**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** the role played by synthetic metalloenzyme analogues in uncovering the relationship between metalloenzyme active site structure, properties, and function at the molecular level. Details are presented in the Microreview by L. M. Brines and J. A. Kovacs on p. 29 ff.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

# Jubilees and Anniversaries

**Karen Hindson**
**Editor, EurJIC**

When 13 societies are co-owners of a journal, it must be quite likely that important milestones in their history overlap. This year several important anniversaries, not only of EurJIC's owner societies but also of the publisher John Wiley & Sons, Inc. and of the journal itself, coincide. EurJIC congratulates the Hungarian Chemical Society (MKE) on 100 years and the French Chemical Society (SFC) on 150 years of service to chemists and chemistry in their countries. The SFC is the oldest society associated with EurJIC, but the countries in Europe awoke to the importance of chemistry within a short spate of time. In the nineteenth and early twentieth centuries, farsighted chemists formed these associations to advance chemistry and promote exchange of knowledge, not only within their countries but across the boundaries. Table 1 lists the dates of foundation of our partner societies, but here I would like to mention the German Chemical Society, which set down its roots 140 years ago; one of the Belgian Societies, La Société Royale de Chemie (SRC), which is 20 years younger; the Czech Society, which is heading into its 15th decade; and the Austrian Chemical Society, which was established in 1897. EurJIC and the other members of the family of European journals bear witness to the success of the societies in one of their goals − the dissemination of knowledge across the world.

The printed word has been the business of John Wiley & Sons for 200 years (see the pages following this editorial). My contact with the company started with my first year at university − it is my pleasure to work for the publisher that probably had the most impact on my career in chemistry. Its excellence in publishing facilitated my studies through comprehensive textbooks and the outstanding journals that are now part of its program.

Finally, the latest anniversary is that of EurJIC itself. Although the journal in this form is only ten years old in 2007, one of the predecessor journals was founded before any of the societies. Yet you can read the first papers electronically in the Chemical Society Backfile Collection and jump to the reference rapidly through CrossRef. One of our projects underway at the moment is to provide electronic access to all the predecessor journals as quickly as possible. All will have the same convenient CrossRef feature.

What else is new in this auspicious tenth year?

Günter Schmid (Essen, Germany) and Ivano Bertini (Sesto Fiorentino, Italy), who since the first issue have worked hard to create this Inorganic Chemistry society journal,

Table 1. The European chemical societies that co-own EurJIC.

| Country | Society | Founded | Web address |
|---|---|---|---|
| Austria | Gesellschaft Österreichischer Chemiker (GÖCh) | 1897 | http://www.goech.at/ |
| Belgium | La Société Royale de Chimie (SRC) | 1887 | http://www.ulb.ac.be/assoc/src/ |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

have retired from the Editorial Board. Ivano in addition served as Chairman for eight years. My sincere thanks go to them for their advice and support. In these days of rapid publishing, it was essential that I could rely on their quick reply for any critical decision. Taking over as Chairman is Jan Reedijk (Leiden, the Netherlands). He brings long experience in publishing and a thorough knowledge of the journal and the Societies' standards to this position. The new members are Maurizio Peruzzini (Sesto Fiorentino), who adds expertise in the core inorganic chemistry areas of coordination chemistry and catalysis, and Ulrich Simon (Aachen, Germany), who has a broad background in inorganic chemistry including the topical nanoscience fields. On behalf of all members of the Board I welcome them and look forward to our closer collaboration in EurJIC.

New Board Members

My thanks are also due to the retiring members of the International Advisory Board. Three, Cornelis Elsevier (Amsterdam, the Netherlands), Bernt Krebs (Münster, Germany) and José González-Calbet (Madrid, Spain), also worked from the start to ensure the successful integration of their societies' journals into the new European Journal and two (Alejandro Vila, Argentina and Kazuko Matsumoto, Japan) joined this Board when, after the successful unification, members were invited from outside Europe. All have worked for EurJIC for many years and we appreciate their support. Their successors are Mauro Botta (Alessandria, Italy), Susumu Kitagawa (Kyoto, Japan), Nils Metzler-Nolte (Bochum, Germany), Barbara Milani (Trieste, Italy) and Joost Reek (Amsterdam).

You probably have already noticed that the Table of Contents has a new look. Our aims were to assist fast browsing of the contents by highlighting the individual papers optimally. A survey on the use of the Table of Contents revealed that although the graphics are useful, an additional short text helps in rapid orientation in the latest issue. The use of colour will make the selection of the graphic much easier in some fields of inorganic chemistry. The two templates available for authors on the homepage (www.eurjic.org) are a guide to the length and style required. Again to enable inorganic chemists to discover the latest developments in their field fast, in 2007 EurJIC will publish 36 issues. The rapid expansion of EurJIC at the beginning of the decade led to a long list of papers in each issue. A shorter Table of Contents, in particular with the key topic flag, ensures that important papers are less likely to be overlooked. *Chemistry – A European Journal* made this change in 2006. Its success persuaded EurJIC and its sister journal EurJOC to follow suit.

Easier To Browse Table of Contents

The Table of Contents of EurJIC – like those of any other journal available on Wiley InterScience – can now be accessed as RSS feeds. An RSS feed delivers updates of text content on web pages, determined by the user, to a computer or even a mobile phone. Once the news reader software program is installed and the Webpage selected, the feeds are automatic. Again, for more information, just visit the homepage of EurJIC and click on the orange RSS icon next to the cover picture. Authors and peer reviewers can also expect changes to simplify their collaboration with the journal. Many authors used our first templates ten years ago for the manuscripts they submitted. The state of the art has, however, changed since then: with peer review by PDF, the need to reduce the number of pages for review has become increasingly important, and graphics placed where they are intended facilitate the assessment. In addition, authors prefer to see how their article is likely to look in print. Soon EurJIC templates that mimic the print version will be available for all article types amongst the tools "for authors" on the journal homepage.

RSS Feeds Available

Templates Help Authors and Reviewers

In honour of the 10th anniversary of EurJIC, the journal will sponsor a poster prize at the 9th FIGIPAS meeting in Vienna from July 4–7, 2007 (http://figipas.tuwien.ac.at/). This European conference was selected, because, like the journal, it covers the full spectrum of Inorganic Chemistry. A special issue is planned to coincide with the conference.

Finally, at the start of this New Year in which Inorganic Chemistry will continue to search for new, improved materials or production protocols for a modern world, as well as for both an understanding of – and solutions for – the problems that exist, I wish all our authors and readers peace and prosperity in all continents of the world and fulfilment as your research contributes to these goals.

# A Passion for Publishing

*History of John Wiley & Sons, Inc.*

***Figure 1.*** Charles Wiley.

### *The Early Years*

**1807** Charles Wiley (Figure 1) opens small printing shop in Manhattan, New York City.

**1814** Wiley becomes a publisher and within five years begins to produce works by New York City's literary set, notably Fitz-Greene Halleck, Washington Irving, and James Fenimore Cooper.

**1826** John Wiley heads family business following his father's death, launching a 65-year career in publishing.

**1836** George Palmer Putman becomes junior partner, a relationship that leads to the publication of outstanding contemporary writers on both sides of the Atlantic. Together they achieve prominence publishing such works as Herman Melville's *Typee: A Peep at Polynesian Life*, Edgar Allan Poe's *The Raven*, and Nathaniel Hawthorne's *Mosses from an Old Manse*. They published the works of European writers such as Hans Christian Andersen, Victor Hugo, Charles Dickens, and Elizabeth Barrett Browning.

### *Changing Course*

**1848** Wiley & Putnam end their association. John Wiley broadens the company's publishing to include works on art, religion, architecture, agriculture, science, and technology.

**1849** Wiley publishes the first volume by art critic John Ruskin.

**1865** John's son Charles joins the firm to form John Wiley & Son.

**1876** William Halsted Wiley, another son of John, enters the business, creating John Wiley & Sons.

**1880** The handbook *Field Engineering* by Williams Searles is published, evidence of William Halsted Wiley's enthusiasm for engineering, railroads, and construction, marking a shift away from general-interest books and the marketing policies of his father. Wiley continues to expand into new fields, including electrical, civil and mechanical engineering, architecture, construction, agriculture, and chemistry (Figure 2).

**1890** William O. Wiley, eldest son of Charles joins the company as Secretary. He is the first member of the fourth generation to work at Wiley.

**1891** John Wiley dies at age 82. William Halsted Wiley becomes the new head of the company.

**1914** Edward Hamilton, nephew of William H. and Charles, joins the company.

**1925** William O. Wiley, eldest son of Charles, succeeds to the presidency after the death of William Halsted Wiley.

**1929** Sales top $1 million. Meanwhile, William O. Wiley begins to emphasize fields other than engineering and science. Wiley branches out into social sciences and business management publishing.

**1932** W. Bradford Wiley becomes the fifth generation to work at Wiley.

**1941** Edward P. Hamilton, a nephew of William Halstead Wiley and Charles Wiley, succeeds William O. Wiley as President. Staff numbers about ninety, including a dozen travellers, a precursor of Sales Representatives today. Travellers canvassed colleges and universities in search of course adoptions for existing titles and manuscript submissions. Sales pass $2 million mark, a new record.

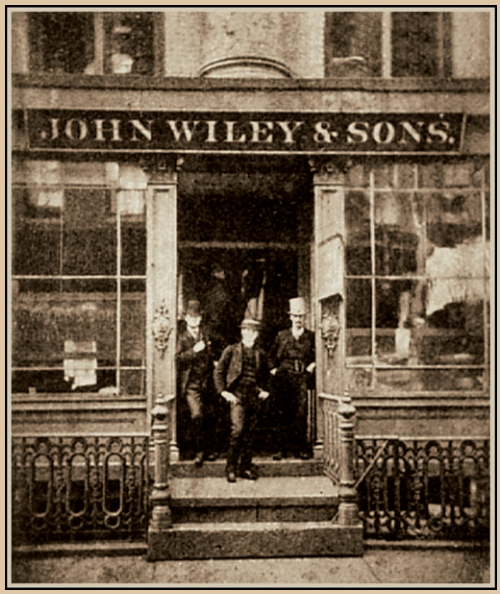

***Figure 2.*** Photo of John Wiley & Sons entrance (1880).

## *Building a Modern Corporation*

**1956** W. Bradford Wiley, age 46, succeeds Hamilton as President.

**1957** Wiley marks 150th anniversary.

**1960** Wiley opens its first international subsidiary in London.

**1962** First public sale of company stock.

**1963** Wiley opens Wiley Australasia in Sydney.

**1965** Sales top $20 million and three years later reach $30 million as operations expand to Mexico, South America, Australia, and Japan.

**1968** W. Bradford Wiley's daughter, Deborah, the sixth generation involved in the family business, joins the company. Wiley opens Canadian office in Toronto.

**1971** Andrew H. Neilly becomes President and Chief Operating Officer of John Wiley & Sons. W. Bradford Wiley becomes Chairman, continuing as Chief Executive Officer.

**1978** Publishing activities are realigned into four major groups: professional, educational, international, and medical.

**1979** Andrew Neilly's responsibilities increase as he becomes Chief Executive Officer, continuing as Chief Operating Officer. Bradford Wiley II, son of W. Bradford, joins the company's Board of Directors.

**1982** Wiley celebrates 175 years of publishing and expanded beyond its traditional businesses into the area of business education and training with the acquisition of Wilson Learning Corporation.

**1984** Peter Booth Wiley, son of W. Bradford Wiley joins the company's Board of Directors.

**1985** The Business, Law, and General book division (later renamed the Professional/Trade publishing division, as it is known today) is founded.

**1988** Ruth McMullin succeeds Andrew Neilly as President and Chief Executive Officer.

**1989** Wiley significantly expands its scientific, technical, and medical publishing program with the acquisition of Alan R. Liss, Inc., a leading publisher of journals and books in the life sciences.

**1990** Charles R. Ellis succeeds Ruth McMullin as President and Chief Executive Officer.

**1993** Brad Wiley II succeeds his father as Chairman of the Board.

## *Planning, Expansion, and Property*

**1995** Wiley first establishes http://www.wiley.com/ the company's Web site. It continues to evolve providing access to Wiley products and services, such as Wiley InterScience.

**1996** Wiley acquires a 90% interest in VCH, an important scientific, technical, and professional publisher based in Weinheim (Figure 3). VCH, founded in 1921, is one of the leading technical publishers in Germany with an emphasis on science. For several years, technical and specialist information in print and electronic form, for professionals and experts, has been a major focus. VCH has a longstanding publishing partnership with the German Chemical Society, and the acquisition of the VCH Group, which now includes Ernst & Sohn, Verlag Helvetica Chimica Acta, and GIT Verlag, further strengthens Wiley's leadership in these markets.

***Figure 3.*** Photo of Wiley-VCH entrance.

**1997** Wiley acquires Van Nostrand Reinhold (VNR), an eminent publishing imprint of books and electronic products for professionals in architecture/design, environmental/industrial science, culinary arts/hospitality, and business technology.

**1998** William J. Pesce (Figure 4) is named President and Chief Executive Officer, becoming the tenth leader of the company. Pesce contributes significantly to the growth and profitability of the company's global publishing program. Wiley is selected as one of the "most respected companies" with "a strong and well thought out strategy," by the *Financial Times* in a global survey of Chief Executive Officers.

**1999** Wiley commercially launches Wiley InterScience (http://www.interscience.wiley.com/) which provides online access to journals, major reference works, and books, as well as such key resources as the Cochrane Library of evidence-based medicine databases. Later Wiley will undertake an initiative to digitize all its journal backfile holdings. When completed Wiley InterScience will be one of the largest archives of its kind with content dating back to 1799, and over 1.6 million articles of scholarly and scientific research.

**1999** Wiley acquires Pearson Education's college textbooks and instructional packages in biology/anatomy and physiology; engineering; mathematics; economics/finance; and teacher education; the San Francisco-based Jossey-Bass, a publisher of books and journals for professionals and executives in business, psychology, education, and health management; and the J. K. Lasser tax and financial guides to enhance its already strong presence in the financial planning market.

**2001** Wiley acquires Hungry Minds, Inc., the largest acquisition in the company's history to date. Through it, a portfolio of high profile brands came under the umbrella, including the *For Dummies* series, the *Webster's New World*™ dictionaries and *CliffsNotes*™ study guides, the *Frommer's*™ travel guides, and the *Betty Crocker*® and *Weight Watchers*® cookbooks.

**2002** Peter Booth Wiley (Figure 4) installed as Chairman, succeeding Brad, who continues to serve as a Board member. Wiley relocates its global headquarters from New York City to a new building on the waterfront in Hoboken, New Jersey.

**2003** *Working Mother* magazine lists Wiley as one of the "100 Best Companies for Working Mothers". The company also receives the Enterprise Award from the New Jersey Business & Industry Association in recognition of the contribution to the state's economic growth.

**2005** FORTUNE magazine names Wiley one of the "100 Best Companies to Work For." Wiley receives this distinction for the second consecutive year in 2006.

**2006** Wiley acquires outstanding shares of Wiley Dreamtech (India) Private Ltd., and renames it, Wiley India Private Ltd. The acquisition enables Wiley to strengthen its presence in India. Wiley Canada is named to Canadian Business magazine's 2006 list of "100 Best Workplaces in Canada," and Wiley Australia receives the Australian governments's "Employer of Choice for Women" citation as it has every year since its inception in 2001. Wiley reaches a significant milestone in fiscal year 2006 and reports revenue of $1 billion. Wiley acquires Blackwell Publishing (Holdings) Ltd., one of the world's foremost academic and professional publishers. The combined Wiley and Blackwell business will publish approximately 1,250 scholarly peer-reviewed journals as well as an extensive collection of books with global appeal.

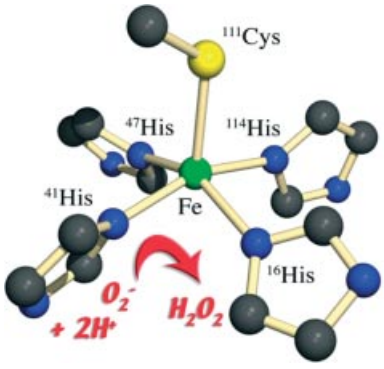
**2007** Wiley celebrates 200 years of publishing.

***Figure 4.*** William J. Pesce, William H. Wiley (picture), and Peter Booth Wiley.

EurJIC European Journal of Inorganic Chemistry

# MICROREVIEW

Synthetic models of the iron enzyme superoxide reductase (SOR) are described that, in combination with biochemical studies, are beginning to generate a clearer picture of the biological mechanism of superoxide reduction. Iron−peroxo species, trapped at low temperatures, are shown to be viable SOR intermediates, and provide key spectroscopic parameters for their identification.



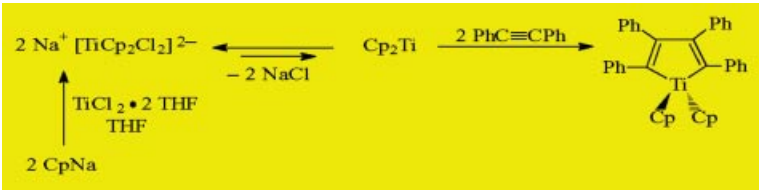
**Functional Metalloenzyme Models**

**L. M. Brines, J. A. Kovacs* ..... 29−38**

Understanding the Mechanism of Superoxide Reductase Promoted Reduction of Superoxide

**Keywords:** Bioinorganic chemistry / Metalloenzymes / Thiolate-ligated nonheme iron / Superoxide

# SHORT COMMUNICATIONS



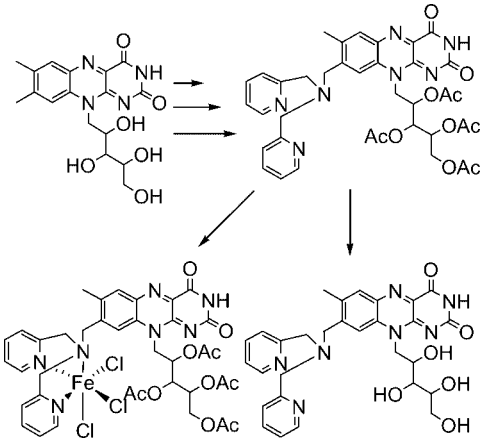
Titanocene(II) has been directly synthesized by the interaction of THF-soluble titanium(II) chloride with two equivalents of cyclopentadienylsodium in THF solution at 0°C. Because of the instability of titanocene(II), it was trapped in high yield as 1,1-bis(cyclopentadienyl)-2,3,4,5-tetraphenyltitanacyclopentadiene with diphenylacetylene.

**Carbenoid Character of Titanocene(II)**

**J. J. Eisch,* A. A. Adeosun, J. M. Birmingham ..... 39−43**

The Transient Titanocene(II): Direct Synthesis from Solvated Titanium(II) Chloride and Cyclopentadienylsodium and Ensuing Interception with Diphenylacetylene as 1,1-Bis-(cyclopentadienyl)-2,3,4,5-tetraphenyltitanacyclopentadiene

**Keywords:** Titanocene / Wilkinson metallocene synthesis / Epititanation



The preparation of the 8α-[bis(2-pyridylmethyl)amine]-*N*-Ac$_4$riboflavin ligand is reported. The trichloroferric complex has been prepared, and together with the low potential reduction wave of the flavin moiety, the presence of a reversible $Fe^{III}$/$Fe^{II}$ couple at a higher potential is observed. The deacetylated ligand 8α-[bis-(2-pyridylmethyl)amine]-*N*-riboflavin can easily be obtained.

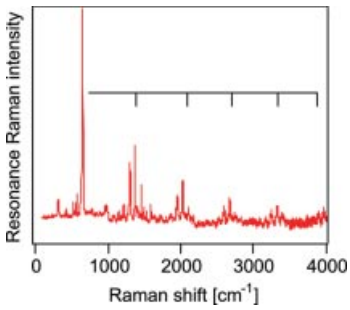
### Resonance Raman Overtones

**R. Beaulac, A. B. P. Lever,* C. Reber* ..... 48–52**

Resonance Raman Spectroscopy with Overtones Involving Metal-Ligand and Ligand-Centered Modes in (*o*-Benzoquinonediimine)ruthenium(II) Complexes

**Keywords:** Raman spectroscopy / Ruthenium complexes / Charge transfer / Density functional calculations / Luminescence



Resonance Raman spectra with visible excitation wavelengths show distinct resonance enhancements and intense overtone and combination bands resulting from charge-transfer excitations. Assignments of fundamental bands are based on theoretical spectra obtained from DFT calculations.

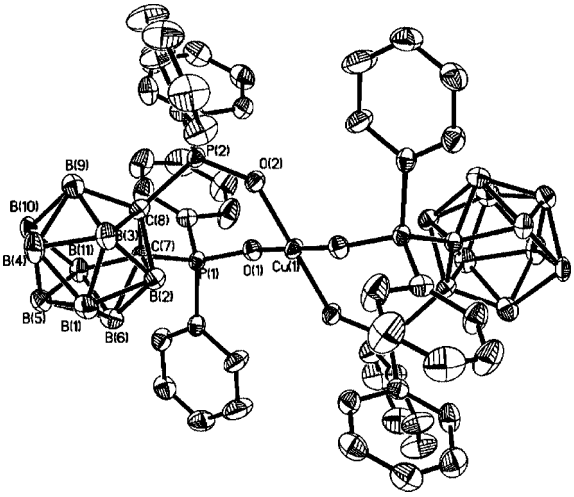
## FULL PAPERS

### Phosphorylcarborane Complexes

**J. M. Dou,* D. P. Zhang, D. C. Li, D. Q. Wang ..... 53–59**

Synthesis and Crystal Structure of Three Carborane Complexes, [M{7,8-(OPPh$_2$)$_2$-7,8-$C_2B_9H_{10}$}$_2$] (M = Cu, Zn) and [Ni(thf)-{7,8-(OPPh$_2$)$_2$-7,8-$C_2B_9H_{10}$}$_2$]·thf, and Two Carborane Compounds, 1-(OPPh$_2$)-2-(PPh$_2$)-1,2-$C_2B_{10}H_{10}$ and H[7,8-(OPPh$_2$)$_2$-7,8-$C_2B_9H_{10}$]·0.25$C_2H_5OH$

**Keywords:** Cu complexes / Zn complexes / Ni complexes / Carborane complexes / Oxidation / Degradation



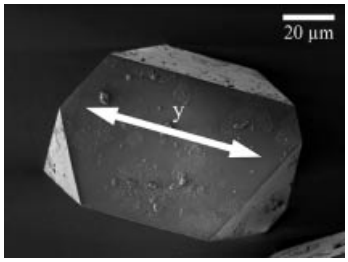
Three new carborane complexes containing a phosphoryl-*nido*-carborane ligand were synthesized by the reactions of 1,2-(PPh$_2$)$_2$-1,2-$C_2B_{10}H_{10}$ with three inorgnic compounds in ethanol in air. Two other phosphoryl compounds were also obtained through the oxidation of the *closo* ligand in air.

### Supported Membranes

**M. Arnold,* P. Kortunov, D. J. Jones, Y. Nedellec, J. Kärger, J. Caro ..... 60–64**

Oriented Crystallisation on Supports and Anisotropic Mass Transport of the Metal-Organic Framework Manganese Formate

**Keywords:** Organic–inorganic hybrid composites / Membranes / Anisotropic mass transport / Oriented crystallisation / Manganese



The MOF manganese formate was examined regarding its ability to be applied in supported gas-separating membranes. For this purpose, the anisotropic mass transport of methanol in the MOF has been investigated by IFM, proving a 1D channel system. Additionally, the oriented crystallisation of the manganese formate on different supports has been investigated by XRD and SEM.

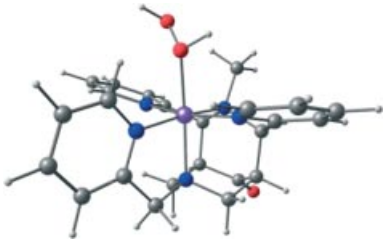
## O−O Bond Cleavage

Density functional theory reveals two distinct pathways for the decomposition of an $LFe^{II}(H_2O_2)$ complex to $LFe^{IV}(O)$ and water. One pathway involves initial O−O bond homolysis followed by hydrogen-atom transfer while in the other proton transfer precedes O−O bond heterolysis. The barriers to the two processes are rather similar, suggesting that subtle changes in the identity of L or in the reaction conditions may cause a complete change in mechanism.



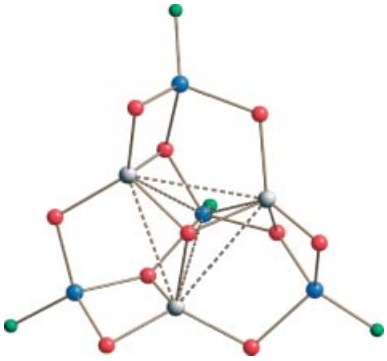
**A. E. Anastasi, A. Lienke, P. Comba, H. Rohwer, J. E. McGrady* ..... 65−73**

Competing Radical and Non-Radical Pathways for the Decomposition of $LFe^{II}(H_2O_2)$ Complexes: a Density Functional Study

**Keywords:** Density functional calculations / Oxido ligands / O−O activation / Electronic structure / Transition states

## Copper-Iron Chalcogenide Clusters

Reactions of mixtures of copper and iron salts with $PhSeSiMe_3$ led in the prescence of phosphanes or ammonium salts to the formation of mixed copper-iron selenolate cluster molecules. Heating of the clusters results in the formation of mixtures of binary $Cu_2Se$ and ternary $CuFeSe_2$.



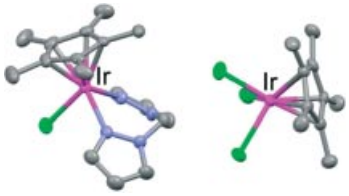
**A. Eichhöfer,* D. Fenske, J. Olkowska-Oetzel ..... 74−79**

Synthesis and Structure of $[n\mathrm{Pr_3N(CH_2)_6N}n\mathrm{Pr_3}][CuFe_3Br_3(SePh)_6]$, $[Cu_5Fe(SePh)_7(PPh_3)_4]$ and $[Cu_4Fe_3(SePh)_{10}(PPh_3)_4]$

**Keywords:** Iron / Copper / Selenium / Cluster compounds

## Bimetallic Ion Pairs

Complexes of the type [Cp*MCl(N−N)][X] (M = Rh and Ir) have been synthesised, where N−N is a series of bidentate ligands with $sp^2$ N-donors and X = $[Cp^*MCl_3]^-$, $Cl^-$ or $BF_4^-$.

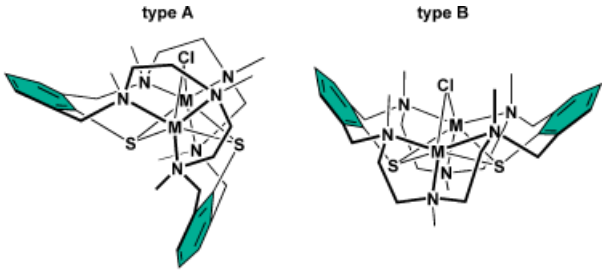


**D. F. Kennedy, B. A. Messerle,* M. K. Smith ..... 80−89**

Synthesis of Cp* Iridium and Rhodium Complexes Containing Bidentate $sp^2$-N-Donor Ligands and Counter-Anions $[Cp^*MCl_3]^-$

**Keywords:** Iridium(III) / Rhodium(III) / N-donor ligands / Cyclopentadienyl ligands

## Ligand Conformation



**M. Gressenbuch, B. Kersting* ..... 90−102**

Synthesis and Characterisation of Dinuclear Nickel(II) and Cadmium(II) Complexes of *N*-Alkylated Derivatives of Hexaazadithiophenolate Macrocycles

**Keywords:** Macrocyclic ligands / N ligands / S ligands / Nickel / Cadmium

The effect of *N*-alkylation on the coordination properties of macrocyclic $N_6S_2$ ligands has been examined. The ligand conformation adopted depends on the type of the coligand, the metal ion radius, and the *N*-alkylation grade.

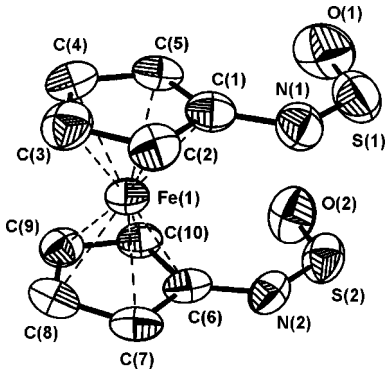
# CONTENTS

## (Sulfinylamino)ferrocenes

**B. Wrackmeyer,* E. V. Klimkina, W. Milius, M. Siebenbürger, O. L. Tok, M. Herberhold ..... 103–109**

Ferrocenes Bearing Sulfinylamino Groups

**Keywords:** Ferrocenes / Sulfinylamine pendant groups / Electronic structure



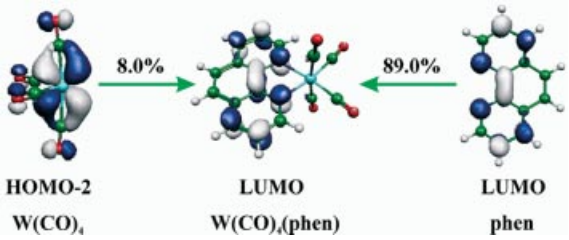
Three new (sulfinylamino)ferrocenes [1,1'-bis(sulfinylamino)ferrocene, 6-amino-1-sulfinylaminoferrocene, 1-sulfinylamino-6-(trimethylsilylamino)ferrocene] were prepared and characterised by X-ray structural analysis in the solid state, and by $^{1}H$, $^{13}C$, $^{14}N$, $^{15}N$, $^{29}Si$ and $^{57}Fe$ NMR spectroscopy in solution.

## Structure–Back Bonding Correlation

**C. Makedonas, C. A. Mitsopoulou* ..... 110–119**

$W(CO)_4$(diimine) Structure Revised – Correlating Structure to π* Back-Bonding

**Keywords:** Tungsten / Pi interactions / N ligands / Carbonyls / Ligand effects



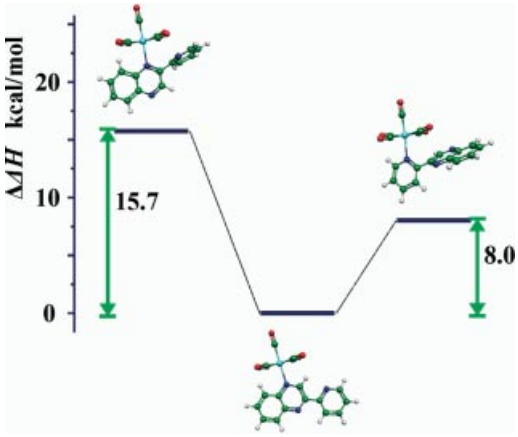
DFT calculations carried out on a series of $W(CO)_4$(diimine) compounds reveal that the best indices for the extent of back donation are both the deviation of C–W–C and O–C–W angles from orthogonality and linearity, respectively. This is quantitatively described by a structure–properties relation.

## Conformation and Electronic Structure

**C. Makedonas, I. Veroni, C. A. Mitsopoulou* ..... 120–131**

Pentacarbonyl[2-(2′-pyridyl)quinoxaline-κ$N^4$]tungsten: A Combined Study of Its Conformational and Electronic Structure Based on Experimental and DFT-TDDFT Data

**Keywords:** Pentacarbonyl complexes / Monodantatepyridyl)quinoxaline / Tungsten / TD-DFT calculations / Pi stacking



The title compound is isolated en route to photolytic $W(CO)_4$pq chelate ring closure and it is the first example where the pq ligand is coordinated in a monodentate fashion. The preference of the coordinated nitrogen atom is elucidated both experimentally by spectroscopic and crystallographic methods and theoretically by means of DFT and TDDFT calculations.

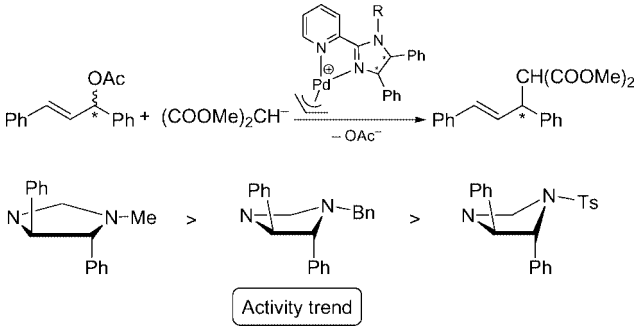
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

## Pd/Imidazolines in Allylic Alkylations

**A. Bastero, A. F. Bella, F. Fernández, S. Jansat, C. Claver,* M. Gómez,* G. Muller, A. Ruiz, M. Font-Bardía, X. Solans ..... 132–139**

First Allylpalladium Systems Containing Chiral Imidazolylpyridine Ligands – Structural Studies and Catalytic Behaviour

**Keywords:** Palladium / Chiral imidazolines / Catalysis / Allylic alkylation / Intermediates / Heterocycles



Palladium/chiral imidazolylpyridines systems were tested in allylic alkylation of *rac*-3-acetoxy-1,3-diphenyl-1-propene and 3-acetoxy-1-phenyl-1-propene, paying particular attention to the influence of the amine nitrogen hybridisation on their catalytic behaviour. Allylpalladium intermediates containing phenylallyl groups were synthesised and fully characterised both in solution (NMR) and the solid state (single-crystal X-ray diffraction).

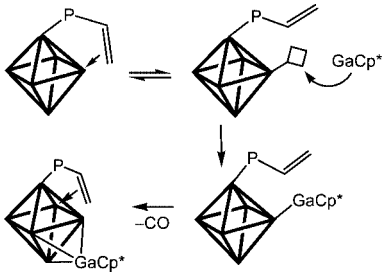
## Hemilabile Clusters

**E. V. Grachova, G. Linti, H.-G. Stammler, B. Neumann, S. P. Tunik,* H. Wadepohl ..... 140–146**

Reactions of GaCp* with a Hemilabile Derivative of $Rh_6(CO)_{16}$ – Synthesis and Structural Characterization of Two Novel Heterometallic Clusters: $Rh_6(CO)_{13}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)$ and $Rh_6(CO)_{13}(\kappa^1\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)_2$

**Keywords:** Cluster compounds / Heterometallic complexes / Phosphane ligands

Reaction of the $Rh_6(CO)_{14}(Ph_2PCH{=}CH_2)$ cluster containing hemilabile diphenylvinylphosphane with GaCp* (Cp* = $C_5Me_5$) affords two novel heterometallic clusters, $Rh_6(CO)_{13}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)$ and $Rh_6(CO)_{13}(\kappa^1\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)_2$.

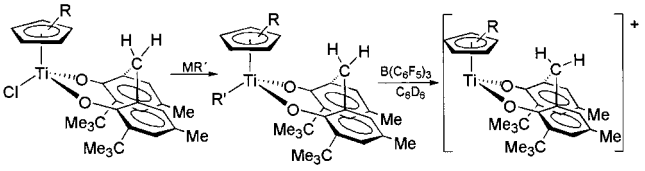


## Ti Complexes in Polymerisation

**M. González-Maupoey, T. Cuenca,* L. M. Frutos, O. Castaño, E. Herdtweck, B. Rieger ..... 147–161**

Alkylmono(cyclopentadienyl)titanium Complexes Containing the 2,2′-Methylenebis(6-*tert*-butyl-4-methylphenoxido) Ligand – Studies on the Nature of the Catalytic Species Present in α-Olefin Polymerisation Processes

**Keywords:** Titanium / Chelates / Olefin polymerisation / Density functional calculations



The synthesis of 2,2′-methylenebis(6-*tert*-butyl-4-methylphenoxido)titanium complexes is described. Structural data are derived from DFT methods and X-ray diffraction studies. The complexes polymerise α-olefins when activated with MAO or $[Ph_3C][B(C_6F_5)_4]$, while they are inactive in the presence of $B(C_6F_5)_3$. Stoichiometric reactions with Lewis acids were studied by NMR spectroscopy.

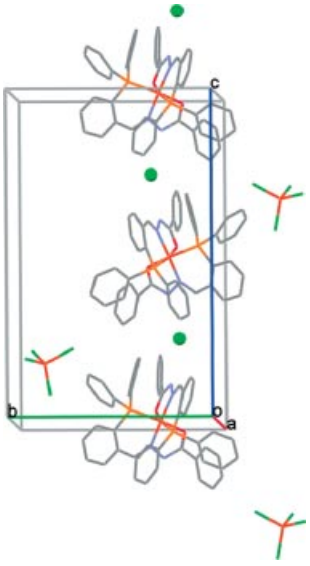
## Iron Complexes with Tridentate Ligands

**P. Pelagatti,* A. Bacchi, M. Balordi, A. Caneschi, M. Giannetto, C. Pelizzi, L. Gonsalvi, M. Peruzzini, F. Ugozzoli ..... 162–171**

A Ligand-Driven Geometry Switch in Octahedral and Trigonal-Bipyramidal Iron Complexes Containing (H)PNO and PNN Ligands

**Keywords:** Iron / N,P ligands / Ligand effects



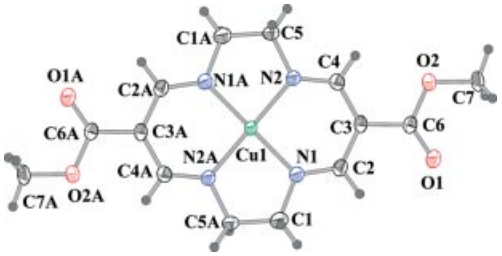
Complexation reactions of $Fe^{II}$ and $Fe^{III}$ salts with the tridentate ligands (H)PNO and PNN are reported. (H)PNO leads to the formation of the octahedral cation *fac*-$[Fe\{\kappa^3\text{-(H)PNO}\}_2]^{n+}$ ($n$ = 2 or 3), while PNN leads to the formation of the trigonal-bipyramidal complex [*mer*-Fe($\kappa^3$-PNN)$Cl_2$].

## Tetraazamacrocyclic Complexes

**A. Rybka, R. Koliński, J. Kowalski, R. Szmigielski, S. Domagała, K. Woźniak,* A. Więckowska, R. Bilewicz,* B. Korybut-Daszkiewicz* ..... 172–185**

Tuning the Properties of Neutral Tetraazamacrocyclic Complexes of Copper(II) and Nickel(II) for Use as Host–Guest Compounds with Bismacrocyclic Transition Metal Cations

**Keywords:** Macrocyclic ligands / Copper / Nickel / Cyclic voltammetry / Template synthesis



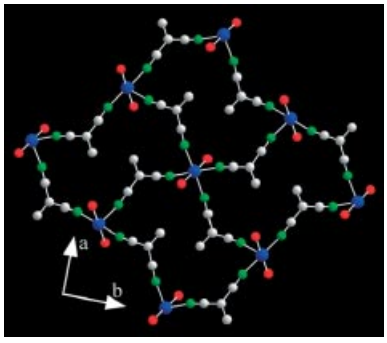
Deviations from planarity increase with increasing size of the tetraazamacrocyclic ligands and their neutral and protonated 14-, 15-, and 16-membered complexes of $Cu^{II}$ and $Ni^{II}$. As a consequence, the donor properties are weaker, the redox potential is shifted towards more positive values, and contribution of chemical reactions can also be observed. The formation of host–guest complexes between the strongest metal-containing donors and transition-metal-containing bismacrocyclic acceptors of suitable size is proved in solution and the gas phase by voltammetric and ESI MS methods. The transition metal building blocks described in this contribution could be applied in the synthesis of new redox-active rotaxane and catenane systems.

## Coordination Polymers

**S. Benmansour, F. Setifi, S. Triki,* J.-Y. Salaün, F. Vandevelde, J. Sala-Pala, C. J. Gómez-García,* T. Roisnel 186–194**

New Multidimensional Coordination Polymers with $\mu_2$- and $\mu_3$-dcno Cyano Carbanion Ligand {dcno$^-$ = $[(NC)_2CC(O)O(CH_2)_2OH]^-$}

**Keywords:** Cyano carbanions / Bridging ligands / Coordination polymers / Multidimensional networks / Magnetic properties



This study involves the design of multidimensional transition metal compounds with the cyano carbanion dcno$^-$ acting as $\mu_2$- and $\mu_3$-bridging ligand. The bonding affinity and flexibility of the cyano carbanion ligand towards transition metal ions are clearly illustrated.

**If not otherwise indicated in the article, papers in issue 24 were published online on December 6, 2006**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

## 1.General Information

The *European Journal of Inorganic Chemistry (EurJIC)* publishes 36 issues per year.

**Manuscripts should be submitted online** using our online submission service at http://www.manuscriptXpress.org. You should prepare a **single file containing all tables, graphics, supporting information (where appropriate) etc.** Acceptable file formats are **Microsoft Word, Rich Text Format, Postscript and PDF**. Avoid the use of page breaks even between the title page and the introduction. If graphics are included at the end of the manuscript, try to fit as many as possible onto a single page. The file should have margins of 2 cm and be 1.5-line spaced.

Authors can follow the progress of their manuscript on their **personal homepage**, which is created automatically upon initial registration. This homepage is the same for the family of Wiley-VCH European journals and can be used to **store the latest version of a submitted paper** and to **upload the document file after acceptance**. Your referee reports for the family of Wiley-VCH European journals are also archived here.

**No paper copies of the manuscript are required when using this system.**

- EurJIC does not publish manuscripts that have already appeared in print or electronically. **The author must inform the editor of manuscripts submitted, soon to be submitted, or in press at other journals that have a bearing on the manuscript being submitted.** If a manuscript is, in fact, a revised/extended version of a manuscript previously rejected by EurJIC, **the author must inform the editor about the previous submission in the cover letter and explain in detail which changes have been made**. The *Ethical Guidelines for Publication in Journals and Reviews* issued by the European Association for Chemical and Molecular Sciences (EuCheMS) are followed and applied by the editors of EurJIC. **Authors should reveal all sources of funding for the work presented in the manuscript and should declare any conflict of interest.**
- Manuscripts containing **animal experiments** must include a statement in the Experimental Section to state that permission was obtained from the relevant national or local authorities. The institutional committees that have approved the experiments must be identified and the accreditation number of the laboratory or of the investigator given where applicable. If no such rules or permissions are in place in the country where the experiments were performed, then this must also be clearly stated. Manuscripts with experiments with **human subjects** or **tissue samples** from human subjects must contain a disclaimer in the Experimental Section to state that informed signed consent was obtained either from the patient or from next of kin.
- The correspondence author of a Microreview will receive a complimentary copy of the journal along with a PDF file of his/her paper restricted to 50 printouts; the correspondence author of other articles will receive a PDF file restricted to 25 printouts. Colour figures can be reproduced. Unless the editor deems colour to be essential for the understanding of a paper, authors will be requested to make a contribution towards the costs of colour reproduction. Details will be provided after acceptance of the manuscript.
- We encourage authors to submit pictures for the cover page. A template of our cover page, **eurjiccover.pdf**, can be reached by clicking the link "For Authors" on our journal homepage (http://www.eurjic.org), to help you visualize the final effect of your design.

**IMPORTANT:** Any manuscript already available on personal/group web pages will be considered by the editors as already published and will not be accepted.

On behalf of our authors who are also US National Institutes of Health (NIH) grantees, Wiley-VCH will deposit the peer-reviewed version of the manuscript in PubMed Central (PMC). PMC may display the material 12 months after Wiley-VCH has published the article. By assuming this responsibility, we will ensure that our authors are in compliance with the NIH request and make certain that the appropriate version of the manuscript is deposited. We await the release by PMC of the protocols regarding manuscript submission. We reserve the right to change or rescind this policy.

## 2. Types of Contributions

**EurJIC publishes articles on inorganic, organometallic, bioinorganic, physical inorganic and solid-state chemistry. EurJIC is a fully peer-reviewed journal. An author may appeal against the decision on his/her manuscript, in writing. Three types of contributions are accepted for publication:**

- **Full Papers** are articles with an Experimental Section that describe a significant contribution to the development of an area of research of importance. There are no restrictions placed on the length of a Full Paper.
- **Short Communications** are brief reports on results of high significance and urgency. Generally, they are no longer than 8–10

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.5-line-spaced pages or 3–4 typeset pages. An Experimental Section (as a separate paragraph or as part of the references) is desirable; if it is not included in the paper, the experimental data should be submitted as Supporting Information for refereeing purposes, and marked as such. A justification for urgent publication should accompany submission.

- **A Microreview** is a highly focused overview of a selected topic. In general it includes a concise overview of the author's own research; reference to all appropriate work by others is essential, but the Experimental Sections of the original papers should not be repeated. As a rule, Microreviews are written on invitation, although unsolicited articles are also welcome. It is recommended, however, to contact the editor before submitting an unsolicited Microreview. The content should balance scope with depth in 25–30 1.5-line-spaced pages or 10–12 typeset pages. Microreviews will undergo peer review.

## 3. Manuscript Preparation

### 3.1 General

The whole of the manuscript should be 1.5-line spaced and in a large script (Times New Roman, 12 pt). We recommend that you prepare your text with **Microsoft Word (PC or Macintosh versions)** (see Section 3.2). Page numbers are essential: use the automatic pagination function incorporated in your word processing software. Leave a 2-cm margin around the perimeter of each page. **The figures, schemes and graphical abstract in the accepted version should be camera-ready**. Consult a current issue of the journal for an overview of the format. A manuscript should comprise: ✧ Title Page ✧ Keywords ✧ Abstract ✧ Main Text including Introduction, Results and Discussion etc. ✧ Experimental Section ✧ Acknowledgments (optional) ✧ Captions ✧ Tables ✧ References ✧ Schemes and Figures ✧ Graphical Abstract including a short text (max. 350 characters) and a graphical element (use of free colour is strongly recommended). Refer to the homepage Table of Contents template (http://www3.interscience.wiley.com/cgi-bin/jabout/27721/2005_guidelines.html). ✧ For Microreviews only: Biographical sketches and a portrait-quality photograph of all authors (when several authors from one institution are involved, group photographs are preferred).

### 3.2 Text

The text should be typed with carriage returns (hard returns) only at the end of a paragraph, title, heading and similar features. Avoid end-of-line word divisions.

**Abbreviations and acronyms** should be used sparingly and consistently. Where they first appear in the text, the complete term – apart from the most common ones such as NMR, IR, thf, *t*Bu etc. – should also be given.

**In the Experimental Section**, quantities of reactants, solvents etc. should be included in parentheses [e.g. A solution of triphenylphosphane (500 mg, 1.91 mmol) in dichloromethane (15 mL) was added to...].

**NMR spectroscopic data** should be quoted as in the following example: $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.3 (s, 18 H, $SiMe_3$), 0.9 (d, $^3J_{H,H}$ = 5.7 Hz, 2 H, 2-H) ppm. For each chemical shift, additional information should be given in the order: multiplicity, coupling constant, number of protons, assignment.

**The purity of all new compounds** should be verified by elemental analysis to an accuracy within ±0.4%. In special cases, for instance when the compound is unstable or not available in sufficient quantities for complete analysis, the exact relative molecular mass obtained from a high-resolution mass spectrum and a clean $^{13}$C NMR spectrum (as additional material for inspection by the referees) should be supplied.

**Symbols of physical quantities**, but not their units (e.g. *T* for temperature, *J*, $\lambda$), stereochemical information (*cis*, *trans*, *Z*, *R*), locants (*N*-methyl), symmetry and space groups ($P2_1/c$), and prefixes in formulas (*t*Bu) or compound names (*tert*-butyl) **must be in italics**. Latin phrases, such as "in situ", should not.

**Stereochemical descriptors**, such as D- and L-, and molar (M) or normal (N) should be in **small capitals**. Use character formatting for italic and bold characters. Avoid any *special style sheets* to format these features. Write *capital letters* using the keyboard (shift + letter key), **not** the format "Capital letter" in Word.

**Use only characters from the Symbol and Normal Text character sets**, especially when inserting Greek letters and characters with umlauts, accents, tildes, etc.: α, ä, à, ã, Å.

There are three types of hyphens: normal dashes (-), en dashes (–), and em dashes (—). Use these as illustrated — spacing is important too — in the following examples:

| | |
|---|---|
| well-known reaction | C–H bond |
| six-membered ring | Tables 2–4 |
| 3-position of the ring | carbon–oxygen bond |
| signal-to-noise ratio | C–N stretch |
| Mo-$K_\alpha$ | Diels–Alder reaction |
| 1,2-dicyanobutane | structure–activity relationship |
| *p*-*tert*-butylphenol | 80–100 mg |
| (–)-tartaric acid | carried out at –10 °C |
| [$M^+$ – CH3] | $cm^{-1}$ |

Use the symbol × where appropriate, rather than the letter x:

... washed with water (2 × 150 mL) ...

Use the double quotation marks "..." rather than „...“, "..." or «...».

**Graphics (including structural formulas, schemes, figures, equations and small graphical items that appear in captions) must be submitted camera-ready on separate pages after acceptance of the manuscript (see Section 3.5).**

**Lines** or **arcs**, for example to indicate ring compounds, cannot be used within the text. Another method for indicating such compounds must be devised. Please contact the Editorial Office if any help is needed.

If practical, authors should use a systematic name (IUPAC or Chemical Abstracts) for each title compound in the Experimental Section. Please avoid complicated, multi-line names if a simpler version (e.g. alcohol **4**, ketone **5**, compound **6**) could be used instead. EurJIC follows the IUPAC rules of nomenclature as updated by the latest recommendations and revisions.

According to a recent recommendation [N. G. Connelly, T. Damhus, R. M. Hartshorn, A. T. Hutton (Eds.), *Nomenclature of Inorganic Chemistry IUPAC Recommendations 2005*, RSC Publishing, Cambridge, UK, **2005**]:

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

- "Names of anionic ligands, whether inorganic or organic, are modified to end in 'o'. In general, if the anion name ends in 'ide', 'ite' or 'ate', the final 'e' is replaced by 'o', giving 'ido', 'ito' and 'ato', respectively. It follows that halide ligands are named fluorido, chlorido, bromido and iodido, and coordinated cyanide is named cyanido. In its complexes, except for those of molecular hydrogen, hydrogen is always treated as anionic, and therefore 'hydrido' is used for hydrogen coordinating to all elements including boron."
- "In the formulae for coordination entities, ligands are now ordered alphabetically according to first symbol of the abbreviation or formula used for the ligand, *as written*, irrespective of the charge."
- "No numerical subscript should follow the square bracket used to enclose a whole coordination entity of a neutral (formal) coordination compound."

For further details, please see the "Frequently Asked Questions" section (http://www3.interscience.wiley.com/cgi-bin/jabout/27721/2005_faq.html) at the journal website and IUPAC publications and websites.

### 3.3 Tables

Use the Insert Table command from the Table menu or use the Insert Table button on the Standard toolbar for creating tables, and use tabs ONLY to move between cells.

### 3.4 References

We strongly recommend the use of the Endnotes feature of Word. If you prefer not to use this function, references should be indicated by numbers in square brackets as superscripts and, if applicable, after punctuation (example: text.[1]). Use the Format Font menu.

Journal titles should be abbreviated according to the Chemical Abstracts Service Source Index (CASSI).

The Author is responsible for correct citations. The *European Journal of Inorganic Chemistry* is a member of Cross Ref. (http://www.crossref.org), a service which links reference citations to the online content that those references cite. This can only function if the citations are accurate. Please ensure that a composite reference is subdivided into parts a), b) etc. For example:

[1] a) A. Einstein, A. N. Other, *Eur. J. Inorg. Chem.* **2003**, 1–15; b) R. Schoenfeld, *The Chemist's English*, 3rd ed., VCH, Weinheim, **1990**, p. 111.

If a paper has been published online but has not appeared in print yet, it is cited by listing the author names and then the abbreviated title of the journal followed by the DOI number, e.g.:

[1] J. J. Schneider, J. Engstler, *Eur. J. Inorg. Chem.*, DOI: 10.1002/ejic.200501145.

### 3.5 Graphics

Graphics are schemes, figures, equations and small graphical items that appear in captions. Graphics differ fundamentally from the text portion of your manuscript in that they must be scanned or electronically processed. Schemes should be self-explanatory: reaction conditions should therefore be given above the arrows rather than in the caption.

In the revised version please submit **each graphic in its own file** within a graphic folder. For good reproduction, the following formats are preferred: *.cdr, *.cdx, *.tif, *.pdf, *.psd, *.ai, *.fh, *.qxd, *.pct, *.eps. The resolution should be a minimum of 300 dpi and 600 dpi for bitmap graphics.

Consult the following table for the appropriate size of lettering. Lettering smaller than 3.0 mm will reproduce poorly. Please use only one size of lettering per graphic and the same letter font for all graphics.

Table 1. Guide for preparing graphics

| | | Maximum Graphic Width[a] | |
|---|---|---|---|
| **Letter Size** | **Font** | **1-Column Format** | **2-Column Format** |
| | Times New Roman | | |
| 3.0 mm | 12 | 13 cm | 26 cm |
| **3.5 mm** | **14** | **15 cm**[b] | – |
| **4.0 mm** | **16** | **17 cm**[b] | – |
| 4.5 mm | 18 | 19 cm | – |

[a] Most graphics are in 1-column format. [b] We prefer lettering of 3.5 or 4.0 mm with maximum graphic widths of 15 or 17 cm, respectively.

The settings for one-column graphics constructed with Chem Draw are: Print Setup: Orientation Portrait. Caption and Label Settings: Font Times New Roman, Font Style Standard, Size 12. These settings help ensure the correct letter-size-to-graphic-width ratio for best reproduction.

Use abbreviations such as $R^1$, $R^2$ (not $R_2$), R′, R′′, Ph, Me, Et, *i*Pr, *t*Bu, Ph, Bn (benzyl), Bz (benzoyl), Hal, L, M (metal), X (heteroatom).

## 4. Crystallographic Data

Authors must deposit the data of X-ray structure analyses in a crystallographic database before submitting their manuscript, so that referees can access the information electronically. The two databases, the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have the same procedure for the deposition of data and both will be pleased to provide help. In general, you will receive a depository number from the database two working days after electronic deposition. Send your data to the appropriate address below and quote the standard text, including the depository number, in your manuscript.

- **For all compounds without C–H bonds**

Fachinformationszentrum Karlsruhe (FIZ)
76344 Eggenstein-Leopoldshafen, Germany
Phone: +49-(0)7247/808-205
Fax: +49-(0)7247/808-666
E-mail: crysdata@fiz-karlsruhe.de
FTP: ftp.fiz-karlsruhe.de (under path /pub/csd)
WWW: http://www.fiz-karlsruhe.de (under "Products and Services")
Further details of the crystal-structure investigation(s) may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number(s) CSD-....

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

- **For all compounds with at least one C–H bond:**

Cambridge Crystallographic Data Centre (CCDC)
12 Union Road, Cambridge CB2 1EZ, UK
Phone: +44-(0)1223/336-408
Fax: +44-(0)1223/336-033
E-mail: deposit@ccdc.cam.ac.uk
WWW: http://www.ccdc.cam.ac.uk
CCDC-****** contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**NOTE:** Please use the free online **Checkcif** service provided by the International Union of Crystallography and submit the Checkcif report along with your manuscript: http://journals.iucr.org/services/cif/checkcif.html.

Finally, before you return your revised manuscript, please update your database entry if necessary.

## 5. Electronic Supporting Information

A manuscript may include Electronic Supporting Information which will be accessible only on the WWW. Authors must keep a copy to make available to readers who do not have access to the internet. As this material [text, tables, schemes, figures **but not crystallographic (CIF) data**, which must be submitted to either the FIZ or the CCDC] undergoes the peer review process, it must be included, clearly marked as "Supporting Information to be published electronically", when the paper is submitted. The following file formats are accepted: MS Winword or ASCII (*.doc, *.txt), MS Excel (*.xls), Encapsulated Postscript (*.eps), Portable Document Format (*.pdf), graphics embedded in MS Winword; if you wish to submit other formats, please consult the Editorial Office. When preparing such material, authors should keep in mind that − once accepted − it will be made available as provided by the author and not edited. Material accepted for electronic publication will be available mostly as PDF files (Adobe Acrobat Reader required) by following the Table of Contents link of EurJIC's WWW home page. A standard text will be added on the first page of the article in the printed version:

- Supporting information for this article is available on the WWW under http://www.eurjic.org or from the author.

The supporting information file must start with the title of the paper, the authors and the CASSI abbreviation of the journal to which it was submitted (e.g. *Eur. J. Inorg. Chem.*).

## 6. Basic Keyword List

To increase the relevance of articles found by search engines of Wiley InterScience, we have compiled a keyword catalogue common to our chemistry journals that is printed here and is also available online (http://www.eurjic.org).

To assist you in finding keywords they are listed according to categories. You may choose keywords from any category. As with all such records, a few guidelines facilitate the catalogue's use, and these are briefly explained below:

1. As many as possible, but at least two, of the maximum of five keywords assigned to an article must come from this list.

2. Named reactions will be incorporated only in exceptional cases. Generally the reaction type is selected instead. For example, Diels–Alder reactions will be found under "Cycloadditions" and Claisen rearrangements under "Rearrangements".

3. Heteroanalogues of compounds are mainly classified under the C variants, for example, (hetero)cumulenes, (hetero)dienes. A few aza and phospha derivatives are exceptions.

4. Compounds with inorganic components that are central to the article are listed under the element, for instance, iron complexes under "Iron". Some group names like "Alkali metals" exist alongside the names of important members of the group like "Lithium". In such cases the group name is used for these members only when comparative studies are described. The members not appearing separately are also categorized under the group name.

5. A keyword in the form "N ligand" is only chosen if a considerable portion of the paper deals with the coordination of any ligand ligating through the atom concerned.

6. Spectroscopic methods are assigned as keywords only if the article is about the method itself, or if the spectroscopic technique has made an important contribution to the problem under investigation.

7. "Structure elucidation" is intended only if the crux of the paper is a structural elucidation or if a combination of several spectroscopic techniques were needed for conclusive solution of the structure.

8. An attempt has been made to avoid synonyms and to select more general concepts rather than specialized terms. Thus, the term "Double-decker complexes" is excluded in favour of "Sandwich complexes".

This list will be a "living" catalogue to be flexible enough to absorb the new developments in chemistry. We therefore welcome all suggestions from our authors that might improve its user-friendliness.

# Understanding the Mechanism of Superoxide Reductase Promoted Reduction of Superoxide

**Lisa M. Brines[a] and Julie A. Kovacs*[a]**

**Keywords:** Bioinorganic chemistry / Metalloenzymes / Thiolate-ligated nonheme iron / Superoxide

Superoxide reductases (SORs) are nonheme, iron-containing enzymes which reduce superoxide ($O_2^-$) to hydrogen peroxide ($H_2O_2$) in anaerobic organisms. In contrast to the classical superoxide dismutases (SODs), SORs selectively reduce, rather than disproportionate, superoxide at an unusual [Fe(NHis)$_4$SCys] catalytic site. Studies of the native enzyme and mutants have suggested the formation of a transient ferric-(hydro)peroxide intermediate in SOR's catalytic cycle, with subsequent protonation to yield hydrogen peroxide and a glutamate-bound ferric resting state. With the synthesis of small molecular model compounds of the enzyme's active site, analogous intermediates can be more thoroughly investigated in order to understand how the structure at the nonheme iron active site affects its function. Specific goals include the understanding of the role of the *trans* cysteinate in the promotion of SOR chemistry, as well as the role of the protons in the mechanism of the reaction. Because hydrogen peroxide formation requires two protons, investigation of the proton-dependence of the formation of ferric-(hydro)peroxo model complexes, as well as their subsequent reactivity with proton donors, yields important information about possible mechanisms. As new biochemical data on SORs become available, synthetic modeling, biophysical characterization, and DFT calculations continue to be important tools in the identification of viable mechanistic pathways.

## 1. Introduction

Organisms exposed to molecular oxygen inevitably encounter reactive oxygen species that are formed by the adventitious reduction of $O_2$ by redox-active enzymes.[1] These species include superoxide, $O_2^-$, the one-electron-reduced product of dioxygen. Elevated superoxide levels have been implicated in a number of diseases including diabetes[2] and the cell death and tissue damage that occurs following a stroke or heart attack.[3] Severe neurological disorders such as Parkinson's[4,5] and Alzheimer's[6,7] diseases may also be related to nerve cell damage caused by $O_2^-$. Additionally, some types of cancer are thought to arise from mutations induced by $O_2^-$ damage to DNA.[8,9] Organisms have evolved two known defenses for the detoxification of superoxide. In particular, two classes of enzymes have been identified whose function is the reduction and/or oxidation of superoxide: the superoxide dismutases (SODs) and the superoxide reductases (SORs).[10–16] The classical SODs disproportionate superoxide to hydrogen peroxide and dioxygen. In contrast, SORs selectively reduce superoxide to hydrogen peroxide in anaerobic organisms without the formation of dioxygen as a byproduct. How SORs are able to selectively reduce $O_2^-$ and avoid SOD activity is still not well understood. The active site's redox potential and access to protons are key parameters that govern this reactivity (vide infra).

In order to confirm the viability of the proposed intermediates in the mechanism of enzymatic superoxide reduction, synthetic models have proven useful in the establishment of spectroscopic parameters with which the biochemical data can be compared. Interpretation of the protein structure in relation to its function can be complicated by a lack of resolution of the spectra or the inability to trap intermediates because of solvent constraints. Small molecules are often used to trap and characterize key intermediates that may not be observable in the enzyme. In combination, biochemical and synthetic modeling data have begun to generate a clearer picture of the mechanism of superoxide reduction. These data include information on the role of the *trans* thiolate in the nonheme iron active site and the effect of spin-state on the reactivity of the proposed peroxo-bound ferric intermediates. Furthermore, exploration of the reactivity of synthetic peroxide intermediates with proton donors in a controlled fashion may help elucidate the identity and role of proton donors in the SOR-catalyzed reduction of $O_2^-$ to $H_2O_2$.

## 2. Superoxide Reductases (SORs)

Five crystal structures of SOR have been reported from four different bacterial sources: *Pyrococcus furiosus*,[17] *Desulfovibrio desulfuricans*,[18] *Treponema palladium*,[19] and *Desulfoarculus baarsii*.[20] In the catalytically active reduced state, SORs contain a high-spin ($S$ = 2) $Fe^{II}$ center (center II) ligated by four equatorial histidine units and one apical cysteinate residue *trans* to an open site (Figure 1). Additionally, a number of SORs also contain a second rubredoxin-like [$Fe(SCys)_4$] center (center I) and are sometimes termed 2Fe-SORs to indicate the presence of a second iron site.[16] The C13S mutant of *D. vulgaris* 2Fe-SOR leads to the loss of center I, but does not prevent SOR activity.[21] Thus, center I is not believed to participate in the catalytic cycle. In the oxidized resting state, the active site is high-spin ($S$ = 5/2) and contains a glutamate moiety coordinated to the sixth axial site. This glutamate ($Glu^{14}$ or $Glu^{47}$, depending on the organism) is attached to a solvent-exposed flexible loop region of the protein and moves to a distance of 7.1 Å away from the metal ion upon reduction to the $Fe^{II}$ state.[17] This flexible loop region also contains a conserved lysine ($Lys^{47}$ or $Lys^{48}$) unit that has been proposed to play an essential role in the promotion of the catalytic activity of SOR by the attraction of the anionic superoxide ion to the enzyme's active site via coulombic forces.[22,23] The ammonium group of this lysine unit lies 6–12 Å away from the iron center. Because two protons are necessary to form $H_2O_2$, protonation of (Fe–$\eta^2$-$O_2$) or (Fe–$\eta^1$-OOH) intermediates plays an important role in the overall mechanism of superoxide reduction by SOR. The identity of the two proton sources is currently under investigation in the wild-type (WT) and mutant enzymes and through the study of synthetic enzyme active site models.

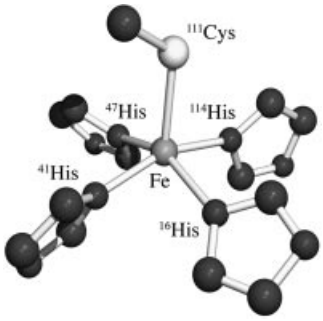

Figure 1. Active site of the reduced catalytically active form of the nonheme iron enzyme superoxide reductase (SOR).

### 2.1 SOD versus SOR

SODs disproportionate $O_2^-$ into hydrogen peroxide and dioxgen in aerobic organisms.[13,14,24] In contrast, SORs selectively reduce $O_2^-$ to hydrogen peroxide; this avoids the formation of dioxygen, which would otherwise be toxic to the anaerobic organisms that contain them.[10,12,25] Bacterial SODs typically contain either nonheme iron or manganese at the active site (FeSOD or MnSOD) although copper–zinc (Cu, ZnSOD) and nickel (NiSOD) enzymes are also known.[26,27] Reduced FeSODs contain a nonheme iron active site ligated by three histidine units, an aspartate group, and a $H_2O/OH^-$ ligand ($pK_a$ = 8.5) supported by a conserved H-bonding network. The azide-inhibited oxidized form has been crystallographically characterized and possesses the structure shown in Figure 2. A coordination environment with a 2His-1-carboxylate motif is common among nonheme iron enzymes.[28] In contrast, SOR is part of a new class of nonheme iron enzymes that contain a thiolate moiety in the coordination sphere.[29] Recent reviews describe the superoxide dismutase (SOD) mechanism and biophysical properties in more detail.[13,14,26]

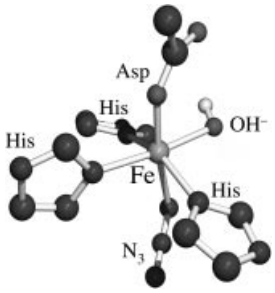

Figure 2. Active site of the oxidized azide-inhibited form of iron superoxide dismutase (Fe-SOD).

FeSODs and MnSODs are homologous and catalyze the disproportionation of superoxide through a cyclic (ping-pong) mechanism that involves $O_2^-$ oxidation at $M^{3+}$ followed by proton-induced $O_2^-$ reduction at $M^{2+}$.[13,14,24] By poising the SOD redox potential half-way between the potentials at which superoxide is oxidized and reduced, the redox active metal center of SOD is able to both oxidize and reduce superoxide depending on the protonation states of the nearby residues and the oxidation state of the metal. In contrast to SOR, the SOD catalytic cycle does not re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

quire an external source of electrons. The redox potential of the SOD $Fe^{2+}/Fe^{3+}$ couple is pH-dependent, and falls in the range from +0.03 to –0.31 V versus SCE.[14,30,31] The redox potential of the SOR $Fe^{2+}/Fe^{3+}$ couple (reported range: 0.00 to –0.15 V versus SCE[29]) is similar to that of SOD, which indicates that the redox potential alone cannot be responsible for the two distinct reactions that are catalyzed. Differences in the protein structure might be responsible. Because the active site of SOR is close to the surface of the protein, a constant source of protons is available from the solvent.[17] In contrast, the active site of SOD is buried within the protein, which makes it easier to control proton delivery. The amount of protons available is perhaps limited when the metal ion is in its 3+ oxidation state so as to favor superoxide oxidation. The redox potential of superoxide ($O_2^-$) is highly dependent on the pH of the system and it is significantly easier to reduce under acidic conditions. At pH = 0, superoxide is reduced at a potential of +1.27 V versus SCE, whereas at pH = 7.5 and pH = 14, it is reduced at +0.83 and –0.041 V, respectively. Protons are probably used to raise the redox potential of superoxide and to drive its reduction by SOR. Given that superoxide reduction by SOR has been shown to occur via an inner sphere mechanism (vide infra), redox potentials are somewhat less important. However, they can influence the reaction pathway in a more indirect manner by determining the energy of the frontier (LUMO) orbitals.

Another barrier to SOD activity in SOR may involve the reorganizational energy that is required to convert from a six- to a five-coordinate structure.[10] In SOD, the ferric state is five-coordinate which would be amenable to rereduction by superoxide via an inner sphere mechanism. In contrast, the resting state of SOR is a six-coordinate ferric site, and the low levels of superoxide present may not be able to effectively compete with the solvent (or the glutamate moiety) and bind to the metal ion.[10]

### 2.2 Enzymatic SOR Data

Superoxide has been shown to bind to the reduced $Fe^{II}$ state of SOR at diffusion controlled rates ($> 10^9$ $M^{-1}s^{-1}$). The transfer of an electron from the metal ion to the bound substrate via an inner sphere pathway is then proposed to afford one or two $Fe^{III}$-peroxide intermediates, depending on the organism. These intermediates have been observed in pulse radiolysis experiments by electron absorption spectroscopy.[32,33] Consistent with an inner sphere pathway, exogenous ligands such as azide, nitric oxide, and cyanide have also been shown to bind to the iron site of SOR.[34–36] The putative peroxide intermediate displays a charge-transfer band at 600 ($\sim 3500$ $M^{-1}cm^{-1}$) nm and releases $H_2O_2$ at a rate of 40–50 $s^{-1}$.[32,33,37] The intense low-energy charge-transfer (CT) band was originally assigned as a combination peroxide/sulfur-to-metal charge-transfer transition,[32] but more recently it was suggested that this band is too low in energy for the peroxide to be involved.[38] This comes as somewhat of a surprise given that a number of $Fe^{III}$–OOR (R = alkyl, H) model complexes have been synthesized which display a peroxide-to-metal CT band in the range 500–600 nm, at least when the iron is low-spin.[39] High-spin $Fe^{III}$–OOH species are extremely rare so there is less known about their spectroscopic properties. Upon the release of hydrogen peroxide from SOR, a nearby glutamate ($Glu^{14}$ or $Glu^{47}$) coordinates to the iron center to afford the six-coordinate $Fe^{III}$-oxidized resting state.[17,23]

When the $Glu^{47}$ residue is replaced with an alanine group (in an E47A SOR mutant of *D. baarsii*), a transient species is observed by resonance Raman spectroscopy upon the addition of hydrogen peroxide.[40] Stretches are observed for the O–O and Fe–O bonds at 850 and 438 $cm^{-1}$, respectively, which shift to 802 and 415 $cm^{-1}$ in the $^{18}O$-labeled spectrum.[40] Stretching frequencies in this range are consistent with a metal–peroxide species. Mössbauer parameters for this E47A intermediate enriched in $^{57}Fe$ include an isomeric shift of $\delta = 0.54(1)$ mm/s, with $\Delta E_Q = -0.80(5)$ mm/s, and an asymmetry parameter $\eta = 0.60(5)$ mm/s.[41] These data are consistent with the assignment of the $H_2O_2$-generated mutant species as a monomeric, high-spin ($S = 5/2$) ferric–peroxo. EPR, resonance Raman, and pulse radiolysis experiments have also been reported for the SOR isolated from *Treponema pallidum*.[42] Data consistent with the formation of an $Fe^{III}$–peroxo species was also observed upon treatment of the ferric or ferrous E48A mutant of *Treponema pallidum* SOR with $H_2O_2$. The same $Fe^{III}$–peroxo species could also be trapped in the corresponding wild-type, *D. baarsii* and *T. pallidum*, upon the addition of $H_2O_2$ but with much lower yields.[42] Mononuclear $Fe^{III}$–peroxide species have also been proposed, or identified, in the catalytic cycles of the antitumor drug bleomycin,[43] heme oxygenase,[44] cytochrome P450,[45–48] and Rieske dioxygenases.[49–51] DFT calculations comparing the stabilities of possible SOR intermediates suggest that a side-on peroxide would be much less stable than an end-on peroxide.[38]

Because two protons are needed to form $H_2O_2$, the active site's access to proton donors is a key consideration in the mechanism of SOR. In an attempt to identify potential proton donors, the pH-dependence of the spectroscopic and redox properties of WT and mutant (E47A and K48I) *D. baarsii* SOR has been recently examined.[52] With an increase in the pH, the S→$Fe^{III}$ absorption band of center II exhibited an 84 nm shift from 644 to 560 nm in both the WT and the mutants. However, this shift occurred at a higher pH for the WT enzyme than for the mutants. This observation is consistent with the presence of an additional base other than $Lys^{48}$ or $Glu^{47}$ ($Glu^{14}$ in *D. baarsii*), whose $pK_a$ is influenced by the presence of these residues. The nearby Lys and Glu residues are highly conserved among SORs; however, only the Lys unit has been shown to noticeably influence the catalytic activity of the enzyme.[21,22] The Glu residue is proposed to play an important role in the structural reorganization that accompanies iron oxidation, whereas the positively charged Lys residue is believed to provide an electrostatic driving force that guides superoxide toward the reduced iron.[53] Resonance Raman spectroscopic data for $K_2IrCl_6$-oxidized WT and mutant *D. baarsii*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

SOR, collected at various pHs, revealed a pH-dependent stretch that is consistent with the formation of a previously unidentified $Fe^{III}$–OH species.[54] Resonance Raman spectroscopy revealed that the stretches observed for these species (in the range $\nu$ = 466–471 $cm^{-1}$) were sensitive to isotopic labeling with $H_2{}^{18}O$ or $^2H_2O$ buffer. This indicates that an oxygen atom that is derived from the solvent that contains an exchangeable proton is coordinated to the ferric site. This $Fe^{III}$–OH species (Figure 3) is proposed to be the previously observed base responsible for the pH-dependence of the SOR electronic absorption spectrum.[52] The protonated base (i.e. solvent = $H_2O$) is then presumed to be the second proton donor needed for $H_2O_2$ formation. This would allow the release of $H_2O_2$ with concomitant formation of the $Fe^{III}$–OH species (Figure 3).[54] Currently, the involvement of a solvent water molecule is proposed to only affect the second protonation step because $Fe^{III}$–OH formation cannot occur until $H_2O_2$ is released. The mechanism of $H_2O_2$ release, whether by an associative or dissociative process, however, is still unclear. The rate constant of $H_2O_2$ release by *D. baarsii* is estimated to be slow ($< 5\ s^{-1}$) but has not been directly measured.[52] Furthermore, the dependence of this second protonation step on pH still requires further study.

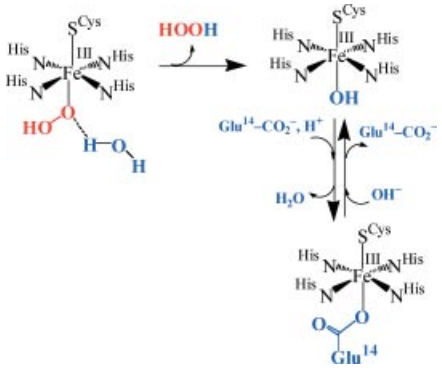

Figure 3. Proposed mechanism (see ref.[54]) for the solvent-induced $H_2O_2$ release from the putative $Fe^{III}$–OOH SOR intermediate, to initially afford a hydroxide-bound $Fe^{III}$–OH species, which converts to the glutamate-bound resting state $Fe^{III}$–OC(O)Glu under acidic conditions.

Nitric oxide (NO), a substrate analogue, has also been shown to bind to the active site of reduced *P. furiosus* SOR.[35] Reaction of ascorbate-reduced SOR with NO results in the reversible formation of a stable six-coordinate derivative with NO bound *trans* to the cysteinate ligand. EPR spectroscopy of the NO adduct shows a near-axial $S$ = 3/2 ground state with $E/D$ = 0.06 and $D = (12 \pm 2)\ cm^{-1}$.[35] Resonance Raman studies indicate that the NO ligand is most likely in a bent conformation *trans* to the cysteinate ligand, with $\nu$(N≡O) = 1721 $cm^{-1}$, $\nu$(Fe–NO) = 475 $cm^{-1}$, and $\nu$(Fe–S) = 291 $cm^{-1}$, confirmed by $^{15}NO$ and $^{34}S$ isotopic labeling.[35] The best electronic description of the $S$ = 3/2 $\{FeNO\}^7$ unit is that of a high-spin ($S$ = 5/2) $Fe^{III}$ center, antiferromagnetically coupled to an ($S$ = 1) $NO^-$ anion, which indicates that NO oxidatively adds to the $Fe^{II}$ center. These observations are consistent with the first step of the SOR mechanism that involves oxidative addition of superoxide to form the proposed ferric peroxide intermediate.

To regenerate the $Fe^{II}$-active state, rubredoxin has been proposed to serve as an electron donor on the basis of genetic and biochemical evidence.[55] Rubredoxin is a small (ca. 6 kDa) iron-containing protein which contains a single [$Fe(SCys)_4$] site. These proteins are found in many anaerobic bacteria and archaea where they serve as one-electron carriers involved in numerous electron transfer chains. *D. vulgaris* rubredoxin has been found to efficiently catalyze the reduction of *D. vulgaris* 2Fe-SOD.[55] Rubredoxin has also been shown to act as an electron donor for neelaredoxin (a 1Fe-SOR) in vitro.[56] Additionally, rubredoxins have been shown to be reduced in vivo by NAD(P)H:rubredoxin oxidoreductase (NROR), and this reduction pathway was recently reconstituted in vitro with the use of recombinant proteins.[57]

### 2.3 Biomimetic Models of SOR

The spectroscopic characterization and isolation of $Fe^{III}$–peroxo complexes is extremely challenging because of their high reactivity, thermal instability, and photolability.[29,58] Que[39] (Figure 4) and Girerd[59] have reported the most extensively characterized set of synthetic nonheme iron peroxides. Both groups have shown that when ligated by nitrogen ligands, a side-on ferric peroxide [$Fe^{III}(\eta^2\text{-}O_2)$] will convert to an end-on ferric hydroperoxide species [$Fe^{III}(\eta^1\text{-}OOH)$] upon protonation.[60–63] In the published examples, the side-on peroxides are high-spin ($S$ = 5/2), and the end-on hydroperoxides are low-spin ($S$ = 1/2). The $\nu_{O-O}$ stretching frequencies of these side-on peroxides appear at higher energies than those of the corresponding end-on hydroperoxides. The $\nu_{Fe-O}$ stretch shifts to higher energies upon protonation, a spin-state change from $S$ = 5/2 to $S$ = 1/2 occurs, and, as predicted by Solomon,[64,65] the O–O bond weakens. Because protons are needed for SOR catalysis, any side-on peroxide that is possibly formed in wild-type SOR probably converts to an end-on hydroperoxide prior to the release of $H_2O_2$.

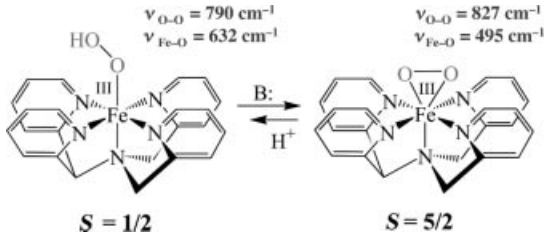

Figure 4. Que's synthetic end-on and side-on peroxide complexes, $[(N_4Py)Fe^{III}(\eta^2\text{-}O_2)]^+$ and $[(N_4Py)Fe^{III}(\eta^1\text{-}OOH)]^{2+}$, and their respective vibrational data and spin-states.

None of the synthetic complexes described above contain thiolate ligands. An obvious question related to SOR concerns how a thiolate sulfur would affect $H_2O_2$ formation and release. The *trans* positioning of the thiolate moiety in SOR has been suggested to provide a pathway for electron delivery to the iron site. Additionally, the *trans*-effect of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thiolate ligand would cause the Fe–O bond to become labile, which favors peroxide release.[34] As established for porphyrin-containing systems,[66–68] a thiolate would be expected to perturb the spectroscopic and magnetic properties of $Fe^{III}$-peroxide species and their preferred reaction pathways relative to those not containing a thiolate ligand. The correlation between the peroxide binding mode, spin-state, and vibrational parameters, established for nitrogen-ligated nonheme iron systems,[39] would not necessarily hold true for thiolate ligated systems. For example, the π-donor sulfur ligand may favor a high-spin $Fe^{III}$–OOH species with a weaker Fe–O bond, which would then favor peroxide release (vide infra). In order to confirm these hypotheses, thiolate-ligated $Fe^{III}$–OOH complexes are needed. Thiolate-ligated $Fe^{III}$–OOH species are, however, difficult synthetic targets because thiolates tend to reduce $Fe^{III}$, are easily oxidized by peroxides, and form μ-SR bridged dimers.[29]

Halfen and coworkers have successfully modeled the square pyramidal structure of reduced SOR with a pyridyl appended diazacyclooctane ligand (Figure 5).[69] Aromatic thiolate groups coordinate to the apical position of the reduced, high-spin ($S = 2$) complex *trans* to an open coordination site, which affords a fairly accurate structural model of the reduced form of SOR ($SOR_{red}$), $[L_8py_2Fe(SC_6H_4\text{-}m\text{-}CH_3)]^+$ (**1**). Although **1** is stereochemically very similar to $SOR_{red}$, its electronic structure is notably different.[70] Electronic absorption, magnetic circular dichroism (MCD), and variable-temperature variable-field MCD (VTVH-MCD) spectroscopy, in conjunction with density functional theory (DFT) and semiemperical INDO/S-CI calculations, showed that the π-acceptor pyridine ligands stabilize the reduced state of **1** relative to that of SOR. This, coupled with the poor sigma-donor properties of the aromatic thiolate compared with those of alkyl thiolate cysteinates, causes a blue-shift in the $S\rightarrow Fe^{II}$ CT manifold of **1** by 9,000 $cm^{-1}$ relative to that of the enzyme. Initially, the oxidation of **1** was found to be irreversible, which resulted in the formation of disulfides.[69] No reaction was reported with superoxide. More recently, *t*BuOOH was shown to react with **1** to afford a high-spin ($S = 5/2$) ferric alkylperoxide complex, $[L_8py_2Fe(SC_6H_4\text{-}m\text{-}CH_3)(OOR)]^+$ (**2**).[71] The resonance Raman spectrum of **2** shows vibrations that are consistent with an end-on $Fe^{III}$–OOR species.[71]

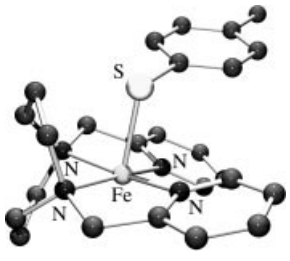

Figure 5. Halfen's thiolate-ligated, pyridyl-appended diazacyclooctane iron complex $[L_8py_2Fe(SC_6H_4\text{-}m\text{-}CH_3)]^+$ (**1**, see ref.[69]).

In 2001, Shearer and Kovacs showed that when the thiolate sulfur is incorporated into a multidentate ligand, biomimetic SOR reactivity is observed.[72,73] This occurs even though the thiolate moiety is coordinated *cis* to the open site and not *trans* to the open site as in the enzyme. In the model, five-coordinate thiolate-ligated $[Fe^{II}\{S^{Me2}N_4(tren)\}]^+$ (**3**, Figure 6) reacts with superoxide (solubilized as an 18-crown-6-$K^+$ salt in THF) to afford $H_2O_2$ and solvent-ligated $[Fe^{III}\{S^{Me2}N_4(tren)\}(solv)]^{2+}$ (solv = $MeO^-$ or MeCN). The reaction requires a proton source (such as MeOH or a trace amount of water from MeCN) and does not occur in rigorously dried THF. At low temperatures (≤ –78 °C), a transient hydroperoxide intermediate, $[Fe^{III}\{S^{Me2}N_4(tren)(OOH)\}]^+$ (**4**, Figure 7), is observed that has been characterized by electronic absorption, EPR, IR, and XAS spectroscopies.[73] The orange peroxide intermediate displays a charge-transfer band at 452 (2780 $M^{-1}cm^{-1}$) nm and is low-spin ($S = 1/2$; $g_{\|} = 2.14$, $g_{\perp} = 1.97$). Peroxide bound **4** displays a Fermi doublet in the IR spectrum at 788 and 781 $cm^{-1}$ which collapses to a singlet at 784 $cm^{-1}$ upon deuteration with $D_2O$.[73] A new $\nu_{O\text{–}O}$ stretch is observed at 752 $cm^{-1}$ when $^{18}O$-labeled superoxide is used, which confirms the $\nu_{O\text{–}O}$ assignment. This 31 $cm^{-1}$ shift is close to that predicted (44 $cm^{-1}$) for a diatomic oxygen species. Fits to the EXAFS data of **4** required the addition of a new short Fe–O bond at 1.86(3) Å that is not present in either the $Fe^{II}$ precursor (**3**) or the $MeO^-$-bound product.[73] The XANES spectrum is consistent with a six-coordinate oxidized $Fe^{III}$ intermediate. Addition of an outer sphere oxygen at 2.79(6) Å improved the EXAFS fits slightly. The small Debye-Waller factor that is associated with this outer sphere oxygen suggests that it is highly ordered, possibly due to H-bonding between the hydroperoxide and the *cis* thiolate sulfur. This hydrogen bonding may also help explain the shift in the $S\rightarrow Fe^{III}$ charge-transfer band to higher energies in the absorption spectrum relative to that of the enzyme (452 nm versus 600 nm). More likely, notable differences that distinguish **4** from the enzyme intermediate are responsible. These differences include the low-spin state and the *cis* positioning of the thiolate group relative to the peroxide of **4** compared with the high-spin state and the *trans* positioning of the thiolate group in the enzyme intermediate. Hydrogen peroxide is released from **4** at a rate of 65(1) $s^{-1}$ (at 298 K), which is comparable to the rate of $H_2O_2$ release in the SOR enzyme, and a stable solvent-bound species $[Fe^{III}\{S^{Me2}N_4(tren)(solv)\}]^{2+}$ is afforded. Together, these data are consistent with a mechanism that involves the inner sphere oxidative addition of superoxide to $[Fe^{II}\{S^{Me2}N_4(tren)\}]^+$ to form an end-on $Fe^{III}(\eta^1\text{-OOH})$ intermediate, $[Fe^{III}\{S^{Me2}N_4(tren)(OOH)\}]^+$. This represents the first example of a thiolate-ligated peroxide species.

The role of protons in the formation of $Fe^{III}$–peroxide model complex **4** has been examined in more detail in order to help identify viable proton donors in the SOR mechanism.[74] The source of the first proton in SOR is unclear and is dependent on the local pH. Under acidic conditions, $^{14}Glu\text{-}CO_2H$ has been proposed to serve as the proton donor. The solvent was shown to be capable of providing protons in *D. baarsii* SOR.[52] A highly conserved $Lys\text{-}NH_3^+$ residue ($^{15}Lys$ or $^{48}Lys$), essential for the catalytic activity of the enzyme, has been shown to affect rates

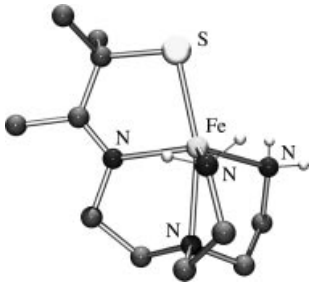

Figure 6. Kovacs' reactive *cis*-thiolate-ligated iron complex $[Fe^{II}\{S^{Me2}N_4(tren)\}]^+$ (**3**), which has been shown to convert superoxide to $H_2O_2$ via a $Fe^{III}$–OOH intermediate in a proton-dependent mechanism (see refs.[73,74]).

Figure 7. The hydroperoxide-bound intermediate $[Fe^{III}\{S^{Me2}N_4(tren)(OOH)\}]^+$ (**4**) shown to be involved in superoxide reduction by reduced **3** (see ref.[73]).

of $H_2O_2$ formation, which implies its involvement in the mechanism.[12,23] In order to explore this, the rate of formation of the synthetic peroxide intermediate $[Fe^{III}\{S^{Me2}N_4(tren)(OOH)\}]^+$ (**4**) was examined in dry THF with a variety of proton donors including HOAc and $NH_4^+$ as analogs for glutamic acid and lysine.[74] No reaction occurs between pre-purified **3** and superoxide in rigorously dried solvents, which rules out a mechanism that involves $H^+$ or H-atom abstraction from the ligand. The rates of formation of **4** are also dependent on the p$K_a$ of the proton donor: for the reaction to occur at comparable rates, the concentration of EtOH must be ca. 500 times higher than that of $NH_4^+$.[74] Although the p$K_a$'s (both relative and absolute) of these proton donors are likely to differ dramatically in THF (versus $H_2O$), and at low temperatures, the observation that EtOH will serve as a proton source to afford **4** suggests that the initial protonation site is rather basic. Additionally, superoxide is quite basic in aprotic solvents [p$K_a(HO_2)$ = 25.3 in DMF],[75] which indicates that these observations do not rule out a mechanism that involves the initial protonation of the superoxide anion prior to its oxidative addition to the metal ion. Protonated superoxide, $HO_2$, is a more potent oxidant than $O_2^-$, and the kinetic experiments needed to distinguish between these mechanisms are ongoing.

Subsequent addition of a second proton to **4** results in the release of hydrogen peroxide to afford the solvent-bound complex $[Fe^{III}\{S^{Me2}N_4(tren)(solv)\}]^{2+}$.[74] The second protonation step requires strong acids such as HOAc, $HBF_4$, or $HClO_4$ (Figure 8). Weaker acids (e.g. $NH_4^+$, a lysine analogue, and MeOH) do not release $H_2O_2$ from **4** in MeOH at reasonable rates at –78 °C. Noncoordinating acids ($HBF_4$, $HClO_4$) cleanly afford a common purple intermediate, $[Fe^{III}\{S^{Me2}N_4(tren)(MeOH)\}]^{2+}$ (**5**). Acetic acid also reacts with **4** to form **5** (Figure 8), which then converts to acetate-bound $[Fe^{III}\{S^{Me2}N_4(tren)(OAc)\}]^+$ at ambient temperature. Reaction rates are dependent on the p$K_a$ of the proton donor and are complete in seconds with strong acids ($HBF_4$, $HClO_4$) versus hours with HOAc. Glutamic acid-promoted $H_2O_2$ release by SOR could occur via a similar mechanism involving a solvent-bound intermediate. The common MeOH-bound intermediate **5** observed in all three reactions suggests that $H_2O_2$ release occurs via a proton-induced dissociative mechanism. An associative mechanism that involves nucleophilic displacement is ruled out because $NH_4^+OAc^-$ does not release $H_2O_2$ from **4**.

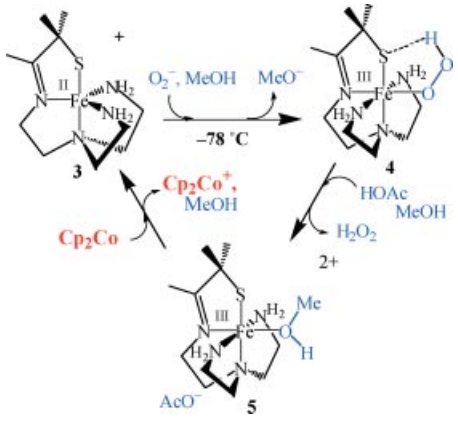

Figure 8. The catalytic cycle involving $[Fe^{II}\{S^{Me2}N_4(tren)\}]^+$ (**3**) promoted reduction of superoxide, which involves sequential protonation and $Cp_2Co$ promoted reduction to afford $H_2O_2$.

To mimic the reduction of the oxidized $Fe^{III}$ state of SOR, and to complete the catalytic cycle, cobaltacene was added as a source of electrons to oxidized solvent-bound **5**. This resulted in the regeneration of reduced $[Fe^{II}\{S^{Me2}N_4(tren)\}]^+$ (**3**), which subsequently reacts with additional superoxide to regenerate the peroxide intermediate (Figure 8). Eight turnovers have been achieved in this stepwise manner.[74] The catalytic activity is believed to be limited because of the decomposition of the catalyst by $H_2O_2$. Conditions are currently being optimized to remove the $H_2O_2$ that is formed in situ, in hopes of increasing the lifetime of the catalyst.

Cyanide, azide, and acetate all bind to oxidized solvent-bound $[Fe^{III}\{S^{Me2}N_4(tren)(MeCN)\}]^{2+}$ to afford models for the $CN^-$-inhibited, $N_3^-$-bound, and Glu-bound resting state of SOR.[76] Cyanide and azide do not bind to reduced **3**, and do not prevent **3** from stoichiometrically reducing superoxide. Azide- and acetate-coordinated $[Fe^{III}\{S^{Me2}N_4(tren)(N_3)\}]^+$ (**6**) and $[Fe^{III}\{S^{Me2}N_4(tren)(OAc)\}]^+$ (**7**) each have an $S$ = 1/2 ground state with a thermally accessible higher spin state. Cyanide-bound $[Fe^{III}\{S^{Me2}N_4(tren)(CN)\}]^+$ (**8**), on the other hand, is $S$ = 1/2 over a wide temperature range (2–300 K). Cyanide also dramatically alters the magnetic properties of SOR: CN-SOR is low-spin ($S$ =

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1/2), whereas $N_3$-SOR and Glu-SOR are high-spin ($S$ = 5/2). These differences in spin-state do not come as a surprise given the differences in ligand field strengths of $N_3^-$ versus $RCO_2^-$ versus $CN^-$. The redox properties of these model complexes show a similar trend. Azide- and OAc-ligated **6** and **7** are reduced at comparable potentials of –410 and –335 mV (versus. SCE), respectively, whereas CN-ligated **8** is reduced at a much more anodic potential of –805 mV versus SCE.[76] If cyanide were to cause an anodic shift in the redox potential of SOR by approximately the same amount ($|\Delta E| \geq 470$ mV), then the reduction potential of the catalytic iron center would fall well-below those of its biological reductants (center I, –236 mV versus SCE; rubredoxin, reported range –191 to –291 versus SCE). Thus, cyanide by preventing the enzyme from turning over because it prevents the regeneration of the reduced, catalytically active $Fe^{2+}$ state of SOR. There is no data to support such a mechanism with the SOR enzyme; however, cyanide has been shown to inhibit superoxide dismutase in this manner.[77] Given that electron transfer plays a prominent role in SOR chemistry, inhibition may occur if these redox processes are interfered with.

With the use of a rigid macrocyclic ligand with tertiary amines and an appended alkyl thiolate, Halfen was more recently able to synthesize a high-spin ($S$ = 2) $SOR_{red}$ model, $[Fe^{II}(Me_3\text{-cyclam-EtS})]^+$ (**9**, Figure 9), which displays an absorption spectrum similar to that reported for the reduced SOR enzyme ($SOR_{red}$). This suggests that this model accurately mimics key elements of the electronic structure of the enzyme's active site, specifically its highly covalent Fe–S π- and σ-bonding interactions.[70] The geometry of **9** is distorted from the square pyramidal architecture, which results in a shift of the redox active orbital from the equatorial $N_4$ plane, as it occurs in SOR, to an axial ($d_{yz}$) position. Although **9** does not appear to react with superoxide, it reacts with either $H_2O_2$ in MeOH or *m*-chloroperbenzoic acid (*m*CPBA) in the presence of a base at –60 °C to afford a high-valent $Fe^{IV}$=O species, $[(Me_3\text{-cyclam-EtS})Fe^{IV}(O)]^+$ (**10**).[78] The Mössbauer parameters associated with $^{57}$Fe-enriched **10** ($\delta$ = 0.19 mm/s; $\Delta E_Q$ = 0.22 mm/s) are consistent with related $Fe^{IV}$=O cyclam-ligated complexes {i.e. $[(Me_4\text{-cyclam})Fe^{IV}(O)(MeCN)]^{2+}$} that have been crystallographically characterized,[79] but which do not contain a thiolate sulfur in the coordination sphere. Bond lengths of **10**, as determined by EXAFS and DFT methods, include a short Fe–O bond of 1.70(2) Å, 3 Fe–N/O bonds of 2.09(2) Å, and one Fe–S bond of 2.33(2) Å. The formation of **10** presumably occurs via the cleavage of the O–O bond of a transient peroxide species. Thus, the reactivity of **9** appears to better mimic that of the heme enzyme cytochrome P450[45] rather than SOR. The tertiary amines possibly contribute to this (vide infra).

If secondary amines are incorporated into **9** in place of the tertiary amines and an extra methylene is inserted into the apical arm, the resulting thiolate-ligated complex $[Fe^{II}(cyclam)\text{-PrS}]^+$ (**11**, Figure 10) reacts with superoxide (solubilized as an 18-crown-6 salt in THF) in $CH_2Cl_2$ to form a metastable burgundy-colored peroxide species

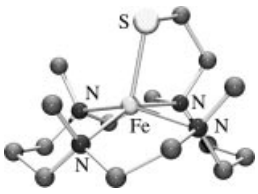

Figure 9. Halfen's $SOR_{red}$ model, $[Fe^{II}(Me_3\text{-cyclam-EtS})]^+$ (**9**), which has been shown[70,78] to react with *m*CPBA to afford a high-valent $Fe^{IV}$=O species, $[(Me_3\text{-cyclam-EtS})Fe^{IV}(O)]^+$ (**10**).

[$\lambda_{max}$ = 530(1350) nm], $[Fe^{III}(cyclam\text{-PrS})(OO(H))]^+$ (**12**), upon the addition of a proton donor (e.g. MeOH).[80] This intermediate is high-spin ($g$ = 7.72, 5.40, 4.15), and displays $\nu_{O-O}$, $\nu_{Fe-O}$, and $\nu_{Fe-S}$ stretches in the resonance Raman spectrum at 891 $cm^{-1}$ (a Fermi doublet), 419 $cm^{-1}$, and 352 $cm^{-1}$, respectively.[80] The $\nu_{O-O}$ and $\nu_{Fe-O}$ peaks shift to 856 $cm^{-1}$ and 400 $cm^{-1}$, respectively, upon the introduction of an isotopic label derived from $K^{18}O_2$ (50% enriched). The $\nu_{Fe-O}$ stretch of **12** (419 $cm^{-1}$) is unusually low, and the $\nu_{O-O}$ stretch (891 $cm^{-1}$) is unusually high, compared with other reported synthetic nonheme iron peroxo species (reported range: 450–639 $cm^{-1}$ for $\nu_{Fe-O}$ and 820–860 $cm^{-1}$ for $\nu_{O-O}$),[39] but compares well with that of the only reported SOR peroxide species ($\nu_{Fe-O}$ = 438 $cm^{-1}$ and $\nu_{O-O}$ = 850 $cm^{-1}$).[40] These vibrational data, along with the calculated force constant ($k_{Fe-O}$ = 1.20 mdynes $cm^{-2}$), indicate that *the Fe–O(peroxide) bond is significantly weakened upon the introduction of a trans thiolate into the coordination sphere*. An increased lability of the Fe–O bond supports this conclusion. Peroxide-ligated **12** releases $H_2O_2$ much more rapidly (on the order of minutes) than does *cis* thiolate ligated $[Fe^{III}\{S^{Me2}N_4(tren)(OOH)\}]^+$ (**4**, $t_{1/2}$ = 69 h), and represents the first example of a *trans* thiolate-ligated $Fe^{III}$-peroxo.[80] The more rapid rate of $H_2O_2$ release from **12** versus that of **4** suggests that the *trans* positioning of the thiolate in **12** (as well as in the SOR enzyme) plays an important functional role in the promotion of the rapid release of $H_2O_2$ and perhaps explains why this stereochemical arrangement is utilized by the enzyme.

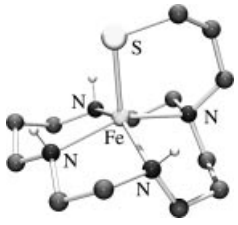

Figure 10. Kovacs' secondary amine-ligated $SOR_{red}$ model, $[Fe^{II}(cyclam)\text{-PrS}]^+$ (**11**), which was recently shown[80] to react with superoxide to afford $H_2O_2$ via the peroxo intermediate $[Fe^{III}(cyclam\text{-PrS})(OO(H))]^+$ (**12**).

### 2.4 SOR versus Cytochrome P450

Cytochrome P450 is a heme (i.e. porphyrin-containing) iron enzyme involved in the metabolism of drugs and xenobiotics, the biosynthesis of key steroid hormones, and the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

conversion of polyunsaturated fatty acids to biologically active molecules.[45] Like SOR, the P450 catalytic cycle proceeds via an end-on hydroperoxide intermediate (Figure 11).[45] However, the subsequent reactivity of the hydroperoxide is different in each case and has been shown to be dependent on the site of protonation as well as the spin-state of the molecule.[64,81–83] In SOR, $Fe^{III}$–OOH is presumably protonated at the proximal oxygen (the oxygen bound to the metal ion) to weaken the Fe–O bond, release hydrogen peroxide, and generate the oxidized $Fe^{III}$ state. In P450, protonation occurs at the distal oxygen, which polarizes the O–O bond, liberates $H_2O$, and affords a high-valent $Fe^{IV}$=O π cation radical.[45] Initially, this difference in reactivity was ascribed to the presence of a porphyrin ring in cytochrome P450.[48,84] The highly conjugated, negatively charged porphyrin is able to delocalize excess positive charge, which allows for the formation of high-valent "$Fe^{V}$=O" in this environment. However, Que et al. have observed $Fe^{IV}$=O outside of a porphyrin environment and have definitive X-ray crystallographic evidence for examples of these species.[79] Another explanation for the differences in reactivity of SOR versus P450 may involve differences in the spin-state of the hydroperoxide intermediate.[29] The low-spin Fe–OOH of P450 and synthetic analogues have been shown to favor a reaction pathway that involves cleavage of the O–O bond.[64,82,85] In contrast, a high-spin Fe-peroxide ($S$ = 5/2) would favor a reaction pathway that involves cleavage of the Fe–O bond because it would possess populated antibonding σ*(Fe–O) orbitals. The peroxide species formed upon the reaction of the E47A SOR mutant with $H_2O_2$ is high-spin ($S$ = 5/2); however, this may not be true for the native enzyme intermediate. Recent calculations suggest that the peroxide-bound SOR intermediate is low-spin ($S$ = 1/2);[38] however, there is no experimental evidence to confirm this. There is no evidence for oxygenase activity with SOR, which suggests that O–O bond cleavage does not occur, and reduced $Fe^{II}$-SOR is believed to be unreactive towards $O_2$.

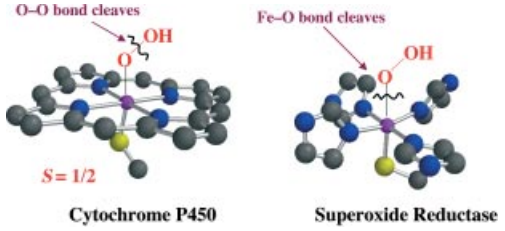

Figure 11. The hydroperoxide intermediates formed during catalysis by the heme iron oxygenase enzyme cytochrome P450 and non-heme iron enzyme SOR, which shows how their reaction pathways (i.e. O–O versus Fe–O bond cleavage) differ.

## 3. Perspective

The accumulation of biochemical and modeling data has begun to generate a clearer picture of the mechanism of superoxide reduction by SOR, but some questions still remain. How SOR is able to selectively reduce superoxide rather than disproportionate $O_2^-$ to $O_2$ and $H_2O_2$ (i.e. SOD activity) is not completely understood. Furthermore, how O–O bond cleavage is avoided in SOR remains unclear. The spin-state of the intermediate peroxide seems to play an important role in determining whether the Fe–O or O–O bond cleaves. It is still unknown whether the peroxide intermediate that is observed during catalysis of wild-type SOR is high- or low-spin. If such an intermediate can be detected in wild-type SOR, then resonance Raman experiments of the peroxide should be carried out with doubly-labeled superoxide, $^{16}O^{18}O^-$, in order to conclusively determine whether this intermediate contains an end-on or a side-on peroxide.

The position of the thiolate (*trans* versus *cis* to the peroxide) does not appear to be critical for the reduction of superoxide given that a five-coordinate $Fe^{II}N_4S$ SOR model complex with the thiolate positioned *cis* to the open site has been shown to reduce superoxide. However, the mechanism of superoxide reduction, and the rate of superoxide binding and hydrogen peroxide release, is likely to be affected by the position of the sulfur moiety. When a *trans* thiolate sulfur is incorporated into a macrocyclic five-coordinate $Fe^{II}N_4S$ SOR model complex, the $Fe^{III}$–OOH intermediate is high-spin and hydrogen peroxide is released more rapidly. The $\nu_{Fe-O}$ is also lower than any iron peroxide, with the exception of the SOR-peroxide. This suggests that the *trans* thiolate weakens the Fe–O bond and favors $H_2O_2$ release. However, one other *trans* thiolate-ligated five-coordinate non-heme $Fe^{II}N_4S$ model complex has been reported that does not reduce superoxide, yet reacts with $H_2O_2$ to afford a high-valent $Fe^{IV}$=O species via cleavage of the O–O bond analogous to that observed in P450. Clearly, more than just the stereochemical relationship between the thiolate and the peroxide is important in the determination of the favored reaction pathway. A more thorough investigation that involves a series of structurally-related compounds is needed to correlate Fe–O (versus O–O) bond-cleaving properties with the spin-state of the molecule, the positioning of the thiolate sulfur (*cis* versus *trans* to the peroxide), redox properties, as well as proximal peroxide oxygen basicity.

# The Transient Titanocene(II): Direct Synthesis from Solvated Titanium(II) Chloride and Cyclopentadienylsodium and Ensuing Interception with Diphenylacetylene as 1,1-Bis(cyclopentadienyl)-2,3,4,5-tetraphenyltitanacyclopentadiene[‡]

**John J. Eisch,*[a] Adetenu A. Adeosun,[a] and John M. Birmingham[b]**

**Keywords:** Titanocene(II) / Wilkinson metallocene synthesis / Epititanation / 1,1-Bis(cyclopentadienyl)titanacyclopropenes / 1,1-Bis(cyclopentadienyl)titanacyclopentadienes

For the first time the unstable titanocene(II) has been directly synthesized by the Wilkinson metallocene approach, namely the interaction of a THF-soluble form of titanium(II) chloride with two equivalents of cyclopentadienylsodium in THF solution at 0°–25 °C. Because of the transient existence of the titanocene(II) thereby obtained, it could only be chemically trapped in high yield as 1,1-bis(cyclopentadienyl)-2,3,4,5-tetraphenyltitanacyclopentadiene by two equivalents of diphenylacetylene, if the acetylene was added at 25 °C, *without* removal of the by-product LiCl and NaCl. If the addition of the acetylene was delayed, in order to filter off the LiCl and NaCl from the reaction mixture, then no trace of the titanacyclopentadiene derivative was found upon hydrolytic workup. Instead, a significant portion of the acetylene was found to have undergone hydrotitanation. This finding is clear evidence that the titanocene(II) had undergone a precedented rearrangement to a known dimer having the structure of a titanocene(III) hydride with a fulvalene bridge between the titanium centers. We suggest that the LiCl and NaCl present in the unfiltered reaction mixture form a dichloro complex with titanocene(II) and thereby retard its dimerizing rearrangement to the titanocene(III) hydride.

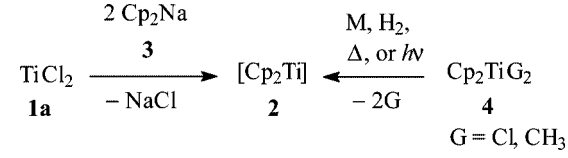
## Introduction

Shortly after the serendipitous synthesis and discovery of ferrocene through the independent routes of Pauson and Kealy[2] and of Miller and co-workers[3] the systematic synthesis of analogous cyclopentadienyl derivatives of transition metals was undertaken with great success by both the Wilkinson and the Fischer research groups.[4] From group 4 tetrahalides the bis(cyclopentadienyl)metal(IV) dihalides were the most readily formed and isolated. Although the preparation of bis(cyclopentadienyl)titanium(III) halides was achieved by the activated metal reduction of $Cp_2TiX_2$ in donor, nonprotic solvents,[5,6] the preparation of bis(cyclopentadienyl)titanium(II) or titanocene(II) (**2**) has received the attention of many researchers during the period of 1956–1976 with an overall indecisive outcome.[7]

The attempted preparations of titanocene(II) (**2**) have involved either the direct reaction of polymeric $TiCl_2$ (**1a**) in ethereal suspension with two equiv. of bis(cyclopentadienyl)-sodium (**3**)[8a,8b] or the α-elimination of the two groups G from $Cp_2TiG_2$ (**4**) (G = Cl, or $CH_3$) by an active metal for G = Cl,[9] dihydrogen,[10] heat,[11] or light[12] for G = $CH_3$ (Scheme 1). None of the socalled "titanocene" products thus generated could be isolated in a crystalline form suitable for single-crystal X-ray structure analysis.



Scheme 1.

A range of different "titanocene" products have been accordingly isolated, varying in color (green, brown, violet or black) and in spectroscopic as well as magnetic properties. It is generally agreed that none of these products is titanocene (**2**) itself, which should be very reactive due to its carbenoid nature.[13,14] Therefore, in order to take into account the anticipated high reactivity of authentic titanocene (**2**), provision was made to capture **2** as it was purportedly formed by the reduction of $Cp_2TiCl_2$ with the sodium–naphthalene adduct in THF.[9a] When diphenylacetylene (**5**) was included as the trapping agent in the reaction, the titanacyclopentadiene **6** was isolated in low yield. This finding was taken as convincing evidence that titanocene (**2**) had

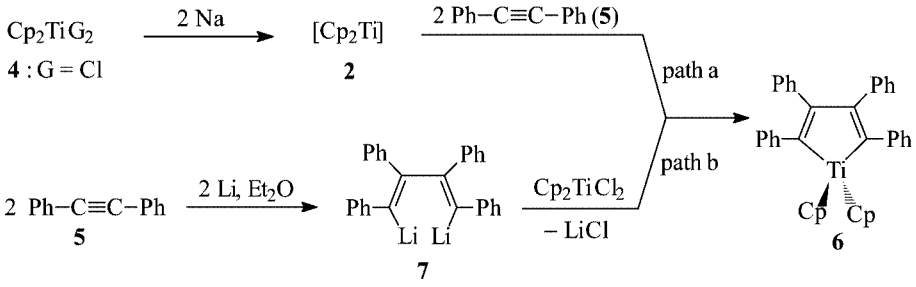

Scheme 2.

been generated [**4** (G = Cl)→**2**] and had been captured by diphenylacetylene (**5**) (path a, Scheme 1, **2**→**6**).[15] However, the conclusion that titanocene (**2**) has been captured in this experiment is ambiguous and thus inconclusive. It has long been recognized that alkali metals in general and lithium metal in particular can effect the reductive dimerization of diphenylacetylene in ethers (**5**→**7**, Scheme 2).[16,17] The 1,4-dilithiobutadiene of proven (*E*,*E*)-configuration has been successfully employed for the synthesis of **6** and several other metallacyclopentadienes.[18,19] Thus the titanocycle **6** isolated from the reaction of $Cp_2TiCl_2$ and diphenylacetylene with sodium could equally as well have been formed from path b in Scheme 2 (**5**→**7**→**6**) and would *not* have required the presence of free titanocene (**2**), as in path a.

## Results and Discussion

In the present research the direct reaction of titanium(II) chloride with bis(cyclopentadienyl)sodium (**3**) was again investigated but with one significant difference. Instead of employing the insoluble, polymeric form, $[TiCl_2]_x$ (**1a**), obtainable by the high-temperature disproportionation of titanium(III) chloride, a newly discovered, THF-soluble form of titanium(II) chloride (**1b**), $[TiCl_2{\cdot}THF]_n$, generated by the alkylative reduction of titanium(IV) chloride,[20] has been used to great advantage [Equations (1) and (2)]. The degree of aggregation (*n*) of **1b** is not yet known with certainty but the existence of the paramagnetic open-chain, trimeric biradical, $[Ti(OiPr)_2]_3$, supports the proposal that the diamagnetic **1b** may form a cyclic trimer in which a core of 3 titanium atoms is bonded as a triangular structure.[1]

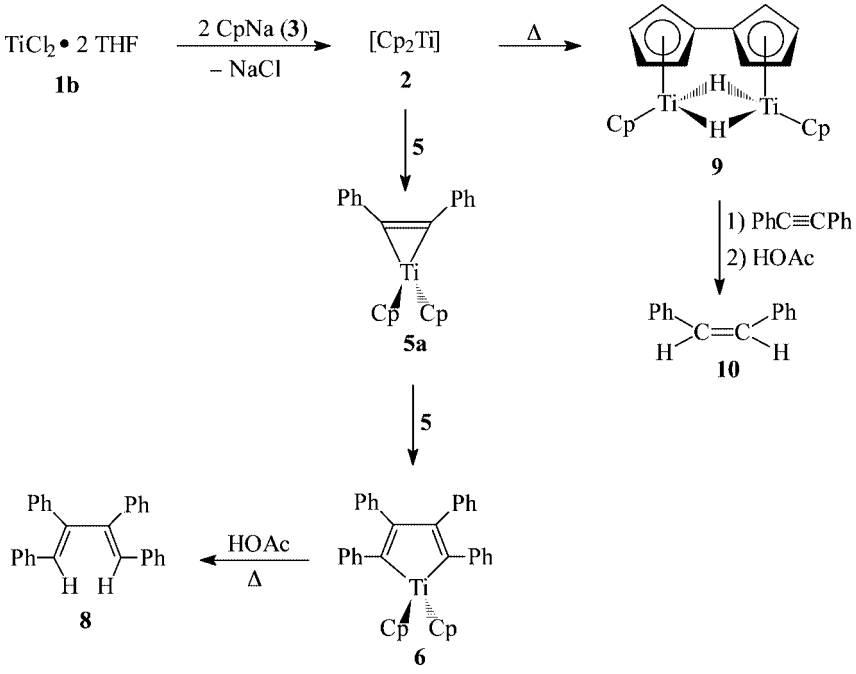
(2)

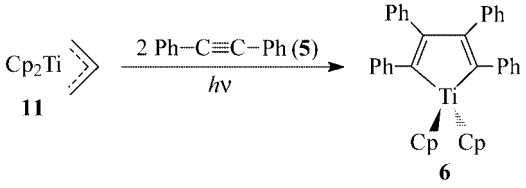


Scheme 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

A THF solution of 0.10 mmol of freshly prepared **1b**, still containing the LiCl by-product, was treated at 0 °C with 0.22 mmol of bis(cyclopentadienyl)sodium (**3**). The black reaction mixture, presumably containing titanocene(II) (**2**), was brought to 25 °C and the LiCl and NaCl solids filtered off. Treating the filtrate with diphenylacetylene (**5**), however, produced no trace of 1,1-bis(cyclopentadieny)-l-2,3,4,5-tetraphenyltitanacyclopentadiene (**6**). This conclusion was reached after protolysis of the reaction mixture with acetic acid was shown to produce no (*E*,*E*)-1,2,3,4-tetraphenyl-1,3-butadiene (**8**) (Scheme 3), the expected protolysis product that would have arisen from **6**, which would have formed by the trapping of **2** by diphenylacetylene (**5**) (path a, Scheme 2). That on the other hand *cis*-stilbene (**10**) was isolated as the sole protolysis product is consistent with the view that any **2** formed from **1b** and **3** had undergone the known rearrangement to **9** before it could be intercepted by **5**.[7b] The resultant **9** could then have hydrotitanated acetylene **5** and hence have generated *cis*-olefin **10**, upon protolysis.

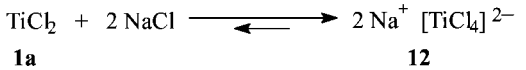
In our further attempt to intercept any titanocene(II) (**2**) formed from **1b** and **2**, we repeated the reaction between **1b** and **2** at 0 °C, brought the reaction mixture to 25 °C, but this time immediately added the diphenylacetylene (**5**) *without attempting to filter off the suspended LiCl and NaCl*. A nonhydrolytic workup involving removal of any solids from the hexane extracts of the final reaction mixture led, via epititanation to titanacyclopropene **5a**,[14] to the isolation of **6** in 83% yield. Its identity was confirmed by $^1$H NMR and IR spectral comparisons with an authentic sample of **6** prepared according to a previously outlined method,[21] whose details are published here for the first time [Equation (3)]. Furthermore, the sample of **6** isolated from **1b** and **2** was smoothly protolyzed to yield solely **8** in high yield (Scheme 3).



(3)

The success of this present procedure for generating **2** from **1b** and **3** and in trapping titanocene(II) (**2**) before it could rearrange to **9** we ascribe to two factors: 1) the shorter time the THF solution of **2** stood at 25 °C before acetylene **5** was introduced; and 2) the presence of LiCl and NaCl, which furnish an ample source of Lewis basic chloride ions, capable of coordinating with monomeric $Cp_2Ti$ and thereby retarding its rearrangement to **7** [Equation (4)]. A relevant precedent is the complex **12** formed from **1a** and NaCl as shown in Equation (5).[22]

(4)



(5)

## Conclusions

From the foregoing experiments we have now shown that the transient titanocene(II) can also be prepared by the classic method introduced by the Wilkinson group some 50 years ago. Its existence, although short, has been firmly established by its chemical trapping with diphenylacetylene as the titanacyclopentadiene **6**.[23]

## Experimental Section

**Starting Materials, Reaction Conditions and Instrumentation:** The starting $TiCl_4$ employed was of at least 98% purity as commercially available and the *n*-butyllithium used was as a 1.60 M solution in hexane. The cyclopentadiene was obtained from the thermolysis of commercial dicyclopentadiene under argon and collected in an ice bath. The sample for the preparation of cyclopentadienylsodium resulted from a redistillation of the monomer just before use.[24] The titanium(II) chloride in THF, containing 2 equiv. of the by-product, LiCl, was obtained from the treatment of $TiCl_4$ in THF with 2 equiv. of *n*-butyllithium at low temperatures according to the published procedure.[20] In the same reference are given experimental details for removing LiCl from the product and obtaining analytically pure $TiCl_2$·THF.[20] However, for its reaction here with cyclopentadienylsodium, the titanium(II) chloride/lithium chloride mixture was used directly. Finally, the diphenylacetylene used in trapping reactions was 99% pure and was shown by TLC and $^1$H NMR spectroscopy to be free of *cis*- or *trans*-stilbene. All reactions, transfers and separations were carried out under a positive pressure of anhydrous, oxygen-free argon.[25] All solvents employed, mainly tetrahydrofuran, heptane and toluene, with these air- and moisture-sensitive reagents were dried and distilled from a sodium metal benzophenone ketyl mixture prior to use.[25]

The $^1$H and $^{13}$C NMR spectra were recorded with a Bruker spectrometer, model AM-360, with tetramethylsilane ($Me_4Si$) as the internal standard. The chemical shifts reported are expressed on the $\delta$-scale in parts per million (ppm) from the $Me_4Si$ reference signal.

**1,1-Bis(cyclopentadienyl)-2,3,4,5-tetraphenyltitanacyclopentadiene (6):** Although an authentic sample of this known compound can be prepared by a number of previous published methods,[12,15] a method developed in our laboratory proved most convenient,[21] because its starting material, **11** is available through a verified experimental procedure.[26,27] A 100-mL quartz phototube, having ground-glass joints at the upper end for attachment to the argon source and for a rubber septum, respectively, was repeatedly evacuated and filled with argon gas. Then a solution of $\eta^3$-allylbis(cyclopentadienyl)titanium(III) (365 mg, 1.67 mmol) prepared under argon in anhydrous, deoxygenated cyclohexane (25 mL) was introduced into the tube through the septum, after which a similarly prepared solution of diphenylacetylene (594 mg, 3.34 mmol) in 10 mL of purified cyclohexane was introduced. The reaction solution was irradiated for 48 h in a Rayonet photochemical reactor, model 100, equipped with a cylindrical array of phototubes emitting radiation at 254 nm. The cylindrical cavity of the lamp bank had a diameter of 24 cm. During this time the initial purple color of the reaction mixture became greenish-yellow. The cyclohexane

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was removed from the photolysate under reduced pressure and the dark green residue was extracted under argon with 3 × 10-mL portions of hexane. Such combined extracts were filtered and then concentrated. Storage of the hexane solution at 0 °C led to the deposition of between 339 mg to 491 mg of dark green **6** (38–55%) in two different runs; m.p. (capillary under argon) 148.5–150 °C [lit. 150 °C];[17] $^1$H NMR ($C_6D_6$): $\delta$ = 6.06(s, 10 H), 6.4–6.9 (m, 20 H) ppm. IR (KBr): $\tilde{\nu}$ = 697 cm$^{-1}$ (vs), 725 (m), 750 (m), 770 (s), 780 (m), 800 (vs), 807 (vs), 830 (sh), 840 (w), 905 (vw), 945 (vw), 1015 (s), 1075 (s), 1095 (sh), 1145 (sh), 1155 (w), 1180 (w), 1245 (w), 1260 (w), 1362 (w), 1370 (sh), 1440 (s), 1480 (s), 1590 (s), 3040 (w), 3060 (w), 3080 (w) cm$^{-1}$.

**Interaction of Bis(cyclopentadienyl)sodium (3) with Titanium(II) Chloride–Bis(tetrahydrofuran) (1b) in Tetrahydrofuran**

**1) Reaction at 0 °C, Removal of Alkali Metal Salts by Filtration and Reaction of the Titanocene Filtrate with Diphenylacetylene (5):** A solution of titanium(IV) chloride (1.90 g, 10 mmol) in toluene (10 mL) was added to dry THF (60 mL) and the mixture cooled to –78 °C to yield a yellow suspension. Then *n*-butyllithium (20 mmol) in hexane (2.50 M) was introduced into the yellow slurry dropwise. Allowing this reaction mixture to come to 25 °C over 1 h produced a black slurry of $TiCl_2$·THF (**1b**) in solution with suspended LiCl by-product, as has been established by a published procedure.[22] Then an orange solution of the cyclopentadienylsodium **3** (22 mmol), previously prepared from sodium metal dispersion (0.51 g, 22 mmol) and freshly distilled cyclopentadiene (1.50 g, 23 mmol) in THF (50 mL) was added rapidly to the solution of **1b** maintained at 0 °C. The resulting reaction mixture was allowed to stand at 25 °C for 2 h before the suspended salts (LiCl and NaCl) were filtered off on a glass frit under argon. The filtration step required about 90 min. The green-black filtrate was then treated with a solution of diphenylacetylene (**5**) (3.56 g, 20 mmol) in THF (40 mL). This final mixture was allowed to stand at room temp. for 10 h and then heated at reflux for 6 h. Treatment of an aliquot of the reaction mixture with glacial acetic acid and usual hydrolytic workup of the dried organic extract showed that 35% of the diphenylacetylene initially introduced had been converted into *cis*-stilbene (**10**) (7.0 mmol.). Equally noteworthy was the absence of any (*E*,*E*)-1,2,3,4-tetraphenyl-1,3-butadiene (**8**), the protolysis product expected to arise if any **6** had been formed from the reaction of the titanocene(II) **2** with the added diphenylacetylene.

**2) Reaction at 25 °C, Followed by the Immediate Addition of Diphenylacetylene (5) without the Removal of Alkali Metal Salts:** Parallel to the foregoing procedure, a freshly prepared black slurry of $TiCl_2$·THF (**1b**, 10 mmol) and LiCl (20 mmol) in THF (60 mL) was treated dropwise at 0 °C with **3** (22 mmol) in THF (50 mL). The resulting mixture was allowed to stand for 2 h at 20–25 °C, after which time a solution of diphenylacetylene (**5**) (3.56 g, 20 mmol) in THF (40 mL) was added rapidly. The final reaction mixture was kept at room temp. for 10 h and then heated at reflux for 6 h. After removal of all volatiles under reduced pressure the residue was extracted with 4 × 15-mL portions of warm hexane, the combined extracts filtered and the filtrate concentrated to about half its volume. Storage of the hexane solution at 0 °C deposited 4.27 g (83%) of dark green crystals of **6**, m.p. 148–150 °C, whose $^1$H NMR ($C_6D_6$) and IR (KBr) spectra were identical with those of the authentic sample. Treatment of a sample of such a product with hot glacial acetic acid, followed by the usual hydrolytic workup, afforded pure (*E*,*E*)-1,2,34-tetraphenyl-1,3-butadiene (**8**), m.p. 181–183 °C, as the only nonvolatile organic product. $^1$H NMR ($CDCl_3$): $\delta$ = 6.40 (s, 2 H), 6.98–7.38 (m, 20). When the protolysis of **6** was repeated with glacial *O*-deuterioacetic acid (99%), the resulting **8** lacked the $^1$H NMR singlet at $\delta$ = 6.40 ppm, showing that this sample of **8** was deuteriated at the $C^1$ and $C^4$ sites.

# The Design of Metal Chelates with a Biologically Related Redox-Active Part: Conjugation of Riboflavin to Bis(2-pyridylmethyl)amine Ligand and Preparation of a Ferric Complex

**Nasser K. Thallaj,[a] Dominique Mandon,*[a] and Kristen A. White[a]**

**Keywords:** N ligands / Iron complexes / Riboflavin / Electrochemistry / Electron mediators

Reaction of a twofold molar excess of bis(2-pyridylmethyl)-amine DPA with 8α-bromoAc4riboflavin in dry DMF over 24 h affords the 8α-[bis(2-pyridylmethyl)amine]-*N*-$Ac_4$riboflavin ligand. This compound can be described as a tweezer in which the flavin moiety acts as a potential electron mediator. The trichloroferric complex has been prepared, and together with the low potential reduction wave of the flavin moiety, the presence of a reversible $Fe^{III}/Fe^{II}$ couple at a higher potential is observed. The deacetylated ligand 8α-[bis(2-pyridylmethyl)amine]-*N*-riboflavin can easily be obtained.

## Introduction

One of the most fascinating aspects of chemical sciences is the way chemists can affect Nature's legacy by modification of biological material, especially when going as far as to design artificial proteins or enzymes that lead to new and sometimes unexpected reactivities.[1–4]

Flavin analogues are well-known as versatile catalysts and are involved in various reactions such as oxidation of tertiary amines, sulfides and ketones, generally with the use of $H_2O_2$ as the oxidant;[5–7] some cases of oxidation by molecular oxygen have also reported.[8] The idea of linking flavin derivatives to biological compounds in order to access artificial proteins is not new: early examples in which flavins were covalently linked to small proteins like papain for instance encountered some success in the oxidation of dihydronicotinamides.[4] In that case, the flavin fragment acted as the site where the reaction took place. Flavins and derivatives, however, are also known as major electron mediators in biological oxidation processes. It is therefore tempting to associate these derivatives with systems that require electron delivery. First attempts to link flavin derivatives with hemes were reported a long time ago, with an example of a semisynthetic hydroxylase that displayed P-450 activity without a reductase.[9] More recently, covalent binding between a riboflavin and protoporphyrin IX allowed reductive activation of dioxygen by an artificial myoglobin.[10] In these examples, the porphyrin/flavin binds the protein through the porphyrin side. Flavin derivatives, however, can bind proteins by themselves. The ability of riboflavin to bind low potential electron carriers, such as flavoproteins for instance, to produce stable complexes is now well-documented.[11–13] The fact that the flavin/flavodoxin complex can function as a one-electron carrier at a potential close to that of the hydrogen electrode[13] makes the design of flavin appended ligands that can accommodate a redox-active metal highly desirable in order to carry out further redox-assisted chemistry.

For several years now, we have been studying dichloroferrous complexes of pyridylmethyl-amine containing ligands, and we have reported cases of fast biomimetic reactions of dioxygen with the metal centre.[14–16] The end product recovered after oxygenation of the ferrous complex can sometimes be reduced back to ferrous, which prefigures the metal centre for further redox chemistry. It was thus tempting to prepare a system in which a pyridylmethylamine-containing ligand would be covalently attached to a riboflavin derivative, the latter acting here as a redox mediator. Examples of substituted DPA ligands with electron mediators can be found in the literature.[17,18] However, those mediators are synthetic compounds and, to the best of our knowledge, there is currently no example of conjugation with a universal and biologically relevant mediator such as riboflavin. We thus report in this communication the first example of synthesis and characterization of such a ligand, 8α-[bis(2-pyridylmethyl)amine]-*N*-riboflavin, as well as the preparation of an air-stable trichloroferric complex of the acetylated precursor. In addition to standard analytical methods used in synthesis, both acetylated precursor and complex have been characterized by cyclic voltammetry. As a result,

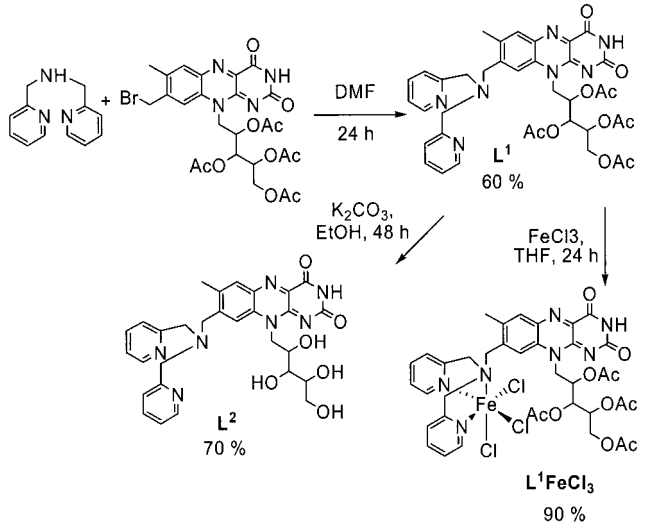
riboflavin can indeed be considered as a redox active mediator in future artificial constructions built around such compounds.

## Results and Discussion

As depicted in Scheme 1, ligand $L^1$ 8α-[bis(2-pyridylmethyl)amine]-*N*-$Ac_4$riboflavin was prepared by reaction of a twofold molar excess of bis(2-pyridylmethyl)amine DPA[19] with 8α-Bromo$Ac_4$riboflavin[20] in dry DMF over 24 h, by adaptation of the procedure published for the preparation of 8α-*N*-imidazolylriboflavin.[21] The brownish–orange solid obtained upon crystallization from a $CH_2Cl_2$/$Et_2O$ solution is a stable compound and was obtained in a 60% yield. Deprotection of the acetyl groups was performed by conventional methods with $K_2CO_3$ in dry EtOH at room temperature within 48 h. The solution was then neutralized with Amberlite IR–120 exchange resin and afforded, upon concentration, $L^2$ as a brownish solid moderately soluble in most organic solvents.



Scheme 1. Access to the DPA-riboflavin derivatives $L^1$, $L^2$ and ferric complex $L^1FeCl_3$.

$L^1$ and $L^2$ were characterized by mass spectroscopy, elemental analysis and $^1$H- and $^{13}$C NMR spectroscopy. Complex $L^1FeCl_3$ was prepared by stirring ligand $L^1$ with an equimolar amount of anhydrous $FeCl_3$ under an inert atmosphere in dry THF (although $L^1FeCl_3$ is air stable). Following a standard workup,[22] a brownish–yellow solid was obtained in 90% yield. In the $^1$H NMR spectrum, $L^1FeCl_3$ displayed extremely broad resonances at $\delta$ = 108 and 93 ppm (mid-intensity peak width, 1800 and 1500 Hz, respectively – signals accounting for the DPA moiety[22]), which is in line with a high-spin state for the metal. The flavin part lies further away from the paramagnetic metal than the DPA moiety and related signals appear as broadened resonances between 12 and 3 ppm. The complex was also characterized by mass spectroscopy, elemental analysis, and UV/Vis spectroscopy. The second absorption at $\lambda$ = 327 nm exhibited a molecular extinction coefficient ($\varepsilon$ = $11.31 \cdot 10^3$ $mmol^{-1} \cdot cm^2$) significantly higher than that of the free organic compounds ($\varepsilon$ = 7.72 and $5.83 \cdot 10^3$ $mmol^{-1} \cdot cm^2$ for $L^1$ and $L^2$, respectively), which indicates the presence of an extra LMCT component due to coordination of the ferric ion.[22]

The cyclic voltammogram ($CH_3CN$, $TBAPF_6$ 0.1 M, SCE as reference electrode, 100 mV/s – all traces displayed in Figure 1) of $L^1$ exhibited one reversible reduction wave at $E_{1/2}$ = –0.726 V ($\Delta_E$ = 130 mV) and is assigned to the reduction of the acetylated riboflavin moiety [the $Ac_4$riboflavin recorded as a blank underwent reversible reduction at $E_{1/2}$ = –0.770 V ($\Delta_E$ = 50 mV) under the same conditions]. In oxidation, an irreversible anodic signal was found at 1.183 V, which corresponds to the oxidation of the aliphatic amine of the DPA moiety. Upon metallation, this latter signal completely disappeared and a new reversible wave, which accounts for the $L^1Fe^{III}/L^1Fe^{II}$ couple, was observed at $E_{1/2}$ = 0.002 V ($\Delta_E$ = 85 mV). For comparison, a reversible couple has already been reported for $DPAFeCl_3$ at $E_{1/2}$ = –0.019 V.[23]

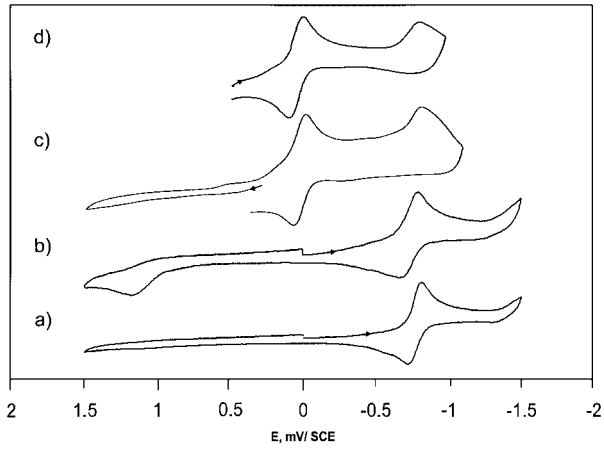


Figure 1. Cyclic voltammograms ($CH_3CN$, $TBAPF_6$ 0.1 M, SCE as reference electrode, 100 mV/s) of: a) tetraacetyl riboflavin; b) ligand $L^1$; c) complex $L^1FeCl_3$; d) detail of $L^1FeCl_3$ at 200 mV/s.

The reduction of the acetylated riboflavin fragment was found at $E_c$ = –0.838 V, with a signal pattern strongly suggestive of aggregation of the reduced compound at the electrode. Scanning up to 1000 mV/s allowed improvement of the reversibility pattern; however, it remained slightly different from what was expected for an ideally reversible couple. From Figure 1d, the potential is estimated to $E_{1/2}$ = –0.804 V ($\Delta_E$ = 68 mV), that is cathodically shifted by 78 mV with respect to $L^1$. This difference may reflect the presence of a ferrous centre close to the flavin side.

To summarize, a ligand system in which a ubiquitous redox mediator – riboflavin, that is vitamin B2 – is covalently linked to a tridentate nitrogen chelate is now available. A trichloroferric complex with a reversible $Fe^{III}/Fe^{II}$ redox couple can easily be obtained. All compounds reported are stable and easy to handle. We thus believe that the syntheses reported in this communication represent a significant step towards the preparation of functional artificial systems with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

DPA-based complexes in which the active metal-containing site is linked through the flavin part to proteins. This approach is currently under investigation in our laboratory.

## Experimental Section

$^1$H- and $^{13}$C NMR spectroscopic data were recorded with a Bruker AC 300 spectrometer and chemical shifts are standardized to the residual signal of the solvent as a reference. UV/Vis spectra were recorded with a Varian Cary 05 E UV/Vis NIR spectrophotometer. Cyclic voltammetry measurements were obtained with a EG&G PAR 173A potentiostat in a 0.1 M acetonitrile solution of $TBAPF_6$ (supporting electrolyte), with platinum electrodes and saturated calomel electrode as reference. Traces are given in the text. Elemental analyses were carried out by the Service Central d'Analyses du CNRS in Vernaison, France. Mass spectroscopy was carried out with a MicroTOF instrument in the positive mode.

**Preparation and Characterization of 8α-[Bis(2-pyridylmethyl)amine]-*N*-Ac$_4$riboflavin (L$^1$):** Bis(2-pyridylmethyl)amine (5 g, 25.2 mmol) in a solution of DMF (10 mL) was added to a solution of 8α-BromoAc$_4$riboflavin (8 g, 12.8 mmol) in DMF (100 mL). The mixture was stirred for 24 h at ambient temperature. DMF was then removed in vacuo, and the resulting oil was dissolved in $CH_2Cl_2$ (50 mL). This phase was washed twice with distilled water. The organic phase was dried with magnesium sulfate, reduced to 15 mL and a brownish–yellow compound was obtained as a solid by the addition of cold diethyl ether (100 mL). Upon drying, compound L$^1$ was obtained (5.75 g, 60%). Further recrystallization yielded a compound for which the elemental analysis was satisfactory. L$^1$·2H$_2$O: $C_{37}H_{43}N_7O_{12}$ (777.30): calcd. C 57.14, H 5.53, N 12.61; found C 56.83, H 5.11, N 12.57. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.69 (d, $J$ = 4.0 Hz, 2 H, DPA α), 8.53 (s, 1 H, NH), 7.92 (s, 1H Ar), 7.71 (t, $J$ = 7.6 Hz, 2 H, DPA γ), 7.56 (s, 1 H, Ar), 7.46 (d, $J$ = 7.6 Hz, 2 H, DPA β′), 7.23–7.19 (m, 2 H, DPA β), 5.59 (d, 1 H, ribityl CH), 5.46 (m, 2 H, ribityl $CH_2$), 5.3–5.1 (m, 2 H, N-$CH_2$), 4.44–4.39 (dd, $J$ = 2.2–1.8 Hz, 1 H, aliphatic), 4.31–4.23 (m, 1 H, aliphatic), 4.11–3.98 (dd, $J$ = 14.0–13.9 Hz, 4 H, $CH_2$-DPA), 3.82 (s, 2 H, $CH_2$-ribofl.), 2.55 (s, 3 H, methyl), 2.42 (s, 3 H, acetyl), 2.32 (s, 3 H, acetyl), 2.26 (s, 3 H, acetyl), 2.19 (s, 3 H, acetyl) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 170.6–169.4 (4 acetyl C=O), 159.4 (flavin C=O), 157.8 (2 $C_{quat}$), 154.7 (flavin C=O), 150.6 ($C_{quat}$), 149.4 (2 $CH_{pyridyl}$), 148.0 ($C_{quat}$), 136.5 (2$CH_{pyridyl}$), 134.5 (2 $C_{quat}$), 132.9 (2$CH_{pyridyl}$), 123.5 ($CH_{pyridyl}$), 122.6 ($CH_{pyridyl}$), 115.5 (2 $CH_{Ar}$), 70.4, 69.4, 69.1 (3 CH), 61.9 ($CH_2$ ribofl.), 59.7 (2 $CH_{2pyridyl}$), 55.1 ($CH_2$), 45.0 ($CH_2$), 21.4, 21.1, 21.0, 20.8, 20.7 ($CH_3$) ppm. UV/Vis: $\lambda$ ($\varepsilon$, $10^3$ mmol·cm$^2$) = 443.6 (9.47), 342.0 (7.72), 268.8 (24.94) nm. MS ( ES$^+$, $CH_3CN$ + 0.1% formic acid): $m/z$ = 742.32 [M + H]$^+$.

**Preparation and Characterization of Complex L$^1$FeCl$_3$:** The procedure outlined in ref.[22] was followed. To a solution of 8α-[bis(2-pyridylmethyl)amine]-*N*-Ac$_4$riboflavin (L$^1$; 100 mg, 0.135 mmol) in dry THF (30 mL), was added a solution of anhydrous $FeCl_3$ (22 mg, 0.135 mmol) in dry THF (20 mL). Although the compounds are air stable, the reaction was carried out by using Schlenk tubes and cannula. The mixture was stirred for 24 h, and the solvent was then evaporated. The brownish solid was dissolved in $CH_3CN$, filtered and the solution was concentrated (rotary evaporator). Addition of dry diethyl ether allowed precipitation of L$^1$FeCl$_3$, as a brown, air-stable solid. After washing with diethyl ether and drying, the product was obtained (110 mg, 90%). The compound was recrystallized from acetonitrile/diethyl ether several times. L$^1$FeCl$_3$·4H$_2$O: $C_{37}H_{47}N_7O_{14}FeCl_3$ (974.16): calcd. C 45.51, H 4.81, N 10.04; found C 45.17, H 4.47, N 10.12. $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = presence of two very broad signals at 108 and 93 ppm (mid-intensity peak width 1800 and 1500 Hz, respectively). Weak signal at $\delta$ = 52 ppm with mid-intensity peak width of 600 Hz. Presence of moderately broadened signals between 3 and 12 ppm. UV/Vis: $\lambda$ ($\varepsilon$, $10^3$ mmol·cm$^2$) = 445.3 (8.57); 326.9 (11.31); 267.0 (26.78) nm. MS (ES$^+$, $CH_3CN$ = 0.1% formic acid) $m/z$ = 927.07 [M + Na]$^+$, 890.13 [M + Na – Cl]$^+$.

**Preparation and Characterization of 8α-[Bis(2-pyridylmethyl)amine]-*N*-riboflavin (L$^2$):** To a solution of potassium carbonate (3 g, 21.3 mmol) in absolute ethanol (150 mL), 8α-[bis(2-pyridylmethyl) amine]-*N*-Ac$_4$riboflavin (L$^1$; 3 g, 4.3 mmol) was added. The mixture was stirred for 48 h at ambient temperature. After neutralization with AMBERLITE IR-20 resin, the solution was filtered and concentrated in vacuo until a brownish solid precipitated. The solution was washed several times with ether and dried in vacuo. The compound was dissolved in DMF and precipitated by the addition of diethyl ether. The solid was dried in vacuo to afford the product (1.75 g, 70%). Microcrystals of this compound could be obtained from an ethanolic solution by slow evaporation of the solvent. These were kept for elemental analysis and NMR spectroscopy. The $^1$H NMR spectrum is poorly defined, especially in the aliphatic area. This might be due to agitation of the ribityl moiety and interaction with residual water of the DMSO. $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 11.6–11.3 (4 H, OH), 10.32 [OH (EtOH)], 8.73 (d, $J$ = 4.4 Hz, 2 H, DPA α), 8.31 (s, 1 H, NH), 8.04 (m, 2 H, DPA β), 7.91 (s, 1 H, Ar), 7.85 (s, 1 H, Ar), 7.72 (d, $J$ = 6.2 Hz, 2 H, DPA β′), 7.56 (m, 2 H, DPA γ), 5.20–4.10 (broad signal, ribityl protons and residual water of the DMSO), 4.19 (broad, 2 H, $CH_2$), 3.65 (broad, 4 H, DPA $CH_2$), 3.44 [q, $J$ = 7.1 Hz, $CH_2$ (EtOH)], 2.47 (s, 3 H, $CH_3$), 1.05 [t, $J$ = 7.1 Hz, $CH_3$ (EtOH)] ppm. $^{13}$C NMR (75 MHz, [D$_6$]DMSO) $\delta$ = 159.4 (flavin C=O), 157.8 (2 $C_{quat}$), 154.7 (flavin C=O), 150.6 ($C_{quat}$), 149.4 (2 $CH_{pyridyl}$), 148.0 ($C_{quat}$), 136.5 (2 $CH_{pyridyl}$), 134.5 (2 $C_{quat}$), 132.9 (2 $CH_{pyridyl}$), 123.5 ($CH_{pyridyl}$), 122.6 ($CH_{pyridyl}$), 115.5 (2 $CH_{Ar}$), 74.0, 73.2, 69.1 (3 CH), 63.8 ($CH_2$), 63.7 (2 $CH_{2pyridine}$), 58.2 (4 $CH_{2EtOH}$), 56.4 ($CH_2$), 50.1 ($CH_2$), 21.2 ($CH_3$), 19.2 (4 $CH_{3EtOH}$). UV/Vis: $\lambda$ ($\varepsilon$, $10^3$ mmol·cm$^2$) = 447.0 (6.85), 344.7 (5.83), 269.5 (19.03). MS (ES$^+$, $CH_3CN/H_2O$ + 0.1% formic acid): $m/z$ = 574.24 [M + H]$^+$. L$^2$·4EtOH: $C_{37}H_{55}N_7O_{10}$ (757.40): calcd. C 58.65, H 7.26, N 12.94; found C 58.37, H 7.60, N 12.30.

# Resonance Raman Spectroscopy with Overtones Involving Metal-Ligand and Ligand-Centered Modes in (*o*-Benzoquinonediimine)ruthenium(II) Complexes

**Rémi Beaulac,[a] A. B. P. Lever,*[b] and Christian Reber*[a]**

**Keywords:** Raman spectroscopy / Ruthenium complexes / *o*-Benzoquinonediimine / Electronic structure / Covalency / π-Back donation / Charge transfer / Density functional calculations / Overtones / Combination bands / Luminescence / Absorption

Resonance Raman spectra of (*o*-benzoquinonediimine)ruthenium(II) complexes measured with visible excitation wavelengths show distinct resonance enhancements and intense overtone and combination bands. Assignments of the most prominent fundamental bands are made on the basis of comparisons with theoretical spectra obtained from DFT calculations. Excited state distortions are determined from the resonance Raman intensities and lead to calculated luminescence and absorption spectra in good agreement with experiment.

## Introduction

Resonance Raman spectroscopy can be used as a powerful technique to study excited-state structure, in particular for systems with broad, unresolved absorption transitions that do not provide detailed information through resolved vibronic structure.[1–5] Charge-transfer processes in transition-metal complexes, in particular those of ruthenium(II), are of particular interest for spectroscopic investigations, as detailed spectra combined with theoretical models provide quantitative insight on the structural and dynamics aspects of these important excited states.[6,7] In the vast majority of reported resonance Raman studies on ruthenium(II) complexes only fundamental bands are observed.[7–10,11]

The ligand *o*-benzoquinonediimine (BQDI) and its derivatives are of interest because of the extensive delocalization of Ru 4d electron density over the BQDI ligand.[12–18] This delocalization has been discussed in terms of metal–ligand orbital mixing or donor–acceptor electronic coupling. The covalent interactions between the metal and the ligand can be separated into ligand-to-metal donation and metal-to-ligand back-donation.[12–18] Complexes with these ligands, in particular [Ru(BQDI)(acac)$_2$] and [Ru(BQDI)(NH$_3$)$_2$Cl$_2$], show resonance Raman spectra with exceptionally rich patterns involving harmonics and combination bands. We present and analyze these spectra in the following report.

## Results and Discussion

Resonance Raman spectra of [Ru(BQDI)(acac)$_2$] and [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] were measured with excitation wavelengths near the lowest-energy intense absorption maximum at ca. 20000 cm$^{-1}$, and are shown in Figure 1. Strong resonance enhancements are accompanied by an exceptionally detailed series of overtones and combination bands (identified by the labels I, II, III), which provide relevant information on excited-state distortions in the title complexes. Raman spectra measured with off-resonance excitation at 12700 cm$^{-1}$ are compared to the resonance Raman spectra in Figure 2. It is likely that each peak observed in the off-resonance Raman spectra corresponds to a fundamental transition, as overtones and combination bands are too weak to be observed in the absence of resonance enhancements; we can identify on the order of 16–18 experimental vibrational frequencies as listed in Table 1. The comparison of resonance and off-resonance spectra shows very clearly

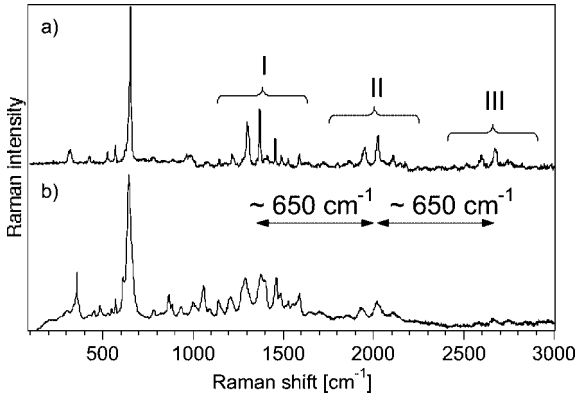

Figure 1. Comparison of resonance Raman spectra (solid samples, 77 K) of a) [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] ($\lambda_{exc}$ = 488 nm) and of b) [Ru(BQDI)(acac)$_2$] ($\lambda_{exc}$ = 514 nm). The baseline was corrected to remove the luminescence onset and the total integrated intensity of each spectrum was normalized.

that all peaks observed at frequencies between 1700 $cm^{-1}$ and 3000 $cm^{-1}$ correspond to resonance-enhanced overtones or combination bands. Calculated Raman spectra obtained from DFT are in good agreement with the experimental spectra, as shown by the dotted traces in Figure 2. In particular, the calculated spectra do not show any bands where overtones and combination bands are observed, and they indicate a larger number of bands in the 1200 to 1500 $cm^{-1}$ region for [Ru(BQDI)(acac)$_2$] than for [Ru(BQDI)(NH$_3$)$_2$Cl$_2$], providing a qualitative rationale for the large, poorly resolved feature observed for the former complex in this wavenumber range. The Raman peaks in the off-resonance spectrum of [Ru(BQDI)(acac)$_2$] are weak and broad, especially in the 1200 to 1500 $cm^{-1}$ region, complicating the identification of fundamental bands. Only the peaks that can clearly be assigned as fundamentals involved in the resonance Raman spectrum were labeled as such in Figure 2 and in Table 1.

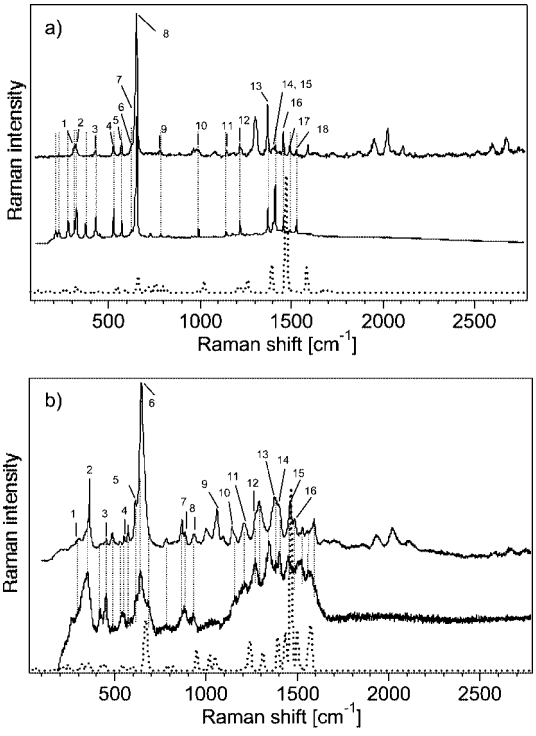

Figure 2. Comparison of resonance Raman (top spectrum) and off-resonance Raman (middle spectrum) in solid phase at 77 K and (lower) DFT calculated spectrum. a) [Ru(BQDI)(NH$_3$)$_2$Cl$_2$], top: $\lambda_{exc}$ = 488 nm, middle: $\lambda_{exc}$ = 788 nm. b) [Ru(BQDI)(acac)$_2$], top: $\lambda_{exc}$ = 514 nm, middle: $\lambda_{exc}$ = 788 nm. The number labels refer to Table 1.

All peaks observed in the resonance Raman spectra not corresponding to fundamental frequencies are assigned as harmonics or combination bands built on one or several of the fundamental frequencies listed in Table 1. The analysis of the Raman spectra of [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] is more straightforward because the identification of the fundamental frequencies in the off-resonance Raman spectrum is obvious. In both systems, it appears clearly that the peaks labeled II and III in Figure 1 observed at Raman shifts of approximately 2000 $cm^{-1}$ and 2600 $cm^{-1}$ are not fundamentals, and their spacing of approximately 650 $cm^{-1}$ corresponds to the Raman shift of the most intense peak in each resonance Raman spectrum, observed at 655 and 646 $cm^{-1}$ in [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] and [Ru(BQDI)(acac)$_2$], respectively. The high relative intensities of the transitions at 655 and 646 $cm^{-1}$ show directly that the largest distortions between the ground-state and the excited-state structures probed here occur along the normal coordinates of these modes and that the peaks in regions II and III are combination bands involving these modes. The peaks in region I are not as easily identified, as both fundamental bands and the first overtone of the most intense fundamental occur at the Raman shifts of approximately 1300 $cm^{-1}$ corresponding to this region and calculated spectra have to be used to identify individual transitions.

Table 1. Observed vibrational frequencies $\omega_k$ [$cm^{-1}$] and calculated excited-state distortions $\Delta_k$ [dimensionless] of the modes observed in the resonance Raman spectra of [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] and [Ru(BQDI)(acac)$_2$]. The index $k$ refers to the numerical labels shown in Figure 2 and numbers the normal coordinates in Equation (3); the parameters $E_{00}$ and $\Gamma$ refer to Equation (2).

| | [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] | | [Ru(BQDI)(acac)$_2$] | |

| 18 | 1528 | 0.2 | | |
| Total distortion $\sum_k \Delta_k$ | | 11.1 | | 11.2 |
| $E_{00}$ [$cm^{-1}$] | | 17250 | | 16830 |
| $\Gamma$ [$cm^{-1}$] | | 150 | | 400 |

The DFT calculations are used to assign the most prominent observed Raman transitions. Calculated at 665 $cm^{-1}$ and 662 $cm^{-1}$ are the Ru–NH(BQDI) stretching modes for [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] and [Ru(BQDI)(acac)$_2$], respectively, which involve fairly large breathing motion in the BQDI ring for both complexes. These frequencies are higher by 10 and 16 $cm^{-1}$ than the experimental values, illustrating the excellent quantitative agreement. The 1394 and 1392 $cm^{-1}$ peaks correspond to the C=NH vibration coupled strongly to the CH bonds localized on the BQDI ligand. The calculated frequencies are higher than the experimental values by 24 and 14 $cm^{-1}$ for [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] and [Ru(BQDI)(acac)$_2$], respectively. The calculated vibrational frequencies tend to be slightly higher than the experimental values,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

possibly due to the B3LYP functional slightly over-emphasizing the covalent contribution to the Ru–N bonds,[19] but overall the agreement between calculated and observed frequencies is excellent.

A quantitative analysis of the resonance Raman intensities leads to a more precise picture of excited-state distortions and allows us to identify similarities and differences between the two compounds studied here. The resonance Raman intensities can be calculated very efficiently using the time-dependent approach described previously by Heller, Zink and associates.[1,3,4,20–22] The simplest approach, used here, is based on a single electronic excited state and the Raman intensity $I_{i\rightarrow f}$ at frequency $\omega_s$ is given by Equation (1):

$$I_{i\rightarrow f} \propto \omega_I \omega_S{}^3 \left[\alpha_{fi}\right]^* \left[\alpha_{fi}\right] \quad (1)$$

with Equation (2):

$$\left[\alpha_{fi}\right] = \frac{i}{\hbar}\int_0^\infty \left\langle \phi_f \middle| \phi(t)\right\rangle \cdot exp\left(-iE_{00}t - \Gamma t\right) \cdot \exp\left(i\left(\omega_i + \omega_I\right)t\right)dt \quad (2)$$

where $\Gamma$ is a constant damping factor (in $cm^{-1}$), $\hbar\omega_i$ is the zero-point energy of the ground electronic potential energy surface and $\hbar\omega_I$ is the energy of the incident radiation. $\langle\phi_f|\phi(t)\rangle$ is the autocorrelation function, which takes a simple analytical form if it is assumed that (a) the force constants are the same in both ground and excited states, (b) the potential energy surfaces are harmonic, (c) the transition dipole moment is independent of the normal coordinates and (d) the normal coordinates are not coupled, see Equation (3).

$\omega_k$ and $\Delta_k$ denote the wavenumber (in $cm^{-1}$) and the difference between potential-energy minima of the ground and excited states along the $k$th normal coordinate, respectively, and $n_k$ is the vibrational quantum number of the $k$th normal mode in the ground electronic state. As an example, the combination band ($2\nu_1 + \nu_2$) in a three-mode case would have $n_1 = 2$, $n_2 = 1$ and $n_3 = 0$. Equation (1) can be used to calculate the excitation profile for each fundamental, harmonic and combination band involved in the resonance Raman spectrum. The experimental spectra in Figure 1 and Figure 2 do not provide full excitation profiles, but an analysis is still possible. The approach consists of adjusting the ratio of intensities between calculated profiles for different modes by fitting the displacements $\Delta_k{}^{n_k}$ in Equation (3) until the ratios of calculated intensities are in agreement with the experiment. Adjusting as many parameters as there are in Table 1 can be tedious, but the task is somewhat facilitated by using Savin's approximation to estimate the relative displacements between two modes $k$ and k' in the resonance Raman spectrum [Equation (4)].[4]

$$\frac{I_k}{I_{k'}} = \left(\frac{\Delta_k \omega_k}{\Delta_{k'} \omega_{k'}}\right)^2 \quad (4)$$

The best parameter values obtained in this way are given in Table 1 for both complexes; the calculated intensities are compared to the experimental resonance Raman spectra in Figure 3 and Figure 4 for $[Ru(BQDI)(NH_3)_2Cl_2]$ and $[Ru(BQDI)(acac)_2]$, respectively. These calculations involve all modes identified as fundamentals in the experimental Raman spectra, in contrast to the simplified analysis for $[Ru(BQDI)(NH_3)_2Cl_2]$,[18] where only five modes were considered. Figure 3 and Figure 4 illustrate the very good agreement between calculated and experimental intensities of the resonance Raman spectra. An additional criterion to compare model calculations and experimental spectra is provided by the intensities of overtones and combination bands, which are also reproduced well, as shown for the first overtone of the 650 $cm^{-1}$ mode in Figure 3 and Fig-

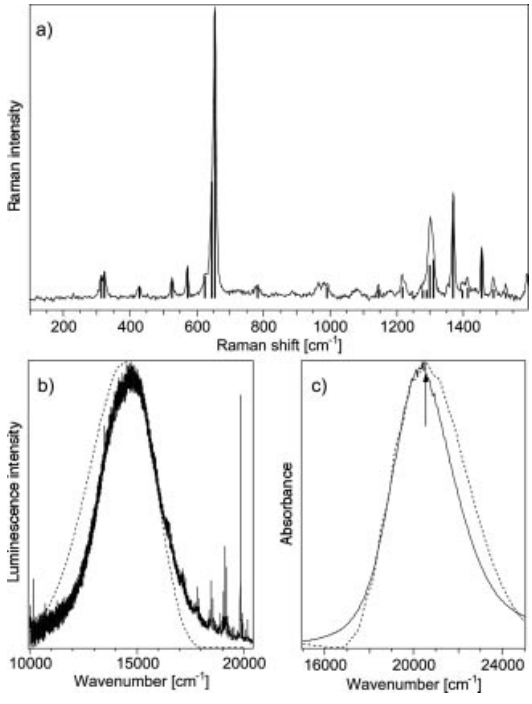

Figure 3. Comparison of calculated and experimental spectra for $[Ru(BQDI)(NH_3)_2Cl_2]$. a) Resonance Raman, b) 77 K solid-state luminescence and c) room-temperature absorption in dimethylformamide solution. The calculated spectra in b) and c) are given as dotted lines. The vertical arrow in c) indicates the resonance Raman excitation wavelength (488 nm).

$$\left\langle \phi_f \middle| \phi(t)\right\rangle = \prod_k \left\{ \exp\left[-\frac{\Delta_k^2}{2}\left(1-\exp\left(-i\omega_k t\right)\right) - \frac{i\omega_k t}{2}\right] \times \left(1-\exp\left(-i\omega_k t\right)\right)^{n_k} \times \frac{\left(-1\right)^{n_k}\Delta_k^{n_k}}{\left(2^{n_k} n_k!\right)^{1/2}} \right\} \quad (3)$$

ure 4. Identical total distortions are obtained for both complexes, further corroborating the consistency of our analysis. The luminescence and absorption spectra for both complexes studied here can be calculated from the parameters in Table 1 and are shown for comparison in Figure 3 and Figure 4. These spectra are calculated without any adjustable parameters and the good agreement further illustrates that the parameters in Table 1 are physically meaningful.

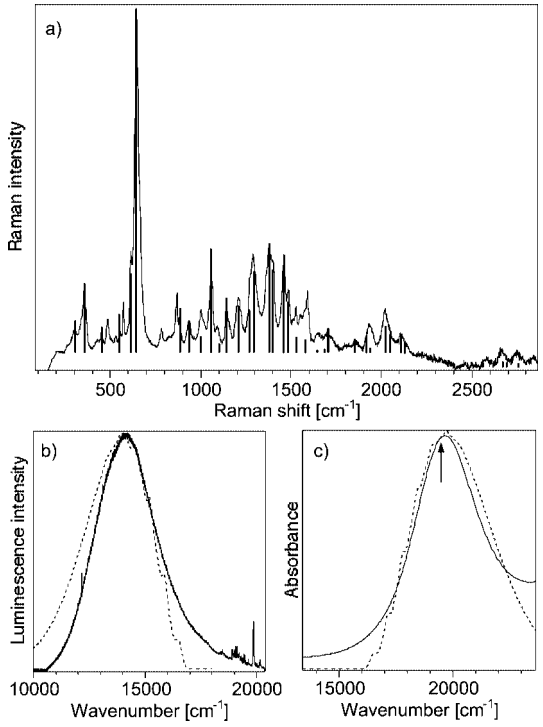

Figure 4. Comparison of calculated and experimental spectra for [Ru(BQDI)(acac)$_2$]. a) Resonance Raman, b) 77 K solid-state luminescence and c) room-temperature absorption in dimethylformamide solution. The calculated spectra in b) and c) are given as dotted lines. The vertical arrow in c) denotes the resonance Raman excitation wavelength (514 nm).

The calculations show that the largest excited state distortion occurs along the coordinate associated to the mode with a frequency of approximately 650 cm$^{-1}$, in agreement with the qualitative observation made before, and distortions of identical magnitude are obtained for both complexes. The quantitative analysis allows more general observations to be made. We can separate the excited-state distortions into two groups, one containing modes whose frequencies are between 300 and 650 cm$^{-1}$ and whose displacements are relatively high, and another group containing modes with higher frequencies between 1000 and 1500 cm$^{-1}$ and lower displacements. The latter group can be assigned to ligand-centered modes, whereas the former is clearly related to metal-ligand modes. This observation is in agreement with the proposed MLCT character of the transition, and shows that both complexes are quite similar, despite the minor differences discussed previously. This suggests that the BQDI ligand plays a major role in the electronic transition, as acceptor of charge, and that the auxiliary ligands modify the electronic structure of the entire complex in a slightly different manner for the two complexes studied here, as shown by the resonance Raman intensities and the analysis based on time-dependent theory. Much larger effects of auxiliary ligands on a variety of chemical properties of this category of complexes are discussed elsewhere.[18] However, it is critical to note that the primary changes in geometry in the excited MLCT states occur within the Ru–N$^a$H=C–C=N$^b$H(*Ru–N$^b$*) metallacycle, which is quasi aromatic (6-electron ring) with much less distortion within the six membered benzene ring of BQDI. Indeed one might describe the transitions as mainly π–π* within the quasi aromatic metallocycle ring system. Our results show that the excited-state distortions in the title complexes can be explored by resonance Raman spectroscopy in unprecedented detail not accessible for other charge-transfer excited states in ruthenium(II) complexes.

## Experimental Section

The species [Ru(BQDI)(NH$_3$)$_2$Cl$_2$] and [Ru(BQDI)(acac)$_2$] were prepared by literature methods.[18,23] Raman spectra were measured with a Renishaw 3000 Raman imaging microscope at 488, 514 and 788 nm excitation laser wavelengths. The microscope was used to focus the light onto a spot of approximately 1 μm in diameter and to collect the scattered light. The backscattered Raman light was detected with a Peltier cooled CCD detector. This instrument was also used to measure luminescence spectra. Absorption spectra were measured with a Varian Cary 5E spectrometer.

Density functional theory (DFT) spin-restricted calculations were performed using the Gaussian 03 program (Revision C.01 and C.02).[24] Optimized geometries were calculated by using the B3LYP exchange-correlation functional[25,26] with the LanL2DZ basis set.[27–30] The SWIZARD program[31] was used to extract the calculated Raman spectra from the Gaussian output files with a line width of 15 cm$^{-1}$.

# Synthesis and Crystal Structure of Three Carborane Complexes, [M{7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$] (M = Cu, Zn) and [Ni(thf){7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$]·thf, and Two Carborane Compounds, 1-(OPPh$_2$)-2-(PPh$_2$)-1,2-C$_2$B$_{10}$H$_{10}$ and H[7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$]·0.25C$_2$H$_5$OH

**Jianmin Dou,*[a] Daopeng Zhang,[a] Dacheng Li,[a] and Daqi Wang[a]**

**Keywords:** Cu complexes / Zn complexes / Ni complexes / Carborane complexes / Oxidation / Degradation

Three new carborane complexes containing the bis(phosphoryl)-*nido*-carborane ligand, [Cu{7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$] (**1**), [Zn{7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$] (**2**), and [Ni(thf){7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$]·thf (**3**), were synthesized by the reactions of 1,2-(PPh$_2$)$_2$-1,2-C$_2$B$_{10}$H$_{10}$ with CuCl$_2$·2H$_2$O, ZnCl$_2$, and NiCl$_2$·6H$_2$O, respectively, in ethanol in air. Two other compounds, 1-(OPPh$_2$)-2-(PPh$_2$)-1,2-C$_2$B$_{10}$H$_{10}$ (**4**) and H[7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$]·0.25C$_2$H$_5$OH (**5**), were also obtained through the oxidation of the *closo* ligand in air. All new compounds were characterized by elemental analysis, FT-IR, $^1$H and $^{13}$C NMR spectroscopy, and single-crystal X-ray diffraction. In complexes **1** and **2**, the metal atoms are coordinated to the four oxygen atoms of the two bidentate bis(phosphoryl) ligands [7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$]$^-$ and adopt a square-planar geometry. For complex **3**, the molecular structure reveals that the geometry at the nickel atom is square-pyramidal, with four oxygen atoms from the four OPPh$_2$ groups and one additional one from a thf molecule.

## Introduction

The synthesis and properties of dicarba-*closo*-dodecaborane, 1,2-C$_2$B$_{10}$H$_{12}$, and the -*nido*-species, [7,8-C$_2$B$_9$H$_{12}$]$^-$, were first reported in the early 1960s.[1–4] Since then, both *closo*- and *nido*-carboranes have proven to be excellent bulky and stable building blocks that allow for the synthesis of a wide range of carborane derivatives and have shown a lot of potential in various applications, including medicinal chemistry, especially Boron Neutron Capture Therapy (BNCT) of tumors, solvent extraction, materials science, catalysis, host–guest chemistry, and coordination chemistry,[5–18] which made carborane chemistry all along an interesting growth area.

In recent years, the 1,2-bis(phosphanyl) derivative of *o*-carborane, 1,2-(PPh$_2$)$_2$-1,2-C$_2$B$_{10}$H$_{10}$, and its partially degraded anion, *nido*-[7,8-(PPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$]$^-$, have attracted much attention because of the coordinating capabilities of the two phosphorus atoms. Up to now, complexes containing the 1,2-(PPh$_2$)$_2$-1,2-C$_2$B$_{10}$H$_{10}$ and *nido*-[7,8-(PPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$]$^-$ ligands and Cu$^{I}$,[19] Ru$^{II}$,[20] Ag$^{I}$,[21,22] Au$^{I}$,[23–29] Pd$^{II}$,[30–33] and Rh[34] have been reported and characterized by single-crystal X-ray diffraction. We are also interested in these kinds of complexes and have reported on the synthesis and crystal structures of Cu$^{I}$,[35] Au$^{I}$,[36] Ni$^{II}$, Pd$^{II}$, and Pt$^{II}$ complexes,[37] and we investigated the effect of different reaction conditions on the products. When the reaction of 1,2-(PPh$_2$)$_2$-1,2-C$_2$B$_{10}$H$_{10}$ with NiCl$_2$·6H$_2$O was carried out in air, a new complex containing one bis(phosphanyl)-*nido*-carborane ligand and one unsymmetrical semi-oxidized (phosphoryl)(phosphanyl) ligand with the formula [Ni{7-(OPPh$_2$)-8-(PPh$_2$)-7,8-C$_2$B$_9$H$_{10}$}{7,8-(PPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}] were obtained.[38]

This result indicates that the environment has an obvious influence on the reaction. To continue with the reactions of the bis(phosphanyl)-*closo*-carborane ligand with different metal ions without the protection of inert gases, we investigated three reactions of the bis(phosphanyl)-*closo*-carborane ligand with CuCl$_2$·2H$_2$O, ZnCl$_2$, and NiCl$_2$·6H$_2$O in air and obtained three new carborane complexes containing the *nido*-[7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$]$^-$ anion, [Cu{7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$] (**1**), [Zn{7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$] (**2**), and [Ni(thf){7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$}$_2$]·thf (**3**). To the best of our knowledge, there has been no report on the metal ion complex of the bis(phosphoryl)carborane ligand [7,8-(OPPh$_2$)$_2$-7,8-C$_2$B$_9$H$_{10}$]$^-$, which has been reported by Teixidor's group.[39] In addition, the oxidation and degradation process of the free bis(phosphanyl)-*closo*-carborane ligand, 1,2-(PPh$_2$)$_2$-1,2-C$_2$B$_{10}$H$_{10}$, in air was studied for the first time.

## Results and Discussion

### Synthesis and Spectral Characterization

In our recent work[38] we found that, with or without the protection of N$_2$, results of the reactions of the bis(phos-

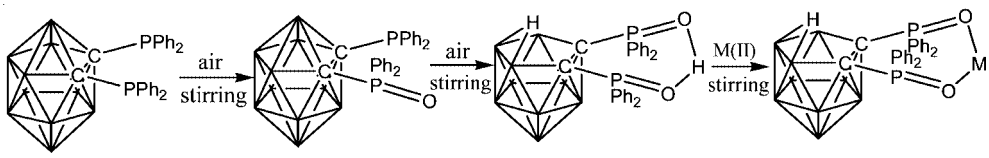
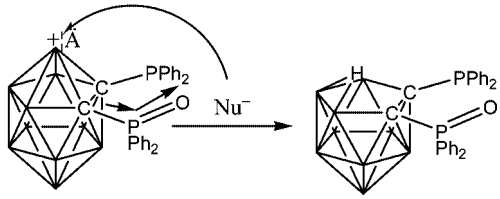


Scheme 1. The rational reaction process for the preparation of the complexes **1** to **3** [M = Cu(**1**), Zn(**2**), Ni(**3**)].

phanyl)-*closo*-carborane ligand 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ with some $Ni^{II}$ compounds were very different, indicating that the reaction environment could play an important role during the reaction process. By stirring the mixture of $NiCl_2{\cdot}6H_2O$ and the *closo* ligand for 6 h in ethanol at room temperature, we obtained the complex [Ni{7-$(OPPh_2)$-8-$(PPh_2)$-7,8-$C_2B_9H_{10}$}{7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$}]. However, when the stirring time was increased to 12 h in air, both P atoms of the initial bis(phosphanyl)-*closo*-carborane ligand were oxidized, and a new complex containing the bis(phosphoryl)-*nido*-carborane ligand [7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$]$^-$ was obtained. This result showed that both of the P atoms could be oxidized, but the oxidation of the two P atoms did not take place at the same time. Subsequently, the reactions between $CuCl_2{\cdot}2H_2O$, $ZnCl_2$, and the bis(phosphanyl)-*closo*-carborane ligand in a molar ratio of 1:1 in ethanol were carried out. After the stirring process was continued for 6 h in air at room temperature, two complexes with the formula [Cu{7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$}$_2$] and [Zn{7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$}$_2$] were obtained. As indicated by their similar crystal data, listed in Table 2, these two complexes are isostructural. The difference in the reaction times of the above three reactions implied that the metal atom itself could also affect the reaction process. The rational reaction process for the preparation of these three complexes is shown in Scheme 1.

With an aim to find out whether the phosphorus atom of the *closo* ligand could be oxidized and the carborane skeleton could be converted from *closo* to *nido* by oxygen without the presence of the metal ion, we studied another experiment. The free *closo* ligand 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ was suspended in ethanol, and the mixture was stirred for 8 h, while air was continually and slowly bubbled into the reaction mixture. Contrary to our expectation, a compound containing the *closo*-carborane skeleton, but not the *nido* form, with the formula 1-$(OPPh_2)$-2-$(PPh_2)$-1,2-$C_2B_{10}H_{10}$ (**4**), was obtained, in which also only one phosphorus atom was oxidized. A marked difference from the complex [Ni{7-$(OPPh_2)$-8-$(PPh_2)$-7,8-$C_2B_9H_{10}$}{7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$}] was that the *closo*-carborane skeleton in this compound was maintained. Following the procedure for the synthesis of compound **4**, the mixture was stirred for 18 h, and a compound with the formula H[7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$]$\cdot$ $0.25C_2H_5OH$ (**5**) was obtained. This compound is very similar to another neutral compound H[7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$], which has been obtained with very high yield (94–97%) by oxidation of 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ with $H_2O_2$ in thf at 0 °C.[39] The aim of oxidizing another phosphorus atom of the semi-oxidized (phosphoryl)(phosphanyl)-*closo*-carborane ligand was fulfilled, but the *closo*-carborane skeleton degraded. The proposed mechanism for the partial degradation of the semi-oxidized (phosphoryl)(phosphanyl)-*closo*-carborane ligand, which is similar to the degradation of 1-SR-2-$PPh_2$-1,2-$C_2B_{10}H_{10}$,[40] is shown in Scheme 2.



Scheme 2. Proposed mechanism for the partial degradation of compound **4**.

The $C_{cage}$–P=O group pulls electron density off the cage, and its electron-withdrawing capacity favors the removal of the B(3) atom (the boron atom adjacent to the carbon atom), especially under the attack of the nucleophilic solvent. According to these results, we think that compound **4** is an intermediate formed during the oxidation and degradation process of the *closo* ligand. This process may be accomplished in three steps which occur in the following order: (1) the oxidation of one phosphorus atom, (2) the degradation of the *closo*-carborane skeleton, and (3) the oxidation of another phosphorus atom.

All the three carborane complexes and two bis(phosphoryl)carborane compounds were characterized by FT-IR, $^1H$ and $^{13}C$ NMR spectroscopy. The IR spectra of compounds **1**–**5** are very similar to each other and exhibit absorptions characteristic of terminal B–H vibrations at 2510–2550 $cm^{-1}$, which fall in the normal range of B–H vibration from 2450 to 2625 $cm^{-1}$.[41] The absorption at about 3100 $cm^{-1}$ may be attributed to the $\nu_{C-H}$ stretching vibration of the benzene rings. Several peaks are found between 1689 and 1400 $cm^{-1}$, which may be assigned to the $\nu_{C=C}$ stretching vibration. The peak at ca. 1400 $cm^{-1}$ is the in-plane deformation mode of the benzene ring, and the peak at ca. 1100 $cm^{-1}$ is the absorption of $\nu_{C(aryl)-P}$, which is a little shifted, in keeping with phosphorus coordination to the carborane moiety. The strong absorption at about 1250–1260 $cm^{-1}$ in all the compounds may be attributed to the P=O bond. The absorption at 700–750 $cm^{-1}$ shows the existence of the deformation cage. The $^1H$ NMR spectra (400.15 MHz) of these carborane compounds display a common resonance pattern at about 7.1–7.6 ppm, which can be attributed to the aryl-H of the $PPh_2$ groups. The resonance at ca. –2.2 ppm is the bridging H atom of B–H–B in the three complexes.[19] In the $^{13}C$ NMR spectra (100.63 MHz), the resonance at about 132–139 ppm can be

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

assigned to the benzene-ring C atoms, and that at ca. $\delta = 77$ can be attributed to the carbon atom of carborane cage.[42]

### X-ray Crystallographic Study

The molecular structures of the new compounds **1**–**5** are shown in Figure 1, Figure 2, Figure 3, Figure 4, and Figure 5 respectively, and the selected bond lengths and angles of the three carborane complexes are listed in Table 1. A common feature of the complexes **1**–**3** is that they all contain the same bis(phosphoryl)-*nido*-carborane ligand [7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}]^-$. The average P–$C_{cage}$ distances in the three metal complexes are 1.804, 1.809, 1.816 Å, respectively, which are slightly shorter than the mean value 1.87 Å in $[NH_4][7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}]$,[43] indicating that in these *nido* species the oxidation of the P atom has an influence on the P–$C_{cage}$ bond length. This conclusion could also be proved by the corresponding bond lengths in $[Ni\{7\text{-}(OPPh_2)\text{-}8\text{-}(PPh_2)\text{-}7,8\text{-}C_2B_9H_{10}\}\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}]$[38] [P–C(7): 1.769(7), P–C(8): 1.867(7) Å]. The C(7)–C(8) bond lengths, ranging from 1.593(7) to 1.606(8) Å in **1**–**3** are in good agreement with the corresponding distance 1.61(2) Å in $[NH_4][7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}]$,[43] but obviously shorter than 1.697(4) Å in the *closo* ligand 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$.[44] The angles P(1)–C(7)–C(8) and P(2)–C(8)–C(7) in complexes **1**–**3** [120.4(3)–

[a] Symmetry transformations used to generate equivalent atoms: complex **1**: $-x+1, -y+1, -z$; complex **2**: $-x+1, -y+1, -z+2$.

124.6(3)°] are slightly larger than the corresponding angles [113.4(9) and 116.5(9)°] in $[NH_4][7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}]$. The P=O bond lengths are within a narrow range from 1.488(4) to 1.525(4) Å, which is basically consistent with the average values 1.528 Å in $H[7,8\text{-}(OPPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}]$, 1.483(5) Å in $[Ni\{7\text{-}(OPPh_2)\text{-}8\text{-}(PPh_2)\text{-}7,8\text{-}C_2B_9H_{10}\}\{7,8\text{-}(PPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}\}]$, and 1.486(6) Å in $1\text{-}(OPPh_2)\text{-}2\text{-}(PPh_2)\text{-}1,2\text{-}C_2B_{10}H_{10}$.

The structures of complexes **1** and **2** are symmetrical, with the $M^{II}$ (M = Cu, Zn) atom as the symmetry center. Symmetry transformations used to generate equivalent atoms are $-x+1, -y+1, -z$ for **1** and $-x+1, -y+1, -z+2$ for **2**. The bis(phosphoryl) ligand $[7,8\text{-}(OPPh_2)_2\text{-}7,8\text{-}C_2B_9H_{10}]^-$ is coordinated in a bidentate fashion through the O atoms to the $M^{II}$ ion. The $M^{II}$ and four oxygen atoms can form a perfect plane in complexes **1** and **2**, and the O(1), M, O(1)# and O(2), M, O(2)# (# denotes the equivalent atom generated by symmetry) are in an ideal line. The two bis(phosphoryl)carborane moieties are located at two opposite sides of this plane with a *trans* conformation. The average M–O distances are 1.907 and 1.919 Å in complexes **1** and **2**, respectively, which are slightly shorter than the corresponding values of 2.113 Å in $[Cu(dppf)(odppf)]^{+}$[45] and 1.968 Å in $ZnBr_2(OPPh_3)_2$.[46] The O–M–O angles in these two complexes are almost equal to each other with a value of about 90°. As M, C(7), and C(8) are all out of the plane O(1) P(1)P(2)O(2) in the same orientation, a boat conformation between the seven atoms of the chelating ring between the ligand and the metal is formed, in which the O(1)P(1)P(2) O(2) plane can be used as the bottom of the boat.

As shown in Figure 3, the crystal structure of the complex **3** is a little different from the above two complexes. Although the two bis(phosphoryl) ligands are still coordinated in a bidentate fashion to the Ni atom, and a plane is also formed by the four oxygen atoms, the coordination sphere of the Ni atom has been changed by one tetra-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

hydrofuran molecule whose oxygen atom is coordinated to the $Ni^{II}$ atom. The Ni atom is therefore out of the plane by 0.1884 Å, positioned towards the fifth Ni–O bond. Therefore, the coordination sphere of the metal atom should be characterized as a square pyramid, different from the square-planar coordination mode in complexes **1** and **2**. Another difference is the P–O–M angles in the seven-membered ring formed by two P, two O, two $C_{cage}$ atoms and the Ni atom. These two angles in complex **3** are 141.4(2) and 161.7(2)°, respectively, whereas there is no noticeable difference between these two angles in complexes **1** and **2**. In complex **3**, the five Ni–O bond lengths are almost equal to each other within a narrow range 1.992(4)–2.011(3) Å, which is obviously shorter than the average value of 2.112 Å in $[Ni\{CH_2(OPPh_2)_2\}_3(ClO_4)_2]\cdot CH_3OH$.[47]

## Conclusions

In this work, we reported two free compounds with a *closo*- or *nido*-carborane skeleton and three new metal–carborane complexes containing the bis(phosphoryl)-*nido*-carborane ligand, which were obtained by the reactions of the *closo* ligand 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ with some inorganic metal compounds in air. The obtainment of the two free bis(phosphoryl)carborane compounds could give us some information for understanding the oxidation and degradation of the *closo* ligand in air. The results obtained from this paper and our recent work[38] indicated that the oxidation process occurs before the partial degradation, and that the oxidation of the two phosphorus atoms is not synchronous.

## Experimental Section

**Materials and Measurements:** All reactions and subsequent manipulations were carried out in air. 1,2-bis(diphenylphosphanyl)-1,2-dicarba-*closo*-dodecaborane(10) was prepared according to the literature procedure.[48] All chemicals were purchased and used as received. Infrared spectra were recorded in the range 400–4000 $cm^{-1}$ from KBr pellets with a Nicolet-460 FT-IR spectrophotometer. Elemental analysis (C, H) was carried out with a Perkin–Elmer 2400 II elemental analyzer. The $^1H$ and $^{13}C$-NMR were recorded with a Varian Mercury 400 spectrometer in $CDCl_3$ solution, with tetramethylsilane (TMS) as the internal standard, at 400.15 and 100.63 MHz, respectively. The $^{13}C$ spectra are broadband proton decoupled. The chemical shifts are reported in parts per million with respect to the references and are stated relative to external TMS for $^1H$ and $^{13}C$ NMR spectroscopy.

### Synthetic Procedures

**Synthesis of [Cu{7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$}$_2$] (1):** To a suspension of 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (51.2 mg, 0.10 mmol) in ethanol (10 mL, 95%) was added $CuCl_2\cdot 2H_2O$ (17.1 mg, 0.10 mmol). The mixture was stirred for about 6 h in air at room temperature. The blue solid formed was filtered off and dried in vacuo (20.9 mg, 36.96%). M.p. 215–216 °C. A suitable crystal for X-ray diffraction was grown from a dichloromethane/*n*-hexane solution. FT-IR: $\tilde{\nu}_{KBr}$ = 3090 (m), 2550 (m), 1670 (s), 1400 (m), 1255 (s), 1100 (m), 756 (m), 660 (s), 530 (m) $cm^{-1}$. $^1H$ NMR (400.15 MHz, $CDCl_3$): $\delta$ = 7.128–7.400 (40 H, Aryl-H); –2.312 (2 H, B–H–B) ppm. $^{13}C$ NMR (100.63 MHz, $CDCl_3$): $\delta$ = 25.212–135.856 (48 C, Aryl-C), 77.101 (4 C, $C_{cage}$) ppm. $C_{52}H_{60}B_{18}CuO_4P_4$ (1131.00): calcd. C 55.22, H 5.35; found C 55.30, H 5.38.

**Synthesis of [Zn{7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$}$_2$] (2):** $ZnCl_2$ (13.6 mg, 0.10 mmol) and 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (51.2 mg, 0.10 mmol) were mixed in ethanol (10 mL, 95%). The stirring process was continued for about 6 h in air at room temperature. The white solid was filtered off and dried in vacuo (19.7 mg, 34.78%). M.p. > 300 °C (dec.). A suitable crystal for X-ray diffraction was obtained from a dichloromethane solution after partial evaporation of the solvent. FT-IR: $\tilde{\nu}_{KBr}$ = 3100 (m), 2557 (m), 1625 (s), 1454 (m), 1263 (s), 1120 (m), 735 (m), 690 (s), 510 (m) $cm^{-1}$. $^1H$ NMR (400.15 MHz, $CDCl_3$): $\delta$ = 7.284–7.563 (40 H, Aryl-H), –2.301 (2 H, B–H–B) ppm. $^{13}C$ NMR (100.63 MHz, $CDCl_3$): $\delta$ = 23.421–136.000 (48 C, Aryl-C), 76.863 (4 C, $C_{cage}$) ppm. $C_{52}H_{60}B_{18}O_4P_4Zn$ (1132.83): calcd. C 55.13, H 5.34; found C 55.10, H 5.30.

**Synthesis of [Ni{7-$(OPPh_2)$-8-$(PPh_2)$-7,8-$C_2B_9H_{10}$}{7,8-$(PPh_2)_2$-7,8-$C_2B_9H_{10}$}]:** $NiCl_2\cdot 6H_2O$ (23.8 mg, 0.10 mmol) and 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (51.2 mg, 0.10 mmol) were mixed in ethanol (10 mL, 95%). The stirring process was continued for about 6 h at room temperature in air, and then the yellow solid was filtered off, washed with ethanol, and dried in vacuo (27.5 mg, 51.01%). M.p. 207–208 °C. A single crystal for X-ray diffraction was grown from a dichloromethane/*n*-hexane solution. FT-IR: $\tilde{\nu}_{KBr}$ = 3000 (m), 2545 (m), 1475 (m), 1250 (s), 730 (m) $cm^{-1}$. $^1H$ NMR (400.15 MHz, $CDCl_3$): $\delta$ = 7.20–7.58 (40 H, Aryl-H); –2.24 (2 H, B–H–B) ppm. $^{13}C$ NMR (100.63 MHz, $CDCl_3$): $\delta$ = 125.913–134.942 (48 C, Aryl-C); 76.198 (4 C, $C_{cage}$) ppm. $C_{52}H_{60}B_{18}NiOP_4$ (1078.17): calcd. C 57.92, H 5.61; found C 57.85, H 5.55.

**Synthesis of [Ni(thf){7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$}$_2$]·thf (3):** $NiCl_2\cdot 6H_2O$ (23.8 mg, 0.10 mmol) was added to a suspension of 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (51.2 mg, 0.10 mmol) in ethanol (10 mL, 95%). After the mixture was stirred for 12 h in air at room temperature, the yellow solid was filtered off, washed with ethanol, and dried in vacuo (18.4 mg, 32.68%). M.p. 198–199 °C. A single crystal suitable for X-ray analysis was obtained from a tetrahydrofuran solution after partial evaporation of the solvent. FT-IR: $\tilde{\nu}_{KBr}$ = 3120 m, 2540 (m), 1689 (s), 1425 (m), 1260 (s), 1078 (m), 725 (m), 680 (s), 490 (m) $cm^{-1}$. $^1H$ NMR (400.15 MHz, $CDCl_3$): $\delta$ = 7.187–7.594 (40 H, Aryl-H), –2.222 (2 H, B–H–B) ppm. $^{13}C$ NMR (100.63 MHz, $CDCl_3$): $\delta$ = 26.334–139.114 (48 C, Aryl-C), 77.007 (4 C, $C_{cage}$) ppm. $C_{60}H_{76}B_{18}NiO_6P_4$ (1270.38): calcd. C 56.72, H 6.03; found C 56.67, H 5.98.

**Synthesis of [1-$(OPPh_2)$-2-$(PPh_2)$-1,2-$C_2B_{10}H_{10}$] (4):** 1,2-$(PPh_2)_2$-1,2-$C_2B_{10}H_{10}$ (51.2 mg, 0.10 mmol) was added to ethanol (10 mL, 95%). The suspension was stirred for 8 h; air was continuously and slowly bubbled into the mixture at room temperature. The white solid was filtered off and dried in vacuo (36.5 mg, 69.06%). M.p. 232–233 °C. A single crystal suitable for X-ray analysis was obtained from a dichloromethane/*n*-hexane solution. FT-IR: $\tilde{\nu}_{KBr}$ = 3045 (m), 2510 (m), 1669 (s), 1415 (m), 1250 (s), 1083 (m), 707 (m), 672 (s), 510 (m) $cm^{-1}$. $^1H$ NMR (400.15 MHz, $CDCl_3$): $\delta$ = 7.057–7.784 (20 H, Aryl-H) ppm. $^{13}C$ NMR (100.63 MHz, $CDCl_3$): $\delta$ = 25.886–137.553 (24 C, Aryl-C), 76.825 (2 C, $C_{cage}$) ppm. $C_{26}H_{30}B_{10}OP_2$ (528.54): calcd. C 59.08, H 5.72; found C 59.11, H 5.80.

**Synthesis of H[7,8-$(OPPh_2)_2$-7,8-$C_2B_9H_{10}$]·0.25$C_2H_5OH$ (5):** In a manner similar to the procedure for the preparation of compound **4**, the mixture was stirred for 18 h. The white solid was filtered off and dried in vacuo (46.4 mg, 84.94%). M.p. 208–209 °C. A suitable crystal for X-ray diffraction was grown from a dichloromethane solution layered with *n*-hexane. FT-IR: $\tilde{\nu}_{KBr}$ = 3050 (m), 2520 (m),

### X-ray Structure Determination

The collections of the crystallographic data for the three carborane complexes and two carborane compounds were carried out with a Bruker Smart-1000 CCD diffractometer, by using graphite-monochromatized Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) at 298(2) K. The structures were solved by direct methods and expanded by using Fourier difference techniques with the SHELXTL-97 program package.[49] The solvent content in compound **5** is disordered. Partially occupied atoms of the solvent molecule were refined with isotropic displacement parameters, but the rest of the non-hydrogen atoms were refined anisotropically by full-matrix least-squares calculations on $F^2$. All the H atoms were located in a difference Fourier map and thereafter refined isotropically, except the H atoms of the solvent $C_2H_5OH$ of compound **5**. The bridging H atoms of the *nido* carborane skeleton were refined isotropically with fixed *U*. Details of the crystal parameters, data collection, and refinement are summarized in Table 2.

CCDC-602225 (for **1**), -602226 (for **2**), -602227 (for **3**), -607283 (for **4**), and -609307 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Oriented Crystallisation on Supports and Anisotropic Mass Transport of the Metal-Organic Framework Manganese Formate

Mirko Arnold,*[a] Pavel Kortunov,[b] Deborah J. Jones,[c] Yannig Nedellec,[c] Jörg Kärger,[b] and Jürgen Caro[a]

**Keywords:** Organic–inorganic hybrid composites / Membranes / Anisotropic mass transport / Oriented crystallisation / Manganese

The oriented in situ crystallisation of microporous manganese(II) formate [$Mn(HCO_2)_2$] on different porous supports (e.g. porous alumina and graphite) has been investigated. The anisotropic growth of $Mn(HCO_2)_2$ was examined by X-ray diffraction (XRD) and scanning electron microscopy (SEM). The intracrystalline diffusion of methanol in $Mn(HCO_2)_2$ was studied by observation of the sorption kinetics by interference microscopy (IFM). It was found that untreated discs of porous alumina and graphite supports exhibit poor densities of $Mn(HCO_2)_2$ crystals per supported area. Even lower crystal densities are found for activated supports such as for alumina after basic treatment and for oxidized graphite supports. Improved results have been achieved by replacing formic acid by sodium formate in the synthesis route. Crystal growth on graphite gives results superior to those on alumina with respect to the crystal density as well as the relative orientation of the 1D channel network to the support surface. Methanol uptake from the vapour phase is similar at 25 and 40 °C and gives an adsorption capacity of about 95 $mL\,g^{-1}$. The BET surface area was found to be 280 $m^2\,g^{-1}$. IFM indicates that diffusion occurs only along one crystallographic axis, thus proving the presence of a 1D channel system. Diffusion coefficients of about $10^{-12}$ $m^2\,s^{-1}$ for methanol in microporous $Mn(HCO_2)_2$ were found. These results can be used to prepare supported metal–organic framework (MOF) membranes for molecular sieving.

## Introduction

Commonly used porous materials for gas-separating membranes are zeolites and metal oxides such as $Al_2O_3$, $TiO_2$ and $SiO_2$. These materials offer high thermal stability and permanent porosity. Furthermore, zeolites present well-defined channels and cavities, which allow them to be used as molecular sieving membranes.[1]

Despite these outstanding properties, the demand for novel microporous materials remains high because the rational design of zeolites and other inorganic materials with pore diameters less than about 0.4 nm is still difficult and the separation of small molecules (e.g. $H_2$, $N_2$, $O_2$, $CH_4$) by molecular sieving membranes has not yet been achieved successfully. Metal–organic frameworks (MOFs), which are a new class of porous materials, are novel candidates for molecular sieving membranes. MOFs represent an interface between organic and inorganic compounds since they consist of metal ions linked by organic molecules (ligands). MOFs comprise ionic organic–inorganic hybrid materials,[2] such as the manganese formate[3,4] studied in this paper, as well as coordination polymers based on di- to tetravalent carboxylic acids.[5–8] This novel approach for preparing porous materials exhibits a rational and even more flexible design of the network compared to the already known inorganic materials. In addition to these advanced properties, access to the entire pore volume, as well as variable nanoscale pore sizes, indicates that MOFs are clearly an attractive new class of porous materials.

As might be expected, the first reports of MOFs in prospective industrial processes have already been published.[9] Possible applications for MOFs are catalysis,[10] gas purification and gas storage, which needs information on the molecular transport in MOFs.[11] The employment of MOFs as heterogeneous catalysts might be a promising field in view of their great structural and compositional variety and possible accessibility of the metal ion sites in the structure.[9] Recently, Chen reported the application of MOFs in GC columns in order to segregate alkane isomer mixtures with good separation capabilities.[12] In spite of the considerable attention given to these promising materials, only a handful MOFs with permanent porosity have been reported so far, in part because framework stability after template removal in these materials has emerged as a serious problem. Studies on functional aspects, especially the application in mem-

branes, accumulate rather slowly, and thus only one example using MOFs in a gas-separating membrane is known. In a unique approach, Won et al.[13] embedded a $Cu^{II}$ complex in a polymer matrix to yield membranes with high $H_2$ selectivities and remarkable permeabilities. In the work presented here, the novel porous manganese formate, first reported by Dybtsev et al. and at around the same time by Wang et al.,[3,4] was chosen due to its high thermal stability, selective, high $H_2$ adsorption rates and facile preparation route. Synthesis follows a solvothermal route using formic acid, manganese(II) chloride and 1,4-dioxane as the structure-directing agent. After removal of 1,4-dioxane, the framework becomes a porous structure with a 1D channel system, where each $Mn^{II}$ cation is coordinated by six formate ligands to give a network of corner- and edge-shared $MnO_6$ octahedra, as shown in Figure 1. The porous network exhibits thermal stability up to 300 °C, as indicated by XRD and TG/DTA studies (see Supporting Information). In order to use microporous materials (e.g. zeolites, porous $SiO_2$) as gas-separating materials in membrane technology they need to be grown on porous substrates. Commonly, zeolite crystals are grown on substrates like porous alumina and titania, which offer high thermal and mechanical stability, in order to obtain composite membranes and thus to be able to use them as gas-separating membranes. Due to the similarity between zeolites and MOFs, in this work the oriented growth of microporous manganese formate on different substrates is investigated.

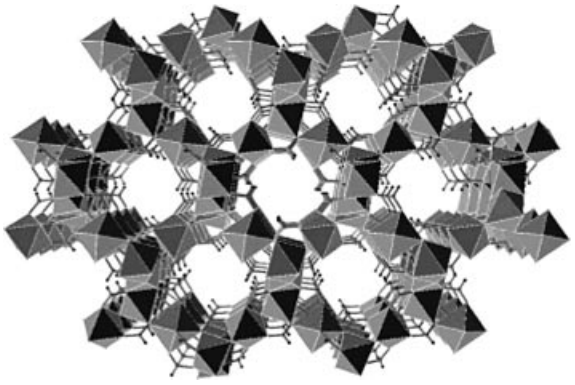

Figure 1. Schematic drawing of the guest-free framework along the *b* axis. Corner- and edge-shared $MnO_6$ octahedra as well as the formate ligands are shown, according to Dybtsev et al.[3]

## Results and Discussion

Significant uptake of methanol from the vapour phase was observed, the total amount adsorbed being similar at 25 and 40 °C. The sorption isotherms obtained in gravimetric experiments have a shape characteristic of a microporous solid, as shown in Figure 2.

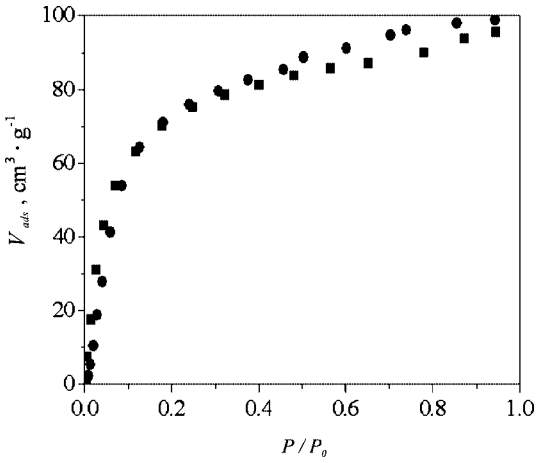

Figure 2. Adsorption isotherms of methanol in $Mn(HCO_2)_2$ at 25 °C (■) and 40 °C (●). $V_{ads}$ represents the STP volume of the adsorbed amount of methanol.

Volumetric experiments were also performed (not shown), and a small hysteresis was observed between adsorption and desorption branches. The BET surface area was calculated to be 278 $m^2 g^{-1}$, which is in excellent agreement with that obtained from previously reported $H_2$ (240 $m^2 g^{-1}$) or $CO_2$ (297 $m^2 g^{-1}$) sorption isotherms.[3]

IFM studies were performed to gain more information about the diffusion kinetics as well as to demonstrate the presence of a 1D channel system. Figures 3b and c show the time-dependent intracrystalline concentration profiles of methanol (0–10 mbar) in an $Mn(HCO_2)_2$ single crystal (Figure 3a). Uptake was found only along the *y* axis, with no significant transport along the *z* and *x* axes. This result confirms the existence of a 1D channel system along the crystallographic *b* axis in Figure 1. Furthermore, no evidence for an intergrowth structure was observed, and methanol was found to be distributed homogeneously throughout the whole crystal. The molecular diffusivity evaluated in the middle part of the chosen crystal from Fick's Second Law does not depend on the methanol concentration, and its average value ($9.15 \times 10^{-13}$ $m^2 s^{-1}$) is in good agreement with data obtained from the uptake rate ($1.05 \times 10^{-12}$ $m^2 s^{-1}$) using the $t^{1/2}$ approach. However, the sorption uptake concentration profiles cannot be described exclusively by intracrystalline diffusion. The sorption uptake is determined to a minor extent by surface permeability, which, most remarkably, is found to depend on the methanol concentration. Values for the surface permeability of $2 \times 10^{-1}$ $m s^{-1}$ for 0.2 of the final loading and $3 \times 10^{-1}$ $m s^{-1}$ for 0.9 of the final methanol loading (95 mL $g^{-1}$) are estimated.

Initial attempts to prepare a composite membrane of $Mn(HCO_2)_2$ grown on alumina and graphite were carried out without any treatment of the support surfaces. The growth of $Mn(HCO_2)_2$ crystals on alumina discs resulted in only poor densities (10 crystals/mm$^2$). In situ crystallisation on graphite shows, in general, a more distinct growth of $Mn(HCO_2)_2$ crystals on support surfaces (80 crystals/mm$^2$).

Arrows indicate the 1D channel system along the *b* axis. 2D intracrystalline concentration profiles for methanol sorption by an $Mn(HCO_2)_2$ single crystal in the same orientation as shown in (a), obtained by IFM at room temperature (b), and the corresponding 1D intracrystalline concentration profiles (c).

To increase the crystal density, different methods for support activation were evaluated.

In order to increase the crystal growth on alumina, the supports were treated with sodium hydroxide. Alumina surfaces treated with sodium hydroxide are even less suitable for $Mn(HCO_2)_2$ crystal growth as virtually no crystals were observed after in situ crystallisation on those supports

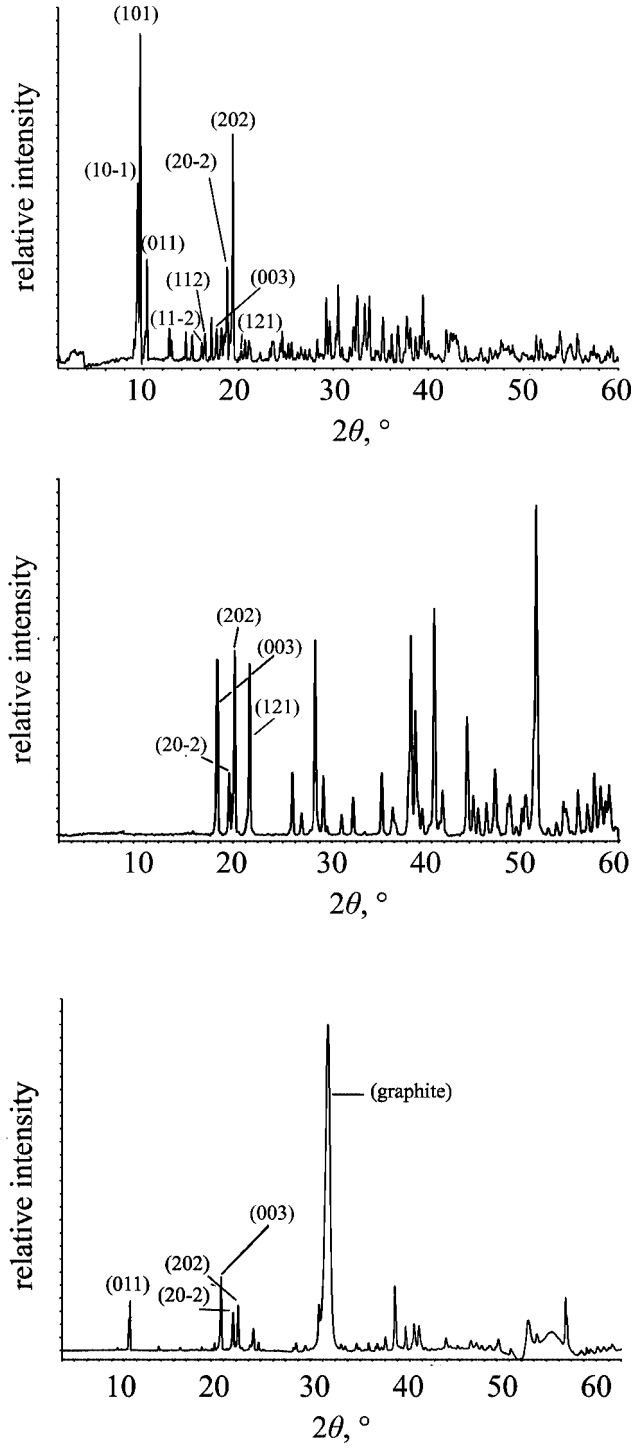

Figure 4. Powder XRD pattern of as-synthesised $Mn(HCO_2)_2$ (a), $Mn(HCO_2)_2$ grown on alumina support discs showing the peaks for the (202), (20$\bar{2}$) and (003) planes are dominant (b) and $Mn(HCO_2)_2$ grown on graphite supports by the "formate" route showing an additional dominant peak for the (011) plane (c).

(1 crystal/mm$^2$). The commonly used seeding method resulted in an increase in the crystal density to 150 crystals/mm$^2$. It must be stressed, however, that despite an improved density of $Mn(HCO_2)_2$ crystals on the surface, the orientation of the 1D channel system was undesirable. This was concluded by comparing the XRD pattern of $Mn(HCO_2)_2$ grown on the alumina support (see Figures 4a and b). This indicates that the 1D channel system lies parallel to the support surface. With this orientation, no mass transfer would occur through membranes prepared with this method. Oxidised graphite supports show a trend similar to the alumina supports treated with sodium hydroxide, since crystal growth on these supports exhibits a lower crystal density than the untreated ones (40 crystals/mm$^2$).

The crystal density achieved by this method underlines the influence of electrostatic interactions during the growth of $Mn(HCO_2)_2$ on these supports. As activated supports – treatment with sodium hydroxide in the case of alumina and oxidation in the case of graphite – lead to poor crystal densities, a different synthesis method using sodium formate rather than formic acid was developed. This is based on the assumption that positively charged surfaces could inhibit the formation of crystals on the surface because of electrostatic repulsion. $Mn(HCO_2)_2$ crystals grown on oxidized carbon supports by the formate route are characterised by advanced crystal densities (see Figure 5a) as well as a reasonable tilt angle of 34° of the 1D channel system to the support surface (see Figures 4a and c). Additionally, it was found that $Mn(HCO_2)_2$ crystals were grown into the porous graphite to a certain extent, which suggests a proper connection to the support (see Figure 5b).

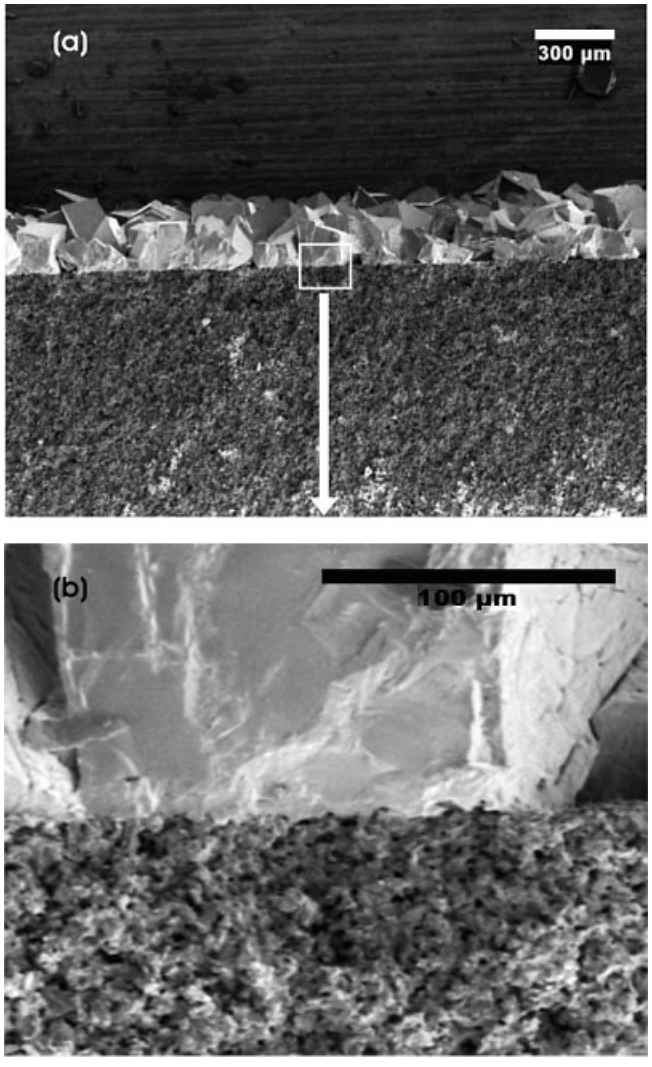

Figure 5. Profile of $Mn(HCO_2)_2$ crystals grown on a graphite support disc after two in situ crystallisations by the "formate" route (a). The magnified image shows intergrowth between the carbon support and $Mn(CO_2)_2$ (b).

## Conclusions

It has been shown that the synthesis of supported MOF composite membranes based on manganese(II) formate [$Mn(HCO_2)_2$] is possible in principle. The amount of crystals grown on the supports and the orientation of the 1D channel system on the surface depends strongly on the selected support as well as on the synthesis route. While membrane-quality coatings have still not been achieved, this study has identified factors that are important for the production of continuous layered $Mn(HCO_2)_2$ membranes. Future work should focus on a detailed examination of the surface charges during synthesis, and the obtained results can be applied in a direct modification of in situ synthesis and/or surface treatment in order to increase the amount of crystals on the supports. Additionally, in situ crystallisation of other promising MOFs for new composite molecular sieving membranes seems to be reasonable. For instance, Pan et al. have published the synthesis of a porous, lanthanum-containing MOF with stability up to 450 °C and high and selective $H_2$ adsorption rates.[14]

## Experimental Section

Porous $Mn(HCO_2)_2$ was synthesised according to Dybtsev et al.[3] in a steel autoclave with Teflon-lined insert ("formic acid" route). $MnCl_2 \cdot 2H_2O$ (2.5 g, 12.5 mmol) and $HCO_2H$ (0.94 mL, 25 mmol) were dissolved in 1,4-dioxane (25 mL) and 50 mL of *N*,*N*-diethylformamide (50 mL). The solution was then autoclaved at 115 °C for 48 h. The obtained crystals were filtered and washed with acetone. In order to remove the 1,4-dioxane template molecules, the crystals were heated to 150 °C for 24 h under reduced pressure. All employed chemicals were used as delivered without any purification.

In order to maintain the advantage of the high thermal stability of $Mn(HCO_2)_2$, the in situ crystallisation was performed on supporting discs of porous $\alpha$-$Al_2O_3$ (Inocermic GmbH, Germany) and porous graphite (Poco Graphite Inc., USA) with a diameter of 18 mm and a thickness of 1 mm to form composite membranes in the same manner as zeolite membranes. Before in situ crystallisation, supports were cleaned with deionised water and acetone to remove impurities from the surface. Finally, they were dried at 80 °C for 1 h.

To improve the crystal growth on the support, they were treated differently before in situ crystallisation: $\alpha$-$Al_2O_3$ supports were au-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

toclaved at 150 °C for 4 h with a solution of 50% NaOH to increase the concentration of free OH groups, which are possible connecting nodes for $Mn(HCO_2)_2$. Another approach for increasing the crystal growth on alumina supports consists of placing seed crystals on the surface. For this purpose, ground $Mn(HCO_2)_2$ was simply rubbed onto the alumina surface.

The activity of graphite supports was increased by heating in air at 300 °C for 12 h to increase the concentration of several different functional groups, especially carbonyl, carboxyl and hydroxy groups, on the carbon surface.[15] Since a positively charged surface might reduce the crystal growth, an alternative synthesis method that replaces formic acid with sodium formate was also developed ("formate route").

The adsorption–desorption isotherms of methanol in microporous $Mn(HCO_2)_2$ were measured by monitoring the mass uptake of the sample, recorded with a Sartorius S3D-V microbalance, following successive injections of known amounts of methanol in the vapour phase. To monitor the equilibrium pressure and to calculate the amount of injected vapour, two pressure gauges (Edwards) were used, with ranges from $10^{-5}$ to 1 Torr and from 10 to 1000 Torr. Secondary vacuum was achieved with a Varian Turbomolecular drag pump coupled to a dry primary pump. Prior to each experiment, the sample was introduced into a specially designed glass cell and weighed. The cell was then fixed to the suspending rod of the microbalance, and equilibrated with a reference cell. After a short time to allow the balance to stabilize, the sample was heated in situ at 150 °C, and out-gassed under vacuum for 24 h.

To confirm the structure of $Mn(HCO_2)_2$ crystals and to determine the orientation of the crystals on supports, X-ray diffraction data were obtained with a Philips X′PERT diffractometer and evaluated using the software WinXPOW. Reflections were collected in the range from $2\theta = 5$ to 90° (step width: 0.01°; time per step: 10 s) at a voltage of 40 kV and a current of 40 mA. In order to confirm the structure of the obtained $Mn(HCO_2)_2$ crystals, powder XRD data were collected from ground samples. The obtained data were used to determine the preferred orientation of crystal growth on the applied supports. The dominant planes in the XRD pattern obtained from $Mn(HCO_2)_2$ on the employed supports were taken to be perpendicular to the surface. The tilt angle between the 1D channel system and the support surface could then be determined by calculating the angle between the 1D channel system and the vertical to the support plane of $Mn(HCO_2)_2$.

Both the crystal morphologies and the quantitative growth of $Mn(HCO_2)_2$ on different supports were evaluated with a field-emission scanning electron microscope (JEOL JSM 6700F). In view of the metal–organic nature of the $Mn(HCO_2)_2$ only low accelerating voltages (1 kV) were applied in order to avoid decomposition of the structure and charging of the sample surface.

Interference microscopy (IFM) measurements allow in situ observation of the sorption uptake of gaseous species in porous media with a spatial resolution of 0.5 μm.[16,17] Methanol sorption was studied with a pressure step from 0 to 10 mbar at room temperature. For these measurements, the calcined MOF sample was introduced into an optical cell and prior activated under reduced pressure at 150 °C for 24 h. The IFM setup consists of a vacuum system, a Carl Zeiss Jenapol interference microscope and a Mach-Zehnder type interferometer. Interference patterns were recorded with a CCD camera (XC-77CE, Sony).

**Supporting Information** (see footnote on the first page of this article): Figure S1 shows the TG/DTA analysis of as-synthesised $Mn(HCO_2)_2$ still containing 1,4-dioxane template molecules. The first weight loss (140–280 °C, 16.5%) is clearly related to the selective removal of the template molecules. The XRD patterns before (a) and after template removal (b) (Figure S2) show that even after template removal the framework remains stable.

# Competing Radical and Non-Radical Pathways for the Decomposition of $LFe^{II}(H_2O_2)$ Complexes: a Density Functional Study

**Anna E. Anastasi,[a] Achim Lienke,[b] Peter Comba,[c] Heidi Rohwer,[c] and John E. McGrady*[d]**

**Keywords:** Density functional calculations / Oxido ligands / O–O activation / Electronic structure / Transition states

Density functional theory has been used to explore the mechanism of hydrogen peroxide decomposition when coordinated to a bispidone iron(II) complex. Two quite distinct pathways are identified, one involving O–O bond homolysis followed by a "rebound" hydrogen atom abstraction, the other involving proton transfer followed by O–O bond heterolysis. A water molecule in the second coordination sphere plays a key role in both pathways.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Mononuclear non-heme iron enzymes are involved in many different types of biological oxidation reactions, including hydroxylation and hydroperoxidation of C–H bonds, cleavage of aromatic rings and oxidative ring closure.[1–3] As a result, there has been a great deal of interest in synthesising model complexes that mimic aspects of the structure and reactivity of these enzymes. The chemistry of model complexes with multidentate nitrogen-donor ligands such as N4Py,[4] trispicene[5] and the pentadentate $N_2Py_3$ bispidones,[6] $L^1$ and $L^2$ (Scheme 1) is particularly well developed. The $Fe^{II}$ complexes are known to be potent bleaching catalysts,[7] reacting with excess $H_2O_2$ to form hydroperoxide species, $LFe^{III}(OOH)$,[4–6,8] which then generate $LFe^{IV}(O)$ by homolytic cleavage of the O–O bond.[9] Whilst the mechanism of decomposition of the $LFe^{III}(OOH)$ species has been extensively explored by both experiment and theory, the initial formation of the $Fe^{III}$ species has received comparatively little attention. There are, however, obvious parallels with classic Fenton chemistry, where $H_2O_2$ is used to oxidise aqueous solutions of $Fe^{II}$, eventually yielding $Fe^{III}$ if no substrate is present.[10] Although the Fenton reagent has been used extensively in organic chemistry for over a century, the precise identity of the active intermediate remains a topic of debate.[11] The Haber–Weiss mechanism,[12,13] first proposed in 1934, identifies OH radicals as the active oxidant, a suggestion that has been substantiated by radical trapping experiments and also kinetic comparisons with radiolytically generated radicals. Alternatively, the reactive species may be a high-valent iron complex such as $Fe^{IV}(O)$ as first suggested by Bray and Gorin in 1932.[14] The participation of high-valent oxido–iron species has been supported by a detailed kinetic analysis by Kremer,[15] which suggested that the $Fe^{III}$ products were formed by comproportionation of an intermediate $Fe^{IV}(O)$ species with excess $Fe^{II}$.

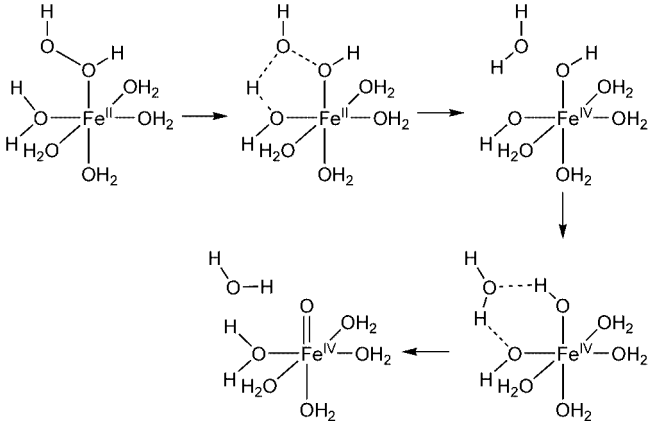
Buda et al. have recently used density functional theory to explore the energetics of the reaction between aqueous $Fe^{II}$ and $H_2O_2$.[16,17] The first step in their proposed reaction pathway (Scheme 2) involves a ligand-substitution reaction where $H_2O_2$ replaces a molecule of water in the first coordination sphere of $[Fe(H_2O)_6]^{2+}$, giving $[(H_2O)_5Fe^{II}(H_2O_2)]^{2+}$. Meyerstein and co-workers have argued that coordination of the $H_2O_2$ is a necessary precursor to bond cleavage, as the alternative, outer-sphere electron transfer, is energetically unfavourable.[11d,18] Homolytic cleavage of the O–O bond then leads directly to an $Fe^{IV}$ species, $[(H_2O)_4Fe^{IV}(OH)_2]^{2+}$, which subsequently rearranges by proton-transfer to the product, $[Fe^{IV}(H_2O)_5(O)]^{2+}$. A critical feature of the pathway is that as the O–O bond elongates, the developing OH radical abstracts a hydrogen atom from a neighbouring water ligand, and so is effectively trapped in the first coordination sphere. Thus, although the O–O bond cleavage is homolytic, no free radicals are released into solution. The putative $Fe^{IV}(O)$ intermediate in Scheme 2, $[(H_2O)_5Fe^{IV}(O)]^{2+}$, has recently been obtained by oxidation of aqueous $Fe^{II}$ with ozone, and characterised using a combination of Mössbauer and X-ray absorption spectroscopy.[19] Consistent with Kremer's scheme, this species does indeed comproportionate with excess $[Fe^{II}(H_2O)_6]^{2+}$ to form an $Fe^{III}$ dimer $[(H_2O)_4Fe^{III}(OH)_2Fe^{III}(H_2O)_4]^{4+}$. The latter is *not*, however, observed when $H_2O_2$ is used in place of $O_3$, suggesting that $[(H_2O)_5Fe^{IV}(O)]^{2+}$ is not the active Fenton intermediate, at least in aqueous solution.



Scheme 2. Mechanism for the decomposition of $[Fe^{II}(H_2O)_5(H_2O_2)]^{2+}$ proposed by Buda et al.[16]

The presence of chelating nitrogen-donor ligands such as the bispidones, $L^1$ and $L^2$, will clearly alter the electron density at the metal centre relative to the aqua complex. Perhaps more significantly, the pentadentate nature of the ligand means that the coordination of additional water molecules is blocked in the putative intermediates, $[LFe^{II}(H_2O_2)]^{2+}$, and the all-important trapping of the developing OH radical in the first coordination sphere (Scheme 2) is therefore not possible. Nevertheless, Que and co-workers have shown that, in the case of $[(N4Py)Fe^{II}(CH_3CN)]^{2+}$, the addition of precisely 0.5 equiv. of $H_2O_2$ still gives quantitative oxidation to $Fe^{III}$ {present as a mixture of $[(N4Py)Fe^{III}(OH)]^{2+}$ and the oxido-bridged dimer, $[(N4Py)Fe^{III}(O)Fe^{III}(N4Py)]^{4+}$} with no evidence of ligand oxidation.[4] Girerd and co-workers have observed similar behaviour in the reaction of $Fe^{II}$ complexes of the trispicene ligand with $H_2O_2$, where the intermediate was tentatively assigned as $[LFe^{III}Cl]^{2+}$.[5c] From a mechanistic perspective, the clean oxidation of $Fe^{II}$ to $Fe^{III}$ with 0.5 equiv. of $H_2O_2$ seems inconsistent with the generation of free OH radicals, which would cause ligand degradation and therefore reduce the yield of $Fe^{III}$. The direct formation of transient $Fe^{IV}(O)$, followed by comproportionation with excess $Fe^{II}$, as proposed by Kremer, seems more consistent with this observation. Very recently, Comba and co-workers have studied the formation of $[L^2Fe^{IV}(O)]^{2+}$ from a mixture of the bispidone complex $[L^2Fe^{II}(BF_4)_2]$ and $H_2O_2$.[6c] The presence of clear isosbestic points in the UV/Vis spectrum, along with second-order kinetics and a large negative entropy of activation support a mechanism where binding of $H_2O_2$ to the $Fe^{II}$ centre is followed by direct conversion to $Fe^{IV}(O)$ by O–O bond heterolysis. This pathway is quite different from the O–O bond *homolysis* proposed for the aqua complex,[16] and poses a number of intriguing questions regarding the precise role of the pentadentate ligand in the reaction.

In this paper, we use density functional theory to explore possible pathways that can lead to a high-valent $[LFe^{IV}(O)]^{2+}$ species from $[LFe^{II}(H_2O_2)]^{2+}$, where L is a member of the bispidone family. Specifically, we focus on the bispidone ligand $L^1$ shown in Scheme 1 above – a comparison of the properties of complexes of $L^1$ and $L^2$ will form the basis of a subsequent communication. In all cases, the ester groups on the ligand backbone have been replaced by hydrogen atoms to simplify the computational model. We identify two distinct mechanisms for decomposition of the hydrogen peroxide. The first is qualitatively similar to the homolytic fission pathway proposed for the aqua complex,[16] except in this case the developing OH radical is trapped in the vicinity of the metal centre only by non-covalent interactions. The second pathway, in contrast, involves proton transfer, mediated by a water molecule in the second coordination sphere, followed by heterolysis of the O–O bond, and so is very similar to the mechanism proposed in ref.[6b] The barriers to the two processes prove to be comparable, suggesting that subtle changes in ligand structure and/or reaction conditions could shift the balance from one to the other.

## Results and Discussion

In the initial section, we present a detailed description of the electronic structure of the aqua complex, $[L^1Fe^{II}(H_2O)]^{2+}$, which we take as the starting point for these calculations, along with the various metal-based species that may play a role in the decomposition of $H_2O_2$: viz. the hydrogen peroxide adduct, $[L^1Fe^{II}(H_2O_2)]^{2+}$, the $Fe^{III}$ intermediate, $[L^1Fe^{III}(OH)]^{2+}$ and the product $[L^1Fe^{IV}(O)]^{2+}$. We subsequently consider mechanisms for their interconversion, paying particular attention to the possible role of solvent.

### Electronic Structure of $[L^1Fe^{II}(H_2O)]^{2+}$, $[L^1Fe^{II}(H_2O_2)]^{2+}$, $[L^1Fe^{III}(OH)]^{2+}$ and $[L^1Fe^{IV}(O)]^{2+}$

The optimised structures of the most stable spin states of $[L^1Fe^{II}(H_2O)]^{2+}$, $[L^1Fe^{II}(H_2O_2)]^{2+}$, $[L^1Fe^{III}(OH)]^{2+}$ and $[L^1Fe^{IV}(O)]^{2+}$ are shown in Figure 1, and the structural parameters for all accessible spin states are collected in Table 1. For both the aqua and hydrogen peroxide complexes, the optimised $S = 0$ and $S = 2$ structures show the typical features of low-spin/high-spin $Fe^{II}$ species, with the metal–ligand bonds approximately 0.2 Å longer in the latter. A strong Jahn–Teller distortion is present in the triplet state, resulting in very long bonds to the $H_2O$ and $H_2O_2$ ligands. The O–O bond in the hydrogen peroxide ligand is relatively insensitive to spin state, although the marginal elongation in the singlet can be ascribed to the better back-donating ability of low-spin $Fe^{II}$. The quintet is the most stable spin state in both systems, with relatively large gas-phase separations of ca. 35 kJ mol$^{-1}$ to the singlet and ca. 45 kJ mol$^{-1}$ to the intermediate spin[20] ($S = 1$) state. The inclusion of solvation through the PCM approach stabilises the $S = 0$ and, to a lesser extent, $S = 1$ states relative to the $S = 2$ ground state. The solvation energy in these systems is dominated by electrostatic interactions between the solvent continuum and the +2 charge on the solute, and its magnitude is therefore largely determined by the size of the solute cavity. The preferential stabilisation of states of lower multiplicity is therefore a general observation in these systems, and simply reflects the shorter Fe–N and Fe–O bonds, which lead in turn to a smaller solute cavity, and hence to stronger electrostatic interactions.

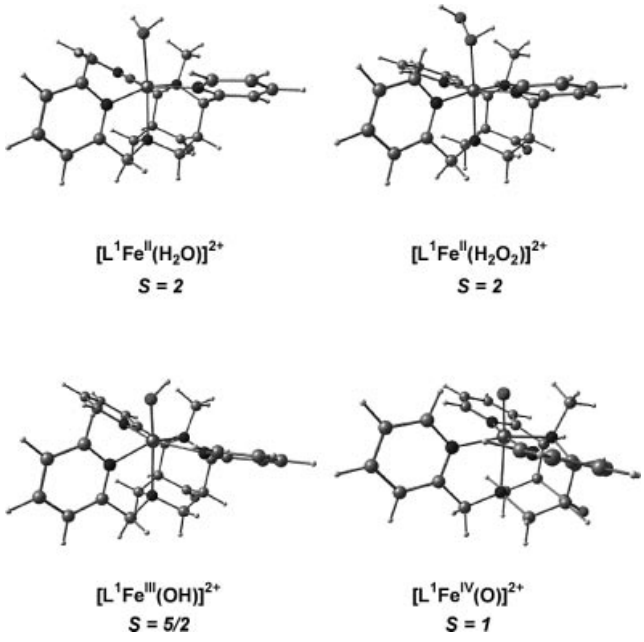

Figure 1. Optimised structures of the ground states of $[L^1Fe^{II}(H_2O)]^{2+}$, $[L^1Fe^{II}(H_2O_2)]^{2+}$, $[L^1Fe^{III}(OH)]^{2+}$ and $[L^1Fe^{IV}(O)]^{2+}$.

For the $Fe^{III}$ intermediate, $[L^1Fe^{III}(OH)]^{2+}$, we have located distinct minima for $S = 1/2$, 3/2 and 5/2 spin states. The structures show the usual trend towards longer bonds in the higher multiplicity states, most obviously in the comparison of the equatorial Fe–N distances in the $S = 1/2$ and S = 5/2 states. In the gas phase, the sextet (shown in Figure 1c) is the most stable, but the doublet is only 8 kJ mol$^{-1}$ higher in energy. We have noted above the tendency of solvation to stabilise lower spin states, and in this case it leads to a reversal of the order, with $S = 1/2$ lying 10 kJ mol$^{-1}$ *below* $S = 5/2$. There has been considerable debate over the ability of density functional theory to accurately model spin-state splittings, and the case of $Fe^{III}$ seems to be particularly problematic.[21] This uncertainty, along with the approximate nature of the PCM solvation model, precludes a definitive conclusion on the multiplicity of the ground state of $[L^1Fe^{III}(OH)]^{2+}$. Neither $[L^1Fe^{III}(OH)]^{2+}$ nor $[L^1Fe^{III}(Cl)]^{2+}$ has been isolated experimentally, although the hydroperoxide complex, $[L^1Fe^{III}(OOH)]^{2+}$, is known to have a doublet ground state.

The $d^4$ configuration of the $[L^1Fe^{IV}(O)]^{2+}$ species leads to $S = 0$, 1 and 2 spin states. Of these, the ground state (Figure 1, d) is clearly the triplet (gas phase and in solution), a situation typical of $d^4$ metal–oxido species, where two of the three $t_{2g}$-based orbitals are strongly destabilised by M–O π*-interactions. The open-shell singlet state ($<S^2> = 1.03$) has almost identical bond lengths and angles, and lies 38 kJ mol$^{-1}$ higher in energy. High-spin states of $Fe^{IV}(O)$ have attracted considerable attention since the identification of such a species in the active site of the enzyme tauD,[3] but in this case the quintet lies 20 kJ mol$^{-1}$ above the ground state, sufficient to rule out its participation in the oxidation pathway.

Table 1. Optimised Fe–N and Fe–O bond lengths [Å] and relative energies [kJ mol$^{-1}$] of the various spin states of $[L^1Fe^{II}(H_2O)]^{2+}$, $[L^1Fe^{II}(H_2O_2)]^{2+}$, $[L^1Fe^{III}(OH)]^{2+}$ and $[L^1Fe^{IV}(O)]^{2+}$. Energies are given relative to the most stable spin state for each species.

### Thermodynamics of the Decomposition of $[L^1Fe^{II}(H_2O_2)]^{2+}$ into $[L^1Fe^{IV}(O)]^{2+}$

The balanced equation for the decomposition of $[L^1Fe^{II}(H_2O_2)]^{2+}$ to $[L^1Fe^{IV}(O)]^{2+}$ via the putative $[L^1Fe^{III}(OH)]^{2+}$ intermediate is:

$$[L^1Fe^{II}(H_2O_2)]^{2+} \rightarrow [L^1Fe^{III}(OH)]^{2+} + OH \rightarrow [L^1Fe^{IV}(O)]^{2+} + H_2O$$

The first step, the homolytic cleavage of the O–O bond, is strongly endothermic [$\Delta E_{(gas\text{-}phase)} = +34\ kJ\,mol^{-1}$], while the second is highly exothermic [$\Delta E_{(gas\text{-}phase)} = -114\ kJ\,mol^{-1}$], and as a result the decomposition of $[(H_2O)_5Fe^{II}(H_2O_2)]^{2+}$ to $[L^2Fe^{IV}(O)]^{2+} + H_2O$ is strongly favoured [$\Delta E_{(gas\text{-}phase)} = -80\ kJ\,mol^{-1}$]. On purely thermodynamic grounds, therefore, the direct generation of $Fe^{III}$, along with the liberation of free OH radicals, seems rather unlikely. The alternative pathway to $Fe^{III}$, by comproportionation of $Fe^{IV}(O)$ with excess $Fe^{II}$ is, in contrast, exothermic [$\Delta E_{(gas\text{-}phase)} = -62\ kJ\,mol^{-1}$], confirming it as the more likely source of $Fe^{III}$ in this case:

$$[L^1Fe^{II}(H_2O)]^{2+} + [L^1Fe^{IV}(O)]^{2+} \rightarrow 2\,[L^1Fe^{III}(OH)]^{2+}$$

### Influence of Solvent

When considering possible pathways that might link the various species discussed in the previous section, we need to pay careful attention to the motion of hydrogen atoms as well as the cleavage of the O–O bond. Indeed, the role of a water ligand as a hydrogen-atom shuttle has been highlighted previously.[16] We have noted above that water is excluded from the first coordination sphere by the pentadentate bispidone ligand, and so for the exploration of reaction pathways we choose the solvated species $[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O$ as our minimal model, where the second coordination sphere water can, at least in principle, play the same role as the water ligand in $[(H_2O)_5Fe^{II}(H_2O_2)]^{2+}$. The balanced equation for the decomposition of the $H_2O_2$ complex is then:

$$[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O \rightarrow [L^1Fe^{III}(OH)]^{2+}\cdot H_2O\cdot OH \rightarrow [L^1Fe^{IV}(O)]^{2+}\cdot 2H_2O$$

Representative structures of the important hydrated species are shown in Figure 2, and the optimised energies and bond lengths are collected in Table 2. The oxygen and hydrogen atoms on the hydrogen peroxide are labelled as proximal (p) and terminal (t), while those on the water molecule are labelled "w" (see Figure 2, inset, for a schematic diagram of the hydrogen-bonded network). In the hydrogen peroxide complexes ($S = 0$, 1 and 2), the water molecule is aligned such that one lone pair interacts with the more acidic proton on the proximal (coordinated) oxygen centre. A comparison of Table 1 and Table 2 confirms that the additional water molecule has only a marginal impact on the metal–ligand bond lengths and the relative stabilities of the different spin states. The only exception is the highly distorted $S = 1$ state, where the increased basicity of the proximal oxygen atom on the $H_2O_2$ ligand results in a significant contraction of the Fe–O and Fe–$N^2$ bonds.

We have identified minima corresponding to the caged radical species $[L^1Fe^{III}(OH)]^{2+}\cdot H_2O\cdot OH$ in four distinct spin states ($S = 0$, 1, 2 and 3). The optimised structure of the most stable gas-phase species ($S = 2$) is shown in Fig-

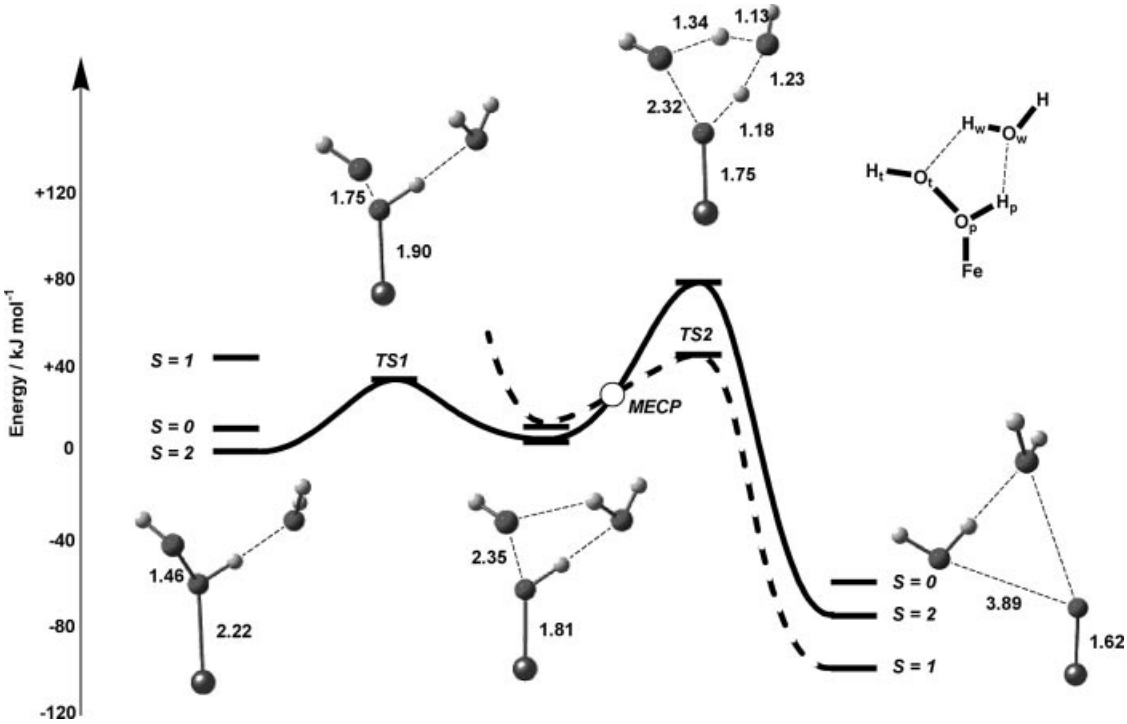

Figure 2. Potential energy surface for the O–O homolysis pathway for decomposition of $[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O$. Energies include the effects of solvation introduced by the PCM model. For clarity, the bispidone ligand is not shown in the structures.

ure 2, and bond lengths for all four spin states are collected in Table 2. The complex spin-state manifold in this region of the potential energy surface arises from parallel (ferromagnetic) or antiparallel (antiferromagnetic) alignment of the spins on the $[L^1Fe^{III}(OH)]^{2+}$ ($S$ = 1/2, 3/2, 5/2) and OH radicals ($S$ = 1/2), giving rise to coupled spin states with total $S$ = 0, 1, 2 and 3. The description of the $S$ = 3 spin state is unambiguous – it can only be achieved through parallel alignment of the spin vectors on $S$ = 5/2 $Fe^{III}$ and $S$ = 1/2 OH, and indeed the structural parameters and net spin densities (4.22 on Fe, 0.94 on $O_t$) confirm this to be the case. Likewise, the $S$ = 0 state arises unambiguously from the antiparallel alignment of $S$ = 1/2 $Fe^{III}$ and $S$ = 1/2 OH (net spin densities 0.95 on Fe, –0.93 on $O_t$). In contrast, the $S$ = 1 and $S$ = 2 states could, in principle, contain intermediate spin ($S$ = 3/2) $Fe^{III}$. However, the rather high energy of this spin state in isolated $[L^1Fe^{III}(OH)]^{2+}$ (Table 1) suggests that this is unlikely, and indeed the Fe–N and Fe–O bond lengths in the $S$ = 1 and $S$ = 2 states are almost identical to those in $S$ = 0 and $S$ = 3, confirming the presence of low- and high-spin $Fe^{III}$, respectively. When the alignment of spins is antiparallel ($S$ = 0, 2), the separation between proximal oxygen atom ($O_p$) and the hydroxyl radical ($O_t$) is somewhat smaller than where the alignment is parallel ($S$ = 1, 3), but the rather small energy differences between $S$ = 0 and 1 (7 kJ mol$^{-1}$) and between $S$ = 2 and 3 (5 kJ mol$^{-1}$) are indicative of only weak coupling.

The most stable spin state ($S$ = 2 in the gas phase) lies only 11 kJ mol$^{-1}$ above the reactants, representing a substantial stabilisation relative to the fully separated reactants, $[L^1Fe^{III}(OH)]^{2+}$ and OH ($\Delta E$ = +34 kJ mol$^{-1}$). The much lower energy required to cleave the O–O bond is due to the residual electrostatic attraction between the OH radical and the +2 cation in the "caged radical" species, $[L^1Fe^{III}(OH)]^{2+}\cdot H_2O\cdot OH$, that is absent in the separated species. As was the case for the isolated $[L^1Fe^{III}(OH)]^{2+}$ molecule, solvation (introduced through the PCM model) has a significant impact on the manifold of spin states, selectively stabilising those containing the smaller low-spin $Fe^{III}$ centre ($S$ = 0, 1) relative to those containing high-spin $Fe^{III}$ ($S$ = 2, 3). As a result, the $S$ = 0 state becomes the most stable at this level of theory, and the caged radical is now almost isoenergetic with the hydrogen peroxide complex. At this point, it is useful to contrast the pathway shown in Figure 2 with that described for $[(H_2O)_5Fe(H_2O_2)]^{2+}$.[16] In this aqua complex, the incipient OH radical is "trapped" by abstracting a hydrogen atom from a neighbouring water molecule, and the strength of the resultant Fe–OH bonds stabilises the intermediate, such that it lies over 80 kJ mol$^{-1}$ below the hydrogen peroxide complex. In the case of $[L^1Fe^{II}(H_2O_2)]^{2+}$, the free OH radical is trapped only by electrostatic interactions with the +2 charge on the metal core, along with hydrogen bonding with the solvent cage, and as a result, the O–O homolysis step is less favourable ($\Delta E$ = 11 kJ mol$^{-1}$, in the gas phase and +1 kJ mol$^{-1}$ at the PCM level of theory). In the context of the reaction chemistry, the weak trapping of the radical means that diffusion to neighbouring organic species may be competitive with a "rebound" reaction with the $Fe^{III}(OH)$ unit. Caged radicals such as these have previously been proposed to play a role in oxidation chemistry.[6b,22]

In the $[L^1Fe^{IV}(O)]^{2+}$ complex, the presence of the two additional water molecules has a negligible impact on either the relative energies of the spin states or on the bond lengths in the first coordination sphere. The interaction energy between the complex and the solvent molecules is again dominated by the electrostatic interaction with the +2 charge on the metal core, and so the presence of the additional water molecule stabilises the products by 19 kJ mol$^{-1}$ relative to the hydrogen peroxide complex.

In terms of the overall energetics of the reaction, the picture is largely unaffected when we consider the "supermolecule" $[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O$ rather than the fully separated species The intermediate and products are stabilised by electrostatic interactions between the dicationic core and the OH or $H_2O$ unit that is generated by cleavage of the O–O bond, but this serves only to increase the already substantial thermodynamic driving force for the cleavage of the O–O bond. It is also important to note that the mixture of explicit and continuum models for solvent described above

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

is problematic, particularly where a solvent molecule is involved in the reaction[23] {in our case one molecule of $H_2O$ is formed in the reaction $[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O \rightarrow [L^1Fe^{IV}(O)]^{2+}\cdot 2H_2O$}. In the context of this work, the non-cancellation of errors that arises through the mixture of continuum and explicit solvent models introduces significant uncertainties in the accuracy of the computed energies of the different asymptotes. In the remainder of this paper, we therefore focus on the qualitative mechanistic picture, and do not place undue emphasis on the absolute values of the computed energies.

In the following sections we describe two distinct pathways that lead to the formation of an $Fe^{IV}(O)$ species – the first where O–O bond homolysis is followed by hydrogen-atom abstraction, the second where proton transfer induces O–O bond heterolysis. In both cases, we pay particular attention to the various spin states that are accessible at different points on the potential energy surface. This latter point is critical here because the ground states of the $[L^1Fe^{II}(H_2O_2)]^{2+}$ and $[L^1Fe^{IV}(O)]^{2+}$ species are a quintet and a triplet, respectively. Intersystem crossing from one potential energy surface to the other is therefore an integral component of the reaction coordinate.

### O–O Bond Homolysis Pathway

We have located a transition state, **TS1**, linking the reactant, $[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O$, and the caged radical, $[L^1Fe^{III}(OH)]^{2+}\cdot H_2O\cdot OH$, on the $S = 2$ surface. The O–O bond is significantly elongated at the transition structure (1.75 Å vs. 1.46 Å in the reactants), and the imaginary frequency is clearly associated with the O–O stretching mode. The Fe–O separation is also significantly reduced compared to the reactants, due to the partial oxidation of the metal centre. We have also located transition states (**TS2**) linking the radical intermediates with the $[L^1Fe^{IV}(O)]^{2+}\cdot 2H_2O$ asymptote on both quintet and triplet surfaces. At this point, the $O_p$–$H_p$ distance is significantly elongated while the separation between this hydrogen atom and the OH radical is much reduced, and the imaginary frequency corresponds to an $O_p$–$H_p$ stretch. The net effect is that the solvent water molecule acts as a hydrogen atom shuttle, mediating the abstraction of a hydrogen atom from the coordinated OH ligand by the OH radical. The energy of **TS2** is highly dependent on the spin state – the triplet lies significantly *below* the quintet, reflecting its product-like nature. The shape of the potential energy surfaces also dictates that the crossover between the quintet and triplet surfaces must occur at some point between the radical intermediate ($S = 2$) and **TS2** ($S = 1$). We have located the minimum energy crossing point (MECP1) between these surfaces, and the structural changes leading up to this point are largely associated with the metal–ligand bonds, all of which contract significantly from the intermediate to the MECP. The separation between the metal fragment and the OH radical is, in contrast, essentially unchanged. We therefore conclude that the crossover from the quintet to triplet surfaces involves a localised $S = 5/2 \rightarrow S = 1/2$ transition on the $Fe^{III}$ centre, and the nature of the interaction between the metal centre and the OH radical remains unchanged. In the gas phase, the MECP lies 46 kJ mol$^{-1}$ above the $S = 2$ intermediate, but this is reduced to 31 kJ mol$^{-1}$ when solvation is included, as a result of the contracted metal–ligand bonds in the former. It is important to emphasise, however, that the effects of solvation are only included post-optimisation. We have noted previously that solvation stabilises low-spin states, and indeed the $S = 1$ and $S = 2$ caged radical species are almost isoenergetic when solvation effects are included. If the energies of these two states were, in fact, reversed, then the $S = 2 \rightarrow S = 1$ spin crossover would occur before, rather than just after, the radical intermediate. Given the intrinsic uncertainties in determining accurate spin-state energies with DFT and the approximate nature of the PCM solvation model, we are unable to reach a definitive conclusion on this point. It will not, however, have a major impact on the potential energy surface: the nature of the crossover – viz. a localised high-spin/low-spin transition on the $Fe^{III}$ centre – remains unchanged.

To summarise, the early part of the reaction coordinate shown in Figure 2 lies along the quintet surface, and involves homolysis of the O–O bond. The resulting intermediate contains an $[L^1Fe^{III}(OH)]^{2+}$ species, weakly coupled to an OH radical, the whole unit being held together by electrostatic interactions with the dicationic metal core and hydrogen bonding within the solvent cage. A localised high-spin/low-spin transition on the $Fe^{III}$ centre then causes a crossover to the triplet surface, after which the OH radical abstracts a hydrogen atom from the coordinated OH ligand. Whilst the initial O–O bond homolysis step was marginally endothermic, the hydrogen atom abstraction step is highly exothermic, and the $[L^1Fe^{IV}(O)]^{2+}$ product is 101 kJ mol$^{-1}$ more stable than the reactants. In comparison, a value of 117 kJ mol$^{-1}$ was reported for the aqua complex.[16] Thus, the major difference between the two pathways lies not in the overall exothermicity of the decomposition of the $H_2O_2$ complex, but rather in the details of the intervening potential energy surface. In the aqua complex, the O–O homolysis and hydrogen atom abstraction steps are concerted, while in the case of $[L^1Fe^{II}(H_2O_2)]^{2+}$, the absence of an additional water ligand effectively separates the two processes, leading to an identifiable $Fe^{III}(OH)$ intermediate. The rate-determining step in this reaction clearly depends on the relative energies of the two transition states, **TS1** and **TS2** shown in Figure 2. In the gas phase, **TS2** (79 kJ mol$^{-1}$) lies substantially above **TS1** (40 kJ mol$^{-1}$), suggesting that the OH "rebound" step should be rate-determining. In these circumstances, diffusion of the OH radical into solution should be competitive with formation of the $Fe^{IV}(O)$ species. However, when solvation is included, **TS2** is strongly stabilised relative to **TS1** because the latter contains the smaller low-spin $Fe^{III}$ centre, and the two barriers are now rather similar (34 and 44 kJ mol$^{-1}$, respectively). We return to a discussion of this point in the concluding remarks.

### O–O Bond Heterolysis Pathway

In the previous section we identified a pathway linking the two asymptotes, $[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O$ and $[L^1Fe^{IV}(O)]^{2+}\cdot 2H_2O$, via an intermediate containing a weakly trapped OH radical. Comba, Que and co-workers have proposed an alternative pathway involving proton (as distinct from hydrogen atom) transfer, followed by O–O heterolysis, to account for the observed decomposition of $[L^2Fe^{II}(H_2O_2)]^{2+}$.[6c] We have considered this possibility, and identified a further transition state, **TS3**, that directly links the reactants and products for each of the three spin states ($S$ = 0, 1, 2). The structure of the most stable transition state ($S$ = 2) is shown in Figure 3, and key bond lengths for all three are collected in Table 2. The most remarkable feature of the transition structures is the near-identical geometry of the $H_2O_2\cdot H_2O$ unit in each case. The proton initially attached to the proximal oxygen atom of the hydrogen peroxide has been almost completely transferred to the water molecule ($O_p\cdots H_p$ = 1.72–1.74 Å, $H_p$–$O_w$ = 1.02 Å), suggesting that the reaction coordinate leading up to the transition state is a simple proton transfer. The Fe–O bond lengths contract somewhat as a result of the removal of the proximal proton (by 0.24 Å for $S$ = 2), but the equatorial and axial Fe–N distances remain largely unchanged. The marginal elongation of the O–O bond (1.52–1.54 Å, c.f. 1.45–1.46 in the equilibrium structures) also confirms that O–O bond cleavage is not well advanced at the transition state. The imaginary frequency in each spin state corresponds to the transfer of the proton from $H_3O^+$ to the terminal oxygen atom of the hydrogen peroxide, and a small displacement along this mode results in decomposition to the hydrated $[L^1Fe^{IV}(O)]^{2+}\cdot 2H_2O$ species, with no further barrier. Given that the motion along the reaction coordinate prior to the transition state is almost entirely centred on the $H_2O_2\cdot H_2O$ unit, it is unsurprising that the barriers, measured relative to the reactant, are essentially independent of the spin state of the iron centre (87–89 kJ mol$^{-1}$, Figure 3). The lowest energy pathway therefore lies along the quintet surface until well after the transition state. Intersystem crossing between the $S$ = 2 and $S$ = 1 surfaces must again occur at some later stage on the reaction coordinate, and will correspond to a localised high-spin/low-spin transition on the developing $Fe^{IV}(O)$ unit. In summary, although the proton-transfer mechanism leading to O–O bond cleavage is concerted and does not involve any stable intermediates, it is also highly asynchronous. The reaction coordinate prior to the transition state involves deprotonation of the hydrogen peroxide ligand at the proximal oxygen atom, while afterwards transfer of the proton to the terminal oxygen leads to spontaneous cleavage of the O–O bond. This mechanism is qualitatively similar to that proposed by Que and Comba for the decomposition of $[L^2Fe^{IV}(H_2O_2)]^{2+}$, with the subtle difference that it is the proton transfer, rather than the O–O bond heterolysis, that determines the magnitude of the barrier.

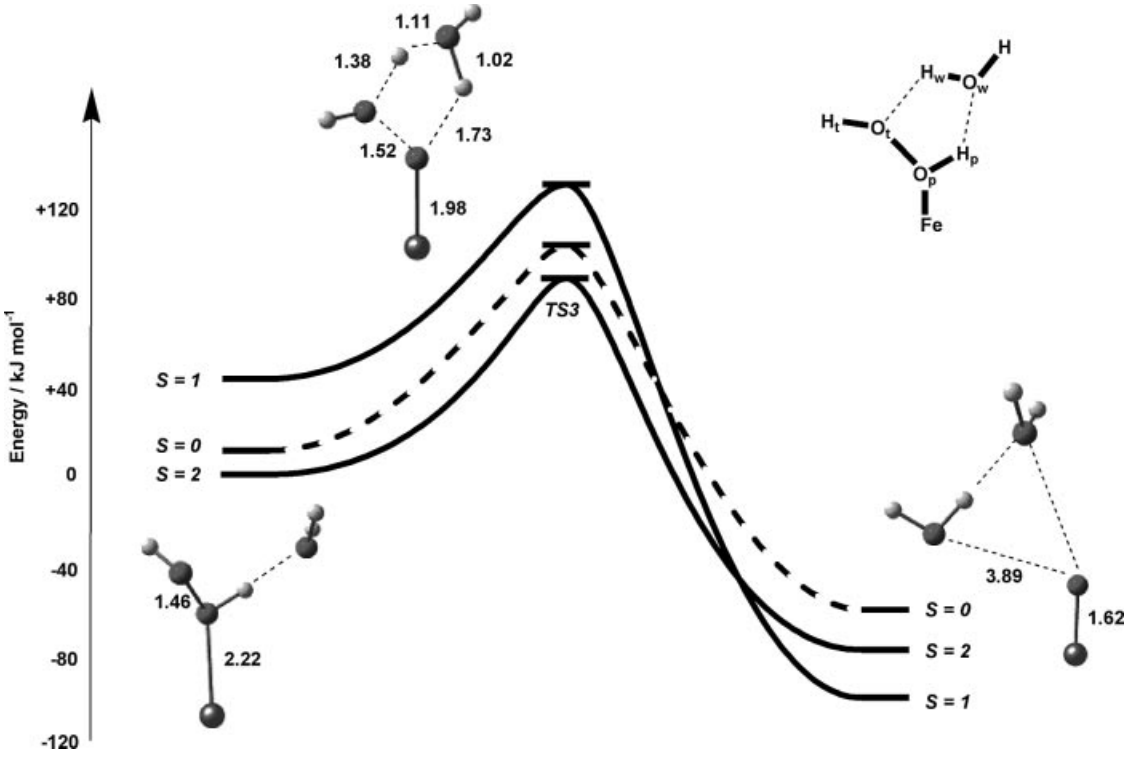

Figure 3. Potential energy surface for the O–O bond heterolysis mechanism for decomposition of $[L^1Fe^{II}(H_2O_2)]^{2+}\cdot H_2O$. Energies include the effects of solvation introduced by the PCM model.

## Conclusions

The key features of the two possible pathways for O–O bond cleavage are compared in Figure 4. Returning to the question of radical (Haber–Weiss) vs. non-radical (Bray–Gorin) mechanisms, we can identify three quite distinct scenarios, depending on the relative energies of the three transition states **TS1**, **TS2** and **TS3**. If **TS3** < **TS1**, the concerted mechanism will dominate, and any $Fe^{III}$ product must be generated by comproportionation of the initially formed $Fe^{IV}(O)$ with excess $Fe^{II}$. If, in contrast, **TS3** > **TS1**, then the homolytic pathway will dominate, and this in turn can lead to two distinct outcomes depending on the energies of **TS1** and **TS2**. If **TS1** > **TS2**, rebound of the transient OH radical will be rapid, leading again to formation of $Fe^{IV}(O)$, but in this case via transient $Fe^{III}(OH)$. In contrast, if **TS2** > **TS1**, the products of the reaction will depend critically on the rate of the rebound step (**TS2**) relative to the rate of diffusion through the solvent. If the latter is rapid, then the OH radicals are likely to escape and oxidise the ligand, solvent or any other accessible substrate. The presence of three distinct scenarios offers a possible explanation for the very complex nature of Fenton chemistry, and in particular for the apparent generation of radicals in some cases but not others.[11] It also provides a framework for understanding the way in which changes in ligand can perturb the reaction pathway.

## Calculation Details

In all cases, the bispidone ligand was simplified by replacing the ester groups with hydrogen atoms. All calculations described in this paper were performed using the Gaussian03 package.[24] The B3LYP[25b,25c] functional was used throughout, in conjunction with the 6-31G* basis set on all atoms. Full geometry optimisations were performed without symmetry constraints, and stationary points were characterised as minima or transition states by vibrational analysis. Minimum energy crossing points (MECPs) were located using the code developed by Harvey and co-workers.[26] Solvation energies were calculated by Tomasi's reaction field method using the polarized continuum model (PCM) with a dielectric constant ($\varepsilon$) of 78.39.

*Dedicated to Michael Binnewies on the occasion of his 60th birthday*

**Keywords:** Iron / Copper / Selenium / Cluster compounds

CuBr and $Fe(OOCCH_3)_2$ react with $PhSeSiMe_3$ in acetonitrile in the presence of the diammonium salt $[n\mathrm{Pr_3N(CH_2)_6N}n\mathrm{Pr_3}]\mathrm{Br_2}$ to yield ionic $[n\mathrm{Pr_3N(CH_2)_6N}n\mathrm{Pr_3}][\mathrm{CuFe_3Br_3(SePh)_6}]$. The neutral complexes $[\mathrm{Cu_5Fe(SePh)_7(PPh_3)_4}]$ and $[\mathrm{Cu_4Fe_3(SePh)_{10}(PPh_3)_4}]$ were obtained by similar reactions of different stoichiometric mixtures of $CuOOCCH_3$ and $FeCl_2$ with $PPh_3$ and $PhSeSiMe_3$. The crystal structures of the compounds were determined by single-crystal X-ray analysis to give new structural types of molecular cluster compounds formed by copper, iron and selenium. Thermal treatment of $[\mathrm{Cu_5Fe(SePh)_7(PPh_3)_4}]$ and $[\mathrm{Cu_4Fe_3(SePh)_{10}(PPh_3)_4}]$ results in the formation of mixtures of binary $Cu_2Se$ and ternary $CuFeSe_2$.

## Introduction

The synthesis of ternary cluster molecules has attracted interest recently. Examples of different compounds include $(PPh_4)[Cu_6In_3(SEt)_{16}]$,[1] $[M^I{}_6M^{III}{}_8Cl_4E_{13}(PPh_3)_6]$ ($M^I$ = Cu, Ag; $M^{III}$ = Ga, In; E = S, Se),[2] $[Cu_{11}In_{15}Se_{16}(SePh)_{24}(PPh_3)_4]$,[3] $[Ag_{26}In_{18}S_{36}Cl_6(dppm)_{10}(thf)_4][InCl_4(thf)]_2$,[4] $[Hg_{15}Cu_{20}S_{25}(Pn\mathrm{Pr_3})_{18}]$,[5,6] $[Cu_4Nb_2Se_6(PMe_3)_8]$,[7] $[Ta_4Cu_{12}Cl_8S_{12}(PMe_3)_{12}]$,[8] $[(N,N'\text{-tmeda})_5Zn_5Cd_{11}Se_{13}(SePh)_6(thf)_2]$,[9] and $[(py)_8Ln_4M_2Se_6(SePh)_4]$ (Ln = Er, Yb, Lu; M = Cd, Hg).[10] Interest in these compounds lies in the characterization of their structures and an investigation of their properties. In this context, Kanatzidis et al. have studied the suitability of mixed copper/indium chalcogenolates as precursor materials for the photovoltaic materials $CuInE_2$ (E = S, Se).[1,11] Corrigan et al. have observed room-temperature fluorescence for the ternary 12-12′-16 cluster (12 = Zn; 12′ = Cd; 16 = Se) $[(N,N'\text{-tmeda})_5Zn_5Cd_{11}Se_{13}(SePh)_6(thf)_2]$,[9] while binary cadmium or zinc selenide clusters show weak luminescence only at temperatures below 50 K.[12,13] Strong infrared fluorescence behavior has been observed to occur in the heterometallic chalcogenido cluster molecules $[(py)_8Ln_4M_2Se_6(SePh)_4]$ (Ln = Er; M = Cd, Hg).[10]

The ternary phase $CuFeS_2$ has been known to be a semiconductor material for a long time and was one of the first compounds to be used for the construction of radio frequency detectors,[14] while information about $CuFeSe_2$ is limited and only a few papers have been devoted to this compound during the last five years.[15] Until now only a limited number of cluster compounds have been synthesized that contain copper, iron and sulfur or selenium; these include $[Fe_3Cu(Si\mathrm{Pr})_6Cl_3]^{2-}$,[16] $[Fe_3Cu(Se\mathrm{Pr})_6Cl_3]^{2-}$, and $[Fe_2Cu_4(Si\mathrm{Pr})_8Cl_3]^{2-}$.[17] Here we report the synthesis and characterization of three new compounds of this type, namely $[n\mathrm{Pr_3N(CH_2)_6N}n\mathrm{Pr_3}][\mathrm{CuFe_3Br_3(SePh)_6}]$, $[\mathrm{Cu_5Fe(SePh)_7(PPh_3)_4}]$ and $[\mathrm{Cu_4Fe_3(SePh)_{10}(PPh_3)_4}]$.

## Results and Discussion

### Synthesis

Reaction of a 1:3 mixture of CuBr and $Fe(OOCCH_3)_2$ with $PhSeSiMe_3$ in acetonitrile in the presence of the diammonium salt $[n\mathrm{Pr_3N(CH_2)_6N}n\mathrm{Pr_3}]\mathrm{Br_2}$ yielded, after layering with diethyl ether, dark red-orange crystals of **1** after a few days (Scheme 1).

The use of the neutral ligand $PPh_3$ instead of the diammonium salt $[n\mathrm{Pr_3N(CH_2)_6N}n\mathrm{Pr_3}]\mathrm{Br_2}$ in reactions of $CuOOCCH_3$ and $FeCl_2$ with $PhSeSiMe_3$ led to the formation of dark-red solutions from which red crystals of **2** (Scheme 2) grew over the course of several days.

A similar reaction with a 1:0.8 ratio of $CuOOCCH_3$ and $FeCl_2$ yielded red-orange crystals of **3** (Scheme 3).

## Crystal Structures

Ionic **1** crystallizes in the trigonal space group $P\bar{3}$ with three crystallographically independent $[CuFe_3Br_3(SePh)_6]^{2-}$ cluster anions, two of which reside on a threefold and one on a $\bar{3}$ axis (see Experimental Section for further details). Because the structures of the cluster cores, including bond lengths and angles, are quite similar for all three, only one of them is discussed in the following. The cluster anion $[CuFe_3Br_3(SePh)_6]^{2-}$ (Figure 1) consists of a six-membered $Fe_3(SePh)_3$ ring in a chair conformation that is capped by a nearly trigonal-planar $Cu(SePh)_3$ unit [Cu, Se(1), Se(1′), Se(1′′); Se–Cu–Se = 119.96(1)°]. A threefold axis runs through the copper atom and the center of the hexanuclear ring, and the copper atom is slightly shifted by 4.7 pm from the triangular selenium face towards the iron atoms (mean Cu–Fe distance of 339.2 pm). Each of the iron atoms is additionally coordinated by a terminal bromido ligand to give a distorted tetrahedral coordination environment for the iron atoms [Fe–Br = 241.7(2) pm]. The metal–selenium distances are found to be longer for iron [246.7–246.8(2) pm] than for copper [234.2–234.3(1) pm], which is most probably a result of the different coordination modes. This adamantoid cluster core in **1** is therefore similar to the structures of $[CuFe_3Cl_3(EiPr)_6]^{2-}$ (E = Se, S), which have been crystallized previously with singly charged ammonium cations.[16,17]

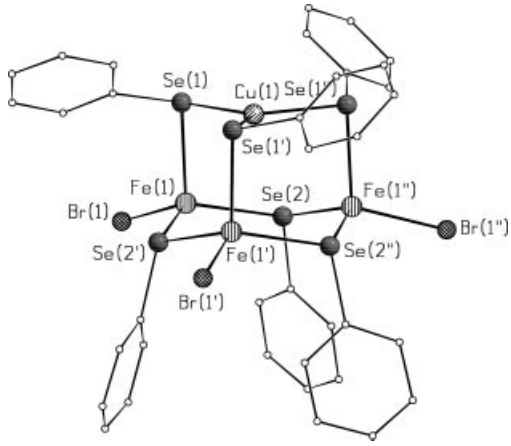

Figure 1. Molecular structure of the cluster anion $[CuFe_3Br_3(SePh)_6]^{2-}$ in $[nPr_3N(CH_2)_6NnPr_3][CuFe_3Br_3(SePh)_6]$ (**1**). C and H atoms omitted for clarity. Selected bond lengths [pm] and angles [°]: Se(1)–Cu(1) 234.2(1), Se(1)–Fe(1) 247.3(2), Se(2)–Fe(1) 246.7(2), Se(2)–Fe(1′) 246.8(2), Cu(1)–Se(1′′) 234.3(1), Cu(1)–Se(1′) 234.3(9), Br(1)–Fe(1) 241.7(2), Fe(1)–Se(2′′) 246.8(2); Fe(1)–Se(2)–Fe(1′) 112.64(6), Se(1)–Cu(1)–Se(1′′) 119.96(1), Se(1)–Cu(1)–Se(1′) 119.96(1), Se(1′′)–Cu(1)–Se(1′) 119.96(1), Br(1)–Fe(1)–Se(2) 109.71(6), Br(1)–Fe(1)–Se(2′′) 115.11(6), Se(2)–Fe(1)–Se(2′′) 118.86(6), Br(1)–Fe(1)–Se(1) 108.00(6), Se(2)–Fe(1)–Se(1) 103.55(6), Se(2′′)–Fe(1)–Se(1) 99.87(6). Symmetry transformations for the generation of equivalent atoms: ′: $1 - y, x - y, z$; ′′: $-x + y + 1, -x + 1, z$.

Cluster **2** crystallizes in the monoclinic space group $P2_1/c$ (Figure 2). The structure comprises a central $Cu_3Fe$ trigonal pyramid formed by Cu(1), Cu(2), Cu(3), and Fe(1) [Cu···Cu = 430.1–451.4(1); Cu···Fe = 403.0–417.2(1) pm] with the six edges bridged by $SePh^-$ ligands [Se(1)–Se(6); Cu–Se = 244.4–270.9(1); Fe(1)–Se = 242.9–249.5(1) pm]. One additional copper atom [Cu(4)] is bonded to this adamantoid cluster cage through the three selenium atoms of the basal six-membered ring [Se(1)–Se(3); Cu–Se = 242.0–249.0(1) pm], which displays only a weak chair conformation [maximum deviation of 66.5 pm for Se(3) from the trigonal plane formed by Cu(1)–Cu(3)]. The coordination environment of Cu(4) is trigonal-planar [sum of Se–Cu(4)–Se angles is 360°]. The copper atoms Cu(1)–Cu(3) which form the basal plane of the $Cu_3Fe$ pyramid are each additionally coordinated by a terminal $PPh_3$ ligand to result in an overall distorted tetrahedral coordination environment for these atoms. Fe(1), at the apex of the $Cu_3Fe$ pyramid, is additionally coordinated by another $SePh^-$ ligand [Se(7)], and a further $CuPPh_3$ unit is attached through this and two other $SePh^-$ ligands [Se(5), Se(6), Se(7)] to the adamantoid cluster cage.

Compound **3** crystallizes in the monoclinic space group $P2_1/c$ (Figure 3). Similar to **1**, the structure contains a central $CuFe_3$ trigonal pyramid formed by Fe(1), Fe(2), Fe(3), and Cu(4) [Fe···Cu = 393.1–420.5(2); Fe···Fe = 402.1–410.2 pm]. Thus, three iron atoms define the vertices of the basal triangular plane, which is bridged by a $\mu_3$-$SePh^-$ ligand [Fe–Se(10) = 250.1–251.2(2) pm], while the apex of the pyramid is occupied by a $CuPPh_3$ unit [Cu(4)–P(4) =

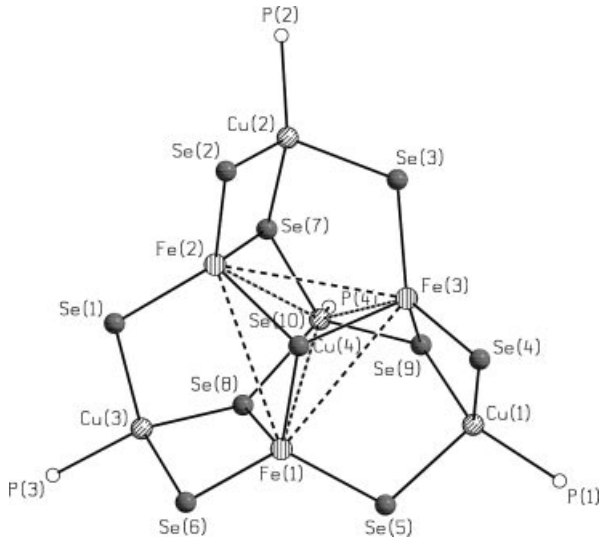

Figure 3. Molecular structure of $[Cu_4Fe_3(SePh)_{10}(PPh_3)_4]$ (**3**). C and H atoms omitted for clarity. Selected bond lengths [pm]: Se(7)–Fe(2) 249.4(2), Se(7)–Cu(4), 251.6(2) Se(7)–Cu(2) 252.1(2), Se(8)–Cu(4) 246.9(2), Se(8)–Fe(1) 247.3(2), Se(8)–Cu(3) 250.6(2), Se(9)–Cu(4) 246.9(2), Se(9)–Fe(3) 247.4(2), Se(9)–Cu(1) 256.9(2), Se(10)–Fe(2) 250.1(2), Se(10)–Fe(1) 250.9(2), Se(10)–Fe(3) 251.2(2), Se(1)–Fe(2) 244.8(2), Se(1)–Cu(3) 247.5(2), Se(2)–Fe(2) 245.5(2), Se(2)–Cu(2) 248.7(2), Se(3)–Fe(3) 246.6(2), Se(3)–Cu(2) 250.6(2), Se(4)–Fe(3) 244.1(2), Se(4)–Cu(1) 247.4(2), Se(5)–Fe(1) 244.0(2), Se(5)–Cu(1) 245.6(2), Se(6)–Fe(1) 243.1(2), Se(6)–Cu(3) 250.3(2), Cu(1)–P(1) 226.1(3), Cu(2)–P(2) 224.7(3), Cu(3)–P(3) 226.1(3), Cu(4)–P(4) 223.7(3); shortest nonbonding metal–metal distances: Cu(1)–Fe(3) 301.6(2), Cu(2)–Fe(2) 306.4(2), Cu(3)–Fe(1) 304.5(2) (not drawn), Cu(4)–Fe(1) 397.1(2), Cu(4)–Fe(2) 420.5(2), Cu(4)–Fe(3) 393.0(2), Fe(1)–Fe(2) 409.7(2), Fe(1)–Fe(3) 410.2(2), Fe(2)–Fe(3) 402.0(2) (dashed lines).

223.7(3) pm]. The other faces of the pyramid are capped by three distorted tetrahedral $PPh_3Cu(SePh)_3$ units in such a way that six $SePh^-$ ligands [Se(1)–Se(6)] adopt a $\mu_2$- and three [Se(8)–Se(9)] a $\mu_3$-bridging mode, which results in an overall distorted tetrahedral coordination of the metal atoms. All copper atoms are surrounded by two $\mu_2$-$SePh^-$ moieties [mean Cu–Se distance of 248.4(2) pm], one $\mu_3$-$SePh^-$ [mean Cu–Se distance of 250.8(2) pm], and a terminal $PPh_3$ ligand [mean Cu–P distance of 252.2(3) pm]. The iron atoms are four-coordinated by two $\mu_2$-$SePh^-$ [mean Fe–Se distance of 244.7(2) pm] and two $\mu_3$-$SePh^-$ ligands [mean Fe–Se distance of 249.5(2) pm]. Obviously, the core of the cluster complex comprises a pseudo-threefold axis running through Se(10), Cu(4), and P(4); however, the organic ligands do not have this symmetry.

### Optical Spectra

The UV/Vis spectra of **1**–**3** measured as a mull in nujol between quartz plates display several absorption features in the region between 600 and 220 nm. The spectrum of **1** displays a very broad shoulder around 370 nm, another one at 275 nm, and a peak at 249 nm. The spectrum of **2** consists of two shoulders around 450 and 290 nm, while that of **3** shows a broad absorption maximum at 440 nm followed by a shoulder at 280 nm (Figure 4). In solution (**1** in $CH_3CN$; **2**, **3** in thf), the ratio of the maxima and shoulders at higher wavelengths to those below 350 nm increases compared to the spectra measured in nujol. Compounds **1** and **3** display a shoulder at 390 ($\varepsilon$ = 7409) and 415 nm ($\varepsilon$ = 6868), respectively, while the corresponding feature of **2** is most probably obscured by the tail of the following intense band with a maximum at 272 nm ($\varepsilon = 8.87 \times 10^4$ $M^{-1}cm^{-1}$). This band is followed by a very weak shoulder at 252 nm ($\varepsilon = 8.756 \times 10^4$ $M^{-1}cm^{-1}$). Two similar features are observed for **3** at 270 ($\varepsilon = 1.092 \times 10^5$) and 255 nm ($\varepsilon = 1.142 \times 10^5$ $M^{-1}cm^{-1}$), while **1** displays only one broad additional absorption maximum at 250 nm ($\varepsilon = 6.802 \times 10^4$ $M^{-1}cm^{-1}$). A detailed assignment of the bands is complicated as there are several possible absorption processes for the compounds. However, due to their relatively low extinction coefficients of about 7000 $M^{-1}cm^{-1}$, it is possible that the broad bands at higher wavelengths originate from spin-allowed d–d transitions in tetrahedrally coordinated $Fe^{2+}$ while the intense bands at lower wavelengths correspond to either Se→Cu or Se→Fe charge-transfer bands partially overlapped by π–π* transitions of the $SePh^-$ and/or $PPh_3$ ligands.

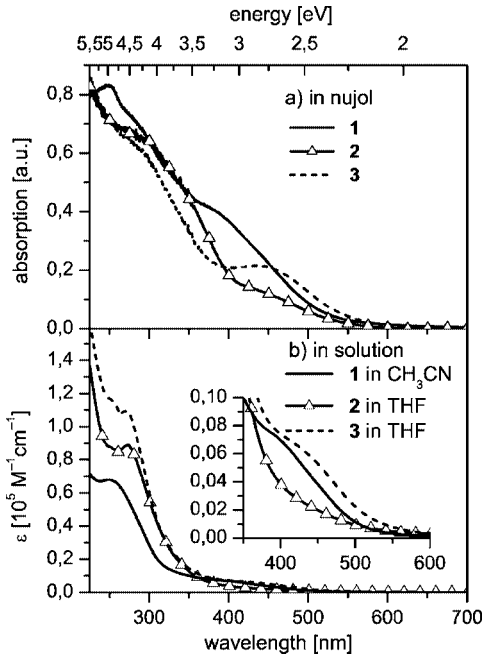

Figure 4. UV/Vis spectra of $(n\text{Pr}_3\text{N}(\text{CH}_2)_6\text{N}n\text{Pr}_3)[\text{CuFe}_3\text{Br}_3(\text{SePh})_6]$ (**1**), $[\text{Cu}_5\text{Fe}(\text{SePh})_7(\text{PPh}_3)_4]$ (**2**), and $[\text{Cu}_4\text{Fe}_3(\text{SePh})_{10}(\text{PPh}_3)_4]$ (**3**) as mulls in nujol (a) and in solution (b).

### Thermogravimetric Analysis

The decomposition of **2** and **3** upon heating was monitored by TGA in vacuo (Figure 5). The mass changes of **2** and **3** both display one-step processes due to the cleavage of most of the ligands, although the temperature range of the cleavage is much narrower for **3** (125–275 °C) than for **2** (125–375 °C). The observed mass losses of 76.2% (**2**) and 75.1% (**3**) agree with the calculated values [loss of 3.5 $\text{SePh}_2$ and four $\text{PPh}_3$ molecules for **2** (76%) and five $\text{SePh}_2$ and four $\text{PPh}_3$ molecules for **3** (73.7%)]. The powder diffraction patterns (Figure 6) of the residues indicate the formation of mixtures of the known phases $\text{Cu}_2\text{Se}$[18] and $\text{CuFeSe}_2$.[19] The thermal treatment of **2** should result in a powder with the theoretical composition $\text{Cu}_5\text{FeSe}_{3.5}$. The ratio of the peak intensities of the different patterns reveals a higher amount of $\text{Cu}_2\text{Se}$ in comparison to $\text{CuFeSe}_2$, although two peaks at $2\theta$ = 44.8° and 47.9°, which have been marked with an asterisk, could not be assigned. For **3**, the residue should have the composition $\text{Cu}_4\text{Fe}_3\text{Se}_5$, which is much closer to the formula of the ternary solid-state phase $\text{CuFeSe}_2$ than that of the residue of **2**. In agreement with this, the powder pattern corresponds to a larger fraction of $\text{CuFeSe}_2$ and a smaller fraction of $\text{Cu}_2\text{Se}$.

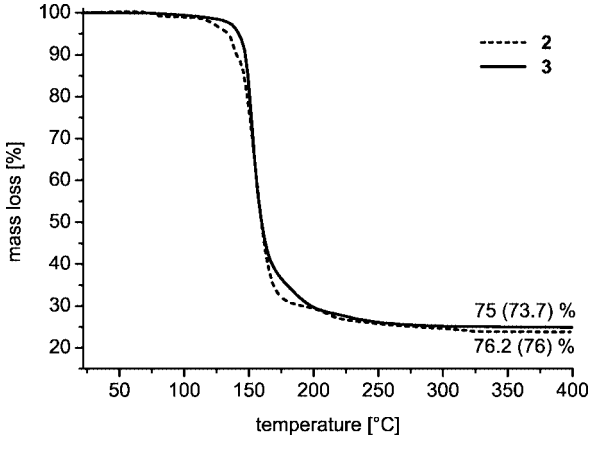

Figure 5. Thermogravimetric analysis of $[\text{Cu}_5\text{Fe}(\text{SePh})_7(\text{PPh}_3)_4]$ (**2**) and $[\text{Cu}_4\text{Fe}_3(\text{SePh})_{10}(\text{PPh}_3)_4]$ (**3**) in vacuo. Theoretical values for the calculated mass loss of 4 $\text{PPh}_3$/3.5 $\text{SePh}_2$ in **2** and 4 $\text{PPh}_3$/5 $\text{SePh}_2$ in **3** are given in parentheses.

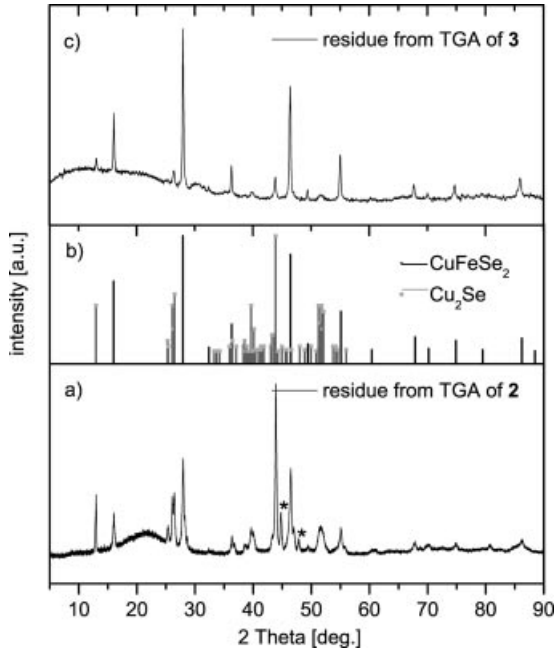

Figure 6. Powder diffraction patterns of a) the residue of the TGA of $[\text{Cu}_5\text{Fe}(\text{SePh})_7(\text{PPh}_3)_4]$ (**2**). Peaks marked by an asterisk cannot be assigned; b) monoclinic α-$\text{Cu}_2\text{Se}$ (grey lines)[18] and tetragonal $\text{CuFeSe}_2$ (black lines);[19] c) residue of the TGA of $[\text{Cu}_4\text{Fe}_3(\text{SePh})_{10}(\text{PPh}_3)_4]$ (**3**).

## Conclusion

The raction of mixtures of copper and iron salts with $\text{PhSeSiMe}_3$ can be used for the synthesis of mixed-metal Cu/Fe/Se cluster molecules. Different structures are formed depending on the kind of ligands and the ratio of the precursor compounds. Thermal cleavage of the organic ligands results in the formation of mixtures of binary $\text{Cu}_2\text{Se}$ and ternary $\text{CuFeSe}_2$, the ratio of which depends on the ratio of the elements in the precursor cluster molecules.

## Experimental Section

**Synthesis:** Standard Schlenk techniques were employed throughout the syntheses using a double-manifold vacuum line ($10^{-3}$ mbar) with high-purity nitrogen (99.9999%). Diethyl ether, and dme were dried with sodium/benzophenone, $\text{CH}_3\text{CN}$ with $\text{CaH}_2$, and all were distilled under nitrogen. CuCl was washed with HCl, $\text{CH}_3\text{OH}$, and diethyl ether to remove traces of $\text{CuCl}_2$, and then dried under vac-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

uum. $CuOOCCH_3$[20] and $PhSeSiMe_3$[21] were prepared according to literature procedures.

**Physical Measurements:** UV/Vis absorption spectra of cluster molecules in solution were measured with a Varian Cary 500 spectrophotometer in quartz cuvettes. Solid-state UV/Vis spectra were measured as a mull in nujol between quartz plates with a Labsphere integrating sphere. Thermogravimetric analyses were run with a thermobalance STA 409 from Netzsch in vacuo (heating rate 2 K min$^{-1}$).

**[*n*Pr$_3$N(CH$_2$)$_6$N*n*Pr$_3$]Br$_2$:** 1,6-Diaminohexane (8.3 mL, 0.07 mol), *n*-propyl bromide (39.4 mL, 0.43 mol) and $NaHCO_3$ (28 g, 0.33 mol) were added to 120 mL of a 1:1 mixture of $H_2O$ and $CH_3CN$. Two liquid phases and one solid phase were formed. The mixture was then heated under reflux and the formation of $CO_2$ indicated the reaction progress. After 2 d, once the solid phase had disappeared, the organic phase was separated and the solvent evaporated to dryness. The residue was then treated with 100 mL of $CHCl_3$ to precipitate NaBr. Removal of this solid by filtration and renewed evaporation of the solvent yielded [*n*Pr$_3$N(CH$_2$)$_6$N*n*Pr$_3$]Br$_2$ as a pale-yellow precipitate. Yield: 8.56 g (23%). $C_{24}H_{54}Br_2N_2$ (531.61): calcd. C 54.38, H 10.26, N 5.28, found C 53.13, H 10.82, N 5.06.

**[*n*Pr$_3$N(CH$_2$)$_6$N*n*Pr$_3$][CuFe$_3$Br$_3$(SePh)$_6$] (1):** CuBr (50 mg, 0.35 mmol), Fe(OOCCH$_3$)$_2$ (183 mg, 1.05 mmol), and [*n*Pr$_3$N(CH$_2$)$_6$N*n*Pr$_3$]Br$_2$ (185 mg, 0.35 mmol) were suspended in 40 mL of $CH_3CN$. After 1 d of stirring, $PhSeSiMe_3$ (0.44 mL, 2.1 mmol) was added at 0 °C and the mixture warmed to room temperature which led to the formation of red-orange crystals of **1**. Yield: 530 mg (73%). $C_{60}H_{84}Br_3CuFe_3N_2Se_6$ (1644.6): calcd. C 40.5, H 4.8, N 1.6; found C 40.9, H 4.9, N 1.8.

**[Cu$_5$Fe(SePh)$_7$(PPh$_3$)$_4$] (2):** $CuOOCCH_3$ (100 mg, 0.82 mmol), $FeCl_2$ (21 mg, 0.16 mmol), and $PPh_3$ (0.32 g, 1.2 mmol) were suspended in 30 mL of dme. After 1 d of stirring, $PhSeSiMe_3$ (0.32 mL, 1.39 mmol) was added at –30 °C and the mixture warmed to room temperature to give a clear red solution. After 1 d, the reaction solution was layered with 50 mL of pentane by autothermal condensation. Red, needle-like crystals of **2** grew over several days. Yield: 308 mg (75%). $C_{114}H_{95}Cu_5FeP_4Se_7$ (2515.1): calcd. C 54.4, H 3.81; found C 54.5, H 4.10.

**[Cu$_4$Fe$_3$(SePh)$_{10}$(PPh$_3$)$_4$] (3):** $CuOOCCH_3$ (100 mg, 0.82 mmol), $FeCl_2$ (86 mg, 0.68 mmol), and $PPh_3$ (0.86 g, 3.3 mmol) were suspended in 100 mL of dme. After 1 d of stirring, $PhSeSiMe_3$ (0.57 mL, 2.46 mmol) was added to give a red solution. After another day, approximately 1/3 of the solvent was removed by condensation, which resulted in the immediate crystallization of orange, plate-like needles of **3**. Yield: 460 mg (74%). $C_{132}H_{110}Cu_4Fe_3P_4Se_{10}$ (3031.5): calcd. C 52.3, H 3.7; found C 52.6, H 4.0.

**Crystallography:** Crystals suitable for single-crystal X-ray diffraction were taken directly from the reaction solution of the compound and then selected in perfluoroalkyl ether oil. Single-crystal X-ray diffraction data of **1** and **2** were collected using graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) with a STOE IPDS II (Imaging Plate Diffraction System) equipped with a Schneider rotating anode. Single-crystal X-ray diffraction data of **3** were collected using synchrotron radiation ($\lambda$ = 0.80 Å) with a STOE IPDS II (Imaging Plate Diffraction System) at the ANKA synchrotron source in Karlsruhe. Further details are given in Table 1. The structures were solved with the direct-methods program SHELXS[22] of the SHELXTL PC program suite, and were refined with the use of the full-matrix least-squares program SHELXL.[22] Molecular diagrams were prepared using SCHAKAL 97.[23] All Cu, Fe, Se, Br, P, Cl, and C atoms of the cluster molecules were refined with anisotropic displacement parameters with the exception of **3**, whose C atoms were refined isotropically. In addition, split positions with isotropic displacement parameters were calculated in **1** for the C atoms of the phenyl rings C11, C12, C20, C21, and C22 as well as of the *n*-propyl groups of the ammonium salt C43, C44, C45, and C57. N and C atoms of the solvent molecules were refined isotropically. H atoms were calculated in fixed positions for **2** and **3**. CCDC-612653 (**1**), -612654 (**2**) and -612655 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif. X-ray powder diffraction patterns were recorded with a STOE STADI P diffractometer (Cu-$K_{\alpha1}$ radiation, germanium monochromator, Debye–Scherrer geometry) in sealed glass capillaries.

Table 1. Crystallographic data for [*n*Pr$_3$N(CH$_2$)$_6$N*n*Pr$_3$][CuFe$_3$Br$_3$(SePh)$_6$] (**1**), [Cu$_5$Fe(SePh)$_7$(PPh$_3$)$_4$] (**2**), and [Cu$_4$Fe$_3$(SePh)$_{10}$(PPh$_3$)$_4$] (**3**).

**Keywords:** Iridium(III) / Rhodium(III) / N-donor ligands / Cyclopentadienyl ligands

Complexes of the type $[Cp^*MCl(N–N)][X]$ (M = Rh and Ir) have been synthesised, where N–N is a series of bidentate ligands with $sp^2$ N-donors: bis(pyrazol-1-yl)methane (bpm), bis(1-methylimidazol-2-yl)methane (bim), bis(3,5-dimethylpyrazol-1-yl)methane (dmbpm), bis(1-methylimidazol-2-yl) ketone (bik), bis(2,4,6-trimethylphenylimino)acenapthene (mesBIAN), 2,4,6-trimethylphenylimino-(1-methyl-2-imidazolyl)methane (mesim–mim), and X = $Cl^-$, $BF_4^-$ and the unusual anion $[Cp^*MCl_3]^-$. All of these complexes were synthesised by treatment of $[Cp^*MCl_2]_2$ with 2 equivalents of ligand and were isolated as air stable solids. The solid-state structures of $[Cp^*MCl(bpm)][Cp^*MCl_3]$ (M = Rh and Ir) and $[Cp^*IrCl(bim)][Cp^*IrCl_3]$ have been determined by single-crystal X-ray diffraction analysis. All of the structures of the bimetallic species displayed a "piano stool" configuration about the both the anionic and cationic metal centre. The solid-state structures of the monometallic iridium species $[Cp^*IrCl(N–N)][BF_4]$, where N–N = bim, mesBIAN, and mesim-mim, were also determined using single-crystal X-ray diffraction analysis.

## Introduction

Complexes containing rhodium(I) and iridium(I) metal centres have found wide application in homogeneous catalysis. Reactions catalysed by these complexes include the hydrosilylation of imines,[1,2] the hydroamination and hydroalkoxylation of alkynes,[3–9] the hydroamination and hydroaminomethylation of olefins,[10,11] and the Pauson–Khand reaction.[12,13] Increasingly, metal complexes containing $Ir^{III}$ and $Rh^{III}$ metal centres are being investigated as catalysts for a variety of transformations. Unlike $Ir^I$ and $Rh^I$ catalysts, $Ir^{III}$ and $Rh^{III}$ complexes can not promote reactions which require the initial oxidative addition of a substrate. However, $Ir^{III}$ and $Rh^{III}$ metal centres are reactive and have the potential to catalyse a range of other transformations not reliant on oxidative addition. Work by Bergmann et al. with the complexes $Cp^*(PMe_3)Ir(CH_3)(OTf)$, and $Tp^{Me2}(PMe_3)Ir(CH_3)(OTf)$ illustrated the ability of $Ir^{III}$ complexes to effect C–H activation.[14,15] Recent work by Crabtree et al. has utilised an $Ir^{III}$ hydride complex to catalyse the intramolecular hydroamination and hydroalkoxylation of alkynes.[16] $[Cp^*IrCl_2]_2$ is effective as a catalyst for the hydroborylation of styryl sulfonamides,[17] the *N*-alkylation of amines with alcohols[18] and also the transfer hydrogenation of ketones[19] and quinolines.[20] $Rh^{III}$ complexes are known to be effective in catalysing carbon–carbon bond formation,[21] and $[Cp^*RhCl_2]_2$ has been shown to effect transfer dehydrochlorination of aryl chlorides.[22]

1,2,3,4,5-Pentamethylcyclopentadienyl (Cp*) is ubiquitous as a ligand in organometallic complexes. Many complexes incorporating this ligand are important as active catalysts, largely due to the electron-rich nature of the Cp* group and also the ability of Cp* to completely block one face of the complex, imparting steric bulk and structural rigidity. $Ir^{III}$ and $Rh^{III}$ complexes incorporating both the Cp* ligand and bidentate $sp^2$-nitrogen donor ligands have been synthesised previously.[23–31] In particular, the complex $[Cp^*Ir(bipy)(H_2O)]SO_4$ (bipy = 2,2′-bipyridine) was found to be active as a catalyst for the hydration of phenylacetylene in water,[32] and the complex $[Cp^*Rh(i\text{Pr-pymox})]^{2+}$ (pymox = pyridyloxazoline) was found to promote the enantioselective Diels–Alder reaction of methacrolein with cyclopentadiene.[27]

In the course of the study of both $Ir^{III}$ and $Rh^{III}$ complexes as potential catalysts we have synthesised a series of 1,2,3,4,5-pentamethylcyclopentadienyl complexes incorporating bidentate N donor ligands. Here, we report the synthesis and characterisation of $Rh/Ir^{III}$ complexes of the type $[Cp^*MCl(N–N)][X]$ (M = Rh and Ir), where N–N is a series of bidentate ligands with $sp^2$ N-donors: bis(pyrazol-1-yl)-methane (bpm), bis(1-methylimidazol-2-yl)methane (bim), bis(3,5-dimethylpyrazol-1-yl)methane (dmbpm), bis(1-methylimidazol-2-yl) ketone (bik), bis(2,4,6-trimethylphenylimino)acenapthene (mesBIAN), 2,4,6-trimethylphenylimino-(1-methyl-2-imidazolyl)methane (mesim–mim), and X = $Cl^-$, $BF_4^-$ and the unusual anion $[Cp^*MCl_3]^-$ (Fig-

ure 1). The solid-state structures of the complexes **1c**, **2b**, **2c**, **3c**, **7b** and **8b** have been determined by single-crystal X-ray diffraction analysis. The complexes **1c**, **2c** incorporate the novel anion $[Cp^*IrCl_3]^-$, and complex **3c** incorporates the rare anion $[Cp^*RhCl_3]^-$.

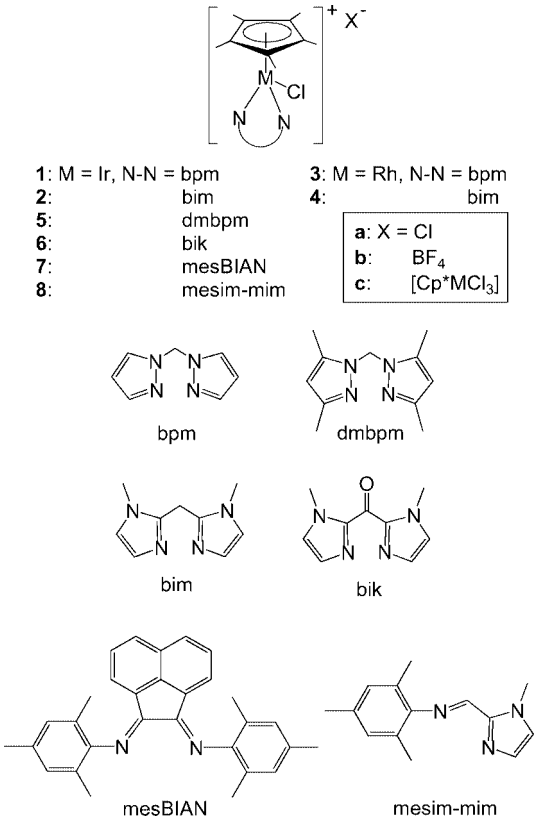

Figure 1. The general structure of complexes **1a**–**8b** and **1a**–**3c** where N–N = bpm = bis(pyrazol-1-yl)methane; bim = bis(1-methylimidazol-2-yl)methane; dmbpm = bis(3,5-dimethylpyrazol-1-yl)-methane; bik = bis(1-methylimidazol-2-yl) ketone; mesBIAN = bis(2,4,6-trimethylphenylimino)acenapthene; mesim–mim = (2,4,6-trimethylphenyl)imino-(1-methylimidazol-2-yl)methane.

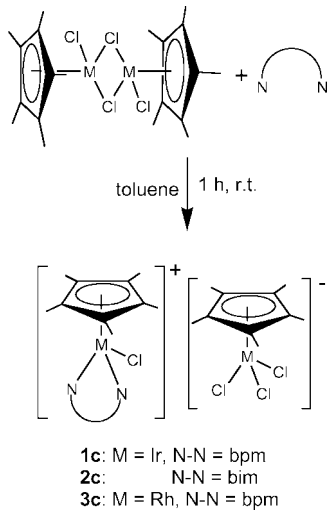
## Results and Discussion

### Synthesis of Complexes [Cp*MCl(N–N)][Cp*MCl$_3$] 1c, 2c, and 3c

Toluene suspensions of the metal precursors $[Cp^*IrCl_2]_2$ and $[Cp^*RhCl_2]_2$ were treated with two molar equivalents of the bidentate nitrogen donor ligands bpm and bim (Scheme 1) to generate the ion pairs $[Cp^*IrCl(bpm)][Cp^*IrCl_3]$ (**1c**), $[Cp^*IrCl(bim)][Cp^*IrCl_3]$ (**2c**), and $[Cp^*RhCl(bpm)][Cp^*RhCl_3]$ (**3c**) (Scheme 1). Using the same approach, **2c** was obtained in low yield as the minor product, with $[Cp^*IrCl(bim)]Cl$ (**2a**) being formed as the major product. Complexes **1c**, **2c**, and **3c** were thermally and air stable over extended periods. The sterically hindered ligand mesBIAN failed to bind to $[IrCp^*Cl_2]_2$.



Scheme 1.

The $^1H$ NMR spectra of complexes **1c**–**3c** showed the presence of two molar equivalents of bound Cp* per mol of ligand. $^1H$ NOESY NMR spectrum confirmed that for each of the complexes **1c**–**3c** the sharper singlet occurring slightly downfield at $\delta$ = 1.66, 1.61 and 1.69 ppm, respectively, was due to the $CH_3$ protons of the Cp* moiety bound to the cationic fragment (Table 1). The $^1H$ NMR spectra also show that the two bridging methylene backbone protons of the N–N ligands, $H_a$ and $H_b$, are in magnetically distinct environments for each of the complexes **1c**, **2c** and **3c**. For all of the complexes, the resonances due to $H_a$ and $H_b$ occur as doublets. The assignment of these resonances was established using $^1H$ NOESY NMR, and the resonances due to $H_a$ were consistently shifted significantly downfield relative to the resonances due to $H_b$ (Table 1).

Table 1. Selected chemical shifts for complexes **1c**–**3c**.

| Compound | $\delta$ (ppm) | | | |
|---|---|---|---|---|
| | $H_a$ | $H_b$ | Cp* in cation | Cp* in anion |
| $[Cp^*Ir(bpm)Cl][Cp^*IrCl_3]$ (**1c**) | 8.35 | 5.67 | 1.66 (s) | 1.58 (br. s) |
| $[Cp^*Ir(bim)Cl][Cp^*IrCl_3]$ (**2c**) | 5.01 | 4.73 | 1.61 (s) | 1.54 (br. s) |
| $[Cp^*Rh(bpm)Cl][Cp^*RhCl_3]$ (**3c**) | 8.07 | 5.84 | 1.69 (s) | 1.61 (br. s) |

The complexes **1c** and **2c** contain the novel anion $[Cp^*IrCl_3]^-$. Complex **3c** contains the analogous anion $[Cp^*RhCl_3]^-$ which has been reported recently by Severin et al.[33] as the anion in the ruthenium complex $[Cp^*Ru(C_6H_6)][Cp^*RhCl_3]$.[33] The $[Cp^*RhCl_3]^-$ anion has also been observed in equilibrium in solution with the hydrazine-bridged dimer $[(Cp^*RhCl_2)_2(\mu\text{-}NH_2NHMe)]$ by Maitlis et al.[34]

The relative binding strengths of the N-donor ligands correlates to the nature of the products formed on reaction with the dimeric Ir/Rh starting materials. The strongly coordinating bim ligand brings about the complete dissociation of the metal precursor dimer ($[Cp^*IrCl_2]_2$) and primarily formation of the product monomer, [Cp*IrCl-

(bim)]$^+$Cl, **2a**. The more weakly coordinating bpm ligand leads to the formation of bimetallic ion pairs, [Cp*MCl(bpm)][Cp*$MCl_3$] **1c** and **3c**. The mesBIAN ligand is unable to bind to Ir with sufficient strength to split the iridium precursor dimer, due to both the weaker binding ability of the imine N-donors and the large steric bulk imparted by the mesityl groups. The complexes **1c**–**3c**, which contain bimetallic pairs, are of interest from the perspective of coordination chemistry. For the purposes of catalysis, the fact that molecules **1c**–**3c** contain two metal centres makes them inefficient in terms of the proportion of metal involved, as only the cationic fragment of the metal complex is catalytically active. To increase the efficiency of the synthesis with respect to the quantity of metal used, the complexes incorporating the alternate counterion $BF_4^-$ were synthesised.

### Solid-State Structures of 1c, 2c and 3c

The solid-state structures of **1c**, **2c** and **3c** with thermal ellipsoids at the 50% probability level are shown in Figure 2. Selected bond lengths and angles for **1c**, **2c** and **3c** are presented in Table 2 and crystal structure and refinement data are given in Table 5.

The cationic fragments of **1c**, **2c** and **3c** have very similar structures. The metal centres of **1c**, **2c** and **3c** exist in the piano-stool conformation with the six-membered metallocycle formed by coordination of the bidentate ligands to the metal centres in each case existing in the boat configuration. The N–M–N angles for **1c**, **2c** and **3c** are between 83.8(2)° and 85.25(9)°, which is significantly larger than the values for related [IrCp*Cl(N–N)][X] complexes reported in the literature, where the N–N ligand defines a five-membered metallocycle (values of between 75.6 and 77.5° have been reported previously).[32,23,27,31] The N–M–N bite angles are, however, similar to those reported for other Ir complexes containing the bim and bpm ligand (values of 85.9° and 86.8°).[35,36] N–M–Cl angles of between 85.06(15)° and 88.56(7)° for **1c**, **2c** and **3c** are consistent with literature values of between 83.1° and 91.9° for similar complexes.[32,23,27] The M–N distances in each of the complexes are also comparable to those previously reported in the literature with M–N(pyrazole) distances of 2.107(4) and 2.114(2) Å for **1c** and **3c** respectively and a slightly shorter Ir–N(imidazole) distance of 2.089(5) Å for **2c**. Literature values range from 2.028 and 2.230 Å depending on the nature of the N-donor ligand.[15,23,24,26]

In all of the solid-state structures for **1c**–**3c**, the anions [Cp*$MCl_3$]$^-$ have the same piano-stool geometry described by the three chloride atoms and the $\eta^5$-Cp* ligand around the iridium(III) or rhodium(III) metal centres. The piano-stool geometry is frequently reported for Cp* iridium(III) or rhodium(III) complexes.[24,26,37] The equivalent conformation was also previously observed for the anion of the complex [Cp*Ru($C_6H_6$)][Cp*$RhCl_3$].[33] The M–Cl bond lengths reported for this complex were between 2.409 and 2.434 Å, which are comparable to the M–Cl bond lengths of between 2.4100(16) and 2.4335(7) Å for the anions of complexes **1c**–**3c**.

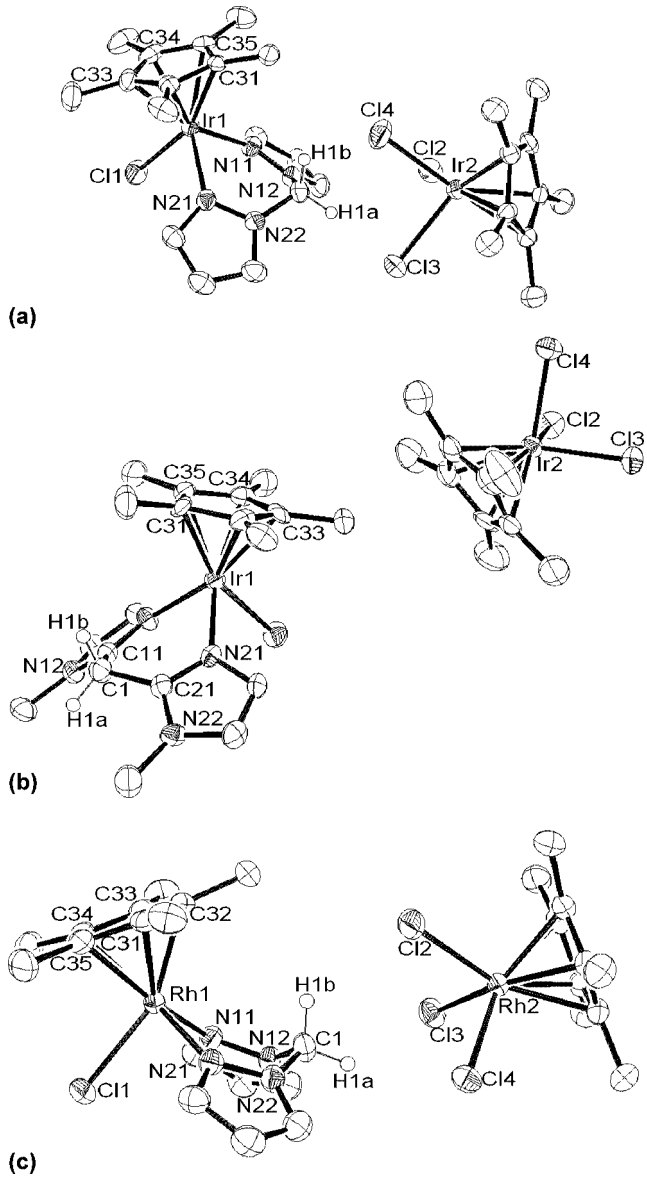

Figure 2. ORTEP depiction of (a) [Cp*IrCl(bpm)][Cp*$IrCl_3$] (**1c**); (b) [Cp*IrCl(bim)][Cp*$IrCl_3$] (**2c**); and (c) [Cp*RhCl(bpm)]-[Cp*$RhCl_3$] (**3c**) at 50% thermal ellipsoids for the non-hydrogen atoms.

### Synthesis of Complexes [Cp*MCl(N–N)][$BF_4$] 1b, 2b, 3b, 4b, 5b, 6b, 7b and 8b

Treatment of toluene suspensions of [$MCp^*Cl_2$]$_2$ with two molar equivalents of a bidentate nitrogen donor ligand (N–N) and two molar equivalents of $NaBF_4$ in MeOH at room temperature resulted in the formation of the complexes [Cp*IrCl(N–N)]$BF_4$, [N–N = bpm (**1b**), bim (**2b**) and dmbpm (**5b**), bik (**6b**), mesBIAN (**7b**) and mesim-mim (**8b**)] and [Cp*RhCl(N–N)]$BF_4$, [N–N = bpm (**3b**), bim (**4b**)] in good to moderate yields (Scheme 2). Selected $^1$H NMR

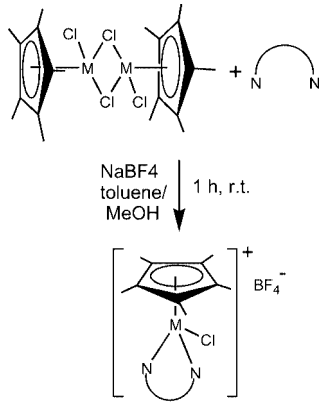
[a] Estimated standard deviation in the least significant figure are given in parentheses.

chemical shifts for these complexes are presented in Table 3. As already observed for the complexes **1c**–**3c**, the two methylene protons ($H_a$ and $H_b$) of the bridging carbon atoms of the bidentate ligands of the complexes **1b**–**5b** exist in very different magnetic environments, with the $^1H$ NMR chemical shifts for $H_a$ protons being significantly deshielded. The $^1H$ chemical shift of the resonance due to the -$CH_3$ groups of the Cp* ligand of complex **7b** (at $\delta$ = 1.27 ppm) is shifted significantly relative to that of the corresponding resonances of the other iridium complexes in this series (complexes **1b**–**5b**), which lie between 1.53 and 1.59 ppm, most likely a result of ring current effects due to the mesityl substituents on the mesim-mim ligand.



**1b**: M = Ir, N-N = bpm
**2b**: bim
**5b**: dmbpm
**6b**: bik
**7b**: mesBIAN
**8b**: mesim-im
**3b**: M = Rh, N-N = bpm
**4b**: bim

Scheme 2.

Table 3. Selected chemical shifts for complexes **1b**–**8b**.

| Compound | $\delta$ (ppm) $H_a$ | $H_b$ | Cp* |
|---|---|---|---|
| [Cp*Ir(bpm)Cl]$BF_4$ (**1b**) | 7.03 | 5.68 | 1.56 (br. s) |
| [Cp*Ir(bim)Cl]$BF_4$ (**2b**) | 4.52 | 4.14 | 1.59 (s) |
| [Cp*Rh(bpm)Cl]$BF_4$ (**3b**) | 7.28 | 6.00 | 1.71 (br. s) |
| [Cp*Rh(bim)Cl]$BF_4$ (**4b**) | 4.47 | 4.16 | 1.60 (s) |
| [Cp*Ir(dmbpm)Cl]$BF_4$ (**5b**) | 6.48 | 5.67 | 1.56 (s) |
| [Cp*Ir(bik)Cl]$BF_4$ (**6b**) | – | – | 1.53 (s) |
| [Cp*Ir(mesBIAN)Cl]$BF_4$ (**7b**) | – | – | 1.27 (s) |
| [Cp*Ir(mesim-mim)Cl]$BF_4$ (**8b**) | – | – | 1.49 (s) |

The [Cp*IrCl(N–N)]$BF_4$ complex **7b** (N–N = mesBIAN) was made in good yield, however, the synthesis of the corresponding rhodium complex was unsuccessful. This was attributed to the steric bulk of the mesityl groups on this ligand, which may hinder binding of the ligand to the rhodium metal centre.

The interconversion of the bimetallic ion pair **1c** to **1b**, the analogous $BF_4^-$ salt, was investigated. A toluene solution of **1c**, 1 equivalent of bpm and 1 equivalent of $NaBF_4$ with a small amount of MeOH was stirred at room temperature. **1b** was isolated from the reaction mixture as the only product and its identity was confirmed using $^1H$ and $^{13}C$ NMR spectroscopy. The addition of MeOH to the reaction is necessary for the conversion of $[IrCp^*Cl_3]^-$ and anion exchange to occur as both $BF_4^-$ and $Cl^-$ are poorly solubilised by toluene.

**Solid-State Structures of 2b, 7b and 8b**

Crystals suitable for X-ray structure determination were obtained for **2b**, **7b** and **8b** and ORTEP depictions of their solid-state structures are depicted in Figure 3. Selected bond lengths and angles for **2b**, **7b** and **8b** are presented in Table 4, and crystal structure and refinement data are given in Table 6.

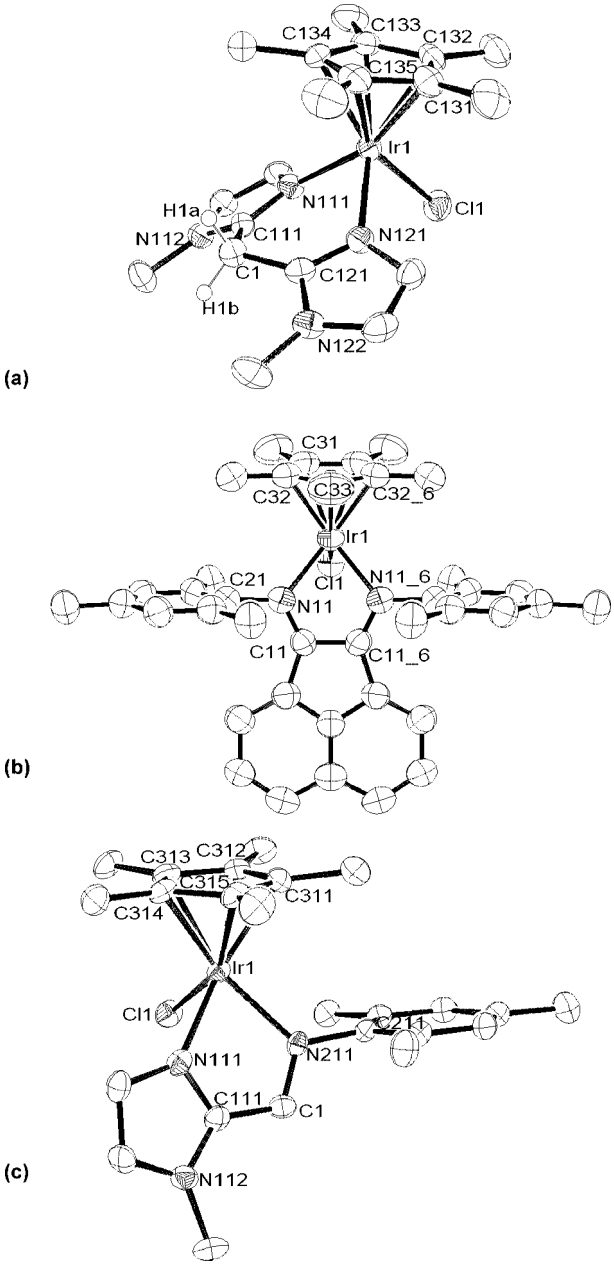

Figure 3. ORTEP depiction of (a) $[Cp^*IrCl(bim)]^+$ (**2b**); (b) $[Cp^*IrCl(mesBIAN)]^+$ (**7b**) and (c) $[Cp^*IrCl(mesim\text{-}mim)]^+$ (**8b**) at 50% thermal ellipsoids for the non-hydrogen atoms.

The solid-state structure of **2b** is very similar to that of **2c** with comparable N–Ir–N bite angles of 83.51(11)° and 83.8(2)°, respectively, and Ir–N bond lengths of 2.095(3) and 2.101(3) Å for **2b** and 2.089(5) and 2.090(5) Å for **2c**. The two Ir–N bond lengths of **7b** are 2.122(5) Å. The Ir–N bond lengths for complex **8b** are 2.100(5) and 2.121(4) Å for the Ir–N(imidazole) and Ir–N(imine) bonds, respectively. These are comparable to the Ir–N(imidazole) and Ir–N(imine) bond lengths in complexes **2b** and **7b**, respectively. All of the Ir–N bond lengths are comparable to the distances found in the literature for similar complexes (values between 2.076 and 2.128 Å).[23,24,26]

The length of the Ir–Cp* bond was dependent on the nature of the cation as well as the nature of the ligand. The Cp*–Ir bond lengths are slightly larger on average for the $BF_4^-$ salt **2b** (2.144–2.181 Å), compared with the equivalent bond lengths in the bimetallic ion pair **2c** (2.143–2.160 Å). The Cp*–Ir bond length in the solid-state structure of **7b** is significantly longer than in **2b** and **2c** (2.171–2.193 Å) due to the high degree of steric hindrance caused by the bulky mesBIAN ligand. The Cp*–Ir bond lengths for complex **8b** (2.158–2.189 Å) containing the hybrid mesitylimine-imidazole ligand are midway between those of complexes **2b** containing the imidazolium ligand, and **7b** which contains the bulky mesBIAN ligand. The Cp*–Ir bond lengths for all of these complexes are within the range previously described in the literature (2.110–2.195 Å).[23,24]

## Conclusions

Complexes of the type [Cp*MCl(N–N)][X] were synthesised (M = $Rh/Ir^{III}$), with a series of bidentate N-donor ligands. Where N–N was bpm or bim and there was no alternate counterion present, bimetallic complexes formed containing the counterion X = $[Cp^*MCl_3]^-$. In the case of the sterically hindered N-donor ligands, these bimetallic complexes did not form. In the presence of the counterion $BF_4^-$, the complexes where X = $BF_4^-$ were synthesised successfully.

The three dimensional solid-state structures of the cationic fragments of the bimetallic complexes **1c**, **2c** and **3c** were all very similar. Changing the counterion from the $[Cp^*MCl_3]^-$ fragment to the smaller $BF_4^-$ anion, did not significantly change the structure of the cationic fragment. The chemical shift of the resonance due to the -$CH_3$ protons of the Cp* of the Ir complex containing the mesBIAN ligand $[Cp^*IrCl(mesBIAN)]BF_4$ (**7b**) was significantly shifted upfield relative to the same resonance of the remaining Ir complexes, and this was attributed to the presence of the aromatic rings of the mesBIAN ligand.

The catalytic activity of the complexes reported in this paper is currently under investigation and will be reported in a future paper.

## Experimental Section

**General Procedures:** All manipulations of metal complexes and air-sensitive reagents were carried out using standard Schlenk techniques or in a nitrogen- or argon-filled drybox. All solvents were distilled under argon. *n*-Hexane, *n*-pentane and toluene were distilled from sodium benzophenone ketyl. Dichloromethane was dis-

[a] Estimated standard deviation in the least significant figure are given in parentheses.

tilled from calcium hydride. $CD_2Cl_2$ was dried with calcium hydride and vacuum-distilled before use. 1,2,3,4,5-Pentamethylcyclopentadiene was purchased from Lancaster and used without further purification. Iridium(III) chloride hydrate and rhodium(III) chloride hydrate were obtained from Precious Metals Online (PMO) and were used without further purification. $[IrCp^*Cl_2]_2$, $[RhCp^*Cl_2]_2$,[37] bis(1-pyrazolyl)methane,[38] bis(1-methylimidazol-2-yl)methane,[39] bis(1-methylimidazol-2-yl) ketone,[40] bis(2,4,6-trimethylphenylimino)acenapthene[41,42] and 2-formyl-1-methylimidazole[43] were prepared following literature methods.

$^1H$, $^{13}C$ and $^{19}F$ NMR spectra were recorded with Bruker DPX300 and DMX500 spectrometers. All spectra were recorded at 298 K unless otherwise specified. $^1H$ NMR and $^{13}C$ NMR chemical shifts were referenced internally to residual solvent resonances. $^{19}F$ NMR was referenced externally using α,α,α-trifluorotoluene in $CDCl_3$. Melting points were recorded using a Mel-Temp apparatus and are uncorrected. IR spectra were recorded using an ATI Mattson Genesis Series FT-IR spectrometer. Electrospray mass spectra were performed by the Biomedical Mass Spectrometry Facility (BMSF) at the University of New South Wales, Sydney, Australia. Elemental analyses were performed by the Campbell Microanalytical Laboratory at the University of Otago, New Zealand. Single-crystal X-ray structure analyses were obtained at the Research School of Chemistry at the Australian National University, Canberra, Australia.

**Synthesis of [Cp*IrCl(bpm)][Cp*IrCl$_3$] (1c):** A toluene suspension (25 mL) of $[IrCp^*Cl_2]_2$ (90 mg, 0.11 mmol) was stirred for 30 min and a toluene solution (10 mL) of bis(pyrazolyl)methane, bpm (38 mg, 0.25 mmol) was added dropwise. On addition of the ligand, the suspension immediately changed colour from orange–red to yellow. The mixture was stirred for a further 45 min. The yellow solid was collected by filtration, washed with toluene (2 × 5 mL) and dried in vacuo to give the compound as a yellow air stable solid. The solid was recrystallised by slow diffusion of pentane into a $CH_2Cl_2$ solution of the complex to give **1c** as small orange crystals which were suitable for X-ray analysis. Yield: 31% (32 mg). M.p. > 230 °C. $C_{27}H_{38}Cl_4Ir_2N_4$ (944.9): calcd. C 34.32, H 4.05, N 5.93; found C 34.23, H 4.14 N 5.30. IR (KBr): ṽ = 3475 (br), 3111 (m), 2962 (w), 2915 (m), 2341 (w), 1635 (w), 1558 (w), 1421 (vs), 1273 (vs), 1096 (m), 1067 (m), 1031 (m), 772 (m), 754 (m) cm$^{-1}$. MS (ES$^+$, $CH_2Cl_2$): *m*/*z* (%) = 511 (10) [Cp*IrCl(bpm)]$^+$, 363 (100) [Cp*IrCl]$^+$. $^1H$ NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.79 (d, $^3J_{H5\text{-}H4}$ = 2.3 Hz, 2 H, H5), 8.35 (d, $^2J_{Ha\text{-}Hb}$ = 15.1 Hz, 1 H, Ha), 7.60 (d, $^3J_{H3\text{-}H4}$ = 2.3 Hz, 2 H, H3), 6.44 (m, 2 H, H4), 5.67 (d, $^2J_{Ha\text{-}Hb}$ = 15.1 Hz, 1 H, Hb), 1.66 [s, 15 H, $CH_3(Cp^*)_{cation}$], 1.58 [s, 15 H, $CH_3(Cp^*)_{anion}$] ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75 MHz): $\delta$ = 143 (C5), 136 (C3), 107 (C4), 88 (Cp*), 84 ($CH_2$), 8.8 [$CH_3$(Cp*)], 8.6 [$CH_3$(Cp*)] ppm.

**Synthesis of [Cp*IrCl(bim)][Cp*IrCl$_3$] (2c) and [Cp*IrCl(bim)]Cl (2a):** A toluene suspension (25 mL) of $[IrCp^*Cl_2]_2$ (99 mg, 0.11 mmol) was stirred for 30 min. A toluene solution (10 mL) of bis(1-methylimidazol-2-yl)methane, bim, (43 mg, 0.24 mmol) was then added dropwise and the mixture was stirred for 45 min. The yellow solid was collected by filtration, washed with toluene (2 × 5 mL) and recrystallised from dichloromethane and pentane. A yellow powder was isolated by filtration and dried in vacuo. This crude compound was a mixture of [Cp*IrCl(bim)]Cl and [Cp*IrCl(bim)][Cp*IrCl$_3$] and was recrystallised by slow diffusion of petroleum into a $CH_2Cl_2$ solution of the complex. Two sets of analytically pure crystals were obtained; microcrystalline yellow [Cp*IrCl(bim)]Cl Yield: 28% (40 mg) and large red cubic crystals of [Cp*IrCl(bim)][Cp*IrCl$_3$]$_3$. Yield: 17% (16 mg). The crystals of **2a** and **2c** were separated physically. The red cubic crystals of **2c** were suitable for X-ray crystal structure analysis.

(d, $^2J_{Hb-Ha}$ = 19.2 Hz, 1 H, Ha), 4.73 (d, $^2J_{Ha-Hb}$ = 19.2 Hz, 1 H, Hb), 4.04 (s, 6 H, N–$CH_3$), 1.61 [s, 15 H, $CH_3(Cp^*)_{cation}$], 1.54 [s, 15 H, $CH_3(Cp^*)_{anion}$] ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75 MHz): $\delta$ = 141.8 (C2), 128.1 (C4), 122.5 (C5), 86.9 (Cp), 35.9 (N–$CH_3$), 25.2 ($CH_2$), 8.8 [$CH_3(Cp^*)$] ppm.

**Synthesis of [Cp*RhCl(bpm)][Cp*RhCl$_3$] (3c):** $[RhCp^*Cl_2]_2$ (215 mg, 0.35 mmol) and bpm (383 mg, 2.5 mmol) were suspended in toluene and stirred for 3 h. The orange-brown solid which formed was collected by filtration and was recrystallised by layering a $CH_2Cl_2$ solution of the compound with pentane. The product crystallised both as large red plates and small orange crystals. Both crystal forms were found to be analytically pure [Cp*RhCl(bpm)][Cp*RhCl$_3$]. The red plates of [Cp*RhCl(bpm)][Cp*RhCl$_3$] were suitable for X-ray crystal structure analysis. Yield: 32% (105 mg). M.p. > 310 °C. IR (KBr disc): $\tilde{\nu}$ = 3409 (br), 3120 (w), 2965 (w), 1635 (m), 1522 (m), 1489 (m), 1458 (m), 1403 (s), 1375 (m), 1288 (s), 1264 (m), 1096 (s), 1058 (s), 1017 (s), 799 (s), 168 (s) cm$^{-1}$. $^1H$ NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.76 (d, $^3J_{H5-H4}$ = 2.5 Hz, 2 H, H5), 8.07 (d, $^2J_{Hb-Ha}$ = 15.1 Hz, 1 H, Ha), 7.60 (d, $^3J_{H3-H4}$ = 2.3 Hz, 2 H, H3), 6.39 (m, 2 H, H4), 5.84 (d, $^2J_{Ha-Hb}$ = 15.1 Hz, 1 H, Hb), 1.69 [s, 15 H, $CH_3(Cp^*)_{cation}$], 1.61 [br. s, 15 H, $CH_3(Cp^*)_{anion}$] ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75 MHz): $\delta$ = 145.0 (C5), 137.5 (C3), 108.3 (C4), 97.3 (d, $^1J_{Rh-Cp^*}$ = 8.7 Hz, Cp), 64.3 ($CH_2$), 9.8 (Cp–$CH_3$), 9.6 [$CH_3(Cp^*)$] ppm.

**Synthesis of [Cp*IrCl(bpm)]BF$_4$ (1b):** $[IrCp^*Cl_2]_2$ (53 mg, 0.067 mmol) was suspended in toluene (10 mL) and stirred for 10 min. A toluene (5 mL) solution of bpm (23 mg, 0.16 mmol) was added and the mixture was stirred for 30 min before a methanol solution (5 mL) of $NaBF_4$ (14 mg, 0.127 mmol) was added. The solid dissolved to generate a yellow solution which was allowed to stir overnight. The solvent volume was reduced to ca. 5 mL, filtered and layered with pentane (10 mL). The resulting precipitate was collected by filtration, washed with pentane (5 mL) and dried in vacuo to give [Cp*IrCl(bpm)]BF$_4$ as a yellow solid. Yield: 53% (42 mg). M.p. 275–285 °C. $C_{17}H_{23}Cl_1BF_4Ir_1N_1$ (597.2): calcd. C 34.15, H 3.88, N 9.37; found C 34.18, H 3.91, N 9.14. IR (KBr disc): $\tilde{\nu}$ = 3649 (w), 3427 (br), 3119 (m), 3081 (m), 2984 (w), 2913 (w), 1636 (m), 1489 (w), 1456 (m), 1418 (s), 1288 (s), 1277 (m), 1084 (vs), 989 (vs), 764 (m) cm$^{-1}$. MS (ES$^+$, $CH_2Cl_2$): *m/z* (%) = 511 (100) [Cp*IrCl(bpm)]$^+$), 509 (80), 513 (80). $^1H$ NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.07 (d, $^3J_{H5-H4}$ = 2.7 Hz, 2 H, H5), 7.58 (d, $^3J_{H3-H4}$ = 2.5 Hz, 2 H, H3), 7.03 (d, $^2J_{Hb-Ha}$ = 14.5 Hz, 1 H, Ha), 6.43 (dd, $^3J_{H5-H4}$ = 2.7 Hz, $^3J_{H5-H4}$ = 2.5 Hz, 2 H, H4), 5.68 (d, $^2J_{Ha-Hb}$ = 14.5 Hz, 1 H, Hb), 1.56 [br. s, 15 H, $CH_3(Cp^*)$] ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75 MHz): $\delta$ = 144.8 (C3), 135.0 (C5), 108.7 (C4), 88.8 (Cp*), 62.7 ($CH_2$), 8.7 [$CH_3(Cp^*)$] ppm. $^{19}F$ NMR ($CD_2Cl_2$, 282.41 MHz): $\delta$ = –151.4 ppm.

**Synthesis of [Cp*IrCl(bim)]BF$_4$ (2b):** $[IrCp^*Cl_2]_2$ (58.8 mg, 0.073 mmol), bim (27.2 mg, 0.154 mmol) and $NaBF_4$ (19.2 mg, 0.175 mmol) were dissolved in toluene (10 mL) and MeOH (5 mL) and stirred for 2 h. The solution was reduced in volume, filtered and layered with pentane. The product was allowed to precipitate overnight, collected by filtration, washed with pentane and dried in vacuo to isolate [Cp*IrCl(bim)]BF$_4$ as a yellow powder. Yield: 73% (67.3 mg). Yellow crystals of [Cp*IrCl(bim)]BF$_4$ obtained by layering a $CH_2Cl_2$ solution of **2b** with petroleum in air were suitable for X-ray crystal structure analysis. M.p. 273–278 °C. $C_{19}H_{27}ClBF_4IrN_4{\cdot}H_2O$ (625.9): calcd. C 35.44, H 4.54, N 8.70; found C 35.81, H 4.37, N 8.73%. MS (ES$^+$, $CH_2Cl_2$): *m/z* (%) = 554 (100), 552 (95), 555 (92), 553 (90) [Cp*IrCl(bik)]$^+$), 551 (50). $^1H$ NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 7.52 (d, $^3J_{H5-H4}$ = 1.10 Hz, 2 H, H4 or H5), 7.36 (d, $^3J_{H5-H4}$ = 1.10 Hz, 2 H, H4 or H5), 4.23 (s, 6 H, N–Me) 1.53 [s, 15 H, $CH_3(Cp^*)$] ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75 MHz): $\delta$ = 172.7 (C=O), 132.7 (C2), 129.9 (C4), 128.0 (C5), 88.5 (Cp*), 38.2 (N–Me), 8.3 [$CH_3(Cp^*)$] ppm. $^{19}F$ NMR ($CD_2Cl_2$, 282.41 MHz): $\delta$ = –153.9 ppm

**Synthesis of [Cp*IrCl(mesBIAN)]BF$_4$ (7b):** A toluene (20 mL) suspension of $[IrCp^*Cl_2]_2$ (110.5 mg, 0.139 mmol) was stirred for 30 min prior to the addition of a toluene solution (5 mL) of 1,2-bis(2,4,6-trimethylphenylimino)acenapthene, mesBIAN, (129.2 mg, 0.310 mmol). The suspension was stirred for 30 min before drop wise addition of a MeOH/toluene solution (5 mL, 1: 4) of $NaBF_4$ (34.1 mg, 0.310 mmol). The dark brown solution was stirred overnight; the solvent was removed in vacuo to give a brown solid. The solid was recrystallised from $CH_2Cl_2$, by slow diffusion of pentane. Dark brown crystals of [Cp*IrCl(mesBIAN)]BF$_4$ were collected,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

washed with pentane (2 5 mL) and dried. Yield: 54% (129 mg). The dark brown crystals of **6b** obtained were suitable for X-ray crystal structure analysis. M.p. > 230 °C. $C_{40}H_{43}BClF_4IrN_2{\cdot}H_2O{\cdot}CH_2Cl_2{\cdot}CH_3OH$[44] (1001.3): calcd. C 50.38, H 5.13, N 2.80; found C 50.07, H 4.75, N 2.80%. IR (KBr disc): $\tilde{\nu}$ = 3629 (w), 3588 (w), 3433 (br), 2917 (w), 2361 (w), 1624 (w), 1064 (m),1473 (m) 1436 (m), 1417 (m), 1382 (m), 1302 (m), 1058 (vs), 1031 (vs), 778 (m) $cm^{-1}$. MS ($ES^+$, $CH_2Cl_2$): *m*/*z* (%) = 782 (100) [Cp*IrCl(mesBIAN)]$^+$), 783 (60), 784 (10), 743 (10). $^1H$ NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.19 (d, $^3J_{H5\text{-}H4}$ = 8.4 Hz, 2 H, H5), 7.55 (m, 2 H, H4), 7.23 (s, 2 H, H10), 7.10 (s, 2 H, H12), 6.89 (d, $^3J_{H3\text{-}H4}$ = 7.3 Hz, 2 H, H3), 2.48 (s, 6 H, *o*-Me), 2.46 (p, 6 H, *p*-Me), 1.92 (s, 6 H, *o*′-Me), 1.27 [s, 15 H, $CH_3$(Cp*)] ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75 MHz): $\delta$ = 178.7 (C1), 145.0 (C7), 142.1 (C8), 139.9 (C11), 133.2 (C5), 132.0 (C6), 131.7 (C9), 131.5 (C10), 130.6 (C12), 130.0 (C4), 129.2 (C13), 126.8 (C2), 125.5 (C3), 93.5 (Cp*), 21.3 (*p*-Me), 20.5 (*o*-Me), 18.6 (*o*′-Me), 8.6 [$CH_3$(Cp*)] ppm. $^{19}F$ NMR ($CD_2Cl_2$, 282.41 MHz): $\delta$ = –154.0 (br. s, $BF_4$) ppm.

**Synthesis of [(2,4,6-Trimethylphenyl)imino](1-methyl-2-imidazolyl)-methane:** 2-Formyl-1-methylimidazole (1.38 g, 12.5 mmol) and 2,4,6-trimethylaniline (4 mL, 26.5 mmol) were dissolved in ethanol (12 mL) and heated to reflux for 3 h. The solvent was removed in vacuo to give a brown oil which was purified by kugelrohr distillation. The product [(2,4,6-trimethylphenyl)imino](1-methyl-2-imidazolyl)methane was obtained as a viscous yellow oil. Yield: 25% (878 mg). $C_{14}H_{17}N_3$ (227.3): calcd. C 73.98, H 7.54, N 18.49; found C 73.49, H 7.88, N 17.73. MS (GC-EI, $CH_2Cl_2$): *m*/*z* (%) = 120 (100), 135 (90) [$M^+$]. $^1H$ NMR ([$D_6$]acetone, 300 MHz): $\delta$ = 8.18 (s, 1 H, N=CH), 7.27 (s, 1 H, H5), 7.12 (s, 1 H, H4), 6.87 (s, 2 H, *m*-H), 4.14 (s, 3 H, N–Me), 2.23 (s, 3 H, *p*-Me), 2.11 (s, 6 H, *o*-Me) ppm. $^{13}C\{^1H\}$ NMR ([$D_6$]acetone, 75 MHz): $\delta$ = 154.8 (N=CH), 148.4 (C7), 142.9 (C1), 129.4 (C4), 128.6 (*p*), 128.5 (*o*), 126.5 (*o*), 126.0 (C5), 35.0 (N–Me), 19.9 (*p*-Me), 17.6 (*o*-Me) ppm.

**Synthesis of [Cp*IrCl(mesim-mim)]$BF_4$ (8b):** $[IrCp^*Cl_2]_2$ (75.6 mg, 0.095 mmol) and 2,4,6-trimethylphenylimino-(1-methyl-2-imidazolyl)methane (**7**) (86.3 mg, 0.400 mmol) were dissolved in toluene (10 mL) and stirred for 30 min prior to the addition of a methanol solution (5 mL) of $NaBF_4$ (24.2 mg, 0.221 mmol). The dark orange solution was stirred for 2 h before the volume was reduced, filtered and the solution was layered with pentane (10 mL). Orange crystals of [Cp*IrCl(mesim-mim)]$BF_4$ were collected in air and dried. Yield: 38% (49.1 mg) M.p. 283–288 °C. $C_{24}H_{32}BClF_4IrN_3$ (677.0): calcd. C 42.58, H 4.76, N 6.21; found C 42.44, H 4.74, N 6.09. IR (KBr disc): $\tilde{\nu}$ = 3853 (w), 3736 (w), 3394 (br), 3153 (w), 2190 (m), 1584 (m), 1488 (m), 1424 (s), 1386 (m), 1309 (m), 1298 (m), 1142 (m), 1061 (vs), 989 (m), 853 (m), 782 (m) $cm^{-1}$.

MS ($ES^+$, $CH_2Cl_2$): *m*/*z* (%) = 590 (100) [Cp*IrCl(mesim-mim)]$^+$) 588 (80), 592 (50). $^1H$ NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.57 (s, 1 H, H6), 7.42 (d, $^3J_{H5\text{-}H4}$ = 1.51 Hz, 1 H, H5) 7.32 (d, $^3J_{H4\text{-}H5}$ = 1.51 Hz, 1 H, H4), 6.96 (s, 1 H, H10), 6.93 (s, 1 H, H12), 3.99 (s, 3 H, N–Me), 2.26 (s, 3 H, *p*-Me), 2.20 (s, 3 H, *o*′-Me), 2.00 (s, 3 H, *o*-Me), 1.49 [s, 15 H, $CH_3$(Cp*)] ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 75 MHz): $\delta$ = 156.6 (C6), 149.8 (C2), 144.7 (C8), 138.5 (C11), 131.9 (C13), 130.0 (C12), 129.9 (C9), 128.6 (C4), 128.3 (C5), 89.7

### X-ray Crystallography

Details of the crystals and their refinements are given in Table 5 and Table 6. CCDC- 291178, -291179, -291180, -291478, -609638 and -609639 contain the supplementary crystallographic information for **1c**, **7b**, **2c**, **3c**, **8b** and **2b**, respectively. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We gratefully acknowledge financial support from The University of New South Wales, The Australian Research Council and the Australian government for an Australian Postgraduate Award (D.F.K.). We acknowledge Bradley Man for assistance.

# Synthesis and Characterisation of Dinuclear Nickel(II) and Cadmium(II) Complexes of *N*-Alkylated Derivatives of Hexaazadithiophenolate Macrocycles

**Mathias Gressenbuch[a] and Berthold Kersting*[a]**

**Keywords:** Macrocyclic ligands / N ligands / S ligands / Nickel / Cadmium

The effect of *N*-alkylation on the ligating properties of the Robson-type 24-membered hexaazadithiophenolate macrocycle $H_2L^1$ [13,27-bis(*tert*-butyl)-3,6,9,17,20,23-hexaazatricyclo[23.3.1$^{11,15}$]triaconta-1(28),11,13,15(30),25,26-hexaene-29,30-dithiol] has been examined. Two new derivatives ($H_2L^3$ and $H_2L^4$) of $H_2L^1$ have been prepared. $H_2L^3$ is a dimethylated derivative of $H_2L^1$ and $H_2L^4$ is a tetraethylated derivative of $H_2L^3$. A series of complexes of the type $[(L^R)M^{II}_2(\mu\text{-}Cl)]^+$ [R = 1, M = Cd (**10**), R = 3, M = Ni (**8**), M = Cd (**12**), R = 4, M = Ni (**9**), M = Cd (**13**)] have been prepared and structurally characterised. The X-ray crystal structure determination of these dioctahedral complexes with an $N_3M(S)_2(\mu\text{-}Cl)MN_3$ core structure has revealed two conformations of the supporting ligands. In **8**, **9**, **10** and **12** the ligands adopt a folded $C_s$-symmetric conformation of type A whereas in the cadmium complex **13** the alternative $C_{2v}$-symmetric "bowl-shaped" conformation (type B) is present. A structural comparison has allowed us to determine the factors that determine the ligand conformations. It has been established that the ligand conformations adopted depend not only on the co-ligand but also on the metal ion radius and the *N*-alkylation grade.

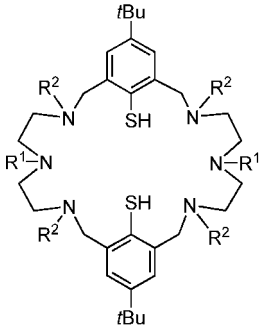
## Introduction

Macrocyclic ligands containing 14 or more ring atoms are known to have a rather flexible structure, and it is often observed that such ligands can adopt several different conformations.[1,2] Typical examples are the $N_4$ macrocycle cyclam and its countless *N*-alkylated derivatives,[3] which can have planar (*trans*) or folded (*cis*) conformations in octahedral complexes.[4–6] It is well-known that the physical and chemical properties of macrocyclic complexes are highly dependent on the conformations of the supporting ligands. This is of importance for a number of applications, since often only one of several possible conformational isomers exhibits the desired property.[7] Thus, in macrocyclic chemistry it is of importance to establish the factors that are responsible for the stabilisation/destabilisation of the various structural forms.

We recently reported the synthesis of the hexaazadithiophenolate macrocycle $H_2L^1$ and its permethylated derivative



$H_2L^1$ ($R^1 = R^2 = H$)
$H_2L^2$ ($R^1 = R^2 = CH_3$)
$H_2L^3$ ($R^1 = CH_3$, $R^2 = H$)
$H_2L^4$ ($R^1 = CH_3$, $R^2 = CH_2CH_3$)

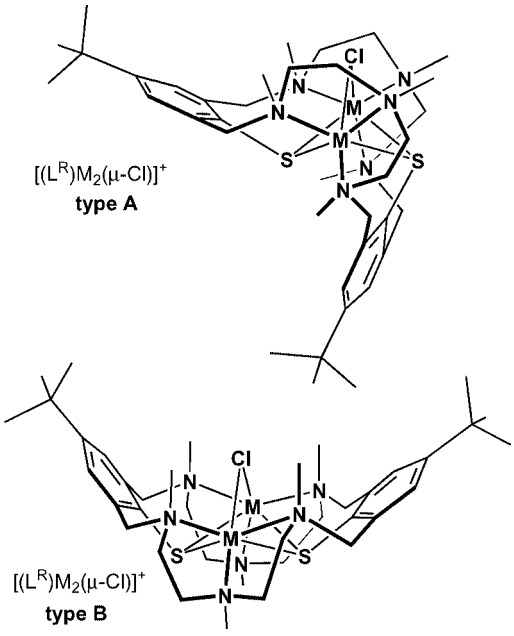
Examination of the structures of the chlorido-bridged $[(L^R)M^{II}_2(\mu\text{-Cl})]^+$ complexes has revealed that the octadentate ligands most often adopt a folded $C_s$-symmetric conformation of type A (e.g. complexes **6** and **7**, see Scheme 2).[11,12] Very recently, however, the alternative $C_{2v}$-symmetric "bowl-shaped" conformation of type B was detected for the chlorido-bridged cadmium complex **11**.[13] These findings encouraged us to look for the factors that determine these ligand conformations.



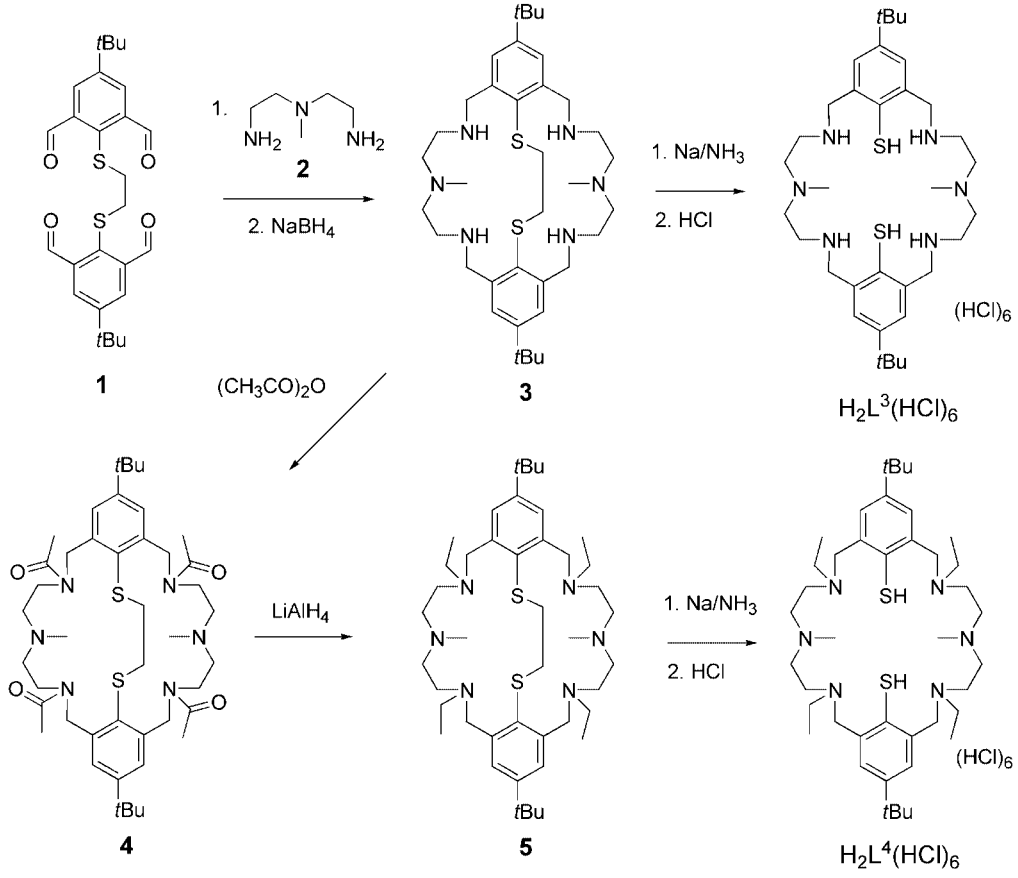
Scheme 2. Schematic representation of the two ligand conformations of the octadentate macrocycles $(L^R)^{2-}$ observed in the chlorido-bridged $[(L^R)M_2(\mu\text{-Cl})]^+$ complexes **6**, **7** and **11**.[11,13]

In this study we describe the synthesis and characterisation of a series of chlorido-bridged Ni and Cd complexes of the type $[(L^R)M_2(\mu\text{-Cl})]^+$ supported by 24-membered hexaazadithiophenolate ligands $(L^R)^{2-}$ with different *N*-alkylation grades and patterns (see Scheme 1 for ligand abbreviations). We have obtained single crystals of the complexes **8**, **9**, **10**, **12** and **13** suitable for X-ray structure determinations, which has allowed us to study the ligating properties of the supporting ligands as a function of the *N*-alkylation grade. The solution-state structures of the cadmium complexes **10**–**13** derived from NMR studies and the solid-state structure of one proligand are also presented.

## Results and Discussion

### Ligand Synthesis

The synthetic route to the new ligands $H_2L^3$ and $H_2L^4$ is outlined in Scheme 3. The bicyclic macrocycle **3** was prepared by a [2 + 1] condensation reaction between tetraaldehyde **1**[14] and bis(aminoethyl)methylamine (**2**) in an etha-



Scheme 3. Synthesis of the ligands $H_2L^3$ and $H_2L^4$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nol/dichloromethane mixed solvent system, followed by reduction of the intermediate imine functions with $NaBH_4$. To prevent the formation of higher condensation products the cyclisation reaction was performed under high dilution conditions. Thus, proligand **3** was obtained in nearly quantitative yield upon workup. Subsequent deprotection of the thioether functions was achieved in the usual way,[14] with sodium in liquid ammonia followed by acidic workup. The second ligand system was prepared according to a protocol used for the alkylation of triazacyclononane[15] and cyclam.[16] Acylation of the four benzylic nitrogen donors of **3** was accomplished with acetic anhydride. The subsequent $LiAlH_4$ reduction of the resulting tetraamide **4** furnished the tetraethylated macrobicycle **5** in good yield. The final deprotection of the masked thiophenolate functions with sodium in liquid ammonia followed by acidic workup gave $H_2L^4$ as its hexahydrochloride salt. These new ligands were obtained in good overall yields without the need for metal templates. All new compounds were characterised by elemental analysis, IR, $^1H$ and $^{13}C$ NMR spectroscopy (see Exp. Sect.), and compound **5** also by X-ray crystallography. The hydrochloride salts of the ligands $H_2L^3$ and $H_2L^4$ could not be obtained in analytically pure form. Nevertheless, they were of sufficient purity for metal complex syntheses.

### Synthesis of Complexes

A series of chlorido-bridged nickel(II) and cadmium(II) complexes of the type $[(L^R)M_2(\mu\text{-}Cl)]^+$ were prepared in order to systematically investigate the effect of *N*-alkylation on metal ion complexation and metal complex structures. The synthesised complexes and their labels are collected in Scheme 1. Of these, $[(L^1)Ni_2(\mu\text{-}Cl)]^+$ (**6**),[11] $[(L^2)Ni_2(\mu\text{-}Cl)]^+$ (**7**)[17] and $[(L^2)Cd_2(\mu\text{-}Cl)]^+$ (**11**)[13] have been reported previously. The complexation reactions of the macrocycles with $NiCl_2{\cdot}6H_2O$ (or $CdCl_2{\cdot}H_2O$) in the presence of triethylamine proceeded smoothly and yielded yellow or colourless solutions of the respective $[(L^R)M_2(\mu\text{-}Cl)]^+$ monocations, which could be readily isolated as their crystalline perchlorate or tetraphenylborate salts. The new compounds gave satisfactory elemental analyses and were characterised by spectroscopic methods (IR, UV/Vis, $^1H$ and $^{13}C$ NMR spectroscopy) and compounds **8**$[BPh_4]$, **9**$[BPh_4]$, **10**$[BPh_4]$, **12**$[BPh_4]$ and **13**$[BPh_4]$ also by X-ray structure analysis.

### Spectroscopic Characterisation: IR and UV/Vis Spectroscopy

The infrared spectra of all compounds display the bands expected for the macrocyclic ligands and counterions, but are not informative with respect to the conformations of the supporting ligands. The electronic absorption spectra of the nickel complexes were recorded in the range 300–1600 nm in acetonitrile solution. Selected spectroscopic data are reported in Table 1. The data for complexes **6** and **7** have been reported previously and are included for comparative purposes.[11] The spectra of the nickel complexes are similar but not identical. Each compound displays three weak absorption bands above 500 nm. The absorption band in the range 620–670 nm can be attributed to the $\nu_2$ transition $[^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)]$ of an octahedral nickel(II) ($d^8$) ion. The bands between 900 and 1100 nm can be assigned to the $\nu_1$ transition $[^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)]$, which is split presumably due to lower symmetry. The slight differences in the positions of the d–d transitions indicate that each complex retains its integrity in solution. This is also supported by the NMR spectroscopic data for the cadmium complexes **10**, **12** and **13** described below.

Table 1. Synthesised complexes, their labels, structure type and selected UV/Vis data.

| Complex | Structure type | $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}\,cm^{-1}$])[a] | Ref. |
|---|---|---|---|
| **6** $[(L^1)Ni_2(\mu\text{-}Cl)]^+$ | A | 625 (58), 894 (54), 941 (56) | [11] |
| **7** $[(L^2)Ni_2(\mu\text{-}Cl)]^+$ | A | 658 (41), 920 (59), 1002 (80) | [11] |
| **8** $[(L^3)Ni_2(\mu\text{-}Cl)]^+$ | A | 623 (76), 902 (63), 960 (68) | this work |
| **9** $[(L^4)Ni_2(\mu\text{-}Cl)]^+$ | A | 675 (31), 928 (62), 1013 (82) | this work |
| **10** $[(L^1)Cd_2(\mu\text{-}Cl)]^+$ | A | | this work |
| **11** $[(L^2)Cd_2(\mu\text{-}Cl)]^+$ | B | | [13] |
| **12** $[(L^3)Cd_2(\mu\text{-}Cl)]^+$ | A | | this work |
| **13** $[(L^4)Cd_2(\mu\text{-}Cl)]^+$ | B | | this work |

[a] The UV/Vis spectra were recorded for the perchlorate salts. Spectra were recorded in $CH_3CN$ solution at 295 K for solutions with a concentration of about $1.0\times10^{-3}$ M for **6** and **7** and $1.9\times10^{-3}$ M for complex **8**.

### NMR Spectroscopy

Selected $^1H$ and $^{13}C$ NMR spectroscopic data for the cadmium complexes **10**, **12** and **13** are presented in Table 2. The data for complex **11** have been reported previously and are included for comparative purposes.[13] The $^1H$ NMR spectra of the dicadmium complexes **10** and **12** are different from those of **11** and **13**. For example, the signals for the aromatic protons and the *tert*-butyl protons are split into two singlets. Similarly, the $^{13}C$ NMR spectra of **10** and **12** display eight signals for the aromatic carbon atoms labelled $C^{11}$–$C^{18}$, whereas only four signals are seen for the respective atoms in **11** and **13**. These data are indicative of a ligand conformation of type A for **10** and **12** and of type B for **11** and **13**. Thus, in contrast to the nickel complexes above, the ligand conformations in the $[(L^R)Cd_2(\mu\text{-}Cl)]^+$ complexes clearly depend on the *N*-alkylation grade. This conclusion is also borne out by the single-crystal X-ray structure determinations of **10**, **12** and **13** described below.

### X-ray Crystallography

The X-ray crystal structures of the proligand **5** and the complexes **8**$[BPh_4]{\cdot}3EtOH$, **9**$[BPh_4]{\cdot}5MeCN$, **10**$[BPh_4]{\cdot}5MeOH$, **12**$[BPh_4]{\cdot}2MeCN$ and $\{$**13**$[BPh_4]{\cdot}3.5MeCN\}_2$ were determined in order to establish the geometries about the metal ions and the bonding modes of the supporting ligands.

[a] Spectra were recorded in $CD_3CN$ (**11**–**13**) or $CD_3OD$ (**10**) solution at 295 K. [b] The resonances for the methylene protons of the ethyl substituents are obscured by the resonances of the ethylene groups. [c] Spectra were recorded in $CD_3CN$ (**11**–**13**) or [$D_6$]DMSO (**10**) solution at 295 K.

### *Compound 5*

The molecular structure of the proligand **5** is shown in Figure 1. The thioether adopts a highly folded conformation that is typical for such large macrocycles.[18] The two phenyl rings are not really coplanar to each other, the dihedral angle being 30.9°. The ethyl substituents bonded to N(3) and N(3′) point into the central cavity, partly filling the void between the phenyl rings. The distance between their centroids amounts to 6.216 Å. There are no unusual features as far as bond lengths and angles are concerned. The C–S sulfur bond lengths involving the $sp^2$-hybridized carbon atoms (C1, C1′) [1.786(2) Å] are shorter than the ones involving the $sp^3$-hybridized carbon atoms [1.820 Å] C22 and C22′. Virtually the same distances are seen in the permethylated derivative.[19]

### *[($L^3$)$Ni^{II}_2$(μ-Cl)][$BPh_4$]·3EtOH (8[$BPh_4$]·3EtOH) and [($L^4$)$Ni^{II}_2$(μ-Cl)][$BPh_4$]·5MeCN (9[$BPh_4$]·5MeCN)*

cations, tetraphenylborate anions and ethanol or acetonitrile molecules of solvent of crystallisation. ORTEP plots of **8** and **9** are displayed in Figures 2 and 3, respectively. The atomic numbering scheme for the central $N_3Ni(\mu\text{-}S)_2(\mu\text{-}Cl)NiN_3$ core in **8** is used throughout to facilitate structural comparisons. Selected bond lengths and angles are listed in Tables 3 and 4. The corresponding values for $[(L^1)Ni_2(\mu\text{-}Cl)]^+$ (**6**) and $[(L^2)Ni_2(\mu\text{-}Cl)]^+$ (**7**) are included for comparative purposes.

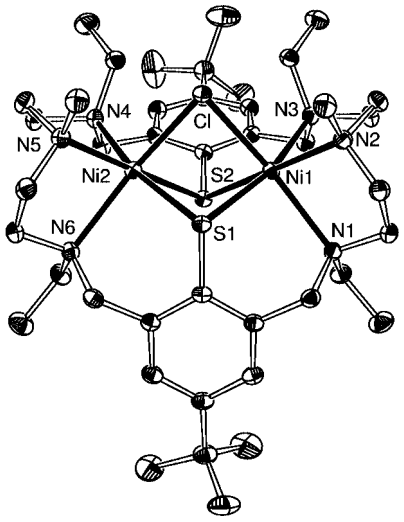

Figure 3. Molecular structure of **9** with atomic numbering for key atoms (30% probability thermal ellipsoids). Hydrogen atoms have been omitted for clarity.

The structures of the chlorido-bridged dinickel(II) complexes **8** and **9** are very similar and, with the exception of the *N*-alkyl substituents, almost superimposable with those of **6** and **7**.[11] The structure of **8** is representative for all complexes. As can be seen from Figure 2, the supporting ligand adopts a saddle-shaped, $C_s$-symmetric conformation that is reminiscent of the "partial-cone" conformation of calixarenes.[20] The metal ions are in a strongly distorted octahedral $N_3S_2Cl$ environment, being coordinated by two sulfur and three facially oriented nitrogen atoms of the macrocycle and a symmetrically bridging chloride ion to give an $N_3Ni^{II}(\mu\text{-}SR)_2(\mu\text{-}Cl)Ni^{II}N_3$ core. The distortions from the ideal octahedral geometry are manifested in the *cis* and *trans* L–M–L bond angles, which deviate by as much as 18.2° from their ideal values (see Table 4). The diethylenetriamine units coordinate facially with one larger and two smaller N–M–N bond angles. This is commonly observed in complexes with this tridentate unit.[21]

As can be seen in Table 3, the metal–ligand bond lengths in **6**–**9** clearly depend on the type of nitrogen donor atoms. Thus, upon conversion of the six secondary amines in **6** to tertiary amine functions in **9**, the average M–N bond length increases by about 0.15 Å. This, in turn, results in a large decrease in the M–Cl bond lengths by about 0.25 Å. In other words, the larger the number of tertiary amine donors the shorter the distance between the metal ions and the co-ligand. Similar effects have been reported for nickel complexes of other azamacrocycles and their peralkylated deriv-

[a] *Average values.* [b] *Average deviations* from the ideal 90° or 180° L–M–L bond angles of a perfect octahedron. [c] There are two crystallogrphically independent molecules in the asymmetric unit. Values in square brackets refer to molecule B.

atives.[22] The dependence of the bond angles on the type of N donors is not so pronounced. The most visible changes across the series include the M–Cl–M bond angles, which increase by around 10° upon going from **6** to **9**. In summary, all $N_6S_2$ macrocycles support the formation of dinuclear nickel complexes of type A. As we will show below, a completely different situation is seen in the case of the cadmium complexes **10**–**13**.

### *Description of the Crystal Structures of [(L¹)Cd$^{II}_2$(μ-Cl)][BPh$_4$]·5MeOH (10[BPh$_4$]·5MeOH) and [(L³)-Cd$^{II}_2$(μ-Cl)][BPh$_4$]·2MeCN (12[BPh$_4$]·2MeCN)*

The crystal structure determinations of the two title compounds revealed the presence of dioctahedral complex cations, tetraphenylborate anions and methanol or acetonitrile molecules of solvent of crystallisation. ORTEP plots of **10**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and **12** are displayed in Figures 4 and 5, respectively. Selected bond lengths and angles are collected in Tables 3 and 4. The structure of the $[(L^2)Cd_2^{II}(\mu\text{-}Cl)]^+$ complex **11** has been reported previously,[13] and its metrical parameters are also given for comparison. The conformation adopted by the supporting ligands in **10** and **12** is that of type A. For reasons that are still unclear, however, the configuration at N(3) in **12** is opposite to that found in **10** and in the nickel complexes above. Each cadmium atom is coordinated by two S and three N atoms from the supporting ligand and a bridging chloride in a severely distorted octahedral fashion. The distortions from the ideal octahedral geometry are somewhat more pronounced than in the nickel complexes above and in the cadmium complexes of type B described below, which is probably a consequence of the larger ionic radius of cadmium(II) (Cd$^{II}$: 1.06 Å; Ni$^{II}$: 0.83 Å).[23] The average Cd–N bond lengths of 2.390(5) (**10**) and 2.399(7) Å (**12**) are normal for six-coordinate cadmium complexes with amine donors.[24,25] The same holds for the average Cd–S [2.671(2) and 2.647(2) Å][26] and Cd–Cl distances [2.701(3) and 2.770(1) Å].[27–29] As expected, the Cd–N(secondary amine) distances in **10** and **12** are shorter (by about 0.04 Å) than the corresponding Cd–N(tertiary amine) bonds in **11** and **13**. The same trend was observed in the series of nickel complexes above.

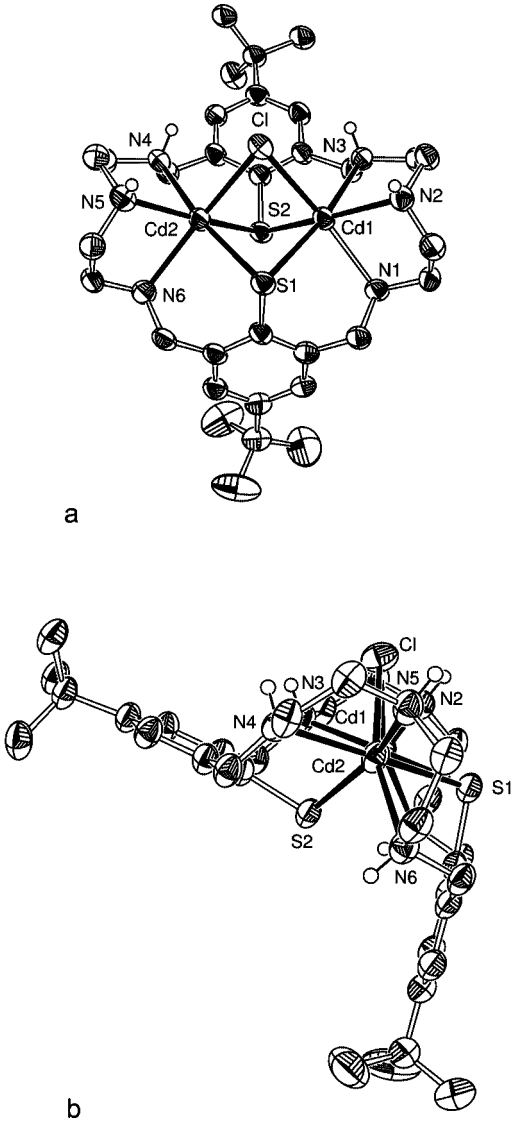

Figure 4. Two perspective views of the molecular structure of **10** with atomic numbering for key atoms (30% probability thermal ellipsoids). Hydrogen atoms (except those bonded to N atoms) have been omitted for clarity.

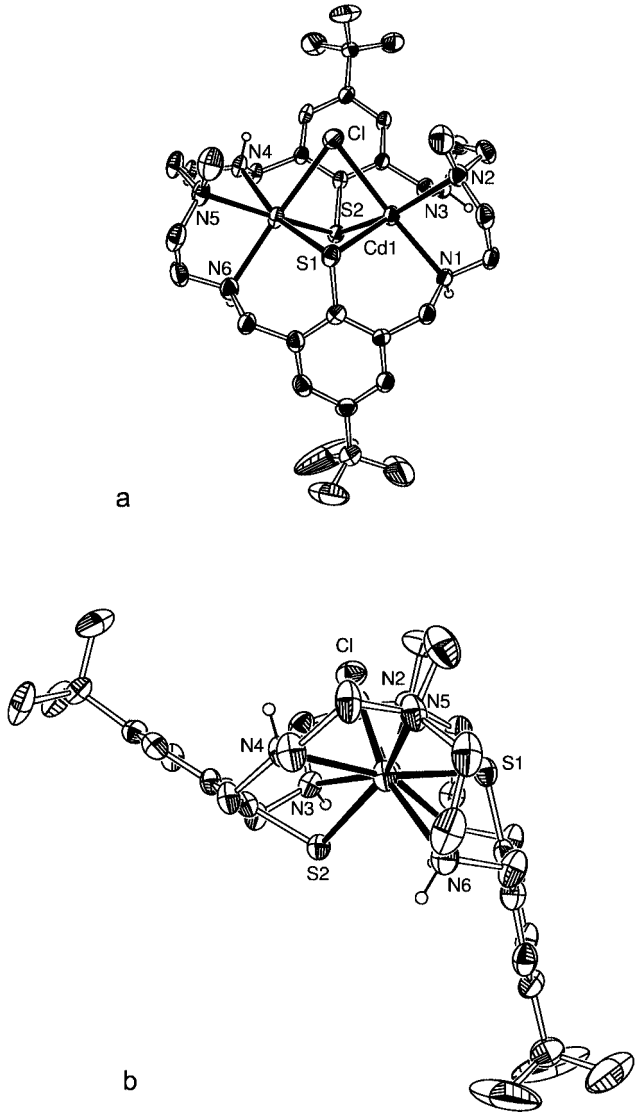

Figure 5. Two perspective views of the molecular structure of **12** with atomic numbering for key atoms (30% probability thermal ellipsoids). Hydrogen atoms (except those bonded to N atoms) have been omitted for clarity.

### *Description of the Crystal Structure of {[(L$^4$)Cd$^{II}_2$(μ-Cl)][BPh$_4$]·3.5MeCN}$_2$ {13[BPh$_4$]·3.5MeCN}$_2$*

Crystals of the title complex grown from a mixed acetonitrile/ethanol solution are monoclinic with space group $P2_1/n$. The asymmetric unit contains two crystallographically independent molecules. A perspective view of the structure of molecule A is displayed in Figure 6. The structure of molecule B is identical to that of molecule A and is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

not considered further. The $[(L^4)Cd_2(\mu\text{-}Cl)]^+$ complex **13** is isostructural with the $[(L^2)Cd_2(\mu\text{-}Cl)]^+$ cation **11**, with the macrocycle having a type-B conformation. There are no unusual features as far as bond lengths and angles are concerned. The average Cd–(μ-Cl) [2.661(1) Å], Cd–N [2.436(4) Å] and Cd–S [2.681(1) Å] bond lengths are very similar to the corresponding values in **11**. As in **11**, the two metal ions are coordinated in a distorted octahedral fashion by the two *fac*-$N_3(\mu\text{-}S)_2$ donor sets of the doubly deprotonated macrocycle and the bridging chloride. The diethylene triamine units are facially coordinated, with one larger and two smaller N–M–N bond angles. The same situation is observed in **11** and other complexes with this tridentate unit.[21] Likewise, the M–N bond lengths involving the four benzylic nitrogen donors are invariably longer (by around 0.1 Å) than the ones comprising the central nitrogen atoms of the linking diethylenetriamine units. This is also normal for complexes of this ligand system. The most salient feature of the structure of **13** is that $(L^4)^{2-}$ adopts a bowl-shaped, $C_{2v}$-symmetric conformation, an effect that may be traced to the more optimal L–Cd–L bond angles. In fact, it can be readily seen from Table 4 that there is a consistent decrease in the deviations of the *cis*- and *trans*-L–Cd–L bond angles upon going from **12** to **13** (or from **10** to **11**). Thus, for the present $[(L^R)M_2(\mu\text{-}Cl)]^+$ complexes the conformation adopted depends not only on the *N*-alkylation grade but also on the metal ion radius.

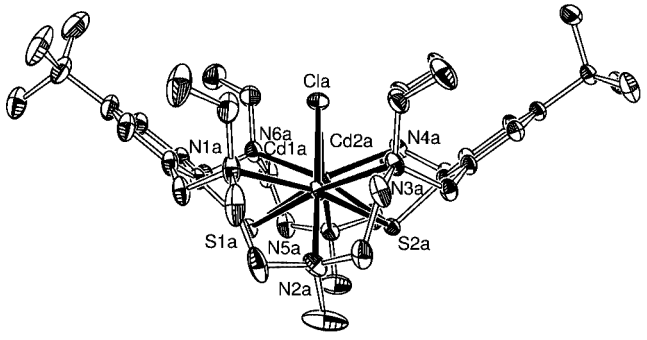

Figure 6. Molecular structure of **13** with atomic numbering for key atoms (30% probability thermal ellipsoids). Hydrogen atoms have been omitted for clarity.

## Conclusions

The main findings of this investigation are as follows: a) *N*-alkylated variants of $H_2L^1$ with different *N*-alkylation grades and patterns can be readily prepared by a [2 + 1] condensation reaction of tetraaldehyde **1** with bis(aminoethyl)methylamine followed by acylation and reduction of the resultant hexaamine dithioether compound **3**. b) All ligand systems are effective dinucleating ligands that support the formation of dioctahedral $[(L^R)M_2(\mu\text{-}Cl)]^+$ cations (M = $Ni^{II}$ and $Cd^{II}$). c) The macrocycles adopt either a saddle-shaped (type A) or a bowl-shaped (type B) conformation. d) The actual conformation adopted depends not only on the type of co-ligand,[30] but also on the metal ion radius and the *N*-alkylation grade. Two trends are apparent for the present $[(L^R)M_2(\mu\text{-}Cl)]^+$ cations. In the case of small metal ions such as $Ni^{II}$, the conformation is always that of type A, irrespective of the *N*-alkylation grade, whereas for the larger $Cd^{II}$ ion a clear correlation exists between the *N*-alkylation grade and the macrocycle conformation. Here, the higher the *N*-alkylation grade the more preferred the conformation of type B. e) Finally, it has also been demonstrated that the complexes exist as single isomers in solution. Computational studies are underway to determine the energy differences between the two complex conformations.

## Experimental Section

**Materials and Methods:** Compounds **1** and $H_2L^1$ were prepared as described in the literature.[14] The syntheses of the metal complexes were carried out under a protective atmosphere of argon. Melting points were determined in open glass capillaries and are uncorrected. NMR spectra were recorded with a Bruker Avance DPX-200 spectrometer or a Bruker Avance DRX 400 spectrometer at 298 K. Chemical shifts are referred to solvent signals. Infrared spectra were recorded with a Bruker Vector 22 FT-IR spectrometer and electronic absorption spectra with a Jasco V-570 UV/VIS/NIR spectrometer. Elemental analyses were recorded with a VARIO EL-elemental analyzer. ESI-FTICR mass spectra were recorded with a Bruker Apex II instrument using dilute $CH_2Cl_2$/MeOH solutions.

***CAUTION!*** *Perchlorate salts are potentially explosive and should therefore be prepared only in small quantities and handled with appropriate care.*

**Preparation of Compound 3:** Solutions of 1,2-bis(4-*tert*-butyl-2,6-diformylphenylthio)ethane (**1**; 3.00 g, 6.37 mmol) in dichloromethane (100 mL) and bis(aminoethyl)methylamine (**2**; 1.51 g, 12.9 mmol) in ethanol (100 mL) were added simultaneously over a period of 3 h to a mixture of dichloromethane (300 mL) and ethanol (300 mL). After complete addition, the reaction mixture was stirred at room temperature for 18 h. The dichloromethane was removed under reduced pressure and a solution of sodium borohydride (1.21 g, 32.0 mmol) in ethanol (50 mL) was added. After stirring at room temperature for 2 h, the reaction mixture was acidified to pH 1 with conc. hydrochloric acid and the resulting colourless suspension was evaporated to dryness. The residue was taken up in aqueous potassium hydroxide (3 M, 80 mL) and extracted with dichloromethane (4 × 100 mL). The combined organic fractions were dried with magnesium sulfate. Evaporation of the solvent gave **3** (3.96 g, 97%) as a colourless, foamy solid. M.p. 84 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.29 [s, 18 H, ArC($CH_3$)$_3$], 2.31 (s, 6 H, N$CH_3$), 2.69 (m, 8 H, N$CH_2$ $CH_2$N), 2.93 (m, 8 H, N$CH_2CH_2$N), 3.07 [s, 4 H, (ArS$CH_2$)$_2$], 3.99 (s, 8 H, Ar$CH_2$N), 7.49 ppm (s, 4 H, Ar*H*). $^{13}$C{$^1$H}NMR (50 MHz, $CDCl_3$): $\delta$ = 30.2 [C($CH_3$)$_3$], 33.6 [*C*($CH_3$)$_3$], 34.9 (S$CH_2$), 40.7 (N$CH_3$), 46.6 (Ar$CH_2$N), 52.7 (N$CH_2CH_2$N), 56.7 (N$CH_2CH_2$N), 125.7 ($C^{Ar}$H), 127.9 ($C^{Ar}$S), 143.2 ($C^{Ar}CH_2$N), 150.9 ppm ($C^{Ar}t$Bu). IR (KBr): $\tilde{\nu}$ = 3425 (w), 3307 (w), 3049 (vw), 2952 (vs), 2902 (s), 2867 (s), 2801 (s), 2370 (w), 2273 (vw), 1641 (vw), 1630 (vw), 1596 (w), 1564 (vw), 1554 (vw), 1534 (vw), 1512 (vw), 1459 (s), 1393 (w), 1362 (m), 1330 (w), 1293 (w), 1262 (m), 1223 (m), 1203 (m), 1119 (s), 1045 (s), 926 (vw), 884 (w), 800 (m), 744 (w), 653 (vw), 631 cm$^{-1}$ (vw). $C_{36}H_{60}N_6S_2{\cdot}H_2O$ (641.03 + 18.02): calcd. C 65.61, H 9.48, N 12.75, S 9.73; found C 65.40, H 9.28, N 12.39, S 10.52.

**Preparation of Compound 4:** A solution of **3** (3.40 g, 5.30 mmol) in acetic anhydride (150 mL) was stirred at 50 °C for 6 h. After re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

moval of the solvent under reduced pressure, the residue was taken up in aqueous potassium hydroxide solution (3 M, 100 mL) and extracted with dichloromethane (3 × 100 mL). The combined organic phases were dried with magnesium sulfate and the solvents evaporated to dryness. The residue was taken up in methanol and purified by flash chromatography on silica gel using a methanol/water (9:1) mixture as eluting solvent. Drying in vacuo gave **4** (3.56 g, 83%) as a colourless solid. M.p. 116 °C. $^1$H NMR (300 MHz, [D$_6$]-DMSO, 373 K): $\delta$ = 1.21 [s, 18 H, C(C*H*$_3$)$_3$], 2.31 (s, 6 H, NC*H*$_3$), 2.49–2.65 (m, 8 H, NC*H*$_2$CH$_2$N), 2.91 (s, 4 H, ArSC*H*$_2$), 3.03 (s, 12 H, COC*H*$_3$), 3.34 [m, 8 H, CH$_3$N(CH$_2$C*H*$_2$N)$_2$], 4.73 (s, 8 H, ArC*H*$_2$N), 6.99 ppm (s, 4 H, Ar*H*). IR (KBr): $\tilde{\nu}$ = 3442 (w), 2963 (s), 2868 (w), 2796 (w), 1649 [vs, $\nu$(CO)], 1559 (vw), 1467 (s), 1413 (s), 1362 (m), 1298 (w), 1261 (m), 1231 (m), 1149 (m), 1083 (w), 1024 (m), 976 (w), 940 (w), 873 (vw), 801 (w), 730 (w), 698 (vw), 660 (vw), 602 (w), 572 (vw), 535 (vw), 463 cm$^{-1}$ (vw). $C_{44}H_{68}N_6O_4S_2$·$H_2O$ (809.18 + 18.02): calcd. C 63.89, H 8.53, N 10.16, S 7.75; found C 63.77, H 8.28, N 9.88, S 7.52.

**Preparation of Compound 5:** A solution of **4** (620 mg, 0.766 mmol) in tetrahydrofuran (40 mL) was added dropwise to a suspension of lithium aluminium hydride (429 mg, 11.3 mmol) in tetrahydrofuran (40 mL). After refluxing the reaction mixture for 12 h, the oil bath was removed. Water (5 mL) was carefully added to the hot reaction mixture in small portions followed by 3 M potassium hydroxide solution (20 mL). The reaction mixture was stirred for an additional hour without heating. The organic layer was decanted off from a white residue, which was rinsed with boiling tetrahydrofuran (2 × 50 mL). The solvent was removed by distillation under reduced pressure. The residue was treated with 3 M potassium hydroxide solution (50 mL) and the resulting mixture was extracted with dichloromethane (3 × 50 mL). The combined organic layers were dried with potassium carbonate. Evaporation of the solvent gave the product as a colourless, foamy solid (568 mg, 98%). The crude material was purified by recrystallisation from a dichloromethane/ethanol (1:1) mixed solvent system. M.p. 146 °C. $^1$H NMR (200 MHz, CDCl$_3$): $\delta$ = 0.87 (t, $^3J$ = 7 Hz, 12 H, NCH$_2$C*H*$_3$), 1.22 [s, 18 H, C(C*H*$_3$)$_3$], 2.19 (s, 6 H, NC*H*$_3$), 2.30 (q, $^3J$ = 7 Hz, 8 H, NC*H*$_2$CH$_3$), 2.42–2.52 (m, 16 H, NC*H*$_2$C*H*$_2$N), 2.83 (s, 4 H, ArSC*H*$_2$), 3.66 (s, 8 H, ArC*H*$_2$N), 7.36 ppm (s, 4 H, Ar*H*). $^{13}$C{$^1$H}NMR (50 MHz, CDCl$_3$): $\delta$ = 11.9 (NCH$_2$*C*H$_3$), 31.3 [C(*C*H$_3$)$_3$], 34.6 [*C*(CH$_3$)$_3$], 36.5 (S*C*H$_2$), 43.6 (N*C*H$_3$), 47.6 (N*C*H$_2$CH$_3$), 51.4 (N*C*H$_2$CH$_2$N), 55.2 (Ar*C*H$_2$), 57.8 (NCH$_2$*C*H$_2$N), 125.2 (C$^{Ar}$H), 128.7 (C$^{Ar}$S), 144.2 (*C*$^{Ar}$CH$_2$N), 150.8 ppm (C$^{Ar}$*t*Bu). IR (KBr): $\tilde{\nu}$ = 3425 (vw), 2965 (vs), 2868 (s), 2798 (vs), 1595 (w), 1559 (vw), 1461 (w), 1407 (w), 1384 (m), 1366 (s), 1335 (w), 1312 (m), 1296 (w), 1274 (m), 1260 (m), 1217 (w), 1187 (m), 1163 (w), 1123 (s), 1100 (m), 1081 (m), 1039 (s), 1002 (w), 979 (w), 950 (w), 936 (w), 915 (w), 898 (w), 882 (w), 791 (w), 770 (w), 730 (vw), 683 (w), 653 (w), 607 (vw), 575 (vw), 555 (vw), 529 (vw), 475 cm$^{-1}$ (vw). $C_{44}H_{76}N_6S_2$·$H_2O$ (753.24 + 18.02): calcd. C 68.52, H 10.19, N 10.90, S 8.31; found C 68.35, H 10.16, N 10.57, S 7.92. This compound was additionally characterised by X-ray crystallography.

**Preparation of $H_2L^3$·6HCl:** A solution of **3** (3.80 g, 5.93 mmol) in tetrahydrofuran (50 mL) was added dropwise to a solution of sodium (2.0 g, 87 mmol) in liquid ammonia (150 mL). The resulting blue reaction mixture was stirred for a further 3 h at –76 °C. Solid ammonium chloride was then added to destroy the excess reducing agent. The resulting colourless suspension was warmed to room temperature. After 12 h, the remaining solvent was distilled off under reduced pressure. The residue was taken up in water (20 mL) and the solution was acidified to pH 1 with conc. hydrochloric acid. To remove sodium chloride and ammonium chloride from the product, the residue was triturated with methanol (3 × 50 mL) and filtered. The crude product was further purified by recrystallisation from a mixed methanol/ethanol (1:1) solvent system. This material (3.55 g, 72%) was used without further purification. M.p. 259 °C. $^1$H NMR (400 MHz, CD$_3$OD): $\delta$ = 1.34 [s, 18 H, C(C*H*$_3$)$_3$], 3.00 (s, 6 H, NCH$_3$), 3.67 (m, 16 H, NC*H*$_2$C*H*$_2$N), 4.64 (s, 8 H, ArC*H*$_2$N), 7.80 ppm (s, 4 H, Ar*H*) ppm. $^{13}$C{$^1$H} NMR (100 MHz, CD$_3$OD): $\delta$ = 31.5 [C(*C*H$_3$)$_3$], 35.9 [*C*(CH$_3$)$_3$], 42.1 (NCH$_3$), 43.4 (N*C*H$_2$), 52.2 (N*C*H$_2$), 53.6 (N*C*H$_2$), 130.4 (C$^{Ar}$H), 132.1 (C$^{Ar}$S), 135.8 (*C*$^{Ar}$CH$_2$N), 153.8 ppm (C$^{Ar}$*t*Bu). IR (KBr): $\tilde{\nu}$ = 3425 (vs), 2961 (vs), 2869 (s), 2640 (s), 1724 (vw), 1629 (w), 1601 (w), 1512 (vw), 1462 (s), 1366 (w), 1231 (w), 1161 (vw), 1019 (vw), 993 (vw), 895 (vw), 786 (vw), 753 (vw), 663 (vw), 557 cm$^{-1}$ (vw). $C_{34}H_{64}Cl_6N_6S_2$·1.5EtOH (830.28 + 69.04): calcd. C 49.22, H 8.15, Cl 23.56, N 9.31, S 7.10; found C 48.8, H 8.38, Cl 23.53, N 9.13, S 7.55.

**Preparation of $H_2L^4$·6HCl:** The preparation of this ligand was analogous to that of $H_2L^3$·6HCl except that compound **5** was used instead of **3**. Yield: 672 mg (71%). The hexahydrochloride salt could not be obtained in analytically pure form, but it was pure enough for the preparation of the metal complexes. $^1$H NMR (200 MHz, CD$_3$OD): $\delta$ = 1.24–1.70 [m, 30 H, C(C*H*$_3$)$_3$ and NCH$_2$C*H*$_3$], 2.67–3.05 (m, 6 H, NC*H*$_3$), 3.17–3.99 (m, 24 H, NC*H*$_2$), 7.42–8.15 ppm (m, 4 H, Ar*H*). $^{13}$C{$^1$H}NMR (100 MHz, CD$_3$OD): $\delta$ = 9.04 (NCH$_2$*C*H$_3$), 31.6 [C(*C*H$_3$)$_3$], 35.2 [*C*(CH$_3$)$_3$], 41.3 (N*C*H$_3$), 47.7 (N*C*H$_2$CH$_3$), 50.1 (Ar*C*H$_2$N), 52.5 (N*C*H$_2$CH$_2$N), 59.5 (NCH$_2$*C*H$_2$N), 132.2 (C$^{Ar}$H), 132.6 (C$^{Ar}$S), 135.4 (*C*$^{Ar}$CH$_2$N), 148.9 ppm (C$^{Ar}$*t*Bu). IR (KBr): $\tilde{\nu}$ = 3404 (vs), 2964 (vs), 2870 (s), 2604 (vs), 1633 (w), 1602 (w), 1467 (vs), 1414 (s), 1398 (s), 1366 (m), 1232 (w), 1202 (vw), 1164 (w), 1081 (w), 1046 (m), 992 (vw), 959 (vw), 897 (vw), 795 (w), 737 cm$^{-1}$ (vw).

**Preparation of [(L$^3$)Ni$_2$(Cl)][ClO$_4$] (8[ClO$_4$]) and [(L$^3$)Ni$_2$(Cl)][BPh$_4$] (8[BPh$_4$]):** A solution of NiCl$_2$·6H$_2$O (261 mg, 1.10 mmol) in methanol (2 mL) was added to a suspension of $H_2L^3$·6HCl (460 mg, 0.552 mmol) in methanol (15 mL). A solution of NEt$_3$ (448 mg, 4.43 mmol) in methanol (3 mL) was then added dropwise to give a dark red solution. The solution was stirred for a further 2 d at room to give a yellow solution. Solid LiClO$_4$·3H$_2$O (882 mg, 5.50 mmol) was added and half of the solvent was removed in vacuo. The resulting yellow precipitate was filtered off, recrystallised once from a few millilitres of acetonitrile, and dried in vacuo. Yield: 416 mg (87%). M.p. 299 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3430 (m), 3286 (w), 3256 (w), 3095 (vw), 2955 (m), 2870 (m), 2023 (vw), 1629 (w), 1461 (m), 1393 (w), 1363 (w), 1333 (vw), 1307 (vw), 1258 (w), 1229 (w), 1156 (m), 1094 [vs, $\nu$(ClO$_4^-$)], 1000 (w), 975 (w), 957 (vw), 930 (w), 894 (vw), 871 (w), 854 (w), 806 (vw), 750 (w), 623 (m), 568 (vw), 546 (vw), 472 cm$^{-1}$ (vw). UV/Vis (CH$_3$CN): $\lambda_{max}$ ($\varepsilon$) = 623(76), 902 (63), 960 nm (68 M$^{-1}$ cm$^{-1}$). $C_{34}H_{56}Cl_2N_6Ni_2O_4S_2$ (865.27): calcd. C 47.20, H 6.52, N 9.71, S 7.41; found C 47.20, H 6.29, N 9.32, S 7.10. The tetraphenylborate salt **8**[BPh$_4$] was prepared by adding NaBPh$_4$ (342 mg, 1.00 mmol) to a solution of **8**[ClO$_4$] (86.5 mg, 0.100 mmol) in methanol (40 mL). The yellow microcrystalline solid was isolated by filtration, washed with ethanol, and dried in air. Yield: 96.2 mg (89%). M.p. 249 °C (decomp). IR (KBr): $\tilde{\nu}$ = 3440 (w), 3275 (m), 3055 (w), 2963 (m), 2872 (m), 1948 (vw), 1658 (w), 1578 (vs), 1479 (m), 1457 (s), 1426 (s), 1392 (w), 1362 (w), 1311 (w), 1260 (w), 1229 (w), 1151 (w), 1081 (m), 1057 (w), 1032 (w), 984 (w), 930 (w), 877 (w), 849 (w), 733 [m, $\nu$(BPh$_4^-$)], 705 [s, $\nu$(BPh$_4^-$)], 612 (m), 545 (vw), 464 (vw) cm$^{-1}$. $C_{58}H_{76}BClN_6Ni_2S_2$ (1085.05): calcd. C 64.20, H 7.06, N 7.75, S 5.91; found C 63.81, H 7.14, N 7.44, S 5.64. The tetraphenylborate salt was additionally characterised by X-ray crystallography.

**Preparation of [($L^4$)$Ni_2$(Cl)][$ClO_4$] (9[$ClO_4$]) and [($L^4$)$Ni_2$(Cl)][$BPh_4$] (9[$BPh_4$]):** A solution of $NiCl_2·6H_2O$ (59.4 mg, 0.250 mmol) in methanol (2 mL) was added to a suspension of $H_2L^4·6HCl$ (118 mg, 0.125 mmol) in methanol (15 mL). A solution of $NEt_3$ (101 mg, 1.00 mmol) in methanol (3 mL) was then added to give a dark red solution. The solution was stirred for a further 2 d at room temp. to give a yellow solution. Solid $LiClO_4·3H_2O$ (200 mg, 1.25 mmol) was added and half of the solvent was removed in vacuo. The resulting yellow precipitate was filtered off, recrystallised once from a few millilitres of acetonitrile, and dried in vacuo. Yield: 78 mg (64%). M.p. 296 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3438 (m), 2963 (s), 2891 (s), 2018 (vw), 1629 (w), 1460 (s), 1377 (m), 1363 (m), 1314 (w), 1259 (w), 1232 (w), 1201 (vw), 1158 (m), 1098 (vs, $\nu ClO_4^-$), 1058 (m), 1023 (m), 988 (vw), 968 (vw), 955 (vw), 925 (vw), 907 (w), 883 (w), 809 (vw), 778 (m), 732 (w), 673 (vw), 624 (m) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) = 675 (31), 928 (62), 1013 (82 $M^{-1}cm^{-1}$). $C_{42}H_{72}Cl_2N_6Ni_2O_4S_2·H_2O$ (977.48 + 18.02): calcd. C 50.67, H 7.49, N 8.44, S 6.44; found C 50.5, H 7.51, N 8.09, S 6.56. The tetraphenylborate salt **9**[$BPh_4$] was prepared by adding $NaBPh_4$ (342 mg, 1.00 mmol) to a solution of **9**[$ClO_4$] (100 mg, 0.100 mmol) in methanol (40 mL). The yellow microcrystalline solid was filtered, recrystallised from a few millilitres of acetonitrile, and dried in air. Yield: 113 mg (94%). M.p. 205 °C (decomp). IR (KBr): $\tilde{\nu}$ = 3427 (m), 3055 (m), 3033 (m), 2963 (vs), 2894 (s), 2866 (s), 1816 (vw), 1615 (w), 1579 (w), 1478 (vs), 1461 (vs), 1429 (m), 1379 (m), 1362 (m), 1343 (w), 1312 (w), 1262 (w), 1233 (w), 1201 (vw), 1184 (vw), 1157 (w), 1096 (vs), 1058 (s), 1032 (s), 988 (w), 954 (w), 907 (w), 884 (w), 844 (w), 807 (w), 777 (m), 732 [vs, $\nu(BPh_4^-)$], 704 [vs, $\nu(BPh_4^-)$], 630 (w) 612 (m) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) = 658 (25), 928 (48), 1018 nm (63 $M^{-1}cm^{-1}$). $C_{66}H_{92}BClN_6Ni_2S_2·3H_2O·CH_3CN$ (1197.26 + 95.10): calcd. C 63.20, H 7.88, N 7.59, S 4.96; found C 62.90, H 7.64, N 7.73, S 5.36. The tetraphenylborate salt was additionally characterised by X-ray crystal structure analysis.

**Preparation of [($L^1$)$Cd_2$(Cl)][$ClO_4$] (10[$ClO_4$]):** A solution of $CdCl_2·H_2O$ (402 mg, 2.00 mmol) in MeOH (10 mL) was added to a suspension of $H_2L^1·6HCl$ (806 mg, 1.00 mmol) in MeOH (30 mL). A solution of triethylamine (809 mg, 8.08 mmol) in MeOH (3 mL) was then added. After stirring at ambient temperature for 2 d, solid $LiClO_4·3H_2O$ (1.60 g, 10.0 mmol) was added. The precipitate was filtered and purified by recrystallisation from MeCN. Yield: 432 mg (46%). IR (KBr): $\tilde{\nu}$ = 3445 (m), 3229 [s, $\nu$(NH)], 2953 (s), 2902 (s), 2855 (s), 1623 (m), 1456 (m), 1395 (w), 1363 (m), 1344 (w), 1297 (w), 1268 (vw), 1227 (m), 1151 (m), 1100 (s), 1078 (m), 1024 (m), 942 (m), 910 (m), 873 (m), 850 (m), 812 (w), 780 (w), 747 (vw), 627 (m) $cm^{-1}$. $^1H$ NMR (400 MHz, $CD_3OD$, for atom labels see inset of Table 2): $\delta$ = 1.26 (s, 9 H, $C^1H_3$ or $C^4H_3$), 1.32 (s, 9 H, $C^1H_3$ or $C^4H_3$), 2.40–3.70 (m, 20 H, $C^{6-9,6'-9'}H_2$ + $C^{5,5',10,10'}H$*H*), 4.30–4.40 (m, 4 H, $C^{5,5',10,10'}H$H), 7.16 (s, 2 H, $C^{13,13'}H$ or $C^{17,17'}H$), 7.34 ppm (s, 2 H, $C^{13,13'}H$ or $C^{17,17'}H$). $^{13}C\{^1H\}$NMR (100 MHz, [$D_6$]DMSO): $\delta$ = 31.2 ($C^1$ or $C^4$), 31.3 ($C^1$ or $C^4$), 33.7 ($C^2$ or $C^3$), 33.8 ($C^2$ or $C^3$), 47.4, 48.9, 49.2, 54.2, 55.2, 56.0 ($C^{5-10,5'-10'}$), 127.5, 127.8 ($C^{13,13',17,17'}$), 137.3, 137.4 ($C^{12,12',16,16'}$), 138.2, 139.1 ($C^{11,15}$), 145.0, 145.1 ($C^{14,18}$) ppm. ESI-MS: *m*/*z* 905.3 (100%) [($L^1$)$Cd_2$(Cl)]$^+$. The tetraphenylborate salt **10**[$BPh_4$] was prepared by adding $NaBPh_4$ (674 mg, 1.97 mmol) to a solution of **10**[$ClO_4$] (186 mg, 0.197 mmol) in methanol (50 mL). The resulting colourless microcrystalline solid was isolated by filtration, washed with ethanol, and dried in air. Yield: 172 mg (74%). IR (KBr): $\tilde{\nu}$ = 3445 [m, $\nu$(OH)], 3279 [s, $\nu$(NH)], 3054 [m, $\nu$(Ar)], [2962 (vs), 2864 (s)] [$\nu$(CH)], 1616 (w), 1580 (w), 1477 (s), 1455 (s), 1394 (w), 1365 (w), 1300 (w), 1253 (w), 1227 (w), 1202 (vw), 1152 (w), 1098 (w), 1072 (w), 1033 (w), 909 (m), 849 (m), 735 (vs), 707 (vs), 612 (m) $cm^{-1}$. $^1H$ NMR (400 MHz, $CD_3OD$): $\delta$ = 1.26 (s, 9 H, $C^1H_3$ or $C^4H_3$), 1.32 (s, 9 H, $C^1H_3$ or $C^4H_3$), 2.50–3.75 (m, 20 H, $C^{6-9,6'-9'}H_2$ + $C^{5,5',10,10'}H$*H*), 4.35–4.41 (m, 4 H, $C^{5,5',10,10'}H$H), 6.82 (t, *J* = 8 Hz, 4 H, $BPh_4^-$), 6.96 (t, *J* = 8 Hz, 8 H, $BPh_4^-$), 7.16 (s, 2 H, $C^{13,13'}H$ or $C^{17,17'}H$), 7.29 (m, 8 H, $BPh_4^-$), 7.33 ppm (s, 2 H, $C^{13,13'}H$ or $C^{17,17'}H$). $^{13}C\{^1H\}$NMR (100 MHz, [$D_6$]DMSO): $\delta$ = 31.1 ($C^1$ or $C^4$), 31.2 ($C^1$ or $C^4$), 33.7 ($C^2$ or $C^3$), 33.8 ($C^2$ or $C^3$), 47.4, 48.6, 49.1, 49.3, 54.2, 55.2 ($C^{5-10,5'-10'}$), 127.5, 127.8 ($C^{13,13',17,17'}$), 138.0, 138.2 ($C^{12,12',16,16'}$), 139.0, 139.9 ($C^{11,15}$), 140.0, 145.8 ($C^{14,18}$), 121.5 ($BPh_4^-$), 125.3 ($BPh_4^-$), 135.5 ($BPh_4^-$), 164.0 ppm ($BPh_4^-$). This salt was additionally characterised by X-ray crystallography.

**Preparation of [($L^3$)$Cd_2$(Cl)][$ClO_4$] (12[$ClO_4$]) and [($L^3$)-$Cd_2$(Cl)][$BPh_4$] (12[$BPh_4$]):** A solution of $CdCl_2·H_2O$ (223 mg, 1.10 mmol) in MeOH (2 mL) was added to a suspension of $H_2L^3·6HCl$ (460 mg, 0.552 mmol) in MeOH (15 mL). A solution of triethylamine (445 mg, 4.40 mol) in MeOH (3 mL) was then added to give a colourless solution. After stirring at ambient temperature for 4 d, solid $LiClO_4·3H_2O$ (118 mg, 0.735 mmol) was added to give the perchlorate salt **12**[$ClO_4$] as a white microcrystalline solid. The precipitate was filtered and purified by recrystallisation from MeCN. Yield: 432 mg (80%). M.p. 332 °C (decomp.). $^1H$ NMR (200 MHz, $CD_3CN$, for atom labels see inset of Table 2): $\delta$ = 1.25 (s, 9 H, $C^1H_3$ or $C^4H_3$), 1.29 (s, 9 H, $C^1H_3$ or $C^4H_3$), 2.65 [s, 6 H, $CH_3(R^1)$], 2.70–3.60 (m, 20 H, $C^{6-9,6'-9'}H_2$ + $C^{5,5',10,10'}H$), 4.25–4.43 (m, 4 H, $C^{5,5',10,10'}H$), 7.17 (s, 2 H, $C^{13,13'}H$ or $C^{17,17'}H$), 7.32 ppm (s, 2 H, $C^{13,13'}H$ or $C^{17,17'}H$). $^{13}C\{^1H\}$NMR (75 MHz, $CD_3CN$): $\delta$ = 31.61 ($C^1$ or $C^4$), 31.74 ($C^1$ or $C^4$), 34.84 ($C^2$ or $C^3$), 34.93 ($C^2$ or $C^3$), 49.48 ($CH_3$, $R^1$), 50.68, 55.19, 56.20, 58.06, 58.17, 60.37 ($C^{5-10,5'-10'}$), 129.01, 129.28 ($C^{13,13',17,17'}$), 138.95, 139.46 ($C^{12,12',16,16'}$), 138.45, 140.24 ($C^{11,15}$), 147.96, 148.21 ppm ($C^{14,18}$). C 60.76, H 7.11, N 6.44, S 4.92; found C 60.94, H 6.85, N 6.37, S 5.42. The tetraphenylborate salt was additionally characterised by X-ray crystal structure analysis.

**Crystal Structure Determinations:** Large single crystals of **5** were obtained by slow evaporation of a $CH_2Cl_2/CH_3OH$ solution. Crystals of **8**[$BPh_4$]·3EtOH, **9**[$BPh_4$]·5MeCN, **12**[$BPh_4$]·2MeCN and {**13**[$BPh_4$]·3.5MeCN}$_2$ were obtained by slow evaporation from a mixed MeCN/EtOH (1:1) solvent system. Crystals of **10**[$BPh_4$]·5MeOH were grown by recrystallisation from MeOH. The diffraction experiments were carried out with Bruker CCD (for **5**, **8** and **12**) or STOE IPDS-2T X-ray diffractometers (for **9**, **10** and **13**). The intensity data were processed with the programs SAINT (**5**, **8**, **12**) or STOE X-AREA (**9**, **10**, **13**). Structures were solved by direct methods and refined by full-matrix least-squares on the basis of all data against $F^2$ using SHELXL-97.[31] PLATON was used to search for higher symmetry.[32] H atoms were placed in calculated positions and treated isotropically using the 1.2-fold $U_{iso}$ value of the parent atom, except for methyl protons, which were assigned the 1.5-fold $U_{iso}$ value of the parent C atoms. Unless otherwise noted, all non-hydrogen atoms were refined anisotropically. ORTEP-3 was used for the artwork of the structures.[33] Experimental crystallographic data are summarised in Table 5. Further data are available in the Supporting Information.

In the crystal structure of **5** and **10**[$BPh_4$]·5MeOH a *tert*-butyl group is disordered over two positions. Two split positions were successfully refined to give the following site occupancies: C(19a)-C20(a)C(21a)/C(19b)C20(b)C(21b) = 0.60(1)/0.40(1) (for **5**), C(26a)C(27a)C(28a)/C(26b)C(27b)C(28b) = 0.60(2)/0.40(2) (for **10**[$BPh_4$]·5MeOH). The C, N, and O atoms of the solvates in **8**[$BPh_4$]·3EtOH, **9**[$BPh_4$]·5MeCN and {**13**[$BPh_4$]·3.5MeCN}$_2$ were refined isotropically.

CCDC-600010 to -600014 and -622729 (see Table 5 for assignments) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We are particularly grateful to Prof. Dr. H. Vahrenkamp, Prof. Dr. E. Hey-Hawkins and Prof. Dr. H. Krautscheid for providing facilities for NMR and X-ray crystallographic measurements. This work was supported by the Deutsche Forschungsgemeinschaft (priority programme "Sekundäre Wechselwirkungen", KE 585/3-3).

# Ferrocenes Bearing Sulfinylamino Groups

**Bernd Wrackmeyer,*[a] Elena V. Klimkina,[a] Wolfgang Milius,[a] Miriam Siebenbürger,[a] Oleg L. Tok,[a] and Max Herberhold[a]**

*Dedicated to Professor Dr. Walter Siebert on the occasion of his 70th birthday*

**Keywords:** 1,1′-Diaminoferrocene / 1,1′-Bis(trimethylsilylamino)ferrocene / Thionyl chloride / Sulfinylamines

1,1′-Diaminoferrocene (**2**) and 1,1′-bis(trimethylsilylamino)-ferrocene (**3**) have been converted into sulfinylamines by treatment with thionyl chloride in the presence of triethylamine. In the case of **2** the 1:2 reaction affords 1,1′-bis(sulfinylamino)ferrocene (**5**) and the 1:1 reaction gives 6-amino-1-sulfinylaminoferrocene (**6**). Bis(trimethylsilylamino)ferrocene reacts with thionyl chloride in a 1:1 molar ratio to give 1-sulfinylamino-6-(trimethylsilylamino)ferrocene (**8**). In contrast, the reaction of *N*,*N*′-dilithiobis(trimethylsilylamino)ferrocene (**4**) with thionyl chloride gives the [3]ferrocenophane **9**, which contains an N–S(O)–N bridge, rather than sulfinylamines or a sulfur diimide. The molecular structures of **5** and **8** were determined by X-ray analysis. The $^{57}$Fe NMR chemical shift ($\delta$ = +2597.0 ppm) for **5** indicates the strong π-acceptor properties of the NSO groups. Dynamic $^{1}$H and $^{13}$C NMR spectra prove the hindered rotation of the NSO group about the C–N bonds in **5**, **6** and **8**.

## Introduction

The combination of the rich chemistry of ferrocenes[1] with that of sulfinylamines[2] is an attractive target. Convenient routes for the synthesis of sulfinylamines (R-NSO) start either from the corresponding primary amines ($RNH_2$) or from *N*-trimethylsilylamines [RN(H)-$SiMe_3$].[2] The latter approach has been successful in the case of ferrocenylsufinylamine (Fc-NSO, **1**), which has been structurally characterised in the solid state.[3] The structure of **1** in solution has been established by various physical methods, including routine NMR spectroscopy[3] and also $^{57}$Fe NMR spectroscopy.[4] The synthesis of 1,1′-diaminoferrocene [fc$(NH_2)_2$, **2**][5] has recently been improved,[6] therefore access to *N*,*N*′-disubstituted derivatives of 1,1′-diaminoferrocene, such as 1,1′-bis(trimethylsilylamino)ferrocene (**3**)[6] or its dilithiated derivative **4**,[7] has become more feasible. This is mirrored by advances in the synthesis of numerous [*n*]ferrocenophanes, for example with *n* = 3, with various elements between the nitrogen atoms.[7–12] In the present work, we describe attempts to convert the ferrocenes **2**–**4** into sulfinylamines, aiming particularly for NMR spectroscopic studies in solution and structural characterisation in the solid state.

## Results and Discussion

The reaction of **2** with thionyl chloride in the presence of an excess of triethylamine leads to the ferrocenes **5** or **6**, depending on the ratio of the starting compounds (Scheme 1). The complete conversion of **2** into 1,1′-bis(sulfinylamino)ferrocene (**5**) requires two equivalents of thionyl chloride. Complex **5** was isolated as a violet-blue, air- and moisture-sensitive solid, which gave violet crystals after recrystallisation. The 1:1 reaction affords 6-amino-1-sulfinylaminoferrocene (**6**), which, however, is contaminated with **2** and **5**. Purification by repeated crystallisation gave pure **6** as a blue powder. The availability of **5** calls for an attempt to prepare the sulfur diimide **7**. However, the reaction of **5** with KO*t*Bu in DMF[2,3] gave only **6**, most likely as the result of partial hydrolysis of **5**.

Another route to sulfinylaminoferrocenes is conceivable from the reaction of 1,1′-bis(trimethylsilylamino)ferrocene (**3**) with thionyl chloride in the presence of triethylamine (Scheme 2). The product of the 1:1 reaction, 1-sulfinylamino-6-(trimethylsilylamino)ferrocene (**8**), is formed along with a small amount of **5**, and **8** was isolated after recrystallisation as a blue crystalline solid.

*N*,*N*′-Dilithiation of **3** gives **4**, and its 1:1 reaction with thionyl chloride leads to the [3]ferrocenophane **9** (Scheme 3). The formation of **9** is accompanied by decomposition leading mainly to **3**. The elimination of hexamethyldisiloxane [$O(SiMe_3)_2$] from **9** to give the sulfur diimide **7** was not observed.

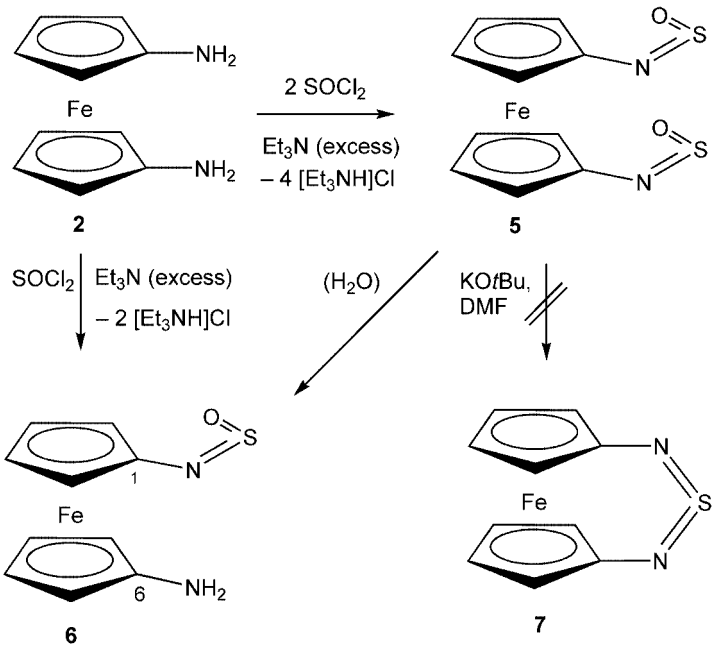
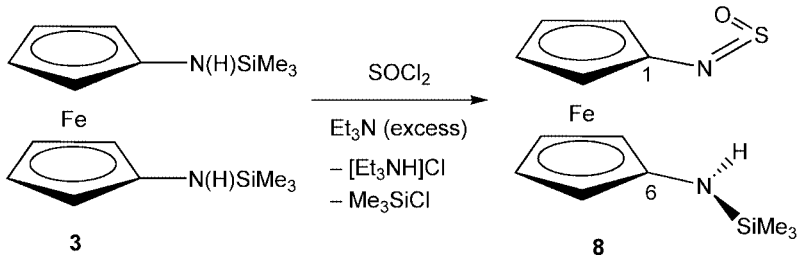
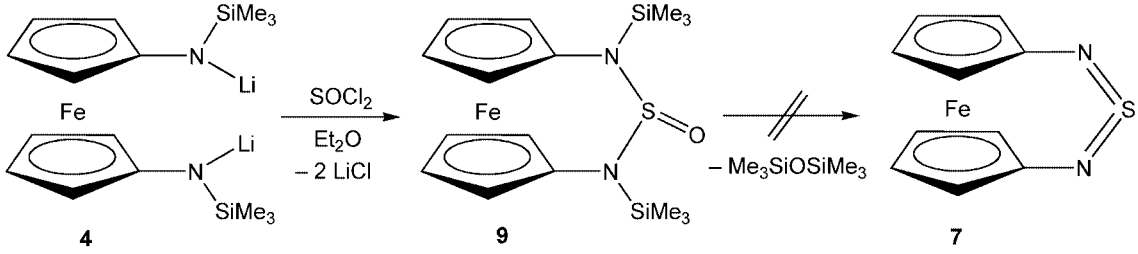


Scheme 1. Reaction of 1,1′-diaminoferrocene (**2**) with thionyl chloride and attempted synthesis of the sulfur diimide **7**.



Scheme 2. Reaction of 1,1′-bis(trimethylsilylamino)ferrocene (**3**) with thionyl chloride .



Scheme 3. Reaction of *N*,*N*′-dilithio-1,1′-bis(trimethylsilylamino)ferrocene (**4**) with thionyl chloride — another failure to obtain the sulfur diimide **7**.

### NMR Spectroscopic Studies in Solution

Relevant NMR spectroscopic data for the ferrocenes **1** (for comparison), **5**, **6**, **8** and **9** are given in Table 1 and in the Experimental Section ($^1$H NMR). The cyclopentadienyl groups are clearly identified by the $^1$H and $^{13}$C NMR spectroscopic data measured at room temperature. The presence of the NSO group is evident both from characteristic $^{14}$N NMR signals at high frequencies[13] and the symmetric and antisymmetric NSO stretching vibrations[2] in the IR spectra. The $^{15}$N NMR spectra ($^1$H coupled) prove the existence of the $NH_2$ and $N(H)SiMe_3$ groups in **6** and **8**, respectively. The $^{29}$Si NMR signal of **8** is notably different from that of the [3]ferrocenophane **9**, and $^{29}$Si nuclear deshielding is rather typical for the ring closure in **9**.[9–12]

Owing to the low NMR receptivity of $^{57}$Fe nuclei, $^{57}$Fe NMR spectra have rarely been reported.[14] However, careful setting of experimental parameters allows the measurement of meaningful spectra within a reasonable time.[4,15,16] The $^{57}$Fe nuclear shielding in ferrocene derivatives is sensi-

[a] Measured in $CDCl_3$ (**1**) or $CD_2Cl_2$ (**5**, **6**, **8** and **9**); $^1J(^{29}Si,^{13}C)$ coupling constants (±0.5 Hz) are given in parentheses; n.o. = not observed. [b] Assignment might be reversed.

tive to π-acceptor substituents, and deshielding is usually observed if the ferrocene structural geometry remains fairly undistorted.[4,16] According to the $\delta^{57}Fe$ value of **1**, the NSO group is a strong π-acceptor; this is also supported by the molecular structure of **1**, where the planes of the NSO group and the substituted cyclopentadienyl rings almost coincide.[3] Frequently, the contributions to $^{57}Fe$ nuclear shielding in ferrocenes are approximately additive for any substituents in 1,1′-positions.[17] Thus, the rather extreme $^{57}Fe$ nuclear deshielding observed for **5** ($\delta^{57}Fe$ =

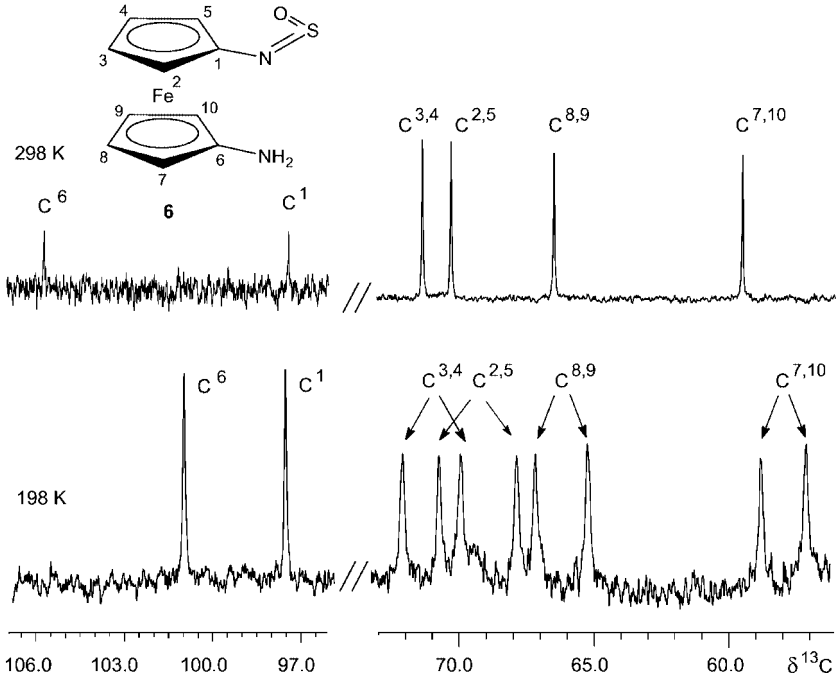

Figure 1. 62.9 MHz $^{13}C\{^1H\}$ NMR spectra of **6** at 298 K (upper trace) and 198 K (lower trace).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

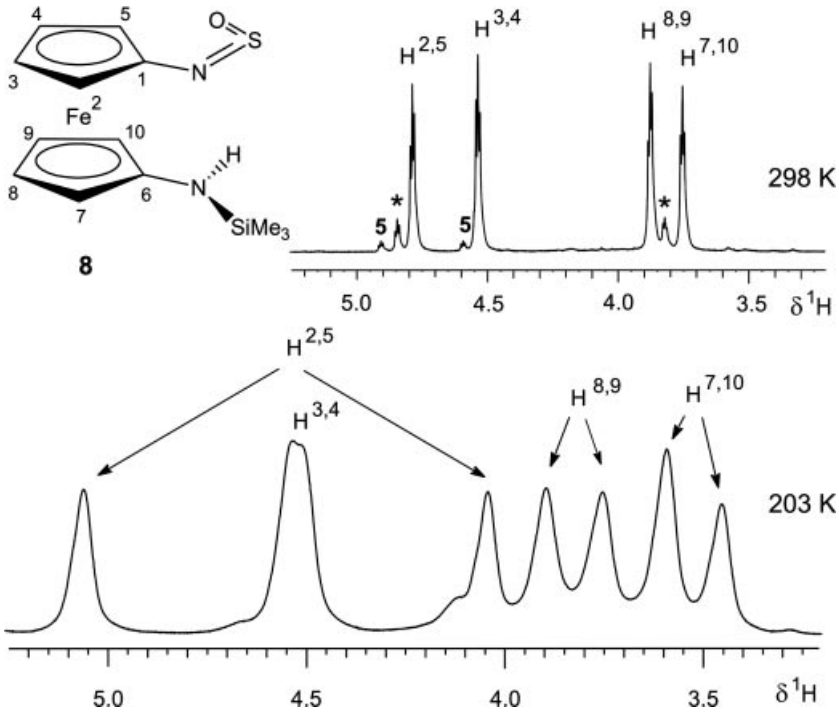

Figure 2. Parts of the 250.1 MHz $^1$H NMR spectra of the ferrocene **8** at 298 K (upper trace) and 203 K (lower trace). Signals of a side product are marked with asterisks.

+2597.0 ppm), when compared with ferrocene itself ($\delta^{57}$Fe = +1538.4 ppm[15]), is expected; the $\delta^{57}$Fe value for **8** ($\delta^{57}$Fe = +2131.0 ppm) is close to that of **1** ($\delta^{57}$Fe = +1966.3 ppm).

The π-acceptor properties of the NSO group should be reflected by restricted rotation about the C$^1$–N or C$^{1'}$-N bonds. Indeed, this is evident from the low-temperature $^1$H and $^{13}$C NMR spectra (Table 1, Figure 1 and Figure 2). In the case of **5**, the $^1$H and $^{13}$C NMR signals become broad at low temperature just before the complex crystallises, and in the cases of **6** and **8**, splitting of the C$^{2,5}$-H and C$^{3,4}$-H NMR signals into two signals each is observed (Figure 1 and Figure 2). In the cases of **6** and **8**, the barrier to rotation about the C$^1$–N(SO) bond can be estimated[18] as 43.0 ± 1 kJ mol$^{-1}$ at –65 °C (coalescence) from both $^1$H and $^{13}$C NMR spectra. The preferred orientation of the NSO group at low temperature is also indicated by the changes in the positions of the $^{13}$C$^6$ NMR signals in **6** and **8**.

### X-ray Structural Studies of the Sulfinylaminoferrocenes 5 and 8

The molecular structures of **5** and **8** are shown in Figures 3 and 4, respectively, and selected structural param-

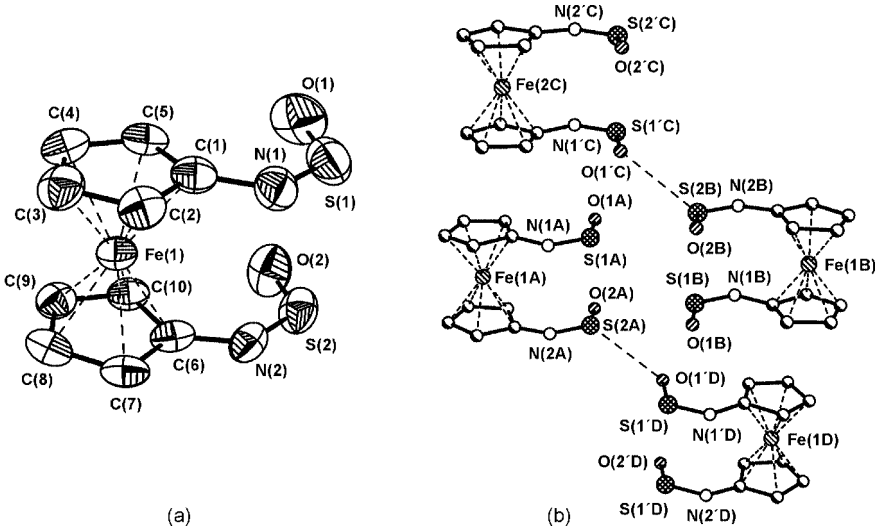

Figure 3. (a) Molecular structure of **5** (ORTEP plot, 50% probability; hydrogen atoms are omitted for clarity). S(1A)···S(2A) = 328.4, S(1′C)···S(2′C) 325.9 pm. For other selected distances and angles see Table 2. (b) Positions of the molecules of **5** in the lattice showing close intermolecular contacts: S(2A)···O(1′D) = 327.0, S(2B)···O(1′C) = 327.0 pm.

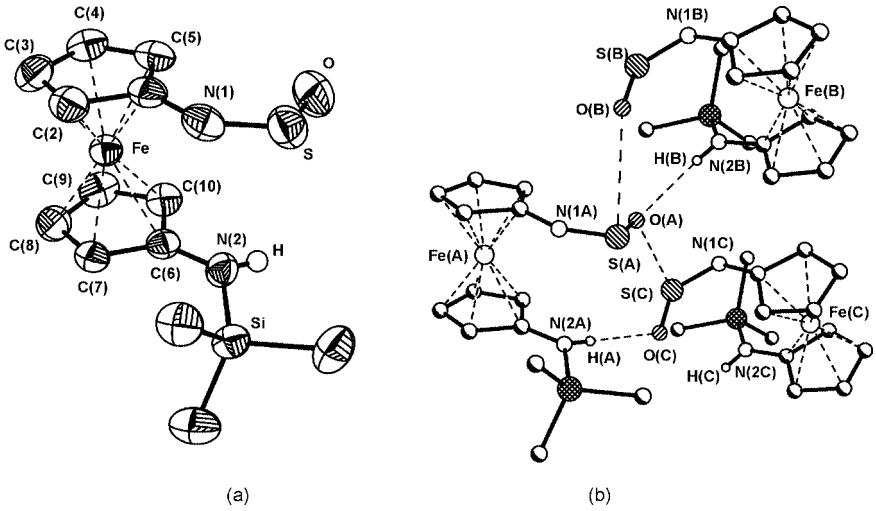

Figure 4. (a) Molecular structure of **8** (ORTEP plot, 50% probability; hydrogen atoms are omitted for clarity). For selected distances and angles see Table 2. (b) Positions of the molecules of **8** in the lattice showing close intermolecular contacts: O···H–N = 229.1, S···O = 328.9 pm.

eters are given in Table 2. In both cases, intermolecular interactions have to be considered, namely S···O contacts in **5** (Figure 3, b) and N–H···O bridges in **8** (Figure 4, b). It is tempting to trace the identical orientations of both NSO groups in **5** primarily to intermolecular interactions. However, there may also be important intramolecular contacts between the NSO groups, as indicated, for example, by the S···S contact (328.4 pm). The C–N vectors are slightly bent toward the iron atom ($\beta$ = 4.1° and 5.7°[19]), and the $C_5$ rings are almost exactly in eclipsed positions ($\tau$ = 0.1° and 0.4°[19]). The bond lengths and angles of **5** are in the usual range and compare favourably with those found for **1**.[3]

In the case of **8**, the C–N(SO) vector points toward iron (5.0°), whereas the C–N(Si) vector points away from iron

[a] See ref.[19] for the definition of the angles $\alpha$, $\beta$, $\gamma$ and $\tau$. [b] Taken from ref.[3]. [c] Data for two different molecules in the unit cell, as given in ref.[3]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(2.9°). The deviation from the eclipsed position of the cyclopentadienyl rings is again small ($\tau$ = 2.2°). Otherwise, the positions of the SO and the $SiMe_3$ groups are ideal for minimising steric interactions. The surroundings of the amino nitrogen atoms are close to trigonal planar.

## Experimental Section

**General:** All syntheses and the handling of the samples were carried out observing necessary precautions to exclude traces of air and moisture. Carefully dried solvents and oven-dried glassware were used throughout. The deuterated solvents $CD_2Cl_2$ and $CDCl_3$ were distilled from $CaH_2$ under argon. All other solvents were distilled from Na metal in an atmosphere of argon. The starting materials 1,1′-diaminoferrocene (**2**),[6] 1,1′-bis(trimethylsilylamino)ferrocene (**3**)[6] and *N*,*N*′-dilithio-1,1′-bis(trimethylsilylamino)ferrocene (**4**) and $[fc(NSiMe_3)_2Li_2]$[7] were prepared as described in the literature. Triethylamine was distilled from Na prior to use. DMF was purchased from Aldrich and distilled from KOH. Other starting materials were purchased from Aldrich [butyllithium (1.6 M in hexane)] or Acros ($SOCl_2$, KO*t*Bu), and used without further purification. NMR measurements: Bruker ARX 250: $^1H$, $^{13}C$, $^{14}N$, $^{15}N$ and $^{29}Si$ NMR (refocused INEPT[20] based on $^2J_{^{29}Si,^1H}$ = 7 Hz); Bruker DRX 500: $^{57}Fe$ NMR; Varian INOVA 400: $^1H$, $^{13}C$ NMR; chemical shifts are given with respect to $Me_4Si$ [$\delta^1H$ ($CHDCl_2$) = 5.33 ppm; $\delta^{13}C$ ($CD_2Cl_2$) = 53.5 ppm; $\delta^{29}Si$ = 0 ppm for $\Xi(^{29}Si)$ = 19.867184 MHz]; $\delta^{14}N$ = 0 ppm [external neat $MeNO_2$ with $\Xi(^{14}N)$ = 7.226324 MHz], $\delta^{15}N$ = 0 ppm [external neat $MeNO_2$ with $\Xi(^{15}N)$ = 10.136767 MHz]; $\delta^{57}Fe$ = 0 ppm [external neat $Fe(CO)_5$ with $\Xi(^{57}Fe)$ = 3.237798 MHz]. IR spectra: Perkin–Elmer Spectrum 2000 FTIR. EI-mass spectra: Finnigan MAT 8500 spectrometer (ionisation energy 70eV) with direct inlet; the *m*/*z* data refer to the isotopes $^1H$, $^{12}C$, $^{14}N$, $^{16}O$, $^{32}S$, $^{28}Si$, and $^{56}Fe$. The melting points (uncorrected) were determined using a Büchi 510 melting point apparatus.

**1,1′-Bis(sulfinylamino)ferrocene (5):** A suspension of 1,1′-diaminoferrocene (**2**; 295 mg, 1.37 mmol) in $Et_2O$ (20 mL) and triethylamine (0.91 mL, 6.52 mmol) was prepared. The suspension was cooled to –78 °C and $SOCl_2$ (326 mg, 0.20 mL, 2.74 mmol) dissolved in $Et_2O$ (3 mL) was injected slowly with a syringe. The reaction mixture was stirred at –78 °C for 1 h; then it was allowed to reach ambient temperature and kept stirring for 1.5 h. Insoluble materials were filtered off, washed with $Et_2O$ (20 mL), and volatile materials were removed from the filtrate in vacuo. The remaining violet-blue solid was dissolved in $Et_2O$ (30 mL) and the violet solution was filtered. After removal of the solvent in vacuo the product **5** (220 mg; 52%) was left as a violet-blue solid. Crystallisation from $CD_2Cl_2$, after 2 weeks at –20 °C, gave violet crystals of **5** (m.p. 149–151 °C). $^1H$ NMR (250.1 MHz, $CD_2Cl_2$, 298 K): $\delta$ = 4.60 (m, 4 H, $H^{3,4,3',4'}$), 4.90 ppm (m, 4 H, $H^{2,5,2',5'}$). $^1H$ NMR (250.1 MHz, $CD_2Cl_2$, 203 K): $\delta$ = 4.63 (m, 4 H, $H^{3,4,3',4'}$), 4.55 ppm (br. m, 4 H, $H^{2,5,2',5'}$). EI-MS (70 eV) for $C_{10}H_8FeN_2O_2S_2$ (308.15): *m*/*z* (%) = 308 (100) [$M^+$], 244 (6) [$M^+ - SO_2$], 212 (85) [$M^+ - 2SO$], 182 (12), 166 (7), 134 (40), 116 (16), 108 (14), 82 (16), 56 [$Fe^+$] (74). IR (toluene) $\tilde{\nu}$ = 1261 $cm^{-1}$ ($\nu_{as}$), 1093 ($\nu_s$) (NSO).

**6-Amino-1-(sulfinylamino)ferrocene (6). Method A:** The same procedure was employed as for **5**, except that an equimolar amount of $SOCl_2$ (175 mg, 1.48 mmol) in $Et_2O$ (4 mL) was used and the reaction mixture was kept stirring for 20 h. A mixture was obtained (72 mg) which, according to NMR spectra, contained **6** (ca. 35%) and **5** (ca. 15%), together with a lot of **2** (ca. 50%), as a violet-blue solid. This solid was dissolved in hexane (20 mL) and the blue solution was filtered. After removing the solvent in vacuo **6** was left as blue solid which still contained some **5** (5%). Crystallisation from hexane at –30 °C, gave a blue powder of **6** (m.p. 79–81 °C).

**Method B:** Freshly distilled DMF (20 mL) was added to a mixture of **5** (38 mg; 0.12 mmol) and KO*t*Bu (15 mg; 0.13 mmol). The colour of the violet solution changed to blue. The reaction mixture was stirred for 1 h, and volatile materials were removed in vacuo. The remaining blue solid was dissolved in $Et_2O$ (20 mL) and the blue solution was filtered. After removing the solvent in vacuo **6** (28 mg; 88%) was left as a blue solid. $^1H$ NMR (250.1 MHz, $CD_2Cl_2$, 298 K): $\delta$ = 2.75 (br. s, 2 H, NH), 3.82 (m, 2 H, $H^{7,10}$), 3.87 (m, 2 H, $H^{8,9}$), 4.54 (m, 2 H, $H^{3,4}$), 4.84 ppm (m, 2 H, $H^{2,5}$). $^1H$ NMR (250.1 MHz, $CD_2Cl_2$, 198 K): $\delta$ = 2.95 (br. s, 2 H, NH), 3.58 (m, 2 H, $H^{7,10}$), 3.78, 3.87 (m, m, 1 H, 1 H, $H^{8,9}$), 4.10, 5.03 (m, m, 1 H, 1 H, $H^{2,5}$), 4.51 ppm (m, 2 H, $H^{3,4}$). EI-MS (70 eV) for $C_{10}H_{10}FeN_2OS$ (262.11): *m*/*z* (%) = 262 (100) [$M^+$], 214 (12) [$M^+ - SO$], 198 (12) [$M^+ - SO - NH_2$], 197 (11), 187 (12), 185 (6), 152 (6), 137 (13), 135 (16), 133 (18), 108 (6), 80 [$CpNH_2^+$] (56), 56 [$Fe^+$] (31). IR (toluene) $\tilde{\nu}$ = 1261 $cm^{-1}$ ($\nu_{as}$), 1097 ($\nu_s$) (NSO).

**1-(Sulfinylamino)-6-(trimethylsilylamino)ferrocene (8):** A solution of 1,1′-bis(trimethylsilylamino)ferrocene (**3**; 240 mg, 0.67 mmol) in $Et_2O$ (20 mL) and triethylamine (0.19 mL, 1.36 mmol) was prepared. The solution was cooled to –78 °C, and $SOCl_2$ (79 mg, 0.049 mL, 0.67 mmol) dissolved in $Et_2O$ (4 mL) was injected slowly with a syringe. The reaction mixture was stirred at –78 °C for 1 h, then it was allowed to reach ambient temperature and kept stirring for 20 h. Insoluble materials were filtered off, and volatiles were removed from the filtrate in vacuo to give 185 mg of a mixture containing **8** (ca. 90%) and **5** (ca. 10%) as a blue solid. This solid was dissolved in hexane (20 mL) and the blue solution was filtered. After removing the solvent in vacuo **8** was left as a blue solid. Crystallisation from hexane/$CH_2Cl_2$ (1:1), after 2 weeks at –30 °C, gave blue crystals of **8** (m.p. 89–91 °C). $^1H$ NMR (250.1 MHz, $CD_2Cl_2$, 298 K): $\delta$ = 0.20 (s, 9 H, $Me_3Si$), 2.30 (br. s, 1 H, NH), 3.75 (m, 2 H, $H^{7,10}$), 3.88 (m, 2 H, $H^{8,9}$), 4.53 (m, 2 H, $H^{3,4}$), 4.79 ppm (m, 2 H, $H^{2,5}$). $^1H$ NMR (250.1 MHz, $CD_2Cl_2$, 203 K): $\delta$ = 0.08 (s, 9 H, $Me_3Si$), 2.60 (br. s, 1 H, NH), 3.45, 3.59 (m, m, 1 H, 1 H, $H^{7,10}$), 3.75, 3.89 (m, m, 1 H, 1 H, $H^{8,9}$), 4.04, 5.06 (m, m, 1 H, 1 H, $H^{2,5}$), 4.51, 4.53 ppm (m, m, 1 H, 1 H, $H^{3,4}$). EI-MS (70 eV) for $C_{13}H_{18}FeN_2OSSi$ (334.29): *m*/*z* (%) = 334 (100) [$M^+$], 286 (6) [$M^+ - SO$], 271 (10) [$M^+ - CH_3SO$], 234 (9), 205 (13), 182 (7) [$FeCpNSO^+$], 178 (6), 152 (20) [$CpN(H)SiMe_3^+$], 134 (22) [$FeCpN^+$], 108 (6), 73 [$SiMe_3^+$] (71), 56 [$Fe^+$] (13). IR (toluene) $\tilde{\nu}$ = 1261 $cm^{-1}$ ($\nu_{as}$), 1096 ($\nu_s$) (NSO).

**1,3-Bis(trimethylsilyl)-2-oxo-1,3,2-diazathia-[3]ferrocenophane (9):** Freshly prepared $fc(NSiMe_3)_2Li_2$ (**4**; 300 mg, 0.83 mmol) was dissolved in $Et_2O$ (20 mL), the solution was cooled to –78 °C, and $SOCl_2$ (55 mg, 0.034 mL, 0.46 mmol) dissolved in $Et_2O$ (4 mL) was injected slowly with a syringe. The reaction mixture was stirred at –78 °C for 0.5 h, then it was allowed to reach ambient temperature and kept stirring for 20 h. Volatile materials were removed in vacuo, and the resulting oil was dissolved in hexane (20 mL). Insoluble materials were separated by centrifugation, and the clear liquid was collected. The solvent was removed in vacuo to give 204 mg of a mixture containing **9** (ca. 25%) and **3** (ca. 75%) as a green oil. $^1H$ NMR (250.1 MHz, $CD_2Cl_2$, 298 K): $\delta$ = 0.26 (s, 18 H, $Me_3Si$), 3.82, 3.86 (m, m, 2 H, 2 H, $H^{2,3,2',3'}$), 4.13, 4.19 (m, m, 2 H, 2 H, $H^{4,5,4',5'}$).

**Crystal Structure Determinations of the Ferrocenes 5 and 8:** Details pertinent to the crystal structure determinations are listed in

# $W(CO)_4$(diimine) Structure Revised – Correlating Structure to π* Back-Bonding

**Christodoulos Makedonas[a] and Christiana A. Mitsopoulou*[a]**

**Keywords:** Tungsten / Pi interactions / N ligands / Carbonyls / Ligand effects

The bending of axial and equatorial carbonyls, one of the main structural features of the $M(CO)_4$(diimine) compounds (M = Cr, Mo, and W), is elucidated in terms of the π* back-bonding theory by a frontier molecular orbital analysis. Employing $W(CO)_4$(phen) (phen = 1,10-phenanthroline) as a reference compound has proved that the deviation from orthogonality stabilizes the structure by a total amount of 2.95 kJ/mol. Moreover, by an extended comparison of several $W(CO)_4$(diimine) structures, the importance of the magnitude of the binding angle in determining the bonding in these complexes in comparison to the traditional approach of the W–C and C–O bond lengths is underlined. As a result, it is proposed that the correct indices of the extent of back-donation are the deviations of the C–W–C angles from orthogonality and the O–C–W angles from linearity. It is indicated for the first time that the larger the existing deviation the stronger the back-donation. Moreover, a structure-to-properties relation is provided that correlates the bending of the carbonyls to the extent of back-donation. Back-donation is expected to be correlated to the electronic properties of the compounds, such as the extent of solvatochromism.

## 1. Introduction

The complexes of the type $M(CO)_4$(diimine) (M = Cr, Mo, and W) play an important role in our understanding of the spectroscopic, photophysical, and photochemical behavior of chromophores with low-lying metal-to-ligand (MLCT) charge-transfer excited states.[1–3] These compounds combine an electron-rich, low-valent, typically $d^6$ metal atom, which is stabilized by the presence of four carbonyl groups along with the good π*-accepting *a*-diimine ligand. The observed lowest lying MLCT state is responsible for several interesting features, such as the negative solvatochromism and the solution luminescence, while it is associated with large, second-order molecular hyperpolarizabilities. This state arises from the transition between a metal/CO localized HOMO–2 and a diimine LUMO (both of $b_1$ symmetry in the case of the $C_{2v}$ point group).[4,5] Thus the electronic properties of $M(CO)_4$(diimine) make their use quite essential in areas such as the investigation of polymerization processes,[2] the labeling of biomolecules,[6] and the exploitation of solar energy.[7]

All the structures of tetracarbonyl diimine compounds, which are either crystallographically elucidated or theoretically predicted, share two common features. Both of these features are related to the nonorthogonality of the $W(CO)_4$ fragment. More specifically, according to all published structures, the axial carbonyls bend away from the diimine moiety. Moreover, in the majority of the known structures, the two equatorial carbonyl groups bend away from each other. In both cases the linearity of the two CO units is no longer valid.[4–5,8–9] It is also worth mentioning that the M–C–O angle often changes upon electronic excitation.[4] These above-mentioned two features have been observed several times in the past, but they have never been explained in the literature. Herein, these structural characteristics are studied by means of DFT calculations, and our approach is divided into two parts. Firstly, by employing the highly symmetric $W(CO)_4$(phen) complex (phen = 1,10-phenanthroline) we attempted to investigate and discuss their structure from an electronic point of view in terms of the π* back-bonding theory. To proceed with our analysis, we performed a fragments' molecular orbital analysis (FMO) using DFT electron density calculations. Recently, this procedure was successfully used in the case of a related tungsten compound.[5] Secondly, we discussed the same characteristics as they evolved through a series of bidentate N-donor ligands. In the latter case, we succeeded in extracting the structure-to-properties relation (SPR) that governs these compounds.

## 2. Results and Discussion

### 2.1. Evolution of Back-Donation in $W(CO)_4$(phen)

We started our analysis with $W(CO)_4$(phen) (**1**). Despite this complex being one of the most extensively studied

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

among compounds of this type it was only recently that Vlček et al. described its electronic ground state and elucidated its emission behavior.[4c,4d] Apart from being easily produced[12] and having an interesting photochemistry it is usually employed for its high symmetry. It belongs to the $C_{2v}$ point group and this makes its structure elucidation, through spectra, significantly easier. Theoretical calculations are also favored for the same reason. In such a molecule, bending of the CO ligands should be clear and free from the difficult to describe nonorthogonal dihedral angles, as in the case of W(CO)$_4$(pq) [pq = 2-(2′-pyridyl)-quinoxaline] where the calculated dihedral angle for $N_{py}$–$N_{qn}$–W–$C_{ax}$ is –92.6°.[5]

In the literature, three crystal structures exist as reported in ref.[10a,10c,11] In our case, ground-state calculations have been performed with the aid of Gaussian 98 packages, employing the well-known B3LYP functional, under $C_{2v}$ molecular symmetry. The final structure, obtained by full geometry optimization, is essentially equivalent to the ones that have been previously reported.[4] Nevertheless, there are some differences arising from the comparison with the crystal structure reported in the work of Xiong et al.[11] Specifically, the bending of the two axial carbonyl groups is not identical in the solid phase. This is also depicted by the observed differences in the dihedral angles (78.2 and 151.9° as compared to –103.4 and –177.2° for the dihedral angles $O_{ax}$–$C_{ax}$–W–$N^1$ and $O_{ax}$–$C_{ax}$–W–$N^2$, respectively). These differences are due to the extended hydrogen bonding developed between the oxygen atom of the CO group and a diimine hydrogen atom present in the crystal. Some of the ground-state structural features of the complex that were theoretically derived and experimentally extracted are presented in Table 1. For uniformity purposes the structure under study is the one derived from the calculation.

[a] The average value of symmetry related distances or angles is provided.

In order to accomplish the aforementioned task of structure elucidation in terms of back-donation we decided to design a theoretical model. We introduced four theoretical nonexisting structures for the system under study, which represent steps that are equal in number towards orthogonality. Thus, in **1a** the bending of axial oxygen atoms towards one another no longer exists and the W–C–O moiety is linear, while in **1b** the CO groups take up a position along the *x*-axis of the molecule. In **1c**, starting from structure **1**, equatorial oxygen atoms are placed in such a way that the angle W–C–O becomes 180°. Finally, all the above changes are incorporated into structure **1d**. We should underline that all the encountered distances are kept constant. Another constraint, in terms of the selected strategy, is the fixed position of the W–diimine part. By keeping the W–diimine part constant we succeed in revealing the developed electronic forces. Otherwise the system would relax in several directions, leaving the comparison worthless. The above analysis is depicted in Figure 1. The small structural changes that we introduced induce a relative change in the electronic structure of the complex. These changes, along with several electronic characteristics of the five structures, are depicted in Table 2. Frontier molecular orbitals for all the cases are summarized in Table 3.

metal orbital of proper symmetry, whereas a filled metal π orbital forms a second dative overlap with an empty CO π orbital. Up to a point, the π-bonding formation strengthens the σ bond and vice versa.

Back-donation also occurs in the case of other π*-accepting ligands, such as 1,10-phenanthroline. On the basis of group theory concepts back-bonding can occur through an overlap with the $d_{xz}$, $d_{xy}$ and $d_{x^2-y^2}$ metal orbitals, with the latter being more realistically envisioned as a linear combination of $d_{z^2}$. Under the framework of the above discussion the diimines in the complexes under study certainly act competitively (*trans* influence) with the equatorial carbonyls. Furthermore, the molecules develop their conformation in space in a way that diminishes steric hindrance and electronic repulsion. This electronic repulsion is formed from several interactions among occupied fragment orbitals. $W(CO)_4$(diimine) compounds have a first coordination sphere of octahedral geometry and consequently steric hindrance does not play a significant role in the observed structure. As a result, the interesting structural features that we described seem to arise from a compromise between back-bonding and other electronic repulsions.

According to data presented in Table 3, the three highest occupied molecular orbitals are very close in energy, with the major contributions coming from the d orbitals of the metal and the π* character of the carbonyl group. The high diimine contribution to the HOMO–2 describes the W → diimine π* back-bonding. This energetic similarity holds for all the other complexes of the same type[1] indicating that HOMO–2 is spectroscopically the most important of the

higher occupied orbitals. The main difference between the HOMO and both the HOMO–1 and HOMO–2 is that the character of the carbonyl group is not the same. The HOMO is mainly dominated by the equatorial COs, while HOMO–1 and HOMO–2 are dominated by the axial ones. These three orbitals are related to the $t_{2g}$ orbital set in W(CO)$_6$[13] concerning their π*-back-bonding character. We have to keep in mind that a splitting to $a_1$, $a_2$, and $b_1$ is caused by the $C_{2v}$ symmetry. On the other hand, HOMO–3 to HOMO–5 are localized on the diimine moiety, as well as LUMO, LUMO+1, and LUMO+2, with the first being very close in energy. LUMO+3 and LUMO+4 arise mainly from the axial carbonyls.

The metal $d_{xz}$ contribution to the LUMO and the W/diimine mixing in the HOMO–2 (it contains bonding interactions between the d orbital of the metal and the π* orbitals of the carbonyl groups) are consistent with the π-back-bonding theory. To gain more insight into the bonding scheme of **1** we envisioned the molecule as consisting of two fragments, namely W(CO)$_4$ and phen, acting as a donor and acceptor of electron density, respectively.[14] The derived picture of this fragment orbital analysis is demonstrated in Figure 2 for the HOMO–2 to LUMO. The FMOs of the central unit W(CO)$_4$ are presented on the left side of the diagram, whereas those of the diimine are on the right side. As indicated, the HOMO and HOMO–1 are predominantly localized on the W(CO)$_4$ fragment, with the LUMO being a combination of the LUMO from the diimine and the HOMO–2 from the metal–carbonyls. Of course we have to keep in mind that an increased back-donation of the metal to the heteroligand (N ligand) results in a decreased back-donation to the carbonyl ligands. The aforementioned combination along with the localization of HOMO–2 are indicative of the back-donation procedure. To be more precise, the HOMO–2 of the complex is a mixture of 86.2% of the HOMO–2 of W(CO)$_4$ and 6.5% of the LUMO of phen. This reveals the back-donation path of the electron density from the main core back to the diimine, for a total amount of 0.022 e$^-$, as computed by the Frenking et al.[14] charge decomposition method.

Recently, an analogous treatment of the W(CO)$_4$(pq) complex yielded an amount of 0.054 e$^-$, revealing a more effective back-bonding pathway.[5] At this point we should emphasize that mixing of frontier orbitals is an important parameter of the system and is connected to the negative solvatochromism and the existence of NLO properties for these types of compounds.

According to the aforementioned scheme we could expect the back-donation to the CO groups to be more effective if **1** had not adopted its existing bent geometry. Even if we adopt the atomic angular overlap model it is clear that more electron density is necessary to keep the W(CO)$_4$ fragment together when the structure deviates from orthogonality.

In the current analysis, we examine the bending of the axial carbonyl as a two-step procedure, **1b**→**1a**→**1**. Stated otherwise, we keep the bend of the equatorial CO units towards each other constant and monitor the axial ones

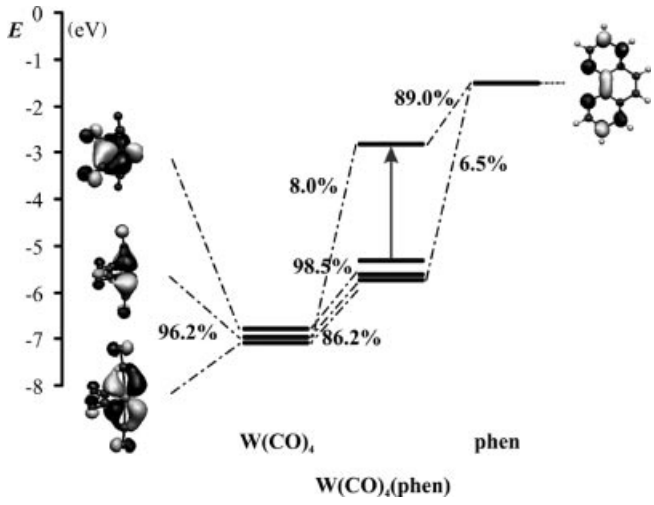

Figure 2. Schematic energy diagram of the induced structural changes in **1**.

deviating from orthogonality. From a frontier orbital point of view, the first step induces major changes, as is expected by the relative geometrical ones. Metal and equatorial carbonyl orbitals are significantly stabilized, while axial carbonyl orbitals seem to become destabilized as well. Diimine orbitals are less destabilised. This finding justifies the inverse order of HOMO–2 (the main, spectroscopically relevant orbital in **1**) and HOMO–1 in **1a**. These trends have an immediate effect on the HOMO–LUMO gap, which according to our calculations increases from 2.30 eV to 2.39 eV in the first step, while it is minimized to 2.37 eV in the second step. This second step is connected to the slight diimine orbital stabilization, whereas the rest of the molecule is destabilized to the same extent. Both steps offer a total 1.92 kJ/mol stabilization to the system. From a partial charges point of view, as calculated by Mulliken's population analysis (provided as Supporting Information), we ascertain that, along the series, the metal and diimine gain electron density at the expense of the carbonyls.

Considering all the aforementioned data, from the back-bonding concept we conclude that the diimine ligation is very crucial. As soon as phenanthroline binds, it demands, as a π acceptor, more electron density. The latter is moved from the carbonyls to phenanthroline. We will try to clarify this concept in terms of a fragment orbital analysis. First of all, starting from **1b**, we confirm that the σ donation of the diimine to the system reduces as we move towards **1**. This is also clearly demonstrated by the contributions of the W(CO)$_4$ empty orbitals to the formation of $27b_2$ (HOMO–5) and $35a_1$ (HOMO–8) orbitals (3.9% and 4.9% for **1b**, 3.8% and 4.6% for **1a** and **1**). The total donation is reduced from 0.398 to 0.394 and 0.385 e$^-$, respectively. On the other hand, back-donation to *o*-phenanthroline is increased when going from **1b** to **1a**, as expected. Back-bonding occurs through the transfer of electron density from the HOMO–2 of W(CO)$_4$ to the $5b_1$ and $6b_1$ of the diimine, forming the $13b_1$ and $14b_1$ orbitals of the complex. Thus,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the contribution of the empty orbitals of the diimine to the formation of $13b_1$ increases from 7.9% to 8.6%, while the contribution of the $W(CO)_4$ fragment to $5b_1$ of the diimine increases from 7.5% to 8.2%. Back-donation reduces slightly when going from **1a** to **1** and this is where the electron repulsion concept is applied. $W(CO)_4$ and phenanthroline filled orbitals repulse each other and the oxygen atoms bend in order for these forces to reach equilibrium. But this is rather the result than the cause (vide infra).

Up to this point we determined the nature of the driving forces that bend the system from **1b** to **1**, through **1a**. In summary, the major effect comes from the existence of phenanthroline. The system adopts the geometry that minimizes the electron repulsion for all the present ligands. This is further enhanced by the need for diminishing the electron repulsion of the fragment. If the system has a perfect octahedral geometry before these changes started to occur then another feature must also be explained. The bend of the axial carbonyls is sensitive to the back-bonding of the equatorial diimine ligands. Thus, the axial COs deviate from linearity by 3.25°, while the related differentiation in the case of the equatorial COs is only 1.35°. This means that the axial ligands are the most sensitive to the coordination diimines on the metal atom. The aforementioned conclusion is rather peculiar if the *trans* influence is kept in mind, along with the fact that the bite angle of the equatorial COs certainly has to be enlarged in order for the phenanthroline σ bonding to be effective. A natural arising question is why that happens. To provide a satisfactory answer we should examine the way back-donation evolves in space. As we have already mentioned back-bonding to phenanthroline is set through the $5d_{xz}$ orbital ($b_1$ in symmetry) of the metal and consequently the carbonyls that compete with the diimine are the axial and not the equatorial ones.

To proceed with our analysis, the bending of oxygen atoms should be further explained. As we have already mentioned, in the axial sites the carbonyls bend towards the "inside", while in the equatorial ones they bend towards the "outside". According to a frontier orbitals point of view, bending in the latter case causes stabilization of the orbitals centered on both carbonyls and the metal, whereas it destabilizes the diimine orbitals in a complete inverse way as compared to **1a**→**1**. Thus **1c**→**1** offers 0.86 kJ/mol to the system. This is slightly less than the 1.14 kJ/mol for **1a**→**1**. The induced stabilization, as an absolute value, is in both cases rather small. On the other hand, if compared to the relative value for **1b**→**1a**, which arises from changes in back-donation, it is considered relatively high and this finding becomes more valuable if we take into account the significantly smaller geometric change in this case.

Going from **1c** to **1** the back-donation to the carbonyls increases (0.3% rise in the carbonyl LUMO contribution to $36a_1$). This happens because carbonyls have a better overlap with the $5d_{x^2-y^2}$ of the metal, which is the most suitable d orbital for back-donation, because of its orthogonal arrangement to the *yz* plane. Furthermore, a linear combination of $d_{z^2}$ and $d_{x^2-y^2}$ is also present. This situation leads us to reevaluate the C to O σ donation. In order to reevaluate this process we used the concept of natural hybrid orbitals, which are derived by a natural bond orbital analysis.[15] Before we proceed we have to clarify that although the absolute values, which are extracted from the NBO analysis, are different from those extracted through the Mulliken population analysis applied in the rest of this report, the following results and described trends are in total accordance. Indeed, σ bonding through the equatorial W–C–O unit is also favored. Calculated deviations between the geometrical direction of the bond and the related direction of the hybrid orbital are reduced by up to 1.9° for W–C and 4.7° for C–O. This is a direct consequence of the diimine ligation to the system.

The case of **1a**→**1** seems to be analogous. It is clear that axial carbonyls accept electron density from the metal $d_{xy}$ orbital. Unfortunately, in each case changes in fragment contributions and relative energy are below the method precision. The hybrid orbitals of the complex seem to slightly change their conformation due to a best alignment of the carbon atoms to the π-orbital of the tungsten, at the expense of carbon–oxygen overlap and σ bonding.

Trying to summarize the above facts, we must emphasize that the suitable orbitals for back-donation are the $d_{xz}$, $d_{xy}$, and $d_{x^2-y^2}/d_{z^2}$ metal orbitals, which offer electron density to the diimine and also the axial and equatorial carbonyls. The bending of the C–O bonds is, in each case, the result of the tendency of the system to adopt a configuration in space that minimizes the electron repulsions between the bonds involved in the complex formation. The whole situation is best described by **1d**, which contains all the aforementioned changes. As demonstrated in Table 2 this structure shows the greatest destabilization, giving a final value of 2.95 kJ/mol. Despite the fact that this value is relatively low it is indicative of the energy stabilization that is offered to the system from the arrangement of the ligand in space, in such a way that is convenient from an electronic point of view.

### 2.2. Relation Between Structure, Back-Bonding, and Electron Properties

At the second level of our approach, we tried to discover the trends that govern the structural features of the complexes under study, such as the bending of axial carbonyls in terms of the ability of the ligand to partake in back-donation. As already mentioned (vide supra), these features are anticipated to be correlated to the electronic properties of the compound. This is an essential hypothesis, which we try to test in this report.

There are three important factors that govern the electronic structure of $W(CO)_4$(diimine) complexes. First of all, the σ-donating ability of the coordinating nitrogen atoms, followed by the existence of π*-orbitals of proper energy and symmetry, which are suitable for the evolution of back-donation, and thirdly the magnitude of the binding N–W–N angle. Taking all these factors into consideration we properly selected eight ligands in order to demonstrate probable induced differences in compound structure and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

electronic behavior. First of all, we employed 1,10-phenanthroline (phen – compound **1**) and 2,2′-bipyridine (bpy – compound **2**), which are two of the most widely used aromatic ligands in synthesis. In order to test the influence of symmetry and binding angle we also employed two pyridine moieties (2py – compound **3**), in a sense that they would create an aromatic, but not a chelated first coordination sphere, around the metal. Consequently, we selected 1,4-diazabutadiene (DAB – compound **4**), *N*,*N*′-bis-methyl-1,4-diazabutadiene (Me-DAB – compound **5**) and *N*,*N*′-bis-isopropyl-1,4-diazabutadiene (*iPr*-DAB – compound **6**). These are highly symmetric aliphatic diimines and their properties will be compared to those of the aromatic ones. Finally, we introduced 1,2-ethylenediamine (en – compound **7**), since it is a bidentate diamine without any orbitals suitable for back-bonding and two ammonia ligands (2 $NH_3$ compound **8**) with almost the same σ-donating ability to the en, but without any steric constraints present.

Structural characteristics of compounds **2**–**8** are depicted in Table 4. Relative data for **1**, extracted from Table 1 and Table 2 (vide supra) are also reported for uniformity purposes. All data presented are extracted at the G98-B3LYP level of theory and show satisfactory agreement with other reported computational results and crystal structures.[4,9,11] To the best of our knowledge, compound **8** has not yet been prepared, but is included in our analysis for comparison purposes.

All of the complexes under study adopt a distorted pseudo-octahedral geometry. We started our analysis with the approximation described in all standard textbooks.[16] Within the framework of π* back-bonding different structures are compared based on the magnitude of the W–L and C–O bond lengths. In our case, the axial W–C bonds are significantly longer than the relative equatorial ones. The length of the W–N bond is increased in the order **4** < **5** ≈ **6** ≈ **2** < **1** < **3** < **8** < **7**. Thus, bonding of the N ligand seems to be stronger in the case of the DAB ligands as compared to the aromatic ones, while the amine complexes demonstrate weaker bonding along the series. This series is also indicative of the nitrogen hybridization where $sp^3$ hybridization (present in the amines) affords longer W–N bonds. The relative series, regarding the W–$C_{eq}$, W–$C_{ax}$, C–$O_{eq}$, and C–$O_{ax}$ bonds, is **8** < **3** ≈ **1** ≈ **2** < **7** < **4** < **6** ≈ **5**, **8** ≈ **3** < **1** ≈ **2** < **4** ≈ **7** < **6** ≈ **5**, **5** < **6** < **7** < **4** < **3** ≈ **1** ≈ **2** ≈ **8**, and **5** ≈ **6** < **7** < **4** < **1** ≈ **2** < **3** ≈ **8**, respectively. According to the above bonding scheme we conclude that diazabutadiene ligands are better π* acids than *a*-diimines and amines, a finding that definitely make sense. Nevertheless, there are some points in the above series that certainly deserve to be further explained. First of all, within the R-DAB ligands it seems that the series of π* acidity that holds is H- < Me- < *iPr*-. In other words, the increase of the electron-releasing character of the substituents on the nitrogen atoms in the R-DAB ligands increases the electron-donating character of the σ bond and in consequence it increases the π-acceptor character. The observed trend is certainly not normally expected. Secondly, the first coordination sphere of **7** seems to resemble that of the R-DAB ligands, while several similarities exist between **3** and **8**. This trend should be further explained on the basis of important differences in nature between these organic substances.

To proceed with our analysis we examined, at first, a structural feature that is certainly underestimated in the existing literature in the field. This is the binding and bending angles of the carbonyl moieties. In Figure 3 and Figure 4 these features are schematically depicted. Thus, we observe that the N–W–N bite angle increases in the series **5** ≈ **4** ≈ **6** < **2** < **7** ≈ **1** < **3** ≈ **8**, while the relative series in the case of $C_{eq}$–W–$C_{eq}$/$O_{eq}$–W–$O_{eq}$ ($\varphi_1$/$\varphi_2$) and $C_{ax}$–W–$C_{ax}$/$O_{ax}$–W–$O_{ax}$ ($\varphi_3$/$\varphi_4$) is **8** < **3** ≈ **7** < **2** ≈ **1** < **6** < **5** < **4** and **4** < **6** <

**5** < **2** ≈ **1** < **7** ≈ **3** < **8**, respectively. All the complexes under study share the same structural features, described earlier (vide supra). The $W(CO)_4$ fragment deviates from orthogonality with the axial carbonyls bending away, while the equatorial ones bend towards the N ligand. In both cases, the bending of the oxygen atoms is larger. Moreover, several other features deserve attention. First of all, both axial and equatorial carbonyls deviate from orthogonality in an analogous way and the following relations, Equation (1) and (2), are extracted.

$$\varphi_1 = -0.5935\ \varphi_3 + 195.03\ (r = 0.97) \quad (1)$$

$$\varphi_2 = -0.6372\ \varphi_4 + 202.59\ (r = 0.95) \quad (2)$$

$\varphi_1$ and $\varphi_2$ are the angles $C_{eq}$–W–$C_{eq}$ and $O_{eq}$–W–$O_{eq}$ and $\varphi_3$ and $\varphi_4$ the angles $C_{ax}$–W–$C_{ax}$ and $O_{ax}$–W–$O_{ax}$, respectively.

Moreover, as it is depicted in Figure 3 and Figure 4 in both cases the deviation from linearity observed in the carbonyl moiety is enhanced, in general terms, with the deviation of the whole group from orthogonality. Thus, in the case of the axial carbonyls, the largest deviation is observed for **6** and **4** and the smallest for **8** and **9**, whereas for the equatorial carbonyls the largest deviation is observed in **4** and the smallest are also in **8** and **9**. Last but not least, the trend followed within the $W(CO)_4$ moiety is reversed in the case of the W–heteroligand bite angle. Nevertheless, we

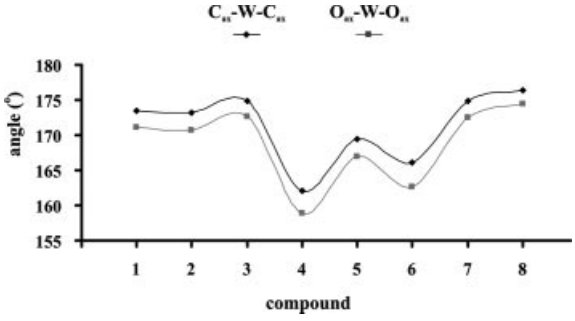

Figure 3. Schematic diagram of the $C_{ax}$–W–$C_{ax}$ and $O_{ax}$–W–$O_{ax}$ angles for compounds **1**–**8**.

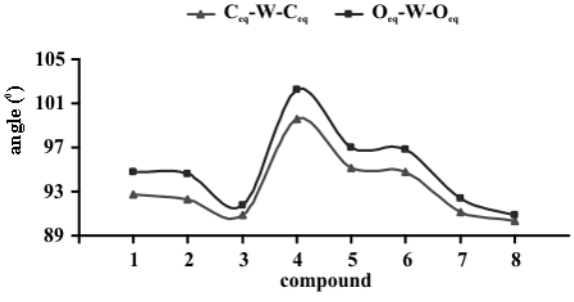

Figure 4. Schematic diagram of the $C_{eq}$–W–$C_{eq}$ and $O_{eq}$–W–$O_{eq}$ for compounds **1**–**8**.

should emphasize the fact that the two compounds without a bidentate ligand, namely **3** and **8**, show the same N–W–N angle, despite the different nature of the nitrogen ligands.

Proceeding with our discussion in electronic terms the contribution of different fragments to the frontier orbitals of the complexes is depicted in Table 5. Complex **2** has a framework of frontier orbitals analogous to the aforementioned one for **1** (vide supra), with the expected changes that arise from the fact that they have different aromatic diimine groups. For example, the first unoccupied diimine based $a_2$ orbital lies at a lower energy in **1** as compared to **2**. On the contrary in compounds **4**–**6** a different pattern is observed. The LUMO+3/+4 in **2** are stabilized and become the LUMO+1/+2 in **3**. These are predominantly axial carbonyl in character. The HOMO manifold for these compounds remains localized, mainly on the metal giving a relevant bonding scheme.

Complex **3** contains two pyridine moieties and not a bidentate ligand. The relaxed structure, in which the two pyridines are twisted from the planar disposition in order to minimize the hindrance that appears between the pyridine *ortho*-H atoms, destabilizes the frontier orbitals and affects the back-donation pathway. As a result back-bonding is no longer evolved through an orbital of b symmetry. In the case of pyridine ligands a metal $d_{x^2-y^2}/d_{z^2}$ ($a_1$ in $C_{2v}$ first coordination sphere) linear combination interacts with a pyridine-based a* orbital (Figure 5).

Finally, in the case of the diamine and bis-amine complexes the bonding scheme, apart from the three highest occupied orbitals, is different. Most of the unoccupied orbitals are carbonyl localized, with the contribution of the heteroligand being of low to only moderate importance (e.g. LUMO+3 in **7** and LUMO+2 in **8**). Moreover, an unoccupied orbital with a predominant d(σ*) character was not found in any of the above compounds. In cases where this sort of contribution existed it corresponded to only a part of a highly delocalized orbital. Thus, low-lying LF states contradict the arguments of the traditional ligand field theory. This fact is consistent with previous work done by Vlček et al.[4]

In terms of back-donation to the N ligand the main pathway followed for all cases (apart from **3**) is the out-of-phase interaction between an orbital of $d_{xz}$ tungsten/π*-axial carbonyl character and a π* heteroligand. This is best demonstrated by the HOMO–2 and LUMO (vide supra). Through an FMO analysis, analogous to that described in the previous paragraph, we concluded the following series of increasing back-donation, **8** ≈ **7** < **3** < **1** < **2** < **5** ≈ **6** < **4**, with the diamine and bis-amine compounds showing trivial back-bonding and **4**, which contains the DAB ligand, having the maximum back-bonding in the series. The comparison was based on the interaction of the HOMO–2 of the $W(CO)_4$ fragment (HOMO in the case of **3**) with the π* orbitals of the heteroligand (LUMO to LUMO+2 of proper symmetry), as demonstrated in Table 4. The same series in terms of the ligands is $NH_3$ ≈ en < py < bpy < phen < Me-DAB ≈ *iPr*-DAB < DAB. Thus, aliphatic diimines interact stronger with the metal fragment than aromatic ones,

with the amines not showing back-donation at all. This conclusion certainly makes sense and it certainly reflects the nitrogen hybridization changing from $sp^3$ for $NH_3$ to $sp^2$ for DAB.

Taking the aforementioned findings into consideration we verified that the bond lengths do not demonstrate the correct behavior according to the induced back-donation. On the contrary, the C–W–C deviation from orthogonality and C–O deviation from linearity follow the back-donation trends! In other words, the stronger the back-donation the larger the deviations. This observation is originally presented in this report. Indeed, C–W–C and O–W–O angles correlate effectively with the observed back-donation magnitude (bd), as proven from the following relations [bd can also be provided as a function of the angles $\varphi_1$ and $\varphi_2$, through Equations (1) and (2) since the deviation of the equatorial ligands are a consequence of the bending of the axial ones]. In these relations bd is the total percentage of contribution of unoccupied π*-type heteroligand orbitals in the back-donation pathway.

From the above Equation (3) and (4) we verify that the bite angles of the CO groups are not only indicative of π* back-donation but they are also correlated to back-donation in a linear fashion. In other words, it is proved that the structural indices that best describe back-donation in symmetric compounds of the type W(CO)$_4$(NN) or W(CO)$_4$N$_2$, are the deviations of the C–W–C angles from orthogonality and O–C–W angles from linearity. The larger the existing deviation the stronger the back-donation. This contradicts the traditional concept of bond lengths, which does not always lead to correct results. This conclusion

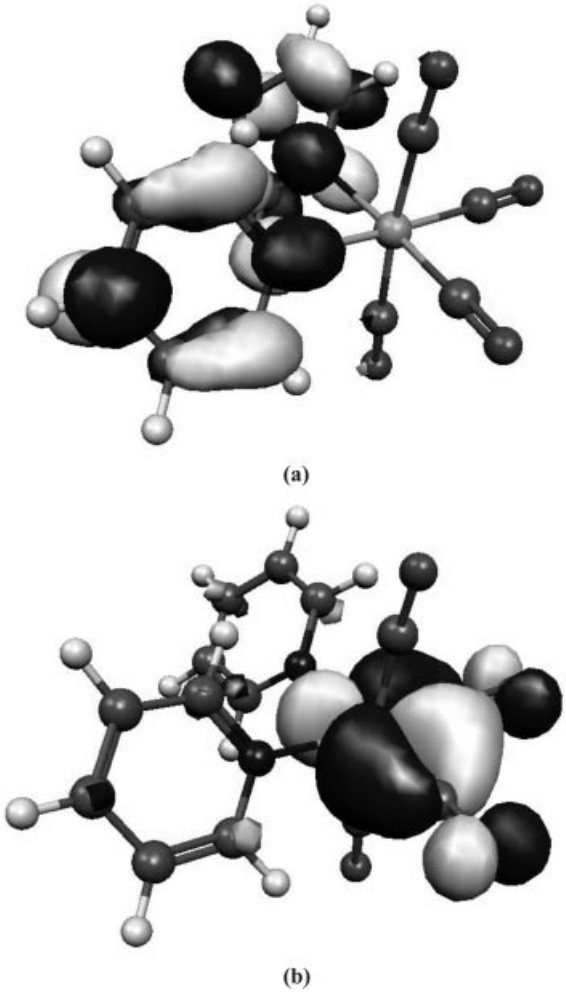

Figure 5. Contour plots of the HOMO (a) and LUMO (b) for compound **3**.

should also apply to the symmetric carbonyl compounds with other types of ligands, such as phosphanes and phosphites.

$$bd = -2.1238\ \varphi_3 + 375.51\ (r = 0.97) \quad (3)$$

$$bd = -1.9562\ \varphi_4 + 341.63\ (r = 0.97) \quad (4)$$

## 3. Concluding Remarks

In the present report, we tried to study the structures of $W(CO)_4(NN)$ and $W(CO)_4N_2$ compounds in terms of π* back-donation. Our approach was divided into two parts. Firstly, we proved, for the first time, that the observed structural deviations from orthogonality, regarding C–W–C bite angles and deviations from the linearity of the O–C–W angles present in complexes of this type, have their origin in the evolution of the necessary back-donation pathways. The energy difference between the two structures (the bent and the totally orthogonal one) is computed to be 2.95 kJ/mol.

Secondly, we analyzed the back-donation pathways of a series of compounds having different types of ligands. We proved that this is achieved through a $d_{xz} \rightarrow$ N-ligand electron donation, except in the case of the $W(CO)_4(py)_2$ compound. Moreover, we showed that back-donation is correlated to the above-mentioned structural features in a linear manner.

Keeping this scheme in mind, along with the fact that among all the ligands studied in our series DAB is involved in the maximum back-bonding and $NH_3$ the minimum, we can develop a new structure-to-properties type scale regarding back-donation. From a multiple regression analysis of the aforementioned data (Figure 6) we developed the following relation (details for the linear regression are supplied in the Supporting Information) which implies that the magnitude of back-donation is a linear combination of the four angles of the CO groups (since $\varphi_1$ and $\varphi_2$ are dependant on $\varphi_3$ and $\varphi_4$, respectively), see Equation (5).

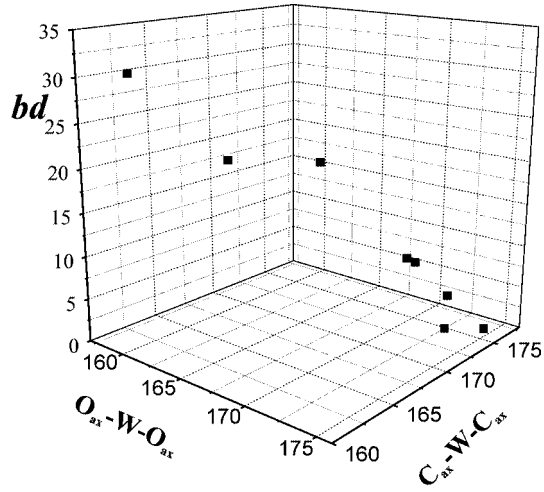

Figure 6. Scatter plot of bd = $f(\varphi_3, \varphi_4)$. $R^2 = 0.98$ (from multiple regression analysis).

$$bd = 510.15 - 10.58\ \varphi_3 + 7.79\ \varphi_4 \quad (5)$$

The standard deviation is 2.34.

Moreover, if we define the π* acidity related to the DAB (100% π* acid) and ammonia molecules (0% π* acid) we get Equation (6).

$$bd' = 3.00\ bd \quad (6)$$

On the basis of Equation (6) we can attribute a 29% of π*-accepting ability to bpy compared with DAB.

The extent of back-donation and thus the bending of the $W(CO)_4$ group should be correlated to other properties of the system such as the slope of solvatochromic plots.[8] It is well known that the complexes under study exhibit a large negative solvatochromism, which refers to the blue shift of the low energy MLCT transition of the complex, with a simultaneous increase in the polarity of the solvent. This phenomenon is directly related to a difference between the ground- and excited-state dipole moment. The ground-state dipole moment is certainly determined by the geometry of the compounds and this geometry has its origin in the extent of back-donation as we have already proved (vide infra). As a result the extent of solvatochromism should be correlated to the extent of back-donation.

## 4. Computational Details

Ground-state electronic structure calculations of all complexes under study have been performed using density functional theory (DFT)[17] methods by employing the Gaussian 98 software package.[18] The functional that was used throughout this study is the B3LYP, consisting of a hybrid exchange functional, as defined by Becke's three-parameter equation[19] and the Lee–Yang–Par correlation functional.[20] The ground-state geometries were obtained in the gas phase by full geometry optimization and the optimum structures, located as stationary points on the potential energy surfaces, were verified by the absence of imaginary frequencies. Moreover, the derived wave functions were free from internal instabilities. Structures were regularized in order to satisfy the $C_{2v}$ geometry in **1**–**2** and **4**–**6**. Complex **3** was optimized under no symmetry constraint. The optimum structure obtained a practically $C_2$ symmetry and the optimization was repeated in this point group. Complex **7** was optimized also under the $C_2$ symmetry, whereas complex **8** was optimized without any symmetry constraint. The basis set used throughout this study is the full double-ζ LANL2DZ basis function, together with the corresponding effective core potential for tungsten.[21] Percentage compositions of molecular orbitals from the four contributing fragments (the metal, the N ligand, the axial and equatorial carbonyls) were calculated and analyzed using the AOMix and AOMix-CDA programs, with the latter being extensively used for the fragment molecular orbital (FMO) analysis.[22] The graphics presented here were drawn with the aid of Molekel.[23] An NBO population analysis has been performed with the NBO 3.1 program as implemented in Gaussian.[15b] Finally, a multiple regression analysis was carried out using the commercial Origin 6.0 software package.

**Supporting Information** (see also the footnote on the first page of this article): Mulliken charges for compounds **1** and **1a**–**1d** (Table S1), details for the linear regression provided for Equation (5) and calculated atomic coordinates (S2–S9) for all compounds under study.

# Pentacarbonyl[2-(2′-pyridyl)quinoxaline-κ$N^4$]tungsten: A Combined Study of Its Conformational and Electronic Structure Based on Experimental and DFT-TDDFT Data

**Christodoulos Makedonas,[a] Irene Veroni,[a] and Christiana A. Mitsopoulou*[a]**

**Keywords:** Pentacarbonyl complexes / 2-(2-Pyridyl)quinoxaline / Tungsten / DFT calculations / TD-DFT calculations / Pi stacking

Photolysis of $W(CO)_6$ in the presence of 2-(2′-pyridyl)quinoxaline (pq) results in the formation of $W(CO)_4$(pq) via an intermediate product $W(CO)_5(N^4$-pq) (**1**). In **1** the pq ligand that has three nitrogen atoms – two pyridine and one quinoxaline type – is coordinated in a monodentate fashion. This is the first example, where the pq ligand is coordinated in a monodentate fashion and especially from a quinoxaline nitrogen atom ($N^4$). Complex **1** has been fully characterized and its crystal structure has unambiguously demonstrated that pq is preferably coordinated through $N^4$ rather than the $N^1$ and $N^{1'}$ atoms, while its packing is governed by π–π interactions and hydrogen bonds. The almost perfect "face-to-face" alignment of the condensed quinoxaline rings is attributed to the existence of the electron-withdrawing groups, namely $W(CO)_5$ and the pyridine ring. The aforementioned preference for $N^4$ atoms has been elucidated by thermodynamic means and explained in terms of the frontier orbitals. Time-dependent density functional theory has been used for the investigation of the excited states of **1**. The calculated vertical excitation energies are consistent with the experimental data showing that the low-lying solvatochromic band of **1** in the UV/Vis spectra is best described by the term MLCT/LLCT.

## 1. Introduction

Both the photochemical substitution of complexes such as $M(CO)_6$ and the organometallic complexes between transition-metal carbonyls and N-containing heterocycles continues to be the subject of intense interest.[1] The photochemical and electronic properties, along with the potential of these complexes in industrial applications, have led to many studies for use as photosensitizers, catalysts, and conducting coordinating polymers.[2–4] Photolysis of the group VI metal hexacarbonyl compounds in the presence of potentially bidentate diimine-type ligands N–N [2,2′-bipyridines, 1,4-diazabutadienes, or 2-(2′-pyridyl)quinoxaline] ultimately results in the formation of the respective $M(CO)_4$(N–N) chelate complexes.[1,5–6] This process reportedly involves the initial photosubstitution of one CO group, leading to an intermediate product of type $M(CO)_5$(N–N) in which the N–N ligand is coordinated in a monodentate fashion. The importance of asymmetrical transition-metal complexes, namely $M(CO)_5L$ where M = Cr, W and L = π-conjugated ligand, in the field of second-order NLO materials is now very well documented.[7]

Among the aforementioned bidentate N–N ligands our attention has been attracted by 2-(2′-pyridyl)quinoxaline (pq), which combines the bridging properties of quinoxalines along with the chelating efficiency of 2,2′-bipyridine. The former can be explained by the discovery that polypyridyl ligands, which own low-lying LUMOs and contain more than one nucleophilic center, play an important role in the synthesis of metallo–organic compounds with various applications in material chemistry. Besides, the quinoxaline structure is widely recognized as an important component of a great number of natural compounds with applications in areas as diverse as antibacterial, antiviral, anticancer, antifungal, antihelmintic, insecticidal agents,[8] electron-withdrawing groups in p-conjugated polymer chemistry,[9] fluorescent dyes,[10,11] and optical-based sensors for anions in organic media.[12] While the vast majority of these materials are based on organic molecules there has been a growing interest in developing metal–containing compounds over the last few years. The central motivation behind this effort has been to combine the unique properties of transition-metal complexes (e.g. color, redox behavior) with those associated with the existence of the two nitrogen atoms in suitable bridging *para* positions, which can easily be functionalized allowing one to tailor their properties.[13]

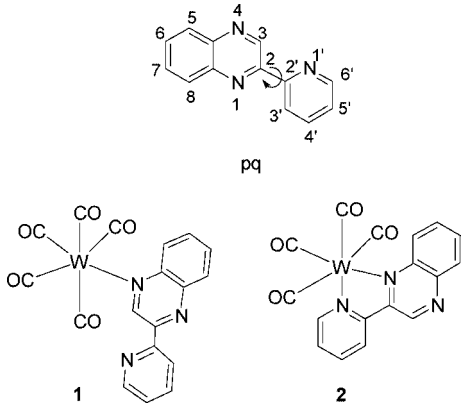
 WILEY InterScience DISCOVER SOMETHING GREAT © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Up until now, a plethora of metal complexes have been reported where pq is bicoordinated through the $N^1$ and $N^{1'}$ atoms,[5,6,14,15] but there has never been any undoubted proof for coordination of a metal at a $N^4$ atom. In spite of this semi-empirical calculations have shown that the HOMO of pq is mostly a "lone" electron pair on $N^1$ and $N^4$,[16] thus these two nitrogen atoms should share almost the same propensity for coordination. The thermodynamic stability that offers the chelation of pq after its coordination at $N^1$ should be the major reason for the above experimental observation.

During the photolysis of $W(CO)_6$ in THF in the presence of pq we surprisingly discovered that the photogenarated ring closure reaction of $W(CO)_4$(pq) goes through $W(CO)_5$($N^4$-pq) (**1**);[17] the latter has been isolated and fully characterized. In order to explain the preference of the $N^4$ atom over the $N^1$ and $N^{1'}$ atom upon ligation (Scheme 1), and explain the electronic spectra of **1**, we have undertaken a DFT and TDDFT study and combined the data with the experimental results.



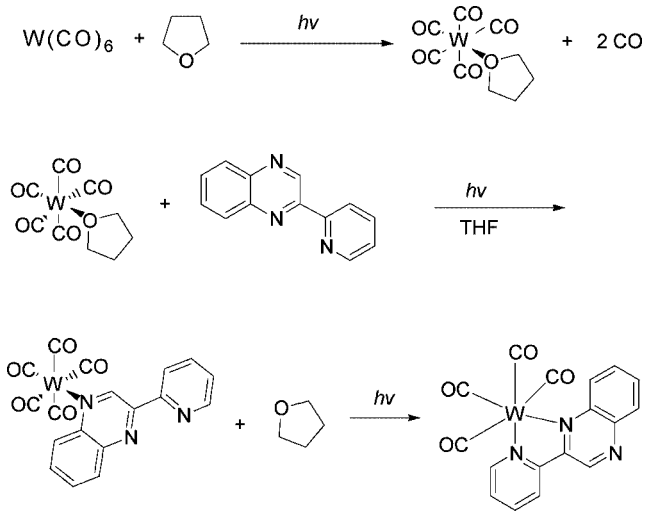
Scheme 1.

The main part of this report is organized as follows: in Section 2.1 a discussion of experimental data such as 2D NMR spectra indicating the coordinating nitrogen atom and crystal packing of **1** on the basis of the developed intermolecular forces is given. The theoretical results are critically analyzed and compared with experimental data in Section 2.2. This section is subdivided into two subsections. In the first subsection the ground state of **1** along with the structure of the other two possible isomers are discussed in terms of DFT data compared with the experimental structures. In the second part the predominant conformation structure is given in thermodynamic terms. Finally, in the last section, the UV/Vis spectrum is fully characterized by TD-DFT means.

## 2. Results and Discussion

### 2.1. NMR Spectroscopic Data and Crystal Packing

The complex $W(CO)_5$(pq) (**1**) is an intermediate product from the photolysis of $W(CO)_6$ in THF in the presence of pq leading to the photogenerated ring closure reaction $W(CO)_4$(pq). Surprisingly, the coordinated nitrogen atom is $N^4$ and not the usually referenced $N^1$. Of course, **1** is not the only intermediate product but it is the main one (yield 70%). The $W(CO)_5$($N^4$-pq) (**1**) complex was isolated photochemically by a two-stage reaction (Scheme 2).



Scheme 2.

On the basis of a method by Strohmeier and Müller[18] the photolysis of $W(CO)_6$ in THF yields the mononuclear THF adduct $W(CO)_5$(THF), which on further photochemical reaction with an excess of pq after a short irradiation time (about 10 min) gives **1** as an orange solid in good yield; further irradiation yields **2**.

A first indication of the coordination site is provided by both $^1$H NMR and HMBC $^1$H-$^{15}$N NMR spectra of **1**. The HMBC $^1$H-$^{15}$N NMR spectrum of pq in $CDCl_3$ (Figure 1) was considered as a first probe for the partial charges on the nitrogen atoms of the free ligand that could be extrapolated so as to provide us with the necessary evidences for the coordinated nitrogen atom in **1**. The aforementioned spectrum contains three independent *J* networks, where each nitrogen atom couples across two or three bonds with the adjacent protons. The nitrogen atoms are of the pyridine type, that is, they provide only one 2p electron to the involved π-electron system and they have their lone pairs in the plane of the conjugated system, in this way keeping their basicity. This is illustrated by the positions of the $^{15}$N NMR chemical shifts that are characteristic of $sp^2$ hybridized nitrogen atoms.[19] Unfortunately, $N^1$ and $N^4$ cannot be assigned unequivocally as the long-range connectivity of both $N^1$ and $N^4$ with $H^3$ and correspondingly with $H^8$ and $H^5$ are not particularly enlightening since $H^8$ and $H^5$ are NMR equivalent. Nevertheless, it has been reported that the chemical shift of $N^4$ is relatively insensitive to the different heteroaromatic substituents at the 2-position of the quinoxaline ring,[20] while the $^{15}$N NMR chemical shift of $N^1$ is found to be strongly dependent on these substituents. On this basis, the most downfield shifted nitrogen atom is $N^4$ ($\delta$ = 331 ppm), followed by $N^1$ ($\delta$ = 319 ppm) and $N^{1'}$ ($\delta$ = 311 ppm), this is in accordance with the semi-empirically calculated partial charges on the nitrogen atom

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

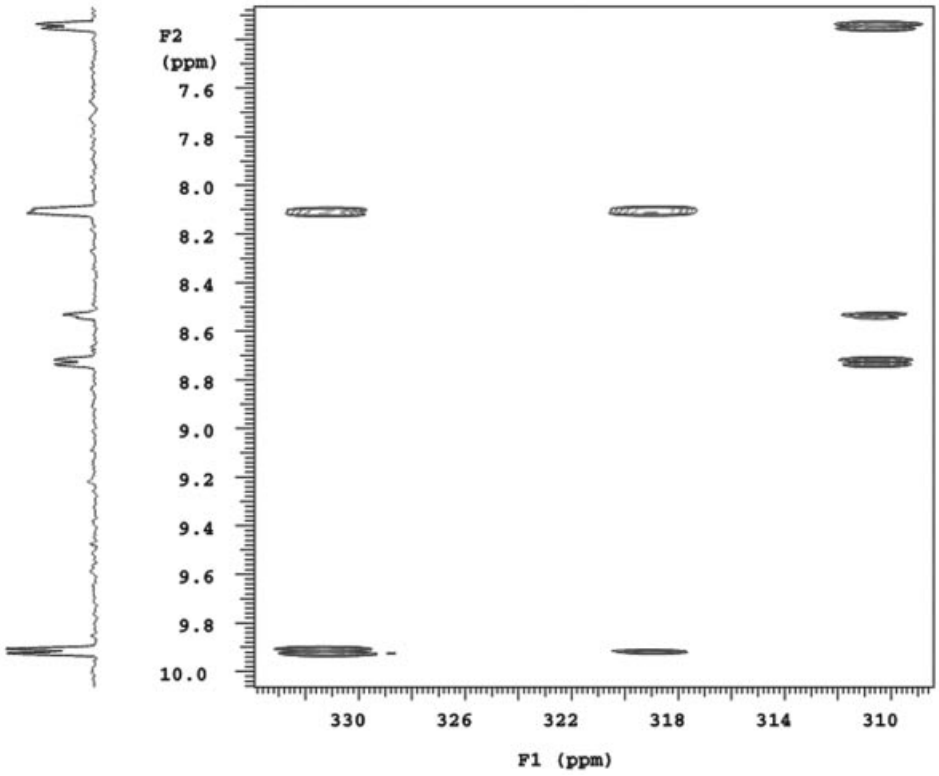


Figure 1. HMBC $^{1}H$-$^{15}N$ NMR spectra of **1**.

of pq.[19] The planarity of pq should establish an inter-annular conjugation between its quinoxaline and pyridyl moiety that allows the π-deficient quinoxaline moiety to accept π electron density from the pyridyl ring. This is illustrated by the downfield shift (deshielding) of the pyridine N in pq, in comparison to the $^{15}N$ NMR chemical shift in the (2-methyl)pyridine molecule.[19]

The ligation of pq to the $W(CO)_5$ moiety through the $N^4$ atom has been proven unambiguously by the elucidation of its structure by single-crystal X-ray diffraction methods.[17] Complex **1** crystallizes in the $P2_1/c$ space group. It is stacked in two different columns in a V-type assembly. In Figure 2, the crystal packing of the complex is depicted along the a axis. In each column the individual molecules are stacked in a "face-to-face" arrangement creating couples (Figure 3). The intermolecular distance of the N-ligand atoms (or planes) involved in this couple is 3.37 Å, suggesting π stacking with strong π–π interactions. Moreover, an almost perfect "face-to-face" alignment of the quinoxaline rings is observed, which is extremely rare.[21] This might be

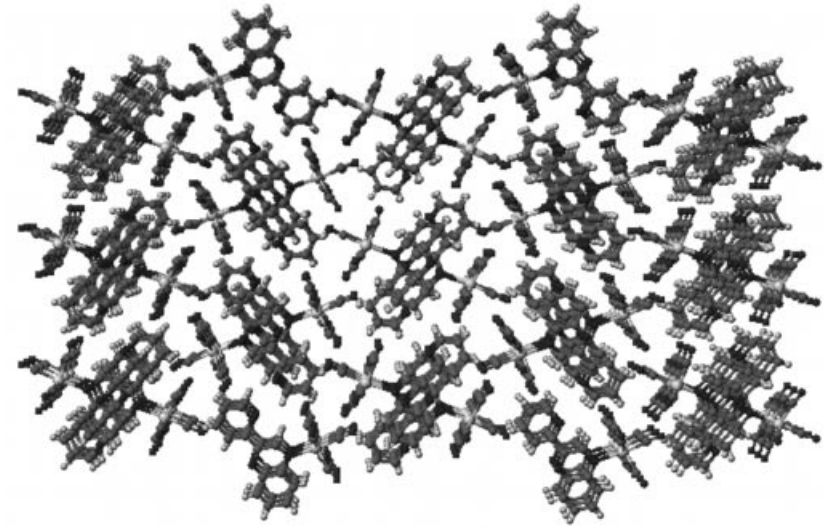

Figure 2. Crystal packing of **1** as it is viewed along the a axis.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

because of the existence of the two electron-withdrawing groups present on the same quinoxaline ring, namely the $W(CO)_5$ fragment and the pyridine moiety, which cause a decrease in π-electron density on the parent ring and consequently the π–π repulsion. The aforementioned observations are of fundamental importance for the further development of inorganic supramolecular chemistry and the tuning and prediction of crystal structures. Moreover, an interesting feature observed in the crystal structure of **1** is the existence of two internal hydrogen bonds $H^{3'}$–$N^2$ [2.548 (0.060) Å and C–H···N = 101.59 (4.10)°] and $H^3$–$N^1$ [2.453 (0.54) Å and C–H···N = 103.37 (4.90)°] and two intermolecular hydrogen bonds between H atoms of the pq ligand and CO groups [$H^5$–$O_{tr}$ 2.382(0.054) Å and 132.12 (4.63)° and $H^8$–$O^4$ 2.514 (0.060) Å and 164.01 (5.18)°], which probably reflects their stacking.

Figure 3. π–π Interactions in complex **1**. A "face-to-face" alignment of quinoxaline rings that overlap with their nitrogen–carbon atoms.

### 2.2. Ground-State Structure

2-(2′-Pyridyl)quinoxaline with its three nitrogen atoms can adopt three different conformations when acting as a monodentate ligand to the $W(CO)_5$ fragment. The first conformation arises from ligation through the pyridine $N^1$, giving structure **N1**, the second arises from ligation through the $N^{1'}$ atom of the first quinoxaline, giving structure **N2**, whereas the third conformation leads to complex **1**, through ligation to **N4**, as pictorially depicted in Figure 4. During the photolytic procedure the parent compound $W(CO)_6$ reacts with the ligand in order to first afford the title complex. In the following sections, its ground-state and electronic behavior are studied by means of DFT calculations.

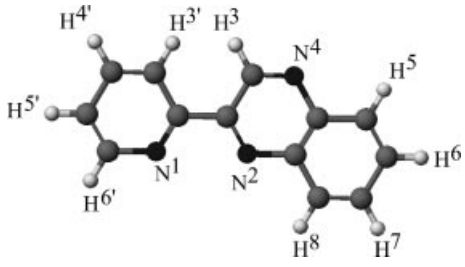

Figure 4. The three different coordination sites of the 2-(2′-pyridyl)quinoxaline ligand along with the numbering system of the H atoms.

#### 2.2.1. Calculation of the Ground-State Structure

In $W(CO)_5$(pq) the tungsten has a distorted octahedral coordination sphere, as is expected, with the diimine ligand to adopt an *anti* conformation. DFT calculations were performed on complex **1** in the gas phase starting from crystallographic data. The main structural features that were taken from both the crystal structure **1** and the calculation **N4** are summarized in Table 1. In the same table structural characteristics of the other two possible isomers are also depicted (vide infra). All theoretical structures under study are viewed in a manner such that the coordinated nitrogen ligand (e.g. the quinoxaline in **N4**) bisects the $W(CO)_4$ fragment, while the noncoordinating nitrogen (e.g. the pyridine in **N4**) lies at the back side of the molecule. In this scheme the numbering of the equatorial carbonyls starts from the front right site of the molecule and continues clockwise. According to data presented in Table 1 the overall agreement between the theoretical (**N4**) and experimental (**1**) structures is generally satisfactory. Nevertheless, the geometrical features (distances and angles) associated with carbonyls 1 and 2 do not follow the general trend. The difference in W–C–O angles, along with the followed numbering scheme, is depicted in Figure 5.

Optimization of the molecule has been performed without any symmetry constraints. This, along with the successful application of the same combination of functional/core potential/basis set in the completely relevant case of the $W(CO)_4$(pq) complex[6] where the 2-(2′-pyridyl)quinoxaline acts as a bidentate ligand through $N^1$ and $N^2$, lead us to hypothesize that electronic effects on their own are not enough to cause carbonyls 1 and 2 to bend by at least 5° more than that of the carbonyls 3 and 4. In order to clarify this difference an inspection of the crystal structure of **1** is essential.

As we have already mentioned the packing of **1** in the solid state is governed by π–π interactions and hydrogen bonding. In Table 2 all the observed C–H···O short contacts are depicted. The entries printed in **bold** refer to the hydrogen bonds that we already mentioned (vide supra), two more entries shown printed in regular font type represent strong interactions, while six short contacts are also given in *italics*.

Both π-stacking and hydrogen bonding stabilize couples of molecules within the same column. Moreover, hydrogen bonds determine the final conformation of **1** within the $P2_1/c$ space group. We believe that the existence of these hydrogen bonds reflects the aforementioned structural differences between **1** and **N4**. In the case where the bonding scheme of $CO^1$ was exactly the same as that of $CO^4$ (88.6° for the N–W–C angle and 176.9° for the W–C–O angle) a decrease in the $CO^1$–$H^{4'}$ interaction (from 2.63 Å and 130.4° to 2.16 Å and 118.8°) and consequently the strengthening of the second short contact ($CO^1$–$H^{3'}$, from 3.03 Å and 130.4° to 2.46 Å and 106.2°) will occur. As a result the parent molecule will take a new position closest to the neighboring one and this could destabilize the packing. Taking into consideration the fact that, for electronic

reasons, carbonyl coordination must be equal in couples (1–2 and 3–4) we conclude that the difference in binding angles arises in order for the stacking to be energetically more favorable.

On the basis of both experimental and theoretical results there are some points that certainly deserve to be further analyzed. Firstly, as it has already been mentioned (vide supra), tungsten has a distorted octahedral coordination sphere, and both the bonds W–N and $W–C_{tr}$ are almost equal to the relative bond lengths W–N(qn) and W–C11 (*trans* to the coordinated nitrogen atom) in $W(CO)_4(pq)$.[6] This implies a similar bonding behavior of the quinoxaline part of the ligand whatever the coordinated nitrogen atom. The induced *trans* influence from the N-donor is postulated by the W–C and C–O distances on the equatiorial plane. The $W–C_{tr}$ bond length is shorter than the relative distances in the equatorial plane, whereas the $C–O_{tr}$ bond is elongated. Secondly, the characteristic bending of carbonyls observed in several other carbonyl compounds is also present here.

To further discuss the aforementioned trend the orbital energies along with the contributions from the different ligands and the metal are given in Table 3. According to data presented in Table 3 the three highest occupied molecular orbitals of **N4** are close in energy and predominantly consist of metal d orbitals [$d_{xz}$ in HOMO, $d_{yz}$ in HOMO–1 and $d_{z^2}$ (as a linear combination with $d_{x^2-y^2}$) in HOMO–2] with a significant contribution from the carbonyl π* orbitals.

These three orbitals are related to the $t_{2g}$ orbital set in $W(CO)_6$[6,22] regarding their π*-back-bonding character. They are mainly dominated by π-type W–C bonding and C–O antibonding interactions and are indicative of the W→CO π* back-bonding. In the HOMO–2 these interactions are mainly localized on the equatorial plane, while in HOMO and HOMO–1 the contribution of the axial carbonyl group is ca. 12.8%. On the other hand, the orbitals HOMO–3 to HOMO–5 are localized on the quinoxaline moiety of the organic ligand; more precisely, HOMO–3 is

delocalized over the three rings of the ligand, whereas HOMO–4 and HOMO–5 are localized mainly on the pyridine and quinoxaline moiety, respectively. The LUMO and LUMO+1 are dominated by quinoxaline π* orbitals of the ligand, whereas LUMO+2 to LUMO+4, also of π* character, arise mainly from the equatorial carbonyls. The HOMO and LUMO of **N4** are depicted in Figure 6.

An unoccupied orbital with a predominant d(σ*) character was not found among the spectroscopically important orbitals. In cases where this sort of contribution exists it corresponds to only a part of a highly delocalized orbital. Thus, low lying LF states, contradictory to the arguments of the traditional ligand field theory, are not expected. This is consistent with previous work done by Vlček et al.[23–27]

### *2.2.2. Conformational Analysis*

Complex **1** can adopt three conformations in space as has already been mentioned. These conformations are depicted in Figure 7 and their structural characteristics are presented in Table 1.

The plane formed by the binding organic ring lies in an *anti* conformation to the $W(CO)_4$ fragment in **N4** with a $C^3$–N–W–$C_{(CO^3)}$ dihedral angle of 45.3°. This is more or less the same case for **N2** with a dihedral angle of 34.4°. On the contrary, in **N1** a *gauche* conformation is adopted, since the dihedral angle is 83.0°. The aforementioned difference for **N1** has a great impact on the structure, since the orthogonality holds only for the first coordination sphere around the central metal. Thus, the pyridine ligand bends away from the $CO^3$ moeity and the observed $C^{6'}$–N–W–$C_{tr}$ dihedral angle is 45.7°. In other words, the structure is folded. But the most important structural difference between **N4** and **N1** and **N2** is that all the three aromatic rings of the ligand adopt a coplanar conformation in **N4**, but not in **N1** and **N2**. More specifically, a $N^1$–$C^{2'}$–$C^2$–$N^2$ dihedral angle of 127.5° and 64.4° is observed in **N1** and **N2**, respectively, in accordance with the one observed in the free ligand. This twisting around the single bond $C^2$–$C^{2'}$ is necessary for the system, otherwise if a coplanar arrangement was adopted there would be strong intramolecular interactions between

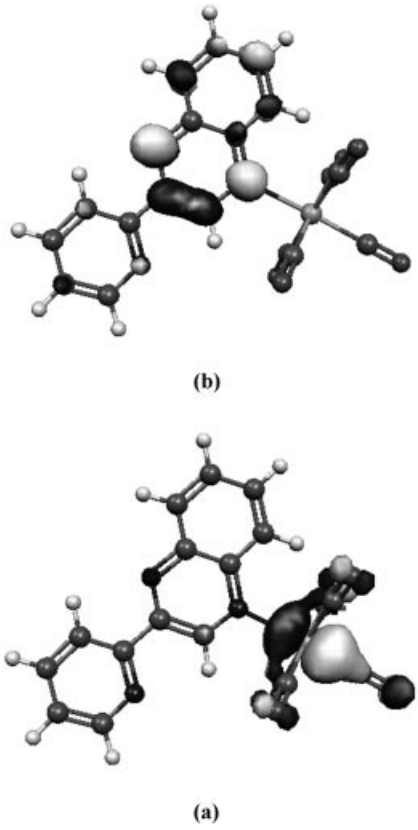

Figure 6. 0.05 a.u. contour plots of the HOMO (a) and LUMO (b) of complex **N4**.

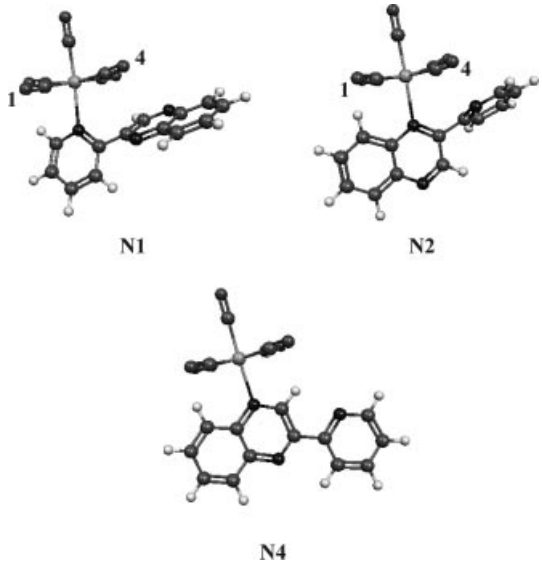

Figure 7. The three different conformations of the $W(CO)_4$(pq) complex. In the case of **N1** and **N2** the numbering of the carbonyls in front is also presented.

the noncoordinating organic ring and carbonyls 3 and 4. The W–N–C angles, as presented in Table 1, are indicative of these interactions. Thus, the values of the W–N–$C_{(CO^3)}$ [and W–N–$C_{(CO^4)}$] are larger than the relative values for W–N–$C_{(CO^1)}$ [and W–N–$C_{(CO^2)}$].

During the photolytic route to the $W(CO)_4$pq chelate ring closure, complex **1**, having the conformation **N4**, is the main intermediate product. In order to better understand this result, we performed a conformational analysis of the three isomers under study. Our results are summarized in Figure 8.

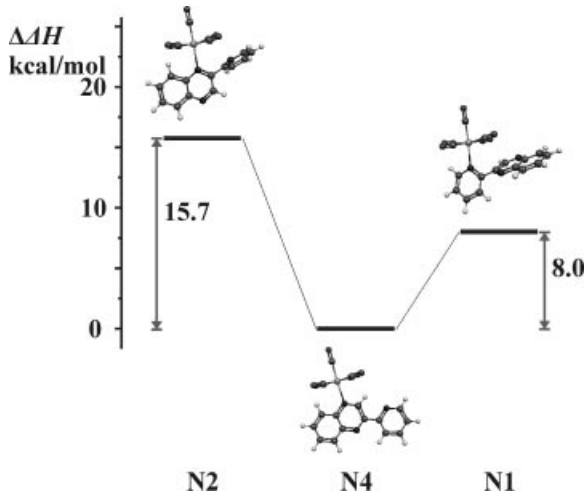

Figure 8. Energy differences among the conformations under study.

According to data presented in Figure 8, we concluded that the isomer **N4** has the most stable structure among the three conformational isomers. It is more stable by 8.0 kcal/mol than **N1** and by 15.7 kcal/mol than **N2**. The latter seems to be the less favorable isomer to be formed in the reaction process. The calculated difference in the stability of the isomers is attributed to electronic and steric repulsions between carbonyls 3 and 4 and the noncoordinating organic ring. In Figure 9, the three isomers are depicted using the space-filling model. The destabilization of the conformations **N1** and **N2** may attribute to the intramolecular $O_{(CO^4)}$–N interaction; the latter is not present in **N4**. More specifically, the $O_{(CO^4)}$–$N^1$ distance is 3.04 Å in **N2**, while in **N1** the $O_{(CO^4)}$–N2 and $O_{(CO^4)}$–$N^4$ distances are 3.38 Å and 3.53 Å, respectively.

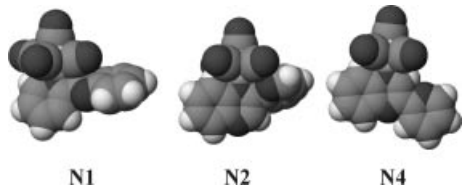

Figure 9. The structure of the three isomers with the space-filling model.

From an orbital point of view (Table 3 and Figure 10), we observe that the HOMO to HOMO–2, having a significant $d_\pi$-metal character, are destabilized in **N2** as compared with **N1** and **N4**. Moreover, an orbital inversion occurs. The HOMO of **N4**, mainly of a $d_{xz}/\pi^*$(CO) character of **N4** becomes HOMO–1 in the other two isomers. This inversion

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

happens since the HOMO–1 in **N4**, which contains a large contribution from the metal $d_{yz}$ orbital, is destabilized from the presence of the twisted organic ring and becomes HOMO in **N1** and **N2**. Taking into consideration that tungsten-centered $d_{xz}$ and $d_{xy}$ orbitals in **1** are nearly degenerate the geometrical changes predicted in conformations **N1** to **N4** can cause intercrossing of the HOMO and HOMO–1. A nonextensive delocalization of electron cloud on the carbonyls in the HOMO and HOMO–1 has its origin in the presence of the twisted rings in **N1** and **N2** conformations. Thus, in **N4** the electron cloud is equipartitioned on the equatorial carbonyls; the situation is different in the case of the isomers **N1** and **N2**, with the asymmetry being more obvious in **N2**. This is another reason for the increase in the HOMO energy in the latter case. Moreover, in **N4** the diimine accepts more electron density from the $W(CO)_5$ core, through back-donation, as compared with **N1** and **N2**. This is postulated by the contributions of the coordinated organic ring to the HOMO in **N4** and to the HOMO–1 in the other two isomers. Finally, there is a substantial difference in the LUMO of the three isomers. In both **N2** and **N4** the LUMO is mainly localized on the coordinating ring of the ligand. On the contrary, in **N1** the contribution of the orbitals of the noncoordinated quinoxaline moiety to the LUMO is double that of the contribution of the coordinated pyridine ring. This reflects a significant increase in the energy of the **N1** LUMO, which becomes less stable. The HOMO and LUMO of conformations **N1** and **N2** are depicted in Figure 11 and Figure 12, respectively.

### 2.3. Electronic Transitions and Excited States

The electronic absorption spectra of **1** in two solvents are indicated in Figure 13 and the corresponding data are included in Table 4. As a whole the spectra consist of three main bands: a broad and structured high-energy band extending from 309 to 380 nm, a shoulder at 398 nm, and a broad low-energy band. The change of the solvent mainly affects the low-energy band that is blue-shifted as the polarity of the solvent increases (negative solvatochromism).

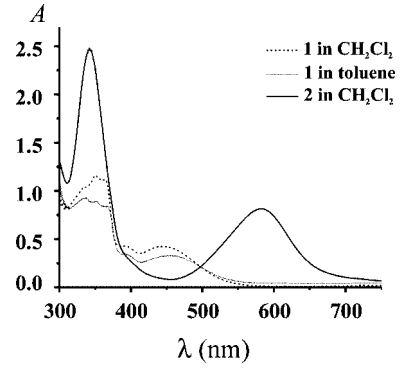

Figure 13. UV/Vis spectra of **1** and **2** in toluene and dichloromethane.

The shape along with the position and the solvent dependence of the low-energy band denote its (W)$d_\pi \rightarrow \pi^*$(L) charge-transfer (MLCT) character, which agrees with previous interpretations of many mononuclear metal pentacarbonyl complexes.[28] In order to investigate the lowest-lying singlet states of **1**, TDDFT calculations have been performed. Selected calculated low-lying singlet states along

| Toluene | 459 |
| THF | 424 |

with their vertical excitation energies and oscillator strengths are displayed in Table 5. The transitions under study fulfill the criteria posed by Casida.[29]

The lowest in energy, highly solvatochromic transition of **1** can be assigned predominantly to the HOMO→LUMO ($n \rightarrow \pi^*$) transition since the contributions from several other transitions to the final state are minor. It is observed at 483 nm in $CCl_4$ and 455 nm in $CHCl_3$ and has W/CO → pq character. The fact that ca. 40% of the HOMO electron density is localized on parts of the molecule other than the metal (Table 3) contradicts the widely accepted MLCT notation for this transition; it could be characterized as an oversimplification. Therefore, we adopted the term MLCT/LLCT, suggested by Vlček and coworkers,[30] and employed it for the characterization of excited states of the relevant compound $W(CO)_4$(pq).[6] In the literature two other relative notations exist and can also be employed in our case. These are metal-ligand-to-ligand charge transfers (MLLCT)[31] and mixed-metal-ligand-to-ligand charge transfers (MMLL′CT).[32] The aforementioned transition arises from orbitals in total accordance with the case of the complex $W(CO)_5$(pyCN) described by Vlček and coworkers.[23] The shoulder of the main band on the high energy side, computed around 405 nm, is attributed to a superposition of several transitions with close energies and mainly to two MLCT($CO_{eq}$) transitions of W/CO→$CO_{eq}$ character. Finally, the higher-intensity broad band centered at 351 nm presenting a triple splitting and computed around 344 nm is mainly attributed to a double π–π*(pq) transition of the HOMO–3/HOMO–5 → LUMO character and a transition of MLCT/LLCT character. The MO picture given here is totally inconsistent with the traditional view that contains low-lying LF transitions. All calculated valence orbitals that contain metal contribution are highly delocalized. Thus no orbital of net $d_{\sigma^*}$ character has been found with relatively low energy. So transitions with a predominant d–d charac-

ter are not expected to be observed in the UV/Vis spectra of **1**. In Figure 13, the UV/Vis spectrum of $W(CO)_4(pq)$[6] (**2**) in $CH_2Cl_2$ is also presented. Bidentate coordination of the pq ligand, with the simultaneous abstraction of the CO moiety, induces several optical effects. The most important is that the main solvatochromic W/CO → qn/py transition exhibits a strong red shift (≈0.66 eV), because of the destabilization of the orbitals localized on carbonyl ligands. The latter is a consequence of the chelation of pq that results in a less efficient back-donation from the metal to the carbonyls. Thus, the optically active HOMO in **1**, which also reflects the back-donation to the N-ligand becomes HOMO–2 in **2** ($\Delta E$ = 0.34 eV). Moreover, if we consider that $CO_{tr}$ of **1** is analogous to $CO_{eq}$ of **2** then HOMO–1 and HOMO–2 in **1** become HOMO ($\Delta E$ = 0.74 eV) and HOMO–1 ($\Delta E$ = 0.91 eV) in **2**, respectively. On the other hand, the LUMO and LUMO+1, localized on pq, are stabilized in **2** as the pq contribution is increased from 10% in **1** to 25% in **2**. On the other hand, the ligand based π–π* transitions are kept almost constant in both complexes as depicted in Figure 13. Finally, comparing the molar absorptivities of both complexes (1600 $M^{-1}cm^{-1}$ for **1** and 3600 $M^{-1}cm^{-1}$ for **2**) we observe that they are in total accordance with the oscillator strengths, where *f* is 0.1049 (Table 5) and 0.1158[5] for **1** and **2**, respectively. The larger oscillator strength of **2** can be related to a better overlap between the contributed orbitals of the transition. In other words, a better overlap among the orbitals of pq and the $W(CO)_4$ fragment is obtained when the pq is coordinated in a bidentate fashion as in **2** compared with a monodentate one as in **1**.

## 3. Conclusions

The isolation of the monodentate intermediate $W(CO)_5$-($N^4$-pq) (**1**), en route to photolytic $W(CO)_4$(pq) chelate ring closure has been achieved. This is the first example where the ligand pq is coordinated in a monodentate fashion. Complex **1** has been fully characterized and its crystal structure has unambiguously demonstrated that pq is preferably coordinated through $N^4$ rather than the $N^1$ and $N^2$ atoms, while its packing is governed by π–π interactions and hydrogen bonds. The face-to-face alignment of condensed quinoxaline rings is attributed to the existence of the electron-withdrawing groups, namely $W(CO)_5$ and the pyridine ring.

The aforementioned preference for the $N^4$ atom has been elucidated both by theoretical (structural and thermodynamic) means and in terms of the frontier orbitals. The theoretical calculations reveal that the coplanarity of the pq ligand, which exists in the **N4** conformation in accordance with the experimental results, no longer exists in the **N1** and **N2** conformations. Actually, the coordinated pyridine moiety of the ligand to the $W(CO)_5$ fragment in **N1**, keeping a *gauche* conformation, causes a twist and fold of the whole pq molecule; whereas the same ring in **N2**, which is noncoordinated, is twisted along the $C^2$–$C^{2'}$ bond. This results in a destabilization of the electronic distribution as is indicated by the energies of the frontier orbitals and leads to new intramolecular interactions. This situation is best described by DFT thermodynamic calculations. Thus, it is predicted that the **N4** conformation should be more stable than the other two conformations (8.0 kcal/mol vs. **N1** and 15.7 kcal/mol vs. **N2**).

Moreover, the ground state of **1** has been fully elucidated by DFT means. Thus, the HOMO and HOMO–1 of **1** are nearly degenerate and predominantly consist of tungsten 5d orbitals with near equal contributions from quinoxaline and carbonyl ligands. The LUMO is energetically well separated and is practically a pure π* orbital localized on the quinoxaline moiety of the ligand. Finally, the electronic transitions of **1** have been fully characterized by TD-DFT calculations, indicating that its low lying solvatochromic band is best ascribed as a HOMO to LUMO transition. Since it has a W/CO → pq character the term MLCT/LLCT is adopted.

## Experimental Section

**Materials and Equipment:** The ligand 2,2′-pq was synthesized as described previously.[5,6] The complex $W(CO)_6$ along with THF, which was used in the syntheses, were obtained from Aldrich Chemicals and used after being dried. The solvents used in UV/Visible spectroscopic studies were purified to spectroscopic quality by standard methods.[33] The deuterated solvents, which were utilized in the NMR spectroscopic experiments were purchased from Aldrich and were of 99.99% purity.

The photolysis experiment was carried out with a 1000 W Xenon lamp with an Oriel, model 68820, Universal Arc. Lamp source selected with an appropriate interference filter (Corning). FT-IR spectra in solution and with KBr pellets were recorded with a Nicolet Magna IR 560 spectrophotometer with a 1.0 $cm^{-1}$ resolution. Electronic absorption spectra were recorded with a Varian Cary 300 spectrometer with a circulating thermostat. The solute concentration was about $10^{-5}$ M and the samples were prepared just before the measurements were taken. The $^1H$-$^{15}N$ HMBC NMR spectra were recorded with a Varian INOVA 500-MHz NMR spectrometer using $NH_3$ as the external standard. Microanalyses were performed with a Euro Vector EA 3000 analyzer

**Synthesis of the $W(CO)_5(N^4$-pq) Complex 1:** A tetrahydrofuran solution (50 mL) of the parent hexacarbonyltungsten (0.351 g, 1 mmol) was deoxygenated by continuous nitrogen purging and then irradiated with a 1000 W Xenon lamp at 25 °C for 20 min. An excess amount of pq (0.269 g, approximately 30%) was then added to the reaction vessel and the irradiation was continued for 10 more minutes. The tetrahydrofuran was slowly evaporated under atmospheric pressure and the residue was passed through a silica gel column using hexane as the eluent. After slow evaporation of the hexane, complex **1** was obtained as an orange solid in 70% (0.372 g) yield. $C_{18}H_9N_3O_5W$ (531.12): calcd. C 40.60, H 1.72, N 7.91, O, 15.12, W 34.81; found C 40.70, H 1.71, N 7.89, O 15.00. IR (in DCM): $\tilde{\nu}_{CO}$ = 2073 (w), 1932 (st), 1904 (m) $cm^{-1}$.

**Computational Details:** Ground-state electronic structure calculations of all compounds under investigation have been performed using density functional theory (DFT)[34] methods employing the GAUSSIAN 2003 software package.[35] The functional that was used throughout this study is the B3LYP, consisting of a hybrid exchange functional as defined by Becke's three-parameter equa-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion[36] and the Lee–Yang–Parr correlation functional.[37] The ground-state geometries were obtained in the gas phase by full geometry optimization starting from structural data. The optimum structures located as stationary points on the potential energy surfaces were verified by the absence of imaginary frequencies. The derived wave functions were found free from internal instabilities. The basis set used throughout this study is the full double-ζ LANL2DZ basis functions along with the corresponding effective core potential for tungsten.[38] The thermodynamic data given in this report include zero-point energy (ZPE) and thermal corrections, without the introduction of scaling factors. Percentage compositions of molecular orbitals from the contributing fragments (the central metal, the diimine, and the axial and equatorial carbonyls) were calculated and analyzed using the AOMix and AOMix-S progams.[39] The first 21 singlet excited states of the closed shell complex were calculated within the TDDFT formalism.[40] The percentage of different transitions contributing to a state and the simulations of calculated IR spectra, when needed, were calculated with the aid of SWizard.[41] The graphics presented in the report have been prepared with the aid of the Molekel[42] and CAChe[43] programs.

# First Allylpalladium Systems Containing Chiral Imidazolylpyridine Ligands – Structural Studies and Catalytic Behaviour

**Amaia Bastero,[a] Antonio F. Bella,[a] Fernando Fernández,[b] Susanna Jansat,[b] Carmen Claver,*[a] Montserrat Gómez,*[b,c] Guillermo Muller,[b] Aurora Ruiz,[a] Mercè Font-Bardía,[d] and Xavier Solans[d]**

**Keywords:** Palladium / Chiral imidazolines / Catalysis / Allylic alkylation / Intermediates / Heterocycles

Palladium/chiral imidazolylpyridine systems were tested in allylic alkylation of *rac*-3-acetoxy-1,3-diphenyl-1-propene (*rac*-**I**) and 3-acetoxy-1-phenyl-1-propene (**II**), paying particular attention to the influence of the amine nitrogen hybridisation on their catalytic behaviour. Allylpalladium complexes **9**–**11** containing optically pure imidazolines were synthesised and fully characterised both in solution (NMR) and the solid state (single-crystal X-ray diffraction). NMR studies showed four species in solution for complex **9** containing the unsymmetrical 1-phenylallyl group, while for **10** and **11**, involving the symmetrical 1,3-diphenylallyl moiety, two species, *endo* and *exo*, were identified. In the solid state, only *endo* isomers crystallised for each complex.

## Introduction

In comparison with ligands containing oxazoline groups,[1] chiral imidazolines have been used less in catalysis, despite the structural analogy between the two heterocycles.[2] For imidazolines, the additional nitrogen atom in place of oxygen provides a further point for tuning the ligand basicity by changing the nature of the $R^3$ group, and consequently a new modifiable region to be considered in selective catalytic processes (Figure 1).

Figure 1. Oxazoline and imidazoline heterocycles.

The first enantioselective catalytic application of chiral imidazolines appeared in 1997 when Achiwa and co-workers published their research about Pd-catalysed allylic alkylation using chiral thioimidazoline ligands, obtaining moderate activities but excellent enantioselectivities (up to 96% *ee*),[3] comparable to those obtained with thioether–oxazolines.[4] Later, chiral phosphanylimidazolines were tested in Ir-catalysed enantioselective hydrogenation,[5,6] giving in some cases better asymmetric inductions than those involving analogous phosphanyloxazolines.[5] This kind of ligand has also been used in Pd-catalysed asymmetric Heck reactions, yielding better enantioselectivities than BINAP and phosphanyloxazolines.[7] Besides mono(imidazolines), bis(imidazolines) have also been used in catalysis. Therefore, chiral tridentate 2,6-bis(imidazolinyl)pyridines, structurally analogous to pybox ligands,[8] have been tested in Ru-catalysed asymmetric epoxidation reactions.[9] In addition, $C_2$-symmetric bis(imidazolines) have also been prepared and successfully used in Pd-catalysed allylic alkylation,[10,11] giving asymmetric inductions comparable to those obtained with analogous bis(oxazolines).[1d]

Concerning imidazolylpyridines, our investigation on Pd-catalysed copolymerisation of carbon monoxide and styrene, which represents the first catalytic work involving this type of ligand,[12] showed that the electronic nature of the $R^3$ substituent (Figure 1) could somehow control the stereoregularity of the polyketones obtained,[13,14] in contrast to the comparable oxazolylpyridine systems, affording invariably highly syndiotactic polymers.[15] At the same time, Davies et al. reported the use of chiral imidazolylpyridines in Ru-catalysed Diels–Alder reactions and the synthesis and full characterisation of the first complex containing a chiral imidazoline group.[16]

With regard to structural studies, few metal complexes containing chiral imidazoline moieties have been fully characterised.[17] Only our palladium complexes of type [PdClR(κ²-*N*,*N*′-L*)] (R = Cl, Me),[13,14] rhodium compounds, [Rh(cod)(κ²-*N*,*N*′-L*)]$BF_4$,[14] and Davies' ruthenium complexes, [RuCl(1,3,5-trimethylbenzene)(κ²-*N*,*N*′-L*)]$SbF_6$,[16] have been published involving chiral imidazolylpyridines.

Following our research in allylic alkylation,[18] we have carried out a catalytic and structural study with imidazolylpyridines (Figure 1) to compare their behaviour with those containing analogous oxazoline derivatives (like ligands **7** and **8**, see Table 4).[19,20] For this purpose, we have chosen a short family of imidazolylpyridines coming from 1,2-diphenylethylenediamine, by varying the substituent nature on the amine nitrogen atom (R = H, Me, Bn, Ts, Figure 2). The influence of heterocycle stereochemistry on catalysis has also been considered [(*R*,*R*)-**1**, (*S*,*S*)-**2** and *rac*-(*R*,*S*)-**3**, Figure 1]. Allylpalladium intermediates have been synthesised and fully characterised in order to show a relationship with the catalytic behaviour observed.

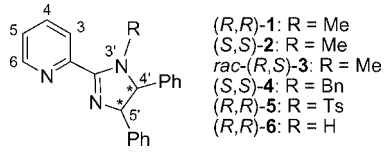

Figure 2. 2-(4′,5′-Diphenyl-3′-R-imidazolyl)pyridines **1**–**6** with numbering scheme.

## Results and Discussion

### Palladium Complexes

Ionic palladium complexes **9**–**11** containing 1-phenyl- (**9**) and 1,3-diphenylallyl groups (**10** and **11**) were prepared from the corresponding palladium precursor and the appropriate chiral imidazolylpyridine ligand, (*R*,*R*)-**1** for **9**, (*S*,*S*)-**2** for **10** and (*S*,*S*)-**4** for **11**, in the presence of ammonium hexafluorophosphate (Scheme 1), according to the methodology previously described.[19,21]

These compounds were obtained as monometallic complexes of general formula [Pd(η³-1-Ph-3-R-$C_3H_n$)(L)]$PF_6$ [**9**: R = H, *n* = 4, L = (*R*,*R*)-**1**; **10**: R = Ph, *n* = 3, L = (*S*,*S*)-**2**; **11**: R = Ph, *n* = 3, L = (*S*,*S*)-**4**], where L acts as a κ²-*N*,*N*′-bidentate ligand affording a five-membered palladacycle. Complexes **9**–**11** were fully characterised by the usual techniques. IR spectra showed strong signals at 1559–1549 $cm^{-1}$ corresponding to the C=$N_{imine}$ moiety and at about 835 $cm^{-1}$ assigned to P–F stretching of the $PF_6$ anion. Mass spectra exhibited a peak corresponding to the [Pd(η³-1-Ph-3-R-$C_3H_n$)(L)]⁺ fragment.

Suitable monocrystals of **9**, **10** and **11** for X-ray diffraction measurements were obtained from dichloromethane solutions of the corresponding complexes by slow diffusion of hexane.

In these structures (Figure 3), the palladium atom shows a distorted square-planar coordination, bonded to two nitrogen (N7 and N1) and two terminal allylic carbon atoms (Table 1), which are nearly coplanar (N1–C12–C14–N7 is about 4.8° for **9** and **10**, and 1.9° for **11**). These complexes crystallised as *endo* isomers, meaning that the central allylic carbon atom and the phenyl substituent at 5′-position on the imidazoline ring point in opposite directions.

In a previous study based in neutral and cationic Pd complexes involving this kind of ligand, it was found that the C–N bond lengths were sensitive to the R substituents at 3′-position, providing information about the electronic delocalisation through the amidine fragment.[14] Therefore, in order to analyse the electronic density involved in the C–N bonds, $N_{amine}$ (N4) and $N_{imine}$ (N1) with their common bonded C atom (C5), we have compared the bond length difference between C5–N4 and C5–N1. For **9** and **10**, the difference is slightly smaller than for **11** [Δ(N1–C5 – N4–C5) = 0.051 Å for **9**; Δ(N1–C5 – N4–C5) = 0.054 Å for **10**; Δ(N1–C5 – N4–C5) = 0.069 Å for **11** (Table 1)]. Comparing these figures with those of related compounds, [PdClMe(*R*,*R*-**2**)] (Δ = 0.037 Å) and [PdClMe(*R*,*R*-**5**)] (Δ = 0.139 Å),[14] we can state that complexes containing ligands (*R*,*R*)-**1** and (*S*,*S*)-**2** {complexes **9**, **10** and [PdClMe(*R*,*R*-**1**)]} have C–N bonds of a similar nature, with bond lengths intermediate between those for single and double bonds; while for **11**, containing (*S*,*S*-**4**), both single and double bonds are present. In addition, IR spectra for **9**–**11** exhibit C=N stretching absorptions (1559–1549 $cm^{-1}$, see Experimental Section) at lower frequency than those observed for allylpalladium complexes containing bis(oxazolines) (1650–1670 $cm^{-1}$)[22,18a] or oxazolinylpyridines (1630–1660 $cm^{-1}$);[19] consequently, weaker C=$N_{imine}$ bonds for imidazoline than for oxazoline derivatives are observed. These structural data point out an electronic delocalisation between the two nitrogen atoms of the imidazoline heterocycle, mainly when the substituent on the $N_{amine}$ atom is a methyl group [ligands (*R*,*R*)-**1** and (*S*,*S*-**2**)].

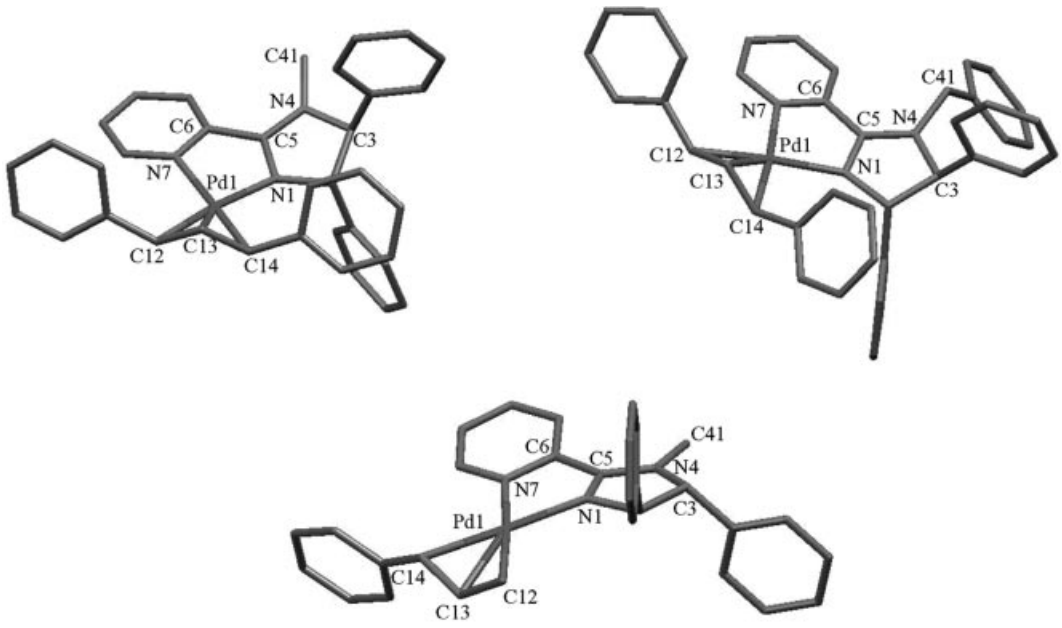

Figure 3. View of the molecular structures of complexes **9** (bottom), **10** (top left) and **11** (top right). Hydrogen atoms and hexafluorophosphate anion are omitted for clarity.

Table 1. Selected bond lengths [Å] and bond angles [°] for **9**, **10** and **11** (with esds in parentheses).

| | **9** | **10** | **11** |
|---|---|---|---|
| Pd1–N1 | 2.053(4) | 2.096(4) | 2.109(3) |
| Pd1–N7 | 2.124(4) | 2.147(5) | 2.137(3) |
| Pd1–C12 | 2.168(5) | 2.173(5) | 2.173(4) |
| Pd1–C13 | 2.087(5) | 2.122(5) | 2.145(4) |
| Pd1–C14 | 2.107(5) | 2.137(5) | 2.163(4) |
| N1–C5 | 1.289(6) | 1.304(6) | 1.291(5) |
| N4–C5 | 1.340(6) | 1.358(6) | 1.360(5) |
| N1–Pd1–N7 | 77.24(15) | 77.64(15) | 76.53(12) |
| C12–Pd1–C14 | 67.9(2) | 67.77(18) | 68.11(15) |

Concerning the planarity around $N_{amine}$, the angle between the two planes around this atom has been considered. The C5–C41–C3–N4 angle is less than 7° for **9** (2.4°) and **10** (6.9°), and 10.2° for **11**. Comparing with two other related complexes, the corresponding angles are 0.6° for [PdClMe(*R*,*R*-**1**)] and 21.6° for [PdClMe(*R*,*R*-**5**)].[14] Likewise, the distance of C41 to N1–C5–N4 is 0.025, 0.133 and 0.365 Å for **9**, **10** and **11**, respectively. Then a quasi-$sp^2$ hybridisation for [PdClMe(*R*,*R*-**1**)], **9** and **10** can be inferred, in contrast to an $N_{amine}$ $sp^3$ hybridisation for [PdClMe(*R*,*R*-**5**)]; for **11**, containing the (*S*,*S*)-**4** ligand, a significant planarity deviation is observed. This prominent feature about the $sp^2$ character for nitrogen atoms of the imidazoline ring has been recently stated from the X-ray structural analysis of a bis(imidazolinyl)pyridine ligand.[23]

The Pd–C distances in *trans* position to both nitrogen atoms, Pd1–C12 versus Pd1–C14, point to a higher *trans* influence for $N_{imine}$ than for $N_{pyridine}$. Therefore, the differences in the distance between palladium and both terminal allylic carbon atoms [Δ(Pd1–C12 – Pd1–C14)] are 0.036 and 0.010 Å for **10** and **11** respectively. However, the electronic effect of the R substituent on $N_{amine}$ is not reflected in the Pd–C distances in *trans* position to $N_{imine}$, as they are the same (Pd1–C12 = 2.173 Å for **10** and **11**). But the small increase observed in the Pd–C distances in *cis* position to $N_{imine}$ (Pd1–C14), 2.137 versus 2.163 Å for **10** and **11**, respectively, is probably due to the electronic and also steric effect of the substituent on $N_{amine}$.

$^1$H NMR spectroscopy allowed the determination of the structure of these complexes in solution.[19,24] For complex **9**, four isomers were observed in deuterated chloroform solution at room temperature, with a relative ratio 46:31:15:8 for **9a**/**9b**/**9c**/**9d**. Only for the two major isomers, **9a** and **9b**, were all carbon and proton atoms assigned. The isomers detected are formed because of (i) the relative position of the central allylic carbon atom and the phenyl substituent at the 5′-position on the imidazoline ring (giving *exo* and *endo* isomers, see above) and (ii) the substitution on the allyl moiety. 2D NOESY experiments exhibited interconversion between **9a** and **9d** and between **9b** and **9c**, but no π-σ-π allyl isomerisation was observed.

Concerning relative chemical shifts, the signals of the terminal allyl protons ($H^3$ and $H^4$, Table 2) for the two major isomers (δ = 2.19–3.33 ppm for **9a** and **9b**) are upfield-shielded relative to those of the other two isomers (δ = 3.51–4.25 ppm for **9c** and **9d**), a fact that can be attributed to the spatial proximity of the phenyl group at the heterocycle 5′-position; similarly, the signal of the $H^2$ proton of **9c** is also upfield-shifted with respect to **9a** and **9b** [δ = 3.96 (**9c**) vs. 4.52 and 4.53 ppm for **9a** and **9b**, respectively, Table 2]; $H^5$ is also sensitive to the allyl group and for **9c** its signal is more than 1 ppm upfield-shifted because of the close allylphenyl group [δ = 3.86 (**9c**) vs. 4.84 and 5.00 ppm for **9a** and **9b**, respectively]. Consequently, the two major isomers could be attributed to *exo* and *endo* isomers where the phenylallyl group is located in *cis* position relative to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the pyridine nitrogen atom, while **9c** corresponds to one of the minor isomers where the phenylallyl group is located in *trans* position relative to the pyridine nitrogen atom. These data lead us to propose the structures shown in Figure 4.

Table 2. Selected $^1$H NMR ($CDCl_3$, 400 MHz, 298 K) chemical shifts for **9** (signal multiplicity in parentheses).[a]

| | **9a** | **9b** | **9c** | **9d**[b] |
|---|---|---|---|---|
| $H^1$ (central) | 5.76 (td) | 5.69 (td) | 5.87–5.95 (m) | n.d. |
| $H^2$ (*anti*-Ph) | 4.52 (d) | 4.53 (d) | 3.96 (d) | n.d. |
| $H^3$ (*anti*) | 2.19 (ddd) | 2.72 (d) | 3.51 (d) | n.d. |

| $H^6$ | 4.90 (d) | 4.86 (d) | 4.41 (d) | n.d. |
| $H^{7–9}$ ($CH_3$) | 3.31 (s) | 3.29 (s) | 3.21 (s) | n.d. |

[a] Proton labels:  [b] n.d. means not distinguished.

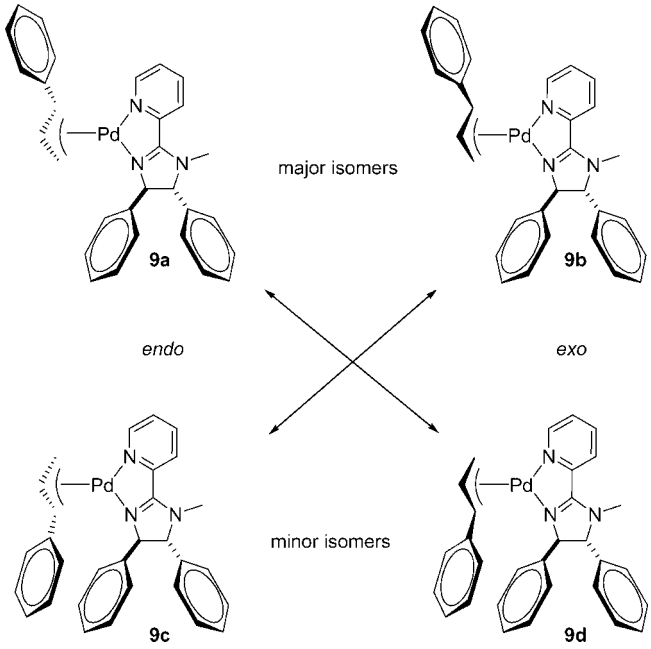

Figure 4. Proposed structures for the four isomers of **9** observed in solution (arrows indicate the isomer interconversion observed by 2D NOESY, between **9a** and **9d**, and **9b** and **9c**).

For complexes **10** and **11**, only two isomers were observed in deuterated chloroform solution, with a relative ratio of about 6:1. Most of the resonances for minor isomers are overlapped by signals corresponding to those of major species. 2D NOESY experiments exhibited, in both cases, interconversion between both isomers and no π-σ-π allyl isomerisation was detected. Because of the steric hindrance between both phenyl groups, from the imidazoline ring and allyl group, the major species for each complex could be assigned to the *endo* isomer.

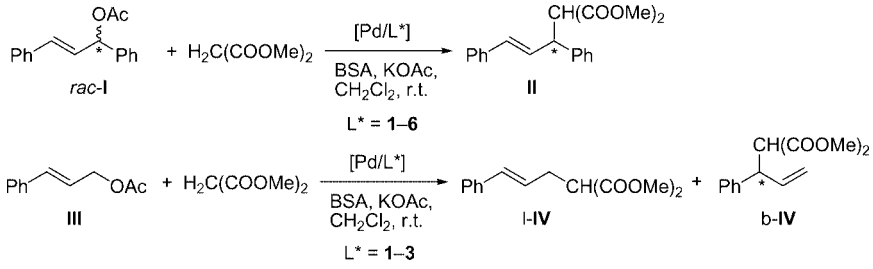
## Pd-Catalysed Allylic Alkylation

Asymmetric allylic alkylation of the racemic substrate *rac*-3-acetoxy-1,3-diphenyl-1-propene (*rac*-**I**) and 3-acetoxy-1-phenyl-1-propene (**III**) with dimethyl malonate under basic Trost conditions[25] was carried out using a Pd catalytic systems containing 2-(4′,5′-diphenyl-5′-substituted-imidazolyl)pyridines **1**–**6** (Scheme 2). The results are summarised in Table 3. Catalytic precursors were generated in situ from $[PdCl(C_3H_5)]_2$ and the appropriated ligand (Pd/L = 1:1.25).

For the allylic alkylation of *rac*-**I**, we observed that the most active palladium systems were those containing a methyl group in the 5′-position of the imidazolyl ring, ligands (*R*,*R*)-**1**, (*S*,*S*)-**2** and *rac*-(*R*,*S*)-**3** (Entries 2, 4 and 5, Table 3). Benzyl and tosyl derivatives [ligands (*S*,*S*)-**4** and (*R*,*R*)-**5**, respectively] led to less active catalysts (Entries 7 and 9, Table 3), especially the Pd/(*R*,*R*)-**5** system, which showed a very low conversion [36% after 48 h of reaction (Entry 9, Table 3)].

The activity trend shown by these Pd/**L*** systems correlates quite well with the $N_{amine}$ hybridisation character. Actually, methyl derivatives containing $sp^2$-hybridised $N_{amine}$ (ligands **1**, **2** and **3**) are more active than benzyl [(*S*,*S*)-**4**], whose $N_{amine}$ atom exhibits a significant $sp^3$ character and is clearly more active than the tosyl derivative, which contains an $sp^3$-hybridised $N_{amine}$ atom (Entries 2, 4, 5, 7 and 9, Table 3).

Concerning the enantioselectivity, only the Pd/(*S*,*S*)-**4** system gave a significant asymmetric induction, up to 19% *ee* (Entry 7, Table 3). The low enantioselectivity observed is probably due to the higher *trans* influence of $N_{imine}$ than that of $N_{pyridine}$ (see above), directing the nucleophile attack towards the terminal allylic carbon atom *trans* to the imine nitrogen atom. In that position no steric hindrance coming



Scheme 2. Allylic alkylation of *rac*-**I** and **III** catalysed by Pd/**L*** systems (**L*** = **1**–**6**).

| 11 | **1** | **III** | 24 | 100 | – | 13:1 |
| 12 | **2** | **III** | 24 | 100 | – | 13:1 |

[a] Results from duplicated experiments. Pd/**L***/substrate = 1:1.25:50. See Scheme 2. [b] Conversions based on substrate **I** or **III** determined by $^1$H NMR spectroscopy; enantiomeric excesses (absolute configuration in parentheses) determined by HPLC and l(inear)/b(ranched) ratio, by GC.

from the 6-position of the pyridine group exists to discriminate this attack between both *endo* and *exo* isomers. In addition, the electronic effect due to the $N_{amine}$ substituent can contribute to this lack of enantioselectivity. An increase of pyramidal arrangement around the $N_{amine}$ atom means a decrease of π-electron delocalisation between the amine and imine nitrogen atom (see above) and consequently $N_{imine}$ becomes a better donor Lewis centre, favouring the stability of cationic intermediate catalytic species responsible for the enantioselectivity control. The lack of enantioselectivity for (*R*,*R*)-**5** (Entries 9 and 10, Table 3) could be due to electronic factors.

The Pd/(*R*,*R*)-**6** system was not active, doubtless because of the NH deprotonation of the imidazoline group under the basic catalytic conditions used. In this case, the plausible palladium intermediate containing the anionic imidazolylpyridine ligand could induce a less electrophilic character on the allyl moiety than cationic allylic intermediates involving bidentate neutral ligands.

The most active catalytic systems [Pd/(*R*,*R*)-**1** and Pd/(*S*,*S*)-**2**] were used in the allylic alkylation of 3-acetoxy-1-phenyl-1-propene (**III**), under the same conditions described above for *rac*-**I**, showing a high regioselectivity towards the linear isomer, l-**IV**/b-**IV** ratio = 13:1 (Entries 11 and 12, Table 3).

From a structural point of view, the imidazoline ring is close to the oxazoline heterocycle. When we compare the catalytic results obtained for *rac*-**I** alkylation with (5′-phenyl-oxazolinyl)pyridine and (4′,5′-disubstituted)oxazolinylpyridine ligands **7** and **8**, respectively (Table 4), we observe that Pd/**7** and Pd/**8** catalysts are more active and selective than the most active and selective imidazoline derivatives [ligands (*R*,*R*)-**1**, (*S*,*S*)-**2** and (*S*,*S*)-**4**, respectively; Entries 4 and 5 vs. 1, 2 and 3, Table 4].

[a] Conversions based on substrate **I** determined by $^1$H NMR spectroscopy; enantiomeric excesses (absolute configuration in parentheses) determined by HPLC. [b] Determined by $^1$H NMR spectroscopy using Eu(hfc)$_3$ as the chiral shift reagent.

The higher electronegativity of oxygen with respect to nitrogen avoids any π-delocalisation between oxygen and nitrogen atoms in the oxazoline heterocycle. Then the Lewis base character of the $N_{imine}$ atom in oxazolines is more important than that for analogous imidazolines, especially for those containing an sp$^2$-hybridised amine nitrogen atom. Therefore, this behaviour becomes crucial to understand the activity and selectivity diminution of imidazolylpyridines compared to related oxazolines.

## Conclusion

We have found the fine-tuning effect of the remote $N_{amine}$ centre on the Pd-catalysed allylic alkylation reaction. The delocalisation of the nonbonding electron pair of $N_{amine}$ causes a basicity diminution in $N_{imine}$, which is directly bonded to the metal atom. This effect seems to be directly related with the activity and asymmetric induction of Pd/imidazolylpyridine catalytic systems.

## Experimental Section

**General Remarks:** All compounds were prepared under purified nitrogen using standard Schlenk and vacuum-line techniques. The solvents were purified by standard procedures and distilled under nitrogen.[26] [Pd(η$^3$-1-phenylallyl)(μ-Cl)][27] and ligands (*R*,*R*)-**1**,[14]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(*S*,*S*)-**2**,[16] (*R*,*R*)-**5**[14] and (*R*,*R*)-**6**[14] were prepared as described previously. NMR spectra were recorded with Varian XL-500 ($^1$H, standard $SiMe_4$), Varian Gemini ($^1$H, 200 MHz; $^{13}$C, 50 MHz; standard $SiMe_4$), Bruker DRX 250 ($^{13}$C, 62.9 MHz, standard $SiMe_4$) and Varian Mercury 400 ($^1$H, 400 MHz; $^{13}$C, 100 MHz, standard $SiMe_4$) spectrometers, using $CDCl_3$ as solvent, unless stated otherwise. Chemical shifts were reported downfield from standards. IR spectra were recorded with FTIR Nicolet 520 and Nicolet 5700 spectrometers. Electron-spray mass spectra were obtained with a Mass ZQ Micromass instrument. High-resolution mass spectra were obtained with a Waters LCT Premier spectrometer operated in ESI mode. The GC analyses were performed with a Hewlett-Packard 6890-Network GC system gas chromatograph [30 m HP5 (5% phenyl)methylpolysiloxane column] with an FID detector. Enantiomeric excesses were determined by HPLC on a Chiralcel OD column. Elemental analyses were carried out by the Serveis Cientifico-Tècnics de la Universitat de Barcelona with an Eager 1108 microanalyser. Optical rotations were measured with a JASCO P-1030 polarimeter.

**(4′*R*,5′*S*)-2-(3′-Methyl-4′,5′-diphenyl-2′-imidazolyl)pyridine [*rac*-(*R*,*S*)-3]:** (4′*R*,5′*S*)-2-(4′,5′-Diphenyl-2′-imidazolyl)pyridine[12] (0.100 g, 0.33 mmol) was dissolved in THF (3 mL) and treated with NaH (9.5 mg, 0.4 mmol) for 1 h. MeI (22.4 μL, 0.36 mmol) was then added dropwise at room temperature. After 7 h, the solvent was removed under reduced pressure, giving a paste, which was purified by column chromatography yielding a white solid (77.8 mg, 75%). $^1$H NMR (200 MHz, $CDCl_3$, 298 K): $\delta$ = 8.72–7.26 (m, 14 H, aromatic), 4.99 (d, 1 H, $J$ = 10.4 Hz), 4.36 (d, 1 H, $J$ = 10.4 Hz), 2.99 (s, 3 H) ppm. $^{13}$C NMR (100.6 MHz, $CDCl_3$, 298 K): $\delta$ = 164.6 (C=N), 149.2 (CH), 137.1 (CH), 129.2–127.11 (CH), 125.3 (CH), 124.9 (CH), 79.0 (CH), 77.4 (CH), 34.4 ($CH_3$) ppm. HRMS-ESI: *m*/*z* calcd. for $C_{21}H_{20}N_3$ 314.1657; found 314.1647 $[M + H]^+$.

**(4′*S*,5′*S*)-2-(3′-Benzyl-4′,5′-diphenyl-2′-imidazolyl)pyridine [(*S*,*S*)-4]:** (4′*S*,5′*S*)-2-(4′,5′-Diphenyl-2′-imidazolyl)pyridine[16] (0.100 g, 0.33 mmol) was dissolved in THF (3 mL) and treated with NaH (9.5 mg, 0.4 mmol) for 1 h. Benzyl bromide (42.5 μL, 0.36 mmol) was then added dropwise at room temperature. After 5 h, the solvent was removed under reduced pressure, giving a brown paste, which was purified by column chromatography yielding a white solid (96.6 mg, 75%). $^1$H NMR (400 MHz, $CDCl_3$, 298 K): $\delta$ = 8.73–6.97 (m, 19 H, aromatic), 5.67 (d, 1 H, $J$ = 15.6 Hz), 5.03 (d, 1 H, $J$ = 9.2 Hz), 4.45 (d, 1 H, $J$ = 9.2 Hz), 3.96 (d, 1 H, $J$ = 15.6 Hz) ppm. $^{13}$C NMR (100.6 MHz, $CDCl_3$, 298 K): $\delta$ = 162.8 (C=N), 148.5 (CH), 136.9 (CH), 128.8–126.9 (CH), 125.6 (CH), 122.6 (CH), 77.4 (CH), 73.6 (CH), 49.1 ($CH_2$) ppm. HRMS-ESI: *m*/*z* calcd. for $C_{27}H_{24}N_3$ 390.1970; found 390.1980 $[M + H]^+$. $[\alpha]_D^{20}$ –4.90 (*c* = 0.88, $CHCl_3$).

**($\eta^3$-1-Phenylallyl)[(4′*R*,5′*R*)-2-(3′-methyl-4′,5′-diphenyl-2′-imidazolyl)pyridine-*N*,*N*]palladium(II) Hexafluorophosphate (9):** Ligand (*R*,*R*)-**1** (0.050 g, 0.160 mmol) and $[Pd(\mu\text{-}Cl)(\eta^3\text{-}1\text{-}Ph\text{-}C_3H_4)]_2$ (0.043 g, 0.083 mmol) were dissolved in dichloromethane (25 mL) at room temperature under nitrogen overnight. $NH_4PF_6$ (0.156 g, 0.960 mmol) was then added and the mixture was stirred for 3 h. Then the mixture was washed with water (6 × 20 mL). The aqueous phase was extracted with dichloromethane (3 × 10 mL). All the organic extracts were dried with $Na_2SO_4$, filtered off and the solvent was then evaporated to afford a yellow solid. The product was recrystallised from a mixture of dichloromethane and hexane (0.061 g, 56% yield). 8.8 Hz, H), 4.41 (d, *J* = 14.4 Hz, H), 4.50 (d, *J* = 6.4 Hz, H), 4.83 (d, *J* = 9.6 Hz, H), 5.05 (d, *J* = 14.4 Hz, H), 6.31 (t, *J* = 9.2 Hz, H), 6.87–7.97 (aromatic protons, 29 H) ppm. $^{13}C\{^1H\}$ NMR (100.6 MHz): **Isomer a** (86%): $\delta$ = 49.6 ($CH_2$), 72.3 (CH), 74.4 (CH), 76.9 (CH), 79.6 (CH), 107.8 (CH), 126.0 (CH), 126.0 (CH), 126.8 (CH), 127.7 (CH), 128.0 (CH), 128.1 (CH), 128.2 (CH), 128.4 (CH), 128.9 (CH), 129.1 (CH), 129.3 (CH), 129.4 (CH), 130.2 (CH), 136.4 (C), 137.4 (C), 138.4 (C), 141.0 (C), 141.1 (CH), 145.9 (C), 149.6 (CH), 165.6 (C=N) ppm.

**Palladium-Catalysed Allylic Alkylation of *rac*-3-Acetoxy-1,3-diphenyl-1-propene (I):** The catalytic precursor was generated in situ from $[Pd(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)]_2$ and the appropriate ligand (0.02 mmol of Pd source and 0.025 mmol of chiral ligand) in $CH_2Cl_2$ (2 mL) for 30 min before adding the substrate. *rac*-3-Acetoxy-1,3-diphenyl-1-propene (0.252 g, 1 mmol), dissolved in $CH_2Cl_2$ (2 mL), was added followed by dimethyl malonate (0.396 g, 3 mmol), BSA (0.610 mg, 3 mmol) and a catalytic amount of KOAc. The mixture was stirred at room temperature until total conversion of the substrate (monitored by TLC, unless stated otherwise). The solution was then diluted with diethyl ether, filtered through Celite, and washed with saturated ammonium chloride solution ($4\times10$ mL) and water ($4\times10$ mL). The organic phase was dried with anhydrous $Na_2SO_4$, filtered and the solvent was removed under reduced pressure. The product was purified by column chromatography ($SiO_2$; ethyl acetate). The enantiomeric excesses were determined by HPLC on a Chiralcel OD column, using hexane/2-propanol, 99:1, as eluent in a flow of 0.3 mL/min.

**Palladium-Catalysed Allylic Alkylation of (*E*)-3-Acetoxy-1-phenyl-1-propene (III):** The procedure was analogous to the one described for *rac*-3-acetoxy-1,3-diphenyl-1-propene (**I**). The product was purified by column chromatography ($SiO_2$; ethyl acetate). Regioselectivity was determined by GC.

**X-ray Crystallographic Study:** Yellow crystals of **9**, **10** and **11** were selected and mounted on a Bruker SMART-CCD-1000 area detector single crystal diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Crystal data are summarised in Table 5. Preliminary unit cell constants were calculated with a set of 45 narrow-frame (0.3° in $\omega$) scans. Data were collected using the φ-ω scan method. Absorption corrections were applied using the SADABS program.[28] The structures were solved by direct methods using the SHELXS-97 computer program[29] for crystal structure determination and refined by full-matrix least-squares method on $F^2$, with the SHELXL-97 computer program.[30] The weighting schemes employed were $w = 1/[\sigma^2\{F_o^2 + (0.08259P)\}^2 + 0.0000P]$ for **9**, $w = 1/[\sigma^2\{F_o^2 + (0.0678P)\}^2 + 0.0000P]$ for **10** and $w = 1/[\sigma^2\{F_o^2 + (0.0079P)\}^2 + 4.7017P]$ for **11**, where $P = (|F_o|^2 + 2|F_c|^2)/3$. Hydrogen atoms were included in calculated positions and refined in riding mode. CCDC-291543 (for **9**), -614143 (for **10**) and -613925 (for **11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

The authors wish to thank the Ministerio de Educación y Ciencia (CTQ2004-01546/BQU) and the Generalitat de Catalunya for financial support. The authors also thank the Unidade de RaiosX of the Universidade de Santiago de Compostela for their X-ray crystallographic contribution.

# Reactions of GaCp* with a Hemilabile Derivative of $Rh_6(CO)_{16}$ – Synthesis and Structural Characterization of Two Novel Heterometallic Clusters: $Rh_6(CO)_{13}$-($\mu,\kappa^3$-$Ph_2PC_2H_3$)($\mu_3$-GaCp*) and $Rh_6(CO)_{13}$($\kappa^1$-$Ph_2PC_2H_3$)($\mu_3$-GaCp*)$_2$

**Elena V. Grachova,[a] Gerald Linti,[b] Hans-Georg Stammler,[c] Beate Neumann,[c] Sergey P. Tunik,*[a] and Hubert Wadepohl[b]**

**Keywords:** Cluster compounds / Heterometallic complexes / Phosphane ligands

The reaction of $Rh_6(CO)_{14}(Ph_2PCH{=}CH_2)$ with a twofold excess of GaCp* (Cp* = $C_5Me_5$) affords two novel heterometallic clusters $Rh_6(CO)_{13}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)$ (**1**) and $Rh_6(CO)_{13}(\kappa^1\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)_2$ (**2**) in a moderate yield. The hemilabile behavior of coordinated diphenylvinylphosphane in the starting cluster allows the easy insertion of GaCp* into the cluster coordination sphere, which eventually gives the cluster **1** with face-bridging coordination of the gallium fragment and the phosphane ligand recoordinated in an edge-bridging position. The further substitution of the vinyl function in **1** for the second GaCp* ligand affords cluster **2**, where recoordination of the double bond is blocked by steric hindrance from adjacent GaCp* fragments. Both clusters were structurally characterized by X-ray crystallography in the solid state and by IR and NMR spectroscopy in solution. Hemilability of diphenylvinylphosphane in **1** was independently confirmed by the cluster reaction with CO, which gives the $Rh_6(CO)_{14}(\kappa^1\text{-}Ph_2PC_2H_3)(GaCp^*)$ adduct (**3**) with the phosphane ligand only coordinated through the phosphorus atom.

## Introduction

Syntheses of heterometallic complexes with a direct bond between transition and nontransition metals has attracted considerable attention because of their unusual physico–chemical properties and their potential application in material science.[1–3] In this area the chemistry of gallium containing compounds has been significantly developed over the last years owing to the use of GaCp* as a ligand in the coordination chemistry of mono-[4–8] and polynuclear[9–12] complexes. Recently we reported the synthesis and structural characterization[13,14] of a series of "very-mixed-metal" clusters containing GaCp* fragments in $\mu_3$- and $\mu_2$-bridging positions over the $Rh_6$ and $Ru_6(C)$ metal frameworks. An extension of these studies in our laboratory was aimed at the modification of the cluster properties through further substitution of CO for such typically modifying ligands as the phosphanes. However, neither of the straightforward approaches, reactions of the phosphane substituted derivatives with GaCp* or treatment of the gallium containing clusters with phosphanes, gave positive results. To explore this chemistry further we attempted to prepare analogous heterometallic complexes using a hemilabile phosphanyl-alkenyl derivative of the $Rh_6(CO)_{16}$ cluster.[15] In general, the hemilabile ligands in cluster compounds facilitate substitution reactions and make it possible to direct the coordination of an incoming ligand to the position initially occupied by the labile function that determines the stereochemistry of the substituted product and mode of transformation of the coordinated substrate.[16–18] This approach proved to be successful and in this paper we report on the synthesis, structural characterization, and reactivity of three novel clusters: $Rh_6(CO)_{13}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)$ (**1**), $Rh_6(CO)_{13}(\kappa^1\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)_2$ (**2**), and $Rh_6(CO)_{14}(\kappa^1\text{-}Ph_2PC_2H_3)(GaCp^*)$ (**3**).

## Results and Discussion

The low temperature reaction of the starting $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)$ cluster with a twofold excess of GaCp* gives a mixture of the $Rh_6(CO)_{13}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)$ (**1**) and $Rh_6(CO)_{13}(\kappa^1\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)_2$ (**2**) clusters together with $Rh_6(CO)_{16-x}(GaCp^*)_x$ derivatives, and the latter were identified by their characteristic IR spectra.[13,14] Solid-state structures of **1** and **2** were established by X-ray crystallographic analysis. Selected structural pa-

rameters of these molecules are given in Table 1, ORTEP views of **1** and **2** are shown in Figures 1 and 3, respectively.

The crystal structure of the cluster **1** appears disordered because of the presence of two isomers (approximate ratio 7:3), which differ in the orientation of the "$PhPCH{=}CH_2$" moiety with respect to the $Rh_3$ triangle it is coordinated to. The remaining part of the molecule is essentially identical for both isomers. The molecule of **1** consists of a $Rh_6$ octahedron with a face-bridging GaCp* and an edge-bridging $\mu,\kappa^3$-diphenylvinylphosphane coordinated over opposite faces of the octahedron. The ligand shell of the metal cluster is completed by three face-bridging and ten terminal CO

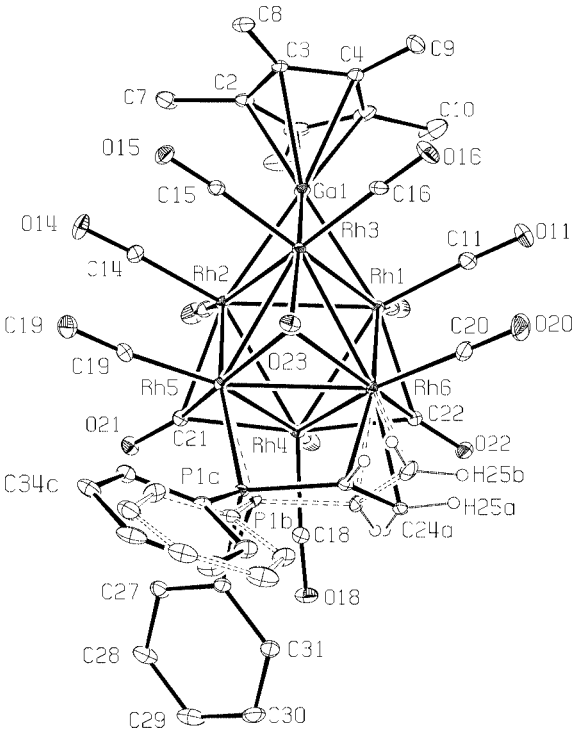

Figure 1. The ORTEP view of the $Rh_6(CO)_{13}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)$ (**1**). Thermal ellipsoids are drawn at the 50% level.

ligands. The stoichiometry of **1** results in 86 valence electrons, which is consistent with the *closo* octahedral structure of the metal framework[19,20] as in the parent $Rh_6(CO)_{16}$[21] and its substituted derivatives.[15,21–24] The general structural motif of **1** is closely analogous to that of $[Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)]$[15] apart from the presence of the GaCp* fragment in **1** instead of a face-bridging CO.

The effects of both substituting ligands ($Ph_2PC_2H_3$ and GaCp*) are nearly independent and their influence is observed in the vicinity of the substitution sites, see Table 1. Coordination of the short-bite vinylphosphane moiety results in contraction of the Rh–Rh edge spanned by the phosphane ligand. This bond is the shortest [2.7065(3) Å] metal–metal distance in the molecule. Very similar to the monosubstituted $Rh_6(CO)_{15}GaCp^*$ cluster[13] the metal–metal bonds in the rhodium triangle capped by the gallium ligand are considerably elongated. This is a typical electronic effect of the weak π acceptor and was found earlier in the clusters $Rh_6(CO)_{16-x}(GaCp^*)_x$[13] and $Ru_6(C)(CO)_{17-x}(GaCp^*)_x$.[14] The Ga–Rh distances fall into quite a narrow range (2.551–2.580 Å), which indicates an essentially symmetric coordination of the GaCp* moiety to the rhodium triangle.

The two isomers of **1** differ in the orientation of the P–C=C fragment of the vinylphosphane ligand relative to the Rh(4)Rh(5)Rh(6) triangle, Figure 2. In the major isomer the Rh–P distance [2.260(5) Å] is considerably shorter [cf. 2.351(11) Å in the minor species], which is indicative of a stronger metal-to-phosphorus bonding. A comparison of the angular parameters that characterize the P–Rh(5) interaction also points to a less strained bonding mode of the phosphorus atom to the octahedral framework in the major isomer. The Rh(4)–Rh(5)–P and Rh(6)–Rh(5)–P angles are equal to 96.8° and 78.0° (major isomer), and 88.3° and 73.8° (minor isomer), whereas the *cis* Rh–Rh–C(O) angles in the parent (unstrained) $Rh_6(CO)_{16}$ are equal to ca. 97°.[21] On the contrary, distances from the carbon atoms of the coordinated vinyl moiety to Rh(6) are somewhat longer in the major species (Table 1), which is evidently a geometrical consequence of the strong phosphorus-to-rhodium bond mentioned above. Similar to the $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)$ cluster[15] both isomers display short (<2.9 Å) nonbonding contacts between atoms of the vinyl fragment and adjacent face-bridging C(22)O and C(23)O ligands. This steric hindrance results in the shift of the C(23)O group from the substituted Rh(5) and Rh(6) centers to Rh(3), opposite to the regular shift caused by the electronic effect of a heteroligand.[15,21,22,25] It is worth noting that the present crystallographic study, which revealed two conformations of the P–C=C fragment in the solid-state structure of **1**, independently confirmed the structural models of the $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)$ isomers suggested in our earlier work, which was solely based on NMR spectroscopic data.[15] The disposition of the vinyl moiety over the metal triangle in the minor conformer of the parent $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)$ cluster[15] matches well the structural pattern shown in part b of Figure 2.

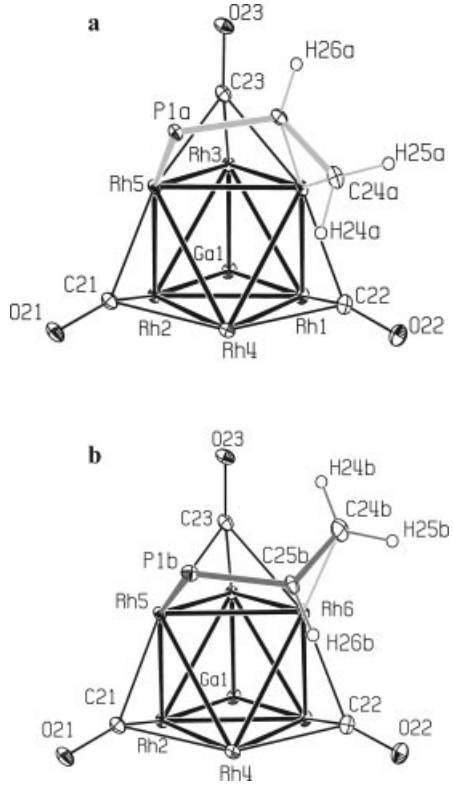

Figure 2. Two isomers of the **1** cluster; (a) major isomer, (b) minor isomer. For the sake of simplicity terminal CO ligands are omitted.

The $^1H$ and $^{31}P$ NMR spectroscopic study of **1** showed that in solution this cluster exists as a mixture of two isomers, the structures of which obviously match those found

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the solid state. The chemical shifts and coupling constants of the signals observed in the $^1H$ spectrum are completely consistent with the data obtained earlier for the conformers of $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)$.[15] It is also worth noting that the Rh–P coupling constants of the isomers of **1** are in agreement with the Rh–P bond lengths in these species. The stronger Rh–P bond in the major isomer gives rise to a higher value of the corresponding coupling constant. These two forms of the vinyl fragment coordination easily convert into each other; the rate of the dynamic process is slow at 273 K and gives the low-temperature-limiting spectrum shown in Figure S1 (S denotes data in Supporting Information file). The resonances from the minor isomer broaden on heating and eventually disappear into the baseline at 313 K. This behavior is very similar to the dynamics observed in $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)$,[15] however, the exchange rate in the latter case is slightly higher.

The $Rh_6(CO)_{13}(\kappa^1\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)_2$ cluster (**2**) is evidently a result of the hemilabile vinyl function substitution for GaCp* followed by the rearrangement of the ligand sphere to give the face-bridging coordination of the GaCp* moiety (Figure 3). The substitution does not change the electron count for **2**, which is in agreement with the *closo* octahedral structure of the cluster framework. In contrast to **1** the phosphane ligand is only coordinated through the phosphorus atom, occupying a terminal position at the Rh(6) center. Possible coordination of the vinyl double bond to either Rh(4) or Rh(5) is obviously prevented by steric hindrance from the Ga(2)Cp* ligand. Local changes of the cluster geometry in **2** are in line with the regular effects of face-bridging GaCp*[13,14] and terminal phosphane ligands.[21] Metal–metal distances inside the rhodium triangles capped by GaCp* are significantly elongated ($d^{av}$ = 2.824 Å) compared with the bond lengths of the rest of the octahedron ($d^{av}$ = 2.783 Å). In the latter group the two bonds *cis* to the phosphane ligand are the longest (see Table 1), which is consistent with the general trend observed in the substituted $Rh_6(CO)_{16}$ derivatives.[21] The NMR spectroscopic data of **2** indicate that the structure found in the solid state remains unchanged in solution. The $^1H$ NMR spectrum of this cluster displays a broad multiplet of phenyl rings centered at 7.5 ppm, two singlets of slightly inequivalent Cp* methyl groups (2.17 and 2.19 ppm), and three resonances of the vinyl protons {$\delta$ =5.02 ppm [H(34)], 5.83 ppm [H(35b)], and 6.61 ppm [H(35a)]}, which are considerably low-field shifted compared with the spectrum of the coordinated vinyl fragment in **1** (see Experimental Section) and in $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PCH{=}CH_2)$,[15] and demonstrate a very good agreement with the proton NMR spectrum of free diphenylvinylphosphane (see Figure S2). This observation clearly indicates that in solution the vinyl functionality remains uncoordinated as found in the solid state.

The $^{13}C$ NMR spectrum (see Experimental Section and Figure S3 in Supporting Information file) also fits well the structure found in the solid state. The spectrum displays resonances of two phenyl rings and the signals of inequivalent GaCp* ligands. The spectroscopic pattern observed in the carbonyl region of the spectrum displays three doublets and two dd resonances of terminal CO groups together with a quartet of the face bridging ligand that is in agreement with the presence of the symmetry plane through the Rh(1), Rh(6), C(33), and P(1) atoms. Additional phosphorus–car-

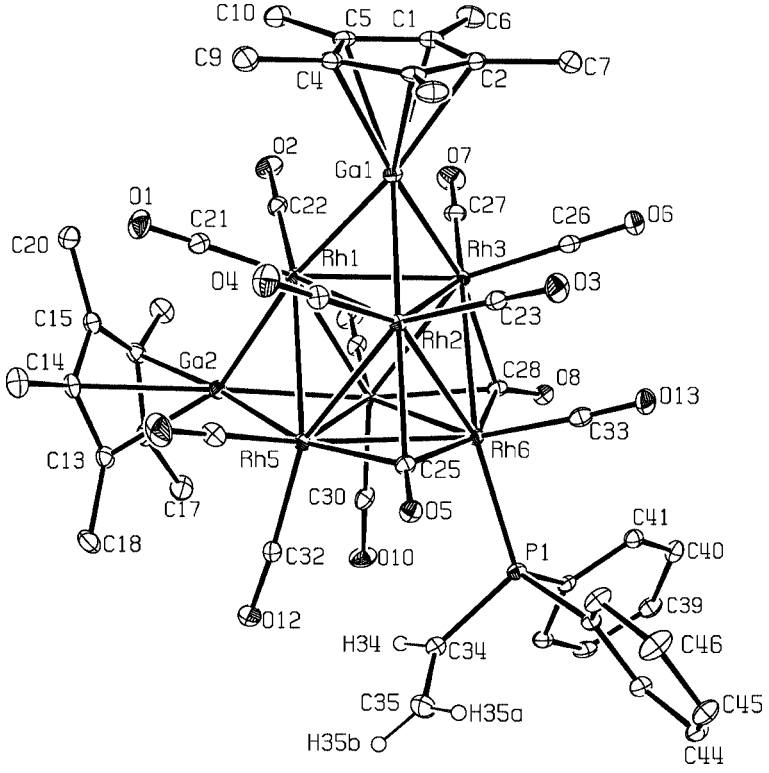

Figure 3. The ORTEP view of the $Rh_6(CO)_{13}(\mu,\kappa^1\text{-}Ph_2PC_2H_3)(\mu_3\text{-}GaCp^*)_2$ (**2**). Thermal ellipsoids are drawn at the 50% level.

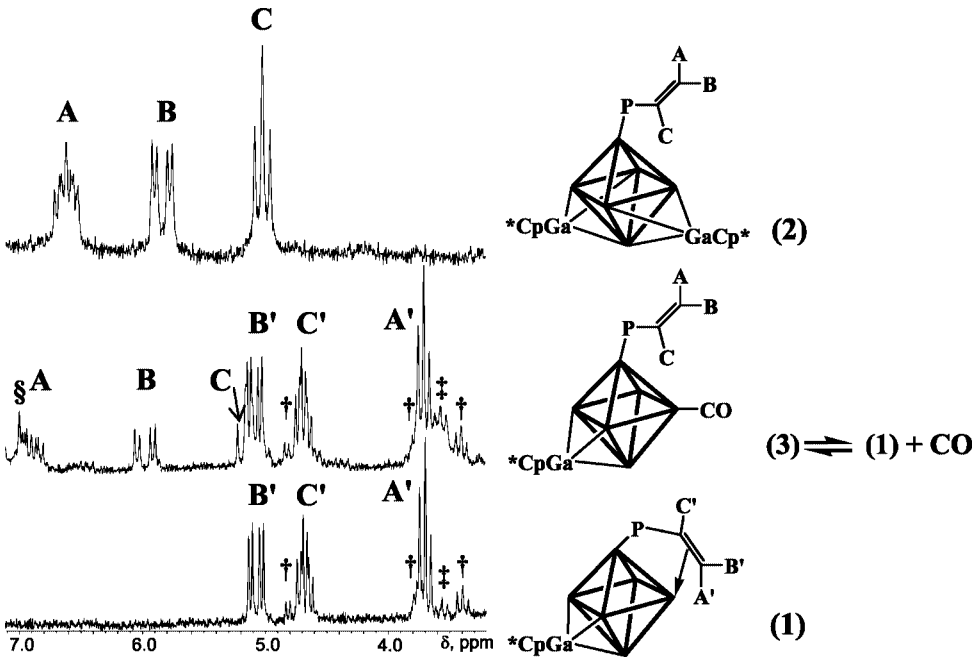

Figure 4. $^1$H NMR spectra of **1**, **2**, and **3**; $CDCl_3$, 25 °C. The structures of the corresponding molecules are schematically shown on the right side of the figure. The admixture of the $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PC_2H_3)$ starting cluster is marked by ‡. The signals of minor isomer **1** are marked by †. A signal of an unidentified impurity is marked by §.

bon couplings $^2J_{P–C(33)}$ and $^3J_{P–C(24,27)}$ are completely consistent with the stereochemistry of the intervening nuclei. It is interesting to note that this molecule is stereochemically rigid at room temperature in contrast with the $Rh_6(CO)_{15}PR_3$ derivatives that display low-temperature exchange between terminal and face-bridging CO groups bonded to the phosphane substituted rhodium atoms.[25] A similar C(33)O ↔ C(28)O, C(25)O exchange is still mechanistically possible in **2** but the electronic effect of the $\mu_3$-GaCp* ligands in some way enlarges the barrier of these dynamics.

It has to be noted that the closest analogs of the starting cluster $[Rh_6(CO)_{14}(\mu\text{-dppm})]$ and $Rh_6(CO)_{14}(\mu,\kappa^2\text{-}Ph_2PPy)$, which contain non-hemilabile bridging phosphanes,[15,22] do not react with GaCp*, neither in the presence of $Me_3NO$ nor under heating up to 50 °C. These observations stress a crucial role of the vinyl function hemilability in the chemistry under study. Initial coordination of the gallium ligand is at the terminal vacancy and this is followed by its migration into the thermodynamically stable face-bridging position. At the first stage this migration is accompanied by the recoordination of the vinyl function to keep it apart from the GaCp* moiety as shown in Figure 4. In the case of the cluster **2** the recoordination is sterically hindered because all available edge-bridging (with respect to phosphorus) positions are adjacent to $\mu_3$-GaCp* ligands. This keeps the vinyl function in **2** uncoordinated.

Hemilabile behavior of the vinylphosphane in **1** was confirmed by the reaction of this cluster with gaseous CO. Saturation of the $CDCl_3$ solution of **1** with CO followed by the proton (Figure 4) and $^{31}$P NMR (Figure S4) spectroscopic measurements showed that under these conditions **1** exists in equilibrium with the CO adduct **3**. Three multiplets of the vinyl protons in the adduct are very similar in location to those of cluster **2**, as are the spin-spin couplings (see Experimental Section), which clearly points to decoordination of the vinyl moiety. The $^{31}$P NMR spectrum of the CO saturated solution of **1** is also very similar to that of $Rh_6(CO)_{14}(\mu,\kappa^3\text{-}Ph_2PCH{=}CH_2)$ under similar conditions (Figure S4). It was shown earlier[15] that the latter cluster easily substitutes the vinyl functionality with CO and similar spectroscopic characteristics of CO saturated solutions of these clusters implies a similarity in the chemistry that has occurred. A relative amount of the adduct **3** is ca 10–15% and purging of the reaction mixture with argon easily converts **3** into **1**.

In conclusion, this study has shown that hemilabile ligands in cluster complexes may provide easy access to various substituted products including those that contain such unusual substituents as GaCp* moieties. The presence of additional phosphane ligands in the coordination sphere of the starting cluster determines the stoichiometry of the products and their stereochemistry because of the mutual influence of the phosphane and incoming ligands.

## Experimental Section

**General Comments:** All operations were carried out under an atmosphere of dry argon using standard Schlenk techniques. All solvents were distilled under an inert atmosphere over the appropriate drying agents prior to use. Commercial grade $Ph_2PC_2H_3$ (Aldrich) was used without additional purification. The starting $Rh_6(CO)_{14}(Ph_2PC_2H_3)$[15] cluster and the GaCp*[26] complex were synthesized according to literature procedures. Infrared spectra were recorded using a Specord M80 spectrometer. $^1$H, $^{13}$C{$^1$H}, and $^{31}$P{$^1$H}

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NMR spectra were recorded in $C_6D_6$ and $CDCl_3$ at room temperature using a Bruker DPX-300 instrument. The chemical shifts were referenced to residual solvent resonances for the $^1H$ and $^{13}C$ NMR spectra and external 85% $H_3PO_4$ for the $^{31}P$ NMR spectra. Microanalyses were carried out in the Microanalytical Laboratory of St. Petersburg State University. FAB mass spectra were obtained with a VG Autospec instrument (Institute of Organic Chemistry, University of Heidelberg). The observed isotopic distribution patterns completely fit the calculated ones. The products were purified by column chromatography on silica, 5–40 mesh, Merck Kieselgel 60.

**Synthesis of 1 and 2:** $Rh_6(CO)_{14}(Ph_2PC_2H_3)$ (50 mg, 0.041 mmol) was dissolved in THF (20 mL) and frozen in a Schlenk vessel by liquid nitrogen. A glass capillary tube with GaCp* (20 mg, 0.097 mmol) was placed into the vessel. The reaction mixture was warmed to room temperature under vigorous stirring, which broke the capillary tube immediately. After an hour all volatile components of the reaction mixture were removed in vacuo to leave a brown-greenish precipitate, which was washed with *n*-hexane (10 mL) and dried once more in vacuo. The residue was redissolved in $CH_2Cl_2$ (10 mL) and diluted with *n*-hexane (30 mL). The solution was transferred onto a chromatographic column (3 × 10 cm). Elution with *n*-hexane/$CH_2Cl_2$ (3:1 v/v) gave the following bands in the order of elution: $Rh_6(CO)_{12}(GaCp^*)_4$, $Rh_6(CO)_{13}(GaCp^*)_3$, $Rh_6(CO)_{13}(Ph_2PC_2H_3)(GaCp^*)_2$ (**2**, 23 mg), $Rh_6(CO)_{15}(GaCp^*)$, and $Rh_6(CO)_{13}(Ph_2PC_2H_3)(GaCp^*)$ (**1**, 14 mg). Removal of the solvents from the third and fifth bands gave brown and green-brown crystalline materials, respectively. The other components of the reaction mixture were identified by comparison of their IR spectroscopic characteristics with the literature data.[13]

**1:** IR ($CH_2Cl_2$): $\tilde{\nu}_{max}$(CO) = 2076 (w), 2052 (s), 2040 (s), 2016 (m), 1780 (m br), 1768 (m br) $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): **Major isomer:** $\delta$ = 2.24 (s, 15 H, $C_5Me_5$), 3.67 [ddd, $^2J_{H(24a)-H(25a)}$ = 2.0, $^3J_{H(24a)-H(26a)}$ = 14.0, $^3J_{H(24a)-P(1a)}$ = 14.0, 1 H, *H*(24a)], 4.68 [ddd, $^3J_{H(26a)-H(24a)}$ = 14.0, $^2J_{H(26a)-P(1a)}$= 14.0, $^3J_{H(26a)-H(25a)}$ = 10.0, 1 H, *H*(26a)], 5.07 [ddd, $^3J_{H(26a)-H(25a)}$ = 10.0, $^2J_{H(25a)-H(24a)}$ = 2.0, $^3J_{H(25a)-P(1a)}$ = 26.0, 1 H, *H*(25a)], 7.36–8.14 (m, 10 H, *phenyl rings*) ppm. **Minor isomer:** $\delta$ = 2.25 (s, 15 H, $C_5Me_5$), 3.40 [dd, $^3J_{H(24b)-H(26b)}$ = 14.0, $^3J_{H(24b)-P(1b)}$ = 14.0, 1 H, *H*(24b)], 3.74 [ddd, $^3J_{H(26b)-H(25b)}$ = 10.0, $^2J_{H(26b)-P(1b)}$ = 14.0, $^3J_{H(26b)-H(24b)}$ = 10.0, 1 H, *H*(26b)], 4.77 [dd, $^3J_{H(25b)-H(26b)}$ = 10.0, $^3J_{H(25b)-P(1b)}$ = 26.0, 1 H, *H*(25b)], 7.36–8.14 (m, 10 H, *phenyl rings*) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$) **Major isomer:** $\delta$ = 17.0 [dd, $^1J_{Rh(5)-P(1a)}$ = 130, $^2J_{Rh(2)-P(1a)}$ = 7, 1 P, *P*(1a)] ppm. **Minor isomer:** $\delta$ = 27.0 [d, $^1J_{Rh(5)-P(1b)}$ = 122, 1 P, *P*(1b)] ppm. $C_{37}H_{28}GaO_{13}PRh_6$: calcd. ratio **1/3** equals 7:1. The cluster **3** is unstable and readily converts back to **1** after purging the CO saturated solution with argon.

**3:** $^1$H NMR (300 MHz, $CDCl_3$, ambient temperature): $\delta$ = 2.21 (s, 15 H, $C_5Me_5$), 5.15 {dd, $^3J_{H(26)-H(24)}$ 18.5, $^2J_{H(26)-P(1)}$ 20.0, 1 H, *H*(26)], 5.97 [dd, $^3J_{H(25)-P(1)}$ 37.2, $^2J_{H(25)-H(24)}$ 12.2, 1 H, *H*(25)], 6.89 [ddd, $^3J_{H(26)-H(24)}$ 18.5, $^2J_{H(25)-H(24)}$ 12.2, $^2J_{H(24)-P(1)}$ 29.0, 1 H, *H*(24)], 7.36–8.14 (m, 10 H, *phenyl rings*) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$, ambient temperature): $\delta$ = 20.0 [d, $^1J_{Rh(5)-P}$ = 131, *P*(1)] ppm. A resolution enhancement procedure was used to obtain spin-spin coupling constants in the $^1$H spectrum of **3**.

**X-ray Crystal Structure Determinations**

**Complex 1:** Intensity data were collected at low temperature with a Bruker AXS Smart1000 CCD diffractometer, and corrected for absorption and other effects.[27] The structure was solved by the Patterson method and refined by full-matrix least-squares based on $F^2$. All non-hydrogen atoms were given anisotropic displacement parameters. Hydrogen atoms were inserted in calculated positions. The calculations were performed using the programs DIRDIF[27] and SHELXL.[28]

**Complex 2:** Single crystals of **2** (dimensions $0.30 \times 0.30 \times 0.05$ mm) were used for data collection at 100 K with a Bruker-Nonius KappaCCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structure was solved by direct methods. The program package used was SHELXL 97.[28] Full-matrix least-squares refinement on $F^2$ was carried out anisotropically for the non-hydrogen atoms. Hydrogen atoms were included at calculated positions using a riding model.

The crystallographic data are summarized in Table 2. Selected bond lengths and angles for **1** and **2** are shown in Table 1.

**Supporting Information** (see also the footnote on the first page of this article): VT $^1$H NMR spectra of **1**, $^1$H NMR spectrum of free diphenylvinylphosphane, $^{13}$C NMR spectrum of **2**, $^{31}$P NMR spectra of **1**, **2** and **3**.

# Alkylmono(cyclopentadienyl)titanium Complexes Containing the 2,2′-Methylenebis(6-*tert*-butyl-4-methylphenoxido) Ligand – Studies on the Nature of the Catalytic Species Present in α-Olefin Polymerisation Processes

**Marta González-Maupoey,[a] Tomás Cuenca,*[a] Luis Manuel Frutos,[b] Obis Castaño,[b] Eberhardt Herdtweck,[c] and Bernhard Rieger[d]**

**Keywords:** Titanium / Chelates / Olefin polymerisation / Density functional calculations

The mono(alkyl)bis(phenoxido)titanium complexes [TiR′($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)] [R = H, R′ = Me (**4**), $CH_2Ph$ (**5**), Ph (**6**), $CH_2SiMe_3$ (**7**); R = Me, R′ = Me (**8**), $CH_2Ph$ (**9**), $CH_2SiMe_3$ (**10**); $\eta^2$-mbmp = 2,2′-methylenebis(6-*tert*-butyl-4-methylphenoxido)] have been prepared in good yields by reaction of the appropriate alkylating reagent with the corresponding chlorido(cyclopentadienyl)bis(phenoxido)titanium derivative. Compound **6** reacts in toluene with traces of water to afford the μ-oxidotitanium complex {Ti($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)}$_2$(μ-O) (**11**). Compounds **8**, **9** and **11** have been characterised by single-crystal X-ray crystallography, and density functional calculations have been performed in order to elucidate the energetic and structural properties of these compounds. The activity of these complexes in the presence of methylaluminoxane (MAO), $B(C_6F_5)_3$ or $[Ph_3C][B(C_6F_5)_4]$ as co-catalysts in the polymerisation of propylene and styrene has been studied. In an effort to model the nature of the catalytic species generated from these precursors, the reactions of the mono(cyclopentadienyl)bis(phenoxido)chlorido- and -alkyltitanium derivatives with Lewis acids were examined. $B(C_6F_5)_3$ reacts with the neutral complexes [TiR′($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)] by abstraction of the alkyl group R′ to give the highly stable species [Ti($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)][$MeB(C_6F_5)_3$] (**12**), [Ti($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)][$(PhCH_2)B(C_6F_5)_3$] (**13**), [Ti($\eta^5$-$C_5Me_5$)($\eta^2$-mbmp)][$MeB(C_6F_5)_3$] (**14**) and [Ti($\eta^5$-$C_5Me_5$)($\eta^2$-mbmp)][$(PhCH_2)B(C_6F_5)_3$] (**15**), which are inactive in propylene and styrene polymerisation. In contrast, the reaction between the neutral alkyl derivatives and $[CPh_3][B(C_6F_5)_4]$ affords species that are active in α-olefin polymerisation. Treatment of the mono(chlorido) compound [TiCl($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)] with 1 equiv. of $AlMe_3$ affords the methyl derivative **4** as essentially the only reaction product. When an excess of $AlMe_3$ is used, transmetallation reactions of the bis(phenoxido) ligand from titanium to aluminium are observed. Reactions of the bis(phenol) $mbmpH_2$ with $AlMe_3$ or $AlClMe_2$ yield $[AlMe(mbmp)]_2$ (**16**) and $[AlCl(mbmp)]_2$ (**17**).

## Introduction

Alkoxido derivatives of transition metals are used as catalysts in a wide range of homogeneous reactions, and early transition metal elements are strongly stabilized in high oxidation states by alkoxido (or phenoxido) ligands.[1–3] Alkoxidotitanium and -zirconium compounds combined with a co-catalyst (MAO) are highly active catalysts in α-olefin polymerisation.[4–9] The synthesis of dialkyl(alkoxido) derivatives of group 4 elements is very difficult as they are sensitive to atmospheric moisture and to light. The reaction of $[MR_{4-x}(OAr)_x]$ complexes with the Lewis acid $B(C_6F_5)_3$ has been reported to give the zwitterionic species $[M(CH_2Ph)(OAr)_2][B(\eta^6\text{-}C_6H_5CH_2)(C_6F_5)_3]$ for the benzyl derivatives and a mixture of $[Ti(C_6F_5)Me(OAr)_2]$ and $BMe(C_6F_5)_2$ for the methyl complexes.[10]

In a previous paper we reported the synthesis and characterisation of the mono(cyclopentadienyl)titanium complexes [TiClCp′($\eta^2$-mbmp)] [Cp′ = $\eta^5$-$C_5H_5$ (**1**), $\eta^5$-$C_5Me_5$ (**2**), $\eta^5$-$C_5H_4SiMe_2Cl$ (**3**)] containing the bis(phenoxido) bidentate dianionic ligand 2,2′-methylenebis(6-*tert*-butyl-4-methylphenoxido) ($\eta^2$-mbmp). Density functional calculations developed for these complexes provide remarkable conclusions about their structural behaviour, which were subsequently confirmed by X-ray diffraction studies in the solid state. After activation with MAO, these mono(cyclopentadienyl)titanium derivatives are suitable catalysts for olefin (propylene, styrene and isoprene) polymerisation.[11]

To elucidate the influence of the co-catalyst used in these studies on the activity of the catalyst, as well as on the poly-

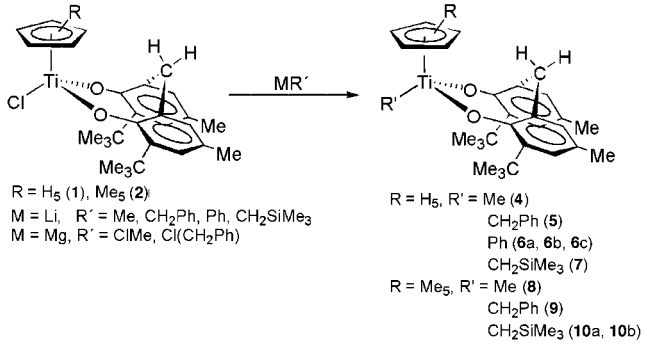
merisation mechanism, we have synthesised new alkylmono(cyclopentadienyl)titanium systems containing the mbmp ligand. Here we report the synthesis of [TiR′($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)] (R = H, Me; R′ = Me, $CH_2Ph$, Ph, $CH_2SiMe_3$) derivatives, their reactions with Lewis acids {$AlMe_3$, $B(C_6F_5)_3$ and $[CPh_3][B(C_6F_5)_4]$} as well as their catalytic application in α-olefin polymerisation, in which different co-catalysts and temperature conditions were employed. The synthesis of a dinuclear μ-oxidotitanium derivative [{Ti($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)}$_2$(μ-O)] and dinuclear aluminium compounds [AlX(mbmp)]$_2$ (X = Cl, Me) with a μ-$\eta^1$,$\eta^2$ disposition of the mbmp ligand are also reported. The X-ray molecular structures of [TiR′($\eta^5$-$C_5Me_5$)($\eta^2$-mbmp)] (R′ = Me, $CH_2Ph$) and [{Ti($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)}$_2$(μ-O)] complexes were determined by diffraction methods and density functional calculations performed for [TiR′($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)] (R′ = Me, $CH_2Ph$, Ph).

## Results and Discussion

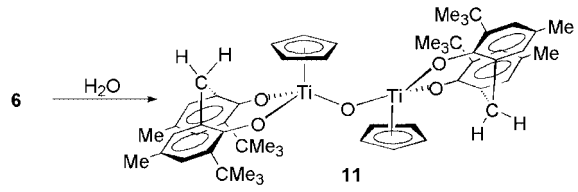
### Synthesis of Complexes

The reaction of the chlorido derivatives [TiCl($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)] [R = H (**1**), Me (**2**); $\eta^2$-mbmp = 2,2′-$CH_2$-bis(6-*t*Bu-4-$CH_3C_6H_2$-1-O)],[11] with 1.2 equiv. of MR′ (M = Li, R′ = Me, $CH_2Ph$, Ph, $CH_2SiMe_3$; M = Mg, R′ = $ClCH_2$, $ClCH_2Ph$), in hexane at –78 °C, affords the alkylmono(cyclopentadienyl) complexes [TiR′($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)] [R = H, R′ = Me (**4**), $CH_2Ph$ (**5**), Ph (**6**), $CH_2SiMe_3$ (**7**); R = Me, R′ = Me (**8**), $CH_2Ph$ (**9**), $CH_2SiMe_3$ (**10**)] containing a bidentate bis(phenoxido) ligand (Scheme 1). The compounds were isolated as yellow-orange solids in 60–80% yield.



Scheme 1.

When compound **6** reacts in toluene with traces of water at room temperature crystals of a dimetallic complex with an oxygen atom bridging two titanium atoms and identified as [{Ti($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)}$_2$(μ-O)] (**11**) were obtained (Scheme 2).



Scheme 2.

Compounds **4**–**10** are soluble in chlorinated solvents (chloroform and dichloromethane) and aromatic (benzene, toluene) and aliphatic hydrocarbons (pentane and hexane), while complex **11** only presents low solubility in toluene and chlorinated solvents (chloroform and dichloromethane). They can be stored under an inert gas in solution for months and are stable for some weeks in the solid state without decomposition. They were characterised by elemental analysis and NMR spectroscopy. The elemental analysis values found for **5** were inaccurate due to the presence of small amounts of impurities which could not be removed, although this compound has been characterised by spectroscopic methods. The analytical composition fits the proposed formulation exactly. The molecular structures of **8**, **9** and **11** have been determined by X-ray diffraction.

The NMR spectra ($C_6D_6$ and $CDCl_3$, room temperature) of complexes **4**–**10** show patterns for the mbmp fragment similar to those described for compounds containing the same bis(phenoxido) ligand.[11] The two $CH_2$ protons appear in the $^1$H NMR spectra as a pair of doublets; the value of the chemical shift difference ($\Delta\delta$, $C_6D_6$) between their chemical shifts varies between 2.13 and 0.28 ppm. This difference seems to be due to changes in the configuration of the metallacyclic ring in solution.[11] Both equivalent *tert*-butyl groups and the two methyl substituents on the phenyl rings appear as singlets between $\delta$ = 1.49–1.20 and 2.18–2.07 ppm in $C_6D_6$, respectively. The protons at the 3- and 5-positions on the phenyl ring give two doublets, corresponding to AA′ spin systems, with a $^4J_{H,H}$ coupling constant of 1.83 Hz. Singlets are observed for the cyclopentadienyl and the methylcyclopentadienyl ring protons in the expected region of the spectra. For all of these compounds, structural features similar to those determined by $^1$H NMR spectroscopy can be deduced from the $^{13}C\{^1H\}$ NMR spectra ($C_6D_6$, room temperature). These spectroscopic data are consistent with $C_s$-symmetrical molecules. In the $^1$H NMR spectra, the alkyl substituents at the titanium centre show the expected behaviour for this kind of group in $C_s$ molecules, namely one singlet for the methyl group, two singlets that integrate for two and nine protons for the $CH_2SiMe_3$ substituent, one singlet and signals of aromatic protons for the $CH_2Ph$ group and resonances of aromatic protons for the phenyl group, with the corresponding resonances in the $^{13}C\{^1H\}$ NMR spectra.

The $^1$H NMR spectrum of **11** shows two doublets for the methylene protons with a chemical shift difference between them of 1.00 ppm ($C_6D_6$). The *tert*-butyl and methyl groups of each bis(phenoxido) ligand are not equivalent and appear as two singlets. The protons in the 3- and 5-positions

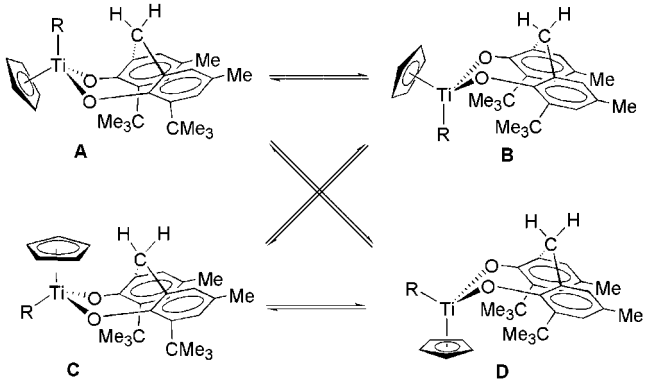
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

on the phenyl rings are also not equivalent and appear as four doublets. However, the molecule is symmetric as a result of the presence of a $C_2$ axis through the bridging oxygen atom that runs perpendicular to the titanium–oxygen bonds. As a consequence, each fragment of the phenoxido ligand of one titanium centre is equivalent to the opposite fragment of the phenoxido ligand of the other titanium centre, as shown in Scheme 2. The molecular structure determined by X-ray diffraction confirms this proposed arrangement, thus indicating that the solid-state structure is maintained in solution.

The $^1$H NMR spectra of analytically pure samples of **4**, **5** and **7** show only one pattern for the signals discussed. The study of the phenyl derivative **6** showed the presence of three different isomers (**6a**, **6b** and **6c**). Isomers **6a** and **6b** can be separated as pure samples by repeated recrystallisation from toluene because of their different solubility. A solution of **6b** in deuterated benzene evolves to a 1:1 molar ratio mixture of **6b** and **6c** at room temperature in 3 h, while a solution of **6a** under the same conditions remains unaltered for a long time. The formation of a single compound was observed spectroscopically for the pentamethylcyclopentadienyl derivatives **8** and **9**, while the $^1$H NMR spectrum of **10** shows two sets of signals, thus indicating that this complex is obtained in solution as a mixture of two isomers (**10a/10b**) in a 10:1 molar ratio. Theoretical studies (see below) permitted us to understand this behaviour.

### Study of the Molecular Structure – Theoretical and Conformational Studies and Crystal Structure of [TiMe($\eta^5$-$C_5Me_5$)($\eta^2$-mbmp)] (8), [Ti($CH_2Ph$)($\eta^5$-$C_5Me_5$)($\eta^2$-mbmp)] (9) and [{Ti($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)}$_2$(μ-O)] (11)

For the [TiR′Cp($\eta^2$-mbmp)] type of compounds the existence of four possible conformers related by two different conformational change processes, i.e., by ring inversion and boat/chair interconversion (Scheme 3) can be proposed.[11]



Scheme 3.

The HF method with B3LYP hybrid exchange-correlation energy functional[12] implemented in the Gaussian suite of programs[13] using a 3-21g* basis set was employed in order to explore the potential energy surface (PES) and to locate the minima involved in the related processes. All the structures were optimised at this level of theory. To study the character of the stationary points found, an analysis of the approximate Hessian was made, which confirmed all these points as minima on the PES. In our search, three different conformers (**I**, **II**, and **III**) were found (Figure 1).

The equilibrium Ti–O bond length, the relative electronic energies and the relative population based on Boltzmann's equilibrium distribution at 298 K of these three conformers for compounds **4**–**6** and previously reported **1**[11] are listed in Table 1.

For almost all of the complexes studied, the most stable conformer (**I**) has a geometry intermediate between a boat and a chair conformation (intermediate between **C** and **B** in Scheme 3, although slightly closer to the boat than to the chair), with the Cp ligand close to the methylene bridge between the phenyl groups and short Ti–O bond lengths (1.78–1.807 Å).

The second calculated conformer (**II** in Figure 1, corresponding to a disposition similar to **A** in Scheme 3 but intermediate between **A** and **D**) has a similar arrangement to conformer **I**, with the Cp and alkyl ligands interchanged. The Ti–O bond lengths are analogous (1.79–1.803 Å) to those found for conformer **I**. These calculations suggest a clear degree of multiple bonding in the Ti–O link close to sp hybridisation for both conformers. For complex **6**, we can see how the high planarity of the C–O–Ti–O–C fragment makes isomers **I** and **II** very close in energy.

The third conformer (**III** in Figure 1, corresponding to a disposition close to **D** in Scheme 3) exhibits different behaviour to **I** and **II** as a result of its geometrical structure. It presents a closer $sp^2$ oxygen angle and a larger Ti–O bond length (1.81–1.814 Å).

As a result of the calculations, two boat conformers (**I** and **II**) related through a ring-inversion process could be expected. Conformer **III**, in which the oxygen atoms move toward $sp^2$ hybridisation, is the most unstable due to Ti–O bond weakening, which raises the energy by around 13 kcal mol$^{-1}$ with respect to the most stable conformer for compounds **1** and **4**. The stability of each conformer is reflected in the Ti–O bond order in such a way that the shorter the bond the greater the stability. The preference to adopt conformation **I** or **II** depends on the steric impediment exerted by the cyclopentadienyl ring and the alkyl substituent at the titanium centre.

As shown in Table 1, **I** is the most stable conformer for compounds **1**, **4** and **6**, in which the Cp ligand is located towards the methylene bridge. A small difference in stability between **I** and **II** is predicted for compound **6**, while for compounds **1** and **4** higher differences in the related energies are deduced; only for complex **5** is conformation **II** more stable than **I** due to the high steric hindrance produced between the *t*Bu groups of the bis(phenoxido) ligand and the ring of the benzyl substituent. The high relative energies of conformations **I** and **III** for complex **5** are comparable as a result of this steric hindrance, which in **III** is due to the steric hindrance between the cyclopentadienyl

ligand and the *t*Bu groups. These theoretical results are in agreement with the NMR experimental data. Although complexes **1**, **4** and **5** could exist in three different conformations, the high stability of disposition **I** for **1** and **4** (or **II** for **5**) is enough to make these the only preferred conformations, which leads to the formation of one unique isomer, as observed spectroscopically.

For complex **6**, the theoretical studies predict the possibility of two boat conformations (**I** and **II**) with similar energies and therefore both species can coexist in solution at room temperature. These theoretical studies explain the presence of two of the three patterns of signals found in the NMR spectra. In contrast, the value of the chemical shift difference for the two methylene protons of the bis(phenoxido) ligand in the $^1$H NMR spectrum is initially an excellent probe for the detection of the metallacycle conformation.[11] Taking into account the relationship between this value and the conformation found in the X-ray structures elucidated for this type of complex (see below and ref.[11]), a $\Delta\delta_{CH_2}$ value of around or below 1.00 ppm points to a boat conformation. In this sense, conformations **I** and **II** would correspond to isomers **6a** and **6b**. The third pattern (**6c**) could correspond to conformer **III**, which, although it is not found by the theoretical calculations, is experimentally plausible and would explain why a pure solution of **6b** interconverts at room temperature to an equimolecular mixture of **6b** and **6c**.

To establish and to confirm the structural details of the molecular geometry in the solid state for this type of compound, X-ray crystal structure analyses of **8**, **9** and **11** were carried out. Single crystals of **8** obtained by slow recrystallisation from hexane solution were of good enough quality to be analysed by X-ray diffraction. The crystal structure of **8** is shown in Figure 2. Crystals of **9** were also obtained

from hexane solution at –20 °C but were not good enough for X-ray crystallography. However, it was possible to determine its molecular structure, which is depicted in Figure 3. Table 2 summarises selected bond lengths and angles.

The mbmp ligand adopts a puckered chelate disposition with the typical boat conformation in the solid state with the methylene bridge pointing toward the cyclopentadienyl ring.[9,14,15] The observed structural parameters correlate

well with those calculated for the most stable conformer determined by density functional calculations. This confirms that the preferred structure for these complexes in the solid state is the boat conformation, in agreement with the theoretical results, from which a similar boat conformation is predicted for the analogous complexes bearing an $\eta^5$-$C_5H_5$ ligand.

The coordination geometry around the titanium atom is a pseudo-three-legged piano stool, as expected for complexes of the type $TiCpL_3$.[16] The metal–oxygen bond lengths in **8** (av. 1.8367 Å) and **9** (av. 1.8300 Å) are in the expected range for titanium complexes with a linked bis(phenoxido) ligand with ($\sigma + \pi$) donor oxygen atoms.[3,17] Compared with the related structure of the chlorido derivative **2**,[11] the presence of a less electronegative alkyl group increases the electronic density at the metal centre, which leads to longer average Ti–O bonds and a more open O1–Ti–O2 angle.

The geometry adopted for these complexes is a compromise situation where the least steric hindrance between the pentamethylcyclopentadienyl ring and the methylene bridge is produced and the methyl substituent is located far away from the *tert*-butyl groups of the bis(phenoxido) ligand.

Crystals of compound **9** diffracted poorly, as indicated by the weak diffraction patterns, the high thermal parameters and the high *R* values. The pentamethylcyclopentadienyl ring is disordered but the refinement shows undoubtedly that complex **9** is present as described. As can be seen in Figure 3, complex **9** presents a boat conformation with the methylene bridge pointing toward the pentamethylcyclopentadienyl ring, in a similar manner to conformation **I** obtained in the theoretical study. This study for the analogous benzylmono(cyclopentadienyl) complex **5** predicted a boat conformation of type **II**, with the benzyl substituent far away from the *tert*-butyl groups of the bis(phenoxido) ligand. Nevertheless, the difference in steric relaxation between the benzyl group and the pentamethylcyclopentadienyl ring near the *tert*-butyl groups should not be significant for compound **9**, which prefers to adopt the most stable type-**I** conformation, which is the preferred conformation for the chlorido-, methyl- and phenyl(cyclopentadienyl) derivatives deduced from the theoretical study.

The structure of compound **11** was confirmed by X-ray diffraction analysis. A view of the molecular structure is given in Figure 4 and selected bond lengths and angles are listed in Table 3.

The coordination sphere around the metal centre is a four-legged piano stool. The bite angles of the bis(phenoxido) ligands [O(1)–Ti(1)–O(2) = 103.23(6)° and O(3)–Ti(2)–O(4) = 103.97(6)°] are larger than 90° and in the same range

as those obtained for complexes containing the mbmp ligand, such as [Ti(mbmp)$_2$] [106.24(7)° and 107.28(8)°],[3] [$TiCl_2$(mbmp)] [106.5(2)°],[18] [$TiMe_2$(mbmp)] [112.7(2)°],[18] [Ti(mbmp)($BH_4$)$_2$] [103.9(2)°],[19] and the mono(cyclopentadienyl)bis(phenoxido)titanium complexes [CpTiX($OC_6H_3$-*i*$Pr_2$)$_2$] [X = Cl, *t*Bu and Me; 103.0(3)°, 107.7(9)° and 109.0(5)°, respectively].[20] The dihedral angles between both phenyl rings are 115.92(19)° and 115.52(18)°, more open than those found for analogous ligands with different bridging units {S in tmbp and Te in tebp [tmbp = 2,2′-thiobis(6-*tert*-butyl-4-methylphenoxido), tebp = 2,2′-tellurobis(6-*tert*-butyl-4-methylphenoxido)]; [Ti(mbmp)($BH_4$)$_2$] = 64.1(2)°,[19] [$TiCl_2$(mbmp)(thf)] = 113.4(3)°,[21] [$TiCl_2$(tmbp)]$_2$ = 102.9(3)°,[5] [CpTiCl(tmbp)] = 107.3(1)°[9] and [$TiCl_2$(tebp)]$_2$ = 96.0(2)°}.[15]

The mbmp ligand adopts a typical boat conformation in the solid state, with one of the methylene bridge protons pointing towards the metal centre and the other away from it and with both in the proximity of the cyclopentadienyl ring.[9,15] The metal–oxygen bond lengths [Ti(1)–O(1) = 1.808(2), Ti(1)–O(2) = 1.843(2), Ti(2)–O(3) = 1.809(2) and Ti(2)–O(4) = 1.857(2) Å] are short but in the expected range for titanium complexes with a linked bis(phenoxido) ligand with (σ + π) donor oxygen atoms, such as [Ti(mbmp)$_2$] [av. 1.802(6) Å],[3] [$TiCl_2$(mbmp)(thf)] [av. 1.791(2) Å],[21] [$TiCl_2$(tmbp)]$_2$ [av. 1.818(4) Å],[5] [$TiCl_2$(tebp)]$_2$ [av. 1.801(9) Å],[15] [CpTiCl(tmbp)] [av. 1.827(2) Å][9] and [Ti($CH_2Ph$)$_2${2,2′-(4-MeO-6-*t*Bu$C_6H_2O$)$_2$}] [av. 1.810(7) Å],[7] and slightly larger than those found in analogous compounds such as [$TiCl_2$(mbmp)] [av. 1.751(4) Å][18] and [$TiBr_2$(ebmp)] [ethylene-bridged analogue; av. 1.750(9) Å].[17] Similar results were found in titanium complexes with non-linked phenoxido ligands, such as [CpTiX($OC_6H_3$*i*$Pr_2$)$_2$] [X = Cl, *t*Bu, Me; av. 1.801(5), 1.79(2) and 1.817(9) Å, respectively], due to the presence of a cyclopentadienyl ligand, which decreases the π-donation from the oxygen atoms to the metal centre.[20] Finally, the angle at the oxygen bridge atom is crystallographically restricted to 174.30(8)° and the metal–bridging oxygen bond lengths of 1.826(1) and 1.816(1) Å are typical for bridged titanium oxides.[22]

## Olefin Polymerisation

Using MAO in excess or $B(C_6F_5)_3$ or [$CPh_3$][$B(C_6F_5)_4$] [1:1 molar ratio with respect to the precursor in the presence of triisobutylaluminium (TIBA) as scavenger] as co-catalysts, complexes **4**, **5**, **8** and **9** were studied as α-olefin polymerisation catalysts under various conditions.

Propylene polymerisation was investigated by using 27 μmol of catalyst in 150 mL total volume of toluene with a 1000:1 Al(MAO)/Ti or 250:1:1 Al(TIBA)/Ti/[$CPh_3$][$B(C_6F_5)_4$] molar ratio at different temperatures and monomer pressures (conditions and results are summarised in Tables 4 and 5). Only traces of polymer or no polymerisation was found when the reaction was carried out at 30 °C with 5 atm of monomer and MAO as co-catalyst (runs 1, 4, 7 and 10). However, polymer was found at 0 °C using liquid propylene and MAO as co-catalyst for complexes **4** and **5** (runs 2 and 5), while compounds **8** and **9** (runs 8 and 11) showed poor activity. Decomposition of the catalyst system in the presence of the monomer at high temperatures could be a possible explanation for this behaviour. The activity [7.4 kg PP (mol Ti)$^{-1}$ h$^{-1}$] at 0 °C for the chlorido(cyclopentadienyl) system **1**/MAO[11] is markedly higher than that found for the corresponding alkyl derivatives **4** and **5**. Polymerisation runs at 0 °C resulted in the formation of PP with a molecular weight ($M_w$) of around $10^5$ for the pentamethylcyclopentadienyl derivatives **8** and **9** (2.5–$5.6 \times 10^5$), one order of magnitude higher than the corresponding non-substituted alkyl(cyclopentadienyl) derivatives **4** and **5**, probably due to the more electron-donating capability of the $\eta^5$-$C_5Me_5$ ligand, which prevents β-elimination processes.

When the salt [$CPh_3$][$B(C_6F_5)_4$] was used as co-catalyst, complexes **4** and **5** exhibited analogous activity (runs 3 and 6), but the activity was greatly increased for compounds **8** and **9** (runs 9 and 12), producing around 20–40 kg PP (mol Ti)$^{-1}$ h$^{-1}$. A similar behaviour is observed with the molecular weight of the polymer synthesised, and the high value found with systems **8**/[$CPh_3$][$B(C_6F_5)_4$] and **9**/[$CPh_3$][$B(C_6F_5)_4$] is worthy of mention, with each reaching values of $2–3 \times 10^6$, with similar polydispersity values to those reported in the literature.[7,15,20,23] For these samples, values of $T_g$, $T_m$ and $\Delta H$ similar to those found with the **1**/MAO system[11] are observed.

The use of the borane salt produces a decrease in the stereoselectivity of the process, as shown in Table 5 from an analysis of the degree of isotacticity in the samples by $^{13}C$ NMR spectroscopy. The activation of the precursors with MAO at 0 °C gives isotactic PP with an isotacticity (mmmm) of 24–30% (runs 2 and 5) for the cyclopentadienyl complexes **4** and **5**. However, activation with

[a] From $^{13}$C NMR spectra.

$[CPh_3][B(C_6F_5)_4]$ produces atactic PP (runs 3 and 6). The pentamethylcyclopentadienyl complexes **8** and **9** activated with either MAO or $[CPh_3][B(C_6F_5)_4]$ afford atactic PP. The high molecular weights of the samples obtained in runs 9 and 12 impeded the detection of their degree of isotacticity due to their lack of solubility in the deuterated solvents used for the spectroscopic analysis.

The results obtained at different temperatures and the microstructures of the polymers synthesised with MAO as co-catalyst are similar to those found with the **1**/MAO system[11] and resemble those reported by Ewen[24] for PP obtained with the achiral metallocene $[TiCp_2Ph_2]$, which is very unusual for monocyclopentadienyl compounds. This analysis permits us to conclude that the polymer obtained at low temperature with precursors **4** and **5** activated with MAO contains large isotactic stereoblocks produced by a chain-end control mechanism with a certain atactic character due to 2,1-enchainments. Nevertheless, it is noteworthy that the activation of precursors **8** and **9** with $[CPh_3][B(C_6F_5)_4]$ co-catalyst produces atactic PP with a high molecular weight of $10^6$.

Styrene polymerisation was studied using 40 mL total volume of reaction and 5 mL of monomer (conditions and results are summarised in Table 6). When the precursors are activated with MAO (runs 3, 7, 11 and 15), the activity of the cyclopentadienyl complexes **4** and **5** is higher (7–$8 \times 10^5$) than the activity found for the pentamethylcyclopentadienyl compounds **8** and **9** (2–$3 \times 10^5$), in all cases leading to syndiotactic PS (>95% syndiotacticity). Increased activity can be achieved with donor substituents in

the cyclopentadienyl ring, while the presence of bulky substituents results in a decrease in activity. The bulky substituents would inhibit 2,1-insertion through steric effects and simultaneously inhibit the generation of the active species.

When $[CPh_3][B(C_6F_5)_4]$ is used as co-catalyst (runs 1, 5, 9 and 13) the activity is of the same order of magnitude as that obtained with MAO as co-catalyst. However, and in agreement with the results obtained in the propylene polymerisation, activation with the borane salt affords atactic PS (>92% of atactic microstructure). The similarity in the activity values found for the four alkyl complexes studied when the borane salt is used as co-catalyst is noteworthy and shows that the nature of the cyclopentadienyl ring has no influence on the activity. The addition of TIBA as scavenger in the precursor/$[CPh_3][B(C_6F_5)_4]$ systems (runs 2, 6, 10 and 14) dramatically decreased the activity. No polymerisation was found for the precursor/$[B(C_6F_5)_3]$ system (runs 4, 8, 12 and 16). The molecular weight of the PS obtained with the precursor/$[CPh_3][B(C_6F_5)_4]$ systems is very low but increases when MAO is used as co-catalyst, reaching an order of magnitude of $10^5$ with the pentamethylcyclopentadienyl compounds **8** and **9**.

### Reaction with Lewis Acids

In order to gain a better knowledge of the nature of the active species and the chemical behaviour of the mono(alkyl)bis(phenoxido) precatalyst systems in the α-olefin polymerisation processes, the reactions of the methyl and benzyl derivatives **4**, **5**, **8** and **9** with Lewis acids such as $B(C_6F_5)_3$ and $[CPh_3][B(C_6F_5)_4]$ were studied using a stoichiometric 1:1 Ti/B ratio and monitored by $^1H$ NMR spectroscopy. Likewise, the reaction of the chloromono(cyclopentadienyl) derivative **1** with trimethylaluminium was examined. All the procedures were carried out in NMR tubes fitted with Teflon valves to prevent water and oxygen entry and with $C_6D_6$ as reaction solvent at room temperature.

After addition of $C_6D_6$ to a mixture of $B(C_6F_5)_3$ and the corresponding neutral derivative **4**, **5**, **8** or **9** at room temperature in an NMR tube in a glovebox, the samples were quickly introduced into the spectrometer and the spectra recorded at 25 °C over a period of time. The reaction produces an appreciable change in the solution's colour from yellow for the methyl derivatives or orange for the benzyl compounds to dark red. After 1 h at room temperature, formation of the ionic species $[Ti(\eta^5\text{-}C_5H_5)(\eta^2\text{-}mbmp)][MeB(C_6F_5)_3]$ (**12**) and $[Ti(\eta^5\text{-}C_5H_5)(\eta^2\text{-}mbmp)][(PhCH_2)B(C_6F_5)_3]$ (**13**; Scheme 4) was detected. For the $\eta^5\text{-}C_5Me_5$ derivatives it was necessary to heat the reaction mixtures at 100 °C for 24 h to complete the reaction and to obtain the ionic compounds $[Ti(\eta^5\text{-}C_5Me_5)(\eta^2\text{-}mbmp)][MeB(C_6F_5)_3]$ (**14**) and $[Ti(\eta^5\text{-}C_5Me_5)(\eta^2\text{-}mbmp)][(PhCH_2)B(C_6F_5)_3]$ (**15**; Scheme 4). However, the reaction of **4** with an equimolecular amount of $[CPh_3][B(C_6F_5)_4]$ at room temperature in $C_6D_6$ gave an intractable mixture of unidentified products.

Complexes **12**–**15** are partially soluble in $C_6D_6$ and are stable in solution at room temperature over long periods of time (days). The $^1H$ NMR spectra ($C_6D_6$, 25 °C) show signals of equivalent *t*Bu and Me groups and two resonances for the phenyl protons of the bis(phenoxido) ligand, consistent with a $C_s$ symmetry. The resonances of the cyclopentadienyl protons are shifted to low field with respect to the neutral precursors, as expected. The methyl group of the $[MeB(C_6F_5)_4]^-$ fragment gives signals at $\delta$ = 0.84 and 0.91 ppm for derivatives **12** and **14**, respectively, suggesting a certain interaction between the anionic and the cationic centres.[25–29] The signals of the methylene protons of the benzylborate anion $[(PhCH_2)B(C_6F_5)_4]^-$ appear at $\delta$ = 3.14 and 2.90 ppm for derivatives **13** and **15**, respectively. It is not easy to establish a limit to determine the coordination or non-coordination of the anionic and cationic centres by analysing the methylene benzylborate anion resonances. Generally, values of $\delta_{CH_2B} < 3.0$ ppm seem to indicate the existence of an anion–cation interaction for the $[(PhCH_2)B(C_6F_5)_4]^-$ anion,[10,25,30,31] although exceptions to this rule have been found.[8,32] The resonance of the $C_{ipso}$ phenyl ring of the benzylborate anion is a good probe to determine the type of interaction with the metal centre. The $^{13}C$ NMR spectra ($C_6D_6$, 25 °C) for derivatives **13** and **15** show signals at $\delta$ = 152.5 and 160.3 ppm assignable to the $C_{ipso}$ phenyl ring carbon atom. This indicates a certain degree of $\eta^6$-coordination of the phenyl ring of the benzylborate anion to the cationic metal centre ($\delta$ = 148.6 ppm in the free anion).[33,34] The $^{19}F$ NMR spectra of the cationic species **12**–**15** give $\Delta\delta(p,m\text{-F})$ values of 3.52, 3.40, 3.41 and 5.10 ppm, respectively, indicating the existence of interactions between the ion pairs that are particularly strong for the pentamethylcyclopentadienyl ionic species **15** with the benzylborate anion.[25,35]

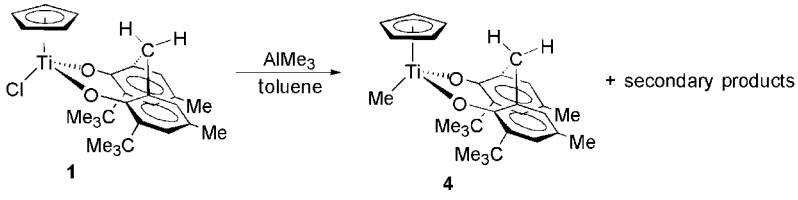
These results permit us to conclude that the Lewis acid $B(C_6F_5)_3$ reacts with the neutral complexes [TiR′($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)] by abstraction of the alkyl group R′ to give the highly stable cationic species [Ti($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)]$^+$, which retains the Ti–O bonds and the bidentate bis(phenoxido) ligand bonded to the titanium centre. Formation of such a stable species exhibiting strong interactions with the anionic unit prevents coordination of the olefin and, as a consequence, these systems are inactive in propylene and styrene polymerisation. With $[CPh_3][B(C_6F_5)_4]$ we could initially assume a similar reactivity. However, the $[B(C_6F_5)_4]^-$ unit is a less coordinating anion than $[RB(C_6F_5)_4]^-$ to afford [Ti($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)][$B(C_6F_5)_4$], which is active in styrene polymerisation. In the absence of olefin, these $[B(C_6F_5)_4]^-$ systems show a lack of stability, with fast and immediate decomposition observed in solution.

A new family of compounds containing only one metal–alkyl bond that are active in olefin polymerisation has been reported recently. Mechanistic pathways to explain the efficient α-olefin polymerisation of these compounds activated with boron reagents have been proposed.[36–39] In the absence of TIBA, the olefin polymerisation activity observed for complexes **4**, **5**, **8** and **9** with $[CPh_3][B(C_6F_5)_4]$ as co-catalyst can be explained by these mechanistic pathways.

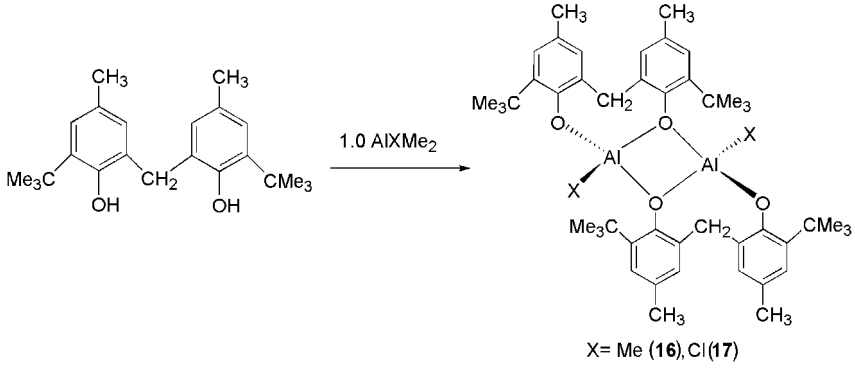
Aluminium compounds are normally used as co-catalysts (MAO) to generate the active species or as scavenger reagents (TIBA) during olefin polymerisation. The former occurs by replacement of the halo groups in the precursor with alkyl groups and then abstraction of one of these alkyl groups to give cationic alkyl species, which are considered to be the active species in the process. As our neutral species with general formula [TiCl($\eta^5$-$C_5R_5$)($\eta^2$-mbmp)] [$\eta^5$-$C_5R_5$ = $\eta^5$-$C_5H_5$ (**1**), $\eta^5$-$C_5Me_5$ (**2**), $\eta^5$-$C_5H_4SiMe_2Cl$ (**3**)][11] only possess one chlorido group at the metal centre, we were motivated to investigate the reactivity of compound **1** with $AlMe_3$. Thus, a solution of the mono(chlorido) compound [Ti($\eta^5$-$C_5H_5$)($\eta^2$-mbmp)Cl] (**1**) was treated with 1 equiv. of $AlMe_3$ in toluene at –78 °C (Scheme 5). $^1$H NMR spectroscopic analysis revealed complex **4** to be essentially the only reaction product, thereby indicating alkylation of the Ti–Cl bond and selective formation of the methyl derivative. The NMR spectra also show the presence of traces of signals assignable to secondary products containing the bis(phenoxido) ligand. The intensity of these signals increases when an excess of $AlMe_3$ is used as reagent, along with the disappearance of the signals assignable to compound **4**. Transmetallation reactions of the bis(phenoxido) ligand from titanium to aluminium could explain the formation of these secondary products.[20,40]

In an attempt to identify the nature of these secondary products, we performed the reaction of the bis(phenol) $mbmpH_2$ with $AlMe_3$ or $AlClMe_2$ in a 1:1 molar ratio in toluene at –78 °C. White solids were obtained in both cases, which were characterised by elemental analysis and NMR spectroscopy as the compounds $[AlMe(mbmp)]_2$ (**16**) and $[AlCl(mbmp)]_2$ (**17**; Scheme 6). The thf adduct monomer species [AlCl(mbmp)(thf)] obtained by reaction of $mbmpH_2$ with $AlClEt_2$ in thf has been described previously, although the dimeric species was not characterised.[41]

Complexes **16** and **17** are insoluble in aliphatic hydrocarbons (hexane, pentane), scarcely soluble in aromatic solvents and highly water-sensitive. They can be stored for months under an inert gas without decomposition. The $^1$H NMR spectra ($C_6D_6$ and $CDCl_3$, 25 °C) show AB spin systems for the methylene protons, indicating coordination of the bis(phenoxido) ligand. The *tert*-butyl and methyl groups are not equivalent, with each appearing as two singlets. A



Scheme 5.



Scheme 6.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

high-field-shifted signal assignable to equivalent Al–Me groups is also observed for complex **16**. The $^{13}C\{^1H\}$ NMR spectra show twelve signals for the phenyl rings and a pair of signals for the *tert*-butyl and methyl groups. These spectroscopic data agree with the structure proposed in Scheme 6.

Comparison of the spectroscopic data rules out the presence of complexes **16** and **17** in the final products obtained in the reaction of **1** with $AlMe_3$, although transmetallation reactions of the bis(phenoxido) ligand from titanium to aluminium could produce bis(phenoxido)aluminium derivatives of different composition.

The complexes $[TiR'(\eta^5\text{-}C_5R_5)(\eta^2\text{-mbmp})]$ have only one alkyl ligand coordinated to the metal centre. We therefore assume that in these polymerisation reactions the aluminium reagents (MAO used as co-catalyst or TIBA used as scavenger) react with these precursors through transmetallation processes of the bis(phenoxido) ligand from titanium to aluminium to generate active cationic alkyltitanium species in a Ziegler–Natta-type olefin polymerisation.

## Concluding Remarks

We have described the synthesis and characterisation of mono(alkyl)mono(cyclopentadienyl)titanium complexes $[TiR'(\eta^5\text{-}C_5R_5)(\eta^2\text{-mbmp})]$ containing the bis(phenoxido) bidentate dianionic ligand 2,2′-methylenebis(6-*tert*-butyl-4-methylphenoxido) ($\eta^2$-mbmp). The μ-oxido compound $[\{Ti(\eta^5\text{-}C_5H_5)(\eta^2\text{-mbmp})\}_2(\mu\text{-O})]$ is also obtained by reaction of $[TiPh(\eta^5\text{-}C_5H_5)(\eta^2\text{-mbmp})]$ with traces of water in toluene. Density functional calculations for these complexes have provided remarkable conclusions about their structural behaviour, which have been confirmed by X-ray diffraction studies in the solid state. After activation with MAO or $[CPh_3][B(C_6F_5)_4]$, these alkylmono(cyclopentadienyl)titanium derivatives are suitable for olefin (propylene and styrene) polymerisation, while reaction with $B(C_6F_5)_3$ produces inactive species. Polypropylene containing large isotactic stereoblocks obtained by a chain-end control mechanism is produced at low temperature. The nature of the active species in the olefin polymerisation processes has been examined spectroscopically.

## Experimental Section

**General Considerations:** All manipulations were performed under argon using Schlenk and vacuum-line techniques or in a glovebox (model HE-63). The solvents were purified by distillation under argon before use in the presence of the appropriate drying/deoxygenating agent. Deuterated solvents were stored under an inert gas over activated molecular sieves (4 Å) and degassed by several freeze-pump-thaw cycles. LiMe, MgClBz, LiPh, $mbmpH_2$ [2,2′-$CH_2$-bis(6-*t*Bu-4-$CH_3C_6H_2$-1-OH)], $AlMe_3$ (2.0 M hexane solution), $AlClMe_2$ (1.0 M hexane solution) were purchased (Aldrich) and used without further purification. $Li_2mbmp$,[3] $[B(C_6F_5)_3]$,[42] $[CPh_3][B(C_6F_5)_4]$[43] and $LiCH_2SiMe_3$[44] were prepared by known procedures. Polymerisation-grade propylene from Aldrich was purified by passage through two columns packed with activated alumina and molecular sieves (4 Å). Styrene was distilled at reduced pressure from calcium hydride and stored in the refrigerator. Methylaluminoxane (MAO, 10% solution in toluene) was purchased from WITCO GmbH. C, H and N microanalyses were performed with a Perkin–Elmer 240B and/or Heraeus CHN-O-Rapid microanalyzer. Polymer melt endotherms were determined with a Perkin–Elmer DSC-4 differential scanning calorimeter. NMR spectra, measured at 25 °C, were recorded with Varian Unity FT-300 ($^1H$ NMR at 300 MHz, $^{13}C$ NMR at 75 MHz) or Unity-Plus FT-500 ($^1H$ NMR at 500 MHz, $^{13}C$ NMR at 125 MHz) spectrometers, and chemical shifts ($\delta$, ppm) are referenced to $SiMe_4$ relative to the carbon resonances ($^{13}C$) and the residual protons ($^1H$) of the solvent. $^{19}F$ NMR spectra were recorded with a Varian Unity FT-500 and chemical shifts ($\delta$, ppm) are referenced to $CFCl_3$.

**$[TiMe(\eta^5\text{-}C_5H_5)(\eta^2\text{-mbmp})]$ (4):** A 1.5 M solution of LiMe in diethyl ether (0.30 mL, 0.45 mmol) was added at –78 °C to a solution of **1** (0.22 g, 0.45 mmol) in hexane (50 mL). The reaction mixture was slowly warmed to room temperature and stirred overnight. The solvent was completely removed and after extraction with hexane and concentration of the combined extracts, a bright yellow solid was obtained which was recrystallised from cold hexane and characterised as **4** (0.16 g, 75% yield). $C_{29}H_{38}O_2Ti$ (466.50): calcd. C 74.70, H 8.16; found C 74.57, H 8.19. $^1H$ NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.13, 7.00 (AA′ spin system, 2 × 2 H, Ph), 6.13 (s, 5 H, $C_5H_5$), 3.83, 3.43 (AB spin system, $\Delta\delta$ = 0.40 ppm, $^2J_{H,H}$ = 13.5 Hz, 2 × 1 H, $CH_2$), 2.17 (s, 6 H, $CH_3$Ph), 1.38 [s, 18 H, $C(CH_3)_3$], 1.31 (s, 3 H, $TiCH_3$) ppm. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.07, 6.89 (AA′ spin system, 2 × 2 H, Ph), 6.53 (s, 5 H, $C_5H_5$), 3.76, 3.40 (AB spin system, 2 × 1 H, $CH_2$), 2.25 (s, 6 H, $CH_3$Ph), 1.28 [s, 18 H, $C(CH_3)_3$], 1.14 (s, 3 H, $TiCH_3$) ppm. $^{13}C$ NMR (125 MHz, $C_6D_6$, 25 °C): $\delta$ = 161.6, 137.3, 136.5, 130.2, 129.3, 126.2 (all Ph), 114.98 ($C_5H_5$), 52.8 ($TiCH_3$), 36.0 ($CH_2$), 35.5 [$C(CH_3)_3$], 30.9 [$C(CH_3)_3$], 21.4 ($CH_3$-Ph) ppm.

**$[Ti(CH_2Ph)(\eta^5\text{-}C_5H_5)(\eta^2\text{-mbmp})]$ (5):** A 2.0 M solution of MgClBz in thf (0.30 mL, 0.62 mmol) was added at –78 °C to a solution of **1** (0.30 g, 0.62 mmol) in hexane (50 mL). The reaction mixture was slowly warmed to room temperature and stirred overnight and the solvent was then completely removed under vacuum. Recrystallisation from hexane gave a light orange solid which was characterised as **5** (0.23 g, 70% yield). Correct elemental analysis data could not be obtained, although satisfactory spectroscopic data were obtained. $^1H$ NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.28 (m, 5 H, $CH_2Ph$), 7.11, 7.01 (AA′ spin system, 2 × 2 H, Ph), 6.01 (s, 5 H, $C_5H_5$), 3.84, 3.36 (AB spin system, $\Delta\delta$ = 0.48 ppm, $^2J_{H,H}$ = 13.7 Hz, 2 × 1 H, $CH_2$), 3.24 (s, 2 H, $TiCH_2$Ph), 2.18 (s, 6 H, $CH_3$Ph), 1.47 [s, 18 H, $C(CH_3)_3$] ppm. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.07, 6.92 (AA′ spin system, 2 × 2 H, Ph), 7.30 (t, $J_{H,H}$ = 8.0 Hz, 2 H, *m*-$CH_2Ph$), 7.17 (d, $J_{H,H}$ = 7.9 Hz, 2 H, *o*-$CH_2Ph$), 7.01 (t, $J_{H,H}$ = 8.1 Hz, 1 H, *p*-$CH_2Ph$), 6.27 (s, 5 H, $C_5H_5$), 3.83, 3.38 (AB spin system, 2 × 1 H, $CH_2$), 2.99 (s, 2 H, $TiCH_2$Ph), 2.25 (s, 6 H, $CH_3$Ph), 1.41 [s, 18 H, $C(CH_3)_3$] ppm. $^{13}C$ NMR (125 MHz, $C_6D_6$, 25 °C): $\delta$ = 161.8, 137.1, 137.0, 130.0, 129.3, 126.4 (all Ph), 152.0 (*ipso*-$CH_2Ph$), 128.6 (*p*-$CH_2Ph$), 126.0 (*m*-$CH_2Ph$), 123.4 (*o*-$CH_2Ph$), 117.0 ($C_5H_5$), 77.2 ($TiCH_2$Ph), 36.1 ($CH_2$), 35.4 [$C(CH_3)_3$], 30.8 [$C(CH_3)_3$], 21.0 ($CH_3$-Ph) ppm.

**$[TiPh(\eta^5\text{-}C_5H_5)(\eta^2\text{-mbmp})]$ (6a, 6b, 6c):** A 1.8 M solution of LiPh in diethyl ether (0.35 mL, 0.62 mmol) was added at –78 °C to a solution of **1** (0.30 g, 0.62 mmol) in hexane (50 mL). The reaction mixture was slowly warmed to room temperature and stirred for 12 h. The resulting solution was concentrated under vacuum and a brown oily solid was obtained; spectroscopic analysis revealed a mixture of three isomers **6a**, **6b** and **6c**. Two isomers were obtained

**[AlMe(mbmp)]$_2$ (16):** $AlMe_3$ (0.3 mL of a 2.0 M solution in hexane, 0.59 mmol) was added to a solution of mbmp$H_2$ (0.2 g, 0.59 mmol) in 25 mL of toluene at room temperature. After a few minutes, a white solid appeared and the reaction mixture was stirred for 5 h. The solution was filtered and the white solid was washed twice with hexane and characterised as **16** (0.29 g, 65% yield). $C_{48}H_{66}Al_2O_4$ (761.02): calcd. C 75.80, H 8.68; found C 75.67, H 8.90. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.41, 7.21, 7.04, 6.88 (AA′ spin systems, 4×2 H, Ph), 4.70, 3.69 (AB spin system, 2×2 H, $\Delta\delta$ = 1.01 ppm, $CH_2$), 2.32, 1.83 (s, 2×6 H, *CH*$_3$Ph), 1.40, 1.37 [s, 2×18 H, $C(CH_3)_3$], 0.15 (s, 6 H, $AlCH_3$) ppm. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.07, 7.03, 6.98, 6.95 (AA′ spin systems, 4×2 H, Ph), 4.33, 3.53 (AB spin system, $\Delta\delta$ = 0.80 ppm, $^2J_{H,H}$ = 13.7 Hz, 2×2 H, $CH_2$), 2.30, 2.22 (s, 2×6 H, *CH*$_3$Ph), 1.36, 1.21 [s, 2×18 H, $C(CH_3)_3$], –0.33 (s, 6 H, $AlCH_3$) ppm. $^{13}$C NMR (125 MHz, $CDCl_3$, 25 °C): $\delta$ = 151.2, 144.3, 140.9, 137.7, 134.4, 132.7, 130.6, 130.5, 127.8, 127.4, 127.1, 126.3 (all Ph), 35.0 ($CH_2$), 36.1, 34.5 [*C*$(CH_3)_3$], 31.8, 29.7 [C(*C*$H_3)_3$], 21.1, 21.0 (*C*$H_3$-Ph), 14.2 ($AlCH_3$) ppm.

**[AlCl(mbmp)]$_2$ (17):** $AlClMe_2$ (0.9 mL of a 1.0 M solution in hexane, 0.88 mmol) was added to a solution of mbmp$H_2$ (0.3 g, 0.88 mmol) in 25 mL of toluene at room temperature. After a few minutes, a white solid appeared and the reaction mixture was stirred for 3 h. The solution was filtered and the white solid was washed twice with hexane and toluene and characterised as **17** (0.37 g, 53% yield). $C_{46}H_{60}Al_2Cl_2O_4$ (801.85): calcd. C 68.90, H 7.54; found C 68.83, H 7.49. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 7.41, 7.18, 7.05, 6.88 (AA′ spin systems, 4×2 H, Ph), 4.83, 3.90 (AB spin system, 2×2 H, $\Delta\delta$ = 0.93 ppm, $CH_2$), 2.27, 1.79 (s, 2×6 H, *CH*$_3$Ph), 1.44, 1.43 [s, 2×18 H, $C(CH_3)_3$] ppm. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.09, 7.05, 7.02, 6.97 (AA′ spin systems, 4×2 H, Ph), 4.35, 3.68 (AB sin systems, $\Delta\delta$ = 0.67 ppm, $^2J_{H,H}$ = 14.6 Hz, 2×2 H, $CH_2$), 2.31, 2.22 (s, 2×6 H, *CH*$_3$Ph), 1.40, 1.23 [s, 2×18 H, $C(CH_3)_3$] ppm. $^{13}$C NMR (125 MHz, $CDCl_3$, 25 °C): $\delta$ = 149.9, 140.8, 138.5, 135.9, 132.8, 131.0, 130.2, 129.1, 128.9, 128.2, 128.0, 126.7 (all Ph), 35.2 ($CH_2$), 36.1, 34.5 [*C*$(CH_3)_3$], 32.3, 29.8 [C(*C*$H_3)_3$], 21.1, 21.0 (*C*$H_3$-Ph) ppm.

**Polymerisation of Propylene:** A 250-mL Büchi reactor equipped with a mechanical stirrer was first evacuated and then charged with dried scavenger (MAO) and toluene (150 mL). A 10-mL pressure tube was charged with the titanium complex solution in toluene (4 mL). The reactor was purged three times with the monomer by pressurizing and venting. The monomer was then equilibrated with the toluene in the reactor for 30 min at the polymerisation temperature and pressure (kept constant at 1 atm over the run) with constant stirring. In the runs in which liquid propylene was used, the reactor was first equilibrated at 0 °C with constant stirring and then fed with the monomer. The reaction was initiated by injecting the solution containing the catalytic system under argon pressure. After the desired reaction time, the reactor was vented and the polymer was precipitated into 10% HCl in methanol, washed with clean methanol and dried in a vacuum oven at 60 °C to constant weight.

**Polymerisation of Styrene:** A 100-mL glass pressure bottle with magnetic stirrer was vented and charged with toluene, MAO and 5 mL of the monomer. The mixture was then equilibrated at the polymerisation temperature with constant stirring and the reaction was initiated by injecting the solution of the catalyst in toluene (4 mL). After the desired reaction time, the reactor was vented and the polymer was precipitated into 10% HCl in methanol, washed with clean methanol and dried in a vacuum oven at 40 °C to constant weight. The polymer was extracted with refluxing thf for 5 h and dried again to constant weight in order to determine the sPS portion of the polymer obtained.

**Polymer Analyses:** Molecular weights were determined by high-temperature gel permeation chromatography using propylene and polystyrene as GPC calibration standards and 1,2,4-trichlorobenzene as eluent. The glass transition temperature and melting temperature were determined at a heating rate of 20 °C min$^{-1}$. $^1$H and $^{13}$C NMR measurements were performed at 363 K in [$D_2$]1,1,2,2-tetrachloroethane and referenced using the solvent peaks. The areas of the nine peaks in the methyl region determined from spectral integrations in polypropylene samples were used to characterise the sample microstructure. Analyses of the polymer properties were performed at the University of Ulm (Germany), Inorganic Chemistry II Department.

**Single-Crystal X-ray Structure Determination of Compounds 8, 9 and 11·0.75$C_6H_{14}$:** Crystal data and details of the structure deter-

[a] $R1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$; $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; $GOF = \{\Sigma[w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$.

mination are presented in Table 7. Suitable single crystals for the X-ray diffraction study were grown from hexane in all cases. A clear orange fragment was stored under perfluorinated ether, transferred into a Lindemann capillary, fixed, and sealed. Preliminary examination and data collection were carried out with an area detecting system (Nonius, MACH3, κ-CCD) at the window of a rotating anode (Nonius, FR591) with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The unit-cell parameters were obtained by full-matrix least-squares refinement of 6411 (6477, 10431) reflections. Data collection was performed at 153 (173, 123) K (Oxford Cryosystems) in the range 2.48°< $\theta$ < 25.35° (1.65°< $\theta$ < 25.32°, 1.85°< $\theta$ < 25.38°) for a total of nine (nine, seven) data sets in rotation scan mode with $\Delta\varphi/\Delta\omega$ = 1.0° (1.0°, 1.0°). A total of 80030 (62663, 59488) intensities were integrated. Raw data were corrected for Lorentz, polarisation, and, arising from the scaling procedure, latent decay and absorption effects. After merging [$R_{int}$ = 0.044 (0.034, 0.042)] a total of 6157 (6249, 10449) (all data) and 4990 (5495, 8948) [$I > 2\sigma(I)$] reflections remained and all these data were used in the subsequent refinement. The structures were solved by a combination of direct methods and difference Fourier syntheses. All non-hydrogen atoms were refined with anisotropic displacement parameters. For **8** and **9**, all hydrogen atoms were placed in ideal positions (riding model). For **11**·0.75 $C_6H_{14}$, all hydrogen atoms located at the titanium complex were found in the difference map calculated from the model containing all non-hydrogen atoms. The hydrogen positions were refined with individual isotropic displacement parameters. All hydrogen positions located at the disordered hexane solvent molecule were placed in calculated positions (riding model). Full-matrix least-squares refinements with 348 (405, 920) parameters were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with the SHELXL-97 weighting scheme and stopped at shift/err < 0.001 (0.001, 0.001). The final residual electron density maps showed no remarkable features. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for Crystallography. All calculations were performed with an Intel Pentium II PC, with the STRUX-V system, including the programs PLATON, SIR92 and SHELXL-97.[45–50] In **8**, a problem with an unresolvable solvent molecule was resolved with the PLATON[49] *Calc Squeeze* procedure. For **9**, a disorder [0.821(4):0.179(4)] of the cyclopentadienyl ring was clearly resolved. For **11**·0.75 $C_6H_{14}$, the solvent molecule appeared to be disordered over three positions (3:2:1) with an overall occupancy factor of 0.75. CCDC-631035 (**8**), -631036 (**9**) and -631037 (**11**·0.75 $C_6H_{14}$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): $^{13}C$ NMR spectra for the PP sample obtained in run 2 and run 6 (Table 5).

## Acknowledgments

Financial support for this research by DGICYT (project MAT2004-02614), CAM (project S-0505-PPQ/0328-02) and the European Commission (contract no. HPRN-CT2000-00004) is gratefully acknowledged. M. G.-M. acknowledges the Comunidad de Madrid (CAM) for the award of a Fellowship.

# A Ligand-Driven Geometry Switch in Octahedral and Trigonal-Bipyramidal Iron Complexes Containing (H)PNO and PNN Ligands

**Paolo Pelagatti,*[a] Alessia Bacchi,[a] Marcella Balordi,[a] Andrea Caneschi,[c] Marco Giannetto,[a] Corrado Pelizzi,[a] Luca Gonsalvi,[b] Maurizio Peruzzini,[b] and Franco Ugozzoli[a]**

**Keywords:** Iron / N,P ligands / Ligand effects

Complexation reactions of $Fe^{II}$ and $Fe^{III}$ salts with the tridentate ligands 2-(diphenylphosphanyl)benzaldehyde benzoylhydrazone [(H)PNO] and *N*-[2-(diphenylphosphanyl)benzylidene]-2-(2-pyridyl)ethanamine (PNN) was carried out. For (H)PNO, reaction of a stoichiometric amount of anhydrous $FeCl_2$ in the presence of a primary alcohol such as MeOH, EtOH or *n*BuOH gave the mixed-valence $Fe^{II}/Fe^{III}$ paramagnetic complex $[Fe\{\kappa^3\text{-}(H)PNO\}_2]Cl[FeCl_4]$, whereas the reaction between $FeCl_2$ and a twofold excess of (H)PNO in the presence of AgOTf (OTf = triflate, $OSO_2CF_3$) led to the isolation of the bis-chelate paramagnetic ferrous complex $[Fe\{\kappa^3\text{-}(H)PNO\}_2][OTf]_2$. A diamagnetic bis-chelate ferrous complex $[Fe\{\kappa^3\text{-}(PNO)_2\}]$ was instead obtained from the reaction of $FeCl_2$ with a twofold excess of (H)PNO in the presence of NaOMe. In the case of the PNN ligand, the 1:1 reaction with $FeCl_2$ gave the neutral paramagnetic trigonal-bipyramidal complex $[Fe(\kappa^3\text{-PNN})Cl_2]$. The X-ray structures of $[Fe\{\kappa^3\text{-}(H)PNO\}_2]Cl[FeCl_4]$, $[Fe_2\{\kappa^3\text{-}(H)PNO\}_2Cl_6]$ and $[Fe(\kappa^3\text{-PNN})Cl_2]$ are reported, together with CV and magnetic susceptibility measurements and an ab initio study aimed at rationalizing the different stoichiometries and structures observed with the two tridentate ligands.

## Introduction

The interest in five-coordinate iron(II) complexes with tridentate ligands stems mainly from their high catalytic activity in olefin polymerisation. The most active and studied systems are those containing the 2,6-bis(arylimino)-pyridyl moiety (NNN ligands),[1] although examples with ONN[2] and PNP[3] ligands have also been reported. Recently, cobalt complexes containing tridentate ligands have also been combined with iron to create mixed-valence and heterometallic [2 × 2] grid-like arrays,[4] spin-crossover complexes,[5] models of enzyme active sites such as catechol dioxygenases[6] and nitrile hydratase,[7] and asymmetric sulfide oxidation catalysts.[8] Some of us have been involved in the study of the coordinating behaviour of asymmetric tridentate ligands towards transition metals for several years.[9] The most thoroughly investigated ligand, 2-(diphenylphosphanyl)benzaldehyde benzoylhydrazone [(H)-PNO, Scheme 1], has been used to synthesise $Pd^{II}$ and $Ru^{II}$ complexes that are active catalysts in alkene hydrogenation[10] and addition of benzoic acid to terminal alkynes,[11] respectively. The importance of the iron complexes containing the Fe(LLL) moiety (LLL = tridentate ligand) prompted us to investigate the coordinating behaviour of (H)PNO towards $FeCl_2$. This study was subsequently extended to another tridentate ligand, namely *N*-[2-(diphenylphosphanyl)benzylidene]-2-(2-pyridyl)ethanamine (PNN),[12] which bears a 2-(2-aminoethyl)pyridine function

instead of an (H)NC(O)Ph arm (Scheme 1). The ligand PNN differs from HPNO as it is aprotic and forms two six-membered chelate rings instead of a six- and a five-membered chelation ring as for (H)PNO upon complexation.

In this paper we describe the synthesis and full characterisation of a series of iron complexes obtained by reaction between (H)PNO and anhydrous $FeCl_2$ or hydrated $FeCl_3$ and PNN and anhydrous $FeCl_2$. The X-ray structures of $[Fe\{\kappa^3\text{-(H)PNO}\}_2]Cl[FeCl_4]$ (**1**), $[Fe_2\{\kappa^3\text{-(H)PNO}\}_2Cl_6]$ (**2**) and *mer*-$[Fe(\kappa^3\text{-PNN})Cl_2]$ (**6**) are also reported. A rationalisation of the different stoichiometries and geometries observed for the iron complexes with the two tridentate ligands is also provided on the basis of ab initio calculations.

## Results and Discussion

### Complexes Containing HPNO

Tridentate aroyl hydrazones easily form iron complexes containing the octahedral entity $[FeL_2]^{n+}$ (L = tridentate aroyl hydrazone, $n$ = 0, 2 or 3), where the charge depends on the anionic or neutral character of the ligands as well as on the oxidation state of the metal. These complexes, which are usually synthesised by employing an L:Fe molar ratio of 2:1, are generally very stable, and aroyl hydrazones are in fact being studied as sequestrating agents for the treatment of iron overload diseases.[13] As octahedral bis-chelate complexes are usually considered to be ineffective in catalysis, our first aim was to isolate five-coordinate iron(II) species of the type *mer*-$[Fe\{\kappa^3\text{-(H)PNO}\}Cl_2]$ (Scheme 1) with a trigonal-bipyramidal or square-pyramidal geometry. Therefore, we initially treated a dichloromethane solution of (H)PNO with a stoichiometric amount of anhydrous $FeCl_2$ dissolved in *n*-butanol[14] at room temperature. The reaction gave a purple solid of formula *mer*-$[Fe\{\kappa^3\text{-(H)PNO}\}_2]Cl[FeCl_4]$ (**1**) in good yield. The same product could also be isolated by carrying out the reaction at reflux in other alcohols such as MeOH or EtOH, by reverting the sequence of addition of the reagents, or by adding the ligand-containing solution dropwise to the alcoholic solution of the iron salt. The use of neat thf as solvent as well as an (H)PNO:$FeCl_2$ molar ratio of 1:5 did not change the reaction course either. Complex **1** contains the ferrous cationic fragment $[Fe\{\kappa^3\text{-(H)PNO}\}_2]^{2+}$, the tetrahedral tetrachloroferrate anion $[FeCl_4]^-$ and a free chloride ion (Scheme 1).

Two ligands bind to the iron(II) ion in a neutral tridentate fashion through the phosphorus, the imine nitrogen and the amide oxygen in the octahedral cation. The neutral character of the (H)PNO ligands is indicated by a weak IR stretching band at 3255 $cm^{-1}$ for the N–H groups, while a single band at 1607 $cm^{-1}$ indicates that both C=O groups are involved in the coordination.[9a,9g] The FAB(+) spectrum shows the presence of the fragment $m/z$ = 1070 belonging to the cation $[\{Fe(HPNO)_2\}\{FeCl_4\}]^+$. Another intense cluster signal is centred at $m/z$ = 871 belonging to the fragment $[Fe\{(H)PNO\}(PNO)]^+$, while a signal at $m/z$ = 463 accounts for the fragment $[Fe(PNO)]^+$. In the ESI(+) spectrum of a methanol solution of **1**, the signal generated by the loss of the $Cl^-$ is absent, while the cluster at $m/z$ = 871 is well visible. Importantly, the ESI(–) spectrum shows a signal at $m/z$ = 198 due to the $[FeCl_4]^-$ anion.

The electronic spectrum of an acetonitrile solution ($10^{-7}$ M) of **1** shows the following bands in the region 250–1000 nm: 261 ($\varepsilon$ = 55483 $M^{-1}cm^{-1}$), 306 (39774), 357 (29000) and a broad absorption band at 518 nm (7081). The bands at 261, 306 and 518 nm are typical of bis-chelate $Fe^{II}$ complexes containing tridentate benzoylhydrazones, and are attributed to LMCT processes.[15] The absorption peak at 357 nm can be tentatively assigned to the $[FeCl_4]^-$ anion.[16] The alternative formula $[Fe^{III}\{\kappa^3\text{-(H)PNO}\}_2]Cl[Fe^{II}Cl_4]$ for complex **1** is unlikely because of the sensitivity of the $[FeCl_4]^{2-}$ anion to air[16a] and because of the soft character of the (H)PNO ligand (due to the phosphane moiety), which is expected to stabilize $Fe^{II}$. A further confirmation comes from the voltammetric measurements. Figure 1 shows the cyclic voltammogram of compound **1** (third of three scans) recorded in acetonitrile solution: the anodic signal at about +0.0025 V and the cathodic wave at about –0.2 V can be assigned, respectively, to the oxidation of the complexed $Fe^{II}$ to $Fe^{III}$ and the corresponding reduction back to $Fe^{II}$. The weak signal at about 0.75 V is ascribable to the ligand, which was also characterised by means of the same technique. The potential values observed for the $Fe^{II}$/$Fe^{III}$ couple are, in fact, unusual for uncomplexed iron, such as $FeCl_4^-$ counterions. Moreover, cyclic voltammetric measurements carried out on a freshly prepared solution of anhydrous $FeCl_3$ in acetonitrile, under the same experimental conditions employed for the studied complex, show a system of anodic and cathodic signals at potential values above +0.250 V.

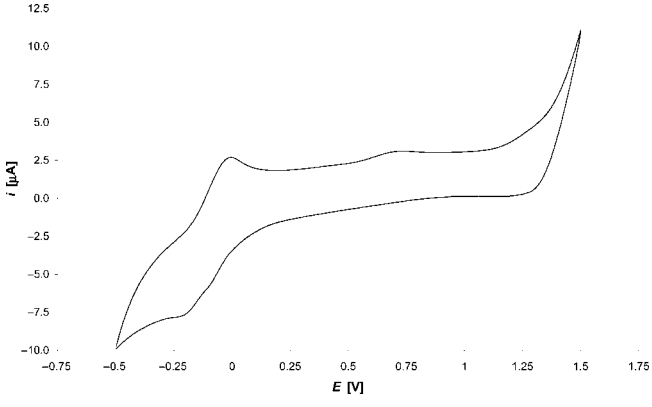

Figure 1. Cyclic voltammogram of compound **1** (third of three scans) recorded in acetonitrile solution. Scan rate: 0.1 $V s^{-1}$.

The $^1H$ NMR spectrum of **1** shows very broad signals in the 300–233 K temperature range owing to the presence of the paramagnetic $[FeCl_4]^-$ anion. However, the $^{31}P\{^1H\}$ NMR spectrum recorded at 300 K shows a singlet at $\delta$ = 63.4 ppm, as expected for two magnetically equivalent phosphorus nuclei in the complex cation. The paramagnetic character of **1** is evidenced by its magnetic behaviour. $\chi T$ vs. $T$ data were recorded in the range 50–300 K with an applied field of 1 T, where the zero-field splitting contri-

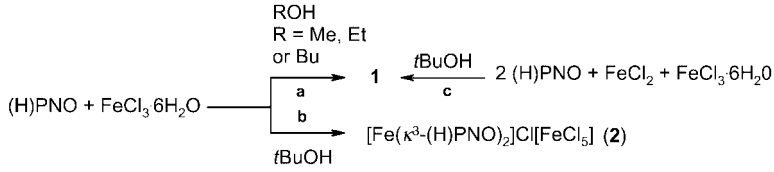

Scheme 2.

bution is not attended and saturation effects should not be yet present. These data show a Curie behaviour of around 4.2 emu mol $K^{-1}$ in the whole temperature range, quite close to the expected $S = 5/2$ value for an isolated spin with $g = 2.0$ (4.375 emu mol $K^{-1}$).

Complex **1** was also obtained by treating (H)PNO with $FeCl_3 \cdot 6H_2O$ in methanol or ethanol at 80 °C, as confirmed by X-ray diffraction analysis on a single crystal isolated from the mother liquor and by IR and UV spectroscopy and elemental analysis (Scheme 2, pathway a). The X-ray structure of **1** is shown in Figure 2, where the $Cl^-$ and $[FeCl_4]^-$ anions have been omitted for clarity.

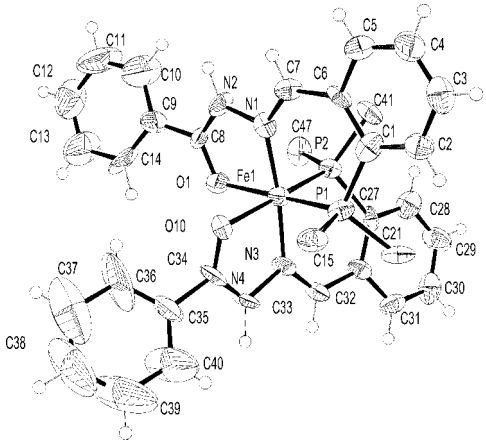

Figure 2. Perspective view and labelling scheme of *mer*-[Fe{κ$^3$-(H)-PNO}$_2$]$^{2+}$ in **1**. Thermal ellipsoids are shown at the 50% probability level. Phenyl groups C16–C20 (at C15), C22–C26 (at C21), C42–C46 (at C41), C48–C52 (at C47) have been omitted for clarity. A $Cl^-$ and a $FeCl_4^-$ complete the structure.

Table 1 lists the main bond lengths and angles for **1**. The conformation of the two ligands is almost identical, and the complex shows a non-crystallographic symmetry around a twofold axis bisecting the O1–Fe1–O10 and the P1–Fe1–P2 angles. The PNO coordination forms a five-membered and a six-membered chelation ring for each ligand. In both cases the former is planar within 0.06 Å, while in the latter the P atom deviates significantly (0.5 Å) from the average plane defined by the remaining five atoms; this deformation is characteristic of most instances of coordinated 2-(diphenylphosphanyl)benzaldehyde hydrazones.[9g] However, even taking into account the out-of-plane deformation involving the P atoms, the overall conformation of the ligand backbone is planar within 0.30 Å. This feature will be a matter for comparison with complex **6**. The steric crowding of the diphenylphosphanyl groups belonging to the two ligands in the bis-chelate coordination induces intramolecular parallel stacking (3.5 Å) between the benzaldehyde aromatic ring of each ligand and one free phenyl of the other ligand. The complex cations are bridged by $Cl^-$ anions through the hydrogen bonds N4–H···Cl5 [N···Cl = 3.04(1) Å; N–H···Cl = 160(10)°] N2–H···Cl5($x$, 0.5 – $y$, 0.5 + $z$) [N···Cl = 3.10(5) Å; N–H···Cl = 154(6)°] to form a chain motif (Figure 3, left).

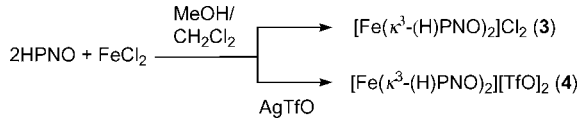
The formation of **1** from the ferric salt clearly requires the presence of a reductant; since no traces of oxidized ligand were detected or isolated [two possible oxidative processes could involve the (H)PNO ligand: oxidation of the phosphane moiety to the corresponding phosphane oxide or oxidation of the aroyl hydrazone to diacyl hydrazine[13a]], the oxidation of the primary alcohols to the corresponding aldehyde must be invoked. The oxidation of primary alcohols promoted by $Fe^{III}$ species is a rather uncommon process which, to the best of our knowledge, has been reported only rarely.[16a,17] Regrettably, repeated attempts to detect the expected aldehydes failed. However, the in situ iron(III) → iron(II) reduction was proved by treating (H)PNO with $FeCl_3·6H_2O$ and $FeCl_2$ in a 2:1:1 molar ratio in a *t*BuOH/$CH_2Cl_2$ mixture heated at reflux. The reaction gave complex **1** in high yield and purity, as demonstrated by the IR, UV and FAB mass spectra and microanalysis. Moreover, when the reaction between (H)PNO and $FeCl_3·6H_2O$ was repeated under reflux in a tertiary alcohol, such as *t*BuOH, which cannot undergo oxidative processes, a complex containing two $Fe^{III}$ nuclei of stoichiometry $[Fe_2\{\kappa^3\text{-}(H)PNO\}_2Cl_6]$ (**2**) formed, as evidenced by elemental analysis (Scheme 2, pathway b).

Unfortunately, the mass (FAB and ESI) and IR spectra are not informative as they are identical to those of **1**. Cyclic voltammograms of complex **2** show a pattern comparable to **1**. This behaviour can be explained by considering that $Fe^{III}$ is initially reduced to $Fe^{II}$ in the first stage of the scan, starting from –0.5 V. The tendency to undergo reduction shown by the octahedral $Fe^{III}$ centre in **2** explains the similarity of the mass spectra of complexes **1** and **2**, since redox processes can occur during such analysis.[18]

Crystals of **2** suitable for X-ray diffraction analysis were collected from the mother liquor. Compound **2**, with stoichiometry $[Fe_2\{\kappa^3\text{-}(H)PNO\}_2Cl_6]$, contains the $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{3+}$ cation, one chloride anion, and an apparent mixture of $[FeCl_4]^{2-}$ and $[FeCl_5]^{2-}$ anions disordered over two sites 3.7 Å apart (Figure 3, right).

The Fourier map of the region occupied by the complex anions was interpreted in terms of a substitutional disorder where some $[FeCl_4]^{2-}$ replaces the $[FeCl_5]^{2-}$ anions in a 60:40 proportion, even though this would imply a reduction of $[FeCl_5]^{2-}$, whose oxidized products have not been detected. The same disorder pattern was found when repeating the structure determination on crystals grown from different batches. Due to structural disorder and to the consequent poor quality of the refinement, the geometry of the trivalent bis-chelate cation is not significantly different from the divalent one crystallised with pure $[FeCl_4]^-$ in **1** and therefore does not allow us to assign unequivocally the oxidation state of the Fe atom based uniquely on the comparison of the Fe–P distances. The structure is based on chains of cations bridged by chloride anions via N–H···Cl hydrogen bonds; in both cases these chains are aligned along the 21 Å axis, which, however, has different symmetry properties in the two crystals (Table 3). These result in an array of heterochiral complexes generated by a *c* glide in **1** and in a homochiral chain generated by a $2_1$ screw axis in **2**. In fact, the presence of a relevant amount of $[FeCl_5]^{2-}$ causes a remarkable rearrangement of the symmetry elements between the two compounds accompanied by a repositioning of the complex anions, which occupy different sites along the chains in the two cases (Figure 3).

When a methanol solution of anhydrous $FeCl_2$ was treated with a twofold excess of (H)PNO dissolved in dichloromethane at reflux, a purple solid of formula $[Fe\{\kappa^3\text{-}(H)PNO\}_2]Cl_2$ (**3**) was obtained (Scheme 3).



Scheme 3.

The ESI(+) mass spectrum of **3** shows a unique cluster centred at *m*/*z* = 871 due to the octahedral unit $[Fe\{(H)PNO\}(PNO)]^+$. The electronic spectrum does not show the band at 357 nm while the charge-transfer absorptions at 261, 306 and 507 nm are well visible. The IR spectrum shows a weak stretching band at 3220 $cm^{-1}$, which is indicative of the protic character of the ligands, whereas a band at 1603 $cm^{-1}$ confirms that the C=O groups of the two PNO ligands are both involved in the coordination. Broad and uninformative bands are present in the $^1H$ NMR spectrum recorded at 300 K, while the $^{31}P\{^1H\}$ NMR spectrum shows a singlet at $\delta$ = 64.4 ppm that is compatible with the presence of the octahedral cation $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$; a small singlet at $\delta$ = 36.8 ppm is also visible, probably due to the partial oxidation of the phosphane P-atom of the (H)PNO ligand. On lowering the temperature to 233 K, the $^1H$ NMR signals do not sharpen. Careful inspection of the solid showed a substantial heterogeneity, as evidenced by the presence of differently coloured agglomerates (from red to deep purple). Regrettably, repeated recrystallisations did not improve the analytical quality of the product leading, in some cases, to decomposition and, in general, to irreproducible elemental analyses. On the basis of magnetic susceptibility measurements, the paramagnetic character of **3** seems imputable to traces of iron(III) species, probably due to aerobic oxidation. A rough evaluation of the $\chi T$ versus $T$ value in the temperature range 50–300 K with an applied field of 1 T for compound **3** gives a coarse percentage of about 10% of noninteracting iron(III) versus diamagnetic iron(II).

A clearer picture was obtained by treating (H)PNO with $FeCl_2$ in the presence of silver triflate; the removal of the chlorides led to the smooth formation of the bis-chelate complex $[Fe\{\kappa^3\text{-}(H)PNO\}_2][OTf]_2$ (**4**; Scheme 3). The reaction occurred with precipitation of silver chloride, which was separated by filtration to leave a red solution, from which a red powder was isolated. In this case, the elemental analysis is in agreement with the expected stoichiometry. The ESI(+) mass spectrum of a dichloromethane solution of **4** shows a cluster centred at *m*/*z* = 1021, corresponding to the loss of a triflate anion, and a second cluster centred at *m*/*z* = 871, corresponding to the fragment $[Fe\{(H)$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

PNO}(PNO)]$^+$. The UV spectrum does not show the band at 357 nm, as expected due to the absence of the $[FeCl_4]^-$ anion. The IR spectrum agrees with the presence of two neutral (H)PNO ligands bound to the metal, as indicated by the stretching bands of the N–H and C=O groups at 3198 and 1605 cm$^{-1}$, respectively. The presence of the triflate anion is testified by intense IR bands at 1027 cm$^{-1}$ [$\nu_s(SO_3)$], 1157 cm$^{-1}$ [$\nu_{as}(CF_3)$], 1238 cm$^{-1}$ [$\nu_s(CF_3)$] and 1296 cm$^{-1}$ [$\nu_{as}(SO_3)$].[19] The $^1$H NMR spectrum indicates a paramagnetic character of the complex, as inferred by the broad bands observed even at 233 K, while the $^{31}P\{^1H\}$ NMR spectrum shows a unique sharp signal at $\delta$ = 62 ppm, even at room temperature, as expected for two magnetically equivalent P nuclei. The cyclic voltammograms of complex **4** show a quite different behaviour with respect to complex **1** as these complexes contain different counterions. The presence of the triflate anion shifts both the anodic and cathodic peaks to potential values above +0.75 V. A higher value of $\Delta E_p$ (difference between anodic peak potential and cathodic peak potential) is also detected. These phenomena could be interpreted by considering the possibility that, in complex **1**, the metallic centre contained in the $[FeCl_4]^-$ counterion is actively involved in the electron-transfer mechanism of the coordinated iron.[20]

It is well known that a reinforced ligand–metal interaction favours a high crystal-field separation and leads preferentially to low-spin complexes that, in the case of d$^6$ metals in an octahedral environment, are diamagnetic. With the aim of isolating a neutral diamagnetic octahedral complex of the type [Fe($\kappa^3$-PNO)$_2$] (**5**), a dichloromethane solution of (H)PNO was at first treated with a stoichiometric amount of NaOMe dissolved in methanol and the NaPNO salt thus formed was treated with a methanol solution of anhydrous $FeCl_2$ (ligand/metal = 2:1; Scheme 4).

$$2(H)PNO + FeCl_2 \xrightarrow[NaOMe]{MeOH/CH_2Cl_2} [Fe(\kappa^3\text{-}PNO)_2]\ (\mathbf{5})$$

Scheme 4.

The elemental analysis of the isolated purple solid agrees with the expected stoichiometry and the CI mass spectrum shows an intense cluster at $m/z$ = 871 corresponding to [**5**+H]$^+$. The absence of the IR stretching bands of the N–H and C=O groups indicates that the two deprotonated ligands bind iron in an anionic PNO tridentate fashion. Measurements of the magnetic susceptibility at an applied magnetic field of 1 T suggest that the complex is diamagnetic in the temperature range 10–300 K. However, the $^1$H NMR spectrum of a $CDCl_3$ solution of **5** recorded at 300 K contains very broad signals, which sharpen on lowering the temperature to 233 K. At this temperature the C(H)=N proton resonates at $\delta$ = 9.42 ppm as a singlet, while a doublet is observed at $\delta$ = 7.71 ppm ($^3J_{H,H}$ = 7.05 Hz) due to the two phenyl protons adjacent to the C=O group of the benzoyl function. The $^{31}P\{^1H\}$ NMR spectrum recorded at 233 K shows a singlet at $\delta$ = 69.2 ppm and a small singlet at around $\delta$ = –17 ppm. The first signal corresponds to the two magnetically equivalent P nuclei of the two coordinated (H)PNO ligands, while the more shielded singlet is indicative of a partial decoordination of a phosphorus. Because complex **5** is diamagnetic at 300 K, the broadening of the $^1$H NMR lines at this temperature must be caused by molecular motions in solutions, which are absent at 233 K. Because the broadening involves the entire $^1$H NMR spectrum, the fluxionality seems to be due to the decoordination and subsequent re-entering of the P (as further indicated by $^{31}P\{^1H\}$ NMR spectroscopy) and N-imine donors in the coordination sphere. This can reasonably be imputed to the isomerisation between the two $\Delta$ and $\Lambda$ isomers that are expected to coexist in solution.

### A Complex Containing the PNN Ligand

Substitution of the (H)NC(O)Ph arm with the 2-(2-aminoethyl)pyridine function certainly makes the ligand PNN more flexible than (H)PNO. This allows for different coordination modes, such as *mer*-$\kappa^3$-PNN with Pd$^{II}$[12,21] and Rh$^{I–III}$,[22] *fac*-$\kappa^3$-PNN or $\kappa^2$-PN with Cr, Mo and W,[23] $\mu$-$\kappa^3$-PNN and even $\mu$-$\kappa^4$-PNCN with Os clusters.[24] The reaction between equimolar amounts of anhydrous $FeCl_2$ and PNN in a $MeOH/CH_2Cl_2$ mixture at room temperature led to the isolation of the trigonal bipyramidal complex [*mer*-Fe(PNN)Cl$_2$]·1/2$CH_2Cl_2$ (**6**; Scheme 1) in good yield. The complex is a paramagnetic orange crystalline solid. The IR spectrum shows a shift of the IR stretching band of the C(H)=N moiety with respect to the free ligand, from 1653 to 1629 cm$^{-1}$, which is indicative of a Fe–N(imine) coordination. The FAB(+) mass spectrum shows a high degree of fragmentation of the analyte, which does not allow any simple interpretation. However, after amplification of the signal a small cluster at $m/z$ = 63, corresponding to **6**, becomes visible. The structure of complex **6** was confirmed by single-crystal X-ray analysis. The tridentate PNN ligand in **6** occupies two apical and one equatorial sites of a trigonal bipyramidal coordination, which is completed by two Cl$^-$ ligands at the remaining equatorial sites (Figure 4). Table 1 lists the main bond lengths and angles for **6**. The tridentate coordination of PNN to the metal generates two six-membered chelation rings whose conformation is highly puckered, in contrast to the almost planar geometry observed for the coordination of (H)PNO in **1**. The ring formed by chelation of N1 and N2 is best described as a half-chair with the vector N2–C8 twisted relative to the ring plane (Cremer and Pople[25] puckering coordinates: $Q_T$ = 0.56 Å, $\phi$2 = –91°, $\theta$2 = 44°), while the ring defined by chelation of N2 and P1 is intermediate between half-boat and a twisted chair, with a major displacement of P and Fe from the average ring plane (puckering coordinates: $Q_T$ = 0.95 Å, $\phi$2 = 149°, $\theta$2 = 117°). The dramatic distortion from planarity observed in **6** is a consequence of the enlargement of the chelate ring by replacement of the hydrazonic arm of (H)PNO with a $CH_2CH_2N$ system in PNN. The insertion of the ethyl segment in the chelate ring is necessarily accompanied by a deviation of C9 out of the local plane de-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fined by C6, C7, N2 and C8 around the iminic double bond. Consequently, the pyridine attached to C9 is rotated relative to the iminic plane (P–Fe–N2–C7 = 43°), and the phosphane group on the other side of the molecule is constrained to follow this rotation in order to maintain the *trans* geometry for the P–Fe–N1 angle. The overall molecular deformation of **6** relative to the planar tridentate chelation observed in **1** can be viewed as a rotation of the apical axis P–Fe–N1 of the coordination polyhedron around the hinge represented by the Fe–N2 vector. A similar deformation, with P–M–N=C torsion angles ranging between 17° and 44°, has been observed in the four other occurrences of complexes containing the PNN ligand[12,23a,26] characterised in the solid state.

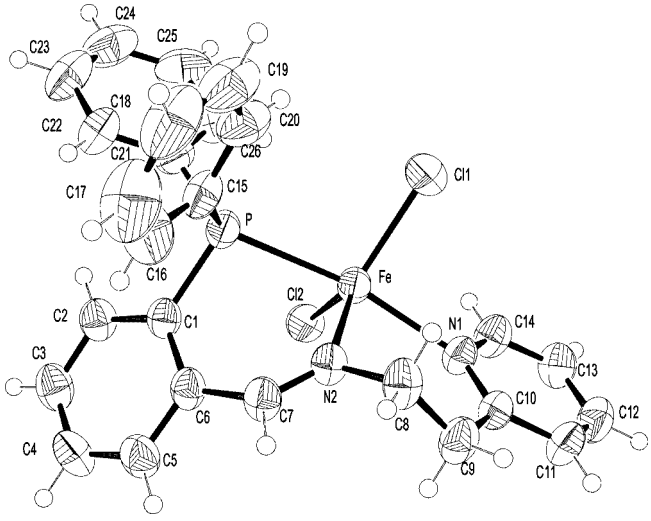


Figure 4. Perspective view and labelling scheme of *mer*-[Fe($\kappa^3$-PNN)$Cl_2$] in **6**. Thermal ellipsoids are shown at the 50% probability level.

## Modelling

To clarify the reasons for the formation of the octahedral cation $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ rather than the analogous cation $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$, we have undertaken theoretical calculations to predict and then to investigate their molecular structures.

The optimised geometries of the two ions were obtained by ab initio calculations using the semi-empirical PM3 method[27] in the Spartan 04 program[28] and are illustrated in Figure 5. The calculated bond lengths and angles in the five- and six-membered chelate rings are collected in Table 2. The results of the calculations indicate that the distances are consistent with the values reported in the literature. However, although the Fe–P distance in the $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ ion (2.264 Å) falls just in the middle of the range observed from a perusal of the data available in the CSD (from 2.2 to 2.3 Å), the analogous distance calculated from the $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ ion (2.413 Å) is significantly longer and, to the best of our knowledge, is unprecedented in the solid-state structures reported in the CSD file.

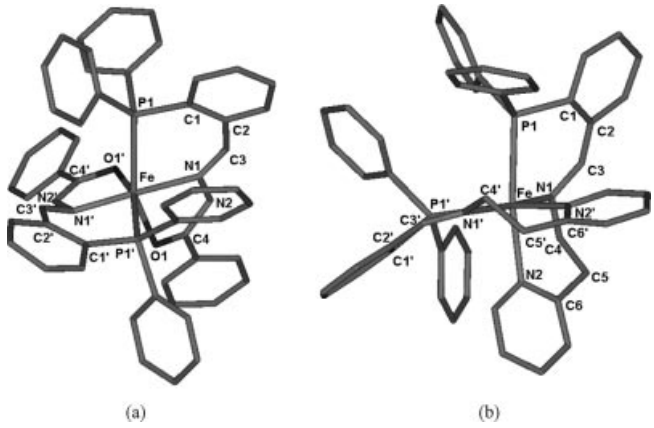

Figure 5. Optimised geometries obtained for the two cationic fragments $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ (a) and $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ (b). Hydrogen atoms have been omitted for clarity.

This suggests that the increase of the Fe–P bond lengths in $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ compared to that in $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ may be the reason why formation of the former cationic fragment is not observed. To further investigate this aspect we have studied in detail the electron density distribution along the Fe–P bond in the two cations. This was done by comparing the molecular isodensity surfaces in the two fragments at the same electron density value (for a large series of electron density values). We observed that the elec-

Table 2. Bond lengths and angles in the optimised geometries of the $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ and $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ complexes obtained with the semi-empirical PM3 method. The distances between primed atoms are identical to those between unprimed ones (see Figure 5).

tron density along the Fe–P bond is much larger in $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ than in $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$. Figure 6 shows, as an example, that two voids in the electron density along the two Fe–P bonds in $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ are evident in the molecular isodensity surfaces calculated at 0.1 e Å$^{-3}$ obtained by PM3 calculations for the two ions.

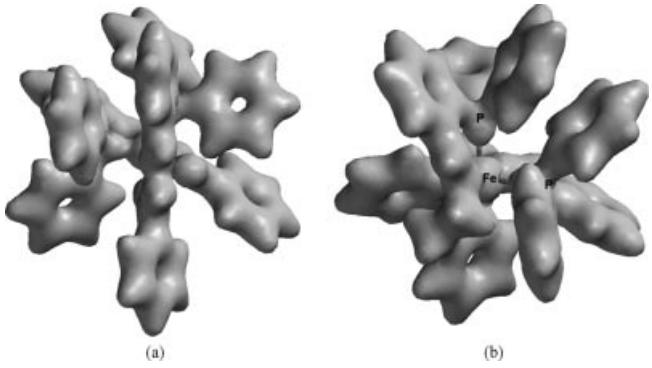

Figure 6. Molecular isodensity surfaces (obtained from the PM3 calculations) drawn at 0.1 e Å$^{-3}$ for $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ (a) and $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ (b).

Although the choice of the 0.1-e Å$^{-3}$ value is arbitrary, it is noteworthy that the molecular surface of $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ drawn at the same isodensity value does not show analogous voids. This fact seems to suggest that the higher stability of $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ with respect to that of $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ could be attributed to the different stability (length) of the Fe–P bond in the two fragments, thus explaining the impossibility of forming the bis-chelate octahedral species containing the PNN ligand.

## Conclusions

This work has described the synthesis and full characterisation of a new series of iron complexes containing two different tridentate ligands, namely (H)PNO and PNN. Both molecules behave as *mer*-tridentate ligands towards $Fe^{II}$, but while the benzoyl hydrazone (H)PNO forms the bis-chelate octahedral cation $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{n+}$ ($n$ = 2, 3), the Schiff base PNN forms exclusively the neutral trigonal-bipyramidal complex $[Fe(\kappa^3\text{-}PNN)Cl_2]$. The formation of complex **1** from hydrate $FeCl_3$ in primary alcohols is worthy of note. The reduction from $Fe^{III}$ to $Fe^{II}$ occurs with oxidation of the alcohol to the corresponding aldehydes, as demonstrated by treating $FeCl_2$, $FeCl_3$ and (H)PNO in *t*BuOH. The different stoichiometries and geometries originated by the two ligands have been investigated by ab initio calculations in order to compare the relative stability of the structurally characterised cationic fragment $[Fe\{\kappa^3\text{-}(H)PNO\}_2]^{2+}$ and the simulated $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$. The results indicate that the $[Fe(\kappa^3\text{-}PNN)_2]^{2+}$ cation is less stable because, due to the long Fe–P distances, the electron density along these bonds is not enough to stabilize the complex. Thus, although the planarity of the aroyl hydrazone (H)PNO makes the embedding of two ligand molecules to form an octahedral entity possible, the high puckering of the chelation rings generated by PNN does not allow the construction of the same coordination geometry.

## Experimental Section

All reactions were performed under an atmosphere of dry nitrogen, unless otherwise stated, employing standard Schlenk techniques. Solvents were dried prior to use and stored under an atmosphere of nitrogen. Elemental analyses (C, H, N, S) were performed with a Carlo Erba Mod. EA 1108 apparatus. IR spectra were recorded with a Nicolet 5PCFT-IR spectrophotometer in the 4000–400 cm$^{-1}$ range from KBr disks. Electronic spectra were recorded in the range 250–1000 nm with a Perkin–Elmer Lambda 25 spectrophotometer, employing quartz cuvettes ($d$ = 1 cm). The concentration of the solutions in acetonitrile was $10^{-7}$ M. $^1$H NMR spectra were obtained at 300 K with a Bruker 300 FT spectrometer by using $SiMe_4$ as an internal standard. Low-temperature $^1$H NMR spectra were recorded with a Bruker AC200 spectrometer operating at 200.13 MHz. Peak positions are quoted relative to tetramethylsilane and were calibrated against the residual solvent resonance. $^{31}P\{^1H\}$ NMR spectra were recorded on the same instrument operating at 81.01 MHz. Chemical shifts were measured relative to external 85% $H_3PO_4$, with downfield shifts considered positive. CI mass spectra (methane) were collected with a Finnigan SSQ 710, FAB mass spectra with a EVG Autospec M, and ESI mass spectra with a Quattro LC triple quadrupole instrument (Micromass, Manchester, UK) equipped with an electrospray interface and Masslynx v. 3.4 software (Micromass). The nebulizing gas (nitrogen, 99.999% purity) and the desolvation gas (nitrogen, 99.998% purity) were delivered at a flow rate of 80 and 500 L h$^{-1}$, respectively. ESI mass analyses were performed by operating the mass spectrometer in positive-ion (PI) mode, acquiring mass spectra over the scan range $m/z$ = 100–1300 with a step size of 0.1 Da and a scan time of 1.2 s. The operating parameters of the interface were as follows: source temperature: 70 °C; desolvation temperature: 70 °C; ES(+) voltage: 3.0 kV; cone voltage: 30 and 50 V; rf lens: 0.3 V.

All the magnetic susceptibility measurements were performed with a Cryogenic Ltd. S600 SQUID magnetometer. Measurements were always performed on powder samples contained in a thin Teflon film. Data were corrected for the magnetism of the sample holder, which was independently determined at the same temperature range and field. The underlying diamagnetism of the samples was estimated from Pascal's constants.

The cyclic voltammetry experiments were carried out with a computerized potentiostat (PGSTAT 20, Ecochemie) controlled by customized software (GPES 4.8). All measurements were conducted in dry acetonitrile solutions of the studied compound ($10^{-3}$ M) and tetrabutylammonium hexafluorophosphate ($10^{-1}$ M) as supporting electrolyte. Voltammetric characterisations were conducted in oxygen-free solutions that had been previously purged with $N_2$ for 5 min. Voltammograms were recorded with a scan rate of 0.1 V s$^{-1}$. A Pt disk electrode with a surface of 7 mm$^2$ and a Pt rod electrode were used as working and counter electrodes, respectively. Ag/AgCl/3 M KCl was employed as reference electrode.

The ligands (H)PNO[29] and PNN[12] were synthesised according to literature methods. Anhydrous $FeCl_2$, $FeCl_3{\cdot}6H_2O$ and AgOTf (OTf = triflate) were purchased from Aldrich and used as received.

**$[Fe\{\kappa^3\text{-}(H)PNO\}_2]Cl[FeCl_4]$ (1) – Method 1:** (H)PNO (150 mg, 0.368 mmol) was dissolved in 20 mL of dichloromethane and added dropwise to an ethanol solution (15 mL) containing $FeCl_2$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(50 mg, 0.394 mmol). The resulting red solution was stirred at room temperature for 3 h, concentrated under vacuum and, after the addition of 20 mL of *n*-hexane, cooled to –18 °C overnight. The deep-red solid thus formed was filtered off, washed with *n*-hexane and dried under vacuum. Crystal data and structure refinement for **1** are shown in Table 3. Yield: 130 mg (50%). M.p. 191 °C (dec.). $^{31}P\{^{1}H\}$ NMR ($CDCl_3$, 233 K): $\delta$ = 63.4 ppm (s). IR: $\tilde{\nu}$ = 3255 $cm^{-1}$ (w) (N–H), 1607 (m) (C=O). MS (FAB+): *m*/*z* = 1070 $\{[Fe\{(H)PNO\}_2][FeCl_4]\}^+$, 871 $[Fe\{(H)PNO\}(PNO)]^+$, 463 $[Fe(PNO)]^+$. MS (ESI+): *m*/*z* = 871, 463, 409 $[(H)PNO + H^+]^+$. MS (ESI–): *m*/*z* = 198 $[FeCl_4]^-$. $C_{52}H_{42}Cl_5Fe_2N_4O_2P_2 \cdot 2CH_2Cl_2$ (1275.7): calcd. C 50.82, H 3.61, N 4.39; found C 50.74, H 3.58, N 4.19.

**Method 2:** $FeCl_3 \cdot 6H_2O$ (90 mg, 0.333 mmol) was dissolved in 15 mL of ethanol and the solution was thermostated at 80 °C. (H)PNO (140 mg, 0.343 mmol) was dissolved in 20 mL of ethanol and added dropwise to the iron-containing solution. The resulting red solution was stirred for 48 h, then the volume was reduced under vacuum. After the addition of 20 mL of *n*-hexane and refrigeration at –18 °C prismatic red crystals suitable for X-ray analysis formed. Yield: 270 mg (73%). M.p. 195 °C (dec.). $C_{52}H_{42}Cl_5Fe_2N_4O_2P_2 \cdot 1/2CH_2Cl_2$ (1148.3): calcd. C 54.90, H 3.74, N 4.88; found C 54.53, H 3.75, N 4.35.

**Method 3:** $FeCl_2$ (16 mg, 0.130 mmol) and $FeCl_3 \cdot 6H_2O$ (35 mg, 0.130 mmol) were dissolved in 10 mL of methanol. (H)PNO (110 mg, 0.270 mmol) was dissolved in 20 mL of dichloromethane and the two solutions were mixed and stirred at room temperature for 5 h to give a deep-red solution. The solvent was then removed under vacuum and the solid residue redissolved in dichloromethane. After the addition of *n*-hexane and refrigeration at –18 °C, a purple solid was collected. Yield: 140 mg (71%). M.p. 192 °C (dec.). $C_{52}H_{42}Cl_5Fe_2N_4O_2P_2 \cdot CH_2Cl_2$ (1190.78): calcd. C 53.43, H 3.70, N 4.70; found C 53.44, H 3.51, N 4.74.

**$[Fe_2\{\kappa^3\text{-}(H)PNO\}_2Cl_6]$ (2):** (H)PNO (140 mg, 0.343 mmol) was dissolved in dichloromethane (20 mL) and added dropwise to a *t*BuOH solution (15 mL) of $FeCl_3 \cdot 6H_2O$ (90 mg, 0.343 mmol). The resulting red solution was heated at reflux overnight and the microcrystalline red solid formed was filtered off, washed with *n*-hexane and vacuum dried. Crystal data and structure refinement for **2** are shown in Table 3.Yield: 290 mg (88%). M.p. 214–216 °C. ESI(+) MS: *m*/*z* = 872 $[Fe\{(H)PNO\}(PNO)]^+$. MS (ESI–): *m*/*z* = 198 $[FeCl_4]^-$. $C_{52}H_{42}Cl_6Fe_2N_4O_2P_2$ (1141.29): calcd. C 54.74, H 3.71, N 4.91; found C 55.01, H 3.74, N 4.96.

**$[Fe\{\kappa^3\text{-}(H)PNO\}_2]Cl_2$ (3):** $FeCl_2$ (40 mg, 0.315 mmol) was dissolved in methanol (15 mL) and the solution was heated at 80 °C. (H)-PNO (280 mg, 0.686 mmol) dissolved in 20 mL of dichloromethane was added, and the resulting red solution stirred for 7 h. The solution was then reduced in volume under vacuum and refrigerated at –18 °C overnight. A microcrystalline red solid was filtered off and washed with *n*-hexane. Yield: 220 mg (74%). M.p. 166–173 °C. Owing to oxidation, irreproducible microanalyses were obtained. IR: $\tilde{\nu}$ = 3220 (w) (NH), 1608 (s) (C=O) $cm^{-1}$. MS (ESI+): *m*/*z* = 871 $[Fe\{(H)PNO\}(PNO)]^+$.

**$[Fe\{\kappa^3\text{-}(H)PNO\}_2][TfO]_2$ (4):** $FeCl_2$ (20 mg, 0.157 mmol) was dissolved in 15 mL of methanol, and (H)PNO (100 mg, 0.245 mmol) dissolved in 20 mL of dichloromethane was added. The resulting red solution was stirred at room temperature for a few minutes and then AgOTf (70 mg, 0.273 mmol) was added. After 1 h the precipitated AgCl was filtered off and the remaining red solution stirred overnight. The solvent was then removed under vacuum to give a red solid. Yield: 200 mg (70%). M.p. 167–171 °C. $^{31}P\{^{1}H\}$ NMR ($CDCl_3$, 233 K): $\delta$ = 62 ppm (s). IR: $\tilde{\nu}$ = 3441 (w) (N–H), 1605 (s) (C=O), 1296 (s) $(SO_3)_{as}$, 1238 (s) $(CF_3)_s$, 1157 (s) $(CF_3)_{as}$, 1027 (s) $(S=O)_s$ $cm^{-1}$. MS (ESI+): *m*/*z* = 1022 $\{[Fe\{(H)PNO\}_2][TfO]\}^+$, 871 $[Fe\{(H)PNO\}(PNO)]^+$. $C_{54}H_{42}F_6FeN_4O_8P_2S_2 \cdot CH_2Cl_2$ (1255.79): calcd. C 55.38, H 3.59, N 4.79, S 5.47; found C 55.65, H 3.57, N 4.97, S 5.00.

**$[Fe(\kappa^3\text{-}PNO)_2]$ (5):** NaOMe (30 mg, 0.564 mmol) was dissolved in the minimum amount of methanol and (H)PNO (230 mg, 0.563 mmol) dissolved in 15 mL of dichloromethane was added. $FeCl_2$ (35 mg, 0.282 mmol) was then added and the deep-red solution thus obtained was stirred at room temperature for 48 h. After partial removal of the solvent under vacuum, a red solid was filtered off and washed with *n*-hexane. Yield: 200 mg (80%). M.p. 193–196 °C. $^{1}H$ NMR ($CDCl_3$, 233 K): $\delta$ = 9.60 (s, 1 H, CH=N), 7.68–6.80 (m, 19 H, Ph) ppm. $^{31}P\{^{1}H\}$ NMR ($CDCl_3$, 233 K): $\delta$ = 69.2 (s) ppm. MS (CI+): *m*/*z* = 871 $[\mathbf{5} + H^+]^+$.

**X-ray Analysis:** Mo-*Kα* radiation (λ = 0.71073 Å), *T* = 293 K for all compounds (SMART AXS 1000 CCD diffractometer). Lorentz, polarization, and absorption corrections were applied.[30] Structures solved by direct methods by using SIR97[31] and refined by full-matrix least-squares on all $F^2$ by using SHELXL97[32] implemented in the WingX package.[33] Hydrogen atoms partly located on Fourier difference maps and refined isotropically and partly introduced in calculated positions. Anisotropic displacement parameters refined for all non-hydrogen atoms. In **6** a partially occupied (50%) $CH_2Cl_2$ molecule is found in the asymmetric unit, with traces of residual electron density around the central carbon in the final map. Compound **2**, with stoichiometry $[Fe_2\{\kappa^3\text{-}(H)\text{-}PNO\}_2Cl_6]$, shows substitutional disorder which has been modelled as a replacement between $[FeCl_5]^2$- and $[FeCl_4]^2$- anions; the poor quality of diffraction data, however, did not allow for the establishment of an accurate description of the disordered entities, and quite high electron density residuals were present in the final maps in the disordered region. Molecular and crystal geometries have been analyzed with SHELXL97[32] and PARST97[34], and extensive use was made of the Cambridge Crystallographic Data Centre packages[35]. Table 3 summarizes crystal data and structure determination results. CCDC-616781 (for **1**), -616782 (for **2**) and -616783 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Prof. Maria Carmen Rodriguez Argüelles (University of Vigo, Spain) is thanked for the FAB-MS analyses, while Dr. Elisa Elviri (University of Parma) is thanked for the ESI-MS analyses. The authors wish to thank the C.I.M. (Centro Interfacoltà di Misure G. Casnati) of the University of Parma for the instrument facilities.

# Tuning the Properties of Neutral Tetraazamacrocyclic Complexes of Copper(II) and Nickel(II) for Use as Host–Guest Compounds with Bismacrocyclic Transition Metal Cations

**Anita Rybka,[a,b] Ryszard Koliński,[b] Jarosław Kowalski,[c] Rafał Szmigielski,[c] Sławomir Domagała,[d] Krzysztof Woźniak,*[d] Agnieszka Więckowska,[d] Renata Bilewicz,*[d] and Bohdan Korybut-Daszkiewicz*[a,c]**

**Keywords:** Macrocyclic ligands / Copper / Nickel / Cyclic voltammetry / Template synthesis

The synthesis and structural properties of tetraazamacrocyclic ligands and their neutral and protonated 14-, 15- and 16-membered complexes of $Cu^{II}$ and $Ni^{II}$ are described. Molecules of the free 14-membered ligands have a nonplanar, step-like structure of the central molecular fragments. Conformational changes are introduced upon protonation, with the protons pointing above and below the macrocycle plane. This prevents the formation of intramolecular N–H···N hydrogen bonds. On insertion of the transition metal ions a planar structure of the macrocycle is obtained, which has consequences for the electrochemical behaviour of the complexes. The deviations from planarity increase with increasing macrocycle size. As a consequence the donor properties are weaker, the redox potential is shifted towards more positive values and the contribution of chemical reactions can be observed. The formation of host–guest complexes between the strongest metal-containing donors and transition-metal-containing bismacrocyclic acceptors of suitable size is proved in solution and the gas phase by voltammetric and ESI MS methods. The transition metal building blocks described in this contribution can be applied in the synthesis of new redox-active rotaxane and catenane systems.

## Introduction

The well-known ability of azamacrocyclic ligands to stabilize unusual oxidation states of coordinated transition metal ions makes them a promising tool for the construction of molecular devices. Recently, we have reported the self-assembly of [2]catenanes built from an electron-rich component (dibenzo-24-crown-8) and an electron-deficient unsaturated bis-macrocyclic [14]cyclidene complex that coordinates two metal ions [either the same[1] or different (copper and nickel) [2]]. The electron-rich benzene rings of the interlocked crown ether in these compounds adopt a conformation that maximizes the donor–acceptor interactions with the bismacrocyclic subunit. By applying appropriate potentials, the coordinated metal ions can be oxidized selectively to the higher oxidation state (+3), which favours the interaction of these centres with the π-electron-rich aromatic rings of the crown unit. As a consequence, the relocation of the crown towards the oxidized metal centre takes place.

The introduction of an additional transition metal centre into similar supramolecular systems would enhance the prospects for the control of their properties. Therefore, the aim of this work is to synthesise some neutral macrocyclic complexes of the transition metals which could be used as π-electron-rich building blocks for the self-assembly of intertwined molecules. We have focused on dianionic tetraimine macrocyclic ligands substituted in the *meso* positions with some reactive groups. These groups could then be used for the extension of the ligand superstructure. The synthesis of the 14-membered tetraimine **4** (see Scheme 1) was recently reported by Takamura,[3a] although the 15- (**5**) and 16-membered (**6**) analogues were not accessible by this procedure. We have synthesised the 15- and 16-membered derivatives following a template Jäger synthetic strategy[4,5] from 2-formyl-3-hydroxypropenoic methyl ester and the appropriate diamines.

In this paper, we describe the synthesis of a series of neutral azamacrocyclic complexes of Cu and Ni and characterise their structures and redox properties. We also demonstrate their unique complexing abilities, which can be tuned simply by changing the size of the macrocycles in the host and guest molecules. The latter property is of special importance since the macrocyclic complexes may be considered as building blocks for new rotaxane-like meccano-molecular devices, which are one of the long-term goals of our project.

## Results and Discussion

### Synthesis

The synthesis of the nickel(II) and copper(II) complexes **4Ni**, **4Cu**, **5Ni**, **5Cu**, **6Ni** and **6Cu** is summarised in Scheme 1. The 14-membered ligand **4** was obtained by direct condensation of an equimolar mixture of 2-formyl-3-hydroxypropenoic methyl ester[3b] and ethylenediamine.[3a] Refluxing the ligand **4** with nickel(II) or copper(II) acetate in methanol solution gave the neutral complexes **4Ni** and **4Cu**, respectively. The reaction of 2-formyl-3-hydroxypropenoic methyl ester with diamines in a 2:1 ratio followed by complexation with nickel or copper acetate gave the complexes **2Ni** or **3Ni** and **2Cu** or **3Cu**, respectively.[6] The template reaction with a second diamine molecule afforded the 15- and 16-membered complexes. However, the reaction of the chelates **2Ni** and **2Cu** with an excess of ethylenediamine produced mainly the 14-membered complexes **4Ni** and **4Cu**, respectively.

The decomplexation of **5Cu** and **6Ni** by treatment with an excess of methanesulfonic acid in aqueous solution, followed by precipitation with $NH_4PF_6$, afforded the free ligands as their diprotonated hexafluorophosphates **5[HPF$_6$]$_2$** and **6[HPF$_6$]$_2$**, respectively (Scheme 2).

### Structural Properties

Figure 1 shows thermal ellipsoid representation of atoms with atomic labels for the series of neutral and protonated macrocyclic compounds studied and their complexes with $Ni^{II}$ or $Cu^{II}$ ions. All compounds crystallise in centrosymmetric space groups with molecules located at special positions (inversion centre or mirror plane). Therefore, only half of all atoms constituting a given molecule and corresponding solvent molecules, or counterions, are independent in all cases (see the Experimental Section for crystallographic details).

All the compounds described are composed of tetraazamacrocyclic rings with different numbers of atoms (14, 15 or 16). The electron density of the 16-membered rings is delocalised over the chelate rings and the functional groups. As a result, a bond-length alternation is present in those parts of the molecules. In the case of **4Cu**, **4Ni**, **5Ni**, **6Ni** and **10Ni**[4,5,7] the $Cu^{II}$ or $Ni^{II}$ ions are coordinated by the nitrogen atoms from the macrocyclic ligands to form square-planar complexes. In the free ligands (**4[HCl]$_2$** and **6[HPF$_6$]$_2$**), all of the nitrogen atoms are protonated and the conformation of the molecule is completely different. In all cases, except for **10Ni**, the macrocyclic ring is functionalised with two methoxycarbonyl groups, which can adopt either *trans* or *cis* conformations (see Figure 1, parts h and i). The 14-membered ring of **10Ni** has two types of substituents, namely two acyl and two methyl groups located *trans* to each other, thus confirming the structural results of Alcock et al.[7] and contrary to earlier reports.[4,5] The 14-membered macrocyclic ring in the structure of the free ligand **4** is not coplanar. Due to the coordination of Cu and Ni by the nitrogen atoms of the ring, the structures of the complexes formed (**4Cu**, **4Ni**, **5Ni**, **6Ni** and **10Ni**) are more planar than those of the free ligands. The RMS deviation of the fitted atoms to the least-square plane $L^1$ varies from 0.04 to 0.09 Å for the 14-membered complexes, whereas for the free ligands it is equal to 0.23 Å. Some smaller values of the angles between the previously defined plane and the plane fitted to the atoms of the ethylene bridges $L^2$ for Ni and Cu complexes indicate the more planar nature of the complexes (see Table 1 and Figure 2).

Table 1. Values of the RMS deviation [Å] of all the fitted atoms and angles [°] between the least-squares planes $L^1$ and $L^2$. $L^1$ is defined by the following sequence of atoms: M1, N1, N2, C2, C3, C4, N1#1, N2#1, C2#1, C3#1, C4#1, where M is a metal ion, and $L^2$ is based on the ethylene or propylene (**5Ni** and **6Ni**) groups: C1, C5, C1#1, C5#1 or C1A C5A, C1B, C5B and C6B for **5Ni**.[a]

|---|---|---|---|---|---|---|
| $L^1$ | 0.2291 | 0.0400 | 0.0696 | 0.0910 | 0.1413 | 0.2189 |
| $L^1$–$L^2$ angle | 36.4(1) | 22.4(2) | 26.9(1) | 26.6(1) | 41.4(3) | 46.65(4) |

[a] Symmetry transformations used to generate equivalent atoms: #1 1 – *x*, 1 – *y*, 1 – *z*.

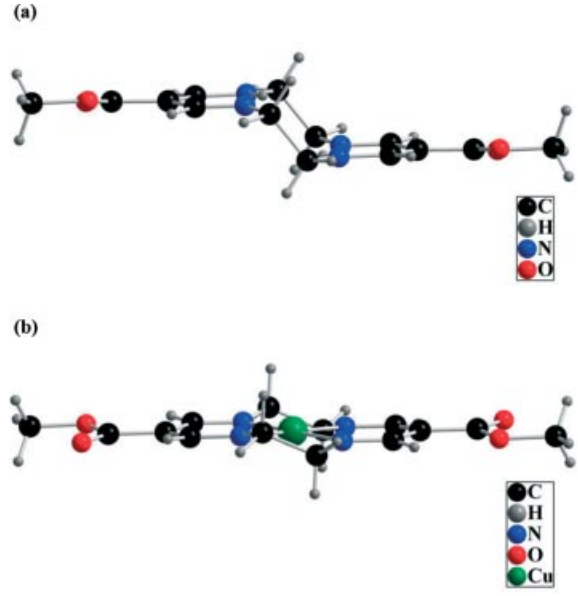

Figure 2. The structure of **4** (a) and **4Cu** (b).

The Ni–N and Cu–N distances vary within the ranges 1.836–1.890 and 1.912–1.922 Å and are typical for Ni and Cu complexes (see Table 2). The Ni–N distance increases with increasing size of the main macrocyclic ring (**4Ni**, **5Ni**, **6Ni**).

The compounds **4[HCl]$_2$** and **6[HPF$_6$]$_2$** have totally different structures. As a result of demetallation of the corresponding complexes, both imine nitrogen atoms in these compounds are protonated to form ammonium groups. Due to some steric hindrance coming from the interactions between the closely located hydrogen atoms, a change of the

conformation of the whole moiety takes place. The CHNH groups are rotated about the C–N bond, thus the N–H bonds are oriented outside of the ring whereas the C–H bonds are directed inside. Therefore, the distance between the ethylene bridges is elongated whereas the separation between the methoxycarbonyl groups decreases. Such a conformation is stabilized by numerous intramolecular hydrogen bonds formed between the nitrogen and oxygen atoms from the ester groups (see Table 3 and Figure 3).

In neutral compounds, hydrogen bonds are formed between the macrocycles and some solvent molecules (**10Ni**) or between the nitrogen atoms in the main macrocyclic ring (**4**).

The crystal packing of the compounds is shown in Figure 4. The molecules of the neutral compounds create parallel and slightly shifted stacks in the crystal lattice. The distances between the neighbouring macrocyclic rings in the crystal lattice vary from 3.062 to 3.617 Å and are given in Table 2.

In the structures of **4Ni** and **5Ni**, disordered solvent (toluene) molecules are located at special positions and form layers of molecules sandwiched between layers of the macrocyclic moieties. The toluene molecules are oriented so as to maximize the C–H···π interaction between the electron-rich benzene rings and the hydrogen atoms from the ethylene bridges. These compounds crystallise in the $P\bar{1}$ space group, whereas the protonated compounds crystallise in different space groups. The voids between neighbouring molecules in the structures are filled with counterions in the case of protonated ligand salts or solvent molecules.

### Voltammetry

The linear-scan, differential and normal-pulse voltammograms recorded for **4Cu**, **5Cu** and **6Cu** indicate a striking difference in the formal potentials with no major deviations from reversibility (see Figure 5). Upon increasing the macrocycle size, the donor abilities of the $Cu^{II}$ complex become weaker — the mid-potential $(E_{p_c} + E_{p_a})/2$ is shifted towards more positive potentials by as much as 330 mV. The peak current is also smaller, although the complex is soluble in the supporting electrolyte solution. This shift is not seen for the corresponding $Ni^{II}$ complexes (Figure 6) and reveals that the smaller ring in **4Cu** has a more planar coordination environment of the copper centre, which allows reversible oxidation to the $Cu^{III}$ complex. We have noted a similar dependence on the macrocycle size for other tetraazamacrocyclic complexes of copper.[8] In these compounds a decrease of the $Cu^{III}$ reduction current was observed together with a shift to more positive potentials. This indicates that the electron-transfer reaction is followed by a chemical reaction.

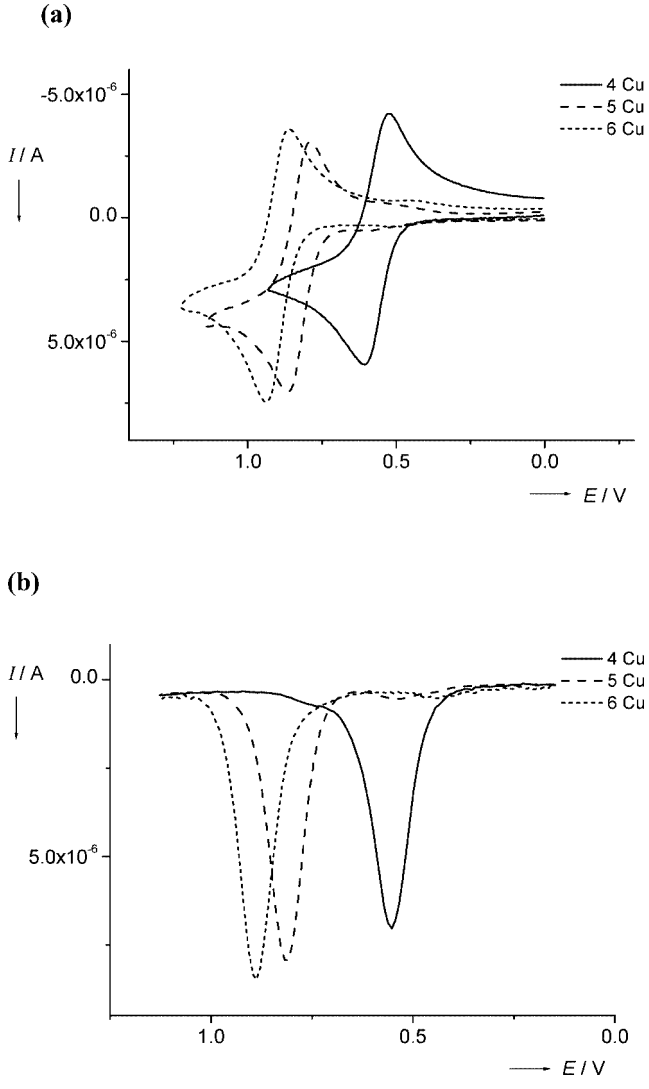

Figure 5. Cyclic voltammograms (a) and differential pulse voltammograms (b) for 0.5 mM **4Cu**, **5Cu** and **6Cu** complexes recorded using a GCE in 0.1 M tetrabutylammonium hexafluorophosphate (TBAHFP)/acetonitrile (AN) solution.

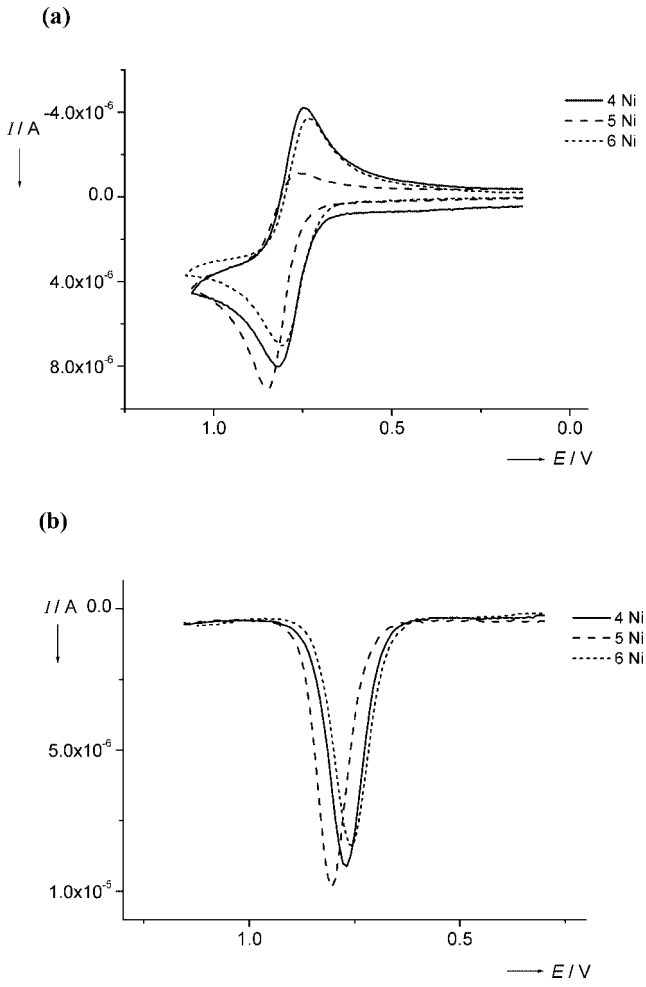

Figure 6. Cyclic voltammograms (a) and differential pulse voltammograms (b) for 0.5 mM **4Ni**, **5Ni** and **6Ni** recorded using a GCE in 0.1 M TBAHFP/AN solution.

In the compounds presented in this contribution, the electrode processes of all copper complexes clearly remain close to reversible and no chemical reactions are involved. The changes in the redox potential with increasing macrocycle size can be explained by assuming increased non-planarity of the complex. The structures of the larger systems[7,8] show deviations from planarity. On the other hand, in the case of **5Ni** a diminished cathodic peak reveals an instability of $Ni^{III}$ and involvement of further chemical reactions. The redox properties and diffusion coefficient values, based on the voltammetry peaks or limiting currents, are collected in Table 4.

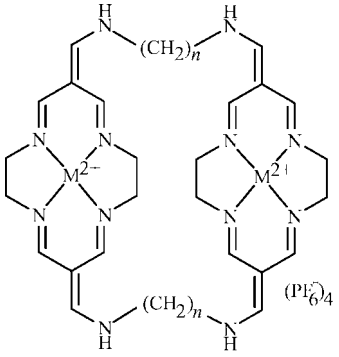
## Host–Guest Interactions

The bis-macrocyclic receptors shown in Scheme 3[9,10] have been shown to form host–guest complexes with π-electron-rich aromatic guests.[11] Their structures are based on donor–acceptor interactions between the π-electron-rich aromatic rings and π-electron-deficient cyclidene units. The same type of interactions should result in the affinity of such receptors towards the planar, neutral complexes **4Cu** and **4Ni**.



$n = 5$, M = Ni **7NiNi**
$n = 7$, M = Ni **8NiNi**
$n = 7$, M = Cu **8CuCu**
$n = 9$, M = Ni **9NiNi**
$n = 9$, M = Cu **9CuCu**

Scheme 3. Structures of the host complexes.

The changes of the cyclic voltammogram for **4Cu** alone, and after mixing with bis-macrocyclic receptor **8NiNi**, are shown in Figure 7. The midpoint potential $E^{o\prime} = (E_{pa} + E_{pc})/2$ is shifted by 20 mV towards less positive potentials upon mixing with the excess of bis-macrocycle, thereby indicating the stronger donor properties of the complex. These stronger donor properties may be interpreted as an indication of the associative properties of the bis-macrocyclic complex towards the **4Cu** moiety. Thus, **8NiNi** may be acting as a receptor molecule towards the guest planar **4Cu** complex. These unique complexing properties were probed by electrospray mass spectrometry (ESI-MS).

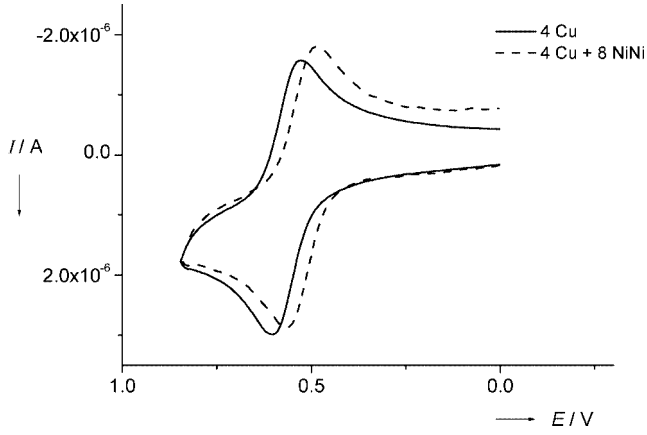


Figure 7. Cyclic voltammograms for $1 \times 10^{-4}$ M **4Cu** and its 1:10 mixture with **8NiNi** after 5 d. Scan rate: 0.1 $V s^{-1}$. GCE in 0.1 M TBAHFP/AN solution.

Despite the fact that ESI-MS might not reflect the solution binding affinities accurately, it provides important information on host–guest complexes and the nature of their interactions.[12] The ESI mass spectra of an equimolar mixture ($10^{-3}$ M) of neutral complexes **4Cu** or **4Ni** and bis-macrocyclic receptors **8NiNi** or **8CuCu** in dichloromethane/acetonitrile (1:3) solution confirmed the formation of the host–guest complexes. New peaks at *m*/*z* 437.2, 438.9, 440.5, 442.2 corresponding to the formation of the 1:1 adducts **8NiNi+4Ni**, **8NiNi+4Cu**, **8CuCu+4Ni** and **8CuCu+4Cu**, respectively, with a +4 charge, were observed in the spectra of their mixtures. In order to compare the affinities of bis-macrocyclic receptors towards neutral guests, the ESI mass spectra of equimolar mixtures of **7NiNi**, **8NiNi** and **9NiNi** with **4Cu** were measured (Figure 8, a). The spectra show that the cavity size in **7NiNi**, which contains $(CH_2)_5$ linkers, is too small to accommodate the guest molecules and no common peaks were recorded. On the other hand, the cavity size in **9NiNi**, which contains $(CH_2)_9$ linkers, is too large to enable simultaneous and equally strong interactions of guest molecules with both sides of the receptor cation, therefore the intensity of the common peak (*m*/*z* 457.5) is very low in comparison with the peak of the **8NiNi+4Cu** associate (*m*/*z* 438.9). A comparison of the dinickel (**8NiNi**) and dicopper (**8CuCu**) receptors (Figure 8, b) shows their similar affinities towards the **4Cu** guest. On the other hand, the neutral **4Cu** complex forms a more stable associate with **8NiNi** than its nickel(II) analogue **4Ni** (see Figure 8, c).

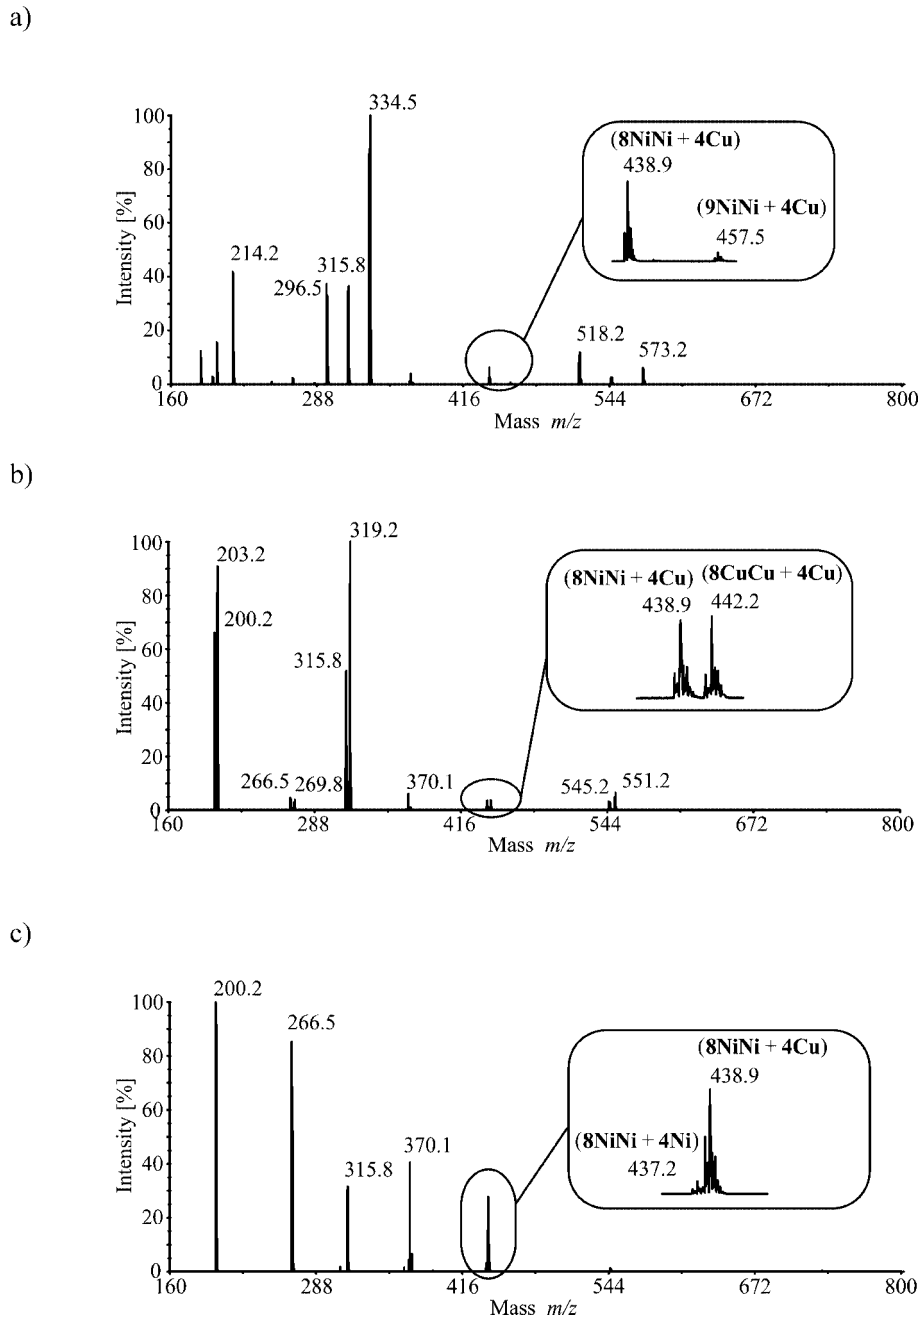

Figure 8. ESI mass spectra of equimolar mixtures of **7NiNi**, **8NiNi** and **9NiNi** with **4Cu** (a), **8NiNi** and **8CuCu** with **4Cu** (b) and (c) **4Ni** and **4Cu** with **8NiNi**.

## Conclusions

In this work we have presented the synthesis and structural properties of ligands and their neutral 14-, 15- and 16-membered complexes with $Cu^{II}$ and $Ni^{II}$. It appears that molecules of the free 14-membered ligands have a non-planar, step-like structure of the ethylene bridges. Significant changes in the geometry of the central macrocyclic fragments are observed on protonation as the protons no longer occupy the central positions of the ring but point above and below the macrocycle plane. This prevents the formation of intramolecular N–H···N hydrogen bonds. The insertion of transition metal ions is accompanied by an increased planarity of the structures of the complexes, which has consequences for the electrochemical reversibility and redox potentials of the complexes. The deviations from planarity increase with increasing macrocycle size and, as a consequence, the redox potential is shifted towards more positive values. In the case of the $Ni^{II}$ complexes, a contribution of chemical reactions is detected by the decrease of the reduction peak.

The formation of host–guest complexes with bis-macrocyclic cations can be achieved by appropriate tuning of the properties of the macrocyclic complexes, as demonstrated for planar, neutral macrocyclic guests associating with the bis-macrocyclic **8NiNi** (or **8CuCu**) cation receptors. This type of interaction, which leads to a new transition-ion complex structure, is of special interest in the design of new rotaxane-like systems for mechano-molecular devices, and work in this direction is currently underway in our laboratories.

## Experimental Section

**Synthesis:** 6,13-Bis(methoxycarbonyl)-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraene (**4**),[3] ligands **2** and **3** as well as their nickel(II) [(**2Ni**)$_2$·Ni(CH$_3$COO)$_2$·2CH$_3$OH and **3Ni**] and copper(II) complexes (**2Cu** and **3Cu**)[6] were obtained according to procedures described elsewhere. Crystals of the neutral nickel(II) complex **10Ni**[4,5] were obtained by slow evaporation of its solution in a 1:1 dichloromethane/methanol mixture.

**Spectroscopic Measurements:** The NMR spectra were obtained with Varian Mercury 400 and Varian Gemini 2000BB spectrometers. Signals are reported in ppm relative to the residual solvent signal. IR spectra (paraffin oil mulls) were recorded with a Perkin–Elmer Spectrum 2000 FT-IR spectrometer. UV/Vis absorption spectra were recorded with a Shimadzu UV-3100 spectrometer. ESI mass spectra were measured with a Mariner Perseptive Biosystem mass spectrometer.

**Voltametry:** Linear-scan, differential-pulse and normal-pulse voltammetry experiments were performed with an Autolab potentiostat (ECO Chemie, Netherlands) in a three-electrode arrangement with silver/silver chloride (Ag/AgCl) as the reference electrode, platinum foil as the counter electrode and a glassy carbon electrode (GCE, BAS, 3 mm diameter) as the working electrode. The reference electrode was separated from the working solution by an electrolytic bridge filled with 0.1 M TBAHFP/AN solution. The reference electrode potential was calibrated by using ferrocene oxidation process in the same TBAHFP/AN solution. AN containing 0.1 M TBAHFP was used as the supporting electrolyte solution. Argon was used to deaerate the solution and an argon blanket was maintained over the solution during the experiments.

**6,13-Bis(methoxycarbonyl)-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraenato(2–)-κ$^4$N$^{1,4,8,11}$nickel(II) (4Ni). (a) From Ligand 4:** Macrocyclic ligand **4** (0.62 g, 0.002 mol) and nickel acetate tetrahydrate (0.55 g, 0.0022 mol) were refluxed in methanol (200 mL) for 1 h. The reaction mixture was cooled down and left in a refrigerator for crystallisation. The resulting orange precipitate was filtered off and recrystallised from a dichloromethane/methanol mixture (1:5, 300 mL). Yield: 0.64 g (88%).

**(b) From Complex 3Ni:** Complex **3Ni** (0.341 g, 0.001 mol) was dissolved in ethylenediamine (2.5 mL). The mixture was refluxed for 1 h, cooled and diluted with 25 mL of water. The resulting orange precipitate was filtered off and purified by chromatography on neutral alumina (Merck) with chloroform/methanol (99:1) as eluent. The eluate was evaporated to dryness and the residue recrystallised from dichloromethane/methanol (1:5). Yield: 0.275 g (77%); m.p. 284 °C. Slow evaporation of a solution of **4Ni** in dichloromethane/toluene (1:1) gave crystals suitable for X-ray data collection. $C_{14}H_{20}N_4NiO_4$ (365.0): calcd. C 46.1, H 5.0, N 15.3; found C 46.2, H 5.1, N 15.3. ESI MS: *m/z* 365.3 [$C_{14}H_{20}N_4O_4Ni$ + H]$^+$, 387.3 [$C_{14}H_{20}N_4O_4Ni$ + Na]$^+$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 7.81 (s, 4 H, =CH-N), 3.73 (s, 6 H, $CH_3$), 3.38 (s, 8 H, N-$CH_2$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 154.9 (=CH-N), 168.2 (O-C=O), 98,2 (-C=), 51.2 ($CH_3$), 58.7 (N-$CH_2$) ppm. UV/Vis (methanol): $\lambda_{max}$ ($\varepsilon$) = 201 nm (25020 M$^{-1}$ cm$^{-1}$), 229 (30220), 316 (40640), 374 (5310), 497 (275). IR (nujol): $\tilde{\nu}$ = 1677 vs. (C=O), 1598 vs. (C=N), 1539 m (C=C) cm$^{-1}$.

**6,13-Bis(methoxycarbonyl)-1,4,8,11-tetraazacyclotetradeca-4,6,11,13-tetraenato(2–)-κ$^4$N$^{1,4,8,11}$copper(II) (4Cu):** This complex was obtained following the same procedures: (a) from ligand **4** with copper(II) acetate instead of nickel(II) acetate. Yield: 77%; (b) condensation of **3Cu** with ethylenediamine. Yield: 51%, m.p. 295 °C. $C_{14}H_{20}CuN_4O_4$ (369.9): calcd. C 45.5, H 4.9, N 15.2; found C 45.4, H 5.1, N 15.0. ESI MS: *m/z* 370.2 [$C_{14}H_{20}N_4O_4Cu$ + H]$^+$, 392.2 [$C_{14}H_{20}N_4O_4Cu$ + Na]$^+$. UV/Vis (methanol): $\lambda_{max}$ ($\varepsilon$) = 205 nm (24540 M$^{-1}$ cm$^{-1}$), 238 (11730), 286 (64380), 318 (20670), 550 (140). IR (nujol): $\tilde{\nu}$ = 1678 vs. (C=O), 1596 vs. (C=N), 1547 m (C=C) cm$^{-1}$.

**6,14-Bis(methoxycarbonyl)-1,4,8,12-tetraazacyclopentadeca-4,6,12,14-tetraenato(2–)-κ$^4$N$^{1,4,8,12}$nickel(II) (5Ni):** Complex **3Ni** (0.341 g, 0.001 mol) was dissolved in 1,3-propylenediamine (2.5 mL). The mixture was refluxed for 2 h, cooled and diluted with 25 mL of water. The resulting red precipitate was filtered off and purified by chromatography on neutral alumina (Merck) with chloroform methanol (99:1) as eluent. The eluate was evaporated to dryness and the residue recrystallised from dichloromethane/methanol (1:5). Yield: 0.370 g (91%); m.p. 231 °C. Crystals of **5Ni** used for X-ray data collection were obtained by slow evaporation of a dichloromethane/toluene solution. $C_{15}H_{20}N_4NiO_4$ (379.1): calcd. C 47.5, H 5.3, N 14.8; found C 47.6, H 5.4, N 14.4. ESI MS: *m/z* 379.3 [$C_{15}H_{20}N_4O_4Ni$ + H]$^+$, 401.2 [$C_{15}H_{20}N_4O_4Ni$ + Na]$^+$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 7.61 (s, 2 H) and 7.60 (s, 2 H, =CH-N), 3.72 (s, 6 H, $CH_3$), 3.36 (t, *J* = 6.7 Hz, 4 H, N-$CH_2$), 3.18 (s, 4 H, N-$CH_2$), 1.87 (quint, *J* = 6.7 Hz, 2 H, $CH_2$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 154.9 and 157.9 (=CH-N), 168.2 (O-C=O), 97.3 (-C=), 50.7 ($CH_3$), 58.7 and 58.7 (N-$CH_2$), 28.0 ($CH_2$) ppm. UV/Vis (methanol): $\lambda_{max}$ ($\varepsilon$) = 238 nm (28995 M$^{-1}$ cm$^{-1}$), 299 (39510), 370 (5230), 539 (170). IR (nujol): $\tilde{\nu}$ = 1674 m (C=O), 1604 vs. (C=N), 1539 m (C=C) cm$^{-1}$.

**6,14-Bis(methoxycarbonyl)-1,4,8,12-tetraazacyclopentadeca-4,6,12,14-tetraenato(2–)-κ$^4$N$^{1,4,8,12}$copper(II) (5Cu):** This complex was obtained from **3Cu** following the same procedure as for **5Ni**. Yield: 33%, m.p. 238 °C. $C_{15}H_{20}CuN_4O_4$·0.5$H_2O$ (392.9): calcd. C 45.9, H 5.4, N 14.3; found C 45.7, H 5.1, N 14.4. ESI MS: *m/z* 384.1 [$C_{15}H_{20}N_4O_4Cu$ + H]$^+$, 406.1 [$C_{15}H_{20}N_4O_4Cu$ + Na]$^+$. UV/Vis (methanol): $\lambda_{max}$ ($\varepsilon$) = 203 nm (20700 M$^{-1}$ cm$^{-1}$), 281 (66080), 314 (21250), 510 (12910), 662 (130). IR (nujol): $\tilde{\nu}$ = 1682 m (C=O), 1613 vs. (C=N), 1549 m (C=C) cm$^{-1}$.

**3,11-Bis(methoxycarbonyl)-1,5,9,13-tetraazacyclohexadeca-1,3,9,11-tetraenato(2–)-κ$^4$N$^{1,5,9,13}$nickel(II) (6Ni):** This complex was obtained from **2Ni** and 1,3-propylenediamine following the same procedure as for **5Ni**. Yield: 23%, m.p. 198 °C. $C_{16}H_{22}N_4NiO_4$ (393.1): calcd. C 48.9, H 5.6, N 14.3; found C 49.1, H 5.9, N 14.0. ESI MS: *m/z* 393.2 [$C_{16}H_{22}N_4O_4Ni$ + H]$^+$, 415.3 [$C_{16}H_{22}N_4O_4Ni$ + Na]$^+$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 7.36 (s, 4 H, =CH-N), 3.72 (s, 6 H, $CH_3$), 3.36 (t, *J* = 6.4 Hz, 8 H, N-$CH_2$), 1.84 (quint, *J* = 6.4 Hz, 4 H, $CH_2$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 157.3 (=CH-N), 168.3 (O-C=O), 98.2 (-C=), 50.6 ($CH_3$), 54.3 (N-$CH_2$), 27.9 ($CH_2$) ppm. **Single Crystal X-ray Diffraction:** Single crystal X-ray measurements of **10Ni**, **4Cu**, **4Ni**, **5Ni**, **6Ni**, **4**, **4[HCl]$_2$** and **6[HPF$_6$]$_2$** were performed on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation at 100 K (**4Ni**, **5Ni**, **6Ni**, **4[HCl]$_2$**, **6[HPF$_6$]$_2$**) or at 120 K (**10Ni**, **4Cu**, **4**). The single crystal was positioned at a distance of 65 mm from the KM4CCD camera. A total of 1150 (**6Ni**), 1204 (**10Ni**, **4Cu**, **4Ni**, **5Ni**, **4**, **4**[HCl]$_2$) and 1332 (**6**[HPF$_6$]$_2$) frames were measured at 1.0° (**10Ni**, **4Cu**, **4Ni**, **5Ni**, **6Ni**, **4**, **4**[HCl]$_2$) and at 0.9° (**6**[HPF$_6$]$_2$) intervals with a counting time of 15 s (**4Cu**, **4**), 20 s (**6**[HPF$_6$]$_2$), 22 s (**5Ni**), 25 s (**10Ni**, **4Ni**), and 30 s (**6Ni** and **4**[HCl]$_2$). The data were corrected for Lorentz and polarisation effects, and a numerical absorption correction was applied for **4Cu** and **6Ni**). Data collection, cell refinement and data reduction were carried out with the Kuma Diffraction programs: CrysAlis CCD and CrysAlis RED.[13]

The structures were solved by direct methods[14] and refined using SHELXL.[15] The refinements were based on $F^2$ for all reflections except those with very negative $F^2$ values. Weighted *R* factors (*wR*) and all goodness-of-fit ($\sigma$) values are based on $F^2$. Conventional *R* factors are based on *F* with *F* set to zero for negative $F^2$. The $F_o^2 > 2\sigma(F_o^2)$ criterion was used only for calculating *R* factors and is not relevant to the choice of reflections for the refinement. The *R* factors based on $F^2$ are about twice as large as those based on *F*. Most of the hydrogen atoms were located from a differential map and refined isotropically. All remaining hydrogen atoms were located in idealised averaged geometrical positions and allowed to ride on the heavy atoms. The disorder of the toluene molecules located at special positions was resolved (**4Ni** and **5Ni**). Some of the atoms of the counterions were refined isotropically (**6[HPF$_6$]$_2$**). Scattering factors were taken from Tables 6.1.1.4 and 4.2.4.2 in ref.[16]

# New Multidimensional Coordination Polymers with $\mu_2$- and $\mu_3$-dcno Cyano Carbanion Ligand {dcno$^-$ = $[(NC)_2CC(O)O(CH_2)_2OH]^-$}

**Samia Benmansour,[a,b] Fatima Setifi,[a][‡] Smail Triki,*[a] Jean-Yves Salaün,[a] Fanny Vandevelde,[a] Jean Sala-Pala,[a] Carlos J. Gómez-García,*[b] and Thierry Roisnel[c]**

**Keywords:** Cyano carbanions / Bridging ligands / Coordination polymers / Multidimensional networks / Magnetic properties

New polymeric materials $[M(dcno)_2(H_2O)_2]$ [M = $Fe^{II}$ (**1**), $Co^{II}$ (**2**)] and $[M(dcno)_2]$ [M = $Cu^{II}$ (**3**), $Mn^{II}$ (**4**)] with dcno$^-$ = $[(NC)_2CC(O)O(CH_2)_2OH]^-$ = 2,2-dicyano-1-(2-hydroxyethoxy)ethenolate anion have been synthesised and characterised by IR spectroscopy, X-ray crystallography and magnetic measurements. In compounds **1** and **2**, each organic ligand acts in a bridging mode with its two nitrogen atoms bound to two different metal ions, while in compounds **3** and **4**, each organic anion acts as a $\mu_3$-bridging ligand through its two nitrogen atoms and the oxygen atom of the OH group. Each metal ion has a pseudo-octahedral *trans*-$MN_4O_2$ environment with four nitrogen atoms from four different organic ligands and two oxygen atoms from two water molecules in compounds **1** and **2** and from the OH group of the cyanocarbanion ligand in compounds **3** and **4**. These coordination modes give rise to 1D, 2D and 3D arrangements for compounds **1**, **2** and **3**–**4**, respectively. Magnetic measurements show weak antiferromagnetic coupling between metal centres in the four compounds.

## Introduction

Cyano carbanions and cyano azacarbanions are interesting ligands for the preparation of a large variety of discrete and extended molecular structures due to the fact that their cyano groups are disposed in such a way that they cannot coordinate to the same metal ion and that association of the π-electronic system of the nitrile groups with the π-system of the central fragment induces an electronic delocalisation that facilitates transmission of electronic effects between the metal centres (Scheme 1).[1,2]

Thus, reaction of such anions with d-block transition-metal ions leads to the isolation of a variety of new compounds displaying rich structural topological features and unusual magnetic properties;[3–16] most of them concern those involving the simplest anions such as the dicyanamide and the tricyanomethanide anions (dca$^-$ and tcm$^-$, respectively).[3–9] In this regard, binary (dca)metal and (tcm)metal complexes, $M(dca)_2$ and $M(tcm)_2$ (M = $Cr^{II}$, $Mn^{II}$, $Fe^{II}$, $Co^{II}$, $Ni^{II}$ and $Cu^{II}$), built from tricoordinate dca and tcm ligands exhibit 3D rutile-like architectures and some of them show long-range magnetic ordering, hard magnetic behaviour or spin-canted antiferromagnetism.[4,5] In addition to these binary dca and tcm compounds, a few binary examples involving sophisticated cyano carbanions and cyano azacarbanions have been reported by others and us.[11–15] Obviously, in these compounds, structural and physical properties are greatly affected by the number of donor groups and by the nature of the central fragment of the anionic ligand; we therefore find it interesting to study new ligands involving two cyano groups, as in the dca ligand, as well as one oxygen atom able to act as a donor or to participate in hydrogen bonds. Thus, using the 2,2-dicyano-1-ethoxyethenolate anion (dcne$^-$) and its methyl analogue (dcnm$^-$) (Scheme 1) led us and Kremer et al. to new compounds whose structures are built from monodimensional chains of 12-membered dimetallacycles.[11,12] These studies showed that the terminal oxygen atom does not enter in the coordination sphere of the metal ion, as the negative charge of the $[(NC)_2CC(O)OR]^-$ anion is not mainly located on this terminal oxygen atom. In an effort to increase the dimensionality of the structural arrangements as observed in the dicyanamide binary systems having a rutile-like structure, we have prepared the dcno$^-$ anion, where an $-O(CH_2)_2OH$ group replaces the –OEt group of the dcne$^-$ anion. This can affect the electronic delocalisation of the whole ligand and modify the role of the terminal oxygen atoms of the organic ligand and, therefore, its coordination mode around the metal ion. Herein, we report the syntheses, structural characterisation and magnetic properties of new polymeric compounds of formula $[M(dcno)_2(H_2O)_2]$

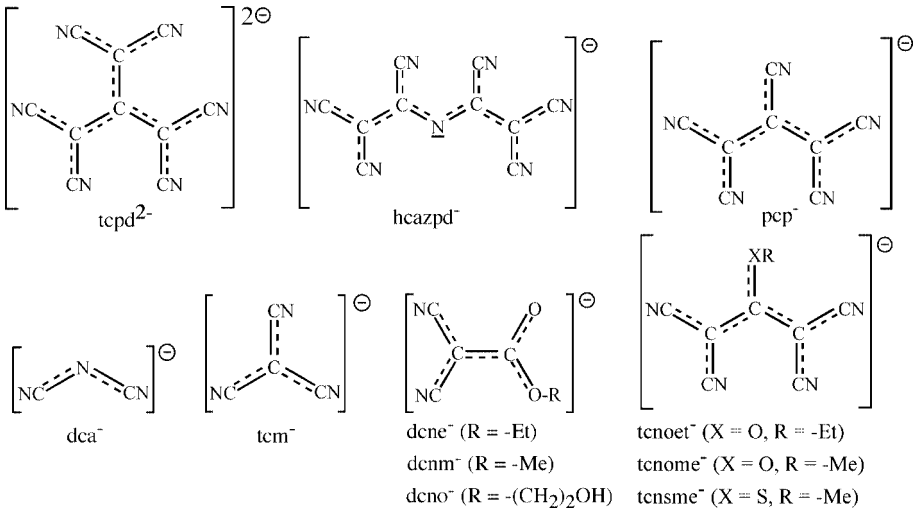


Scheme 1.

[M = $Fe^{II}$ (**1**), $Co^{II}$ (**2**)] and [M(dcno)$_2$] [M = $Cu^{II}$ (**3**), $Mn^{II}$ (**4**)] containing the bridging 2,2-dicyano-1-(2-hydroxyethoxy)ethenolate anion {dcno$^-$ = [(NC)$_2$CC(O)O(CH$_2$)$_2$-OH]$^-$}.

## Results and Discussion

### Syntheses and Characterisation

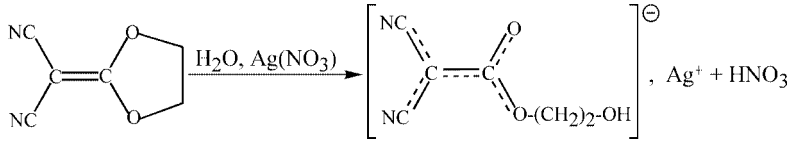
Silver 2,2-dicyano-1-(2-hydroxyethoxy)ethenolate [Ag(dcno)] was prepared by smooth hydrolysis of 2-(1,3-dioxolan-2-ylidene)malononitrile in the presence of an excess of silver nitrate; the pH of the aqueous solution (initial value: 6.5) decreased to 1.0 after boiling the solution for a few minutes in agreement with the reaction in Scheme 2. The tetraethylammonium salt was obtained as a white powder by reaction with 1 equiv. of [(C$_2$H$_5$)$_4$N]Cl. Its $^{13}$C NMR spectrum (see Experimental Section) is in good agreement with the proposed structure. However, it is worth noting the presence of a single signal for the two nonequivalent C≡N groups. This observation suggests a fast rotation, compared to the NMR detection around the central "C=C" bond resulting from an efficient electron delocalisation along the molecule induced by the presence of the two electron-withdrawing C≡N groups. Treatment of a saturated solution of Ag(dcno) with a saturated aqueous solution of the corresponding metal salt ($MCl_2 \cdot nH_2O$) in a dcno$^-$/$M^{II}$ ratio of 2 gave, after slow concentration, the new compounds [M(dcno)$_2$(H$_2$O)$_2$] [M = $Fe^{II}$ (**1**), $Co^{II}$ (**2**)] and [M(dcno)$_2$] [M = $Cu^{II}$ (**3**), $Mn^{II}$ (**4**)]. All compounds can also be prepared in the same way as the silver salt by direct reaction in aqueous solution of 2-(1,3-dioxolan-2-ylidene)-malononitrile with the corresponding transition-metal salt (Scheme 2).

The IR spectra of compounds **1**–**4** show similar patterns with two strong absorption bands assigned to $\nu_{CN}$. In agreement with the coordination of the organic ligand through its nitrile groups, these bands are slightly shifted to higher wavenumbers (2190–2260 cm$^{-1}$) than those of the corresponding tetraethylammonium salt containing the uncoordinated dcno$^-$ moiety (2169–2197 cm$^{-1}$).

### Crystal Structures

The two compounds of formula [M(dcno)$_2$(H$_2$O)$_2$] [M = $Fe^{II}$ (**1**), $Co^{II}$ (**2**)] display two different structures although generated by similar asymmetric units consisting of a metal ion and a water molecule, both on special positions [(0,–*y*,3/4) and (0,0,0) for **1** and **2**, respectively], and one dcno$^-$ organic ligand located on a general position. Each metal ion is linked to four nitrogen atoms from four organic ligands and to two symmetrically equivalent water molecules in a *trans* configuration.

In compound **1**, the coordination sphere of the metal atom can be described as a noncentrosymmetric *trans*-$FeN_4O_2$ pseudo-octahedron formed by an $FeN_4$ plane, arising from four nitrogen atoms (N1$^{(b)}$, N1$^{(c)}$, N2, N2$^{(a)}$), and two water molecules (O4 and O4$^{(a)}$) in axial positions (Figure 1). The six bond lengths are almost equivalent [ranging from 2.137(3) to 2.141(4) Å]. The structure involves 12-membered [Fe(NCCCN)$_2$Fe] dimetallacycles, as two bridging dcno$^-$ ligands connect two $Fe^{II}$ ions (Figure 1). These



Scheme 2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

almost planar rings (larger deviation from the corresponding mean plane of 0.04 Å) share metal ions to give a chain of dimetallacycles running along the [010] direction (Figure 1).

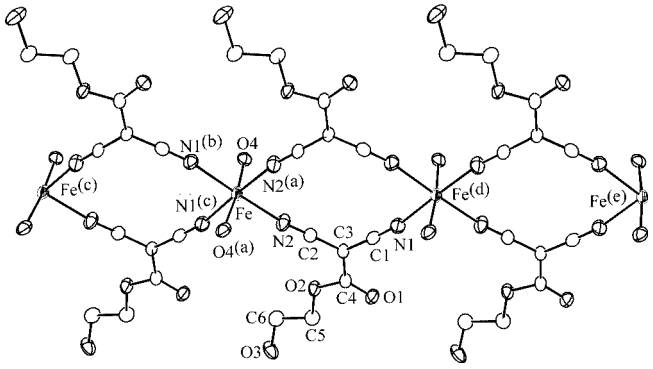


Figure 1. ORTEP perspective view of **1** (50% probability ellipsoid) showing the atom-labelling scheme, the $Fe^{II}$ environment and the 1D structure generated by the $\mu_2$-dcno ligand. Codes of equivalent positions: (a) 1 – *x*, *y*, 3/2 – *z*; (b) 1 – *x*, –1 + *y*, 3/2 – *z*; (c) *x*, –1 + *y*, *z*; (d) *x*, 1 + *y*, *z*; (e) *x*, 2 + *y*, *z*.

The intrachain Fe···Fe distance [7.450(1) Å], slightly shorter than the shortest interchain one [7.8660(6) Å], is close to that observed in the iron–dicyanamide compounds $[Fe(dca)_2(CH_3OH)_2]$[4d] and $\{[Fe(4,4'\text{-bpy})(dca)_2]\cdot bt\}$[16] (bt = 2,2′-bithiazoline) involving similar chains [7.392(1) and 7.418(1) Å, respectively].

In compound **2** each metal ion has a *trans*-$CoN_4O_2$ octahedral environment formed by four nitrogen atoms from four organic ligands (N1, $N1^{(a)}$, $N2^{(b)}$ and $N2^{(c)}$) and two equivalent water molecules (O4 and $O4^{(a)}$) (Figure 2a); this environment, essentially similar to that observed in compound **1**, is centrosymmetric here. As in **1**, the organic ligand acts in a bridging mode, with its two nitrogen atoms, N1 and N2, bound to two different cobalt ions (Figure 2a); but here the coordination mode leads to a two-dimensional structure, as the four organic ligands of one $[Co(dcno)_4]$ fragment are linked to four different $Co^{II}$ ions (Figure 2b). Thus, the two structures **1** and **2**, despite their essentially equivalent asymmetric units, display two very different molecular arrangements.

As shown in Figure 2b, the 2D layers of **2** can be described as formed by a succession of nonplanar [Co(NCCCN)Co(NCCCN)Co(NCCCN)Co(NCCCN)] cycles; these 24-membered tetrametallacycles are of course clearly different from the essentially planar 12-membered dimetallacycles described above for compound **1**. The shortest intramolecular Co···Co distance [7.929(1) Å] is shorter than that observed between the adjacent layers [8.421(1) Å]. This relatively long interlayer distance can be explained by the steric effects due to the nonplanar metallacycles, as clearly shown in Figure 2c. Careful examination of the interlayer distances reveals the presence of hydrogen bonds between the coordinated water molecule (O4) and the oxygen atom of the $-(CH_2)_2OH$ group of the $dcno^-$ ligand (O3) [O3···O4 2.81(1) Å]. This gives rise to the overall 3D structure depicted in Figure 2c.

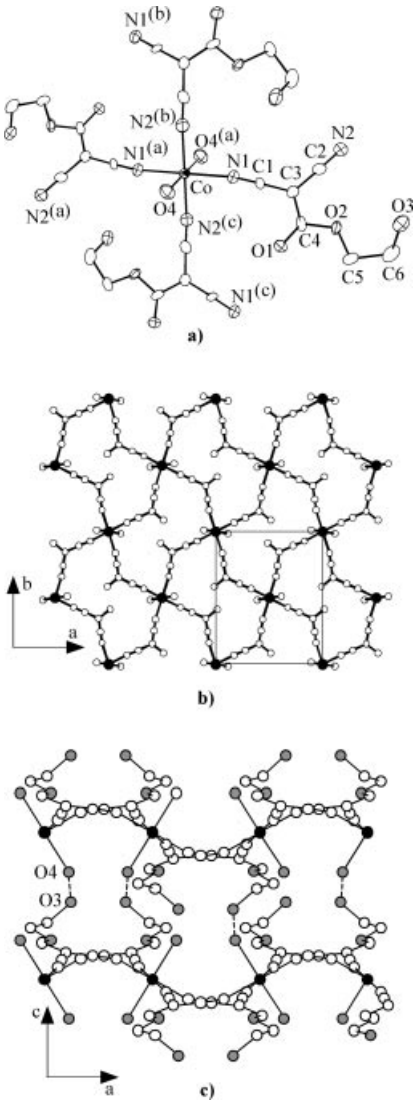

Figure 2. Structure of **2**. a) ORTEP perspective view (50% probability ellipsoid) showing the atom-labelling scheme and the $Co^{II}$ environment. Codes of equivalent positions: (a) –*x*, –*y*, –*z*; (b) –1/2 – *x*, 1/2 + *y*, *z*; and (c) 1/2 + *x*, –1/2 – *y*, –*z*. b) Two-dimensional structure in the *ab* plane; noncoordinated groups [–O and $-OCH_2CH_2OH$] omitted for clarity. c) Projection of two adjacent 2D layers in the *ac* plane showing hydrogen bonds in **2** [O3···O4 2.81(1) Å]. Shortest interlayer Co···Co distance: 8.421(1) Å.

Compounds **3** and **4** are isostructural. In both cases, the asymmetric unit contains a metal ion located on a special position (0,0,0) and a $dcno^-$ ligand on a general position (Figure 3). Each metal ion has a centrosymmetric *trans*-$MN_4O_2$ distorted octahedral environment formed by an $MN_4$ plane arising from four nitrogen atoms (N1, $N1^{(a)}$, $N2^{(c)}$ and $N2^{(e)}$) of four organic ligands, and two oxygen atoms from OH groups ($O3^{(b)}$ and $O3^{(d)}$) of two other $dcno^-$ ligands (Figure 3). Thus, in contrast to compounds **1** and **2**, here the metal ions are linked to six organic ligands.

Examination of the crystallographic data depicted in Table 1 reveals that the $Cu^{II}$ octahedral environment of compound **3** is much more distorted than that of the $Mn^{II}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

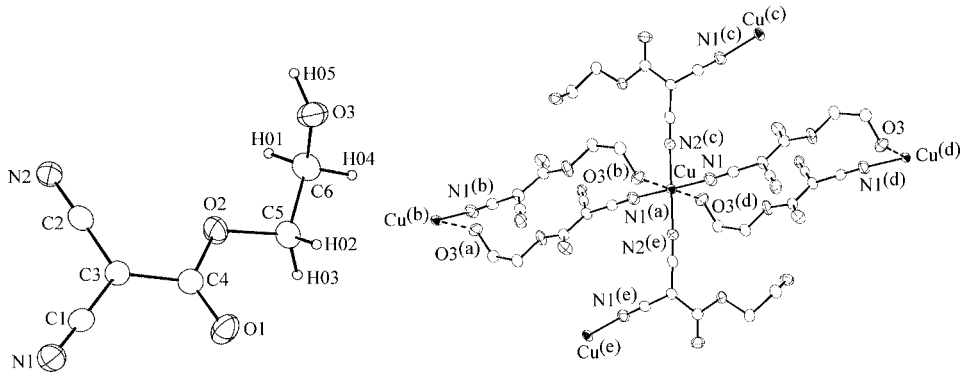

Figure 3. Structure of **3** and **4**. ORTEP view of **3** (50% probability ellipsoid) showing the atom-labelling scheme and the $Cu^{II}$ environment. M···M distances [Å] in **3**: Cu···Cu$^{(c)}$ 7.5648(4), Cu···Cu$^{(b)}$ 10.1242(4); in **4**: Mn···Mn$^{(c)}$ 7.740(5), Mn···Mn$^{(b)}$ 10.264(5). Codes of equivalent positions: (a) $-x, -y, -z$; (b) $x, y, -1 + z$; (c) $1/2 - x, -1/2 + y, 1/2 - z$; (d) $-x, -y, 1 - z$; (e) $-1/2 + x, 1/2 - y, -1/2 + z$.

ion in **4**, as the six metal–ligand bond lengths in **4** are almost equivalent [from 2.197(2) to 2.230(2) Å], while in the Cu compound **3**, the $CuN_4$ equatorial plane involves four essentially equivalent Cu–N bond lengths [1.995(2) and 1.998(2) Å], which are significantly shorter than the two axial Cu–O ones [2.359(2) Å]. These bond lengths clearly show the presence of Jahn–Teller distortions, as usually observed in octahedral $Cu^{II}$ complexes. The coordination mode of the dcno$^-$ ligand is different from that observed for compounds **1** and **2**, as, here, this ligand acts as a $\mu_3$-bridging ligand through its two nitrogen atoms (N1 and N2) and its oxygen atom (O3) of the OH group (Figure 3), leading to the overall three-dimensional structure depicted in Figure 4b.

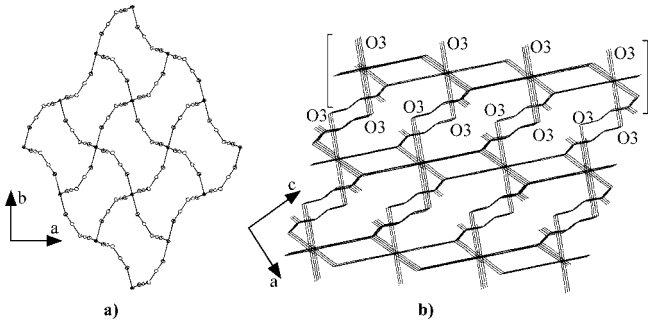

Figure 4. Sophisticated three-dimensional structure of **3** and **4**. a) 2D motif generated by the $C(CN)_2$ fragment in **3**; –C(O)($OCH_2$-$CH_2OH$) group of the dcno$^-$ ligand omitted for clarity. b) 3D structure of **3** showing the 2D motifs linked through the OH group (O3 atom) of the dcno$^-$ ligand.

The shortest $M^{II}$···$M^{II}$ distance through the dcno$^-$ ligand corresponds to that observed between two metal ions linked by the $C(CN)_2$ fragment [Cu···Cu$^{(c)}$ 7.5648(4) Å; Mn···Mn$^{(c)}$ 7.740(5) Å]; whereas the $M^{II}$···$M^{II}$ distance observed through the $NCCCO(CH_2)_2OH$ fragment (see Figure 3) is significantly longer [Cu···Cu$^{(b)}$ 10.1242(4) Å; Mn···Mn$^{(b)}$ 10.264(5) Å] (Figure 4b). It is worth noting that the best way to describe this complicated 3D molecular arrangement is to consider the 2D elemental unit generated by the $\mu_2$-$C(CN)_2$ fragment as shown in Figure 4a. These layers are connected to each other through the $M^{II}$–O3 bridges leading to the 3D structure of **3** and **4**.

Examination of bond lengths and bond angles clearly shows that the crystallographic parameters of the dcno$^-$ ligand are not significantly different in compounds **1**–**4** (Table 1 and Figure 3). With the exception of the

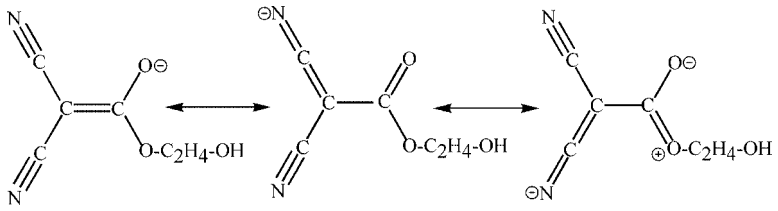
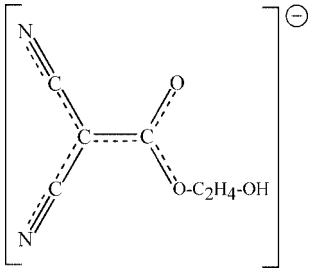


Scheme 3.

"–$CH_2CH_2OH$" group, the organic ligand is essentially planar within a maximum deviation of 0.06 Å from the corresponding mean plane. This is in agreement with an $sp^2$ hybridisation of the two central carbon atoms (C3 and C4), also shown by the bond angles around these atoms in each compound (sums of bond angles around C3 and C4 range from 359.9 to 360.1°), associated with an sp hybridisation of the carbon atoms of the cyano groups. Crystallographic data depicted in Table 1 for these compounds clearly show that the cyanocarbanion ligand includes a highly delocalised conjugated system. The electronic delocalisation is clearly shown by (i) a rather short terminal C4–O1 bond (1.22–1.23 Å) that strongly deviates from a normal C–O single bond (1.50 Å); (ii) a central C3–C4 bond (1.43–1.44 Å) longer than a normal C=C double bond (1.34 Å) [this low double-bond character is in good agreement with the $^{13}C$ NMR spectrum, as only a single signal was observed for the two C≡N groups of the free dcno$^-$ anion (see Experimental Section)]; and (iii) two C–CN bonds (1.39–1.41 Å) and a C4–O2 bond (1.33–1.35 Å), all presenting some multiple character. These observations indicate that the bonding in the dcno$^-$ ligand cannot be explained by a simple Lewis structure; this organic ligand must be considered as a resonance hybrid of different canonical structures (Scheme 3).

These canonical forms, and their symmetrical ones (not shown in Scheme 3), give rise to the mean electronic structure of Scheme 4, in agreement with the planarity of the $[(NC)_2CC(O)O]$ group and with the structural data (Table 1). Thus, it is clear that in this ligand the negative charge is not mainly located on the terminal oxygen atom and therefore, as also observed in the dcne$^-$ anion (Scheme 1),[11] it is not surprising that this atom does not enter in the coordination sphere of the metal ion.



Scheme 4.

## Magnetic Properties

The thermal variation of the product of the molar susceptibility times the temperature ($\chi_M T$) for compound **1** shows a room-temperature value of 3.2 emu K mol$^{-1}$. When cooling down, $\chi_M T$ remains constant to about 30 K, where a progressive decrease is observed, to reach a value of about 0.6 emu K mol$^{-1}$ at 2 K (Figure 5).

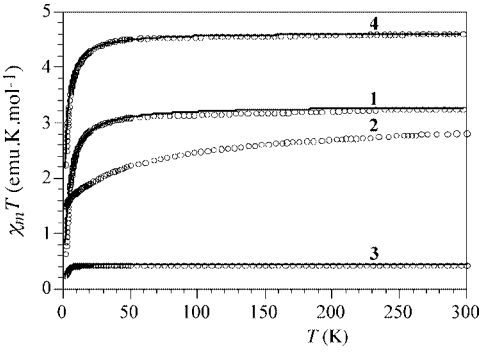


Figure 5. Thermal variation of $\chi_M T$ for compounds **1**–**4**. Solid lines represent the best fit to the models (see text).

Compound **2** shows a room-temperature $\chi_M T$ value of 2.8 emu K mol$^{-1}$ and a continuous decrease when the temperature is lowered, reaching a value of about 1.5 emu K mol$^{-1}$ at 2 K (Figure 5).

Finally, compounds **3** and **4** show a similar behaviour to that of compound **1**: they present room-temperature $\chi_M T$ values of 0.4 and 4.6 emu K mol$^{-1}$, respectively, which remain constant down to about 15 K (for **3**) and about 50 K (for **4**), where a progressive decrease is observed in both compounds, reaching values at 2 K of 0.2 and 2.2 emu K mol$^{-1}$, respectively. In compounds **1**, **3** and **4** the room-temperature $\chi_M T$ values are very close to the expected ones for high-spin $Fe^{II}$ ($S$ = 2), $Cu^{II}$ ($S$ = 1/2) and $Mn^{II}$ ($S$ = 5/2) ions with spin-only contribution (3.0, 0.375 and 4.375 emu K mol$^{-1}$, respectively). In compound **2**, the $\chi_M T$ value (2.8 emu K mol$^{-1}$) is in the range of the observed values for high-spin octahedral monomeric $Co^{II}$ ions (2.7–3.4 emu K mol$^{-1}$), where a significant orbital contribution is expected due to its orbitally degenerated $^4T_{1g}$ ground state.[17] The decrease observed at high temperatures in compound **2** is due to the presence of spin-orbit coupling, as expected for paramagnetic $Co^{II}$ compounds.[18] In compounds **1**, **3** and **4**, the decrease observed in $\chi_M T$ at low temperatures can be attributed to the presence of weak, although noticeable, antiferromagnetic interactions. Note that for compounds **1** and **4** we cannot exclude the presence of a zero-field splitting (ZFS), which may also account for the decrease observed in $\chi_M T$ at low temperatures. Note also that the decrease observed in compound **3** (where no ZFS is to be expected) and the structural similarities in all

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compounds (same kind of –NC–C–CN– bridges between metal centres) indicate that the ZFS cannot be the only reason for the decrease in $\chi_M T$ at low temperatures and, therefore, that there must be a weak antiferromagnetic coupling in all cases. Furthermore, although the attempts to fit the $\chi_M T$ product for compounds **1** and **4** to isolated monomers with ZFS satisfactorily reproduce the magnetic properties in the whole temperature range, the $|D|$ values obtained are unrealistically high (above 16 and 10 K for **1** and **4**, respectively), confirming the presence of a weak, although not negligible, antiferromagnetic coupling.

From the structural data that show the presence of a chain of dimetallacycles in compound **1**, we have reproduced the magnetic behaviour of **1** with the model derived by Fisher for a regular antiferromagnetic chain (with $S$ = 2 in compound **1**);[19] $N$ is the Avogadro number, $k$ is the Boltzmann constant and $\beta$ is the Bohr magneton.

$$\chi_M = \frac{Ng^2\beta^2 S(S+1)}{3kT}\left[\frac{1+u}{1-u}\right], \text{ where } u = \coth\left[\frac{JS(S+1)}{kT}\right] - \left[\frac{kT}{JS(S+1)}\right]$$

This model very satisfactorily reproduces the magnetic behaviour of compound **1** in the whole temperature range (solid line in Figure 5) with $g$ = 2.094(3) and $J$ = –0.78(1) K = –0.54(1) cm$^{-1}$ (the Hamiltonian is written as $H = -J\,\Sigma S_i S_{i+1}$).

In compounds **3** and **4** the structure shows the presence of a 2D lattice with identical exchange pathways (NC–C–CN) in the two directions and an extra connection through a very long NCCC(O)$(CH_2)_2$OH bridge. In a first approximation we can consider that the magnetic exchange is mainly due to the shorter NC–C–CN bridges and, accordingly, we have used the antiferromagnetic square 2D model (Quadratic Layer Antiferromagnet) proposed by Lines[20] to reproduce the magnetic data of these compounds:

$$\chi_M = \frac{Ng^2\beta^2}{J}\left(3\theta + \sum_n \frac{C_n}{\theta^{n-1}}\right)^{-1}, \text{ where } \theta = \frac{kT}{JS(S+1)}$$

The six first $C_n$ coefficients are: 4.0, 2.667, 1.185, 0.149, –0.191 and 0.001 for $S$ = 1/2 (compound **3**) and 4.0, 1.448, 0.228, 0.262, 0.119 and 0.017 for $S$ = 5/2 (compound **4**). This model very satisfactorily reproduces the magnetic behaviour of compounds **3** and **4** in the whole temperature range (solid lines in Figure 5) with $g$ = 2.195(3) and $J$ = –0.92(3) K = –0.64(2) cm$^{-1}$ for **3** and $g$ = 2.054(1) and $J$ = –0.128(1) K = –0.089(1) cm$^{-1}$ for **4** (the Hamiltonian is written as $H = -J\,\Sigma S_i S_j$).

These results indicate that the antiferromagnetic coupling is very weak in the three compounds, as expected from the presence of identical M–NC–C–CN–M bridges, and that the long bridges present in the structures of compounds **3** and **4** do not play an important role in the magnetic interactions. Furthermore, the $J$ values are very similar to those obtained in the related family of compounds $[M(dcne)_2(H_2O)_2]$ and $[Cu(dcne)_2(H_2O)]$, where similar NC–C–CN bridges are present.[11] An additional confirmation of the weak antiferromagnetic interactions in the four compounds is provided by the isothermal magnetisation measurements at 2 K. These measurements show in each case a behaviour close to that expected for isolated magnetic centres and can be well reproduced with the Brillouin function but with lower $g$ values due to the non-negligible population of the $S$ = 0 ground state, confirming the presence of antiferromagnetic exchange interactions in all compounds.

## Conclusions

This study involves the design of multidimensional transition-metal compounds with dcno$^-$ cyano carbanion acting as $\mu_2$- and $\mu_3$-bridging ligand. Previous work showed that reactions of the $[(NC)_2CC(O)(OR)]^-$ ligands (dcnm$^-$ for R = Me and dcne$^-$ for R = Et) with transition-metal ions afford 1D coordination polymers resulting from coordination of both ligands by their two nitrile groups.[11,12] A slight modification of the alkyl group leads us to the dnco$^-$ anion, for which the coordination modes in its metal ion binary systems strongly differ from those observed in the corresponding (dcnm)M and (dcne)M systems. However, as observed in the dcne$^-$ coordination polymers,[11] the highly conjugated $[(NC)_2CC(O)O]$ group of the organic ligand precludes any localisation of the negative charge on the terminal oxygen atom and, therefore, its coordination to the metal centres. Thus, in the compounds $[M(dcno)_2(H_2O)_2]$ [M = Fe$^{II}$ (**1**), Co$^{II}$ (**2**)], this anion acts as a $\mu_2$ ligand, leading to 1D and 2D molecular arrangements respectively, while in the binary systems $[M(dcno)_2]$ [M = Cu$^{II}$ (**3**), Mn$^{II}$ (**4**)] with the 3D networks, this anion acts as a $\mu_3$ bridging ligand. This clearly illustrates the bonding affinity and flexibility of the cyanocarbanion ligand towards transition-metal ions. These unexpected structural differences can be partially explained by the less restricting coordination preferences of Cu$^{II}$ (due to Jahn–Teller distortions) and Mn$^{II}$ (due to its larger ionic radius). In contrast, in compounds **1** and **2** the dcno$^-$ ligand is not flexible enough to link the Fe$^{II}$ and the Co$^{II}$ ions through its terminal OH group (O3) as the metal–oxygen bonds should be shorter than the corresponding ones observed (and expected) for the Mn$^{II}$ and Cu$^{II}$ compounds [M–O distances observed in **1**–**4**: 2.141(3), 2.144(5), 2.359(2) and 2.197(2) Å, respectively]. This lack of flexibility induces the presence of water molecules in axial positions, leading to materials with low dimensionalities. In an effort to facilitate formation of 3D systems, syntheses of new parent cyanocarbanion ligands involving more flexible groups such as –O$(CH_2)_n$OH ($n$ = 3, 4, …) are in progress.

## Experimental Section

**General:** All reactions were performed under aerobic conditions. The reagents $AgNO_3$, $MnCl_2{\cdot}4H_2O$, $FeCl_2{\cdot}4H_2O$, $CoCl_2{\cdot}6H_2O$ and $CuCl_2{\cdot}2H_2O$ were purchased from commercial sources and used as received. 2-(1,3-Dioxolan-2-ylidene)malononitrile was prepared according to ref.[1g] IR spectra were recorded in the range 4000–200 cm$^{-1}$ as KBr pellets with an FTIR NEXUS NICOLET Spectrometer. NMR spectra were recorded with a Bruker AMX 400 MHz instrument. Elemental analyses were obtained from the Service de microanalyses, CNRS, Gif sur Yvette, France. The mag-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

netic studies were carried out on powder samples enclosed in medical caps. The magnetic susceptibility measurements were performed at 0.1 T, in the temperature range 2–300 K, with a SQUID magnetometer MPMS-XL-5 from Quantum Design. The molar susceptibility was corrected from the sample holder and diamagnetic contributions of all atoms (Pascal's tables).

**Synthesis of the Silver Salt of 2,2-Dicyano-1-(2-hydroxyethoxy)-ethenolate [Ag(dcno)]:** Silver 2,2-dicyano-1-(2-hydroxyethoxy)-ethenolate [Ag(dcno)] was prepared by smooth hydrolysis of 2-(1,3-dioxolan-2-ylidene)malononitrile in the presence of an excess of silver nitrate; the pH of the aqueous solution (initial value: 6.5) decreased to 1.0 after boiling the solution for a few minutes. An excess of $AgNO_3$ (4.077 g, 24 mmol) was added to a hot aqueous solution (30 mL) of 2-(1,3-dioxolan-2-ylidene)malononitrile (1.633 g, 12 mmol). The solution was stirred and heated until the solid dissolved. Slow concentration of the resulting solution at room temperature gave crystals of silver 2,2-dicyano-1-(2-hydroxyethoxy)-ethenolate as white needles (58% yield). $C_6H_5AgN_2O_3$ (260.99): calcd. C 27.6, H 1.9, Ag 41.3, N 10.7; found C 27.9, H 1.9, Ag 40.9, N 10.6. IR (KBr): $\tilde{\nu}$ = 3451 br, 2963 m, 2204 s, 2177 s, 1803 s, 1777 s, 1642 s, 1480 w, 1385 s, 1319 s, 1181 m, 1134 s, 1079 s, 975 m, 901 m, 824 m, 777 m, 755 m, 719 m, 553 m $cm^{-1}$. Because of the low solubility of this salt in most organic solvents, we prepared, by metathesis, its tetraethylammonium homologue by reaction of [Ag(dcno)] with 1 equiv. of $[(C_2H_5)_4N]Cl$ in $CH_3CN$ in order to record the NMR spectrum and perform the IR study of the noncoordinated $dcno^-$ anion. IR (KBr): $\tilde{\nu}$ = 3456 br, 2988 s, 2952 m, 2396 w, 2197 s, 2169 s, 1802 s, 1776 s, 1649 s, 1396 br, 1173 s, 1125 s, 1076 s, 1033 w, 1002 s, 974 w, 894 m, 825 m, 787 s, 756 m, 717 w, 555 m $cm^{-1}$. $^{13}C$ NMR ([D$_6$]acetone): $\delta$ = 170 [C(O)O], 123.7 (CN), 72.9 ($CH_2$), 65.4 ($CH_2$), 46.7 [$C(CN)_2$; 52.6, 7.4 $(C_2H_5)_4N$] ppm.

**Syntheses of $[M(dcno)_2(H_2O)_2]$ [M = $Fe^{II}$ (1), $Co^{II}$ (2)] and $[M(dcno)_2]$ [M = $Cu^{II}$ (3), $Mn^{II}$ (4)]:** The four compounds were prepared in the same way by treating aqueous solutions (10 mL) of the corresponding metal chloride (1 mmol) with aqueous solutions (15 mL) of silver 2,2-dicyano-1-(2-hydroxyethoxy)ethenolate (2 mmol, 0.384 g). The samples were stirred at room temperature for about 30 min and left to stand. Slow concentration of the resulting solutions at room temperature gave prismatic crystals for compounds **1**–**4** that were filtered and air-dried. All compounds were satisfactory analysed for C, H and N. All compounds can also be prepared in the same way as the silver salts by direct reaction in aqueous solution of 2-(1,3-dioxolan-2-ylidene)malononitrile with the corresponding transition-metal salt, but this procedure does not allow the isolation of the pure $dcno^-$ anion as the starting ligand and yields less pure compounds **1**–**4**, as the hydrolysis of the precursor is not complete.

**1:** Yield: 0.219 g (55%). $C_{12}H_{14}FeN_4O_8$ (398.11): calcd. C 36.2, H 3.5, N 14.1; found C 35.9, H 3.7, N 14.3. IR (KBr): $\tilde{\nu}$ = 3411 br, 3075 br, 2231 s, 2191 s, 1656 s, 1487 w, 1383 s, 1359 m, 1334 m, 1310 s, 1280 m, 1158 s, 1070 m, 1043 s, 986 w, 849 m, 815 m, 749 s, 585 w, 563 m $cm^{-1}$.

**2:** Yield: 0.233 g (58%). $C_{12}H_{14}CoN_4O_8$ (401.20): calcd. C 35.9, H 3.5, N 14.0; found C 35.6, H 3.6, N 14.3. IR (KBr): $\tilde{\nu}$ = 3411 br, 2250 s, 2215 s, 1623 s, 1457 w, 1437 w, 1392 m, 1326 s, 1284 m, 1265 w, 1171 s, 1075 m, 1013 w, 900 w, 758 w, 668 w, 553 w $cm^{-1}$.

**3:** Yield: 0.288 g (78%). $C_{12}H_{10}CuN_4O_6$ (369.78): calcd. C 39.0, H 2.7, N 15.2; found C 38.6, H 2.8, N 15.5. IR (KBr): $\tilde{\nu}$ = 3315 br, 2252 s, 2199 s, 1646 s, 1478 m, 1406 m, 1374 s, 1328 s, 1282 s, 1145 s, 1022 m, 810 w, 754 s, 556 s, 493 w, 431 m, 386 m $cm^{-1}$.

**4:** Yield: 0.173 g (48%). $C_{12}H_{10}MnN_4O_6$ (361.18): calcd. C 39.9, H 2.8, N 15.5; found C 40.3, H 2.6, N 15.2. IR (KBr): $\tilde{\nu}$ = 3401 br, 2232 s, 2196 s, 1650 s, 1615 s, 1460 m, 1400 s, 1383 m, 1285 w, 1229 w, 1160 s, 1087 m, 1070 m, 1020 w, 902 m, 758 m, 640 w, 558 m $cm^{-1}$.

**X-ray Crystallography:** Data for compounds **1**–**3** were collected with an Xcalibur 2 diffractometer (Oxford Diffraction) at room temperature (294 K for **1** and **2** and 288 K for **3**). The three structures were solved by direct methods and successive Fourier difference syntheses, and were refined, on *F*, by weighted anisotropic full-matrix least-squares methods.[21] The hydrogen atoms were located by difference Fourier map, except those of the "$CH_2$–$CH_2$" group of the $dcno^-$ ligand in **1** and **2**, which were calculated [*d*(C–H) = 0.95 Å]; the thermal parameters were taken as $U_{iso} = 1.3U_{equ}(C)$ and therefore included as isotropic fixed contributors to $F_c$. Note

that the hydrogen atoms of the water molecule and of the terminal "OH" group of the dcno⁻ ligand in **2** were not calculated. It is noteworthy that it was difficult to collect correct X-ray data for compounds **1** and **2** because of their low diffracting power, essentially because of the low dimensions of the single crystals. However, the corresponding bond lengths and bond angles (see Table 1) are relatively correct, as they are in the normal range when compared to their corresponding values observed in the parent compounds **3** and **4**. For **4**, no pure single crystal was found. φ-χ scans performed on the KCCD diffractometer at 288 K and combined with the use of DIRAX program[22,23] revealed the existence of two misaligned crystal components with identical unit-cell parameters. Finally, the collected frames were integrated using the EVAL program considering both orientation matrices.[24] An HKLF5 file for the SHELX refinement program was created with a list of integrated intensities for the two observed contributors. For all integrated reflections, a reflection index specifying the quality of the reflection (pure #1, pure #2 or common reflection) was given. The structure was then solved by direct methods and successive Fourier difference syntheses, and was refined, on $F^2$, by weighted anisotropic full-matrix least-squares methods.[25] All the hydrogen atoms were located by difference Fourier map and were refined isotropically. In the least-square refinement procedure, a supplementary parameter defining the fractional contribution of the second component was refined. Note that because of the bicrystalline character of the studied object, the $R_{int}$ parameter has no significance and so is not calculated by the refinement program. Scattering factors and corrections for anomalous dispersion were taken from the International Tables for X-ray Crystallography.[26] The thermal ellipsoid drawings were created with the ORTEP program.[27] Selected bond lengths and bond angles are listed in Table 1. Pertinent crystal data are mentioned in Table 2. CCDC-604823 to -604826 (for **1**–**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

The authors gratefully acknowledge the Centre National de la Recherche Scientifique (CNRS) and the framework of a French–Spanish Integrated Action (PICASSO 2005/No. 07137XK and HF2003-258) for financial support. F. S. thanks the "Agence Universitaire pour la Francophonie" for a postdoctoral grant.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** a water pipe (wire-frame representation in blue), constructed solely from solvent water molecules that are present in the crystal lattice of an organic–inorganic hybrid compound $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2][Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$. The supramolecular interactions of the water pipe with its surrounding (that includes a heteropolyanion, $[Al(OH)_6Mo_6O_{18}]^{3-}$, shown as red polyhedra and a copper dimeric complex, shown as magenta ball-and-stick models) stabilise the compound so that it can be observed crystallographically. The background depicts the unit-cell packing of the water pipes in the relevant crystal. Details are described in the Short Communication by S. K. Das et al. on p. 231ff. The artwork was designed by Ms. Sabbani Supriya.

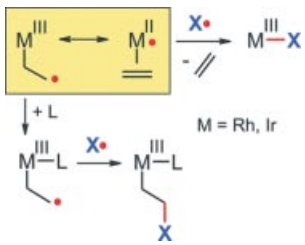
## MICROREVIEW

### Radical Organometallic Chemistry

**B. de Bruin,***
**D. G. H. Hetterscheid ..... 211–230**

Paramagnetic (Alkene)Rh and (Alkene)Ir Complexes: Metal or Ligand Radicals?

**Keywords:** Rhodium / Iridium / Alkene ligands / Metallo-radicals / Ligand radicals

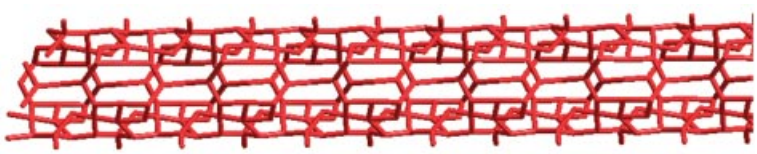


Paramagnetic alkene rhodium and iridium complexes reveal features of both metallo-radicals and ligand radicals. This dual-mode behavior is reflected by their high and diverse reactivity, as discussed in this review.

## SHORT COMMUNICATIONS

### Water Pipe in Inorganic Matrix

**V. Shivaiah, T. Chatterjee, K. Srinivasu, S. K. Das* ..... 231–234**



A Water Pipe Held Up by a Polyoxometalate Supported Transition Metal Complex: Synthesis and Characterization of $[Cu_2(phen)_2(CH_3COO)\text{-}(CH_3COOH)(H_2O)_2][Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$

**Keywords:** Heteropolyanion / Copper acetate dimer / Crystal structure / Lattice waters / Hydrogen bonds / Supramolecular chemistry

A water pipe, shown in wire-frame representation, is constructed by hydrogen-bonding interactions solely from solvent water molecules that are present in the crystal lattice of an inorganic–organic hybrid compound, $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2]\text{-}[Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$. This is a unique example of a water tube, observed crystallographically in a polyoxometalate-based hybrid material.

### Linear Metal Clusters

**K. Mashima,* Y. Shimoyama, Y. Kusumi, A. Fukumoto, T. Yamagata, M. Ohashi ..... 235–238**

Formation of a Dative Bond Between $Pt^0$ and $Mo^{II}$ in Linear $Pt^0–Mo^{II}–Mo^{II}–Pt^0$ Complexes, $Mo^{II}_2Pt^0_2(pyphos)_4(PR_3)_2$, and Unique 1,4-Oxidative Addition Reaction of Diaryl Disulfides Giving $Mo^{II}_2Pt^{I}_2(pyphos)_4(SAr)_2$ (pyphos = 6-Diphenylphosphanyl-2-pyridonato)

**Keywords:** Linear clusters / Dative bonds / Oxidative addition / Thiolates / Platinum / Molybdenum

The addition of diaryl disulfides to the $Pt^0\cdots Mo^{II}$ datively bonded $Pt^0–Mo^{II}–Mo^{II}–Pt^0$ complex **4a** afforded dithiolate $Pt^I$ complexes $Mo_2Pt_2(SAr)_2(pyphos)_4$ (**5**) by 1,4-oxidative addition.

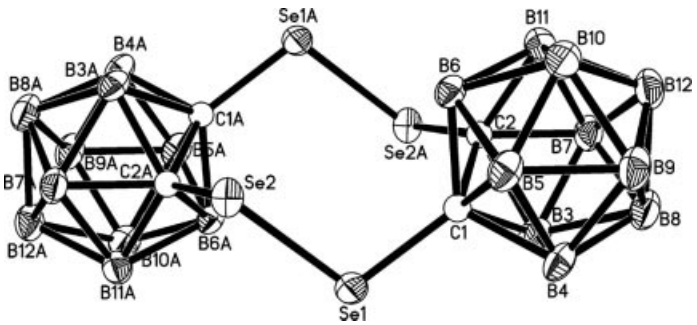
# FULL PAPERS

## Tetraselenide Oxidative Coupling



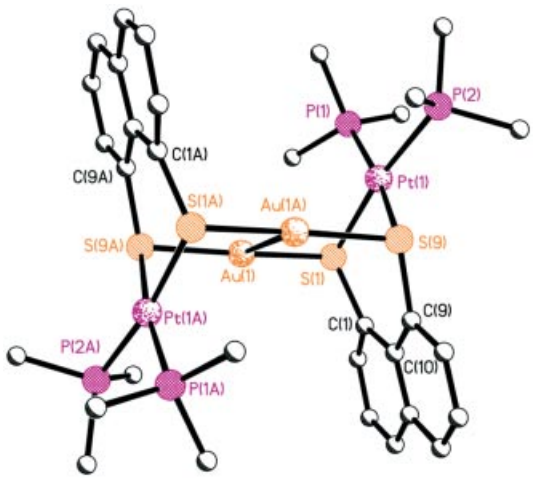
**B. Wrackmeyer,* Z. Garćia Hernández, R. Kempe, M. Herberhold ..... 239–246**

Novel 1,2-Dicarba-*closo*-dodecaborane(12) Derivatives of Selenium

**Keywords:** Carboranes / Selenium / Platinum / Oxidative addition / NMR spectroscopy

Oxidative coupling of the 1,2-diselenolato-1,2-dicarba-*closo*-dodecaborane(12) dianion gives the cyclic eight-membered bis(diselane) with annellated carborane moieties. This tetraselenide reacts with ethenebis(triphenylphosphane)platinum(0) by oxidative addition to give the platinum(II) complex, which contains the chelating 1,2-diselenolato-1,2-dicarba-*closo*-dodecaborane(12) ligand. The molecular structures of the tetraselenide and the $Pt^{II}$ complex were determined by X-ray analysis, and by $^{1}H$, $^{13}C$, $^{31}P$, $^{77}Se$ and $^{195}Pt$ NMR spectroscopy in solution.

## Multimetallic Systems



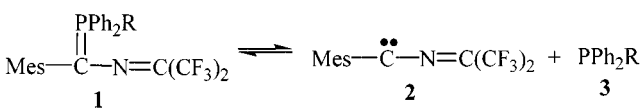
**S. D. Robertson, A. M. Z. Slawin, J. D. Woollins ..... 247–253**

Constructing Multimetallic Systems with the Naphthalene-1,8-bis(thiolato) Ligand

**Keywords:** Sulfur ligand / Multimetallic systems / Gold / Bridging ligands / X-ray structure

The construction of multimetallic systems from sulfur donor ligands can be achieved by using a simple building-block approach.

## Dissociation of P=C Ylidec Bonds



**I. Shevchenko,* A. Rogalyov, A. B. Rozhenko, G.-V. Röschenthaler ..... 254–258**

Dissociation of the P=C Ylidic Bond

**Keywords:** Ylides / Carbenes / Phosphanes / Density functional calculations

Phosphorus ylides **1** [R = Ph, $Ph_2P(O)CH_2$] in solutution undergo reversible dissociation of the P=C ylidic bond to give carbene **2** and phosphanes **3**. Carbene **2** can be trapped as carbene or as mesomeric nitrile ylide.

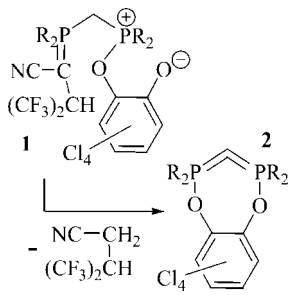
## Decomposition of Zwitterions

**I. Shevchenko,* V. Andrushko, E. Lork, G.-V. Röschenthaler* ..... 259–262**

Oxidation of Phosphanes with Orthoquinones: An Unusual Decomposition of an Unexpectedly Stable Zwitterion

**Keywords:** Ylides / Phosphanes / Zwitterions / Carbodiphosphorane



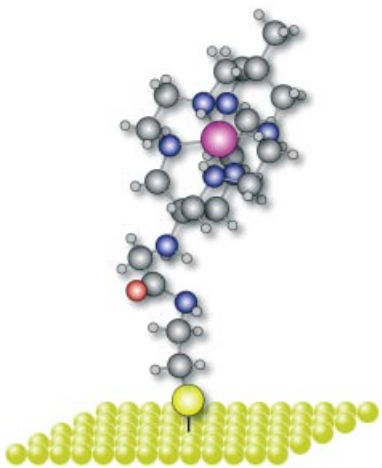
Oxidation of the appropriate phosphane with tetrachlororthobenzoquinone gives unexpectedly stable zwitterion **1** which undergoes an unusual decomposition into symmetrical carbodiphosphorane **2** and hexafluoroisovaleronitrile.

## Sarcophagines

**J. M. Harrowfield, G. A. Koutsantonis,* H.-B. Kraatz, G. L. Nealon, G. A. Orlowski, B. W. Skelton, A. H. White ..... 263–278**

Cages on Surfaces: Thiol Functionalisation of $Co^{III}$ Sarcophagine Complexes

**Keywords:** Sarcophagine / Amino acids / Disulfides / Cobalt / Self-assembled monolayers / Electrodeposition



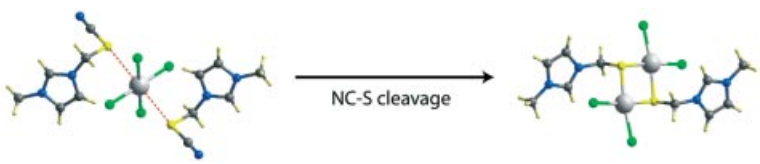
New cage cobalt complexes with oligopeptide tethers have been immobilised on Au surfaces via terminal mercaptoethylamide units. Their electrochemistry on the surface and of the untethered complexes in solution have been investigated.

## Ionic Liquids

**D. Zhao, Z. Fei, W. H. Ang, R. Scopelliti, P. J. Dyson* ..... 279–284**

Thiocyanate Functionalised Ionic Liquids: Synthesis, Characterisation and Reactivity

**Keywords:** Ionic liquids / Thiocyanate / Palladium complexes / Imidazolium salts



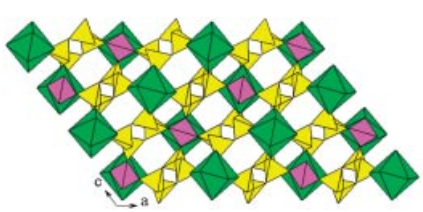
A series of novel thiocyanate functionalised ionic liquids based on the 1-thiocyanomethyl-3-methylimidazolium cation was prepared. Their solid-state structures were investigated, including their reactivity with palladium(II) chloride under acidic conditions.

## Lithium Rare Earth Polyphosphates

**J. Zhu, W.-D. Cheng,* D.-S. Wu, H. Zhang, Y.-J. Gong, H.-N. Tong, D. Zhao ..... 285–290**

A Series of Lithium Rare Earth Polyphosphates [$LiLn(PO_3)_4$] (Ln = La, Eu, Gd) and Their Structural, Optical, and Electronic Properties

**Keywords:** Density functional calculations / UV/Vis spectroscopy / Rare earths / Phosphates



A series of lithium rare earth polyphosphates $LiLn(PO_3)_4$ (Ln = La, Eu, Gd) crystallizes in the monoclinic space group *C*2/*c* with $Z = 4$. Their unit-cell parameters decrease as the ionic radius of $Ln^{3+}$ decreases ($La^{3+} > Eu^{3+} > Gd^{3+}$). In the structure, both $(PO_4)^{3-}$ zig-zag chains and infinite chains formed by the alternative connection of $LnO_8$ polyhedra and $LiO_4$ tetrahedra run parallel to the *b*-axis.

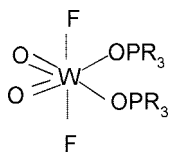
Rare-Earth Nitroquinolinates: Visible-Light-Sensitizable Near-Infrared Emitters in Aqueous Solution

**Keywords:** Rare earth metals / Luminescence / Chelates / N,O ligands / Sensing

## Tungsten Chemistry

Phosphane oxide complexes of dioxidotungsten(VI), $[WO_2X_2(OPR_3)_2]$ (X = Cl or Br), have been prepared under anhydrous conditions from $WX_6$ and $(Me_3Si)_2O$ in $CH_2Cl_2$, followed by addition of $OPR_3$. The difluorido-dioxido complexes $[MO_2F_2(OPR_3)_2]$ (M = Mo or W) have been prepared by fluorination of the corresponding chlorido complexes with $Me_3SnF$ in $CH_2Cl_2$.



**M. F. Davis, W. Levason,* R. Ratnani,***
**G. Reid,* T. Rose, M. Webster .. 306–313**

Synthesis and Characterisation of $W^{VI}$ Complexes of Phosphane Oxide Ligands, $[WO_2X_2(OPR_3)_2]$ (X = F, Cl or Br; R = Me or Ph), and of the $[MoO_2F_2(OPR_3)_2]$

**Keywords:** Tungsten / Molybdenum / Phosphane oxide / Crystal structures / Fluoride

## Valence-State Distributions

DFT-supported experimental results suggest that the valence formulation of $[Ru(trpy)(Cl)(L^{1/2})]^+$ ($\mathbf{1}^+/\mathbf{2}^+$) can be best interpreted as spin-coupled $Ru^{III}-L_{Sq}$ with a minority contribution from the diamagnetic $Ru^{II}-L_Q$ state and the involvement of d(Ru)- and (L)-based frontier orbitals, respectively, in the successive oxidation processes and preferential involvement of Ru-based orbitals in the first reduction step.

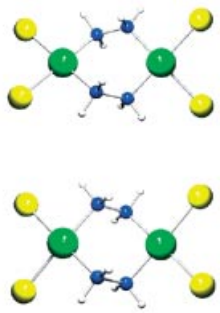
# CONTENTS

## Chiral Discrimination

**O. Picazo, I. Alkorta,* J. Elguero, M. R. Sundberg,* J. Valo ..... 324–332**

Bonding Properties Related with Chiral Discrimination in Dinuclear Metal Complexes of Group 10

**Keywords:** Ab initio calculations / Coordination chemistry / Chiral discrimination / Bonding properties / *trans* influence



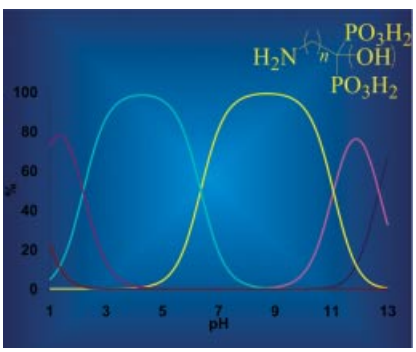
Homo- and heterochiral complexes formed by hydrazine, a metal atom of group 10, and halogen atoms have been studied by means of DFT, NBO and QTAIM methods.

## Bis(phosphonate) Complexes

**V. Kubíček,* J. Kotek, P. Hermann, I. Lukeš ..... 333–344**

Aminoalkylbis(phosphonates): Their Complexation Properties in Solution and in the Solid State

**Keywords:** Phosphonates / Complexation / Stability constants / Potentiometry



Acid–base and complexation properties of (aminoalkyl)bis(phosphonates) were studied by potentiometry. The crystal structures of the ligands, determined by X-ray diffraction analysis, show a different degree of protonation. Dimeric units of the $Cu^{2+}$ complex of pamidronate in the solid state form a coordination polymer with a short metal–metal distance.

## Functional Coordination

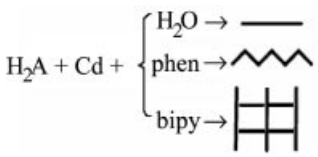
Three Novel Functional $Cd^{II}$ Dicarboxylates with Nanometer Channels: Hydrothermal Synthesis, Crystal Structures, and Luminescence Properties

**Keywords:** Carboxylate / Supramolecular chemistry / Fluorescence / Coordination modes



Three novel functional cadmium(II) dicarboxylates were obtained by the skilful combination of carboxylate, the other coligands and cadmium nitrate. Their luminescent properties were also changed by the coordination modes.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** a water pipe (wire-frame representation in blue), constructed solely from solvent water molecules that are present in the crystal lattice of an organic–inorganic hybrid compound $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2][Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$. The supramolecular interactions of the water pipe with its surrounding (that includes a heteropolyanion, $[Al(OH)_6Mo_6O_{18}]^{3-}$, shown as red polyhedra and a copper dimeric complex, shown as magenta ball-and-stick models) stabilise the compound so that it can be observed crystallographically. The background depicts the unit-cell packing of the water pipes in the relevant crystal. Details are described in the Short Communication by S. K. Das et al. on p. 231ff. The artwork was designed by Ms. Sabbani Supriya.

# Paramagnetic (Alkene)Rh and (Alkene)Ir Complexes: Metal or Ligand Radicals?

**Bas de Bruin*[a] and Dennis G. H. Hetterscheid[b]**

*Dedicated to Professor Karl Wieghardt on occasion of his 65th birthday*

**Keywords:** Rhodium / Iridium / Alkene ligands / Metallo-radicals / Ligand radicals

In this review a detailed overview is given of the (electronic) structure and reactivity of open-shell (paramagnetic) alkene rhodium and iridium complexes $M^x$(alkene) (M = Rh, Ir; $x$ = 0, +II). In most cases these species are highly reactive, but some notable exceptions of stable species for which not much reactivity has been described are also included (section 2). Understanding the electronic structure of the reactive nitrogen-ligand-based [$M^{II}$(por)(alkene)] and [$M^{II}$(alkene)(N-ligand)]$^{2+}$ species (section 3) is complicated by a substantial spin distribution over the metal and the alkene ligand. This dual-mode metallo-radical and ligand radical behavior is reflected by their high and diverse reactivity. Metallo-radical character is demonstrated by a variety of metal-to-radical coupling reactions with a series of other radicals, as well as metal-based allylic hydrogen atom abstractions from $M^{II}$(α-alkene) species. On the other hand, (donor induced) ligand radical character is crucial in a variety of M–C and C–C radical coupling reactions, C–O bond formation by oxygenation of $M^{II}$(alkene) species and alkene "insertions" into (por)M–H bonds. The review concludes with some speculations about possible roles of paramagnetic M(olefin) (M = Rh, Ir) species in catalytic olefin oxygenation and carbene transfer reactions.

## 1. Introduction

Our understanding of Rh and Ir organometallic chemistry is mainly based on studies of diamagnetic complexes in homogeneous solutions. Much less is known of the structure, reactivity and physical properties of their *paramagnetic* analogs. Interest in the properties and reactivity of such open-shell organometallic species is however rising.[1] This is triggered by the idea that such species might reveal special reactivity patterns, perhaps even as crucial intermediates in some catalytic reactions.[2]

*Bas de Bruin obtained his PhD in 1999 from the Radboud University Nijmegen (the Netherlands). In the same year he joined the group of Prof. Karl Wieghardt at the Max-Planck Institute for Bio-Inorganic Chemistry in Mülheim/Ruhr (Germany) as an Alexander-von-Humboldt fellow. A year later he returned to the Metal-Organic Chemistry group of Prof. Anton W. Gal in Nijmegen as an assistant professor (UD). In 2005 he received a national NWO-VIDI grant to start up an independent research-line. November 2005 he moved to the University of Amsterdam (UvA) to join the Homogeneous and Supramolecular Catalysis group.*

*Dennis Hetterscheid obtained his master's degree in Chemistry in 2002 at the Radboud University Nijmegen (the Netherlands). Currently he is finishing his PhD at the same university (under supervision of Bas de Bruin), dealing with the synthesis, characterization and reactivity of mononucleair $Rh^{II}$ and $Ir^{II}$ complexes. July 2006 he obtained a national NWO-Rubicon grant for a two-year postdoc abroad, which he will carry out at the Massachusetts Institute of Technology in the group of Prof. Richard R. Schrock.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Paramagnetic Rh and Ir species are frequently more reactive than their closed-shell counterparts, and reveal a very different reactivity. Most of these metallo-radicals are low-spin 17- or 19-VE (valence electron) species with the unpaired spin-density located *at the metal*. Consequently, most of these species reveal metal-centered radical-type reactivity like halogen-atom abstraction, hydrogen abstraction and capture of other radicals by the metal (which includes dimerization with formation of metal–metal bonds).[3] Even more reactive $Rh^{II}$ porphyrin species are capable of breaking C–H bonds of rather inert substrates such as methane and methanol.[4] The reactivity of these "metallo-radicals" thus closely resembles that of an organic radical.

With increasing number of papers reporting about paramagnetic mononuclear Rh and Ir species,[5] their alkene adducts are still quite rare. This is not surprising, because these species tend to be very reactive and reveal a remarkable diversity of different radical-type reactions, both at the metal and at the alkene fragment.

Interestingly, the π-accepting alkene fragment is a potentially "redox non-innocent"[6] ligand (Figure 1), and "metallo-radical" and "alkene radical" descriptions both contribute to the electronic structure of a paramagnetic $M^x$(alkene) complex (M = Rh, Ir; $x$ = 0, +II). Species with an increased "alkene radical" contribution generally have a stronger tendency to undergo ligand-centered radical-type reactions. Such reactions are potentially useful as new alkene functionalization reactions, very different from those in traditional organometallic chemistry. Such species might participate in (new or existing) catalytic alkene transformation reactions, such as oxygenation, cyclopropanation and other alkene functionalization reactions.

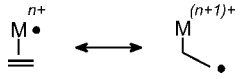

Figure 1. Ligand "redox non-innocence" in open-shell alkene transition-metal complexes.

In most cases the "metallo-radical" and "alkene radical" descriptions are limiting resonance structures of the real electronic structure, and frequently the "metallo-radical" description prevails (Figure 1). But the other extreme, in which the alkene accepts most of the spin density, can also play an important role. For example, "alkene radicals" of the type $Ir^{III}$–$CH_2$–$CH_2^{\cdot}$ are plausible intermediates in a series of radical-type reactions triggered by coordination of an additional ligand to otherwise stable $Ir^{II}$(ethene) species.[7,8]

In this review we provide an up-to-date overview of the unusual chemistry of paramagnetic $M^x$(alkene) species (M = Rh, Ir; $x$ = 0, +II). We start with a short description of species for which not much reactivity has been reported; i.e. sterically protected species and species where spin delocalization over other parts of the molecule deprives much of the radical character of the M(alkene) fragment. This review however focuses at the intriguing reactivity of paramagnetic M(alkene) species, underlining their dual-mode "metallo-radical" and "alkene-radical" behavior.

## 2. M(Alkene) Species Deprived of Metal- and Alkene-Radical Behavior

In this section we summarize the properties of a few rather inert paramagnetic M(alkene) radicals (M = Rh, Ir) for which not much reactivity has been reported. This includes sterically protected species and a series of species in which the unpaired spin is highly delocalized and/or located at another part of the molecule, thus depriving much of the radical character of the M(alkene) fragment.

### 2.1 Highly Delocalized Radicals and Paramagnetic M(Alkene) Species Bearing the Spin Density at Other Parts of the Molecule

Compared to alkenes, some well-known other "redox non-innocent" ligands are even more inclined to accept unpaired electrons from the metal to form ligand radicals. Paramagnetic M(alkene) species containing other "redox non-inocent" ligands are less inclined to undergo metal- or alkene-centered radical reactions. The radical is usually substantially stabilized when the spin density is spread out over an extended π system of the "redox non-innocent" ligand. Delocalization of unpaired spin density over multiple metal atoms of multinuclear species and clusters is another way to stabilize open-shell M(alkene) species (M = Rh, Ir). Such examples are summarized in this section.

#### *Spin Delocalization over Multiple Metal Atoms*

Several paramagnetic organometallic clusters, multinuclear wires and dinuclear species involving platinum, palladium, rhodium and iridium have been reported, among them a number of alkene complexes. The unpaired electron of such species is usually strongly delocalized over multiple metal centers, and consequently they do not behave like reactive M(alkene) radicals. It is not our intention to give a full comprehensive overview of all paramagnetic multinuclear species here. We will restrict ourselves to a very concise description of some of these species, and then proceed with a focus on the radical-type chemistry of mononuclear M(alkene) species.

Most multinuclear paramagnetic clusters and wires are connected by metal–metal bonds, often supported by bridging ligands. Examples are the wire-like tri- and tetranuclear Rh and Ir compounds of the type $[Rh_3(\mu_3\text{-}L)_2(CO)_2(\eta_4\text{-}cod)_2]^{2+}$,[9] $[Rh_2Ir(\mu_3\text{-}OMe_2napy)_2(CO)_2(cod)_2]^{2+}$,[10] and $[M_4(\mu\text{-}PyS_2)_2(bis\text{-}alkene)_4]^{+}$ (M = Rh, Ir).[11] These "molecular wires" have the unpaired electron delocalized over multiple metal centers, suggestive of potential conducting properties of such wires. The delocalization of the unpaired spin density contributes to the relative stability of these species. Several mixed-valent dinuclear rhodium and iridium complexes of the type $[M_2]^{3+}$ and $[M_2]^{5+}$ have been reported (M = Rh, Ir). These species are formally $M^{II}$ species bound to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

closed-shell $M^{I}$ or $M^{III}$ ions by metal–metal interactions. However, the actual electronic configuration of the $[Rh_2]^{5+}$ species is highly dependent on the type and number of ligands bound to the axial sites.[12–15] For example, in the complexes $[Rh(\eta^4\text{-cod})(\mu\text{-RNNNR})_2Ir(CO)_2]^+$ and $[Ir(\eta^4\text{-cod})(\mu\text{-RNNNR})_2Rh(CO)_2]^+$, the M(cod) fragment contains most of the unpaired electron density (80% and 75%, respectively).[16] This is even more drastic in case of $[I_2Rh(\mu\text{-RNNNR})_2Pd(\eta^3\text{-}C_3H_5)]^-$, which has 90% of the unpaired electron spin density located at the rhodium atom, with only 10% at palladium.[17] The steric bulk of these species likely protects these cod species from decomposing via allylic C–H activation (vide infra).

### *Semiquinone-Type Ligands*

Catecholate/quinone-type ligands are nowadays well-known "redox non-innocent" ligands.[18] The metal quinone, $M^{I}(Q)$, metal semi-quinone, $M^{II}(SQ^{\cdot-})$, and metal catecholate, $M^{III}(Cat^{2-})$, are description of either one electronic ground state (mesomeric form) or are distinct electronic states which are in equilibrium (redox isomerism) (Figure 2).

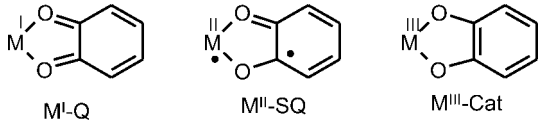

Figure 2. "Redox non-innocence" of catecholate/quinone-type ligands.

In 1992, when the "redox non-innocent" behavior of such ligands was not as well established as it is by now, formation of a paramagnetic $Ir^{IV}$(cod) species containing two 3,6-di-*tert*-butylcatecholate (3,6-DBCat) ligands was claimed.[19] A broad EPR resonance (200 G, $g$ = 1.986) was observed in solution. In frozen solution, the signal splits to give a rhombic spectrum with components $g_{11}$ = 1.948, $g_{22}$ = 1.942 and $g_{33}$ = 2.006, indicative of a mainly ligand-centered radical. Considering the meanwhile well-known "redox non-innocence" of catecholate/quinone-type ligands, the $[Ir^{III}$(3,6-DBCat)(3,6-DBSQ)(cod)] might thus be a better description of the electronic structure of this stable species.

### *Pyridine-2,6-diimine Complexes*

Pyridine-2,6-diimine ligands are meanwhile also well-known to be "redox non-innocent".[20] This also seems to play a role in their Rh chemistry. Reaction of alkyl pyridine-2,6-diimine rhodium(I) complexes with dihydrogen (Figure 3) leads to the formation of a paramagnetic $[Rh^{III}(H)_2(L^{-1})]$ or $[Rh^{I}(L^{-1})(X)]$ species (X = arene solvent, dinitrogen or dihydrogen).[21] The EPR spectrum of this species in frozen toluene shows an axial signal indicative of an $S = {}^1/_2$ species [$g_{\parallel}$ = 1.9775, $g_{\perp}$ = 2.0169, $A_{\parallel}$(N) = 40 MHz] with the unpaired electron being mainly located in one of the π* orbitals of the 2,6-pyridine-diimine ligand.[21,22] The mechanism by which these species are generated is not entirely clear.

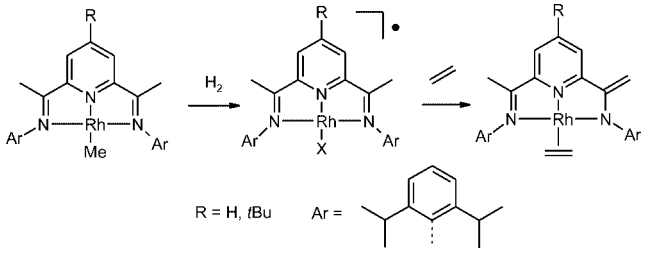

Figure 3. Chemistry of pyridine-diimine-supported alkyl rhodium(I) compounds involving open-shell intermediates.

Treatment of this species with an excess of alkenes eventually yields diamagnetic $[Rh^{I}(L_{-H})$(alkene)] species. The paramagnetic intermediate seems to be a hydrogenation catalyst of primary and secondary alkenes in the presence of $H_2$. The unpaired spin density in the π system of the pyridine-2,6-diimine ligand apparently has little influence on the intrinsic reactivity of Rh, as hydrogenation activity is most commonly observed for closed-shell Rh species.[21,22]

### *Aminyl Radical Complexes and Related Species Based on Trop-Type Ligands*

The Grützmacher group has extensively used tropylidene (trop) type ligands to stabilize a series of paramagnetic rhodium and iridium complexes (Figure 4, Figure 5). Remarkably, these complexes all appear to be "ligand radicals" and/or highly delocalized radicals.

For example, trop-type ligands allow isolation of $Rh^{I}$-coordinated aminyl radicals. Deprotonation of cationic $[Rh^{I}(trop_2NH)(bpy)]^+$ species generates a stable (under inert atmosphere) neutral amido complex $[Rh^{I}(trop_2N^{-})(bpy)]$. Remarkably, one-electron oxidation of the latter with $[Fc]^+$ does not result in the expected $Rh^{II}$ species, but yields an aminyl radical complex $[Rh^{I}(trop_2N^{\cdot})(bpy)]^+$ (see Figure 4). This is the first example of a stable aminyl radical coordinated to a transition metal ever reported.[23] Both detailed EPR spectroscopic investigations ($g_{11}$ = 2.0822, $g_{22}$ = 2.0467, $g_{33}$ = 2.0247, $A^{N}_{iso}$ = 45 MHz), and DFT calculations revealed that the unpaired electron is delocalized over the $R_2N$ (ca. 57%) fragment and Rh (ca. 30%), but with a clear preference for the N atom (Figure 4, top).

The nitrogen-centered radical is stable in organic solvents for days, and even when samples are brought in contact with air or water the EPR signals persist for hours. The aminyl radical fragment nevertheless behaves as a nucleophilic radical, capable of hydrogen atom abstraction reactions from $Bu_3Sn$–H or RSH (R = Ph, *t*Bu, $CH_2COOMe$), thus regenerating the $[Rh^{I}(trop_2NH)(bpy)]^+$ starting compound and $Bu_3Sn$–$SnBu_3$ or RS–SR coupled products. Despite a still significant spin density at the metal, metal-centered radical reactions were not observed. In later studies

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

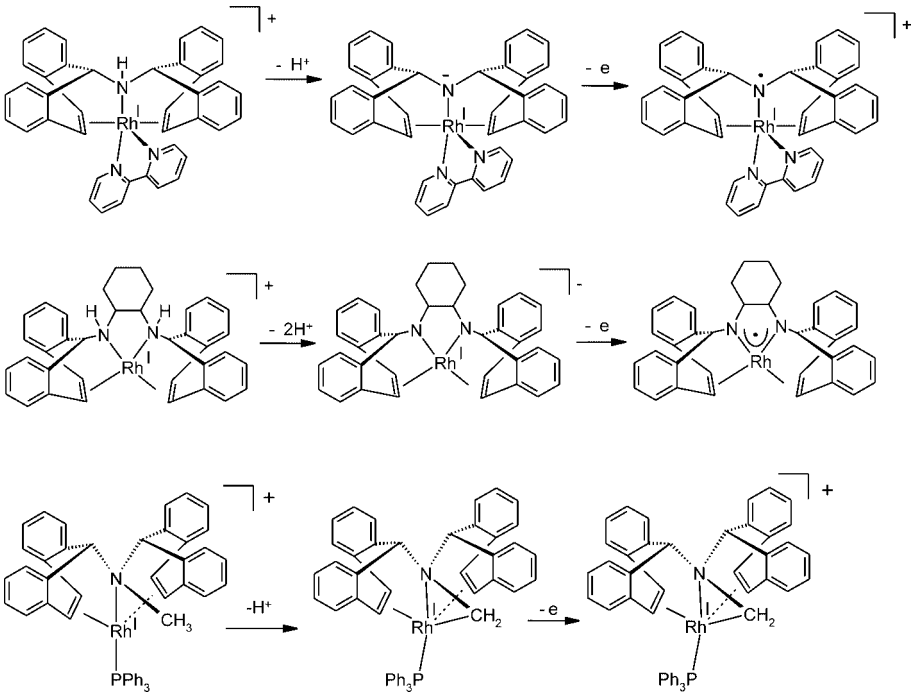

Figure 4. Top: Formation of a stable aminyl-$Rh^{I}$ radical complex by one-electron oxidation of a amido-$Rh^{I}$ complex. Middle: Formation of a trop-based N–M–N delocalized radical. Bottom: Formation of a highly delocalized rhoda-aza-cyclopropane radical from $trop_2N$-Me ligands.

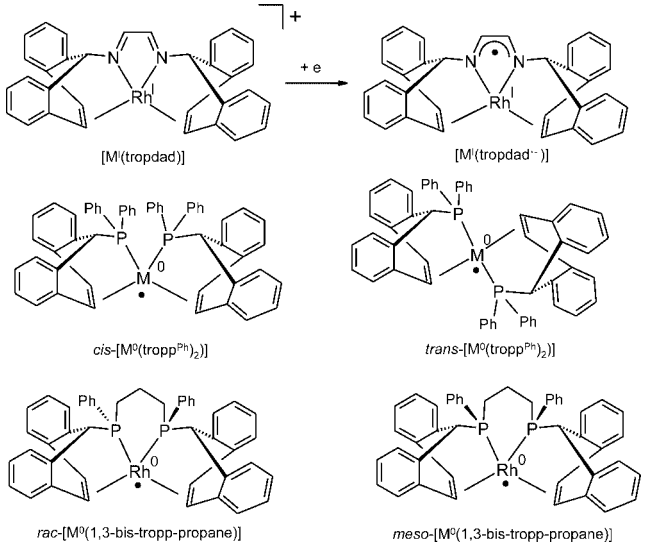

Figure 5."Low-valent" species based on the trop-type ligands.

the group also demonstrated the synthesis of a square-planar analog, in which the radical is substantially delocalized over Rh (ca. 41%) and the N atoms of two $NR_2$ fragments (ca. 24–28% each), see Figure 4.[24] The species still behaves as a nucleophilic *N*-centered radical, abstracting a hydrogen atom from $Bu_3Si$–H, despite a reduced spin localization per N atom.

Similar experiments were performed with a rhodium complex of the methyl-substituted $trop_2N$–Me ligand (Figure 4, middle). Deprotonation of $[Rh^{I}(trop_2N–Me)(PPh_3)]^+$ occurs at the methyl moiety of the $trop_2N$–Me ligand, resulting in formation of a rhoda-aza-cyclopropane ring structure.[25] The $[Rh^{I}(trop_2N–CH_2–)(PPh_3)]$ complex reveals a reversible oxidation wave in the cyclic voltammogram at a remarkably low potential (–0.51 V vs. $Fc/Fc^+$). Preparative one-electron oxidation of this species yields a stable cationic radical analog. The EPR data ($g_{11}$ = 2.121, $g_{22}$ = 2.014, $g_{33}$ = 2.016) reveal hyperfine couplings to Rh, N, the aza-cyclopropane methylene carbon and hydrogen atoms, and the trop olefinic carbon and hydrogen atoms. DFT calculations reveal that the unpaired electron is strongly delocalized over rhodium (47%), the methylene (14%), and the four olefinic carbon atoms (15%, 15%, 3% and 3%). This species is perhaps best described as a highly delocalized radical.

### *"Low-Valent" Species*

Tropylidene (trop) type ligands have also been used to stabilize a series of "low-valent" species. Electrochemical reduction of $[M^{I}(tropdad)]$ complexes, containing a "redox non-innocent" α-diimine fragment (Figure 5, top), leads to species in which the unpaired electron is located in the α-diimine π system.[26] Consistent with this formulation, the axial EPR spectra (M = Rh: $g_{\|}$ = 2.0113, $g_{\perp}$ = 1.9977, M = Ir: $g_{\|}$ = 2.0332, $g_{\perp}$ = 1.9870) have small deviations of the *g* values from $g_e$, and reveal small hyperfine couplings with Rh (no Ir hyperfine couplings were observed), and comparably stronger superhyperfine couplings with two equivalent N nuclei and two equivalent protons.

A further series of "low-valent" M(alkene) complexes were supported by tropylidene-phosphane (tropp) ligands (Figure 5). These species were also prepared by one-electron

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

reduction of their $M^I$ precursors (requiring strong reducing agents, such as metallic Li, Na or K). With the bidentate tropp$^{Ph}$ ligands, mixtures of *cis* and *trans* isomers of [$M^0$(tropp$^{Ph}$)$_2$] (M = Rh, Ir) were obtained. The EPR spectra reveal axial *g* tensors (*cis*-[(Rh$^0$(tropp$^{Ph}$)$_2$]: $g_\parallel$ = 2.030, $g_\perp$ = 2.014; *trans*-[(Rh$^0$(tropp$^{Ph}$)$_2$]: $g_\parallel$ = 2.050, $g_\perp$ = 2.030; *cis*-[(Ir$^0$(tropp$^{Ph}$)$_2$]: $g_\parallel$ = 2.030, $g_\perp$ = 2.060; *trans*-[(Ir$^0$-(tropp$^{Ph}$)$_2$]: $g_\parallel$ = 1.980, $g_\perp$ = 2.150. Detailed EPR characterization of these species reveal (super)hyperfine couplings with Rh (16–23 MHz) and the two equivalent P atoms of the tropp ligand (40–80 MHz). Remarkably, Ir hyperfine couplings were not observed, and Rh hyperfine couplings are quite small. The [(Rh$^0$(1,3-bis-tropp-propane)] analog (Figure 5) was prepared as a mixture of the *rac* and *meso* forms, but also in a pure *rac* form. The solution EPR spectrum of the *rac* form ($g_{iso}$ = 2.021) reveals superhyperfine coupling with two equivalent P nuclei (84 MHz). The *meso* form ($g_{iso}$ = 2.014) reveals superhyperfine coupling with two non-equivalent P nuclei (82 MHz and 51 MHz), likely caused by a distortion along one of the P–Rh bonds.

The *g* values of these "zero-valent" M(alkene) complexes are quite close to $g = g_e$. Their small *g* anisotropy and quite weak metal hyperfine couplings suggest that these species might not be real $d^9$ metal-centered radicals, but are perhaps better described as highly delocalized systems in which the unpaired spin density is substantially spread out over the metal and the trop ligand fragments. This is, however, not very clear and theoretical investigations are probably required to understand the electronic structure of these species. Spin delocalization to π-accepting CO and olefin ligands seems to be more general, and other Rh$^0$ complexes also reveal small deviations from $g = g_e$ (with weak metal hyperfine couplings), e.g. [Rh$^0$(cod)$_2$]: $g_{iso}$ = 2.030 ($A^{Rh}_{iso}$ not resolved);[27] [Rh$^0$(CO)$_4$]: $g_{iso}$ = 2.006 ($A^{Rh}_{iso}$ = 21 MHz).[28] The same holds for a series of Rh$^0$ complexes with π-accepting P ligands, which reveal larger phosphorus superhyperfine couplings than metal hyperfine couplings.[29] DFT calculations are in progress, and will hopefully lead to a more detailed understanding of the electronic structure of these Rh$^0$ species in the near future.[30] Notably, Rh$^0$ complexes of phosphinine-ring (P-analogs of pyridines, $R_5C_5P$) containing macrocyclic ligands (known to accommodate electrons) reveal similar EPR parameters ($g_{iso}$ = 2.0016, $A^P_{iso}$ = 49, $A^{Rh}_{iso}$ not resolved; $g_{iso}$ = 2.0180, $A^P_{iso}$ = 271 MHz, $A^{Rh}_{iso}$ = 27 MHz). According to DFT calculations (supported by EPR property calculations) these latter species are best described as ligand radicals.[31]

## 2.2 Sterically Protected Species

### *Sterically Protected M$^0$(alkene) Species*

Rh$^0$(cot) complexes (cot = cyclooctatetraene) with the very bulky $CpPh_5^-$ ligand have been prepared electrochemically.

Electrochemical reduction of [Rh$^I$(CpPh$_5$)(1,5-η$^4$-cot)] (cot = cyclooctatetraene) initially leads to the 1,5-COT Rh$^0$ analog, but this species quickly converts to the more stable 1,3-cot Rh$^0$ isomer (Figure 6). As a consequence, reoxidation of the Rh$^0$(1,3-cot) species occurs at a less negative potential (–1.37 V vs. Fc/Fc$^+$, Fc/Fc$^+$ = ferrocene/ferrocenium) than reduction of the Rh$^I$(1,5-cot) species (ca. –2.7 V vs. Fc/Fc$^+$). The EPR spectrum of [Rh$^0$(CpPh$_5$)(1,3-η$^4$-cot)] reveals a rhombic spectrum with $g_1$ = 2.064, $g_2$ = 2.014 and $g_3$ = 1.893. The $g_2$ line reveals a resolved Rh hyperfine coupling (ca. 20 MHz). No further reactivity has been reported.

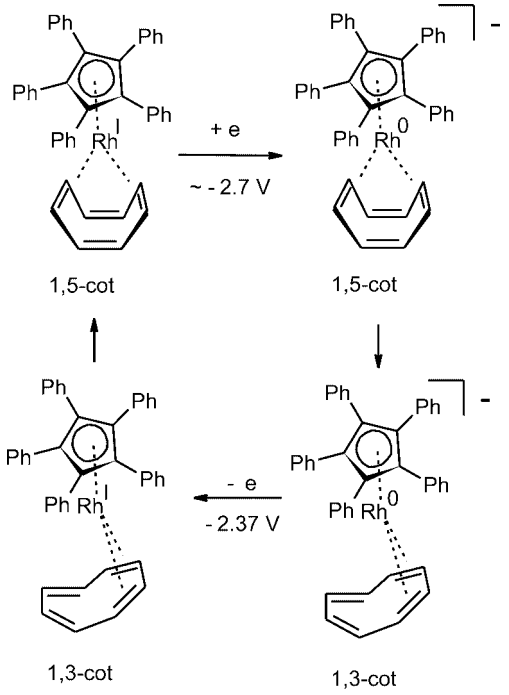

Figure 6. Formation of [Rh$^0$(CpPh$_5$)(1,3-η$^4$-cot)] upon one-electron reduction of [Rh$^I$(CpPh$_5$)(1,5-η$^4$-cot)].

Not much is known about the intrinsic reactivity of "zero-valent" M(alkene) species. Metal or alkene reactivity has not been reported for any of the above species, but this might be because these species are protected by steric bulk and/or substantial delocalization of their spin density. The situation might be different for species which are less delocalized and better accessible. This seems to be the case for [Rh$^0$(cod)$_2$], the only "zero-valent" species for which metal and alkene radical reactivity has been reported (to our best knowledge). [Rh$^0$(cod)$_2$] was prepared by electrochemical reduction of the [Rh$^I$(cod)$_2$]$^+$ precursor (cod = *Z,Z*-1,5-cyclooctadiene).[32] At low temperatures, the 17 VE (VE = valence electron) species is sufficiently long-lived for EPR measurements, revealing rhombic *g* values $g_1$ = 2.056, $g_2$ = 2.019 and $g_3$ = 2.016. Poorly resolved Rh hyperfine couplings (ca. 40–60 MHz) were observed. In chlorinated solvents such as $CH_2Cl_2$, the species abstracts a Cl atom from the solvent to form [{Rh$^I$(μ$_2$-Cl)(cod)}$_2$]. In acetone, the fate of [Rh$^0$(cod)$_2$] is less clear, but NMR spectroscopic data point to formation of diamagnetic species containing π-allylic moieties derived from cod, as is also observed for $M^{II}$(cod) species with an accessible metal center (see section 3.3).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *Sterically Protected $M^{II}$(alkene) Species*

Most divalent $M^{II}$(alkene) complexes are based on hard multidentate N-donor ligands (see section 3). Exceptions are a couple of stable $M^{II}$-cod complexes (cod = cyclooctadiene) stabilized by very bulky σ-aryl $C_6Cl_5^-$ and pentaphenylcyclopentadienyl ($\eta^5$-$CpPh_5^-$) type ligands, namely $[Ir^{II}(C_6Cl_5)_2(cod)]$,[33] $[Rh^{II}(C_6Cl_5)_2(cod)]$,[34] $[Rh^{II}(\eta^5$-$C_5Ph_5)(1,5\text{-cod})]^+$,[35] and $[Rh^{II}(\eta^5$-$C_5Ph_5)(1,3\text{-cod})]^+$,[35] see Figure 7. Steric shielding of the metal by the bulky ligands apparently results in stable species, and these complexes can be kept in solution for many hours without decomposition.

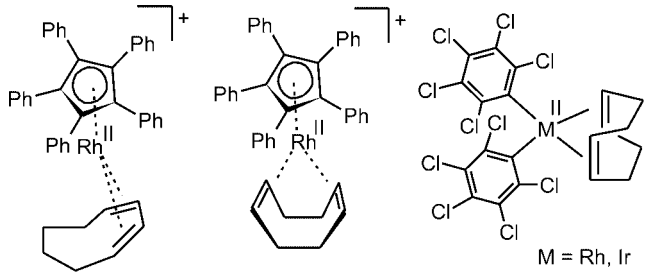

Figure 7. Stable $M^{II}$(alkene) complexes stabilized by $\eta^5$-$CpPh_5$ and σ-aryl-type ligands.

Rhombic EPR spectra have been observed for $[Ir^{II}(C_6Cl_5)_2(cod)]$ ($g_{11}$ = 3.00, $g_{22}$ = 2.79, $g_{33}$ = 1.85) and $[Rh^{II}(C_6Cl_5)_2(cod)]$ ($g_{11}$ = 2.55, $g_{22}$ = 2.45, $g_{33}$ = 1.99). The large *g* anisotropies are consistent with the proposed electronic structures, with the unpaired electron mainly residing in a $d_{xy}$ or $d_{z^2}$ orbital (with the *z* axis perpendicular to the coordination plane of rhodium). Substantially larger spin–orbit couplings are observed for the Ir compound ($g_{av}$ = 2.55) than for the Rh compound ($g_{av}$ = 2.32) which is usual for third row-compared to second-row transition metals. As expected, the $[Rh^{II}(\eta^5$-$C_5Ph_5)(1,3\text{-cod})]^+$ radical also gives rise to a rhombic EPR spectrum ($g_{11}$ = 2.329, $g_{22}$ = 2.120, $g_{33}$ = 2.003). The 1,5 isomer $[Rh^{II}(\eta^5$-$C_5Ph_5)(1,5\text{-cod})]^+$ reveals an axial EPR spectrum ($g_{\|}$ = 2.181, $g_{\perp}$ = 1.997) indicative of an approximate $C_{2v}$ symmetry. Neither of the species reveals resolved hyperfine couplings with the $^{103}$Rh nucleus, preventing assignments of the orbital composition of the SOMO.

Electrochemically reversible oxidation has been reported for the related complex $[Rh^{I}(Cp)(ethene)_2]$. Coulometrically generated samples revealed a broad spectrum around *g* = 1.9855 without a resolved hyperfine structure in dimethoxyethane solution at –70 °C (frozen solutions at 20–100 K would have probably resulted in more informative spectra).[36,37] A detailed characterization of this radical cation, which is only stable at low temperatures, is lacking so far. Clearly such $Cp^-$ complexes are much less stable than the above sterically protected $CpPh_5^-$ species.

More information about the intrinsic reactivity of $M^{II}$(alkene) species has been gathered using N-ligands. This is described in section 3.

## 3. Reactive $M^{II}$(alkene)(N-ligand) Species. Metal or Alkene Radicals?

Apart from the above exceptions, all other $M^{II}$(alkene) complexes (M = Rh, Ir), and reactions of $M^{II}$ radicals with alkenes, have been studied using mononuclear complexes with multidenate N-donor ligands. Neutral-type complexes of the $[M^{II}(por)]$-type based on dianionic porphyrinato ($por^{2-}$) ligands and dicationic complexes of the type $M^{II}(N_4\text{-ligand})]^{2+}$ and $[M^{II}(N_3\text{-ligand})]^{2+}$ based on neutral, podal $N\{CH_2Py\}_n$ (*n* = 2, 3) type ligands have so far dominated these studies (Figure 8).

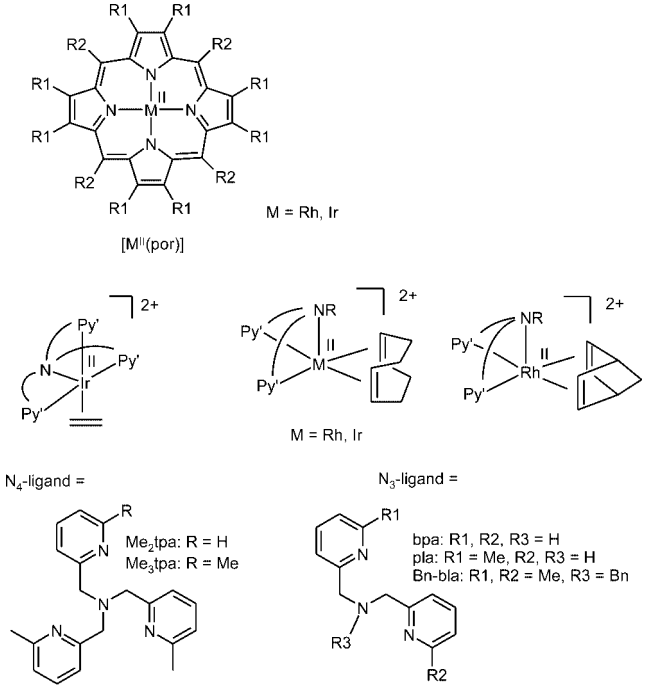

Figure 8. Structure of neutral $[M^{II}(por)]$ and dicationic $[Ir^{II}(N_4\text{-ligand})(ethene)]^{2+}$, $[Rh^{II}(N_3\text{-ligand})(nbd)]^{2+}$ and $[M^{II}(N_3\text{-ligand})(cod)]^{2+}$ species.

### 3.1 Geometries and Electronic Structures

Before we continue with a more detailed description of the geometry and electronic structures of complexes of the type $[M^{II}(por)]$ and $[M^{II}(N\{CH_2Py\}_n)]^{2+}$ (*n* = 2, 3) (section 3.1.2 and 3.1.3), let us first consider the most important differences between these types of species which are most relevant for their reactivity.

#### *3.1.1 Metal or Ligand Radicals?*

First of all, the porphyrinato complexes have *trans* vacant sites, and although perhaps not entirely impossible, *cis* reactivity patterns of alkenes and other substrates are not very likely for $[M^{II}(por)(alkene)]$ species. This should not be a problem for the dicationic $[M^{II}(alkene)(N_4\text{-ligand})]^{2+}$ and $[M^{II}(bis\text{-alkene})(N_3\text{-ligand})]^{2+}$ species, having a "vacant site" *cis* to the alkene (half occupied by the unpaired electron). Alkenes have a low affinity for $[M^{II}(por)]$ radicals, and once formed such alkene adducts tend to be very reac-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tive. As a result, alkene adducts of $[M^{II}(por)]$ radicals cannot be isolated, although they do reveal interesting reactions towards alkenes (section 3.2.1–3.3). Alkenes bind much stronger to dicationic $[M^{II}(N_4\text{-ligand})]^{2+}$- and $[M^{II}(N_3\text{-ligand})]^{2+}$-type complexes, allowing isolation and detailed characterization of the alkene adducts (section 3.1.2).

For the neutral $[M^{II}(por)]$ species, alkene→metal σ bonding is expected to be weaker than the dicationic $[M^{II}(N_4\text{-ligand})]^{2+}$ and $[M^{II}(N_3\text{-ligand})]^{2+}$ complexes (Figure 8). On the other hand, metal→alkene π(back)bonding, which contributes substantially to the metal–alkene interaction (Chatt–Dewar–Duncanson model), is expected to be stronger for the neutral $[M^{II}(por)]$ species. Therefore, one cannot ascribe the different alkene affinities *only* to the charge differences.

Another important difference between these types of complexes is the orbital symmetry. The $[M^{II}(N_4\text{-ligand})]^{2+}$ and $[M^{II}(N_3\text{-ligand})]^{2+}$ complexes have an empty $d_{x^2-y^2}$ and an empty p orbital available for alkene→metal σ bonding. The planar $[M^{II}(por)]$ species, however, have the *half-filled* $d_{z^2}$ orbital and the higher lying empty p orbital available for alkene→metal σ bonding, further weakening this interaction (Figure 9). A consequence of the $d_{z^2}$ orbital being involved in binding of the alkene in 17-VE $[M^{II}(por)(alkene)]$ species is that the alkene ligand will always bear a significant part of the unpaired spin density, thus making the alkene fragment sensitive to radical reactions. This is clearly reflected by the reactivity of $[M^{II}(por)(alkene)]$ species (see sections 3.2–3.3).

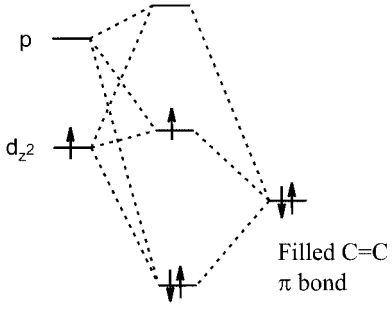

Figure 9. Alkene→metal σ bonding in $[M^{II}(por)(alkene)]$ species.

The alkene ligands of the 17-VE dicationic $[M^{II}(alkene)(N_4\text{-ligand})]^{2+}$ and $[M^{II}(di\text{-alkene})(N_3\text{-ligand})]^{2+}$ complexes do not bear much spin density (< 5%). The $d_{z^2}$ orbital, in which the unpaired electron is located, predominantly interacts with $N_{amine}$ donors, leaving the alkene ligands virtually unaffected.

### *Donor-Induced Metal to Ligand Radical Transformations in "19-VE" Species*

Binding of a 6th ligand to 17-VE five-coordinate $M^{II}$-(alkene) species substantially influences the reactivity of these species. Binding of an additional σ-donor ligand without loss of the alkene should be more easy for the dicationic $[M^{II}(alkene)(N_4\text{-ligand})]^{2+}$ and $[M^{II}(bis\text{-alkene})(N_3\text{-ligand})]^{2+}$ complexes compared to the neutral $[M^{II}(por)(alkene)]$ species. Indeed, indications for formation of such 19-VE intermediates have thus far only been obtained for $[Ir^{II}(ethene)(Me_ntpa)]^{2+}$ ($n$ = 2, 3) complexes.

Although the PyMe groups shield the "vacant site" of $[Ir^{II}(Me_ntpa)(ethene)]^{2+}$ species ($n$ = 2, 3) from attack by bulky reagents, MeCN is small enough to coordinate to iridium *trans* to the amine (Figure 10). Obviously, this is most easy for the least hindered $Me_2tpa$ species ($n$ = 2). Binding of MeCN (or other small ligands) causes these otherwise inert species to undergo alkene radical reactions (see sections 3.2.1 and 4).

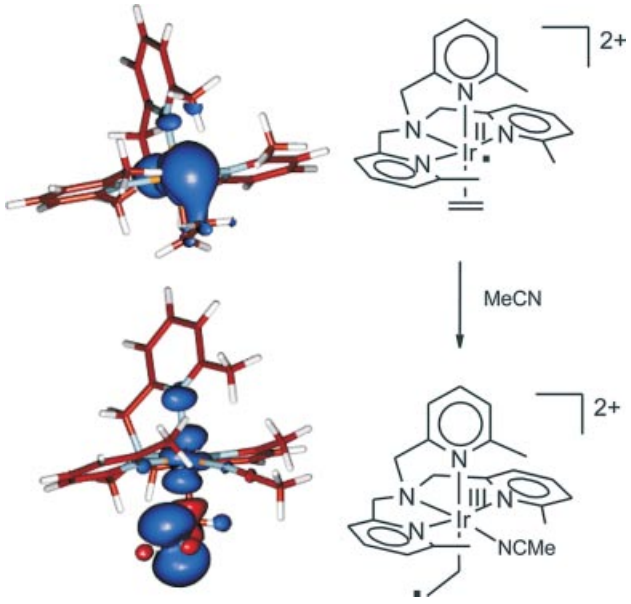

Figure 10. Spin density plots of $[Ir^{II}(Me_3tpa)(CH_2{=}CH_2)]^{2+}$ (above) and $[Ir^{III}(\text{-}CH_2\text{-}CH_2^{\cdot})(Me_3tpa)(NCMe)]^{2+}$ (below).

According to DFT calculations, these MeCN adducts have the ethene fragment coordinated in a "slipped" way. Whereas the α-carbon of the "slipped alkene" fragment seems to be tetrahedral and $sp^3$-hybridized, the β-carbon atom is planar and $sp^2$-hydridized. A spin-density plot (Figure 10) reveals that these species are not real 19 VE species, but are intermediate between a 19 VE "slipped alkene" description $Ir^{II}\text{–}CH_2\text{–}CH_2^+$ and an 18 VE ethyl radical description $Ir^{III}\text{–}CH_2\text{–}CH_2^{\cdot}$, but the 18 VE ethyl radical description prevails.[7] Thus, MeCN binding apparently leads to a donor induced shift of the spin density from the metal to the alkene with formation of $Ir^{III}\text{–}CH_2\text{–}CH_2^{\cdot}$ radicals. This substantially influences the reactivity of these species (see sections 3.2.1 and 4), and constitutes a new approach to tuning the reactivity of open-shell metal-alkene complexes.

### *3.1.2 (Electronic) Structure of Dicationic 17-VE $M^{II}$(alkene)(N{$CH_2Py$}$_n$) Radicals*

Species of the type $[Ir^{II}(N_4\text{-ligand})(ethene)]^{2+}$,[7,38,39] $[Rh^{II}(N_3\text{-ligand})(nbd)]^{2+}$[40] (nbd = norbornadiene) and $[M^{II}(N_3\text{-ligand})(cod)]^{2+}$[41,42] have been obtained from their

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$M^I$ precursors by one-electron oxidation using either $[Fc]^+$ or $Ag^+$ as an oxidant (Figure 8).

Cyclic voltammograms of these complexes revealed reversible waves for the $M^I/M^{II}$ couple in all cases, except for some of the less bulky cyclooctadiene complexes. The $M^{II}/M^{III}$ couple was not observed at potentials below oxidation of the solvent. Direct electron-transfer (ET) disproportionation of the dicationic $M^{II}$ species to monocationic $M^I$ and tricationic $M^{III}$ species is substantially endergonic (> 92–125 kJ mol$^{-1}$ in both acetone and $CH_2Cl_2$), and thus an unlikely decomposition pathway of these species.

The X-ray structures of $[Ir^{II}(Me_3tpa)(ethene)]^{2+}$[7,38] and $[Rh^{II}(Bn\text{-}bla)(cod)]^{2+}$[42] as well as their $M^I$ precursors have been reported. The $M^I$ species adopt a trigonal-bipyramidal geometry. Upon oxidation the geometry changes to a square pyramid with the amine at the apical position and the alkene(s) and the pyridines coordinating in the basal plane. The pyridylmethyl groups shield the "vacant position" *trans* to the amine (Figure 11). On going from $M^I$ to $M^{II}$, the M→alkene π backbonding becomes weaker, resulting in longer M–C and shorter C=C bonds. The M–N interactions become stronger. The structures elucidated by X-ray diffraction are consistent with DFT calculations and EPR data.

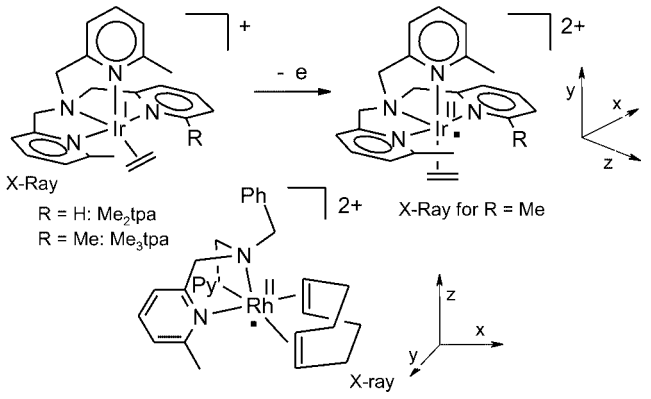

Figure 11. Sterically protected $[Ir^{II}(Me_ntpa)(ethene)]^{2+}$ and $[Rh^{II}(Bn\text{-}bla)(cod)]^{2+}$ species.

$[Rh^{II}(N_3\text{-ligand})(nbd)]^{2+}$ and $[Rh^{II}(N_3\text{-ligand})(cod)]^{2+}$ show EPR spectra with $g_x$, $g_y > 2$ and $g_z \approx 2$, with $g_z$ revealing a strong (super)hyperfine coupling with both the metal and the apical $N_{amine}$ donor.[40–42] These data suggest that the unpaired electron resides in the $d_{z^2}$ orbital, in good agreement with results from DFT calculations. For all analogous Ir compounds the $g_z$ value is notably lower than $g_e$, pointing to some mixing of the $d_{z^2}$ orbital with a $d_{x^2-y^2}$ orbital ($d_{xy}$ for the cod complexes) in the SOMO.

The EPR parameters calculated with DFT are in satisfactory agreement with the experimentally derived parameters. Experimental ENDOR measurements, as well as DFT spin density plots reveal that the spin density is substantially delocalized over the $N_{amine}$ donor (15–18%) and the metal (73–78%).[42] Delocalization of the unpaired electron over the metal and the amine might contribute to the relative stability of these species.

### *3.1.3 (Electronic) Structure of Neutral 17-VE $M^{II}$(alkene)(por) Radicals*

Radical-type chemistry of neutral square-planar $N_4$-ligand $Rh^{II}$ species has been mainly studied with porphyrinato ($por^{2-}$) ligands, but similar chemistry for the dianionic planar coordinating $N_4$-ligands TMTAA,[43] OETAP,[44] and DBPB[45] (Figure 12) has been reported.

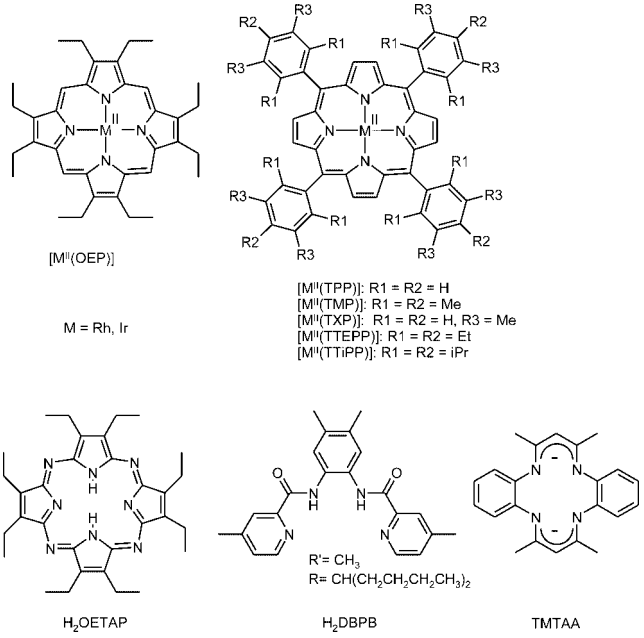

Figure 12. Porphyrinato $Rh^{II}$ and $Ir^{II}$ complexes and related N-ligands used in the organometallic chemistry of planar $Rh^{II}$ metallo-radicals.

Generally, mononuclear $[M^{II}(por)]$ species (Figure 12) are prepared by thermally or photo-chemically induced homolytic M–M, M–H or M–C bond splitting of their corresponding M–M, $M^{III}$–Me or $M^{III}$–H precursors.[46] Occasionally, also (electro)chemical reduction or oxidation has been applied.[47–49]

In all cases the mononuclear square planar $d^7$ complexes are very reactive. As a result, the least hindered complexes containing the porphyrins OEP (octaethylporphyrinato), TPP tetraphenylporphyrinato, TTP (tetratolylporphyrinato) and TXP [tetrakis(3,5-dimethylphenyl)porphyrinato] easily dimerize (Figure 13) to form diamagnetic metal–metal-bonded dinuclear species (in which a description as $M^I$–$M^{III}$ is indistinguishable from a antiferromagnetically coupled $M^{II}$–$M^{II}$ system). The Rh–Rh bond is, however, rather weak and allows thermal homolytic Rh–Rh bond splitting to study the reactivity of the mononuclear species. To promote dissociation of the dinuclear Rh–Rh species in mononuclear square planar $d^7$ species, porphyrin ligands have been supplied with bulky groups at their periphery. The steric bulk of the porphyrin dianion decreases in the order TTiPP > TTEPP > TMP > TXP > TTP > TPP > OEP

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(see Figure 12). More bulky porphyrins result in weaker Rh–Rh bonds (Rh–Rh bond dissociation enthalpies: OEP: 69 kJ mol$^{-1}$; TXP: about 50 kJ mol$^{-1}$; TMP: about 0 kJ mol$^{-1}$) and consequently more reactive systems.[50–52]

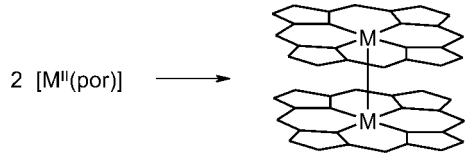

Figure 13. Formation of dinuclear M–M bonded species from [M$^{II}$(por)] species (M = Rh, Ir).

The complexes [Rh$^{II}$(TMP)], [Rh$^{II}$(TTEPP)], [Rh$^{II}$-(TTiPP)], [Ir$^{II}$(TTEPP)] and [Ir$^{II}$(TTiPP)] are sufficiently bulky to completely prevent dimerization [TMP = tetramesitylporphyrinato; TTEPP = tetra(2,4,6-triethylphenyl)porphyrinato TTiPP = tetra(2,4,6-triisopropylphenyl)porphyrinato]. EPR spectroscopy, $^1$H NMR paramagnetic shifts and line broadening studies have proven useful to study the (electronic) structure of these paramagnetic complexes (and their adducts with ethene, see below).[52–54] EPR parameters of the rhodium complexes [Rh$^{II}$(TMP)] and [Rh$^{II}$-(TTiPP)] are consistent with a prevalent $d_{z^2}$ SOMO associated with a $(d_{xy})^2(d_{xz,yz})^4(d_{z^2})^1$ ground state. Remarkably, the iridium complex [Ir$^{II}$(TTiPP)] does not reveal an observable EPR spectrum, which was explained by the presence of one or more excited states with energies close to the ground state, causing rapid electron-spin relaxation.[55] This was further confirmed by the thermal behavior of the pyrrole chemical shifts. While a linear dependence of the paramagnetic shift of [Rh$^{II}$(TTiPP)] against 1/T (inverse of the temperature) indicates a simple Curie paramagnetic behavior associated with a single contributing state [$(d_{z^2})^1$], the curvature of the plot for [Ir$^{II}$(TTiPP)] suggests that several states are thermally populated. The upfield chemical shifts of the pyrrole hydrogen atoms ($\delta_{pyr}$ = –20.9 ppm) compared to the downfield chemical shift of [Rh$^{II}$(TTiPP)] ($\delta_{pyr}$ = +17.5 ppm) was taken as evidence for spin population of the porphyrin π*-orbitals in case of iridium. This can be explained by assuming an $(d_{xy})^2(d_{z^2})^2(d_{xz,yz})^3$ground state, in contrast to the $(d_{xy})^2(d_{xz,yz})^4(d_{z^2})^1$ ground state observed for the rhodium analog.

### 3.2 Reactivity of M$^{II}$(alkene)(N-ligand) Species without Allylic Hydrogen Atoms

#### *3.2.1 M–C and C–C Coupling Reactions*

A variety of alkenes react with [Rh$^{II}$(OEP)] (Figure 12) to form binuclear alkyl-bridged [Rh$^{III}$(OEP)(μ-CH$_2$CHR-)-Rh$^{III}$(OEP)] complexes (Figure 14). The reaction of [Rh$^{II}$-(OEP)] with styrene was claimed to proceed by a radical chain mechanism.[56] In the absence of [Rh$^{III}$(OEP)(H)], the initially formed [Rh$^{II}$(OEP)(CH$_2$=CHPh)] intermediate reacts with another [Rh$^{II}$(OEP)]$_2$ complex abstracting a [Rh$^{II}$(por)] radical, thus yielding the alkyl-bridged species [Rh$^{III}$(OEP)(μ$_2$-CH$_2$CHPh-)Rh$^{III}$(OEP)]. In the presence of [Rh$^{III}$(OEP)(H)], the intermediate [Rh$^{II}$(OEP)(CH$_2$=CHPh)] abstracts a hydrogen atom from [Rh$^{III}$(OEP)(H)] to form a mononuclear alkyl complex [Rh$^{III}$(OEP)(CH$_2$CH$_2$Ph)] (Figure 14).

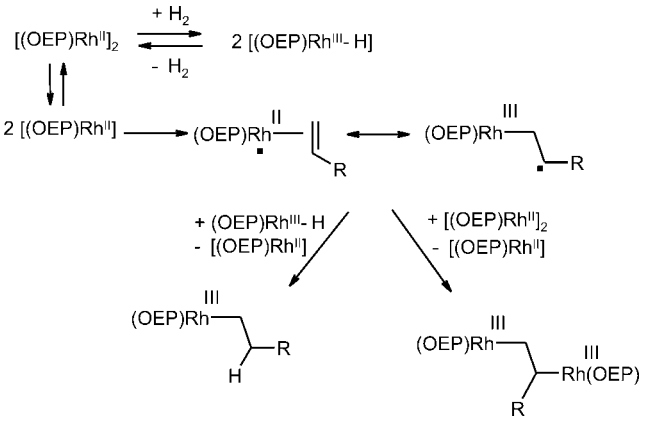

Figure 14. Reactivity of [Rh$^{II}$(por)] and [Rh$^{III}$(por)(H)] towards alkenes without allylic hydrogen atoms.

Other alkenes like acrylates[57] give similar alkyl-bridged species [Rh$^{III}$(OEP)(μ$_2$-CH$_2$CHR-)Rh$^{III}$(OEP)], and acetylenes give the corresponding μ$_2$-CH=CR-bridged species [Rh$^{III}$(OEP)(μ$_2$-CH=CHR-)Rh$^{III}$(OEP)].[58]

A series of more hindered [Rh$^{II}$(por)] complexes with por = TMP, TTEPP and TTiPP provide further insight in the behavior of the [Rh$^{II}$(por)(alkene)] intermediates. Like [Rh$^{II}$(OEP)], the least hindered [Rh$^{II}$(TMP)] reacts with ethene to form the diamagnetic ethylene-bridged species [Rh$^{III}$(TMP)(μ$_2$-C$_2$H$_4$-)Rh$^{III}$(TMP)] by a bimolecular M–C coupling reaction.[59] Increasing the steric bulk by using TTEPP prevents direct M–C coupling, and [Rh$^{II}$(TTEPP)] reacts with ethene via a bimolecular C–C coupling between two rhodium–ethene radicals to form the butylene-bridged species [Rh$^{III}$(TTEPP){μ$_2$-CH$_2$CH$_2$–CH$_2$CH$_2$–Rh$^{III}$-

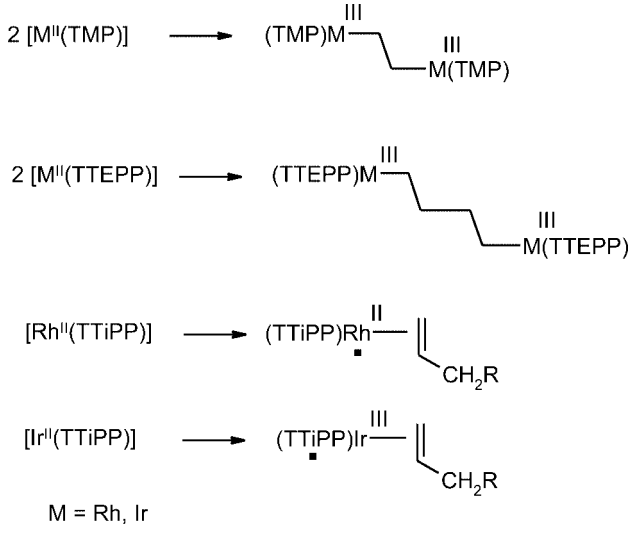

Figure 15. The reactivity of [M$^{II}$(por)] species changes from M–C to C–C coupling to no coupling at all upon increasing the steric bulk.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(TTEPP)}], see Figure 15.[60] A similar intermolecular $C_{alkene}$–$C_{alkene}$ bond formation involving two cot ligands was observed following oxidation of [$Rh^{I}$(Cp)(cot)].[61]

Neither for [$Rh^{II}$(TMP)] nor for [$Rh^{II}$(TTEPP)] any intermediates were observed with EPR spectroscopy. However, a further increase of the steric bulk by using [$Rh^{II}$(TTiPP)] gives rise to a reasonably stable paramagnetic ethene adduct [$Rh^{II}$(TTiPP)($CH_2$=$CH_2$)]$^{\cdot}$, revealing a rhombic EPR spectrum at 90 K ($g$ values: $g_1$ = 2.323, $g_2$ = 2.222 and $g_3$ = 1.982). A substantial spin population at ethene (ca. 0.29) was derived from the $^{13}$C hyperfine couplings of [$Rh^{II}$(TTiPP)($^{13}CH_2$=$^{13}CH_2$)] ($A_{zz}$: 38 MHz, $A_{xx}$ = $A_{yy}$ ≈ 5 MHz).[60,62] The spin population at rhodium was estimated at about 0.67. The equivalence of the two $^{13}$C atoms in the EPR spectrum reveals a symmetrically bound ethene π complex, and the delocalization of the unpaired electron to the ethene fragment (29%) occurs almost entirely by the $C_{2p}$ orbitals. At temperatures > 200 K [$Rh^{II}$(TTiPP)(ethene)] loses the ethene fragment to form [$Rh^{II}$(TTiPP)].[63]

Reactions of the iridium complexes [$Ir^{II}$(TMP)] and [$Ir^{II}$(TTEPP)] with ethene proceed analogously to the above described rhodium analogs (Figure 16).[64] Like its rhodium analog, reaction of [$Ir^{II}$(TTiPP)] with ethene does not result in M–C or C–C coupling, and formation of the ethene adduct is witnessed by NMR, UV/Vis ($\lambda_{max}$ = 444 nm and 730 nm) and EPR spectroscopy [$<g>$ = 1.987 (290 K); $g_{\|}$ = 1.96, $g_{\perp}$ = 1.998 (90 K)]. However, these spectroscopic data are indicative of a donor-induced intramolecular electron transfer from the $Ir^{II}$ center to the porphyrin ligand π* orbital to yield a $Ir^{III}$(por$^{\cdot 3-}$) species. This contrasts the results obtained by ethene binding to [$Rh^{II}$(TTiPP)], where the unpaired electron remains in the $d_{z^2}$ orbital.

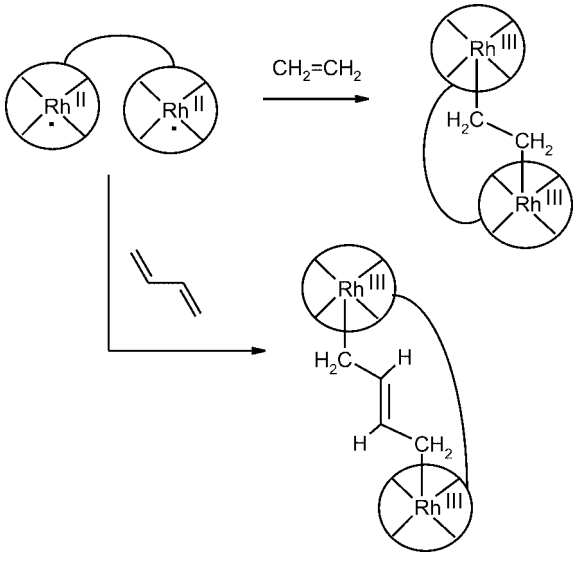

Figure 16. Reaction of alkenes with tethered (por)$Rh^{II}$ complexes.

Selective binding of ethene and butadiene between the two rhodium sites of a tethered bimolecular bis(por)Rh species with steric demands comparable to TMP, results in selective intramolecular coupling (Figure 16).[65] This gives further support to the idea that formation of alkyl-bridged species from alkenes and [$M^{II}$(por)] requires a concerted action of two metallo-radical sites.[60]

The reactions of [$Rh^{II}$(por)] with alkenes reveal that the [$Rh^{II}$(por)(alkene)] intermediates have a substantial spin density at the alkene fragment. This prompted the Wayland group to investigate attempts to initiate radical polymerization of acrylates with these species.[57] Although photo-promoted radical initiation (involving homolytic Rh–C bond splitting) was achieved, direct radical initiation with [$Rh^{II}$(OEP)] or [$Rh^{II}$(TMP)] proved not possible.

On the basis of an estimated Rh–$CH_2$R bond dissociation enthalpy (BDE) of ca. 209 kJ mol$^{-1}$, the energy associated with alkene binding to [$Rh^{II}$(por)] estimated at 0–33 kJ mol$^{-1}$,[57,63] and the energy required to convert ethene into its diradical $^{\cdot}CH_2$–$CH_2^{\cdot}$ (268 kJ mol$^{-1}$), formation of an intermediate [$Rh^{III}$(por)($CH_2$–$CH_2^{\cdot}$)] species with 100% spin population at the β-carbon atom requires about 59 kJ mol$^{-1}$. Relaxation of this species to the more stable π complex [$Rh^{II}$(por)($CH_2$=$CH_2$)] should be exothermic by about 59–92 kJ mol$^{-1}$.[57] On the basis of these arguments (and the above EPR results), the authors argued that [$Rh^{II}$(por)(alkene)] complexes are not authentic alkyl radicals and therefore cannot initiate alkene polymerization reactions (Figure 17).

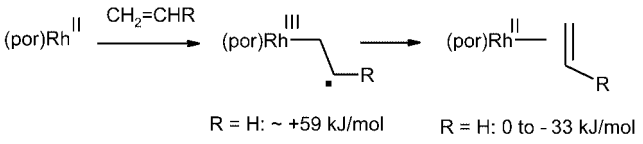

Figure 17. [$Rh^{II}$(por)(alkenes)]; metal- or carbon-centered radicals?

These arguments also imply that formation of "slipped olefin"/ethyl radical species [$M^{II}$(por)($CH_2$–$CH_2^{\cdot}$)] could be rather unfavorable for these complexes. On the other hand, coupling of two [$M^{II}$(por)(alkene)] species with C–C bond formation to yield $M^{III}$–$CH_2CH_2$–$CH_2CH_2$–$M^{III}$ are most likely to proceed via species having at least some [$Rh^{III}$(por)($CH_2$–$CH_2^{\cdot}$)] contribution to their electronic structure. Furthermore, substituents known to stabilize radicals should favor the [$Rh^{III}$(por)($CH_2$–$CHR^{\cdot}$)] contribution [e.g. R = Ph, C(O)R, CN, alkyls in Figure 17].

Binding of an additional σ-donor ligand to neutral 17-VE [$M^{II}$(por)(alkene)] species might not be very easy, but might nevertheless facilitate formation of such bent [$Rh^{III}$(por)($CH_2$–$CH_2^{\cdot}$)] intermediates. This is inspired by recent investigations concerning the reactivity of [$Ir^{II}$($Me_3$tpa)(ethene)]$^{2+}$ with a variation of substrates in MeCN as a solvent. Unlike the [$M^{II}$(por)(alkene)] species, these [$Ir^{II}$($Me_3$tpa)(ethene)]$^{2+}$ complexes do not spontaneously form butylene or ethylene-bridged dinuclear $M^{III}$–$CH_2$-$CH_2CH_2CH_2$–$M^{III}$ or $M^{III}$–$CH_2CH_2$–$M^{III}$ species. In the presence of MeCN, however, such reactivity is triggered (Figure 18). These reactions likely proceed via the $Ir^{III}$–$CH_2$–$CH_2^{\cdot}$-type radicals shown in Figure 10 (see section 3.1.1). A stronger M–C bond of Ir compared to Rh is per-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

haps a further contributing factor to stabilization of the bent alkene structure in $[Ir^{III}(Me_3tpa)(MeCN)(CH_2–CH_2^{\cdot})]^{2+}$ compared to $[Rh^{II}(por)(alkene)]$.

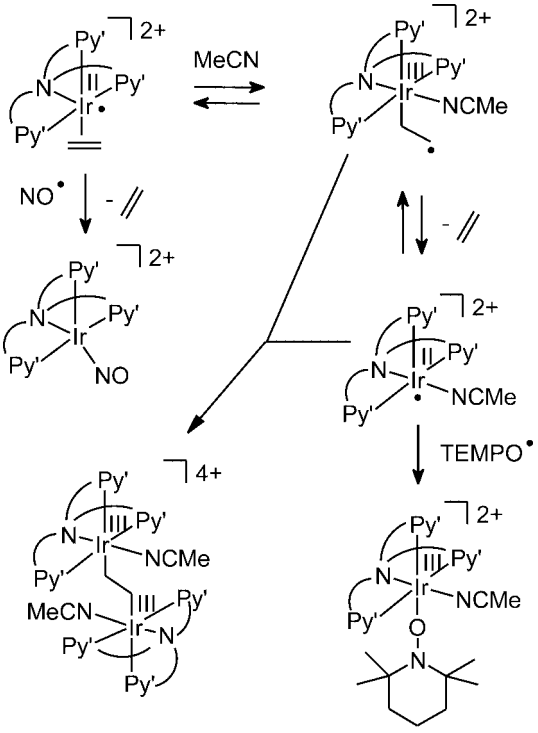

Figure 18. Formation of $Ir^{III}–CH_2CH_2–Ir^{III}$ and $Ir^{III}$-TEMPO via $Ir^{III}(CH_2CH_2^{\cdot})$(NCMe) and $Ir^{II}$(NCMe) species.

Dissociation of ethene from $[Ir^{III}(CH_2CH_2^{\cdot})(Me_3tpa)(NCMe)]^{2+}$ leads to the reactive metallo-radical $[Ir^{II}(Me_3tpa)(NCMe)]^{2+}$. This species contains only N-donor ligands and has its unpaired electron located in an orbital which is not sterically shielded by the ligand bulk. Although there is no spectroscopic evidence for formation of $[Ir^{III}(CH_2CH_2^{\cdot})(Me_3tpa)(NCMe)]^{2+}$ nor $[Ir^{II}(Me_3tpa)(NCMe)]^{2+}$, their existence can be rationalized from the reaction products of the $Ir^{II}$(ethene) species in acetonitrile. In the presence of the stable radical TEMPO, radical coupling of the metallo-radical $[Ir^{II}(Me_3tpa)(NCMe)]^{2+}$ with TEMPO takes place, leading to the formation of $[Ir^{III}(TEMPO^{-})(Me_3tpa)(NCMe)]^{2+}$. In the absence of TEMPO, $[Ir^{II}(Me_3tpa)(NCMe)]^{2+}$ couples with $[Ir^{II}(Me_3tpa)(CH_2CH_2)]^{2+}$, or perhaps more likely $[Ir^{III}(CH_2CH_2^{\cdot})(Me_3tpa)(MeCN)]^{2+}$ to form an ethylene-bridged species (Figure 18).[7,39] The increased reactivity on going from $Me_3tpa$ to the less bulky $Me_2tpa$ complex in formation of the ethylene-bridged species, is in good agreement with the proposed associative addition of acetonitrile to $[Ir^{II}(Me_ntpa)(ethene)]^{2+}$ being the first step of the dimerization process.

In contrast to reactions of $[M^{II}(por)]$ with alkenes, no butylene-bridged species were formed. Apparently, the concentration of $[Ir^{III}(CH_2CH_2^{\cdot})(N_4\text{-ligand})(MeCN)]^{2+}$ is too low for carbon–carbon coupling reactions to take place, and metal–carbon couplings with $[Ir^{II}(N_4\text{-ligand})(NCMe)]^{2+}$ species prevail.

The formation of the similar products $[\{Ir^{III}(Me_3tpa)(NCMe)\}_2(\mu_2\text{-}CH_2CH_2)]^{4+}$, $[\{Ir^{III}(Me_3tpa)(NCPh)\}_2(\mu_2\text{-}CH_2CH_2)]^{4+}$ and $[\{Ir^{III}(Cl)(Me_3tpa)\}_2(\mu_2\text{-}CH_2CH_2)]^{2+}$ indicate that this chemistry is not restricted to acetonitrile and expands to other σ-donors (nitrils, $Cl^{-}$, $H_2O$).[7,8]

### *3.2.2 [$Rh^{II}$(por)(alkene)] Intermediates in Alkene Insertions into Rh–H Bonds*

Insertion reactions of alkenes into the Rh–H bonds of the less hindered porphyrinato complexes $[Rh^{III}(OEP)(H)]$ and $[Rh^{III}(TPP)(H)]$ are strongly related to the above described reactivity of $[M^{II}(por)]$ radicals with alkenes. Because $[Rh^{III}(por)(H)]$ species lack any *cis* vacant sites, these insertion reactions are quite remarkable and do not likely proceed via a common (migratory) insertion requiring coordination of the olefinic substrates *cis* to the Rh–H bond. In fact the insertion reactions are reported to proceed through radical mechanisms. The hydride species are in equilibrium with the $[Rh^{II}(por)]_2$ dimeric species (Figure 14) through bimolecular reductive elimination of $H_2$ (a process not accessible for the more hindered TMP or TTiPP complexes).[66] Then, thermal homolytic bond splitting of the Rh–Rh bond allows formation of a reactive mononuclear $Rh^{II}$(alkene) adduct, which subsequently reacts with $H_2$ or $[Rh^{III}(por)(H)]$ to abstract a hydrogen atom to give the "insertion" product $[Rh^{III}(por)(CH_2CH_2R)]$. Similar "insertions" of alkenes into the Rh–H bond of $[Rh^{III}(TPP)(H)]$ (via similar radical pathways) have been used to obtain $Rh^{III}–CH_2–$(alkyl)–Nu*H* species (Nu*H* = OH, NH) using alkenes functionalized with end-on -OH and -NH functionalities. Under basic conditions, intramolecular $S_N2$-type attack of the Nu at the α-carbon atom of $Rh^{III}–CH_2–$(alkyl)–Nu yields $[Rh^{I}(TPP)]^{-}$ and cyclic organic products [–$CH_2$–(alkyl)–Nu–], see Figure 19. Protonation of $[Rh^{I}(TPP)]^{-}$ then allows regeneration of $[Rh^{III}(TPP)(H)]$. The combination of these reactions constitutes a new method for selective intramolecular anti-Markovnikov hydrofunctionalization of alkenes with O–H and N–H functionalities.[67] In this way three- and five-membered ring compounds (epoxides, furan deriv-

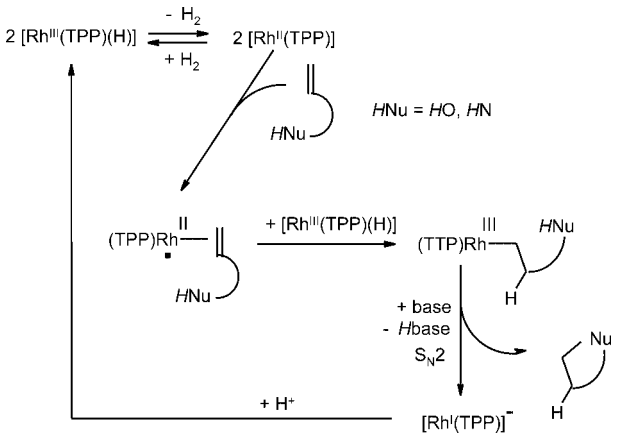

Figure 19. Selective intramolecular anti-Markovnikov hydrofunctionalization of alkenes with O–H and N–H functionalities via radical insertion of alkenes in the Rh–H bond.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atives, pyrrolidine derivatives) were readily obtained. Formation of four- or six-membered rings proved not possible, and lead to regeneration of the starting alkenes instead (by a net β-hydrogen elimination).

The (TPP)Rh system efficiently mediates all steps, but the system is not capable of mediating the anti-Markovnikov hydro-functionalization reactions in a one-pot catalytic reaction. So far, the reaction conditions required for the different reaction steps proved incompatible.

### *3.2.3. [M$^{II}$(por)(alkene)] Intermediates in Reactions of [M$^{III}$(por)(alkyl)] Species with Nitroxyl Radicals*

[M$^{II}$(por)(alkene)] species (M = Rh, Ir) also seem to be important intermediates in reactions of [M$^{III}$(por)(alkyl)] species with TEMPO and related nitroxyl radicals (M = Rh, Ir, por = TTP, TMP and some less common OMP, BTPP and BOCP porphyrinato ligands shown in Figure 20).

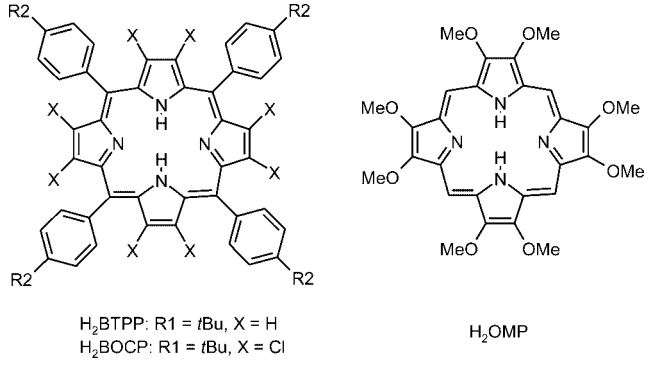

Figure 20. Ligand coding of the porphyrins BTPP, BOCP and OMP.

The [M$^{III}$(por)(alkyl)] complexes lacking β-hydrogen atoms do not react with nitroxyl radicals, but (por)Rh–alkyl species with β-hydrogen atoms eliminate alkene fragments upon heating in the presence of TEMPO.[68,69] For R = –CH$_2$–CH$_2$–Ph, formation of styrene was confirmed with NMR (Figure 21).

Abstraction of β-hydrogen atoms from alkyl species [M$^{III}$(por)(–CH$_2$CH$_2$R)] yields alkyl radical species [M$^{III}$(por)(–CH$_2$CHR$^{\cdot}$)], which are in fact the same activated β-alkyl radicals resulting from increasing the M–C–C angle of [M$^{II}$(por)(CH$_2$=CHR)] species. These [M$^{III}$(por)(–CH$_2$CHR$^{\cdot}$)] species should thus easily relax to the more stable alkene complexes [M$^{II}$(por)(CH$_2$=CHR)]. Because [Rh$^{II}$(por)] species have only a weak affinity for alkenes,[63] [M$^{II}$(por)(CH$_2$=CHR)] should readily lose the alkene (Figure 21). The resulting 15 VE [Rh$^{II}$(por)] species subsequently react with TEMPO to form [Rh$^{III}$(por)(CH$_3$)] by a C–C bond activation reaction with net abstraction of a methyl radical from TEMPO. Formation of [Rh$^{II}$(TMP)(R)] species by a net abstraction of an alkyl radical R$^{\cdot}$ from a nitroxyl radical (R′R$_2$C)$_2$NO$^{\cdot}$ has also been observed for isolated [Rh$^{II}$(TMP)] species in the presence of nitroxyl radicals (see Figure 21).[70] The mechanisms of the latter reactions are not very clear yet.

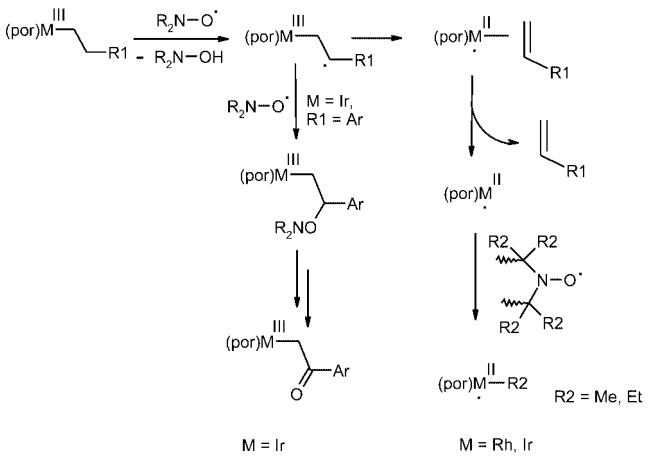

Figure 21. Reaction of TEMPO and related nitroxyl radicals with [M$^{III}$(por)(alkyl)] species (M = Rh, Ir) via [M$^{II}$(por)(alkene)] intermediates.

For the analogous iridium complexes [Ir$^{III}$(TTP)(R)], similar results were obtained upon reaction with TEMPO. Complexes lacking β-hydrogen atoms did not react, and non-aromatic alkyl complexes eliminate alkenes allowing formation of [Ir$^{III}$(TTP)(CH$_3$)] by C–C activation of TEMPO by [Ir$^{II}$(TTP)]. Arylethyl complexes [Ir$^{III}$(TTP)(–CH$_2$CH$_2$Ar)], however, reveal different products, which further support the proposed radical abstraction mechanism.[71] Under N$_2$, TEMPO oxidizes the [Ir$^{III}$(TTP)(–CH$_2$CH$_2$Ar)] species selectively at the β position to yield [Ir$^{III}$(TTP){–CH$_2$C(O)Ar}] (Figure 21). The mechanism proposed for this reaction involves abstraction of a β-hydrogen atom from [Ir$^{III}$(TTP)(–CH$_2$CH$_2$Ar)] by TEMPO to give [Ir$^{III}$(TTP)(–CH$_2$CH$^{\cdot}$Ar)] and TEMPO*H*. Apparently, due to stabilization of the β-carbon radical by the aromatic group and a substantially stronger Ir–C bond compared to a Rh–C bond, this species is sufficiently long-lived to react with a second TEMPO moiety. Coupling of the [Ir$^{III}$(TTP)(–CH$_2$CH$^{\cdot}$Ar)] radical with the TEMPO radical was proposed to yield a [Ir$^{III}$(TTP)(–CH$_2$CHAr–O–NR$_2$)] intermediate. The latter could then decompose to the observed [Ir$^{III}$(TTP){–CH$_2$C(O)Ar}] species, either directly through a hydrogen shift (with elimination of R$_2$NH) or by abstraction of the remaining β-hydrogen by an additional TEMPO moiety.

### 3.3 Reactivity of M$^{II}$(alkene)(N-ligand) Species Bearing Allylic Hydrogen Atoms

Reaction of [Rh$^{II}$(OEP)] with alkenes (CH$_2$=CHR) containing allylic hydrogen atoms such as allylbenzene (R = CH$_2$Ph), allyl cyanide (R = CH$_2$CN) and 1-hexene (R = CH$_2$C$_3$H$_8$) results in formation of σ-allyl complexes [Rh$^{III}$(OEP)(CH$_2$CH=CHR)] in about 50% yield (Figure 22).[58] A more detailed study concerning the behavior of [Rh$^{II}$(OEP)] towards propene was reported.[72] Propene initially forms the alkyl-bridged species [Rh$^{III}$(OEP){μ$_2$-CH$_2$CH(Me)-}Rh$^{III}$(OEP)]. This species reveals an interest-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing 1,2-exchange of the two metal sites, reflecting the lability of the Rh–C bond. The species is not stable and converts over the course of some days to a 1:1 mixture of the σ-allyl species [$Rh^{III}$(OEP)($CH_2CH{=}CH_2$)] and the propyl species [$Rh^{III}$(OEP)($CH_2CH_2CH_2$)], which likely involves a net transfer of an allylic hydrogen atom from [$Rh^{II}$(OEP)-(propene)] to another [$Rh^{II}$(OEP)(propene)] species (obtained from [$Rh^{III}$(OEP)($\mu_2$-$CH_2CH$(Me)-)$Rh^{III}$(OEP)] by Rh–C homolysis), see Figure 22.

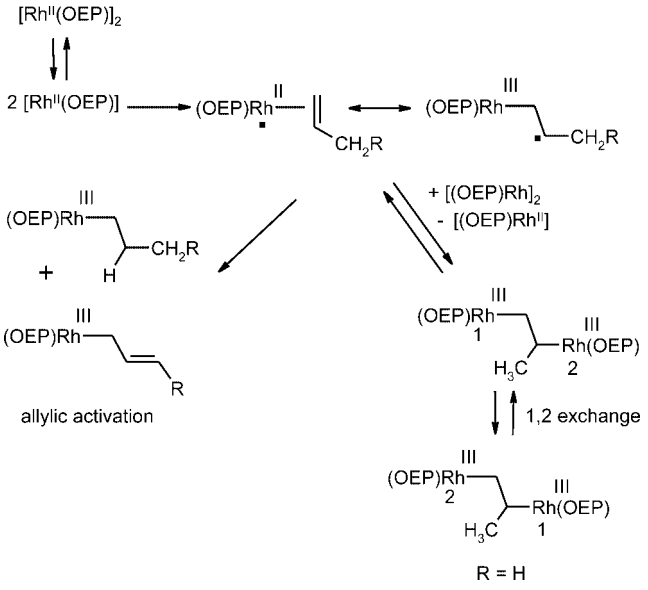

Figure 22. Reactivity of [$Rh^{II}$(por)] species towards alkenes containing allylic hydrogen atoms.

A comparable allylic activation of methyl methacrylate [$CH_2$=C(Me)(COOMe)] was reported to give a 1:1 mixture of [$Rh^{III}$(OEP){$CH_2C$(COOMe)=$CH_2$}] and [$Rh^{III}$(OEP)-{$CH_2CH$(Me)(COOMe)}]. Reaction of the sterically more hindered [$Rh^{II}$(TMP)] with methyl metacrylate yields a 1:1 mixture of [$Rh^{III}$(TMP){$CH_2C$(COOMe)=$CH_2$}] and [$Rh^{III}$(TMP)(H)]. The reactions were proposed to proceed by abstraction of an allylic hydrogen atom from the metallo-radical alkene complex [$Rh^{II}$(por){$CH_2$=C-(Me)(COOMe)}] by the metallo-radical [$Rh^{II}$(por)] to yield directly the σ-allyl complex [$Rh^{III}$(por){$CH_2C$-(COOMe)=$CH_2$}] and the hydride species [$Rh^{III}$(por)(H)]. As described above, the OEP complexes allow "insertion" reactions into the Rh–H bond, which for methyl methacrylate yields [$Rh^{III}$(OEP){$CH_2CH$(Me)(COOMe)}]. Alkene "insertion" into the Rh–H bond of the TMP complexes does not occur, presumably for steric reasons.

Further evidence for allylic C–H activation of $M^{II}$(α-alkene) species proceeding via bimolecular abstraction of an allylic hydrogen by another $M^{II}$ species was gathered by studying the decomposition of dicationic [$M^{II}$(cod)($N_3$-ligand)]$^{2+}$ species. Although the [$M^{II}$(cod)($N_3$-ligand)]$^{2+}$ species can be isolated as pure compounds, in solution they decompose through an allylic C–H activation process. The [$M^{II}$($N_3$-ligand)(cod)]$^{2+}$ complexes invariably decompose to 1:1 mixtures of [$M^{III}$($N_3$-ligand)(cyclooctadienyl)]$^{2+}$ and species that could be described as "protonated $M^{I}$(cod)" species. For the "protonated $M^{I}$(cod)" species the position of the proton depends on the nature of the metal. The proton ends-up at the metal for iridium, forming [$Ir^{III}$(H)($N_3$-ligand)(cod)]$^{2+}$, and at the $N_3$-ligand Py moiety for rhodium, forming [$Rh^{I}$($N_3$-ligand*H*)(cod)]$^{2+}$ (Figure 23).[41,42] The reaction rates decrease upon increasing the steric bulk of the $N_3$-ligand.

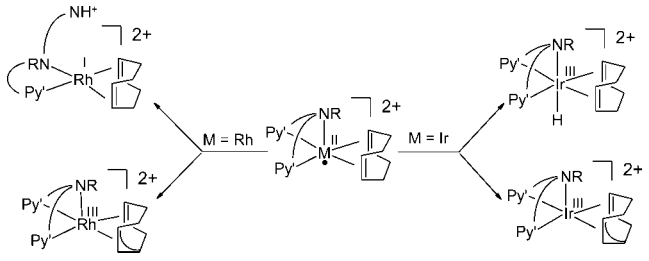

Figure 23. Selective conversion of the [$M^{II}$($N_3$-ligand)(cod)]$^{2+}$ complexes to allyl species [$M^{III}$(cyclooctadienyl)($N_3$-ligand)]$^{2+}$ (M = Rh, Ir) and equimolar amounts of [$Rh^{I}$($N_3$-ligandH)(cod)]$^{2+}$ (for M = Rh) or [$Ir^{III}$(H)($N_3$-ligand)(cod)]$^{2+}$ (for M = Ir).

The product ratio can be explained by a hydrogen-atom transfer from one $M^{II}$(cod) species to another $M^{II}$(cod) species. An electron-transfer (ET) disproportionation reaction between two $M^{II}$(cod) species to give $M^{I}$(cod) and $M^{III}$-(cod) followed by a proton transfer from an allylic position of $M^{III}$(cod) to $M^{I}$(cod) was ruled out.[41,42] A direct hydrogen-atom abstraction (at least in case of the more hindered Bn-dla ligands) of an allylic hydrogen atom of $M^{II}$(cod) by another $M^{II}$ species also seems unlikely, because the metal is rather shielded by the $N_3$-ligand PyMe bulk. The kinetic rate expression $v = k_{obsd.}$ [$M^{II}$]$^2$ in acetone, with $k_{obsd.} = k$[$H^+$][S] and [S] being the concentration of additional coordinating reagents (MeCN), is in agreement with a solvent-assisted dissociation of one of the pyridine donors.[42] Pyridine dissociation results in formation of more open, reactive species. Protonation of the non-coordinating pyridine increases the concentration of this species, and thus [$H^+$] appears in the kinetic rate expression. Both the rate expression and the kinetic activation parameters ($\Delta H^{\#}$ = 50 ± 8 kJ mol$^{-1}$, $\Delta S^{\#}$ = –113 ± 42 J K$^{-1}$ mol$^{-1}$ and $\Delta G_{289K}{}^{\#}$ = 84 ± 21 kJ mol$^{-1}$) are in agreement with a subsequent bimolecular hydrogen-atom transfer from an allylic $M^{II}$(cod) position to another $M^{II}$ species (Figure 24).

Formation of $M^{III}$(allyl) species from $M^{II}$(alkene) species (M = Rh, Ir) bearing allylic hydrogen atoms seems to be a more general decomposition pathway of such species. As described above, it has been observed as a decomposition pathway of [$M^{II}$(cod)($N_3$-ligand)]$^{2+}$ compounds, and in reactions of α-alkenes with [$Rh^{II}$(por)] species. Formation of [$Rh^{III}$($R_3$-Cp)(allyl)]$^+$ (allyl) species was also reported for in situ generated [$Rh^{II}$($R_3$-Cp)(cod)]$^+$.[73] Furthermore, one-electron oxidation of [$Ir^{I}$($Me_2$tpa)(propene)]$^+$ with [Ag]$PF_6$ in acetonitrile afforded the $Ir^{III}$(allyl) species [$Ir^{III}$($\eta^3$-propenyl)($Me_2$tpa)]$^{2+}$ in about 50% yield ($Me_2$-tpa = *N*-(2-pyridylmethyl)-*N*,*N*-bis[(6-methyl-2-pyridyl)methyl]amine), see Figure 25.[42]

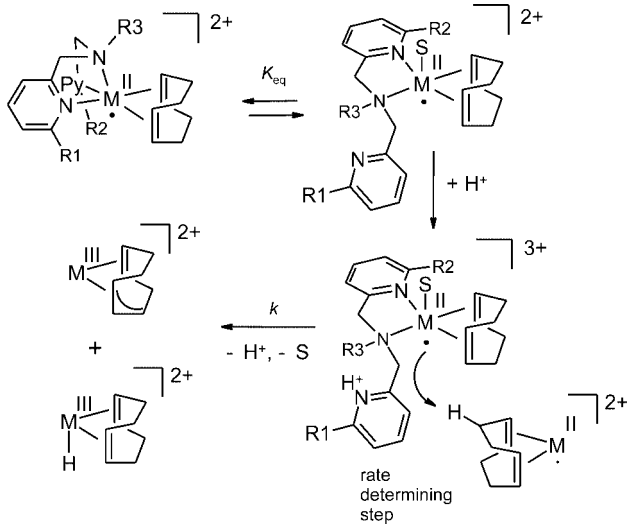

Figure 24. Proposed mechanism for the hydrogen-atom transfer between two $M^{II}$(cod) species.

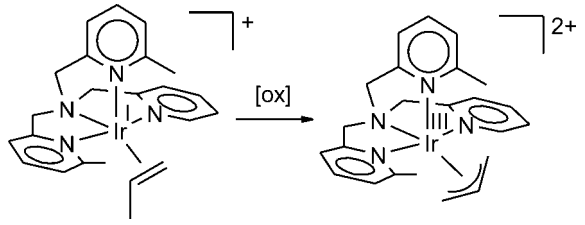

Figure 25. Formation of an $Ir^{III}$(allyl) species by oxidation of $[Ir^{I}(propene)(Me_2tpa)]^+$.

Notable exceptions to the general tendency of $M^{II}$(α-alkene) species (M = Rh, Ir) decomposing to $M^{III}$(allyl) species are the complexes $[M^{II}(C_6Cl_5)_2(1,5\text{-cod})]$ (M = Rh, Ir), $[Rh^{II}(\eta^5\text{-}C_5Ph_5)(1,5\text{-cod})]^+$ and $[Rh^{II}(\eta^5\text{-}C_5Ph_5)(1,3\text{-cod})]^+$, which are stable at room temp.[33–35] These species are sterically rather shielded around the metal, which might explain their relative stability. This can be taken as a further indication that such decomposition pathways proceed through bimolecular allylic H-atom abstraction by metal-centered radicals.

## 4. $M^{II}$(alkene) Species as Intermediates in Rh- and Ir-Catalyzed Alkene Oxygenation?

Though less well-known than Pd, both Rh and Ir are able to catalyze oxidation of alkenes with $O_2$ and $H_2O_2$,[74] Rh generally being more effective than Ir. Oxidation of terminal alkenes almost invariably results in formation of methyl ketones. Oxidation of internal alkenes leads to epoxides, allylic alcohols, ethers or ketones. The mechanistic picture of rhodium-catalyzed oxidations is complex with several mechanisms being proposed for various catalysts under different conditions: Wacker-type reactivity, reaction of a metal peroxide with the alkene to a peroxymetallacycle, formation of an intermediate hydroperoxo or alkylperoxo complex which reacts with the alkene, and some early work on alkene oxidation with peroxo Rh and Ir complexes was shown to proceed through free-radical pathways. In attempts to collect mechanistic information about rhodium- and iridium-catalyzed oxygenation of alkenes, stoichiometric oxygenation of N-ligand $Rh^{I}$- and $Ir^{I}$-alkene complexes by $O_2$ has been investigated in detail over the past years.[74,75] Oxygenation products strongly vary with the N-ligand, the alkene (ethene, propene, 1,5-cyclooctadiene and other dienes) and the central metal (Rh, Ir), see Figure 26.

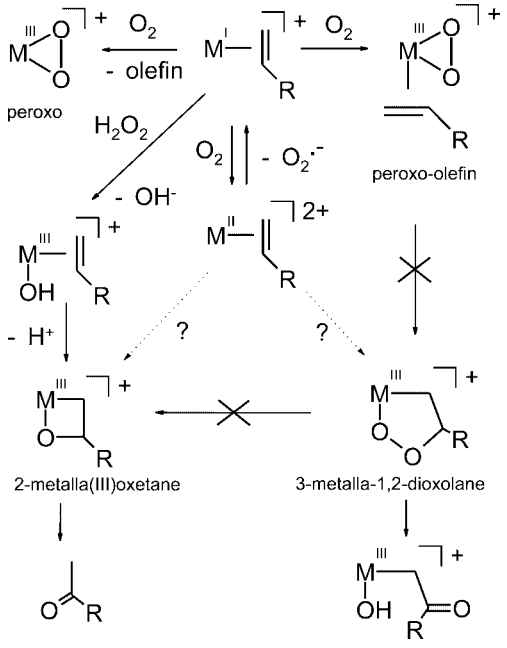

Figure 26. Oxygenation products from reaction of $[M^{I}(alkene)(N\text{-ligand})]^+$ species with $O_2$.

The reactivity of N-ligand $Rh^{I}$ and $Ir^{I}$-alkene fragments towards dioxygen varies between alkene displacement, formation of mixed $O_2$-alkene complexes, C–O bond formation (giving a 3-metalla-1,2-dioxolane), and combined O–O bond breaking/C–O bond making (giving a 2-metallaoxetane). Isolated peroxo complexes showed no further reactivity towards alkenes or alkene complexes, and isolated peroxo–ethene complexes did not contract to the corresponding peroxo-metallacycles (Figure 26). Isolated 3-metalla-1,2-dioxolanes, which were proposed as key-intermediates in the catalytic reactions, do not eliminate methyl ketones at all, but instead convert to formylmethyl-hydroxido complexes (Figure 26). The isolated 2-metalla(III)oxetanes, despite not being proposed in the catalytic reactions previously, proved actually much more likely candidates to be such key-intermediates. These species readily eliminate methyl ketones (acetaldehyde in case of the ethene precursor); the exact same products as obtained in the catalytic reactions. Formation of methyl ketones could not be demonstrated for any of the peroxo, peroxo–alkene or metal-dioxolane species. An important unanswered question is the mechanism of 2-metalla(III)oxetane formation in these reactions. Formation of 2-metalla(III)oxetanes from $M^{I}$-(alkene) and $H_2O_2$ seems straightforward (a net $OH^+$ transfer to the metal, followed by alkene insertion into the $M^{III}$–OH fragment,[74] see Figure 26), but the essential C–O

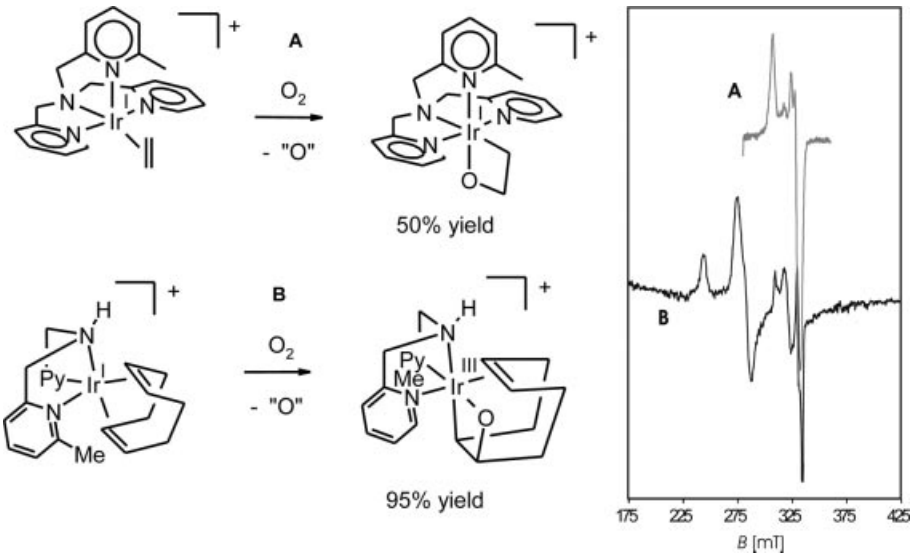

Figure 27. Formation of metallaoxetanes from reaction of $Ir^{I}$-alkene fragments with $O_2$ and the detection of possible $Ir^{II}$ and $Ir–O_2^{\cdot-}$ intermediates.

bond making step in oxygenation reactions of $M^{I}$(alkene) species with $O_2$ remains rather unclear.

Notably, for some of the more interesting reactions in Figure 26 leading to C–O bond formation with $O_2$, paramagnetic species were detected accompanying product formation. For example, reaction of $[Ir^{I}$(ethene)(Metpa)$]^+$ and $[Ir^{I}$(cod)(bpaMe)$]^+$ with $O_2$ in $CH_2Cl_2$ leads to formation of the corresponding 2-metallaoxetanes (Figure 27) in about 50% and 95% yield, respectively. These reactions consume only one O atom of $O_2$ per metal complex. The fate of the other O atom is not known.[76,77] Interestingly, during the course of these reactions, weak EPR signals were observed pointing to formation of paramagnetic Ir species, which are either intermediates or side products.[78,79]

To shed some light on the possible role of paramagnetic $M^{II}$(alkene) complexes in the essential C–O bond formation steps of these reactions, the reactivity of isolated $[M^{II}$-(alkene)(N-ligand)$]^{2+}$ species towards $O_2$ has been investigated in detail.

Treatment of $[Ir^{II}(Me_3tpa)(ethene)]^{2+}$ and $[M^{II}$(dpa)-(cod)$]^{2+}$ with dioxygen leads to formation of new EPR spectra.[8,38,41,42] A substantial decrease in the *g* anisotropy indicates a shift of the spin density from the metal to dioxygen. The observed spectra are consistent with formation of the superoxide complexes $[Ir^{III}(O_2^{\cdot})(Me_3tpa)(ethene)]^{2+}$ and $[M^{III}(O_2^{\cdot})$(dpa)(cod)$]^{2+}$. Formation of superoxide complexes from $[M^{II}(N_3$-ligand)(cod)$]^{2+}$ and $O_2$ appears to be reversible. Increasing the N-ligand steric bulk decreases the oxygen affinities. Reaction of $[Rh^{II}$(pla)(cod)$]^{2+}$ with $O_2$ only leads to small concentrations of $[Ir^{III}(O_2^{\cdot})$(pla)(cod)$]^{2+}$. The $[Rh^{II}$(R-bla)(cod)$]^{2+}$ (R = H, Bn) and $[Rh^{II}$(pla)-(nbd)$]^{2+}$ complexes proved to be air stable as a result of shielding by the bulky Py–Me groups.

No C–O bond-formation reactions were observed for any of the $[M^{III}(O_2^{\cdot})(N_3$-ligand)(cod)$]^{2+}$ complexes. These species decompose to the same mixture of compounds as observed for $[M^{II}(N_3$-ligand)(cod)$]^{2+}$ in absence of $O_2$ (see above).[41,42] Thus, unless these species play a role as co-catalysts, it seems unlikely that $M^{II}$(cod) species are intermediates in formation of 2-metalla-oxetanes from $M^{I}$(cod) complexes and $O_2$. For ethene complexes the situation might be different. $[Ir^{II}(Me_2tpa)(ethene)]^{2+}$ reacts rapidly with $O_2$, but not selectively (all solvents). The fate of the more hindered analog $[Ir^{III}(O_2^{\cdot})(Me_3tpa)(ethene)]^{2+}$ depends on the solvent. The reaction in acetone leads to yet unidentified products. The reaction in MeCN takes a different course (as described hereafter). To shed some light on these reactions, $[Ir^{III}(O_2^{\cdot})$(ethene) $(Me_3tpa)]^{2+}$ was trapped with DMPO.[8] This led to dissociation of ethene and formation of a C–O bond between the superoxide and DMPO (Figure 28). The peroxide-bridged species likely rearranges to a species with an acetal group, thus explaining the absence of proton hyperfine couplings in EPR. The unusual large N hyperfine coupling ($A^{N}_{average}$ = 74 MHz) compared to trapped organic radicals ($A^{N}$ = 42 MHz) indicates that the unpaired electron resides mainly at the nitrogen part of the nitroxyl group.[80] Therefore, DMPO appears to be coordinated to the iridium center. This is confirmed by the unusually large *g* anisotropy ($g_{11}$ = 2.036, $g_{22}$ = 2.014, $g_{33}$ = 1.986) for a DMPO-trapped radical (Figure 28). At room temperature this species converts to a diamagnetic species with a coordinated oxygenated DMPO fragment. This likely involves hydrogen abstraction from the solvent and elimination of $H_2O$ (Figure 28). Remarkably, such obtained solvent radicals were trapped by $Ir^{II}$ species, rather than the spin-trap DMPO. ESI-MS indicated clear formation of $[Ir^{III}(CH_2CN)(Me_3tpa)]^{2+}$ in acetonitrile and $[Ir^{III}(CH_2COCH_3)(Me_3tpa)]^{2+}$ in acetone.

The reactions of $[Ir^{III}$(ethene)$(N_4$-ligand)$]^{2+}$ species with dioxygen in the presence of MeCN result in formation of $Ir^{III}–CH_2C(O)H$ species. These reactions likely proceed via $[Ir^{III}(CH_2CH_2^{\cdot})(N_4$-ligand)(MeCN)$]^{2+}$ intermediates, which are easily formed upon contact with MeCN as described in section 3.1.1 (Figure 10). Quite likely, the triplet biradical

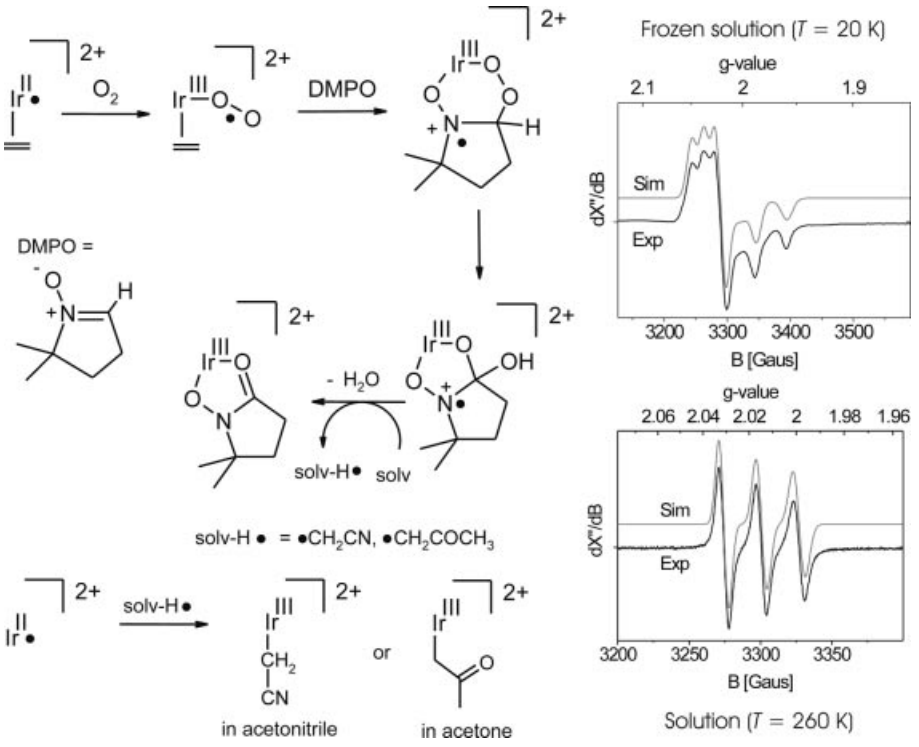

Figure 28. Proposed mechanism for the oxygenation of DMPO at $Ir^{II}$ and the EPR spectra belonging to the paramagnetic Ir–$O_2$–DMPO intermediate.

dioxygen reacts directly with the β-carbon-centered radical of $[Ir^{III}(CH_2CH_2^{\cdot})(N_4\text{-ligand})(MeCN)]^{2+}$ to give $Ir^{III}$–$CH_2CH_2OO^{\cdot}$ species. The latter alkylperoxo radical species then abstracts a hydrogen atom from acetonitrile, leading to a hydroperoxo intermediate $Ir^{III}$–$CH_2CH_2OOH$, which eliminates water to give the observed $Ir^{III}$–$CH_2C(O)H$ species (Figure 29).[8,38] Also in this case, the remaining solvent radical is trapped by the $Ir^{II}$ starting material. An alternative mechanism via $[Ir^{III}(O_2^{\cdot})(N_4\text{-ligand})(ethene)]^{2+}$ species cannot be ruled out completely though.

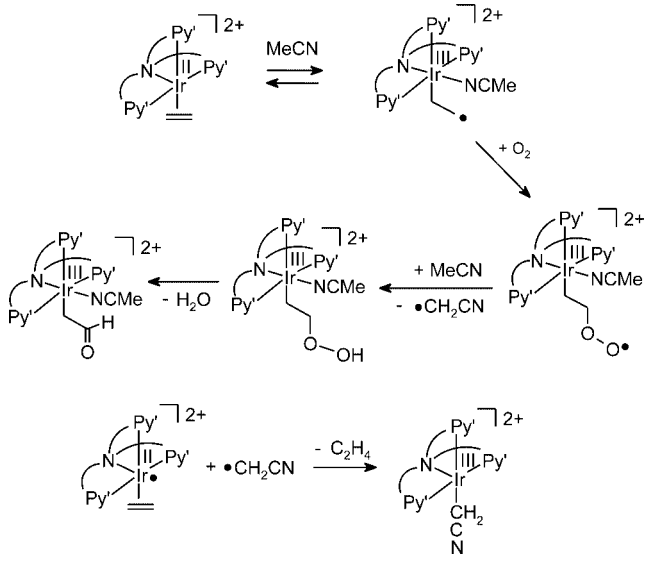

Figure 29. Proposed mechanism for the mono-oxygenation of $[Ir^{II}(Me_3tpa)(ethene)]^{2+}$ in acetonitrile.

With the exception of $M^{II}$(ethene) species, $M^{II}$(α-alkene) species are not very likely to be directly involved in the C–O bond-making processes of rhodium- and iridium-catalyzed alkene oxygenation reactions described by Mimoun, Read, Drago and others.[74] It seems that even in the presence of $O_2$, allylic C–H activation is the preferred kinetic decomposition pathway of such α-alkene complexes. Generally, such obtained (kinetically inert) $M^{III}$(allyl) species are not reactive towards $O_2$. $M^{II}$ species without a coordinated alkene might be involved though, perhaps facilitating formation of peroxides from $O_2$ and a sacrificial reductant (often an alcohol in the catalytic reactions). Such peroxides easily react with $M^{I}$(α-alkene) species to yield methyl ketones [via 2-metalla(III)oxetanes as intermediates, as described above, see Figure 26].

Somewhat related to this topic, $M^{II}$(nbd) species are potential Wacker-type catalysts for oxidation of norbornadiene to norbornenone. Dicationic $[M^{II}(bis\text{-alkene})(N_3\text{-ligand})]^{2+}$ species are stable towards ET disproportionation. The situation, however, changes in the presence of chloride anions, which trigger ET disproportionation. Formation of dicationic $[M^{III}(Cl)]$ products is probably less unfavorable than formation of tricationic $M^{III}$ species. Interestingly, $Cl^-$ triggered disproportionation of $[Rh^{II}(pla)(nbd)]^{2+}$ in the presence of water or alcohols led to formation of $[Rh^{I}(pla)(nbd)]^{+}$ and $[\{Rh^{III}(Cl)(nbd\text{-}OR)(pla)\}_2]^{2+}$ (Figure 30). The latter species likely result from a Wacker-type attack of water/alcohols to the $[Rh^{III}(Cl)(pla)(nbd)]^{2+}$ intermediate.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Heating $[\{Rh^{III}(Cl)(nbd\text{-}OH)(pla)\}_2]^{2+}$ in the presence of an excess of the oxidant $FeCl_3$ led to catalytic formation of norbornenone, albeit with only low total turnover numbers.[40] These reactions are nevertheless noteworthy, because no Wacker oxidation catalysts for norbornadiene have been reported and oxidation of other bis-alkenes also gives poor results or diketones.[81] The main problem with palladium-mediated Wacker oxidation of bis-alkenes is that attack of $OH^-$ or $H_2O$ to the $Pd^{II}$(bis-alkene) complex usually yields a $\eta^3$-3-hydroxy-enyl σ–π complex, in which coordination of the second double bond prevents easy β elimination.[82]

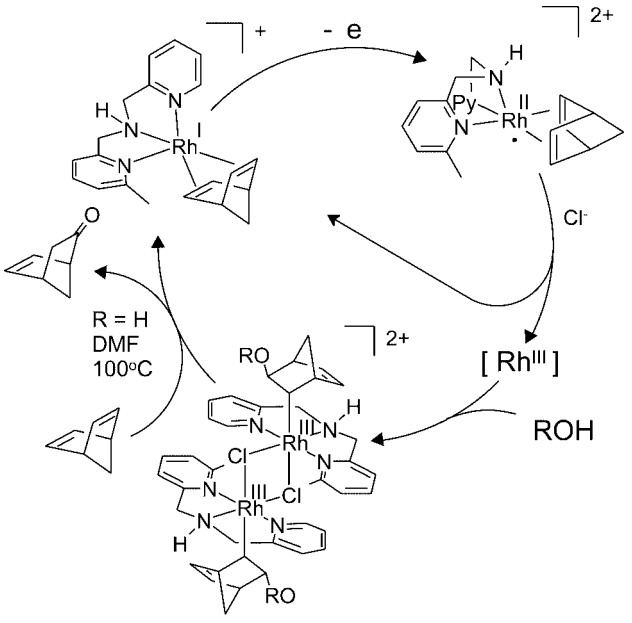

Figure 30. Catalytic formation of norbornenone through chloride-triggered disproportionation of $[Rh^{II}(pla)(nbd)]^{2+}$.

## 5. $Rh^{II}$-Alkene Species as Intermediates in Catalytic Carbene Transfer Reactions?

Diamagnetic dinuclear carboxylate-bridged $Rh^{II}$–$Rh^{II}$ species have been extensively studied as a catalysts for carbene-transfer reactions.[83] It has always been assumed that the $Rh^{II}$–$Rh^{II}$ species stay intact during catalysis, but this was never really proven. A study by Bergman clearly reveals that mononuclear $Rh^{II}$ species can also be active catalysts for carbene-transfer reactions. $[Rh^{II}(Cl)(Tf)(bisoxozaline)]$ ($Tf^-$ = triflate) is an active alkene cyclopropanation catalyst. Although the catalytic precursor does not contain Rh-alkene fragment, the carbene-transfer reaction is highly likely to involve such species as intermediates.

The catalytic activity is enhanced by addition of $NaBAr_F$, yielding $[Rh^{II}(bisoxozaline)(Cl)(CH_2Cl_2)]^+$ {$BAr_F^-$ = tetrakis[3,5-bis(trifluoromethyl)phenyl]borate}.[84] The active species is believed to be a low-valent 15 VE species with two (bis)oxozaline nitrogen atoms in mutual *trans* positions and a chlorido ligand occupying a third position. Two sites of the rhodium center are sterically hindered by the (bis)-oxozaline methyl groups and the bridging arene. In the *trans* position to the chloro ligand, a labile triflate anion or dichloromethane ligand is bound allowing easy formation of a vacant site. In the presence of diazoacetates, dimerization to fumarates and maleates takes place, indicative of carbene-transfer reactions.[84] Also selective cyclopropanation (Figure 31) of alkenes and formation of aziridines from imines is catalyzed by these complexes. With these results, one might consider open-shell species to play an active role in other carbene-transfer reactions as well.

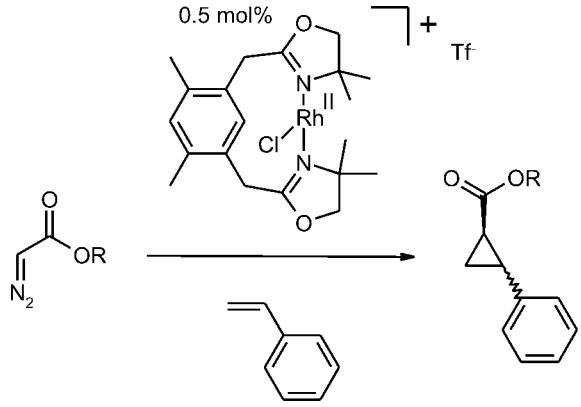

Figure 31. Cyclopropanation of styrene-mediated by a mononuclear $[Rh^{II}(Cl)_2(benbox)]^+$ complex.

For example, in the recently discovered Rh-mediated stereoselective polymerization of carbenes from diazoacetates, $Rh^{II}$(alkene) radicals might well be important (Figure 32).[85] It was shown that $[Rh^{I}$(prolinate)(cod)] is a catalyst precursor for polymerization of carbenes from diazoacetates, leading to formation of new, stereoregular (most likely syndiotactic) ester-functionalized polymethylenes. This new family of polymers contain a functional side group at each carbon of the polymer backbone. Polymers with molecular weights up to 190000 ($M_w$) were obtained as solid materials with interesting material properties. Notably, only about 1% of the Rh material becomes active in the polymerization reaction. Therefore, it is interesting to note that EPR measurements have indicated formation of (very) low concentrations of radical species during the reaction.[78] Whereas these radicals are just side products, or are involved as intermediates in the polymerization reaction needs to be established in future studies.

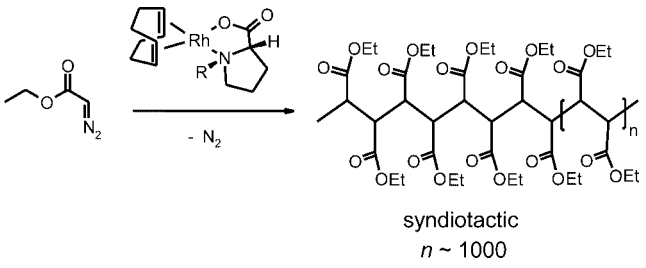

Figure 32. Are radical species involved in the recently discovered stereoselective Rh-mediated polymerization of "carbenes"?

## 6. Conclusions

Paramagnetic rhodium and iridium alkene species, especially the nitrogen-ligand-based $[M^{II}(por)(alkene)]$ and $[M^{II}(alkene)(N\text{-ligand})]^{2+}$ species, reveal a remarkable variety of radical-type reactions. The five-coordinate $[M^{II}(por)(alkene)]$ species, for which mixing of the $d_{z^2}$ and alkene orbitals ensures that part of the unpaired electron density is located at the olefinic ligand, are especially reactive. These alkene adducts cannot be isolated due to fast M–C and C–C radical couplings leading to alkylene-bridged species. Attempts to sterically prevent these reactions leads to alkene adducts which easily lose the alkene. Alkenes bind stronger to dicationic five-coordinate $[M^{II}(N_4\text{-ligand})]$ and $[M^{II}(N_3\text{-ligand})]$ complexes containing neutral tetradentate or tridentate podal $N\{CH_2Py\}_n$ ($n$ = 2,3) type ligands. The orbital arrangement of these species is different, so that the $d_{z^2}$ orbital containing the unpaired electron interacts with a $N_{amine}$ donor instead of the alkene. Consequently, the alkene fragments do not reveal much radical-type reactivity without activation. The situation changes upon binding of a strong coordinating solvent (e.g. MeCN), resulting in a donor-induced shift of the spin-density from the metal to the π* orbitals of the alkene. Most of the spin density of the resulting $M^{III}(NCMe)(CH_2CH_2^{\cdot})$ species is located at the β-carbon of the "slipped" alkene, thus triggering radical-type reactivity at the alkene/ethyl radical fragment. This donor-induced shift of the spin density from the metal to the alkene constitutes a new approach to tuning the reactivity of open-shell metal-alkene species.

Stable examples of $M^{II}$(α-alkene) complexes, containing reactive allylic hydrogen atoms, all have their metal center sterically protected. All other examples tend to decompose with formation of $M^{III}$(allyl) and $M^{III}$(H) species. The presence of unpaired spin density at the alkene is of less concern for these decomposition pathways, as they proceed through a dinuclear pathway in which an allylic hydrogen atom of one $M^{II}$(alkene) species is abstracted by another $M^{II}$(alkene) radical *at the metal*.

Although limited in number, there are a few examples in which experimental evidence for the involvement of paramagnetic rhodium and iridium species in catalytic reactions is quite strong. For example, paramagnetic intermediates might play a role in the catalytic alkene oxygenation reactions described in the 1970s and early 1980s by Mimoun, Drago, Read and others.[74,75] Whether or not this concerns paramagnetic alkene species remains a question. $M^{II}$(α-alkene) species perhaps too easily undergo allylic C–H activation, making them less attractive candidates to be intermediates in the C–O bond formation processes. C–O bond formation through oxidation of diamagnetic $M^{I}$(alkene) species (by peroxides for example) to 2-metalla(III)oxetane intermediates seems a more likely pathway. Paramagnetic $M^{II}$ species might nevertheless be important in these reactions, e.g. by facilitating peroxide formation from $O_2$ and a sacrificial reductant (e.g. an alcohol). On the other hand, the situation may strongly depend on the olefinic substrate. Model reactions of $[Ir^{II}(ethene)(N_4\text{-ligand})]^{2+}$ species with $O_2$ have revealed that with these ethene species, lacking reactive allylic hydrogens, facile C–O bond formation is certainly possible. This reaction likely proceeds via external attack of the "alkene radical" species $M^{III}(NCMe)(CH_2CH_2^{\cdot})$ by $O_2$. This demonstrates the potential of donor induced generation of "alkene radicals" from $M^{II}$(alkene) species as a new approach to steer the reactivity of open-shell M(alkene) species.

Catalytic cyclopropanation of alkenes with ethyl diazoacetate mediated by well defined $Rh^{II}$(alkene) species has been demonstrated,[84] and it is well possible that open-shell $M^{II}$(alkene) species are also active in other carbene-transfer reactions. Wacker-type oxidation of norbornadiene to norbornenone is another reaction which definitely proceeds via discrete $Rh^{II}$(alkene) species.[40]

The rich chemistry displayed by paramagnetic M(alkene) species is fascinating. Whether or nor these species will turn out to be important in new or existing catalytic reactions remains a question to be answered in the future.

# A Water Pipe Held Up by a Polyoxometalate Supported Transition Metal Complex: Synthesis and Characterization of $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2][Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$

**Vaddypally Shivaiah,[a] Tanmay Chatterjee,[a] Khandregula Srinivasu,[a] and Samar K. Das*[a]**

**Keywords:** Heteropolyanion / Copper acetate dimer / Crystal structure / Lattice waters / Hydrogen bonds / Supramolecular chemistry

A water pipe, formed exclusively from lattice water molecules, is stabilized in an organic–inorganic hybrid material $Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2][Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$ (**1**). Compound **1** consists of an Anderson-type heteropolyanion, a copper acetate dimer, and 28 lattice water molecules. Once the relevant crystal is removed from the mother liquor it loses water molecules, which results in the demolition of the water pipe.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

Water is a major constituent of our planet earth and it plays an important role in many natural systems, but it is not a fully understood liquid. There has been extensive investigation of water structures in recent years in which helical protein matrixes act as a stabilizing host[1] because water aggregations are prevalent in many biological systems. Studies on small water clusters and their noncovalent interactions are significant because these stabilize the supramolecular systems both in solution and in the solid state and there is a clear need to understand how such aggregates influences the overall structures of their surroundings.[2] It has been demonstrated that a giant icosahedral metaloxide-based spherical polyoxometalate (POM) cluster can encapsulate an icosahedral $(H_2O)_{100}$ cluster.[3] Other POM clusters are also found to stabilize small water clusters.[4] There are reports on several types of water polymers that have been crystallographically identified; these include chains,[5] tapes/layers,[6] and helices[7] etc. Infantes and Motherwell have described the patterns of water clusters within the Cambridge Structural Database (CSD), and they have classified them as discrete rings and chains, infinite chains and tapes, and layer structures.[8] According to their CSD search, a water pipe/tube was not known until 2002. There are two reports of water tubes in recent time: both are stabilized with inorganic coordination compounds.[9] Very recently, Mascal et al. have written a popular article on water oligomers in crystalline hydrates by choosing 17 random recent publications that describe unprecedented assemblies of water molecules and compared these structures against those already in the CSD.[10] However, the context of a water pipe/tube is not discussed in this essay. We describe here the crystallographic observation of a new type of water pipe that was identified in supramolecular channels and formed in a polyoxometalate-based inorganic–organic hybrid compound, $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2][Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$ (**1**).

Compound **1** was synthesized in an organo–aqueous medium containing copper nitrate, sodium molybdate, aluminum chloride, acetic acid, acetonitrile, and sodium acetate. The blue crystals of **1** with block morphology were separated on standing at room temperature in 28% yield (based on Mo). These crystals are unstable when they are removed from the mother liquor, loss of crystallinity was registered. Thus, the data collection was performed on a single-crystal of **1** suspended in a capillary that contained frozen mother liquor (at liquid nitrogen temperature).

Compound **1** consists of an Anderson anion, $[Al(OH)_6Mo_6O_{18}]^{3-}$, a dimeric copper complex cation $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2]^{3+}$ and 28 lattice water molecules. Thus, the asymmetric unit in the crystal of compound **1** is composed of half of a dimeric complex cation, half of the Anderson heteropolyanion, and 14 solvent water molecules as shown in Figure 1. An Anderson anion $[Al(OH)_6Mo_6O_{18}]^{3-}$ consists of seven edge-shared octahedra, six of which are molybdenum octahedra arranged hexagonally surrounding the aluminum octahedra (see Figure S4 in Supporting information). In compound **1**, copper dimer $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)]^{3+}$ acts as a cation that compensates for the anionic charge of the Anderson anion resulting in the formation of the title compound. The copper ion adopts a square pyramidal geome-

try, whereby the basal sites are occupied by two phenanthroline nitrogen atoms and two acetate oxygen atoms (Cu–N = 2.01 Å; Cu–O = 1.956 Å), and the axial position is occupied by water oxygen atoms. The axial Cu–O distance is 2.154 Å, which is relatively longer than those in the basal plane. Intradimer Cu···Cu separation of 2.988 Å has been observed, which is comparable to the Cu···Cu separation of 3.05 Å in the similar dimer reported in the literature.[11] The phenanthroline ligands of the copper dimer are almost parallel to each other and they are also ring-to-ring stacked, which reveals intramolecular π-π interactions [$C_t$–$C_t$ = 3.632 (2) Å; MPS = 3.355 Å].

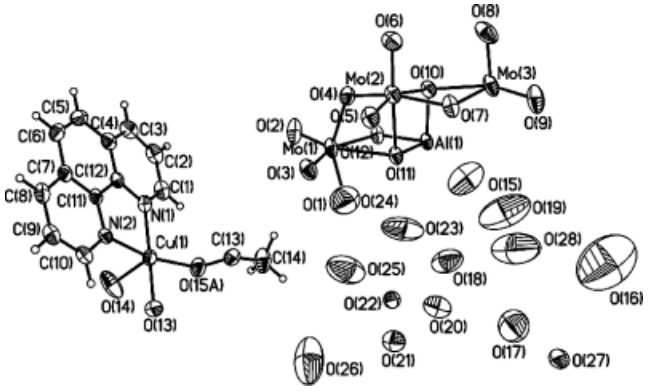

Figure 1. Thermal ellipsoidal plot (at 50% probability) of the asymmetric unit in compound **1**, which consists of half of the dimeric copper complex cation, half of the Anderson heteropolyanion and 14 solvent water molecules.

The most fascinating aspect of this work is the formation of a water pipe that is formed exclusively from lattice water molecules present in the crystal of **1**. There are 14 lattice water molecules in the asymmetric unit in the crystal structure of **1** (see Figure 1). These are O(15) through O(28). Out of these 14 lattice water molecules, 13 are involved in the formation of a $(H_2O)_{13}$ cluster [the O(24) water is not involved in hydrogen bonding interactions] as shown in Figure 2. The growing and repetitive arrangement of the $(H_2O)_{13}$ cluster leads to the construction of a new type of water pipe as shown in Figure 3. The relevant O···O hydrogen bond lengths are given in Table 1. Water hydrogen atoms could not be located in the crystal structure. Among the 13 lattice water molecules that are involved in the construction of the water pipe, two water molecules [O(22) and O(26)] are disordered. Each of these is disordered over two positions [O(22), O(22A) and O(26), O(26A), respectively].

The dimensions of the inner diameter of the water tube are found to be $8.527 \times 8.061$ Å$^2$. The packing of the water pipes in the unit cell is shown in Figure 4. The existence of such an unstable pipe (vide supra) has been made possible by the interactions with its surroundings that include an Anderson heteropolyanion and a dimeric copper complex cation. There are extensive hydrogen bonding interactions between surface oxygens of the Anderson anion (terminal, bridging, and $\mu_3$-O oxygens), crystal waters (water tube), and copper coordinated waters as shown in Figure 5a (see also Figures S10–S12 in Supporting information for detailed interactions between the water pipe and its surrounding). The packing of the Anderson heteropolyanions and the dimeric copper complex cations in the crystal forms a grid-type supramolecular framework having channels (when viewed looking down the crystallographic *c* axis). These channels accommodate the water pipes that run along the crystallographic *c* axis too (see Figure 5b).

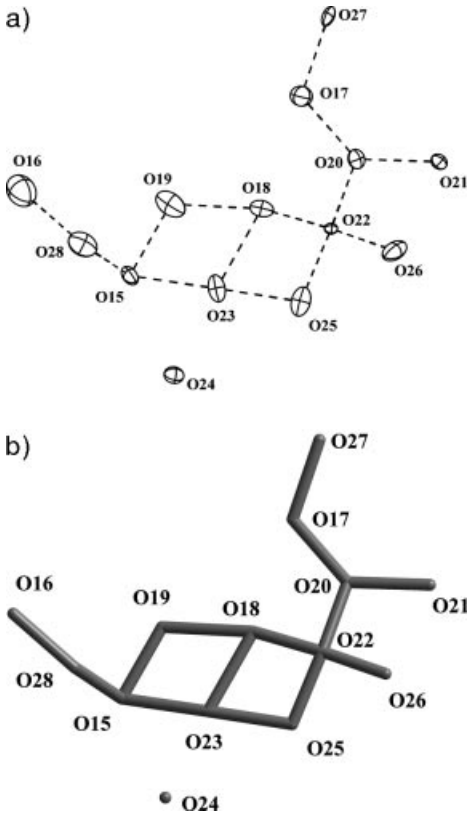

Figure 2. Hydrogen bonding interactions among lattice water molecules O(15) through O(28), which results in the formation of a $(H_2O)_{13}$ cluster. O(24) water remains non-hydrogen bonded in the crystal. (a) thermal ellipsoidal and (b) wire-frame representations. The disordered part of O(22) and O(26) are not shown.

Figure 3. The generation of a water pipe formed by the repetition of $(H_2O)_{13}$ cluster (as shown in Figure 2).

Table 1. O···O hydrogen bond lengths [Å] in water tube (see Figure 2).

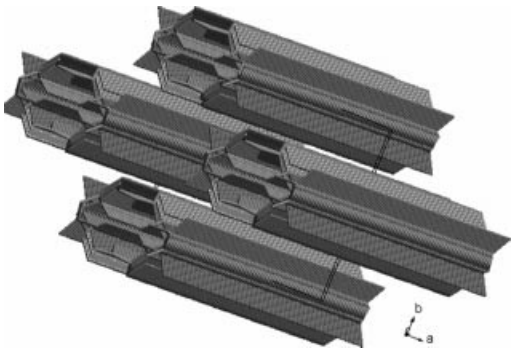

Figure 4. The packing of the water tubes in the unit cell excluding the Anderson anions and dimeric copper complex cations.

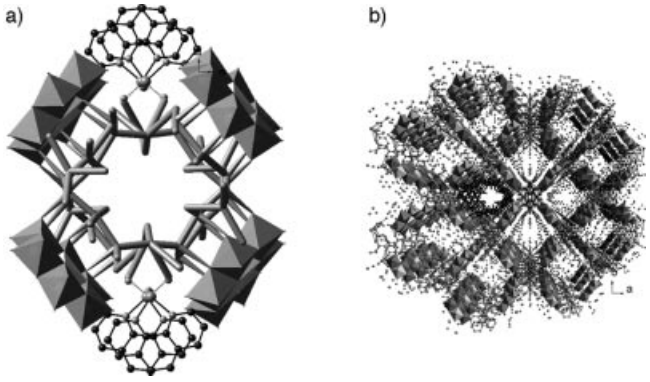

Figure 5. (a) Front view of the water pipe, supported by its surroundings that include dimeric copper complex cations and Anderson heteropolyanions through noncovalent interactions. Anderson anion is shown in polyhedral representation and water tube in sticks representation. Acetate carbons and hydrogens are not shown for clarity. (b) The perspective view of the water tubes in the square-grid channels ($3 \times 3$ cell). Only one water tube is shown for clarity. The view is along the crystallographic *c* axis.

In the present study, we could not determine the precise number of water molecules forming the water pipe by thermogravimetric (TG) studies because once the relevant crystals are removed from the mother liquor (synthesis), they lose their single crystallinity and form a powdery material. TG studies were performed on the powdery compound. The TG curve shows the first weight loss starts at around 100 °C with the loss of 13.50%. This corresponds to the loss of ca.16 crystal water molecules. The molecules lost at this stage were identified as water molecules from the corresponding mass spectrum (TGA-Mass). This clearly tells us that the relevant crystal already looses 12 water molecules at room temperature before its TG measurements start. This is consistent with the X-ray powder diffraction studies and the visual observation (single-crystals convert to powder) during the process of removing the crystals from the mother liquor.

In conclusion, we have described here the crystallographic observation of a supramolecular water pipe that is exclusively constructed from solvent/lattice water molecules. We believe that the heteropolyanion and the copper dimeric complex play an important role in the stabilization of such an unusual and unstable water tube. Conversely, the water pipe acts as a support to hold the host chemical entities (grid-framework) as evidenced by the loss of crystallinity that occurs when lattice water molecules are lost during the drying process of the relevant crystal at room temperature. To the best of our knowledge, this is the first crystallographically characterized water tube in a POM-based hybrid material.

## Experimental Section

**General:** Infrared spectra were recorded with a JASCO-5300 FTIR spectrophotometer. Powder X-ray diffraction data were collected with a Phillips PW 3710 diffractometer. EDAX analyses were performed with Philips XL 30 SEM equipment.

**Synthesis of $[Cu_2(phen)_2(CH_3COO)(CH_3COOH)(H_2O)_2][Al(OH)_6Mo_6O_{18}]\cdot 28H_2O$ (1):** To a stirred aqueous (50 mL) solution of aluminum chloride (1.5 g, 6.21 mmol), a solution of sodium molybdate (3.5 g, 14.46 mmol) in water (100 mL) was mixed followed by the addition of an aqueous methanolic solution (100 mL; water/MeOH, 1:1) of 1,10-phenanthroline (0.2 g, 1 mmol) and copper acetate (1 g, 5 mmol). To this reaction mixture, sodium acetate (3 g, 22.04 mmol) was added. Finally, the whole reaction mixture was acidified with glacial acetic acid until the pH reached 3.4. The mixture was then stirred for 10 min and filtered in a 250 mL conical flask. Blue crystals of **1** were obtained after one week from the filtrate. Yield: 1.5 g (28% based on molybdenum).

**Note:** Crystals of **1** lose single crystallinity when they are removed from the mother liquor. The single-crystals lose a considerable amount of solvent/lattice water molecules (as is evidenced by TGA studies, vide infra) immediately after they are separated from the mother liquid and convert to a powdery form.

**X-ray Crystallographic Study:** One single crystal of dimensions $0.45 \times 0.22 \times 0.10\ mm^3$ was placed in a capillary tube with its mother liquor and cooled to liquid nitrogen temperature with immediate effect (for details see Supporting Information). CCDC-613002 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Synthesis, X-ray powder diffraction studies, TGA studies, structure refinement data, structural description and interactions of compound **1**

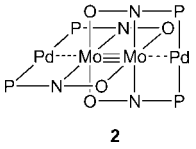
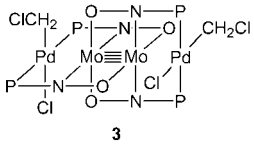
## Introduction

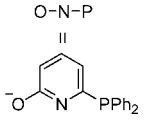
Low-dimensional multimetallic molecules have attracted much interest in view of their fundamental bonding nature as well as their potential as magnetic, electronic, and optical materials.[1] They are mainly constructed by assembling dinuclear metal units[1,2] by using appropriate multidentate ligands,[3–9] or by electrochemical methods.[10–15] We previously reported the preparation of *linear heterometallic clusters* with the use of a quadruply bonded dimolybdenum(II) complex, $Mo_2(pyphos)_4$ (**1**) (pyphos = 6-diphenylphosphanyl-2-pyridonato), as a core part of metal strings, and their unique reactivity arising from the electronic anisotropy involving dative metal–metal bonds:[16] the oxidative reaction of 2 equiv. of dichloromethane to a $Pd^0$ cluster, $Mo_2Pd_2(pyphos)_4$ (**2**), which has two $Pd^0\cdots Mo^{II}$ dative bonds, proceeded under mild conditions to give a $Pd^{II}$ cluster, $Mo_2Pd_2Cl_2(CH_2Cl)_2(pyphos)_4$ (**3**).[16d] Thus, the presence of the $Pd^0\cdots Mo$ dative bond of **2** enhances its reactivity toward oxidants,[16d] which is relevant to the fact that some dinuclear metal complexes with a bonding interaction between $d^{10}$ metal centers exhibit higher reactivity compared with the corresponding mononuclear complexes.[17] In this contribution, we report the structural and spectral characterization of the $Pt^0\cdots Mo^{II}$ dative bond of linear tetrametal complexes, $Mo_2Pt_2(pyphos)_4(PR_3)_2$ (**4**), whose reactivity was assessed by an unprecedented 1,4-oxidative addition reaction of diaryl disulfides, which gives dithiolate $Pt^I$ complexes, $Mo_2Pt_2(SAr)_2(pyphos)_4$ (**5**).



**2**



**3**



Treatment of $Mo_2(pyphos)_4$ (**1**) with 2 equiv. of $Pt(PPh_3)_4$ in THF afforded a tetrametal cluster, $Mo_2Pt_2(pyphos)_4(PPh_3)_2$ (**4a**), with a $Pt^0$–$Mo^{II}$–$Mo^{II}$–$Pt^0$ array in 85% yield. The triphenylphosphane bound to each platinum(0) atom was labile[18] and readily replaced by adding excess $PMe_3$, $PMe_2Ph$, $PMePh_2$, and $P(OMe)_3$ in THF to give the corresponding complexes $Mo_2Pt_2(pyphos)_4(L)_2$ [**4b**: $L$ = $PMe_3$; **4c**: $L$ = $PMe_2Ph$; **4d**: $L$ = $PMePh_2$; **4e**: $L$ = $P(OMe)_3$] (Scheme 1). All complexes **4a**–**e** were unequivocally characterized by spectroscopic data and combustion analysis. The $^{31}P\{^1H\}$ NMR spectra of **4a**–**e** provided two peaks with a coupling constant $J_{P\text{-}P}$ = 140–192 Hz, the value of which was comparable to the coupling constant ($J_{P\text{-}P}$ = 110 Hz) reported for a dinuclear trigonal planar complex, $Pt_2(\mu\text{-dppm})_3$.[19] This clearly indicates that complexes **4a**–**e** adopt a trigonal planar geometry at each Pt center, and this was further confirmed by X-ray analysis of **4e** (Figure 1).[20] Each platinum atom in **4e** is coordinated by two phosphorus atoms of the pyphos ligands and $P(OMe)_3$, which forms a trigonal planar geometry with P–Pt–P angles of 123.95(4), 116.98(4), and 118.96(4)° for Pt1, with a sum = 359.89°, and 124.95(4), 117.87(4), and

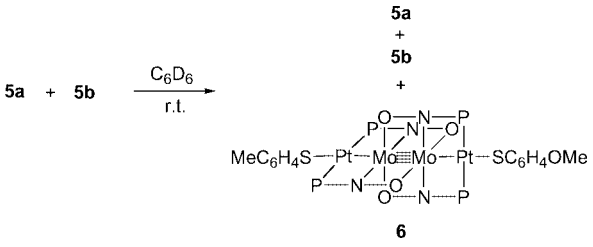
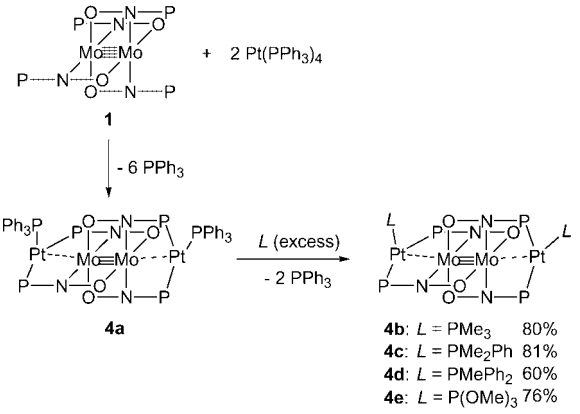
117.15(5)° for Pt2, with a sum = 359.97°, respectively. Notably, the trigonally coordinated $d^{10}$ center, such as $Pt^0$ and $Au^I$, interacts by attracting heavier $s^2$ metals such as $Tl^I$ and $Pb^{II}$.[21] Similar angles [114.9(2)–123.1(2)°] are reported for trigonal planar complexes such as $Pt(PPh_3)_3$[22] and $Pt_2(\mu\text{-dppm})_3$.[19,23] Each platinum atom of **4e** was slightly out of reach of the $Mo_2$ vector [Pt1–Mo1–Mo2 = 170.66(2)°; Pt2–Mo2–Mo1 = 167.94(2)°]. Although the distances of Pt1–Mo1 [2.9082(4) Å] and Pt2–Mo2 [2.9276(4) Å] are long, the distance of Mo1–Mo2 [2.1198(5) Å] is longer than that of quadruply-bonded $Mo^{II}_2$ complexes such as **1** [2.098(2) Å],[16a,16b] a $Pt^{II}$ complex, $Mo_2Pt_2Cl_4(pyphos)_4$ [2.101(2) Å],[16b] $Mo_2(O_2CCH_3)_4$ [2.0934(8) Å],[24] and $Mo_2(mhp)_4$ [2.065(1) Å, mhp = 6-methylpyridonate],[25] and slightly shorter than that of the triple bond of the $Pt^I$ complex $Mo_2Pt_2Cl_2(pyphos)_4$ [2.134(1) Å],[16b] which indicates that each platinum atom interacts by attracting the $Mo_2$ part to form a dative bond.[26] This is further supported by the Raman active ν(Mo–Mo) frequencies (382–388 $cm^{-1}$) observed for complexes **4a**–**e**, whose values are comparable to that of the triple bonded $Mo_2$ in $Mo_2Pt_2Cl_2(pyphos)_4$ (381 $cm^{-1}$) and its palladium derivative $Mo_2Pd_2Cl_2(pyphos)_4$ (386 $cm^{-1}$), but lower than that of the quadruply bonded $Mo_2$ in **1** (394 $cm^{-1}$) and $Mo_2Pt_2Cl_4(pyphos)_4$ (403 $cm^{-1}$).

Complex **4a** showed unique reactivity toward diaryl disulfides. The addition of excess ArSSAr (Ar = $C_6H_4Me$-4, $C_6H_4OMe$-4, $C_6H_3Me_2$-2,6, $C_6H_5$) to a solution of **4a** in THF yielded the corresponding 1,4-bis(thiolate) tetrametal complexes $Mo_2Pt_2(SAr)_2(pyphos)_4$ [**5a**: Ar = $C_6H_4Me$-4; **5b**: $C_6H_4OMe$-4; **5c**: $C_6H_3Me_2$-2,6; **5d**: $C_6H_5$] [Equation (1)], whose formulation was confirmed by NMR spectroscopic data and combustion analysis together with X-ray analysis of **5c**. A 1,4-addition of disulfides to the tetrametal skeleton of **4a** resulted in the formation of two $Pt^I$–$Mo^{II}$ single bonds as a consequence of one-electron oxidation of each platinum.



(1)



Scheme 1. Synthesis of complexes **4a**–**e**. O–N–P = 6-diphenylphosphanyl-2-pyridonato.

X-ray analysis of **5c** (Figure 2)[27] revealed that the two $Pt^I$ centers adopt a square-planar geometry where two phosphorus atoms of the pyphos ligands occupy *trans* positions and the sulfur atom and the molybdenum atom are placed at the opposing corners of the square planar, which results in the formation of a linear tetrametal $Pt^I$–$Mo^{II}$–$Mo^{II}$–$Pt^I$ skeleton with the angles of Pt1–Mo1–Mo2 [174.92(3)°] and Pt2–Mo2–Mo1 [173.37(3)°]. The bond lengths of Pt–Mo [2.6916(5) and 2.7306(5) Å] are short enough to have a single bond, which is comparable with that of $(CO)_3Mo(\mu\text{-}PPh_2)_2Pt(PEt_3)$ [2.766(1) Å].[28] The significantly longer Mo–Mo bond length [2.1413(8) Å] than that of **1** [2.098(2) Å][16a,16b] and **4e** [2.1196(5) Å] led us to conclude that the Mo–Mo bond had a bond order of three. The lower-shift of the ν(Mo–Mo) frequency (379 $cm^{-1}$) for **5c** also supported the elongated Mo–Mo bond.

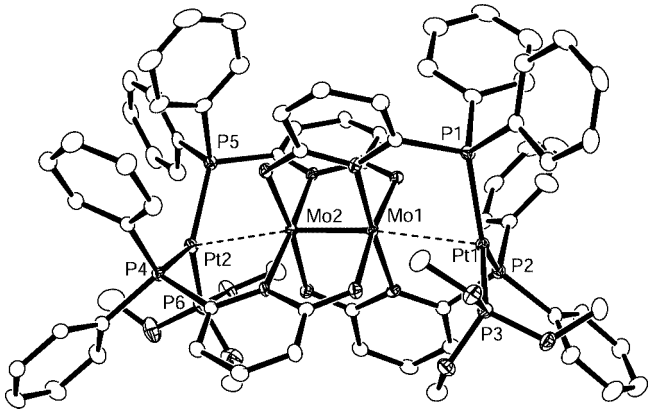


Figure 1. Molecular structure of complex **4e** with the numbering scheme. Hydrogen atoms and solvent molecules are omitted for clarity.

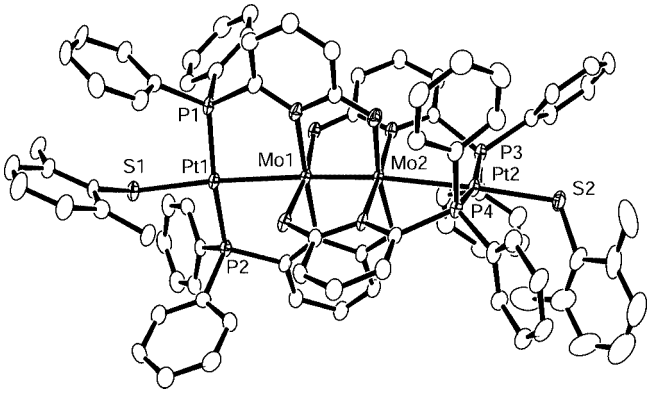

Figure 2. Molecular structure of complex **5c** with the numbering scheme. Hydrogen atoms and solvent molecules are omitted for clarity.

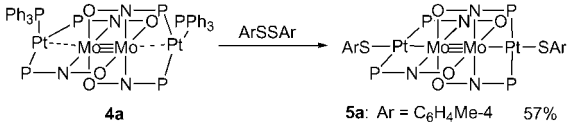
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

By mixing isolated thiolate complexes **5a** and **5b** in $C_6D_6$, a new mixed thiolate complex, $Mo_2Pt_2(SC_6H_4Me\text{-}4)(SC_6H_4OMe\text{-}4)(pyphos)_4$ (**6**), was generated whose $^{31}P\{^1H\}$ NMR spectrum showed new singlet signals at $\delta$ = 30.8 and 30.9 ppm [Equation (2)]. Additionally, the reaction of **5a** with 1 equiv. of bis(4-methoxyphenyl) disulfide produced complex **6** together with **5b**. In contrast, dark conditions suppressed these reactions as judged by $^{31}P\{^1H\}$ NMR spectroscopy. In a reverse reaction, the addition of 10 equiv. of $PPh_3$ to **5c** in $C_6D_6$ resulted in the slow formation of the corresponding disulfide $(XylS)_2$ (18%) together with the precipitation of **4a** after 12 h at room temperature, as monitored by $^1H$ NMR spectroscopy. Thus, these experimental observations suggested that the formation and cleavage of the Pt–SAr bond proceeded through a radical process.



(2)

In conclusion, we successfully prepared tetranuclear $Pt^0$–$Mo^{II}$–$Mo^{II}$–$Pt^0$ clusters supported by four pyphos and two phosphane or phosphite ligands, and we provided clear structural and spectral evidence for the dative bond between two $Pt^0$ atoms and the $Mo_2$ core. The 1,4-oxidative addition of diaryldisulfides to the two platinum(0) centers linked by an $Mo_2$ core gave unique tetranuclear complexes with a linear ArS–$Pt^I$–$Mo^{II}$–$Mo^{II}$–$Pt^I$–SAr skeleton. Further investigation on the propensity of such a dative bond in the cluster system is in progress.

**Supporting Information** (see footnote on the first page of this article): Preparation of $Mo_2Pt_2(pyphos)_4(PPh_3)_2$ (**4a**–**e**), oxidative addition of bis(4-methoxyphenyl) disulfide to **4a**, view of $[Mo_2Pt_2Cl_2(C_{17}H_{13}NOP)_4(C_3H_9O_3P)_2]\cdot 1.5(hexane)$, and PLUTO view of $[Mo_2Pt_2(C_{17}H_{13}NOP)_4(2,6\text{-}Me_2C_6H_4S)_2]\cdot 4(C_4H_8O)$.

[20] Crystal data for **4e**·1.5hexane: $Fw$ = 2072.48 (0.27 × 0.20 × 0.10 mm), space group $P\bar{1}$ (#2), $a$ = 14.35524(17), $b$ = 16.24695(7), $c$ = 19.5725(3) Å, $\alpha$ = 108.9657(8), $\beta$ = 97.8677(6), $\gamma$ = 106.1829(6)°, $V$ = 4013.86(8) Å$^3$, $Z$ = 2, calculated density = 1.715 Mg/m$^3$. Data were collected with Rigaku RAXIS RAPID imaging plate area detector with graphite monochromated Mo-$K_\alpha$ radiation at a temperature of 100(2) K to a maximum 2$\theta$ value of 63.0°. A total of 240 oscillation images were collected. Of the 99273 reflections that were collected, 26544 were unique ($R_{int}$ = 0.0920); equivalent reflections were merged. The linear absorption coefficient, $\mu$, for Mo-$K_\alpha$ radiation of 3.960 mm$^{-1}$ was applied, which resulted in transmission factors ranging from 0.4898 to 0.6740. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (SHELXL-97) and refined on $F^2$ by full-matrix least-squares methods by using SHELXL-97.[29] Final $R$ factors, $R1$ and $wR2$ are 0.0507 and 0.0825 for 20546 reflections with $I > 2.0\sigma(I)$, respectively. $R1$ and $wR2$ for all data are 0.0771 and 0.0891 for 26544 reflections. The number of parameters was 964. GOF values are 1.045 for $I > 2.0\sigma(I)$ and 1.045 for all data, respectively.

# Novel 1,2-Dicarba-*closo*-dodecaborane(12) Derivatives of Selenium

**Bernd Wrackmeyer,*[a] Zureima García Hernández,[a] Rhett Kempe,[a] and Max Herberhold[a]**

**Keywords:** Carboranes / Selenium / Platinum / Oxidative addition / NMR spectroscopy

Lithiation of 1,2-dicarba-*closo*-dodecaborane(12) (**1**) followed by insertion of selenium into both C–Li bonds leads to the 1,2-diselenolato-1,2-dicarba-*closo*-dodecaborane(12) dianion (**3**), which is converted by oxidative coupling into the cyclic eight-membered bis(diselane) **4** with annellated carborane moieties. Oxidative addition of **4** to ethenebis(triphenylphosphane)platinum(0) gives the bis(triphenylphosphane)platinum(II) complex **7**, which contains a chelating 1,2-diselenolato-1,2-dicarba-*closo*-dodecaborane(12) ligand, by symmetric cleavage of the eight-membered ring in **4** and displacement of ethene. The molecular structures of **4** and **7** were determined by X-ray analysis. The solution-state structures of the new compounds are supported by multinuclear NMR data ($^{1}H$, $^{11}B$, $^{13}C$, $^{29}Si$, $^{31}P$, $^{77}Se$, $^{195}Pt$).

## Introduction

An important aspect of the rich chemistry of 1,2-dicarba-*closo*-dodecaborane(12) (**1**) ("*ortho*-carborane") is the variation of substituents at the carbon atoms in the 1,2-positions.[1,2] Most conveniently, this chemistry starts with metallation at the carbon atom(s), for example to form the dilithiated carborane 1,2-$Li_2$-1,2-$C_2B_{10}H_{10}$ (**2**), followed by further transformations.[1,2] We and others became interested in the 1,2-dichalcogenolato-1,2-dicarba-*closo*-dodecaborane(12) anions $[1,2\text{-}(1,2\text{-}C_2B_{10}H_{10})E_2]^{2-}$ (E = S, Se, Te) as chelating ligands,[3–10] and this chemistry has been further developed into various areas.[11–15] Tellurium derivatives are rarely studied since clean access to the anion $[1,2\text{-}(1,2\text{-}C_2B_{10}H_{10})Te_2]^{2-}$ appears to be difficult.[16,17] However, the corresponding anions with sulfur or selenium are more readily accessible, and the anion containing selenium $[1,2\text{-}(1,2\text{-}C_2B_{10}H_{10})Se_2]^{2-}$ (**3**) is particularly attractive considering the useful NMR properties of $^{77}Se$[18] ($I$ = 1/2; natural abundance 7.58%; about three times more sensitive in NMR experiments than $^{13}C$). In the present work, we report on observations of oxidative coupling of **3**, or derivatives of **3**, and cleavage of the resulting Se–Se bonds by oxidative addition to $[Pt(PPh_3)_2(CH_2{=}CH_2)]$.

## Results and Discussion

Formation of the anion $[1,2\text{-}(1,2\text{-}C_2B_{10}H_{10})Se_2]^{2-}$ (**3**) and its conversion into the cyclic bis(diselane) **4** are shown in Scheme 1. The reaction of **3** with an excess of $Me_3SiCl$ gave the disilylated derivative **5** in high yield along with a small amount of 1-$Me_3SiSe$-1,2-$C_2B_{10}H_{11}$ (**6**) and unreacted carborane **1**, thus indicating the preferred conversion of **1** into **2**, followed by double insertion of selenium into the C–Li bonds to give **3**. In context with the chemistry of heterosubstituted tropylium derivatives we have attempted to prepare a 1,2-bis(tropyliumseleno)-1,2-dicarba-*closo*-docecaborane(12) by cleavage of the Se–Si bonds. Surprisingly, the reaction of **5** with two equivalents of tropylium bromide, $C_7H_7Br$, gave **4** as the final product of a complex redox reaction together with the expected $Me_3SiBr$ and various organic compounds. The oxidative coupling of **3** with iodine led directly to **4**, as expected. Attempts to prepare a spirosilane from the reaction of **3** with $SiCl_4$ again gave **4** together with unidentified materials. The bis(diselane) **4** could be isolated as yellow crystals from benzene or toluene solutions and its molecular structure was determined by X-ray analysis (vide infra).

Diselanes are known as reagents for oxidative addition reactions.[19] Thus, the reaction of $[Pt(PPh_3)_2(CH_2{=}CH_2)]$ with **4** was studied (Scheme 2). Monitoring of the reaction by $^{31}P$ NMR spectroscopy showed that the eight-membered ring in **4** was cleaved symmetrically to give the platinum(II) complex **7** in essentially quantitative yield. Orange crystals of **7** were isolated and studied by X-ray analysis (vide infra). Complexes of type **7** or their palladium analogues are potential catalysts of the *cis*-addition of the Se–Se bond to the C≡C bond in alkynes.[19c,19d]

Addition of an excess of methyl iodide to a solution of **7** in dichloromethane led to cleavage of the Pt–Se bonds to give a mixture containing in the beginning *cis*-$[PtI_2(PPh_3)_2]$, and the anionic complexes $[PtI_3(PPh_3)]^-$ and

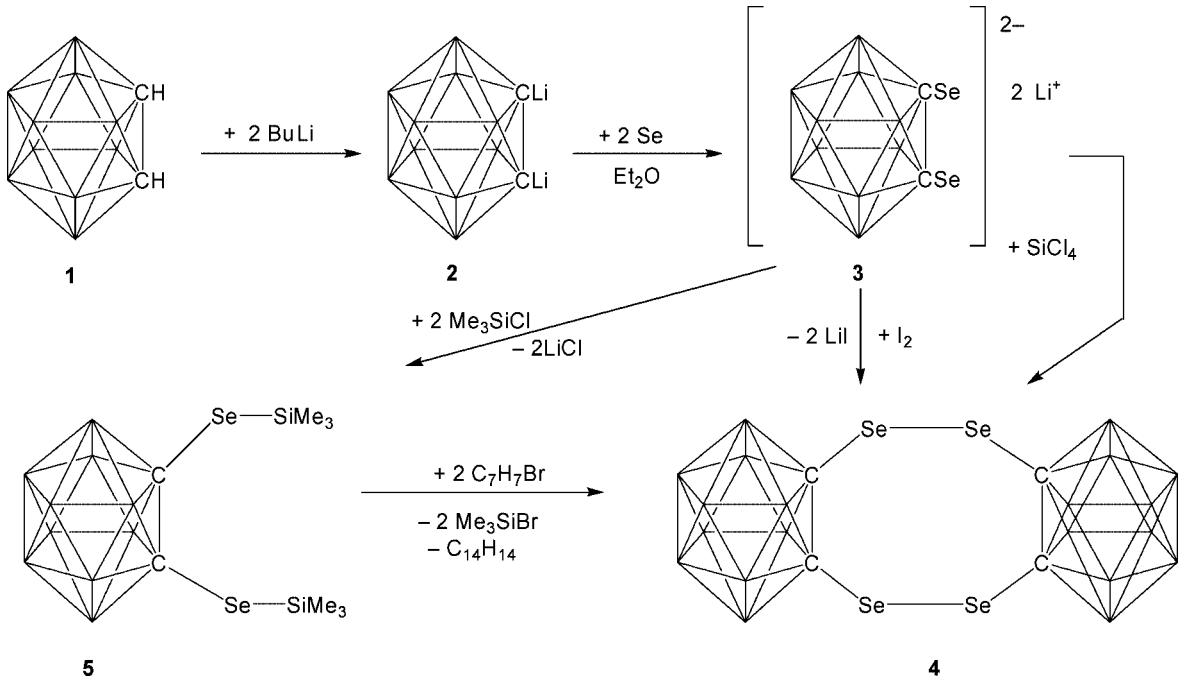
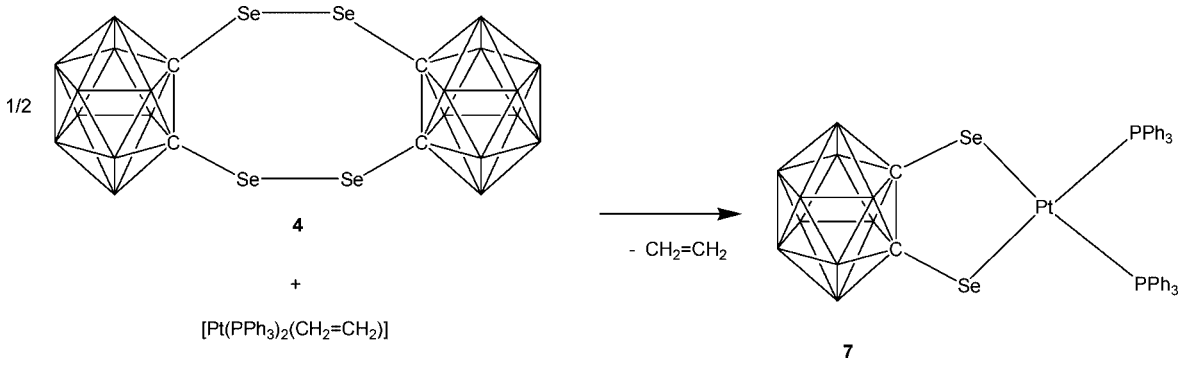


Scheme 1. Oxidative coupling: three routes to the bis(diselane) **4**.



Scheme 2. Oxidative addition of the bis(diselane) **4** to give the platinum(II) complex **7**.

$[PtI_4]^{2-}$ with $[P(Me)Ph_3]^+$ as the counterion. The complex *cis*-$[PtI_2(PPh_3)_2]$ slowly rearranges into the more stable *trans*-isomer.

## NMR Spectroscopic Studies in Solution

The proposed structures of the new compounds are fully supported by the solution-state NMR spectroscopic data (see Table 1 and Experimental Section). The $^{13}C$(carborane) NMR signals are frequently not reported in the literature since they tend to be weak and broad.[1a,20] However, careful setting of the experimental conditions enables the measurement of these signals readily, and further information is provided by observation of $^{77}Se$ satellite signals, as shown in the case of **5** (Figure 1). The $^1J_{^{77}Se,^{13}C}$ and $^2J_{^{77}Se,^{13}C}$ coupling constants measured here are the first examples for this type of carbon atom. The magnitude of $^1J_{^{77}Se,^{13}C}$ in **5** (158.9 Hz) is markedly increased when compared with phenylselenium derivatives[18a,21,22] (e.g. in $Ph_2Se$: $^1J_{^{77}Se,^{13}C}$ = 103.1 Hz[21]).

$^{29}Si$ NMR spectra helped us to monitor the reaction of **5** with tropylium bromide (Scheme 1), and they also established the formation of the monosubstituted species **6** as a side product (Figure 2). The presence of the $^{77}Se$ satellite signals corresponding to $^1J_{^{77}Se,^{29}Si}$ indicates the presence of an Si–Se bond; the magnitude of $^1J_{^{77}Se,^{29}Si}$ is similar in **5** and **6** and also to data reported for other silylselanes.[23,24]

The formation of complex **7** is best monitored by $^{31}P$ NMR spectroscopy. The $^{31}P$ NMR signal of **7** is accompanied by $^{195}Pt$ and $^{77}Se$ satellites. The magnitude of the coupling constant $^1J_{^{195}Pt,^{31}P}$ is in the usual range for this type of complex.[25] The situation is somewhat more complex for the $^2J_{^{77}Se,^{31}P}$ data. In the literature, the *cis* and *trans* coupling pathway for comparable complexes has not been clearly distinguished.[19a,26a,26b] In the case of a platinum(II) diselenolene complex containing the ligand tri(1-cyclohepta-2,4,6-trienyl)phosphane, this discrimination was

[a] NMR measurements in $CD_2Cl_2$ at 23 °C, coupling constants $J$ are given in Hz. [b] $\delta^{13}C$(phenyl) ($^nJ_{^{31}P,^{13}C}$): 138.1 (45) $C^{ipso}$, 134.9 (11) $C^{ortho}$, 128.3 (11) $C^{meta}$, 131.5 $C^{para}$. [c] The signal appears as a multiplet, typical of an AA′X spin system, for which $\Sigma(^3J_{^{31}P,Pt,Se,^{13}C}\,cis + {}^3J^3{}_{^{31}P,Pt,Se,^{13}C}\,trans) = 16$ Hz can be determined from the spectrum. Simulation suggests that $^3J_{^{31}P,Pt,Se,^{13}C}$ values are around 20 and 4 Hz, with opposite signs, and that $|^2J_{^{31}P,^{31}P}| = 15$ Hz. [d] Coupling appears to be similar for *cis* and *trans* coupling pathway.

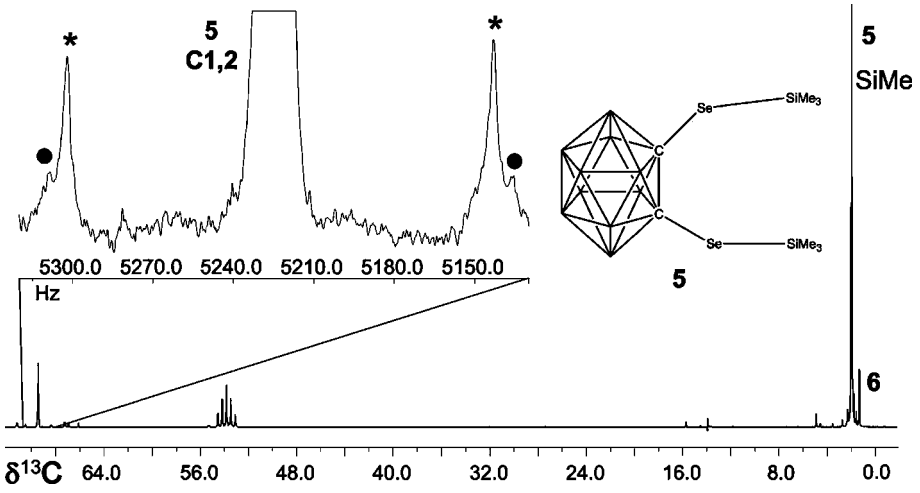

Figure 1. $^{13}C\{^1H\}$ NMR spectrum (75.4 MHz) of a mixture of [1,2-$(Me_3SiSe)_2$-1,2-$C_2B_{10}H_{10}$] (**5**) together with a small amount of [1-$Me_3SiSe$-1,2-$C_2B_{10}H_{11}$] (**6**; in $CD_2Cl_2$ at 23 °C). The $^{77}Se$ satellites marked by asterisks due to $^1J_{^{77}Se,^{13}C} = 158.9$ Hz are clearly visible in the expanded spectral region. The weak outer lines (marked by full circles) arise from the isotopomer containing one $^{13}C$ and two $^{77}Se$ nuclei and correspond to the transitions of an AA′X spin system, separated by $\Sigma(^1J_{^{77}Se,^{13}C} + {}^2J_{^{77}Se,^{13}C}) = 172.8$ Hz, from which the magnitude of $^2J_{^{77}Se,^{13}C}$ (13.9 Hz) can be deduced. Both the one- and two-bond coupling constants possess the same sign (<0). Simulation suggests that $|^3J_{^{77}Se,^{77}Se}|$ is between 20 and 40 Hz.

straightforward and a positive sign of $^2J_{^{77}Se,^{31}P}\,cis,trans$ was determined [$^2J_{^{77}Se,^{31}P}\,cis$ = 35.1 Hz and $^2J_{^{77}Se,^{31}P}\,trans$ = 88.7 Hz].[26c] The observation of only one pair of satellites with approximately correct intensities in the case of **7** (Figure 3) indicates that the magnitude of these two-bond coupling constants is similar. Simulation of the spectrum as an AA′X spin system for the $^{77}Se$ and two $^{31}P$ nuclei suggests that $^2J_{^{31}P,^{31}P}\,cis$ is of the order of 15–20 Hz (vide infra) and of either sign, and that the values for $^2J_{^{77}Se,^{31}P}\,cis,trans$ can range between about 45 and 60 Hz, but are more likely to be close to 50 Hz for both coupling constants. The simulation suggests that their signs should be alike. The $^{13}C$(carborane) signals of **7** reveal a pattern corresponding to an AA′X spin system, and reasonable agreement between simulated and experimental spectra is observed if the signs of $^3J_{^{31}P,Pt,Se,^{13}C}$ are opposite and $^2J_{^{31}P,^{31}P} \approx 15$ Hz.

The evidence from the $^{31}P$ NMR spectra is supported by the $^{77}Se$ NMR spectrum (Figure 4), which reveals an apparently simple triplet accompanied by $^{195}Pt$ satellites ($^1J_{^{195}Pt,^{77}Se}$ = 313.7 Hz). The value of this coupling is similar to that reported for a platinum(II) diselenolene complex[26c] ($^1J_{^{195}Pt,^{77}Se}$ = –327.6 Hz), where the $^{31}P$ nucleus is *trans* with

respect to selenium. The $^{195}Pt$ NMR spectrum shows a triplet accompanied by $^{77}Se$ satellites with the same splitting as in the $^{31}P$ and $^{77}Se$ NMR spectra, respectively.

### X-ray Structural Studies of the Bis(diselane) 4 and the Platinum(II) Complex 7

The molecular structures of the bis(diselane) **4** and of the platinum(II) complex **7** are shown in Figures 5 and 6, respectively. Selected structural data are listed in Table 2, together with some data for the tellurium analogue of **4**.[17]

The geometry of the carborane moiety[1] in molecules **4** and **7** is scarcely affected by the various substituents at carbon. The C–C bond lengths appear to be slightly elongated when compared with the *ortho*-carborane itself, although it is difficult to relate these data owing to different experimental conditions. The Se–Se bond lengths are found in the usual range for diselanes (2.28–2.39 Å).[27] A comparison between the crystal systems of **4** and its tellurium analogue[17] is meaningless since the former crystallises with benzene.

The cycle Pt–Se–C–C–Se is close to planar within the experimental error. The Pt–Se bond lengths in **7** [2.4372(6) and 2.4371(6) Å] tend to be slightly shorter than in *cis*-$[Pt(PPh_3)_2(SePh)_2]$[26a] [2.4885(3) and 2.4506(3) Å]. The Pt–Se distance for the selenium *trans* to phosphorus in the platinum(II) diselenolene complex is also fairly short [2.4310(8) Å], and the one for selenium *trans* to the $\eta^2$-C=C bond is even shorter [2.3698(9) Å]. However, the data reported here for **7** compare well with other Pt–Se bond lengths given in the literature.[28] The Pt–P bond lengths in $Pt^{II}$ complexes (2.22–2.32 Å) depend on the polarizing ability of the other ligands, mainly on the *trans* ligand.[29] Thus, the Pt–P distances found here are typical of selenium in a

*trans* position, as evident, for example, by comparison with the data for *cis*-$[Pt(PPh_3)_2(SePh)_2]$[26a] [2.2900(6) and 2.2937(6) Å].

## Experimental Section

**General:** All syntheses and the handling of the samples were carried out in the absence of air and moisture. Carefully dried solvents and oven-dried glassware were used throughout. The complex $[Pt(PPh_3)_2(C_2H_4)]$,[30] 1,2-dicarba-*closo*-dodecaborane-1,2-diselenolate[16] and tropylium bromide[31] were prepared according to established procedures; the *ortho*-carborane 1,2-$C_2B_{10}H_{12}$ (Katchem), BuLi (1.6 M in hexane), iodomethane and selenium (Aldrich) were commercially available. NMR measurements: Bruker ARX 250, Varian Inova 300 and Varian Inova 400 NMR spectrometers; chemical shifts are given relative to $SiMe_4$ [$CD_2Cl_2$: $\delta_{^1H}$ = 5.33; $\delta_{^{13}C}$ = 53.8; $\delta_{^{29}Si}$ = 0 ppm for $\Xi(^{29}Si)$ = 19.867184 MHz], external $Et_2O{\cdot}BF_3$ [$\delta_{^{11}B}$ = 0 ppm for $\Xi(^{11}B)$ = 32.083971 MHz], external 85% aqueous $H_3PO_4$ [$\delta_{^{31}P}$ = 0 ppm for $\Xi(^{31}P)$ = 40.480747 MHz], external $Me_2Se$ [$\delta_{^{77}Se}$ = 0 for $\Xi(^{77}Se)$ = 19.071523 MHz]. $\Xi(^{195}Pt)$ = 21.4 MHz for $\delta_{^{195}Pt}$ = 0 ppm. Except for the $^{29}Si$ NMR spectra (refocused INEPT[32]) all other NMR spectra were recorded by single pulse methods. The melting points (uncorrected) were determined using a Büchi 510 melting point apparatus.

**1,2-Bis(trimethysilylseleno)-1,2-dicarba-*closo*-dodecaborane(12) [1,2-$(Me_3SiSe)_2$-1,2-$C_2B_{10}H_{10}$] (5):** Butyllithium (2.94 mL of a 1.6 M solution in hexane 4.7 mmol) was added to a solution of *ortho*-carborane **1** (0.34 g, 2.35 mmol) in diethyl ether (100 mL) at room temperature. A white suspension was obtained and stirred for 2 h. Addition of selenium (0.37 g; 4.7 mmol) gave, after 24 h, a yellow solution containing **3**, which was cooled to –78 °C and added to a cold (–78 °C) solution of chlorotrimethylsilane (1.2 mL, 9.40 mmol) in diethyl ether (50 mL). A white precipitate was formed; the mixture was stirred overnight, concentrated, insoluble materials were filtered off and washed with 30 mL of pentane. Volatile materials were then removed in vacuum, and compound **5** was obtained as the main product in a mixture. The NMR analysis showed the presence of the monoselenosilylated derivative **6** along with unreacted carborane as minor products.

**5:** $^1H$ NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 0.59 ppm (s, 18 H, $SiMe_3$). $^{11}B\{^1H\}$ NMR (96.2 MHz, $CD_2Cl_2$): $\delta$ = –4 (2 B), –8 ppm (8 B).

**6:** $^1H$ NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 0.11 (s, 9 H, $SiMe_3$), 2.25 ppm (s, 1 H, CH). $^{11}B\{^1H\}$ NMR (96.2 MHz, $CD_2Cl_2$): $\delta$ = –2 (s, 2 B), –8 (s, 2 B), –9 (s, 2 B), –14 ppm (s, 4 B).

**3,4,7,8-Bis(1,2-dicarba-*closo*-dodecaborano[1,2])-1,2,5,6-tetraselenacyclooctane, [1,2-(1,2-$C_2B_{10}H_{10}$)-Se-Se-]$_2$ (4). Method A:** In an NMR tube, tropylium bromide (0.15 g, 0.88 mmol) was added to a solution of compound **5** (0.1 g, 0.224 mmol) in deuterated toluene (1.0 mL). A yellow solution was observed and analysed by NMR spectroscopy. The NMR analysis showed the mixture consisted of $[(B_{10}H_{10})C_2]_2Se_4$ (**4**) and organic compounds, e.g. $(C_7H_7)_2$ and bromotrimethylsilane. After one month, the formation of yellow crystals was observed on the walls of the NMR tube; the crystals (yield: 12%; 0.012 g; 0.02 mmol; m.p. 170 °C decomp.) were isolated and analysed by NMR and X-ray diffraction.

**Method B:** Addition of an ethereal solution of iodine (0.22 g, 0.9 mmol) to a solution of **3** (starting from 0.9 mmol of *ortho*-carborane) in diethyl ether (100 mL) gave the instantaneous formation of an orange-red suspension, which was stirred overnight at room temperature. The precipitate was filtered off, washed three times with pentane and diethyl ether, dried under high vacuum, and identified as **4** (yield: 150 mg, 30%).

**Method C:** A solution of **3** (0.89 mmol) in $Et_2O$ (100 mL) was added to a solution of $SiCl_4$ (0.075 g, 0.44 mmol) in pentane (100 mL) at –78 °C. After 24 h of stirring at room temperature, the mixture was concentrated, and insoluble materials were separated. After removal of the solvents under vacuum, a yellow solid was obtained and analysed by NMR spectroscopy. It contained mainly **4** (yield 0.19 g, 72%) along with a small amount of unidentified compounds.

**4:** $^1H\{^{11}B\}$ NMR (250 MHz, $CD_2Cl_2$): $\delta$ = 1.56 (br., 1 H), 2.25 (br., 1 H), 2.44 (br., 2 H), 2.53 (br., 2 H), 2.72 (br., 3 H), 3.27 ppm (br., 1 H). $^{11}B\{^1H\}$ NMR (80.2 MHz, $CD_2Cl_2$): $\delta$ = –1.0 (2 B), –7.0 (4 B), –8.0 (2 B), –11.0 ppm (2 B).

**1,2-Diselenolato-1,2-dicarba-*closo*-dodecaboranebis(triphenylphosphane)platinum [$Pt(PPh_3)_2$(1,2-$Se_2$-1,2-$C_2B_{10}H_{10}$)] (7):** A solution of bis(*ortho*-carboran-1,2-diyl)tetraselenide (**4**; 0.0125 g, 0.017 mmol) in $CD_2Cl_2$ (0.5 mL) was added to a solution of ethenebis(triphenylphosphane)platinum(0) (0.02 g, 0.033 mmol) in $CD_2Cl_2$ (0.5 mL) at room temperature. A yellow-orange solution was obtained. After one day the formation of orange crystals was observed, which were isolated in essentially quantitative yield (m.p. 344 °C, decomp.) and characterised as complex **7** by NMR and X-ray diffraction. $^1H$ NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 1.0–3.5 (br., m, 10 H, $B_{10}H_{10}$), 7.35 ppm (m, 30 H, $PPh_3$). $^{11}B\{^1H\}$ NMR (96.2 MHz, $CD_2Cl_2$): $\delta$ = –1.0 (2 B), –7.0 (2 B), –8.0 (4 B), –12.0 ppm (2 B).

**Reaction of [$Pt(PPh_3)_2$(1,2-$Se_2$-1,2-$C_2B_{10}H_{10}$)] (7) with Methyl Iodide:** An excess of methyl iodide (0.46 g, 3.2 mmol) was added to a solution of complex **7** (0.005 g, 0.005 mmol) in $CD_2Cl_2$ (0.5 mL). A yellow solution was obtained, and the reaction mixture was analysed by $^{31}P$ NMR spectroscopy. The spectrum of the equilibrated mixture showed the formation of *cis*-$[PtI_2(PPh_3)_2]$ ($\delta_{^{31}P}$ = 12.5 ppm, $^1J_{^{195}Pt,^{31}P}$ = 3454 Hz; decreasing signal), *trans*-$[PtI_2(PPh_3)_2]$ ($\delta_{^{31}P}$ = 13.0 ppm, $^1J_{^{195}Pt,^{31}P}$ = 2486 Hz; increasing signal), $[MePh_3P]^+$ ($\delta_{^{31}P}$ = 22.5 ppm; the cation was also evident from the $^{13}C\{^1H\}$ NMR spectrum) and $[PtI_3(PPh_3)]^-$ {$\delta_{^{31}P}$ = 12.0 ppm, $^1J_{^{195}Pt,^{31}P}$ = 3633 Hz}; one weak signal at $\delta_{^{31}P}$ = 12.3 ppm ($^1J_{^{195}Pt,^{31}P}$ = 3472 Hz) could

not be assigned. The assigned data are similar to those reported previously.[25b,25c]

**Crystal Structure Determinations of the Bis(diselane) 4 and the Platinum Complex 7:** Details pertinent to the crystal structure determinations are listed in Table 3. The X-ray crystal structural analyses were carried out for single crystals using a STOE IPDS II system equipped with an Oxford Cryostream low-temperature unit. Crystals of appropriate size were selected in perfluorinated oil at room temperature, and the data collections were carried out at 193(2) K (for **4**) and 191(2) K (for **7**). Structure solution and refinement were accomplished using SIR97,[33] SHELXL-97,[34] and WinGX.[35]

# Constructing Multimetallic Systems with the Naphthalene-1,8-bis(thiolato) Ligand

**Stuart D. Robertson,[a] Alexandra M. Z. Slawin,[a] and J. Derek Woollins*[a]**

**Keywords:** Sulfur ligand / Multimetallic systems / Gold / Bridging ligands / X-ray structure

Addition of 1 equiv. $(Ph_3P)Au(ClO_4)$ (formed by ion exchange of $Ph_3PAuCl$ with $AgClO_4$) to [naphthalene-1,8-bis(thiolato)]-bis(triphenylphosphane)platinum results in the formation of a novel dimetallic cationic complex with a (triphenylphosphane)gold moiety attached to the sulfur of the naphthalene-1,8-bis(thiolato) ligand. NMR spectroscopic evidence suggests that this gold-containing fragment is fluxional in its bonding and X-ray crystallography confirms the asymmetric complex, which shows this gold atom attached to one of these sulfur atoms. Addition of more than 1 equiv. $(Ph_3P)Au(ClO_4)$ results in the formation of a tetrametallic sandwich complex with two bridging gold atoms between the sulfur atoms of the two $PtS_2C_3$ rings. Tri- and tetrametallic silver-containing complexes can be prepared by addition of 0.5 and 1 equiv. $AgClO_4$ to $(Ph_3P)_2Pt(S_2C_{10}H_6)$, respectively.

## Introduction

Heterometallic complexes formed by reaction of sulfur-containing platinum(II) complexes with a group 11 complex have been well documented recently and are of great interest as they have a variety of possibilities for coordination of the group 11 metal to the platinum complex. This can partly be attributed to the presence of sulfur in the platinum complex because gold and silver have a great affinity for sulfur. Any heterometallic complex formed by bonding of an Au or Ag complex to sulfur may or may not contain a Pt–M bond, depending on the geometry of the two metals around the sulfur centre. One of the most common starting materials is the highly nucleophilic complex $[\{Pt(PPh_3)_2(\mu\text{-}S)\}_2]$.[1] For example, the $AuPPh_3$ unit is inserted between the two sulfur atoms to give a trigonal-planar structure with no Pt···Au interaction.[2] Similarly, the analogous silver complex has also been obtained,[3] again with no interaction between the two metal atoms.

A number of complexes containing a gold(III) atom bridging the two sulfur atoms in a square-planar configuration have also been described recently.[4,5] These are formed by reaction of the platinum starting material with a gold(III) dichloride such as $Au(pap)Cl_2$ [pap = $\eta^2$ ligand, 2-(2-pyridylamino)phenyl]. The reaction of 2 equiv. $[Ag(PR_3)_2]^+$ with $[Pt(mnt)_2]^{2-}$ (mnt = maleonitriledithiolate, a bidentate S,S-bound ligand) also results in the insertion of silver between two sulfur atoms.[6] In this case, one Ag unit lies above the plane of the $PtS_4$ unit bound to two *cis* sulfur atoms, while the other lies between the other two sulfur atoms but below the plane.

Gold-containing species have also been treated with $[\{Pt(PPh_3)_2(\mu\text{-}S)\}_2]$ to give products where the gold fragment ($Au\text{–}PPh_3$) is bound to only one sulfur atom but not to the other so that it is not bridging.[7,8] Silver has also been seen bound to one or two sulfur atoms of ethylenedithiolato complexes in the form of $Ag(PPh_3)_2$.[9] This work has been extended so that both sulfur atoms bind to a different metal with no bridges between the two sulfur atoms, both in the gold[8,10] and silver complexes.[10,11]

While in all these examples the group 11 atom is in a configuration without Au/Ag···platinum interactions, examples are also known where an $MPPh_3$ fragment is bound to only one of the two platinum-bound sulfur atoms in a configuration with a Pt···M interaction.[12] In this case, the platinum starting material is not the butterfly-core-containing $[\{Pt(PPh_3)_2(\mu\text{-}S)\}_2]$ but is cyclometallated $[Pt\{CH_2C_6H_4P(C_6H_4Me\text{-}o)_2\}(S_2CNMe_2)]$.

While the previously mentioned examples have included complexes where one gold or silver atom is bridging between the two platinum-bound sulfur atoms, it is also possible for this bridge to contain two gold or silver atoms. For example, the hexametallic compound $[Au_2\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2]Cl_2$ is formed by reaction of 1 equiv. $[\{Pt(PPh_3)_2(\mu\text{-}S)\}_2]$ with 1 equiv. $AuCl(SMe_2)$.[10] This complex has a hexanuclear $\{Au_2Pt_4\}$ cage-framework comprising two hinged $\{Pt_2S_2\}$ groups anchored across an Au–Au bond as shown in Figure 1.

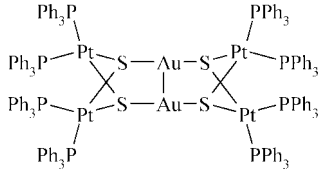

Figure 1. Structure of the dication of $[Au_2\{Pt_2(PPh_3)_4(\mu_3\text{-}S)_2\}_2]Cl_2$; the two anions are omitted for clarity.

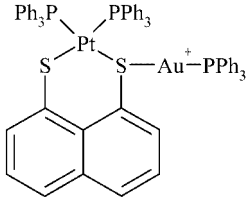
Silver examples of this structure are also known, formed from $[\{Pt(PPh_3)_2(\mu\text{-}S)\}_2]$ and $AgBF_4$,[13] $AgNO_3$[13] and $AgClPPh_3$.[11] A similar complex exists where the two sulfur atoms share only a single platinum atom rather than two platinum atoms.[9] In each case, X-ray crystallographic data suggests that the two silver atoms are within bonding distance.

Examples are also known where two gold atoms attached to either sulfur atom are weakly bound or not bound to each other, but are connected through a larger phosphorus-containing backbone.[7] In this case, the starting materials are $[\{Pt(PPh_3)_2(\mu\text{-}S)\}_2]$ and either $Au_2Cl_2$(dppm) or $Au_2Cl_2$(dppf) [dppm = (diphenylphosphanyl)methane, dppf = (diphenylphosphanyl)ferrocene]. When the backbone is dppm, the two gold atoms are in close proximity (approximately 2.9 Å) such that a considerable aurophilic interaction can be considered to exist. In the case of dppf, the Au–Au distance is much larger [3.759(3) Å] and can be considered non-bonding.

We have a longstanding interest in the coordination and bridging effects of sulfur donor ligands.[14a,14b] Here, we report gold and silver complexes of $(Ph_3P_2)PtS_2C_{10}H_6$ where the sulfur atoms of one molecule of this complex are bridged to another molecule by either one or two group 11 atoms.

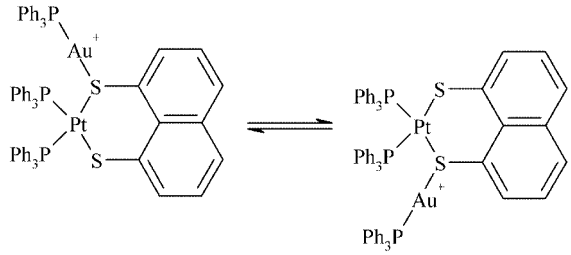
## Results and Discussion

The anionic exchange of the gold complex $Ph_3PAuCl$ with $AgClO_4$ proceeds smoothly in a mixture of dichloromethane and acetonitrile at room temperature. The product is freed of AgCl by removing all solvent and re-dissolving the desired product in dichloromethane before filtering. The resultant gold complex reacts with $(Ph_3P)_2Pt(S_2C_{10}H_6)$ to give the cationic complex $[(Ph_3P)_2Pt(S_2C_{10}H_6)(AuPPh_3)]^+$-$ClO_4^-$ (**1**).



**1**

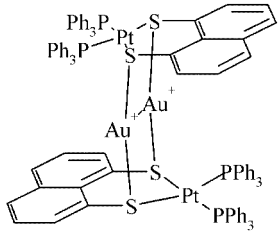
The $^{31}P$ NMR spectrum of **1** shows a peak at $\delta$ = 32.7 ppm corresponding to the triphenylphosphane group attached to the gold atom and a peak at $\delta$ = 17.6 ppm corresponding to the two triphenylphosphane groups bonded to the central platinum atom. The expected platinum satellites are also evident, with a coupling constant of 3080 Hz, [over 100 Hz higher in magnitude than that of the starting material].[13] The asymmetry of complex **1** caused by the gold-containing fragment bonded to one sulfur atom suggests that the two platinum-bound phosphorus atoms should be non-equivalent and therefore should display an AB spin system. However, fluxionality of this gold fragment from one sulfur atom to the other, as seen in Scheme 1, causes these two Pt-coordinated phosphane groups to appear equivalent down to temperatures as low as –80 °C, suggesting that this flipping from one sulfur atom to the other is relatively facile in solution.



Scheme 1. The equilibrium in complex **1**. Perchlorate anion is omitted for clarity.

The $^{195}Pt$ NMR spectrum displays the expected peak at –4674 ppm with the corresponding phosphorus coupling. The mass spectrum ($ES^+$) of complex **1** shows the parent ion at *m*/*z* 1367–1370 in the predicted pattern with the primary peak at 1368. The identity of the counteranion is proved by the $ES^-$ mass spectrum, which shows two peaks at 99 and 101 in the correct ratio.

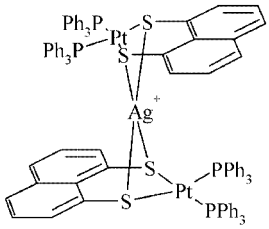
Complex **2** is formed by the reaction of more than one equilavent of $Ph_3PAu^+ClO_4^-$ with $(Ph_3P)_2Pt(S_2C_{10}H_6)$ in dichloromethane. This tetrametallic dication is charge-balanced with two perchlorate ions.



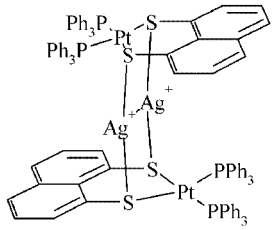
**2**

Complexes **3** and **4** are formed by addition of a solution containing 0.5 and 1 equiv. $AgClO_4$ (in acetronitile) to $(Ph_3P)_2Pt(S_2C_{10}H_6)$ (in tetrahydrofuran), respectively. It is somewhat surprising that we could not obtain a simple gold analogue of **3** [especially considering the lability of the Au–P bond in the formation of **2**], and this may reflect the very strong preference for linear geometry in $Au^I$; we did attempt to prepare gold complexes from $HAuCl_4$ but obtained intractable mixtures.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



**3**



**4**

Isolation of the final complexes was achieved by removing the mixed solvent in vacuo, redissolving in a minimum volume of dichloromethane and precipitating by slow addition of diethyl ether while stirring. The final products are obtained as an orange and a yellow powder, respectively.

The $^{31}P$ NMR spectra of complexes **3** and **4** show a peak at $\delta$ = 6.8 and 18.3 ppm, respectively, with platinum satellites. The coupling constants for these sets of peaks are 2989 Hz (complex **3**) and 3122 Hz (complex **4**). This value for complex **4** is close to that of the digold analogue **2**. The $^{195}Pt$ NMR spectrum of **3** displays a triplet at –4698 ppm. Unfortunately, no peak was observed in the $^{195}Pt$ NMR spectrum of **4**, possibly because the sample was not sufficiently concentrated. The mass spectrum ($ES^+$) of complex **3** is excellent, displaying the parent ion at 1927–1932 in the predicted pattern with the primary peak at 1929. The mass spectrum of **4** displays the expected peaks in the region 1016–1019, half the mass of the complex, which is expected since this complex carries a 2+ charge. The identity of the counteranion in both cases is again proved by the $ES^-$ mass spectrum, which shows two peaks at 99 and 101 in the correct ratio.

## X-ray Crystallography

The crystal structures of complexes **1**–**4** are shown in Figures 3–7, and selected bond lengths and angles are in Table 1 and Table 2. The crystal structure of $(Me_3P)_2Pt(S_2C_{10}H_6)$[15] is also shown (Figure 2 as this complex is closely related to the starting material $(Ph_3P)_2Pt(S_2C_{10}H_6)$, which has never been crystallographically characterised, and is useful for comparison with the complexes **1**–**4**. The X-ray analysis of complex **1** (see Figure 3 and Table 1) shows that the $AuPPh_3$ unit is attached to only one of the sulfur atoms, S(1)–Au(1) = 2.3614(12) and S(9)–Au(1) = 2.979(1) Å. These values, along with the virtually linear S(1)–Au(1)–P(3) angle [174.71(4)°] are similar to those of other disulfur complexes containing a Au–$PPh_3$ arm on one of the sulfur atoms[7,8] and longer than, for example, the Au–S distances in linear $[RS–Au–SR]^-$ containing anionic S donors.[15] The Au(1)–P(3) bond length is also similar to those seen previously. The addition of the Au–$PPh_3$ arm also changes the geometry around S(1) so that it is now in a distorted trigonal-planar structure. This distortion is proven since the largest of the three angles around this sulfur atom is only 104°, a significant deviation from perfect trigonal planarity (120°). This suggests that the geometry around this sulfur atom can possibly be considered as trigonal pyramidal. This new gold fragment considerably reduces the Pt–S(1)–C(1) angle by almost 10°. This forces the naphthalene backbone to realign slightly, which results in the dihedral angle [deviation form planarity between the Pt(1)–S(1)–S(9) and C(10)–S(1)–S(9) planes] being markedly reduced from 136° in $(Me_3P)_2Pt(S_2C_{10}H_6)$ to only 121°. The effect of the gold-containing arm on the geometry around the Pt atom is only slight, a 3° tightening of the S–Pt–S angle is noticed, which in turn is compensated for by a 4° widening of the P–Pt–P angle, resulting in a more distorted square-planar arrangement around the platinum centre with respect to the square-planar platinum complex $(Me_3P)_2Pt(S_2C_{10}H_6)$. This tightening of the S–Pt–S bond also results in a smaller splay angle (18.6°) in complex **1**, as expected. The changes in bond lengths relative to those in $(Me_3P)_2Pt(S_2C_{10}H_6)$ are negligible.

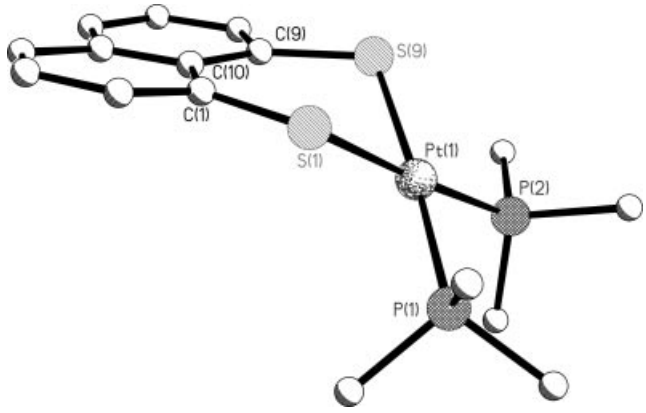


Figure 2. Crystal structure of $(Me_3P)_2Pt(S_2C_{10}H_6)$.[15] This complex is closely related to the starting material $(Ph_3P)_2Pt(S_2C_{10}H_6)$, which has never been crystallographically characterised, and is useful for a comparison with the complexes **1**–**4**.

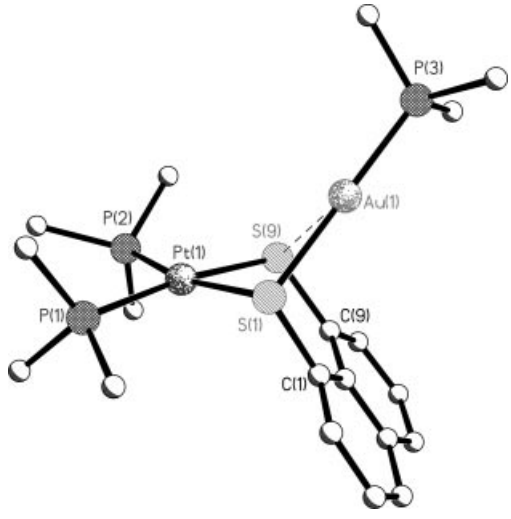

Figure 3. Crystal structure of $[(Ph_3P)_2Pt(S_2C_{10}H_6)(AuPPh_3)]^+ClO_4^-$ (**1**); $ClO_4^-$ anion is omitted for clarity.

We found no intermolecular packing effects in the solid-state structure of **1**, which would account for the longer Pt–S(9) distance.

Complex **3** consists of two $[P_2PtS_2]$ units connected by a single bridging silver atom connected to all four sulfur atoms (see Figure 4. Both $[P_2PtS_2]$ units are similarly affected by the introduction of a silver atom between the two sulfur atoms. It is notable that the Ag–S distance is longer in **3** than in **4** (vide infra) and other $Pt_2Ag_2$ systems.[9] The silver atom pulls the two sulfur atoms closer together, as shown by the tighter S–Pt–S and Pt–S–C angles and the reduced splay angles on the naphthalene-1,8-bis(thiolato) backbone. With regard to the geometry around platinum, the reduced S–Pt–S angle is again compensated for by an increase in the P–Pt–P angle, and the configuration around the platinum atom deviates from square planarity. Similarly to complex **1**, the effect of the silver atom is such that the geometry around all the sulfur atoms changes to distorted trigonal pyramidal, with the largest angle around sulfur [C(1)–S(1)–Ag(1) = 112.7(5)°] displaying that there is considerable deviation from trigonal planarity. The presence of the silver atom has also forced the naphthalene backbone and the triphenylphosphane groups closer together, as proven by the reduced dihedral angles in complex **3**. The silver atom can be considered four coordinate and can probably best be described as having a heavily distorted tetrahedral geometry. The metal–sulfur bonds are in the range 2.537(4)–2.690(4) Å. The S(1)–Ag–S(9) and S(51)–Ag–S(59) bond angles are approximately 75°, but the other S–Ag–S angles (i.e. those involving two sulfur atoms from opposite molecules) have a large range, which displays the deviation away from a tetrahedral geometry. The smallest of these angles is only 94.31(12)°, while the largest is 148.85(13)°.

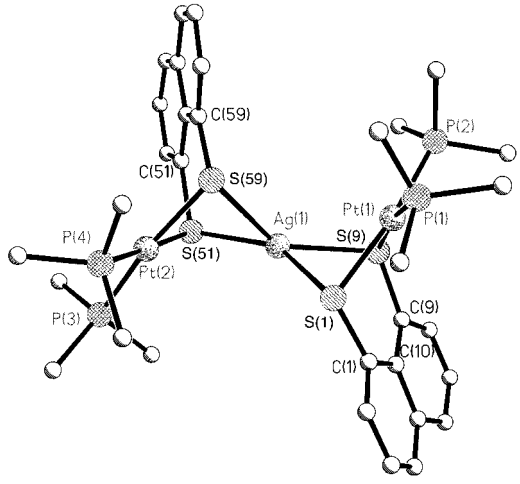

Figure 4. Crystal structure $Ag[(Ph_3P)_2Pt(S_2C_{10}H_6)]_2^+ClO_4^-$ (**3**); $ClO_4^-$ anion is omitted for clarity.

Complex **2** was found to crystallise in two different unit cells, one monoclinic (Figure 5) and one triclinic (Figure 6). In each case, however, the bond lengths and angles are very similar (Table 2). Complex **4** gave a triclinic unit cell (Figure 7), and the structure is again similar to those obtained for **2**. In these structures, the two $[P_2PtS_2]$ units are linked to each other by two metal atoms as opposed to one metal atom in complex **3** such that there are two S–M–S bridges. The Au–S distances are shorter than the Ag–S distances as a consequence of the difference in the covalent radii of the metals. The distances reported here are comparable with those in ethylenethiolato $Pt_2M_2$ complexes, which also dis-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

play similar $Pt_2M_2S_2$ six-membered chair conformation rings.[9] The bridging has a great effect on the geometry of the original platinum structures, although bond angles have changed by a negligible and unremarkable amount. While **3** was found to contain a six-membered $MS_2C_3$ ring, **2** and **4** contain seven-membered $M_2S_2C_3$ rings. This has had a converse affect as the insertion of the two new metal atoms actually increases the sulfur–sulfur distances and also the splay angles with respect to $(Me_3P)_2Pt(S_2C_{10}H_6)$. This results in the S–Pt–S angles widening slightly to almost exactly 90°. The P–Pt–P angles also increase slightly, but in this case, not as much as in complex **3**. This allows us to consider the platinum centre to be in a less distorted square-planar configuration than in $(Me_3P)_2Pt(S_2C_{10}H_6)$.

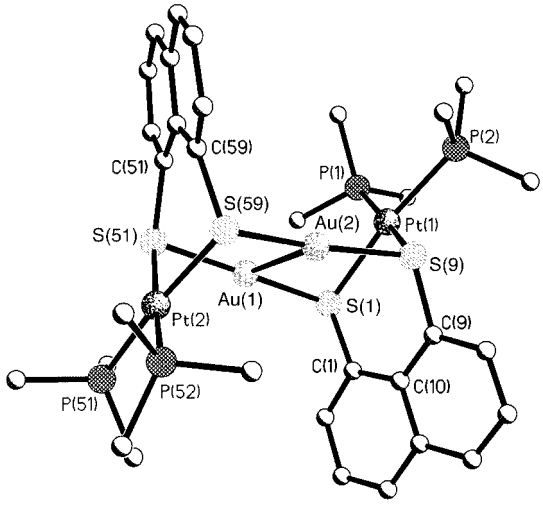

Figure 5. Crystal structure of $[Au(Ph_3P)_2Pt(S_2C_{10}H_6)]_2^{2+}2ClO_4^-$ (**2**); $ClO_4^-$ anions are omitted for clarity.

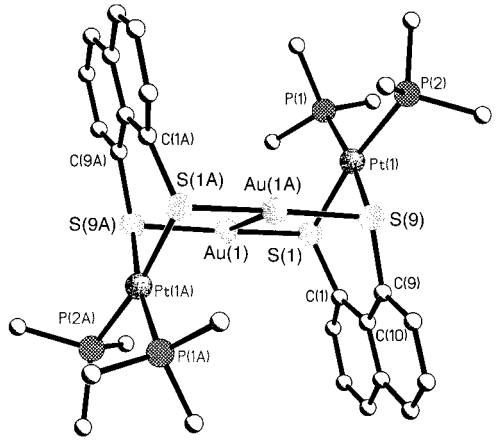

Figure 6. Crystal structure of $[Au(Ph_3P)_2Pt(S_2C_{10}H_6)]_2^{2+}2ClO_4^-$ (**2′**); $ClO_4^-$ anions are omitted for clarity.

Again, the geometry around the sulfur atoms is trigonal pyramidal, but it is slightly closer to a trigonal planar geometry than that in **3** since the presence of the other metal atom pushes the metal atom closer to the plane of the S, C and Pt atoms. This is evidenced by a general increase in the bond angles around the sulfur atoms, moving towards 120°.

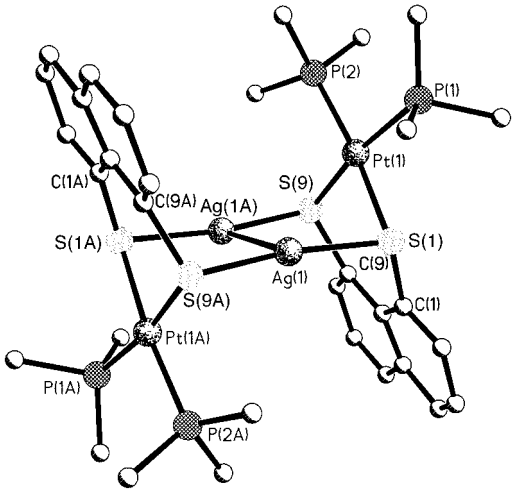

Figure 7. Crystal structure of $[Ag(Ph_3P)_2Pt(S_2C_{10}H_6)]_2^{2+}2ClO_4^-$ (**4**); $ClO_4^-$ anions are omitted for clarity.

The metal–metal bond lengths [2.9801(4), 3.0042(14) and 3.069(4) Å] are larger than those seen in similar sulfur–platinum complexes containing a gold–gold[10] or silver–silver[13] bond, but are still short enough to confirm a metal–metal interaction. Metal–sulfur bond lengths are similar and unremarkable. The M–M–S angles are in the range 90.77(4)–95.10(10)°, and the S–M–S angles are in the range 171.28(16)–175.56(6)°. This signifies that the metal atoms are in only slightly distorted T-shaped environments. Again, these values are close to those of previously studied examples.[10,13] One major point worth mentioning is that the presence of two metal atoms in the bridge actually pushes the sulfur atoms more into the plane of the Pt and C(10) atoms, giving these structures a greater dihedral angle than in $(Me_3P)_2Pt(S_2C_{10}H_6)$, as opposed to a smaller dihedral angle in the case of complex **3**. These values now lie in the range 142–150° compared with 136° in $(Me_3P)_2Pt(S_2C_{10}H_6)$ and 121–124° in complexes **1** and **3**.

## Conclusions

This paper illustrates the ability of sulfur-donor atoms to bridge metal centres. It is apparent that the planar naphthalene backbone used here is sterically undemanding with respect to. bridging systems, and thus these ligands may be capable of supporting many different multimetallic systems.

## Experimental Section

**General:** Manipulations were performed under anoxygen-free nitrogen atmosphere using standard Schlenk techniques and glassware. Solvents were dried, purified and stored according to common procedures.[16] [Naphthalene-1,8-bis(thiolato)]bis(triphenylphenylphosphane)platinum was prepared according to literature procedures.[14] $^{31}P\{^1H\}$ (109.4 MHz) and $^{195}Pt$ (58.1 MHz) NMR spectra were recorded with a Jeol DELTA GSX270 spectrometer with $\delta(^{31}P)$ referenced to external 85% $H_3PO_4$ and $\delta(^{195}Pt)$ to external $H_2PtCl_6$. $ES^+$ mass spectra were carried out by the University of St Andrews Mass Spectrometry Service.

**$[(Ph_3P)_2Pt(S_2C_{10}H_6)(AuPPh_3)][ClO_4]$ (1):** $Ph_3PAuCl$ (0.049 g, 0.1 mmol) was dissolved in dichloromethane (5 $cm^3$), and $AgClO_4$ (0.021 g, 0.1 mmol) in acetonitrile (1 $cm^3$) was added. The mixture was stirred in the dark for 2 h. A white solid precipitated, which was then dried in vacuo, redissolved in dichloromethane (10 $cm^3$) and filtered to remove insoluble AgCl. Solid $(Ph_3P)_2Pt(S_2C_{10}H_6)$ (0.091 g, 0.1 mmol) was added in one portion, and the mixture was allowed to stir overnight. The resulting solution was filtered through celite and washed with dichloromethane (20 $cm^3$). The solution was reduced in volume to approximately 1 $cm^3$, and the final product was precipitated by slow addition of diethyl ether (15 $cm^3$). The final product was filtered off and dried in vacuo as a yellow powder. Yield 0.079 g, 58%. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 17.6 [$^1J(P_A,Pt)$ = 3080 Hz, Pt–*P* ], 32.69 (Au–*P*) ppm. $^{195}Pt$ NMR ($CD_2Cl_2$): $\delta$ = –4674 ppm. $ES^+$ MS: *m*/*z* = 1368 $[M]^+$. $ES^-$ MS: *m*/*z* = 99 $[ClO_4]^-$.

**$[Au(Ph_3P)_2Pt(S_2C_{10}H_6)]_2[ClO4]_2$ (2):** $Ph_3PAuCl$ (0.098 g, 0.2 mmol) was dissolved in dichloromethane (5 $cm^3$), and $AgClO_4$ (0.042 g, 0.2 mmol) in acetonitrile (1 $cm^3$) was added. The mixture was stirred in the dark for 2 h. A white solid precipitated, which was then dried in vacuo, redissolved in dichloromethane (10 $cm^3$) and filtered to remove insoluble AgCl. Solid $(Ph_3P)_2Pt(S_2C_{10}H_6)$ (0.091 g, 0.1 mmol) was added in one portion, and the mixture was allowed to stir overnight. The resulting solution was filtered through celite and washed with dichloromethane (20 $cm^3$). The solution was reduced in volume to approximately 1 $cm^3$, and the final product was precipitated by slow addition of diethyl ether (15 $cm^3$). The final product was filtered off and dried in vacuo as a yellow powder. Yield 0.074 g, 67%. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 14.4 [$^1J(P_A,Pt)$ = 3134 Hz] ppm. $^{195}Pt$ NMR ($CD_2Cl_2$): $\delta$ = –4563 ppm. $ES^+$ MS: *m*/*z*= 1107 $[1/2\ M]^+$. $ES^-$ MS: *m*/*z* = 99 $[ClO_4]^-$.

**$Ag[(Ph_3P)_2Pt(S_2C_{10}H_6)]_2[ClO_4]$ (3):** $(Ph_3P)_2Pt(S_2C_{10}H_6)$ (0.150 g, 0.165 mmol) was dissolved in tetrahydrofuran (15 $cm^3$), and a solution of $AgClO_4$ (0.017 g, 0.0825 mmol) in acetonitrile (10 $cm^3$) was slowly added. The mixture was stirred for 3 h. The resulting solution was dried in vacuo, redissolved in a minimum volume of dichloromethane, and the final product was precipitated by slow addition of diethyl ether (20 $cm^3$). The final product was filtered off and dried in vacuo as an orange powder. Yield 0.081 g, 51%. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 6.83 [$^1J(P_A,Pt)$ = 2989 Hz] ppm. $^{195}Pt$ NMR ($CD_2Cl_2$): $\delta$ = –4698 ppm. $ES^+$ MS: *m*/*z* = 1928 $[M]^+$. $ES^-$ MS: *m*/*z* = 99 $[ClO_4]^-$.

**$[Ag(Ph_3P)_2Pt(S_2C_{10}H_6)]_2[ClO_4]_2$ (4):** $(Ph_3P)_2Pt(S_2C_{10}H_6)$ (0.150 g, 0.165 mmol) was dissolved in tetrahydrofuran (15 $cm^3$), and a solution of $AgClO_4$ (0.034 g, 0.165 mmol) in acetonitrile (10 $cm^3$) was slowly added. The mixture was stirred for 3 h. The resulting solution was dried in vacuo, redissolved in a minimum volume of dichloromethane, and the final product was precipitated by slow addition of diethyl ether (20 $cm^3$). The final product was filtered off and dried in vacuo as a yellow powder. Yield 0.101 g, 60%. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 18.29 [$^1J(P_A,Pt)$ = 3122 Hz] ppm. $ES^+$ MS: *m*/*z* = 1928 $[M]^+$. $ES^-$ MS: *m*/*z* = 99 $[ClO_4]^-$.

**Crystal-Structure Analysis:** Table 3 lists the details of data collections and refinements. Intensities were corrected for Lorentz-polarisation and for absorption. For **1**, **2** and **2′**, data were collected at 93 K by using Mo-$K_\alpha$ radiation from a high brilliance Rigaku MM007 generator and a Rigaku Mercury ccd detector, and for **3** and **4**, at 93 K using a Rigaku Saturn70 ccd detector. The structures were solved by the heavy-atom method or by direct methods. The positions of the hydrogen atoms were idealised. Refinements were performed by full-matrix least-squares based on $F^2$ with SHELXTL.[17] CCDC-614032–614036 for **1**–**4** contain the supple-

# Dissociation of the P=C Ylidic Bond

**Igor Shevchenko,*[a] Alexey Rogalyov,[a] Alexander B. Rozhenko,[b] and Gerd-Volker Röschenthaler[c]**

*Dedicated to Professor Edgar Niecke*

**Keywords:** Ylides / Carbenes / Phosphanes / Density functional calculations

The phosphorus ylides $RPh_2P{=}C(Mes)N{=}C(CF_3)_2$ [R = Ph, $Ph_2P(O)CH_2$] in solution undergo reversible dissociation of the P=C ylidic bond to give phosphanes $RPh_2P$ and the carbene $MesC(:)N{=}C(CF_3)_2$. The latter can be trapped as its mesomeric nitrile ylide by treatment with cyclohexene or phenyl isocyanate to give cyclic addition products.

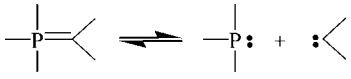
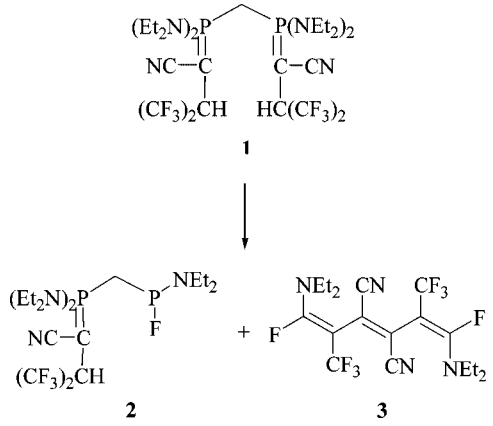
## Introduction

The formation of phosphorus ylides by the reaction of trivalent phosphorus compounds with unstable carbenes generated in situ is well established (Scheme 1).[1]



Scheme 1.

The use of stable carbenes[2] in reactions with phosphanes, however, is almost unknown.[3] Although the chemistry of phosphorus ylides is rather well studied[4] and a large number of unstable ylides have been synthesised, the reverse process, namely decomposition of phosphorus ylides to give carbenes and phosphanes, has not been known up to now. We have reported previously that diylide **1**, which contains bulky diethylamino groups at phosphorus[5a] rather than dimethylamino groups,[5b] is not stable and undergoes an unusual decomposition reaction to give ylide **2** and triene **3** almost quantitatively. The most probable route for formation of the symmetric triene **3** is the dimerisation of the appropriate carbene, whose appearance in the reaction mixture can be explained in terms of cleavage of the ylidic bond to phosphorus (Scheme 2).



Scheme 2.

Whilst this paper was being prepared for publication a report was published on the cleavage of a phosphorus ylidic bond forming part of a strained four-membered ring to give a stable carbene.[6] We now have evidence to show that acyclic non strained ylides can also undergo such a decomposition.

## Results and Discussion

We have found that ylides **4** and **7** are capable of reversible cleavage of the P=C bond in solution with the formation of carbene (nitrile ylide) **6** and phosphanes **5** and **8**, respectively. The equilibrium is shifted to the ylidic side. The amounts of phosphane and carbene in the reaction solution are too low for NMR spectroscopic observation,

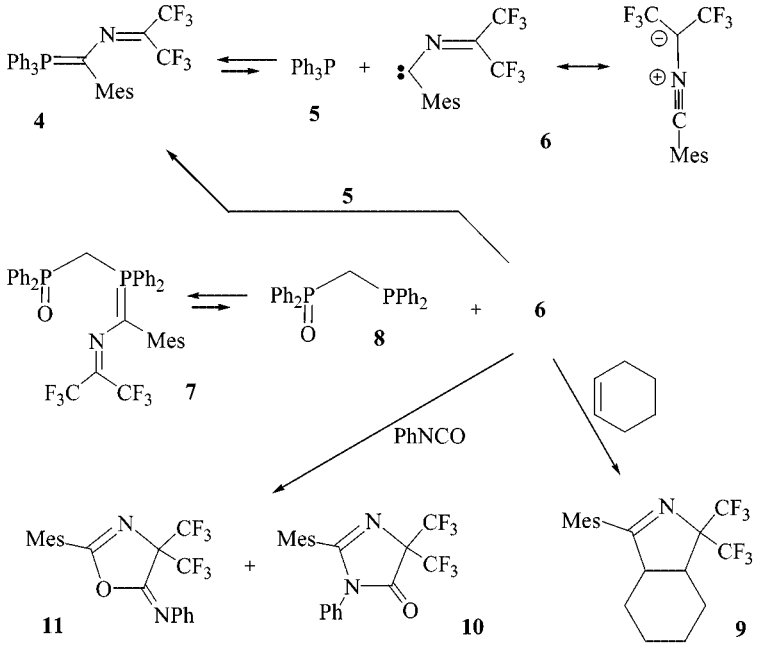
even upon heating to 50 °C. Although nitrile ylide **6** contains the bulky mesityl group it is not stable at 50–70 °C.[7] Because of the different thermodynamic stabilities of the starting ylides **4** and **7** their decomposition rates are also different. For example, ylide **7** decomposes completely in solution after 3–4 h at 70 °C whereas 80% of ylide **4** remains unchanged under the same conditions after 24 h. The $^{31}P$ NMR spectra of the reaction mixtures only display signals for the appropriate phosphanes **5** or **8** after completion of the decomposition.

The reversible character of the P=C ylidic bond cleavage as well as the presence of carbene **6** (or the mesomeric nitrile ylide) in the reaction mixture is in agreement with the fact that the rate of decomposition of the starting ylides becomes drastically shorter in the presence of trapping agents. For example, compound **6** reacts as a nitrile ylide with cyclohexene or phenyl isocyanate to give stable cyclic products **9** or **10** and **11** (Scheme 3). Other phosphanes that form more thermodynamically stable P=C bonds with **6** than the starting ylide can also be used as trapping agents. For example, heating of a solution of ylide **7** with triphenylphosphane (**5**) gave ylide **4** and compound **8** quickly and almost quantitatively.

The formation of carbene **6** and the appropriate phosphane is due to the dissociation of the $P^+$–$C^-$ ylidic bond and can be considered as a self-reduction reaction of the phosphorus ylides **4** and **7**. One could assume that the $P^+$–$C^-$ bond in these compounds should be longer than the normal ylidic bond. Indeed, our DFT calculations (RI-BP86/TZVP, see Experimental Section) show that the P–C1 bond length in compound **4** (Figure 1, a) is 1.81 Å, which is about 0.15 Å longer than the standard ylidic bond and comparable with the value of a phosphorus–carbon single bond.[8] This could be due to steric repulsion between the mesityl group at the carbon atom and the $PPh_3$ moiety. The decomposition of analogous ylides in which the mesityl group is replaced by the less bulky phenyl group proceeds in the same way but requires more time and a higher temperature. At first sight, this is in line with the suggestion made above. However, calculations carried out for the analogous compound with the Ph group (**4a**; Figure 1, b) indicate almost the same P=C bond length (1.80 Å). There is only one structural difference which can be related to the steric properties of the two aromatic moieties: the dihedral angle between the phenyl ring and the C1–N2–C3 plane in **4a** is about 66° whereas the Mes substituent in **4** is orthogonal ($C^{ortho}$–C4–C1–N2 angles are 99.2° and –86.5° and $C^{ortho}$–C4–C1–P5 angles are 86.8° and –87.5°). Additionally, similar C1–N2–C3 bond angles (ca. 137°) are found for both structures. This supports a significant contribution of the mesomeric structures **B** and **C**, where negative charge is formally localised on the terminal imino carbon and is additionally delocalised on the electron-withdrawing $CF_3$ substituents. This means that positive charge is localised simultaneously on phosphorus and at least partially on nitrogen due to the contribution of the form **C**. This latter formal positive charge on nitrogen is sufficiently counterbalanced by the polarisation of the C–N σ- and π-bonds towards nitrogen due to its higher electronegativity. Thus, the elongation of the P–C ylidic bond in **4** to 1.81 Å (compared with the classical polarised ylidic bond) is accounted for by the contribution of mesomeric structures **B** and **C**. The large Ar–C–N bond angle (approximately 131°) and the short C–N distances (1.31 and 1.32 Å for the central and terminal C–N bonds, respectively) are also in agreement with the contribution of form **C** (Scheme 4). This mesomeric form literally predetermines the P–C bond dissociation. The reaction product, nitrile ylide **6**, keeps



Scheme 3.

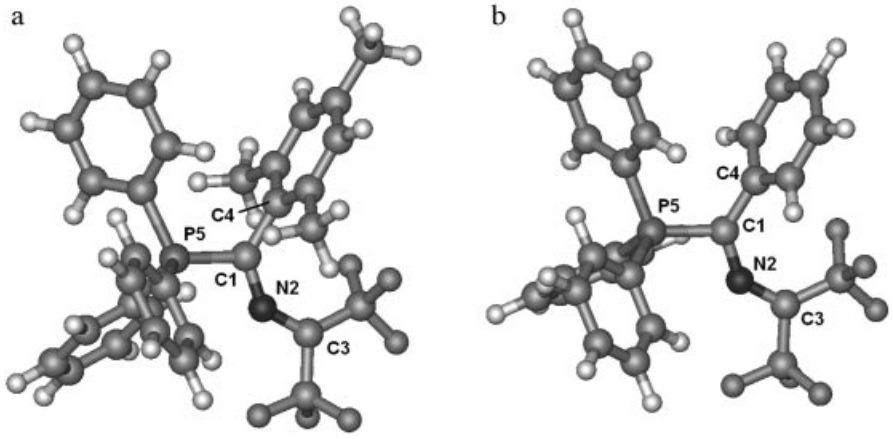

Figure 1. The equilibrium (RI-BP86/TZVP) structures of **4** (a) and **4a** (b). The most important bond lengths [Å] and bond angles [°] for **4** and **4a**, respectively, are: C1–N2 1.324, 1.327; N2–C3 1.312, 1.310; C1–C4 1.497, 1.493; C1–P5 1.808, 1.803; C1–N2–C3 137.0, 137.2; N2–C1–C4 131.2, 131.3; N2–C1–P5 107.6, 108.6; C4–C1–P5 120.4, 119.8.

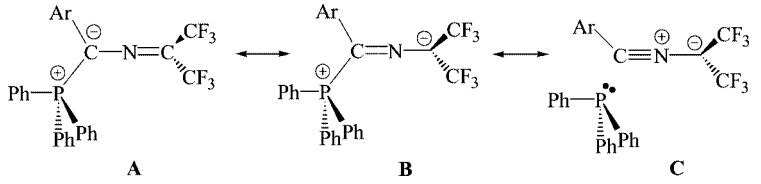

Scheme 4.

many structural features inherent to this fragment as part of the starting ylide (Figure 2).

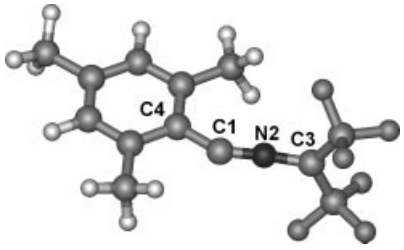

Figure 2. The equilibrium (RI-BP86/TZVP) structure of **6**. The most important bond lengths [Å] and bond angles [°] are: C1–N2 1.198, N2–C3 1.310, C1–C4 1.424; C1–N2–C3 173.7, N2–C1–C4 147.2.

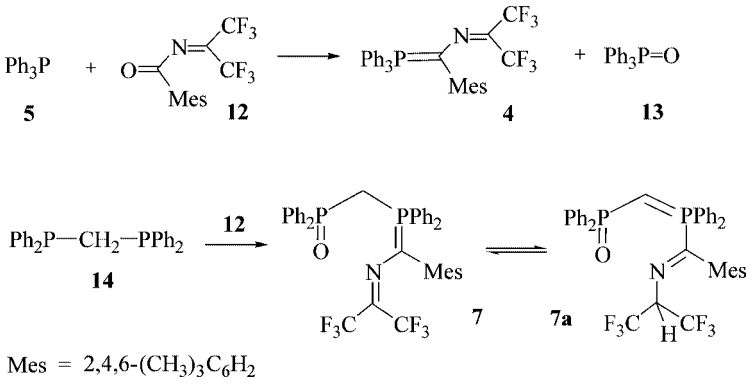
Ylides **4** and **7** were synthesised by the reaction of triphenylphosphane (**5**) or bis(diphenylphosphanyl)methane (**14**) with the acylimine **12** of hexafluoroacetone. These reactions are quite interesting because they occur with complete cleavage of the C=O double bond. The formation of new bonds by the interaction of an electrophilic carbonyl group with trivalent phosphorus usually proceeds with the cleavage of only one bond of the carbonyl function. For this reason the formation of cyclic products is frequently observed. For example, the reaction of acylimines of hexafluoroacetone with phosphites has been shown to give $\Delta^4$-1,4,2$\lambda^5$-oxazaphospholines.[9]

In solution, compound **7** exists in equilibrium with its structural isomer **7a** because of prototropic migration (Scheme 5). The isomers differ from each other in the positions of the ylidic bond and one of the protons. The distribution between the isomers depends on the polarity of the solvent used. In dichloromethane, for example, the equilibrium is shifted to isomer **7** whereas in hexane it is shifted to isomer **7a**. The isomers are readily distinguishable in the $^{19}$F NMR spectrum by the signals of the non-equivalent $CF_3$ groups (compound **7**) and equivalent $CF_3$ groups (compound **7a**) bonded to $sp^2$ and $sp^3$ carbon atoms, respectively. The ylide **7a** contains a stabilizing diphenylphosphane oxide group at the ylidic bond and does not decompose on heating, isomerizing into the other isomer **7** as it disintegrates to form phosphane **8** and carbene **6**. No products that could result from the decomposition of isomer **7a** were found after the thermolysis either in the presence of trapping agents or without them.

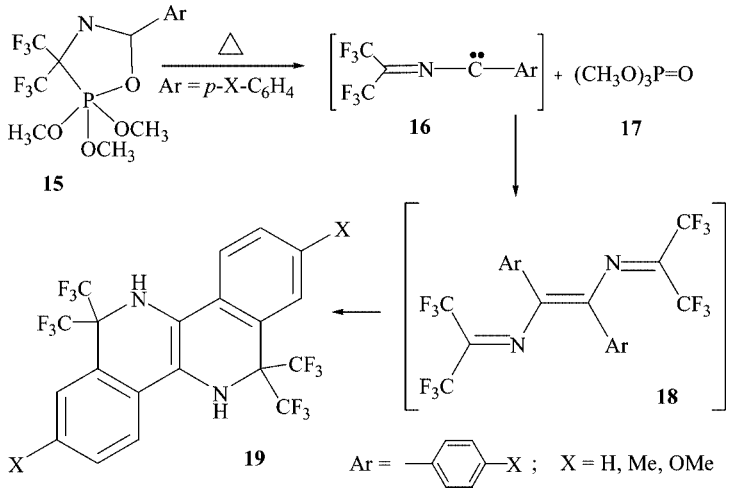
Taking into account the reversible character of the formation of carbene **6** from ylides **4** and **7**, one can conclude that the formation of these ylides also includes the reaction of the same carbene with appropriate phosphanes. This conclusion is in agreement with our calculations. As the ArC–N bond angle of **6** was found to be 147.2°, this compound can display carbene-like properties. The intermediate formation of unstable carbenes has been indirectly confirmed in another deoxygenation reaction of a carbonyl group by phosphanes.[10]

In general, there are only a few examples known of the behaviour of nitrile ylides as imine-substituted carbenes, all of which are devoted to their dimerisation.[11] For example, the imine-stabilized carbene **16**, which results from the thermolysis or photolysis of 4,5-dihydro-1,2,3$\lambda^5$-dioxaphosphole (**15**), has been postulated as one of the intermediates in the formation of compound **19** (Scheme 6).[12]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 5.



Scheme 6.

In summary, our results show that nitrile ylides can display their carbene-like properties not only in dimerisation reactions but also in their reaction with phosphanes.

## Experimental Section

**General Remarks:** All operations were performed under nitrogen in a dry box. The solvents were dried by the usual procedures. The NMR spectra were recorded with Varian Gemini 400 MHz and JEOL FX-90Q spectrometers. The mass spectrum of compound **9** was recorded with an Agilent 1100 LC/MSD spectrometer. The $^{1}H$ and $^{13}C$ chemical shifts are referenced to tetramethylsilane (TMS) and $^{19}F$ to $CFCl_3$. The $^{31}P$ chemical shifts were measured using 85% aqueous $H_3PO_4$ as an external standard.

**Compound 4:** Acylimine **12** (26 mg, 0.083 mmol) in thf (0.4 mL) was added to a solution of triphenylphosphane (**5**; 52 mg, 0.198 mmol) in thf (0.4 mL) at room temperature. After 24 h the NMR spectra of the light-yellow reaction mixture showed quantitative formation of ylide **4** and triphenylphosphane oxide (**13**). This mixture was used for the decomposition of **4** without further purification. $^{1}H$ NMR ($CDCl_3$): $\delta$ = 2.19 (s, 3 H, Me), 2.35 (s, 6 H, Me), 6.6–8.1 (m, 17 H, Ar) ppm. $^{19}F$ NMR ($CDCl_3$): $\delta$ = –56.83 (q, $^{4}J_{F,F}$ = 8.5 Hz, 3 F), 59.25 (qd, $^{4}J_{F,F}$ = 8.5, $J_{P,F}$ = 3.4 Hz, 3 F) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 4.28 (s) ppm.

**Compounds 7 and 7a:** A solution of methylenebis(diphenylphosphane) (50 mg, 0.13 mmol) in $CDCl_3$ (0.4 mL) was added, whilst stirring, to a solution of acylimine **12** (50 mg, 0.16 mmol) in $CDCl_3$ (0.6 mL) over 2 min at 20 °C. After 10 min the NMR spectra showed almost quantitative formation of the isomers **7** and **7a**. This mixture was used for further reactions without purification.

**7:** $^{1}H$ NMR ($CDCl_3$): $\delta$ = 2.13 (s, 3 H, Me), 2.28 (s, 6 H, Me), 4.16 (dd, $^{2}J_{P,H}$ = 10.7, $^{2}J_{P,H}$ = 15.1 Hz, 2 H, P-C$H_2$-P), 6.57–8.05 (m, 22 H, Ar) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 10.78 (dm, $J_{P,C}$ = 180.0 Hz, 1 C, P*C*CN), 26.22 (dd, $^{1}J_{P,C}$ = 25.4 Hz, $^{1}J_{P,C}$ = 85.8 Hz, P*C*P), 36.60 (d, $^{2}J_{P,C}$ = 2.9 Hz, 2 C, $NMe_2$), 36.76 (d, $^{2}J_{P,C}$ = 3.9 Hz, 2 C, $NMe_2$), 40.40 (d, $^{2}J_{P,C}$ = 15.6 Hz, 4 C, $NMe_2$), 45.62 [sept dd, $^{2}J_{P,C}$ = 16.6 Hz, $J_{P,C}$ = 5.9 Hz, $^{2}J_{F,C}$ = 29.3 Hz, 1 C, *C*H($CF_3$)$_2$], 124.20 (q, $^{1}J_{F,C}$ = 282.9 Hz, 2 C, *C*$F_3$), 125.02 (d, $^{2}J_{P,C}$ = 10.8 Hz, *C*N) ppm. $^{19}F$ NMR ($CDCl_3$): $\delta$ = –56.6 (qd, $^{4}J_{F,F}$ = 8.5 Hz, $J_{P,F}$ = 2.5 Hz, 3 F), –58.5 (qd, $^{4}J_{F,F}$ = 8.5 Hz, $J_{P,F}$ = 3.4 Hz, 3 F) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 6.3 (br. d, $^{2}J_{P,P}$ = 14.0 Hz), 23.7 (d, $^{2}J_{P,P}$ = 14.0 Hz) ppm.

**7a:** $^{1}H$ NMR ($CDCl_3$): $\delta$ = 1.33 (s, 1 H, P-C*H*-P), 1.82 (s, 3 H, Me), 1.97 (s, 6 H, Me), 4.27 (sept., $^{3}J_{F,H}$ = 5.9 Hz, 1 H, $CF_3$-C*H*-$CF_3$), 6.57–8.05 (m, 22 H, Ar) ppm. $^{19}F$ NMR ($CDCl_3$): $\delta$ = –68.48 (d, $^{3}J_{H,F}$ = 5.9 Hz, 6 F) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 20.8 (d, $^{2}J_{P,P}$ = 20.3 Hz), 27.5 (d, $^{2}J_{P,P}$ = 20.3 Hz) ppm.

**Compound 9:** Ylide **7** (550 mg) was obtained in chloroform as described above. The solvent was removed in vacuo and the residue was dissolved in cyclohexene (1600 mg). The mixture was heated at 75 °C for 2 h. The excess of cyclohexene was removed and the residue was extracted twice with hexane (2 × 5 mL). Column chromatography on silica gel (hexane/toluene, 3:1) of the solid re-

maining after evaporation of hexane afforded 50 mg of a white product. M.p. 164–165 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 1.3–1.9 (m, 8 H), 2.20 (s, 6 H, Me), 2.28 (s, 3 H, Me), 2.90 (m, 1 H),, 3.38 (m, 1 H), 6.87 (br. s, 2 H, Ar) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 20.03 (br. s), 20.35 (s), 20.51 (s), 20.67 (s), 21.47 (s), 39.90 (s), 52.93 (s), 85.25 (m), 123.63 (q, $^1J_{F,C}$ = 284 Hz, $CF_3$), 124.50 (q, $^1J_{F,C}$ = 284 Hz, $CF_3$), 128.76 (s), 128.85 (s), 130.79 (s), 134.34 (br. s), 135.80 (br. s), 138.71 (s), 190.64 (s) ppm. $^{19}$F NMR ($CDCl_3$): $\delta$ = –67.56 (q, $^4J_{F,F}$ = 10.2 Hz, 3 F), –73.80 (q, $^4J_{F,F}$ = 10.2 Hz, 3 F) ppm. MS (APCI): *m*/*z* 378 $[M + H]^+$.

The same product was obtained when ylide **4**, obtained as described above (together with $Ph_3PO$), was heated in cyclohexene at 75 °C for 6 h.

**Compounds 10 and 11:** PhNCO (0.8 mL) was added to a reaction solution of ylide **4** obtained from acylimine **12** (50 mg) and triphenylphosphane (100 mg) in thf (0.8 mL) as described above and the mixture was heated at 60 °C for 10 h. The $^{19}$F NMR spectrum showed almost quantitative formation of the isomers **10** and **11** ($\delta$ = –72.7 and –74.0 ppm, respectively; both 6 F), which were isolated chromatographically as described previously.[13]

When a solution of ylide **7** in $CDCl_3$ was heated at 55 °C in the presence of PhNCO the yield of compounds **10** and **11** was substantially lower (about 20%). The main process in this case is an addition reaction between PhNCO and ylide **4**. This product will be described in a subsequent paper.

**Computational Details:** All of the structures were fully optimised without symmetry constraints. The BP86 functional[14,15] with an approximate treatment of the electronic Coulomb interaction [resolution of identity (RI)[16] algorithm] and the triple-zeta valence (TZV) quality basis sets[17] implemented in the TURBOMOLE program set[18] was used for the geometry optimisation. One set of polarisation functions was added for all atoms (the standard TZVP basis sets included in the TURBOMOLE packet). An SCF convergence criterion SCFConv = $1.0 \times 10^{-8}$ Hartree and the finest grid value (grid = 5) was used in the optimisation. All the structures were proved to be local minima in energy; the vibration analyses were performed by computing analytical first- and second-order derivatives.[19] A full account of the optimised geometries is given in the Supporting Information. The VMD program packet[20] was used for the graphical presentation of the calculated structures.

# Oxidation of Phosphanes with Orthoquinones: An Unusual Decomposition of an Unexpectedly Stable Zwitterion

**Igor Shevchenko,*[a] Vasyl Andrushko,[a] Enno Lork,[b] and Gerd-Volker Röschenthaler*[b]**

**Keywords:** Ylides / Phosphanes / Zwitterions / Carbodiphosphorane

Oxidation of the ylide $(Et_2N)_2P[=C(CN)CH(CF_3)_2]CH_2P(NEt_2)_2$ (**3**) with tetrachloroorthobenzoquinone (TOB) does not give the expected 1,3,2-dioxaphospholane but stops at the formation of the unusually stable intermediate zwitterion **6**. The molecular structure of **6** was established by X-ray analysis. In solution at temperatures above 15 °C zwitterion **6** undergoes an unusual decomposition into symmetrical carbodiphosphorane **7** and hexafluoroisovaleronitrile **8**.

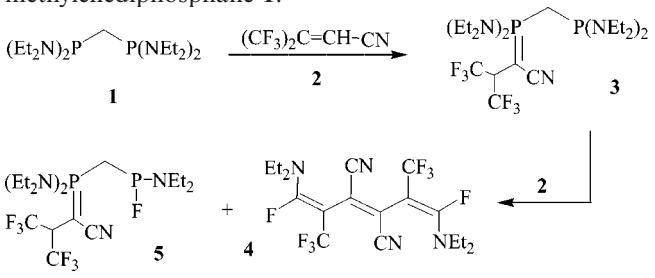
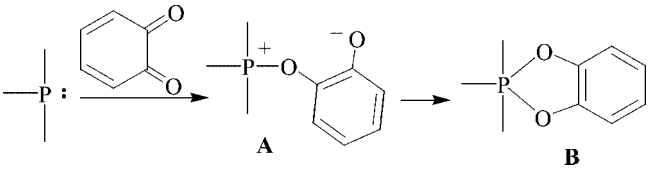
## Introduction

Previously we have described the addition of 4,4,4-trifluoro-3-(trifluoromethyl)-2-butenenitrile (**2**) to bis[bis(dimethylamino)phosphanyl]methane (**1**) to give the monoylide **3**. The reaction of **3** with a second equivalent of **2** does not give the expected symmetrical diylide but leads unexpectedly to the almost quantitative formation of the fluorinated triene **4**.[1,2] The second product of this reaction was identified as the fluorine-substituted ylide **5**. These two reactions can be combined in one and triene **4** can be easily prepared by adding two equivalents of **2** to the starting methylenediphosphane **1**.



The most probable route for formation of the symmetric molecule of triene **4** is the dimerization of the appropriate carbene, and the only possible way for this to form is by dissociation of the ylidic P=C bond. We reasoned that if this is not a particular case, then an analogous cleavage may also be observed if the trivalent phosphorus atom of **3** were to react with other electrophilic reagents.

Here we wish to report on the rather unusual reaction of mono ylide **3** with tetrachloro-orthobenzoquinone (TOB). The oxidation of phosphanes with orthobenzoquinones normally leads to the formation of five-coordinate phosphoranes in which two oxygen atoms are connected to phosphorus to form 1,3,2-dioxophospholane **B**. Such reactions proceed in two steps via intermediate zwitterionic compounds **A**, which are very unstable and can only be detected by NMR spectroscopy at low temperatures.[3] The increase of steric hindrance stabilizes the zwitterionic intermediate. For example, the use of the more bulky phenanthrenequinone instead of benzoquinone in the reaction with triphenylphosphane gave the appropriate intermediate of type **A**, which is stable at room temperature.[4] Unfortunately, X-ray investigation of this compound could not be performed.



We have found that the reaction of compound **3** with TOB does not lead to the expected phosphorane structure, but stops at the formation of zwitterionic intermediate **6**. This compound crystallizes easily from the reaction mixture in diethyl ether in 65% yield as colorless crystals that turned out to be unusually stable. The detailed molecular structure of **6** (Figure 1) was established by X-ray analysis.

The bonding situation around phosphorus P(2) does not correspond to the trigonal-bipyramidal coordination geometry typical of a $\lambda^5P^5$ configuration but displays the tetrahedral geometry of the phosphonium structure $\lambda^4P^5$. The appearance of a positive charge at phosphorus P(2) causes some shortening of the P(2)–C(1) bond in comparison with

the starting compound **3** (179.5 and 187.6 pm, respectively). The negatively charged oxygen O(2) is situated between the two positively charged phosphorus atoms. The P(1)–O(2) and P(2)–O(2) distances (415.9 and 320.1 pm, respectively) are substantially longer than the P(2)–O(1) bond [157.93(19)], which excludes bonding between the atoms. The structure around the ylidic phosphorus P(1) does not differ substantially from that of the starting compound **3**. The two adjacent nitrogen atoms N(1) and N(2) have slightly different configuration. The N(1) atom is almost flat, whereas the N(2) atom has a more pronounced tetrahedral geometry [the sums of angles are 358.5(6)° and 348.0(1)°, respectively]. In solution, however, both diethylamino groups are equivalent and display common signals in the $^1$H NMR spectrum.

The ylidic carbon C(10) has an ideal flat conformation accounting for the delocalization of the negative charge on the nitrile group. That is why the P(1)–C(10) bond (171.4 pm) is somewhat longer than a normal ylidic bond (168 pm),[5] whereas the C(1)–C(2) distance is considerably shorter (139.7 pm) than the average single C–C bond. These data are consistent with the structure of the other nitrile-substituted phosphorus ylides.[6–8]

Considering that the ylidic P(1)–C(10) bond is highly polarized, the molecule contains two positively charged phosphorus atoms and negatively charged oxygen and carbon atoms. The $^{31}$P NMR spectrum of **6** displays two doublets at $\delta$ = 44.51 and 57.20 ppm ($^2J_{P,P}$ = 11.2 Hz). These values are typical for ylidic and positively charged tetracoordinate phosphonium structures, respectively. If phosphorus P(2) were connected to the second oxygen O(2) it would have a five-coordinate phosphorane structure and a chemical shift of about $\delta$ = –50 ppm. The methylene group between the two electron-withdrawing phosphonium centers displays a doublet of doublets at $\delta$ = 4.74 ppm in the $^1$H NMR spectrum. This value suggests that the acidity of the $CH_2$ protons is comparable with that of $CH_2Cl_2$. In the presence of the adjacent anionic centers in the molecule this may lead to the appearance of other prototropic forms. Indeed, the $^1$H NMR spectrum of compound **6** in chloroform displays a temperature-dependent equilibrium between zwitterionic form **6** and other possible forms **6a**,**b** resulting from the migration of one of the protons to the negatively charged oxygen O(2).

At +15 °C the position of the equilibrium is completely shifted to the zwitterionic form **6** and the P–$CH_2$–P methylene protons display a broad doublet of doublets at $\delta$ = 4.74 ppm. At 0 °C two additional very broad signals at $\delta$ = 9.46 and 2.46 ppm appear in the spectrum. The low-field signal belongs to the OH proton and the chemical shift value of the second one is more in agreement with the P=CH–P proton of isomer **6a**. This proton is connected to the negatively charged ylidic carbon atom and is thus shifted to higher field than that of structure **6b**. The intensity of the signals of the OH-containing isomers increases upon lowering the temperature. The contribution of structure **6b** probably increases at low temperature because the broad signal of the CH proton shifts gradually to lower field ($\delta_H$ = 2.94 ppm at –40 °C). The ratio between isomers **6** and **6a**,**b** at this temperature reaches 40:60. We did not find signals for the fourth possible prototropic form **6c** in the $^1$H NMR spectrum.

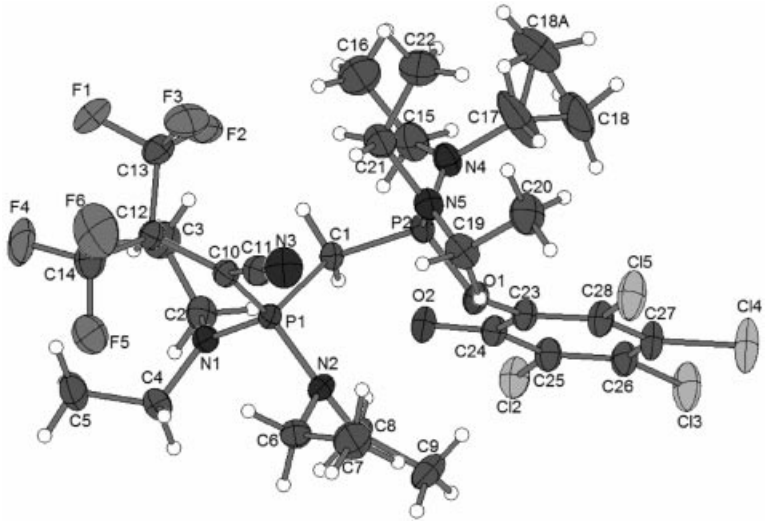

Figure 1. Perspective view and labeling scheme for **6**. Selected interatomic distances [pm] and bond angles [°]: P(1)–C(10) 171.4(3), P(1)–C(1) 183.0(3), C(1)–P(2) 179.5(2), P(1)–N(1) 165.3(2), P(1)–N(2) 165.5(2), P(2)–N(4) 161.2(2), P(2)–N(5) 162.3(2), C(10)–C(11) 139.7(4), C(11)–N(3) 116.1(4), C(10)–C(12) 151.3(3), P(2)–O(1) 157.93(19), O(2)–P(1) 415.9, O(2)–P(2) 320.1; C(10)–P(1)–C(1) 115.05(12), P(2)–C(1)–P(1) 122.90(14), C(11)–C(10)–C(12) 118.6(2), C(11)–C(10)–P(1) 122.0(2), C(12)–C(10)–P(1) 119.37(19), N(3)–C(11)–C(10) 178.8(3), O(1)–P(2)–C(1) 107.57(11), N(4)–P(2)–C(1) 106.08(12).

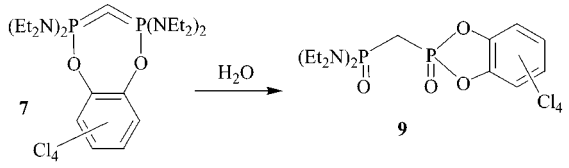
It is interesting that the $^{31}P$ NMR spectrum does not reflect all these changes of the molecule and shows two well-resolved doublets with constant chemical shifts at all temperatures below 20 °C.

In crystalline form zwitterion **6** is stable at room temperature under an inert atmosphere. For example, after 12 h we did not find additional signals in the NMR spectra. In chloroform solution compound **6** is stable up to 15 °C, and at 20 °C irreversible decomposition begins. The two doublets of **6** in the $^{31}P$ NMR spectrum become broad and unresolved and a new, sharp singlet appears at $\delta$ = 56.8 ppm. After about 25–30 h the spectrum contains only traces of the starting material. The conversion of two doublets due to the two inequivalent phosphorus nuclei into one singlet, and its chemical shift value, indicate that compound **6** rearranges into the symmetrical carbodiphosphorane **7**, which contains magnetically equivalent phosphorus nuclei. In the $^{19}F$ NMR spectrum the decomposition of **6** is shown by the disappearance of the doublet at $\delta$ = –66.42 ppm ($^3J_{H,F}$ = 8 Hz) and the growth of a new doublet at $\delta$ = –68.04 ppm ($^3J_{H,F}$ = 6.5 Hz), which belongs to six equivalent fluorine atoms of the second decomposition product [hexafluoroisovaleronitrile (**8**)]. This compound is a colorless, volatile liquid that can be easily distilled from the reaction mixture together with the solvent (chloroform). Its structure was confirmed by NMR spectroscopy and mass spectrometry. The decomposition rate depends on the properties of the solvent used. In chlorobenzene it is twice as fast as in chloroform.

Unlike other known unstable zwitterions of this type, the negatively charged oxygen atom O(2) of the former orthoquinone unit does not form the expected 1,3,2-dioxaphospholane cycle with phosphorus P(2), but attacks the other positively charged phosphorus P(1). The mechanism of the decomposition should include the dissociation of the P(1)–C(10) ylidic bond and the elimination of two hydrogen atoms from the methylene unit. There is no clue as to whether these processes proceed consecutively or are concerted. Taking into account our previous results,[1,2] as well as the recently reported P=C bond dissociation of strained four-membered cyclic ylides,[9] the homolytic cleavage of the P(1)–C(10) ylidic bond of **6** with the intermediate formation of the reactive carbene in this reaction cannot be excluded. Another possible mechanism of the decomposition of **6** may include, for example, an intermediate formation of compound **6d** which, because of steric hindrance around phosphorus P(1), may eliminate **8** to give carbodiphosphorane **7**.

In the early stages of the decomposition of zwitterion **6** carbodiphosphorane **7** is the only product and no other signals except for those of the starting material and the product are observed in the $^{31}P$ and $^{19}F$ NMR spectra. However, after completion of the process the content of numerous byproducts in the $^{31}P$ NMR spectrum reaches 30–40%. Carbodiphosphorane **7** is rather stable in the reaction solution and its signal decreases only gradually on heating to 70 °C during 10 h. However, our attempts to isolate the product in crystalline form failed. The structure of **7** was confirmed by its reaction with water. This process includes the formation of several intermediate compounds which finally give the product **9**. Unlike carbodiphosphorane **7**, this compound is not symmetrical and contains two magnetically inequivalent phosphorus atoms that appear as two doublets of an AB spin system at $\delta$ = 18.00 and 30.72 ppm ($^2J_{P,P}$ = 5.5 Hz) in the $^{31}P$ NMR spectrum. The signal at $\delta$ = 18 ppm, when recorded without proton decoupling, appears as a characteristic doublet of triplets. It belongs to the phosphorus atom of the 1,3,2-dioxaphospholane system because of the interaction with only two P–$CH_2$–P protons. Compound **9** was isolated as colorless crystals and its structure was additionally confirmed by $^1H$ NMR and HR mass spectrometry.



## Experimental Section

**General Remarks:** All operations were performed under nitrogen in a dry box. The solvents were dried by the usual procedures. The NMR spectra were recorded with Varian Gemini-400 and JEOL FX-90Q spectrometers. The $^1H$ and $^{13}C$ chemical shifts were referenced to tetramethylsilane (TMS). The $^{19}F$ and $^{31}P$ chemical shifts were measured using $CFCl_3$ and 85% aqueous $H_3PO_4$ as standards, respectively. The digital resolutions were 0.25, 0.5, 1.0, and 1.25 Hz for $^1H$, $^{13}C$, $^{19}F$, and $^{31}P$ NMR spectra, respectively.

**Zwitterionic Compound 6:** A solution of tetrachlororthobenzoquinone (37 mg, 0.150 mmol) in 2 mL of dry diethyl ether was added in portions of 5–8 drops to a solution of compound **3** (85 mg, 0.153 mmol) in 3 mL of diethyl ether at –10 °C. Each portion of TOB was added at an interval of 2–3 min. The reaction solution was left for 12 h at –10 °C and then for 48 h at –30 °C. The colorless crystals of **6** formed over this time were separated from the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mother liquor, washed with cold diethyl ether, and dried in vacuo (0.05 Torr). Yield: 73 mg (59%). $^1$H NMR ($CDCl_3$, 15 °C): $\delta$ = 1.12 (t, $^3J_{H,H}$ = 7.1 Hz, 12 H, $NCH_2CH_3$), 1.13 (t, $^3J_{H,H}$ = 7.1 Hz, 12 H, $NCH_2CH_3$), 2.62 (dd, $^2J_{P,H}$ = 16.5, $^2J_{P,H}$ = 21.1 Hz, 1 H, P–C*H*–P), 3.02–3.29 (m, 16 H, $NCH_2CH_3$), 3.47 [sept, $^3J_{F,H}$ = 6.9 Hz 1 H, $CH(CF_3)_2$], 4.74 (br. dd, $^2J_{P,H}$ = 18.4, $^2J_{P,H}$ = 21.8 Hz, 1 H, P–$CH_2$–P) ppm. $^{19}$F NMR ($CDCl_3$): $\delta$ = –66.4 ppm (d, $^3J_{H,F}$ = 7.5 Hz, 6 F). $^{31}$P NMR ($CDCl_3$): $\delta$ = 44.5 (d, $^2J_{P,P}$ = 11.2 Hz), 57.0 ppm (d, $^2J_{P,P}$ = 11.2 Hz).

**Decomposition of 6:** A solution of freshly crystallized zwitterionic compound **6** in $CDCl_3$ was left at 20 °C for 24 h.

**Carbodiphosphorane 7:** $^{31}$P NMR ($CDCl_3$): $\delta$ = 56.8 ppm (s).

**Hexafluoroisovaleronitrile 8:** $^1$H NMR ($CDCl_3$): $\delta$ = 2.93 (d, $^3J_{H,H}$ = 6.5 Hz, 2 H, $CH_2CN$), 3.37 ppm [m, $^3J_{H,H}$ = 6.5, $^3J_{F,H}$ = 7.0 Hz, 1 H, $(CF_3)_2CH$]. $^{19}$F NMR ($CDCl_3$): $\delta$ = –68.0 ppm (d, $^3J_{H,F}$ = 7.0 Hz, 6 F). MS (EI, 70 eV, 250 °C): *m*/*z* (%) 191 (2) [$M^+$], 172 (36) [M – F]$^+$, 122 (100) [M – $CF_3$]$^+$. HRMS [M – F]: calcd. 172.01857; found 172.01787 (–4.0 ppm, –0.7 mmu).

**Compound 9:** A solution of **6** (100 mg, 0.18 mmol) in $CH_2Cl_2$ (2 mL) was left at 20 °C for 24 h, then water (50 mg) was added and the mixture was stirred for 48 h at 20 °C. The solvent was evaporated, the residue was dried in vacuo (0.05 Torr), washed with diethyl ether and crystallized from toluene/hexane (at –20 °C) to give 15 mg of a colorless solid. $^1$H NMR ($CDCl_3$): $\delta$ = 1.09 (t, $^3J_{H,H}$ = 7.3 Hz, 12 H, $NCH_2CH_3$), 2.40 (dd, $^2J_{P,H}$ = 16.5, $^2J_{P,H}$ = 20.8 Hz, 2 H, P–$CH_2$–P), 3.04 (m, 8 H, $NCH_2CH_3$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 18.0 (d, $^2J_{P,P}$ = 5.6 Hz), 30.7 (d, $^2J_{P,P}$ = 5.6 Hz) ppm. MS (CI, negative, $NH_3$, 200 °C): *m*/*z* (%) 496 (90) [M]; (EI, 70 eV, 207 °C): *m*/*z* (%) 496 (10) [$M^+$], 424 , (35) [M – $Et_2N$]$^+$. HRMS [$M^+$]: calcd. 495.98090; found 495.97677 (–8.3 ppm, –4.1 mmu); calcd. for [M – $Et_2N$]: 423.89957; found 423.89897 (–1.4 ppm, –0.6 mmu).

**X-ray Crystallographic Study:** The single-crystal X-ray structure determination was performed at 173(2) K on a Siemens P4 diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 71.073 pm) and an LT2 low temperature device. The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELX-97 program system.[10]

Crystal data for **6** ($C_{28}H_{43}Cl_4F_6N_5O_2P_2$): $M_w$ = 799.46, triclinic, space group $P\bar{1}$, $a$ = 1199.2(2), $b$ = 1279.93(15), $c$ = 1428.87(17) pm, $\alpha$ = 82.875(8)°, $\beta$ = 89.202(12)°, $\gamma$ = 85.148(11)°, $V$ = 2.1685(6) nm$^3$, $Z$ = 2, $D_c$ = 1.484 Mg m$^{-3}$, $\mu$ = 0.654 mm$^{-1}$; 11563 reflections collected, 256 parameters refined using 9956 unique reflections ($R_{int}$ = 0.0334) to final indices $R_1$ [$I > 2\sigma(I)$] = 0.0745 and $wR_2$ (all data) = 0.1465 {$w = 1/[\sigma^2(F_o^2) + (0.0698\,P)^2 + P]$}, where $P = (2F_c^2 + F_o^2)/3$. All non-hydrogen atoms were refined anisotropically and the position of the hydrogen atoms was calculated as a riding model. The final residual Fourier positive and negative peaks were equal to 1.024 and –1.034 e Å$^{-3}$. One ethyl group of one $NEt_2$ moiety is disordered. The terminal C(18) atom is split over two positions with an occupancy of 70% for C(18) and 30% for C(18a). The distances C(17)–C(18) and C(17)–C(18a) were set to be equal. The Cl atoms of one solvent molecule are disordered over two positions (50% occupancy). The distances C(30)–Cl(8), C(30)–Cl(9), C(30)–Cl(8a) and C(30)–Cl(9a) were set to be equal.

CCDC-610625 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Cages on Surfaces: Thiol Functionalisation of $Co^{III}$ Sarcophagine Complexes

**Jack M. Harrowfield,[a,b] George A. Koutsantonis,*[b] Heinz-Bernhard Kraatz,[c] Gareth L. Nealon,[b] Grzegorz A. Orlowski,[c] Brian W. Skelton,[b] and Allan H. White[b]**

**Keywords:** Sarcophagine / Amino acids / Disulfides / Cobalt / Self-assembled monolayers / Electrodeposition

A number of new (sarcophagine)cobalt compounds containing oligopeptide substituents terminated by a mercaptoethylamide unit, $[Co(R)(R')sar]_2^{6+}$ (R = $NH_2$, $CH_3$; R′ = NHpeptide-$CONHCH_2CH_2S$–), have been prepared utilising the carboxymethyl complexes $[Co(R)\{N(CH_2CO_2H)\}sar]^{3+}$ (R = $NH_2$, $CH_3$), and subsequently characterised. The amino acid residues, terminating with cystamine groups, were introduced into the carboxymethyl complexes using standard peptide coupling chemistry. The solid-state structures of $[Co(CH_3)\{N(CH_2CO_2H)\}sar]Cl_4\cdot H_2O$, $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]Cl_3\cdot 2H_2O$ and $[Co(CH_3)\{N(CH_2CO_2)_2\}sar]Cl\cdot 6.5H_2O$ were determined by single-crystal X-ray diffraction experiments, the first two forming lattices containing homochiral sheets of cations in planes parallel to [0,0,1]. In the structure of $[Co(CH_3)\{N(CH_2CO_2H)\}sar]Cl_4\cdot H_2O$, the cations are of the same absolute configuration, but this alternates from one sheet to the next. In the dihydrate, $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]Cl_3\cdot 2H_2O$, the structure appears to be very similar. The sheet alternation is different from the structure of the monohydrate, $[Co(CH_3)\{N(CH_2CO_2H)\}sar]Cl_4\cdot H_2O$. The deprotonated imidodiacetate complex, $[Co(CH_3)\{N(CH_2CO_2)_2\}sar]Cl\cdot 6.5H_2O$, was prepared in an unrelated reaction; the structure displays hydogen-bonding interactions involving the carboxylate groups and coordinated NH units. The solution electrochemistry of these compounds has been investigated using both cyclic voltammetry and differential pulse voltammetry. The compounds exhibited pH-dependent, quasi-reversible redox behaviour. A monolayer was prepared by the interaction of $[Co(R)sar(GlyNHCH_2CH_2S–)]_2^{6+}$ and a gold microelectrode using both conventional "self assembly" (SAM) and electrodeposition (EDM) techniques. Surface cyclic voltammograms were measured, which, after a period of induction associated with surface reorganisation, were typical of an ordered monolayer. The monolayer was characterised by XPS, showing peaks assigned to the presence of S, Co, N, O and C. Ellipsometry gave a film thickness of $7 \pm 1$ Å, consistent with the formation of a mono- rather than a multi-layer.

## Introduction

Reagent immobilisation on surfaces is a sophisticated pathway to materials with a wide range of applications,[1,2] heterogeneous catalysis being one obvious application, such applications depending on the functionality introduced with the bound reagent, as well as upon the ease and convenience of the immobilisation procedure and the stability of the final product. Given the remarkable stability and varied electronic, magnetic and redox properties of metal complexes of the macrobicyclic polyamines known as "sarcophagines" (Figure 1),[3] these are species of particular appeal as entities for attachment to surfaces and for various related applications.[4] Reduction potentials for readily accessible species span a range of 2 V,[5] subject to modification in an interfacial environment,[6] and outer-sphere redox processes involving Co complexes are, for example, known to be rapid steps in reactions leading to photoinduced hydrogen production[7–10] and the reduction of oxygen to hydrogen peroxide.[11] Of practical importance in relation to immobilisation of such complexes is the facile synthesis of the ligand in forms with reactive "external" functional groups R (Figure 1).[12]

Limited earlier work on surface-bound cage complexes has involved modification of electrodes by impregnation of thin Nafion films on graphite with simple cage complexes,[5] electropolymerisation of a thiophenylmethylamino cage complex on Pt,[12] and carbodiimide coupling of carboxyl groups on partially oxidised graphite to a diamino cage complex.[13] Amphiphilic cages[14,15] have also proved to have interesting biological properties, probably associated with their ability to be bound within membranes.[15] As a simple approach to the immobilisation of cage complexes on surfaces, we are currently exploring the use of the well-established surface chemistry of disulfides[1] to form monolayers of (sarcophagine)cobalt complexes on gold. This is based on the introduction of peptide substituents associated with cystamine units onto the cage, a facile synthesis when starting from readily synthesised glycylated derivatives.[16] The use of peptide-based tethering groups is advantageous as the length of the spacer between the surface and the cage moiety can be increased incrementally with relative ease, using common peptide synthetic techniques,[17] and tightly packed monolayers can be formed, presumably by hydrogen bonding between the amide groups.[18] A similar approach has been applied to the synthesis of ferrocene-decorated peptides as probes for elucidation of the mechanism(s) of electron transfer in proteins.[19]

Our immediate aim in the present work was to synthesise a series of disulfides bearing peptido cage complex substituents, evaluate their solution electrochemical characteristics, and determine a suitable method for their immobilisation onto gold electrodes. Because only a single disulfide substituent is required for surface tethering, our focus has been on obtaining derivatives of the monosubstituted cage complex $[Co(CH_3)(NH_2)sar]^{3+}$, though the more complicated syntheses of monofunctionalised derivatives of $[Co(NH_2)_2sar]^{3+}$ have also been investigated. These $Co^{III}$ complexes exist in stable enantiomeric forms and thus the formation of diastereomeric forms of their oligopeptide derivatives was anticipated, though prior work suggested that differences between such diastereomers should be small.[12]

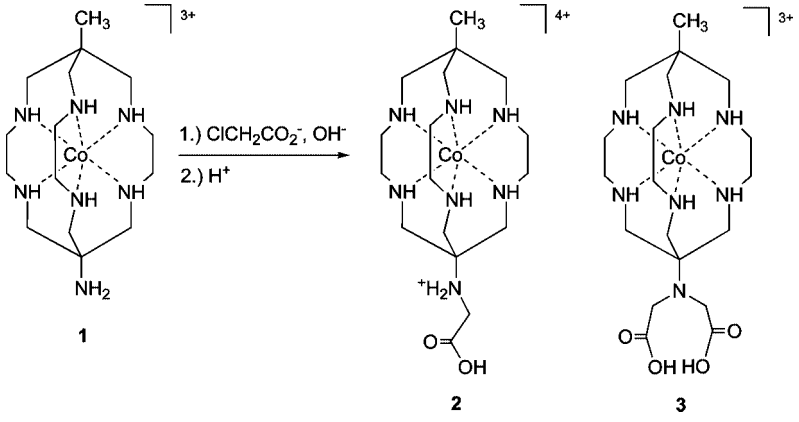
## Results and Discussion

### Synthesis

The primary amine group on a cage complex such as $[Co(NH_2)_2sar]^{3+}$ is a relatively poor nucleophile,[16] the proximity of the cationic metal centre diminishing this property, and, in cases where it is not convenient to use either the amine or an attacking electrophile in large excess, the cage complex is not an appropriate reagent for efficient synthesis, despite the fact that reactions of this type can be conducted.[13,20] Logically, it is more appropriate to use an electrophilic centre attached to the cage, because this property should be enhanced by the adjacent charge and indeed it is known that carboxymethyl derivatives of $[Co(NH_2)_2sar]^{3+}$ can be used efficiently in amide and peptide formation reactions.[21] Acceptably efficient carboxymethylation of $[Co(CH_3)(NH_2)sar]^{3+}$ (**1**) can be achieved under conditions involving reaction with a large excess of chloroacetate, which are similar to those used to obtain carboxymethyl derivatives of $[Co(NH_2)_2sar]^{3+}$.[16] Thus, the complexes $[Co(CH_3)(NHCH_2CO_2H)sar]^{3+}$ and $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]^{3+}$ were obtained as outlined in Scheme 1. These complexes, along with $[Co(NH_2)(NHCH_2CO_2H)sar]^{3+}$,[16] provided reactants to which standard peptide coupling methodologies could be applied to obtain derivatives incorporating cystamine residues as disulfide units linking two cages (Scheme 2).

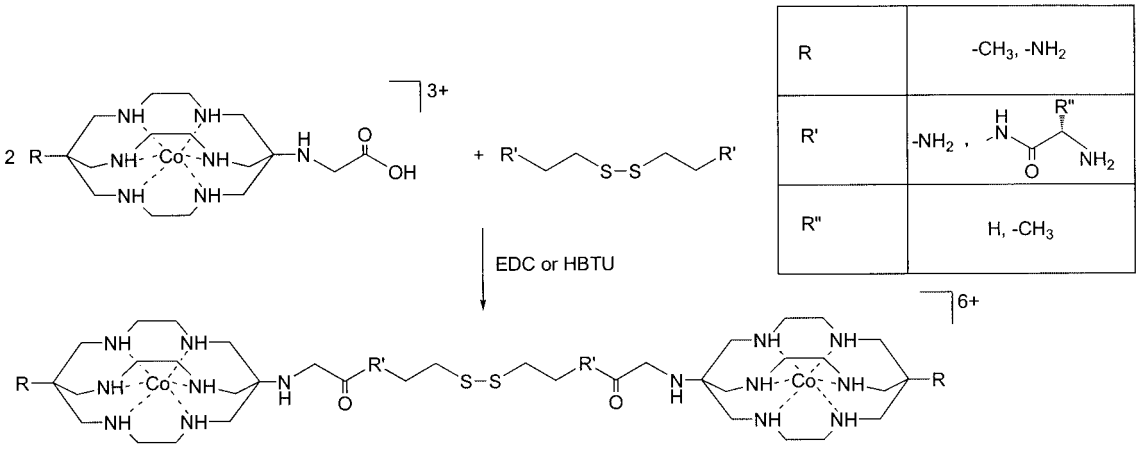
In one reaction unrelated to peptide elaboration, crystals of the deprotonated diacid, $[Co(CH_3)\{N(CH_2CO_2)_2\}sar]^{+}$, were obtained (as the chloride) from an aqueous solution containing complex **3** held at a pH of approximately eight. We include below a discussion of the structure of this compound.

The syntheses produced mixtures that were readily separated by ion-exchange chromatography on Sephadex SP (using sodium citrate elution) due to the fact that the bis(cage) product has a charge of 6+ in neutral to basic solution, enabling facile discrimination between it and the less highly charged mono(cage) intermediate and any unreacted starting material.

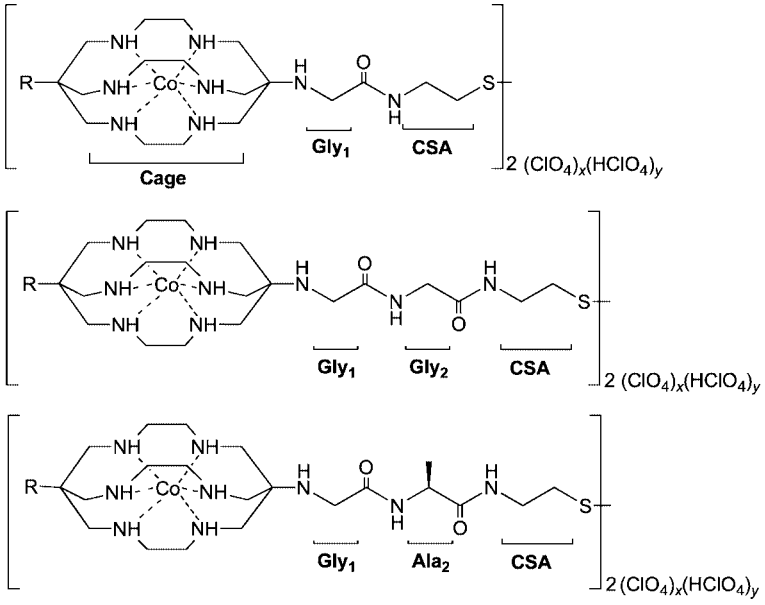


Scheme 1. Synthesis of carboxymethylated starting materials $[Co(CH_3)(NH_2CH_2CO_2H)sar]^{4+}$ (**2**) and $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]^{3+}$ (**3**).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Synthetic methodology used for the preparation of the disulfide complexes.



The method commonly employed to isolate $Co^{III}$ complexes of the present type from Sephadex SP column eluates, including absorbing them on Dowex 50W strong acid resin, re-eluting with HCl and then concentrating to dryness,[16] proved to lead here to some hydrolysis of the peptides. Fortunately, the complexes could be readily isolated from the citrate eluates by precipitation as their very insoluble picrates. These could readily be converted into the perchlorates, preferred to the chlorides for electrochemical studies involving gold electrodes. It is worth noting that, despite the modest isolated yields reported for the compounds, the major band in the ion-exchange chromatography was always the disubstituted disulfide, indicating a relatively efficient reaction to give the desired product.

## NMR Spectroscopy

All compounds synthesised (Table 1) exhibited NMR spectra consistent with their proposed structures. Evidence for the introduction of the carboxymethyl substituent to give the compounds **2** and **3** was observed with peaks between $\delta \approx 3.6$ and 3.7 ppm in their $^1$H NMR and two peaks at $\delta = 43.6$, 52.5 ($-CH_2-$) and $\delta = 172.5$, 176.8 (C=O) ppm in their $^{13}$C NMR spectra. The compounds **4**, **7** and **8** displayed a single amide –NH– peak ($\delta = 7.9$–8.0 ppm) in their $^1$H NMR and a single C=O peak ($\delta \approx 170$ ppm) in their $^{13}$C NMR spectra due to their CSA moieties. The compounds **5**, **6**, **9** and **10** displayed two peaks in both their $^1$H NMR ($\delta = 7.8$–8.2 ppm) and $^{13}$C NMR ($\delta = 168.7$–172.2 ppm) spectra, corresponding to the inequivalent NH and carbonyl centres of the amino acid (Gly or Ala) and CSA. The complex multiplets observed in the $^1$H NMR spectra in the region between $\delta \approx 2$ and 3.5 ppm due to the methylene group resonances of the $[Co(CH_3)(NH_2)sar]^{3+}$ and $[Co(NH_2)_2sar]^{3+}$ moieties sometimes obscured other peaks corresponding to the $Gly_1$ $-CH_2-$ group and/or the $-CH_2-N$ group of CSA. The presence and position of the obscured peaks was deduced from the overall integration of the protons in this region, as well as cross-peaks observed in the 2D NMR experiments. $^{13}$C NMR spectra reflected

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the complete asymmetry of the compounds, except for the compounds **8**, **9** and **10** in which two cage methylene signals were coincident. This was determined from the high intensity of the composite peak relative to the other cage methylene signals and by 2D NMR experiments. It is presumed that the use of racemic $[Co(CH_3)(NHCH_2CO_2H)sar]^{3+}$ as a reactant leads to the production of a mixture of *meso* and *rac* forms of the bis(cage) peptides but only in the case of compound **6** was any spectroscopic evidence for the presence of such a mixture obtained. The $^{13}C$ NMR spectrum of this complex shows some doubling of signals, similar to that observed in a dipeptide derivative of racemic $[Co(NH_2)(NHCH_2CO_2H)sar]^{3+}$.[21] This could reflect some racemisation of the amino acid during the synthesis but the product presently obtained by reaction of Δ-$[Co(NH_2)(NHCH_2CO_2H)sar]^{3+}$ with (L-Ala)$_2$CSA shows only sharp singlets in its $^{13}C$ NMR spectrum, indicating that this is not the case.

Table 1. List of compounds synthesised.

| Compound | R | Cage | R′ |
|---|---|---|---|
| **2** | $-CH_3$ | racemic | –Gly-OH |
| **3** | $-CH_3$ | racemic | $-N(CH_2CO_2H)_2$ |
| **4** | $-CH_3$ | racemic | –Gly-CSA- |
| **5** | $-CH_3$ | racemic | –Gly-Gly-CSA- |
| **6** | $-CH_3$ | racemic | –Gly-Ala-CSA- |
| **7** | $-NH_2$ | racemic | –Gly-CSA- |
| **8** | $-NH_2$ | Δ-enantiomer | –Gly-CSA- |
| **9** | $-NH_2$ | Δ-enantiomer | –Gly-Gly-CSA- |
| **10** | $-NH_2$ | Δ-enantiomer | –Gly-Ala-CSA- |

## Mass Spectrometry

Electrospray mass spectrometry (ESMS) has been recognised as a valuable method for obtaining molecular weights of cage complexes with little to no fragmentation.[22] ESMS spectra of compounds **2** and **3** display peaks consistent with the molecular ions corresponding to a loss of $H^+$ from the cation, and some peaks consistent with an additional association of chloride anions. ESMS spectra of compounds **4**–**10** in several cases display multiple peaks, corresponding to the molecular ion in charge states of 2+, 3+ and 4+, which are assigned as successive losses of $H^+$ from the parent ion, sometimes accompanied by association of a perchlorate anion. Loss of $H^+$ from a coordinated –NH– group of the cage is known and the resolution of the measurements here are sufficient to distinguish this possibility from that of $Co^{III}$ reduction to $Co^{II}$ in the mass spectrometer, as has also been observed.[22] There also appears to be no cleavage of the disulfide link during volatilisation.

## Structure Determinations of Salts of Cations 2 and 3

The crystal structure determinations, modelled as $[Co(CH_3)(NH_2CH_2CO_2H)sar]Cl_4{\cdot}H_2O$, [**2**]$Cl_4{\cdot}H_2O$, $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]Cl_3{\cdot}2H_2O$, [**3**]$Cl_3{\cdot}2H_2O$, and $[Co(CH_3)\{N(CH_2CO_2)_2\}sar]Cl{\cdot}6.5H_2O$, [**3**–2H]$Cl{\cdot}6.5H_2O$ confirm the nature of the functionalisation (indicated by the given formulae) of the original cage complex $[Co(CH_3)(NH_2)sar]^{3+}$ expected on the basis of the method of synthesis and spectroscopic measurements; in the first two complexes, one, in the latter, two, formula units, devoid of crystallographic symmetry, comprise the asymmetric unit of the structure. The experimental details and refinement details are collected in Table 2, while structural representations showing the atom numbering schemes of the cations are given in Figure 2. Table 3 collects pertinent hydrogen-bonding data for the complexes. In [**2**]$Cl_4{\cdot}H_2O$, the O- and N-sites of the glycyl functional are both protonated, whereas in [**3**]$Cl_3{\cdot}2H_2O$, although a zwitterionic form is possible, the two carboxyl groups appear to retain their pro-

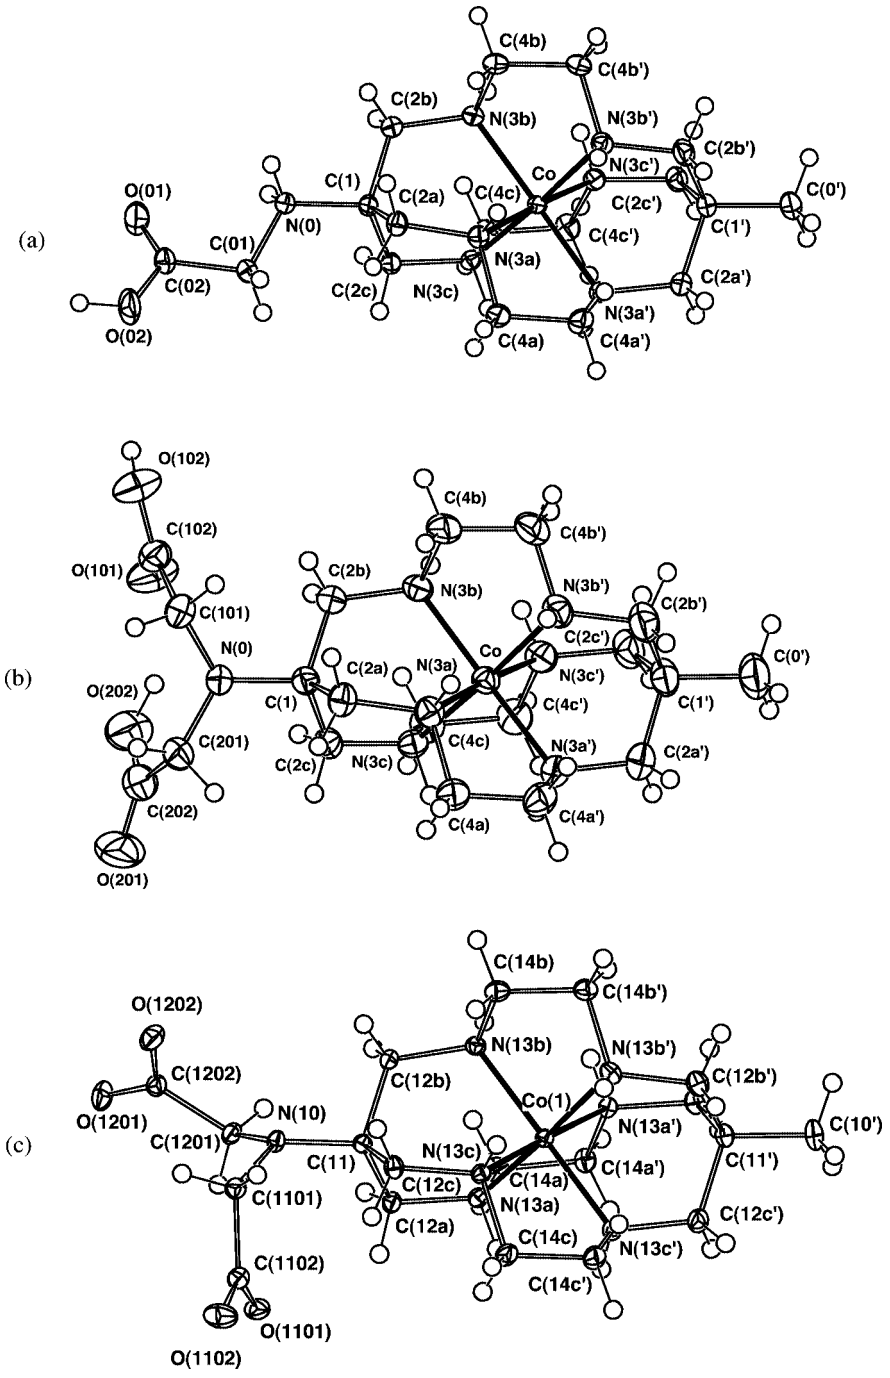

Figure 2. Structural representation of the cations in complexes (a) $[Co(CH_3)(NH_2CH_2CO_2H)sar]Cl_4{\cdot}H_2O$ [**2**]$Cl_4{\cdot}H_2O$, (b) $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]Cl_3{\cdot}2H_2O$, [**3**]$Cl_3{\cdot}2H_2O$ and (c) one of the two cations in $[Co(CH_3)\{N(CH_2CO_2)_2\}sar]Cl{\cdot}6.5H_2O$, [**3**–2H]$Cl{\cdot}6.5H_2O$. Probability ellipsoids shown at 50 [(a), (c)] and 20% (b) amplitude.

tons and the N-centre is unprotonated. This is despite the fact that the two complexes were isolated under essentially identical conditions from quite concentrated HCl solutions, though of course it need not be the case that the dominant species in solution are those which crystallise. The carboxylate groups are deprotonated in [**3**–2H]$Cl{\cdot}6.5H_2O$. All cation cores are of $lel_3$ conformation.

A view of the lattice of [**2**]$Cl_4{\cdot}H_2O$ along the *a* axis shows [Figure 3(a)], edge-on, sheets of cations lying in planes parallel to [0,0,1] which appear to form pairs separated by sheets of chloride ions. Within any given sheet, all cations are of the same absolute configuration, which alternates from one sheet to the next, and all adopt the $lel_3$ conformation. As has been discussed in detail elsewhere,[23] this conformation of amine cage complexes of $Co^{III}$ is frequently associated with "hydrogen-bonding chelation" in which two coordinated NH centres on an open octahedral edge bind to the one unit, very commonly a chloride ion, just as is the case here [Figure 3(b)]. Each of the three chloride ions involved in such chelation by every cation has a third con-

tact at a similar or slightly shorter distance to oxygen, in two cases that of water molecules and in the third (the shortest of all contacts), that of a carboxyl group and specifically of its hydroxy unit. [The presence of the proton on the carboxyl group is clearly reflected in the asymmetry of the C–O distances of 1.198(2) and 1.327(3) Å.] The sheets of chloride ions which appear to separate the double sheets of cations contain this last "chelated" chloride ion plus the fourth chloride ion, which has one short contact [2.975(2) Å] to N of the pendent arm plus some rather remote CH contacts. Both can be considered as part of a centrosymmetric unit involving enantiomeric cations. It is also possible to identify centrosymmetric units linking the

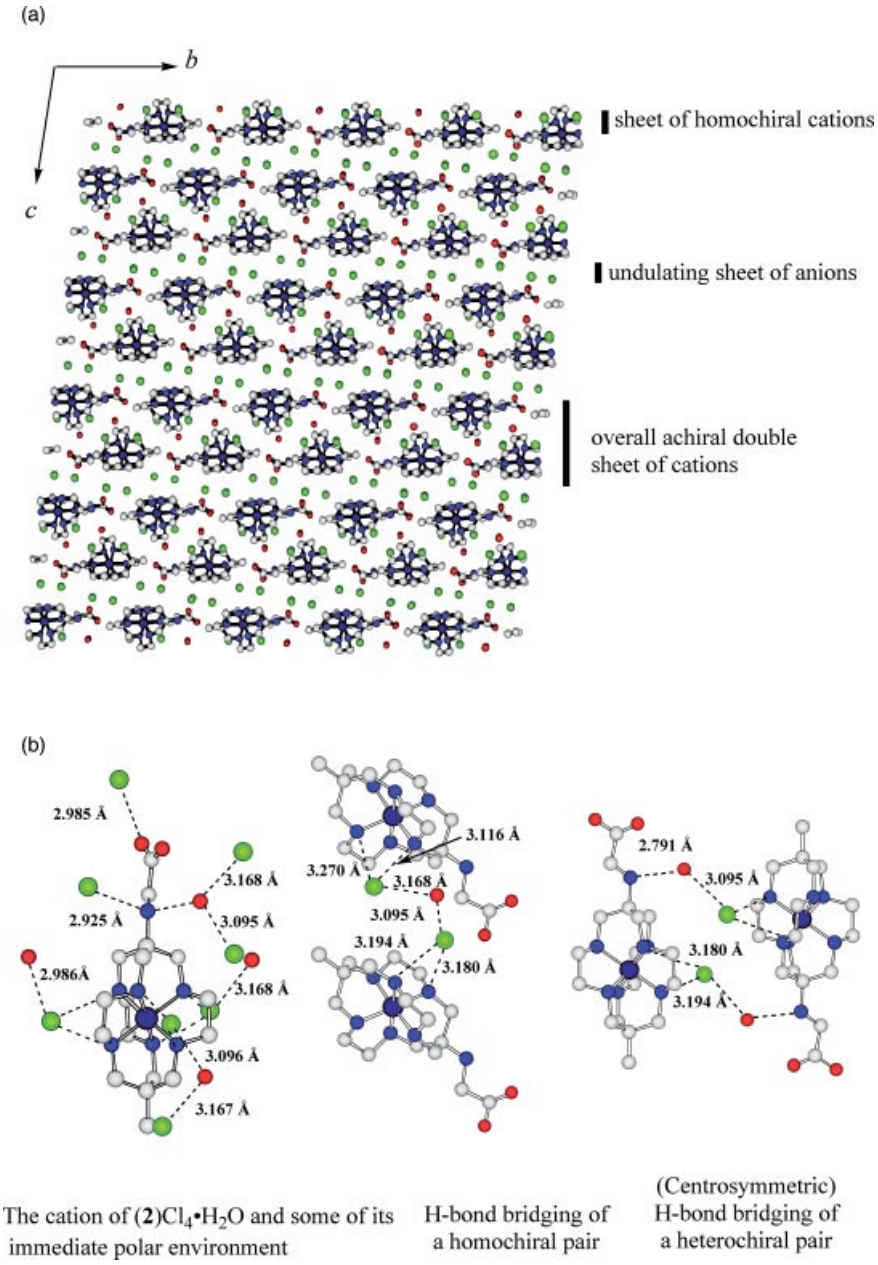

Figure 3. (a) View along the *a*-axis of the lattice of [Co(CH$_3$)(NH$_2$CH$_2$CO$_2$H)sar]Cl$_4$·H$_2$O, [**2**]Cl$_4$·H$_2$O; (b) representations of [Co(CH$_3$)(NH$_2$CH$_2$CO$_2$H)sar]Cl$_4$·H$_2$O, [**2**]Cl$_4$·H$_2$O, showing close contacts.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

double sheets where the water molecule and one of the chelated chloride ions with which it interacts provide hydrogen-bond bridges between the cations. The water molecule serves further as part of a hydrogen-bond network (involving its second chelated chloride neighbour) that links the homochiral columns of cations running parallel to the *a*-axis within any cation sheet. Hydrogen bonding, presumably to be regarded as "charge-assisted" within the formally ionic lattice, would appear to be the principal force determining the form of the lattice array.

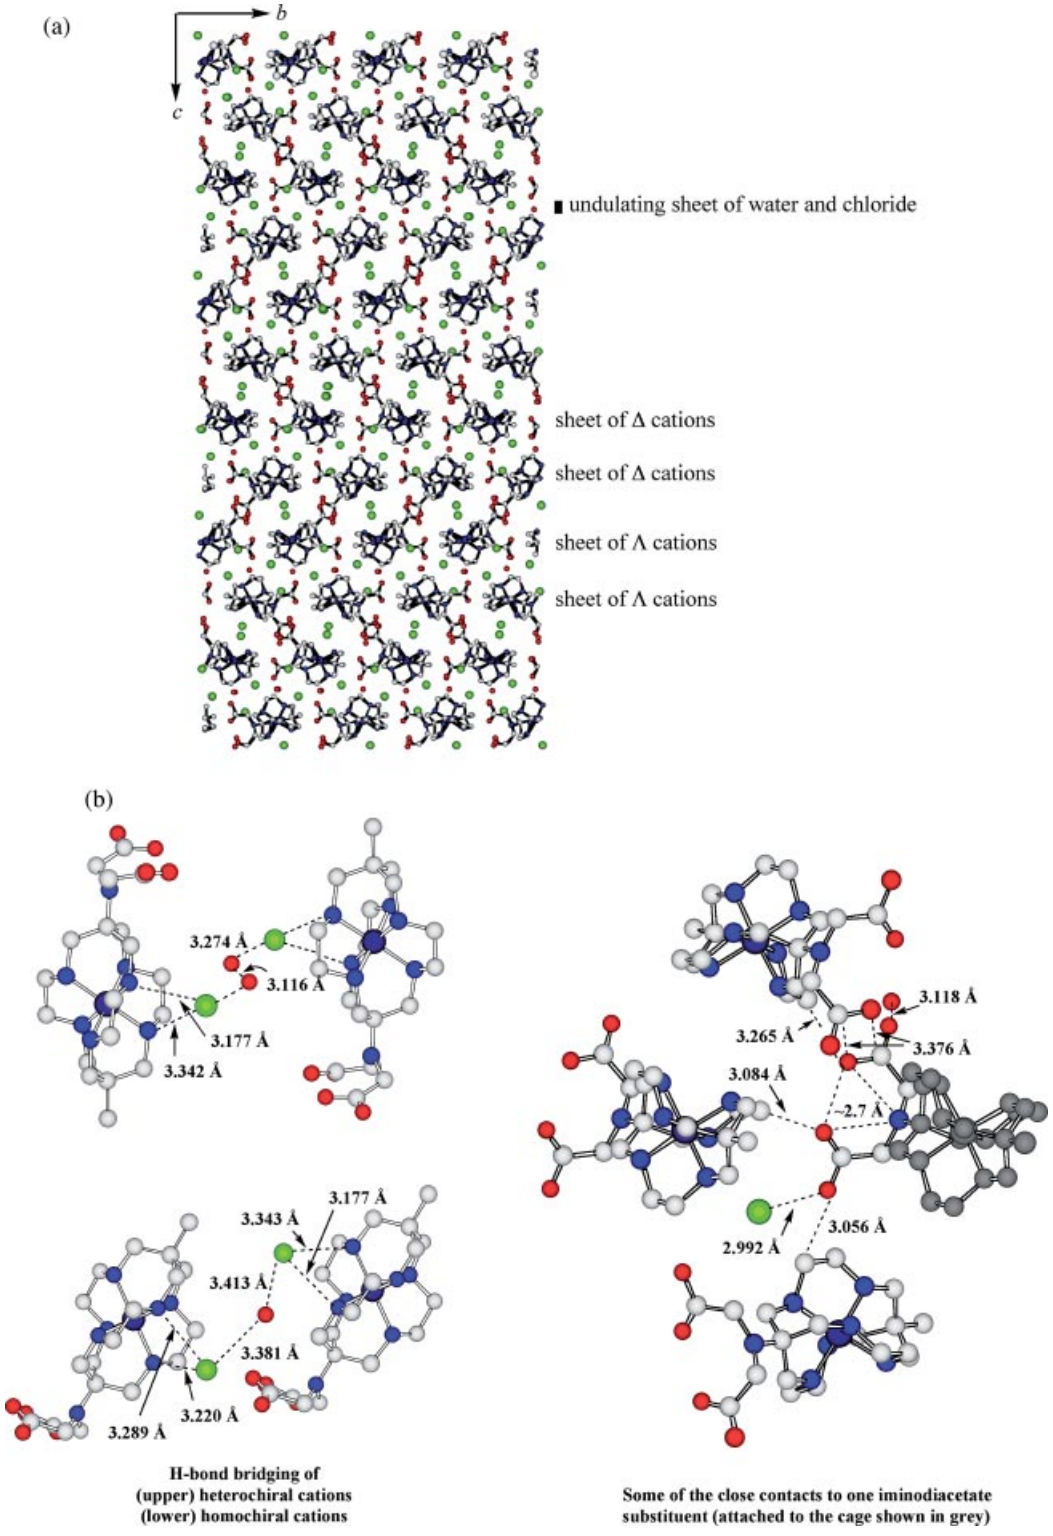

Figure 4. (a) Lattice of $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]Cl_3{\cdot}2H_2O$, **[3]**$Cl_3{\cdot}2H_2O$, along the *a*-axis; (b). Close contacts for $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]Cl_3{\cdot}2H_2O$, **[3]**$Cl_3{\cdot}2H_2O$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The lattice of $[Co(CH_3)\{N(CH_2CO_2H)_2\}sar]Cl_3{\cdot}2H_2O$, [**3**]$Cl_3{\cdot}2H_2O$, shows many close similarities to that of [**2**]-$Cl_4{\cdot}H_2O$ [Figure 4(a)]. When viewed again along the *a*-axis, homochiral cation sheets, parallel to [0,0,1], can be discerned edge-on and pairs of such sheets can be considered to be separated by undulating layers of chloride ions and water molecules. Such paired sheets are of opposite chirality, but sheets separated by the chloride/water layer are homochiral, so that the sheet alternation here is ...(Δ Λ)(Λ Δ)(Δ Λ)... and not ...Δ Λ Δ Λ Δ Λ... as in (**2**)$Cl_4{\cdot}H_2O$.

A network of conventional hydrogen bonds involving the NH, chloride and water entities serves to link cations of the same and opposite chirality but there is also more convincing evidence here that CH···O and even stacking interactions may play some role in the lattice construction [Figure 4(b)]. In this regard, the iminodiacetate pendent group in (**3**)$Cl_3{\cdot}2H_2O$ has several interesting features. The protons are clearly associated with O(*n*02), on the basis of difference map and geometrical evidence [C(102)–O(101, 202) 1.201(3), 1.309(3); C(202)–O(201, 202) 1.204(4), 1.314(4) Å]. The N-atom and the two "internal" O-atoms from separate carboxylate units form a nearly equilateral triangle ca. 2.7 Å on edge, indicating that one proton may in fact interact with all three, in a mode similar to that in which iminodiacetate can act as a tridentate ligand towards a metal ion. The external carboxyl hydroxy O-atom of the iminodiacetate entity has a relatively short contact [2.993(2) Å] to a chloride ion but is also within 3.056(3) Å of an ethylene bridge C-atom and within 3.470(4) Å of the methyl group carbon atom of different adjacent cations of the same chirality. The internal carboxyl carbonyl O-atom has, in addition to its N- and O-contacts mentioned above, two relatively short contacts [3.084(3), 3.184(3) Å] to carbon atoms of an ethylene bridge on another cation of the same chirality. The internal carboxyl hydroxy O-atom has a contact of 3.265(3) Å to a cap methylene C-atom, and the carboxyl group of which it is part lies in a plane parallel to that of another carboxyl group such that there are mutual C···O contacts (stacks?) of 3.376(3) Å, both these contacts involving an enantiomorphic cation. The external carboxyl carbonyl O-atom has a contact of 3.328(3) Å to an ethylene bridge C-atom and probably a more significant contact of 3.119(3) Å to a water oxygen atom which is hydrogen-bonded to a symmetry-related water molecule and thus connected to an enantiomorphic cation. The latter contacts, coupled to the stacking just mentioned, give rise to an infinite column parallel to *a*, linking sheets of both chiralities. In view of the nonlocation of the water molecule hydrogen atoms, and the lack of close contacts to other charged or polar components, reflected in (very) high displacement parameters for the residues assigned as oxygen atoms, hydrogen bonding plays a less dominant role in the lattice array seen for (**3**)$Cl_3{\cdot}2H_2O$ although clearly it remains a major influence.

In (**3**–2H)$Cl{\cdot}6.5H_2O$, the pendents are deprotonated, and devoid of any polar NH or OH hydrogen atoms; rather, the pendent groups themselves are now charged and are competitive with the halide ions (now deficient in numbers, there being only one per cation) in their interactions with the core NH sites and the water molecules. In each of the cations, one chloride ion is chelated between one pair of unprimed and primed NH groups from adjacent cage strings, one single carboxylate oxygen atom from the alternate cation of the asymmetric unit between a second, and a carboxylate pair, also from the alternate cation (symmetry-related) between the third. "Chelation" does not appear to impact on the carboxylate geometries in the manner that protonation does, there being no substantial distinction between the geometries of *O*,CO- and *O*,*O*C-chelated carboxylate groups, C–O tightly ranged between 1.252 and 1.265(3) [< > 1.258(4) Å], O–C–O similarly 123.6–124.7(2) [< > 124.1(5)°]. The interactions of each of the chloride ions are again {(chelate-H)$_2$ plus water molecule-H}. The interactions of the carboxylate oxygen atoms are such that

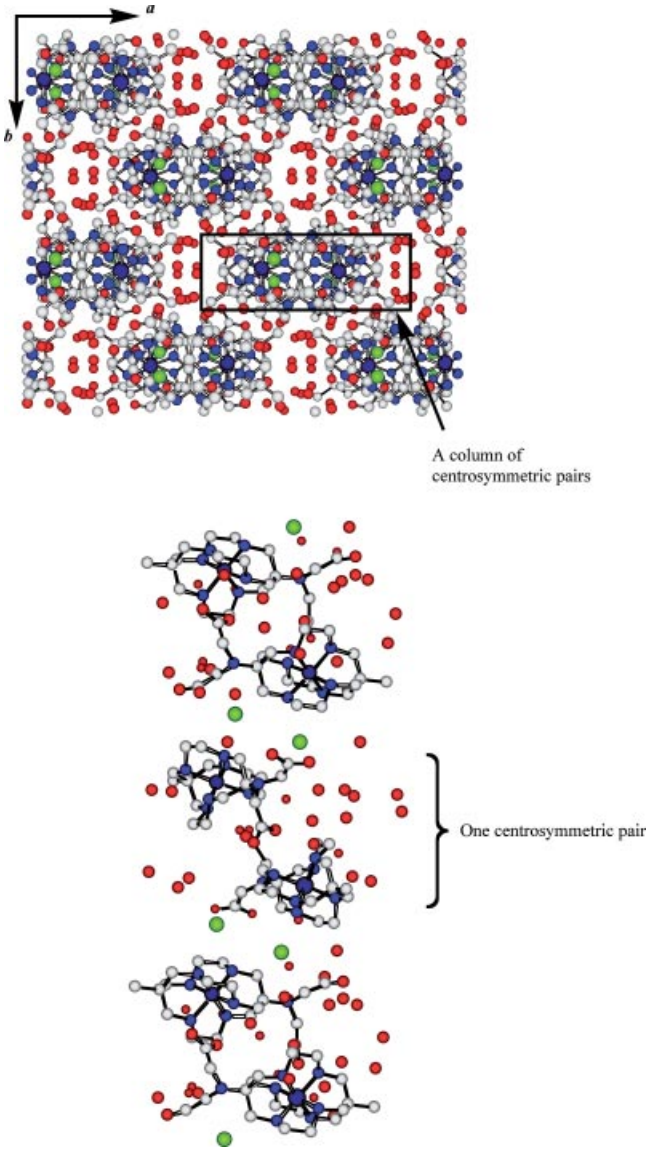

Figure 5. View of the unit cell of [**3**–2H]$Cl{\cdot}6.5H_2O$ along the *c*-axis (top) and perpendicular to one of the columns of the centrosymmetric pairs (bottom).

each is associated with two hydrogen atoms: O(1101, 2201) are associated with/chelated by 2× NH, O(1202, 1202, 2102, 2102) are each associated with one NH group and one water molecule hydrogen atom, and O(1102, 2202) each with a pair of water molecule hydrogen atoms, the overall result being the formation of columns of centrosymmetric pairs of complex cations [Co(1)···Co(2) 8.3943(6) Å] along *c*; the pairs sandwich pairs of chloride ions, with associated Co(1)···Co(2) (*x*, 1½ – *y*, *z* – ½) 8.6617(6) Å involving cations of opposite chirality (Figure 5). A number of the water molecules (7, 9, 12, 13) are involved in hydrogen-donor interactions only to other water molecules, none forming aggregates in isolation, but, rather, linking the columns together.

## Solution Electrochemistry

The solution electrochemistry of compounds **2**–**10** was investigated by cyclic voltammetry (CV) and differential pulse voltammetry (DPV) performed in aqueous solution using $NaClO_4$ as the supporting electrolyte, and selected data are presented in Table 3. Figure 6 depicts typical CV and DPV data for two of the complexes, **4** and **7**. The electrochemical behaviour of the compounds was found to be pH-sensitive and was often complicated by adsorption effects, particularly at Au or Pt working electrodes, which is consistent with previous work performed on the parent cages.[24] Adsorption behaviour at an Au electrode was confirmed by quartz crystal microbalance (QCM) measurements, whereby an increase in mass at the working electrode was observed at the potential corresponding to the pre-wave attributed to an adsorption phenomenon. In order to obtain reproducible results, the electrochemistry was performed in aqueous $NaClO_4$ adjusted to pH = 7.3 utilising a tris(hydroxymethyl)aminomethane (TRIS)/$HClO_4$ buffer. As the data in Table 3 show, the compounds display quasi-reversible redox behaviour, as determined from the $\Delta E$ values ($> 0.059$ V) and the peak current ratio $I_a/I_c$ being lower than unity for most of the compounds. It is known that the $E_{1/2}$ values for the cages are sensitive to the nature of the apical substituents[24] and this is evident for the compounds synthesised here. The $E_{1/2}$ for compound **2** with one glycyl substituent is shifted by 55 mV to a more positive potential than that for compound **3**, which is terminated with an iminodiacetate moiety. The nature of the terminal group in compounds **4**–**10** also affects the $E_{1/2}$ value in that there is a significant shift (ca. 60–70 mV) to more positive potentials when the methyl group at the apex of the cage is replaced by an amino group. It is worth noting, however, that the $E_{1/2}$ value does not change when moving from the Gly-CSA to Gly-Gly-CSA and Gly-Ala-CSA derivatives if the group (–$CH_3$ or –$NH_2$) at the apex is held constant. This implies that changing the nature of the substituent beyond the initial –Gly- group does not affect the electronic environment about the Co centre and therefore explains the absence of any significant differences between diastereomers. The lack of an effect on the resulting $E_{1/2}$ value is important when considering the possible use of the complexes as electrocatalysts.

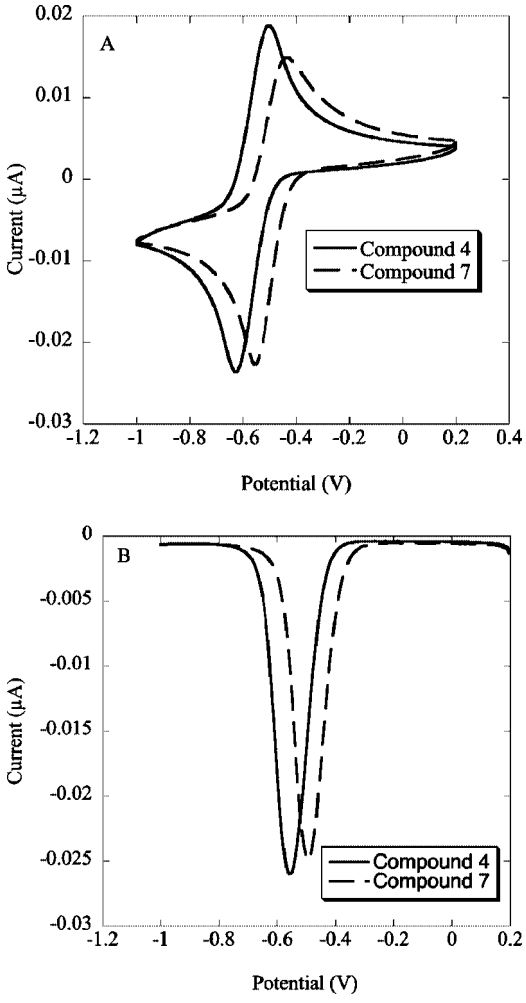

Figure 6. (a) Solution CVs of compounds **4** and **7** with GC working electrode at pH = 7.3, vs. Ag/AgCl (100 mV $s^{-1}$, 0.1 M $NaClO_4$). (b) DPVs of the reduction processes (scan rate 20 mV $s^{-1}$, pulse amplitude 50 mV).

## Surface Electrochemistry

Preparation of gold microelectrodes modified by a film of one of the cage disulfides was achieved using both conventional "self-assembly" (SAM) by soaking the electrodes in aqueous solutions of the disulfides for 5 d, and by electrodeposition (EDM).[18] All surface cyclic voltammograms (CVs) were carried out in $H_2O$ and in the presence of 2 M $NaClO_4$ as the supporting electrolyte in order to minimise the *iR* drop. Determination of the surface concentration of the cage was achieved by integration of the Faradaic peak currents of the cyclic voltammograms. Some of the characteristics of the film are shown in Table 4.

During repeated experiments it became clear that the films that formed immediately after the electrodeposition and washing steps displayed some unusual characteristics. CVs performed on the fresh films often displayed very small

Table 4. Comparison of electrochemical data and surface coverage using ED and SA films for compound **4**. $E_{fwhm}$ values reported for reduction waves. Values in parentheses indicate standard deviations from five measurements.

| Technique | $E°$ [mV] | $\Delta E$ [mV] | $I_a/I_c$ | $E_{fwhm}$ [mV] | Specific area [Å$^2$] | $\Gamma$ [mol cm$^{-2}$] |
|---|---|---|---|---|---|---|
| ED | –619(4) | 56(8) | 0.94(8) | 195(12) | 150(30) | $1.1(2) \times 10^{-10}$ |
| SA | –602(20) | 66(6) | 0.84(4) | 193(15) | 150(40) | $1.2(3) \times 10^{-10}$ |

or unobservable current peaks corresponding to the cage species, and if they were present, the $E_{1/2}$ values were shifted to more negative potentials than the normal "equilibrium" potentials. It was found that repeated cycling of the potential, at scan rates from 0.1 to 10 V s$^{-1}$, for periods of up to and above 30 min produced CVs that displayed sharper and more intense peak currents, with a reduction in charging current (Figure 7). This effect could be explained by a random distribution of molecules on the surface at the start of the electrochemical experiment, which gradually changes to give a more ordered film. It is worth pointing out that the electrostatic repulsion between the cationic Co conjugates is likely to induce an initial disorder in the film as the Co headgroups maximise their physical separation. Electrochemical cycling might allow greater penetration of the anions into the film, and the enhanced charge neutrality would promote better packing within the film. As the film becomes more ordered, the Co centres become more thermodynamically homogeneous, which helps explain the reduction in peak half-widths during the experiment. A more ordered film would also help to explain the lower charging current observed with time, as a more effective "blocking layer" is formed. A similar effect has been observed in films produced from immobilised $Ni^{II/III}$ redox species[25] whereby a reduction in capacitive current and sharper Faradaic current peaks were observed with longer exposure times of the modified electrode to the disulfide solution. To interpret the results, the authors proposed a process whereby an initially random (disordered) film was replaced by a more ordered and compact film by replacement of surface molecules present in defective sites with fresh molecules in solution, whilst the total surface coverage ($\Gamma$) remained constant. Whilst replacement of surface-bound molecules with those in solution is clearly not possible here,

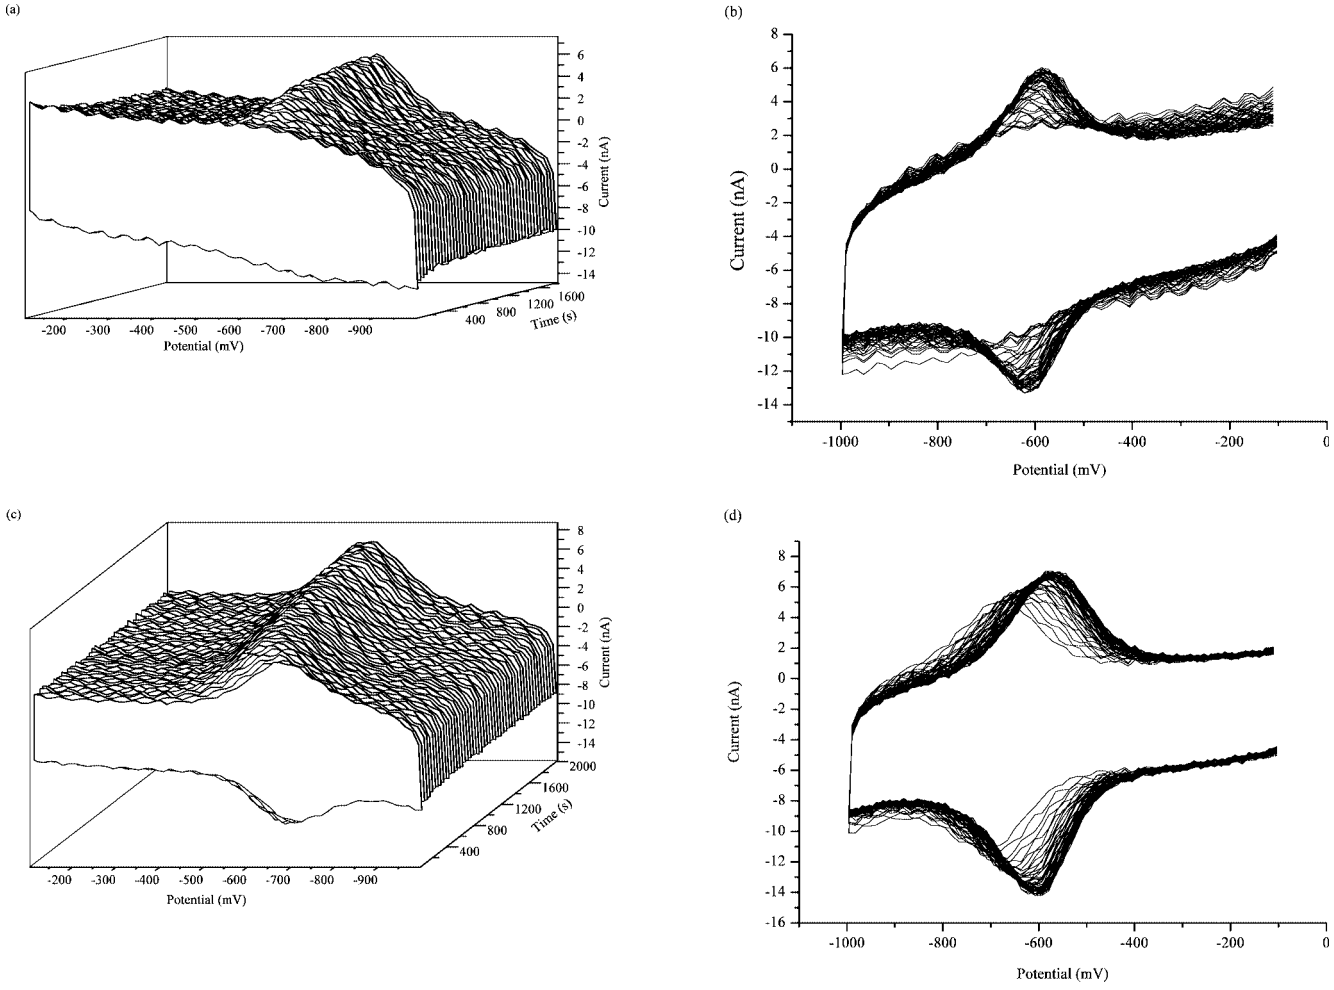

Figure 7. (a) Plot of repeated CVs vs. time for compound **4** immediately after ED and washing (10 V s$^{-1}$) [Note: Potential axis reversed for clarity in (a) and (c)]; (b) plot (a) viewed along the current/potential plane; (c): same as (a) but for SA; (d) plot (c) viewed along the current/potential plane.

if a surface reorganisation effect is taking place, for example by surface migration of the gold thiolate molecules[26] or the potentially slow cleavage of the disulfide bond, the results between the two experiments would be almost identical. It is worth noting that this effect was more pronounced for the films produced by ED, when compared to those prepared by SA, and this phenomenon may be explained by the relative rates at which the two films are formed. Rapid film formation during ED might not allow the molecules enough time to orient themselves on the surface, which could be exacerbated by the negative potential "pulling" the cationic cage units to the surface, whereas the long time and lack of applied potential in SA would overcome and obviate these effects (Figure 8). Thus, in order to obtain stable and reproducible CVs, all freshly prepared films were subjected to the above electrochemical treatment before the determination of the electrochemical parameters shown in Table 4.

Plotting the peak current against scan rate for monolayers of compound **4** prepared using both SA and ED shows a linear relationship (Figure 9), which is expected for a surface-adsorbed species.[27] These results indicate the successful immobilisation of compound **4** onto the gold surface using both ED and SA techniques.

The stability of the monolayers was examined by repeated electrochemical cycling, from the open circuit potential (ca. –100 mV) to –1000 mV with a scan rate of 100 $V s^{-1}$ (Figure 10). The signal due to the reduction of the surface-bound $Co^{III}$ conjugate shows virtually no loss in signal in-

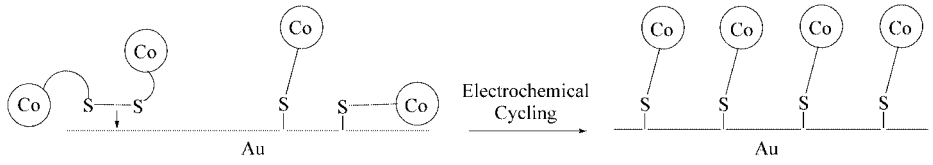

Figure 8. Diagram illustrating the possible reorganisation process leading to the observed increase in peak current and concomitant sharpening of peaks.

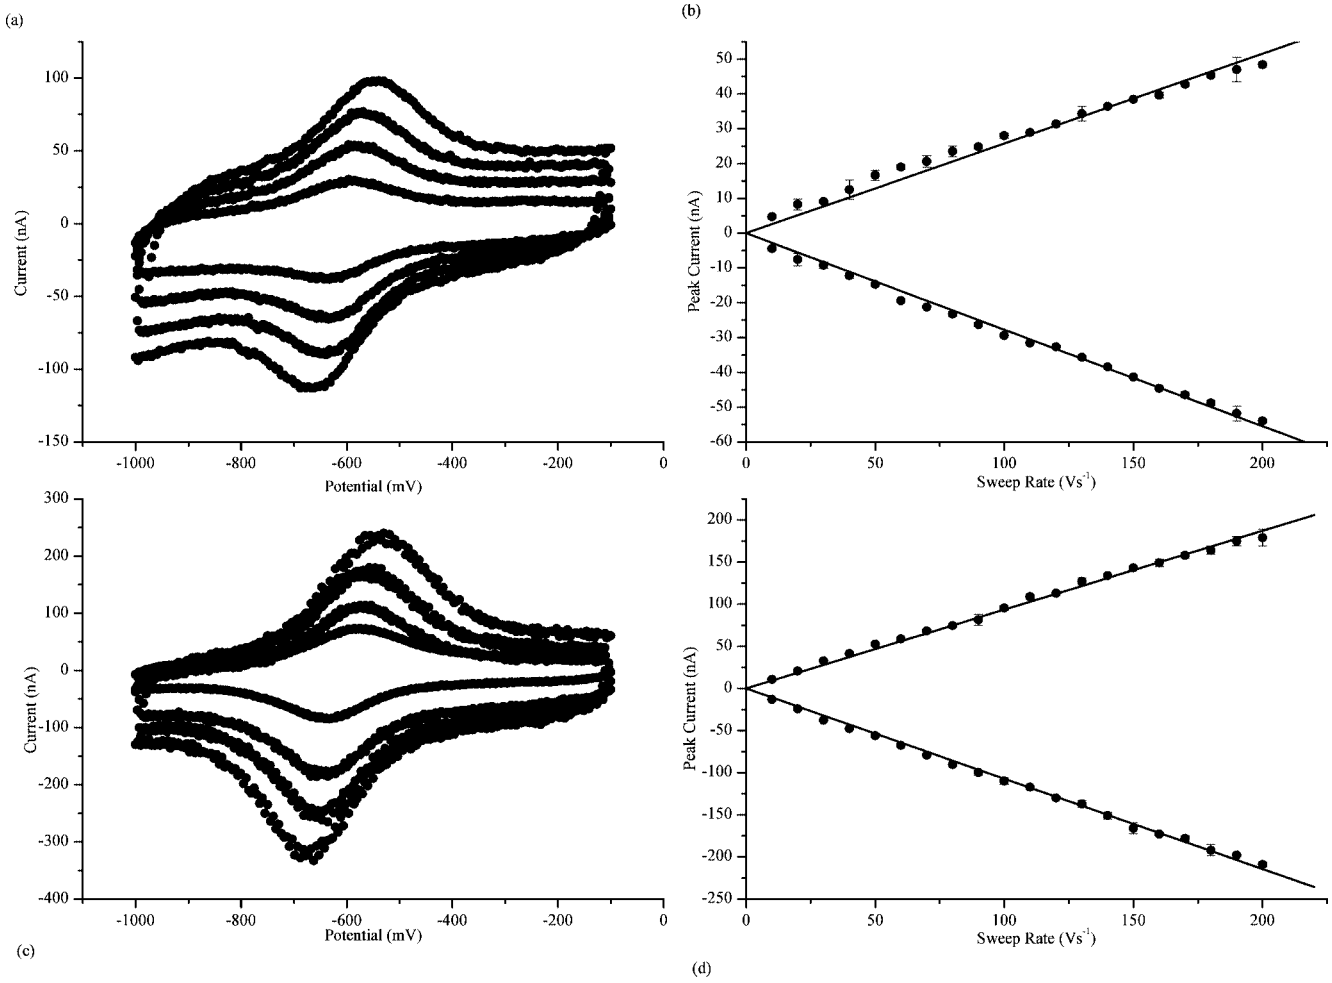

Figure 9. (a) CVs obtained at 50, 100, 150 and 200 $V s^{-1}$ for an EDM of compound **4**; (b) plot of peak current vs. scan rate for monolayer in plot (a); (c): as in plot (a) but for SAM; (d) as in plot (b) but for SAM.

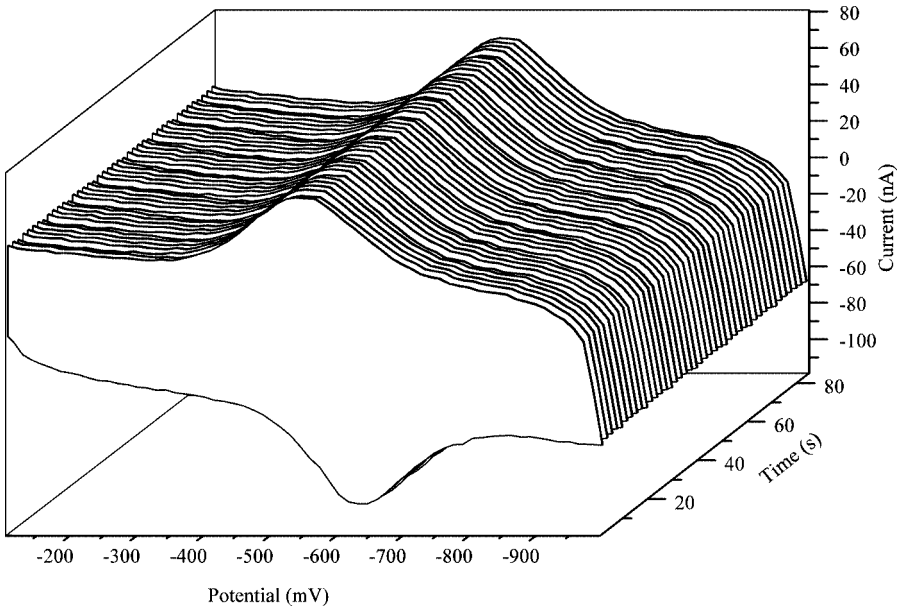

Figure 10. Repeated electrochemical cycling for film of compound **4** (100 $V s^{-1}$). (Note: Potential axis reversed for clarity.).

tensity upon repeated cycling for 100 s, indicating a stable monolayer has been formed.

As the data in Table 4 indicates, the monolayers formed using both the ED and SA techniques display very similar properties. The experimentally determined values for both films are virtually identical. Both films exhibit a reversible reduction of the $Co^{III}$ cage at $E° = –619(4)$ mV vs. Ag/AgCl, which is anodically shifted compared to the solution electrochemistry. The peak separation is nonzero but significantly reduced compared to the solution electrochemistry, indicating potentially an increase in the reversibility of the process on the surface. This also signifies that there is some barrier for electron transfer through the spacer. As would be expected, the molecular footprint is larger than the more compact and neutral ferrocene conjugates.[18,28] This can be rationalised considering the electrostatic repulsion between the positively charged (sarcophagine)$Co^{III}$ conjugates on the surface, and the large $E_{fwhm}$ of ca. 200 mV is consistent with this, as theoretical treatments[29,30] predict a broadening of Faradaic peaks when the film consists of repulsive entities. However, it is important to point out that the footprint and thus the surface concentration for films deposited electrochemically and prepared by self-assembly are identical. All of the experimentally determined values for $E_{1/2}$, and importantly, the surface concentration and the related specific area of the molecule are in agreement between the two techniques. This shows that both methods can be used to generate monolayers of the compounds on a gold electrode.

SAMs of compound **4** on Au-coated silicon wafers were also prepared, displaying contact angles of 57(2)° (advancing) and 26(5)° (receding), indicating the presence of a polar

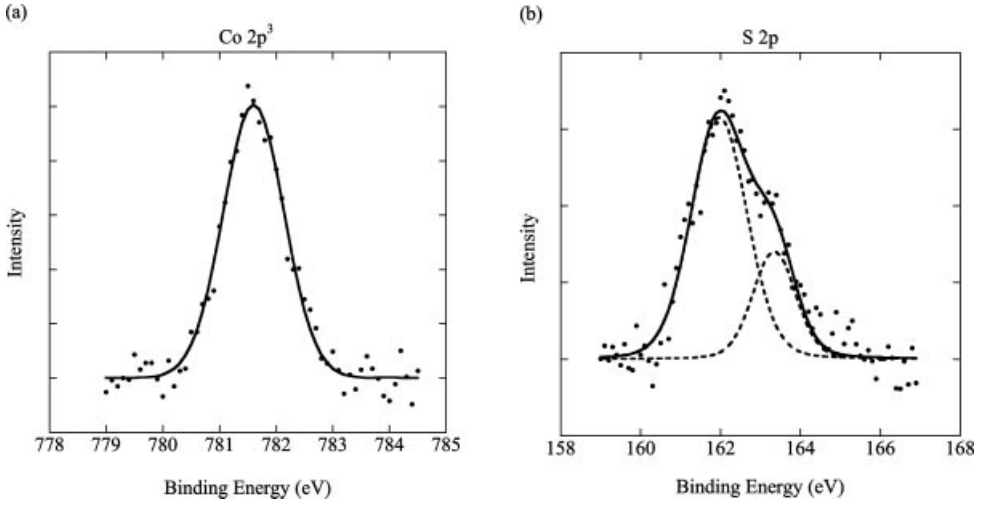

Figure 11. (a) XPS of the Co($2p^3$) region; (b) XPS of the S(2p) region. Closed circles represent experimental spectrum, solid line represents calculated spectrum and dashed lines indicate deconvoluted peaks.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

species on the surface. Evidence for a monolayer was obtained through the use of ellipsometry, which indicated a film thickness of ($7 \pm 1$ Å) which is lower than the value expected for a fully extended molecule of compound **4** (ca. 15 Å). A low value for the film thickness could be due to the molecules lying at an angle to the surface and/or poor surface coverage, but it does suggest that the surface is modified by a monolayer and not a multilayer.

An XPS analysis of a SAM prepared on an Au-coated silicon substrate of compound **4** was undertaken in order to define the nature of the adsorption of the compound onto the gold surface. Disulfide chemisorption onto gold is generally believed to occur through a process in which the disulfide bond is broken to give two chemically independent molecules on the surface, bound as thiolates.[26] Peaks corresponding to S, Co, N, O and C are observed in the XPS spectrum which demonstrates the presence of compound **4** on the substrate. Figure 11 shows the major peak in the S(2p) region at 162 eV, which is consistent with the formation of an Au–S bond,[31] allowing us to conclude that the compound is bound as a thiolate on the surface. The Co binding energy of 781.5 eV is higher than the reported binding energy of 780.5 eV for the related $[Co(NO_2)_2sar]Cl_3$,[32] but does fall within the range of binding energy values for the $Co^{III}$ $N_6$ complexes $[Co(en)_3]Cl_3$ and $[Co(NH_3)_6]Cl_3$ of 780.2–781.8 eV,[32,33] which indicates the cobalt atom is present as $Co^{III}$.

## Conclusions

In this paper we have described the synthesis and solution electrochemical behaviour of a series of cobalt cage complexes bridged with short disulfide-containing peptides. In this way we have demonstrated the efficacy of this synthetic strategy which will allow us to tune "tail" length in a number of applications. We have also shown that it is possible, at least in one case, to immobilise a complex on a gold substrate utilising the disulfide linkage present. We believe that this undergoes facile cleavage to give initially species which lack ordering and subsequent electrochemical cycling allows them to attain thermodynamically stable surface ordering, although this phenomenon requires further study.

The surface attachment of these peptide-tethered sarcophagine complexes has allowed us to form modified surfaces containing redox-active centres and promise entry to an exciting range of applications.

## Experimental Section

**General:** Nuclear magnetic resonance (NMR) spectra were acquired with a Bruker ARX 300 ($^1H$ at 300 MHz and $^{13}C$ at 75.5 MHz), Bruker AV 500 ($^1H$ at 500.13 MHz and $^{13}C$ at 125.8 MHz), or Bruker AV 600 ($^1H$ at 600.13 MHz and $^{13}C$ at 150.9 MHz). Chemical shifts for samples measured in $D_2O$ are expressed in ppm relative to an internal standard of acetone which was taken as being $\delta = 2.22$ ppm for $^1H$ NMR spectra and $\delta = 30.89$ ppm for $^{13}C$ NMR relative to TMS. Chemical shifts for samples measured in $[D_6]$DMSO were referenced to the residual solvent peak. Assignments were made with the aid of either the DEPT or HSQC techniques. Mass spectra were recorded using the electrospray technique (positive ion trap) with a VG Autospec instrument or QSTAR XL-MS/MS. Microanalyses for carbon, nitrogen and hydrogen were carried out by The Australian National University Microanalytical Service. All samples were thoroughly dried under vacuum at 50 °C for at least 4 h prior to their analysis. Ion exchange chromatography was performed under gravity flow using SP Sephadex C25 ($Na^+$ form, 200–400 mesh) or $H^+$ form Dowex 50Wx2 (200–400 mesh) cation exchange resin. Deionised water was used in all preparations. DMF was predried with molecular sieves (4 Å) prior to use. Dichloromethane was dried by distillation from $CaH_2$ and stored over molecular sieves (3 Å). Trisodium citrate ($Na_3Cit$) (Ajax), chloroacetic acid (Ajax), sodium picrate (BDH), *N*-[3-(dimethylamino)propyl]-*N*′-ethylcarbodiimide hydrochloride (EDC·HCl) (Aldrich), cystamine dihydrochloride (CSA·2HCl) (Aldrich), diisopropylethylamine (DIPEA) (Lancaster), *N*-hydroxysuccinimide (HOSu) (Aldrich), 2-benzotriazole-*N*,*N*,*N*,*N*,-tetramethyluronium hexafluorophosphate (HBTU) (Auspep), trifluoroacetic acid (TFA) (Aldrich), Boc-protected amino acids (Auspep), and trifluoromethanesulfonic (triflic) acid (Lancaster) were used as received. Solution electrochemical experiments were carried out at room temperature ($23 \pm 1$ °C) with a MacLab Potentiostat or CHInstruments potentiostat model 660B or 440 in 0.1 M $NaClO_{4(aq)}$ adjusted to pH = 7.3 with tris(perchlorate) buffer, and an analyte concentration of 1 mM. A three-electrode cell system consisting of glassy carbon (BAS, 3.0 mm diameter) as the working electrode, Pt wire as the counter electrode and Ag/AgCl (3.0 M KCl) as the reference electrode was employed. The carbon electrodes were cleaned by polishing with a micro-cloth pad with $Al_2O_3$ slurry (0.05 μm) and washed thoroughly with water before use. For the cyclic voltametric (CV) studies the scan rate was 100 mV $s^{-1}$ and for the DPV experiments a scan rate of 20 mV $s^{-1}$ and pulse amplitude of 50 mV was used. Cyclic voltammograms (CVs) were scanned in the potential range of 0.2 to –1.0 V vs. Ag/AgCl. $[Co(CH_3)(NH_2)sar]Cl_3·HCl·0.5H_2O$,[34] *rac*- and Δ-$[Co(NH_2)(NH_2CH_2CO_2H)sar]Cl_3·2HCl$,[16] [Boc-Gly-CSA]$_2$ and [Boc-Ala-CSA]$_2$[35] were all synthesised as reported previously.

**Structure Determinations:** Full spheres of CCD area-detector diffractometer data were measured ($\omega$-scans; monochromatic Mo-$K_\alpha$ radiation, $\lambda = 0.7107_3$ Å). $N_{t(otal)}$ reflections were obtained, these merging to $N$ unique ($R_{int}$ cited) after "empirical"/multiscan absorption correction (proprietary software), $N_o$ with $F > 4\sigma(F)$ considered "observed" and used in the full-matrix least-squares refinements on $F^2$, refining anisotropic displacement parameter forms, $(x,y,z,U_{iso})_H$ being included constrained at estimates. Conventional residuals $R$, $R_w$ {weights: $[\sigma^2(F^2) + n_wF^2]^{-1}$} are cited at convergence. Neutral atom complex scattering factors were employed within the context of the Xtal 3.7 program system.[36] Pertinent results are given above and in Tables 2 and 3 and Figure 2. In (**3**)$Cl_4·2H_2O$, a pair of substantial difference map residues were assigned as water molecule oxygen atoms, site occupancies unity after trial refinement, albeit with high displacement parameters, associated hydrogen atoms not being located. CCDC-605503 to -605505 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrodeposition:** All electrodeposition experiments were performed using a three-electrode cell system consisting of Au (25 μm diameter) as the working electrode, Pt wire as the counter electrode and Ag wire as the reference electrode. Electrodeposition was ac-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complished by placing a freshly oxidised microelectrode (electrochemical cycling from –0.4 to +1.2 V vs. Pt wire in 0.5 M $H_2SO_4$) into a 1 mM solution of the analyte in 0.1 M $NaClO_{4(aq)}$ and applying –1.5 V for 30 min. After this period, the electrode was washed with water, then suspended in a vigorously stirred beaker of water for 10 min, and then 2 M $NaClO_{4(aq)}$ for 30 s. All electrochemical measurements were performed using a custom-built potentiostat in 2 M $NaClO_{4(aq)}$ using a three-electrode cell system consisting of Au (25 μm diameter) as the working electrode, Pt wire as the counter electrode and Ag/AgCl as the reference electrode, which was placed in a separate cell and connected to the analyte cell with a salt bridge ($KNO_3$). The electrochemical cell was enclosed in a grounded Faraday cage, and all electrolytes were degassed with a flow of $N_{2(g)}$ prior to the experiments, and an $N_{2(g)}$ blanket maintained throughout the course of the measurements. All electrochemical measurements were performed on at least five different microelectrodes to ensure reproducibility.

**Self-Assembly:** Monolayers were formed by soaking a freshly cleaned electrode (electrochemical cycling from –0.4 to +1.2 V vs. Pt wire in 0.5 M $H_2SO_4$) in a 1 mM aqueous solution of the complex for 5 d. After this period, the electrodes were treated exactly as above for the electrodeposited materials.

**X-ray Photoelectron Spectroscopy:** XPS measurements were performed using an Axis-165 X-ray Photoelectron Spectrometer (Kratos Analytical) with a monochromatic Al-$K_a$ X-ray source (1486.7 eV). Survey spectra (0–1100 eV) were taken at constant analyser pass energy of 160 eV and high-resolution spectra of Au4f, C1s, N1s, O1s, S2p and Co2p, were acquired with a pass energy of 20 eV and a down time of 200 ms. The take-off angle measured as the angle between the film surface and the photoelectron energy analyser was 90°. The typical operating pressure in the analysing chamber was ca. $5 \cdot 10^{-10}$ Torr. Number of scans for high resolution required obtaining high signal/noise ratio varied from 4 for Au to 40 for Co, and 60 for S. The binding energies were referenced to Au4f7/2 at 84.0 eV.

**[Co(CH$_3$)(NH$_2$CH$_2$CO$_2$H)sar]Cl$_4$·H$_2$O (2)Cl$_4$·H$_2$O and [Co(CH$_3$)-{N(CH$_2$CO$_2$H)$_2$}sar]Cl$_3$·2H$_2$O (3)Cl$_3$·2H$_2$O:** [Co(CH$_3$)(NH$_2$)sar]-$Cl_3$·HCl·0.5$H_2O$ (2.10 g, 4.0 mmol) was dissolved in $H_2O$ (ca. 20 mL) in a three-necked round-bottomed flask, and the pH adjusted to ca. 10 by the addition of NaOH(aq). A solution of Na-$CO_2CH_2Cl$ (25 g, 0.21 mol) in water (ca. 100 mL) was then added, and the pH again adjusted to ca. 10 by addition of more NaOH(aq). The solution was then heated at 80 °C under Ar(g) for 7 d, and the pH maintained at ca. 9–10 by dropwise addition of NaOH(aq). The reaction was monitored on micro-columns of $Na^+$ form SP C25 Sephadex by elution with 0.1 M $Na_3Cit$. More Na-$CO_2CH_2Cl$ was added after 3 d (25 g, 0.21 mmol) and 5 d (10 g, 0.09 mmol), and after 7 d, the reaction mixture was acidified with acetic acid (pH < 5), diluted to 2 L in water, and applied to a column of $H^+$ form Dowex 50Wx2 cation exchange resin. The column was washed with water (500 mL), 1 M HCl (500 mL, to remove $Na^+$) and finally the products eluted with 3 M HCl. The fraction containing the products was then dried in the rotary evaporator, and the solid thus obtained dissolved into water (1 L) and applied to a column of $Na^+$ form Sephadex cation exchange resin. Elution with 0.05 M $Na_3Cit$ produced three bands, the first being a minor yellow band, the second the major orange band, and the third a minor orange band. The three bands were applied to $H^+$ form Dowex 50Wx2 cation exchange resin separately, and treated with water (500 mL), 1 M HCl (500 mL) and eluted with 3 M HCl. The product from Band 1 was dried in a rotary evaporator, dissolved in hot water and precipitated by the addition of EtOH and finally $Et_2O$ and cooling in the freezer. The product was collected by suction filtration, washed with a little cold EtOH, then finally $Et_2O$, and dried under vacuum to give (**3**)$Cl_3$·2$H_2O$ (0.22 g, 0.35 mmol) as orange crystals. $^1$H NMR (300 MHz, $D_2O$): $\delta$ = 0.9 (s, 3 H, –$CH_3$), 2.4–3.5 (m, 24 H, cage –$CH_2$–), 3.6 (s, 4 H, 2 iminodiacetate –$CH_2$–). $^{13}$C NMR (75.5 MHz, $D_2O$): $\delta$ = 20.1 (–$CH_3$), 42.3 (C of methyl cage cap), 52.1 (cage –$CH_2$–), 52.5 (iminodiacetate –$CH_2$–), 54.4, 54.7, 55.2 (cage –$CH_2$–), 64.5 (C of amino cage cap), 176.8 (C=O). ES-MS: *m*/*z* = 243.64 [$C_{19}H_{39}CoN_7O_4$ – $H^+$]$^{2+}$, 486.21 [$C_{19}H_{39}CoN_7O_4$ – 2 $H^+$]$^+$, 522.22 [$C_{19}H_{39}CoN_7O_4$ – $H^+$ + $Cl^–$]$^+$. $C_{19}H_{43}Cl_3CoN_7O_6$ [(**3**)$Cl_3$·2$H_2O$, 630.88]: calcd. C 36.17, H 6.87, N 15.54; found C 36.49, H 6.52, N 15.70. Crystals of (**3**)$Cl_3$·2$H_2O$ suitable for an X-ray structure determination were grown by slow concentration of a 2 M $HCl_{(aq)}$ solution of the complex. The product from Band 2 was treated as above for Band 1 to give (**2**)$Cl_4$·$H_2O$ (1.26 g, 2.13 mmol) as orange crystals. $^1$H NMR (500 MHz, $D_2O$): $\delta$ = 0.93 (s, 3 H, –$CH_3$), 2.4–3.5 (m, 24 H, cage –$CH_2$–), 3.69 (AB q, 2 H, Gly –$CH_2$–). $^{13}$C NMR (126 MHz, $D_2O$): $\delta$ = 19.9 (–$CH_3$), 42.8 (C of methyl cage cap), 43.6 (Gly –$CH_2$–), 52.0, 55.1, 55.2, 55.3 (cage –$CH_2$–), 60.8 (C of amino cage cap), 172.5 (C=O). ES-MS: *m*/*z* = 464.21 [$C_{17}H_{37}CoN_7O_2$ – $H^+$ + $Cl^–$]$^+$, 428.23 [$C_{17}H_{37}CoN_7O_2$ – 2 $H^+$]$^+$, 500.16 [$C_{17}H_{37}CoN_7O_2$ + 2 $Cl^–$]$^+$. $C_{17}H_{40}Cl_4CoN_7O_3$ [(**2**)$Cl_4$·$H_2O$, 591.29]: calcd. C 34.53, H 6.82, N 16.58; found C 34.58, H 6.72, N 16.62. Crystals of (**2**)$Cl_4$·$H_2O$ suitable for an X-ray structure determination were grown by slow concentration of a 2 M $HCl_{(aq)}$ solution of the complex. The triflate of [Co(CH$_3$)(NHCH$_2$CO$_2$H)sar]$^{3+}$ was obtained by dissolution of the chloride in neat triflic acid at ca. 50 °C whilst a constant stream of $N_2$ was bubbled though the solution for at least 1 h. The orange solution thus obtained was then cooled on ice and $Et_2O$ added slowly with stirring to precipitate the triflate as a yellow-orange powder, which was collected by suction filtration and washed with copious quantities of $Et_2O$. The product from Band 3 was determined from $^1$H NMR spectroscopy to be the starting material (0.35 g, 0.67 mmol).

**[Co(CH$_3$)(Gly-NHCH$_2$CH$_2$S-)sar]$_2$(ClO$_4$)$_6$·HClO$_4$ (4)(ClO$_4$)$_6$·HClO$_4$:** [Co(CH$_3$)(NH$_2$CH$_2$CO$_2$H)sar](CF$_3$SO$_3$)$_4$ (0.60 g, 0.58 mmol) was dissolved in DMF (30 mL), and *N*-hydroxysuccinimide (0.067 g, 0.58 mmol) was added to the orange solution, followed by DIPEA (0.4 mL, 2.3 mmol) and EDC·HCl (1.0 g, 5.2 mmol) and the orange mixture was stirred for 10 min. Cystamine dihydrochloride (CSA·2HCl) (0.063 g, 0.28 mmol) was then added, causing a precipitate to form immediately, which redissolved after ca. 10 min to give an almost clear solution. The mixture was stirred for 24 h, during which time a white precipitate had formed. The reaction mixture was then diluted into water (500 mL) and applied to a column of $Na^+$ form SP Sephadex SP 25 resin, which was washed with water (500 mL), then elution was commenced with 0.05–0.2 M $Na_3Cit$, which began to remove four bands, the fourth by far the major component. Band 4 was treated with a concentrated aqueous solution of sodium picrate (NaPic), until the precipitation of a very fine bright yellow solid ceased. The precipitate was collected on a sintered glass frit, at first by gravity, and then suction filtration. This material was washed well with water, and the moist yellow solid obtained was then suspended in water (ca. 100 mL) containing ca. 3 mL of concd. $HClO_{4(aq)}$, and to this was added EtOAc and the mixture stirred vigorously. Stirring was stopped periodically and the top layer of EtOAc decanted off and replaced with fresh solvent, until all of the solid had dissolved, leaving an orange aqueous phase, which was subsequently transferred to a separating funnel and extracted with EtOAc until the organic phase was colourless. The aqueous phase was then concentrated in a rotary evaporator until precipitation of an orange solid

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

commenced, then placed on ice to complete the precipitation. The orange precipitate was collected on a sintered glass frit and washed with EtOH and then $Et_2O$ and air-dried to give (**4**)$(ClO_4)_6$·$HClO_4$ (0.32 g, 0.19 mmol). The sample was recrystallised from warm $H_2O$/EtOH by the addition of $Et_2O$. $^1H$ NMR 600 MHz, [$D_6$]-DMSO): $\delta$ = 0.8 (s, 6 H, 2 $–CH_3$), 2.20–2.48 and 2.85–3.15 (m, 48 H, 2 cage $–CH_2–$), 2.53 (t, ca. 2 H, 2 cage pendent –NH–), 2.79 (t, 4 H, 2 $–CH_2–$S), 3.18 (m, 4 H, 2 $Gly_1$ $–CH_2–$), 3.39 (q, 4 H, 2 CSA $–CH_2–$N), 6.5 (br., 12 H, cage –NH–), 7.95 (t, 2 H, 2 CSA amide NH). $^{13}C$ NMR (151 MHz, [$D_6$]DMSO): $\delta$ = 19.5 ($–CH_3$), 37.0 (CSA $–CH_2–$S), 37.8 (CSA $–CH_2–$N), 42.1 (C of methyl cage cap), 44.3 ($Gly_1$ $–CH_2–$), 52.0, 53.5, 54.0, 54.2 (cage $–CH_2–$), 60.3 (C of amino cage cap), 171.0 (C=O). # Thiocyanate Functionalised Ionic Liquids: Synthesis, Characterisation and Reactivity

**Dongbin Zhao,[a] Zhaofu Fei,[a] Wee Han Ang,[a] Rosario Scopelliti,[a] and Paul J. Dyson*[a]**

**Keywords:** Ionic liquids / Thiocyanate / Palladium complexes / Imidazolium salts

The reaction of chloromethyl thiocyanate with 1-methylimidazole affords the imidazolium salt, 1-thiocyanomethyl-3-methylimidazolium chloride, [$C_1$SCNmim]Cl (**1a**). Exchange of the chloride anion in **1a** by $[PF_6]^-$, $[BF_4]^-$, $[Tf_2N]^-$ or $[AuCl_4]^-$ affords salts **1b**, **1c**, **1d** and **1e**, respectively. Salts [$C_1$SCNmim][$BF_4$] (**1c**) and [$C_1$SCNmim][$Tf_2N$] (**1d**) melt below 100 °C and can therefore be classified as ionic liquids. The reaction of **1a** with $PdCl_2$ affords [$C_1$SCNmim]$_2$[$PdCl_4$] (**2a**), whereas **1c** reacts with $PdCl_2$ to form the complex [$PdCl_2${$C_1$SCNmim}$_2$][$BF_4$]$_2$ (**2c**). In the presence of $HNO_3$ both **1a** and **1c** react with $PdCl_2$ with the loss of HCN to form a sulfide-bridged palladium dimer [$PdCl_2${$C_1$Smim}]$_2$ (**3**). The structures of **1a**, **1e**, **2a** and **3** have been determined in the solid state by single-crystal X-ray diffraction.

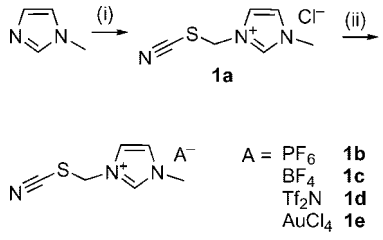
## Introduction

Ionic liquids incorporating functional groups on the cation and/or anion have started to receive extensive attention as media for a wide range of applications, in particular in homogeneous and heterogeneous catalysis, but also in material science.[1] In certain instances, when a functional group is incorporated into an ionic liquid structure, highly specific properties are imparted to the liquid, and in such cases these functional ionic liquids are often referred to as task-specific ionic liquids.[2] Many different functional groups have already been incorporated onto ionic liquid cations, for example, alkenes,[3–5] alkynes,[6,7] amines,[8] amides,[9] ethers, alcohols,[10] acids,[11] thiols,[12–14] urea and thiourea,[2] fluorous chains,[15] glycidyl chains,[16] phosphoryl,[17] and ferrocenyl groups.[18] In addition, ionic liquids with functional anions have also been reported, for example, with transition metal carbonyl anions,[19,20] perfluoroalkyl-[21] and nitrile-functionalised[22] trifluoroborate anions, as well as numerous others.[23]

We have previously reported the synthesis, characterisation and reactivity of ionic liquids carrying the nitrile functionality based on both imidazolium[24] and pyridinium[25] cations. It was shown that the nitrile-functionalised ionic liquids were excellent solvents for conducting Suzuki and Stille coupling reactions employing $PdCl_2$ as a precatalyst.[26] While the nitrile group was shown to coordinate to the palladium(II) centre following dissolution in the ionic liquids, it was found that under the catalytic conditions palladium nanoparticles formed. Transmission electron microscopy (TEM) revealed the presence of nanoparticles with a typical diameter of 5 nm and the nanoparticles showed superior stability to those isolated from nonfunctionalised ionic liquids. Thus, we thought that it might be interesting to see if related thiocyanate ionic liquids could be prepared and used in a similar fashion and in this paper we describe the synthesis, characterisation and the reactivity of a series of imidazolium ionic liquids incorporating the thiocyanate functionality.

## Results and Discussion

The synthetic route used to prepare the thiocyanate-functionalised imidazolium salts described herein is illustrated in Scheme 1. In the first step chloromethyl thiocyanate and 1-methylimidazole are stirred at 0 °C in acetone to afford the new imidazolium salt, [$C_1$SCNmim]Cl (**1a**). The product precipitates from the reaction and is obtained as a fine colourless microcrystalline material following filtration and washing.



Scheme 1. Synthesis of thiocyanate-functionalised imidazolium salts; Reagents and conditions: (i) $ClCH_2SCN$, acetone, 0 °C; (ii) $HPF_6$, Li[$Tf_2N$] or $HAuCl_4$ in water, $NaBF_4$ in acetone, room temp.

Single crystals of **1a** suitable for X-ray diffraction analysis were grown by slow diffusion of diethyl ether into a saturated acetonitrile solution of the compound at room temperature. The structure of **1a** that corroborates the spectroscopic data obtained in solution (see below) is shown in Figure 1 with key bond parameters given in the caption. The imidazolium ring is almost perfectly planar, bond angles in the rings range from 106.7(2) to 107.6(2)° and distances from 1.331(3) to 1.379(3) Å. The –S–C≡N moiety is essentially linear with a C–N distance of 1.147(3) Å, which is in the expected range.

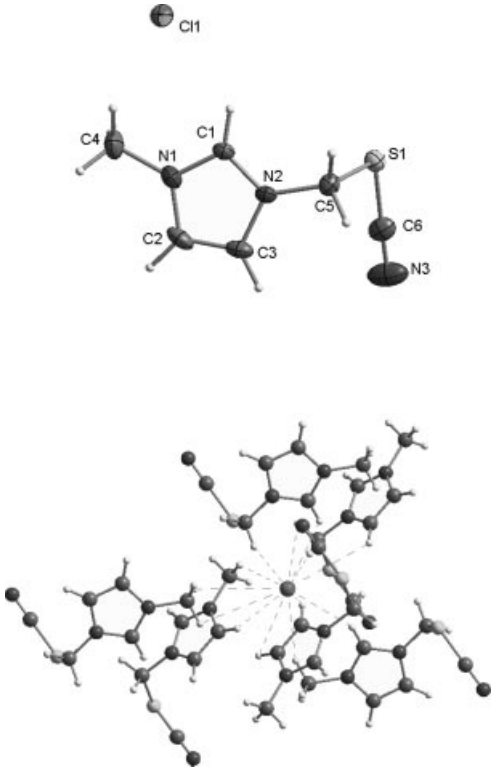

Figure 1. ORTEP representation of **1a** (top) and its packing diagram (bottom) indicating the positions of the imidazolium cations with respect to the chloride anion; atoms are represented by ellipsoids at the 50% probability level. Key bond lengths [Å] and angles [°]: C1–N1, 1.331(3); C1–N2, 1.338(3); N1–C4, 1.468(3); N2–C5, 1.453(3); C5–S1, 1.825(2); S1–C6, 1.704(3); C6–N3, 1.147(3); N1–C1–N2, 107.6(2); C1–N1–C4, 124.8(2); C1–N2–C5, 125.0(2); N2–S1–C6, 113.1(2); C5–S1–C6, 98.4(2); S1–C6–N3, 177.7(2).

The lattice of **1a** is characterised by extensive H bonding between the imidazolium cations and the chloride anion (see Figure 1 for **1a**), resulting in a compact structure held together by short contacts.

Subsequent reaction of **1a** with $HPF_6$, $NaBF_4$, $LiTf_2N$ [$Tf_2N$ = bis(trifluoromethanesulfonyl)imide] or $HAuCl_4$ in water or acetone affords [$C_1$SCNmim][$PF_6$] (**1b**), [$C_1$SCNmim][$BF_4$] (**1c**), [$C_1$SCNmim][$Tf_2N$] (**1d**) and [$C_1$SCNmim][$AuCl_4$] (**1e**), respectively (see Scheme 1). Salts **1b**–**1e** are all solids at room temperature with melting points of 120, 78, 47 and 150 °C, respectively, and thus **1c** and **1d** can be considered as ionic liquids on the basis of the widely accepted definition.[26]

Salts **1a**–**1e** were characterised using electrospray ionisation mass spectrometry (ESI-MS) and IR, $^1$H NMR and $^{13}$C NMR spectroscopy. The positive ion ESI mass spectra of **1a**–**1e** in methanol disclose a parent peak at *m*/*z* = 154 corresponding to the cation [$C_1$SCNmim]$^+$. In the negative ion mode intense peaks corresponding to the anticipated anions in **1a**–**1e** are observed. In keeping with previous observations, aggregates are also observed but dissipate when the spectra are recorded under high dilution conditions.[21]

The main feature in the IR spectra of **1a**–**1e** is the characteristic –S–C≡N vibrations. For **1a**, the stretching vibrations of C–S and C≡N bands are observed at 730 and 2159 cm$^{-1}$, respectively. For **1b**–**1e**, the C–S vibrations are essentially the same, however, the C≡N vibration shifts to higher wavenumbers, ca. 2169 cm$^{-1}$. The $^1$H and $^{13}$C NMR spectra of **1a**–**1e** in $CD_3CN$ or [$D_6$]DMSO are as expected with little change in the spectra as the anion is varied. The proton at the 2-position in the imidazolium ring is observed at 9.05 pm for compound **1a** in $D_2O$ solution. Compounds **1b**, **1c** and **1d** are poorly soluble in $D_2O$, the chemical shifts of the proton at the 2-position are 8.63, 8.72 and 8.78 ppm

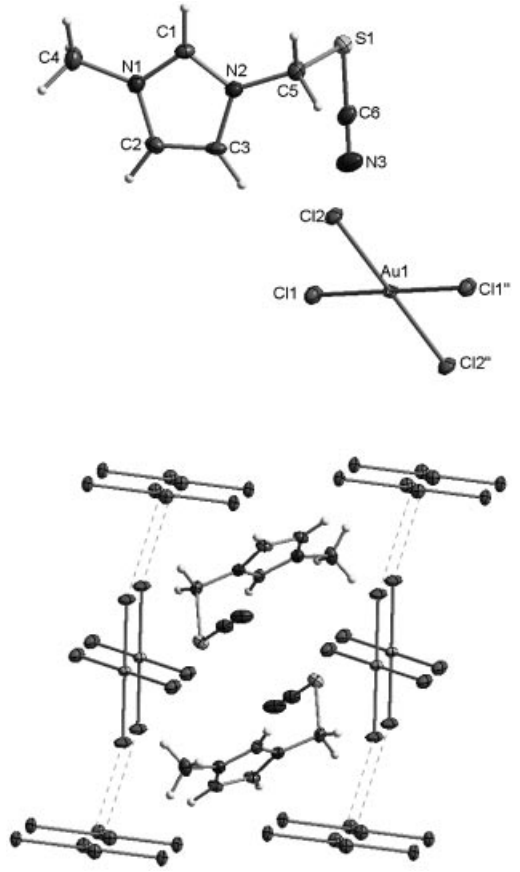

Figure 2. ORTEP representation of **1e** (top) and its packing diagram (bottom); atoms are represented by ellipsoids at the 50% probability level. Key bond lengths [Å] and angles [°]: C1–N1, 1.329(4); C1–N2, 1.334(4); N1–C4, 1.472(4); N2–C5, 1.453(4); C5–S1, 1.840(3); S1–C6, 1.698(3); C6–N3, 1.149(4); Au1–$Cl_{ave}$, 2.290(2); N1–C1–N2, 108.0(3); C1–N1–C4, 125.5(3); C1–N2–C5, 125.0(3); N2–S1–C6, 112.3(2); C5–S1–C6, 96.6(2); S1–C6–N3, 177.9(3).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

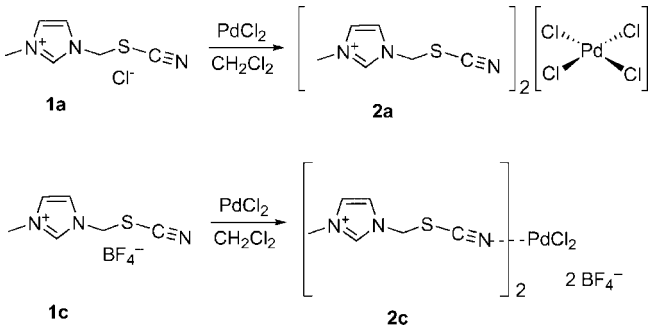
in $CD_3CN$, respectively. The other ring protons have chemical shifts between 7.4 and 7.6 ppm. The $-CH_3$ and $-CH_2-$ protons exhibit peaks at ca. 5.70 and 3.90 ppm, respectively, and these values differ only slightly as the anion varies from **1a** to **1d**.

Single crystals of the $AuCl_4^-$ **1e** compound suitable for X-ray crystallographic analyses were obtained from aqueous solutions by slow evaporation. The structure of **1e** is shown in Figure 2 and key bond parameters are given in the caption. The solid-state structures of the related salts $[C_2mim][AuCl_4]$ and $[C_4mim][AuCl_4]$ have previously been reported[27] and the crystal structure of complex **1e** is very similar to these earlier reported salts, i.e. forming a pseudo-rhombic structure with the imidazolium cation encased within a box composed of the $[AuCl_4]^-$ anions. In addition, the Au–Cl bond lengths within the square planar $[AuCl_4]^-$ anion and the intermolecular $Cl\cdots AuCl_4$ distance [3.445(1) Å] are comparable to those in $[C_2mim][AuCl_4]$ and $[C_4mim][AuCl_4]$ [3.356(3) and 3.452(3) Å, respectively].

### Reactivity of the Thiocyanate-Functionalised Ionic Liquids with Palladium(II) Chloride

A dichloromethane solution of **1a** was treated with 0.5 equiv. $PdCl_2$, affording $[C_1SCNmim]_2[PdCl_4]$ (**2a**) as shown in Scheme 2. The reaction requires several days to reach completion, presumably because of the low solubility of **1a** and $PdCl_2$ in this solvent. Related compounds containing the $[PdCl_4]^{2-}$ with other imidazolium cations have previously been reported.[26,28] In contrast to the chloride salt, the tetrafluoroborate salt (**1c**) reacts with $PdCl_2$ in dichloromethane at room temperature to form $[PdCl_2\{C_1SCNmim\}_2][BF_4]_2$ (**2c**).

Both of the palladium compounds have been characterised by $^1H$ and $^{13}C$ NMR spectroscopy, although this provided only limited information. A comparison of their IR spectra was, however, very informative; the stretching vibration of the C≡N group remains essentially unchanged in **2a**, relative to the imidazolium precursor **1a**, whereas in **2c**, the $\upsilon_{C\equiv N}$ stretching band is observed at a higher wavenumber, 2219 $cm^{-1}$, indicating coordination of the nitrile



Scheme 2. Synthesis of complexes **2a** and **2c**.

group to the palladium(II) centre. Single crystals of **2a** suitable for X-ray diffraction analysis were grown from aqueous solution by slow evaporation and the structure of **2a** is shown in Figure 3, and key bond parameters are given in the caption. Indeed, the CN moieties do not interact with the Pd centre, instead the S atoms of the thiocyanate moiety are directed towards the Pd centre with a Pd···S distance of 3.513(1) Å. A common feature of square-planar $Pd^{II}$ and $Pt^{II}$ complexes in the solid state is long interactions in the axial positions so as to form pseudo-octahedral structures.[29]

The thiocyanate group is relatively reactive and the cleavage of the carbon–sulfur bond can occur in both acidic and basic media[30] such that the resulting mercaptan anion can potentially coordinate to a metal centre. Accordingly, the reaction of **1a** or **1c** with $PdCl_2$ in 20% $HNO_3$ solution slowly affords orange-red crystals, which were characterised as $[PdCl_2\{C_1Smim\}]_2$ (**3**) by X-ray crystallographic analysis. The structure of **3** is shown in Figure 4, with key bond parameters given in the caption, and contains a mercaptoimidazolium zwitterion as a ligand. In keeping with other related $Pd^{II}$ complexes[31] the geometry around the Pd centres is distorted square planar with the mercapto-S atoms functioning as a bidentate-bridging ligand. The dimer complex contains numerous intramolecular H-bonding interactions between the chloro atoms and the H atoms on the imidazolium moiety.

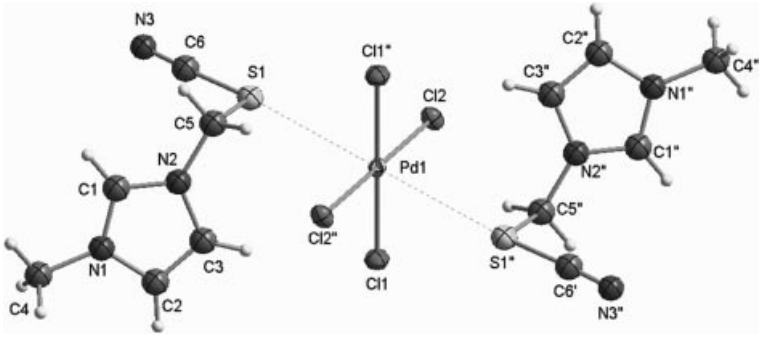


Figure 3. ORTEP representation of **2a**; atoms are represented by ellipsoids at the 50% probability level. The dotted lines (for visual purposes only) show the alignment of the thiocynate bonds towards Pd1. Key bond lengths [Å] and angles [°]: C1–N1, 1.319(4); C1–N2, 1.345(4); N1–C4, 1.464(14); N2–C5, 1.453(4); C5–S1, 1.818(3); S1–C6, 1.699(4); C6–N3, 1.141(4); Pd1–$Cl_{ave}$, 2.31; N1–C1–N2, 108.6(3); C1–N1–C4, 125.7(3); C1–N2–C5, 125.1(3); N2–S1–C6, 113.9(2); C5–S1–C6, 98.3(2); S1–C6–N3, 177.3(3).

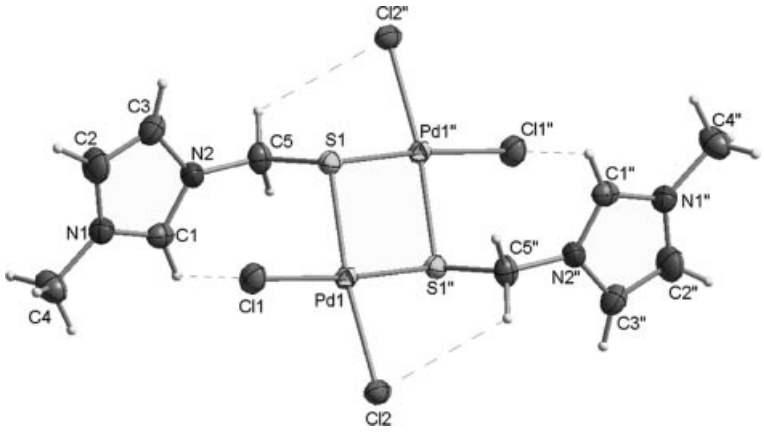

Figure 4. ORTEP representation of **3**; atoms are represented by ellipsoids at the 50% probability level. Key bond lengths [Å] and angles [°]: C1–N1, 1.331(14); C1–N2, 1.334(14); N1–C4, 1.474(14); N2–C5, 1.471(13); C5–S1, 1.828(11); Pd1–$Cl_{ave}$, 2.346(3); N1–C1–N2, 107.7(9); C1–N1–C4, 123.6(9); C1–N2–C5, 126.0(9); N2–S1–C6, 113.7(7).

## Concluding Remarks

In the present study, a series of thiocyanate-functionalised imidazolium salts were prepared, two of which can be classified as ionic liquids. According to the nature of the anion, viz. coordinating or noncoordinating, the salts react differently with palladium(II) chloride. However, in the presence of nitric acid cleavage of the C–S bond is induced and the same palladium dimer is formed irrespective of the type of anion present. Since none of the thiocyanate-functionalised imidazolium salts are liquid at room temperature, and the C–S bond is susceptible to cleavage, it was decided not to use them for palladium-catalysed reactions.

## Experimental Section

1-Methylimidazole, 1-chloromethyl thiocyanate, $HPF_6$, $NaBF_4$, $LiTf_2N$ and $HAuCl_4$ were obtained commercially and used as received. The synthesis of **1a** was performed under an inert atmosphere of dry nitrogen using standard Schlenk techniques in solvents dried using the appropriate reagents and distilled prior to use. All other compounds were made without precautions to exclude air or moisture. IR spectra were recorded with a Perkin–Elmer FT-IR 2000 system. NMR spectra were measured with a Bruker DMX 400, using $SiMe_4$ as the external standard for the $^1H$ NMR spectra at 20 °C. Electrospray ionization mass spectra (ESI-MS) were recorded with a ThermoFinnigan LCQ™ Deca XP Plus quadrupole ion trap instrument on samples diluted in solvents (methanol, water or DMSO). Samples were infused directly into the source at 5 μL min$^{-1}$ using a syringe pump and the spray voltage was set at 5 kV and the capillary temperature at 50 °C.[32] Elemental analysis was carried out at the Institute of Chemical Science and Engineering at the EPFL.

**Synthesis of [$C_1$SCNmim]Cl (1a):** A solution of 1-methylimidazole (8.21 g, 0.10 mol) and $ClCH_2SCN$ (12.9 g, 0.12 mol) in acetone (20 mL) was stirred at room temp. for 1 h during which time a white precipitate formed. The precipitate was washed with THF (3 × 30 mL) and dried under vacuum for 24 h. Yield: 18.6 g, 98%. M.p. 145 °C. Crystals suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into a saturated acetonitrile solution of the compound at room temp. ESI-MS ($H_2O$) (*m*/*z*) positive ion: 154 [$C_1$SCNmim], negative ion: 35 [Cl]. $^1H$ NMR ($D_2O$): $\delta$ = 9.05 (s, 1 H), 7.69 (s, 1 H), 7.54 (s, 1 H), 5.85 (s, 2 H), 3.92 (s, 3 H) ppm. $^{13}C$ NMR ($D_2O$): $\delta$ = 136.98, 124.32, 122.60, 111.62, 50.43, 36.36 ppm. IR (neat): $\tilde{\nu}$ = 3134, 3064 ($\upsilon_{C-H}$ aromatic), 2980, 2920, 2848, 2821 ($\upsilon_{C-H}$ aliphatic), 2159 ($\upsilon_{C\equiv N}$), 1731 ($\upsilon_{C=N}$), 730 ($\upsilon_{C-S}$) cm$^{-1}$. $C_6H_8ClN_3S$ (189.66): calcd. C 38.00, H 4.25, N 22.15; found C 37.97, H 4.26, N 22.18.

**Synthesis of [$C_1$SCNmim]$PF_6$ (1b):** $HPF_6$ (8.03 g, 60 wt.-%, 0.033 mol) was added to a solution of **1a** (5.7 g, 0.03 mol) in water (50 mL) at room temp. After 10 min the white solid that had formed was collected by filtration and washed with ice water (3 × 15 mL), and then dried under vacuum. Yield: 8.07 g, 90%. M.p. 120 °C. ESI-MS (methanol) (*m*/*z*) positive ion: 154 [$C_1$SCNmim], negative ion: 145 [$PF_6$]. $^1H$ NMR ($CD_3CN$): $\delta$ = 8.63 (s, 1 H), 7.60 (s, 1 H), 7.47 (s, 1 H), 5.63 (s, 2 H), 3.90 (s, 3 H) ppm. $^{13}C$ NMR ($CD_3CN$): $\delta$ = 136.74, 124.99, 122.28, 109.79, 50.34, 36.55 ppm. IR (neat): $\tilde{\nu}$ = 3167, 3125, 3106 ($\upsilon_{C-H}$ aromatic), 2987, 2938 ($\upsilon_{C-H}$ aliphatic), 2169 ($\upsilon_{C\equiv N}$), 1713 ($\upsilon_{C=N}$), 726 ($\upsilon_{C-S}$) cm$^{-1}$. $C_6H_8PF_6N_3S$ (299.18): calcd. C 24.09, H 2.70, N 14.05; found C 23.97, H 2.65, N 14.08.

**Synthesis of [$C_1$SCNmim]$BF_4$ (1c):** A mixture of **1a** (5.7 g, 0.03 mol) and $NaBF_4$ (3.62 g, 0.033 mol) in acetone (50 mL) was stirred at room temp. for 48 h. After filtration and removal of the solvent the resulting colourless solid was washed with THF and diethyl ether to give the product. Yield: 6.7 g, 93%. M.p. 78 °C. ESI-MS ($H_2O$) (*m*/*z*) positive ion: 154 [$C_1$SCNmim], negative ion: 87 [$BF_4$]. $^1H$ NMR ($CD_3CN$): $\delta$ = 8.78 (s, 1 H), 7.64 (s, 1 H), 7.50 (s, 1 H), 5.70 (s, 2 H), 3.91 (s, 3 H) ppm. $^{13}C$ NMR ($CD_3CN$): $\delta$ = 136.93, 124.98, 122.33, 109.90, 50.33, 36.47 ppm. IR: (neat): $\tilde{\nu}$ = 3156, 3117, 3093 ($\upsilon_{C-H}$ aromatic), 2989, 2901 ($\upsilon_{C-H}$ aliphatic), 2169 ($\upsilon_{C\equiv N}$), 1713 ($\upsilon_{C=N}$), 727 ($\upsilon_{C-S}$) cm$^{-1}$. $C_6H_8BF_4N_3S$ (241.02): calcd. C 29.90, H 3.35, N 17.43; found C 29.93, H 3.32, N 17.38.

**Synthesis of [$C_1$SCNmim][$Tf_2N$] (1d):** $LiTf_2N$ (8.61 g, 0.03 mol) was added to a solution of **1a** (5.7 g, 0.03 mol) in water (50 mL) at room temp. After 10 min the pale yellow liquid that had formed was collected by decantation and washed with ice water (3 × 15 mL) and then dried under vacuum. The liquid slowly crystallised from water at room temp. Yield: 11.60 g, 89%. M.p. 47 °C. ESI-MS (methanol) (*m*/*z*) positive ion: 154 [$C_1$SCNmim], negative ion: 280 [$Tf_2N$]. $^1H$ NMR ($CD_3CN$): $\delta$ = 8.72 (s, 1 H), 7.60 (s, 1 H), 7.48 (s, 1 H), 5.72 (s, 2 H), 3.91 (s, 3 H) ppm. $^{13}C$ NMR ($CD_3CN$): $\delta$ = 136.65, 124.97, 122.29, 109.66, 50.34, 36.49 ppm. IR: (neat): $\tilde{\nu}$ = 3145, 3112, 3091 ($\upsilon_{C-H}$ aromatic), 2988, 2901 ($\upsilon_{C-H}$ aliphatic), 2168 ($\upsilon_{C\equiv N}$), 1718

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

($\upsilon_{C=N}$), 731 ($\upsilon_{C-S}$) $cm^{-1}$. $C_8H_8F_6N_4O_4S_3$ (434.36): calcd. C 22.12, H 1.86, N 12.90, found C 22.15, H 1.87, N 12.87.

**Synthesis of $[C_1SCNmim]AuCl_4$ (1e):** A mixture of $HAuCl_4$ (340 mg, 1.0 mmol) and **1a** (378 mg, 1.00 mmol) in water (10 mL) was stirred at room temp. for 10 min. The resulting suspension was heated to 100 °C to give a clear solution. After cooling to room temp. the resulting orange crystals were collected by filtration and dried under vacuum to give the product. Yield: 335 mg, 68%. M.p. 150 °C. ESI-MS ($H_2O$) (*m*/*z*) positive ion: 154 [$C_1SCNmim$], negative ion: 337 [$AuCl_4$]. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 9.76 (s, 1 H), 7.93 (s, 1 H), 7.85 (s, 1 H), 6.06 (s, 2 H), 3.94 (s, 3 H) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 137.70, 125.19, 122.75, 111.82, 50.99, 36.80 ppm. IR: (neat): $\tilde{\nu}$ = 3135, 3111 ($\upsilon_{C-H}$ aromatic), 2977, 2901 ($\upsilon_{C-H}$ aliphatic), 2169 ($\upsilon_{C\equiv N}$), 1714 ($\upsilon_{C=N}$), 729 ($\upsilon_{C-S}$) $cm^{-1}$. $C_6H_8AuCl_4N_3S$ (492.98): calcd. C 14.62, H 1.64, N 8.52; found C 14.64, H 1.68, N 8.57.

**Synthesis of $[C_1SCNmim]_2PdCl_4$ (2a):** A mixture of $PdCl_2$ (177 mg, 1.0 mmol) and **1a** (378 mg, 2.00 mmol) in acetonitrile (5 mL) was stirred at room temp. for 7 d. After removal of the solvent the resulting orange solid was washed with dichloromethane (2 × 2 mL), and dried under vacuum to give the product. Yield: 549 mg, 99%. M.p. 146 °C. ESI-MS (DMSO) (*m*/*z*) positive ion: 154 [$C_1SCNmim$], negative ion: 124, 1/2 $[PdCl_4]^{2-}$. $^1H$ NMR ([D$_6$]-DMSO): $\delta$ = 9.76 (s, 1 H), 7.93 (s, 1 H), 7.85 (s, 1 H), 6.06 (s, 2 H), 3.94 (s, 3 H) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 137.70, 125.19, 122.75, 111.82, 50.99, 36.80 ppm. IR: (neat): $\tilde{\nu}$ = 3139, 3116, 3088 ($\upsilon_{C-H}$ aromatic), 2989, 2911 ($\upsilon_{C-H}$ aliphatic), 2168 ($\upsilon_{C\equiv N}$), 1718 ($\upsilon_{C=N}$), 734 ($\upsilon_{C-S}$) $cm^{-1}$. $C_{12}H_{16}Cl_4N_6PdS_2$ (556.63): calcd. C 25.89, H 2.90, N 15.10;. found C 25.91, H 2.88, N 15.17.

**Synthesis of $[C_1SCNmim]_2PdCl_2[BF_4]_2$ (2c):** A mixture of $PdCl_2$ (177 mg, 1.0 mmol) and **1c** (482 mg, 2.00 mmol) in dichloromethane (5 mL) was stirred at room temperature for 7 d. After removal of the solvent the resulting orange solid was washed with dichloromethane (2 × 2 mL), and dried under vacuum to give the product. Yield: 652 mg, 99%. M.p. 144 °C. ESI-MS (DMSO) (*m*/*z*) positive ion: 154 [$C_1SCNmim$]. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 9.25 (s, 1 H), 7.83 (s, 1 H), 7.77 (s, 1 H), 5.91 (s, 2 H), 3.91 (s, 3 H) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 137.38, 125.20, 122.89, 111.71, 50.71, 36.71 ppm. IR: (neat): $\tilde{\nu}$ = 3144, 3109, 3084 ($\upsilon_{C-H}$ aromatic), 2911 ($\upsilon_{C-H}$ aliphatic), 2219 ($\upsilon_{C\equiv N}$) $cm^{-1}$. $C_{12}H_{16}B_2Cl_2F_8N_6PdS_2$ (659.37): calcd. C 21.86, H 2.45, N 12.75; found C 21.89, H 2.47, N 12.70.

**Synthesis of 3:** **1a** or **1c** (0.2 mmol) was added to an aqueous solution of $PdCl_2$ in 20% $HNO_3$ (20 mmol $L^{-1}$, 10 mL) at room temp. After 5 d red crystals precipitated from the solution, which were collected by filtration. Yield: 11 mg, 9%. M.p. 137 °C. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 9.76 (s, 1 H), 7.88 (s, 1 H), 7.83 (s, 1 H), 3.94 (s, 3 H) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 137.81, 122.90, 121.66, 110.81, 35.97 ppm. IR: (neat): $\tilde{\nu}$ = 3158, 3117, 3066 ($\upsilon_{C-H}$ aromatic), 2911 ($\upsilon_{C-H}$ aliphatic), 733 ($\upsilon_{C-S}$) $cm^{-1}$. $C_{10}H_{16}C_{l4}N_4Pd_2S_2$ (610.99): calcd. C 19.66, H 2.64, N 9.17; found C 19.66, H 2.67, N 9.14.

**Structural Characterisation in the Solid State:** Relevant details about the structure refinements are compiled in Table 1 and selected bond lengths and angles are given in the figure captions. For **1a**, **2a** and **3** the data collection was performed with a four-circle Kappa goniometer equipped with an Oxford Diffraction KM4 Sapphire CCD at 140(2) K and data reduction was performed using CrysAlis RED.[33] For **1e** data collection was carried out with a Bruker Nonius APEX II CCD at 100(2) K and data reduction was performed using EVALCCD. Structure solution was carried out using SiR92,[34] and refined by full-matrix least-squares refinement (against $F^2$) using SHELXTL software.[35] All non-hydrogen atoms were refined anisotropically while hydrogen atoms were placed in their geometrically generated positions and refined using the riding model. Empirical absorption corrections were applied for **1a**, **2a** and **3** using DELABS[36] and **1e** using SADABS,[35] and graphical representations of the structures were made with the program Diamond.[37]

Table 1. Crystallographic data.

| Compound | **1a** | **1e** | **2a** | **3** |
|---|---|---|---|---|
| Formula | $C_6H_8ClN_3S$ | $C_6H_8Cl_4AuN_3S$ | $C_{12}H_{16}Cl_4N_6PdS_2$ | $C_{10}H_{16}Cl_4N_4Pd_2S_2$ |

# A Series of Lithium Rare Earth Polyphosphates [$LiLn(PO_3)_4$] (Ln = La, Eu, Gd) and Their Structural, Optical, and Electronic Properties

**Jing Zhu,[a] Wen-Dan Cheng,*[a] Dong-Sheng Wu,[a] Hao Zhang,[a] Ya-Jing Gong,[a] Hua-Nan Tong,[a] and Dan Zhao[a]**

**Keywords:** Density functional calculations / UV/Vis spectroscopy / Rare earths / Phosphates

The structural, optical, and electronic properties of a series of lithium rare earth polyphosphates [$LiLn(PO_3)_4$] [Ln = La (**1**), Eu (**2**), Gd (**3**)] have been investigated by means of single-crystal X-ray diffraction, elemental analyses, and spectroscopic measurements, as well as calculations of energy-band structures, density of states, and optical response functions by density functional methods. These $LiLn(PO_3)_4$ systems are monoclinic with space group $C2/c$ and $Z = 4$. Their unit-cell parameters decrease as the ionic radius of $Ln^{3+}$ decreases ($La^{3+} > Eu^{3+} > Gd^{3+}$). Both $(PO_4)^{3-}$ zig-zag chains and infinite chains formed by the alternate connection of $LnO_8$ polyhedra and $LiO_4$ tetrahedra run parallel to the *b*-axis in the structure. The energy-band structures, density of states, the chemical bonds, and optical properties have been investigated by density functional methods for some of the title compounds.

## Introduction

Rare earth phosphate materials have been extensively investigated due to their structural diversity[1–3] and potential properties (magnetism,[4] electricity,[5] and optics[6]). Furthermore, their chemical and thermal stability ensures their utility in industrial applications. The common basic structural unit of these materials is the $PO_4$ group, and the varied condensations of $PO_4$ groups result in several structural families,[7–10] one of which is polyphosphates with the general formula [$MLn(PO_3)_4$] (M = alkali metal, Ln = rare earth metal).[11] Some polyphosphates with interesting optical properties have been reported in this family. For example, Yamada et al. have reported the use of [$LiNd(PO_3)_4$][12,13] as a solid-state laser material whose relatively large Nd–Nd distance gives rise to a lesser degree of fluorescence quenching. Parreu et al. have investigated noncentrosymmetric [$KLn(PO_3)_4$] (Ln = Nd, Gd) crystals[14,15] and explored their second harmonic generation, and Naili et al. have reported the crystal structures of [$MGd(PO_3)_4$] (M = K, Cs).[16,17] Recently, [$NaLa(PO_3)_4$][18] was synthesized in our laboratory. In addition, some phosphates involving lithium, such as [$LiMPO_4$] (M = Fe, Co, Ni),[19] exhibit excellent electrochemical properties with potential applications in lithium ion batteries. Although the lattice parameters of [$LiLn(PO_3)_4$] (Ln = La, Eu) have been reported previously,[20,21] no X-ray crystal structural determinations were able to support these parameters.

Here we will report the structures and optical properties of [$LiLn(PO_3)_4$] [Ln = La (**1**), Eu (**2**), Gd (**3**)]. We will also describe their electronic properties and the results of calculations of the crystal energy bands, density of states (DOS), and optical response functions of **1** and **3** by density functional methods in order to analyze the chemical bonding properties and electronic origins of the optical transitions.

## Results and Discussion

### Crystal Structure Descriptions

Crystals of **1**–**3** are isostructural and crystallize in the monoclinic space group $C2/c$ (see Supporting Information). The asymmetric units of **1**–**3** have the same number of crystallographically distinct atoms. As expected, the unit-cell parameters of **1**–**3** decrease as the ionic radius of $Ln^{3+}$ decreases ($La^{3+} > Eu^{3+} > Gd^{3+}$). Selected bond lengths and angles are given in Table 1. The structure can be simply described as a three-dimensional framework made up from $(PO_4)^{3-}$ zig-zag chains and infinite chains involving $LnO_8$ and $LiO_4$ polyhedra. We will discuss their structural characterization by taking **1** as an example. Figure 1 shows a projection of the structure of **1** along the *b*-axis. The basic structural units are $PO_4$, $LaO_8$, and $LiO_4$ polyhedra. Two crystallographically distinct $P(1)O_4$ and $P(2)O_4$ tetrahedra form $(PO_4)^{3-}$ zig-zag chains by corner-sharing along the *b*-axis. The P(1) atom is connected to O(1), O(2), O(3), and O(4), and the P(2) atom is connected to O(2), O(3), O(5), and O(6). All P–O bond distances vary from 1.483(4) to

1.606(4) Å, and the O–P–O angles range from 101.5(2)° to 119.5(2)° (Table 1), thus indicating that these $PO_4$ tetrahedra are distorted. The largest distance is the P–O bond in the P–O–P bridge and the shortest one corresponds to that in the nonbridging connections. The $(PO_4)^{3-}$ chains are isolated from each other and surrounded by $LaO_8$ and $LiO_4$ polyhedra. In addition, an alternating arrangement of $LaO_8$ and $LiO_4$ polyhedra forms infinite chains along the *b*-axis by edge-sharing (Figure 2), each of which is surrounded by neighboring $(PO_4)^{3-}$ zig-zag chains. The La atom is coordinated by eight O atoms and the $LaO_8$ polyhedra are distorted, with La–O bond lengths ranging from 2.437(3) to 2.636(4) Å (Table 1). Each $LaO_8$ polyhedron is corner-connected to eight different $PO_4$ tetrahedra and edge-connected to two $LiO_4$ tetrahedra. The isolation of the $LaO_8$ polyhedra gives rise to large La–La distances, the shortest of which is 6.5690(3) Å. The Li atom is four-coordinate, with the Li–O bond distance ranging from 1.945(8) to 1.985(8) Å. Each $LiO_4$ tetrahedron shares all four O atoms with two $LaO_8$ polyhedra and four different $PO_4$ tetrahedra. The edge-sharing of $LaO_8$ and $LiO_4$ polyhedra results in infinite chains along the *b*-axis.

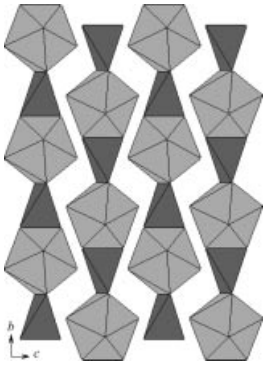

Figure 2. Projection of the structure of **1** along the *a*-axis showing the alternating arrangement of $LaO_8$ polyhedra and $LiO_4$ tetrahedra (the P atoms have been omitted for clarity).

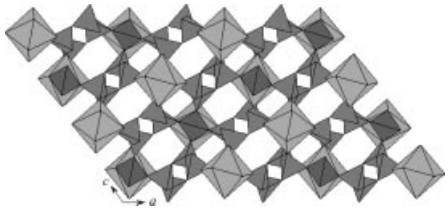

Figure 1. Projection of the structure of **1** along *b*-axis.

### Band Structure, Density of States, and Chemical Bonds

The energy band structures and density of states (DOS) of **1** and **3** were calculated by density functional methods. For **3**, the spin-polarization was properly taken into account by considering the unpaired f-electron effect of the $Gd^{3+}$ ion (α and β represent spin-up and spin-down, respectively). The calculated band structure of **1**, as shown in Fig-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 3, displays similar features, except for the f-band, to that of **3**, which is given as Supporting Information. In order to assign these bands, the total density of states (TDOS) and partial DOS (PDOS) of **1** and **3** are shown in Figure 4.

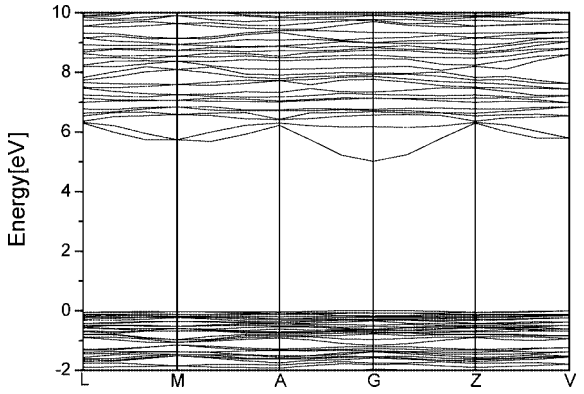

Figure 3. Calculated band structure of **1**.

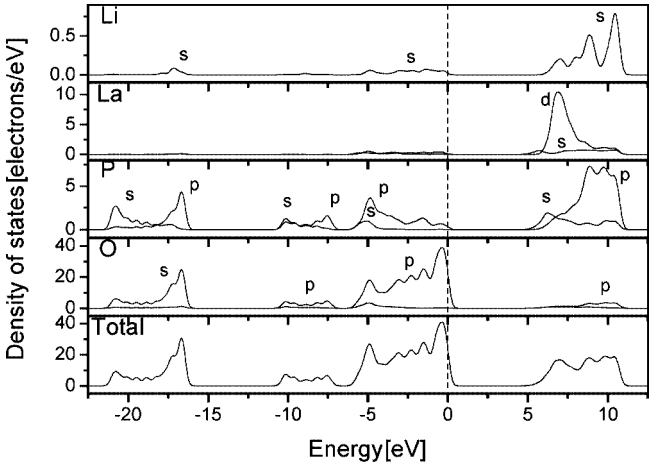
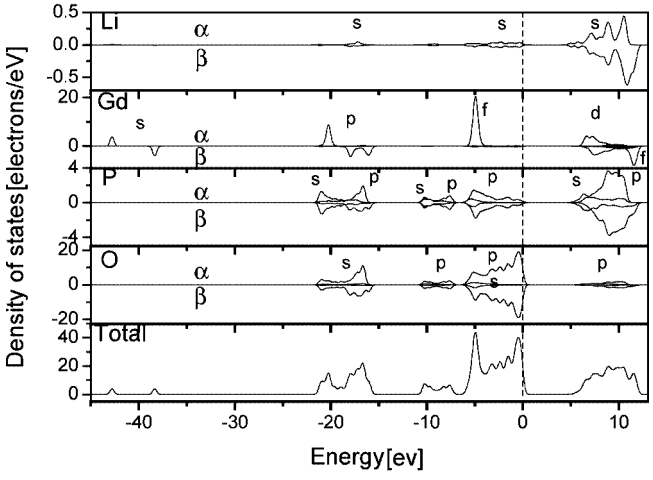


(a)



(b)

Figure 4. Total and partial densities of states of **1** (a) and **3** (b).

The calculated band structures of **1** and **3** exhibit similar features. It is observed that the top of the valence bands (VBs) is nearly flat and close to the Fermi level (0.0 eV), and the bottom of the conduction bands (CBs) exhibits obvious dispersion. The lowest energy of the CBs is localized at G (Figure 3), which means that **1** and **3** show an insulator character with a direct bandgap of around 5.02 and 4.99 eV, respectively. According to Figure 4, the O 2p states are the main contributors to the VBs ranging from –10.7 eV to the Fermi level, and the O 2s states form the VBs between –21.5 and –16.0 eV. In addition, the CBs between 5.0 and 11.0 eV are mostly formed by the P 3p states. The La 5d and Gd 5d states also give rise to CBs in **1** and **3**, respectively. Furthermore, for **3**, the VBs near about –40.0, –20.0, and –5.0 eV also result from the Gd 5s, Gd 5p, and Gd 4f states, respectively.

We also elucidated the features of the chemical bonds for **1** and **3** on the basis of the total and angular momentum projected DOS (Figure 4). In the range from –10.7 eV to the Fermi level the O 2p and P 3p states exist simultaneously, although the DOS is much larger for the former, which indicates that some P 3p electrons transform into the VBs and take part in the covalent interactions between P and O atoms and that hybridization between the P 3p and O 2p states takes place. The chemical bonding properties were also confirmed by means of the population analysis. The calculated bond orders of **1** and **3** in the unit cell are 0.45–0.82, 0.20–0.30, and 0.02–0.03 e for P–O, Ln–O, and Li–O bonds, respectively. It is well known that a covalent single-bond order is generally 1.0 e. Accordingly, the covalent character of the P–O bond is larger than that of the Ln–O bond, and the ionic character of the Li–O bond is larger than that of the Ln–O bond.

## Optical Properties

Figure 5 illustrates the absorption and emission spectra of **1**–**3**. The absorption spectra were determined by the diffuse-reflectance technique. $F(R)$ and $R$ are linked by $F(R) = (1 - R)^2/2R$, where $R$ is the reflectance and $F(R)$ is the Kubelka–Munk remission function. The minima in the second-derivative curves of the Kubelka–Munk function are taken as the position of the absorption bands. Their absorption edges are around 320 (3.88), 330 (3.76), and 350 nm (3.55 eV), respectively. A strong absorption peak only appears at around 245 nm (5.07 eV) for **1**, 250 nm (4.97 eV) for **2**, and 260 nm (4.78 eV) for **3**.

In order to assign these experimental spectra, we examined the linear optical response properties of crystals **1** and **3**. We calculate the imaginary part $\varepsilon_2(\omega)$ and the real part $\varepsilon_1(\omega)$ of the frequency-dependent dielectric function without the DFT scissor-operator approximation, as displayed in Figure 6. The $\varepsilon_2(\omega)$ part can be used to describe the real transitions between the occupied and unoccupied electronic states. There are distinct peaks at around 7.50 and 8.50 eV for **1** and **3**, respectively, which correspond to those of the experimental spectra [Figure 5(a)]. According to Figure 4,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

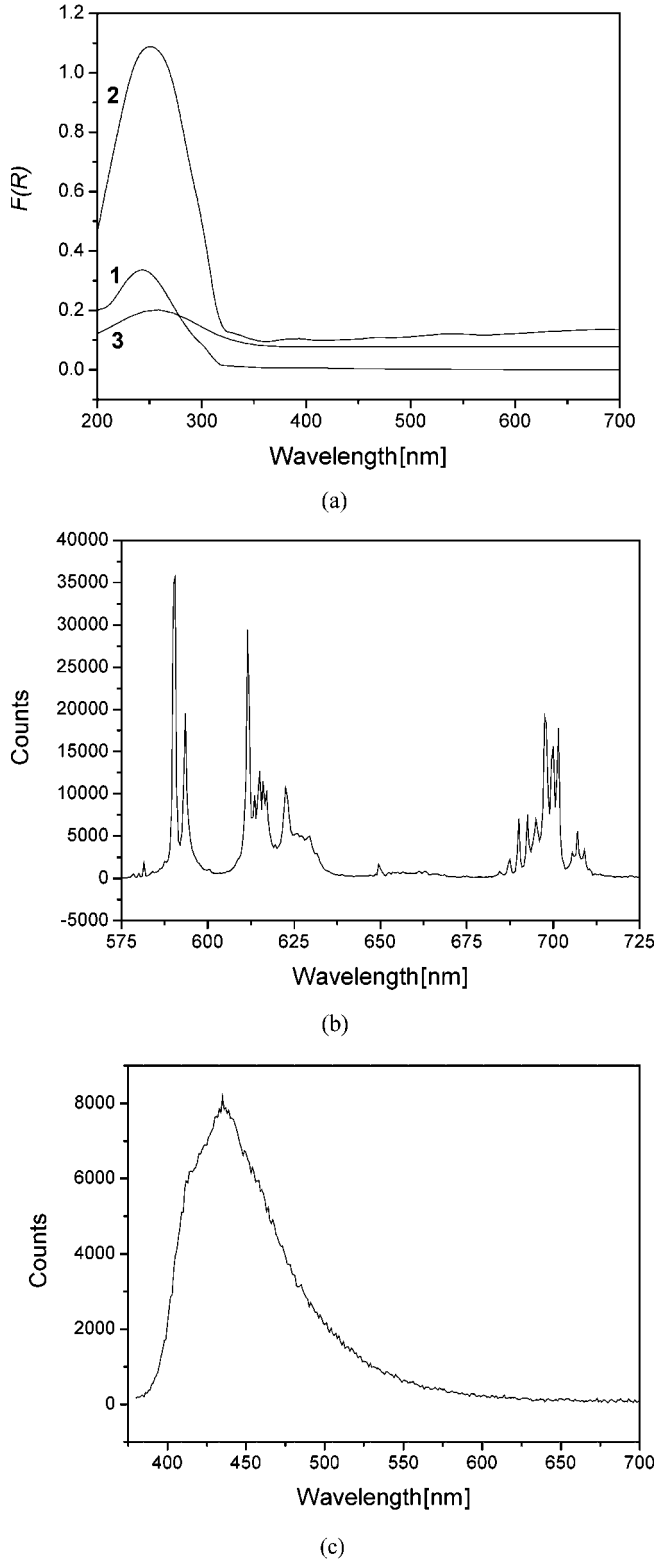


Figure 5. Absorption spectra of **1**–**3** (a); emission spectrum of **2** upon excitation at 295 nm (b); emission spectrum of **3** upon excitation at 365 nm (c).

these peaks are due to the electronic transitions from the O 2p to La 5d states for **1** and from the O 2p to Gd 5d states for **3**. In addition, comparing the calculated UV/Vis absorption edges (about 5.20 eV for **1** and 4.60 eV for **3**) of the crystals with the experimental ones (about 3.88 eV for **1** and 3.55 eV for **3**) of the powder samples shows that the transmission width is larger for the crystals than the powder samples, which indicates that the result of the calculation is reasonable. For **3**, the emission peak is located at 435 nm (2.86 eV) at an excitation wavelength of 365 nm [Figure 5(c)]. The emission energy is less than the experimental absorption edge of 3.55 eV, which means that the emission peak probably originates from defects or excitons. For **2**, the emission spectrum displays the characteristic yellow-red emissions that result from the intraconfigurational electronic $^5D_0$–$^7F_J$ transitions ($J$ = 0–4) of the $Eu^{3+}$ ion[22] in the range from 575 to 725 nm under excitation at 295 nm [Figure 5(b)]. Five emission regions correspond to 582 ($^5D_0$–$^7F_0$), 590–595 ($^5D_0$–$^7F_1$), 610–630 ($^5D_0$–$^7F_2$), 650 ($^5D_0$–$^7F_3$), and 685–710 nm ($^5D_0$–$^7F_4$), respectively. The presence of only one narrow band for the $^5D_0$–$^7F_0$ transition of the $Eu^{3+}$ ion implies that there is only one such

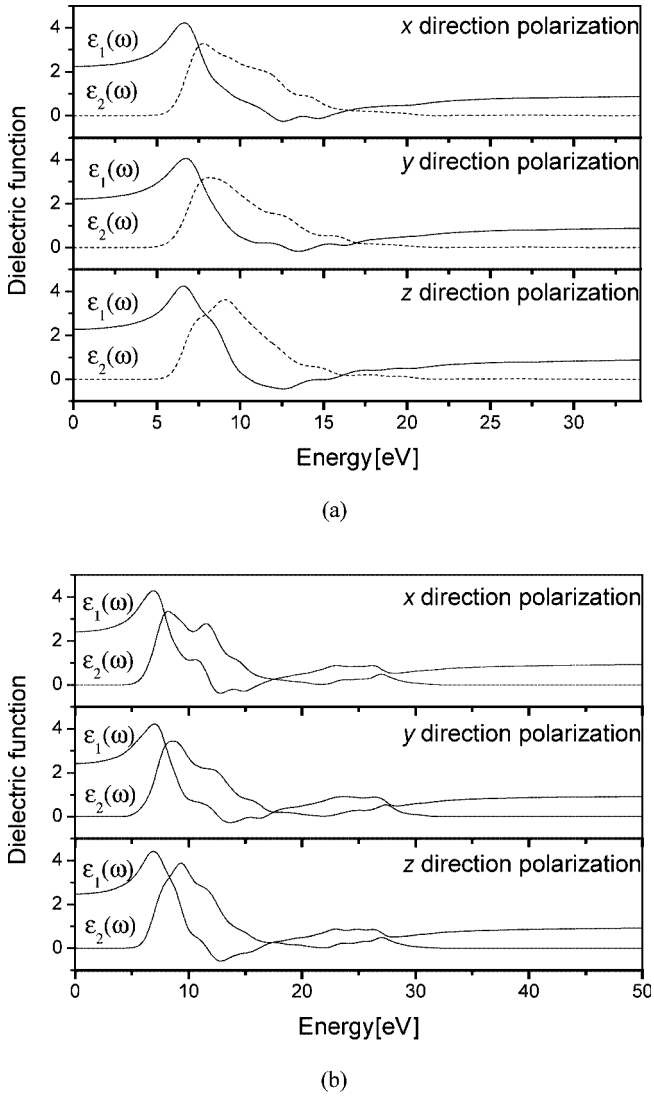

Figure 6. Calculated real and imaginary parts of the dielectric functions in different polarization directions for **1** (a) and **3** (b).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coordination environment, which is consistent with the above-mentioned structural data for **2**.

We also investigated the calculated dielectric constants of the static case, $\varepsilon(0)$, and the refractive indices, $n$, of **1** and **3**. The refractive index is linked to the dielectric constant by the relation $n^2(\omega) = \varepsilon(\omega)$. The calculated dielectric constants of the static case in the $x$, $y$, and $z$ directions are 2.2378, 2.2135, and 2.2768 for **1** and 2.4142, 2.4232, and 2.4645 for **3**, respectively. The corresponding refractive indices in the different directions at 1064 nm are 1.5034, 1.4951, and 1.5165 for **1** and 1.5614, 1.5645, and 1.5775 for **3**. It should be noted that the calculated dielectric constants of the static case and refractive indices at 1064 nm are larger for **3** than for **1**. Since the refractive indices of **1** and **3** have not been measured or reported, we compared the calculated results with the observed refractive indices of the other phosphate crystals, which generally range from 1.40 to 1.6;[23] the calculated refractive indices of **1** and **3** are therefore reasonable.

## Conclusions

In summary, a series of isostructural lithium rare earth polyphosphates [LiLn(PO$_3$)$_4$] (Ln = La, Eu, Gd) have been synthesized by a high-temperature solution reaction. Their crystallographic data obtained by single-crystal X-ray diffraction show that their structures belong to the monoclinic space group $C2/c$. The unit-cell parameters of **1**–**3** decrease as the ionic radius of $Ln^{3+}$ decreases ($La^{3+} > Eu^{3+} > Gd^{3+}$). Both $(PO_4)^{3-}$ zig-zag chains and infinite chains with an alternating arrangement of $LaO_8$ and $LiO_4$ polyhedra run along the $b$-axis. The Li–O bond exhibits ionic character, and the P–O bond is more covalent than the Ln–O bond. Spectral measurements and theoretical computations show that **1**–**3** are insulators. [LiEu(PO$_3$)$_4$] displays the characteristic yellow-red emissions that result from the intraconfigurational electronic $^5D_0$–$^7F_J$ transitions ($J$ = 0–4) of the $Eu^{3+}$ ion. In addition, the dielectric constants of the static case, $\varepsilon(0)$, and refractive indices, $n$, of [LiLa(PO$_3$)$_4$] and LiGd(PO$_3$)$_4$ have also been estimated. Further studies aimed at synthesizing new phosphate materials with other alkali and rare earth metals are currently in progress.

## Experimental Section

**Syntheses:** Single crystals of **1**–**3** were prepared by a high-temperature solution reaction from $Li_2CO_3$, $La_2O_3$ (**1**), $Eu_2O_3$ (**2**), or $Gd_2O_3$ (**3**), and $NH_4H_2PO_4$ with an Li/Ln/P molar ratio of 7:1:12. The excess $Li_2CO_3$ and $NH_4H_2PO_4$ formed the flux. The starting mixtures were finely ground in an agate mortar to ensure the best homogeneity and reactivity, then placed in a platinum crucible and heated at 473 K for 4 h. The mixtures were then reground and heated to 1173 K for 24 h. Finally, the mixture was cooled to 773 K at a rate of 2 K h$^{-1}$, followed by air-quenching to room temperature. A few colorless, block-shaped crystals were obtained from the melt of the mixtures.

**Crystal Structure Determinations:** Single crystals of **1**–**3** with dimensions $0.18 \times 0.10 \times 0.03$ (**1**), $0.20 \times 0.04 \times 0.02$ (**2**), and $0.30 \times 0.12 \times 0.08$ mm (**3**) were selected for X-ray diffraction determination. The diffraction data for **1** were collected with a Siemens SMART CCD diffractometer with graphite-monochromated Mo-$K_a$ radiation ($\lambda$ = 0.71073 Å) using the $\omega/2\theta$-scan mode at a temperature of 293 K, and those for **2** and **3** were collected with a Rigaku Mercury CCD diffractometer with graphite-monochromated Mo-$K_a$ radiation ($\lambda$ = 0.71073 Å) using the $\omega$-scan mode at a temperature of 293 K. Lorentz and polarization corrections were applied to all data. The structures were solved by direct methods and refined on $F^2$ by the full-matrix least-squares method with SHELXL97.[24] The positions of the La, Eu, and Gd atoms were refined by direct methods and the remaining atoms were located in successive difference Fourier syntheses. In order to confirm the chemical compositions of the four compounds, the single crystals of **1**–**3** investigated with the diffractometer were analyzed by energy-dispersive X-ray spectroscopy (EDX) using a JSM6700F scanning electron microscope. The obtained results are in good agreement with those obtained by the refinement of the crystal structures. No impurity elements were detected, although the light element Li could not be satisfactorily determined by the EDX measurement. The results of the elemental analyses are given as Supporting Information. Crystal data for **1**: LiLa(PO$_3$)$_4$ (461.73), monoclinic, space group $C2/c$, $T$ = 293(2) K, $a$ = 16.6230(3), $b$ = 7.1198(1), $c$ = 9.905 Å, $\beta$ = 126.43°, $V$ = 943.19(2) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 3.252 g cm$^{-3}$, $F(000)$ = 864, $\mu$(Mo-$K_a$) = 5.272 mm$^{-1}$, 2461 reflections collected, 891 unique ($R_{int}$ = 0.0335), $R_1$ = 0.0282, $wR_2$ = 0.0685 [$I > 2\sigma(I)$], $R_1$ = 0.0284, $wR_2$ = 0.0686 (all data) and final Gof = 1.017. Crystal data for **2**: LiEu(PO$_3$)$_4$ (474.78), monoclinic, space group $C2/c$, $T$ = 293(2) K, $a$ = 16.3300(9), $b$ = 7.0330(4), $c$ = 9.6465(6) Å, $\beta$ = 126.14(3)°, $V$ = 894.7(0) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 3.525 g cm$^{-3}$, $F(000)$ = 888, $\mu$(Mo-$K_a$) = 7.794 mm$^{-1}$, 3389 reflections collected, 1032 unique ($R_{int}$ = 0.0412), $R_1$ = 0.0259, $wR_2$ = 0.0584 [$I > 2\sigma(I)$], $R_1$ = 0.0279, $wR_2$ = 0.0596 (all data) and final Gof = 1.000. Crystal data for **3**: LiGd(PO$_3$)$_4$ (480.07), monoclinic, space group $C2/c$, $T$ = 293(2) K, $a$ = 16.330(1), $b$ = 7.0327(4), $c$ = 9.6450(8) Å, $\beta$ = 126.12(4)°, $V$ = 894.8(1) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 3.564 g cm$^{-3}$, $F(000)$ = 892, $\mu$(Mo-$K_a$) = 8.195 mm$^{-1}$, 3313 reflections collected, 1030 unique ($R_{int}$ = 0.0426), $R_1$ = 0.0319, $wR_2$ = 0.0820 [$I > 2\sigma(I)$], $R_1$ = 0.0323, $wR_2$ = 0.0822 (all data) and final Gof = 1.025. Further details of the crystal-structure investigations may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository numbers CSD-416877 to -416879 (for **1**–**3**, respectively).

**Spectral Measurements:** The purity of the polycrystalline samples for spectral measurements of **1**–**3** was confirmed by powder XRD studies using a Rigaku DMAX2500 diffractometer with Cu-$K_a$ radiation (step size of 0.05° and $2\theta$ range of 10–80°). The powder XRD patterns of **1**–**3** are given as Supporting Information. The absorption spectra were recorded with a Lambda-35 UV/Vis spectrophotometer in the wavelength range 200–800 nm. The emission spectra were measured with an FLS920 time-resolved fluorescence spectrometer using an Xe lamp at room temperature.

**Computational Details:** The crystallographic data of **1** and **3** determined by single-crystal X-ray diffraction were used to calculate their electronic band structures. Calculations of electronic band structures were performed at the density functional theory (DFT) level using one of the three nonlocal gradient-corrected exchange-correlation functionals (GGA-PBE) and with the CASTEP code,[25,26] which uses a plane wave basis set for the valence electrons and norm-conserving pseudopotential[27] for the core states. The number of plane waves included in the basis was determined by a cutoff energy, $E_c$, of 550 eV. Pseudoatomic calculations were performed for O ($2s^2 2p^4$), P ($3s^2 3p^3$), Li ($2s^1$), La ($5d^1 6s^2$), and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Gd ($4f^7 5s^2 5p^6 5d^1 6s^2$). The calculating parameters and convergent criteria were set by the default values of the CASTEP code.[25] The linear optical properties were also calculated; $\varepsilon_2(\omega)$ can be thought of as detailing the real transitions between occupied and unoccupied electronic states. Since the dielectric constant describes a causal response, the real and imaginary parts are linked by the Kramers–Kronig transformation,[28] where P is the principal value of the integral. This transformation is used to obtain the real part of the dielectric function, $\varepsilon_1(\omega)$.

$$\varepsilon_1(\omega) - 1 = \frac{2}{\pi} \mathrm{P} \int_0^\infty \frac{\omega' \varepsilon_2(\omega') d\omega'}{\omega'^2 - \omega^2} \quad \text{and} \quad \varepsilon_2(\omega) = -\frac{2\omega}{\pi} \mathrm{P} \int_0^\infty \frac{\varepsilon_1(\omega') d\omega'}{\omega'^2 - \omega^2}$$

**Supporting Information** (see footnote on the first page of this article): Full results of elemental analysis for **1**–**3**. Experimental and simulated X-ray powder diffraction patterns of **1**–**3**. The calculated band structure of **3**.

# Synthesis, Structural and Spectroscopic Studies on the Lanthanoid *p*-Aminobenzoates and Derived Optically Functional Polyurethane Composites

**Timothy Fiedler,[a][‡] Matthias Hilder,[b] Peter C. Junk,*[b] Ulrich H. Kynast,[a] Marina M. Lezhnina,*[a][‡‡] and Marek Warzala[a]**

**Keywords:** Luminescence / Lanthanoids / Polyurethane composites / Carboxylates

Aromatic carboxylates of the rare earths are known for highly efficient luminescence, thus holding the promise of applicability in optical devices, but may be problematic to apply as such due to their structure, which is polymeric in nature. Therefore, means of conversion into molecular species or eventually polymer embeddings are sought, while at the same time maintaining their advantageous optical features. For these purposes, co-ligations of rare earth *p*-aminobenzoates with bidentate bipyridine and phenanthroline, tridentate terpyridine and polyurethanes, which may also be perceived as polydentate ligands, have been carried out. The materials were characterised with focus on their structure and optical performance. Brightly luminescing composites were obtained from reactions with aromatic and aliphatic diisocyanates. Prolonged UV-irradiation of the materials proved hexamethylene diisocyanates to be superior with regard to photodegradation. Transparent polyurethane monoliths with emission quantum yields between 40 % and 55 % were eventually prepared from covalent attachement of Tb(*p*-aminobenzoate)$_3$ and its bipyridine co-ligated complexes to a hexamethylene diisocyanate/polyol system.

## 1. Introduction

Efficiently luminescing complexes of the rare earths are not only spectacular visually, but also of interest in numerous photophysical applications, ranging from sensors over light emitting devices (LEDs, OLEDs) to luminescent immunoassays. Practically, it is frequently desirable to incorporate them into matrices in order to render them applicable, or even appropriately functional in corresponding devices. As such, sol-gel matrices, zeolites and various polymers have been utilised.

Although the principle "local" intramolecular luminescence mechanism of the complexes is understood comparably well, especially in β-diketonates,[1–5] a reliable and comprehensive description of the structural factors influencing the optical performance appears to be lacking, especially with regard to carboxylates.

This lack of understanding is particularly true for the group of aromatic carboxylates imbedded in mentioned hosting matrices, which includes some of the most efficiently luminescing rare earth species. Rare earth aromatic carboxylates generally form coordination-polymeric associates with corresponding short-range interactions rather than isolated molecular entities.[6] Resulting insolubility and low vapour pressure pose a practical shortcoming with regard to matrix incorporation schemes, as the destruction of the original rare earth coordination polymer often quenches or diminishes the luminescence efficiencies. Bipyridines ("bipy") and phenanthrolines ("phen"), acting both as co-chelating and co-sensitizing ligands, can help to circumvent the solubility or volatility problem by forming new molecular coordination complexes. At the same time, they can help to keep the immediate chemical environment of the ion free from water, which is frequently encountered in the pure carboxylates. In addition to these bidentate co-ligands, we have additionally used terpyridine ("terpy") as a co-ligand. Also, some matrices may analogously be understood in terms of co-ligation, in that they may also occupy the rare earth coordination sphere in polydentate fashion as well, e.g. oxygen atoms of silica based matrices or silicones.

In this report, we focus on *p*-aminobenzoic acid ("pabaH"), because we learnt from single crystal structure data that the amino group might be chemically accessible for covalent attachment to a matrix on one hand, and, e.g. Tb(*p*-aminobenzoate)$_3$ ["Tb(paba)$_3$"], show intense luminescence

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

as the pure coordination polymer on the other hand, which can be enhanced by co-coordination,[7] and even be maintained on incorporation into zeolite matrix.[8] While this research was in progress, some of the crystal structures were confirmed by reports from other groups, or were previously published.[9] We will additionally provide results on the interaction of $Tb(paba)_3$, $Tb(paba)_3$phen and $Tb(paba)_3$bipy with isocyanates and eventually a polyurethane matrix and their behaviour under prolonged UV irradiation.

$$LnCl_3{\cdot}n(H_2O) + 3\ Na(paba) \xrightarrow{H_2O} [Ln(paba)_3H_2O]_n + 3\ NaCl \quad (1)$$

$$TbCl_3{\cdot}n(H_2O) + 3\ Na(paba) \xrightarrow[1,10\text{-phen}]{H_2O} [Tb(paba)_3(H_2O)_2]_2{\cdot}2\ H_2O + 3\ NaCl \quad (2)$$

## 2. Results and Discussion

### 2.1. Coordination Polymers

A $[Ln(paba)_3{\cdot}H_2O]_n$ series with the members [Ln = Eu (**1**), Gd (**2**) and Tb (**3**); pabaH = *p*-aminobenzoic acid], were conveniently synthesised in good yield by treatment of an aqueous solution of the respective lanthanoid chloride with sodium *p*-aminobenzoate [Equation (1)]. We could also obtain a modified phase of the terbium complex, being the dimeric $[Tb(paba)_3(H_2O)_2]_2{\cdot}2H_2O$ (**4**), which was obtained in a similar manner [Equation (2)], but in the presence of 1,10-phenanthroline, in an attempt to prepare phenanthroline co-coordinated complexes of the series. In the case of compound **4**, phenanthroline was not incorporated in the final product, rather a different structural phase (of a previously published structure[9d]) of the terbium *p*-aminobenzoate was isolated. This was therefore not characterised further because it was a previously known compound.

The FTIR spectra of all compounds showed significant changes in the carbonyl stretching frequency compared with the free ligand (see the representative representation of $[Eu(paba)_3H_2O]$, and $[Tb(paba)_3H_2O]$ in comparison with H(paba) in Figure 1). In *p*-aminobenzoic acid, the C=O stretch occurs at 1655 $cm^{-1}$, whereas in the lanthanoid complexes, the band is shifted to significantly lower wave numbers and is split into two distinct bands around 1390 and 1500 $cm^{-1}$. In the compounds **1**–**3** there are increased absorbances in the 3300–3450 $cm^{-1}$ region attributable to water in the metal complexes. The complexes **1**–**3** were pure by $Na_2EDTA$ titration for lanthanoid content and carbon microanalysis for the composition $[Ln(paba)_3H_2O]$ as suggested by the X-ray crystal structures (below).

To ascertain the thermal stability of a representative sample of the $[Ln(paba)_3H_2O]$ series, the Eu analogue was analysed by thermogravimetric analysis. The exothermic release of water (peak maximum at 200 °C), which takes place in the temperature range of 120–220 °C is accompanied by a weight loss of 3% which is identical to the weight loss expected for the stated composition. This reaction can be described by Equation (3).

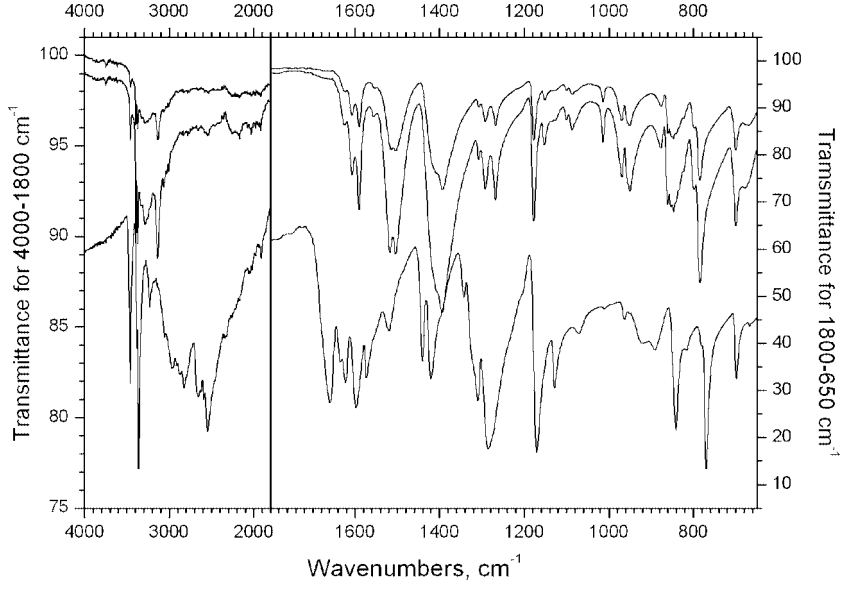

Figure 1. FTIR spectra of H(paba) (bottom), $Tb(paba)_3H_2O$ (middle) and $Eu(paba)_3H_2O$ (top).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$Eu(C_6H_4NH_2COO)_3(H_2O) \rightarrow Eu(C_6H_4NH_2COO)_3 + H_2O \quad (3)$$

The thermal decay starts at 330 °C and continues to 810 °C. It is accompanied by several endothermic events (390, 430, 500, and 740 °C). Although the slope of the TG curve is very steady, there is a slight change in the gradient (330–460 °C) accompanied by a weight loss of 30%. This is the weight loss expected for the formation of the dimeric europium benzoate complex connected by an oxo bridge. A plausible reaction sequence is shown in Equations (4), (5) and (6).

$$Eu(C_6H_4NH_2COO)_3 + 3\ O_2 \rightarrow Eu(C_6H_5COO)_3 + 1.5\ H_2O + 3\ NO \quad (4)$$

$$Eu(C_6H_5COO)_3 + 7.5\ O_2 \rightarrow Eu(C_6H_5COO)_2(OH) + 2\ H_2O + 7\ CO_2 \quad (5)$$

$$2\ Eu(C_6H_5COO)_2(OH) \rightarrow (C_6H_5COO)_2Eu{-}O{-}Eu(C_6H_5COO)_2 + H_2O \quad (6)$$

In the range of 460–810 °C the final oxidation product is formed. The total mass loss of 70% is very close to the expected (69%) as shown in Equation (7).

$$(C_6H_5COO)_2Eu{-}O{-}Eu(C_6H_5COO)_2 + 30.5\ O_2 \rightarrow Eu_2O_3 + 10\ H_2O + 28\ CO_2 \quad (7)$$

Single crystals of compound **2** were grown by slow concentration of aqueous samples and its solid-state structures determined using X-ray crystallography. $[Gd(paba)_3H_2O]_n$ is isomorphous and structurally identical to that previously published for $[Ln(paba)_3H_2O]_n$ Ln = La, Ce, Pr, Nd, Sm, Eu, Tb, Dy, Er,[9] effectively establishing this structural type for the lighter and larger lanthanoids extends to Ln = Er. Compound **2** crystallises in the monoclinic space group $P2_1/n$ with one whole monomeric unit in the asymmetric unit. The lanthanoid metal centre is eight coordinate being bound by one chelating carboxylate, four monodentate carboxylates, one water molecule and perhaps surprisingly, one $N_{(amino)}$ group [Figure 2, a)]. Each of the monodentate carboxylate groups bridge to an adjacent Ln centre, while the chelating carboxylate is solely bound to one Ln centre. The overall structure is thus a three-dimensional polymeric species [Figure 2, b)] which is additionally extended through O–H···O and N–H···O hydrogen bonds. The Ln–O and Ln–N bond lengths (see Figure 2, caption) demonstrates well the lanthanoid contraction when compared with the other lanthanoid analogues,[9] with all internuclear distances about the Ln centres diminishing across the series in line with the reduction in ionic radii of the metal.[10] It is rather surprising that the lanthanoid centre is coordinated by an amine, given the compound was crystallised from water. It may be expected that water would complete the coordination sphere of the oxophilic rare-earth metal and presumably, binding of the amine to the metal, arises from a packing effect. It is worthy to mention the Ln···Ln internuclear distances, particularly with respect to the possibility of Ln···Ln energy transfer (see later). The Ln···Ln distances for this series of compounds are approximately 4.50 to 4.80 Å and for compound **2**, this distance is 4.725(3) Å.

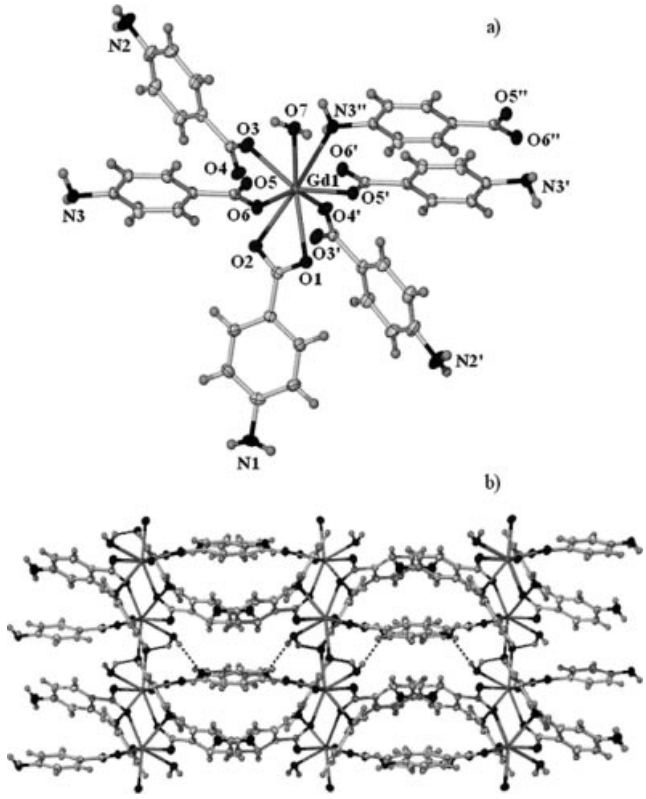

Figure 2. a) X-ray crystal structure of coordination sphere about Gd in polymeric $[Gd(paba)_3]\cdot H_2O$ (**2**). Thermal ellipsoids are at the 50% probability level. Selected bond lengths [Å]: Gd(1)–O(1) 2.461(2), Gd(1)–O(2) 2.455(2), Gd(1)–O(3) 2.336(2), Gd(1)–O(4) 2.304(2), Gd(1)–O(5) 2.342(2), Gd(1)–O(6) 2.349(3), Gd(1)–O(7) 2.513(3), Gd(1)–N(3) 2.668(3). b) X-ray crystal structure of polymeric $[Gd(paba)_3]\cdot H_2O$ (**2**). Thermal ellipsoids are at the 50% probability level.

Single crystals of compound **6** suitable for X-ray diffraction studies were grown from an aqueous solution of $[Tb(paba)_3H_2O]_n$ in the presence of 1,10-phenanthroline. The structure of this phase of the terbium analogue is isomorphous to that established for $[Ln(paba)_3(H_2O)_2]_2\cdot 2H_2O$ (Ln = Tb,[9d] Dy,[11] Ho,[9d] Y,[9d] Yb,[9d,12] Lu[9d]) and thus an example of the heavier structural type for the *p*-aminobenzoates of the lanthanoids and will not be discussed further. Significantly, by crystallisation of the terbium analogue as both structural phases, the structural boundary for the lanthanoid *p*-aminobenzoates existing as a dimer has now been established to start at Tb ranging to Lu, while the polymeric phase extends from La to Er. The reason for the isolation of two different phases presumably lies in the mode of crystallisation. We isolated the dimer phase in the presence of 1,10-phenanthroline and this presumably affects the solubility of the polymeric phase.

X-ray powder diffraction patterns of bulk material of compounds **1** to **3** were compared with patterns calculated from X-ray single crystal experiments and established that the structure of the bulk materials in all cases was identical to that obtained in the single crystals.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The $Tb^{3+}$ analogue of this series showed significant and exploitable luminescence in the visible, while $Eu^{3+}$ is quenched by charge-transfer states and MLCT,[13] additionally supported by vibrational quenching.[14] $Gd^{3+}$ is known to promote ligand phosphorescence at 24445 $cm^{-1}$,[15] we observe corresponding broad emission bands in $Gd(paba)_3$ at 420 nm and 478 nm, however, accompanied by a comparably strong emission due to minute $Tb^{3+}$ impurities (see below).

The luminescence of $Tb(paba)_3$ relies on the following successive steps:[16,17] 1. singlet–singlet absorption of the ligand ($^1S_0 \rightarrow {}^1S^*$, $\pi$–$\pi$ in nature), 2. intersystem crossing (ISC, $^1S^* \rightarrow {}^3T$, promoted by the spin-orbit coupling due to the $Tb^{3+}$ ion), 3. (exchange resonance driven) energy transfer Ligand($^3T$)$\rightarrow Tb^{3+}(^5D_4)$. Emission, excitation end reflectance spectra of solid $Tb(paba)_3H_2O$ are given in Figure 3.

As may be seen clearly, excitation can most efficiently be accomplished in this complex at a comparably short wavelength of approximately 310 nm. The quantum yield of the complex amounts to an unexpectedly high value (88%, e.g. $\lambda_{exc}$ = 340 nm), which is very surprising in view of the coordination of both, -$NH_2$ and $OH_2$ as ligands, as they are usually both essential vibrational deactivators of the excited state. However, it should be noted that both the Ln–$OH_2$ distance (261 pm) and the Ln–$NH_2$ distance (276 pm) are fairly long and multiphoton emission may thus be of secondary importance only, which is even more pronounced due to fairly strong hydrogen bonding.

A significant shortcoming for further utilisation of the complexes is that their strong degree of association [see Figure 2, b)] prevents, for example, evaporation without decomposition or dissolution in aprotic organic solvents. We could obtain solutions from $[Tb(paba)_3H_2O]$ only in refluxing DMF, albeit to a high cost in luminescence efficiency.

### 2.2. Co-coordinated Complexes

To explore further the luminescence properties of derivatives of the paba series above, we co-coordinated $[Tb(paba)_3H_2O]$ with the bidentate ligands bipyridine and phenanthroline as well as the tridentate terpyridine. The complexes were accessed by crystallisation from solutions of pabaH and bipy, phen, or terpy, respectively, in ethanol, to which aqueous $TbCl_3$ was added. In order to identify the immediate $Tb^{3+}$ coordination environment in the complexes obtained {$[Tb(paba)_3(bipy)(H_2O)]_2 \cdot 2H_2O$ (**5**), $[Tb(paba)_3(phen)(H_2O)]_2 \cdot 2H_2O$ (**6**), $[Tb(paba)_3(terpy)(H_2O)]_2 \cdot 6.7H_2O$ (**7**)}, single crystals grown from these solutions by slow evaporation were subjected to single-crystal structure analyses. The X-ray crystal structure of $[Tb(paba)_3(bipy)(H_2O)]_2 \cdot 2H_2O$ was previously reported.[18] For comparison, the La and Eu and analogues involving 1,10-phenanthroline were also structurally investigated. It is of importance to understand the structural variation of the rare earth series when investigating their luminescence properties. For example, we have shown that in the coordination polymer $Na[Tb(pic)_4] \cdot 1.5H_2O$ (picH = 2-picolinic acid) one-dimensional energy migration occurs, which can be utilised to transfer energy to $Eu^{3+}$ if the latter is co-doped into the material.[19] However, co-doping is only successful in these compounds, if the structural integrity of the parent compound is not compromised, a factor, which we have observed in the above-mentioned picolinates, if lanthanum was introduced. Therefore, we typically address the structural characteristics of several of the lanthanoid series.

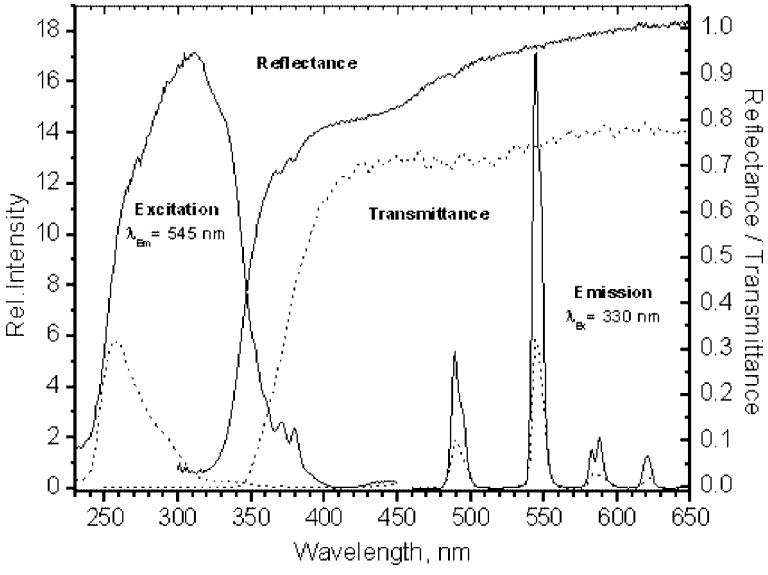

Figure 3. Comparison of optical spectra of the free complex $Tb(paba)_3H_2O$ (powder, solid line) and the polymer composite $Tb(paba)_3$PU (monolith, broken line).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Therefore, we also present the X-ray structural characterisation of $[Eu(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (**8**) and $[La(paba)_3(pabaH)(phen)_2]{\cdot}H_2O$ (**9**). Additional support for the significance of detailed structural data will be provided at the end of this paragraph.

In the published structure of $[Tb(paba)_3(bipy)(H_2O)]_2{\cdot}2H_2O$ (**5**) the compound exists as a dimer, with each terbium atom eight-coordinate. Each Tb atom is bound by a bidentate bipy ligand, a monodentate water molecule and three carboxylates, each with different binding modes. One carboxylate is chelating bidentate, the second is a monodentate-bound ligand, while the third bridges to the other Tb atom. There is a water molecule in the lattice and the *p*-amino groups of the paba ligands are not coordinated to the Tb atoms. The Tb···Tb distance in the dimer is 5.554(3) Å, thus allowing energy migration between the ions within the dimer.

$[Tb(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (**6**) crystallises in the triclinic space group $P\bar{1}$ with one whole monomer comprising the asymmetric unit. The compound dimerises through hydrogen bonding from a Tb-bound water molecule to the O atom of a Tb-bound carboxylate group (Figure 4). Each Tb atom is nine-coordinate, being bound by a bidentate 1,10-phenanthroline ligand, three chelating bidentate carboxylate groups and a water molecule. There are also two lattice water molecules per hydrogen-bonded dimer. The Tb···Tb distance in the hydrogen-bonded dimer is 5.884(5) Å. $[Eu(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (**8**) is isomorphous with **6** (Figure 4).

Figure 4. X-ray crystal structure of dimeric, hydrogen-bonded $[Tb(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (**6**); hydrogen atoms on the aromatic groups are omitted for clarity. Thermal ellipsoids are at the 50% probability level. $[Eu(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (**8**) is isostructural.

In compound **8** the Eu···Eu distance is 5.909(5) Å and is slightly longer due to the larger ionic radius of Eu over Tb.[10]

$[Tb(paba)_3(terpy)(H_2O)]_2{\cdot}6.7H_2O$ (**7**) crystallises in the triclinic space group $P\bar{1}$ with one whole $[Tb(paba)_3(terpy)(H_2O)]_2$ dimer and another half dimer (as well as 10 lattice water molecules) comprising the asymmetric unit. Each Tb atom is nine-coordinate, being bound by a tridentate terpy molecule, a monodentate water molecule, a bidentate carboxylate group, a monodentate carboxylate group and a monodentate carboxylate group that bridges to the other Tb atom (Figure 5). The Tb···Tb distance in this dimer is 5.312(8) Å.

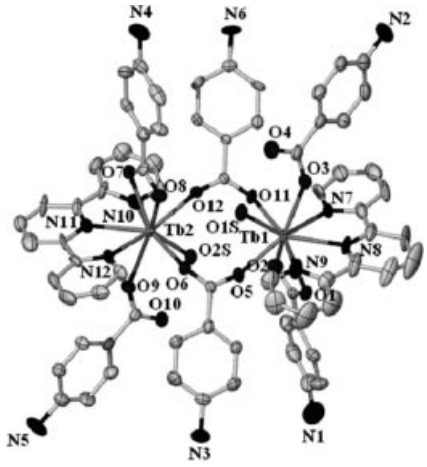

Figure 5. X-ray crystal structure of dimeric, hydrogen-bonded $[Tb(paba)_3(terpy)(H_2O)]_2{\cdot}H_2O$ (**7**); hydrogen atoms on the aromatic groups are omitted for clarity. Thermal ellipsoids are at the 50% probability level.

$[La(paba)_3(pabaH)(phen)_2]{\cdot}H_2O$ (**9**) crystallises in the monoclinic space group $P2_1/c$ with one whole mononuclear unit and one lattice water molecule comprising the asymmetric unit of the structure. The nine-coordinate lanthanum centre is now bound by two bidentate 1,10-phenanthroline ligands, one bidentate carboxylate, two unidentate carboxylate and one unidentate carboxylic acid molecule (Figure 6). It is significant that the lanthanum centre is now bound by a unidentate carboxylic acid molecule rather than by water (or ethanol) molecules, from which the compound was crystallised.

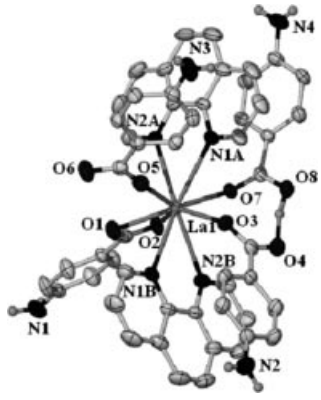

Figure 6. X-ray crystal structure of mononuclear $[La(paba)_3(pabaH)(phen)_2]_2$ (**9**); hydrogen atoms on the aromatic groups are omitted for clarity. Thermal ellipsoids are at the 50% probability level.

The proton on the bound carboxylic acid molecule is involved in hydrogen bonding with one of the O atoms of a unidentate bound carboxylate group. The fact that this compound is a new structural type for this chemistry, and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

also that it is mononuclear is exciting, because we now intend to expand this chemistry to the Eu and Tb analogues, where luminescence may be enhanced due to decreased possibility of Ln···Ln quenching. The shortest La···La distance in compound **9** is 10.594(2) Å.

In all compounds comprising the bidentate bipy or phen or tridentate terpy, bond lengths are unexceptional between ligands and metal centres. A noteworthy feature of these compounds, when compared with the parent $[Ln(paba)_3(H_2O)]$ compounds, is that the *para*-nitrogen atoms of the paba group are not involved in binding to the lanthanoid centre (cf. above).

The optical properties of $[Tb(paba)_3(bipy)(H_2O)]_2{\cdot}2H_2O$ and $[Tb(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ are depicted in Figure 7. In comparison to $[Tb(paba)_3{\cdot}H_2O]_n$ the excitation maximum has been red-shifted by approximately 50 nm on bipy-co-coordination and about 70 nm on phen-co-coordination $[Tb(paba)_3(bipy)(H_2O)]_2{\cdot}2H_2O$.

This redshift is of high applicatory interest; because the excitation now falls in the range of commercially available and ever improving semiconductor LED excitation sources, and may thus be used in a broader range of low-cost devices. Furthermore, the quantum yield of $[Tb(paba)_3(bipy)(H_2O)]_2{\cdot}2H_2O$ now even amounts to 95% under excitation at 350 nm. This somewhat unusual result may, just as argued for $[Tb(paba)_3H_2O]$ above, once more be interpreted in terms of the molecular structure, displaying long Tb–$OH_2$ distances and hydrogen bonding. Unfortunately, that high a quantum efficiency is not maintained in $[Tb(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$, where a drop to 38% is measured at 380 nm.

It was furthermore striking to us to note that the short Ln···Ln distances of 4.725(3) Å found in $[Gd(paba)_3H_2O]$ have an immediate impact on the luminescence spectra: terbium impurities (sub-percent level, $< 0.01\%$) in the Gd complex lead to a strong $Tb^{3+}$ emission, which had approximately 10 times the intensity of the corresponding ligand phosphorescence. Characteristically, the sensitisation of $Tb^{3+}$ is already 4 times weaker in $[Gd(paba)bipy(H_2O)_2]$ (Ln···Ln ca. 5.5 Å) and is not detectable in $[Gd(paba)phen(H_2O)_2](H_2O)_{1.5}$. (Ln···Ln ca. 5.9 Å). This behaviour signals the importance of detailed structural data in the interpretation of luminescent properties. Unfortunately, suitable crystals of the Gd analogue to $[La(paba)_3(pabaH)(phen)_2](H_2O)$ with a La···La distance 10.594(2) Å could not be obtained as yet, but may in the future be an interesting system to evaluate the details of Ln···Ln energy transfer in rare earth metallo-organic complexes.

### 2.3. Reactions with Isocyanates

The amino group of the paba complexes appeared to be a suitable reaction centre for the attachment of the complexes to polymeric backbones, isocyanates and polyurethanes ("PUs") in particular. As suitable polymer matrices,

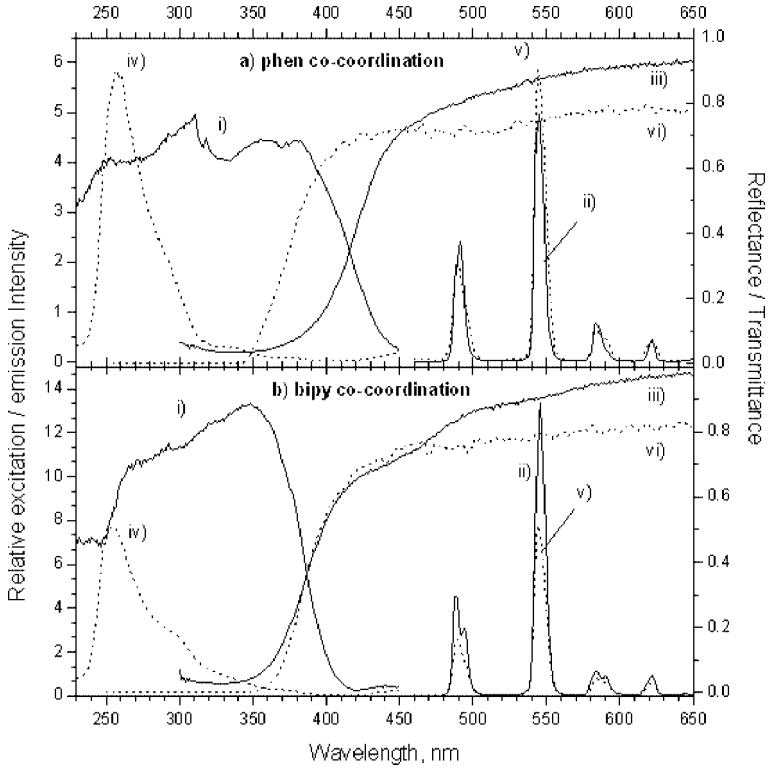

Figure 7. Comparison of free and polymer-imbedded complexes. Top, solid line: $Tb(paba)_3phen$; broken line: $Tb(paba)_3phenPU$. Bottom, solid line: $Tb(paba)_3bipy$; broken line: $Tb(paba)_3bipyPU$. i) excitation, ii) emission ii) reflectance of pure complexes; iv) excitation, v) emission, vi) reflectance of PU composites.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

hexamethylene diisocyanates [O=C=N–$(CH_2)_6$–N=C=O, "HDIs"] and derived prepolymers were chosen rather than e.g. methylenebis(1,4-phenylene) diisocyanate (O=C=N–$C_6H_4$–$CH_2$–$C_6H_4$–N=C=O, "DPDIs") or 1,4-phenylene diisocyanate (O=C=N–$C_6H_4$–N=C=O, "PDIs"), because their optical transparency still allows optical measurements of the complexes imbedded, which might otherwise be obscured due to the extended π electrons, if DPDIs or PDIs were chosen as the matrix. However, reactions of $Tb(paba)_3$ with pure HDI, PDI and MDI were tested as "concentrated polymers" without further crosslinkers [see reaction schemes Figure 8, Equation (8)]. In the following, "$Tb(paba)_3$HDI", "$Tb(paba)_3$PDI" and "$Tb(paba)_3$DPDI" exclusively designate the reaction products of $Tb(paba)_3$ with HDI, PDI and DPDI, respectively, according to Equation (8), while "$Tb(paba)_3$PU" refers to a complete polyurethane matrix, based on HDI and a polyol, in which doping with $Tb(paba)_3$ substitutes a corresponding amount of the polyol [Equation (9)]. Analogously, $Tb(paba)_3$bipy and $Tb(paba)_3$phen have been reacted with HDI and polyol to give $Tb(paba)_3$bipyPU and $Tb(paba)_3$phenPU. The "concentrated" polymeric $Tb(paba)_3$PDI, $Tb(paba)_3$DPDI and $Tb(paba)_3$HDI are obtained as white powders, which are insoluble in all polar and apolar solvents tested; it was not possible to obtain transparent layers or monoliths from these materials. The excitation spectra of these reaction products are represented in Figure 9 in comparison to $Tb(paba)_3$; the corresponding emission spectra only differ in intensities and are not reproduced. Evidently, PDI linkage leads to a slight increase in intensity accompanied by a redshift of the excitation maximum to approximately 330 nm. Unfortunately, due to cloudiness (i.e. light scat-

tering), shape and morphology of the polymer layers, reliable data on quantum efficiencies could not be determined, however, a crude visual comparison with diluted samples of $Tb(paba)_3$ in PU [$Tb(paba)_3$PU, see following paragraph] suggests comparable efficiencies.

Transparent composite materials, $Tb(paba)_3$PU, could eventually be prepared using DMF solutions of $Tb(paba)_3$ in a polyol (see experimental section), to which HDI was added [Equation (9)] in Figure 8, R = $(CH_2)_6$. As opposed to that, for reasons not obvious to us, the reactions of polyol-dissolved $Tb(paba)_3$ with PDI and DPDI only gave turbid products. The optical spectra of transparent $Tb(paba)_3$-PU are given in Figure 3. The comparison with pure $Tb(paba)_3$ immediately demonstrates the shortcomings of the composite. The onset of absorption is red-shifted to approximately 400 nm due to matrix contributions, which do not produce a noteworthy emissive response down to 320 nm, while the excitation maximum is blueshifted to 260 nm. The overall emission quantum yield is thus reduced by a factor of two to four (42%, $\lambda_{exc}$ = 260 nm; 17%, $\lambda_{exc}$ = 300). However, some error in this value may arise from differing sample and reference shapes (see Exp. Sect.). Correspondingly, the extended conjugation brought about by the –$C_6H_4$–NH–CO–NH– substituents [see Figure 8, Equation (2)] may be held responsible for the redshift of the absorption. At the same time, the coordination numbers of six for the $Tb^{3+}$ ion, as sketched for simplicity in Figure 8, is most unlikely in the polymer. Instead, coordination of N and O atoms of neighbouring fragments may be expected, thus giving rise to radiationless deactivation by high frequency vibrations.

The initial idea of using bipyridine and phenanthroline as co-ligands to increase their solubility in the (pre-)polymers did not lead to the desired results with respect to efficiency. Although bipyridine co-coordinated $Tb(paba)_3$ could eventually be used to form a clear polymer ["$Tb(paba)_3$bipyPU"], if the $Tb(paba)_3$bipy was initially dissolved in excess HDI followed by addition/crosslinking with polyol, its efficiency is again lowered by a factor of two to three (55%, $\lambda_{exc}$ = 260 nm to 28%, $\lambda_{exc}$ = 300 nm) in comparison to pure $Tb(paba)_3$. If $Tb(paba)_3$bipy was dissolved in the polyol prior to HDI addition, bipyridine appeared to be liberated, as indicated by the excitation spectrum, which is then again in resemblance of $Tb(paba)_3$PU, albeit at much lower intensity, at least partly due to the radiation "lost" to bipy absorption. This behaviour is yet more pronounced and evident in $Tb(paba)_3$phen, where a blue emission of phen indicates the presence of the uncoordinated co-ligand. The emission of phen is here seen to a similar extent, regardless of the addition sequence (dissolution in polyol followed by addition of HDI, or dissolution in HDI, followed by polyol admixture). The loss of phen is clearly visible from the spectral agreement of $Tb(paba)_3$PU (broken line in Figure 3) with $Tb(paba)_3$phenPU (broken line in Figure 7, a); the substitution of the bidentate co-ligands by the polydentate polymer fragments may then be interpreted in terms of an entropy increase. Due to the blue ligand emission, we refrained from the determination of quantum yields of $Tb(paba)_3$phenPU, but from the excitation spectra, they may be estimated to amount to > 40% under 260 nm excitation.

For eventual applications of the polymers described, knowledge on further material parameters next to the optical performance will be required, among them the durability and stability of the emission intensity. We have therefore also invested some effort into the characterisation of the emissive properties under prolonged irradiation with UV light. For this purpose, pressed sample polymer disks of approximately uniform thickness of approximately 1 mm to grant complete absorption were irradiated and the depreciation of the $Tb^{3+}$ 545 nm emission line ($^5D_4 \rightarrow {}^7F_5$) was monitored. For comparison, pure $Tb(paba)_3$ was pressed to a powder disk and included in the series. The results of the ageing experiments on $Tb(paba)_3$PDI, $Tb(paba)_3$DPDI and $Tb(paba)_3$HDI and $Tb(paba)_3$ are contained in Figure 9.

The evaluation of the depreciation of $Tb(paba)_3$PDI, which shows the highest initial efficiency, reveals that a maintenance crossover with pure $Tb(paba)_3$ is reached after only a few minutes, indicating that the aromatic polymer backbone of PDI is liable to relatively fast photodegradation. Similarly, $Tb(paba)_3$DPDI shows very similar degradation behaviour, albeit at a lower efficiency level. Remarkably, the aliphatic HDI based polymer is comparably stable, even more so than the pure complex. All curves could be fitted as single exponentials, if the initial degradation delay observed for $Tb(paba)_3$ and $Tb(paba)_3$HDI was taken into account. Based on extrapolation, the maintenance level of $Tb(paba)_3$HDI can accordingly be estimated to amount to almost 80% after 10000 h of operation. Future efforts will thus be directed towards luminescence improvement of aliphatic polyurethanes.

## Conclusions

Stimulated by high luminescence efficiencies of *p*-aminobenzoates of $Tb^{3+}$ (quantum yields > 80%), detailed structural investigations have been performed in order to derive materials from $Tb(paba)_3$, which are applicable in photoluminescenct applications, e.g. luminescent markers, or, eventually electrooptical devices, such as OLEDs. Typically, in the series of rare earth *p*-aminobenzoates coordination polymers are formed, which were broken down to molecular species for further manufacture. Such can in part be accomplished using chelating ligands such as bipyridine, phenanthroline, or terpyridine, although crystal structure determinations reveal that they essentially still exist as dimeric units and disadvantageously contain coordinated water. Nevertheless, on co-coordination of with bipyridine, a slight increase in quantum yield is accomplished (> 90%) in the case of $Tb^{3+}$, while phenanthroline reduces the overall efficiency (36%). The *p*-aminobenzoates of $Tb^{3+}$ were linked to aliphatic and aromatic diisocyanates through the benzoate amino group, yielding brightly green luminescing, insoluble polymer composites. Consecutively, transparent polyurethane monoliths incorporating backbone-linked *p*-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

aminobenzoates of $Tb^{3+}$ and co-ligated complexes could be fabricated using aliphatic diisocyanates, and polyols as additional components. These "doped" polyurethanes show photoluminescence with quantum yields in the range between 40 and 55%, albeit at lowered excitation wavelengths. In anticipation of potential applications, the photodegradation of some aromatic and aliphatic composites were evaluated. In these experiments, aliphatic polymer backbones proved to be superior, but had lower initial efficiencies. Future work will thus focus on increasing the *p*-aminobenzoate composite efficiencies. Additionally, we are currently testing other benzoic acid derivatives.

## Experimental Section

Lanthanoid salts were purchased from Rhodia, Chempur and Aldrich with specified purity levels of in excess of 99.9%; *p*-aminobenzoic acid was obtained from Aldrich. All starting materials were used without further purification. Deionised water was used in all syntheses. Infrared spectra were recorded on sodium chloride plates as Nujol mulls or pressed into KBr disks (Figure 1) on a Perkin–Elmer Spectrum One FTIR spectrometer. Lanthanoid metal analyses were determined titrimetrically using the $Na_2EDTA$ method. Carbon analyses were carried out using a C-analyser with IR-detection unit (ELTRA, Germany). Melting points were performed in unsealed tubes.

**Synthesis:** The complexes **1**–**3** were synthesised following a similar procedure. Thus, sodium *p*-aminobenzoate (obtained by the reaction of the free *p*-aminocarboxylic acid with sodium hydrogencarbonate) was added to and aqueous solution of lanthanoid chloride. The crystals were obtained from slightly acidic aqueous medium. The samples were evaporated until large crystals of the complexes deposited. Complex **4** was synthesised in a similar manner, except 1,10-phenanthroline was added to the reaction mixture. Details of the properties for each compound follow. Yields reported are for isolated crystalline material. Yields of these reactions can be enhanced by precipitation of the compounds by addition of acetone to a saturated aqueous solution or increasing the pH value to just below 8 with 2 M ammonia.

**$[Tb(paba)_3(H_2O)_2]_2{\cdot}2H_2O$ (4):** From one attempted synthesis of co-crystallising $[Tb(paba)_3(H_2O)]$ with phenanthroline, we obtained crystals of the title compound that were isostructural with the previously reported complex.[9d] Unit cell data for compound **4**: triclinic, space group $P\bar{1}$ (No. 2), $a$ = 10.7819(7), $b$ = 12.0981(8), $c$ = 13.2695(9) Å, $\alpha$ = 72.407(1), $\beta$ = 66.679(1), $\gamma$ = 87.981(1)°, $V$ = 1508.0(2) $Å^3$.

**$[Tb(paba)_3(bipy)(H_2O)]_2{\cdot}2H_2O$ (5) and $[Tb(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (6), $[Tb(paba)_3(terpy)(H_2O)]_2{\cdot}6.7H_2O$ (7), $[Eu(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (8) and $[La(paba)_3(pabaH)(phen)_2].H_2O$ (9), $[Gd(paba)_3(bipy)(H_2O)]_2{\cdot}2H_2O$ (10) $[Gd(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$ (11):** $[Tb(paba)_3(bipy)(H_2O)]_2{\cdot}2H_2O$ was prepared by adding an aqueous solution of $TbCl_3$ (0.25 g) to an ethanol/water ($C_2H_5OH/H_2O$, 1:1) solution of *p*-aminobenzoic acid (0.2 g) and bipyridine (0.3 g), to give a volume of ca. 30 mL. The colourless crystals were obtained by slowly evaporating the mixture at room temperature for several days.

Analogously, the preparation of $[Ln(paba)_3(phen)(H_2O)]_2{\cdot}2H_2O$, [Ln = Eu, (**8**) Tb (**6**), Gd (**11**)] involved the addition of an aqueous $LnCl_3$ (Eu, Tb, Gd) solution (0.2 g) to an ethanol solution of *p*-aminobenzoic acid (0.3 g) and 1,10 phenanthroline (0.3 g) after two weeks in an open vessel afforded small light yellow crystals suitable for single crystal structure determination.

"Working amounts" of **5**, **6**, **10** and **11** were obtained using H(paba) (3 mmol) and bipy (or phen) (2 mmol), dissolved in of water/ethanol mixture (20 mL, 1: 1), adjustment of the pH to 5 using 2 M ammonia solution. An aqueous solution of $Tb^{3+}$ [1 mmol of from of 0.5 M $TbCl_3$ ($GdCl_3$) stock solution] was then slowly added to the ligand solution under vigorous stirring. Almost complete and immediate precipitation occurs after slowly raising the pH of this solution to just below 8.0. The complexes were filtered and dried at 60 °C. The products deviated in their composition from the material used for crystal structure determination due to the drying procedure (loss of lattice water): $[Gd(paba)_3bipy(H_2O)_2]$: calcd. C 48.95; found 48.96; $[Gd(paba)_3phen(H_2O)_2](H_2O)_{1.5}$: calcd. C 48.83; found C 48.90].

For the synthesis of crystals of $[Tb(paba)_3(terpy)(H_2O)]_2{\cdot}6.7H_2O$ (**7**) terpyridine (0.3 g) and *p*-aminobenzoic acid (0.2 g) were dissolved in 50% ethanol (3 mL). To the resulting clear solution, $TbCl_3$ solution (0.2 g in 3 mL water) was added dropwise. The reaction was stirred for 5 h. A few light-yellow crystals were received on partial evaporation of the solvent.

Single crystals of $[La(paba)_3(pabaH)(phen)_2]{\cdot}H_2O$ (**9**) were prepared as for compounds **6** and **8** except $LaCl_3$ solution was used in place of $LnCl_3$(Ln = Eu, Tb).

**$Tb(paba)_3HDI$, $Tb(paba)_3PDI$ and $Tb(paba)_3DPDI$:** The complex polymer composites were synthesised by adjusting a procedure described in the literature.[20] All operations were carried out providing for the exclusion of water (standard Schlenk techniques). Vacuum dried $Tb(paba)_3$ ($10^{-3}$ mbar, 140 °C, 5 h, 0.010 mol) was dissolved in dry DMF (20 mL). To this solution the pure diisocyanate (0.017 mol) was added dropwise. The reaction was carried out within 14 h at 80 °C under argon. After solvent evaporation, the residue was dried in vacuo and powdered using a mortar and pestle.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**$Tb(paba)_3PU$, $Tb(paba)_3bipyPU$ and $Tb(paba)_3phenPU$:** For the preparation of the transparent polyurethanes a commercial system consisting of a hexamethylene diisocyanate prepolymer and a polyol was used (from Lackwerke Peters, 47906 Kempen, Germany, VT 3402 KK). To determine the exact amounts of polyol to be substituted by the corresponding Tb complexes, the NCO content was determined using chlorobenzene as solvent, dibutylamine as reagent and bromothymol blue as the indicator for the HDI, for the OH number of the polyol, pyridine, phthalic anhydride and phenolphthalein were used, according to procedures previously described.[21] Analytically, 5.40 mmol NCO/g diisocyanate and 5.34 mmol OH/g polyol were found.

To obtain dilute samples for efficiency measurements, the complexes (2 mmol) were dissolved in DMF and added to the hexamethylene diisocyanate (1 g, ratio paba: NCO group approximately 1:100), DMF was evaporated in vacuo and the complex solution in diisocyanate thus obtained was mixed with the polyol (1:1 ratio), the mixture was placed in a transparent cuvette of 1 cm path length, air bubbles were removed under vacuum. The polymerisation to give the polyurethane was carried out at 60 °C in a drying chamber. Polymers containing more than $1{\cdot}10^{-2}$ mol complex/L could be prepared in an analogous manner. For such samples, the consumption of HDI by $Tb(paba)_3$ or was accounted for in that a lower amount of polyol was used. However, the emission intensities (not quantum yields) were at a maximum at approximately $1{\cdot}10^{-2}$ mol complex/L.

**Optical Characterisation:** All emission and excitation intensities in the spectra reproduced are scaled against each other, such as to grant direct comparability.

Emission and excitation spectra of the solids were recorded at an angle of incidence of ca. 50° using a praying mantis type of set up to allow horizontal sample positioning without a cover. Reflectance spectra were obtained using an integrating sphere with a diameter of 70 mm and 10 mm port openings vs. commercial white and black references (Labsphere), and $BaSO_4$, respectively. Two Acton 300 Monochromators of 300 mm focal length were thus synchronously scanned. The intensity of the 450 W Xe source was detected with an Acton Photomultiplier tube P2, the gratings had 1200 $gmm^{-1}$. The excitation spectra of $Tb(paba)_3HDI$, $Tb(paba)_3PDI$ and $Tb(paba)_3DPDI$ presented in Figure 9 were corrected for the lamp and spectrometer profiles with $BaMgAl_{10}O_{17}$: Eu ("BAM"). $Tb(paba)_3$, $Tb(paba)_3bipy$, $Tb(paba)_3phen$ were also measured against Lumogen Red doped PMMA powders (doping level 50 ppm), whose quantum yield was taken as a constant 42% in the excitation range between 250 nm and 500 nm. Relative quantum yields of the clear PU composite monoliths [$Tb(paba)_3PU$, $Tb(paba)_3bipyPU$, $Tb(paba)_3phenPU$], prepared in 1 cm cuvettes, were determined relative to a Lumen Red/PMMA disk of 3 mm thickness. Due to the confinement in the reference disk of lower thickness, some loss due to lateral propagation of emitted light within the disk is possible, but could not be accounted for, because neither sample cuvette nor reference disk could be inserted into the integrating sphere. Additionally, we would like to point out that the quantum efficiencies given, while reproducible within our optical setup, may still carry imprecisions, not the least owing to the lack of a suitable green emitting standard with continuous quantum yield in the spectral excitation range between 250 and 500 nm (estimated imprecision margin ±10%). However, the general trends described and discussed will not be affected.

The photochemical degradation data of the samples presented in Figure 9 were collected under irradiation with a 150-W Xe lamp that was shone onto an area of 400 $cm^2$ through a UV band pass filter (from Schott, Germany, UG11, 3 mm). The change of emission was monitored through a green interference filter (from LOT-Oriel, 64293 Darmstadt, Germany, 546FS10-50) and focussed on a CCD camera (from Acton Research, Spectrum MM) through a Nikon® lens at a distance of 25 cm. Light source, filters and detection unit were attached to a housing, which contained the samples at the bottom. A freshly prepared Al mirror (thermal evaporation, 25 $cm^2$) was used to turn the horizontally entering beam onto the samples at the bottom, the camera was aligned on top of the housing. Background radiation was accounted for by subtraction of $BaSO_4$ measurements prior to interpretation.

**Xray Crystallography Studies:** For all compounds X-ray quality crystals were sealed and mounted in thin-walled capillaries, with hemispheres of data collected at room temperature with a Bruker SMART CCD diffractometer (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) using the omega scan mode. Data sets were corrected for absorption using the program SADABS.[22] For all structures, the position of the heavy atoms were found using the Patterson method for heavy atoms and refined on $F^2$ using SHELXL97–2[23] with X-SEED as the graphic interface.[24] All non-hydrogen atoms were located and were refined with anisotropic thermal parameters. Hydrogen atoms were placed in calculated positions (riding model) and were not refined. For compounds **2**, **6**, **8** and **9** hydrogen atoms were located on the $NH_2$ groups and on water molecules and were refined isotropically. For compound **7** hydrogen atoms were not located on heteroatoms and were not included in the refinement. Crystal data, and a summary of data collection are listed below.

CCDC-607965 (for **2**), -607966 (for **6**), -607967 (for **7**), -607968 (for **8**) and -607969 (for **9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal Data for Compound 2:** $C_{21}H_{20}GdN_3O_7$, $M$ = 583.65, $0.24\times0.18\times0.15$ mm, monoclinic, space group $P2_1/n$ (No. 14), $a$ = 9.7452(9), $b$ = 22.736(2), $c$ = 9.8229(9) Å, $\beta$ = 99.9290(10)°, $V$ = 2143.9(3) $Å^3$, $Z$ = 4, $D_c$ = 1.808 $g/cm^3$, $F(000)$ = 1148, 9744 reflections collected, 3072 unique ($R_{int}$ = 0.0665). # Rare-Earth Nitroquinolinates: Visible-Light-Sensitizable Near-Infrared Emitters in Aqueous Solution

Rik Van Deun,*[a] Pascal Fias,[a] Peter Nockemann,[a] Kristof Van Hecke,[a] Luc Van Meervelt,[a] and Koen Binnemans[a]

**Keywords:** Rare earth metals / Luminescence / Chelates / N,O ligands / Sensing

Water-soluble, stable, and easily synthesizable 1:4 complexes of rare-earth ions with 8-hydroxy-5-nitroquinolinate ligands have been prepared. These complexes can be sensitized by visible light with wavelengths up to 480 nm and show near-infrared emission in aqueous solution. The incorporation of a nitro group in the quinoline moiety shifts its absorption bands to longer wavelengths and also increases its molar absorptivity by a factor of 2.5, thereby significantly enhancing its light-harvesting power. The presence of the nitro group also increases the solubility of the resulting complexes, making them water-soluble.

## Introduction

Research towards efficient near-infrared emitting lanthanide systems that are compatible with aqueous media is becoming increasingly popular.[1–6] There are several reasons for this. First of all, in vivo imaging using near-infrared radiation has the advantage of being noninvasive and tissue-friendly because of the longer emission wavelengths used. Secondly, although several rare-earth complexes have been reported to show bright near-infrared emission, most of these systems are soluble in (deuterated) organic solvents only. Moreover, because of the small energy gap between the excited states of the near-infrared emitting lanthanide ion and its lower lying energy levels, the introduction of water into these systems provides a very efficient route for radiationless deactivation, which quenches the luminescence and makes these systems useless for applications.

Lanthanide complexes that exhibit visible emission should preferentially have antenna ligands with triplet levels at rather high energy in order to prevent energy back-transfer from the accepting energy level of the lanthanide ion to the triplet level of the ligand. This usually means that the excitation wavelength of such systems is located in the ultraviolet spectral region, although some visible-light-sensitizable systems have been reported.[7–11] In the case of biosensing applications, it is obvious that excitation with visible light offers the advantage of being less harmful towards living tissue. In lanthanide complexes that emit in the near-infrared, the position of the triplet level can be much lower because of the lower lying emission levels of the lanthanide ion. However, in many cases, excitation of these systems still requires ultraviolet radiation.

Here, we report the visible light sensitization of lanthanide complexes with nitrated 8-hydroxyquinoline ligands. The ligand 8-hydroxy-5-nitroquinoline (Figure 1) forms water-soluble 4:1 complexes with trivalent lanthanide ions that show visible-light-sensitized near-infrared emission in aqueous media. In addition, these complexes can be made in an easy one-step synthetic method.

## Results and Discussion

8-Hydroxyquinoline has historically been used as a gravimetric agent for the determination of a large variety of metal ions, so its application was mainly based on its good complexing properties and on the low solubility of the resulting complexes in aqueous media.[12] Recently, we have shown that complexes of 8-hydroxyquinoline and its derivatives with trivalent rare-earth ions possess a rich structural chemistry that results in the formation of hydrated 3:1 tris structures, 4:1 tetrakis structures, and 8:3 trimeric species.[13] Because of the promising near-infrared luminescence properties of the quinolinates of trivalent erbium, ytterbium, and neodymium, interest in these materials has in-

creased substantially in the last years, resulting in the appearance of several literature reports.[14–20]

This paper is the first, however, to report on complexes of 8-hydroxy-5-nitroquinoline as near-infrared emitting materials. Introduction of the nitro group in the 5-position of the 8-hydroxyquinoline moiety changes its physical and chemical properties significantly. The resulting complex is soluble in water at ambient temperature, whereas the non-nitrated equivalents are not. The electron-withdrawing properties of the nitro group decrease the basicity of the coordinating oxygen atom, resulting in the preferential formation of 4:1 tetrakis complexes rather than 8:3 trimeric oxygen-bridged species (an electron-poor oxygen atom is less capable of bridging two rare-earth ions, which is needed to form 8:3 trimeric species). Also, the use of excess ligand and of excess cations in the synthetic procedure stimulates the formation of 4:1 tetrakis complexes instead of 8:3 trimers even though no substituents are present in the 7-position of the quinoline ligand (see Experimental Section). The molecular structure of the yttrium(III) complex of 8-hydroxy-5-nitroquinoline with a tetraethylammonium counterion is shown in Figure 2; the crystal structure data are summarized in the Experimental Section.

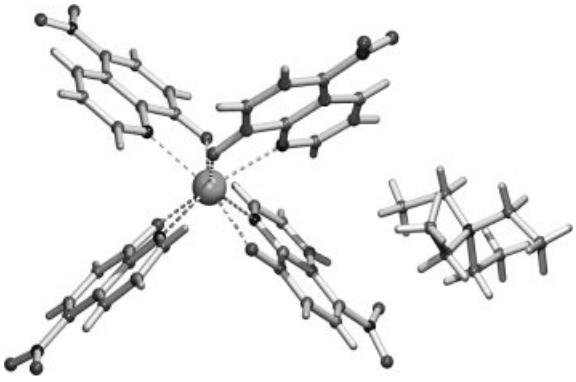

Figure 2. Detail of the molecular structure of the yttrium(III) complex of 8-hydroxy-5-nitroquinoline with a tetraethylammonium counterion.

The structure contains only one tetrakis(nitroquinolinate) complex in the asymmetric unit, together with one tetraethylammonium counter cation. The yttrium(III) ion is surrounded by four nitroquinolinate ligands. The coordination number of the yttrium(III) ion is eight, and the coordination polyhedron can be described as a slightly distorted square antiprism. No solvent molecules are coordinated to the yttrium(III) ion.

Because of the more pronounced electron delocalization in the nitro group, the electronic absorption spectrum of the ligand also differs from that of the non-nitrated equivalents. The absorption spectrum of a nitrated rare-earth quinolinate is shown in Figure 3 along with the luminescence spectra of aqueous solutions of the neodymium(III) and ytterbium(III) complexes of 8-hydroxy-5-nitroquinoline with a tetraethylammonium counterion. The absorption spectrum shows the typical features of deprotonated 8-hydroxyquinolines, namely two absorption bands corresponding to $\pi \rightarrow \pi^*$ transitions. The longer wavelength transition is associated with a shift of electron density from the phenolate oxygen to the $\pi^*$ orbitals of the aromatic ring.[21] It can easily be seen that the longer wavelength transition allows excitation with visible light with wavelengths of up to 480 nm. Another important effect of the incorporation of the nitro substituent is a significant increase in the molar absorptivity of the complex, which results in an enhanced light harvesting power: the $\varepsilon$ value of the neodymium(III) complex of 8-hydroxy-5-nitroquinoline with a tetraethylammonium counterion, measured at the absorption maximum (445 nm), is 36800 $M^{-1}\,cm^{-1}$, whereas the $\varepsilon$ value of the comparable neodymium(III) complex of 5,7-dichloro-8-hydroxyquinoline with a tetraethylammonium counterion measured at the absorption maximum (405 nm) is only 14300 $M^{-1}\,cm^{-1}$.[22]

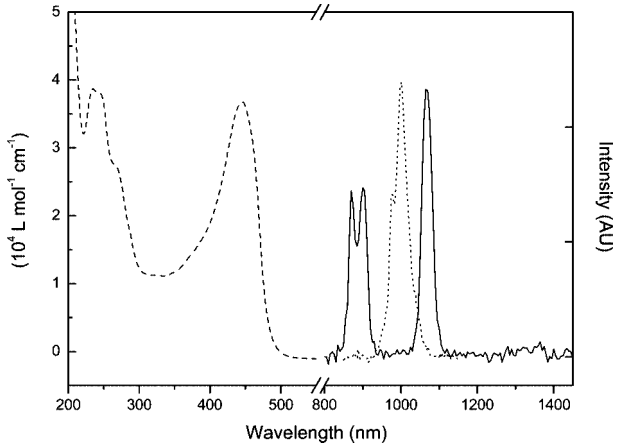

Figure 3. Absorption (dashed line) and emission spectra of the neodymium (solid line) and the ytterbium complexes (dotted line) of 8-hydroxy-5-nitroquinoline with tetraethylammonium counterions in water ($c \approx 10^{-5}$ M; $\lambda_{exc}$ = 445 nm).

The luminescence spectrum of the neodymium(III) complex shows the typical bands of the ion, two of which are very distinct ($^4F_{3/2} \rightarrow {}^4I_{9/2}$ at 902 nm and $^4F_{3/2} \rightarrow {}^4I_{11/2}$ at 1067 nm), whereas the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ transition can be observed at about 1350 nm, albeit very weak, because of the strong light absorption by water in that spectral region. The luminescence spectrum of the ytterbium(III) complex shows only one band, corresponding to the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition, centered at 1001 nm. The concentrations of the solutions were between $10^{-6}$ and $10^{-5}$ M. An overview of the luminescence decay times, $\tau$, and the calculated level quantum efficiencies, $\Phi$, of the neodymium(III) and ytterbium(III) complexes of 8-hydroxy-5-nitroquinoline, both in water and in thf, is given in Table 1. Because of the difficulties involved in performing reliable quantum yield measurements, we decided not to measure these values but to calculate approximate values by comparing the luminescence decay time, $\tau$, with the radiative lifetime, $\tau_0$, of the ions, taken from the literature: $\Phi = \tau/\tau_0 \times 100\,\%$. The radiative lifetime, $\tau_0$, of $Nd^{3+}$ was taken to be 0.25 ms, whereas that of $Yb^{3+}$ is 2 ms.[23]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 1. Luminescence decay times, $\tau$, of the $Nd^{3+}$ ($^4F_{3/2}$) and $Yb^{3+}$ ($^2F_{5/2}$) levels and calculated level quantum efficiencies $\Phi$.[a]

| $Ln^{3+}$ | Solvent | $\tau$ [μs] | $\Phi$ [%] |
|---|---|---|---|
| $Nd^{3+}$ | thf | 0.51 | 0.20 |
| | water | 0.47 | 0.19 |
| $Yb^{3+}$ | thf | 8.3 | 0.41 |
| | water | 1.4 | 0.07 |

[a] Lifetimes measured at room temperature; $\lambda_{exc}$ = 355 nm; $c \approx 10^{-5}$ M.

The luminescence decay times of the neodymium(III) and ytterbium(III) complexes in thf (Table 2) are typical for complexes of these ions in an organic solvent.[24] In water, two striking features become obvious: 1) there is hardly any difference in the efficiency of the neodymium(III) complex in water as compared to thf, and 2) the efficiency of the ytterbium(III) complex in water is much lower than in thf. The first feature can be explained by looking at the crystal structure (Figure 2), from which it is obvious that no solvent molecules are coordinated to the central metal ion. It seems that the four ligands form a very efficient shell around the lanthanide ion.[25,26] These values compare well with those found by Imbert et al.[5] and Comby et al.,[6] who reported luminescence decay times for neodymium(III) complexes of a hydroxyquinoline-containing podand in water of between 0.13 and 0.25 μs. In these reports, however, the efficiencies of the ytterbium(III) complexes are much better than those of the neodymium(III) complexes, which is in line with what one would expect. A possible explanation for the aberrant behavior of the ytterbium(III) complex in our system could be the nitro substituent on the quinoline moiety, although the difference in redox potentials between the neodymium(III) and ytterbium(III) ions is also known to have an influence.[27] We are currently investigating the energy-transfer properties of these nitroquinolinate complexes in more detail.

## Conclusions

In conclusion, we have shown that visible-light-sensitizable near-infrared emission can be obtained from neodymium(III) and ytterbium(III) complexes of 8-hydroxy-5-nitroquinoline in aqueous solution. This is the first report in which this nitrated quinoline has been used as a ligand for near-infrared-emitting lanthanide ions. The incorporation of a nitro group in the quinoline moiety shifts its absorption bands to longer wavelengths and also increases its molar absorptivity by a factor of 2.5, thereby significantly enhancing its light-harvesting power. Furthermore, the resulting 4:1 complexes are water-soluble.

## Experimental Section

**Equipment and Techniques:** Absorption spectra were recorded with a Varian Cary 5000 spectrophotometer. The steady-state near-infrared luminescence spectra and the decay time measurements were recorded on an Edinburgh Instruments FS920P near infrared spectrometer, with a 450-W xenon lamp as the steady-state excitation source, a double excitation monochromator with 1800 lines per millimeter, an emission monochromator with 600 lines per millimeter, and a liquid-nitrogen-cooled Hamamatsu R5509-72 near-infrared photomultiplier tube. For luminescence decay time measurements, the setup includes a Continuum Minilite Nd:YAG laser, equipped with 2nd, 3rd and 4th harmonic crystals, which allows excitation at 1064, 532, 355, and 266 nm. Repetition rate: 10 Hz; pulse width: 3–5 ns. Standard quartz 1-cm fluorescence cuvettes (Hellma type QS-111) were used. CHN elemental analyses were performed with a CE Instruments EA-1110 elemental analyzer.

**Synthesis:** 8-Hydroxy-5-nitroquinoline was purchased from Acros. Sodium hydroxide, sodium chloride, tetraethylammonium hydroxide, tetraethylammonium chloride, yttrium(III) chloride hexahydrate, neodymium(III) chloride hexahydrate, and ytterbium(III) chloride hexahydrate were purchased from Aldrich.

**$NEt_4[Y(Q5N)_4]\cdot 2H_2O$ (HQ5N = 8-hydroxy-5-nitroquinoline):** In a first step, 0.75 mmol of 8-hydroxy-5-nitroquinoline was added to 50 mL of water together with 0.75 mmol of tetraethylammonium hydroxide solution and 3 mmol of tetraethylammonium chloride (to have a large excess of the counterion). The solution was then heated to 60 °C until the ligand had completely dissolved. The pH was checked and, if lower than 7.5, some extra hydroxide base was added. Subsequently, 0.15 mmol of yttrium(III) chloride hexahydrate in 10 mL of water was slowly added and the resulting solution was stirred for an hour. After cooling, the water was removed by evaporation under reduced pressure. The resulting oily product was dissolved in a small amount of methanol (approx. 5 mL). The precipitate formed was washed with small amounts of water and ethanol. Yield: 64 mg (34%). $C_{44}H_{40}N_9O_{12}Y\cdot 2H_2O$ (1011.8): calcd. C 52.23, H 4.38, N 12.46; found C 52.49, H 4.31, N 12.14. $^1$H NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 1.15 [t, 3 H, $N(CH_2CH_3)_4$], 3.17 [q, 2 H, $N(CH_2CH_3)_4$], 6.62 (d, 1 H, H$^7$), 7.74 (dd, 1 H, H$^3$), 8.46 (d, 1 H, H$^4$), 8.96 (d, 1 H, H$^6$), 9.26 (d, 1 H, H$^2$) ppm. MS (ESI$^-$): *m*/*z* 845 $[Y(Q5N)_4]^-$.

**$Na[Nd(Q5N)_4]\cdot H_2O$:** In a first step, 0.75 mmol of 8-hydroxy-5-nitroquinoline was added to 50 mL of water together with 0.75 mmol of sodium hydroxide solution and 3 mmol of sodium chloride (to have a large excess of the counterion). The solution was then heated to 60 °C until the ligand had completely dissolved. The pH was checked and, if lower than 7.5, some extra hydroxide base was added. Subsequently, 0.15 mmol of neodymium(III) chloride hexahydrate in 10 mL of water was slowly added and the resulting solution was stirred for an hour. After cooling, a precipitate formed, which was filtered off and washed with small amounts of water and ethanol. Yield: 102 mg (58%). $C_{36}H_{20}N_8NaNdO_{12}\cdot H_2O$ (941.84): calcd. C 45.91, H 2.35, N 11.90; found C 46.12, H 2.29, N 11.78. The solubility in EtOH/chloroform was too low to obtain good mass spectra.

**$NEt_4[Yb(Q5N)_4]\cdot 3H_2O$:** In a first step, 0.75 mmol of 8-hydroxy-5-nitroquinoline was added to 50 mL of water together with 0.75 mmol of tetraethylammonium hydroxide solution and 3 mmol of tetraethylammonium chloride (to have a large excess of the counterion). The solution was then heated to 60 °C until the ligand had completely dissolved. The pH was checked and, if lower than 7.5, some extra hydroxide base was added. Subsequently, 0.15 mmol of ytterbium(III) chloride hexahydrate in 10 mL of water was slowly added and the resulting solution was stirred for an hour. After cooling, the water was removed by evaporation under reduced pressure. The resulting oily product was dissolved in a small amount of methanol (approx. 5 mL). The precipitate formed was washed with small amounts of water and ethanol. Yield: 84 mg

(40%). $C_{44}H_{40}N_9O_{12}Yb{\cdot}3H_2O$ (1113.9): calcd. C 47.44, H 4.16, N 11.32; found C 47.58, H 4.01, N 11.22. MS ($ESI^-$): *m*/*z* 930 $[Yb(Q5N)_4]^-$.

**Crystal Data for the Yttrium(III) Complex of 8-Hydroxy-5-nitroquinoline:** Crystals were obtained by diffusion of diethyl ether into a solution of the compound in dmf. Intensity data were collected on a SMART 6000 diffractometer equipped with a CCD detector using Cu-$K_\alpha$ radiation ($\lambda$ = 1.54178 Å). The images were interpreted and integrated with the program SAINT from Bruker.[28] $[C_8H_{20}N][C_{36}H_{20}N_8O_{12}Y]$, $M$ = 975.76, monoclinic, $P2_1/c$, $a$ = 17.771(2), $b$ = 13.994(1), $c$ = 16.893(2) Å, $\beta$ = 96.063(6)°, $V$ = 4177.7(8) Å$^3$, $T$ = 100 K, $Z$ = 4, $D_c$ = 1.551 g cm$^{-3}$, $\mu$(Cu-$K_\alpha$) = 2.632 mm$^{-1}$, $F$(000) = 2008, crystal size 0.3 × 0.3 × 0.1 mm$^3$, 7338 independent reflections ($R_{int}$ = 0.1359). Final $R$ = 0.0918 for 3940 reflections with $I > 2\sigma(I)$ and $\omega R_2$ = 0.2488 for all data. See Table 2 for further details. The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXTL program package.[29] Non-hydrogen atoms were refined anisotropically and the hydrogen atoms in the riding mode with isotropic temperature factors fixed at 1.2-times $U$(eq) of the parent atoms (1.5-times for methyl groups). The refinement of the data was difficult due to the low diffraction intensity at higher $2\theta$ angles.

Table 2. Summary of crystal data, intensity measurements, and structure refinement of the yttrium complex.

# Synthesis and Characterisation of $W^{VI}$ Complexes of Phosphane Oxide Ligands, $[WO_2X_2(OPR_3)_2]$ (X = F, Cl or Br; R = Me or Ph), and of the $[MoO_2F_2(OPR_3)_2]$

**Martin F. Davis,[a] William Levason,*[a] Raju Ratnani,*[b] Gillian Reid,*[a] Tim Rose,[a] and Michael Webster[a]**

**Keywords:** Tungsten / Molybdenum / Phosphane oxide / Crystal structures / Fluoride

Phosphane oxide complexes of dioxidotungsten$^{VI}$, $[WO_2X_2(OPR_3)_2]$ (X = Cl or Br, M = Ph or Me) have been prepared under anhydrous conditions from the reaction of $WX_6$ with $(Me_3Si)_2O$ in $CH_2Cl_2$, followed by addition of $OPR_3$. Some diphosphane dioxide analogues have been made similarly, viz, $[WO_2X_2(L–L)]$ {L–L = $Ph_2P(O)(CH_2)_nP(O)Ph_2$ ($n$ = 1 or 2), $o$-$C_6H_4[P(O)Ph_2]_2$}. The complexes have been characterised by elemental analysis, IR and NMR ($^1H$ and $^{31}P\{^1H\}$) spectroscopy, and the structures of $[WO_2Br_2(OPPh_3)_2]$ and $[WO_2Cl_2(OPMe_3)_2]$ determined, revealing distorted six-coordinate tungsten centres with *cis*-$WO_2$ and *trans*-$WX_2$ units. The difluorido-dioxido complexes $[MO_2F_2(OPR_3)_2]$ (M = Mo or W) and $[WO_2F_2(L'–L')]$ (L'–L' = 2,2'-bipyridyl, 1,10-phenanthroline) have been prepared by fluorination of the corresponding chlorido complexes with $Me_3SnF$ in $CH_2Cl_2$. These are characterised similarly and by $^{19}F\{^1H\}$ NMR spectroscopy. Attempts to make $[MO_2I_2(OPR_3)_2]$ were unsuccessful. No adduct formation occurs between $CrO_2Cl_2$ and $OPPh_3$ under rigorously anhydrous conditions. Crystal structures of $[Me_3SnCl(OPPh_3)]$ and two forms of $[WO_2Cl_2(1,10\text{-phen})]$ are also reported and discussed.

## Introduction

The coordination chemistries of $Mo^{VI}$ and $W^{VI}$ continue to attract much research effort, their importance including such diverse areas as metalloenzymes,[1] oxido-transfer reagents, catalyst precursors and epoxidation catalysts.[2–4] Complexes of the $MoO_2X_2$ (X = Cl or Br) with a wide range of O- and N-donor ligands are known and can be obtained by direct reaction of $MoO_2X_2$ [5,6] or $MoO_3$/aqueous HX[7] with the ligands, or more rarely by halogenation of $[Mo(CO)_4(ligand)]$.[8] The $WO_2X_2$ (X = Cl or Br) are insoluble and relatively unreactive and their chemistry has been less thoroughly explored. Some complexes were initially obtained by reaction of $WO_2X_2$ with excess molten ligand,[9] but more recently routes based upon the reaction of $WOCl_4$ with a disiloxane to produce $WO_2Cl_2$ in situ, followed by reaction with the ligand have been developed.[10] Little is known about $WO_2F_2$[11] and the only structurally characterised adduct, $[WO_2F_2(2,2'\text{-bipy})]$, was isolated from the decomposition of $[WOF_4(2,2'\text{-bipy})]$.[12] The dark green $WO_2I_2$[13] is known, but no complexes have been reported. A small number of adducts of $MO_2F_2$ (M = Mo or W) with phosphane oxides have been prepared from $MO_3$/aqueous HF and the ligands,[7,14] and the structure of $[MoO_2F_2(OPPh_2Me)_2]$ determined, although spectroscopic data are limited. The structure of $[MoO_2F_2(thf)_2]$, obtained by hydrolysis of $[MoF_4(NCl)]$, has also been reported.[15] We are interested in developing the chemistry of high-valent, early transition metals with softer donors such as thio- or seleno-ethers, and have reported examples with $MoO_2X_2$ (X = Cl or Br),[16] $TiX_4$, $ZrCl_4$ and $HfCl_4$.[17] Currently we are exploring routes to $W^{VI}$ complexes with these ligands, and because complexes of this type are very moisture sensitive and the ligands prone to oxidation or C–S(Se) bond fission under forcing conditions, many of the routes described above are not suitable. As a prelude to this work, we describe here the synthesis and characterisation of a series of phosphane oxide complexes of $WO_2X_2$ (X = Cl or Br) using anhydrous conditions and a route based upon $WX_6$/$(Me_3Si)_2O$. We also describe the (anhydrous) synthesis of fluorido analogues with both $Mo^{VI}$ and $W^{VI}$ using $Me_3SnF$[18] as fluorinating agent. Attempts to obtain $[MO_2I_2(OPR_3)_2]$ are also briefly discussed.

## Results and Discussion

### $[WO_2X_2(OPR_3)_2]$ (X = Cl or Br) Complexes

As expected, attempts to react commercial $WO_2Cl_2$ directly with $OPR_3$ (R = Me or Ph) in $CH_2Cl_2$ solution were unsuccessful, even after prolonged reflux. In contrast,

"$WO_2Cl_2$" made in situ from reaction of $WCl_6$ with hexamethyldisiloxane, $(Me_3Si)_2O$, in anhydrous $CH_2Cl_2$, reacted readily with both phosphane oxides to produce [$WO_2Cl_2(OPR_3)_2$] in good yields as white powders, moderately soluble in chlorocarbon solvents. Similar reactions using $WBr_6/(Me_3Si)_2O$ gave the corresponding cream [$WO_2Br_2(OPR_3)_2$]. To obtain pure products it is important to allow the $WX_6/(Me_3Si)_2O$ reaction to go to completion before adding the neutral ligand; similar observations were made by Dreisch et al.[10a] who examined the synthesis of [$WO_2Cl_2$(dme)] (dme = $MeOCH_2CH_2OMe$) from $WOCl_4/(Me_3Si)_2O$ in some detail and observed significant amounts of $W^V$ complexes under some conditions. Gibson et al.[10c] reported that $WO_2Cl_2$ could not be isolated from $CH_2Cl_2$ solution at ambient temperatures by this route, rather off-white tungsten siloxanes were formed. We obtained white materials, which although we did not isolate or characterise them, reacted in situ with $OPR_3$ to give high yields of [$WO_2Cl_2(OPR_3)_2$], and the spectroscopic data showed no -$OSiMe_3$ present in the products. Extension of this route was also successful in affording diphosphane dioxide complexes [$WO_2X_2$(L–L)] {L–L = $Ph_2P(O)CH_2P(O)Ph_2$, $Ph_2P(O)CH_2CH_2P(O)Ph_2$, and *o*-$C_6H_4[P(O)Ph_2]_2$} (Table 1), although these are only slightly soluble in chlorocarbons, and it is necessary to use larger volumes of solvent and longer reaction times, and also to recrystallise the products to obtain pure samples. The spectroscopic data on the [$WO_2X_2(OPR_3)_2$] complexes (Table 1) are consistent with the limited literature data[9] and the geometries were confirmed by crystal structures of two examples (below). In particular two medium intensity features in the IR spectra in the range 900–965 $cm^{-1}$ are the $\upsilon_{sym}$ and $\upsilon_{asym}$ vibrations of the *cis*-$WO_2$ group [for the $OPMe_3$ complexes $\rho(PMe_3)$ modes in the same region complicate the assignments – see Table 1], whilst the *trans*-$WX_2$ units have single bands at ca. 310 $cm^{-1}$ (X = Cl) or ca. 240 $cm^{-1}$ (X = Br). The $\upsilon$(PO) modes occur as broad features typically shifted to low frequency by 40–70 $cm^{-1}$ from the values in the parent $OPR_3$. Trends in the spectroscopic data with changes in halogen and between corresponding Mo and W complexes are discussed further in a later section.

The structures of [$WO_2Br_2(OPPh_3)_2$] and [$WO_2Cl_2(OPMe_3)_2$] are shown in Figure 1 and Figure 2 and selected bond lengths and angles are in Table 2 and Table 3. Both structures show distorted octahedral coordination at tungsten with *trans*-halides and with the phosphane oxide *trans* to W=O and with the X–W–X bent towards the neutral ligands and away from the $WO_2$ groups. The data can be compared with that for [$WO_2Cl_2(OPPh_3)_2$][9b] which has W=O 1.706(8), 1.702(9) Å, W–Cl 2.385(3), 2.366(3) Å, and W–O(P) 2.175(8), 2.163(7) Å, P–O 1.499(8), 1.500(7) Å, O=W=O 102.2(4)° and Cl–W–Cl 163.5(1)°. Thus for [$WO_2X_2(OPPh_3)_2$] (X = Cl or Br), the W=O, W–O(P) and P–O distances are the same within experimental error. The same basic features are present in the structure of [$WO_2Cl_2(OPMe_3)_2$]. The structures are also very similar to those of the molybdenum analogues reported previously.[6,7] As noted before, the M–O–P angle is rather variable. Within each structure, the M–O–P angles at the two phosphane

### $[MO_2F_2(OPR_3)_2]$ (M = Mo or W) Complexes

The $[MoO_2Cl_2(OPR_3)_2]$[6] complexes were dissolved in anhydrous $CH_2Cl_2$ and stirred with a 50% excess of powdered $Me_3SnF$ for ca. 24 h, which slowly dissolves as the reaction proceeds, to form $[MoO_2F_2(OPR_3)_2]$ and $Me_3SnCl$. The completion of the reaction is best monitored by checking the $^{31}P\{^1H\}$ NMR spectrum of the reaction mixture for complete loss of the resonance of the $[MoO_2Cl_2(OPR_3)_2]$ starting material, because we found that reaction times were quite variable, ranging from ca. 4–20 h. The polymeric $Me_3SnF$ is insoluble in chlorocarbons and only dissolves as the reaction proceeds, and this solid-solution reaction probably accounts for the highly variable reaction times. It is also important to use sufficient solvent volume to prevent the product complexes from separating out on the suspended $Me_3SnF$. When reaction is complete, unreacted $Me_3SnF$ was removed by filtration, the solvent and most of the $Me_3SnCl$ pumped off in vacuo, and the residue washed thoroughly with *n*-hexane to remove any residual $Me_3SnCl$ ($Me_3SnCl$ is easily detected in the $^1H$ NMR spectra as singlet at $\delta$ = 0.62 ppm with $^{119/117}Sn$ satellites). The corresponding reactions of $[WO_2Cl_2(OPR_3)_2]$ with $Me_3SnF$ were carried out similarly, although the reaction times required are longer, and sometimes insoluble by-products are formed, which contain broad IR bands 850–700 $cm^{-1}$ presumably due to W–O–W bridges. In attempts to overcome these problems we explored the effects of using $[WO_2Cl_2(OPR_3)_2]/Me_3SnF$ ratios of 1:2 (stoichiometric), 1:3 and 1:4, and also adding excess $OPR_3$ (ca. 2 mol. equiv.) to suppress oligomerisation, because it is known that the W=O groups exhibit a *trans* labilising effect.[14] In fact we find that the best route is to use rigorously anhydrous conditions, stoichiometric $[WO_2Cl_2(OPR_3)_2]/Me_3SnF$ ratio (1:2), without added $OPR_3$, and dilute solutions. Excess phosphane oxide forms adducts with the $Me_3SnX$ (see below) making it harder to remove after the reaction is complete. After removing all volatiles in vacuo, the products were washed with anhydrous hexane, and the residue recrystallised from anhydrous $CH_2Cl_2$, discarding any insoluble material. The $^{31}P\{^1H\}$ NMR spectra obtained during the reactions show an additional resonance intermediate in chemical shift between those of the dichlorido- and difluorido-species, almost certainly due to $[WO_2ClF(OPR_3)_2]$ (although no attempt was made to isolate these), indicating that fluorination occurs stepwise. We also made $[WO_2F_2(OPMe_3)_2]$ by adding excess $OPMe_3$ in ethanol to a solution of "tungstic acid" (hydrated $WO_3$) in aqueous HF and allowing the solution to evaporate in air,[14] until very small colourless crystals separated (ca. 3 d). The products from the two routes were spectroscopically identical.

A small number of white crystals were isolated as a by-product from the $[WO_2Cl_2(OPPh_3)_2]/Me_3SnF$ reaction and were identified by a crystal structure determination as $[Me_3SnCl(OPPh_3)]$. The structure (Figure 3, Table 4) reveals a trigonal-bipyramidal tin centre with equatorial methyl groups. The structure of the parent molecule $Me_3SnCl$ is also composed of distorted trigonal-bipyramidal units with axially disposed asymmetric chlorine bridges [Sn–Cl 2.430(2), 3.269(2) Å].[19] The Sn–C bonds are not significantly different between the parent [2.119 Å (av)] and the phosphane oxide adduct [2.120 Å (av)], and in the adduct the $OPPh_3$ simply replaces the longer Sn–Cl bridging interaction. The weak coordination of the phosphane oxide is evident in the long *d*(Sn–O) = 2.375(2) Å and short *d*(P–O) = 1.497(2) Å, which may be compared with values in $[SnX_4(OPPh_3)_2]$, which range from *d*(Sn–O) = 2.050(3) Å (X = F) to 2.13 Å (av) (X = I) and *d*(P–O) range from

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.523(3)–1.485 Å.[20] The compound has been reported several times before[21] and the $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopic data in $CH_2Cl_2$ solution are little different from those of the constituents, suggesting only weak interaction in solution.

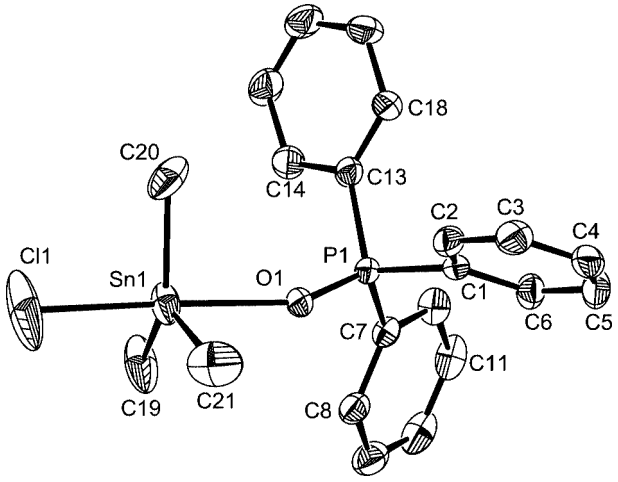

Figure 3. View of the structure of [$Me_3SnCl(OPPh_3)$] with numbering scheme adopted. H atoms have been omitted for clarity and the ellipsoids are drawn at the 50% probability level.

Table 4. Selected bond lengths [Å] and angles [°] for [$Me_3SnCl(OPPh_3)$].

The spectroscopic data on the four fluorido $Mo^{VI}$ and $W^{VI}$ complexes are given in Table 1. The *trans*-$MF_2$ units exhibit a strong IR vibration ca. 550–590 $cm^{-1}$. The [$MoO_2F_2(OPR_3)_2$] exhibit sharp singlet $^{19}F$ NMR resonances at $\delta$ = –51.7 (R = Ph) or –57.2 (R = Me), and the $^{95}Mo$ resonances appear as broad triplets at $\delta$ = –114 (R = Ph) or –93 (R = Me) with $^1J(^{95}Mo\text{-}^{19}F)$ ca. 115–120 Hz. Literature data on molybdenum fluorides are sparse, and the only closely related species appears to be [$MoO_2F_2$-(acac)]$^-$ which has $\delta(^{19}F)$ = –53.0, $\delta(^{95}Mo)$ = –76.3 (t) $^1J(^{95}Mo\text{-}^{19}F)$ = 114 Hz.[22] The [$WO_2F_2(OPR_3)_2$] complexes exhibit $^{19}F$ NMR resonances in a similar region to the molybdenum analogues (Table 1), with $^{183}W$ satellites $^1J(^{183}W\text{-}^{19}F)$ ca. 90–110 Hz. The $^{19}F$ resonances are significantly to low frequency of those in $WF_6$ or $WOF_4$ adducts.[23]

As a further test of this method, the [$WO_2Cl_2$(L–L)] (L–L = 2,2′-bipy, 1,10-phen), originally obtained from $WO_2Cl_2$ and the molten diimines,[9a] were prepared from $WCl_6$/$(Me_3Si)_2O$ and the appropriate diimine, and then fluorinated with $Me_3SnF$, in these cases under reflux for 48 h, due to the poor solubility of reagents and products. The [$WO_2F_2$(L–L)] are poorly soluble, white powders (Table 1), with the data in good agreement with those reported[12] for [$WO_2F_2$(L–L)] made from [$WOF_4$(2,2′-bipy)] or from [$WOF_2(OEt)_2$]. During this work two different crystalline forms of [$WO_2Cl_2$(1,10-phen)] were obtained, an unsolvated form (the structure of which has been reported previously)[24a] and a 1:1 $CH_2Cl_2$ solvate. The structures of both were determined (see Table 5 and Figure 4 and Figure 5). The distortions from regular octahedal angles at W are similar to those observed above for the phosphane oxides, but with the O=W=O angle ca. 4° larger and the Cl–W–Cl angle ca. 6° smaller in the 1,10-phenanthroline complexes. The tungsten residues in these two structures have very similar bond lengths and angles and they provide good examples of the effect of chemical environment on molecular geometry.[24b] The data on the unsolvated form agree well with that reported.[24a] Comparison of the data show that *d*(W=O) and *d*(W–Cl) differ little from the values in the phosphane oxide adduct, indicating that these are the dominant bonds to tungsten, with the neutral ligands filling the remaining coordination sites.

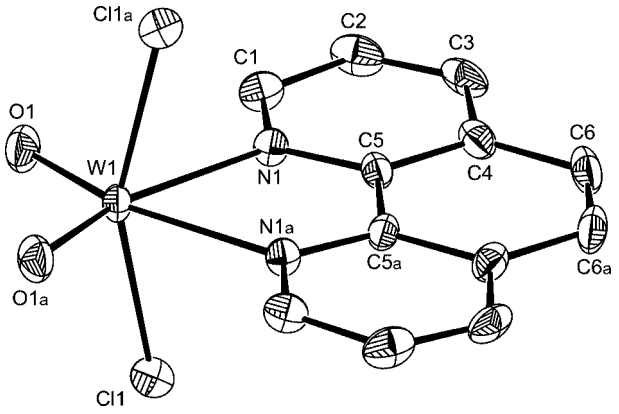

Figure 5. View of the structure of $[WO_2Cl_2(1,10\text{-phen})]$ with numbering scheme adopted. H atoms have been omitted for clarity and the ellipsoids are drawn at the 50% probability level. The molecule has crystallographic twofold symmetry. Symmetry operation: $a = 1-x, y, 1/2-z$.

### Attempted Preparation of $[MO_2I_2(OPR_3)_2]$

A $CH_2Cl_2$ solution of $[MoO_2Cl_2(OPPh_3)_2]$ treated with 2.5 equiv. of $Me_3SnI$, slowly developed a dark green colour. After ca. 24 h an in situ $^{31}P\{^1H\}$ NMR spectrum showed that the $[MoO_2Cl_2(OPPh_3)_2]$ had been completely consumed, and there were no new phosphorus resonances. Evaporation of the solution gave a paramagnetic green-brown solid which showed no evidence of $\upsilon(MoO_2)$ vibrations in the IR spectrum, and the UV/Vis spectrum contained, in addition to intense bands $> 25000\ cm^{-1}$, a broad, weak feature ca. $16000\ cm^{-1}$ assignable as a d–d transition, consistent with the reduction of the molybdenum to a lower oxidation state. The reaction of $[WO_2Cl_2(OPPh_3)_2]$ with $Me_3SnI$ was very slow, but after 7 d a yellow solution formed and a $^{31}P\{^1H\}$ NMR spectrum of this solution showed that all the chlorido complex had reacted. However, neither the IR nor the $^{31}P\{^1H\}$ NMR spectra of the product(s) were consistent with the formation of $[WO_2I_2(OPPh_3)_2]$, and we conclude that the latter is not formed by this route.

### Some Comparisons

The spectroscopic data on the $[MO_2X_2(OPR_3)_2]$ complexes show no systematic variation in $\upsilon(PO)$ or $\upsilon(MO_2)$, for which the broadness of the bands and probably some coupling to other modes are responsible. However, systematic trends are evident in the multinuclear NMR spectroscopic data. The $^{31}P\{^1H\}$ NMR chemical shifts of the coordinated phosphane oxides show high frequency shifts F < Cl < Br (Table 1 and Table 6), the opposite of that expected on electronegativity grounds, and probably reflecting less effective $\pi(X)\rightarrow Mo$ donation as the halogen orbitals become larger. Similarly, the $^{95}Mo$ chemical shifts show an inverse halogen dependence, also seen in $MoO_2X_2$ (X = Cl or Br) complexes with N-donor ligands,[25] although this appears to be the first time data have been available for complexes containing F. (Our attempts to record $^{183}W$ NMR spectroscopic data for that series of compounds were unsuccessful due to the poor solubility of the complexes and the inherent insensitivity of the W nucleus.) The changes between the corresponding Mo and W complexes are also systematic for fixed $OPR_3$ and X, the $^{31}P\{^1H\}$ chemical shift is always slightly to higher frequency for M = W than Mo, whilst the $^{19}F$ chemical shifts in the fluorides are to lower frequency for the tungsten complexes.

Table 6. $^{95}Mo$ and $^{31}P\{^1H\}$ NMR spectroscopic data.[a]

### Attempted Synthesis of Chromium(VI) Analogues

The extensive data obtained on the series of $Mo^{VI}$ and $W^{VI}$ $[MO_2X_2(OPR_3)_2]$ compounds, prompts the consideration of the 3d analogues containing $Cr^{VI}$. Chromyl fluoride, $CrO_2F_2$, is an orange gas and a powerful fluorinating agent,[26] whilst $CrO_2Br_2$ is very unstable, decomposing rapidly above ca. 210 K,[27] seemingly ruling out any coordination chemistry. However, the commercially available $CrO_2Cl_2$ was briefly examined. The UV/Vis spectrum of a solution of freshly distilled chromyl chloride in anhydrous $CH_2Cl_2$ exhibited a strong broad band at ca. $26000\ cm^{-1}$ and a weak broader feature at ca. $18000\ cm^{-1}$,[28] and these bands were unchanged on addition of dry $OPPh_3$, indicating no adduct formation. Over a few hours the initially deep orange-red solution turns red-brown and new weak features appear at low energy, which we assign to reduction to $d^1$ $Cr^V$. Decomposition is much faster in the presence of moisture or in bright light. The $^{31}P\{^1H\}$ NMR spectrum of a mixture of $CrO_2Cl_2$ and $OPPh_3$ in rigorously anhydrous $CH_2Cl_2$ also shows no reaction, but in the presence of traces of moisture a resonance at $\delta$ ca. +46 ppm appears due to the formation of $Ph_3POH^+$.[29] On a preparative scale, the reaction of $CrO_2Cl_2$ and $OPPh_3$ (1:1 mol. ratio) in anhydrous $CH_2Cl_2$ gave a deep red solution, which on removal of all volatiles in vacuo at 25 °C, left a sticky red-brown, paramagnetic solid. The IR spectrum of the solid showed no uncoordinated $OPPh_3$, but a broad feature at ca. $1140\ cm^{-1}$ was assignable to coordinated phosphane oxide, and features at ca. 970 and $875\ cm^{-1}$ may be $\upsilon(CrO)$ modes. The evidence points to the red-brown solid being a $Cr^V$ species (or mixture of $Cr^V$ compounds), and there is no evidence that $CrO_2Cl_2$ forms adducts with phosphane oxides. This contrasts with the behaviour of $VOCl_3$ which forms $[VOCl_3(OPPh_3)]$ and $[VOCl_3(OPMe_3)_2]$.[30] A few adducts of $CrO_2Cl_2$ with N-heterocycles, amines or amides have been claimed on the basis of analytical and IR spectro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

scopic data,[31] but it appears that these are chloridooxidochromate(V) species with protonated N-base cations.[32] A literature search failed to find any clearly established examples of $Cr^{VI}$ compounds with coordination numbers > 4, except in the oxide-fluorides[26] or imido complexes.[33]

## Conclusions

A route to [$WO_2X_2(OPR_3)_2$] (X = Cl or Br) compounds using anhydrous conditions has been developed, and the (also anhydrous) fluorination of these and related complexes achieved using $Me_3SnF$. These routes should allow the synthesis of highly moisture sensitive $WO_2X_2$ (X = F, Cl or Br) complexes of soft ligands containing heavier groups 15 or 16 donors, and work is underway to test this approach in our laboratories.

## Experimental Section

Infrared spectra were recorded as Nujol mulls between CsI plates with a Perkin–Elmer 983G spectrometer over the range 4000–200 $cm^{-1}$. $^1H$ and $^{19}F\{^1H\}$ NMR spectra were recorded with a Bruker AV300 spectrometer and referenced to TMS and $CFCl_3$, respectively. $^{31}P\{^1H\}$ and $^{95}Mo$ NMR spectra were recorded with a Bruker DPX400 spectrometer and are referenced to external 85% $H_3PO_4$ and aqueous $Na_2MoO_4$ at pH = 11, respectively. Microanalyses were undertaken by the University of Strathclyde microanalytical service. Solvents were dried prior to use and all preparations were undertaken using standard Schlenk techniques under $N_2$. $WCl_6$, $OPMe_3$ and $OPPh_3$ were obtained commercially (Alfa or Aldrich), while the other phosphane oxides were obtained by oxidation of the parent phosphane by the literature method.[34] The $OPMe_3$ was freshly sublimed in vacuo before use. $WBr_6$ was obtained by treatment of solid [$W(CO)_6$] with $Br_2$.[35] $Me_3SnF$ was obtained by the literature methods.[36] $CrO_2Cl_2$ (Aldrich) was freshly distilled, and freeze/thaw degassed immediately before use.

**[$WO_2Cl_2(OPMe_3)_2$]:** $WCl_6$ (0.23 g, 0.58 mmol) and $(Me_3Si)_2O$ (0.19 g, 1.7 mmol) were stirred in anhydrous $CH_2Cl_2$ (30 $cm^3$) under $N_2$ when the red solution rapidly turned orange ($WOCl_4$) and then colourless. After 2 h, $OPMe_3$ (0.12 g, 1.3 mmol) in $CH_2Cl_2$ (10 $cm^3$) was added. The solution was stirred for a further ca. 2 h. The resulting colourless solution was filtered and the solvent removed in vacuo. The white solid was washed thoroughly with hexane (100 $cm^3$) and dried in vacuo. Yield 0.26 g, 95%. $C_6H_{18}Cl_2O_4P_2W$ (470.9): calcd. C 15.3, H 3.9; found C 15.2, H 4.1. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.82 (d, $^2J_{PH}$ = 13.2 Hz, Me) ppm.

**[$WO_2Cl_2(OPPh_3)_2$]:** Method as above to give a white solid. Yield 91%. $C_{36}H_{30}Cl_2O_4P_2W{\cdot}CH_2Cl_2$ (928.2): calcd. C 47.9, H 3.5; found C 47.5, H 3.2. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.30–7.75 (m, Ph) ppm.

**[$WO_2Cl_2\{Ph_2P(O)CH_2P(O)Ph_2\}$]:** Method as above to give a white solid. Yield 89%. $C_{25}H_{22}Cl_2O_4P_2W$ (703.2): calcd. C 42.7, H 3.1; found C 42.8, H 3.1. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.86 (t, 2 H, $CH_2$), 7.35–7.90 (m, 20 H, Ph) ppm.

**[$WO_2Cl_2\{Ph_2P(O)CH_2CH_2P(O)Ph_2\}$]:** Method as above to give a white solid contaminated with $WO_2Cl_2$. The [$WO_2Cl_2\{Ph_2P(O)CH_2CH_2P(O)Ph_2\}$] was then re-dissolved in $CH_2Cl_2$ (10 $cm^3$) and filtered (to remove the $WO_2Cl_2$). Addition of $Et_2O$ gave the complex as a white solid. Yield 64%. $C_{26}H_{24}Cl_2O_4P_2W$ (717.8): calcd. C 43.6, H 3.4; found C 44.3, H 3.4. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.50–7.85 (m, 20 H, Ph), 2.67 (d, $^2J_{PH}$ = 10.5 Hz, 4 H, $CH_2$) ppm.

**[$WO_2Cl_2\{o\text{-}C_6H_4[P(O)Ph_2]_2\}$]:** Method as for [$WO_2Cl_2\{Ph_2P(O)CH_2CH_2P(O)Ph_2\}$] above to give a white solid. Yield 60%. $C_{30}H_{24}Cl_2O_4P_2W{\cdot}(C_2H_5)_2O$ (839.3): calcd. C 48.7, H 4.0; found C 49.6, H 4.3. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 7.30–7.90 (m, aromatic CH) ppm.

**[$WO_2Br_2(OPMe_3)_2$]:** $WBr_6$ (0.17 g, 0.26 mmol) with $(Me_3Si)_2O$ (0.08 g, 0.52 mmol) were stirred in $CH_2Cl_2$ (30 $cm^3$) under $N_2$ for 3 h until a pale cream solution was obtained and then $OPMe_3$ (0.05 g, 0.54 mmol) was added, and the solution was stirred overnight. The resulting solution was filtered and pumped to dryness. The white solid obtained was washed thoroughly with hexane (100 $cm^3$) and dried in vacuo. Yield 0.11 g, 76%. $C_6H_{18}Br_2O_4P_2W$ (559.8): calcd. C 12.9, H, 3.3; found C 13.5, H 4.4. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.02 (d, $^2J_{PH}$ = 13.5 Hz, Me) ppm.

**[$WO_2Br_2(OPPh_3)_2$]:** Method as [$WO_2Br_2(OPMe_3)_2$] to give a white solid. Yield 82%. $C_{36}H_{30}Br_2O_4P_2W$ (932.2): calcd. C 46.4, H 3.2; found C 47.3, H 3.2. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.35–7.80 (m, Ph) ppm.

**[$WO_2Br_2\{Ph_2P(O)CH_2P(O)Ph_2\}$]:** Method as [$WO_2Br_2(OPMe_3)_2$] to give a light yellow solid. Yield 94%. $C_{25}H_{22}Br_2O_4P_2W$ (792.1): calcd. C 37.9, H 2.8; found C 38.0, H 2.9. $^1H$ NMR ($CDCl_3$): $\delta$ = 4.12 (t, 2 H, $CH_2$), 7.40–7.95 (m, 20 H, Ph) ppm.

**[$WO_2Br_2\{o\text{-}C_6H_4[P(O)Ph_2]_2\}$]:** Method as for [$WO_2Cl_2\{Ph_2P(O)CH_2CH_2P(O)Ph_2\}$] above to give a yellow solid. Yield 69%. $C_{30}H_{24}Br_2O_4P_2W{\cdot}(C_2H_5)_2O$ (928.3): calcd. C 43.9, H, 3.7; found C 44.1, H 3.0. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.33–7.85 (m, aromatic CH) ppm.

**[$MoO_2F_2(OPPh_3)_2$]:** [$MoO_2Cl_2(OPPh_3)_2$][6] (0.22 g, 0.29 mmol) was dissolved in dry dichloromethane (10 $cm^3$), powdered anhydrous $Me_3SnF$ (0.158 g, 0.87 mmol) added and the mixture stirred for 24 h. The solution was filtered, and the filtrate treated dropwise with hexane (5 $cm^3$) to precipitate the complex as a white solid. This was filtered off, rinsed with hexane (5 $cm^3$) and dried in vacuo. Yield 0.18 g, 86%. $C_{36}H_{30}F_2MoO_4P_2{\cdot}CH_2Cl_2$ (807.5): calcd. C 55.0, H 4.0; found C 54.9, H 3.9. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.20–7.80 (m, Ph) ppm.

**[$MoO_2F_2(OPMe_3)_2$]:** Was prepared similarly. Yield 91%. $C_6H_{18}F_2MoO_4P_2{\cdot}CH_2Cl_2$ (471.1): calcd. C 19.3, H 4.6; found C 19.2, H 4.7. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.65 (d, $^2J_{PH}$ = 13.0 Hz, Me) ppm.

**[$WO_2F_2(OPPh_3)_2$]:** [$WO_2Cl_2(OPPh_3)_2$] (0.18 g, 0.24 mmol) was dissolved in dry $CH_2Cl_2$ (20 $cm^3$), powdered $Me_3SnF$ (0.088 g, 0.48 mmol) added and the mixture stirred for 24 h. The solution was taken to dryness in vacuo, the residue washed with anhydrous hexane (20 $cm^3$), filtered, and the solid dissolved in anhydrous $CH_2Cl_2$ (50 $cm^3$). Any insoluble material was filtered off and discarded, and the filtrate concentrated to ca. 5 $cm^3$ and treated dropwise with hexane (5 $cm^3$) to precipitate the complex as a white solid. This was filtered off, rinsed with hexane (5 $cm^3$) and dried in vacuo. Yield 0.13 g, 64%. $C_{36}H_{30}F_2O_4P_2W$ (810.4): calcd. C 53.4, H 3.7. (Repeated attempts to obtain carbon analyses on samples of this compound gave values 5–8% low and with poor reproducibility; we believe this is a combustion problem, since the samples appeared identical and spectroscopically pure). $^1H$ NMR ($CDCl_3$): $\delta$ = 7.20–7.80 (m, Ph) ppm.

**[$WO_2F_2(OPMe_3)_2$]. Method 1:** In a Teflon® beaker, tungstic acid ("$H_2WO_4{\cdot}nH_2O$") (0.15 g, ca. 0.5 mmol) was dissolved in a mixture of 40% HF (5 $cm^3$) and water (5 $cm^3$) with gentle warming to give

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a colourless solution. The solution was cooled, decanted from any solid and a solution of $OPMe_3$ (0.184 g, 2.0 mmol) in ethanol (15 $cm^3$) added. The solution was stirred for 2 h, then allowed to evaporate at room temperature. After 3 d colourless small crystals formed, the mother liquor was decanted off, the crystals rinsed with diethyl ether (5 $cm^3$) and dried in vacuo. Yield 0.12 g 54%.

**Method 2:** $[WO_2Cl_2(OPMe_3)_2]$ (0.11 g, 0.24 mmol) was dissolved in dry $CH_2Cl_2$ (50 $cm^3$), powdered $Me_3SnF$ (0.09 g, 0.50 mmol) and the mixture stirred for 48 h. The solution was taken to dryness in vacuo, the residue stirred with anhydrous hexane (50 $cm^3$) for 3 h, the solid filtered off and dissolved in anhydrous $CH_2Cl_2$ (20 $cm^3$). Any insoluble material was filtered off and discarded, and the filtrate concentrated to ca. 5 $cm^3$ and treated dropwise with hexane (5 $cm^3$) to precipitate the complex as a white solid. This was filtered off and dried in vacuo. Yield 0.06 g, 57% Spectroscopically the two methods gave identical products. $C_6H_{18}F_2O_4P_2W$ (438.0): calcd. C 16.5, H 4.1; found C 16.4, H 3.8. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.65 (d, $^2J_{PH}$ = 13 Hz) ppm.

**$[WO_2Cl_2(1,10\text{-phen})]$:** $WCl_6$ (0.27 g, 0.68 mmol) was suspended in dry $CH_2Cl_2$ (10 $cm^3$) and $(Me_3Si)_2O$ (0.22 g, 1.4 mmol) added, and the mixture stirred for 2 h during which time it turned colourless. A solution of 1,10-phen (0.12 g, 0.68 mmol) in dry $CH_2Cl_2$ (20 $cm^3$) was added and the mixture stirred for 2 h. The solution was filtered, and the product precipitated from the filtrate by slow addition of hexane (100 $cm^3$), filtered off, washed thoroughly with hexane (100 $cm^3$) and dried in vacuo. Yield 0.32 g, 84%. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.06 (m, 4 H), 8.64 (m, 2 H), 9.83 (m, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 936, 919 $\upsilon(WO_2)$, 320 $\upsilon(WCl)$ $cm^{-1}$.

**$[WO_2Cl_2(2,2'\text{-bipy})]$:** This was made analogously to the 1,10-phenanthroline complex above. Yield 85%. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.08 (m, 2 H), 8.30 (m, 4 H), 9.60 (m, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 952, 915 $\upsilon(WO_2)$, 338 $\upsilon(WCl)$ $cm^{-1}$.

**$[WO_2F_2(1,10\text{-phen})]$:** $[WO_2Cl_2(1,10\text{-phen})]$ (0.16 g, 0.34 mmol) was suspended in anhydrous $CHCl_3$ (80 $cm^3$), powdered anhydrous $Me_3SnF$ (0.18 g, 0.98 mmol) added and the mixture refluxed for 48 h. The mixture was filtered and the filtrate concentrated to ca. 5 $cm^3$, then treated with hexane (5 $cm^3$) to precipitate the product, which was separated and dried in vacuo. Yield 0.10 g, 73%. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.07 (m, 4 H), 8.68 (m, 2 H), 9.85 (m, 2 H) ppm.

**$[WO_2F_2(2,2'\text{-bipy})]$:** Was made similarly to the above. Yield 78%. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 7.78 (m, 2 H), 8.24 (m, 4 H), 9.43 (m, 2 H) ppm.

**X-ray Crystallography:** Details of the crystallographic data collection and refinement parameters are given in Table 7. Colourless crystals of $[WO_2Cl_2(OPMe_3)_2]$ and light-yellow crystals of $[WO_2Br_2(OPPh_3)_2]$ were obtained by cooling a solution of the appropriate complex in $CH_2Cl_2$. Crystals of $[WO_2Cl_2(1,10\text{-phen})]\cdot CH_2Cl_2$ were obtained by layering *n*-hexane onto a $CH_2Cl_2$ solution of the complex and the non-solvated complex isolated from an attempted synthesis of $[WO_2F_2(1,10\text{-phen})]$. Colourless crystals of $[Me_3SnCl(OPPh_3)]$ were obtained from the reaction mixture used to prepare $[WO_2F_2(OPPh_3)_2]$. Data collections used a Bruker-Nonius Kappa CCD diffractometer fitted with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and either a graphite monochromator or confocal mirrors. The crystals were held at 120 K in a nitrogen gas stream. Structure solution and refinement were routine[37–39] with H atoms introduced into the models in calculated positions. The choice of space group for $[Me_3SnCl(OPPh_3)]$ depended on a few 0*k*0 reflections. The reflections in this group were weaker than other zones and the choice of $P2_1/c$ or *Pc*-$P2/c$ was not as clear cut as one would wish. Both $P2_1/c$ and *Pc* were explored and $P2_1/c$ used on the basis of providing as good a fit to the data with less parameters and avoiding the high correlations found in *Pc* with two molecules in the asymmetric unit. The structure agrees with unpublished work.[40] Selected bond lengths and angles are given in Table 2, Table 3, Table 4 and Table 5.

CCDC-615946 (for W/Br/Ph), -615947 (for W/Cl/Me), -615949 (for W/Cl/N/$CH_2Cl_2$), C-615948 (for W/Cl/N), and -615950 (for Sn/Cl) contain the supplementary crystallographic data for this paper (the atoms in parentheses indicate the species in the compounds). These

# Valence-State Distribution in the Ruthenium *o*-Quinonoid Systems [Ru(trpy)(Cl)($L^1$)]$^+$ and [Ru(trpy)(Cl)($L^2$)]$^+$ ($L^1$ = *o*-Iminobenzoquinone, $L^2$ = *o*-Diiminobenzoquinone; trpy = 2,2′:6′,2′′-Terpyridine)

**Somnath Maji,[a] Srikanta Patra,[a] Saumen Chakraborty,[a] Deepa Janardanan,[a] Shaikh M. Mobin,[a] Raghavan B. Sunoj,*[a] and Goutam Kumar Lahiri*[a]**

**Keywords:** Ruthenium / Quinonoid ligands / Valence-state distributions / Density functional calculations / Spectroelectrochemistry

Valence-state distributions in the ruthenium quinonoid (L) frameworks of [Ru(trpy)(Cl)($L^1$)]$ClO_4$ (**1**-$ClO_4$) and [Ru(trpy)(Cl)($L^2$)]$ClO_4$ (**2**-$ClO_4$) ($L^1$ = *o*-iminobenzoquinone, $L^2$ = *o*-diiminobenzoquinone, and trpy = 2,2′:6′,2′′-terpyridine) have been examined by structural, spectroelectrochemical, and density functional studies. The structural data, in corroboration with the DFT-calculated bond lengths, suggest that the primary valence formulation of $\mathbf{1}^+$ and $\mathbf{2}^+$ is a spin-coupled singlet configuration of [$Ru^{III}$(trpy)(Cl)($L_{Sq}$)]$^+$ with a minority contribution from diamagnetic [$Ru^{II}$(trpy)(Cl)($L_Q$)]$^+$. Consequently, the closely spaced successive two oxidation processes of $\mathbf{1}^+$ and $\mathbf{2}^+$ can be assigned to $Ru^{III} \rightarrow Ru^{IV}$ and $L_{Sq} \rightarrow L_Q$, which involve the HOMO and HOMO–3 levels, respectively. The one-electron-oxidized species $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$ display sharp EPR signals with *g* values of 2.011 and 2.014 at 77 K, respectively. The free radical EPR signal ($g \approx 2.0$) of the one-electron-reduced species **1** or **2** signifies the preferential involvement of the ruthenium-based orbitals in the first reduction process to yield [$Ru^{II}$(trpy)(Cl)($L_{Sq}$)], although the LUMO is calculated to be a mixture of dπ(Ru) (≈24 %) and π*(L) (≈ 70 %). The subsequent second ($\mathbf{1}^-/\mathbf{2}^-$) and third ($\mathbf{1}^{2-}/\mathbf{2}^{2-}$) reduction steps in each case are associated simply with the terpyridyl-based orbitals (≥90 %). The lowest energy charge-transfer transitions of $\mathbf{1}^+$ and $\mathbf{2}^+$ at 556 and 509 nm are predicted to be HOMO → LUMO+1 and HOMO–1 → LUMO+1 transitions, respectively. In the successive oxidations $\mathbf{1}^+/\mathbf{2}^+ \rightarrow \mathbf{1}^{2+}/\mathbf{2}^{2+} \rightarrow \mathbf{1}^{3+}/\mathbf{2}^{3+}$ the lowest energy charge-transfer transitions undergo a blue shift with a substantial reduction in intensity. The lowest energy charge-transfer transitions, however, are red shifted with a reduction in intensity on going from ($\mathbf{1}^+/\mathbf{2}^+$) to **1/2**. The origin of the transitions in the $\mathbf{1}^{2+}/\mathbf{2}^{2+}$ and **1/2** systems is predicted by TDDFT analysis.

## Introduction

The ground-state formulation of a particular mononuclear quinonoid system [(AL)$Ru^n$–$L^{m+}$] ["*n*" and "*m*" are the formal charges associated with the electronic states of the metal and quinonoid ligand (L)] can either be any of the possible valence-localized tautomeric forms, [(AL)$Ru^{II}$–$L°_Q$] ↔ [(AL)$Ru^{III}$–$L^{\cdot-}_{Sq}$] ↔ [(AL)$Ru^{IV}$–$L^{2-}_{Cat}$] or a mixed M(dπ)-L(pπ) delocalized situation depending on the electronic aspects of all the associated entities ($Ru^n$, $L^m$ and AL) in the complex frameworks (Cat = fully reduced dianionic catecholate form; Sq = intermediate monoanionic radical form; Q = fully oxidized quinine form, Scheme 1; AL = ancillary ligands). The remarkable mixing of redox-facile-metal-ion- and ligand-based frontier orbitals in the ruthenium quinonoid (L) frameworks often introduces considerable ambiguities in assigning their precise valence configurations in the native state, as well as preferential involvement of the metal- or ligand-based orbitals in the accessible electron-transfer processes.[1,2] For example, experimental results have convincingly established the $Ru^{III}L_{Sq}$ formulation[3] of [Ru(acac)$_2$(L)] [acac$^-$ = acetylacetonate; L = iminoquinone (X = O, Y = NH) or iminothioquinone (X = S, Y = NH); Scheme 1] but subsequent theoretical studies suggest that the alternate resonance form of $Ru^{II}L_Q$ also contributes in the native state to some extent.[4] Thus, establishing the primary contributing electronic forms of the metal ion and L in such complexes is a formidable challenge. Although a wide variety of mononuclear ruthenium-*o*-quinonoid systems have been scrutinized over the past years, the complexities vary substantially from one molecule to another depending on the nature of X and Y in the quinonoid (L) framework (Scheme 1) and the electronic nature of the ancillary ligands (AL) associated with the complex moieties. For instance, distinct localized {$Ru^{II}L_{Cat}$} and {$Ru^{II}L_{Sq}$} configurations have been stabilized in [(tap)$_2$RuL][5] [tap = 2-(*m*-tolylazo)pyridine] and [($PPh_3$)$_2$$RuL_2$],[6]

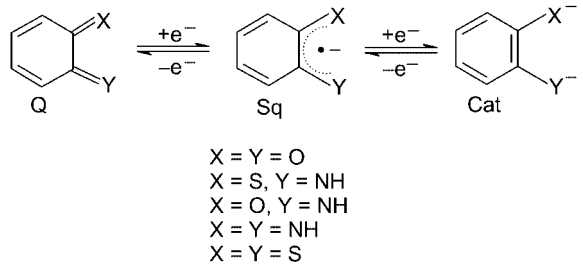
respectively, although the $[(bpy)_2RuL]^+$ (bpy = 2,2′-bipyridine) and $[(t\text{Bupy})_2RuL_2]$ analogs (L = X = Y = O, Scheme 1) have been described as RuL charge-delocalized systems.[2b,2u] Similarly, the RuL valence-state features in [(Cl/OAc)(trpy)RuL] (L = X = Y = O; trpy = 2,2′:6′,2′′-terpyridine, Scheme 1) have been addressed as a resonance equilibrium between $Ru^{II}L_{Sq}$ and $Ru^{III}L_{Cat}$.[7] This unique electronic characteristic of metal quinonoids justifies their continuous experimental and theoretical explorations with newer molecules.[1,2,8] This indeed is the origin of the present work, which scrutinizes the valence-state distribution profile of {RuL} coordinated to the hitherto relatively less explored terpyridine as ancillary ligand.[7,9]

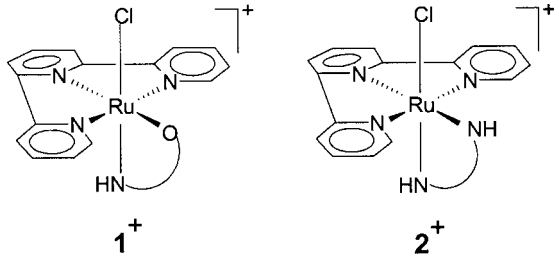


Scheme 1.

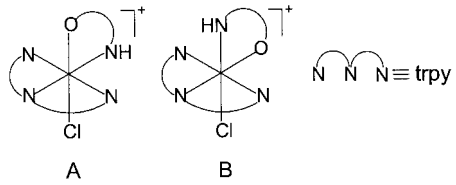
This work deals with two such conceptually simple ruthenium *o*-quinonoid species, namely $[Ru(trpy)(Cl)(L^1)]ClO_4$ (**1**-$ClO_4$) and $[Ru(trpy)(Cl)(L^2)]ClO_4$ (**2**-$ClO_4$), where $L^1$ and $L^2$ are *o*-iminobenzoquinone (X = O and Y = NH) and *o*-diiminobenzoquinone (X = Y = NH) respectively (Scheme 1). Unlike many other apparently similar systems, establishment of the {RuL} redox configurations in $\mathbf{1}^+$ and $\mathbf{2}^+$ was not as straightforward as we envisaged (see below),[3,5,6] therefore the primary objectives of the present article are to address the charge-distribution phenomena of $\{Ru^nL^m\}$ in $\mathbf{1}^+$ and $\mathbf{2}^+$ by parallel considerations of experimental results and the theoretically generated information on their optimized geometries.

## Results and Discussion

The diamagnetic complexes $[Ru(trpy)(Cl)(L^1)]ClO_4$ (**1**-$ClO_4$) and $[Ru(trpy)(Cl)(L^2)]ClO_4$ (**2**-$ClO_4$) ($L^1$ = *o*-iminobenzoquinone and $L^2$ = *o*-diiminobenzoquinone; trpy = 2,2′:6′,2′′-terpyridine) were prepared by the reaction of $[RuCl_3(trpy)]$ with *o*-aminophenol and *o*-phenylenediamine, respectively, in the presence of $NEt_3$ as a base, in refluxing ethanol, followed by chromatographic purification on a neutral alumina column.



The unsymmetrical $L^1$ in combination with the meridional configuration of trpy in $\mathbf{1}^+$ is expected to give rise to an isomeric mixture of **A** and **B**. However, the preferential crystallization of isomer **B** was confirmed by its crystal structure (see below).



Complexes **1**-$ClO_4$ and **2**-$ClO_4$ are 1:1 conductors in acetonitrile and exhibit satisfactory microanalytical data (see Exp. Sect.). The positive-ion electrospray mass spectra show molecular ion peaks at 476.90 and 475.85 (Figure S1, Supporting Information) for $\mathbf{1}^+$ (calcd.: 477.00) and $\mathbf{2}^+$ (calcd.: 475.92), respectively. The presence of the $ClO_4^-$ counteranion was confirmed by the appearance of characteristic $\nu(ClO_4^-)$ frequencies at 1100 and 630 $cm^{-1}$ in their IR spectra; the NH vibrations appear near 3300 $cm^{-1}$ (see Exp. Sect.). The $^1H$ NMR spectra of $\mathbf{1}^+$ and $\mathbf{2}^+$ exhibit the expected fifteen (eleven from trpy and four from $L^1$ or $L^2$), although partially overlapping, aromatic signals. The $D_2O$ exchangeable one and two NH proton signals of coordinated $L^1$ and $L^2$ in $\mathbf{1}^+$ and $\mathbf{2}^+$, respectively, are observed in the downfield region (Figure S2, Supporting Information; see Exp. Sect.).[10] The synthesis of **2**-$ClO_4$ by a different synthetic route and its electronic spectrum [in $H_2O$; $\lambda_{max}$ ($\varepsilon$) = 506 nm (16000 $M^{-1}cm^{-1}$), 316 (22000), 280 (20000), 274 (21000), 232 (28000)] and metal oxidation potential (0.96 V vs. Ag/AgCl in $CH_3CN$) have been reported earlier.[11]

The structures of **1**-$ClO_4$ and **2**-$ClO_4$ were authenticated by their single-crystal X-ray structures (Figures 1 and 2, respectively, and Table 1). The geometrical constraint that arises due to the usual meridional mode of the tridentate trpy ligand is reflected in the *trans* angles (Table 1).[12,13] The chloride is preferentially *trans* to N1H in $\mathbf{1}^+$ (structural form **B**). As a consequence of the small bite angle involving the coordinated ligand $L^1$ [N1–Ru–O1 78.1(3)°] or $L^2$ [N1–Ru–N5 78.0(3)°], the N1–Ru–Cl *trans* angle is tilted by about 10°. The Ru–Cl and Ru–N(trpy) bond lengths and the associated angles are in good agreement with the data reported for related molecules.[12–14] The Ru–N distances involving $L^1$ [1.942(8) Å] and $L^2$ [1.985(6) and 1.991(7) Å] are appreciably shorter than the corresponding Ru–N(trpy) distances (2.022 Å in $\mathbf{1}^+$ and 2.043 Å in $\mathbf{2}^+$; Table 1), which implies significant mixing of dπ(Ru) and π* of L in the respective LUMOs (see below).[15]

The C1–O1 and C6–N1H bond lengths pertaining to $L^1$ in $\mathbf{1}^+$ are 1.270(11) and 1.312(12) Å, respectively [C–O/C–NH distances to individual localized oxidation states (Sq and Q) are 1.30/1.35 and 1.22/1.31 Å, respectively, based on hundreds of structure of *o*-quinonoid molecules determined since 1985[8b]]. This, together with the two short C–C intraring distances in $L^1$ [C2–C3 1.322(13) and C4–C5 1.377(14) Å], suggests that $\mathbf{1}^+$ is primarily in a $\{Ru^{III}–Sq\}$ state, with a minor contribution from the alternate reso-

nance form {$Ru^{II}$–Q}. On the other hand, C1–N5H, C6–N1H and the two short intra-ring bond lengths (C2–C3 and C4–C5) of $L^2$ in $\mathbf{2}^+$ [1.316(9), 1.317(9), 1.310(13) and 1.331(13) Å, respectively] indicate a charge-delocalized resonance form of $Ru^{III}$–Sq ↔ $Ru^{II}$–Q. Thus, the 1:1 conducting behavior and singlet ($S$ = O) ground states of $\mathbf{1}^+$ and $\mathbf{2}^+$ can be addressed in terms of a valence tautomeric formulation of spin-coupled $[Ru^{III}(trpy)(Cl)(L_{Sq})]^+$ and diamagnetic $[Ru^{II}(trpy)(Cl)(L_Q)]^+$, as observed in $[(bpy)_2RuL]^+$ (L = X = Y = O; X = Y = NH; X = O, Y = NH).[2b,2i,7,16] However, the corresponding Ru-trpy-dioxolene derivatives [(Cl/OAc)(trpy)RuL] (L = X = Y = O, Scheme 1) are described as a resonance equilibrium between $Ru^{II}L_{Sq}$ and $Ru^{III}L_{Cat}$.[7] Hence, density functional calculations at the B3LYP level were performed for $\mathbf{1}^+$ and $\mathbf{2}^+$ in order to obtain additional structural insights from the optimized geometries.[17] In addition, geometry optimizations of the oxidized and reduced species were also performed.

The optimized geometries of $\mathbf{1}^+$ and $\mathbf{2}^+$ are shown in Figure 3, and a selected list of calculated geometric parameters is provided in Table 1 (coordinates for $\mathbf{1}^+$ and $\mathbf{2}^+$ are given in Table S1 in the Supporting Information). In general, the computed structural parameters of $\mathbf{1}^+$ and $\mathbf{2}^+$ are in reasonably good agreement with the experimental ones (Table 1). The calculated intra-ligand C–C distances of $L^1$ and $L^2$ in $\mathbf{1}^+$ and $\mathbf{2}^+$, respectively, also show two short distances (C4–

C5 1.369/1.368 and C2–C3 1.372/1.367 Å; Table 1). More importantly, the C1–O1/C6–N1H and C1–N5H–C6–N1H distances of 1.280/1.335 and 1.326/1.329 Å in $\mathbf{1}^+$ and $\mathbf{2}^+$, respectively, also suggest the charge delocalization situation of $\{Ru^{III}\text{–}Sq\} \longleftrightarrow \{Ru^{II}\text{–}Q\}$.

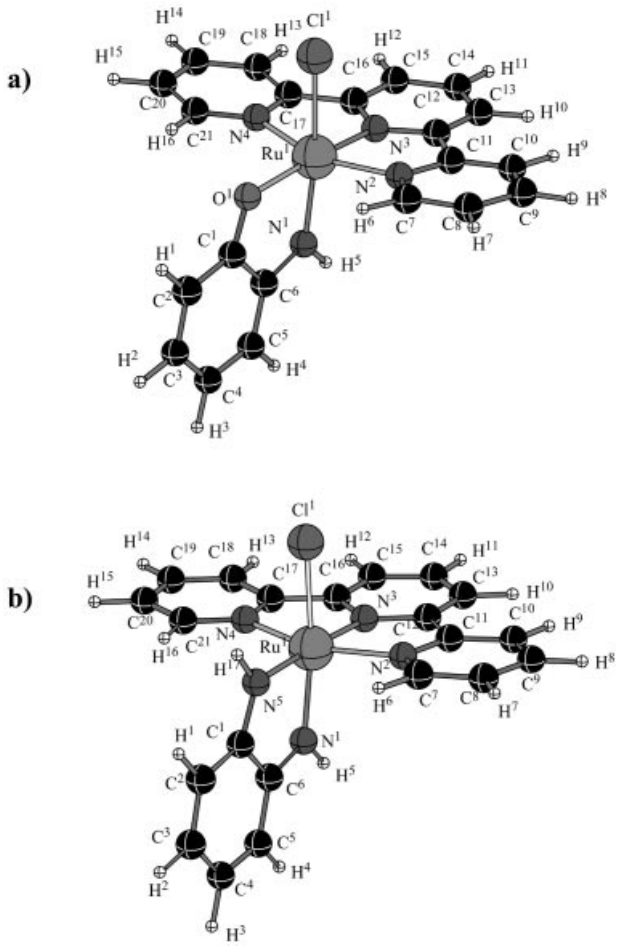

Figure 3. The B3LYP/SDD,6-31G* optimized geometries for the singlet ground state of (a) $\mathbf{1}^+$ and (b) $\mathbf{2}^+$.

Thus, a combination of the experimental and calculated structural data of $\mathbf{1}^+$ and $\mathbf{2}^+$ provide justification for the preferential ground-state formulation of $[Ru^{III}(trpy)(Cl)(L_{Sq})]^+$, with a minority contribution from $[Ru^{II}(trpy)(Cl)(L_Q)]^+$.

Both $\mathbf{1}^+$ and $\mathbf{2}^+$ show two closely spaced successive oxidation (couples I and II) and three reduction processes (couples III–V) in the potential ranges 0.94 to 1.45 and –0.26 to –1.79 V, respectively, vs. SCE (Figure 4, Table 2). The large separations in potentials between the first oxidation (couple I) and reduction (couple III) processes, $\Delta E$ = 1.45 and 1.49 V for $\mathbf{1}^+$ and $\mathbf{2}^+$, respectively, translate to comproportionation constants ($K_c$) of $10^{24.6}$ and $10^{25.2}$ [$RT\ln K_c = nF(\Delta E)$],[18] thereby reflecting the high stability of the native states. The more basic character of the diimine-based ligand ($L^2$) in $\mathbf{2}^+$ makes the first oxidation process (couple I) easier and the first reduction process (couple III) more difficult relative to iminoquinone-based $L^1$ in $\mathbf{1}^+$ (Table 2).[19] Although the separation in potential between couples I and II is greater in $\mathbf{2}^+$ than in $\mathbf{1}^+$, the reverse order is observed for couples III and IV, thus implying the greater and lower stabilities of the intermediate oxidized $\mathbf{2}^{2+}$ and reduced **2**, respectively, relative to the corresponding $\mathbf{1}^{2+}$ and **1**. Moreover, the irreversible profile of couples I and II for $\mathbf{1}^+$ (Figure 4a) also suggests that, unlike $\mathbf{2}^{2+/3+}$, the oxidized species $\mathbf{1}^{2+/3+}$ are not stable even on the cyclic voltammetric timescale. The relatively higher energy HOMO of complex $\mathbf{2}^+$ also points to its easier oxidation than complex $\mathbf{1}^+$ (Figure 5, Table 3). The presence of the semiquinone form of $L^{\cdot-}$ along with the anionic $Cl^-$ in $\mathbf{1}^+$ and $\mathbf{2}^+$ makes the $Ru^{III}$–$Ru^{II}$ potential substantially negative (approx. –0.3 V, see below), which, in turn, facilitates the stabilization of the $Ru^{III}$ state under the atmospheric reaction conditions. Since the $Ru^{III}$ and $L_{Sq}$ states are each susceptible to one-electron oxidation to $Ru^{IV}$ and $L_Q$, respectively, couples I and II can therefore be assigned to ruthenium(III)→ruthenium(IV) and coordinated $L_{Sq}\rightarrow L_Q$ processes, respectively, or vice versa.[20] The correspondence of couples I and II with metal- ($Ru^{III}\rightarrow Ru^{IV}$) and ligand-based ($L_{Sq}\rightarrow L_Q$) processes is supported by the fact that the HOMOs of $\mathbf{1}^+$

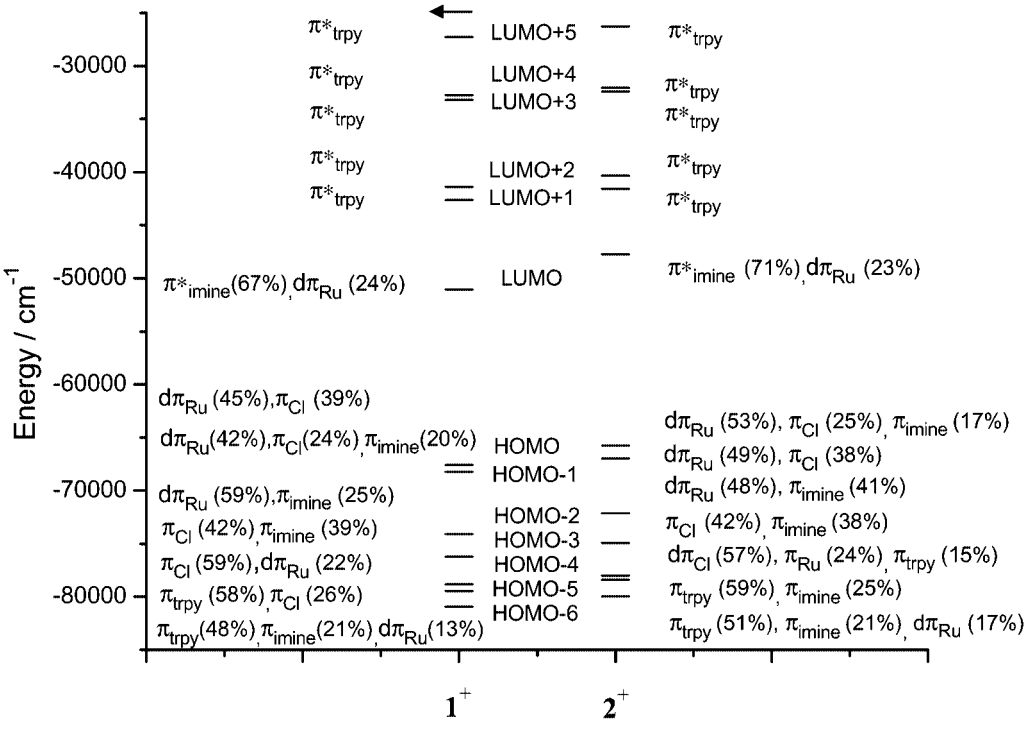

Figure 5. Orbital energy diagrams for $\mathbf{1}^+$ and $\mathbf{2}^+$ computed at the B3LYP/SDD,6-31G* level of theory.

and $\mathbf{2}^+$consist of 45% and 53% of dπ(Ru) with zero and 17% contributions from π($L^1$) and π($L^2$), respectively, and the HOMO–3s are dominated by π($L^1$) (39%) and π($L^2$) (38%), with slight metal contributions of 5.7% and 11% for $\mathbf{1}^+$ and $\mathbf{2}^+$, respectively (Figure 5, Table 3). The electrochemically generated one-electron-oxidized $Ru^{IV}$–$L_{Sq}$ states in $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$ exhibit free radical EPR signals in $CH_3CN$ with *g* values of 2.011 (peak-to-peak separation: 18 G) and 2.014 (peak-to-peak separation: 15 G), respectively.

The DFT results also suggest that the mixing of π($L^2$) and dπ(Ru) orbitals at both the HOMO and HOMO–3 levels is more pronounced in $\mathbf{2}^+$.[15,21] It is interesting to note that HOMO and HOMO–3 exhibit a fairly good mixing with chloride π orbitals (39/25% and 42% for $\mathbf{1}^+$ and $\mathbf{2}^+$, respectively), as observed in the analogous isomeric ruthenium terpyridine complexes [Ru(trpy)(Cl){3-amino-6-(3,5-dimethylpyrazol-1-yl)-1,2,4,5-tetrazine}].[13]

The observed Ru- and L-based successive two-step oxidation processes (couples I and II) in $\mathbf{1}^+$ and $\mathbf{2}^+$ also support their primary valence-state composition of $\{Ru^{III}–L_{Sq}\}$ in solution instead of the alternate possible formulation of $\{Ru^{II}–L_Q\}^+$ in which only a ruthenium-based oxidation process is expected due to the fully oxidized nature of $L_Q$. Similarly, the first reduction (couple III) could either be associated with the ruthenium(III) or $L_{Sq}$ center as both are susceptible to one-electron reduction and the resultant reduced species (**1/2**) would then be formulated as $[Ru^{III}(trpy)(Cl)(L_{Sq})]^+$ ($\mathbf{1}^+/\mathbf{2}^+$) + $e^- \rightarrow [Ru^{II}(trpy)(Cl)(L_{Sq})]$ or $[Ru^{III}(trpy)(Cl)(L_{Cat})]$ (**1/2**), leaving the unpaired spin predominantly on the $L_{Sq}$ or $Ru^{III}$. The semiquinone-based free radical EPR signals (*g* = 2.0023 and 2.0051, with peak-to-peak separations of 17 and 20 G for **1** and **2**, respectively;[22] see Figure 6), however, suggest a preferential metal-based reduction process to form $[Ru^{II}(trpy)(Cl)(L_{Sq})]$. The separation in potentials of approximately 1.5 V between the first oxidation (couple I) and reduction (couple III) processes in $\mathbf{1}^+$ and $\mathbf{2}^+$ also matches well with the earlier observed ruthenium-based average potential difference of about 1.5 V between the $Ru^{IV/III}$ and $Ru^{III/II}$ couples.[23]

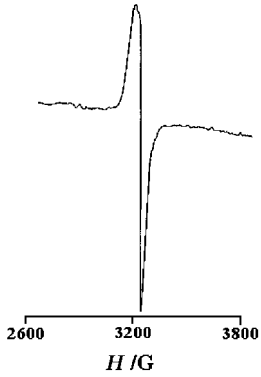

Figure 6. EPR spectrum of **1** in $CH_3CN/Et_4NClO_4$ at 77 K. The expected nitrogen hyperfine lines cannot be resolved at 77 K.

LUMOs is predicted to be lower than that of $L_{Sq}$. The contributions of $Ru/L_{Sq}$ orbitals to the LUMOs are found to be 24/66% and 23/70%, respectively, for $\mathbf{1}^+$ and $\mathbf{2}^+$ (Figure 5, Table 3). Hence, a comparatively lower, but still significant, metal contribution favors the metal-centered reduction process in a mixed Ru(dπ)/L(π*) situation.[21] The subsequent higher energy unoccupied MOs such as LUMO+1 and LUMO+2 are primarily localized on the trpy ligand with a composition of >90% π*(trpy) orbitals along with a slight metal contribution (2–7%), which implies that the second (couple IV) and third (couple V) reductions are trpy-based (Figure 4, Table 2).[24]

In order to get further insights into the reduced species the spin densities[25] for one-electron-reduced species **1** and **2** were computed at the same level of theory. The results are in accordance with the nature of the LUMOs described earlier. The overall spin density of the complexes was found to be distributed over the metal and $L^1/L^2$, thus supporting an "Sq" formalism for the reduced species (Figure S3, Supporting Information). It is also worth mentioning that the contribution of the trpy ligand to the first reduction process is negligible.

Natural population analysis (NPA) for $\mathbf{1}^+$ and $\mathbf{2}^+$ at the B3LYP/SDD,6-31G* level[8c,26] suggest a d-orbital population of 6.98 and 7.03 electrons for $\mathbf{1}^+$ and $\mathbf{2}^+$, respectively (Table 4). The extra population of about $2e^-$ is expected to be an effect of charge transfer from the anionic forms of the ligands ($Cl^-$ is a $2e^-$ donor and $L^{\cdot -}_{Sq}$ a $1e^-$ donor). The d-electron population further indicates a relatively high electron density for $\mathbf{2}^+$, in agreement with its easier oxidation than $\mathbf{1}^+$ (Table 2, Figures 4 and 5).

Table 4. Valence shell electron population of the Ru centers in $\mathbf{1}^+$ and $\mathbf{2}^+$ computed at the B3LYP/SDD, 6-31G* level.

| Complex | Valence shell population | |
|---|---|---|
| | 5s | 4d |
| $\mathbf{1}^+$ | 0.30 | 6.98 |
| $\mathbf{2}^+$ | 0.30 | 7.03 |

Both $\mathbf{1}^+$ and $\mathbf{2}^+$ display multiple charge-transfer transitions in the visible region in addition to intense ligand-based bands in the UV region (Figure 7, see Exp. Sect.). Selected computed vertical excitation energies with the TD-DFT/B3LYP formalism for the B3LYP/SDD,6-31G* geometries of $\mathbf{1}^+$ and $\mathbf{2}^+$ in their singlet ground states are summarized in Table 5 (complete lists are given in Tables S2 and S3 in the Supporting Information).[27] A comparison between the observed and computed transitions was performed by examining the transitions of comparable intensities guided by their respective oscillator strengths and absorptivity values.[28] The nature of the excited states is assigned based on the percent Kohn–Sham orbital contributions of the orbitals involved in the electronic transitions. Based on the predicted values for the oscillator strengths it is found that the most intense long-wavelength transition at 556 nm (calcd.: 522 nm) for $\mathbf{1}^+$ is from the HOMO [dπ(Ru) (45%) and π(Cl) (39%)] to the LUMO+1 [π*(trpy) (90%)] (Figure 8, a). The other two closely spaced higher energy transitions at 483 and 459 nm (calcd.: 482 and 458 nm) are due to HOMO–3→LUMO/HOMO–1→LUMO+2 and HOMO→LUMO+2 transitions, respectively (Table 5, Figure 8, a).

Similarly, the lowest energy charge-transfer band for $\mathbf{2}^+$ appears at 509 nm, which is very much in agreement with

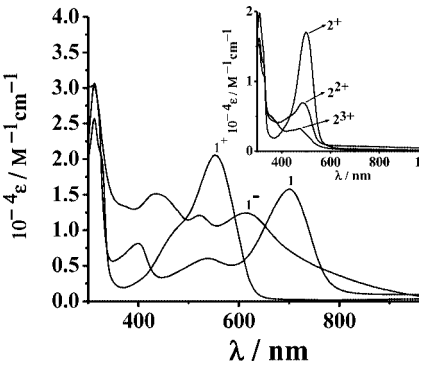

Figure 7. Electronic spectra of $\mathbf{1}^+$, **1**, and $\mathbf{1}^-$ in $CH_3CN/Et_4NClO_4$. The inset shows the electronic spectra of $\mathbf{2}^+$, **2**, and $\mathbf{2}^{2+}$ in $CH_3CN/Et_4NClO_4$.

the calculated value of 494 nm, and is due to a HOMO–1 [dπ(Ru) (49%) and π(Cl) (38%)]→LUMO+1 [π*(trpy) (91%)] transition, which is again a MLLCT transition as in $\mathbf{1}^+$. The other two closely spaced predicted transitions at 458 and 425 nm (HOMO–3→LUMO; Figure 8 (b), Table 5) could not be resolved experimentally.

On electrochemical successive oxidations of $\mathbf{1}^+$ to $\mathbf{1}^{2+}$ and $\mathbf{1}^{3+}$ and $\mathbf{2}^+$ to $\mathbf{2}^{2+}$ and $\mathbf{2}^{3+}$ the lowest energy charge-transfer bands are blue shifted from 556 to 475 and 436 nm and 509 to 487 and 476 nm, respectively, with a substantial reduction in intensity [Figure 7 (inset); see Exp. Sect.], thus indicating a lower degree of delocalization in the oxidized states. The predicted transitions for $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$, respectively, are 491 nm [HOMO–3 {π($L^1$), dπ(Ru)}→LUMO+1 {π*($L^1$), dπ(Ru)}] and 465 nm [HOMO–3 {π(Cl), π($L^2$), dπ(Ru)}→LUMO {π*($L^2$)}] (Table S4).

During the one-electron reduction $\mathbf{1}^+ \rightarrow \mathbf{1}$ the lowest energy charge-transfer band undergoes a substantial red shift from 556 to 702 nm with a slight decrease in intensity that suggests a comparable extent of delocalization in both states. However, on further reduction to $\mathbf{1}^-$ the bands are blue shifted and undergo a reasonable intensity reduction, which implies a relatively localized state (Figure 7 and Exp. Sect.). Similar spectral features have also been observed with **2** and $\mathbf{2}^-$ (see Exp. Sect.).[4c,4d] TD-DFT calculations on the reduced species indicate that during the one electron reductions $[\mathbf{1}]^+ \rightarrow \mathbf{1}$ and $[\mathbf{2}]^+ \rightarrow \mathbf{2}$, the lowest energy charge transfer (MLLCT) bands undergo a red shift to 604 and 556 nm, respectively. These bands are predicted to have contributions from intra-ligand transitions as well, namely HOMO–2 [dπ(Ru) (58%), π($L^1$) (32%)]→LUMO [π*($L^1$) (48%), π*(trpy) (44%)] and HOMO–2 [dπ(Ru) (55%), π($L^2$) (32%)]→LUMO [π*($L^2$) (7%), π*(trpy) (91%)], respectively (Table S4). The deviation of the predicted value from the experimental one might be due to the absence of solvent effects in our calculations.

The frontier orbital analysis further indicates that the nature of the HOMOs and LUMOs remains essentially the same after oxidation. For instance, the composition of the HOMO changes only from 45% (Ru) and 39% (Cl) in $\mathbf{1}^+$ to 43% (Ru) and 46% (Cl) in $\mathbf{1}^{2+}$ upon oxidation, whereas the contribution of the ligand orbital to the frontier orbitals

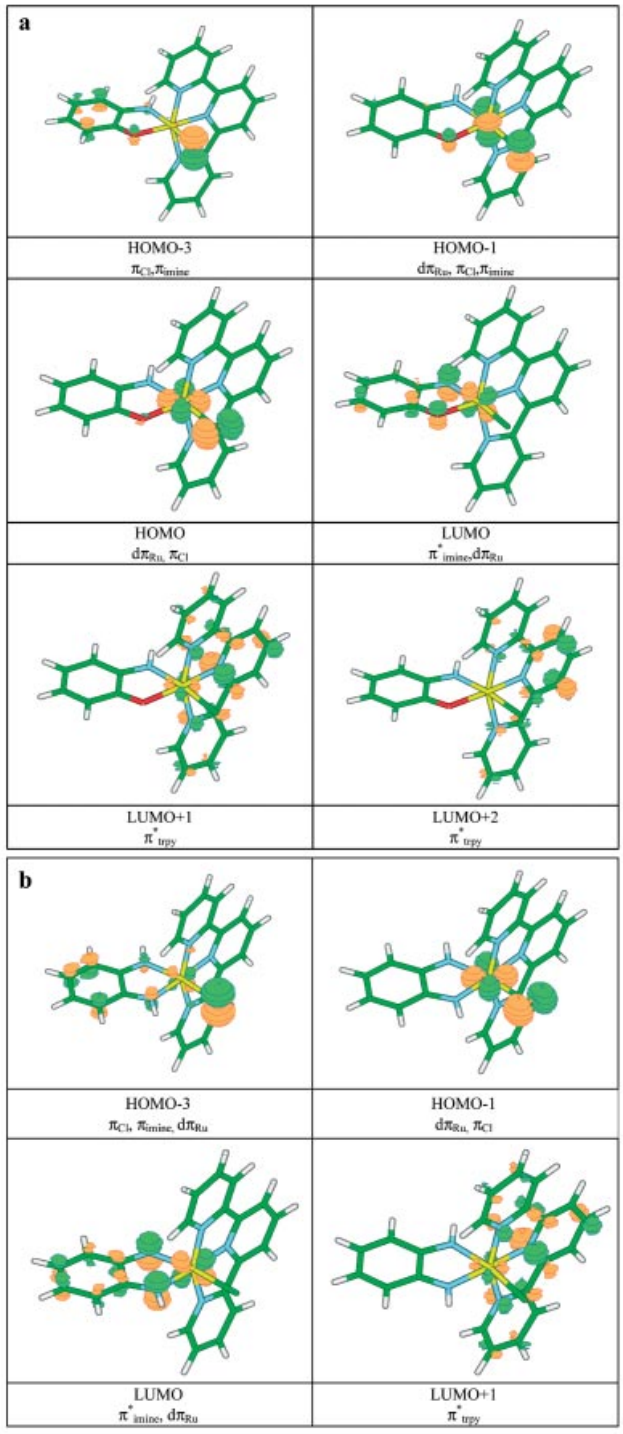

Figure 8. a) Kohn–Sham orbital contours of the frontier MOs of $\mathbf{1}^+$ involved in the intense long-wavelength transitions. b) Kohn–Sham orbital contours of the frontier MOs of $\mathbf{2}^+$ involved in the intense long-wavelength transitions.

increases to a greater extent upon reduction to **1**. The LUMO becomes primarily ligand centered and is composed mainly of $L^1$- (48%) and trpy-based (44%) orbitals along with less than 10% Ru contribution. However, the HOMOs are essentially dominated by L — the Ru/L contributions

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are 19/74 and 18/77%, respectively, for **1** and **2** (Tables S5 and S6).

It should be noted that the experimental results reported for similar molecules $[Ru^{III}(acac)_2(L_{Sq})]$ ($acac^-$ = acetylacetonate; L corresponds to X = O, Y = NH/X = S, Y = NH, Scheme 1) established the preferential involvement of $L_{Sq}$ in the oxidation and reduction processes, which leaves the unpaired spin on the ruthenium(III) ion.[3] However, the DFT-supported experimental results for the present molecules $\mathbf{1}^+$ and $\mathbf{2}^+$ demonstrate a metal-based first oxidation and first reduction, which leaves the resultant spin on the ligand center (L). Thus, the present study further emphasizes that ruthenium quinonoid systems of apparently similar chemical structures may exhibit substantial variations in their electronic features both in native and accessible redox states, which indeed justifies the need for further critical explorations with the newer molecular frameworks.

In conclusion, a combination of experimental and DFT results suggests the following: (i) the ground-state valence formulation of $[Ru(trpy)(Cl)(L^{1/2})]^+$ ($\mathbf{1}^+/\mathbf{2}^+$) can be best interpreted as spin-coupled $Ru^{III}$–$L_{Sq}$ in combination with a minority contribution from diamagnetic $Ru^{II}$–$L_Q$; (ii) the involvement of dπ(Ru)- and π(L)-based frontier orbitals, respectively, in the successive oxidation processes (couples I and II); (iii) the preferential involvement of Ru-based orbitals in the first reduction step (couple III), although the LUMO is calculated to be a mixture of dπ(Ru) (≈ 24%) and π*(L) (≈ 70%) orbitals; (iv) the primary participation of π*(trpy) orbitals in the subsequent second and third reductions (couples IV and V).

## Experimental Section

**Materials and Instrumentation:** The precursor complex $[Ru(trpy)Cl_3]$ was prepared according to the reported procedure.[29] 2,2′:6′,2′′-Terpyridine (trpy), *o*-aminophenol and *o*-phenylenediamine were procured from Aldrich, USA. Other chemicals and solvents were reagent grade and used as received. HPLC-grade solvents were used for spectroscopic and electrochemical studies.

UV/Vis spectral studies were performed with a Perkin–Elmer Lambda-950 spectrophotometer. FT-IR spectra were recorded with a Nicolet spectrophotometer with samples prepared as KBr pellets. Solution electrical conductivity was checked using a Systronic 305 conductivity bridge. $^1$H NMR spectra were obtained with a 400 MHz Varian FT spectrometer. The EPR measurements were performed with a Varian model 109C E-line X-band spectrometer fitted with a quartz dewar for measurements at 77 K. Cyclic voltammetric, differential pulse voltammetric, and coulometric measurements were carried out using a PAR model 273A electrochemistry system. Platinum wire working and auxiliary electrodes and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. The supporting electrolyte was $Et_4NClO_4$ and the solute concentration was around $10^{-3}$ M. The half-wave potential, $E°_{298}$, was set equal to $0.5(E_{pa} + E_{pc})$, where $E_{pa}$ and $E_{pc}$ are the anodic and cathodic cyclic voltammetric peak potentials, respectively. A platinum wire-gauze working electrode was used in coulometric experiments. All measurements were carried out under dinitrogen. The magnetic susceptibility was measured with a Faraday balance (CAHN Instruments Inc.; Serial no. 76240). Electrospray mass spectra were recorded with a Micromass Q-ToF mass spectrometer.

**$[Ru(trpy)(Cl)(L^1)]ClO_4$ (1-$ClO_4$) and $[Ru(trpy)(Cl)(L^2)]ClO_4$ (2-$ClO_4$):** These complexes were prepared by following the same general procedure. $[Ru(trpy)Cl_3]$ (100 mg, 0.226 mmol), *o*-aminophenol (24 mg, 0.220 mmol) or *o*-phenylenediamine (25 mg, 0.226 mmol), and $NEt_3$ (0.4 mL, 2.86 mmol) were taken in 20 mL of ethanol and the mixture was heated at reflux for 5 h under atmospheric conditions. The initial dark brown color changed to purple or red. The solvent of the reaction mixture was evaporated to dryness under reduced pressure. The solid mass thus obtained was dissolved in a minimum volume (5 mL) of $CH_3CN/CH_3OH$ (4:1) and reprecipitated by addition of a saturated aqueous solution of $NaClO_4$. The dark precipitate was filtered off and washed thoroughly with ice-cold water. The product was dried in vacuo over $P_4O_{10}$. It was then purified on an alumina (neutral) column. The purple or red product was eluted with $CH_2Cl_2$/$CH_3CN$ (1:1). Evaporation of the solvent under reduced pressure afforded the pure complexes.

**1-$ClO_4$:** Yield: 55 mg (42%). $C_{21}H_{16}Cl_2N_4O_5Ru$: calcd. C 43.73, H 2.80, N 9.72; found C 43.56, H 2.87, N 9.51. Molar conductivity in acetonitrile: $\Lambda_M$ = 110 $\Omega^{-1}cm^2M^{-1}$. $^1$H NMR [400 MHz, $(CD_3)_2SO$, 298 K]: $\delta$ = 15.31 (s, 1 H, NH), 8.85 (d, $J$ = 7.6 Hz, 2 H), 8.72 (d, $J$ = 7.6 Hz, 2 H), 8.34 (t, $J$ = 8.4, 8.0 Hz, 1 H), 8.16 (m, 3 H), 7.89 (d, $J$ = 9.2 Hz, 1 H), 7.54 (t, $J$ = 6.4, 6.0 Hz, 2 H), 7.43 (d, $J$ = 5.6 Hz, 2 H), 7.27 (d, $J$ = 8.8 Hz, 1 H), 7.02 ppm (t, $J$ = 6.4, 7.2 Hz, 1 H). **X-ray Crystallography:** Single crystals of **1**-$ClO_4$ and **2**-$ClO_4$ were grown by slow evaporation of their 1:1 acetonitrile/methanol and 1:1 acetonitrile/toluene solutions, respectively. Diffraction data for **1**-$ClO_4$ and **2**-$ClO_4$ were collected with Enraf–Nonius CAD-4 (MACH-3) and OXFORD XCALIBUR-S CCD single-crystal X-ray diffractometers, respectively. The structures were solved and refined by full-matrix least-squares techniques on $F^2$ using SHELX-97.[30] The absorption corrections for **1**-$ClO_4$ and **2**-$ClO_4$ were done by psi-scans and multi-scans, respectively. All the data were corrected for Lorentz and polarization effects, and the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the refinement process as per the riding model. See Table 6 for further details.

Table 6. Crystallographic data for **1**-$ClO_4$ and **2**-$ClO_4$.

| | (**1**-$ClO_4$) | (**2**-$ClO_4$) |
|---|---|---|
| Formula | $C_{21}H_{16}Cl_2N_4O_5Ru$ | $C_{21}H_{17}Cl_2N_5O_{4.50}Ru$ |

CCDC-606479 (for **1**-$ClO_4$) and -606480 (for **2**-$ClO_4$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** Full geometry optimizations of $\mathbf{1}^+$ and $\mathbf{2}^+$ were carried out using the density functional theory method at the (U)B3LYP level.[31a,31b] All elements except ruthenium were assigned the 6-31G* basis set. The SDD basis set with effective core potential was employed for the ruthenium atoms.[31c,31d] Calculations were performed with Gaussian 98 and Gaussian 03.[31e,31f] Vertical electronic excitations based on the B3LYP-optimized geometries were computed using the time-dependent density functional theory (TD-DFT) formalism,[31g] with the B3LYP functional using the above combination of basis sets. Natural population analysis was performed using the NBO 3.1 program package as implemented in Gaussian98.[31h,31i] The spin densities of complexes were computed using the CUBE option as implemented in Gaussian 03. Visual inspection of the key orbitals was done with MOLDEN,[31h] to assign the nature of the various electronic transitions. Molecular orbital compositions were analyzed using the AOMIX program.[31i,31j]

**Supporting Information** (see also the footnote on the first page of this article): Optimized coordinates (Table S1), excitation energies (Tables S2/S3/S4), MO compositions (Tables S5/S6), mass and NMR spectra (Figures S1/S2), spin densities (Figure S3), Kohn–Sham orbitals (Figures S4/S5).

## Acknowledgments

Financial support received from the Department of Science and Technology and Council of Scientific and Industrial Research, New Delhi, India is gratefully acknowledged. X-ray structural studies for **1**-$ClO_4$ and **2**-$ClO_4$ were carried out at the National Single Crystal Diffractometer Facility, Indian Institute of Technology, Bombay. Special acknowledgment is made to the Sophisticated Analytical Instrument Facility (SAIF) and the Computer Center, Indian Institute of Technology, Bombay, respectively, for providing the EPR and computational facilities.

# Bonding Properties Related with Chiral Discrimination in Dinuclear Metal Complexes of Group 10

**Oscar Picazo,[a] Ibon Alkorta,*[a] José Elguero,[a] Markku R. Sundberg,*[b] and Jaana Valo[b]**

**Keywords:** Ab initio calculations / Coordination chemistry / Chiral discrimination / Bonding properties / *trans* influence

A series of neutral dinuclear homo- and heterochiral complexes formed by hydrazine (a molecule with axial chirality), a metal atom of group 10 (Ni, Pd, Pt), and halogen atoms (F, Cl, Br, I) was studied by computational methods including density functional theory. In the optimized structures the heterochiral complexes were always found to be energetically favored. The chiral discrimination depends on the contributions coming from the metal atoms and the halogen anions attached to them. Moreover, the relative energies of the optimized complexes are correlated with the electronegativity of the metals and the halogens as well as with the relative distances of the bond critical points in the metal–nitrogen bonds. Also the smaller deviation of the ligand–metal–ligand angles from the ideal value of 90° corresponds to the heterochiral complexes. An analysis of the bonding properties reveals a complex mechanism for the behavior of the electron lone pairs of the nitrogen and halogen atoms. The electronic properties of the optimized complexes were studied by NBO (Natural Bond Orbital) and QTAIM (Quantum Theory of Atoms in Molecules) methods. An NBO analysis of the energy differences between the stabilizing energies related to the interactions between an electron lone pair of the coordinated nitrogen atom and the opposite M–X antibonding orbital explain the differences of the total energies between the diastereomeric heterochiral and homochiral complexes. The stabilizing energies have systematically more negative values in the heterochiral complexes; this can be interpreteted as a measure of the *trans* influence. Small energy values related to the *cis* influence were found mainly in the nickel complexes. The M–N bonds in the heterochiral complexes are more polar with a higher bond order than that in the homochiral ones, as shown by QTAIM methods.

## Introduction

In order to understand the chemical properties of a compound it is necessary to know not only the structure, but also the electronic properties and their mutual relationship. Computational methods offer a means to elucidate both aspects. We employ here DFT (Density Functional Theory) calculations to evaluate the structural and electronic characteristics of dinuclear hydrazine complexes formed by group 10 metals displaying chiral discrimination. To understand the correlations between structural and electronic properties in metal complexes it is necessary to consider concepts related with the deformations in the coordination polyhedra.

Chiral recognition is an important concept in many chemical processes, for which nonlinear effects in asymmetric synthesis and stereoselective reactions are some examples.[1] Peroxides and hydrazine present axial chirality with low racemization barriers.[2,3] The presence of different chiral molecules of hydrazine has been used to explain the experimental results of clusters in the gas phase.[4] A topic that has received only a limited experimental interest so far is chiral biodiscrimination based upon axial chirality. As an example, mutations at the putative distal site of cytochrome P450 have been shown to be dependent on axial chirality.[5]

The factors leading to chiral discrimination have been computationally studied only a few times in metal complexes or related systems. The effect of fluoro substitution on the chiral discrimination has been discussed in bis(diphenylborate)s and isoelectronic structures.[6] In addition, 1:1 and 2:1 complexes of chiral bis(5*H*-pyrrole)s and bis(oxazoline)s with the lithium cation have been shown to favor the heterochiral complexes, except for the *tert*-butyl derivatives.[7]

The *trans* influence, also called structural *trans* effect, is one of the key concepts in understanding the structure-bonding relation in metal complexes.[8] The concept involves the idea that a bond *trans* to a donor atom should be longer and weaker than that in a *cis* position. The influence has been evaluated by using statistical methods applied

to existing structural data[9] by using a theoretical approach[10] as well as computational methods.[11–14] Related to the *trans* influence there is also an analogous *cis* influence. Their mutual relative magnitude is obviously dependent on the electron configuration of a central metal atom.[9]

In an earlier study on (phosphane)molybdenum complexes[12] the amount of *trans* influence was found to be dependent on the angular distortion on the coordination sphere and consequently on the overlap between the metal d orbital and the phosphane σ* orbitals. The importance of the electronic occupation on antibonding orbitals was established earlier by Burdett and Albright.[11] A correlation between the *trans* influence and bond order values was found in *cis*-dichloridobis(triphenylstibane)platinum.[15] Interestingly, the *trans* influence has been shown to have an important role in creating new $Pd^{II}$ complexes with nonlinear optical properties.[16]

In general, the geometry around a central metal atom in the complexes is dependent on the electronic properties. Among the concepts to be taken into account are the Jahn–Teller effect, the pseudo-Jahn–Teller effect, and Bent's rule. In our case, only the last concept might be relevant, since the planar complexes of the group 10 metals do not have an electronic configuration involving unpaired electrons.

There have been discussions about the applicability of Bent's rule on transition metal complexes. When applied to the main group elements, Bent's rule states that the more electronegative substituents are related with more central-atom p-orbital character resulting in smaller angles, whereas the less electronegative subsituents obtain more s-orbital character and consequently wider angles.[17] However, the bonding in transition metal complexes involves not only s- but essentially also d-orbitals, and thus the situation is essentially different.[18] Although Bent's rule has been reformulated by Frenking et al.,[19] it seems that Bent's rule will be of limited use for transition metal complexes.[20]

The studied complexes are related to *cis*-platinum and the newly described asymmetric *trans*-platinum(II) complexes, which have shown anticancer activity.[21] In addition, hydrazine in the presence of manganese and copper ions has been evaluated for site-specific DNA damage.[22] On the other hand, both platinum and palladium have the propensity to form dinuclear complexes.[23] The idea surrounding the synthesis of hydrazine-bridged dinuclear platinum complexes is that they should be able to crosslink two adjacent bases of DNA without bending the double helix.[24] Some dinuclear platinum complexes containing N-mediated bridges have been shown to be cytotoxic.[25,26] However, none of these contained two similar bridges. In our preliminary communication we have shown, by computational methods, how the doubly hydrazine-bridged dinuclear complexes formed by halogens and group 10 metal cations display axial discrimination.[27]

In this paper we study the electronic properties of the doubly bridged hydrazine complexes in more detail by using computational methods. The basic question related to our work is whether electronic properties could explain the differences in the energies between the diastereomer homochiral and heterochiral complexes. Special emphasis was placed on the importance of the electron lone pairs of the coordinated atoms and their role in complex formation.

## Results and Discussion

### 1. Energy

The complexes under study are dinuclear with two neutral hydrazine molecules acting as bridges. The planar coordination sphere around each metal atom of group 10 (Ni, Pd, Pt) is formed by two nitrogen atoms of two hydrazine molecules and two halogen atoms (F, Cl, Br, I). The axial chirality (noted as subscript a) of hydrazine results in two diastereomeric complexes, namely homochiral [($R_a$/$R_a$) or ($S_a$/$S_a$)] and heterochiral [($R_a$/$S_a$) or ($S_a$/$R_a$)] complexes. Hereafter, the notifications *RR* and *RS* will be used for the homochiral and heterochiral enantiomers, respectively.

The optimized geometry of the complexes presents $D_2$ and $C_{2h}$ symmetry for all the homochiral and heterochiral cases, respectively. Typical structures are shown in Figure 1.

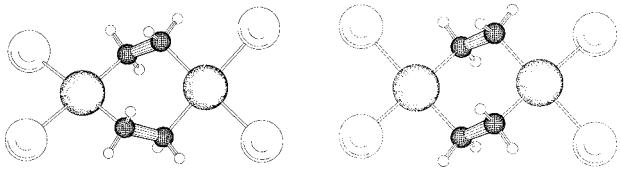

Figure 1. The *RS* (left) and *RR* (right) diasteromers of dinuclear metal complexes formed by hydrazine molecules and halogen atoms.

The energies for the optimized complexes at the B3LYP/LANL2DZ level of theory are shown in Table 1, as well as the relative energies, $E_{rel}$. The relative energy $E_{rel}$ is defined as $E_{rel} = E_{RS} - E_{RR}$.

In all the hydrazine derivatives the heterochiral complexes are favored over the homochiral ones, with energy differences that range between 1.4 and 3.8 kcal/mol. As the size of the metal atom increases the differences also increase; the opposite takes place with the size of the halogen atoms, the largest differences are found for fluorine and the smallest for iodine for a given metal complex. Although the differences are relatively small, it is possible to see some trends by using statistical methods, as shown below.

A Free–Wilson correlation[28] [Equation (1)] was found between the presence/absence of each metal and halogen atom and the relative energy of the homo-/heterochiral pairs. The underlying hypothesis in a Free–Wilson approach is the independence of the effects of halogens and metals. In the equation the coefficient corresponding to the presence of Pt has been arbitrarily fixed to 1 and thus the rest of the contributions can be compared. The coefficient for each variable provides the energy contribution to the chiral selectivity in each pair using as a reference the homochiral system. It must be underlined that the Free–Wilson method gives no direct physicochemical interpretation.

| $PtBr_2$ | *RS* | –514.964730 | –2.716 |
| $PtI_2$ | *RR* | –507.847389 | 0 |
| $PtI_2$ | *RS* | –507.851357 | –2.491 |

$$E_{rel}\,[\text{kcal/mol}] = -4.89(\text{F}) - 4.03(\text{Cl}) - 3.69(\text{Br}) - 3.45(\text{I}) + 2.10(\text{Ni}) + 1.80(\text{Pd}) + 1.00(\text{Pt}) \quad (1)$$

The statistical $r^2$ value in Equation (1) is 0.996. The coefficients for the halogens are always negative and for the metals positive. Moreover, the absolute values of the weights for the halogen atoms are larger than those of the metal atoms. The smaller and more electronegative a counter anion is, the larger its negative weight will be. Such a clear relation between the coefficients of Equation (1) and the electronegativity values for the group 10 metal atoms does not exist.

The energy differences are also strongly correlated with the electronegativity values of the participating metals and halogens [Equation (2), where $\chi$ refers to the Pauling electronegativity values recalculated by Allred[29]].

$$E_{rel} = 4.13 - 1.11\chi\text{Hal} - 1.29\chi\text{Met} \quad (2)$$

The $r^2$ value for the correlation is 0.991. According to the original idea of Linus Pauling, electronegativity describes the electron-withdrawing capacity of an atom. It is clear that the electron-withdrawing capacity must be distance-dependent. Therefore, we may assume at this stage that the relative energies should correlate with the M–L bond lengths.

Both of the equations contain parameters that are isotropic. However, we may well assume that the energy differences should be because of the differences in bonding in the complexes. On the other hand, the bonds have a directionality, thus destroying the spherical symmetry. Therefore, the bonds and their properties should be examined.

The parameter connected with the deformation of spherical symmetry is the bond angle. Selected bond angles of the optimized complexes are gathered in Table 2 in which there are two additional parameters displayed. The first one, Σdef, gives the sum of the absolute values of the deformation of the angles from the ideal value of 90°. The second one, ΔΣdef, is the difference between the Σdef values between the heterochiral and homochiral complexes.

Table 2. Selected geometrical parameters of the hydrazine complexes optimized at the B3LYP/LANL2DZ level (bond lengths in Å, bond angles and dihedral angles in °).

| Fragment | Chirality | X–M–X | N–M–N | X–M–N | Σdef | ΔΣdef |

The ΔΣdef values are always negative (between –1.30 and –3.19°) meaning that the angles are closer to the ideal value of 90° for the heterochiral complexes. It is important to note that for the dications of the group 10 metals the empty d-orbital is the $d_{x^2-y^2}$. This orbital is used in the bond formation between a metal cation and the four ligand atoms. The plausible explanation for the relative stability of the heterochiral complexes is obviously the bigger overlap between the metal $d_{x^2-y^2}$-orbital and the electron lone pairs of the ligand atoms.

There are also some trends in the bond lengths. In the first two families (Ni and Pd) and for each pair of complexes the homochiral metal–halogen bond length is slightly shorter than the heterochiral one. Interestingly, the$M–N bond lengths tend to have larger values in the Pd and Pt complexes, whereas in the nickel complexes no trend can be seen. For all the metals studied here, the shortest M–X distances correspond to X = F, followed by Cl, Br and the longest ones are with I. This ordering is in accordance with the covalent radii of the halogen atoms and electronegativ-

ity scale of the X atoms. There is a correlation between the M–X and M–N bond lengths, which is shown in Figure 2.

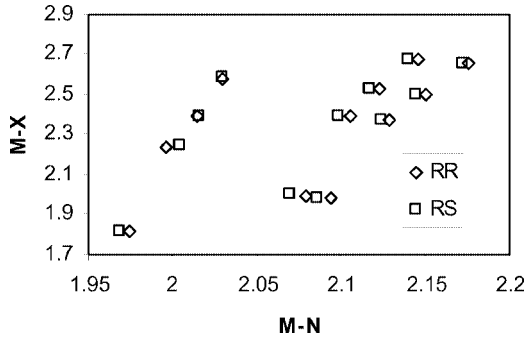

Figure 2. Scatter plot displaying the M–X vs. M–N bond length [Å]. There are six almost linear correlations to be seen, three of them corresponding to the *RS* and three to the *RR* families. From left to right the order is Ni, Pt, and Pd.

If the chirality is not taken into account, the analysis of the metal–halogen vs. metal–nitrogen bond lengths for the analogous complexes show good correlations for every metal family ($r^2$ values of 0.99 and higher).

It was not possible to establish any correlation with the relative energies and the M–L bond lengths, however, although this was expected based on the reasoning related to Equation (2). It is very important to note, however, that in the heterochiral complexes the M–N bond lengths have the propensity to be shorter than in their homochiral analogs. The opposite holds for the M–X bond lengths.

Owing to the different point groups, there are also differences in the torsional angles related to the hydrazine molecules. The homochiral and heterochiral complexes can be divided into two categories based on the torsional angles X–M–N–N and X–M–N–$H_{eq}$. Furthermore, there is a strong linear correlation between the torsional angles, as seen in Figure 3.

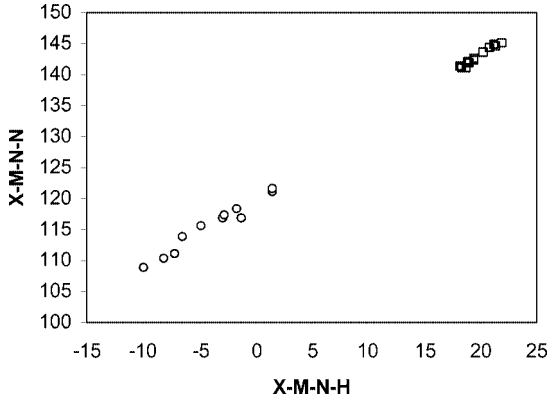

Figure 3. Scatter plot of the X–M–N–N and X–M–N–H torsional angles (in °). The hydrogen atom refers to that in the equatorial position. The spheres refer to the heterochiral complexes and the squares to the homochiral diasteromers.

## 2. Electronic Properties

To explain the differences in energy for the hetero- and homochiral complexes it is necessary to study the influence of the electron lone pairs of the coordinated atoms. To obtain qualitative numerical values to characterize the influence both QTAIM and NBO methods were employed. Since both N–M–N angles and M–N bond lengths are relatively strongly affected by the central metal atom and the halogen atoms, special emphasis was laid on the bonding properties of the M–N bonds.

### *2.1 Topological Analysis of Charge Density*

In QTAIM theory a bond between two atoms is characterized by a line of maximum electron density (i.e. the bond path), which connects the two nuclei and intersects a zero-flux surface in the gradient field at a (3,–1) saddle point (i.e. the bond critical point). There are several descriptive parameters at the bond critical point that can be used to characterize the interaction between two atoms. These are the electron density $\rho(r)$ and its Laplacian $\nabla^2\rho(r)$. The Laplacian of the electronic charge density characterizes the two extreme conditions: either the charge density is locally concentrated [$\nabla^2\rho(r) < 0$] or it is locally depleted [$\nabla^2\rho(r) > 0$]. In the former case the bond has a covalent character, whereas in the latter case the interaction can be understood in terms of a closed-shell interaction. The eigenvalues $\lambda_1$, $\lambda_2$, and $\lambda_3$ of the Hessian describe the curvature of the gradient field at the bond critical point. The ellipticity $\varepsilon$ of a bond is defined as $\varepsilon = \lambda_1/\lambda_2 - 1$. Furthermore, the local electronic energy density $E_d(r)$ is the sum of the local kinetic and potential energy density, $E_d(r) = G(r) + V(r)$. A detailed discussion of the parameters can be found in ref.[27] Descriptive QTAIM parameters related to the bond critical points for the M–N bonds are given in Table 3.

The M–N bonds are all polar bonds, as is the case usually with the coordinate bonds.[31] This is seen in the positive Laplacian [$= \nabla^2\rho(r)$] values, which indicate charge depletion in the bond critical points. The charge depletion is clearly seen in Figure 4 where the negative Laplacian contour plot is given for the heterochiral $[NiF_2(hydrazine)]_2$ compound.

The ratio $|\lambda_1|/\lambda_3$, which is expected to be smaller than 1 in ionic bonds,[30a] shows very small values. As will be shown in the discussion related with the NBO results the coordinated nitrogen atoms carry a significant negative charge. Accordingly, the bonds also have a significant ionic nature. The potential electronic energy density dominates the kinetic electronic energy density at the bond critical points, and thus all $E_d(r)$ values are negative, thus indicating sharing of charge.[30a]

There is also an interesting difference seen in the coordination of fluorine and nitrogen in Figure 4. Both nitrogen atoms have an electron lone pair pointing approximately towards the central nickel atom, whereas the fluorine atoms have an almost isotropic distribution of the Laplacian of the charge density. This phenomenon will be discussed later on in more detail in connection with the NBO analysis.

It has been shown by Matta and Hernandez-Trujillo that there is a linear correlation between bond order and ellipticity.[32] As seen in Table 3, the ellipticity values always have larger values for the M–N bonds in the heterochiral

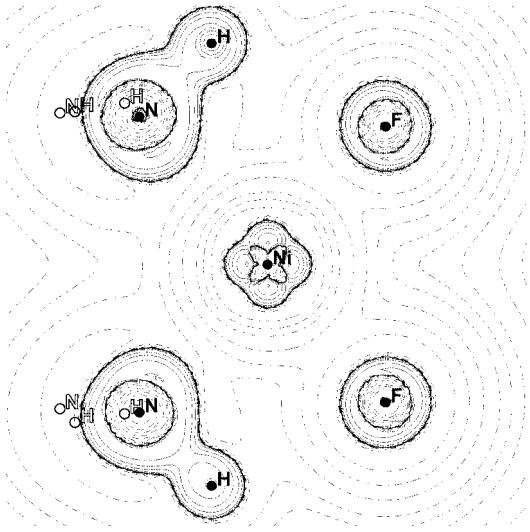

Figure 4. Laplacian contour map for *RS*-$[NiF_2(hydrazine)]_2$ (solid black line refers to positive values and the dotted ones to negative values of the Laplacian).

complexes, thus indicating a higher bond order in these bonds.

The only significant correlation to explain the relative energy $E_{rel}$ with the parameters at the bond critical points was found with the relative distance $D_{rel}$ of a bond critical point from a metal atom ($D_{rel} = D_{RR} - D_{RS}$) in the M–N bonds. The equation of the fitted model is Equation (3).

$$E_{rel} = -2.474 - 2374D_{rel} \quad (3)$$

Since the $P$ value in the ANOVA (Analysis of Variance)[33] result is less than 0.05, there is a statistically significant relationship between $E_{rel}$ and $D_{rel}$ at the 95% confidence level. The $r^2$ statistic indicates that the model as fitted explains 89.3% of the variability in $E_{rel}$. The correlation coefficient equals –0.945, indicating a relatively strong relationship between the variables.

The differences between the positions of the bond critical points are thus correlated with the energy differences. The longer the distance of the bcp from a metal atom in an *RR* complex is with regard to the point in an *RS* analog, the more favored the *RS* complex will be in terms of energy. This is in accordance with the finding that the bond order is higher in the *RS* diastereomers.

### *2.2 NBO Analysis*

To obtain a wider insight into the influence of the halogen ions on the M–N bonds and especially on the relative stabilities of the diastereomers we carried out additional analyses employing NBO methods.

There were no differences in the electronic configurations for the metals between different diastereomers. (The hybridization of the metals varied depending on the counter anion and metal species itself.) Thus, we may say that Bent's rule does not seem to play any significant role in explaining chiral discrimination. NBO charges for the metal, nitrogen, and halogen atoms are shown in Table 4.

The metal atom charges tend to have larger values in the heterochiral complexes than in their homochiral diastereomers. This tendency increases concomitantly with increasing $Z$. The highest absolute values are found for the nickel complexes and the lowest ones for the platinum complexes. The range of the charges goes from 0.3210 to 0.9889. The range for the halogen atom charges is also quite wide, from –0.3254 to –0.6567. The charge is always more negative in a heterochiral complex. The charges of the nitrogen

atoms vary considerably less, the range being from –0.6921 to –0.7487. Again there is a difference between the heterochiral and homochiral complexes; in the former ones the halogen charges are more negative than in the latter ones. This means that the M–X bonds in the heterochiral complexes have more ionic character than in the homochiral diastereomers.

To study the M–N bonds in more detail, an NLMO analysis was carried out. (A full description of the electron lone pair compositions is given as Supporting Information.) There was a profound difference between the halogen and nitrogen atoms. The nitrogen atoms clearly showed the expected hybridization, but the halogen atoms did not. In the halogen atoms the electron lone pair participating in the coordination to the metal atom always had a clear p-orbital character. The main components of the nitrogen lone pairs are given in Table 5.

According to the results, the electron lone pair of nitrogen in terms of the NLMO consists only partly of the localized electron lone pair of nitrogen but also of the halogen *trans* to the nitrogen and the metal atom. The electron lone pair is systematically more delocalized in the heterochiral complexes. The interpretation of the delocalization can be expressed by two different mechanisms. In the case of the metals, the delocalization can be interpreted simply by covalency of a metal–nitrogen bond, which is higher in the M–N bonds of the heterochiral complexes. As for the halogens, their contribution is opposite to the mechanism of the *trans* influence, where the electron transfer should take place to an antibonding orbital. In our case the stabilizing energy found for this contribution is less than 0.1 kcal/mol. Instead, the contribution can be explained in terms of 3c–4e bonding. The NBO analyses were not able to directly find the M–N or X–M–N bonds because of the pronounced polarity of these bonds, and an illustration (Figure 5) for the formal M–N bonding orbital produced by NBOView corroborates this assumption. Furthermore, the interactions are found in the NLMO listings.

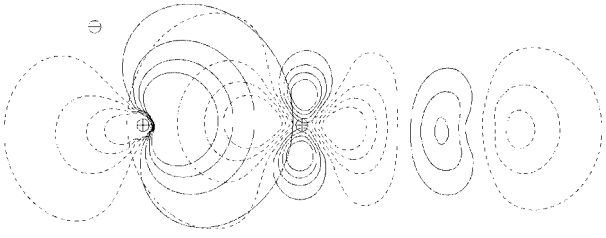

Figure 5. NBO contour plot illustrating the interaction between an electron lone pair of nitrogen with an antibonding Pd–Cl orbital in *R*,*R*-bis[($\mu_2$-hydrazine)$PdCl_2$].

To evaluate the role of the *trans* and *cis* influence, we carried out a second-order perturbation theory analysis of the Fock matrix with the NBO basis set. There are several charge transfers to be taken into account. These involve the charge transfer from the lone pair of nitrogen and a lone pair of halogen. In the former case the charge transfer takes place to an antibonding molecular orbital of the halogen atom *trans* to the nitrogen atom. The NBO delocalization energies were computed based on the deletion of off-diagonal elements between M–X bond orbitals and lone pairs of the nitrogen atom. There are some (mainly nickel) complexes, where there is a small but significant additional charge transfer to an antibonding molecular orbital of the halogen atom *cis* to the nitrogen atom. In the former case the related stabilization energy is defined as $E_{trans}$, and in the latter case $E_{cis}$. Furthermore, we shall use, for compari-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

son purposes, an additional parameter, $\Delta E_{trans}$, which is the difference between the stabilizing energies of the heterochiral and homochiral pairs. As for the charge transfers involving a lone pair of the halogen, there are two different antibonding orbitals that receive the charge, namely antibonding N–N and N–$H_{equatorial}$ molecular orbitals. In both cases the atoms involved are vicinal to the halogen atom. The related stabilizing energies are given as $E_{XNN}$ and $E_{XNH}$ [kcal/mol]. The values are shown in Table 6. Interestingly, there is no charge transfer from the coordinated electron lone pair to an antibonding M–N molecular orbital *trans* to the halogen atom.

The results clearly show that there is always a charge transfer from a nitrogen lone pair to an antibonding M–X molecular orbital with a marked stabilization energy involved. Furthermore, the stabilization energy is always larger in the heterochiral complexes. There is also a correlation between the relative stabilization energies $\Delta E_{trans}$ and the relative total energies ($E_{rel}$), as shown in Figure 6. The $r^2$ value for the linear correlation is 0.854.

The $E_{XNN}$ and $E_{XNH}$ stabilization energies are clearly different in heterochiral and homochiral complexes. However, the effects are reversed so that the stabilizing energies $E_{XNN}$ have larger values for homochiral complexes while the opposite holds true for the $E_{XNH}$ values. Furthermore, the values tend to cancel out each other pairwise leaving $E_{trans}$ to act as an explaining factor described in Figure 6.

The differences between the relative stabilization energies are obviously due to the different geometries caused by different orientations of the hydrazine molecules in the homo-

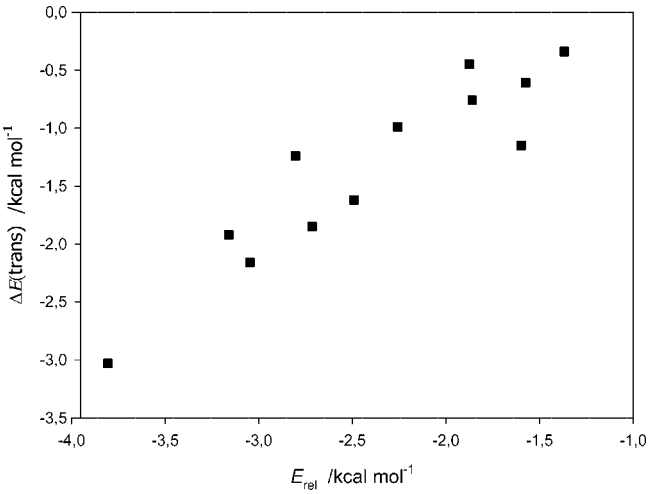

Figure 6. Scatter plot showing the correclation between the relative total energies $E_{rel}$ and the relative stabilization energies indicating the *trans* influence.

and heterochiral complexes. This might also give a plausible explanation for the differences in the bond order and covalency of the M–N bonds. In the heterochiral complexes the values are higher, which might be explained by the smaller charge transfer into antibonding orbitals of the nitrogen atom. Furthermore, the different orientations also result in different L–M–L angles in the coordination spheres. In the heterochiral complexes the deviations are smaller leading to enhanced overlapping of the metal $d_{x^2-y^2}$-orbital and the electron lone pairs of the ligand atoms.

There is also a charge transfer from an electron lone pair of the nitrogen atom to another M–X antibonding molecular orbital. The stabilizing energies related to this *cis* influence are more than ten times smaller than the respective energies related to the *trans* influence in the nickel complexes. In the palladium and platinum complexes no *cis* influence was found, with the exception of the compounds composed of palladium and fluorine. Presumably, the *cis* influence might be correlated with the differences concerning the nickel complexes presented in Figure 3.

To conclude, we have shown that the electron lone pairs of the coordinated ligand atoms have a marked yet complicated role in bonding, and have not been properly considered in some important previous studies concerning bonding to platinum.[34]

## Conclusions

Based upon the optimizations carried out at the B3LYP/LANL2DZ level of theory, the heterochiral complexes are more stable than the homochiral ones. The relative stability is correlated with the nature of both the metals and the anions. Moreover, the relative stability is correlated with the electronegativity values of the metals and the halogens. The QTAIM and NBO results indicated that the M–X bonds have marked ionic character with the halogen atoms show-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing no hybridization. The coordinate M–X bonds are formed by an electron pair resting essentially on a p-type orbital of a halogen. Another profound difference is that the halogen atoms do not show any marked charge transfer to an antibonding M–N molecular orbital related to the *trans* influence. Instead, the contribution is seen in the composition of the electron lone pair of the nitrogen atom *trans* to the halogen atom. In sharp contrast to this, there is always a marked stabilization energy for the charge transition from the electron lone pair of nitrogen to an antibonding M–X orbital *trans* to the nitrogen atom. The M–N bonds formed formally by the electron lone pair of nitrogen also contain a contribution from the metal atom, thus indicating covalency of the bonds. The covalency, as well as the bond order, have a larger contribution in the M–N bonds of the heterochiral complexes. There is also a correlation between the relative distance of the bond critical points in the M–N bonds and the relative energy.

Although there are no experimental structures available, which could corroborate the calculated chiral discrimination, we feel confident that the predicted trends are correct.

## Computational Methods

The geometries of the compounds were optimized by applying DFT methods and using Becke's three-parameter hybrid exchange functional in combination with the gradient-corrected correlation functional of Lee, Yang, and Parr.[35] The basis set applied in every calculation was LANL2DZ to include the relativistic effect.[36] The presence of true energy minima were checked by frequency calculations. No imaginary frequencies were found for the optimized structures. For every nickel complex it was necessary to check the stability of the wave function to see whether any instability existed from unrestricted contributions. We found instability in every case. After the check, the wave function was optimized to remove the contributions. The structures were then reoptimized using the optimized wave functions, their wave function stabilities rechecked, and frequencies recalculated. The calculations were carried out with the Gaussian 03 program suite.[37] The electronic properties were evaluated by QTAIM (Quantum Theory of Atoms in Molecules)[38] and NBO (Natural Bond Orbital) methods.[39] The NBO program used was the version installed in Gaussian 03. The QTAIM-based programs were MORPHY98,[40] AIMPAC,[41] and AIM2000.[42] We verified that similar geometries were obtained for some test cases using the Turbomole[43] program at the B3LYP/TZVP level of theory. Accordingly, the inclusion of polarization does not result in significant changes.

# Aminoalkylbis(phosphonates): Their Complexation Properties in Solution and in the Solid State

Vojtěch Kubíček,*[a] Jan Kotek,[a] Petr Hermann,[a] and Ivan Lukeš[a]

**Keywords:** Phosphonates / Complexation / Stability constants / Potentiometry

Five geminal bis(phosphonates) containing an amino group in the α, γ or δ position of the carbon chain have been synthesised and their acid–base and complexation properties with $Cu^{2+}$, $Zn^{2+}$, $Ca^{2+}$, $Mg^{2+}$ and $Na^{+}$ ions studied by potentiometry. Determination of the stability constants of the complexes with divalent metal ions is complicated by the formation of precipitates. The results of these studies show a negligible effect of the hydroxo group in the α position on the acid–base and complexation properties of the ligands. The presence of an amino group in the α position, however, decreases the basicity, which results in a lower complexation ability of the bis(phosphonates). The crystal structures of the three ligands with different degrees of protonation have also been determined. The structure of the triammonium salt of aminomethylbis(phosphonic acid) shows that the proton is bound to the nitrogen atom in monoprotonated species. The structure of the $Cu^{2+}$ complex of pamidronate $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$ shows the presence of dimeric units with a relatively short distance (2.99 Å) between the metal centres. These units form a coordination polymeric chain.

## Introduction

Pyrophosphate is an important regulator of calcium metabolism in living organisms. Replacement of the bridging oxygen atom of pyrophosphate with methylene or a substituted methylene group results in the formation of geminal bis(phosphonic acids), hereafter referred to simply as bis(phosphonates). This group of compounds has been intensively studied over the last fifty years. As the central carbon atom can be substituted with many different organic groups, a huge number of bis(phosphonates) have been synthesised. Their low toxicity, high biological stability (they are not metabolized) and high affinity for calcium and calcified tissues have made them suitable for many biomedical applications.[1] After adsorption on the bone surface, bis(phosphonates) can affect the functioning of bone cells such as osteoclasts and osteocysts, which are responsible for bone formation and desorption. Because of this, bis(phosphonates) can be used in the treatment of osteoporosis, Paget disease and other diseases of calcified tissues. The large variability of bis(phosphonates) provides a wide scope of therapeutic effects, and some of the bis(phosphonates) used therapeutically nowadays are shown in Table 1. Bis(phosphonates) form complexes with divalent and trivalent transition metal ions, and these complexes have been applied in bone radiotherapy and for palliation of pain associated with metastatic bone cancer.[1]

Recently, attention has been paid to tissue-specific imaging and therapy. Attachment of a biologically active molecule to a molecule of contrast agent results in the binding of such species to specific tissue and increases their local concentration. This provides a better contrast and leads to the use of lower doses of the contrast agents and therapeutic agents. In these applications, bis(phosphonates) can play the role of a targeting group as their conjugate with the medically active molecule can be swiftly and strongly adsorbed on the surface of bones and other calcified tissues.[2,3] Recently, we have contributed to this field by studying the bis(phosphonate)-modified macrocyclic ligand $H_4$dota (1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid), which is useful for targeted visualisation of calcified tissues by magnetic resonance imaging (MRI) or other radiodiagnostic/therapeutic treatment.[4]

Most of the clinically used bis(phosphonates) contain an amino group in the carbon chain. These aminoalkylbis(phosphonates) strongly complex transition metal ions. Despite this fact, only a few studies have concentrated on their acid–base and complexation properties,[5–13] and generally only protonation constants have been determined. In the case of some ligands, their complexing behaviour with $Cu^{2+}$ ions has also been studied.[5,6,11,13] Unfortunately, the reported results are not always consistent. Some of the dissociation/protonation constants are beyond the lower or higher limits of the applied methods and, therefore, they were not determined. Furthermore, most of the studies were performed in presence of $Na^{+}/K^{+}$ ions.[5,6,9–13] As these ions are complexed by the bis(phosphonates),[14,15] all reported values of dissociation/protonation and complex stability

constants are disturbed by the formation of such complexes.

In light of this we decided to use the non-complexing tetramethylammonium cation in the supporting electrolyte to avoid alkali metal complex formation. In this work, we report on the results of a solution study of four bis(phosphonates) containing an amino group in the side chain. Furthermore, as the bis(phosphonate) moiety is often connected by a peptidic bond in the bifunctional ligands, we chose a new amide derivative $H_4$aca as a model compound for comparison (Figure 1). The protonation constants and stability constants with $Cu^{2+}$, $Zn^{2+}$, $Ca^{2+}$, $Mg^{2+}$ and $Na^+$ ions are presented. The crystal structures of three ligands and one $Cu^{2+}$ complex have also been determined by single-crystal X-ray diffraction analysis.

## Results and Discussion

### Acid–Base Properties

Phosphonic acids undergo their first deprotonation in the strongly acidic ($pK_1 \leq 2$) and the second one in the weakly acidic region ($pK_2$ = 5–6).[16] A different situation occurs in the case of bis(phosphonates), where a strong electrostatic interaction between the two geminal phosphonic acid groups results in a large enhancement of the basicity of the moiety. Furthermore, the presence of an amino group brings another protonation site into the molecule, which affects the other protonation constants. The highest dissociation constants were determined by NMR titration following the procedure described recently in the literature.[17]

The ligands $H_4$pam, $H_4$ale, $H_4$meth and $H_4$prop exhibit similar acid–base behaviour, with five protonation constants spread over the whole pH range (Table 2). The first two $pK_a$'s lie in the strongly acidic region and correspond to the first deprotonation of each phosphonic acid group. The next constant is found close to the neutral region and represents release of the third proton from the bis(phosphonic acid) group, and the last two constants lie in the strongly alkaline region. The lower one is usually ascribed to the last deprotonation of the bis(phosphonic acid) moiety, and the last deprotonation occurs from the amino group.[18] The last proton is bound to the nitrogen atom in almost all poly(aminophosphonates).[19] This assignment can be supported by the crystal structure of the tris(ammonium) salt of $H_4$meth (see below), whose structure contains a fully deprotonated bis(phosphonic acid) group, whereas the amino group remains protonated. The $pK_a$ values of $H_4$meth are somewhat distinct from those of the other ligands, with the most significant difference being observed for the $pK_a(HL^{3-})$ and $pK_a(H_2L^{2-})$ values, which are between one and two units lower than those found for the other ligands. Such behaviour can be explained by steric and/or electronic effects. The protonated amino group on the same carbon atoms can efficiently interact intramolecularly (electrostatically and/or through hydrogen bonds[20]) with only one negatively charged phosphonate group. The

[a] Determined by NMR titration. No control of the ionic strength.

other ligands with a more flexible carbon chain can be present in conformations where such convenient interaction(s) with both phosphonate groups are maximized. The strongest interaction should then be expected for $H_4$pam, which contains the shortest ethylene chain, and, indeed, it exhibits the most basic last deprotonation. Alternatively, the presence of electron withdrawing (protonated) amino and phosphonic acid moieties on the same carbon atom (α to each other) can decrease the values of all dissociation constants. A comparison of ligands $H_4$pam and $H_4$prop shows a small effect of the α-hydroxo group on the acid–base properties of ligands.

The ligand $H_4$aca contains an amide nitrogen atom instead of an amino group, which means that only four deprotonation steps can occur. The first one lies in the strongly acidic region, with two more in the neutral and the last one in the rather alkaline region. When compared with other bis(phosphonates) [e.g. methanediphosphonic acid: p$K$($HL^{3-}$) = 10.6, p$K$($H_2L^{2-}$) = 7.05, p$K$($H_3L^{-}$) = 2.77, p$K$($H_4L$) = 1.6],[21] $H_4$aca shows higher overall basicity due to the higher value of p$K$($H_3L^{-}$).

We carried out all measurements in the presence of non-complexing tetramethylammonium cations to avoid alkali metal ion complex formation, therefore our results differ from those reported in the literature (determined in the presence of $Na^+$ or $K^+$ ions).[5,6,9–13] The differences are particularly pronounced in the value of the last dissociation constant. In the presence of $Na^+/K^+$ ions, the values reported in the literature are lower by one or even two orders of magnitude due to alkali metal ion assisted deprotonation (see Table S2 in the Supporting Information). Although the stabilities of the $K^+$ complexes of bis(phosphonates) are much lower than those with $Na^+$, this interaction cannot be negligible[14,15] and the values of the dissociation/protonation constants should be changed.

## Complexation Properties

In order to simplify the following text we will use a three-digit code to describe the composition of the complexes. The first digit represents the number (stoichiometric coefficient) of protons, the second one is the number of ligand molecules and the third is the number of metal ions. A negative value of the first digit represents a hydroxo complex or untypical release of a proton(s) from, under common conditions, a fully deprotonated ligand molecule, for example alkoxide anion formation. As an example, a complex with an $[H_2L_2M]$ stoichiometry is referred to as [221] and the value of its overall stability constant as log$\beta_{221}$. The charges of the complexes are omitted, and throughout the following text pH means –log$[H^+]$.

### *Divalent Metal Ions*

Speciation of the complexes with biogenic metal ions ($Cu^{2+}$, $Zn^{2+}$, $Ca^{2+}$ and $Mg^{2+}$) in aqueous solution was studied by potentiometry (Figure 2). Following the procedure described in the Experimental Section, three sets of data with ligand-to-metal ratios 1:1, 2:1 and 1:2 were recorded for each ion. All these measurements were complicated by precipitate formation. In general, the precipitation started with increasing abundance of the uncharged [211] complex at a pH between 2.5 and 6.0. The precipitate was usually fully dissolved under basic conditions (pH 9–11, depending on the ligand and metal combination and ratio; see Table S1). Additionally, in some cases data could not be recorded due to extended precipitate formation over a wide pH range, especially for systems containing $H_4$meth or for mixtures with an excess of metal ion. Obviously, the stability constants of the species abundant mostly in the pH range where the precipitates were present were not accessible, which means that a chemical model for many systems does not involve non-protonated species and direct comparison of the complexation properties of different ligands is somewhat difficult. The results are compiled in Table 3, and all distribution diagrams are provided as Supporting Information (Figures S2–S7).

The chemical models for speciation of $H_4$pam, $H_4$ale, $H_4$meth and $H_4$prop complexes are similar. Complexation starts below pH 2 with formation of the [311] complex. At higher pH, less protonated species are present. The high negative charge of the fully deprotonated bis(phosphonate) group of the ligands disfavours formation of the [021] complexes and only the [121] and [221] species can be found in mixtures with an excess of the ligands. From a comparison of the constants corresponding to coordination of the first and second ligand molecules in their monoprotonated form (i.e. formation of the [111] and [221] complexes; Table 4), it is clear that the second consecutive stability constants are only slightly lower than the first ones. This fact indicates negligible steric crowding due to coordination of the first protonated ligand molecule.

In equimolar solutions and at metal excess, 1:2 L:M complexes are formed under neutral and alkaline conditions. As one ligand molecule binds two metal ions, all the protons

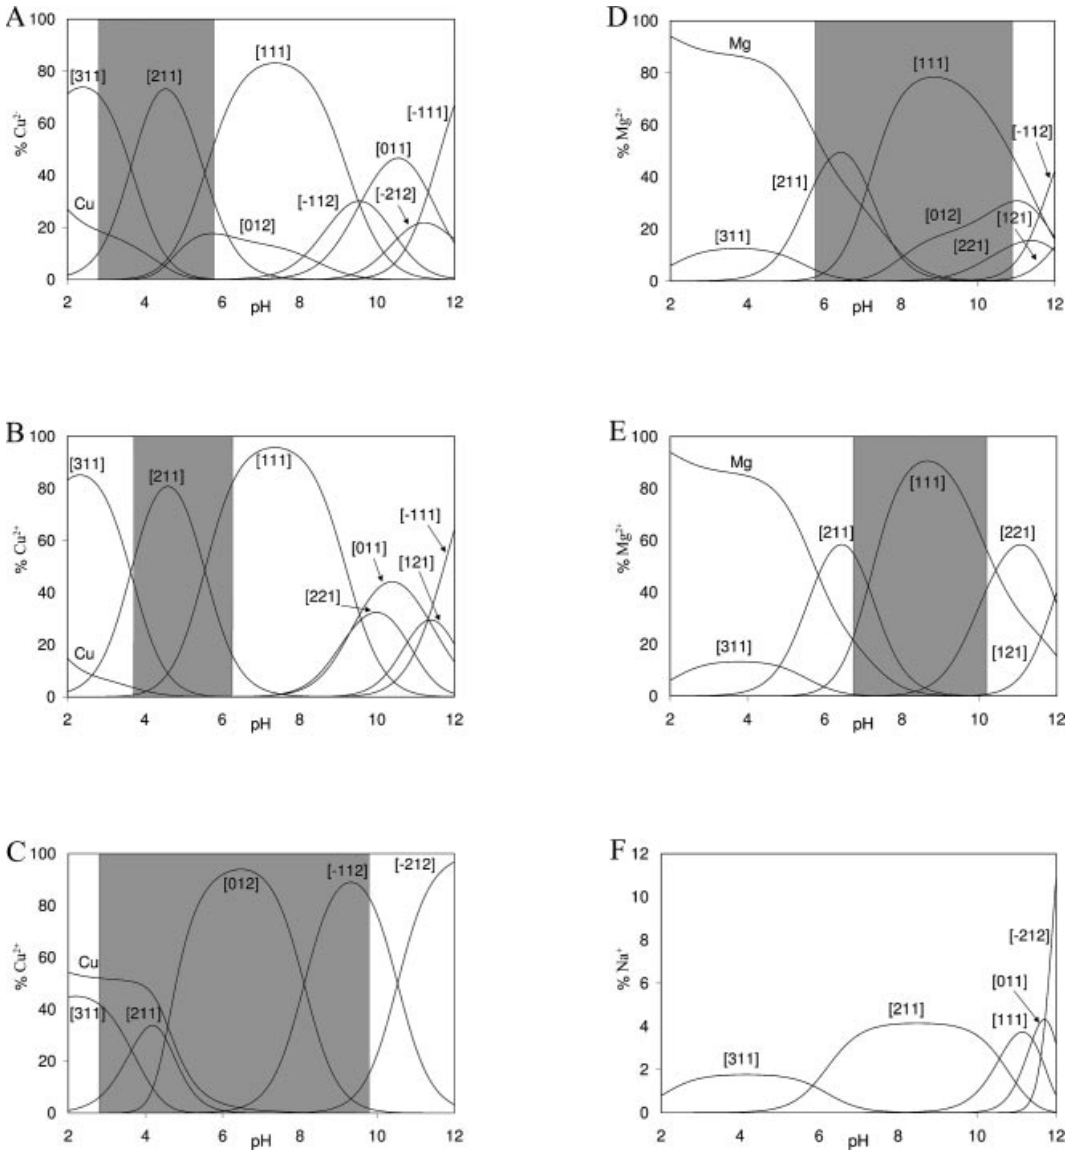

Figure 2. Species distribution plot for aqueous solutions of $Cu^{2+}$ and $H_4$ale with metal/ligand ratios of 1:1 (A), 1:2 (B) and 2:1 (C); $Mg^{2+}$ and $H_4$ale 1:1 (D) and 1:2 (E); $Na^+$ and $H_4$ale 10:1 (F). The grey areas were not studied during the experiment due to formation of a precipitate.

are released and these complexes do not exist in a protonated form. All systems containing $Cu^{2+}$ and $Zn^{2+}$ exhibit a high abundance of the [–111], [–112] and [–212] species in the alkaline region. In these complexes, deprotonation of the coordinated water molecule and/or deprotonation of the hydroxy group of ligands $H_4$pam and $H_4$ale has to occur, although these two possibilities could not be distinguished by potentiometry due to a proton ambiguity. As expected, the stability of the complexes follows the order $Cu^{2+} > Zn^{2+} > Mg^{2+} > Ca^{2+}$. The stabilities of the complexes with $H_4$pam, $H_4$ale and $H_4$prop are similar, whereas the presence of an amino group in the α position decreases the basicity of $H_4$meth and leads to a lower stability of its complexes.

As $H_4$aca contains an amide group instead of an amino group it prefers to form less protonated complexes and the complexation process starts at higher pH. The same effect was observed for 2:1 L:M complexes, where the [021] complex was found in all systems containing $H_4$aca. The stability constants of $H_4$aca complexes are between the values found for $H_4$meth and those found for the other ligands. In conclusion, the stabilities of the complexes follow the general order $H_4$pam ≈ $H_4$ale ≈ $H_4$prop > $H_4$aca > $H_4$meth.

The solid-state structures of bis(phosphonate) complexes typically show oligomeric or polymeric coordination chains with the bis(phosphonic acid) group acting as a bridging moiety.[22] Therefore, the presence of these complicated structures in solution is expected as well.[18] Unfortunately, the complexity of the studied systems did not allow us to take these multinuclear/polymeric complexes into account during the refinement of the potentiometric data.

### *Sodium*

As expected, the complexes with $Na^+$ ion exhibit the lowest stability constants of all the metal ions studied (Table 3),

[a] These systems were not studied due to extensive precipitate formation.

Table 4. Formation constants of the [111] and [221] complexes.

| | $Cu^{2+}$:$H_4$ale | $Zn^{2+}$:$H_4$ale | $Zn^{2+}$:$H_4$prop | $Mg^{2+}$:$H_4$pam | $Mg^{2+}$:$H_4$ale | $Mg^{2+}$:$H_4$meth |
|---|---|---|---|---|---|---|
| $M + HL \rightleftharpoons MHL$ | 24.7 | 22.7 | 24.4 | 20.1 | 19.8 | 18.2 |
| $MHL + HL \rightleftharpoons M(HL)_2$ | 17.0 | 17.8 | 20.5 | 17.2 | 16.4 | 14.4 |

therefore a 1:10 L:M ratio was used to obtain a reasonable abundance of the complexes in solution. No precipitation was observed in these systems. For $H_4$pam, $H_4$ale, $H_4$meth and $H_4$prop, interaction starts below pH 2 with formation of the [311] complex. $H_4$aca exhibits similar differences to those described above (complexation starts at higher pH (3–4) with formation of the [211] complex). Despite a tenfold excess of $Na^+$ ions, less than 60% of the ligand is present in the form of complexes below pH 10, where only 1:1 L:M complexes are present. Under strongly alkaline conditions, the 1:2 L:M hydroxo species are present in significant abundance. Formation of the [–112] and [–212] species can be explained by deprotonation of the water molecules coordinated to the $Na^+$ ion and/or deprotonation of α-hydroxo group. Although formation of the $Na^+$ hydroxo complexes is unusual, their inclusion in the calculations significantly improves the fit of the experimental data (Figure S1). The presence of a hydroxide anion in the solid-state structure of trisodium phosphate is well known.[23,24] The stability order of the complexes is the same as that found for the divalent metal ions ($H_4$pam ≈ $H_4$ale ≈ $H_4$prop > $H_4$aca > $H_4$meth).

### Simulation of Speciation under Physiological Conditions

At physiological pH, all studied aminoalkylbis(phosphonates) are present mostly in their doubly protonated form $(H_2L)^{2-}$. As the third dissociation constant of the amide derivative $H_4aca$ is 7.49, both $(Haca)^{2-}$ and $(H_2aca)^-$ are present in almost equimolar concentrations at a pH of around 7. As strongly acidic conditions are necessary for protonation of bis(phosphonates) to form $H_4L$ species, these compounds remain in the ionised form in living organisms, thus disfavouring their absorption in the gastrointestinal tract upon oral administration.[1]

To demonstrate the speciation of aminoalkylbis(phosphonates) in body liquids, we chose the commercially applied ligand Aledronate ($H_4ale$). With the concentrations of metal ions commonly found in human blood plasma ($Cu^{2+}$: 0.15 μM; $Zn^{2+}$: 0.2 μM; $Ca^{2+}$: 3 mM; $Mg^{2+}$: 1 mM; $Na^+$: 0.138 M)[25] and at physiological pH (7.4), we obtained the abundances shown in Figure 3. It is evident that the majority of the ligand (approx. 90%) is bound in the form of $Ca^{2+}$, $Mg^{2+}$ and $Na^+$ complexes. The complexes are uncharged or singly negatively charged. As the form (free acid/complex, charge, polarity etc.) could dramatically change the pharmacological behaviour of the studied compound, formation of the above-mentioned complexes should be carefully taken into account during all medical and biological studies dealing with bis(phosphonates). Whereas alkali and alkaline earth metal complexes are preferentially formed due to high concentration of these metal ions at higher Aledronate concentrations, at lower Aledronate concentrations ($<10^{-5}$ M) the high stabilities of the transition metal complexes become important and increasing abundances of $Cu^{2+}$ and $Zn^{2+}$ complexes are obtained. The high stability of these complexes could decrease the bioavailability of the bis(phosphonate). In real living systems, we should expect a slightly lower abundance of these complexes due to the presence of many natural ligands (acetate, citrate, amino acids, phosphates etc.) that compete with bis(phosphonate) ligands. The effect of bioligands on the abundance of complexes with alkali and alkaline earth metal ions is probably negligible due to the low stability of the complexes with these bioligands.

### Crystal Structures

The crystal structures of $H_4meth$, $H_4aca$ and $H_4prop$ with various degrees of protonation and the $Cu^{2+}$ complex of $H_4pam$ were determined.

The phosphonate groups in the structure of $H_4aca{\cdot}thf$ are fully protonated (Figure 4). A lower hydrophilicity of the amide-containing ligand results in the formation of a solvate with one molecule of thf and two layers in the crystal. One layer consists of the ligand molecules, which are connected to each other by hydrogen bonds, and the second one is formed by thf molecules (Figure 5, Table S3). The

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

position of the thf molecules is stabilized by hydrogen bonds between the ether oxygen atom and the phosphonate hydroxo groups of the ligand. The geometry around the phosphorus atoms is roughly tetrahedral, with slightly longer P–O distances to the protonated oxygen atoms than to the phosphoryl oxygen atom (Table 5).

A lower degree of protonation was found in $(NH_4)(H_3prop)·H_2O$ (Figure 6). Each phosphonic acid group and the amino group binds one proton. The P–O bonds are noticeably longer to the protonated oxygen atoms, and the geometry around the phosphorus atoms is tetrahedral (Table 5). The crystal structure is stabilized by an extensive three-dimensional framework of hydrogen bonds between the phosphonate oxygen atoms, the ligand amino group, the ammonia cations and co-crystallised water molecule (Table S4).

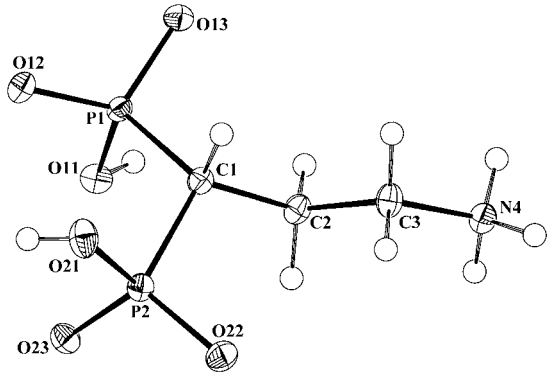

Figure 6. The molecular structure of $H_3prop^-$ in the crystal structure of $(NH_4)(H_3prop)·H_2O$.

The bis(phosphonic acid) group in the single crystals of $(NH_4)_3(Hmeth)·H_2O$ is fully deprotonated (Figure 7). The negative charge of the bis(phosphonic) unit is compensated by three ammonium cations and the protonated amino group of the ligand molecule. All phosphonate oxygen atoms are equivalent due to charge delocalisation (Table 5). An extended hydrogen-bond framework is also found in this structure. The ammonia cations are bound to phosphonate oxygen atoms by strong hydrogen bonds (O–N distances in the range 2.68–3.01 Å, Table S5). In addition, the co-crystallised water molecule forms hydrogen bonds with the phosphonate oxygen atoms (Ow–O distances of 2.77 and 2.90 Å, Table S5). This is the first reported structure to directly confirm the expected protonation scheme of aminoalkylbis(phosphonates). As the last proton is localised on the amino group, this supports the assumption that the final dissociation constant corresponds to a release of the proton from this group.

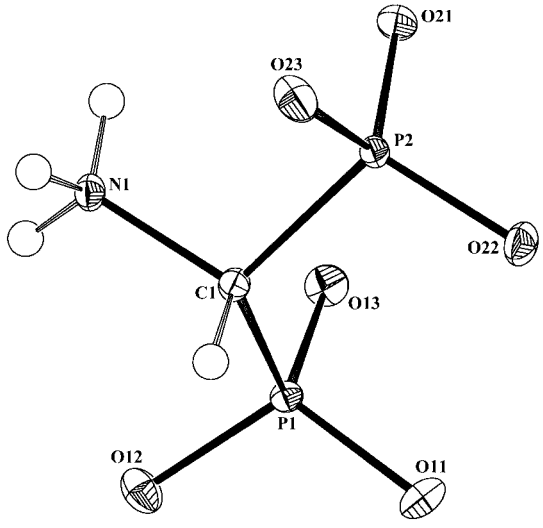

Figure 7. Molecular structure of $(Hmeth)^{3-}$ in the crystal structure of $(NH_4)_3(Hmeth)·H_2O$.

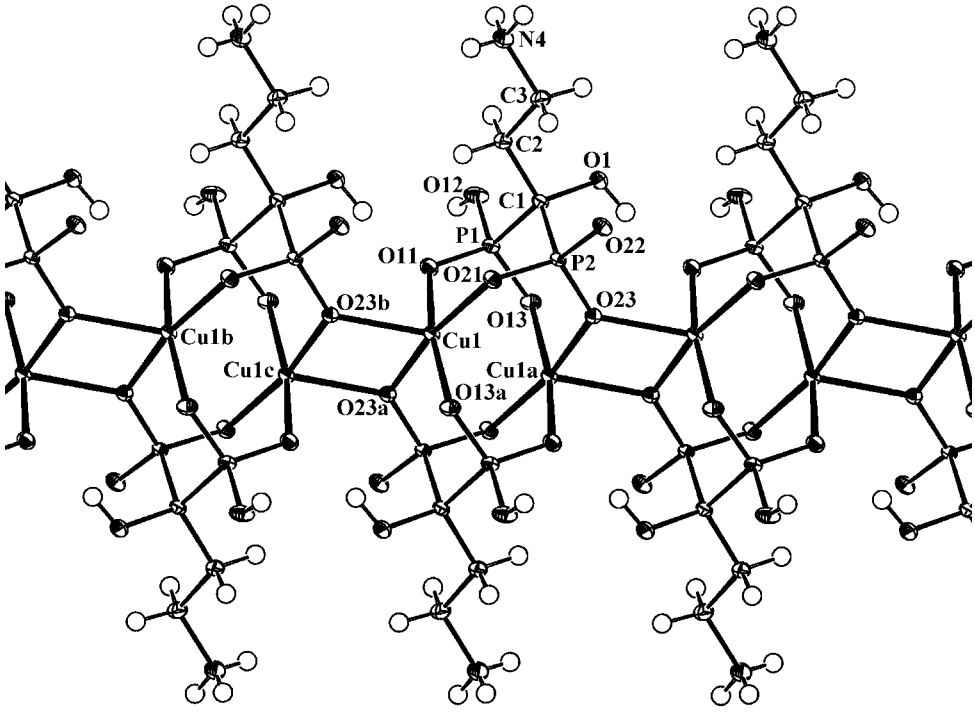

Figure 8. Chain design of $[Cu_2(H_2pam)_2]_n$ from the crystal structure of the $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$. Symmetry operations: a: $-x + 2, -y + 1, -z + 1$; b: $x - 1, y, z$; c: $-x + 1, -y + 1, -z + 1$.

The crystal structure of $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$ shows an infinite linear polymeric chain. The coordination sphere of the $Cu^{2+}$ ion is square-pyramidal (Figure 8, Table 6). The basal plane of the pyramid is formed by one oxygen atom of each phosphonic acid group of two different ligand molecules (O11, O21, O13a and O23a), and one of the oxygen atoms of the basal plane of the neighbouring unit is coordinated to the $Cu^{2+}$ ion in the apical position (O23b) to form a four-membered metallacycle with a Cu1–Cu1c separation of 3.21 Å. Each tetragonal pyramid is linked by a bridging ligand to a neighbouring molecule lying below the basal plane, with a Cu1–Cu1a separation of 2.99 Å. The geometrical parameter $\tau$ has a value of 0.005, which corresponds to an almost ideal square pyramid (theoretical value of $\tau = 0$, compared to an ideal trigonal bipyramid with $\tau = 1$).[26] One uncoordinated phosphonate oxygen atom is protonated as well as an amino group, and the coordination polymeric chains are connected by hydrogen bonds (Table S6).

[a] Symmetry operations: a: $-x + 2, -y + 1, -z + 1$; b: $x - 1, y, z$; c: $-x + 1, -y + 1, -z + 1$.

The Cu1–Cu1a distance of 2.99 Å in the $Cu_2(pam)_2$ moiety is too long for metal–metal bond formation. A similar design was previously found for $Cu^{2+}$ complexes of 1-hydroxyethyl-1,1-bis(phosphonic acid),[27] with protonated diaminoalkanes as counter cations. These compounds show a moderately strong antiferromagnetic interaction.[27,28]

## Conclusions

We have reported the acid–base and complexation behaviour of five bis(phosphonate) ligands containing an amino group in the side chain. The protonation constants and stability constants of their complexes with $Cu^{2+}$, $Zn^{2+}$, $Ca^{2+}$, $Mg^{2+}$ and $Na^{+}$ ions have been determined by means of potentiometric titrations. The bis(phosphonic acid) group exhibits four dissociation constants — two in the strongly acidic region, the third in the neutral region and the last one in the alkaline region. The amino groups undergo deprotonation under strongly alkaline conditions. Determi-

nation of the stability constants was complicated by the precipitation of insoluble complexes. The stability constants of the complexes follow the order $H_4$pam ≈ $H_4$ale ≈ $H_4$prop > $H_4$aca > $H_4$meth. Complicated chemical models containing complexes with 1:1, 2:1 and 1:2 L:M ratios and various degrees of protonation were found for all systems with divalent metals. In $Na^+$-containing systems, 1:1 complexes cover the whole pH scale except strongly alkaline conditions, where 2:1 complexes are present. A comparison of the properties of the studied ligands has shown a negligible effect of the α-hydroxy group on the acid–base and coordination properties of the bis(phosphonates), whereas the presence of the amino group in the α position significantly decreases the overall basicity of the ligand and the stability of its complexes. Simulation of Aledronate ($H_4$ale) speciation in human blood plasma shows a high abundance of $Ca^{2+}$, $Mg^{2+}$ and $Na^+$ complexes. At lower overall concentrations of bis(phosphonate), increasing abundances of $Cu^{2+}$ and $Zn^{2+}$ complexes are expected. The crystal structures of the ligands show a different degree of protonation. The structure of the triammonium salt of aminomethylbis(phosphonic acid), which contains a monoprotonated ligand molecule, nicely documents the protonation scheme of the studied compounds — the last proton is released from the amino group. The crystal structure of the $Cu^{2+}$ complex of $H_4$pam shows a polymeric coordination chain. The square-pyramidal coordination sphere of $Cu^{2+}$ contains five oxygen atoms from five different phosphonic acid groups. In the polymeric chain, two tetragonal pyramids are oriented towards each other and their basal planes are linked together with a Cu–Cu distance of 2.99 Å.

## Experimental Section

**Materials and Methods:** Commercially available chemicals were of synthetic purity and were used as received. Acetonitrile was dried by distillation from $P_2O_5$. Elemental analyses were performed at the Institute of Macromolecular Chemistry (Academy of Science of the Czech Republic, Prague). $^1$H (400 MHz) and $^{31}$P (161.9 MHz) NMR spectra were recorded with a Varian UNITY *PLUS*-400 spectrometer in 5-mm sample tubes. NMR experiments were performed at 298 K. For the measurements in $D_2O$, *tert*-butyl alcohol was used as an internal standard with the methyl signal referenced to $\delta$ = 1.20 ppm ($^1$H). For the measurements in $CDCl_3$, tetramethylsilane was used as an internal standard with the methyl signal referenced to $\delta$ = 0.00 ppm ($^1$H). The $^{31}$P chemical shifts were measured with respect to 1% $H_3PO_4$ in $D_2O$ as an external standard (substitution method). Mass spectra were recorded with a Bruker Esquire 3000 spectrometer equipped with an electrospray ion source and an ion trap detector. All measurements were carried out in the positive-ion mode.

**Synthesis:** Ligands $H_4$pam,[29] $H_4$ale,[29] $H_4$meth[30] and $H_4$prop[31] were prepared by modification of reported procedures. The ligands were chemically pure (NMR, MS) and composition of the samples was checked by elemental analysis; see the Supporting Information for full experimental and analytical details, and discussion of the synthesis.

**Tetraethyl Acetamidomethylbis(phosphonate):** A solution of tetraethyl aminomethylbis(phosphonate)[30] (4.0 g, 13.2 mmol) in dry acetonitrile (50 mL) was added dropwise to a solution of acetyl chloride (3.0 g, 38.2 mmol) and $Na_2CO_3$ (5.2 g, 49 mmol) in dry acetonitrile (50 mL) at –40 °C. After the addition was finished, the mixture was warmed slowly to room temperature and stirred overnight. After treatment with charcoal and filtration, the unreacted acetyl chloride was removed by repeated vacuum evaporation with toluene. The product was obtained as a colourless oil in a yield of 4.4 g (97%). $C_7H_{17}NO_8P_2$: calcd. C 29.28, H 5.27, N 4.88; found C 29.42, H 5.41, N 4.25. $^1$H NMR ($CDCl_3$): $\delta$ = 1.34 (m, 12 H, $CH_2CH_3$), 2.08 (s, 3 H, $CH_3CO$), 4.19 (m, 8 H, $OCH_2$), 5.06 (td, $^2J_{P,H}$ = 21.4, $^3J_{H,H}$ = 10.4 Hz, 1 H, PC*H*P), 6.75 (br. s, 1 H, N*H*) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 17.0 ppm (d, $^2J_{H,P}$ = 21.4 Hz). ESI/MS: calculated 368.3; found 368.3 [M + $Na^+$].

**Acetamidomethylbis(phosphonic acid) ($H_4$aca):** Tetraethyl acetamidomethylbis(phosphonate) (3.0 g, 8.7 mmol) was dissolved in 30% HBr/AcOH (50 mL) in a 100-mL flask and stirred for 24 h at room temperature. After removal of the volatiles on a rotary evaporator, the resulting oil was dissolved in EtOH (30 mL). Precipitation of the crude product from solution occurred on standing. After 3 h, the precipitate was filtered off and extracted with boiling EtOH (100 mL). After filtration with charcoal, volatiles were removed in vacuo. The crude product was recrystallised from water by addition of thf. The product was filtered, washed with thf and dried at room temperature over $P_2O_5$. Yield: 1.7 g (63%) as adduct **6**·thf. $C_7H_{17}NO_8P_2$: calcd. C 27.55, H 5.61, N 4.59; found C 27.62, H 5.60, N 4.35. $^1$H NMR ($D_2O$/NaOD): $\delta$ = 1.63 (m, 4 H, $CH_2CH_2CH_2$ thf), $\delta$ = 1.94 (s, 3 H, $CH_3CO$), $\delta$ = 3.49 (m, 4 H, $CH_2CH_2O$ thf), 4.46 (t, $^2J_{P,H}$ = 21.3 Hz, 1 H, PC*H*P) ppm. $^{31}$P NMR ($D_2O$/NaOD): $\delta$ = 17.0 ppm (d, $^2J_{H,P}$ = 21.3 Hz). ESI/MS: calculated 256.0; found 255.8 [M + $Na^+$].

**Crystal-Structure Determination:** Single crystals of $H_4$aca·thf were selected from the recrystallised matter before the filtration. Single crystals of $(NH_4)(H_3prop)\cdot H_2O$ were prepared by the following method: $H_4$prop was dissolved in concentrated ammonia, the solution was evaporated, and the oily residue was dissolved in water and crystallised by slow vapour diffusion of *i*PrOH into the solution. Single crystals of $(NH_4)_3$(Hmeth)·$H_2O$ were prepared by slow vapour diffusion of EtOH into a solution of $H_4$meth in 5% ammonia. Single crystals of $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$ were prepared by hydrothermal synthesis. Thus, $H_4$pam (352.5 mg, 1.50 mmol) and $CuCO_3$ (185.1 mg, 1.50 mmol) were suspended in water (30 mL) and the mixture was heated at 70 °C in a closed flask. After three weeks, shiny greenish-blue needles of $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$ had formed. They were decanted off and dried in air. Yield: 446.3 mg (95%). $C_6H_{20}Cu_2N_2O_{15}P_4$: calcd. C 20.79, H 3.30, N 4.58; found C 21.05, H 3.48, N 4.39.

The selected crystals were mounted on glass fibres in a random orientation in silicone grease or epoxide glue. Diffraction data were collected using graphite-monochromated Mo-$K_\alpha$ radiation with an Enraf–Nonius KappaCCD diffractometer at 150(1) K [Cryostream Cooler (Oxford Cryosystem)] or 294(1) K and analysed using the HKL DENZO program package.[32] The structures were solved by direct methods, and refined by full-matrix least-squares techniques (SIR92,[33] SHELXL97[34]). The scattering factors used for neutral atoms were included in the SHELXL97 program. In the case of $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$ a Gaussian absorption correction was applied.[35] Further details are given in Table 7.

All non-hydrogen atoms were refined anisotropically. In the structure of $H_4$aca·thf, the molecule of tetrahydrofuran solvate was found to be very disordered. This disorder was refined by splitting the carbon chain into two positions with occupancies of 61:39. The hydrogen atoms of the ligand molecule were localised in the electronic density difference map, however, they were fixed in theoreti-

cal (H–C) or original (H–O,N) positions with thermal parameters $U_{eq}$(H) = 1.2 $U_{eq}$(C) or 1.3 $U_{eq}$(N,O) as the free refinement led to unrealistic bond lengths and angles. Hydrogen atoms belonging to solvate thf molecule were fixed in theoretical positions using a riding model. In the structure of $(NH_4)_3$(Hmeth)·$H_2O$, all hydrogen atoms were refined isotropically. In the structures of $(NH_4)(H_3$prop)·$H_2O$ and $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$, the hydrogen atoms were localised in the electronic density difference map, but they were fixed in theoretical (H–C) or original (H–O,N) positions using a riding model with $U_{eq}$(H) = 1.2 $U_{eq}$(C) or 1.3 $U_{eq}$(N,O) as the free refinement led to unrealistic bond lengths and angles. The independent unit of $(NH_4)(H_3$prop)·$H_2O$ consists of a ligand molecule, two ammonium cations occupying special positions (with half-occupancy) and one water molecule. In the other structures, no special positions are occupied. The non-centrosymmetric structure of $(NH_4)_3$(Hmeth)·$H_2O$ was refined with a contribution of racemic twinning with a ratio between both antipodes 62:38.

CCDC-612685 ($H_4$aca·thf), -612687 [$(NH_4)(H_3$prop)·$H_2O$], -612686 [$(NH_4)_3$Hmeth·$H_2O$] and -612688 $[\{Cu_2(H_2pam)_2\}\cdot H_2O]_n$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

### Determination of Dissociation and Stability Constants

**Chemicals and Stock Solutions for Potentiometric Titrations:** Water was purified with a Milli-Q (Millipore) purification system. The stock solution of hydrochloric acid (ca. 0.03 M) was prepared from a 35% aqueous solution (puriss., Fluka). Commercial $NMe_4Cl$ (99%, Fluka) was recrystallised from boiling *i*PrOH and the solid salt was dried with $P_2O_5$ in vacuo to constant weight (this dried salt is extremely hygroscopic).[36] Carbonate-free $NMe_4OH$ solution (ca. 0.2 M) was prepared from this $NMe_4Cl$ by ion exchange on Dowex 1 ($OH^-$ form, under argon, with carbonate-free water). The hydroxide solution was standardised against potassium hydrogen phthalate and the HCl solution against the approx. 0.2 M $NMe_4OH$ solution. Stock solutions of the individual metal cations were prepared by dissolving hydrates of $M(NO_3)_2$ or dried NaCl. The divalent metal ion contents in the stock solutions were determined by titration with standard $Na_2H_2$edta solution. The analytical concentration of ligand stock solution was determined together with refinement of protonation constants with the OPIUM[37] software package (see below).

**Potentiometric Titrations:** Titrations were carried out in a vessel thermostatted at 25.0 ± 0.1 °C, at an ionic strength $I$ = 0.1 M ($NMe_4Cl$) and in the presence of extra HCl in the pH range 1.7–11.9 (protonation constants and complex with $Na^+$) using a PHM 240 pH-meter, a 2-mL ABU 900 automatic piston burette and a GK 2401B combined electrode (all from Radiometer, Denmark). For systems with divalent metal ions, a precipitate was usually present at pH's between about 4 and 9, so data for this region were not collected. The initial volume was 5 mL and the concentration of the ligand was about 0.004 M. L:M molar ratios of 1:10 ($Na^+$ system), 1:1, 2:1 and 1:2 (other systems) were used. Five parallel titrations were carried out for each ratio, with each titration consisting of 40–50 points. An inert atmosphere was ensured by constant passage of argon saturated with the vapour of the solvent used in the measurements.

The constants (with their standard deviations) were calculated with the program OPIUM.[37] This program minimizes the criterion of the generalized least-squares method using the calibration function

$$E = E_0 + S\log[H^+] + j_1[H^+] + j_2 K_w/[H^+]$$

where the additive term $E_0$ contains the standard potentials of the electrodes used and the contributions of inert ions to the liquid-junction potential, $S$ corresponds to the Nernstian slope, the value

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of which should be close to the theoretical value of 59.159 mV, and $j_1[H^+]$ and $j_2 K_w/[H^+] = j_2[OH^-]$ terms are contributions of the $H^+$ and $OH^-$ ions to the liquid-junction potential. The $j_1$ and $j_2$ parameters for the calibration titrations before and after each titration show only minor changes. It is clear that $j_1$ (values between –50 and 50) and $j_2$ (values between 100 and 200) cause deviation from a linear dependence between $E$ and pH only in strongly acidic and basic solutions. The calibration parameters were determined by titration of standard HCl with standard $NMe_4OH$ before each ligand or ligand-metal titration to give a pair calibration/titration, which was used for calculation of the constants. The protonation constants $\beta_n$ are defined by $\beta_n = [H_nL]/([H]^n[L])$ [they can be transferred to the dissociation constants by the relationships $pK_a(HL^{3-}) = \log\beta_1$ and $pK_a(H_nL^{n-4}) = \log\beta_n - \log\beta_{n-1}$]. The stability constants are defined by $\beta_{hlm} = [H_hL_lM_m]/([H]^h[L]^l[M]^m)$. The water ion product $pK_w$ used was 13.81. The stability constants of $M^{2+}$–$OH^-$ systems were included in the calculations and were taken from the literature.[21,38] Speciation of the studied systems was solved with the OPIUM[37] software package. The concentration of ligand supposed from the exactly weighed sample was in very good agreement with the concentration determined together with refinement of the protonation constants using OPIUM.

**NMR Titrations:** The $^{31}P\{^1H\}$ NMR titration experiments for determination of the highest protonation constant (pH in range 11.5–13.6, about 15 points) were carried out under conditions close to the potentiometric titrations (no control of ionic strength, $NMe_4Cl$, 25.0 °C, ligand concentration about 0.004 M). A coaxial capillary tube with $D_2O$ and $H_3PO_4$ was used for the lock and referencing. Protonation constants were calculated with OPIUM[37] from the dependence of $\delta_P$ of the phosphonate groups on $-\log[H^+]$.

**Supporting Information** (see also the footnote on the first page of this article): Discussion and experimental details dealing with the ligand synthesis. Figure S1 shows an example ($Na^+$:$H_4$prop system) of the fitting with and without hydroxo species. Table S1 shows the pH ranges skipped during titration due to the precipitate formation. Table S2 shows a comparison of the dissociation constant with those reported in the literature. The distribution diagrams of all systems studied are shown in Figures S2–S7. The hydrogen-bond parameters in the crystal structures are reported in Tables S3–S6.

# Three Novel Functional $Cd^{II}$ Dicarboxylates with Nanometer Channels: Hydrothermal Synthesis, Crystal Structures, and Luminescence Properties

**Yu-Peng Tian,*[a–c] Yong-Min Zhu,[a] Hong-Ping Zhou,*[a] Peng Wang,[a] Jie-Ying Wu,[a] Xu-Tang Tao,[b] and Min-Hua Jiang[b]**

**Keywords:** Carboxylate / Supramolecular chemistry / Fluorescence / Coordination modes

Three novel functional transition-metal complexes with $H_2A$ ($H_2A$ = 9-ethylcarbazole-3,6-dicarboxylic acid), $Cd(HA)_2(H_2O)_2$ (**1**), $[Cd(A)(phen)]\cdot 1.5H_2O$ (**2**) (phen = 1,10-phenanthroline), and $Cd(HA)_2(bipy)$ (**3**) (bipy = 4,4′-bipyridine), have been successfully synthesized by a hydrothermal synthetic method and characterized by single-crystal X-ray diffraction, infrared spectroscopy, elemental analysis, thermogravimetric analysis, and photoluminescence. The results show that all of the complexes contain nanometer channels, while the coordination modes were changed by the addition of the mixed ligands. The 2D supramolecular open-framework **1** is constructed through hydrogen-bond and aromatic π–π interactions. 2D coordination polymer **2** is constructed by π–π interactions between adjacent metal-organic polymeric coordination chains. Interestingly, the 3D supramolecular architecture of **3** first formed 2D grid layers from 1D chains by intermolecular hydrogen bonds and then extended into a 3D structure through aromatic π–π interactions. Furthermore, strong emissions from these complexes were also changed by the coordination modes in the solid state. However, complexes **1**–**3** show high thermal stability.

## Introduction

In recent years, metal complexes have been investigated in luminescent materials for potential applications as light-emitting diodes (LEDs).[1] Metal carboxylate supramolecular open frameworks as a kind of metal complex have been the focus of recent research interest because of their interesting supramolecular compositions and versatile framework topologies, as well as their potential as functional materials in gas storage,[2] ion recognition,[3] catalysis,[4] sensor technology,[5] and nanotechnology.[6] The aromatic multicarboxylate ligands, such as 1,3,5-benzenetricarboxylic acid and 1,2,4,5-benzenetetracarboxylic acid, have been extensively introduced in the preparations of metal-organic supramolecular open frameworks.[7] However, the small π-conjugation system inhibited their potential application in luminescent materials. It is popular to extend the π-conjunction system of some widely used fluorophore precursors, such as rhodamine,[8] xylene,[9] and so forth, to get new analogs, although their synthesis and further modification may be difficult and laborious. On the other hand, emission properties of many luminescent materials can be tuned by incorporating the functional ligands into a polymeric structure, such as an all-organic polymer, or into a mixed inorganic/organic polymer.[10] Carbazole has been extensively exploited as a convenient basic building block for the application of the electroluminescent (EL) device because of its good hole transporting and luminescent properties.[11] Modification of the carbazole on the 3- and 6-positions represents a possible approach for designing carbazole-based luminescent materials.

On the other hand, $Cd^{II}$-containing coordination compounds have received considerable interest recently because of their ability to form bonds with different donors, their large radius, their various coordination modes, and the special properties of the $Cd^{II}$ ion. To date, four- to eight-coordinate $Cd^{II}$ complexes and their potential applications in catalysis,[12] luminescent materials,[13] and NLO materials[14] have been explored. Also, a hydrothermal synthetic method has been demonstrated as an effective, simple, and environmentally friendly technique in crystal engineering.[15] Considering all these aspects, we used a functional organic ligand that we had established previously,[16] 9-ethylcarbazole-3,6-dicarboxylic acid ($H_2A$), and cadmium nitrate as building blocks. 2D supramolecular open-framework $[Cd(HA)_2(H_2O)_2]_n$ (**1**) was obtained using hydrothermal synthesis. The skilful combination of carboxylates, the other coligands, and metal ions may generate many interesting coordination architectures as well as different emission properties. Pyridine, Schiff base, and polyamine derivatives were widely used as coligands. However, the selection of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coligand remains a challenge for us because two different kinds of ligands must coexist and compete in coordinating to the same metal ion. In this paper, we introduced a luminescent rigid chelated ligand (phen) and a flexible bridge ligand (bipy) into the reaction system, obtaining 2D coordination polymer $\{[Cd(A)(phen)]\cdot 1.5H_2O\}_n$ (**2**) and 3D supramolecular open framework $[Cd(HA)_2(bipy)]_n$ (**3**) respectively. The emission wavelengths are tuned by changing coordination architectures.

## Result and Discussion

### Synthesis

The hydrothermal synthetic method is a useful way of growing complex crystals because of its effectiveness, simplicity, and environmental friendliness. Also, the formation of these complexes is greatly influenced by the base. We have tried NaOH, $Na_2C_2O_4$, pyridine, and triethylamine, and only $Na_2C_2O_4$ was successfully used in the formation of these compounds, suggesting that it is a compatible base for deprotonation of $H_2A$. The formations of **1**–**3** are shown in Scheme 1.

$$H_2A + Cd(NO_3)_2\cdot 4H_2O + \begin{cases} \xrightarrow[165\ ^\circ C]{H_2O,C_2H_5OH} Cd(HA)_2(H_2O)_2 & (1) \\ \xrightarrow[phen\ \ 165\ ^\circ C]{H_2O,C_2H_5OH} Cd(A)(phen)\cdot 1.5H_2O & (2) \\ \xrightarrow[bipy\ \ 165\ ^\circ C]{H_2O,C_2H_5OH} Cd(HA)_2(bipy) & (3) \end{cases}$$

Scheme 1.

### Description of Crystal Structure

#### *$Cd(HA)_2(H_2O)_2$ (1)*

Complex **1** crystallized with a monoclinic space group *C*2/*c*. The crystallographic analysis of complex **1** featured a 2D framework containing nanometer channels with a repeating unit $[Cd(HA)_2(H_2O)_2]_n$. The symmetric unit contains one cadmium atom, two $H_2A$ groups, and two $H_2O$ molecules. Part a of Figure 1 illustrates the ORTEP structure of compound **1**. Each cadmium ion is hexacoordinated by four O atoms [Cd(1)–O(1) 2.247(2) Å; Cd(1)–O(2) 2.489(2) Å; Cd(1)–O(1A) 2.247(2) Å; Cd(1)–O(2A) 2.489(2) Å] from two different $H_2A$ ligands and two O atoms [Cd(1)–O(5) 2.187(3) Å; Cd(1)–O(5A) 2.187(3) Å] from two $H_2O$ molecules and forms a distorted octahedral geometry. The dihedral angle of the two carbazole planes of $H_2A$ is 83.57°. As for the $H_2A$ ligand, it shed one proton and chelated to the cadmium atom while the other carboxylate group connected to the coordinated $H_2O$ and carboxylate group of another $H_2A$ by intermolecular hydrogen bonds (Figure 1, b). The C–O bond [C2AC–O3AC 1.306 Å] is much longer than the C=O bond [C2AC–O4AC 1.219 Å] in the carboxy group, so C2AC–O4AC can be assigned as a double bond and C2AC–O3AC as a single bond, and H is linked to O3AC. The O–H···O intermolecular hydrogen bond formed by the $H_2A$ ligand and $H_2O$ has a O···O distance of 2.659 Å (O–H–O 172.53°), while the other O–H···O intermolecular hydrogen bond formed by two $H_2A$ ligands has a O···O distance of 2.686 Å (O–H–O 175.89°). Those units connected to each other and formed a 1D chain by intermolecular hydrogen bonds (O–H···O 2.712 Å, O–H–O 163.61°) (Figure 2). The 2D supramolecular open

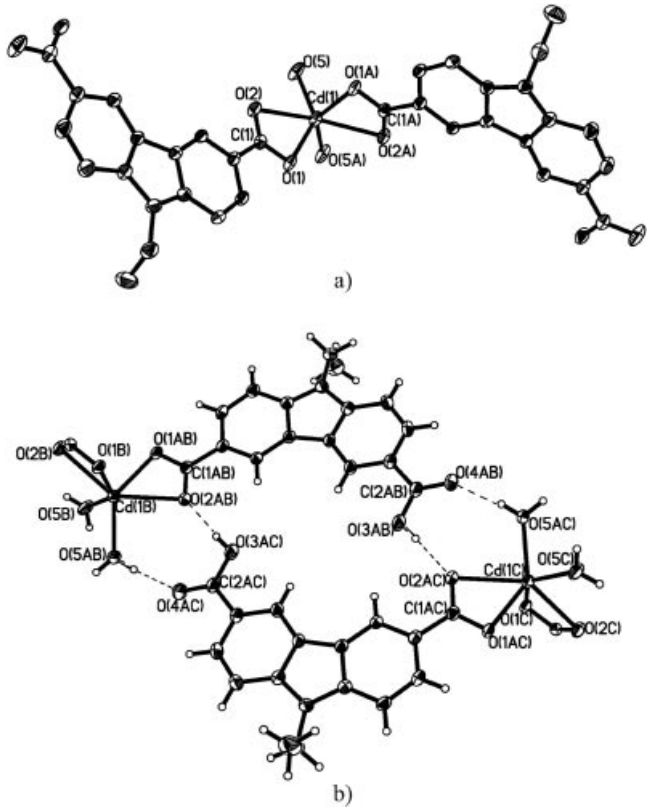

Figure 1. Perspective view of (a) the coordination environment of the cadmium atom in **1** and (b) the coordination mode of the $H_2A$ ligand; all hydrogen atoms in (a) are omitted for clarity.

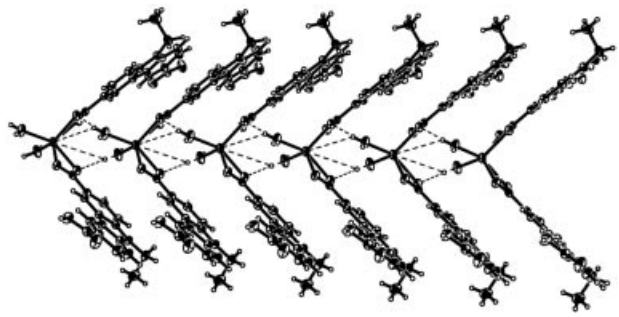

Figure 2. 1D structure of **1** along the *b* axis by intermolecular hydrogen bonds O–H···O.

framework contains 10.984 × 7.584 Å channels A formed by intermolecular hydrogen bonds and π–π interactions along the *b* axis with a distance of 3.41 Å (Figure 3).

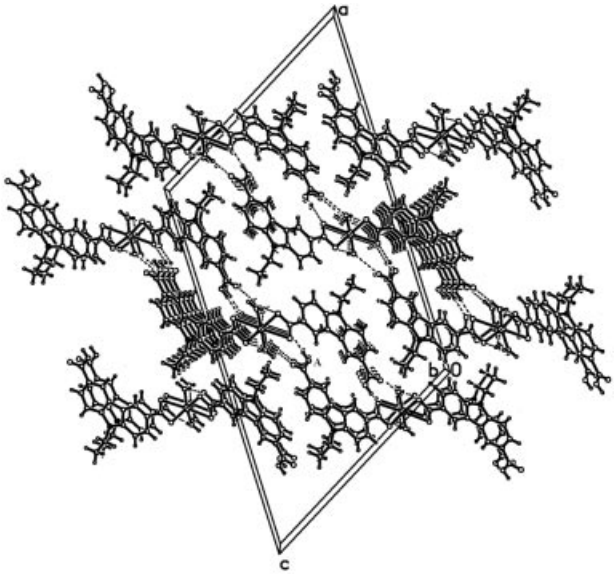

Figure 3. 2D structure containing nanometer channel A (10.984 × 7.584 Å) of **1** along the *a* axis by intermolecular hydrogen bonds O–H···O and π–π interactions.

### *[Cd(A)(phen)]·1.5H$_2$O (2)*

Complex **2** crystallized in the monoclinic space group *P*2/*c* with a formula $\{[Cd(A)(phen)]\cdot 1.5H_2O\}_n$. The structure featured a 2D polymeric pattern containing nanometer channels. The asymmetric unit contains one cadmium atom, one $H_2A$ group, and one phen molecule. Figure 4 illustrates the ORTEP structure of complex **2**. The cadmium atom is six-coordinate through coordination of one chelating carboxylate group [Cd(1)–O(1) 2.468(4) Å; Cd(1)–O(2) 2.315(3) Å], one chelating phen molecule [Cd(1)–N(2) 2.362(4) Å; Cd(1)–N(3) 2.372(4) Å], and two bridging carboxylate groups [Cd(1)–O(3A) 2.196(3) Å; Cd(1)–O(4B) 2.256(3) Å]. The coordination mode of $H_2A$ is different from complex **1**. It shed two protons and chelated to the metal atom [O(1B)–C(13B)–O(2B) 120.1(4)°] through one of the carboxylate groups, while the other carboxylate group bridged to two metal atoms [O(4B)–C(14B)–O(3B) 125.0(4)°]. The basic units first formed rings and then formed a zigzag 1D chain (Figure 5) with the 73.57° dihedral angle of the ring planes. The phen molecules chelated to the metals from the two sides of the chains one by one. Two adjacent phen molecules connected to each other by π–π stacking interactions with a plane–plane distance of 3.38 Å. The 2D open framework contains 10.537 × 9.232 Å nanometer channel B formed by π–π interactions along the *b* axis with a distance of 3.48 Å (Figure 6). Two kinds of distorted guest water molecules filled the channels. One kind filled the channel in the form of a distorted single $H_2O$ molecule (H–O–H 102.60°) by hydrogen bond (O–H···O 2.899 Å, O–H–O 128.47°) to the carboxylate group, while the other kind filled the channel in the form of distorted dimeric $H_2O$ molecules (H–O–H 107.22°) by hydrogen bond (O–H···O 2.695 Å, O–H–O 132.46°) to the carboxylate group.

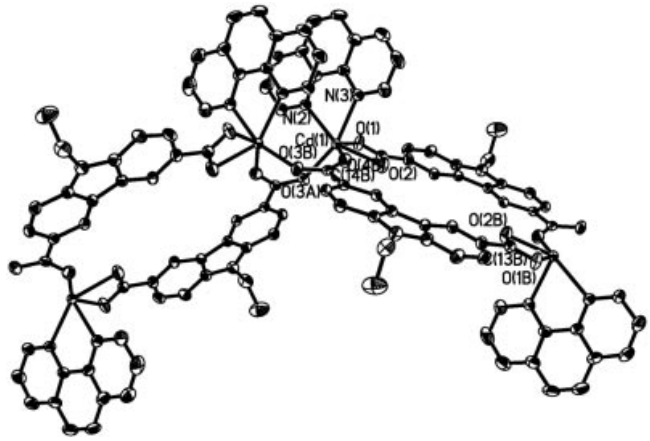

Figure 4. The ORTEP structure of **2** with atomic labeling scheme; all hydrogen atoms are omitted for clarity.

Figure 5. 1D zigzag chains of **2** formed by the basic units; all hydrogen atoms are omitted for clarity.

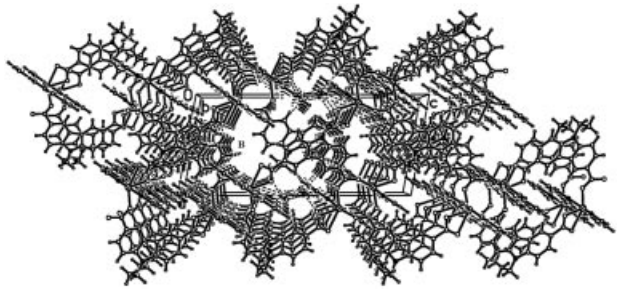

Figure 6. 2D structure containing nanometer channel B (10.537 × 9.232 Å) of **2** along the *b* axis by π–π interactions.

### *Cd(HA)$_2$(bipy) (3)*

Complex **3** (Figure 7) crystallized with a monoclinic space group *C*2/*c* with the formula $[Cd(HA)_2(bipy)]_n$. X-ray crystallographic analysis reveals that complex **3** is 3D open framework with nanometer channels. The symmetric unit contains one cadmium atom, two $H_2A$ groups, and two pyridine groups. The cadmium atom adopts a distorted octahedral geometry by coordinating to four oxygen atoms [Cd(1C)–O(1AC) 2.303(5) Å; Cd(1C)–O(2AC) 2.490(6) Å; Cd(1C)–O(1C) 2.303(5) Å; Cd(1C)–O(2C) 2.490(6) Å] of two chelating $H_2A$ ligands and two nitrogen atoms [Cd(1C)–N(2C) 2.218(8) Å; Cd(1C)–N(3C) 2.299(9) Å] of two different bipyridines. These basic units form a 1D chain. The coordination mode of $H_2A$ ligand is the same as that of complex **1**. It shed one proton and chelated to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the cadmium atom through one of the carboxylate groups while the other carboxylate group connected to the chelated carboxylate group by a hydrogen bond (O–H···O 2.583 Å, O–H–O 170.37°), combining the 1D chains into the 2D grid layer (Figure 8 and Figure 9). The C–O bond (C16A–O3A 1.324 Å) is much longer than the C=O bond (C16A–O4A 1.228 Å) in the carboxy group, so C16A–O4A can be assigned as a double bond and C16A–O3A as a single bond, and the hydrogen atom is linked to O3A. 2D grid layers were extended along the *a* axis and formed a 3D supramolecular framework with 9.437 × 7.620 Å nanometer channel C by π–π interactions with a distance of 3.47 Å (Figure 10).

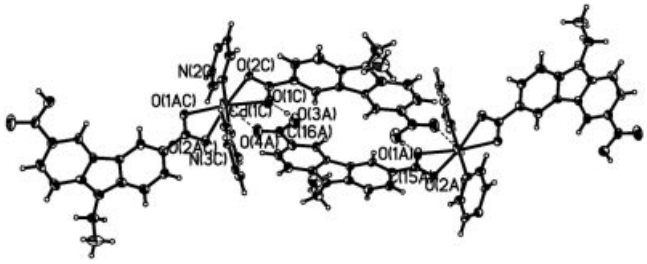

Figure 7. The ORTEP structure of **3** with atomic labeling scheme.

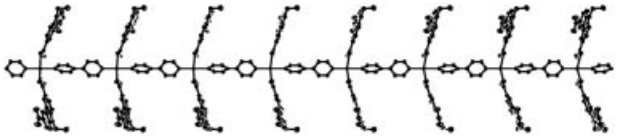

Figure 8. 1D chains of **3** formed by the basic units; all hydrogen atoms are omitted for clarity.

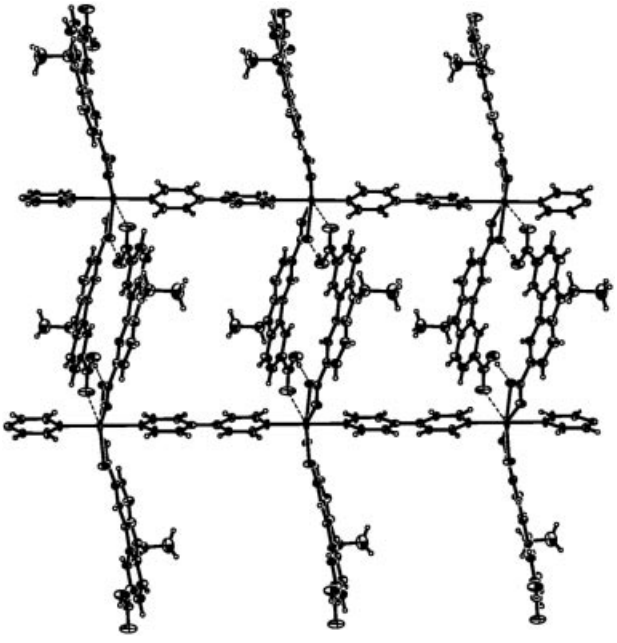

Figure 9. 2D grid layer based on 1D chains formed by intermolecular hydrogen bonds O–H···O.

Traditionally, flexible carboxylate ligands are able to produce more unique frameworks with aesthetic and useful properties than the rigid carboxylate ligands because of their flexibility and conformational freedom. However, in complexes **1**–**3**, the coordination modes were changed by the addition of the other ligand. With the exception of the different coordination mode in these complexes, many O–H···O hydrogen bonding interactions were observed in the crystal structure. Generally, the carboxylate groups are the main part of hydrogen-bonded networks. The hydrogen bonds of complex **1** are more numerous and more complicated than the others, because of the coordinated water. These strong O–H···O hydrogen bonds play an important role in the formation of the 2D or 3D supramolecular open frameworks containing nanometer channels. It should also be noted that, in comparison with **1** and **3**, the $H_2A$ ligand in **2** shed all the protons, which suggests that phen may potentially act as a base for deprotonation of $H_2A$. All of the nanometer channels had similar dimensions, which may be due to the formation of these channels by two $H_2A$ ligands. The small difference in size is a result of the different coordination modes and distorted stacking of aromatic rings.

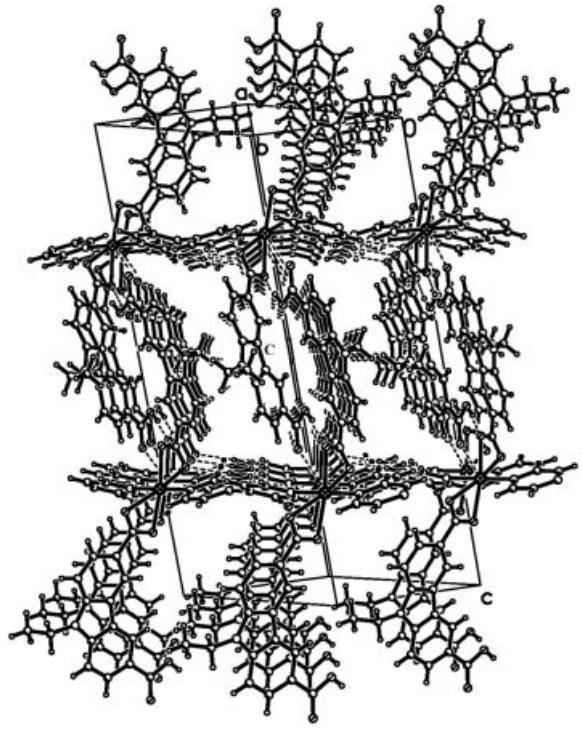

Figure 10. 3D structure containing nanometer channel C (9.437 × 7.620 Å) of **3**.

## Thermogravimetric Analysis

Thermogravimetric analyses (TGA) of complexes **1**–**3** were performed on single crystal samples in the range of 20–650 °C under nitrogen. Complexes **1**–**3** exhibit high thermal stability. For complex **1**, the first weight loss occurred in stages starting at 164 °C and completing at 227 °C, corresponding to the loss of two coordinated water molecules. The anhydrous complex suffered from serious mass loss upon heating to 277 °C, attributable to decomposition of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the organic composition. For complex **2**, the first major weight loss from 77 °C to 140 °C corresponded to the loss of guest water molecules. The main structure decomposed at 404 °C, exhibiting high thermal stability. Complex **3** also exhibits high thermal stability, as there is no weight loss below 361 °C.

## Fluorescent Properties

Fluorescent transition-metal complexes containing rigid multichromophoric ligands with a large π-conjugation system have been studied intensively because of their potential use. On the other hand, to extend the π-conjugation only by synthesis and modification of organic composition may be difficult and tedious. Synthesis of inorganic/organic coordination complexes by using functional ligands gained from simplified synthetic approaches, some coligands, and transition-metal centers can be a useful method to obtain new photoluminescent materials. The luminescent properties of the free ligand $H_2A$ and complexes **1**–**3** were investigated in solid state at room temperature (Figure 11). The nanosecond range of lifetime in the solid state at room temperature reveals that the emission is fluorescent in nature. The emission for free $H_2A$ ligand is at 422 nm ($\lambda_{exc}$ = 269 nm), which can be assigned to the $\pi^* \rightarrow \pi$ transition of the carbazole moiety.[17] Complex **1** exhibits a broad emission band with the maximal emission at 453 nm ($\lambda_{exc}$ = 268 nm), which is 31 nm red-shifted compared to the free ligand. These emissions may be attributed to ligand-to-ligand charge transfer (LLCT).[18] The shoulder at 390 and 369 nm may be assigned to the excimer emission of the ligand because of the interaction between the molecules.[19] The emission of complex **2** is at 492 nm ($\lambda_{exc}$ = 269 nm), which is red-shifted 70 nm compared to the free ligand; it can be assigned to the ligand-to-metal charge transfer (LMCT).[18] Generally, the intraligand and fluorescence emission is determined by the energy gap between π and π* molecular orbitals of the free ligand, which is simply related to the extent of π conjugation in the system.[20] Complex **3** exhibits strong emission at 396 nm ($\lambda_{exc}$ = 270 nm), which can be assigned to the intraligand fluorescent emission of coordinated $H_2A$ ligands. It is 26 nm blue-shifted compared to the free ligand and 57 nm blue-shifted compared to complex **1**, which may be due to the increase of the π–π stacking distance of the ligands [3.41 Å for **1**; 3.48 Å ($H_2A$), 3.38 Å (phen) for **2**; and 3.47 Å for **3**].

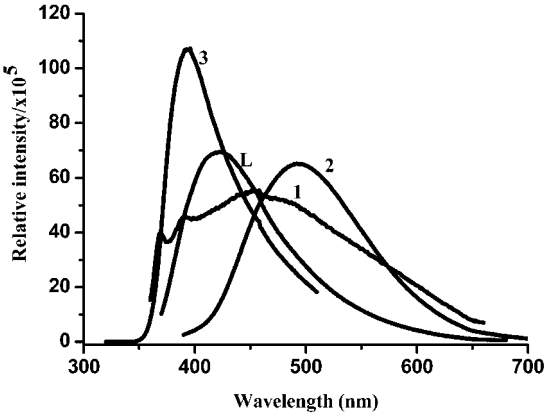

Figure 11. Photoluminescent spectra of $H_2A$ and complexes **1**–**3** in the solid state at room temperature.

## Conclusions

In this work, three supramolecular networks with strong luminescence as well as high thermal stability were obtained by hydrothermal synthesis. All of them contain nanometer channels formed by hydrogen bonds and π–π stacking. We have started to alter the luminescent properties and coordination modes by transforming the mixed ligands. This should lead to new, tunable, fluorescent materials. A novel 2D supramolecular network based on $H_2A$ ligand and $Cd(NO_3)_2{\cdot}4H_2O$ has been obtained by hydrothermal synthesis. When the phen molecule was added, the coordination mode was changed and a 2D coordination polymer was obtained. When phen was changed into bipy, a 3D supramolecular network was obtained. The maximum emission wavelengths of complexes **1**–**3** are 453, 492, and 396 nm, respectively. In addition to their strong emissions and reasonable thermal stability, they are almost insoluble in common polar and nonpolar solvents such as ethanol, chloroform, acetone, acetonitrile, benzene, and water. In conclusion, these compounds may be good candidates as advanced materials for light-emitting diode devices. The paper also shows that transforming the mixed ligands is an excellent way of changing the coordination modes and luminescent properties.

## Experimental Section

**General Remarks:** All chemicals and solvents were dried and purified by the usual methods. Elemental analysis data (C,H,N) were obtained using a Perkin–Elmer 240 analyzer. IR spectra were recorded with a Nicolet FTIR 170SX instrument (KBr discs) in the region of 4000–400 $cm^{-1}$. The luminescent spectra were measured on power samples at room temperature (room temp.) using a model Perkin–Elmer LS55 fluorescence spectrophotometer. TGA analyses were recorded with a Perkin–Elmer Pris-1 DMDA-V1 analyzer in nitrogen at a heating rate of 5 °C $min^{-1}$.

**9-Ethylcarbazole-3,6-dicarboxylic Acid:** The $H_2A$ ligand was synthesized using the established literature procedure.[16]

**Compound 1:** Complex **1** was synthesized using the established literature procedure.[16]

**Compound 2:** A mixture of $Cd(NO_3)_2{\cdot}4H_2O$ (0.117 g, 0.38 mmol), phen (0.0760 g, 0.38 mmol), $H_2A$ (0.0530 g, 0.19 mmol), $Na_2C_2O_4$ (0.0251 g (0.19 mmol), $H_2O$ (15 mL), and 15 drops of $C_2H_5OH$ was placed in a 25-mL Teflon-lined stainless steel vessel and then heated to 165 °C for 3 d and the reactant was cooled at a rate of 5 °C $min^{-1}$. The yellow crystals were obtained with a yield of 0.0780 g (70.2%) based on $H_2A$. $C_{28}H_{22}CdN_3O_{5.50}$ (600.89): calcd. C 55.97, H 3.69, N 6.99; found C 55.85, H 3.65, N 7.03. It is difficult to obtain reliable elemental analytical data because of the sensitivity of the analyzer. IR (KBr): $\tilde{\nu}$ = 3409 (m), 3066 (m), 2930

**Single-Crystal Structure Determination:** Data collection was performed at 298 K for **2** and **3** and 293 K for **1** using a Siemens Smart CCD area detector diffractometer with Mo-$K_\alpha$ radiation with an $\omega$-scan mode ($\lambda$ = 0.71073 Å). The structure was solved with direct methods using the SHELXTL program and refined anisotropically with SHELXTL using full-matrix least-squares procedure. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were added theoretically and not refined. The crystallographic data for **1**–**3** are listed in Table 1, and selected bond lengths and angles for **1**–**3** are presented in Table 2.

CCDC-278329 (for $[Cd(HA)_2(H_2O)_2]$), -299277 (for $[Cd(A)(phen)]\cdot 1.5H_2O$), and -299279 (for $[Cd(HA)_2(bipy)]$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

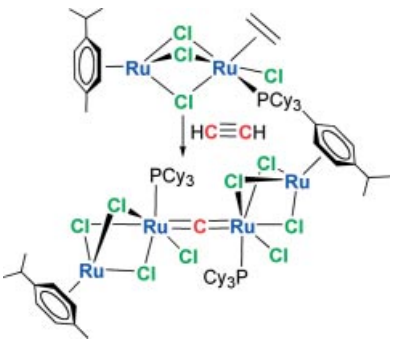
## SHORT COMMUNICATIONS

### Organometallic Chemistry

**E. Solari, S. Antonijevic, S. Gauthier, R. Scopelliti, K. Severin* ..... 367–371**

Formation of a Ruthenium μ-Carbide Complex with Acetylene as the Carbon Source

**Keywords:** Carbide ligands / Organometallic complexes / Ruthenium / Solid-state NMR spectroscopy / Vinylidene complexes



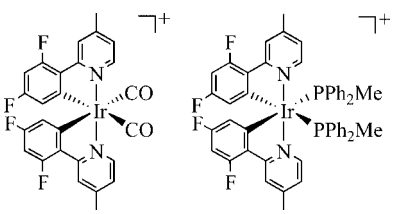
A tetranuclear μ-carbide complex was obtained by reaction of the dinuclear ruthenium complex [(*p*-cymene)Ru(μ-Cl)$_3$RuCl($C_2H_4$)($PCy_3$)] with acetylene as evidenced by single-crystal X-ray analysis as well as by solid-state NMR spectroscopy. Experiments with fully $^{13}$C-labelled acetylene demonstrate that acetylene was the carbon source for the carbide ligand.

### Light-Emitting Materials

**C. S. Chin,* M.-S. Eum, S. y. Kim, C. Kim, S. K. Kang ..... 372–375**

Blue-Light-Emitting Complexes: Cationic (2-Phenylpyridinato)iridium(III) Complexes with Strong-Field Ancillary Ligands

**Keywords:** Iridium / Luminescence / Blue-emitter / Strong field ligand



**2a$F_2$Me** **2b$F_2$Me**

Blue-light emission is obtained from cationic complexes **2a**$F_2$Me and **2b**$F_2$Me which contain strong-field ancillary ligands, CO and $PPh_2Me$, and a modified ppy ligand, $F_2$Meppy.

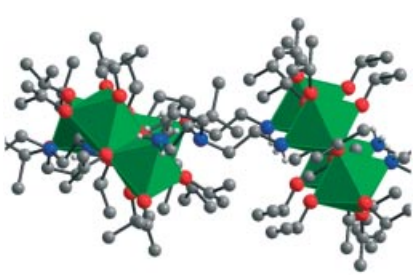
## FULL PAPERS

### Ti and Zr Coordination Polymers

**H. Fric, M. Puchberger, U. Schubert* ..... 376–383**

Two- and Three-Dimensional Coordination Polymers From the Reaction of Bis- and Tris(2-aminoethyl)amine with Titanium and Zirconium Alkoxides

**Keywords:** Titanium / Zirconium / Coordination polymers / N ligands



The chain-like coordination polymers [$M_2$-($OiPr)_8$($H_2NCH_2CH_2NHCH_2CH_2NH_2$)]$_\infty$, where only the $NH_2$ groups of the amine are coordinated to the $M_2(OiPr)_8$ units, are formed by reaction of the parent alkoxides [M($OiPr)_4$] (M = Ti, Zr) with an amine. These adducts dissociate into the starting compounds upon dissolution in $CD_2Cl_2$ but slowly re-form the solid-state structures over several weeks.

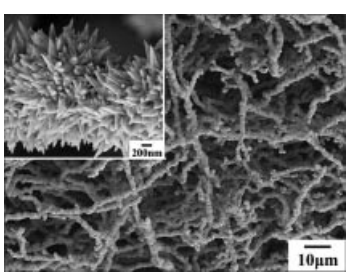
Reticular Nickel Microwires with Assembled Nanostructures: Synthesis, Magnetism and Catalysis for the Growth of Carbon Nanotubes

**Keywords:** Nickel / Nanostructures / Chemical reduction / Crystal growth



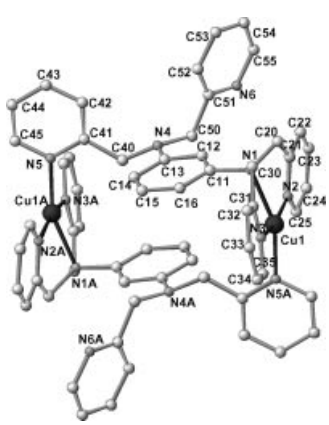
Reticular nickel microwires assembled from thorn-like nanocrystals are fabricated by a simple, complex-assisted chemical reduction route that does not require the use of surfactants or an external magnetic field. These nickel nanostructures exhibit high catalytic efficiency for the growth of carbon nanotubes in pyrolyzing acetone.

## A Versatile Ligand in Coordination Chemistry

**S. Foxon, J.-Y. Xu, S. Turba, M. Leibold, F. Hampel, F. W. Heinemann, O. Walter, C. Würtele, M. Holthausen, S. Schindler* ..... 429–443**

Syntheses, Characterization and Reactivity of Iron(II), Nickel(II), Copper(II) and Zinc(II) Complexes of the Ligand *N,N,N′,N′*-Tetrakis(2-pyridylmethyl)benzene-1,3-diamine (1,3-tpbd) and Its Phenol Derivative 2,6-Bis[bis(2-pyridylmethyl)amino]-*p*-cresol (2,6-tpcd)

**Keywords:** Iron / Copper / Zinc / Ligand effects



Redox active metal centers such as iron or copper ions demonstrate that *N,N,N′,N′*-Tetrakis(2-pyridyl methyl)benzene-1,3-diamine (1,3-tpbd) is a non-innocent ligand. Theoretical calculations support the formation of a dinuclear side-on copper peroxo complex during the reaction of the copper(I) complex with dioxygen. Most interestingly is a reaction if one equivalent of Cu(II) together with one equivalent of Zn(II) is reacted with one equivalent of 1,3-tbpd. Here $[Cu_2(1,3\text{-tpbd})_2(H_2O)_2](ClO_4)_4$ a so called "dimetallocyclophane" formed.

# Formation of a Ruthenium μ-Carbide Complex with Acetylene as the Carbon Source

**Euro Solari,[a] Sasa Antonijevic,[a] Sébastien Gauthier,[a] Rosario Scopelliti,[a] and Kay Severin*[a]**

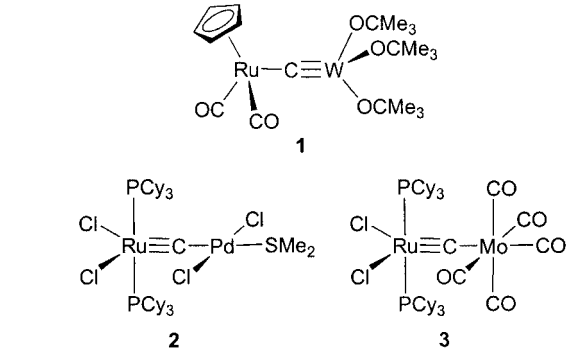
**Keywords:** Carbide ligands / Organometallic complexes / Ruthenium / Solid-state NMR spectroscopy / Vinylidene complexes

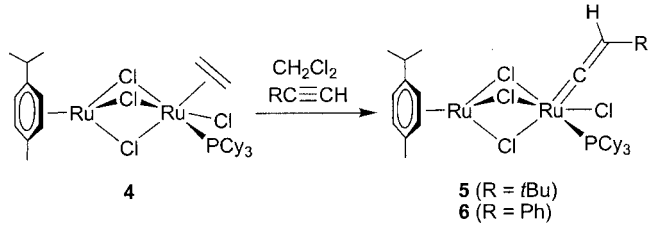
Reactions of the dinuclear ruthenium complex [(*p*-cymene)-$Ru(\mu\text{-}Cl)_3RuCl(C_2H_4)(PCy_3)$] with phenylacetylene or *tert*-butylacetylene gave the vinylidene complexes [(*p*-cymene)-$Ru(\mu\text{-}Cl)_3RuCl(=C=CHR)(PCy_3)$] (R = *t*Bu, Ph), which were characterized crystallographically. With acetylene, however, a tetranuclear μ-carbide complex was obtained as evidenced by single-crystal X-ray analysis as well as by solid-state NMR spectroscopy. Experiments with fully $^{13}C$-labelled acetylene showed that acetylene was the carbon source for the carbide ligand.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

A complex containing a single carbon atom as a bridging ligand between a metalloporphyrin and a second metal-fragment was described for the first time in 1979.[1] Since then, several structurally related compounds with porphyrinato or phthalocyaninato ligands have been reported.[2] Well-characterized μ-carbide complexes without these ligands are still rare.[3] An early example was published by Latesky and Selegue in 1987.[3e] They showed that the reaction between $[CpRu(C{\equiv}CMe)(CO)_2]$ and $[W(\equiv CEt)(OCMe_3)_3]$ proceeds with elimination of 2-pentyne to give the heteronuclear μ-carbide complex $[Cp(CO)_2Ru{-}C{\equiv}W(OCMe_3)_3]$ (**1**). More recently, it was observed that the terminal carbide complex $[RuCl_2(\equiv C)(PCy_3)_2]$[4] can act as a 'σ-donor ligand' for other metals to form bimetallic complexes such as **2** and **3**.[3b] In the following, we describe a tetranuclear complex containing an unusual {Ru=C=Ru} unit. This complex was obtained by a novel reaction from acetylene by cleavage of the carbon triple bond.

Over the last years, we investigated ruthenium complexes as catalysts for atom transfer radical reactions.[5] The halogeno-bridged complex [(*p*-cymene)$Ru(\mu\text{-}Cl)_3RuCl(C_2H_4)$-$(PCy_3)$] (**4**), which can easily be obtained from commercial $[(p\text{-cymene})RuCl_2]_2$, was found to display an exceptionally high activity for atom transfer radical addition reactions under mild conditions.[5c] In order to further explore the reactivity of this complex, we have investigated the reaction of **4** with alkynes. When phenylacetylene or *tert*-butylacetylene was added to a solution of complex **4** in $CH_2Cl_2$ or benzene, the rapid and quantitative formation of a new complex was observed as evidenced by in situ $^{31}P$ NMR spectroscopic experiments (Scheme 1). The products **5** and **6** were isolated in nearly quantitative yields by evaporation of the solvent and washing with hexane.





Scheme 1.

Both complexes were characterized by NMR spectroscopy ($^1H$, $^{13}C$, $^{31}P$; see Supporting Information), elemental analysis and single-crystal X-ray analysis (Figure 1 and Figure 2). The structures of **5** and **6** can be described as face-bridged dimers with a (*p*-cymene)Ru fragment con-

nected by three chlorido bridges to a RuCl(=C=CHR)-($PCy_3$) fragment.[6] The Ru1–C1 distances [1.817(6) Å for **5**; 1.778(8) Å for **6**] are comparable to those of other coordinatively saturated Ru–vinylidene complexes such as [TpRuCl(=C=CHPh)($PPh_3$)] [1.801(4) Å][7] or [{RuCl($i$Pr$_2$-$PCH_2CH_2OMe)_2$(=C=CHPh)}(OTf)] [1.790(3) Å].[8] Apart from the vinylidene ligand, the bond lengths for **5** and **6** are similar to those for the starting material **4**. However, there is one notable exception: the Ru1–Cl1 bonds are significantly longer [2.6551(13) Å for **5**; 2.630(2) Å for **6**] than that of complex **4** [2.4878(6) Å]. This can be ascribed to the stronger *trans* influence of the vinylidene ligands relative to that of the ethylene ligand.

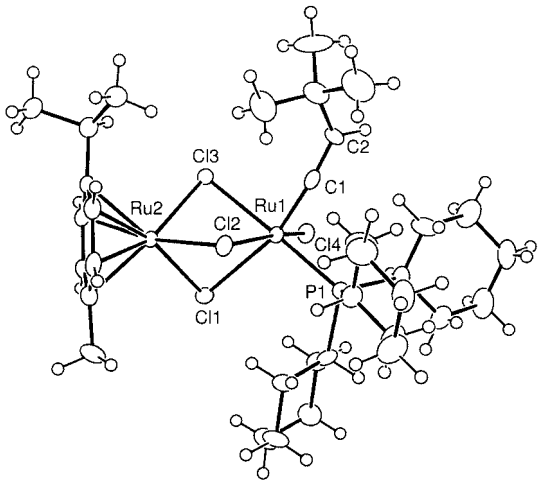

Figure 1. Graphical representation of the molecular structure of **5** in the crystal. The solvent molecules ($CH_2Cl_2$, 0.5 toluene) are not shown for clarity. Selected bond lengths [Å] and angles [°]: Ru1–Cl1 2.6551(13), Ru1–Cl2 2.4221(14), Ru1–Cl3 2.5246(13), Ru1–Cl4 2.3672(14), Ru1–P1 2.3129(14), Ru1–C1 1.817(6), C1–C2 1.299(8), Ru2–Cl1 2.4376(15), Ru2–Cl2 2.4607(12), Ru2–Cl3 2.4397(13); Cl1–Ru1–C1 163.93(17), Cl4–Ru1–Cl2 165.61(5), Cl4–Ru1–P1 91.33(5).

The formation of **5** and **6** can be rationalized by the displacement of the ethylene ligand by the respective acetylene followed by an alkyne-to-vinylidene transformation.[9] A related reaction with a face-bridged Ru dimer was reported by Fogg et al., who found that the addition of *tert*-butylacetylene to [(dcypb)ClRu(μ-Cl)$_3$Ru(dcypb)($N_2$)] {dcypb = 1,4-bis(dicyclohexylphosphanyl)butane} gave the vinylidene complex [(dcypb)ClRu(μ-Cl)$_3$Ru(=C=CH–$t$Bu)(dcypb)] by displacement of the dinitrogen ligand.[10]

When a solution of the olefin complex **4** in $CH_2Cl_2$ was treated with acetylene, the formation of a black product was observed, which was not characterized further. However, when a stoichiometric amount (1.2 equiv.) of acetylene was used in combination with thf as the solvent, a yellow-orange complex (**7**) precipitated.[11] Complex **7** displayed a very low solubility in all solvents. A detailed solution NMR analysis of **7** was therefore not possible, but crystals of sufficient quality for a single-crystal X-ray analysis were obtained from a dilute $CH_2Cl_2$ solution. Surprisingly, it was found that a tetranuclear μ-carbide complex had formed

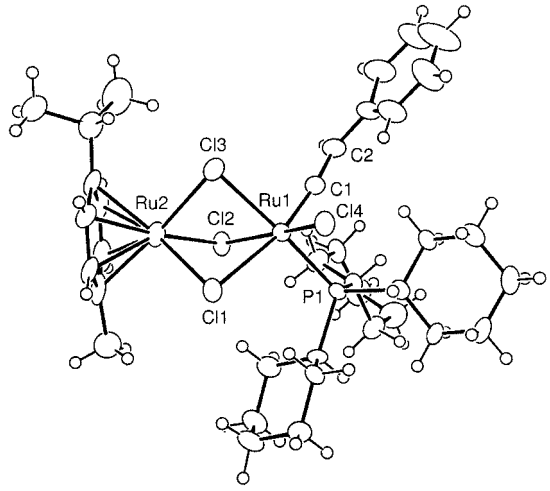

Figure 2. Graphical representation of the molecular structure of **6** in the crystal. The solvent molecules (2 toluene) are not shown for clarity. Selected bond lengths [Å] and angles [°]: Ru1–Cl1 2.630(2), Ru1–Cl2 2.403(2), Ru1–Cl3 2.541(2), Ru1–Cl4 2.362(2), Ru1–P1 2.325(2), Ru1–C1 1.778(8), C1–C2 1.329(11), Ru2–Cl1 2.427(2), Ru2–Cl2 2.428(2), Ru2–Cl3 2.437(2); Cl1–Ru1–C1 167.0(3), Cl4–Ru1–Cl2 164.32(8), Cl4–Ru1–P1 92.76(8).

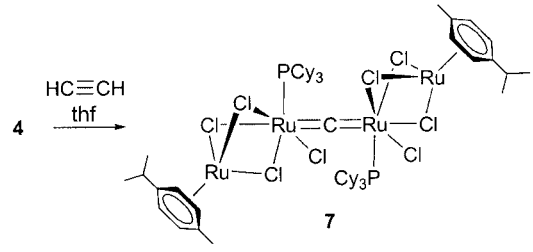
(Scheme 2 and Figure 3). The elemental analysis of **7** was in agreement with this result, and the total yield with respect to the starting material was 56%.



Scheme 2.

The molecular structure of complex **7** in the crystal consists of two symmetry-related[12] {(*p*-cymene)Ru(μ-Cl)$_3$-RuCl($PCy_3$)} fragments connected by a carbide ligand in a nearly linear fashion [Ru1–C1–Ru1_2 = 178.8(9)°] (Figure 3). The Ru1–C1 bond length [1.7877(9) Å] is longer than that of the carbide complex **2** [1.662(2) Å][3b] and similar to the Ru–C distances found for the vinylidene complexes **5** and **6**. This confirms the {Ru=C=Ru} structure of complex **7** as depicted in Scheme 2. The octahedral geometry around Ru1 is highly distorted. Noteworthy is the long Ru1–Cl1 distance of 2.685(3) Å, which demonstrates that the μ-carbide ligand also has a very strong *trans* influence.

A priori, the carbon atom sandwiched between the two ruthenium atoms could have resulted from an acetylene-induced splitting of the ethylene ligand of complex **4** or from acetylene itself. To clarify this issue, the reaction was repeated with fully $^{13}$C-labelled acetylene. The resulting product was investigated by solid-state MAS NMR spectroscopy. The $^{13}C\{^1H\}$ cross-polarized MAS NMR spectra of complex **7** show a strong signal at $\delta$ = 430.5 ppm (Figure 4), which can clearly be attributed to the bridging car-

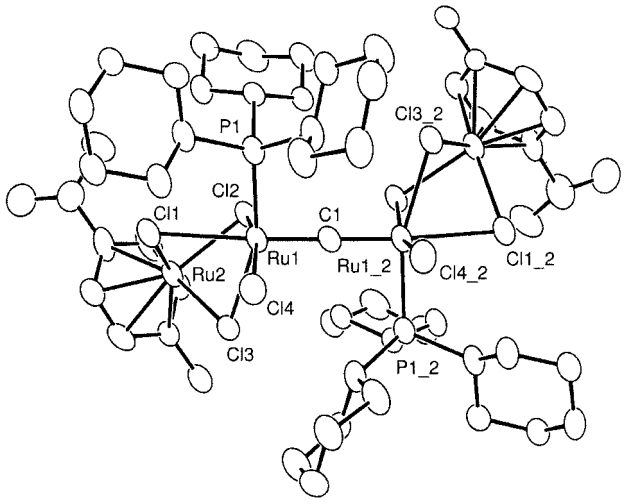

Figure 3. Graphical representation of the molecular structure of **7** in the crystal. The solvent molecules ($5\,CH_2Cl_2$) and the hydrogen atoms are not shown for clarity. Selected bond lengths [Å] and angles [°]: Ru1–C1 1.7877(9), Ru1–Cl1 2.685(3), Ru1–Cl2 2.439(3), Ru1–Cl3 2.548(3), Ru1–Cl4 2.365(3), Ru1–P1 2.350(4); Cl1–Ru1–C1 169.7(4), Cl4–Ru1–Cl2 162.99(11), Cl4–Ru1–P1 93.46(12), P1–Ru1–Cl3 161.75(11), Ru1–C1–Ru1_2 178.8(9).

bide ligand. The position of the signal is within the expected range as structurally related complexes such as **2** and **3** display resonances in the same region (**2**: $\delta$ = 381.2 ppm; **3**: $\delta$ = 446.3 ppm).[3b] These results demonstrate that the source of the μ-carbide ligand of complex **7** is indeed the acetylene.

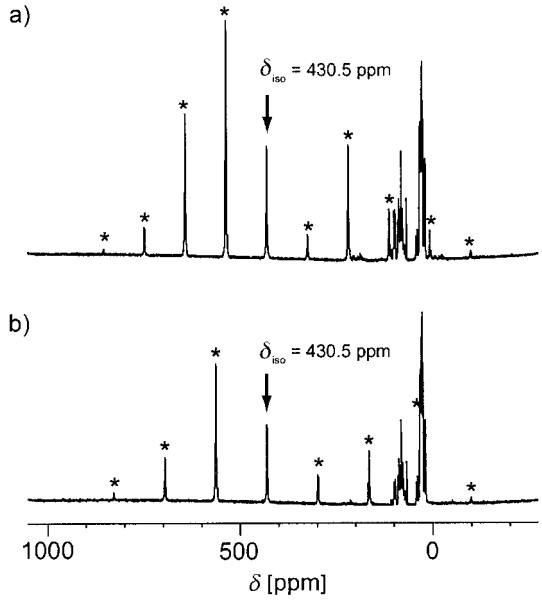

Figure 4. $^{13}C\{^1H\}$ cross-polarized (CP) MAS NMR spectra of solid complex **7** recorded at the spinning rates of (a) 8 kHz and (b) 10 kHz. The centreband, the isotropic chemical shift $\delta_{iso}$ = 430.5 ppm, of the C5 carbon resonance is indicated with an arrow, while the spinning sidebands are indicated by an *. The spectra are the result of averaging 12800 transients with a recycle interval of 3 s. The CP contact time was 5 ms.

In order to obtain information about possible side products of this unusual reaction, we investigated the mother liquor, from which complex **7** had precipitated, by solution NMR spectroscopy. The $^{31}P$ NMR spectrum shows several peaks with two dominant signals at $\delta$ = 61.82 and 66.00 ppm (see Supporting Information). The first signal appears as a doublet with a coupling constant of 17.9 Hz to a $^{13}C$ NMR signal at $\delta$ = 204.17 ppm. The second signal appears as a doublet of a doublet with a coupling constant of 20.2 Hz to a $^{13}C$ NMR signal at $\delta$ = 206.17 ppm and of 10.1 Hz to a $^{13}C$ signal at –10.46 ppm. The latter $^{13}C$ signal is assigned to a $CH_3$ group as evidenced by a $^{13}C$ NMR spectrum with coupling to $^1H$. The high-field position of the signal suggests a Ru-bound methyl group. On the basis of this data we propose that the two major phosphane complexes in solution contain a Ru($^{13}CX$)($PCy_3$) fragment (species at $\delta$ = 61.82 ppm) and a Ru($^{13}CX$)($^{13}CH_3$)($PCy_3$) fragment (species at $\delta$ = 66.00 ppm). The nature of the group/fragment 'X′ is currently not clear. From the chemical shift of the $^{13}C$ NMR signal at ca. 200 ppm, it can be excluded that X = Ru, and H-coupled spectra demonstrate that there are no protons directly bound to the $^{13}C$ carbon atom.

In summary, we have described the reaction of the dinuclear complex [(*p*-cymene)Ru(μ-Cl)$_3$RuCl($C_2H_4$)($PCy_3$)] (**4**) with alkynes. Whereas the vinylidene complexes **5** and **6** were obtained for phenylacetylene and *tert*-butylacetylene, the μ-carbide complex **7** was formed for reactions with acetylene. The latter represents a rare example of a structurally characterized Ru(μ-C)Ru complex. The available experimental data do not allow for the proposal of a mechanism for this unusual reaction. A plausible intermediate is the vinylidene complex [(*p*-cymene)Ru(μ-Cl)$_3$RuCl(C=$CH_2$)-($PCy_3$)], which undergoes subsequent transformations. It should be noted that Ru(=C=$CH_2$) complexes are not intrinsically unstable as evidenced by the isolation of, for example, the complex [RuHCl(=C=$CH_2$)(P*t*$Bu_2$Me)$_2$].[13] The fact that complex **4** can promote the splitting of a carbon triple bond of acetylene at room temperature is further evidence for its high reactivity,[5c] and other organometallic transformations of this complex are currently being investigated in our laboratory.

## Experimental Section

**General:** The synthesis of all complexes was performed under an atmosphere of dry argon by using standard Schlenk techniques. The complex [(*p*-cymene)Ru(μ-Cl)$_3$Ru($PCy_3$)($C_2H_4$)Cl] (**4**) was prepared as described before.[5c] The fully $^{13}C$-labelled acetylene (99%) was obtained from Cambridge Isotope Laboratories, Inc. The $^1H$- and $^{13}C$ NMR spectra in solution were recorded on Bruker Advance DPX 400, Advance 600 and Advance 800 instruments by using the residual protonated solvents as internal standards. Solid-state NMR spectra were recorded on a Bruker DRX 300 spectrometer equipped with a 7.0 widebore magnet and utilising a 4-mm CPMAS probehead. A nicely powdered sample was packed under a $N_2$ atmosphere into a 4-mm outer diameter $ZrO_2$ rotor. Chemical shifts of $^{13}C$ are reported in ppm relative to an external TMS standard.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Synthesis of Complex 5:** [(*p*-cymene)Ru(μ-Cl)$_3$Ru(PCy$_3$)(C$_2$H$_4$)Cl] (**4**) (100 mg, 128 μmol) and *tert*-butylacetylene (19 μL, 154 μmol) in $CH_2Cl_2$ (5 mL) were stirred for 2 h under an inert atmosphere. After evaporation of the solvent under reduced pressure, the product was washed with hexane and dried under vacuum (isolated yield: 103 mg, 96%). Orange crystals were obtained from cold toluene. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.15 (s, 9 H, *t*Bu), 1.20–1.32 (m, 9 H, PCy$_3$), 1.32 [d, $^3J$ = 7 Hz, 3 H, CH(C$H_3$)$_2$], 1.34 [d, $^3J$ = 7 Hz, 3 H, CH(C$H_3$)$_2$], 1.54–2.13 (m, 24 H, PCy$_3$), 2.30 (s, 3 H, $CH_3$), 2.96 [sept, $^3J$ = 7 Hz, 1 H, C*H*(CH$_3$)$_2$], 3.83 (d, $^4J_{PH}$ = 3 Hz, 1 H, C*H*-*t*Bu), 5.37 (d, $^3J$ = 6 Hz, 2 H, CH, cymene), 5.50 (d, $^3J$ = 6 Hz, 1 H, CH, cymene), 5.58 (d, $^3J$ = 6 Hz, 1 H, CH, cymene) ppm. $^{13}$C NMR (101 MHz, $CDCl_3$): $\delta$ = 18.73 ($CH_3$, cymene), 22.07, 22.14 [CH(*C*H$_3$)$_2$, cymene], 26.32 ($CH_2$, PCy$_3$), 27.64 (d, $^3J_{PC}$ = 10 Hz, $CH_2$, PCy$_3$), 28.82 (d, $^2J_{PC}$ = 19 Hz, $CH_2$, PCy$_3$), 31.01 [*C*H(CH$_3$)$_2$, cymene], 33.13 (*t*Bu), 35.07 (d, $^1J_{PC}$ = 24 Hz, CH, PCy$_3$), 78.56, 78.78, 79.03, 79.78 (CH, cymene), 96.44, 101.19 (C, cymene), 122.23 (Ru=C=*C*), 352.55 (d, $^2J_{PC}$ = 19 Hz, Ru=C) ppm. $^{31}$P NMR (162 MHz, $CDCl_3$): $\delta$ = 54.48 (s) ppm. $C_{34}H_{57}Cl_4PRu_2$ (840.74): calcd. C 48.57, H 6.83; found C 48.84, H 6.73.

**Synthesis of Complex 6:** The synthesis was performed analogously to that of complex **5** by using phenylacetylene (18 μL, 154 μmol) (isolated yield: 105 mg, 95%). Orange crystals were obtained from cold toluene. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.12–1.35 (m, 9 H, PCy$_3$), 1.34 [d, $^3J$ = 7 Hz, 3 H, CH(C$H_3$)$_2$], 1.36 [d, $^3J$ = 7 Hz, 3 H, CH(C$H_3$)$_2$], 1.52–2.17 (m, 24 H, PCy$_3$), 2.29 (s, 3 H, $CH_3$), 2.96 [sept, $^3J$ = 7 Hz, 1 H, C*H*(CH$_3$)$_2$], 4.91 [d, $^4J_{PH}$ = 4 Hz, 1 H, C*H*(Ph)], 5.41 (d, $^3J$ = 6 Hz, 2 H, CH, cymene), 5.55 (d, $^3J$ = 6 Hz, 1 H, CH, cymene), 5.64 (d, $^3J$ = 6 Hz, 1 H, CH, cymene), 6.88–7.14 (m, 5 H, Ph) ppm. $^{13}$C NMR (101 MHz, $CDCl_3$): $\delta$ = 18.80 ($CH_3$, cymene), 22.06, 22.35 [CH(*C*H$_3$)$_2$, cymene], 26.28 ($CH_2$, PCy$_3$), 27.69 (d, $^3J_{PC}$ = 11 Hz, $CH_2$, PCy$_3$), 28.89 (d, $^2J_{PC}$ = 15 Hz, $CH_2$, PCy$_3$), 31.16 [*C*H(CH$_3$)$_2$, cymene], 35.07 (d, $^1J_{PC}$ = 24 Hz, CH, PCy$_3$), 78.28, 78.79, 79.52, 80.04 (CH, cymene), 97.03, 101.12 (C, cymene), 114.10 (Ru=C=*C*), 124.42, 125.85, 128.06, 131.07 (Ph), 356.11 (d, $^2J_{PC}$ = 19 Hz, Ru=C) ppm. $^{31}$P NMR (162 MHz, $CDCl_3$): $\delta$ = 54.21 (s) ppm. $C_{36}H_{53}Cl_4PRu_2$ (860.73): calcd. C 50.23, H 6.21; found C 50.14, H 6.24.

**Synthesis of Complex 7:** A fixed volume of acetylene (35 mL, 1.5 mmol) was connected to a 100-mL flask containing [(*p*-cymene)Ru(μ-Cl)$_3$Ru(PCy$_3$)(C$_2$H$_4$)Cl] (**4**) (1.00 g, 1.30 mmol) and thf (50 mL). The suspension was stirred for 24 h at room temperature during which the colour changed from orange-red to yellow-orange. The product was collected on a filter and dried in vacuo (yield: 560 mg, 56%). $C_{57}H_{94}Cl_8P_2Ru_4$ (1529.21): calcd. C 44.77, H 6.19; found C 44.65, H 6.11. Single crystals were obtained from $CH_2Cl_2$.

**X-ray Analyses:** Data collection was performed at 140(2) K with an Oxford Diffraction KM4 Sapphire CCD. Data reduction was carried out with CrysAlis RED, release 1.7.0.[14] Absorption correction was applied to both data sets. Structure solution and refinement were performed with the SHELXTL software package, release 5.1.[15] The structures were refined by using the full-matrix least-squares on $F^2$ with all non-H atoms anisotropically refined. H atoms were placed in calculated positions by using the 'riding model'. CCDC 624643–624645 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal Data for Complex 5·$CH_2Cl_2$·0.5$C_6H_5CH_3$:** $C_{38.5}H_{63}Cl_6PRu_2$, $M$ = 971.70, triclinic, $a$ = 10.3246(7), $b$ = 13.0596(9), $c$ = 17.2481(10) Å, $\alpha$ = 77.248(5), $\beta$ = 85.836(5), $\gamma$ = 73.173(6)°, $V$ = 2171.1(2) Å$^3$, $T$ = 140(2) K, space group $P\bar{1}$, $Z$ = 2, $\mu$(Mo-$K_\alpha$) = 0.71073 Å, 13023 reflections collected, 6716 independent reflections, $R_{int}$ = 0.0307, $R_1$ [$I > 2\sigma(I)$] = 0.0457, $wR_2$ (all data) = 0.1281.

**Crystal Data for Complex 6·2$C_6H_5CH_3$:** $C_{50}H_{69}Cl_4PRu_2$, $M$ = 1044.96, monoclinic, $a$ = 9.6774(4), $b$ = 16.9682(9), $c$ = 30.2874(17) Å, $\beta$ = 97.243(4)°, $V$ = 4933.7(4) Å$^3$, $T$ = 140(2) K, space group $P2_1/c$, $Z$ = 4, $\mu$(Mo-$K_\alpha$) = 0.71073 Å, 28793 reflections collected, 7990 independent reflections, $R_{int}$ = 0.0587, $R_1$ [$I > 2\sigma(I)$] = 0.0648, $wR_2$ (all data) = 0.1549.

**Crystal Data for Complex 7·5$CH_2Cl_2$:** $C_{62}H_{104}Cl_{18}P_2Ru_4$, $M$ = 1953.77, monoclinic, $a$ = 17.8078(15), $b$ = 23.903(3), $c$ = 18.5150(17) Å, $\beta$ = 91.104(7)°, $V$ = 7879.7(13) Å$^3$, $T$ = 140(2) K, space group $C2/c$, $Z$ = 4, $\mu$(Mo-$K_\alpha$) = 0.71073 Å, 22389 reflections collected, 6566 independent reflections, $R_{int}$ = 0.1115, $R_1$ [$I > 2\sigma(I)$] = 0.0905, $wR_2$ (all data) = 0.2645.

**Supporting Information** (see footnote on the first page of this article): $^{13}$C- and $^{31}$P NMR spectra of the mother liquor of the reaction between complex **4** and fully $^{13}$C-labelled acetylene.

# Blue-Light-Emitting Complexes: Cationic (2-Phenylpyridinato)iridium(III) Complexes with Strong-Field Ancillary Ligands

**Chong Shik Chin,*[a] Min-Sik Eum,[a] Song yi Kim,[a] Choongil Kim,[a] and Sung Kwon Kang[b]**

**Keywords:** Iridium / Luminescence / Blue-light emitter / Strong-field ligand

The emission $\lambda_{max}$ are strikingly shorter (451, 482 nm) for the cationic dicarbonyl complex $[Ir(ppy)_2(CO)_2]^+$ (**2a**) than those (473, 495 nm) of the anionic dicyano complex $[Ir(ppy)_2(CN)_2]^-$, where CO and $CN^-$ are both sp carbon coordinating ligands and known to be strong-field ligands showing a high *trans* effect. Sky-blue-light emission ($\lambda_{max}$ = 441–443 and 470–471 nm) could be obtained by modifying the ppy ligand to $F_2$Meppy (2,4-difluoro-2-phenyl-*m*-methylpyridinato anion) to prepare $[Ir(F_2Meppy)_2LL']^+$ [LL′ = $(CO)_2$ (**2a**$F_2$Me), $(PPh_2Me)_2$ (**2b**$F_2$Me)].

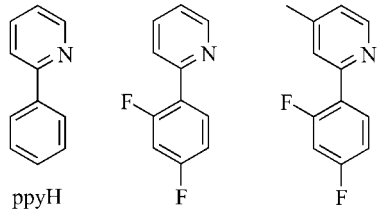
## Introduction

Research of blue-light-emitting materials is currently under thorough investigation because efficient blue-light emitters are in need in the display industry.[1] Iridium complexes of ppy (2-phenylpyridinato) have drawn much attention as they emit phosphorescence in the visible region with high quantum yields and the emission $\lambda_{max}$ can be tuned by modification of the ligands.[1–4] Theoretical calculations for $[Ir(ppy)_3]$,[2c] $[Ir(ppy)_2L_2]$,[4b] and [Pt(ppy)(acac)][5] suggest that the HOMO of these metal complexes include dπ-orbitals of the metal and orbitals of $L_2$[4b] or acac.[5] Spectroscopic data analysis for $Ir(C\text{^}N)_2LL'$ ($C\text{^}N$ = ppy and its derivatives)[4b] revealed that ancillary ligands (L, L′) alter the $^1$MLCT energy mainly by changing the HOMO energy level. The HOMO energy level may then be lowered by strong-field ancillary ligands, which causes a large d-orbital energy splitting. It is also likely that strong-field ancillary ligands L and L′ lengthen the bond lengths of Ir–C (ppy) *trans* to L and L′ to lower the energy levels of the dπ-orbitals of the metal as strong-field ligands are known to show a high *trans* effect.

Cationic complexes $[Ir(C\text{^}N)_2L_2]^+$ (L = neutral ligands such as CO) would be harder to oxidize than anionic complexes $[Ir(C\text{^}N)_2A_2]^-$ (A = anionic ligands such as $CN^-$) when L and A are the ligands having comparable ligand-field strength. One could expect, therefore, a larger energy gap between the HOMO and LUMO of the cationic complexes than that of the anionic complexes. A cationic complex such as $[Ir(C\text{^}N)_2(CO)_2]^+$ (not reported previously) would show a blueshifted emission $\lambda_{max}$ from that of the anionic complex $[Ir(C\text{^}N)_2(CN)_2]^-$ because both CO and $CN^-$ are well-known strong-field ligands that give large d-orbital energy splitting between dπ-orbitals ($e_g$) and dσ-orbitals ($t_{2g}$). One advantageous application of cationic complexes is their use for single-layer electroluminescent devices.[6]

We now wish to report new cationic complexes $[Ir(C\text{^}N)_2L_2]^+$ and $[Ir(C\text{^}N)_2LL']^+$ [$C\text{^}N$ = ppy, $F_2$ppy, $F_2$Meppy; L, L′ = strong-field ligands: CO, $PPh_2Me$, $P(OPh)_3$] and their photoluminescent characteristics in the blue color region.



## Results and Discussion

Cationic complexes $[Ir(ppy)_2L_2]^+$ (**2**) and $[Ir(ppy)_2LL']^+$ (**3**, **4**) have been newly prepared (Scheme 1) and unambiguously characterized in detail by $^1$H-, $^{13}$C-, $^{31}$P NMR, IR spectral and elemental analysis data and also X-ray diffraction data analysis for single crystals of $[Ir(ppy)_2(PPh_3)(NCMe)]^+$ (**4a**). Assignment of the spectral signals is straightforward by comparison with those of related compounds previously reported (see Supporting Information).

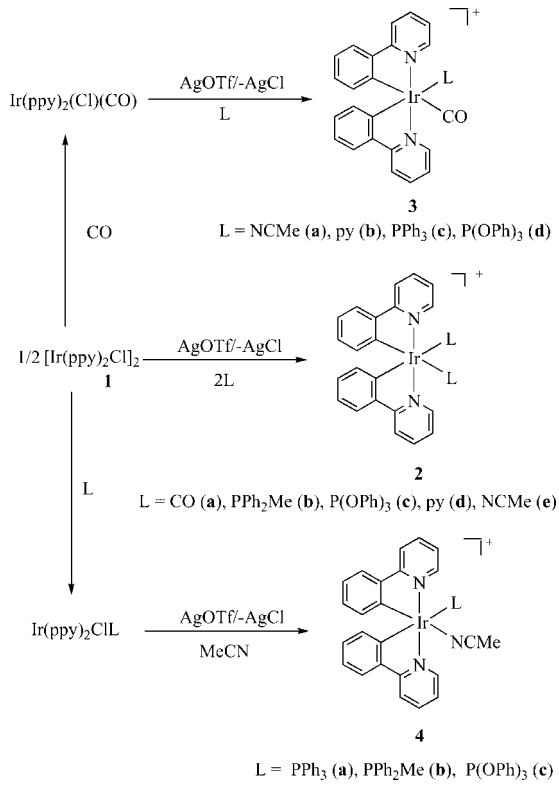
For example, the $Ir(ppy)_2$ moiety is unambiguously identified by detailed $^1H$- and $^{13}C$-NMR spectroscopic data while carbonyl (CO), cyano (CN), and MeCN complexes are characterized by IR absorptions due to ν(C≡O), ν(C≡N), and ν(N≡C).



Scheme 1. Synthetic routes for $[Ir(ppy)_2L_2]^+$ (**2**), $[Ir(ppy)_2(CO)L]^+$ (**3**), and $[Ir(ppy)_2(NCMe)L]^+$ (**4**).

Attempts to prepare bis($PPh_3$) complex $[Ir(ppy)_2(PPh_3)_2]^+$ have been unsuccessful probably because $PPh_3$ is too large for the *cis*-$Ir(ppy)_2$ moiety to have two $PPh_3$ in the *cis* positions. Figure 1 shows that replacement of the MeCN ligand of **4a** with another $PPh_3$ would make the metal center too crowded to give the stable bis($PPh_3$) complex. A smaller phosphane ($PPh_2Me$) and a less congested phosphite [$P(OPh)_3$] fit into the *cis* positions of $[Ir(ppy)_2L_2]^+$ to give stable complexes, **2b** and **2c**.

Dicarbonyl complex $[Ir(ppy)_2(CO)_2]^+$ (**2a**) was the first complex synthesized in this study because the ligand-field strength of CO is as strong as that of $CN^-$ and photophysical data for the anionic complex $[Ir(ppy)_2(CN)_2]^-$ (**5**)[4a] are available to compare with those of **2a**.

Cationic complex **2a** shows emission $\lambda_{max}$ at 451 and 482 nm which are much shorter than those (473, 495 nm) of anionic complex **5** (see Table 1). Cationic complexes **2b** and **2c** with other strong-field ligands $PPh_2Me$ and $P(OPh)_3$ also emit blue color, whereas a longer emission $\lambda_{max}$ (480, 508 nm) is measured for complex **2d** containing the medium-strength-field ligand pyridine (Figure 2). Complex **2e** with the other N-based ligand MeCN shows the emission at $\lambda_{max}$ at 469 and 500 nm in MeCN where the dissociation of the labile MeCN ligand from **2** is suppressed, although no measurable emission is found in $CH_2Cl_2$ for **2e** as reported previously by Watts.[7]

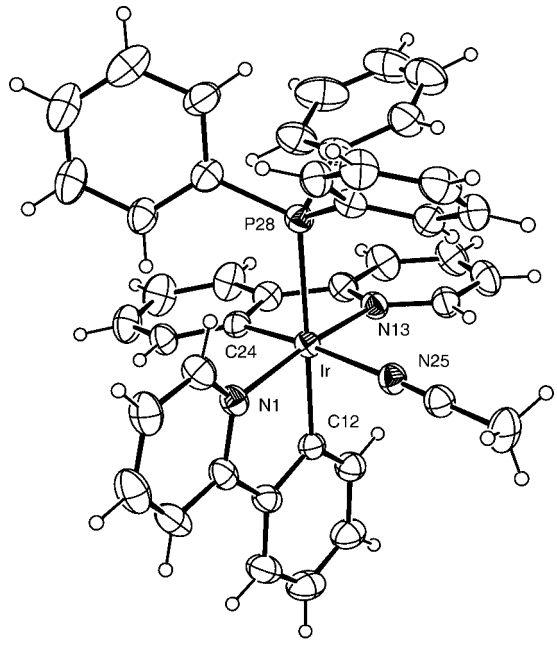


Figure 1. ORTEP drawing of $[Ir(ppy)_2(NCMe)(PPh_3)]^+$ (**4a**) with 50% thermal ellipsoids probability. Selected bond lengths [Å]: Ir–$N^1$ = 2.081(6); Ir–$N^{13}$ = 2.046(6); Ir–$N^{25}$ = 2.111(7); Ir–$C^{12}$ = 2.052(7); Ir–$C^{24}$ = 2.026(8), Ir–$P^{28}$ = 2.4342(19). Selected bond angles [°]: $N^1$–Ir–$N^{13}$ = 171.3(2); $C^{12}$–Ir–$P^{28}$ = 178.44(19); $C^{24}$–Ir–$N^{25}$ = 171.3(3).

| **5** | (CN)(CN) | 473, 495 | 0.79[b] | 2.6 |

[a] Compounds **2a**–**d** and **3b**–**d** in $CH_2Cl_2$ and **2e**, **3a**, **4a**–**4c**, and **5** in $CH_3CN$ at 298 K under an atmosphere of Ar. [b] Measured in this study and in agreement with the reported value,[4a] within experimental errors. [c] Calculated employing *fac*-$Ir(ppy)_3$ ($\Phi_{PL}$ = 0.40[8]) as the standard.

The quantum yields of complexes **2a**–**d** decrease significantly with a shift of the emission $\lambda_{max}$ to shorter wavelengths (see Table 1 and Figure 2). These results agree with the suggestion that the luminescence quantum yields decline with increasing emission energies.[4b] Among complexes prepared in this study, complex **2d** shows the longest emission $\lambda_{max}$ and the highest quantum yield. Both emis-

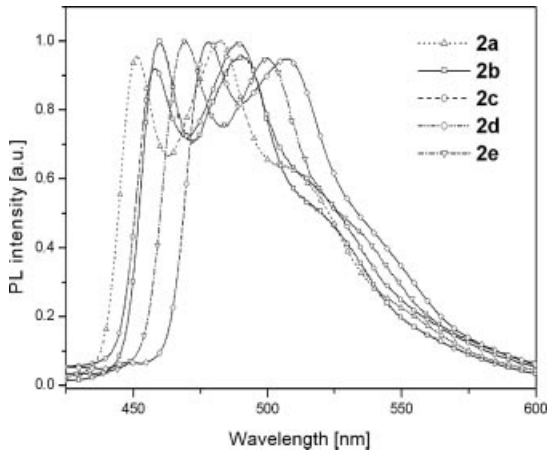

Figure 2. Normalized emission spectra of $[Ir(ppy)_2L_2](OTf)$ (**2**, $1 \times 10^{-4}$ M) in $CH_2Cl_2$ (**2a**–**d**), and MeCN (**2e**) at room temperature;·L = CO (**2a**), $PPh_2Me$ (**2b**), $P(OPh)_3$ (**2c**), py (**2d**), MeCN (**2e**).

sion $\lambda_{max}$ and quantum yield of cationic complex **2d** ($\lambda_{max}$ = 480, 508 nm; $_{PL}$ = 0.73 in $CH_2Cl_2$) are close to those of anionic complex **5** ($\lambda_{max}$ = 473, 495 nm; $\Phi_{PL}$ = 0.79 in MeCN) although pyridine is a much weaker-field ligand than $CN^-$. The lifetimes of cationic complexes prepared in this study are significantly shorter than that of anionic complex **5** and shorter lifetimes are measured for the complexes with relatively higher quantum yields (see Table 1).

The results observed for $[Ir(ppy)_2(L)_2]^+$ (**2**) agree with the anticipation that the emission $\lambda_{max}$ would be blueshifted by the strong-field (high *trans* effect) ancillary ligands L such as C- and P-based ligands, whereas a longer emission $\lambda_{max}$ would be seen for medium-field ligands L such as N-based ligands.

Complexes having two different strong-field ligands, $[Ir(ppy)_2(CO)(PPh_3)]^+$ (**3c**) and $[Ir(ppy)_2(CO)\{P(OPh)_3\}]^+$ (**3d**) also show shorter emission $\lambda_{max}$, whereas those with one MeCN or py (**3b** and **4a**–**c**) show $\lambda_{max}$ at relatively longer wavelengths (Table 1). It seems certain that among the N-based ligands, the sp N-based ligand MeCN gives shorter emission $\lambda_{max}$ than does the $sp^2$ N-based ligand pyridine as observed for **2d**, **2e**, **3a**, and **3b** (see Table 1). The effect of the field strength of the ancillary ligand on the emission energy is unambiguously confirmed again by replacing medium-field ligand pyridine with stronger-field ligand CO, which causes the emission $\lambda_{max}$ to be blueshifted from 480 and 508 nm for $[Ir(ppy)_2(py)_2]^+$ (**2d**) to 466 and 487 nm for $[Ir(ppy)_2(py)(CO)]^+$ (**3b**).

It is noticed that the quantum yield is relatively higher for $P(OPh)_3$ complex **3d** (0.19) than it is for both MeCN (**3a**) and $PPh_3$ (**3c**) complexes although the emission $\lambda_{max}$ is shorter for **3d** than it is for **3a** and **3c**, which may be understood by the fact that $P(OPh)_3$ is more basic than $PPh_3$ and MeCN and less dissociation of the ligand from the metal is expected for **3d** than for **3a** and **3c**.

Unlike bis-MeCN complex **2e**, mono-MeCN complexes **3a** and **4a**–**c** exhibit measurable emission in $CH_2Cl_2$ even in the absence of excess MeCN. Dissociation of the labile MeCN ligand, however, seems significant for most MeCN containing complexes and much lower quantum yields and redshifted emission $\lambda_{max}$ are observed in the absence of excess MeCN.

Cyclic voltammetric measurements for complexes prepared in this study show, in general, poorly resolved reversible waves for both oxidation and reduction. It is, however, confirmed that cationic complex **2a** clearly shows a more positive oxidation potential at 1.15 V than anionic complexes **5** (0.9 V)[4a] in $CH_2Cl_2$ (vs. $Fc^{2+}/Fc^+$) while **5** shows a more negative reduction potential (–1.70 V)[4a] than **2a** (–1.20 V) (see Supporting Information for voltammograms).

In order to see the effects of ppy ligand modification on the emission of $[Ir(ppy)_2L_2]^+$ (**2**), complexes of $F_2$ppy and $F_2$Meppy (**2a**$F_2$, **2a**$F_2$Me, **2b**$F_2$, **2b**$F_2$Me) have been prepared by the same method used for the preparation of **2** (Scheme 1). The blueshifts of the emission $\lambda_{max}$ caused by the modification of the ppy ligand are somewhat larger for the bisphosphane complexes (**2b**) than for the dicarbonyl complexes (**2a**) (see Table 2 and Figure 3). It should be

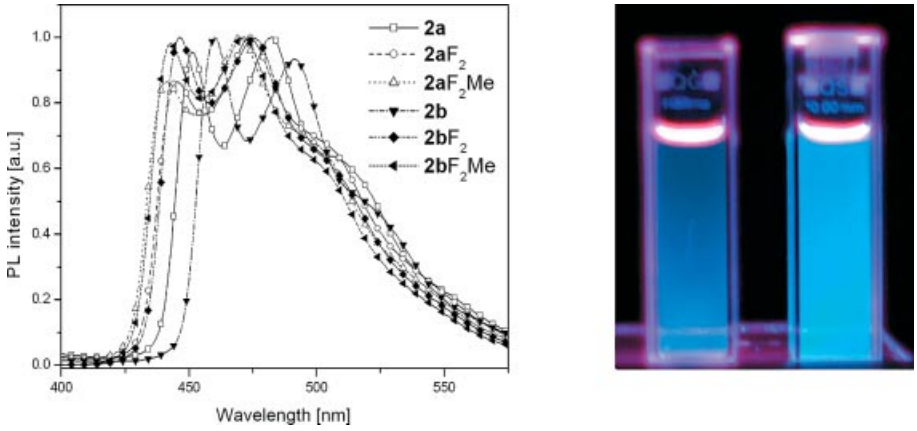

Figure 3. Normalized emission spectra of $[Ir(ppy)_2(CO)_2]^+$ (**2a**), $[Ir(F_2ppy)_2(CO)_2]^+$ (**2a**$F_2$), $[Ir(F_2Meppy)_2(CO)_2]^+$ (**2a**$F_2$Me), $[Ir(ppy)_2(PPh_2Me)_2]^+$ (**2b**), $[Ir(F_2ppy)_2(PPh_2Me)_2]^+$ (**2b**$F_2$) and $[Ir(F_2Meppy)_2(PPh_2Me)_2]^+$ (**2b**$F_2$Me) in $CH_2Cl_2$ at 25 °C. Complex **2a**$F_2$Me (left) displays somewhat of a more bluish emission than does **2b**$F_2$Me (right).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mentioned that blue-light emission is obtained by modification of the ppy ligand to produce **2a**$F_2$, **2a**$F_2$Me, **2b**$F_2$, and **2b**$F_2$Me while complexes **2a** and **2b** emit only greenish-blue light.

Increases in both the quantum yield and the lifetime of the emission are significant for phosphane complexes (**2b**, **2b**$F_2$, **2b**$F_2$Me), whereas no notable increase in the lifetime is observed for carbonyl complexes (**2a**, **2a**$F_2$, **2a**$F_2$Me) (see Table 2).

Table 2. Emission spectral data for $[Ir(C^{\wedge}N)_2L_2]^+$ (**2**) in $CH_2Cl_2$ at 25 °C.

| Complex | $C^{\wedge}N$ | L | $\lambda_{max}$ [nm] | $\Phi_{PL}$ | $\tau$ [μsec] |
|---|---|---|---|---|---|
| **2a**$F_2$ | $F_2$ppy | (CO) | 445, 474 | 0.079 | 0.17 |
| **2a**$F_2$Me | $F_2$Meppy | (CO) | 441, 470 | 0.097 | 0.15 |
| **2b**$F_2$ | $F_2$ppy | ($PPh_2$Me) | 446, 475 | 0.71 | 1.41 |
| **2b**$F_2$Me | $F_2$Meppy | ($PPh_2$Me) | 443, 471 | 0.80 | 1.16 |

In summary, the emission $\lambda_{max}$ of $[Ir(ppy)_2(L)_2]^+$ and $[Ir(ppy)_2(L)(L')]^+$ significantly shifts to shorter wavelengths with strong-ligand-field ancillary ligands (L and L′) such as CO and phosphorus-based ligands [$PPh_3$, $PPh_2$Me, $P(OPh)_3$] compared with the emission $\lambda_{max}$ of less-strong-field ligands such as nitrogen-based ligands (MeCN, py). For ancillary ligands of comparable ligand-field strengths such as CO and $CN^-$, the cationic complex $[Ir(ppy)_2(CO)_2]^+$ emits shorter wavelength than does the anionic one $[Ir(ppy)_2(CN)_2]^-$. Blue-light emission is obtained from cationic complexes **2a**$F_2$Me and **2b**$F_2$Me which contain strong-field ancillary ligands, CO and $PPh_2$Me, and a modified ppy ligand, $F_2$Meppy.

CCDC-619899 (for **4a**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Two- and Three-Dimensional Coordination Polymers From the Reaction of Bis- and Tris(2-aminoethyl)amine with Titanium and Zirconium Alkoxides

**Helmut Fric,[a] Michael Puchberger,[a] and Ulrich Schubert*[a]**

*Dedicated to Professor Bernhard Kräutler on the occasion of his 60th birthday*

**Keywords:** Titanium / Zirconium / Coordination polymers / N ligands

The reaction of bis(2-aminoethyl)amine with M(O*i*Pr)$_4$ (M = Ti, Zr) affords the chain-like coordination polymers [M$_2$(O*i*Pr)$_8$(H$_2$NCH$_2$CH$_2$NHCH$_2$CH$_2$NH$_2$)]$_\infty$, where only the NH$_2$ groups of the amine are coordinated to the M$_2$(O*i*Pr)$_8$ units. 2D NMR spectroscopy shows that the adducts dissociate into the starting compounds when dissolved in CD$_2$Cl$_2$ but are slowly re-formed in solution over a period of two weeks. Puckered layers of condensed six-membered rings of [Ti$_2$(O*i*Pr)$_8$]$_3$[N(CH$_2$CH$_2$NH$_2$)$_3$]$_2$ are formed when [Ti(O*i*Pr)$_4$] is treated with tris(2-aminoethyl)amine. The voids in the center of the rings are filled by non-coordinated Ti$_2$(O*i*Pr)$_8$ guest molecules. In contrast, chains of [Zr$_2$(O*i*Pr)$_8$(H$_2$NCH$_2$CH$_2$NR′CH$_2$CH$_2$NH$_2$)]{R′=CH$_2$CH$_2$NH$_2$[Zr$_2$(O*i*Pr)$_8$(HO*i*Pr)]} are formed upon treatment of tris(2-aminoethyl)amine with [Zr(O*i*Pr)$_4$].

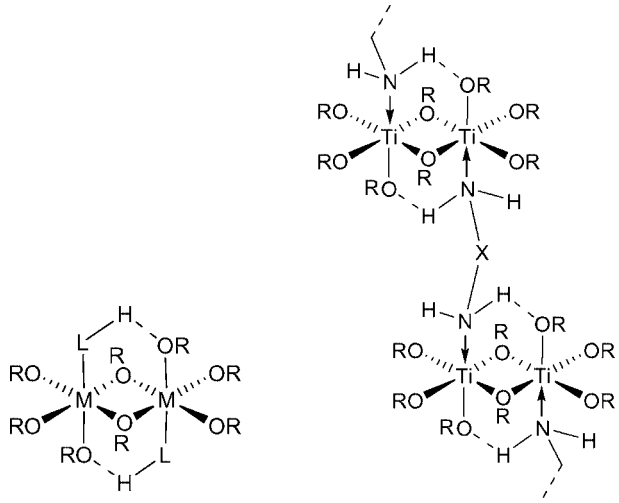
## Introduction

An understanding of the Lewis acidity of metal alkoxides is the key for understanding their chemistry, for example in sol–gel processes or as catalysts. One consequence of the acidic properties of the metal center in these alkoxides is their tendency to form oligomers [M(OR)$_x$]$_n$ with alkoxido bridges between two or three metal atoms, i.e. by interaction of the Lewis basic alkoxido groups with the Lewis acidic metal centers. The physical properties as well as the chemical reactivity of the metal alkoxides are influenced by the degree of aggregation. In alcoholic solution, for instance, addition of solvent molecules to the metal center competes with the formation of alkoxido bridges. The stability of the adducts increases for given alkoxido groups with increasing Lewis basicity of the alcohol, increasing Lewis acidity of the metal atom, and increasing coordination number of the metal. Thus, the adducts [M$_2$(O*i*Pr)$_8$(*i*PrOH)$_2$] (M = Ce,[1,2] Zr,[2] Hf[2,3]) can be isolated, whereas the analogous adducts [Ti$_2$(OR)$_8$(ROH)$_2$] are only stable when the Lewis acidity of the metal is raised by more electronegative substituents.[4–6] The metal atoms in the dimeric adducts [M$_2$(OR)$_8$(ROH)$_2$] are octahedrally coordinated owing to both the formation of alkoxido bridges and the coordination of alcohol molecules (Scheme 1, LH = ROH). The coordinated alcohol is stabilized by hydrogen bonding with the neighboring alkoxido ligand.



Scheme 1. General structure of the adducts [Ti$_2$(OR)$_8$(LH)$_2$] (LH = R′OH or R′NH$_2$; --- represents hydrogen bonds) and polymeric [Ti$_2$(OR)$_8$(NH$_2$XNH$_2$)].

The stability of the adducts can also be increased by stronger Lewis bases. We recently succeeded in crystallizing a number of amine adducts [M$_2$(OR)$_8$(NH$_2$R′)$_2$] (M = Ti, Zr) when M(OR)$_4$ was treated with the corresponding primary amines.[7,8] These amine adducts (Scheme 1, LH = R′NH$_2$) have similar structures to the alcohol adducts [M$_2$(OR)$_8$(ROH)$_2$], including the hydrogen bond between the amino group and the adjacent OR ligand. However, comparison of the adducts of different amines showed that

the Lewis basicity of the amine nitrogen is not the decisive parameter for the stability of the adducts. Instead, the strength of the NH···O hydrogen bond appears to be the main parameter. Any electronic or steric effect weakening the hydrogen bond thus weakens the stability of the adducts.

The general structure of $[Ti_2(OiPr)_8(NH_2R')_2]$ was extended to insoluble coordination polymers with the chain structures shown in Scheme 1 when $[Ti(OR)_4]$ was treated with diamines $H_2NXNH_2$ (X = hydrocarbon spacer).[7–9] An open question of previous work was whether the observed structures are retained in solution and whether coordination equilibria exist, because the obtained $^{15}N$ NMR spectra were rather inconclusive. The use of $NH(CH_2CH_2NH_2)_2$ and $N(CH_2CH_2NH_2)_3$ has now allowed us to answer this question. This is discussed in this paper, together with the interesting structural chemistry of the corresponding adducts.

## Results and Discussion

### Solid-State Structures

When bis(2-aminoethyl)amine was treated with an equimolar amount, or a slight excess, of $[Ti(OiPr)_4]$ in 2-propanol or $[Zr(OiPr)_4]$ in heptane, the compounds $[M_2(OiPr)_8(H_2NCH_2CH_2NHCH_2CH_2NH_2)]$ (**1**: M = Ti; **2**: M = Zr) were obtained in high yield. Although the starting amine contains three basic nitrogen atoms, only the two primary amino groups were found by X-ray structure analysis to coordinate to the metal alkoxide moieties. As a result, chain-like coordination polymers are formed (Figures 1 and 2), as previously found for $[Ti_2(OiPr)_8(H_2NXNH_2)]_\infty$ with hydrocarbon spacers (X) between the primary amino groups.

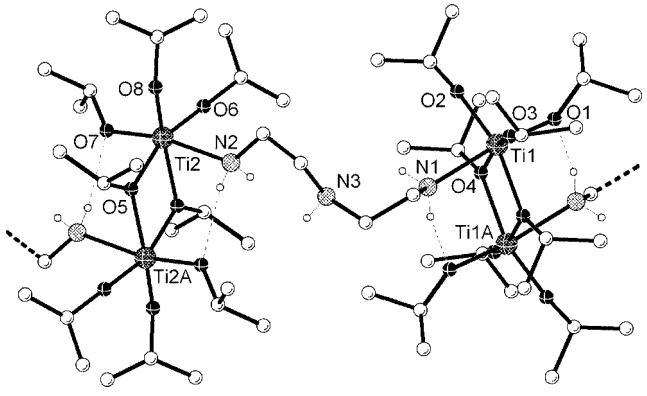

Figure 1. The chain structure of $[Ti_2(OiPr)_8(H_2NCH_2CH_2NHCH_2CH_2NH_2)]_\infty$ (**1**). The dotted lines represent NH···O hydrogen bonds. Selected bond lengths [pm] and angles [°]: Ti(1)–N(1) 229.2(2), Ti(1)–O(3) 180.7(2), Ti(1)–O(4) 205.0(2), Ti(1)–O(4A) 208.8(2), Ti(1)–O(1) 183.9(2), Ti(1)–O(2) 183.9(2), N(1)···O(1) 294.1(3), Ti(2)–N(2) 229.9(2), Ti(2)–O(7) 186.6(2), Ti(2)–O(5) 204.9(2), Ti(2)–O(4A) 209.8(2), Ti(2)–O(6) 181.4(2), Ti(2)–O(8) 182.6(2), N(2)···O(7) 293.7(3); N(1)–Ti(1)–O(1) 169.56(8), N(2)–Ti(2)–O(7) 168.65(9), N(1)–Ti(1)–Ti(1A) 77.97(6), N(2)–Ti(2)–Ti(2A) 76.75(7), O(1)–Ti(1)–Ti(1A) 91.75(6), O(7)–Ti(2)–Ti(2A) 92.42(7).

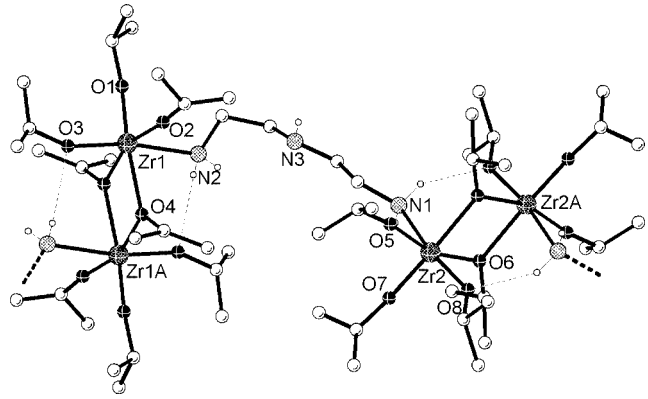

Figure 2. The chain structure of $[Zr_2(OiPr)_8(H_2NCH_2CH_2NHCH_2CH_2NH_2)]_\infty$ (**2**). The dotted lines represent NH···O hydrogen bonds. Selected bond lengths [pm] and angles [°]: Zr(1)–N(2) 241.7(3), Zr(1)–O(3) 196.9(3), Zr(1)–O(4) 219.0(2), Zr(1)–O(4A) 220.2(3), Zr(1)–O(1) 195.0(3), Zr(1)–O(2) 195.5(3), N(2)···O(3) 315.2(5), Zr(2)–N(1) 243.9(4), Zr(2)–O(8) 198.4(3), Zr(2)–O(6) 219.3(3), Zr(2)–O(6A) 219.2(3), Zr(2)–O(5) 195.1(3), Zr(2)–O(7) 195.0(3), N(1)···O(8) 308.8(5); N(2)–Zr(1)–O(3) 170.0(1), N(1)–Zr(2)–O(8) 168.4(1), N(2)–Zr(1)–Zr(1A) 76.77(9), N(1)–Zr(2)–Zr(2A) 76.24(9), O(3)–Zr(1)–Zr(1A) 93.41(9), O(8)–Zr(2)–Zr(2A) 92.70(9).

We have observed previously that secondary amines are less prone to coordinate to $M(OR)_4$ and have attributed this finding to the less pronounced ability of secondary amines to engage in the hydrogen bonding that stabilizes the M–N interaction.[8] Although the NH group in **1** and **2** does not interact with the metal alkoxides, it is probably responsible for the much better solubility of **1** and **2** compared to related coordination polymers with hydrocarbon spacers X. As will be discussed later, this fact allows us to investigate the solution structures by NMR spectroscopy.

Apart from different conformations of the bis(2-aminoethyl)amine units, the polymeric structures of **1** and **2** follow the same construction principle. The amine is a two-directional linker for the $M_2(OiPr)_8$ units, i.e. each $NH_2$ group of bis(2-aminoethyl)amine is coordinated to another $M_2(OiPr)_8$ unit. The chains are close-packed, with an interchain distance of about 870 pm in **1** and 910 pm in **2**

The metal alkoxide units are centrosymmetric dimers of the general composition $M_2(OR)_8(NH_2R)_2$ in which the octahedrally coordinated metal atoms are bridged by two OR groups. The amines are coordinated axially to the $M_2(\mu\text{-}OR)_2$ ring and hydrogen-bonded to neighboring alkoxido ligands (see Scheme 1 and Figures 1 and 2). The N···O separations [293.7(3) and 294.1(3) pm for **1**; 308.8(5) and 315.2(5) pm for **2**] are in the typical range of NH···O hydrogen bonds.[10] To enable hydrogen bonding, the M–M–N angles are reduced to 76–78° by bending of the amino ligand towards the center of the $M_2(\mu\text{-}OR)_2$ ring. The M–O distances *trans* to the amine ligand are in between the (long) M–O distances of the bridging OR groups and the (short) M–O distances of the equatorial terminal OR groups.

When $[Ti(OiPr)_4]$ was treated with 0.67 molar equivalents of tris(2-aminoethyl)amine, colorless crystals of $[\{Ti_2(OiPr)_8\}_3\{N(CH_2CH_2NH_2)_3\}_2 \cdot Ti_2(OiPr)_8]$ (**3**) were obtained after recrystallization from $CH_2Cl_2$. All $NH_2$ groups of tris(2-aminoethyl)amine coordinate to $Ti_2(OiPr)_8$ units. The crystal structure of **3** is thus a two-dimensional coordination polymer with $N(CH_2CH_2NH_2)_3$ as a three-directional linker and the $Ti_2(OR)_8$ units as two-directional connectors. The framework of **3** is formally related to that of black phosphorus, i.e. the framework of **3** is a puckered layer of condensed six-membered, centrosymmetric rings (Figures 3 and 4) with $CH_2CH_2NH_2[Ti_2(OiPr)_8]NH_2CH_2CH_2$ edges and pyramidal nitrogen atoms as the corners. The geometry of the $Ti_2(OiPr)_8(NH_2R)_2$ units of the framework structure corresponds to the general structure shown in Figure 1 (left), including the hydrogen bonds (N···O 297–302 pm). Furthermore, the Ti–N distances in **3** [230.5(4)–231.9(5) pm] are the same as in molecular or chain-like complexes with mono- or diamines.

The $[Ti_2(OiPr)_8]_3[N(CH_2CH_2NH_2)_3]_2$ network structure contains a large free volume due to the very large ring size (about 1.4 nm in diameter). In the crystals obtained in the reaction of $[Ti(OiPr)_4]$ with $N(CH_2CH_2NH_2)_3$, the voids in the center of the rings are filled with $Ti_2(OiPr)_8$ guest molecules, which do not undergo any bonding interaction with the host structure. The Ti–Ti vectors of the $Ti_2(OiPr)_8$

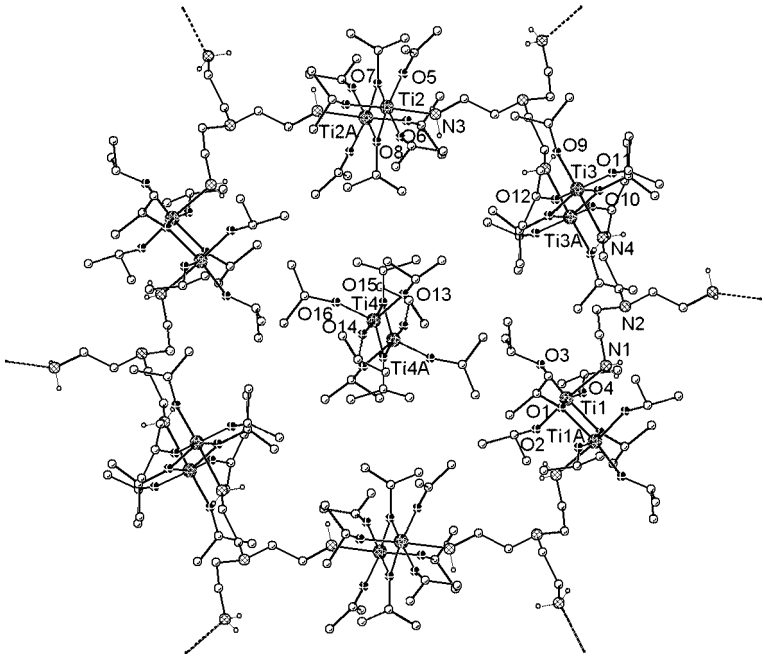

Figure 3. Perspective view (approximately perpendicular to the layer) of a six-membered ring from which the layer structure of **3** is composed. Most hydrogen atoms have been omitted for clarity. Selected bond lengths [pm]: Ti(1)–N(1) 233.5(5), Ti(2)–N(3) 231.4(4), Ti(3)–N(4) 231.7(4), N(1)···O(2) 302.0(6), N(3)···O(6) 296.7(6), N(4)···O(9) 298.2(6).

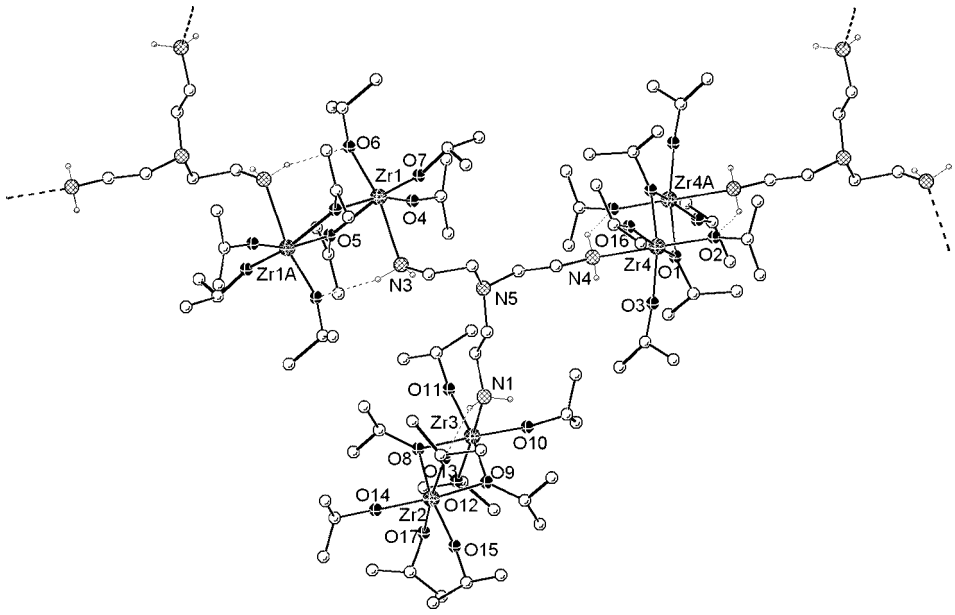

Figure 5. The chain structure of $[\{Zr_2(OiPr)_8\}\{Zr_2(OiPr)_8(HOiPr)\}\{(H_2NCH_2CH_2)_3N\}]_\infty$ (**4**). Selected bond lengths [pm]: Zr(1)–N(3) 244.8(6), Zr(3)–N(1) 243.0(7), Zr(4)–N(4) 243.3(6), Zr(2)–O(17) 232.1(6) (coordinated *i*PrOH), N(1)···O(13) 308(1), N(3)···O(6) 309.2(9), N(4)···O(2) 308(1), O(17)···O(12) 270.6(8).

guests are approximately perpendicular to the layer of the host structure. The structure of the entrapped titanium alkoxide dimers can be described as two trigonal bipyramids sharing a common axial–equatorial edge. Related structures of dimeric, nonsolvated titanium alkoxides with five-coordinate titanium atoms are known for bulky OR groups, such as $[Ti_2(OCH_2tBu)_8]$,[11] $[Ti_2(OiPr)_6(OAr)_2]$ (Ar = 2,4,6-$Me_3C_6H_2$[12] or 2,6-$iPr_2C_6H_3$[13]) and $[Ti_2(OiPr)_4\{OCH(CF_3)_2\}_4]$.[4] The crystal structure of **3** thus contains two structurally different $Ti_2(OiPr)_8$ moieties: the guest molecules with five-coordinate titanium atoms and the $Ti_2(OiPr)_8$ units with six-coordinate titanium atoms being part of the framework structure. Framework structures such as **3** have not yet been observed in the chemistry of transition metal alkoxides. It may be speculated that other guests could be incorporated in the same way into the host structure of $[Ti_2(OiPr)_8]_3[N(CH_2CH_2NH_2)_3]_2$.

The analogous reaction of $[Zr(OiPr)_4]$ with tris(2-aminoethyl)amine resulted in a compound with different composition and crystal structure. The structure of the obtained complex $[Zr_2(OiPr)_8][Zr_2(OiPr)_8(HOiPr)][(H_2NCH_2CH_2)_3N]$ (**4**) can be formally derived from the layer structure of **3** by decoordinating one $NH_2$ group per $N(CH_2CH_2NH_2)_3$ and replacing it with an 2-propanol molecule. This results in a chain structure of the type $Zr_2(OiPr)_8(H_2NCH_2CH_2NR'CH_2CH_2NH_2)$, where R′ is a $CH_2CH_2NH_2[Zr_2(OiPr)_8(HOiPr)]$ moiety (Figure 5). Formation of a layered structure is thus inhibited because one coordination site at one zirconium is blocked by an alcohol molecule. As mentioned in the Introduction, alcohol adducts of $[Zr(OiPr)_4]$ are stable while those of $[Ti(OiPr)_4]$ are not; this allows the alcohol to compete with the amine for coordination. It is interesting to note at this point that reaction of $M(OiPr)_4$ with benzylamine results in the same structure $[M_2(OiPr)_8(NH_2CH_2Ph)_2]$ for both Ti and Zr.[8] The bond lengths and angles of the zirconium atoms in **4** coordinated to $NH_2$ groups are basically the same as those in **2**, while those of the sixth zirconium atom, to which an 2-propanol molecule is coordinated, are very similar to those in $[Zr_2(OiPr)_8(iPrOH)_2]$, including the hydrogen bond between the coordinated alcohol and the adjacent O*i*Pr ligand.[2]

## NMR Investigations in Solution

The coordination polymers **1**–**4** described above can be recrystallized, which is a strong indication that the amine adducts are relatively stable and may persist in solution. Nevertheless, coordination equilibria may exist upon dissolution of the compounds. This is not simply an academic question but is also important for the use of metal alkoxides in sol–gel processes, where coordination polymers may offer the possibility to pre-organize metal alkoxides prior to hydrolytic polycondensation.

A section of the $^1H$ NMR spectrum of the dissolved crystals of **1** is reproduced at the top of Figure 6. The $^1H/^{13}C$ HSQC spectrum shows one correlation at $\delta$ = 4.51 ($^1H$) and 76.5 ppm ($^{13}C$) for a CH unit of the time-averaged isopropoxide ligands and two correlations at $\delta$ = 2.84 ($^1H$)/52.8 ppm ($^{13}C$) and 2.54 ($^1H$)/42.2 ppm ($^{13}C$) corresponding to the two $CH_2$ units of the amine ligand. The latter two signals are very similar to the signals of the free ligand at $\delta$ = 2.57/2.68 ppm ($^1H$) and 41.7/57.7 ppm ($^{13}C$), respectively. The $^1H/^{15}N$ HMBC spectrum of **1** (Figure 7, left) shows two correlations at $\delta$ = 9.1 (NH) and –3.2 ppm ($NH_2$), which are almost the same as the shifts for the uncoordi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nated ligand ($\delta$ = 9.1 and –2.3 ppm). The two protons of the $NH_2$ groups appear as a broad signal at $\delta$ = 1.09 ppm. This indicates that most of the amine ligand is not coordinated to the metal center.

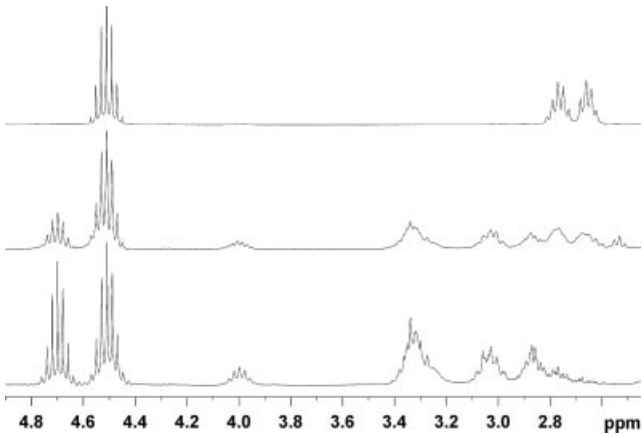

Figure 6. $^1$H NMR spectra of $[Ti_2(OiPr)_8(NH_2CH_2CH_2NHCH_2CH_2NH_2)]$ (**1**) in $CD_2Cl_2$. Top: immediately after dissolving the crystals; center: after one week; bottom: after two weeks.

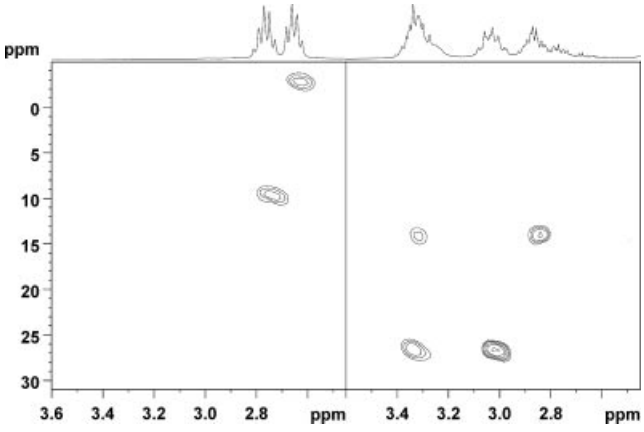

Figure 7. $^1$H/$^{15}$N HMBC spectrum of **1** in $CD_2Cl_2$. Left: immediately after dissolving the crystals; right: after two weeks.

This picture changed completely when NMR spectra of the same solution were recorded again after one week. The $CH_2$ region of the amine now showed five new broad and unresolved multiplets beside the previous two signals, which were broader (Figure 6, center) and with lower intensity. In a third spectrum measured after two weeks (Figure 6, bottom), nearly no starting signals were left, but instead four new broad multiplets were observed. The signals for the two nitrogen atoms had shifted to $\delta$ = 14.0 (typical shift range for coordinated $NH_2$) and 26.5 ppm (NH) (Figure 7, right). This indicated strongly that the amine is now coordinated. This conclusion was supported by the pair-wise splitting of the proton signals of the $CH_2$ groups in the $^1$H/$^{13}$C HSQC spectrum (Figure 8). Correlations were found at $\delta$ = 3.32/2.86 ($^1$H) and 48.7 ppm ($^{13}$C) as well as $\delta$ = 3.33/3.02 ($^1$H) and 39.6 ppm ($^{13}$C). The splitting of the proton resonance is due to the fact that the protons become non-equivalent upon coordination of the $NH_2$ groups to the metal centers.

The two protons of the $NH_2$ group are also split into two broad signals (proton trace in Figure 8) at $\delta$ = 5.69 and 2.39 ppm. This is evidence for the formation of stable N–H···O hydrogen bonds, as observed in the solid-state structure. Four different signals of isopropoxide groups were identified in the $^1$H/$^{13}$C HSQC spectrum at this point (Figure 8). Two signals overlap in the proton region at $\delta$ = 4.69 ppm ($^1$H) and show $^{13}$C correlations to the signals at $\delta$ = 78.3 and 76.7 ppm; the third is located at $\delta$ = 4.51 ($^1$H) and 76.1 ppm ($^{13}$C). The signals at $\delta$ = 3.97 ($^1$H) and 64.1 ppm ($^{13}$C) are due to non-coordinated *i*PrOH. The NMR spectra after two weeks, especially the number and intensity ratio of the O*i*Pr ligand signals, correspond with the local symmetry [two axial O*i*Pr (*trans* to $NH_2$), four equatorial and two bridging] of **1** in the solid-state structure. The presence of noncoordinated 2-propanol is either due to incomplete removal of adsorbed alcohol during drying of the crystals or minor hydrolysis during the long measuring period.

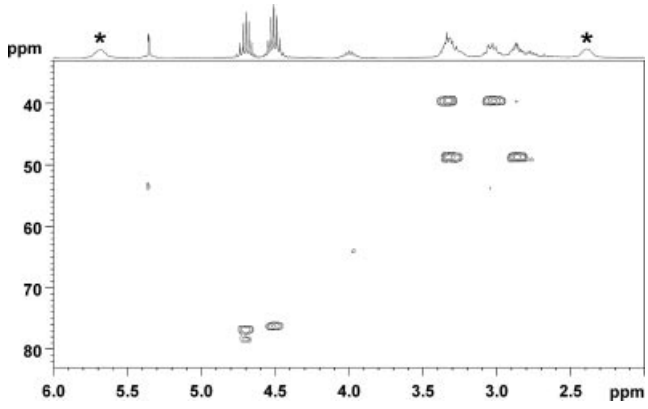

Figure 8. $^1$H/$^{13}$C HSQC spectrum of **1** in $CD_2Cl_2$ after two weeks. The two proton signals marked with an asterisk are from $NH_2$.

We interpret the spectroscopic findings by proposing that the polymeric adduct of **1** dissociates into $[Ti_2(OiPr)_8]$ and $NH(CH_2CH_2NH_2)_2$ upon dissolution in $CD_2Cl_2$. The NMR spectra measured immediately after dissolution of the crystals thus correspond to a mixture of the starting compounds. The adduct is formed again in a slow reaction in solution, and the NMR spectra after two weeks correspond to the amine adduct **1**. This notion was supported by the following experiment. When $[Ti(OiPr)_4]$ and bis(2-aminoethyl)amine were mixed in a 2:1 ratio (same Ti:amine ratio as in crystalline **1**) in $CD_2Cl_2$ the same changes in the spectra were observed over a period of two weeks as when crystals of **1** were dissolved. Only the signals of the starting materials were present after mixing, whereas an identical signal pattern was observed after two weeks as for the dissolved crystals.

The corresponding complex $[Zr_2(OiPr)_8(NH_2CH_2CH_2NHCH_2CH_2NH_2)]$ (**2**) shows almost the same solution behavior as **1**, with the exception that **2** is less soluble, which leads to rather faster crystallization in the NMR tube. The crystals recovered from the NMR tube had identical cell parameters as the original crystals.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As a result of the NMR investigations described above, it is now possible to prove adduct formation even if the compounds do not crystallize and thus no solid-state structures are available. Figure 9 shows the NMR spectra of a 1:1 mixture of $[Ti(OiPr)_4]$ and *N*-(trimethoxysilylpropyl)-ethylenediamine in $CD_2Cl_2$. To prove whether coordination occurs in solution, spectra were recorded over a period of two months. New signals were observed one week after mixing the starting compounds (Figure 9, center), and after two months (Figure 9, bottom) almost no signals of the starting compounds were left. $^{15}N$ NMR signals at $\delta$ = 14.3 (NH) and 2.7 ppm ($NH_2$) were found after mixing the compounds, compared to $\delta$ = 13.4 (NH) and –4.0 ppm ($NH_2$) for the ethylenediamine derivative before addition of $[Ti(OiPr)_4]$, which shifted to $\delta$ = 37.8 (NH) and 31.3 ppm ($NH_2$) after two months. The signals for the *i*OPr ligands after two months correspond roughly to the symmetry of a $[Ti_2(OiPr)_8(NH_2R)_2]$ complex. These NMR spectra thus strongly indicate that the ligand is almost completely coordinated and compound **5** is formed.

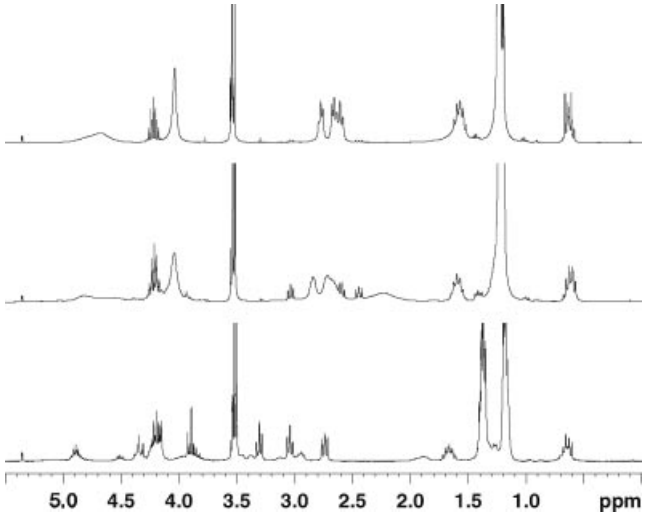

Figure 9. $^1H$ NMR spectrum of $[Ti(OiPr)_4]$ and $H_2NCH_2CH_2NHCH_2CH_2CH_2Si(OMe)_3$ in a 1:1 ratio in $CD_2Cl_2$. Top: after mixing; center: after one week; bottom: after two months.

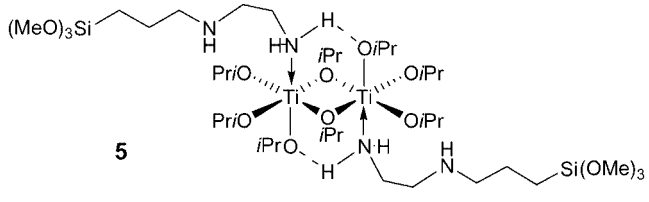

**5**

In the $^1H$ NMR spectrum of $[\{Ti_2(OiPr)_8\}_3\{N(CH_2CH_2NH_2)_3\}_2{\cdot}Ti_2(OiPr)_8]$ (**3**) (Figure 10, top) four broad multiplets were observed between $\delta$ = 3.40 and 2.80 ppm immediately after dissolving the crystals, and the $CH_2$ region in the $^1H/^{13}C$ HSQC spectrum (Figure 11) showed four different pairwise correlations to $^{13}C$ atoms, with two of them belonging to the same $CH_2CH_2$ unit ($\delta$ = 36.4–53.3 and 38.6–60.0 ppm). An EXSY spectrum of this compound showed exchange peaks between these $CH_2CH_2$ units along the diagonal. An explanation for this observation might be that not all three $CH_2CH_2$ units are coordinated in solution and therefore show time-averaged $^1H$ and $^{13}C$ signals. The $^{15}N$ signals were found at $\delta$ = 36.3 (N) and 14.8 ppm (coordinated $NH_2$).

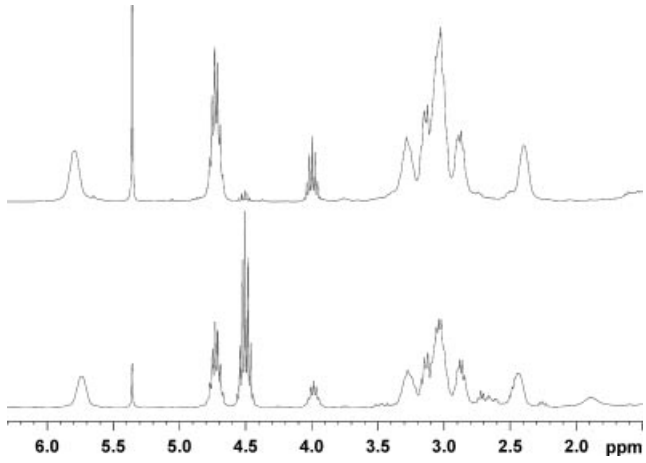

Figure 10. Top: $^1H$ NMR spectrum of $[\{Ti_2(OiPr)_8\}_3\{N(CH_2CH_2NH_2)_3\}_2{\cdot}Ti_2(OiPr)_8]$ (**3**) immediately after dissolving the crystals in $CD_2Cl_2$. Bottom: $[Ti(OiPr)_4]$ and tris(2-aminoethyl)-amine in $CD_2Cl_2$ mixed in a 2:1 ratio after two weeks.

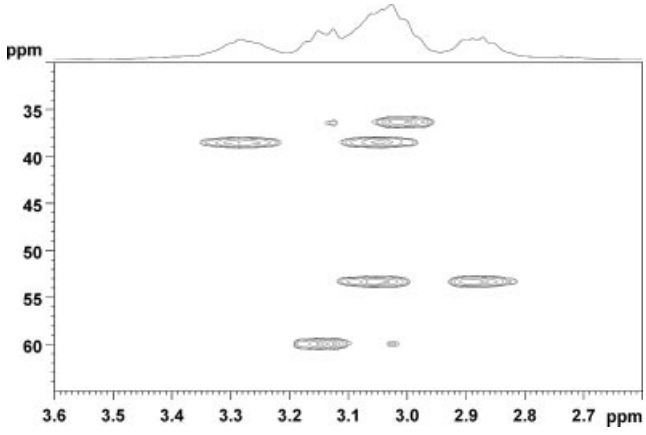

Figure 11. $^1H/^{13}C$ HSQC spectrum of the $CH_2$ region of **3** in $CD_2Cl_2$.

Mixing $[Ti(OiPr)_4]$ and tris(2-aminoethyl)amine in a 2:1 ratio in $CD_2Cl_2$ again showed a very similar peak pattern for the $CH_2$ region of the amine after two weeks (Figure 10, bottom). It is worth mentioning that the signals in the CH region of the isopropoxide ligand have different intensities, which might be due to either different concentrations of the product or to different amounts of free 2-propanol. The spectra of **3** suggests that this compound does not dissociate (completely) into the starting compounds, contrary to what had been observed for **1** and **2**. We cannot exclude that part of the $NH_2$ groups dissociate, but the observed spectra after dissolution of the crystals of **3** are distinctly different to a mixture of $[Ti(OiPr)_4]$ and tris(2-aminoethyl)-amine. The interpretation of the O*i*Pr signals in the spectra was complicated by the presence of the $Ti_2(OiPr)_8$ guests in the crystal lattice.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The corresponding zirconium derivative **4** is almost insoluble in $CD_2Cl_2$, therefore no detailed NMR investigations were carried out.

## Conclusions

We have shown that the previously observed formation of chain-like coordination polymers upon reaction of $[M(OR)_4]$ (M = Ti, Zr) with diamines can be extended to the formation of layered structures. Layers of $[Ti_2(OiPr)_8]_3$-$[N(CH_2CH_2NH_2)_3]_2$, consisting of condensed six-membered rings, are obtained from $[Ti(OiPr)_4]$ and tris(2-aminoethyl)amine. The voids of the rings are occupied by $Ti_2(OiPr)_8$ nonsolvated guest molecules.

The amine adducts of $[M(OR)_4]$ (M = Ti, Zr) are retained in solution. Although **1** and **2** dissociate into $[M(OiPr)_4]$ and bis(2-aminoethyl)amine when dissolved in $CD_2Cl_2$, the adducts slowly form again in solution. We are aware that this may be different in other solvents. There is strong spectroscopic evidence that the network structure of **3** is retained upon dissolution of the crystals, at least partially.

An important consequence for sol-gel processing is that amine adducts must be taken into account when $[M(OR)_4]$ is used in the presence of compounds with $NH_2$ groups. Adduct formation will probably influence the reactivity of the alkoxides and may also result in morphological changes of the gels. We will further investigate the possibility to preorganize gels by di- and triamine adducts.

## Experimental Section

All operations were carried out in a moisture- and oxygen-free atmosphere of argon. $[Ti(OiPr)_4]$ (97%, Aldrich), $[Zr(OiPr)_4]$ (70–75% in heptane, ABCR), bis(2-aminoethyl)amine (99%, Aldrich) and tris(2-aminoethyl)amine (96%, Aldrich ) were used as received. The solvents were dried and purified by standard techniques.

**Synthesis of $[Ti_2(OiPr)_8(H_2NCH_2CH_2NHCH_2CH_2NH_2)]$ (1):** Bis(2-aminoethyl)amine (315 mg, 3.05 mmol) was added, whilst stirring, to a solution of $[Ti(OiPr)_4]$ (882 mg, 3.10 mmol) in 1 mL of 2-propanol at room temperature. The clear reaction solution was then stored at 4 °C and colorless crystals were obtained after 12 h. The product was recrystallized twice from $CH_2Cl_2$ and dried in vacuo. Yield: 736 mg (83%).

**Dissolved Crystals or Mixture of Starting Compounds:** $^1$H NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 4.51 (sept, $J$ = 6.1 Hz, OC*H*Me$_2$), 2.84–2.54 (m, C$H_2$C$H_2$NH$_2$), 1.26 [d, $J$ = 6.1 Hz, OCH(C$H_3$)$_2$], 1.08 (br., N$H_2$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 76.5 (O*C*HMe$_2$), 52.8 [HN(*C*H$_2$)$_2$], 42.2 [H$_2$N(*C*H$_2$)$_2$], 26.5 [OCH(*C*H$_3$)$_2$] ppm. $^{15}$N{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = –3.2 (H$_2$*N*), 9.1 (*N*H) ppm.

**After Two Weeks at Room Temperature:** $^1$H NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 5.68 (br., N$H_2$/N*H*), 4.70, 4.51 (sept, $J$ = 6.1 Hz, OC*H*Me$_2$), 4.00 (sept, $J$ = 6.1 Hz, HOC*H*Me$_2$), 3.43–2.58 (m, C$H_2$C$H_2$NH$_2$), 2.39, 1.56 (br., N$H_2$/N*H*), 1.26 [d, $J$ = 6.1 Hz, OCH(C$H_3$)$_2$], 1.19 [d, $J$ = 6.1 Hz, HOCH(C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 78.3, 76.7, 76.2 (O*C*HMe$_2$), 64.1 (HO*C*HMe$_2$), 48.7 (HN*C*H$_2$), 39.6 (H$_2$N*C*H$_2$), 26.1 [OCH(*C*H$_3$)$_2$/HOCH(*C*H$_3$)$_2$] ppm. $^{15}$N{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 14.0 (H$_2$*N*), 26.5 (*N*H) ppm.

**Synthesis of $[Zr_2(OiPr)_8(H_2NCH_2CH_2NHCH_2CH_2NH_2)]$ (2):** Bis(2-aminoethyl)amine (209 mg, 2.03 mmol) was slowly added, whilst stirring, to 1029 mg (2.20 mmol) of a 70–75% solution of $[Zr(OiPr)_4]$ in *n*-heptane that was diluted with 2 mL of *n*-heptane. The resulting white precipitate was dissolved in a mixture of 4 mL of 2-propanol and 2 mL of $CH_2Cl_2$ under reflux. The product was recrystallized twice from $CH_2Cl_2$ and dried in vacuo. Yield: 972 mg (94%).

**Dissolved Crystals:** $^1$H NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 4.91, 4.39 (sept, $J$ = 6.1 Hz, OC*H*Me$_2$), 3.98 (sept, $J$ = 6.1 Hz, HOC*H*Me$_2$), 2.80 [br., HN(C$H_2$)$_2$], 2.69 [br., H$_2$N(C$H_2$)$_2$], 1.32, 1.30 [d, $J$ = 6.1 Hz, OCH(C$H_3$)$_2$], 1.20 [d, $J$ = 6.1 Hz, HOCH(C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 69.8, 69.2 (O*C*HMe$_2$), 63.6 (HO*C*HMe$_2$), 42.1 [H$_2$N(C$H_2$)$_2$], 52.6 [HN(C$H_2$)$_2$], 32.1, 27.2 [OCH(C$H_3$)$_2$], 24.8 [HOCH(C$H_3$)$_2$] ppm.

**Synthesis of $[\{Ti_2(OiPr)_8\}_3\{(H_2NCH_2CH_2)_3N\}_2{\cdot}Ti_2(OiPr)_8]$ (3):** Tris(2-aminoethyl)amine (365 mg, 2.50 mmol) was added dropwise, whilst stirring, to a solution of 1051 mg (3.70 mmol) of $[Ti(OiPr)_4]$ in 2 mL of $CH_2Cl_2$ at room temperature under argon. The colorless solution was refluxed for 5 min and then concentrated to half its volume. The vessel was then stored at 4 °C to afford colorless crystals after 3 d. The product was recrystallized twice from $CH_2Cl_2$ and dried in vacuo. Yield: 732 mg (62%). The same product, but in lower yields, was obtained when 2-propanol was used as the solvent.

**Dissolved Crystals:** $^1$H NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 5.81 (br., N$H_2$), 4.73, 4.51 (sept, $J$ = 6.1 Hz, OC*H*Me$_2$), 3.41–2.66 [m, N(C$H_2$C$H_2$NH$_2$)$_3$], 2.40 (br., N$H_2$), 1.26 [d, $J$ = 6.1 Hz, OCH(C$H_3$)$_2$], 0.96 (b, N$H_2$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 79.0, 76.9, 76.3 (O*C*HMe$_2$), 60.2 (non-coordinated), 53.5 [N(*C*H$_2$CH$_2$NH$_2$)$_3$], 38.5 (non-coordinated), 36.5 [N(CH$_2$*C*H$_2$NH$_2$)$_3$], 26.0 [OCH(*C*H$_3$)$_2$] ppm. $^{15}$N{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 36.8 (*N*), 14.2, 13.5 (*N*H$_2$) ppm.

**Synthesis of $[Zr_2(OiPr)_8][Zr_2(OiPr)_8(HOiPr)][(H_2NCH_2CH_2)_3N]$ (4):** Tris(2-aminoethyl)amine (207 mg, 1.42 mmol) was slowly added, whilst stirring, to 737 mg (1.58 mmol) of a 70–75% solution of $[Zr(OiPr)_4]$ in *n*-heptane that was diluted with 3 mL of 2-propanol. The reaction solution was refluxed for 5 min and then concentrated to half its volume. The closed vessel was then stored at room temperature to yield colorless crystals after three weeks. The product was recrystallized twice from $CH_2Cl_2$ and dried in vacuo. Yield: 461 mg (89%).

**Dissolved Crystals:** $^1$H NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 4.48, 4.35, 4.22 (sept, $J$ = 6.1 Hz, OC*H*Me$_2$), 3.13 (br., C$H_2$CH$_2$NH$_2$), 2.98 (br., CH$_2$C$H_2$NH$_2$), 1.44–0.98 [m, OCH(C$H_3$)$_2$/HOCH(C$H_3$)$_2$] ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 71.4, 70.8, 70.3, 68.9 (O*C*HMe$_2$), 52.5 [N(*C*H$_2$CH$_2$NH$_2$)$_3$], 37.4 [N(CH$_2$*C*H$_2$NH$_2$)$_3$], 26.6, 26.3, 25.4 [OCH(*C*H$_3$)$_2$] ppm. $^{15}$N{$^1$H} NMR ($CD_2Cl_2$, 21 °C): $\delta$ = 30.85 (*N*), 9.09 (H$_2$*N*) ppm.

**X-ray Structure Analyses:** The crystals were mounted on a Siemens SMART diffractometer (area detector) and measured in a nitrogen stream. Mo-$K_\alpha$ radiation ($\lambda$ = 71.069 pm, graphite monochromator) was used for all measurements. The data collection at 173 K covered a hemisphere of the reciprocal space, by a combination of three or four sets of exposures. Each set had a different $\phi$ angle for the crystal, and each exposure took 15 or 20 s and covered 0.3° in $\omega$. The crystal-to-detector distance was 5 cm. Further details can be found in Table 1. The data were corrected for polarization and Lorentz effects, and an empirical absorption correction (SADABS) was employed. The cell dimensions were refined with all unique reflections. The structures were solved by direct methods

[a] The high $R$ values of **3** are due to disorder of the guest $Ti_2(OiPr)_8$ molecule.

(SHELXS-97). Refinement was performed by the full-matrix least-squares method based on $F^2$ (SHELXL-97) with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were inserted in calculated positions and refined as riding on the corresponding atom. The C–O and C–C distances of the $Ti_2(OiPr)_8$ guest molecule in **3** were refined using geometric restraints (DFIX, DANG).

CCDC-616750 (for **1**), -616751 (for **2**), -269602 (for **3**) and -616752 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**NMR Investigations:** All NMR spectra were recorded with a Bruker Avance 300 spectrometer ($^1$H at 300.13, $^{13}$C at 75.47 MHz, $^{15}$N at 30.41 MHz) equipped with a 5 mm, inverse-broadband probe head with a $z$-gradient unit at room temperature. 2D NMR spectra (EXSY, mixing time was usually 1 s; HSQC; HMBC) were measured with Bruker standard pulse sequences. Gas-tight Young tubes were used for all measurements, and $CD_2Cl_2$ (99.8%, euriso-top) was used as the solvent. $^{15}$N shifts were referenced externally against an aqueous solution of $^{15}NH_4Cl$. To remove most of the residual amine and free alcohol previous to the measurement, the crystals were dissolved in $CD_2Cl_2$, the solvent was removed again in vacuo, and the residue was dried for more than 8 h at $4\times10^{-4}$ mbar. The dried precipitate was then used for NMR investigations.

## Acknowledgments

# Synthesis, Structures, and Electronic Spectroscopy of Luminescent Acetylene- and (Buta-1,3-diyne)platinum Complexes

**Ke Zhang,[a] Jian Hu,[a] Kwok Chu Chan,[b] Kwok Yin Wong,[b] and John H. K. Yip*[a]**

**Keywords:** Spectroscopy / Luminescence / Platinum / Acetylene / Charge-transfer

The electronic absorption and emission spectroscopy of a series of diphenylacetylene- and (buta-1,3-diyne)-$Pt^0$ complexes (L)Pt[(1,2-$\eta^2$)-R–(C≡C)$_n$–R] and [(dppp)Pt]$_2$[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-R–(C≡C)$_2$–R] {R = Ph or $CH_3$, L = dppp or $(PPh_3)_2$, $n$ = 1 or 2} was investigated. The structures of (dppp)Pt[(1,2-$\eta^2$)-Ph–C≡C–Ph], (dppp)Pt[(1,2-$\eta^2$)-PhC$_4$Ph] and [(dppp)Pt]$_2$[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-Ph–(C≡C)$_2$–Ph] were characterized by X-ray diffraction. The complexes all display intense absorptions that were attributed to Pt→P(dπ*) and Pt→acetylene($\pi_x$*) transitions. Except for the $CH_3C_4CH_3$ complexes, the complexes all exhibit two emissions at 380–550 nm and 500–800 nm. The higher energy emission could arise from the $^3$[P(dπ*)→Pt] transition, and the lower energy emission, which has a longer lifetime than the higher energy one, was attributed to the $^3$[acetylene($\pi_x$*)→Pt] transition. The energy of the MLCT absorption and emission was affected by the electronic properties of the acetylenes and the ancillary phosphanes.

## Introduction

Recent interest in linear organometallics that have a low-lying metal-to-ligand charge-transfer (MLCT) excited state arose from their potential as molecular devices.[1] For example, it had been demonstrated that the intense MLCT absorption of $Ru^{II}$ acetylides is associated with their large second-order nonlinear optical effect.[1c] In addition, MLCT excitation is accompanied with charge separation, which is pertinent for the operation of photonic wires.[2]

Currently, organometallic complexes containing π-conjugated ligands are receiving a lot of attention mainly because of their wire-like geometry and the ability of π-conjugated carbon chains to mediate electron transfer.[3] Most of the studies have focused on metal acetylides and metal polyyne σ complexes. One way to lower the MLCT energy is to increase π-conjugation of the polyyne ligand. For instance, the complex [Re(L)(CO)$_3$(C≡CC≡C)Re(L)(CO)$_3$] (L = 4,4′-di-*tert*-butyl-2,2′-bipyridine) displayed a low-energy MLCT transition [dπ(Re)→π*(C≡CC≡C–Re)] and $^3$MLCT emission.[4] However, a potential drawback of this approach is that the gap between the metal dπ- and the ligand π-orbitals is reduced, resulting in substantial mixing of the orbitals, and hence introduction of significant intraligand ππ* character to the MLCT excited state. In principle, the mixing could be subdued if the metal orbitals are much higher in energy than the ligand orbitals. This requires an electron-rich metal center. In search of organometallics showing low-energy MLCT transition, our attention was therefore drawn to acetyleneplatinum(0) π complexes, which possess an electron-rich metal center and low-lying π*-orbitals.

Although the π complexes have a fairly long history,[5] most studies to date focus on the structures and reactivity aspects of the compounds.[6] On the other hand, electronic spectroscopy and photophysics of the complexes remain sparsely studied.[7] The luminescent properties of a series of acetylene-$Pt^0$ complexes have been reported by Forniés and co-workers.[7a] They assigned the vibronic phosphorescence exhibited by [$(PPh_3)_2Pt_2$]$_2$(HC≡C–1,4-C$_6$H$_4$–C≡CH) to $^3$MLCT emission. The assignment was supported by extended Hückel calculations that showed that the HOMO contains a substantial metal character and the LUMO is mainly localized in the π*-orbital of the acetylene.

A better understanding of the electronic structures and photophysics of the complexes could be achieved by expanding the scope of spectroscopic study to cover molecules that contain different acetylenes and ancillary ligands. To this end, we have carried out a comparative study of a series of acetylene- and (buta-1,3-diyne)platinum(0) (LPt)[(1,2-$\eta^2$)-R–(C≡C)$_n$–R] {L = $(PPh_3)_2$ or dppp [1,3-bis(diphenylphosphanyl)propane]; R = Ph or $CH_3$; $n$ = 1 or 2} and binuclear [(dppp)Pt]$_2$[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-R–(C≡C)$_2$–R] complexes (Scheme 1). The complexes are different by the substituents attached to the C≡C bond, extent of conjugation, number of metal atoms or ancillary phosphane atoms.

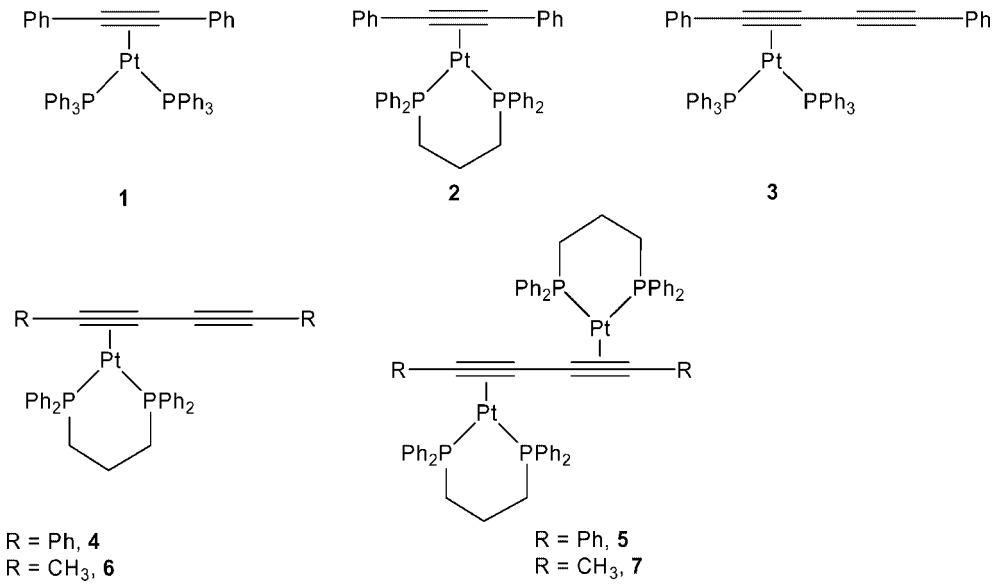

Scheme 1.

Except for complexes **1** and **3**, all of the complexes are new. While binuclear metal complexes of buta-1,3-diyne in μ-(1,2-$\eta^2$):(3,4-$\eta^2$) coordination mode are known, the complex **5** is the first $Pt_2$-butadiyne π complex ever characterized by X-ray crystallography.[8] The first diplatinum complex of $PhC_4Ph$, $[(PPh_3)_2Pt]_2$[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-$PhC_4Ph$], was synthesized by Stone but its crystal structure was not available.[9]

## Results and Discussion

### (A) Synthesis and Characterization

There are two literature methods for the preparation of acetylene-$Pt^0$ complexes. The first method[10] involves reduction of the $Pt(PPh_3)_2Cl_2$ ion by $N_2H_4$ in the presence of the acetylene ligand in alcohol. In this work, $(PPh_3)_2Pt$[(1,2-$\eta^2$)-$PhC_2Ph$] (**1**) and $(PPh_3)_2Pt$[(1,2-$\eta^2$)-$PhC_4Ph$] (**3**) were prepared by this method. However, synthesis of (dppp)-Pt[(1,2-$\eta^2$)-$PhC_2Ph$] (**2**) and (dppp)Pt[(1,2-$\eta^2$)-$PhC_4Ph$] (**4**) by the same methods was not successful. Instead the stronger reductant $NaBH_4$ is needed to reduce $Pt(dppp)Cl_2$ to $Pt^0$(dppp). This could be due to the fact that dppp is more electron-donating than $PPh_3$, making $Pt(dppp)Cl_2$ more difficult to reduce than $Pt(PPh_3)_2Cl_2$. Another literature method[9] involves substitution of ethylene in $(R_3P)_2$-$Pt(C_2H_4)$ by acetylenes. This method was used to prepare (dppp)Pt[(1,2-$\eta^2$)-$CH_3C_4CH_3$] (**6**) and the dinuclear $[(dppp)Pt]_2$[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-$PhC_4Ph$] (**5**) and $[(dppp)Pt]_2$-[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-$CH_3C_4CH_3$] (**7**).

The ESI-MS spectra of the complexes all show peaks attributable to the corresponding molecular ion $M^+$. The IR spectra of **1** and **2** display weak bands at 1741 and 1748 $cm^{-1}$, respectively, which are assigned to stretching of the coordinated C≡C bonds. Absorption bands of similar frequency and intensity have been observed for other reported acetylene-$Pt^0$ complexes.[5,6] The low stretching frequency is due to the metal-to-ligand π-back donation.[11] The IR spectra of **3**, **4** and **6** show two resonance signals at 1719–1749 and 2160–2196 $cm^{-1}$ arising from stretching of the coordinated and the uncoordinated C≡C bonds. The dinuclear complexes **5** and **7** show only a single peak at 1758 and 1705 $cm^{-1}$ for $\nu$(C≡C), respectively. This indicates that both C≡C bonds in the complexes are equivalent.

### (B) Structures

The complexes **2**, **4**, and **5** were characterized by single-crystal X-ray diffraction analysis, while crystal structures of **1**[12] and **3**[6b] have been previously reported by other research groups (Table 3). The selected bond lengths and angles are listed in Table 1.

#### (dppp)Pt[(1,2-$\eta^2$)-$PhC_2Ph$] (2)

There are two independent molecules **2a** and **2b** of very similar structure in a unit cell of crystal **2**·THF (Figure 1 for structure of **2a**).

Like the reported structure of **1**, complex **2** displays an approximate $C_{2v}$ symmetry. The acetylene bond length (C1–C1A) [1.301(7) Å] is significant longer than the average C≡C bond length (ca. 1.2 Å). This indicates a weakening of the bond due to σ-donation from the acetylene to the metal and π-back donation from the metal to the acetylene. The Pt center adopts a distorted square-planar coordination geometry with a small dihedral angle of 2.98° between the two C1–Pt1–C1A and P1–Pt1–P1A triangles. The Pt–C and the Pt–P bond lengths are normal. Similar to **1**, the linear C2–C1≡C1A–C2A backbone is distorted with the C2–C1–C1A angle being 144.5(2)°. It is slightly smaller

than the corresponding angles of 140 and 139° in **1**. The phenyl rings and the coordination triangle C1–Pt1–C1A are not coplanar, showing a dihedral angle of 26.89°.

### (dppp)Pt[(1,2-η$^2$)-PhC$_4$Ph] (4)

The molecular structure of complex **4** (Figure 2) is similar to that of {[(PPh$_3$)$_2$Pt](PhC$_4$Ph)} (**3**) reported by Deeming.[6b] The lengths of the coordinated C≡C bond (C1–C2) and the uncoordinated one (C3–C4) are 1.299(6) and 1.201(6) Å.

The coordination geometry at the Pt center in **4** is also nearly planar with the dihedral angle between triangles of C1–Pt1–C2 and P1–Pt1–P2 being 4.31°. The two Pt–C and Pt–P bond lengths are almost identical [Pt1–C1, 2.044(4) Å; Pt1–C2, 2.043(4) Å; Pt1–P1, 2.2629(10) Å; Pt1–P2, 2.2686(10) Å]. While the C5–C1–C2–C3 linkage is bent [∠C5–C1–C2 137.7(4)°; ∠C1–C2–C3 146.7(4)°] like that in **2a**, the uncoordinated triple bond remains linear [∠C2–C3–C4 = 174.7(5)°; ∠C3–C4–C6 176.5(5)°]. The dihedral angle between the coordination triangle of C1–Pt1–C2 and the adjacent phenyl ring of the acetylene is 18.36°.

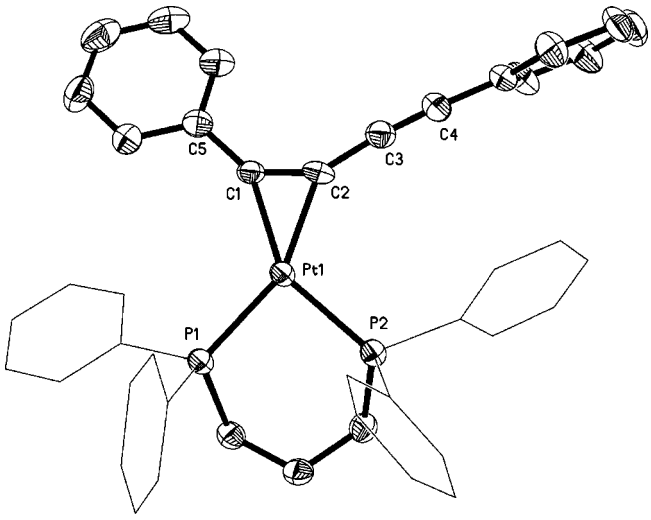

Figure 2. ORTEP diagram (thermal ellipsoid = 50%) of **4**. H atoms and solvent molecules are omitted.

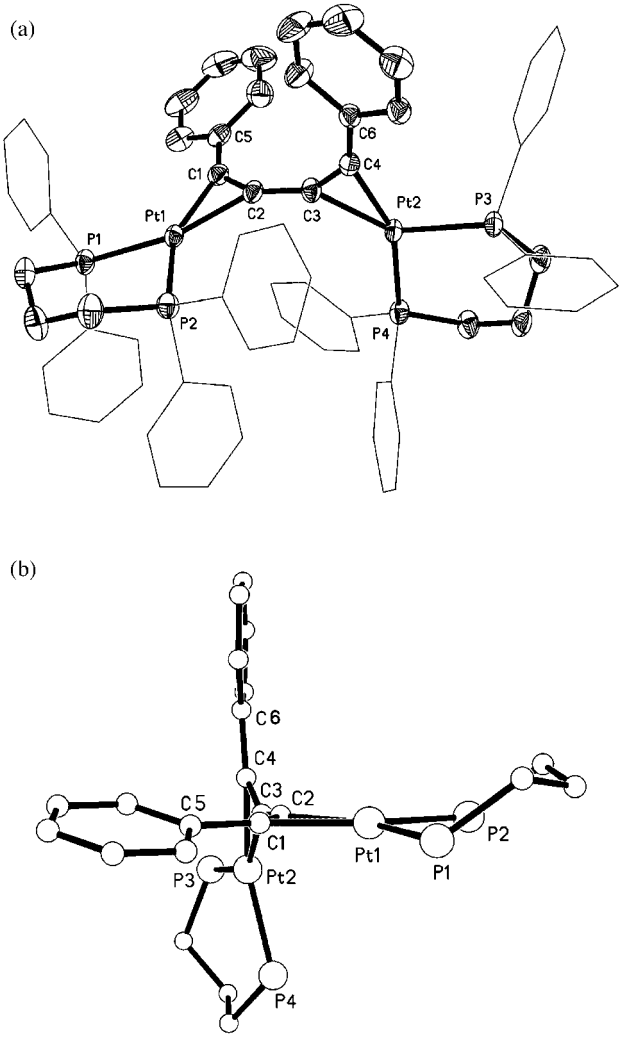

Figure 3. (a) ORTEP diagram (thermal ellipsoid = 50%) of **5**. H atoms and solvent molecules are omitted; (b) a side view showing the staggered conformation of **5**.

### [(dppp)Pt]$_2$[{μ-(1,2-η$^2$):(3,4-η$^2$)-PhC$_4$Ph}] (5)

The molecular structure of complex **5** is shown in Figure 3. The butadiyne is coordinated to the two Pt atoms in μ-(1.2-η$^2$):(3,4-η$^2$) mode. Both Pt atoms show nearly square-planar coordination geometry. The C1–C2–C3–C4 backbone of the butadiyne shows a *gauche* conformation with a torsion angle of 94.79°. Similar conformation has been observed in the μ-(1,2-η$^2$):(3,4-η$^2$)-butadiyne complexes (PyCl$_4$W)$_2$(Me$_3$SiC≡CC≡CPh),[8d] (Cp$_2$V)$_2$(Me$_3$Si–C≡CC≡C–SiMe$_3$),[8e] and [(R$_2$PCH$_2$CH$_2$PR$_2$)Ni]$_2$-(R′C≡CC≡CR′)[8f] (R = *i*Pr, R′ = H or R = *t*Bu, R′ = Ph) which display a torsion angle of 74–98°. The two Pt atoms are related by a $C_2$-rotation. The C1–Pt1–C2 and C3–Pt2–C4 metallacycles show a *gauche* conformation with a dihedral angle of 86.01°. The lengths of the two acetylene bonds are 1.303(5) Å (C1–C2) and 1.296(5) Å (C3–C4), similar to the acetylene bond lengths observed in **2a** and **4**.

Notably, the "inner" Pt–C bonds, Pt1–C2 [2.051(3) Å] and Pt2–C3 [2.063(3) Å] and the "inner" Pt–P bonds, Pt1–P2 [2.2581(9) Å] and Pt2–P4 [2.2755(9) Å], are slightly but consistently longer than the "outer" Pt1–C1 [2.034(3) Å], Pt2–C4 [2.017(3) Å], and Pt1–P1 [2.2478(9) Å] and Pt2–P3 [2.2423(8) Å], respectively. Such differences could be caused by the steric repulsions between two neighboring dppp ligands. Similar to compounds **1**–**4**, the carbon atoms at the two ends of the acetylene bond are bent away from the metal atom. The phenyl rings of the butadiyne are almost coplanar with the PtC$_2$ unit, showing dihedral angles of 15.14 and 16.95°.

### $^{31}$P-NMR Spectroscopy

The $^{31}$P NMR spectra of all the complexes are consistent with the X-ray crystal structures of the complexes. The spectra of **1** and **2** show only two singlets at $\delta$ = 27.07 and 4.11 with Pt satellites ($^1J_{Pt\text{-}P}$ = 3448 and 3155 Hz, respectively), and the spectrum of **3** shows two doublets of triplets at $\delta$ = 26.53 and 26.19 ppm ($^1J_{Pt\text{-}P}$ = 3521 and 3456 Hz, $^2J_{P\text{-}P}$ = 22.9 Hz). The spectra of **4** and **6** show similar [AB]$_2$ splitting patterns. On the other hand, the spectrum of **5** is poorly resolved, because of the similar chemical shifts of different P atoms in the complexes (4.18 and 3.94 ppm, $^2J_{P\text{-}P}$ = 26.7 Hz). In the spectrum of **7** the signals of the two phosphorus atoms are isochronous at $\delta$ = 8.54 ppm with very close $^1J_{Pt\text{-}P}$ (3227 and 3258 Hz). Although the X-ray crystal structures of **6** and **7** are not available, the similar NMR spectra suggest the molecular structures of **6** and **7** should resemble their PhC$_4$Ph counterparts, **4** and **5**, respectively.

### (C) Absorption Spectroscopy

The UV/Vis absorption spectra of complexes **1**, **2**, and the parent ligand diphenylacetyleme are shown in Figure 4. The ligand displays intense ($\varepsilon > 10^4$ M$^{-1}$cm$^{-1}$) vibronic absorptions at 250–310 nm. Similar vibronic bands are ob-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

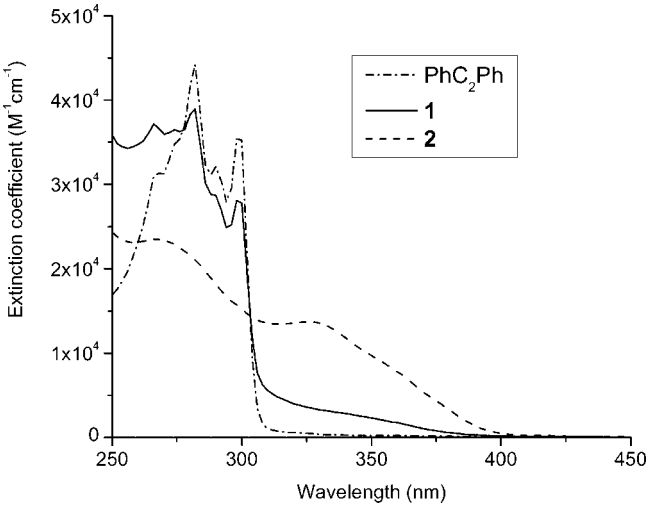

Figure 4. UV/Vis absorption spectra of complexes **1**, **2**, and ligand $PhC_2Ph$ in $CH_2Cl_2$ at room temperature.

served in the spectrum of **1**. In addition, the spectrum displays a broad and moderately intense absorption ($\varepsilon$ = 1–$3.5 \times 10^3$ M$^{-1}$cm$^{-1}$) ranging from 310–400 nm. No vibronic structure is observed in the spectrum of **2**. Instead the spectrum shows a broad and intense band peaked at 270 nm ($\varepsilon_{max} = 2.34 \times 10^4$ M$^{-1}$cm$^{-1}$) and a broad intense absorption at 300–420 nm. The latter absorption consists of more than one band, showing a peak at 327 nm ($\varepsilon_{max}$ = $1.38 \times 10^4$ M$^{-1}$cm$^{-1}$) and a shoulder at ca. 355 nm ($\varepsilon$ = $9.1 \times 10^3$ M$^{-1}$cm$^{-1}$).

The absorption spectrum of the ligand $PhC_4Ph$ shows a clear vibronic structured band at 270–340 nm with a progression of 2000 cm$^{-1}$ which should be associated with the vibration of the C≡C bond in the ππ* excited state (Figure 5). The three complexes exhibit very intense absorption around 250 nm with no distinct vibronic peak. While the parent ligand does not absorb beyond 350 nm, the complexes display broad intense absorption bands extending to 450 (**3** and **4**) or 500 nm (**5**). The low energy absorption

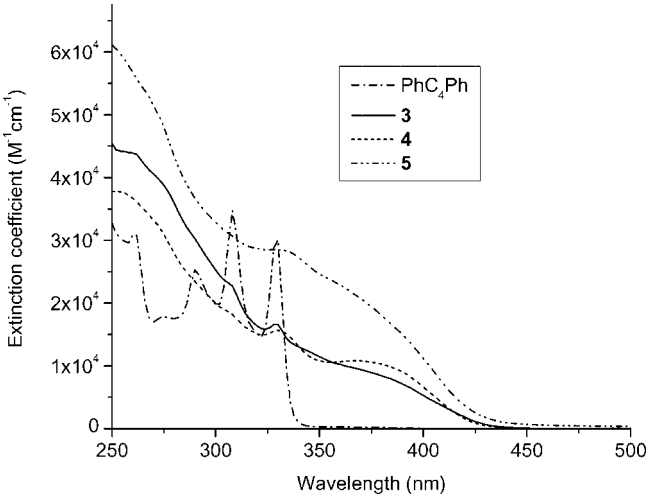

Figure 5. UV/Vis absorption spectra of complexes **3**, **4**, **5**, and ligand $PhC_4Ph$ in $CH_2Cl_2$ at room temperature.

bands of **3** and **4** maximize at 370 nm ($\varepsilon_{max}$ = $9 \times 10^3$ M$^{-1}$cm$^{-1}$) and 374 nm ($\varepsilon_{max}$ = $1.09 \times 10^4$ M$^{-1}$cm$^{-1}$), respectively. The low energy absorption ($\lambda_{max} \approx$ 360 nm, $\varepsilon_{max} = 2.31 \times 10^4$ M$^{-1}$cm$^{-1}$) of **5** is more intense than that of **3** and **4**.

The absorption spectra of **6**, **7**, and $CH_3C_4CH_3$ are shown in Figure 6. Unlike $PhC_2Ph$ and $PhC_4Ph$, the spectrum of $CH_3C_4CH_3$ shows little absorption at wavelengths longer than 250 nm ($\varepsilon < 200$ M$^{-1}$cm$^{-1}$). However, the spectra **6** and **7** show intense absorption bands around 250 nm and a less intense band at ca. 320 nm ($\varepsilon_{max}$ = $4.3 \times 10^3$ M$^{-1}$cm$^{-1}$) and 315 nm ($\varepsilon_{max}$ = $1.3 \times 10^4$ M$^{-1}$cm$^{-1}$), respectively.

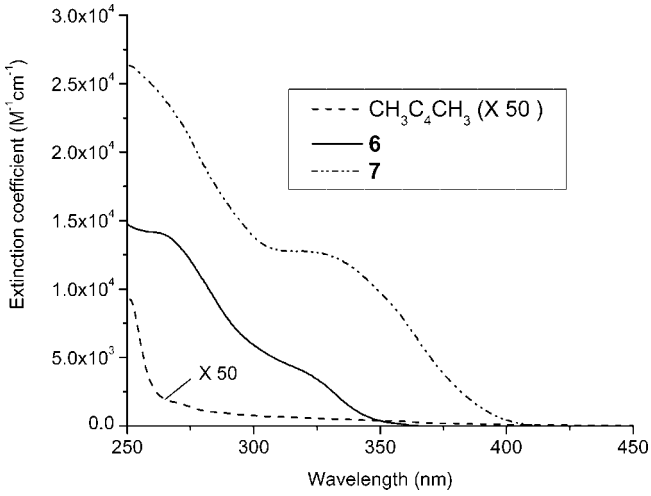

Figure 6. UV/Vis absorption spectra of complexes **6**, **7**, and $CH_3C_4CH_3$ in $CH_2Cl_2$ at room temperature.

### (D) Emission Spectroscopy

Table 2 summarizes the photophysical data of the complexes. The complexes are all not luminescent in degassed solution at room temperature. On the other hand, the solids of **1**–**5** are emissive at room temperature, showing two emission bands at 380–550 nm and 520–800 nm (Figure 7). The lifetimes ($\tau$) of the higher energy emissions are shorter than the detection limit of our nanosecond laser flash photolysis set-up (<0.1 μs), but the 520–800 nm emissions show long lifetimes ($\tau$ = 1.57–3.86 μs).

Table 2. Photophysical data of the acetylene-Pt complexes.

| | Emission (in EtOH, frozen at 77 K) $\lambda_{max}$ [nm] ($\tau$ [μs]) | Emission (solid state at 298 K) $\lambda_{max}$ [nm] ($\tau$ [μs]) |
|---|---|---|
| **1** | 447 (<0.1), 547 (58.32) | 446 (<0.1), 562 (3.86) |
| **2** | 429 (<0.1), 570 (39.97) | 443 (<0.1), 588 (2.19) |
| **3** | 404 (<0.1), 589 (21.76) | 457 (<0.1), 597 (2.72) |
| **4** | 475 (<0.1), 622 (10.07) | 459 (<0.1), 617 (1.57) |
| **5** | 468 (<0.1), 605 (5.65) | 458 (<0.1), 630 (too weak to be measured) |
| **6** | 490 (19.00) | No emission |
| **7** | 518 (29.20) | No emission |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

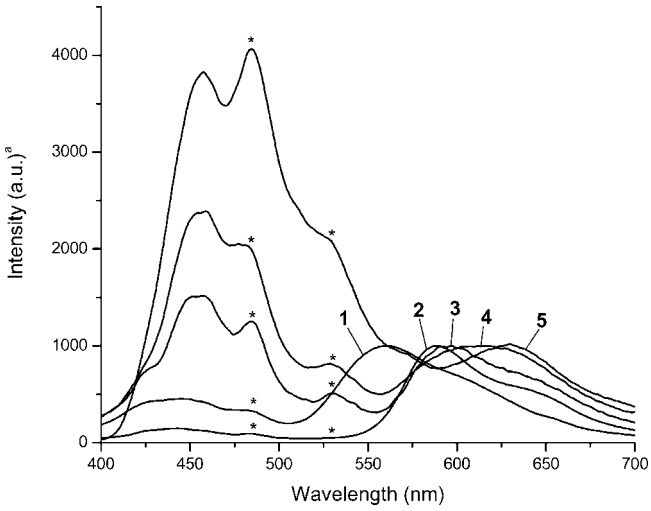

Figure 7. Solid-state emission spectra of complexes **1**–**5** at room temperature [a: intensities of the emission maximum in the low energy region (550–700 nm) are normalized; asterisks at ca. 485 and 529 nm denote instrumental artifacts]. The excitation wavelength is 320 nm.

The energy of the long-lived emissions of $PhC_4Ph$ complexes **3**, **4**, and **5** ($\lambda_{max}$ = 594–630 nm) is lower than $PhC_2Ph$ complexes **1** ($\lambda_{max}$ = 562 nm) and **2** ($\lambda_{max}$ = 588 nm). Apart from the acetylene, the emission energy is also affected by the ancillary phosphane atoms: the $PPh_3$-containing complexes **1** and **3** emit at slightly higher energy than their dppp counterparts **2** and **4**.

The emission spectra of 77 K frozen EtOH solutions of **1** and **2** are shown in Figure 8. Excitation at 320 nm leads to relatively weak emissions of short lifetimes ($\tau < 0.1$ μs) located at 350–500 nm. In addition, the spectra of **1** and **2** display more intense lower energy emissions of long lifetimes at 547 nm ($\tau$ = 58.32 μs) and 570 nm ($\tau$ = 39.97 μs), respectively.

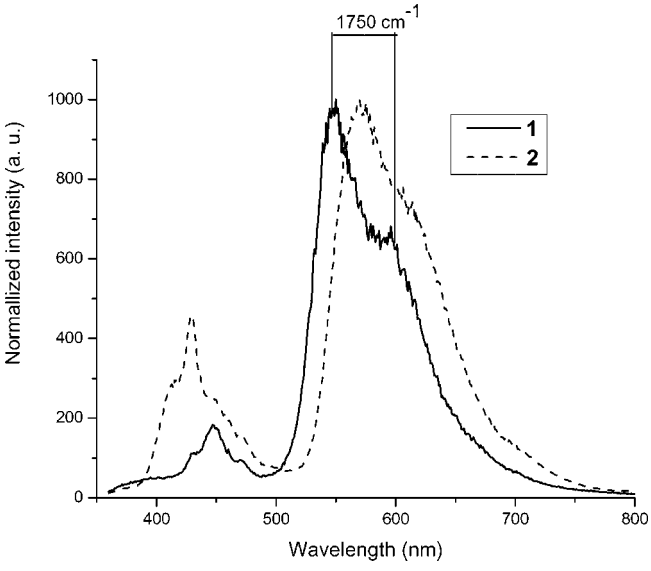

Figure 8. 77 K frozen ethanol solution emission spectra of complexes **1** and **2**. The excitation wavelength is 320 nm.

The lower energy emissions show vibronic shoulders. The spacing is estimated at 1750 $cm^{-1}$ in the spectrum of **1**.

The emission spectra of frozen solutions of **3**, **4**, and **5** at 77 K (supporting materials) also show two bands at 380–550 and 520–750 nm. Similar to the solid-state emission, the energy of the lower energy luminescence ($\lambda_{max}$ = 590–620 nm) is slightly lower than the corresponding emissions of **1** and **2**. The lifetime of the low energy emissions ($\tau$ = 5.65–21.76 μs) is much longer than that of the higher energy ones ($\tau < 0.1$ μs).

Unlike the $PhC_4Ph$ and $PhC_2Ph$ complexes, **6** and **7** are not emissive in the solid state at room temperature. At 77 K, the solids show weak emission at ca. 500 nm with $\tau$ of 5.10 μs (**6**) and 3.25 μs (**7**). The frozen solution spectra display similar emissions at 490 nm (**6**, $\tau$ = 19.00 μs) and 518 nm (**7**, $\tau$ = 29.20 μs) (Figure 9). The emissions of **6** and **7** are far less intense than those of **1**–**5**.

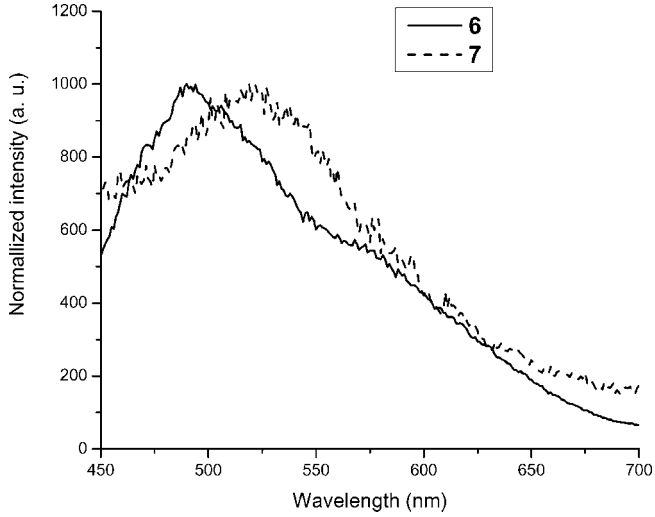

Figure 9. 77 K frozen ethanol solution emission spectra of complexes **6** and **7**. The excitation wavelength is 320 nm.

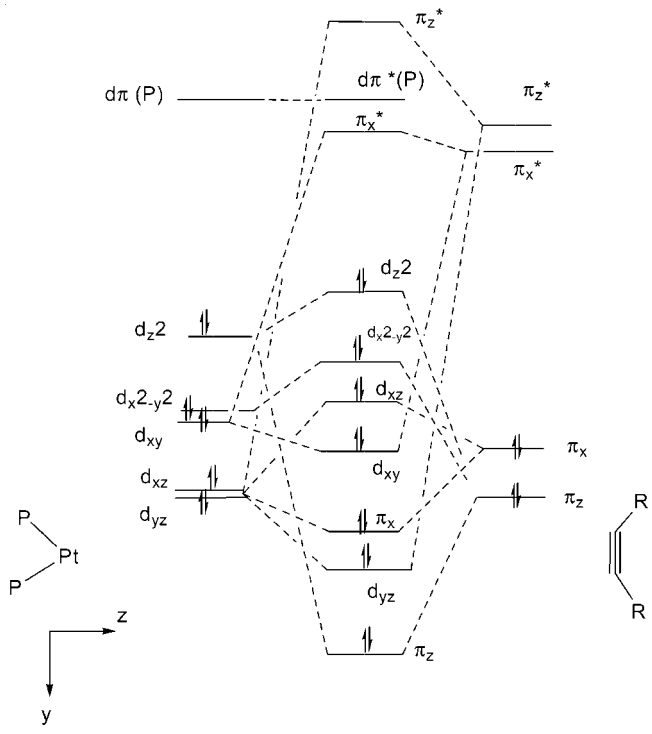
## Spectroscopic Assignments

In previous spectroscopic studies on acetylene-$Pt^0$ complexes, the low energy absorptions, which were absent in the spectra of the free acetylenes, were assigned to the Pt(5d)→acetylene(π*) charge transfer transition.[7a,7c] This assignment was further supported by semi-empirical calculations showing that the HOMO and LUMO are mainly composed of the $d_{z^2}$-orbital and acetylene π*-orbital.[7a] Likewise, the complexes **1**–**7** all exhibit intense absorption bands that are lower in energy than the ligand absorptions.

Scheme 2 shows a qualitative molecular orbital of acetylene-Pt complexes constructed from orbital interactions between a two-coordinate phosphane-$Pt^0$ and a bent acetylene.

Three metal orbitals $d_{z^2}$, $d_{xz}$, and $d_{x^2-y^2}$ are destabilized by interacting with either the $\pi_x$- or the $\pi_z$-orbital of the acetylenes. The $d_{z^2}$-orbital is expected to be the HOMO of the complexes as its energy is raised by the strong antibonding interactions with the $\pi_z$-orbital. Similarly, the $d_{x^2-y^2}$ or-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

bital is involved in σ-interaction with the $\pi_z$-orbital but the interactions should be weak because of the poor overlap. The $d_{xz}$ is in the correct symmetry to overlap with the $\pi_x$-orbital. On the other hand, the $d_{yz}$-orbital should be strongly stabilized via π-back bonding with the $\pi_z$*-orbital. The $d_{yx}$-orbital is involved in δ-interactions with the $\pi_x$*-orbital and should be slightly lowered in energy.

The $\pi_z$*-orbital of the acetylene, strongly destabilized by the back bonding, should be higher energy than the $\pi_x$*-orbital which is slightly destabilized by the weak δ-interactions. In this molecular orbital picture, the lowest energy allowed Pt→acetylene transition is the $^1(d_{z^2}\rightarrow\pi_x^*)$ transition. The $^1(d_{xz}\rightarrow\pi_x^*)$ and $^1(d_{x^2-y^2}\rightarrow\pi_x^*)$ transitions should be close in energy to the $^1(d_{z^2}\rightarrow\pi_x^*)$. Because of the mixing between the metal and ligand orbitals, these transitions have some intraligand character. Especially the $^1(d_{xz}\rightarrow\pi_x^*)$ transition, which could mix with the $^1(\pi_x\rightarrow\pi_x^*)$ transition, should be more intense than the other two transitions. Apart from the Pt→acetylene transition, a Pt→P(dπ*) charge transfer from Pt to the dπ*-orbitals of the phosphane atoms is also possible. Gray showed that the complex $Pt^0(dppp)_2$ exhibited an intense $Pt(d_{x^2-y^2}, d_{z^2})\rightarrow(d\sigma^*, d\pi^*)$ charge transfer absorption ($\varepsilon_{max}$ = 24,000 $M^{-1}cm^{-1}$) at 360 nm.[13] As $PhC_2Ph$ and $PhC_4Ph$ are better π-acceptors and weaker σ-donors than dppp, it is likely that the Pt→P(dπ*) transitions in the present complexes locate at wavelengths shorter than 360 nm in view of the position and energy of the very intense bands peaked at ca. 320 nm in the spectra of **2**, **6**, and **7**. Both position and intensity of the absorption bands are consistent with the Pt→P(dπ*) transition.

The low energy absorption of the complexes at wavelengths longer than 320 nm should belong to the Pt→P(dπ*) and Pt→acetylene($\pi_x$*) transitions. The order of these MLCT transitions primarily depends on the energy gap between the d-orbitals and $\pi_x$*-orbitals. Results of semi-empirical calculations show that the HOMO and the LUMO of the acetylene are mainly composed of $\pi_x$ and $\pi_x$* of the acetylene, respectively. The HOMO–LUMO gap is 8.25, 8.38, and 10.48 eV for $PhC_4Ph$, $PhC_2Ph$, and $CH_3C_4CH_3$, respectively (supporting information), and is consistent with the order of the π→π* absorption energy of the acetylenes. Because of the π-conjugation, the order of the LUMO energy is $PhC_4Ph$ (–0.65) < $PhC_2Ph$ (–0.51 eV) < $CH_3C_4CH_3$ (0.73 eV). On the other hand, the HOMOs of $PhC_4Ph$ and $PhC_2Ph$ have almost the same energy (–8.89 eV) and are higher energy than the HOMO of $CH_3C_4CH_3$ (–9.75 eV). Although the acetylenes in the complexes are distorted from linearity, the energy order of the HOMOs and LUMOs should be the same as that of the free ligands. Accordingly, the Pt→acetylene($\pi_x$*) MLCT transition energy of the complexes should follow the order **3**, **4**, **5** < **1**, **2** < **6**, **7**. The same trend is observed in the absorption of the complexes. Given their low-lying $\pi_x$*-orbitals, the Pt→acetylene($\pi_x$*) transitions in **1**, **2**, **3**, **4**, and **5** should be lower in energy than the Pt→P(dπ*). In addition, it is reasonable to expect the MLCT transitions of **3** and **4** to be lower in energy than those of **1** and **2**. Indeed, the MLCT absorption of the $PhC_4Ph$ complexes extends to 500 nm while the $PhC_2Ph$ complexes do not absorb beyond 400 nm. On the other hand, the energy of the Pt→acetylene($\pi_x$*) transition could be close to or even higher than that of the Pt→P(dπ*) for the complexes **6** and **7** as the $\pi_x$*-orbitals of $CH_3C_4CH_3$ are high in energy.

The solid state and frozen solution emission spectra of **1**–**5** show emissions of short lifetimes at ca. 380–550 nm and of longer lifetimes at ca. 500–800 nm. The long lifetimes of the lower energy emission suggests that luminescence arises from a triplet excited state. It is further supported by the large Stoke shift between the absorption and the emission. The frozen solution spectrum of **1** shows a vibronic spacing of ca. 1750 $cm^{-1}$, that is close to the ground state stretching frequency of the coordinated acetylene. This suggests the excited state could be $^3$MLCT($\pi_x$*) arising from the Pt→acetylene($\pi_x$*) excitation. The order of the emission energy is **3**, **4**, **5** < **2** < **1** and is in agreement with the energy of the $\pi_x$*-orbitals of the complexes and hence the MLCT assignment. That the MLCT emission of **1** is slightly higher in energy than that of **2** could be due to the fact that the $PPh_3$ in **1** is a strong electron-acceptor and weaker electron-donor than the dppp in **2**.

The short-lived 350–550 nm emission displayed by **1**–**5** could arise from an intraligand (acetylene) ππ* excited state and/or a $^3$MLCT(dπ*). $PhC_2Ph$ and $PhC_4Ph$ fluoresce at 330 and 365 nm in solution, respectively (supporting information), while $CH_3C_4CH_3$ is not emissive. To a different extent, the metal–ligand interactions in the acetylene complexes stabilize the $\pi_x$- and $\pi_z$-orbitals and destabilize the $\pi_x$*- and $\pi_z$*-orbitals. Accordingly, the lowest energy intrali-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gand $\pi_x \rightarrow \pi_x^*$ transition, and hence the corresponding $\pi\pi^*$ emission should be blue shifted from that of the free acetylene. Possibly, the higher energy emissions of the complexes come from a $^3$MLCT(d$\pi^*$) that arises from the Pt→P(d$\pi^*$) transition. It should be noted that the complex $Pt^0(dppp)_2$ exhibits $^3$MLCT(d$\pi^*$) phosphorescence at 622 nm. As the Pt center in the acetylene complexes is less electron rich than the one in $Pt^0(dppp)_2$, it is reasonable for the $^3$MLCT(d$\pi^*$) emission to occur at a higher energy.

Unlike the other complexes, **6** and **7** are not luminescent at room temperature and show a single emission at low temperature. The emission energy is slightly higher than that of **1**–**5** by 1800–3800 cm$^{-1}$. Given the fact that the $\pi_x^*$-orbital of $CH_3C_4CH_3$ is about ca. 1.3 eV or 10000 cm$^{-1}$ higher than those of $PhC_4Ph$ and $PhC_2Ph$, it is unlikely the emissive state in **6** and **7** is $^3$MLCT($\pi_x^*$). The emissive excited state is therefore tentatively assigned to the $^3$MLCT($d\pi^*$).

## Concluding Remarks

In this work, MLCT emission of a series of phosphane-supported acetylene-$Pt^0$ complexes in both the solid state and frozen solution was observed. All of the complexes display intense charge transfer absorptions. Dual emissions are observed in the spectra of **1**–**5**. The higher energy emission could arise from intraligand $\pi\pi^*$ and/or $^3$MLCT(d$\pi^*$) excited states. It is demonstrated that the MLCT emission energy is subject to the electron-donating ability of the phosphane atom and the electronic structures of the acetylene. The lowest energy emissive excited state of **1**–**5** is assigned to $^3$MLCT($\pi_x^*$) as the $\pi_x^*$-orbitals of $PhC_4Ph$ and $PhC_2Ph$ are substantially stabilized via conjugation with the phenyl rings. On the other hand, we assign the phosphorescence of **6** and **7** to $^3$(d$\pi^*\rightarrow$Pt) transitions. It is believed that for the two complexes, the d$\pi^*$-orbitals of dppp are lower in energy than the $\pi_x^*$-orbitals.

## Experimental Section

**General Methods:** All reactions were carried out using standard Schlenk techniques. 1,4-diphenylbuta-1,3-diyne, $PPh_3$, dppp, $NaBH_4$, and $N_2H_4{\cdot}H_2O$ purchased from Aldrich, 2,4-hexa-1,3-diyne purchased from TCI, and $PtCl_2$ purchased from Oxkem were used without further purification. Diphenylacetylene and ethylene were obtained from Aldrich. All solvents used for syntheses and spectroscopic measurements were purified according to literature methods. $Pt(CH_3CN)_2Cl_2$ was prepared by refluxing $PtCl_2$ in a large excess of $CH_3CN$. *cis*-$Pt(PPh_3)_2Cl_2$ and $Pt(dppp)Cl_2$ were prepared by reacting 2 equiv. of $PPh_3$ and 1 equiv. of dppp, respectively, with $Pt(CH_3CN)_2Cl_2$ in $CH_2Cl_2$. (dppp)Pt[(1,2-$\eta^2$)-$CH_2$=$CH_2$] was prepared by reduction of $Pt(dppp)Cl_2$ in the presence of ethylene in ethanol. **1**[5a] and **3**[6b] were synthesized according to the reported methods. Their NMR spectra are identical to the reported ones.

### Synthesis

**(dppp)Pt[(1,2-$\eta^2$)-$PhC_2Ph$] (2):** $Pt(dppp)Cl_2$ (0.26 g, 0.39 mmol) was added to a 30-mL ethanolic solution of diphenylacetylene (0.085 g, 0.42 mmol). Slow addition of $NaBH_4$ (0.1 g, 2.6 mmol) to the mixture gave a pale yellow suspension. The reaction mixture was stirred overnight at room temperature. The yellow solid collected by filtration was washed with excess ethanol. Analytically pure product was obtained by recrystallization in THF/*n*-hexane. Yield: 0.25 g (80%). $C_{41}H_{36}P_2Pt$ (785.8): calcd. C 62.7, H 4.6; found C 62.5, H 4.5. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.66–6.96 (m, 30 H, Ph), 2.61–2.58 (m, 4 H, -$CH_2$-P-Pt-), 2.05–1.91 (m, 2 H, -C-$CH_2$-C-) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CDCl_3$): $\delta$ = 4.11 [$^1J$(PtP) = 3155 Hz] ppm. IR (KBr): $\nu$(C≡C) = 1748 (w) cm$^{-1}$. ESI-MS (*m*/*z*, assignment): 786 [M]$^+$. Single crystals of **2**·THF for X-ray diffraction analysis were obtained by slow diffusion of *n*-hexane into a concentrated THF solution of **2**.

**(dppp)Pt[(1,2-$\eta^2$)-$PhC_4Ph$] (4):** The procedures were similar to those for preparing **2**. Yield: 70%. $C_{43}H_{36}P_2Pt$ (809.8): calcd. C 63.8, H 4.5; found C 63.9, H 4.3. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.74–7.01 (m, 30 H, Ph), 2.64–2.55 (m, 4 H, -$CH_2$-P-Pt-), 2.09–1.94 (m, 2 H, -C-$CH_2$-C-) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CDCl_3$): $\delta$ = 4.87 [$^2J$(PP) = 15.3 Hz, $^1J$(PtP) = 3349 Hz], 3.20 [$^2J$(PP) = 15.3 Hz, $^1J$(PtP) = 3086 Hz] ppm. IR (KBr): $\nu$(C≡C) = 2160 (m, uncoordinated), 1719 (m, coordinated) cm$^{-1}$. ESI-MS (*m*/*z*, assignment): 810 [M]$^+$. Single crystals of **4** for X-ray diffraction analysis were obtained by slow diffusion of *n*-hexane into a concentrated $CH_2Cl_2$ solution of **4**.

**[(dppp)Pt]$_2$[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-$PhC_4Ph$] (5):** **4** (0.11 g, 0.14 mmol) and 1 mol equiv. of $Pt(dppp)(CH_2{=}CH_2)$ (0.086 g, 0.14 mmol) were added to diethyl ether (15 mL) and stirred at room temperature for 24 h. The pale yellow suspension was then filtered and washed with diethyl ether. The pale yellow crude product was recrystallized from THF/diethyl ether to give the pure product. Yield: 0.11 g (55%). $C_{70}H_{62}P_4Pt_2$ (1417.3): calcd. C 59.3, H 4.4; found C 59.2, H 4.4. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 6.81–7.91 (m, 50 H, Ph), 2.24 (m, 8 H, -$CH_2$-P-Pt-), 1.61–1.68 (m, 4 H, -C-$CH_2$-C-) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = 4.18 [$^2J$(PP) = 26.7 Hz, $^1J$(PtP) = 3258 Hz], 3.94 [$^2J$(PP) = 26.7 Hz, $^1J$(PtP) = 3267 Hz] ppm. IR (KBr): $\nu$(C≡C) = 1758 (m) cm$^{-1}$. ESI-MS (*m*/*z*, assignment): 1417 [M]$^+$. Single crystals of **5** for X-ray diffraction analysis were obtained by slow diffusion of diethyl ether into a concentrated THF solution of **5**.

**(dppp)Pt[(1,2-$\eta^2$)-$CH_3C_4CH_3$] (6):** $Pt(dppp)(CH_2{=}CH_2)$ (0.108 g, 0.17 mmol) was treated with twofold excess of 2,4-hexadiyne (0.027 g, 0.34 mmol) in diethyl ether at room temperature for 24 h. The pale yellow suspension was then filtered and washed with a small amount of diethyl ether. The product was purified by recrystallization in THF/diethyl ether. Yield: 0.08 g (70%). $C_{33}H_{32}P_2Pt$ (685.6): calcd. C 57.8, H 4.7; found C 57.5, H 4.5. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 7.98–7.92, 7.71–7.65 and 7.10–6.98 (m, 20 H, Ph), 2.76 [doublet of triplets, $^3J$(PtH) = 39.7 Hz, $^4J$(PH) = 7.6 Hz, 3 H, $CH_3$ on the coordinated C≡C], 2.15 (m, 4 H, -$CH_2$-P-Pt-), 1.90 [doublet of triplets, $^5J$(PtH) = 18.8 Hz, $^6J$(PH) = 3.5 Hz, 3 H, $CH_3$ on the uncoordinated C≡C], 1.62 (m, 2 H, -C-$CH_2$-C-) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = 8.47 [$^2J$(PP) = 31.1 Hz, $^1J$(PtP) = 3353 Hz], 7.29 [$^2J$(PP) = 31.1 Hz, $^1J$(PtP) = 3124 Hz] ppm. IR (KBr): $\nu$(C≡C) = 2196 w (uncoordinated), 1749 s (coordinated) cm$^{-1}$. ESI-MS (*m*/*z*, assignment): 686 [M]$^+$.

**[(dppp)Pt]$_2$[μ-(1,2-$\eta^2$):(3,4-$\eta^2$)-$CH_3C_4CH_3$] (7):** The preparative procedures for **7** were similar to those for preparing **5**. Yield: 40%. $C_{60}H_{58}P_4Pt_2$ (1293.2): calcd. C 55.7, H 4.5; found C 55.5, H 4.5. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 8.06–8.00, 7.86–7.80 and 7.10–6.93 (m, 40 H, Ph), 2.51 (m, 6 H, $CH_3$), 2.26 (br., 8 H, -$CH_2$-P-Pt-), 1.74 (br., 4 H, -C-$CH_2$-C-) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = 8.54 [$^1J$(PtP) = 3227 and 3258 Hz] ppm. IR (KBr): $\nu$(C≡C) = 1705 (w) cm$^{-1}$. ESI-MS (*m*/*z*, assignment): 1293 [M]$^+$.

**Physical Measurements:** Elemental analyses of all the compounds prepared were carried out in the microanalysis laboratory in the Department of Chemistry, the National University of Singapore. $^1$H- and $^{31}$P{$^1$H}-NMR spectra were recorded at room temperature with a Bruker ACF 300 spectrometer. Electrospray ionization mass spectra (ESI-MS) were measured with a Finnigan MAT 731 LCQ spectrometer. IR spectra (KBr) were recorded using a Bio-Rad Win-IR spectrophotometer. UV/Vis absorption spectra were recorded with a Shimadzu UV-1601PC UV/Vis spectrophotometer. Emission spectra were recorded with a SPEX-Fluorolog2 model F111A1 fluorescence spectrofluorometer. The lifetimes were measured using the Quanta Ray DCR3 Nd:YAG laser with a pulsewidth of 8 ns and excitation wavelength of 355 nm. Sample solutions for 77 K frozen glass emission spectra measurement were prepared as follows: (i) a small amount of solid samples were added to ethanol solution; (ii) the solutions were then dissolved using the ultra-sonic bath; (iii) the solutions were filtered; (iv) the filtrates were introduced into a quartz tube; (v) the quartz tubes were immersed in liquid nitrogen in a quartz optical Dewar flask for measuring.

**Molecular Orbital Calculations:** The calculations were performed using the SPARTAN semiempirical program SGI/R10K, release 5.1.3, with geometry optimization. The model RHF/PM3 was used in the calculations.

**X-ray Crystallography:** The diffraction experiments were carried out with a Bruker AXS SMART CCD 3-circle diffractometer at $T$ = 223 K (except that: $T$ = 295 K for crystal **2**·THF), 2θ-ω scan with a sealed tube at 23 °C using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The software used were: SMART[14] for collecting frames of data, indexing reflection, and determination of lattice parameters; SAINT[14] for integration of intensity of reflections and scaling; SADABS[15] for empirical absorption correction; and SHELXTL[16] for space group determination, structure solution, and least-squares refinements on $|F|^2$. The crystals were mounted at the end of glass fibers and used for the diffraction experiments. Anisotropic thermal parameters were refined for the rest of the non-hydrogen atoms. The hydrogen atoms were placed in their ideal positions. The X-ray crystal data and parameters used in structural refinements are summarized in Table 3.

CCDC-623835 (for **2**), -623836 (for **4**), and -623837 (for **5**) contain the supplementary crystallographic data. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Molecular orbitals of the acetylenes, emission spectra of diphenylacetylene and 1,4-diphenyl-buta-1,3-diyne, emission spectra of frozen glass solutions of **3**–**5** at 77 K, syntheses and characterizations of **1** and **3**.

# Towards Polymer Diagnostic Agents − Copolymers of *N*-(2-Hydroxypropyl)-methacrylamide and Bis(2-pyridylmethyl)-4-vinylbenzylamine: Synthesis, Characterisation and $Re(CO)_3$-Labelling

**Peter C. Kunz,*[a] Nadine E. Brückmann,[a] and Bernhard Spingler[b]**

**Keywords:** Rhenium / Carbonyl ligands / Polymer diagnostics / Copolymers / Cancer / Diagnosis / EPR effect

Diagnosis of early stage angiogenic tumours is fundamental for cancer therapy. In this study we present the synthesis and characterisation of functionalised HPMA-copolymers with optimal molecular weights that meet the demands of the enhanced permeability and retention (EPR) effect. Rhenium tricarbonyl complexes of the tripodal ligands bis(2-pyridylmethyl)benzylamine (**1a**) and bis(2-pyridylmethyl)-4-vinylbenzylamine (**1b**) were prepared and characterised by $^1H$ NMR and IR spectroscopy, mass spectrometry and X-ray diffraction. Ligand **1b** was copolymerised with *N*-(2-hydroxypropyl)methacrylamide (HPMA), and the resulting copolymer was treated with $(nBu_4N)_2[Re(CO)_3Br_3]$ to yield a $Re(CO)_3$-labelled copolymer.

## Introduction

Polymer–drug conjugates are an interesting concept in medicinal chemistry. The conjugation of prodrugs to hydrophilic polymers provides an opportunity to solubilise poorly water-soluble drugs, improve tumour targeting and reduce drug toxicity.[1] Several polymer–drug conjugates have already entered phase-I/II clinical trials as anticancer agents.[2] The improved tumour targeting is due to the so called enhanced permeability and retention (EPR) effect, which concerns the passive accumulation of macromolecules in solid tumours because of the high vascular density in tumours, the increased permeability and defective architecture of tumour vessels, as well as suppressed lymphatic drainage from the tumour interestitium. The molecular weight ($M_w$) of macromolecular systems is more important than their nature (proteins, lipids or synthetic polymers) for the EPR effect. Macromolecules with molecular weights above 40 kDa are found to remain at high levels in circulating blood.[3] On the other hand, nephritic excretion is restricted to macromolecules with molecular weights below about 50 kDa.[4]

Although polymers are now widely used in therapeutic approaches, only a few examples of diagnostically used polymer conjugates exist.[5] We are interested in developing organometallic polymer-based tumour diagnostic agents. *N*-(2-Hydroxypropyl)methacrylamide (HPMA) was chosen as a copolymer base since its copolymers are water-soluble, biocompatible and non-immunogenic macromolecular carrier systems.[5a] Furthermore, the molecular weight of HPMA copolymers can be easily varied. Organometallic and coordination chemistry with relation to biological and medicinal chemistry is an increasingly important field. The use of technetium is of particular interest due to the short half-life of $^{99m}Tc$ ($T_{1/2}$ = 6 h, $E_\gamma$ = 140 keV), which makes this isotope one of the workhorses of diagnostic nuclear medicine.[6] The chemistry of this element is closest to its heavier congener rhenium, which itself has become interesting for therapeutic purposes as the isotope $^{188}Re$ ($T_{1/2}$ = 16.9 h, $E_\beta$ = 2.1 MeV). Since the development of new, simple routes for the synthesis of *fac*-$[^{99m}Tc(H_2O)_3(CO)_3]^+$ and *fac*-$[^{188}Re(H_2O)_3(CO)_3]^+$, several groups have begun to develop ligand systems for these $M(CO)_3$ fragments.[7] Therefore, a macromolecule that is able to bind $M(CO)_3$ (M = Tc, Re) would be interesting for diagnostic as well as therapeutic approaches.

Here, we report the synthesis and characterisation of HPMA-co-bis(2-pyridylmethyl)-4-vinylbenzylamine copolymers with different average molecular weights and the coordination of the $Re(CO)_3$ fragment to these copolymers.

## Results and Discussion

The ligand bis(2-pyridylmethyl)benzylamine (**1a**) was prepared from picolyl chloride and benzylamine by modifying a synthesis originally reported by Dick.[8] This ligand serves as a model for the coordination environment of the $Re(CO)_3$ moiety in the polymer. The co-monomer ligand

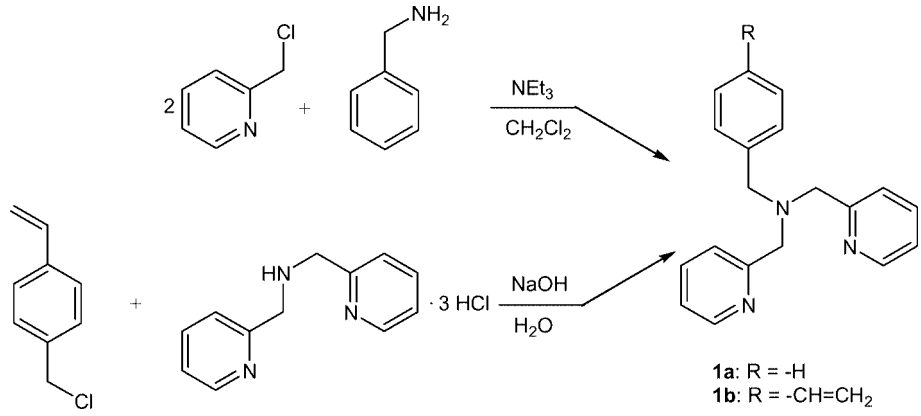
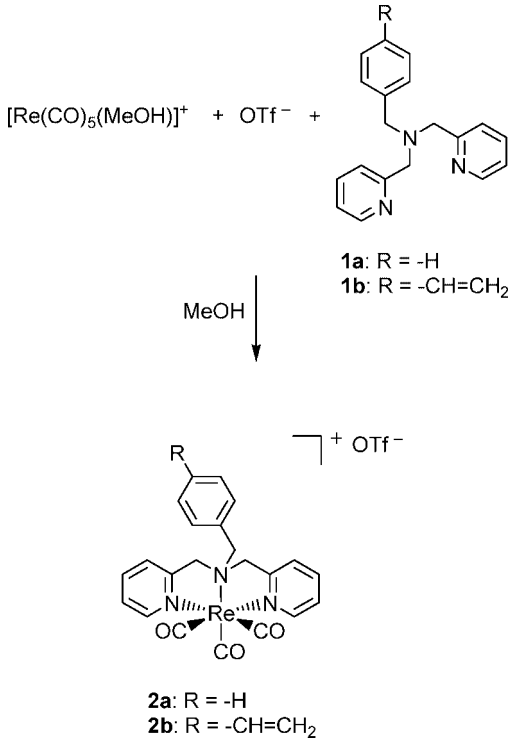


Scheme 1. Synthetic routes to the ligands **1a** and **1b**.

bis(2-pyridylmethyl)-4-vinylbenzylamine (**1b**) was prepared by the reaction of bis(2-pyridylmethyl)amine with 4-vinylbenzyl chloride (Scheme 1).

In the $^1$H NMR spectra in deuteriochloroform both ligands show singlets at $\delta$ = 3.7 and 3.8 ppm in a 2:4 ratio for the $CH_2$ groups attached to the amine. The aromatic protons of the phenyl ring and the protons of the pyridyl rings (H3, H4 and H5) appear in the region $\delta$ = 7.1–7.9 ppm, whereas $H6_{py}$ is at a lower field of $\delta$ = 8.6 ppm. In addition, **1b** exhibits signals for the three vinyl protons at $\delta$ = 5.23, 5.75 and 6.72 ppm, with the characteristic splitting pattern of two doublets ($^3J_{cis}$ = 11, $^3J_{trans}$ = 18 Hz) for the terminal protons and a doublet of doublets for the α-proton of the vinyl group. The FAB$^+$ mass spectra of **1a** and **1b** exhibit peaks for the molecular ion at the expected *m*/*z* value together with a characteristic fragmentation pattern.



Scheme 2. Formation of complexes of **1a** and **1b** with [Re(CO)$_5$Br] in the presence of AgOTf.

Both **1a** and **1b** form complexes of the composition [LRe(CO)$_3$]OTf when Re(CO)$_5$Br, AgOTf and ligand are mixed in an equimolar stoichiometry in refluxing methanol (Scheme 2).

Upon coordination, the signals of the $CH_2$ groups directly bound to the amine nitrogen atom are shifted by about 1 ppm towards lower field. Additionally, the methylene protons of the 2-pyridylmethyl groups at $\delta$ = 4.8 ppm are no longer chemically equivalent due to the $C_s$-symmetry of complexes **2a** and **2b** and form an AB spin-system. The aromatic protons of the phenyl and pyridyl rings as well as the protons of the vinyl group in **2b** do not shift upon coordination. The IR spectra of **2a** and **2b** show the characteristic bands of the ligands and the two bands of a nearly $C_{3v}$-symmetrical Re(CO)$_3$ fragment, with the doubly degenerate *E* band slightly split (**2a**: 2028, 1922 cm$^{-1}$; **2b**: 2028, 1920 cm$^{-1}$). This splitting has also been observed in the Mo$^{I}$(CO)$_3$ complex of **1a**.[9] The FAB$^+$ mass spectra of **2a** and **2b** exhibit peaks for the molecular ion at the expected *m*/*z* values (both 100%) together with the characteristic $^{187/185}$Re isotope pattern.

## Solid-State Structures of 2a·$CH_2Cl_2$·$H_2O$ and 2b·$CH_2Cl_2$

For a better understanding of the Re(CO)$_3$ binding in the functionalised polymer we determined the structures of the molecular "model" complexes **2a** and **2b** by X-ray analysis. Both complexes can be crystallised by slow diffusion of *n*-hexane into a solution of the corresponding complex in dichloromethane. Complex **2a**·$CH_2Cl_2$·$H_2O$ crystallises in the triclinic space group $P\bar{1}$ (Figure 1). The co-crystallised water molecule is disordered. Interestingly, the achiral complex **2b**·$CH_2Cl_2$ crystallises in the chiral space group $P2_1$ (Figure 2). The rhenium centre in both structures is in a slightly distorted octahedral coordination environment, with the *N*,*N*,*N* ligands and the three carbonyl ligands coordinating facially. As expected, both structures are very similar at first glance. In the structure of **2a** the angles between the carbonyl ligands are close to 90° and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the maximum deviation of the Re1–$C_n$–$O_n$ ($n$ = 1–3) angles from 180° is less than 1.5°. Interestingly, the $Re(CO)_3$ fragment in **2b** shows significant distortion: the carbonyl groups are slightly bent towards each other and the C1–Re1–C3 angle is only 85.7°. In addition, the Re1–$C_n$–$O_n$ angles deviate significantly from 180°. The maximum deviation is found for the Re1–C3–O3 angle, which is 174.8°. Selected bond lengths and angles are summarised in Tables 1 and 2.

### $Re(CO)_3$-Labelled HPMA-Copolymer

In order to obtain HPMA-co-bis(2-pyridylmethyl)-4-vinylbenzylamine copolymer (**3**), freshly synthesised ligand **1b** and HPMA were dissolved in dry acetone and azobis(isobutyronitrile) (AIBN) added as initiator.[10] The reactions were carried out at 50 °C for 24 h. The resulting polymeric product was precipitated from a mixture of acetone and diethyl ether.

The $^1$H NMR spectrum of **3** (Figure 3) exhibits signals of the ligand as well as of HPMA. These signals are broadened due to the polymeric character of the examined molecules. Fortunately, there is almost no signal overlap and all signals can be assigned. The signals at $\delta$ = 3.8 and 3.9 ppm arise from the protons of the $CH_2$ groups attached to the amine, and the resonances deriving from the aromatic protons of the phenyl ring and the protons of the pyridyl rings appear in the region $\delta$ = 7.1–8.5 ppm. The other broad resonances can be assigned to HPMA and to the $CH_2$ group in the polymer backbone.

In the IR spectrum, the two $\nu_{C=C}$ bands of the aromatic pyridyl and phenyl rings occur at 1597 and 1572 cm$^{-1}$ and the carbonyl vibration deriving from the HPMA occurs at $\nu_{C=O}$ = 1730 cm$^{-1}$. Furthermore, the three aliphatic $CH_2$ and $CH_3$ vibrations are found in the region between 2980 and 2800 cm$^{-1}$. With monomer ratios of 10:1, 20:1 and 40:1 (HPMA:ligand) an average molecular weight of between 13.5 and 52 kDa can be obtained, as confirmed by size exclusion chromatography in DMF (Table 3).

The copolymer was labelled with $Re(CO)_3$ by refluxing $(n Bu_4N)_2[Re(CO)_3Br_3]$, AgOTf and copolymer in methanol. The IR spectrum clearly shows the vibrational bands of the copolymer as well as the two characteristic carbonyl bands from the pseudo $C_{3v}$-symmetrical $Re(CO)_3$ fragment.

In order to determine whether the $Re(CO)_3$ fragment is coordinated to the ligand system in the copolymer chain or whether it is non-specifically bound to the copolymer, the same reaction was carried out with poly-HPMA. In this case, the two bands of the carbonyl vibration can also be seen in the IR spectrum, thus indicating that $Re(CO)_3$ fragments are present in this sample as well. A Soxhlet extrac-

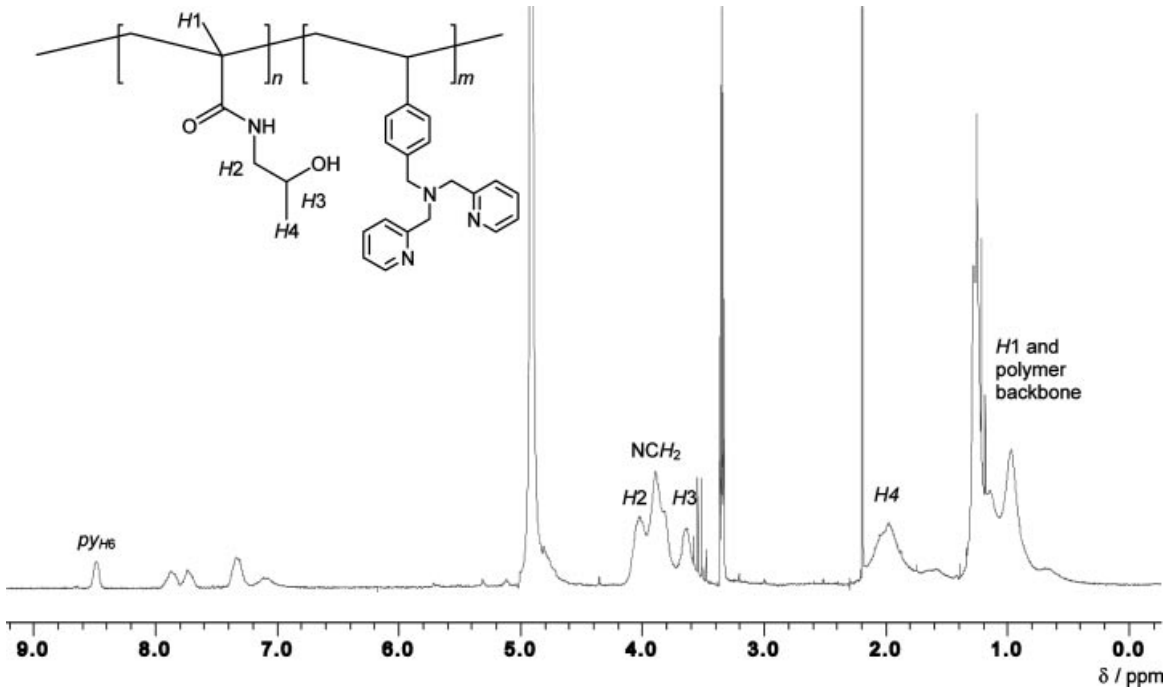

Figure 3. $^1$H NMR spectrum of HPMA-co-bis(2-pyridylmethyl)-4-vinylbenzylamine copolymer **3a**.

Table 3. Average molecular weights of the copolymers **3** obtained with different monomer and AIBN ratios.

| Copolymer | Monomer ratio | HPMA/**1b**/AIBN | $M_w$ [kDa] | Polydispersity |
|---|---|---|---|---|
| **3a** | 10:1 | 2 g/440 mg/30 mg | 13.5 | 1.4 |
| **3b** | 20:1 | 2 g/239 mg/15 mg | 20.0 | 1.2 |
| **3c** | 20:1 | 2 g/235 mg/20 mg | 18.0 | 1.6 |
| **3d** | 20:1 | 2 g/253 mg/20 mg | 22.5 | 1.5 |
| **3e** | 40:1 | 2 g/121 mg/15 mg | 52.0 | 1.8 |

tion of both labelled polymers was carried out using water as solvent. After extraction, only the IR spectrum of the copolymer sample shows the two carbonyl bands with high intensity (Figure 4); the IR spectrum of the extracted poly-HPMA sample shows the carbonyl bands with very low intensity (Figure 5). This proves that $Re(CO)_3$ is in fact coordinated to **3** and, in addition, that non-coordinated $Re(CO)_3$ can be washed out in order to obtain the pure product.

## Conclusions

We have presented a novel, water-soluble co-polymer of HPMA, namely HPMA-co-bis(2-pyridylmethyl)-4-vinylbenzylamine. The average molecular weight can be controlled by variation of the co-monomers and radical starter. With copolymer **3e**, a polymer having a molecular weight (52 kDa) suitable for the EPR effect was obtained. The copolymers can be labelled with $[Re(CO)_3Br_3]^{2-}$ at the bis(2-pyridylmethyl)amine unit and it has been shown that the $Re(CO)_3$ labels are not easily lost in aqueous medium. This makes these copolymers interesting carriers for the diagnostically used $^{99m}Tc$.

The solid-state structures of the bis(2-pyridylmethyl)-amine-derived complexes **2a**·$CH_2Cl_2$·$H_2O$ and **2b**·$CH_2Cl_2$ have been determined by X-ray crystallography. The IR spectra of these complexes and the $Re(CO)_3$-labelled copolymer are identical, they therefore resemble the structure of the binding sites in the labelled copolymer.

## Experimental Section

2-Picolyl chloride hydrochloride, benzylamine and 4-vinylbenzyl chloride were used as purchased from Aldrich and Fluka. Bis(2-pyridylmethyl)amine tris(hydrochloride),[11] $Re(CO)_5Br$[12] and $(NBu_4)_2[Re(CO)_3Br_3]$[7a] were prepared according to literature procedures. The preparation of the complexes was carried out in Schlenk tubes under an atmosphere of dry nitrogen using anhydrous solvents purified according to standard procedures. Crystals suitable for X-ray structure analysis were prepared by slow diffusion of *n*-hexane into a solution of the complexes in dichloromethane. $^1H$ NMR spectra were recorded with a Bruker AM 200 and Bruker DRX 500 spectrometer. $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker DRX 500 spectrometer. The $^1H$ and $^{13}C\{^1H\}$ NMR spectra were calibrated against the residual proton signals and the carbon signals of the solvents as internal references ([$D_1$]chloroform: $\delta_H$ = 7.30 ppm and $\delta_C$ = 77.0 ppm). The FAB mass spectra were recorded with a Finnigan MAT 8200 mass spectrometer in an NBA matrix. IR spectra were recorded with a Bruker IFS 66 FT-IR spectrometer. Size-exclusion chromatography was performed with a Viskotec GPCmax VE 2001 GPC solvent/sample module with a Viskotec VE 3580 RI detector.

**Bis(2-pyridylmethyl)benzylamine (1a):** 2-Picolyl chloride hydrochloride (2.05 g, 12.5 mmol) and benzylamine (0.67 g, 6.3 mmol) were dissolved in 15 mL of water and heated to 60 °C. To this solution 5 mL of aqueous NaOH (5 M) were added dropwise over a period of 30 min and the resulting mixture stirred for an additional 60 min. The cooled solution was extracted three times with 20 mL of dichloromethane, the combined organic layers were dried with $Na_2SO_4$, filtered and the solvent removed in vacuo. The product was obtained as a viscous brown oil (1.51 g, 83%). $^1H$ NMR (500 MHz, $CDCl_3$): $\delta$ = 3.64 (s, 2 H, NC$H_2$Ph), 3.76 (s, 4 H, py$CH_2$), 7.1–7.9 (m, 11 H, aromatic *H*), 8.62 ppm (m, 2 H, py*H6*). $^{13}C\{^1H\}$ NMR (500 MHz, $CDCl_3$): $\delta$ = 58.9, 60.3, 122.5, 123.3, 127.5, 129.1, 129.4, 127.0, 139.1, 149.4, 160.0 ppm. IR (KBr): $\tilde{\nu}$ = 2923, 2819, 1590, 1570, 760, 699 $cm^{-1}$. $FAB^+$ MS (NBA matrix): *m*/*z* (%) 290 (100) $[(pyCH_2)_2NCH_2Ph + H]^+$, 197 (47) $[pyCH_2NCH_2Ph]^+$, 93 (49) $[pyCH_2]^+$, 91 (60) $[CH_2Ph]^+$.

**Bis(2-pyridylmethyl)-4-vinylbenzylamine (1b):** Under an inert gas atmosphere, 4-vinylbenzyl chloride (1.3 g, 8 mmol), bis(2-pyridylmethyl)amine trishydrochloride (2 g, 6.5 mmol) and triethylamine (4 mL, 40 mmol) were dissolved in 30 mL of dichloromethane and stirred for 8 h. The white precipitate of triethylamine hydrochloride was removed by filtration. The organic solution was extracted twice with 10 mL of water and dried with $Na_2SO_4$. The solvent was removed in vacuo to give the product as an orange viscous liquid (1.4 g, 68%). $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 3.71

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(s, 2 H, NC$H_2$Ph), 3.84 (s, 4 H, pyC$H_2$), 5.23 (d, $^3J_{cis}$ = 11 Hz, 1 H, *cis*-C$H_2$CH), 5.75 (d, $^3J_{trans}$ = 18 Hz, 1 H, *trans*-C$H_2$CH), 6.72 (dd, 1 H, $CH_2CH$), 7.1–7.9 (m, 10 H, aromatic *H*), 8.56 ppm (m, 2 H, py*H*6). $^{13}C\{^1H\}$ NMR (500 MHz, $CDCl_3$): $\delta$ = 58.6, 60.4, 113.9, 123.2, 126.6, 129.4, 129.4, 136.9, 136.9, 137.0, 139.0, 149.4, 160.2 ppm. IR (KBr): $\tilde{\nu}$ = 2922, 2821, 1629, 1590, 1569, 825, 760 $cm^{-1}$. FAB$^+$ MS (NBA matrix): *m*/*z* (%) 316 (59) $[(pyCH_2)_2NCH_2PhCHCH_2 + H]^+$, 223 (45) $[pyCH_2NCH_2PhCHCH_2]^+$, 198 (26) $[(pyCH_2)_2N]^+$, 117 (100) $[CH_2C_6H_4CHCH_2]^+$, 93 (56) $[pyCH_2]^+$.

**General Procedure for the Preparation of Re(CO)$_3$ Complexes:** Under an inert gas atmosphere, AgOTf (129 mg, 500 μmol) and $Re(CO)_5Br$ (0.2 g, 0.5 mmol) in methanol were heated to reflux for 60 min. The AgBr precipitate was removed by filtration and 0.5 mmol of the ligand (**1a** or **1b**) dissolved in 5 mL methanol was added. The solution was refluxed for an additional hour. After cooling to ambient temperature the solvent was removed in vacuo and the residue dissolved in a minimum of dichloromethane. *n*-Hexane was added to the solution and colourless crystals deposited after a few days.

**[(1a)Re(CO)$_3$]OTf (2a):** Yield: 0.28 g (76%). $^1$H NMR (500 MHz, $CDCl_3$); $\delta$ = 4.69 (s, 2 H, PhC$H_2$), 4.82 (m, 4 H, $[AB]_2$, pyC$H_2$), 7.1–7.9 (m, 11 H, aromatic *H*), 8.6 ppm (m, 2 H, py*H*6). IR (KBr): $\tilde{\nu}$ = 2028, 1922, 1612 $cm^{-1}$. FAB$^+$ MS (NBA matrix): *m*/*z* (%) 560 (100) $[(\mathbf{1a})Re(CO)_3]^+$. $C_{23}H_{19}F_3N_3O_6ReS{\cdot}CH_2Cl_2{\cdot}C_6H_{14}$ (879.80): calcd. C 39.0, H 2.7, N 5.9; found C 38.6, H 2.7, N 5.8.

**[(1b)Re(CO)$_3$]OTf (2b):** Yield: 0.27 g (75%). $^1$H NMR (500 MHz, $CDCl_3$); $\delta$ = 4.67 (s, 2 H, PhC$H_2$), 4.82 (m, 4 H, $[AB]_2$, pyC$H_2$), 5.31 (d, $^3J_{cis}$ = 11 Hz, 1 H, *cis*-C$H_2$CH), 5.78 (d, $^3J_{trans}$ = 18 Hz, 1 H, *trans*-C$H_2$CH), 6.69 (dd, 1 H, $CH_2CH$), 7.1–7.9 (m, 10 H, aromatic *H*), 8.6 (m, 2 H, py*H*6). IR (KBr): $\tilde{\nu}$ = 2028, 1920, 1560 $cm^{-1}$. FAB$^+$ MS (NBA matrix): *m*/*z* (%) 585 (100) $[(\mathbf{1b})Re(CO)_3]^+$. $C_{25}H_{21}F_3N_3O_6ReS{\cdot}CH_2Cl_2{\cdot}C_6H_{14}$ (905.84): calcd. C 40.9, H 2.9, N 5.7; found C 40.1, H 2.6, N 5.6.

**General Procedure for the Preparation of HPMA-co-bis(2-pyridylmethyl)-4-vinylbenzylamine Copolymers (3):** HPMA and bis(2-pyridylmethyl)-4-vinylbenzylamine were dissolved in 15 mL of acetone in a Schlenk tube under an inert gas atmosphere. After addition of AIBN, the solution was heated to 50 °C and stirred for 24 h. The polymer was then precipitated by pouring the reaction mixture into a mixture of acetone and diethyl ether (1:1), the precipitate was filtered off and dried in vacuo to give **3a** (1.5 g, 67%). $^1$H NMR (200 MHz, [D$_4$]methanol): $\delta$ = 1.0 [C$H_2$ (polymer backbone), HPMA-H1], 2.0 (HPMA-H4), 3.6 (HPMA-H3), 3.8 (NC$H_2$Ph), 3.9 (pyC$H_2$), 4.0 (HPMA-H2), 7.1–7.9 (aromatic *H*), 8.6 ppm (py*H*6). IR (KBr): $\tilde{\nu}$ = 2980, 2800, 1597, 1572, 749 $cm^{-1}$.

**General Procedure for the Preparation of Re(CO)$_3$-Labelled HPMA-co-bis(2-pyridylmethyl)-4-vinylbenzylamine Copolymers (4):** Under an inert gas atmosphere, $(n\mathrm{Bu}_4\mathrm{N})_2[Re(CO)_3Br_3]$ (0.1 g, 0.13 mmol) and AgOTf (0.11 g, 0.39 mmol) were heated to reflux in methanol for 60 min. Precipitated AgBr was removed by filtration and 0.458 g of the copolymer **3a** dissolved in 10 mL methanol was added. The solution was refluxed for an additional hour and then cooled to room temperature. The polymer was then precipitated in a mixture of acetone and diethyl ether (1:1), filtered off and dried in vacuo (0.46 g, 93%). $^1$H NMR ([D$_4$]methanol): $\delta$ = 1.0 [C$H_2$ (polymer backbone), HPMA-H1], 2.0 (HPMA-H4), 3.6 (HPMA-H3), 3.9 (pyC$H_2$), 4.0 (HPMA-H2), 7.1–7.9 (aromatic *H*), 8.5 ppm (py*H*6). IR (KBr): $\tilde{\nu}$ = 2980, 2800, 2033 ($\nu_{CO}$), 1933 ($\nu_{CO}$), 1612, 1598, 749 $cm^{-1}$.

**X-ray Crystallographic Study:** Crystallographic data were collected with a Stoe IPDS diffractometer at 183(2) K using a graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Suitable crystals were covered with Paratone N oil, mounted on a glass fibre and immediately transferred to the diffractometer. 8000 Reflections distributed over the whole limiting sphere were selected by the program SELECT and used for unit cell parameter refinement with the program CELL.[13] Data were collected for Lorentz and polarisation effects as well as for absorption (numerical). Structures were solved by direct methods using SIR97[14] and were refined by full-matrix least-squares methods on $F^2$ with SHELXL-97.[15]

CCDC-617234 and -617235 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The Complexes $[OsCl_2(azole)_2(dmso)_2]$ and $[OsCl_2(azole)(dmso)_3]$: Synthesis, Structure, Spectroscopic Properties and Catalytic Hydration of Chloronitriles

**Iryna N. Stepanenko,[a] Berta Cebrián-Losantos,[a] Vladimir B. Arion,*[a] Artem A. Krokhin,[a] Alexey A. Nazarov,[a] and Bernhard K. Keppler*[a]**

**Keywords:** Osmium / N ligands / Homogeneous catalysis / Hydration

Two families of mixed-ligand osmium(II) complexes, namely *trans*,*cis*,*cis*-$[Os^{II}Cl_2(azole)_2(dmso)_2]$ [azole = indazole (**1**), pyrazole (**2**), benzimidazole (**3**) and imidazole (**4**)] and *cis*,*fac*-$[Os^{II}Cl_2(azole)(dmso)_3]$ [azole = indazole (**5**), pyrazole (**6**), benzimidazole (**7**) and imidazole (**8**)] have been prepared by taking advantage of the destabilising *trans* effect of the *S*-bonded dmso ligands. These complexes have been characterised by microanalysis, IR, UV/Vis, $^1H$ and $^{13}C$ NMR spectroscopy, electrospray mass spectrometry, cyclic voltammetry and X-ray crystallography. They have been found to catalyse the hydration of trichloroacetonitrile to trichloroacetamide and dichloroacetonitrile to dichloroacetamide with high selectivity. The catalyst efficiency depends strongly on the nature of the complex and the azole ligand present. The highest turnover (TON of 412 for trichloroacetamide and 578 for dichloroacetamide) and product yield (82.7 % for trichloroacetamide and 75.3 % for dichloroacetamide) have been achieved with complex **7**.

## Introduction

The coordination chemistry of dimethyl sulfoxide has been the subject of intensive studies in the past[1–3] and continues to attract the attention of researchers today.[4,5] Of the platinum group metals, the most extensively studied appear to be ruthenium-dmso complexes, some of which are endowed with potent antitumour properties[6,7] or have found application in catalytic processes.[8–10] In addition, $Ru^{II}$-dmso complexes have been successfully employed as precursors for the synthesis of a large variety of compounds, and, in particular, of $[Ru^{II}Cl_2(azole)_2(dmso)_2]$ geometric isomers,[11–16] with $[Ru^{II}Cl_2(4\text{-}NO_2Him)_2(dmso)_2]$ possessing radiosensitising properties. Quite recently, we discovered that *trans*,*trans*,*trans*-$[RuCl_2(Hind)_2(dmso)_2]$ (s in italics means coordination via sulfur) and *trans*,*cis*,*cis*-$[RuCl_2(Hind)_2(dmso)_2]$ species are able to mediate the insertion of the C≡N group of acetonitrile in the N1–H bond of the N2-coordinated indazole, these being the first examples of the metal-assisted iminoacylation of indazole.[17]

Comparison of the chemistry of ruthenium(II) dmso complexes with that of osmium(II) dmso species has permitted us to unravel expected similarities between these two types of complexes, but also remarkable, although less pronounced, differences. In particular, both ruthenium(II) and osmium(II) have been shown to form *cis*,*fac*-$[MCl_2(dmso)(dmso)_3]$ and *trans*-$[MCl_2(dmso)_4]$ isomers, the first of which contains three facially S-coordinated dmso ligands and one dmso molecule O-ligated to the metal ion, with the second containing four S-coordinated dmso ligands. However, the third (linkage) isomer *cis*-$[MCl_2(dmso)_4]$, with all dmso ligands coordinated via sulfur, has been isolated only for osmium(II).[18] In addition, it should be noted that despite the similarity between ruthenium(II) dmso and osmium(II) dmso complexes, the latter have, in general, rarely been used as precursors in inorganic synthesis. Examples reported in the literature have been confined to reactions of *trans*-$[OsCl_2(dmso)_4]$, *trans*-$[OsBr_2(dmso)_4]$ or *cis*,*fac*-$[OsCl_2(dmso)(dmso)_3]$ with chelating ligands containing Te, Sb or P as donor atoms.[19–21] This observed difference in the number of documented reactions can probably, in part, be explained by stronger Os–L bonds and higher ligand substitution activation energies in comparison with the case of ruthenium analogues.[22] In addition, it must be stressed that the position of the two metals in the periodic table is important, but not sufficient for the successful synthesis of the desired osmium complexes. This cannot be performed in a routine way simply by following the protocols for ruthenium species, and very often particular skills and experience are required. With this in mind, we set out to use the $Os^{II}$ dmso isomers available as starting compounds and to study their reactivity toward azole heterocycles, especially indazole (Hind), pyrazole (Hpz), benzimidazole (Hbzim) and imidazole (Him; see Scheme 1).

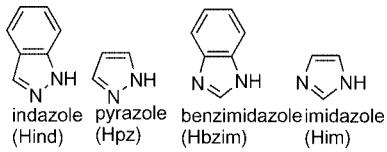


Scheme 1.

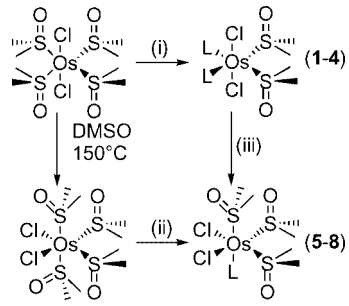
We anticipated (i) the isolation of "pure" isomers of composition [$OsCl_2$(azole)$_2$(dm*so*)$_2$], due to the distinct kinetic inertness of $Os^{II}$ complexes over $Ru^{II}$ species, without any competing isomerisation reactions interfering, (ii) the isolation of other species, the formation of which under similar reaction conditions does not occur in the case of ruthenium analogues, and (iii) the elucidation of previously unknown facets of the reactivity profile of the compounds prepared. In particular, in order to establish the scope of the recently discovered metal-assisted iminoacylation of indazole,[17] we checked the reactivity of the isolated *trans*,*cis*,*cis*-[$Os^{II}Cl_2$(Hind)$_2$(dm*so*)$_2$] isomer towards $CH_3CN$ and $CCl_3CN$. We show that no insertion of the C≡N group into the N1–H bond of the N2-coordinated indazole takes place. Instead, with trichloroacetonitrile we observed hydration of this solvent and set out to examine this reaction in more detail.

Herein we report the synthesis of two different families of compounds, namely *trans*,*cis*,*cis*-[$Os^{II}Cl_2$(azole)$_2$(dm*so*)$_2$] [azole = Hind (**1**), Hpz (**2**), Hbzim (**3**), Him (**4**)] and *cis*,*fac*-[$OsCl_2$(azole)(dm*so*)$_3$] [azole = Hind (**5**), Hpz (**6**), Hbzim (**7**) and Him (**8**)] and their structural and spectroscopic characterisation both in the solid state and in solution. In addition, the results of the study of the hydration reaction of chloronitriles catalysed by the prepared complexes are reported.

## Results and Discussion

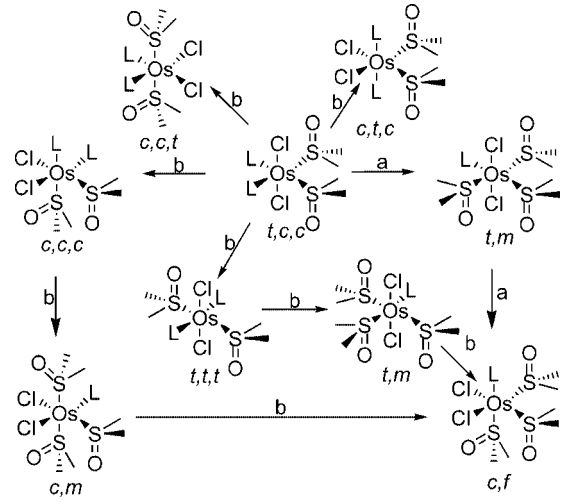
### Synthesis

While treatment of *trans*-[$OsCl_2$(dm*so*)$_4$] with two equivalents of azole ligand in boiling absolute ethanol afforded the isomers *trans*,*cis*,*cis*-[$OsCl_2$(azole)$_2$(dm*so*)$_2$] (**1**–**4**) in 80–88% yield (Scheme 2), the reaction under similar conditions starting from *cis*-[$OsCl_2$(dmso)$_4$] resulted in the formation of complexes *cis*,*fac*-[$OsCl_2$(azole)(dm*so*)$_3$] (**5**–**8**) in 46–85% yield. We also discovered that heating complexes **1**–**4** in dimethyl sulfoxide at 125 °C led to their conversion into **5**–**8**, respectively, in 70–75% yield. It should be noted that the synthesis of ruthenium analogues of **5**–**8** is possible under mild conditions by selective replacement of the *O*-bonded dmso in *cis*,*fac*-[$RuCl_2$(dm*so*)(dm*so*)$_3$] by treatment with a stoichiometric amount of the corresponding azole ligand.[12,15a,16b] If, however, the azole ligand is added in excess and the reaction is carried out at elevated temperatures, isomers of the composition [$RuCl_2$(azole)$_2$(dm*so*)$_2$] are produced.[13,14,15a]



Scheme 2. Synthesis of complexes *trans*,*cis*,*cis*-[$OsCl_2L_2$(dm*so*)$_2$] [L = Hind (**1**), Hpz (**2**), Hbzim (**3**), Him (**4**)] and *cis*,*fac*-[$OsCl_2L$(dm*so*)$_3$] [L = Hind (**5**), Hpz (**6**), Hbzim (**7**) and Him (**8**)]. Reaction conditions: (i) 2 equiv. L, EtOH, 80–87 °C, 1–3 h; (ii) 2 equiv. L, EtOH, 80–87 °C, 40 min–2 h; (iii) dmso, 125 °C, 45 min–2 h. The complex *trans*-[$OsCl_2$(dm*so*)$_4$] at 150 °C undergoes isomerisation into *cis*-[$OsCl_2$(dmso)$_4$] in dmso.[21]

The formation of **1**–**4** from *trans*-[$OsCl_2$(dm*so*)$_4$] and **5**–**8** from *cis*-[$OsCl_2$(dmso)$_4$] can be explained by a remarkable destabilising *trans* effect of the *S*-bonded dmso molecules. The *trans* and *cis* isomers have two and one of these destabilising vectors, respectively, therefore substitution at these sites predetermined by structural differences between the isomers is favoured. Two pathways for the conversion of **1**–**4** into **5**–**8** can be proposed (Scheme 3): (a) the azole ligand is substituted by a molecule of dmso to give *trans*,*mer*-[$OsCl_2$(azole)(dm*so*)$_3$], which then isomerises to *cis*,*fac*-[$OsCl_2$(azole)(dm*so*)$_3$]; (b) another four isomers can theoretically exist along with *trans*,*cis*,*cis*-[$OsCl_2$(azole)$_2$(dm*so*)$_2$]. Taking into account that the *cis*,*cis*,*trans* and *cis*,*trans*,*cis* isomers have not been reported for ruthenium,[17] we postulate that the formation or emergence of the other two isomers (*trans*,*trans*,*trans* and *cis*,*cis*,*cis*) is more likely. Substitution of one of the two azole ligands by dmso, followed by isomerisation, results in *cis*,*fac*-[$OsCl_2$(azole)(dm*so*)$_3$]. The intermediate species could not be identified by the analyti-



Scheme 3. Proposed transformation pathways (a and b) of **1**–**4** into **5**–**8**. Abbreviations used: *c* – *cis*, *t* – *trans*, *m* – *mer*, *f* – *fac*.

cal techniques available and the mechanism of this transformation remains uncertain. Nevertheless, the first pathway is shorter and simpler, which makes it more plausible.

### $^1$H and $^{13}$C NMR Spectra

In the $^1$H NMR spectra of **1/5** and **3/7** one set of signals of equal intensity for the Hind and Hbzim ligands [at $\delta$ = 12.74, 8.68, 7.65, 7.47, 7.40 and 7.16 ppm (**1**); $\delta$ = 14.43, 9.20, 7.73, 7.51, 7.43 and 7.19 ppm (**5**); $\delta$ = 12.87, 8.41, 7.87, 7.47, 7.13 and 6.91 ppm (**3**); $\delta$ = 13.18, 8.78, 8.21, 7.59, 7.29 and 7.24 ppm (**7**)] is observed. Likewise, one set of $^{13}$C resonances is seen for Hind in **1** and **5** and Hbzim in **3** and **7**. In addition, the singlet at $\delta$ = 3.37 (**1**) and 3.27 ppm (**3**), of sixfold intensity in comparison to the indazole or benzimidazole proton resonances present in the spectra, was assigned to the dmso methyl protons coordinated to osmium(II) via sulfur. Note that the downfield shift of dmso protons when coordinated through oxygen is much less with respect to the metal-free dmso.[18] In *cis*-[OsCl$_2$(dms*o*)(dm*s*o)$_3$], for example, this signal is observed at $\delta$ = 2.76 ppm. In the $^{13}$C NMR spectrum the dmso resonance is present at $\delta$ = 45.4 (**1**) and 45.6 ppm (**3**). Two resonances in the $^1$H NMR spectrum at $\delta$ = 3.64 and 3.35 ppm, with a 2:1 relative intensity in **5**, and three signals of equal intensity at $\delta$ = 3.59, 3.45 and 3.28 ppm in **7**, are indicative of the presence of three dmso ligands coordinated through sulfur. Three resonances for *S*-bonded dmso ligands at $\delta$ = 48.8, 48.1 and 45.8 (**5**) and 48.9, 47.1 and 45.7 ppm (**7**) are seen in the $^{13}$C NMR spectra of **5** and **7**. This is in agreement with the $C_2$ symmetry of **1** and **3** and the $C_1$ symmetry of **5** and **7** in solution. Significant downfield shifts of the resonances of the protons nearest to the Os$^{II}$ centre (NH and C3-H) in **1** and **5** with respect to the position of the same signals for the metal-free indazole ($\delta$ = 10.01 and 8.09 ppm) and in **3** and **7** with respect to the position of the NH, C2-H and C4-H/C7-H signals for the metal-free benzimidazole ($\delta$ = 12.44, 8.21 and 7.61 ppm) are also worthy of note.

The presence of singlet resonances at $\delta$ = 3.34 (**2**), 3.13 (**4**), 3.60, 3.59 and 3.29 (**6**), and 3.51, 3.45 and 3.25 ppm (**8**) in the $^1$H NMR spectra of **2**, **4**, **6** and **8** indicates coordination of the dmso ligands to osmium(II) through sulfur. In the $^{13}$C NMR spectra the resonances of the dmso carbon atoms are found at $\delta$ = 45.6 (**2**), 45.5 (**4**), 48.7, 47.9 and 45.8 (**6**) and 48.5, 47.2 and 46.0 ppm (**8**). Four signals for the pyrazole and imidazole protons and three carbon resonances in **2**, **4**, **6** and **8** (see Experimental Section) are indicative of the $C_2$ symmetry of molecules of **2** and **4** and the $C_1$ symmetry of **6** and **8** in solution. As for **1**, **3**, **5** and **7**, significant downfield shifts of the resonances of the protons nearest to the Os$^{II}$ centre (NH and C3-H in **2** and **6** and NH, C2-H and C4-H in **4** and **8**) with respect to the position of the same signals for the metal-free pyrazole [$\delta$ = 10.26 (NH) and 7.63 ppm (C3-H and C5-H)] and imidazole [$\delta$ = 12.03 (NH), 7.64 (C2-H) and 7.01 ppm (C4-H and C5-H)] are observed.

### Crystal Structures of 1–8

The asymmetric unit of **1** contains two crystallographically distinct [Os$^{II}$Cl$_2$(Hind)$_2$(dm*s*o)$_2$] molecules **1A** (Figure 1) and **1B** (Figure S1). Selected bond lengths and angles are listed in Table 1. Essentially octahedral coordination around the osmium atom is found in both molecules. The two chlorido ligands are mutually *trans*, while the two dmso and the two indazole ligands are correspondingly *cis* coordinated to each other. Thus, the configuration of the two independent complexes can be described as *trans*,*cis*,*cis*-[Os$^{II}$Cl$_2$(Hind)$_2$(dm*s*o)$_2$]. The Os–Cl bond lengths [2.4138(12) and 2.3984(11) Å in **1A** and 2.3989(12) and 2.4127(12) Å in **1B**] are similar to the Ru–Cl bond lengths in two independent molecules of *trans*,*cis*,*cis*-[Ru$^{II}$Cl$_2$(Hind)$_2$-(dm*s*o)$_2$] [2.4105(7), 2.4137(7), 2.4069(7) and 2.4147(7) Å], whereas the Os–S bond lengths [2.2250(11) and 2.2453(11) in **1A** and 2.2460(11) and 2.2245(11) Å in **1B**] are somewhat shorter than the Ru–S bond lengths [2.2439(13), 2.2588(8), 2.2477(7) and 2.2578(14) Å] and the Os–N interatomic distances [2.130(4), 2.137(4) (**1A**) and 2.122(4), 2.139(3) Å (**1B**)] are slightly longer than the Ru–N distances [2.1177(18), 2.1255(14), 2.1159(14) and 2.1244(19) Å]. The orientation of the *cis*-arranged indazole ligands in **1A** can be described by the torsion angles $\Theta_{Cl2–Os1–N1–N2}$ [17.5(3) °] and $\Theta_{Cl2–Os1–N3–N4}$ [–0.1(3)°] and is stabilised by the intramolecular hydrogen bonds N2–H2···Cl2 (N2–H2 0.880, H2···Cl2 2.572, N2···Cl2 3.115 Å; N2–H2–Cl2 120.69°) and

| S1–Os1–S2/S3–Os2–S4 | 91.47(4) | 91.01(4) | 94.51(2) |
| Cl1–Os1–Cl2/Cl3–Os2–Cl4 | 176.23(4) | 174.94(4) | 174.556(17) |

N4–H4A···Cl2 (N4–H4A 0.880, H4A···Cl2 2.530, N4···Cl2 3.086 Å; N4–H4A–Cl2 121.78°). The water molecules are involved in a number of hydrogen-bonding interactions with coordinated dmso and indazole molecules that stabilise the crystal lattice.

The X-ray diffraction study of **2** showed that the complex has a distorted octahedral geometry around the central metal ion (Figure 1). As in **1**, the two chlorido ligands are *trans* to each other, with Os1–Cl1 and Os1–Cl2 bond lengths of 2.4293(8) and 2.4053(8) Å, respectively. Two pyrazole ligands bind in a monodentate fashion with a *cis* arrangement [Os1–N1 2.1202(17) and Os1–N6 2.1365(17) Å] and the remaining positions of the coordination polyhedron are occupied by dmso ligands through the Os–S bond [Os1–S1 2.2498(6) and Os1–S2 2.2386(6) Å]. Intramolecular hydrogen bonding is evident between N2 and Cl1 [N2–H2 0.880, H2···Cl1 2.531, N2···Cl1 3.098 Å; N2–H2–Cl1 122.87°] and between N7 and Cl2 [N7–H7 0.880, H7···Cl2 2.518, N7···Cl2 3.086 Å; N7–H7–Cl2 123.00°]. These determine the orientation of the pyrazole rings, which can be described by the torsion angles $\Theta_{Cl1–Os1–N1–N2}$ [–12.59(15) °] and $\Theta_{Cl2–Os1–N6–N7}$ [3.67(14)°].

The results of X-ray diffraction studies of **3** and **4** are shown in Figure 2. Selected bond lengths and angles are listed in Table 2.

Table 2. Selected bond lengths [Å] and angles [°] in **3** and **4**.

| | **3** | **4** |
|---|---|---|
| Os1–N1 | 2.146(2) | 2.138(4) |
| Os1–N3 | 2.138(3) | 2.120(5) |
| Os1–S1 | 2.2273(7) | 2.2166(12) |
| Os1–S2 | 2.2282(8) | 2.2254(11) |
| Os1–Cl1 | 2.4170(8) | 2.402(2) |
| Os1–Cl2 | 2.4142(8) | 2.428(3) |
| S1–O1 | 1.480(2) | 1.495(4) |
| S2–O2 | 1.481(2) | 1.482(5) |
| N1–Os1–N3 | 83.44(9) | 84.25(17) |
| S1–Os1–S2 | 90.22(3) | 91.42(4) |
| Cl1–Os1–Cl2 | 175.69(3) | 175.24(10) |

The X-ray diffraction study of **5**–**8** revealed that the the $Os^{II}$ ion in all these complexes has a distorted octahedral geometry (see Figures 3 and 4). The coordination sites of osmium(II) are occupied by three sulfur atoms of three dmso molecules, one N atom of the corresponding azole heterocycle and two $Cl^-$ ligands, which are arranged *cis* to each other. Selected bond lengths and angles are given in Table 3. For the axial dmso and azole molecules the Cl2–Os1–S1 and Cl2–Os1–N1 bond angles are 89.53(4)° and 84.83(9)° (**5**), 89.52(3)° and 84.02(9)° (**6**), 91.55(3)° and 85.00(7)° (**7**) and 92.40(3)° and 85.68(6)° (**8**), respectively,

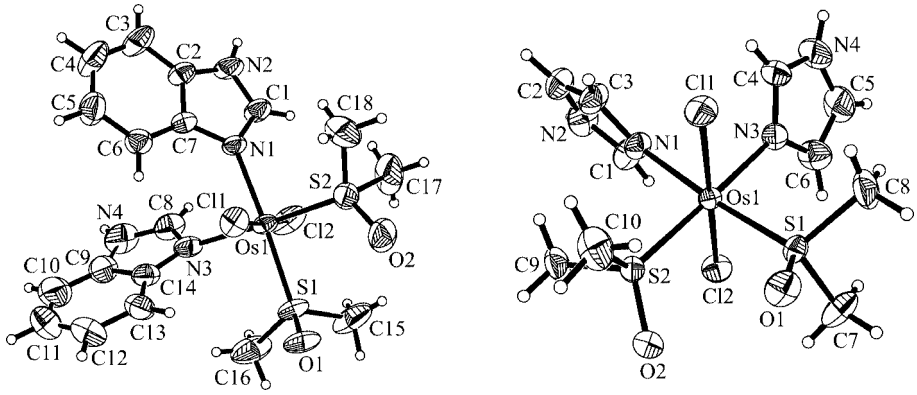

Figure 2. Molecular structures of *trans*,*cis*,*cis*-[$Os^{II}Cl_2$(Hbzim)$_2$(dmso)$_2$] (**3**; left) and *trans*,*cis*,*cis*-[$Os^{II}Cl_2$(Him)$_2$(dmso)$_2$] (**4**; right), showing the atom-numbering schemes. Thermal ellipsoids are drawn at the 50% probability level.

thus indicating notable steric constraints of the axial dmso group, which is pushed towards the chlorido ligands. The S2–Os1–S3 bond angle is 90.95(4)°, 91.40(4)°, 97.16(3)° and 93.55(3)° in **5**–**8**, respectively, while the Cl1–Os1–Cl2 angle of 86.41(3)°, 86.78(4)°, 86.92(3)° and 85.98(3)°, respectively, deviates more significantly from the ideal value of 90°. The $\Theta_{Cl2–Os1–N1–N2}$ torsion angle of –33.9°, which describes the orientation of the indazole ring in **5**, is probably determined by the bifurcated hydrogen bond between N2 and Cl2 [N2–H2 0.880, H2···Cl2 2.596, N2···Cl2 3.056 Å; N2–H2–Cl2 113.53°] and O2($x$ + 1/2, –$y$ + 2, $z$) [N2–H2 0.880, H2···O2 2.247, N2···Cl2 2.999 Å; N2–H2–O2 143.27°]. The significant difference (ca. 35 σ) in the bond lengths between Os1 and the two equatorial dmso ligands in **5** can probably be explained, in part, by the involvement of these dmso ligands in two different strong hydrogen-bonding interactions, the former with a lattice ethanol molecule [O4–H4 0.840, H4···O3($x$ + 1/2, –$y$ + 1, $z$) 1.921, O4···O3 2.753 Å; O4–H4–O3 170.49°] and the latter with N2 of the neighbouring indazole ligand (vide supra). The orientation of the pyrazole ring in **6** is determined by the intramolecular hydrogen bonding between N2 of the pyrazole and O3 of the

dmso ligand [N2–H2 0.880, H2···O3 1.850, N2···O3 2.635 Å; N2–H2–O3 147.58°], which results in a small $\Theta_{S3-Os1-N1-N2}$ torsion angle of 4.1(3)°. The imidazole ligand in **8** is hydrogen bonded to lattice ethanol [N3–H3 0.880, H3···O4(–*x* + 1, –*y*, –*z* + 2) 1.917, N3···O4 2.771 Å; N3–H3–O4 163.16°], which, in turn, acts as a hydrogen-bond donor to one of the dmso ligands [O4–H4 0.840, H4···O2 1.897, O4···O2 2.735 Å; O4–H4–O2 175.04°].

### Electrochemical Study

The electrochemical properties of osmium(II) complexes **1**, **2**, **5** and **6** and **3**, **4**, **7** and **8** were studied by cyclic voltammetry in acetonitrile (0.15 M [*n*$Bu_4$N][$BF_4$]) and dmf (0.15 M [*n*$Bu_4$N][$BF_4$]), respectively. Voltammetric data are given in Table 4, and the cyclic voltammogram of **2** is shown in Figure 5. One oxidative response is found for all complexes. Taking into account the similar responses in the analogous ruthenium complexes,[17] these electron-transfer processes are assigned to $Os^{II}$–$Os^{III}$ oxidation.

Table 4. Cyclic voltammetric data for **1**–**8**[a] and their estimated redox potential values.

| | $E_{1/2}^{ox}$ found[b,c] [V vs. NHE] | $E_{1/2}^{red}$ calcd. [V vs. NHE] |
|---|---|---|
| **1**[d] | 0.94 (60) | 0.79 |
| **2**[d] | 0.89 (60) | 0.67 |
| **3**[e] | 0.80 (70) | 0.61 |
| **4**[e] | 0.71 (60) | 0.51 |
| **5**[d] | 1.66 (65) | 1.10 |
| **6**[d] | 1.57 (60) | 1.04 |
| **7**[e] | 1.51 (70) | 1.01 |
| **8**[e] | 1.40 (60) | 0.96 |

[a] Supporting electrolyte: [*n*$Bu_4$N][$BF_4$]; scan rate: 0.2 V $s^{-1}$. [b] $E_{1/2} = 0.5(E_{pa} + E_{pc})$, where $E_{pa}$ and $E_{pc}$ are the anodic and cathodic peak potential, respectively. [c] $\Delta E_p = E_{pa} - E_{pc}$ [mV]. [d] In acetonitrile. [e] In dmf.

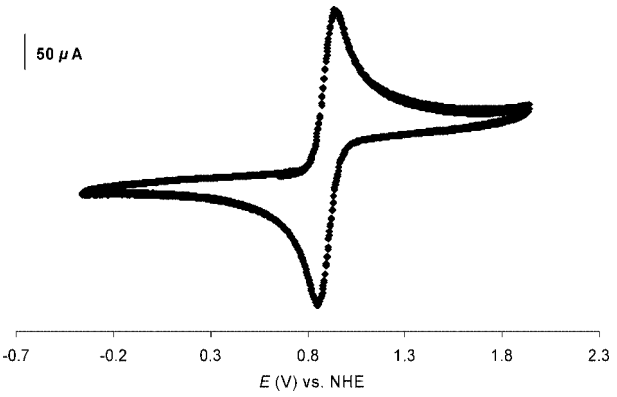

Figure 5. Cyclic voltammogram of *trans*,*cis*,*cis*-[$Os^{II}Cl_2$(Hpz)$_2$(dmso)$_2$] in acetonitrile solution (0.15 M [*n*$Bu_4$N][$BF_4$]) at a scan rate of 0.2 V $s^{-1}$.

The oxidation potentials for **1**–**4** (0.94–0.71 V) are markedly lower than those for **5**–**8** (1.66–1.40 V), which is in agreement with the stronger net electron-acceptor character of the S-coordinated dmso as compared with the azole ligands, which are more effective σ-donors. In addition, the redox potentials of the complexes are in the following order in the two series of compounds: $E_{1/2}^{ox}$(**1**, **5**) > $E_{1/2}^{ox}$(**2**, **6**) > $E_{1/2}^{ox}$(**3**, **7**) > $E_{1/2}^{ox}$(**4**, **8**), which agrees with the relative electron-donor character of the N-ligands [$E_L$(Hind) > $E_L$(Hpz) > $E_L$(Hbzim) > $E_L$(Him)] and their basicity [p$K_a$(Hind) < p$K_a$(Hpz) < p$K_a$(Hbzim) < p$K_a$(Him)[23]). The responses are reversible or quasi-reversible and are characterised by a peak-to-peak separation ($\Delta E_p$) of 60–70 mV and an anodic peak current ($i_{pa}$) that is almost equal to the cathodic peak current ($i_{pc}$) (or slightly different), as expected for reversible electron-transfer processes. The one-electron nature of the observed oxidation was verified by comparing its current height ($i_{pa}$) with that of a standard ferrocene/ferrocenium couple under identical experimental conditions.

The $E_{1/2}^{ox}$ values for complexes **1**–**4** and **5**–**8** are larger than those expected on the basis of the general Lever equation, by using the known values of $S_m$ and $I_m$ (1.01 and –0.40, respectively) for the $Os^{II}/Os^{III}$ redox couple and the $E_L$ values for the various ligands [$E_L$(Cl) = –0.24, $E_L$(dmso) = 0.57,[24] $E_L$(Hind) = 0.26, $E_L$(Hpz) = 0.20, $E_L$(Hbzim) = 0.17, $E_L$(Him) = 0.12[25]) due to the influence of the stereochemistry on the electronic distribution in the complexes.

### The Reactivity of Complexes 1–8 Towards Nitriles

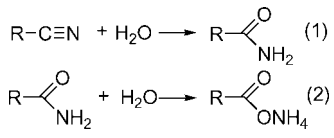
Recently we have reported the first example of a ruthenium(II)-mediated coupling reaction of acetonitrile with 1*H*-indazole.[17] We found that the reaction of *trans*,*cis*,*cis*-[$Ru^{II}Cl_2$(Hind)$_2$(dmso)$_2$] with acetonitrile at room temperature proceeds with displacement of one indazole ligand from the coordination sphere of ruthenium and formation of an amidine ligand isolated as [$Ru^{II}Cl_2${HN=C(Me)-ind}(dmso)$_2$]·$H_2O$. As a logical consequence of this finding we studied the behaviour of the osmium analogue *trans*,*cis*,*cis*-[$Os^{II}Cl_2$(Hind)$_2$(dmso)$_2$] (**1**) and complexes **2**, **5** and **6** in acetonitrile. No amidine formation was observed in an acetonitrile solution of **1** at room temperature after five days. Even after heating the solutions of **1**, **2**, **5** and **6** at 80 °C for 1–2 h the complexes remained intact and could be recovered after evaporation of acetonitrile at reduced pressure, as verified by $^1$H NMR spectroscopy. It should, however, be noted that the solutions become coloured both at room temperature and on heating, although the minor species responsible for this colour change could not be identified. It is known[26] that the direct synthesis of amidines from a nitrile and an amine can be realised when the nitrile is activated by a strong electron-acceptor group such as $CCl_3$. With this in mind, we studied the reactivity of complexes **1** and **2** towards trichloroacetonitrile. Heating the solutions of **1** and **2** in $CCl_3CN$/methanol (1:1, v/v) at 65 °C for 1 h, $CCl_3CN$/hexane (1:6, v/v) at 80 °C for 2 h or prolonged refluxing (up to 16 h) of compounds **1** and **2** in neat $CCl_3CN$ at 85 °C did not result in the desired amidine. Removal of the volatiles after the reaction of **2** with neat $CCl_3CN$ left a solid residue, which was washed with diethyl

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ether. This solid was shown by $^1$H NMR spectroscopy to contain the starting complex **2**. On slow evaporation of the diethyl ether washing solution a few colourless crystals separated, which proved to be suitable for an X-ray diffraction study. The determined cell parameters were in excellent agreement with those documented in the literature for trichloroacetamide.[27] Being intrigued by this disclosure, we decided to find out whether complexes **1**–**8** might play a catalytic role in the hydration of trichloroacetonitrile to give trichloroacetamide.

### Catalytic Hydration of Chloronitriles by 1–8

Trichloroacetamide and its derivatives exhibit fungicidal,[28] germicidal,[29] cardiovascular[30] and antitumour[31] activity. In addition, some of them are used as insect chemosterilants[32] or nitrification inhibitors.[33] They are also important agents and building blocks in preparative organic chemistry,[34] and, in particular, in peptide synthesis.[35] Although the synthetic approaches to trichloroacetamide are well-optimised,[36] they usually require the use of ammonia gas, which means that a route based on the catalytic hydration of trichloroacetonitrile would appear to be more appealing and environmentally friendly (Scheme 4).



Scheme 4.

The selective hydration of nitriles to carboxamides is currently an important laboratory and industrial reaction.[37,38] The conversion of acrylonitrile into acrylamide, which is an important industrial reagent, for instance, is of considerable practical significance.[38,39] Such reactions are often base or acid catalysed. The main disadvantage of these catalysts is that the undesirable further hydrolysis of carboxamides into carboxylic acids (or their salts) occurs [Equation (2) in Scheme 4]. To avoid such a scenario transition metal complexes should be used in neutral conditions. Complexes **1**–**8** exhibit catalytic activity in the hydration of trichloroacetonitrile in solution. In our model reaction, we converted trichloroacetonitrile into trichloroacetamide and ammonium trichloroacetate. In the control experiments, the hydration of trichloroacetonitrile was carried out in the absence of osmium(II) complexes. A small amount of $CCl_3CONH_2$ (0.6%) was detected after the reaction of 1 mL of trichloroacetonitrile with 1.3 mL of water at 75 °C for 24 h. These conditions were found to be optimal for catalytic hydration of acetonitrile to acetamide by other osmium(II) compounds.[40] Depending on the azole ligands present in complexes **1**–**8**, the yields of the main product trichloroacetamide varied from 1.05 to 82.72%, with turnover numbers (TON) ranging from 6.22 to 412 (Table 5). The selectivity of formation of this product is remarkable (Table 5). The yields of ammonium trichloroacetate are commonly rather low and do not exceed 0.3%.

Complexes **5**–**8**, which contain three dmso ligands, are more efficient hydration catalysts than **1**–**4**, which contain two coordinated dmso ligands. Complexes **3** and **4** exhibit higher catalytic activity than **1** and **2**. Analogously, compounds **7** and **8** are significantly more efficient catalysts than **5** and **6**. It is worth noting that **7** shows the highest catalytic activity, with a turnover that is an order of magnitude higher than the second best catalyst and with good selectivity. Experiments with the hydrolysis of $CHCl_2CN$ mediated by complex **7** gave the following yields (%) and TON values for $CHCl_2CONH_2$ and $CHCl_2COONH_4$: 75.3, 578 and 1.7, 12.7, while those with $CH_2ClCN$ as substrate in the presence of the same complex afforded $CH_2ClCONH_2$ in a very low yield (2.2%) with low TON value (22) and the ammonium salt of monochloroacetate in 0.48% yield and very low turnover (TON = 5). The catalytic activity of the starting compound *trans*-[$OsCl_2$(dm*s*o)$_4$] has not been studied since its NMR spectrum showed full decomposition after heating the reaction mixture at 75 °C for 1 h.

Compounds **1**–**8** have no free coordination site to allow either water or trichloroacetonitrile binding to $Os^{II}$. As a possible mechanism for nitrile hydration we propose the substitution of one of the dmso molecules in light of the fact that traces of free dmso are found in the NMR spectra after performing the catalytic reaction. It should also be noted that *cis*,*fac*-[$RuCl_2$(Hind)(dm*s*o)$_3$] has been shown to

Table 5. Comparison of some catalysts for the hydrolysis of trichloroacetonitrile at 75 ± 1 °C.[a]

| Complex | Yield of $CCl_3CONH_2$ [mg (%)] | Turnover number | Yield of $CCl_3COONH_4$ [mg (%)] | Turnover number | Molar ratio $CCl_3CONH_2$/ $CCl_3COONH_4$ |
|---|---|---|---|---|---|
| **1** | 17 (1.1) | 6.2 ± 0.4 | 2.4 (0.13) | 0.8 ± 0.2 | 7.9 |
| **2** | 18.5 (1.2) | 6.4 ± 0.1 | 3.6 (0.20) | 1.1 ± 0.2 | 5.7 |
| **3** | 28 (1.7) | 10.5 ± 0.1 | 3.2 (0.18) | 1.1 ± 0.1 | 9.7 |
| **4** | 109 (6.7) | 36.4 ± 0.4 | 2.2 (0.12) | 0.6 ± 0.1 | 55.0 |
| **5** | 53 (3.3) | 19.4 ± 0.1 | 0.9 (0.05) | 0.3 ± 0.1 | 65.3 |
| **6** | 103.5 (6.4) | 35.0 ± 2.1 | 2.4 (0.13) | 0.7 ± 0.1 | 47.9 |
| **7** | 1090 (82.7) | 412 ± 30 | 5.4 (0.30) | 1.8 ± 0.1 | 224.2 |
| **8** | 147 (9.1) | 49 ± 3 | 1.2 (0.07) | 0.3 ± 0.1 | 136.0 |

[a] When the experiment was performed without catalyst under identical conditions (1 mL of $CCl_3CN$ and 1.3 mL of triply distilled water at 75 °C for 24 h), no more than 10 mg (0.6%) of $CCl_3CONH_2$ was obtained.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

undergo replacement of indazole by acetonitrile at room temperature with formation of *cis*,*fac*-[$RuCl_2$(MeCN)-(dm*so*)$_3$].[17] This suggests another possible catalytic pathway for chloronitrile hydration, but does not explain the different efficiency of catalysts **5**–**8**. The catalytic nitrile hydration mechanism proposed by Chottard et al.[41] for cobalt(III) complexes with sulfenato-S ligands under mildly acidic conditions exploits the nucleophilic properties of coordinated sulfenates. This might be another option for osmium(II) sulfoxide-S complexes as well. Density functional calculations on the subject are currently underway in our laboratory.

## Conclusions

Two novel families of osmium(II) complexes, namely *trans*,*cis*,*cis*-[$OsCl_2$(azole)$_2$(dm*so*)$_2$] and *cis*,*fac*-[$OsCl_2$-(azole)(dm*so*)$_3$], have been prepared and characterised by exploring the destabilising *trans* effect of *S*-bonded dmso ligands to osmium in *trans*-[$Os^{II}Cl_2$(dm*so*)$_4$] and *cis*-[$Os^{II}$-$Cl_2$(dmso)$_4$]. In both series of complexes osmium(II) shows a preference for sulfur binding. In contrast to their ruthenium congeners, the complexes *trans*,*cis*,*cis*-[$OsCl_2$(Hind)$_2$-(dm*so*)$_2$] and *cis*,*fac*-[$OsCl_2$(Hind)(dm*so*)$_3$] do not undergo a coupling reaction with acetonitrile to give amidine chelate formation. Instead, complexes **1**–**8** have been found to catalyse the selective hydration of trichloroacetonitrile to trichloroacetamide, and dichloroacetonitrile to dichloroacetamide. The more acidic complexes of the type *cis*,*fac*-[$OsCl_2$(azole)(dm*so*)$_3$] commonly show higher activity than *trans*,*cis*,*cis*-[$OsCl_2$(azole)$_2$(dm*so*)$_2$]. In addition, the catalyst efficiency is also dependent on the azole ligand bonded to osmium(II). The highest yields (82.7 and 75.3%) and turnovers (TON values 412 and 578), with high selectivity for trichloroacetamide and dichloroacetamide, respectively, have been achieved with *cis*,*fac*-[$OsCl_2$(Hbzim)(dm*so*)$_3$]. These preliminary results are interesting and inspire us to investigate the hydration of acrylonitrile (where the selectivity is often not high), since the vinyl group resembles the $CHCl_2$ group in its electron-withdrawing ability.

## Experimental Section

**General:** The synthesis of all complexes was performed under an atmosphere of dry argon, using standard Schlenk techniques. *trans*-[$OsCl_2$(dm*so*)$_4$] and *cis*-[$OsCl_2$(dmso)$_4$] were prepared according to literature protocols.[18]

***trans*,*cis*,*cis*-[$OsCl_2$(Hind)$_2$(dm*so*)$_2$] (1):** A suspension of indazole (0.10 g, 0.85 mmol) and *trans*-[$OsCl_2$(dm*so*)$_4$] (0.20 g, 0.35 mmol) in dry ethanol (10 mL) was stirred at room temperature for 1 h and then heated at 80 °C for a further hour. The yellow-green solution was concentrated by evaporating part of the solvent off under reduced pressure until a yellow solid separated. The product was filtered off, washed with diethyl ether and dried in vacuo. Yield: 0.18 g (80%). $C_{18}H_{24}Cl_2N_4O_2OsS_2$ (653.64): calcd. C 33.08, H 3.70, N 8.57, S 9.81; found C 33.11, H 3.73, N 8.39, S 9.60. MS ($ESI^+$): *m*/*z* 677 $[M + Na]^+$; ($ESI^-$): *m*/*z* 653 $[M - H]^-$. IR (CsI): $\tilde{\nu}$ = 253 and 273 m ν(Os–N) and σ(Os–N–C); 315 m ν(Os–Cl); 382 m σ(C–S–O); 433 and 451 s ν(Os–S); 1018, 1072 s and 1091 vs ν(*S*–O); 1239 m, 1356 s, 1423, 1510 and 1627 m ν(C–C), ν(C–N) and σ(C–H); 3040, 3070 and 3125 w ν(C–H); 3239 and 3303 $cm^{-1}$ s ν(N–H). UV/Vis (MeOH): $\lambda_{max}$ (ε) = 210 nm (63676 $M^{-1}cm^{-1}$), 240 sh (18469), 277 (32733), 290 sh (29318), 302 sh (22529), 345 (5264). $^1H$ NMR (400.13 MHz, $CDCl_3$): δ = 12.74 (s, 2 H, NH), 8.68 (s, 2 H, CH=N), 7.65 (d, *J* = 8.0 Hz, 2 H, C4-H), 7.47 (d, *J* = 8.0 Hz, 2 H, C7-H), 7.40 (t, *J* = 7.3 Hz, 2 H, C6-H), 7.16 (t, *J* = 7.3 Hz, 2 H, C5-H), 3.37 (s, 12 H, $CH_3$) ppm. $^{13}C\{^1H\}$ NMR (100.63 MHz, $CDCl_3$): δ = 139.9 (C8), 135.5 (C3), 128.9 (C6), 122.6 (C9), 122.4 (C5), 121.3 (C4), 110.4 (C7), 45.4 ($CH_3$) ppm. Single crystals suitable for X-ray structure analysis were crystallised from an ethanol solution saturated with diethyl ether.

***trans*,*cis*,*cis*-[$OsCl_2$(Hpz)$_2$(dm*so*)$_2$] (2):** A suspension of pyrazole (0.05 g, 0.73 mmol) and *trans*-[$OsCl_2$(dm*so*)$_4$] (0.20 g, 0.35 mmol) in dry ethanol (10 mL) was stirred at room temperature for 2 h and then heated at 80 °C for a further 2 h. The yellow-green solution was concentrated under reduced pressure until a yellow solid separated. The product was filtered off, washed with diethyl ether and dried in vacuo. Yield: 0.16 g (85%). $C_{10}H_{20}Cl_2N_4O_2OsS_2$ (553.52): calcd. C 21.70, H 3.64, N 10.12, S 11.58; found C 21.67, H 3.43, N 9.82, S 11.49. CH=N), 7.49 (s, 1 H, C4-H), 7.15 (s, 1 H, C5-H), 3.51 (s, 6 H, $CH_3$), 3.45 (s, 6 H, $CH_3$), 3.25 (s, 6 H, $CH_3$) ppm.$^{13}C\{^1H\}$ NMR (100.62 MHz, $D_2O$): $\delta$ = 140.2 (C2), 130.2 (C4), 117.0 (C5), 48.5 ($CH_3$), 47.2 ($CH_3$), 46.0 ($CH_3$) ppm. Crystals of **8**·$C_2H_5OH$ suitable for X-ray data collection were obtained from a solution of **8** in ethanol.

**Catalytic Hydration of Chloronitriles by a Metal Complex in Solution:** Typically, a solution/suspension of [$Os^{II}Cl_2$(azole)$_2$(dm*so*)$_2$] or [$Os^{II}Cl_2$(azole)(dm*so*)$_3$] (ca. 10 mg) in a mixture of chloronitrile (1 mL) and water (1.3 mL) was stirred at 75 °C for 24 h in a Schlenk flask equipped with a magnetic stirring bar. The metal complex:chloronitrile and chloronitrile:water molar ratios were 1:600 and 1:7, 1:650 and 1:6, 1:760 and 1:6 for trichloroacetonitrile, dichloroacetonitrile and chloroacetonitrile, respectively. Control experiments regarding hydration of the corresponding chloronitrile were carried out under similar conditions but in the absence of the osmium(II) complex. In all cases solvents were removed under reduced pressure and at moderate temperature (≤40 °C) to avoid sublimation of the carboxamide. The amount of product was determined by $^1H$ NMR experiments in [$D_6$]dmso by using 1,3,5-trimethoxybenzene as internal reference. The following lines were integrated: $CCl_3CONH_2$: $\delta$ = 8.35 (d, $J_{N,H}$ = 46.5 Hz) ppm; $CCl_3COONH_4$: $\delta$ = 7.12 (t, $J_{N,H}$ = 51.1 Hz) ppm; $CHCl_2CONH_2$: $\delta$ = 7.80 (d, $J_{N,H}$ = 82.1 Hz), 6.32 (s, H, $CHCl_2$) ppm; $CHCl_2COONH_4$: $\delta$ = 7.12 (t, $J_{N,H}$ = 50.1 Hz) ppm; $CH_2ClCONH_2$: $\delta$ = 7.50 (d, $J_{N,H}$ = 103.3 Hz), 4.02 (s, 2 H, $CH_2Cl$) ppm; $CH_2ClCOONH_4$: $\delta$ = 7.22 (t, $J_{N,H}$ = 51.1 Hz) ppm; $C_6H_3$-($OCH_3$)$_3$: $\delta$ = 6.08 (s, 3 H), 3.70 (s, 9 H) ppm.

**Physical Measurements:** Elemental analyses were carried out with a Carlo–Erba microanalyser at the Microanalytical Laboratory of the University of Vienna. Electrospray ionisation mass spectra were recorded with a Bruker esquire$_{3000}$ ion-trap mass spectrometer equipped with an orthogonal electrospray interface (Bruker Daltonics, Bremen, Germany) in both positive- and negative-ion modes. The Bruker Daltonics esquire 5.2 software bundle consisting of Bruker esquire Control 5.2 and Bruker Data Analysis 3.2 was used for acquiring spectra and data analysis, respectively. The sample solution in methanol was delivered at a flow rate of 3 μL min$^{-1}$ using a syringe pump 74900 from Cole–Parmer Instrument Company (Vernon Hills, IL, USA); $N_2$ was used as both drying and nebulising gas (flow rate: 5 L min$^{-1}$). Expected and experimental isotope distributions were compared. IR spectra were obtained from CsI pellets with a Perkin–Elmer FT-IR 2000 instrument (4000–200 cm$^{-1}$). UV/Vis spectra were recorded with a Perkin–Elmer Lambda 20 UV/Vis spectrophotometer from samples dissolved in methanol. $^1H$ NMR spectra were recorded with a Bruker DPX400 (Ultrashield™ Magnet) spectrometer at 298 K. The residual $^1H$ present in $CDCl_3$ ([$D_6$]dmso, [$D_7$]DMF, $D_2O$) was

used as internal reference. The assignment was confirmed by 2D NMR ($^{13}C,^{1}H$; $^{1}H,^{1}H$ and $^{13}C,^{1}H$ via long-range couplings) and NOE (1D and 2D) spectroscopy. Cyclic voltammograms were measured in a three-electrode cell using a 0.2-mm-diameter platinum disc working electrode, a platinum auxiliary electrode and an $Ag|Ag^{+}$ reference electrode containing 0.1 M $AgNO_3$. Measurements were performed at room temperature using an EG&G PARC 273A potentiostat/galvanostat. Deaeration of solutions was accomplished by passing a stream of argon through the solution for 5 min prior to the measurement and then maintaining a blanket atmosphere of argon over the solution during the measurement. The potentials were measured in 0.15 M $[n\mathrm{Bu_4N}][\mathrm{BF_4}]/\mathrm{CH_3CN}$ (dmf) using $[\mathrm{Fe}(\eta^5\text{-}\mathrm{C_5H_5})_2]$ ($E_{1/2}^{ox}$ = +0.69 V vs. NHE)[42] as internal standard, and are quoted relative to NHE.

**Crystallographic Structure Determination:** X-ray diffraction measurements were performed with a Nonius Kappa CCD and X8AP-EXII CCD diffractometers. Single crystals were positioned at 35, 30, 40, 40, 35, 30, 40 and 35 mm from the detector, and 620, 344, 1001, 1089, 404, 344, 1885 and 538 frames were measured, each for 15, 30, 60, 60, 10, 10, 60 and 30 s over a 1, 2, 0.5, 0.5, 2, 2, 0.5 and 1.5° scan width for **1**–**8**, respectively. The data were processed using the Denzo-SMN or SAINT-Plus software package.[43,44] Crystal data, data collection parameters and structure-refinement details for **1**–**8** are given in Table 6. The structures were solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms were placed in geometrically calculated positions and refined as riding atoms in the subsequent least-squares model refinements. The isotropic thermal parameters were estimated to be 1.2-times the values of the equivalent isotropic thermal parameters of the atoms to which hydrogens are bonded. The following computer programs were used: structure solution: SHELXS-97;[45] refinement: SHELXL-97;[46] molecular diagrams: ORTEP;[47] computer CPU: Pentium® IV; scattering factors were taken from the literature.[48]

CCDC-606815 (for **1**), -606816 (for **2**), -606811 (for **3**), -606814 (for **4**), -606817 (for **5**), -606818 (for **6**), -606813 (for **7**) and -606812 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): ORTEP view of the second independent molecule 1B (Figure S1); cyclic voltammograms of complexes **1** and **3**–**8** (Figures S2–S8).

## Acknowledgments

The authors are indebted to FWF and COST for financial support. We also thank Prof. G. Giester and Mr. A. Roller for X-ray data collection, and Dr. M. Galanski for NMR measurements. Dr. S. Shova and Mr. N. A. Sheddan are acknowledged for stimulating discussions.

# Two Novel Reactions of a Ruthenium-Coordinated Phenazine – Oxidative Aromatic Ring Hydroxylation and Dimerization via a New C–N Bond Formation

**Priyabrata Banerjee,[a] Golam Mostafa,[b] Alfonso Castiñeiras,[c] and Sreebrata Goswami*[a]**

**Keywords:** Metal-mediated reaction / Phenazine / Ruthenium / Redox chemistry

The reaction of $[Ru(CH_3OH)_2(N\wedge N)_2]^{2+}$ [N∧N = 2,2′-bipyridine (bpy) and 1,10-*ortho*-phenanthroline(phen)] with the phenazine ligand, [$HL^1$ = 6-*p*-anisyl-2-(*p*-anisylamino)-3(4*H*)-*p*-anisylimine-9-methoxyphenazine] in the presence of a base ($NEt_3$) afforded two mononuclear ruthenium complexes, $[Ru(L^1)(N\wedge N)_2]X$ (**2**), and $[Ru(LO)(N\wedge N)_2]X_2$ (**3**), [LO = 7-methoxy-5-(4-methoxyphenyl)-2,3-bis(4-methoxyphenylimino)-3,5-dihydro-2*H*-phenazin-1-one] together with a diruthenium complex $[(N\wedge N)_2RuL^2Ru(N\wedge N)_2]X_3$ (**4**), [$L^2$ = 7,8′-dimethoxy-5,10′-bis(4-methoxyphenyl)-2,3′-bis(4-methoxyphenylamino)-3,2′-bis(4′-methoxyphenylimino)-3,5,2′,10′-tetrahydro-[1,5′]biphenazinyl-5′-ylium], (X = $ClO_4^-$ or $CF_3SO_3^-$). The complexes **3** and **4** were also obtained from the pure complex **2** under two different experimental conditions. Oxidative aromatic ring hydroxylation of the complex **2** produced **3** while the diruthenium complex, **4**, was formed by dimerization of **2** via a new C–N bond formation. The products were thoroughly characterized with the help of $^1H$ NMR and ESI-MS spectral measurements. Final authentication of the two complexes of the transformed phenazine ligands viz. **3** and **4** were made by single-crystal X-ray structure determination of the two representative complexes. These compounds are intensely colored and show transitions in the visible region, which are ascribed as metal-to-ligand charge transfer (MLCT). Notably, intensities of the two MLCT of the compound **4** are significantly higher than those of **2** and **3**. Redox properties of the complexes are reported. Electrochemical oxidation of compound **2**, even in the presence of trace moisture, produced compound **3**. Cyclic voltammetry of compound **3** shows a reductive response near –0.35 V. Its one-electron reduced product is blue and shows an intense EPR signal at $g$ = 2.001. The voltammogram of the diruthenium complex **4** consists of two responses near 0.70 and 0.85 V.

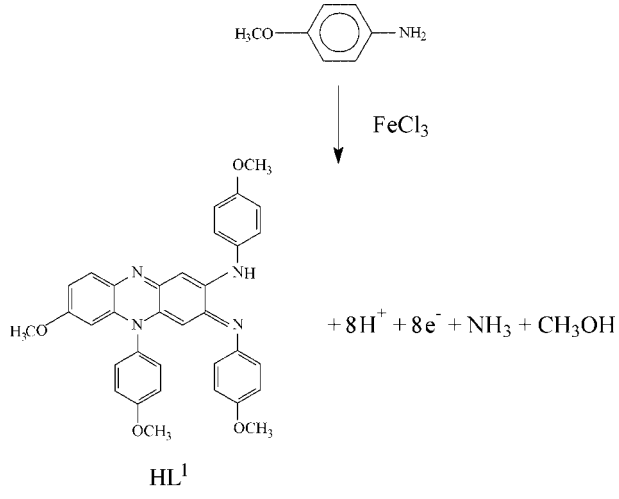
## Introduction

Transition-metal mediated functionalization of C–H bonds is one of the most vigorously pursued[1–4] areas of current synthetic research. In many instances these reactions lead to the synthesis of unusual molecules, which otherwise are difficult or even impossible to synthesize using conventional procedures. In recent years we have been working[5–6] on transition-metal promoted aromatic amine fusion reactions, via C–H functionalization, for the synthesis of new organic ligands whose coordination chemistry is rich with novel features. One such example[7] is the ferric chloride-mediated oxidative polymerization of *p*-anisidine, which produces *N*-substituted 2-amino-3-iminophenazines via a multiple C–N bond fusion reaction (Scheme 1).



$HL^1$

Scheme 1.

Our interest[6] in the coordination chemistry of 1,2-diimine ligands and their redox partners prompted us to explore the ligand chemistry of [$HL^1$]. We have shown[7] that

the deprotonated phenazine ligand coordinates to the $[Ru(pap)_2]^{2+}$ moiety [pap = 2-(phenylazo)pyridine] spontaneously. The redox behavior of the resultant complex $[Ru(L^1)(pap)_2]^+$ (**1**) was of particular interest, since it seemed to follow[7] the EC-type pathway to produce a new ruthenium complex, following the oxidation of complex **1**. In practice, however, chemical oxidation of complex **1** resulted in a mixture of several products from which no pure compound could be isolated. The ESI-MS spectrum of the above crude mixture showed the presence of a moderately intense peak at $m/z$ = 1041 amu. For comparison we note here that the parent complex, **1**, showed a strong ESI-MS signal at $m/z$ = 1026 amu due to the $[Ru(L^1)(pap)_2]^+$ ion. The difference in mass between the two compounds indicates the addition of an oxygen atom to the parent complex **1**. Subsequently, we have found that the similar ruthenium complexes of $[L^1]^-$, $[Ru(L^1)(N\wedge N)_2]^+$ [N∧N = 2,2′-bipyridine (bpy) or 1,10-*ortho*-phenanthroline (phen)] also undergo similar chemical transformations upon oxidation. In these cases the transformed compounds are stable and suitable for following the above-mentioned metal-mediated redox reactions.

In this paper we report the results of the reaction of the 2-amino-3-iminophenazine, $HL^1$ and $[Ru(CH_3OH)_2(N\wedge N)_2]^{2+}$. The chemical reaction resulted in the formation of the three products **2**–**4**, of which the complexes **3** and **4** are formed due to an unprecedented type of chemical transformation of the coordinated ligand $[L^1]^-$ in the complex **2**. While oxidative hydroxylation of the ligand produced a ruthenium complex **3** of the oxidized phenazine ligand (LO), dimerization of it, on the other hand, produced a diruthenium complex **4** of a diphenazine bridge $[L^2]^-$. The latter reaction is associated with a new C–N bond fusion process. In the present context it is relevant to add that the coordination chemistry of the phenazine ligands, in general, has been developed in recent years; however, this work is confined[8] mostly to the complexes of pyridyl-containing phenazines. Some of these bind DNA and RNA and are an important class of molecular probes.[9] In contrast, the coordination chemistry of the related 2-amino-3-iminophenazine or its redox partners is not available in the literature. Thus, the reference reactions are noteworthy in the context of understanding the metal-mediated redox processes that are operative in amino-imino-phenazine[10] and related systems.

## Results and Discussion

The synthetic reaction involved refluxing a methanolic solution of $[Ru(N\wedge N)_2(CH_3OH)_2]^{2+}$, generated in situ,[11] with an equimolar quantity of $HL^1$ in the presence of a base ($NEt_3$) for 6 h. The initial red brown color of the solution mixture gradually turned bluish-violet and finally it became blue. The complexes were precipitated as their perchlorate or triflate salts. The crude mass, so formed, was a mixture of three major products: blue **2**, violet **3** and blue **4**, which were successfully separated on a preparative alumina TLC plate. The first blue complex **2** was unstable and with time slowly converted into the violet product **3** in air even at room temperature. The **2** → **3** conversion was much faster in boiling aqueous methanol.

Prolonged boiling of compound **2** in a dry and inert atmosphere, on the other hand, produced a stable blue compound **4** as the major product (vide infra). Schematic presentation of the reaction along with compound identification numbers are summarized in Scheme 2.

The sum total of the yields of the above three products exceeded 85%. There were a few minor fractions, which could not be purified and their identities remain uncertain.

The complexes gave satisfactory elemental analyses (see Exp. Sect.). These showed characteristic infrared stretches of the phenazine and coordinated ancillary ligands viz. bpy and phen. The most notable feature in the infrared spectra of **3a** and **3b** is the appearance of a sharp band at ca. 1680 $cm^{-1}$, which confirms the presence of a carbonyl function[12] (vide infra). These complexes are diamagnetic and displayed $^1H$ NMR resonances in the normal range. The spectral patterns in the aromatic region ($\delta$ = 5–9) are complex in nature (see Figure S1, supporting information) owing to the presence of a large number of unique protons. The methyl resonances were, however, diagnostic and useful for assessing their preliminary identities (Figure 1). For example, while the compounds **2** and **3** showed four –OMe signals each in the range $\delta$, 3.38–3.75, compound **4** displayed eight –OMe resonances in the range $\delta$ = 3.25–3.80. For comparison, the uncoordinated ligand, $[L^1]^-$, displayed four[7] such resonances at $\delta$ = 3.55–3.85. Thus, the $^1H$ NMR spectrum of complex **4** indicated the presence of two phenazine moieties. Electrospray mass spectra of the complexes were found to be informative for the identification of the complexes. The charge state distributions of these ranging from (+1) to (+3) are clearly observed, which exactly corroborated with the ionization of the respective complexes in the acetonitrile solution. For example an abundant peak, called a base peak, was observed for $[\mathbf{2a}\text{-}ClO_4^-]^+$ at $m/z$ = 971 amu. The complex **3a** showed a weak signal at $m/z$ = 1085 amu, and was accompanied by a strong signal at $m/z$ = 493 amu. These were ascribed to the $[\mathbf{3a} - ClO_4^-]^+$ and $[\mathbf{3a} - 2ClO_4^-]^{2+}$ ions, respectively. The compound **4a** exhibited peaks at 1020 and 647 amu, respectively. The peak at 647 amu was most intense and ascribed to the $[\mathbf{4a} - 3ClO_4^-]^{3+}$ ion. Similarly, the substituted complexes viz. **2b**, **3b** and **4b** displayed peaks at expected $m/z$ values (Exp. Sect.). From the ESI-MS spectral nature it is inferred that complex **4** is a dimetallic compound with a relatively high molecular weight. Notably, the experimental ESI-MS spectral features of the above compounds exactly corresponded to simulated patterns for the given formulations. Three representative ESI-MS spectra of **2**–**4**, are submitted as supplementary materials (Figure S2). Electrolytic natures of dilute acetonitrile (1 mM) solutions of the complexes were of different type: **2**, 1:1, **3**, 1:2 and **4**, 1:3.

Preliminary characterization of the above compounds was made from their physicochemical data. However, X-ray crystal analyses of the two complexes (**3** and **4**) of the

transformed ligands were indeed necessary for authentication of their formulations and structures.

The solutions of the complexes **2a** and **2b** were found to undergo chemical transformations to **3a** and **3b**, respectively, hence X-ray quality crystals of the parent complex, $[Ru(N\wedge N)_2(L^1)](X)$ (**2**) could not be grown. However, a complete characterization was obtained (vide supra) from the physicochemical data. The two representative complexes of the transformed ligands viz. **3b** and **4a** formed single crystals suitable for X-ray structure determination.

### $[Ru(phen)_2(LO)](CF_3SO_3)_2{\cdot}2H_2O$ (3b)

A view of the cationic part of the molecule $[Ru(phen)_2(LO)](CF_3SO_3)_2{\cdot}2H_2O$ is shown in Figure 2 and selected bond lengths and angles are collected in Table 1. In this complex, two bidentate 1,10-*ortho*-phenanthroline (phen) ligands and a neutral phenazine ligand [LO], formed via successive hydroxylation and oxidation of the coordinated ligand $[L^1]^-$, surround a ruthenium(II) center. The complex as a whole is dicationic and the crystallographic asymmetric unit also contains two triflate anions and two water molecules. Hydroxylation of the phenazine ligand occurred at the α-carbon (C13) to a *N*-aryl imine function [C(12)–N(11)]. The C(13)–O(130) bond length, 1.209(4) Å, indicates a localized double bond. The two C–N (imine) bond lengths, 1.300(4) Å [C(12)–N(11)] and 1.290(6) Å [C(25)–N(26)], respectively confirm[6a,13] their double bond character. The six Ru–N lengths are similar, and lie in the range 1.997–2.083 Å. The average of chelate bite angles of the phen ligand is 79.1(2)°, while the corresponding N(11)–Ru(1)–N(26) angle of the phenazine ligand has a value of 76.71(12)°.

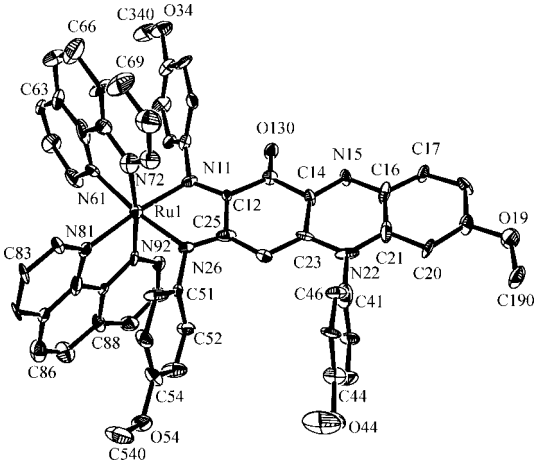

Figure 2. ORTEP and atom numbering scheme for **3b**. Hydrogen atoms are omitted for clarity.

### $[(bpy)_2RuL^2Ru(bpy)_2](ClO_4)_3$ (4a)

Figure 3 shows the ORTEP and atom numbering scheme for the cationic complex $[\mathbf{4a}]^{3+}$ and its bond parameters are collected in Table 1. Herein, two $[Ru^{II}(bpy)_2]$ moieties are bridged across a dimeric phenazine ligand $[L^2]^-$, formed via an unusual type of C–N fusion between the two $[Ru(bpy)_2L^1]^+$ units. In this reaction a new C–N bond is formed between the free pyrazine nitrogen N(9) of one unit and the α-carbon C(36) of the second unit. The bridging ligand, $[L^2]^-$, is a zwitterion with two anionic chelating sites and a cationic pyrazine nitrogen. The bridging ligand is thus mono-negative and coordinates to two ruthenium(II) centers in a bis chelating tetradentate fashion. The resulting diruthenium complex as a whole is tri-cationic and the asymmetric unit contains three perchlorate counterions. The C–N lengths viz. C(35)–N(5) 1.387(4) Å, C(40)–N(6) 1.314(4) Å, C(71)–N(11) 1.343(4) Å and C(72)–N(12) 1.348(4) Å are all longer than the corresponding distances in coordinated LO in the compound **3b** (Table 1). Notably, the C(35)–N(5) length is appreciably longer than C(40)–N(6) suggesting that the anionic charge in this part of the bridging ligand is localized on N(5). In contrast the two C–N lengths of the other part viz. C(71)–N(11) and C(72)–N(12) are nearly identical indicating effective charge delocalization over the N(11)–C(71)–C(72)–N(12) skeleton. The average of the above C–N lengths of $L^2$ lies in between a single and a double C–N bond length. The five-membered chelate rings of the bridging ligand have the expected bite angles, N(5)–Ru(1)–N(6) 76.12(9)° and N(11)–Ru(2)–N(12) 76.94(11)°.

The two reference chemical transformations, viz. **2** → **3** and **2** → **4**, occur due to induced C–H activation[6,14] at the ortho carbon of the coordinated phenazine. The plausible initial step for the formation of **3** is the oxidation reaction, **2** → $\mathbf{2}^+$. The oxidized product $\mathbf{2}^+$ is then converted to **3** in the presence of water and aerial oxygen. Water adds to the polarized phenazine ring and the hydroxo-intermediate, so formed, is oxidized to **3** in air. Exposure of an aqueous methanolic solution of **2** to air thus produces the com-

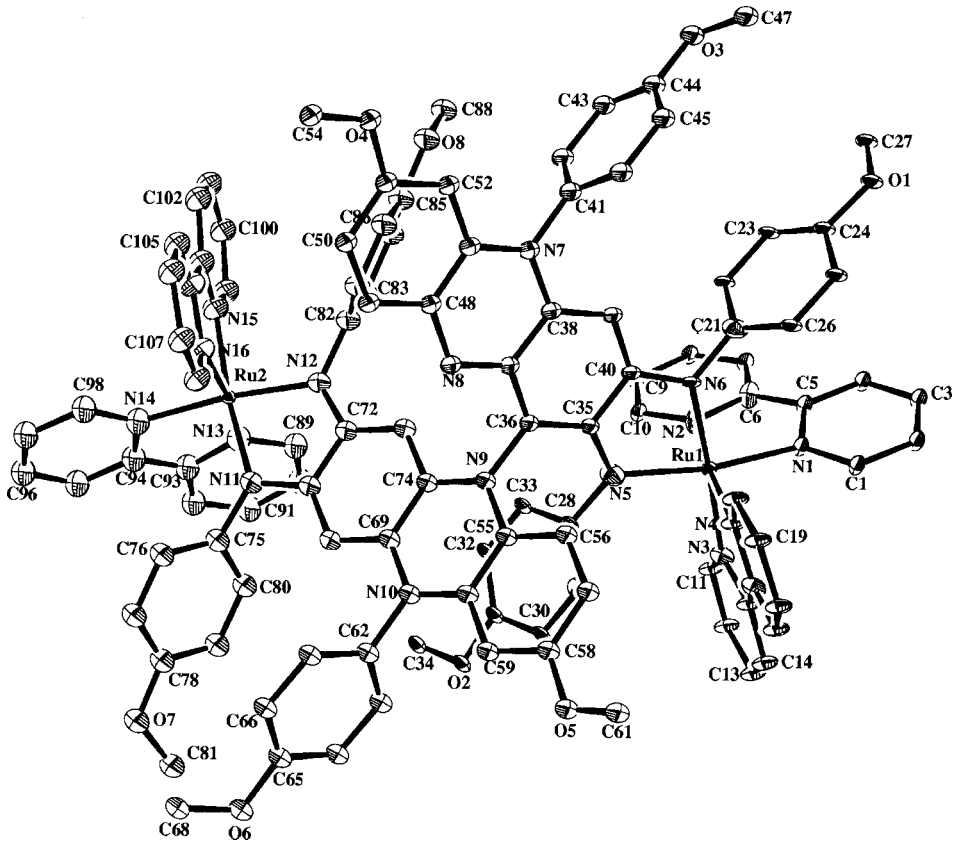

Figure 3. ORTEP and atom numbering scheme for **4a**. Hydrogen atoms are omitted for clarity.

pound **3** in almost quantitative yield. The plausible steps of this transformation[15] are shown in Scheme 3. Since the oxidation potential of complex **2** is low (vide infra), the aerial oxidation, $\mathbf{2} \rightarrow \mathbf{2}^{+}$ is reasonable and is believed to be the key step for the formation of **3** from **2**. Furthermore, the fact that electrochemical oxidation of the complex **2** (vide infra) produces the compound **3**, also supports our proposition. The conversion of **2** to **4** occurs only in dry and boiling methanol. Nucleophilic attack of the phenazine nitrogen of one molecule of **2** at the activated *ortho* C–H of another molecule followed by ($-H^{+} - 2e^{-}$) transfer produces the compound **4**.

Hence, we conclude that $\mathbf{2} \rightarrow \mathbf{3}$ conversion is facilitated by the initial oxidation of the ruthenium(II) center of **2**. However, if the initial oxidation of **2** is arrested, dimerization of the phenazine occurs preferably so as to initiate the formation of the dimetallic complex **4**. The results are summarized in Scheme 4.

The electronic spectroscopic data of all the complexes are collected in Table 2 and their representative spectra are displayed in Figure 4. The visible range spectra of these complexes consisted of strong absorptions. For example, the mononuclear complexes **2a** and **3a** each showed an allowed transition at 585 nm ($\varepsilon$ = 16385 $M^{-1}cm^{-1}$) and 565 nm ($\varepsilon$ = 23490 $M^{-1}cm^{-1}$), respectively. These are ascribed to charge transfer, $Ru^{II}(d\pi) \rightarrow \pi^{*}$(phenazine) (MLCT). The bimetallic compound **4a** displayed two intense transitions at 690 nm ($\varepsilon$ = 36450 $M^{-1}cm^{-1}$) and 645 nm ($\varepsilon$ = 32300 $M^{-1}cm^{-1}$), respectively. Notably, the two-phenazine moieties in the bridging ligand $[L^{2}]^{-}$ are not identical and hence the two major transitions in the visible region are believed to be due to the presence of two acceptor chromophores in the bridging ligand. Interestingly, the intensities of MLCT transitions in **4** are significantly higher than those of the mononuclear compounds **2** and **3**. This spectral behavior of the polynuclear complexes with repeating acceptor chromophores has been reported[6b] in the literature. The complexes also showed multiple UV-range transitions, which are assigned to inter- or intra-ligand transitions.

The redox behavior of the complexes **2**–**4** was studied in dichloromethane {maintaining $10^{-3}$ M concentration of the complex and $10^{-1}$ M concentration of the supporting electrolyte, $[n\mathrm{Bu_4N}](\mathrm{ClO_4})$} in the potential range 2.0 to –1.5 V by using platinum or glassy carbon working electrodes. The reported potentials (Table 2, Figure 5) are referenced to the saturated calomel electrode (SCE). The value for the ferrocene/ferrocenium couple under our experimental conditions was 0.39 V.

The mononuclear complex $[Ru(bpy)_2L^{1}]ClO_4$ (**2a**) showed an electrochemically reversible $Ru^{III}/Ru^{II}$ response at 0.15 V. Associated with it is an irreversible response, which appeared at a potential of 1.05 V. The redox behavior of the closely related system, $[Ru(phen)_2L^{1}]ClO_4$ **2b**, is similar to that of **2a**. Constant potential coulometry at 0.40 V of both **2a** and **2b** resulted in rapid transformations to **3a** and **3b**, respectively. The voltammetric behavior of the com-

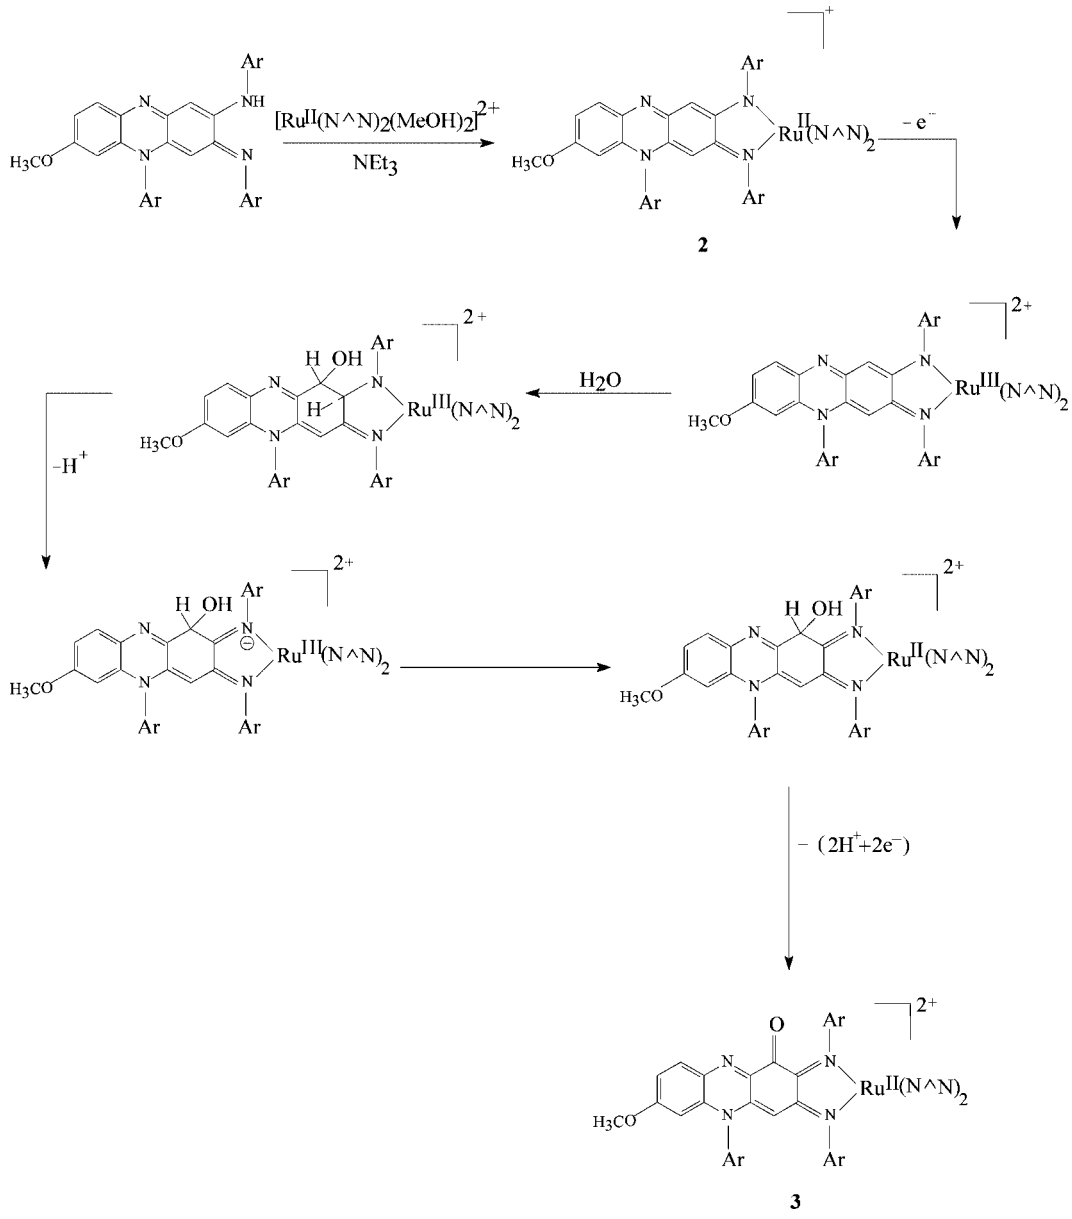
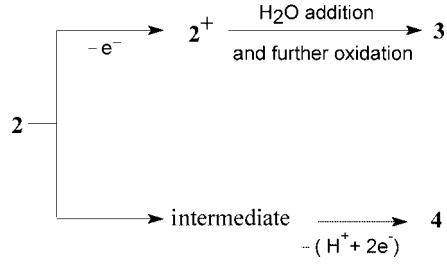


Scheme 3.



Scheme 4.

plexes, **3a** and **3b** was similar. These showed a reversible reductive response near –0.35 V. Exhaustive electrolysis of **3a** at –0.60 V produced a blue solution, which reverted to the parent bivalent complex, **3a** under our experimental conditions. However, we managed to record an EPR spectrum of the reduced complex, by performing the controlled potential bulk electrolysis of **3a** at 260 K and quickly freezing the electrolyzed solution at 77 K. The EPR spectrum showed (Figure S3) an intense signal at $g$ = 2.001 without any $g$-anisotropy, indicating large free radical[16] (ligand) contributions to the SOMO. We thus conclude that upon reduction of **3a**, an electron is added to the ketonic function of the phenazine ligand to result in a free radical-containing phenazine ligand $[LO^{\cdot}]^{-}$ that resembles[10] pyocyanine. The main feature of the cyclic voltammogram of the dimetallic complexes **4a** and **4b** consisted of two closely spaced responses at 0.70, 0.85 V and 0.75, 0.90 V, respectively. These are assigned to two successive electron transfers at the two

ruthenium centers. The magnitude of $\Delta E$ signifies moderate electronic interactions between the ruthenium centers.

Our present work has demonstrated that the phenazine ligand [6-*p*-anisyl-2-(*p*-anisylamino)-3(4*H*)-*p*-anisylimine-9-methoxyphenazine], $HL^1$, upon coordination to ruthenium is susceptible to fascinating metal-mediated chemical transformations leading to isolation of the three new ruthenium complexes **2**–**4** of three different ligands (viz. $[L^1]^-$, LO and $[L^2]^-$) from the reaction of $[Ru(CH_3OH)_2(N\wedge N)_2]^{2+}$ and $HL^1$. The latter two ligands are formed in situ due to oxidative hydroxylation and dimerization reactions of the coordinated ligand, $[L^1]^-$. To authenticate these transformations, X-ray structure analyses of a mononuclear ruthenium complex of LO as well as a diruthenium complex of the bridging ligand $[L^2]^-$ were analyzed. Presently, we are pursuing our work to understand the effects of ancillary ligands and the metal ions on the chemical transformations of the reference phenazine ligands.

## Experimental Section

**Materials:** The precursor compounds *cis*-[Ru(bpy)$_2$Cl$_2$]·2H$_2$O and *cis*-[Ru(phen)$_2$Cl$_2$]·2H$_2$O were prepared according to the reported procedures.[17] The ligand $HL^1$ was synthesized as before.[7] Silica gel and aluminum oxide for TLC were obtained from Merck, India and Sisco Research Laboratories Pvt. Ltd., Bombay. RuCl$_3$·$n$H$_2$O was purchased from Arora Mathey Ltd., and 2,2′-bipyridine and 1,10-phenanthroline monohydrate were obtained from Qualigens and Merck, India, respectively. Tetrabutylammonium perchlorate (TBAP) was used as the supporting electrolyte, for spectroscopic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and electrochemical studies HPLC-grade solvents were used. Other chemicals and reagents were of reagent-grade and used as received.

**Physical Measurements**

Microanalytical data (C, H and N) were collected with a Perkin–Elmer 240C elemental analyzer. A Perkin–Elmer 783 spectrophotometer was used for the measurement of IR spectral data. $^1$H NMR spectroscopic data was recorded with a Bruker Avance 300 spectrometer using $SiMe_4$ as an internal standard. Electrochemical measurements were performed at 298 K under a dry nitrogen atmosphere on a PC-controlled PAR Model 273A electrochemistry system with a gas tight single-compartment cell. Voltammetric experiments were carried out in dichloromethane maintaining the sample concentration at ca. $10^{-3}$ M. The solution was degassed with the flow of dry nitrogen and the working electrode surface was polished before each measurement. A platinum disk working electrode, platinum wire auxiliary electrode and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. All redox potentials in this work are reported against the saturated calomel electrode. The value for the ferrocenium/ferrocene couple under our experimental conditions was 0.39 V. EPR spectral measurements were carried out with a Varian Model 109C E-line X-band spectrometer as described before,[18] fitted with a quartz Dewar for measurements at 77 K, and the spectroscopic data were calibrated against the spectrum of DPPH. Electrospray mass spectra were recorded with a micro mass Q-TOF mass spectrometer (Serial no. YA. 263). Electronic spectroscopic data were recorded with a Perkin–Elmer Lambda 950 UV/Vis spectrophotometer.

***CAUTION!*** *Although no problems were encountered in this work, transition metal perchlorate complexes with organic ligands are potentially explosive. Heating of dried samples must be avoided; handling of small quantities must proceed with great caution using proper protection.*

**Syntheses**

The complexes **2**–**4** were synthesized following a general procedure. Specific details for representative complexes are given below.

**Reactions of $[Ru(bpy)_2(MeOH)_2]^{2+}$with $HL^1$:** A mixture of *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (0.065 g, 0.125 mmol) and $AgNO_3$ (0.042 g, 0.25 mmol) in dry methanol (25 mL) was heated at reflux for 2 h. The initial violet solution changed to orange red. The cooled solution was filtered through Whatman 42 filter paper to remove the precipitated AgCl. The ligand $HL^1$ (0.070 g, 0.125 mmol) along with two drops of $NEt_3$ was then added to the above filtrate. The resulting mixture was heated at reflux for 6 h. The solution finally became blue and its volume was reduced to ca. 10 mL. The concentrated solution was then poured into diethyl ether (50 mL) to precipitate a dark product. The crude product was then subjected to chromatography on a preparative alumina TLC plate for purification. It was first eluted with $CHCl_3$; a small band of unreacted phenazine ligand was first separated, which was followed by a blue (**2**) band. The unmoved dark band was collected and was again loaded on a fresh TLC plate and chloroform/acetonitrile (3:2) was then used as the eluent. This resulted in the separation of two distinct bands, viz. violet (**3**) and blue (**4**). The compounds **2**–**4** were collected by complete evaporation of the eluates. Recrystallization of these from different solvent mixtures yielded the products in their crystalline states. The yields and characterization data of the complexes are as follows.

**$[Ru(bpy)_2(L^1)](ClO_4)$ (2a):** This was crystallized from a dichloromethane/hexane (1:1) solvent mixture. Yield: 0.015 g (10%). $C_{54}H_{45}ClN_8O_8Ru$ (1069.50): calcd. C 60.58, H 4.20, N 10.47; found C 60.56, H 4.25, N 10.45. IR (KBr): $\tilde{\nu}$ = 1615 s, 1560 s, 1502 s, 1464 m, 1446 m, 1423 m, 1285 w, 1245 s, 1115 vs, 1100 vs, 838 m, 770 s, 625 s cm$^{-1}$. ESI-MS: *m*/*z* (%): 971 $[M - ClO_4^-]^+$, where *M* = molecular mass of the compound. $\Lambda_M$ in acetonitrile at 25 °C: 130 $\Omega^{-1}$ cm$^2$ M$^{-1}$.

**$[Ru(bpy)_2(LO)](ClO_4)_2$ (3a):** This was crystallized from an acetonitrile/toluene (1:4) solvent mixture. Yield: 0.069 g (45%). $C_{54}H_{44}Cl_2N_8O_{13}Ru$ (1184.10): calcd. C 54.72, H 3.71, N 9.46; found C 54.73, H 3.74, N 9.41. IR (KBr): $\tilde{\nu}$ = 1670 s, 1605 s, 1550 s, 1504 s, 1463 m, 1444 m, 1278 w, 1248 s, 1248 s, 1115 s, 1090 s, 836 m, 767 s, 620 s cm$^{-1}$. ESI-MS: *m*/*z* (%): 493 $[M - 2ClO_4^-]^{2+}$. $\Lambda_M$ in acetonitrile at 25 °C: 250 $\Omega^{-1}$ cm$^2$ M$^{-1}$.

**$[(bpy)_2RuL^2Ru(bpy)_2](ClO_4)_3$ (4a):** Evaporation of the third fraction from the TLC plate yielded the dimeric blue **4a**. Yield: 0.054 g (35%). This fraction was recrystallized from acetonitrile/toluene. $C_{108}H_{89}Cl_3N_{16}O_{20}Ru_2$ (2239.38): calcd. C 57.87, H 3.97, N 10.00; found C 57.95, H 4.00, N 10.01. IR (KBr): $\tilde{\nu}$ = 1605 s, 1565 w, 1504 s, 1481 m, 1464 w, 1445 m, 1382 vs, 1250 s, 1115 vs, 1030 s, 837 w, 768 s, 625 s cm$^{-1}$. ESI-MS: *m*/*z* (%): 647 $[M - 3ClO_4^-]^{3+}$. $\Lambda_M$ in acetonitrile at 25 °C: 370 $\Omega^{-1}$ cm$^2$ M$^{-1}$.

**Reactions of $[Ru(phen)_2(MeOH)_2]^{2+}$ with $HL^1$:** This reaction was performed as described above, except that *cis*-$Ru(phen)_2Cl_2$ was used in place of *cis*-$Ru(bpy)_2Cl_2$. The yields and characterization data of the complexes are collected below.

**$[Ru(phen)_2(L^1)](ClO_4)$ (2b):** This was recrystallized using a dichloromethane/THF/hexane solvent mixture (1:1:1). Yield: 0.013 g (8%). $C_{58}H_{45}ClN_8O_8Ru$ (1117.50): calcd. C 62.28, H 4.02, N 10.02; found C 62.25, H 4.10, N 9.98. IR (KBr): $\tilde{\nu}$ = 1610 s, 1548 m, 1504 s, 1427 s, 1384 s, 1245 s, 1175 m, 1100 m, 1027 w, 721 m, 620 s cm$^{-1}$. ESI-MS: *m*/*z* (%): 1018 $[M - ClO_4^-]^+$. $\Lambda_M$ in acetonitrile at 25 °C: 140 $\Omega^{-1}$ cm$^2$ M$^{-1}$.

**$[Ru(phen)_2(LO)](CF_3SO_3)_2\cdot 2H_2O$ (3b):** Crystalline compound of **3b** was obtained by slow evaporation of the solution of the compound in a dichloromethane/acetonitrile (1:2) solvent mixture. Yield: 0.075 g (47%). $C_{60}H_{48}F_6N_8O_{13}RuS_2$ (1368.21): calcd. C 52.62, H 3.50, N 8.18; found C 52.55, H 3.60, N 8.10. IR (KBr): $\tilde{\nu}$ = 1670 s, 1610 s, 1552 s, 1505 m, 1463 w, 1430 w, 1412 w, 1276 vs, 1250 s, 1163 m, 1116 s, 1030 s, 840 m, 721 w, 638 s cm$^{-1}$. ESI-MS: *m*/*z* (%): 517 $[M - 2CF_3SO_3^-]^{2+}$. $\Lambda_M$ in acetonitrile at 25 °C: 270 $\Omega^{-1}$ cm$^2$ M$^{-1}$.

**$[(phen)_2RuL^2Ru(phen)_2](ClO_4)_3$ (4b):** The thin rod-shaped crystalline compound was obtained from an acetonitrile/toluene (1:1) solvent mixture. Yield: 0.040 g (25%). $C_{116}H_{89}Cl_3N_{16}O_{20}Ru_2$ (2333.64): calcd. C 59.65, H 3.81, N 9.60; found C 59.63, H 3.87, N 9.55. IR (KBr): $\tilde{\nu}$ = 1605 s, 1564 w, 1502 s, 1481 s, 1427 w, 1408 m, 1383 vs, 1130 s, 1029 m, 842 m, 610 s cm$^{-1}$. ESI-MS: *m*/*z* (%): 678 $[M - 3ClO_4^-]^{3+}$. $\Lambda_M$ in acetonitrile at 25 °C: 400 $\Omega^{-1}$ cm$^2$ M$^{-1}$.

**Syntheses of Compounds 3 and 4 from 2. 2a→3a Conversion:** A solution of the compound $[Ru(bpy)_2(L^1)](ClO_4)$ (**2a**) [50 mg in 250-mL aqueous methanol (1:9)] was heated at reflux in air for 0.5 h. The blue solution became violet. The mixture was evaporated to dryness and the crude product was purified on an alumina TLC plate using a chloroform/acetonitrile (3:2) solvent mixture as the eluent. A violet band of the compound **3a** was collected. It was finally crystallized from an acetonitrile/toluene solvent mixture, yield 90%.

The compound **3b** was similarly obtained from **2b**, the yield was 86%.

**2a→4a Conversion:** A solution of the compound **2a** in dry methanol was heated at reflux under a dry nitrogen atmosphere for 6 h. The resultant blue solution was evaporated to dryness and was loaded on an $Al_2O_3$-TLC plate for purification. A minor violet

band (**3a**, yield 5%) and a major blue band (**4a**, yield 75%) were eluted using a chloroform/acetonitrile (3:2) solvent mixture.

The compound **4b** was similarly obtained from **2b**. The yield of **4b** was 80%.

**X-ray Crystallography:** Single crystals of $[Ru(phen)_2(LO)](CF_3SO_3)_2 \cdot 2H_2O$ (**3b**) were grown by slow evaporation of an acetonitrile/dichloromethane (2:1) solvent mixture and the single crystals of $[\{(bpy)_2Ru\}_2(L^2)^-](ClO_4)_3$ (**4a**) were grown by slow diffusion of an acetonitrile solution of **4a** into toluene. Crystallographic data are collected in Table 3 and further details are noted below.

Table 3. Crystallographic data and refinement results for **3b** and **4a**.

| Compound | **3b** | **4a** |
|---|---|---|
| Empirical formula | $C_{60}H_{48}F_6N_8O_{13}RuS_2$ | $C_{108}H_{89}Cl_3N_{16}O_{20}Ru_2$ |
| Molecular mass | 1368.25 | 2239.44 |
| $T$ [K] | 293(2) | 273(2) |
| Wavelengths [Å] | 0.71073 | 0.71073 |
| Crystal system | monoclinic | triclinic |
| Space group | $P21/c$ (no. 14) | $P$-1 (no. 2) |
| $a$ [Å] | 11.3828(13) | 11.6057(18) |
| $b$ [Å] | 22.640(2) | 15.236(2) |
| $c$ [Å] | 24.2105(19) | 33.086(5) |
| $\alpha$ [°] | 90 | 79.286(3) |
| $\beta$ [°] | 109.044(4) | 89.143(3) |
| $\gamma$ [°] | 90 | 75.031(3) |
| $V$ [Å$^3$] | 5897.7(10) | 5550.0(15) |
| $Z$ | 4 | 2 |
| $D_{calcd.}$ [mg m$^{-3}$] | 1.541 | 1.340 |
| Crystal dimensions [mm] | $0.23 \times 0.18 \times 0.16$ | $0.03 \times 0.16 \times 0.21$ |
| $\theta$ range for data collection [°] | 1.27–28.08 | 1.3–26.1 |
| Reflections collected | 28248 | 21643 |
| Unique reflections | 13468 | 15050 |
| Largest diff. between peak and hole [eÅ$^{-3}$] | –1.085, 2.731 | –0.64, 1.36 |
| Final $R$ indices $[I > 2\sigma(I)]$ | $R_1 = 0.0451$ $wR_2 = 0.1597$ | $R_1 = 0.0695$ $wR_2 = 0.1021$ |

**$[Ru(phen)_2(LO)](CF_3SO_3)_2 \cdot 2H_2O$ (3b):** X-ray quality crystals of **3b** were obtained by slow evaporation of an acetonitrile/dichloromethane (2:1) solvent mixture. A crystal of dimension ($0.23 \times 0.18 \times 0.16$ mm$^3$) was mounted, data were collected with a Bruker SMART CCD 1000 diffractometer equipped with a graphite crystal incident beam monochromator having Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), and were processed with SAINT.[19] These were corrected for absorption using SADABS[20] (transmission factors: 1.000–0.742). A total of 24248 reflections were collected of which 13468 were unique ($R_{int}$ = 0.0436) and these were used in subsequent analysis. The structure was solved by direct methods using the program SHELXS-97[21] and refined by full-matrix least-squares techniques against $F^2$ using SHELXL-97.[22] Positional and anisotropic atomic displacement parameters were refined for all non-hydrogen atoms. Hydrogen atoms were included in geometrically idealized positions employing appropriate riding models with isotropic displacement parameters constrained. Crystallographic drawings were prepared using the programs PLATON[23] and SCHAKAL.[24]

**$[(bpy)_2RuL^2Ru(bpy)_2](ClO_4)_3$ (4a):** X-ray quality crystals of **4a** were obtained by slow diffusion of an acetonitrile solution of the compound into toluene. A crystal of dimension ($0.03 \times 0.16 \times 0.21$ mm$^3$) was mounted, and the data were collected with a Bruker Smart CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 273 K. These were corrected for Lorentz polarization effects and an empirical absorption correction was made with the help of the SAINT[19] program. A total of 21643 reflections were measured, of which 15050 reflections were unique ($R_{int}$ = 0.060). The data [$I > 2\sigma(I)$] were used for solution and refinement by full-matrix least-squares on $F^2$ using the SHELXL-97 package.[22] The non-hydrogen atoms having full occupancies were refined using anisotropic thermal parameters. Hydrogen atoms were included in the structure factor calculation at idealized positions, but not refined. The refinement was converged at $R$ = 0.0695 and $wR_2$ = 0.1021 with residual electron density 1.36 eÅ$^3$ and –0.64 eÅ$^3$. The maximum electron densities have no chemical significance as they were located at ca. 0.7 Å from a heavy atom. The calculations were performed using the Bruker Smart 5.63 software for data reduction, all other calculations and graphics were done using the PLATON[23] software package and ORTEP.[25]

Crystal data and refinement details are listed in Table 3. CCDC-290869 (for **3b**) and -290868 (for **4a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): NMR spectra of a class of representative complexes (Figure S1). Observed ESI-MS spectra for representative complexes (a) $(\mathbf{2a})^+$, (b) $(\mathbf{3a})^{2+}$, (c) $(\mathbf{4a})^{3+}$ (Figure S2) and EPR spectrum of a frozen acetonitrile/toluene glass (1:1) of $(\mathbf{3a})^-$ at 77 K (Figure S3).

## Acknowledgments

Financial support received from the Department of Science and Technology, and the Council of Scientific and Industrial Research, New Delhi is gratefully acknowledged. P. B. is thankful to the Council of Scientific and Industrial Research, New Delhi, for his fellowship. We are also thankful to the School of Chemistry, University of Hyderabad, for X-ray data collection for one of the samples.

# Reticular Nickel Microwires with Assembled Nanostructures: Synthesis, Magnetism and Catalysis for the Growth of Carbon Nanotubes

Xiaomin Ni,[a] Qingbiao Zhao,[a] Yongfeng Zhang,[b] and Huagui Zheng*[a]

**Keywords:** Nickel / Nanostructures / Chemical reduction / Crystal growth

Reticular nickel microwires assembled from different-shaped building blocks are fabricated by a simple, one-pot method in the absence of any surfactants or external magnetic field. The synthetic process involves the chemical reduction of a nickel complex with hydrazine under controlled reaction conditions. Our strategy focuses on the modulation of the reaction rate to control the shape of the subunits and their spontaneous assembly behavior, which avoids the need for surfactants or an external force. The nickel wires can be reproducibly created with the assistance of various complexants, such as citrate, tartrate, lactate, ethylenediamine, triethanolamine and diethanolamine, which proves the generality of this method. These nickel wires show variable magnetic properties and catalysis for the growth of carbon nanotubes in pyrolyzing acetone due to the nature of their microstructures.

## Introduction

Assembled nanostructures have attracted considerable interest from materials scientists due to their potential applications in nanodevices.[1] In particular, magnetic assemblies have received more attention due to their unique properties and uses in electronic, magnetic, and biomedical applications, amongst others.[2] Generally, there are two routes for the assembly of magnetic nanoparticles into organized structures. The first of these harnesses the spontaneous noncovalent interactions between surfactants or polymer-modified building blocks, including van der Waals forces, π–π interactions, electrostatic forces, and hydrogen bonding.[3] For example, a three-dimensional spherical assembly of magnetite nanoparticles has been fabricated in the presence of ternary surfactant combinations[4] and the assembly of maghemite has been achieved in the presence of a block copolypeptide.[5] In the presence of polymers, monodisperse FePt nanoparticles self-assemble into films with controllable thicknesses and dimensions.[6] In these systems, the content of surfactants or polymers is relatively high, which usually damages their magnetic properties or makes their practical application difficult.[7] The other efficient method for the assembly of magnetic nanoparticles makes use of an external magnetic field. The application of a magnetic field to a suspension of magnetic particles typically produces one-dimensional (1D) chains of particles with their magnetic dipoles aligned head-to-tail and parallel to the magnetic field.[8] For instance, application of an external perpendicular magnetic field to a solution of $CoPt_3$ nanocrystals in toluene drives the formation of 1D microwires,[9] and $Fe_3O_4$ nanoparticles in the size range 8–12 nm self-assemble into elongated clusters on a GaAs substrate in the presence of a strong magnetic field, with the predominant orientation lengthwise along the field direction.[10] Colloidal nickel nanoparticles self-assemble into nanochains when subjected to a magnetic field with a strength of about 250 G.[11] However, these assemblies always require an external magnetic field to remain stable, and when the external magnetic field is removed they become unstable.[12] Currently, it is still challenging to explore simple and convenient approaches for the synthesis of assembled nanostructures.

Nanosized particles of nickel show diverse applications as catalysts, magnetic recording media, conducting materials, and in medical diagnosis.[13] In the past decades, many different-shaped nickel nanocrystals, including nanotubes, hollow spheres, nanobelts, nanorods, and nanoprisms, have been successfully created and their properties and applications found to depend on their morphology.[7,14] Some of these assembled nickel nanostructures, such as microwires assembled by acicular nanocrystals and chains consisting of nanospheres, were created with the aid of surfactants or an external magnetic field.[11,15] However, the assembly mechanism has not been investigated thoroughly and to date little work has been reported on the synthesis of assembled nickel architectures by methods other than those mentioned above.

In this manuscript we report a facile kinetic-control method for the preparation of wire-like assembled nanostructures of nickel that does not require surfactants or an external magnetic field. This synthetic methodology focuses on the modulation of the reaction rate to control the shapes of the building blocks and their spontaneous assembly behavior and has the advantage of being simple to perform and easy to control. The thus-prepared nickel wires with different-shaped subunits show variable magnetic properties and catalytic activity for the formation of carbon nanotubes in pyrolyzing acetone, depending on their microstructures.

## Results and Discussion

Figure 1 shows a typical X-ray diffraction (XRD) pattern of sample1 (S1), in which all the diffraction peaks can be well indexed as ace-centered-cubic (fcc) nickel (JCPDS 01-1260). No peaks of nickel oxides or nickel hydroxides can be detected, thus indicating that pure fcc nickel is obtained by the current synthetic procedure.

The morphology of S1 is shown in Figure 2. The panoramic field emission scanning electron microscopy (FE-SEM) image in Figure 2 (a) indicates that the sample consists of reticular microwires with a diameter of about 2 μm and lengths of up to several hundred micrometers. The magnified images in parts b and c of Figure 2 demonstrate that the wires are prickly and are constructed from thorn-like particles with lengths of 200–400 nm. Figure 2 (d) is the TEM image of one wire and reveals the same characteristics as the SEM observations. Parts e, f and g of Figure 2 show a typical thorn-like subunit and the corresponding selected-area electron diffraction (SAED) and high-resolution TEM image. The pattern of spots reveals that the thorn is single-crystalline and the electron beam could be set along the

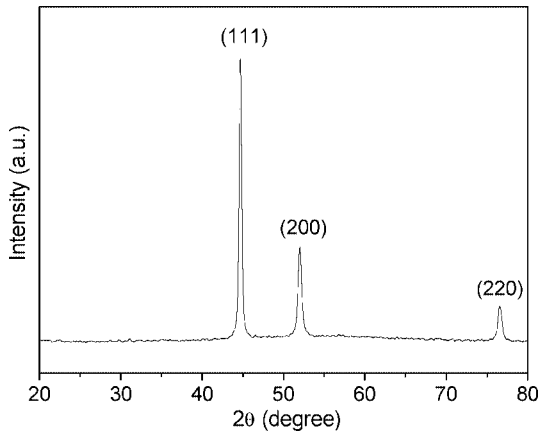

Figure 1. A typical XRD pattern of sample 1.

[$\bar{1}\bar{1}2$] zone axis. The spacing of the observed lattice planes is 0.20 nm, which is consistent with the separation of the (111) planes of fcc nickel. This demonstrates that the growth direction of the thorn is along the (111) plane. Analysis of several thorns gives a similar picture, thus suggesting that all the subunits have the same orientation.

In order to study the formation process of the wires, time-dependent TEM observations of the evolution of S1 were conducted; the results are shown in Figure 3. After 2 h, the product is present as small, granular nanocrystals with a diameter of 20–30 nm (Figure 3a). After heating the reaction mixture for 4 h thorns protrude from the particles and some prickly particles begin to aggregate due to their natural magnetic attraction, as shown in Figure 3b. After 8 h microwires consisting of thorn-like nanocrystals had formed (seen in Figure 3c). Figure 3d shows the HRTEM image recorded at the join of two neighboring subunits of the product heated for 8 h. It can be seen that the lattice

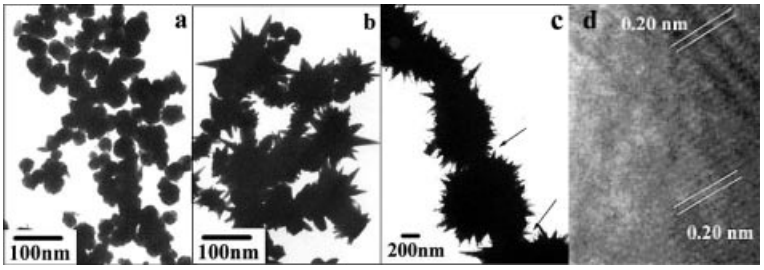

Figure 3. SEM images of the samples prepared at different reaction stages: (a) 2 h, (b) 4 h, (c) 8 h; (d) HRTEM image of the join of two neighboring thorn-like building blocks.

fringes prolongate across the two subunits without interruption by an apparent boundary, thus indicating that the building units have fused together. These results reveal that formation of the assembly wires occurs with a continuous aggregated growth rather than by direct aggregation of preformed, thorn-like particles.

Contrast experiments were carried out to investigate the factors that influence the formation of these nickel microwires. The redox reaction we employ here can be formulated as:

$$2\,[Ni(C_6H_5O_7)]^- + N_2H_4 + 4\,OH^- \rightarrow 2\,Ni + N_2 + 4\,H_2O + 2\,C_6H_5O_7^{3-}$$

Citrate was introduced here as the complexant to form the complex $[Ni(C_6H_5O_7)]^-$. Formation of this complex could sharply reduce the free $Ni^{2+}$ concentration in solution and thus result in a relatively slow reaction rate, which is favorable for the oriented growth of nickel crystals.[16] To examine the effect of citrate ions on the formation of the wires, SEM images of the samples obtained at different molar ratios of citrate to $Ni^{2+}$ ions ($\omega$) were compared. In the absence of citrate, the reaction was complete after 30 min and the product consisted of irregular spherical particles (Figure 4, a). When $\omega$ was set to 0.5, where the amount of citrate is not sufficient to form the complex, the reaction time was prolonged to 4 h and the product was found to be a mixture of dispersed spherical particles and microwires (Figure 4, b). When $\omega$ was increased to 1.0, about 7 h was needed to complete the reaction and the product was dominated by microwires. These results indicate that citrate ions play a significant role in the formation of the wires.

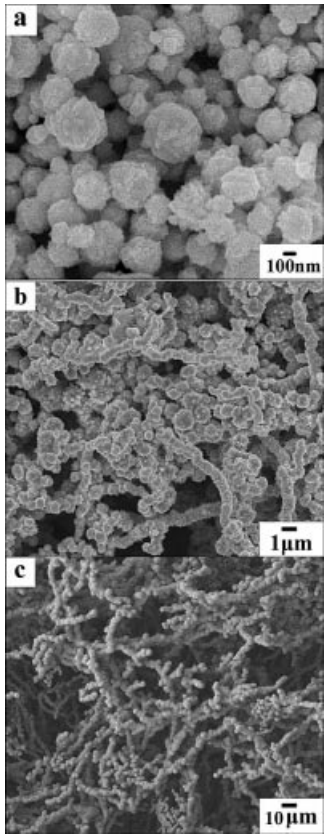

Figure 4. SEM images of the samples prepared at different molar ratios ($\omega$) of citrate to $Ni^{2+}$ ions: (a) $\omega$ = 0, (b) $\omega$ = 0.5, (c) $\omega$ = 1.0. The other reagent concentrations were kept the same.

The concentration of NaOH is another important parameter that affects the product morphology. It is known that a basic medium can increase the reducing power of hydrazine. Consequently, by adjusting the NaOH concentration, the reaction rate was correspondingly changed. Nickel wires were only obtained in a certain range of base concentrations when keeping the other conditions the same. Table 1 summarizes the reaction times and the product morphologies of the samples obtained at different base concentrations. The corresponding SEM images are shown in Figure 5. It can be seen that with an increase of base concentration the product gradually changes from wires into discrete particles and the reaction time is correspondingly shortened. A lower base concentration results in a relatively slow reaction rate, which facilitates the oriented growth of the nickel particles into thorns and their spontaneous assembly into wires. The fast reaction rate produced at high base concentrations only leads to bigger isolated particles.

The effect of temperature on the formation of the wires was also studied. It was found that the nickel wires could be fabricated in a wide temperature range of 70–140 °C. As the temperature decreases, the reaction time is obviously prolonged; for example, 2 h is sufficient to complete the reaction at 140 °C, while 36 h is needed for the reaction at 70 °C. No significant change of morphology and size was observed for the product obtained at different temperatures. In summary, an increase of reaction temperature accelerates the formation of the nickel wires but has little influence on their morphology and size.

Generally, nickel nanoparticles connect to each other due to magnetic interactions, although this magnetic dipole in-

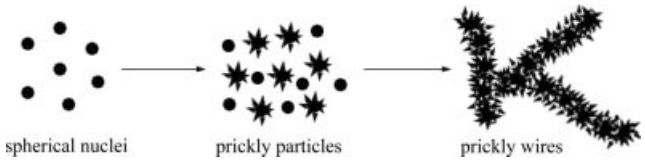
Table 1. Reaction times and product morphologies of the samples prepared at different base concentration with the other conditions remaining the same.

| Sample | NaOH conc. [M] | Reaction time [h] | Product morphology |
|---|---|---|---|
| 1 | 0.05 | 10 | microwires consisting of nanoplates (diameter of the wire: 2 μm) |
| 2 | 0.10 | 8 | microwires consisting of nanoplates (diameter of the wire: 1 μm) |
| 3 | 0.15 | 5 | microwires consisting of nanoparticles (diameter of the wire: 0.5 μm) |
| 4 | 0.30 | 3 | pearl-necklace-like microwires (diameter of the wire: 0.3 μm) |
| 5 | 0.40 | 1 | discrete particles with a diameter of 100 nm |

teraction is rather weak and the aggregates can usually be dispersed by strong ultrasonication. Nevertheless, our wire-like assemblies show a high stability and even ultrasonication for 1 h could not destroy them. This indicates that the wire is not a loose aggregate of thorn-like nanocrystals but an integrated hierarchical structure. The assembly of magnetic particles is a complex process that is affected by several factors such as the velocity of crystal growth, dipolar interactions, spatial hindrance, and other kinetic factors. Based on the above studies of the evolution process and experimental parameters, the formation of our reticular hierarchical wires can be ascribed to the cooperative effect of the reaction rate and the inherent magnetic interactions. The reaction rate is controlled mainly by adjusting the reaction temperature and reagent concentration. During the first stage of the reaction spherical particles form as the nucleus. Then, anisotropic, thorn-like crystals develop from the active parts of the existing nuclei under the kinetic control of complexant and base and form prickly particles. Under the influence of the magnetic dipole interactions, the prickly particles tend to join with each other to acquire a low magnetic anisotropic energy. As the reaction proceeds, the contacting particles gradually fuse into each other and the separation between the joints disappears, which finally results in long wires. A schematic illustration of the possible formation process is presented in Scheme 1. During this process, there is a thermodynamic driving force for the aggregated growth because the surface energy is reduced substantially when the interface is eliminated.[17] As a result, reticular wires are observed.



Scheme 1. Schematic illustration of the possible formation process of the prickly nickel microwires.

We have found that the diameter of the wire is not uniform and the narrower parts imply that the wires develop by the joining of discrete units. A relatively slow reaction rate is crucial for the formation of the thorn-like particles and their spontaneous aggregation into microwires. High base concentrations or low $\omega$ values lead to a high reaction rate, which means that the nucleus grows so fast into isolated spherical particles that oriented growth and simultaneous assembly essentially do not occur, while low base concentrations or high $\omega$ values allow a relatively slow reaction rate, which provides enough time for the oriented development of the nickel nuclei and their subsequent assembly. Such shape variations of nickel nanostructures with the basicity of the medium or complexant concentrations are the result of kinetic control of the crystal growth pro-

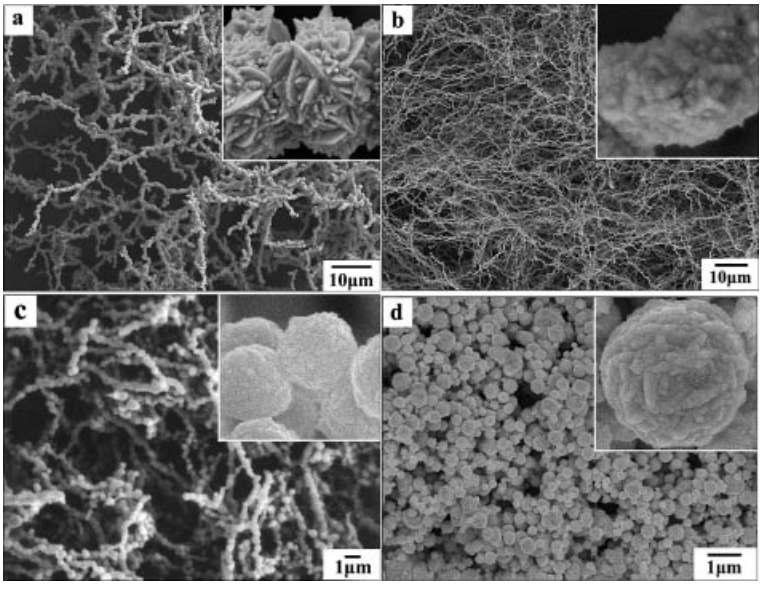


Figure 5. SEM images of the samples prepared at different NaOH concentrations: (a) 0.10 M, (b) 0.15 M, (c) 0.30 M, (d) 0.40 M. The other reagent concentrations were the same, namely $[NiCl_2]$ = 0.025 M, [citrate] = 0.10 M, $[N_2H_4]$ = 0.20 M.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cess. The wire formation observed within a specific range of base and complexant concentrations and temperatures therefore corresponds to an optimal combination of the reduction rate and crystal growth rate that allows organization of the building blocks.

In light of the formation mechanism proposed above, we conducted a series of experiments by replacing sodium citrate with other complexants such as sodium tartrate, sodium lactate, ethylenediamine, triethanolamine, and diethanolamine. In all cases we found similar results, namely that the base and complexant concentrations strongly influence the crystal morphology and assembly behavior. Wires with assembled nanostructures could only be reproducibly fabricated in a certain range of reagent concentrations. This result further proves the above aggregation growth mode, which is controlled by the complexant and inherent magnetic interactions. With the other conditions fixed, the base concentrations best suited to the formation of nickel wires in the presence of different complexants are summarized in Table 2 (their typical morphology images are given as Figure S1 in the Supporting Information).

Table 2. NaOH concentrations suitable for the formation of nickel microwires in the systems containing different complexants.[a]

| Complexant | Conc. of complexant | Conc. of NaOH |
|---|---|---|
| Citrate | 0.10 M | 0.03–0.3 M |
| Tartrate | 0.10 M | 0.03–0.4 M |
| Lactate | 0.10 M | 0.06–0.2 M |
| Ethyleneamine | 0.10 M | 0.50–2.0 M |
| Triethanolamine | 0.10 M | 0.40–1.2 M |
| Diethanolamine | 0.10 M | 0.40–1.0 M |

[a] The other reaction conditions were kept the same: $[NiCl_2]$ = 0.025 M, $[N_2H_4]$ = 0.2 M, hydrothermal treatment at 120 °C.

## Magnetic Properties

It is known that the magnetic properties of nanomaterials are strongly dependent on their size, morphology, crystallinity, synthetic methods, etc. Four samples (samples 1, 2, 3, and 5) with different morphologies were selected as the subjects for investigation; their M-H hysteresis loops are presented in Figure 6. These samples show a coercivity (Hc) of 268, 257, 202, and 173 Oe, respectively. The corresponding saturation magnetism (Ms) is about 29.21, 27.36, 22.96, and 15.81 emu $g^{-1}$. All four samples show a much higher coercivity than bulk nickel (Hc = 100 Oe).[18] As ultrafine ferromagnetic particles often exhibit enhanced coercivity relative to the corresponding bulk material, the small size of the samples may be responsible for the increased Hc values.[19] The lower Ms values with respect to that of bulk nickel (55 emu $g^{-1}$) can be ascribed to the surface spin disorder and inevitable slight surface oxidation of the nanoscale subunits, which significantly reduce the total magnetic moments.[20] Moreover, it was found that the Hc and Ms values decrease gradually from sample 1 (S1) to sample 5 (S5) and that the wires with the thorn-like subunits have the highest Hc and Ms values, possibly due to the relatively higher shape anisotropy of their subunits.[21] This demonstrates that the microstructure of the samples greatly influences their magnetic properties, and the building blocks with higher shape anisotropy can effectively improve the magnetic properties of the assembly.

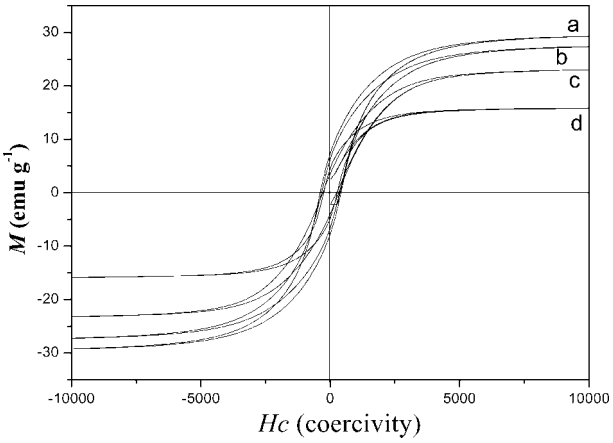

Figure 6. M–H hysteresis loops of four samples with different morphologies: (a) sample 1, (b) sample 2, (c) sample 4, (d) sample 5.

## Catalytic Activity for the Formation of Carbon Nanotubes

Nickel is a commonly used catalyst for the formation of carbon particles.[22] Here, we studied the catalysis of the as-prepared nickel wires for the growth of carbon nanotubes in pyrolyzing acetone. Figure 7 shows the SEM and the corresponding TEM images of the obtained carbon particles catalyzed by S1–S5. In contrast to the product obtained without any metal particles, which appears as aggregated carbon particles without regular shapes (Figure 7, f), the five nickel samples all show catalytic activity for the creation of carbon nanotubes, but with different performances. Samples 1 and 2 both give carbon nanotubes with a yield of above 95% according to SEM observations (Figure 7, a, b). In the product catalyzed by sample 3 (S3), however, the yield of carbon nanotubes is only about 70% and some irregular particles are observed (seen in Figure 7, c). As for the reaction catalyzed by sample 4 (pearl-necklace-like chain), the yield of the tubes decreased to 40% and the length of the nanotubes obviously shortened (Figure 7, d). When it came to the reaction catalyzed by sample 5 (dispersed particles), much more irregular carbon particles were formed and only a few nanotubes (about 10%) could be detected, as seen in Figure 7 (e). These contrasting results clearly demonstrate that the catalytic activity of these nickel samples depends strongly on their microstructure. Since the structure and surface area of the catalyst are important factors affecting their activity, the samples with a relatively high surface area have more surface accessible to the reagents, which is believed contributive to their improved activity for the nucleation of carbon nanotubes,[23] although further research is needed to explore the detailed mechanism.

## Conclusion

In summary, we have reported a simple complex-assisted hydrazine reduction method for the synthesis of hierarchical nickel microwires by controlling the reaction rate. The morphological details of the building blocks and their assembly behavior can be tailored by adjusting the reagent concentration. These nickel wires can be reproducibly created with the aid of various complexants, which proves the generality of this approach. The thus-prepared nickel wires show microstructure-dependent magnetic properties and catalytic activity for the growth of carbon nanotubes in pyrolyzing acetone, and they show superior magnetic properties and catalytic performance to the discrete particles. Our synthetic methodology is a facile route for assembling nanosized building blocks into desired structures through kinetic control that avoids the use of any surfactants or an external magnetic field. Such a method is expected to be extendable to the synthesis of other magnetic nanostructures.

## Experimental Section

All chemicals were of analytical grade and were used without purification. A typical experiment for the preparation of nickel wires is as follows: trisodium citrate dihydrate ($Na_3C_6H_5O_7{\cdot}2H_2O$; 1.0 g) was dissolved in 30 mL of an aqueous solution of 0.025 M $NiCl_2$ whilst stirring. Then, 1.0 mL of hydrazine hydrate ($N_2H_4{\cdot}H_2O$ 80%) and a certain amount of dilute NaOH solution were added. The whole mixture was stirred for another 10 min to obtain a homogeneous solution and subsequently transferred into a 40-mL autoclave, which was sealed and maintained at 120 °C for 2–10 h. After the heating treatment was over, the black fluffy particles floating on the solution were collected, rinsed with distilled water and absolute ethanol, and finally dried under vacuum. The samples obtained at NaOH concentrations of 0.05, 0.10, 0.15, 0.30, and 0.40 M are denoted as samples 1 (S1), 2 (S2), 3 (S3), 4 (S4), and 5 (S5), respectively.

For the synthesis of carbon particles, 20 mg of the thus-prepared nickel sample was added to two 20-mL stainless autoclaves containing 12 mL of acetone. The autoclave was then sealed, heated at a rate of 5 °C $min^{-1}$ to 550 °C, and kept at this temperature for 10 h. After the heating treatment was over, the autoclave was cooled naturally to room temperature and the black precipitates were collected and immersed in dilute $HNO_3$ solution whilst stirring for 12 h. The product was then centrifuged, rinsed with distilled water and absolute ethanol, and finally vacuum dried at 50 °C for 2 h.

X-ray diffraction (XRD) patterns of the samples were recorded with a Philips X′pert diffractometer with Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å). The morphology and structure of the sample were studied by field emission scanning electron microscopy (FE-SEM, JEOL JSM-6300F) and transmission electron microscopy (TEM, Hitachi, H-800) with an accelerating voltage of 200 kV. High-reso-

lution TEM images were recorded with a JEOL-2010 TEM at an acceleration voltage of 200 kV. Magnetization–hysteresis (M-H) loops were recorded with a BHV-55 vibrating sample magnetometer (VSM) at room temperature.

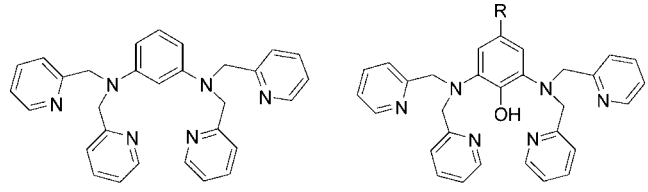
## Introduction

Previously we have demonstrated that the ligand *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)benzene-1,3-diamine (1,3-tpbd) shown in Figure 1 can coordinate two copper ions in close proximity.[1–3] In this regard copper complexes of 1,3-tpbd or its phenol derivative 2,6-bis[bis(2-pyridylmethyl)-amino]-*p*-cresol (2,6-tpcd) (Figure 1) represent good structural models of the histidine-rich environments found in many dinuclear copper proteins (such as *hemocyanin and tyrosinase*).[1,4–7]



**1,3-tpbd** **2,6-tpcd**

Figure 1. The ligands *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)benzene-1,3-diamine (1,3-tpbd) and 2,6-bis[bis(2-pyridylmethyl)amino]-*p*-cresol (2,6-tpcd; R = CH$_3$).

Furthermore, the intramolecular magnetic coupling observed in a series of copper(II) complexes with 1,3-tpbd could be tuned from ferromagnetic to antiferromagnetic.[2,3] Similar ferromagnetic coupling has been observed for copper complexes with a related *m*-phenylenediamine-based ligand system.[8,9] Recently, a 1,3-tpbd platinum complex has been used in mechanistic studies.[10] However to date, only

a small number of transition-metal complexes of related derivatives of the 1,3-tpbd ligand system have been investigated.[11–21]

To gain further understanding of the ligating ability of 1,3-tpbd, we herein describe the synthesis and characterization of a series of iron(II), zinc(II) and copper(II) complexes with 1,3-tpbd as well as a copper(II) complex of the phenol analogue of 1,3-tpbd. A similar complex with the phenol derivative ligand shown in Figure 1 (R = *tert*-butyl) and its interesting properties (e.g. interactions with DNA) was recently reported by Karlin and co-workers.[15,16]

## Results and Discussion

***N*,*N*,*N*′,*N*′-Tetrakis(2-pyridylmethyl)benzene-1,3-diamine (1,3-tpbd):** 1,3-tpbd was prepared in modest yields from commercially available *m*-phenylenediamine and picolyl chloride hydrochloride as previously reported.[1] Single crystals of 1,3-tpbd, suitable for structural characterization, were obtained by slow evaporation of a methanol solution of 1,3-tpbd in a glove box. Attempts to recrystallize the ligand outside of the glovebox often caused the formation of nearly colorless crystals in a slightly brown mother liquor. The solution turned to an intense red color during a couple of days affecting the crystals as well (most likely the ligand is partially oxidized) and as a consequence numerous attempts to solve the crystal structure failed due to poor refinement. A summary of crystal structure data and refinement parameters is presented in Table 2, selected bond lengths and angles in Table 1. The molecular structure of 1,3-tpbd is shown in Figure 2. The two pyridyl units bonded at each amine nitrogen atom are separated from each other by a large distance similar to the previously reported molecular structure of 1,4-tpbd.[18] 1,3-tpbd crystallizes with one additional methanol solvent molecule per unit, hydroxyl hydrogen atom of the methanol solvent molecule were located in a difference Fourier map and isotropically refined.

Protonation of 1,3-tpbd or coordination of 1,3-tpbd to metal ions has the consequence that the pyridyl units move much closer together. In Figure 3 the molecular structure of the cation of $[1,3\text{-tpbdH}_2](ClO_4)_2$ is shown (crystal structure data and refinement parameters, bond lengths and angles are presented in Table 2 and Table 1).

$[1,3\text{-tpbdH}_2](ClO_4)_2$ crystallizes with two molecules per crystallographically independent unit of the unit cell together with three molecules of acetonitrile. Two of the $ClO_4^-$ anions are disordered. The H atoms of the protonated N atoms were localized in a difference Fourier map and refined isotropically. The crystal structures of 1,3-tpbd and $[1,3\text{-tpbdH}_2]^{2+}$ display similar metrical parameters. The immediate geometry around the aliphatic amine nitrogen atoms is nearly planar with C1–N1 1.388(2) Å in 1,3-tpbd and C13–N1 1.396(4) Å in $[1,3\text{-tpbdH}_2](ClO_4)_2$ indicating delocalization of the nitrogen lone pair of electrons with the aromatic π systems. All the interbond angles around the aliphatic amine nitrogen atoms are close to 120°. However, as discussed above, the positions of the pyridine rings in 1,3-tpbd and its protonated derivative are quite different. In $[1,3\text{-tpbdH}_2]^{2+}$ adjacent pyridine nitrogen atoms on each ligand "arm" [N2 and N3, N5 and N6] are strongly hydrogen-bonded to one another. The average distance between the hydrogen-bonded pyridine nitrogen atoms is 2.741 Å. Additionally, we obtained the protonated triflate salt of 1,3-tpbd (see Supporting Information; for Supporting Information see also the footnote on the first page of this paper) of which the cation is identical to $[1,3\text{-tpbdH}_2](ClO_4)_2$. However, the two crystal structures differ from each other due to the crystal-packing arrangement of the anions, and furthermore the inclusion of additional solvent molecules. In principle these protonated ligand salts are comparable to the metal complexes (see below) and the protons in $[1,3\text{-tpbdH}_2]^{2+}$ can be regarded as small metal cations. The previously reported crystal structure of $[1,4\text{-tpbdH}_2]^{2+}$ displays similar bond lengths and angles to the $[1,3\text{-tpbdH}_2]^{2+}$ structure described above.[18]

**Iron Complexes:** Ligands capable of coordinating two iron ions in close proximity have been employed as structural models for dinuclear iron metalloproteins (e.g. the oxygen carrier protein hemerythrin).[22–24] Prior to the investigations of the oxygen-sensitive iron(II) model compounds, we tried to synthesize and structurally characterize an iron(III) complex of 1,3-tpbd. However, all our efforts to date in obtaining an 1,3-tpbd iron(III) complex were unsuccessful. Numerous attempts (employing different reaction conditions) to synthesize $[Fe_2(1,3\text{-tpbd})]^{6+}$ derivatives, such as $[Fe_2(1,3\text{-tpbd})(DMF)_6]^{6+}$ or $[Fe_2(1,3\text{-tpbd})(RCOO)_n]^{(6-n)+}$, by the reaction of 1,3-tpbd with $Fe(ClO_4)_3$ in different solvents (coordinating or non-coordinating), with and without addition of anions such as $AsO_4^{3-}$, $C_6H_5COO^-$, $CH_3COO^-$ or $Cl^-$, only afforded the protonated free ligand and unreacted iron salts. Over a period of weeks single crystals, suitable for X-ray structural analysis, of $[1,3\text{-tpbdH}_2](SO_3CF_3)_2$ (see supp. inf. and Experimental Section) and $[1,3\text{-tpbdH}_2](ClO_4)_2$ described above (Figure 3) were obtained. Furthermore, efforts in obtaining an 1,3-tpbd iron(III) complex by oxidizing the corresponding iron(II) precursor complex (described below) failed. These results clearly indicate that the 1,3-tpbd ligand has a low affinity for iron(III). In the presence of water, protonation of the ligand occurs, however in the absence of protons no complexation of the iron(III) ions was observed either. Other pyridyl containing ligands are known to stabilize iron(II) relative to iron(III), however in these cases it was still possible to synthesize, isolate and characterize the according iron(III) complexes.[25]

An iron(II) complex of 1,3-tpbd was prepared and single crystals of $[Fe_2(1,3\text{-tpbd})(CH_3CN)_6](ClO_4)_4{\cdot}2CH_3CN{\cdot}0.5H_2O$ (**1**) were grown. The molecular structure of the cation $[Fe_2(1,3\text{-tpbd})(CH_3CN)_6]^{4+}$ of **1** is shown in Figure 4 (crystal structure data and refinement parameters, bond lengths and angles are presented in Table 2 and Table 1). The unit cell of **1** consists of two sets of crystallographically independent dinuclear cations, $[Fe_2(1,3\text{-tpbd})(CH_3CN)_6]^{4+}$,

[a] $-x+1$, $-y+1$, $-z+1$.

and uncoordinated perchlorate anions, four acetonitrile solvent molecules and one water molecule. There are only minor structural differences between the two dinuclear cations. In each cation, the intramolecular Fe···Fe separation is 7.488(1) and 7.697(2) Å, respectively. The 1,3-tpbd ligand coordinates each iron(II) center through two pyridine nitrogen atoms and one aliphatic amine nitrogen atom, displaying $N_{amine}$–Fe–$N_{pyridine}$ angles averaging ca. 81° to accommodate the five-membered chelate rings.

As has been observed previously for $Fe^{II}$TPA complexes, the Fe–$N_{amine}$ distances ranging from 2.095(2) to 2.280(3) Å are characteristically longer than the Fe–$N_{pyridine}$ bond lengths of 1.966(3) to 2.188(3) Å.[26–28] Three *fac*-coordinated acetonitrile molecules occupy the remaining coordination sites to complete the slightly distorted octahedral coordination geometry around each iron(II) center, with Fe–N–C angles ranging from 166.7(3) to 177.1(3)° and the Fe–N distances ranging from 1.953(3) to 2.183(3) Å. These

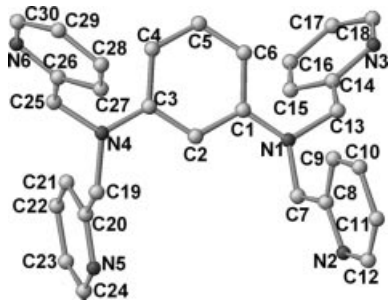

Figure 2. Molecular structure of 1,3-tpbd; hydrogen atoms are omitted for clarity.

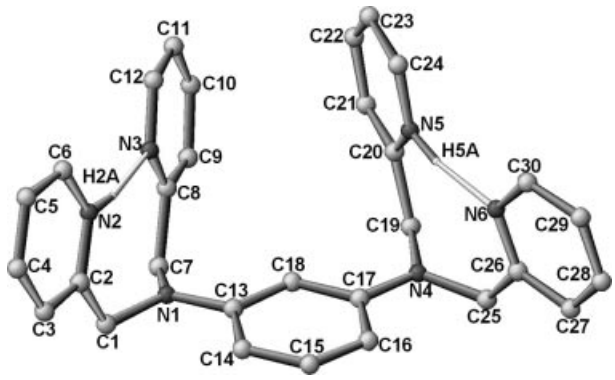

Figure 3. Molecular structure of the cation of $[1,3\text{-tpbdH}_2](ClO_4)_2$; only hydrogen atoms involved in hydrogen bonding are shown.

shorter Fe–N distances indicate that the nitrile groups of the acetonitrile solvent molecules are strongly coordinated to the iron(II) center. Intermolecular π···π interactions (ca. 3.675 Å) exist between C26–C27–C28–C29–C30–N6 and C56–C57–C58–C59–C60–N15 of adjacent pyridine rings from two independent dinuclear cations.

Furthermore, a second iron(II) complex, $[Fe_2(1,3\text{-tpbd})(DMF)_6](ClO_4)_4$ (**2**), was prepared. The molecular structure of the cation of complex **2** is shown in Figure 5 (crystal structure data and refinement parameters, bond lengths and angles are presented in Table 2 and Table 1). Compound **2** crystallizes with half a molecule per crystallographic independent unit of the unit cell, the other half is generated by the crystallographic twofold axis of the space group. Each iron(II) center lies in a distorted $N_3O_3$ octahedral coordination environment. The equatorial plane around Fe(1) comprises two pyridyl nitrogen atoms [N(2) and N(3)] from the *fac*-coordinated 1,3-tpbd ligand and two oxygen atoms [O(1) and O(2)] from coordinated DMF solvent molecules. Apical positions are occupied by the tertiary amine nitrogen N(1) of 1,3-tpbd and oxygen atom O(3) from a third DMF solvent molecule. The $Fe–N_{pyridine}$ bond lengths [2.152(2)–2.174(2) Å] are characteristically shorter than those of $Fe–N_{amine}$ [2.312(2) Å] and the *cis* $N_{pyridine}–Fe–N_{pyridine}$ angles [92.03°] are entirely consistent with

Table 2. Crystallographic data for 1,3-tpbd ligand and compounds **1**, **2** and **4**.
