å] and W(3)–As(2) [2.626(5) Å] are slightly shorter.[15] The endocyclic bond length As(1)–C(7) [1.911(3) Å] may be envisaged as a multiple bond elongated

Table 1. Crystal data and data collection parameters.

| Compound | **14** | **15** |

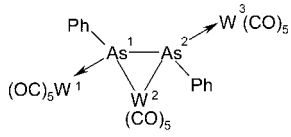
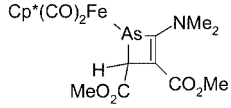
by π-coordination. Generally, unsupported As=C bond lengths in acyclic arsaalkenes range from 1.789(3) Å in (*Z*)-Mes*As=C(Br)SiMe$_3$[6] to 1.867(9) Å in *t*Bu–As=C(F)-NEt$_2$.[16] For the As=C distance in 1-arsaallene **2** an even shorter value [1.754(2) Å] was determined.[6] The iron–arsenic bond of 2.4416(5) Å in **14** is markedly longer than in the 2-phospha-1-arsaallyl complex **7a** [2.4098(4) Å][9b] or in the ferrioarsacyclobutene **21** [2.396(1)].[11]



**20**



**21**

The carbon–carbon double bond C(7)–C(8) [1.348(4) Å] in **14** is lengthened with respect to the one in **2** [1.314(3) Å].[6] The angle As(1)–C(7)–C(8) of 129.0(2)° is strongly compressed when compared with the one in 1-arsaallene **2** [169.72(19)°]. Carbon atom C(8) is located in the plane defined by the atoms W(1), As(1) and C(7). Thereby the As atom is roughly placed in a *trans* disposition to the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nitrosyl ligand, whereas C(7) and the carbonyl group are *trans*-oriented.

Single crystals of complex **15** were grown from a diethyl ether solution at –30 °C. As given with compound **14**, the X-ray analysis displays an arsaallene ligand attached to the metal centre whereby a three-membered metalloheterocycle of atoms W(1), As(1) and C(1) is formed (Figure 2, Table 1).

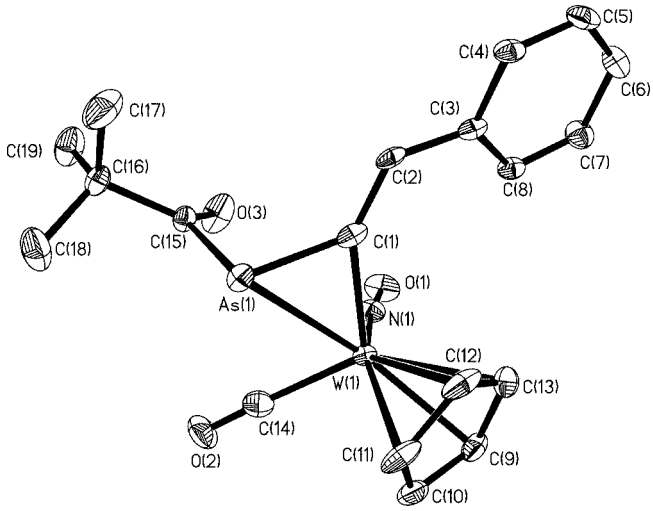


Figure 2. Molecular structure of **15** in the crystal. Selected bond lengths [Å] and angles [°]: W(1)–C(14) 2.034(7), W(1)–N(1) 1.806(5), W(1)–C(1) 2.134(6), W(1)–As(1) 2.690(1), W(1)–C(9-13) 2.336(6)–2.388(7), As(1)–C(1) 1.909(6), As(1)–C(15) 2.065(6), C(15)–O(3) 1.207(7), C(1)–C(2) 1.360(9), C(2)–C(3) 1.472(9), O(2)–C(14) 1.137(8), N(1)–O(1) 1.216(7); N(1)–W(1)–C(14) 88.3(3), N(1)–W(1)–C(1) 93.0(2), C(14)–W(1)–As(1) 73.3(2), N(1)–W(1)–As(1) 110.8(2), W(1)–As(1)–C(15) 101.2(2), C(1)–As(1)–C(15) 95.4(2), As(1)–C(15)–C(16) 114.5(4), As(1)–C(15)–O(3) 122.4(5), C(16)–C(15)–O(3) 123.0(6), As(1)–C(1)–C(2) 131.6(5), C(1)–C(2)–C(3) 129.6(6), W(1)–C(14)–O(2) 176.8(6), W(1)–N(1)–O(1) 174.0(5), W(1)–C(1)–C(2) 145.2(5).

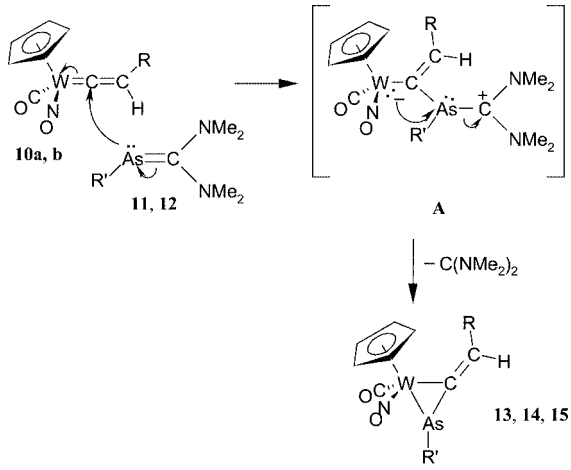
The structural parameters of **15** are essentially the same as in complex **14**, with bond lengths of W(1)–As(1) = 2.690(1) Å, W(1)–C(1) = 2.134(6) Å and As(1)–C(1) = 1.909(6) Å. The single bond length As(1)–C(15) of 2.065(6) Å is on the upper end of the range 1.97–2.00 Å, usually determined for such single bonds, and matches well with the corresponding bond in **7d** [2.063(2) Å]. In precursor *t*BuC(O)–As=C(NMe$_2$)$_2$ the respective As–C(O) bond is considerably shorter [1.938(4) Å],[17] which may be due to some π-delocalisation with the As=C bond. The angle As(1)–C(1)–C(2) [131.6(5)°] is comparable to that in **14**. Atoms As(1), C(1) and C(2) constitute a plane to which vector As(1)–C(15) forms an angle of 100.4°. The phenyl ring is twisted out of the plane through the atoms As(1), C(1), C(2) and C(3) by 18.9°.

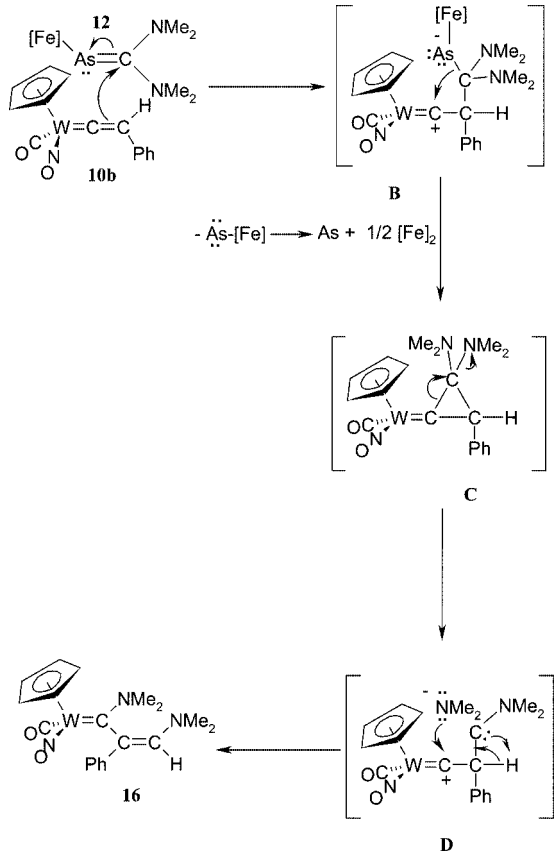
## Mechanistic Considerations

In line with previous observations concerning the electrophilicity of the α-C atom in vinylidene complexes it is conceivable that the formation of complexes **13**–**15** is initiated by the nucleophilic attack of arsaalkenes **11** or **12** by their As atom on this C atom of **10a**,**b** to give adduct **A**. Ring closure and extrusion of the carbene lead to the final products **13**, **14** and **15** (Scheme 7).



Scheme 7. Proposed mechanism for the formation of **13**, **14** and **15** {R = Ph, *t*Bu; R′ = *t*BuC(O), [Cp*(CO)$_2$Fe]}.

The formation of the aminocarbene complex **16** may be initiated by the electrophilic attack of arsaalkene **12** through its electrophilic carbon atom at the nucleophilic β-C atom of **10b** affording zwitterion **B**, from which a ferrioarsanediyl moiety is liberated to give the cyclopropanediyl complex **C**. Dissociation of a dimethylamide ion and ring opening afford carbene **D**. The addition of the dimeth-



Scheme 8. Proposed mechanism for the formation of **16**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ylamide ion at the α-C atom and a 1,2-hydrogen shift give the final product **16** (Scheme 8).

## Conclusions

The previously observed transition-metal-induced cleavages of inversely polarised arsaalkenes to give cyclotriarsanes,[18] an $\eta^2$-diarsene complex[19] or $\eta^3$-1-arsa-2-phosphaallyl complexes[9] were extended to the smooth generation of $\eta^2$-1-arsaallene complexes **13**, **14** and **15**, which underline the ability of arsaalkenes to act as convenient sources for arsanediyl (arsinidene) units under mild conditions.

## Experimental Section

**General:** All manipulations were performed under dry, oxygen-free nitrogen using standard Schlenk techniques. Solvents were rigorously dried with an appropriate drying agent and freshly distilled under $N_2$ before use. The following compounds were prepared according to literature procedures: $[Cp(CO)_2(NO)W]$,[20] $[Cp^*(CO)_2Fe–As=C(NMe_2)_2]$ (**12**),[11] $Me_3Si–As=C(NMe_2)_2$.[11] IR spectra: Bruker FTIR VECTOR 22. $^1H$, $^{13}C$ NMR spectra in $C_6D_6$ at room temperature; Bruker AM Avance DRX 500 ($^1H$: 500.13 Hz; $^{13}C$: 125.75 MHz); reference: $SiMe_4$. Florisil (Merck), pivaloyl chloride, phenylacetylene and *tert*-butylacetylene were purchased commercially.

**Improved Synthesis of 10a and 10b:** A solution of *n*BuLi (1.6 M) in hexane (12.5 mL, 20 mmol) was added dropwise to a chilled solution (–30 °C) of *tert*-butylacetylene (1.64 g, 20 mmol) or phenylacetylene (2.04 g, 20 mmol) in diethyl ether (60 mL). The solution of R–C≡CLi was slowly warmed up to 20 °C, then transferred into a dropping funnel and added dropwise to a solution of $[Cp(CO)_2(NO)W]$ (5.02 g, 15 mmol) in cold diethyl ether (–30 °C, 100 mL). After stirring at –30 °C for 5 h, the solution was warmed up to 0 °C and concentrated HCl (3 mL), diluted with oxygen-free water (50 mL), was added. The organic phase was separated, washed with saturated aqueous sodium hydrogen carbonate (30 mL) and saturated aqueous sodium chloride (30 mL). After removal of solvents under reduced pressure, compounds **10a** (5.72 g, 98%) and **10b** (5.89 g, 96%) were isolated as red solids. The spectroscopic data of the products are identical to those reported in the literature.[10]

**[Cp(CO)(NO)W{η²-*t*BuC(O)AsC=C(H)*t*Bu}] (13):** A chilled solution (–30 °C) of arsaalkene **11** (1.81 mmol) in diethyl ether (20 mL) was added dropwise to a well-stirred cold solution (–30 °C) of complex **10a** (0.70 g, 1.81 mmol) in diethyl ether (25 mL). It was slowly warmed to ambient temperature and stirring was continued for 12 h. The reaction mixture was freed from solvent and volatile components. The black residue was dissolved with diethyl ether (10 mL), then Florisil (5 g) was added and the slurry was concentrated to dryness. The coated Florisil was transferred on top of a column ($d$ = 1.5 cm, $l$ = 6 cm) charged with Florisil (20 g). A yellow zone was eluted with diethyl ether. Removal of the solvent from the eluate afforded yellow microcrystalline **13** (0.50 g, 50%). IR (KBr): $\tilde{\nu}$ = 1982 (C≡O), 1693 (C=O), 1649 (N=O) $cm^{-1}$. $^1H$ NMR: $\delta$ = 1.24 (s, 9 H, *t*Bu), 1.25 (s, 9 H, *t*Bu), 4.81 (s, 5 H, Cp), 7.86 (s, 1 H, *t*BuC*H*) ppm. $^{13}C\{^1H\}$ NMR: $\delta$ = 25.5 [s, $(CH_3)_3C$], 26.6 [s, $(CH_3)_3C$], 37.8 [s, $(CH_3)C$], 51.2 [s, $(CH_3)_3C$], 96.0 (s, Cp), 158.3 (s, $C_\beta$), 174.8 (s, $C_\alpha$), 216.7 (s, C≡O), 227.5 (s, C=O) ppm. $C_{17}H_{24}AsNO_3W$ (569.15): calcd. C 37.18, H 4.40, N 2.55; found C 36.88, H 4.15, N 2.99.

**[Cp(CO)(NO)W{η²-[Cp*(CO)₂Fe]AsC=C(H)*t*Bu}] (14):** Analogously, combination of **12** (0.76 g, 1.81 mmol) in diethyl ether (20 mL) with **10a** (0.70 g, 1.81 mmol) in diethyl ether (25 mL) at –30 °C and similar work up (Florisil, pentane) afforded dark red crystalline **14** (0.94 g, 73%). IR (KBr): $\tilde{\nu}$ = 1973, 1943, 1917 (C≡O), 1620 (N=O) $cm^{-1}$. $^1H$ NMR [two isomers (2:1)]; first isomer: $\delta$ = 1.41 (s, 9 H, *t*Bu), 1.59 (s, 15 H, $Me_5C_5$), 5.08 (s, 5 H, Cp), 8.01 (s, 1 H, *t*BuC*H*) ppm; second isomer: $\delta$ = 1.35 (s, 9 H, *t*Bu), 1.51 (s, 15 H, $Me_5C_5$), 5.33 (s, 5 H, Cp), 8.03 (s, 1 H, *t*BuC*H*) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 9.4 (s, $C_5Me_5$), 9.5 (s, $C_5Me_5$), 30.6 [s, $C(CH_3)_3$], 31.5 [s, $C(CH_3)_3$], 36.3 [s, $C(CH_3)_3$], 37.9 (s, $C(CH_3)_3$), 95.1 (s, $C_5Me_5$), 95.7 (s, $C_5Me_5$), 96.3 (s, $C_5H_5$), 96.8 (s, $C_5H_5$), 156.1 (s, $C_\beta$), 156.1 (s, $C_\beta$), 175.7 (s, $C_\alpha$, $J_{CW}$ = 109 Hz), 178.8 (s, $C_\alpha$, $J_{CW}$ = 118 Hz), 216.1 (s, FeCO), 216.9 (s, FeCO), 217.1 (s, FeCO), 217.7 (s, FeCO), 219.3 (s, WCO), 219.9 (s, WCO). $C_{24}H_{30}AsFeNO_4W$ (711.11) calcd. C 40.54, H 4.25, N 1.97; found C 40.54, H 4.35, N 2.00.

**[Cp(CO)(NO)W{η²-*t*BuC(O)AsC=C(H)Ph}] (15):** A chilled solution (–30 °C) of arsaalkene **11** (1.81 mmol) in diethyl ether (20 mL) was added dropwise to a well-stirred cold solution (–30 °C) of complex **10b** (0.74 g, 1.81 mmol) in diethyl ether (25 mL). Stirring at –30 °C was continued for 4 h before the reaction mixture was slowly warmed to room temperature. The solvent was removed in vacuo and the brown residue was dissolved in diethyl ether (10 mL). Florisil (5 g) was added and the slurry was concentrated to dryness. As described before, the crude material was chromatographed on a Florisil column ($d$ = 1.5 cm, $l$ = 6 cm) charged with Florisil (20 g). An orange zone was eluted with a pentane/diethyl ether mixture (5:1). Removal of solvents from the eluate afforded orange crystalline thermolabile **15** (0.30 g, 29%). IR (KBr): $\tilde{\nu}$ = 1960 (C≡O), 1634 (br., N=O, C=O) $cm^{-1}$. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.24 (s, 9 H, *t*Bu), 4.72 (s, 5 H, Cp), 7.08 (t, $J_{(H,H)}$ = 7.5 Hz, 1 H, Ph), 7.20 (t, $J_{(H,H)}$ = 7.5 Hz, 2 H, Ph), 7.60 (d, $J_{(H,H)}$ = 7.5 Hz, 2 H, Ph), 8.69 (s, 1 H, PhC*H*) ppm. $^{13}C\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 31.0 [s, $(CH_3)_3C$], 38.4 [s, $(CH_3)_3C$], 96.5 (s, Cp), 127.2 (s, Ph), 128.4 (s, Ph), 128.5 (s, Ph), 142.1 (s, Ph), 144.7 (s, $C_\beta$), 183.3 (s, $C_\alpha$), 221.9 (s, C=O), 223.0 (s, C≡O) ppm. $C_{19}H_{20}AsNO_3W$ (569.13): calcd. C 40.10, H 3.54, N 2.46; because of the pronounced thermolability of the compound it was not possible to obtain reliable elemental analyses. A second, orange zone was diluted with diethyl ether to obtain a few crystals of compound **16**.

**Cp(CO)(NO)W=C(NMe₂)C(C₆H₅)=C(H)NMe₂ (16):** A chilled solution (–30 °C) of arsaalkene **12** (0.76 g, 1.81 mmol) in diethyl ether (20 mL) was added dropwise to a well-stirred cold solution (–30 °C) of complex **10b** (0.74 g, 1.81 mmol) in diethyl ether (25 mL). It was slowly warmed to ambient temperature and stirring was continued for 12 h. The reaction mixture was freed from solvent and volatile components. The black residue was dissolved with diethyl ether (10 mL) and filtered. The residue was identified as elemental arsenic. Florisil (5 g) was then added to the solution and the slurry was concentrated to dryness. The coated Florisil was transferred on top of a column ($d$ = 1.5 cm, $l$ = 6 cm) charged with Florisil (20 g). A deep red zone was eluted with pentane. Removal of the solvent from the eluate afforded black microcrystalline $[Cp^*Fe(CO)_2]_2$ (0.45 g, 82%). A second, orange zone was eluted with diethyl ether. Removal of solvents to the beginning of crystallisation and storage at –30 °C yielded **16** (0.64 g, 69%) as red crystals. IR (KBr): $\tilde{\nu}$ = 1899 (C≡O), 1768 (N=O) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.92 (s, 6 H, $NMe_2$), 3.33 (s, 3 H, $NMe_2$), 3.73 (s, 3 H, $NMe_2$), 5.41 (s, 5 H, Cp), 5.65 (s, 1 H, PhC=C*H*), 6.89 (d, $J_{(H,H)}$

= 7.5 Hz, 2 H, Ph), 7.02 (t, $J_{(H,H)}$ = 6.9 Hz, 1 H, Ph), 7.20 (t, $J_{(H,H)}$ = 7.5 Hz, 2 H, Ph) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 42.6 (s, $NMe_2$), 44.4 (s, $NMe_2$), 49.3 (s, $NMe_2$), 96.0 (s, Cp), 118.8 (s, $C_\gamma$) 124.3 (s, Ph), 128.4 (s, Ph), 128.6 (s, Ph), 129.3 (s, Ph), 140.6 (s, $C_\beta$), 233.2 (s, CO), 260.8 (s, $C_\alpha$) ppm. $C_{19}H_{23}N_3O_2W$ (509.26): calcd. C 44.81, H 4.55, N 8.25; found C 44.77, H 4.43, N 8.28.

**X-ray Crystallography:** Crystallographic data were collected with a Nonius Kappa CCD diffractometer with Mo-$K_\alpha$ (graphite monochromator, $\lambda$ = 0.71073 Å) at 100 K. Crystallographic programs used for structure solution and refinement were from SHELXS-97,[21] SIR-97[22] and SHELXL-97.[21] The structures were solved by direct methods and were refined by using full-matrix least squares on $F^2$ of all unique reflections with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were included at calculated positions with $U$(H) = 1.2$U_{eq}$ for $CH_2$ groups and $U$(H) = 1.5$U_{eq}$ for $CH_3$ groups. Crystal data of the compounds are listed in Table 1. CCDC-297420 (for **14**) and -297421 (for **15**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Characterization of Zirconium and Hafnium Aryloxide Compounds and Their Reactivity Towards Lactide and ε-Caprolactone Polymerization

**Kun-Chun Hsieh,[a] Wen-Yi Lee,[a] Li-Feng Hsueh,[a] Hon Man Lee,[a] and Jui-Hsien Huang*[a]**

**Keywords:** Hafnium aryloxide / Zirconium aryloxide / Lactide / Caprolactone / Hafnium / Zirconium

Reactions of 2 equiv. pyrrole with $[C_4H_3N(CH_2NMe_2)\text{-}2]_2M(NEt_2)_2$ in toluene generated tetra-pyrrolyl metal compounds $[C_4H_3N(CH_2NMe_2)\text{-}2]_2M(C_4H_4N)_2$ (**3**, M = Zr; **4**, M = Hf) in moderate yields. Similarly, treatment of metal amides $[C_4H_3N(CH_2NMe_2)\text{-}2]_2M(NEt_2)_2$ with 2,6-dimethylphenol or 2,6-diisopropylphenol in heptane resulted in the elimination of diethylamine along with the formation of the corresponding metal alkoxides $[C_4H_3N(CH_2NMe_2)\text{-}2]_2M(OR)_2$ (**5**, M = Zr, R = $C_6H_3$-2,6-$Me_2$; **6**, M = Hf, R = $C_6H_3$-2,6-$Me_2$; **7**, M = Zr, R = $C_6H_3$-2,6-*i*$Pr_2$; **8**, M = Hf, R = $C_6H_3$-2,6-*i*$Pr_2$) in moderate yields. All the new compounds were characterized by $^1H$ and $^{13}C$ NMR spectroscopy and the structures of **3**, **4**, **6**, **7**, and **8** have also been determined by X-ray crystallographic studies. The aryloxides and the substituted pyrrolyl ligands in both compounds **5** and **6** show fluxionality as observed by $^1H$ NMR signals. A kinetic study on the ring-opening polymerization of lactide exhibits a first-order reaction of lactide monomer with compound **8**. The catalytic properties of all the metal complexes have been studied for the ring-opening polymerization of ε-caprolactone.

## Introduction

Poly-ε-caprolactone (PCL) and polylactide (PLA) are considered as biodegradable polyesters for medical and ecological applications.[1–4] PCL and PLA are mainly synthesized by ring-opening polymerization using $Sn(OR)_2$ as catalysts.[5–8] However, the study of polyesters generated from ring-opening polymerization using non-tin metal alkoxides as catalysts has just started to attract researchers' attention. Among those metal alkoxides, aluminum,[9–15] lithium,[16,17] titanium,[18–21] and some lanthanide metals[22–27] have been studied by different groups. We have previously examined the ring-opening polymerization of ε-caprolactone and lactide with aluminum alkoxides supported by monoanionic bidentate ketiminate ligands.[28] Herein we report the synthesis and characterization of zirconium and hafnium metal complexes containing substituted pyrrolyl ligands and their applications as catalysts on the ring-opening polymerization of ε-caprolactone and lactide.

## Results and Discussion

### Synthesis of Compounds 1–8

The zirconium and hafnium amide complexes $[C_4H_3N(CH_2NMe_2)\text{-}2]_2M(NEt_2)_2$ (**1**, M = Zr; **2**, M = Hf) were prepared following the published procedures (see experimental section) by treatment of $M(NEt_2)_4$ with 2 equiv. of substituted pyrrolyl ligands (Scheme 1). Reactions of 2 equiv. pyrrole with **1** and **2** in toluene generated tetrapyrrolyl metal compounds $[C_4H_3N(CH_2NMe_2)\text{-}2]_2M(C_4H_4N)_2$ (**3**, M = Zr; **4**, M = Hf) in moderate yields. Similarly, treatment of metal amides **1** and **2** with a stoichiometric amount of 2,6-dimethylphenol or 2,6-diisopropylphenol in heptane resulted in the elimination of diethylamine with the formation of the corresponding metal alkoxides $[C_4H_3N(CH_2NMe_2)\text{-}2]_2M(OR)_2$ (**5**, M = Zr, R = $C_6H_3$-2,6-$Me_2$; **6**, M = Hf, R = $C_6H_3$-2,6-$Me_2$; **7**, M = Zr, R = $C_6H_3$-2,6-*i*$Pr_2$; **8**, M = Hf, R = $C_6H_3$-2,6-*i*$Pr_2$) in moderate yields (Scheme 1). The resulting metal alkoxide compounds **3**–**8** were characterized by $^1H$ and $^{13}C$ NMR spectroscopy.

### Molecular Structures for Compounds 3, 4, 6, 7, and 8

Compounds **3**, **4**, **6**, **7**, and **8** were structurally characterized and selected bond lengths and angles are listed in Table 1. The molecular geometries are shown in Figure 1, Figure 2, Figure 3, Figure 4, and Figure 5 where the molecular geometries are highly dependent on the steric hindrance of the ligands. Compounds **3**, **4**, **6**, and **8** all contain solvent molecules in their unit cells. For compound **4**, there are two independent molecules in the asymmetrical unit. However, the bond lengths and angles of the two molecules are very similar; therefore, only one molecule is discussed

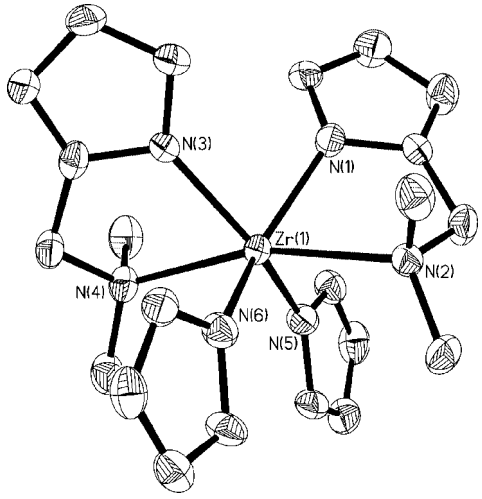

Figure 1. The molecular structure for compound **3**; thermal ellipsoids were drawn at 50% probability level. Toluene and hydrogen atoms were omitted for clarity.

here. The structures for compounds **3**, **4**, and **6**, with less steric congestion, are quite similar and show a highly distorted octahedral geometry, which can also be described as an *anti*-trigonal prism. The two nitrogen atoms of the dimethylamino fragments in compounds **4** and **6** have *trans* positions with bond angles of 162.1(2)° and 159.24(19)°, respectively. The sterically congested compounds **7** and **8** exhibit regular octahedral geometries. For the sterically congested compound **8**, the aryloxide ligands are *trans* to the dimethylamino fragments and the two pyrrolyl fragments are *trans* to each other; where the bond angles of the three axes for the octahedral geometry are 170.47(7)°,

### NMR Study of the Structures in Solution

For compounds **3** and **4**, the $^1$H NMR spectra of the 2-[(dimethylamino)methyl] fragments at room temperature exhibit sharp singlets for the methylene and methyl protons at $\delta$ = 3.60 and 2.43 ppm for **3** and $\delta$ = 3.18 and 1.87 ppm for **4**. The proton-coupled $^{13}$C NMR spectra of the methylene fragments for compounds **3** and **4** both show a triplet resonance at $\delta$ = 62.6 and 62.5 ppm with $^1J_{CH}$ coupling constants of 136 and 139 Hz, respectively. In the solid-state structures of **3** and **4**, there is nonsymmetrical geometry; the $NMe_2$ and the $NCH_2$ of the substituted pyrrolyl ligands, and the NCH and CCHC of the pyrrolide anion should have different resonance signals. However, the room temperature NMR spectroscopic data for **3** and **4** indicate either the solution structures are different from the solid ones and/or equilibria are occurring. In order to elucidate eventual dynamic phenomena (rotation of the pyrrolide anions) and/or the *cis*/*trans* isomerization of the complex, a variable temperature NMR investigation and $^1$H–$^1$H NOESY spectra were carried out. The results show the resonance signals for the substituted pyrrolyl ligands and pyrrolides remain unchanged at 250 K, which indicates a fast rotation of the pyrrolide anions and a fast equilibrium of the *cis*/*trans* isomerization must exist at the same time.

The bulkiness of the aryloxide groups indeed affects the M–O bond rotation rate and the fluxionality of the substituted pyrrolyl ligands. The methyl fragments of the aryloxides and the dimethylaminomethyl groups in compounds **5** and **6** show broad $^1$H NMR signals at room temperature. Use of bulkier 2,6-diisopropylphenyl groups in compounds **7** and **8** results in greater stereorigidity of the molecular structures in which the methyl groups of the isopropyl fragments were split into four doublet signals, whereas the methyl groups of the dimethylamino fragments were split into two singlets. For compound **6**, $^1$H, $^{13}$C and $^1$H–$^{13}$C HSQC NMR spectra were recorded in the range of 320–250 K in $CDCl_3$ with a 300 MHz NMR spectrometer in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

order to resolve its structure in solution at various temperatures. Variable temperature $^1$H NMR spectra of compound **6** are shown in Figure 6. The $^1$H and $^1$H–$^{13}$C HSQC NMR spectra clearly identified that the methyl groups of aryloxides and dimethylamino fragments appeared as sharp singlets at $\delta$ = 2.22 and 2.46 ppm, respectively, at 320 K. The methylene protons of the $CH_2NM_2$ fragments also show a sharp singlet at 320 K. The methyl groups of the aryloxides and dimethylamino fragments were split into complicated singlets at $\delta$ = 2.45, 2.58, 2.51, 2.30, 2.02, and 1.40 when the temperature was lowered to 250 K. Similarly, the methylene protons of the $CH_2NM_2$ fragments showed splitting of signal from a sharp singlet at $\delta$ = 3.87 to a complicated overlapping of two doublets and a broad singlet when the temperatures were lowered from 320 to 250 K. The observed patterns at 250 K are indicative of complex solution dynamics. As far as the $NCH_2$ signal is concerned, the splitting of the singlet at room temperature into two doublets and a singlet at low temperature could indicate that two isomers, namely *cis* and *trans*, may be present in solution at low temperature. The two doublets may result from a solution structure similar to the solid state one (the *cis* form) and the singlet may result from a more symmetrical solution structure such as a more symmetrical pseudo-$C_2$ symmetry of *trans* geometry (the *trans* form with the phenoxide anions in an axial arrangement and the bidentate ligands in the equatorial plane with an unpredictable mutual arrangement). Interestingly, in accordance with this, six methyl resonances are observed and assignable to (i) the two nonequivalent methyls of the phenoxide anions; (ii) the two nonequivalent $NMe_2$ methyls of the *cis* isomers; and (iii) the $NMe_2$ moiety and the two equivalent methyls of the reasonably freely rotating phenoxide of the *trans* isomer. A $^1$H NOESY experiment of **6** was performed at 250 K; however, because of the complication of methyl resonances we are unable to determine the *cis* and *trans* forms of **6**.[35]

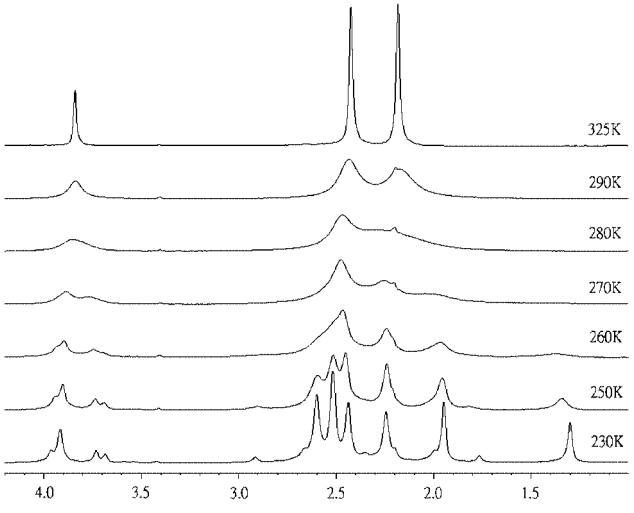

Figure 6. Variable $^1$H NMR spectra of compound **6** in $CDCl_3$ using a 300 MHz NMR spectrometer. Spectra ranges are drawn in the range of $\delta$ = 1.0–4.2.

### Kinetic Study of Lactide Polymerization Initiated by 8

The reactions of **8** with *rac* lactides proceeded in $CDCl_3$ at 70 °C and were monitored with a $^1$H NMR spectrometer. The consumptions of lactide were measured from the integration of the $^1$H NMR signals. Plots of ln([lactide]$_0$/[lactide]) versus time give straight lines (Figure 7), indicating the lactide polymerization is first-order with respect to the monomer.[36]

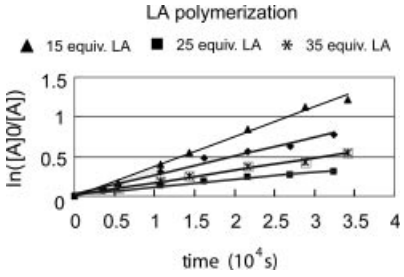

Figure 7. Plot of ln([lactide]$_0$/[lactide]) vs. time for the reaction of **8** with *rac* lactide in $CDCl_3$ at 70 °C.

### Polymerization of ε-Caprolactone

Polymerizations of ε-caprolactone by using zirconium or hafnium complexes as catalysts have been seen in the literature.[37–39] Here we use the synthesized metal complexes as catalysts to study their reactivity toward ε-caprolactone. All the compounds have been studied as catalysts for the ring-opening polymerization of ε-caprolactone. The results of polymerization studies of ε-caprolactone initiated by compounds **3**–**8** are shown in Table 2. It is found that compounds **3**–**8** catalyzed the ring-opening polymerization of ε-caprolactone to give a moderate molecular weight of PCL (range 11000–53000) with a rather broad molecular weight distribution (PDI = 1.38–2.63). There are no noticeable differences toward the ring-opening polymerization relating to metals (Zr or Hf) or bulkiness of the substituted aryloxides and pyrrolyl ligands of compounds **3**–**8**.

Table 2. Ring-opening polymerization of ε-caprolactone initiated by complexes **3**–**8**.

| Entry | Catalyst | [M]/[cata] | *T* (°C) | Yield (%) | Mn | PDI |
|---|---|---|---|---|---|---|
| 1 | **3** | 100 | 25 | 96 | 18457 | 2.63 |
| 2 | **3** | 100 | 65 | 98 | 15612 | 2.38 |

| 8 | **8** | 100 | 50 | 94 | 10907 | 1.23 |

## Experimental Section

**General Procedure:** All reactions were performed under dry nitrogen using standard Schlenk techniques or in a glovebox. Toluene, heptane, diethyl ether, and tetrahydrofuran were dried by refluxing over sodium benzophenone ketyl. $CH_2Cl_2$ was dried with $P_2O_5$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

All solvents were distilled and stored in solvent reservoirs which contained 4 Å molecular sieves and were purged with nitrogen. $^1$H and $^{13}$C NMR spectra were recorded with a Bruker AC 200 or an Avance 300 spectrometer. Chemical shifts for $^1$H and $^{13}$C spectra were recorded in ppm relative to the residual protons and $^{13}$C of $CDCl_3$ ($\delta$ = 7.24, 77.0) and $C_6D_6$ ($\delta$ = 7.16, 128.0). Elemental analyses were performed with a Heraeus CHN-OS Rapid Elemental Analyzer at the Instrument Center, NCHU. $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Zr(NEt_2)_2$, $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Hf(NEt_2)_2$,[40,41] $C_4H_3NH(CH_2NMe_2)\text{-}2$,[42,43] and $M(NEt_2)_4$ (M = Zr, Hf)[44] were prepared according to previously reported procedures.

**$[C_4H_3N(CH_2NMe_2)\text{-}2]_2Zr(NC_4H_4)_2$ (3):** Pyrrole (0.1 mL, 1.44 mmol) was added to a solution of $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Zr(NEt_2)_2$ (0.345 g, 0.72 mmol) in toluene (15 mL) at 0 °C with a micro syringe. The solution was stirred at room temperature for 10 h after the addition was completed. The volatiles were removed under vacuum, and the residue was recrystallized from a toluene solution to yield 0.181 g of colorless crystals in 53.9% yield. $^1$H NMR ($CDCl_3$): $\delta$ = 2.43 (s, 12 H, N*Me*$_2$), 3.60 (s, 4 H, C*H*$_2$N), 5.97 (m, 2 H, pyrrolyl C*H*), 6.17 (m, 6 H, pyrrolyl C*H*), 6.70 (m, 4 H, pyrrolyl C*H*), 6.97 (m, 2 H, pyrrolyl C*H*) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 47.1 (q, $J_{CH}$ = 138 Hz, N*Me*$_2$), 62.6 (t, $J_{CH}$ = 136 Hz, *C*H$_2$N), 104.2 (d, $J_{CH}$ = 167 Hz, pyrrolyl *C*H), 109.2 (d, $J_{CH}$ = 168 Hz, pyrrolyl *C*H), 125.5 (d, $J_{CH}$ = 179 Hz, pyrrolyl *C*H), 127.7 (d, $J_{CH}$ = 190 Hz, pyrrolyl *C*H), 135.9 (s, pyrrolyl *C*$_{ipso}$) ppm. One pyrrolyl carbon resonance was not observed because of overlapping ($\delta$ = 109.2 ppm). $C_{22}H_{30}N_6Zr$ (467.74): calcd. C 56.25, H 6.44, N 17.89; found C 55.83, H 6.53, N 17.85.

**$[C_4H_3N(CH_2NMe_2)\text{-}2]_2Hf(NC_4H_4)_2$ (4):** This compound was prepared in a manner analogous to that described for the synthesis of **3** using $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Hf(NEt_2)_2$ (1.0 g, 1.76 mmol) and pyrrole (0.248 mL, 3.52 mmol) as starting material. Colorless crystals of **4** were obtained from a toluene solution (0.812 g, 83% yield). $^1$H NMR ($C_6D_6$): $\delta$ = 1.87 (s, 12 H, N*Me*$_2$), 3.18 (s, 4 H, C*H*$_2$N), 6.12 (m, 2 H, pyrrolyl C*H*), 6.40 (m, 4 H, pyrrolyl C*H*), 6.49 (m, 4 H, pyrrolyl C*H*), 6.68 (m, 2 H, pyrrolyl C*H*) ppm. $^{13}$C NMR ($C_6D_6$): $\delta$ = 46.5 (q, $J_{CH}$ = 138 Hz, N*Me*$_2$), 62.5 (t, $J_{CH}$ = 139 Hz, *C*H$_2$N), 105.6 (d, $J_{CH}$ = 166 Hz, pyrrolyl *C*H), 110.4 (d, $J_{CH}$ = 168 Hz, pyrrolyl *C*H), 111.0 (d, $J_{CH}$ = 171 Hz, pyrrolyl *C*H), 126.9 (d, $J_{CH}$ = 180 Hz, pyrrolyl *C*H), 128.5 (d, $J_{CH}$ = 181 Hz, pyrrolyl *C*H), 136.1 (s, pyrrolyl *C*$_{ipso}$) ppm.

**$[C_4H_3N(CH_2NMe_2)\text{-}2]_2Zr(OC_6H_3Me_2\text{-}2,6)_2$ (5):** A solution of 2,6-dimethylphenol (0.254 g, 2.08 mmol) in heptane (15 mL) was added to a heptane solution (20 mL) of $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Zr(NEt_2)_2$ (0.50 g, 1.04 mmol) dropwise over 10 min. The solution was stirred at room temperature for 3 h after the addition was completed. The volatiles were removed under vacuum, and the residue was recrystallized from a dichloromethane solution to yield 0.45 g of colorless crystals in 73.8% yield. $^1$H NMR ($CDCl_3$): $\delta$ = 2.23 (br. s, 12 H, N*Me*$_2$), 2.47 (br. s, 12 H, Ph-*Me*), 3.87 (br. s, 4 H, C*H*$_2$N), 5.29 (s, 2 H, C*H*$_2$Cl$_2$), 6.02 (m, 2 H, pyrrolyl C*H*), 6.16 (m, 2 H, pyrrolyl C*H*), 6.70 (m, 2 H, pyrrolyl C*H*), 6.93 (m, 4 H, *Ph*), 7.33 (br., 2 H, *Ph*) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 17.8 (q, $J_{CH}$ = 126 Hz, Ph-*Me*), 48.2 (q, $J_{CH}$ = 140 Hz, N*Me*$_2$), 61.6 (t, $J_{CH}$ = 137 Hz, *C*H$_2$N), 104.5 (d, $J_{CH}$ = 168 Hz, pyrrolyl *C*H), 108.2 (d, $J_{CH}$ = 166 Hz, pyrrolyl *C*H), 120.2 (d, $J_{CH}$ = 162 Hz, *Ph*), 126.5 (s, Ph *C*$_{ipso}$), 128.6 (d, $J_{CH}$ = 158 Hz, *Ph*), 128.8 (d, $J_{CH}$ = 180 Hz, pyrrolyl *C*H), 136.3 (s, pyrrolyl *C*$_{ipso}$), 159.2 (s, Ph *C*$_{ipso}$) ppm. $C_{30}H_{40}N_4O_2Zr{\cdot}CH_2Cl_2$ (664.82): calcd. C 56.00, H 6.37, N 8.43; found C 55.72, H 6.54, N 8.43.

**$[C_4H_3N(CH_2NMe_2)\text{-}2]_2Hf(OC_6H_3Me_2\text{-}2,6)_2$ (6):** This compound was prepared in a manner analogous to that described for the synthesis of **5** using $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Hf(NEt_2)_2$ (1.0 g, 1.76 mmol) and 2,6-dimethylphenol (0.429 g, 3.52 mmol) as starting material. Colorless crystals of **6** were obtained from a $CH_2Cl_2$ solution (0.74 g, 63.2% yield). $^1$H NMR ($CDCl_3$): $\delta$ = 2.25 (br. s, 12 H, Ph-*Me*), 2.50 (br. s, 12 H, N*Me*$_2$), 3.90 (br. s, 4 H, C*H*$_2$N), 5.29 (s, 2 H, C*H*$_2$Cl$_2$), 6.09 (m, 2 H, pyrrolyl C*H*), 6.22 (m, 2 H, pyrrolyl C*H*), 6.69 (m, 2 H, pyrrolyl C*H*), 6.95 (m, 4 H, *Ph*), 7.39 (br., 2 H, *Ph*) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 17.9 (q, $J_{CH}$ = 128 Hz, Ph-*Me*), 48.4 (q, $J_{CH}$ = 145 Hz, N*Me*$_2$), 53.5 (t, $J_{CH}$ = 177 Hz, *C*H$_2$Cl$_2$), 61.6 (t, $J_{CH}$ = 137 Hz, *C*H$_2$N), 105.1 (d, $J_{CH}$ = 166 Hz, pyrrolyl *C*H), 109.1 (d, $J_{CH}$ = 166 Hz, pyrrolyl *C*H), 120.0 (d, $J_{CH}$ = 161 Hz, *Ph*), 126.8 (s, Ph *C*$_{ipso}$), 128.6 (d, $J_{CH}$ = 155 Hz, *Ph*), 129.4 (d, $J_{CH}$ = 179 Hz, pyrrolyl *C*H), 136.5 (s, pyrrolyl *C*$_{ipso}$), 159.0 (s, Ph *C*$_{ipso}$) ppm. $C_{30}H_{40}HfN_4O_2{\cdot}CH_2Cl_2$ (752.09): calcd. C 49.51, H 5.63, N 7.45; found C 49.80, H 5.65, N 7.48.

**$[C_4H_3N(CH_2NMe_2)\text{-}2]_2Zr(OC_6H_3iPr_2\text{-}2,6)_2$ (7):** This compound was prepared in a manner analogous to that described for the synthesis of **5** using $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Zr(NEt_2)_2$ (1.0 g, 2.08 mmol) and 2,6-diisopropylphenol (0.74 g, 4.16 mmol) as starting material. Colorless crystals of **7** were obtained from a $CH_2Cl_2$ solution (0.85 g, 59.2% yield). $^1$H NMR ($CDCl_3$): $\delta$ = 0.72 (d, 6 H, CH*Me*$_2$), 0.82 (d, 6 H, CH*Me*$_2$), 1.27 (d, 6 H, CH*Me*$_2$), 1.47 (d, 6 H, CH*Me*$_2$), 2.12 (s, 6 H, N*Me*$_2$), 2.31 (s, 6 H, N*Me*$_2$), 3.45 (d, 2 H, C*H*$_a$H$_b$NMe$_2$), 3.51 (m, 2 H, C*H*Me$_2$), 4.00 (m, 2 H, C*H*Me$_2$), 4.21 (d, 2 H, CH$_a$*H*$_b$NMe$_2$), 5.27 (s, C*H*$_2$Cl$_2$), 6.00 (d, 2 H, pyrrolyl C*H*), 6.13 (d, 2 H, pyrrolyl C*H*), 6.85 (m, 4 H, pyrrolyl + phenyl C*H*), 7.07 (m, 2 H, phenyl C*H*), 7.38 (m, 2 H, phenyl C*H*) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 23.0 (q, $J_{CH}$ = 126 Hz, CH*Me*$_2$), 24.2 (q, $J_{CH}$ = 122 Hz, CH*Me*$_2$), 25.56 (q, $J_{CH}$ = 127 Hz, CH*Me*$_2$), 25.61 (q, $J_{CH}$ = 127 Hz, CH*Me*$_2$), 25.63 (d, $J_{CH}$ = 123 Hz, *C*HMe$_2$), 26.8 (d, $J_{CH}$ = 123 Hz, *C*HMe$_2$), 47.2 (q, $J_{CH}$ = 137 Hz, N*Me*$_2$), 50.3 (q, $J_{CH}$ = 140 Hz, N*Me*$_2$), 54.3 (t, $J_{CH}$ = 177 Hz, *C*H$_2$Cl$_2$), 61.9 (t, $J_{CH}$ = 135 Hz, *C*H$_2$N), 105.3 (d, $J_{CH}$ = 165 Hz, pyrrolyl *C*H), 108.3 (d, $J_{CH}$ = 167 Hz, pyrrolyl *C*H), 121.2 (d, $J_{CH}$ = 161 Hz, phenyl *C*H), 123.6 (d, $J_{CH}$ = 151 Hz, phenyl *C*H), 123.7 (d, $J_{CH}$ = 151 Hz, phenyl *C*H), 127.7 (d, $J_{CH}$ = 180 Hz, pyrrolyl *C*H), 135.8 (s, phenyl *C*$_{ipso}$), 136.1 (s, pyrrolyl *C*$_{ipso}$), 139.2 (s, phenyl *C*$_{ipso}$), 155.8 (s, phenyl *C*$_{ipso}$). $C_{38}H_{56}N_4O_2Zr{\cdot}0.5CH_2Cl_2$ (734.57): calcd. C 62.95, H 7.82, N 7.63; found C 62.31, H 8.09, N 7.34.

**$[C_4H_3N(CH_2NMe_2)\text{-}2]_2Hf(OC_6H_3iPr_2\text{-}2,6)_2$ (8):** This compound was prepared in a manner analogous to that described for the synthesis of **5** using $[C_4H_3N(CH_2NMe_2)\text{-}2]_2Hf(NEt_2)_2$ (0.3 g, 0.53 mmol) and 2,6-diisopropylphenol (0.19 g, 1.06 mmol) as starting material. Colorless crystals of **8** were obtained from a $CH_2Cl_2$ solution (0.20 g, 44% yield). $^1$H NMR ($CDCl_3$): $\delta$ = 0.67 (d, 6 H, CH*Me*$_2$), 0.78 (d, 6 H, CH*Me*$_2$), 1.24 (d, 6 H, CH*Me*$_2$), 1.45 (d, 6 H, CH*Me*$_2$), 2.13 (s, 6 H, N*Me*$_2$), 2.31 (s, 6 H, N*Me*$_2$), 3.47 (m, 4 H, C*H*$_a$H$_b$NMe$_2$ + C*H*Me$_2$), 3.96 (m, 2 H, C*H*Me$_2$), 4.15 (m, 2 H, CH$_a$*H*$_b$NMe$_2$), 6.02 (m, 2 H, pyrrolyl C*H*), 6.12 (m, 2 H, pyrrolyl C*H*), 6.83 (m, 4 H, pyrrolyl + phenyl C*H*), 7.03 (m, 2 H, phenyl C*H*), 7.33 (s, 2 H, phenyl C*H*) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 22.8 (q, $J_{CH}$ = 127 Hz, CH*Me*$_2$), 24.3 (q, $J_{CH}$ = 126 Hz, CH*Me*$_2$), 25.5 (d, $J_{CH}$ = 131 Hz, CH*Me*$_2$), 25.7 (q, $J_{CH}$ = 123 Hz, CH*Me*$_2$), 25.8 (d, $J_{CH}$ = 126 Hz, *C*HMe$_2$), 26.6 (d, $J_{CH}$ = 126 Hz, *C*HMe$_2$), 47.2 (q, $J_{CH}$ = 141 Hz, N*Me*$_2$), 50.7 (q, $J_{CH}$ = 141 Hz, N*Me*$_2$), 61.9 (t, $J_{CH}$ = 137 Hz, *C*H$_2$N), 105.8 (d, $J_{CH}$ = 167 Hz, pyrrolyl *C*H), 109.0 (d, $J_{CH}$ = 167 Hz, pyrrolyl *C*H), 120.9 (d, $J_{CH}$ = 160 Hz, phenyl *C*H), 123.6 (d, $J_{CH}$ = 155 Hz, phenyl *C*H), 123.7 (d, $J_{CH}$ = 155 Hz, phenyl *C*H), 128.7 (d, $J_{CH}$ = 181 Hz, pyrrolyl *C*H), 136.1 (s, phenyl *C*$_{ipso}$), 136.4 (s, pyrrolyl *C*$_{ipso}$), 139.1 (s, phenyl *C*$_{ipso}$), 155.5 (s, phenyl *C*$_{ipso}$). $C_{38}H_{56}HfN_4O_2{\cdot}CH_2Cl_2$ (864.30): calcd. C 54.20, H 6.76, N 6.48; found C 54.13, H 6.63, N 6.06.

**X-ray Structure Determination of Compounds 3, 4, 6, 7, and 8:** The crystals were sealed in glass fibers under nitrogen and transferred to a goniostat. Data were collected with a Bruker SMART CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation with a radiation wavelength of 0.71073 Å at 293(2) K. Structural determinations were made using the SHELXTL package of programs. A SADABS absorption correction was made. All refinements were carried out by full-matrix least-squares using anisotropic displacement parameters for all non-hydrogen atoms. All the hydrogen atoms are placed with the use of a riding model. The crystal data are summarized in Table 3.

CCDC-279540 (for **3**), -279541 (for **4**), -279543 (for **6**), -279542 (for **7**), and -279544 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Kinetic Study of *rac*-Lactide Polymerization Initiated by 8:** Compound **8** and lactides were placed in a J-Young NMR tube and $CDCl_3$ (0.5 mL) was added. The solution was placed in a preheated oil bath (70 °C) and reactions were monitored by a $^1$H NMR spectrometer constantly.

**General Procedure for the Polymerization of ε-Caprolactone:** General procedures for ε-caprolactone polymerization catalyzed by the new zirconium and hafnium complexes are as follows. In a glovebox, the monomer (ε-caprolactone) and catalyst were placed in separate Schlenk flasks and then moved out of the glovebox. Toluene (10 mL) was added with a syringe to the catalyst and heated to the desired temperature followed by the addition of the monomer. The reactions proceeded in the desired conditions and were quenched with methanol. Solids were obtained by filtration, washed with methanol to remove excess metal catalysts, and dried under vacuum.

## Acknowledgments

We thank the National Science Council of Taiwan for financial support and the National Changhua University of Education for purchasing the Bruker CCD X-ray diffractometer.

# Facile and Selected-Control Synthesis of β-$MnO_2$ Nanorods and Their Magnetic Properties

**Guangli Wang,[a] Bo Tang,*[a] Linhai Zhuo,[a] Jiechao Ge,[a] and Mei Xue[a]**

**Keywords:** β-Manganese dioxide / Nanostructures / Hydrothermal synthesis / Magnetic properties

Single crystal β-$MnO_2$ nanorods were successfully synthesized employing a facile in-situ redox precipitation hydrothermal process. The effects of various experimental conditions on the morphology of the products were investigated. The mechanism of formation of the nanorods was investigated and discussed based on the experimental results. The magnetic measurement of the nanorods with a diameter of 25–40 nm and a length of 240–440 nm indicates that the Néel magnetic transition temperature is about 6 K higher than that of the bulk β-$MnO_2$ crystal.

## 1. Introduction

One-dimensional (1D) nanocrystals such as nanorods, nanowires, and nanotubes have been the focus of considerable interest.[1–3] As a consequence of their low dimensionality and quantum confinement effect, they can show unique electronic, optical, and magnetic properties that are anomalous when compared to the bulk materials.[4–7] Manganese dioxide can form many kinds of polymorph, such as α-, β-, γ-, and δ-types, each offering distinctive properties and applications. Applications include as molecular sieves, ion sieves, in catalysis, as cathode materials for secondary rechargeable batteries, and as new magnetic materials.[8–12] Bach et al.[13] have especially pointed out that the electrochemical properties of $MnO_2$ strongly depend on parameters such as powder morphology, crystalline structure, and bulk density. One-dimensional nanostructures are the smallest structures known for the efficient transport of electrons, and they may provide the possibility of detecting the theoretical operating limits of a lithium battery.[14–15] $MnO_2$ also possesses an interesting magnetic structure.[16–20] To date we have found nothing in the literature on the magnetic properties of nanosized $MnO_2$. Therefore, development of a controllable synthesis method for one-dimensional $MnO_2$ nanostructures was deemed very important to be able to explore their novel properties as well as examine potential applications for $MnO_2$. Much effort has been put into preparing nanocrystalline $MnO_2$ with different crystallographic forms; such as nanorod-shaped and nanofibrous α- and Tokorokite-type $MnO_2$,[21] β-$MnO_2$ nanorods,[22] γ-$MnO_2$ nanowires,[23] and δ-$MnO_2$ nanofibers.[24] Although Li et al. have reported on the hydrothermal synthesis of α-$MnO_2$ nanowires and β-$MnO_2$ nanorods by oxidizing $MnSO_4$ with $KMnO_4$ or $K_2S_2O_8$, respectively,[22] the control of both morphology and the phase of the one-dimensional β-$MnO_2$ nanostructures using the direct reaction route is still challenging.

In this paper, we report a facile in-situ redox precipitation hydrothermal synthesis method for the selected control synthesis of single-crystal β-$MnO_2$ nanorods. The effects of various experimental conditions on the morphology and particle size of the products were studied. The mechanism of formation of the nanorods was investigated and discussed. The magnetic properties of the as-obtained nanorods with diameters of 25–40 nm and lengths of 240–440 nm were characterized.

## 2. Results and Discussion

### 2.1. Characterization

X-ray powder diffraction (XRD) patterns reveal the phase and purity of the as-obtained products. As shown in Figure 1, all of the reflection peaks can be indexed to a pure tetragonal phase of β-$MnO_2$ [JCPDS 24-0735, space group $P4_2/mnm$(136)] with lattice constants $a$ = 4.3998 Å and $c$ = 2.8695 Å. The sharp peaks indicate that the product is perfectly crystallized. No other impurity peaks were observed, demonstrating the high purity of the products obtained under current experimental conditions.

A typical TEM image of the as-prepared sample is shown in Figure 2 (a), which indicates that the final product consists of nanorods with diameters of 25–40 nm and lengths ranging from 240 to 440 nm. More detailed structural information for these nanorods was obtained from

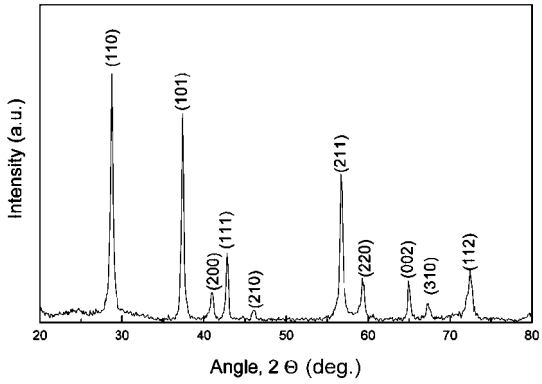

Figure 1. XRD pattern of the as-obtained product.

high-resolution transmission electron microscopy (HRTEM) images and selected area diffraction (SAED) patterns. The HRTEM image (Figure 2, b) of an individual nanorod shows that the nanorod is structurally uniform with an interplanar spacing of about 0.315 nm, which corresponds to the (110) plane of tetragonal β-$MnO_2$. Selected area electron diffraction patterns taken from the individual nanorod (shown in the inset image in Figure 2, b) reveal its single crystal nature, and can be indexed to the [001] zone axis of tetragonal β-$MnO_2$.

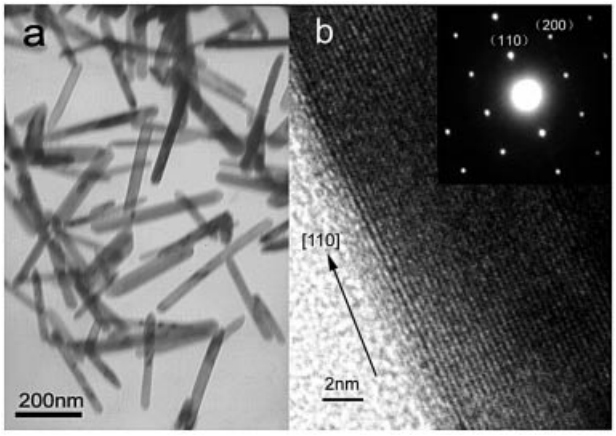

Figure 2. The (a) TEM image and (b) HRTEM and SAED (inset image) patterns of the as-prepared sample.

A typical room temperature X-ray photoelectron spectrum of the as-synthesized sample is shown in Figure 3. Only the peaks of Mn(2p3/2, 2p1/2) and O1s can be observed. The binding energies of Mn(2p3/2) and Mn(2p1/2) are 642.32 and 653.95 ev, respectively, which are well in accordance with $MnO_2$ [Mn(2p3/2) = 642.1 ev and Mn(2p1/2) = 653.8 ev].[25] The estimated relative ratio of O to Mn is 2.16:1, which is caused by the interference of oxygen in the air for the XPS study.

## 2. 2. The Effect of Reaction Conditions on the Morphology and Particle Size of the Products

### *2. 2. 1. The Effects of Ammonia on the Morphology and Particle Size of the Products*

It was found that the concentration of ammonia as well as the way the ammonia was added had significant effects on the morphology of the products. Uniform nanorods were obtained (as shown in Figure 2, a) when ammonia was added dropwise. Pouring ammonia into the mixture of $Mn(NO_3)$ and $H_2O_2$ led to the product being composed of big rod-like structures (200–400 nm in diameter and more than 10 μm in length) and nanoparticles (Figure 4, a). The concentration of ammonia also significantly affected the morphology of the products. In our synthetic system, the concentrations of $Mn(NO_3)_2$ and $H_2O_2$ were kept constant and ammonia was added dropwise with different concentrations. As the concentration of ammonia was varied (0.25, 0.5, 1, 2 M) the morphology changed from a spindle morphology (Figure 4, b), to nanorods (Figure 2, a), a mixture of nanorods and nanoparticles (Figure 4, c), and finally to nanoparticles (Figure 4, d). From the above results, we can see that the precipitator ammonia in our synthetic system has significant effects on the morphology of the products.

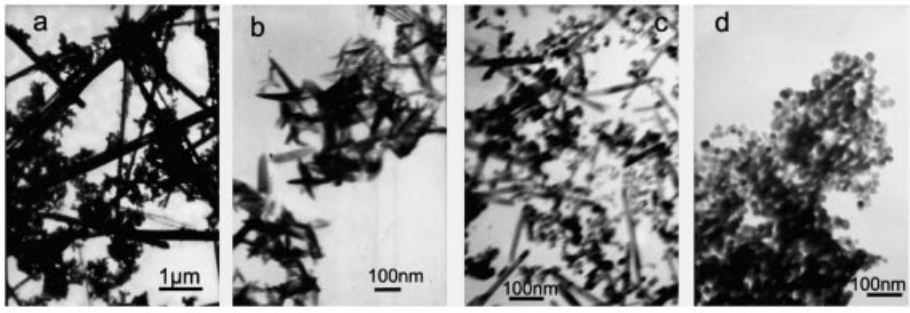

Figure 4. (a) 0.5 M ammonia was added by pouring, (b–d) ammonia was added dropwise with different concentrations; (b) 0.25 M; (c) 1 M; (d) 2 M.

#### *2.2.2. Effects of $H_2O_2$ on the Morphology of the Products*

Increasing the amount of $H_2O_2$ to 2 mL, while the other experimental conditions were kept constant, led to a morphology of the products similar to that shown in Figure 4 (a). The as-obtained products are composed of rod-like structures (400–500 nm in diameter and 10–20 μm in length) and nanoparticles.

#### *2.2.3. Effects of Temperature on the Morphology of the Products*

Temperature also affected the morphology and particle size of the final products. At a lower temperature such as 130 °C, only nanoparticles could be obtained (Figure 5, a). Upon increasing the temperature to 140 °C, we obtained a mixture of nanoparticles and nanorods (Figure 5, b). Nanorods could be obtained in the temperature range 180–250 °C. The TEM image in part c of Figure 5 shows that $MnO_2$ obtained at 180 °C consists of uniform nanorods with a diameter of 15–30 nm and lengths of 150–200 nm, whereas the product obtained at 210 °C is on average 20–30 nm in diameter and has a length of 200–300 nm as shown in part d of Figure 5. Upon increasing the temperature to 250 °C, the product was found to consist of uniform nanorods with a diameter of 25–40 nm and lengths of up to 240–440 nm as shown in Figure 2 (a). From the above results, we can see that the diameter and length of the nanorods increase slightly with increasing temperature. It is apparent that higher temperatures favor the anisotropic growth of the crystals and nanorod formation.

The phases of nanorods obtained in the temperature range 180–250 °C were examined by the X-ray powder diffraction technique, which demonstrated that all the phases were pure β-$MnO_2$. In contrast to solution-based methods for the growth of one-dimensional nanostructures in which the problem of phase control of the products often exists,[22] the present synthetic process can be performed over a wide range of hydrothermal reaction temperatures.

### 2.3. Possible Growth Mechanism of the Nanorods

The chemical reaction can be formulated as:

$$Mn^{2+} + H_2O_2 + 2\ NH_3{\cdot}H_2O \rightarrow MnO_2{\cdot}xH_2O + 2\ NH_4^+ + H_2O \quad (1)$$

$$MnO_2{\cdot}xH_2O \xrightarrow[\text{reaction}]{\text{hydrothermal}} MnO_2 + x\ H_2O \quad (2)$$

As illustrated in the chemical equation above, when ammonia was added to the mixture of hydrogen peroxide and manganese nitrate, the precipitation and oxidation reaction occurred together [Equation (1)], accompanied by the decomposition of hydrogen peroxide. After the in-situ redox precipitation process, we obtained $MnO_2{\cdot}xH_2O$. In the hydrothermal process, $MnO_2{\cdot}xH_2O$ dehydrated to $MnO_2$ [Equation (2)]. In order to investigate the growth process of

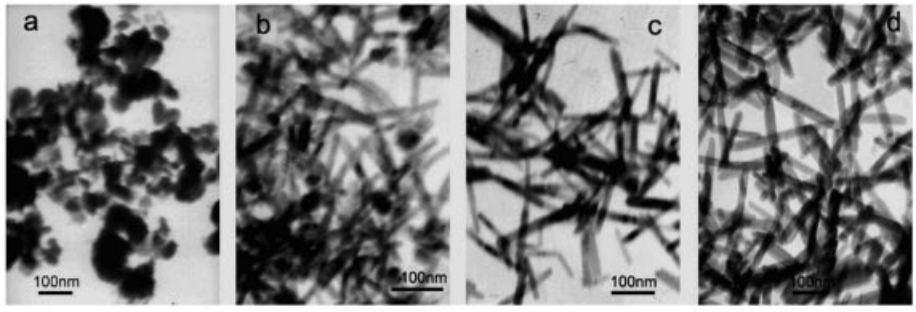

Figure 5. The products obtained at different hydrothermal reaction temperatures for 12 h: (a) 130 °C; (b) 140 °C; (c) 180 °C; (d) 210 °C.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

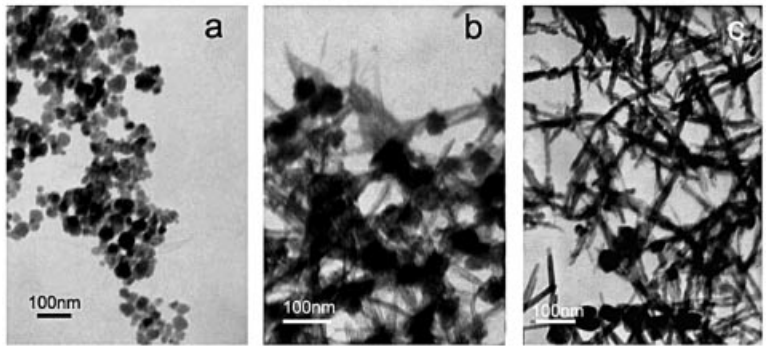

Figure 6. TEM image of the as-obtained samples at different hydrothermal reaction times: (a) 5 min; (b) 15 min; (c) 1 h.

the nanorods, we carried out the hydrothermal reaction at 250 °C for different periods of time. Figure 6 (a) shows the TEM image of the sample obtained after heating for 5 min, there are only nanoparticles with a diameter of 15–60 nm. The sample was characterized by XRD, but no peak was detected, indicting that crystallization did not occur for these nanoparticles. Figure 6 (b) shows the samples obtained after heating for 15 min, which indicates that there are nanoparticles with diameters of 40–60 nm and a few short nanorods. The smaller nanoparticles in Figure 6 (a) are not seen in Figure 6 (b). After heating for 1 h, the amount of nanorods is more than that shown in Figure 6 (b), and the amount of nanoparticles has dramatically decreased (Figure 6, c). The TEM image of the product obtained after heating for 12 h indicates that the product is composed of nanorods and the nanoparticles are no longer seen (Figure 2, a). The above study demonstrates that the nanorods are grown from the small nanoparticles. We believe that the mechanism of formation of the $MnO_2$ nanorods follows the Ostwald ripening process.[26]

## 3. Magnetic Property of the As-Synthesized β-$MnO_2$ Nanorods

The magnetic properties of the as-synthesized β-$MnO_2$ nanorods with a diameter of 25–40 nm and a length of 240–440 nm were characterized. Figure 7 shows the magnetization vs. temperature curve of the as-synthesized β-$MnO_2$ nanorods at an applied field of 1000 Oe. A kink is observed at 98 K in Figure 7, which corresponds to the Néel magnetic transition temperature $T_N$. This temperature is higher than that of the bulk $MnO_2$ crystal ($T_N$ = 92 K),[27–28] which may be because of the special morphology and the effect of surface spins of the as-obtained nanorods.[29–30] Strangely, a discontinuity is seen in the temperature range 30–50 K in Figure 7. From the XRD and XPS studies, we know that the products we obtained were of high purity. So the reason for the discontinuity cannot be any impurity in the products, but may be caused by the special morphology and uncompensated surface spins of the nanorods.[29,31–32] At 293 K, a nearly linear M–H curve (Figure 8) reveals that a superparamagnetic state exists at this temperature.

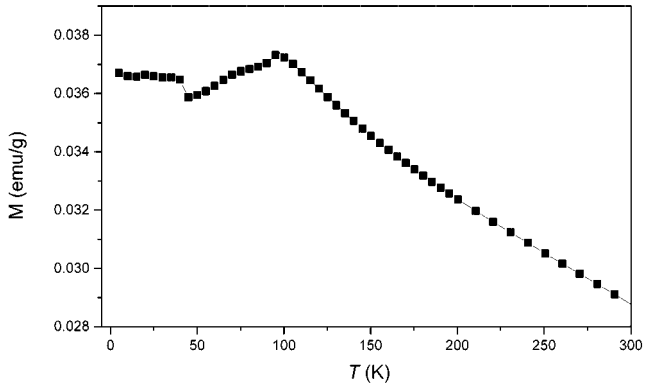

Figure 7. Magnetization vs. temperature curve of the as-obtained nanorods at an applied field of 1000 Oe.

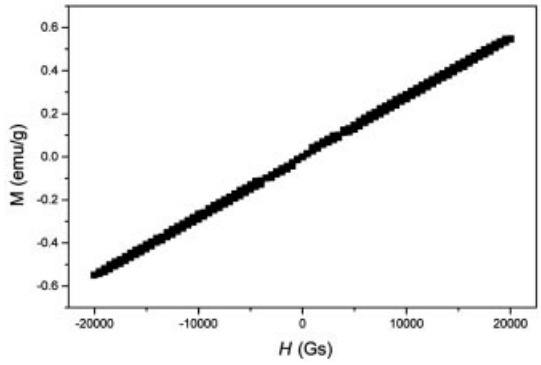

Figure 8. The magnetization vs. applied magnetic field of the as-obtained nanorods.

## 4. Conclusion

In summary, a simple in-situ redox precipitation hydrothermal synthesis method has been developed to synthesize single-crystal β-$MnO_2$ nanorods. The reactant ammonia and peroxide hydrogen as well as the hydrothermal reaction temperatures can greatly influence the morphology of the final products. Compared to the previous solution-based methods for the growth of 1D nanostructures in which the problem of phase control of products often exists, the present synthetic process can be performed over a wide range of hydrothermal temperatures. The magnetic measurements

indicate that the Néel temperature of the as-synthesized β-$MnO_2$ single crystals is about 98 K, which is about 6 K higher than that of the bulk β-$MnO_2$ crystals. The nanorod materials produced also may show possible novel electronic and catalytic properties induced by their dimensionality.

## Experimental Section

$MnO_2$ nanorods were obtained by an in-situ redox precipitation hydrothermal synthesis method. In a typical experiment, hydrogen peroxide (1 mL, 30%) was added to an aqueous solution of manganese nitrate (12 mL, 0.3 mol/L) whilst stirring to form a homogeneous solution, then ammonia (5 mL, 0.5 mol/L) was added to the mixture dropwise. Upon the addition of ammonia, the precipitation of $Mn^{2+}$ by ammonia to $Mn(OH)_2$ and the oxidization of $Mn(OH)_2$ by $H_2O_2$ were achieved immediately accompanied by the decomposition of $H_2O_2$. A brown suspension of $MnO_2{\cdot}xH_2O$ precipitated during the in-situ redox precipitation reaction. The resulting suspension was transferred into a 20-mL Teflon-lined autoclave up to 80% of the total volume. The sealed autoclave was heated at 250 °C for 12 h. The resulting black solid product was collected, washed several times with distilled water and absolute ethanol, centrifuged, and dried under vacuum at 60 °C for 3 h.

The phase and purity of the products were identified using X-ray powder diffraction (XRD) patterns collected with a Japan Rigaku Dmax-γA X-ray diffractometer with Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å). A scan rate of 4°/min was applied to record the patterns in the $2\theta$ range from 10 to 80°.The morphology and particle size of the products were determined with a Hitachi Model H-800 transmission electron microscope (TEM) operated at 200 kv. Structural information for the nanocrystals was obtained from selected area diffraction (SAED) patterns and high-resolution transmission electron microscopy (HRTEM) images obtained using a JEOL-2010F transmission electron microscope at an acceleration voltage of 200 kv. Electron diffraction patterns were obtained from samples during HRTEM measurements. X-ray photoelectron spectra were collected with a PHI5300 model XPS spectrometer with an Al-$K_\alpha$ radiation source. Magnetic properties were investigated with a superconducting quantum interference device (SQUID) magnetometer (MPMS-7).

## COVER PICTURE

**The cover picture shows** the structural changes in tertiary carboxamide groups induced by coordination of the electrically neutral nitrogen atom to a metal ion. Changing the hybridization from $sp^2$ to $sp^3$ results in pyramidalization at the nitrogen atom. This is expressed by the parameter $\chi_N$ which ranges from 0° ($sp^2$) to 60° ($sp^3$). Werner complexes with relatively weak $M-N^{amide}$ bonds are known with $\chi_N$ values between 30° and 47°. Full $sp^3$ hybridization with complete lifting of the resonance and a value of 58° for $\chi_N$ is achieved in a complex in which the copper(II) ion is in the centre of the tetraazamacrocyclic amide ligand *tert*-butoxycarbonyl-alanyl-cyclam. Details of its synthesis and structure are discussed in the article by R. Alsfasser et al. on p. 2357 ff.

# Artificial Light-Harvesting Systems by Use of Metal Coordination

**Yoshiaki Kobuke*[a]**

**Keywords:** Energy conversion / Complementary coordination / Porphyrinoids / Phthalocyanines / Perylenebisimide / Bi(ter)pyridyl complex

Construction of artificial light-harvesting systems by metal coordination is reviewed. Light absorbing dyes include porphyrin, phthalocyanine, perylenebisimide and polypyridyl metal complexes. The supramolecular assemblies are obtained by ligand coordination to metal ions in the center or exterior of the chromophores. Supermolecules of discrete structures even in the solution phase are focused on, and methodologies to acquire large association constants are discussed. Complementary or multitopic coordination to the $Zn^{2+}$ ion gives satisfactory results in obtaining stable and discrete supramolecular structures while maintaining the singlet excited state. Fast energy transfers among the chromophore units are analyzed satisfactorily to examine the properties of light-harvesting antennae. Use of transition-metal ions provides strong coordination, but intersystem crossing of the singlet excited state to the triplet becomes significant. Photophysical properties of such triplet excited species are reported in a limited number of cases and their properties are discussed in view of the light-harvesting antenna function.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## 1. Introduction

Photosynthetic oxidation-reduction reactions start at the reaction center by ejecting an electron from the photoexcited primary electron donor, the chlorophyll dimer of the so-called special pair or monomeric chlorophyll in more evolved systems to the primary electron acceptor. This reaction center is surrounded by a large number of light-harvesting antenna chlorophylls in order to make the maximum use of the incoming photons. When a photon hits one of the chlorophyll molecules, the excitation energy must be transferred to the far reaction center without losing the energy. There are several decay processes to lose the singlet excited state: intersystem crossing to the corresponding triplet state, emission through fluorescence, and nonemissive internal conversions. Since the lifetime of the singlet excited chlorophylls is generally of the order of nanoseconds, the energy transfer must take place with time constants faster than the order of a nanosecond.

An artificial light-harvesting system is interesting from various viewpoints. Understanding the way that nature per-

*Yoshiaki Kobuke obtained his Bachelor degree from the Department of Synthetic Chemistry, Faculty of Engineering in 1964 at Kyoto University, where he worked under the supervision of Prof. Ryohei Oda. He joined the group of Prof. Junji Furukawa at the same Department as a graduate student in 1964. His thesis work for which he received his Ph.D. in Engineering was on the study of mechanisms of stereospecific polymerization and endo-exo stereoselectivities of Diels–Alder reactions. In 1969 he joined the Department of Synthetic Chemistry, Faculty of Engineering at Kyoto University as an Assistant Professor and collaborated with Prof. Junji Furukawa. In the period of 1972–1973 he joined the group of Prof. Robert Burns Woodward as a research associate in the Department of Chemistry at Harvard University for the total syntheses of Vitamin B12 and erythromycin. After the retirement of Prof. Furukawa in 1977, he collaborated with Prof. Iwao Tabushi. In 1980 he was promoted to Associate Professor. In 1990, he was appointed to Professor in the Department of Materials Science, Faculty of Engineering at Shizuoka University. The main research target was the synthesis of artificial ion channels and their characterization by single channel current observations. In 1998 he moved to the Graduate School of Materials Science, Nara Institute of Science and Technology. During 1998–2003 he was a project leader of CREST (Core Research for Evolutionary Science and Technology from the Japan Science and Technology Corporation). His research interest is artificial photosynthesis focusing on its initial events, i.e. antenna function and charge separation. Studies on novel two photon absorbing materials and artificial ion channels are under way.*

**MICROREVIEWS:** This feature introduces the readers to the authors' research through a concise overview of the selected topic. Reference to important work from others in the field is included.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

forms intricate functions should be of profound interest. In the case of light-harvesting antenna, visually aesthetic crystallographic structures are already known. Their well-organized structure is thought to correlate closely with the functions they perform. If we succeed in establishing the nature of the structure-function relationship, we will obtain the method by which the photo-excited energy is stored in molecules or molecular systems, and transferred with minimum loss. This knowledge can then be applied not only to the construction of artificial photosynthetic systems and solar energy conversion systems, but also to the development of photonic and electronic materials by the use of chromophores having expanded π-electronic systems.

An artificial light-harvesting system may best be achieved by mimicking the purple bacterial system, since the structure-function relationship may be understood best in the simplest way. Therefore, macrocyclic arrangements of porphyrins and other chromophores will be the first choice. Covalent linking is the most classical and productive method. There are numerous examples reported, and also review articles.[1–5] Alternatively, a supramolecular approach to this target may have special importance, since the natural structure is one of the best examples as will soon be explained. In this article, the author will focus on the supramolecular approach to the construction of a light-harvesting system. As a requisite to clear discussions based on structural information, the species having discrete structures in solution will be treated. In view of strong coordination and definite coordination angle, metal coordination may play the most important role.[6–16]

Nature uses only the singlet excited state for photosynthesis and specially protects against the formation of the triplet state. This does not necessarily mean that the artificial systems should use the singlet excited species. The triplet excited species have longer lifetimes and the $[Ru(bpy)_3]^{2+}$ complex and its derivatives have been successfully used for dye-sensitized solar cells. However, the detailed analysis of the triplet energy transfer processes is accompanied by added difficulties compared with that for the singlet species. Therefore many potential complexes are prepared by using transition-metal ions, without mentioning the photophysical properties. Here, discussion will focus on supermolecules and the measurement of their photophysical properties.

## 2. Natural Light-Harvesting Systems

In order to achieve effective charge separation, Nature has designed a most sophisticated molecular system for the reaction center. It is not clever to place such a system in all the light-receiving spots so the reaction center is instead accompanied by a large number of light-harvesting devices in the surrounding space. This system resembles a central factory system appropriate for mass production, and is maintained by the supply of light harvesting devices of simple structure for the unitary function.

The arrangement of a bacterial photosynthetic system was first analyzed by X-ray crystallography in 1995.[17–22] The light-harvesting complex LH2 from purple bacteria is composed of B800 and B850. B800 contains nine bacteriochlorophylls arranged in a planar circle form. In contrast, B850 contains 18 bacteriochlorophylls in a barrel form arranged perpendicularly to B800. The light energy absorbed by B800 is transferred to B850 according to the cascading energy transfer. The excitation energy travels further to other B850s and finally reaches LH1. Here, 30 bacteriochlorophylls are arranged in a barrel form similar to B850, except for having one open exit. In addition, LH1 contains the reaction center in the central space. Therefore, the excitation energy reaching LH1 is transferred effectively to the special pair initiating the charge separation. The arrangements of B850, LH1, and interestingly even the special pair are given by coordination of the imidazolyl side chains in transmembrane helices to the central $Mg^{2+}$ ion in the bacteriochlorophyll. The energy transfer rates in the supramolecular arrangements (Figure 1) are as fast as the order of picoseconds within lifetimes of the order of nanoseconds.[23–30]

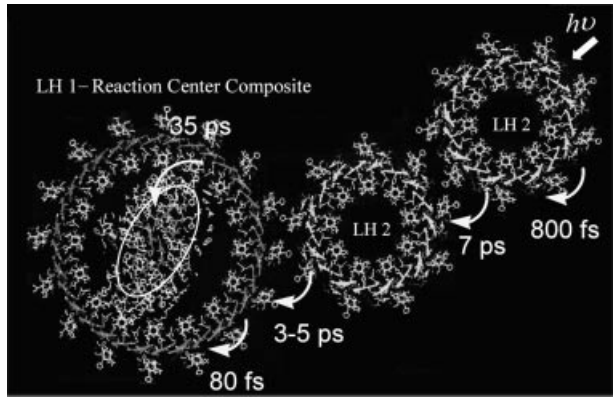

Figure 1. Scheme of light harvesting in photosynthetic purple bacteria.[22]

As seen above, the light-harvesting system of bacteria employs very regular arrangements of bacteriochlorophylls. This is not general for all the light-harvesting antenna systems. Antennae in plants and cyanobacteria, both being very similar, seem to use a totally different architecture.[31–35] Figure 2 shows the crystallographic structure of cyanobacterial photosystem I as a trimer, which represents the existing form also in vivo. The monomer contains a large number of chromophores of 90 chlorophyll *a* molecules and 22 carotenoids. This is a core antenna system and is accompanied further by separately existing antenna components, which are normally associated with photosystem II. It must be noted that a plant employs almost the same architecture as cyanobacteria. It is remarkable that the system employed by cyanobacteria 2.5 billion years ago is still effective even 1 billion years after plants first evolved. Almost no evolutional change of the structure may signify that the perfect form of the antenna system has been arrived at. However, it seems extremely difficult to extract a simple constitutional principle from the apparently random architecture.

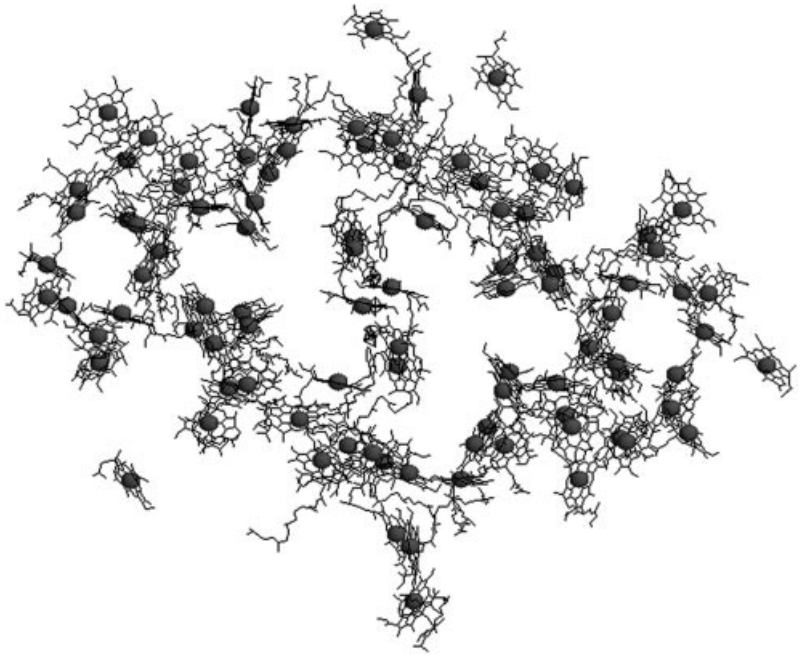

Figure 2. Crystal structure of cyanobacterial photosystem I. Prepared from Brookhaven Data Bank file 1JB0.[31]

## 3. Chromophores

In light-harvesting devices, incoming light energy must be captured efficiently by one of the chromophores distributed widely in the surrounding space and transferred efficiently to the reaction center. For this purpose, nature employs chlorophyll-*a* and -*b* or the corresponding bacteriochlorophylls as the light-absorbing unit. They have extinction coefficients as large as $10^5$–$10^6$ $cm^{-1}$ $M^{-1}$ near the regions at 400 and 600 nm. Chromophores closely related to chlorophyll derivatives are porphyrin and phthalocyanine. Recently, the use of perylenebisimide has been demonstrated to be excellent for such purposes. Ruthenium tris-bipyridine or bis-terpyridine have unique characteristics for such purposes and are widely used for photocurrent generation systems. The typical characteristics of these chromophores are compared in Table 1. Figure 3 shows the absorption spectra at the same extinction coefficient scale for easy comparison of their relative magnitudes.

The photosynthetic reaction is conducted through the singlet excited state and its conversion to the triplet is strictly protected by several mechanisms. It is important to

transfer the singlet excitation energy within the lifetime. Therefore, close inter-chromophore distances are critical to ensure the successful fast excitation energy transfers, as observed for the B850 and LH1 systems. The close interchromophoric distance induces strong exciton interaction as shown schematically in Figure 4. Face-to-face interaction induces a blue shift of the absorption wavelength, while head-to-tail interaction shifts the absorption band to a longer wavelength.[51] The excited state of the face-to-face interaction tends to lose its excitation energy through internal conversion to the vibrational energy and decay without fluorescence emission. On the other hand, excitons with a head-to-tail orientation can maintain the excited state and transfer the excitation energy within the lifetime. By using the red shift of the absorption wavelength, a vectorial energy transfer pathway can be constructed.

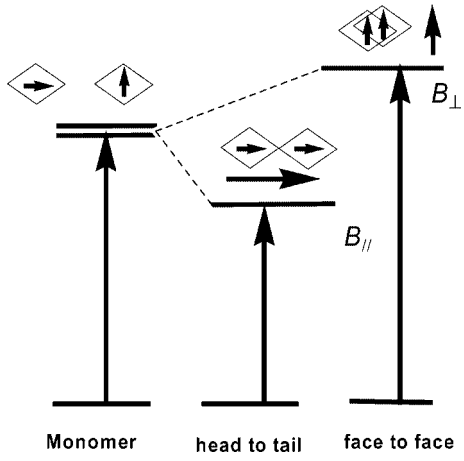

Figure 4. Exciton interaction of transition dipoles.[51]

## 4. Methods of Coordination Assembly

The assembly formation sometimes induces the formation of an energy sink, where the singlet excitation energy is lost through internal conversion to vibrational states. Random assembly of chromophores induces this kind of unfavorable defect formation, and for this reason regular arrangement of the chromophores is desirable. There are several methods to assemble chromophores through supramolecular assembling.

Coordination to metal ions provides the strongest intermolecular forces among others such as hydrogen bonds, ionic interactions, and π-π stacking interactions. It is important to obtain chromophore assemblies of discrete structure for the discussion based on a clear molecular basis. From this viewpoint, metal coordination provides the best intermolecular force for chromophore assembly. Other intermolecular forces are also used in combination with metal coordination, but are hardly expected to obtain supermolecules of discrete structure in solution by using their weak intermolecular forces alone.[52,53]

The nature of metal ions has a large effect on the characteristics of the resulting metal-coordinated chromophore assemblies. Metal ions of typical groups and $d^{10}$ transition-metal ions do not have much influence on the singlet excited state. However, transition-metal ions having odd electron spins tend to quench the singlet excitation energy through interaction with their odd spin. Therefore, the use of paramagnetic transition-metal ions for the assembly formation must be primarily avoided. The former class of metal ions, however, in general provides only a weak ligand field with small stability constants and allows equilibrium with free ligands. Assemblies have been obtained with due consider-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ation of the above characteristics and limitations. The modes of complexation will be classified into two types as illustrated in Figure 5.

Type I: Coordination of the chromophore's ligand to metallochromophore.

Type II: Coordination of the chromophore's ligand to external metal ions.

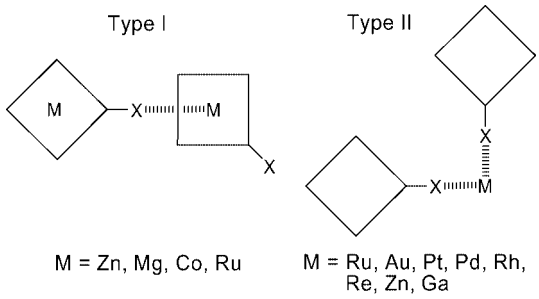

Figure 5. Mode of assembly formation by coordination, with the square and X representing chromophore and coordinating ligand, respectively.

As chromophores containing metal ions, porphyrin and phthalocyanine provide the most typical examples for Type I assembly formation. Chlorophyll employs $Mg^{2+}$ but artificial systems use $Zn^{2+}$ as the most typical substitute, since $Zn^{2+}$ has a $d^{10}$ electronic configuration without odd spin. $Zn^{2+}$ complexes are practically stable toward heat, acidic condition, and oxidation. The artificial system prefers $Zn^{2+}$ in most cases based on these properties, although its fluorescence quantum yield is inferior to $Mg^{2+}$ systems. Since $Zn^{2+}$ cannot provide a strong ligand field, the stability constant is not inherently very large, unless multitopic or complementary coordination is designed. Unique ideas have therefore been developed for obtaining stable assemblies.

When transition-metal ions are incorporated into the central core of porphyrins and phthalocyanines, even mono-axial coordination can afford large stability constants. However, the intersystem crossing of singlet to the triplet states occurs and light harvesting through the triplet pathway must become the main route.

When the assembly inducing metal ion locates outside the chromophore, the flexibility of the molecular design for assembly formation increases. Chelation may be powerful for obtaining stable complexes. Nanoparticles developed recently may also be interesting.

## 5. Porphyrin with an Inner-Ring Metal Ion

Central metals accommodated in the macrocyclic structure allow one or two axial coordinations of ligand depending on the metal ion species. Penta-coordinating $Zn^{2+}$ accepts only one axial coordination. Neutral nitrogen ligands generally afford large stability constants, but simple monocoordination is not strong enough to maintain the discrete structure under μM concentrations for which special molecular designs are required. Kobuke proposed the idea of complementary coordination of an imidazolyl substituent of one porphyrin to the $Zn^{2+}$ center of another porphyrin, whose imidazolyl coordinated back to $Zn^{2+}$ in the original porphyrin.[54,55] The stability constant reaches $10^{11}$ $M^{-1}$ in nonpolar solvents. The factor that contributes most to such a large stability constant is the complementarity of the imidazolyl–Zn–porphyrin. Compared with other potential ligands such as pyridyl, imidazolyl has the following advantages (see Figure 6):

(1) High basicity leading to high coordination ability.

(2) Smaller angle strain from the ideal (vertical to the macrocyclic plane) coordination angle.

(3) Smaller steric hindrance from substituents at positions α to the ligating N atom.

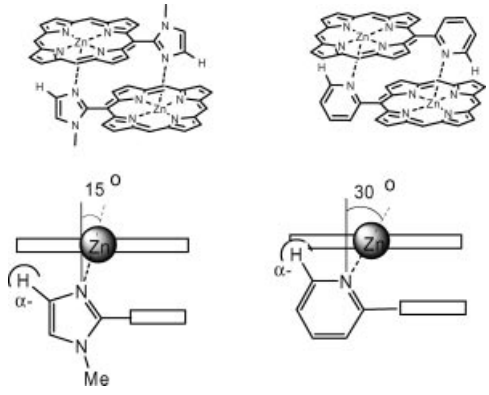

Figure 6. Complementary coordination of imidazolyl and pyridyl to $Zn^{2+}$, where the rectangle denotes porphyrin.

This motif can be applied to the formation of linear and macrocyclic species, both of which are regarded as excellent light harvesting antennae. Firstly, in order to obtain linear porphyrin arrays based on complementary coordination, two imidazolyl–Zn–porphyrin units were connected directly at their *meso* positions, as shown in compound **1**. Since the coordination grows to both sides opposite to each other, the successive complementary coordination leads to a linear multi-porphyrin array **2** (Figure 7A).[56] The molecular weight was extremely high reflecting the large stability constant of the complementary coordination and the number of the longest porphyrin unit reached 800 porphyrin units with a distribution peak of 160 units. However, the coordination bond is cleaved and regenerated by adding and eliminating coordinating solvents, respectively. An example was shown by GPC elution curves (A) and (B) in part B of Figure 7. A mixture of *meso*-*meso*-linked bisporphyrin **1** and monoimidazolylporphyrin **3** showed the corresponding two peaks in $CHCl_3$ (A). When methanol was added to the chloroform solution, followed by evaporation to cleave and regenerate the coordination, bisporphyrin oligomers terminated by monomeric porphyrins **4** were obtained (B).

It is noteworthy that this linear assembly does not induce fluorescence quenching. Evaluation of the energy transfer rate along the one-dimensional array is not as easy as in the degenerated array of the ring. Therefore, fluorescence-quenching Mn–porphyrins were attached at both the terminals of the linear array by using hetero-complementary coordination of imidazolyl–Mn–porphyrin **5** to the terminal

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

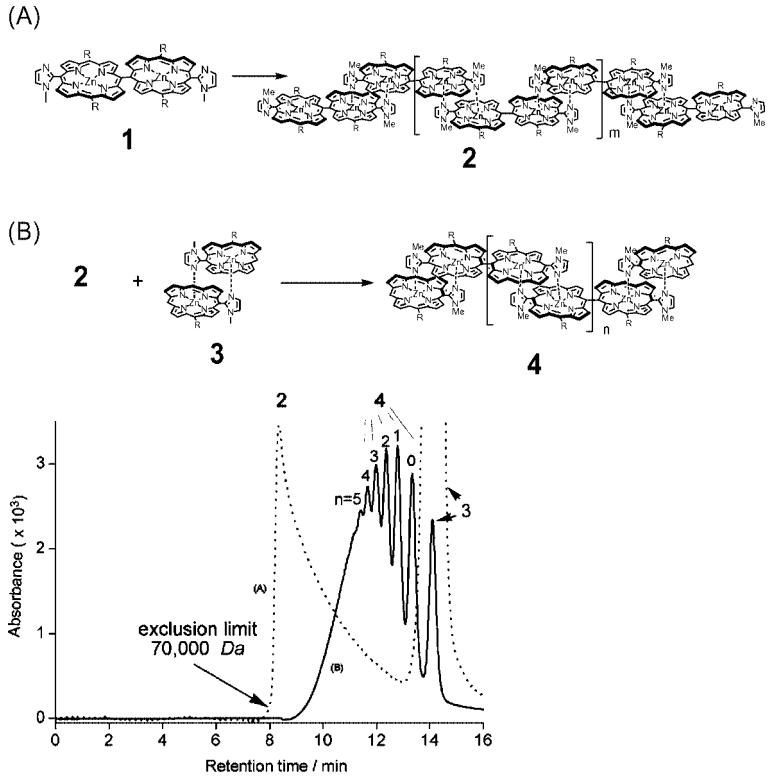

Figure 7. (A) Linear array formation of bis(imidazolylzincporphyrin) and (B) linear array with terminal monoimidazolylporphyrins and its GPC characterization.[56]

imidazolyl–Zn–porphyrin (Figure 8).[57] It is possible to design the array **6** of 200 Zn-porphyrin arrays terminated by Zn–Mn hetero-coordination by considering the relative strength of hetero Mn–Zn and homo Zn–Zn and Mn–Mn complementary coordinations. Under such conditions, photoexcitation of any porphyrin in the terminal 130 arrays leads to quenching by the terminal Mn–porphyrins, suggesting that rapid and efficient energy transfer is occurring along the linear array.

The linear porphyrin arrays are characterized by two important properties: no fluorescence quenching on array formation and efficient energy transfer along the array. Photocurrent generation by use of a dye-modified flat electrode may provide interesting applications for fields other than the conventional surface-coated porous semiconductor materials. In the former case, the efficient light-harvesting system becomes critical to compensate for the decreased surface area. Imidazolyl–Zn–porphyrin appended with an ω-mercaptoalkyl group is employed as a key element connecting the Au electrode surface and the porphyrin arrays.[58,59] Porphyrin appended with thiol **7** can modify the Au surface simply by a dipping process and an imidazolyl–Zn–porphyrin array can grow by a simple immersion procedure into a solution of *meso*-*meso*-coupled imidazolyl-zinc-porphyrin dimer **8**. After rinsing, the complementary coordination pair can be immobilized by covalent linking of *meso*-allyl ether substituents by a ring-closing metathesis reaction.[60,61] This series of procedures can be repeated until multi-porphyrin layers **9** are accumulated as detected by the gradual increase in the characteristic porphyrin absorption

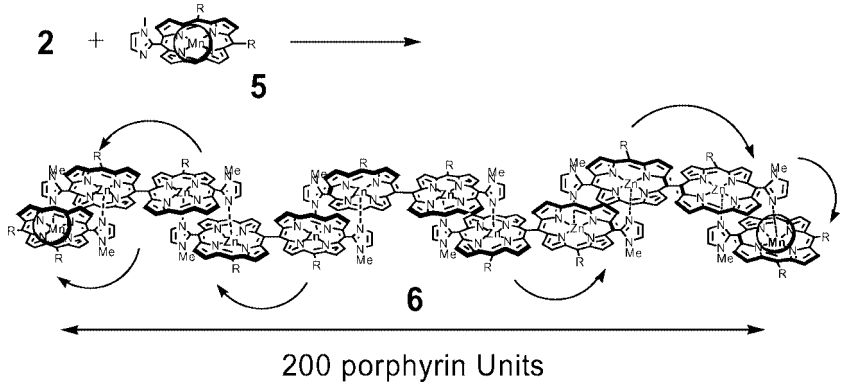

Figure 8. Hetero linear array formation from Zn and Mn porphyrins.[57]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(Figure 9).[62] Light-induced cathodic current was increased as a function of the accumulated amount of the porphyrin, suggesting the light harvesting effect.

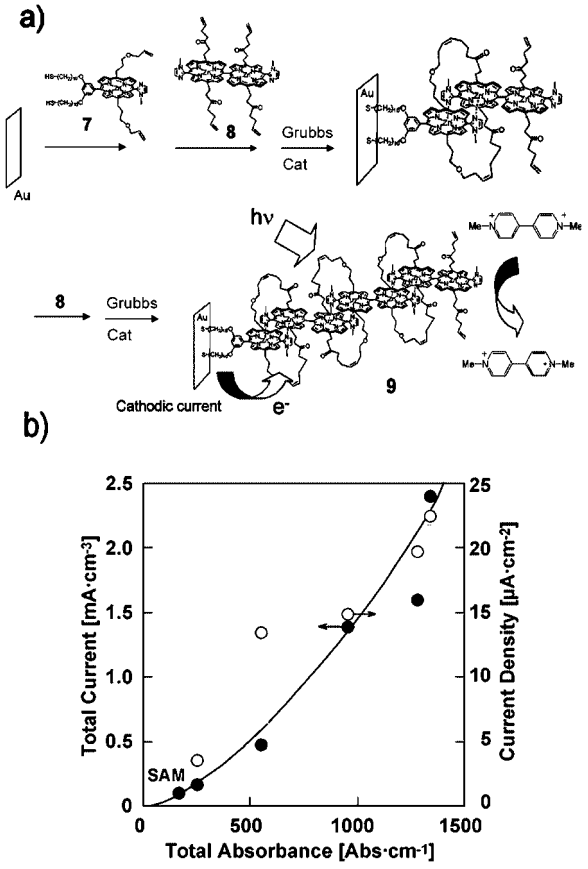

Figure 9. (a) Multiporphyrin array formation on a Au surface and metathesis linking. (b) Dependence of photocurrent on surface grafting.[62]

Two imidazolyl-zinc-porphyrins were then connected through a *m*-phenylene group to adjust the dihedral angle between two porphyrins to 120°, so that bifunctional bis-(imidazolyl–Zn–porphyrin) **10** may be organized into macrocycles, most optimistically to a strain-free hexamer (Figure 10).[63,64] The results were not so simple, but the newly developed reorganization procedure opened up a path to interesting supramolecular methodology leading selectively to macrocyclization. Here, the dynamic nature of imidazolyl-to-zinc coordination plays a critical role. Coordination under normal concentrations (>mM) leads to oligomerization rather than macrocyclization, since the latter process is entropically unfavorable. Then the mixture **11** is first subjected to equilibrium conditions by the addition of coordinating additives, usually MeOH, under high dilution. The successive solvent evaporation leads almost quantitatively to a mixture of macrocycles. The hexamer **12** was accompanied by an equal amount of pentamer **13**, suggesting that the balance of enthalpy and entropy governs the product distribution. Enthalpically, there is no choice of pentamer formation, since it leads to angular strain from the ideal 120°. Entropically a smaller ring is favored, since the encountering probability of two terminal imidazolyl–Zn–porphyrins becomes smaller for a larger ring. In the case of the *m*-phenylene-bridged bisporphyrin, the competition seems equally high for pentamer and hexamer, but far less so for tetramer and heptamer.

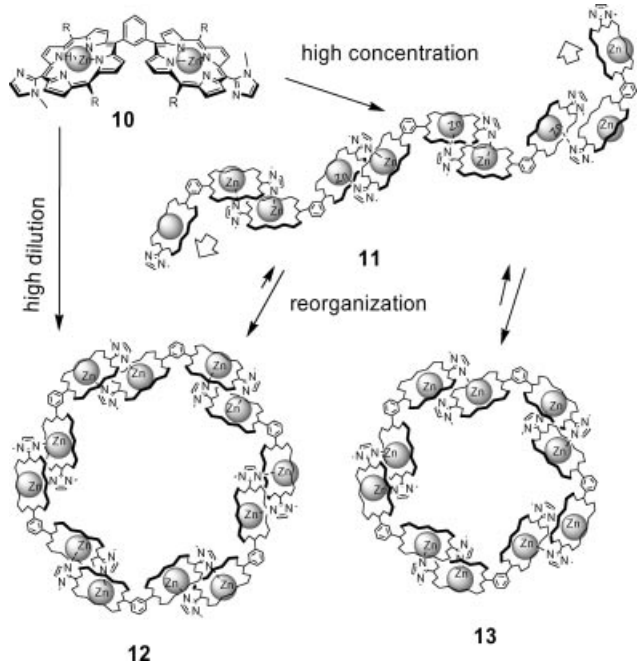

Figure 10. *m*-Phenylene-connected bis(imidazolyl)zincporphyrin and coordination organization.[63]

The assembled macrocycles never lose the fluorescence properties and maintain almost the same quantum yield and lifetime in their fluorescence emission. The energy hopping time constants through the coordination dimer units were determined by the analysis of anisotropy depolarization of the transient absorption spectra after polarized light excitation.[65] At the same time, exciton-exciton annihilation rates were obtained from pump-power dependence on the transient absorption. The coincident time constants from two methods were 8.3 and 5.3 ps for the pentamer and hexamer, respectively (Figure 11). The size-dependent rate constants may represent the effect of orientation factors. Considering the fluorescence lifetime of 2.2 ns, rapid energy transfer should take place 300–400 times during its excited state lifetime. These combined properties prove the excellent light-harvesting antenna models of the B850 type not only in their structure, but also in their function.

When three porphyrins are connected through *m*-phenylene groups and imidazolyls are appended at molecular terminals as in **14**, the self-complementary coordination results in a macrocyclic trimer **15** with a high selectivity under similar reorganization conditions. In this case, the competitive formation of dimer or tetramer is hardly observed because of two unfavorable strain energies. It is interesting that this macrocyclic trimer, which contains three coordination-free zinc-porphyrins, can accommodate tripodal ligand **16** in its hole by multitopic and cooperative coordination (Figure 12).[66] Then, UV and fluorescence titration of this macrocycle with tetrapyridyl ligand **17** in toluene suggested

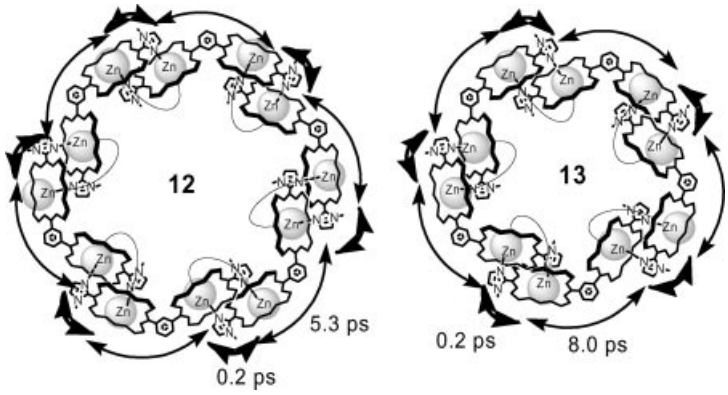

Figure 11. Macrocyclic hexamer and pentamer with excited energy hopping times. The metathesized links in the rear positions are abbreviated.[65]

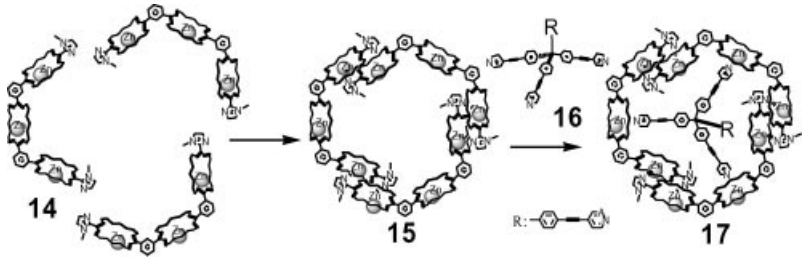

Figure 12. Macrocyclic trimer of trisporphyrin accommodating a tripodal pyridyl ligand.[66]

a stable 1:1 complex with a stability constant of $8 \cdot 10^8$ M$^{-1}$. When an electron acceptor is appropriately substituted at the fourth arm, the macrocycle can be regarded as a model of an LH1-type antenna.

4-Pyrazolylporphyrin instead of 2-(1-methylimidazolyl)-porphyrin can afford the cyclic trimer according to its angular requirement for coordination.[67,68] The trimer formation is somewhat cooperative, but its stability constant is estimated to be $9.0 \cdot 10^8$ M$^{-2}$ in dichloromethane at 22 °C. In accord with this stability constant, NMR and UV spectra of the trimer species are temperature and concentration dependent in the μM–mM concentration range.

Introduction of an ester group at the *ortho*-position of *para*-phenyl substituent increases the stability constant up to $6.0 \cdot 10^{13}$ M$^{-2}$ through the contribution of additional hydrogen bonding. These trimers have shown similar fluorescence quantum yields and lifetimes to the starting monomeric porphyrin, suggesting no significant perturbation in their $S_1$ states despite the strong interaction in the $S_2$ states.

Placement of a nitrogen atom at the 3-position in *meso*-pyridyl derivatives such as the 3-pyridyl or 5-(2-aminopyrimidyl) substituent results in the macrocyclic structure to satisfy the angular dependency.[69,70] The crystal structure suggests the macrocyclic tetramer **18** and **19** as shown in Figure 13, while the structure in solution shows a dynamic equilibrium between the cyclotetramer and other forms depending on other *meso*-substituents, as well as concentration and temperature. Thermochromic change is associated with complexation/decomplexation dynamics in solution at the concentration ca. $1 \cdot 10^{-4}$ M.

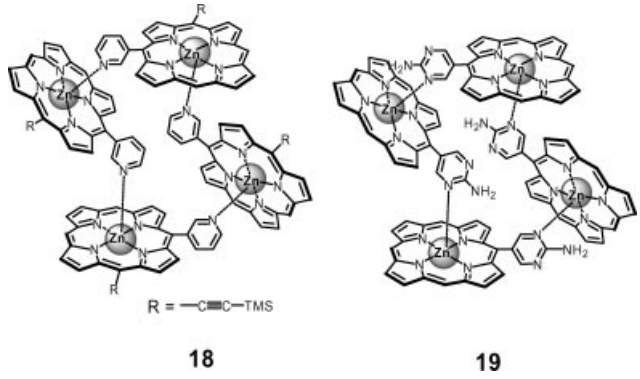

Figure 13. Cyclic tetramer formation from *m*-pyridyl- and pyrimidylzincporphyrins.[69,70]

The control of coordination angle is important for performing the desired cooperativity. The 2,6-dicarbamoylpyridine unit has internal hydrogen bonds to adopt a conformation that orients two arms approximately perpendicular to one another. A rectangular macrocycle **20** using a complementary coordination of the pyridyl unit to zincporphyrin was obtained (Figure 14). The stability constant was evaluated in $CHCl_3$ as $2 \cdot 10^8$ M$^{-1}$, from which the effective molarity was calculated as 6 M on the basis of the intrinsic binding constant for zinc-pyridine interaction.[71]

Two zincporphyrin units were connected by using this angle-constraining 2,6-dicarbamoylpyridine unit, **21**. Then tetrapyridyl free-base porphyrin **22**, in which intramolecular hydrogen bonds constrain the rotation of the pyridyl li-

**20**

Figure 14. Adjustment of coordination angle by hydrogen bonding.[71]

gands, assembled two units of the zincporphyrin by multitopic coordination into a 2:1 mixture of **21** and **22** (Figure 15).[72] The multitopic coordination interaction afforded the stability constant of $2.0 \pm 0.5 \times 10^6$ M$^{-1}$ for each binding event. The overall arrangement constructed a photosynthetic model containing four zincporphyrin units around the free-base porphyrin. The fluorescence intensity of the 2:1 complex **23** showed biphasic decay with a faster component of 490 ps along with a 1330-ps component of the **21**. The energy transfer occurred from **21** to **22** with the rate constant of $2 \cdot 10^9$ s$^{-1}$ and with a quantum yield of 73%. There are several examples of multitopic coordination of pyridyl-appended porphyrins to antenna macrocycles according to covalent approaches.[73–75]

A three-dimensional (3D) box formation is produced by cooperative coordinations. When two porphyrins are connected at the *meso* position, orthogonal conformation is favored by steric repulsion. When 5-(*p*-pyridyl)porphyrin is coupled at the 1-*meso* position, the product becomes a chiral mixture. The mixture is organized by self-coordination to a chiral mixture of three-dimensional bisporphyrin tetramers through homochiral self-sorting processes. The 3D box is favored by its rigidity and is more stable than the monocyclic tetramer from monopyridylporphyrin.[76,77] ω-Pyridyl(phenylene)$_n$-appended zincporphyrins gave similar porphyrin boxes. The energy hopping rates among the unit porphyrins for these box-type assemblies were analyzed by time-resolved spectroscopic methods in conjunction with polarization anisotropy measurements. The data were analyzed by assuming an exciton coherence length of L = 2 for the *meso*-*meso*-coupled dimer. The time constant was explained by a Förster-type incoherent energy hopping model. Therefore, the excitation energy hopping times between the dimeric zincporphyrin units were 48, 98, and 361 ps for **24a**, **24b**, and **24c**, respectively, showing exciton-exciton distance dependence by the bridging (phenylene)$_n$ units (Figure 16).[78]

When porphyrins are connected through a mono- or bisalkynylene unit, two porphyrins prefer to adopt a planar conformation due to a beneficial π-conjugation effect despite the rotational freedom around the triple bond. The zinc complex of bisporphyrin with *meso*-pyridyl functionalities, **25**, self-assembles by coordination to a box-shaped cyclic tetramer **26**, where two conformers, perpendicular and planar, are allowed (Figure 17).[79] In the case of the monoalkynylene-bridge, a planar conformer was the exclusive product reflecting the conformational preference at the monomer level. In the case of the bisalkynylene-bridge, on the contrary, the perpendicular conformer becomes predominant probably because of effective cancellation of the dipole moment, which is induced by the directions of the pyridyl groups in the tetramer.

As discussed earlier, the use of transition-metal ions in the porphyrin metal center cannot be the method of singlet energy harvesting. Although many studies on the structure formation are reported, photophysical studies on the triplet states are rare due to the inherent difficulty of the studies. The following few reports identify the decay processes after the excitation.

Scandola reported on the photophysical behavior of the system of a pentad porphyrin arising from coordination of tetra-*m*-pyridylporphyrin to four Ru(CO)TPP units (**27**)

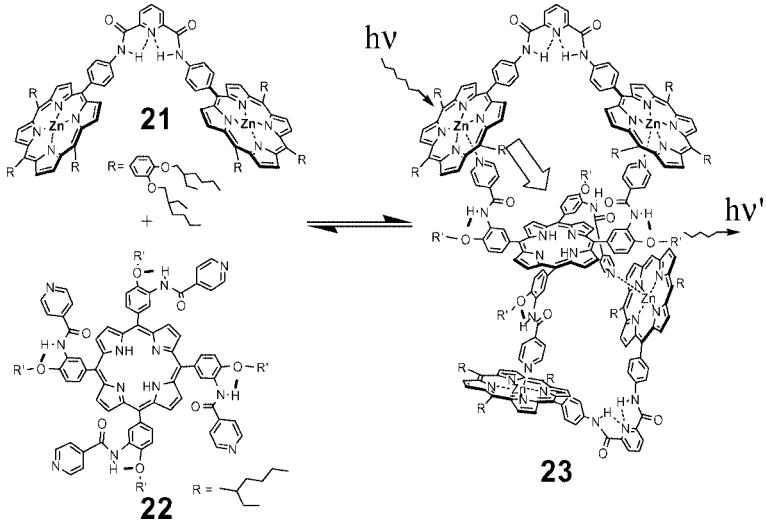

Figure 15. Complementary 2:1 complexation of zinc- and free base porphyrins and internal energy transfer.[72]

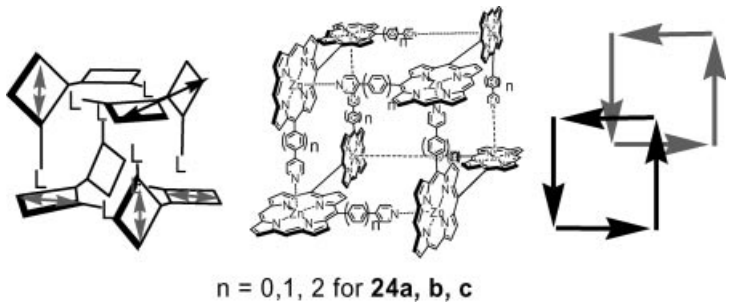

Figure 16. Box formation from *meso-meso* coupled bisporphyrin appended with pyridyl ligand and exciton energy transfer in the box assembly.[77,78]

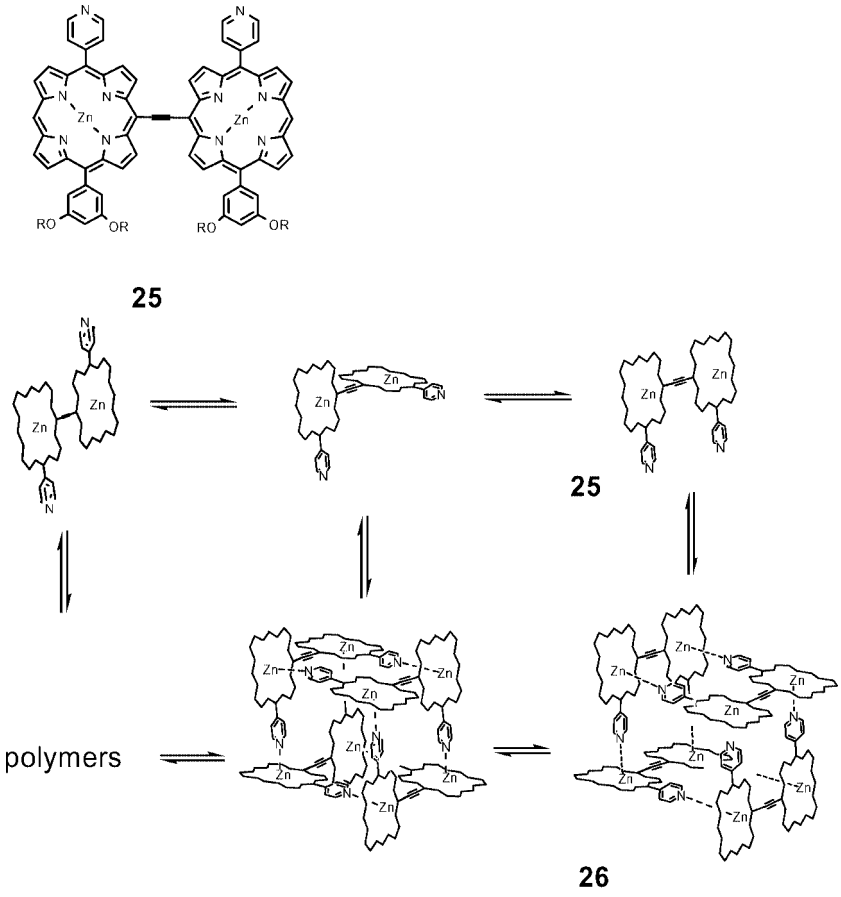

Figure 17. Acetylene-linked bis(pyridylporphyrin) and its coordination organization.[79]

(Figure 18).[80] The lifetime of the free-base porphyrin is shortened significantly to 0.5 ns from around 9 ns for TPP because of the efficient (95%) Ru-facilitated intersystem crossing to $^3$*Fb by spin-orbit perturbation. Excitation of the Ru porphyrin part leads also to $^3$*Ru with a much faster time constant (<30 ps) with 100% efficiency, then followed by irreversible energy transfer to $^3$*FbRu again with 100% efficiency due to the large driving force from Fb$^3$*Ru to $^3$*FbRu. The triplet energy transfer rate was estimated to be in the range $10^8$–$10^9$ $s^{-1}$. When zinc porphyrin is used as the axial ligating unit, the higher energy level of $^3$*Zn makes the energy difference between $^3$*ZnRu and Zn$^3$*Ru smaller and the equilibrium between two triplet states is established prior to deactivation.

Ruthenium porphyrin was connected by another chromophore, pyridyl-substituted perylenebisimide to afford a side-to-face supramolecular array of chromophores (**28**).[81] The absorption spectrum covers the full range of 350–620 nm with an extinction coefficient larger than $10^4$ $M^{-1}$ $cm^{-1}$. The photophysical properties obtained by using nano- and femtosecond time-resolved techniques are summarized in Figure 19. When the perylenebisimide (PBI) part (585 nm) is irradiated, the characteristic strong fluorescence ($\lambda_{max}$ = 620 nm) of the parent PBI is completely

**27** M = $H_2$, Zn

Figure 18. Axial coordination of tetrakis(pyridyl)porphyrin to four $Ru^{2+}$(CO)porphyrins.[80]

quenched ($\Phi$ = 0.001), compared with $\Phi$ = 0.96 for free PBI. The spectral change was characterized by the rise of the typical absorption band of the radical anion of PBI near 780 nm, associated with the formation of the Ru(TPP)CO radical cation. The change, with a time constant of 5.6 ps, clearly shows electron transfer from Ru(TPP)CO to $^1$*PBI. Excitation of the Ru(TPP)CO part (530 nm, although accompanied with PBI excitation), on the other hand, leads to the formation of $^3$*Ru(TPP)CO by fast intersystem crossing within 1 ps. Then energy transfer occurs from $^3$*Ru to PBI to generate a new species of $^3$*PBI. The triplet species of $^3$*PBI with a lifetime of 9.8 μs in deaerated $CH_2Cl_2$ is therefore obtainable by the irradiation of the Soret band region of the Ru(TPP)CO site.

## 6. Porphyrin with an Outer-Ring Metal Ion

The use of transition-metal ions from external sources is a powerful tool for obtaining various self-assemblies and has been well documented. Fujita and Ogura introduced first an elegant way of coordination organization, in which the combination of *cis*-coordination transition-metal ions and linear bridging ligands gave the most thermodynamically stable macrocycles after equilibrium.[82–85] When a porphyrin is employed as the component of the linear bridging ligand, macrocycles composed of porphyrin units are easily obtained. Alessio has already addressed these examples focusing on this methodology in his review.[11] However, the resulting assembly in most cases loses its fluorescence and photophysical studies through phosphorescence emission are rather limited.

Scandola examined the effect of external Ru complexes, which connect pyridyl-porphyrins, on the quenching of the porphyrin singlet. It was found that two mechanisms are operative in the adducts and that their contributions are dependent on the type of Ru complex. One is an enhanced intersystem crossing from Por($S_1$) to Por($T_1$) by interaction with centers of Type I Ru complexes (Figure 20).[86] The singlet quenching is proportional to the number of Ru centers. The other mechanism is singlet-triplet energy transfer from Por($S_1$) to Ru($T_1$) of the centers of Type II Ru complexes and provides an additional channel. The latter contribution depends on the energy level of the Ru($T_1$) state in the coordination environment at the Ru center. The energy levels of Ru($T_1$) with weak field ligands, such as DMSO, are low compared with the ones with strong field ligands, such as CO. The fluorescence lifetimes of the compounds **29**–**31** are reasonably explained by these mechanisms.

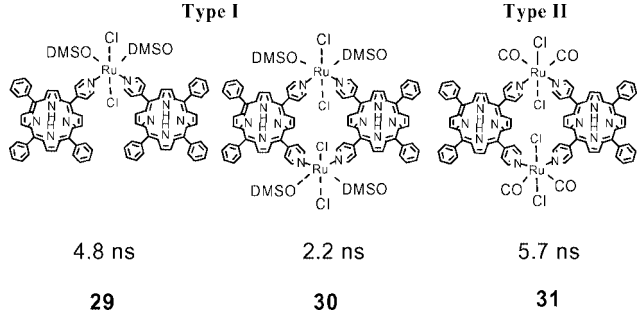

Figure 20. Organization of porphyrin by using external $Ru^{2+}$ coordination.[86]

The square porphyrin nonamer **33** is formed in solution by the addition of *trans*-coordinating bis(benzonitrile)$Pd^{2+}$ dichloride to a stoichiometric mixture of one central X-shaped unit (porphyrin **32a**), four T-shaped units (porphyrin **32b**), and four L-shaped units (porphyrin **32c**) (Figure 21).[87,88] The fluorescence emission of the solution mixture is quenched to greater than 90%. In accord with this observation, the fluorescence lifetime is shortened from 12 ns (the average lifetime for the initial mixture) to less than 1 ns. The claim of a light-harvesting effect must await analysis of how the triplet excited state behaves.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

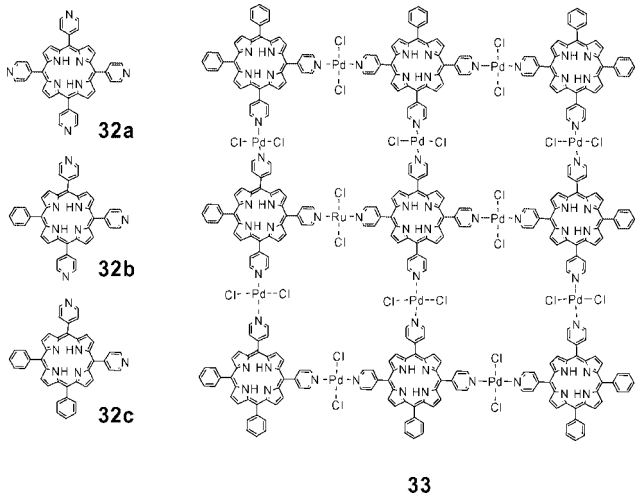

Figure 21. 2D porphyrin array by using *trans*-$Pd^{2+}$ complex.[87]

Rhenium tetramers of free-base and $Zn^{2+}$ porphyrins **34a** and **34b** may be a rare example of fluorescent metallamacrocycles (Figure 22).[89] Into this host cavity, tetrakis(4-pyridyl)porphyrin is incorporated as in **35** with a stability constant of $4 \cdot 10^7$ $M^{-1}$ by apparently cooperative multitopic coordination. The host emission is quenched by this incorporation without emission from the central guest.

As a chelating ligand, 8-hydroxyquinoline (oxine) is interesting, since quenching-free metal ions such as $Al^{3+}$ and $Ga^{3+}$ are known to give very stable octahedral complexes. Therefore, the *meso*-oxinyl-appended porphyrin was synthesized and its *fac*-tris(oxinylporphynyl) gallium complex **36** was obtained. In the complex, three porphyrins are arranged like a pinwheel. The center-to-center distances between two porphyrin units a-b, b-c, and c-a in Figure 23 were 15, 17, and 18.5 Å, respectively.[90,91] The fluorescence intensity was increased in the coordination complex compared with the free porphyrin. The fluorescence anisotropy decay analyzed the energy transfer rate between three porphyrin components as ca. 10 ps. Considering the fluorescence lifetime of 8.6 ns, the energy is stored in the trisporphyrin complex that allows an energy transfer 800 times to neighboring porphyrins in its excited lifetime. The introduction of two oxinyl groups at the facing *meso*-positions extends the coordination organization further to a dendritic structure **37**. Even in such a large assembly, the fluorescence intensity was larger than that of the starting free porphyrin.

As a quenching-free external metal ion, $Zn^{2+}$ may also be used for chelation organization. For this class of porphyrin assembly, Groves synthesized mono- and bisphenanthrolinyl-porphyrins, **38** and **39**, respectively.[92] Addition of the $Zn^{2+}$ ion to **38** induced a red shift of the Soret band by head-to-tail interaction of porphyrins of orthogonal orientation (Figure 24). For the case of **39**, a larger shift and

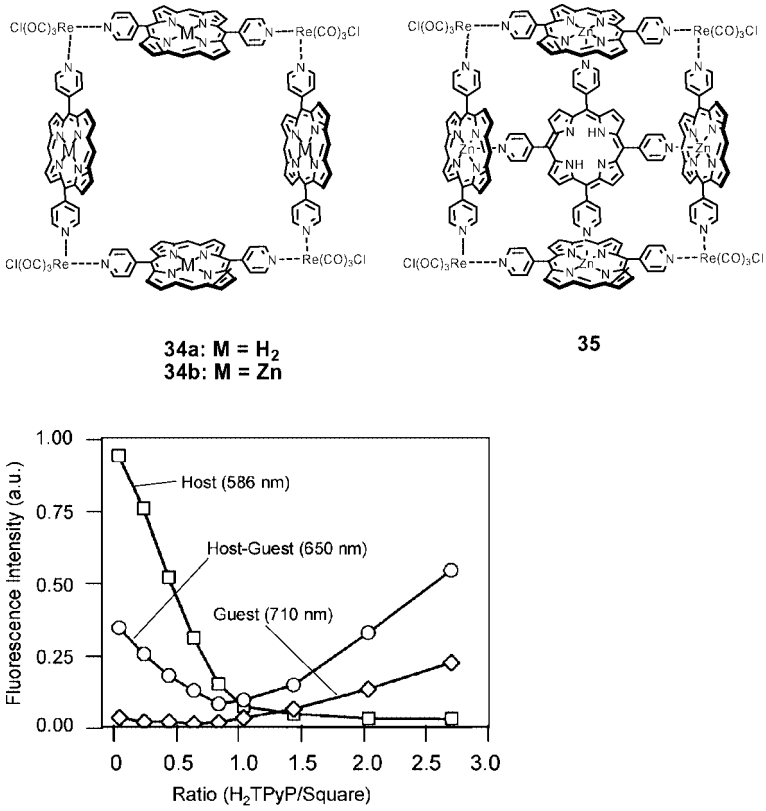

Figure 22. Fluorescence emission change on guest complexation into $Re^{2+}$-organized porphyrin square.[89]

broadening of the Soret band were observed to show the development of exciton interaction. The average chain length of oligomer **40** was estimated from the complexation rate constant and estimated as 12.3 ± 0.5. The oligomeric products are potentially fluorescent.

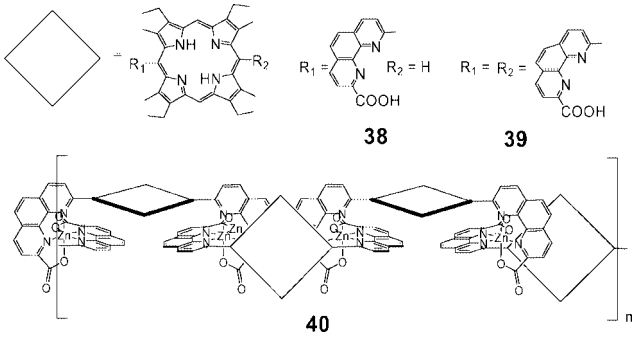

Figure 24. Mono- and bis(phenanthrolinyl)porphyrins and their $Zn^{2+}$ complexation.[92]

The use of a flat electrode surface instead of a porous semiconductor one for a dye-sensitized solar cell may provide an interesting possibility. The problems arising from the decreased surface area must, however, be overcome. Gold nanoparticles have attracted wide interest in view of physical properties that are different from bulk materials. Nano-sized particles should have large surface areas that can be modified by appropriate functionalities. The surface can be modified and protected by alkanethiolate. Therefore, an ω-porphyrin-bearing alkanethiolate with or without simple alkanethiolate was employed to modify the gold nanoparticles so as to afford **41** and **42** (Figure 25).[93]

The fluorescence of porphyrin gold particles **41** and **42** showed a double exponential decay. The lifetime of the parent compound (9.5 ns in THF) was perturbed to contain short major components 0.15 ns (86%) and 0.17 ns (97%), for **41** and **42**, respectively. The average lifetimes are therefore calculated as 1.4 ns for **41** and 0.41 ns for **42**. This means that the fluorescence of the porphyrin is significantly quenched even on the surface of gold nanoparticles. However, the degree of quenching is smaller compared with the case in which the same porphyrin is modified on a two-dimensional Au(111) surface, the latter fluorescence lifetime being 0.04 ns. A fewer number of gold atoms on the 3D surface of nanoparticles compared with the planar Au(111) electrode surface is involved in energy transfer quenching. The decay rate ($7.7 \cdot 10^9$ $s^{-1}$) of the absorption at 460 nm agreed with the rise of the excited plasmon band at about 600 nm. This means that any electron-transfer system faster than 130 ps can compete favorably with this energy transfer quenching.[94–96]

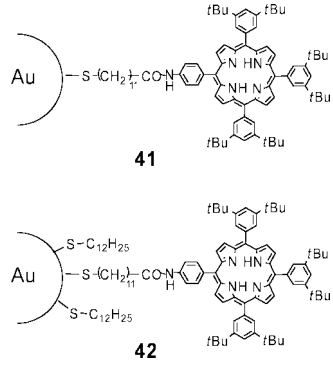

Figure 25. Porphyrin grafting on gold nanoparticle.[93]

The gold nanoparticles coated with a porphyrin-alkanethiolate **43** monolayer as in **44** were then treated with fullerene. Broad absorption appeared in the 700–800 nm region as a sign of a charge-transfer absorption band due to the π-complex formation between porphyrin and $C_{60}$. At the same time, these nanoparticles (**45**) were clusterized in solution as shown in **46** (Figure 26) and deposited on a $SnO_2$ electrode. The photocurrent action spectrum shows that the IPCE value increases with high concentrations of $C_{60}$ and reaches ca. 30% at 490 nm. The excited singlet state porphyrin is quenched efficiently by $C_{60}$ via electron transfer in the porphyrin-$C_{60}$ complex rather than energy transfer to gold nanoparticles.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

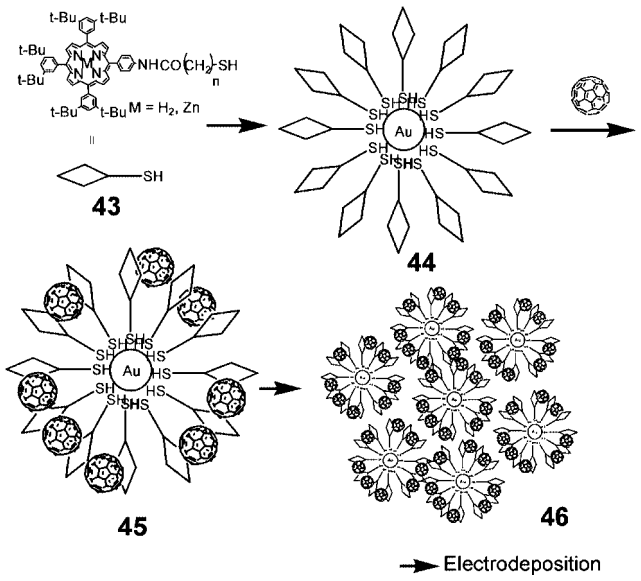

Figure 26. High order organization of porphyrin and fullerene with gold nanoparticles.[96]

The photoinduced charge separation is facilitated in the supramolecular complex of the porphyrin and $C_{60}$. The reduced $C_{60}$ injects the electron into the conduction band of $SnO_2$ nanocrystallites, or the electron is relayed through hopping among the $C_{60}$ molecules in the cluster. On the other hand, the oxidized porphyrin is regenerated by electron-transfer reduction with iodide in the electrolyte.[97]

## 7. Phthalocyanine

Compared with porphyrins, phthalocyanines have higher extinction coefficients in the Q-band region at longer wavelengths and emit fluorescence with much higher quantum yields. The metal-assisted organization of phthalocyanine in the past resulted in most cases in the quenching of singlet excitation energy. The author has been interested in incorporating phthalocyanine into supramolecular systems by using metal coordination. The first example is the use of the strategy of complementary coordination of an imidazolyl-zinc-porphyrin. Here the phthalocyanine unit is connected to the porphyrin as the *meso*-substituent. Two phthalocyanines are then connected through a complementary porphyrin dimer as **47**.[98] The absorption spectrum is a sum of two chromophores and covers a wide range of the visible region, just like the natural chlorophyll chromophores, but with an even larger extinction coefficient as illustrated in Figure 27. Excitation of any absorption range of porphyrin and phthalocyanine falls into the $S_1$(Q) state of phthalocyanine via efficient energy transfer to the lowest excited state. The fluorescence quantum yield from this state is as high as 0.71. Overall, the supermolecule is regarded as an excellent antenna composite having broad and strong absorption bands of both $S_2$ of porphyrin and $S_1$ of phthalocyanine and with a high fluorescence quantum yield from the lowest excited state of phthalocyanine.

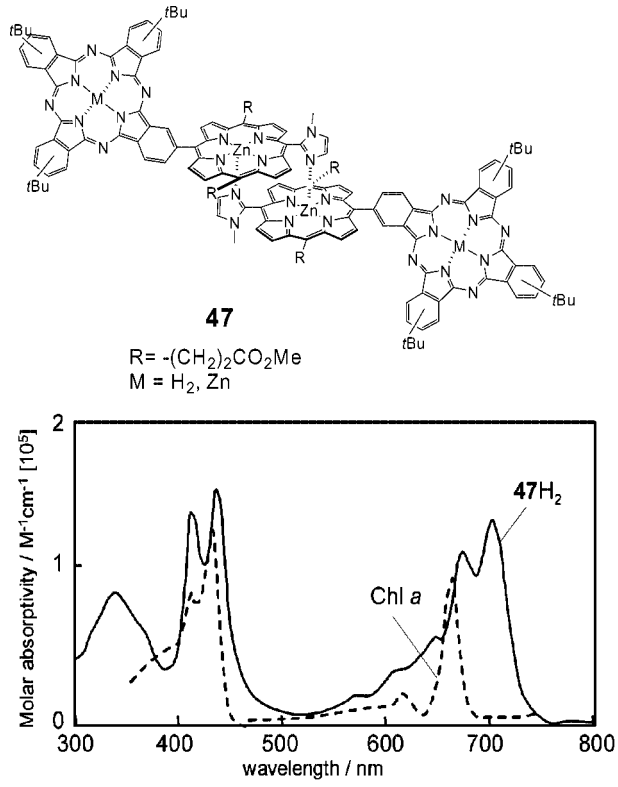

Figure 27. Complementary dimer formation of imidazolylzincporphyrin with phthalocyanine and comparison of the absorption spectrum with that of chlorophyll *a*.[98]

The above method is interesting in that phthalocyanines are brought into a highly fluorescent supermolecule. At the same time, it is challenging to develop a methodology to organize phthalocyanines themselves. Applying the same methodology as for porphyrins, an imidazolyl substituent was introduced at one of the benzo-groups of metallophthalocyanine.[99] A very stable dimer **48** (Figure 28) was formed with use of $Zn^{2+}$ or $Mg^{2+}$-phthalocyanine, as observed by NMR, UV/visible and mass spectra. The Q-bands split by exciton interaction in the dimer converge into a single band on titrating with *N*-methylimidazole through a clear isosbestic point. That a large excess of competitive ligand was required to cleave the coordination bond reflects the large stability constant. The values were evaluated as large as $1.4 \cdot 10^{11}$–$1.1 \cdot 10^{12}$ $M^{-1}$ for $Zn^{2+}$- and $Mg^{2+}$-phthalocyanines. The interaction of complementary coordination of imidazolyl-to-$Zn^{2+}$ or $Mg^{2+}$ was confirmed by characteristic higher-field shifts of the imidazolyl and the half of the ring protons that face each other to the large π-electronic system of phthalocyanine. The fluorescence of this dimer is not quenched on this assembly formation. The fluorescence quantum yields of the dimers from Zn(*t*Bu)$_3$, Zn(OBu)$_6$, and Mg(*t*Bu)$_3$-phthalocyanines were 0.26, 0.45, and 0.76, respectively. These values were almost identical to those of the starting monomeric species. The coordination organization of imidazolyl-porphyrin has thus been introduced into the field of phthalocyanine. A new version of supramolecular chemistry in the field of phthalocyanine will be interesting.

## 8. Perylenebisimide

As briefly overviewed in the general characteristics of chromophores, perylenebisimide shows excellent properties in light absorption and emission. The high aggregation tendency through the overlap of planar π-orbitals can be reduced when bulky substituents such as tetraaryloxy groups are introduced at the 1, 6, 7, and 12-positions.[100–104] According to the coordination organization proposed by Fujita, linear ligands were prepared most easily by introducing ligands at the imide nitrogen atoms of perylenebisimide. Then M(dppp), where dppp represents 1,3-bis(diphenylphosphanyl)propane, afforded in quantitative yields macrocyclotetramers **49** of perylenebisimides appended with various aryloxy groups with use of M = $Pt^{2+}$ and $Pd^{2+}$ (Figure 29).[105] These complexes remain intact at concentrations as low as ca. $10^{-6}$ M. Even if transition-metal ions are used in this case, the fluorescence quantum yield of the starting perylenebisimide in the square remained largely intact at a level of nearly 90%.

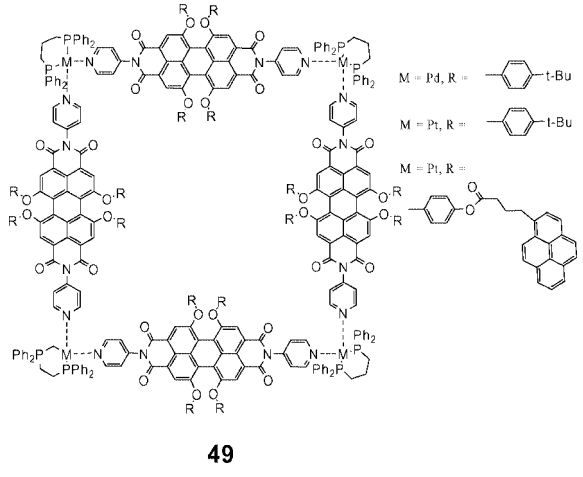

Figure 29. Macrocyclo-tetramerization of pyridyl-appended tetraaryloxyperylenebisimide by $Pd^{2+}$ or $Pt^{2+}$ complex.[105]

When pyrene is introduced at the 1, 6, 7, and 12 positions as the aryloxy substituent, the square has a large number of chromophores, 16 pyrene and four perylenebisimide chromophores, appropriate for light harvesting to cover a wide range of wavelengths with high molar extinction coefficients. Photophysical measurements were undertaken by steady state and time-resolved emission and transient absorption spectroscopy. Compared with the simple phenyl-substituted square, efficient (90%) and fast (0.2 ns) energy transfer from the pyrene to the perylenebisimide chromophores quenched almost completely the pyrenyl fluorescence. At the same time, very fast and efficient (>94%) electron transfer from pyrene to perylene reduced significantly the fluorescence from the perylene.

When bis(terpyridyl)-functionalized perylenebisimide **50** was subjected to self-assembly by metal coordination, linear metallo-supramolecular polymers (**51**) could be obtained (Figure 30).[106–109] Isothermal titration calorimetry studies of the terpyrydine ligand with various transition-metal ions established that $Zn^{2+}$ afforded a very stable bis(terpyridyl) complex with the successive stability constants $K_1 > 10^8$ M$^{-1}$ and $K_2 > 10^{10}$ M$^{-1}$, demonstrating a clear tendency for stable 2:1 complex formation. The complexes exhibited intense red fluorescence ($\lambda_{max}$ = 620 nm) with the quantum yield of ca. 0.9. The complexation with $Zn^{2+}$ has virtually no effect on the fluorescence quantum yield, although the use of $Fe^{2+}$ for the assembly formation induces a quenching down to $\Phi_{fl} < 0.1$. Likewise, fluorescence lifetimes of $Zn^{2+}$ dimer and polymer complexes were the same as that of the uncomplexed ligand, showing no electronic interaction between $Zn(tpy)_2$ and perylene sites. The complex showed reversibility of the binding event within a short timescale less than 1 min.

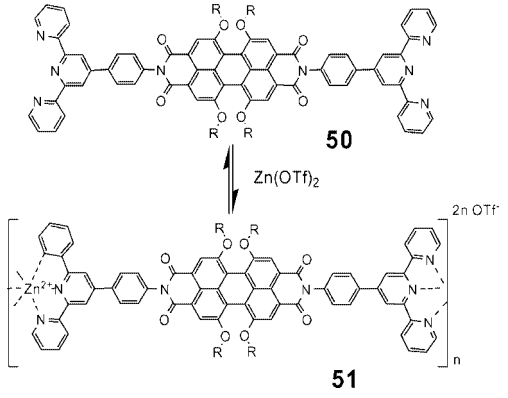

Figure 30. Bis(tpy)-connected polymerization of tetraaryloxyperylenebisimide.[106]

The process was monitored by fluorescence anisotropy titration. When fluorescence anisotropy $r$ is plotted as a function of the $Zn^{II}$/perylene monomer ratio, the $r$ value increased almost linearly to a maximum of $r$ = 0.133 at a 1:1 ratio of $Zn^{2+}$/**50**. The observations are compatible with the reversibility of the assembly formation, since the anisotropy decay due to the rotational diffusion of polymer must be slower. In the linear rigid coordination polymer, the transition-dipole moments align along the N–N axis of the perylenebisimide unit, and energy transfer within the perylenebisimide units along the same polymeric chain will not induce the anisotropy decrease. After 1:1 stoichiometry, a fragmentation process leading to the oligomeric units occurs and the anisotropy tends to decrease again, but never reaches the value of the monomer unit.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The dynamic character of ligand exchange was tested in solution by mixing two different perylenebisimide ligands **I** and **II** in a 1:1 molar ratio.[110] These ligands have the same molecular length and differ only in their alkyl groups at the phenoxy substituents. $^{1}H$ and $^{31}P$ NMR spectra after the equilibrium suggested the formation of an ideal statistical mixture. Mass spectra proved the existence of all the molecular squares **A**, **B**, **C**, **D**, **E**, and **F** (Figure 31) in the resulting solution.

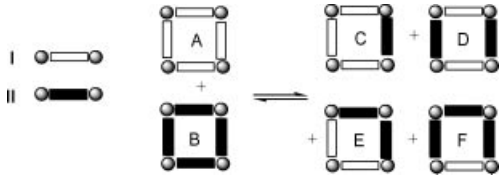

Figure 31. Ligand exchange equilibrium after mixing two molecular squares.[110]

## 9. Polypyridyl Metal Complexes

Bipyridyl (bpy), terpyridyl (tpy), phenanthrolyl (phen) metal complexes belong to this class and afford stable complexes with various metal ions. The ruthenium tris(bpy) complex and its derivatives play important roles on dye-sensitized solar cells.

The emission quantum yield from $^{3}MLCT$ of $Ru(bpy)_3$ is relatively high at 0.04, but $[Ru(tpy)_2]^{2+}$ emits with a low quantum yield of $1\cdot10^{-5}$ with a lifetime of 250 ps. The terpyridine complex is characterized by a directed connection and its large stability constant. When two tpy units are connected through a *m*-phenylene group its complexation with $Ru^{2+}$ ion affords automatically a macrocyclic hexamer of the $[Ru(tpy)_2]^{2+}$ complex **52** (Figure 32).[111] When carbazole is substituted as the central connecting unit, pentameric macrocycles are self-assembled by complexation with $Zn^{2+}$, $Ru^{2+}$, and $Fe^{2+}$ ions (**53**).[112] Although carbazole itself is highly fluorescent, the pentamacrocyclic $Ru^{2+}$ complex does not show fluorescence at all. On the other hand, the $Zn^{2+}$ macrocycle shows a strong emission at 560 nm. The macropentacyclic $[M(tpy)_2]^{2+}$ complexes were used for coating of nanocrystalline $TiO_2$ in a Grätzel-type solar cell device. The $Ru^{2+}$ complex gave the highest photoconversion efficiency ($\eta$) of the cell, $\eta$ being 1.53, 0.73, and 0.49% for the $Ru^{2+}$, $Zn^{2+}$. and $Fe^{2+}$ cases, respectively.

The $[Ru(tpy)_2]^{2+}$ complex is suitable for connecting other chromophores in a linear fashion. When $Ru(tpy)_2$ connects porphyrins as in **54**, the energy absorbed by the porphyrin is transferred to the lowest triplet state with 100% efficiency (Figure 33).[113] Triplet energy transfer from $^{3}PAu\text{-}Ru\text{-}PH_2$ to $PAu\text{-}Ru\text{-}^{3}PH_2$ with a center-to-center separation of 21 Å was examined. The energy transfer was mediated by the interposed Ru complex by an exchange mechanism at 77 K with a rate constant of $2.5\cdot10^{7}\ s^{-1}$, which is as fast as the arylene-connected case.

Hanan reports that the lifetime of $^{3}MLCT$ emission from $[Ru(tpy)_2]^{2+}$ increases significantly by the introduction of

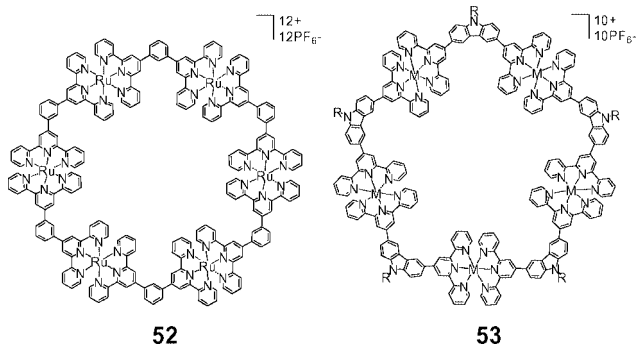

Figure 32. Macrohexamer and pentamer of $[Ru(tpy)_2]^{2+}$.[111,112]

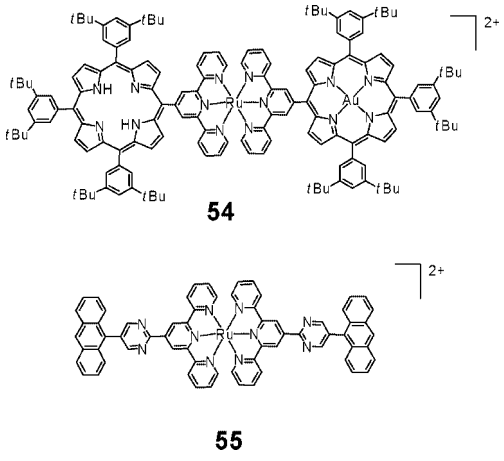

Figure 33. Connection of porphyrins through $[Ru(tpy)_2]^{2+}$ complex and $[Ru^{2+}(anthracenyl\text{-}tpy)_2]^{2+}$ complex.[113,114]

an anthracene moiety as in **55**.[114] The luminescence decay lasts up to 1.8 μs at room temperature. The phenomenon is explained by the equilibrium between the initially formed $^{3}MLCT$ state of $[Ru(tpy)_2]^{2+}$ and the low-lying anthracene-based triplet states. Introduction of organic chromophores having triplet excited states of energies close to the $^{3}MLCT$ is claimed to be an efficient way to prolong the short excited-state lifetime of the $[Ru(tpy)_2]^{2+}$.

The dendritic Ru(biscarbazolyl-phenanthroline)$_3$ complex **56** shows a red shift of absorption and emission maxima compared to $Ru(phen)(bpy)_2$ **57** (Figure 34).[115] The excitation spectrum resembles the absorption spectrum and

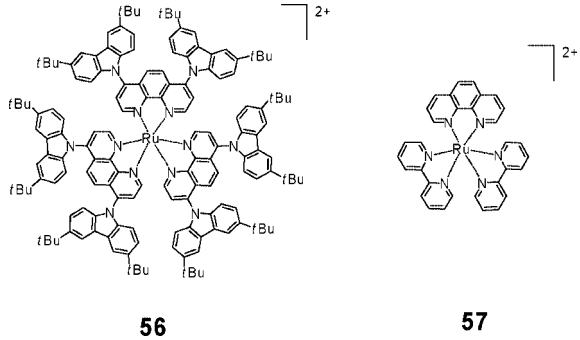

Figure 34. Ru(biscarbazolyl-phenanthroline)$_3$ and $Ru(phen)(bpy)_2$ complexes.[115]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the fluorescence from the carbazolyl part is completely quenched. These properties suggest its potential usefulness for the antenna function.

## 10. Conclusion and Outlook

The research on light-harvesting antenna has been much inspired by very aesthetic X-ray crystallographic structures of antenna complexes of the photosynthetic purple bacteria. The energy degeneracy of each component in the ring structure is important for transferring the energy efficiently to targets in any direction. Many chromophores having large extinction coefficients in the visible wavelength region have been organized into macrocyclic structures. New supramolecular methodologies have been developed and have succeeded in providing macrocycles of not only 2D but also 3D arrangements. Photophysical studies have elucidated the rate of the fast excitation energy hopping process by anisotropy decay after polarized light excitation and also by exciton-exciton annihilation. In the development of artificial antenna complexes, noncyclic systems are important too. Linear arrays without loss of excitation energy have also been developed. In order to obtain stable supramolecular complexes, transition-metal ions have been frequently used. In most cases, intersystem crossing leads to the triplet state. The analysis of such systems becomes difficult in most cases and awaits further photophysical studies.

## Acknowledgments

We thank our collaborators and co-workers, whose work is reported in this article. # Synthesis and Structural Characterization of a Halide-Free Rhombohedral Silver-Alkynyl Cage Complex $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$

**Omar M. Abu-Salah,*[a] Mohammed H. Ja'far,[a] Abdel Razzak Al-Ohaly,[a] Khalid A. Al-Farhan,[a] Hamda S. Al-Enzi,[a] Oleg V. Dolomanov,[b] and Judith A. K. Howard[b]**

**Keywords:** Silver / Clusters / Silver alkynyls / Alkynyl cluster / Cationic silver complex / Silver cage complex / Rhombohedral silver cage

The novel cationic complex $[Ag_{14}(C_2tBu)_{12}]^{2+}$ has been synthesized by four reactions: reaction of $[Ag(C_2tBu)]_n$ and $AgBF_4$ in acetone in a 6:1 mole ratio, that of $HC{\equiv}CtBu$ and $AgBF_4$ in water in the absence of a base, treatment of $[AgC_2tBu]_n$ with $HBF_4$ in acetone or that of $\{[Ag_3(C_2tBu)_2][BF_4]\}_n$ with $[Ag(C_2tBu)]_n$ in a 1:4 mole ratio. Single-crystal X-ray studies showed it to be a hexacapped cube of silver(I) atoms, with twelve $\eta^1$, $\mu^3$-$C_2tBu$ ligands.

## Introduction

Since the pioneering work of Nast[1] on acetylide complexes, dramatic developments in the field, parallel to the advances in organometallic chemistry, have been accomplished. The versatile mode of bonding of the alkynyl ligand resulted in numerous polynuclear alkynyl complexes.[2,3] Different aspects of the subject have been reviewed extensively.[2,4] Luminescence properties, particularly of mixed-metal platinum(II)-copper(I) and -silver(I) alkynyl complexes have been studied widely.[5] In the field of pure coinage metal alkynyls, new aspects of organometallic chemistry emerged when bis(phenylethynyl) metallates $[M(C_2Ph)_2]^-$ (M = Cu, Ag, Au) were treated with metal phenylacetylide polymers $[M(C_2Ph)]_n$ (M = Cu, Ag, Au). Consecutive steps of ethynylation and condensation of the formed anionic and cationic moieties resulted in the formation of homonuclear $[Ag_5(C_2Ph)_6]^-$ and heteronuclear $[Au_2Cu(C_2Ph)_4]^-$, $[Au_3M_2(C_2Ph)_6]^-$ (M = Cu, Ag), $[Ag_6Cu_7(C_2Ph)_{14}]^-$ and $[AuAg_6Cu_6(C_2Ph)_{14}]^-$ complexes.[6] Extension of ethynylation reactions to neutral complexes resulted in the complexes $[Au_2Ag_2(C_2Ph)_4(PPh_3)_2]$, $[Ag_2Cu_2(C_2Ph)_4(PPh_3)_4]$, $[AuAg(C_2Ph)_2]_n$, $[AuCu(C_2Ph)_2]_n$ and $[AgCu(C_2Ph)_2]_n$.[6i,7] Silver cages of various structures encapsulating the dianion $C_2^{2-}$, which is isoelectronic with $CN^-$, have been reported.[8] Recently anion-templated, rhombohedral silver-alkynyl cages $[Ag_{14}(C_2tBu)_{12}X]^+$ (X = F, Cl, Br) were synthesized and structurally identified.[9] Earlier we reported the synthesis and structure of the novel cationic silver alkynyl polymer $[Ag_3(C_2tBu)_2]_n[BF_4]_n$.[10] We now report new aspects of the chemistry resulting from the synthesis of halide-free rhombohedral silver alkynyl complex $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$ and its structure.

## Results and Discussion

The addition of $AgBF_4$ to $[Ag(C_2tBu)]_n$ in a 1:6 mole ratio in acetone gave a clear solution. Normal workup resulted in the slow precipitation of colourless crystals of $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$. Elemental analysis agrees very well with this formulation. The infrared spectrum has a strong $\nu(C{\equiv}C)$ signal at 2036 $cm^{-1}$. This frequency is dramatically lower than that of the linear complex $[Ag(C_2Ph)_2]^-$[6i] (by ca. 50 $cm^{-1}$), which indicates a bridging mode of bonding. A very strong band at 1077 $cm^{-1}$ was assigned to $BF_4^-$.

Single-crystal X-ray structure determination showed that the fourteen silver atoms are arranged in a hexacapped cube of silver atoms (rhombohedral dodecahedron) with twelve $\eta^1$, $\mu^3$-alkynyl ligands, each pair of alkynyl groups are almost linearly bonded to each capping silver atom, and every ligand bridges two nearby silver atoms on each edge of the cube (Figure 1).

This metal cage is similar to the cage of $[Ag_{14}(C_2tBu)_{12}X][BF_4]$ (X = F, Cl, Br), in which the $X^-$ anion is located at the centre of the cage.[9] We found, however, that halide ions are not a prerequisite to the formation and stability of the cage as claimed by other workers.[9] Unlike the case in complexes $[Ag_{14}(C_2tBu)_{12}X][BF_4]$,[9a,9b] the $BF_4^-$ anions are unambiguously located here. There is a weak Ag···F interaction [2.499(4) Å]. The $^{19}F$ NMR spectrum showed two reso-

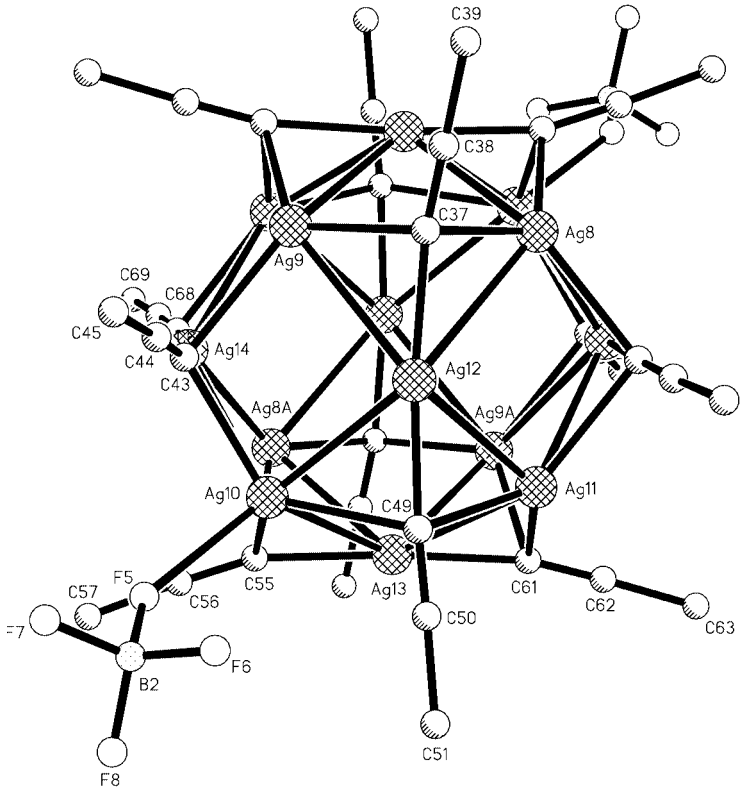

Figure 1. Structure of $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$. Methyl groups of tertiary butyl groups have been omitted for clarity.

nances characteristic for $BF_4^-$ at –151.62 and –151.57 ppm.[9a,9b]

The most interesting finding that emerges from the comparison of the encapsulated halide-anion $Ag_{14}$ cages[9a,9b] with the present anion-free $Ag_{14}$ cage is that the encapsulated fluoride anion shrinks the $Ag_{14}$ cage, while the bromide ion expands it. The mean Ag–Ag bond length in the anion-free cage is 2.9747(7) Å, which is almost equal to the corresponding value in the chloride-encapsulated cage [2.971(2) Å], but is 0.015 Å shorter and 0.064 Å longer than the corresponding bond lengths in the bromide- and fluoride-encapsulated cages, respectively.

This cationic cluster represents the highest homoleptic finite polynuclear monosubstituted alkynyl complex to be synthesized and structurally identified. Although neutral ligands and anions[11,12] are known to depolymerize monosubstituted alkynyl coinage metal polymers $[M(C_2R)]_n$ (M = Cu, Ag, Au), this reaction represents the first cationic depolymerization reaction for these polymers.

The same complex was also prepared by the reaction of $HC_2tBu$ and $AgBF_4$ in water by using different mole ratios in the absence of a base. The reactions in aqueous $NH_3$, which afford $[Ag(C_2R)]_n$, are well known for the identification of monosubstituted alkynes; nevertheless, no report has been documented for the reaction in the absence of a base. If the above reaction is carried out in ether, the cationic polymer $[Ag_3(C_2tBu)_2]_n[BF_4]_n$[10] is obtained. On the other hand, using $AgNO_3$ with $HC_2tBu$ in water results in the formation of the neutral polymer $[Ag_3(C_2tBu)_2NO_3]_n$, which was reported recently.[9b] The other product of the above reactions is $HBF_4$ [Equation (1), Equation (2)]:

$$7\ AgBF_4 + 6\ HC{\equiv}C\text{–}tBu \rightarrow \frac{1}{2}\{[Ag_{14}(C_2tBu)_{12}][BF_4]_2\} + 6\ HBF_4 \quad (1)$$

$$3\ AgBF_4 + 2\ HC{\equiv}C\text{–}tBu \rightarrow \frac{1}{n}\{[Ag_3(C_2tBu)_2][BF_4]\}_n + 2\ HBF_4 \quad (2)$$

The acid was determined by titration and by measuring the pH of the solution. This implies that these complexes are stable in strongly acidic media.

A third procedure for the synthesis of the same complex is the reaction of $HBF_4$ with $[Ag(C_2tBu)]_n$ in acetone. The product was identified by usual methods and by comparison with an authentic sample. If excess acid is used, $\{[Ag_3(C_2tBu)_2][BF_4]\}_n$ is obtained [Equation (3), Equation (4)]:

$$HBF_4 + \frac{7}{n}[Ag(C_2tBu)]_n \rightarrow \frac{1}{2}\{[Ag_{14}(C_2tBu)_{12}][BF_4]_2\} + HC_2tBu \quad (3)$$

$$HBF_4 + \frac{3}{n}[Ag(C_2tBu)]_n \rightarrow \frac{1}{n}\{[Ag_3(C_2tBu)_2][BF_4]\}_n + HC_2tBu \quad (4)$$

A fourth route for the same complex involves the reaction of $\{[Ag_3(C_2tBu)_2][BF_4]\}_n$ and $[Ag(C_2tBu)]_n$ in acetone in a 1:4 mole ratio [Equation (5)]:

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$\frac{1}{n}\{[Ag_3(C_2tBu)_2][BF_4]\}_n + \frac{4}{n}[Ag(C_2tBu)]_n \rightarrow \frac{1}{2}\{[Ag_{14}(C_2tBu)_{12}][BF_4]_2\} \quad (5)$$

The cage structure of the complex indicates without doubt that a halide template is not necessary for the formation and stability of such cages. The different reactions described for the synthesis of the complex might be of general use in the synthesis of homo- and heteronuclear group 11 metal-alkynyl cluster complexes.

## Experimental Section

**Synthesis of $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$**

**Method 1:** Silver tetrafluoroborate, $AgBF_4$ (98 mg, 0.5 mmol), was added to a suspension of $[Ag(C_2tBu)]_n$ (567 mg, 3.0 mmol) in acetone(20 mL). The reaction mixture was stirred for 24 h and then filtered. The solution was concentrated to a small volume and was left for crystallization. Colourless crystals of $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$ (540 mg, 81%) were obtained in two crops; m.p. 187–190 °C. IR (KBr disc):$\tilde{\nu}$ = 2036 (vs) $cm^{-1}$ (C≡C). $^1H$ NMR (400 MHz, [D$_6$]-acetone, TMS): $\delta$ = 1.46 ppm. $C_{72}H_{108}Ag_{14}B_2F_8$ (2657.41): calcd. C 32.68, H 4.12; found C 32.58, H 4.04.

**Method 2:** *tert*-Butylacetylene (1.96 mL, 16.0 mmol) was added to $AgBF_4$ (389 mg, 2.0 mmol) in water (20 mL) in an ice bath. The mixture became turbid within a few minutes, and a white, floating precipitate formed. After stirring for 12 h, the white precipitate of $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$ was filtered off and dried (224 mg, 59%); m.p. 190 °C. IR (KBr disc):$\tilde{\nu}$ = 2037 (vs) $cm^{-1}$ (C≡C). $C_{72}H_{108}Ag_{14}B_2F_8$ (2657.41): calcd.: Ag 56.62; found C 32.20, H 4.15, Ag 57.80, measured pH 1.79.

**Method 3:** Tetrafluoroboric acid, $HBF_4$ (0.103 mL, 0.46 mmol), was added to a suspension of $[Ag(C_2tBu)]_n$ (567 mg, 3.0 mmol) in acetone (25 mL) with stirring in a nitrogen atmosphere at room temperature. A clear solution was obtained within 10 min. The filtrate was concentrated to half volume. Addition of hexane (30 mL) effected the precipitation of colourless crystals of $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$ (470 mg, 77%). IR (KBr disc):$\tilde{\nu}$ = 2037 (vs) $cm^{-1}$ (C≡C); identical in all respects to an authentic sample described above.

**Method 4:** Silver *tert*-butylacetylide (378 mg, 2.0 mmol) was added to solution of $\{[Ag_3(C_2tBu)_2][BF_4]\}_n$ (287 mg, 0.5 mmol) in acetone (25 mL). A clear solution was obtained within 15 min. Filtration and addition of hexane gave $[Ag_{14}(C_2tBu)_{12}][BF_4]_2$ (400 mg, 60%). IR (KBr disc): $\tilde{\nu}$ = 2037 (vs) $cm^{-1}$ (C≡C); $C_{72}H_{108}Ag_{14}B_2F_8$ (2657.41): found C 32.56, H 4.05; identical in all respects to an authentic sample described above.

**Reaction between *tert*-Butylacetylene and Silver Nitrate**

*tert*-Butylacetylene, $HC_2tBu$ (1.96 mL, 16.0 mmol), was added to $AgNO_3$ (340 mg, 2.0 mmol) in water (20 mL) in an ice bath. The mixture became turbid within a few minutes, and a white precipitate formed. After stirring for 12 h, the white precipitate of $[Ag_3(C_2tBu)_2(NO_3)]_n$ was filtered off, washed with water and dried (220 mg, 60%). IR (KBr disc): $\tilde{\nu}$ = 2023.5 (vs) $cm^{-1}$ (C≡C); ref.[9b] 2022 $cm^{-1}$. $C_{12}H_{18}Ag_3NO_3$ (547.88): calcd. C 26.31, H 3.31, N 2.56; Ag 59.06; found C 26.00, H 3.19, N 2.69, Ag 58.80.

**Crystal Data:** $[C_{72}H_{108}Ag_{14}B_2F_8]$ $M$ = 2657.38, triclinic, P$\bar{1}$, $a$ = 13.725(1), $b$ = 13.793(1), $c$ = 24.466(2) Å, $\alpha$ = 95.16(1), $\beta$ = 94.33(1), $\gamma$ = 106.99(1)°, $V$ = 4386.3(6) Å$^3$, $Z$ = 2, $D_{calcd.}$ = 2.012 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 3.10 mm$^{-1}$, $T$ = 120(2) K, colourless block; 52607 measured reflections, 23128 independent ($R_{int}$ = 0.046 after semiempirical absorption correction), least-squares refinement of 924 parameters against $F^2$, $R(F)$ = 0.051 on 14969 independent reflections with $I>2\sigma(I)$, w$R(F^2)$ = 0.122 on all data. The structure contains two independent clusters, both at inversion centres. In one cluster, two Ag atoms are ordered, whereas twelve are disordered between two sets of positions in a 4:1 ratio (distances between alternative positions of the same atoms are 0.40 to 0.57 Å); six ethynyl ligands are disordered by a rotation around the quaternary C atom (which remains ordered), probably in concert with the disorder of the metal core. There is also rotational disorder of *t*Bu groups and monodentate $BF_4$ ligands. The second cluster is ordered, except for rotational disorder of two *t*Bu groups. CCDC-290250 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Copper(II) Complexes of the Tetraazamacrocyclic Tertiary Amide Ligand Alanyl-Cyclam

**Christian Schickaneder,[a] Frank W. Heinemann,[a] and Ralf Alsfasser*[b]**

**Keywords:** Copper / Cyclam / Bioinorganic chemistry / Electrophilic activation / Winkler–Dunitz parameters

Hydrogen bonding to the electrically neutral tertiary carboxamide nitrogen atom of peptidyl-prolyl groups is known to facilitate the C–N bond rotation during peptide and protein folding. Since metal complexes with nitrogen-coordinated tertiary amide ligands are formally analogous, they may be used to model this so-called electrophilic activation. In this paper we report on the synthesis of a monoacylated cyclam complex, [(Boc-Ala-cyclam)Cu]$(CF_3SO_3)_2$ (**8**; Boc: *tert*-butyloxycarbonyl, Ala: alanine, cyclam: 1,4,8,11-tetraazacyclotetradecane). It contains a fully $sp^3$-hybridized metal-bound amide nitrogen atom. The resonance is completely cancelled and the observed C–N distance of 147 pm is consistent with a single bond. These features are exceptional among Werner-type complexes and define the maximal possible electrophilic distortion of an amide bond.

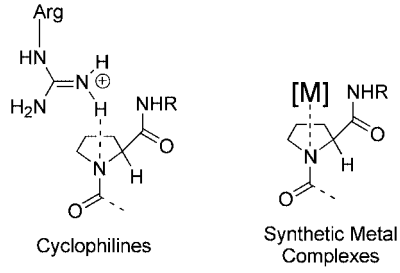
## Introduction

The activation of tertiary carboxamides towards hydrolytic cleavage and C–N bond rotation is a topic of considerable interest. Two catchwords are the hydrolysis of β-lactam antibiotics[1] and the *cis*-*trans* isomerization about peptidyl–prolyl bonds in proteins.[2] The latter is often the slow step during protein folding and supposed to play an important role as a functional switch in different processes such as enzymatic substrate recognition[3] or neurodegenerative protein aggregation.[4] Isomerases, PPIases, are known to facilitate the amide rotation. How exactly they operate is not known, although different means to lower the rotational barrier have been discussed.[5] Particularly interesting for coordination chemists is a motif observed in the catalytic centre of cyclophilines,[6] and in histidyl peptides:[7] hydrogen bonding to the amide nitrogen atom is proposed to stabilize the pyramidal transition state structure at the nitrogen atom. This is formally analogous to the coordination of a metal ion as it has been proposed to explain the effect of siver(I) ions on the rotational barrier of dimethylacetamide.[8] An illustration of an arginine hydrogen bond in comparison with a coordinated metal center is shown in Scheme 1.



Scheme 1. Electrophilic activation of a tertiary amide group; hydrogen bonding in peptides and proteins (left), or metal coordination (right).

Based on this analogy, Lectka and colleagues have suggested that metal complexes could be developed into synthetic catalysts to trigger biological proline switches.[9] This perspective is highly interesting but suffers from the lack of information on coordination complexes containing nitrogen-bound tertiary carboxamide ligands. We have therefore started a systematic study of these unusual compounds.[10] Here we describe the synthesis and structural properties of copper(II) complexes with macrocyclic alanyl-cyclam ligands. Our aim was to place a metal ion in close proximity to an amide nitrogen atom in order to achieve full pyramidalization and complete cancellation of resonance. This limiting case is an important missing piece required for a quanitative understanding of the electrophilic amide activation.

## Results and Discussion

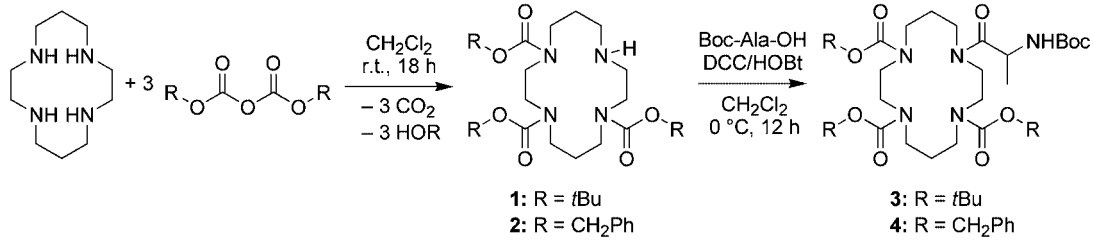
### Synthesis

Our first aim was to prepare a cyclam ligand in which one of the amine functions is converted into a tertiary amide. Prior to monoacylation, three of the cyclam nitrogen atoms had to be protected. Scheme 2 shows the synthesis of triple-protected cyclam. We have synthesized the tris(*tert*-butoxycarbonyl) (Boc) and tris(benzoxycarbonyl) (Cbz) derivatives **1** and **2** according to a slightly modified route reported by Brandes et al.[11] The yields of 35–50% after flash column chromatography on silica gel were moderate in both cases. Coupling with *N*-*tert*-butoxycarbonyl-(*S*)-alanine [Boc-(*S*)-Ala-OH] was achieved by the well-established DCC/HOBt (DCC = dicyclohexylcarbodiimide, HOBt = *N*-hydroxybenzotriazole) method.[12] We have applied this method earlier to the synthesis of ruthenium-modified 1,4,7,10-tetraazacyclodecane (cyclen) ligands.[13] The isolated yields were moderate in the case of Boc-(*S*)-Ala-cyclam-$Boc_3$ (**3**, 70%) and low in the case of Boc-(*S*)-Ala-cyclam-$Cbz_3$ (**4**, 26%). The structures and the synthesis of both compounds are shown in Scheme 2.

Acid deprotection of Boc-(*S*)-Ala-cyclam-$Boc_3$ was achieved with aqueous HCl in dioxane.[13] Scheme 3 shows the structure of the tris(hydrochloride) salt **5** which was characterized by an X-ray structure analysis (Figure 1). In order to facilitate binding of a copper(II) ion inside the macrocyclic ring and to enhance the solubility of the ligand in organic aprotic solvents, we attempted to remove most of the HCl. An interesting and revealing result was obtained with a ligand sample obtained by passing an $NH_3$ stream through a suspension of **5** in chloroform. The soluble product was isolated and reacted with copper(II) triflate in acetonitrile. Unfortunately, we were not able to obtain single crystals of the complex formed. However, its IR spectrum shows a shift of the carbonyl band from 1625 $cm^{-1}$ to 1592 $cm^{-1}$. This clearly indicates that the metal ion does not bind to the amide nitrogen atom which would cause a high energy shift due to the reduced amide resonance.[14] We propose the structure **6** shown in Scheme 3 with a bidentate ethylenediammine part of the cyclam ligand and two chloride ions coordinated to the copper(II) ion. This is based on the analogy to observations in related acylated triazacyclononane complexes by Houser et al.[15] and supported by C,H,N,S elemental analysis data. The shift of the carbonyl IR band indicates that the amide oxygen atom may also coordinate.

We concluded from the results summarized in Scheme 3 that complete removal of HCl from the ligand **5** is a prerequisite for the coordination of the tertiary amide nitrogen atom in copper complexes. Since this required a strong base, NaOH in dichloromethane was applied to prepare the acid-free ligand. Subsequent reaction with $Cu(CF_3SO_3)_2$ in acetonitrile and layering with diethyl ether yielded a violet material with elemental analysis data indicating the constitution $[(Ala\text{-}cyclam)(H_2O)Cu](CF_3SO_3)_2 \cdot 0.25Et_2O$. There is no evidence for the presence of chloride in the sample and an IR band at 1756 $cm^{-1}$ is consistent with a nitrogen-bound amide ligand. However, a second IR band at 1592 $cm^{-1}$ with a shoulder at 1649 $cm^{-1}$ indicates that a mixture of N- and O-coordinated tertiary amide complexes is present and we were not able to separate these species. It is not yet clear whether trace impurities of chloride or an unknown coordination mode involving the free amine function of the amino acid moiety is responsible for this behaviour.

Our failure to obtain well-defined N-coordinated amide complexes from the protonated ligand **5** reflects the difficulties involved in the synthesis of such compounds. Even though the cyclam framework should strongly favour coordination of a copper(II) ion within the ring, the system avo-



Scheme 2. Synthesis of the Boc- and Cbz-protected Boc-(*S*)-alanylcyclam derivatives Boc-(*S*)-Ala-cyclam-$Boc_3$ (**3**) and Boc-(*S*)-Ala-cyclam-$Cbz_3$ (**4**).

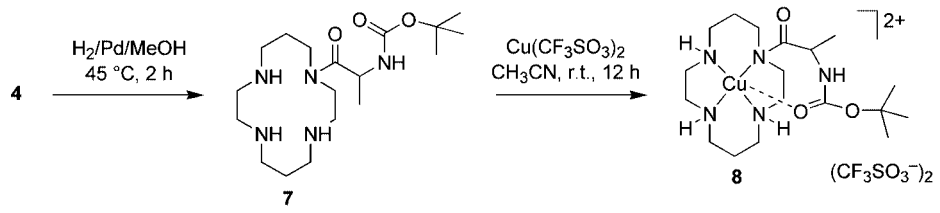

Scheme 4. Hydrogenation of the Cbz-protected compound **4** to the free ligand **7** and synthesis of the copper complex [{Boc-(*S*)-Ala-cyclam}Cu]$(CF_3SO_3^-)_2$ (**8**).

ids coordination of the weak amide donor. It is therefore not surprising that amide nitrogen coordination was unknown before the 1990s and has been categorically ruled out in several important older articles on amide complexes.[16] We reasoned that in our case a protecting group would be preferable which can be removed without protonation of the ligand. The Cbz function turned out to be a good choice.[17] It is cleaved off by hydrogenation in the presence of a palladium catalyst in methanol. This and the following reaction of Boc-(*S*)-Ala-cyclam (**7**) with $Cu(CF_3SO_3)_2$ is shown in Scheme 4. The copper complex [{Boc-(*S*)-Ala-cyclam}Cu]$(CF_3SO_3)_2$ (**8**) was obtained with a yield of 74%. Its composition was confirmed by C,H,N,S elemental analysis and FAB mass spectrometry. The IR spectrum shows two bands at 1742 $cm^{-1}$ for the amide function and 1658 $cm^{-1}$ for the Boc protecting group. The blue shift of the amide band is in excellent agreement with our data on a $Cu(CF_3SO_3)_2$ of dipicolyl-*N*-boc-glycylamide[10a] and confirms amide nitrogen coordination in the bulk sample. An X-ray structure analysis of the complex is discussed below.

### X-ray Structure Analyses

Single crystals were obtained from the ligand tris(hydrochloride) salt **5** and the copper complex **8**. An ORTEP plot representing the structure of the cation in **5** is shown in Figure 1. All hydrogen atoms were localized in the electron density map. The alanyl nitrogen atom N5 and the two cyclam atoms N2 and N4 are positively charged. Hydrogen bonds between those ammonium functions and the chloride ions loosely connect individual molecules in a three-dimensional network. Most important for our study is the geometry of the tertiary amide function. Deviations from planarity are most conveniently described by two quantitative parameters defined by Winkler and Dunitz.[18] One is the twist angle $\tau$ between the C1–C10 and the C12–O1 axes which ranges from 0° to 90°. The second is the pyramidalization $\chi_N$ at the nitrogen atom. It varies between 0° for a planar environment and ca. 60° for a fully pyramidal geometry. We will later discuss how the binding of metal ions deplanarize an amide group and how this activation affects the C–N bond length. In this context, ligand structures are useful for comparison. The C11–N1 bond length in **5** of 135.7 pm and the small twist angle $\tau$ = 9.3° are typical for an undistorted amide function. Interestingly, a significant pyramidalization at the nitrogen atom of $\chi_N$ = 17.7° is observed. This is larger than in related dipicolylamide derivatives[10b] although not unusual for carboxamides. Large deviations from planarity are possible because the energy barrier for out-of-plane wagging is rather low.[19] An examination of amide structures by Gilli et al. reveals that $\chi_N$ can reach values of over 20° without a significant elongation of the C–N bond.[20] Much effort of organic chemists focused on the effects of distortion on non-planar amides which model different stages during the C–N-bond rotation.[21] It was shown that geometric strain can enforce significant twisting and pyramidalization. However, the effects on the C–N bond lengths are generally rather small and the variety of different compounds having the amide group as a part of an acyclic, cyclic, or polycyclic structure make quantitative correlations difficult. An examination of different structures leads to the conclusion that the amide C–N bond is only affected when $\chi_N$ reaches values of ca. 30°. This has not been specifically addressed by other authors but it is interesting in the context of our observations on metal complexes. We will show below that the latter provide a better basis for quantitative structure correlations since their amide groups are not forced into a rigid structure which may obscure changes in the C–N bond length. A key compound in our studies is the copper complex **8** which contains a fully pyramidalized amide nitrogen atom.

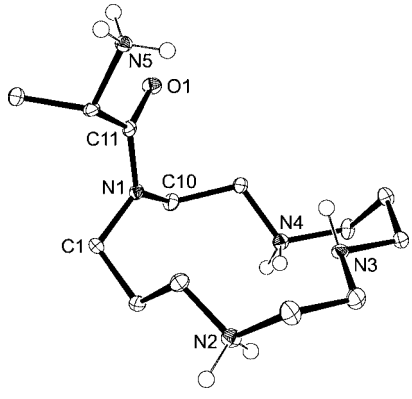

Figure 1. ORTEP plot at 50% probability of the cation Ala-cyclam·$3H^+$ (**5**) (hydrogen atoms except for NH are omitted for clarity); selected bond lengths [pm], angles [°], $\tau$ [°], and $\chi_N$ [°]: C11–N1 135.7(2), C11–O1 123.3(2); C1–N1–C10 118.1(2), C1–N1–C11 124.3(2), C10–N1–C11 115.3(2); $\tau$ = 9.3; $\chi_N$ = 17.7.

Compound **8** crystallizes in the acentric space group $P2_1$ with two independent complexes **A** and **B** in the asymmetric unit. They are depicted in Figure 2. In complex **8A** the copper ion is bound in the center of the cyclam ligand which

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coordinates in the typical *trans*-III mode[22] with one five-membered chelate ring in the δ, one in the λ, and both six-membered rings in the chair configuration. The Boc protecting group is weakly bound at a distance Cu1–O2 of 248.8 pm and a triflate ion is positioned in the apical position of a distorted octahedron with a long contact of Cu1–O63 of 278.9 pm. The second complex **8B** also has a *trans*-III type cyclam ligand but one of the six-membered chelate rings is in the rare boat form.[23] As a consequence, the proton H20b of the central methylene group is only 270.5 pm away from the copper centre and there is no room for an apical triflate ion. The coordinated Boc group compensates for the lack of σ-donation and binds at a distance of Cu2–O5 of 230.5 pm, which is 13.3 pm shorter than the corresponding contact in **8A**. However, the coordinated tertiary amide function is not much affected by these differences.

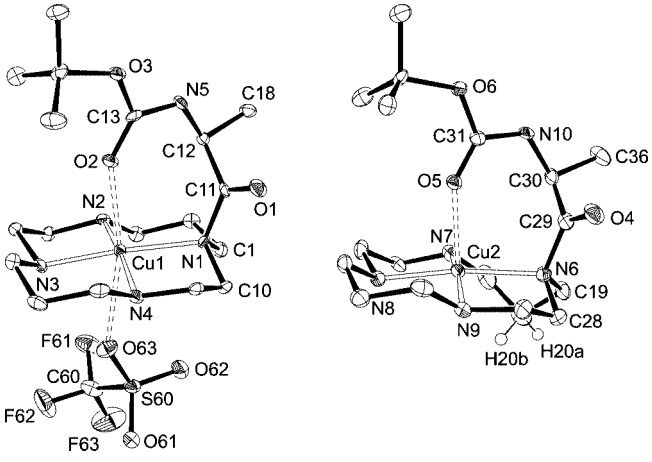

Figure 2. ORTEP plots at 50% probability of the two complexes **A** and **B** observed in the structure of [{Boc-(*S*)-Ala-cyclam}Cu]$(CF_3SO_3)_2$ (**8**) (hydrogen atoms except for those located at C20 in complex **B**, and the three non-coordinating triflate ions are omitted for clarity); selected distances [pm], angles [°], $\tau$ [°], and $\chi_N$ [°] of **A**: Cu1–N1 212.7(3), Cu1–N2 201.2(3), Cu1–N3 202.1(3), Cu1–N4 200.5(3), Cu1–O2 248.8(2), Cu1–O63 278.9, C11–N1 146.9(4), C11–O1 120.2(4); N1–Cu1–N2 95.3(2), N1–Cu1–N3 175.7(2), N1–Cu1–N4 86.7(2), N1–Cu1–O2 92.4(2), N2–Cu1–N3 86.7(2), N2–Cu1–N4 170.3(2), N2–Cu1–O2 92.7(2), N3–Cu1–N4 90.7(2), N3–Cu1–O2 91.4(2), N4–Cu1–O2 96.7(2), Cu1–N1–C1 112.4(2), Cu1–N1–C10 100.6(2), Cu1–N1–C11 112.8(2), C1–N1–C10 109.8(3), C1–N1–C11 112.8(2), C10–N1–C11 109.3(2); $\tau$ = 35.8; $\chi_N$ = 58.5; selected distances [pm], angles [°], $\tau$ [°], and $\chi_N$ [°] of **B**: Cu2–N6 214.7(3), Cu2–N7 203.1(3), Cu2–N8 200.9(3), Cu2–N9 202.1(3), Cu2–O5 230.5(2), Cu2–H20b 270.5, C29–N6 146.2(5), C29–O4 119.9(5); N6–Cu2–N7 96.3(2), N6–Cu2–N8 172.02(2), N6–Cu2–N9 85.3(2), N6–Cu2–O5 92.2(2), N7–Cu2–N8 85.5(2), N7–Cu2–N9 165.7(2), N7–Cu2–O5 97.3(2), N8–Cu2–N9 91.1(2), N8–Cu2–O5 93.3.4(2), N9–Cu–O5 96.8(2), Cu2–N6–C19 112.5(2), Cu2–N6–C28 102.6(2), Cu2–N6–C29 109.2(2), C19–N6–C28 110.4(3), C19–N6–C29 110.9(3), C28–N6–C29 111.1(2); $\tau$ = 30.6; $\chi_N$ = 56.9.

The stereochemistry of the amino acid part is in both cases (*S*) at the stereogenic α-carbon atom and (*Rp*) with respect to the chiral plane defined by the amide function. This implies that the methyl group is *exo* with respect to the seven-membered chelate ring formed by the coordinating Boc group and is analogous to the situation in a cadmium(II) complex of dipicolyl-Boc-alanylamide.[10a] The Cu–N(amide) distances (**8A**: 212.7 pm; **8B**: 214.7) are not much longer than the contacts between the copper ion and the secondary amine group which have typical values of 200–203 pm. A comparison with the few known copper(II) complexes with N-coordinated tertiary amide ligands shows that the Cu–N(amide) bond in **8** is unusually short. A recently published diisopropyl-triazacyclononane acetamide copper(II) chloride complex by Watkinson et al. has a Cu–N distance of 251.1 pm[24] and a paper by Schröder et al. reports on a related triazacyclononane derivative with a distance of 261.1 pm.[25] The closest contact observed in a dipicolylamide derivative is 216.4 pm in a copper(II) triflate complex from our group.[10c] The short Cu–N(amide) distance in **8** corresponds to a fully pyramidalized nitrogen atom as is evident from the pyramidalization parameter $\chi_N$ of almost 60° (**8A**: 58.5°; **8B**: 56.9°). Again, these values are exceptional in that they are the highest observed in Werner-type complexes to date.

In accord with this finding the C–N distance of 146 pm is typical for a single bond (147 pm[26]) and indicates that the amide resonance[27] is completely cancelled. It is interesting to compare this result with the situation in Schröder's complex with its long Cu–N(amide) distance of 261.1 pm which is significantly larger than the sum of the ionic radii of a six-coordinate $Cu^{2+}$ ion (87 pm) and the van der Waals radius of a nitrogen atom (160 pm).[26] This weak electrostatic interaction suffices to induce a significant pyramidalization at the nitrogen atom ($\chi_N$ = 30°), whereas the C–N distance of 135.7 pm is typical for an undistorted organic carboxamide. Further support for this interpretation is provided by Schindler et al.[28] who described the pyramidalization of a secondary amide group located 282.7 pm above the copper(II) ion the apical position of a square-pyramidal complex. These data are very important and confirm that with our new complex **8** Werner-type nitrogen-coordinated tertiary carboxamide complexes now span the whole range of electrophilic amide activation.

## Conclusions

With the crystallographic characterization of **8**, we have shown that forcing a metal center into a macrocyclic cyclam ring with a neutral amide N-donor produces a completely non-resonant tertiary carboxamide. The complex defines an upper limit for nitrogen pyramidalization and C–N bond elongation achievable by purely electrophilic activation without geometric strain. In this respect, it complements the generation of a purely organic amino ketone in Kirby's most twisted amide, 3,5,7-trimethyl-1-azaadamantan-2-one.[29]

## Experimental Section

**General Methods:** Spectra were recorded with the following instruments: IR: Mattson Polaris FT IR. UV/Vis: Varian Cary 1G spectrophotomer. $^1H$ and $^{13}C$ NMR: Bruker Avance DPX 300. All chemical shifts are referenced to TMS ($CDCl_3$) or TSP ($D_2O$) as

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

internal standards, with high frequency shifts recorded as positive. MS: Varian MAT 212 (FD, FAB) and Micromass ZabSpec (FAB) mass spectrometer. Elemental analysis: Carlo Erba Elemental Analyser 1106 (C,H,N), and Carlo Erba Elemental Analyser 1108 (C,H,N,S). All reactions except for the syntheses of cyclam-$Boc_3$ (**1**) and cyclam-$Cbz_3$ (**2**) were carried out in absolute solvents under dry nitrogen. The subsequent workup was performed under ambient laboratory conditions unless stated otherwise. The synthesis of cylam-$Boc_3$ is a slight modification of a literature procedure.[11] Absolute solvents ($CH_2Cl_2$, $Et_2O$, $CH_3CN$) were purchased from Fluka, stored under nitrogen and used without further purification. All other chemicals and deuterated solvents were obtained from Aldrich.

**Syntheses**

**Cyclam-$Boc_3$ (1):** A solution of di-*tert*-butyl pyrocarbonate ($Boc_2O$, 2.72 g, 12.5 mmol) in 150 mL of $CH_2Cl_2$ was added dropwise at room temperature over a period of 6 h to a stirred solution of cyclam (1.00 g, 5.00 mmol) in 300 mL of $CH_2Cl_2$. Stirring was continued for 12 h and the solvent stripped by rotary evaporation. The oily residue was dissolved in a minimum amount of diethyl ether. Rapid stripping of all solvent and drying under vacuum yielded a pale-yellow foam which was re-dissolved in $CH_2Cl_2$/$CH_3OH$ (95:5) and purified by flash column chromatography on silica; using the solvent as the eluent yielded 1.08 g (2.13 mmol, 51.1%) of cyclam-$Boc_3$ as a colourless, hygroscopic solid. FD-MS [$CHCl_3$; $C_{25}H_{48}N_4O_6$ (500.68)]: *m*/*z* = 501 [$M^+$]. $^1$H NMR ($CDCl_3$): $\delta$ = 1.45 (s, 27 H, Boc), 1.70 (m, 2 H, cyclam), 1.92 (m, 2 H, cyclam), 2.61 (t, 2 H, cyclam), 2.78 (t, 2 H, cyclam), 3.27–3.39 (m, 12 H, cyclam) ppm.

**Boc-(*S*)-Ala-cyclam-$Boc_3$ (3):** Boc-Ala-OH (1.02 g, 5.40 mmol), **1** (2.45 g, 4.90 mmol), *N*-hydroxybenzotriazole (0.71 g, 5.22 mmol), and $NEt_3$ (1.41 mL, 9.98 mmol) were dissolved in 300 mL of $CH_2Cl_2$ and the mixture was stirred with cooling at 0 °C. Dicyclohexylcarbodiimide (1.76 g, 8.47 mmol) in 20 mL of $CH_2Cl_2$ was added in one portion. The solution was warmed slowly to room temperature after which stirring was continued for 12 h. The resulting mixture was filtered and the volume of the filtrate was reduced to 1/2 by rotary evaporation. Filtration was repeated after storage at –18 °C overnight. The filtrate was washed 3 times with aqueous 5% $NaHCO_3$ and 3 times with saturated aqueous NaCl, dried with solid $MgSO_4$ and filtered. All solvent was removed by rotary evaporation and the residue purified by flash column chromatography on silica gel using $CH_2Cl_2$/$CH_3OH$ (95:5) as the eluent. All solvent was removed by rotary evaporation and the solid residue dissolved in a minimum amount of diethyl ether. Rapid stripping of the solvent and drying under vacuum yielded 2.42 g (3.60 mmol, 73.5%) of **3** as a colourless hygroscopic solid. $C_{33}H_{61}N_5O_9$·0.33$H_2O$ (671.87+6.00): calcd. C 58.47, H 9.17, N 10.33; found C 58.65, H 10.59, N 10.33. FD-MS ($CHCl_3$): *m*/*z* = 672 [$M^+$]. $^1$H NMR ($CDCl_3$): $\delta$ = 1.31 (t, 3 H, $^{\beta}CH_3$), 1.45 (m, 36 H, Boc), 1.74 (m, 4 H, cyclam), 3.14–3.69 (m, 16 H, cyclam), 4.56 (m, 1 H, $^{\alpha}$CH), 5.19–5.50 (m, 1 H, NH) ppm.

**(*S*)-Ala-cyclam·3HCl (5):** Compound **3** (2.42 g, 3.60 mmol) was treated with 15 mL of a cold 4 N HCl/dioxane solution with stirring at 0 °C. Stirring was continued without further cooling for 12 h. The product Boc-Ala-cyclam·3HCl·4$H_2O$ formed 1.36 g (3.00 mmol, 83.4%) of a colourless precipitate which was collected on a glass filter funnel, washed with hot ethanol (3 × 50 mL) and diethyl ether (3 × 20 mL), and dried under vacuum. $C_{13}H_{29}N_5O$·3HCl·4$H_2O$ (452.79): calcd. C 34.45, H 8.83, N 15.46; found C 34.39, H 9.15, N 15.29. $^1$H NMR ($D_2O$): $\delta$ = 1.46 (d, 3 H, $^{\beta}CH_3$), 2.22 (m, 4 H, cyclam), 2.92–4.00 (m, 16 H, cyclam), 4.40 (q, 1 H, $^{\alpha}$CH) ppm. IR (KBr): $\tilde{\nu}$ = 3178 ($NH_3^+$), 1646 (amide) $cm^{-1}$.

**[(Boc-Ala-cyclam$H_2$)$CuCl_2$]($CF_3SO_3$)$_2$ (6):** Tris(hydrochloride) salt **5** (2.51 g, 6.02 mmol) was suspended in 100 mL of $CHCl_3$ and the solution cooled to 0 °C. A slow stream of $NH_3$ gas was passed through the reaction mixture. After 1.5 h, the mixture was warmed to room temperature. Precipitated ammonium chloride was filtered off, the filtrate concentrated to dryness and the residue treated with 50 mL of $CH_2Cl_2$. Insoluble material was removed by filtration and all solvent by rotary evaporation. Drying under vacuum afforded a colourless resin (1.62 g). This compound (1.31 g) was dissolved in 200 mL of $CH_3CN$. A solution of Cu($CF_3SO_3$)$_2$ in 150 mL of $CH_3CN$ was added dropwise with stirring over a period of 1 h. The reaction mixture turned deep blue. Stirring was continued at room temperature for 12 h. The solution was concentrated to dryness and the residue re-dissolved in a minimum amount of $CH_3CN$. Layering with diethyl ether and storage at –18 °C overnight afforded the product **6** as a blue precipitate which was isolated by filtration and dried under vacuum [2.46 g, 3.49 mmol, 72.2% based on Cu($CF_3SO_3$)$_2$]. $C_{15}H_{31}Cl_2CuF_6N_5O_7S_2$ (706.01): calcd. C 25.52, H 4.43, N 9.92, S 9.08; found C 25.42, H 4.34, N 9.63, S 8.92. IR (KBr): $\tilde{\nu}$ = 3244 (R–$NH_3^+$), 1592 (amide) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ (lg$\varepsilon$) = 619 (2.17 $M^{-1}cm^{-1}$) nm. FAB-MS (nitrobenzyl alcohol): *m*/*z* = 483 [M – 2 HCl – $CF_3SO_3$]$^+$.

**[(Ala-cyclam)($H_2O$)Cu]($CF_3SO_3$)$_2$·0.25$Et_2O$:** A mixture of **5** (450 mg, 1.08 mmol) and excess $NaOH^{(s)}$ was suspended in ca. 50 mL of $CH_2Cl_2$ at room temperature. The suspension was stirred for 24 h. Insoluble material was removed by filtration and the clear filtrate concentrated to dryness. Drying under vacuum afforded the free base as a colourless oily residue. It was dissolved in 50 mL of $CH_3CN$ and Cu($CF_3SO_3$)$_2$ (340 mg, 0.94 mmol) was added in small portions to the stirred solution. Stirring was continued for 12 h. The mixture was filtered and the clear blue filtrate layered with $Et_2O$. Upon storage at –18 °C the product precipitated as a violet oily residue. Separation and drying under vacuum afforded the product (446 mg, 0.73 mmol, 77.7%) as a violet solid. FD-MS ($CH_3CN$): *m*/*z* = 484 [MH – $CF_3SO_3$]$^+$. $C_{15}H_{29}CuF_6N_5O_7S_2$·1$H_2O$·0.25$Et_2O$ (651.10+18.53): calcd. C 28.70, H 5.04, N 10.46; found C 28.60, H 4.78, N 10.17. IR (KBr): $\tilde{\nu}$ = 3342, 3226 ($NH_3^+$), 1756, 1649 (shoulder), 1592 $cm^{-1}$.

**cyclam-$Cbz_3$ (2):** A solution of dibenzyl pyrocarbonate ($Cbz_2O$, 7.20 g, 25.00 mmol) in 500 mL of $CH_2Cl_2$ was added dropwise at room temperature over a period of 6 h to a stirred solution of cyclam (2.00 g, 10.00 mmol) in 200 mL of $CH_2Cl_2$. Stirring was continued for 12 h and the solvent stripped by rotary evaporation. The oily residue was dissolved in a minimum amount of dichloromethane and the pale yellow solution was filtered through silica gel. The filtrate which contained benzyl alcohol was discarded and the compound was eluted with methanol. All solvent was removed by rotary evaporation and drying under vacuum. The residue was re-dissolved in a minimum amount of $CH_2Cl_2$/$CH_3OH$ (98:2) and purified by flash column chromatography on silica using the solvent as the eluent. The colourless, oily compound was repeatedly treated with small quantities of diethyl ether which was stripped under vacuum until formation of a foam; 1.80 g (2.99 mmol, 35.9%) of the product **2** was obtained as a highly hygroscopic, colourless resin. FD-MS [$CHCl_3$; $C_{34}H_{42}N_4O_6$ (602.72)]: *m*/*z* = 603 [$M^+$]. $^1$H NMR ($CDCl_3$): $\delta$ = 1.64 (m, 2 H, cyclam), 1.93 (m, 2 H, cyclam), 2.55 (m, 2 H, cyclam), 2.76 (m, 2 H, cyclam), 3.10–3.52 (m, 12 H, cyclam), 5.03 (s, 2 H, Ph-$CH_2$), 5.12 (s, 4 H, Ph-$CH_2$), 7.33 (m, 15 H, $C_6H_5$) ppm.

**Boc-Ala-cyclam-$Z_3$ (4):** Boc-Ala-OH (0.62 g, 3.28 mmol), **2** (1.79 g, 2.97 mmol), *N*-hydroxybenzotriazole (0.43 mg, 3.17 mmol), and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$NEt_3$ (0.85 mL, 6.06 mmol) were dissolved in 150 mL of $CH_2Cl_2$ and the mixture stirred with cooling at 0 °C. Dicyclohexylcarbodiimide (1.07 g, 5.14 mmol) in 10 mL of $CH_2Cl_2$ was added in one portion. The solution was warmed slowly to room temperature after which stirring was continued for 12 h. The resulting mixture was filtered and the volume of the filtrate was reduced to 1/2 by rotary evaporation. Filtration was repeated after storage at –18 °C overnight. The filtrate was washed 3 times with aqueous 5% $NaHCO_3$ and 3 times with saturated aqueous NaCl, dried with solid $MgSO_4$ and filtered. All solvent was removed by rotary evaporation and the residue purified by flash column chromatography on silica gel using $CH_2Cl_2/CH_3OH$ (95:5) as eluent. All solvent was removed by rotary evaporation and the solid residue dissolved in a minimum diethyl ether. Drying under vacuum yielded 595 mg (0.77 mmol, 25.9%) of **4** as a colourless hygroscopic solid. $C_{42}H_{55}N_5O_9 \cdot 0.5Et_2O$ (773.91+37.06): calcd. C 65.16, H 7.46, N 8.64; found C 65.46, H 8.27, N 8.90. FD-MS ($CHCl_3$): *m*/*z* = 774 [$M^+$]. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.26 (m, 3 H, $^{\beta}CH_3$), 1.43 (2 s, 9 H, Boc), 1.71 (m, 4 H, cyclam), 3.05–3.75 (m, 16 H, cyclam), 4.45 (m, 1 H, $^{\alpha}CH$), 4.86–5.19 (m, 7 H, Ph-$CH_2$ + NH), 7.13–7.45 (m, 15 H, $C_6H_5$) ppm.

**Boc-Ala-cyclam (7):** A solution of **2** (315 mg, 0.41 mmol) in absolute methanol was transferred to a flask containing catalytic amounts of Pd/C and equipped with a hydrogen inlet, a reflux condenser, a magnetic stir bar, and a mineral oil bubbler. Nitrogen was passed over the suspension for 15 min. The mixture was heated to 45 °C in an oil bath and a slow stream of $H_2$ was applied for 2 h. The flask was then flushed with $N_2$ and the suspension filtered through Celite at room temperature. Rotary evaporation of the solvent and drying under vacuum yielded 116 mg (0.31 mmol, 76.0%) of **4** as a hygroscopic resin. It was characterized by $^1H$ NMR spectroscopy and used without further purification. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.29 (m, 3 H, $^{\beta}CH_3$), 1.42 (s, 9 H, Boc), 1.59–2.00 (m, 6 H, cyclam), 2.45–3.12 (m, 10 H, cyclam), 3.19–3.80 (m, 4 H, cyclam), 4.59 (m, 1 H, $^{\alpha}CH$ ), 5.41 (m, 1 H, NH) ppm.

**[(Boc-Ala-cyclam)Cu]($CF_3SO_3$)$_2$ (8):** Boc-Ala-cyclam (116 mg, 0.31 mmol) was dissolved in 25 mL of absolute acetonitrile and a solution of anhydrous $Cu(CF_3SO_3)_2$ (112 mg, 0.31 mmol) in 25 mL of absolute acetonitrile was added dropwise with stirring over a period of 30 min. The blue solution gradually turned deep purple. Stirring was continued at room temperature overnight and all solvent removed by evaporation under vacuum. The crude product was re-dissolved in $CH_2Cl_2$ and insoluble materials were removed by filtration. Drying of the filtrate under vacuum yielded the product as a deep purple solid; yield 209 mg (0.29 mmol, 92.0%). $C_{20}H_{37}CuF_6N_5O_9S_2 \cdot 2CH_2Cl_2$ (903.11): calcd. C 29.26, H 4.58, N 7.76; found C 29.34, H 4.60, N 8.05. IR (KBr): $\tilde{\nu}$ = 1742 (amide); 1658 (Boc) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ (lg$\varepsilon$) = 540.4 (1.89 $M^{-1}cm^{-1}$) nm. FAB-MS (nitrobenzyl alcohol): *m*/*z* = 583 [M – $CF_3SO_3$]$^+$.

**X-ray Structure Analyses:** Colorless blocks of Ala-Cyclam·3HCl (**5**) were obtained by precipitation from diethyl ether/ethanol and recrystallization of the solid from $D_2O$ upon slow evaporation of the solvent at room temperature. The copper complex salt **8**·1/8$H_2O$ crystallized upon slow concentration of a dichloromethane/acetonitrile solution. Details of the X-ray structure analyses are summarized in Table 1. Suitable single crystals were embedded in protective perfluoropolyether oil and data were collected at 100 K with a Bruker-Nonius KappaCCD diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å, graphite monochromator). Images were taken using $\varphi$- and $\omega$-rotations with a rotation angle of 2.0° for **5** and 1.8° for **8**·1/8$H_2O$. An irradiation time of 80 s per frame was applied for **5** and 432 s per frame for **8**·1/8$H_2O$. Lorentz and polarization corrections were applied. Semi-empirical absorption corrections based on equivalent reflections were made using the program SADABS.[30] All structures were solved by direct methods and refined using full-matrix least-squares procedures on $F^2$ using the program package SHELXTL NT 6.12.[31] All non-hydrogen atoms were refined anisotropically. One of the triflate ions in **8**·1/8$H_2O$ was disordered. Two positions with occupation factors of 0.75 and 0.25 were refined. All hydrogen atoms in **5** were located in the difference Fourier map and refined with isotropic displacement parameters being 1.2 or 1.5 times *U*(eq) of the corresponding C or N atom. All hydrogen atoms in **8**·1/8$H_2O$ (except for those of the water which were located in the difference Fourier map and not refined) were geometrically positioned with isotropic displacement parameters being 1.2 or 1.5 times *U*(eq) of the corresponding C, N or O atom. CCDC-262792 (**5**) and -262793 (**8**·1/8$H_2O$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 1. Details of the crystal structure analyses.

| Compound | **5** | **8**·1/8$H_2O$ |
|---|---|---|
| Empirical formula | $C_{13}H_{32}Cl_3N_5O$ | $C_{20}H_{37.25}CuF_6N_5O_{9.125}S_2$ |

# An Analogous Solution-Liquid-Solid (ASLS) Growth Route to InP Hollow Spheres and a Honeycomb-Like Macroporous Framework

Xiuwen Zheng,[a,b] Changzeng Liu,[a] and Yi Xie*[b]

**Keywords:** Materials science / Mesoporous materials / Semiconductors / Synthesis design

Hollow spheres and a honeycomb-like macroporous framework structure of InP have been successfully fabricated by employing Au/In core/shell composite colloid droplets formed in situ as the template and catalyst for a simple analogous solution-liquid-solid (ASLS) growth route. SEM images show that the morphology of the obtained InP is mostly micrometer-scale hollow spheres (>80 %) accreted with honeycomb-like structures (<5 %). These hollow spheres have well-defined voids and homogeneous walls, and the surface of the obtained InP hollow spheres is porous, which indicates that the building blocks are InP nanoparticles formed by solidification on the surface of Au/In core/shell droplets. A possible growth mechanism for the micrometer hollow spheres and honeycomb-like macroporous framework is proposed.

## Introduction

Over the past decade, hollow microspheres and highly porous inorganic materials with well-defined pore sizes have become an important area of research.[1] The main thrust of these intensive investigations stems from their wide application,[2] such as small containers for microencapsulation, catalysis, controlled delivery, artificial cells, light fillers, acoustic insulation, photonic crystals, optical devices, etc.[3] Porous spherical beads can also be used to improve the properties of materials by increasing the accessible surface. Macroporous materials with pore sizes > 50 nm and with well-defined and controllable porosity have attracted particular interest because of their unique optical, catalytic, and mechanical properties.[4] Macroporous supports can be designed to provide optimal flow and improved efficiencies in catalysis and large-molecule separation processes, as well as to permit immobilization and stabilization of large guest molecules.[5] Due to the importance of these specific morphologies and assemblies, notable progress has been made in structural, compositional, and morphological control, in processing aspects of porous solids, and new applications of these materials. Some important synthetic strategies have also been reported for the control and preparation of these peculiar hollow microspheres and ordered three-dimensional macroporous framework. Among these methods, templating techniques are the most appropriate and versatile method to produce hollow spheres and macroporous materials. The templates used include polystyrene latex spheres,[4a,6] liquid crystals,[7] surfactant vesicles,[8] macroporous active carbon,[9] emulsions,[4b] etc. So far, various hollow spheres and macroporous materials have been fabricated by this universally applied template-directed synthesis, including oxides,[4a,6] graphite and diamond,[10] semiconductor Si,[11] CdS,[1a] and metals.[1f]

Recently, III–V semiconductor nanoparticles, which are well-known electronic and optoelectronic materials, have received renewed interest due to their technological importance.[12] InP is an especially intriguing target for research because of its extensive use in the sources and detectors in fiber optic communications and high-speed electronic applications. Several new strategies have been developed to synthesize InP nanocrystals with different morphologies, such as high-quality InP nanocrystals obtained in a noncoordinating solvent[13] or aqueous solution,[14] InP nanowires or nanotubes by a laser ablation process by a vapor-liquid-solid (VLS) growth mechanism,[15] or a solution-phase synthesis by a solution-liquid-solid (SLS) mechanism,[16] with the goal of lowering the processing temperature and avoiding complex reactions and toxic precursors. In addition, the widespread research into porous III–V semiconductors is fuelled by the exhibition of new properties and a large potential for applications in nonlinear optical materials.[17] The porosity of a III–V compound induces bandgap widening and further results in blue and ultraviolet luminescence.[18] For example, two-dimensionally nanostructured porous GaP membranes exhibit a strongly enhanced optical second harmonic generation in comparison with the bulk materials.[19] Our group has made significant progress towards the synthesis of III–V semiconductors, such as InP,[20] GaP,[14] and InAs,[21] with desired morphologies by simple and effective solvothermal methods. Up to now,

most effort has been focused on the formation of one-dimensional III–V semiconductors. One of the most important growth mechanisms for one-dimensional nanostructures is the VLS mechanism in chemical vapor deposition (CVD) or laser ablation using Au as the catalyst.[15] Recently, the VLS mechanism was extended in solution for the preparation of InAs quantum rods with controlled lengths and diameters by applying a nanocrystalline gold catalyst to the reaction of $InCl_3$ with tris(trimethylsilyl)arsane [$As(TMS)_3$] at 360 °C,[22] which can also be considered as an improved SLS route.[16] A detailed investigation of these reported methods helped us find that there is one common factor, namely the existence of alloy liquid droplets that serve as a nucleation catalyst for the formation of one-dimensional nanostructures at the given elevated temperature, such as the In–Au alloy liquid droplets in the formation of InP and InAs nanowires.[15,22] The essence of the catalytic functions of these liquid droplets is the existence of supersaturation, which supports the whisker growth at the liquid/solid interface. However, a high reaction temperature is a prerequisite for the formation of In–Au alloy liquid droplets in all these reports. We therefore wondered what the results would be if the temperature is too low to form the In–Au alloy in a given reaction system. In order to find the answer to this question we decided to exploit an analogous SLS (ASLS) growth route to synthesize InP spherical assemblies, which can be considered as an extension of the SLS method. The latter has traditionally been applied to grow 1D III–V semiconductors containing low-melting-point metals such as indium by decomposition of indium-containing organometallic complexes as intermediate and catalyst for the directed growth of III–V one-dimensional structures.[16] In our approach, to obtain a solution-controllable synthesis of InP with the desired hollow sphere morphology we introduced gold nanoparticles (formed by reduction of $HAuCl_4$ in solution) into the classical SLS system[16,20,21] and controlled the system temperature at 200 °C. The in-situ formed gold nanoparticles act as a colloidal template for the synthesis of spherical assemblies.

## Results and Discussion

The XRD patterns (Figure 1a) of the samples agree well with the bulk InP reflection,[23] thus indicating the same cubic zinc blende lattice structure. Judging from the XRD pattern, the products have very high crystallinity under the given experimental conditions. No component of the Au catalyst can be detected in Figure 1a, thus indicating that its content is less than the resolution limit of XRD. SEM images, as shown in Figures 2a and b, give a general view of the obtained InP micrometer hollow spheres under low magnification. Many collapsed and hemispherical hollow spheres can also be seen in Figure 2a, thus indicating the hollow structure of the spheres. Figures 2c and d display images of typical, collapsed hemispheres, from which it can be seen that the obtained hollow spheres are about 3–6 μm in diameter with a wall thickness of 1 μm. The opening and collapse are probably due to decomposition of the templates when washing with dilute HCl. Figure 3 displays the SEM images of the obtained InP hollow spheres at high magnification; the porous nature of the surface can clearly be seen. Figure 3 also confirms that the building blocks of the InP hollow spheres are InP nanoparticles. Interestingly and surprisingly, some ordered honeycomb-like macroporous networks are also found to accrete with the hollow spheres, as shown in Figure 4. The pore diameter of the ordered honeycomb-like macroporous network is approximately 2–5 μm. A key feature of these networks is the interconnectedness of their pores; an SEM image at high magnification (Figure 4b, arrowed) shows that some of the voids

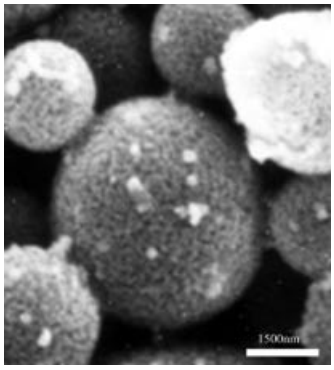

Figure 3. SEM images of obtained InP hollow spheres at high magnification, showing the porous surface structure.

are connected to their neighbors by smaller windows. Such microstructures allow these macroporous networks to be filled with different liquid precursor solutions in the second templating process. These small windows play important roles in the fabrication of the desired morphologies as they provide the necessary channels to allow the precursor solution to flow through and form a shell throughout the entire void. The arrow in Figure 4c shows some InP spheres inlaid in the macroporous network, which further prove the proposed formation mechanism.

XPS spectra were recorded to identify the surface composition of the as-prepared products. The bonding energies obtained from the XPS analysis were corrected for specimen charging by referencing the C 1s line to 287.60 eV. Figure 5a shows the XPS survey spectra of InP. No obvious impurities (besides the Au catalyst and trace amounts of adsorbed $O_2$) can be detected in the samples, thus indicating that the products have high purity and the level of impurities is lower than the resolution limit of XPS (1 at%). The typical high-resolution spectra of In 3d and P 2p are shown in Figure 5b. The binding energy values are 443.74 eV for In $3d_{5/2}$ and 451.38 eV for In $3d_{3/2}$. The P 2p core shows two peaks, one at 128.88 eV corresponding to P from InP and the other at 132.95 eV (arrowed) corresponding to oxidized P species due to exposure to the air. The peak areas of these high-resolution scans were measured and used to calculate the In/P ratio for the product. The quantification of the peaks gives an atomic ratio of In/P of 0.43:0.53. The excess P perhaps comes from the added P raw materials. All of the observed binding energy values for In 3d and P 2p coincide with the reported data within the experimental errors.[24]

In both the reported VLS route and its extension in solution, the noble metal Au and the in-situ formed alloy species function as catalysts for the nucleation and further direct the growth of 1D nanostructures. Thus, the reaction temperature must be higher than the eutectic temperature of the alloy. Once formed, the In–Au alloy liquid droplets dissolve the reactants and the subsequent supersaturation supports one-dimensional structure growth at the liquid/solid interface.[15,22] In our approach, however, the obtained product is spherical rather than the usual one-dimensional nanostructure. Our reaction temperature (200 °C) is lower than that of the melting point of bulk gold and higher than that of the melting point of In and $P_4$ (157 and 44.1 °C, respectively), therefore the Au–In alloy cannot form. Banin has reported that InAs nanorods do not yield one-dimensional growth at a lower reaction temperature of 300 °C, which indicates that reaction temperatures of at least 360 °C are required for the onset of Au melting.[22] This value is consistent with theoretical studies that predict a melting temperature for $Au_{146}$ (diameter ca. 1.6 nm) of ca. 350 °C, increasing to ca. 480 °C for $Au_{459}$ (diameter ca. 2.5 nm).[25] The current low temperature (200 °C) may not suffice to activate the gold particles as catalysts to direct the growth of the one-dimensional nanoscale material. However, the reduced liquid In becomes coated on the newly formed Au nanoparticles due to the physical tendency to reach the lowest energy level and forms Au/In core/shell droplets. These droplets further serve as a second template for the nucleation of InP nanoparticles, therefore the function of the Au/In core/shell droplets is as a template for a spherical structure[16] rather than a nucleation catalyst for the formation of a one-dimensional structure.[15,22] In the region of scattered Au/In core/shell beads, however, the $P_4$ molecules in solution will react with the In on the surface of Au/In beads (Path 1 in Scheme 1). Thereafter, the formed InP nanoparticles solidify to form a compact InP layer on the surface of the Au/In core/shell droplets, which blocks the further

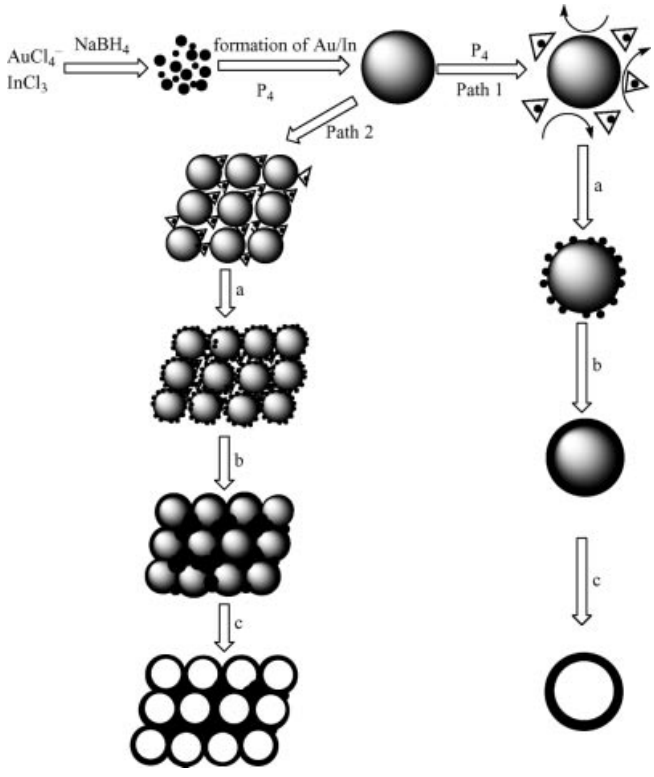
reaction of $P_4$ with In molecules in the beads. As a result, when removing the unreacted In by treatment with dilute HCl solution, the inner Au cores separate from the outermost InP shells and finally produce InP hollow spheres (>80%). Upon removal of the support, some collapsed hollow spheres are formed. The presence of In before the HCl treatment was observed by XRD, as shown in Figure 1b. However, it is reasonable to propose that in the dense and thick regime of Au/In beads, which array in order, $P_4$ molecules in solution filter into and fill the void spaces among the beads of the crystalline array. The reaction of $P_4$ with In molecules and subsequent solidification form a compact InP layer on the surface of the Au/In core/shell beads. This process is similar to the formation of InP hollow spheres. However, due to the highly aggregated nature of the array of Au/In beads, the solidification of the InP spheres connects each other into a compact whole containing unreacted In. After the removal of residual In, an ordered three-dimensional porous structure with an array of interconnected spherical pores is formed (Path 2 in Scheme 1, <5%). In addition, some InP spheres inlaid in the macropores are also found (Figure 4c, arrowed), which further demonstrates the template effect of the Au/In core/shell droplets. This large surface area endows InP with many promising applications in separation and adsorption. Moreover, the periodical pores can also serve as cavities to accommodate diverse guest molecules. Scheme 1 outlines the schematic process of the formation of the desired morphology.



Scheme 1. Schematic illustration of the formation of InP micrometer hollow spheres and the honeycomb-like macroporous network: (a) reaction of $P_4$ with In on the surface of Au/In beads; (b) solidification of InP nanoparticles on the surface of Au/In beads, which leads to the formation of a core/shell structure. (c) removal of In by HCl, leading to the formation of InP hollow spheres or a macroporous network (a triangle represents $P_4$ molecules). The predominant Path 1 gives the hollow spheres and Path 2 leads to the honeycomb-like macroporous network.

A series of comparison experiments were performed to determine the effect of synthetic conditions on the formation of InP hollow spheres and macroporous networks. Detailed investigation helped us determine that the ratio of In/Au is important for controlling the synthesis of InP nanocrystals with different assemblies, and that the optimal molar ratio of In/Au for the formation of these InP hollow spheres and network is 25:1. At this molar ratio the product is mainly microporous hollow spheres (>80%) with a small amount of a three-dimensional ordered macroporous network. We also found that it is difficult to obtain the desired hollow spheres morphology if the molar ration of In/Au is too far above or below this ratio. For example, the obtained products are mainly irregular particles with a small quantity of rough spherical products at a ratio of 50:1. These particles resemble an irregular stack that shows some morphological similarity to that of Figure 2b. However, the amount of obtained microscale spherical structures is less than 10%. With a reduction of the ratio, for example to 10:1, the obtained products are poorly crystalline particles.

In order to understand the formation mechanism of InP hollow spheres, the reaction was carried out without the addition of P; all other experimental conditions and parameters were kept constant. The obtained In/Au composite beads are spherical, as shown in Figures 6a and b, and gold nanoparticles exhibiting high contrast can be discerned in the cores of many of them (Figure 6b), which provides firm evidence for our proposed mechanism.

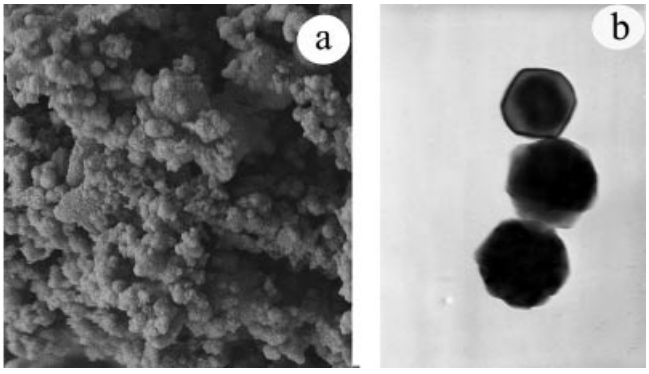

Figure 6. Obtained Au/In spherical composite particles: (a) SEM image, (b) TEM images; gold nanoparticles exhibiting high contrast can be discerned in the cores.

As is well known, it is very important to select appropriate solvents for the design of solid-state compounds by a solvothermal route.[20,26] Based on our control experiments, we found that ethylenediamine plays an important role in the formation of InP particles under our conditions as it can disperse yellow phosphorus to form a brown dispersion and readily dissolve $KBH_4$, which means that it increases the surface area of the reactants and promotes the reaction at given temperatures.[20] When other solvents were used, such as ethanol, benzene, DMF, or pyridine, the reaction either did not take place or the products could not be identified. Strongly polarizing solvents such as ethylenediamine at the appropriate temperature provide conditions that are adequate to greatly enhance solubility, diffusion, and crystallization.

The same route has also been applied to the synthesis of GaP, using $GaCl_3$ instead of $InCl_3{\cdot}4H_2O$ as the source. The obtained GaP micrometer spheres, with a diameter of ca. 3–4 μm, are shown in Figure 7. Some spheres with small openings in the surface can also be observed (inset in Figure 7), thus indicating that the obtained GaP spheres have a hollow structure. However, at the given temperature (200 °C) the obtained GaP hollow spheres are very poorly crystalline.

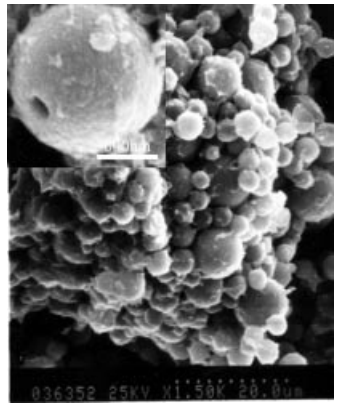

Figure 7. GaP micrometer-sized hollow spheres obtained in the same approach; the inset shows the small openings in the surface of GaP spheres, which indicate the hollow structure of the obtained GaP spheres.

## Conclusions

In summary, we have demonstrated an effective analogous solution-liquid-solid (ASLS) growth route to mesoscale InP hollow spheres accreted with honeycomb-like structures, in which the Au/In core/shell droplets formed in situ serve as the template and catalyst. These hollow spheres have well-defined voids and homogeneous walls. The surface of the InP hollow spheres obtained is porous, which further indicates that the building blocks are InP nanoparticles formed by solidification on the surface of Au/In core/shell droplets. A systematic investigation has shown that the correct ratio of indium/noble metal is a prerequisite for the synthesis of InP novel structures, and that the optimal ratio is 25:1. The same experimental process has been applied to GaP hollow spheres and will be extended to other important metal phosphides with desired morphologies.

## Experimental Section

Analytical-grade reagents and solvents were purchased from Shanghai Chemistry Co. Ltd and used without further treatment. Typical procedure: 40 mL of ethylenediamine, 1.11 g of $InCl_3{\cdot}4H_2O$, 0.5 g of yellow phosphorus, 2 mL of an ethanol solution of $HAuCl_4$ (0.0758 M) and 1.6 g of $KBH_4$ were placed in a 50-mL Teflon-lined autoclave. The autoclave was maintained at 200 °C

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for 10 h, and then cooled to room temperature naturally. The black products were filtered off and washed with absolute alcohol and dilute aqueous HCl (1 M). Finally, the products were dried in vacuo at 50 °C for 1 h. The key to the fabrication of InP hollow spheres and macroporous network is the control of the In/Au ratio. During the formation of the desired InP hollow spheres, the influence of this ratio was investigated in detail and control experiments were performed with different molar ratios of In/Au, such as 120:1, 100:1, 80:1, 50:1, 25:1, and 10:1. In addition, in order to understand the formation mechanism, different solvents, such as ethanol, benzene, DMF, and pyridine were selected to investigate the optimal experimental conditions.

The final products were characterized by various techniques. X-ray powder diffraction (XRD) was carried out with a Rigaku D/max rA X-ray diffractometer with Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å). A scan rate of 0.05° per second was applied to record the pattern in the $2\theta$ range of 20–85°. The morphology and size of as-prepared products were determined from SEM images, which were recorded with an X-650 scanning electronic microanalyzer. To obtain further evidence for the purities and compositions of the as-prepared products, the X-ray photoelectron spectra were recorded with an ESCALab MKII X-ray photoelectron spectrometer, using Mg-$K_\alpha$ radiation as the exciting source.

# Tris(tropolonato)phenanthroline Lanthanide(III) Complexes as Photochemical Devices

**Laura Bertolo,[a] Sergio Tamburini,*[a] Pietro Alessandro Vigato,[a] William Porzio,[b] Giorgio Macchi,[c] and Francesco Meinardi[c]**

**Keywords:** Lanthanides / N ligands / O ligands / Molecular devices / Donor–acceptor systems / Time-resolved spectroscopy / Infrared emitters

The tris-tropolonato erbium(III) complexes [Er(hino)$_3$(phen)] and [{Er(hino)$_3$}$_2$(pdon)] (H-hino = 2-hydroxy-6-isopropylcyclohepta-2,4,6-trien-1-one; phen = 1,10-phenanthroline; pdon = 1,10-phenanthroline-5,6-dione) have been prepared by reaction of [Er(hino)$_3$]$_n$ with the appropriate chelating ligand in alcoholic solution. The complexes were characterized by elemental analyses, TG, ESI MS, $^1$H NMR, and IR spectroscopy, also by comparison with the properties of the analogous Eu$^{III}$ and Yb$^{III}$ complexes. The ESI-MS spectroscopy of the complex with the ditopic ligand pdon parallels the other physico-chemical data (IR, NMR), confirming the occurrence of a dinuclear entity. All the investigated Er$^{III}$ complexes show efficient NIR emissions at about 1550 nm upon excitation at 355 nm in the UV ligand absorption band, emerging as possible candidate as active material for the realization of plastic amplifiers for telecommunications.

## Introduction

Lanthanide complexes with distinct magnetic and optical properties are currently of interest for use in applications involving the fabrications of novel materials, both as active layer in optoelectronic devices and probes in biological systems.[1–5]

Among a wealth of stimulating applications the recent developments of (i) new phosphors for lighting,[6] (ii) high-efficiency electroluminescent devices for light-emitting diodes,[7] (iii) contrast agents for medical magnetic resonance imaging,[8] (iv) NMR shift reagents for cations for transport processes of alkali metal ions through biological membranes,[9] (v) luminescent probes for analytes,[10] (vi) labels for proteins and amino acids,[11] (vii) light-emitting sensors in fluoroimmunoassays,[12] (viii) tags for time-resolved luminescent microscopy,[13] (ix) magnetically addressable liquid crystals,[14] (x) magnetic alloys for refrigeration,[15] (xi) precursors for superconducting materials,[16] (xii) specific redox reagents for chemical transformation[17] or molecular-based information storage,[18] and (xiii) acidic catalysts for sophisticated organic transformations[19,20] or for the cleavage of phosphodiester bridges in RNA[21] fully justify the efforts made to control the metallic sites and to selectively introduce lanthanides into organized assemblies. For more than two decades, systematic investigations of the subtle interplay between the structural control of the coordination sphere and the associated metal-centred electronic properties have led to the design of lanthanide-containing devices whose function can be judiciously addressed and tuned.

The use of optical properties of these metal ions are quite attractive and promising. However, these photophysical properties of these ions depend markedly on their environment. To optimize efficient emissions, for instance, chromophoric ligands have been often employed to transfer absorbed energy efficiently to the appropriate lanthanide ion.

Remarkably, these ligands must be capable of protecting the lanthanide(III) centre from solvent molecules, which can quench emission.

A variety of multidentate cyclic and acyclic ligands, designed to encapsulate the lanthanide ions, have been synthesized and successfully used. Thus, using ligands with appropriate coordination geometry, and/or coordinating anions, it is possible to obtain suitable structure quite effective in keeping solvent and water molecules away from lanthanide(III) centres.

The design and synthesis of lanthanide complexes with charged and/or neutral chelating organic ligands offers the possibility to obtain stable compounds with quite particular optical properties. A relevant aspect of this research consists in the possibility to optimize these properties of a particular lanthanide(III) ion by suitable choice of ligands.

The recent interest towards Organic Light-Emitting Diodes (OLED) based on organolanthanide complexes[22] stems on the fact of the observed peculiar mechanism of

emission in regions different according to the lanthanide. Specifically the ligand acting as antenna, absorbs the light, and then transfers the energy towards the coordinate metal ion ($Er^{3+}$), poorly absorbing in the visible, while efficiently emitting in the near infrared (NIR) region. With the aim to enhance the luminescence efficiency of these materials, the accurate choice of peculiar ligands assumes crucial relevance due to both the window of use and the stability. Quite recently, a versatile approach to the development of lanthanide complexes that emit in the NIR based on tropolone (H-$L_T$) as ligand has been found.[23] Upon deprotonation, tropolones can be used as seven-membered ring, bidentate oxygen-donor chelators that allow direct coordination of the chromophoric group to the $Ln^{III}$ cation. Their hard Lewis base character is suitable for forming strong bonds with $Ln^{III}$. Furthermore, tropolone has a good electronic structure to act as an antenna because the energy of its triplet state (16800 $cm^{-1}$) is compatible for efficient energy transfer to the low accepting levels of several $Ln^{III}$ ions that emit in the NIR such as $Nd^{III}$, $Er^{III}$, $Ho^{III}$, and $Tm^{III}$. In the past, $[Ln(L_T)_3]$ and $M[Ln(L_T)_4]$ ($M = NH_4^+$, $Na^+$) complexes have been prepared.[24] Upon changing the counterion to $K^+$, the complexes $K[Ln(L_T)_4](dmf)$ have been prepared and fully characterized also by X-ray diffraction investigations.[23] In these complexes the coordination around the lanthanide cation has been described as a distorted dodecahedron. Quantitative luminescence measurements indicated that the tropolonato ligands are able to sensitize several lanthanide cations that emit in the NIR domain.[23]

Other studies have been successfully carried out on tris-β-diketonato lanthanide complexes containing also functionalized dipyridine or phenanthroline ligands that are known as very good sensitizers and many excellent papers have been published consequently.[25] In particular, the addition of the phenanthroline ligand acts to saturate the coordination number of $Ln^{III}$ ions and also to improve the fluorescence intensity, volatility and stability of the $Ln^{III}$ complexes[26]

In order to enhance the optical properties we have used as ligand 2-hydroxy-4-isopropylcyclohepta-2,4,6-trien-1-one (4-isopropyltropolone, also known as hinokitiol or β-thujaplicin) (H-hino) and prepared the tris-tropolonato complexes [Er(hino)$_3$(phen)], and [{Er(hino)$_3$}$_2$(pdon)] by reaction of H-hino with $ErCl_3 \cdot 6H_2O$ and 1,10-phenanthroline or 1,10-phenanthroline-5,6-dione in methanol, respectively, in the presence of NaOH. Furthermore, 1,10-phenanthroline-5,6-dione was successfully used as appropriate ditopic ligand for dinuclear lanthanide complexation. In fact, it permits to coordinate two lanthanide(III) ions in the opposite side of the molecule by the $N_2$ and $O_2$ donor atoms allowing an interesting interaction between the two coordinated metal ions. In particular, [{Er(hino)$_3$}$_2$(pdon)] was obtained following a procedure similar to that employed for the phenanthroline analogue. The complexes were characterized by $^1$H NMR, ESI MS and IR spectroscopy and elemental analysis, moreover a photophysical characterization in solution was performed. All the complexes display an absorption in the UV region, while the subsequent emission in the NIR region (≈ 1550 nm) is quite interesting and comparable with the best emitter compounds up to now reported. This paper reports the physicochemical properties arising from this molecular aggregation.

## Results and Discussion

### Synthesis of the Complexes

The tris-tropolonato lanthanide(III) complexes of $Er^{III}$, $Eu^{III}$, and $Yb^{III}$ have been prepared accordingly to Scheme 1.

In particular the tris-tropolonato $Ln^{III}$ complexes obtained by reaction of a methanolic solution of 4-isopropyltropolone (H-hino) with NaOH and the appropriate lanthanide(III) trichloride hexahydrate and recovered from a water/methanol solution, show only trace of water or methanol according to elemental analyses and thermogravimetric and IR investigations. Furthermore, the complexes are stable in air for long periods of time. We suppose that, in order to complete the high coordination number required by these lanthanides(III) ions, the complexes are in the form $[Ln(hino)_3]_n$ ($n$ = 2 or 3). NMR spectra in $CD_3OD$ or $CDCl_3$ show in fact the correct pattern [shifted depending on the paramagnetism of lanthanide(III) metal ion] of the tropolonato ligand with very small amount of free water. Only the $[Eu(hino)_3]_n$ complex in $(CD_3)_2SO$ shows a double pattern of the tropolonato ligand, indicating the different role of the oxygens bridging the $Eu^{III}$ ions.

This is not a very surprising result; many β-diketonate complexes, for instance, can loose a solvent molecule coordinated to the central metal ion giving rise to an easy oligomerization through oxygen bridges of the chelating ligands. The lack of quenching in the fluorescence of these complexes (vide postea) is an additional proof of the absence of water in the coordination environment of the erbium(III) ion.

This dimeric or trimeric complexes can easily turn into the monomeric one in the presence of the chelating ligand 1,10-phenanthroline. The resulting complex [Er(hino)$_3$(phen)]·$H_2O$ is soluble in a variety of solvents, such as MeOH, EtOH, $CHCl_3$, $CH_2Cl_2$, $CH_3CN$, DMSO, but insoluble in $H_2O$ and *i*PrOH. The IR spectra of the complex show the characteristic strong absorption bands at ($cm^{-1}$) 1588 (νC=O), 1504 (νAr, C=C), 1239–1240 (νC–O). Thermogravimetric analyses indicate a 1.71% weight loss at 92 °C, in agreement with the loss of one non-coordinated water molecule. Again the presence of water only in the crystalline framework and not directly bonded to the central metal ion is proved by the photophysical behaviour (vide postea).

The complex appears to be monomeric with the metal ion in an octacoordinated environment.

A further functionalization of the periphery of the chelating nitrogen-containing ligands was introduced in order to allow them to serve as dinucleating ligands towards equal

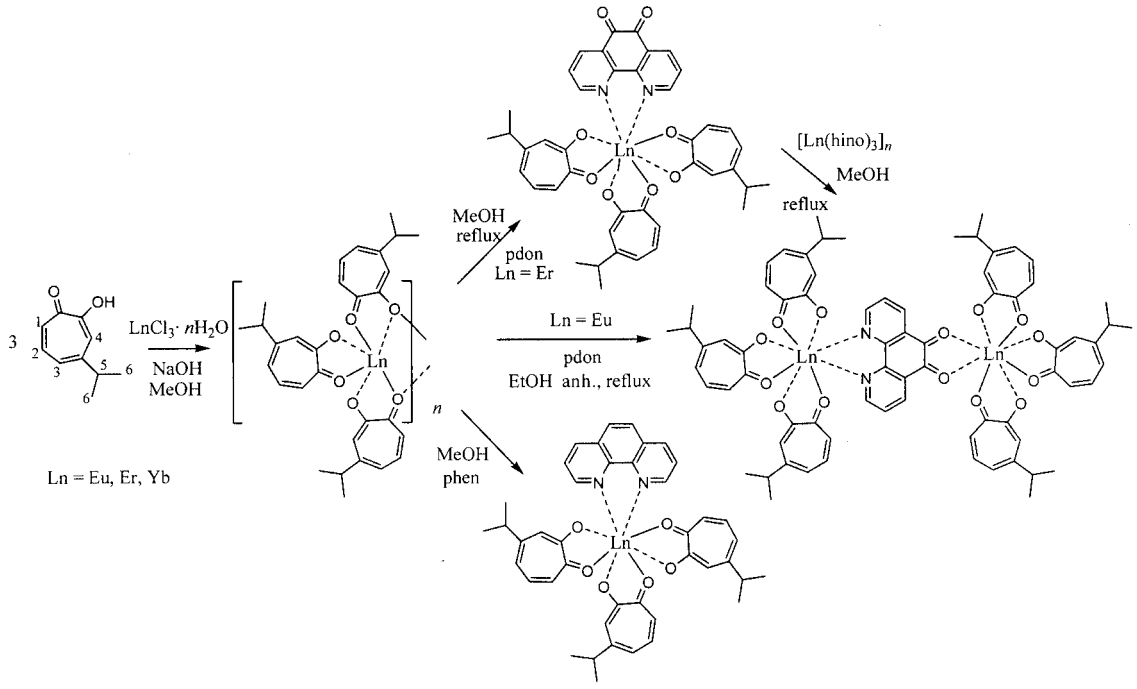

Scheme 1.

or different lanthanide(III) ions. 1,10-Phenanthroline-5,6-dione (pdon) is a suitable ditopic ligand: it contains two well separated coordinating sites, one containing two nitrogen atoms and one containing two oxygen atoms, both suitable for lanthanide(III) complexation. Thus, the reaction of $[Er(hino)_3]_n$ with pdon in anhydrous methanol in a 1:1 molar ratio under reflux affords $[Er(hino)_3(pdon)]\cdot 0.2H_2O$ with the lanthanide(III) ion coordinated to the two nitrogen atoms of the functionalized phenanthroline. In fact, $^1H$ NMR experiments performed in $CD_3OD$ of diamagnetic yttrium and lutetium complexes[27] $[Ln(hino)_3(pdon)]$ show a significant downfield proton shift of CH-N (from 8.95 to 9.12 ppm) and the corresponding upfield shift of CH-C=O (from 8.55 to 8.45 ppm) with respect to the free pdon. This mononuclear complex, by reaction of $[Er(hino)_3]_n$ in anhydrous methanol in a 1:1 ratio under reflux gives rise to the homodinuclear $[\{Er(hino)_3\}_2(pdon)]\cdot H_2O$. Elemental and thermogravimetric analyses of the mononuclear and dinuclear complexes agree with the proposed formulations, whereas IR spectra show nearly the same pattern, with the characteristic strong absorption bands at ($cm^{-1}$) 1688–1689 (νC=O, pdon), 1588 (νC=O), 1504–1505 (νAr, C=C), 1239–1240 (νC–O). The NMR spectra of $[Er(hino)_3(pdon)]\cdot 0.2H_2O$ and $[\{Er(hino)_3\}_2(pdon)]\cdot H_2O$ in $(CD_3)_2SO$ have the same pattern as well, but in the spectrum of the dinuclear complex, the peaks related to the protons of 4-isopropyltropolone are of double intensity (with respect to the pdon proton intensity) compared to those present in the spectrum of the mononuclear complex, therefore showing the presence of six 4-isopropyltropolonate units to one of 1,10-phenanthroline-5,6-dione in the dinuclear complex.

It must be noted that, under anhydrous conditions, using the precursor $[Eu(hino)_3]_n$ and pdon in a 1:1 molar ratio, only the homodinuclear complex $[\{Eu(hino)_3\}_2(pdon)]$ was obtained. This complex, shows the same IR spectrum as that of the related $Er^{III}$ complexes above reported, but a different NMR pattern system, in which the peaks of the two $Eu(hino)_3$ units are shifted each other, as inferred by 2D COSY and NOESY experiments: peaks at $\delta$ = 7.32 (4-H), 6.81 (1-H), 5.94 (3-H), 4.51 (2-H), 2.37 (5-H), 0.86 (6-H) are related to one 4-isopropyltropolonate unit, and peaks at $\delta$ = 4.86 (3′-H), 3.49 (4′-H), 3.28 (1′-H), 3.09 (2′-H), 1.33 (5′-H), 0.08 (6′-H) to the other unit, while the signals at $\delta$ = 8.97, 8.36, and 7.65 correspond to the protons of 1,10-phenanthroline-5,6-dione.

Population of gas phase ions generated by ESI-MS was studied to prove the presence of polynuclear complexes. The structural assignments of such ions are supported by their characteristic isotopic distributions particularly affected by the presence of erbium and europium atoms ($^{166}Er/^{167}Er/^{168}Er$ of 1:1.5:1.25) ($^{151}Eu/^{153}Eu$ of 1:1.1) and exact mass measurements.

The spectra of $[Ln(hino)_3(phen)]$ and $[Ln(hino)_3(pdon)]$, (Ln = Er and Eu) parallel each other and shows a fragmentation pattern consistent with the proposed formulation. In particular, it is interesting to note that, under the experimental conditions used for the spectra acquisition (1% HCOOH in $MeCN/H_2O$, 1:1 solution), the detected peaks are due to species ranging from $[Ln(hino)_2]^+$ to $[Ln(hino)_3\text{-}(H\text{-}hino)_3]^+$, $[Ln(hino)(L)]^{\cdot+}$, and $[Ln(hino)_3(L)]^+$ (L = phen, pdon). Thus, while for $[Er(hino)_3(phen)]$ the parent peak is clearly detectable at the appropriate *m*/*z* value, the

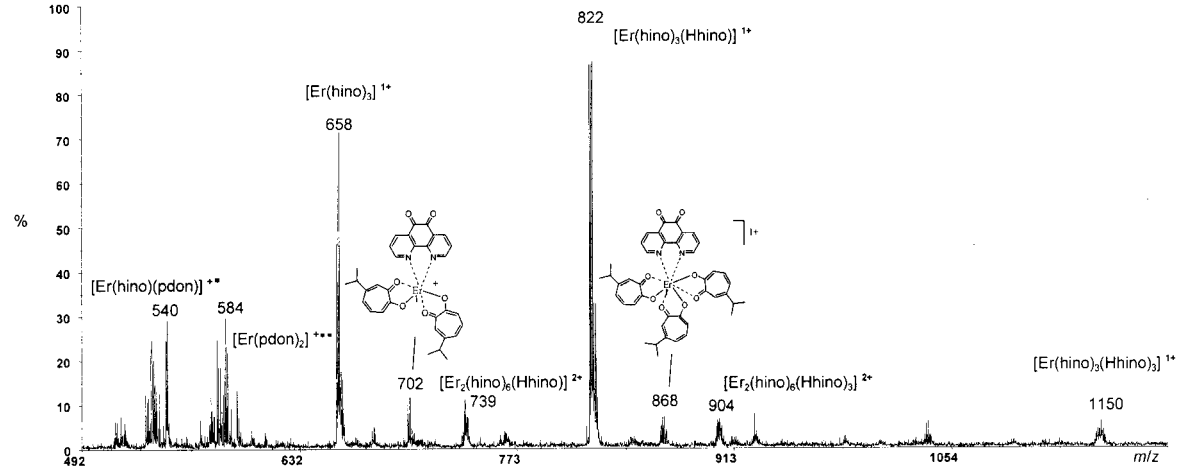

Figure 1. ESI mass spectrum in the positive mode of the methanolic solution of $[Er(hino)_3(pdon)]$.

parent peak of the dinuclear complex $[\{Ln(hino)_3\}_2(pdon)]$ was not detected probably owing to the particular experimental condition adopted.

As an example, the mass spectrum of $[\{Eu(hino)_3\}_2$-(pdon)] is reported in Figure 1; the most relevant species present in solution are indicated. The obtained data clearly show the rearrangement of the starting complex, this favouring the formation of complexes with a progressively higher number of tropolonato ligands about the central metal ion. This is certainly due to the high affinity of this particular α-diketone towards lanthanide(III) ions.

## Photophysical Properties

All the investigated $Er^{III}$ complexes in anhydrous DMSO dilute solution display strong and broad UV absorption band due to transitions between the electronic states of the organic ligand. On the contrary the UV/Vis absorption peaks arising from transition between the $Er^{3+}$ ground and excited states are only barely recognizable because of their small oscillator strength. In particular, as shown in Figure 2 (A) for the $[Er(hino)_3(pdon)]$ complex, only the $^2H_{11/2}$–$^4I_{15/2}$ transition gives rise to a detectable absorption peak at 520 nm.

Upon optical excitation in the absorption bands of the ligand, the characteristic $Er^{3+}$ emission due to the transition $^4I_{13/2}$–$^4I_{15/2}$ can be easily observed [Figure 2, (A)] indicating that an efficient energy-transfer process between the ligand and the manifold of $Er^{3+}$ excited state takes place. The quantum yield (QY) of the IR emission is nearly the same of the corresponding peak observed in a $[Er(Q)_3]$[28] (HQ = 8-hydroxyquinoline), i.e. of the order of few $10^{-4}$, in agreement with the data reported for similar tropolonate-based complexes.[23] The emission bandwidth is about 60 nm, significantly larger than the corresponding one in Er-doped silica, suggesting a high inhomogeneous disorder of $Er^{3+}$ surroundings, which hinder any possible differences among different complexes.

Deeper insight about the processes involved in the IR emission of these complexes can be obtained from time-resolved measurements. In such a way it is possible to evaluate independently the efficiency of the ligand→$Er^{3+}$ energy transfer and the efficiency of the $Er^{3+}$ photoluminescence (PL) quenching processes. Indeed, the PL intensity immediately after the excitation pulse [PL($t$ = 0)] depends only on the efficiency of the energy transfer, because the quenching of the $Er^{3+}$ excited states occurs in a relatively long timescale. On the other hand, the lifetime of the $Er^{3+}$ PL is strongly affected by the presence of non-radiative decay channels but is not related to the efficiency of $Er^{3+}$ excitation processes that take place within few ns. In Figure 3 the PL decay trace is showed for the $[Er(hino)_3(pdon)]$ complex with the corresponding fit obtained using a single exponential function. The found lifetime ($\tau_{tot}$) for the $[Er(hino)_3(pdon)]$ complex is 2.12 μs, while it is not possible to observe any PL rise time. This confirms that the excitation of the $Er^{3+}$ is extremely fast. The agreement between experimental and fitted data is perfect indicating that all the $Er^{3+}$ ions experiment the same mean local environment. Quite similar measurements have been obtained for all the studied complexes, and the corresponding lifetimes and PL efficiencies are reported in Table 1.

Because the radiative lifetime ($\tau_{rad}$) of the $Er^{3+}$ $^4I_{13/2}$–$^4I_{15/2}$ transition is around 10 ms,[29] i.e. about $10^4$ time longer the PL-detected decay time, the origin of the low efficiency of the 1550 nm emission has to be ascribed completely to the presence of fast quenching processes as usual for all the $Er^{3+}$ complexes. Indeed the $^4I_{13/2}$–$^4I_{15/2}$ transition is nearly resonant with both the first overtone of the O–H stretching vibration and the second overtone of the C–H one. By contrast the indirect excitation pathway of the $Er^{3+}$ ion seems to be rather efficient because: i) no 1550 μm PL rise time is detectable, at least in the employed timescale, and ii) the QY evaluated from the ratio between radiative and total PL lifetime (QY = $\tau_{tot}/\tau_{rad}$) and that obtained from the comparison of the integrated PL of tropolone-based complexes and of $[Er(Q)_3]$ are in good agreement. As a confirmation, it should be pointed out that in all considered complexes the distance between the Er atom and the closest H atom (C–H bond), belonging to phenanthroline ligand, has been

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

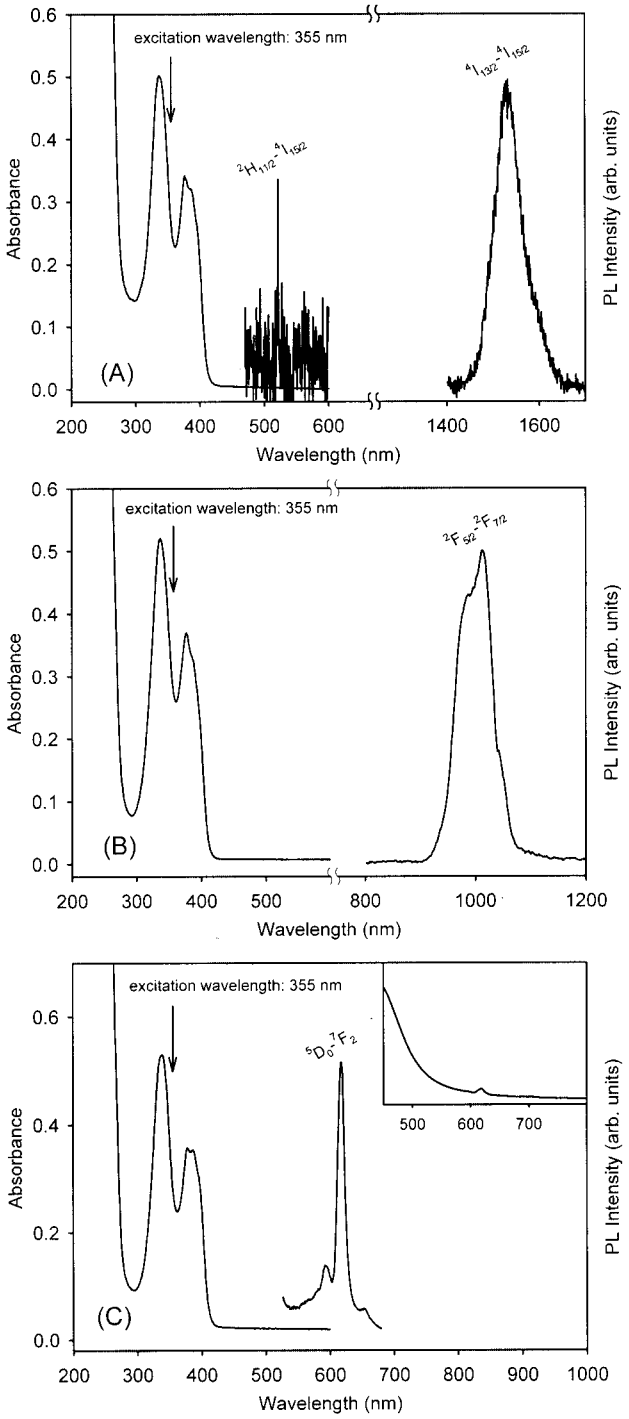

Figure 2. Absorption (left) and emission (right) spectra of the $[Er(hino)_3(pdon)]$, $[Yb(hino)_3]_n$ and $[Eu(hino)_3]_n$ complexes in DMSO at room temperature [(A), (B), and (C)] respectively. The absorption spectrum in the region of the $^2H_{12/2}$–$^4I_{15/2}$ $Er^{3+}$ transition (520 nm) has been multiplied by 100. In the panel (C) the broad PL from the ligand has been subtracted (the recoded spectrum is reported in the inset).

evaluated, from molecular modelling calculations, near to 0.41 nm; hence accounting for a reduced PL in NIR region.

It is interesting to outline that the measured PL decay times ($\tau > 2.10$ μs) are systematically longer in the studied complexes than in $[Er(Q)_3]$ ($\tau = 1.80$ μs), while the PL

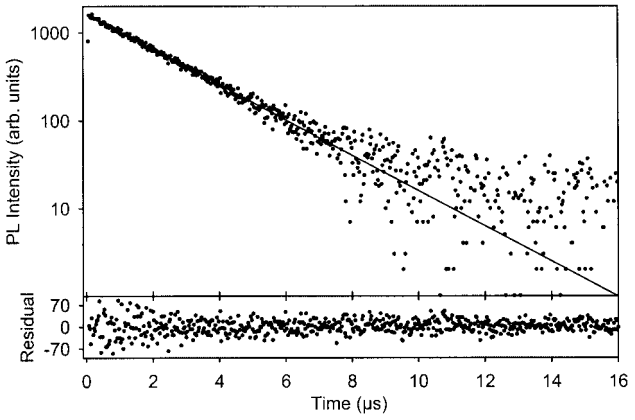

Figure 3. PL decay trace of the $[Er(hino)_3(pdon)]$ complex in DMSO (dots) recorded at 1550 nm complex at room temperature. The continuous line is the fit obtained with a single exponential function. The PL lifetime is 2.12 μs.

Table 1. Main optical data of the studied $Er^{III}$ complexes. All the reported efficiencies have been normalized to the values of $[Er(Q)_3]$ which has been set to 100.

| | Lifetime | Relative transfer efficiency | Relative total efficiency |
|---|---|---|---|
| $[Er(Q)_3]$ | 1.80 μs | 100 | 100 |
| $[\{Er(hino)_3\}_2(pdon)]$ | 2.11 μs | 107 | 125 |
| $[Er(hino)_3(pdon)]$ | 2.12 μs | 91 | 108 |
| $[Er(hino)_3(phen)]$ | 2.15 μs | 106 | 127 |
| $[Er(hino)_3]_n$ | 2.15 μs | 91 | 108 |

($t = 0$) is larger in this reference complex (see Table 1). This behaviour can be tentatively explained assuming that the bond length between the ligand and the rare earth ion are longer in the tropolone-based complexes than in $[Er(Q)_3]$, because both $Er^{3+}$ excitation and PL quenching involve energy-transfer processes which strongly depend on the distance ($R$) between donor and acceptor moieties (the transfer rate is proportional $1/R^6$ or to $e^{-R}$ for the Förster and Dexter mechanisms, respectively). Moreover, also the ability of the synthesized complexes to shield the $Er^{3+}$ ion from water molecules should be rather good, being the O–H vibration of these latter another source of non-radiative decay channels.

In Figure 2 (B, C) also typical absorption/emission spectra of the $[Yb(hino)_3]_n$ and $[Eu(hino)_3]_n$ complexes have been reported. In the case of $Yb^{III}$ complexes, upon the excitation of the ligand at 355 nm, the emission at around 1 μm due to the $^2F_{5/2}$–$^2F_{7/2}$ rare-earth transition is rather strong. Even if quantitative measurements have been not performed, the QY of these complexes is about two order of magnitude larger than in the corresponding $Er^{III}$ complexes. The $^2F_{5/2}$–$^2F_{7/2}$ PL decay is again a single exponential with a lifetime as long as 70–80 μs, which suggest the lack of any efficient quenching process in agreement with the observed high emission efficiency. On the contrary in the $Eu^{III}$ complexes the sharp emission of the lanthanide at 615 nm, even if still detectable, is extremely week and partially overlapped to the low energy tail of the ligand PL

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[Figure 2 (C)]. In particular, in the tropolone-based complexes only the first $Eu^{3+}$ optical transition ($^5D_0$–$^7F_2$) is nearly resonant with the first triplet excited state of the ligand at about 16800 $cm^{-1}$ (595 nm). However, due to its small oscillator strength, this transition can not be excited efficiently via energy transfer.

## Conclusions

The erbium(III) derivatives $[Er(hino)_3]_n$, $[Er(hino)_3(phen)]$, $[Er(hino)_3(pdon)]$, and $[\{Er(hino)_3\}_2(pdon)]$ containing the tropolonato moiety and designed to test the IR emission on varying the chemical surrounds at the metal(III) ion were synthesized and characterized by IR, NMR, thermogravimetry, and both absorption and emission spectroscopy. The PL efficiency at 1550 nm has been measured for the whole series; values larger than that for $[Er(Q)_3]$ were observed, even though they were still affected by quenching due to the relatively short distances between the C–H bonds and the Er atom. However the longer lifetimes with respect to the $[Er(Q)_3]$ complex indicate that in tropolone complexes the number of such short distances should be diminished and and/or their values have been augmented, encouraging to design new ligands where H atoms are placed more far away. The absence of water molecules coordinated to europium(III) ion in $[Eu(hino)_3]_n$ is remarkable and somewhat unexpected. Owing to this and the high stability in the solid state and the easy formation of the phenanthroline adduct $[Eu(hino)_3(phen)]$, it is an excellent starting complex for the preparation of more sophisticated tropolonato-containing complexes.

## Experimental Section

**Materials:** The solvents, the inorganic and organic compounds and the lanthanide chloride hydrates were commercial products, supplied by Aldrich, Riedel-de Haën, Carlo–Erba, or Fluka. They were used as received, without further purification. 4-Isopropyltropolone is a TCI-GR product.

**Preparation of $[Ln(hino)_3]$ (Ln = Er, Yb, Eu):** To a methanolic (40 mL) solution of 4-isopropyltropolone (H-hino) (0.3 mmol), NaOH in methanol was added in a 1:1 ratio. Then $LnCl_3{\cdot}6H_2O$ (Ln = Er, Yb, Eu) (0.1 mmol) was added, and the resulting solution was stirred for 4 h. The solution was reduced in volume and water was added. The precipitate formed was collected by filtration, washed with water and dried in vacuo.

**$[Er(hino)_3]_n$:** IR ($cm^{-1}$): $\tilde{\nu}$ = 1588 (νC=O), 1504 (νAr, C=C), 1239 (νC–O). $C_{30}H_{33}ErO_6$ (656.83): calcd C 54.86, H 5.06; found C 54.80, H 5.17. $^1H$ NMR [$(CD_3)_2SO$, paramagnetic]: $\delta$ = 7.45, 5.45, 3.48, 1.39, 1.07, 0.31, –1.26, –2.83, –3.63, –3.90, –7.34, –10.25 ppm.

**$[Yb(hino)_3]_n$:** IR ($cm^{-1}$): $\tilde{\nu}$ = 1588 (νC=O), 1505 (νAr, C=C), 1241 (νC–O). $C_{30}H_{33}O_6Yb$ (662.61): calcd. C 62.29, H 5.75; found C 60.91, H 5.74. $^1H$ NMR [$(CD_3)_2SO$, paramagnetic]: $\delta$ = 13.06, 8.34, 7.21, 6.57, 5.97, 5.03, 3.28, 2.77, 0.79, 0.63, –0.05, –1.17, –3.42, –7.46, –9.20 ppm.

**$[Eu(hino)_3]_n$:** IR ($cm^{-1}$): $\tilde{\nu}$ = 1588 (νC=O), 1504 (νAr, C=C), 1239 (νC–O). $C_{30}H_{33}EuO_6$ (641.53): calcd. C 56.17, H 5.19; found C 55.92, H 5.02. $^1H$ NMR [$(CD_3)_2SO$, paramagnetic]: $\delta$ = 7.28, 6.79, 5.90, 5.87, 4.82, 4.47, 3.46, 3.09, 2.29, 1.28, 0.78, 0.01 ppm.

**Preparation of $[Er(hino)_3(phen)]$:** To a methanolic solution of 4-isopropyltropolone (40 mL, 0.3 mmol), NaOH in methanol was added in a 1:1 ratio. Then $ErCl_3{\cdot}6H_2O$ (0.1 mmol), was added. The resulting solution was added to a methanolic solution (20 mL) of 1,10-phenanthroline (phen) (0.1 mmol) and stirred for 4 h. The solution was reduced in volume and water was added. The precipitate formed was collected by filtration, washed with water and dried in vacuo.

**$[Er(hino)_3(phen)]{\cdot}1H_2O$:** IR ($cm^{-1}$): $\tilde{\nu}$ = 1588 (νC=O), 1504 (νAr C=C), 1240 (νC–O). $C_{42}H_{43}ErN_2O_7$ (855.05): calcd. C 59.00, H 5.07, N 3.28; found C 59.14, H 4.88, N 3.00. These values are in agreement with thermogravimetric data. $^1H$ NMR [$(CD_3)_2SO$, paramagnetic]: $\delta$ = 9.09, 8.49, 7.99, 7.77, 0.38, –1.34, –2.84, –3.17, –3.77, –7.58, –10.53 ppm.

**Preparation of $[Er(hino)_3(pdon)]$:** $Er(hino)_3$ in anhydrous methanol (40 mL) was added to 1,10-phenanthroline-5,6-dione dissolved in anhydrous methanol (20 mL) in a 1:1 molar ratio, and the resulting solution was refluxed overnight. After refluxing, a brown precipitate appears, that was centrifuged off. The clear solution was evaporated to dryness and the solid was washed with diethyl ether, filtered and dried in vacuo.

**$[Er(hino)_3(pdon)]{\cdot}0.2H_2O$:** IR ($cm^{-1}$): $\tilde{\nu}$ = 1588 (νC=O), 1504 (νC=C Ar), 1240 (νC–O). $C_{42}H_{39.1}ErN_2O_{8.2}$ (870.32): calcd. C 57.00, H 4.67, N 3.17; found C 56.52, H 4.56, N 2.91. $^1H$ NMR [$(CD_3)_2SO$], paramagnetic: $\delta$ = 8,96, 8.36, 7.65, 4.02, 0.37, –1.35, –2.85, –3.85, –7.63, –10.54 ppm.

**Preparation of $[\{Er(hino)_3\}_2(pdon)]$:** $Er(hino)_3$ in anhydrous methanol was added to $[Er(hino)_3(pdon)]$ dissolved in anhydrous methanol in a 1:1 molar ratio, and the solution was refluxed for 1 day. The solution was reduced in volume and diethyl ether was added. The precipitate now formed was collected by filtration and dried in vacuo.

**$[\{Er(hino)_3\}_2(pdon)]{\cdot}H_2O$:** IR ($cm^{-1}$): $\tilde{\nu}$ = 1588 (νC=O), 1505 (νC=C, Ar), 1239 (νC–O). $C_{72}H_{74}Er_2N_2O_{15}$ (1541.85): calcd. C 56.09, H 4.84, N 1.82; found C 55.48, H 4.71, N 1.66. $^1H$ NMR ($(CD_3)_2SO$), paramagnetic: $\delta$ = 8.97 (2 H, pdon), 8.36 (2 H, pdon), 7.66 (2 H, pdon), 3.14, 1.05, 0.34, –1.29, –2.82, –3.69, –3.88, –7.46, –10.42 ppm.

**Preparation of $[\{Eu(hino)_3\}_2(pdon)]$:** $Eu(hino)_3$ dried in vacuo at 100° was dissolved in anhydrous ethanol and 1,10-phenanthroline-5,6-dione in anhydrous ethanol was added in a 1:1 molar ratio. The solution was refluxed for 3 h under nitrogen, then it was reduced in volume. Diethyl ether was added and the precipitate formed was filtered and dried in vacuo.

**$[\{Eu(hino)_3\}_2(pdon)]$:** IR ($cm^{-1}$): $\tilde{\nu}$ = 1588 (νC=O), 1503 (νC=C Ar), 1239 (νC–O). $C_{72}H_{72}Eu_2N_2O_{14}$ (1493.24): calcd. C 57.91, H 4.86, N 1.88; found C 56.79, H 4.59, N 2.21. $^1H$ NMR [$(CD_3)_2SO$, paramagnetic]: $\delta$ = 8.97 (2 H, pdon), 8.36 (2 H, pdon), 7.65 (2 H, pdon), 7.32 (4-H), 6.81 (1-H), 5.94 (3-H), 4.86 (3′-H), 4.51 (2-H), 3.49 (4′-H), 3.28 (1′-H), 3.09 (2′-H), 2.37 (5-H), 1.33 (5′-H), 0.86 (6-H), 0.08 (6′-H) ppm.

**Physico-Chemical Measurements:** Elemental analyses were carried out with a Fison 1108 analyzer. IR spectra were recorded as KBr pellets with a Mattson FTIR spectrometer. NMR spectra ($^1H$, $^{13}C$) were recorded with a Bruker AMX300 spectrometer equipped with direct and inverse broad-band multinuclear probes. The $T_1$ longitudinal relaxation times and the mixing times of NOESY experiments of the paramagnetic europium complex were measured using the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

standard inversion recovery pulse sequence. All ESI-MS spectra measurements were performed with a LCQ mass spectrometry (Finnigam) in methanol solutions of the samples ($10^{-5}$ M) eluted with MeCN/$H_2O$ (1:1) solution with 1% of HCOOH. The water content in the prepared samples was evaluated by thermal analysis curves using a Netzsch STA 429 thermoanalytical equipment. The tests were performed under nitrogen (flux rate 250 mL/min; heating rate 5 °C min$^{-1}$) and in air under the same conditions. Neutral alumina (Carlo–Erba product) was used as reference material.

All the optical characterizations have been performed in anhydrous DMSO dilute solution. As reference, also [Er(Q)$_3$] [tris(8-hydroxyquinolinato)erbium(III)] solutions, which is currently the benchmark for non-fluorinated organolanthanide and coordination complexes, have been prepared. UV/Vis absorption measurements have been done with a Cary 50 (Varian) spectrophotometer. NIR photoluminescence (PL) measurements have been carried out by exciting the samples with the third harmonic of a pulsed ND:YAG laser ($\lambda_{exc}$ = 355 nm, pulse duration ca. 10 ns, repetition rate 20 kHz, power ca. 1 mW). The laser beam was focused on the samples with a cylindrical lens (spot dimension about 7×0.5 mm$^2$) in order to minimize the complex degradation. The PL emission was detected with a Hamamatsu R5509-73 photomultiplier (or with a Spex 2000 CCD in the case of emissions in the visible) coupled with a Cornerstone (Oriel) monochromator (bandwidth 20 nm). The PL spectra and PL decay traces have been recorded in photon counting mode with a Ortec 9353 multichannel scaler. The overall time resolution is better than 30 ns.

# The First Sandwich Complex with an Octa(thioether) Coordination Sphere: Bis(maleonitrile-tetrathia-12-crown-4)silver(I)

**Hans-Jürgen Holdt,*[a] Holger Müller,[a] Matthias Pötter,[a] Alexandra Kelling,[a] Uwe Schilde,[a] Ines Starke,[b] Matthias Heydenreich,[b] and Erich Kleinpeter[b]**

*Dedicated to Professor Eberhard Hoyer on the occasion of his 75th birthday*

**Keywords:** Crown compounds / S ligands / Sandwich complexes / Silver

The new tetrathiacrown ethers maleonitrile-tetrathia-12-crown-4 ($mn12S_4$) and maleonitrile-tetrathia-13-crown-4 ($mn13S_4$) have been prepared and characterised by X-ray crystallographic analysis. These crown ethers form 2:1, 3:2 and 1:1 complexes with AgY (Y = $BF_4$, $PF_6$). The crystal structures of $[Ag(mn12S_4)_2]BF_4$ (**3a**), $[Ag(mn13S_4)_2]BF_4$ (**4a**) and $[Ag_2(mn13S_4)_3](PF_6)_2$ (**6b**) have been determined. Compound **3a** contains the centrosymmetric sandwich complex cation $[Ag(mn12S_4)_2]^+$ where each $mn12S_4$ ligand is coordinated to the Ag centre in an *endo* manner through all four S atoms. The 2:1 complex $[Ag(mn12S_4)_2]^+$ is the first sandwich complex with a tetrathiacrown ether and the first complex with an octa(thioether) coordination sphere. The crystal structure of compound **4a** also reveals a 2:1 complex. This complex, $[Ag(mn13S_4)_2]^+$, exhibits a half-sandwich structure. One $mn13S_4$ ligand coordinates to $Ag^+$ by all four S donor atoms and the other $13S_4$ crown by only one S atom. Compound **6b** contains a dinuclear Ag complex. The Ag complexes **3a**,**b**–**8a**,**b** were also studied by electrospray ionisation mass spectrometry. Collision-induced dissociation (CID) was used to compare the relative stability of 2:1 complexes $[AgL_2]^+$ and 1:1 complexes $[AgL]^+$ (L = $mn12S_4$, $mn13S_4$). The $^{13}C$ NMR chemical shifts of 2:1 and 1:1 Ag complexes and their corresponding free ligands were also estimated and compared. The free energy of the barrier of ring inversion ($\Delta G^{\ddagger}$) for $[Ag(mn12S_4)_2]^+$ was determined to be 64 kJ mol$^{-1}$.

## Introduction

The classical crown ether, 12-crown-4 ($12O_4$), forms sandwich complexes with a number of metal ions.[1] In these complexes, for example $[Na(12O_4)_2]Cl·5H_2O$,[2] $[Mn(12O_4)_2][Br_3]_2$,[3] $[Li(12O_4)_2][PPh_2]$,[4] $[Ag(12O_4)_2][AsF_6]$,[5] $[Fe(12O_4)_2][PF_6]_2$,[6] $[In(12O_4)][SbCl_6]·3CH_3CN$,[7] and $[Zn(12O_4)_2][ZnCl_3H_2O]_2$,[8] the metal ion is coordinated to eight oxygen atoms to form an octa(oxygen) coordination sphere which is not accessible with acyclic ligands. In early studies of crown ether chemistry the structures of bis(12-crown-4)–metal ion sandwich complexes and the properties of the coordinated metal ions were of interest. Later, the ability of 12-crown-4 to coordinate metal ions in sandwich structures was used to separate cations from carbanions in an organometallic compound, such as in the substituted cyclopentadienide salt $[Li(12\text{-crown-}4)_2][1,2,4\text{-}(Me_3Si)_3C_5H_2]$,[9] to stabilize salts, such as $[Na(12O_4)_2][\{(CO)_5Mo\}_2Sn(Cl)_2]$,[10] to synthesise new inorganic polymers, such as $[Cd(12O_4)_2][Cd_2(SCN)_6]$,[11] and to construct novel molecular conductors from supramolecular cations.[12] 12-Crown-4 generally forms sandwich complexes because its cavity (1.2–1.4 Å[13]) is too small to accommodate the metal ion. Moreover, free 12-crown-4 is already preorganized for the formation of sandwich complexes. The global minimum of 12-crown-4 has been shown to be the so-called "square" conformation, which has four identical *gauche*,*gauche*,*anti* conformations for the individual O–C–C–O groups. 12-Crown-4 also adopts a "square" conformation in the solid state.[14] In this conformation all four oxygen atoms are orientated in an endodentate fashion,[15] which is perfect for a sandwich structure.[16]

The cavities of the analogous tetrathia-12-crown-4[17] ($12S_4$) and tetraaza-12-crown-4[18] ($12N_4H_4$) are also too small to accommodate a metal ion, although so far there are no known sandwich complexes with these tetradentate macrocycles. In the case of tetrathia-12-crown-4, this is because of the exodentate orientation of all four sulfur atoms in the free ligand.[17]

For the synthesis of sandwich complexes with tetradentate $S_4$- or $N_4$-crown ether compounds, preorganized derivatives are necessary. With the help of 2,11-diaza[3.3](2,6)-

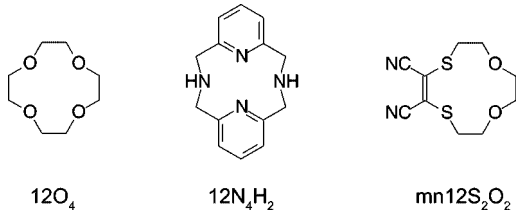
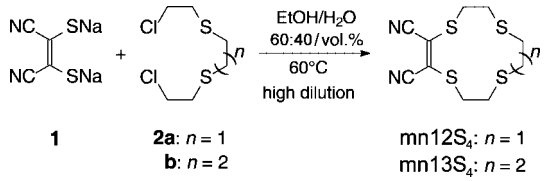
pyridinophane ($12N_4H_2$, Scheme 1), Krüger et al. have synthesised $Fe^{II}$,[19a] $Fe^{III}$[19a] and $Co^{II}$[19b] sandwich-like complexes with $N_8$ coordination spheres. The rigid pyridinophane $12N_4H_2$ is a preorganized macrocyclic $N_4$ ligand that forces a metal ion in a sandwich complex to have a coordination number of eight.



Scheme 1. Tetradentate macrocycles for 2:1 complexes (macrocycle/metal ion) with coordination number eight: 12-crown-4 ($12O_4$), 2,11-diaza[3.3](2,6)pyridinophane ($12N_4H_2$), maleonitrile-dithia-12-crown-4 ($mn12S_2O_2$).

Approaches to the preorganisation of twelve-membered $S_4$ macrocycles for sandwich complexation have, until now, not been carried out. However, tetrathiacrown ethers with larger cavities, for example with thirteen and fourteen members, have been modified at their periphery with different groups (cyclohexyl, phenyl, methyl, benzo, hydroxy) to preorganize the macrocyclic ligands for the "in-cavity" complexation.[20]

Previously, we have found that 1,4-dithiacrown ethers are stabilized in endodentate conformations by incorporating the rigid maleonitrile unit between the two sulfur atoms. The resulting maleonitrile-dithiacrown ethers[21] are preorganized $S_2O_n$ coronands ($n$ = 2–5) for the complexation of $Ag^+$,[22a,22b,23a] $Tl^+$,[22c] $Cs^+$,[21c] $Na^+$,[22d] $HgCl_2$,[22c,23b] and $MCl_3$ (M = Sb, Bi)[22d] in "in-cavity" sandwich or half-sandwich structures with mixed ether/thioether coordination spheres. The twelve-membered maleonitrile-dithia-12-crown-4 ($mn12S_2O_2$, Scheme 1) forms a sandwich complex $[Ag(mn12S_2O_2)_2]^+$ with $Ag^+$.[22a] The overall environment surrounding $Ag^I$ in $[Ag(mn12S_2O_2)_2]^+$ is that of a distorted cubic $S_4O_4$ set of donors. In this paper we report on the synthesis of the maleonitrile-tetrathiacrown ethers $mn12S_4$ and $mn13S_4$ (Scheme 2). These new tetrathiacrown ethers are preorganized $S_4$ macrocycles for the preparation of sandwich and half-sandwich complexes. Maleonitrile-tetrathia-12-crown-4 ($mn12S_4$) forms the sandwich complex $[Ag(mn12S_4)_2]^+$ with $Ag^I$, which is the first complex with an octa(thioether) coordination sphere.



Scheme 2. Synthesis of the maleonitrile-tetrathiacrown ethers $mn12S_4$ and $mn13S_4$.

## Results and Discussion

Using the high-dilution technique, the maleonitrile-tetrathiacrown ethers $mn12S_4$ and $mn13S_4$ were obtained by treating disodium 1,2-dicyanoethene-1,2-dithiolate[24] (**1**) with 1,8-dichloro-3,6-dithiaoctane[25] (**2a**) and 1,9-dichloro-3,7-dithianonane[25] (**2b**), respectively, in ethanol/water solution (Scheme 2). The dichlorides **2a** and **2b** were prepared by chlorination of the corresponding diols with $SOCl_2$ in $CHCl_3$ and were cyclized with the dithiolate **1** without isolation.

The crystal structures of the two new tetrathiacrown ethers were obtained by X-ray crystallographic analysis; details of data collection and refinement are given in the Experimental Section. The crystal structure of $mn12S_4$ is shown in Figure 1 from two different views. The rigid maleonitrile fragment forces the orientation of the sulfur atoms

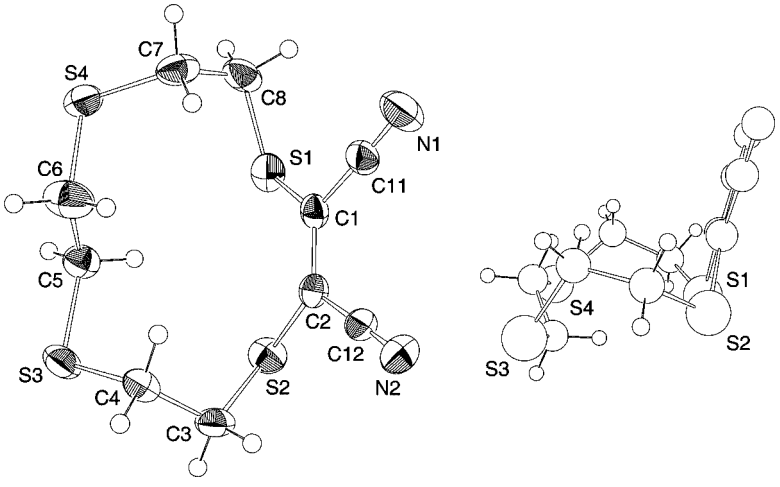


Figure 1. T7o different views of the molecular structure of maleonitrile-tetrathiacrown ether $mn12S_4$. Selected torsion angles [°] of free mn13$S_4$ and of coordinated mn13$S_4$ (in square brackets) in the half-sandwich complex [Ag(mn13$S_4$){mn13$S_4$(A)-κ$^1$-S4A}]$^+$: S1–C1–C2–S2 –2.2(3) [–2.0(2)], C1–C2–S2–C3 –148.29(19) [–146.12(17)], C2–S2–C3–C4 61.8(2) [62.76(18)], S2–C3–C4–S3 61.8(2) [65.93(19)], C3–C4–S3–C5 –101.7(2) [–162.76(16)], C4–S3–C5–C6 –169.01(19) [76.69(19)], S3–C5–C6–C7 –174.14(19) [88.1(2)], C5–C6–C7–S4 67.9(3) [–92.8(2)], C6–C7–S4–C8 –107.1(2) [–73.67(19)], C7–S4–C8–C9 148.76(19) [163.15(16)], S4–C8–C9–S1 –67.5(2) [–62.9(2)], C8–C9–S1–C1 –71.8(2) [–62.67(19)], C9–S1–C1–C2 157.60(19) [145.28(17)].

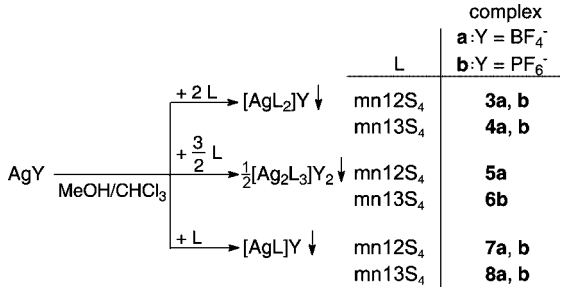
S1 and S2 toward the macrocyclic ring centre (endodentate orientation). Sulfur atom S4 is in a half endo-/half exodentate position, while S3 is fully exodentate.

The preferred conformers of both mn12$S_4$ and mn13$S_4$ were also studied by molecular modelling in the gas state.[26] Two of the three most stable conformations of mn12$S_4$ show orientations for the S-donor atoms as observed in the crystal structure. In conclusion, both the results of the X-ray crystallographic analysis and of the molecular modelling reveal that free mn12$S_4$ adopts preferred conformations in which three of the four S donor atoms are already in an endodentate orientation. Similar positions for the sulfur atoms were also observed in free mn13$S_4$; in the corresponding crystal structure (see Figure 2), S1, S2 and S3 proved to be orientated in an endodentate fashion, and only S4 is exodentate.

$Ag^I$ complexes of the studied tetrathiacrown ethers were obtained by mixing a solution of the crown ether in chloroform with a methanolic solution of $AgBF_4$ or $AgPF_6$. The macrocycles and silver salts were allowed to react in 2:1, 3:2 and 1:1 molar ratios, yielding the $Ag^I$ complexes of corresponding compositions (**3a**,**b**–**8a**,**b**; Scheme 3). The IR spectra of these new $Ag^I$ complexes show the typical ligand and anion bands (see Experimental Section); there is no hint of a coordination of the nitrile groups or anions to the silver cation. Therefore, the silver ions in compounds **3a**,**b**–**8a**,**b** should only be coordinated by the S atoms of the ligands. The crystal structures of the compounds [Ag(mn12$S_4$)$_2$]$BF_4$ (**3a**), [Ag(mn13$S_4$)$_2$]$BF_4$ (**4a**) and [$Ag_2$(mn13$S_4$)$_3$]($PF_6$)$_2$ (**6b**) were determined by X-ray crystallographic analysis; the corresponding data are summarised in the Experimental Section.

Compound **3a** contains the centrosymmetric complex cation [Ag(mn12$S_4$)$_2$]$^+$, with $Ag^I$ sandwiched between the two mn12$S_4$ molecules. Each mn12$S_4$ ligand is coordinated to the $Ag^I$ centre in an *endo* manner through all four S



Scheme 3. Synthesis of the $Ag^I$ complexes.

atoms. Two tetradentate mn12$S_4$ macrocycles force the $Ag^I$ centre to have a closed octa(thioether) coordination sphere. The $S_8$ set of donors exhibits a distorted cubic geometry. The Ag–S bond lengths in the centrosymmetric cation [Ag(mn12$S_4$)$_2$]$^+$ are of different lengths, with four of them being shorter [2.5861(7), 2.7804(6) Å] than the other ones [3.2664(7), 3.2137(7) Å]. This kind of gradation is typical of $Ag^I$ complexes with $S_8$ coordination spheres. For example, in the centrosymmetrical sandwich complex bis(tetraethylcyclotetraarsathiane)silver(I) [Ag{*cyclo*-($C_2H_5AsS$)$_4$}$_2$]$^+$, four Ag–S distances are short [2.716(7), 2.767(5) Å] and four long [3.218(6), 3.328(9) Å].[27] Also, in the recently synthesised complex bis(η$^4$-cyclooctasulfur)silver(I) [Ag(η$^4$-$S_8$)$_2$]$^+$, four Ag–S distances are shorter (2.68–2.99 Å) than the other four (3.20–3.31 Å).[28] In the three complexes [Ag(mn12$S_4$)$_2$]$^+$, [Ag{*cyclo*-($C_2H_5AsS$)$_4$}$_2$]$^+$ and [Ag(η$^4$-$S_8$)$_2$]$^+$ the four short Ag–S distances lie in a plane.

In the sandwich complex [Ag(mn12$S_4$)$_2$]$^+$, the $Ag^+$ ion is located 1.6543(4) Å above the best least-squares plane of the four mn12$S_4$ S atoms. The sandwich complexation of the $Ag^+$ ion by two mn12$S_4$ molecules is possible because the $Ag^+$ ion cannot be accommodated in the cavity of a single crown mn12$S_4$ (1.0–1.25 Å). Moreover, the free mn12$S_4$ S atoms already assume orientations which should

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be favourable for sandwich complexation. This expectation is confirmed by similar conformations of the free and coordinated mn12$S_4$ in the solid state. A comparative conformation analysis reveals only distinct differences for the C(4)$H_2$–S3–C(5)$H_2$–C(6)$H_2$ group, namely *a*, $g^-$ and *a* in the free and $g^-$, $g^-$ and $g^-$ in the coordinated ligand (see caption of Figure 3). The bis(maleonitrile-tetrathia-12-crown-4)silver(I) complex is the first sandwich complex with a tetrathiacrown ether and the first complex with an octa(thioether) coordination sphere.

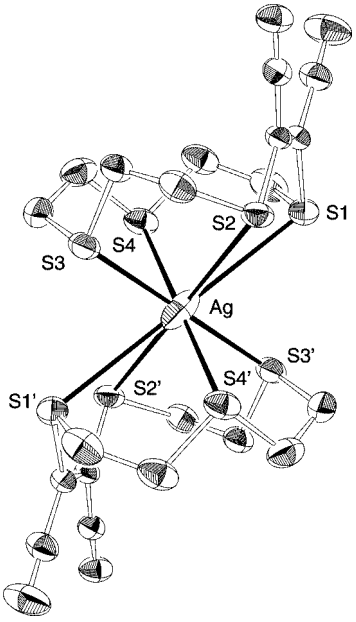


Figure 3. Molecular structure of the sandwich complex cation $[Ag(mn12S_4)_2]^+$ in compound **3a**. Selected bond lengths [Å]: Ag–S1 3.2664(7), Ag–S2 3.2137(7), Ag–S3 2.5861(7), Ag–S4 2.7804(6). For selected torsion angles see caption of Figure 1.

The crystal structure of $[Ag(mn13S_4)_2]BF_4$ (**4a**) reveals a 2:1 complex of the thirteen-membered maleontrile-tetrathia-13-crown-4 with silver(I) (Figure 4). As opposed to the sandwich complex $[Ag(mn12S_4)_2]^+$, the $[Ag(mn13S_4)_2]^+$ complex exhibits only a half-sandwich structure. One mn13$S_4$ ligand coordinates silver(I) by all four S-donor atoms and the other mn13$S_4$ molecule by only one S atom, resulting in an overall $S_5$ environment around $Ag^I$ with a distorted square-pyramidal coordination geometry. The Ag–S bond lengths [2.5020(5)–2.9475(6) Å] are normal for penta(thioether)-coordinated $Ag^+$ ions (2.550–2.995 Å[29]). In the present complex the $Ag^I$ is located only 0.9881(3) Å above the best least-squares plane of the fourfold-coordinated mn13$S_4$, which means that the $Ag^+$ ion dips markedly into the mn13$S_4$ cavity and more than half of its coordination sphere is already shielded. Thus, the second mn13$S_4$ ligand in this complex can only act as a monodentate ligand. The mn13$S_4$ cavity (1.3–1.45 Å) is too large to form a sandwich complex with silver(I), so the twelve-membered homolog mn12$S_4$ is the only one with the right cavity dimensions for preparing sandwich complexes.

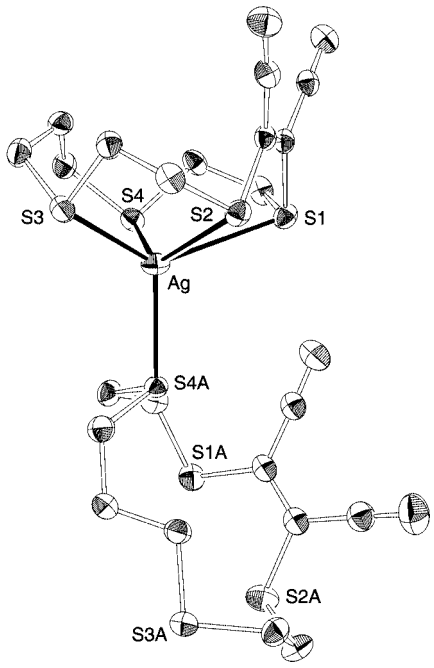

Figure 4. Molecular structure of the half-sandwich complex $[Ag(mn13S_4)\{mn13S_4(A)\text{-}\kappa^1\text{-}S4A\}]^+$ in compound **4a**. Selected bond lengths [Å]: Ag–S1 2.9475(6), Ag–S2 2.8100(6), Ag–S3 2.5508(6), Ag–S4 2.5647(6), Ag–S4A 2.5020(5). For selected torsion angles of the fourfold coordinated mn13$S_4$ molecule see the caption of Figure 2.

$[Ag_2(mn13S_4)_3](PF_6)_2$ (**6b**) contains the dinuclear $Ag^I$ complex $[\{Ag1(mn13S_4)\}\{Ag2[mn13S_4(B)]\}\{\mu_2\text{-}mn13S_4\text{-}(A)\text{-}\kappa^1\text{-}S4A,\text{-}\kappa^1\text{-}S3A\}]$ (see Figure 5). The two half-sandwich moieties $[Ag1(mn13S_4)]^+$ and $[Ag2\{mn13S_4(B)\}]^+$ are connected by the third mn13$S_4$ molecule through the S atoms S4A and S3A. Both $Ag^I$ centres therefore have a distorted square-pyramidal coordination geometry, as was already observed for the $Ag^I$ centre in the complex $[Ag(mn13S_4)_2]^+$.

Electrospray ionisation was used to study the complexes **3a**,**b**, **4a**,**b**, **7a**,**b** and **8a**,**b**. Both $[AgL_2]^+$ and $[AgL]^+$ complexes are observed in the mass spectra with different intensities (see Table 1). The loss of the anions ($PF_6^-$ and $BF_4^-$) seems to be the dominant ionisation process.[30] Additionally, the mn12$S_4$ and mn13$S_4$ ligands form 3:2 complexes **5a** and **6b** but with very low ion intensities (total ion current $< 50$ counts) in the mass spectra.

Collision-induced dissociation (CID) measurements were carried out to compare the relative stability of the $[AgL_2]Y$ and $[AgL]Y$ complexes. The $[AgL_2]Y$ complexes decompose easily by the elimination of one ligand ion. Increasing the collisional energy lowers the relative abundance of the peak of the $[AgL_2]^+$ complex ion, but raises the relative abundance of the peak of the $[AgL]^+$ complex ion. The collision voltage was gradually increased until the relative intensity of the 1:1 complex ion as well as that of the 2:1 complex ion was only 50%: the collision voltages thus obtained give an estimate of the dissociation energies of the corresponding complexes, which are generally higher for the $[AgL]^+$ complexes (22–25 eV) than for the corresponding $[AgL_2]^+$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

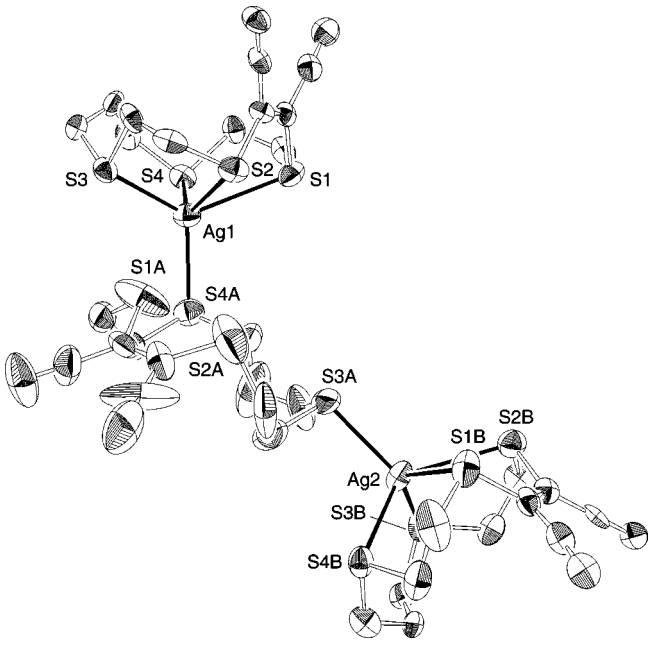

Figure 5. Molecular structure of the dinuclear complex $[\{Ag1(mn13S_4)\}\{Ag2(mn13S_4(B))\}\{\mu_2\text{-}mn13S_4(A)\text{-}\kappa^1\text{-}S4A\text{-}\kappa^1\text{-}S3A\}]^{2+}$ in compound **6b**. Selected bond lengths [Å]: Ag1–S1 2.888(3), Ag1–S2 2.908(3), Ag1–S3 2.556(3), Ag1–S4 2.597(3), Ag1–S4A 2.484(3), Ag2–S1B 2.840(3), Ag2–S2B 2.904(3), Ag2–S3B 2.581(3), Ag2–S4B 2.613(3), Ag2–S3A 2.540(4).

complexes (0–6 eV). Obviously, under electrospray conditions the tetrathiacrown ethers $mn12S_4$ and $mn13S_4$ form much more stable 1:1 complexes than 2:1 complexes.[31] Only minor differences in the CID measurements were observed in the fragmentation of the [AgL] complexes with $mn12S_4$ and $mn13S_4$. In the CID experiments of the $[AgL]^+$ ions, fragmentation occurred in the same way, mainly involving cleavage of the bond between the sulfur atoms and the carbon atom attached to the ethylene unit.

$^{13}C$ NMR spectroscopic investigations of both the complexes **3a**, **4a**, **7a** and **8a** and the free ligands $mn12S_4$ and $mn13S_4$ in solution ([$D_3$]nitromethane) showed no evidence for any equilibrium formation in the case of the complexes or of conformational changes in the case of the free ligands; only one set of signals could be observed at room temperature. The complexation with silver ions changed the chemical shifts of all signals with respect to those of the free ligands. Except for the C atoms in the γ-position to the double bond, the 12-membered complexes **3a** and **7a** and the 13-membered complexes **4a** and **8a**, the difference of the chemical shifts is larger in the 1:1 complex than in the 1:2 complex. Also, the direction of the complex-induced difference of chemical shifts is always the same. However, the signals of the C atoms in the γ-position in the 1:2 complexes are always found downfield with regard to the 1:1 complexes (see Tables 2 and 3).

The $^1H$ NMR spectra of **7a** and **8a** show strongly broadened lines at room temperature. The low-temperature spectra of these compounds gave significant splitting of all groups of signals only in the case of **7a**, which permitted the determination of the free energy of the barrier of ring inversion ($\Delta G^{\ddagger}_{338}$ = 64 kJ mol$^{-1}$). The coalescence temperature of **8a** is very close to room temperature, and cooling to the melting point of the solution gave an insufficient splitting of the signals to estimate the difference of the chemical shifts. Thus, the barrier of ring inversion in **7a** is higher than in the 1:2 complex $[Ag(mn12S_2O_2)_2]^+$, which was determined previously to be 51 kJ mol$^{-1}$.[32] The presence of four S atoms, as well as a generally stronger bonding of the cation in the 1:1 complex **7a**, led us to expect such a behaviour. In general, the complexation in 12-membered ring systems leads to a strongly increased barrier of the ring inversion by fixing the donor atoms. As a comparison, the barriers for cyclododecane (ca. 29 kJ mol$^{-1}$),[33] substituted cyclododecanes (ca. 34–37 kJ mol$^{-1}$)[34] and cyclododecene (ca. 29 and 40 kJ mol$^{-1}$)[35] should be highlighted.

## Conclusion

The maleonitrile-tetrathia-12-crown-4 is the first preorganized tetradentate thiacrown ether that forms sandwich complexes with the coordination number eight. At present we are investigating the complexing properties of $mn12S_4$ and $mn13S_4$ for other metal ions.

## Experimental Section

**General:** All operations were performed under dry argon using standard equipment and vacuum techniques. Solvents were dried by standard methods and distilled prior to use. 1,8-Dichloro-3,6-dithiaoctane,[25] 1,9-dichloro-3,7-dithianonane[25] and disodium (*Z*)-1,2-dicyanoethene-1,2-dithiolate[24] were prepared according to published procedures. Elemental analyses (C, H, N, S) were performed with an Elementar Vario EL elemental analyzer. NMR spectra were recorded with a Bruker Avance 500 or an Avance 300 spectrometer. For preparing the complex solutions, 15 mg was dissolved in 0.7 mL of deuterated chloroform or [$D_3$]nitromethane. Chemical shifts are referenced to TMS (for $^1H$) or to the solvent ($^{13}C$). All 1D and 2D COSY and HMQC pulse sequences were taken from the standard Bruker software. IR spectra were recorded with a Thermo Nicolet NEXUS FTIR instrument. UV/Vis measurements were carried out with an Analytik Jena Specord S 100 spectrophotometer with sealed quartz cuvettes. The ESI and CID spectra were recorded with a Micromass Q-TOF$_{micro}$ mass spectrometer in positive electrospray mode.

**Synthesis of Maleonitrile-tetrathiacrown Ethers $mn12S_4$ and $mn13S_4$:** A solution of disodium (*Z*)-1,2-dicyanoethene-1,2-dithiolate (11.72 g, 63 mmol) in water (0.8 L) was added to a solution of 1,8-dichloro-3,6-dithiaoctane (13.14 g, 60 mmol; synthesis of $mn12S_4$) or 1,9-dichloro-3,7-dithianonane (13.98 g, 60 mmol; synthesis of $mn13S_4$) in ethanol (1.2 L). The solution was stirred at 60 °C for 60 h and the polymeric reaction products were filtered off. The filtrate was concentrated, the residue dissolved in chloroform, the solution washed twice with water and dried with magnesium sulfate. The drying agent was removed by filtration and the filtrate concentrated in vacuo. The residual brown oil was chromatographed on a silica gel 60 gravity column (3 cm diameter × 50 cm length), and was eluted with chloroform to give the maleonitrile-tetrathiacrown ether.

**1,4,7,10-Tetrathiacyclododec-2-ene-2,3-dicarbonitrile ($mn12S_4$):** Yield: 3.4 g (18.7%). $R_f$ = 0.49 (chloroform). M.p. 182 °C (chloroform). IR (KBr): $\tilde{\nu}$ = 2222 m, 2208 m (C≡N); 1504 m (C=C) $cm^{-1}$. UV (chloroform): $\lambda_{max}$ (log $\varepsilon$) = 316 sh, 347 (3.97) nm. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.88 [m, 4 H, C(6)$H_2$], 2.96 [s, 4 H, C(8)$H_2$], 3.37 [m, 4 H, C(5)$H_2$] ppm. $^{13}C$ NMR: See Table 2. ESI(HR)-MS: *m*/*z* calcd. for $C_{10}H_{12}N_2S_4$ $[M]^+$ 287.9883; found 287.9881. $C_{10}H_{12}N_2S_4$ (288.46): calcd. C 41.64, H 4.19, N 9.71, S 44.46; found C 42.38, H 4.24, N 9.62, S 44.47.

**1,4,7,10-Tetrathiacyclotridec-5-ene-5,6-dicarbonitrile ($mn13S_4$):** Yield: 3.05 g (16%). $R_f$ = 0.33 (chloroform). M.p. 152–153 °C (chloroform). IR (KBr): $\tilde{\nu}$ = 2221 m, 2209 m (C≡N); 1507 m (C=C) $cm^{-1}$. UV (chloroform): $\lambda_{max}$ (log $\varepsilon$) = 297 sh, 347 (4.09) nm. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.79 [m, 2 H, C(12)$H_2$], 2.73 [t, $^3J_{H,H}$ = 7.4 Hz, 4 H, C(13)$H_2$], 2.87 [m, 4 H, C(2)$H_2$], 3.35 [m, 4 H, C(3)$H_2$] ppm. $^{13}C$ NMR: See Table 3. ESI(HR)-MS: *m*/*z* calcd. for $C_{11}H_{15}N_2S_4$ $[M + H]^+$ 303.0118; found 303.0133. $C_{11}H_{14}N_2S_4$ (302.49): calcd. C 43.68, H 4.67, N 9.26, S 42.40; found C 44.04, H 4.54, N 9.14, S 41.92.

**Synthesis of $Ag^I$ Complexes 3a,b–8a,b:** A methanolic solution of AgY (Y = $BF_4$, $PF_6$) was added to a stirred solution of the maleonitrile-tetrathiacrown ether in chloroform. After a few seconds, yellow crystals formed and were isolated by filtration.

**$[Ag(mn12S_4)_2]BF_4$ (3a):** Formed from $mn12S_4$ (28.8 mg, 0.1 mmol) in $CHCl_3$ (2 mL) and $AgBF_4$ (9.7 mg, 0.05 mmol) in MeOH (1 mL). Yield: 68 mg (88%). M.p. 194–196 °C. IR (KBr): $\tilde{\nu}$ = 2222 m, 2212 m (C≡N); 1510 m (C=C); 1083 s, 1061 s, 1052 s (B–F) $cm^{-1}$. $^1H$ NMR ($CD_3NO_2$): $\delta$ = 3.18 [s, 4 H, C(8)$H_2$], 3.21 [m, 4 H, C(6)$H_2$], 3.56 [m, 4 H, C(5)$H_2$] ppm. $^{13}C$ NMR: See Table 2. ESI(HR)-MS: *m*/*z* calcd. for $C_{20}H_{24}AgN_4S_8$ $[M - BF_4]^+$ 682.8818; found 682.8812. $C_{20}H_{24}AgBF_4N_4S_8$ (771.59): calcd. C 31.13, H 3.14, N 7.26, S 33.24; found C 30.51, H 3.00, N 6.92, S 32.35.

**$[Ag(mn12S_4)_2]PF_6$ (3b):** Formed from $mn12S_4$ (28.8 mg, 0.1 mmol) in $CHCl_3$ (2 mL) and $AgPF_6$ (12.6 mg, 0.05 mmol) in MeOH (2 mL). Yield: 52 mg (63%). M.p. 193 °C. IR (KBr): $\tilde{\nu}$ = 2222 m, 2213 m (C≡N); 1512 m (C=C); 835 s, 558 m (P–F) $cm^{-1}$. ESI(HR)-MS: *m*/*z* calcd. for $C_{20}H_{24}AgN_4S_8$ $[M - PF_6]^+$ 682.8818; found 682.8825. $C_{20}H_{24}AgF_6N_4PS_8$ (829.75): calcd. C 28.95, H 2.92, N 6.75, S 30.91; found C 28.63, H 2.78, N 6.48, S 31.30.

**$[Ag(mn13S_4)_2]BF_4$ (4a):** Formed from $mn13S_4$ (30.2 mg, 0.1 mmol) in $CHCl_3$ (2 mL) and $AgBF_4$ (9.7 mg, 0.05 mmol) in MeOH (1 mL). Yield: 71 mg (88%). M.p. 190–191 °C. IR (KBr): $\tilde{\nu}$ = 2217 m, 2209 m (C≡N); 1512 m, 1504 m (C=C); 1069 s, 1052 s, 1035 s (B–F) $cm^{-1}$. $^1H$ NMR ($CD_3NO_2$): $\delta$ = 2.06 [m, 2 H, C(12)$H_2$], 3.02 [t, $^3J_{H,H}$ = 6.1 Hz, 4 H, C(13)$H_2$], 3.24 [m, 4 H, C(2)$H_2$], 3.59 [m, 4 H, C(3)$H_2$]. $^{13}C$ NMR: See Table 3. ESI(HR)-MS: *m*/*z* calcd. for $C_{22}H_{28}AgN_4S_8$ $[M - BF_4]^+$ 710.9131; found 710.9136. $C_{22}H_{28}AgBF_4N_4S_8$ (799.64): calcd. C 33.04, H 3.53, N 7.01, S 32.07; found C 32.90, H 3.42, N 6.63, S 32.59.

**$[Ag(mn13S_4)_2]PF_6$ (4b):** Formed from $mn13S_4$ (30.2 mg, 0.1 mmol) in $CHCl_3$ (2 mL) and $AgPF_6$ (12.6 mg, 0.05 mmol) in MeOH (2 mL). Yield: 57 mg (66%). M.p. 193–195 °C. IR (KBr): $\tilde{\nu}$ = 2225 m, 2216 m, 2210 m (C≡N); 1514 m, 1505 m (C=C); 840 s, 558 m (P–F) $cm^{-1}$. ESI(HR)-MS: *m*/*z* calcd. for $C_{22}H_{28}AgN_4S_8$ $[M - PF_6]^+$ 710.9131; found 710.9140. $C_{22}H_{28}AgF_6N_4PS_8$ (857.80): calcd. C 30.80, H 3.29, N 6.53, S 29.90; found C 30.77, H 3.20, N 6.44, S 30.34.

**$[Ag_2(mn12S_4)_3](BF_4)_2$ (5a):** Formed from $mn12S_4$ (21.6 mg, 0.075 mmol) in $CHCl_3$ (2 mL) and $AgBF_4$ (9.7 mg, 0.05 mmol) in MeOH (1 mL). Yield: 31 mg (33%). M.p. 172–185 °C. IR (KBr): $\tilde{\nu}$ = 2223 m, 2213 m (C≡N); 1511 m, 1502 m (C=C); 1053 s, 1037 s (B–F) $cm^{-1}$. ESI(HR)-MS: *m*/*z* calcd. for $C_{30}H_{36}Ag_2BF_4N_6S_{12}$ (< 1) $[M - BF_4]^+$ 1164.7781; found 1164.7758. $C_{30}H_{36}Ag_2B_2F_8N_6S_{12}$ (1254.7): calcd. C 28.72, H 2.89, N 6.70, S 30.66; found C 28.12, H 2.55, N 6.35, S 31.40.

**$[Ag_2(mn13S_4)_3](PF_6)_2$ (6b):** Formed from $mn13S_4$ (22.65 mg, 0.075 mmol) in $CHCl_3$ (2 mL) and $AgPF_6$ (12.6 mg, 0.05 mmol) in MeOH (2 mL). Yield: 42 mg (40%). M.p. 194.5–195.5 °C. IR (KBr): $\tilde{\nu}$ = 2223 m, 2211 m (C≡N); 1510 m, 1503 m (C=C); 845 s, 558 m (P–F) $cm^{-1}$. ESI(HR)-MS: *m*/*z* calcd. for $C_{33}H_{44}Ag_2F_6N_6PS_{12}$ (< 1) $[M - PF_6 + 2\ H]^+$ 1266.8020; found 1266.8044. $C_{33}H_{42}Ag_2F_{12}N_6P_2S_{12}$ (1413.12): calcd. C 28.05, H 3.00, N 5.95, S 27.22; found C 27.81, H 2.92, N 5.83, S 28.40.

**$[Ag(mn12S_4)]BF_4$ (7a):** Formed from $mn12S_4$ (14.4 mg, 0.05 mmol) in $CHCl_3$ (1 mL) and $AgBF_4$ (9.7 mg, 0.05 mmol) in MeOH (1 mL). Yield: 18 mg (75%). M.p. 169–172 °C. IR (KBr): $\tilde{\nu}$ = 2227 m, 2215 m (C≡N); 1511 m, 1504 m (C=C); 1056 s (B–F) $cm^{-1}$. $^1H$ NMR: See text. $^{13}C$ NMR: See Table 2. ESI(HR)-MS: *m*/*z* calcd. for $C_{10}H_{12}AgN_2S_4$ $[M - BF_4]^+$ 394.8934; found 394.8959.

**[Ag(mn13S$_4$)]PF$_6$ (8b):** Formed from mn13S$_4$ (15.1 mg, 0.05 mmol) in $CHCl_3$ (1 mL) and $AgPF_6$ (12.6 mg, 0.05 mmol) in MeOH (2 mL). Yield: 19 mg (68%). M.p. 167–168 °C. IR (KBr): $\tilde{\nu}$ = 2225 m, 2214 m (C≡N); 1510 m, 1502 m (C=C); 840 s, 558 m (P–F) cm$^{-1}$. ESI(HR)-MS: *m/z* calcd. for $C_{11}H_{14}AgN_2S_4$ $[M - PF_6]^+$ 408.9091; found 408.9109. $C_{11}H_{14}AgF_6N_2PS_4$ (555.32): calcd. C 23.79, H 2.54, N 5.04, S 23.09; found C 24.08, H 2.48, N 5.01, S 23.7.

**Electrospray Ionisation:** The ligand and complex solutions ($10^{-5}$ M) for the ESI investigations were prepared with $CH_3CN$ or $CH_3NO_2$. All samples were injected (5–25 μL min$^{-1}$) with a Harvard syringe pump. The capillary voltage was set to 2.5 kV, with a cone voltage of between 15 and 35 V. The source temperature was 80 °C and the desolvation temperature 150 °C. The cone and desolvation gases (nitrogen) were delivered at 50 and 360 μL h$^{-1}$, respectively (Table 2). For MS/MS, after selection of the appropriate precursor ion, argon was used as the collision gas (approx. $5 \times 10^{-5}$ mbar) and the gas cell was maintained between 3 and 40 eV. Elemental compositions were determined by accurate mass measurement with a standard deviation of less than 5 ppm.

**X-ray Structure Determinations for mn12S$_4$, mn13S$_4$, 3a, 4a and 6b:** Crystals of mn12S$_4$ and mn13S$_4$ suitable for the X-ray structure determination were obtained by slow crystallisation from a chloroform solution in a refrigerator at 6 °C. Single crystals of **3a** were selected from a nitromethane solution after standing at 6 °C for 4 d. A solution of **4a** was placed in the narrow region of a crystallisation tube and carefully covered with a heptane layer. After 5 d, yellow crystals, which were suitable for X-ray analysis, were obtained. Crystals of **6b** were grown at 6 °C from a methanol/nitromethane solution during a six-week period. The crystals were mounted on a glass fibre. Diffraction data for mn12S$_4$, mn13S$_4$, **3a** and **6b** were collected with a STOE IPDS-2 diffractometer (Table 4). Data for **4a** were collected with a STOE four-circle instrument. All measurements were performed at 210(2) K using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Spherical absorption corrections were applied for mn12S$_4$ and mn13S$_4$. For **4a**, an empirical absorption correction was performed. The structures were solved by direct methods (SHELXS-97)[36] and refined by full-matrix least-squares on $F^2$ using all reflections (SHELXL-97).[37] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were calculated in their expected positions and refined using a riding model. The packing of **3a** contains disordered tetrafluoroborate anions and two solvate molecules (nitromethane) with small occupancy factors, from which only one solvate molecule could be satisfactorily refined. Therefore only one was involved in the refinement; the other ones were disregarded with the SQUEEZE instruction of the PLATON[38] program. CCDC-266947 to -266951 (for mn12S$_4$, mn13S$_4$, **3a**, **4a** and **6b**,

# Tetranuclear Complexes Containing a Luminescent $Ru_2M_2$ Core [M = $Cu^I$, (allyl)$Pd^{II}$]: Synthesis, Structures and Electrochemical Properties

**Dirk Walther,*[a] Lars Böttcher,[a] Jörg Blumhoff,[a] Sebastian Schebesta,[a] Helmar Görls,[a] Katrin Schmuck,[a] Sven Rau,[a] and Manfred Rudolph[a]**

**Keywords:** Copper / Luminescence / N ligands / Palladium / Ruthenium

The reaction between $[(tbbpy)_2Ru(tmbiH_2)](PF_6)_2$ (tbbpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine; $tmbiH_2$ = 5,5′,6,6′-tetramethyl-2,2′-dibenzimidazole) and LiMe/CuI affords the tetranuclear complex **1** containing the dication $[\{(tbbpy)_2Ru(tmbi)\}_2Cu_2]^{2+}$. The X-ray structure of **1** shows that the two $[(tbbpy)_2Ru(tmbi)]$ units coordinate the two Cu atoms in a twofold monodentate manner. Each copper atom is surrounded by two N-donor atoms of different ruthenium(II) units with N–Cu–N angles of 167.3°. The Cu···Cu separation (2.72 Å) indicates intranuclear contacts. LiMe/$[(allyl)PdCl]_2$ reacts with the starting Ru complex to form **2**, which contains the tetranuclear dication $[\{(tbbpy)_2Ru(tmbi)\}_2\{Pd(\eta^3\text{-allyl})\}_2]^{2+}$. Its crystal structure shows that the $Ru^{II}$ units act as twofold monodentate ligands as well. Each $Pd^{II}$ is in an essentially planar coordination environment containing two nitrogen atoms of two different dibenzimidazolates in the *cis* position with the $\eta^3$-bonded allyl group occupying the two remaining positions. In contrast to **1**, where the Ru–Cu–Cu–Ru unit forms an essentially planar structure, a strongly bent structure is formed in compound **2**. ESI mass spectra of **1** and **2** clearly show that the tetranuclear complexes are present in solution as well. Both complexes are luminescent. In addition, **2** catalyses the Heck coupling at 120 °C in *N*,*N*-dimethylacetamide. In contrast to **1** and **2**, the homodinuclear complex $[(tbbpy)_2Ru(tmbi)Ru(tbbpy)_2]$ (**3**) contains the dibenzimidazolate as a twofold chelating ligand that forms two five-membered chelate rings with the Ru centres. Electrochemical measurements of **2** show two reversible, one-electron oxidation steps, the difference between which ($\Delta E$ = 89 mV) is distinctly larger than the pure entropic effect. Furthermore, four reduction steps are observed, the first two of which are fully reversible.

## Introduction

The construction of oligonuclear metal complexes containing at least two different metals on the opposite side of bridging ligands is an area of general interest not only from synthetic, structural or theoretical points of view but also due to their potential catalytic properties, which often may be different from the related mononuclear species.[1,2] Of special interest in this field is the development of supramolecular combinations consisting of both a photo-redoxactive metal unit ($M^1$) and a reactive metal ($M^2$) connected by bridging ligands that allow electronic communication between the metal centers (for a review see ref.[3]). In these complexes the unit $M^1$ may act as a sensor of reactions at the reactive metal $M^2$. Furthermore, such systems are interesting candidates for studying directional photoelectron transfer processes between the different metals. In addition, in this type of complex the reactivity of $M^2$ may not only be tuned by steric or electronic influences of the $M^1$ units but also by light.[4] An attractive application of this effect would be the development of new photoswitchable catalysts.

We report here on the synthesis, structures and spectroscopic and electrochemical measurements of the two tetranuclear complexes **1** and **2** consisting of two peripheral photoactive $(tbbpy)_2Ru^{II}$ fragments ("$M^1$"), a tetramethyldibenzimidazolate bridging ligand, and either $Cu^I$ or (allyl)$Pd^{II}$ as reactive metal centres ("$M^2$"). In these combinations the bridging system is expected to allow electronic communication between the metals on each side.

## Results and Discussion

### Syntheses and Structures of Complexes 1 and 2

Very recently we have described the new ruthenium complex $[(tbbpy)_2Ru(tmbiH_2)](PF_6)_2$ (tbbpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine; $tmbiH_2$ = 5,5′,6,6′-tetramethyl-2,2′-dibenzimidazole), which is easily accessible by a microwave-assisted reaction.[5] In contrast to the unsubstituted derivative, $[(tbbpy)_2Ru(tmbiH_2)](PF_6)_2$ is more soluble in organic solvents due to the presence of ten methyl groups at the periphery of the complex. Furthermore, the complex contains a free coordination side and should therefore be able

to act as a "metalloligand" after deprotonation, analogous to similar systems (for typical Ru complexes of this type see refs.[5–15]).

The copper(I) complex **1** was obtained as follows. Treatment of $[(tbbpy)_2Ru(tmbiH_2)](PF_6)_2$ in THF with a mixture of copper iodide and methyllithium (molar ratio 1:2) dissolved in diethyl ether at –78 °C resulted in a dark-red solution from which **1** was obtained as a crystalline brown solid after workup. Its electrospray mass spectrum (ESI-MS) performed in $CHCl_3/CH_3OH$ reveals one major peak at *m*/*z* 2123 corresponding to the composition $[\{(tbbpy)_2Ru(tmbi)\}_2Cu_2(PF_6)]^+$, which suggests a structure of the dication according to Figure 1. The calculated isotopic pattern for this tetranuclear species agrees well with the experimentally found one.

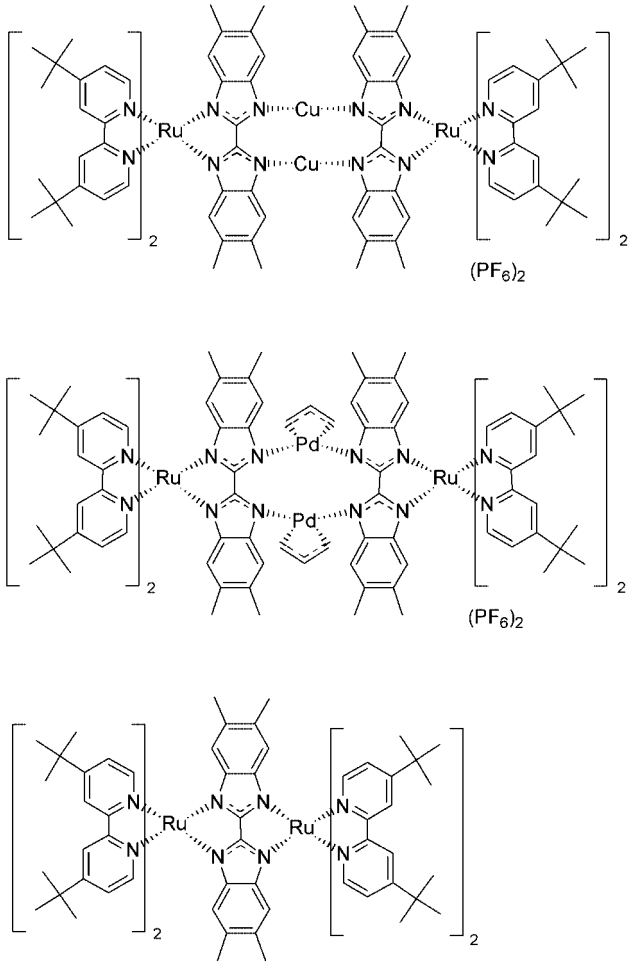

Figure 1. The cations of complexes **1**, **2** and **3**.

The $^1H$ NMR spectrum of **1** in $CDCl_3$ shows the typical resonances for the $[Ru(tbbpy)_2(tmbi)]$ moiety[5,6] although it gives little additional structural information about **1**. It displays two singlets for the methyl protons of the *tert*-butyl groups at $\delta$ = 1.34 and 1.47 ppm, and two singlets for the methyl protons of the bridging ligand at $\delta$ = 2.01, and 2.30 ppm in the expected intensity ratio of 3:3:1:1. The protons for the 2,2′-bipyridine system show the expected set of six signals for H3, H3′, H5, H5′, H6, H6′, respectively. Furthermore, two resonances are observed for the aromatic protons of the bridging tmbi at $\delta$ = 5.36 and 7.66 ppm. In comparison with the mononuclear complex $[(tbbpy)_2Ru(tmbiH_2)](PF_6)_2$, the corresponding signals in **1** are only slightly low-field shifted.

We succeeded in growing single crystals of the complex **1**, which crystallizes with the anions $PF_6^-$ and $Cl^-$ and with some solvent molecules. Figure 2 shows the solid-state structure of the dication of **1** determined by a low-temperature X-ray analysis and contains relevant bond lengths and angles in the caption.

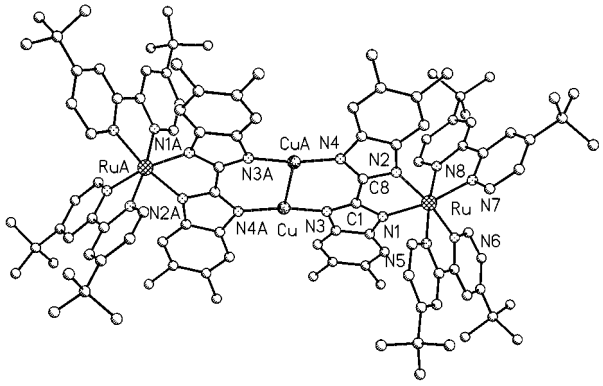

Figure 2. Molecular structure of the dication of complex **1** (the H atoms have been omitted for clarity). Selected bond lengths [Å]: Cu–CuA 2.720(1), Cu–N3 1.852(5), Cu–N4A 1.850(5), Ru–N1 2.087(5), Ru–N2 2.076(5), Ru–N5 2.036(5), Ru–N6 2.041(5), Ru–N7 2.054(6), Ru–N8 2.046(5), C1–C8 1.436(8). Symmetry transformations used to generate equivalent atoms: A $-x+1$, $-y+1$, $-z+1$.

The most remarkable feature is that the two metalloligands do not act as chelating ligands for $Cu^I$ but bind the two Cu atoms in a monodentate manner resulting in an N–Cu–N coordination for each copper(I) centre. There is no additional interaction with the anions. The considerable deviation of the N–Cu–N angles (167.3°) from linearity may be explained by the influence of the other $Cu^I$ centre, which is in close proximity. The Cu···Cu separation is 2.72 Å, which suggests intramolecular contacts (van der Waals radii: 2.8 Å[16]). The Ru···Ru separation is 11.36 Å. Furthermore, the bridging imidazolato rings are essentially planar, and their C–N bond lengths are equal within the experimental error. Since the benzene rings do not lie in this plane, the two tetramethyldibenzimidazolate systems have a boat form with an angle of 163.9° for the centroids of C1–C8, C4–C5 and C11–C12, and C1A–C8A, C4A–C5A and C11A–C12A, respectively.

In addition, the atoms N3–Cu–N4A–N3A–CuA–N4 lie in a plane with extremely small deviations of the Cu atoms from this plane (0.012 Å). The nitrogen atoms N1 and N2, which are coordinated to the $[(tbbpy)_2Ru]$ fragment, lie above this plane (Cu–N3–N1 = 166.6°); the other pair of nitrogen atoms N1A and N2A, which are coordinated to the $[(tbbpy)_2Ru(A)]$ moiety, lies below this plane resulting in a chair arrangement of the eight nitrogen atoms of the two bridging ligands. The unidentate coordination of bridging imidazolates has already been described for a number

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of complexes with other metals, although not with $Cu^{I}$.[1,7] For example, a similar coordination mode for a disilver complex containing π-acidic [2-(phenylazo)pyridine]$_2$Ru fragments at the periphery and the unsubstituted diimidazolate as bridging ligand was recently described by Goswami et al.[7] Furthermore, in a hexametallic $Cu^{II}$ complex containing two $Cu^{II}$ centres and four (bipy)$_2$Ru(bimidazolate) units the diimidazolates also act as monodentate ligands.[8]

Although **1** is coordinatively unsaturated, it does not react with triphenylphosphane. Furthermore, in the solid state no reaction with air was observed.

Treatment of [Ru(tbbpy)$_2$(tmbiH$_2$)](PF$_6$)$_2$ in THF with two equivalents of methyllithium at –78 °C and subsequent treatment with a slight excess of dimeric (allyl)palladium(II) chloride resulted in a dark-red/violet solution from which reddish-brown crystals of **2** were obtained. The ESI mass spectrum performed in $CHCl_3$/$CH_3OH$ showed an envelope of peaks at *m*/*z* 2292 that match well with the isotopic distribution calculated for the fragment ion [{(tbbpy)$_2$-Ru(tmbi-H)}$_2${Pd(allyl)$_2$}(PF$_6$)]$^+$. This indicates that a tetranuclear complex similar to **1** is present in solution as well. The $^1$H NMR spectrum of **2** in $CD_2Cl_2$ shows the typical pattern for the [Ru(tbbpy)$_2$(tmbi)] fragments, with the methyl proton signals at $\delta$ = 1.37 and 1.53 ppm and the methyl protons of the dibenzimidazolate at $\delta$ = 2.03 and 2.33 ppm. In comparison with **1**, these signals and the resonances for the bipy protons and for the aryl signal H7 are shifted slightly downfield.

Single crystals of **2** suitable for an X-ray determination were grown from a mixture of dichloromethane and methanol in the presence of a small amount of water by slow diffusion of dichloroethane into this mixture. Under these conditions, the tetranuclear diaction [{(tbbpy)$_2$Ru-(tmbi-H)}$_2${Pd(allyl)$_2$}]$^{2+}$ crystallizes with both the PF$_6^-$ and the Cl$^-$ anions and with different solvent molecules. Figure 3 shows the molecular structure of the dication and contains relevant bond lengths and angles in the caption.

The two halves of the molecule form an extremely unsymmetrical structure. Similar to complex **1**, the (tbpby)$_2$-Ru(tmbi) metalloligand coordinates in a twofold monodentate manner to the two $Pd^{II}$ centres. Each $Pd^{II}$ is in a distorted planar coordination environment formed by two nitrogen atoms of two different dibenzimidazolates in *cis* positions while the $\eta^3$-bonded allyl group occupies the two remaining positions. The two $C_2PdN_2$ planes are not parallel to each other but are strongly twisted, with a torsion angle of 46.9°. The Pd···Pd separation of 3.06 Å is rather short, suggesting a weak interaction between these metals. The intramolecular Ru···Ru separation is 8.308 Å. In contrast to complex **1**, where the Ru–Cu–Cu–Ru atoms form a planar structure, in compound **2** a strongly bent structure is found. The centroids of the two Pd atoms and the two Ru centres form an angle of 90.7°.

Other bond lengths and angles are in good agreement with typical values found for similar complexes (Figure 3). It is interesting to note that a long-known tetranuclear Pd complex in which four (allyl)$Pd^{II}$ moieties are connected via two dibenzimidazolate bridges has a related structure.[17] In this compound, each of the two imidazolates coordinates an (allyl)$Pd^{II}$ unit to form a chelate ring whereas the other two Pd centres are monodentately coordinated. Although no X-ray studies have been carried out, other mixed complexes containing Pd and Rh may have a similar tetranuclear arrangement.[17] Additionally, related structures have been found in a tetranuclear rhodium carbonyl complex with diimidazolate bridges[18] and in the complex [($\eta^6$-*p*-cumene)ClRu(μ-bbzim)Rh(norbornadiene)$_2$].[1]

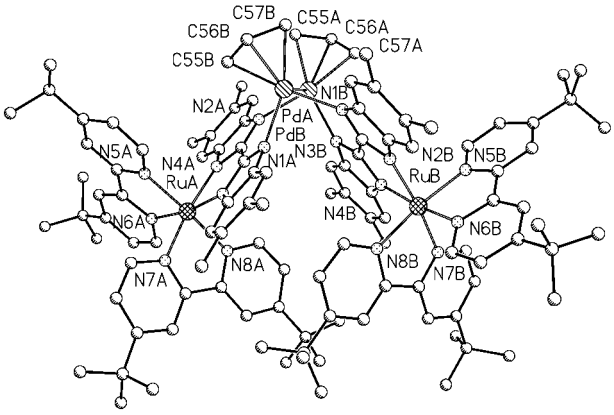

Figure 3. Molecular structure of the dication of complex **2** (the H atoms, the anions PF$_6^-$ and Cl$^-$, and some atom labels have been omitted for clarity). Selected bond lengths [Å]: PdA–N2A 2.092(6), PdA–N3B 2.085(6), PdB–N1A 2.091(5), PdB–N1B 2.111(5), PdA–C55A 2.128(9), PdA–C56A 2.089(9), PdA–C57A 2.096(10), RuA–N4A 2.082(6), RuA–N5A 2.047(6), RuA–N6A 2.049(6), RuA–N7A 2.048(5), RuA–N8A 2.049(6), C1A–C8A 1.450(9), PdB–C55B 2.124(8), PdB–C56B 2.113(12), PdB–C57B 2.153(8), RuB–N4B 2.086(5), RuB–N5B 2.052(5), RuB–N6B 2.045(5), RuB–N7B 2.036(5), RuB–N8B 2.040(5), C1B–C8B 1.460(10).

In contrast to the observed ligand behaviour in these complexes, the structurally similar oxalamidinate ligands act as normal twofold didentate bridging ligands towards $Pd^{II}$ and Cu, forming five-membered chelate rings.[19–22]

The homodinuclear ruthenium tetramethyldibenzimidazolate complex **3** has been prepared using standard procedures.[9] The fully characterised compound was isolated as a mixture of the *rac* and *meso* diastereomers, which exhibit slightly different $^1$H NMR signals. In contrast to both **1** and **2**, the dibenzimidazolato ligand in **3** acts as a twofold chelating ligand. The X-ray crystal structure of its *meso* form (not depicted; see Experimental Section) shows the two Ru centres on the opposite side of the diimidazolate bridging ligand with bond lengths and angles that are typical for such chelate complexes, althoughr with one exception: the bridging tetramethyldibenzimidazolate ligand is kinked within the central C–C bond.[9]

### Electronic Spectra and Catalytic Behaviour of 1–3

The electronic spectra of **1** in THF show an absorption band in the visible region at $\lambda$ = 519 nm which can be attributed to a $^3$MLCT transition from $Ru^{II}$ to the bipy ligand. While the starting compound − the deprotonated

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metalloligand $[(tbbpy)_2Ru(tmbi)]^-$ is not luminescent, coordination of $Cu^I$ switches on emission resulting in an emission band at $\lambda$ = 705 nm. The lifetime of the excited state in THF at room temperature (93 ns) (Table 1) is significantly shorter than that in the protonated compound $[(tbbpy)_2Ru(tmbiH_2)]^{2+}$ (lifetime in THF of 363 ns). We have recently observed a similar behaviour with the unsubstituted dibenzimidazolate complex $[(tbbpy)_2Ru(bbim)]$, which acts as a cation-driven molecular switch due to the formation of emitting systems by reacting with metal ions in solution.[6]

Table 1. Optical and electrochemical data of the complexes **1**–**3** at room temperature.

| | Complex **1** | Complex **2** | Complex **3** |
|---|---|---|---|
| Absorption $\lambda_{max}$ [nm][a] | 519 | 524 | 515 |
| Emission $\lambda_{max}$ [nm][b] | 705 | 653 | 707 |
| Lifetime [ns][c] | 93[d] | 244[d] | 60[e] |
| $E^{[f]}_{1/2}$ (ox) [V] | dec. | +0.146, +0.235 | +0.215, +0.51 |
| $E^{[f]}_{1/2}$ (red) [V] | dec. | –1.989, –2.036 | –1.963, –2.027 |
| | | –2.313, –2.385 | –2.260, –2.338 |

[a] ±2 nm in THF. [b] ±4 nm in THF. [c] ±10%. [d] In THF. [e] In acetonitrile. [f] ±0.004 V in acetonitrile.

In the electronic spectrum of **2** in THF (Table 1) the lowest absorption maximum appears at $\lambda$ = 524 nm which is only slightly shifted compared with **1**. In contrast, a larger difference was observed in the emission spectra in THF, where the emission maximum was found at $\lambda_{em}$ = 653 nm, which represents a hypsochromic shift of 52 nm. In addition, the lifetime of the excited state of 244 ns is significantly longer than that for **1**. A more detailed study of the interesting photophysical behaviour of complex **2** will be described in detail in a separate publication.[23]

The homodinuclear complex **3** has the lowest absorption maximum in THF at $\lambda$ = 515 nm and emits at 707 nm, which compares well with the unsubstituted derivatives.[9]

Preliminary investigations of the catalytic behaviour of **1** and **2** show only low activity of **1** in the catalytic oxidation of 3,5-di-*tert*-butylcatechol to form the *o*-quinone. Complex **2** catalyses the Heck reaction of aryl bromides with substituted aryl olefins. An investigation of the reaction between 4-bromoacetophenone and *n*-butyl acrylate, which is usually chosen as a standard reaction to evaluate the catalyst productivity, at 120 °C in (*N*,*N*-dimethylacetamide) with sodium acetate as the base resulted in 86% conversion after two hours (turnover number: 4300 mol conversion per mol catalyst). At 80 °C the catalysis proceeded slowly, with 37% conversion after 11 h (TON = 1850). In the microwave-assisted Heck coupling 83% conversion was observed after 1 h (TON = 4150; programme 10 s at 175 W, then 1 h at 65 W).

### Electrochemistry of Complexes 2 and 3

Due to the decomposition of **1** during the electrochemical measurements the electrochemistry of this complex could not be studied. In contrast, the palladium complex **2** is stable under these conditions and could be investigated electrochemically (Table 1). For comparison, the dimeric ruthenium complex $[(tbbpy)_2Ru(\mu\text{-}tmbi)Ru(tbbpy)_2]$ (**3**) was also investigated. Complex **3** exhibits two chemically reversible one-electron oxidation steps. The half-wave potentials were found to be at +0.215 and +0.51 V with respect to the ferrocene/ferrocenium couple and the diffusion coefficient of the complex, $D_{LRu–RuL}$, amounts to about $5 \times 10^{-6}$ cm$^2$ s$^{-1}$. Formally the two one-electron steps may be attributed to the oxidation of both the ruthenium(II) centres in the complex. The relatively large difference of these potentials ($\Delta E$ = 295 mV) shows that there is a remarkable electronic communication between the Ru centres.

At first glance the reduction of complex **3** ("LRu–RuL") shown in Figure 4 seems also to proceed in two separate reduction steps at about –2 and –2.3 V, respectively. However, a more detailed analysis of the frequency dependence of the peak heights and peak shapes (using the diffusion coefficient estimated from the oxidation process) revealed that each peak is actually formed by two overlapping one-electron steps. A comparison of experimental square-wave voltammograms (solid line) and those simulated on the basis of the mechanism (M1; open circles) is shown in Figure 4.

$$\begin{aligned}
&LRu-RuL + e^- \rightleftharpoons LRu-RuL^- \quad (E_1^0 = -1.963\ V)\\
&LRu-RuL^- + e^- \rightleftharpoons L^-Ru-RuL^- \quad (E_2^0 = -2.027\ V)\\
&L^-Ru-RuL^- + e^- \rightleftharpoons L^-Ru-RuL^{2-} \quad (E_3^0 = -2.260\ V)\\
&L^-Ru-RuL^{2-} + e^- \rightleftharpoons L^{2-}Ru-RuL^{2-} \quad (E_4^0 = -2.338\ V)
\end{aligned} \tag{M1}$$

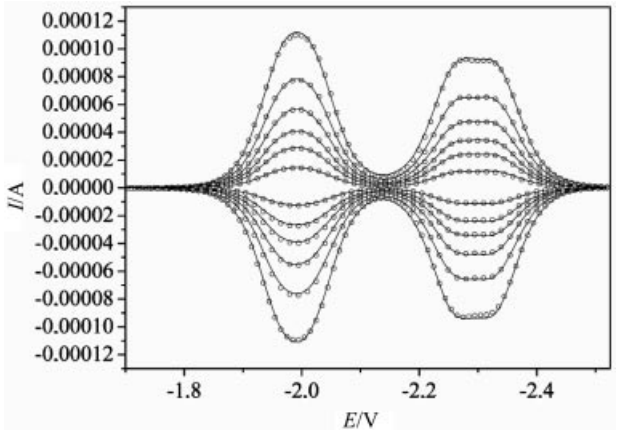

Figure 4. Comparison of experimental (solid line) and simulated (open circles) cyclic square-wave voltammograms for the reduction of a 1.1 mM solution of complex **3** at a mercury drop electrode in acetonitrile. The voltammograms refer to square-wave frequencies of 50, 200, 400, 800, 1500 and 3000 Hz (with increasing peak height) and the potential scale is referenced to the ferrocene/ferrocenium couple. The simulations were executed on the basis of the mechanism M1 with LRu–RuL = complex **3**.

The one-electron steps can be attributed here to the stepwise reduction of the two $(tbbpy)_2Ru$ units involved in the complex assuming fully reversible charge-transfer reactions and identical diffusion coefficients for all species. The dif-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ference $|E_2^0–E_1^0|$ = 64 mV and $|E_4^0–E_3^0|$ = 78 mV is distinctly greater than the limiting value of 35.6 mV resulting from a pure entropic effect. A communication of the complex centres through the bridging ligand is therefore clearly visible in the cathodic charge-transfer processes. Of course, the electronic coupling is even larger if both reduction steps refer to the same $(tbbpy)_2Ru$ moiety ($|E_3^0–E_1^0|$ = 297 mV and $|E_4^0–E_2^0|$ = 311 mV, respectively).

The oxidation of complex **2** by cyclic square-wave voltammetry is shown in Figure 5. This figure reveals that the oxidation of the complex is similar to that reported above for **3**, but in contrast to the latter compound both one-electron steps are no longer well separated. For this reason, reliable results can be evaluated only by subjecting the experimental data to a fitting procedure. The values of the half-wave potentials retrieved for the best fit are +0.146 and +0.235 V, respectively, which is a difference of 89 mV. This value is smaller than that reported above for complex **3** but still distinctly larger than that expected for a pure entropic effect.

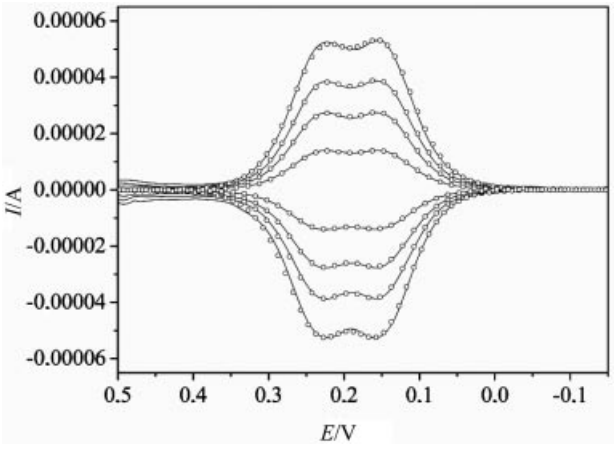

Figure 5. Comparison of experimental (solid line) and simulated (open circles) cyclic square-wave voltammograms for the oxidation of a 1.9 mM solution of complex **2** at a platinum disc electrode in acetonitrile. The voltammograms refer to square-wave frequencies of 50, 200, 400 and 800 Hz (with increasing peak height) and the potential scale is referenced to the ferrocene/ferrocenium couple. The simulations were executed for a reversible E–E mechanism using the standard potentials reported in the text.

The close relationship to the electrochemistry of the LRu–RuL complex **3** also becomes visible when looking at the reduction of **2** using the cyclic square-wave voltammograms (depicted in Figure 6) or at the experiment referring to the highest square-wave frequency ($f_{sw} \geq 200$ Hz) in Figure 7. Figure 6 reveals that the first two one-electron steps proceed in a fully reversible way analogously to that indicated by the first two reactions in (M1) when replacing LRu–RuL by LRu-$^{Pd}$-RuL as a symbol for complex **2**. The half-wave potentials of these processes (evaluated from the data fitting shown in Figure 6) were estimated to be at $E_1°$ = –1.989 and $E_2°$ = –2.036 V, respectively, which means that $|E_2^0–E_1^0|$ is 47 mV. That means that the deviation from the ideal peak shape of an uncoupled system is hardly visible and is only detectable by fitting current curves referring to different time windows.

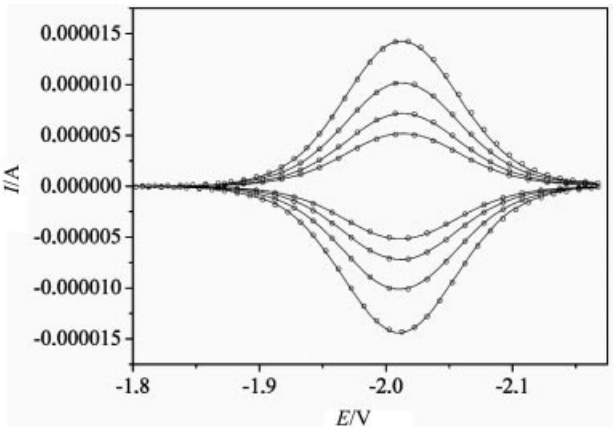

Figure 6. Comparison of experimental (solid line) and simulated (open circles) cyclic square-wave voltammograms for the reduction of a 0.6 mM solution of complex **2** at a mercury-drop electrode in acetonitrile. The voltammograms refer to square wave frequencies of 25, 50, 100 and 200 Hz (with increasing peak height) and the potential scale is referenced with respect to the ferrocene/ferrocenium couple. The simulations were executed taking the first two reactions of the mechanism shown in M2 into consideration.

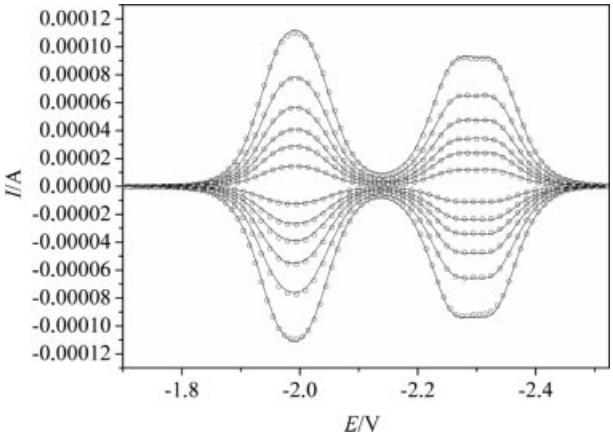

Figure 7. Comparison of experimental (solid line) and simulated (open circles) cyclic square-wave voltammograms for the reduction of a 0.6 mM solution of **2** at a mercury drop electrode in acetonitrile. The voltammograms refer to square wave frequencies of 25, 50, 100 and 200 Hz (with increasing peak height) and the potential scale is referenced with respect to the ferrocene/ferrocenium couple. The simulations were executed taking the reactions M2, M3 and M4 into consideration.

The most striking difference in the electrochemistry of the LRu-$^{Pd}$-RuL complex **2** compared to that of the LRu–RuL complex **3** becomes visible when looking at the low-frequency experiments shown in Figure 7. While the current response of the high-frequency experiment ($f_{sw}$ = 200 Hz) is, at least qualitatively, very similar to the voltammograms of the LRu–RuL complex depicted in Figure 4, an additional shoulder is more and more noticeable at around –2.05 V upon decreasing the square-wave frequency (i.e. more time is needed before the re-oxidation process to the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

starting product takes place). Integrating the cathodic and anodic current in these curves reveals that virtually no charge is lost in the course of the re-oxidation processes. Combining this result with the fact that the first two one-electron steps appear (chemically and electrochemically) fully reversible in Figure 6 gives rise to the conclusion that (after receiving three or four electrons) complex **2** slowly decomposes to another product which is reoxidized and gives the additional shoulder at about –2.05 V. Interestingly, the latter value is very close to one of the reversible half-wave potentials of the deprotonated complex [(tbbpy)$_2$-Ru(tmbi)].[9] This complex exhibits two chemically reversible one-electron reduction steps at –2.07 and –2.364 V, respectively. It therefore appears reasonable to assume that the additional shoulder results from the re-oxidation of reduced [(tbbpy)$_2$Ru(tmbi)] species formed by decomposition of the three- or fourfold reduced complex **3**. Indeed, the experimental square-wave voltammograms shown in Figure 7 (solid lines) are in very good agreement with the simulated ones (open circles) obtained on the basis of a reaction scheme similar to M1

$$\begin{aligned}
&LRu-\overset{Pd}{\underset{Pd}{}}-RuL+e^- \rightleftharpoons LRu-\overset{Pd}{\underset{Pd}{}}-RuL^- \quad (E_1^0 = -1.989\ V)\\
&LRu-\overset{Pd}{\underset{Pd}{}}-RuL^- + e^- \rightleftharpoons L^-Ru-\overset{Pd}{\underset{Pd}{}}-RuL^- \quad (E_2^0 = -2.036\ V)\\
&L^-Ru-\overset{Pd}{\underset{Pd}{}}-RuL^- + e^- \rightleftharpoons L^-Ru-\overset{Pd}{\underset{Pd}{}}-RuL^{2-} \quad (E_3^0 = -2.313\ V)\\
&L^-Ru-\overset{Pd}{\underset{Pd}{}}-RuL^{2-} + e^- \rightleftharpoons L^{2-}Ru-\overset{Pd}{\underset{Pd}{}}-RuL^{2-} \quad (E_4^0 = -2.385\ V)
\end{aligned} \qquad (M2)$$

but includes the decomposition reaction. (Actually, it cannot really be distinguished from the experimental data whether the decomposition reaction starts with the third or only after the fourth reduction step. For convenience, only one follow-up reaction has been taken into consideration.)

$$L^{2-}Ru-\overset{Pd}{\underset{Pd}{}}-RuL^{2-} \rightarrow RuL^{2-} + RuL^{2-} \qquad (M3)$$
$$(k \approx 1\ s^{-1})$$

In the backward scan the re-oxidation proceeds simultaneously by two pathways: firstly, as indicated in M2, and secondly, as re-oxidation of the decomposition products.

$$\begin{aligned}
&RuL^- + e^- \rightleftharpoons RuL^{2-} \quad (E_{2'}^0 = -2.358\ V)\\
&RuL + e^- \rightleftharpoons RuL^- \quad (E_{1'}^0 = -2.075\ V)
\end{aligned} \qquad (M4)$$

The fact that the half-wave potentials $E_{1'}^0$ and $E_{2'}^0$ retrieved by the fitting routine are, within the experimental error, in agreement with those reported above for the deprotonated complex [(tbbpy)$_2$Ru(tmbi)] is a strong indication that the latter species is really formed by the follow-up reaction (M3).

## Conclusions

The tetranuclear complexes **1** and **2** are built up by connecting two (tbbpy)$_2$Ru$^{II}$(tetramethyldiimidazolate) fragments by either Cu$^{I}$ centres or two (allyl)Pd$^{II}$ fragments. In these complexes the dibenzimidazolates act as twofold monodentate ligands resulting in 10-membered metallamacrocycles, which are luminescent at room temperature. Electrochemical measurements show that there is an electronic communication between the Ru centres in **2**. Complex **2** is a good catalyst for the Heck reaction in the dark.

## Experimental Section

**General Procedures:** Infrared spectra were recorded with a Perkin–Elmer 2000 FT-IR, $^1$H NMR spectra were recorded with a Bruker 400 MHz/200 MHz spectrophotometer and UV/Vis spectra were obtained with a Varian Cary 1 UV/Vis or Shimadzu UV 3100 UV/Vis-NIR. The mass spectra were recorded with a SSQ 170, Finnigan Mat spectrometer. Electrospray mass spectra were recorded with a Finnnigan MAT, MAT 95 XL. Values quoted for *m*/*z* are for the most intense peak of the isotope envelope. The measured isotopic pattern for complexes **1** and **2** are in good agreement with the isotopic pattern calculated using the program ICIS (version 8.2.1, Finnigan). Emission spectra were recorded with a Perkin–Elmer LS50B spectrometer equipped with a Hamamatsu R928 red-sensitive detector.

All manipulations were carried out by using modified Schlenk techniques under an atmosphere of argon. Prior to use, THF, diethyl ether and *n*-pentane were dried with potassium hydroxide and distilled from over sodium/benzophenone. Methyllithium (1.6 M solution in diethyl ether, Fluka), 4-bromoacetophenone (Fluka) and sodium acetate (Aldrich) were used as received; [(tbbpy)$_2$Ru-(tbbpy)$_2$Cl$_2$] and [(tbbpy)$_2$Ru(tmbiH$_2$)](PF$_6$)$_2$ was prepared according to a literature procedure.[5]

**Complex 1:** A stirred suspension of bis(4,4′-di-*tert*-butyl-2,2′-bipyridine)-5,6,5′,6′-tetramethyl-2,2′-dibenzimidazolatoruthenium(II) hexafluorophosphate (298 mg, 0.24 mmol) in 30 mL of THF at –78 °C was treated dropwise with a an equimolar amount of lithium dimethylcuprate, prepared by reaction of CuI with MeLi in diethyl ether. The reaction mixture was than stirred for 36 h at room temperature. After filtration the solvent was evaporated and the remaining substance was dried in vacuo. Yield: 266 mg (96%). $^1$H NMR (CDCl$_3$, 200 MHz): $\delta$ = 1.34, 1.47 (s, each 36 H, *tert*-butyl), 2.01, 2.30 (s, each 12 H, CH$_3$ of benzimidazolate), 5.36 (s, 4 H, Ar-H4), 7.15 (dd, $^3J$ = 6.2, $^4J$ = 1.8 Hz, 4 H, bipy-H5′), 7.40 (dd, $^3J$ = 6.2, $^4J$ = 2.0 Hz, 4 H, bipy-H5), 7.66 (s, 4 H, aryl-H7), 7.75 (d, $^3J$ = 6.0 Hz, 4 H, bipy-H6′), 7.91 (d, $^3J$ = 6.2 Hz, 4 H, bipy-H6), 8.13 (d, $^4J$ = 1.4 Hz, 4 H, bipy-H3′), 8.20 (d, $^4J$ = 1.8 Hz, 4 H, bipy-H3) ppm. MS (Micro-ESI in CH$_2$Cl$_2$/methanol): *m*/*z* 2123 [M – PF$_6$]$^+$, 990 [M/2 + H – 2PF$_6$]$^+$. Absorption (THF): $\lambda_{max}$ = 519 nm (intensity = 19526 L mol$^{-1}$ cm$^{-1}$). Emission (THF): $\lambda_{em}$ = 705 nm ($\lambda_{ex}$ = 520 nm); lifetime of the first excited state: 93 ns in THF at room temperature.

Recrystallization from THF/CH$_2$Cl$_2$ resulted in a complex of the composition **1**·2THF·CH$_2$Cl$_2$. C$_{117}$H$_{146}$Cl$_2$CuF$_{12}$N$_{16}$O$_2$Pd$_2$P$_2$Ru$_2$ (2498.4): calcd. C 56.24, H 5.89, N 8.97; found C 55.91, H 5.98, N 8.64. Single crystals of the composition [{(tbbpy)$_2$Ru(tmbi)}$_2$-Cu$_2$](PF$_6$)$_{1.5}$Cl$_{0.5}$·CH$_2$Cl$_2$·2 CH$_3$OH·H$_2$O, were grown from a solution in dichloromethane and methanol in the presence of a small amount of water.

**Complex 2:** A stirred suspension of bis(4,4′-di-*tert*-butyl-2,2′-bipyridine)-5,6,5′,6′-tetramethyl-2,2′-dibenzimidazolatoruthenium(II) hexafluorophosphate (500 mg, 0.41 mmol) in about 20 mL of THF

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was treated dropwise with 0.4 mL of a solution of methyllithium in diethyl ether (1.6 M). Then, (allyl)palladium(II) chloride dimer (100 mg, 0.27 mmol) dissolved in 10 mL of THF was added dropwise at –78 °C. Stirring for about 20 h and evaporation of most the solvent at 0 °C in vacuo gave a dark red precipitate which was dissolved in dichloromethane. After subsequent filtration to remove the lithium salt and evaporation of most of the solvent, complex **2** crystallized as a red, microcrystalline compound. Yield: 432 mg (70%). MS (Micro-ESI in $CHCl_3$/methanol): *m/z* 2292 $[M + H - PF6]^+$, 1073 $[M/2 - 2PF_6]^+$. Absorption (THF): $\lambda_{max}$ = 524 nm (intensity = 13431 $L\,mol^{-1}\,cm^{-1}$). Emission (THF): $\lambda_{em}$ = 653 nm ($\lambda_{ex}$ = 524 nm); lifetime of the first excited state: 244 ns in THF at room temperature. $^1H$ NMR ($CD_2Cl_2$, 200 MHz): $\delta$ = 1.37, 1,53 (each s, *tert*-butyl), 2.03, 2.33 (each s, $CH_3$ of benzimidazolate), 3.10, 3.70, 4.20 (broad, m, allyl), 5.41 (s, aryl-H4), 7.40 (m, Ar-H), 7.5–7.6 (m, bipy-5 + aryl-H7), 7.84, 7.87 (each s, bipy-H6, bipy-H6′), 8.22, 8.29 (each d, bipy-H3 and bipy-H3′) ppm. Recrystallization from $CH_2Cl_2$ resulted in a complex with the composition **2**·4$CH_2Cl_2$. $C_{118}H_{146}Cl_8F_{12}N_{16}P_2Pd_2Ru_2$ (2776.4): calcd. C 51.03, H 5,30, N 8.07; found C 51.29, H 5.59, N 7.75. Single crystals were grown from a mixture of dichloromethane and methanol in the presence of a small amount of water by slow diffusion of dichloroethane into this mixture.

**Complex 3:** Complex 3 was obtained by employing the method described for homologous dinuclear dibenzimidazole complexes[9] using $[Ru(tbbpy)_2Cl_2]$ (233 mg, 0.33 mmol) and $tmbiH_2$ (50 mg, 0.165 mmol). After obtaining the pure fractions recrystallization from acetone/water (50:50) yielded the pure complex. Crystals suitable for X-ray diffraction were grown from acetone/water at –20 °C. Under these conditions the *meso* isomer crystallized. Absorption maximum ($CH_3CN$) at $\lambda_{max}$ = 512 nm, emission maximum ($CH_3CN$) at $\lambda_{em}$ = 709 nm. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 8.23 (d, *J* = 4.9 Hz, 6 H), 8.16 (m, 8 H), 7.84–7.80 (m, 4 H), 7.72 (d, *J* = 6.8 Hz, 2 H), 7.44–7.37 (m, 6 H), 7.10 (s, 2 H), 2.15 (s, 12 H), 1.45 (s, 36 H), 1.31 (s, 36 H) ppm. MS (ESI in MeOH) *m/z* 781 [M/2 – $2PF_6$] 1562 $[M - 2PF_6]^+$; 1707 $[M - PF_6)]^+$ with the expected isotopic pattern. [**3**(acetone)$_4$($H_2O$)$_2$]. $C_{102}H_{140}F_{12}N_{12}O_6P_2Ru_2$ (2122.2): calcd. C 57.77, H 6.65, N 7.92; found C 57.85, H 6.42, N 7.74. Single crystals of the composition [{$(tbbpy)_2Ru(tmbi)_2$}-$(PF_6)_2$] were grown from acetonitrile at –20 °C.

**Crystal Structure Determination:** The intensity data for the compounds were collected on a Nonius KappaCCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz-polarization effects and for absorption effects.[24–26] The structures were solved by direct methods (SHELXS[27]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELXL-97[28]). The hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[28] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

**Crystal Data for 1:**[29] $C_{108}H_{128}N_{16}Cu_2Ru_2{\cdot}1.5PF_6{\cdot}0.5Cl{\cdot}4CH_2Cl_2{\cdot}2CH_3OH{\cdot}H_2O$, $M_r$ = 2635.46 $g\,mol^{-1}$, red-brown prism, size 0.04 × 0.04 × 0.04 $mm^3$, triclinic, space group $P\bar{1}$, *a* = 12.5919(3), *b* = 13.9697(4), *c* = 19.6388(5) Å, *α* = 100.022(2)°, *β* = 93.575(1)°, *γ* = 94.941(1)°, *V* = 3378.7(2) $Å^3$, *T* = –90 °C, *Z* = 1, $\rho_{calcd.}$ = 1.295 $g\,cm^{-3}$, $\mu$(Mo-$K_\alpha$) = 7.78 $cm^{-1}$, multi-scan, $transm._{min.}$ = 0.7326, $transm._{max.}$ = 0.8678, *F*(000) = 1359, 21202 reflections in *h*(–16/16), *k*(–18/17), *l*(–25/24), measured in the range 7.13° ≤ *Θ* ≤ 27.46°, completeness $\Theta_{max}$ = 91.9%, 14231 independent reflections, $R_{int}$ = 0.040, 10166 reflections with $F_o > 4\sigma(F_o)$, 734 parameters, 0 restraints, $R_{1obs}$ = 0.089, $wR_{2obs}$ = 0.218, $R_{1all}$ = 0.130, $wR_{2all}$ = 0.256, GOOF = 1.027, largest difference peak and hole: 3.510/–1.553 e $Å^{-3}$.

**Crystal Data for 3:**[29] $C_{90}H_{112}F_{12}N_{12}P_2Ru_2{\cdot}3C_2H_3N$, $M_r$ = 1977.16 $g\,mol^{-1}$, red-brown prism, size 0.04 × 0.04 × 0.03 $mm^3$, triclinic, space group $P\bar{1}$, *a* = 15.6447(5), *b* = 17.4399(4), *c* = 19.9816(5) Å, *α* = 74.301(2)°, *β* = 80.793(2)°, *γ* = 67.123(2)°, *V* = 4826.4(2) $Å^3$, *T* = –90°C, *Z* = 2, $\rho_{calcd.}$ = 1.361 $g\,cm^{-3}$, $\mu$ (Mo-$K_\alpha$) = 4.22 $cm^{-1}$, *F*(000) = 2056, 33338 reflections in *h*(–20/19), *k*(–22/21), *l*(–25/24), measured in the range 2.48° ≤ *Θ* ≤ 27.51°, completeness $\Theta_{max}$ = 98.6%, 21886 independent reflections, $R_{int}$ = 0.042, 14398 reflections with $F_o > 4\sigma(F_o)$, 1150 parameters, 0 restraints, $R_{1obs}$ = 0.060, $wR_{2obs}$ = 0.128, $R_{1all}$ = 0.109, $wR_{2all}$ = 0.153, GOOF = 1.027, largest difference peak and hole: 0.811/–0.620 e $Å^{-3}$.

**Heck Reactions:** In a typical experiment, 6.25 mmol of 4-bromoacetophenone and 7 mmol of anhydrous sodium acetate as base were placed in a 25-mL two-necked flask equipped with a stirring bar, reflux condenser and septum. The flask was degassed under vacuum and purged with argon to ensure an inert reaction atmosphere. Then, 10 mL of *N*,*N*-dimethylacetamide as solvent, 0.5 g of diethylene glycol/dibutyl ether as GC standard and 6.75 mmol of *n*-butyl acrylate were added through the septum. The reaction mixture was thoroughly stirred and heated to the appropriate reaction temperature at which it was held for 5 min followed by treatment with the catalyst solution containing complex **2** (1.25 μmol in 0.5 mL of THF). After the appropriate time interval the reaction mixture was hydrolyzed with 2 mL of distilled water and extracted with 2 mL of $CH_2Cl_2$. The organic phase was dried with $K_2CO_3$ and stored at –25 °C until GC analysis for determination of the yield. The microwave-assisted Heck coupling was carried out using a Microwave Laboratory Systems MLS EM-2 microwave system (microwave set-up: 10 s at 175 W then 1 h at 65 W).

**Electrochemical Measurements:** Square-wave voltammetric measurements were conducted using a three-electrode technique with a home-built computer-controlled instrument based on the PCI-6110E data acquisition board (National Instruments). The experiments were performed in acetonitrile containing 0.25 M tetrabutylammonium perchlorate under a blanket of solvent-saturated argon. The ohmic resistance, which had to be compensated for, was determined by measuring the impedance of the system at potentials where the faradaic current was negligibly small. The internal reference electrode was an Ag/AgCl electrode in acetonitrile containing 0.25 M tetrabutylammonium chloride. However, for convenience all potentials are reported with respect to the ferrocene/ferrocenium couple. The working electrode was either a hanging mercury drop ($m_{Hg-drop}$ = 3.8–4.4 mg) produced by the CGME instrument or a 1.5 mm platinum disk electrode (both from Bioanalytical Systems, Inc.,West Lafayette, USA; experimental errors for *E* = ±0.004 V; and for $\Delta E_{1/2}$ = ±0.001 V). The electrochemical experiments were

evaluated by fitting theoretical current curves to experimental ones using the freely available DigiElch software (DigiElch can be freely downloaded from www.DigiElch.de). The theoretical background of the simulation method used in this program has been given in a series of accompanying papers.[30] We assumed in all simulations that the diffusion coefficients of the complexes do not depend on the charge of the complex.

# Hypersilylphosphanylidene: A Facile Low-Temperature Generation and Formation of Bis(hypersilyl)diphosphene and the Bis(hypersilyl)triphosphaallyl Anion

**Vittorio Cappello,[a] Judith Baumgartner,[a][‡] Alk Dransfeld,[a][‡‡] Michaela Flock,*[a][‡‡] and Karl Hassler*[a]**

*Dedicated to Prof. Dr. Reint Eujen on the occasion of his 60th birthday*

**Keywords:** Ab initio calculations / Carbene homologues / Phosphanes / Silicon

The reaction of hypersilyl(trimethylsilyl)chlorophosphane $(SiMe_3)_3SiP(SiMe_3)Cl$ (**1**) with *t*BuOK in THF at –60 °C proceeds by Si–P bond cleavage of the trimethylsilyl group and formation of $tBuOSiMe_3$/KCl and bis(hypersilyl)phosphanylidene. The phosphanylidene dimerizes to form bis(hypersilyl)diphosphene (**2**) in excellent yields (≥95%). X-ray diffraction experiments reveal the simultaneous presence of two rotamers in the solid state that differ in their SiSiPP torsion angles. Ab initio calculations for the parent diphosphene $(SiH_3)_3SiP{=}PSi(SiH_3)_3$ at the DFT/6-31+G(d) level predict an energy difference of 2.3 kJ mol$^{-1}$. A *cis* arrangement of the two $Si(SiH_3)_3$ groups raises the energy by about 45 kJ mol$^{-1}$. In the UV/Vis spectrum the $n \rightarrow \pi^*$ excitation is observed at 622 nm, which is in excellent agreement with the ab initio results. In the Raman spectrum, the P=P stretching vibration is easily identified as a strong line at 591 cm$^{-1}$. When a solution of **1** in THF is added to a solution of KO*t*Bu in THF, maintaining an excess of KO*t*Bu during the reaction, the deep-violet bis(hypersilyl)triphosphenide anion $[HypPPPHyp]^-$ (**4**) forms in excellent yields. This anion is also formed when **2** is treated with KO*t*Bu. Compound **2** can be derivatized with 2,3-dimethylbutadiene to give a cyclic diphosphane **5** by [4+2] addition. When a solution of **2** in toluene is heated to 110 °C for 4 h, bis(hypersilyl)cyclotriphosphane ($Hyp_2P_3H$, **6**) is formed, besides some $HypPH_2$ as a byproduct. As an aid for the interpretation of $^{31}P$ NMR spectra, equilibrium structures and phosphorus chemical shifts have been calculated at the DFT and MP2 level for a large number of molecules with phosphorus-containing backbones, which are closely related to those described in the present work. Calculations for disilyldiphosphenes reveal a close correlation between PPSi bond angles and $^{31}P$ NMR chemical shifts, which is useful for predicting NMR spectra.

## Introduction

Over the last two decades a great deal of effort has been devoted to the synthesis of double-bonded systems composed of the heavier elements of group V, such as diphosphenes (RP=PR) and diarsenes (RAs=AsR).[1] Large organic substituents R such as mesityl, supermesityl (2,4,6-tri-*tert*-butylphenyl) or $CH(SiMe_3)_2$ have been used for kinetic stabilisation of the double bonds. Various reactions of these double bonds, such as electrophilic additions or cycloadditions, have also been investigated.

The first disilyldiphosphene, SupP=PSup (Sup = supersilyl = Si*t*Bu$_3$) was obtained by Wiberg in 2002 from the reaction of $PCl_3$ with NaSup. It is formed via $SupPCl_2$ and SupClPPClSup as intermediate products; no crystals suitable for an X-ray investigation could be grown.[2] The same reaction also afforded the bis(supersilyl)triphosphaallyl anion $[SupPPPSup]^-$ a few years earlier, probably via the dianion $[SupPPPPSup]^{2-}$.[3] About ten years before, the synthesis of $[SupAsAsAsSup]^-$ had been described by Jutzi.[4] Both anions could be characterised unambiguously by X-ray diffraction experiments. It is of some note that less bulky silyl groups such as $tBuMe_2Si$ also possess the capability to stabilize unusual structural motifs, for instance SiSi double bonds.[5]

It is a common feature of the chemistry of double bonds between main group elements of period three (and higher) that reactions almost invariably happen at the double bond and not at the substituents, which have to be chosen to be as chemically inert as possible, otherwise they themselves will react with the double bond. The question therefore arises whether substituents can be designed that are large

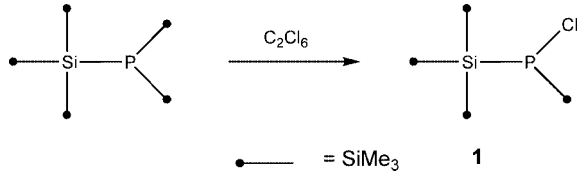
enough to stabilize double bonds but at the same time are sufficiently reactive to allow reactions to be initiated without (at least in the first step) affecting the double bonds. Our experience with oligosilanes led us to the conclusion that oligosilyl groups should be good candidates for this type of substituents for two reasons. First, silyl groups such as $t$Bu$_3$Si can be used successfully for the stabilisation of double bonds (as Wiberg has shown), which supports the idea that oligosilyl groups can serve the same purpose. Second, SiSi bonds readily undergo cleavage reactions under relatively mild conditions, even at low temperatures. In the present publication we explore a method that can be used for the preparation of oligosilylphosphanylidenes, bis(oligosilyl)diphosphenes and bis(oligosilyl)triphosphaallyl anions. The method can probably be used for organo-substituted phosphanylidenes as well. The hypersilyl group Si(SiMe$_3$)$_3$ (denoted as Hyp) was chosen to demonstrate the feasibility of the reactions because it is easily and quickly accessible in large quantities. We will report on the results using other oligosilyl groups in a forthcoming paper.

## Results and Discussion

One of the problems one faces when attempting to prepare silylated diphosphenes is that silyl groups are excellent leaving groups in phosphorus chemistry. For instance, SiMe$_3$ groups are routinely used for the preparation of organodiphosphenes RP=PR by elimination of chlorotrimethylsilane from RPCl$_2$ and RP(SiMe$_3$)$_2$.[6] The question therefore is whether the reaction rates of oligosilyl groups differ sufficiently from those of trimethylsilyl groups to open new paths to tailored diphosphenes. A slower reaction rate of the hypersilyl group would make the synthesis of the hypersilylphosphanylidene and of bis(hypersilyl)diphosphene an accessible goal. Silylphosphanylidenes such as H$_3$SiP are computed to prefer the triplet ground state by 122 kJ mol$^{-1}$ (CASSCF/6-31G** level).[7] At the QCISD(T)/6-311++G(3df2p)//UMP2/6-31G** level, this energy reduces to 107 kJ mol$^{-1}$.[7b] The triplet structure is stable towards rearrangement into the phosphasilene with a barrier of 170 kJ mol$^{-1}$ and a relative energy of the product of 61 kJ mol$^{-1}$. Therefore, a migration of the trimethylsilyl group in triplet (SiMe$_3$)$_3$SiP to form (SiMe$_3$)$_2$Si=P(SiMe$_3$) is unlikely to occur.

### Synthesis

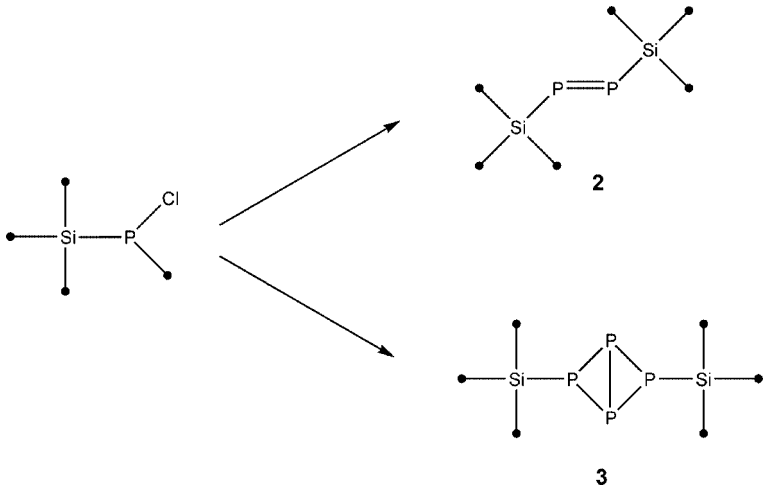
As reported elsewhere, (SiMe$_3$)$_3$SiP(SiMe$_3$)$_2$ reacts with C$_2$Cl$_6$ to form a stable chlorodisilylphosphane **1**, as shown in Scheme 1.[8]



Scheme 1.

A solution of **1** in toluene does not decompose at room temperature or if heated at 90 °C for 2 h, but does so in refluxing toluene (110 °C) with formation of chlorotrimethylsilane and a plethora of compounds, although without any indications of a PP double bond. In contrast, the pure, colourless chlorodisilylphosphane turns light green at 20 °C over a period of a week, and bis(hypersilyl)diphosphene (**2**) can be identified in the reaction mixture by $^{31}$P NMR spectroscopy along with bis(hypersilyl)bicyclotetraphosphane (**3**), as shown in Scheme 2.

From the $^{31}$P NMR spectrum it follows that **2** and **3** form in a ratio of about 2:1, with **2** giving a single line at $\delta$ = 735.0 ppm (as compared to $\delta$ = 818.1 ppm for SupP=PSup). The spectrum of **3** is of first-order ($A_2X_2$) and consists of two triplets at $\delta$ = –329.2 and –155.0 ppm with a $^1J_{P,P}$ coupling constant of 161.8 Hz, which clearly demonstrates that it is the *exo*/*exo* isomer that is formed exclusively. The *exo*/*endo* isomer is expected to give more signals, and the formation of the *endo*/*endo* isomer is extremely unlikely due



Scheme 2.

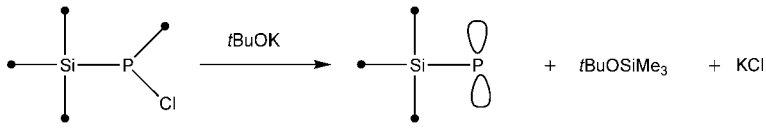


Scheme 3.

to the steric interactions of the large hypersilyl groups. It is worth noting that the analogous supersilyl compound $Sup_2P_4$ has also been observed by Wiberg in the reaction between $SupPCl_2$ and NaSup ($\delta$ = –334.4 and –139.1 ppm, $^1J_{P,P}$ = 170.5 Hz).[2]

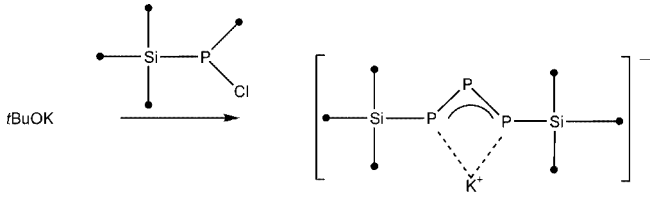
Besides **2** and **3**, the decomposition of **1** also affords trihypersilylheptaphosphane ($P_7Hyp_3$) as well as a second $P_n$ cage or polycycle of as-yet-unknown structure with second-order resonances between $\delta$ = –90 and –220 ppm as minor by-products.

The observed reaction products suggest that under these conditions the diphosphene is formed by dimerisation via HypClP–P($SiMe_3$)Hyp and subsequent elimination of chlorotrimethylsilane. A possible reaction pathway leading to the formation of the diphosphane would be the insertion of hypersilylphosphanylidene (formed from **1** by 1,1-elimination of chlorotrimethylsilane) into the PCl bond of **1**. The occurrence of reaction products such as $Hyp_2P_4$ and $Hyp_3P_7$ indicates that under these conditions the SiP bond of the hypersilyl group also takes part in the reaction, albeit with a much lower reaction rate.

These considerations led us to the expectation that the dimerisation of hypersilylphosphanylidene to form the diphosphene would be the preferred reaction if the phosphanylidene could be generated quickly and in quantitative yield. This is easily achieved by reaction of **1** with KO*t*Bu, to form the phosphanylidene, *t*BuOSi$Me_3$ and KCl, as shown in Scheme 3. Previously we have shown that KO*t*Bu can indeed be used to cleave an SiP bond of $P(SiMe_3)_3$,[9] and that the reaction with $HypP(SiMe_3)_2$ proceeds quickly and selectively with formation of *t*BuOSi$Me_3$ and HypP($SiMe_3$)K.[8] The reaction rate of the hypersilyl group is much slower.

When a solution of KO*t*Bu in THF is added to a solution of HypPCl($SiMe_3$) in THF very slowly at –60 °C to avoid any local excess of the reagent, light-green **2** forms quantitatively (≥95%, by $^{31}$P NMR) without any noticeable by-products. Compound **2** crystallises readily from pentane. The exclusive formation of the diphosphene **2** strongly supports the idea that the reaction indeed proceeds via hypersilylphosphanylidene. Compared to other methods described in the literature that can be used to prepare phosphanylidenes, its generation from RP($SiMe_3$)Cl and KO*t*Bu can be achieved at much lower temperatures. For instance, the phosphoranylidenephosphane $tBu_2P$–P=P$Br(tBu)_2$ decomposes at 20 °C to give the phosphanylphosphanylidene $tBu_2PP$, which has been trapped with 2,3-dimethylbutadiene.[10] The generation of phosphanylidenes from three-membered rings requires even higher temperatures of up to 140 °C.[11]

During these experiments we noticed that if the two solutions are mixed very quickly, the colour immediately changes to a dark-brown, which then slowly turns into a dark-violet. We therefore reversed the reaction sequence described above, adding the solution of HypPCl($SiMe_3$) to the solution of KO*t*Bu, maintaining an excess of KO*t*Bu throughout the whole procedure. In this way potassium 1,3-bis(hypersilyl)triphosphenide (**4**) can be obtained almost quantitatively (≥90%, by $^{31}$P NMR), as shown in Scheme 4.



Scheme 4.

The $^{31}$P NMR spectrum of **4** consists of a triplet at $\delta$ = 705.5 ppm and a doublet at $\delta$ = 197.5 ppm with a coupling constant of 540.4 Hz; values of $\delta$ = 732.5, 212.5 ppm and 552.6 Hz have been reported for the analogous supersilyl derivative.[3] Attempts to crystallise **4** as the [18-crown-6·K]$^+$ salt were not successful.[12] Our experiments showed that treating HypP=PHyp with KO*t*Bu also led to the formation of **4**. Whether the reaction starts with SiP or SiSi bond cleavage remains unknown; the mechanism is under investigation.

### Derivatisation of 2 and 4

When 2,3-dimethylbutadiene is added to a solution of **2** in toluene, the green colour disappears slowly with formation of the [4+2] cycloaddition product **5**, which was identified by NMR spectroscopy. The $^{31}$P nuclei give a singlet at $\delta$ = –137.6 ppm, and the $^{29}$Si NMR spectrum consists of two pseudotriplets at $\delta$ = –9.8 ($SiMe_3$ groups) and –89.5 ppm (see also Experimental Section). The reaction proceeds quantitatively.

2 6

When **4** reacts with trifluoroacetic acid, bis(hypersilyl)cyclotriphosphane $Hyp_2P_3H$ (**6**) forms almost quantitatively, along with some hypersilylphosphane $HypPH_2$. We were not able to obtain crystals suitable for X-ray diffraction, therefore **6** was characterised by $^{31}P$ NMR spectroscopy, including 2D-COSY experiments. Remarkably, **6** also forms when a solution of **2** in toluene is refluxed for several hours. Here again, the major by-product is hypersilylphosphane, which cannot be removed quantitatively by sublimation in vacuo as **6** decomposes slowly upon raising the temperature. A solution of **2** in THF does not decompose, even if held under reflux for 6 h.

The $^{31}P$ and $^{31}P\{^1H\}$ NMR spectra and the COSY spectrum of the cyclotriphosphane are illustrated in Figure 1 (left and right, respectively). The $^{31}P\{^1H\}$ NMR spectrum exhibits signals of an AMP spin system [$\delta_A(P^1)$ = –233.0, $\delta_M(P^2)$ = –241.3, $\delta_P(P^3)$ = –260.9 ppm; $^1J_{P^1,P^2}$ = –142.1, $^1J_{P^1,P^3}$ = –202.3, $^1J_{P^2,P^3}$ = –182.7 Hz]. The larger coupling between $P^1$ and $P^3$ indicates a *cis* orientation of the substituents H and Hyp. In the proton-coupled spectrum, the AMP spin system extends to AMPX [$^1J_{P^1,H}$ = 141.1Hz, $^2J_{P^2,H}$ = 10.0, $^2J_{P^3,H}$ < 3 Hz]. A calculated $^{31}P\{^1H\}$ spectrum assuming negative values for all P–P coupling constants is also included as (c) in Figure 1 (left).

## X-ray Crystallography

An ORTEP plot of the molecular structure of **2** in the crystal as well as the numbering of the atoms is presented in Figure 2; selected bond lengths, bond angles and torsion angles are collected in Table 1. As expected, it is the *trans* isomer that is formed by dimerisation of the phosphanylidene. Surprisingly, two stereoisomers **A** and **B** that differ by a rotation of the hypersilyl group around the PSi bond are observed in the crystal. If viewed along an axis joining the two central Si atoms of the hypersilyl groups, the trimethylsilyl groups in isomer **A** are in a staggered arrangement with dihedral angles between 55° and 65°. The molecule possesses an inversion centre. In isomer **B**, the arrangement of the trimethylsilyl groups is almost eclipsed with the dihedral angles alternating between 5° and 120°, giving approximately a $C_s$-symmetric isomer with differences between the PSiSi and SiSiSi bond angles on both sides of the molecule being smaller than about 2° (Table 1). As described later on, the ab initio calculations for $(SiH_3)_3SiP{=}PSi(SiH_3)_3$ also predict two minima on the potential energy surface corresponding to **A** and **B**. At the level employed for these calculations [B3LYP/6-31+G(d)], **B** becomes a transition structure for $(SiMe_3)_3SiP{=}PSi(SiMe_3)_3$. Obviously, it is stabilized in the crystal due to packing effects.

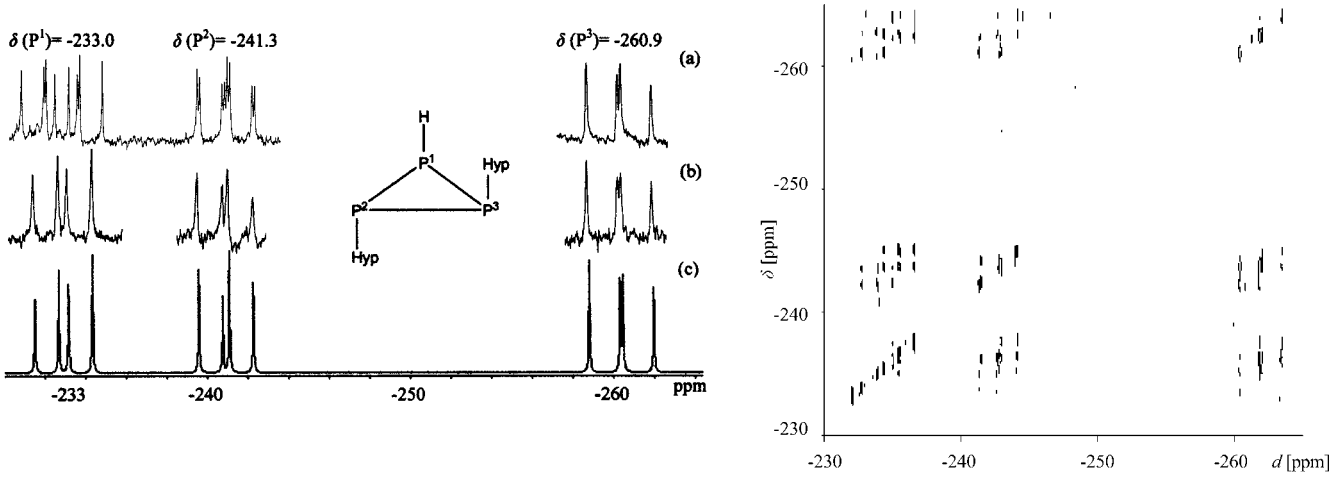

Figure 1. Left: Proton-coupled (a), decoupled (b) and calculated (c) $^{31}P$ NMR spectrum of bis(hypersilyl)cyclotriphosphane (**6**). Right: $^{31}P$ COSY spectrum of **6**.

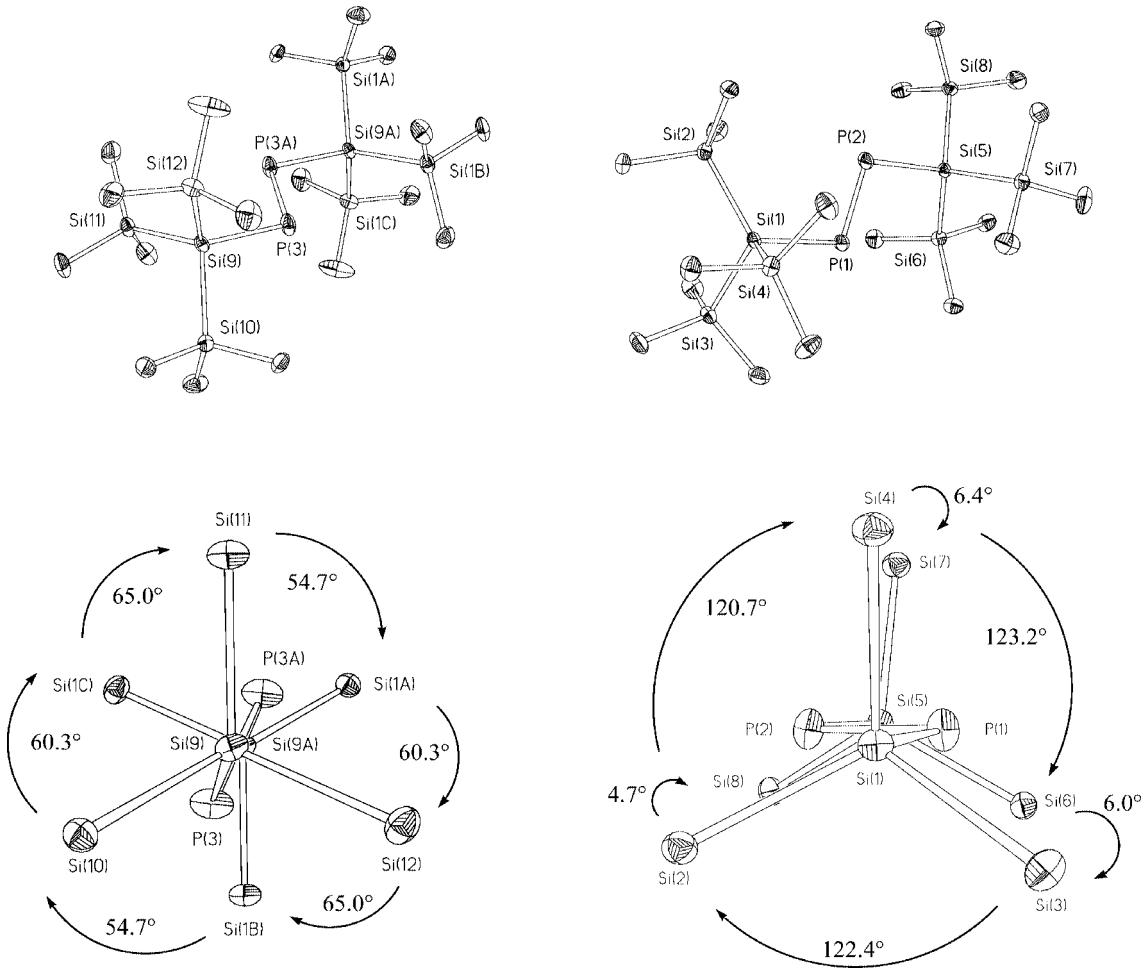

Figure 2. ORTEP plots of the two conformers of bis(hypersilyl)diphosphene in the crystal (top) and projections showing the different dihedral angles between the $SiMe_3$ groups (bottom). Isomer **A** is on the left and isomer **B** on the right side.

Table 1. Selected bond lengths [pm], bond angles [°] and dihedral angles [°] for the two isomers **A** and **B** of bis(hypersilyl)diphosphene.

| | Isomer **A** | Isomer **B** |
|---|---|---|
| PP | 203.0(2) | 202.2(2) |
| PSi | 228.0(2) | 227.0(2), 226.9(2) |
| SiSi | 234.6(2), 235.0(2), 235.3(2) | 234.6(2), 234.6(1), 235.0(2)<br>234.4(2), 234.9(2), 235.5(2) |
| PPSi | 102.7(1) | 103.2(1), 100.9(1) |
| PSiSi | 106.0(1), 104.4(1), 115.6(1) | 100.9(1), 104.7(1), 114.1(1)<br>103.1(1), 106.7(1), 113.5(1) |
| SiSiSi | 107.8(1), 110.9(1), 111.6(1) | 111.0(1), 111.6(1), 113.7(1)<br>111.0(1), 109.9(1), 112.3(1) |
| SiPPSi | 180.0 | –178.2(2) |

The P=P bond lengths of isomer **A** [203.0(2) pm] and **B** [202.2(2) pm] are almost identical, which is also the case for the PSi and SiSi bonds. Moreover, all distances are in the range that is considered normal for P=P, P–Si and Si–Si bonds and need no further discussion.

## Raman and UV Spectra

As diphosphenes possess absorptions in the UV and visible range (usually assigned as π–π* and n–π* transitions), the Raman spectra obtained with excitation sources in the visible or UV range are expected to show resonance or preresonance effects. The two main effects are an intensity enhancement as well as the appearance of an overtone progression for the P=P stretching vibration. So far, wavenumbers for the P=P stretch have been determined for $(Me_3Si)_3CP{=}PC(SiMe_3)_3$ (595 $cm^{-1}$) and ArP=PAr [Ar = 2,4,6-tri-*tert*-butylphenyl (610 $cm^{-1}$) and 2,6-bis(*m*-xylyl)-phenyl (622 $cm^{-1}$)].[13] There seems to be only a limited amount of mixing between the P=P and P–C stretching vibrations despite the fact that they are quite close to each other. This was concluded from a normal coordinate analysis (NCA) of MeP=PMe and $(Me_3Si)_3CP{=}PC(SiMe_3)_3$ by treating the methyl group as a point mass of 15.[14] So far, no NCA for a diphosphene based on an ab initio force field has been reported in the literature.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The Raman spectrum of bis(hypersilyl)diphosphene in the wavenumber range 50–900 $cm^{-1}$ is presented in Figure 3. The green 532-nm line of a frequency-doubled Nd:YAG laser (10 mW) was used to excite the sample. Its interpretation is rather straightforward, even without a NCA.

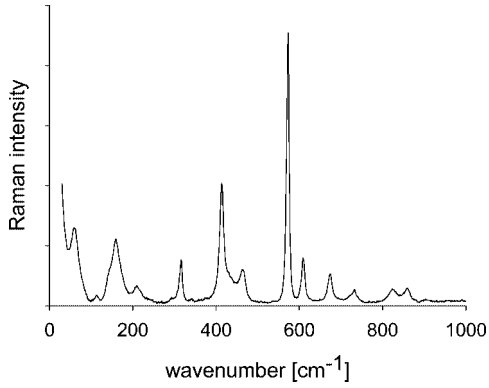

Figure 3. Raman spectrum of solid bis(hypersilyl)diphosphene in the wavenumber range 50–900 $cm^{-1}$.

The strongest line in this range, at 591 $cm^{-1}$, is clearly the P=P stretch, with the symmetric $SiC_3$ stretch at 626 $cm^{-1}$ being quite close. Nevertheless, there is negligible kinetic coupling between these two modes because the SiC bonds are separated from the P=P double bond by two SiSi bonds. This is not the case for the PSi and SiSi modes, which are expected on the low-wavenumber side in the range 300–500 $cm^{-1}$. They are observed at 481 and 450 $cm^{-1}$ [$\nu_{as}(SiSi_3)$], 431 $cm^{-1}$ [$\nu$(PSi)] and 332 and 323 $cm^{-1}$ [$\nu_s(SiSi_3)$]. The SiSiC and CSiC deformations of the trimethylsilyl groups fall in the range 50–240 $cm^{-1}$. No line splittings due to the presence of the two isomers **A** and **B** is observed as their spectra are expected to differ very little. This is confirmed by the ab initio results for the parent molecule $(SiH_3)_3SiP{=}PSi(SiH_3)_3$ (see next section).

For corroboration of the assignments given above, a normal coordinate analysis was carried out for $(H_3Si)_3SiP{=}PSi(SiH_3)_3$ and $(Me_3Si)_3SiP{=}PSi(SiMe_3)_3$ employing the Hessian matrices obtained from ab initio calculations (see next section). The Hessian matrix gives the force constants defined as displacements of Cartesian coordinates and has to be transformed into a force field described in terms of symmetry coordinates that themselves are linear combinations of displacements of internal coordinates such as bond lengths, bond angles and torsion angles. These calculations, known to spectroscopists as Wilson's FG method,[15] were performed using an enlarged version of the program ASYM40.[16] ASYM40 needs the Hessian matrix and the atomic coordinates of the equilibrium geometry as input data as well as the symmetry coordinates, which were chosen according to standard methods described in the literature.[17] Calculated PP, SiP and SiSi stretching force constants are summarised in Table 2. The P=P force constant is predicted as 326 and 332 $N\,m^{-1}$ for $(H_3Si)_3SiP{=}PSi(SiH_3)_3$ and $(Me_3Si)_3SiP{=}PSi(SiMe_3)_3$, respectively. The force constant for a PP single bond, for instance in $(SiMe_3)_2PP(SiMe_3)_2$, is considerably smaller, a value of 195 $N\,m^{-1}$ being obtained from ab initio calculations on this molecule.[18] Furthermore, the calculations of the potential energy distributions (PED) show that $\nu$(P=P) is indeed a group vibration in these diphosphenes, with *f*(PP) contributing as much as 86% to $\nu$(P=P) in $(H_3Si)_3SiP{=}PSi(SiH_3)_3$ and 97% in $(Me_3Si)_3SiP{=}PSi(SiMe_3)_3$. Coupling with other modes can be largely neglected.

Table 2. Experimental and calculated wavenumbers [$cm^{-1}$] for the PP and in-phase SiP and SiSi stretching vibrations and calculated force constants [$N\,m^{-1}$] for the rotational conformers **A**, **B** and **C** of $H_9Si_4P{=}PSi_4H_9$ [B3LYP/6-311+G(d)] and **A** of $Me_9Si_4P{=}PSi_4Me_9$ [B3LYP/6-311+G(d)].

| | $(H_3Si)_3SiP{=}PSi(SiH_3)_3$ | | | $(Me_3Si)_3SiP{=}PSi(SiMe_3)_3$ | |
|---|---|---|---|---|---|
| | **A** | **B** | **C** | **A** | |
| | calcd. | calcd. | calcd. | calcd. | exp. |
| $\nu$(P=P) | 603 | 599 | 597 | 604 | 591 |
| $\nu$(PSi) | 415 | 416 | 391 | 433 | 431 |
| $\nu_s(SiSi_3)$ | 314 | 314 | 278 | 331 | 332 |
| $\nu_{as}(SiSi_3)$ | 437 | 433 | 424 | 479 | 481 |

| *f*(PSi) | 153 | | | 157 | |
| *f*(SiSi) | 157 | | | 157 | |

The UV/Vis spectrum of **2** (solution in *n*-hexane) is presented in Figure 4 for three different concentrations. The absorption maxima corresponding to $\pi\rightarrow\pi^*$ and $n\rightarrow\pi^*$ excitations appear at 400 and 622 nm, respectively, the latter of which causes the green colour (see section on ab initio calculations).

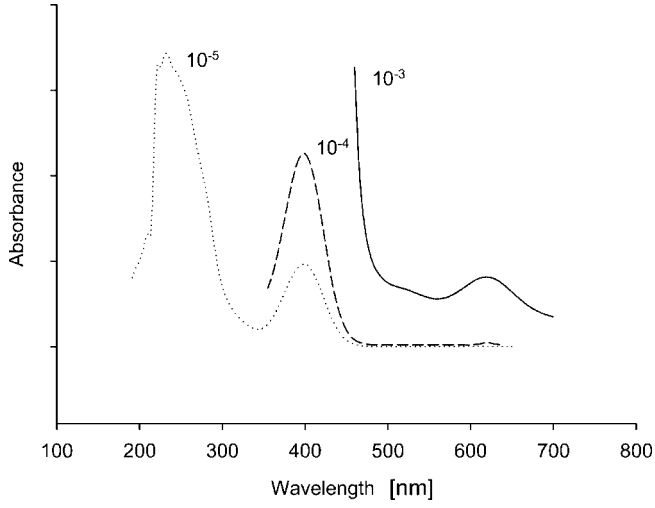

Figure 4. UV/Vis spectrum of bis(hypersilyl)diphosphene (**2**) for concentrations of $10^{-5}$, $10^{-4}$ and $10^{-3}$ M.

## Ab initio Calculations

### *Bis(hypersilyl)diphosphene*

Hyp–P=P–Hyp (**2**) is, with 82 atoms, computationally quite demanding. For our calculations at the B3LYP/6-31+G(d) level, we first used a smaller model created by replacing the hypersilyl groups by $Si(SiH_3)_3$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

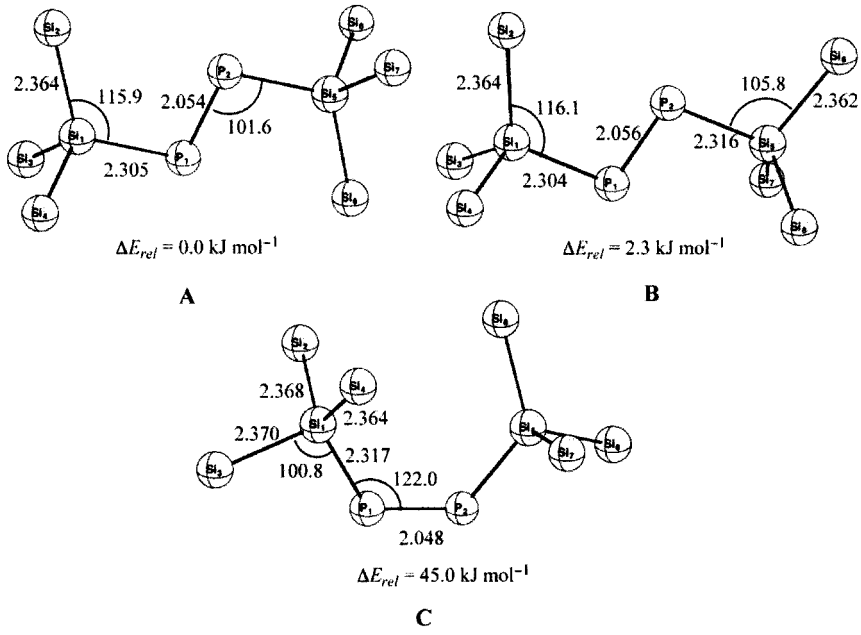

Figure 5. Rotational isomers of $(H_3Si)_3Si–P=P–Si(SiH_3)_3$ at the B3LYP/6-31+G(d) level of theory. The hydrogen atoms have been omitted for clarity.

Three minima were located on the potential energy surface (PES), as depicted in Figure 5.

The low-energy minima **A** and **B** have the Si–P=P–Si backbone in a *trans* orientation corresponding to the structures identified by X-ray spectroscopy. The energy separation ($\Delta E_{rel}$ = 2.3 kJ mol$^{-1}$) is quite small. The $SiH_3$ groups in **A** are oriented *trans* to each other and the conformer possesses a centre of inversion. The reason for the higher stability of this geometric arrangement can be identified by NBO analyses. Negative hyperconjugation occurs between the P lone pair and the respective antibonding Si–Si orbital if the $SiH_3$ group is oriented *cis* to the P=P double bond. Rotation of one $Si(SiH_3)_3$ group around the P–Si bond until the $H_3Si–Si–P–P$ angle is 180° yields the $C_s$-symmetric minimum **B**, destroys one of the LP(P)→σ*(Si–Si) interactions and consequently diminishes the stability.

The negative hyperconjugation also affects the bond lengths and angles. The P–Si bond length shrinks by 0.01 Å and the respective P–Si–Si angle becomes wider. For the full geometry data, see the Supporting Information.

A *cis* orientation of the Si–P=P–Si backbone is quite unfavourable and only one minimum, **C**, with a relative energy of 45.0 kJ mol$^{-1}$ was located on the PES.

The P=P stretching vibrations of the three minima [603 (**A**), 599 (**B**) and 597 cm$^{-1}$ (**C**)] are too close to discern the conformers by Raman spectroscopy. The same is true for the ν(PSi), $\nu_s(SiSi_3)$ and $\nu_{as}(SiSi_3)$ vibrations listed in Table 2.

As the synthesised diphosphene is light-green, we calculated UV/Vis spectra with time-dependent B3LYP and 6-311+G(d) basis sets. The global minimum has a strong absorption band at 358 nm ($f$ = 0.27) corresponding to a π → π* excitation. The HOMO–LUMO transition, corresponding to an n → π* excitation, is found at 562 nm but should not be visible as the oscillator strength is 0.00. However, the oscillator strength of the same transition for minimum **B** at 583 nm is calculated to be 0.0002. There is also a strong π → π* transition at 367 nm ($f$ = 0.21). Minimum **C** shows a similar behaviour, with a weak n →π* excitation at 586 nm ($f$ = 0.0002) and a strong π → π* transition at 359 nm ($f$ = 0.13).

Upon replacment of $Si(SiH_3)_3$ by the full hypersilyl group $Si\{Si(CH_3)_3\}_3$, only structure **A** corresponds to a minimum, while **B** becomes a transition structure at the B3LYP/6-31+G(d) level used. Due to space limitations, we were unable to perform MP2 calculations, which might predict **B** to be a minimum structure, too. The geometric parameters change slightly due to the larger hypersilyl groups. The P=P distance remains at 2.054 Å, but the P–Si bonds elongate by 0.01 Å and the SiPP bond angles become 4° wider. The characteristic Raman frequencies are close to the values of the smaller model, as shown in Table 2.

As expected, the n → π* excitation drifts to larger wavelengths, namely 632 nm. However, as for the smaller model, this HOMO–LUMO transition for **A** is not visible ($f$ = 0.0), although the π → π* excitation at 409 nm is quite strong ($f$ = 0.24).

### *Bis(hypersilyl)triphosphenide*

We also performed ab initio calculations for the bis(hypersilyl)triphosphenide anion at the same level of theory [B3LYP/6-31+G(d)], including calculations of $^{31}P$ chemical shifts. The $C_2$-optimised structure is shown in Figure 6. The Si–Si–P bond angle is only 3° wider in the $Hyp_2P_3$ anion than in $[(H_3Si)_3Si]_2P_3$ and about 8° wider than in the parent $(H_3Si)_2P_3$ (**10a**; see next section). Nevertheless, the P–P–P angle of the allylic backbone is roughly identical for R = Hyp (Figure 6) and $Si(SiH_3)_3$ (106.1°), and only 3° narrower

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

than in the parent. Even though the formal cone angle of hypersilyl is approximately 180°, the P–P–Si arrangement is far from linear. Therefore, investigations of the variation of the steric effect of R are of ongoing interest. A comparison of the DFT-calculated NMR chemical shifts (Figure 6) shows that the values are much too positive. When the correction factor 0.84, which is described in the section "$^{31}$P NMR Shift Calculations", is considered, the shift of the signal of the central phosphorus atom is $\delta$ = 695 ppm, in agreement with the observed value of $\delta$ = 705 ppm. For the terminal phosphorus atoms, which have a direct contact with the counterion, the correction leads to a value of $\delta$ = 229 ppm, which differs by only about 11 ppm from the experimental value.

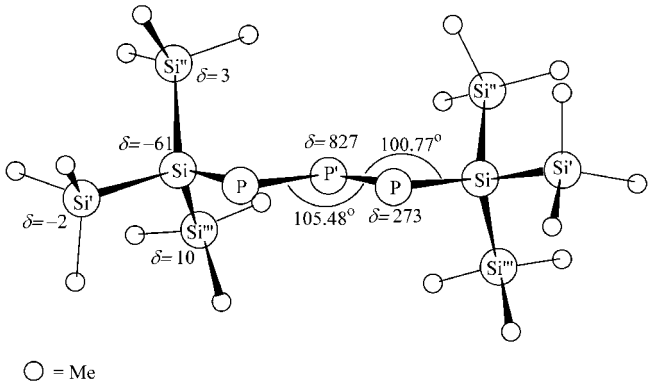

Figure 6. Optimized $C_2$ geometry for bis(hypersilyl)triphosphenide.

### *Geometries of Model Compounds*

To gain a deeper understanding of the steric and electronic influences of the substituents on the structures of molecules with phosphorus-containing backbones, geometry optimisations at the B3LYP/6-31+G* level of theory were performed for **7**–**12**, as shown in Figure 7. The model compounds, which are closely related to compounds **2**–**6**

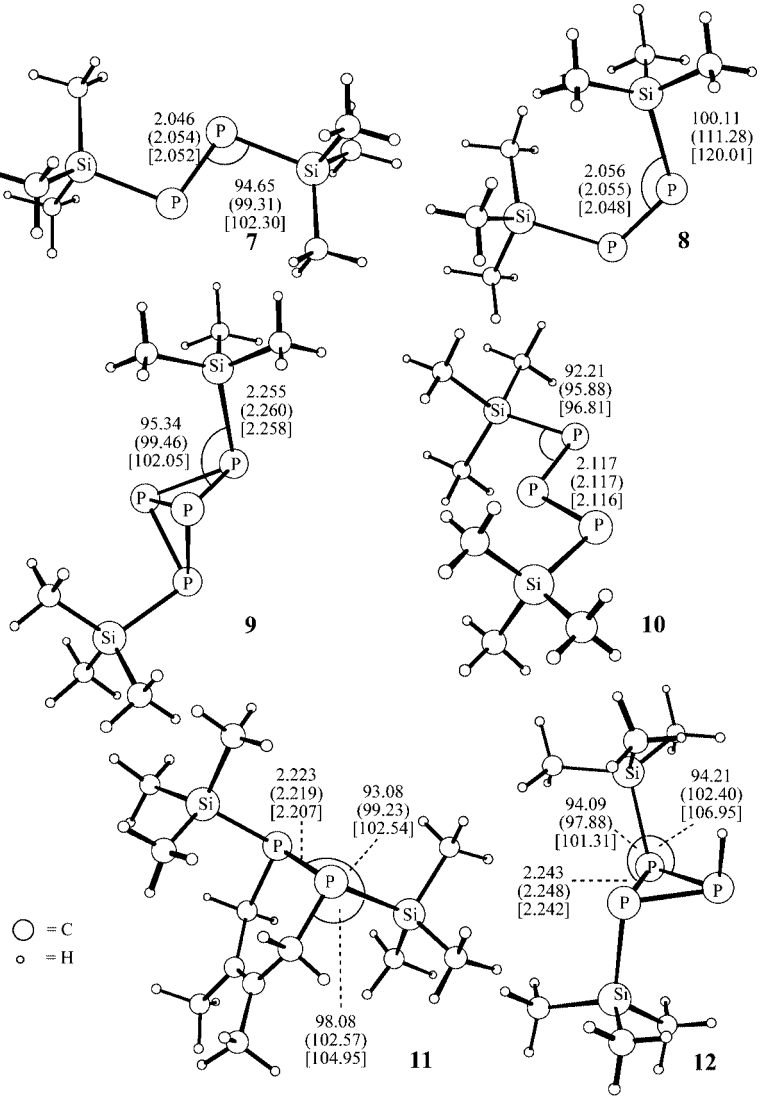

Figure 7. Ab initio (B3LYP/6-31+G*) optimised geometries of molecules with phosphorus-containing backbones (**7**–**12**). Structures for R = H and R = $SiH_3$ are not depicted. Values are given for R = H, with those for R = $SiH_3$ in parentheses and for R = $Si(CH_3)_3$ in square brackets.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

described previously, were *trans*-RP=PR (R = H, **7a**; R = $SiH_3$, **7b**; R = $SiMe_3$, **7c**), *cis*-RP=PR (**8a**–**8c**), $R_2P_4$ (**9a**–**9c**), $[R_2P_3]^-$ (**10a**–**10c**), $R_2(PCH_2CHMe)_2$ (**11a**–**11c**) and $R_2P_3H$ (**12a**–**12c**). The backbones in this set vary from common tricoordinate phosphorus (**9**, **11** and **12**) through phosphorus in an allyl anion framework (**10**) to the P=P double bond in **7** and **8**.

The selected R groups differ only slightly in their inductive effects towards phosphorus, as seen by the Mulliken charges of $RPH_2$, which are –0.03 for R = H, –0.05 for $SiH_3$ and –0.06 for $SiMe_3$. The π-conjugation effect, as expressed by the bond angle sum, Σ$\alpha$, at $PH_2$[19] is difficult to separate from steric influences measured by the cone angle, $\gamma$, of R with P as the cone point.[20] The average cone angles (80.24° for R = H, 94.32° for $SiH_3$ and 125.16° for $SiMe_3$) derived from the //B3LYP/6-31+G* geometries suggest that silyl and trimethylsilyl should show distinctly different steric effects.

In the bicyclotetraphosphanes **9** as well as in the cyclotriphosphanes **12** the substituents R are attached to a $P_3$ ring. The $SiH_3$ substituent has the largest elongating effect on the $P^\alpha$–P bond, and the R–$P^\alpha$–P angle increases from H through $SiH_3$ to $SiMe_3$ (see Figure 7), paralleling the increase of the cone angles. While the R–$P^\alpha$–P and R–$P^\alpha$–C bond angles increase similarly in the six-membered ring **11**, the P–P bond length shrinks with silylation (H: 2.223; $SiH_3$: 2.219; $SiMe_3$: 2.207 Å). The allyl anions **10a**–**10c** with a delocalised π-conjugation show astonishing population effects on the phosphorus atom attached to R with charges –0.27 (H), –0.29 ($SiH_3$) and –0.21 ($SiMe_3$). H and $SiH_3$ behave more similarly than $SiH_3$ and $SiMe_3$. In contrast, the charges of the central P atom follow the trend of the inductive effect (–0.36, –0.16 and –0.18, respectively). The P–P bond length is almost unaffected by the substituents, and the P–P–P angle is smaller in the silyl derivatives, with a range of 107.30–108.58°. Counterion effects on the geometry of the triphosphaallyl anion have been discussed elsewhere.[3]

Compared to the allyl bond length, the P=P double bond is modified slightly more by the substituents, with values of 2.046, 2.054 and 2.052 Å for the *trans*-diphosphenes **7a**–**7c** and 2.056, 2.055 and 2.048 Å for the *cis*-diphosphenes **8a**–**8c**. Substantial changes are obtained for the R–P–P angles, which are 94.65°, 99.32° and 102.30° for the *trans* isomers.

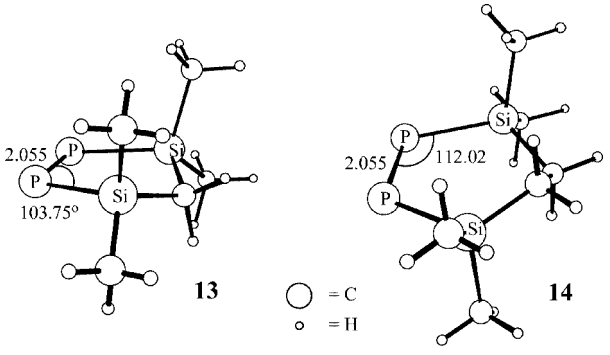

Figure 8. Geometries for model compounds **13** and **14**.

Due to the steric interaction between the substituents, these values are much larger for the *cis* isomers (106.11°, 111.28° and 120.01°). It is also noteworthy that the R–P–P–R torsion angles always differ by less than 1° from 180° (*trans*) or 0° (*cis*), even in *cis*-$Me_3SiP$=$PSiMe_3$.

The model compounds also include two silylated cyclic diphosphenes, which possess a *cis* geometry of the double bond, as shown in Figure 8.

### *$^{31}$P NMR Shift Calculations*

The $^{31}$P chemical shifts of supersilyldiphosphene and hypersilyldiphosphene differ by a striking 83 ppm. The difference is much smaller for other isostructural hypersilyl and supersilyl compounds such as $R_2P_4$ or $R_2P_3H$ and the allyl anion $[R_2P_3]^-$, at less than 25–30 ppm. As both SupP=PSup and HypP=PHyp are too large for high-quality MP2 shift calculations, we have performed a series of calculations for smaller diphosphenes as a test for the accuracy of the DFT calculations. Table 3 lists the chemical shifts for a series of selected diphosphenes (including cyclic derivatives with a *cis* arrangement) calculated at the DFT and various MP2 levels. We employed the B3LYP method with the 6-31G* basis set and the MP2 method with the three basis sets 6-31G* and McLean–Chandler's 6-311G* and 6-311+G**, labelled B3LYP-A, MP2-A, MP2-B and MP2-C further on. From the correlation analysis, the equation $\delta_{^{31}P(MP2\text{-}C)} = 0.84 \times \delta_{^{31}P(DFT\text{-}A)}$, which has a negligible intercept and squared correlation coefficient, *cc*, of 0.984, is obtained. Thus, $^{31}$P chemical shifts can be reliably estimated with this equation from DFT results. The correlation also extends to tetracoordinate phosphorus, as shown by including calculations for $[PH_3PH_2]^+$.

The DFT-A calculations with $C_1$ symmetry predict $\delta_{^{31}P}$ = 917 ppm for HypP=PHyp and 1071 ppm for SupP=PSup. The difference of 154 ppm becomes 129 ppm when taking into account the correlation mentioned above, thus increasing the agreement with the experimental difference (83 ppm).

We next turned to the question as to whether differing PPSi bond angles can cause large shift differences. The DFT-A calculations provide values of 104.55°/104.54° for HypP=PHyp (somewhat larger than the experimental values, see Table 1) and 106.47°/106.60° for SupP=PSup. To search for a bond angle–chemical shift relationship, DFT-A calculations were performed for ten *cis*- and twenty *trans*-RP=PR molecules. The predicted $\delta_{^{31}P}$ values are plotted as functions of the R–P=P angle, $\alpha$, for a large variety of R groups, such as H, F, Cl, $CF_3$,$CH_3$, *t*Bu, $NH_2$, $NMe_2$, $SiH_3$ and $SiMe_3$, in Figure 9. Several cyclic diphosphenes with PC, PN and PSi bonds are also included (see Table 3). In agreement with previous investigations,[21] a regression analysis confirms the impression that there is no general relationship that is valid for all substituents ($cc < 0.2$). Nevertheless, some subsets do display interesting trends that are useful for predicting phosphorus shifts. The data points for the substituents H, F, $SiH_3$, $SiMe_3$, Hyp and Sup correlate nicely with the calculated bond angles with the linear fit $\delta_{^{31}P} = 37 + 2866\alpha$ ($cc = 0.966$). Small changes of the PPSi

| $H_3P^*PH_2^+$ | –111 | –117 | –109 | –107 |

[a] All molecules optimised without symmetry constraints at the B3LYP/6-31G* level. Chemical shifts calculated for these geometries at the GIAO/B3LYP/6-31G* (DFT-A) and GIAO/MP2(fc) with 6-31G* (MP2-A), 6-311G* (MP2-B) and 6-311+G** (MP2-C) levels. Reference $PH_3$ with the same NMR methods at the //B3LYP/6-31+G* level has magnetic shieldings of 585.6 (DFT-A), 646.2 (MP2-A), 613.6 (MP2-B), 607.1 (MP2-C) and a chemical shift of $\delta$ = –240 ppm. [b] The slope and squared correlation coefficient, *cc*, between $\delta_{^{31}P(DFT\text{-}A)}$ and the higher levels of NMR calculation are: $\delta_{^{31}P(MP2\text{-}A)} = 0.77\delta_{^{31}P(DFT\text{-}A)} - 31$ ppm, with $r = 0.989$; $\delta_{^{31}P(MP2\text{-}B)} = 0.86\delta_{^{31}P(DFT\text{-}A)} + 0$ ppm, with $r = 0.988$; and $\delta_{^{31}P(MP2\text{-}C)} = 0.84\delta_{^{31}P(DFT\text{-}A)} + 0$ ppm, with $r = 0.984$. [c] Cyclic compounds with a *cis* arrangement of the P=P double bond; otherwise *trans* conformer.

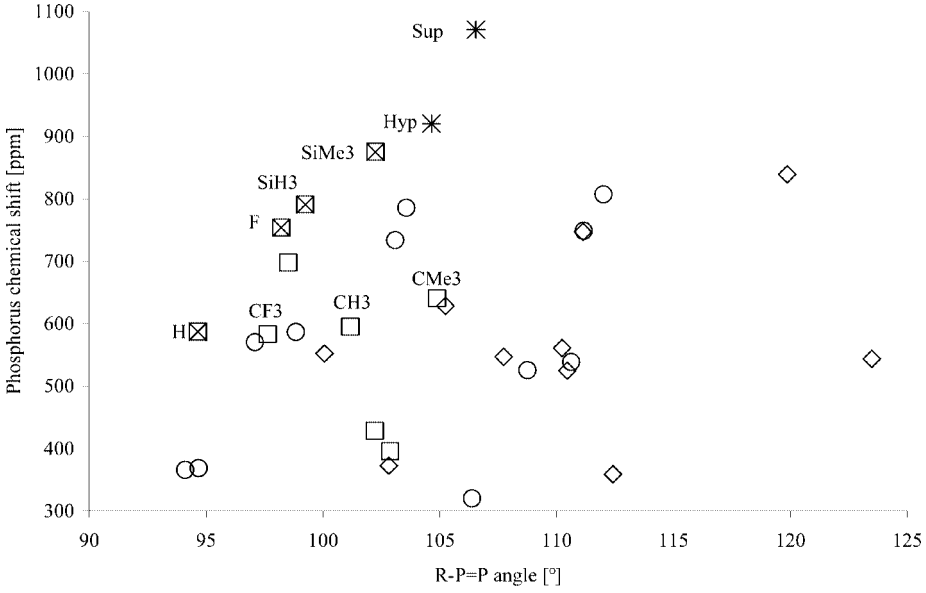

Figure 9. Relation between the R–P=P angle and chemical shifts of phosphorus at ab initio/NMR level DFT-A for *trans* (squares), *cis* (diamonds) and cyclic (circles) diphosphenes. A cross denotes the *trans*-disilylated molecules and the additional cross (forming an asterisk) marks the molecules that are known experimentally.

bond angles of *trans*-disilyldiphosphenes cause a large change of the phosphorus shift, which is different from the *trans* carbon analogues, as shown for the substituents H, $CF_3$, $CH_3$ and $CMe_3$. Here, a difference of the bond angles of more than 10° (see also Table 3) causes a shift change of no more than 50 ppm. As is to be expected, the P=P–R angle and the bulkiness of R correlate so that the shift also correlates with the calculated cone angles, which are 92.9°, 123.2°, 175.9° and 211.2° for $SiH_3$, $SiMe_3$, Hyp and Sup, respectively.

Remarkably, the chemical-shift changes for the *cis* isomers per unit angle change are much smaller. For the *cis* series with H, F, $SiH_3$ and $SiMe_3$, the calculated bond angles are 100.2°, 105.2°, 111.1° and 119.9°, with shift values of $\delta$ = 552, 628, 747 and 839 ppm, respectively, which gives a linear fit $\delta_{^{31}P} = -923 + 15\alpha$ (*cc* = 0.982). In the corresponding alkyl series H, $CF_3$, $CH_3$ and $CMe_3$, the shift is almost independent of the bond angle: all values are between $\delta$ = 525 and 552 ppm with bond angles between 100° and 123°. The shift values for *cis*- and *trans*-$(H_2N)$-P=P$(NH_2)$ and -$(Me_2N)$P=P$(NMe_2)$ do not fit into these correlations as they are much lower (between $\delta$ = 350 and 400 ppm). This is consistent with previous phosphorus NMR investigations that an increased electronegativity of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the atom attached to the phosphorus atom causes an upfield shift.[21] In diphosphenes with P–C or P–Si bonds, β-alkylation, i.e. replacing $CH_3$ or $SiH_3$ by $CH_2R$ and $SiH_2R$, always increases $\alpha$ as the cone angle of the substituent becomes larger and a downfield shift occurs. With the amino-substituted *cis*-diphosphenes $(H_2N)P{=}P(NH_2)$ and $(Me_2N)P{=}P(NMe_2)$ the opposite effect is observed; an upfield shift of about 20 ppm is predicted by the ab initio calculations.

The *cis*-E–P=P–E group in the cyclic compounds shows similar small effects of the bond angle on $\delta_{^{31}P}$. In agreement with a positive angle vs. shift correlation, $\delta_{^{31}P}$ of the six-membered rings increases compared to the corresponding five-membered rings.

All carbon-substituted diphosphenes are predicted to possess phosphorus resonances in the range between $\delta$ = 525 and 641 ppm, which does not overlap with the range for silyl-substituted diphosphenes [$\delta$ = 734 ppm for *cyclo*-1,2-diphospha-3,5-disilacyclopent-1-ene and $\delta$ = 875 ppm for *trans*-$(Me_3Si)P{=}P(SiMe_3)$]. Similarly, the amino-substituted diphosphenes show up with distinguishable chemical shifts in the range $\delta$ = 325–425 ppm, at higher field than the alkyldiphosphenes.

## Conclusions

Along with the synthesis of the first example of a bis(oligosilyl)diphosphene, several synthetic refinements for the generation of phosphorus–phosphorus double bonds have been developed. The concentration-dependent product formation in the reaction of Hyp–PCl–$SiMe_3$ with KO*t*Bu indicates the intermediacy of a hypersilylphosphanylidene. The green colour of the diphosphene is in agreement with the weak n–π* absorption band at 632 nm obtained from DFT calculations. Geometries and GIAO/MP2 as well as GIAO/B3LYP chemical-shift calculations have been performed for the H-, $SiH_3$-, and $SiMe_3$-substituted parents of the experimentally investigated molecules. The relation (*cc* = 0.984; 16 examples with a P=P bond) between the large basis set MP2 and B3LYP/6-31G* results provide an equation [$\delta_P$(MP2-C) = 0.84 × $\delta_P$(B3LYP)] with a negligible intercept. The correction factor has been successfully applied to the bare triphosphaallyl anion, resulting in differences of less than 32 ppm with respect to the NMR spectroscopic data of the complex of the anion with $K(THF)_n$ (**4**). The R–P=P bond angle vs. chemical shift relationship for 33 molecules with an –P=P– moiety has been analysed: *trans*-R–P=P–R shows larger shifts with larger angles (approximately 40 ppm per degree), although little effect is seen for *cis*-R–P=P–R (including endocyclic moieties), probably due to compensation resulting from geometric constraints. While previous model computations only considered R = H and $SiH_3$ (as placeholder for supersilyl) the present set expands the scope to $SiMe_3$ and, in special cases, to hypersilyl, $Si(SiMe_3)$. The change of geometric parameters from the $SiH_3$ to the $SiMe_3$ substituent is most obvious in *cis*-R–P=P–R, with a widening of the P=P–Si angle by 9°. In the other compounds considered this angle changes by only 2° ($P_3$-allyl) or 5° (cyclo-$P_3$). This is in agreement with NMR shifts of cyclotriphosphanes with R = H, Me, *i*Pr, and *t*Bu, which exemplify steric effects reflected in NMR signals.[22]

## Experimental Section

**General Remarks:** All syntheses and manipulations were carried out under either $N_2$ or Ar using standard Schlenk techniques. Solvents were distilled from sodium, potassium, sodium/potassium alloy or $LiAlH_4$ prior to use. Elemental analyses were performed with a Heraeus Vario Elementar.

**Ab Initio Calculations:** The B3LYP/6-31+G* method was used for geometry optimisation, examining all stationary points by analytical frequency calculations with the Gaussian 98 program package.[23] For selected minimum geometries the magnetic shielding was calculated with the GIAO approach at the B3LYP/6-31G* and MP2 level with the basis sets 6-31G*, 6-311G* and 6-311+G**, and transformed into chemical shifts (see Table 3). The UV spectra were obtained by time-dependent DFT calculations with the hybrid B3LYP functional and 6-311+G(d) basis set.

**Spectroscopy:** NMR spectra were recorded with a Bruker MSL 300 or a Varian Unity Inova 300 spectrometer. The $^{29}Si$ and $^{31}P$ NMR spectra were measured for solutions in THF or toluene in 10-mm tubes with capillaries of $D_2O$ serving as external lock. $^{31}P$-$^{31}P$ COSY spectra were recorded at 25 °C from a solution in $C_6D_6$ using 4096 × 4096 data points and a sweep width of 10582 Hz, The time required for an experiment was about 11 h. Raman spectra were recorded with a JobinYvon T64000 triple monochromator equipped with a CCD detector and a frequency-doubled Nd:YAG laser operating at 532 nm with a power of 10 mW. Samples were placed in 1-mm capillaries and sealed under dry, oxygen-free nitrogen. The UV/Vis spectrum of a solution of bis(hypersilyl)diphosphene in *n*-hexane was measured with a Perkin–Elmer Lamda 2S spectrometer in the range 200–700 nm.

**X-ray Structure Analysis of 2:** The crystal was mounted onto the tip of a glass fibre and data collection was performed with a Bruker-AXS SMART APEX CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The data was reduced to $F_o^2$ and corrected for absorption effects with SAINT[24] and SADABS,[25] respectively. The structure was solved by direct methods and refined by full-matrix least-squares methods (SHELXL-97).[26] All non-hydrogen atoms were refined with anisotropic displacement parameters and were located in positions calculated to correspond to standard bond lengths and angles. The diagrams were drawn with 30% probability thermal ellipsoids, with all hydrogen atoms omitted for clarity. Selected data are collected in Table 4. CCDC-291188 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Bis(hypersilyl)diphosphene (2):** Solid $C_2Cl_6$ (0.21 g, 0.87 mmol) was added to a solution of $HypP(SiMe_3)_2$ (0.31 g, 0.73 mmol) in 20 mL of toluene and the reaction mixture was stirred at room temperature overnight. The solvent and all volatile reaction products such as $C_2Cl_4$ and $ClSiMe_3$ were then carefully removed by concentration in vacuo. The oily residue of pure **1** was dissolved in 20 mL of THF and a solution of *t*BuOK (0.09 g, 0.76 mmol) in 10 mL of THF was added dropwise at –70 °C. The colour slowly changed to light-green. The mixture was stirred for another 2 h and then warmed to room temperature. The solvent

was removed by evaporation in vacuo and replaced with pentane. Light-green crystals of **2** (0.19 g, 95%) with a quality suitable for X-ray diffraction were obtained at –30 °C. $C_{18}H_{54}P_2Si_8$ (557.32): calcd. C 38.79, H 9.77; found C 37.90, H 9.52. $^{31}$P NMR: $\delta$ = +735.0 ppm. $^{29}$Si NMR: $\delta$ = –56.7 (pseudo-t, $|^1J_{P,Si} + {}^2J_{P,Si}|$ = 46.0 Hz), –9.9 (pseudo-t, $|^2J_{P,Si} + {}^3J_{P,Si}|$ = 7.1 Hz, $SiMe_3$) ppm.

**Synthesis of Potassium hypersilyltriphosphenide (4):** *t*BuOK (0.22 g, 1.96 mmol) was dissolved in 10 mL of THF and a solution of **1** (0.73 g, 1.88 mmol) in 20 mL of THF was added dropwise at –60 °C over a period of 30 min. The colour of the reaction mixture turned dark brown. After completion, the reaction mixture was warmed to room temperature, whereby the colour changed to deep violet. According to the $^{31}$P NMR spectrum, **4** formed almost quantitatively (>95%) with traces of $HypPH_2$ (<5%) as a by-product. Attempts to crystallise **4** as the [18-crown-6·K]$^+$ salt failed. $^{31}$P NMR: $\delta$ = +705.5 (t), +197.5 (d) ppm.

**Reaction of Bis(hypersilyl)diphosphene with 2,3-Dimethylbutadiene. Formation of 5:** Compound **2** (0.06 g, 0.11 mmol) was dissolved in 1 mL of THF and the solution was transferred into an NMR tube. 2,3-Dimethylbutadiene (0.073 g, 0.188 mmol) was then added. After 1 h at room temperature, the green colour had disappeared. According to the NMR spectra, the [4+2] cycloaddition product **5** had formed almost quantitatively (≥95%). No attempt to crystallise the compound was made. $^{31}$P NMR: $\delta$ = –137.3 (s) ppm. $^{29}$Si NMR: $\delta$ = –89.5 (pseudo-t, $|^1J_{P,Si} + {}^2J_{P,Si}|$ = 37.0 Hz), –9.8 (pseudo-t, $|^2J_{P,Si} + {}^3J_{P,Si}|$ = 10.6 Hz, $SiMe_3$) ppm.

**Thermal Decomposition of Bis(hypersilyl)diphosphene. Formation of 6:** Compound **2** (0.06 g, 0.11 mmol) was dissolved in 10 mL of toluene and refluxed for 4 h. After this period, the green colour had disappeared completely and the signal of **2** could no longer be detected in the $^{31}$P NMR spectrum as **6** had formed almost quantitatively, along with some $HypPH_2$. Not unexpectedly, **6** also formed when **4** was treated with HypCl. Removal of the toluene by concentration in vacuo gave an oily residue, which turned out to be impossible to purify so no crystals could be grown, despite the use of different solvents. Attempts to purify **6** by sublimation failed due to decomposition, therefore no elemental analysis was carried out. $^{31}$P NMR: $\delta$ = –233.0 (q), –241.3 (q), –260.9 (q) ppm. For a discussion of the spectra, see Synthesis section.

**Supporting Information** (see also the footnote on the first page of this article): Cartesian coordinates of the $(H_3Si)_3SiP{=}PSi(SiH_3)_3$ minima obtained by B3LYP/6-31+G(d) calculations with Gaussian98.

# A Self-Sacrificing Template Route to Spinel $M^{II}In_2S_4$ ($M^{II}$ = Mn, Zn, Cd, Fe, Co, Ni) and $M^{I}In_5S_8$ ($M^{I}$ = Cu, Ag) Porous Microspheres

**Shuijin Lei,[a,b] Kaibin Tang*[a,b] Yunxia Qi,[a,b] Zhen Fang,[a,b] and Huagui Zheng[b]**

**Keywords:** Solvothermal synthesis / Spinel phases / Microporous materials / Semiconductors

A facile, self-sacrificing template route has been developed to synthesize spinel $M^{II}In_2S_4$ ($M^{II}$ = Mn, Zn, Cd, Fe, Co, Ni) and $M^{I}In_5S_8$ ($M^{I}$ = Cu, Ag) porous microspheres. The BET surface areas of the products are around 70 $m^2g^{-1}$. The urchin-like $In_{2.77}S_4$ microspheres precursor acts as both starting material and template to confine the growth of the final products. The phase structures and morphologies of the products were characterized by X-ray diffraction, scanning electron microscopy, transmission electron microscopy, and electron diffraction. Possible formation process and growth mechanism for the porous structure are proposed based on the experimental results.

## Introduction

Porous solid materials are of practical significance as useful supports due to their interconnected pore structure, large surface area, and small pore size.[1,2] Recently, the preparation and investigation of nano-/micro-sized porous spheres has attracted considerable attention because of their technical applications in catalysis, drug-delivery systems, separation techniques, photonics, as well as piezoelectric and other dielectric devices.[3,4] Rapid solvent removal,[5] porogen leaching,[6] double-emulsification,[7,8] and solution-induced phase separation[9] have been used to fabricate porous microspheres based on an emulsion–solvent evaporation method. However, these methods are rather complicated for repeatable production and subtle manipulation.

In recent years, multinary chalcogenide compounds have been the subject of intense research,[10,11] and considerable progress has been made in the synthesis and characterization of ternary semiconductor crystallites.[12,13] Various ternary semiconducting compounds with formula $A^{II}B^{III}{}_2X^{VI}{}_4$ have been of special interest due to their unusual properties (e.g. wide transparency intervals, high value of non-linear susceptibility combined with natural birefringence) and potential applications (e.g. electro-photographic films, switches, optical filters, photodetectors, magnetic field control lasers, light modulators, optoelectronics, and Schottky diodes).[14–18] The type I-III-VI ternary semiconductors $CuIn_5S_8$ and $AgIn_5S_8$ are also of great technological and scientific interest because of their possible application in semiconductor devices and optical and quantum electronics.[19]

Both $M^{II}In_2S_4$ and $M^{I}In_5S_8$ show n-type conductivity and crystallize in the spinel-type cubic structure with the space group $Fd\bar{3}m$. There are theoretical and practical reasons to believe that they can all be used as an absorber layer material for a p-n junction solar cell.[18,20,21] Many efforts have been made to study the magnetic, optical, electrical, and semiconducting properties of $M^{II}In_2S_4$[22–26] and the electrical and optical properties of $M^{I}In_5S_8$.[19,27,28]

Conventionally, $M^{II}In_2S_4$ and $M^{I}In_5S_8$ powders are prepared by solid-state reaction methods under high temperature and vacuum conditions for a long time.[19,29,30] Recently, many methods such as metal-organic chemical vapor deposition (MOCVD),[31] chemical vapor transport,[32] precipitation,[33] hydrothermal/solvothermal techniques,[26,34] and a chemical spraying route[18] have been reported for the preparation of $M^{II}In_2S_4$. As for the synthesis of $M^{I}In_5S_8$, spray deposition,[35] pulsed-laser deposition,[36] sequential deposition,[37] and thermal-deposition[38] methods have also been reported. However, the complicated synthesis process and the requirements for special instruments or harsh conditions in these processes are the main disadvantages of these methods. To the best of our knowledge, the extensively applicable self-sacrificing template method has not been reported to be applicable for the fabrication of porous microspheres of a series of $M^{II}In_2S_4$ and $M^{I}In_5S_8$ compounds.

In this paper, we report the successful devolepment of a rational self-sacrificing template route to prepare spinel $M^{II}In_2S_4$ ($M^{II}$ = Mn, Zn, Cd, Fe, Co, Ni) and $M^{I}In_5S_8$ ($M^{I}$ = Cu, Ag) porous microspheres at low temperature (180 °C). The precursor $In_{2.77}S_4$ was obtained by a convenient mixed-solvent/thermal method at 160 °C in an "aqueous solution/water-immiscible organic solvent" system

using $InCl_3{\cdot}4H_2O$ and thiourea (Tu) as the starting materials and a water-immiscible organic solvent (WIOS) plus distilled water as the solvent.

## Results and Discussion

Figure 1 shows the XRD patterns of the as-obtained samples. The XRD pattern of the precursor is shown in Figure 1a; it can be indexed to the cubic spinel structure $In_{2.77}S_4$ with lattice constant $a$ = 10.74 Å, consistent with reported values (JCPDS card file No. 88-2495: $a$ = 10.72 Å). The XRD patterns shown in Figure 1b–i can be indexed to cubic spinel structure $MnIn_2S_4$ (JCPDS card file No. 85-1229), $ZnIn_2S_4$ (48-1778), $CdIn_2S_4$ (27-0060), $FeIn_2S_4$ (80-0608), $CoIn_2S_4$ (79-1015), $NiIn_2S_4$ (79-1016), $CuIn_5S_8$ (24-0361), and $AgIn_5S_8$ (24-1477). All nine XRD patterns are very similar as they have the same crystal structure. No characteristic peaks for other impurities, such as metal sulfides ($In_2S_3$) are observed. The composition of the samples was further analyzed by ICP. The results reveal that the molar ratio of $M^{II}$ ($M^{II}$ = Mn, Zn, Cd, Fe, Co, Ni) to In and S, and $M^{I}$ ($M^{I}$ = Cu, Ag) to In and S is 1:2.03:4.08, 1:1.95:4.03, 1:1.99:4.05, 1:2.02:4.08, 1:2.02:4.07, 1:1.96:3.99, 1:4.91:7.96, and 1:4.96:8.03, respectively.

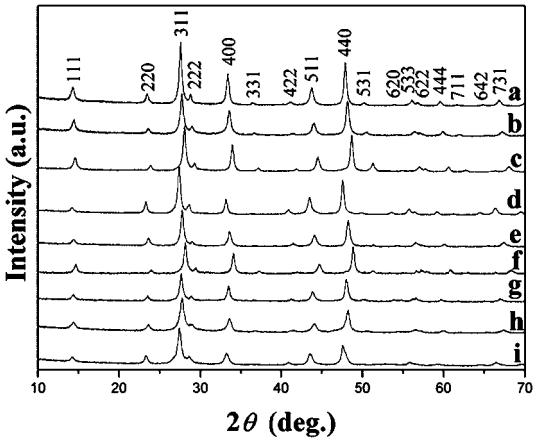

Figure 1. XRD patterns of the as-prepared $In_{2.77}S_4$ precursor (a), $MnIn_2S_4$ (b), $ZnIn_2S_4$ (c), $CdIn_2S_4$ (d), $FeIn_2S_4$ (e), $CoIn_2S_4$ (f), $NiIn_2S_4$ (g), $CuIn_5S_8$ (h), and $AgIn_5S_8$ (i).

Figures 2a and b show SEM images of the as-synthesized precursor $In_{2.77}S_4$ sample, and reveal that the product consists of large-scale porous spheres with a large size distribution (1–6 μm in diameter). It is obvious that the sphere is built up by many interconnected slightly bending flakes with a thickness of about 60 nm, which entangle together to form a network on the surface of the sphere (Figure 2b). Figure 2c is the TEM image of this sample and the inset is the high-magnification TEM image of the surface of the porous microspheres. These images further confirm the spherical urchin-like architecture of the product and the flakes on the surface can also be clearly observed. The corresponding ED patterns in Figure 2d show several diffraction rings, which can be characterized as the (111), (220), (311), (400), (511), and (440) planes (from inner to outer) and further reveal the cubic spinel structure of the product.

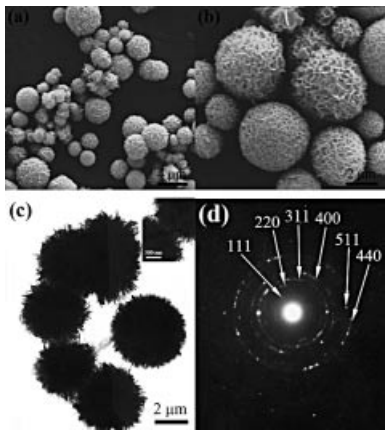

Figure 2. (a), (b) SEM images of the as-prepared $In_{2.77}S_4$ precursor. (c) TEM image of the as-prepared $In_{2.77}S_4$ precursor (inset: TEM image at high magnification). (d) Corresponding ED patterns.

Figure 3 shows an SEM image of the as-synthesized $MnIn_2S_4$ sample using the $In_{2.77}S_4$ precursor as the reactant. It can be seen that the product also consists of porous microspheres, on the surface of which a network of interconnected bending flakes has formed (the SEM image at high magnification is shown in the inset). The TEM images shown in Figures 3b and c also show evidence for the morphological structure, and the corresponding ED patterns (inset of Figure 3b) also reveal that the $MnIn_2S_4$ product has a cubic spinel structure.

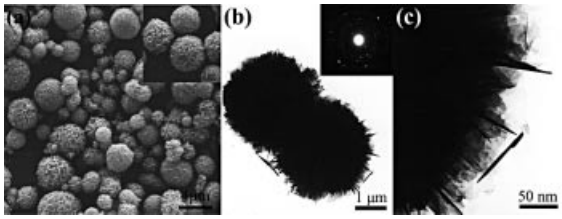

Figure 3. (a) SEM and (b), (c) TEM images of the as-synthesized $MnIn_2S_4$ sample [inset of (a): SEM image at high magnification; inset of (b): corresponding ED patterns].

The SEM images of the other samples, viz. $ZnIn_2S_4$, $CdIn_2S_4$, $FeIn_2S_4$, $CoIn_2S_4$, $NiIn_2S_4$, $CuIn_5S_8$, and $AgIn_5S_8$, are displayed in Figures 4a–h. They all have the same morphology (porous microspheres) as those in Figure 2, which implies that these $M^{II}In_2S_4$ ($M^{II}$ = Mn, Zn, Cd, Fe, Co, Ni) and $M^{I}In_5S_8$ ($M^{I}$ = Cu, Ag) products still keep the morphology of the $In_{2.77}S_4$ precursor. It is therefore reasonable to deduce that the precursor $In_{2.77}S_4$ porous microspheres play a critical role in the formation of the morphology of the final products.

The surface areas of the as-prepared representative products were determined by the BET method. The BET surface areas of the $In_{2.77}S_4$ precursor and $MnIn_2S_4$, $ZnIn_2S_4$, $FeIn_2S_4$, and $CuIn_5S_8$ are 73.6906, 63.6089, 73.4746, 66.9709, and 62.4300 $m^2 g^{-1}$.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

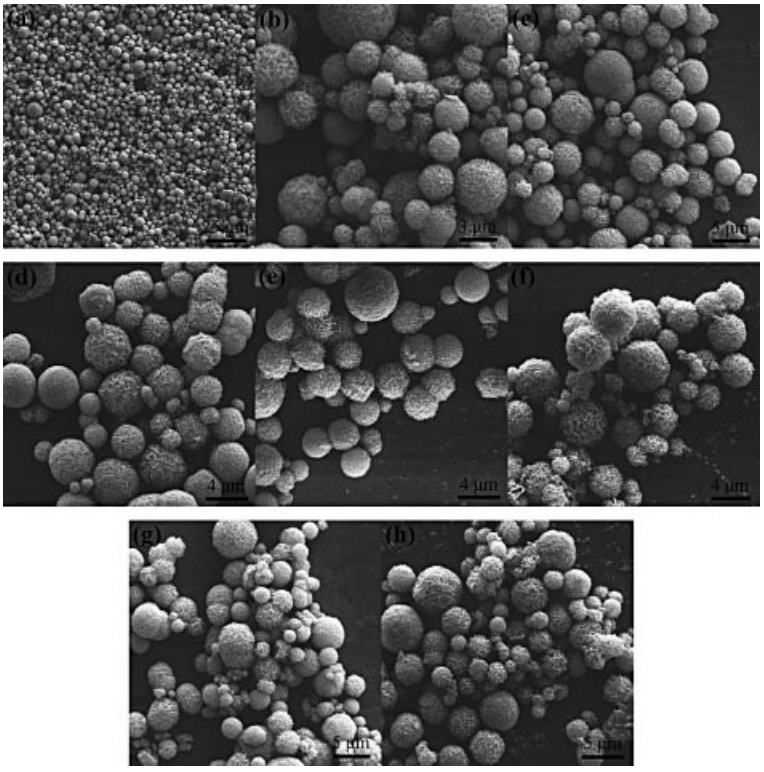

Figure 4. SEM images of as-synthesized (a), (b) $ZnIn_2S_4$, (c) $CdIn_2S_4$, (d) $FeIn_2S_4$, (e) $CoIn_2S_4$, (f) $NiIn_2S_4$, (g) $CuIn_5S_8$, and (h) $AgIn_5S_8$.

Based on the experiments, a possible formation process of $M^{II}In_2S_4$ and $M^{I}In_5S_8$ in this reaction system can be proposed. The reaction of Tu with $H_2O$ can release $S^{2-}$ ions,[39,40] which react with metal ions ($Mn^{2+}$, $Zn^{2+}$, $Cd^{2+}$, $Fe^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Cu^{+}$, $Ag^{+}$) to produce $M^{II}S$ or $M_2^{I}S$. The subsequent reaction of $In_{2.77}S_4$ with $M^{II}S$ or $M_2^{I}S$ results in the formation of $M^{II}In_2S_4$ or $M^{I}In_5S_8$. These processes can be summarized as follows:

$NH_2CSNH_2$ (Tu) + 2 $H_2O \rightarrow H_2S + 2\ NH_3 + CO_2$

$M^{2+} + S^{2-} \rightarrow M^{II}S$ or $M^{+} + S^{2-} \rightarrow M^{I}{}_2S$

$In_2S_3$ ($In_{2.77}S_4$) + $M^{II}S \rightarrow M^{II}In_2S_4$ or 5 $In_2S_3$ ($In_{2.77}S_4$) + $M^{I}{}_2S \rightarrow 2\,M^{I}In_5S_8$

Actually, the spinel structure $In_{2.77}S_4$ can be represented by $(In_{1-x})(In_2)S_4$. When it reacts with metal sulfides, some metal atoms (Mn, Zn, Cd, Fe, Co, Ni, Cu, Ag) occupy part of the tetrahedral sites and the rest of the metal atoms occupy part of the octahedral sites to form the $(M^{II}{}_xIn_{1-x})$-$(M^{II}{}_{1-x}In_{1+x})S_4$ or $(M^{I}{}_{1/2-x}In_{1/2+x})(M^{I}{}_xIn_{2-x})S_4$ spinel structure.

Interestingly, if the $In_{2.77}S_4$ precursor is replaced by the appropriate amount of $InCl_3{\cdot}4H_2O$ and Tu, directly mixed with the metal ($M^{II}$ or $M^{I}$) salt, and loaded into an autoclave, then the product was not pure $M^{II}In_2S_4$ or $M^{I}In_5S_8$. For the synthesis of $MnIn_2S_4$ only $In_{2.77}S_4$ is obtained here, whereas in other procedures unreacted $M^{II}S$ and $M^{I}{}_2S$ impurities still exist, which increases the reaction time and the amount of Tu needed.

The amount of distilled water is also a crucial factor for the formation of pure $M^{II}In_2S_4$ or $M^{I}In_5S_8$. When the volume of distilled water in the reaction system reached 1 mL, $In(OH)_3$ impurities could be observed, which may result from the hydrolysis of the $In_{2.77}S_4$ precursor.

From the above analyses, it can be seen that the $In_{2.77}S_4$ precursor may serve as a "self-sacrificing template" to confine the formation of the $M^{II}In_2S_4$ and $M^{I}In_5S_8$ porous microspheres. To investigate the template effect of the $In_{2.77}S_4$ precursor, some contrast experiments were performed. During the preparation of the $In_{2.77}S_4$ precursor, increasing of the volume of distilled water to 10–40 mL caused the formation of $In_{2.77}S_4$ porous microspheres (marked with arrow I) and smooth microspheres (marked with arrow II) simultaneously, as shown in Figure 5a. When this $In_{2.77}S_4$ precursor was used as the reactant, the obtained $M^{II}In_2S_4$ and $M^{I}In_5S_8$ samples also consisted of porous microspheres (marked with arrow I) and smooth microspheres (marked with arrow II), as shown in Figures 5b and c. The final products still kept the morphology of the precursor, which confirmed the self-sacrificing template effect of the $In_{2.77}S_4$ precursor.

A possible growth mechanism for the porous architecture of the $In_{2.77}S_4$ precursor and obtained $M^{II}In_2S_4$ and $M^{I}In_5S_8$ can also be tentatively proposed. During the synthesis of the $In_{2.77}S_4$ precursor, small $In_{2.77}S_4$ spheres are formed first in the "aqueous solution/water-immiscible organic solvent" system because of the interfacial tension. Subsequently, the $[In(Tu)_n]Cl_3$ complex solution[41] reacts on the surface of the spheres to form $In_{2.77}S_4$ flakes in different directions. These flakes then collide with each other and yield an entangled network morphology. Upon interleaving,

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

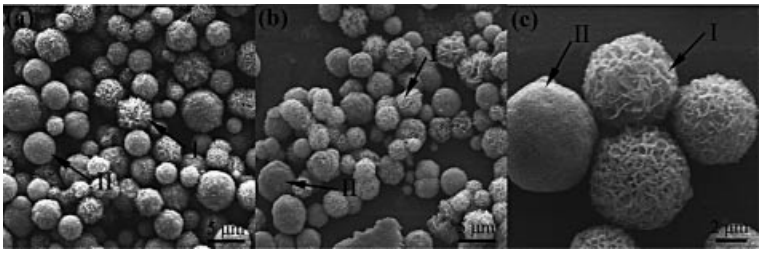

Figure 5. SEM images of (a) as-prepared $In_{2.77}S_4$ precursor with the amount of distilled water increased to 10–40 mL and (b), (c) the $MnIn_2S_4$ sample produced using a mixture of porous and smooth microspheres of $In_{2.77}S_4$ as the reactant.

these newly formed thin flake interfaces become strongly undulated, which results in a slight bending of the flakes in order to relax the strain due to the elongation of the flakes.[42] This process continues until the spheres become completely covered, thereby minimizing the interfacial free energy, to finally give the $In_{2.77}S_4$ porous spheres.[43] Subsequent reaction of the metal salts and Tu on the interface of the $In_{2.77}S_4$ porous spheres gives the final $M^{II}In_2S_4$ and $M^{I}In_5S_8$ porous microspheres. When the amount of distilled water is increased in the preparation of the $In_{2.77}S_4$ precursor, the volume of the aqueous solution increases and many of the initial $In_{2.77}S_4$ spheres are unable to form an interface with the water-immiscible organic solvent, which results in the coexistence of smooth and porous $In_{2.77}S_4$ spheres (Figure 5a). Actually, our experiments showed that the smooth $In_{2.77}S_4$ microspheres occur in the product when the volume of distilled water is above 10 mL. All the obtained $In_{2.77}S_4$ samples consist of porous microspheres and smooth microspheres when the volume of distilled water is in the range 10–40 mL.

## Conclusions

In summary, porous microspheres of the ternary semiconductors $M^{II}In_2S_4$ ($M^{II}$ = Mn, Zn, Cd, Fe, Co, Ni) and $M^{I}In_5S_8$ ($M^{I}$ = Cu, Ag) have been successfully synthesized by a simple self-sacrificing template method using $In_{2.77}S_4$ porous microspheres as the starting material. The possible formation process for the product and a growth mechanism for the porous architecture have been tentatively proposed and discussed in detail. This novel synthesis is performed under ambient conditions and can be easily operated. It is expected to be extendable to the synthesis of other ternary inorganic compounds.

## Experimental Section

**General:** All chemical reagents were of analytical grade, purchased from Shanghai Chemical Reagent Company and used without further purification.

**Preparation of the Precursor $In_{2.77}S_4$ Porous Microspheres:** In a typical procedure, 2 mmol of $InCl_3{\cdot}4H_2O$ (0.586 g) and a slight excess of Tu (0.25 g) were put into a Teflon-lined autoclave of 60 mL capacity and dissolved in 2–3 mL of distilled water to form a solution. The autoclave was then filled with a water-immiscible organic solvent (WIOS, e.g. benzene, toluene, hexane, cyclohexane) up to 90% of the total volume, sealed, and maintained at 160 °C for 12 h. After cooling to room temperature naturally, the final products were filtered off, washed with absolute ethanol and distilled water several times, and then dried under vacuum at 60 °C for 4 h. An orange-red powder was obtained.

**Preparation of $M^{II}In_2S_4$ ($M^{II}$ = Mn, Zn, Cd, Fe, Co, Ni) and $M^{I}In_5S_8$ ($M^{I}$ = Cu, Ag) Porous Microspheres:** A given amount of divalent metal salt [$MnCl_2{\cdot}4H_2O$, $Zn(CH_3COO)_2{\cdot}2H_2O$, $CdCl_2{\cdot}2.5H_2O$, $FeSO_4{\cdot}7H_2O$, $CoCl_2{\cdot}6H_2O$, $NiCl_2{\cdot}6H_2O$] or univalent metal salt (CuCl or $AgNO_3$), the $In_{2.77}S_4$ precursor, Tu, and 2–3 drops of distilled water were loaded into the Teflon-lined autoclave, which was then filled with WIOS up to 90% of the total volume, sealed, and maintained at 180 °C for 20 h. After cooling to room temperature naturally, the products were filtered off, washed with absolute ethanol and distilled water several times to remove impurities, and dried in vacuo at 60 °C for 4 h.

**Sample Characterization:** The X-ray powder diffraction (XRD) patterns were recorded with a Philips X'pert PRO SUPER diffractometer with Cu-$K_\alpha$ radiation ($\lambda$ = 1.541874 Å). Direct elemental analysis was performed by inductively coupled plasma-atomic emission spectrometry (ICP-AES) using an Atomscan Advantage (Thermo Jarrell Ash Corporation) instrument. The SEM images were taken with an X-650 scanning electronic microanalyzer. The TEM images and electron diffraction (ED) patterns were obtained with a Hitachi H-800 transmission electron microscope, at an accelerating voltage of 200 kV. For TEM investigation, one or two drops of the solution containing the as-prepared composites were deposited onto an amorphous carbon film supported on a copper grid and allowed to dry at room temperature in air. The surface areas of the samples were evaluated from nitrogen adsorption data by the Brunauer–Emmett–Teller (BET) technique at 77 K with a Micromeritics ASAP 2000 analyzer.

# Hydrothermal Syntheses, Architectures and Magnetic Properties of Six Novel $Mn^{II}$ Coordination Polymers with Mixed Ligands

**Chang-Yan Sun,[a] Song Gao,*[b] and Lin-Pei Jin*[a]**

**Keywords:** Coordination polymers / Magnetic properties / Manganese / Microporous materials / Organic–inorganic hybrid composites

Six novel manganese(II) coordination polymers, namely $[Mn(oba)(4,4'\text{-bpy})]_n \cdot n(4,4'\text{-bpy})$ (**1**), $[Mn(oba)(phen)(H_2O)]_n$ (**2**), $[Mn_2(oba)_2(2,2'\text{-bpy})_2(H_2O)_2]_n \cdot nH_2oba$ (**3**), $[Mn_2(cca)_2(4,4'\text{-bpy})_2]_n \cdot 2n(4,4'\text{-bpy})$ (**4**), $[Mn(cca)(phen)]_n$ (**5**) and $[Mn(cca)(2,2'\text{-bpy})]_n \cdot 0.25nH_2O$ (**6**) [$H_2oba$ = 4,4′-oxybis(benzoic acid); 4,4′-bpy = 4,4′-bipyridine; phen = 1,10-phenanthroline; 2,2′-bpy = 2,2′-bipyridine; $H_2cca$ = *p*-carboxycinnamic acid] have been synthesised under hydrothermal conditions. Complexes **1** and **4** possess 3D microporous metal-organic frameworks with free 4,4′-bpy ligands in the channels. The $Mn^{II}$ ions in complex **2** are bridged into 1D infinite double-chain structures, and those in complex **3** are bridged into 1D zigzag chains. Hydrogen bonds cause the formation of 3D supramolecular networks for complexes **2** and **3**. Complex **5** is a complicated 3D metal-organic framework, and the $Mn^{II}$ ions in complex **6** are linked into 2D layers with cavities; interpenetration of these 2D layers results in the formation of a 3D supramolecular network. Magnetic susceptibility measurements indicate that complex **2** displays a weak ferromagnetic interaction between the $Mn^{II}$ ions with the following parameters: $J$ = 0.462(3) $cm^{-1}$, $g$ = 2.0387(6), $zJ'$ = –0.0062(3) $cm^{-1}$ and $R = 8.0 \times 10^{-6}$. Complex **4** shows antiferromagnetic coupling between the $Mn^{II}$ ions with $J$ = –0.718(4) $cm^{-1}$, $g$ = 1.986(4) and $R = 2.3 \times 10^{-4}$.

## Introduction

Manganese-based coordination compounds have received considerable interest in the fields of supramolecular chemistry, crystal engineering and materials chemistry. This interest arises not only from their remarkable magnetochemical properties,[1] but also from their rich biochemistry.[2] Furthermore, due to their low cost and toxicity, manganese coordination compounds are growing in importance as homogeneous catalysts.[3] As far as we know, the current focus is on the construction of molecule-based magnetic materials. The main approach is to employ short bridging ligands to connect manganese ions. These short ligands, such as azide,[4] cyanide[5] and oxalate,[6] efficiently mediate the magnetic coupling. Long bridging ligands, because of their large separation and thus their inefficiency in transmitting magnetic interactions, have seldom been used to construct manganese coordination compounds.

It is well-known that the topology of coordination compounds depends both on the coordination geometry of the metal centres and on the coordination behaviour of the organic ligands. When long bridging ligands are used to connect metal ions, their versatile coordination modes may lead to new architectures with novel topologies and interesting properties.

4,4′-Oxybis(benzoic acid) ($H_2oba$) is a typical example of long V-shaped ligands. Its coordination chemistry has been studied and some coordination polymers have been obtained.[7] Because of its two oxo carboxylate groups, $H_2oba$ can coordinate to metal ions in didentate, tridentate, tetradentate, pentadentate and hexadentate modes. *p*-Carboxycinnamic acid ($H_2cca$) also has two oxo carboxylate groups. There is only one cobalt(II) complex known with $H_2cca$,[8] and we are interested in the architecture of metal complexes with this asymmetrical functional carboxylate ligand.

The choice of a suitable co-ligand often has a significant effect on the formation and structure of metal complexes. 4,4′-Bipyridine (4,4′-bpy) has been demonstrated to be one of the most important rigid linear co-ligands and has been extensively used to connect metal ions.[9] Chelating N-containing aromatic ligands, such as 2,2′-bipyridine (2,2′-bpy) and 1,10-phenanthroline (phen), can not only affect the coordination geometry of metal ions but also bring about π-π stacking interactions, which are important for the construction of supramolecular networks.[10]

Taking into account the above-mentioned aspects, we report here the syntheses, structures and magnetic properties

of six novel $Mn^{II}$ coordination compounds, namely $[Mn(oba)(4,4'\text{-bpy})]_n \cdot n(4,4'\text{-bpy})$ (**1**), $[Mn(oba)(phen)(H_2O)]_n$ (**2**), $[Mn_2(oba)_2(2,2'\text{-bpy})_2(H_2O)_2]_n \cdot nH_2oba$ (**3**), $[Mn_2(cca)_2\ (4,4'\text{-bpy})_2]_n \cdot 2n(4,4'\text{-bpy})$ (**4**), $[Mn(cca)(phen)]_n$ (**5**) and $[Mn(cca)(2,2'\text{-bpy})]_n \cdot 0.25nH_2O$ (**6**). All six coordination polymers contain long spacers (oba/cca) and co-ligands (4,4′-bpy/phen/2,2′-bpy), and possess very different structures, ranging from 1D chains to 2D layers and 3D metal-organic frameworks.

## Results and Discussion

### Description of the Structures

#### *[Mn(oba)(4,4′-bpy)]$_n$·n(4,4′-bpy) (1)*

Complex **1** is a 3D porous coordination polymer containing channels with guest 4,4′-bpy molecules. There is only one metal environment in complex **1**, as shown in Figure 1. Each $Mn^{II}$ ion is coordinated to four oxygen atoms of four oba ligands and two nitrogen atoms of two 4,4′-bpy ligands, and is located in a slightly distorted octahedral geometry. The average Mn–N bond length is 2.322 Å and the Mn–O bond lengths are in the range 2.147–2.162 Å. Each oba ligand in complex **1** is severely bent at the ether-oxygen site (C–O–C = 118.6°) and adopts a bis(bridging didentate) mode, linking four $Mn^{II}$ ions (see Scheme 1a). All $Mn^{II}$ ions are connected by oba ligands into 2D pillar-like layers. The nearest Mn···Mn distance in these layers is 4.835 Å. The 4,4′-bpy ligands bridge these layers into a 3D porous framework with channels of about 11 × 14 Å (based on the distance between metal ions), as shown in Figure 2. The channels are big enough to accommodate free 4,4′-bpy molecules.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *[Mn(oba)(phen)($H_2O$)]$_n$ (2)*

Figure 3 shows the coordination environment of the $Mn^{II}$ ions in complex **2**. The coordination geometry around each $Mn^{II}$ ion is $N_2O_4$, with three oxygens from three oba ligands, one oxygen from a coordinated water molecule and two nitrogens from one phen ligand, and can be described as a distorted octahedron. The average Mn–N bond length is 2.271 Å and the Mn–O bond lengths are in the range 2.107–2.158 Å. The oba ligands are also bent (C–O–C: 118.6°), as in complex **1**. The coordination modes in complexes **1** and **2**, however, are different as each oba ligand in complex **2** adopts a tridentate mode, linking three $Mn^{II}$ ions, as shown in Scheme 1b. This coordination mode has not been reported before. The bridging carboxylate oxygen atoms cause the formation of the building blocks of $Mn_2O_2$ cores, in which the Mn···Mn distance is 3.387 Å (Mn–O–Mn angle: 101.81°). These cores are interconnected by oba ligands into 1D double-chain structures. A similar structure has been reported for [Zn(bpndc)(phen)($H_2O$)]$_n$.[11] There are hydrogen bonds between the coordinated water molecules and the uncoordinated carboxylate oxygen atoms (O···O distances of 2.697 and 2.740 Å). In addition, weak π-π stacking interactions exist between phen molecules of neighbouring chains, with an average distance of 3.53 Å. Both the hydrogen bonds and π-π stacking interactions result in the formation of a 3D supramolecular network with channels of about 3 × 13 Å. This is small and means that it is unable to incorporate any guest molecules.

### *[$Mn_2$(oba)$_2$(2,2′-bpy)$_2$($H_2O$)$_2$]$_n$·n$H_2$oba (3)*

There are two kinds of crystallographically different $Mn^{II}$ ions in complex **3**, as shown in Figure 4. Both Mn(1) and Mn(2) are coordinated to three oxygen atoms of two oba ligands, one from a coordinated water molecule and two nitrogen atoms of a 2,2′-bpy ligand, but their bond lengths and bond angles are different. The average Mn(1)–N bond length is 2.261 Å and the Mn(1)–O bond lengths are in the range 2.085–2.408 Å, while the average Mn(2)–N bond length is 2.242 Å and the Mn(2)–O bond lengths are in the range 2.095–2.363 Å. Mn(1) and Mn(2) are bridged by an oba ligand with a distance of 14.365 Å. There are three kinds of oba ligands in complex **3**, two of which coordinate in a tridentate mode linking two $Mn^{II}$ ions (see Scheme 1c). They are bent at the ether-oxygen sites (C–O–C = 118.4° and 119.9°), and connect the $Mn^{II}$ ions into 1D infinite zigzag chains (the Mn···Mn distance within a chain is 14.365 Å). The third kind of oba ligand is protonated and does not coordinate to $Mn^{II}$. It is also bent at the ether-oxygen sites, with a C–O–C angle of 120.2°. There are hydrogen bonds between the coordinated water molecules and the coordinated oba/free $H_2$oba ligands (O···O distances of

2.896, 2.753 and 2.855 Å), forming a 3D supramolecular network, as shown in Figure 5.

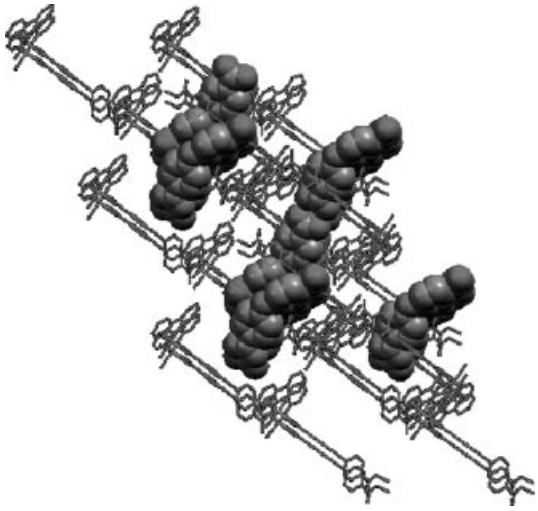

Figure 5. The 3D supramolecular network of complex **3** viewed along the *a* axis, with space-filling models representing the free $H_2$oba ligands.

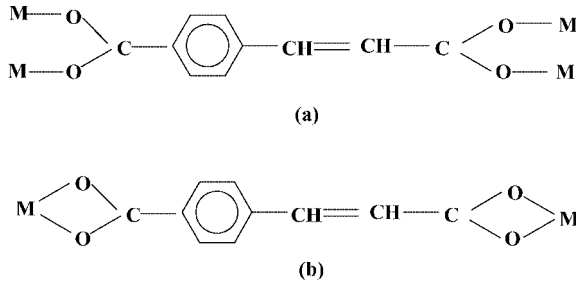
### *[Mn$_2$(cca)$_2$(4,4′-bpy)$_2$]$_n$·2n(4,4′-bpy) (4)*

Complex **4** possesses a 3D porous metal-organic framework whose channels contain free 4,4′-bpy molecules. Similar to complex **3**, there are two types of $Mn^{II}$ environments (see Figure 6). Both Mn(1) and Mn(2) are coordinated to four oxygen atoms of four cca ligands and two nitrogen atoms of two 4,4′-bpy molecules, and are located in slightly distorted octahedra. However, their bond lengths and angles are different. The Mn(1)–N bond length is 2.275 Å and the Mn(1)–O bond lengths are in the range 2.152–2.173 Å, while the Mn(2)–N bond length is 2.299 Å and the Mn(2)–O bond lengths are in the range 2.166–2.197 Å. Mn(1) and Mn(2) are bridged by two carboxylate groups of two cca ligands with a distance of 5.112 Å. Each cca ligand in complex **4** adopts a tetradentate mode, linking four $Mn^{II}$ ions (see Scheme 2a). All $Mn^{II}$ ions are connected by cca ligands into 2D pillar-like layers. These layers are interconnected by 4,4′-bpy ligands, resulting in the formation of a 3D porous framework with channels of about 11 × 11 Å, similar to those in complex **1**. These channels contain free 4,4′-bpy molecules.



Scheme 2. The coordination modes of the cca ligands in complexes **4**–**6**.

### *[Mn(cca)(phen)]$_n$ (5)*

There is only one metal environment in complex **5**, as shown in Figure 7. Each $Mn^{II}$ ion is placed in a distorted octahedron, which is completed by four oxygen atoms of four cca ligands and two nitrogen atoms of one phen molecule with the same Mn–N distance. The Mn–N bond length is 2.317 Å and the Mn–O bond lengths are in the range 2.094–2.203 Å. Each cca ligand adopts a tetradentate mode, linking four $Mn^{II}$ ions (see Scheme 2a). The nearest Mn···Mn distance is 4.587 Å. All $Mn^{II}$ ions are linked by cca ligands into a 3D metal-organic framework with 1D channels. However, chelating phen ligands occupy the diagonal position, which greatly decreases the dimension of the

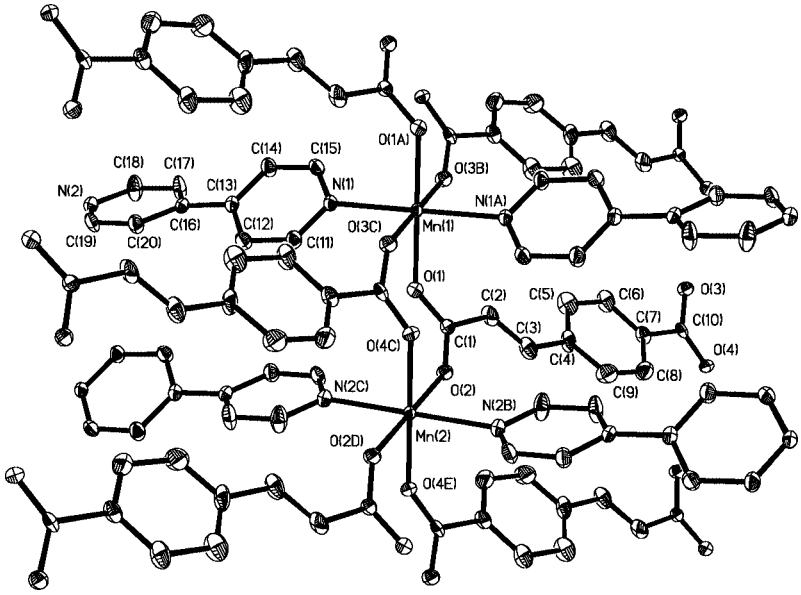


Figure 6. The coordination environments of the $Mn^{II}$ ions in complex **4** with 30% thermal ellipsoids. All hydrogen atoms have been omitted for clarity.

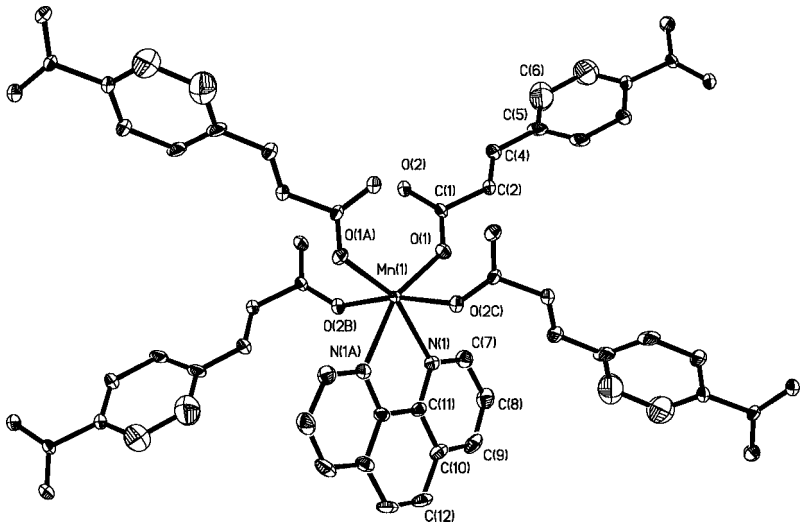

Figure 7. The coordination environment of the $Mn^{II}$ ion in complex **5** with 30% thermal ellipsoids. All hydrogen atoms have been omitted for clarity.

channels. All phen rings are parallel to each other, and the nearest face-to-face distance is 3.29 Å, indicating the presence of π-π stacking interactions.

### *[Mn(cca)(2,2′-bpy)]$_n$·0.25n$H_2O$ (6)*

Because of the disorder of the cca ligands, there are four types of $Mn^{II}$ environment. Figure 8 shows one of them, and the others can be found in the Supporting Information (Figures S1–S3). Each $Mn^{II}$ ion is coordinated to four oxygen atoms of three cca ligands and two nitrogen atoms of one 2,2′-bpy molecule. The cca ligands in complex **6** adopt two kinds of coordination modes, namely bis(bridging didentate) and bis(chelating didentate) (see Scheme 2). The dinuclear species $[Mn_2(cca)_2(2,2'\text{-bpy})_2]$, which has a metal–metal distance of 4.462 Å, can be regarded as a secondary building block. These moieties are linked by cca ligands into 2D grid-like layers with cavities of about 12 × 13 Å, and the 2D layers are interpenetrated, resulting in the formation of a 3D supramolecular network in which weak π-π stacking interactions between 2,2′-bpy molecules (the nearest distance is 3.29 Å) further stabilize the supramolecular structure.

It is obvious from the above descriptions that the carboxylate ligands and the co-ligands have significant effects on the formation and architecture of the resulting complexes. The structures of these six complexes can be simplified as shown in Scheme 3. Although complexes **1**, **2** and **3** contain the same carboxylate ligand oba, they possess different structures. In complex **1**, both V-shaped oba and linear 4,4′-bpy ligands work as bridging ligands, resulting in the formation of a 3D porous structure. The free 4,4′-bpy ligands may be one of the important factors for the construction of the porous structure as they might function as templates and occupy the pores, thus preventing further interpenetration. Complexes **2** and **3** possess infinite 1D chains, which may be attributed to the existence of the terminal ligands phen/2,2′-bpy/$H_2O$. These terminal ligands occupy the coordination sites of the metal ions and prevent the

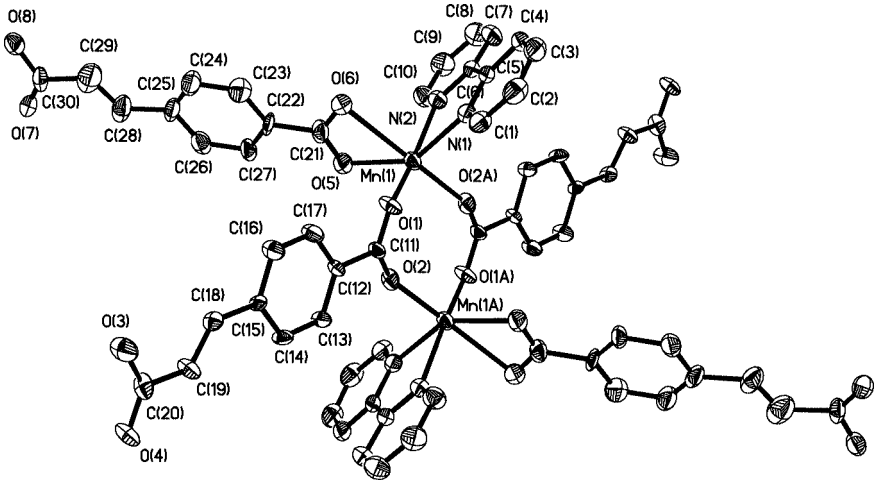

Figure 8. The coordination environment of the $Mn^{II}$ ion in complex **6** with 30% thermal ellipsoids. All hydrogen atoms have been omitted for clarity.

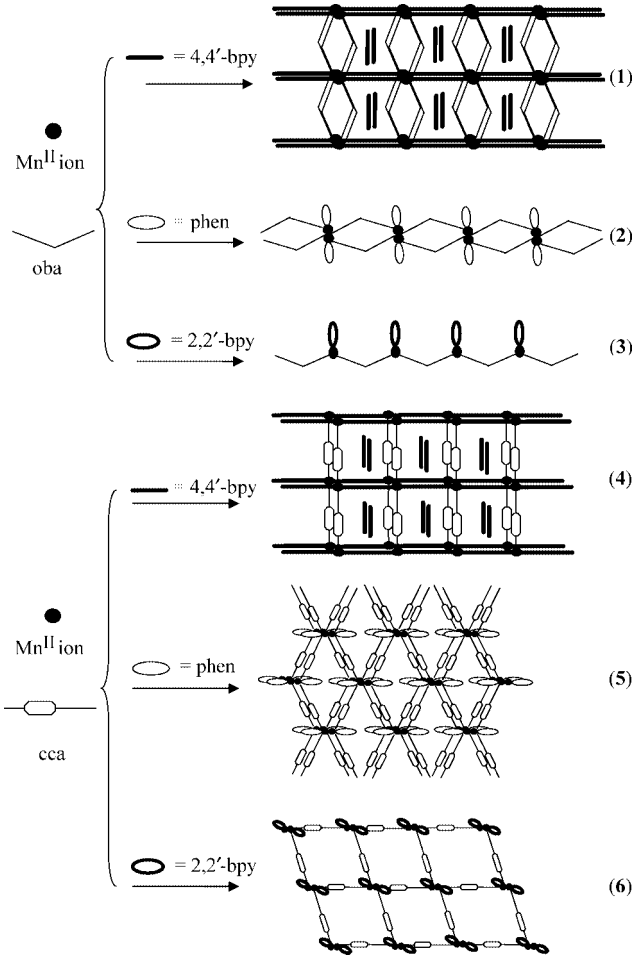
 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structures from extending into higher dimensions. Complex **2** has a double-chain structure while complex **3** has a single-chain structure because the oba ligands adopt different coordination modes in the two complexes (see Scheme 1 i and b). When the oba ligand is replaced by cca, we obtain the box-like structure of complex **4**. Both cca and 4,4′-bpy are bridging ligands that link metal ions into a 3D porous structure. The presence of free 4,4′-bpy works as template, promoting the formation of the 3D porous structure. However, with the terminal ligand phen, complex **5** possesses a 3D metal-organic framework due to the tetradentate bridging ligand cca, and in complex **6** the introduction of 2,2′-bpy as a ligand leads to 2D grid-like layers, where hydrogen bond and π-π stacking interactions result in a 3D supramolecular network.



Scheme 3. A simplified representation of the structures of complexes **1**–**6**.

Both oba and cca have two *exo* carboxylate groups, but there are some differences in their complexes. Comparing complexes **1** and **4**, although they are both 3D porous structures they are quite different: complex **1** possesses dumbbell-like channels while complex **4** possesses regular rhombus channels. This is because oba is V-shaped whereas cca is nearly linear. The introduction of phen and 2,2′-bpy as ligands in the $Mn^{II}$/oba and $Mn^{II}$/cca systems results in different structures. Complexes **2** and **3** are infinite 1D chains, while complex **5** possesses a complicated 3D structure and complex **6** is made up of 2D grid-like layers when only coordination bonds are considered. The existence of coordinated water molecules in complexes **2** and **3** is one important factor for the formation of the chain structures. The V-shaped oxo carboxylate ligand oba is also fundamental for the construction of chains in the presence of terminal ligands such as phen and 2,2′-bpy,[7a,7b,7e] while the linear ligand cca contributes to higher dimensionalities in complexes **5** and **6**, thus showing that the shape of the ligands plays an important role in the architecture of coordination polymers.

## Magnetic Properties

### *Magnetic Properties of Complex 2*

The $\chi_m^{-1}$ and $\chi_m T$ vs. $T$ plots (2–300 K) of complex **2** are shown in Figure 9. The magnetic susceptibility data (10 to 300 K) of complex **2** obey the Curie–Weiss law very well, with a Weiss constant, $\theta$, of +3.2 K and a Curie constant, $C$, of 4.554(1) $cm^3 K mol^{-1}$. The value of $C$ is consistent with one spin-only $Mn^{II}$ ion with $S = 5/2$ and $g = 2.040$. The positive Weiss constant and the increase of $\chi_m T$ upon cooling are typical of a ferromagnetic coupling between the $Mn^{II}$ ions. Based on the structural data, the magnetic susceptibility data of complex **2** can be analysed by using a $Mn_2$ dimer model with an intradimer interaction $J$ and including the contribution of the intermolecular interaction $zJ'$. Assuming an isotropic exchange, the exchange Hamiltonian $H = -2JS_1S_2$, with $S_1 = S_2 = 5/2$, and the expression for magnetic susceptibility may be used to fit the data.[12] The least-squares fit of the experimental data in the whole temperature range gives the following parameters: $J$ = 0.462(3) $cm^{-1}$, $g$ = 2.0387(6), $zJ'$ = –0.0062(3) $cm^{-1}$, and $R = 8.0 \times 10^{-6}$.

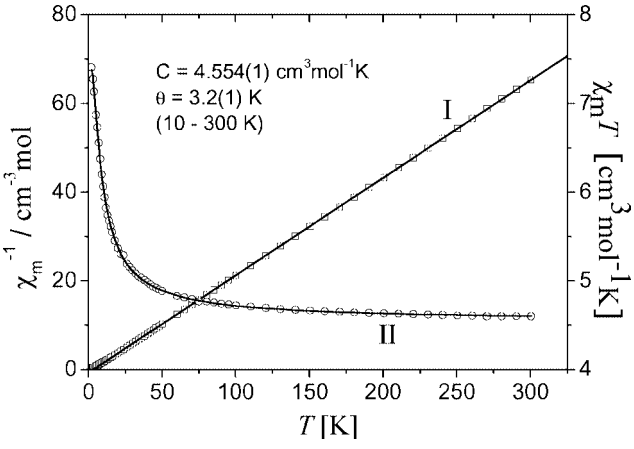


Figure 9. Temperature dependence of $\chi_m^{-1}$ and $\chi_m T$ for complex **2**. Line I is the fit of the Curie–Weiss law and line II is the fit using a dimer model (see text).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Clearly, a weak ferromagnetic interaction is observed in the doubly (μ-O)-carboxylate bridged $Mn^{II}$ dimer, while some structurally similar $Mn^{II}$ dimers show weak antiferromagnetic coupling between the $Mn^{II}$ ions (Table 1).[13] The ferromagnetic coupling in complex **2** may be mainly due to the smaller Mn–O–Mn angle, which facilitates ferromagnetic coupling as in some azido- or chloro-bridged $Mn^{II}$ dimers.[14]

Table 1. Comparison of the magnetic coupling constant $J$ and structural parameters for $Mn^{II}_2(\mu\text{-}O)_2$ complexes.

| Compd. | $J$ [$cm^{-1}$] | Mn···Mn [Å] | Mn–O–Mn [°] | Ref. |
|---|---|---|---|---|
| A | –0.631 | 3.712(2) | 109.1(3), 109.8(3) | [13a] |
| B | –0.655 | 3.726(4) | 108.9(3) | [13a] |
| C | –0.785 | 3.460(1) | 105.04(7), 102.77(7) | [13b] |
| D | +0.462 | 3.387(12) | 101.81(7) | this work |

### *Magnetic Properties of Complex 3*

The $\chi_m^{-1}$ and $\chi_m T$ vs. $T$ plots (2–300 K) of complex **3** are shown in Figure 10. The magnetic susceptibility data (2 to 300 K) of complex **3** obey the Curie–Weiss law very well with a very small Weiss constant of 0.09 K and a Curie constant of 9.004(1) $cm^3\,K\,mol^{-1}$. The value of $C$ is consistent with two non-interacting spin-only $Mn^{II}$ ions with $S$ = 5/2 and $g$ = 2.029. The very small Weiss constant suggests essentially no magnetic coupling between the $Mn^{II}$ ions, which is consistent with the long separation between the $Mn^{II}$ ions in this complex. The peak around 50 K might arise from the effect of oxygen.[15]

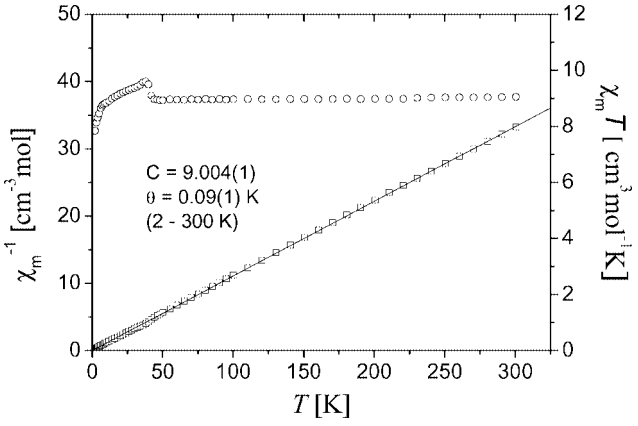

Figure 10. Temperature dependence of $\chi_m^{-1}$ and $\chi_m T$ for complex **3**. The line is the fit of the Curie–Weiss law.

### *Magnetic Properties of Complex 4*

The $\chi_m^{-1}$ and $\chi_m$ vs. $T$ plots (2–300 K) of complex **4** are shown in Figure 11. The magnetic susceptibility data (20 to 300 K) of complex **4** obey the Curie–Weiss law very well with a Weiss constant of –15.8 K and a Curie constant of 8.8355(7) $cm^3\,K\,mol^{-1}$. The value of $C$ is consistent with two non-interacting spin-only $Mn^{II}$ ions with $S$ = 5/2 and $g$ = 2.0098. The negative Weiss constant and the peak in the $\chi_m$ curve for the complex are typical of antiferromagnetic coupling between the $Mn^{II}$ ions. Based on the structural data, complex **4** can be viewed as a 1D uniform chain along the $a$ axis. Consequently, the magnetic susceptibility data of complex **4** can be analysed by using a 1D Fisher model with an intradimer interaction $J$. Assuming isotropic exchange, the exchange Hamiltonian is $H = -2JS_iS_j$ with $S_i = S_j$ = 5/2 and the expression of magnetic susceptibility may be used to fit the data.[16] The least-squares fit of the experimental data in the whole temperature range gives the following parameters: $J$ = –0.718(4) $cm^{-1}$, $g$ = 1.986(4), and $R = 2.3 \times 10^{-4}$. The $J$ value falls in the range for other carboxylato-bridged $Mn^{II}$ compounds.[17]

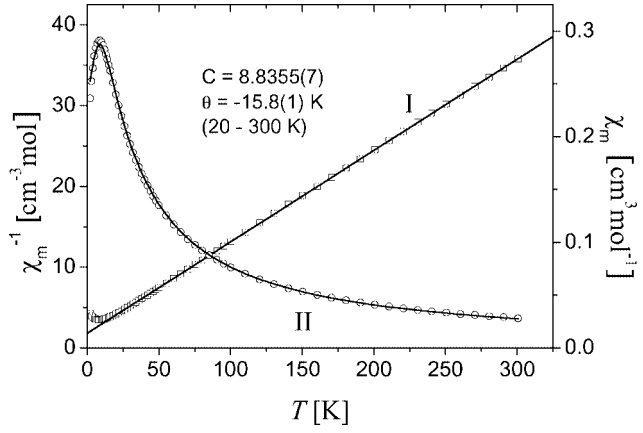

Figure 11. Temperature dependence of $\chi_m^{-1}$ and $\chi_m$ for complex **4**. Line I is the fit of the Curie–Weiss law and line II is the fit using a 1D Fisher model.

## Conclusions

In summary, microporous $Mn^{II}$ coordination polymers (complexes **1** and **4**) are formed by using the V-shaped ligand oba or the linear ligand cca with the rigid ligand 4,4′-bpy. The free 4,4′-bpy ligand acts as a template and also occupies the pore, thus preventing interpenetration. The introduction of terminal ligands such as 2,2′-bpy and phen leads to the formation of 1D chains for complexes **2** and **3**; hydrogen bonds mould these chains into 3D supramolecular networks. In complex **6**, the $Mn^{II}$ ions are coordinated by cca and 2,2′-bpy into 2D layers that interpenetrate to form a 3D supramolecular network. A weak ferromagnetic interaction is observed in the doubly (μ-O)-carboxylate-bridged $Mn^{II}$ dimer in complex **2**, which may be mainly due to the smaller Mn–O–Mn angle.

## Experimental Section

**General Remarks:** All reagents were used as received without further purification. The C, H, N microanalyses were carried out with a Vario EL elemental analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FT-IR spectrometer using the KBr pellet technique. The magnetic susceptibilities were obtained for crystalline

samples using a Quantum Design MPMS SQUID magnetometer. The experimental susceptibilities were corrected for the sample holder and the diamagnetism contributions estimated from Pascal's constants.

**Synthesis of $[Mn(oba)(4,4'\text{-bpy})]_n \cdot n(4,4'\text{-bpy})$ (1):** A mixture of $H_2oba$ (0.026 g, 0.1 mmol), $Mn(OAc)_2 \cdot 4H_2O$ (0.024 g, 0.1 mmol), 4,4′-bpy·$2H_2O$ (0.019 g, 0.1 mmol), NaOH solution (0.3 mL, 0.65 M) and deionized water(5 mL) was sealed in a Teflon-lined stainless-steel vessel (25 mL) and heated at 180 °C for 72 h. The vessel was then cooled slowly to room temperature. Yellow crystals were isolated by filtration, and washed with water and ethanol. Yield: 0.011 g (17.6%). $C_{34}H_{24}MnN_4O_5$ (623.51): calcd. C 65.44, H 3.85, N 8.98; found C 65.82, H 3.93, N 8.80. IR (KBr pellet): $\tilde{\nu}$ = 3439 $cm^{-1}$ (s), 3072 (w), 1648 (m), 1602 (s), 1560 (m), 1532 (m), 1496 (w), 1413 (m), 1386 (s), 1240 (s), 1159 (m), 1097 (w), 1071 (w), 1011 (w), 879 (w), 803 (m), 785 (m), 695 (w).

**Synthesis of $[Mn(oba)(phen)(H_2O)]_n$ (2):** The synthesis of complex **2** followed a similar procedure as for complex **1** but with phen·$H_2O$ (0.020 g, 0.1 mmol) instead of 4,4′-bpy·$2H_2O$. Yield: 0.040 g (78.5%). $C_{26}H_{18}MnN_2O_6$ (509.36): calcd. C 61.25, H 3.53, N 5.50; found C 60.88, H 3.67, N 5.53. IR (KBr pellet): $\tilde{\nu}$ = 3317 $cm^{-1}$ (m), 3049 (w), 1602 (s), 1553 (m), 1519 (m), 1496 (m), 1429 (m), 1384 (s), 1335 (s), 1238 (s), 1160 (m), 1137 (w), 1102 (w), 1047 (w), 1011 (w), 876 (w), 849 (m), 786 (m), 698 (w).

**Synthesis of $[Mn_2(oba)_2(2,2'\text{-bpy})_2(H_2O)_2]_n \cdot nH_2oba$ (3):** The synthesis of complex **3** followed a similar procedure as for complex **1** but with 2,2′-bpy (0.016 g, 0.1 mmol) instead of 4,4′-bpy·$2H_2O$. Yield: 0.032 g (52.1%). $C_{62}H_{46}Mn_2N_4O_{17}$ (1228.9): calcd. C 60.59, H 3.74, N 4.56; found C 60.38, H 3.84, N 4.81. IR (KBr pellet): $\tilde{\nu}$ = 3462 $cm^{-1}$ (m), 3044 (w), 1596 (s), 1565 (m), 1499 (w), 1401 (s), 1316 (w), 1229 (s), 1165 (m), 1100 (w), 1061 (w), 1016 (w), 877 (m), 783 (m), 764 (m), 644 (w).

**Synthesis of $[Mn_2(cca)_2(4,4'\text{-bpy})_2]_n \cdot 2n(4,4'\text{-bpy})$ (4):** A mixture of $H_2cca$ (0.02 g, 0.1 mmol), $Mn(OAc)_2 \cdot 4H_2O$ (0.024 g, 0.1 mmol), 4,4′-bpy·$2H_2O$ (0.038 g, 0.2 mmol), NaOH solution (0.3 mL, 0.65 M) and deionized water (5 mL) was sealed in a Teflon-lined stainless-steel vessel (25 mL) and heated at 140 °C for 72 h. The vessel was then cooled slowly to room temperature. Yellow crystals were isolated by filtration, and washed with water and ethanol. Yield: 0.020 g (35.9%). $C_{60}H_{44}Mn_2N_8O_8$ (1114.9): calcd. C 64.58, H 3.95, N 10.05; found C 64.20, H 4.12, N 9.97. IR (KBr pellet): $\tilde{\nu}$ = 3442 $cm^{-1}$ (s), 1638 (m), 1588 (s), 1550 (s), 1492 (m), 1417 (m),

**Synthesis of [Mn(cca)(phen)]$_n$ (5):** The synthesis of complex **5** followed a similar procedure as for complex **4** except that phen·$H_2O$ (0.020 g, 0.1 mmol) was used instead of 4,4′-bpy·$2H_2O$ and the temperature was 160 °C. Yield: 0.022 g (48.9%). $C_{24}H_{14}MnN_2O_4$ (449.31): calcd. C 62.07, H 3.29, N 6.58; found C 61.75, H 3.43, N 6.86. IR (KBr pellet): $\tilde{\nu}$ = 3439 $cm^{-1}$ (s), 1649 (s), 1606 (m), 1509 (m), 1425 (m), 1381 (s), 1099 (w), 987 (w), 851 (m), 789 (m), 730 (m), 636 (w).

**Synthesis of [Mn(cca)(2,2′-bpy)]$_n$·0.25$n$$H_2O$ (6):** The synthesis of complex **6** followed a similar procedure as for complex **4** except that 2,2′-bpy (0.016 g, 0.1 mmol) was used instead of 4,4′-bpy·$2H_2O$ and the temperature was 120 °C. Yield: 0.017 g (41.9%). $C_{20}H_{14.50}MnN_2O_{4.25}$ (405.78): calcd. C 59.15, H 3.57, N 6.90; found C 58.91, H 3.81, N 6.82. IR (KBr pellet): $\tilde{\nu}$ = 3431 $cm^{-1}$ (m), 3025 (m), 1646 (s), 1616 (s), 1536 (s), 1473 (m), 1439 (s), 1390 (s), 1312 (m), 1245 (m), 1171 (m), 1098 (w), 1016 (m), 984 (m), 862 (m), 763 (m), 737 (m), 647 (m), 625 (w).

**X-ray Crystallographic Study:** Diffraction intensities for the six complexes were collected at 293 K on a Bruker SMART 1000 CCD diffractometer employing graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Semi-empirical absorption correction was applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXS-97 and SHELXL-97 programs, respectively.[18] Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in geometrically calculated positions. The crystallographic data for complexes **1** to **6** are listed in Table 2, and selected bond lengths and angles in Tables 3 and 4.

CCDC-293769 to -293774 (for **1**–**6**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): The other three kinds of coordination environments of the $Mn^{II}$ ion in complex **6**.

# Octahedral $Ru^{II}$ Complexes with [PNO] Hydrazonic Ligands: Synthesis, Structure, Reactivity and Catalytic Activity in the Addition of Benzoic Acid to Alkynes

**Paolo Pelagatti,*[a] Alessia Bacchi,[a] Marcella Balordi,[a] Sandra Bolaño,[b][‡] Francesca Calbiani,[a] Lisa Elviri,[a] Luca Gonsalvi,*[b] Corrado Pelizzi,[a] Maurizio Peruzzini,[b] and Dominga Rogolino[a]**

**Keywords:** Tridentate ligands / Ruthenium / Homogeneous catalysis / Enol esters / Mass spectrometry

A series of $Ru^{II}$ complexes containing [(H)PNO] hydrazonic ligands were synthesised using different ruthenium sources such as $[Ru(PPh_3)_3Cl_2]$, $[Ru(dmso)_4Cl_2]$ and $[Ru(p\text{-cymene})Cl_2]_2$. The complexes were characterised by $^1H$ NMR, $^{31}P\{^1H\}$ NMR, IR, FAB-MS, microanalysis and in some cases by X-ray diffraction analysis on a single crystal. The ligands show a great variety of different coordinating behaviours such as $\kappa^3$-(H)PNO, $\kappa^2$-(H)PN, $\kappa^1$-(H)P and $\kappa^3$-PNO, depending on the ruthenium precursor and on the synthetic experimental conditions. The complexes *trans*-$[Ru(\kappa^3\text{-(H)PNO})(PPh_3)Cl_2]$ reacted with dmso to give the bis-chelate complex $[Ru(\kappa^3\text{-PNO})_2]$, $[Ru(dmso)_4]Cl_2$, $OPPh_3$, HCl and $Me_2S$, through an oxygen-transfer reaction from dmso to $PPh_3$. A catalytic version of this reaction was also developed. The complexes obtained from $[Ru(PPh_3)_3Cl_2]$ were tested as homogeneous pre-catalysts for the coupling between benzoic acid and terminal alkynes to give the corresponding enol esters. High stereo- and regio-selectivity, up to 100 % (determined by $^1H$ NMR), in favour of the (*Z*)-*anti*-Markovnikov products (*Z*)-alk-1-en-1-yl benzoate was observed. An ESI-MS monitoring of the catalytic couplings revealed that the enol ester formation occurs through an intermolecular attack of an external carboxylate anion onto a vinylidene–Ru intermediate of the type $[Ru(PNO)(PPh_3)(C{=}CH{-}C_4H_9)Cl]$.

## Introduction

The use of potentially tridentate [PNO] ligands in the synthesis of transition-metal complexes is scarcely described in the literature.[1] However, $Ru^{II}$ complexes with [PNO] ligands have been shown to be active catalysts in the transfer hydrogenation of ketones,[2] and some of us have reported that [Pd(PNO)(OAc)] and [Pd(PNO)Cl] complexes [PNO = acylhydrazones] promote the catalytic homogeneous hydrogenation of alkenes[3] and the semi-hydrogenation of terminal alkynes,[4] respectively. The use of [PNO] ligands for the preparation of homogeneous catalysts containing *soft* transition metals, is based on two assumptions: *i*) that the chelating PN unit stabilizes the metal fragment under the catalytic conditions and *ii*) that the labile M–O bond makes reactive the metal complex exerting, at the same time, a control upon the accessibility at the metal for an incoming substrate. This last feature can be determinant for the selectivity of the catalytic process. When the [PNO] ligand is protic, as in the case of the acyl hydrazones, a further control on the hemilability of the ligand, from a $\kappa^3$-(H)PNO coordination to a $\kappa^2$-(H)PN one, as well as on the nucleophilicity of the metal, can be exerted as a function of the anionic or neutral character of the ligand.[5]

As our ongoing research on the use of protic [PNO] acyl hydrazones as ligands in the synthesis of transition-metal-containing complexes,[5] we have undertaken a study on the coordinating behaviour of 2-(diphenylphosphanyl)benzaldehyde benzoylhydrazone (Hbidf) and 2-(diphenylphosphanyl)benzaldehyde acetylhydrazone (Haidf) (Scheme 1), towards $Ru^{II}$.

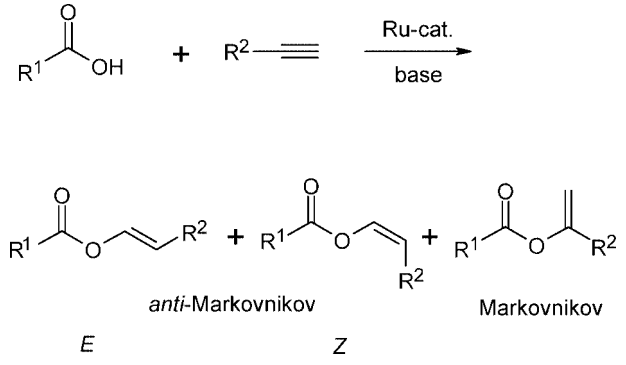
The two ligands have been reacted with $[Ru(PPh_3)_3Cl_2]$ under different reaction conditions, in order to isolate neutral or ionic complexes containing the ligands in either protonated or deprotonated form. All the complexes have been fully characterised by a number of analytical and spectroscopic techniques and, in several cases, by X-ray diffraction analysis on a single crystal. In order to elucidate the reactivity shown by the complexes of the type $[Ru(\kappa^3\text{-}HPNO)(PPh_3)Cl_2]$ with dmso, the syntheses and the characterisations of various Ru complexes obtained by reactions of Hbidf with $[Ru(dmso)_4Cl_2]$ and $[Ru(p\text{-cymene})Cl_2]_2$ are also reported.

Ruthenium is certainly one of the mostly used transition metals in homogeneous catalysis.[6] The Ru-promoted coupling between benzoic acid and terminal alkynes (Scheme 2) is an elegant way to produce vinyl esters, which find industrial applications as polymerising substrates[7] and acylating reagents for the synthesis of amides[8] and halogenated ketones;[9] other applications include cyclopropanation,[10] 1,3-dipolar cycloaddition,[11] asymmetric hydrogenation[12] and hydroformylation reactions.[13]



Scheme 2.

The first report describing this reaction dates back to 1983[14] and deals with the use of $Ru_3(CO)_{12}$ in the coupling of aliphatic and aromatic carboxylic acids to di- and monosubstituted acetylenes. Later on, the process has been developed by Mitsudo,[15] Dixneuf[16] and Verpoort,[17] although other groups have been and are still involved in the field.[18] From the literature it can be inferred that the combination of monodentate phosphanes with different Ru sources generally yields to the Markovnikov product,[15,16a,16b,19] although in some cases the selectivity can be switched to the *anti*-Markovnikov product by replacing inorganic bases with organic (coordinating) ones, such as pyridine derivatives.[18] The same trend has been described by Dixneuf replacing mono- with chelating phosphanes[16d] and by Verpoort adding phosphanes to N-heterocyclic carbene complexes.[17d] With this in our mind, we have argued that the high chelation degree of the acyl hydrazones could induce a good selectivity towards the *anti*-Markovnikov products, thus leading to the formation of the less commonly obtained isomer. In order to test this hypothesis and because of the lack of data concerning the use of pre-catalysts containing tridentate ligands for this particular coupling reaction, we have decided to test the complexes deriving from the combinations of Hbidf and Haidf with $[Ru(PPh_3)_3Cl_2]$ as pre-catalysts in the addition of benzoic acid to terminal alkynes. Aiming at detecting the organometallic intermediates involved in the catalytic cycle, an ESI-MS study has been performed. ESI-MS technique allows for the detection of species at low concentration in solution and this makes it attractive to define the mechanism of metal-promoted catalytic transformations. It has been successfully employed in different reactions, such as the reduction of ketones,[20] epoxidations,[21] olefins polymerisation[22] and C–H bonds activation.[23] To the best of our knowledge, this is the first report dealing with the application of such a technique for the study of the addition of carboxylic acids to alkynes.

## Results and Discussion

Selected spectroscopic data ($^{31}P\{^1H\}$NMR, $^1H$ NMR and FT-IR) of the complexes reported in this work are collected in Table 1.

### Ru Complexes Obtained from $[Ru(PPh_3)_3Cl_2]$

The free ligands Hbidf and Haidf react with a stoichiometric amount of $[Ru(PPh_3)_3Cl_2]$ in dichloromethane at room temperature, leading to the neutral dichloride complexes *trans*-$[Ru(\kappa^3\text{-}(H)PNO)(PPh_3)Cl_2]$, which were isolated as purple solids in good yields (**1** and **2** in Scheme 3, respectively).

The neutral hydrazones coordinate in a tridentate fashion by means of the P, $N_{imine}$ and O donors. The neutral behaviour of the ligands is indicated by the IR stretching bands of the N–H bonds (3148 and 3145 $cm^{-1}$ for **1** and **2**, respectively), while the involvement of the carbonyl group in the coordination is pointed out by the shift to lower wavenumbers of the C=O stretching band (1629 $cm^{-1}$ for both complexes) with respect to the free ligands (1652 and 1678 $cm^{-1}$ for Hbidf and Haidf, respectively). The octahedral coordinations are completed by a $PPh_3$ molecule and by two chloride ligands. The FAB-MS spectra and the elemental analyses confirm the proposed stoichiometries. The complexes **1** and **2** are poorly soluble in chloroform, dichloromethane, THF, toluene, acetonitrile and methanol, while they readily dissolve in strongly coordinating solvents, like dmso and dmf. Based on the reactivity of **1** observed in warm acetonitrile (vide infra), we suppose that the solution of **1** and **2** in dmso or dmf occurs by breaking of a Ru–Cl bond and formation of the cationic complexes $[Ru(\kappa^3\text{-}(H)PNO)(PPh_3)(S)Cl]Cl$ (**1a** and **2a**, S = dmso or dmf). The $^1H$ NMR spectra of the freshly prepared samples recorded in $[D_6]$dmso show singlets belonging to the hydrazonic protons at $\delta$ = 14.11 and 13.65 ppm for **1a** and **2a**, respectively, while the HC=N protons give rise to doublets at $\delta$ = 9.14 ppm and 8.69 ppm, respectively. The somewhat high $^4J_{PH}$ values of 7.5 and 7.7 Hz for **1a** and **2a**, respectively, corresponding to the couplings between the iminic protons

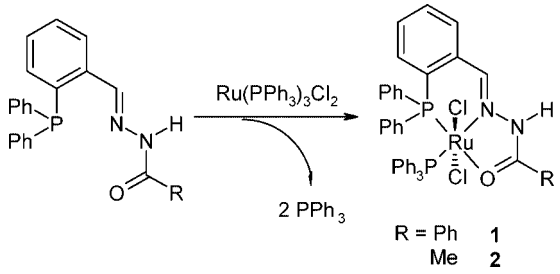

Scheme 3.

and the P atoms of the $PPh_3$ (as established by heteronuclear $^1H$-$^{31}P$ correlation), are indicative of a $PPh_3$ molecule *trans* to the HC=N function.[24] The chloride ligand and dmso occupy the apices of the octahedron. The stereoselectivity of the reaction is indicated by $^{31}P\{^1H\}$-NMR spectroscopy by two doublets centred at 63 and 39.1 ppm for **1a** and 65.3 and 40.8 ppm for **2a**. The more shielded signals are generated by the $PPh_3$ ligands, while the signals at lower fields are generated by the hydrazonic phosphorus nuclei.[24] The small $^2J_{PP}$ values of 32 and 31 Hz for **1a** and **2a**, respectively, are in agreement with a *cis* arrangement of the two P atoms. The isolation of the cationic complexes **1a** and **2a** is not possible because of their reactivity with dmso, as shown by NMR spectroscopy. In fact, on keeping the NMR sample of **1a** at room temperature overnight, two additional $^{31}P\{^1H\}$-NMR doublets appear, centred at $\delta$ = 49 and 32 ppm ($^2J_{PP}$ = 26.5 Hz). Moreover, two small singlets at $\delta$ = 53 and 27 ppm are also visible (see Supporting Information; see also the footnote on the first page of this article). When the tube is warmed at 50 °C for 6 hours, the new signals grow at the expenses of those belonging to the starting complex, and an additional pair of doublets centred at $\delta$ = 54 and 34 ppm ($^2J_{PP}$ = 30 Hz) appears. After 16 hours at 50 °C, the main signals are still those of **1a**, but the singlets at $\delta$ = 53 and 27 ppm have grown considerably while the other two pairs of doublets have diminished. Finally, after 48 hours the spectrum shows only the singlets at $\delta$ = 55 and 29 ppm. The low $^2J_{PP}$ values of the two transient pairs of doublets indicate the formation of two labile Ru complexes containing two mutually *cis* phosphanes, while the final singlets are ascribable to $OPPh_3$ (singlet at $\delta$ = 29 ppm[25]) and to the bis-chelate complex $[Ru(bidf)_2]$ (**12**, singlet at $\delta$ = 55 ppm). The presence of **12** is confirmed by ESI-MS analysis of the warm dmso solution by a cluster at $m/z$ = 917. Complex **12** can be prepared by reaction between $[Ru(PPh_3)_3Cl_2]$ or $[Ru(dmso)_4Cl_2]$ with a twofold excess of Hbidf (vide infra) in the presence of a base. Its $^{31}P\{^1H\}$-NMR spectrum shows a singlet at $\delta$ = 57.7 ppm, which is in good agreement with the value observed for the in situ formed complex. On the basis of the aforementioned observations we propose that the **1** → **12** transformation occurs in agreement with Scheme 4.

Although the detection of $(CH_3)_2S$ is made difficult by its volatility, a singlet at $\delta$ = 2.08 ppm is observed during $^1H$ NMR monitoring of the reaction. The same technique has allowed the detection of $[Ru(dmso)_4Cl_2]$: by repeating the **1** → **12** transformation in dmso, after the complete removal of the solvent, the $^1H$ NMR spectrum of the solid residue recorded in $CDCl_3$ shows, apart from the signals ascribable to **12**, singlets in the region 3.47–2.25 ppm, indicative of the presence of a mixture of *trans*- and *cis*-$[Ru(dmso)_4Cl_2]$.[26] The **1** → **12** transformation must necessarily occur through the transfer of a PNO ligand from a Ru nucleus to another one. Thus, the changes observed in the $^{31}P\{^1H\}$-NMR spectrum of **1a** in dmso may be tentatively explained as follows (Scheme 4): dmso reacts with **1a** causing the displacement of the C=O group of the ligand giving rise to $[Ru(\kappa^2\text{-}(H)PN)(PPh_3)(dmso)_2Cl]Cl$ (**1b**). Complex **1b** gives rise to the pair of doublets at $\delta$ = 49 and 32 ppm, where the more shielded signal is due to $PPh_3$ while the other is due to the $PPh_2$ moiety. The chemical shift of 49 ppm is similar to that found for **13** ($\delta$ =45.5 ppm, vide

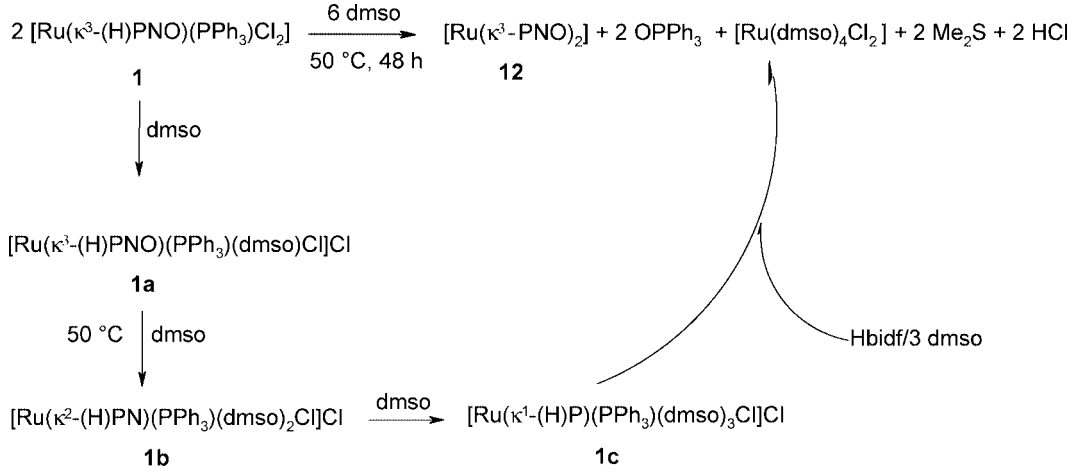

Scheme 4.

infra), where Hbidf coordinates in a (H)PN bidentate fashion. The simple isomerisation of **1b** due, for example, to the shift of $PPh_3$ from the plane to an apex of the octahedron is ruled out by the $^1H$ NMR monitoring of the process: the HC=N function of **1b** gives rise to a doublet centred at $\delta$ = 9.14 ppm with a $^4J_{PH}$ of 8.02 Hz, indicative of a $PPh_3$ *trans* to the imine function. The reaction continues with the decoordination of the imine nitrogen from ruthenium which is replaced by an additional molecule of dmso (probably favoured by the *trans* effect of $PPh_3$), with formation of complex **1c** in which the neutral ligand coordinates in an unidentate fashion through the P atom, giving rise to the pair of doublets at $\delta$ = 54 and 34 ppm. Although one would expect a decrease of the chemical shift on passing from **1b** to **1c** due to the loss of the chelation ring,[27] a chemical shift around 50 ppm is not unusual for Ru complexes containing coordinated monophosphanes and dmso.[28] Moreover, the ability of Hbidf to coordinate Ru in a P-monodentate mode is confirmed by the complex [($\eta^6$-*p*-cymene)-Ru($\kappa^1$-(H)P)$Cl_2$]·3/2 $CHCl_3$ (**15**, vide infra) obtained by the reaction of Hbidf with [Ru(*p*-cymene)$Cl_2$]$_2$. Finally, **1c** further transforms, through a not yet defined pathway, into [Ru(dmso)$_4Cl_2$], $OPPh_3$, $(CH_3)_2S$, HCl and **12**. $PPh_3$ oxidation then occurs through the dmso reduction to dimethyl sulfide. The metal ion-mediated deoxygenation of coordinated sulfoxides has been observed with different metals.[29] The most intensively studied systems are based on oxorhenium[30] and oxomolybdenum compounds,[25,31] the last also being good models of the enzymes belonging to the dmso reductase class.[32] To the best of our knowledge, the only article dealing with the deoxygenation of dmso promoted by ruthenium has been reported by James, describing the reaction of $RuCl_3$·3 $H_2O$ with dmso at high temperatures in the presence of HCl or HBr;[33] in those cases however, although dimethyl sulfide complexes were isolated, the nature of the reductants remained unknown. Interestingly, the oxygen transfer from dmso to $PPh_3$ promoted by **1** can be made catalytic by dissolving the complex in dmso and heating the solution at 100 °C in the presence of a 100-fold excess of $PPh_3$; the reaction is complete within 20 hours as indicated by $^{31}P\{^1H\}$-NMR spectroscopy (disappearance of the $PPh_3$ signal at –7.5 ppm in favour of the $OPPh_3$ signal at $\delta$ = 26.8 ppm). A similar behaviour is conjecturable also for complex **2**, although its reactivity in dmso has not been investigated in details. It is worth noting that this step-by-step ligand decoordination probably corresponds to the reversed way the ligand approaches the metal, a process not always easy to envision with polydentate ligands. The key-role played by dmso in the **1** → **12** transformation is evidenced by the different reactivity shown by **1** in acetonitrile at 50 °C. After 4 hours an almost clear solution has been obtained and the work-up has led to the cationic monochelate complex [Ru($\kappa^3$-(H)PNO)($PPh_3$)($CH_3CN$)Cl]Cl (**11**). The neutral character of the ligand is clearly pointed out by the IR and $^1H$ NMR spectra with a weak band at 3173 $cm^{-1}$ and a singlet at $\delta$ = 10.48 ppm, respectively. The coordinated acetonitrile gives rise to a weak IR band at 2273 $cm^{-1}$ and a singlet at $\delta$ = 1.31 ppm in the $^1H$ NMR spectrum. Complex **11** decomposes within 24 hours in solution and within 24–48 hours in the solid state, without evidencing the formation of **12**.

Treatment of a toluene suspension of **1** or **2** with an excess of triethylamine in the presence of acetonitrile, leads to the isolation of the neutral monochloride complexes [Ru($\kappa^3$-PNO)($PPh_3$)($CH_3CN$)Cl] (**3** and **4** in Scheme 5) as yellow solids in good yields. The reactions occur with the substitution of a chloride ligand (precipitated as $Et_3NHCl$) with an acetonitrile molecule.

The anionic character of the ligand is indicated by the disappearance of the spectroscopic signals of the N–H and C=O bonds.[5] The coupling constants between the P nuclei are again small (24 Hz) to indicate a *cis* arrangement of the $PPh_3$ and $PPh_2$ moieties, while the iminic protons give rise to doublets with appreciable $^4J_{PH}$ values indicative of a HC=N group *trans* to a $PPh_3$[24] (Table 1). The coordinated acetonitrile gives a singlet at $\delta$ = 1.21 ppm in both complexes. The FAB-MS spectrum of **3** shows a cluster centred at *m*/*z* = 806 corresponding to the [Ru($\kappa^3$-PNO)($PPh_3$)Cl]$^+$ fragment, while in the FAB-MS spectrum of **4** the molecular peak is visible at *m*/*z* = 786. By slow evaporation of a

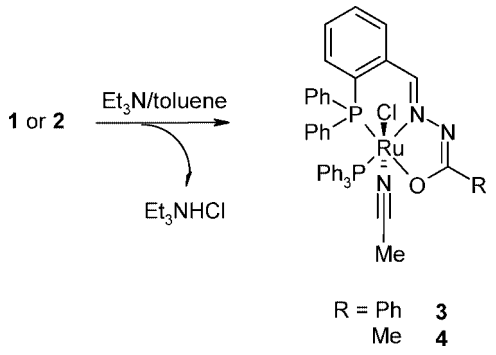

Scheme 5.

dichloromethane/acetonitrile mixture of **4**, crystals suitable for X-ray diffraction have been collected, and the structure of the complex has been unequivocally confirmed. Compound **4** crystallises with the inclusion of two water molecules in the asymmetric unit, which take part in the packing interactions. In **4** the Ru atom is hexacoordinate by the tridentate deprotonated PNO (aidf$^-$) ligand, one triphenylphosphane, *trans* to the N donor, one chloride and one acetonitrile molecule, *trans* each other, in an irregular octahedral geometry. The molecular structure is shown in Figure 1, along with the labelling scheme, while the most relevant geometric features are collected in Table 2.

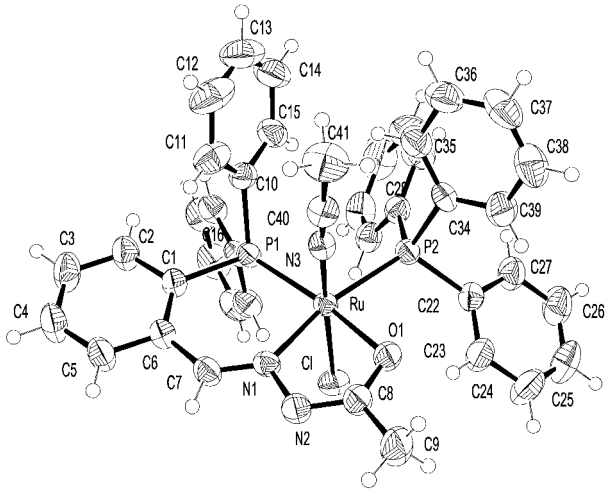

Figure 1. Perspective view and labelling scheme of compound **4**. Rings C16–C21 and C28–C33 are labelled only on the *ipso* carbon for clarity. Thermal ellipsoids at the 50% level.

The tridentate PNO coordination of aidf$^-$ gives rise to two chelation rings, which are both planar within 0.06 Å. The planarity of the six-membered chelation ring containing P1 contrasts with the behaviour generally observed in the family of the similar Pd(aidf) and Pd(bidf) complexes,[3,5c] where the chelation ring is puckered and the phosphorus donor is remarkably out of the average ring plane (values ranging between 0.38 and 0.52 Å). In fact, in the Pd series the Pd–P distances range from 2.184 to 2.212 Å, while in **4** the Ru–P bond is significantly longer [2.2951(3) Å], and can accommodate for ring planarity. By contrast, even if the Ru–O bond [2.1177(5) Å] is longer than the Pd–O bond (2.065 Å) in the [Pd(aidf)(OAc)] analogue,[3] the ligand bond lengths along the five-membered chelation ring are very close to those observed in the palladium complex, from which they do not deviate by more than 0.013 Å. The molecular association in the crystal is based on dimeric aggregates composed by two complexes related by a crystallographic twofold axis, linked by two water molecules which act as hydrogen-bond donors towards chloride and nitrogen as shown in Figure 2 [O2···N2: 2.883(2) Å, O2–H···N2: 149.7(6)°; O2···Cl(i): 2.232(1) Å, O2–H···Cl(i): 152.6(4)°, i: $y, x, 1-z$]. This pattern is conserved in the related structure of **6**.

The dichloride complexes **1** and **2** suspended in a dichloromethane/acetonitrile mixture react with an excess of $KPF_6$ or $NaBPh_4$ leading to the cationic monochloride complexes [Ru($\kappa^3$-(H)PNO)($PPh_3$)($CH_3CN$)Cl][X] [HPNO = Hbidf, X = $PF_6$ (**5**), X = $BPh_4$ (**7**); HPNO = Haidf, X = $PF_6$ (**6**), X = $BPh_4$ (**8**)] and precipitation of KCl or NaCl, respectively (Scheme 6).

As can be inferred from Table 1, the spectroscopic characterisation indicates that the ligands have not varied their coordinating behaviour with respect to the dichloride precursors, and that the $PPh_3$ ligands are still *trans* to the HC=N moieties [the $^{31}P\{^1H\}$-NMR signals range from 55.5 to 59.3 ppm for the $PPh_2$ moiety, and from 35.6 to 40.0 ppm for the $PPh_3$ ligand, with $^2J_{PP}$ values ranging from 24.6 to 29 Hz; the $^4J_{PH}$ values range from 7.2 to 8.1 Hz]. The apices of the octahedron are occupied by the residual chloride and by an acetonitrile molecule, whose presence is confirmed by IR (stretching band in the region 2265–2281 cm$^{-1}$) and $^1H$ NMR spectroscopy (singlets ranging from 0.43 to 1.70 ppm). The [$PF_6$]$^-$ anions originate, in the $^{31}P\{^1H\}$-NMR spectra, multiplets centred at –141.1 and –145.5 ppm, for **5** and **6**, respectively, while in the IR spectra they give rise to an intense band at 845 cm$^{-1}$. The presence of the [$BPh_4$]$^-$ anion in **7** and **8** is pointed out by IR bands at about 850 cm$^{-1}$. The structure of **6** has been unequivocally established by X-ray diffraction analysis conducted on a single crystal grown in a $CH_2Cl_2$/*n*-pentane mixture. In compound **6**, the [Ru(Haidf)]$^+$ cation (Figure 3) is arranged identically to the related deprotonated neutral complex **4**.

The comparison between the two molecules (Figure 4, Table 2) may help to investigate the effect of protonation on [Ru(aidf)($PPh_3$)($CH_3CN$)Cl]. The protonation of the hydrazonic nitrogen N2 seems to localize a larger double-bond character on the carbonylic bond, which shortens by 0.055 Å, while at the same time the adjacent C(O)–N bond elongates by 0.016 Å. Moreover, in the cationic complex **6** the Ru–O bond is longer than in **4** by 0.028 Å, while Ru–P bond is slightly shorter (0.017 Å). The shortening of the Ru–P bond is accompanied by a slight distortion from planarity of the six-membered chelation ring, as P1 deviates by 0.14 Å from the ring plane. The [Ru(Haidf)]$^+$ cations are assembled in dimeric units (Figure 5) by N–H···Cl hydrogen bonds [N2···Cl(ii): 3.300(6) Å, N2–H···Cl(ii): 149(7)°,

acetonitrile. This procedure leads to the neutral complexes *trans*-[Ru($\kappa^3$-PNO)($PPh_3$)($CH_3CN$)$_2$][X] [PNO = bidf, X = $BPh_4$ (**9**); PNO = aidf, X = $PF_6$ (**10**)] in good yields (Scheme 7).

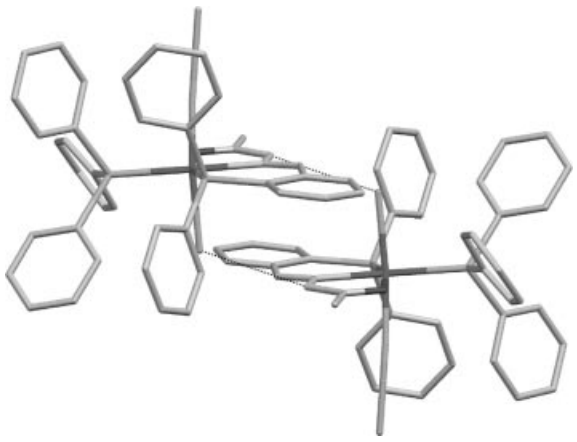

Figure 5. Association in hydrogen-bonded dimers in the crystal structure of **6**.

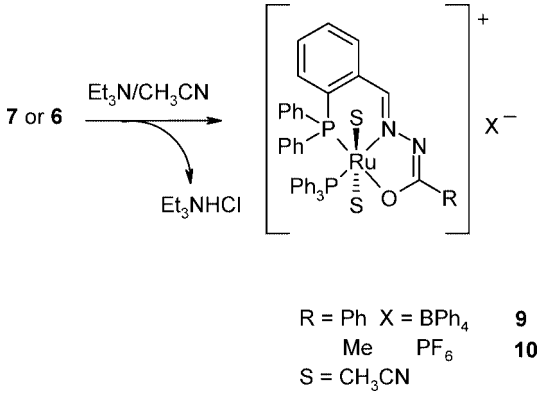

Scheme 7.

The disappearance of the spectroscopic signals of the N–H and C=O bonds agrees with the anionic character of the ligand, while the NMR spectroscopic data similar to those of the precursors indicate that $PPh_3$ has not moved from its *trans* disposition with respect to the imine moiety (Table 1). The entering of the second molecule of acetonitrile is indicated by $^1$H NMR spectroscopy with the appearance of an additional singlet at $\delta$ = 2.37 and 2.34 ppm for **9** and **10**, respectively. These complexes are significantly unstable both in solution and in the solid state.

### Ru Complexes Obtained from [Ru(dmso)$_4$Cl$_2$]

In order to understand the nature of the Ru species involved in the **1** → **12** transformation observed in dmso, the ligand Hbidf has been reacted with [Ru(dmso)$_4$Cl$_2$]. In refluxing EtOH/NaOH [Ru(dmso)$_4$Cl$_2$] reacts with a twofold excess of Hbidf leading to the formation of the bis-chelate octahedral complex [Ru(bidf)$_2$] (**12**) in good yield (Scheme 8). In complex **12** two deprotonated ligands coordinate Ru in a PNO fashion.

The disappearance of the spectroscopic signals of the N–H and C=O bonds is indicative of the deprotonation that occurred in both ligands, while the presence of a singlet at $\delta$ = 57.7 ppm in the $^{31}$P{$^1$H}-NMR spectrum is in agree-

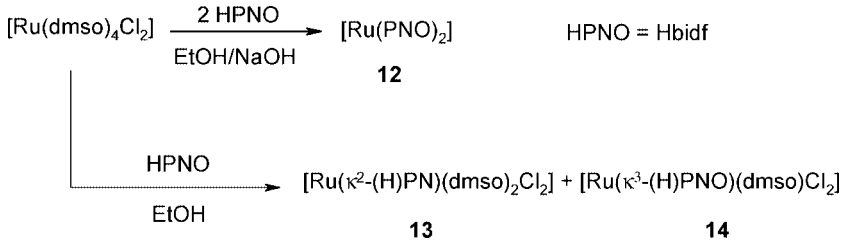

Scheme 8.

ment with two magnetically equivalent phosphorus nuclei. The HC=N proton resonates as a singlet at $\delta$ = 9.18 ppm in the $^1$H NMR spectrum recorded in $CDCl_3$, as expected in the absence of a $PPh_3$ ligand. The CI-MS spectrum exhibits a cluster centred at *m/z* = 916 (molecular peak). The structure of **12** has been unequivocally established by X-ray diffraction analysis on a single crystal obtained from a dmso solution of **13** (vide infra) and is shown in Figure 6. Compound **12** crystallises as a 1:1:1 dmso/$H_2O$ solvate. The principal geometric features are reported in Table 2. The most relevant feature in the geometry of [Ru(bidf)$_2$] is that the steric hindrance due to the bis-chelation produces significant distortions in the planarity of the two coordinated [PNO] ligands. In fact in both ligands the P atom deviates remarkably from the chelation plane (0.64 and 0.59 Å, respectively), and the Ru–P distances are significantly shorter [Ru–P1: 2.2503(9), Ru–P2: 2.2553(9) Å] than in the previous mono-chelated complexes (Table 2). By contrast, the five-membered chelation rings are planar within 0.09 Å, and the bond lengths along the ring are in agreement with those observed in the neutral mono-chelate **4**. The mutual arrangement of the two ligands in **12**·dmso·$H_2O$ favours a remarkable intramolecular π–π stacking between the rings belonging to the ligands main backbone and the diphenylphosphane rings, with C···C separation ranging between 3.3 and 3.9 Å.

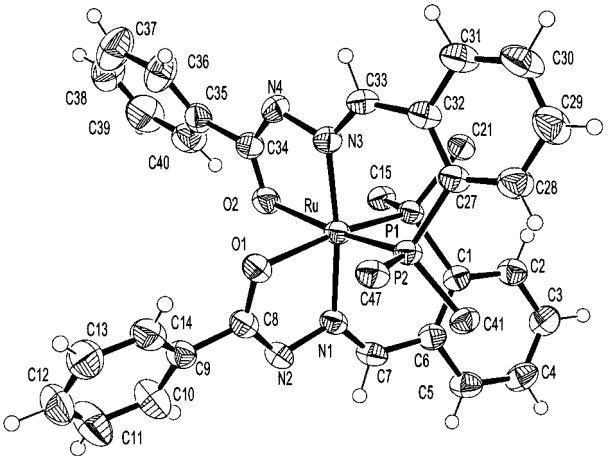

Figure 6. Perspective view and labelling scheme of compound **12**·dmso·$H_2O$. Rings C15–C20, C21–C26, C41–C46 and C47–C52 are represented only by the *ipso* carbon for clarity. Thermal ellipsoids at the 50% level.

The reaction between Hbidf and [Ru(dmso)$_4$Cl$_2$] has been repeated without a base. When the reaction is carried out at room temperature with a Ru/Hbidf = 1:1 molar ratio, a complex mixture of different products forms, whose separation and identification has not been possible so far. A clearer picture is instead obtained when the reaction is performed in refluxing ethanol. Two different Ru$^{II}$ complexes, [Ru(κ$^2$-(H)PN)(dmso)$_2$Cl$_2$] (**13**) and [Ru(κ$^3$-(H)PNO)-(dmso)Cl$_2$] (**14**) form as shown in Scheme 8. In complex **13** the neutral ligand coordinates the metal in a PN bidentate fashion, as evidenced by IR [ν(N–H) = 3249 cm$^{-1}$, ν(C=O) = 1674 cm$^{-1}$] and $^1$HNMR (singlet at $\delta$ = 11.24 ppm) spectroscopy.[4] Two chlorides and two dmso molecules complete the octahedron, as evidenced by the IR [two strong bands at 1088 and 1019 cm$^{-1}$ due to the ν(S=O) and δ(C–H), respectively] and $^1$H NMR (four singlets in the region 3.65–2.84 ppm) spectra as well as by microanalysis. The $^{31}$P{$^1$H}-NMR spectrum shows a singlet at $\delta$ = 45.5 ppm. From a dmso solution of **13** crystals suitable for X-ray analysis have been collected. The diffractometric analysis shows the formation of the bis-chelate complex **12**; this further mono-chelate → bis-chelate transformation is not surprising, because compound **13** is structurally similar to **1b**, a proposed intermediate in the dmso-promoted **1** → **12** transformation.

In complex **14** the neutral ligand coordinates in a PNO fashion as clearly indicated by the IR bands of the N–H (3156 cm$^{-1}$) and C=O (1594 cm$^{-1}$) groups. The hydrazonic proton gives rise to a singlet at $\delta$ = 10.34 ppm in the $^1$H NMR spectrum recorded in $CDCl_3$, while the $^{31}$P{$^1$H}-NMR spectrum shows a singlet at $\delta$ = 61 ppm. The octahedron is completed by two chlorides and a dmso molecule, while a half dmso molecule is outside of the coordination sphere [the $^1$H NMR spectrum recorded in $CDCl_3$ shows four singlets in the region 3.48–2.48 ppm, while the IR spectrum shows strong bands at 1095 and 1023 cm$^{-1}$, attributable to the ν(S=O) and δ(C–H) of the dmso, respectively]. Owing to the lack of structural information, a detailed stereochemical description of the complexes **13** and **14** is not possible at present.

### Ru Complex Obtained from [Ru(*p*-cymene)Cl$_2$]$_2$

[Ru(*p*-cymene)Cl$_2$]$_2$ reacts with Hbidf in chloroform at room temperature, leading to the isolation of [(η$^6$-*p*-cymene)Ru(κ$^1$-(H)P)Cl$_2$]·3/2 $CHCl_3$ (**15**), where the ligand uses only the P atom to bind to ruthenium. The pseudo-octahedral coordination is completed by a η$^6$-coordinated *p*-cymene molecule and by two chloride ligands. The IR

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectrum shows the presence of the N–H and of the C=O groups with two bands at 3311 and 1696 $cm^{-1}$, respectively. The neutral character of the ligand is further substantiated by $^1H$ NMR spectroscopy with a singlet at $\delta$ = 10.31 ppm; the HC=N proton corresponds to a singlet at $\delta$ = 9.08 ppm, while the *p*-cymene protons resonate at the expected chemical shifts (in the range 5.47–5.33 ppm). The $^{31}P\{^1H\}$-NMR spectrum recorded in $CDCl_3$ shows a singlet at $\delta$ = 29.6 ppm. The structure of **15** has been unambiguously elucidated by X-ray diffraction analysis conducted on a crystal collected from a chloroform/diethyl ether mixture which was cooled to –20 °C. The molecular structure is reported in Figure 7, and the most important geometric parameters are listed in Table 2. The neutral Hbidf ligand is coordinated to the Ru atom only by the P donor [Ru–P bond 2.376(5) Å], while the remaining potential N and O donors point away from the metal. The NH is instead on the same side as the P atom, in the opposite conformation with respect to the one observed in the tridentate complexes. The Ru centre completes its pseudo-octahedral coordination by two chloride atoms and the $\eta^6$-*p*-cymene. The conformation of the neutral ligand allows for a favourable contact between the NH and the CH group and one of the coordinated Cl [(N2)H···Cl1: 2.910(5), (C7)H···Cl1: 2.655(5) Å], thus strongly differentiating the intramolecular environment of the two chloride atoms.

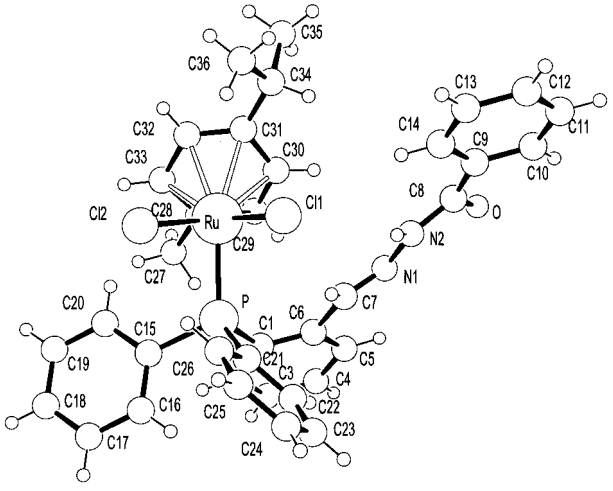

Figure 7. Perspective view and labelling scheme of the ball-and-stick structure of **15**·1.5$CHCl_3$. $\eta^6$-Coordination of the *p*-cymene ligand is represented by empty sticks.

### Addition of Benzoic Acid to Terminal Alkynes

The Ru-catalysed coupling of alkynes with carboxylic acids (Scheme 2) is an elegant way to obtain enol esters, which are starting materials for several important chemical transformations.[7–13] One of the major goals of this catalysis is the development of stereo- and regio-selective processes leading exclusively to one of the three possible enol ester isomers (Scheme 2), thus the preparation of selective catalysts is certainly desirable. Literature data show that the Markovnikov products are those usually produced using several Ru-catalysts containing monodentate ligands.[15,16a,b,19] However, high selectivity towards (*Z*)-alk-1-en-1-yl benzoate (*anti*-Markovnikov product) has been achieved in the coupling of phenylacetylene with 1-hexyne using allyl–$Ru^{II}$ complexes containing chelating diphosphanes such as dppp or dppb.[16d] The same type of selectivity has been achieved by adding coordinating bases, such as pyridines, to *half-sandwich* $Ru^{II}$ complexes containing monodentate phosphanes,[18] or adding monophosphanes to N-hetherocyclic carbene complexes.[17d] As we wanted to test whether the chelation of the acyl hydrazones could determine a good selectivity towards (*Z*)-alk-1-en-1-yl benzoate, we have tested the complexes **1**–**4**, **6**, **7**, **9** and **10** as pre-catalysts in the addition of benzoic acid to phenylacetylene. To the best of our knowledge, this is the first report dealing with Ru complexes containing tridentate ligands employed as pre-catalysts in such a catalytic transformation. The experimental conditions have been kept constant for every catalytic run: toluene as solvent (for concentrations of about $10^{-3}$ M all the complexes are perfectly soluble), $Na_2CO_3$ as base (Ru/base molar ratio = 1:5), $T$ = 120 °C and 1% of catalyst loading. The yields of the reactions (referred to the isolated enol esters) have been checked after 16 hours. The catalytic results are collected in Table 3.

As can be deduced from Entries 1 and 2, the dichloride complexes **1** and **2** are completely inactive in the coupling between 1-hexyne and benzoic acid. This is not unexpected, as it can be imputed to the strongly bound chloride ligands.[8,16a,b,19,34] The substitution of a chloride with a more labile acetonitrile molecule, like in the case of the mono-chloride complexes **3** and **4**, leads to a moderate catalytic activity with 35% and 49% yields (Entries 3 and 4), respectively. However, high stereo- and regio-selectivity in favour of (*Z*)-alk-1-en-1-yl benzoate have been reached in both cases (94% an 99%, respectively). The amount of the Markovnikov product remains very low and no traces of (*E*)-alk-1-en-1-yl benzoate have been detected. The cationic complexes **6** and **7** (Entries 5 and 6) lead to similar yields, but again accompanied by excellent selectivities towards the *Z*-*anti*-Markovnikov product. Finally, the cationic complexes **9** and **10** show catalytic activities comparable to those of the mono-chloride complexes, with a slightly diminished selectivity (10% of the Markovnikov product has been obtained in both cases, Entries 7 and 8). Under the experimental conditions applied, with the only exception of the dichlorides **1** and **2**, the tested Ru complexes result more active than $[Ru(PPh_3)_3Cl_2]$ (Entry 13) which, moreover, leads exclusively to the Markovnikov product. From an inspection of Entries 1–8 of Table 3, it can be inferred that the removal of a chloride ligand is necessary to have catalytic activity accompanied by a good selectivity (compare Entries 1 and 2 with Entries 3 and 4), while the removal of the second chloride ligands does not bring to any improvement of the final yield, but instead provokes a slight decrease in selectivity (compare Entries 3–6 with Entries 7 and 8). The importance of having a vacant coordination site is confirmed by the inertness of the complexes observed in coordinating solvents such as dmso, dmf and acetonitrile;

| 12 | **7** | 1-octyne | 56 | 94 | 6 |
| 13 | $[Ru(PPh_3)_3Cl_2]$ | 1-hexyne | 19 | – | 100 |

[a] Conditions: solvent = toluene; $T$ = 120 °C; Ru/benzoic acid/alkyne/$Na_2CO_3$ = 1:100:100:5. [b] Referred to the isolated product. [c] Determined by $^1H$ NMR spectroscopy.

no traces of enol esters have been detected even after 24 hours of reaction. From the lengthening of the Ru–O bond observed in the solid structure of **6** with respect to the same bond length found in **4**, one could expect a higher catalytic activity for the complexes containing protonated ligands, such as **6** and **7**, on the basis of a hemilabile behaviour of the acyl hydrazones, from a $\kappa^3$-(H)PNO coordination to a $\kappa^2$-(H)PN one. However, these pre-catalysts behave similarly to the complexes containing anionic ligands **3**, **4**, **9** and **10**, and this suggests that the acyl hydrazones remain tridentate throughout the catalytic cycle. An explanation of this levelling effect could certainly reside in the deprotonation of the ligand induced by the excess of $Na_2CO_3$ which forces the acyl hydrazones to an anionic PNO coordination in all cases.

The study of the catalytic behaviour of complex **7** has been extended to other terminal alkynes, such as 1-octyne, phenylacetylene, *p*-tolylacetylene and *tert*-butylacetylene.

Whereas with 1-octyne the catalytic performance is similar to the one observed with 1-hexyne (56% conversion with 94% of *Z-anti*-Markovnikov product and 6% of Markovnikov product, Entry 12), conversions not higher than 36% and lower selectivities have been obtained with the aryl alkynes, (Entries 9 and 10) and with the bulkier *t*Bu-acetylene (Entry 11). Whilst with *t*Bu-acetylene the lower yield can be imputed to steric factors, more difficult is to explain the lower reactivity of the aryl alkynes. Noteworthy is the fact that traces of dimerisation products have been detected neither with phenylacetylene nor with *p*-tolylacetylene, as instead described with Ru–alkylidene complexes bearing N-heterocyclic carbene ligands.[17c] A possible explanation could reside in the bulkiness of the phenyl ring attached to the triple C–C bond of the alkyne which hampers the vinylidene formation (vide infra), but elucidation of this point needs further studies.

## ESI-MS Study

ESI-MS technique has been successfully employed in several metal-catalysed transformations like, for example, reduction of ketones,[20] epoxidations,[21] olefins polymerisation[22] and C–H bonds activation[23] for the detection of the metal-containing intermediates involved in the catalytic cycles. To the best of our knowledge, no report dealing with the use of such a technique for the study of the addition of carboxylic acids to alkynes has appeared in the literature. Mechanistic studies conducted on diphosphanes containing complexes,[15d] have evidenced the formation of a vinylidene intermediate as active catalyst, which undergoes an intermolecular attack of a carboxylate anion to generate the final enol ester. We have therefore undertaken an ESI-MS study aimed at detecting the key intermediates involved in the enol ester synthesis catalysed by our Ru–PNO complexes; complex **5** $[Ru(Hbidf)(PPh_3)(CH_3CN)Cl][PF_6]$ has been chosen as a model. Initially, we have collected the ESI(+) spectrum of a $10^{-3}$ M toluene solution of **5** at room temperature; this shows a predominant cluster centred at $m/z$ = 813 accounting for $[Ru(bidf)(PPh_3)(CH_3CN)]^+$, and minor clusters at $m/z$ = 849 and $m/z$ = 772 accounting for $[Ru(Hbidf)(PPh_3)(CH_3CN)Cl]^+$ and $[Ru(bidf)(PPh_3)]^+$, respectively. The solution has then been heated at 120 °C for 40 minutes and a new ESI(+) spectrum has been collected. This shows again the clusters centred at $m/z$ = 813 and 772, indicating that the complex is preserved under these conditions (Figure 8, a). A small cluster at $m/z$ = 917 shows the presence of **12**, although the isotope pattern points out the presence of a second unknown species with similar mass which tangles the signal up.

To a freshly prepared toluene solution of **5** heated at 120 °C benzoic acid and $Na_2CO_3$ have been added (Ru/acid/$Na_2CO_3$ = 1:5:5 molar ratio); the ESI(+) spectrum shows the disappearance of the signal at $m/z$ = 813 in favour of a cluster centred at $m/z$ = 894 corresponding to the fragment $[Ru(Hbidf)(PPh_3)(C_6H_5COO)]^+$, where a carboxylate anion is coordinated to Ru; the clusters at $m/z$ = 772 and 917 are still visible (Figure 8, b). Subsequently, to a freshly prepared toluene solution of **5** heated at 120 °C 1-hexyne has been added (Ru/alkyne = 1:5 molar ratio); the collected ESI(+) spectrum shows the disappearance of the signal at $m/z$ = 813 and the appearance of a cluster at $m/z$ = 854, corresponding to $[Ru(bidf)(PPh_3)(C{=}CH{-}C_4H_9)]^+$ (Figure 8, c); the cluster at $m/z$ = 800 can be tentatively assigned

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

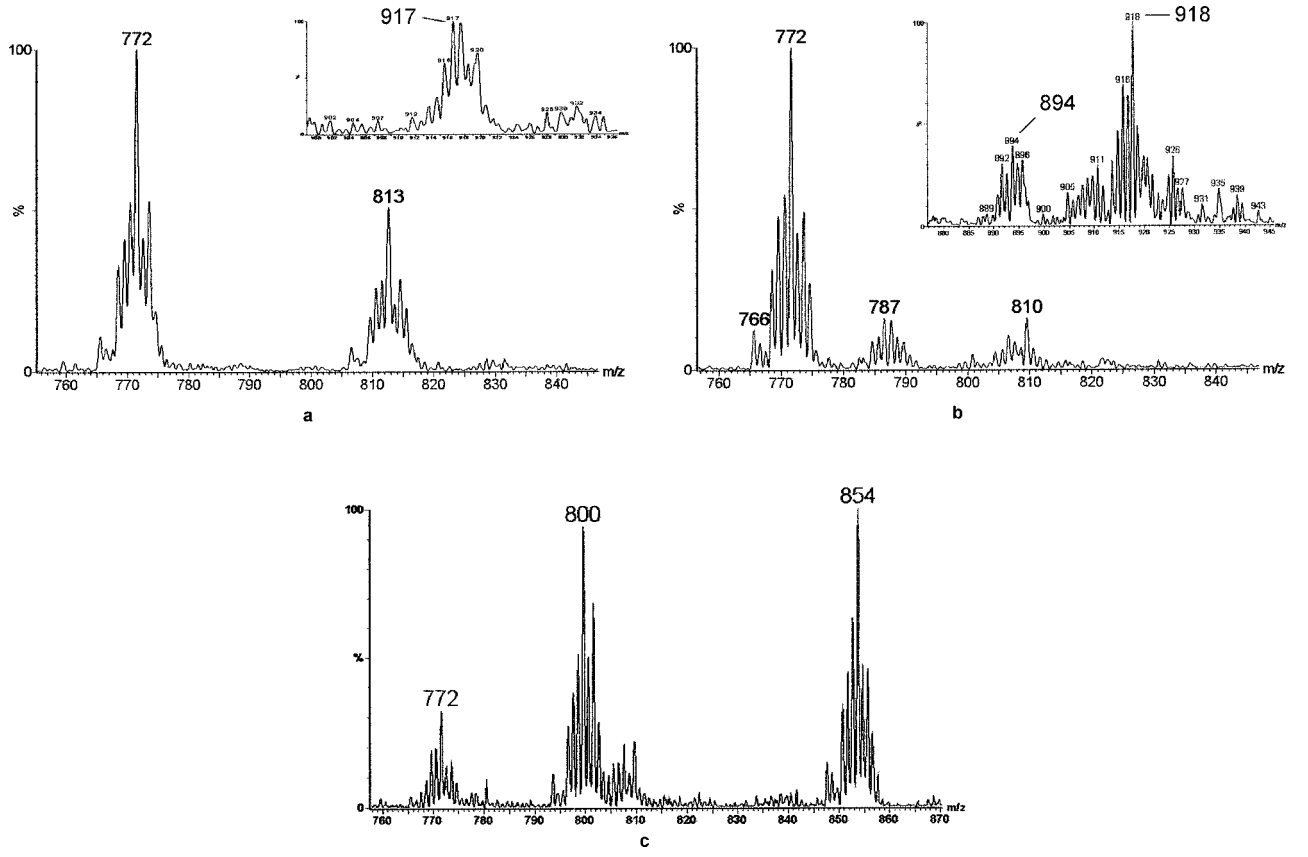

Figure 8. ESI(+) spectra of toluene solutions of **5**: **a**) after one hour at 120 °C; **b**) after the addition of benzoic acid/$Na_2CO_3$; **c**) after the addition of 1-hexyne.

to the loss of butadiene from the vinylidene species, with formation of the cation $[Ru(bidf)(PPh_3)(C_2H_4)]^+$. This last signal however quickly disappears leaving the signal at *m*/*z* = 854. The formation of the vinylidene intermediate is then independent from the presence of benzoic acid. In fact, the addition of 1-hexyne to a toluene solution containing the carboxylate intermediate leads to the immediate disappearance of the signal at *m*/*z* = 894 in favour of that at *m*/*z* = 854. Although the ESI-MS experiments does not give conclusive evidences of the reaction mechanism governing the studied catalytic process, several observations are in favour of the intermolecular nucleophilic attack of the carboxylate anion onto the vinylidene complex $[Ru(bidf)(PPh_3)(C{=}CH{-}C_4H_9)Cl]$, such as: *i*) the formation of the vinylidene intermediate which occurs independently on the presence of the carboxylate ion, *ii*) that the signal of the carboxylate complex quickly disappears in favour of that of the vinilydene intermediate after the addition of the alkyne, and *iii*) that no signal deriving from vinylidene species containing a carboxylate anion has been detected. Unfortunately, repeated attempts aimed at the isolation or detection of $[Ru(PNO)(PPh_3)(C{=}CH{-}C_4H_9)Cl]$ species have been so far unsuccessful.

The observation of ESI-MS signals attributable to the bis-chelate complex **12** can be one of the reasons of the incomplete conversion of the alkyne substrates, as its formation, through a not defined pathway, can in principle account for catalyst deactivation.

## Conclusions

In this work we have reported the synthesis and the full characterisation of several new octahedral $Ru^{II}$ complexes obtained by reaction of $[Ru(PPh_3)_3Cl_2]$ with two protic [PNO] ligands. Depending on the experimental conditions, different coordination modes to Ru can be created, giving rise to neutral or cationic complexes of general formula *trans*-$[Ru(\kappa^3\text{-HPNO})(PPh_3)Cl_2]$, $[Ru(\kappa^3\text{-PNO})(PPh_3)(CH_3CN)Cl]$, $[Ru(\kappa^3\text{-HPNO})(PPh_3)(CH_3CN)Cl][X]$ (X = $PF_6$ or $BPh_4$) and $[Ru(\kappa^3\text{-PNO})(PPh_3)(CH_3CN)_2][X]$. The complexes of the type *trans*-$[Ru(\kappa^3\text{-HPNO})(PPh_3)Cl_2]$ show an interesting reactivity with dmso which leads to the formation of bis-chelate complexes of the type $[Ru(\kappa^3\text{-PNO})_2]$. Such unusual conversion, monitored by $^{31}P\{^1H\}$ spectroscopy, occurs through the stepwise decoordination of the three donors of the [PNO] ligand induced by dmso. Then, the initial detachment of the amide oxygen leads to the formation of intermediate species where the ligands are $\kappa^2$-(H)PN coordinated; subsequently, the nitrogen decoordination leads to P-monodentate behaviour and, finally, a PNO ligand transfer from two different ruthenium atoms takes

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

place with formation of the bis-chelate complex [Ru($\kappa^3$-PNO)$_2$], [Ru(dmso)$_4$Cl$_2$], $Me_2S$, $OPPh_3$ and HCl. The deoxygenation of dmso occurs by oxygen transfer to a $PPh_3$ molcule. Model systems of the spectroscopically detected intermediates have been obtained by reaction of an HPNO ligand with [Ru(dmso)$_4$Cl$_2$] and [Ru(*p*-cymene)Cl$_2$]$_2$. A catalytic version of the oxygen transfer reaction from dmso to $PPh_3$ has also been developed.

Most of the complexes containing $PPh_3$ promote the catalytic coupling between benzoic acid and terminal alkynes in toluene/$Na_2CO_3$ at 120 °C, with 1% of catalyst loading. The reactions proceed with high stereo- and regioselectivity, up to 100% as established by $^1$HNMR, towards the formation of the *anti*-Markovnikov product. Important mechanistic details come from the ESI-MS study applied for the first time to this ruthenium-catalysed coupling reaction: the enol esters form thanks to an intermolecular nucleophilic attack of a uncoordinated carboxylate anion onto a Ru–vinylidene intermediate of the type [Ru(PNO)($PPh_3$)(C=CH–$C_4H_9$)Cl].

## Experimental Section

**General:** All reactions were performed under dry nitrogen employing standard Schlenk techniques. Solvents were dried prior to use and stored under nitrogen. Elemental analysis (C, H, N and S) were performed with a Carlo Erba Mod. EA 1108 apparatus. Infrared spectra were recorded with a Nicolet 5PCFT-IR spectrophotometer in the 4000–400 cm$^{-1}$ range by using KBr disks. $^1$H NMR spectra were obtained with a Bruker 300 FT spectrometer using $SiMe_4$ as internal standard, while $^{31}$P{$^1$H} NMR spectra were recorded with a Bruker AMX 400 FT using $H_3PO_4$ 85% as external standard. Heterocorrelated $^{31}$P-$^1$H NMR spectra were measured with a Bruker Avance 400 MHz. All spectra were collected at 298 K. FAB-MS spectra were performed with a Micromass Autoespec mass spectrometer, employing *m*-nitrobenzyl alcohol as matrix. A Quattro LC triple quadrupole instrument (Micromass, Manchester, UK) equipped with an electrospray interface and a Masslynx v. 3.4 software (Micromass) was used for ESI-MS data acquisition and processing. The nebulizing gas (nitrogen, 99.999% purity) and the desolvation gas (nitrogen, 99.998% purity) were delivered at a flow-rate of 80 and 500 L/h, respectively. ESI-MS analyses were performed by operating the mass spectrometer in positive (PI) ion mode, acquiring mass spectra over the scan range *m*/*z* 100–1300, using a step size of 0.1 Da and a scan time of 1.2 seconds. The operating parameters of the interface were as follows: source temperature 70 °C, desolvation temperature 70 °C, ES(+) voltage 3.0 kV, cone voltage 30 and 50 V, rf lens 0.3 V.

2-(Diphenylphosphanyl)benzaldehyde benzoylhydrazone (**Hbidf**) and 2-(diphenylphosphanyl)benzaldehyde acetylhydrazone (**Haidf**) were synthesised as previously reported.[4b] [Ru($PPh_3$)$_3$Cl$_2$] was synthesised by a literature reported method.[35]

***trans*-[Ru(Hbidf)($PPh_3$)Cl$_2$]·$CH_2Cl_2$ (1):** The ligand (250 mg, 0.613 mmol) was dissolved in 15 mL of $CH_2Cl_2$ at room temperature. After 10 minutes of stirring [Ru($PPh_3$)$_3$Cl$_2$] (590 mg, 0.617 mmol) was added and the resulting purple solution was stirred for 5 hours at room temperature. The solvent was partially removed in vacuo, and the solution was cooled to –18 °C for a night. A purple powder was filtered off, washed with *n*-hexane and diethyl ether and then dried under vacuum. Yield: 430 mg (83%). M.p. 160 °C (dec.). $C_{44}H_{36}Cl_2N_2OP_2Ru$·$CH_2Cl_2$ (927.642): calcd. C 58.25, H 4.10, N 3.02; found C 58.85, H, 4.11, N 3.02. $^1$H NMR ([D$_6$]dmso): $\delta$ = 8.02–6.94 (m, 34 H, Ph), 5.20 (s, 2 H, $CH_2Cl_2$) ppm. FAB-MS: *m*/*z* = 842 [M – $CH_2Cl_2$]$^+$, 807 [M – $CH_2Cl_2$ – Cl]$^+$.

***trans*-[Ru(Haidf)($PPh_3$)Cl$_2$]·1/2 $CH_2Cl_2$ (2):** As for **1** but using ligand **Haidf** (150 mg, 0.433 mmol). Yield: 310 mg (91%). M.p. 160 °C (dec.). $C_{39}H_{34}Cl_2N_2OP_2Ru$·1/2$CH_2Cl_2$ (823.105): calcd. C 57.75, H 4.26, N 3.41; found C 58.38, H 4.16, N 3.40. $^1$H NMR ([D$_6$]dmso): $\delta$ = 7.75–6.87 (m, 29 H, Ph), 5.21 (s, 1 H, $CH_2Cl_2$), 2.25 [s, 3 H, $CH_3C$(O)] ppm. FAB-MS: *m*/*z* = 780 [M – $CH_2Cl_2$ + H$^+$]$^+$, 745 [M – $CH_2Cl_2$ – Cl]$^+$, 709 [M – $CH_2Cl_2$ – HCl – Cl]$^+$.

**[Ru(bidf)($PPh_3$)($CH_3CN$)Cl] (3):** Complex **1** (320 mg, 0.380 mmol) was dispersed in 20 mL of toluene at room temperature. $NEt_3$ (262 μL, 1.900 mmol) and $CH_3CN$ (1 mL) were added, and the purple solution was stirred at room temperature overnight. A yellow solid was filtered off, washed with water and *n*-hexane and then dried under vacuum. Yield: 260 mg (81%). M.p. 180 °C (dec.). $C_{46}H_{41}ClN_3OP_2Ru$ (850.325): calcd. C 62.25, H 4.52, N 4.96; found C 65.90, H 4.98, N 4.65. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 8.16 (dd, 2 H, Ph), 7.30 (t, 2 H, Ph), 7.28–7.14 (m, 28 H, Ph), 7.12 (t, 1 H, Ph), 6.58 (t, 2 H, Ph), 1.21 (s, 3 H, $CH_3CN$) ppm. FAB-MS: *m*/*z* = 806 [M – $CH_3CN$]$^+$, 771 [M – $CH_3CN$ – Cl]$^+$.

**[Ru(aidf)($PPh_3$)($CH_3CN$)Cl] (4):** As for **3** but starting from complex **2**. Yellow solid. Yield: 130 mg (81%). M.p. 174 °C (dec.). $C_{41}H_{36}ClN_3OP_2Ru$ (785.23): calcd. C 62.86, H 4.60, N 5.36; found C 62.98, H 4.75, N 4.95. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 7.80 (t, 2 H, Ph), 7.58–7.11 (m, 24 H, Ph), 6.95 (t, 1 H, Ph), 6.54 (t, 2 H, Ph), 2.36 [s, 3 H, $CH_3C$(O)], 1.21 (s, 3 H, $CH_3CN$) ppm. FAB-MS: *m*/*z* = 786 [M + H$^+$]$^+$, 744 [M – $CH_3CN$]$^+$. For slow evaporation of a dichloromethane/acetonitrile mixture, crystals suitable for X-ray analysis were collected.

**[Ru(Hbidf)($PPh_3$)($CH_3CN$)Cl][$PF_6$] (5):** Complex **1** (250 mg, 0.297 mmol) was dispersed in 45 mL of $CH_2Cl_2$ at room temperature. After 15 minutes of stirring $KPF_6$ (280 mg, 1.521 mmol) and $CH_3CN$ (1 mL) were added. The solution was stirred overnight at room temperature, then filtered and the resulting orange solution was concentrated under vacuum, treated with *n*-hexane and refrigerated at –18 °C. An orange powder was filtered off, washed with *n*-hexane and dried under vacuum. Yield: 210 mg (71%). M.p. 170 °C (dec.). $C_{46}H_{39}ClF_6N_3OP_3Ru$ (993.271): calcd. C 55.65, H 3.93, N 4.23; found C 55.34, H 3.89, N 4.31. **[Ru(bidf)$_2$]·2H$_2$O (12). Method A:** Hbidf (100 mg, 0.244 mmol) was dissolved in ethanol (25 mL) by warming. 1 M NaOH solution was added until a pH ≈ 8 (checked by litmus paper), obtaining a pale yellow solution. $[Ru(dmso)_4Cl_2]$ (59.3 mg, 0.122 mmol) was dissolved in ethanol (10 mL) and added to the ligand solution. After 2 h of reflux the solvent was partially removed under vacuum and the resultant clear solution was refrigerated at –20 °C. The soformed solid was filtered off, washed with cold ethanol and vacuum dried. Yield: 84 mg (75%).

**Method B:** Hbidf (140 mg, 0.343 mmol) was dissolved in 5 mL of $CH_2Cl_2$ at room temperature. A KOH solution (3.75 mL , 0.21 M) was added, and the resulting pale yellow solution was stirred at room temperature for 1 hour. $[Ru(PPh_3)_3Cl_2]$ (160 mg, 0.167 mmol) previously dissolved in 15 mL of $CH_2Cl_2$ was added, and the mixture stirred at room temperature for 3 hours. The solution was then filtered and the solvent partially removed under vacuum. After cooling at –18 °C a yellow solid formed, which was filtered off, washed with diethyl ether and vacuum dried. Yield: 99 mg (63%) M.p. 253–258 °C. $C_{52}H_{40}N_4O_2P_2Ru{\cdot}2H_2O$ (951.966): calcd. C 65.60, H 4.65, N 5.88; found C 65.26, H 4.76, N 5.59. $^1$H NMR ($CDCl_3$): $\delta$ = 7.66 (d, 4 H, Ph), 7.19–6.77 (m, 38 H, Ph) ppm. CI-MS: *m*/*z* = 916 $[M - H_2O]^+$.

**[Ru(Hbidf)(dmso)$_2$Cl$_2$] (13) and [Ru(Hbidf)(dmso)Cl$_2$]·1/2dmso·H$_2$O (14):** $[Ru(dmso)_4]Cl_2$ (59.3 mg, 0.122 mmol) was dissolved in ethanol (15 mL). An equimolar amount of Hbidf dissolved in ethanol (15 mL) was added, and the resulting solution was refluxed for 1 h. A yellow solid precipitated (**13**), which was filtered off, washed with ethanol and vacuum dried for several hours. Yield: 31 mg (35%). M.p. 227 °C (dec.). $C_{30}H_{33}Cl_2N_2O_3PRuS_2$ (736.675): calcd. C 48.91, H 4.51, N 3.80, S, 8.70; found C 48.86, H 4.47, N 3.86; S, 8.78. IR ($cm^{-1}$): $\tilde{\nu}$ = 1088 (vs, S=O); 1019 (s, $\rho C–H)_{dmso}$. $^1$H NMR ($CDCl_3$): $\delta$ = 7.92 (d, 2 H, Ph), 7.79–7.20 (m, 17 H, Ph), 3.65 (s, 3 H, dmso), 3.45 (s, 3 H, dmso), 3.03 (s, 3 H, dmso), 2.84 (s, 3 H, dmso) ppm. By slow evaporation of a dmso solution of **13** crystals of **12**·dmso·H$_2$O suitable for X-ray analysis were collected (see crystallograhic analysis).

After the filtration of **13**, the resulting solution was treated with *n*-hexane observing the precipitation of an orange solid (**14**), which was filtered off, washed with *n*-hexane and vacuum dried. Yield: 34 mg (40%). M.p. 228 °C (dec.). $C_{29}H_{32}Cl_2N_2O_{3.5}PRuS_{1.5}$ (715.625): calcd. C 48.67, H 4.51, N 3.91, S 6.72; found C 48.21, H 4.71, N 4.22, S 7.14. IR ($cm^{-1}$): $\tilde{\nu}$ = 1095 (vs, S=O), 1023 (s, $\rho C–H)_{dmso}$. $^1$H NMR ($CDCl_3$): $\delta$ = 7.78–7.35 (m, 19 H, Ph), 3.48 (s, 3 H, dmso), 2.95 (s, 3 H, dmso) ppm.

**[Ru(Hbidf)(*p*-cymene)Cl$_2$]·2CHCl$_3$ (15):** Hbidf (50 mg, 0.122 mmol) was dissolved in 40 mL of chloroform and $[Ru(p\text{-cymene})Cl_2]_2$ (75 mg, 0.122 mmol) was added. The mixture was stirred at room temperature for 2.5 hours obtaining a deep red solution, which was reduced in volume and treated with diethyl ether. A brown solid precipitated (25 mg) whose characterisation was not possible. From the mother liquors refrigerated at –20 °C, brown crystals suitable for X-ray analysis were collected. Yield: 46.5 mg (40%). M.p. 220 °C (dec.). $C_{36}H_{35}Cl_2N_2OPRu{\cdot}2CHCl_3$ (953.395): calcd. C 47.87, H 3.90, N 2.90; found C 48.20, H 3.80, N 2.30. $^1$H NMR ($CDCl_3$): $\delta$ = 8.07 (d, 2 H, Ph), 7.62–7.03 (m, 17 H, Ph), 5.47 (d, 2 H, *p*-cymene), 5.33 (d, 2 H, *p*-cymene), 2.94 [m, 1 H, C*H*-$(CH_3)_2$], 1.75 [s, 3 H, $CH(CH_3)_2$], 1.28 [s, 3 H, $CH(CH_3)_2$] ppm.

**X-ray Analysis:** Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), $T$ = 293 K, on a SMART AXS 1000 diffractometer equipped with CCD detector was used for compounds **4** and **6** and **12**·dmso·H$_2$O, while Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å), $T$ = 293 K, with a Siemens AED diffractometer equipped with scintillation detector was employed for **15**·1.5CHCl$_3$, which showed a significant crystal decay over the data collection (47% intensity loss, correction applied). Lorentz, polarisation, and absorption corrections were applied.[36] Structures were solved by direct methods using SIR97[37] and refined by full-matrix least-squares on all $F^2$ using SHELXL97[38] implemented in the WingX package.[39] Hydrogen atoms were partly located on Fourier difference maps and refined isotropically, partly introduced in calculated positions. Anisotropic displacement parameters were refined for all non-hydrogen atoms in **4**, **6** and **12**·dmso·H$_2$O, but only for Ru and its coordination environment for **15**·1.5CHCl$_3$. In **12**·dmso·H$_2$O the dmso presents a disorder on the S atom. Final geometries have been analysed with SHELXL97[36] and PARST97,[40] and extensive use was made of the Cambridge Crystallographic Data Centre packages.[41] Table 4 summarises crystal data and structure determination results.

CCDC-294363 (for **4**), -294364 (for **6**), -294365 (for **12**·dmso·$H_2O$) and -294366 (for **15**·1.5 $CHCl_3$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Catalytic Reactions**

**Addition of Benzoic Acid to Terminal Alkynes:** A toluene solution (7 mL) containing the catalyst (0.01 mmol) and the alkyne (1 mmol) was added at room temperature to a toluene solution (6 mL) of benzoic acid containing solid $Na_2CO_3$ (0.05 mmol). The resulting mixture was heated to 120 °C and stirred for 16 hours, then dried under vacuum; the residual solid was treated with 5 mL of $CH_2Cl_2$ and the precipitate was filtered off. Solid $NaHCO_3$ (1 mmol) was added, and the mixture was washed with $H_2O$ three times; the organic layer was dried by anhydrous $Na_2SO_4$ and reduced in volume by vacuum and then filtered through silica gel to remove the catalyst. The solution was finally dried under vacuum and analysed by $^1H$ NMR spectroscopy.

**Oxygen Transfer from Dmso to $PPh_3$:** Compound **1** (11 mg, 0.012 mmol) was dissolved in 8 mL of nitrogen-saturated dmso and $PPh_3$ (326 mg, 1.243 mmol) was added. The yellow solution was refluxed under nitrogen and small samples were withdrawn at regular intervals, added of $CDCl_3$ and analysed by $^{31}P\{^1H\}$-NMR spectroscopy.

**Supporting Information** (see footnote on the first page of this article): $^{31}P\{^1H\}$-NMR spectra of complex **1** recorded in [$D_6$]dmso.

## Acknowledgments

Dr P. Barbaro (ICCOM-CNR) is gratefully thanked for running the heterocorrelated $^{31}P$-$^1H$ spectra, while Dr. Maria Carmen Rodriguez Argüelles (University of Vigo, Spain) is thanked for FAB-MS measurements. SB thanks Xunta de Galicia for a postdoctoral grant. The authors thank ECRF and "Firenze Hydrolab" Project for access to Bruker Avance 400 MHz and the Centro Interfacoltà di Misure G. Casnati of the University of Parma for the instrument facilities.

# Polymers or Supramolecules Generated From a New V-Shaped Bis-monodentate Ligand and the Effect of Steric Hindrance on Coordination Modes of the Ligand

**Caihua Zhou,[a,b] Yaoyu Wang,*[a] Dongsheng Li,[a,b] Lijun Zhou,[a] Ping Liu,[a] and Qizhen Shi [a]**

**Keywords:** Dipyridylamine / Helical structure / Density functional study / Silver / Copper

A new V-shaped bis-monodentate ligand L (L = 2,3′-dipyridylamine) (**1**) has been designed and synthesized by alkylation reaction of pyridylamine. An investigation of the charge distributions of the coordination atoms and single-point energy calculations of four conformers of ligand L based on the geometry of conformers optimized by the DFT (density functional theory) method was carried out. The results show that the four conformers of ligand L take on two stable and two less stable configurations. Theory forecasts that two relatively stable configurations present in complexes as probable coordination motifs of the ligand, and that steric hindrance of pyridine nitrogen atoms in isomers will affect its coordination ability together with the electronic factor. This forecast has been demonstrated by the coordination chemistry of ligand L, that is, configuration (a) and (b) of the ligand occur in the following reported complexes, which combines with $Ag^{I}$ or $Cu^{II}$ through two coordination modes (bidentate bridging or a monodentate mode) resulting in coordination polymers $\{[Ag(L)_2]NO_3\}_n$ (**2**), $[Cu_2(L)_2(maa)_4]_n$ (maa = methacrylic acid) (**3**), and the mononuclear molecule $[Cu(L)_4](ClO_4)_2 \cdot 2CH_3CH_2OH$ (**4**). The ligand assumes different coordination modes in the three complexes because of different levels of steric hindrance of the pyridine nitrogen atoms in the conformers. Interestingly, polymers **2** and **3** assume a 1D helical structure and a linear framework, respectively, and **4** has a 2D supramolecular architecture induced from hydrogen bond interactions. In addition, the magnetic properties of **3** have been explored, which shows a strong antiferromagnetic interaction.

## Introduction

Crystal engineering of coordination polymers and supramolecules have attracted a lot of attention due to their potential as functional materials, as well as their intriguing compositions and topologies. Considerable progress has been made on theoretical forecasting and practical approaches aimed at controlling the topology structure and geometry of the networks.[1–3] However, the general and precise principles for the solid structures of the target products are still subjective because the self-assembly process is highly influenced by several factors such as the structure of ligands, the coordination preference of metal ions, the coordination behavior of counterions, and the solvent system.[4–6] The chemical structure of the organic ligands including the molecular angle, length, and relative orientation of the donor groups plays an extremely important role in dictating polymer topology. So far, much of the research has been concentrated on the exploitation of angular ligands with a molecular angle, such as ligands with a T-shape, V-shape etc, in the construction of versatile coordination polymer architectures.[7–9] Especially, bidentate bridging ligands with a V-shaped structure have been widely used to construct coordination frameworks with a helical structure because of its flexional characteristic and the configuration stability of binding metal ions.[10,11] On the basis of the V-shaped *exo*-bidentate ligand, 2,2′-bis(4-pyridyleneoxy)-1,1′-binaphthalene[12] and 4,4′-oxy-bis(benzoate),[13] several novel helical complexes have been prepared.

With this background in mind, our research has focused on designing new V-shaped ligands and investigating the rational control of their self-assembly with metal centers. In our previous work, we successfully constructed helical structural supramolecular complexes [14] using the V-shaped 3,4′-dipyridylamine ligand. Continuing our investigations on the coordination properties of V-shaped dipyridylamine ligands, we designed another new V-shaped bis-monodentate 2,3′-dipyridylamine ligand. Particularly, this V-shaped molecule is an isomer of the well-documented molecule 2,2′-dipyridylamine, which is widely used as a chelate

ligand in its amine form, or as a tridentate ligand in its deprotonated form.[15,16] In order to investigate the possible coordination modes of 2,3′-dipyridylamine compared to 2,2′-dipyridylamine, we explored the electronic effect of coordination atoms, the single-point energy calculations of four conformers of 2,3′-dipyridylamine based on the geometry of four conformers optimized by the DFT method. According to these guidelines, we used 2,3′-dipyridylamine as the ligand to coordinate with $Ag^{I}$ and $Cu^{II}$, and obtained two 1D polymers with a helical or linear structure and one 2D supramolecule. Herein, we report the syntheses, crystal structures, and characterization of properties of ligand (**1**) and three complexes, namely $\{[Ag(L)_2]NO_3\}_n$ (**2**), $[Cu_2(L)_2(maa)_4]_n$ (**3**), and $[Cu(L)_4](ClO_4)_2 \cdot 2CH_3CH_2OH$ (**4**). At the same time, the magnetic properties of **3** have also been studied.

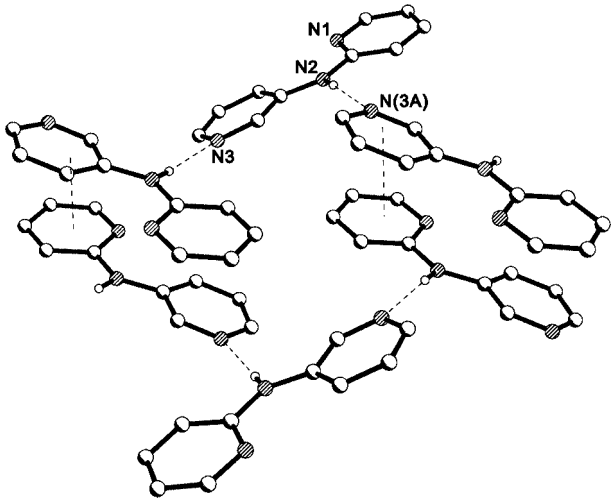

Figure 1. Perspective view of N–H···N hydrogen bonds and π-π stacking interactions in ligand **1**. [N2–N(3A) 3.0949(18) Å; N2–H···N(3A) 168.1(1)°; the distance between the centers of the pyridyl rings is 3.48(8) Å, the angle is 12.5427(4)° between two planes].

## Results and Discussion

### Description of the Structures

#### *Ligand 1*

The single-crystal X-ray structural analysis shows that ligand **1** crystallizes in an orthorhombic system. From the crystal structure of the ligand, it can be seen that the ligand forms zigzag chains in the solid state, and the molecules are held together by a series of N–H···N hydrogen bonds [N2–N(3A) 3.0949(18) Å; N2–H···N(3A) 168.1(1)°]. The two pyridine rings in the ligand are twisted with a dihedral angle of 12.5427(4)°, the ligand molecules are associated in pairs, in a head-to-tail arrangement showing π-π stacking interactions [the distance between the centers of the pyridyl rings is 3.48(8) Å, the dihedral angle is 12.5427(4)°], and give rise to a two-dimensional supramolecular structure (Figure 1).

In addition, single-point energy calculations and charge distributions for four conformers of the ligand have been carried out at DFT levels. Two stable and two less stable configurations have been obtained by structural optimization of the four conformers; the electronic layouts of the four conformers are shown in Figure 2. Single point energies of conformers (a), (b), (c), and (d) are –550.46003, –550.46214, –550.40317, and –550.40293 hartree, and the HOMO–LUMO energy gaps are 0.17477, 0.17273, 0.16899, and 0.16735 eV, respectively. These data reveal that configurations (a) and (b) are relatively more stable than (c) and (d). From the charge layouts of the four conformers, it can be seen that N1 and N3 each have an approximately equal donor electron ability in the four conformational isomers

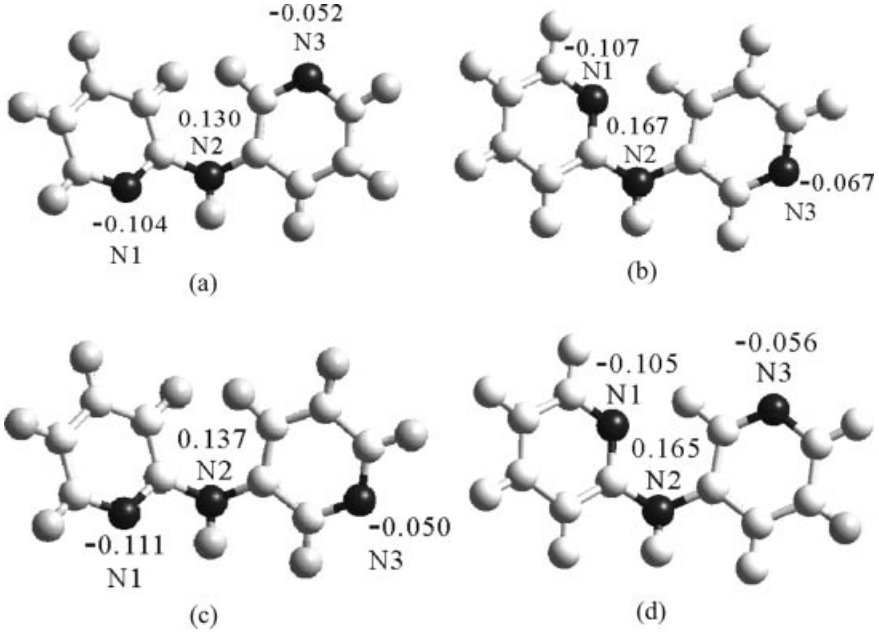

Figure 2. The four optimized conformations of the ligand **1**, as well as the calculated electron distributions.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(but each N1's donor electron ability is slightly stronger than that of each N3), if only considering their electronic effect.[17] However, we can see that the steric hindrance of N1 in configuration (b) and (d) is obviously larger than in configuration (a) and (c). Considering steric hindrance might affect the coordination ability of N1 in different configurations, we further investigated the coordination properties of ligand **1** with transition metal ions by experimental means. Fortunately, the experimental results prove this estimation. In the three synthetic complexes, we find that the ligand only takes on the coordination motifs of configuration (a) and (b). Configuration (b) presents in complex **4**, which combines with metal ions in a monodentate mode, and configuration (a) appears in polymers **2** and **3**, which links with metal ions in a bidentate bridging mode. Therefore, the difference in the coordination ability of N1 between configuration (a) and (b) mainly results from the difference in the steric hindrance of N1.

### *{[Ag(L)$_2$]NO$_3$}$_n$ (2)*

The single-crystal X-ray data shows the structure of **2** consists of one-dimensional (1D) cationic polymeric $\{[Ag(L)_2]\}^+_n$ chains and uncoordinated $NO_3^-$ anions. The ligand adopts a *N*,*N*-bidentate bridging coordination mode by using two pyridine nitrogen atoms to coordinate to the $Ag^I$ centers forming a 1D helical chain (Figure 3, a). The bond angle of N1–Ag1–N(3A) is 165.09(6)°, and the bond lengths of Ag1–N1 and Ag1–N(3A) are 2.193(2) and 2.196(2) Å, respectively, which are the typical values for $Ag^I$–$N_{py}$ coordination distances.[18–21] The helices, parallel to the [010] direction, are generated around a twofold screw axis presented in the space group $P2_1/n$. Pyridine rings through centers of inversion from adjacent helical chains indicate significant π-π stacking interactions. Pyridine rings involving π-π stacking are absolutely parallel and the distances between their centroids are 3.769(6) and 3.593(8) Å, (Figure 3, b). Not only do the intermolecular π-π stacking interactions stabilize the helical frameworks but they also produce a two-dimensional layer parallel to the crystallographic *bc* plane, the same as most reported similar helical structures.[22,23]

A striking feature of **2** is the stacking pattern in the solid state. The packing diagram of **2** shows that the $NO_3^-$ counterions are sandwiched between two layers, and every layer interacts with other close layers by two groups of C–H···O hydrogen bonds between uncoordinated oxygen atoms of $NO_3^-$ and carbon atoms of the pyridine rings [C–O 3.310(2), 3.250(2) Å, C–H···O 146.63(1), and 150.35(3)°] and Ag···O weak interactions, resulting in a 3D supramolecular structure (Figure 3c).

### *[Cu$_2$(L)$_2$(maa)$_4$]$_n$ (3)*

The structure of **3** consists of linear dinuclear one-dimensional polymeric $[Cu_2(L)_2(maa)_4]_n$ chains (Figure 4, a). The basal unit of the chain is a dinuclear $Cu^{II}$ subunit of the paddle-wheel type, the two copper atoms are located at equivalent sites in the dinuclear unit. Each copper atom has a square pyramid coordination environment, with four oxygen atoms from four methacrylic groups, forming an equatorial plane, and one pyridyl nitrogen atom, occupying an axis place. The axial Cu–N distance is longer than the average Cu–O bond length. So the coordination geometry around the copper(II) atom can be regarded as a distorted square pyramid, and the Jahn–Teller effect in the polymer manifests itself as an asymmetric elongation along the axial direction. In the structure of **3**, four methacrylic acid groups are bound to the copper(II) atoms in the form of a symmetrical bridging mode (*syn*,*syn*-$\eta^1$:$\eta^1$:$\mu_2$), thus forming a $Cu_2(maa)_4$ paddle-wheel type linked by L ligands. Just as those reported coordination polymers containing the paddle-wheel type,[24,25] the bridging ligand is located in an axial position in the paddle-wheel type structure. On the other hand, this big paddle-wheel type group hinders further torsion of the two pyridine rings of the bridging ligand, and

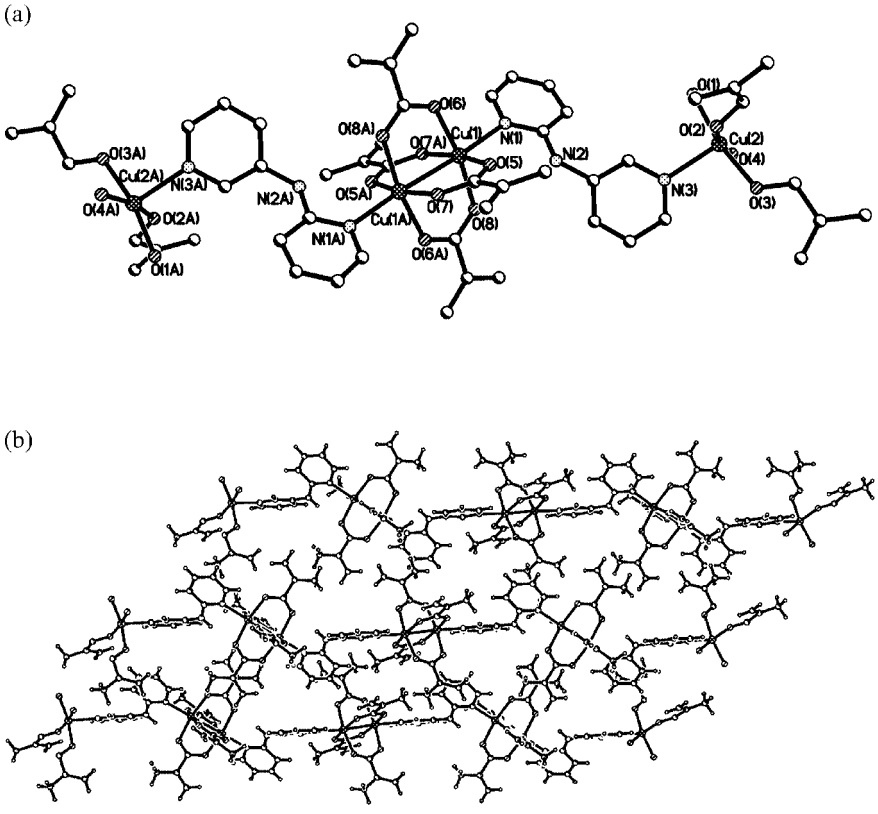

Figure 4. (a) Repeat units of the infinite coordination polymer of **3**; (b) The two-dimensional network of **3** viewed along the *a* axis.

causes the formation of a neutral one-dimensional linear chain rather than a helical chain. The chains self-organize and produce a two-dimensional supramolecular structure (Figure 4b) through C–H···O [C···O 3.513(5) Å, C–H···O 159.18(2)°] hydrogen bonds and C–H···π interaction [C–H···π 3.012(6) Å].

### *[Cu(L)$_4$](ClO$_4$)$_2$·2CH$_3$CH$_2$OH (4)*

Single-crystal X-ray diffraction analysis reveals that **4** is a neutral, mononuclear molecule with the $Cu^{II}$ atom in a square coordination geometry with four pyridine nitrogen atoms of the four different dipyridylamine ligands (Figure 5, a). From the data about the N–Cu–N bond angles [89.14(14), 90.23(10), 90.23(10), and 90.42(13)°] and the Cu–N bond lengths [2.011(2), 2.011(2), 2.019(2), and 2.019(2) Å], it can be seen that the $Cu^{II}$ ions together with the four nitrogen atoms form a perfect square geometry, and this ideal quadrangle structure is rare in the coordination geometry of $Cu^{II}$. A twofold rotary axis along the *b* axis direction presenting in space group *C*2/*c* is the typically symmetrical operation of **4**. The dihedral angles between two pyridine planes are about 28.106(2), 28.106(2), 23.418(2), and 23.418(2)° in the four ligands respectively, which are obviously larger than the free ligand **1**. This indicates that the ligand coordinated to the metal $Cu^{II}$ promoted flexion of the $\sigma_{C-N}$ bond. Interestingly, the four ligands all adopt a monodentate coordination mode and they all present in **4** as configuration (b), which further proves the theoretical judgment that the coordination ability of N1 atoms in configuration (b) has been reduced by a steric barrier. Two O atoms of the uncoordinated $ClO_4^-$ anions form the acceptors of C(4)–H···O(3) [C–O 3.277(5) Å, C–H···O 140.36(2)°] intermolecular hydrogen bonds and $Cu^{II}$···O(1) weak interactions, which link the discrete units to form a 2D supramolecular structure together with the N(2)–H···N(6) [N–N 3.130(4) Å, N–H···N 176.69(3)°] intermolecular hydrogen bonds (Figure 5, b). In this complex, the uncoordinated $ClO_4^-$ anions are an essential part of the structure, which act as a key linker in the 2D supramolecular structure, similar to $BF_4^-$ in the reported complex $[(CH_3OH)_2Co(L)_4](BF_4)_4$.[26] However, the ethonal molecule present in complex **4** only functioned as an acceptor of intramolecular hydrogen bonds between the oxygen atoms of ethonal and amino nitrogen atoms of the ligand, which has little influence on the extended structure of complex **4**.

It is worth noting that **4** has a higher stability than the organic ligand owing to the fact that the single point energy (–2397.66179 hartree) of **4** is far lower than that of **1**. The HOMO–LUMO energy gap of **4** is 0.1332 eV, and the ligand has a high contribution to the front orbit of **4**. In addition, comparing this new ligand with 2,2′-dipyridylamine, we find that there are several differences between them: (i) 2,3′-dipyridylamine is a monodentate or bidentate ligand, and 2,2′-dipyridylamine is a chelate or monodentate ligand[27] in their amine form; (ii) 2,3′-dipyridylamine is an asymmetrical V-shaped molecule that may produce different conformers in complexes, and 2,2′-dipyridylamine is a symmetrical molecule that generally has three coordination modes, *syn-syn*, *syn-anti*, and *anti-anti*;[28] (iii) the *syn-syn* conformation of 2,2′-dipyridylamine builds many linear conformations of metal complexes in its deprotonated form,[29] and 2,3′-dipyridylamine can not form linear chains of metal atoms.

### IR Spectra and TGA Analysis

IR spectra of the three complexes and the L ligand were recorded as KBr pellets in the range 4000–400 $cm^{-1}$. Ligand **1** shows a broad band at 3535 $cm^{-1}$, which can be assigned as the stretch absorption of ν(N–H). The next group of bands appears at 3071 $cm^{-1}$, corresponding to stretching vibrations of ν(C–H). Skeletal vibration of the pyridine ring shows a strong band at 1503 $cm^{-1}$. Because of the formation of intermolecular coordination bonds and hydrogen bonds, these absorption peaks are significantly shifted to lower frequencies in three complexes. In **2**, ν(N–H), ν(C–H), and the pyridine ring skeleton exhibit at 3448, 3017, and 1484 $cm^{-1}$, respectively; there is a strong absorption appearing at 1355.15 $cm^{-1}$ for the noncoordinated anions of nitrate ($NO_3^-$). While in **3** the three characteristic peaks appear at 3526, 2923, and 1496 $cm^{-1}$. Another characteristic absorption for **3** is concerned with the values of asymmetric and symmetric stretching frequencies for the $COO^-$ groups. The difference between $\nu_{as}$(COO) and $\nu_s$(COO) in comparison to the corresponding values in ionic species is currently employed to determine a characteristic coordination mode of the carboxylate group.[30] For **3**, the complex shows strong bands corresponding to $\nu_{as}$(COO) and $\nu_s$(COO) at 1601 and 1415 $cm^{-1}$, respectively. The $\Delta\nu$ is 186 $cm^{-1}$, close to the corresponding values for the sodium methacrylic (178 $cm^{-1}$), indicating that the methacrylic groups coordinate to metal ions in a symmetrical bridging mode (*syn*,*syn*-$\eta^1$:$\eta^1$:$\mu_2$), in agreement with the paddle-wheel type structure of **3**. The IR spectra of **4** is similar to **2**, ν (N–H), ν (C–H), and the pyridine ring skeleton exhibit at 3621, 3206, and 1501 $cm^{-1}$, respectively. There is a slight red shift in **4** compared to **2** and **3** because of the more conjugated pyridine rings presenting in **4**. Meanwhile, a strong absorption band appears at 1131 $cm^{-1}$ for the noncoordinated $ClO_4^-$ anions. The bands appearing below 600 $cm^{-1}$ may be assigned to the M–N frequencies for the three complexes.

The thermogravimetric analysis (TGA) reveals the weight loss of **2** occurs in two stages. The first stage occurs between 208.7 and 428.6 °C with a weight loss of 66.99%, which is equivalent to the loss of the ligands (calculated to be 66.83%). The total thermal effect of decomposition and oxidation of the ligand causes an exothermic peak at 216.5 C. When the temperature is above 440 °C, the $AgNO_3$ begins to decompose and metal silver is the final product, which constitutes 20.86% (calculated to be 20.93%). In contrast to **2**, the TGA shows that the weight of **3** remains almost unchanged from 40 to 180 °C. In the temperature range 180–400 °C, the complex undergoes a large weight loss of 76.67%, which represents weight loss from L and the methacrylic groups (calculated to be 79.12%). The DSC curve shows an exothermic peak at 218.4 °C, and the final product is CuO in 21.33% yield (calculated to be 20.88%). Complex **4** has undergone two steps of weight loss. The first weight loss occurs at 50–180 °C, corresponding to the loss of ethanol molecules. The higher temperature for the release of ethanol molecules is due to the strong hydrogen bonds involving ethanol molecules in

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**4**. At this step, the experimental percentage weight loss is 8.01% (calculated to be 8.85%). The following steps of weight loss represent the pyrolysis of the organic ligand. The residues above 500 °C have a composition of CuO, and the observed residue percentage is 7.31% (calculated to be 7.69%).

### Magnetic Properties

Variable-temperature magnetic susceptibility measurements over a 5–300 K range were carried out for **3**. The temperature dependence of magnetic susceptibilities $\chi_M$ and $\chi_M T$ of complex **3** is shown in Figure 6. It should be noted that polymer **3** exhibits two types of magnetic exchange interaction between two $Cu^{II}$ ions; one is through short bridges via the methacrylic groups and the other is through a long bridge via L. Actually, because of the long L ligand fragment, the possibility of overlap of the magnetic orbital through the C and N atoms of L is negligible. Hence, the $Cu_2(maa)_4$ unit of paddle-wheel type plays an important role in the magnetic properties of polymer **3**. This type of antiferromagnetic interaction is strong because unpaired electron density from both Cu ions is transferred to the same orbital of the bridging methacrylic groups. The $\chi_M$ curve is typical for a very strong antiferromagnetic coupling with a small amount of paramagnetic impurities: the molar magnetic susceptibility decreases to a minimum and then suddenly increases when the temperature is lowered, attaining a maximum. The magnetic datafit to a Bleaney–Bowers equation,[31,32] which was derived from the spin Hamiltonian $H = -JS_1S_2$. The best-fit parameters are $-2J = 316\ cm^{-1}$, $g = 2.09$, and $R = 6.8 \cdot 10^{-4}$ ($R = \Sigma[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2/\Sigma[(\chi_M T)_{obs}]^{1/2}$). In contrast to the reported dinuclear $Cu^{II}$ carboxylates, such as $Cu_2(C_{10}H_9O_2)_4(C_2H_5OH)_2$ ($-2J = 242\ cm^{-1}$),[33] $Cu_2(C_7H_{15}COO)_4$ ($-2J = 320\ cm^{-1}$), and $Cu_2(C_7H_{15}COO)_4(C_6H_7N)_2$ ($-2J = 300\ cm^{-1}$),[34] polymer **3** ($-2J = 316\ cm^{-1}$) shows a considerably stronger antiferromagnetic interaction.

## Conclusions

In summary, a new V-shaped ligand **1** has been designed and synthesized. Density functional calculations at the B3LYP level of theory provide a satisfactory forecast for coordination properties of the ligand with metal ions. That is, two relatively stable conformers of the ligand combine with metal ions by different coordination modes. On the basis of ligand **1**, we have synthesized three novel complexes, $\{[Ag(L)_2]NO_3\}_n$ (**2**), $[Cu_2(L)_2(maa)_4]_n$ (maa = methacrylic acid) (**3**), and $[Cu(L)_4](ClO_4)_2 \cdot 2CH_3CH_2OH$ (**4**). Interestingly, polymers **2** and **3** assume a 1D helical structure and a linear framework, respectively, and **4** has a 2D supramolecular structure. Although the two relatively stable configurations of the ligand have very similar single-point energies and charge distributions, they form different coordination modes in the three complexes. These results indicate that the steric factors of the N atoms play important roles in the coordination modes of the dipyridylamine ligand, which may help us to understand the influence of organic spacers in determining the type and topology of the product.

## Experimental Section

**Physical Measurements:** Elemental analyses (C,H,N) were determined with a Perkin–Elmer 240C elemental analyzer. Infrared spectra on KBr pellets were recorded with a Bruker EQUINOX-55 spectrometer in the range of 4000–400 $cm^{-1}$. Thermal analyses were performed with a Netzsch STA 449C microanalyzer with a heating rate of 10 °C·$min^{-1}$ under air. Magnetic measurements were carried out on a polycrystalline sample with a SQUID magnetometer operating in the 5–300 K temperature range with an applied field of 5 kOe. Diamagnetic corrections were estimated from Pascal constants. $^1H$ NMR spectra were recorded with a Varian INOVA 400-MHz spectrometer. Electronic spectra were recorded with a Cary 300 Bio UV/Visible spectrophotometer. Mass spectra were obtained with a JEOL HX-110 HF double focusing spectrometer operating in the positive ion detection mode.

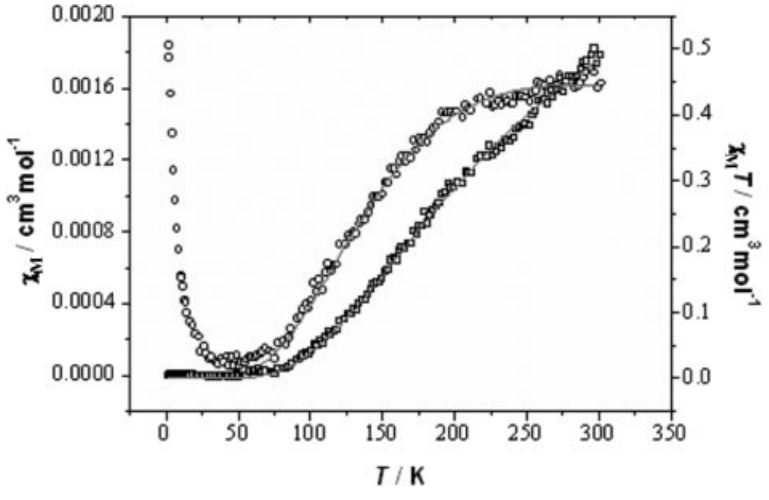

Figure 6. Plot of $\chi_M$ (○) (left scale) and $\chi_M T$ (□) (right scale) per $Cu^{II}$ ion vs. $T$ for **3**. The solid lines represent the best fit to the modified Bleaney–Bowers expression.

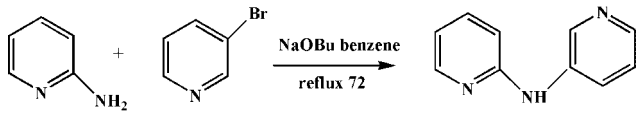
**The Synthesis of Ligand 1:** The reagents and solvents were purchased from commercial sources (Aldrich) and used as received. The 2,3′-dipyridylamine ligand was obtained as follows (Scheme 1): 2-aminopyridine (2.80 g, 34.8 mmol) and NaOBu (6.90 g, 72.9 mmol) were added to a 200 mL flask under nitrogen. Then the solution of 3-bromopyridine (3.44 mL, 34.8 mmol) and dry benzene (100 mL) were added to the container. The resulting solution was stirred for 72 h under reflux, and then cooled to room temperature. The original product was filtered and washed with dry benzene and water several times. The final product was purified by column chromatography on silica gel (dichloromethane/hexane, 1:1) to afford a colorless crystalline solid (4.16 g, 69.82%). $C_{10}H_9N_3$ (171.20): calcd. C 70.17, H 5.263, N 24.54; found C 69.98, H 5.210, N 24.66. IR (KBr): $\tilde{\nu}_{max}$ = 3535 (s), 3434 (s), 3294 (s), 3172 (s), 3071 (m), 3000 (m), 1643 (m), 1592 (m), 1503 (s), 1476 (s), 1421 (s), 1270 (m), 1210 (m), 1051 (s), 902 (m), 824 (m), 732.44 (s), 677 (m), 574 (w) $cm^{-1}$. UV/Vis ($\lambda$/nm): 320, 260, 220. MS (FAB): *m/z* (%) = 171.2 (L). $^1H$ NMR ($CDCl_3$): $\delta$ = 8.59 (s, 1 H, 1-H), 7.05 (s, 1 H, 2-H), 8.02 (d, 1 H, $^3J$ = 4.4 Hz, 3-H), 7.54 (dd, 1 H, $^3J$ = 5.8, $^3J$ = 5.4, 4-H), 7.27 (d, 1 H, $^3J$ = 5.8 Hz, 5-H), 6.80 (d, 2 H, $^3J$ = 6.3 Hz, 6-H), 8.25 (d, 2 H, $^3J$ = 3 Hz, 7-H) ppm.



Scheme 1. The preparation of ligand 2,3′-dipyridylamine.

**The Synthesis of the Complexes**

The formation of **2**, **3**, and **4** with experimental conditions are shown in Scheme 2, their syntheses are given in the sequel.

**{[Ag(L)$_2$]NO$_3$}$_n$ (2):** A solution of silver(I) nitrate (16.9 mg, 0.1 mmol) in $CH_2Cl_2$ (10 mL) was added to a solution of L (17.1 mg, 0.1 mmol) in $CH_2Cl_2$ (10 mL). The reaction mixture was stirred at 25 °C for 1 h, and then the solvent was removed under reduced pressure. The resulting white powder was partially dissolved in acetonitrile (5 mL) ($CH_3CN$). The mixture was filtered,

[a] $R_1 = \Sigma(||F_o| - |F_c|)/\Sigma|F_o|$; $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

and diethyl ether vapor was diffused into this solution. After several days, suitable single crystals for X-ray diffraction could be obtained from the acetonitrile solution. Yield: 83.98% (28.56 mg). $C_{10}H_8AgN_4O_3$ (340.07): calcd. C 35.19, H 2.34, N 16.42; found C 35.13, H 2.40, N 16.67.

**$[Cu_2(L)_2(maa)_4]_n$ (3):** $Cu_2(maa)_4{\cdot}2H_2O$ was prepared according to a similar method reported previously in the literature.[35] A methanol solution (20 mL) of L (17.1 mg, 0.1 mmol) was slowly added to a solution of $Cu_2(maa)_4{\cdot}2H_2O$ (50.4 mg, 0.1 mmol) dissolved in methanol/ethanol (20 mL, v/v = 1:1). The resultant solution was allowed to evaporate slowly for several days at room temperature, and block-shaped green crystals of **1** were obtained. Yield: 66.82% (42.63 mg). $C_{26}H_{29}Cu_2N_3O_8$ (638.68): calcd. C 50.13, H 5.48, N 10.96; found: C 50.12, H 5.45, N 10.94.

**$[Cu(L)_4](ClO_4)_2{\cdot}2CH_3CH_2OH$ (4):** The solution of $Cu(ClO_4)_2{\cdot}6H_2O$ (37.05 mg, 0.1 mmol) in ethanol (10 mL) was carefully layered on top of a solution of L (68.4 mg, 0.4 mmol) in chloroform (10 mL) in a test tube. After several days at room temperature, yellow green single crystals appeared at the boundary between ethanol and chloroform with a yield of 63.66% (66.17 mg). $C_{44}H_{48}Cl_2CuN_{12}O_{10}$ (1039.38): calcd. C 50.85, H 4.65, N 16.17; found C 50.87, H 4.60, N 16.14.

**Crystal Data Collection and Refinement:** Diffraction experiments for **1**, **2**, **3**, and **4** were carried out with Mo-$K_\alpha$ radiation using a Bruker SMART APEXCCD diffractometer at 273(2) K for **1**, **2**, **3**, and 296(2) K for **4**. A summary of the crystallographic data and structure refinement is given in Table 1, and selected bond lengths and angles of the four complexes are listed in Table 2. All structures were solved by direct methods and refined with the full-matrix least-squares technique on $F^2$ using the SHELXS-97[36] and SHELXL-97[37] programs. All non-hydrogen atoms were refined anisotropically.

X-ray crystallographic data in CIF format for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC-277949 (for **1**), -277950 (for **2**), -277951 (for **3**), and -294858 (for **4**). These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Characterization of Two Silver Iodides with One- and Three-Dimensional Hybrid Structures Constructed From Ag···Ag Interactions and Organic Templates

**Hao-Hong Li,[a] Zhi-Rong Chen,[a] Jun-Qian Li,*[a,b] Chang-Cang Huang,[a] Yong-Fan Zhang,[a] and Gui-Xiao Jia[a]**

**Keywords:** Coordination polymers / Iodine / Organic-inorganic hybrid composites / Silver

Two new organically templated silver iodides, namely $[(bmph)(Ag_5I_7)]_n$ (**1**) and $[(Hteda)_4(Ag_{12}I_{16})]_n$ (**2**), have been synthesized with $bmph^{2+}$ and teda [$bmph^{2+}$ = 1,6-bis(4-methylpyridinio)hexane, Hteda = protonated triethylenediamine] as structure-directing agents. Complex **1** consists of a one-dimensional polymer that can be described as edge-sharing $AgI_4$ tetrahedra, whereas **2** is the first example of a three-dimensional Ag/I framework based on Ag···Ag weak interactions and an organic template. Electrostatic interactions between the organic countercations and inorganic moieties are present and contribute to the crystal packing. Both compounds have been further characterized by IR spectroscopy, elemental analysis, TGA, and optical limiting measurements.

## Introduction

There has been remarkable progress and interest in the synthesis and characterization of hybrid organic-inorganic molecular materials owing to their enormous variety of intriguing structural topologies and their fascinating properties, as well as their potential applications in many fields, such as catalysis, materials science, medicine, and magnetochemistry,[1] and the optical properties of polymer hybrids have attracted particular interest from chemists recently.[2] Among the various families of hybrid functional materials, the family of metal halides is an important one. As a branch of the metal halides, silver(I) halides occupy an important position.

In general, predicting the structures of self-assembled $Ag^I$ compounds is difficult because the silver ion is known to adopt a myriad of bonding modes and coordination geometries. So far, considerable progress has been made towards the goal of obtaining specific architectures, such as the recently reported [4 × 5] $Ag_{20}$ grid,[3a] an $Ag_{10}$ quadruple helicate,[3a] and a chiral $Ag^I$ diamondoid polymer,[3a,3b] all of which were prepared on the basis of rational design principles. Most of the reports involve metal-organic compounds that have variable dimensions and topologies, and compounds that contain organic-inorganic hybrid $Ag^I$/amino systems are much less common and only zero- or one-dimensional structures are known.[4] A recent advance in this system is to design the coordination frameworks of silver(I) halides by incorporating various organic structure-directing agents (SDA). It is noteworthy that the introduction of new organic template agents always leads to a dramatic structural change of the basic inorganic phases.[5] It seems that the structure of the inorganic moiety becomes more complicated when the space volume of the SDA increases. Furthermore, the inorganic structure can be different even with the same SDA. In all, the coordination chemistry of silver halides is versatile and the study in this field is in the ascendant. We aim to probe the impact of organic quaternary ammonium cations on the structure of the inorganic moiety. In this paper, we report the preparation, crystal structures, and some physical properties of the one-dimensional hybrid complex $[(bmph)(Ag_5I_7)]_n$ and the first three-dimensional Ag/I coordination polymer $[(Hteda)_4(Ag_{12}I_{16})]_n$, assembled from $bmph^{2+}$ [$bmph^{2+}$ = 1,6-bis(4-methylpyridinio)hexane] and $Hteda^+$ ($Hteda^+$ = protonated triethylenediamine) with $Ag^I$ (Scheme 1).

## Results and Discussion

### Preparation of the Complexes

Variation of the SDA leads to the formation of two silver(I) inorganic components with different stoichiometries. They present dissimilar dimensions whose structures differ greatly in their linkage modes. Colorless block crystals of complexes **1** and **2** crystallize in a weakly acidic environment with pH = 5.0. In particular, **1** must be synthesized by slow condensation of diethyl ether into the DMF solution. The two complexes grow in solutions enriched with NaI, otherwise the crystals are of low quality or even do not form. Overall, many factors determine the anionic substructures, including the concentration and molar ratio of the starting materials, nature of the solvent, and, most importantly, the size, shape, and charge of the counterions.

### Crystal Structures

#### *[(bmph)(Ag$_5$I$_7$)]$_n$ (1)*

According to the structural analysis, the crystal structure of **1** shows a one-dimensional arrangement constructed from $(bmph)^{2+}$ fragments and $(Ag_5I_7)_n^{2-}$ chains, which are held together by electrostatic forces. The $(bmph)^{2+}$ units are discrete, but the inorganic moiety $(Ag_5I_7)_n^{2-}$ is polymeric and exists in the crystal as an extended chain along the *a* axis [Figure 1(a)]. In other words, this structure is a one-dimensional infinite polymeric anion accompanied by discrete cations. It should be mentioned that the chain is almost linear. As shown in Figure 1(b), the $(Ag_5I_7)_n^{2-}$ chain can be discussed in terms of an $Ag_5I_{10}$ building block in which each silver atom has an $I_4$ donor set and tetrahedral geometry when the Ag···Ag interactions are not taken into account. The $Ag_5I_{10}$ building block can be described as the result of five edge-sharing $AgI_4$ tetrahedra and

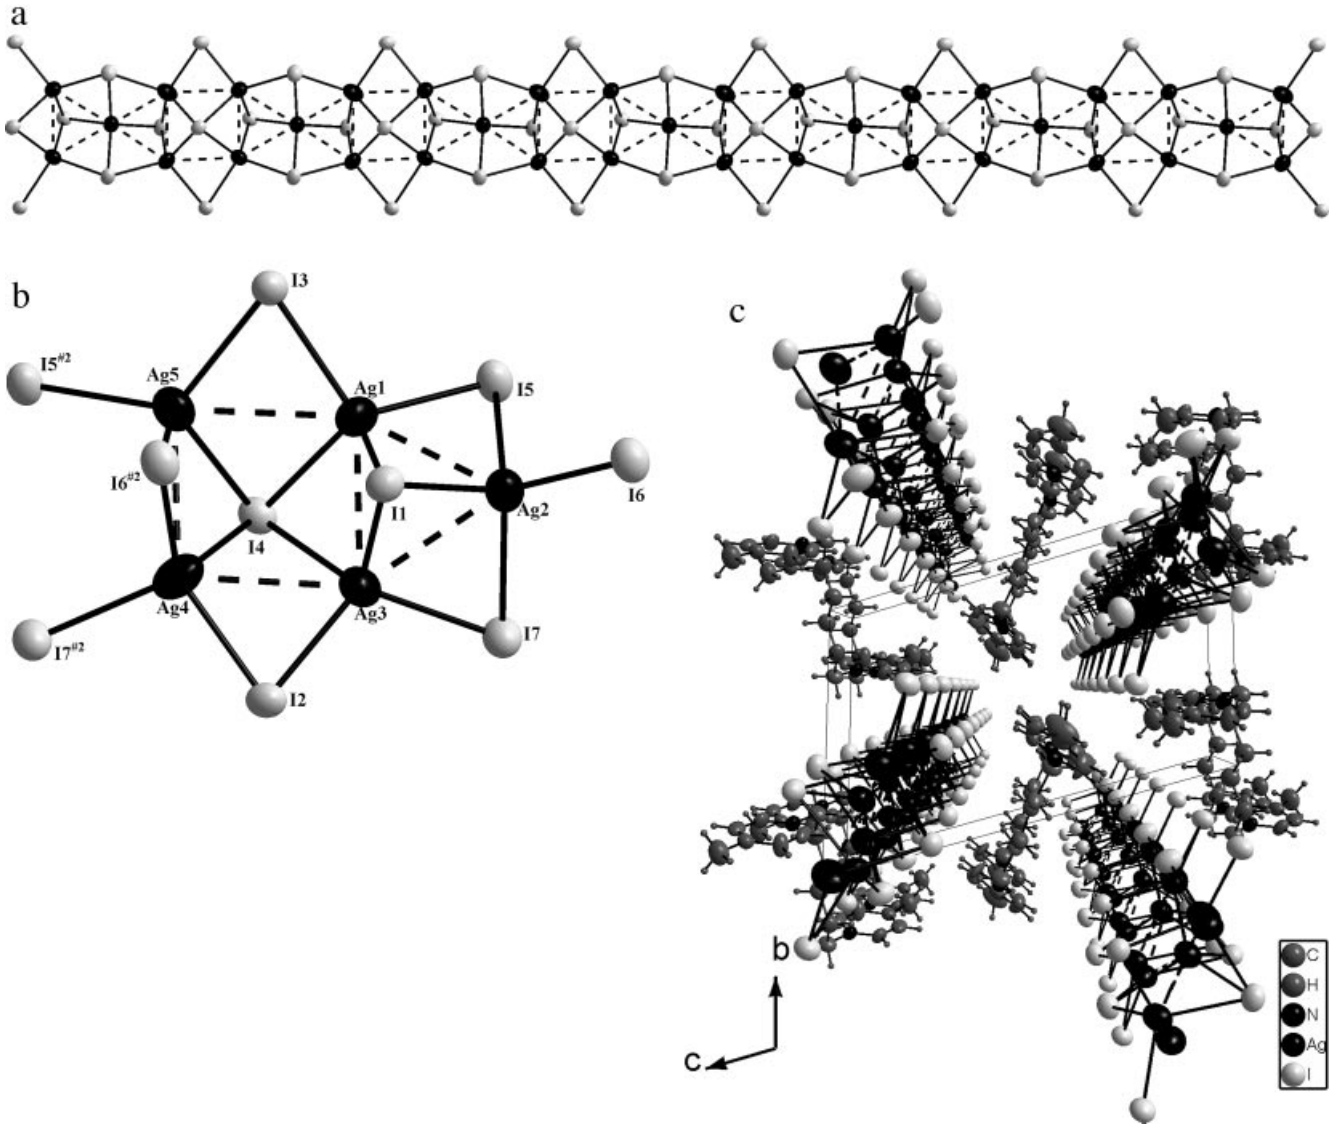

Figure 1. (a) View of the 1D zigzag chain structure of $[Ag_5I_7]_n^{2-}$ along the *a* axis. (b) Diagram of the $Ag_5I_{10}$ building block. (c) Packing diagram of **1** showing SDA molecules contained in the cavities formed by the inorganic chains.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

argentophilic interactions. The infinite chain is built up by *cis*-edge-sharing $Ag_5I_{10}$ building blocks, where the shared edges are I(5)–I(6) and I(6)–I(7).

Ag···Ag interactions have been found in many silver complexes, and the term argentophilicity has been adopted to describe this metal–metal interaction. The attraction between $d^{10}$–$d^{10}$ closed-shell metal atoms promotes the aggregation of silver(I) centers, as supported by spectroscopic and structural evidence.[6] In this work the Ag···Ag distances in **1** range from 3.038(3) [Ag(2)–Ag(4)#1, Ag(4)–Ag(2)#2] to 3.361(3) Å [Ag(3)–Ag(4)], which are longer than that of metallic silver (2.88 Å) but shorter than the van der Waals radius sum of silver (3.44 Å).[7] The Ag···Ag separations [3.312(2)–3.556(3) Å] in $[(Et_4N)_3Ag_6(\mu\text{-}2Br)_6(\mu\text{-}4Br)_3]_n$[8] suggest that weak Ag···Ag interactions may exist. Compounds possessing argentophilicity can be potentially used in silver-containing antibacterial agents.[9]

This polymeric anion contains several very interesting features, the most extraordinary of which is the local environment of the Ag(4) atom. This atom is surrounded by I(2), I(4), I(6)#2, and I(7)#2, although in order to form stable polyanions the distances of Ag(4)–I(4) and Ag(4)–I(7)#2 [3.007(3) and 3.067(3) Å, respectively] are relatively long in comparison with the normal Ag–I distance. The $Ag(4)I_4$ tetrahedron is therefore highly distorted with Ag–I lengths ranging from 2.779(2) to 3.067(3) Å. The distorted pseudo-tetrahedron of $Ag(4)I_4$ can also be extracted from the data of I(2)–Ag(4)–I(6)#2 [125.83(9)°], I(2)–Ag(4)–I(7)#2 [103.16(7)°], and I(2)–Ag(4)–I(4) [96.31(7)°], and furthermore, because Ag(4) is pseudo-tetrahedral, it leads to the tetrahedron of corner-shared Ag(5) to be distorted with three short and one long Ag–I distances [2.826(2), 2.859(2), 2.933(2), and 3.000(3) Å, respectively].

The stacking of **1** is intimately associated with the role played by the electrostatic interaction between the $(bmph)^{2+}$ cations and the silver halide polyanions in the crystal. As can be seen from Figure 1(c), groups of $(bmph)^{2+}$ cations girdle the columnar stacks, and it is this slippage and kinking of the stacks that leads to the recombinatorial structure of the compound, thus forming a so-called organic-inorganic hybrid structure.

### *$[(Hteda)_4(Ag_{12}I_{16})]_n$ (2)*

The single-crystal X-ray analysis reveals that the crystal structure of complex **2** represents a three-dimensional arrangement. As shown in Figure 2, the basic structural unit of **2** is an $Ag_{12}I_{12}$@I building block [Figure 2(a)]. If the terminal I(1) atoms are eliminated, the $Ag_{12}I_6$@I unit forms a quasi-hexagonal antiprism [Figure 2(b)] in which the top and bottom $Ag_3I_3$ hexagons are not coplanar but take on a chair-like configuration. The Ag–I–Ag angles in this $Ag_3I_3$ chair-like arrangement are 116.61(5)° and I–Ag–I angles are 120.70(4)°, so the hexagon is distorted to a small extent. An $IAg_6$ octahedron in the middle of the $Ag_{12}I_6$@I hexagonal antiprism links two $Ag_3I_3$ hexagons through $\mu_3$-I(2) and Ag···Ag interactions. This $IAg_6$ octahedron is greatly distorted, with Ag(2A) and Ag(2A)#6 occupying the axial positions and Ag(2A)#1, Ag(2A)#2, Ag(2A)#3, and Ag(2A)#4 comprising the equatorial plane [symmetry transformations: #1: $-y$, $x-y$, $z$; #2: $x-y$, $x$, $-z$; #3: $y$, $-x+y$, $-z$; #4: $-x+y$, $-x$, $z$; #6: $-x$, $-y$, $-z$; Ag(2) is distorted therefore only Ag(2A) is discussed]. The $\mu_6$-I(3) atom is located at the center of the octahedron (on a $\bar{3}$ site) and is σ-bonded to six Ag atoms, with six equivalent contacts with Ag(2A) of 2.872(3) Å. These values are much shorter than that in $\{I@[AgI(inh)]_6\}$(3.09 Å).[10] The Ag···Ag distances in **2** range from 2.915(3) Å [Ag(1)–Ag(2A)] to 3.286(4) Å [Ag(2A)–Ag(2A)#2], thereby indicating that weak Ag···Ag interactions may exist. The peripheral terminal I(1) atoms bond with Ag(2A) to complete its tetrahedral coordination geometry.

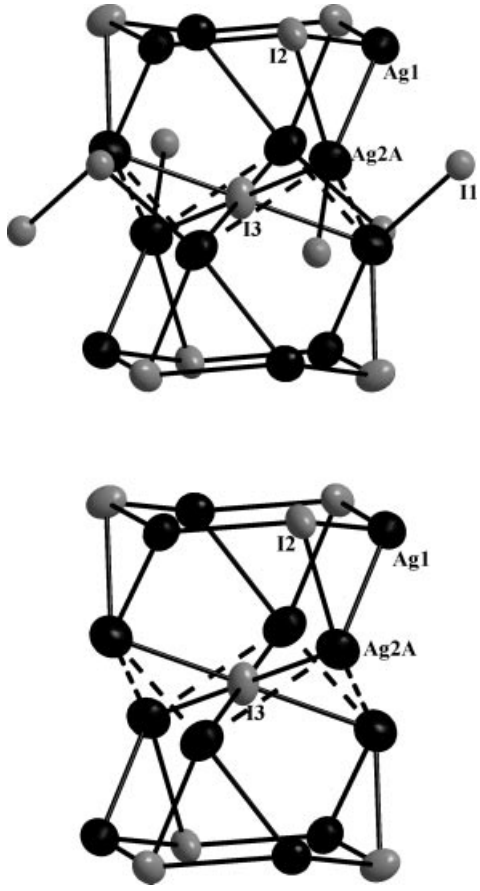

Figure 2. (a) Structure of the $Ag_{12}I_{12}$@I building block. (b) View of the $Ag_{12}I_6$@I quasi-hexagonal antiprism.

Although a series of monomeric $Ag_6$ octahedral clusters[11] and polymeric $Ag_6$ octahedral units centered by anions such as $\mu_6$-I,[10] $\mu_6$-$C_2^{2-}$, $\mu_6$-F, $\mu_3$-F, and $\mu_3$-$CF_3SO_3$[12] have been reported, this $Ag_{12}I_{12}$@I hexagonal prism cluster centered by $\mu_6$-I was unknown until now. The hexagonal surfaces of the hexagonal prism are parallel to the *ab* plane, and each $Ag_{12}I_{12}$@I building block links six $Ag_{12}I_{12}$@I prisms through $\mu_2$-I(4) into a three-dimensional arrangement (Figure 3). The triethylenediamine-based countercations arrange in a parallel fashion between the $Ag_{12}I_{12}$@I hexagonal prism building blocks and play an important structural direction role. The half-protonation of

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

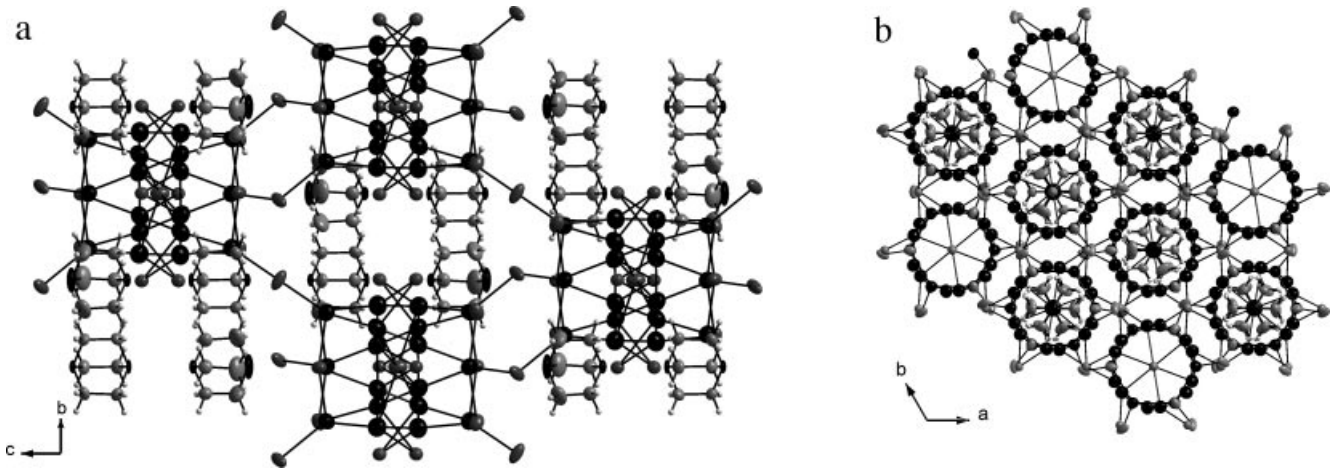

Figure 3. 3D perspective view of **1** based on $Ag_{12}I_{12}$@I building blocks [(a): side view; (b): top view].

triethylenediamine was determined from the charge-balance requirements, although, to our disappointment, the hydrogen atom of the protonated amine could not be found in the Fourier map. The organic cations line up with intermolecular N···N contacts of about 2.8 Å, which clearly indicate H-bonding distances.

A particularly obvious feature of the polymeric structure is the charge-balanced $Hteda^+$ cations trapped within the cavity of the three-dimensional cavities, which act as the nut and bolt of the tube-like combination (Figure 3). It is worth noting that the formation of the 3D polymeric cluster could be a good illustration of a cation-induced self-assembly reaction. In addition, although there are many examples of self-assembly induced or controlled by cations {such as $[(Et_3NC_6H_{12}NEt_3)_2(Ag_5I_7)]_n$ (unpublished work) and $[Ag^{II}(tmc)(BF_4)]_\infty^+$},[13] complex **2** represents the first three-dimensional product of an Ag/I assembly induced by a cation.

It is known that the formation of anionic complexes of the type $[Ag_lX_k]^{(k-l)-}$ is strongly dependent on the countercation and the nature of the halide.[14] In the case of iodide, the ions $[AgI_3]^{2-}$, $[Ag_2I_4]^{2-}$, and $[Ag_4I_8]^{4-}$ have been reported.[3] To the best of our knowledge, polymer **1** is a new example of a 1D Ag/I coordination polymer, and, more importantly, **2** is the first example of a three-dimensional product of Ag/I assembly based on weak Ag···Ag interactions and an organic template.

### Optical Limiting Effect Measurement

The optical limiting results of **1** and **2** are depicted in Figure 4. The result shows that the present compounds exhibit a good optical limiting capacity. The response of the composite is linear to the input energy intensity at the beginning, obeying Beer's law. However, as input energy intensity increases, the light transmittance starts to deviate from the linear response expected due to Beer's law when the input light fluence rises to 0.86 and 0.62 $J\,cm^{-2}$ for **1** and **2**, respectively. The limiting threshold can be defined as the incident fluence at which the solution transmittance falls to 50% of the linear transmittance. The limiting threshold value of **1** and **2** was measured as 1.12 and 0.7 $J\,cm^{-2}$ according to the experimental data. A lower limiting threshold and saturation level provide a greater safety margin for device protection. A comparison of this new compound

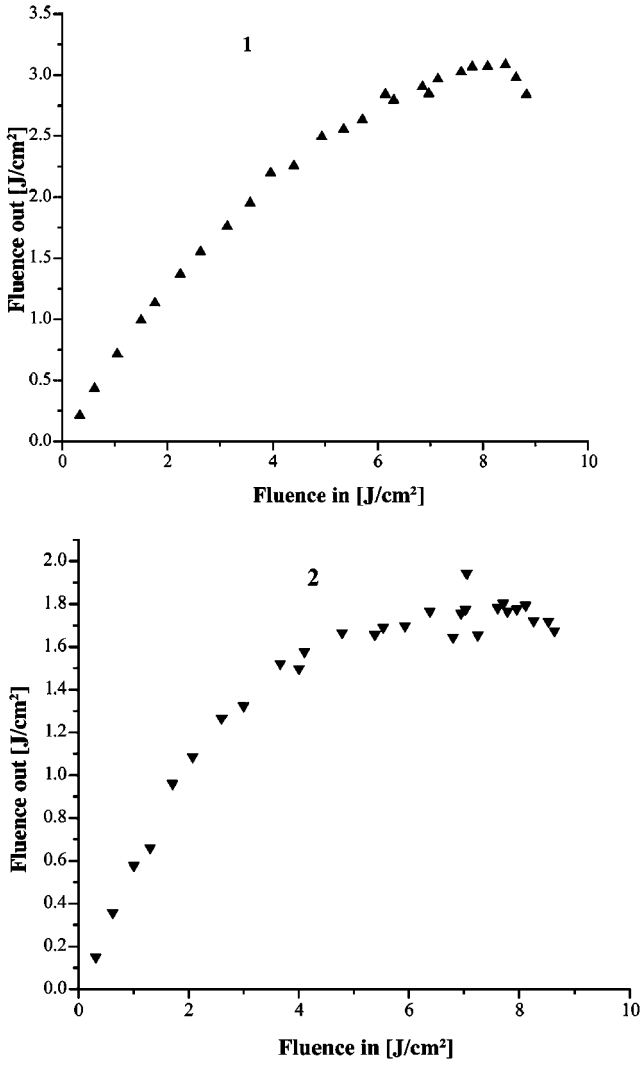

Figure 4. Optical limiting effect of $[(bmph)(Ag_5I_7)]_n$ (**1**) and $[(Hteda)_4(Ag_{12}I_{16})]_n$ (**2**) in a $1.0\times10^{-5}$ M DMF solution.

Table 1. Limiting thresholds of polymeric compounds measured at 532 nm with ns laser pulses.

| Polymeric compound | Structure type | Solvent | Limiting threshold [J cm$^{-2}$] | Ref. |
|---|---|---|---|---|
| $C_{60}$ | | toluene | 1.6 | [15a] |
| {I@[AgI(inh)]$_6$} | 1D polymer | DMF | 0.53 | [9] |
| {[La(Me$_2$SO)$_8$][(μ-WSe$_4$)$_3$Ag$_3$]}$_n$ | 1D polymer | DMF | 0.7 | [15b] |
| [MoS$_4$Cu$_6$I$_4$(py)$_4$]$_n$ | 2D microporous | DMSO | 0.6 | [15c] |
| [Et$_4$N]$_2$[MoS$_4$Cu$_6$(CN)$_4$]$_n$ | 3D cross-framework | DMF | 0.28 | [15d] |
| [(bmph)(Ag$_5$I$_7$)]$_n$ | 1D polymer | DMF | 1.12 | this work |
| [(Hteda)$_4$(Ag$_{12}$I$_{16}$)]$_n$ | 3D cross-framework | DMF | 0.7 | this work |

with other well-known optical limiting materials will be interesting. Table 1 gives the limiting thresholds of **1**, **2**, polymeric clusters, and $C_{60}$.[15] It is clear that the limiting performance of **1** in DMF solution is two times better than that displayed by $C_{60}$. It has been universally accepted that the assembly of monomeric cluster units into a polymer will bring an enhancement of the optical limiting effect.[16] Among the structure–optical limiting (OL) property correlation of clusters and polymers, the heavy atom effect also plays an important role.[2] So, as far as this work is concerned, the heavier atoms Ag and I, together with the polymeric aggregation, play a vital role in determining its OL properties. The successful synthesis of coordination polymeric clusters containing a polyiodide complex paves the way for the quick and facile preparation of novel OL materials.

### Thermogravimetric Analysis

The thermogravimetric analysis (TGA) results for **1** show that the weight loss between 40 and 240 °C is 1.76%, which might correspond to the loss of DMF solvent molecules absorbed on the crystal surface. This complex is thermally stable until around 260 °C, and then loses 30.38% of its weight in the temperature range 260–450 °C. Because isolated $(bmph)^{2+}$ molecules take the role of countercations, the framework collapses during the removal of the organic components. This stage can be attributed to the loss of (bmph)·$I_2$ (calcd. 30.85%).

The polymeric cluster **2** shows remarkable thermal stability. Thermal gravimetric analysis for **2** shows no weight loss up to 310 °C. Weight loss under heating starts at 355 °C and finishes at 980 °C.

## Conclusions

Two organically templated hybrid silver iodides, namely [(bmph)(Ag$_5$I$_7$)]$_n$ (**1**) and [(Hteda)$_4$(Ag$_{12}$I$_{16}$)]$_n$ (**2**), have been obtained as good quality single crystals by a direct method. Structural analyses indicate that both compounds consist of uncoordinated structure-directing molecules and an inorganic moiety that is tuned by organic SDAs. Complex **1** presents a one-dimensional chain structure, whereas the inorganic moiety of **2** is the first example of an Ag/I coordination polymer based on Ag···Ag weak interactions and an organic template. Both compounds possess optical limiting activity.

## Experimental Section

**General Remarks:** All chemicals except bmph·$I_2$ were of reagent grade quality from commercial sources and were used without further purification. C, H, N analyses were carried out with a Vario EL III element analyzer. IR spectra were recorded with a Nicolet Co. Magna-IR 750 spectrometer as KBr pellets in the region 4000–400 cm$^{-1}$. Thermal stability (TG-DTA) studies from room temperature to 800 °C (for **1**) and 1200 °C (for **2**) under nitrogen with a heating rate of 10 °C min$^{-1}$ were performed with a Perkin–Elmer TGA 7 instrument. The optical limiting behaviors were investigated by fluence-dependent transmittance measurements. Radiation with a wavelength of 532 nm was provided by a Q-switched Nd:YAG laser with a pulse duration of 8 ns.

**Synthesis of bmph·$I_2$:** bmph·$I_2$ was prepared as reported in the literature:[17]

**Synthesis of $[(bmph)(Ag_5I_7)]_n$ (1):** A suspension of AgI (0.234 g, 1.0 mmol), NaI (0.225 g. 1.5 mmol), and bmph·$I_2$ (0.262 g, 0.5 mmol) in DMF (10 mL) was stirred at 60 °C for 40 min. During the course of stirring, a small amount of NaI was added until the solution became colorless and clear. The resultant solution was adjusted to pH = 5.0 with 10% HI solution. After filtration, diethyl ether (10 mL) was slowly condensed into the solution. Colorless block crystals of **1** were isolated with a yield of 0.132 g (38.9%, based on Ag) after 4 d. $C_{18}H_{26}Ag_5I_7N_2$ (1698.1): calcd. C 12.73, H 1.54, N 1.64; found C 12.75, H 1.52, N 1.65. IR: $\tilde{\nu}$ = 3049 (m), 2932 (s), 2854 (m), 2445 (s), 1790 (s), 1637 (s), 1571 (m), 1510 (m), 1465 (s), 1384 (s), 1365 (s),1304 (w), 1256 (m), 1177 (s), 1115 (w), 1031 (m), 835 (s), 811 (s), 731 (m), 700 (m) $cm^{-1}$.

**Synthesis of $[(Hteda)_4(Ag_{12}I_{16})]_n$ (2):** A mixture of AgI (0.117 g, 0.5 mmol), NaI (0.225 g. 1.5 mmol), and teda (0.247 g, 2.2 mmol) in 10 mL of DMF was stirred until it became colorless and clear and was then adjusted to pH = 5.0 with 10% HI solution. Colorless crystals of **2** were isolated with a yield of 54.3% after 5 d. $C_{12}H_{26}Ag_6I_8N_4$ (1888.8): calcd. C 7.63, H 1.39, N 2.97; found C 7.69, H 1.35, N 2.80. IR: $\tilde{\nu}$ = 3437 (s), 2968 (m), 2890 (w), 2788 (m), 2637 (m), 1685 (w), 1637 (s), 1459 (s), 1177 (s), 1051 (m), 983 (s), 897 (s), 844 (s), 788 (s), 599 (s) $cm^{-1}$.

**X-ray Crystallography:** X-ray data for both complexes were collected at 293(2) K with a Rigaku Weissenbery IP diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation [$\lambda$ = 0.71069 Å]. Correction for Lp factors and multi-scan absorption corrections were applied. The structures were solved by direct methods and refined by full-matrix least-squares techniques on $F^2$ using SHELXTL-97.[18] All non-hydrogen atoms of **1** and **2** were treated anisotropically. CH hydrogen atoms were generated geometrically. Experimental X-ray data are listed in Table 2, and selected bond lengths and angles are given in Table 3. CCDC-289211 (**1**) and -280903 (**2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# A Hydrothermal Reduction Route to Single-Crystalline Hexagonal Cobalt Nanowires

By-Qin Xie,[a,b] Yitai Qian,*[a,b] Shuyuan Zhang,[a] Shenquan Fu,[a] and Weichao Yu[b]

**Keywords:** Cobalt / Hydrothermal synthesis / Magnetic properties / Nanostructures

Hexagonal close-packed (hcp) cobalt nanowires with diameters of 150–300 nm and lengths of up to several hundreds of micrometers have been synthesized by a hydrothermal reduction method. These cobalt nanowires were generated by the reduction of cobalt(II) citrate complexes by hypophosphite ($H_2PO_2^-$) in basic solution at 160 °C. High-resolution TEM and SAED reveal that the as-prepared Co nanowires have a single-crystalline structure with a [001] growth direction. The room-temperature hysteresis loop of these nanowires shows a ferromagnetic behavior with enhanced coercivity. A formation mechanism for these Co nanowires is proposed.

## Introduction

Magnetic nanomaterials have attracted considerable interest due to their novel properties and many applications in magnetic recording media, sensors and other devices.[1–4] In particular, nanocrystalline Co has sparked intensive studies not only due to its multiple crystal structures (hcp, fcc, and ε), but also because of its structure-dependent magnetic and electronic properties.[5] It has been reported that the anisotropic high magnetic coercivity of hcp-Co is the preferred structure for permanent magnet applications, as compared with the more symmetric low coercivity fcc phase used for soft magnetic applications.[6] A series of possible techniques have been applied for the structure-controlled synthesis of Co nanocrystals. For example, ε-Co nanoparticles (2–17 nm) have been synthesized in a mixture of an organic solvent and surfactant by the pyrolysis of carbonyl compounds[6,7] or a solution-phase metal salt reduction.[8,9] Thermodynamically stable hcp-Co nanorods have been obtained by the decomposition of [Co($\eta^3$-$C_8H_{13}$)($\eta^4$-$C_8H_{12}$)] in the presence of oleic acid and a long amine ligand.[10]

Anisotropic magnetic nanoparticles are expected to exhibit interesting properties because of their shape anisotropy,[11,12] and an hcp-Co nanowire array has been fabricated by an electrochemical deposition technique using polycarbonate membranes,[13] porous AAO,[14] and mesoporous silica films[15] as templates. However, most Co nanowires obtained by electrodeposition techniques are either very wide in diameter (380–420 nm) or polycrystalline.

Wet chemical methods have proved to be very effective for the production of single-crystalline, low-dimensional hexagonal cobalt nanocrystals. For example, hcp-Co nanodisks and their assembly of ribbons have been prepared by rapid decomposition of carbonylcobalt in the presence of trioctylphosphane (TOP) and oleic acid (OA),[16] and a superlattice of monodisperse hcp-Co nanorods and nanowires has been selectively synthesized by the decomposition of organometallic precursors in the presence of a mixture of long-chain amines and acid molecules.[17] A surfactant-assisted hydrothermal reduction route has been used to synthesize hexagonal cobalt nanobelts (diameter: 200–500 nm) in a mixed solvent of water and ethanol.[18] Up to now, the preparation of shape-anisotropic magnetic nanomaterials by wet chemical methods has mainly been achieved in a hot organic solvent containing a surfactant. However, recent studies have shown that low-dimensional magnetic nanostructures (such as Ni nanobelts[19] and nanoflowers[20] and $Fe_2O_3$ nanorod arrays[21]) can be formed in aqueous solution under properly controlled conditions even without the presence of surfactants. Herein, we report a facile hydrothermal method to synthesize single-crystalline hcp-Co nanowires, in which citrate salts have been introduced as a complexing reagent and shape modifier to control the growth process. The chemical reduction can be formulated as follows:

$$[Co(C_6H_5O_7)_2]^{4-} + H_2PO_2^- + 3\ OH^- \rightarrow Co + 2\ C_6H_5O_7^{3-} + HPO_3^{2-} + 2\ H_2O$$

## Results and Discussion

The crystalline nature of the phase and its purity were determined by X-ray diffraction (XRD). A representative

XRD pattern of the as-prepared product is shown in Figure 1a. All the diffraction peaks can be well indexed to hexagonal-phase cobalt, with lattice constants of $a$ = 2.506 and $c$ = 4.072 Å, which is consistent with the standard values reported in JCPDS 05-0727 (space group $P6_3/mmc$). No characteristic peaks due to the impurities of cobalt oxides or hydroxides were detected, which indicates that the nanostructures obtained by the present synthetic route consist of a pure hcp phase. In addition, the relative intensity of the peaks corresponding to the (002)/(100) and (002)/(101) planes is significantly higher than the standard values, which indicates a different growth tropism of the products. X-ray energy dispersive (EDS) microanalysis (shown in Figure 1b) of the Co nanowires indicated that the sample is essentially pure Co. Only a very small amount of oxygen (element ratio: 0.54%) was detected, which was possibly from slight oxidation of the surface. Considering that the experiment was carried out in air, it is not difficult to explain this.

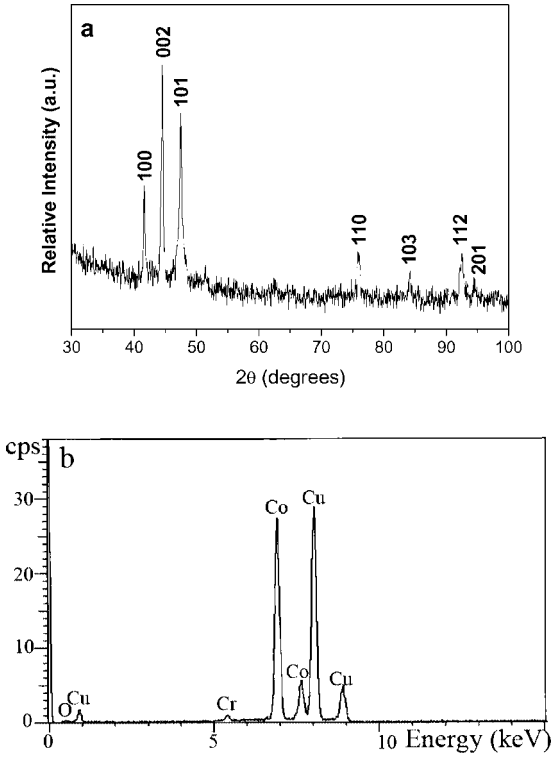

Figure 1. (a) XRD pattern of the final product obtained at 160 °C after 20 h. (b) EDS pattern of the final product (Cr and Cu signals can be attributed to the copper microgrid supporting the sample).

The morphologies and structures of the as-prepared products were examined by SEM and TEM. SEM observation (in Figure 2a) shows that the products consist of a large quantity of wire-like nanostructures. The nanowires range from several tens to several hundreds of micrometers in length. Figures 2b and c are TEM images that show the morphology of the nanowires. Each nanowire has a uniform width over its entire length, and the typical diameter of the wires is in the range 150–300 nm. Figure 2c displays the twist feature of a nanowire with an "M" shape, thus indicating the flexibility of the nanowire.

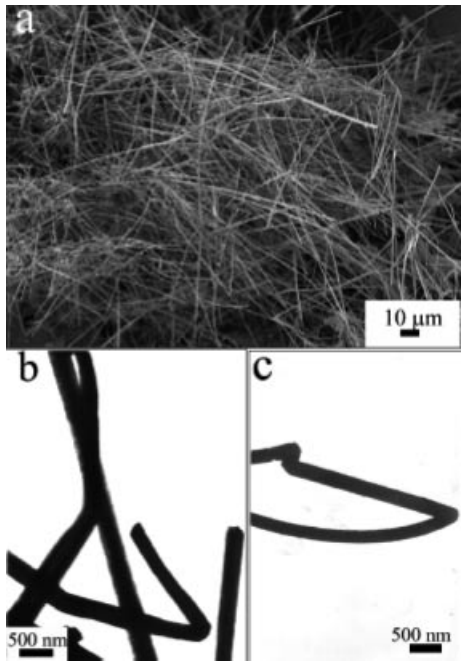

Figure 2. SEM and TEM images of the sample: (a) typical SEM image of the as-prepared Co nanowires; (b) and (c) TEM images of the Co nanowires, displaying the twist feature of the nanowire (c).

A more detailed study of the nanowires was performed by high-resolution TEM (HRTEM). Figure 3a shows a TEM image of an individual Co nanowire with a diameter of 200 nm. Figure 3b is a typical selected-area electron diffraction (SAED) pattern that was recorded from this nanowire. These pattern spots demonstrate the single-crystalline nature of this Co nanowire. Figure 3c is an HRTEM image recorded near the edge of this Co nanowire. The fringe spacing of 2.04 Å corresponding to the separation of the {002} planes of hcp-Co can be seen from Figure 3c; this also shows that the nanowire is single-crystalline. Further studies of both the HRTEM image and SAED patterns confirm that the single-crystalline nanowire grows along the [001] direction. The preferential crystal growth direction along the $c$ axis is the magnetic easy axis of hexagonal cobalt crystals.[22]

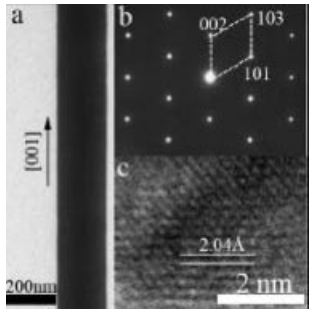

Figure 3. (a) Typical nanowire with a diameter of 200 nm. (b) SAED pattern recorded from this nanowire. (c) HRTEM image taken from the edge of this nanowire.

To investigate the nucleation and growth process of these nanowires, the evolution of the Co nanostructures was studied at various growth stages of the hydrothermal reaction by XRD and SEM techniques. Figure 4 shows the XRD patterns of samples that were taken after hydrothermal treatment for 6, 12, and 18 h. After heating for 6 h, the blue color of the mixture had disappeared and a large amount of grey solid product had formed. The XRD pattern (shown in Figure 4a) of the sample obtained at this stage indicates that hexagonal-phase cobalt had been produced. The SEM image (Figure 5a) shows that the sample is composed of cobalt particles and that they aggregate, driven by their natural magnetism. When the hydrothermal reaction time was extended to 12 h, the diffraction peaks of cobalt strengthened (Figure 4b). The SEM image (Figure 5b) reveals that radial nanowires were generated on the particles, and the surfaces of nanowires were covered with large numbers of nanoparticles. The inset of Figure 5b shows a magnified view of this radial structure. This image distinctly demonstrates that the Co nanowires grow from the particles. After 18 h, the diffraction peak of (002) planes has clearly strengthened, as shown in Figure 4c, which indicates that the sample has preferential tropism. The SEM image shown in Figure 5c shows that most of the products evolve into nanowires with smooth surfaces. After 20 h, the yield of cobalt nanowires was above 90%.

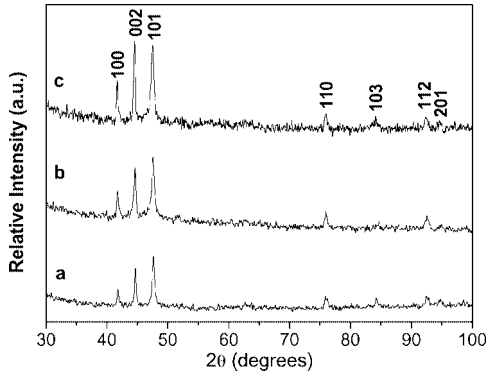

Figure 4. XRD patterns of the as-prepared samples at various growth stages of the hydrothermal process: (a) 6 h, (b) 12 h, and (c) 18 h.

On the basis of previous investigations on the evolution of cobalt nanowires, we found that this growth mode is very similar to the recent reports for the growth of one-dimensional metals in solution.[19,23] Under the present conditions, the formation of Co nanowires can also be attributed to nucleation and continuous growth by Ostwald ripening. In this mechanism, the small particles are generated by reduction of the cobalt(II) citrate complex by $H_2PO_2^-$ in basic solution in the initial stage of the hydrothermal process. In a subsequent step, the larger particles will grow at the expense of the smaller nanoparticles through the Ostwald ripening process. In the presence of citrate, most particles grow into nanowires. Finally, the nanoparticles are gradually consumed, resulting in the formation of long nanowires (shown in Figure 2a).

The presence of citrate ions is crucial for the formation of Co nanowires. Control experiments have shown that without citrate ions, only Co particles (diameter ca. 500 nm) are obtained (Figure 6a), and at a low concentration of citrate ions (0.04 M), the product (shown in Figure 6b) is a flower-like aggregation of plates (width 200 nm). In addition, we also found that by keeping all other reaction conditions the same, wire-like structures can be obtained in the presence of either citric acid or potassium citrate, but cannot be obtained in the presence of other complexing reagents such as tartrate and ethylenediamine tetraacetate. This indicates that citrate anions play a crucial role in the formation of Co nanowires. Furthermore, the different stability and structures of the Co complex precursors may affect the reaction conditions for the formation of wire-like structures, as reported for the ligand-mediated synthesis of shape-controlled materials.[20,24]

Citrate is an important biological ligand for metal ions and at high concentrations (ca. 0.2 mM) forms strong complexes with metal ions such as $Ag^+$, $Ca^{2+}$, $Mg^{2+}$, $Ni^{2+}$, and $Zn^{2+}$.[25] Citrate has been used as a shape modifier for the synthesis of ZnO complex structures[26] and Ag nanowires.[27] Citrate plays two major roles in our system. First, citrate ions can coordinate with cobalt ions to form $[Co(C_6H_5O_7)_2]^{4-}$ complexes in the excess citrate solution,[28,29] which decreases the free $Co^{2+}$ concentration in solution and results in the slow generation of Co nanoparticles. The relatively slow reaction rate may be favorable for the subsequent growth of Co nanostructures along the easy magnetic axis of the hexagonal cobalt, namely the [001] direction. In addition, citrate may bind to certain crystal faces of the cobalt particles through its $COO^-$ and OH functions. An FT-IR spectrum of the sample, hydrothermally treated in 0.2 M citrate solution for 12 h and unwashed before measurement, is shown in Figure 6c. It exhibits the characteristic absorption for the carbonyl groups of the citrate carbox-

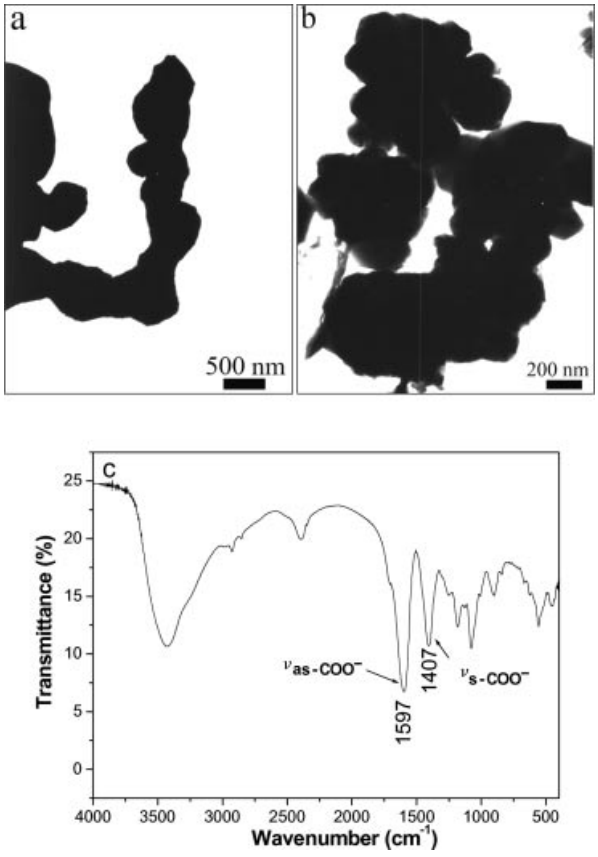

Figure 6. TEM images of products from syntheses with no sodium citrate (a) and 0.04 M sodium citrate solution (b). (c) FT-IR spectrum of the sample hydrothermally treated in 0.2 M citrate solution for 12 h and unwashed before measurement.

ylate ligands in the asymmetric and symmetric vibration regions. The asymmetric stretching vibrations $\nu_{as\text{-}COO^-}$ appear at 1597 cm$^{-1}$ and the symmetric stretching vibration $\nu_{s\text{-}COO^-}$ at 1407 cm$^{-1}$. The bands are shifted to lower frequencies compared to those of free citric acid, which suggests some interaction between metal and citrate ligand. These interactions could force the nanoparticles to grow along only one axis. In this case, citrate plays a similar role to that in the formation of Ag nanowires.[27]

Other reaction conditions, such as the concentration of NaOH in the reaction system and the reaction temperature, are also important factors in determining the shape of the final product. We found that a low concentration of NaOH solution (1 M) led to the formation of bamboo-like nanostructures with an average diameter of 300 nm (shown in Figure 7a). The reaction at a higher concentration of NaOH solution (4 M) produced Co dendrites (Figure 7b). Furthermore, if the other reaction conditions were maintained and the reaction temperature was reduced to less than 140 °C, the product was only aggregated particles. A higher temperature (such as 180 °C) resulted in wider wire-like structures and even some dendritic Co crystals. A temperature between 140 and 160 °C is therefore optimal for the growth of Co nanowires.

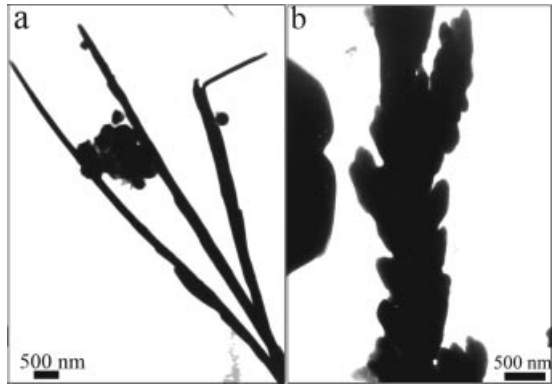

Figure 7. TEM images of the samples prepared at different NaOH concentrations: (a) 1 M NaOH solution, (b) 4 M NaOH solution.

The $M/H$ hysteresis loop (Figure 8) of the powdered Co nanowires measured at room temperature (300 K) shows a ferromagnetic behavior. The coercivity ($H_c$) and saturation magnetization ($M_s$) values are 166.8 Oe and 133.1 emu g$^{-1}$, respectively. The saturation magnetization is reduced relative to the bulk value (168 emu g$^{-1}$).[30] Surface oxidation at grain boundaries has been shown to cause a decrease in saturation magnetization.[30,31] Under the present experimental conditions, such a surface oxidation could be the reason for the decrease of $M_s$. In addition, although the

sample was washed before the measurement, a very small quantity of citrate molecules adsorbed on the Co nanowires could quench the magnetic moment through electron exchange between the ligand and surface atoms, which would partly result in the reduction of saturation magnetization.[32] Compared to the value for bulk material (a few tens of oersteds),[33] Co nanowires exhibit enhanced coercivity, which may be attributed to the small size and anisotropic shape of the nanowires. However, the coercivity value is much lower than that of the 2D and 3D superlattice of nanorods (740, 3200, and 7200 Oe)[17] or nanobelts (410.6 Oe)[18] with smaller sizes. Because a higher coercivity is an important factor for high-density information storage, further experiments are in progress to improve the coercivity of these nanowires.

## Conclusions

In summary, we have reported a simple hydrothermal reduction route for the synthesis of hexagonal Co nanowires in high yield. Citrate salts are introduced as a reagent and shape modifier to control the growth of Co nanostructures. The effects of the reaction temperature and the concentration of sodium citrate and NaOH have also been discussed. The as-prepared Co nanowires show ferromagnetism with a greater coercivity ($H_c$) than the bulk materials. Such a simple and environmentally friendly synthetic route may be extended to the fabrication of one-dimensional structures of other transition metals or their alloys.

## Experimental Section

All the reagents used were of analytical grade (purchased from Shanghai Chemical Industrial Co.) In a typical procedure for the preparation of cobalt nanowires, 10 mmol of $Na_3C_6H_5O_7{\cdot}2H_2O$, 2 mmol of $CoCl_2{\cdot}6H_2O$, and 10 mmol of $NaH_2PO_2$ were dissolved in 40 mL of distilled water, and then NaOH (10 M, 10 mL) aqueous solution was added with constant magnetic stirring. The final concentration of the raw materials in solution was 40 mM $Co^{II}$, 0.2 M citrate, 0.2 M $NaH_2PO_2$, and 2 M NaOH. The mixture was stirred for 10 min and then transferred into a 55-mL Teflon-lined autoclave. The autoclave was sealed and maintained in a furnace at 160 °C for 20 h, and then cooled to room temperature naturally. The grey powders were collected and washed with alcohol and distilled water several times and then dried in a vacuum oven at 60 °C for 5 h.

The X-ray diffraction (XRD) pattern was recorded with a Rigaku (Japan) D/max-rA X-ray diffractometer equipped with graphite-monochromated Cu-$K_\alpha$ radiation ($\lambda$ = 0.154187 nm). The SEM images were obtained with a field emission scanning electron microscope (FESEM, JEOL-6300F) or a Hitachi X-650 SEM. The TEM images were captured with a Hitachi Model H-800 instrument at an acceleration voltage of 200 kV. The high-resolution transmission electron microscopy (HRTEM) images and the corresponding selected area electron diffraction (SAED) pattern were taken with a JEOL 2010 high-resolution transmission electron microscope with X-ray energy-dispersive spectroscopy (EDS) performed at 200 kV. The FT-IR spectrum was recorded with a Bruker Vector-22 FT-IR spectrometer from 4000 to 400 $cm^{-1}$ at room temperature on KBr mulls. The magnetic measurement of the sample was carried out with a superconducting quantum interference device (SQUID) magnetometer (Quantum Design MPMS XL-7) with 6.4 mg of sample sealed in a small cylindrical vessel.

# The Relationship Between Aromaticity and Charge-Transfer Transitions: A Combined Study of Square-Planar Metal Complexes Based on DFT, NMR and Nucleus-Independent Chemical Shifts

**Christodoulos Makedonas[a] and Christiana A. Mitsopoulou*[a]**

*Dedicated to the memory of Professor Dimitris F. Katakis*

**Keywords:** Aromaticity / Density functional calculations / N ligands / S ligands / Transition metals

The aromaticity of square-planar metal complexes, in this case mixed diiminodithiolate complexes of group VIII metals, has been investigated by $^{1}H$ and $^{1}H$-$^{15}N$ NMR spectroscopy, both experimentally and theoretically, as well as NICS indices. The electron-donating/-attracting ability of the substituent group and the metal ion interact with each other and control the aromaticity of the chelated rings and, as a consequence, the extent of the delocalization in the molecular plane. Evolution of the nucleus-independent chemical shift (NICS) of the ligands upon complexation is consistent with the change in their electron distribution. At the same time, and in analogy with the EMF in closed circuits, a positive difference of the NICS value ($\Delta_{NICS}$) between two points (where HOMO and LUMO are located) can be envisioned as the driving force for charge-transfer transitions.

## Introduction

Despite the lack of a unique and precise definition, the concept of aromaticity is one of the most frequently used in organic chemistry[1] and nowadays in inorganic and organometallic chemistry as well.[2] Aromaticity is associated with the widely understood concept of electron delocalization, but until recently was mainly related to cyclic π-systems. Today, the Hückel $(4n+2)$ π-electron rule is known to be just an ideal case and aromaticity is no longer limited to fully conjugated organic rings or even nonmetals. The terms σ-aromaticity, δ-aromaticity, and even σ/δ-antiaromaticity that are currently in use imply the contribution of highly or not delocalized σ-, π-, and δ-type (referring to the symmetry) molecular orbitals.[3] Moreover, the concept of multiple (π- *and* δ-) aromaticity has been introduced for metal heterocyclic compounds, such as planar bis- and tris(dithiolene) complexes,[4,5] while a 3D aromaticity of relevant complexes has also been proved.[6] The former not only explains the peculiar properties of this class of compounds but also the "non-innocent" character of the dithiolene ligand. The latter has a significant role over a wide range of chemistry since complexes with ligands of this class are widely applicable in bioinorganic chemistry[4c] and catalysis,[4d] and as magnetic and non-linear optics materials.[4e] Here, one should stress that aromaticity/antiaromaticity in all the aforementioned systems will not manifest itself exactly the same way as in organic chemistry. Many specific deviations are expected. Nevertheless, it is believed that the overall chemical bonding picture and most of the molecular properties of these compounds should be explainable using the concepts of aromaticity and antiaromaticity.

With all this in mind, we tried to "measure" the aromaticity, or more accurately, the existence or not of significant diatropic ring currents, of a different class of compounds that bear dithiolate ligands, namely the mixed α-diiminodithiolate complexes. The latter have attracted researchers' attention since their first introduction by Miller and Dance[7] due to their interesting chemistry and their potential applications as new materials and photosensitizers.[8–11] The combination of a good π*-donor (the dithiolate ligand) and a good π*-acceptor (the diimine) leads to systems that possess intriguing properties, namely photoluminescence in solution, electrical conductivity in the solid state, large molecular hyperpolarizabilities, and large excited oxidation potentials. These properties are the result of the existence of a mixed metal-ligand-to-ligand charge transfer (MMLL′CT) band in the low-energy region of the UV/Vis/NIR spectrum, as has been indicated both experimentally[8] and theoretically.[11d]

As aromaticity is not defined exactly, since it is not a directly measurable quantity, we had to use one of the in-

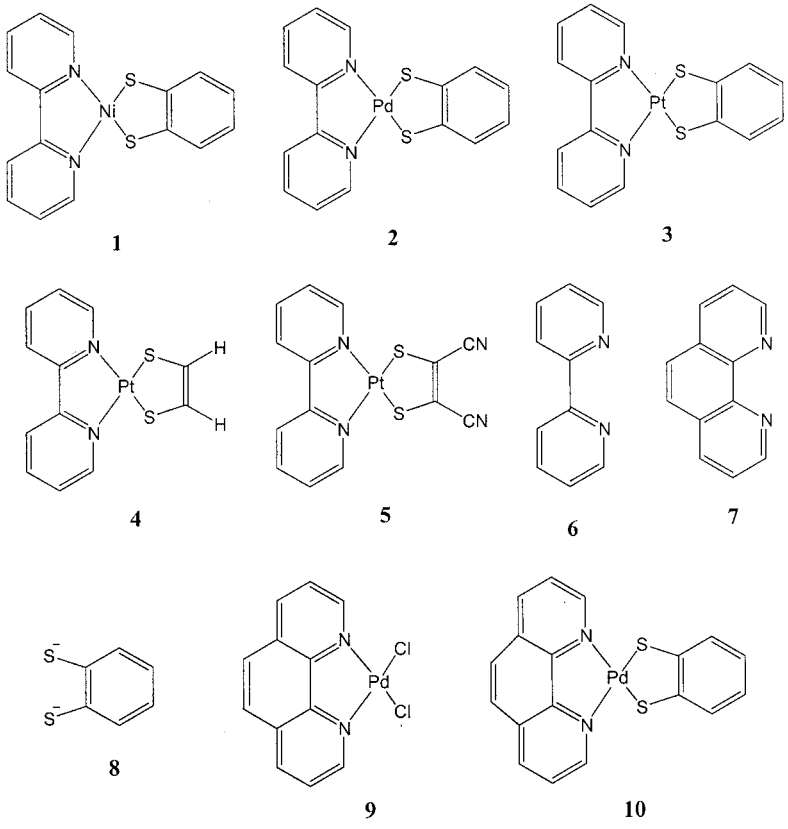
dices available in the literature. Some of the main criteria on which aromatic behavior are based are the geometrical indices, $^1$H NMR chemical shifts, ASE (aromatic stabilization energy) on the basis of homodesmotic reactions, the exaltation of magnetic susceptibility ($\Lambda$), and HOMA (harmonic oscillator model of aromaticity),[12] none of which, however, has proved to be generally applicable.[13] On the contrary, the NICS (nucleus-independent chemical shift), which is a magnetism-based index,[14] is not only widely used to characterize the aromaticity and antiaromaticity of organic rings[15] but it is also well accepted as one of the most efficient tools for the understanding and interpretation of ring currents[16] of organic compounds, boranes and fullerenes,[17] and inorganic[18] and organometallic[2] complexes. NICS values have been defined by Schleyer et al.[14] based on the absolute magnetic shieldings computed at the ring center at the ab initio, density functional, and semi-empirical (MNDO) levels; the signs are reversed to conform to the NMR chemical shift convention (negative upfield and positive downfield). Significantly negative NICS values in the interior positions of rings or cages indicate aromaticity or diatropic ring currents, whereas positive values denote antiaromaticity or paratropic ring currents.[14] Moreover, the σ-contribution can be separated from the π-contribution by using NICS(1) instead of NICS(0) values.[16a] NICS(1) refers to the location 1 Å above the center of the ring plane, where local contributions of σ-bonds are reduced in favor of the π-effects.

The above examples of the application of NICS encouraged us to undertake a systematic study, firstly to find out if mixed diiminodithiolate complexes have an aromatic character and, as a consequence, gain some hints about their electronic structure, and secondly to reveal the role of the metal atom or the substituents on the chelating ligands in the extent of delocalization of the electron current. To the best of our knowledge, although there are a few papers[2b,2c] dealing with NICS in coordination compounds, this is the first attempt at a systematic use of NICS as a probe of the change of "aromatic" delocalization in mixed-ligand metal complexes by changing the metal ion or the substituents on the conjugated rings.

## Results and Discussion

The compounds employed for this study are displayed in Scheme 1. The selection of these ten compounds was done as follows. First of all, in the formal oxidation state +2 the mixed diiminodithiolate complexes have a square-planar coordination and two planar didentate ligand systems. In other words, compounds **1**–**5** and **10** contain the metal ion as a link between two planar ligands, forming a coplanar compound with five-membered conjugated rings. The metal ion is part of a delocalized π-electron system. This delocalized system is mainly composed of the metal $d_{xz}$ orbitals, the sulfur $3p_z$, the nitrogen $2p_z$, and the carbon $p_z$ orbitals.



Scheme 1.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Complexes **1**–**3** consist of an aromatic α-diimine and an aromatic dithiolate ligand coordinated to a formally $d^8$ metal atom. Both ligands are characterized by their medium-strength π*-donating/-accepting ability and are suitable for the investigation of the metal's role. Thus, changes in the diatropic ring currents of the chelated ligands induced by tuning the metal ion will be discussed.

The next series of compounds, **3**–**5**, were employed in order to determine the substituents' effect on the dithiolate chelate ring. The dithiolate ligand in these complexes acts as a strong σ-donor, whereas its π*-donating role is reduced along the series $edt^{2-} > bdt^{2-} > mnt^{2-}$.[8,11d] The influence of the substituents' π*-accepting ability on the MMLL′CT band and the complexes' electron properties is very well established.[7–11] Finally, based on compounds **7**–**10** we will try to reveal the way that ring currents arise upon complexation.

Selected structural data for compounds **1**–**10**, optimized by DFT, are collected in Table 1 along with the available experimental data. From a close inspection of the data we can see that the DFT M–X bond lengths systematically exceed the corresponding X-ray values by about 0.04 Å, which is generally anticipated. All other parameters are in accordance with the experimental ones, thus revealing the overall agreement between theory and experiment.

Since ring currents are very sensitive to geometrical characteristics, a closer inspection of the structural data is necessary. Firstly, in the series **1**–**5** and **10** the M–N bonds are longer than those observed in M–diimine complexes, while the M–S bonds are shorter by 0.02 Å than the M–S bond of M–dithiolene complexes.[2b] This is consistent with the significant *trans* influence in similar compounds.[8d] Secondly, the C–S bond lengths in these complexes are in close agreement with the typical S–C($sp^2$) distance (1.751 Å), indicating that the observed delocalization in similar dithiolene complexes (S–C = 1.704 Å) is not seen in the mixed diiminodithiolate ones.

Focusing on the central metal's structural role, a comparison of the M–N and M–S bond lengths in the series **1**–**3** must be made. Inspection of the data collected in Table 1 shows that the above bond lengths are sensitive to the nature of the metal. Thus, the M–N bond lengths increase in the order Ni–N < Pt–N < Pd–N; Ni has a significantly smaller bonding radius than Pd and Pt. According to the contribution of each fragment and the relative energies of the bonding orbitals (Table 2), we can conclude that the better overlap between the metal atom and the dithiolate ligand in Pd complexes reduces the electron density of the M–N bonds. On the other hand, as both $Pd^{2+}$ and $Pt^{2+}$ have almost the same radius (86 and 85 pm, respectively), they can successively overlap with both conjugated ligands, thus providing the series Ni–S > Pd–S ≈ Pt–S on passing from Ni to Pt.

For chelated five-membered rings, the C–C bond should be an indicator of the cyclic electron delocalization. Thus, for a dithiolate ring the C–C bond length changes from 1.341 Å for **4** to 1.365 Å for **5** and 1.402 Å for **3**, which is close to the bond length in benzene [1.40 Å; for comparison, ($sp^2$)C=C($sp^2$) = 1.331 Å]. According to the above bond lengths the degree of bond delocalization decreases in the order **3** > **5** > **4**, thereby indicating that diatropic ring currents are reinforced by the presence of π*-accepting substituents on the dithiolate ring, in accordance with the benzene derivatives. Here, it could be argued that a C–C bond is expected to be the longest in the case of **3** since the benzene ring would try to achieve its aromatic sextet as much as possible by following the Clar rule; although this is generally true, the overall assignment must be considered to be correct as it is completely consistent with the π*-accepting ability of the substituents. The last assertion has also been stated for dithiolene complexes.[2b,2c] In the series **3**–**5**, the C–C bond lengths in the diimine-containing conjugated ring are nearly constant (1.466 Å). Thus, these bonds are practically unaffected by the substituents on the dithiolate

ligands. However, in the series **1**–**3** the C–C bond lengths in the diimine-containing conjugated ring decrease in the order **2** > **1** ≈ **3**, while the corresponding bond for the dithiolate ring remains practically the same (1.401 Å). This observation reveals the significant role of the metal in determining the extent of delocalization. Complexes **2** and **10** have identical structural characteristics, as anticipated, since bpy and phen have almost the same σ-donating and π*-accepting behavior.

Finally, the Pd–N bond of **9** is shorter than that of **10** due to the weaker *trans* influence of the chlorine atoms, whereas the phenanthroline moiety **7** is slightly affected by complexation (changes of ±0.015 Å in bond lengths). On the other hand, the C–C bond lengths of benzedithiolate **8** (1.454 Å) are more benzene-like after complexation (1.401 Å in **10**).

Considering the data in Table 2, one could suppose that the HOMO–LUMO gap can be used as an index of aromaticity.[19] However, this is quite a complicated task for the

Table 2. Contribution of different fragments to the valence orbitals of the complexes. HOMOs and LUMOs are shown in bold.

complexes under study as both the HOMO and LUMO are located in different parts of the complex (on the dithiolate ring and the diimine ring, respectively). Thus, proceeding with our analysis of the delocalization of the ring currents in M(diimine)(dithiolate) complexes by studying the NMR data and NICS indices, a cage of sampling points was built around every molecule at distances of 0, 0.5, and 1 Å above the ring plane. The grid of points includes the NICS(0) and NICS(1), as calculated by definition. NICS(0) and NICS(1) constants for all compounds under investigation are displayed in Table 3, and the $^1$H NMR frequencies of selected nuclei are shown in Table 4. The selected sampling points are indicated in Figure 1.

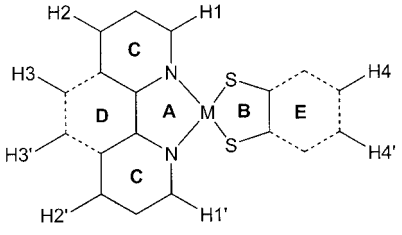

Figure 1. Sampling grid of NICS values and selected nuclei.

Specific proton nuclei were selected as indicators for the electron delocalization for the following reasons. For both bipyridine and phenanthroline complexes, H1-H1′ are close to the chelated ring – they are coupled through two bonds to the nitrogen atom and three to the metal atom – whereas protons H2-H2′ (for bpy), H3-H3′ (for phen), and H4-H4′ (for bdt) lie furthest from the metal atom and, as a result, are the most effective indicators of alterations in the π-electron current.

Based on NICS values in the ring centers (Table 3), the aromaticity of the dithiolate ring (B) is only marginal (maximum of around –5 ppm vs. around –10 ppm for benzene) while the diimine ring (A) is not aromatic (maximum NICS about –3 ppm). The nonaromatic character of the diimine ring (A) can be explained by the large difference in electronegativity between nitrogen (3.04), carbon (2.55), and the metal (2.28 for Pt and 2.20 for Pd), which leads to localization of electron density on the nitrogen atom; on the other hand, delocalization is observed in the dithiolate ring (B) due to the similar electronegativities of carbon (2.55) and sulfur (2.58). Moreover, differences in NICS values are observed with changes of metal or the substituents, thereby providing us with the opportunity to monitor changes of the diatropic current in the complexes. Thus, in the series **3**–**5** the NICS(1) values of the dithiolate ring (B) decrease in the order **5** > **3** > **4**, thereby indicating the enhanced ring diatropicity in the presence of substituents with a relatively high electron-withdrawing ability. The reverse order is found for the diimine ring, as the NICS values for (A) decrease from **4** to **3** and **5**. The electron-withdrawing groups on the dithiolate ring tend to stabilize the HOMO, thus increasing the HOMO–LUMO gap, as has been proved experimentally[8] and further supported by our calculations.[11] This stabilization has its origin in the better overlap of the central metal atom with the dithiolate ligand and causes the shielding of the latter. Moreover, the NICS(1) values of (C) (considering also the free ligand) decrease in the order **6** > **5** > **3** > **4**, in accordance with the HOMO stabilization (Table 2).

At this point we should comment on the reverse direction of $^1$H NMR and NICS(1) values that is observed on moving from free bipyridine ligand to the coordinated one. According to the NICS(1) values of (C), diatropic ring currents on the pyridine moieties diminish as a consequence of σ-donation of electron density to the metal atom through the nitrogen atoms. On the other hand, the $^1$H NMR chemical shifts (H2-H2′, Table 4) indicate that the protons of complexed bipyridine are more deshielded than those of the free ligand due to the paratropic effect of the metal atom. The asymmetrical charge-distribution in the valence orbitals of the metal atom is responsible to a large extent for the strong diamagnetic shift of the nucleus bound to it.[24] The resulting paramagnetic moment deshields the metal atom, but shields the other nucleus as in a synergic procedure. For the complexes under study, this is clearly demonstrated by the $^{15}$N NMR chemical shifts, which upon complexation are shielded from $\delta$ = 313.13 ppm for free phenanthroline to $\delta$ = 240.45 ppm for **10** (Figure 2). As a result, the rest of the bipyridine molecule is deshielded, with the effect being more apparent for the H1-H1′ nuclei (Table 4); since complexation has taken place, the $^1$H NMR and NICS(1) values are in total accordance within the series **5** > **3** > **4** provided that relativistic effects for heavy metals (i.e. Pt) are taken

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

into account even for the NICS values. In this class of complexes, the bipyridine also acts as a weak π*-acceptor, with its vacant π-orbitals interacting with filled metal d-orbitals. As H1-H1′ is deshielded in the series **4** > **3** > **5**, we expect the metal atom to be deshield in the same order. Our results are in close agreement with those reported by Bereman and Purrington et al. in their extensive study of various dithiolene complexes.[22]

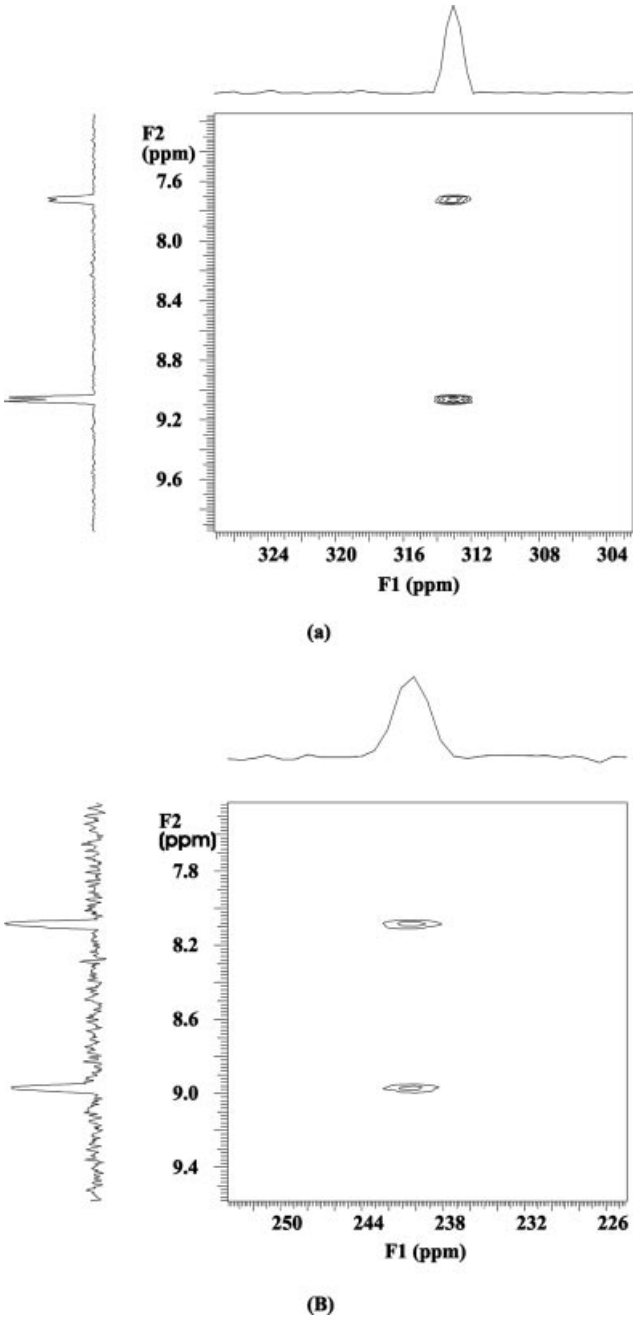

Figure 2. $^{1}H$-$^{15}N$ HMBC spectra of 1,10-phenanthroline (a) and Pd(phen)(bdt) (b).

The role of the central metal is revealed by studying the series **1**–**3**. First of all, the diatropic ring current of the dithiolate (bdt) chelate ring (B) decreases in the order **1** > **3** > **2** while the corresponding one for the (bpy) diimine conjugated ring (A) decreases in the order **3** > **2** ≈ **1**, in accordance with the energy of the MMLL′CT of these complexes. The former order was derived by Lauterbach and Fabian for a series of bis(dithiolenes).[2b] As a matter of fact, based on NICS(1) values for the bpy ring (–3.27 ppm) and the bdt ring (–4.61 ppm) complex **3** can be considered as aromatic, as opposed to **1** and **2**, where only the dithiolate ring (–5.29 and –3.77 ppm, respectively) is considered marginally aromatic. The conjugated electronic system of complex **3** appears more delocalized than the corresponding ones of **1** and **2**. The above differences can only be due to the metal atom since both chelating ligands are the same for all three complexes. Ni has not only the smallest bonding radius but also low-lying π-orbitals that could interact with the dithiolate ones; the dithiolate ligand is a π*-donor to the metal atom. Thus, the dithiolate ring in **1** is more aromatic or, more accurately, diatropic (–5.29 ppm) than the other two complexes. Due to Ni's smaller size, the overlap with the diimine orbitals is quite as effective and, as a consequence, the five-membered diimine ring is paratropic (–1.18 ppm). Pt enhances the aromaticity of both rings, as compared to Pd, probably due to the extension of its 5d orbital in spaces, which causes a better overlap with the ligand's valence orbitals, as supported by the extended delocalization of valence orbitals (Table 2).

Based on NICS(1) values for the benzenedithiolate ligand (E) (Table 3), we can conclude that its aromaticity decreases in the order **1** > **3** ≈ **2** due to its proximity to another aromatic ring. The $^{1}H$ NMR chemical shifts change very slowly in the direction **3** > **2** > **1** due to the paramagnetic influence of the central metal.

Finally, we determined the changes of diatropic and paratropic currents upon complexation by applying a procedure completely analogous to that of the synthesis, namely **7** → **9** → **10** ← **8**. First of all, phenanthroline is a highly aromatic compound, with the diimine rings being more aromatic than the benzenoid one, as is also observed in phenanthrene.[14] Complex **9** also possesses an aromatic phenanthroline ligand, but the benzenoid ring (D) is slightly more aromatic after coordination, whereas the chelated five-membered ring is slightly paratropic (+0.88 ppm). The $^{1}H$ NMR chemical shifts are, in general, consistent with the above discussion apart from a slight deviation of H1-H1′ due to the paratropic effect of the metal atom.

Complex **10** results from coordination of **8** to **9**, and several changes are induced in the ring currents. First of all, the aromaticity of the whole phenanthroline ligand is reduced, which is also confirmed by the $^{1}H$ NMR chemical shifts. NICS(1) of the diimine five-membered ring indicates a slight diatropic current (–0.45 ppm) but still the ring is not aromatic. On the other hand, the conjugated dithiolate ring is more diatropic (–3.20 ppm) and its aromaticity is marginal, while the aromaticity of the benzenoid ring (E) is maximized (–6.31 ppm for the free bdt to –8.70 ppm for the coordinated one). This behavior is expected since the interaction of the metal atom with the good σ-donor/π*-donor $bdt^{2-}$ focuses electron density on the dithiolate and benzenedithiolate ring, thereby reducing ring currents in the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

diimine rings. Moreover, the aforementioned complexation route is in favor of the delocalization of the conjugated electronic system. A graphic representation of selected NICS values is shown in Figure 3.

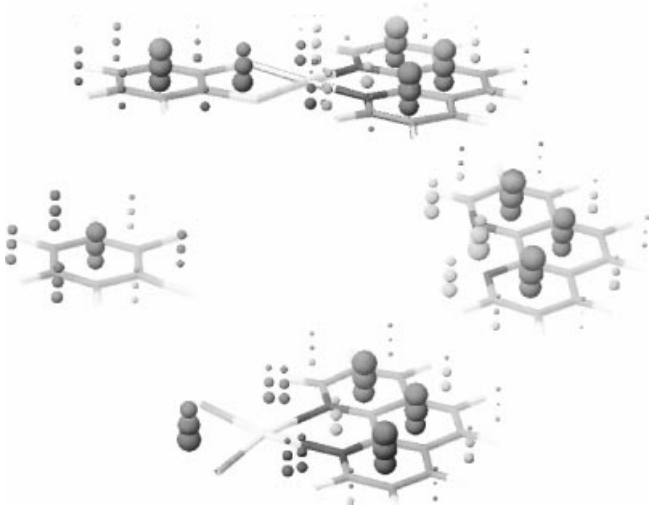

Figure 3. Graphic representation of NICS values for the selected grid for Pd(phen)(bdt), $Pd(phen)Cl_2$, phen, and $bdt^{2-}$. Dark grey spheres: diatropicity. Light grey: paratropicity.

Summarizing the effects on **10**, we suggest that a motion of diatropicity from the diimine to the dithiolate ligand is observed in a manner that is opposite to the route the electron cloud follows during the mixed metal-ligand-to-ligand transition. In that sense, the positive difference of the NICS value ($\Delta_{NICS}$) between two points where the orbitals involved in the charge-transfer transition are located can be envisioned as a difference in electron distribution and, in analogy with the EMF (electromotive force), in close circuits, as the driving force for charge-transfer transitions.

The aforementioned conclusions suggest that NICS values are not only probes for the extent of aromatic electron delocalization in cyclic conjugated systems[3a] but also in square-planar bis(chelated) metal complexes. Moreover, the evolution of the NICS during complexation is consistent with the evolution of the diatropicity of the rings and implies, at the same time, the direction of the charge-transfer transition.

## Conclusions

In the present report, structural aspects, $^1H$- and $^1H$-$^{15}N$ NMR data, as well as NICS constants are employed in order to determine the aromaticity of the mixed-ligand complexes of the type M(diimine)(dithiolate). The following are the principal results and conclusions of this investigation:

1) All complexes and ligands were fully optimized in the gas phase, giving structures in accordance with those anticipated or crystallographically determined.

2) The aromaticity of the dithiolate chelate ring is marginal, whereas the relative diimine chelate ring can be generally characterized as nonaromatic.

3) The aromatic diimine ligands lose some of their diatropicity upon complexation, an effect which is not immediately obvious from the $^1H$ NMR chemical shifts due to the presence of the metal atom but is revealed by NICS(1) values.

4) Aromatic substituents on dithiolate ligands enhance their aromaticity upon complexation as a direct consequence of the complexes' electronic properties and the Clar rules.

5) Electron-withdrawing groups as substituents on the coordinated dithiolate ring tend to enhance its diatropicity and have the opposite effect on the chelated diimine ring.

6) The role of the central metal is significant in determining the aromaticity of the complexes as it is part of the delocalized π-electron system.

The most important conclusion is:

7) In light of the diatropicity changes induced by complexation and the MMLL′CT transition which characterize these complexes, the difference in NICS values between the chelated rings (where the valence orbitals are located) can be regarded as an electronic analogue of the EMF and is the driving force of the transition. This conclusion can be applied in every case, and $\Delta_{NICS}$ for charge-transfer transitions could be analogous to $\Delta E°$ for oxidative processes.

## Experimental Section

**General:** All reactions and manipulations were conducted under argon using standard Schlenk techniques. Solvents were purified by standard procedures prior to use.[25] The chemicals 1,10-phenanthroline (phen), 2,2′-bipyridine (bpy), 1,2-benzenedithiol ($H_2bdt$), disodium maleonitriledithiolate ($Na_2mnt{\cdot}2H_2O$), [$PdCl_2$(phen)], [$PtCl_2$(bpy)], were purchased from Aldrich and used as received. The complexes [Pt(bpy)(bdt)],[20,21] [Pt(bpy)(mnt)],[8d] [Pt(bpy)(edt)],[22] [Pd(bpy)(bdt)],[20] [Ni(bpy)(bdt)],[20] and [Pd(phen)(bdt)][11a,11d] were prepared according to literature procedures. Their physical properties are consistent with those reported. $^1H$ NMR and $^1H$-$^{15}N$ HMBC spectra were recorded with Varian UNITYplus spectrometers operating at 300 and 600 MHz, respectively. Chemical shifts are reported in ppm downfield from tetramethylsilane (TMS), using the solvent peaks as an internal reference.

**Computational Methods:** DFT[26] quantum chemical calculations were carried out using the 1998 release of the GAUSSIAN suite of programs.[27] The functional used throughout this study is B3LYP (BLYP was also tested and does not influence our results in a qualitative way), which consists of a hybrid exchange functional as defined by Becke's three-parameter equation[28] and the Lee–Yang–Parr correlation functional.[29] The ground-state geometries were obtained in the gas phase by full geometry optimization, starting from structural data,[20–22,24] and were regularized in order to satisfy the $C_{2v}$ symmetry. The VeryTight option was used in all cases, which demands tighter convergence criteria than the default ones, while numerical integration was performed using the UltraFine option, which requests a pruned (99,590) grid. The optimum structures located as minima on the potential energy surfaces were verified by the absence of imaginary frequencies. No imaginary frequencies were found apart from two cases. 2,2′-bipyridine at the $C_{2v}$ symmetry is a first-order saddle point that corresponds to the transition state that links the two energy minima at the potential energy surface through rotation of the C1–C1′ bond. We preferred to use this structure because it is the one which the compound has during the complexes' formation. Every attempt to optimize

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[$PdCl_2$(phen)] in the $C_{2v}$ point group by employing basis sets with a quality superior to double-ζ was unsuccessful, giving a second-order saddle point. Optimization of the same complex with the selected basis sets under no symmetry constraint yielded a structure that is essentially equivalent (based on geometrical and NICS criteria) to that derived previously. Therefore, in our analysis we will use the first structure for uniformity reasons. The derived wavefunctions were found to be free from internal instabilities. The basis set used for all non-metal atoms was the well-known valence triple-zeta 6-311+G*.[30] The quasi-relativistic Stuttgardt–Dresden effective core potential of the type ECP28MWB and ECP60MWB was used when the central metal was Pd and Pt, respectively.[31] In the case of the Ni complex, a small core potential of the type ECP10MDF was used.[31] The core potentials were complemented by the respective valence basis sets. For all other calculations related to the investigation an additional diffuse and a polarization function was added to the hydrogen atoms. Preliminary calculations showed that the addition of a p-type polarization function to the metals' valence basis sets[2b] gave practically the same results and its addition was not selected in order to avoid further computational cost. NICS constants were calculated with the gauge-independent atomic orbital method (GIAO).[32] Finally, Mulliken population analysis was performed with the AOMix program.[33]

## Acknowledgments

Financial support by the Greek Ministry of Education and the program EPEAEK "Pythagoras I" is gratefully acknowledged. We are very grateful to Dr. D. Fox from Gaussian Inc., and Prof. P. von Ragué-Schleyer for their valuable help in the beginning of our calculations and Dr. D. Argyropoulos from Varian Inc. for recording some of the NMR spectra.

# First Experimental Observation of Gas-Phase Nitrosyl Thiocyanate

Li Yao,[a,b] Xiaoqing Zeng,[a,b] Maofa Ge,*[a] Weigang Wang,[a,b] Zheng Sun,[a] Lin Du,[a,b] and Dianxun Wang[a]

**Keywords:** Gas phase generation / Nitrosyl thiocyanate / Photoelectron spectroscopy / Time-of-flight mass spectrometer

The unstable nitrosyl thiocyanate molecule has been generated in the gas phase for the first time from an in situ heterogeneous reaction at low temperature. The product was detected and characterized by a photoelectron spectrometer-photoionization mass spectrometer (PES-PIMS). The electronic and geometric structures of the molecule were investigated with the help of quantum chemical calculations at the B3LYP, CBS-QB3, and CCSD(T) levels. The joint spectroscopic and theoretical studies provided evidence for the formation of nitrosyl thiocyanate, and indicated that the molecule adopts an open-chain, bent structure with the NO and SCN groups bonding by a relatively strong interaction.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

## Introduction

The generation and spectroscopy of sulfur–nitrogen compounds, which are known to be extremely unstable and highly reactive, is one of the very active areas of chemistry.[1,2] The thiocyanate group, SCN, is ambidentate and has the potential to bond through sulfur or nitrogen forming RSCN or RNCS type molecules. In vivo thiocyanate originates from smoking cigarettes and dietary items that contain or generate nitriles. It forms during detoxification of cyanide and normally occurs in blood at a concentration less than 2 mg per 100 mL.[3] Given the biochemical significance of NO/$NO^+$, nitrosyl thiocyanate, ONSCN, (**1**) is a species of potential biochemical interest.

ONSCN is a highly unstable blood-red compound known only in solution, which is formed by mixing a very acidic solution of sodium nitrite with a solution of potassium thiocyanate.[4] At room temperature ONSCN decomposes into NO and $(SCN)_2$ and shows the typical nitrosyl and thiocyanate group reactions [see Equation (1) and (2)].

$$H^+ + HNO_2 + SCN^- \rightleftharpoons ONSCN + H_2O \quad (1)$$

$$2\ ONSCN \rightleftharpoons 2\ NO + (SCN)_2 \quad (2)$$

Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

Despite the instability, it is widely used as a nitrosating agent in organic chemistry and biochemistry.[5,6] However, its structure is unknown since it is very unstable at high concentration and room temperature. Westwood et al. pointed out that potential media for generating and investigating **1** are the dilute gas-phase or an inert low-temperature matrix, which would provide important information on its full electronic and geometric characterization.[7]

The calculated results predicted that **1** has planar, bent structures and that isomer ON–SCN (**1a**) is more stable than ON–NCS (**1b**),[7–9] in agreement with the notion that S–nitrosation is more favourable through a soft-soft interaction, characterized by a large charge transfer from the nucleophile to the electrophile.[7,8,10]

On the other hand, there has been interest in simple, often transient, species containing triatomic pseudohalide groups e.g. –SCN, –NCO, –NNN. Recently several of these have been detected and spectroscopically characterized. Klapötke et al. have successfully isolated nitrosyl azide ON–$N_3$ at low temperature.[11] They studied the reaction of AgOCN with $ClNO_2$, ClNO, and BrNO by means of gas-phase IR spectroscopy, and proposed a reaction mechanism involving the formation of two neutral intermediates OCN–$NO_2$ and OCN–NO.[12] Our group recently reported the in situ generation of ONNCO in the gas phase and the subsequent characterization by photoelectron spectroscopy.[13] Thiazyl thiocyanide NS–SCN has been produced by an online process using NSCl passed over heated AgSCN and monitored by gas-phase FTIR spectroscopy.[14] Westwood and colleagues tried to observe the very interesting NS–NCO molecule from the reaction of $NSCl_{(g)}/AgNCO_{(s)}$, but in fact they observed another species, $S_2N_2CO$, recorded by HeI photoelectron, photoionization mass and mid-infrared spectroscopy.[15] The unexpected result has prompted them

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to carried out an ab initio study of some isomers of $CN_2OS$,[7] which also includes the ONSCN compound.

In this work we report the first gas phase generation and characterization of the unstable molecule **1** and its investigation by HeI photoelectron spectroscopy−photoionization mass spectroscopy and quantum chemical calculations.

## Results and Discussion

### Molecular Geometries

Given that both the thiocyanate and isothiocyanate exist for the $CH_3$ derivatives, we have performed an identical calculation for the molecules **1a** and **1b**. As shown by ab initio calculations[7–9], **1a** and **1b** both have planar, bent structures. Each molecule has, in principle, two rotational isomers, the *cis* and *trans* isomers. The calculated structural parameters are compiled in Table 1 (Figure 1).

Table 1. Calculated structures of planar nitrosyl thiocyanate.[a]

| | *cis*-**1a** | *trans*-**1a** | *cis*-**1b** | *trans*-**1b** |
|---|---|---|---|---|
| *r*(O–N) | 1.136 | 1.142 | 1.140 | 1.154 |
| *r*(N–S) or *r*(N–N) | 2.081 | 2.043 | 1.686 | 1.552 |
| *r*(S–C) | 1.667 | 1.676 | 1.567 | 1.561 |
| *r*(C–N) | 1.160 | 1.158 | 1.213 | 1.219 |
| (S–C–N) | 174.5 | 179.6 | 178.7 | 176.7 |
| (O–N–S) or (O–N–N) | 115.2 | 114.4 | 115.3 | 112.4 |
| (N–S–C) or (N–N–C) | 95.35 | 94.45 | 116.3 | 119.6 |

[a] Bond lengths in Å and angles in degrees at B3LYP/6-311++G(3d) level.

All calculations predict **1a** to be the more stable in the gas phase. According to the CCSD(T)/6-311++G(3d) level of theory, the more stable *cis*-**1a** isomer gives a total energy less than that of *cis*-**1b** by 11.2 kcal mol$^{-1}$.

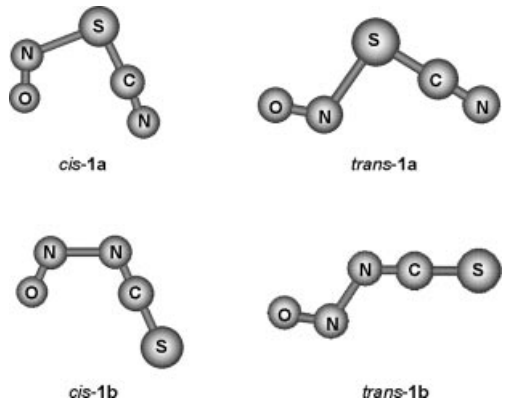

Figure 1. Stable conformers of nitrosyl thiocyanate.

Figure 2 shows a limited 3D plot of the potential energy surface, which indicates that both the *cis* and *trans* conformers of **1a** lie in a deep well with respect to the N–S coordinate and need only rotate around the long N–S bond with a low barrier. At the CBS-QB3 level the energy gap between the *cis* and *trans* conformers is calculated to be 2.0 kcal mol$^{-1}$, and the transition state resides just 4.5 kcal mol$^{-1}$ above the *trans* conformer.

In several molecules containing triatomic pseudohalide groups e.g. –SCN, –NCO, –NNN, etc., it has been established that the atoms are not colinear. When combining the SCN ligand with NO, the SCN angle shows a deviation of about 5° from linearity, which is similar to those of XSCN (X = CN[16], SCN[17], Cl[18], Br[18]). Comparing the predicted NO bond with experimentally determined bond lengths of similar molecules, we find that the predicted O–N bond of **1** (1.136–1.154 Å) lies between the diatomic NO (1.151 Å)[19] and ClNO (1.139 Å)[20], favoring ClNO slightly. However, on considering the linearity from the

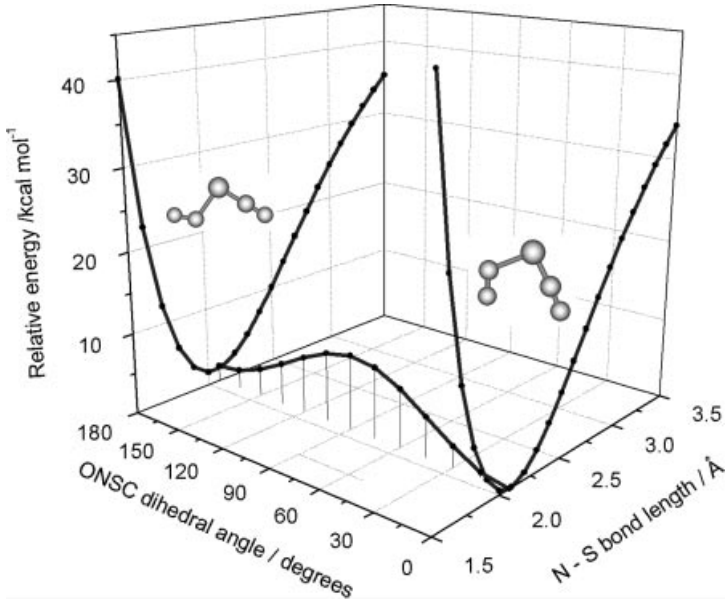

Figure 2. Calculated [B3LYP/6-311++G(3d)] potential-energy surfaces for the *cis* and *trans* conformers along the N–S coordinate together with the interconnecting surface obtained by torsion of the N–S bond in **1a**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

point of the whole molecule **1a** the calculated N–S bond length (2.043–2.081 Å) is much longer than that of $S_2N_2$ (1.65 Å)[21] and NSCN (1.49 Å)[22], and the NSC angle (95.35–94.45°) is much smaller than the NSC in NSCN[22] (109.3°) and ∠SSC in $(SCN)_2$[17] (108.2°). These data indicate that a strong interaction exists between the NO and SCN groups.

### Photoionization Mass Spectroscopy

The HeI photoionization mass spectrum (Figure 3) observed at –60 °C is relatively simple. The main peaks in the spectrum are $NO^+$, $SCN^+$, $ON–SCN^+$, and $Cl^+$, respectively, with the dominant feature being the $NO^+$ peak. Since there are no NO, SCN, and Cl photoelectron peaks in the PE spectrum (Figure 4), it is suggested that the signals of $NO^+$, $SCN^+$, and $Cl^+$ come from the dissociation of parent ions. For some molecules, HeI photoionization produces a fragmentation ion distribution similar to that of electron-impact ionization.[23] This may be rationalized by a similar energy deposition mechanism for the two methods, as the interaction energies (some tens of electronvolts) are comparable. The dominant fragment ions $NO^+$ and $X^+$ (X = SCN) in the HeI photoionization mass spectra are analogous to those of other ONX molecules (X = Cl, $CH_3$) in the electron impact spectra. They mostly result from the direct dissociation of the parent ions $ONX^+$. Although there is no parent ion peak for ClNO in the photoionization mass spectra of the products, the PE bands of the ClNO molecule appear in the photoelectron spectrum (Figure 4). This indicates that the signals of $Cl^+$ and a part of $NO^+$ originate from the dissociation of $ClNO^+$, which is very unstable and dissociates to $Cl^+$/NO or $NO^+$/Cl once it is formed. This also agrees with the electron impact mass spectrum of ClNO, which also shows no $ClNO^+$ peak. In a word, we demonstrated that we generated **1** under our experimental conditions though we could not distinguish

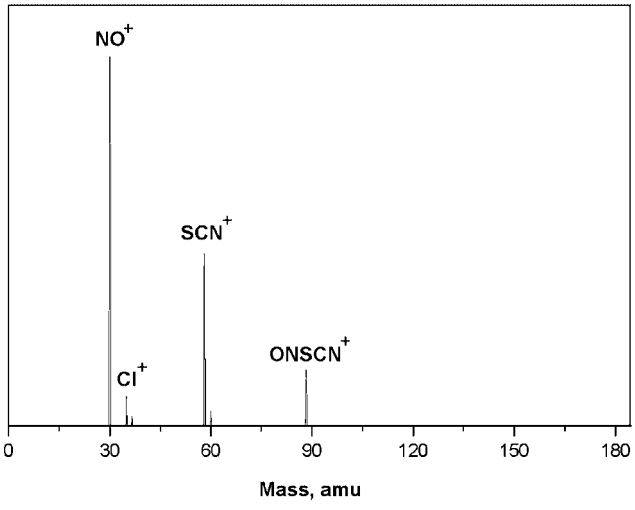

Figure 3. The HeI photoionization mass spectrum of nitrosyl thiocyanate.

**1a** and **1b** isomers from a photoionization mass spectroscopy study.

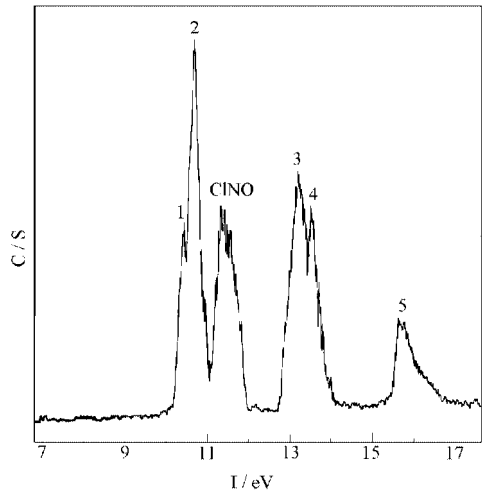

Figure 4. The HeI photoelectron spectrum of nitrosyl thiocyanate.

### Photoelectron Spectroscopy

The HeI photoelectron spectrum of **1** recorded at –60 °C is shown in Figure 4. It does not show any of the decomposing products but only the reactant ClNO[20] with an unnumbered band between 11.0 and 12.0 eV. The reaction was also monitored simultaneously by photoionization mass spectroscopy. The PE spectrum clearly shows a group of distinct bands below 11 eV, another group in the 12.5–14 eV range, and one additional band above 15 eV. In previous photoelectron spectroscopy experiments, XSCN (X = Cl, Br), instead of XNCS, was produced by passing gaseous halogen over solid AgSCN.[18] Our photoelectron spectroscopic experimental results also agree better with the ROVGF and CBS-QB3 calculations on **1a** than those on **1b** (see Table 2), though we cannot completely exclude the existence of **1b**. There is no noticeable difference between the orbital energies of the two most stable conformers of *cis*- and *trans*-**1a**. So our discussion is reduced to the analysis of the slightly more stable conformer *cis*-**1a** only. The experimental and calculated ionization energies for the *cis*- and *trans*-**1a** are collected in Table 2. It is noted that the ROVGF results are in good agreement with the experimental data.[13,24]

The unstable nitrosyl thiocyanate (**1**) can be characterized by its three groups of bands, which can be attributed to the lone electron pair of sulfur, the π system, and the S–C bond. Therefore, the study of these bands may reflect the extent and character of the intramolecular interactions. The electronic structure of the SCN group can be explained in two ways. One can assume a single S–C bond and a triple C≡N bond. In this case the appearance of two new bands resulting from the C≡N π bonds is expected in the low-energy region of the spectrum. Another interpretation is that the SCN unit is considered as a two perpendicular four-electron three-centre π system, which suggests four

Table 2. Experimental and computed ionization energies (eV) for the isomers of **1**.

| Exp. $I_v$ | Calcd. *cis*-**1a** | | *trans*-**1a** | | *cis*-**1b** | *trans*-**1b** |
|---|---|---|---|---|---|---|
| 10.45 | 10.338[a] | 10.485[b] | 10.440[a] | 10.407[b] | 9.840[a] | 10.154[a] |
| 10.65 | 10.733[a] | | 10.686[a] | | 10.195[a] | 10.198[a] |
| 13.20 | 13.423[a] | | 13.455[a] | | 12.673[a] | 12.389[a] |
| | 13.454[a] | | 13.485[a] | | 13.792[a] | 14.070[a] |
| 13.46 | 13.716[a] | | 13.767[a] | | 13.868[a] | 14.148[a] |
| 15.68 | 15.604[a] | | 15.732[a] | | 15.543[a] | 15.733[a] |

[a] According to $C_s$ symmetry using the ROVGF/6-311++G(3d) method. [b] According to $C_s$ symmetry using the CBS-QB3 method.

new bands in the spectrum: the high-energy bonding in- and out-of-plane π orbitals [$\pi_b(a')$ and $\pi_b(a'')$] and the low-energy nonbonding in- and out-of-plane π orbitals [$\pi_{nb}(a')$ and $\pi_{nb}(a'')$]. If the molecule is linear, the perpendicular MO pairs are degenerate. In the case of the strongly bent ONSCN, we would expect, using HeI radiation, to observe ionization from the six highest filled molecular orbitals. The appearance of all the $\pi_{SCN}$ bands is expected on the basis of the calculations. And the S lone pair in the SCN group is a part of the π system. The additional bands of a pσ type orbital ($\sigma_{SCN}$, localized mainly on N) and a σ type orbital (S–C bonding) are expected in the photoelectron spectrum.

The shape and intensity of the first group of bands suggest that it should be attributed to two ionization processes. Consistent with analogous molecules XSCN (X = H[25], $CH_3$[26], Cl[18], Br[18], I[27]), the first two bands are assigned to the nonbonding in- and out-of-plane π orbitals [$\pi_{nb}(a')$ and $\pi_{nb}(a'')$] partially localized on the pseudohalide group. In the molecule ONNCO[13], the first two orbitals $\pi_{nb}(a')$ and $\pi_{nb}(a'')$ are distributed fairly evenly over the whole molecule, whereas for *cis*-**1a** there is a dominant S 3p involvement in the first two π orbitals as indicated by the two relatively low ionization potentials. These are also supported by the quantum chemical calculated results. The first band of ONNCO at 10.71 eV is attributed to an in-plane combination of a strong antibonding $\pi_{NO}$ and nonbonding $\pi_{NCO}$ with the same a′ symmetry.[13] Therefore, the first ionization process of ON–SCN can easily be assigned by combining the NO and SCN moieties.

The vertical ionization potential of the first band (10.45 eV) is in good agreement with the calculated ionization energy of *cis*-**1a** (10.338 eV by ROVGF method and 10.485 eV by CBS-QB3). It is a structureless band and can be compared to the first PE band of $CH_3NO$[28] at 9.70 eV and ONCN[29] at 11.50 eV. The HOMO 18a′ (Figure 5) for this ionization process can be described as an in-plane combination of nonbonding $\pi_{SCN}$ and antibonding $\pi_{NO}$. It also shows that an interaction may exist between both of the moieties. The second band at 10.65 eV is sharp and characteristic of a nonbonding orbital with considerable lone-pair character. It derives from the ionization of the 4a′′ orbital and coincides with the calculation value of 10.733 eV. This band is ascribed to the nonbonding out-of-plane $\pi_{SCN}$ [$\pi_{nb}(a'')$], mainly localized on the sulfur atom. This orbital can also be regarded as the antisymmetric combination of the out-of-plane sulfur lone-pair and $\pi_{CN}$ orbital.

An interesting and important feature for PE spectra of compounds containing SCN is that the energetic order of the first two highest occupied orbitals is $\pi_{nb}(a'') < \pi_{nb}(a')$, such as for XSCN (X = H, $CH_3$, Cl, Br, I).[18,25–27] However, this trend is reversed in ONSCN, as is the case in ONNCO.[13] Because of the extensive incorporation of the $\pi_{NO}$ antibonding character into the 18a′, with $\pi_{nb}(a')$ character, its ionization becomes less energetic. Compared with analogous molecules XSCN (X = $CH_3$, Cl, Br, I)[18,26,27] the separation of $\pi_{nb}(a')$ and $\pi_{nb}(a'')$ is also quite narrow. The obvious decrease of the separation of nonbonding π orbitals ($\pi_{nb}$) in *cis*-**1a** reflects the direct interaction between the $\pi_{SCN}$ and $\pi_{NO}$ moieties. This interaction is so strong that it shifts the $\pi_{nb}(a')$ band causing the exchange in the sequence of the $\pi_{nb}(a')$ and $\pi_{nb}(a'')$ bands.

The two bands between 12.5–14.0 eV come from the ionization of the two bonding π orbitals (a′ and a′′) and a terminal –SCN pσ type orbital, as considerable mixing between orbitals of the same symmetry often occurs for the XSCN molecule.[18,26,27] Combining our calculated ROVGF results and the assignments of the PE spectrum of other XSCN molecules, we assigned the third band as arising from the ionizations of the in-plane bonding $\pi_{CN}$ orbital 17a′ and out-of-plane bonding $\pi_{SCN}$ orbital 3a′′, and the fourth band at 13.46 eV as arising from the ionization of the 16a′ pσ type orbital. This is in good agreement with the calculation value 13.716 eV, which is also in good agreement with the corresponding experimental values of the PE band from pσ type orbitals in ClSCN[18] at 13.66 eV and BrSCN[18] at 13.43 eV.

The PE band at 15.68 eV is the ionization of the 15a′ orbital, which is in agreement with the calculated value 15.604 eV. The primary MO character is $\sigma_{(S-C)}$ bonding with considerable s character on all the atoms; similar bands occur in the PE spectrum of HSCN[25] (Figure 5).

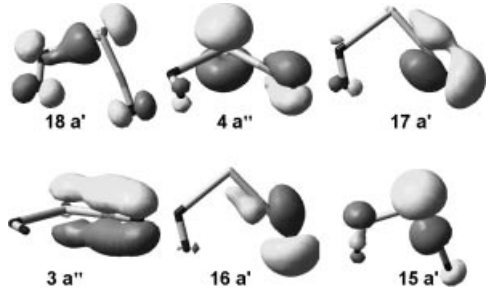

Figure 5. Characters of the first six highest occupied molecular orbitals for *cis*-**1a**.

Based on the above discussion, we consider the photoelectron spectrum shown in Figure 4 to be that of **1** and the assignment of the photoelectron spectroscopic bands is reasonably supported by previous studies on analogous molecules, as well as the ROVGF and CBS-QB3 calculations. From the experimental PE spectra of **1** and some thiocyanate with similar symmetry, a clear correlation of the respective bands can be seen. One important difference

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

is the inversion in the sequence of the $\pi_{nb}(a')$ and $\pi_{nb}(a'')$ bands, which has relations with the interaction between the $\pi_{SCN}$ and $\pi_{NO}$ moieties in **1**. However, the isomers **1a** and **1b** cannot be reliably distinguished by our photoelectron spectroscopy experiment. It is hoped that this study could stimulate further experimental work to enable the different isomers of this important unstable species to be distinguished.

## Conclusions

The unstable molecule **1** has been generated in the gas phase for the first time by means of an online reaction of gaseous nitrosyl chloride with silver thiocyanate at low temperature. Using the home-made PES-PIMS we have obtained the photoelectron and mass spectra of **1**. With the help of theoretical studies, the electronic and geometric structures of **1** were investigated by photoelectron spectroscopy. The assignment of the photoelectron spectroscopic bands is reasonably supported by previous studies on analogous molecules, as well as by the ROVGF and CBS-QB3 calculations. Both the spectroscopic and theoretical investigations have proved the formation of **1**, and suggest that the molecule adopts an open-chain, bent structure. It is indicated that the NO and SCN moieties bond by means of a relatively strong interaction, which is related to the inversion of the first two π orbitals. This fact proves that our home-made PES-PIMS can be used as a powerful tool for the investigation of transient species in the gas phase.

## Experimental Section

Over the past decades, ultraviolet photoelectron spectroscopy (UPS) has established itself as one of the important techniques used to obtain a direct measure of atomic and molecular energy levels. Moreover, some groups using photoelectron spectroscopy have made great progress and extended the application to transient or unstable species. Using photoelectron spectroscopy and infrared matrix isolation spectroscopy, Dyke et al. studied the thermal decomposition of organic azides.[30–32] By combining HeI photoelectron spectroscopy with mid-infrared absorption and mass spectroscopy, Westwood and colleagues investigated ground, excited, and ionic states of various small unstable molecules.[33–35]

To improve our ability of studying the transient species, our group has built a photoelectron spectrometer-photoionization mass spectrometer (PES-PIMS) as described elsewhere.[23] A schematic diagram of the PES-PIMS is shown in Figure 6. The modification of the spectrometer was based on the HeI photoelectron spectrometer. An important feature of our experiment is the measurement of both mass and PE spectra. The ions are produced by soft ionization of transient species with HeI (21.2 eV) radiation. The ions formed are transferred by a set of electrostatic lenses. The field-free drift region has a length of 120 cm. A dual MCP is used to detect charged particles. The signal is recorded using a 500 MHz digital oscilloscope (Tektronix, TDS2024) and then transferred to a PC for storage and analysis.

The photoelectron spectrum was recorded on a double chamber UPS machine-II,[36,37] which was built specifically to detect transient species at a resolution of about 30 meV as indicated by the $Ar^+(^2P_{2/3})$ photoelectron band. Experimental vertical ionization energies (Iv in eV) are calibrated by simultaneous addition of a small amount of argon and methyl iodide to the sample.

When the mass spectra are measured, pulsed positive voltages are applied to the repelling and attracting electrodes, and then the cation is extracted into the time-of-flight drift region. Proper pulsed voltages $U_1$ and $U_2$ are chosen to meet the requirement of the first spatial focus to pursue the high mass resolution. The optimum mass resolution can reach 410 at $m/z$ = 254. When the photoelectrons are collected, both $U_1$ and $U_2$ are set to 0. Hence, the photoelectron can fly directly to the energy analyzer through the electron path. Thus, the photoelectron and photoionization mass spectra can be recorded within a few seconds.

In general, we can observe the electronic structure by the photoelectron spectrum and the dissociation of molecular ions by mass spectra with this experimental apparatus. The joint spectrometer is characterized by at least two advantageous features. Firstly, the reaction conditions can be optimized online to improve the yield of the desired species. It can be used to investigate not only general gaseous samples but also transient species produced by gas-solid reactions or microwave discharge etc. Other inlet modifications with high-temperature furnaces or low-temperature cells can also be easily attached to the spectrometer. Secondly, with the advances of fast detection and high sensitivity TOFMS will help us to resolve some problems of photoelectron spectroscopy in complicated systems.

### Generation and Detection of ONSCN

The intermediate **1** was generated at –60 °C by passing gaseous ClNO over finely powdered AgSCN, similarly for producing other

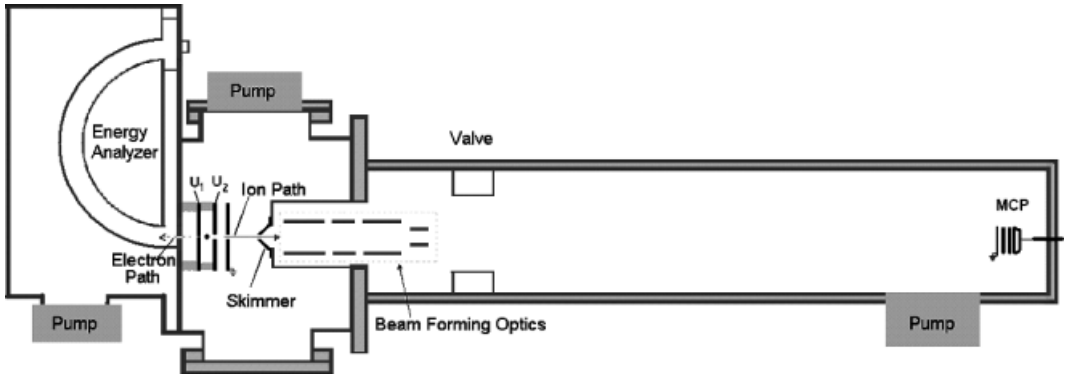

Figure 6. Schematic diagram of the experimental apparatus PES-PIMS. It mainly consists of an ultraviolet photoelectron spectrometer and a home-made time-of-flight mass spectrometer (TOFMS). The photo source (HeI) in the ionization region is marked with a dot.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

unstable species like ONNCO[13] and NSSCN[14]. The reaction was monitored simultaneously in situ by photoelectron and photoionization mass spectra. The reaction is be represented by Equation (3).

$$ClNO\ (g) + AgSCN(s) \xrightarrow{-60\ ^{o}C} ONSCN\ (g) + AgCl\ (s) \quad (3)$$

AgSCN (ACROS) was dried in vacuo ($10^{-4}$ Torr) for 2 h at 60 °C before the experiment was performed. ClNO was prepared as reported[38] and identified by photoelectron[20] and photoionization mass spectroscopy.

**Quantum Chemical Calculations**

On the basis of the previous theoretical discussions on the isomers of $CN_2OS$[7], we have only considered the four most stable isomers, *cis*- and *trans*-**1a**, *cis*- and *trans*-**1b**, which are related to our experiment. The geometries were optimized at the B3LYP/6-311++G(3d) level, which is a hybrid functional method based on the Becke's three-parameter nonlocal exchange functional[39], with the nonlocal correlation due to Lee, Yang, and Parr.[40] To determine the barrier between the *cis* and *trans* rotamers, the potential energy surface scans for internal rotation around the N–S bond were carried out at the B3LYP/6-311++G(3d) level before the appropriate transition states were optimized at the CBS-QB3 level.[41] The ionization energies for *cis* and *trans* isomers were calculated at the ab initio level according to Cederbaum's outer valence Green's function (OVGF) [42] method at the 6-311++G(3d) basis set, and by taking the difference between the energy of the neutral atom and the ion (CBS-QB3 calculation). All the calculations were performed using the Gaussian 03 program package.[43]

**Supporting Information** (see footnote on the first page of this article): HeI photoionization mass spectra of ClNO, and reaction products of $NOCl_{(g)}/AgSCN_{(s)}$ at room temperature are included.

## Acknowledgments

This project was supported by the Chinese Academy of Sciences (Hundred talents fund) and the National Natural Science Foundation of China (Contract No. 20577052, 20473094, 50372071, 20503035). # Bis(2-amino alcohol-κ*N*)dicarboxylatoplatinum(II) Complexes – Elegant Synthesis via Ring-Opening of Bis(2-amino alcoholato-κ$^2$*N*,*O*)platinum(II) Species with Dicarboxylic Acids

**Kristof Meelich,[a] Markus Galanski,*[a] Vladimir B. Arion,[a] and Bernhard K. Keppler[a]**

**Keywords:** Bioinorganic chemistry / Platinum / N,O ligands / Antitumor agents / Drug design

Synthesis and purification of bis(2-amino alcohol-κ*N*)dicarboxylatoplatinum(II) complexes is problematic because of the use of light-sensitive silver(I) salts and the competing ring-closing side-reactions, especially after release of the chloro- or iodo ligands of the dihalogeno starting platinum(II) species. A novel synthetic procedure, namely selective synthesis of doubly ring-closed bis(2-amino alcoholato-κ$^2$*N*,*O*)platinum(II) compounds as the purification step and subsequent coordination of dicarboxylates in the absence of silver(I) via a ring-opening reaction, yielded a series of new complexes, which were characterized by elemental analysis, NMR spectroscopy, and X-ray crystallography. Exemplarily, the ring-opening of bis(2-aminoethanolato-κ$^2$*N*,*O*)platinum(II) was performed in the NMR tube by means of oxalic acid and investigated by $^1$H and $^{195}$Pt NMR spectroscopy. The reaction was found to be highly efficient: within 3 h complete transformation to the dicarboxylatoplatinum(II) complex was observed. Contrary, when sodium oxalate was used, no reaction could be detected at all during a period of one day.

## Introduction

Cisplatin, carboplatin, and oxaliplatin are the only metal-based chemotherapeutic drugs routinely used in the clinics in the fight against cancer (Figure 1).[1–4] In nearly 50% of all tumor therapies, platinum complexes are involved; in the case of testicular cancer, cisplatin demonstrates extraordinary tumor-inhibiting properties with real cure rates beyond 90%. Nevertheless, severe toxic side-effects and success of platinum complexes in only a limited number of solid tumors led to extensive attempts in the synthesis of a plethora of new platinum compounds.[5–7] In this context, hydrolysis of the administered drug was decreased by the use of dicarboxylato ligands (e.g., 1,1-cyclobutanedicarboxylate in carboplatin) resulting in significantly reduced systemic toxicity. Research has also focused on improving the solubility of the drugs for example by using oxalate (e.g., oxaliplatin) instead of chloro ligands (Figure 1).

Additionally, monodentate 2-amino alcohol or hydroxyethyl-substituted bidentate diamine ligands have been introduced in the drug development process in order (i) to increase the solubility, (ii) to further use the functional group for subsequent derivatization,[8,9] or (iii) to take advantage of the OH groups as donor or acceptor for hydrogen bonds with the DNA, the primary target of anticancer platinum complexes.[10,11]

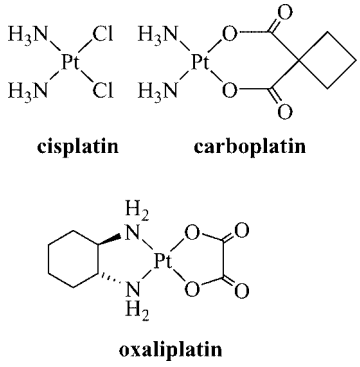

Figure 1. Chemical structures of established platinum-based anticancer drugs in world-wide clinical use.

Synthesis of bis(2-amino alcohol-κ*N*)platinum(II) complexes with dicarboxylato ligands, which would combine both structural features, is a logical consequence of the aforementioned considerations and seems to be straightforward from the chemical point of view. But only one publication by Khokhar et al. deals with this type of complex.[12] This is explainable by a set of problems arising during the synthetic procedure. Here we present an elegant and novel strategy in the preparation of bis(2-amino alcohol-κ*N*)dicarboxylatoplatinum(II) complexes as well as their characterization by elemental analysis, NMR spectroscopy, and X-ray crystallography. As the purification step, doubly ring-closed bis(2-amino alcoholato-κ$^2$*N*,*O*)platinum(II) com-

plexes were prepared, now allowing us to omit silver(I) salts in the very last reaction step.

## Results and Discussion

In almost every case, dicarboxylatoplatinum(II) compounds have been synthesized starting from dichloro- or diiodoplatinum(II) complexes (Figure 2) followed by release and precipitation of the halide through addition of silver(I) salts (predominantly $AgNO_3$ or $Ag_2SO_4$). After filtration, the activated platinum species is brought to reaction with the respective sodium dicarboxylate (commercially available or synthesized in situ via addition of NaOH). A second variant is based directly on the use of silver dicarboxylates, offering the advantage that separation from $NaNO_3$ or $Na_2SO_4$ in the case of highly soluble dicarboxylatoplatinum(II) compounds is not required. However, in both instances reactions including light-sensitive silver salts are inherently problematic especially in the last reaction step.[13] In the case of a slight excess of $Ag^+$, difficulties in the purification of the reaction product can be expected. Furthermore, $Ag^+$ itself is biologically active, leading to false positive or false negative results during the evaluation of the anticancer properties.

Consequently, one strategy is to take substoichiometric amounts of the silver salt,[14,15] which then could lead to a contamination with monochloro- or monoiodoplatinum(II) species, depending on the solubility of the target platinum compounds. Additionally, and this is a characteristic feature of bis(2-amino alcohol-κ*N*)platinum(II) complexes, intramolecular ligand exchange reactions leading to singly and doubly ring-closed analogues must be taken into consideration. This facet has been studied in detail by NMR spectroscopy and was published recently in the case of (*SP*-4–2)-bis(2-aminoethanol-κ*N*)dichloroplatinum(II) and (*OC*-6–22)-bis(2-aminoethanol-κ*N*)tetrachloroplatinum(IV).[16] For activated platinum complexes (no halogeno ligand), an effective ring-closing side reaction should logically be expected.

In order to circumvent these synthetic difficulties, namely to avoid the use of silver salts in the very last reaction step

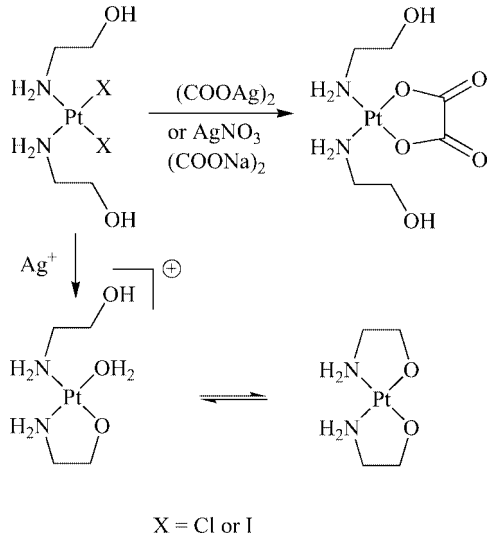

Figure 2. General synthesis of dicarboxylatoplatinum(II) complexes [e.g., (*SP*-4–2)-bis(2-aminoethanol-κ*N*)oxalatoplatinum(II)]; in the case of amino alcohol ligands, undesired side reactions to the singly and doubly ring-closed species are observed.

and to suppress side reactions as much as possible, a novel and elegant synthetic strategy was evaluated for its general applicability in the preparation of bis(2-amino alcohol-κ*N*)-dicarboxylatoplatinum(II) complexes. The basis of this procedure is the selective synthesis of the doubly ring-closed platinum species **2a**–**d** (which are in the above-mentioned synthetic pathway one of the unwanted side products) directly starting from the diiodoplatinum(II) compounds **1a**–**d** (Figure 3).

This is in contrast to our previously published pathway, where the dichloro analogues have been used.[17] Release of the iodo ligands is thereby accomplished (i) in the presence of substoichiometric amounts of $AgNO_3$ and (ii) additionally by the use of a basic anion exchanger (IRA 402), which further accelerates the ring formation process by a high pH value. The doubly ring-closed platinum(II) complexes **2a**–**d** were isolated and characterized by elemental analysis, NMR spectroscopy and in the case of **2c**(***S***) and **2d**(***S***) (*S*-enantiomers of complexes **2c** and **2d**) by X-ray diffraction

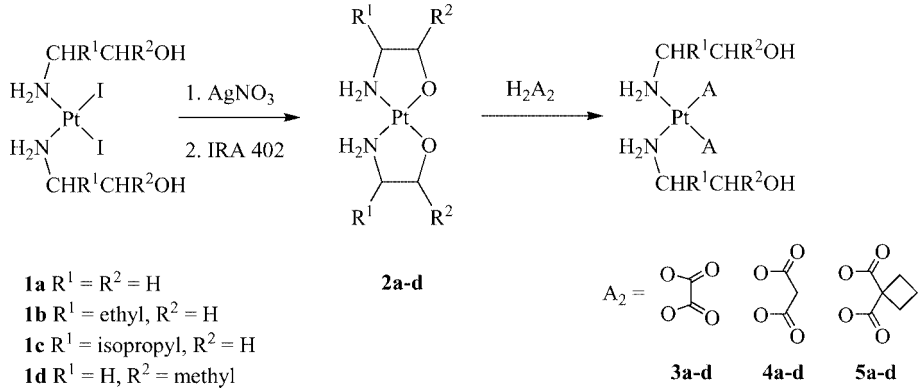

Figure 3. Synthesis of the target bis(2-amino alcohol-κ*N*)dicarboxylatoplatinum(II) complexes **3a**–**5d** via ring-opening with dicarboxylic acids (stereochemistry omitted).

analysis (Figure S1 and S2, Table S1 and S2, Supporting Information). The analytical data are in agreement with recently published results.[16] Most indicative for the success of the ring-closing reaction are the $^{1}H$ and $^{13}C$ chemical shifts of the methylene (**2a**–**c**) or methine (**2d**) group as well as the $^{195}Pt$ satellites of the C*H*R$^{2}$OPt protons. The latter, deriving from a $^{3}J(^{1}H,^{195}Pt)$ coupling are only visible in the case of the ring-closed complexes. In proton NMR spectra, the C*H*R$^{2}$OPt protons display an upfield shift in **2a**–**c** (e.g., **2a**, 2.97 ppm, corresponding dichloro complex, 3.76 ppm).

Typically, for the *C*HR$^{2}$OPt carbon atoms of **2a**–**d** resonances in the region between $\delta$ = 69.3 and 75.1 ppm can be detected. This is about 10 ppm downfield from the signals of the analogous ring-opened dichloro complexes (e.g., **2a**, 69.3 ppm, corresponding dichloro complex, 60.8 ppm). As could be shown earlier, addition of HCl or DCl results in the formation of the dichloro counterparts.[18] But addition of NaCl to the doubly ring closed species even in a 35-fold excess (without decrease of the pH value) shifts the equilibrium slightly towards the mono- but not to the dichloro complex (Figure S3). Consequently, **2a**–**d** have been used as starting complexes for the synthesis of compounds **3a**–**5d** via direct reaction with oxalic-, malonic-, and 1,1-cyclobutanedicarboxylic acid in water without addition of any other reagent. The products **3a**–**5d** were characterized by elemental analysis, NMR spectroscopy, and X-ray single crystal diffraction (**3a** and **5a**). Products **3a**–**d** were investigated by $^{1}H$ and $^{13}C$ NMR spectroscopy, whereas in the case of the analogous dicarboxylates **4a**–**5d** only $^{1}H$ NMR spectra have been performed for comparison.

In analogy to the reactions with HCl and NaCl, ring-opening could only be performed by means of dicarboxylic acids. When the respective sodium salt (e.g., sodium oxalate) was used, no reaction could be observed at all during a period of 24 h, as could be demonstrated by $^{1}H$ NMR spectroscopy (Figure S4). Formation of the bis(2-amino alcohol-κ*N*)dicarboxylatoplatinum(II) complexes **3a**–**5d** can best be judged by significant changes in $^{1}H$ NMR spectra. An apparent downfield shift of C*H*R$^{2}$OH proton resonances from 2.97–3.41 ppm in **2a**–**d** to 3.74–4.11 ppm in **3a**–**5d** was detected in conjunction with loss of the $^{3}J(^{1}H,^{195}Pt)$ coupling. Within the series of dicarboxylates (e.g., **3a**, **4a**, and **5a**, the same amine ligand, but different dicarboxylato ligand) the C*H*R$^{2}$OH chemical shifts showed marginal deviations within 0.04 ppm. In $^{13}C$ NMR spectra of the oxalato complexes **3a**–**d** noteworthy changes were observed for *C*HR$^{2}$OH carbon atoms (between $\delta$ = 60.5 and 66.9 ppm) in comparison to the ring-closed species **2a**–**d** (between $\delta$ = 69.3 and 75.1 ppm). Furthermore, in oxalato complexes **3a**–**d** $^{13}C$OO signals of the coordinated carboxylato ligands were detected in a narrow range at $\delta$ = 169.2 and 169.3 ppm (oxalic acid, 161.9 ppm; sodium oxalate, 173.8 ppm). The elemental analysis data of all new complexes were found in accordance with the expected values, proving their identity as well.

For complexes **3a** and **5a** it was possible to determine their solid-state structure by X-ray diffraction. Structural features of the square-planar platinum(II) complex **3a** are revealed in Figure 4. Selected bond lengths and angles are given in Table 1.

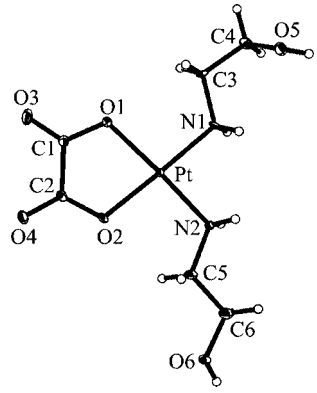

Figure 4. ORTEP diagram of **3a** displaying thermal ellipsoids at 50% probability.

Table 1. Bond lengths [Å] and angles [°] in the platinum(II) coordination polyhedron of **3a** and **5a**.

| atom1–atom2 | **3a** | atom1–atom2 | **5a** |
|---|---|---|---|
| Pt–O1 | 2.032(5) | Pt–O3 | 2.012(2) |
| Pt–O2 | 2.033(5) | Pt–O5 | 2.023(2) |
| Pt–N1 | 2.050(6) | Pt–N1 | 2.027(2) |
| Pt–N2 | 2.038(6) | Pt–N2 | 2.037(2) |
| C1–O1 | 1.311(9) | C5–O3 | 1.305(3) |
| C1–O3 | 1.248(9) | C5–O4 | 1.228(3) |
| C2–O2 | 1.293(9) | C10–O5 | 1.296(3) |
| C2–O4 | 1.238(9) | C10–O6 | 1.233(3) |
| atom1–atom2–atom3 | | atom1–atom2–atom3 | |
| O1–Pt–O2 | 82.0(2) | O3–Pt–O5 | 91.17(8) |
| N1–Pt–N2 | 86.6(3) | N1–Pt–N2 | 91.19(10) |

A projection of the molecule of **5a** on the coordination plane through PtN1N2O3O5 is shown in Figure 5. Selected bond lengths and angles are listed in Table 1. In **5a** the Pt atom has a square-planar coordination geometry. The Pt–O bond lengths are 2.012(2) and 2.023(2) Å, while the Pt–N bonds are 2.027(2) and 2.037(2) Å. These parameters are comparable with those in Pt(EtNH$_2$)$_2$(1,1-cyclobutanedicarboxylato)·H$_2$O [Pt–O 2.000(4) and 2.015(4) Å, Pt–N 1.992(5) and 2.020(5) Å].[19] As expected the C–O bonds (involving coordinated oxygens) at 1.305(3) and 1.296(3) Å are significantly longer than the two C=O bonds [C5–O4 1.228(3) and C10–O6 1.233(3) Å]. The angles inside the cyclobutane ring vary between 87.69(19) and 89.2(2)°, in agreement with those reported for Pt{*trans*-(–)-1,2-cyclohexanediamine}(1,1-cyclobutanedicarboxylate).[20] The mean deviation of the four atoms forming the four-membered ring from the best plane through C6, C7, C8, and C9 does not exceed 0.129 Å. The dihedral angle between the cyclobutane ring and the Pt coordination plane is ca. 70.9°. The two ethanolamine ligands and the cyclobutane ring are all on the same side of the Pt coordination plane. The six-membered malonate chelate cycle has a boat conformation. The mean deviation of O3, C5, O5, and C10 from the best plane through these four atoms is 0.0041 Å, with Pt and C6

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms on the same side of the plane with deviations of 0.6858 and 0.6290 Å. The two carbonyl oxygen atoms O4 (deviation –0.4585 Å) and O6 (deviation –0.4667 Å) are oriented towards the other side of the plane. Of note is also the intramolecular hydrogen bond O1–H1···O3 [O1–H1 0.84, H1···O3 2.457, O1···O3 3.159 Å, ∠O1H1O3 141.72°] (see Figure 5).

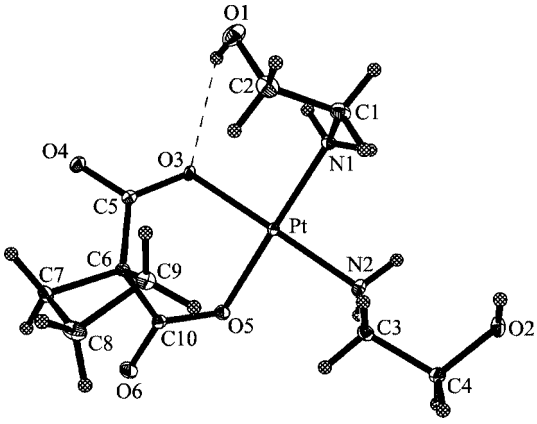

Figure 5. ORTEP diagram of **5a** displaying thermal ellipsoids at 50% probability.

Additionally, ring-opening of **2a** and formation of the dicarboxylatoplatinum(II) complex **3a** were studied directly in the NMR tube (Figure 6). As can be deduced from the $^{1}H$ and $^{195}Pt$ NMR spectra the reaction of oxalic acid with **2a** was very efficient. Three hours after mixing of **2a** (10.0 mg, 0.032 mmol) with oxalic acid (3.0 mg, 0.033 mmol) dissolved in 0.6 mL of $D_2O$, the dicarboxylato complex **3a** was formed and was detected as the sole species in both $^{1}H$ and $^{195}Pt$ NMR spectra (note that this is in clear contrast to the reaction with sodium oxalate, where no ring-opening could be observed at all during a period of 24 h; compare Figure S4). Ring-opening and dicarboxylate formation is reflected by significant downfield shifts of $^{1}H$ and $^{195}Pt$ resonances. In the case of $CH_2N$ protons, chemical shift differences are consequently smaller (**2a**, 2.27 ppm; **3a**, 2.67 ppm) than for $CH_2O$ protons (**2a**, 2.98 ppm; **3a**, 3.76 ppm) since the oxygen atom is released from the platinum(II) center (Figure 6).

Unresolved $^{195}Pt$ satellites deriving from a $^{3}J(^{1}H,^{195}Pt)$ coupling were detected for $CH_2N$ and $CH_2OPt$ protons (marked with asterisks in Figure 6) at the base of the respective resonances. In **3a** the $CH_2OH$ signals do not display such satellites, further proving the ring-opening reaction. Moreover, a remarkable downfield shift in the $^{195}Pt$ NMR spectra from –621 (**2a**) to –255 ppm (**3a**) finally documents the success of the conversion from **2a** to **3a**.

## Conclusions

The synthesis of bis(2-amino alcohol-κ*N*)dicarboxylatoplatinum(II) complexes was advantageously performed via a ring-opening reaction of the respective bis(2-amino alcoholato-κ$^2$*N*,*O*)platinum(II) species with dicarboxylic acids. This novel synthetic strategy is independent from the use of light-sensitive silver(I) salts in the last reaction step, which could cause problems during the purification and isolation of the target compounds. As could be exemplarily shown by $^{1}H$ and $^{195}Pt$ NMR spectroscopy for the reaction of bis(2-aminoethanolato-κ$^2$*N*,*O*)platinum(II) with oxalic acid, the transformation to the dicarboxylato complex is considerably fast and efficient. In contrast, reaction with sodium oxalate did not result in any detectable product during a period of one day.

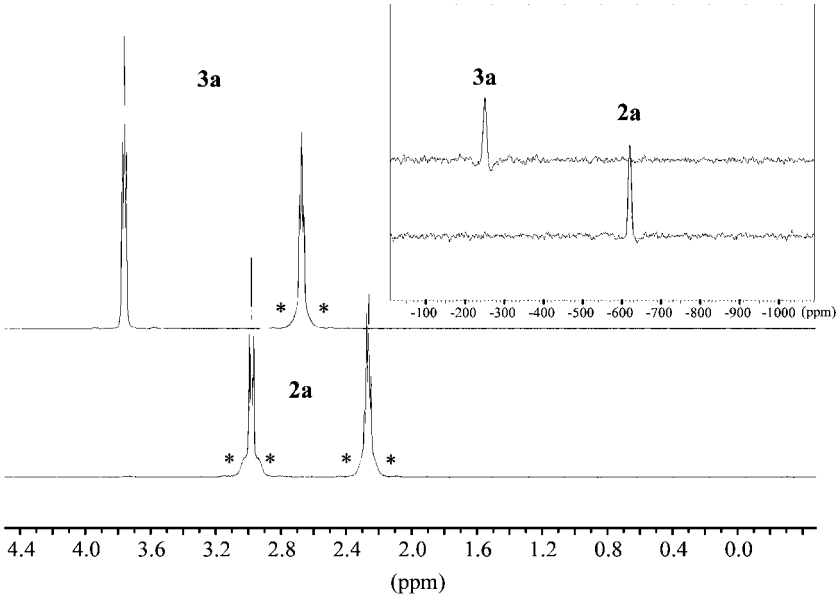

Figure 6. $^{1}H$ and $^{195}Pt$ (small insert) NMR spectra of the conversion of **2a** to **3a** through addition of an equivalent amount of oxalic acid; reaction was directly performed in the NMR tube, $^{195}Pt$ satellites are marked with asterisks.

## Experimental Section

All chemicals were purchased from commercial suppliers; $K_2PtCl_4$ was obtained from Johnson Matthey. Deionized water (reverse osmosis) was doubly distilled before use. All reactions were carried out under protection from light and for stirring a glass-coated magnetic stirrer was used. The $^1H$, $^{13}C$, and $^{195}Pt$ NMR spectra were recorded with a Bruker DPX 400 (Ultrashield™ Magnet) at 400.13, 100.62, and 86.11 MHz, respectively at 25 °C, using standard pulse programs. $^{195}Pt$ chemical shifts were referenced relative to external $K_2PtCl_4$. The elemental analyses were performed using a Perkin–Elmer 2400 CHN Elemental Analyzer by the microlaboratory of the Institute of Physical Chemistry, University of Vienna.

(*SP*-4–2)-Bis(2-aminoethanol-κ*N*)diiodoplatinum(II), **1a**, (*SP*-4–2)-bis[(*S*)-2-amino-1-butanol-κ*N*]diiodoplatinum(II), **1b(*S*)**, and (*SP*-4–2)-bis[(*R*)-2-amino-1-butanol-κ*N*]diiodoplatinum(II), **1b(*R*)**, were synthesized as described elsewhere.[16]

**(*SP*-4–2)-Bis[(*S*)-2-amino-3-methyl-1-butanol-κ*N*]diiodoplatinum(II) [1c(*S*)]:** $K_2PtCl_4$ (5.997 g, 14.45 mmol) was dissolved in water (50 mL) and treated with KI (12.0 g, 72.29 mmol). After stirring for 30 min at room temperature, a solution of (*S*)-2-amino-3-methyl-1-butanol (3.428 g, 33.23 mmol) in water (10 mL) was added in small portions and the brown reaction mixture was stirred for 10 h at room temperature. Precipitation of a yellow solid was completed by cooling the mixture for 12 h at 4 °C. The product was filtered off, washed with cold water (three times, 2 mL), and dried in vacuo over $P_4O_{10}$. Yield: 4.408 g (47%). $C_{10}H_{26}I_2N_2O_2Pt$ (655.21): calcd. C 18.33, H 4.00, N 4.27; found C 18.37, H 3.87, N 4.15.

**(*SP*-4–2)-Bis[(*R*)-2-amino-3-methyl-1-butanol-κ*N*]diiodoplatinum(II) [1c(*R*)]:** The synthesis was carried out as described for **1c(*S*)**, starting from $K_2PtCl_4$ (1.574 g, 3.79 mmol). Yield: 1.760 g (71%). $C_{10}H_{26}I_2N_2O_2Pt$ (655.21): calcd. C 18.33, H 4.00, N 4.27; found C 18.38, H 3.80, N 4.17.

**(*SP*-4–2)-Bis[(*S*)-1-amino-2-propanol-κ*N*]diiodoplatinum(II) [1d(*S*)]:** $K_2PtCl_4$ (618 mg, 1.49 mmol) was dissolved in water (ca. 5 mL) and treated with KI (1.235 g, 7.44 mmol). After stirring for 30 min at room temperature, a solution of (*S*)-1-amino-2-propanol (224 mg, 2.98 mmol) in water (1 mL) was added dropwise. The mixture was stirred for 3 h at room temperature. Precipitation of a yellow solid could be observed, which was completed by cooling for 1 h at 4 °C. The product was filtered off, washed with ice-cold water (three times, 1 mL), and dried in vacuo over $P_4O_{10}$. Yield: 640 mg (72%). $C_6H_{18}I_2N_2O_2Pt$ (599.11): calcd. C 12.03, H 3.03, N 4.68; found C 12.08, H 2.86, N 4.48.

**(*SP*-4–2)-Bis[(*R*)-1-amino-2-propanol-κ*N*]diiodoplatinum(II) [1d(*R*)]:** The synthesis was carried out as described for **1d(*S*)**, starting from $K_2PtCl_4$ (2.100 g, 5.06 mmol). Yield: 2.078 g (69%).

**(*SP*-4–2)-Bis(2-aminoethanolato-κ²*N*,*O*)platinum(II) (2a): 1a** (5.660 g, 9.91 mmol) was suspended in water (80 mL), mixed with $AgNO_3$ (3.198 g, 18.83 mmol), and stirred for 24 h at room temperature. AgI was filtered off and the clear solution was mixed with a preconditioned basic anion exchange resign, IRA 402 (the commercially available chloride form was treated with 2 M NaOH for 30 min and washed with deionized water until a pH of 7). After stirring for 12 h at room temperature, the liquid was decanted from the resign, which was washed three times with water. The combined aqueous solutions were filtered and thereafter concentrated to ca. 1 mL under reduced pressure at 30 °C. Crystallization of the product occurred at room temperature and was completed at 4 °C. The white product was isolated by filtration, rinsed with a few drops of ice-cold water, and dried in vacuo over $P_4O_{10}$. Yield: 1.337 g (45%). $C_4H_{12}N_2O_2Pt$ (315.23): calcd. C 15.24, H 3.84, N 8.89; found C 15.33, H 3.68, N 8.69. $^1H$ NMR ($D_2O$): $\delta$ = 2.97 (t, $^3J_{H,H}$ = 5.4 Hz, 4 H, C$H_2$O), 2.25 (t, $^3J_{H,H}$ = 5.5 Hz, 4 H, C$H_2$N) ppm. $^{13}C$ NMR ($D_2O$): $\delta$ = 69.3 (2 C, *C*$H_2$O), 50.8 (2 C, *C*$H_2$N) ppm.

**(*SP*-4–2)-Bis[(*S*)-2-amino-1-butanolato-κ²*N*,*O*]platinum(II) [2b(*S*)]: 1b(*S*)** (2.860 g, 4.56 mmol) was suspended in water (60 mL), treated with $AgNO_3$ (1.405 g, 8.27 mmol), and stirred for 24 h. After filtration of AgI, the clear solution was treated with preconditioned IRA 402 as described for **2a**; the reaction was stirred for 48 h. After removal of the ion exchange resign and filtration, the solution was concentrated until a solid product appeared. Precipitation was completed first at room temperature and later at 4 °C. The white product was isolated by filtration, rinsed with a few drops of ice-cold water, and dried in vacuo over $P_4O_{10}$. Yield: 745 mg (48%). $C_8H_{20}N_2O_2Pt$ (371.33): calcd. C 25.88, H 5.43, N 7.54; found C 26.05, H 5.21, N 7.47. $^1H$ NMR ($H_2O/D_2O$, 9:1): $\delta$ = 3.01 (m, 2 H, C$H_2$O), 2.88 (m, 2 H, C$H_2$O), 2.48 (m, 2 H, C*H*N), 1.53 (m, 2 H, $CH_3CH_2$), 1.34 (m, 2 H, $CH_3CH_2$), 0.80 (t, $^3J_{H,H}$ = 7.3 Hz, 6 H, C$H_3$) ppm. $^{13}C$ NMR ($H_2O/D_2O$, 9:1): $\delta$ = 73.0 (2 C, *C*$H_2$O), 64.1 (2 C, *C*HN), 22.9 (2 C, $CH_3CH_2$), 10.8 (2 C, *C*$H_3$) ppm.

**(*SP*-4–2)-Bis[(*R*)-2-amino-1-butanolato-κ²*N*,*O*]platinum(II) [2b(*R*)]:** The synthesis was carried out as described for **2b(*S*)**, starting from **1b(*R*)** (1.260 g, 2.01 mmol). Yield: 366 mg (52%). $C_8H_{20}N_2O_2Pt$ (371.33): calcd. C 25.88, H 5.43, N 7.54; found C 25.99, H 5.14, N 7.50. $^1H$ NMR ($H_2O/D_2O$, 9:1): $\delta$ = 3.06 (m, 2 H, C$H_2$O), 2.94 (m, 2 H, C$H_2$O), 2.54 (m, 2 H, C*H*N), 1.59 (m, 2 H, $CH_3CH_2$), 1.42 (m, 2 H, $CH_3CH_2$), 0.86 (t, $^3J_{H,H}$ = 7.6 Hz, 6 H, C$H_3$) ppm. $^{13}C$ NMR ($H_2O/D_2O$, 9:1): $\delta$ = 72.9 (2 C, *C*$H_2$O), 64.1 (2 C, *C*HN), 22.9 (2 C, $CH_3CH_2$), 10.8 (2 C, *C*$H_3$) ppm.

**(*SP*-4–2)-Bis[(*S*)-2-amino-3-methyl-1-butanolato-κ²*N*,*O*]platinum(II) [2c(*S*)]: 1c(*S*)** (2.058 g, 3.14 mmol) was suspended in water (70 mL), treated with $AgNO_3$ (1.024 g, 6.03 mmol), and stirred for 24 h. After filtration of AgI, the clear solution was treated with preconditioned IRA 402 as described for **2a**; the reaction was stirred for 48 h. After removal of the ion exchange resign and filtration, the solution was concentrated until a solid product appeared. Precipitation was completed first at room temperature and later at 4 °C. The white product was isolated by filtration, rinsed with a few drops of ice-cold water, and dried in vacuo over $P_4O_{10}$. Yield: 103 mg (8%). $C_{10}H_{24}N_2O_2Pt{\cdot}H_2O$ (417.40): calcd. C 28.77, H 6.28, N 6.71; found C 28.78, H 6.02, N 6.68. $^1H$ NMR ($D_2O$): $\delta$ = 3.09 (m, 2 H, C$H_2$O), 2.99 (m, 2 H, C$H_2$O), 2.30 (m, 2 H, C*H*N), 1.62 [m, 2 H, $(CH_3)_2CH$], 0.85 (d, $^3J_{H,H}$ = 7.8 Hz, 12 H, C$H_3$) ppm. $^{13}C$ NMR ($D_2O$): $\delta$ = 71.9 (2 C, *C*$H_2$O), 68.5 (2 C, *C*HN), 28.8 [2 C, *C*$H(CH_3)_2$], 20.4 (2 C, *C*$H_3$), 18.9 (2 C, *C*$H_3$) ppm.

**(*SP*-4–2)-Bis[(*R*)-2-amino-3-methyl-1-butanolato-κ²*N*,*O*]platinum(II) [2c(*R*)]:** The synthesis was carried out as described for **2c(*S*)**, starting from **1c(*R*)** (1.700 g, 2.59 mmol). Yield: 112 mg (11%). $C_{10}H_{24}N_2O_2Pt{\cdot}H_2O$ (417.40): calcd. C 28.77, H 6.28, N 6.71; found C 28.78, H 6.02, N 6.68. $^1H$ NMR ($D_2O$): $\delta$ = 3.06 (m, 2 H, C$H_2$O), 2.97 (m, 2 H, C$H_2$O), 2.29 (m, 2 H, C*H*N), 1.60 [m, 2 H, $(CH_3)_2CH$], 0.84 (t, $^3J_{H,H}$ = 7.8 Hz, 12 H, C$H_3$) ppm. $^{13}C$ NMR ($D_2O$): $\delta$ = 71.8 (2 C, *C*$H_2$O), 68.4 (2 C, *C*HN), 28.6 [2 C, *C*$H(CH_3)_2$], 20.2 (2 C, *C*$H_3$), 18.7 (2 C, *C*$H_3$) ppm.

**(*SP*-4–2)-Bis[(*S*)-1-amino-2-propanolato-κ²*N*,*O*]platinum(II) [2d(*S*)]: 1d(*S*)** (3.026 g, 5.05 mmol) was suspended in water (80 mL), treated with $AgNO_3$ (1.647 g; 9.70 mmol), and stirred for 24 h. After filtration of AgI, the clear solution was treated with preconditioned IRA 402 as described for **2a**; the reaction was stirred for 48 h. After removal of the ion exchange resign and filtration, the solution was concentrated until a solid product appeared. Precipitation was completed first at room temperature and later at 4 °C. The white

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

product was isolated by filtration, rinsed with a few drops of ice-cold water, and dried in vacuo over $P_4O_{10}$. Yield: 186 mg (10%). $C_6H_{16}N_2O_2Pt·1.5H_2O$ (370.30): calcd. C 19.46, H 5.17, N 7.56; found C 19.60, H 4.87, N 7.33. $^1$H NMR ($D_2O$): $\delta$ = 3.42 (m, 2 H, C*H*O), 2.28 (dd, $^3J_{H,H}$ = 3.5 Hz, $^3J_{H,H}$ = 11.5 Hz, 2 H, C$H_2$N), 2.01 (dd, $^3J_{H,H}$ = 11.4 Hz, 2 H, C$H_2$N), 1.03 (d, $^3J_{H,H}$ = 6.0 Hz, 6 H, C$H_3$) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 75.2 (2 C, *C*HO), 55.3 (2 C, *C*$H_2$N), 17.7 (2 C, *C*$H_3$) ppm.

**(*SP*-4-2)-Bis[(*R*)-1-amino-2-propanolato-κ$^2$*N*,*O*]platinum(II) [2d(*R*)]:** The synthesis was carried out as described for **2d(*S*)**, starting from **1d(*R*)** (2.022 g, 3.37 mmol). Yield: 429 mg (39%). $C_6H_{16}N_2O_2Pt$ (343.28): calcd. C 20.99, H 4.70, N 8.16; found C 20.76, H 4.99, N 7.86. $^1$H NMR ($D_2O$): $\delta$ = 3.41 (m, 2 H, C*H*O), 2.27 (dd, $^3J_{H,H}$ = 3.4 Hz, $^3J_{H,H}$ = 11.5 Hz, 2 H, C$H_2$N), 2.00 (dd, $^3J_{H,H}$ = 10.7 Hz, 2 H, C$H_2$N), 1.03 (d, $^3J_{H,H}$ = 6.3 Hz, 6 H, C$H_3$) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 75.1 (2 C, *C*HO), 54.9 (2 C, *C*$H_2$N), 17.6 (2 C, *C*$H_3$) ppm.

**(*SP*-4-2)-Bis(2-aminoethanol-κ*N*)oxalatoplatinum(II) (3a): 2a** (122 mg, 0.39 mmol) and oxalic acid dihydrate (50 mg, 0.40 mmol) were dissolved in water (2 mL) and stirred for 20 h at room temperature. The solution was filtered and reduced in a hood air stream until crystallization of colorless needles occurred. The product was separated and dried in vacuo over $P_4O_{10}$. Yield: 140 mg (89%). $C_6H_{14}N_2O_6Pt$ (405.26): calcd. C 17.78, H 3.48, N 6.91; found C 17.82, H 3.28, N 6.73. $^1$H NMR ($D_2O$): $\delta$ = 3.76 (t, $^3J_{H,H}$ = 5.3 Hz, 4 H, C$H_2$O), 2.68 (m, 4 H, C$H_2$N) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 169.3 (2 C, *C*OO), 60.5 (2 C, *C*$H_2$O), 48.3 (2 C, *C*$H_2$N) ppm.

**(*SP*-4-2)-Bis[(*S*)-2-amino-1-butanol-κ*N*]oxalatoplatinum(II) [3b(*S*)]: 2b(*S*)** (49 mg, 0.13 mmol) and oxalic acid dihydrate (17 mg, 0.13 mmol) were dissolved in water (1 mL) and stirred for 18 h at room temperature. The solution was filtered and concentrated under reduced pressure over $P_4O_{10}$ until a crystalline product appeared, which was washed with water (two times with 0.5 mL) and dried in vacuo over $P_4O_{10}$. Yield: 28 mg (46%). $C_{10}H_{22}N_2O_6Pt$ (461.37): calcd. C 26.03, H 4.81, N 6.07; found C 25.98, H 4.70, N 5.94. $^1$H NMR ($D_2O$): $\delta$ = 3.92 (dd, $^3J_{H,H}$ = 3.6 Hz, $^3J_{H,H}$ = 12.0 Hz, 2 H, C$H_2$O), 3.63 (dd, $^3J_{H,H}$ = 5.1 Hz, $^3J_{H,H}$ = 12.0 Hz, 2 H, C$H_2$O), 2.59 (m, 2 H, C*H*N), 1.72 (m, 2 H, $CH_3CH_2$), 1.54 (m, 2 H, $CH_3CH_2$), 0.89 (t, $^3J_{H,H}$ = 7.5 Hz, 6 H, C$H_3$) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 169.3 (2 C, *C*OO), 62.4 (2 C, *C*$H_2$O), 59.1 (2 C, *C*HN), 24.3 (2 C, *C*$H_2CH_3$), 9.9 (2 C, *C*$H_3$) ppm.

**(*SP*-4-2)-Bis[(*R*)-2-amino-3-methyl-1-butanol-κ*N*]oxalatoplatinum(II) [3c(*R*)]: 2c(*R*)** (76 mg, 0.19 mmol) and oxalic acid dihydrate (24 mg, 0.19 mmol) were dissolved in water (5 mL) and stirred for 48 h at room temperature. The solution was concentrated under reduced pressure at 35 °C to ca. 1 mL and stored at room temperature for 12 h. A white product was isolated and dried in vacuo. Yield: 75 mg (81%). $C_{12}H_{26}N_2O_6Pt$ (489.44): calcd. C 29.45, H 5.35, N 5.72; found C 29.44, H 5.13, N 5.59. $^1$H NMR ($D_2O$): $\delta$ = 4.02 (dd, $^3J_{H,H}$ = 3.7 Hz, $^3J_{H,H}$ = 12.0 Hz, 2 H, C$H_2$O), 3.73 (dd, $^3J_{H,H}$ = 5.6 Hz, $^3J_{H,H}$ = 12.0 Hz, 2 H, C$H_2$O), 2.45 (m, 2 H, C*H*N), 1.99 [m, 2 H, $(CH_3)_2CH$], 0.91 (d, $^3J_{H,H}$ = 6.8 Hz, 6 H, C$H_3$), 0.87 (d, $^3J_{H,H}$ = 6.8 Hz, 6 H, C$H_3$) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 169.3 (2 C, *C*OO), 63,2 (2 C, *C*HN), 61.5 (2 C, *C*$H_2$O), 29.4 [2 C, *C*$H(CH_3)_2$], 18.9 (2 C, *C*$H_3$), 18.1 (2 C, *C*$H_3$) ppm.

**(*SP*-4-2)-Bis[(*R*)-1-amino-2-propanol-κ*N*]oxalatoplatinum(II) [3d(*R*)]: 2d(*R*)** (157 mg, 0.46 mmol) and oxalic acid dihydrate (58 mg, 0.46 mmol) were dissolved in water (5 mL) and stirred for 48 h at room temperature. The solution was reduced to 1 mL and stored at room temperature for 12 h. A white precipitate was separated from the residual solution and dried in vacuo. Yield: 79 mg (40%). $C_8H_{18}N_2O_6Pt$ (433.32): calcd. C 22.17, H 4.19, N 6.46; found: C 22.40, H 3.97, N 6.31. $^1$H NMR ($D_2O$): $\delta$ = 4.07 (m, 2 H, C*H*O), 2.65 (m, 2 H, C$H_2$N), 2.41 (m, 2 H, C$H_2$N), 1.11 (d, $^3J_{H,H}$ = 6.4 Hz, 6 H, C$H_3$) ppm. $^{13}$C NMR ($D_2O$): $\delta$ = 169.2 (2 C, *C*OO), 66.9 (2 C, *C*HO), 53.2 (2 C, *C*$H_2$N), 20.1 (2 C, *C*$H_3$) ppm.

**(*SP*-4-2)-Bis(2-aminoethanol-κ*N*)malonatoplatinum(II) (4a): 2a** (200 mg, 0.63 mmol) and malonic acid (66 mg, 0.65 mmol) were dissolved in water (10 mL) and stirred for 24 h at room temperature. The colorless solution was filtered and the solvent was removed slowly under reduced pressure over $CaCl_2$. A white crystalline product was isolated and dried in vacuo over $P_4O_{10}$. Yield: 230 mg (86%). $C_7H_{16}N_2O_6Pt$ (419.30): calcd. C 20.05, H 3.85, N 6.68; found C 20.18, H 3.69, N 6.53. $^1$H NMR ($H_2O/D_2O$, 9:1): $\delta$ = 3.75 (t, $^3J_{H,H}$ = 5.2 Hz, 4 H, C$H_2$O), 3.57 (s, 2 H, C$H_2$COO), 2.64 (m, 4 H, C$H_2$N) ppm.

**(*SP*-4-2)-Bis[(*R*)-2-amino-1-butanol-κ*N*]malonatoplatinum(II) [4b(*R*)]: 2b(*R*)** (200 mg, 0.54 mmol) and malonic acid (56 mg, 0.55 mmol) were dissolved in water (10 mL) and stirred for 24 h at 40 °C. The solution was filtered and the solvent was removed under reduced pressure at 40 °C. The residual yellow oil was treated with diethyl ether (15 mL) for 30 s in an ultra sonic bath, then the solvent was immediately evaporated. This procedure was repeated five times. The solid product was dried in vacuo, recrystallized from acetone/ethanol (3:1), and finally dried in vacuo. Yield: 82 mg (32%). $C_{11}H_{24}N_2O_6Pt$ (475.40): calcd. C 27.79, H 5.09, N 5.89; found C 27.58, H 4.80, N 5.65. $^1$H NMR ($H_2O/D_2O$, 9:1): $\delta$ = 3.92 (m, 2 H, C$H_2$O), 3.60 (m, 2 H, C$H_2$O), 3.58 (s, 2 H, C$H_2$COO), 2.58 (s, 2 H, C*H*N), 1.71 (m, 2 H, C$H_2CH_3$), 1.53 (m, 2 H, C$H_2CH_3$), 0.87 (m, 6 H, C$H_3$) ppm. $^{13}$C NMR ($H_2O/D_2O$, 9:1): $\delta$ = 178.4 (2 C, $CH_2COO$), 62.6 (2 C, *C*$H_2$O), 58.7 (2 C, *C*HN), 48.0 (1 C, *C*$H_2$COO), 24.3 (2 C, *C*$H_2CH_3$), 9.9 (2 C, *C*$H_3$) ppm.

**(*SP*-4-2)-Bis[(*R*)-2-amino-3-methyl-1-butanol-κ*N*]malonatoplatinum(II) [4c(*R*)]:** Malonic acid (52 mg, 0.51 mmol) was dissolved in water (10 mL). To this solution **2c(*R*)** (200 mg, 0.48 mmol) was added and the mixture was stirred for 24 h at 35 °C. The solution was filtered, the solvent was removed, and the residual yellow paste-like solid was treated with ether as described for **4b(*R*)**. A white solid product was isolated and dried in vacuo. Yield: 103 mg (43%). $C_{13}H_{28}N_2O_6Pt$ (503.45): calcd. C 31.01, H 5.61, N 5.56; found C 31.23, H 5.39, N 5.33. $^1$H NMR ($H_2O/D_2O$, 9:1): $\delta$ = 4.01 (dd, $^3J_{H,H}$ = 3.8 Hz, $^3J_{H,H}$ = 11.9 Hz, 2 H, C$H_2$O), 3.70 (dd, $^3J_{H,H}$ = 6.0 Hz, $^3J_{H,H}$ = 12.1 Hz, 2 H, C$H_2$O), 3.57 (s, 2 H, C$H_2$COO), 2.46 (m, 2 H, C*H*N), 2.04 [m, 2 H, C$H(CH_3)_2$], 0.91 (d, $^3J_{H,H}$ = 7.1 Hz, 6 H, C$H_3$), 0.86 (d, $^3J_{H,H}$ = 6.8 Hz, 6 H, C$H_3$) ppm.

**(*SP*-4-2)-Bis[(*R*)-1-amino-2-propanol-κ*N*]malonatoplatinum(II) [4d(*R*)]: 2d(*R*)** (175 mg, 0.51 mmol) and malonic acid (53 mg, 0.51 mmol) were dissolved in water (10 mL) and stirred for 24 h at room temperature. The solution was filtered and lyophilized. A white product was isolated and dried in vacuo over $P_4O_{10}$. Yield: 216 mg (95%). $C_9H_{20}N_2O_6Pt$ (447.34): calcd. C 24.16, H 4.51, N 6.26; found C 23.86, H 4.56, N 6.05. $^1$H NMR ($H_2O/D_2O$, 9:1): $\delta$ = 4.11 (m, 2 H, C*H*O), 3.56 (s, 2 H, C$H_2$COO), 2.63 (m, 2 H, C$H_2$N), 2.38 (m, 2 H, C$H_2$N), 1.12 (d, $^3J_{H,H}$ = 6.4 Hz, 6 H, C$H_3$) ppm.

**(*SP*-4-2)-Bis(2-aminoethanol-κ*N*)cyclobutane-1,1-dicarboxylatoplatinum(II) (5a): 2a** (200 mg, 0.63 mmol) and cyclobutane-1,1-dicarboxylic acid (91 mg, 0.63 mmol) were dissolved in water (10 mL) and stirred for 48 h at room temperature. The solution was concentrated in a hood air stream until crystallization could be observed. The colorless product was collected and dried in vacuo over $P_4O_{10}$. Yield: 220 mg (75%). $C_{10}H_{20}N_2O_6Pt$ (459.35): calcd. C 26.15, H 4.39 N 6.10; found C 26.22, H 4.16, N 5.98. $^1$H NMR ($D_2O$): $\delta$ =

| GOF[c] | 1.120 | 1.026 |

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. [c] GOF = $\{\Sigma[w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$, where *n* is the number of reflections and *p* is the total number of parameters refined.

X-ray diffraction measurements were performed with Nonius Kappa CCD and Bruker X8APEX II CCD diffractometers for **2c(*S*)**, **2d(*S*)**, **3a**, and **5a**, respectively. Single crystals were positioned at 35, 30, 37.5, and 30 mm from the detector and 747, 371, 673, and 379 frames were measured, each for 10, 15, 40, and 8 s over 1, 2, 1, and 2° scan width [complexes **2c(*S*)**, **2d(*S*)**, **3a**, and **5a**, respectively]. The data were processed using Denzo-SMN software.[21] Crystal data, data collection parameters, and structure refinement details for **2c(*S*)** and **2d(*S*)** are given in Table S2, whereas those for **3a** and **5a** are given in Table 2. The structures were solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms were calculated and allowed to ride. Computer programs: structure solution, SHELXS-97,[22] refinement, SHELXL-97,[23] molecular diagrams, ORTEP,[24] computer: Pentium II; scattering factors.[25]

CCDC-298141 (for **2c*S***), -298142 [for **2d(*S*)**], -298144 (for **3a**), and -298143 (for **5a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): ORTEP drawings and Tables with bond lengths, angles, and crystallographic data of **2c(*S*)** and **2d(*S*)**. NMR spectra for the reaction of **2a** with NaCl and sodium oxalate.

## Acknowledgments

We are thankful to Prof. G. Giester and Mr. A. Roller for the collection of X-ray data. The support of the FWF (Fonds zur Foerderung der wissenschaftlichen Forschung), the Austrian Council for Research and Technology Development, Faustus Forschung Translational Drug Development AG and COST (European Cooperation in the Field of Scientific and Technical Research) is gratefully acknowledged.

# $^{195}$Pt NMR Spectra of Head-to-Head and Head-to-Tail Amidato-Bridged Platinum(III) Dinuclear Complexes

Satoshi Iwatsuki,*[a] Eigo Isomura,[b] Atsushi Wada,[b] Koji Ishihara,*[b,c] and Kazuko Matsumoto*[b,d]

**Keywords:** Platinum / $^{195}$Pt NMR / α-Pyridone / α-Pyrrolidone / Pivalamide / NMR spectroscopy

$^{195}$Pt chemical shifts and $^{1}J_{Pt-Pt}$ coupling constants were measured for a series of head-to-head (HH) and head-to-tail (HT) amidato-bridged *cis*-diammineplatinum(III) dinuclear complexes involved in the axial water substitution reactions with halide ions ($X^-$ = $Cl^-$, $Br^-$): HH-$[Pt_2(NH_3)_4(\mu\text{-amidato})_2L^1L^2]^{n+}$ ≡ $[L^1\text{–}Pt(N_2O_2)\text{–}Pt(N_4)\text{–}L^2]^{n+}$ (amidato = α-pyridonato, α-pyrrolidonato, and pivalamidato) and HT-$[Pt_2(NH_3)_4(\mu\text{-}\alpha\text{-pyridonato})_2L^1L^2]^{n+}$ ≡ $[L^1\text{–}Pt(N_3O)\text{–}Pt(N_3O)\text{–}L^2]^{n+}$; the diaqua ($L^1$, $L^2$ = $H_2O$, $n$ = 4), the aquahalo ($L^1$ = $X^-$, $L^2$ = $H_2O$, $n$ = 3), and the dihalo complexes ($L^1$, $L^2$ = $X^-$, $n$ = 2). The $^{195}$Pt NMR spectroscopic data were considered in relation to the lability in the axial ligand substitution reaction and the electron distribution along the Pt–Pt bond. The NMR spectroscopic data suggested different electron distributions along the Pt–Pt bonds in all the HH dimers and in the HT aquahalo dimers, such as $[L^1\text{–}Pt^{IV}(N_2O_2)\text{–}Pt^{II}(N_4)\text{–}L^2]^{n+}$ and $[X\text{–}Pt^{IV}(N_3O)\text{–}Pt^{II}(N_3O)\text{–}OH_2]^{3+}$, respectively. Relative shifts of the $^{195}$Pt NMR signals for each substitution step indicate that the replacement of the axial water ligand by $X^-$ affects more effectively the electron density of the opposite Pt atom than that of the substituted one.

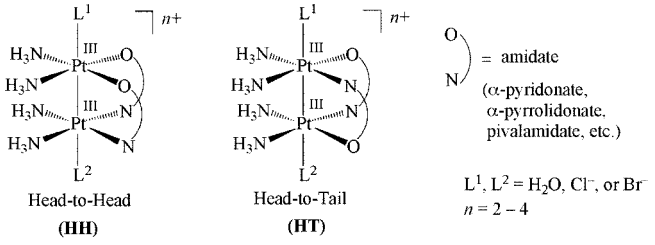
## Introduction

Head-to-head (HH) and head-to-tail (HT) amidato-bridged platinum(III) dinuclear complexes having a metal–metal bond between the two $d^7$ platinum atoms have two inorganic axial ligands, and the substitution reactions at the axial sites are well known synthetically[1–3] and kinetically.[4–8]

The two platinum atoms in the HH complex are not equivalent, that is, one is coordinated by two amidate oxygen atoms and two ammine nitrogen atoms [$Pt(N_2O_2)$], whereas the other is coordinated by four nitrogen atoms [$Pt(N_4)$]. On the other hand, the HT complex has two equivalent Pt atoms [$Pt(N_3O)$].



The axial ligand substitution with halide ion ($X^-$ = $Cl^-$, $Br^-$) on both the HH and HT diaqua $Pt^{III}$ complexes occurs consecutively in two steps [Equations (1) and (2)].[4–6]

$$[(H_2O)Pt(NH_3)_2(\mu\text{-amidato})_2Pt(NH_3)_2(OH_2)]^{4+} + X^- \overset{\text{step 1}}{\rightleftharpoons} [(H_2O)Pt(NH_3)_2(\mu\text{-amidato})_2Pt(NH_3)_2(X)]^{3+} + H_2O \quad (1)$$

$$[(H_2O)Pt(NH_3)_2(\mu\text{-amidato})_2Pt(NH_3)_2(X)]^{3+} + X^- \overset{\text{step 2}}{\rightleftharpoons} [(X)Pt(NH_3)_2(\mu\text{-amidato})_2Pt(NH_3)_2(X)]^{2+} + H_2O \quad (2)$$

In step 1 [Equation (1)] for the reaction of the diaqua $Pt^{III}$ dinuclear complexes, deprotonation of the aqua ligands occurs preferentially on the $Pt(N_4)$ atom and substitution occurs on the $Pt(N_2O_2)$ atom in HH diaqua $Pt^{III}$ complexes, whereas deprotonation occurs on one of the two equivalent $Pt(N_3O)$ atoms and substitution occurs on the other $Pt(N_3O)$ atom in HT diaqua $Pt^{III}$ complexes. There are two parallel reaction paths in step 1 for both HH and

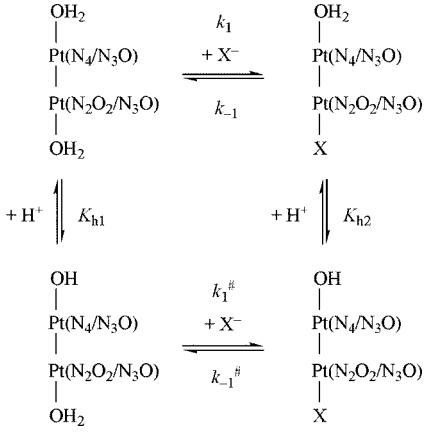
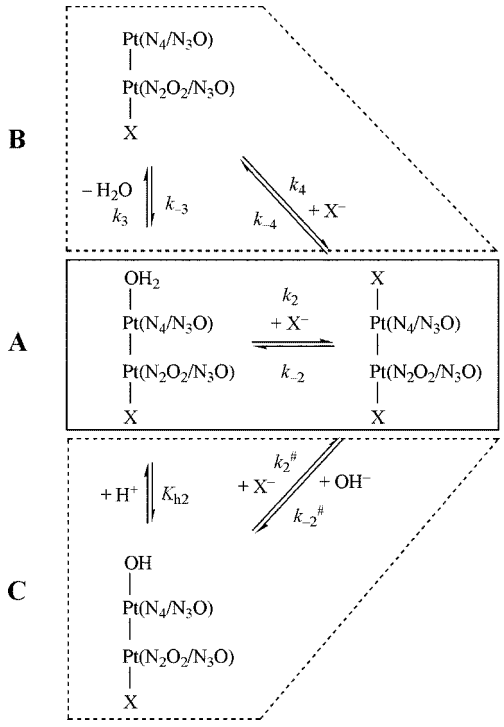
HT complexes ($k_1$ and $k_1^{\#}$ in Scheme 1), because the diaqua complex exists in equilibrium with the aquahydroxo complex, and both complexes undergo substitution with $X^-$.[4–8] In step 2 [Equation (2)], there are three possible pathways (Scheme 2), and step 2 proceeds by either one or two paths of the three, depending on the axial ligand ($X^-$). One of the three paths is the direct substitution path (**A**), the second path (**B**) is by dissociation of the water molecule on the $Pt(N_4)$ atom or on the $Pt(N_3O)$ atom, and the third (**C**) is the unusual path of $OH^-$ replacement.[4–6] The substitution lability of the second step is influenced strongly by the first halide ligand on the opposite axial site, which is explained as follows: the extent of the charge localization in the Pt–Pt bond in the dinuclear complex {the contribution of $[X–Pt^{IV}(NH_3)_2(\mu\text{-amidato})_2Pt^{II}(NH_3)_2–OH_2]^{3+}$ as compared to $[X–Pt^{III}(NH_3)_2(\mu\text{-amidato})_2Pt^{III}(NH_3)_2–OH_2]^{3+}$} depends largely on the electron-donating ability of the first substituted ligand ($X^-$), which is reflected in the reaction mechanisms examined so far for several amidato-bridged $Pt^{III}$ dinuclear complexes. The different extent of the Pt–Pt bond polarization leads to variations of the substitution lability and coordination stability of the axial aqua ligand, thus affecting the substitution reaction mechanism. When $X^-$ is less electron-donating, paths **A** and **C** or only path **A** take place in the reactions of the HT α-pyridonato-bridged and HH α-pyrrolidonato-bridged complexes, whereas paths **A** and **B** are preferred in these complexes when $X^-$ is more electron-donating, though paths **A** and **B** are preferred irrespective of $X^-$ in the reaction of the HH α-pyridonato-bridged complex.[4–6] In contrast, however, paths **A** and **C** are involved in the reaction of the HH pivalamidato-bridged complex for more electron-donating $X^-$ (Scheme 2 and Table 1).[6]



Scheme 1. Reaction paths in step 1 for the reaction of the HH and HT amidato-bridged $Pt^{III}$ dimer with $X^-$ ($X^-$ = $Cl^-$ or $Br^-$).

In this paper we present the systematic [195]Pt NMR spectroscopic data for a series of the HH and HT amidato-bridged *cis*-diammineplatinum(III) dinuclear complexes involved in the axial water substitution reactions with halide ions ($X^-$ = $Cl^-$, $Br^-$): HH-$[Pt_2(NH_3)_4(\mu\text{-amidato})_2L^1L^2]^{n+}$ (amidato = α-pyridonato, α-pyrrolidonato, and pivalamidato) and HT-$[Pt_2(NH_3)_4(\mu\text{-α-pyridonato})_2L^1L^2]^{n+}$; the diaqua ($L^1$, $L^2$ = $H_2O$, $n$ = 4), the aquahalo ($L^1$ = $X^-$, $L^2$ = $H_2O$, $n$ = 3), and the dihalo complexes ($L^1$, $L^2$ = $X^-$, $n$ = 2). The electron localization and consequently the axial ligand substitution must be reflected in the [195]Pt NMR spectroscopic data. The exceptional reactivity observed for the second step (step 2) of the HH pivalamidato-bridged $Pt^{III}$ dinuclear complex (Scheme 2 and Table 1) may be reflected in and related to the chemical shift and the Pt–Pt coupling constant of the [195]Pt NMR spectra.



Scheme 2. Three possible reaction paths in step 2 for the reaction of the HH and HT amidato-bridged $Pt^{III}$ dimer with $X^-$ (= $Cl^-$ or $Br^-$).

## Results and Discussion

### Assignment of [195]Pt NMR Signals

Figure 1 shows the [195]Pt NMR spectra of the HH diaqua complex bridged by α-pyridonate {the HH-$[Pt_2(NH_3)_4(\mu\text{-α-pyridonato})_2(OH_2)_2]^{4+}$ complex}. A set of two signals at higher and lower fields both with a couple of satellite signals due to Pt–Pt coupling was successfully assigned to $Pt(N_4)$ and $Pt(N_2O_2)$, respectively, based on the multiplicity

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the lines [9 for $Pt(N_4)$ and 5 for $Pt(N_2O_2)$ because of $^{195}Pt$–$^{14}N$ coupling]. Similar assignable signals were observed for all the other HH α-pyridonato-bridged $Pt^{III}$ dimers, that is, the aquachloro (Figure 2), aquabromo (Figure S1), dichloro (Figure S2), and dibromo complexes (Figure S3). The signal of the $Pt(N_2O_2)$ moiety of all the HH α-pyridonato-bridged $Pt^{III}$ dimers is always observed at a lower field, and the $Pt(N_4)$ signal at a higher field. For the HH α-pyrrolidonato-bridged and the pivalamidato-bridged complex systems, the signal assignments similar to those of α-pyridonato-bridged dimers are applied to the aquahalo and dihalo complexes. The $^{195}Pt$ NMR signals for the α-pyrrolidonato-bridged and the pivalamidato-bridged HH diaqua complexes could not be assigned; the Pt–Pt coupling was observed with no distinguishable Pt–N couplings such as those mentioned above (Figures S12 and S13). Therefore, the assignment for these diaqua dimers was performed according to the result of the HH α-pyridonato-bridged diaqua complex. The $^{195}Pt$ chemical shifts ($\delta_{Pt}$) and Pt–Pt coupling constants ($^1J_{Pt-Pt}$) for the present HH amidato-bridged $Pt^{III}$ dinuclear complexes are summarized in Table 2.

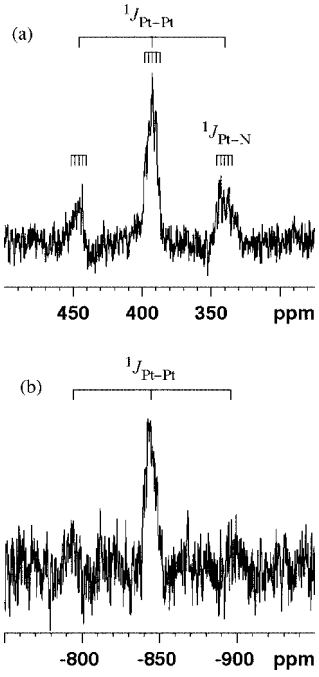

Figure 1. $^{195}Pt$ NMR signals of the $Pt(N_2O_2)$ (a) and the $Pt(N_4)$ (b) moieties in the HH α-pyridonato-bridged diaqua dimer in $DClO_4$ (1.2 M)/$D_2O$.

The HT α-pyridonato-bridged $Pt^{III}$ dimer complexes with the same axial ligands (the diaqua, dichloro, and dibromo dimers) showed a single $^{195}Pt$ NMR signal (Figure S14), as the two platinum atoms are equivalent: $[L^1$–$Pt(N_3O)$–$Pt(N_3O)$–$L^2]^{n+}$ where $L^1 = L^2$. On the other hand, the HT aquahalo complexes afforded two different $^{195}Pt$ signals (Figures S15 and S16) that have similar Pt–Pt (a couple of satellite) and Pt–N couplings [a multiplicity of 7 due to $Pt(N_3O)$ moieties] to those of the HH complexes. Therefore, the assignment of these HT aquahalo dimers was

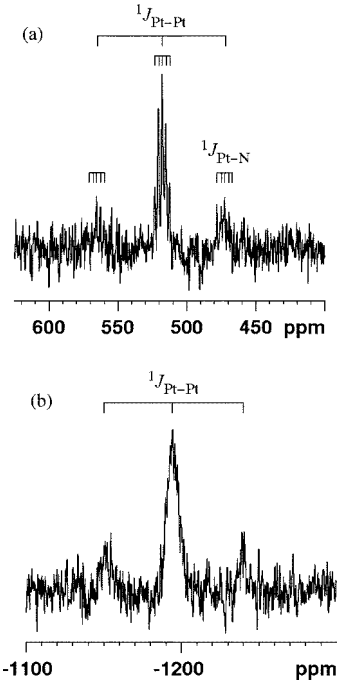

Figure 2. $^{195}Pt$ NMR signals of the $Pt(N_2O_2)$ (a) and the $Pt(N_4)$ (b) moieties in the HH α-pyridonato-bridged aquachloro dimer in $DClO_4$ (1.2 M)/$D_2O$.

done based on the results of the corresponding HH amidato-bridged $Pt^{III}$ aquahalo complexes; a lower-field signal was assigned to $X$–$Pt(N_3O)$, while a higher-field signal was assigned to $Pt(N_3O)$–$OH_2$. In Table 2 the $\delta_{Pt}$ and $^1J_{Pt-Pt}$ values obtained for the HT α-pyridonato-bridged $Pt^{III}$ dimers are also listed.

The $^{195}Pt$ NMR spectra of the HH and HT amidato-bridged $Pt^{III}$ aquahydroxo complexes could not be measured because of the gradual decomposition of the complexes in less acidic aqueous solution for a prolonged measuring time (> ca. 8 h).

In general, the $^{195}Pt$ chemical shifts of $Pt^{IV}$ complexes tend to be at lower fields than those of $Pt^{II}$ complexes (Table S1).[9,10] Therefore, the HH amidato-bridged $Pt^{III}$ dimer seems to be polarized close to $[L^1$–$Pt^{IV}(N_2O_2)$–$Pt^{II}(N_4)$–$L^2]^{n+}$ ($L^1$, $L^2$ = $H_2O$, $Cl^-$, or $Br^-$). Our previous studies on the reaction of the diaqua complex, $[H_2O$–$Pt^{IV}(N_2O_2)$–$Pt^{II}(N_4)$–$OH_2]^{4+}$, with $X^-$ showed that the first substitution always occurs at the $Pt^{IV}(N_2O_2)$ atom and the acid dissociation occurs preferentially at the axial $H_2O$ ligand of the $Pt^{II}(N_4)$ atom.[5,6] It is known that $Pt^{II}$ complexes are usually inert for substitution, and $Pt^{IV}$ complexes are even more inert.[11] In the HH amidato-bridged $Pt^{III}$ dimer, however, the axial site of the $Pt(N_2O_2)$ atom having $Pt^{IV}$ character is more substitution-active than that of the $Pt(N_4)$ atom having $Pt^{II}$ character, which suggests that both the $Pt(N_2O_2)$ and the $Pt(N_4)$ atoms still have a $Pt^{III}$ character to a substantial extent in the polarized $Pt^{III}$ complexes. In all these complexes, deprotonation occurs preferentially at the $H_2O$–$Pt^{II}(N_4)$ moiety having a shorter Pt–$OH_2$ bond, whereas the first substitution occurs at the $Pt^{IV}(N_2O_2)$ atom having a longer Pt–$OH_2$ bond.

[a] Relative to aqueous $H_2PtCl_6$ ($\delta$ = 0 ppm) or $K_2PtCl_4$ ($\delta$ = –1622 ppm) as external references. [b] The signals could not be assigned experimentally. [c] The assignments are performed based on the trends of the chemical shift change in the HH complex systems. [d] Refs.[15,16]

### $^{195}$Pt Chemical Shifts and $^1J_{Pt-Pt}$ Coupling Constants

Variations of the $^{195}$Pt chemical shift for the diaqua, dichloro, and dibromo complexes of HH-[$L^1$–$Pt(N_2O_2)$–$Pt(N_4)$–$L^2$]$^{n+}$ and HT-[$L^1$–$Pt(N_3O)$–$Pt(N_3O)$–$L^2$]$^{n+}$ ($L^1$ = $L^2$) are shown in Figure 3. For the HH diaqua and dihalo complexes, both of the $Pt(N_2O_2)$ and the $Pt(N_4)$ signals shift to higher field, when both of the axial aqua ligands are changed to $Cl^-$ and $Br^-$, though the $\Delta\delta$ (= $\delta_{Pt(N_2O_2)}$ – $\delta_{Pt(N_4)}$) values are almost constant (Table 2). A similar tendency is observed for the chemical shift of the $Pt(N_3O)$ signal in the HT complex. On the other hand, when only the aqua ligand on the $Pt(N_2O_2)$ atom in the HH diaqua dimer is changed to $Cl^-$ and $Br^-$, the $Pt(N_2O_2)$ signals shift to much lower fields and the $Pt(N_4)$ signals shift to much higher fields, compared to those of the diaqua, dichloro (Figure 4a), and dibromo complexes (Figure 4b). The X–$Pt(N_3O)$ and $H_2O$–$Pt(N_3O)$ signals of the HT dimer shift similarly (Figure 4). These indicate that the Pt–Pt bonds in the monosubstituted (aquahalo) complexes are more polarized as X–$Pt^{IV}(N_2O_2/N_3O)$–$Pt^{II}(N_4/N_3O)$–$OH_2$, compared to those of the $Pt^{III}$ dimer complexes having the same axial ligands (the diaqua and dihalo complexes).

Variation of the Pt–Pt coupling constants with the axial ligands is depicted in Figure 5. The coupling constants in each HH dimer system tend to decrease in the order: $H_2O$–$Pt(N_2O_2)$–$Pt(N_4)$–$OH_2$ > Cl–$Pt(N_2O_2)$–$Pt(N_4)$–$OH_2$ > Br–$Pt(N_2O_2)$–$Pt(N_4)$–$OH_2$ > Cl–$Pt(N_2O_2)$–$Pt(N_4)$–Cl > Br–$Pt(N_2O_2)$–$Pt(N_4)$–Br. In all of the HH aquahalo and dihalo complexes, the coupling constants decrease in the order: pivalamidato-bridged dimer > α-pyrrolidonato-bridged di-

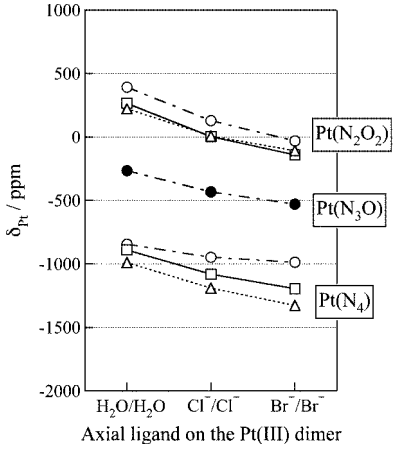

Figure 3. Dependence of $\delta_{Pt}$ on the axial ligands in the diaqua, dichloro, and dibromo complexes of the HH α-pyridonato-bridged (○), α-pyrrolidonato-bridged (□), and pivalamidato-bridged (Δ) dimers [$Pt(N_2O_2)$ and $Pt(N_4)$] and the HT α-pyridonato-bridged (●) dimer [$Pt(N_3O)$].

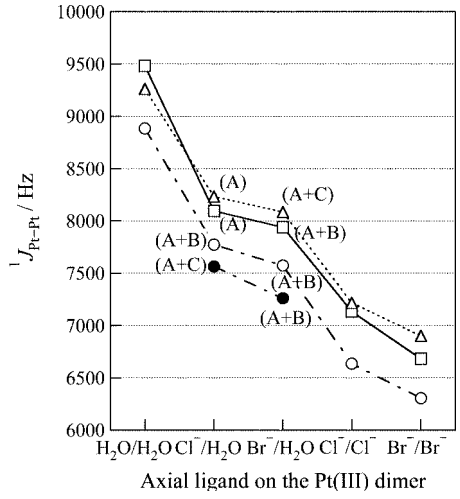

Figure 5. Dependence of $^1J_{Pt-Pt}$ on the axial ligands in the HH α-pyridonato-bridged (○), α-pyrrolidonato-bridged (□), and pivalamidato-bridged (Δ) dimers and the HT α-pyridonato-bridged (●) dimer.

mer > α-pyridonato-bridged dimer, but for the HH diaqua complexes the order is different, that is, the coupling constant of the pivalamidato-bridged dimer is smaller than that of the α-pyrrolidanato-bridged dimer.

### $^{195}$Pt NMR Spectroscopic Data and Ligand Substitution Mechanism

Both of the $^{195}$Pt NMR chemical shifts and the Pt–Pt coupling constants should be taken into account to understand the electronic structure of the Pt–Pt bonds and the mechanism of the axial substitution reactions. The deprotonation and the substitution lability of the diaqua dimers mentioned earlier in this paper suggest that the $L^2$–$Pt(N_4)$ bond having a higher-field chemical shift would be stronger and less labile than the $L^1$–$Pt(N_2O_2)$ bond having a lower-field shift in each complex, that is, the diaqua, aquahalo, and dihalo complexes. In other words, the Pt atom having the stronger axial Pt–L bond would give the higher-field chemical shift in the present HH amidato-bridged dimer complexes. Thus, both of the $L^1$–$Pt(N_2O_2)$ and the $L^2$–$Pt(N_4)$ bonds become stronger in the order: diaqua dimer < dichloro dimer < dibromo dimer. On the other hand, the Pt–Pt bond becomes weaker in the same order, based on the Pt–Pt coupling constants in Figure 5.

In the aquachloro complexes $\{[Cl–Pt(N_2O_2)–Pt(N_4)–OH_2]^{3+}\}$, all of the axial bonds, $Cl–Pt(N_2O_2)$, Pt–Pt, and $Pt(N_4)–OH_2$ bonds, would be strengthened in the order: α-pyridonato-bridged dimer < α-pyrrolidonato-bridged dimer < pivalamidato-bridged dimer, as the resonance fields (opposite order in the chemical shifts) and the coupling constants increase in the same order (Figure 4a and Figure 5). The same is true for a series of aquabromo dimers (Figure 4b and Figure 5). These orders of the axial bond strengths in the aquahalo dimers explain the variation of the axial water substitution mechanism in step 2 (Scheme 2) among the HH dimer systems. (1) For the HH dimer + $Cl^-$ systems, the reaction of the HH α-pyridonato-bridged aquachloro dimer proceeds through paths **A** and **B**, while the reactions of the α-pyrrolidonato-bridged and the pivalamidato-bridged aquachloro dimers proceed only by path **A**, because the $H_2O–Pt(N_4)$ bond in the former dimer is relatively weak compared to that of the latter. (2) For the HH dimer + $Br^-$ systems, both of the α-pyridonato-bridged and α-pyrrolidonato-bridged aquabromo dimers prefer paths **A** and **B**, because of the weaker $H_2O–Pt(N_4)$ bonds. In contrast, however, the pivalamidato-bridged dimer reacts with $Br^-$ by paths **A** and **C** in step 2. The exceptional behavior would be because deprotonation of the $H_2O$ ligand at the $Pt(N_4)$ atom is easier owing to the stronger $H_2O–Pt(N_4)$ bond. This is strongly supported by the highest field in the chemical shifts and the coupling constant of the pivalamidato-bridged aquabromo dimer among the present HH dimer + $Br^-$ systems (Figures 4b and 5).

The p$K_a$ values of the diaqua complexes are reported to be 1.71, 1.74, and 2.88 for the α-pyridonato-bridged dimer, the α-pyrrolidonato-bridged dimer, and the pivalamidato-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bridged dimer, respectively,[6,12] which is the opposite of the result expected from the chemical shift data of these diaqua complexes. The $^{1}J_{Pt–Pt}$ values of the diaqua dimers, which would involve the effects of all of the axial bonds as well as of the equatorial (bridging) ligands, decrease in the order: α-pyrrolidonato-bridged dimer > pivalamidato-bridged dimer > α-pyridonato-bridged dimer (Figure 4). These differences would be explained by: the chemical shifts and the coupling constants reflect the electronic distributions around the Pt atoms in the $H_2O$–$Pt(N_2O_2)$–$Pt(N_4)$–$OH_2$ moiety, while p$K_a$ reflects the Pt–$OH_2$ bond strength. It seems that the effects of both the bridging ligands and the axial ligands are important in determining the substitution reaction path.

The exceptional reactivity of the HH pivalamidato-bridged $Pt^{III}$ dinuclear complex (Scheme 2 and Table 1), as mentioned above, could not be explicitly reflected in the chemical shift and coupling constant of the $^{195}$Pt NMR spectroscopy. This may suggest that not only electronic effects that are reflected in the NMR spectroscopic data but also (dynamic) steric effects due to bridging ligands, complementary ligands, solvent, etc. contribute significantly and complicatedly to the determination of the ligand substitution mechanism for the present systems. That is, the $^{195}$Pt NMR spectroscopic data would be reproduced by detailed DFT calculations including solvent effect, relativistic effect, etc.,[13] but the calculations do not serve the ligand substitution mechanism.

### Comparison Between the Amidato-Bridged $Pt^{III}$ Dinuclear Complexes and the Lantern-Type $Pt^{III}$ Dinuclear Complexes

In Table 2, the $^{195}$Pt chemical shifts of the lantern-type complexes are at much lower field than those of the amidato-bridged complexes, and the $\Delta\delta$ values of the aquahalo lantern-type complexes are much smaller than those of the amidato-bridged aquahalo dimers, that is, much less electron localization occurs in the lantern-type complexes, suggesting that the reactivities of the two-type complexes are different. Indeed, the axial ligand substitution occurs in two steps in the present amidato-bridged complexes, whereas it is one step in the hydrogenphosphato-bridged lantern-type complex.[14] In the amidato-bridged diaqua complexes, the two Pt centers behave differently and independently, because the electron distribution along the Pt–Pt bond of the intermediate (the aquahalo complex) after step 1 of the amidato-bridged complexes is very different from that of the original diaqua complex. This fact and the $^{195}$Pt NMR spectroscopic data again support the higher flexibility of the Pt–Pt bond in the amidato-bridged complexes compared to those of the lantern-type complexes, as mentioned in the previous report.[14] In Table 2, two opposite assignments of $^{195}$Pt NMR for the same complex, $[(L)Pt(\mu\text{-}HPO_4)_4Pt(OH_2)]^{n-}$ (L = $Cl^-$, $Br^-$, $SCN^-$, $NO_2^-$, $CN^-$, $NH_3$, etc.) are reported by Appleton et al.: (a) a higher field is assigned to Pt–L and a lower field to Pt–$OH_2$ for L = $Cl^-$, $Br^-$, and $SCN^-$, and (b) a lower field is assigned to Pt–L and a higher field to Pt–$OH_2$ for L = $NO_2^-$, $CN^-$, and $NH_3$.[15,16] All of the assignments of the aquahalo amidato-bridged complexes, which are based on the Pt–N coupling pattern of HH α-pyridonato-bridged complexes, are consistent with assignment (b). Table 2 and Figure 4 show that axial ligand substitution has much more influence on the opposite Pt atom [$Pt(N_4)$] than the Pt atom directly coordinated with $X^-$ [$Pt(N_2O_2)$].

## Conclusions

$^{195}$Pt NMR spectroscopic data (the chemical shifts and Pt–Pt coupling constants) were systematically obtained for a series of HH and HT bis(amidato-bridged) platinum(III) dinuclear complexes existing in the axial water ligand substitution reactions with $Cl^-$ and $Br^-$. Polarization of the Pt–Pt bond is observed in the $^{195}$Pt NMR spectra for the HH amidato-bridged diaqua $Pt^{III}$ dinuclear complex similarly to the HH aquahalo $Pt^{III}$ complexes, that is, the Pt–Pt bond is polarized approximately to $[H_2O–Pt^{IV}(N_2O_2)–Pt^{II}(N_4)–OH_2]^{4+}$. The first substitution of $H_2O$ on the $Pt^{IV}(N_2O_2)$ atom with $X^-$ enhances the electron localization to form the more polarized aquahalo complex having very different axial Pt–$OH_2$ bond lengths from that of the original diaqua complex. More pronounced electron localization was observed for the HT complex. The second substitution of the $H_2O$ ligand on the $Pt^{II}(N_4)$ atom in $[X–Pt^{IV}(N_2O_2)–Pt^{II}(N_4)–OH_2]^{3+}$ with $X^-$ reduces the electron polarization to an extent similar to the diaqua complex.

## Experimental Section

**Materials:** *cis*-$[Pt(NH_3)_2Cl_2]$ was prepared from $K_2[PtCl_4]$ (Tanaka Kikinzoku Kogyo K. K., Tokyo) according to Dhara's method.[17] α-Pyridone (97+%, Wako Pure Chemical Industries Ltd., Osaka) was recrystallized twice from water. Reagent grade α-pyrrolidone (Kanto Chemical Co. Inc., Tokyo) was purified once by vacuum distillation. Pivalamide (98%, Kanto) was recrystallized twice from water. HT-$[(NO_3)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(NO_3)](NO_3)_2\cdot 0.5H_2O$ (HT α-pyridonato-bridged dimer), HH-$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_4NO)_2Pt(NH_3)_2(NO_3)](NO_3)_3\cdot 2H_2O$ (HH α-pyridonato-bridged dimer), HH-$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_4H_6NO)_2Pt(NH_3)_2(H_2O)](NO_3)_4\cdot 2H_2O$ (HH α-pyrrolidonato-bridged dimer), and HH-$[(H_2O)Pt(NH_3)_2(\mu\text{-}C_5H_{10}NO)_2Pt(NH_3)_2(H_2O)](NO_3)_4\cdot 2H_2O$ (HH pivalamidato-bridged dimer) were prepared according to the literature.[18–21] Sodium chloride (99.99%, Aldrich) and sodium bromide (99.99%, Aldrich) were used without further purification. The NMR sample solution was prepared by using $D_2O$ (99.9 atom-%, Isotec) and [D]perchloric acid (68 wt.-% in $D_2O$, Aldrich).

**Measurements:** The $^{195}$Pt NMR spectra were recorded with a Bruker Avance 400 spectrometer operating at 85.9 MHz at ambient temperature (20 ± 2 °C). The chemical shift was referenced to $H_2PtCl_6$ ($\delta$ = 0 ppm) or $K_2PtCl_4$ ($\delta$ = –1622 ppm) as external standards. The sample solution was prepared by using an acidic $D_2O$ solution ($DClO_4/D_2O$) to suppress deprotonation of the diaqua complexes; acid dissociation constants: $-\log K_{h1}$ = 1.98 (HT α-pyridonato-bridged dimer),[4] 1.71 (HH α-pyridonato-bridged dimer),[5]

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.74 (HH α-pyrrolidonato-bridged dimer),[6,12] and 2.88 (HH pivalamidato-bridged dimer).[6] The concentration of the platinum(III) dimer ($C_{Pt}$) was adjusted to appropriately 5–40 mM according to the solubility of each compound in $D_2O$. The concentration of halide ion ($C_X$) in the monohalo and dihalo complex solutions was adjusted considering each equilibrium constant ($K_1^X$, $K_2^X$); $\log K_1^{Cl}$ = 5.27 and $\log K_2^{Cl}$ = 3.83 (HT α-pyridonato-bridged dimer + $Cl^-$),[4] $\log K_1^{Br}$ = 5.53 and $\log K_2^{Br}$ = 4.44 (HT α-pyridonato-bridged dimer + $Br^-$),[4] $\log K_1^{Cl}$ = 5.93 and $\log K_2^{Cl}$ = 3.71 (HH α-pyridonato-bridged dimer + $Cl^-$),[5] $\log K_1^{Br}$ = 6.20 and $\log K_2^{Br}$ = 4.55 (HH α-pyridonato-bridged dimer + $Br^-$),[5] $\log K_1^{Cl}$ = 5.61 and $\log K_2^{Cl}$ = 3.73 (HH α-pyrrolidonato-bridged dimer + $Cl^-$),[6] $\log K_1^{Br}$ = 5.50 and $\log K_2^{Br}$ = 4.68 (HH α-pyrrolidonato-bridged dimer + $Br^-$),[6] $\log K_1^{Cl}$ = 5.04 and $\log K_2^{Cl}$ = 3.21 (HH pivalamidato-bridged dimer + $Cl^-$),[6] and $\log K_1^{Br}$ = 5.93 and $\log K_2^{Br}$ = 3.91 (HH pivalamidato-bridged dimer + $Br^-$).[6]

**Supporting Information** (see footnote on the first page of this article): $Pt^{195}$ NMR chemical shifts of $Pt^{IV}$ and $Pt^{II}$ complexes (Table S1) and $^{195}Pt$ NMR spectra of all the other HH and HT $Pt^{III}$ dimers measured in this study except for the spectra shown in Figures 1 and 2 (Figures S1–S16).

# A Series of One- to Three-Dimensional Copper Coordination Polymers Based on N-Heterocyclic Ligands

Xiang He,[a] Can-Zhong Lu*[a] Chuan-De Wu,[a] and Li-Juan Chen[a]

**Keywords:** Coordination polymers / Copper / Luminescence / Nitrogen heterocycles / Organic–inorganic hybrid composites

A family of copper coordination polymers containing different N-heterocyclic ligands, namely $[Cu(CN)(dmpyz)]_n$ (**1**), $[Cu_2(CN)_2(imz)]_n$ (**2**), $[Cu_3(CN)(trz)_2]_n$ (**3**), $[Cu_6(CN)_6(dmtrz)_3]_n$ (**4**), $[Cu_2(CN)(5\text{-metta})]_n$ (**5**), $[Cu_2(CN)(5\text{-phtta})]_n$ (**6**), and $\{[Cu_6(CN)_6(dmtrz)]_2[Cu_2(CN)_2(dmtrz)_2]\}_n$ (**7**) has been prepared and structurally characterized by X-ray crystallography. The crystal structures of **1** and **2** are 1D chain frameworks. Compound **3** is a twofold interpenetrating 2D supramolecular framework in which the cyanide groups act as bridging ligands to link the copper centers into an unusual bilayer motif with large channels. Compounds **4**–**6** all possess 3D networks. Compound **4** is constructed by two parts: 2D rectangular-grid layers and $\{Cu_2(CN)_2(dmtrz)_2\}$ building blocks. Compound **5** is built up by X-shaped chains that connect each other in an ABAB arrangement to generate the 3D network. The structure of **6** is a 3D network including one-dimensional square-grid channels, with a shortest Cu2···Cu2A (A: $-x + 1, -y + 1, -z$) distance of about 2.347(1) Å. Compound **7** features a peculiar 3D + 1D network in which 1D guest metal-organic polymer chains are filled in an unusual 3D architecture constructed by double helical host tubes. Compounds **1**–**7** show a systematic variation in dimensionality from 1D to 3D to 3D + 1D. The luminescence properties of these compounds have been also studied.

## Introduction

Considerable attention has been paid to the study of metal coordination polymers not only because these polymers may possess intriguing architectures but also because of their potential applications in the fields of catalysis, molecular-based magnets, electrical conductivity, and zeolite-like materials.[1–3] Among these metal coordination polymers, copper cyanide systems have received special interest due to their fascinating structural frameworks, physical and chemical properties, and potential applications in many fields.[4–7] When studied from a coordination chemistry viewpoint, the structural variety of copper cyanide coordination polymers might be the result of two main factors. Firstly, the cyanide group is a versatile ligand that can act as a monodentate ligand as well as a $\mu_2$-, $\mu_3$-, or $\mu_4$-bridging ligand to generate interesting compounds that may exhibit intriguing topological architectures.[8,9] Secondly, the copper atom has versatile coordination properties and normally adopts three-, four-, five-, or six-coordination to form diverse geometries; the ligand geometry also plays an important role in controlling the structural dimensionalities and stereochemistry of the copper center.[10] On the other hand, from a synthetic chemistry viewpoint, cyanide-containing systems may be prepared either by assembling cyanometalates and metal complexes or by multicomponent self-assembly of cyanide, metal ions, and multidentate ligands. Although the majority of synthetic processes in these systems still follow the conventional solution route, attention has recently turned to solvothermal techniques.[11] To understand the construction of supramolecular architectures further, it is important to continue the investigations on the effect of organic ligands when fabricating multidimensional polymers. We are currently interested in using CuCN, $K_3Fe(CN)_6$, and a series of five-membered N-heterocyclic ring ligands (Scheme 1) as precursors to obtain some homometallic cyanide-bridged coordination polymeric compounds under hydrothermal conditions. In this article we report seven copper polymeric compounds, namely $[Cu(CN)(dmpyz)]_n$ (**1**), $[Cu_2(CN)_2(imz)]_n$ (**2**), $[Cu_3(CN)(trz)_2]_n$ (**3**), $[Cu_6(CN)_6(dmtrz)_3]_n$ (**4**) $[Cu_2(CN)(5\text{-metta})]_n$ (**5**), $[Cu_2(CN)(5\text{-phtta})]_n$ (**6**), and $\{[Cu_6(CN)_6(dmtrz)]_2[Cu_2(CN)_2(dmtrz)_2]\}_n$ (**7**), which exhibit variation dimensionalities.

## Results and Discussion

### Synthetic Considerations

In order to study the overall factors affecting the structural frameworks of the cyanide-bridged systems, we varied the reaction conditions (including reagent, temperature, and metal/ligand ratio). Firstly, we used $K_3Fe(CN)_6$ as a precursor instead of KCN to provide $CN^-$, based on the following consideration: (1) free cyanide might be released from the dissociation of ferricyanide anions under hydrothermal conditions; (2) the slow release of $CN^-$ might play an important role in the formation of various compounds; (3) cyanide-bridged iron(II)–copper(I) dimetallic compounds might be obtained under appropriate conditions.[12] Secondly, different kinds of N-heterocyclic ligands have an important impact on the final structures of the compounds obtained. Thirdly, the role of temperature in determining the structures of the products can be observed. Under hydrothermal conditions, we used $K_3Fe(CN)_6$ as a precursor to successfully obtain these new cyanide-bridged copper coordination polymers. Compound **7** is obtained at 180 °C, while at a lower temperature of 140 °C, violet, plate-like crystalline $K[Cu(CN)_3]_n{\cdot}H_2O$[13,14] is obtained instead of compound **7**. Interestingly, varying the composition of the reaction mixture gives **4** instead of **7**. During the synthesis of compound **3**, when $CuCl_2$ is used instead of CuCN under otherwise identical reaction conditions compound **3** is again obtained. The design and synthesis of novel coordination architectures controlled by varying the reaction conditions (including temperature,[15] metal/ligand ratio,[16] and counteranions[17]) are of great interest in coordination chemistry.

### Crystal Structures

#### *[Cu(CN)(dmpyz)]$_n$ (1)*

As shown in Figure 1, the structure exhibits a backbone constructed by a zigzag {Cu(CN)} chain. Each $Cu^I$ ion is in a trigonal-planar geometry, defined by one nitrogen atom from the 3,5-dimethylpyrazole ligand [Cu(1)–N(1) = 1.988(7) Å] and two cyanide groups [Cu(1)–X(6) = 1.870(11), Cu(1)–X(7) = 1.986(8) Å; X(6)–Cu(1)–X(7A) = 125.0(4)°], which bridge neighboring copper atoms to form the parent chain. The distance between the aromatic rings of the 3,5-dimethylpyrazole ligands from adjacent chains is 3.221 Å, which indicates the presence of a π–π stacking interaction.

#### *[Cu$_2$(CN)$_2$(imz)]$_n$ (2)*

The structure of **2** is similar to that of **1**, as shown in Figure 2. This compound contains two coordination modes for the $Cu^I$ ions: one is coordinated by three cyanide groups [Cu(1)–X(1) = 1.916(5), Cu(1)–X(2) = 1.920(4) Å; X(1)–Cu(1)–X(2) = 119.94(14)°], and the other is nonlinearly coordinated by one cyanide group and one imidazole ligand [Cu(2)–X(3) = 1.843(6), Cu(2)–N(4) = 1.877(5) Å; N(4)–Cu(2)–X(3) = 170.1(3)°]. The structure also exhibits a backbone constructed from a zigzag {Cu(CN)} chain, with [Cu(CN)(imz)] groups projecting from the chain as side-arms.

#### *[Cu$_3$(CN)(trz)$_2$]$_n$ (3)*

The structure of **3** is an interesting twofold interpenetrated 2D supramolecular framework. As shown in Figure 3, the structure of **3** possesses six unique metal sites. Three metal centers [Cu(2), Cu(3), and Cu(5)] are all in distorted trigonal geometries. However, the detailed coordination environment of these copper atoms is different as Cu(2) and Cu(5) are coordinated by two triazole ligands and one $\mu_2$-bridging cyanide group while Cu(3) is coordinated by two triazole ligands and one $\mu_3$-1,2κC:3κN cyanide group, with Cu–X bond lengths ranging from 1.881(10) to 1.889(9) Å, and a Cu(3)–$N_{CN}$ bond length of 1.886(10) Å. Cu(1) is in a tetrahedral geometry and is coordinated by two triazole ligands and two $\mu_3$-1,2κC:3κN cyanide groups [Cu(1)–C(3) = 2.221(11) Å], the Cu(1)–C(3) bond being much longer than that to the $\mu_2$-bridging cyanide group. The remaining sites [Cu(4) and Cu(6)] are in linear geometries and are coordinated by two triazole ligands with N–Cu–N bond angles of 178.1(4)° and 176.7(4)°, respectively.

The $\{Cu_2N_4\}$ ring formed by atoms Cu(3) and Cu(5) [or Cu(1) and Cu(2)] and the 1- and 2-nitrogen donors of the trz ligands is nonplanar, and the dihedral angle between the Cu(3)Cu(5)N(6)N(7) and Cu(3)Cu(5)N(6B)N(7B) moieties is 20.85(12)°. Cu(3) and Cu(5) are bridged by two trz ligands with a Cu···Cu separation of 3.5316(16) Å, and these ligands bond through their $N^4$ sites to Cu(4) to form a two-coordinate linear geometry, which means that the deprotonated triazole binds in a $\mu_3$-bridging mode to link the copper

ions into linear chains along the *b* axis, with Cu(4), Cu(3), and Cu(5) in one chain and Cu(6), Cu(2), and Cu(1) in the other. In addition, the cyanide groups not only act as $\mu_2$-bridges to link these chains into a wave-like layer structure but also as $\mu_3$-bridges to link Cu(1) and Cu(6) from two different layers together to form an unusual bilayer motif (Figure 4a), which exhibits large channels with dimensions of approximately $11.69 \times 13$ Å$^2$ along the *b* axis. These bilayers pass through each other to generate the interpenetrating 2D network (Figure 4b). In addition, there are π–π stacking interactions between adjacent aromatic rings of triazole ligands with a separation of about 3.299 Å.

Although several types of double-layered architectures have been reported by the assembly of T-shaped or rectangular building blocks,[18–20] this ring-shaped network, to the best of our knowledge, is unprecedented. A view along the *b* axis shows that the actual crystal structure of **3** is a twofold interpenetrating 2D supramolecular framework (Figure S1). This is consistent with the fact that crystal structures with such large cavities are stabilized either by inclusion of suitable guests or by interpenetrating lattices.[21]

### *[Cu$_6$(CN)$_6$(dmtrz)$_3$]$_n$ (4)*

The 3D network of compound **4** is made up of two parts: one is a 2D rectangular grid layer and the other is a $\{Cu_2(CN)_2(dmtrz)_2\}$ building block. As shown in Figure 5, the crystal structure has six crystallographically independent Cu atoms bridged by cyanide groups and dmtrz ligands. The copper atoms adopt two kinds of coordination modes, namely three- and four-coordination. Cu(2), Cu(3), Cu(6), and Cu(1) are in distorted trigonal geometries, of

which the former three are three-coordinated by two dmtrz ligands [Cu–$N_{dmtrz}$ = 1.967(3)–2.014(3) Å] and one $\mu_2$-bridging cyanide group, with Cu–X bond lengths ranging from 1.888(4) to 1.895(4) Å, while Cu1 is coordinated by three cyanide groups, two of the being in $\mu_2$-bridging modes [Cu–X = 1.899(4)–1.992(4) Å] and the other in a $\mu_3$-bridging mode [Cu(1)–N(14) = 1.896(3) Å]. Cu(4) and Cu(5) are both in tetrahedral geometries and are coordinated to four cyanide groups. However, the coordination environments of these two copper atoms are different as Cu(4) is coordinated by two $\mu_3$-bridging [Cu(4)–C(20) = 2.055(4), Cu(4)–C(20A) = 2.142(4) Å] and two $\mu_2$-bridging cyanide groups [Cu(4)–X = 1.967(3)–2.007(3) Å], while Cu(5) is coordinated by three $\mu_3$-bridging and one $\mu_2$-bridging cyanide groups.

In the $\{Cu_2(CN)_2(dmtrz)_2\}$ building block (Figure 6a), the $\{Cu_2N_4\}$ ring formed by the *endo* Cu atoms and the 1- and 2-nitrogen donors of the dmtrz ligands is almost planar, with a dihedral angle between the Cu(2)Cu(3)N(5)N(6) and Cu(2)Cu(3)N(1)N(2) planes of 5.23(7)°. The adjacent Cu(2)Cu(3)N(5)N(6)N(1)N(2) and Cu(6)Cu(6A)N(9)N(10)N(9A)N(10A) ring planes in this building block are nearly parallel, with a dihedral angle of 3.519°.

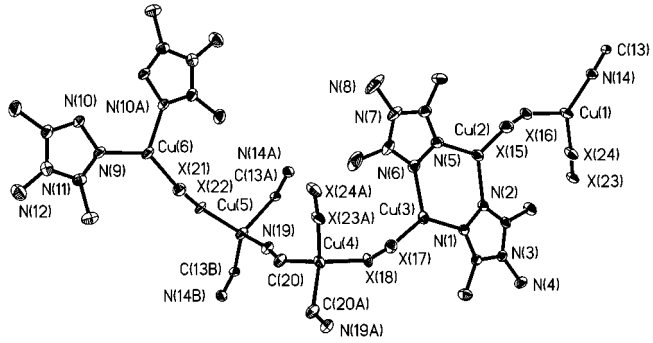

Figure 5. ORTEP representation of the polymeric structure of **4**, showing the coordination environments of the Cu centers (30% probability thermal ellipsoids; hydrogen atoms have been omitted for clarity). Atoms from the disordered CN bridging groups are labeled as X.

The structure consists of 2D rectangular grid layers (Figure 6b), parallel to the *ab* plane, constructed by six-mem-

bered nonplanar centrosymmetric rings of metal atoms in which the metal centers are bridged by cyanide groups. These rings all adopt a chair conformation for the Cu4–Cu1–Cu5–Cu4′–Cu1′–Cu5′ unit, with a ring size of $8.9 \times 8.0$ Å$^2$. The strong Cu···Cu interaction, with a separation of 2.442(8) Å, is double-bridged by two cyanide groups. Although the shortest known $Cu^I$···$Cu^I$ separation is 2.412(1) Å,[22] the Cu···Cu distance in the present compound is notably shorter than those found in other $Cu^I$ compounds[23] that show strong Cu···Cu interactions.

The parallel 2D rectangular grid layers are linked by $\{Cu_2(CN)_2(dmtrz)_2\}$ building blocks to form a 3D framework (Figure 6c and Figure S2); π–π stacking interactions are present between adjacent $\{CuN_4\}$ planes in compound **4**, with a plane–plane separation of about 3.327 Å and a centroid–centroid distance of 3.407 Å.

### *[Cu$_2$(CN)(5-metta)]$_n$ (5)*

The structure of **5** is a 3D supramolecular framework composed of X-shaped one-dimensional chains. As shown in Figure 7, the structure consists of two crystallographically independent Cu atoms that adopt two kinds of coordination modes, namely three- and four-coordination. Cu(1) trigonally coordinates to two N atoms from different 5-metta ligands and one N atom from a $\mu_3$-bridging cyanide group, while Cu(2) is tetrahedrally coordinated by two N atoms from two 5-metta ligands and two C atoms from different $\mu_3$-bridging cyanide groups. The X-shaped one-dimensional chains are formed by copper atoms bridged by 5-metta ligands in a $\mu_4$-tetrazolyl mode with a Cu2···Cu2B

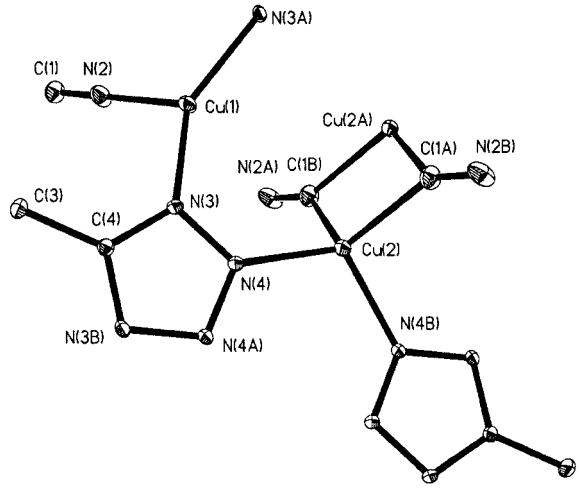

Figure 7. ORTEP representation of the polymeric structure of **5**, showing the coordination environments of the Cu centers (30% probability thermal ellipsoids; hydrogen atoms have been omitted for clarity). Atoms from the disordered CN bridging groups are labeled as X.

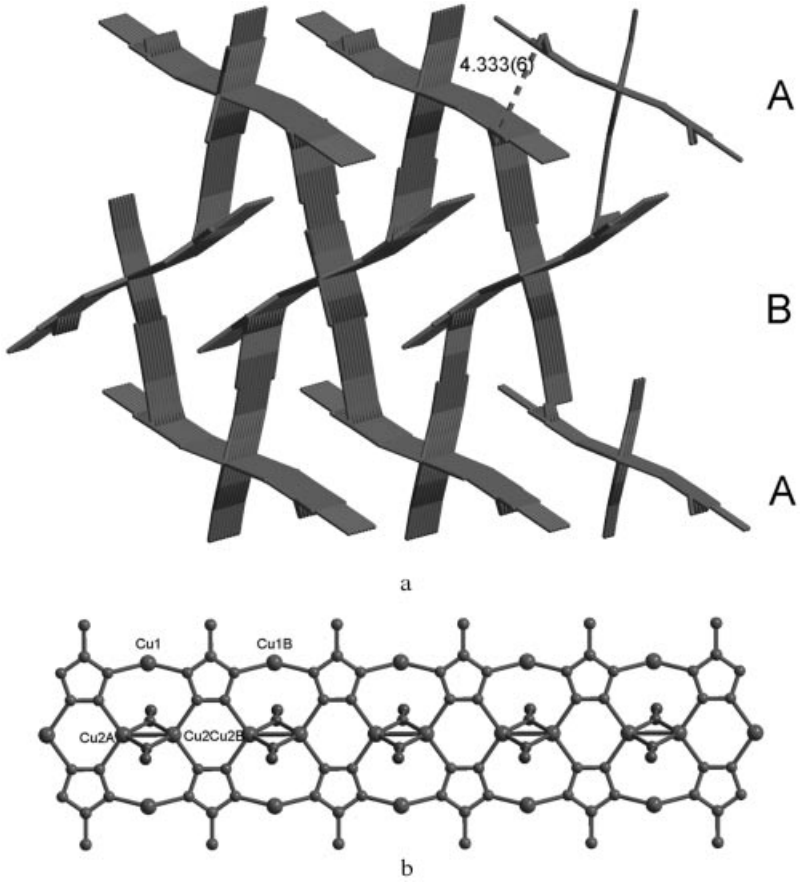

Figure 8. (a) 3D structure constructed by the X-shaped one-dimensional chains. (b) One-dimensional chain bridged by 5-metta ligands and cyanide groups [Cu2···Cu2A (A: $x + 1$, $y + 1$, $z$) = 2.347(1) Å].

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(B: $x$, $y$, $-z + 1$) distance of 3.586(1) Å and a Cu1···Cu1B (B: $x$, $y$, $-z + 1$) distance of 5.933(7) Å and two cyanide groups doubly bridging Cu2···Cu2A (A: $-x + 1$, $-y + 1$, $-z$) with a distance of 2.347(1) Å. Rare examples with such short values have been found for other $Cu^{I}$ compounds.[24] The adjacent chains are parallel to each other in the same layer, with a Cu···Cu distance of 4.333(6) Å, while they are linked by a cyanide group between adjacent layers (Figure 8). These X-shaped chains connect to each other in an ABAB arrangement to generate an interesting 3D network (Figure S3); π–π stacking interactions between adjacent aromatic rings of tetrazole also exist in compound **5**, with a plane–plane separation of about 3.370 Å.

### *[Cu$_2$(CN)(5-phtta)]$_n$ (6)*

The structure of **6** is a 3D network (Figure 9). There is one crystallographically independent $Cu^{I}$ center, which adopts three-coordination in a distorted trigonal geometry, coordinated by two $\mu_4$-5-phtta ligands and one $\mu_2$-cyanide group [$N_{phtta}$–Cu(1) = 1.966(2)–2.0867(18), X–Cu(1) = 1.876(2) Å; N(X)–Cu(1)–N(X) = 102.88(7)–140.47(9)°]. The 5-phtta ligands bind in a $\mu_4$-tetrazolyl mode to bridge four copper atoms to form a one-dimensional chain with a Cu···Cu separation of 3.512(2) and 3.794(2) Å along the $c$ axis (Figure 10a). Each chain is bridged by a cyanide group to form a square-grid structure that exhibits large channels with approximate dimensions of 8.472 × 9.259 Å$^2$, although the effective pore size is partly reduced by the phenyl groups of the 5-phtta ligands Furthermore, these one-dimensional chains are linked to each other by cyanide groups to form the 3D framework (Figure 10b and Figure S4).

### *{[Cu$_6$(CN)$_6$(dmtrz)]$_2$[Cu$_2$(CN)$_2$(dmtrz)$_2$]}$_n$ (7)*

The crystal structure of **7** is comprised of two distinct and crystallographically independent polymeric motifs packed together to form a 3D architecture, which comprises interesting double helical host tubes filled by 1D metal-organic polymeric chains as guests, i.e. {[$Cu_6(CN)_6$(dmtrz)]$_n$}$_2$ (**A**) and [$Cu_2(CN)_2$(dmtrz)$_2$]$_n$ (**B**).

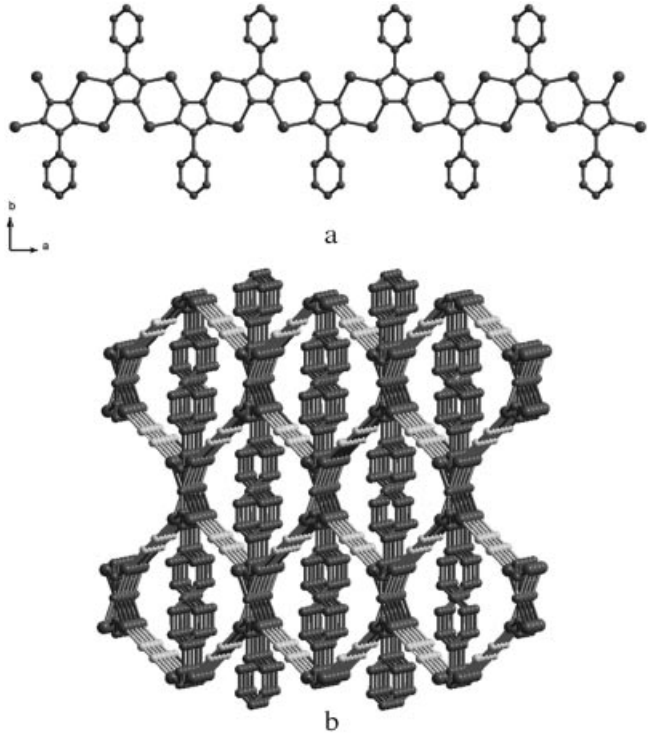

Figure 10. (a) One-dimensional chain constructed by 5-phtta ligands. (b) 3D structure of compound **6**.

The crystal structure has six crystallographically independent Cu atoms bridged by cyanide groups and a dmtrz ligand in polymer **A** (Figure 11). The copper atoms adopt two kinds of coordination modes, namely two- and three-coordination. Cu4, Cu5, and Cu6 are in linear geometries, coordinated by two $\mu_2$-bridging cyanide groups [Cu–X = 1.839(4)–1.866(4) Å; X–Cu–X = 166.3(2)–170.4(2)°], while Cu7 and Cu8 are in distorted trigonal geometries and are coordinated by three $\mu_2$-bridging cyanide groups [Cu–X = 1.895(4)–1.993(4) Å; X–Cu–X = 111.21(18)–133.42(18)°], while Cu3 is also in a distorted trigonal geometry and is

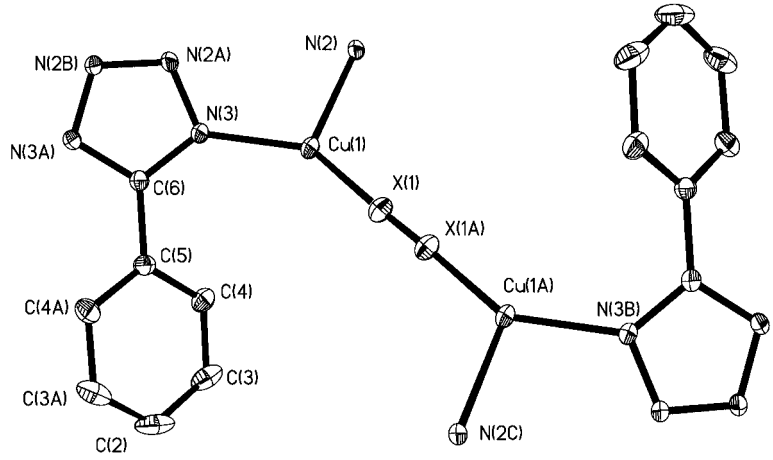

Figure 9. ORTEP representation of the polymeric structure of **6**, showing the coordination environments of the Cu centers (30% probability thermal ellipsoids; hydrogen atoms have been omitted for clarity). Atoms from the disordered CN bridging groups are labeled as X.

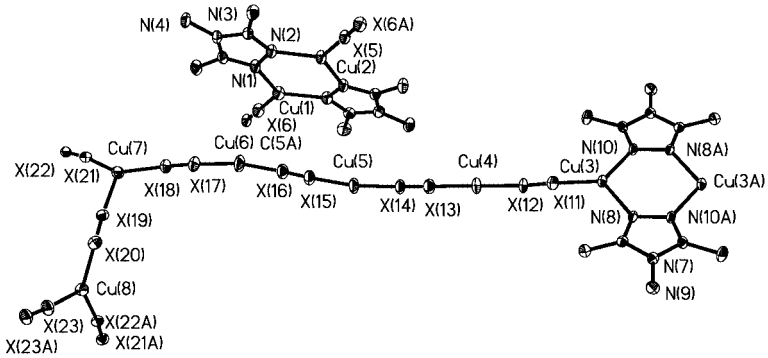

Figure 11. ORTEP representation of the polymeric structure of **7**, showing the coordination environments of the Cu centers (30% probability thermal ellipsoids; hydrogen atoms have been omitted for clarity). Atoms from the disordered CN bridging groups are labeled as X.

coordinated by two dmtrz ligands [Cu3–$N_{dmtrz}$ = 1.967(3)–2.014(3) Å] and one $\mu_2$-bridging cyanide group [Cu3–X11 = 1.886(4) Å] The host polymer **A** consists of two kinds of helical chains, namely mode I and mode II (Figure 12a). Six copper atoms bridged by six cyanide ions form a honeycomb-shaped helical chain (mode I) when viewed along the *b* axis. The unclosed Cu–CN linkage in this structure gives rise to two types of helices with opposite chiralities (Figure S5). The left- and right-handed helices are coupled with each other to form helical tubes of approximately $4.99 \times 5.00$ Å$^2$ with opposite chirality (calculated from opposite metal ion centers of the hexagon; Figure 12b). The helical chain along the $2_1$ screw axis has a long pitch of 12.898(1) Å (Figure 13a). The helical chain of mode II is composed of 22 copper atoms bridged by 20 cyanide ions and four dmtrz ligands to form a distorted hexagon. To the best of our knowledge, this is the first compound constructed from such a long chain of cyanide-bridged copper atoms. The left- and right-handed helical chains of mode II form helical channels of $42.26 \times 4.99$ Å$^2$ with opposite chirality (calculated from the opposite metal ions of the hexagon). The long pitch of the helical chain along the $2_1$ screw axis is 59.985(6) Å (Figure 13b). Two chemically independent polymers **A** interweave to form a 3D architecture with double-stranded helical channels along two spiral directions (Figure S6).

There are two crystallographically independent Cu atoms bridged by cyanide groups and dmtrz ligand in polymer **B**

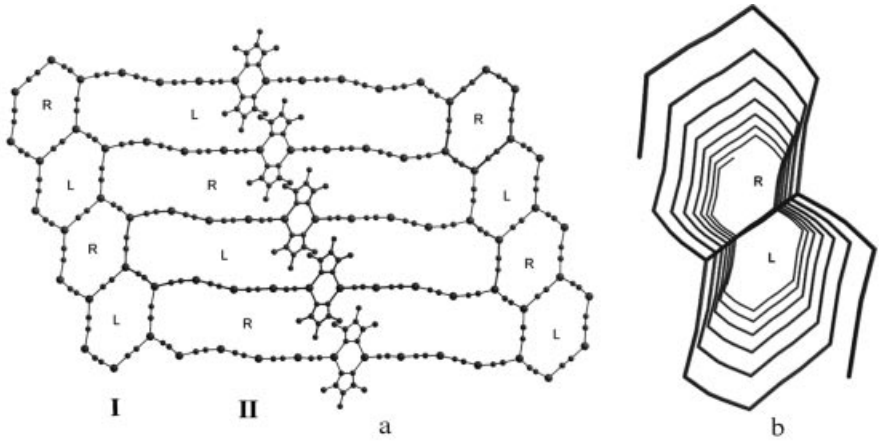

Figure 12. (a) Two kinds of helical chains (modes I and II) in polymer **A**. (b) Right- and the left-handed helical tubes of mode I.

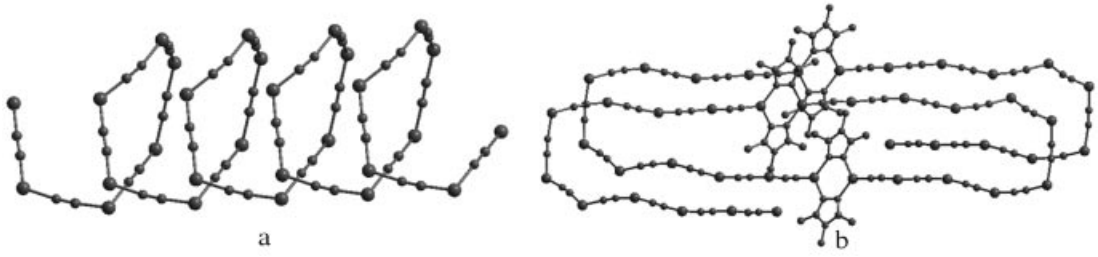

Figure 13. (a) Structure of a helical chain of mode I with a pitch of 12.898(1) Å running along the screw axis. (b) Structure of a helical chain of mode II with a pitch of 59.985(6) Å running along the screw axis.

(Figure 14). Cu1 and Cu2 are in distorted trigonal geometries and are coordinated by two dmtrz ligands [Cu–$N_{dmtrz}$ = 1.967(3)–2.014(3) Å] and one $\mu_2$-bridging cyanide group [Cu–X = 1.885(5)–1.897(6) Å], with Cu···Cu separations of 3.652(1) Å. These building blocks are linked further by cyanide ions to form cable-like linear chains. The polymers **B** are present in the helical channels with opposite chirality constructed by helical chains of mode II. The guest polymers play an important role in the formation of double-stranded helical channels through specific host–guest interactions (Figure 15).

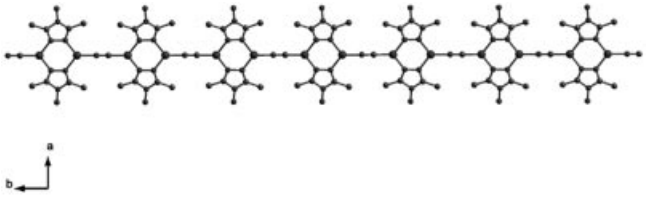

Figure 14. One-dimensional chain of polymer **B**.

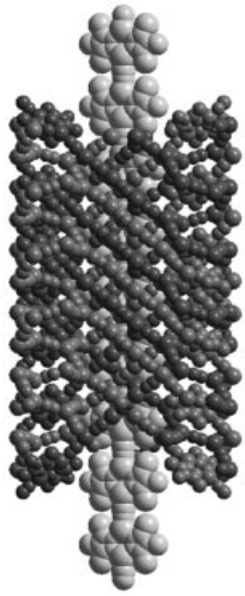

Figure 15. One-dimensional chain of polymer **B** filled in the mode II helical channel of polymer **A**.

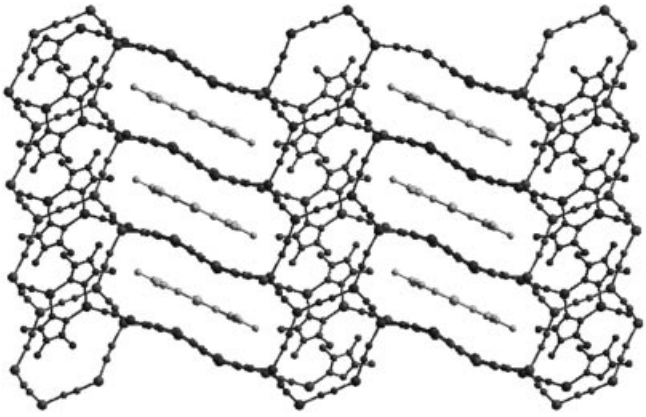

Figure 16. 3D + 1D structure of compound **7**, with the 1D polymer **B** filled in the two independent helical 3D polymers **A**.

Two independent helical substructures of polymer **A** $\{[Cu_6(CN)_6(dmtrz)]_n\}$ interweave into a 3D network with double-stranded helical channels that host 1D linear polymers **B** $\{[Cu_2(CN)_2(dmtrz)_2]_n\}$ to form a novel 3D supramolecular architecture (Figure 16).

This compound is interesting in that it contains two supramolecular isomers in the same crystal, infinite double helices with large channels in the spiral direction, and two kinds of helical channels with opposite chirality constructed by helical chains I and II in the same polymer.

### Summary of the Structures

A series of compounds of a new copper cyanide/organoamine family have been synthesized by a hydrothermal method and structurally characterized. Compounds **1** and **2** contain a one-dimensional network. In contrast to the two one-dimensional chains mentioned above, compound **1** does not contain side-arms but has only N-heterocyclic ligands directly bound to the parent chains, whereas compound **2** has side arms, which represent an extra part with an additional {Cu(CN)} subunit. The cyanide groups only adopt $\mu_2$-bridging modes in these compounds.

The 2D compound **3**, in which triazole ligands and cyanide groups all act as bridging ligands to link the copper atoms into a 2D structure, is obtained with the $\mu_3$-bridging triazole ligand. This structure can be compared with that of **4**, which contains $\mu_2$-dmtrz ligands instead of $\mu_3$-triazole ligands, and therefore contains structurally different dimensionalities. The steric demands of the bulky substituents on the 3-, 4-, and 5-positions may be the cause of the change of coordination number around the copper atom. It has previously been pointed out that the use of triazole derivatives gives interesting coordination compounds.[5]

Compounds **5** and **6**, in which the cyanide groups exhibit two different coordination modes in a 3D structure, are obtained with the $\mu_4$-bridging tetrazole ligand. In the structures of compounds **5** and **6**, which contain the polycyclic N-heterocyclic ligands 5-metta and 5-phtta, respectively, all the ligands are $\mu_4$-bridging and link four copper atoms. Steric effects might be the major factors controlling the structures of these compounds, although the different coordination modes of the cyanide groups also affect the structural framework.

Although they contain the same ligand, two different structures are present in compounds **4** and **7**. One is a 3D network and the other is a 3D + 1D network. It can be seen that the different arrangement of the cyanide groups results in different dimensionalities. In compound **7**, all the cyanide groups adopt a $\mu_2$-bridging coordination mode, while $\mu_2$-bridging and $\mu_3$-bridging modes are found in compound **4**. The versatility of the connectivity motifs linking the copper atoms therefore provides a rich structural chemistry.

### Photoluminescent Properties

It is well known that numerous mono- and polynuclear $Cu^I$ compounds show excellent luminescence properties.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Metal-to-ligand charge-transfer is the most common assignment of the lowest electronic excited state, although copper-centered emission, ligand-centered emission, and interligand charge-transfer are also possible.[25] We have studied the luminescence properties of compounds **1**–**7** (Figure 17). The emission spectra have a maximum at 523, 622, 508, 589, 505, and 481 nm, with an excitation maximum at 307, 348, 345, 316, 352, and 352 nm for **1**, **2**, **3**, **4**, **6**, and **7**, respectively. The emission may be tentatively assigned to a metal-to-ligand charge transfer (MLCT: Cu→CN) because the oxidation state of the copper atoms bridged by cyanide ions in these compounds is +1 and this is also consistent with the results of the IR spectra and is similar to the situation in other cyanide complexes.

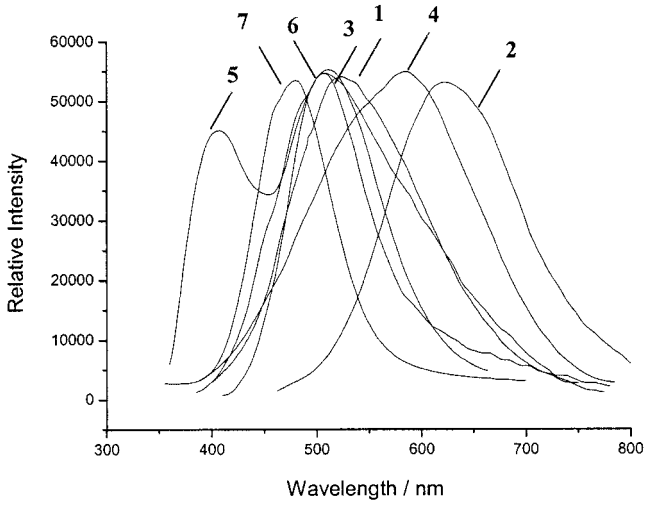

Figure 17. Emission spectra of compounds **1**–**7** measured in the solid state at room temperature.

The emission spectrum of compound **5** has a low-energy transition at around 408 nm and a high-energy one at around 502 nm, with an excitation maximum at 338 nm. The high-energy transition can be assigned as metal-to-ligand transfer (MLCT: Cu→CN), whereas the low-energy transition may be attributed to intraligand (π–π*) fluorescence in the 5-metta ligands, which is in reasonable agreement with literature examples.[26–28]

### IR Spectra

The IR bands corresponding to the CN stretching vibrations for compounds **1**–**7** appear in the range 2080–2158 $cm^{-1}$, which is typical for bridging cyanide groups and higher than that of terminal cyanide ions (approx. 2050 $cm^{-1}$).[29] For compounds **1**, **5**, and **6** there is only one $\nu$(CN) absorption, thus indicating the existence of one type of cyanide group in the crystal lattice, while there are two absorptions in compounds **2**–**4** and **7**, thus indicating the existence of two types of cyanide groups. Although the cyanide groups are only in $\mu_2$-bridging modes in compounds **2** and **7**, the reason for the two absorptions might be the different distances of the $Cu^I$–C/N bond as the coordination number around copper(I) atoms increases. For cyanide-bridged $Cu^I$ compounds, $Cu^I$–C/N distances are found to increase with coordination number around the copper(I) atoms. For instance, the $Cu^I$–C/N distances range from 1.82–1.86 Å for nearly linear two-coordinate systems whereas they increase to 1.92–1.98 Å in three-coordinate systems; $\nu$(CN) increases as the $Cu^I$–CN distances decreases. This trend has also been observed for other compounds.[30,31]

## Conclusions

We have obtained seven new copper cyanide/N-heterocycle compounds with a variety of one-, two-, three-, and one/three-dimensional frameworks by a hydrothermal method. We have found that organic ligands with specific geometric requirements affect the structure of these compounds. Triazole and tetrazole ligands bridge the copper centers to propagate a variety of structural styles that form multi-dimensional networks, while pyrazole and imidazole serve as terminal ligands that restrict the spatial extension of the structure. Other factors, such as the subtle interplay of metal coordination preferences, ligand type, spatial extension, and steric constraints, also play important roles in the formation of novel multidimensional open framework materials. The successful isolation of seven compounds demonstrates that it is possible to apply $K_3Fe(CN)_6$ as a precursor and other N-heterocyclic ligands to prepare coordination compounds with various structures under hydrothermal conditions. Some compounds display strong fluorescence emissions at different wavelengths, and these might be used as new emitting materials. The structure–function relationships of such components will begin to emerge and will provide further guidelines for synthetic methodologies.

## Experimental Section

**General Remarks:** All syntheses were performed in poly(tetrafluoroethylene)-lined stainless steel autoclaves under autogenous pressure. Reagents were purchased commercially and were used without further purification. Elemental analyses for C and H were performed with an EA1110 CHNS-0 CE elemental analyzer. IR spectra (KBr pellets) were recorded with a Nicolet Magna 750FT-IR spectrometer. Fluorescence data were collected with an Edinburgh FL-FS920 TCSPC system.

**General Method for the Preparation of Compounds 1–6:** A mixture of CuCN (0.27 g, 3 mmol), $K_3Fe(CN)_6$ (0.32 g, 1 mmol), and the corresponding N-heterocyclic ligand (1 mmol; Scheme 1) in 15 mL of $H_2O$ was stirred at room temperature for 20 min, then the mixture was transferred into a 25-mL Teflon-lined stainless steel vessel and the mixture was heated at 180 °C under autogenous pressure for 3 d. After the reaction mixture had slowly cooled to room temperature, suitable crystals for X-ray diffraction were produced, which were collected by filtration and washed with distilled water and dried in air.

**X-ray Crystallographic Study:** Suitable single crystals of the compounds were carefully selected and glued to thin glass fibers with epoxy resin. Crystal structure measurements for compounds **1**–**7** were performed with a Rigaku Mercury CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature. The structures were solved by direct methods and refined on $F^2$ with the SHELXL-97 program.[32] For all compounds the $\mu_2$-bridging cyanide group between two $Cu^I$ atoms indicated disorder with respect to the C and N termini; this disorder was treated by adopting 50% C and N occupancies at those sites. The disordered C/N positions are labeled as X. All non-hydrogen atoms were refined with anisotropic displacement parameters, and the hydrogen atoms were treated as riding atoms using the SHELX-97 default parameters. For **2**, the imidazole hydrogen atoms were neither found nor calculated, and the disorder was treated by assuming half occupancies of the C and N atoms. The crystallographic data and details of refinements for compounds **1**–**7** are summarized in Table 1; selected bond lengths and angles are listed in Table 2. CCDC-284132 (**1**), -284133 (**2**), -284136 (**3**), -284137 (**4**), -284138 (**5**), -284139 (**6**), and -284140 (**7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 1. Crystal and structural refinement data for compounds **1**–**7**.

# Transformation of a Tetranuclear Copper(II) Complex Bridged by Sugar Phosphates into Nucleotide-Containing $Cu_4$ Aggregations

**Merii Kato,[a] Ajay Kumar Sah,[a] Tomoaki Tanase,*[a] and Masahiro Mikuriya[b]**

**Keywords:** Coordination chemistry / Copper / Nucleic acids / Carbohydrates / Clusters

Reaction of $[Cu_4(\mu\text{-OH})\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(L)_4(H_2O)_2]X_3$ (**1a**: L = bpy, X = $NO_3$, α-D-Glc-1P = α-D-glucopyranose-1-phosphate) with $Na_2[H_2ATP]$ (ATP = adenosine 5′-triphosphate) readily afforded the ATP-bridged tetranuclear copper(II) complex $[Cu_4(\mu\text{-ATP})_2(bpy)_4]$ (**3**), which was characterized by X-ray crystallographic analysis to consist of four linearly dispersed $\{Cu^{II}(bpy)\}^{2+}$ fragments bridged by two triphosphate groups of the ATP tetravalent anions. The sugar and adenine base parts of the ATP moieties are away from the copper(II) centers, but the structure was stabilized by weak intramolecular π–π stacking between the ATP purine ring and two bpy ligands and intermolecular hydrogen bonding between the adenine base pairs. The variable-temperature magnetic susceptibility of complex **3** exhibited only weak antiferromagnetic couplings between the four linearly dispersed $Cu^{II}$ ions. A similar reaction of **1a** or **2** (L = phen, X = $NO_3$) with $Na_2$[IMP] (IMP = inosine 5′-monophosphate) yielded a different type of tetracopper(II) complex formulated as $[Cu_4\{\mu\text{-(IMP-H)}\}_2(L)_4(H_2O)_4](NO_3)_2$ [L = bpy (**5**), phen (**6**)], in which the IMP moieties are deprotonated at the N-1 position of the nucleobase, forming IMP-H trianions, and four $\{Cu(bpy)(H_2O)\}^{2+}$ fragments are connected through the N-1, N-7, and O-6 atoms of the nucleobase and the monodentate 5′-phosphate group. Reaction of **1b** (L = bpy, X = Cl) with $Na_2$[UMP] (UMP = uridine 5′-monophosphate) resulted in a polymeric compound formulated as $\{[Cu\{\mu\text{-(UMP-H)}\}(bpy)(H_2O)]_2[Cu_4(\mu\text{-OH})\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]Cl\}_n$ (**7**). The N-3 deprotonated $[UMP\text{-}H]^{3-}$ anions connect $\{Cu(bpy)(H_2O)\}^{2+}$ fragments through the N-3 nitrogen atom and the phosphate oxygen atoms to afford $C_2$-helical coordination polymers and the tetracopper(II) complex cations, $[Cu_4(\mu\text{-OH})\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]^{3+}$, are incorporated between the polymer chains with a $C_2$-chiral arrangement of the $\{Cu_4(\mu\text{-OH})(\mu\text{-}PO_4)_2(bpy)_4(H_2O)_2\}$ framework constrained to the *Λ*-form through inter- and intramolecular stacking interactions between the bpy ligands.

## Introduction

The interaction of metal ions with nucleotides and polynucleotides (DNA and RNA) has been extensively studied with a variety of bioinorganic interests, concerning metalloenzymes that promote cleavage of nucleotide phosphate ester bonds, such as DNA polymerase I ($Mg^{2+}$, $Mn^{2+}$, $Zn^{2+}$), P1 nuclease ($Zn^{2+}$), and RNase H ($Mg^{2+}$, $Mn^{2+}$), and so forth,[1] a number of bioenergetic processes coupled with phosphoryl transfer reactions of high-energy nucleotides, usually adenosine triphosphate (ATP), mediated by metal ions ($Mg^{2+}$, $Mn^{2+}$, etc.),[2] and the action of $Pt^{II}$ complexes as anticancer drugs,[3] and so on. To elucidate the nucleotide–metal interaction in such biological processes, a number of binary and ternary transition-metal complexes involving nucleotides have been reported; however, most are mononuclear complexes or polymeric compounds containing mononuclear metal centers.[4] Whereas nucleotides are potentially ambivalent with their multiple metal-binding sites, phosphate groups, hydroxy groups of the sugar moiety, and nitrogen and oxygen atoms of the nucleobase, studies of discrete, multinuclear transition-metal complexes with nucleotides have been extremely scarce thus far. As to the complexes of nucleotides having di- and triphosphate groups, successfully isolated multimetallic complexes are only two examples with dinuclear $Zn^{2+}$ and $Cu^{2+}$ systems, $[Zn_2(\mu\text{-}H_2ATP)_2(bpy)_2]$ (**8**)[5] and $[Cu_2(\mu\text{-}H_2ATP)_2(phen)_2]$ (**9**)[6] (bpy = 2,2′-bipyridyl, phen = 1,10-phenanthroline). The reason for the lack of studies may not only be the difficulty of getting crystalline compounds because of their ambivalent properties, but also the fact that most divalent metal ions catalyze the nonenzymatic hydrolysis of the nucleotide phosphate groups. Notably, one of the best characterized DNA cleavage reactions is that promoted by $[Cu(phen)_2]^{2+}$.[7] Even for thermodynamically stable nucleoside monophosphate esters, a very restricted number of structures are available for multinuclear transition-metal complexes, $[Cu_4\{\mu\text{-(IMP-H)}\}(phen)_4(H_2O)_2](NO_3)_2$ (**6**, IMP-H = N-1 deprotonated inosine 5′-monophosphate),[8] $[\{Ru(\mu\text{-AMP})(\eta^6\text{-}p\text{-}MeC_6H_4iPr)\}_3]$ (AMP = adenosine 5′-monophosphate),[9] $Na_2[Mo_5O_{15}(\mu\text{-HAMP})_2]$,[10] and

$[Mo_2(\eta^5\text{-}C_5H_5)_4(\mu\text{-dGMP})_2]$ (dGMP = 2′-deoxyguanosine 5′-monophosphate),[11] and for dicopper(II) complexes involving the $\{LCu(\mu\text{-}OPO)_2CuL\}$ eight-membered macrocycles with nucleoside 5′-monophosphates [L = bpy, phen, and bis(2-pyridyl)amine].[12]

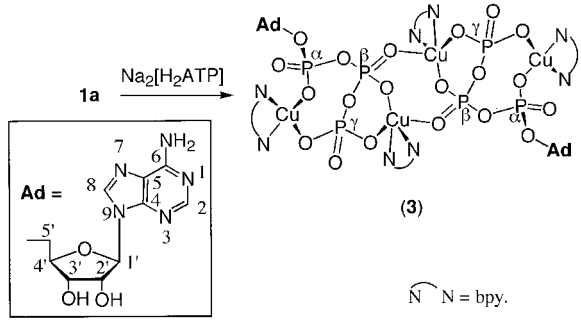
Recently, we synthesized a tetranuclear copper(II) complex bridged by α-D-glucose-1-phosphate (α-D-Glc-1P) dianions, $[Cu_4(\mu\text{-OH})\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(L)_4(H_2O)_2]X_3$ [L = bpy, X = $NO_3$ (**1a**), Cl (**1b**), Br (**1c**); L = phen, X = $NO_3$ (**2**)] (Figure 1a).[13] Complex **2** was structurally characterized as the first example of a transition-metal complex containing free sugar monophosphates, in which four $\{Cu(phen)\}^{2+}$ fragments are held together by a hydroxo bridge and two phosphate groups of α-D-Glc-1P moieties to result in a trapezoidal $Cu^{II}_4$ framework with the D-glucopyranosyl pendants away from the metal centers.[13] In the crystal structure of **2**, two $C_2$-chiral structures with respect to the arrangement of bpy ligands, *Δ* (cation A) and *Λ* (cation B), were observed in a 1:1 ratio; both are coupled to a different orientation of α-D-glucopyranosyl pendants, upward and downward, respectively (Figure 1b, c). In addition, complex **1a** was found to readily undergo a phosphate ester exchange reaction and be transformed into an ATP-stabilized tetracopper(II) complex, $[Cu_4(\mu\text{-ATP})_2(bpy)_4]$ (**3**). These results prompted us to investigate the reactions of **1** and **2** with several nucleotides. In the present study, we wish to report the full details of synthesis and characterization of **3**, together with those for $[Cu_4\{\mu\text{-}(IMP\text{-}H)\}_2(L)_4(H_2O)_4](NO_3)_2$ [L = bpy (**5**), phen (**6**)] and the polymeric compound formulated as $\{[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]_2[Cu_4(\mu\text{-OH})\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]Cl\}_n$ (**7**, UMP-H = N-3 deprotonated uridine 5′-monophosphate). Although the structure of **3** was briefly reported,[13a] the detailed ATP-bridging structure in **3** compared with related compounds and its magnetic property are presented in this report. The present reaction may also provide an efficient route to a series of tetranucler ternary $Cu^{II}$ complexes with IMP moieties and diimine auxiliary ligands. In addition, the structure of **7** revealed an interesting chiral influence transfer from the $C_2$-helical structure of the polymer $\{[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]^-\}_n$ to the $C_2$-chiral structure of the tetranuclear $Cu^{II}$ units involved in **7**, $[Cu_4(\mu\text{-OH})\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]^{3+}$, through inter- and intramolecular bpy–bpy stacking interactions.

Gray bars represent the phen ligands which are arranged in *Δ* and *Λ* configurations with respect to the pseudo-$C_2$ axis for cations **A** and **B**, respectively.

## Results and Discussion

### Synthesis and Structure of $[Cu_4(\mu\text{-ATP})_2(bpy)_4]$ (3)

When the tetranuclear copper(II) complex bridged by a sugar phosphate, $[Cu_4(\mu\text{-OH})\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2](NO_3)_3$ (**1a**), was treated with $Na_2[H_2ATP]$ in a 1:2 ratio at room temperature, a phosphate ester exchange reaction readily proceeded to result in the formation of an ATP-bridged tetracopper(II) complex, $[Cu_4(\mu\text{-ATP})_2(bpy)_4]$ (**3**), in good yield (56%) and crystalline form (Scheme 1).



Scheme 1.

The IR spectrum showed the presence of ATP anions and bpy ligands, and the CD spectral pattern around the d–d transition region for $Cu^{II}$ ions is quite different from that of the starting complex **1a**, indicating an introduction of ATP on the tetranuclear centers. From the mother liquor, a very small amount of a pyrophosphate-bridged dicopper complex, $[Cu_2(\mu\text{-}P_2O_7)(bpy)_2(H_2O)_2]$ (**4**),[14] was obtained, suggesting that hydrolytic cleavage of the triphosphate group occurred to a small extent during the reaction. It should be noted that complex **3** was not obtained just by mixing $Cu(NO_3)_2{\cdot}3H_2O$ with $Na_2[H_2ATP]$ and bpy, demonstrating that the tetranuclear $Cu^{II}$ centers of **1a** provide a suitable platform to stabilize the triphosphate unit of ATP.

The structure of **3** was determined by X-ray crystallographic analysis; an ORTEP plot with the atomic numbering scheme is given in Figure 2a and selected bond lengths and angles are listed in Table 1. The structure consists of four linearly dispersed $\{Cu^{II}(bpy)\}^{2+}$ fragments bridged by two ATP tetravalent anions with interatomic distances of Cu1···Cu2 = 3.444(1) Å, Cu3···Cu4 = 3.4523(8) Å, and Cu2···Cu4 = 5.0613(7) Å. The triphosphate group of ATP exclusively connects two $Cu^{II}$ ions, each ligated by a bpy ligand, to afford the square-planar dicopper(II) unit, $\{Cu_2(\mu\text{-ATP})(bpy)_2\}$. The adenine bases and D-ribofuranosyl parts are away from the metal centers without any inter-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

actions. The two dinuclear fragments are further connected through the axial coordination of β-phosphate oxygen atoms [Cu2–O23 = 2.263(4) Å, Cu4–O10 = 2.247(4) Å], resulting in a characteristic eight-membered puckered ring of the central part (Figure 2b). Whereas metal complexes with ATP could provide useful insights to elucidate bioenergetic processes, characterized examples are still rare and most are mononuclear species[15] and their sodium salts.[16] In particular, those containing multimetallic centers are strictly limited; the only available structures with multinuclear transition-metal ions are the dinuclear complexes $[Zn_2(\mu\text{-}H_2ATP)_2(bpy)_2]$ (**8**)[5] and $[Cu_2(\mu\text{-}H_2ATP)_2(phen)_2]$ (**9**),[6] and with the present complex **3** the first crystal structure of a tetranuclear transition-metal complex with ATP anions is available. Both complexes **8** and **9** possess an essentially identical structure with the triphosphate group chelating to a metal ion through the three α-, β-, and γ-phosphate oxygen atoms in a facial mode, and another γ-phosphate oxygen atom attached to the other metal ion, forming an $[MOPO]_2$ eight-membered macrocycle. The metal centers adopt an $[N_2O_4]$ octahedral geometry. In contrast, in the present structure, the bridging behavior of the ATP triphos-

phate group in the dimeric unit of **3** is remarkably different, as two $Cu^{II}$ ions are held together by the bridges from α- and β-phosphate oxygen atoms [Cu1–O5 = 1.943(4) Å, Cu3–O18 = 1.922(4) Å; Cu2–O9 = 1.982(4) Å, Cu4–O22 = 1.935(4) Å] and from two oxygen atoms of the γ-phosphate unit [Cu1–O11 = 1.951(4) Å, Cu2–O12 = 1.934(4) Å; Cu3–O25 = 1.919(4) Å, Cu4–O24 = 1.921(4) Å], resulting in an unprecedented bridging structure of the ATP triphosphate group (Figure 2b). While the triphosphate backbones are folded, as indicated by the angles P1–P2–P3 = 86.11(4)° and P4–P5–P6 = 88.23(5)°, like complexes **8** and **9**, strain involved in the triphosphate parts of **3** might be released to some extent, in comparison with those in the dimers of **8** and **9** and the mononuclear complexes.[5,6,15] In complex **3**, the eight-membered chelate ring by the α- and γ-phosphate oxygen atoms is fused with the six-membered chelate ring by the β- and γ-oxygen atoms, which should be contrasted with two fused six-membered chelate rings from α-/β- and β-/γ-phosphate oxygen atoms in **8** and **9**. The $\{Cu_4(\mu\text{-}P_3O_{10})_2(bpy)_4\}$ core structure, except the adenosine moieties, possesses a pseudocentrosymmetry; the outer two copper ions (Cu1, Cu3) take an $[N_2O_2]$ square-planar geometry and the inner two (Cu2, Cu4) are in an $[N_2O_3]$ square-pyramidal environment with usual bond lengths and angles. It should be noted that, by using the $HADP^{2-}$ anion, a related tetranuclear copper(II) complex, $[Cu_4(\mu\text{-HADP})_2(NO_3)_2(bpy)_2(H_2O)_2]^{2+}$, was prepared and involves a central eight-membered macrocycle very similar to that of **3** (ADP = adenosine 5′-diphosphate).[17]

The adenosine residues take *anti*–C2′*–endo* conformation without any direct interaction with metal ions, but weak intramolecular π–π stacking between the purine ring and two bpy ligands is observed, as in complexes **8** and **9**.[5,6] The adenine–bpy and bpy–bpy intramolecular stacking interactions in **3** (Figure 2c) enhance its stability and may prevent coordination of the adenosine moieties to the metal centers. In the lattice packing, the N-7 imino and the N-6 amino groups of the adenine base are hydrogen-bonded to the same functional pair of ATP anchoring on the neighboring molecule [N2···N10* = 2.870(6) Å, N5···N7* = 2.980(6) Å; the atoms with * are generated by a symmetry operation of $x - 1$, $y$, $z + 1$], these hydrogen-bonding networks further stabilizing the ATP moieties trapped onto the tetracopper(II) aggregation.

The temperature-dependent magnetic susceptibility data for complex **3** are shown as plots of $\chi_M$ and $\mu_{eff}$ versus $T$ over a range of 4.5–300 K (Figure 3), indicating a very weak antiferromagnetic interaction with $\mu_{eff}$ per $Cu_4$ of 4.24 $\mu_B$ (300 K) and 3.22 $\mu_B$ (4.5 K). The magnetic susceptibility data were fitted by a theoretical expression derived from the van Vleck equation with the $J_1$ and $J_2$ spin-exchange coupling constants [Equation (1)] to afford the best-fitted values of $g = 2.33$, $J_1 = -1.2$ cm$^{-1}$, and $J_2 = -3.1$ cm$^{-1}$. The results clearly demonstrate that antiferromagnetic spin-exchange couplings are not effective in the triphosphate-bridged dimer and interdimers, which was consistent with the structural features involving no effective pathway for metal-to-metal magnetic interactions.

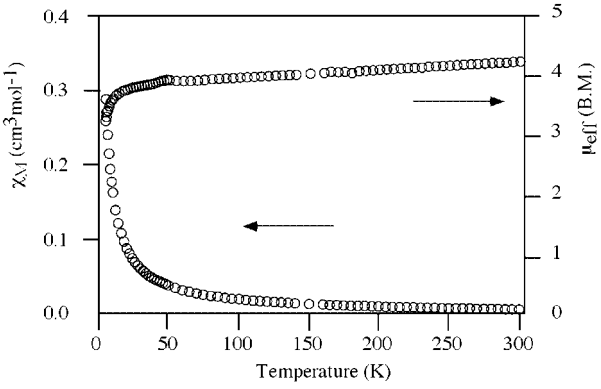

Figure 3. Plots of magnetic susceptibility ($\chi_M$) and $\mu_{eff}$ vs. $T$ for **3**.

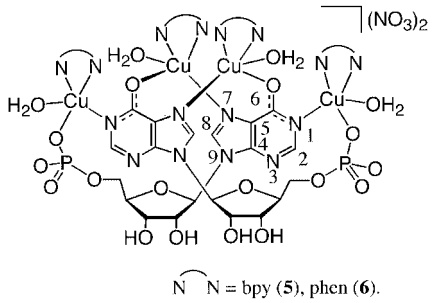
### Synthesis and Structure of $[Cu_4\{\mu\text{-(IMP-H)}\}_2(L)_4(H_2O)_4](NO_3)_2$ [L = bpy (5), phen (6)]

The tetranuclear copper complexes **1a** and **2** readily reacted with $Na_2$[IMP] in water to yield green block-shaped

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

crystals of $[Cu_4\{\mu\text{-}(IMP\text{-}H)\}_2(L)_4(H_2O)_4](NO_3)_2$ [L = bpy (**5**) 64%; phen (**6**) 26%], where the abbreviation of IMP-H represents the N-1 deprotonated inosine 5′-monophosphate trianion (Scheme 2). The IR spectral patterns of **5** and **6** are very similar, indicating the presence of IMP and nitrate anions as well as the diimine ligands. The circular dichroism spectra of **5** and **6** also resemble each other, suggesting incorporation of the nucleotide moieties into the tetranuclear $Cu^{II}$ centers. The ESI mass spectra for aqueous solutions containing **5** and **6** exhibit divalent cationic peaks corresponding to $\{Cu_4(IMP\text{-}H)_2(L)_4\}^{2+}$ at 783.16 for **5** (L = bpy) and 831.14 for **6** (L = phen).



Scheme 2.

A detailed structure of **6** was determined by low-temperature X-ray crystallography using a CCD detector. As the present crystallographic structure for **6**·21.5$H_2O$ is almost identical within the experimental errors to the structure for **6**·14$H_2O$ reported by Bau,[8] except for the number of identified solvent water molecules, we wish to describe the structural features briefly as follows. An ORTEP plot for the complex cation of **6** with the atomic numbering scheme is given in Figure 4 and some selected bond lengths and angles are listed in Table 2. In the complex cation of **6**, four $\{Cu(phen)(H_2O)\}^{2+}$ fragments are held together by two inosine monophosphate anions to result in a pseudo-$C_2$-symmetrical structure [Cu1···Cu2 = 3.431(1) Å, Cu1···Cu3 = 4.232(1) Å, Cu2···Cu4 = 4.254(1) Å]. Each inosine monophosphate moiety is deprotonated at the N-1 position of the nucleobase and bridges four $Cu^{II}$ ions

Table 2. Selected bond lengths [Å] and angles [°] for complex **6**.

through the deprotonated N-1 nitrogen atom [Cu3–N7 = 2.021(5) Å, Cu4–N3 = 2.042(5) Å], the oxygen atom at C-6 position [Cu1–O21 = 1.980(4) Å, Cu2–O11 = 1.955(4) Å], the N-7 nitrogen atom [Cu1–N2 = 2.018(4) Å, Cu2–N6 = 2.018(4) Å], and the monodentate phosphate oxygen atom [Cu3–O16 = 1.943(4) Å, Cu4–O26 = 1.946(4) Å]. There is no interaction between the D-ribose units and the metal centers. All four $Cu^{II}$ ions take an $[N_3O_2]$ square-pyramidal coordination geometry with the water at its apical site (av. Cu–O = 2.205 Å). The structural features are essentially identical to those already reported.[8]

### Transformation of 1b to $[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]_2[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-}D\text{-}Glc\text{-}1P)\}_2(bpy)_4(H_2O)_2]Cl$ (7)

When complex **1b** was treated with uridine 5′-monophosphate disodium salt ($Na_2$[UMP]) in water, blue crystals formulated as $[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]_2[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-}D\text{-}Glc\text{-}1P)\}_2(bpy)_4(H_2O)_2]Cl$ (**7**) were obtained in moderate yield (30%) (Scheme 3), which were characterized by elemental analysis, IR, UV/Vis, and CD spectroscopic data, and X-ray crystallographic analysis. The X-ray crystal structure revealed that compound **7** is composed of a dis-

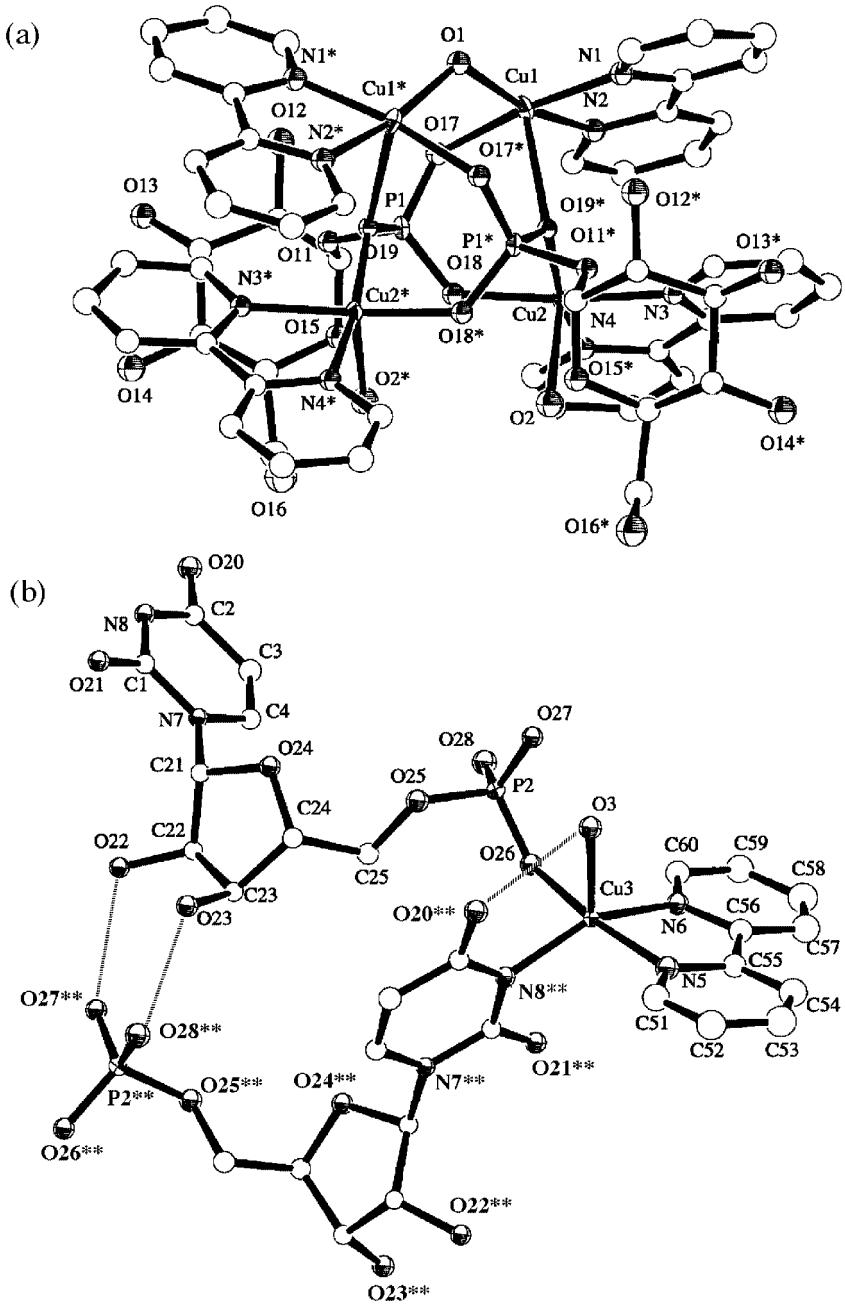

Figure 5. ORTEP diagrams for (a) the tetracopper(II) unit, $[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-}D\text{-}Glc\text{-}1P)\}_2(bpy)_4(H_2O)_2]^{3+}$, and (b) the polymer part, $\{[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]^-\}_n$, of **7**. Hydrogen atoms are omitted for clarity and hydrogen-bonding interactions are indicated by dotted thin lines.

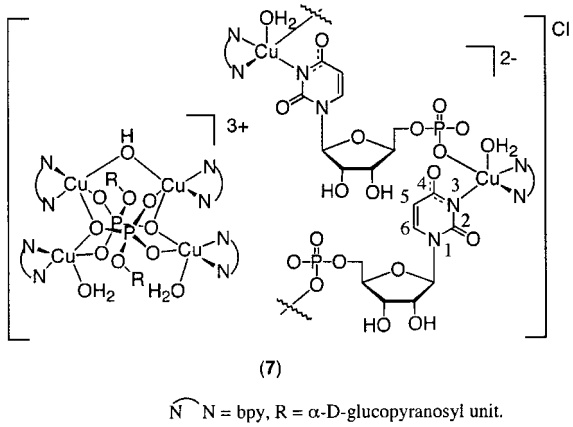

Scheme 3.

crete tetranuclear $[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]^{3+}$ cation (Figure 5a), a coordination polymer with a $[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]^-$ monoanionic unit (Figure 5b), and a chloride anion, in a 1:2:1 ratio. Selected bond lengths and angles are listed in Table 3.

In the polymeric structure of $\{[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]^-\}_n$ (Figure 5b), the uridine 5′-monophosphate moieties are deprotonated at the N-3 position of the nucleobase to form the $[UMP\text{-}H]^{3-}$ trianions, which connect mononuclear $Cu^{II}$ ions through the N-3 deprotonated nitrogen atom [Cu3–N8** = 2.033(8) Å] and the phosphate oxygen atom in a monodentate fashion [Cu3–O26 = 1.917(7) Å]. The Cu3···Cu3** interatomic distance is 12.170(2) Å. The $Cu^{II}$ center is further ligated by two nitrogen atoms of bpy [Cu3–N5 = 2.015(9) Å, Cu3–N6 = 1.997(9) Å] and a water oxygen atom [Cu3–O3 = 2.360(7) Å] to complete a square-pyramidal $[N_3O_2]$ coordination geometry. The Cu atom deviates toward the apical O3 atom by 0.224(4) Å from the basal mean plane, and consequently the geometrical structure is deformed, with a $\tau$ value of 0.31.[18] On the basis of the N–C and O–C bond lengths, the negative charge generated upon N-3 deprotonation should be delocalized in the neighboring O-4 and O-2 oxygen atoms, and notably, the O-4 oxygen atom is hydrogen-bonded to the apical water ligand [O3···O20** = 2.76(1) Å], and the O-2 oxygen atom weakly interacts with the Cu ion at the sixth semi-coordination site [Cu3···O21** = 2.732(7) Å]. These structural features may contribute to fix the uracil base orientation with respect to the copper center. The polymeric structure is further supported by the intrapolymer hydrogen-bonding interaction between the two hydroxy groups of the D-ribofuranosyl unit and the two oxygen atoms of the phosphate group [O22···O27** = 2.68(1) Å, O23···O28** = 2.57(1) Å]. The overall structure of the polymer possesses a $C_2$-helical symmetry along the *b* axis, as illustrated in Figure 6.

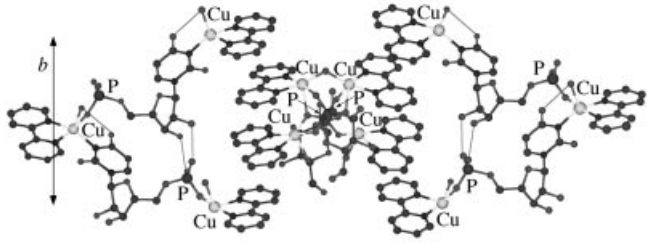

Figure 6. Perspective drawing for a part of the packing structure of **7** viewed vertically to the *b*-axis, showing the stacking interactions between the bpy ligands bound to the polymeric and the tetranuclear $Cu^{II}$ units.

The tetracopper(II) complex cation (Figure 5a), $[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]^{3+}$, has a crystallographically imposed $C_2$ symmetry with the axis passing through the O1 atom and the middle point between the Cu1 and Cu1* atoms, and is comprised of four $Cu^{II}$ ions bridged by a hydroxo and two α-D-glucose-1-phosphate dianions together with auxiliary ligations of four bpy and two water molecules. The tetracopper framework is trapezoidal in which the upper two Cu atoms are connected by μ-OH and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

two μ-1,3-OPO′ bridges, the basal two Cu atoms by two μ-1,3-OPO′ bridges, and the upper and basal Cu pairs by μ-1,1-O and μ-1,3-OPO′ bridges of the phosphate groups [Cu1···Cu1* = 3.342(3) Å, Cu1···Cu2 = 3.480(2) Å, Cu2···Cu2* = 4.366(2) Å]. An intramolecular π–π stacking interaction between the bpy ligands bound to the upper and basal metal ions is observed, as in complex **2** with phen ligands. The structure is essentially similar to those observed in the crystal structure of **2**,[13] except the $C_2$-chiral structures of the $\{Cu_4(\mu\text{-}OH)(\mu\text{-}PO_4)_2(L)_4(H_2O)_2\}$ core depending on the orientation of sugar pendants. Without any chiral molecules other than the sugar phosphate as in **2**, two enantiomeric structures arose (Figure 1b, c) presumably to avoid steric repulsive interaction between the sugar pendants and phen moieties and to increase the π–π stacking stabilization of phen ligands. In the present case of **7**, the observed $C_2$ configuration is *Λ* with downward orientation of the sugar pendants; the C-6 hydroxymethyl groups of the sugar residues are away from the upper $Cu_2(\mu\text{-}OH)$ unit. Namely, only one $C_2$-chiral structure of the tetracopper complex cation is stabilized through interaction with the coordination polymers containing the chiral biomolecule UMP linkers. As shown in Figure 6, the $\{[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]^-\}_n$ coordination polymers adopt a $C_2$-helical secondary structure along the *b*-axis with a pitch of 11.866(2) Å, and between the polymers, the tetracopper(II) cations are well trapped, with an intermolecular π–π stacking interaction between the bpy ligands and their $C_2$-chiral configuration regulated to be *Λ*. The present structural system could be regarded as an interesting chiral transfer mechanism mediated not by direct hydrophilic interaction between the chiral nucleotide and sugar phosphate, but by amplified hydrophobic stacking interaction between the bpy ligands.

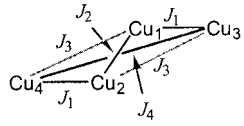
## Conclusions

The present study revealed that tetracopper(II) complexes, $[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(L)_4(H_2O)_2]^{3+}$ [L = bpy (**1**), phen (**2**)], were readily transformed into different types of nucleotide-containing coordination compounds with tetranuclear $Cu^{II}$ aggregations, $[Cu_4(\mu\text{-}ATP)_2(bpy)_4]$ (**3**), $[Cu_4\{\mu\text{-}(IMP\text{-}H)\}_2(L)_4(H_2O)_4]^{2+}$ [L = bpy (**5**), phen (**6**)], and $\{[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]_2[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]Cl\}_n$ (**7**). The structural analyses for the obtained compounds provided molecular-based important information concerning the ternary systems with $Cu^{II}$, nucleotide, and diimine ligand. In complex **3**, the triphosphate group of ATP exclusively assembles tetranuclear $Cu^{II}$ ions in an unprecedented fashion and the adenine nucleobase is protected from metal binding by intramolecular stacking with a bpy moiety and intermolecular hydrogen bonding between the adenine base pairs. In addition, the crystal structure of **7** interestingly demonstrated that the $C_2$-helical structure of the polymer $\{[Cu\{\mu\text{-}(UMP\text{-}H)\}(bpy)(H_2O)]^-\}_n$ regulated the $C_2$-chiral structure of the tetranucler $Cu^{II}$ complex cation, $[Cu_4(\mu\text{-}OH)\{\mu\text{-}(\alpha\text{-D-Glc-1P})\}_2(bpy)_4(H_2O)_2]^{3+}$, through inter- and intramolecular bpy–bpy stacking interactions.

## Experimental Section

**Materials:** All reagents were of the best commercial grade and used as received. Complexes **1a**·$10H_2O$, **1b**·$14H_2O$, and **2**·$6H_2O$ were prepared according to the methods already reported.[13] The following abbreviations are used: adenosine 5′-triphosphate disodium salt, $Na_2[H_2ATP]$; uridine 5′-monophosphate disodium salt, $Na_2[UMP]$; inosine 5′-monophosphate disodium salt, $Na_2[IMP]$.

**Measurements:** Electronic absorption spectra were recorded with a Shimadzu UV-3100 spectrometer and circular dichroism spectra with a Jasco J-720 spectropolarimeter. IR spectra were measured in KBr pellets with a Jasco FTIR 410 spectrometer. The electrospray mass spectra were recorded with an Applied Biosystems model Mariner. Variable-temperature magnetic susceptibility measurements were carried out with an MPMS-5S Quantum Design SQUID magnetometer over a range of 4.5–300 K and the obtained magnetic susceptibility data were corrected for diamagnetism using Pascal's constants. Considering an idealized $C_i$-symmetrical structure of **3**, the four exchange parameters, $J_1$–$J_4$, were introduced to simplify the Heisenberg spin exchange Hamiltonian to $\boldsymbol{H} = -2J_1(\boldsymbol{S}_1\cdot\boldsymbol{S}_3 + \boldsymbol{S}_2\cdot\boldsymbol{S}_4) - 2J_2\boldsymbol{S}_1\cdot\boldsymbol{S}_2 - 2J_3(\boldsymbol{S}_1\cdot\boldsymbol{S}_4 + \boldsymbol{S}_2\cdot\boldsymbol{S}_3) - 2J_4\boldsymbol{S}_3\cdot\boldsymbol{S}_4$, where $J_3$ and $J_4$ were set to zero because of their long interatomic distances.



The magnetic susceptibility data were fitted by a theoretical expression derived from the van Vleck equation with the resulting energy matrix [Equation (1)], in which $A = J_1 + (1/2)J_2$, $B = -J_1 + (1/2)J_2$, $C = -(1/2)J_2 - (J_1^2 + J_2^2)^{1/2}$, $D = -(1/2)J_2 + (J_1^2 + J_2^2)^{1/2}$, and $E = (4J_1^2 + J_2^2 - 2J_1J_2)^{1/2}$. The values of *p* (ratio of paramagnetic impurity) and *Nα* (temperature-independent paramagnetism) were estimated to be 0 and $60\times10^{-6}$ emu mol$^{-1}$ per $Cu^{II}$ ion, respectively.

$$\chi_M = (1-p)\left(\frac{N\mu_B^2g^2}{kT}\right)\frac{10\exp(A/kT)+2\exp(B/kT)+2\exp(C/kT)+2\exp(D/kT)}{5\exp(A/kT)+3\exp(B/kT)+3\exp(C/kT)+3\exp(D/kT)+\exp((-A-E)/kT)+\exp((-A+E)/kT)} + p\left(\frac{N\mu_B^2g^2}{kT}\right)+4N\alpha \quad (1)$$

**Preparation of $[Cu_4(\mu\text{-}ATP)_2(bpy)_4]\cdot15H_2O$ (3·15$H_2O$):** $Na_2[H_2ATP]$ (32 mg, 0.058 mmol) in $CH_3OH$ (3 mL) was added to an aqueous solution (5 mL) of **1a**·$10H_2O$ (50 mg, 0.027 mmol). The reaction mixture was stirred at room temperature for 12 h, and was concentrated under reduced pressure to about 1 mL. Slow concentration of the solution afforded block-shaped blue crystals of $[Cu_4(\mu\text{-}ATP)_2(bpy)_4]\cdot15H_2O$ (**3**·15$H_2O$) in 56% yield (33 mg), which were collected and dried under vacuum. $C_{60}H_{90}Cu_4N_{18}O_{41}P_6$ (2159.50): calcd. UV/Vis ($H_2O$): $\lambda_{max}$ ($\varepsilon$) = 658 ($2.66\times10^2$ $M^{-1}cm^{-1}$) nm. CD ($H_2O$): $\lambda_{max}$ ($\Delta\varepsilon$) = 708 ($-1.86\times10^{-2}$), 601 ($0.58\times10^{-2}$), 465 ($0.24\times10^{-2}$ $M^{-1}cm^{-1}$) nm.

**Crystallographic Studies:** Slow concentration of aqueous solutions afforded X-ray-quality crystals of **3**·20.5$H_2O$, **6**·21.5$H_2O$, and **7**·22$H_2O$, which were quickly coated with Paraton N oil and mounted on a glass fiber at low temperature. Crystal data and experimental conditions are summarized in Table 4. All data were collected at –120 °C with a Rigaku AFC8R/Mercury CCD diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ radiation using a rotating-anode X-ray generator. A total of 2160 oscillation images, covering the whole sphere of $2\theta < 55°$, were collected with exposure rates of 120 (**3**, **6**) and 128 (**7**) s/° by the $\omega$-scan method ($-62° < \omega < 118°$) with $\Delta\omega = 0.25°$. The crystal-to-detector ($70\times70$ mm) distance was set to 60 mm. The data were processed using the Crystal Clear 1.3.5 program (Rigaku/MSC)[19] and corrected for Lorentz polarization and absorption effects. The structures of complexes **3**, **6**, and **7** were solved by direct methods (SIR-92/97 for **3** and **7**; DIRDIF94 Patty for **6**),[20,21] and refined on $F^2$ with full-matrix least-squares techniques with SHELXL-93/97.[22] In the refinement of **3**, all non-hydrogen atoms, except the solvent water oxygen atoms, were refined with anisotropic thermal parameters. The solvent water O atoms were refined isotropically. The carbon- and nitrogen-bound hydrogen atoms were placed in ideal positions, and the hydrogen atoms of the D-ribose hydroxy groups were determined from difference Fourier syntheses (H atom bound to O1 was not determined). All hydrogen atoms were fixed in the refinement. In the refinement of **6**, all non-hydrogen atoms, except the nitrate anions and the solvent water oxygen atoms, were refined with anisotropic thermal parameters. The solvent water O atoms were refined isotropically. The two nitrate anions were disordered and refined with the four-site model at special positions, each possessing 0.5 occupancy. The carbon-bound hydrogen atoms were placed at ideal positions, and the hydrogen atoms of the D-ribose hydroxy groups were determined from difference Fourier syntheses. All hydrogen atoms were fixed in the refinement. In the refinement of **7**, the Cu, Cl, and P atoms were refined anisotropically and other non-hydrogen atoms were refined with isotropic temperature factors. The positions of C–H hydrogen atoms were calculated and

Table 4. Experimental and crystallographic data for **3**·20.5$H_2O$, **6**·21.5$H_2O$, and **7**·22$H_2O$.

were fixed in the refinement. The O–H hydrogen atoms were not determined. The Cl atom is disordered at two positions with each having 0.25 occupancy. The absolute configurations for the structures of **3**, **6**, and **7** were determined by using the chiral carbon centers of the sugar moieties, α-D-glucose and/or D-ribose units, as internal references, which was further confirmed by consistency with Flack parameters. All calculations were carried out with a Pentium PC with the Crystal Structure package 3.6[23] and a Silicon Graphics O2 station with the teXsan crystallographic software package.[24] CCDC-239857 (for **3**), -294065 (for **6**), and -294066 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## COVER PICTURE

**The cover picture shows** the structure and IR spectrum of a novel triple-decker complex $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ obtained by density functional calculations. Similar results on a series of $(C_nH_n)M(B_6X)M(C_nH_n)$ (M = Fe, Ru, Mn, Re; X = B, C, N; $n$ = 5, 6) complexes containing planar hexacoordinate carbon or other nonmetal atoms at the centers of the $B_6X$ middle-deckers were also obtained. Natural orbital analyses indicate that the nonmetal centers X follow the octet rule in these complexes, and effective d−π coordination interactions exist between the partially filled Fe 3d orbitals and the delocalized π orbitals of the three parallel ligands. This work provides strong theoretical evidence to facilitate future experimental characterization of the long-sought planar hexacoordinate carbon atom and expands the structural domain of traditional sandwich-type transition-metal complexes. Details are discussed in the article by S.-D. Li et al. on p. 2567 ff.

# Design of Cyano-Bridged Coordination Polymers Based on Tetrahedral Rhenium Cluster Cyanide Complexes and 3d Transition Metals

**Olga A. Efremova,[a] Yuri V. Mironov,*[a] and Vladimir E. Fedorov[a]**

**Keywords:** Cluster compounds / Cyanides / N ligands / Rhenium / Transition metals

This microreview surveys some novel possibilities in the design of coordination polymers using the tetrahedral rhenium cluster chalcocyanide complexes $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = S, Se, Te) and 3d transition metals. The large number of cyano groups in the cluster complexes $[Re_4Q_4(CN)_{12}]^{4-}$, their ambidentate character and their strong ability to form cyano-bridged structures lead to the formation of a wide variety of coordination polymers with different architectures that depend on the reaction conditions. The diversity of the coordination environment of the transition metals has been used as one of the most important factors to control the dimensionality of the crystal structures of the target compounds.

## 1. Introduction

Tetranuclear cluster complexes are well known for most of the transition metals.[1–4] These compounds contain the $M_4Q_4$ cluster core as the main structural fragment, which can be represented as two interpenetrating $M_4$ and $Q_4$ tetrahedra. In these $M_4Q_4$ cluster cores, the inner $\mu_3$-Q ligands are most often chalcogenide ions. In this paper we will review only those tetrahedral rhenium cluster chalcocyanide complexes that have the stoichiometry $[Re_4Q_4(CN)_{12}]$ (Q = $S^{2-}$, $Se^{2-}$ and $Te^{2-}$) where each rhenium atom is additionally coordinated by three outer-sphere CN ligands. Within the framework of the ion-covalent model the formal oxidation state of rhenium in similar clusters is 4+ (the $d^3$ configuration), therefore there are six covalent metal–metal bonds in the $Re_4$ tetrahedron (two electrons for each edge of the tetrahedron).

Significant progress in the developing chemistry of $Re_4$ cluster compounds was achieved after synthesis of the chalcogenide-halide clusters $[Re_4Q_4(TeX_2)_4X_8]$ (Q = S, Se, Te; X = Cl;[5] Q = Te, X = Br[6]). The tellurium-containing complex $[Re_4Te_4(TeCl_2)_4Cl_8]$ was prepared by the reaction of $ReCl_5$ with elemental tellurium at 350 °C. Complexes with Q = S and Se were synthesised by the reaction of $ReCl_5$ with mixtures of elemental tellurium and sulfur or selenium, respectively, at 400 °C.

*Olga Efremova graduated from the Natural Science Department of the Novosibirsk State University in 2005. Because of her excellent academic record during her education at the University she was awarded several Fellowships. Her diploma work was devoted to the synthesis and study of the structure and properties of coordination polymers based on tetrahedral chalcocyanide rhenium cluster complexes. At present, Olga is working in the group of Prof. Yuri Mironov in the Laboratory of Prof. Fedorov (Nikolaev Institute of Inorganic Chemistry, Russian Academy of Sciences) where she is continuing her experimental studies as a PhD student. Her current research is devoted to the development of different approaches to the design of nanomaterials with different dimensionalities using cluster anionic complexes and 3d or 4f transition metal cations possessing tailored ligand environment as building blocks. She teaches students of the Natural Science Department of NSU.*

*Yuri Mironov graduated from the Natural Science Department of the Novosibirsk State University in 1981 and received his PhD from the Institute of Inorganic Chemistry of the Russian Academy of Sciences in 1990. In 2000 he received his highest scientific degree − Doctor of Chemical Sciences − and habilitated as Professor of Chemistry. He is an experienced researcher in coordination and cluster chemistry. His research interests cover the realm of synthesis, reactivity, structures and properties of cluster halides, chalcogenides and chalcohalides of the early transition metals (V, Nb, Mo, W, Re). Prof. Mironov and his students have synthesised and characterised more than two hundred new cluster compounds and published about a hundred articles. He has been awarded several grants from different foreign foundations, like the Alexander von Humboldt Foundation (with Prof. W. S. Sheldrick, Bochum University, Germany) and the NSF (with Prof. J. A. Ibers, Northwestern University, USA), and has also received a Korean Fellowship (with Prof. S.-J. Kim, Ewha Womans University, Seoul, Korea).*

*Vladimir Fedorov graduated from the Leningrad Institute of Technology and obtained his Dipl. Ing. in 1959. The same year he went as an engineer to the plant of advanced ceramics and composites in Novosibirsk where he spent three years. From 1963 to 1966 he studied inorganic, coordination and solid-state chemistry at the Natural Science Department of the Novosibirsk State University, where he completed his thesis and received his PhD. From 1966 to the present day V. Fedorov has been working at the Nikolaev Institute of Inorganic Chemistry, Russian Academy of Sciences (Novosibirsk). Further research in cluster chemistry led to the award of his highest scientific degree − Doctor of Chemical Sciences − in 1990. He then habilitated the position of Full Professor of Inorganic Chemistry. Currently he is head of the laboratory of synthesis of cluster compounds and materials and a lecturer at the Natural Sciences Department of the Novosibirsk State University, where he teaches cluster chemistry of the transition metals. The main research interests of Prof. Fedorov lie in cluster, coordination and medical chemistry, including the synthesis and design of materials, the study of crystal and electronic structures, and the investigation of different physico-chemical properties of solids and solutions. Prof. Fedorov's studies have resulted in more than 350 scientific publications, two monographs and several patents.*

The $[Re_4Q_4(TeCl_2)_4Cl_8]$ compounds are insoluble both in water and common organic solvents but readily react with various compounds in aqueous solution or organic solvents or even with the solvents themselves upon heating or occasionally at room temperature. All such transformations proceed with the replacement of the outer-sphere ligands ($TeCl_2$ or $Cl^-$) of the cluster complexes, resulting in the formation of compounds with different outer ligands (fluoride, polysulfide, thiocyanate, cyanide, acetamide, DMF etc.; see Scheme 1).[7–12]

The cyanide complexes $[Re_4Q_4(CN)_{12}]^{4-}$ are of particular interest among these compounds. Due to their ambidentate character, the CN groups can serve as bridging ligands to give polymeric compounds of different dimensionalities. Such an approach has been applied for the preparation of coordination polymers based on $Re_6$[13–19] cluster chalcocyanides and very recently was successfully used for $W_6$[20] and $Nb_6$[21–22] cyano complexes. $Re_4$ cluster complexes have 12 CN ligands (three for each Re atom), in contrast to the six CN ligands (one for each Re atom) in $M_6$ cluster complexes. This difference leads to a greater variety of coordination complexes of $Re_4$ chalcocyanides with transition metals. In recent years, we have carried out systematic studies of the synthesis of cyano-bridged coordination polymers based on the tetrahedral rhenium cluster complexes $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = S, Se or Te) and 3d metal complexes. The use of polydentate ligands in the coordination sphere of transition metals offers additional possibilities for controlling the dimensionality of the resulting cyano-bridged compounds.

For the convenience of structure description in cases where two transition metal cations are coordinated by one cluster anion we offer the following labels for the CN ligand couples that take part in binding (Table 1).

One of the important experimental factors for the reactions mentioned below is the reaction medium. The compounds described in this review were obtained either in aqueous solution or in aqueous ammonia solution.

## 2. The Interaction of $[Re_4Q_4(CN)_{12}]^{4-}$ Anions with Aqua Complexes of Transition Metals

The reaction of water solutions of $K_4[Re_4Te_4(CN)_{12}]$ and $CuCl_2$ in a gel based on sodium silicate leads to the cluster complex $[Cu_4(\mu_3\text{-}OH)_4][Re_4(\mu_3\text{-}Te)_4(CN)_{12}]$ (**1**).[23] The structure of this compound contains layers built up from tetranuclear $[Cu_4(\mu_3\text{-}OH)_4]^{4+}$ cations and $[Re_4Te_4(CN)_{12}]^{4-}$ cluster anions (Figure 1). Eight of the twelve $CN^-$ ligands of the cluster anion coordinate copper atoms in the layer; the four remaining $CN^-$ ligands are directed perpendicular to the layer and are bonded to the OH groups of cations from adjacent layers. In the $[Cu_4(\mu_3\text{-}OH)_4]^{4+}$ cation, which is synthesised by a self-assembly reaction, the four copper atoms and four $OH^-$ groups form a cubane-like structure with two short and four long Cu–Cu distances of 2.99 and 3.18 Å, respectively.

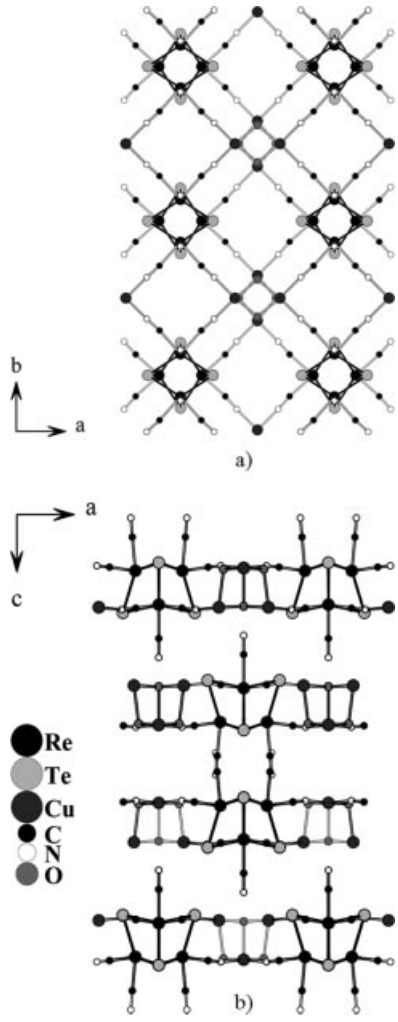

Figure 1. a) The covalent layer in **1** (projection along the *ab* plane). b) The packing of the layers (projection along the *ac* plane). Hydrogen atoms have been omitted for clarity in this figure and others.

If the reaction of $K_4[Re_4Te_4(CN)_{12}]$ and $CuCl_2$ is carried out in 1 M hydrochloric acid solution the three-dimensional cluster complex $[\{Cu(H_2O)_2\}\{Cu(H_2O)_2\}Re_4Te_4(CN)_{12}]$ (**2**) is formed.[11] There are two copper cations with different coordination environments in the structure of this compound. The Cu1 cation is coordinated by four nitrogen atoms of CN groups and by two oxygen atoms of water molecules to form a two-dimensional network in which the cluster units are linked through Re–C≡N–Cu–N≡C–Re bridges, whereas the Cu2 cation is coordinated by two nitrogen atoms of CN groups and two oxygen atoms of water molecules to give a square-planar environment of the Cu2 atoms (Figure 2). The Cu2 cation bridges two-dimensional networks to give a complicated three-dimensional packing.

The ions $Cd^{2+}$ and $Mn^{2+}$ give two related cluster complexes, namely $[\{Cd(H_2O)_2\}\{Cd(H_2O)_4\}Re_4Te_4(CN)_{12}]$ (**3**) and $[\{Mn(H_2O)_2\}\{Mn(H_2O)_4\}Re_4Te_4(CN)_{12}]$ (**4**).[11] They are isostructural to the copper complex **2** although, unlike the Cu2 cation, Cd2 and Mn2 demand an octahedral environment. Such a coordination preference results in disordering of the M2 cations over two crystallographically

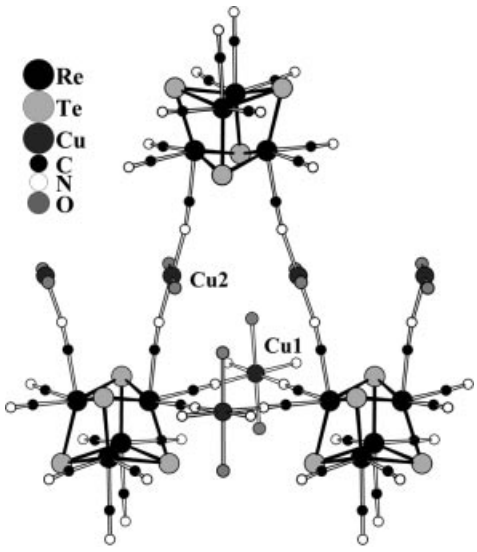

Figure 2. A fragment of the crystal structure of compound **2**.

equivalent positions with equal contributions in complexes **3** and **4**. This cation is coordinated by two nitrogen atoms of CN groups and four oxygen atoms of water molecules. M2–M2 dimers are present in the structure, with two water molecules and a cluster anion coordinated as bridges (Figure 3).

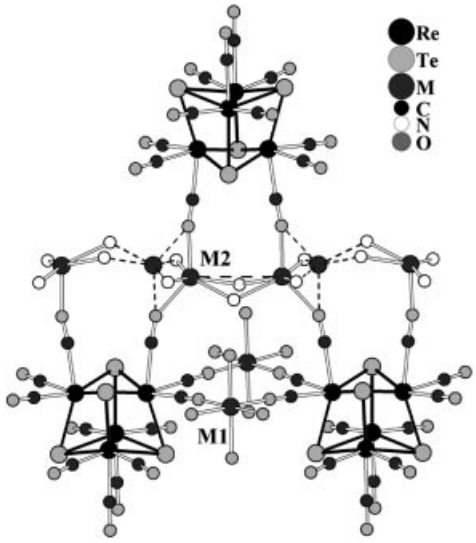

Figure 3. The M(2)···M(2) dimers in the structures of **3** and **4**. The second, disordered positions of M(2) are shown by dashed bond lines.

## 3. The Interaction of $[Re_4Q_4(CN)_{12}]^{4-}$ Anions with Amino Complexes of Transition Metals

The interaction of cluster anions with amino complexes of metal cations such as $Ni^{2+}$, $Cd^{2+}$ and $Cu^{2+}$ gives different products to those obtained with aqua complexes.

The compound $[\{Ni(NH_3)_5\}_2\{Re_4Te_4(CN)_{12}\}]\cdot 3.4H_2O$ (**5**) was prepared from $NiCl_2$ and $K_4[Re_4Te_4(CN)_{12}]$ in aqueous ammonia solution.[24] The molecular structure of this compound contains two $[Ni(NH_3)_5]^{2+}$ cations bonded to one cluster anion through the nitrogen atoms of the *gem*-CN groups. The coordination polyhedron of the Ni atoms is practically a regular octahedron (Figure 4).

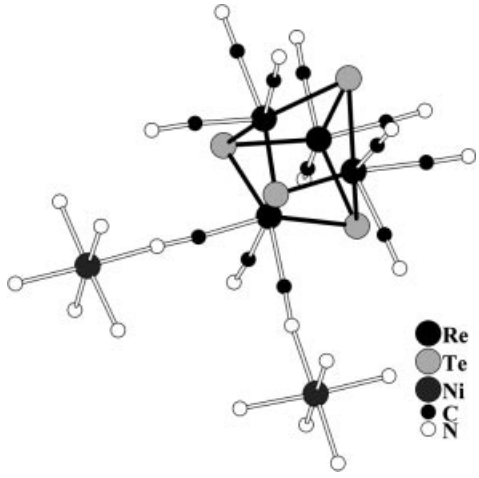

Figure 4. View of the $[\{Ni(NH_3)_5\}_2Re_4Te_4(CN)_{12}]$ molecule in **5**.

The use of $CdSO_4$ instead of $NiCl_2$ leads to the formation of a compound formulated as $[\{Cd(NH_3)_5\}\{Cd(NH_3)_3\}\{Re_4Te_4(CN)_{12}\}]\cdot 4H_2O$ (**6**).[24] This compound contains two types of cations: a terminal $[Cd(NH_3)_5]^{2+}$ cation and a bridging $[Cd(NH_3)_3]^{2+}$ one. Whereas the $[Cd(NH_3)_5]^{2+}$ cations are coordinated by only one cyanide group, the $[Cd(NH_3)_3]^{2+}$ cations are coordinated by three CN groups of different cluster anions to form a chain-like structure (Figure 5).

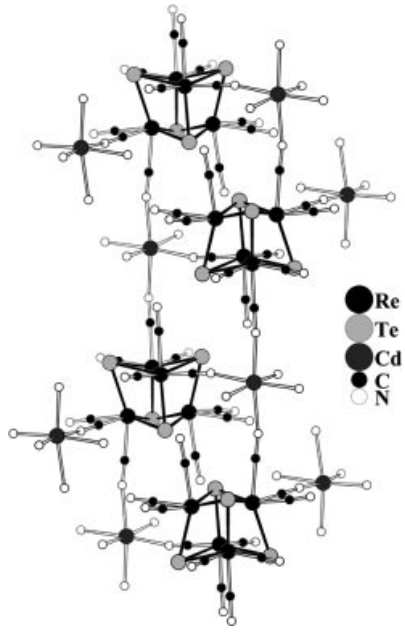

Figure 5. A fragment of the crystal structure of **6**.

The reaction of aqueous $K_4[Re_4Q_4(CN)_{12}]$ solutions with an ammonia solution of $CuCl_2$ give the complexes $[\{Cu(NH_3)_3\}_2\{Re_4Q_4(CN)_{12}\}]\cdot nH_2O$ [Q = S (**7**), Se (**8**)] (Figure 6) and $[\{Cu(NH_3)_3\}_{1.7}\{Cu(NH_3)_4\}_{0.3}Re_4Te_4(CN)_{12}]$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(**9**).[25] In compounds **7** and **8** the $[Re_4Q_4(CN)_{12}]^{4-}$ cluster units are linked by cyanide bridging ligands through $[Cu(NH_3)_3]^{2+}$ to give chains that extend along the *c* axis. In the case of Q = Te these chains have a discrete character because some of the copper atoms are coordinated by four ammonia molecules (Figure 7). These copper cations have a distorted square-pyramidal coordination environment formed by three ammonia molecules and the N atom of the CN ligand in the equatorial plane, and additionally by the N atom of the CN ligand in the apical position.

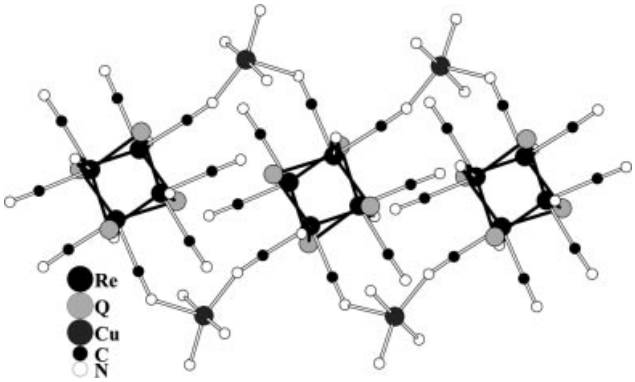

Figure 6. A fragment of the crystal structure of compound **7**.

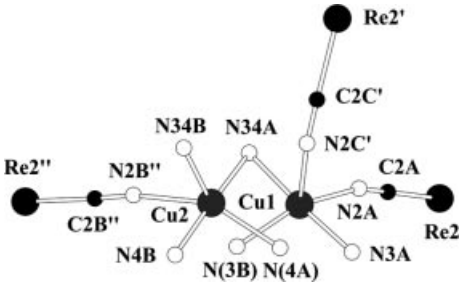

Figure 7. Disordering of the Cu atoms over two positions in the crystal structure of compound **9**.

Compounds **7**–**9** have a one-dimensional topology similar to **6**. However, there are several differences. For instance, the Cd atoms have an octahedral coordination environment whereas the Cu atoms have a square-pyramidal environment, and in **6** only half of the Cd atoms are bridged linking three clusters at once.

The reaction of an aqueous $K_4[Re_4Te_4(CN)_{12}]\cdot 5H_2O$ solution with a $ZnCl_2$ ammonia solution leads to formation of $[\{Zn(H_2O)_2\}\{Zn(H_2O)_4\}Re_4Te_4(CN)_{12}]$ (**10**), which has a structure similar to that of compounds **3** and **4**. Compound **10** dissolves when ammonia is added and can be recrystallised by removing this ammonia.[26]

Thus, the formation of compounds **5**–**9** can be considered as stages in the formation of **2**–**4**. In this scheme, the polymeric complex **10** is the final product.

## 4. The Interaction of $[Re_4Q_4(CN)_{12}]^{4-}$ Anions with Amino Complexes of Transition Metals in the Presence of Polydentate N-Donor Ligands

One of the most convenient and effective ways to change the dimensionality of structures is by using polydentate ligands, which can effectively block coordination sites around the transition metal cations and thus control the number of coordination sites available for binding with CN groups. Partial or complete blocking of coordination sites allows the directional regulation of structure dimensionality. A wide assortment of polydentate ligands having N-donor atoms, such as ethylenediamine (en), diethylenetriamine (dien), triethylenetetraamine (trien) and *threo*-tetraaminobutane (*threo*-tab), have been used for such a purpose. These ligands can block two, three or four coordination sites around the transition metal, and also can behave as bridges.

### 4.1. Complexes with Ethylenediamine

The interaction of $M^{2+}$ transition metal cations having different coordination numbers [$n$ = 6 (Ni, Zn, Cu) and 5 (Cu)] with bidentate ethylenediamine in water or aqueous ammonia solution leads to the formation of complexes with different M/en ratios. This can be described by the stepwise complex formation shown in Equations (1), (2) and (3) (L = $H_2O$, $NH_3$).

$$[ML_n]^{2+} + en \rightarrow [ML_{n-2}(en)]^{2+} + 2L \quad (1)$$

$$[ML_{n-2}(en)]^{2+} + en \rightarrow [ML_{n-4}(en)_2]^{2+} + 2L \quad (2)$$

$$[ML_{n-4}(en)_2]^{2+} + en \rightarrow [M(en)_3]^{2+} + 2L \quad (3)$$

Generally, all cationic forms coexist simultaneously in solution and can interact with cluster anions to give compounds of different stoichiometry. The predominance of one form or another depends on the ligand concentration, i.e. the M/en ratio in solution, and the stability constants of the corresponding complexes; the form that reacts with the cluster anion to give the solid depends on these factors and its solubility too.

#### *4.1.1. Compounds Containing $[Ml_{n-2}(en)]^{2+}$*

The interaction of $K_4[Re_4Se_4(CN)_{12}]$ with an equimolar mixture of $CuCl_2$ and en in aqueous ammonia solution leads to the formation of $[\{Cu(en)\}\{Cu(NH_3)(en)\}Re_4Se_4(CN)_{12}]\cdot 5H_2O$ (**11**)[27] in which the chemical form $[CuL_3(en)]^{2+}$ (L = CN and $NH_3$; $n$ = 5) is observed. There are two copper cations in the structure of this compound, both of which have a distorted square-pyramidal environment but different coordination compositions. The Cu1 cation is coordinated by two amino groups of an en molecule and three nitrogen atoms of CN ligands of different cluster anions, whereas Cu2 bridges only two cluster anions so it is coordinated by two N atoms of CN ligands, en and ammonia molecules. As a result this compound has a complicated polymeric structure in which two infinite chains directed along *b* axes are linked through Re–CN–Cu1 bridges (Figure 8).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

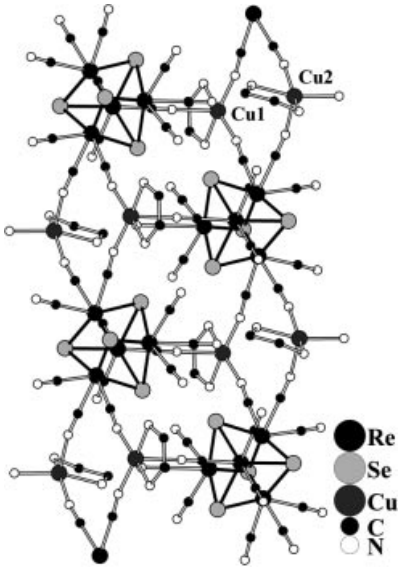

Figure 8. A fragment of the structure of complex **11**.

### *4.1.2. Compounds Containing a Mixture of $[ML_{n-2}(en)]^{2+}$ and $[ML_{n-4}(en)_2]^{2+}$*

A mixture of chemical forms corresponding to the first and the second steps of complex formation, in a 1:1 ratio, was observed in complexes $[Ni(NH_3)_4(en)][\{Ni(NH_3)(en)_2\}Re_4Te_4(CN)_{12}]\cdot 2H_2O$ (**12**) and $[Zn(NH_3)_2(en)_2][\{Zn(NH_3)_2(en)\}Re_4Te_4(CN)_{12}]\cdot H_2O$ (**13**) (L = $NH_3$ and CN).

Compound **12** was obtained from an aqueous ammonia solution containing $K_4[Re_4Te_4(CN)_{12}]$, $NiCl_2$ and ethylenediamine (Ni/en ratio of 1:1.5).[28] The structure of **12** is ionic, with an $[Ni(NH_3)_4(en)]^{2+}$ cation and an $[\{Ni(NH_3)(en)_2\}Re_4Te_4(CN)_{12}]^{2-}$ anion (Figure 9). The $[Ni(NH_3)_4(en)]^{2+}$ cation corresponds to the $[ML_{n-2}(en)]^{2+}$ chemical form in Equation (1) for an octahedral environment. At the same time, the $[\{Ni(NH_3)(en)_2\}Re_4Te_4(CN)_{12}]^{2-}$ anion can be described as the result of substitution of an ammonia molecule by the $[Re_4Te_4(CN)_{12}]^{4-}$ cluster anion in the coordination environment of a *cis*-$[Ni(NH_3)_2(en)_2]^{2+}$ complex cation.

Compound **13** also has an ionic structure, with an *cis*-$[Zn(NH_3)_2(en)_2]^{2+}$ cation corresponding to the $[ML_{n-4}(en)_2]^{2+}$ ($n$ = 6) chemical form and a $[\{Zn(NH_3)_2(en)\}Re_4Te_4(CN)_{12}]_n^{2n-}$ anion, which has a zigzag chain-like structure (Figure 10).[26] Once again, the anion formation can be viewed as the result of substitution of *cis*-ammonia molecules by nitrogen atoms of two different cluster anions in the $[ML_{n-2}(en)]^{2+}$ chemical form.

It should be noted that only these two compounds out of the whole series of tetrahedral rhenium cluster complexes including $[ML_{n-4}(en)_2]^{2+}$ units contain *cis*-$[ML_2(en)_2]^{2+}$ cations. An analysis of the structural data of all compounds deposited in the CCDC (CSD v.5.25) shows that the number of *trans*-$[ML_2(en)_2]^{2+}$ complexes is much higher than that of *cis*-$[ML_2(en)_2]^{2+}$ complexes. Apparently, *trans*-$[ML_2(en)_2]^{2+}$ complexes are energetically more stable than the *cis*-$[ML_2(en)_2]^{2+}$ form. However, the isolation of this form from solution has proved to be possible upon crystallisation with cluster anions.

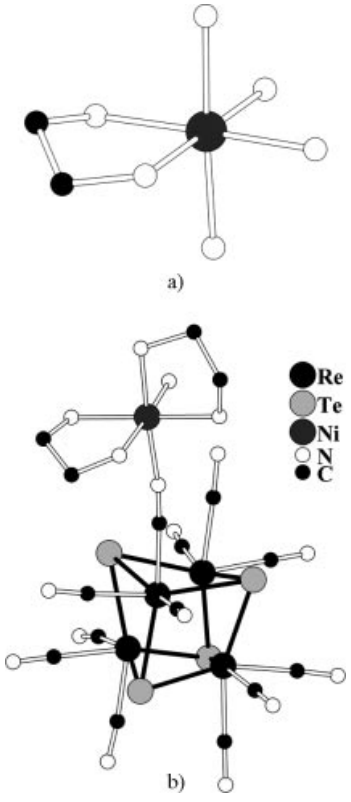

Figure 9. Structure of the complex $[Ni(NH_3)_4(en)]^{2+}$ cation (a) and the $[\{Ni(NH_3)(en)_2\}Re_4Te_4(CN)_{12}]^{2-}$ anion (b) in compound **12**.

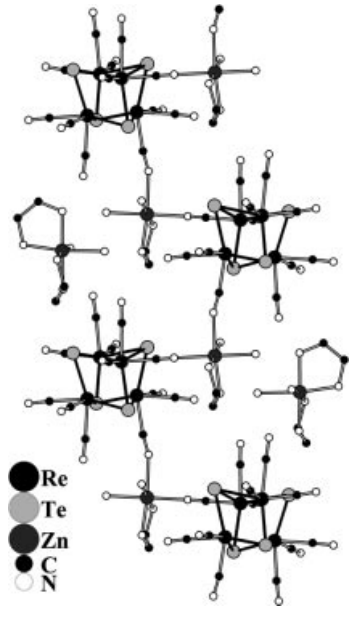

Figure 10. A fragment of structure of **13**.

### *4.1.3. Compounds Containing Only $[ML_{n-4}(en)_2]^{2+}$*

All compounds synthesised in the presence of ethylenediamine with an M/en ratio of 1:2 contain *trans*-$[ML_{n-4}(en)_2]$ units. Such complexes are known with bridging $\{M(en)_2\}$

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(M = $Ni^{2+}$, $Cu^{2+}$ and $Zn^{2+}$) groups or terminal $\{Cu(en)_2\}$ ($n$ = 5) groups coordinated to CN ligands of the cluster anion.

The compound $[\{Cu(en)_2\}_2Re_4S_{3.83}Te_{0.17}(CN)_{12}]\cdot H_2O$ (**14**) has a polymeric grid structure in which the $[Re_4S_{3.83}Te_{0.17}(CN)_{12}]^{4-}$ cluster anions are situated at the cross-points of this lattice and are linked by $[Cu(en)_2]^{2+}$ cationic units, as depicted in Figure 11. Each Cu atom in the cationic part has a [4+2] coordination environment: it is coordinated by four $NH_2$ groups of two ethylenediamine units in the equatorial plane and by two N atoms of CN ligands of different cluster anions with longer Cu–N distances (2.367 and 2.759 Å).[29]

The isostructural compounds $[\{Ni(en)_2\}_2Re_4Se_4(CN)_{12}]\cdot 3.25H_2O$ (**15**)[18] and $[\{Zn(en)_2\}_2Re_4S_{3.60}Te_{0.41}(CN)_{12}]\cdot 3.75H_2O$ (**16**)[29] have a polymeric grid structure with $[Re_4Q_4(CN)_{12}]^{4-}$ cluster anions at the cross-points and $[M(en)_2]^{2+}$ moieties on the edges (Figure 12). However, two of these lattices are arranged differently. In the case of **14** four CN groups of two rhenium atoms (2+2) take part in binding; whereas in of **15** and **16** four CN ligands belonging to three Re atoms (2+1+1) of the cluster anion are involved in formation of the polymeric structure. In this context, the different bridging modes have a crucial influence on the packing characteristics. The bent bridging modes in **14** result in the formation of wavy layers (Figure 13, a), whereas the tentatively flat binding of **15** and **16** generates approximately planar layers (Figure 13, b).

The compound of composition $[Ni(NH_3)_2(en)_2][\{Ni(en)_2\}_3\{Re_4Te_4(CN)_{12}\}_2]\cdot 38H_2O$ (**17**) was obtained under the same reaction conditions as those of **15**. However, the structure of this compound differs dramatically. Figure 14 shows the structure of the $[\{Ni(en)_2\}_3\{Re_4Te_4(CN)_{12}\}_2]^{2-}$ anion, in which $[Re_4Te_4(CN)_{12}]^{4-}$ clusters are linked by $\{Ni(en)_2\}^{2+}$ units to form hexagonal layers. There are two types of channels in this structure: large hexagonal and smaller triangular ones, which are filled with water molecules and $[Ni(NH_3)_2(en)_2]^{2+}$ counterions. The volume of the large cavity is 1590 $Å^3$ and the volume of each of the two smaller ones is 640 $Å^3$. The total available volume for solvent per unit cell is 2870 $Å^3$, corresponding to about 37% of the unit cell volume. Compound **17** is the first example of a highly porous structure derived from the tetrahedral $Re_4Q_4$ cluster core. The en molecules coordinated to the Ni atoms make the framework in **17** robust and prevent its collapse after dehydration. Indeed, powder diffraction studies of samples left in air for weeks at room temperature and after heating to 120 °C (a temperature at which the material is completely dehydrated according to thermal analysis) indicate that the original crystal structure remains essentially unchanged. The walls of the large channels of the framework in **17** are decorated by twelve N atoms from the terminal CN ligands of the $[Re_4Te_4(CN)_{12}]^{4-}$ cluster anion in every sheet. This feature makes this robust framework an attractive matrix for inclusion of molecules or ions of corresponding size and shape based on "host–guest" prin-

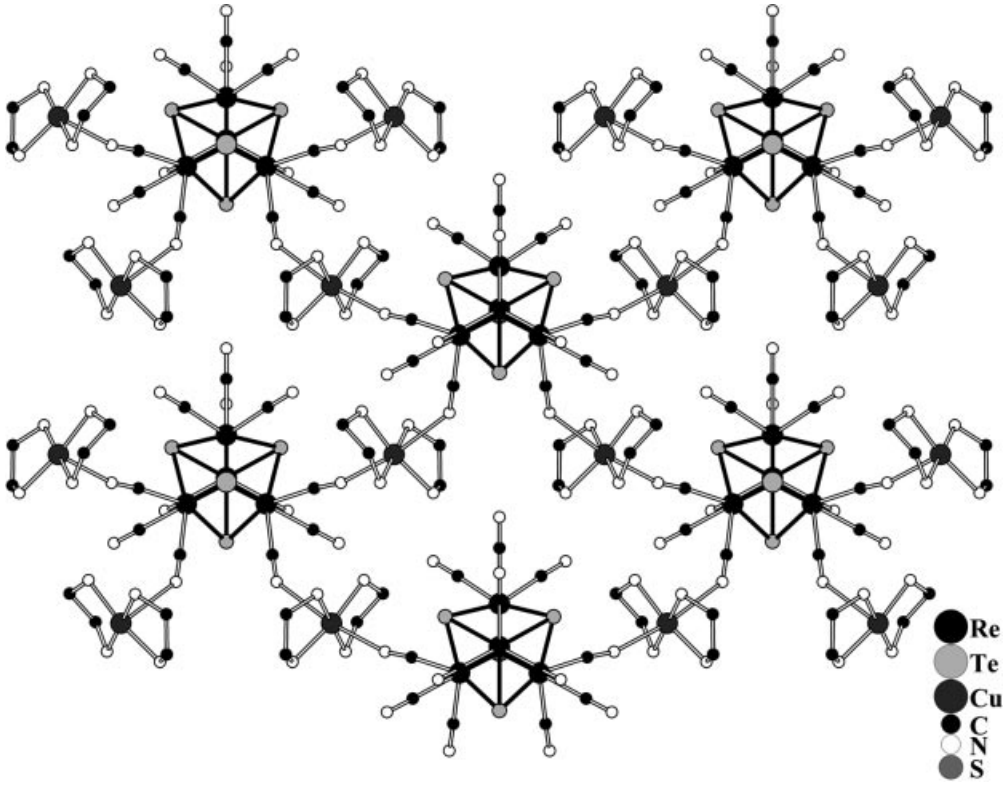

Figure 11. A fragment of the layer in compound **14**.

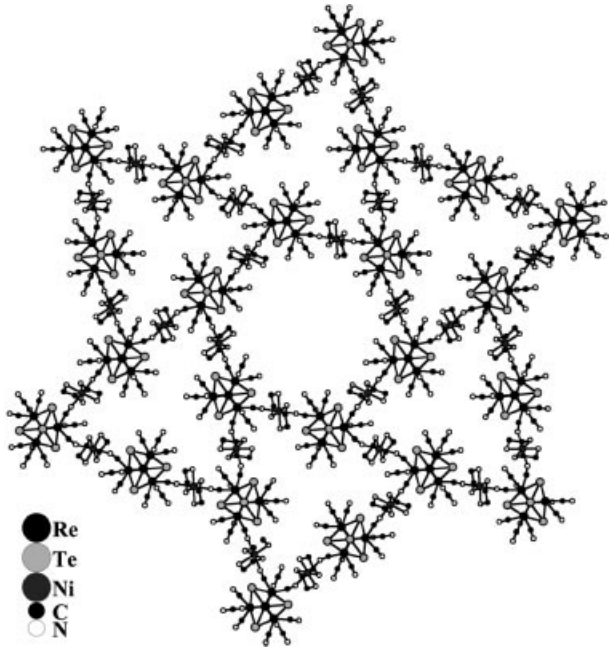

Figure 14. View down the *c* axis of the crystal packing of the $[\{Ni(en)_2\}_3\{Re_4Te_4(CN)_{12}\}_2]^{2-}$ polymeric anion in **17**.

ciples. The N atoms directed into the channel are able to form both covalent bonds, with any N-acceptor atoms such as transition metals, and hydrogen bonds, with H-containing molecules such as alcohols, to guest molecules.[30] Apparently, the reason for formation of such differently arranged structures as that of **15** and **17** is the different cluster core composition ($Re_4Se_4$ in **15** and $Re_4Te_4$ in **17**).

The use of $[Cu(en)_2Cl_2]$ instead of $[Ni(en)_2Cl_2]$, which was used for the synthesis of **15** and **17**, gives the formation of the molecular compounds $[\{Cu(en)_2\}_2Re_4Q_4(CN)_{12}]\cdot 5H_2O$ [$Q_4 = Te_4$ (**18**),[31] $STe_3$ (**19**)[32]], which have different structures. In these compounds the $[Re_4Q_4(CN)_{12}]^{4-}$ cluster anions are coordinated by two $\{Cu(en)_2\}^{2+}$ units in opposite directions (Figure 15). To put it another way, every *trans*-$\{Cu(en)_2\}$ unit is linked to only one CN ligand of the cluster anion, which means that *n* in this case is equal to 5; this results in the formation of a molecular structure.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

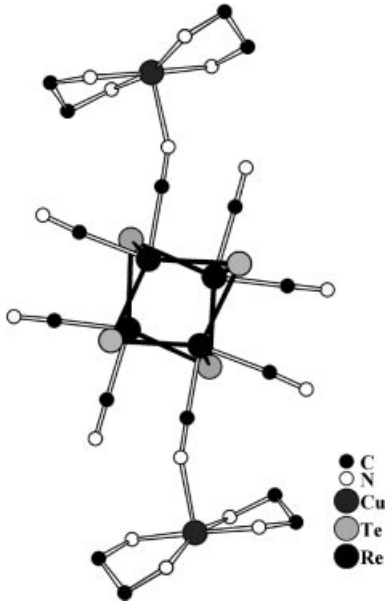

Figure 15. View of the $[\{Cu(en)_2\}_2Re_4Te_4(CN)_{12}]$ molecule in **18**.

Thus, the interaction of $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = S, Se, Te) cluster anions with $Ni^{2+}$, $Cu^{2+}$ and $Zn^{2+}$ metal cations in the presence of a chelate ligand such as ethylenediamine leads to the formation of compounds with various structures made up of cluster anions and cationic units corresponding to the different chemical forms that coexist in solutions containing a transition metal salt and en.

### 4.2. Complexes with Diethylenetriamine

The diethylenetriamine ligand can block one, two or three coordination sites around a transition metal cation. It can also bridge two cations. Table 2 shows the labels of three different coordination modes of the dien molecule.

Table 2. Labels of the coordination modes of the dien molecule.

| Labeling | Coordination mode |
|---|---|
| (1,2,3)-mode |  |
| (1)-(3)-mode |  |
| (1,2)-(3)-mode |  |

All three coordination modes have been found in complexes containing tetrahedral chalcocyanide rhenium cluster anions and transition metal cations bonded with dien. The (1,2,3)-coordination mode is present in all compounds but the bridging mode only exists in compounds with a dien/M molar ratio greater than 1. A possible reason for this situation is that the $K_1$ stability constant of $[M(dien)]^{2+}$ (M = Ni, Cu and Zn) is higher than the $K_2$ constant.

#### *4.2.1. Complexes with Only the (1,2,3)-Coordination Mode*

Five complexes containing $\{ML_{n-3}(dien)\}$ cationic units (where L is either ammonia molecules or nitrogen atoms of CN ligands) have been obtained by the reaction of $M^{2+}$ cations (M = Ni, Cu or Zn) with $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = S, Se, Te) cluster anions in the presence of diethylenetriamine (M/dien = 1:1) in aqueous ammonia solution.

The $[Ni(NH_3)_3(dien)]^{2+}$ chemical form was observed in the ionic compound $[Ni(NH_3)_3(dien)]_2[Re_4Se_4(CN)_{12}]\cdot 5.5H_2O$ (**20**), which contains *fac*-$[Ni(NH_3)_3(dien)]^{2+}$ cations (Figure 16). The compound $[\{Ni(NH_3)_2(dien)\}_2Re_4Te_4(CN)_{12}]\cdot 2.5H_2O$ (**21**) can be considered the result of an ammonia molecule substitution in a *fac*-$[Ni(NH_3)_3(dien)]^{2+}$ cationic unit by the nitrogen atom of a CN ligand (Figure 17).[28]

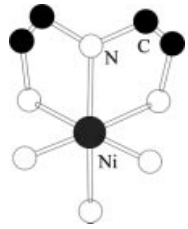

Figure 16. Structure of the complex $[Ni(NH_3)_3(dien)]^{2+}$ cation in compound **20**.

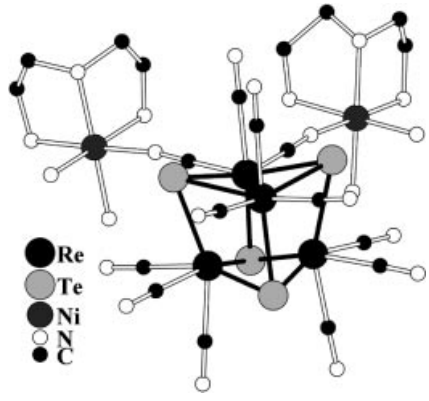

Figure 17. View of the $[\{Ni(NH_3)_2(dien)\}_2Re_4Te_4(CN)_{12}]$ molecule in **21**.

At the same time, the formation of compounds $[\{Cu(NH_3)(dien)\}_2Re_4S_{3.64}Te_{0.36}(CN)_{12}]\cdot 3H_2O$ (**22**)[29] and $[\{Cu(NH_3)(dien)\}_2Re_4Se_4(CN)_{12}]\cdot 2.5H_2O$ (**23**)[33] can be presented as the result of coordination of a CN ligand to a $[Cu(NH_3)(dien)]^{2+}$ unit with a square-planar structure. The structures of **22** and **23** have only one distinction: in the case of **22** *gem*-CN ligands are bonded to two cationic units, whereas in **23** these bridging ligands have an *ortho* orientation (Figure 18).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

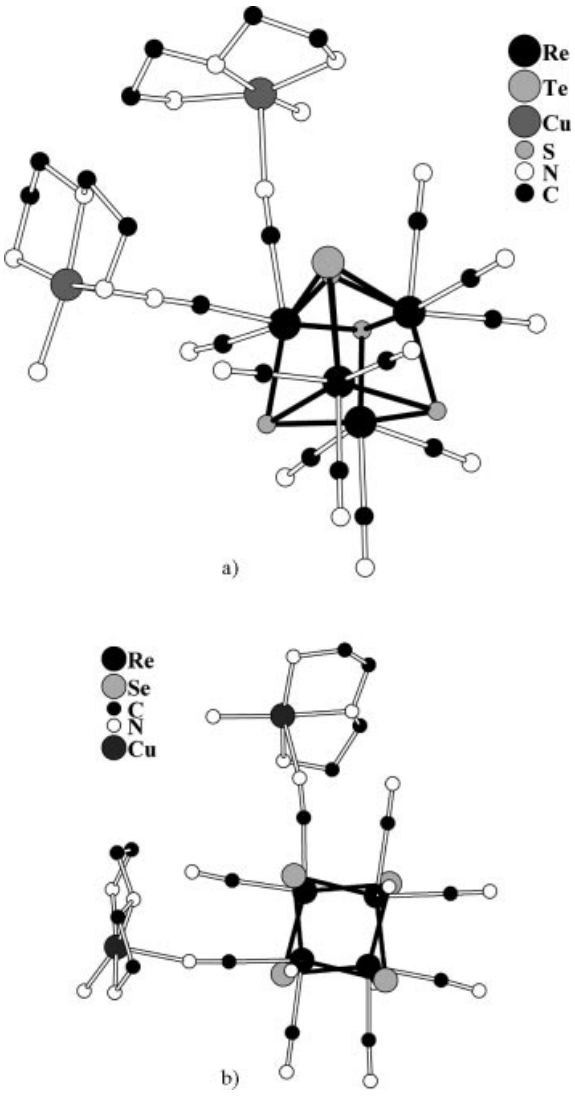

Figure 18. View of the $[\{Cu(dien)(NH_3)\}_2Re_4S_{3.45}Te_{0.55}(CN)_{12}]$ molecule in compound **22** (a) and $[\{Cu(dien)(NH_3)\}_2Re_4Se_4(CN)_{12}]$ molecule in compound **23** (b).

The next step of complication can be viewed in $[\{Cu(dien)\}_2Re_4Te_4(CN)_{12}]\cdot 9H_2O$ (**24**).[27] This compound has a chain-like structure in which the cluster anions are linked to each other through two complex $\{Cu(dien)\}^{2+}$ cations. An alternation of the -2Cu(dien)-cluster-2Cu(dien)- fragments gives rise to a coordination-chain polymer whose structure is shown in Figure 19. Thus, the formation of this compound can be considered as a two-step process. First, the molecular complex $[\{Cu(NH_3)(dien)\}_2Re_4Te_4(CN)_{12}]$, similar to that described for **22**, is formed, and in the next step these molecular units are condensed by means of substitution of an ammonia molecule in the equatorial plane of the copper cation by a nitrogen atom from an adjacent cluster anion.

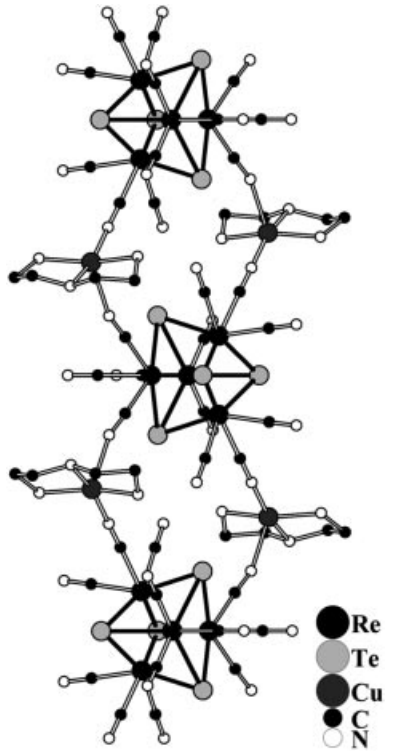

Figure 19. A fragment of the chain in structure of **24**.

We have described above analogous chain structures for compounds **7** and **8** in which the cluster anions are linked to each other by two cationic $\{Cu(NH_3)_3\}^{2+}$ fragments. In the ammonium analog, four CN groups of one cluster anion involved in the formation of the polymeric structure are coordinated to two Re atoms [2 + 2], whereas the bridging CN ligands in the compound with dien are coordinated to three Re atoms [2 + 1 + 1].

#### *4.2.2. A Complex with the (1,3)-Coordination Mode*

Decreasing the dien/$M^{2+}$ ratio leads to the formation of complexes in which dien molecules exhibit bridged coordi-

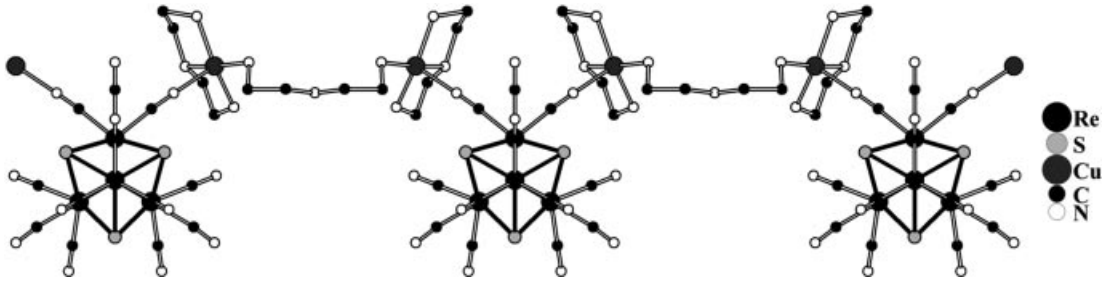

Figure 20. Chain fragment of the structure of compound **25**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nation modes along with the (1,2,3)-coordination mode. The (1,3)-coordination mode has been found only in the case of $[\{Cu_2(dien)_3\}Re_4S_4(CN)_{12}]$ (**25**),[33] which has a polymeric structure where the $[Re_4S_4(CN)_{12}]^{4-}$ cluster anions are bridged by $[(dien)Cu\text{-}dien\text{-}Cu(dien)]^{4+}$ cationic chains (Figure 20). Each Cu atom in the cationic chain-like building blocks is coordinated by one dien molecule with (1,2,3)-coordination mode and one amino group of bridged dien molecule with (1)-(3)-coordination mode. On the other hand the formation of this compound can be also considered as a result of two-step process. On the first step the formation of $[\{Cu(NH_3)(dien)\}_2Re_4S_4(CN)_{12}]$ takes place analogously to that described for **22**. And then these molecular units are linked by dien molecules which substitute ammonia molecule in equatorial plane of copper cation by terminal amino groups.

### *4.2.3. The Complexes with (1,2)-(3)-Coordination Mode*

The two isostructural compounds $[\{Cu_2(dien)_3\}Re_4Q_4(CN)_{12}]\cdot nH_2O$ [Q = Se (**26**) and Te (**27**)] have been synthesised following the same synthetic procedure.[33] It is very interesting to note that both these compounds have a compositions similar to that of **25**, but their structures are sufficiently different. Whereas compound **25** has a chain-like polymeric structure, **26** and **27** are molecular (Figure 21) and consist of $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = Se, Te) cluster anions and non-binding $[Cu_2(dien)_3]^{4+}$ cationic units, the structure of which differs noticeably from the corresponding cation in **25**. Both Cu atoms in **25** are crystallographically equivalent and are coordinated by N atoms of CN ligands of different clusters. In **26** and **27**, however, the Cu atoms exhibit different coordination environments: one Cu atom has a similar arrangement to the Cu atom in compound **25**, whereas the second Cu atom is coordinated by three N atoms of one dien ligand and by two N atoms of another dien ligand, in a (1,2)-(3)-mode, which bridges the two Cu atoms of the cationic unit through its third N atom. Such a coordination type prevents the formation of a polymeric structure. A comparison of **26** and **27** with **25** shows that the structure of the latter can be transformed into the structure of **26** and **27** by the rupture of one Cu–NC bond and the formation of a new bond with the middle amino group of the bridging dien ligand.

The composition of $[\{Zn_2(dien)_3\}Re_4Te_4(CN)_{12}]\cdot 6H_2O$ (**28**)[26] is similar to that of **26** and **27**. However, its molecular structure looks like **26** and **27** only partially. The structure of the $[Zn_2(dien)_3]^{4+}$ cationic unit is analogous to $[Cu_2(dien)_3]^{4+}$ in **26** and **27**, but it is bonded to the cluster cation through not one but two CN ligands, i.e. in this case both metal cations are coordinated by nitrogen atoms of CN ligands (Figure 22). Thus, there are interesting structural transitions between **25** and **26** (or **27**), and then **28**, in which the dimensionality initially decreases from 1D to 0D due to the rupture of an M–NC bond, with an adjustment of the cluster cation and the formation of a new bond inside one molecular unit.

If the $Cu^{2+}$ concentration is reduced the isostructural compounds $[K(H_2O)_2]_2[\{Cu_3(dien)_4\}\{Re_4Q_4(CN)_{12}\}_2]\cdot 8H_2O$ [Q = Se (**29**) and Te (**30**)] can be obtained.[33] The anionic unit of this structure is provided by the complex $[\{Cu_3(dien)_4\}\{Re_4Te_4(CN)_{12}\}_2]^{2-}$ (Figure 23), in which two $[Re_4Te_4(CN)_{12}]^{4-}$ cluster anions are bridged by the cation $[Cu_3(dien)_4]^{6+}$, which can be described as [(dien)Cu-(dien)-Cu(dien)-Cu(dien)]. There are two symmetry-equivalent Cu atoms, each coordinated by three N atoms of one dien ligand, one N atom of the bridging dien ligand [(1,2)-(3)-coordination mode], and by one N atom of a CN ligand of the $[Re_4Q_4(CN)_{12}]^{4-}$ anion. The third Cu atom lies at the centre of this cation and is symmetrically coordinated by four N atoms of two bridging dien ligands and at the same time by two additional *trans*-situated N atoms of CN ligands of two different anions (Figure 23). Thus, this Cu atom is octahedrally coordinated and bridges the $[\{Cu_3(dien)_4\}\{Re_4Te_4(CN)_{12}\}_2]^{2-}$ anionic units to construct the polymeric structure. The negative charge of this one-dimensional network is compensated by $K^+$ cations.

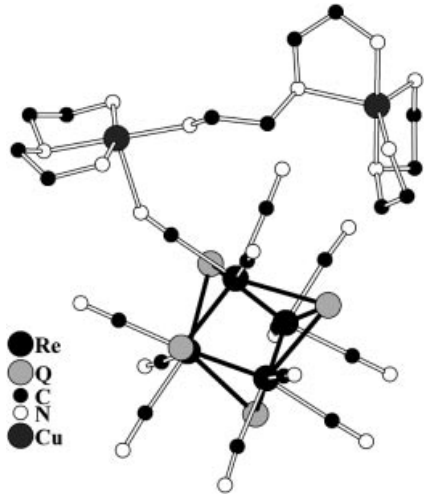

Figure 21. View of the $[\{Cu_2(dien)_3\}Re_4Se_4(CN)_{12}]$ molecule in compound **26** and **27**.

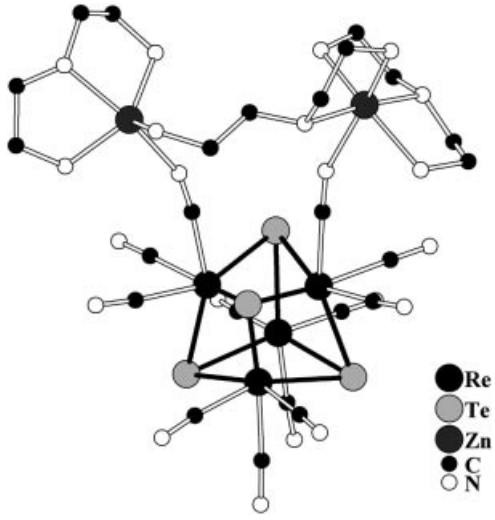

Figure 22. View of the $[\{Zn_2(dien)_3\}Re_4Te_4(CN)_{12}]$ molecule in compound **28**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

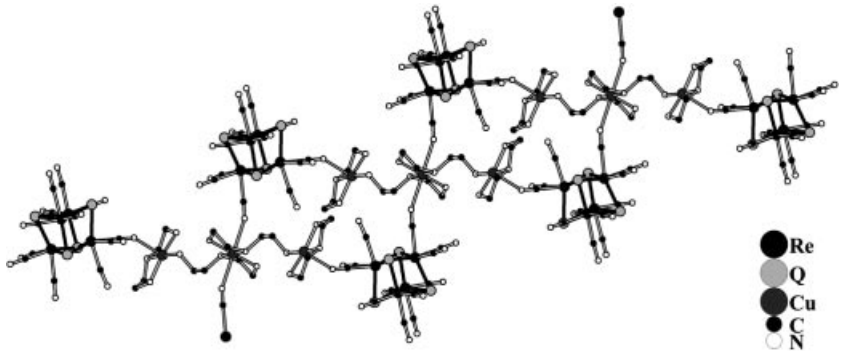

Figure 23. Anionic connectivity pattern in the crystal structure of compounds **29** and **30**.

Thus, the interaction of $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = S, Se, Te) cluster anions with $Ni^{2+}$, $Cu^{2+}$, and $Zn^{2+}$ in the presence of the tridentate ligand diethylenetriamine leads to the formation of a number of complex cluster compounds containing different cationic units: mononuclear $\{M(NH_3)_{n-4}(dien)\}$ or polynuclear $\{M_2(dien)_3\}^{4+}$ and $\{Cu_3(dien)_4\}^{6+}$. The obtained complexes allow us to trace the structural connection between the compounds formed in this system. The parameters affecting the structural type are:

*Ratio of reagents*: When the M/dien ratio is 1:1 compounds with a (1,2,3)-coordination mode of dien are formed. The M/cluster anion ratio is also important. Although in all these reactions the concentration of $M^{2+}$ ions was sufficient to form complexes containing only $M^{2+}$ cations, two compounds (**29** and **30**) were obtained that crystallise with additional $K^+$ cations. This may be due to structural factors: these compounds contain longer oligomeric cations $\{Cu_3(dien)_4\}^{6+}$.

*The cluster core composition*: The influence of this parameter is obvious in the case of **25**, **26**, and **27**, where, on going from Q = S to Q = Se and Te, the structure changes from chain-like to molecular.

*The coordination polyhedron of the transition metal cation*: The $Ni^{2+}$ cation prefers a rigid octahedral environment, $Cu^{2+}$ a square-pyramidal [4+1] or distorted octahedral [4+2] environment, and $Zn^{2+}$, with $n$ = 5 or 6, can have various coordination polyhedra.

Compounds **25**–**30** are of particular interest because they contain cations ($Cu^{2+}$, $Zn^{2+}$) with bridging coordination modes of the dien molecule. Such coordination modes have not previously been observed in M complexes; in all similar complexes three N atoms of the dien ligand are always coordinated to one M atom as, for example, in $[Cu(dien)]_3[Fe(CN)_6]_2 \cdot 6H_2O$.[34] There are only two known examples of metal compounds (both Ag-containing complexes) with bridging dien ligands.[35] Compound **23** is the first example in which the (1,3)-coordination of dien is realized.

### 4.3. Complexes with Triethylenetetraamine

Complexes have also been obtained with the next member of this homologous series, namely triethylenetetraamine. The interaction of $Cu^{2+}$ with $[Re_4Q_4(CN)_{12}]^{4-}$ ($Q_4$ = $Se_4$, $Te_4$, $STe_3$) cluster anions in the presence of trien leads to the formation of complexes formulated as $[\{Cu(trien)\}_2Re_4Q_4(CN)_{12}] \cdot nH_2O$ ($Q_4 = Se_4$ (**31**),[27] $Te_4$ (**32**),[36] $STe_3$ (**33**)[32]). *trien* is present in these compounds as a tetradentate ligand occupying four coordination sites. The fifth coordination site is occupied by a nitrogen atom of a bridging CN ligand (Figure 24). In the structures of the compounds, two crystallographically independent $[Cu(trien)]^{2+}$ cations are bonded by the nitrogen atoms of the *meta*-CN ligands of one $[Re_4Q_4(CN)_{12}]^{4-}$ anion. Thus, the formation of these complexes can be considered as a result of coordination of CN groups of the cluster anion to two $[Cu(trien)]^{2+}$ complex cations. It should be noted that this chemical form is the most stable in solution.

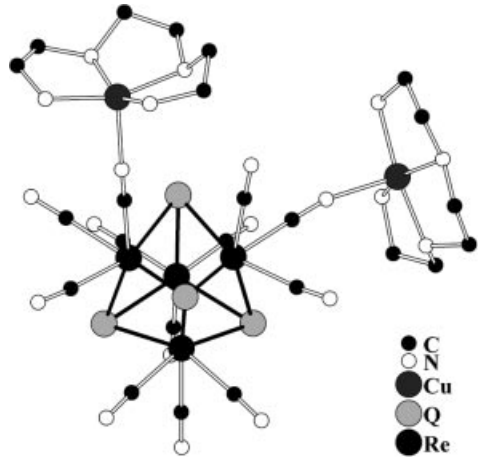

Figure 24. View of the $[\{Cu(trien)\}_2Re_4Q_4(CN)_{12}]$ molecule in compounds **31**–**33**.

Several examples of compounds containing a $[Cu(trien)]^{2+}$ complex cation with a square-pyramidal copper atom, namely [CuL(trien)] compounds (L = $SCN^-$,[37] $NCS^-$,[38] $I^-$,[39] $N(CN)_2^-$,[40]) and also three recently obtained $[Cu(NH_3)(trien)]_2[Re_6Q_8(CN)_6] \cdot nH_2O$ (Q = S, Se, Te)[41] complexes have been described in the literature. In all these cases the coordination environment of the copper atoms is formed by a triethylenetetraamine molecule in the equatorial plane with an L ligand or $NH_3$ molecule in the apical positions with structures close to those of **31**–**33**.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The reaction of $Ni^{2+}$ with $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = S, Se) cluster anions in the presence of trien leads to the formation of $[Ni(NH_3)_2(trien)][\{Ni(NH_3)(trien)\}Re_4Se_4(CN)_{12}]\cdot 2.5H_2O$ (**34**) and $[\{Ni(trien)\}_2Re_4S_4(CN)_{12}]\cdot 3H_2O$ (**35**), which have various crystal structures. The *trien* ligand in these complexes is also tetradentate, occupying four coordination sites in the Ni atom environment; two more coordination sites are occupied either by ammonia molecules or by nitrogen atoms of CN ligands.[28] The $[Ni(NH_3)_2(trien)]^{2+}$ chemical form is observed in **34**. The structure of the $[\{Ni(NH_3)(trien)\}Re_4Se_4(CN)_{12}]^{2-}$ anion (Figure 25) can be viewed as the result of substitution of an ammonia molecule in $[Ni(NH_3)_2(trien)]^{2+}$ by a nitrogen atom of a CN ligand. However, there is a difference in the conformations of the trien ligands in the cationic and anionic complexes. In **35**, the nitrogen atoms of the CN ligands of various cluster anions substitute two ammonia molecules in $[Ni(NH_3)_2(trien)]^{2+}$, binding each other and giving a 1D structure (Figure 26, a). It should be noted that **35** also shows conformational disorder (Figure 26, b and c), the reason for which seems to be the presence of various chemical forms in solution corresponding to different coordination types of triethylenetetraamine.

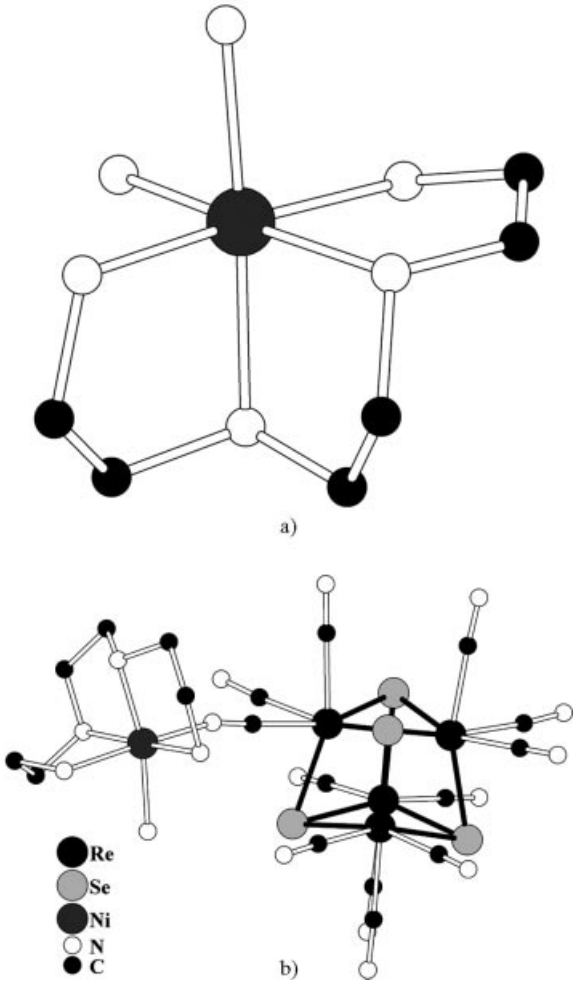

Figure 25. Structure of the complex $[Ni(NH_3)_2(trien)]^{2+}$ cation (a) and $[\{Ni(NH_3)(trien)\}Re_4Se_4(CN)_{12}]^{2-}$ anion (b) in compound **34**.

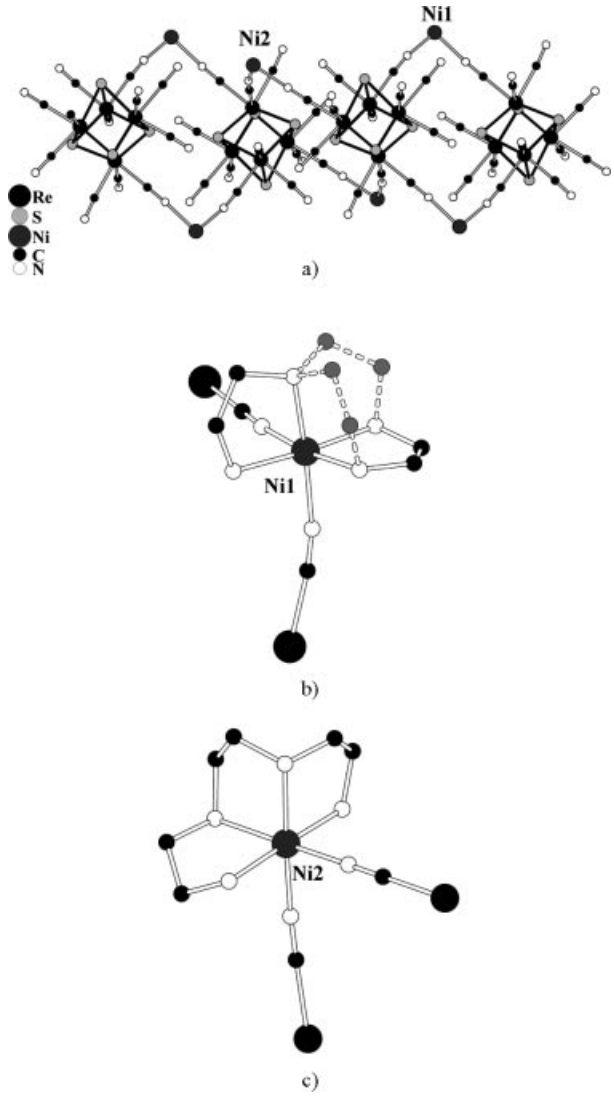

Figure 26. a) A fragment of the structure of **35**; trien ligands have been omitted for clarity. b) The coordination environment of the Ni1 cations. c) The coordination environment of the Ni2 cations.

The chain-like structure of **35** is similar to that of **24**. Based on these two compounds, the connection between ligand denticity, the coordination number of the metal cation, and the formation of a certain structural type can be traced easily. In **24**, the dien molecule occupies three coordination sites in the copper atom environment such that the copper atoms have $n = 5$. Correspondingly, there are two coordination sites open for bonding to CN ligands. An analogous situation is observed in **35** with only one difference: the trien molecule occupies four coordination sites in the environment of nickel atoms with $n = 6$.

### 4.4. Complexes with *threo*-Tetraaminobutane

(1,2*S*,3*S*,4)-Tetraaminobutane, like triethylenetetraamine, has four amino groups, however, this ligand coordinates preferably in a bis-didentate mode with a metal–metal separation of about 7 Å. The bis-didentate coordination mode

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

arises from steric constraints, which prevent binding of the four amino donor atoms to the same metal centre. As has been shown previously,[42] this results in the formation of chiral {...(*threo*-tab)-Cu-(*threo*-tab)...}$_n$ oligomeric species with a linear chain structure and square-planar {$CuN_4$} units. Additional binding of a bridging unit to the axial positions of the $Cu^{2+}$ centres would thus provide a route to new, two-dimensional and chiral metal organic frameworks with an open structure. The bridging unit would serve as a spacer, and its size and structure could be used to adjust the distance between individual {[Cu(*threo*-tab)]$^{2+}$}$_\infty$ strands.

This strategy has been exploited by using [$Re_4Q_4(CN)_{12}$]$^{4-}$ clusters as bridging units to interlink linear [{Cu(*threo*-tab)}$^{2+}$]$_\infty$ strands. The crystalline solids [{Cu(*threo*-tab)}$_2$$Re_4Te_4(CN)_{12}$]·6.5$H_2O$ (**36**) and [{$Cu_2(NH_3)$(*threo*-tab)$_2$}$Re_4Te_4(CN)_{12}$]·4$H_2O$ (**37**) were prepared by direct combination of *threo*-tab, $Cu^{2+}$, and the rhenium cluster anion in aqueous ammonia solution.[43,44]

There is a clear influence of the individual steric properties of the bridging units possessing different compositions on the grid structure. In the [$Re_4Te_4(CN)_{12}$]$^{4-}$ ion, for example, the high number of cyano ligands enables different types of Cu-cluster-Cu interactions, and two of them are realized in **36** and **37**. The nitrogen atoms of four CN ligands of the cluster anion take part in binding in compound **36**, and this mode of binding means that all copper atoms are coordinated by CN ligands; at the same time, all copper atoms are equal and have a distorted octahedral [4+2] environment formed by nitrogen atoms (Figure 27).

In compound **37**, two of the twelve CN groups of the cluster anions take part in binding. In this case, only every second copper atom is coordinated by a CN ligand; the remaining copper atoms are coordinated by ammonia molecules. Half of the copper atoms are in a [4+2] environment and the others are in a [4+1] environment. The one-dimensional {...*threo*-tab-Cu-*threo*-tab-Cu-*threo*-tab...}$_\infty$ strands formed by $Cu^{2+}$ cations and *threo*-tab molecules have a complicated zigzag structure (Figure 28).

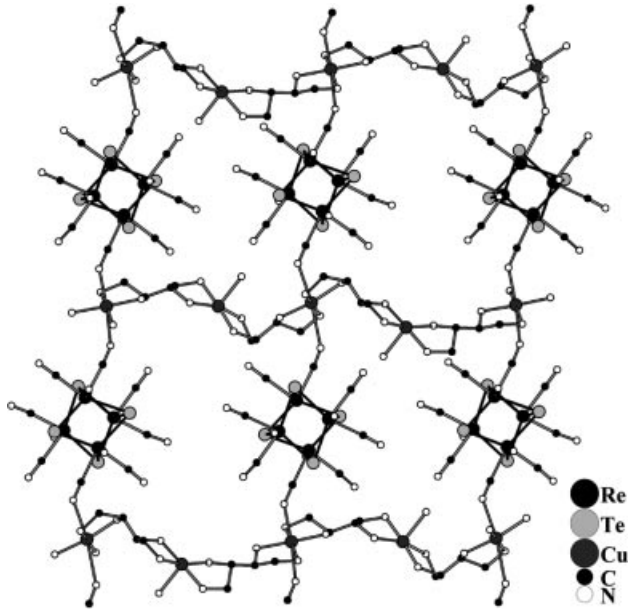

Figure 28. A fragment of the [{$Cu_2(NH_3)$(*threo*-tab)$_2$}$Re_4Te_4(CN)_{12}$] polymer layer in **37**.

The third type of packing is realized in the compound [{Cu($NH_3$)(*threo*-tab)}]$_2$[$Re_4S_{3.4}Te_{0.6}(CN)_{12}$]·1.25$H_2O$ (**38**),[44] which contains undulating, infinite {...*threo*-tab-Cu-*threo*-tab...}$_\infty$ chains that are weakly bonded to cluster anions. The nearest Cu–N(CN ligand) distance is 2.95 Å. In this case, the cluster anions are situated in voids formed by chain packing. The $Cu^{2+}$ cations have a typical five-coordinate environment with four nitrogen atoms from *threo*-tab and an ammonia molecule (Figure 29).

The question as to what caused the structures to be so different in these systems was answered when it was found that in the case of tetrahedral rhenium complexes the structure of the formed coordination polymer depends on two factors, namely the method of synthesis and the cluster core structure.[44]

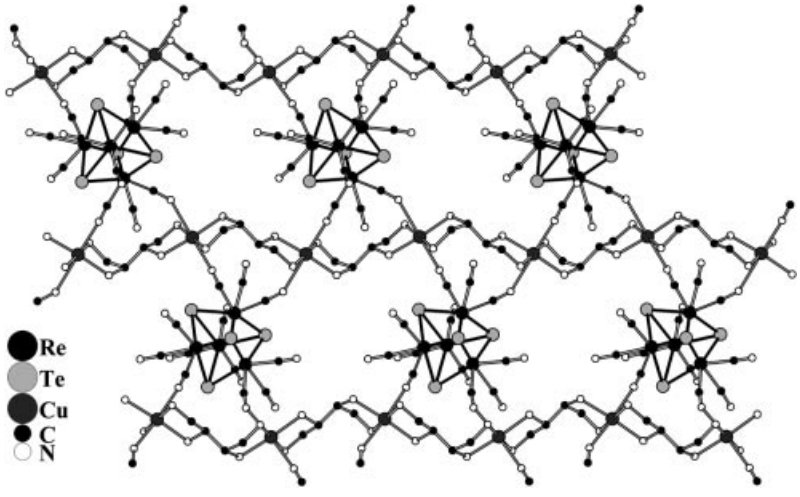

Figure 27. A fragment of the [{Cu(*threo*-tab)}$_2$$Re_4Te_4(CN)_{12}$] polymer layer in **36**.

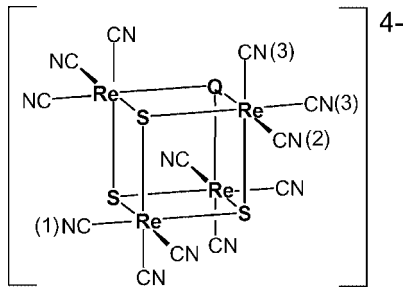
### 4.5. Complexes Containing $Re_4S_{4-x}Te_x$ Cluster Cores

According to the single crystal diffraction analyses, compounds **14**, **16**, **19**, **22**, **33** and **38** contain mixed S/Te chalcogenide ligands in the cluster core $\{Re_4S_{4-x}Te_x\}$. The starting cluster compound $K_4[Re_4S_{4-x}Te_x(CN)_{12}]$ has been synthesised accidentally during preparation of the cluster $K_4[Re_4S_4(CN)_{12}]$ from $[Re_4S_4(TeCl_2)_4Cl_8]$ by boiling with KCN as described for $K_4[Re_4Se_4(CN)_{12}]\cdot 6H_2O$.[11] According to elemental analysis, the compound obtained contains tellurium. This could be due to a sulfur shortage during the preparation of $[Re_4S_4(TeCl_2)_4Cl_8]$ from $ReCl_5$, S and Te.[10]

In compounds **14**, **16** and **22** there are two different cluster anions, with compositions $[Re_4S_4(CN)_{12}]^{4-}$ and $[Re_4S_3Te(CN)_{12}]^{4-}$. In the latter cluster one sulfur atom is substituted by a tellurium atom. In the structures of all three compounds the $Re_4S_4$ and $Re_4S_3Te$ cluster cores are ordered in such a way that three positions of the $Q_4$ tetrahedron are equivalent and occupied by only sulfur atoms; the fourth position is occupied by either a sulfur or a tellurium atom.

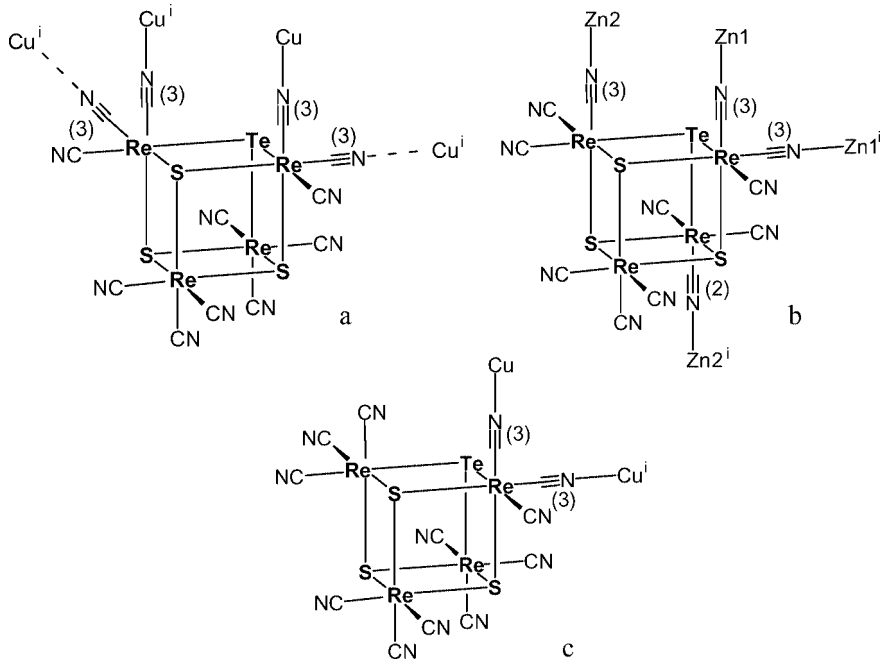
It should be noted that in all three structures the metal cations are bound to the CN groups that are closest to the tellurium atom position. To understand the reason for this density functional theory calculations have been carried out on different $[Re_4S_3Q(CN)_{12}]^{4-}$ (Q = S, Se, Te) cluster anions with the ADF program.[45] According to these calculations, there are several types of CN ligands in these cluster anions. Considering each Re atom to be octahedrally coordinated, without taking Re–Re bonds into account (Scheme 2), there are three CN groups bonded to the $ReS_3$ fragment (type 1). The remaining CN ligands are coordinated to three $ReS_2Q$ (Q = Se, Te) fragments. Within the $ReS_2Q(CN)_3$ units, one CN group is more distant from the Q atom than the other two groups (these ligands are denoted types 2 and 3, respectively). For CN ligands of types 1 and 2 the changes are negligible, but for six CN groups of the third type they are considerable and increase with a decrease of the electronegativity of the chalcogen atoms. The increase of negative charge on the N atoms of type 3 results in a considerable preference for the metal ions to coordinate to these atoms.



Scheme 2.

All copper atoms in compound **14** are coordinated by CN groups of type 3 to give a polymeric structure (Scheme 3, a). This differs slightly from compound **16**, in which the Zn1 atoms are coordinated by two CN groups of type 3 whereas the Zn2 cations are linked to CN groups of both types 2 and 3. To put it another way, only three of the four bridging CN ligands of one cluster anion are of type 3, while the fourth one is of type 2 (Scheme 3, b). In molecular

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3.

compound **22**, two bridging CN groups also belong to type 3 (Scheme 3, c).

It was also interesting to study the behaviour of the $\{Re_4STe_3\}$ cluster core in similar systems. For this, the cluster salt $K_4[Re_4STe_3(CN)_{12}]\cdot 5H_2O$ (**I**) was synthesised and characterised.[32] However, in compounds **19** and **33** the expected ordering of sulfur positions was not observed. The sulfur atoms are disordered over two (**19**) or four (**33**) of the apexes of the tetrahedron. One of the possible reasons for this might be the cluster core composition of the starting materials, which could contain $\{Re_4S_2Te_2\}$ and $\{Re_4Te_4\}$ clusters as well as $\{Re_4STe_3\}$.

## 5. Conclusions

Throughout this microreview we have mainly reported the isolation and characterisation of various complexes based on tetranuclear rhenium cluster anions $[Re_4Q_4(CN)_{12}]^{4-}$ (Q = S, Se, Te) and transition metal cations, the coordination sites of which are fully or partially occupied by water molecules or N-donor ligands, particularly ammonia, ethylenediamine, diethylenetriamine, triethylenetetraamine and chiral *threo*-tetraaminobutane. The structures of all compounds have been confirmed by single-crystal X-ray analysis.

We should emphasise, again, that the composition and structure of the obtained compounds are determined by several parameters, namely:

1) the reagent ratio: $M^{2+}$ cation/polydentate ligand or $M^{2+}$ cation/cluster anion;
2) the $M^{2+}$ cation coordination environment;
3) the coordination number and coordination polyhedron of the $M^{2+}$ cations;
4) the cluster core composition.

It has been shown that the reaction of chalcocyanide rhenium cluster complexes $[Re_4Q_4(CN)_{12}]^{4-}$ with cations of 3d-transition metals ($Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$) in the presence of chelating ligands gives many complex compounds with various structures (ionic, molecular or polymeric). Complicated cluster complexes with polymeric structures containing bridging polydentate ligands, namely diethylenetriamine and *threo*-tetraaminobutane, were obtained for the first time.

We have also introduced a new and straightforward synthetic pathway to heterometallic and chiral coordination polymers. The use of oligonuclear bridging units has proved to be of particular interest because it allows the design of open networks with sufficiently large voids for host–guest interactions. More importantly, the use of the chiral, bisdidentate *threo*-tab ligand guarantees the formation of a chiral crystal structure which has the ideal prerequisites for the coating of suitable surfaces with a chiral monolayer.

Complexes containing mixed-ligand $\{Re_4S_{4-x}Te_x\}$ cluster cores have been obtained and characterised for the first time. Their structural data supplement previous research and show that six CN groups of the cluster anion can be activated for interaction with metal cations by substituting one sulfur atom by a tellurium atom in the $Re_4S_4$ cluster core; these groups are those nearest to the Te atom.

# A Theoretical Rationale for the Formation, Structure and Spin State of Pentacyanochromate(II)

**Robert J. Deeth*[a]**

**Keywords:** Density functional theory / Ligand field theory / Angular overlap model / COSMO / Solvation effects

The pentacyanochromate(II) complex is unusual in two respects. Firstly, it is one of the few homoleptic cyanide species with a high-spin ground state. Secondly, it was synthesised during an attempt to make the hexacoordinate complex. A combination of qualitative ligand field theory and quantitative density functional theory including solvation effects is applied to rationalise these observations. The spin state depends on the d orbital energy differences and how the promotion energy, PE, associated with a change in spin state compares to the d–d spin pairing energy, SPE. The calculations show that PE > SPE for octahedral $[Cr^{II}(CN)_6]^{4-}$, hence it has a spin triplet $S = 1$ ground state, while PE < SPE for $[Cr^{II}(CN)_5]^{3-}$, hence it is high spin with $S = 2$. The hexacyanide is stabilised in aqueous solution by solvation. In less polar solvents such as acetonitrile, the unfavourable electrostatic interactions dominate and the reaction stops at the pentacyano complex. In both complexes, the cyanide behaves as a strong-field ligand and is both a good σ donor and π acceptor.

## Introduction

Ligand Field Theory (LFT)[1] classifies the cyanide ligand as strong field and, therefore, the normal expectation is for homoleptic complexes to exhibit low-spin configurations. Octahedral cyanide complexes are invariably low spin, but there are some interesting exceptions for other coordination numbers. For example, low-spin (i.e. $S = 1$) $[Cr(CN)_6]^{4-}$ can be synthesised from aqueous solution providing excess cyanide is present but in acetonitrile, pentacyanochromate(II) is produced with magnetic properties consistent with a high-spin $S = 2$ $d^4$ configuration. Both the higher spin state and lower coordination number were not anticipated.[2]

An explanation of this behaviour is amenable to computation. This communication describes the first detailed computational study of $[Cr(CN)_5]^{3-}$ and $[Cr(CN)_6]^{4-}$ using both qualitative ligand field theory (LFT) and quantitative density functional theory (DFT) calculations. Theory successfully explains not only why $[Cr(CN)_5]^{3-}$ is high spin, but also why the change in medium from aqueous solution to acetonitrile causes the reaction to stop at coordination number five.

## Results and Discussion

Hexacyanochromate(II) is extremely air sensitive[3] which goes some way to explain the relative lack of experimental data. However, the crystal structure of $Na_4[Cr(CN)_6]\cdot(H_2O)_{10}$ has been reported some years ago[4] and $[Cr(CN)_6]^{4-}$ remains of interest in the context of molecular magnets.[2,5] Indeed, it was in the search for new molecular magnetic materials that Nelson et al.[2] attempted a non-aqueous route to $[Cr^{II}(CN)_6]^{4-}$ which resulted in the unexpected preparation of the very interesting pentacyanochromate(II) anion. Their work highlighted two intriguing aspects of the chemistry of $[Cr(CN)_5]^{3-}$. Firstly, why does the system display a high-spin $S = 2$ state given that high-field ligands such as cyanide are conventionally associated with low-spin configurations? Secondly, why is a pentacyano complex isolated from the non-aqueous synthetic procedure rather than the expected hexacoordinate complex, which can be made in aqueous solution provided an excess of cyanide is present?

In principle, modern computational chemistry should be able to address these issues quantitatively although, apart from an early Xα study,[6] there appears to be no other computational work on either $[Cr^{II}(CN)_6]^{4-}$ nor $[Cr^{II}(CN)_5]^{3-}$.

The spin state is a balance between one-electron (orbital) and two-electron (interelectronic repulsion) effects. The d–d interelectron repulsion term favours a high-spin configuration (maximum quantum mechanical exchange, minimal spin pairing energy, SPE) while the one-electron term relates to d orbital splittings and favours low-spin configurations (minimum electronic promotion energy, PE). Note that, depending on the symmetry, low spin need not necessarily imply diamagnetic properties. For example, the low-spin configuration for octahedral $d^4$ species is $t_{2g}^4$ which still has two unpaired electrons. Critically, the d orbital

splittings are ligand- and geometry-dependent while, to a first approximation, the spin-pairing energy is not.

The X-ray crystallographic study of $(NEt_4)_3[Cr^{II}(CN)_5]$·MeCN·1/8THF reveals four chromium complexes in the unit cell displaying geometries which are distorted to varying degrees away from either ideal square-pyramidal (SPY) or trigonal-bipyramidal (TBP) structures.[2] The question then is how the promotion energy for pentacoordinate systems compares to $\Delta_{oct}$.

The d orbital energies can be conveniently expressed in terms of the Angular Overlap Model (AOM).[7] For an octahedral complex of "linear ligator" ligands like cyanide, $\Delta_{oct} = 3e_\sigma - 4e_\pi$, where $e_\sigma$ and $e_\pi$ are respectively the AOM parameters describing M–CN σ and π bonding. The expressions for individual d orbital energies are given in Equations (1), (2), (3) and (4) for SPY and (5), (6) and (7) for TBP and include group theory labels appropriate to $C_{4v}$ and $D_{3h}$ symmetry, respectively. In Equations (1)–(4), $\alpha$ refers to the angle between the apical and equatorial ligands.

$$E(d_{x^2-y^2}) = E(b_1) = 3/4(1 - \cos 2\alpha)^2 \cdot e_\sigma(eq) + (\sin^2 2\alpha) \cdot e_\pi(eq) \quad (1)$$

$$E(d_{z^2}) = E(a_1) = 1/4(1 + 3\cos 2\alpha)^2 \cdot e_\sigma(eq) + e_\sigma(ax) + 3(\sin^2 2\alpha) \cdot e_\pi(eq) \quad (2)$$

$$E(d_{xy}) = E(b_2) = 4(\cos^2 2\alpha) \cdot e_\pi(eq) \quad (3)$$

$$E(d_{xz}, d_{yz}) = E(e) = 3/2(\sin^2 2\alpha) \cdot e_\sigma(eq) + 2(\cos^2 2\alpha) \cdot e_\pi(eq) + e_\pi(ax) \quad (4)$$

$$E(d_{z^2}) = E(a_1) = 3/4e_\sigma(eq) + 2e_\sigma(ax) \quad (5)$$

$$E(d_{x^2-y^2}, d_{xy}) = E(e') = 9/8e_\sigma(eq) + 3/2e_\pi(ax) \quad (6)$$

$$E(d_{xz}, d_{yz}) = E(e'') = 1/2e_\pi(eq) + 2e_\pi(ax) \quad (7)$$

The relevant orbital energy differences corresponding to the promotion energy which must be overcome for a high-spin $d^4$ configuration are shown in Figure 1.

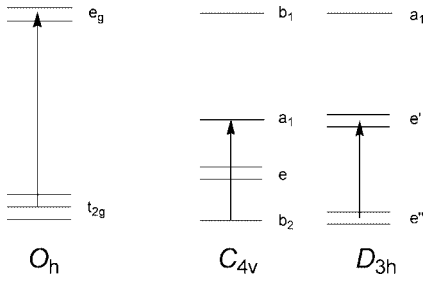

Figure 1. Qualitative d orbital energy level diagrams for octahedral ($O_h$), SPY ($C_{4v}$) and TBP ($D_{3h}$) symmetries illustrating the high-spin promotion energy for a $d^4$ configuration.

Figure 1 is not drawn to scale. A numerical comparison can be based on Equations 1–7. Hence, the promotion energies, PE, are Equations (8), (9), and (10).

$$PE(O_h) = 3e_\sigma - 4e_\pi \quad (8)$$

$$PE(C_{4v}) = 0.83e_\sigma(eq) + e_\sigma(ax) + 0.35e_\pi(eq) - 3.53e_\pi(eq) = 0.65e_\sigma(eq) + e_\sigma(ax) - 3.18e_\pi(eq) \quad (9)$$

$$PE(D_{3h}) = 9/8e_\sigma(eq) - 1/2\{e_\pi(eq) + e_\pi(ax)\} \quad (10)$$

In arriving at these expressions, the angle $\alpha$ between apical and equatorial cyanides in the SPY structure has been taken as 100° and cyanide was assumed to be a π acceptor (i.e. $e_\pi < 0$). We return to the latter issue below.

Assuming $e_\lambda(ax) = e_\lambda(eq)$, λ = σ, π, Equations (8)–(10) collapse to Equations (11), (12), and (13)].

$$PE(O_h) = 3e_\sigma - 4e_\pi \quad (11)$$

$$PE(C_{4v}) = 1.65e_\sigma - 3.18e_\pi \quad (12)$$

$$PE(D_{3h}) = 1.13e_\sigma - e_\pi \quad (13)$$

This is a very crude assumption because the AOM parameters will vary strongly with distance. Nevertheless, the difference between $O_h$ and $C_{4v}$ or $D_{3h}$ promotion-energies expressions is so great that the assertion that the promotion energies for pentacoordinate symmetries would be substantially less than for an octahedral complex seems secure. The observation of high-spin $[Cr(CN)_5]^{3-}$ is thus simply a function of the coordination number and symmetry. Cyanide may continue to be a strong-field ligand in the sense that the AOM parameter values could be identical in all symmetries. That is, strong-field ligands do not necessarily have to be associated with low-spin electronic configurations – e.g. the tetrahedral complex $[Mn(CN)_4]^{2-}$ is high spin consistent with the well-known result that the tetrahedral splitting $\Delta_{tet} \approx 1/2\ \Delta_{oct}$.

However, while LFT can easily rationalise why $[Cr(CN)_5]^{3-}$ is high spin, it cannot address the issue of why is forms in the first place. For this we require a more sophisticated quantum mechanical approach like DFT.

DFT has effectively revolutionised the application of quantum chemistry to transition-metal systems,[8] but it is by no means a perfect model. In particular, current functionals may not give a good description of spin state energy differences.[9–13] Our experience with $Fe^{II}$ and $Fe^{III}$ complexes shows that although there can be large numerical differences, most pure functionals give the correct qualitative trend.[9] Others have focussed on tuning the amount of exact exchange in the B3LYP functional to give more accurate results for spin-crossover systems.[11,13] The present problem is less delicate, which probably means that almost any gradient corrected functional will be at least qualitatively reasonable. To test this, the DFT protocol was first validated against $[Cr(CN)_6]^{4-}$, which is known to be a low-spin, $t_{2g}^4$ $S = 1$ system (see Table 1).

In octahedral symmetry, high-spin $[Cr(CN)_6]^{4-}$ has a $^5E_g$ state, which is expected to display a strong Jahn–Teller distortion hence the second optimisation in $D_{4h}$ symmetry which allows for an orbitally-nondegenerate state leading to the expected elongated octahedral structure. Similarly, the

[a] $D_{4h}$ Symmetry, axial elongation. [b] $D_{2h}$ symmetry.

spin triplet state in octahedral symmetry is $^3T_{2g}$ and is also formally Jahn–Teller active. However, compared to the $^5E_g$ case, the Jahn–Teller effect for the $^3T_{2g}$ state is much more complicated but since it is dominated by π effects, it is also much weaker. A complete analysis has not been attempted. Instead, the geometry was reoptimised in $D_{2h}$ symmetry as an example of one possible distortion mode. Finally, the spin singlet state is clearly going to be higher than the $S = 1$ state and, although in $O_h$ symmetry, this too is formally orbitally degenerate, only the octahedral geometry has been computed.

The DFT results in Table 1 are in good agreement with experiment. They correctly predict the spin-triplet $S = 1$ ground state with an optimised Cr–CN bond length (in $O_h$ symmetry) only about 0.03 Å longer than the average Cr–CN distance reported for $Na_4[Cr(CN)_6]\cdot 10H_2O$.[4] Note that in the absence of solvation, the optimised Cr–C distance for octahedral, $S = 1$ hexacyanochromate(II) extends 0.08 Å to 2.12 Å. In the gas phase, many occupied orbitals have physically unreasonable positive energies. This leads to an expansion of the Cr–C bond. The solvation field stabilises the anionic charge, lowers the orbital energies and generates a better optimal structure.

Further vindication that DFT (with solvation) describes these systems well can be seen in Table 2 where DFT data for $[Cr(CN)_5]^{3-}$ are presented.

For both symmetries, the spin state energies increase quintet < triplet < singlet. The $^5B_1$ state in $C_{4v}$ and the $^5A_1$ state in $D_{3h}$ are orbitally non-degenerate, and thus Jahn–Teller inactive as is the $^3A_1$ state in $C_{4v}$ derived from the $b_2^2e^2$ configuration. The remaining triplet and the two singlet states are much higher in energy and, even though some are orbitally degenerate, the effect is not large enough to alter the overall conclusion that the predicted DFT ground state of $[Cr(CN)_5]^{3-}$ is a spin quintet.

The computed structures are also reasonable, although compared to $[Cr(CN)_6]^{4-}$ DFT now gives somewhat shorter Cr–C distances than observed for $[Cr(CN)_5]^{3-}$. Both SPY and TBP structures are predicted to have virtually identical energies consistent with the somewhat distorted structures observed in the crystal structure and with the general notion that five-coordinate systems are not rigid.

DFT can also be applied to explain the relative stabilities of $[Cr^{II}(CN)_6]^{4-}$ vs. $[Cr^{II}(CN)_5]^{3-}$. The data in Table 1 and Table 2 clearly demonstrate the critical importance of the environment of the complex. Thus, the reaction energy for the process

$$[Cr(CN)_5]^{3-} + CN^- \rightarrow [Cr(CN)_6]^{4-}$$

is –87 kJ·mol$^{-1}$ when the COSMO solvation energies are included, but an enormous +794 kJ·mol$^{-1}$ from just the electronic energies alone. Obviously, there is a strong repulsive interaction when trying to bring a monoanion like cyanide up to a complex which already carries three negative charges, but because the solvation energy is proportional to $Z^2$, the additional solvation energy of a tetraanion vs. a trianion amounts to an extra 1100–1200 kJ·mol$^{-1}$, which is sufficient to overcome this repulsive term. Because the solvation energy depends on $(1 - 1/\varepsilon)$, where $\varepsilon$ is the dielectric constant, large solvation energies are associated with a high dielectric constant. Acetonitrile is simply not polar enough to support the reaction hence the hexacyano complex cannot form.

Having established that the relative spin states are well described (with and without solvation energies) and seen that the complex formed depends strongly on the solvent,

Table 2. DFT results for $[Cr(CN)_5]^{3-}$ for different spin states ($S$) and symmetries – $C_{4v}$ for SPY and $D_{3h}$ for TBP. Bond lengths in Å, energies in kJ·mol$^{-1}$. $E_{tot}$ is total DFT energy and equals the sum of the electronic energy, $E_{el}$, and the COSMO solvation energy, $E_{sol}$. $\Delta E$ is the energy difference between $E_{tot}$ for that entry and the lowest $E_{tot}$ overall. Experimental data[2] in parentheses.

the issue of whether cyanide is always a "strong-field" ligand requires an assessment of whether the fundamental nature of the Cr–CN bonding changes radically with coordination number. In the spirit of LFT, let us use the DFT structures and orbital energies as the basis of a ligand-field analysis.

The octahedral complex is our starting point. Although the electronic spectrum of $[Cr(CN)_6]^{4-}$ has been reported,[3] no assignments were offered due to the broad nature of the diffuse reflectance bands. The DFT estimate of ca. 32000 $cm^{-1}$ may be compared to the values in Table 3, which also include computed results for other hexacyanides.

Table 3. Experimental[14] and calculated $\Delta_{oct}$ values [$cm^{-1}$] for hexacyanometallate complexes.

| Complex | $\Delta_{oct}$ | $\Delta_{oct}$ (calcd.) |
|---|---|---|
| $[Cr(CN)_6]^{3-}$ | 26600 | 29815 |
| $[Cr(CN)_6]^{4-}$ | – | 31989 |
| $[Mn(CN)_6]^{3-}$ | 34000 | 32400 |
| $[Mn(CN)_6]^{4-}$ | 30000 | 33777 |
| $[Fe(CN)_6]^{3-}$ | 34950 | 35614 |
| $[Fe(CN)_6]^{4-}$ | 33800 | 36426 |

It appears that the DFT spherical configuration orbital energy differences (see Computational Details section) generally overestimate $\Delta_{oct}$. Experimentally, one normally sees larger values for higher metal oxidation states. Hence, given an experimental value for $[Cr^{III}(CN)_6]^{3-}$ of 26600 $cm^{-1}$ and a threshold value at which a first-row octahedral $d^4$ species switches from quintet to triplet spin of about 23500 $cm^{-1}$,[15] $\Delta_{oct}$ for $[Cr(CN)_6]^{4-}$ should lie between 23500 and 26600 $cm^{-1}$. The DFT estimate is ca. 32000 $cm^{-1}$.

For the Cr(II) complex $\Delta_{oct}$ is probably quite close to that for $Cr^{III}$. Because both are low spin, the lower oxidation state, which has more d electrons, has a larger ligand field stabilisation energy (LFSE) at least in terms of $\Delta_{oct}$ values. Hence, the $M^{II}$–C bond lengths are actually shorter than the $M^{III}$–C distances despite the latter's higher formal oxidation state and smaller ionic radius. The relative change in LFSE increases from 20% for the $d^5/d^6$ $Fe^{III}/Fe^{II}$ couple to 25% for $d^4/d^5$ $Mn^{III}/Mn^{II}$ to 33% for the $d^3/d^4$ $Cr^{III}/Cr^{II}$, which correlates reasonably well with bond–length contractions of 0.02, 0.05 and 0.05 Å, respectively. Given the large percentage change in $\Delta_{oct}$, the decrease in Cr–C distance and the DFT prediction that $\Delta_{oct}$ for $M^{II}$ gets larger relative to that for $M^{III}$ in the series Fe < Mn < Cr, the assertion that $\Delta_{oct}$ for $[Cr^{II}(CN)_6]^{4-}$ and $[Cr^{III}(CN)_6]^{3-}$ are about the same seems reasonable.

While a better theoretical treatment along the lines of, say, ligand field DFT,[16] time-dependent DFT[17] or CASPT2[18] may provide better quantitative agreement with experiment, the precise value of $\Delta_{oct}$ is not important for the present analysis because the errors seems to be propagated more or less systematically between $[Cr^{II}(CN)_6]^{4-}$ and $[Cr^{II}(CN)_5]^{3-}$. The aim is to see whether the AOM parameter values deduced from the DFT orbital energies of $[Cr(CN)_6]^{4-}$ generate AOM d orbital energies for $[Cr(CN)_5]^{3-}$, which in turn agree with the DFT equivalents. If so, then the ligand-field strength is essentially the same in both complexes.

Of course, as $\Delta_{oct} = 3e_\sigma - 4e_\pi$, unique values for both AOM parameters cannot be extracted from a single value of $\Delta_{oct}$. By applying a small tetragonal distortion to the molecule, the "d" orbitals will split, which will provide three degrees of freedom but now there are four parameters, $e_\sigma$(eq), $e_\sigma$(ax), $e_\pi$(eq) and $e_\pi$(ax). The number of free variables can be halved if the distance dependence is established. Lengthening the Cr–C bonds, $r$, from 2.038 to 2.078 Å lowers the computed $\Delta_{oct}$ from 31989 to 29233 $cm^{-1}$. Assuming all AOM parameters depend on $r^{-m}$ yields $m$ = 4.6, which is close enough to the electrostatic theory value of $m$ = 5. Applying an axial elongation to the two ligands on the $z$ axis ($r_{ax}$ = 2.078, $r_{eq}$ = 2.038 Å) gives a "d" orbital sequence of $b_{2g} < e_g < a_{1g} < b_{1g}$ and because in the AOM $E(b_{2g}) = e_\pi(eq)$, $E(e_g) = 2e_\pi(eq) + 2e_\pi(ax)$, and $|e_\pi(eq)| > |e_\pi(ax)|$ because $r_{eq}$ is shorter, the DFT calculations are consistent with $e_\pi < 0$ – i.e. cyanide is behaving as a π acceptor. Assuming $m$ = 5, the $e_g - b_{2g}$ and $b_{1g} - a_{1g}$ DFT orbital energy differences equate to effective AOM parameter values of $e_\sigma$ = 8767 and $e_\pi$ = –1398 $cm^{-1}$ at the octahedral geometry.

The optimised $C_{4v}$ structure for $[Cr(CN)_5]^{3-}$ has $r_{ax}$ = 2.14 and $r_{eq}$ = 2.08 Å corresponding to $e_\sigma$(ax) = 6869, $e_\pi$(ax) = –1095, $e_\sigma$(eq) = 7918 and $e_\pi$(eq) = –1263 $cm^{-1}$. Substituting these values into Equations (1)–(4) with $\alpha$ = 101° gives the energy difference between the highest and lowest energy d functions, $d_{x^2-y^2}(b_1)$ and $d_{xy}$, of 26222 $cm^{-1}$ vs. the DFT spherical configuration estimate of 28136 $cm^{-1}$. Hence, the assumption that cyanide remains a strong ligand generates quite good agreement with the DFT electronic structure.

Moreover, using the AOM parameter values for $r$ = 2.038 Å in Equations (11)–(13) yields rough promotion energies of ca. 32000, 19000 and 11000 $cm^{-1}$ for $O_h$, $C_{4v}$ and $D_{3h}$ symmetries, respectively, the former clearly being more than, while the latter two are clearly less than the spin crossover threshold of 23500 $cm^{-1}$.

## Conclusions

A combination of AOM and DFT arguments and calculations provides a simple explanation for the high-spin quintet ground state of $[Cr(CN)_5]^{3-}$ – the cost of promoting an electron to give an $S$ = 2 state is less than the cost of spin pairing. The reverse applies in octahedral symmetry and a triplet $S$ = 1 configuration results. In both cases, the combination of the BP86 functional and COSMO solvation provides a DFT protocol which successfully predicts good structures and the correct order of spin state energies. COSMO is critical for obtaining good structural data but does not alter the predicted lowest energy spin state. Spin contamination is minimal.

Given the highly charged species involved, the COSMO aqueous solvation energies are large and predict that the

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

formation of hexacyanochromate(II) from the pentacyanide precursor is favourable by 79 kJ·mol$^{-1}$. However, the "raw" electronic energies show that the powerful electrostatic interactions disfavour the process by over 700 kJ·mol$^{-1}$ and hence in less polar media such as acetonitrile, there is insufficient solvation energy to form the tetraanionic species.

An AOM ligand-field analysis based on DFT orbital energies for $[Cr(CN)_6]^{4-}$ suggests that cyanide is both a strong σ donor and reasonably strong π acceptor with typical $e_\sigma$ and $e_\pi$ values around 8500 and –1400 cm$^{-1}$, respectively. Assuming that cyanide remains a strong-field ligand for pentacyanochromate(II) yields AOM-derived d orbital energies in good agreement with their DFT counterparts. However, due to the change in coordination number and symmetry, even a strong-field ligand cannot force the ground state to a lower spin degeneracy.

Strong M–CN binding results in relatively large changes in energy as a function of coordination number and/or symmetry. Hence, the theoretical predictions tolerate larger errors and are more robust. In particular, DFT, in conjunction with a treatment of the environment, provides a reasonable basis for describing the chemistry of Cr(II)–cyanide complexes and, most likely, metallocyanides in general.

## Computational Details

All DFT calculations employed ADF version 2005.[19] After some preliminary testing, the Becke Perdew (BP86) functional was chosen in conjunction with triple-ζ plus polarisation basis sets (TZP) and frozen cores[20] up to 2p for the metals and 1s for C and N. Geometries were optimised with full point group symmetry as appropriate in the presence of a COSMO solvation field as implemented in ADF, with atomic radii C: 1.4 Å, N: 1.5 Å[21] and M: 2.58 Å. Where appropriate, all calculations were run spin-unrestricted, and the extent of spin contamination monitored by the calculation of $<S^2>$, which was generally within 0.03 of the ideal value except for $S = 1$, where the worst case was $<S^2> = 2.05$ for Cr systems and 2.08 for $[Mn(CN)_6]^{3-}$, and for $S = 2$, where the worst case was $<S^2> = 6.08$. Orbital energy differences were computed at the relevant optimised geometry using "spherical configurations", which we have used successfully in the past[22,23] and is a modification of the Average Over Configuration approach implemented in ADF and recently described by Atansov and Daul.[24] The five molecular orbitals, which are predominantly d antibonding in character, are identified and then assigned populations of $m/5$ where $m$ is the notional number of d electrons for the idealised metal oxidation state. A spin-restricted single-point calculation is then run to SCF convergence. Angular Overlap Model (AOM) expressions were derived from Figgis and Hitchman.[7]

# First Example of Dendrons as Topological Amplifiers

**Cédric-Olivier Turrin,[a] Alexandrine Maraval,[a] Germinal Magro,[a] Valérie Maraval,[a] Anne-Marie Caminade,*[a] and Jean-Pierre Majoral*[a]**

*Dedicated to the memory of our friend, the late Professor Marcial Moreno-Mañas*

**Keywords:** Dendrons / Dendrimers / Macrocycles / Phosphorus / NMR spectroscopy

A phosphorus-containing dendron was synthesized and grafted to a tetraphosphorus macrocycle. The presence of such bulky substituents allowed for the first time the amplification of topological differences in the macrocycle. These differences become detectable by $^{31}P$ NMR spectroscopy, with the appearance of several signals for the phosphorus atoms included in the macrocycle.

## Introduction

Dendrons,[1] also called dendritic wedges,[2] play an important role in dendritic macromolecular science, generally as large building blocks for the convergent synthesis of dendrimers[3] or dendronized polymers,[4] and for the elaboration of complex dendritic architectures.[5] Besides these classical uses of dendrons, their very particular topological features have already found more original applications, for instance in steric protection responsible for site isolation,[6] in new modes of self-organization,[7] in enantiomer separation of dendronized molecular knots,[8] as light harvesting antenae,[9] or as rotaxane stoppers.[10] However, to the best of our knowledge, dendrons were never used as amplifiers of local topological phenomena. We thought that such big, ramified, and conical substituents could facilitate the detection of previously undetectable phenomena, by amplifying the local difference.

Being interested since a long time in the synthesis and applications of dendrimers[11] and dendrons,[5,12] generally based on phosphorus,[13,14] we decided to test this assumption by grafting dendrons to compounds in which stereoisomers must exist but were never detected. We previously reported the synthesis of a series of phosphorus macrocycles,[15] obtained quantitatively by condensation reactions between 2 equiv. of phosphorylated dialdehydes and 2 equiv. of phosphodihydrazides.[16] These compounds appeared as the most suitable objects to confirm or invalidate our hypothesis about the role of dendrons as topological amplifiers. More precisely, we used macrocycle **1**,[17] constituted of 4 tetracoordinate phosphorus atoms ($P^{IV}$), two of them being included in O–P–O linkages, the two others in N–P–N linkages. The four $P^{IV}$ atoms are functionalized by an azide group as noncyclic substituent. This macrocycle possesses 4 asymmetric phosphorus centres, which can be easily functionalized through the reactivity of the azide groups (Figure 1).

Obviously, the presence of diastereoisomers in macrocycle **1** can be anticipated, and the zero value found for its optical rotation strongly suggests a 50:50 ratio for the stereoisomers on each phosphorus atom. If the macrocycle is relatively planar or if it is flexible, five diasteroisomers should be present; if the macrocycle exists in stable bent forms, as shown by the X-ray diffraction structure of a related macrocycle,[18] nine diasteroisomers should exist. However, the existence of such diastereoisomers was never detected previously. Even $^{31}P$ NMR spectroscopy, which is very useful for the detection of topological differences in constraint small cycles,[19] is inefficient with unconstraint large cycles such as **1**. The $^{31}P$ NMR spectrum of this 36-membered ring is shown in Figure 1; the 4 phosphorus atoms give two sharp singlets, one for the O–P–O linkages ($P_c$) and one for the N–P–N linkages ($P'_c$).

In a first attempt to detect the presence of diastereoisomers, a small but relatively hindered compound was grafted to the macrocycle. We used a Staudinger reaction between the azide groups and the functionalized phosphane **2**.[20] The creation of the P=N double bond occurs easily with the azide groups connected to the O–P–O linkages, and more slowly with the azide groups connected to the N–P–N linkages, as shown by $^{31}P$ NMR spectroscopy after 1 h. Indeed, the singlet corresponding to the O–P–O linkage has

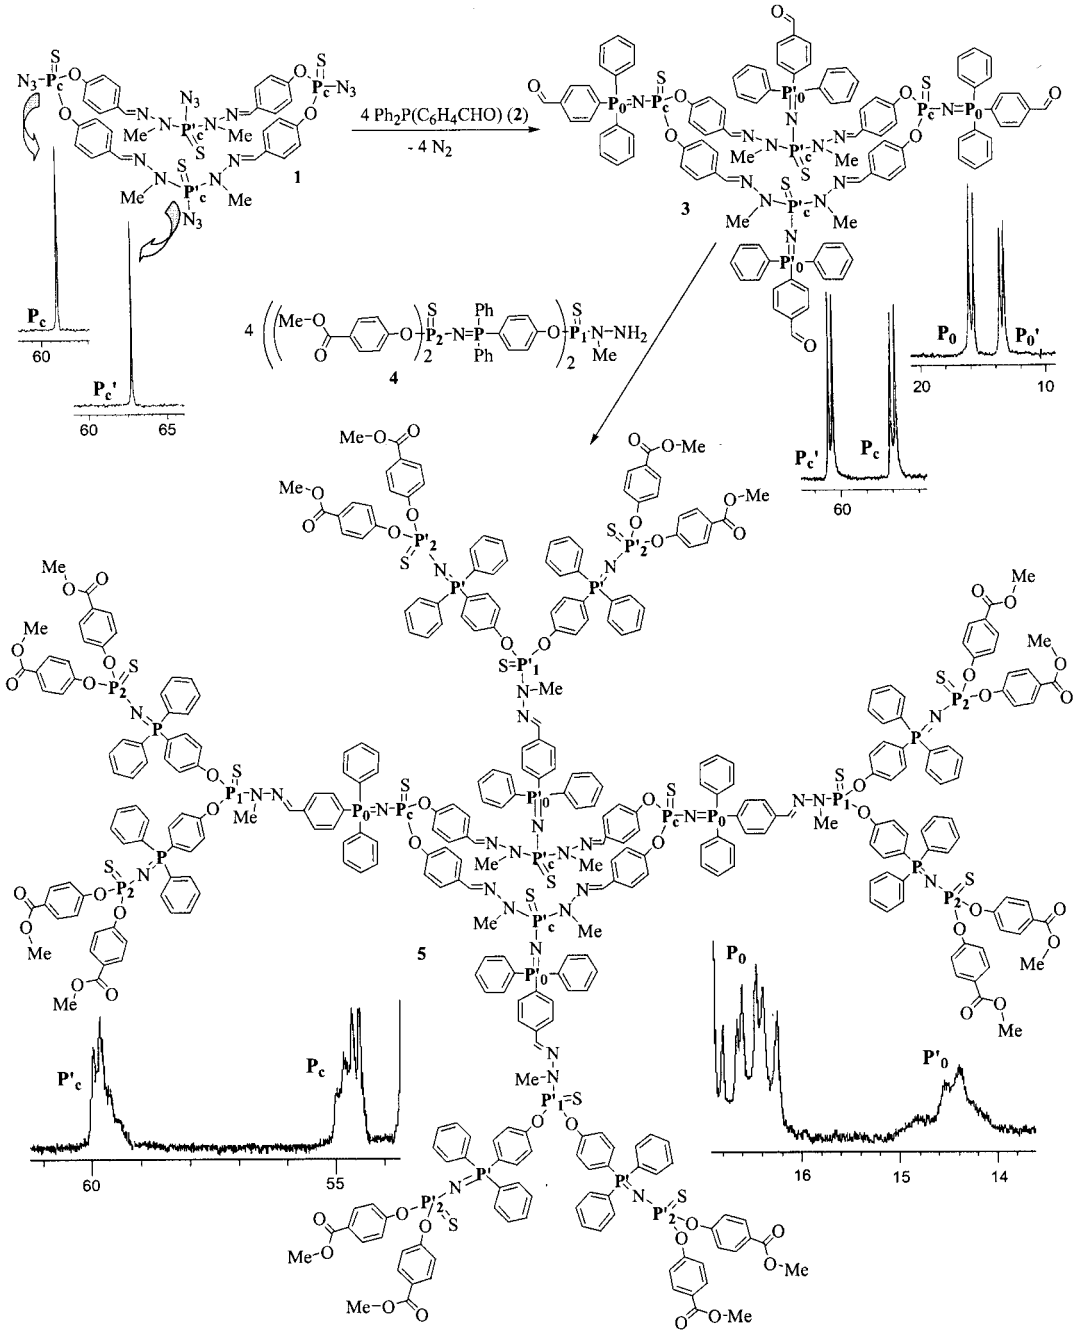

Figure 1. Synthesis of the macrocycle substituted by 4 dendrons and detection of diastereoisomers by $^{31}P$ NMR spectroscopy. Only the parts of the spectrum corresponding to $P_c$–N=$P_0$ and $P'_c$–N=$P'_0$ are shown for compound **5**. The spectra were recorded at 25 °C for **1** and **3**, at 80 °C for **5**.

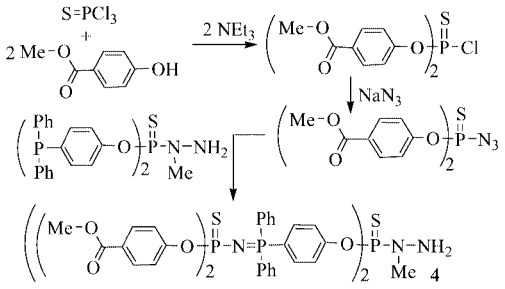
disappeared on behalf of two doublets at $\delta$ = 16.2 ppm (P=N) and 55.7 ppm (P=S), whereas the singlet corresponding to the N–P–N linkages remains unchanged. This difference in the reactivity of both types of azide groups could be ascribed to a higher electron-withdrawing influence of the O–Aryl groups compared to the N–Me substituents, favouring the reaction.[21] However, the macrocycle **3** is finally isolated in nearly quantitative yield after reaction overnight. The $^{31}P$ NMR spectrum gives two sets of two sharp doublets corresponding to two types of P=N–P=S linkages as expected.[22] No trace of diastereoisomers could be detected even with these relatively bulky substituents (Figure 1).

In order to graft dendrons on the 4 aldehyde groups of **3** (one for each phosphorus atom included in the macrocycle), it was necessary to build a dendron possessing one $NH_2$ group at the core, preferably pertaining to an hydrazine or hydrazide linkage to ensure the stability of the future CH=N bond. The size of the dendron is also of crucial importance, because it must be large enough to induce de-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tectable differences, but not too large to allow the signals of the macrocycle to be still detectable. For this purpose, we synthesized the second-generation dendron **4**, obtained by a Staudinger reaction between $H_2NNMeP(S)(OC_6H_4PPh_2)_2$[23] and $N_3P(S)(OC_6H_4CO_2Me)_2$, synthesized according to a method we reported previously[24] (Scheme 1).



Scheme 1.

In the last step, 4 equiv. of the dendron **4** are condensed with the aldehyde groups of macrocycle **3**, to afford the second-generation dendrimer **5**, (Figure 1) as shown by the disappearance of the signal corresponding to the CHO group by $^1H$, $^{13}C$ NMR, and IR spectroscopy. The $^{31}P$ NMR spectrum of compound **5** at room temperature gives relatively sharp signals as expected for the phosphorus atoms pertaining to the dendrons (a single singlet for $P_1$ and $P'_1$, a single doublet for $P_2$ and $P'_2$, and a single doublet for P and P′, not shown in Figure 1). Indeed, no particular steric hindrance or lock of bonds is foreseeable around these phosphorus atoms. However, broad signals are observed for the P=N–P=S linkages in which the P=S group is part of the macrocycle, in contrast to the 4 sharp doublets obtained for the same atoms in macrocycle **3**. Such behaviour is generally characteristic of a "frozen" internal structure; we have observed previously such a phenomenon for high-generation polycationic phosphorus dendrimers,[25] but never for such small generations. Variable-temperature $^{31}P$ NMR experiments carried out in DMSO up to 80 °C improved only slightly the definition of the signals. A slightly better resolution is observed for the P=N groups linked to the macrocycle ($P_0$ and $P'_0$), compared to the P=S groups included in the macrocycle ($P_c$ and $P'_c$), whose degree of freedom is smaller. The better resolution observed for $P_0$ compared to $P'_0$ is presumably due to the higher degree of freedom of $P_c$ compared to $P'_c$. Indeed, all the X ray structure determinations carried out up to now for $P_cN(Me)NC{=}CHC_6H_4OP'_c$ linkages have shown that all atoms from $P_c$ to O lie in a same plane, whereas $P'_c$ is out of this plane.[26] At least 3 sharp doublets can be distinguished for $P_0$, which might correspond to the three main topological features expected; indeed, the dendron connected to $P_0$ can be surrounded with either zero, one or two dendrons, in the half space to which it belongs, defined by the average plane of the macrocycle (Figure 2). In form **A**, the dendrons linked to $P_c$ and $P'_c$ have two interactions, thus inducing a large modification of angles at the level of the $S{=}P_c{-}N{=}P_0$ and $S{=}P'_c{-}N{=}P'_0$ linkages. The same level of modification of angles occurs for the $S{=}P'_c{-}N{=}P'_0$ linkage in form **B**, and for the $S{=}P_c{-}N{=}P_0$ linkage in form **C**. Dendrons having a single interaction should induce a moderate modification of angles, for the $S{=}P'_c{-}N{=}P'_0$ linkage in forms **C** and **D**, and for the $S{=}P_c{-}N{=}P_0$ linkage in forms **B** and **D**. Finally, no interaction should occur for dendrons linked to the $S{=}P'_c{-}N{=}P'_0$ linkage in forms **B** and **E**, and for dendrons linked to the $S{=}P_c{-}N{=}P_0$ linkage in forms **C** and **E**. It is known that $^{31}P$ NMR chemical shifts are sensitive to modification of the angles around the phosphorus atom.[19] The minimization of interactions between the end groups of the dendrons linked to some diastereoisomers of the macrocycle necessitates modification of the angles at the level of their "root" ($P_c{-}N{=}P_0$ and $P'_c{-}N{=}P'_0$ linkages), which is translated into variation of the chemical shift. Thus, one may attribute the phenomenon observed here by $^{31}P$ NMR spectroscopy to the existence of diastereoisomers. It demonstrates without any ambiguity that our assumption concerning the role of dendrons as amplifiers of local phenomena was correct, and could be usefully applied to other systems.

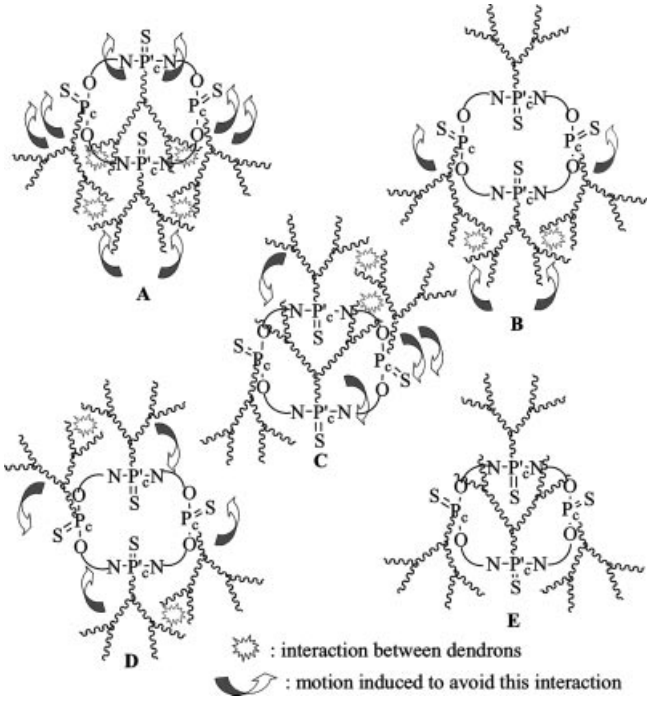


Figure 2. Schematization of the five diastereoisomers of compound **5**, showing the interactions between dendrons, and the movement to avoid these interactions, which modify the angles around the $P_c$ (and $P_0$), and $P'_c$ (and $P'_0$) phosphorus atoms.

## Experimental Section

**General:** All manipulations were carried out with standard high-vacuum and dry-argon techniques. The solvents were freshly dried and distilled (THF and diethyl ether with sodium/benzophenone, pentane and $CH_2Cl_2$ with phosphorus pentoxide). Classical $^1H$, $^{13}C$, $^{31}P$ NMR spectra were recorded with Bruker AC 200, AC 250, DPX 300, or AMX 400 spectrometers. References for NMR chemical shifts are 85% $H_3PO_4$ for $^{31}P$ NMR, $SiMe_4$ for $^1H$ and

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$^{13}C$ NMR spectroscopy. The attribution of $^{13}C$ NMR signals has been done using $J_{mod}$, two-dimensional HMBC, and HMQC, broad-band or CW $^{31}P$ decoupling experiments when necessary. The numbering used for NMR assignments is depicted in Figure 3. IR analyses were recorded with Perkin–Elmer FT 1725x. Elemental analyses were performed by the Service d'Analyse du LCC, Toulouse, France. Compounds **1**,[17] **2**,[20] and $H_2NNMeP(S)(OC_6H_4PPh_2)_2$[23] were synthesized according to methods previously reported.

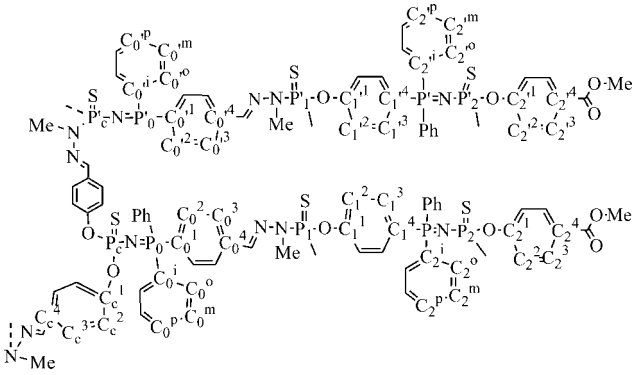

Figure 3. Numbering scheme used for NMR assignments.

**Synthesis and Characterization of 3:** To a solution containing 51 mg (0.050 mmol) of **1** in dichloromethane (5 mL) at room temp. was added 67 mg (0.23 mmol, slight excess) of $Ph_2P(C_6H_4CHO)$. The reaction mixture was stirred at room temp. overnight and concentrated to dryness. The crude residue was washed with a THF/pentane mixture to afford **3** as a white powder in 92% yield (95 mg). $^{31}P\{^1H\}$NMR (81.015 MHz, $CDCl_3$): $\delta$ = 13.4 (d, $^2J_{PP}$ = 27 Hz, $P'_c$ = N), 15.8 (d, $^2J_{PP}$ = 32 Hz, $P_c$=N), 55.9 (d, $^2J_{PP}$ = 32 Hz, $P_0$=S), 60.8 (d, $^2J_{PP}$ = 27 Hz, $P'_0$=S) ppm. $^1H$ NMR (200.132 MHz, $CDCl_3$): $\delta$ = 3.14 (br. d, $^3J_{HP}$ = 7.5 Hz, 12 H, NMe), 6.94–7.91 (m, 76 H, CH=N, $H_{arom}$), 9.91 (s, 2 H, CHO), 9.95 (s, 2 H, CHO) ppm. $^{13}C\{^1H\}$ NMR (62.896 MHz, $CDCl_3$): $\delta$ = 32.65 (d, $^2J_{CP}$ = 9.4 Hz, NMe), 121.57 (br. s, $C_c^2$), 126.96 (s, $C_c^3$), 127.66 (d, $^1J_{CP}$ = 108.5 Hz, $C_0^i$), 128.60 (d, $^3J_{CP}$ = 12.0 Hz, $C_0^m$), 128.81 (d, $^3J_{CP}$ = 12.3 Hz, $C_0'^m$), 129.07 (d, $^3J_{CP}$ = 12.0 Hz, $C_0'^3$), 129.11 (d, $^1J_{CP}$ = 108.4 Hz, $C_0'^i$), 129.25 (d, $^3J_{CP}$ = 11.6 Hz, $C_0^3$), 131.19 (s, $C_0^p$, $C_0'^p$), 132.62 (d, $^2J_{CP}$ = 11.0 Hz, $C_0^o$), 132.80 (d, $^2J_{CP}$ = 12.0 Hz, $C_0'^o$), 132.90 (s, $C_c^4$), 133.33 (d, $^2J_{CP}$ = 11.8 Hz, $C_0^2$), 133.52 (d, $^2J_{CP}$ = 11.8 Hz, $C_0'^2$), 134.21 (s, $C_0^4$), 134.44 (s, $C_0'^4$), 135.21 (d, $^1J_{CP}$ = 102.2 Hz, $C_0^1$), 136.47 (d, $^1J_{CP}$ = 101.8 Hz, $C_0'^1$), 138.51 (d, $^3J_{CP}$ = 10.0 Hz, CH=N), 151.57 (d, $^2J_{CP}$ = 9.6 Hz, $C_c^1$), 191.70 (s, CHO) ppm. $C_{108}H_{92}N_{12}O_8P_8S_4$ (2062.02): calcd. C 62.91, H 4.50, N 8.15; found C 63.02, H 4.61, N 7.92.

**Synthesis and Characterization of 4:** To a solution containing 663 mg (1.1 mmol, slight excess) of $H_2NNMeP(S)(OC_6H_4PPh_2)_2$ in dichloromethane (10 mL) at room temp. was added 815 mg (2 mmol) of $N_3P(S)(OC_6H_4CO_2Me)_2$. The reaction mixture was stirred at room temp. overnight and concentrated to dryness. The crude residue was flash-chromatographed on silica gel (dichloromethane as eluent) to afford **4** as a white powder in 90% yield (1.28 g). $^{31}P\{^1H\}$NMR (81.015 MHz, $CDCl_3$): $\delta$ = 16.1 (d, $^2J_{PP}$ = 30.6 Hz, P), 53.8 (d, $^2J_{PP}$ = 30.6 Hz, $P_2$), 68.51 (s, $P_1$) ppm. $^1H$ NMR (250.133 MHz, $CDCl_3$): $\delta$ = 3.19 (d, $^3J_{HP}$ = 10.8 Hz, 3 H, NMe), 3.87 (s, 12 H, OMe), 7.17–7.94 (m, 44 H, $H_{arom}$) ppm. $^{13}C\{^1H\}$ NMR (62.896 MHz, $CDCl_3$): $\delta$ = 41.35 (d, $^2J_{CP}$ = 13.7 Hz, NMe), 52.11 (s, OMe), 121.13 (dd, $^3J_{CP}$ = 6.3 Hz, $^3J_{CP}$ = 15.3 Hz, $C_1^2$), 121.40 (d, $^3J_{CP}$ = 5.8 Hz, $C_2^2$), 125.02 (dd, $^1J_{CP}$ = 108.3 Hz, $^3J_{CP}$ = 4.6 Hz, $C_1^4$), 128.15 (dd, $^1J_{CP}$ = 108.2 Hz, $^3J_{CP}$ = 4.4 Hz, $C_2^i$), 128.80 (d, $^2J_{CP}$ = 12.3 Hz, $C_2^m$), 131.06 (s, $C_2^3$), 132.68 (d, $^2J_{CP}$ = 11.7 Hz, $C_2^o$), 132.85 (s, $C_2^p$), 132.91 (s, $C_2^4$), 134.75 (d, $^2J_{CP}$ = 12.0 Hz, $C_1^3$), 154.16 (d, $^2J_{CP}$ = 7.9 Hz, $C_1^1$), 155.75 (d, $^2J_{CP}$ = 8.2 Hz, $C_2^1$), 166.61 (s, C=O) ppm. IR (KBr): $\tilde{\nu}$ = 1718 $cm^{-1}$ (CO). $C_{69}H_{61}N_4O_{14}P_5S_3$ (1421.31): calcd. C 58.31, H 4.33, N 3.94; found C 58.42, H 4.51, N 3.80.

**Synthesis and Characterization of $N_3P(S)(OC_6H_4CO_2Me)_2$:** To a solution containing 4.000 mL (39.3 mmol) of $PSCl_3$ in THF (100 mL) at –95 °C was added dropwise a solution of 15.584 g (82.7 mmol, slight excess) of methyl 4-hydroxybenzoate and 16.5 mL (82.7 mmol, slight excess) of triethylamine in THF (150 mL). The reaction mixture was allowed to reach room temperature overnight and the white precipitate was filtered off. After solvent removal under reduced pressure, the crude oil was dissolved in acetone (50 mL) and treated with 5.850 g (90 mmol, slight excess) of sodium azide at room temperature for 2 d. The precipitate was removed by filtration, and after solvent removal under reduced pressure, the azide was extracted from the crude oily product with pentane. Evaporation of pentane afforded the expected compound as a white powder in 75% yield (12.00 g). $^{31}P\{^1H\}$ NMR (81.015 MHz, $CDCl_3$): $\delta$ = 61.3 (s) ppm. $^1H$ NMR (250.133 MHz, $CDCl_3$): $\delta$ = 3.89 (s, 6 H, OMe), 7.27 (d, $^3J_{HH}$ = 7.6 Hz, 4 H, $H_{arom}$), 8.06 (d, $^3J_{HH}$ = 7.6 Hz, 4 H, $H_{arom}$) ppm. $^{13}C\{^1H\}$ NMR (62.896 MHz, $CDCl_3$): $\delta$ = 52.33 (s, OMe), 121.17 (d, $^3J_{CP}$ = 4.4 Hz, $C_b$), 128.23 (s, $C_d$), 131.66 (s, $C_c$), 153.22 (d, $^2J_{CP}$ = 8.0 Hz, $C_a$), 165.96 (s, C=O) ppm. $C_{16}H_{14}N_3O_6PS$ (407.34): calcd. C 47.18, H 3.46, N 10.32; found C 47.19, H 3.52, N 10.19.

**Synthesis and Characterization of 5:** To a solution containing 65 mg (0.032 mmol) of **3** in dichloromethane (5 mL) at room temp. was added 182 mg (0.128 mmol) of **4**. The reaction mixture was stirred at room temp. overnight and the residue was precipitated with diethyl ether, filtered and washed twice with 20 mL of diethyl ether to afford **5** as a white powder in 95% yield (230 mg). $^{31}P\{^1H\}$ NMR (161.975 MHz, $CDCl_3$): $\delta$ = 14–15 (m, $P'_0$=N), 16.3 (d, $^2J_{PP}$ = 31 Hz, $P_0$=N), 16.5 (d, $^2J_{PP}$ = 31 Hz, $P_0$=N), 16.7 (d, $^2J_{PP}$ = 31 Hz, $P_0$=N), 17.05 (d, $^2J_{PP}$ = 30 Hz, P=N, P′=N), 53.2 (d, $^2J_{PP}$ = 30.0 Hz, $P_2$=S, $P'_2$=S), 54.6 (d, $^2J_{PP}$ = 31 Hz, $P_c$=S), 54.9 (m, $P_c$=S), 59.3–60.0 (m, $P'_c$=S), 63.2 (s, $P_1$, $P'_1$) ppm. $^1H$ NMR (400.130 MHz, $CDCl_3$): $\delta$ = 3.21 (br. s, 12 H, $P'_0$-NMe), 3.37 (br. s, 12 H, $P_1$-NMe and $P'_1$-NMe), 3.84 (s, 48 H, $CO_2Me$), 7.02–7.98 (m, 256 H, CH=N, $H_{arom}$) ppm. $^{13}C\{^1H\}$ NMR (100.613 MHz, $CDCl_3$): $\delta$ = 33.23–33.86 (m, NMe), 52.53 (s, OMe), 121.78 (d, $^3J_{CP}$ = 4.8 Hz, $C_2^2$, $C_2'^2$, $C_c^2$), 122.05 (dd, $^3J_{CP}$ = 5.2 Hz, $^3J_{CP}$ = 12.9 Hz, $C_1^2$, $C_1'^2$), 125.85 (d, $^1J_{CP}$ = 108.2 Hz, $C_1'^4$, $C_1^4$), 128.35 (d, $^1J_{CP}$ = 108.1, $C_2^i$, $C_2'^i$), 128.53 (s, $C_c^3$), 128.96 (s, $C_2^4$, $C_2'^4$), 129.24 (br. d, $^3J_{CP}$ = 13.1 Hz, $C_0^m$, $C_2^m$, $C_0^3$, $C_0'^m$, $C_2'^m$, $C_0'^3$), 131.48 (s, $C_2^3$, $C_0^p$, $C_2'^3$, $C_0'^p$), 133.05 (br. d, $^2J_{CP}$ = 10.8 Hz, $C_0^o$, $C_2^o$, $C_0'^o$, $C_2'^o$), 133.34 (br. s, $C_0^4$, $C_2^p$, $C_0'^4$, $C_2'^p$), 133.80 (br. s, $C_0^2$, $C_0'^2$), 135.18 (d, $^2J_{CP}$ = 11.9 Hz, $C_1^3$, $C_1'^3$), 138.81–139.68 (m, CH=N), 152.17 (br. s, $C_c^1$), 154.25 (br. s, $C_1^1$, $C_1'^1$), 156.15 (d, $^2J_{CP}$ = 8.9 Hz, $C_2^1$, $C_2'^1$), 166.92 (s, C=O) ppm. IR (KBr): $\tilde{\nu}$ = 1718 $cm^{-1}$ (CO). $C_{384}H_{328}N_{28}O_{60}P_{28}S_{16}$ (7675.2): calcd. C 60.09, H 4.31, N 5.11; found C 60.01, H 4.40, N 5.01.

# DFT-Verified Crystallographic Mechanism of Cycloplatination

**Stefanus Otto,*[a][‡] Arani Chanda,[b] Pavel V. Samuleev,[c] and Alexander D. Ryabov*[b]**

**Keywords:** Platinum / C-H activation / Metallacycles / X-ray diffraction / Density functional calculations

Two key intermediates in the mechanistic cycle of cycloplatination of aryl oximes by $Pt^{II}$ complexes were crystallographically characterized. *trans*-[$PtCl_2(SOMe_2)$(*N*-acetophenone oxime)] is an active precursor on the C–H cleavage reaction coordinate. The formation of *trans*-[$PtCl_2$(*N*-benzaldehyde oxime)$_2$] accounts for the rate retardation by excess oxime. DFT calculations support the crystallographic evidence that provides unequivocal proof for the electrophilic nature of cycloplatination.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2006)

Disclosure of mechanisms of cyclometalation by transition-metal complexes is a difficult task.[1a] Cyclometalation is a multistep event that should include (i) ligand coordination to a metal center through its usually N, P, O, or S donor site (X), and (ii) a stepwise metal-involved cleavage of the C–H bond (Scheme 1).

Step (i) is an intermolecular ligand substitution, which may occur through associative, dissociative, or interchange pathways. Step (ii) is a combination of intramolecular ligand substitution and C–H cleavage. Options for the C–H cleavage include oxidative addition/reductive elimination, electrophilic substitution, or multicentered activation (σ-bond metathesis).[1a,1b] Agostic interactions[2] are also often included in a mechanistic picture.[3] Consequently, extensive efforts are required for the unequivocal understanding of cyclometalation mechanisms. A complicating factor is that mechanistic studies are often performed with excess incoming ligand X~C–H and may result in the binding of more than one ligand to the metal center.

All stated above apply to cycloplatination by the $Pt^{II}$ sulfide and sulfoxide complexes [$PtCl_2(SR_2)_2$] or [$PtCl_2(SOR_2)_2$]. These metalating agents are very convenient for performing various cycloplatination reactions,[4] and the use of chiral sulfoxides SORR′ allows for the synthesis of platinacycles with the planar[5a] and central carbon chirality.[5b] We recently reported on the mechanism of cycloplatination of aryl oximes by [$PtCl_2(SR_2)_2$] or *cis*-[$PtCl_2(SOR_2)_2$] (R = Me) as shown in Scheme 2.[6] Evidence was presented that the cycloplatination is a multistep process and the principal reaction steps were recognized. The key intermediate was identified as complex **A**, which supports the views of other authors.[7] The formation of dichlorobis(*N*-oxime)platinum(II) **B** was postulated to account for the rate retardation by excess acetophenone oxime. Our deductions were based on kinetic and $^1$H NMR spectroscopic data that may leave room for alternative interpretations. In this communication, we report X-ray crystallographic data for the compounds matching the intermediates **A** and **B**. They are complexes **1** and **2**, respectively. Although mechanistic chemists should apply caution when using solid-state information for the interpretation of kinetic data obtained in solution, the structures of complexes **A** and **B** are exceptionally mechanistically informative towards the dynamics of intramolecular C–H bond activation by $Pt^{II}$. The mech-

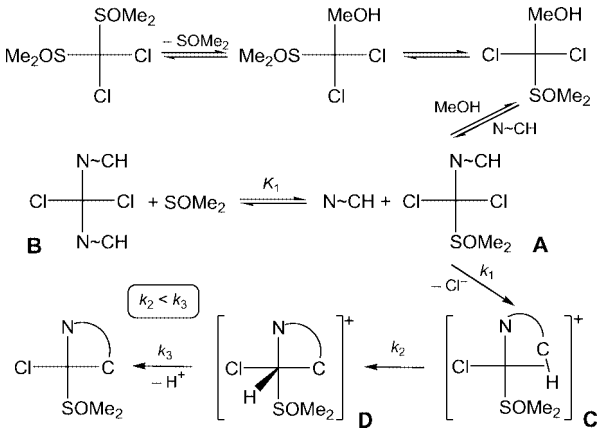
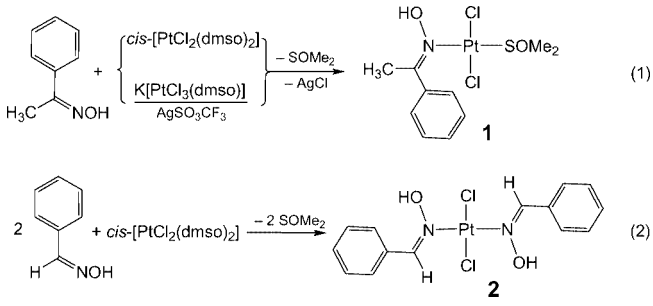
anistic conclusions made were verified, supported, and refined by theoretical analysis of key participants in Scheme 2 with DFT calculations.



Scheme 2. Mechanism of cycloplatination of aryl oximes by *cis*-$[PtCl_2(dmso)_2]$ suggested in ref.[6]

Compounds **1** and **2** were synthesized according to Equations (1) and (2), respectively, and characterized by $^1H$ NMR spectroscopy, analytical data, and X-ray crystallography. Crystal structures of **1** and **2** are displayed in Figure 1. Both complexes exhibit a square-planar geometry. The N-atom of the acetophenone oxime is in *trans* position relative to the sulfur atom of dmso in complex **1**. The phenyl plane of the oxime ligand is orientated almost perpendicularly to the metal plane with a Cl(1)–Pt–N–C(10) torsion angle of 69.1°. The phenyl ring is in the axial position with a closest Pt···C(16) contact of 3.153 Å [Pt···H(16) 2.852 Å]. The Pt–S(1) and Pt–N(1) bond lengths of 2.206(3) and 2.051(9) Å, respectively, are within normal ranges for bonds of this type. The Pt–Cl(1) and Pt–Cl(2) bond lengths of 2.287(3) and 2.293(3) Å, respectively, do not differ significantly and are within expected ranges.



Compound **2** crystallizes with the inversion center in the triclinic space group $P\bar{1}$ resulting in a mutually *trans* configuration of the oxime and chloro ligands with the oxime ligands located in the coordination plane. The hydroxy group is directed towards a chloro ligand, typical of many oxime complexes of Pd and Pt.[8] There is a Cl···H–O interaction, with Cl···O and Cl···H separations of 3.056 and 2.408 Å, respectively. The Pt–Cl(1) and Pt–N(1) bond lengths of 2.3053(19) and 2.021(6) Å, respectively, are within normal ranges for complexes of this type.

Crystallographically characterized species **1** and **2** do prove unambiguously the existence of the proposed intermediates **A** and **B**, respectively, shown in Scheme 2. Importantly, both structural and DFT (see below) data provide evidence why complex **B** is not on the reaction coordinate. In contrast, **A** is adequately pre-organized for subsequent metalation of the C–H bond. The azomethine unit geometry is an essential feature. Data in Figure 1 confirm the (*E*) and (*Z*) configuration of the C=N unit in complexes **1** and **2**, respectively. To avoid any confusion, all assignments are made for imaginary free aryl oximes, which are *not* bound to $Pt^{II}$. The (*Z*) geometry in **2** implies that the *trans*-bis(oxime)platinum(II) unit should be unreactive towards cyclometalation. The *ortho* C–H bonds are located too far from the metal center with a shortest Pt···H–C(16) distance of 4.916 Å. In contrast to **2**, the geometry at the C=N unit in

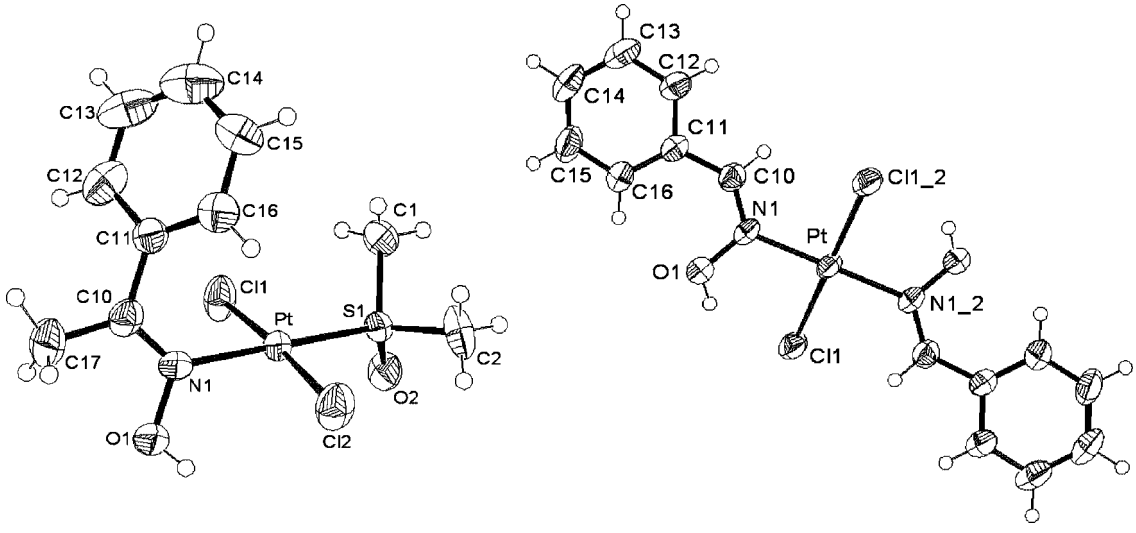


Figure 1. ORTEP diagrams of **1** (left) and **2** (right) at 30% probability level. Hydrogen atoms are of arbitrary size. Selected bond lengths [Å]: **1**: Pt–Cl(1) 2.287(3), Pt–Cl(2) 2.293(3), Pt–N(1) 2.051(9), Pt–S(1) 2.206(3); **2**: Pt–Cl(1) 2.3053(19), Pt–N(1) 2.021(6).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the mono(aryl oxime) complex **1** is (*E*) resulting in **1** being much better arranged for the subsequent C–H bond activation. In fact, different geometries at the C=N moiety in monomeric bis- and mono(oxime) complexes of $Pt^{II}$ is a notable observation because the aspect of geometric isomerization at the C=N bonds was rather confusing. This is understandable because the geometry of ligands in free and cyclometalated states may be different. For example, azomethines are sometime involved in (*E*) → (*Z*) isomerization during cyclometalation.[4j] As in the case of **1**, the binding of the (*E*) form of the aryl oxime delivers its *ortho* C–H bond to the proximity of the metal center. The Pt···C(16) separation is only 3.153 Å. For comparison, $Pt^{II}$ is further away from the C–H bond of the Cp ring in *trans*-[$PtCl_2(CpFeC_5H_4CMe{=}NPh)$dmso] and therefore an additional external base is needed to facilitate the C–H bond cleavage.[9] Note that cycloplatination of **1** occurs spontaneously in methanol without basic co-catalyst.

Assuming that the short Pt···C(16) separation is evidence that complex **1** is on the reaction coordinate, several comments could be made based on mutual atom arrangement in **1**. The C(16) atom is located right above the Pt–N bond and H(16) is directed at Cl(2). Therefore, there is a favorable setup of all key groups involved in cycloplatination for an easy conversion of **A** into **C** (Scheme 2). Essential is just the dissociation of chloride Cl(2) that gives intermediate **C**. Based on the data reported here, elsewhere,[6,10,11] and the results of DFT analysis of this particular system (see below) we suggest a first DFT-verified "crystallographic" mechanism of cycloplatination by *cis*-[$PtCl_2(SOMe_2)_2$] (Figure 2), which actually involves all major steps of the "kinetic" mechanism in Scheme 2. A strength of the "crystallographic" mechanism is that ***all*** the compounds in Figure 2 have now been characterized by X-ray crystallography including the starting complex *cis*-[$PtCl_2(SOMe_2)_2$] and the incoming aryl oxime.

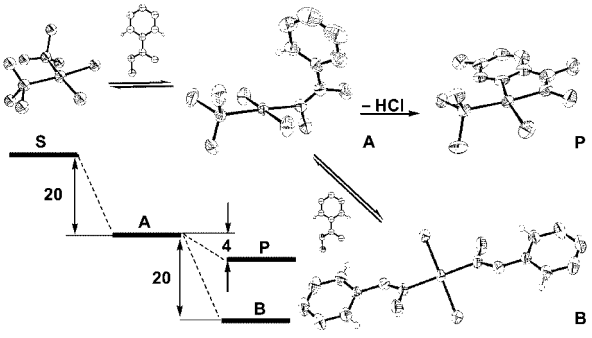

Figure 2. "Crystallographic" mechanism of cycloplatination of aryl oximes by *cis*-[$PtCl_2(SOMe_2)_2$]. X-ray data for $Pt^{II}$ complexes **S** and **P** are from ref.[10] and ref.[6], respectively; structures **A** and **B** are reported in this work. A structure of (*E*)-acetophenone oxime was published by Gieren, et al.[11] At the bottom left is the DFT-calculated diagram with energies in kcal mol$^{-1}$.

The geometries of all structures in Figure 2 are optimized using Becke's three-parameter hybrid potential (B3LYP) with LANL2DZ basis set as provided by Gaussian 03.[12] Optimizations are done in the absence of any solvent. The optimized geometries are in general agreement with the experimental bond lengths/angles. Longer Pt–Cl and Pt–S but shorter Cl···HO bond lengths (all by 0.1–0.2 Å) were, however, observed. Substitution of the S- by the N-donor ligand to form intermediate **A** is energetically favorable (ca. 20 kcal mol$^{-1}$), as well as the second exergonic substitution leading to **B**. As a result, *Z* configured intermediate **B** is in a deep energy well and its C–H bonds are inaccessible for cycloplatination (Figure 2).

Our theoretical simulations indicate that the C–H bond activation (**A** → **P**) ***never*** occurs when both chloride ions are bound to $Pt^{II}$. In other words, there is no C–H breaking pathway through an axial agostic contact. The evidence for the C–H bond activation begins to emerge after enforced dissociation of chloride as shown in Figure 3. Here, complex **A′** is generated by removing one chloride ion from the DFT-optimized structure of **A**. Geometry optimization of **A′** results in **C′**, which matches nicely the postulated intermediate **C** in Scheme 2. Remarkably, the C–H bond carbon atom in **C′** aligns itself *in the metal plane* and is almost ideally *trans* to the chloro ligand with a C···Pt–Cl angle of 165°. Hence, the in-plane disposition of the C–H bond is absolutely crucial for the reaction to happen. The Pt–C distance changes from 3.153 Å (in **A**) to 2.519 Å in **C′** to become finally 2.021 Å in **P**. The Mulliken charge on the carbon atom varies drastically as well, viz. –0.304 (**A**) → –0.449 (**C′**) → –0.193 (**P**), indicating a major development of a carbanion character of the C–H bond carbon atom in high-energy intermediate **C′**. Elongation of the $C^1$–$C^2$ bond (1.438 vs. average 1.410 Å for other aryl C–C bonds of **C′**, Figure 3) supports also the "carbanionic" hypothesis. This also shows that the hydrogen atom should dissociate rather as proton in an electrophilic substitution sequence. DFT calculations show that the cycloplatination of the C–H bond (**A** → **P**) is 4–5 kcal mol$^{-1}$ favorable when the leaving HCl is allowed to interact with product **P**.[13] If the energies of **P** and HCl are calculated separately, the cycloplatination reaction is ca. 10 kcal mol$^{-1}$ endergonic. This scenario may be different in the presence of methanol as solvent where H-bonding should play a significant role. Apparently, the chloro ligand is somehow involved in the stabilization of the leaving hydrogen atom. Mechanistic options are either chloride interacts with $H^+$ as a base, thus precluding reverse

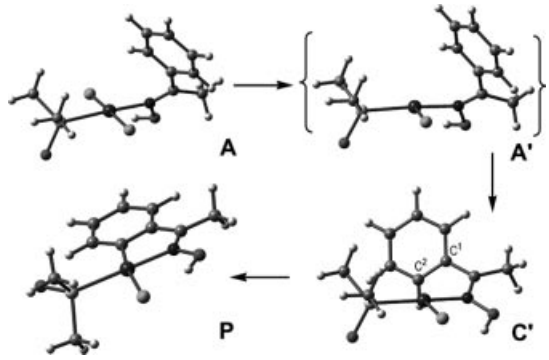

Figure 3. DFT-optimized structures of intermediates **A**, **C′**, and product **P**, see text for details.

protonolysis of the Pt–C bond of **P**, or its role is a compensation of a positive charge of intermediate **D** in Scheme 2.

In conclusion, a combination of kinetic and X-ray structural data plus theoretical DFT information generated a unified, self-consistent detailed mechanistic picture of the electrophilic C–H bond cyclometalation by platinum(II). The DFT routine filled elegantly the mechanistic gaps, about which kinetics and crystallography are usually silent.

## Experimental Section

**Chemicals:** Acetophenone oxime (Acros), benzaldehyde oxime (Acros), $SOMe_2$ (Merck) and $AgSO_3CF_3$ (Aldrich) were used as received, methanol (Riedel–de Haën) was of analytical grade and was freshly distilled from $CaH_2$ under dinitrogen prior to use.

**NMR Measurements:** The $^1H$ NMR spectra were recorded at 295 K as $CD_3OD$ or $CDCl_3$ solutions with either a Bruker 300 MHz or a Varian Unity 300 spectrometer operating at 299.78 MHz; the spectra were calibrated relative to TMS at $\delta = 0$ ppm.

**Preparation of Complexes:** $K[PtCl_3(SOMe_2)]$ and *cis*-$[PtCl_2(SOMe_2)_2]$ were prepared according to literature procedures.[14,15]

***trans*-[PtCl$_2${HO–N=C(CH$_3$)C$_6$H$_5$}(SOMe$_2$)] (1). (a)** A homogeneous solution of *cis*-$[PtCl_2(SOMe_2)_2]$ (104 mg, 0.246 mmol) was prepared in methanol (30 mL) by gently heating with effective stirring for 2 h. Acetophenone oxime (35 mg, 0.26 mmol) in methanol (5 mL) was added at ambient temperature and the solution was stirred for 30 min. The reaction mixture was concentrated to 20 mL under a flow of nitrogen and left at 15 °C to crystallize by slow evaporation of methanol. Crystals of **1** suitable for X-ray diffraction were obtained. **(b)** $AgSO_3CF_3$ (64 mg, 0.25 mmol), dissolved in methanol (5 mL), was added to a solution of $K[PtCl_3(SOMe_2)]$ (100 mg, 0.239 mmol), also in methanol (25 mL). The resulting mixture was stirred for 15 min to facilitate the precipitation of AgCl and was subsequently filtered to yield a clear solution. Acetophenone oxime (34 mg, 0.25 mmol) in methanol (5 mL) was added at ambient temperature and the solution was stirred for 10 min. Evaporation of the methanol resulted in isolation of **1** in almost quantitative yield. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.50 (s, 3 H, $CCH_3$), 3.24 (t, $^3J_{PtH}$ 19 Hz, 6 H, $SCH_3$), 7.50 (m, 3 H, 2-H, 4-H, 6-H), 7.90 (m, 2 H, 3-H, 5-H), 8.00 (s, 1 H, OH) ppm. $C_{10}H_{15}Cl_2NO_2PtS$ (477.98): calcd. C 25.1, H 3.2, N 2.9; found C 25.4, H 3.6, N 2.7.

***trans*-[PtCl$_2$(HO–N=CHC$_6$H$_5$)$_2$] (2):** Benzaldehyde oxime (592 mg, 4.89 mmol) was added to a solution of $K[PtCl_3(SOMe_2)]$ (210 mg, 0.50 mmol) in methanol (25 mL) and the reaction mixture was subsequently refluxed for 4 d. The reaction progress was monitored by $^1H$ NMR spectroscopy as described previously.[6] Yield 119 mg (48%). $^1H$ NMR ($CDCl_3$): $\delta$ = 7.4–7.6 (m, 6 H, 2× 2-H, 2× 4-H, 2× 6-H), 7.93 (m, 4 H, 2× 3-H, 2× 5-H), 8.19 (t, $^3J_{PtH}$ = 22 Hz, 2 H, 2× CH), 9.56 (s, 2 H, 2× OH) ppm. $C_{14}H_{14}Cl_2N_2O_2Pt$ (507.01): calcd. C 33.1, H 2.8, N 5.5; found C 33.4, H 3.0, N 5.4.

**Crystallography:** The data collections were carried out with a Siemens SMART CCD diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and ω-scans at 293(2) K. After completion of the data collection, the first 50 frames were repeated to check for decay, of which none was observed. All reflections were merged and integrated using SAINT[16] and were corrected for Lorentz, polarization and absorption effects using SADABS.[17] The structure was solved by the heavy-atom method and refined through full-matrix least-squares cycles using the SHELXL97[18] software package with $\Sigma(|F_o| - |F_c|)^2$ being minimized. All non-H atoms were refined with anisotropic displacement parameters while the H atoms were placed in geometrically idealized positions and constrained to ride on their parent atoms (aromatic C–H 0.93 Å, aliphatic C–H 0.96 Å, O–H 0.82 Å). For both structures the minimum and maximum residual electron densities were located within 1 Å of the platinum nuclei indicating no physical meaning. The crystal data and details of the data collection and refinement are given in Table S1 with selected geometrical parameters in Table S2. Crystallographic data have been deposited with the Cambridge Crystallographic Data Center as supplementary publications CCDC-290273 and -290274 (**2** and **1**, respectively). These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Crystal data and structure refinement parameters, bond lengths and bond angles in Tables S1 and S2.

# Triple-Decker Transition-Metal Complexes $(C_nH_n)M(B_6C)M(C_nH_n)$ (M = Fe, Ru, Mn, Re; $n$ = 5, 6) Containing Planar Hexacoordinate Carbon Atoms

**Si-Dian Li,*[a] Chang-Qing Miao,[a] Guang-Ming Ren,[a] and Jin-Chang Guo[a]**

**Keywords:** Planar hexacoordinate carbon / Triple-decker transition-metal complexes / Density functional theory / Geometric structures / Electronic structure / IR spectroscopy

A density functional theory investigation is presented in this work on a new class of triple-decker complexes $(C_nH_n)M(B_6X)M(C_nH_n)$ (M = Fe, Ru, Mn, Re; X = B, C, N; $n$ = 5, 6) containing almost perfect planar hexacoordinate carbon atoms and other planar hexacoordinate nonmetals at the centers of the $B_6X$ middle-deckers. Effective d–π coordination interactions between the partially filled 3d orbitals of the transition-metal center and the delocalized π orbitals of the three parallel ligands maintain the stabilities of these triple-decker complexes. The strong IR absorption peaks of $(C_nH_n)M(B_6X)M(C_nH_n)$ complexes mainly originate from the in-plane and off-plane vibrations of their planar hexacoordinate nonmetal centers. The results obtained in this work provide a possible new approach to characterize planar hexacoordinate carbon-containing systems in future experiments and expand the structural domain of transition-metal complexes by introducing inorganic $B_6X$ middle-deckers into traditional sandwich-type structures.

## Introduction

As a challenge to tetrahedral carbon, which has dominated organic chemistry and biochemistry for over 130 years, planar tetracoordinate carbon (ptC) was first proposed by Hoffmann et al.[1] about 30 years ago and was recently observed in gas phases in $D_{4h}$ $Al_4C^-$,[2] $C_{2v}$ $Al_3XC$, $Al_3XC^-$ (X = Si, Ge),[3,4] and $[CAl_4]^{2-}$.[5] The smallest anion with a ptC at its center is $D_{2h}$ $C_5^{2-}$, which has been incorporated in various neutral molecules.[6] Theoretical studies on planar coordinate carbon atoms also include planar pentacoordinate carbon atoms (ppCs) in $B_3C_2H_2C$ and extended systems[7] and planar hexacoordinate carbon atoms (phCs) in the $B_6C^{2-}$ dianion.[8] Designing and characterizing new forms of planar coordinate C atoms remains a huge challenge in chemistry. In a series of recent works at density functional theory (DFT) level, our group developed a strategy to incorporate planar coordinate group IV elements at the centers of various hydrometal polygons, including ptC in $M_4H_4C$ (M = Cu, Ni),[9] ppC in $Cu_5H_5X$ (X = B, C, N, O),[10] planar pentacoordinate silicon (ppSi) in $M_5H_5X$ (M = Pd, Pt; X = Si, Ge),[11] and planar hexacoordinate silicon (phSi) in $Cu_6H_6X$ (X = Si, Ge) complexes.[12] Employing $B_6C^{2-}$ as an aromatic ligand, in a recent communication,[13] we incorporated quasi-phCs in a new class of sandwich-type complexes $(B_6C)_2M$ (M = Mn, Fe, Co, Ni). In this work at DFT level, we introduce $B_6C^{2-}$ to a novel class of triple-decker complexes $(C_nH_n)M(B_6C)M(C_nH_n)$ (M = Fe, Ru, Mn, Re; $n$ = 5, 6) that contain almost perfect phCs at the centers of the $B_6C$ middle-deckers. Similar results are also obtained for their isoelectronic complexes with planar hexacoordinate boron (phB) or planar hexacoordinate nitrogen (phN) centers. In the triple-decker[14] and multi-decker[15] complexes reported before, the hexanuclear benzene-centered tris(alkynyl triple-decker) complex[14] is particularly interesting, in which the three ligands around the benzene core are typical triple-decker complexes with a $C_2B_3$ ring as the middle-decker. However, to the best of our knowledge, there have been no triple-decker complexes with phCs, phBs, or phNs reported to date in the literature.

## Theoretical Method

As the phC-containing $B_6C^{2-}$ unit[8] is a 6π-electron aromatic dianion, while $C_5H_5^-$ is a 6π-electron monoanion, to meet the 18-electron requirements of the two $Fe^{II}$ centers, the most possible triple-decker structure of a dinuclear neutral $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ would contain a $B_6C^{2-}$ middle-decker to balance the overall molecular charge of the system, while the two $C_5H_5^-$ rings serve as terminal ligands, with the whole complex possessing a $C_{2v}$ symmetry. But a singlet $C_{2v}$ $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ turned out to be a transition state with one imaginary frequency. Relaxing the system in the imaginary vibrational mode leads to a slightly distorted $C_2$ structure that is a true minimum. The initially optimized structures with $C_2$ symmetries obtained at the hybrid DFT-B3LYP/6-31+G(d) level were refined comparatively with the bigger bases of 6-311+G(d,p) and 6-

[a] Institute of Materials Sciences and Department of Chemistry, Xinzhou Teachers' University, Xinzhou 034000, Shanxi, P. R. China

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

311+G(3df,p) and the optimized results turned out to be quite insensitive to the bases employed. When $C_5H_5^-$ terminal ligands are replaced with two neutral benzene molecules $C_6H_6$, two $Mn^I$ centers are required to replace $Fe^{II}$ to follow the 18-electron rule. Natural bond orbital (NBO) analyses[16] and zero-point energy (ZPE) corrections were performed in the frequency analyzing processes. Results obtained at B3LYP/6-311+G(d,p) level are presented in this work hereafter for the first-row transition-metal complexes. For heavy transition-metal complexes, we choose the basis of 6-31+G(d,p) for nonmetal atoms and Lanl2dz[17] (which contains an effective core potential for transition metals) for the second- and third-row transition metals. Figure 1 depicts the optimized structures that are true minima on their potential energy surfaces and Table 1 tabulates their geometrical and electronic properties. Figure 2 shows the typical molecular orbitals (MOs) of $C_2$ $(C_5H_5)Fe(B_6C)$-$Fe(C_5H_5)$ involving Fe 3d orbitals and the delocalized π orbitals of the three parallel ligands and Figure 3 demonstrates the calculated IR spectra of $C_2$ $(C_5H_5)Fe(B_6C)$-$Fe(C_5H_5)$ and $C_2$ $(C_6H_6)Mn(B_6C)Mn(C_6H_6)$ to facilitate future spectroscopic investigations. All the calculations in this work were performed using the Gaussian 03 program.[18]

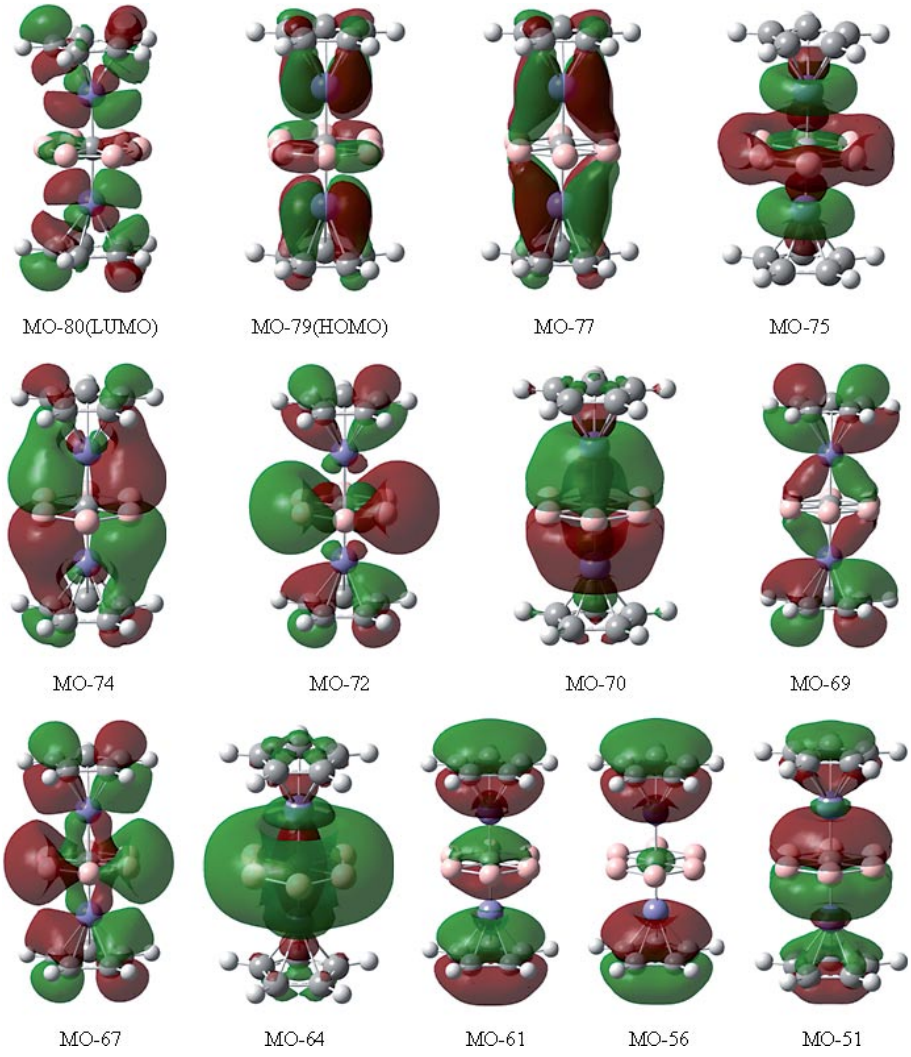

Figure 2. Typical MO pictures of $C_2$ $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ involving Fe 3d and the delocalized π orbitals of the three parallel ligands. For doubly degenerate orbitals, only one of them is depicted.

## Results and Discussion

As shown in Figure 1, all the triple-decker structures possess a real lowest vibrational frequency corresponding to rotations of the three parallel ligands about the M–phX–M molecular axis (with the two $C_nH_n$ terminal ligands rotating clockwise while the $B_6X$ middle-decker rotates anticlockwise) with a small energy barrier of about 2 kcal/mol, similar to the lowest-energy rotary vibrational modes of the well-known sandwich-type $(C_5H_5)_2Fe$ and $(C_6H_6)_2Cr$. But a singlet $C_2$ $(C_5H_5)Fe(B_6N)Fe(C_5H_5)^+$ monocation turned out to be a transition state with one imaginary frequency at 62i $cm^{-1}$ (an up-and-down movement of the $B_6$ ring along the Fe–phN–Fe axis). Structural analyses indicate that the three quasiplanar ligands intervened by two Fe atoms in the prototypic $C_2$ $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ are almost perfectly parallel to one another, with the three axial atoms of Fe, phC, and Fe being nearly collinear with the bond angle of $\theta_{Fe–phC–Fe}$ = 177.8° and the averaged bond lengths of $r_{Fe–C}$ = 2.057 Å, $r_{Fe–B}$ = 2.474 Å, $r_{Fe–phC}$ = 1.884 Å, and $r_{B–B}$ = 1.603 Å. All the $(C_nH_n)M(B_6X)M(C_nH_n)$ complexes (M = Fe, Ru; X = B, C, N; $n$ = 5, 6) possess very similar triple-decker structures featured with the $B_6X$ middle-deckers, which are almost perfect hexagons with phX atoms located at their geometrical centers and approximately equal B–B and phX–B bond lengths ($r_{B–B} \approx r_{phX–B}$). The B–B bond lengths in the middle-deckers of these complexes (see Table 1 for details) are slightly longer than the corresponding B–B distance of 1.594 Å in free $B_6C^{2-}$.[8] The calculated Fe–C bond lengths of 2.057 Å in $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ turned out to be very close to the corresponding measured values of 2.064 Å in ferrocene $(C_5H_5)Fe(C_5H_5)$,[19] while the Fe–phC distances of 1.884 Å are 0.224 Å longer than the corresponding Fe–phC distance in half-sandwich-type $(B_6C)Fe$.[13] This suggests that a triple-decker $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ complex could be constructed by inserting a half-sandwich-type $(B_6C)Fe$ into a ferrocene molecule $(C_5H_5)Fe(C_5H_5)$. The middle-decker $B_6C^{2-}$ in structure **2** acts as a bridge to link two half-sandwich-type $(C_5H_5)Fe$ together by forming two Fe–phC inter-

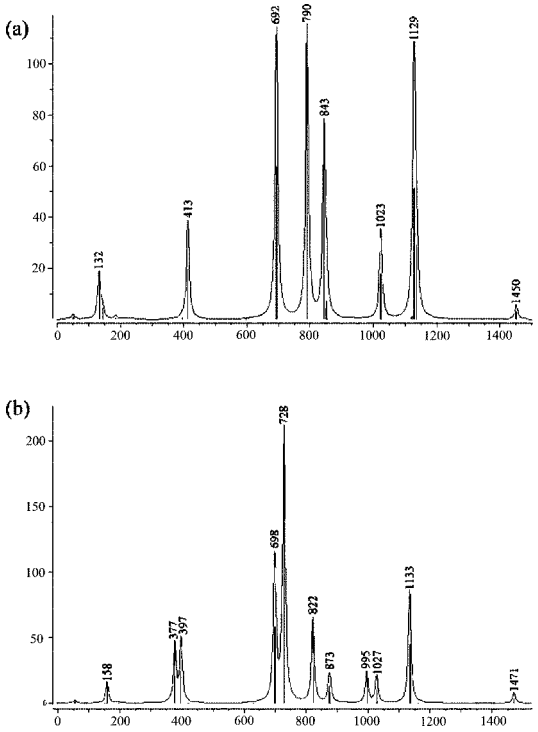

Figure 3. Calculated IR spectra (in $cm^{-1}$) of $C_2$ $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ (a) and $C_2$ $(C_6H_6)Mn(B_6C)Mn(C_6H_6)$ (b).

actions. Heavy transition-metal complexes $(C_5H_5)Ru(B_6X)Ru(C_5H_5)$ (X = C, B) with $C_2$ symmetries were confirmed to be transition states. With the $C_2$ symmetry constraints removed during structural optimization, these structures were slightly distorted to $C_1$ symmetries with the lowest frequencies ($\tilde{\nu}_{min}$) of 9 and 16 $cm^{-1}$ for X = C and B, respectively.

A triple-decker $(C_6H_6)Mn(B_6C)Mn(C_6H_6)$ (**5**) with a phC center and two neutral $C_6H_6$ terminal ligands has the averaged bond lengths of $r_{Mn-C}$ = 2.104 Å, $r_{Mn-phC}$ = 1.919 Å, $r_{Mn-B}$ = 2.500 Å, and $r_{B-B}$ = 1.603 Å. The three ligands are almost perfectly parallel to one another and the Mn–C distances of 2.104 Å are well in line with the measured Cr–C distance of $r_{Cr-C}$ = 2.15 Å in $D_{6h}$ $(C_6H_6)_2Cr$. With two $C_6H_6$ terminal ligands, both phB and phN can be stabilized at the centers of the $B_6X$ middle-deckers, as indicated in Figure 1 for structures **4** and **6**, which have bond lengths of $r_{Mn-phB}$ = 1.956 Å and $r_{B-B}$ = 1.624 Å in **4** and $r_{Mn-phN}$ = 1.871 Å and $r_{B-B}$ = 1.618 Å in **6**. A triple-decker $(C_6H_6)Re(B_6C)Re(C_6H_6)$ also turned out to be a stable singlet species with $\tilde{\nu}_{min}$ = 16 $cm^{-1}$.

The stabilities of the phC-containing $C_2$ $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ and $C_2$ $(C_6H_6)Mn(B_6C)Mn(C_6H_6)$ are supported by the negative thermodynamic quantity changes of the following processes starting from stable reactants [Equation (1)].

$$(C_5H_5)_2Fe(D_5) + (B_6C)Fe(C_{6v}) = (C_5H_5)Fe(B_6C)Fe(C_5H_5)(C_2) \quad (1)$$

$$(C_6H_6)_2Mn^+(D_{6h}) + (B_6C)Mn^-(C_{6v}) = (C_6H_6)Mn(B_6C)Mn(C_6H_6)(C_2) \quad (2)$$

In Equation (2), the monocation $(C_6H_6)_2Mn^+$ with $\tilde{\nu}_{min}$ = 32 $cm^{-1}$ and monoanion $(B_6C)Mn^-$ with $\tilde{\nu}_{min}$ = 301 $cm^{-1}$ are isoelectronic with $D_{6h}$ $(C_6H_6)_2Cr$ and $C_{6v}$ $(B_6C)Fe$,[13] respectively. With ZPE corrections included, $\Delta E(1)$ = –124.8, $\Delta H(1)$ = –122.8, $\Delta G(1)$ = –87.1, and $\Delta E(2)$ = –596.2, $\Delta H(2)$ = –594.9, $\Delta G(2)$ = –554.0 kJ/mol. These negative values indicate that the desired products are favored in thermodynamics relative to the corresponding reactants. Detailed kinetic studies are beyond the reach of available computing resources at this stage.

NBO analyses indicate that all the component atoms in these complexes follow the octet rule. For example, atoms in $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ (**1**) possess the total Wiberg bond indices (WBIs) of $WBI_{phC}$ = 3.85, $WBI_C$ = 3.96, $WBI_B$ = 3.50, $WBI_H$ = 0.94, and $WBI_{Fe}$ = 2.98, respectively. The middle-decker $B_6C$ in the complex has the bond orders of $WBI_{B-B}$ = 1.14 and $WIB_{B-phC}$ = 0.56, well in line with the corresponding bond orders of $WBI_{B-B}$ = 1.29 and $WIB_{B-phC}$ = 0.63 in free $B_6C^{2-}$.[8] The slight bond-order difference is well compensated for by two extra phC–Fe interactions in vertical directions with $WBI_{phC-Fe}$ = 0.20 and $WBI_{phC}$ = 3.85 to satisfy the bonding requirement of the central carbon atom. It is also interesting to notice that the phC centers in $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ (**2**), $(C_5H_5)Ru(B_6C)Ru(C_5H_5)$ (**3**), and $(C_6H_6)Mn(B_6C)Mn(C_6H_6)$ (**5**) carry approximately unitary negative charges, with $q_{phC}$ = –0.96|e|, –1.02|e|, and –0.90|e|, respectively. This implies that the phC centers possess approximately an extra electron in triple-decker complexes. It is this extra electron, which occupies the delocalized phC $2p_z$ orbital perpendicular to the $B_6C$ middle-decker, that helps to stabilize the phC center in the complex (see Figure 2), similar to the situation of three $sp^2$ hybrids plus a doubly occupied $2p_z$ orbital in ptC-containing systems.[1,6d,9]

NBO analyses help to understand the bonding nature of these triple-decker structures. As indicated in Table 1, all these complexes possess negative HOMO energies and their HOMO–LUMO energy gaps are greater than 3.25 eV. Orbital coefficients and the MO pictures shown in Figure 2 indicate that both the degenerate HOMO(MO-79) and MO-77 of $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ mainly involve the contributions from Fe $3d_{xy}$ and $3d_{x^2-y^2}$, while MO-75, MO-70, and MO-64 are mostly composed of different interactions between Fe $3d_{z^2}$ and the delocalized π or σ orbitals of the $B_6C^{2-}$ middle-decker. The degenerate MO-74 consists almost purely of the delocalized π orbital of the middle-decker $B_6C^{2-}$. Fe $3d_{xz}$ and $3d_{yz}$ orbitals mainly participate in the formations of the degenerate MO-72, MO-69, and MO-67, while MO-61, MO-56, and MO-51 originate almost purely from the out-of-phase or in-phase interactions between the totally delocalized π orbitals of the three parallel ligands (MO-51 also involves the in-phase contribution from Fe $3d_{z^2}$). It is these d–π and π–π interactions that work together to maintain the stabilities of these triple-decker structures. MO-80, the lowest unoccupied molecular orbital with a negative orbital energy of –2.18 eV, is mainly composed of the out-of-phase overlap between Fe $3d_{yz}$ and the delocalized π orbitals of the $C_5H_5^-$ ligands.

Frequency analyses indicate that the two strong IR absorptions of $C_2$ $(C_5H_5)Fe(B_6C)Fe(C_5H_5)$ at 692 $cm^{-1}$ and 1129 $cm^{-1}$ in Figure 3 (a) mainly originate from two in-plane vibrations of the phC center within the $B_6$ ring, while the other strong peak at 790 $cm^{-1}$ corresponds to an off-plane movement of the phC center perpendicular to its $B_6$ ligand. The unsymmetrical off-plane swings of the 10 H atoms in $C_5H_5$ ligands produce the IR absorption at 843 $cm^{-1}$ and their in-plane movements result in the absorption peak at 1023 $cm^{-1}$. The weak peak at 132 $cm^{-1}$ is the result of the up-and-down movements of the $B_6$ ring along the molecular axis; meanwhile, the peak at 413 $cm^{-1}$ corresponds to unsymmetrical swings of the two $C_5H_5$ ligands and the weakest peak at 1450 $cm^{-1}$ originates from their in-plane twisting vibrations. As shown in Figure 3 (b), similar vibrational modes exist for $C_2$ $(C_6H_6)Mn(B_6C)Mn(C_6H_6)$, with the off-plane vibrational mode of the phC center shifted to 728 $cm^{-1}$ while all the other absorption bands are basically maintained. The obvious correspondence in IR spectra between Figure 3a and Figure 3 (b) indicates that these complexes vibrate in similar vibrational modes that are closely related with the triple-decker geometries they possess.

## Summary

In summary, planar hexacoordinate nonmetal centers following the octet rule have been stabilized in triple-decker complexes $(C_nH_n)M(B_6X)M(C_nH_n)$ (M = Fe, Ru, Mn, Re; X = B, C, N; $n$ = 5, 6) in which the hexagonal $B_6X$ middle-deckers are well maintained, the metal–ligand ($M–C_nH_n$) distances possess normal M–C coordination bond lengths, and phX centers carry approximately unitary natural charges. It is the effective coordination interactions between the partially filled 3d orbitals of the transition-metal centers and the delocalized π orbitals of the three parallel ligands that help to stabilize these triple-decker structures. The strong IR absorptions of these complexes mainly originate from the in-plane and off-plane vibrational modes of their phX centers. As a complement to the initial proposal of $B_6C^{2-}$,[8] this work has introduced phCs and other nonmetal centers phXs at the centers of inorganic $B_6X$ middle-deckers to transition-metal triple-decker complexes, providing a possible new approach to synthesize phC-containing systems in future experiments.

# High-Zirconium-Content Nano-Sized Bimodal Mesoporous Silicas

David Ortiz de Zárate,[a] Andrés Gómez-Moratalla,[a] Carmen Guillem,[a] Aurelio Beltrán,[a] Julio Latorre,[a] Daniel Beltrán,[a] and Pedro Amorós*[a]

**Keywords:** Mesoporous materials / Zirconia / Surfactants / Nanoparticles / Bimodal porous materials

Silica-based nanoparticulated bimodal mesoporous materials with high Zr content ($43 \geq Si/Zr \geq 4$) have been synthesized by a one-pot surfactant-assisted procedure from a hydroalcoholic medium using a cationic surfactant (CTMABr = cetyltrimethylammonium bromide) as structure-directing agent, and starting from molecular atrane complexes of Zr and Si as hydrolytic inorganic precursors. This preparative technique allows optimization of the dispersion of the Zr guest species in the silica walls. The bimodal mesoporous nature of the final high surface area nano-sized materials is confirmed by XRD, TEM, and $N_2$ adsorption–desorption isotherms. The small intraparticle mesopore system (with pore sizes around 2–3 nm) is due to the supramolecular templating effect of the surfactant, while the large mesopores (around 12–24 nm) have their origin in the packing voids generated by aggregation of the primary nanometric mesoporous particles. The basicity of the reaction medium seems to be a key parameter in the definition of this last pore system. The effects induced by the progressive incorporation of Zr atoms on the mesostructure have been examined, and the local environment of the Zr sites in the framework has been investigated by UV/Vis spectroscopy. Observations based on the consequences of post-treatments of the as-synthesized materials with HCl/ethanol mixtures corroborate that the atrane method leads to Zr-rich materials showing enhanced site accessibility and high chemical homogeneity throughout the pore walls.

## Introduction

Silicon/zirconium mixed oxides, $(SiO_2)_{1-x}(ZrO_2)_x$, have attracted considerable attention for a long time because of their mechanical (low thermal-expansion coefficient) and chemical (resistance to alkaline attack) properties.[1–7] Moreover, they are also interesting materials in catalysis. Indeed, they exhibit catalytic activity due to both their moderate acidity and oxidizing capability, and also can be used as catalyst supports.[8] However, the possibility for industrial applications has been limited because these materials generally show low surface area and no size selectivity.[9,10] Hence, the search for improved-performance (high surface area) catalysts stimulated the preparation of $(SiO_2)_{1-x}(ZrO_2)_x$ solids in the form of particulated xerogels, which was approached through a diversity of sol-gel routes starting from alkoxide precursors.[11–13] The structure of these xerogels was studied some time ago by SAXS and WAXS techniques,[14] which revealed a very open architecture (involving interconnected 3D pore systems) that has been recently referred to as optimal for catalytic applications.[15] In practice, the $(SiO_2)_{1-x}(ZrO_2)_x$ particulated xerogels are high surface area catalysts displaying strong acidity and showing satisfactory activity in a diversity of organic reactions (cumene dealkylation, alcohol dehydration, alkene isomerization).[16–18]

However, the use of these $(SiO_2)_{1-x}(ZrO_2)_x$ xerogels as catalysts presents a certain limitation derived from their lack of size selectivity.[9,10] Until now, the most promising strategies to overcome this problem have been those conceived to incorporate Zr atoms into the frameworks of molecular sieves or high surface area silica-based materials.[19–21] Thus, there are reports on Zr-containing materials derived from both microporous solids (such as zeolites and also ALPOS)[22–25] and mesoporous silicas (Zr-MCM-41, Zr-MCM-48, Zr-HMS, Zr-MSU, Zr-SBA-15),[26–39] which simultaneously display high surface area and size selectivity. Hence, a diversity of both small and large substrates could be processed with the help of such a variety of Zr-containing molecular sieves.

In short, the preparative procedures implemented for incorporating zirconium in silica-based porous matrices can be referred to as one-pot (cohydrolysis) methods[26,32,34–36,38,39] or postsynthesis (grafting) treatments.[33,37] Independent of the synthesis strategy used, an important condition for having very active supported zirconia catalysts (high-Zr-content materials) lies in site isolation: the Zr atoms must be isolated and well dispersed throughout the silica walls, thus avoiding the formation of $ZrO_2$ domains.[40] In fact, while the preparation of doped mesoporous silicas is straightforward and usually leads to a relatively homogeneous distribution of cations, the situation changes when high dopant loads are required, and we must

face a complex chemistry plagued with problems, which often results in the absence of chemical homogeneity, phase segregation or mesostructure collapse.[41] Careful manipulation of the templating chemistry is thus required.

The origin of these problems lies in the different hydrolytic reactivity of elements such as Si and Zr (unequal hydrolysis and condensation reaction rates).[36,41] In practice, zirconium species usually hydrolyze faster than silicon precursors. In most cases, this results in partial segregation of $ZrO_2$ domains (together with a decrease of the Zr/Si molar ratio in the resulting mixed oxide with respect to the mother solution). Insofar as the catalysts' efficacy substantially depends on their purity and chemical homogeneity, phase segregation must be avoided. The goal of a variety of one-pot (cohydrolysis) synthesis procedures developed over the past few years was to circumvent this reactivity problem. Among the alternatives described, we can emphasize the utilization of Zr-complexing precursor species,[36,42] the use of single-source molecular precursors,[43] the optimization of the inorganic precursors and the pH,[44] the use of microwaves in the processing,[34] the application of hydrothermal post-treatments,[39] or chemical control based on adjusting the reaction conditions.[35] In this context, our group reported on how [using the atrane route,[45,46] that is to say starting from kinetically inert molecular atrane precursors (complexes of Si and Zr containing triethanolamine-derived ligands)] it is possible to orchestrate the Zr and Si hydrolytic reaction rates, thus leading to thermally stable Zr-MCM-41 porous silicas whose composition ranges from doped silicas to very-high-Zr-content materials ($\infty \geq Si/Zr \geq 0.3$).[36]

It should be emphasized that the main concern in these previous valuable investigations is the heteroelement (Zr) incorporation. Less attention has been paid to the site accessibility and connectivity in these silica-based catalysts, which also is a key for catalytic efficiency.[15] A strategy to deal with the site accessibility problem that recently has attracted interest is conceptually based on the consequences of decreasing the mesoporous particle size in the nanoparticle range.[15] This necessarily implies, at first, the shortening of the mesopore length, whereas the particle packing would generate supplementary interparticle porosity. The one-pot synthesis of functionalized (with inorganic elements and/or organic groups) nanoparticulated bimodal porous silicas was initially described by Pauly et al.[47] (Al-HMS materials) and El Haskouri et al.[48,49] (M-UVM-7 solids, M = Al, Ti, V, and Zr; HPNOs), who used in their processes a single surfactant (non-ionic, HMS; cationic, M-UVM-7, and HPNOs). In order to find applications, Pauly et al. demonstrated the benefits of this nanoparticle-based architecture by showing how the use of Al-HMS (average particle size $< 200$ nm) instead of Al-MCM-41 improves the yield in the catalytic alkylation of 2,4-di-*tert*-butylphenol with cinnamyl alcohol.[47] A two-step process for obtaining similar materials has recently been reported.[50] In any case, it must be noted that, until now, the heteroelement amounts which have been possible to incorporate into these nanoparticulated catalysts have not been too high (in the zirconia-supported materials we are dealing with, the upper limit was established at Si/Zr = 50 in ref.[48] vs. Si/Zr = 20 in ref.[50], although in this last case there is insufficient analytical information).

As mentioned in this Introduction, following previous work on related materials, we recently succeeded in synthesizing a novel family of nanoparticulated bimodal mesoporous pure and doped silicas, and published some of our preliminary results as a short communication.[48] On this basis, insofar as the interest on improved zirconia catalysts remains, we considered the possibility of transferring the mentioned nanoparticulated organization from the already explored limit of doped silicas up to the field of truly $(SiO_2)_{1-x}(ZrO_2)_x$ mixed oxides. We have succeeded in this aim, and this work describes the one-pot reproducible surfactant-assisted procedure that has allowed us to synthesize high-Zr-content nanoparticulated bimodal mesoporous silicas displaying high chemical homogeneity (good dispersion of the active sites) and a considerable amount of accessible Zr centers. The resulting Zr-UVM-7 solids bring together high heteroelement contents, the size selectivity provided by the surfactant-generated mesopores, and the high accessibility typical of xerogels. The effects of the presence of Zr atoms on the mesostructure have been examined, and the main features characterizing the Zr sites in the framework have been elucidated.

## Results and Discussion

### Synthesis Strategy

Bimodal mesoporous materials of the UVM-7 type that are rich in Zr atoms have been synthesized through a one-pot approach using CTABr as surfactant in a $TEAH_3$/water medium (CTABr = cetyltrimethylammonium bromide; $TEAH_3$ = triethanolamine) (see Exp. Sect.). Summarized in Table 1 are the main synthesis variables and physical data concerning the Zr-UVM-7 materials prepared in this way.

Our synthesis strategy has been designed both to overcome problems associated with the great reactivity differences that characterize the most usual Zr and Si precursor species (because of the lower electronegativity of Zr and its tendency to exhibit multiple coordination states) and to preserve, as far as possible, the nanoparticulated bimodal porous organization typical of UVM-7 silicas.[48] As mentioned above, this protocol is a modification of the so-called "atrane route", a simple preparative technique whose main points have been described previously in detail.[45] In fact, such a method has allowed us to successfully prepare a diversity of unimodal mesoporous single and mixed oxides, including the Zr-MCM-41 materials,[36] working under strongly basic conditions (pH = 11–12).[51–56] In contrast, in the case we are dealing with, the synthesis pH was buffered at ca. 9. It has been proven that these comparatively mild basic conditions favor the nucleation and growth of silica-based small nanoparticles,[48] thus avoiding the formation of relatively large particles typical of the MCM-41-like materials. In any case, the presence of atrane complexes

in solution at the working pH, before and after water addition, has been confirmed by FAB-MAS. This study has been carried out firstly on independent Si- or Zr-containing solutions in which the reagent proportions are the same used in the preparation of the Zr-UVM-7 porous materials described in this work. In the absence of water, the majority species for both Si and Zr solutions correspond to M(TEA)-$(TEAH_2)$ [M = Si (100%) or Zr (100%)] monomers, and only in the Si case have additional entities been detected [$Si_2(TEA)_2TEAH$ and $Si_3(TEA)_4$], in very low proportions (12 and 15%, respectively). The relative intensities have been calculated without considering the peaks associated with the dissolvent. In contrast to previous experiments carried out at pH = 11,[36] the presence of oligomers is now practically negligible. Immediately after water addition, and independent of the pH ($9 < pH < 11$), both the Si and Zr atrane complexes remain in solution as monomers, $M(TEA)^+$ and M(TEA)OH (M = Si or Zr) being the majority hydrolyzed species. Later, the corresponding FAB signals progressively disappear as the sol evolves to gel. On the other hand, it must be emphasized that additional FAB-MAS experiments carried out on solutions containing both elements (Si and Zr) reveal (before and after water addition) the presence of the same species as in the independent solutions, which allows us to reasonably conclude that formation of binary (containing both Si and Zr entities) atrane complexes can be discarded. Thus, the precursor solution appears to mainly consist of a random intimate mixture of independent Zr and Si molecular monomeric fragments. In conclusion, although the proportion of oligomer species in the absence of water is dependent on the basicity of the medium, the use in the present case of moderately basic conditions (pH ≈ 9) to favor the formation of nanoparticulated materials does not seem to alter the nature of the Si and Zr species in hydroalcoholic solution (with regard to previous synthesis in more basic media). In other words, irrespective of the nature (condensation degree) of the starting atranes (pH-dependent), the hydrolyzed species become similar. In this way, the already studied role played by $TEAH_3$ in order to orchestrate the hydrolytic reactions of the Si and Zr precursor species[36] is preserved in the current synthesis of the Zr-UVM-7 solids. Finally, once the hydrolytic reactions have been completed, the total concentration of soluble silica can be accounted for by $Si(OH)_4$ and $(HO)_3SiO^-$ species in an approximate ratio of 10:1.6,[57,58] while the majority Zr species should be the $Zr(OH)_5^-$ monomer.[59] The subsequent condensation processes will proceed from these monomeric entities. In this sense, we can refer to a recent study on the condensation processes involving silicon and zirconium alkoxides, which demonstrates the formation of copolymerized tridimensional products in reaction media rich in water.[60] Then, the condensation processes of the hydrolyzed units must provide charged (anionic) binary (Si and Zr) oligomers that could match (by displacement of $Br^-$ anions) with cationic surfactant aggregates [$(CTMA)_{mm}^+$] following an $S^+I^-$ mechanism.

As mentioned above, the pH constitutes the key parameter to obtain nanoparticulated materials of this type. The working conditions (pH ≈ 9) have been selected in order to achieve high hydrolysis and condensation reaction rates and also low silica back solution.[57] Thus, silica polymerization is fastest at pH values in the range of 8–9, and the silica solubility reaches a minimum at pH ≈ 8.[57,58] Under these conditions, we favor (1) supersaturation, a necessary condition for the formation of a large number of small primary mesoporous nanoparticles, and (2) limited particle growth, as a consequence of the low silica solubility. Moreover, the incorporation of Zr helps to decrease the solubility. It is well known that the presence of heteroelements (such as Al or Zr) in the silica framework, even in low proportions, increases in a significant way the insolubility of the resulting doped or mixed oxides with regard to those of the respective individual oxides.[57] This property of Si/Zr mixed oxides has been exploited to prepare alkali-resistant filtration membranes based on mesoporous Zr-MCM-48 materials.[61]

Once the primary particles have been formed, the generation of a large pore system (see below) should be a consequence of their aggregation, which mainly implies the establishment of Si–O–Si interparticle covalent links (which might be kinetically favored in the presence of $Zr^{IV}$).[43] Moreover, as occurs in the case of xerogels, the presence of Zr favors the interparticle condensation reactions and leads to clusters more dense than those originated by the analogous pure silica derivatives.[14] This behavior may be attributed to the development of cross-linking through Zr centers between individual particles (Zr–O–Si or Zr–O–Zr bridges), as expected from the affinity of Zr atoms for higher oxygen coordination environments. Particle aggregation is a sol-gel process, which probably is the result of base-catalyzed interparticle collisions.[57] In short, the Zr incorporation into the silica walls helps to promote the nucleation of very insolu-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ble small nano-sized mesoporous particles, which in turn favors the stabilization of the UVM-7-like organization.

### Characterization

We have used EPMA both to determine the real amounts of Zr incorporated into the framework and also to check the chemical homogeneity of the resulting solids [a relevant objective of our work was to preserve, under the new working conditions, good dispersion of the heteroelement (Zr) in the walls of the resulting materials, which usually is achieved through the atrane route]. Summarized in Table 1 are the corresponding Si/Zr molar ratio values (averaged from data of about 50 different particles) of the resulting solids. EPMA shows that the reported Zr-UVM-7 materials contain Si/Zr molar ratios similar to those present in the mother solutions. This fact indicates that, in general, there is no preferential incorporation of Zr or Si into the final porous walls. However, we observe a certain increase of the Zr proportion in the case of the solids prepared from the precursor solutions having the lowest Zr contents (Si/Zr = 50 and 25). This result could be associated with the comparatively low solubility of the Zr-containing species (with regard to the pure silica ones), the effect of which should decrease as the amount of well-dispersed Zr centers increases. On the other hand, EPMA also shows that all Zr-UVM-7 samples are chemically homogeneous (have regular distributions of Zr and Si atoms) at the micrometer level (spot area $\approx$ 1 μm) with a constant and well-defined composition. Hence, the Zr-UVM-7 solids can be considered as monophasic products. In fact, segregation of extra-framework crystalline $ZrO_2$ can be practically discarded even for the samples having the highest Zr content (although formation of $ZrO_2$-like amorphous nanodomains might progress as the Zr content increases). This result is consistent with the absence of zirconia peaks in the high-angle region of the XRD patterns. In short, according to our initial hypothesis, we can conclude that the use of atrane precursors results in the harmonization of the rates of the hydrolytic processes involving the corresponding Si and Zr species, which facilitates the incorporation of relatively high amounts of the heteroelement (Zr). Indeed, the amounts of Zr which are incorporated into Zr-UVM-7 solids are higher than those usually achieved in other related silica-based materials prepared from conventional Si and Zr sources (for a given Si/Zr initial ratio). Even more, as mentioned above, the use of the atrane route allows very-high-Zr-content porous silicas to be obtained, but the nanoparticulated organization of the material we are looking for is lost when the Si/Zr molar ratio becomes smaller than 4:1.

The TEM images in Figure 1 clearly show that the UVM-7-like organization is maintained in the compositional range of 43 $\geq$ Si/Zr $\geq$ 4. All solids present a continuous nanometric array constructed from aggregates of nano-sized mesoporous particles, which include two different pore systems: (1) the first one can be related to the porogen effect of the surfactant-templating micelles, which generates the small intraparticle regular mesopores organized in a short-range hexagonal-ordering array, and (2) the second one consists of large cage-like interparticle pores and corresponds to the voids appearing as a consequence of the collision and aggregation of the primary nanoparticles. According to its origin, this second pore system presents a nonordered character similar to that defining the cross-linked network in nanoparticulated xerogels.[62,63]

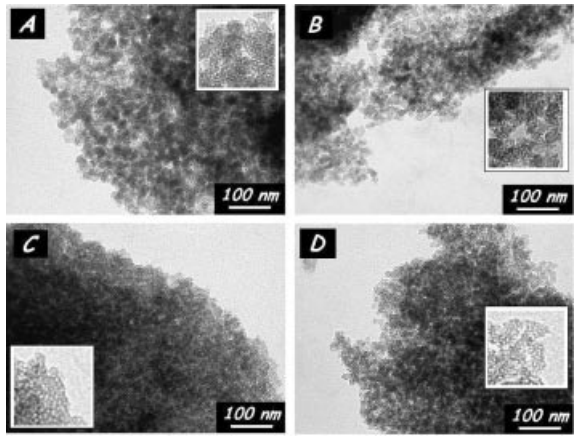

Figure 1. Representative TEM images of Zr-UVM-7 materials: (A) Sample 1 (Si/Zr = 43), (B) Sample 2 (Si/Zr = 19), (C) Sample 3 (Si/Zr = 11), and (D) Sample 4 (Si/Zr = 4). The insets show enlarged (×3) TEM images.

On the other hand, a careful analysis of the TEM images allows certain tendencies in the variation of both the particle morphology and the progress of the cluster-like aggregation with the Zr content to be established. Thus, the average particle size slightly decreases as the Zr content increases. The progressive Zr incorporation also favors the formation of denser aggregates, reflecting a more efficient packing of the primary nanoparticles. Such an evolution of the mesostructure can be firstly related to the solubility decrease induced by the Zr incorporation. Thus, the particle growth decreases as the insolubility of the nanoparticles increases. Moreover, the ability of Zr atoms to increase their coordination number favors the interparticle connectivity (based on Si–O–Si covalent bonds) through (additional) Zr–O–Zr or Zr–O–Si links. This results in an interparticle shrinkage similar to that observed in xerogels.[14] These tendencies can be better appreciated by comparing a pure UVM-7 silica with a Zr-containing derivative (Figure 2). The micrographs in Figure 2 clearly show how the incorporation of Zr atoms also involves a change in the particle morphology. Indeed, while the UVM-7 pure silica exhibits aggregates defined by regular elliptical nanoparticles, these primary building blocks in the Zr-UVM-7 materials present an irregular and angular shape. It is well known that, independently of the particle size (nano- or micrometric Stöber-like silica particles), the incorporation of Zr (or another heteroelement) strongly affects the regular growth of the silica spheres, thus leading to irregular particles. A similar morphologic evolution with the Zr content was described previously for Zr-containing silica xerogels.[14]

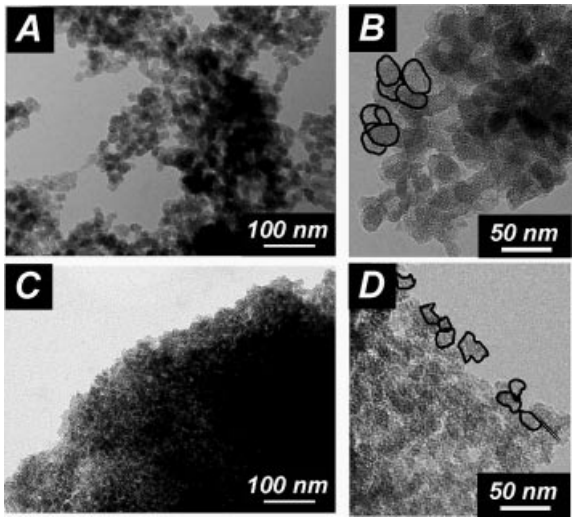

Figure 2. Comparative TEM micrographs of (Zr-free) UVM-7 silica (A and B) and Zr-UVM-7 Sample 3 (C and D).

The characteristics of the intraparticle mesopore array have been further studied by XRD with results that fully correlate to TEM observations. All materials (as-synthesized and calcined) display XRD patterns with at least one strong diffraction peak in the low-angle region, which is characteristic of mesostructured solids. The low-angle region of the XRD patterns corresponding to the mesoporous (calcined) samples is shown in Figure 3. In all these last cases, apart from the intense peak at low $2\theta$ values [associated with the (100) reflection if a basic hexagonal cell is assumed],[64] we can observe a broad signal of relatively low intensity that can be indexed to the overlapped (110) and (200) reflections of the typical hexagonal cell. The observation of this last unresolved broad signal is characteristic of an MCM-41-like short-range hexagonal intraparticle mesopore topology. We can also notice the decrease of the relative intensity of this broad signal with the Zr content (it appears as a shoulder on the main peak for samples in which Si/Zr $\leq$ 19). Such an evolution is indicative of a progressive lowering of order in the mesopore array as the Zr amount incorporated into the silica walls increases. The lattice parameter value remains practically unchanged in the range of 43 $\geq$ Si/Zr $\geq$ 4 for both the as-synthesized (about $5.20 \pm 0.13$ nm) and porous (about $4.64 \pm 0.10$ nm) materials. Assuming the effective incorporation of Zr atoms in the silica framework, this result might seem a priori unreasonable [even more so when compared to the values of the $a_0$ parameter of the mesostructured (5.13 nm) and calcined (4.91 nm) UVM-7 pure silica]. To understand this behavior, it is necessary to consider two opposite phenomena: (1) cell expansion due to the replacement of Si atoms with Zr ones, and (2) strong intraparticle network-shrinkage associated with the cross-linking ability of Zr, which is enhanced after calcination. As shown in Table 1, the contraction of the $a_0$ parameter upon calcination for the Zr-containing materials (about $0.51 \pm 0.07$ nm) is significantly higher than that observed for the Zr-free UVM-7 silica (0.22 nm).[65] It must be emphasized that this significant shrinkage is similar to those observed in the cases of Zr-MCM-41[36] and (pure) $ZrO_2$[66] mesoporous solids prepared through surfactant-assisted procedures.

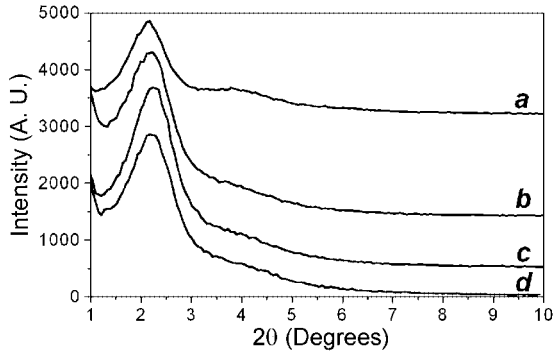

Figure 3. Low-angle XRD patterns of Zr-UVM-7 materials: (a) Sample 1 (Si/Zr = 43), (b) Sample 2 (Si/Zr = 19), (c) Sample 3 (Si/Zr = 11), and (d) Sample 4 (Si/Zr = 4).

The $N_2$ adsorption–desorption isotherms gathered in Figure 4 corroborate that the bimodal pore system typical of nanoparticulated UVM-7 silicas is maintained in the Zr-UVM-7 (43 $\geq$ Si/Zr $\geq$ 4) materials. The curves show, in all cases, two well-defined adsorption steps (at intermediate and high partial pressures). The adsorption at $P/P_0$ values in the range of 0.25–0.50 can be related to capillary condensation of nitrogen inside the cylindrical intraparticle surfactant-templated mesopores. The second adsorption at $P/P_0 > 0.65$ corresponds to the filling of the large cage-like interparticle voids. Application of the BJH model (see Figure 5) allows independent analysis of the evolution with the Zr content of the two pore systems.

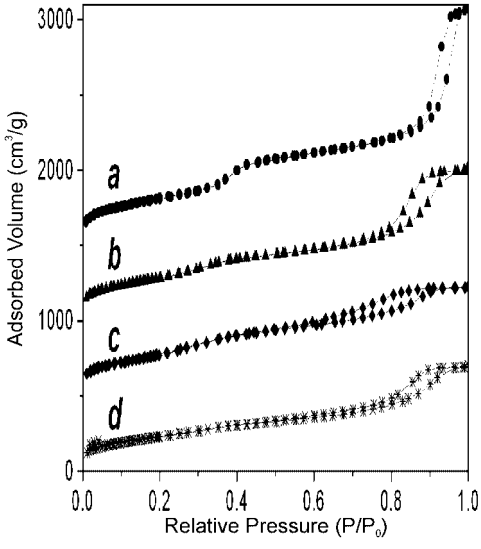

Figure 4. $N_2$ adsorption–desorption isotherms for Zr-UVM-7 materials: (a) Sample 1 (Si/Zr = 43), (b) Sample 2 (Si/Zr = 19), (c) Sample 3 (Si/Zr = 11), and (d) Sample 4 (Si/Zr = 4).

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

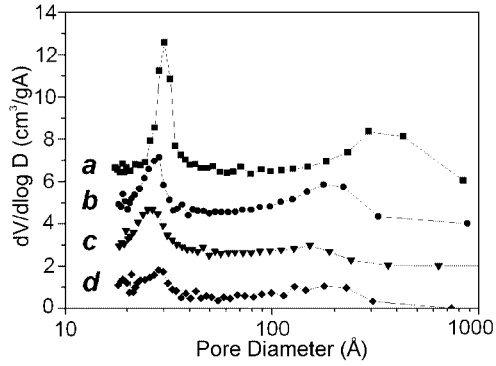

Figure 5. BJH pore size distributions for Zr-UVM-7 materials: (a) Sample 1 (Si/Zr = 43), (b) Sample 2 (Si/Zr = 19), (c) Sample 3 (Si/Zr = 11), and (d) Sample 4 (Si/Zr = 4).

Indeed, the pore size and volume associated with the intraparticle small mesopores gradually decrease with the Zr content (see Table 1), a result which is consistent with an effective heteroelement incorporation into the silica walls. The intraparticle shrinkage commented on above could account for such a BJH pore and volume evolution. On the other hand, we observe similar tendencies for the pore size and volume associated with the interparticle pores in the case of oxides (doped or mixed) with intermediate Zr loads ($43 \geq Si/Zr > 11$). Later, as the Zr content increases ($11 \geq Si/Zr \geq 4$), the pore size and volume seem to be stabilized. At this point, it can be interesting to compare these results with those concerning the interparticle pore system (pore size = 50–60 nm) corresponding to pure (Zr-free) UVM-7 silicas.[48] We can conclude that Zr centers seem to be very effective for interconnecting different nanoparticles (with the consequent pore-size reduction) even for low heteroelement contents. Thus, the incorporation of small amounts of Zr (Si/Zr = 43) already implies a reduction of the large pore size in about 50% with regard to the pure UVM-7 silica. This reduction continues more smoothly until significant Zr contents ($Si/Zr \geq 11$) are reached, for which we might consider that the size and volume of the interparticle pore system is roughly stabilized (about 12.5 nm and 0.67 $cm^3/g$). This general behavior suggests that, in the presence of moderate proportions of interparticle Zr binding sites, the cage-like pore system is controlled by the nanoparticle packing efficiency (physical aspects related to the size and shape of the particles) rather than by the heteroelement amount.

The high BET surface area, characteristic of UVM-7 and MCM-41 materials, is maintained in the whole compositional range studied (Table 1). Incorporation of Zr leads to a small and gradual decrease of the BET area. Insofar as the major surface area corresponds to the intraparticle mesopore system, this evolution must be attributed to disorder induced by Zr in the surfactant-templated pore array. This is a general tendency already observed for M-MCM-41-like samples,[38] which has to be related to the relative lowering of the $S^+I^-$-matching capability of the heteroelement-containing silica oligomers. However, this BET surface area decrease does not necessarily imply a significant loss of porosity, and it could be related to a great extent with the gradual increase of the density of the samples as Zr atoms replace Si ones. Also, the thickness of the pore walls (defined as $Wt = a_0$ – BJH pore size) shows a certain tendency to increase with the Zr content, which should be correlated with the effective incorporation of Zr into the walls.

Once it is unambiguously confirmed that our materials retain the nanometric architecture typical of the UVM-7 silicas, it is possible to gain insight into the characteristics of the local environment and dispersion of the Zr centers in the silica walls with the help of UV/Vis spectroscopy. The diffuse-reflectance UV/Vis spectra corresponding to the anhydrous (i) and hydrated (ii) Zr-UVM-7 compositions we are dealing with (the spectrum of bulk $ZrO_2$ has also been included for comparative purposes) are shown in Figure 6.

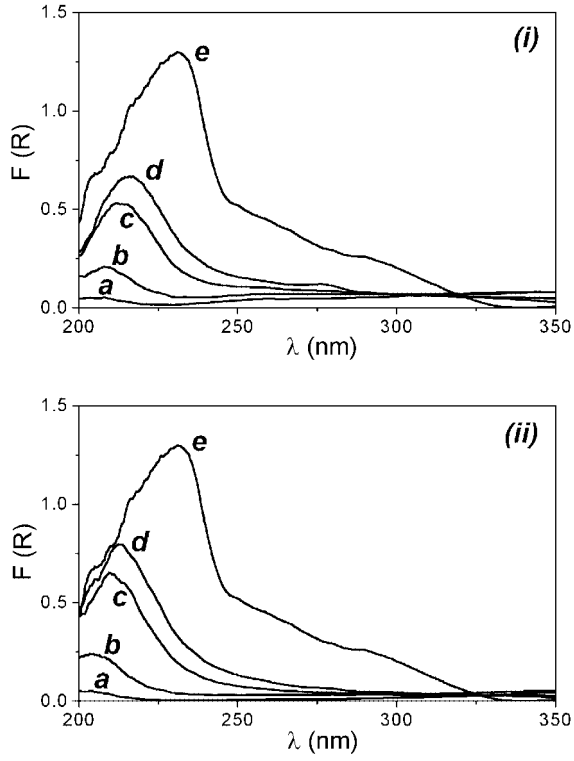

Figure 6. Diffuse-reflectance UV/Vis spectra of (i) anhydrous and (ii) hydrated Zr-UVM-7 samples. (a) Sample 1 (Si/Zr = 43), (b) Sample 2 (Si/Zr = 19), (c) Sample 3 (Si/Zr = 11), (d) Sample 4 (Si/Zr = 4), and (e) $ZrO_2$.

In all cases, the spectra display an intense absorption band at about 210–217 nm whose intensity monotonically increases as the Si/Zr ratio decreases. As can be seen, the spectrum of $ZrO_2$ is clearly different: the most intense absorption band is complex and its maximum appears at comparatively low energy values (about 230–240 nm); moreover it exhibits additional bands in the range of 250–350 nm. The intense adsorption band in the spectra of Zr-UVM-7-related materials is usually attributed to ligand-to-metal charge transfer from oxide entities to isolated $Zr^{IV}$ cations in a tetrahedral environment.[67] This band presents a gradual red-shift as the Zr content increases, but the absorption maximum always falls at wavelengths lower than that corre-

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sponding to pure zirconia, that is to say the band-gap energies for the Zr-UVM-7 materials are larger than for $ZrO_2$.[68] This result further corroborates the lack of extra-framework bulk $ZrO_2$ as a segregate phase in the Zr-UVM-7 samples, and also indicates the presence of isolated Zr centers (or highly dispersed zirconia-based clusters or nanodomains) in the pore walls. FTIR spectroscopic data offer further evidence in this sense. Thus, the relative intensity of the band at ca. 970 $cm^{-1}$, which is usually related to vibrational modes involving Si–O–Zr linkages,[69] clearly increases with the Zr content. Moreover, the detection of a certain UV/Vis absorption in the range of 250–350 nm has been recognized as characteristic of nanoscopic regions containing Zr–O–Zr bonds in related materials.[34] It must be noted that the spectrum of bulk $ZrO_2$ presents, at least, two rather intense adsorption bands in this range. In the case of the Zr-UVM-7 solids, we cannot detect any absorption in this spectral range until reaching the Zr content corresponding to a molar ratio of Si/Zr = 11. Even in the case of the spectrum of the highest-Zr-content material (Si/Zr = 4), we can observe only a small shoulder at ca. 250–275 nm. We cannot disregard, therefore, the presence of a certain proportion of Zr–O–Zr-containing nanodomains in this last sample of high Zr content. Such a shoulder can be better appreciated in the spectrum of the anhydrous Si/Zr = 4 sample. The thermal treatment carried out to eliminate water probably favors a certain intra- and interparticle condensation leading to the formation of new Zr–O–Zr bonds. As discussed above, this observation correlates to the ability of Zr centers to adopt different coordination environments.

Concerning the potential catalytic applications of these materials, it seems relevant to evaluate the proportion of Zr sites that are reagent-accessible. In general, this variable is highly dependent on the synthesis approach used. Thus, when comparing cohydrolysis processes to grafting techniques, we find that, although cohydrolysis usually leads to higher chemical homogeneity, it has an associated drawback: the loss of a significant part of the incorporated, potentially active centers, which are buried inside the pore walls (that is to say inaccessible for the reagents). Then, assuming that the mesoscopic organization of the material is maintained, we can consider that only those Zr centers close to the pore surface should be accessible to different substrates. Our approach to estimating the proportion of Zr-accessible sites in the Zr-UVM-7 materials is based on evaluating the effects of using an alternative procedure for removing the surfactant from the as-synthesized samples. Thus, we chemically extracted the surfactant with the help of HCl/ethanol mixtures. This process has a double effect: it obviously provokes the exchange between $CTMA^+$ species and protons, but also favors the leaching of accessible Zr atoms in the form of chloride complexes. Thus, we observe in all cases that the Zr content, as measured by EPMA, decreases after extraction (see Table 2).

In all samples, at least 1/3 of the Zr centers are accessible under the experimental conditions we have used. Moreover, the proportion of accessible Zr centers increases with the Zr content [from about 40% (Si/Zr = 43) to about 60% (Si/Zr = 4)]. At first glance, this evolution might suggest that there is a certain progressive (with the Zr content) loss of chemical homogeneity of the pore walls, which would result in enrichment in Zr of the surface with regard to the core walls. However, these results must be carefully considered, because the leaching of superficial Zr centers (or $ZrO_2$ nanodomains in the Zr-richest samples) also favors a progressive attack on partially buried Zr species. In practice, this degradation will progress continuously, leading to an enhanced elimination of Zr (internal and a priori inaccessible) cations of the inorganic walls. This process really is very similar to the well-known dealumination and desilication reactions carried out on zeolites to favor the generation of additional hierarchical porosity.[70,71] A possible consequence of the progressive formation of new disordered pores should be mesostructure degradation (partial or total). In fact, a preliminary study (XRD and $N_2$ adsorption–desorption) carried out on chemically extracted samples shows that the process induces significant changes in the (UVM-7) organization of the resulting materials. Thus, according to the XRD patterns in Figure 7, the intraparticle short-range hexagonal ordering mesopore system is maintained only up to Sample 3 (initial molar ratio: Si/Zr = 11), and it practically disappears for the Zr-richest material (Sample 4).

Table 2. Analytical data for Zr-UVM-7 samples before and after treatment with HCl/ethanol.

| Sample | Si/Zr calcined | Si/Zr chemically extracted | Accessible Zr sites (%) |
|---|---|---|---|
| 1 | 43 | 66 | 35 |
| 2 | 19 | 34 | 41 |
| 3 | 11 | 24 | 50 |
| 4 | 4 | 11 | 60 |

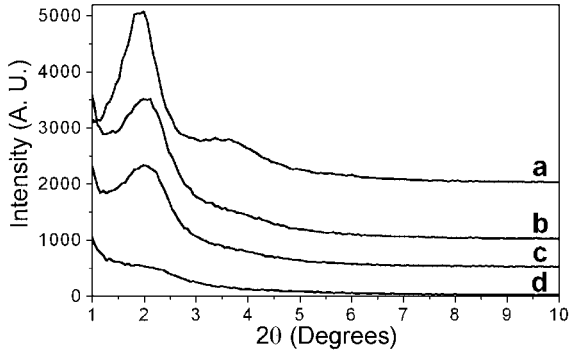

Figure 7. Low-angle XRD patterns of the chemically extracted Zr-UVM-7 materials: (a) Sample 1 (Si/Zr = 66), (b) Sample 2 (Si/Zr = 34), (c) Sample 3 (Si/Zr = 24), and (d) Sample 4 (Si/Zr = 11).

On the other hand, we only observe (see Figure 8) UVM-7-like isotherms (with two well-differentiated adsorption steps) up to Sample 2 (initial molar ratio: Si/Zr = 19). Indeed, as the Zr content increases, the first adsorption step (associated with the intraparticle mesopores) progressively disappears, and the second adsorption step (typical of interparticle voids) in the isotherms evolves to wide pore-size distributions.

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

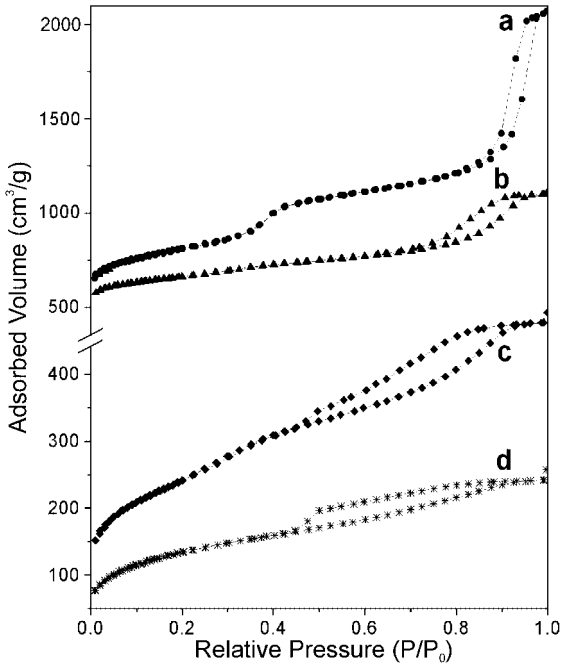

Figure 8. $N_2$ adsorption–desorption isotherms of the chemically extracted Zr-UVM-7 materials: (a) Sample 1 (Si/Zr = 66), (b) Sample 2 (Si/Zr = 34), (c) Sample 3 (Si/Zr = 24), and (d) Sample 4 (Si/Zr = 11).

According to XRD and porosimetry data, we can conclude that the UVM-7-like architecture in chemically extracted materials is preserved only in the compositional range of $43 \geq Si/Zr > 19$ (initial molar ratio values). On the basis of this observation, and taking into account both the proportion of accessible Zr sites estimated for the samples in this range (from 35 to 40%, Table 2) and their wall thickness (Table 1), it is possible to propose a rough structural model for estimating the degree of chemical homogeneity of the pore walls. Then, assuming the existence of a silica-based framework constructed from $Q^4$ centers [*d*(Si–O) = 0.16 nm], about six silica chains are necessary to achieve a wall thickness of ca. 1.7–1.8 nm (Figure 9). Under the reasonable hypothesis that in the low-Zr-content silicas ($Si/Zr > 19$) only the Zr sites located in the more external chains should be eliminated by the treatment with HCl/ethanol mixtures, the proportion of accessible Zr centers for a homogeneous heteroelement dispersion is 1/3, a value very close to those observed for Samples 1 and 2 (35% and 41%, respectively). In any case, although a slight Zr surface enrichment cannot be completely disregarded, we can conclude that the atrane method leads to mesoporous materials with high chemical homogeneity throughout the pore walls. In contrast, an appreciable Zr enrichment of the surface has been detected for mesoporous materials synthesized from conventional reagents.[35] Dealing with the surfactant-exchanged materials in the compositional range of $11 \geq Si/Zr > 4$, it is interesting to point out that, as occurs for zeolites, the gradual degradation of the mesostructure by Zr leaching to induce additional hierarchic porosity may be controlled to increase the material accessibility. In this regard, additional work is currently in progress.

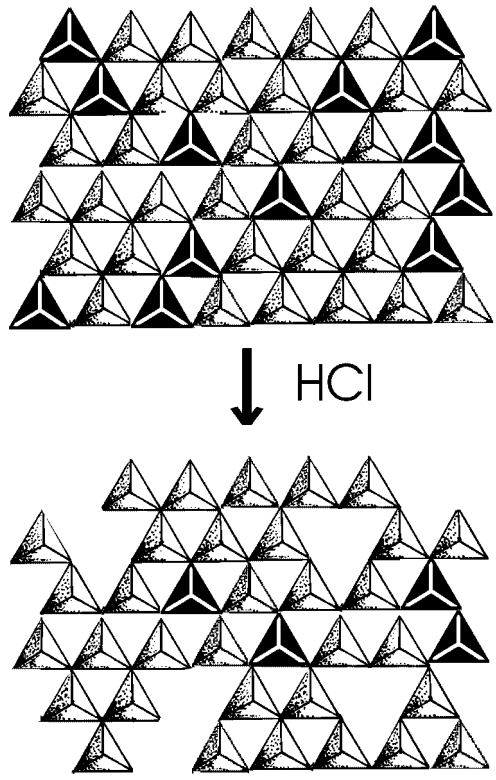

Figure 9. Scheme of the pore wall. Grey and white positions in the framework correspond to Zr and Si sites, respectively.

## Conclusions

In short, we reported here on how, starting from kinetically inert atrane precursors, it is possible to synthesize high-zirconium-content nano-sized bimodal porous silicas by using a cationic surfactant-assisted procedure under controlled pH conditions. The resulting Zr-UVM-7 silica-based materials maintain the typical array of the parent pure silica: aggregates of nano-sized mesoporous particles defining a large interparticle pore system resulting from the imperfect packing of the primary building blocks. The effects of the Zr atoms on the UVM-7 pore morphology are explained on the basis of both the modification of the silica solubility by incorporation of Zr centers into the oligomers and the ability of the Zr atoms to expand their coordination number. The latter aspect favors a significant decrease of the textural porosity with regard to Zr-free UVM-7 materials. Once more, the atrane method proves to be a very efficient tool to achieve a good dispersion of the heteroelement guest species in the silica framework.

## Experimental Section

**Chemicals:** All the synthesis reagents were analytically pure, and were used as received from Aldrich. The Si and Zr primary sources were tetraethyl orthosilicate (TEOS) and zirconium isopropoxide

 © 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(ZrP), respectively. 2,2′,2′′-Nitrilotriethanol or triethanolamine [$N(CH_2–CH_2–OH)_3$, $TEAH_3$] was used for obtaining Si and Zr atrane complexes. The templating agent was cetyltrimethylammonium bromide (CTMABr).

**Synthesis:** The method was a modification of the so-called "atrane route".[36,45,46] The nano-sized Zr-UVM-7 materials were synthesized through a one-pot surfactant-assisted procedure in a homogeneous hydroalcoholic reaction medium (water/$TEAH_3$). The cationic surfactant (CTMABr) acted as a structure-directing agent or supramolecular template (and consequently, as porogen after template extraction). Although the Si and Zr primary sources were commercial alkoxides, the real hydrolytic precursors in this strategy were Si and Zr atranes (relatively inert complexes that include $TEAH_3$-related ligand species).[36,45,46] Together with its complexing ability, the presence of the polyalcohol ($TEAH_3$) was a key because it kept the reaction medium buffered (pH ≈ 9), favoring the formation of nanoparticulated materials.[47,48] Details of a typical synthesis leading to Sample 2 (see Table 1) can be described as follows: (1) Preparation of an adequate mixture of atrane precursors from commercial alkoxides. TEOS (32.1 mL, 0.144 mol) and ZrP (2.56 mL of a 70% in weight solution, 0.0058 mol) were slowly added to liquid $TEAH_3$ (66.9 mL, 0.51 mol) and heated at 150 °C to give atrane complexes. (2) Addition of the structure-directing (porogen) agent. After cooling of the previous solution to 90 °C, CTMABr surfactant (13.68 g, 0.0375 mol) was added. (3) Mesostructure formation. The solution containing the atrane complexes and the template was cooled to 60 °C and mixed with water (240 mL, 13.33 mol). After a few seconds, a white powder appeared. The resulting suspension was allowed to age at room temperature for 24 h. The final (mesostructured) powder was filtered off, washed with water and ethanol, and air-dried. (4) Surfactant removal. In order to open the pore system, the as-synthesized solid was heated at 500 °C under static air for 5 h. In all cases, the molar ratio of the reagents in the mother liquor was adjusted to (2–$x$)Si/$x$Zr/7$TEAH_3$/0.52CTMABr/180$H_2O$ (where $x$ = 0.04, 0.08, 0.15, and 0.33). On the other hand, in order to evaluate the proportion of internal and external (accessible) Zr sites, we used an alternative procedure to remove the surfactant from the as-synthesized samples. Indeed, the surfactant was chemically extracted from some selected samples using an HCl/ethanol solution (about 1 g of powder, 15 mL of HCl 35%, and 150 mL of ethanol 96%) by maintaining the suspension of the mesostructured solid in the solution, while stirring at room temperature for 24 h. The final (porous) material was separated by filtration, washed with ethanol, and air-dried.

**Physical Measurements:** All solids were characterized by electron probe microanalysis (EPMA) using a Philips SEM-515 instrument. The Si/Zr molar ratio values averaged from EPMA data corresponding to about 50 different particles of each sample are summarized in Table 1. Fast atomic bombardment (FAB) coupled to mass spectrometry (MAS) analysis of the precursor solutions was performed to investigate the nature of the atrane precursors (before and after water addition). X-ray powder diffraction (XRD) data were recorded with a Seifert 3000TT $\theta$-$\theta$ diffractometer using Cu-$K_\alpha$ radiation. Low-angle XRD patterns were collected in steps of 0.02° (2$\theta$) over the angular range of 0.65–10° (2$\theta$) for 25 s/step. To detect the presence of some crystalline bulk phase, additional patterns were recorded with a larger scanning step [0.05° (2$\theta$)] over the angular range of 10–70° (2$\theta$) and a lower acquisition time (10 s/step). An electron microscopy study (TEM) was carried out with a JEOL JEM-1010 instrument operating at 100 kV and equipped with a CCD camera. The specimens for TEM analysis were prepared from powders by conventional crushing in an agate mortar, and dispersing the resulting small crystallites in dodecane. Microparticles were then deposited on holey carbon microgrids under ambient conditions. Surface area, pore size, and volume values were calculated from nitrogen adsorption–desorption isotherms (–196 °C) recorded with a Micromeritics ASAP-2010 instrument. Calcined samples were degassed at 130 °C and $10^{-6}$ Torr for 15 h prior to measurement. Surface areas were estimated according to the BET model,[72] and pore size dimensions were calculated by using the BJH method (measures at $P/P_0 < 0.55$ and $P/P_0 > 0.55$ values have been used to characterize the intrananoparticle and the internanoparticle pore systems, respectively).[73] Room-temperature diffuse-reflectance spectra were registered using a Shimadzu UV/Vis 2501PC instrument equipped with an integrated sphere coated with $BaSO_4$, which also is used as standard. IR spectra (KBr pellets) were registered with an FTIR Perkin–Elmer 1750 spectrophotometer.

## Acknowledgments

This work was supported by the Spanish Ministerio de Educación y Ciencia (under grants MAT2002-04329-C03-02 and MAT2003-08568-C03-01) and the Generalitat Valenciana (grant GRUPOS03/099 and GV2004-B-745). D. O. Z. thanks the Spanish Ministerio de Educación y Ciencia for a doctoral grant.
