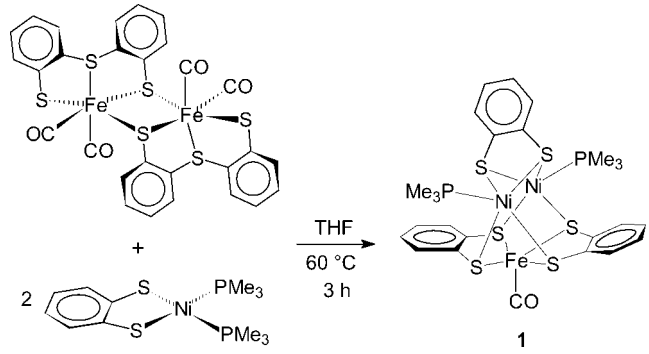
It has already been reported that the trinuclear NiFe complex **1** formed by the reaction of [Fe(CO)$_2$('$S_3$')]$_2$ {'$S_3$'$^{2-}$ = bis(2-mercaptophenyl) sulfide(2–)} with [$Ni(PMe_3)_2$('$S_2$')] according to Scheme 1.[11] In this reaction compound **1** was the only isolated product with 18% yield (it is not possible to give the exact stoichiometry for Scheme 1, however, the given numbers denote only the ratio of the initial reactants used). Both the iron as well as the nickel coordination centers of **1** are chelated by '$S_2$' donors, but surprisingly not with any '$S_3$' ligand. Therefore, it is interesting to know how **1** can be formed from the reactants in which the Fe center is not bearing any '$S_3$' ligand. We can think about two possible pathways for the formation of **1**: in the first route, an initial reductive cleavage of the '$S_3$' ligand at the iron center to an '$S_2$' ligand and subsequent reaction of this intermediate species with [$Ni(PMe_3)_2$('$S_2$')] to form **1**; in the second route, a ligand exchange type of reaction in which all '$S_2$' ligands originate from the reactant [$Ni(PMe_3)_2$('$S_2$')]. If **1** would be formed via the reductive cleavage pathway, the use of a derivatized '$S_3$' ligand in the dinuclear iron precursor complex should result in a new trinuclear NiFe complex containing at least one derivatized '$S_2$' ligand. Conversely if the reaction proceeded via a ligand-exchange pathway, the use of a derivatized '$S_3$' ligand in the dinuclear iron precursor complex should result in exclusively the trinuclear complex **1**. Herein we have chosen the twofold silylated derivative of the '$S_3$' ligand, $^{si}S_3$–$H_2$ {$^{si}S_3^{2-}$ = bis(2-mercapto-3-trimethylsilylphenyl) sulfide(2–)}, for the synthesis of the derivative of the [Fe(CO)$_2$('$S_3$')]$_2$ precursor. Since the $SiMe_3$ group is a good NMR probe, it enables the detection of the reaction pathway of the formation of **1**.



Scheme 1. Synthesis of complex **1**.

The silylated precursor complex [Fe(CO)$_2$($^{si}S_3$)]$_2$ (**2**) was prepared similarly to the synthesis of the unsubstituted parent compound as reported in the literature,[13] except that the reaction was performed under CO atmosphere. Addition of the ligand $^{si}S_3$–$H_2$ to [Fe(bda)(CO)$_3$] (bda = benzylideneacetone) in THF led to a dark green solution and gas evolution. Keeping this solution at –20 °C for two weeks, brown crystals suitable for X-ray structure analysis were obtained. The molecular structure of **2** is shown in Figure 2 and selected bond lengths and bond angles are given in Table 1. The structural parameters of the silylated centrosymmetric compound **2** differ only marginally from the parent compound [Fe(CO)$_2$('$S_3$')]$_2$.[13] Complex **2** consists of two distorted octahedral fragments that are linked by an edge. Within these fragments, the thiolate donors are *cis* to each other. One CO is coordinated *trans* to a bridging thiolate S atom, whereas the other CO is in *trans* position to the thioether S donor. The distances around Fe, including Fe–CO bonds, are in the range usually found for diamagnetic octahedral thiolate-thioether complexes.[12] The Fe–thiolate bond lengths are longer than the Fe–thioether bond lengths. The Fe–Fe distance of 341.51(6) pm indicates that there is no metal–metal interaction.

Compound **2** is diamagnetic and sparingly soluble in most common solvents. However, it is better soluble than the unsubstituted derivative. It is stable in CO saturated solvents for about two weeks. On prolonged standing, it gradually decomposes to form a stable five-coordinate dinuclear species [Fe(CO)($^{si}S_3$)]$_2$ (**3**).

The molecular structure of **3** is depicted in Figure 3 and selected bond lengths and angles are given in Table 1. The molecule can be described as two edge-linked distorted trigonal bipyramids. It contains two 16 valence electron frag-

ments that are linked by thiolate bridges. The CO ligands and thioether donors are in axial positions with the two thiolate donors and iron atoms lying in the base plane. Due to the loss of a CO group the Fe–Fe distance in **3** [271.95(6) pm] decreases by 70 pm compared to that of **2** [341.51(6) pm].

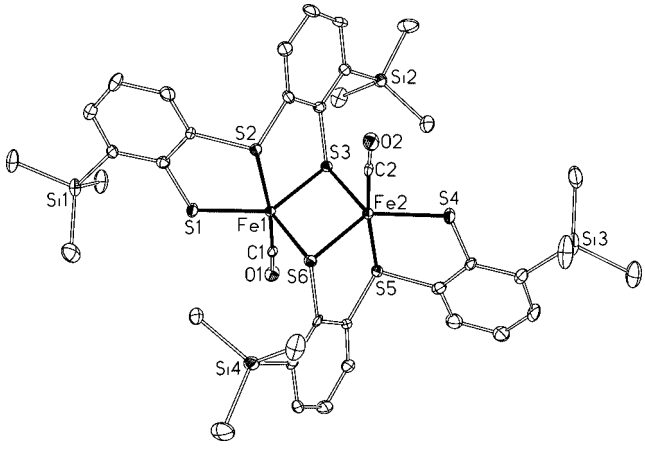

Figure 3. Molecular structure of **3** (50% thermal ellipsoids, H atoms and solvent molecules omitted).

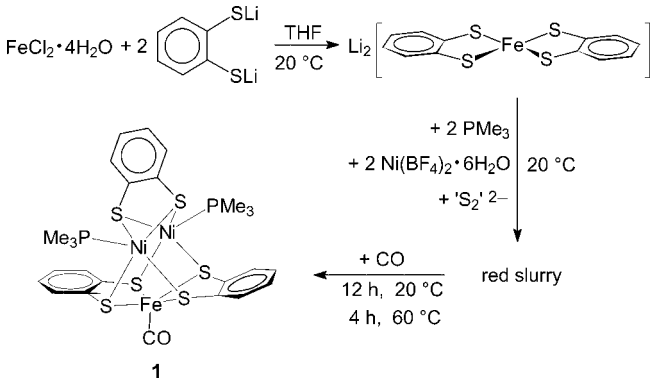
When a solution of **3** in THF is either stirred under an atmosphere of CO for about 30 min or by bubbling of CO gas for about 2 min, compound **2** is formed again. The IR spectroscopic monitoring of the reaction confirmed that the ν(CO) band of **3** at 1975 $cm^{-1}$ vanished and two bands at 2032 $cm^{-1}$ and 1993 $cm^{-1}$ appeared which correspond to the ν(CO) bands of **2**.

In analogy to the synthesis of **1**, complex **2** was treated with $[Ni(PMe_3)_2(‘S_2’)]$ in THF at 60 °C for about 4 h. During the course of the reaction, the green suspension turned into a dark-red solution. The IR spectrum of the solution showed a ν(CO) band at 1916 $cm^{-1}$. Treatment of the solution with methanol resulted in a black-grey microcrystalline material. The $^1H$ and $^{13}C$ NMR spectra of the isolated material (see Experimental Section) showed signals identical to those obtained for **1**. It did not show any signals for $SiMe_3$ groups, indicating the unique formation of **1**. An X-ray structure determination of a single crystal obtained from this material further corroborated this result. Thus, the formation of complex **1** via the ligand exchange type of reaction has unambiguously been proven.

Based upon this encouraging result we devised an alternative way of synthesizing **1** without using the ‘$S_3$’ ligand (Scheme 2). Treatment of $FeCl_2·4H_2O$ with two equivalents of deprotonated ‘$S_2$’$^{2-}$ in THF led to a red solution of $[Fe(‘S_2’)_2]^{2-}$ which was subsequently treated with $PMe_3$ and $Ni(BF_4)_2·6H_2O$. After addition of one more equivalent of ‘$S_2$’$^{2-}$ a slurry formed. Upon diffusion of CO gas into the slurry, a dark red solution formed gradually. The IR spectrum of the solution exhibited a ν(CO) band at 1916 $cm^{-1}$. Further work-up of the mixture afforded complex **1** in an isolable yield of 18%. It is noteworthy that a strict order of addition of the reactants is necessary for the formation of **1** in this one-pot synthesis.



Scheme 2. Alternative synthesis of complex **1**.

## DFT Calculations

Complex **1** readily reacts with protons to give dihydrogen and $[\mathbf{1}]^+$. When the solution of $[\mathbf{1}]^+$ is treated with hydride, the reduced complex **1** is formed again. Both complex **1** and its oxidation product $[\mathbf{1}]^+$ were characterized by single-crystal X-ray structure analysis.[11] In order to gain insight

into this redox process and to determine the details of the electronic structure, DFT calculations were carried out on cluster **1** and its cation $[\mathbf{1}]^+$. The symmetry has been constrained to $C_{2v}$ for both the neutral and the oxidized cluster in all calculations. Therefore, one of the $PMe_3$ groups had to be rotated around the P–Ni bond as compared to the X-ray structures. Test calculations without symmetry constraints showed that the structures with $C_{2v}$ symmetry are indeed lower in energy, thus legitimating this procedure.

As illustrated in Table 2, the theoretical structure determination (geometry optimization) yielded bond lengths and bond angles in very good agreement with the X-ray structure determination. For clarity, the molecular structure of **1** is depicted in Figure 4.

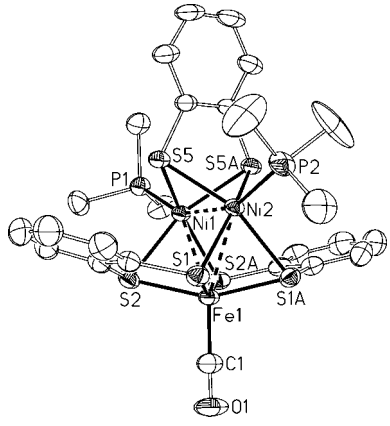

Figure 4. Molecular structure of **1** (50% thermal ellipsoids, H atoms and solvent molecules omitted, dashed lines represent the metal–metal distances).[11]

Differences in experimental bond lengths and bond angles, which are symmetry-equivalent in the DFT calculations, can be attributed to packing effects in the crystals. Therefore the data from the calculations were compared to the average value of these experimental bond lengths and angles. The plane defined by the '$S_2$' ligand coordinating to the nickel atoms (denoted as '$S_2^{Ni}$' in the following) and the axis of the CO ligand are slightly tilted in the experimental structures, while the calculations find a coplanar arrangement. However, it was found that the normal modes describing this movement are very low in both redox states of the cluster (around 50 $cm^{-1}$). Thus, such a distortion should be facile if a small force is exerted on the cluster due to the crystal environment. No significant change of the structural parameters upon oxidation of the cluster **1** is observed both for the experimental and the calculated structures. However, the trend of the changes of the structural parameters upon oxidation, e.g. slight elongation of the Ni1–Ni2 distance and shortening of the Ni1/Ni2–S2/S1 distance, is in general well reproduced by the calculations.

The calculation of the harmonic forcefield results in a frequency of 1955 $cm^{-1}$ (exp. 1910 $cm^{-1}$ in KBr/1916 $cm^{-1}$ in $CH_2Cl_2$) for the ν(CO) band in **1**, and 1998 $cm^{-1}$ (exp. 1952 $cm^{-1}$ in KBr/1976 $cm^{-1}$ in $CH_2Cl_2$) in $[\mathbf{1}]^+$. The experimentally observed blue-shift (42 $cm^{-1}$ in KBr/60 $cm^{-1}$ in $CH_2Cl_2$) upon oxidation is thus confirmed. The Kohn–Sham molecular orbitals were used for analyzing the electronic structure of our complexes. A stability analysis[14] of the restricted Hartree–Fock wavefunction of **1** showed that it is stable with respect to singlet and triplet instabilities. The $S^2$ value of 0.787 ($S^2$ = 0.75 for a doublet without spin contamination) in the unrestricted Hartree–Fock wave function of $[\mathbf{1}]^+$ does not indicate substantial multi-reference character for both compounds which would render such an analysis questionable. The results of several types of population analyses are summarized in Table 3. Note that the assignment of a charge to an atom within a polyatomic molecule cannot be carried out unambiguously. Different kinds of population analyses therefore will give different answers. It should be mentioned that the Mulliken population analysis[15] in particular is strongly dependent on the basis set and doubtful for an extended basis set, as far as absolute values of charges are concerned. Therefore, the common features of a Mulliken analysis, a natural population analysis (NPA),[16] and of a charge analysis based on generalized atomic polar tensors[17] are extracted. The latter is dependent on the basis set only implicitly by the way of the general quantum-mechanical description.

The oxidation states of iron and nickel (represented by their d occupations) do not change upon oxidation of **1** to $[\mathbf{1}]^+$. They are compatible with the formulation of $Fe^{II}$ and $Ni^{II}$. This is consistent with the observation that only very small structural changes take place when **1** is oxidized to its cation. For example, the iron atom lies 4.95(1) pm above the plane defined by the atoms S1, S2, S1A and S2A in the crystal structure of **1**. Its distance from the plane defined by the atoms S1, S2, S3 and S4 in the crystal structure of $[\mathbf{1}]^+$ is with 4.98(2) pm almost identical, indicating that the iron center is not affected by the oxidation. The computed values for these distances in **1** and $[\mathbf{1}]^+$ coincide with the experimental data. No significant differences of the partial charges on any particular atoms are observed upon oxidation of the cluster. This means that the positive charge in $[\mathbf{1}]^+$ cannot be assigned to individual atoms but is distributed over the whole cluster. What at first seems surprising is the fact that no charge ends up on the metal centers. However, this is in line with the negligible changes in the d level occupation. On the other hand the partial charges on all ligands are increased upon oxidation. Thus, main parts of the positive charge in $[\mathbf{1}]^+$ are residing on the '$S_2$' ligands.

The picture is very different for the spin polarization. As opposed to the positive charge, the unpaired electron is confined to a more restricted region of the molecule. A small negative spin polarization arises at the iron atom, but the main part of the spin polarization is located on the $Ni_2$'$S_2^{Ni}$' fragment of the cluster. About two thirds of the magnetic moment are located on the nickel d orbitals and about one third on the '$S_2^{Ni}$' ligand. Approximately two thirds of the spin polarization on the '$S_2^{Ni}$' ligand are located on the thiolate donor functions. This data can be very nicely visualized by an analysis of the molecular orbitals. Upon oxidation an electron is removed from the HOMO of **1** which has essentially the same form as the SOMO in $[\mathbf{1}]^+$ and is mainly formed from d orbitals on the nickel atoms and p orbitals on the adjacent sulfur atoms (Figure 5). The localization of the unpaired electron at these atoms with a small contribution at the iron atom can be clearly seen from a plot of the spin density of $[\mathbf{1}]^+$ (Figure 6). These findings are consistent with EPR measurements, which have been reported in ref.[11]

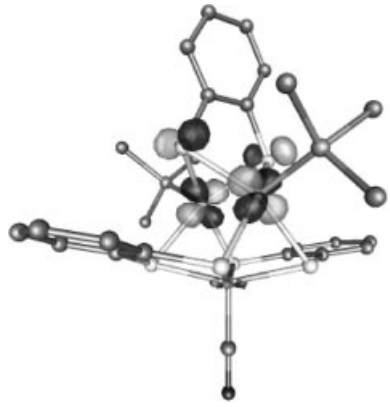

Figure 5. Plot of the highest occupied molecular orbital (HOMO) of **1** (H atoms omitted).

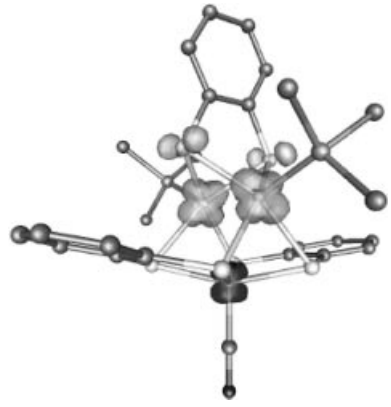

Figure 6. Plot of the spin density in $[\mathbf{1}]^+$ (H atoms omitted).

At first this localization of the spin density on the nickel atoms and the adjacent sulfur atoms seems to be contradictory to the above described delocalization of the positive charge in $[\mathbf{1}]^+$. Things become clear, however, if we imagine the oxidation as a two-step procedure. In the first step an electron is removed from the HOMO, which leaves an *unpaired* electron in an orbital located mainly at the nickel and adjacent sulfur atoms. At the same time the electronic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structure of the complex cation relaxes and a substantial donation of *paired* electrons from the '$S_2$' ligands takes place to compensate for the lack of electrons on the metal centers. Thus, the '$S_2$' ligands serve as a kind of electron density reservoir, which prevent the buildup of positive charge on the nickel atoms upon removal of one electron.

### Constant Potential Coulometry

The cyclic voltammogram of **1** (given in ref.[11]) exhibits three quasi-reversible one-electron waves at –1.071, –0.095, and 0.844 V relative to NHE, which are assigned to the redox couples $\mathbf{1}^{0/-}$, $\mathbf{1}^{0/+}$, and $\mathbf{1}^{+/2+}$, respectively.[11] The potential of the second wave lies within the range which has been observed for several [NiFe] hydrogenase redox reactions.[3c,5d] In addition, the small difference in the X-ray structure parameters of **1** and $[\mathbf{1}]^+$ suggests that the electron transfer should be quite fast as a result of a low reorganization barrier. This exciting result prompted us to check the ability of **1** in catalyzing the reduction of $H^+$ to $H_2$ by constant potential coulometry. A solution of 3.2 mmol of $HBF_4$ in $CH_2Cl_2$ was electrolyzed in the presence of 0.1 mmol of **1** by a platinum electrode at –0.48 V relative to NHE for 2 h. Interestingly, the number of coulombs increases with time (Figure 7). $H_2$ gas evolution was observed during the electrolysis. Samples of the gas phase were taken at 0, 1 and 2 h of electrolysis, and the amount of the formation of $H_2$ was estimated by gas chromatography. After the end of 1 and 2 h of electrolysis $0.09 \pm 0.004$ and $0.15 \pm 0.004$ mmol of $H_2$ was detected, respectively. When the electrolysis was performed under identical conditions but in the absence of the complex, the number of coulombs did not increase with time and no $H_2$ formation was observed. The IR spectrum of the electrolyzed solution exhibited the CO band at 1917 $cm^{-1}$, which confirmed that the CO molecule did not dissociate during electrolysis. These results suggest that complex **1** is capable of mediating the reaction. But, the amount of charge transferred is nearly twice as high as the corresponding amount of $H_2$ produced, which indicates that some side reaction takes place. Nevertheless, **1** seems to be the first [NiFe] complex that mediates the reduction of protons to $H_2$ at a very mild reduction potential. Efforts are needed to optimize the coulometric experimental conditions.

The exact site of **1** where the proton initially interacts and is reduced to $H_2$ is not yet been understood. The reaction may either be preceded via an initial formation of a protonated thiolate species or via a $Ni^{III}$–H like intermediate.[18] According to the DFT studies on **1** and $[\mathbf{1}]^+$, an initial formation of a protonated thiolate species (at the nickel centers) is fairly reasonable, because the HOMO has also a large amplitude on the thiolate donor atoms adjacent to the nickel atoms. Furthermore, a considerable part of the spin density of the oxidized cluster is located on these atoms.

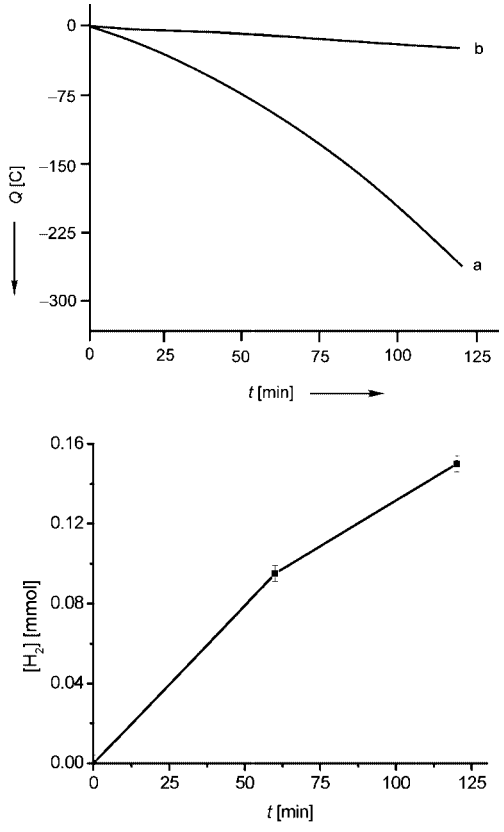

Figure 7. Top: plot of number of coulombs vs. electrolysis time in the presence (a) and in the absence (b) of complex **1**. Bottom: plot of mmols of $H_2$ produced per mmol of **1** vs. electrolysis time.

## Conclusions

The formation of **1** from the reaction between $[Fe(CO)_2('S_3')]_2$ and $[Ni(PMe_3)_2('S_2')]$ was not understood up to now. Through the synthesis of a silylated precursor $[Fe(CO)_2(^{si}S_3)]_2$ (**2**), an earlier observation of the formation of **1** from $[Fe(CO)_2('S_3')]_2$ and $[Ni(PMe_3)_2('S_2')]$ is now understood to be a ligand exchange process. Based on this result, an alternative route for the synthesis of **1** in a one-pot reaction has been developed. The reported trinuclear [NiFe] complex **1** readily reduces protons to $H_2$ and in turn undergoes oxidation to form $[\mathbf{1}]^+$. DFT calculations suggest that the oxidation states of the metal centers are $Fe^{II}$ and $Ni^{II}$ and do not change upon oxidation of **1** to $[\mathbf{1}]^+$. The unpaired electron in $[\mathbf{1}]^+$ is located to a large extent on the nickel atoms and the adjacent thiolate donor functions. The charge, however, is distributed over the whole cluster and main parts reside on the '$S_2$' ligands. These results are compatible with the protonation of a thiolate group as a first step of the reduction mechanism. Preliminary constant potential coulometric results indicate that the trinuclear model complex has catalytic activity for proton reduction under mild potential.

## Experimental Section

**General:** Unless noted otherwise, all manipulations were carried out in absolute solvents under exclusion of air using standard Schlenk techniques. IR spectra of solutions were recorded in $CaF_2$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cuvettes with compensation of the solvent bands, and solids were measured as KBr pellets. NMR spectra were recorded at room temperature and chemical shifts are quoted in $\delta$ scale (downfield shifts positive) with the residual signals of the deuterated solvent used as an internal reference. Mass spectra were measured in the field desorption (FD) or fast atom bombardment (FAB) mode. Physical measurements were carried out with the following instruments: IR: Perkin–Elmer 983, Perkin–Elmer 1600 FTIR, and Perkin–Elmer 16PC FTIR; NMR: JEOL FT-JNM-GX 270, Lambda LA 400. MS: JEOL MSTATION 700. Constant Potential Coulometry: Experiments were performed on Autolab Potentiostat/Galvanostat equipped with a personal computer. A coulometric cell assembly consisting of a Pt-gauge working electrode, a platinum wire counter electrode, and a 1 M SCE reference electrode was used. The reference and counter electrodes were separated from the experimental solution by a glass frit. This closed cell assembly (total cell volume of 310 mL) provides with a probe for sampling. This was fitted with a rubber septum and the gas samples were taken before, during, and at the end of the electrolysis. The amount of $H_2$ gas produced during electrolysis was detected by gas chromatography. The compounds 1,2-Benzenedithiol ('$S_2$'–$H_2$),[19] [Fe(bda)$(CO)_3$],[20] $PMe_3$,[21] bis(2-mercapto-3-trimethylsilylphenyl) sulfide(2–) ($^{si}S_3$–$H_2$),[22] and $(NMe_4)_2$[Fe$(CO)_2$('$S_2$')$_2$][13] were prepared according the literature methods.

**[Fe$(CO)_2$($^{si}S_3$)]$_2$ (2):** All manipulations were carried out under CO atmosphere. To a solution of [Fe(bda)$(CO)_3$] (716 mg, 2.503 mmol) in THF (5 mL) a solution of $^{si}S_3$–$H_2$ (974 mg, 2.473 mmol) in THF (5 mL) was added. A gas evolution was observed and the solution color changed to dark-green. This solution was kept at 20 °C. The black green microcrystal that formed after 15 d, were separated from the mother liquor and dried with a stream of CO. Yield: 250 mg (17.5%); $C_{40}H_{48}Fe_2O_4S_6Si_4$·2THF (1153.46): calcd. C 49.98, H 5.59, S 16.68; found C 50.43, H 5.93, S 16.67. IR (KBr): $\tilde{\nu}$ = 2029, 1988 (CO) cm$^{-1}$. Due to the lability of **2** in solution, NMR spectra that were readily analyzed could not be obtained.

**[('$S_2$')$_2$Ni$(PMe_3)$}$_2$Fe(CO)('$S_2$')$_2$] (1) Starting from 2:** A THF suspension (30 mL) of a mixture of **2** (630 mg, 0.624 mmol) and [Ni$(PMe_3)_2$('$S_2$')] (436 mg, 1.220 mmol) was stirred at 60 °C for 4 h. During the course of time, the suspension changed to a clear dark-red solution. This was filtered, and treated with MeOH (240 mL). Black-grey microcrystals precipitated, were removed after 24 h, washed with MeOH (15 mL) and dried in vacuo. Yield: 90 mg (19%). IR (KBr): $\tilde{\nu}$ = 1910 (CO) cm$^{-1}$. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1916 (CO) cm$^{-1}$. $^1$H NMR (269.6 MHz, $CD_2Cl_2$): $\delta$ = 7.33 (m, 4 H, $C_6H_4$), 6.81 (m, 4 H, $C_6H_4$), 6.67 (m, 2 H, $C_6H_4$), 6.33 (m, 2 H, $C_6H_4$), 1.97 (s, 18 H, $PC_3H_9$) ppm. $^{13}$C{$^1$H} NMR (100.4 MHz, $CD_2Cl_2$): $\delta$ = 207.3 (CO), 146.7, 131.0, 130.3, 125.2, 123.4, ($C_6H_4$), 18.2 ($PMe_3$) ppm. $^{31}$P{$^1$H} NMR (161.7 MHz, $CD_2Cl_2$): $\delta$ = 214.6 ($PMe_3$) ppm. $C_{25}H_{30}FeNi_2OP_2S_6$ (744.09): calcd. C 38.79, H 3.91, S 24.85; found C 38.54, H 3.82, S 24.80.

**Alternative Synthesis of 1:** To a suspension of $FeCl_2$·$4H_2O$ (200 mg, 1.001 mmol) in THF (10 mL) a solution of '$S_2$'–$H_2$ (0.23 mL, 2.001 mmol) and BuLi (2.5 M in *n*-hexane, 1.61 mL, 4.025 mmol) in THF (10 mL) was added. The resulting red solution was treated with $PMe_3$ (0.21 mL, 2.04 mmol) and then with a solution of $Ni(BF_4)_2$·$6H_2O$ (684 mg, 2.001 mmol) in THF (15 mL). To this mixture again a solution of '$S_2$'–$H_2$ (0.12 mL, 1.046 mmol) and BuLi (2.5 M in *n*-hexane, 0.81 mL, 2.025 mmol) in THF (10 mL) was added. A slurry was formed, to this, additional THF (75 mL) was added. Then the Schlenk tube was fitted with a septum. CO gas (60 mL, 2.68 mmol) was allowed to diffuse slowly into the mixture, and the solution was stirred vigorously at 20 °C for 15 h. During the course, the suspension was changed to a clear solution, which was stirred again at 60 °C for 4 h. Half of the solvent was evaporated, the solution was filtered and MeOH (140 mL) was added. Black-grey microcrystals formed, were filtered, washed with MeOH (25 mL) and dried in vacuo. Yield: 140 mg (18%). Characterization: similar as above.

**Density Functional Theory (DFT) Calculations:** The DFT modules of the program package Turbomole[23] were used and the BP86 exchange-correlation functional[24] with a triple-zeta valence-polarized Gaussian basis set[25] was employed for all calculations. The resolution of identity (RI) technique[26] was employed to accelerate the calculations. The natural population analysis (NPA) [16] was done with Gaussian98[27] employing the Kohn–Sham molecular orbitals obtained from the Turbomole calculations. The program gOpenmol[28] was used for the visualizations (Figure 5 and Figure 6). All structures were fully optimized and characterized as true minima on the potential energy hypersurface by means of a vibrational analysis. Accurately converged SCF results (a termination threshold of at least $10^{-8}$ a.u. for the total energy) were used to guarantee satisfactory accuracy in the force constant calculations. The force constants were obtained as numerical first derivatives of the analytical energy gradients as implemented in the parallel PVM code SNF.[29]

**Constant Potential Coulometry:** In a typical experiment, a coulometric cell (320 mL capacity) containing a solution of **1** (80 mg, 0.103 mmol) in $CH_2Cl_2$ (100 mL), $HBF_4$ (54% solution in $Et_2O$, 5 mL, 3.2 mmol) and $NBu_4PF_6$ (3.874 g, 10 mmol) was electrolyzed at –0.15 V vs. 0.1 M SCE for 2 h (25 μL gas samples were taken from the cell at every hour intervals) and the formation of $H_2$ gas was analyzed by GC (TC detector, retention time: 0.733 s). An identical experiment without **1** was also performed.

**X-Ray Structure Determination of [Fe$(CO)_2$($^{si}S_3$)]$_2$·2THF (2·2THF) and [Fe(CO)($^{si}S_3$)]$_2$·3THF (3·3THF):** Suitable single crystals were embedded in protective perfluoro polyether oil. Data were collected at 100 K on a Bruker–Nonius KappaCCD diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 71.073 pm), and a graphite monochromator. A numerical absorption correction was applied.[30] for **2**·2THF, while for **3**·3THF a semiempirical absorption correction based on multiple scans was performed (SADABS).[31] The structures were solved by direct methods; full-matrix least-squares refinement was carried out on $F^2$ using SHELXTL NT 6.12.[32] All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were geometrically positioned; their isotropic displacement parameters were tied to those of their corresponding carrier atoms by a factor of 1.2 or 1.5. In the case of **3**·3THF there is pseudosymmetry which emulates a *Pccn* unit cell, but is not fully supported by the diffraction pattern which is consistent with the correct space group $P2_12_12$. The Flack parameter of approx. 0.5 suggests a centrosymmetric space group, though. A solution of the structure in *Pccn* is possible, but the subsequent refinement results in a dramatical increase of all *R*-values and estimated standard deviations. Therefore, the presence of an inversion twin is the best explanation and consistent with the experimental data. One of the three THF solvent molecules present in the asymmetric unit is disordered on two different crystallographic twofold axes. This disordered solvent molecule has been refined using constraints and no hydrogen atoms have been introduced for it. Selected crystallographic data are summarized in Table 4.

CCDC-608118 and -608119 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Mutual Influences of Ligands as Revealed by $^2$H NMR Shifts and the Angular Overlap Model Parameters: *trans*- and *cis*-[$CrX_2(N)_4$]-Type Complexes with Aliphatic Amine Ligands[‡]

**Yukiko Yamaguchi-Terasaki,[a] Takashi Fujihara,[b] and Sumio Kaizaki*[c]**

**Keywords:** Chromium complexes / Ligand effects / N ligands / NMR spectroscopy / Angular overlap model parameters

We have previously reported the relationship between $^2$H NMR chemical shift differences ($\Delta\delta$) and the angular overlap model (AOM) parameter $e_\sigma$(F), which represents the σ antibonding interaction energy obtained from the solvatochromism, for *trans*-[$CrF_2$([$D_4$]-3,2,3-tet)]$^{n+}$ {[$D_4$]3,2,3-tet = 1,10-diamino-4,7-diazadecane [$NH_2(CH_2)_3NH(CD_2)_2NH(CH_2)_3NH_2$]} and *cis*-α-[$CrF_2$([$D_4$]trien)]$^{n+}$ {[$D_4$]trien = triethylenetetraamine [$NH_2(CH_2)_2NH(CD_2)_2NH(CH_2)_2NH_2$]}. In analogy to these relations, the co-ligand effect on the $\Delta\delta$ values for *cis*-α-[$CrX_2$([$D_4$]trien)]$^{n+}$ and *trans*-[$CrX_2$([$D_4$]3,2,3-tet)]$^{n+}$ is found to be well correlated with the reported $e_\sigma$(X) values for the co-ligands X. This is the first example of the co-ligand effect, or a mutual influence of ligands, associated with variation of the Cr–N and Cr–X bonds in *cis*- and *trans*-[$CrX_2N_4$]-type complexes. This $\Delta\delta$ vs. $e_\sigma$(X) correlation offers an indirect method for estimating the $e_\sigma$(X) values for didentate $X_2$ as well as monodentate X ligands from the $^2$H NMR chemical shifts and ranking them in the two-dimensional spectrochemical series. Plots of $\Delta\delta$ vs. $e_\sigma$(FX) for *trans*-[CrF(X)-([$D_4$]3,2,3-tet)]$^{n+}$ do not necessarily lie on the $\Delta\delta$ vs. $e_\sigma$(X) correlation line for the F(X) complexes with averaged $e_\sigma$(FX) = 1/2[$e_\sigma$(X) + $e_\sigma$(F)] values − $e_\sigma$[F(CN)] is close to $e_\sigma$(F), for example − thereby demonstrating a mutual influence between the $CN^-$ and $F^-$ ligands in the *trans* positions through a push-pull action or π donor–acceptor interaction.

## Introduction

The mutual influence between ligands is one of the fundamental subjects in coordination chemistry since it governs the relative changes in properties upon replacement of one ligand by another.[1] General regularities in mutual influences for SP-4 platinum(II) complexes have been established, such as the *trans* influence, but for OC-6 mixed-ligand complexes they are limited to some *trans*-[$MX_2N_4$]-type complexes where negative correlations have been found between the axial M–X and the basal M–N bond lengths both theoretically and experimentally by X-ray analysis and UV/Vis spectroscopy.[1–5] For example, Bertini et al.[2] and Lever et al.[3] have established negative linear correlations between Ni–N bond lengths and 10 Dq(N) or angular overlap model (AOM) parameter $e_\sigma$(N) values, which represent the σ antibonding energy parameter, for some *trans*-[$NiX_2N_4$] complexes, while Busch et al. have shown that the axial ligand field parameter [10 $Dq^z$(X)] decreases as the basal (in-plane) ligand field parameter [10 $Dq^{xy}$(N)] increases, which they termed the "electronic *cis* effect".[4] Ito et al. have studied this phenomenon extensively using the X-ray structural parameters of a series of $Co^{III}$, $Ni^{II}$, and $Zn^{II}$ macrocyclic tetraamine complexes[5] and a theoretical examination of the relationship between the softness of metal ions in terms of ab initio MO calculations.[6] They found that the lengthening of the average basal M–N bonds on going from smaller to larger macrocyclic tetraamine rings is associated systematically with a shortening of the axial M–NCS or M–Cl bonds and an increase of the overlap population of M–NCS or M–Cl.[6] We have also demonstrated an analogous bond-length variation from solvatochromism and solvent-dependent NMR spectroscopy for the aliphatic amine difluoridochromium(III) complexes *trans*-[$CrF_2$([$D_4$]3,2,3-tet)] {[$D_4$]3,2,3-tet = 1,10-diamino-4,7-diazadecane [$NH_2(CH_2)_3NH(CD_2)_2NH(CH_2)_3NH_2$]} and *cis*-α-[$CrF_2$([$D_4$]trien)]$^+$ {[$D_4$]trien = triethylenetetraamine [$NH_2(CH_2)_2NH(CD_2)_2NH(CH_2)_2NH_2$]}, or their aromatic amine analogs, as well as the amino polycarboxylato $Cr^{III}$ or $Co^{III}$ complexes in terms of the AOM parametrization.[7–11] We also found a negative correlation between the $^2$H NMR shift differences, $\Delta\delta$, and the σ donor AOM parameters $e_\sigma$(X) and $e_\sigma$(N) of the ligands X and N, which manifests itself as an electronic *cis* effect, or a mutual influ-

ence of ligands, for *trans*-[$CrX_2$([$D_4$]3,2,3-tet)].[7] Such a $\Delta\delta$ vs. $e_\sigma$(X) correlation should also be present in *cis*-α-[$CrX_2$([$D_4$]trien)]$^+$ in view of the solvatochromism and solvent-dependent NMR behavior of the corresponding fluorido complex, although no mutual influence has ever been found for *cis*-[$CrX_2N_4$]-type complexes on the basis of X-ray structural data or spectroscopic methods. This could provide a convenient and indirect means of estimating the AOM parameter values for didentate as well as monodentate ligands or for ranking them in the two-dimensional spectrochemical series.[12,13] Furthermore, it may offer the possibility of clarifying numerical ambiguities[14,15] in the AOM parameter values and allow the elucidation of chemical properties in the ground or excited states relevant to the thermodynamics or kinetics of thermal or photochemical reactions.[15] Another mutual influence or compensation due to the π donor–acceptor interaction of X–M–Y systems in a *trans* disposition has been theoretically claimed by Burdett,[16] although no such example has been reported so far. Such a mutual influence is expected to be found by examining the solvent-dependent $^2$H NMR spectra of *trans*-[CrF(CN)([$D_4$]3,2,3-tet)]$^+$.

Herein we will explore the mutual influence of ligands by studying the correlation of the $^2$H NMR shifts and AOM parameters of the X co-ligands in *cis*-α-[$CrX_2$([$D_4$]trien)]$^{n+}$ and *trans*-[CrF(X)([$D_4$]3,2,3-tet)]$^{n+}$ and redefining the solvatochromism and $^2$H NMR spectra of *trans*-[Cr(F or X)$_2$-([$D_4$]3,2,3-tet)]$^{n+}$.

## Results and Discussion

### $^2$H NMR Chemical Shifts and AOM Parametrization for *trans*-[$CrX_2$([$D_4$]3,2,3-tet)]$^{n+}$

One of the main aims of this paper concerns the *cis* effect, or the mutual influence of ligands in low symmetry, of *cis*-α-[$CrX_2$([$D_4$]trien)]$^+$ complexes by examining their $^2$H NMR chemical shifts and AOM parametrization. Prior to this, however, the $^2$H NMR spectra of high-symmetry *trans*-[$CrF_2$(3,2,3-tet)]$^+$ and *trans*-[$CrX_2$(3,2,3-tet)]$^+$ will be reviewed and re-examined.

As shown in Figure 1, two well-separated $^2$H NMR signals are observed due to paramagnetic isotropic contact shifts for inequivalent (axial and equatorial) deuterons in the ethylene backbone of *trans*-[$CrF_2$(3,2,3-tet)]$^+$ (inset of Figure 1) in water. The $^2$H NMR chemical shift differences ($\Delta\delta$) are well correlated with each of the $^4B_2$ and $^4A_2$ tetragonal splitting components in the ligand-field d–d transition region as well as the solvent acceptor number ($A_N$) according to the equation $\Delta\delta = 0.409\,A_N + 66.3$ [correlation coefficient ($r$) = 0.99]. This correlation of $\Delta\delta$ with $A_N$ has been interpreted by a Karplus-like or $\cos^2\theta$ relation for the paramagnetic contact shifts of $Cr^{III}$ complexes according to the following equation:[7] $\Delta\delta = -(3^{1/2}/2)(C{\cdot}A)\sin2\phi$, where $C$ is a constant that varies reciprocally with absolute temperature, $A$ is the hyperfine constant for the spin density of deuterons, and φ is the torsion angle of the Cr–N–C–C chain of the ethylene backbone in 3,2,3-tet. Since a plot of $\Delta\delta$ vs. inverse temperature ($1/T$) gives a constant value, $\Delta\delta$ is proportional to the spin density of the deuterons concerned, although, in view of the temperature-independent nature of sin2φ, there is no conformational change in 3,2,3-tet. In other words the increase of $\Delta\delta$ reflects the increase of the deuteron spin density of C–D or the Cr–N σ-bond interaction energy [$e_\sigma$(N)], which is followed by a decrease in the Cr–F σ-bond interaction energy [$e_\sigma$(F)], associated with an attack of the stronger electron-acceptor solvents on the fluorido ligands.[7] Evaluation of $e_\sigma$(N) and $e_\sigma$(F) values obtained from the tetragonal components of the UV/Vis ligand-field bands was revised by using the appropriate Racah parameter $B$ and involving the configurational interaction between the $^4A_2$ ($^4T_1{}^a$) and $^4A_2$ ($^4T_1{}^b$) states.[7] The revised correlations between the AOM parameters and the NMR shift difference $\Delta\delta$ are $e_\sigma(N_c) = 0.013\,\Delta\delta + 6.02$, where $N_c$ is the amine nitrogen *cis* to the fluorido ligands, and $e_\sigma(F) = -0.048\,\Delta\delta + 11.0$.[17]

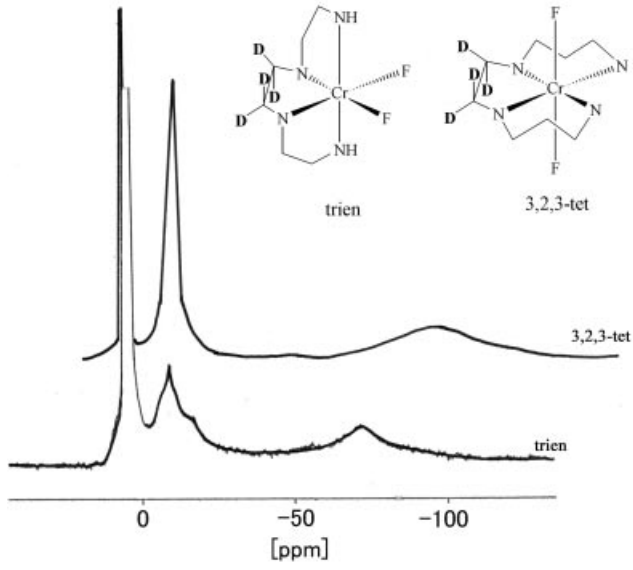

Figure 1. $^2$H NMR spectra of *trans*-[$CrF_2$([$D_4$]3,2,3-tet)]$^+$ and *cis*-α-[$CrF_2$([$D_4$]trien)]$^+$ in dmf at 26 °C. The inset shows the structures of the 3,2,3-tet and trien complexes.

In an analogous manner to the difluorido complex, we also examined whether there is a linear correlation between $\Delta\delta$ and $e_\sigma$(N) or $e_\sigma$(X) for *trans*-[$CrX_2$([$D_4$]3,2,3-tet)]$^{n+}$ complexes. The $^2$H NMR spectrum of *trans*-[$CrF_2$([$D_4$]-3,2,3-tet)]$^+$ in dmf at 26 °C is shown in Figure 1 and Table 1 gives the shift differences ($\Delta\delta$) together with the AOM parameter values for the $X_2$ complexes. We re-examined the previously reported relationship between $^2$H NMR $\Delta\delta$ and $e_\sigma$(X) values by replacing the appropriate $e_\sigma$(X) values for $F^-$, $H_2O$, $NH_3$, and $Br^-$ (Table 1). This gave a slightly better correlation ($r$ = 0.97) for plots of $\Delta\delta$ vs. $e_\sigma$(X) values (Table 1) than obtained previously ($r$ = 0.95),[7] as summarized in Table 1 and shown in Figure 2. However, this should not be over-estimated in view of the ranges of estimated $e_\sigma$(X) values for some ligands, which depend on the complexes used or the estimation methods.[15] Furthermore, $\Delta\delta$ is also correlated with the $e_\sigma$(N) values obtained from

the $^4B_2(^4T_1)$ component [$E = 3e_\sigma(N)$] observed for some $[CrX_2(3,2,3\text{-tet})]^{n+}$ complexes, as reported previously,[7] where the least-squares calculation for the correlation was incorrectly made. In fact, the $e_\sigma(X)$ values decrease and the $e_\sigma(N)$ ones increase with increasing $\Delta\delta$, as shown in Figure 2, which leads to Equations (1) and (2) (in units of $10^3$ cm$^{-1}$).

Table 1. AOM parameter values and $^2$H NMR chemical shift differences for *trans*-$[CrX_2(3,2,3\text{-tet})]^{n+}$ in $H_2O$.

[a] Calculated from Equations (1–3), see text.

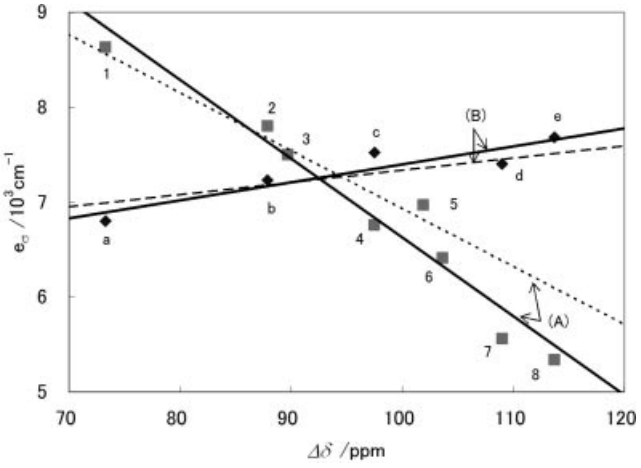

Figure 2. Plots of the AOM parameter values $e_\sigma(X)$ vs. the $^2$H NMR shift difference ($\Delta\delta$) in $H_2O$ for *trans*-$[Cr(X)_2(3,2,3\text{-tet})]^{n+}$ (——). (A): 1–8: $e_\sigma(X)$ values taken from the literature (see text and Table 1); (B) a–d: $e_\sigma(N)$ values obtained from the aqueous absorption data ($^4B_2$ component). 1/a: $(OH)_2$; 2/b: $F_2$; 3: $(CN)_2$; 4: $(NH_3)_2$; 5: $(H_2O)_2$; 6: $(NCS)_2$; 7/c: $Cl_2$; 8/d: $Br_2$. The solid lines are least-squares fits. The dotted lines in (A) and (B) are calculated from $e_\sigma(N_c) = 0.013\Delta\delta + 6.02$ (6) and the solid lines from $e_\sigma(F) = -0.048\Delta\delta + 11.0$ (7) for the difluorido complex [see Equations (f) and (g) in ref.[17]].

$$e_\sigma(X) = -0.083\,\Delta\delta + 14.9 \quad (r = 0.97) \tag{1}$$

$$e_\sigma(N) = 0.019\,\Delta\delta + 5.50 \quad (r = 0.92) \tag{2}$$

Combining these two equations leads to Equation (3).

$$e_\sigma(X) = -4.37\,e_\sigma(N) + 38.9 \tag{3}$$

The slope and intercept of Equation (3) are similar to those of the revised equation $e_\sigma(F) = -3.67\,e_\sigma(N) + 33.1$ (8) [see also caption of Figure 2 and Equation (h) in ref.[17]] for the difluorido complex discussed in ref.[17] It is possible that the change of $e_\sigma(F)$ or $e_\sigma(X)$ can vary 3–4 times as much as $e_\sigma(N)$ since the Cr–F or Cr–X bond is influenced by four *cis*(basal N) ligands, in analogy to the ligand effect reported by Burdett et al.[16] and Timney.[23] The $e_\sigma(X)$ vs. $e_\sigma(N)$ correlation for the $X_2$ complexes is parallel to the $e_\sigma(F)$ vs. $e_\sigma(N)$ correlation for the difluorido complex.[7] This means that a mutual influence between the axial X ligands and the basal amine ligands occurs through the σ-bond interactions in a compensatory way according to the electronic *cis* effect as a result of a cooperative charge redistribution due to the electroneutrality principle through the σ bonds. This σ bond pathway gives more definite and clearer physical meaning to the negative correlation between the axial-basal bond length than the ligand-field parameter 10 Dq (Δ) values consisting of $e_\sigma$ and $e_\pi$ [10 Dq (Δ) = $3e_\sigma - 4e_\pi$] for which correlations between the axial and basal ligands have been claimed for several tetragonal $[MX_2Y_4]$-type complexes.[2–6] The change of $e_\sigma(N)$ associated with the variation of $e_\sigma(X)$ indicates the invalidity of transferring the AOM parameters from one complex to another.

The $e_\sigma[F(X)]$ values for the heteroligand complexes *trans*-$[CrF(X)(3,2,3\text{-tet})]^{n+}$ (X = $NH_3$, $CN^-$, $Cl^-$, $Br^-$) were estimated from the observed $^2$H NMR shift difference ($\Delta\delta$) according to Equation (3). These $e_\sigma(FX)$ values were compared with the average $e_\sigma(FX)$ value $[e_\sigma(F) + e_\sigma(X)]/2$ obtained by assuming holohedralized symmetry, as shown in Table 2. The estimated $e_\sigma(FX)$ values calculated from the $\Delta\delta$ values deviate from the average values by 1.6–9.7%, although the increasing order is not necessarily in line with the predicted one given in Table 2.

Table 2. AOM parameter values and $^2$H NMR chemical shift differences for *trans*-$[CrF(X)(3,2,3\text{-tet})]^{n+}$ in $H_2O$.

| X | $\Delta\delta$ [ppm] | $e_\sigma(FX)$ (est.) [$10^3$ cm$^{-1}$] | $e_\sigma(FX)$ (av.) [$10^3$ cm$^{-1}$] | Error $[e_\sigma(est.) - e_\sigma(av.)]/e_\sigma(av.)$ |
|---|---|---|---|---|
| CN | 86.2 | 7.78 | 7.65 | 0.016 |
| Cl | 93.2 | 7.19 | 6.68 | 0.077 |
| Br | 93.0 | 7.20 | 6.57 | 0.097 |
| $NH_3$ | 98.2 | 6.77 | 7.39 | –0.083 |
| OH | 72.7 | 8.89 | 8.22 | 0.082 |
| $H_2O$ | 95.7 | 6.98 | 7.70 | –0.092 |

The solvent-dependent $^2$H NMR shift behavior for the FX complexes demonstrates a fairly linear correlation of the $\Delta\delta$ values with $A_N$, as shown in Figure 3. Moreover, the least-squares lines for the plots of $\Delta\delta$ vs. $A_N$ lie roughly between those of the $F_2$ and $X_2$ complexes, except for the F(CN) complex (see below). This fact indicates the additivity of the σ interaction as well as the selective solvation, which affects the energies of the d orbitals that point towards the axial ligands in the FX complexes in the same way as in the $F_2$ complex.

For the F(CN) complex, the solvent-dependent NMR shift differences ($\Delta\delta$) tend to deviate from the average values with decreasing solvent acceptor number ($A_N$) and lie closer to those for the $F_2$ complex than the average of the $F_2$ and $(CN)_2$ complexes, as shown in Figure 3. This may be due to a mutual influence through the push-pull action[24] or an additional *trans* influence between the π-donor $F^-$ and π-acceptor $CN^-$ ligands similar to that found for the aromatic amine complexes.[8,25] The larger the σ donor or $e_\sigma(F)$ and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

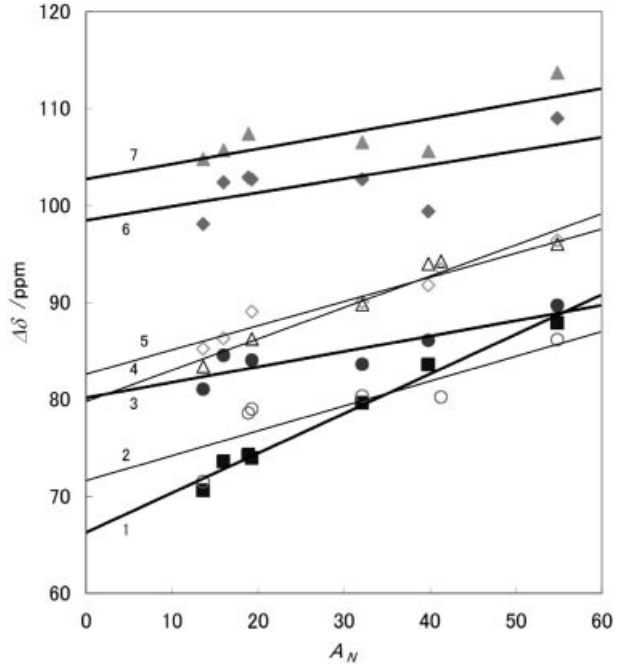

Figure 3. Plots of the $^2$H NMR shift differences ($\Delta\delta$) vs. the acceptor numbers $A_N$ for *trans*-[$CrX_2$(3,2,3-tet)]$^+$. 1: $F_2$; 2: F(CN); 3: $(CN)_2$; 4: F(Cl); 5: F(Br); 6: $Cl_2$; 7: $Br_2$.

the larger the π donor or $|e_\pi(F)|$, then the larger the π acceptor or $e_\pi(CN)$ becomes by the push-pull action, which leads to a smaller $e_\sigma(CN)$ due to the relationship $\Delta = 3e_\sigma(CN) - 4e_\pi(CN)$. The $e_\sigma(F)$ and $e_\sigma(CN)$ values in the F(CN) complex are larger and smaller by $\delta e_\sigma(F)$ and $\delta e_\sigma(CN)$, respectively, than those in the $F_2$ and $(CN)_2$ complexes. The additional parts $\delta e_\sigma(F)$ and $\delta e_\sigma(CN)$ may also be elucidated on the basis of the AOM approach including the quartic terms of Burdett et al.,[16] which gives $\delta e_\sigma(F) \propto e_\sigma(F)[e_\sigma(F) - e_\sigma(CN)]$ and $\delta e_\sigma(CN) \propto e_\sigma(CN)[e_\sigma(CN) - e_\sigma(F)]$. As $e_\sigma(F)$ is larger than $e_\sigma(CN)$, and since the difference $e_\sigma(F) - e_\sigma(CN)$ increases for the $F_2$ and $(CN)_2$ complexes with decreasing $A_N$, $e_\sigma$[F(CN)] is predicted to become closer to that of $e_\sigma(F)$,[26] as found for the solvent-dependent $^2$H NMR spectra (Figure 3). This mutual influence between $F^-$ and $CN^-$ is in accordance with the interpretation for the unusual photochemical reactivity of *trans*-[CrF(CN)$(NH_3)_4$]$^+$.[27] It follows, however, that the additive ligand-field or holohedralized symmetry assumption[13] may not always be confirmed for the F(CN) complex.

### $^2$H NMR Chemical Shifts and AOM Parametrization for *cis*-α-[$CrX_2$([$D_4$]trien)]$^{n+}$

Two well-separated $^2$H NMR signals are observed for *cis*-α-[$CrX_2$([$D_4$]trien)]$^{n+}$, similarly to the *trans*-3,2,3-tet complexes (Figure 1). The chemical shift difference ($\Delta\delta$) values are summarized in Table 3. A plot of $\Delta\delta$ vs. $e_\sigma(X)$ gives a fairly linear correlation for the reported $e_\sigma(X)$ values of the monodentate ligands together with that of the didentate dianionic oxalato ligand (Table 3 and Figure 4). This correlation gives Equation (4).

Table 3. AOM parameter values and $^2$H NMR chemical shift differences for *cis*-α-[$CrX_2$([$D_4$]trien)]$^{n+}$.

| $X_2$ | $\Delta\delta$ [ppm] | $e_\sigma(X)$ [$10^3$ cm$^{-1}$][a] |
|---|---|---|
| $F_2$ | 62.9 | 7.80[18] |
| $Cl_2$ | 85.6 | 5.56[19] |
| $(NCS)_2$ | 80.6 | 6.41[20] |
| $(OH)_2$ | 57.3 | 8.63[19] |
| $(H_2O)_2$ | 70.3 | 6.76[13] |
| ox | 78.3 | 6.75[28] |

[a] Calculated from Equation (4).

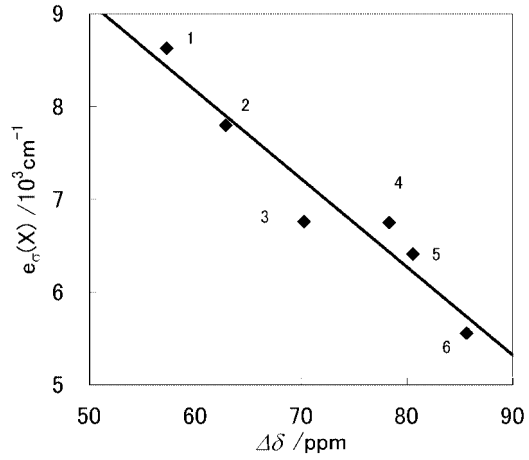

Figure 4. Plots of the AOM parameter values vs. the $^2$H NMR shift difference ($\Delta\delta$) for *cis*-α-[$CrX_2$(trien)]$^{n+}$ in water. 1: $OH^-$; 2: $F^-$; 3: $H_2O$, 4: oxalato$^{2-}$; 5: $NCS^-$; 6: $Cl^-$.

$$e_\sigma(X) = -0.095\Delta\delta + 13.90 \ (r = 0.96) \quad (4)$$

The slope and intercept of this equation are not very different from those of Equation (1) for the *trans*-[$CrX_2$(3,2,3-tet)]$^+$ complexes, which suggests that the variation of $\Delta\delta$ with $e_\sigma(X)$ for the *cis* complexes has the same cause as for the *trans* complexes.

Equation (4) could therefore be used to provide $e_\sigma(X)$ values for didentate and monodentate ligands from the $^2$H NMR shift difference for the deuterated trien complexes. The $e_\sigma$ value for the acac complex [$e_\sigma$(acac)], for example, was estimated from its $\Delta\delta$ value to be 6770 cm$^{-1}$ which is smaller than that (7400–7700 cm$^{-1}$) obtained spectroscopically and by AOM calculations for [Cr(acac)$_3$].[28a] This may be due to the different number of acac ligands in the tris(acac) and mono(acac) complexes as the spin-forbidden transition energy of [Cr(acac)$(en)_2$]$^{2+}$[29] is larger than that of [Cr(acac)$_2$(en)]$^+$[29] and [Cr(acac)$_3$][30] – the mono(acac) complex is less covalent than the tris- and bis(acac) complexes.

## Conclusions

The mutual influence of ligands for both *trans*- and *cis*-[$CrX_2(N)_4$] complexes of aliphatic amines behaves in a fundamentally similar manner to the solvent-dependence of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

AOM parameter $e_\sigma$(F) and the $^2$H NMR chemical-shift difference $\Delta\delta$ in *trans*- and *cis*-[$CrF_2(N)_4$]-type complexes. In view of this significant correlation, the $\Delta\delta$ values are an indicator of the relative strength of the Cr–N and Cr–X σ-bonds: the smaller the $e_\sigma$(N), the larger the $e_\sigma$(X). This suggests that the transferability assumption from one complex to another[13] is invalid for both $e_\sigma$(X) and $e_\sigma$(N).

In general, the AOM parameters have been evaluated by a conventional procedure that involves fitting the absorption bands in the spin-allowed ligand-field d–d transitions to the calculated energy levels by varying the AOM parameter values,[13,18–22] which requires the correct assignment of the well-resolved ligand-field band components. However, the spin-allowed ligand-field bands of most *trans*- and *cis*-[$CrX_2N_4$]-type complexes exhibit poorly defined or no splitting into degenerate or nondegenerate components, except for a limited number of complexes such as *trans*-difluorido tetraamine complexes. Thus, the positions of the absorption bands have to be resolved into their Gaussian components by curve deconvolution techniques for most complexes. This often produces uncertainties in the AOM parameter estimations. The present procedure for estimating the AOM parameters overcomes this major disadvantage of the conventional direct method even though preparation of the deuterated ligands is a tedious process. In addition, this method can be applied to complexes whose ligand-field bands cannot be observed due to overlapping with intraligand transitions of spectroscopically nontransparent ligands or with MLCT bands in the ligand-field band region, as found for complexes of the nitroxide radical.[31]

Once the $e_\sigma$(X) values have been obtained from Equations (1) or (4), the Cr–X π-bond interaction or $e_\pi$(X) parameter values can be estimated from the relation of the available ligand-field parameter $\Delta(X) = 10\,Dq(X) = 3e_\sigma(X) - 4e_\pi(X)$ by substituting the appropriate $e_\sigma$(X) values. Both $e_\sigma$(X) and $e_\pi$(X) for the ligands can then be positioned in the two-dimensional spectrochemical series, which is distinguished from the traditional spectrochemical series by the straightforward reflection of the ground-state electronic properties. Thus, the present complexes *trans*-[$CrX_2$([$D_4$]3,2,3-tet)]$^{n+}$ and *cis*-α-[$CrX_2$([$D_4$]trien)]$^{n+}$ can be used as reference complexes for ranking the two-dimensional spectrochemical series.

The additive nature of the ligand field for *trans*-[CrF(X)(3,2,3-tet)]$^{n+}$, is mostly validated for the FCl and FBr complexes but not for the F(CN) complex, which demonstrates a mutual influence between F and CN through a push-pull action or a donor–acceptor π mutual compensation.

## Experimental Section

### Preparation of the 3,2,3-tet Complexes

***trans*-[CrF($H_2O$)(3,2,3-tet)]($ClO_4$)$_2$:** *trans*-[$CrF_2$(3,2,3-tet)]($ClO_4$)[7] (1.0 g) was stirred with 5 mL of perchloric acid (70%) at 30 °C overnight.[32] The resultant orange crystals were filtered, then washed with acetone and diethyl ether and dried in air. Yield: 52.7%. $C_8H_{24}Cl_2CrFN_4O_9$ (462.20): calcd. C 20.79, H 5.23, N 12.12; found C 20.85, H 5.30, N 12.06.

***trans*-[CrF(X)(3,2,3-tet)]$ClO_4$ (X = Cl, Br):** A mixture of *trans*-[CrF($H_2O$)(3,2,3-tet)]($ClO_4$)$_2$ (0.5 g) and an excess of $NH_4X$ (X = Cl, Br; 0.5 g) was refluxed in methanol at 70 °C for 45 min. The color of the solution turned from orange to red and powdery complexes were obtained after filtration and drying. Yields for the Cl and Br complexes were about 70%. $C_8H_{22}Cl_2CrFN_4O_4$ (380.18): calcd. C 25.27, H 5.83, N 14.74; found C 25.39, H 5.94, N 14.64. $C_8H_{22}BrClCrFN_4O_4$ (424.64): calcd. C 22.63, H 5.22, N 13.19; found. C 22.71, H 5.30, N 13.13.

***trans*-[CrF($NH_3$)(3,2,3-tet)]($ClO_4$)$_2$:** *trans*-[CrBr(F)(3,2,3-tet)]$ClO_4$ was treated with an excess of liquid ammonia in a pressure tube at 0 °C for 2 h. The ammonia was then evaporated at atmospheric pressure at room temperature to give an orange powder. This was recrystallized by adding sodium perchlorate to the aqueous solution. Yield was about 60%. $C_8H_{25}Cl_2CrFN_5O_8$ (461.21): calcd. C 20.83, H 5.46, N 15.19; found C 21.21, H 5.56, N 15.29.

***trans*-[CrF(CN)(3,2,3-tet)]$BPh_4$·0.46$NaBPh_4$·3$H_2O$:** *trans*-[CrF($H_2O$)(3,2,3-tet)]($ClO_4$)$_2$ (0.76 g) was dissolved in 10 mL of DMSO. Sodium cyanide (0.1 g) was added to this solution and the mixture was heated to 140 °C. The solution was then cooled to room temperature and the desired complex was eluted on a column of Sephadex C-25 using 0.1 M sodium bromide solution as the eluent. A small amount of the starting complex remained on the top of the column. The first eluate was collected by filtration and was desalted by condensation a few times. The desired complex precipitated upon addition of sodium tetraphenylborate to the aqueous solution. $C_{44.02}H_{57.2}B_{1.46}CrFN_5Na_{0.46}O_3$ (801.99): calcd. for C 65.96, H 7.19, N 8.73; found C 65.25, H 7.23, N 8.85.

### Preparation of the [$D_4$]3,2,3-tet Complexes

Deuterated [$D_4$]3,2,3-tet was prepared by a previously reported method.[7] The [$D_4$]3,2,3-tet complexes were prepared by the same methods as the corresponding 3,2,3-tet complexes.

### Preparation of the trien Complexes

***cis*-α-[$CrF_2$(trien)]$ClO_4$:** This complex was prepared by a literature method.[33]

*cis*-α-[$CrCl_2$(trien)]Cl, *cis*-α-[$Cr(NCS)_2$(trien)]Cl, and *cis*-α-[Cr(ox)(trien)]$ClO_4$ were also prepared by literature methods.[34]

***cis*-α-[Cr(acac)(trien)]($PF_6$)$_2$:** Acetylacetone (1.0 g) was added to 100 mL of an aqueous solution of *cis*-α-[$CrCl_2$(trien)]Cl (3.3 g). The solution was then neutralized with 1 M NaOH solution, and the mixture was heated in a water bath for 60 min. The color of the solution changed from violet to red. The desired complex was separated by column chromatography on SP-Sephadex $Na^+$ with 0.2 M sodium chloride solution as eluent. The sodium chloride in the eluate was removed by condensation. The $PF_6$ salt was obtained by adding $NaPF_6$ to the aqueous solution. $C_{11}H_{25}CrF_{12}N_4O_2P_2$ (587.27): calcd. C 22.50, H 4.29, N 9.54; found C 22.48, H 4.31, N 9.52.

**Deuteriation of [$D_4$]trien and Its Complexes:** Deuteriated triethylenetetraamine ([$D_4$]trien = $NH_2CH_2CH_2NHCD_2CD_2NHCH_2CH_2NH_2$) was prepared by a previously reported method.[8] The product was used without purification. The [$D_4$]trien complexes were prepared by the same methods as the trien complexes.

**Measurements:** UV/Vis spectra in solution were measured with a Shimazu UV-2100 and/or a Hitachi UV-330 spectrophotometer. $^2$H NMR spectra were measured with a Jeol JMN GX-400 and/or a JEOL JMN GSX-270 spectrometer at 26 °C for products in 2 mM

[17] In ref.[7] the correlation coefficients with the solvatochromism were recalculated by using the newly re-measured UV/Vis spectroscopic data. They are $E(^4B_2) = 0.016A_N + 20.7$ (a) and $E(^4A_2) = -0.034A_N + 30.3$ (b), $\Delta\delta = 0.409A_N + 66.34$ (c). These lead to the following relations: $e_\sigma(N) = E(^4B_2)/3 = 0.0054A_N + 6.90$ (d) and $e_\sigma(F) = -0.020A_N + 7.80$ (e). Equation (e) is obtained by including the configurational interaction between $^4A_2(^4T_2{}^a)$ and $^4A_2(^4T_2{}^b)$ with more appropriate Racah parameter B (650 $cm^{-1}$) than the previous one (460 $cm^{-1}$) by using the observed relation $e_\sigma(N) = E(^4B_2)/3$. Accordingly, Eqs. (c)–(e) give $e_\sigma(N_c) = 0.013\Delta\delta + 6.02$ (f) and $e_\sigma(F) = -0.048\Delta\delta + 11.0$ (g), and Eqs. (f) and (g) give $e_\sigma(F) = -3.67e_\sigma(N_c) + 33.1$ (h). These revisions do not materially alter the discussion.

# Mutual Influences of Ligands as Revealed by the $^2$H NMR Chemical Shifts and the Angular Overlap Model Parameters: *cis*-$[CrX_2(N)_4]$ and *fac*-$[CrX_3(N)_3]$-Type Complexes with Aromatic Amines[‡]

**Yukiko Terasaki,[a] Takashi Fujihara,[b] and Sumio Kaizaki*[c]**

**Keywords:** Chromium complexes / Ligand effects / N ligands / NMR spectroscopy / Angular overlap model parameters

A mutual influence of ligands through a π donor–acceptor interaction is found by examining how the X co-ligands of the aromatic amine complexes *cis*-$[CrX_2([D_4]bpy)_2]^{n+}$ (bpy = 2,2′-bipyridine) and *fac*-$[CrX_3([D_{12}]tpa)]^{n+}$ [tpa = tris(2-pyridyl)amine] affect the $^2$H NMR chemical shifts in connection with the Angular Overlap Model (AOM) parameterization in an analogous manner to our previous study on the solvatochromism and solvent-dependent $^2$H NMR spectra of *cis*-$[CrF_2([D_4]bpy)_2]^+$ and *fac*-$[CrF_3([D_{12}]tpa)]$. The ranking of the AOM parameter for monodentate and/or didentate ligands can be obtained from this co-ligand effect only from the $^2$H NMR shifts. The postulated relative order in the two-dimensional spectrochemical series is $Cl^- > Br^-$ > O or N donors ($mal^{2-} > acac^-$ or $H_2O$ > dmf > $NCS^-$) for the aromatic amine complexes, which contrasts with the order O or N donors > $Cl^- > Br^-$ for the aliphatic amine complexes(see the preceding paper in this issue). This fact suggests that the Cr–Cl and Cr–Br σ bonds are stronger in the soft acidic aromatic amine complexes than those in the hard acidic aliphatic amine complexes. This means they have a higher affinity for soft basic $Cl^-$ and $Br^-$ ligands and can be explained in terms of the hard/soft acid/base (HSAB) concept.

## Introduction

In the preceding paper in this issue[1] we found a linear correlation between the Angular Overlap Model (AOM) parameter $e_\sigma(X)$ for the X co-ligands and the $^2$H NMR chemical shift differences ($\Delta\delta$) for the aliphatic amine complexes *trans*-$[CrX_2([D_4]3,2,3\text{-tet})]^{n+}$ {[D$_4$]3,2,3-tet = 1,10-diamino-4,7-diazadecane $[NH_2(CH_2)_3NH(CD_2)_2NH(CH_2)_3NH_2]$}, and *cis*-$[CrX_2([D_4]trien)]^{n+}$ {[D$_4$]trien = triethylenetetramine $[NH_2(CH_2)_2NH(CD_2)_2NH(CH_2)_2NH_2]$}, which demonstrates a mutual influence between the amine and X ligands. This is based on the fact that the $e_\sigma(X)$ vs. $\Delta\delta$ relation is parallel to the $e_\sigma(F)$ vs. $\Delta\delta$ relation, with a variation of the solvent acceptor number ($A_N$), in the *trans*- and *cis*-$[CrF_2(N)_4]$ complexes. As a result, we devised a more convenient method for estimating the AOM parameter values, even for didentate ligands, which allows them to be positioned in the two-dimensional spectrochemical series. On the other hand, the solvatochromism and solvent-dependent $^2$H NMR spectra of the aromatic amine complexes *cis*-$[CrF_2([D_4]bpy)_2]^+$ (bpy = 2,2′-bipyridine)[2] and *fac*-$[CrF_3([D_{12}]tpa)_3]$ [tpa = tris(2-pyridyl)amine][3] have revealed more direct and clearer evidence for a mutual F–Cr–N(aromatic amine) influence due to the strong Cr–N π acceptor and Cr–F π donor properties in terms of the AOM parametrization, as has been found for the NC–Cr–F bond in *trans*-$[CrF(CN)(3,2,3\text{-tet})]^+$.[1] In an analogous manner to this solvent-dependent spectroscopic behavior for the fluorido aromatic amine complexes as well as the co-ligand effect for *trans*- and *cis*-$[CrX_2(N)_4]$ complexes with aliphatic amines (see ref.[1]), the mutual influence between X ligands and the aromatic amine in *cis*-$[CrX_2([D_4]bpy)_2]^{n+}$ and *fac*-$[CrX_3([D_{12}]tpa)_3]$ is expected to be revealed by examining the $^2$H NMR chemical shifts in terms of the AOM parameterization.

In this paper, the $^2$H NMR chemical shifts of *cis*-$[CrX_2([D_4]bpy)_2]^{n+}$ and *fac*-$[CrX_3([D_{12}]tpa)]^{n+}$ will be explored in terms of the AOM parameterization of the X co-ligands. This could provide a qualitative ranking of the two-dimensional spectrochemical series[4] for the AOM parameters of the co-ligand X in the aromatic amine complexes, which would shed light on how the coordination bond properties differ from each upon replacing the co-ligands and also how they differ from those in the aliphatic amine complexes.

## Results and Discussion

### 2,2′-Bipyridine(bpy) Complexes {*cis*-[Cr($F_2$ or $X_2$)(bpy)$_2$]$^+$}

Of the four $^2$H NMR signals of *cis*-[$CrF_2$([$D_4$]bpy)$_2$]$^+$ shown in Figure 1, the signal at around $\delta$ = –25 ppm for the deuteron at the 4 (*para*)-position and that at around $\delta$ = 30 ppm for the deuteron at the 5 (*meta*)-position of the pyridyl ring of bpy *trans* to F increase and decrease in absolute shift values, respectively, upon increasing the solvent acceptor number ($A_N$), as reported previously.[2] This change is also correlated to the AOM parameter $e_\sigma(N_t)$ ($N_t$ denotes the nitrogen of the pyridyl ring *trans* to F) in terms of the ligand-field band analysis on the basis of a fairly large $A_N$-dependence of the first ligand-field ($^4A_{2g}$-$^4T_{2g}$) band.[2] In other words, the $e_\sigma(N_t)$ and $e_\pi(N_t)$ values change with variation of $A_N$, as shown by the right ordinate and upper abscissa, respectively, in Figure 2,[2] which suggests that the solvent-dependent behavior of the chemical shifts of $\delta$(4) and $\delta$(5) reflects the variation of the Cr–N σ- and π-bond properties, respectively, in the bpy complex: the larger the acceptor number $A_N$, the smaller the $e_\sigma$(F) and $e_\pi$(F) values or the weaker the Cr–F σ and π bonds, and also the larger the $e_\sigma(N_t)$ value or the stronger the Cr–$N_t$ σ bond, the smaller the $|e_\pi(N_t)|$ value or the stronger the Cr–$N_t$ π acceptor bond. This relationship demonstrates the mutual compensation between Cr–N and Cr–F σ and π bonds. The mutual compensation of $e_\pi(N_t)$ and $e_\pi$(F) in *cis*-[$CrF_2$-(bpy)$_2$]$^+$ is confirmed by the solvatochromic shift behavior from the $^2E(^2E_g)$ to $^2E(^2T_{1g})$ emitter in a mixture of dmf and water in solvents with smaller $A_N$ with increasing dmf fraction,[5] as also observed for *trans*-[$CrF_2$(py)$_4$]$^+$.[2] The $^2E(^2T_{1g})$ emitter, or the lowest excited $^2E(^2T_{1g})$ state, results from a lowering, by $\Delta(t_{2g})^2/[E(^2t_{2g}) - E(^2T_{1g})]$, of the large configurational interaction between the $^2E(^2T_{1g})$ and $^2E(^2T_{2g})$ states due to an increase in [$\Delta(t_{2g}) = e_\pi$(F) + $|e_\pi(N_t)|$] caused by the push-pull action between the Cr–F and Cr–N bonds in solvents with smaller $A_N$. This mutual influence is also supported by the Cr–F and Cr–N bond lengths in *cis*-[$CrF_2$(bpy)$_2$]$ClO_4$, where our recent X-ray analysis revealed that the Cr–N bonds *trans* to F [Cr–N2 2.0680(13), Cr–N3 2.0842(14) Å] are significantly longer than those *trans* to another bpy nitrogen atom [Cr–N1 2.0480(14), Cr–N4 2.0511(14) Å].[6]

The four $^2$H NMR signals observed for the 4-,5- and 4′-,5′-deuterons in the *cis*-[$CrX_2$([$D_4$]bpy)$_2$]$^{n+}$ complexes are assigned to two inequivalent deuterons of the pyridyl rings *trans* [$\delta$(4) and $\delta$(5)] and *cis* [$\delta$(4′) and $\delta$(5′)] to the X ligand in analogy to those for the corresponding difluorido complex [$\delta(4) > \delta(4')$ and $\delta(5) > \delta(5')$], as shown in Figure 1. The NMR spectroscopic data are summarized in Table 1.

A plot of $\delta$(4) vs. $\delta$(5) gives the following well-defined linear correlation for the X complexes in water: $-\delta(4) = -1.91\delta(5) + 83.7$ ($r$ = 0.98).

This correlation is similar to that for *cis*-[$CrF_2$([$D_4$]-bpy)$_2$]$^+$ [$-\delta(4) = -1.45\delta(5) + 68.65$ ($r$ = 0.99)], as shown in Figure 2. Since there is no direct method for correlating the ligand-field band with the $^2$H NMR chemical shift for *cis*-

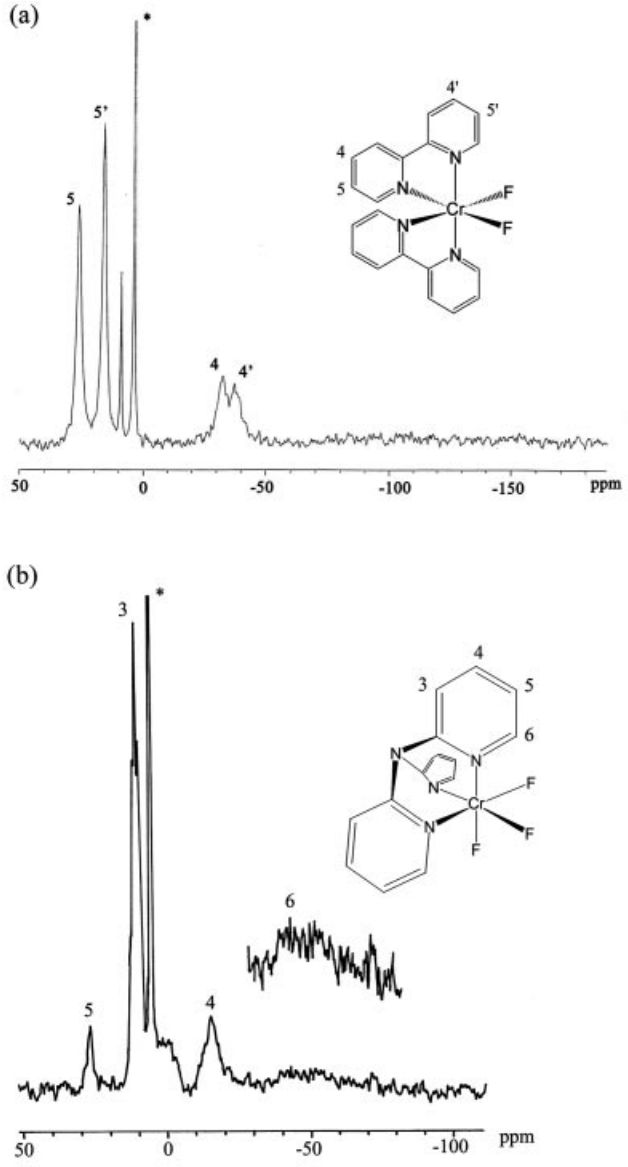

Figure 1. $^2$H NMR spectra of [$CrF_2$([$D_4$]bpy)$_2$]$^+$ in formamide (a) and [$CrF_3$([$D_{12}$]tpa)] in dmf (b). The insets show the structures with the positions of the deuterons used for assignment of the NMR signals labeled. The asterisks indicate solvent signals.

[$CrX_2$(bpy)$_2$]$^{n+}$ complexes, however, the scales for the $e_\sigma(N_t)$ and $e_\pi(N_t)$ values in Figure 2 are not necessarily useful for estimating the AOM parameters. Assuming that the variation of $e_\sigma$(X) results in change in the $e_\sigma$(N) values similar to that found for the aliphatic amine complexes,[1] the increase in $\delta$(4) and the decrease in $\delta$(5) should be associated with the increase in $e_\sigma(N_t)$ and the decrease in $e_\pi(N_t)$, respectively, as a result of the decrease in $e_\sigma$(X) in a manner analogous to that for *cis*-[$CrF_2$([$D_4$]bpy)$_2$]$^+$. The co-ligand dependence of the $^2$H NMR chemical shifts for the bpy complexes shows that $\delta$(4) or $e_\sigma(N_t)$ increase in the order $F^- < Cl^- < Br^- < mal^{2-} < acac^- <$ dmf in dmf and $Cl^- < Br^- < F^- < mal^{2-} < acac^-$ < dmf in $H_2O$, thereby reflecting the increasing order of the Cr–N σ-bond interaction energy or $e_\sigma(N_t)$. Likewise, the decreasing order of $\delta$(4) corre-

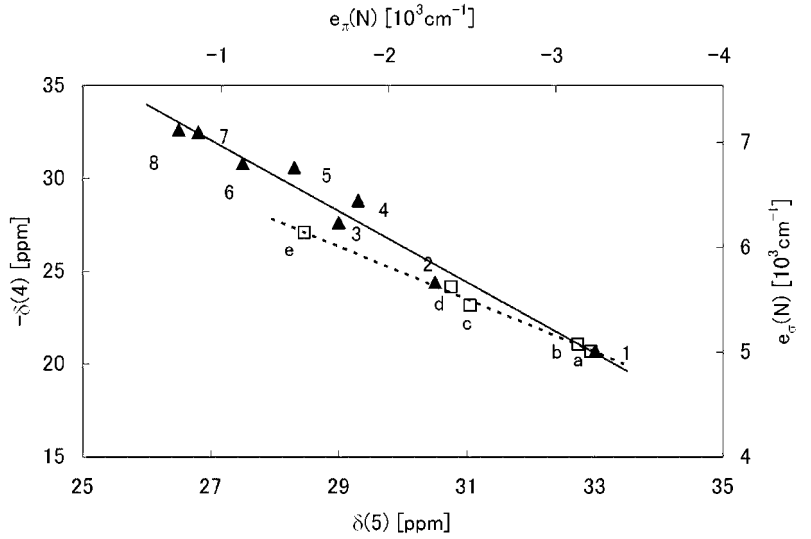

Figure 2. Plots of the $^2$H NMR chemical shifts of the deuterons in the 4- and 5-positions of *cis*-$[CrF_2([D_4]bpy)_2]^+$ (□) in dmf (a), dmso (b), nmf (c), fa (d), and water (e) and for *cis*-$[CrX_2([D_4]bpy)_2]^{n+}$ (▲) [X = F (1), Cl (2), Br (3), mal (4), acac (5), acaCl (6), acaBr (7), and dmf (8)]. The lines shown are the least-squares fit. The right ordinate and upper abscissa show the $e_\sigma(N_t)$ and $e_\pi(N_t)$ values, respectively, for *cis*-$[CrF_2(bpy)_2]^+$.

Table 1. $^2$H NMR chemical shifts (δ values, ppm) of *cis*-$[CrX_2([D_4]bpy)_2]^{n+}$.

| $X_2$ | Chemical shift[a] | |
|---|---|---|
| | $-\delta(4)$ | $\delta(5)$ |
| $F_2$ | 20.7 | 33.0 |
| $Cl_2$ | 24.4 | 30.5 |
| $Br_2$ | 27.6 | 29.0 |
| acac | 30.6 | 28.3 |
| $(dmf)_2$ | 32.6 | 26.5 |
| mal | 28.8 | 29.3 |
| acaCl | 30.8 | 27.5 |
| acaBr | 32.5 | 26.8 |

[a] $-\delta(4) = -1.91\delta(5) + 83.7$ ($r = 0.98$).

sponds to that of $e_\sigma$(X), namely $F^- > Cl^- > Br^- > mal^{2-} > acac^- >$ dmf in dmf and $Cl^- > Br^- > F^- > mal^{2-} > acac^- >$ dmf in water. This order is similar to the rank of the two-dimensional spectrochemical series for $e_\sigma$(X),[1,4,9–11] excluding $Cl^-$ and $Br^-$, rather than the rank for $e_\pi$(X), in other words the Cr–X σ-bond properties or $e_\sigma$(X) are correlated directly with the variation of $e_\sigma(N_t)$ and $e_\pi(N_t)$. Thus, the $^2$H NMR chemical shifts provide a method for evaluating the rank of the AOM parameter $e_\sigma$(X) in the two-dimensional spectrochemical series.

Like the aliphatic amine complex *cis*-α-$[CrX_2([D_4]-trien)]^{n+}$, the bpy complexes are able to provide some information about the as-yet unknown ranking of the AOM parameters even for the didentate ligands. Thus, the $^2$H NMR spectroscopic data of *cis*-$[Cr([D_4]bpy)_2(acaX)]^{2+}$ complexes (X = Cl, Br) containing didentate ligands were examined by plotting $\delta(4)$ vs. $\delta(5)$. As compared with the $-\delta(4)$ or $e_\sigma$(N) values for the acetylacetonate analogues, the Cr–O(acaX) σ bond is a little weaker than the Cr–O(acac) σ bond, although the covalency in Cr–O(acaX) is estimated to be larger than that in Cr–O(acac), as inferred from the nephelauxetic effect estimated from the lowest ligand-field doublet ($^2E_g$) position by the emission for $[Cr(acaX)_3]$[7] and circular dichroism for (+)-$[Cr(acaX)_2(en)]^+$.[8] This may result from a difference in co-ligands between bpy and acac or en (ethylenediamine) and/or in the number of acac ligands as found in the aliphatic amine (acac) complexes.[1]

It should be noted that the rank of $e_\sigma$(X) in the two-dimensional spectrochemical series for the bpy complexes is $F^- > Cl^- > Br^-$ > oxygen donors ($mal^{2-} > acac^-$ > dmf) in dmf and $Cl^- > Br^-$ > oxygen donors ($mal^{2-} > acac^-$ > dmf) > $F^-$ in water, as suggested from the order of $-\delta(4)$. This is contrast to the order of the AOM parameters ($OH^- > F^- > CN^- > NH_3 > NCS^- > H_2O > Cl^- > Br^-$) of 3,2,3-tet and trien complexes.[1,4,9–11] This difference will be discussed in connection with the case of the tpa complexes.

### Tris(2-pyridyl)amine (tpa) Complexes

As shown in Figure 1, *fac*-$[CrF_3([D_{12}]tpa)]$ exhibits four $^2$H NMR signals. A pair of signals at the 4 (*para*)- and 3 (*meta*)-positions is found to demonstrate a linear correlation with variation of $A_N$, as shown in Figure 3 and represented by $-\delta(4) = -4.00\delta(3) + 63.6$ ($r = 0.90$). Such a solvent-dependent NMR behavior is related to the significant solvatochromism observed: the AOM parameters $e_\sigma$(N) and $e_\pi$(N) associated with variation of the Cr–F σ-donor interaction, or $e_\sigma$(F), are evaluated by considering a large trigonal splitting due to the unusual anisotropic π interaction in the ligand-field ($^4T_2$–$^4A_2$) transition.[3]

In analogy to this correlation, *fac*-$[CrX_3([D_{12}]tpa)]$ complexes exhibit a linear relation between the $^2$H NMR chemical shifts of the deuterons at positions 4 ($\delta \approx -20$ ppm) and 5 ($\delta \approx 20$ ppm) with change of X, as shown in Figure 3; the NMR spectroscopic data are summarized in Table 2. In the case of the $X_3$ complexes, $\delta(4)$ is linearly correlated with $\delta(5)$ but not with $\delta(3)$, which gives $-\delta(4) = -2.05\delta(5) + 66.1$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

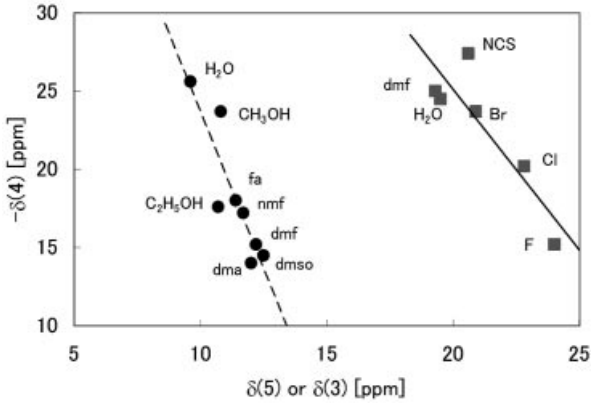

Figure 3. Plots of the $^2$H NMR chemical shifts for the deuterons in the 4- and 3-positions of *fac*-[$CrF_3$([$D_{12}$]tpa)] (●) and the deuterons in the 4- and 5-positions of *fac*-[$CrX_3$([$D_{12}$]tpa)]$^{n+}$ (■). The lines shown are the least-squares fit.

($r$ = 0.88). Although the reason for the discrepancy between $\delta$(3) and $\delta$(5) on going from the F complex to the X complexes is not clear so far, the same situation is encountered, in an electronic sense, for *fac*-[$CrX_3$([$D_{12}$]tpa)]$^{n+}$ as for the fluorido complex, since both 3- and 5-$^2$H of the pyridyl groups in tpa are located at the *meta* position, which makes it likely that the relation between $\delta$(3) and $\delta$(5) in Figure 3 reflects a similar co-ligand dependence on the $e_\sigma$(N) and $e_\pi$(N) values to that found for the bpy complexes (vide supra). This parallel correlation between the F and X complexes means that the variation of $e_\sigma$(X) must be associated with a change of $e_\sigma$(N) and $e_\pi$(N) values. Thus, the variation of $\delta$(4) with change of X ligands corresponds to the changes of the Cr–N σ-bond properties, or $e_\sigma$(N), for *fac*-[$CrX_3$(tpa)]$^{n+}$; the $e_\sigma$(N) values increase in the order $F^- < Cl^- < Br^- < H_2O <$ dmf $< NCS^-$ in dmf. On the other hand, the Cr–X σ-bond properties, or $e_\sigma$(X), decrease in the reverse order ($F^- > Cl^- > Br^- > H_2O >$ dmf $> NCS^-$ in dmf). This order is similar to that for the aliphatic amine complexes except that the $e_\sigma$(Cl) and $e_\sigma$(Br) values are larger than those of the $NCS^-$ and O-donor ligands as well as those for the bpy complexes (see above), thereby corresponding to the ranking in the two-dimensional spectrochemical series.

Table 2. $^2$H NMR chemical shifts (δ values, ppm) for *fac*-[$CrX_3$([$D_{12}$]tpa)]$^{n+}$ in dmf.

| X | Chemical shifts[a] | |
|---|---|---|
| | $\delta$(4) | $\delta$(5) |
| F | –15.2 | 24.0 |
| Cl | –20.2 | 22.8 |
| Br | –23.7 | 20.9 |
| dmf | –25.0 | 19.3 |
| $H_2O$ | –24.5 | 19.5 |
| NCS | –27.4 | 20.6 |

[a] $-\delta(4) = -2.05\delta(5) + 66.1$ ($r$ = 0.88).

The difference in ranking of $e_\sigma$(Cl) and $e_\sigma$(Br) in the two-dimensional spectrochemical series between the aliphatic and aromatic amine complexes can be explained as follows. This difference in Cr–X σ bond is related to the symbiosis[12] in terms of the hard/soft acid/base (HSAB) principle.[13] Since the coordination site at {Cr(bpy)$_2$} or {Cr(tpa)} becomes a softer acid due to the π donor–accepter cooperative interaction through the dπ orbital,[13c] the $Cl^-$ and $Br^-$ ligands, which are soft bases, are more favored in the aromatic amine complexes than in the aliphatic amine complexes. The present result may provide a clue to explaining the confusing experimental results whereby the much greater robustness of the Cr–Cl bond towards acid hydrolysis for aromatic amine complexes than for the corresponding aliphatic amine complexes is not necessarily accompanied by an increased thermodynamic stability of $[CrCl_2(bpy)_2]^+$, which is not very different from that of the corresponding ethylenediamine complex.[14–16]

## Conclusions

We have demonstrated that there are significant correlations between the $^2$H NMR chemical shifts $\delta$(4) and $\delta$(5) of the pyridyl deuterons of *cis*-[$CrX_2$([$D_4$]bpy)$_2$]$^{n+}$ and *fac*-[$CrX_3$([$D_{12}$]tpa)]$^{n+}$. These correlations reflect the variation of the AOM parameters with change of the X co-ligands in an analogous manner to the solvent-dependency of the $^2$H NMR chemical shifts of the fluorido complexes *cis*-$[CrF_2([D_4]bpy)_2]^+$ and *fac*-[$CrF_3$([$D_{12}$]tpa)], and is an indicator of the relative strength of $e_\sigma$(X) for certain didentate as well as monodentate X ligands. The ranking of $e_\sigma$(X) of both the bpy and tpa complexes in the two-dimensional spectrochemical series is different from that for complexes of the aliphatic amines 3,2,3-tet and trien, and this difference has been explained on the basis of the bond nature or a symbiosis in terms of the HSAB principle, which may provide a clue to explaining the robustness of the chlorido and bromido aromatic amine complexes.

## Experimental Section

**Preparation:** *cis*-[$CrF_2$(bpy)$_2$]$ClO_4$,[17] *cis*-[$CrCl_2$(bpy)$_2$]$ClO_4$,[16] and *cis*-[$CrBr_2$(bpy)$_2$]$ClO_4$[16] were prepared by literature methods.

***cis*-[Cr(mal)(bpy)$_2$]$ClO_4$:** This complex was obtained from the reaction of an equimolar mixture of *cis*-[$CrCl_2$(bpy)$_2$]$ClO_4$ and sodium malonate in water. The yield was about 50%. $C_{23}H_{18}ClCrN_4O_8$ (565.86): calcd. C 48.82, H 3.21, N 9.90; found C 48.81, H 3.23, N 9.88.

***cis*-[Cr(acac)(bpy)$_2$](ClO$_4$)$_2$:** *cis*-[Cr(OTf)$_2$(bpy)$_2$](OTf) [OTf = trifluoromethanesulfonate ($CF_3SO_3^-$)] was obtained by treating *cis*-[$CrCl_2$(bpy)$_2$]Cl with HOTf according to the method described for *cis*-[Cr(OTf)$_2$(en)$_2$]Cl.[18] This OTf complex was dissolved in methanol together with an equimolar amount of acetylacetone and urea and the solution was refluxed for 1.5 h at 70 °C in a water bath. After cooling, the solvent was removed on a rotary evaporator under reduced pressure. The solution was chromatographed on a SP-Sephadex $Na^+$ column with 0.2 M sodium chloride solution as eluent. The first orange eluate was desalted by concentration. An orange precipitate was obtained by adding sodium perchlorate to the solution. The precipitate was filtered off, washed with ethanol and diethyl ether and air-dried. The precipitate was recrystallized from acetone by adding ethanol. The crystals were washed with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ethanol and diethyl ether and air-dried. The yield was about 9%. $C_{25}H_{23}Cl_2CrN_4O_{10}$ (662.37): calcd. C 45.33, H 3.50, N 8.46; found C 44.89, H 3.45, N 8.52.

***cis*-[Cr(acaCl)(bpy)$_2$](ClO$_4$)$_2$·0.75H$_2$O and *cis*-[Cr(acaBr)(bpy)$_2$](ClO$_4$)$_2$·0.75H$_2$O:** These complexes were prepared by treating $[Cr(acac)(bpy)_2](ClO_4)_2$ with an equimolar amount of the corresponding *N*-halosuccinimide according to the method reported for the 3-haloacetylacetonato complexes $[Cr(acaX)(en)_2]Cl_2$.[19] The yields for the acaCl and acaBr complexes were about 15 and 22%, respectively. $C_{25}H_{23.5}Cl_3CrN_4O_{10.75}$ (710.33): calcd. C 42.27, H 3.34, N 7.89; found C 41.50, H 3.44, N 8.10. $C_{25}H_{23.5}BrCl_2CrN_4O_{10.75}$ (754.78): calcd. C 39.78, H 3.14, N 7.42; found C 38.76, H 2.99, N 7.35.

***fac*-[CrF$_3$(tpa)] and *fac*-[Cr(H$_2$O)$_3$(tpa)](OTf)$_3$:** These complexes were synthesized by the previously reported method.[2,20]

***fac*-[Cr(NCS)$_3$(tpa)]:** A 1:3 mixture of $[Cr(H_2O)_3(tpa)](OTf)_3$ and sodium thiocyanate was refluxed in ethanol for 50 min. After cooling, the red precipitate was filtered off and washed with ethanol, water, and diethyl ether. The yield was about 73%. $C_{18}H_{12}CrN_7S_3$ (474.53): calcd. C 45.56, H 2.55, N 20.66; found C 45.60, H 2.61, N 20.41.

***fac*-[Cr(dmf)$_3$(tpa)] (OTf)$_3$:** This complex was obtained by leaving *fac*-$[Cr(OTf)_3(tpa)]$ to stand overnight in dmf. The color of the solution changed from violet to pink. Diethyl ether was added to this reaction solution to give an oily residue. The supernatant fluid was then decanted off and the residual oil was treated with diethyl ether to give a pink precipitate, which was filtered off, washed with diethyl ether, and air-dried. The yield was about 88%. $C_{27}H_{33}CrF_9N_7O_{12}S_3$ (966.77): calcd. C 33.54, H 3.44, N 10.14; found. C 33.19, H 3.33, N 10.16.

The deuterated bpy and tpa ligands were obtained by a previously reported method.[2,3] The deuterated bpy and tpa complexes were prepared according to the above methods for the corresponding bpy and tpa complexes.

**Measurements:** The $^2$H NMR spectra were recorded with Jeol JMN GX-400 and/or GSX270 spectrometers at 26 °C for 2 mM solutions. External standards of $CDCl_3$ and $(CH_3)_3SiCD_2CD_2CO_2Na$ (TSP) were assigned chemical shifts of $\delta$ = 7.24 and 0.589 ppm, respectively.

# Unusual Magnetic Behavior of a 2D Citrate-Bridged Dysprosium(III) Coordination Polymer

**Feng-Yan Li,[a] Lin Xu,*[a] Guang-Gang Gao,[a] Li-Hua Fan,[a] and Bo Bi[a]**

**Keywords:** Lanthanides / Coordination chemistry / Magnetic properties / Hydrothermal synthesis

A new lanthanide citrate coordination polymer [Dy(citrate)-$(H_2O)]_n$ (**1**) was hydrothermally synthesized and structurally characterized by elemental analyses, single-crystal X-ray diffraction, IR spectroscopy, thermogravimetric analysis, photoluminescence spectrum, and magnetic measurements. The structure of **1** exhibits a 2D layer structure, in which the $Dy_2O_2$ dimer serves as the building block. The photoluminescence spectrum shows blue luminescence in the solid state at room temperature. Owing to the special frustration structure, unusual magnetic relaxation was found in compound **1**.

## Introduction

The current interest in the synthesis of new metal–organic coordination polymers continues to expand in virtue of not only their intriguing variety of architectures, but also their potential applications in many fields, such as catalysis, material science, medicine, and magnetochemistry,[1–4] which may originate either from the metal centers and/or the organic components. Recently, polycarboxylates have been widely used to produce high-nuclearity magnetic clusters.[5–8] Particularly attractive interest is the construction of lanthanide carboxylates, owing to the wide variety of structures and their unique f–f electronic transitions.

Citric acid, a hydroxy tricarboxylic acid, is well known on account of its important role in biosystems. Moreover, it was found to be a versatile ligand in coordination chemistry by virtue of its conformational flexibility, its ability to deprotonate completely or partially, and its diversity in complexing behavior. A large number of metal–citrate compounds have been structurally characterized.[5–11] However, most of the work in this area has focused on the assembly of the d-block metals. By contrast, less work has been done to date on the lanthanide–citrate systems.[12] Additionally, the reported work of the lanthanide–citrates mostly concentrates on their luminescent properties, whereas the rich magnetic properties of lanthanide–citrate have been neglected. To the best of our knowledge, there has been only one reported lanthanide–citrate polymer that was studied with its magnetic properties, in which ferromagnetic exchange interactions were found between the neighboring magnetic centers.[12d] Hence, the citrate ligand could act as an efficient magnetic coupler owing to its diverse bridging modes.

It is well known that in the f-block the Dy compounds generally exhibit novel magnetic properties as well as the Gd, Tb, Ho, and Er complexes. In the Dy cluster compounds reported in the literature, most of them display frequency-dependent, out-of-phase AC signals, magnetization hysteresis loops, or quantum tunneling behavior, such as the triangular dysprosium compound $[Dy_3(\mu_3\text{-}OH)_2L_3Cl_2(H_2O)_4]$ $[Dy_3(\mu_3\text{-}OH)_2L_3Cl(H_2O)_5]Cl_5\cdot 19H_2O$ (HL = *o*-vanillin),[13a] and the dysprosium–manganese cluster $[Dy_6Mn_6(Hshi)_2(shi)_{10}(CH_3OH)_{10}(H_2O)_2]\cdot 9CH_3OH\cdot 8H_2O$ ($H_3$shi = salicylhydroxamic acid).[13b] Also, in the complex $[Mn_{11}Dy_4O_8(OH)_6(OMe)_2(O_2CPh)_{16}(NO_3)_5(H_2O)_3]\cdot$ 15MeCN, magnetization hysteresis loops and quantum tunneling behavior have been observed.[13c] Noting that dysprosium(III) shows manifold magnetic behavior and the aforementioned features of the citrate, we decided to explore the assembly of the Dy–citrate polymer and investigate its magnetic properties, aiming to obtain new compounds with novel magnetic properties.

In this paper, by using hydrothermal synthesis, which has become a convenient technique for the preparation of a wide range of organic–inorganic hybrid materials, we successfully prepared a lanthanide citrate complex: [Dy-(citrate)$(H_2O)]_n$, which exhibits a 2D layer structure, in which the $Dy_2O_2$ dimer serves as the building block. Weak antiferromagnetic interactions were found between the Dy ions in the layer. With an applied magnetic field, unusual magnetic relaxation was observed owing to the frustration structure.

## Results and Discussion

### Description of the Crystal Structure

Single-crystal X-ray analysis revealed that complex **1** crystallizes in the monoclinic space group *C*2/*c*. In compound **1**, there is one crystallographically independent $Dy^{III}$ ion. The Dy ion has a nine-coordinate environment, seven of which are occupied by seven carboxylate oxygen atoms from four citrate ions, and the other two sites are occupied by one hydroxy oxygen of the citrate ion and one water molecule oxygen. The O4 and O8 atoms from one β-carboxylate are bonded in a chelated mode. Also, the ligand has a tridentate coordination mode and binds through one *α*-carboxylate (O3), one β-carboxylate (O7), and the *α*-hydroxy (O1) oxygen atoms (see Figure 1). The adjacent $Dy^{III}$ ions are edge-shared through O(7) and O($7^{\#2}$), resulting in the formation of a $Dy_2O_2$ dimer (see Figure S1); the dinuclear $Dy_2O_2$ units are firstly linked by the central carboxylate of the citrate to form a ladder chain, and then the ladder chains are additionally bridged into a 2D layer structure by the terminal carboxylate of the citrate (see Figure 2). The adjacent layers are parallel and stack along the *c* axis without interpenetration, leading to a 3D framework by the H-bond interactions. (Figures S2 and S3).

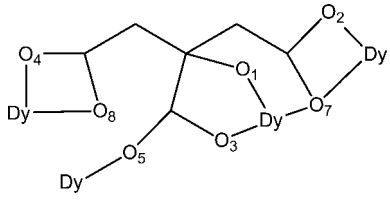

Figure 1. Structure of compound **1**.

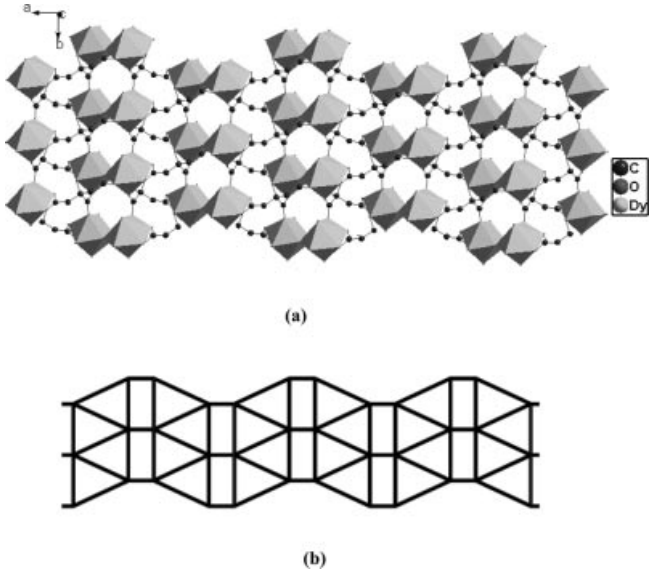

Figure 2. (a) 2D layer structure of compound **1** (viewed along the *c* axis). (b) A schematic illustration of the 2D layer structure.

Among the reported Ln–citrate series, $[Ln(Hcit)(H_2O)]_n$, Ln = La,[12a] Nd,[12b] the chains are bound together by covalent bonds with the citrate ligands, leading to 3D structures. When Ln = Gd, Nd,[12d] and with a relatively low temperature (100 °C) hydrothermal reaction, 1D chain structures are obtained. Whereas when Ln = Dy (this work), Eu, and Tb,[12c] 2D structure coordination polymers are formed. The versatile structures owe to the high coordination number of lanthanide ions and the flexible coordination geometry of citrate ligands.

In compound **1**, each $Dy^{III}$ is coordinated to three symmetry-related citrate ligands whereas each citrate ion is coordinated to four $Dy^{III}$ ions. The Dy–O bond lengths are in the range 2.321(2)–2.608(3) Å with an average of 2.423 Å and the closest distance between two neighboring Dy ions [bridged by $\mu_2$-O(7)] is 4.104 Å (see Figure S1), which is shorter than that in $[Eu(citrate)(H_2O)]_n$[12c] (Eu–Eu: 4.162 Å) and $[Gd(Hcit)(H_2O)_2{\cdot}H_2O]$[12d] (Gd–Gd: 4.321 Å). Within the *ab* plane, square and triangle grids arrange alternately with Dy–Dy separations of 4.104, 6.076, and 6.619 Å (see Figure S4), which can be viewed as geometrically frustration system. Considering that the frustration structure will influence the orientation of the electron spin, we are interested with the magnetic behavior of compound **1**, and the magnetic study of compound **1** was carried out.

### Magnetic Properties

Magnetic measurements were performed on a crystalline sample confined within a gelatin capsule under a field of 1 kOe in the temperature range 2–300 K. A plot of $\chi_m T$ vs. *T* is shown in Figure S5. The $\chi_m T$ value at room temperature is ca. 14.55 emu K mol$^{-1}$ [closed to the expected value for one $Dy^{3+}$ ($S$ = 5/2, $L$ = 5, $^6H_{15/2}$) of 14.18 emu K mol$^{-1}$], which decreases smoothly with decreasing temperature, reaching a minimum value of 13.45 emu K mol$^{-1}$ at 12 K. With a further decrease in the temperature, $\chi_m T$ increases sharply, reaching a maximum value of 14.98 emu K mol$^{-1}$at 2.0 K. The thermal variation of $\chi_m T$ mainly depends on the populations of the Stark levels and on the possible antiferromagnetic or ferromagnetic interactions between the two $Dy^{III}$ ions. It is well known that by interelectronic repulsion and spin-orbit coupling, the $4f^n$ configuration of a $Ln^{III}$ ion is split into $^{2S+1}L_J$ states. The crystal-field perturbation further leads to the splitting into Stark components. At room temperature, all the Stark levels of the 16-fold degenerate $^6H_{15/2}$ ground states are populated. While the temperature decreases, a gradual depopulation of these levels takes place.[14a] Therefore, in order to elucidate the magnetic properties, the field dependence of the $\chi_m T$ product of **1** (Figure S6) was also measured in the range 2–30 K except for the data of thermal dependence at 1 kOe of the $\chi_m T$ product (Figure S5). When the field is less and equal to 10 kOe, the $\chi_m T$ value slightly increases below 5 K, suggesting the occurrence of a weak ferromagnetic interaction arising from $Dy_2O_2$ dimers (Figure S1). When the magnetic field is stronger than 20 kOe the $\chi_m T$ value decreases, which results from the field saturation effect. Because of the presence of the large unquenched orbital angular momentum and spin-orbit coupling, no satisfactory result of the fit is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

obtained by introducing exchange interactions through a simple dimer law deduced from the isotropic spin Hamiltonian.

To investigate the magnetic properties in detail, the field dependence of the magnetization (0–50 kOe) for compound **1** was measured at 2, 5, 10, and 20 K (Figure 3). The magnetization at 2 and 5 K increases very rapidly in low field and reaches the saturation value of ca. 5.5 $N\beta$ at 50 kOe, whereas the magnetization at 10 and 20 K increases slowly as the magnetic field increases. Interestingly, a small hysteresis loop is observed at 2 K with a coercive field ($H_c$) of 10 Oe and remnant magnetization ($M_r$) of 94 Oe emu $mol^{-1}$ (Figure 4), which is an intrinsic behavior, because a single-crystal sample was used in the measurements.

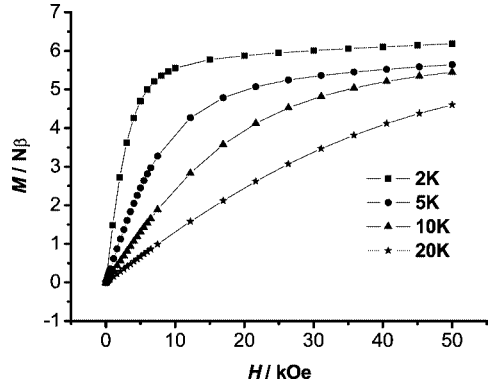

Figure 3. Magnetization vs. applied magnetic field plots at 2, 5, 10, and 20 K of complex **1**.

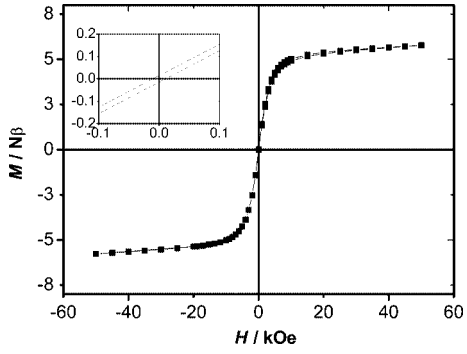

Figure 4. Hysteresis loop at 2 K for **1**. Inset: expansion showing the very small coercivity (left top).

The above unusual magnetic properties drive us to find sufficient reason for explanation. The temperature dependence of the alternating current magnetic susceptibility for compound **1** was thus measured in zero-dc field in the range of 2–20 K at different frequencies (1–1000 Hz) as shown in Figure 5. However, no frequency-dependent cusp was observed for either the in-phase component $\chi'_m$ or the out-of-phase component $\chi''_m$ at zero field, probably owing to weak coupling between Dy ions in **1** considering the long Dy···Dy separation. When a dc field (5 kOe) was applied, two peaks ($T_p$) appeared for both $\chi'_m$ and $\chi''_m$, respectively (Figure 6), indicating a field-dependent magnetic behavior for compound **1**. Moreover, $\chi'_m$ and $\chi''_m$ are strongly frequency-dependent with a larger $\Phi$ value of 0.16 {$\Phi = (\Delta T_p/T_p)/[\Delta(\log f)]$} than that for normal spin glass (<0.1),[14b] displaying an unusual glass-like behavior. Such a result should be attributed to the geometrical frustration for Dy ions in compound **1**, because the 2D connection of the Dy ions in compound **1** appeared in the pattern of the alternately arrayed square and triangle grids (Figure 2b), which is similar to the Shastry–Sutherland lattice in compound $DyB_4$. The Shastry–Sutherland lattice was demonstrated to cause geometrical frustration in some magnetic systems.[15] Without the applied DC magnetic field, the magnetic interactions between the Dy ions in compound **1** are rather weak owing to the long Dy···Dy separations, which leads to the frustration unobserved. When the introduction of a DC field, the antiferromagnetic interaction between Dy ions could be enhanced and became dominant, leading to the unusual field-dependent magnetic relaxation behavior in compound **1**. Similar phenomenon was reported by Gao and co-workers.[16]

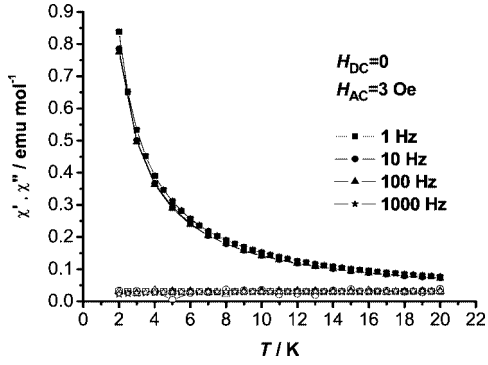

Figure 5. Temperature dependence of the real (top) and imaginary (bottom) components of the ac susceptibility in a zero applied static field with an oscillating field of 3 Oe at a frequency of 1–1000 Hz. The filled symbols are for the in-phase component $\chi'_m$, the open symbols are for the out-of-phase component $\chi''_m$.

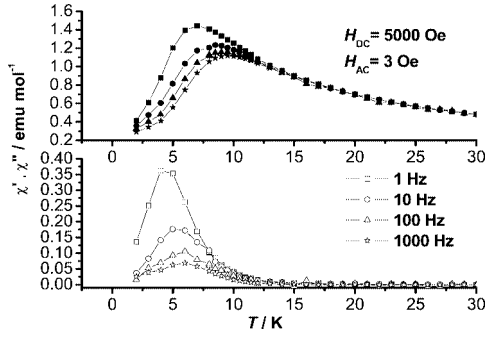

Figure 6. Frequency dependence of the AC susceptibility at 5 kOe applied static field with an oscillating field of 3 Oe at a frequency of 1–1000 Hz. The lines are guides.

### IR Spectrum, Thermogravimetric Analysis (TGA), and Photoluminescence Properties

Strong characteristic absorptions around 1610, 1560, 1430, and 1380 $cm^{-1}$ in the IR spectrum are observed for the carboxyl groups in compound **1**. No signal appears in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the region 1690 and 1730 $cm^{-1}$, indicating the complete deprotonation of the carboxyl groups in the complex. The TGA performed on **1** (as shown in Figure S7), shows that compound **1** is stable up to 250 °C, and the first weight loss in the range of 250–350 °C corresponds to the loss of coordinated water. The complete decomposition of **1** occurs at above 650 °C. The residual mass at 650 °C (55% approximately) corresponds to the formation of $Dy_2O_3$.

The photoluminescence spectrum of complex **1** is shown in Figure 7, which is blue luminescent in the solid state with typical $Dy^{3+}$ emissions at 479, 570, and 620 nm that are ascribed to the characteristic emission $^4F_{9/2} \rightarrow {}^6H_J$ transitions of the $Dy^{3+}$ ion ($J$ = 15/2, 13/2, and 11/2). The strongest emission band is located at 479 nm ($^4F_{9/2} \rightarrow {}^6H_{15/2}$), suggesting the citric acid ligand is suitable for the sensitization of blue luminescence for $Dy^{3+}$.

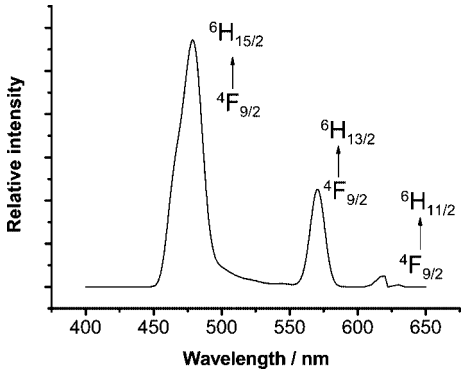

Figure 7. Emission spectra of compound **1** in the solid state at room temperature (excitation at 325 nm).

## Conclusions

A new lanthanide 2D coordination polymer, in which the citrate bridges the $Dy_2O_2$ dimer into a 2D layer, was successfully produced by a hydrothermal reaction. The coordination polymer of dysprosium exhibits interesting magnetic properties in that the geometrical frustration resulting from the structure of the alternately arrayed square and triangle grids in compound **1** causes an unusual magnetic relaxation behavior, providing valuable information for exploring molecular magnetic materials with lanthanides.

## Experimental Section

**Materials and Methods:** All purchased chemicals were of reagent grade and used without further purification. Elemental analyses (C, H, and N) were performed with a Perkin–Elmer 2400 Elemental Analyzer. Dy was determined by a Leaman inductively coupled plasma (ICP) spectrometer. The IR spectra were obtained in the range 400–4000 $cm^{-1}$ with an Alpha Centaure FTIR spectrophotometer by using KBr pellets. Thermogravimetric analysis was performed with a Perkin–Elmer TGA7 instrument in flowing $N_2$ with a heating rate of 5 °C $min^{-1}$. The magnetic susceptibility measurements for **1** were carried out on polycrystalline samples by using a Quantum Design MPMS-XL-5 SQUID magnetometer in the temperature range 2–300 K and magnetic field up to 5 T. Diamagnetic corrections were estimated from Pascal's constants.

**Synthesis:** The title compound was hydrothermally synthesized [Equation (1)] under autogenous pressure. A mixture of $Dy_2O_3$ (0.1 g, 0.27 mmol), citric acid (0.192 g, 1.0 mmol), and water (10 mL) was simply stirred and then sealed in a 15-mL Teflon-lined autoclave, which was heated to 170 °C for 2 d. After slow cooling to room temperature at a rate of 10 °C $h^{-1}$, colorless block crystals of compound **1** were separated in pure phase (80% yield based on Dy). $C_6H_7DyO_8$ (369.59): calcd. C 19.49, H 1.89, Dy 43.98; found C 19.47, H 1.88, Dy 43.99. Compound **1** is insoluble in common organic solvent and water.

**X-ray Crystallography:** Crystal data for **1**: monoclinic, space group $C2/c$; $a$ = 19.145(4), $b$ = 6.076(12), $c$ = 15.577(3) Å; $\beta$ = 103.35(3)°; $V$ = 1762.9(6) $Å^3$; $T$ = 298 K; $Z$ = 8; $\mu$ = 8.5 $mm^{-1}$; 8178 reflections measured, 2013 unique ($R_{int}$ = 0.0269) which were used in all calculations. The structure was solved by direct methods by using the program SHELXS-97 and refined by full-matrix least-squares methods on $F^2$ with the use of the SHELXL-97 program package. Structure solution and refinement based on 2013 independent reflections with $I > 2\sigma(I)$ and 136 parameters gave $R_1(wR_2)$ = 0.0192 (0.0507). The structure of compound **1** was determined by single-crystal X-ray diffraction. A single colorless crystal with approximate dimensions of 0.2 × 0.1 × 0.1 mm was mounted to the end of a glass fiber capillary. Data were collected with a Rigaku R-AXIS RAPID IP diffractometer at 293 K by using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and oscillation scans technique in the range of $3.05 < \theta < 27.47°$. A summary of the crystal data and structure refinement for compound **1** is provided in Table 1. Selected bond lengths and bond angles of **1** are listed in

Table 1. Crystal data and structure refinement of compound **1**.

# Synthesis, Upconversion Luminescence and Magnetic Properties of New Lanthanide–Organic Frameworks with $(4^3)_2(4^6,6^6,8^3)$ Topology

**Danfeng Weng,[a] Xiangjun Zheng,*[a] Xiaobo Chen,[b] Licun Li,[c] and Linpei Jin*[a]**

**Keywords:** Lanthanide–organic frameworks / Codoped coordination polymers / Upconversion properties / Magnetic properties

The synthesis and crystal structures of three new lanthanide–organic frameworks $[Ln(pza)(OH)(H_2O)]_n$ (Ln = Y(**1**), Er(**2**), Yb(**3**); $H_2$pza = 2,3-pyrazinedicarboxylic acid) with helical chains and novel 2D $(4^3)_2(4^6,6^6,8^3)$ topology are reported. The topology is obtained by simplifying the dinuclear metal core as a six-connected node and the ligand as a three-connected linker. The upconversion property measurement gives green and red emissions coming from two-photon excitation of Y: Er, Yb codoped coordination polymer and arising from $Er^{III}$ transitions of $^4S_{3/2}/^2H_{11/2}\rightarrow{}^4I_{15/2}$ and $^4F_{9/2}\rightarrow{}^4I_{15/2}$. The magnetic properties of complexes **2** and **3** are also studied.

## Introduction

The synthesis of metal–organic frameworks (MOFs) is an area of chemistry that has undergone a dramatic advance over recent years. Concerted efforts have been focused on exploiting the synthetic strategies at a level of framework design, with an impetus for illumination of structure–property relationships and an aim at certain properties and possible applications.[1] Various intriguing architectures and novel topologies have been reported,[2] among which the helical coordination polymers attracted special interests.[1f,1g,2d–g] These new materials with exploitable properties like microporosity,[3] chirality,[4] nonlinear optics,[2a,5] magnetism,[4d,6] etc. broaden the potential applications in gas storage and separation, catalysis, information storage and so on. Meanwhile, the multifunctional properties and potential applications of MOFs have gradually received more and more attention.[7] As for lanthanide–organic frameworks, complexes of $Eu^{III}$ and $Tb^{III}$, which show luminescence in the visible region, are the most frequently employed, and their luminescence properties are extensively investigated.[8] To date, lanthanide upconversion phosphors which emit higher-energy photons when excited by lower-energy photons have attracted a great deal of interest, while the upconversion of lanthanide coordination polymers is less studied.[9] Recently, we have synthesized three new lanthanide–organic frameworks $[Ln(pza)(OH)(H_2O)]_n$ (Ln = Y(**1**), Er(**2**), Yb(**3**); $H_2$pza = 2,3-pyrazinedicarboxylic acid), which possess a novel $(4^3)_2(4^6,6^6,8^3)$ topology and multifunctional properties. The magnetic properties of complexes **2** and **3** and the upconversion properties of the codoped lanthanide (Y: Er, Yb) coordination polymers are investigated.

## Results and Discussion

### Structural Description

An X-ray diffraction study reveals that compound **1** adopts a layered, two-dimensional structure consisting of centrosymmetric $Y_2(\mu_2\text{-OH})_2$ units in which two $\mu_2$-OH groups bridge two Y atoms with a Y···Y distance of 3.636 Å. The seven-coordinate environment around each Y centre is completed by two O atoms of two hydroxy groups, two O atoms from two pza ligands, one O atom and one N atom of a chelating pza ligand, and one O atom from one water molecule (see Figure 1). The pza ligand adopts a

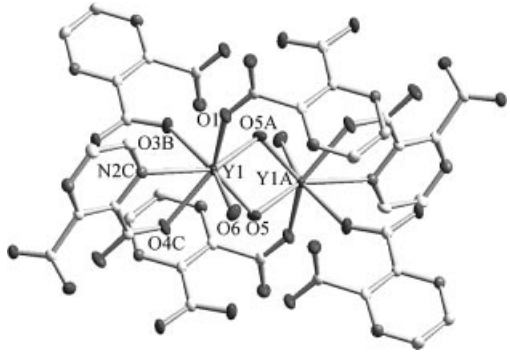

Figure 1. View of the dinuclear unit in complex **1** with ellipsoids drawn at the 50% probability level. All hydrogen atoms are omitted for clarity.

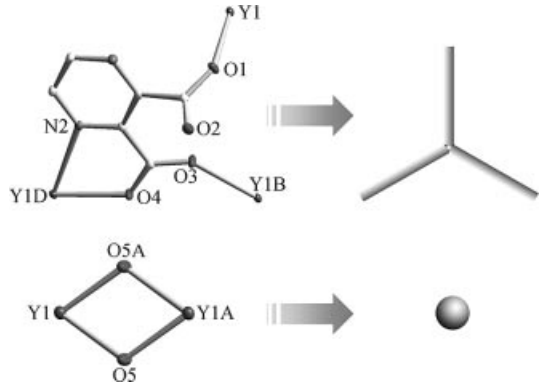
tetradentate coordination mode (Scheme 1). Selected bond lengths and bond angles of **1** are listed in Table 1.



Scheme 1. Coordination mode of the pza ligand and topological simplification of the metal dinuclear unit and ligand.

The dinuclear $Y_2(\mu_2\text{-}OH)_2$ clusters bridged by pza ligands give rise to a neutral 2D grid extended in the (100) plane. Suitable nodes should be defined in order to analyze the network. In this complex, every $Y_2(\mu_2\text{-}OH)_2$ core is connected through six carboxylate groups from six pza ligands, in which there are two chelating N and O atom linkages simplified as monodentate linkers. Thus, the $Y_2(\mu_2\text{-}OH)_2$ core can be regarded as a six-connected node. And the pza ligand can be considered as a three-connected linker as shown in Scheme 1.

When viewed along the *b* axis, outer layers consisting of pza ligands and the dinuclear metal core layer that is embedded inside can be observed. Taking one surface of the pza ligand layer and the metal layer into consideration, the structure can be best described as a 2D network with a $(6^3)$ topology (see Figure 2a). Further investigation of the whole 2D grid implies that two $(6^3)$ topological structures arranged alternately are interweaved by metal nodes. There are six four-membered rings, six six-membered rings and three eight-membered rings around the six-connected metal node, while the three-connected linker is surrounded by three four-membered rings. Because the six-connected nodes and three-connected linkers are arranged in a ratio of $Y_2(OH)_2$/pza = 1:2, the short Schläfli symbol of the topology can be expressed as $(4^3)_2(4^6,6^6,8^3)$ (Figure 2b). The topological study for complex **1** was performed with TOPOS.[10] Furthermore, a supramolecular 3D framework can be built up from the 2D lanthanide–organic framework via hydrogen bonds [O6···N1E, 2.960(4) Å] and the π–π stacking of pyrazine rings with a calculated face-to-face distance of 3.261 Å (Figure 2a).

Another interesting feature of complex **1** is its single-helical chains (Figure 2c). The Y atoms are linked into an extended chain through the O5 atom from $\mu_2$-OH and O1-, O3- carboxylate groups of the pza ligands. The repeating unit can be described as $(–Y1–O1–pza–O3–Y1B–O5B–)_n$, and the pitch of the helix running along the *b* axis is the same as its length (6.125 Å). It is worth noting that the chi-

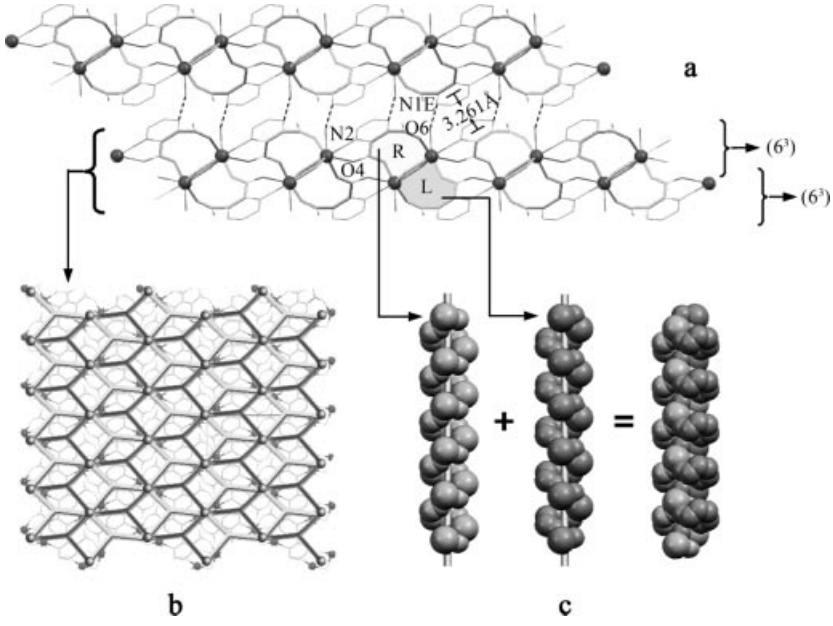

Figure 2. (a) 2D crystal packing diagram along the *b* axis for complex **1** showing interlayer interactions (hydrogen bonds indicated by dashed lines and π–π interactions by arrows and helical chains. (b) Topological representation of complex **1** down the *c* axis. (c) Space-filling model showing the helices constituted from two homochiral chains.

rality of the helices is in the RLLR mode in one layer as shown in Figure 2a. The same chiral helices are linked together through the remaining N2 and O4 atoms of the pza ligands, while two helical chains with opposite chirality are united directly at the metal nodes. This phenomenon may indicate that the twisted conformation of the ligand can effectively transfer the chiral information between the helices. However, packing these helical chains into a chiral solid still remains a challenge, which requires a deeper understanding of the role that the ligand has in the delivery of chirality and the crystal packing.

Complexes **2** and **3** are isomorphous, and their structures are similar to complex **1** (see Table 1 and Table 2), except that complex **1** has a nearly 3-Å larger *c* value and a 10° larger *β* value than those of complexes **2** and **3**.

## Upconversion Properties

In Figure 3 we can see a green emission band in the range 520–550 nm and a weaker red emission at 650–660 nm, which correspond to the transitions $^4S_{3/2}/^2H_{11/2}\rightarrow{}^4I_{15/2}$ and $^4F_{9/2}\rightarrow{}^4I_{15/2}$ respectively, for the codoped complex [(Y: Er, Yb)(pza)(OH)($H_2O$)]$_n$ upon excitation at 975 nm.

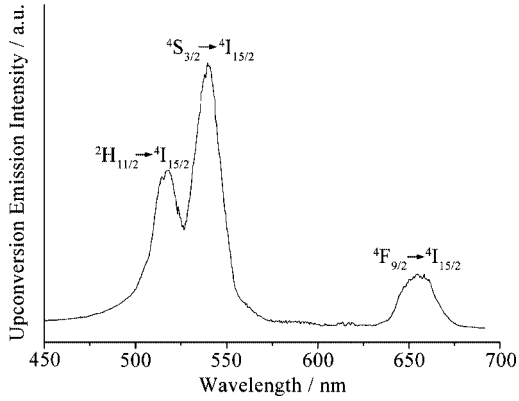

Figure 3. Upconversion emission for the Er$^{III}$ ion in the Y: Er, Yb codoped coordination polymer.

Figure 4 shows the energy levels and upconversion mechanism in the Y: Er, Yb codoped coordination polymer. The Yb$^{III}$ ion was excited by a 975 nm photon from the $^2F_{7/2}$ level to the excited $^2F_{5/2}$ state first. Then the energy was transferred from Yb$^{III}$ to Er$^{III}$ to pump the Er$^{III}$ ion

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

from the $^4I_{15/2}$ state to the $^4I_{11/2}$ state. The $Er^{III}$ ion, populated at the $^4I_{11/2}$ level, may transit to the $^4F_{7/2}$ state by a second-photon promotion. The $^4S_{3/2}$ and $^2H_{11/2}$ states can be populated by nonradiative relaxations from the $^4F_{7/2}$ state in the form of thermal vibration carried by phonons of ca. 2100 $cm^{-1}$ (1620 $cm^{-1}$ + 476 $cm^{-1}$ in the IR spectrum) and 1400 $cm^{-1}$ (1398 $cm^{-1}$ in IR spectrum), respectively. The $Er^{III}$ ions in the $^4S_{3/2}$ and $^2H_{11/2}$ states emit in the green range (518 and 540 nm) when going back to the ground state $^4I_{15/2}$.

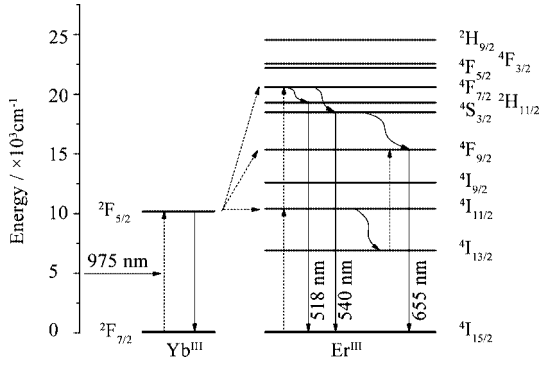

Figure 4. Energy-level diagram for the upconversion mechanism of the Y: Er, Yb codoped coordination polymer with excitation at 975 nm.

The red emission centred at 650 nm is generated by the $^4F_{9/2}$ to $^4I_{15/2}$ transition. There exist two possible routes for this process. The $^4F_{9/2}$ level can be reached by the nonradiative decay from the upper level, $^4S_{3/2}$.[11] However, the green emission ($^4S_{3/2}\rightarrow{}^4I_{15/2}$) was the strongest peak in our system, so this is not the main channel to the $^4F_{9/2}$ level. In the second possible route, $Er^{III}$ ions in the $^4I_{11/2}$ state lose their energy in going to the $^4I_{13/2}$ level with some nonradiative decay involved. There is an energy gap of ca. 3500 $cm^{-1}$ between the two states. The high-energy vibrations from the O–H group make the relaxation ($^4I_{11/2}\rightarrow{}^4I_{13/2}$) much more probable in this system. Then, a second photon energy (975 nm) pumps the $Er^{III}$ from the $^4I_{13/2}$ to the $^4F_{9/2}$ level, and thus the red emission is obtained (see Figure 4).

### Magnetic Properties

We investigated the magnetic properties of complexes **2** and **3** in the solid state at 2 kOe within the temperature range 2–300 K (Figure 5). For **2**, the observed value of $\chi_M T$ per [Er] unit is 12.22 $cm^3\,K\,mol^{-1}$ at room temperature (Figure 5a), which is slightly higher than the value expected for a free $Er^{III}$ ion (11.48 $cm^3\,K\,mol^{-1}$).[12] Upon cooling, the value of $\chi_M T$ increases up to a maximum of 13.90 $cm^3\,K\,mol^{-1}$ at ca. 45 K and then abruptly decreases to reach 4.51 $cm^3\,K\,mol^{-1}$ at 2 K. The plot of $\chi_M^{-1}$ vs. $T$ over the temperature range 50–300 K obeys the Curie–Weiss law [$\chi = C/(T - \theta)$] with $C$ = 1.20 $cm^3\,K\,mol^{-1}$ and $\theta$ = 1.00 K. All of these results indicate that there is a ferromagnetic coupling between the $Er^{III}$ ions. For **3**, the observed value of $\chi_M T$ per [Yb] unit is 2.47 $cm^3\,K\,mol^{-1}$ at room temperature (Figure 5b), which is close to the calculated value (2.57 $cm^3\,K\,mol^{-1}$) for a free $Yb^{III}$ ion.[12] The value of $\chi_M T$ decreases slowly as the temperature decreases, to reach a value of 1.91 emu K $mol^{-1}$ at 2 K. The plot of $\chi_M^{-1}$ vs. $T$ over the temperature range 50–300 K obeys the Curie–Weiss law with $C$ = 2.60 $cm^3\,K\,mol^{-1}$, $\theta$ = –17.13 K. The decrease in $\chi_M T$ and the negative value of $\theta$ are due primarily to the depopulation of the Stark levels of the $Yb^{III}$ ion together with the possible weak antiferromagnetic coupling between the $Yb^{III}$ ions, considering a possible interaction path through hydroxy bridges with a Yb···Yb distance of 3.601 Å.

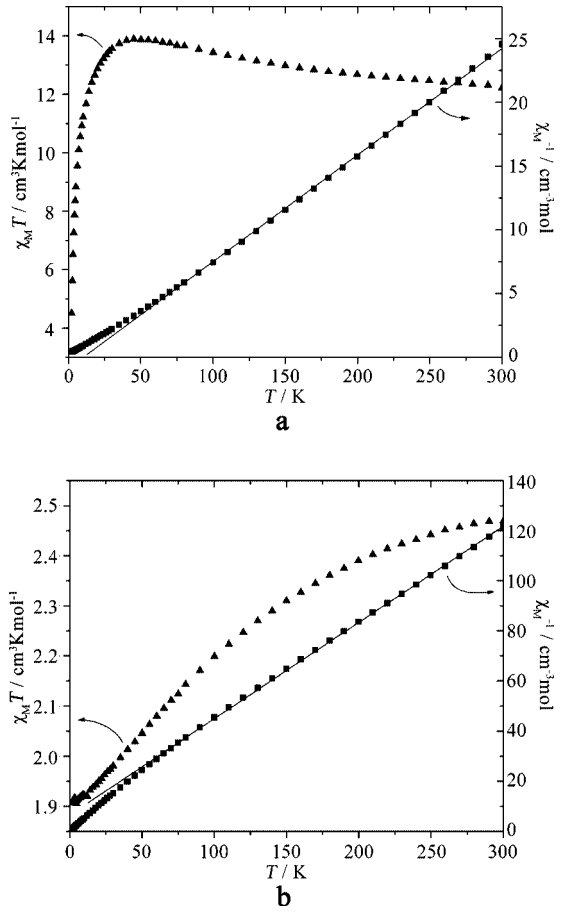

Figure 5. Plots of the temperature dependences of $\chi_M^{-1}$ (■) and $\chi_M T$ (▲) for complexes **2** (a) and **3** (b).

## Conclusions

Three new lanthanide–organic frameworks with unusual $(4^3)_2(4^6,6^6,8^3)$ topology were synthesized under hydrothermal conditions. The arrangement of the helices in one layer in **1**–**3** shows that the twisted conformation of the ligand can effectively transfer the chiral information between the helices. The codoped coordination polymer [(Y: Er, Yb)(pza)(OH)($H_2O$)]$_n$ emits green and red fluorescence by two-photon excitation. In addition, complex **2** shows a ferromagnetic coupling between the $Er^{III}$ ions.

## Experimental Section

**General:** All reagents were commercially available and were used without further purification. Elemental analyses of C, H and N were performed with an Elementar Vario EL analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FTIR spectrometer by using the KBr pellet technique. The inductively coupled plasma (ICP) analysis was performed with a JY ULTIMA spectrometer. The upconversion luminescence spectra were measured by using a fluorescence spectrophotometer with a double-grating monochromator (JY-ISA, Fluorolog-Tau-3). A 975 nm continuous diode laser was used as the pump source. The direction of observation of the fluorescence was perpendicular to the direction of propagation of the pumping laser. Only the fluorescence emitted from the front surface of the samples was collected. The experimental conditions were held unchanged so as to ensure that the measurements for all the samples were comparable. The magnetic susceptibilities were obtained on crystalline samples with a Quantum Design MPMS XL-7 SQUID magnetometer. The experimental susceptibilities were corrected for contributions from the sample holder and the diamagnetism estimated from Pascal's constants.

**$[Y(pza)(OH)(H_2O)]_n$ (1):** The mixture of $YCl_3{\cdot}6H_2O$ (0.030 g, 0.1 mmol), 2,3-pyrazinedicarboxylic acid (0.017 g, 0.1 mmol), $H_2O$ (5 mL) and aqueous NaOH (0.3 mL, 0.65 mol $L^{-1}$) was sealed in a 25-mL stainless steel reactor with a Teflon liner and heated at 190 °C for 72 h. Colourless plate-like crystals of **1** were obtained and washed with water. Yield: 0.020 g (68.96%). $C_6H_5N_2O_6Y$ (290.03): calcd. C 24.85, H 1.74, N 9.66; found C 24.70, H 1.97, N 9.54. IR (KBr): $\tilde{\nu}$ = 3405 (s), 1643 (vs), 1620 (vs), 1566 (m), 1448 (s), 1398 (s), 1360 (s), 1119 (m), 847 (m), 475 (m), 439 (m), 408 (m) $cm^{-1}$.

**$[Er(pza)(OH)(H_2O)]_n$ (2):** This compound was prepared by following the procedure for **1** but using $ErCl_3{\cdot}6H_2O$ instead of $YCl_3{\cdot}6H_2O$. Pink plate-like crystals of **2** were obtained. Yield: 0.019 g (51.58%). $C_6H_5ErN_2O_6$ (368.39): calcd. C 19.56, H 1.37, N 7.60; found C 19.53, H 1.59, N 7.61. IR (KBr): $\tilde{\nu}$ = 3399 (s), 1643 (vs), 1619 (vs), 1567 (m), 1448 (s), 1396 (s), 1363 (s), 1119 (m), 847 (m), 473 (m), 439 (m), 406 (m) $cm^{-1}$.

**$[Yb(pza)(OH)(H_2O)]_n$ (3):** This compound was prepared by following the procedure for **1** but using $Yb(NO_3)_3{\cdot}6H_2O$ instead of $YCl_3{\cdot}6H_2O$. Colourless plate-like crystals of **3** were obtained. Yield: 0.022 g (58.80%). $C_6H_5N_2O_6Yb$ (374.16): calcd. C 19.26, H 1.35, N 7.49; found C 19.17, H 1.35, N 7.34. IR (KBr): $\tilde{\nu}$ = 3406 (s), 1645 (vs), 1620 (vs), 1568 (m), 1450 (s), 1399 (s), 1363 (s), 1120 (m), 848 (m), 477 (m), 443 (m), 401 (m) $cm^{-1}$.

**$[(Y: Er, Yb)(pza)(OH)(H_2O)]_n$:** The codoped compounds were prepared by following the procedure for **1** but using $YCl_3{\cdot}6H_2O$, $ErCl_3{\cdot}6H_2O$ and $Yb(NO_3)_3{\cdot}6H_2O$ (for example, molar ratio: 92.0:4.0:4.0%) instead of 100% $YCl_3{\cdot}6H_2O$. Colourless plate-like crystals were obtained. Yield: 0.018 g (70.17%). $C_6H_5N_2O_6$(Y: Er, Yb) (296.53): calcd. C 24.30, H 1.82, N 9.45; found C 24.42, H 1.93, N9.33. IR (KBr): $\tilde{\nu}$ = 3404 (s), 1646 (vs), 1620 (vs), 1567 (m), 1449 (s), 1398 (s), 1363 (s), 1119 (m), 848 (m), 476 (m), 440 (m), 408 (m) $cm^{-1}$. ICP analysis showed that the molar ratio of Y/Er/Yb was 90.9:4.5:4.6 (%) in the product.

**X-ray Structure Determination:** Intensity data for **1**, **2** and **3** were collected at 294 K with a Bruker SMART 1000 CCD area detector diffractometer, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in $\phi$ and $\omega$ scan modes, $\theta$ ranges 2.7° to 27.9° for **1**, 2.29° to 27.51° for **2**, 2.28° to 26.34° for **3**. Semiempirical absorption corrections were applied by using the SADABS program.[13] The structures were solved by direct methods[14] and refined by full-matrix least-squares on $F^2$ by using the programs SHELXS 97 and SHELXL 97, respectively.[14,15] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms attached to the bridging hydroxy and the coordinated water molecules of **1**, **2** and **3** were located from the difference Fourier map. The other hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinements. Details of crystallographic data of **1**, **2** and **3** are summarized in Table 2. CCDC 635120–635122 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

## Acknowledgments

We acknowledge the support from the National Natural Science Foundation of China (20331010, 20501003) and thank Prof. V. A. Blatov for help with the solution of the structure.

# Synthesis of Half-Sandwich Tungsten Chlorogermyl and Chlorostannyl Complexes

**Holger Braunschweig,*[a] Holger Bera,[a] Barbara Geibel,[a] Rainer Dörfler,[a] Daniel Götz,[a] Fabian Seeler,[a] Thomas Kupfer,[a] and Krzysztof Radacki[a]**

**Keywords:** Half-sandwich complexes / Tungsten complexes / Germanes / Stannanes / Stannylcyclopentadienes

The reaction of the dichlorogermane $Me_2GeCl_2$ and stannanes $R_2SnCl_2$ (R = Me, Bu) with the alkali tungsten salts $M[(\eta^5\text{-}C_5R'_5)L(OC)_2W]$ (L = CO, $PPh_3$; M = Li, Na; R′ = H, Me) yields via alkali salt elimination a range of novel chlorostannyl- and chlorogermyl-functionalized tungsten complexes of the general formula $[(\eta^5\text{-}C_5R'_5)L(OC)_2W(ER_2Cl)]$ (R′ = H, Me; L = CO, $PPh_3$; E = Ge, Sn; R = Me, Bu) (**3a–e**). The use of the phosphane-substituted tungsten anion $Na[(\eta^5\text{-}C_5Me_5)(Ph_3P)(OC)_2W]$ (**1c**) and $Me_2SnCl_2$ leads to a mixture consisting of the mono- (**3e**) as well as the di-substituted stannyl compound $[\{(\eta^5\text{-}C_5H_5)(Ph_3P)(OC)_2W\}_2(SnMe_2)]$ (**4**). Access to **3a** is also given by reaction of $ClMe_2Sn\text{–}C_5H_5$ (**5**) with $[(MeCN)_3W(CO)_3]$ which includes chemoselective tin shift from the cyclopentadiene to the tungsten atom. In addition, a successive chlorination of $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMe_3)]$ (**6**) via $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMe_2Cl)]$ (**3a**) and $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMeCl_2)]$ (**7**) to $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnCl_3)]$ (**8**) is presented. All new compounds have been fully characterized by elemental analyses and in solution by IR and multinuclear NMR spectroscopy. The crystal structures of complexes **3b–d** and **8** were presented and discussed, showing bond lengths of 2.6272(4) Å for Ge–W, 2.7959(5) (**3b**), 2.7866(3) (**3d**) and 2.7244(3) (**8**) Å for the Sn–W bonds.

## Introduction

The first germanium and tin complexes of molybdenum and tungsten have been prepared in the 1960's[1] and since that time [M]–$SnR_3$ bonds are ubiquitous up to the present day.[2] The chemistry of such complexes has been the object of extensive studies due to their potential in many catalytic and stoichiomtric processes.[3] Two important reactions of transition-metal stannyl complexes [M]–$SnR_3$ (R = organic group) are the chlorination with hydrogen halides[4] and the stanna-tropic shift from the transition-metal to the cyclopentadienyl ligand in half-sandwich complexes, induced by a strong base.[5] Despite this fact, the amount of complexes owing a chlorogermyl or chlorostannyl moiety, which allow further functionalization and reaction chemistry, is fairly limited – in particular in the case of germanium, and only little work has been carried out concerning investigations of the Cl–Sn unit of a transition metal. One of them – the most recent work – deals with chloride displacement by nucleophilic sulfur or oxygen groups with the latter (pyridinedicarboxylic acid) leading to an iron complex with fivefold-coordinated tin[6] (Figure 1). Another investigation topic is the Lewis basicity of the $Cl_3Sn$ group. In this context, some interesting molybdenum and tungsten *ansa* complexes were built up showing an intramolecular Lewis acid–base interaction of a cyclopentadienyl-bound donor group (with N and O as donor atoms) and the transition-metal bound $Cl_3Sn$ moiety giving a sixfold-coordinated tin centre[7] (Figure 1).

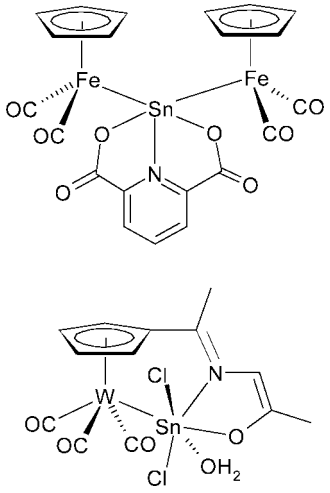

Figure 1. Iron and tungsten half-sandwich complexes with fivefold- and sixfold-coordinated tin atoms.

Nevertheless, with regard to the facile chemistry of $R_3ECl$ (E = Ge, Sn) which includes a wide variety of reactions with alkali metals, organolithium compounds, hydroxides, sulfides, Lewis bases, amides, alkoxides, etc., it seems self-evident that much of it can be yet transferred to chlorogermyl and chlorostannyl transition-metal complexes.

In an extension of our work on the reactivity of boryl-, borylene-,[8] or diborane(4)yl[9] moieties linked to half-sandwich metal fragments (e.g. compound $[(\eta^5\text{-}C_5Me_5)(OC)_2Fe\text{–}(BX_2\leftarrow py)]$ (X = Cl, Br; py = pyridine),[8f] $[(\eta^5\text{-}C_5H_5)(R_3P)(OC)_2W\text{–}\{B(NMe_2)\text{–}B(NMe_2)Cl\}]$ (R = Me, Ph)[9a] in Figure 2) which included the addition of Lewis bases to $BCl_2$ ligands[8f,8i] analogous to $Cl_3Sn$ complexes, we became interested in some aspects of the chemistry of corresponding halogermyl and stannyl complexes.

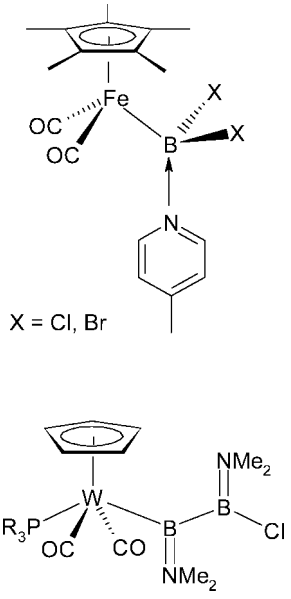

Figure 2. Methylpyridine Lewis base adduct of a $X_2B$-substituted iron complex and phosphane-substituted diborane(4)yl tungsten half-sandwich complex.

In this paper we report on the synthesis, spectroscopic and structural characterisation of the novel chlorodiorgano germyl and stannyl complexes of tungsten. The synthetic method chosen is straightforward and widely variable and so should give access to a range of analogue complexes. Additionally, we have developed three convenient and new methods for a facile preparation of **3a**, and established a chlorination chemistry which allows the facile synthesis of tungsten complexes with mono, di- and trichlorinated stannyl ligands.

## Results and Discussion

The complexes of the general formula $[(\eta^5\text{-}C_5R'_5)L(OC)_2W(ER_2Cl)]$ (R′ = H, Me; L = CO, $PPh_3$; E = Ge, Sn; R = Me, Bu) (**3a**–**e**) are obtained from the corresponding dichlorogermanes and stannanes $R_2ECl_2$ (E = Ge, Sn; R = Me, Bu) (**2a**–**c**) with the alkali tungsten salts $M[(\eta^5\text{-}C_5R'_5)L(OC)_2W]$ (L = CO, $PPh_3$; M = Li, Na; R′ = H, Me) (**1a**–**c**) after 16–22 h reaction time at ambient temperature in diethyl ether, according to Equation (1). The new compounds are isolated as yellow and dark yellow (**3e** and **3a**,**b**), ochre (**3d**) and brown (**3c**) powders in yields between 70% (**3b**) and 85% (**3d**). These results demonstrate that the synthetic method chosen is straightforward and widely variable and hence should give access to a range of analogue complexes. **3a**–**e** show moderate solubility in pentane or hexane and dissolve readily in diethyl ether and aromatic solvents. They can be stored under argon atmosphere at –30 °C for several months without signs of decomposition. **3d** can be even stored at ambient temperature.

The reaction of the triphenylphosphane-substituted tungsten anion **1c** with dichlorodimethylstannane (**2b**) does not give exclusively **3e**. Instead, a product mixture of **3e** and the dinuclear complex **4** is obtained (Figure 3). The ratio of **3e** and **4** is determined by integration of the $^1H$ NMR spec-

trum and amounts to 2:1. The formation of **3e** and **4** proceeds stereospecifically and only the *trans*-products are observed, which is consistent with the synthesis of the parent $[(\eta^5\text{-}C_5H_5)(Ph_3P)(OC)_2W(SnMe_3)]$.[10] Due to the different solubility in hexane both compounds can be easily separated from each other. This reaction demonstrates the higher nucleophilic character of the phosphane-substituted tungsten anion **1c** in comparison to the tricarbonyl derivative (**1b**) in spite of its higher steric demands.

All new complexes were characterised in solution by IR and multinuclear NMR spectroscopy. The complexes **3a**,**c**–**e** show singlets for the dimethyl groups attached to the germanium and tin atom in the $^1$H NMR spectra between 0.87 (**3a**) and 1.17 (**3c**) ppm, characteristic for an element nucleus being deshielded with respect to those of the starting dichlorogermane and stannanes. These values are in good agreement to the corresponding signal found for $[\{H_2C(O)\text{-}C(\eta^5\text{-}C_5H_4)\}(OC)_3W(SnMe_2Cl)]_2$ ($\delta$ = 0.95 ppm).[11] The signals of the Sn-bound methyl moieties are accompanied by $^{117/119}$Sn satellites showing $^2J_{HCSn}$ coupling constants of 45.3, 47.3 (**3a**), 42.5, 44.4 (**3d**) and 40.2, 41.8 (**3e**) Hz, thus reflecting the increasing electron density of the tungsten fragments in this row. The $^{119}$Sn NMR resonances of **3a**,**d**,**e** are detected in close proximity at 227.0 (**3a**), 233.0 (**3d**) and 233.8 (**3e**) ppm, whereas the one of the butyl derivative **3b** differs significantly and appears at $\delta$ = 26.7 ppm due to the electron-releasing effect of the butyl groups. Only in two cases the $^1J_{SnW}$ coupling was observed amounting to 162.8 (**3b**) and 347.0 Hz (**3d**). Due to the fact that in the case of **3e** and **4** the *trans*-product is exclusively formed, in the $^{31}$P NMR spectra appears in each case one resonance at 38.61 (**3e**) and 44.50 ppm (**4**), accompanied by $^{183}$W [$^1J_{WP}$ = 293.6 Hz (**3e**), 267.3 Hz (**4**)] and $^{117/119}$Sn satellites [$^2J_{SnWP}$ = 123.9 and 128.8 Hz (**3e**), 125.4 and 130.8 Hz (**4**)]. As expected, **3a**,**c**,**d** show three CO-stretching frequencies ($A_{(1)}'$, $A''$ and $A_{(2)}'$) each in the IR spectra between 1901 and 2010 cm$^{-1}$, as expected for such tungsten complexes.[11] Surprisingly, the butyl derivative **3b** shows only two bands (1999 and 1981 cm$^{-1}$), one of which, however, is thus possibly indicating an overlap of two bands. In contrast, the observed number of two CO-stretching frequencies for **3e** and **4** is in agreement with phosphane-substituted tungsten stannyl complexes, as loss of a carbonyl group usually decreases the number of absorption bands from 3 to 2. As expected, the carbonyl stretching frequencies decrease in comparison to **3a**,**c**,**d** and are found for **3e** and **4** at 1904, 1835 and 1901, 1832 cm$^{-1}$, respectively which lie very close to those of $[(\eta^5\text{-}C_5H_5)(Ph_3P)(OC)_2W(SnMe_3)]$.[10]

*X-ray diffraction analyses.* The molecular structures of $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnBu_2Cl)]$ (**3b**), $[(\eta^5\text{-}C_5Me_5)(OC)_3W(GeMe_2Cl)]$ (**3c**) and $[(\eta^5\text{-}C_5Me_5)(OC)_3W(SnMe_2Cl)]$ (**3d**) have been confirmed by X-ray diffraction studies and are presented in Figure 4, Figure 5, and Figure 6. Selected bond lengths and angles are listed below each Figure and crystal data and refinement parameters in Table 2 in the experimental section. In all cases, crystals, suitable for X-ray analysis, are obtained upon slow evaporation of saturated benzene solutions at room temperature. The compounds crystallize in triclinic (**3b**) and monoclinic (**3c**,**d**) crystal systems with space groups $P\bar{1}$ (**3b**), $P2_1/c$ (**3c**) and $C2/c$ (**3d**), respectively.

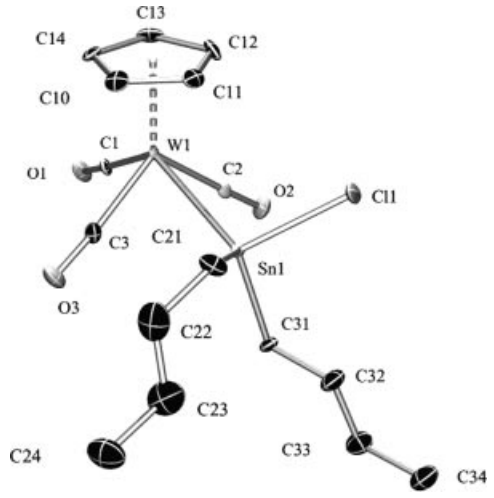

Figure 4. Molecular structure of $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnBu_2Cl)]$ (**3b**) in the solid state with the atom-numbering scheme. Displacement ellipsoids are drawn at the 50% probability level and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: W1–C1 1.983(7), W1–C3 1.984(8), W1–C2 1.985(7), W1–Sn1 2.7959(5), Sn1–C31 2.156(7), Sn1–C21 2.168(8), Sn1–Cl1 2.4203(18), C31–Sn1–C21 114.6(3), C31–Sn1–Cl1 99.1(2), C21–Sn1–Cl1 99.6(2), C31–Sn1–W1 120.56(19), C21–Sn1–W1 114.1(2), Cl1–Sn1–W1 104.34(5).

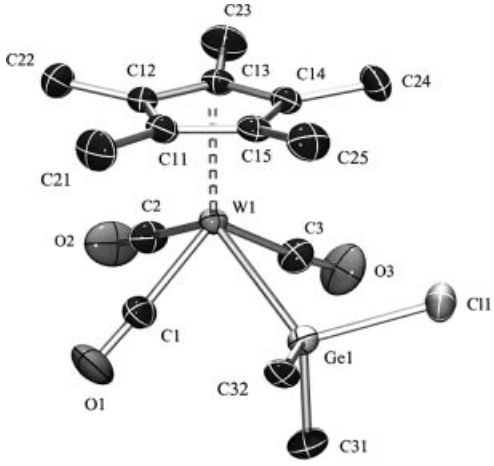

Figure 5. Molecular structure of $[(\eta^5\text{-}C_5Me_5)(OC)_3W(GeMe_2Cl)]$ (**3c**) in the solid state with the atom-numbering scheme. Displacement ellipsoids are drawn at the 50% probability level and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: W1–C1 1.971(4), W1–C2 1.982(4), W1–C3 1.982(4), W1–Ge1 2.6272(4), Ge1–C31 1.948(4), Ge1–C32 2.008(3), Ge1–Cl1 2.2428(10), C1–W1–Ge1 70.04(11), C2–W1–Ge1 123.98(11), C3–W1–Ge1 72.07(12), C31–Ge1–C32 106.44(17), C31–Ge1–Cl1 101.62(13), C32–Ge1–Cl1 101.97(10), C31–Ge1–W1 117.55(13), Cl1–Ge1–W1 109.74(3).

The coordination sphere around each tungsten atom can be considered as a pseudo square-pyramid, with the three carbonyl ligands [mean W–C 1.984 (**3b**), 1.978 (**3c**) and 1.978 Å (**3d**)] and the germyl or rather stannyl group forming the base, while the aromatic ring systems occupie the

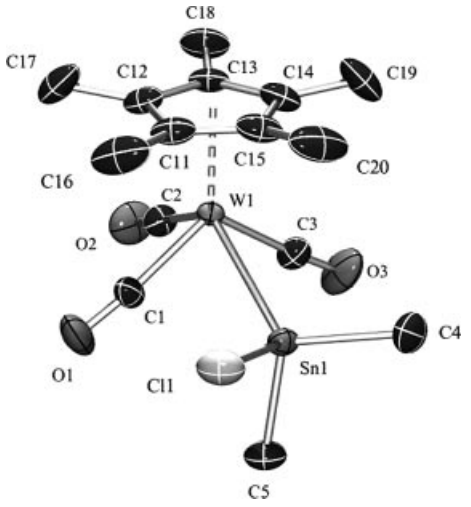

Figure 6. Molecular structure of [($\eta^5$-$C_5Me_5$)$(OC)_3$W($SnMe_2$Cl)] (**3d**) in the solid state with the atom-numbering scheme. Displacement ellipsoids are drawn at the 50% probability level and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: W1–C3 1.976(4), W1–C1 1.977(3), W1–C2 1.982(4), W1–Sn1 2.7866(3), Sn1–C5 2.146(4), Sn1–C4 2.157(4), Sn1–Cl1 2.4215(10), C5–Sn1–C4 107.61(16), C5–Sn1–Cl1 99.75(12), C4–Sn1–Cl1 100.48(13), Cl1–Sn1–W1 108.97(3), C5–Sn1–W1 118.56(11), C4–Sn1–W1 118.31(12).

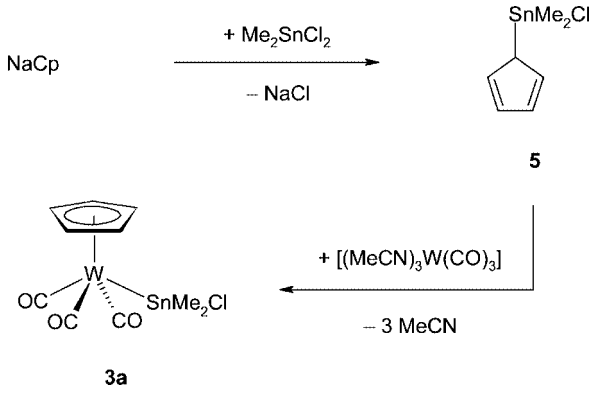
apical position ("four-legged piano stool" complex). In the case of **3c**,**d**, the five methyl groups are slightly bent out of the plane of the cyclopentadienyl ligand [mean 6.7° (**3c**) and 6.5° (**3d**)]. All these structural parameters lie in the range reported in literature for comparable compounds.[7,11,12] The base-forming angles lie all between 70 and 75°. The determined W–Ge distance amounts to 2.6272(4) Å, which is about 0.1 Å shorter than the values in the $PMe_3$-substituted trichlorogermanium complexes *cis*- and *trans*-[($\eta^5$-$C_5Me_5$)$(Me_3P)(OC)_2$W($GeCl_3$)] [2.559(5) (*cis*) and 2.5159(14) Å (*trans*)].[12a] This finding supports the observation that increased electron density at a central transition metal atom – evoked by the introduction of a phosphane ligand – strengthens the transition metal–element bond. The determined Ge–C bond lengths are 1.948(4) (Ge1–C31) and 2.008(3) (Ge1–C32) Å. For the germanium–chlorine bond a length of 2.2428(10) Å is found, which is only slightly longer than the corresponding bonds in the $Cl_3Ge$ derivative [mean 2.206 (*cis*) and 2.199 Å (*trans*)].[12a] The tetrahedral coordination geometry of the germanium atom is strongly distorted indicated by angles in the range from 101.62(13) (C31–Ge1–Cl1) to 117.55(13)° (C31–Ge1–W1). Only Cl1–Ge1–W1 shows an almost ideal tetrahedron angle [109.74(3)°].

The determined W–Sn bond lengths are 2.7959(5) (**3b**) and 2.7866(3) Å (**3d**), thus being in the range of tin-substituted tricarbonyl tungsten complexes.[7,11] The Sn–C bonds of **3b** are slightly longer [2.168(8) (Sn1–C21) and 2.156(7) Å (Sn1–C31)] than those of **3d** [2.146(4) (Sn1–C5) and 2.157(4) Å (Sn1–C4)]. For the tin–chlorine bonds, distances of 2.4203(18) (**3b**) and 2.4215(10) Å (**3d**) are found, which is very similar to those in tungsten complexes with sixfold-coordinated tin atoms, e.g. 2.404(1) and 2.459(2) Å in the tungsten complex in Figure 1.[7] As expected, the tetrahedral coordination geometry of the tin atoms of **3b**,**d** is significantly distorted almost to the same extent as already mentioned for the Ge analogue and thus, angles between 99.1(2) (C31–Sn1–Cl1) and 120.56(19) (C31–Sn1–W1) (**3b**) or rather 99.75(12) (C5–Sn1–Cl1) and 118.56(11) Å (C5–Sn1–W1) (**3d**) were found. Interestingly, in both compounds the W–Sn–C angles are widened whereas the C–Sn–Cl angles are more acute in comparison to the ideal tetrahedron angle. This characteristic could also be observed in the Ge compound and was found in diorganostannyl molybdenum complexes, too.[11,13] In **3b**, there is an interaction of one carbonyl oxygen (O1) with a hydrogen atom of the second molecule of the same cell (H51A) which can be classified as moderate hydrogen bond according to the value of 2.508 Å (O1···H51A).

*Alternative syntheses of **3a** and chlorination reactions.* Even though the following compounds were already mentioned in literature, not all of them have been isolated and their characterisation has not been carried out to full extent. For example, up to now, it was only possible to obtain the di-chlorinated complex **7** together with **3a** as an inseparable mixture by treatment of **6** with hydrogen chloride.[4] Therefore, we developed new and convenient syntheses for these chlorostannyl compounds, isolated them and completed their characterization.

One alternative route leading to **3a** proceeds via the chlorodimethylstannyl-cyclopentadiene **5** which is literature-known,[14] but was here synthesized in a more convenient way. The alkali salt elimination of sodium cyclopentadienide and dichlorodimethylstannane yields after 18 h stirring at ambient temperature **5** according to Scheme 1. **5** is obtained as a yellow oil in 84% and can be stored at –30 °C under Ar atmosphere over a period of months. Due to the fast stannatropic shift of the $ClMe_2Sn$ group with respect to the NMR time-scale, a singlet at $\delta$ = 5.99 ppm is observed for the cyclopentadiene protons at ambient temperature. This chemical shift agrees very well with the literature data ($\delta$ = 6.02 ppm[14a]) and the signal shows the expected



Scheme 1. Alternative synthesis of **3a** via the chlorostannyl-functionalized cyclopentadiene **5** which is obtained from alkali salt elimination of sodium cyclopentadienyl and dichlorodimethyl stannane.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tin satellites with coupling constants of 29.0 and 30.0 Hz. In the $^{119}$Sn NMR spectrum a singlet is observed at $\delta$ = 101.45 ppm.[14b]

In the last step, **5** is treated with $[(MeCN)_3W(CO)_3]$ in refluxing THF over a period of 18 h, leading to **3a** in 90% yield (Scheme 1). **3a** is obtained as an analytically pure yellow solid. The reaction proceeds chemoselectively and only the chlorostannyl group shifts to the tungsten centre – no complex tungsten hydride is observed as by-product. This insertion of a coordinatively unsaturated transition-metal fragment (W) into a Sn–C bond which is accompanied by oxidation of the W centre has precedence but only for trimethylgermanium- and -tin-functionalized cyclopentadienes.[15] In contrast, in $Me_3Si$-substituted cyclopentadienes the Si–C unit tends to remain intact due to a stronger and less polar bond.[15a]

Besides, we developed not only a selective synthesis of **7**, but also a controlled, successive chlorination of the trimethylstannyl tungsten complex **6** to the trichlorostannyl derivative **8** (Scheme 2) via isolable intermediates.

The first Me/Cl exchange is achieved by use of exactly one equivalent of $SnCl_4$ at ambient temperature, leading after two hours exclusively to **3a**. After work up, **3a** can be obtained analytically pure in 92% yield. The second chlorination is realized with a further equivalent of $SnCl_4$ at ambient temperature, too. The reaction is finished after two hours and yields **7** in 88%. The di-chlorination product **7** can also be obtained directly from **6** if an excess of $SnCl_4$ is employed. **7** is characterized by a high stability even towards concentrated hydrochloric acid. For the tin-bound methyl group a singlet at $\delta$ = 1.11 ppm is observed, showing the expected $^{117/119}$Sn satellites of 45.2 and 46.2 Hz, respectively. The $^{119}$Sn signal is detected at $\delta$ = 198.9 ppm. An excess of $SnCl_4$ in refluxing chloroform gives access to the trichlorostannyl complex **8**, when the mixture is heated over a period of six days. **8** can be obtained in 60% as a yellow powder, which can be also exposed to air for a prolonged period without decomposition. The detected $^1$H NMR chemical shift at 5.77 for the Cp is in accordance with literature ($\delta$ = 5.6 ppm) as well as the IR data.[16] The $^{119}$Sn NMR resonance was detected at $\delta$ = –89.4 ppm, which is about 115 ppm shifted to higher field in comparison to the Mo analogue $[(\eta^5\text{-}C_5H_5)(OC)_3Mo(SnCl_3)]$ ($\delta$ = 26 ppm).[6] Due to the fact that only IR data of **7** are published[16] (except for $^1$H NMR of **8**,[16b]), we characterized **7** and **8** by $^1$H, $^{13}$C and $^{119}$Sn NMR as well as elemental and melting point analysis. Some of these data are listed in Table 1.

Table 1. NMR spectroscopic features depending on the chlorination degree of the W-bound tin atom.[a]

| | $[WpSnMe_3]$ (**6**) | $[WpSnMe_2Cl]$ (**3a**) | $[WpSnMeCl_2]$ (**7**) | $[WpSnCl_3]$ (**8**) |
|---|---|---|---|---|
| $^1$H(MeSn) | 0.51 | 0.87 | 1.11 | – |

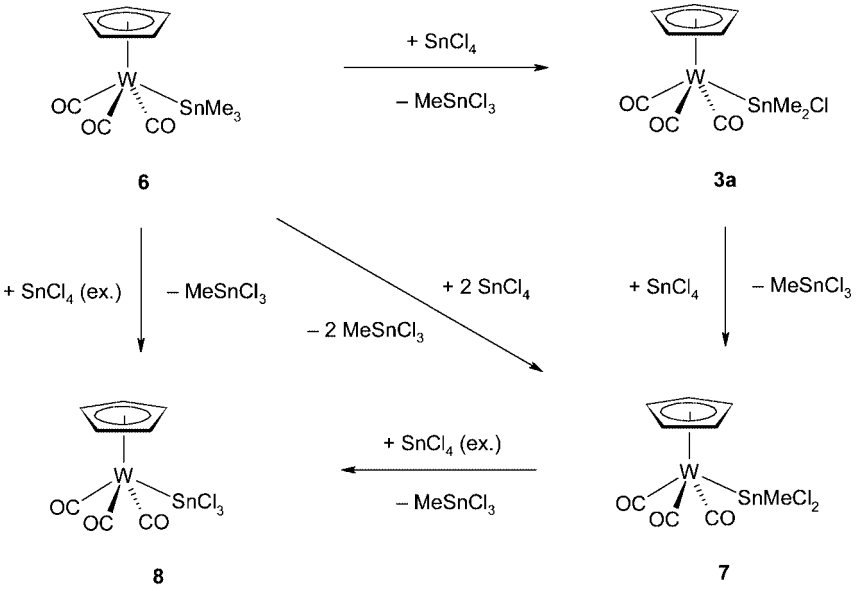
[a] NMR spectroscopic data in ppm (in $C_6D_6$, except **8**: $CDCl_3$), coupling constants in Hz. For a more detailed discussion of the IR data and bonding energies see ref.[16a]. Wp ≡ $(\eta^5\text{-}C_5H_5)(OC)_3W$. [b] $^1J_{SnW}$ = 150.5 Hz. [c] $^1J_{SnW}$ = 596.8 Hz.

For better comparison of the compounds of **6**, **3a**, **7** and **8**, we determined the $^1$H and $^{119}$Sn NMR chemical shifts and the coupling constants $^2J_{HCSn}$ of the Sn-attached methyl groups (Table 1). The trends of the $^1$H NMR chemical shifts in the row $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMe_3)]$ (**6**), $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMe_2Cl)]$ (**3a**), $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMeCl_2)]$ (**7**) and $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnCl_3)]$ (**8**) are very regular and behave as expected – the more electronegative chlorine atoms are bound at the tin atom the higher is the detected chemical shift value. Parallel, the $^2J_{HCSn}$ coupling constants (MeSn) decrease continuously. In contrast to



Scheme 2. Stepwise chlorination of **6** via mono- and dichlorinated stannyl tungsten complexes **3a** and **7** leading to the trichlorostannyl complex **8** and direct synthesis of **7** and **8**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

these findings, the $^{119}$Sn NMR shifts display no regular trend, and after the first Me/Cl substitution a maximum shift value of 227.0 ppm is observed. Further chlorine substitution leads to a decrease of the $^{119}$Sn chemical shift up to –89.4 ppm for **8**. Apparently, two effects are responsible for this feature namely the electronegative character of chlorine as well as the π-back bonding of the *p*-lone pairs of the chlorine. The latter effect increases with a growing number of chlorine atoms due to the fact that the Lewis acid character of the tin atom is increasing at the same time.

*X-ray diffraction analysis.* The molecular structure of $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnCl_3)]$ (**8**) has been confirmed by X-ray diffraction study and is depicted in Figure 7. Selected bond lengths and angles are listed below the Figure and crystal data and refinement parameters in Table 2 in the experimental section. Suitable crystals are obtained upon slow evaporation of saturated $CDCl_3$ solution at room temperature. **8** crystallizes in a triclinic crystal system with space group $P\bar{1}$.

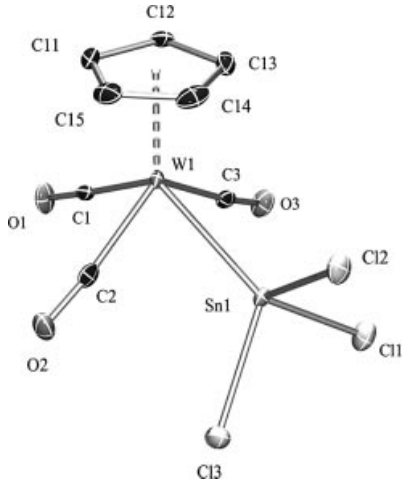


Figure 7. Molecular structure of $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnCl_3)]$ (**8**) in the solid state with the atom-numbering scheme. Displacement ellipsoids are drawn at the 50% probability level and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: W1–C1 1.998(5), W1–C2 2.011(5), W1–C3 2.001(4), W1–Sn1 2.7244(3), Sn1–Cl1 2.3450(11), Sn1–Cl3 2.3616(11), Sn1–Cl2 2.3681(11), C1–W1–Sn1 126.42(12), C3–W1–Sn1 75.08(12), C2–W1–Sn1 76.17(12), Cl1–Sn1–Cl3 96.41(4), Cl1–Sn1–Cl2 98.94(4), Cl3–Sn1–Cl2 99.45(4), Cl1–Sn1–W1 121.81(3), Cl3–Sn1–W1 119.57(3), Cl2–Sn1–W1 116.14(3).

**8** shows the typical piano-stool arrangement as expected for a half-sandwich compound. The geometrical features of **8** in the solid state are very similar to that found for the Mo analogue $[(\eta^5\text{-}C_5H_5)(OC)_3Mo(SnCl_3)]$:[6] the tetrahedral coordination geometry of the tin atom is strongly distorted and resemble a trigonal pyramid also found for the Mo compound. All Cl–Sn–Cl angles are acute (mean: 98.27°) whereas the Cl–Sn–W angles are more obtuse showing values between 116.14(3) (Cl2–Sn1–W1) and 121.81(3)° (Cl1–Sn1–W1). Not only the Sn–Cl distances (mean: 2.358 Å) are similar to those of the Mo complex, but also the transition-metal–tin distances, which amount to 2.7244(3) Å in the tungsten and 2.7223(4) in the molybdenum case. Additionally, we found a short distance of 2.925 Å between the chlorine atom Cl2 and the proton bound to C14, which can be classified as a weak, intramolecular hydrogen bond interaction.

It is known that organotin halides tend to build up associated arrangements with formation of σ-donor bridges in the solid state. It is interesting that **8** shows not such a intermolecular association behaviour. Presumably, this finding is caused by the transition-metal fragment but it remains open whether steric or electronic effects are responsible.

## Conclusions

We were able to show that the alkali salt elimination has to be regarded as a straightforward route to synthesize chlorogermyl and chlorostannyl tungsten complexes and allows the variation of the organo groups being attached to the element as well as the transition-metal fragment itself. The chlorination degree of the transition-metal bound tin atom can be varied successively and selectively by use of $SnCl_4$. Thus, the work reported in this paper opens the door to a range of chlorogermyl and chlorostannyl tungsten complexes which enables further investigations of the chemical behaviour, e.g. with respect to alkali metals, organolithium compounds, hydroxides, sulfides, Lewis bases, amides or alkoxides.

## Experimental Section

All manipulations were conducted either under an atmosphere of dry argon or in vacuo using standard Schlenk line or glovebox techniques. Solvents (benzene and pentane) were purified by distillation from appropriate drying agents (sodium and sodium wire) under dry argon, immediately prior to use. $C_6D_6$ was degassed by three freeze-pump-thaw cycles and stored over molecular sieves. IR spectra were recorded as $CH_2Cl_2$ solutions between KBr plates on a Bruker Vector 22 FT-IR spectrometer. $^1$H, $^{31}$P{$^1$H} and $^{119}$Sn{$^1$H} NMR spectra were acquired on a Bruker Avance 200 NMR spectrometer at 200.1, 121.5 and 111.9 or 186.5 MHz, respectively and referenced to external TMS or $SnMe_4$ ($^{119}$Sn). $^{13}$C{$^1$H} NMR spectra were recorded on a Bruker AMX 400 NMR spectrometer at 125.8 MHz and referenced to the solvent. Microanalyses for C, H and N were performed by Mrs. L. Michels (University of Würzburg) on a Vario Micro instrument (Elementar Analysensysteme). Starting materials were prepared according to literature procedures: $Li[W(\eta^5\text{-}C_5H_5)(CO)_3]$[17] (**1a**), $[(\eta^5\text{-}C_5Me_5)(OC)_3WCl]$,[18] $[(\eta^5\text{-}C_5H_5)(OC)_3WSnMe_3]$[1b] (**6**) and $[(MeCN)_3W(CO)_3]$.[19] The reagents $Me_2GeCl_2$ (**2a**), $Me_2SnCl_2$ (**2b**), $SnCl_4$ and $Bu_2SnCl_2$ (**2c**) were purchased from commercial sources and not further purified prior use.

### Preparation of Starting Material

#### 1. $Li[W(\eta^5\text{-}C_5Me_5)(CO)_3]$ (1b)

#### Lithium Tricarbonyl(pentamethylcyclopentadienyl)tungstate

A solution of 1.80 g (4.45 mmol) of $(\eta^5\text{-}C_5Me_5)(OC)_3WH$ in 15 mL $Et_2O$ was treated with 2.09 mL (5.35 mmol) of BuLi (2.5 M) at 0 °C. The color of the solution changed from yellow to brown and after 15 min **1b** started to precipitate. The mixture was stirred for 1.5 h at ambient temperature. After reaction the precipitate consisting of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**1b** was filtered off, washed twice with 10 mL of hexane and finally dried in vacuo. Yield 1.64 g (4.01 mmol; 90%). Pale brown, pyrophoric powder. Elemental analysis was not carried out due to the pyrophoric behaviour of **1b**.

**2. [(η$^5$-$C_5Me_5$)($Ph_3P$)$(OC)_2$WCl] (9)**

**Dicarbonyl(chloro)(η$^5$-pentamethylcyclopentadienyl)(triphenylphosphanyl)tungsten(II)**

A solution of 3.20 g (7.30 mmol) of [(η$^5$-$C_5Me_5$)$(OC)_3$WCl] and 1.91 g (7.30 mmol) $PPh_3$ in 10 mL benzene in was irradiated with UV light for 5 d. The solvent was removed in vacuo, the crude residue washed with 20 mL hexane and the product dried in vacuo. Yield 4.11 g (6.11 mmol, 84%). Orange powder. $^1$H NMR (300.4 MHz, $C_6D_6$): $\delta$ = 7.62–7.52 (m, 6 H, Ph), 7.08–6.98 (m, 9 H, Ph), 1.65 (s, 15 H, $C_5Me_5$) ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $C_6D_6$): $\delta$ = 250.75 (d, $^2J_{CWP}$ = 18.5 Hz, *cis*-CO), 237.99 (d, $^2J_{CWP}$ = 7.3 Hz, *trans*-CO), 135.85 (d, $^1J_{CP}$ = 47.4 Hz, *ipso*-$C_6H_5$), 132.28 (d, $^3J_{CCCP}$ = 10.1 Hz, *meta*-$C_6H_5$), 130.95 (d, $^4J_{CCCCP}$ = 2.4 Hz, *para*-$C_6H_5$), 128.69 (d, $^2J_{CCP}$ = 9.0 Hz, *ortho*-$C_6H_5$), 112.80 (d, $^2J_{CWP}$ = 1.2 Hz, $H_3CC_5$), 11.00 (s, $H_3CC_5$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = 26.57 (s, $^1J_{PW}$ = 274.6 Hz) ppm. IR ($Et_2O$): $\tilde{\nu}$(C=O) = 1947 (vs), 1870 (m) cm$^{-1}$. $C_{30}H_{30}ClO_2PW$ (672.82): calcd. C 53.55, H 4.49; found C 53.68, H 4.66.

**3. Na[W(η$^5$-$C_5Me_5$)$(CO)_2(PPh_3)$] (1c)**

**Sodium Dicarbonyl(η$^5$-pentamethylcyclopentadienyl)(triphenylphosphanyl)tungstate**

Na amalgam was prepared by dissolving 0.28 g (12.22 mmol) sodium in 50 g mercury. 35 mL THF were added and then 4.11 g (6.10 mmol) of [(η$^5$-$C_5Me_5$)$(Ph_3P)(OC)_2$WCl] (**9**). The reaction mixture was stirred for 18 h at ambient temperature. The suspension was separated from the sodium amalgam and the solvents evaporated to dryness. The crude solid was washed with three 10 mL portions of hexane and dried in vacuo. Yield 3.75 g (5.67 mmol, 93%). Yellow-green, pyrophoric powder. $^1$H NMR (300.4 MHz, [D$_8$]THF): $\delta$ = 7.84–7.82 (m, 6 H, Ph), 7.13–7.02 (m, 9 H, Ph), 1.89 (s, $^4J_{HCCWP}$ = 29.4 Hz, 5 H, Cp) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = 31.44 (s, $^1J_{PW}$ = 278.9 Hz) ppm. IR (THF): $\tilde{\nu}$(C=O) = 1780 (s), 1729 (s) cm$^{-1}$. $C_{30}H_{30}NaO_2PW$ (660.36). Elemental analysis was not carried out due to the pyrophoric behaviour of **1c**.

**Preparation of Germyl and Stannyl Tungsten Complexes**

**1. [(η$^5$-$C_5H_5$)$(OC)_3$W($SnMe_2$Cl)] (3a)**

**Tricarbonyl(chlorodimethylstannyl)(η$^5$-cyclopentadienyl)tungsten(II)**

To a suspension of 635 mg (1.87 mmol) of Li[W($C_5H_5$)$(CO)_3$] (**1a**) in 10 mL diethyl ether were added 411 mg (1.87 mmol) of $Me_2SnCl_2$ and the mixture was stirred at ambient temperature overnight. The solvent was removed in vacuo and the residue was extracted with of hexane (3 × 10 mL). The combined extracts were filtered through celite and the filtrate was evaporated to dryness. Yield 793 mg (1.53 mol, 72%). Dark yellow powder. M.p. 91 °C. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 4.52 (s, 5 H, Cp), 0.87 (s, $^2J_{HCSn}$ = 47.3, 45.3 Hz, 6 H, $SnMe_2$) ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $C_6D_6$): $\delta$ = 89.04 (s, Cp), 2.99 (s, $SnMe_2$) ppm. $^{119}$Sn{$^1$H} NMR (111.9 MHz, $C_6D_6$): $\delta$ = 227 (s) ppm. IR (hexane): $\tilde{\nu}$(C=O) = 2010 (m), 1940 (m), 1911 (m) cm$^{-1}$. $C_{10}H_{11}ClO_3SnW$ (517.20): calcd. C 23.22, H 2.14; found C 23.44, H 2.24.

**2. [(η$^5$-$C_5H_5$)$(OC)_3$W($SnBu_2$Cl)] (3b)**

**(Dibutylchlorostannyl)(tricarbonyl)(η$^5$-cyclopentadienyl)tungsten(II)**

Similar to paragraph **1.** above, from 570 mg (1.68 mmol) of Li[W($C_5H_5$)$(CO)_3$] (**1a**) and 380 mg (1.25 mmol) of $Bu_2SnCl_2$ in 10 mL diethyl ether. The mixture was stirred at ambient temperature overnight. The ether was removed under reduced pressure and the oily residue was extracted with pentane (3 × 10 mL). The combined extracts were filtered through celite and the filtrate was evaporated to dryness. The sticky residue was washed with ice-cold pentane (3 × 2 mL) and was dried in vacuo. Yield 526 mg (0.88 mol, 70%). Dark yellow powder. M.p. 74 °C. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 4.82 (s, 5 H, Cp), 1.91–1.73 (m, 8 H, $CH_2$-$CH_2$), 1.55–1.52 (m, 4 H, $SnCH_2$), 1.05 (t, 6 H, $CH_3$) ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $C_6D_6$): $\delta$ = 88.43 (s, Cp), 31.64 (s, $CH_2$), 27.40 (s, $CH_2$), 19.24 (s, $CH_2$), 13.69 (s, $CH_3$) ppm. $^{119}$Sn{$^1$H} NMR (111.9 MHz, $C_6D_6$): $\delta$ = 26.7 (s, $^1J_{SnW}$ = 162.8 Hz) ppm. IR (hexane): $\tilde{\nu}$(C=O) = 1999 (m), 1981 (m) cm$^{-1}$. $C_{16}H_{23}ClO_3SnW$ (601.35): calcd. C 31.96, H 3.86; found C 32.29, H 3.99.

**3. [(η$^5$-$C_5Me_5$)$(OC)_3$W($GeMe_2$Cl)] (3c)**

**Tricarbonyl(chlorodimethylgermyl)(η$^5$-pentamethylcyclopentadienyl)tungsten(II)**

0.52 g (1.27 mmol) of Li[W(η$^5$-$C_5Me_5$)$(CO)_3$] (**1b**) were suspended in 10 mL $Et_2O$ and treated with 0.18 mL (1.27 mmol, 0.22 g) of $Me_2GeCl_2$. The reaction mixture was stirred for 22 h at ambient temperature. After reaction LiCl was filtered off by use of a celite pad. The filtrate was evaporated to dryness giving a dark brown residue which was washed with 3 mL hexane at –40 °C and dried in vacuo. Yield 0.56 g (81%). Brown solid, m.p. 62 °C. $^1$H NMR (200.1 MHz, $C_6D_6$): $\delta$ = 1.71 [s, 15 H, $C_5(CH_3)_5$], 1.17 [s, 6 H, $Ge(CH_3)_2$] ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $C_6D_6$): $\delta$ = 217.95 (s, CO-*trans*), 202.29 (s, CO-*cis*), 102.52 (s, $C_5Me_5$), 28.67 [s, Ge-($CH_3$)$_2$], 9.00 [s, $C_5(CH_3)_5$] ppm. IR (hexane): $\tilde{\nu}$(C=O) = 2003 (s), 1931 (s), 1907 (s) cm$^{-1}$. $C_{15}H_{21}ClGeO_3W$ (541.23): calcd. C 33.29, H 3.91; found C 32.62, H 3.81.

**4. [(η$^5$-$C_5Me_5$)$(OC)_3$W($SnMe_2$Cl)] (3d)**

**Tricarbonyl(chlorodimethylstannyl)(η$^5$-pentamethylcyclopentadienyl)tungsten(II)**

To a suspension of 0.66 g (1.16) of Li[W(η$^5$-$C_5Me_5$)$(OC)_3$] (**1b**) in 20 mL $Et_2O$ were added 0.36 g (1.64 mmol) of $Me_2SnCl_2$ and the reaction mixture stirred for 17 h at ambient temperature. After reaction LiCl was filtered off over celite and the filtrate evaporated to dryness. The crude brown product was washed with 5 mL of hexane at –40 °C and dried in vacuo. Yield 0.80 g (85%). Ochre solid, m.p. 122 °C. $^1$H NMR (200.1 MHz, $C_6D_6$): $\delta$ = 1.70 (s, 15 H, $C_5Me_5$), 0.91 [s, $^2J_{HCSn}$ = 42.5 and 44.4 Hz, 6 H, $(H_3C)_2Sn$] ppm. $^{13}$C{$^1$H} NMR (125.8 MHz, $C_6D_6$): $\delta$ = 220.89 (s, CO-*trans*), 217.87 (s, CO-*cis*), 103.70 (s, $C_5Me_5$), 10.71 [s, $C_5(CH_3)_5$], 2.48 [s, $^1J_{CSn}$ = 245.5 and 259.9 Hz, $Sn(CH_3)_2$] ppm. $^{119}$Sn NMR (186.5 MHz, $C_6D_6$): $\delta$ = 233.04 [s, $^1J_{WSn}$ = 347.0 Hz] ppm. IR (hexane): $\tilde{\nu}$(C=O) = 1901 (s), 1927 (s), 1997 (s) cm$^{-1}$. $C_{15}H_{21}ClO_3SnW$ (587.33): calcd. C 30.67, H 3.60; found C 30.34, H 3.67.

**5. [(η$^5$-$C_5Me_5$)$(OC)_2(Ph_3P)$W($SnMe_2$Cl)] (3e) and {[(η$^5$-$C_5Me_5$)-$(OC)_2(Ph_3P)$W]$_2$($SnMe_2$)} (4)**

**Dicarbonyl(trimethylstannyl)(η$^5$-pentamethylcyclopentadienyl)(triphenylphosphanyl)tungsten(II)**

600 mg (0.83 mmol) of Na[W(η$^5$-$C_5Me_5$)$(OC)_2(PPh_3)$] (**1c**) were suspended in 20 mL $Et_2O$ and treated with 183 mg (0.83 mmol) of $Me_2SnCl_2$. The reaction mixture was stirred for 16 h at ambient temperature and NaCl filtered through by use of a celite pad. The filtrate was evaporated to dryness and the residue consisting of **3e** and **4** extracted with 25 mL of hexane. **3e** dissolves readily in hexane whereas **4** remains as an yellow solid which was dried in vacuo. The combined hexane extracts were concentrated and crystallized at –30 °C. The hexane phase was separated and the solid dried in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vacuo. **3e**: Yield 340 mg (0.42 mmol, 51%). Yellow solid, m.p. 87 °C. $^1$H NMR (200.13 MHz, $C_6D_6$): $\delta$ = 7.68–7.43 (m, 6 H, Ph), 7.09–6.93 (m, 9 H, Ph), 1.68 (s, 15 H, $Me_5C_5$), 1.05 [s, $^2J_{HCSn}$ = 40.2 and 41.8 Hz, 6 H, MeSn] ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $C_6D_6$): $\delta$ = 230.06 [d, $^2J_{CP}$ = 132.3 Hz, CO], 134.54 [d, $^1J_{CP}$ = 46.6 Hz, *ipso*-$C_6H_5$], 134.29 [d, $^1J_{CP}$ = 10.0 Hz, *meta*-$C_6H_5$], 130.53 [d, $^3J_{CCCP}$ = 2.4 Hz, *para*-$C_6H_5$], 128.56 [d, $^2J_{CCP}$ = 9.9 Hz, *ortho*-$C_6H_5$], 101.16 [s, $^1J_{CW}$ = 5.4 Hz, $C_5Me_5$], 11.25 (s, $C_5Me_5$), 2.88 (s, $CH_3Sn$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = 38.61 [s, $^1J_{PW}$ = 293.6, $^2J_{PWSn}$ = 128.8 und 123.9 Hz] ppm. $^{119}$Sn{$^1$H} NMR (300.13 MHz, $C_6D_6$): $\delta$ = 233.80 [d, $^2J_{SnWP}$ = 132.1 Hz] ppm. IR ($Et_2O$): $\tilde{\nu}$(C=O) = 1904 (vs), 1835 (vs) cm$^{-1}$. $C_{32}H_{36}ClO_2PSnW$ (821.60): calcd. C 46.78, H 4.42; found C 46.67, H 4.25.

**4**: Yield 138 mg (0.11 mmol, 13%). Yellow solid, m.p. 123 °C. $^1$H NMR (300.4 MHz, $C_6D_6$): $\delta$ = 7.68–7.43 (m, 6 H, Ph), 7.09–6.93 (m, 9 H, Ph), 1.78 (s, 30 H, $Me_5C_5$), 0.91 [d, $^4J_{HCSnWP}$ = 1.2, $^2J_{HCSn}$ = 44.0 and 48.0 Hz, 6 H, $H_3CSn$] ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = 44.50 [s, $^1J_{PW}$ = 267.3, $^2J_{PWSn}$ = 130.8 und 125.4 Hz] ppm. IR ($Et_2O$): $\tilde{\nu}$(C=O) = 1901 (vs), 1832 (vs) cm$^{-1}$. $C_{52}H_{46}O_4P_2SnW_2$ (1283.26): calcd. C 48.67, H 3.61; found C 48.47, H 4.05.

### 6. $C_5H_5SnMe_2Cl$ (5)

**(Chlorodimethylstannyl)cyclopentadiene**

A suspension of 418 mg (4.75 mmol) of NaCp and 15 mL $Et_2O$ was treated with 1.04 g (4.75 mmol) of $Me_2SnCl_2$. The mixture was stirred for 18 h at ambient temperature and NaCl was removed by filtration through a celite pad. The filtrate was evaporated under reduced pressure (70 mbar) at ambient temperature. Yield 1.00 g (4.01 mmol, 84%). Yellow oil. $^1$H NMR (200.1 MHz, $C_6D_6$): $\delta$ = 5.99 (s, $^3J_{HCCSn}$ = 30.0 and 29.0 Hz, 5 H, $C_5H_5$), 0.03 [s, $^2J_{HCSn}$ = 59.2 and 56.8 Hz, 6 H, $(H_3C)_2Sn$] ppm. $^{13}$C{$^1$H} NMR (125.8 MHz, $C_6D_6$): $\delta$ = 114.91 (s, $^1J_{CSn}$ = 96.8 Hz, $C_5H_5Sn$), –2.96 [s, $(H_3C)_2Sn$] ppm. $^{119}$Sn NMR (186.5 MHz, $C_6D_6$): $\delta$ = 101.45 (s) ppm. $C_7H_{11}ClSn$ (249.32): calcd. C 33.72, H 4.45; found C 33.34, H 4.67.

### 7. $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMe_2Cl)]$ (3a) by Reaction of 5 with $[(MeCN)_3W(CO)_3]$

A suspension of 450 mg (1.80 mmol) of $C_5H_5SnMe_2Cl$ (**5**), 704 mg (1.80 mmol) of $[(MeCN)_3W(CO)_3]$ and 10 mL THF was refluxed over the period of 18 h. After cooling to room temperature, all volatiles were removed in vacuo and the residue was extracted with hexane (3 × 10 mL). The hexane extracts were combined and filtered through a celite pad. The filtrate was concentrated and stored at –70 °C over the period of one week. The hexane phase was removed and the solid dried in vacuo. Yield 837 mg (1.62 mmol, 90%). Yellow solid.

### 8. $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMe_2Cl)]$ (3a) by Reaction of 6 with $SnCl_4$

A solution of 270 mg (0.54 mmol) of $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMe_3)]$ (**6**) in 5 mL benzene was treated with 142 mg (0.54 mmol) of $SnCl_4$ and the mixture was stirred at ambient temperature for 2 h. All volatiles were removed in vacuo and the residue was extracted with hexane (3 × 19 mL). The combined extracts were filtered through celite and the filtrate was evaporated to dryness. Yield 258 mg (0.50 mmol, 92%). Dark yellow powder.

### 9. $[(\eta^5\text{-}C_5H_5)(OC)_3W(SnMeCl_2)]$ (7) by Reaction of 3a with $SnCl_4$

**Tricarbonyl(dichloromethylstannyl)($\eta^5$-cyclopentadienyl)tungsten(II)**

A solution of 258 mg (0.50 mmol) of $[(\eta^5\text{-}C_5H_5)(OC)_3W\text{-}(SnMe_2Cl)]$ (**3a**) in 5 mL diethyl ether was treated slowly with 131 mg (0.50 mmol) of $SnCl_4$ at 0 °C and the mixture was stirred at ambient temperature for 2 h. All volatiles were removed in vacuo and the residue was extracted with $Et_2O$ (2 × 10 mL). The combined extracts were filtered through celite and the filtrate was evaporated to dryness. Yield 237 mg (0.44 mmol, 88%). Yellow powder. M.p. 189 °C. $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 4.49 (s, 5 H, Cp), 1.11 (s, $^2J_{HCSn}$ = 46.2, 45.2 Hz, 3 H, $SnMe_2$) ppm. $^{13}$C{$^1$H} NMR

**Tricarbonyl(trichlorostannyl)($\eta^5$-cyclopentadienyl)tungsten(II)**

Analogously to paragraph 11., from 326 mg (0.60 mmol) of [($\eta^5$-$C_5H_5$)(OC)$_3$W(SnMe$_3$)] (**6**) and 1.28 mg (4.90 mmol) of $SnCl_4$ in 15 mL chloroform over the period of 6 d. Yield 148 mg (0.26 mol, 55%). Yellow powder.

**Crystal Structure Determination:** The crystal data of **3b**–**d** and **8** (Table 2) were collected with a Bruker Apex2 diffractometer with a CCD area detector and multi-layer mirror monochromated Mo-$K_\alpha$ radiation. The structures were solved by direct methods, refined with the Shelx software package (G. Sheldrick, University of Göttingen, 1997) and expanded using Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were assigned idealized position and were included in structure factor calculations.

CCDC-644418 (for **3b**), -636078 (for **3c**), -636079 (for **3d**) and -640077 (for **8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Spectro-electrochemical Aspects of $[Ru^{II}(trpy)(pdt)(X)]^{n+}$ (trpy = 2,2′:6′,2′′-Terpyridine, pdt = 5,6-Diphenyl-3-pyridyl-*as*-triazine, X = $Cl^-$, $CH_3CN$, $NO_2^-$, $NO^+$, $NO^·$) – Electrophilicity of $\{Ru^{II}–NO^+\}$ and Photolability of $\{Ru^{II}–NO^·\}$

**Somnath Maji,[a] Chandrani Chatterjee,[a] Shaikh M. Mobin,[a] and Goutam Kumar Lahiri*[a]**

**Keywords:** Ruthenium / Nitrosyl complexes / Spectroscopy / Electrochemistry / Reactivity

Nitrosylruthenium derivatives having $NO^+$ and $NO^·$ states have been synthesized in a stepwise manner starting from $[Ru^{II}(trpy)(pdt)(Cl)](ClO_4)$ $\{[\mathbf{1}](ClO_4)\}$ → $[Ru^{II}(trpy)(pdt)(CH_3CN)](ClO_4)_2$ $\{[\mathbf{2}](ClO_4)_2\}$ → $[Ru^{II}(trpy)(pdt)(NO_2)](ClO_4)$ $\{[\mathbf{3}](ClO_4)\}$ → $[Ru^{II}(trpy)(pdt)(NO^+)](ClO_4)_3$ $\{[\mathbf{4}](ClO_4)_3\}$ → $[Ru^{II}(trpy)(pdt)(NO^·)](ClO_4)_2$ $\{[\mathbf{4}](ClO_4)_2\}$ [trpy = 2,2′:6′,2′′-terpyridine, pdt = 5,6-diphenyl-3-pyridyl-*as*-triazine]. The molecular identity of $[\mathbf{1}](ClO_4)$ and $[\mathbf{2}](ClO_4)_2$ and the subsequent stereoretentive transformation of $[\mathbf{1}](ClO_4)$ → $[\mathbf{2}](ClO_4)_2$ have been authenticated by single-crystal X-ray structures. Electrochemical and spectral features are investigated as a function of the monodentate ligands ($Cl^-$, $CH_3CN$, $NO_2^-$, $NO^+$, $NO^·$). The kinetic and thermodynamic aspects of the reaction of the moderately strong electrophilic $\{Ru^{II}–NO^+\}$ center [$\nu$(NO): 1944 $cm^{-1}$] in $[\mathbf{4}]^{3+}$ with a nucleophile such as $OH^-$ have been studied. The nitrosyl species $[Ru^{II}(trpy)(pdt)(NO^+)]^{3+}$ ($[\mathbf{4}]^{3+}$) can be selectively reduced to $[Ru^{II}(trpy)(pdt)(NO^·)]^{2+}$ ($[\mathbf{4}]^{2+}$) electrochemically as well as chemically by hydrazine hydrate. On exposure to light an acetonitrile solution of $[Ru^{II}(trpy)(pdt)(NO^·)]^{2+}$ ($[\mathbf{4}]^{2+}$) undergoes slow photocleavage of the $Ru^{II}–NO$ bond over a period of 4 h, resulting in the corresponding solvated species $[Ru^{II}(trpy)(pdt)(CH_3CN)]^{2+}$ ($[\mathbf{2}]^{2+}$). The rate of photolability of the $Ru^{II}–NO$ bond in $[\mathbf{4}]^{2+}$ has been monitored spectrophotometrically.

## Introduction

The biological[1] and environmental[2] relevance of the nitrosyl molecule has led to a resurgence of interest in the metal–NO interaction. This is primarily due to fundamental issues such as (i) bonding and redox features,[3] (ii) reactivity profile of metal-bound NO function with a variety of nucleophiles,[4] (iii) uses of nitrosylmetal derivatives as antitumor and antiseptic agents,[5] and (iv) photolytic cleavage of the M–NO bond and subsequent transfer of photoreleased "NO" to the biological targets such as myoglobin (Mb) or cytochrome c oxidase.[6]

The stability of possible redox states of the nitrosyl molecule, $NO^+$, $NO^·$, and $NO^-$, in the complex framework of (AL)M–NO depends on a variety of factors, including the nature of the metal ions and the ancillary ligands (AL). For example, in reduced vitamin $B_{12}$, the cobalt center formally binds with the NO in the form of $Co^{III}–NO^-$,[7] while in metmyoglobin the iron center binds with the NO formally as $Fe^{II}–NO^+$.[8] Similarly, electrophilicity of the coordinated NO center in $\{(AL)(trpy)Ru^{II}–NO\}$ (trpy = 2,2′:6′,2′′-terpyridine) can also be nicely tuned primarily depending on the electronic aspects of AL. Thus, the $\nu_{NO^+}$ frequency as well as the $E°(NO^+/NO^·)$ values systematically vary with AL = 2-phenylpyridine (pp),[9] acetylacetone (acac),[10] *N*-methyl-2-(2-pyridyl)benzimidazole (pNMebi),[11] (2-pyridyl)benzimidazole (pbi),[11] 2,2′-dipyridylamine (dpa),[12] bis(2-pyridyl) ketone (dpk),[13] 2,2′-bipyridine (bpy),[14] 2-(2-pyridyl)benzoxazole (pbo),[11] and 2-(phenylazo)pyridine (pap),[15] as shown in Table 1.

The observed distinct role of AL in the complex framework of $\{(AL)(trpy)Ru^{II}–NO^+\}$ (Table 1) has initiated the selective introduction of 5,6-diphenyl-3-pyridyl-*as*-triazine (pdt) as AL to explore its specific effect towards the stability of coordinated NO in accessible redox states. The ligand pdt has been of interest in the field of coordination chemistry as well as organometallic chemistry since early 1964.[16] However, only a limited number of ruthenium complexes of pdt and its derivatives have been reported so far from different perspectives.[17]

The present article thus describes the stepwise synthetic aspects of the nitrosyl complexes starting from $[Ru^{II}(trpy)(pdt)(Cl)](ClO_4)$ $\{[\mathbf{1}](ClO_4)\}$ → $[Ru^{II}(trpy)(pdt)(CH_3CN)](ClO_4)_2$ $\{[\mathbf{2}](ClO_4)_2\}$ → $[Ru^{II}(trpy)(pdt)(NO_2)](ClO_4)$ $\{[\mathbf{3}](ClO_4)\}$ → $[Ru^{II}(trpy)(pdt)(NO^+)](ClO_4)_3$

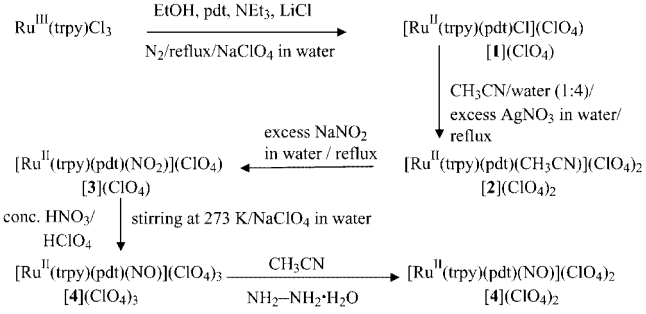
$\{[\mathbf{4}](ClO_4)_3\} \rightarrow [Ru^{II}(trpy)(pdt)(NO^{\cdot})]^{2+}$ $\{[\mathbf{4}](ClO_4)_2\}$. Crystal structures of $[\mathbf{1}](ClO_4)$ and $[\mathbf{2}](ClO_4)_2$ and spectroelectrochemical features of all four complexes are reported. The reactivity of the ruthenium-bound electrophilic $NO^+$ in $[\mathbf{4}](ClO_4)_3$ in the presence of a nucleophile such as $OH^-$ and the aspects of photolytic cleavage of the $Ru^{II}$–$NO^{\cdot}$ bond in $[\mathbf{4}]^{2+}$ are also investigated.

## Results and Discussion

### Synthesis and Characterization

The precursor chlorido complex $[Ru^{II}(trpy)(pdt)(Cl)]^+$ $[\mathbf{1}]^+$ [trpy = 2,2′:6′,2′′-terpyridine, pdt = 5,6-diphenyl-3-pyridyl-*as*-triazine] has been synthesized from $[Ru(trpy)Cl_3]$ and pdt in the presence of excess $Et_3N$ and LiCl in refluxing EtOH. The crude product was subsequently purified by column chromatography on alumina. The product was isolated as its perchlorate salt $[\mathbf{1}](ClO_4)$. The solvated species $[\mathbf{2}](ClO_4)_2$ and the nitro derivative $[\mathbf{3}](ClO_4)$ were prepared from $[\mathbf{1}](ClO_4)$ and $[\mathbf{2}](ClO_4)_2$, respectively, as shown in Scheme 1. The desired nitroso complex $[Ru^{II}(trpy)(pdt)(NO^+)](ClO_4)_3$ $\{[\mathbf{4}](ClO_4)_3\}$ was prepared from the nitro derivative $[\mathbf{3}](ClO_4)$ by using concentrated nitric acid followed by concentrated perchloric acid at 273 K (Scheme 1).



Scheme 1.

The direct synthesis of $[\mathbf{4}](ClO_4)_3$ either from the chlorido $\{[\mathbf{1}](ClO_4)\}$ or solvated $\{[\mathbf{2}](ClO_4)_2\}$ derivative using NO gas or $NOBF_4$ was not successful. Therefore, the stepwise synthetic route as shown in Scheme 1 was followed.

The diamagnetic complexes $[\mathbf{1}](ClO_4)$, $[\mathbf{2}](ClO_4)_2$, $[\mathbf{3}](ClO_4)$, and $[\mathbf{4}](ClO_4)_3$ exhibit expected molar conductivities and microanalytical data (see Experimental Section).

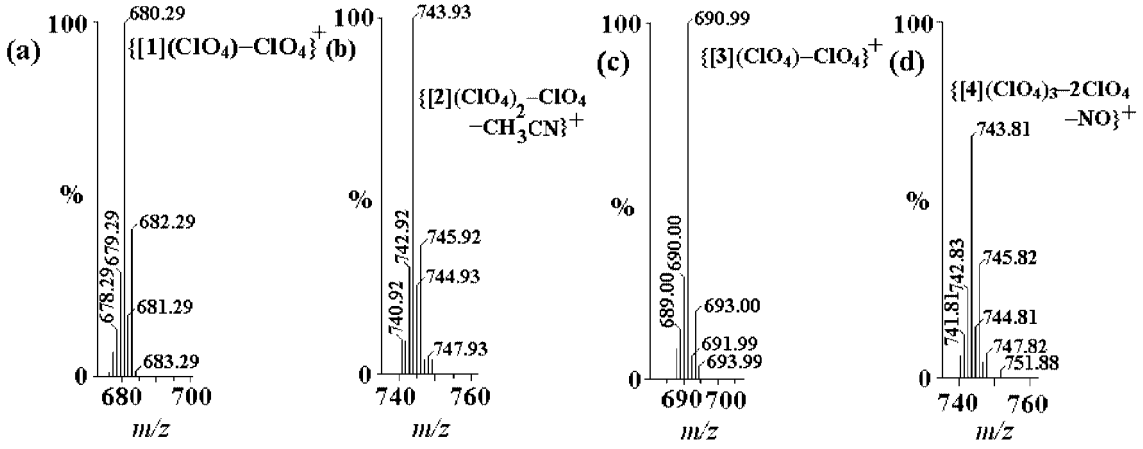

Figure 1. ESI mass spectra of (a) [**1**]($ClO_4$), (b) [**2**]($ClO_4$)$_2$, (c) [**3**]($ClO_4$), and (d) [**4**]($ClO_4$)$_3$ in $CH_3CN$.

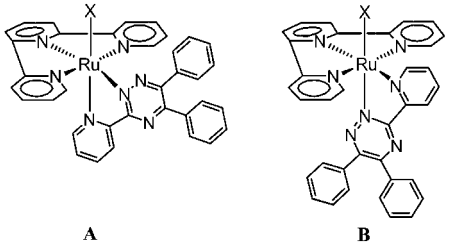
The positive-ion electrospray mass spectra of [**1**]($ClO_4$), and [**3**]($ClO_4$) show molecular ion peaks centered at *m*/*z* = 680.29 and 690.99, respectively, corresponding to [**1**]$^+$ (calculated molecular mass: 680.09) and [**3**]$^+$ (calculated molecular mass: 690.11). Molecular ion peaks for [**2**]($ClO_4$)$_2$ and [**4**]($ClO_4$)$_3$ appear at *m*/*z* = 743.93 and 743.81 corresponding to {[**2**]($ClO_4$)$_2$ – $ClO_4$ – $CH_3CN$}$^+$ (calculated molecular mass: 744.07) and {[**4**]($ClO_4$)$_3$ – 2 $ClO_4$ – NO}$^+$ (calculated molecular mass: 744.15), respectively (Figure 1).

Orientation of the pyridyl or triazine ring of the unsymmetric pdt with respect to the monodentate ligand (X = $Cl^-$ or $CH_3CN$ or $NO_2^-$ or NO) in the complex frameworks gives rise to two possible isomeric structures, **A** and **B**.



However, in practice, only one of the structural forms (**A** or **B**) has been systematically isolated by column chromatography for all the complexes. The preferential crystallization of isomer **A** where the pyridyl nitrogen atom is *trans* to "X" has been established by crystal structure analyses of [**1**]($ClO_4$) and [**2**]($ClO_4$)$_2$.

### Crystal Structures of [1]($ClO_4$) and [2]($ClO_4$)$_2$·3$H_2O$

The crystal structures of [**1**]($ClO_4$) and [**2**]($ClO_4$)$_2$·3$H_2O$ are shown in Figures 2 and 3, respectively. Selected crystallographic and structural parameters are listed in Tables 2 and 4, respectively.

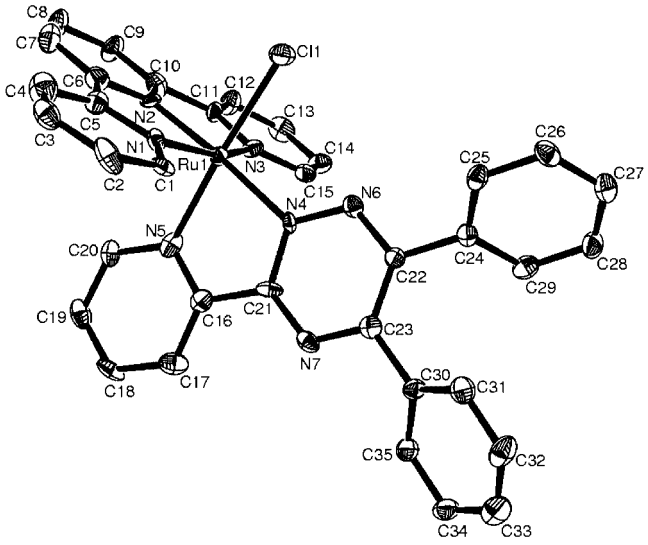


Figure 2. Crystal structure of the cation of [**1**]($ClO_4$).

The trpy ligand in the complexes is coordinated to the ruthenium ion in the expected meridional fashion with the bidentate pdt ligand in *cis* position. The intraligand *trans* angles, N1–Ru–N3 of 159.1(2) and 158.5(2)°, in [**1**]($ClO_4$) and [**2**]($ClO_4$)$_2$, respectively, reflect the usual geometrical constraints due to the meridional binding mode of tridentate trpy.[18] The other two interligand *trans* angles, N2–Ru–N4 and N5–Ru–X, remain close to 180° for both the complexes. As in other Ru–trpy derivatives,[18,19] the central $Ru^{II}$–N2(trpy) bonds {1.954(6) and 1.977(5) Å in [**1**]($ClO_4$) and [**2**]($ClO_4$)$_2$, respectively} are significantly shorter than the corresponding terminal $Ru^{II}$–N(trpy) distances, Ru–N1 [2.058(6) and 2.078(5) Å] and $Ru^{II}$–N3 [2.057(6) and 2.073(5) Å]. The pdt ligand forms a five-membered chelate ring to the metal ion through pyridyl and triazine nitrogen atoms. The coordinated pdt ligand is slightly nonplanar; the dihedral angles between the chelated pyridine and triazine

rings in [**1**]$(ClO_4)$ and [**2**]$(ClO_4)_2$ are 2.80(0.17) and 4.81(0.15)°, respectively. The dihedral angles between the pendant phenyl rings linked to the triazine ring are 52.13(0.26), 49.12(0.30) and 44.84(0.21), 55.09(0.25)° in [**1**]$(ClO_4)$ and [**2**]$(ClO_4)_2$, respectively. The $Ru^{II}$–Cl and $Ru^{II}$–N(pdt/trpy) bond lengths and the associated angles are in good agreement with the reported data on related molecules.[17a,18,19] The coordinated acetonitrile molecule in [**2**]$(ClO_4)_2$ is in its usual nearly linear mode with an N8–C36–C37 angle of 177.8(9)°.[13] The packing diagram of [**2**]$(ClO_4)_2 \cdot 3H_2O$ is shown in Figure S1 (Supporting Information).

### $^1$H NMR, IR, UV/Vis and Emission Spectral Aspects

The $^1$H NMR spectra of [**1**]$(ClO_4)$, [**2**]$(ClO_4)_2$, [**3**]$(ClO_4)$, and [**4**]$(ClO_4)_3$ in $(CD_3)_2SO$ are shown in Figure S2 (Supporting Information and Experimental Section). The complexes display 25 severely overlapping signals in the aromatic region between δ = 7.0 and 9.0 ppm. This matches well with the calculated number of aromatic signals, 11 and 14 resonances from the trpy and pdt ligands, respectively.

The $ClO_4^-$ vibrations are observed at 1096/623, 1089/625, 1097/623, and 1087/626 $cm^{-1}$ for [**1**]$(ClO_4)$, [**2**]$(ClO_4)_2$, [**3**]$(ClO_4)$, and [**4**]$(ClO_4)_3$, respectively. $Ru^{II}$–$NO_2$ stretching frequencies of [**3**]$(ClO_4)$ fall at 1366 $cm^{-1}$ (asym.) and 1276 $cm^{-1}$ (sym.). The $\nu_{NO^+}$ stretching frequency of 1944 $cm^{-1}$ for [**4**]$(ClO_4)_3$ (Figure 4) is comparable to that reported for analogous complexes with AL = pbi, dpa or dpk (Table 1). However, it is much lower than that reported for AL = strongly π-acidic pap, pbo or bpy and much higher with respect to AL = strongly σ-donating pp, acac or pNMebi (Table 1). Thus, the observed reasonably high $\nu_{NO}$ stretching frequency of [**4**]$(ClO_4)_3$ is suggestive of its moderate electrophilic character.

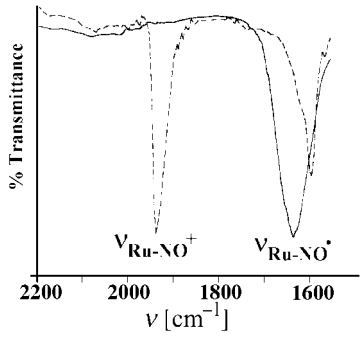

Figure 4. IR spectra (KBr disk) of (a) [**4**]$(ClO_4)_3$ (------) and (b) [**4**]$(ClO_4)_2$ (—) in the region of 2200–1600 $cm^{-1}$.

The complexes exhibit multiple transitions in the UV/Vis region in $CH_3CN$ (Figure 5, Table 3). Intense ligand-based transitions (π → π* and n → π*) are observed in the UV region. The ruthenium(II)-based moderately intense metal-to-ligand charge-transfer (MLCT) transitions appear near 500 nm. The Gaussian analysis of the visible region of the spectra reveals the presence of two close bands in each of $[\mathbf{1}]^+$, $[\mathbf{2}]^{2+}$, and $[\mathbf{3}]^+$ (Table 3 and inset of Figure 5).

These are tentatively assigned to dπ($Ru^{II}$) → π*(pdt)- and dπ($Ru^{II}$) → π*(trpy)-based transitions.[13,17] The MLCT band energy in acetonitrile solution follows the or-

[a] Potentials $E°_{298}$/V ($\Delta E$/mV) vs. SCE. [b] In $CH_3CN$/0.1 M $Et_4NClO_4$. [c] $E_{pc}$ is considered due to the irreversible nature of the wave. [d] In acetonitrile. [e] Bands obtained by Gaussian analysis of the lowest energy transition. [f] Shoulder.

der $Cl^-$ (520 nm) < $NO_2^-$ (482 nm) < $CH_3CN$ (470 nm) < $NO^+$ (467 nm) depending on the relative stabilization of the dπ($Ru^{II}$) level.[20] The tripositive charge as well as pronounced π-acceptor characteristics of $NO^+$ in [**4**]$^{3+}$ are indeed reflected in the relatively higher MLCT band energy and the corresponding redox processes (see later). The 15-nm (666 cm$^{-1}$) blueshift in the MLCT band energy while moving from $Ru^{II}$–$NO_2^-$ [**3**]$(ClO_4)$ (482 nm) to $Ru^{II}$–$NO^+$ [**4**]$(ClO_4)_3$ (467 nm) is much less than that observed for analogous complexes having π-acidic ancillary ligands (dpk, bpy, pap).[13–15] This implies relatively weaker d$\pi Ru^{II}$ → π*($NO^+$) backbonding in [**4**]$(ClO_4)_3$, as is also been evidenced in the $\nu(NO^+)$ stretching frequency (Table 1).

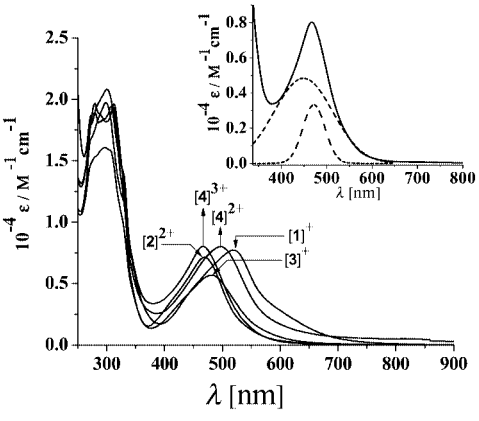

Figure 5. Electronic spectra in acetonitrile of [**1**]$^+$, [**2**]$^{2+}$, [**3**]$^+$, [**4**]$^{3+}$, and [**4**]$^{2+}$. Inset shows the Gaussian analysis (------) of the experimental spectrum (—) of [**2**]$^{2+}$ in the visible region.

Though excitations of [**1**]$^+$, [**3**]$^+$, and [**4**]$^{3+}$ at the lowest energy MLCT bands failed to show emissions even in EtOH/MeOH (4:1) glass (77 K), [**2**]$^{2+}$ exhibits weak emission at 640 nm (Figure S3, Supporting Information). The quantum yield, $\&\pi\eta\iota;$ = 0.026, was calculated with reference to $Ru(bpy)_3^{2+}$ ($\&\pi\eta\iota;$ = 0.34).[21] The observed emission of [**2**]$^{2+}$ can be attributed to the triplet MLCT state.[22]

### Rates and Equilibrium Constant for the Conversion of [$Ru^{II}$(trpy)(pdt)($NO^+$)]$^{3+}$ [**4**]$^{3+}$ → [$Ru^{II}$(trpy)(pdt)($NO_2$)]$^+$ [**3**]$^+$

Unlike earlier reported analogous nitrosyl complexes,[11–13,15] [**4**]$^{3+}$ is found to be quite stable both in the solid state as well as in $CH_3CN$ or even in poorly soluble water medium, in spite of the reasonably high $\nu(NO^+)$ stretching frequency of 1944 cm$^{-1}$. However, in the presence of a strong nucleophile such as $OH^-$, it undergoes slow transformation to the corresponding nitro derivative ([**3**]$^+$) [Equation (1)] (Figure 6). On the other hand, for the aforesaid analogous complexes, a weak nucleophile such as $H_2O$ was found to be effective to perform the reaction stated in Equation (1).

$$\underset{[\mathbf{4}]^{3+}}{[Ru^{II}(trpy)(pdt)(NO^-)]^{3+}} + OH^- \rightarrow \underset{[\mathbf{3}]^{+}}{[Ru^{II}(trpy)(pdt)(NO_2)]^{+}} + H^+ \quad (1)$$

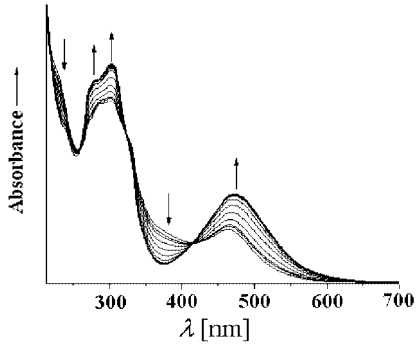

Figure 6. Time evolution of the electronic spectra (5-min time interval) of a changing solution of [$Ru^{II}$(trpy)(pdt)($NO^+$)]$^{3+}$ ($0.4 \times 10^{-4}$ M) + $OH^-$ ($0.1 \times 10^{-2}$ M) → [$Ru^{II}$(trpy)(pdt)($NO_2$)]$^+$ + $H^+$ in $CH_3CN$ at 318 K. Arrows indicate increase or decrease in absorbances with the progression of the reaction.

The rate of conversion of the nitroso derivative ([**4**]$^{3+}$, $0.4 \times 10^{-4}$ M) to the nitro counterpart ([**3**]$^+$) was monitored spectrophotometrically in the temperature range of 298–

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

318 K in $CH_3CN$ solvent using a calculated optimum concentration of aqueous NaOH solution ($0.1 \times 10^{-2}$ M). $CH_3CN$ was chosen as a solvent because of the poor solubility of $[4]^{3+}$ in $H_2O$ and thus the transformation process was monitored without any pH control. The well-defined isosbestic points (Figure 6) imply the involvement of nitrosyl and nitro species as the primary components in the conversion process. The pseudo-first-order rate constant ($k$/s), activation parameters ($\Delta H^{\#}/\Delta S^{\#}$), and equilibrium constant ($K$) values are calculated to be: $4.13 \times 10^{-4}$ (298 K), $7.30 \times 10^{-4}$ (308 K), $1.29 \times 10^{-3}$ (318 K); 42.26 kJ mol$^{-1}$/–110.48 J K$^{-1}$ mol$^{-1}$; 6.6, respectively. The observed appreciably large negative $\Delta S^{\#}$ value confirms that the nucleophilic attack of the electrophilic $NO^+$ site in $[4]^{3+}$ by $OH^-$ occurs through an associatively activated process. The equilibrium constant value of 6.6 indicates the presence of an appreciable concentration of the initial nitrosyl species $[Ru^{II}(trpy)(pdt)(NO^+)]^{3+}$ ($[4]^{3+}$) in the equilibrated situation even under strongly alkaline condition.

### Redox and Spectroelectrochemical Aspects

The $Ru^{III}/Ru^{II}$ potentials of $[1]^+$, $[2]^{2+}$, and $[3]^+$ (couple I, Figure 7a–c; Table 3) vary depending on the electron-donating/-withdrawing nature of the monodentate ligand (X) as well as the electrostatic factor because of the overall charge of the complex moieties. They follow the expected trend of X = $Cl^-$ (0.89) < $NO_2^-$ (1.09) << $CH_3CN$ (1.33 vs. SCE). The potentials are comparable to those of the corresponding $[Ru^{II}(trpy)(AL)(X)]^{n+}$, where AL = dpk,[13] having a π-conjugated electron-withdrawing C=O function (X = $Cl^-$, 0.88; $NO_2^-$, 1.02 V; $CH_3CN$, 1.37 V vs. SCE). However, the potentials are much higher than those of the analogous AL = dpa[12] derivatives incorporating a π-donor amine group (X = $Cl^-$, 0.64; $NO_2^-$, 0.88 vs. SCE). The two ligand-based reductions are observed in the range of –1.0 to –1.5 V (couples II and III, Figure 7a–c, Table 3). The first reduction wave near –1.0 V appears to be less than that typical for the trpy-based reductions (–1.30 and –1.80 V) observed in numerous Ru–trpy complexes.[18–20,23] On the other hand, the free pdt ligand reduces reversibly, $E°_{298}$/V ($\Delta E$/mV) at –1.49 (120) versus SCE in $CH_3CN$ (Figure 7e). Thus, couples II and III are assigned as the reduction processes involving pdt and trpy ligands, respectively.

The nitrosyl complex $[4]^{3+}$ exhibits four successive reduction processes (couples I–IV, Figure 7d, Table 3). The effects of neutrality as well as low basicity of both the pdt and trpy ligands and the highly charged feature of $[4]^{3+}$ facilitate the reversible reduction at the rather positive potential of 0.40 V versus SCE in $CH_3CN$ (couple 1, Figure 7d). The same effect has also been extended even for the second one-electron reduction of $[4]^{3+}$ (couple II, Figure 7d) at a reasonably less negative potential of –0.33 V, though irreversible at the cyclic voltammetric timescale. The potentials of couples I and II are much more positive relative to the reductions involving the coordinated pdt and trpy ligands, –0.90 and –1.11 V (couples III and IV, Figure 7d).

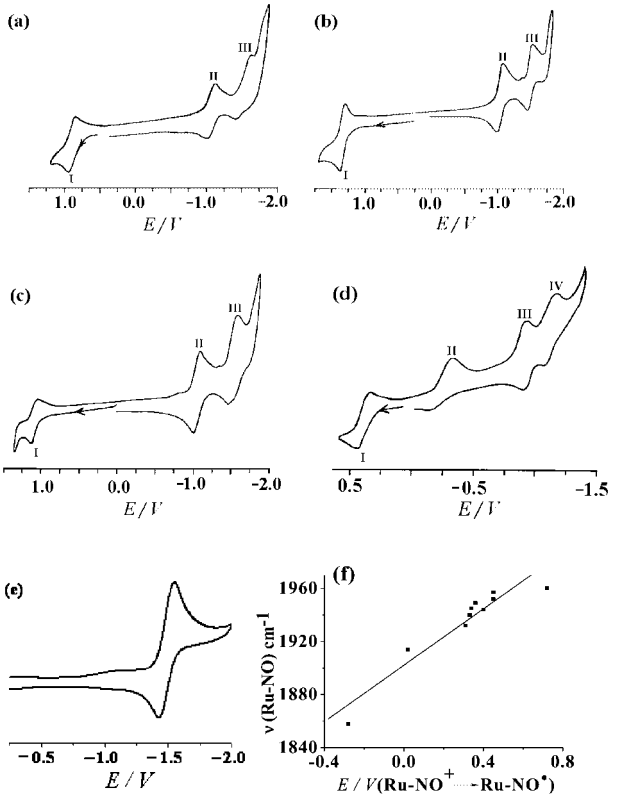

Figure 7. Cyclic voltammograms of (a) $[1]^+$, (b) $[2]^{2+}$, (c) $[3]^+$, (d) $[4]^{3+}$, (e) free ligand, pdt in $CH_3CN$ (scan rate: 50 mV s$^{-1}$), and (f) least-squares plot of $E$/V ($Ru^{II}$–$NO^+$–$Ru^{II}$–$NO^{\cdot}$) vs. $\nu(Ru^{II}–NO^+)$ frequency of $[Ru^{II}(trpy)(AL)(NO^+)]^{3+}$ complexes where AL = pap, bpy, pbo, pdt, dpk, dpa, pbi, pNMebi, acac, and pp as listed in Table 1.

Therefore, couples I and II are logically considered as the expected successive reductions of the redox facile coordinated $NO^+$, that is, $\{Ru^{II}–NO^+\} \rightarrow \{Ru^{II}–NO^{\cdot}\}$ and $\{Ru^{II}–NO^{\cdot}\} \rightarrow \{Ru^{II}–NO^-\}$, respectively. The difference in potential of 0.73 V (couple II/couple I) between the successive NO-centered reductions leads to a large comproportionation constant ($K_c$) value of $10^{12.4}$ ($RT\ln K_c = \Delta E/0.059$)[24] for the intermediate $\{Ru^{II}–NO^{\cdot}\}$ radical species $[4]^{2+}$. The $Ru^{II}–NO^+ \rightarrow Ru^{II}–NO^{\cdot}$ reduction potentials and the corresponding $\nu(NO^+)$ values for the analogous $[Ru^{II}(trpy)(AL)(NO^+)]^{3+}$ complexes with AL = pap,[15] bpy,[14] pbo,[11] dpk,[13] dpa,[12] pbi,[11] pNMebi,[11] acac,[10] and pp[9] (Table 1) follow a general trend. Consequently, the plot of $E_{1/2}$ of the $Ru^{II}–NO^+/Ru^{II}–NO^{\cdot}$ couple versus the $\nu(NO^+)$ frequency for the known $[Ru^{II}(trpy)(AL)(NO^+)]^{3+}$ derivatives yields a reasonably linear relationship (Figure 7f).

Nitrosyl species $[4]^{3+}$ can be quantitatively reduced to $[4]^{2+}$ either coulometrically or by using hydrazine hydrate as a chemical reducing agent. The relevant microanalytical, conductivity, and mass spectrometric data are given in the Experimental Section. On reduction of $[4]^{3+}$ to $[4]^{2+}$, the $\nu(NO)$ frequency is shifted from 1944 to 1633 cm$^{-1}$ (Figure 4) The large $\Delta\nu$ value of 311 cm$^{-1}$ on moving from $[4]^{3+}$ to $[4]^{2+}$ confirms[25] the reduction of coordinated $NO^+$ to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$NO^{\cdot}$. Consequently, the reduced species $[\mathbf{4}]^{2+}$ exhibits a radical-type EPR spectrum ($g$ = 2.003) with partially resolved nitrogen hyperfine splittings.[11–13,26] On reduction to the nitrosyl radical complex $[\mathbf{4}]^{2+}$, the visible-energy charge-transfer band has been reasonably redshifted from 467 to 494 nm (Figure 5). Moreover, two distinct bands involving the singly occupied MO appear at 307 and 281 nm[13] (Figure 5, Table 3). However, the second reduced species $[\mathbf{4}]^{+}$ with the $NO^{-}$ state was found to be unstable even on the coulometric timescale at 298 K.

### Photocleavage of the $Ru^{II}$–NO Bond in $[Ru^{II}(trpy)(pdt)(NO^{\cdot})]^{2+}$ ($[\mathbf{4}]^{2+}$)

Though $[\mathbf{4}]^{2+}$ is quite stable in $CH_3CN$ under ambient light conditions, exposure of an acetonitrile solution of $[\mathbf{4}]^{2+}$ to light (Xenon 350 W lamp) for a period of about 4 h results in quantitative transformation to the solvated species $[\mathbf{2}]^{2+}$ by the selective cleavage of the $Ru^{II}$–$NO^{\cdot}$ bond. The slow but steady progression of photocleavage of the $Ru^{II}$–$NO^{\cdot}$ bond of $[\mathbf{4}]^{2+}$ was monitored spectrophotometrically in $CH_3CN$ (Figure 8) and the presence of isosbesticities suggests the clean conversion of $[Ru^{II}(trpy)(pdt)(NO^{\cdot})]^{2+}$ ($[\mathbf{4}]^{2+}$) to $[Ru^{II}(trpy)(pdt)(CH_3CN)]^{2+}$ ($[\mathbf{2}]^{2+}$). The rate of first-order photolytic release of NO ($k_{NO}$) has been determined to be $4.4\times10^{-3}$ $min^{-1}$ ($t_{1/2}\approx157$ min). This sort of photolytic cleavage of the M–NO bond maintaining the overall integrity of the rest of the molecule is known to have biological relevance.[6] However, because of the insolubility of $[\mathbf{4}]^{2+}$ in aqueous medium, it has not been possible so far to explore the feasibility of transferring the photoliberated NO to biomolecules such as myoglobin or cytochrome c oxidase. Thus, further work in the direction of developing newer classes of water-soluble nitrosyl derivatives is in progress.

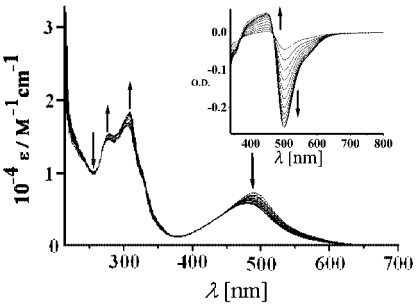

Figure 8. Time evolution of the electronic spectra (20-min time interval) of a changing solution of $[Ru^{II}(trpy)(pdt)(NO^{\cdot})]^{2+}$ ($\mathbf{4}^{2+}$, $0.4\times10^{-4}$ M) in $CH_3CN$ exposed to light (Xe lamp 350 W). Arrows indicate increase or decrease in absorbances with the progression of the reaction. The inset shows the difference spectra of $\mathbf{4}^{2+}$ exposed to light (Xe lamp 350 W) at different time intervals with respect to unexposed $[\mathbf{4}]^{2+}$ in acetonitrile as the reference solution.

## Conclusions

The present work demonstrates the substitutional and electron-transfer aspects of a series of four compounds based on the framework of $[Ru^{II}(trpy)(pdt)X]^{n+}$ {X = $Cl^{-}$ ($[\mathbf{1}]^{+}$), $CH_3CN$ ($[\mathbf{2}]^{2+}$), $NO_2^{-}$ ($[\mathbf{3}]^{+}$), $NO^{+}$ ($[\mathbf{4}]^{3+}$)}. The nitrosyl function in $[\mathbf{4}]^{3+}$ undergoes facile two-step one-electron reductions: $\{Ru^{II}–NO^{+}\}$ to $\{Ru^{II}–NO^{\cdot}\}$ to $\{Ru^{II}–NO^{-}\}$. Unlike earlier reported analogous complexes $\{[Ru^{II}(trpy)(AL)(NO^{+})]^{n+}\}$ with AL = pap, pbo, bpy, dpk, dpa, pbi, pNMebi, $[\mathbf{4}]^{3+}$ is found to be sufficiently stable both in the solid and solution ($CH_3CN$ or poorly in water medium) states in spite of the moderately strong electrophilic character of the nitrosyl function [$\nu(Ru^{II}–NO^{+})$ = 1944 $cm^{-1}$]. $[\mathbf{4}]^{3+}$ transforms slowly and partially to the corresponding nitro derivative $[\mathbf{3}]^{+}$ only in the presence a of strongly alkaline medium. The $NO^{+}$ function in $[Ru^{II}(trpy)(pdt)(NO^{+})]^{3+}$ ($[\mathbf{4}]^{3+}$) can be quantitatively reduced to the corresponding $NO^{\cdot}$ state in $[Ru^{II}(trpy)(pdt)(NO^{\cdot})]^{2+}$ ($[\mathbf{4}]^{2+}$) either electrochemically or chemically by using hydrazine hydrate. Though $[\mathbf{4}]^{2+}$ is stable under ambient light conditions, the exposure of an acetonitrile solution of $[\mathbf{4}]^{2+}$ to light (Xenon 350 W lamp) for a period of 4 h results in the solvated species $[\mathbf{2}]^{2+}$ by the slow photorelease of NO with $k_{NO}$ of $4.4\times10^{-3}$ $min^{-1}$ ($t_{1/2}\approx157$ min).

## Experimental Section

**Materials and Instrumentation:** The precursor complexes $Ru^{III}(trpy)Cl_3$[27] and 5,6-diphenyl-3-pyridyl-*as*-triazine (pdt)[28] were prepared according to reported procedures. 2,2′:6′,2″-Terpyridine, 2-cyanopyridine, and silver nitrate were purchased from Aldrich. Other chemicals and solvents were reagent-grade and used as received. For spectroscopic studies, HPLC-grade solvents were used. Solution electrical conductivity was checked using a Systronic conductivity bridge 305. Infrared spectra were taken with a Nicolet spectrophotometer with samples prepared as KBr pellets. $^1H$ NMR spectra were recorded with a 300-MHz Varian FT spectrometer with $(CD_3)_2SO$ used as solvent. Cyclic voltammetric and coulometric measurements were carried out using a PAR model 273A electrochemistry system. A platinum wire working electrode, a platinum wire auxiliary electrode, and a saturated calomel reference electrode (SCE) were used in a standard three-electrode configuration. Tetraethylammonium perchlorate (TEAP) was used as the supporting electrolyte and the solution concentration was about $10^{-3}$ M; the scan rate used was 50 mV $s^{-1}$. A platinum gauze working electrode was used in the coulometric experiments. All electrochemical experiments were carried out under dinitrogen. UV/Vis spectral studies were performed with a Perkin–Elmer Lambda 950 spectrophotometer. The elemental analyses were carried out with a Perkin–Elmer 240C elemental analyzer. Electrospray mass spectra were recorded with a Micromass Q-ToF mass spectrometer. Steady-state emission experiments were performed using a Perkin–Elmer LS 55 luminescence spectrometer fitted with a cryostat.

**Synthesis of $[Ru^{II}(trpy)(pdt)(Cl)]ClO_4$ {[1](ClO$_4$)}:** $[Ru^{III}(trpy)Cl_3]$ (100 mg, 0.23 mmol) was dissolved in ethanol (20 mL) and 5,6-diphenyl-3-pyridyl-*as*-triazine (pdt) (41.8 mg, 0.227 mmol), excess LiCl (54 mg, 1.3 mmol), and $NEt_3$ (0.4 mL) were added to it. The mixture was heated at reflux under dinitrogen for 5 h. The initial dark brown solution gradually changed to deep purple. The dry mass thus obtained on removal of solvent under reduced pressure was dissolved in a minimum volume of acetonitrile, and excess saturated aqueous solution of $NaClO_4$ was added to it. The resulted solid precipitate was filtered off and washed thoroughly with cold water. The product was dried in vacuo over $P_4O_{10}$. It was then

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

purified on a neutral alumina column. The complex [**1**]($ClO_4$) was eluted with $CH_2Cl_2$/$CH_3CN$ (3:1). Evaporation of the solvents under reduced pressure afforded pure complex [**1**]($ClO_4$). Yield: 113.2 mg (64%). $C_{35}H_{25}Cl_2N_7O_4Ru$ (779.04): calcd. C 53.91, H 3.23, N 12.58; found C 54.27, H 3.08, N 12.27. Molar conductivity in acetonitrile: $\Lambda_M$ = 127 $\Omega^{-1}$ cm$^2$ M$^{-1}$. $^1$H NMR [300 MHz, $(CD_3)_2SO$, 298 K]: $\delta$ = 8.87 (d, $J$ = 8.1 Hz, 1 H), 8.75 (d, $J$ = 8.1 Hz, 2 H), 8.65 (d, $J$ = 8.1 Hz, 1 H), 8.45 (d, $J$ = 8.1 Hz, 1 H), 8.27 (m, 2 H), 8.03 (t, $J$ = 8.1, 6.9 Hz, 3 H), 7.77 (d, $J$ = 4.8 Hz, 2 H), 7.59 (m, 3 H), 7.42 (m, 7 H), 7.23 (t, $J$ = 7.8, 7.5 Hz, 1 H), 7.05 (1 H), 6.94 (d, $J$ = 7.2 Hz, 1 H) ppm.

**Synthesis of [Ru$^{II}$(trpy)(pdt)($CH_3CN$)]($ClO_4$)$_2$ {[2]($ClO_4$)$_2$}:** The chlorido complex [**1**]($ClO_4$) (100 mg, 0.128 mmol) was dissolved in $CH_3CN$ (5 mL), water (20 mL) was added and then the mixture was heated at reflux for 10 min. An excess of $AgNO_3$ (217 mg, 1.28 mmol) was added to the above hot solution and the heating was continued for a further 2 h. The solution was then cooled and the precipitated AgCl was separated by filtration through a sintered glass crucible (G-4). On concentration of the filtrate, the desired solid complex [**2**]($ClO_4$)$_2$ separated. It was filtered and washed with ice-cold water and subsequently dried in vacuo over $P_4O_{10}$. Yield: 90.8 mg (80%). $C_{37}H_{28}Cl_2N_8O_8Ru$ (884.04): calcd. C 50.22, H 3.19, N 12.67; found C 49.99, H 3.13, N 12.45. Molar conductivity ($CH_3CN$): $\Lambda_M$ = 270 $\Omega^{-1}$ cm$^2$ M$^{-1}$. $^1$H NMR [300 MHz, $(CD_3)_2SO$, 298 K]: $\delta$ = 8.99 (d, $J$ = 8.1 Hz, 2 H), 8.83 (t, $J$ = 6.6, 7.8 Hz, 3 H), 8.72 (d, $J$ = 7.8 Hz, 1 H), 8.55 (t, $J$ = 7.8, 8.1 Hz, 1 H), 8.27 (d, $J$ = 4.8 Hz, 1 H), 8.16 (t, $J$ = 7.5, 7.8 Hz, 2 H), 8.07 (t, $J$ = 7.5, 6.6 Hz, 1 H), 7.91 (m, 2 H), 7.79 (d, $J$ = 2.1 Hz,1 H), 7.53 (m, 9 H), 7.25 (t, $J$ = 8.1, 7.5 Hz, 1 H), 6.92 (d, $J$ = 7.2 Hz, 1 H) ppm.

**Synthesis of [Ru$^{II}$(trpy)(pdt)($NO_2$)]($ClO_4$) [3]($ClO_4$):** The complex [**2**]($ClO_4$)$_2$ (100 mg, 0.116 mmol) was dissolved in $CH_3CN$ (5 mL) and then water (20 mL) was added followed by an excess of $NaNO_2$ (200 mg, 2.90 mmol). The mixture was heated at reflux for 2.5 h. The deep red solution of [**2**]($ClO_4$)$_2$ changed to deep orange during the course of the reaction. The pure crystalline nitro complex precipitated when the hot solution cooled to room temperature. The solid [**3**]($ClO_4$) thus obtained was filtered off, washed with ice-cold water, and dried in vacuo over $P_4O_{10}$. Yield: 73.3 mg (82%). $C_{35}H_{25}ClN_8O_6Ru$ (790.06): calcd. C 53.20, H 3.19, N 14.18; found C 53.37, H 3.26, N 13.94. Molar conductivity in acetonitrile: $\Lambda_M$ = 120 $\Omega^{-1}$ cm$^2$ M$^{-1}$. $^1$H NMR [300 MHz, $(CD_3)_2SO$, 298 K]: $\delta$ = 8.99 (d, $J$ = 8.1 Hz, 1 H), 8.85 (m, 2 H), 8.75 (m, 2 H), 8.27 (d, $J$ = 5.1 Hz,1 H), 8.17 (t, $J$ = 6.3, 8.7 Hz, 1 H), 8.05 (m, 2 H), 7.90 (m, 2 H), 7.75 (m, 2 H), 7.49 (m, 10 H), 7.24 (t, $J$ = 7.5, 7.8 Hz, 1 H), 6.95 (d, $J$ = 7.5 Hz, 1 H) ppm.

**Synthesis of [Ru$^{II}$(trpy)(pdt)($NO^+$)]($ClO_4$)$_3$ {[4]($ClO_4$)$_3$}:** Dropwise addition of concentrated $HNO_3$ (2 mL) to the powdered nitro complex [**3**]($ClO_4$) (100 mg, 0.126 mmol) at 273 K whilst stirring resulted in a pasty mass. The pasty mass thus formed was added to ice-cold concentrated $HClO_4$ (6 mL) dropwise with continuous stirring using a glass rod. On further addition of saturated aqueous $NaClO_4$ solution, a yellow solid product formed. The precipitate was filtered off immediately, washed with a little ice-cold water and then dried in vacuo over $P_4O_{10}$. Yield: 98.3 mg (80%). $C_{35}H_{25}Cl_3N_8O_{13}Ru$ (971.96): calcd. C 43.20, H 2.59, N 11.52; found C 43.02, H 2.46, N 11.74. Molar conductivity ($CH_3CN$): $\Lambda_M$ = 310 $\Omega^{-1}$ cm$^2$ M$^{-1}$. $^1$H NMR [300 MHz, $(CD_3)_2SO$, 298 K]: $\delta$ = 9.20 (m, 1 H), 9.08 (d, $J$ = 3.9 Hz, 1 H), 8.96 (m, 1 H), 8.83 (t, $J$ = 7.5, 7.8 Hz, 1 H), 8.57 (m, 3 H), 8.27 (d, $J$ = 5.1 Hz, 1 H), 8.19 (m, 2 H), 8.05 (m, 1 H), 7.88 (m, 3 H), 7.51 (m, 9 H), 6.97 (t, $J$ = 7.1, 6.9 Hz, 1 H), 6.85 (d, $J$ = 7.5 Hz, 1 H) ppm.

**Synthesis of [Ru$^{II}$(trpy)(pdt)($NO^-$)]($ClO_4$)$_2$ {[4]($ClO_4$)$_2$}:** The nitroso complex [**4**]($ClO_4$)$_3$ (100 mg, 0.102 mmol) was dissolved in 5 mL of $CH_3CN$ and excess hydrazine hydrate was added whilst stirring over a period of 5 min. The stirring was continued for a further 1 h. The initial yellow solution of [**4**]($ClO_4$)$_3$ changed to red-brown. The solvent was then removed under reduced pressure and the solid mass thus obtained was washed with a little ice-cold water and then dried in vacuo over $P_4O_{10}$. Yield: 67.4 mg (75%). $C_{35}H_{25}Cl_2N_8O_9Ru$ (873.02): calcd. C 48.11, H 2.89, N 12.83; found C 47.92, H 2.86, N 12.98. Molar conductivity ($CH_3CN$): $\Lambda_M$ = 225 $\Omega^{-1}$ cm$^{-2}$ M$^{-1}$. Magnetic moment (298 K): $\mu_B$ = 1.87. MS: $m/z$ = calcd. for {[**4**]($ClO_4$)$_2$ – $ClO_4$ – NO} 744.15, found 744.31.

***CAUTION!*** *Perchlorate salts of metal complexes with organic ligands are potentially explosive. Heating of dried samples must be avoided and handling of small amounts has to proceed with great caution, using protection.*

**Kinetic Experiments:** For the determination of $k$ of the conversion process of [Ru$^{II}$(trpy)(pdt)($NO^+$)]$^{3+}$ ([**4**]$^{3+}$) → [Ru$^{II}$(trpy)(pdt)-($NO_2$)]$^+$ ([**3**]$^+$) in acetonitrile in the presence of aqueous sodium hydroxide solution, the increase in absorbance ($A_t$) at 482 nm corresponding to $\lambda_{max}$ of the nitro complex was recorded as a function of time ($t$). $A\alpha$ was measured when the intensity changes leveled off. Values of pseudo-first-order rate constants, $k$, were obtained from the slopes of linear least-squares plots of $-\ln(A\alpha - A_t)$ against $t$. The activation parameters $\Delta H^{\#}$ and $\Delta S^{\#}$ were determined from the Eyring plot.[29] The first-order rate constant for the photo release of NO from [**4**]$^{2+}$ was determined from the single-exponential fitting of the plot of Δ(OD) against time, where Δ(OD) is the differential absorbance at 494 nm of [**4**]$^{2+}$ in acetonitrile, exposed to light, with respect to unexposed [**4**]$^{2+}$ in acetonitrile as the reference solution.

**X-ray Crystallography:** Single crystals of [**1**]($ClO_4$) or [**2**]($ClO_4$)$_2$ were grown by slow diffusion of an acetonitrile solution of the complex into toluene, followed by slow concentration. X-ray data were collected using an Oxford Xcalibur-S CCD single-crystal X-ray diffractometer using Mo-$K_\alpha$ radiation. Crystal data and data collection parameters are listed in Table 4. The structures were solved and refined by full-matrix least squares on $F^2$ using SHELX-97 (SHELXTL).[30] Absorption corrections for [**1**]($ClO_4$) and [**2**]-($ClO_4$)$_2$ were performed by multiscan. All the data were corrected

for Lorentz and polarization effects, and the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the refinement process as per the riding model. X-ray analysis revealed the presence of three water molecules as solvent of crystallization in [**2**]$(ClO_4)_2$. CCDC-635850 {for [**1**]$(ClO_4)$} and -635851 {for [**2**]$(ClO_4)_2$} contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Packing diagram of [**2**]$(ClO_4)_2 \cdot 3H_2O$ along the *b* axis (Figure S1), $^1$H NMR spectra of (a) [**1**]$^+$, (b) [**2**]$^{2+}$, (c) [**3**]$^+$, and (d) [**4**]$^{3+}$ in $(CD_3)_2SO$ (Figure S2), and emission spectrum of [**2**]$^{2+}$ in EtOH/MeOH (4:1) glass at 77 K (Figure S3).

## Acknowledgments

Financial support received from the Department of Science and Technology and Council of Scientific and Industrial Research, New Delhi, India is gratefully acknowledged. X-ray structural studies for [**1**]$(ClO_4)$ and [**2**]$(ClO_4)_2$ were carried out at the National Single Crystal Diffractometer Facility, Indian Institute of Technology, Bombay. Special acknowledgment is made to the Sophisticated Analytical Instrument Facility (SAIF) for providing the NMR and EPR facilities.

## Phosphorus Heterocycles

[2+3] Cycloaddition of phosphaalkynes with trimethylsilyldiazomethane derivatives proceeds in spite of the presence of a bulky Mes* (= 2,4,6-$t$Bu$_3$C$_6$H$_2$) group which exceedingly stabilizes the C≡P moiety. The corresponding [2+3] adducts, 1,2,4-diazaphospholes, show dimer or trimer structure connected by hydrogen bonds. The first observed trimer structure of 1,2,4-diazaphosphole includes effects of the bulky aryl group enhancing the molecular aggregation by the CH–π interaction.

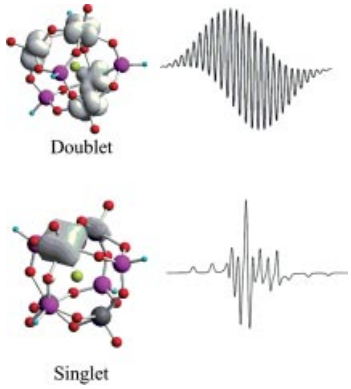
Localization and Delocalization of Spin Density in Mixed-Valence ($V^{IV}/V^{V}$) $[(V_2O_3)_2(PhPO_3)_4\subset F]^{-n}$ ($n$ = 1, 2): Theoretical and Experimental Studies

**Keywords:** Adsorption / DFT calculation / ESR / Hyperfine structure / Vanadium / Cage compounds



DFT calculations were carried out to determine the energies and spin-density distribution for the cage $[(V_2O_3)_2(PhPO_3)_4\subset F]^{-n}$ structures with the symmetries $D_{2d}$, $C_{2v}$, and $C_s$. The calculated hyperfine coupling constants are in a good agreement with those determined by ESR spectroscopy. A proposal is given for the localization/delocalization of spin density based on thermally driven fluctuations of the cage geometry or alternatively by hopping of the unpaired electron inside the cage.

# Chirality Transfer through Helical Motifs in Coordination Compounds

Cheng He,[a] Yonggang Zhao,[a] Dong Guo,*[b] Zhihua Lin,[a] and Chunying Duan*[a]

**Keywords:** Helical structures / Chirality / Building intermediates / Conformational chirality

Helicates obtained by self-assembly have initiated a revolution from classical coordination chemistry to extensive supramolecular concepts. The design of helicates will be described, and the structural features that are necessary for chirality transfer, as well as the extension of chirality from one-dimensional to three-dimensional chiral polymers in complicated chiral architectures will also be addressed. Chiral assembly by using achiral components has been given considerable attention in this review paper. The understanding of the essential processes and mechanisms in the chiral assembly on the basis of helicate supramolecular structures is a fundamental study in a variety of disciplines ranging from biology to materials science.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

The term helicate was introduced by Lehn in 1987 to describe a discrete metal-based helix comprising one or more covalent organic strands wrapped and coordinated to a series of ions defining the helical axis.[1] Such kinds of complexes have elegantly illustrated how the specific formation of architecturally complicated assemblies are directed by the interplay between relatively simple parameters such as the stereoelectronic preference of the metals and the position of the binding sites of the helicands (helicating ligands). Previously, the chemistry of helicates was reviewed thoroughly with a focus on the description of the topologies and conformations of the helical structures, as well as an investigation into the design of special helicates.[2,3]

Chirality is the intrinsic character of helicates. It can be right-handed (plus, *P*) or left-handed (minus, *M*), depending on whether the rotation is clockwise or anticlockwise when a helicate is considered to wind from the eye of the viewer towards a distant point from the viewer. If we neglect the helical domain produced by the spacers between the binding units, the chirality of a helicate would be deduced from the absolute configurations of the metal centers (Figure 1). Clearly, chiral helicates will be created only when the metal ions in the helical axis display the same absolute configuration. Because they are constructed from achiral components, the helical molecular assemblies in the crystalline phase have two possibilities: either the crystals are composed of both *P* and *M* helices (centric space group) to afford an internal racemate or by a spontaneous resolution process where each crystal is enantiomerically pure (*P* or *M* helicity, chiral space group), but the mixture of crystals is racemic, as a so-called conglomerate.[4] A much more interesting case for the latter is homochiral crystallization, by which all the crystals obtained in one crystallization have the same chirality. Usually, the interhelicate interactions associated with donor (or acceptor) groups hosted on the chiral helicates should be always directional and homochiral. If such kinds of interactions are substantially strong, the chiralities of the metal centers could be extended into high-dimensional frameworks to achieve the complicated chiral species. Whereas a large number of chiral superstructures were developed through the covalent arrangements of chiral building blocks at the molecular level by using the "bottom-up" strategy,[5] the chiral assembly from achiral components on the basis of helical motifs is of current interest in both supramolecular chemistry and materials science as one of the most attractive and evocative strategies. This microreview will focus on the current research developments in the structural features and the design of helicates modulating the transfer of chirality between metal ions, and chirality extension in the formation of high-dimensional chiral polymers.

## 2. Discrete Oligonuclear Helicates – Local Chiral Translation in Helicates

Oligonuclear helicates, especially dinuclear helicates, are one kind of classical helicates that have been investigated most extensively. Proverbially, single-, double-, and triple-stranded helicates possess one, two, and three coordinated strands wrapped around the metal ions, respectively. The ligands are obviously partitioned into two or more distinct multidentate (commonly bidentate) binding sites with a spacer linking them together. For a dinuclear double helical architecture, it is postulated that the chosen spacer should have enough rigidity to sterically prevent the two binding sites from coordinating to one single metal center, and in the mean time it should also have enough flexibility to permit it to wrap around the metal–metal axis.[2,3,6] However, investigations on the construction of helicates by using ligands $L^1-L^4$ (Figure 2)[7–10] showed that each ligand spans both metal ions but does not wrap over (from one side to the other) the metal–metal axis (Figure 3). Despite the fact that both the rigidity of the ligands and the close proximity of the two metal centers seem to be unfavorable for the formation of helicates, the absolute configurations of the two metal centers in each molecule are identical. Further structural studies of double and triple helicates with two pyridylimine units linked by a single –N–N– confirm that

the nonplanar bridging mode might be essential for such kinds of ligands to encode metal ions in the formation of helicates.[11] From a mechanistic viewpoint, upon coordination, the rotating freedom of the –N–N– bonds on the ligands is restrained, and the ligands can be locked in an atropisomerically chiral conformation. At the same time, the strong and directional bonding interactions could transmit the original chirality of one metal center to another, leading to the formation of the helical species. Reasonably, it suggests that in both double and triple helicates, there is not any necessary relationship between their formation and the rigidity/flexibility of the spacers in ligands. In other words, the chirality translation between the metal centers only occurs when the bridging modes of the ligands exhibit atropisomeric chiralities in the formation of a helicate.

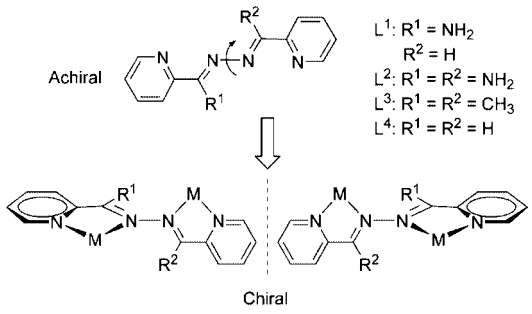

Figure 2. Diazine ligands and generation of conformational chirality.[9]

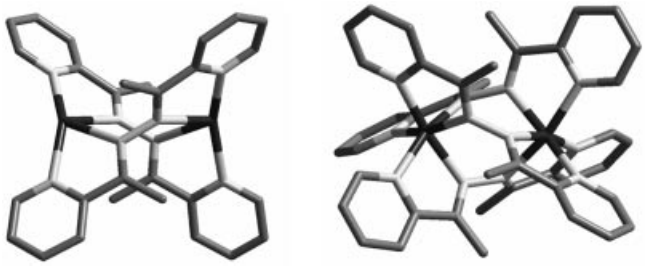

Figure 3. Structures of helicates $Ag_2L^3_2$ (left) and $Co_2L^3_3$ (right). The rigid ligands are twisted but not wrap over the metal centers.[10]

This type of chirality translation through atropisomeric chiral bridging modes of the ligands could also be observed directly in the formation of helicates that are based on biphenyl ligands (Figure 4).[12,13] For example, ligand $L^5$ in solution is achiral due to the free rotation about the two phenyl groups.[12] In the solid state, however, this ligand shows atropisomeric chirality due to the constraint of the rotation around the C–C bond as described as a monohelix. Upon coordination to the metal centers as a bridge, such a special conformation of the ligand induces the formation of helical species with the metal centers being homochiral, even in the case where the two metal centers are bridged by one ligand. Similar atropisomeric chiralities of ligands were observed in several other dinuclear monohelicates of which

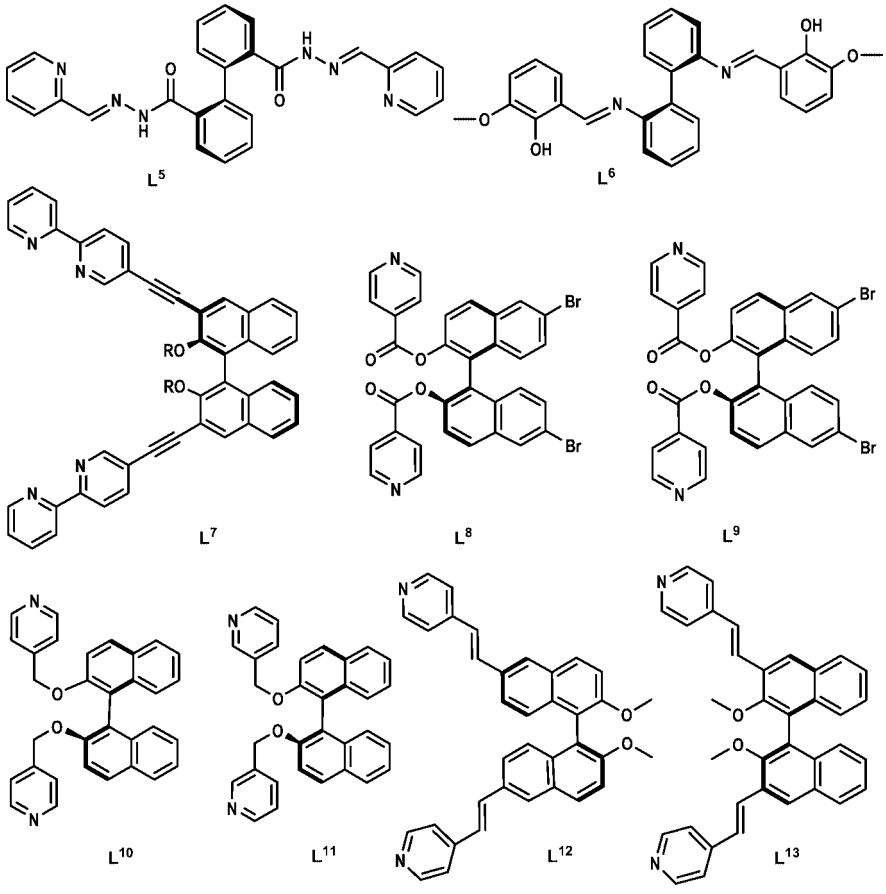

Figure 4. Ligands exhibiting an atropisomerically chiral bridging mode.[12,13,15–18]

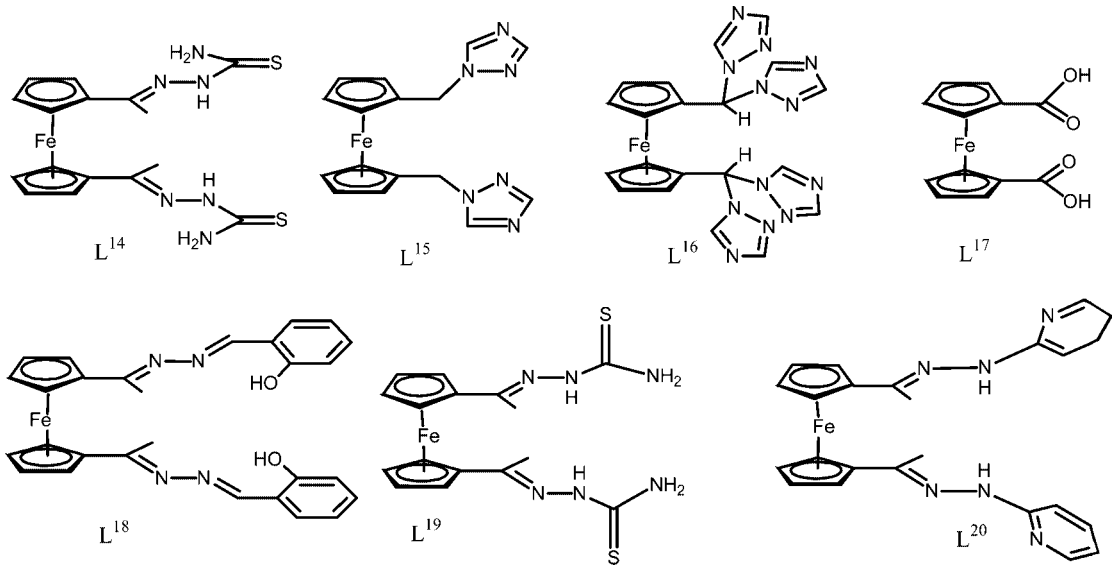

Figure 5. Ferrocene-containing ligands exhibiting a conformationally chiral bridging mode.[19,20,29,30,32]

the chiralities are determined by the helicands themselves rather than the metal centers.[14]

Another evidence to support the above hypothesis comes from the assembly of enantiopure double helicates derived from conformationally chiral ligand $L^7$. Generally, enantiomerically pure chiral ligands only introduce a second source of chirality into the helicates, forming diastereomers according to the screw turn and the arrangement of the ligands. However, in the resulting triple helicate $Zn_2L^7{}_3$, the configurations of the stereogenic metal centers are completely controlled by the atropisomeric chiral configuration of the binaphthyl groups, and the discrete dinuclear complex adopts an overall $D_3$ symmetric *P* configuration with both of the two octahedral metal centers exhibiting the Δ configuration.[15] In fact, a lot of homochiral discrete polynuclear complexes and infinite coordination polymers were constructed by introducing the binaphthyl group as the stereogenic resource of conformational chirality (Figure 4).[16–18]

Two-armed, multidentate, ferrocene-containing compounds are another sort of ligands that could efficiently translate chirality from one transition metal center to the others (Figure 5).[19,20] Generally, the 1,1′-substituted ferrocene derivatives exhibit a planar chirality. When they act as bridging ligands to coordinate to metal centers in the formation of the helicates, atropisomeric chirality of the ligand is generated and replicated with the bridged metal centers being homochiral (Figure 6).

In terms of the structural requirements of bridging ligands for chirality translation between metal centers, the principle obtained from the dinuclear species − *that the chirality transformation between the metal centers occurs only when the bridging mode of the ligands exhibit conformational chiralities* − should be valid to explain the formation of some complicated helicates besides the dinuclear helicates.[21] For example, in the trinuclear $Cu^I$ complex derived from ligand $L^3$ and a variety of other circular helicates,[22–24] the nonplanar bridging modes of these ligands

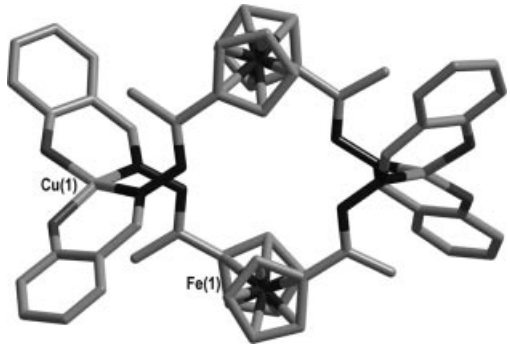

Figure 6. Molecular structure of the copper–ferrocene helicate $Cu_2L^{18}{}_2$.[20]

are likely to facilitate the chirality transfer, which results in homochiral metal centers. Whereas in the metallocycles derived from the ligands containing carboxhydrazone units, the planar bridging conformation causes the formation of achiral species, despite the presence of a similar –N–N– bond within the backbone of the ligands.[25]

Recent developments in the design and assembly of helical species have spanned to the construction of supramolecular architectures by hydrogen bonding and coordination bonding. As shown in Figure 7, two ligands $L^{21}$ coordinate

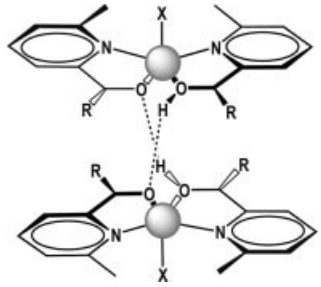

Figure 7. Hydrogen-bond-linked dinuclear helicates $Co_2L^{21a}{}_2X_2$, $L^{21a}$,R = H; $L^{21b}$, R = $CH_3$, X = Cl, Br, $NO_3$.[26,27]

to a cobalt(II) atom in a bis(bidentate) fashion by the pyridyl and alcohol donor groups.[26] Two chelating units are twisted through the O–H···O hydrogen bond, achieving a new conformational chirality, which is transmitted from one cobalt center to another by hydrogen bonds between the alcohol oxygen atoms. Interestingly, when the alcohol carbon atom is stereogenic, the chirality at this point could control the absolute configurations of the metal centers and the helicity sense of the overall structure.

## 3. Aggregation of Oligonuclear Helicates – Chirality Translation in Supramolecular Assemblies

Whereas the basic requirements for the design of a discrete helicate from achiral components have been well-established, the design and control of the formation of homochiral superstructures that are based on helical units still remain a substantial challenge. Assembling small molecular units into complicated aggregations in a controlled fashion is one target of sophisticated supramolecular chemistry.[27] Especially, the assembly of helical units into a homochiral array is of great interest in this case.

Investigation into the superstructures assembled from helicate building blocks reveals that the functional groups attached to the ligands of helicates are able to carry weak interactions to favor the extension of the homochiralities. In principle, if the interactions between helicates are substantially strong and directional without mirror symmetric elements, the local or whole homochiral assembly might be achieved.[28] As shown in Figure 8, the twisted bridging mode of diacetylferrocene thiosemicarbazone $L^{19}$ leads to dinuclear complexes that crystallize in a helical fashion.[29] The imino nitrogen atoms of the thiosemicarbazone moieties attached in the double helicates act as H-bond acceptors paired up with the corresponding amino nitrogen atoms of the thiosemicarbazone group on a parallel neighboring helix through hydrogen bonds. Only the helicates with the same chirality can be connected to each other into an infinite chain such that all the zinc ions in the infinite chiral chain have the same chirality. It is likely that the chirality of the helicates is translated through the discriminative bridges. The same structure is also found in an analogous $Co^{II}$ compound.[30] Weak additional coordination interactions could also be utilized to construct helical chains.[31] In the ferrocene-containing double helicate $CuL^{20}{}_2Cl_2$, the copper center is coordinated by two pyridylimine groups with the fifth coordination site occupied by a chloride ion.[32] In the crystal, a chloride anion bridges two homochiral double helicates featuring a one-dimensional polymer. Each chain exhibits a crystallographic $2_1$ helix with the double helicates in the chain being a single enantiomer.

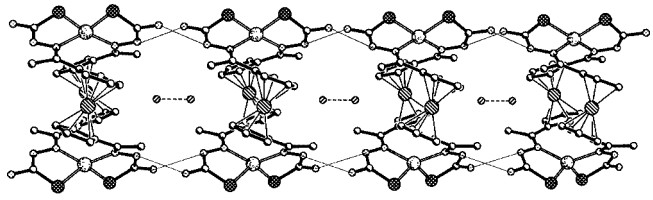

Figure 8. The hydrogen-bonding one-dimensional tube from ferrocenyl-based $Zn_2L^{19}{}_2$ dinuclear helicate with water molecules included.[29]

By introducing multiaromatic rings into the dinuclear helicates, homochiral assemblies and even 3D homochiral conglomerates could be obtained through π–π stacking interactions. Reaction of potentially atropisomeric chiral ligands $L^{22}$ and $L^{23}$ with $Ag^{I}$ generate the silver double helicates $[Ag_2L^{22}{}_2]^{2+}$ and $[Ag_2L^{23}{}_2]^{2+}$, respectively.[33] The symmetry-related helicates are connected together through face-to-face stacking interactions between the pyridine and benzene rings to form an infinite chain around a $3_2$ screw axis (Figure 9). Owing to the twofold symmetry of the dinuclear helicates, these screws align in parallel and maintain the helical chirality, featuring a homochiral 3D structure with the spontaneous resolution occurring. On the basis of solid CD measurements of the 20 crystals of the latter upon crystallization (Figure 10), the *ee* value of 60% clearly reveals the appearance of a chiral selectivity in the bulk crystals. From

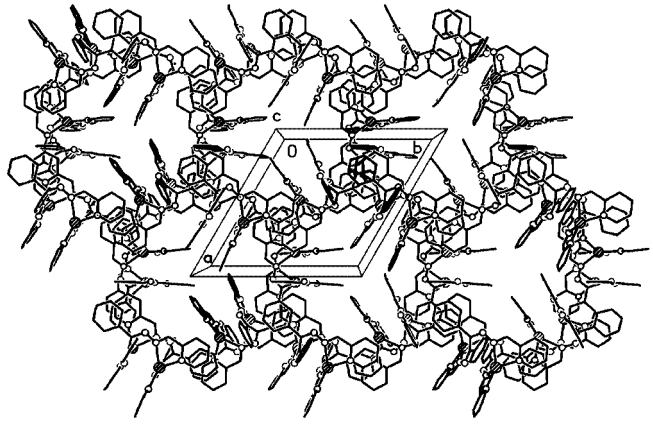

Figure 9. Infinite helical chain for $Ag_2L^{23}{}_2$ with *P* helicate through π–π stacking interactions and the 3D network stabilized by the homochiral interactions.[33]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

further investigations of the crystals in 50 independent crystallizations, it was found that the intensities of the CD signals show a bimodal probability distribution. Such an occurrence of bulk crystal chirality, namely spontaneous resolution, accidentally through a chiral autocatalytic resolution process in the absence of molecular chirality is much more haphazard.

High-dimensional homochiral structures could also be assembled by the helical fragments and adducts as initial components. Chen et al. reported a 2D network built from hydrogen bonds between the connecting water clusters and the helicates.[34] The initial fragment for the assembly is a binuclear $Cd^{II}$ helicate with two spiral-like *N*,*N*′-bis(picolinamide)azine ligands ($L^2$) coordinated to the two $Cd^{II}$ centers. The chiral binuclear helicates are assembled into homochiral layers by water tapes. However, owing to the lack of strong interlayer chiral interactions, the layers are alternatively stacked in a heterochiral fashion to yield the final racemic crystal. Hahn and coworkers reported a triple-stranded helical complex $Na(PNP)_3[Ti_2(L^{25})_3]$ [PNP = bis(triphenylphosphoranylidene)ammonium], where the $Na^+$ ions act as bridges between the $[Ti_2(L^{25})_3]^{4-}$ helicates, leading to the infinite homochiral chains in the crystal lattice.[35] Both metal centers of $[Ti_2(L^{25})_3]^{4-}$ in the crystal are formed with the same configuration, but crystallization in the $P\bar{1}$ acentric space group indicates that the opposite enantiomer must have also formed.

Another interesting example of the aggregation of helical species was reported by Matsumoto et al. He described a fascinating model for the assembly of the homochiral structure.[36,37] The initial building block is a mononuclear $CuL^{26}$ complex containing two imidazole groups. This species could be described as a mononuclear helicate with either Δ (clockwise) or Λ (anticlockwise) enantiomorph (Figure 11) owing to the spiral arrangement of the ligands around the copper(II) ion. In the presence of an equimolar ratio of base, one of the two imidazole groups loses a proton and functions as a hydrogen-bond acceptor to connect with the neighboring protonated imidazole as a donor. For this to occur, the hydrogen bond between the imidazole group and the deprotonated imidazolate group in the two neighboring molecules is asymmetric, and the helicates are linked into a one-dimensional helical chain with the chirality of the initial unit being translated from one to the other, and then extending to the whole helical chain.[36] Similarly, the cobalt(III) complex with achiral tripodal-type ligands consisting of three imidazole groups induces the chiralities of the *C* and *A* enantiomers,[37] The hemideprotonated species $[Co(H_{1.5}L^{27})]^{1.5+}$ functions as a self-complementary chiral building block, generating equal numbers of protonated and deprotonated molecules by an acid–base reaction to form an extended 2D homochiral layer consisting of hexanuclear structures with trigonal void units (Figure 12).

To further develop such a synthetic strategy, an interesting mononuclear helicate $Mn^{II}$ compound was synthesized.[38] The thiosemicarbazone metal complex $MnL^{28}{}_2$ adopts either a Δ or a Λ enantiomorph, depending on the arrangement of the two thiosemicarbazone ligands in which

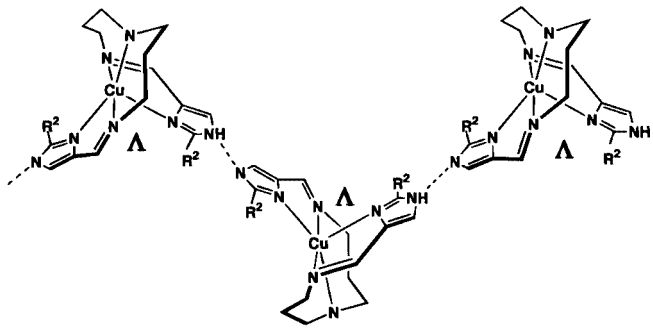

Figure 11. 1D helical chain formed from hydrogen bonds between the imidazole and imidazolate groups of adjacent mononuclear $CuL^{26}$ units ($R^2$ = Me).[36]

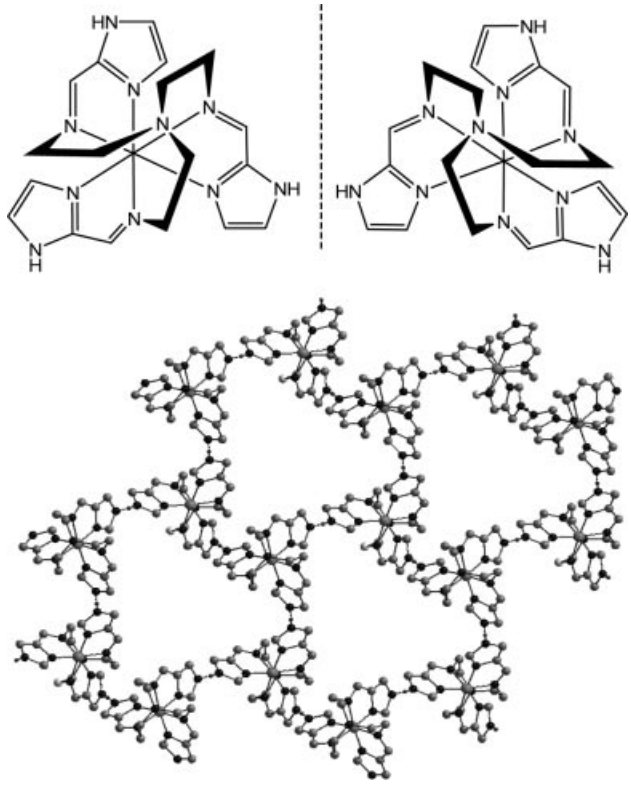

Figure 12. Structures of *C* (clockwise) and *A* (anticlockwise) mononuclear $CoL^{27}$ enantiomers (top), and the top view of the 2D homochiral sheet in which the same enantiomers are linked by the intermolecular imidazole–imidazolate hydrogen bonds (bottom).[37]

the amine groups act as the proton donors and the pyrazine groups as acceptors. The neutral complex functions as chiral building blocks to be assembled into 2D layers through the pyrazine–amino hydrogen bonds (Figure 13). The head-to-tail fashion suggests that the hydrogen bonds that link the neighboring mononuclear units are chirally discriminative and maintains the metal coordinative spheres to exhibit the same absolute configuration. The chirality is then preserved and extended into the whole 2D sheet. Furthermore, the homochiral layers develop parallel to the *ab* plane and stack along the *c* direction through π–π interactions between the neighboring delocalization skeletons of the ligands. Adjacent sheets are related by $4_1$ screw axes and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stack in an ABAB fashion (A and B represent layers with different orientations but with the same chirality, respectively), resulting in a homochiral porous 3D network.

## 4. One-Dimensional Helical Coordination Polymers – Precursors of Chiral Crystals

One-dimensional helicates are intermediates between the discrete molecular helicates and the solid-state helicity (chiral crystals) in the homochiral aggregations from achiral building blocks. Obviously, the construction of chiral solids from one-dimensional metallohelical chains would be more efficient than that from the oligohelicates. As mentioned above, the simple way to ensure the chirality extension within the infinite chain is to use the ligands as bridges that exhibit atropisomeric chirality. For example, assembling silver(I) or copper(I)[22] with helicand $L^4$ facilitates an infinite monohelicate with each metal atom bound to two bis(bidentate) ligands in a distorted tetrahedral geometry, and the ligands chelate and bridge the two metal centers by turns.[10a] Thus, the obstacle that limits the possibility to obtain a chiral solid from one-dimensional helicates hinges on how the chirality of the building fragments can be extended by chiral discriminative interactions.

An interesting example reported by Aoyama et al.[39] is chiral adduct $L^{29}{\cdot}Cd(NO_3)_2{\cdot}H_2O{\cdot}EtOH$, which was prepared from achiral 5-(9-anthracenyl)pyrimidine ($L^{29}$) but crystallizes in a chiral space group $P2_1$. The chirality of this compound arises from the twist of the two pyrimidine rings in a helical array of the pyrimidine/$Cd^{2+}$ coordination polymer, in which the anthracene substituents are arranged in $C_2$ chirality across the chain (Figure 14). The helices are stabilized by intrastrand water–nitrate and ethanol–nitrate hydrogen bonds. The ligand has one extra free proton, which is used to connect the neighboring helix chains with the *same* chirality (helicity) by interstrand water–nitrate hydrogen bonds. Thus, the chirality translation through H-bonds occurs inside the layer and then is preserved on both sides of the resulting sheet across the helices. The sheets are then assembled through herringbone-type packing of the anthracene moieties into the actual 3D structure. Crystals of this adduct exhibit significant CD signals that are consistent with the absolute helicity *P* or *M* with a positive or negative Cotton effect, respectively. All the crystals recovered from one operation of crystallization show the same CD sign with the same chirality (helicity). It is reasonable that the chirality of the crystals is essentially governed by the chirality that happened to the first-separating nucleus serving as the seed for the subsequent crystal growth.

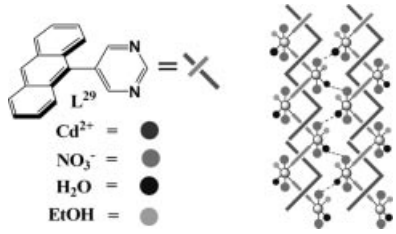

Figure 14. Crystal structure of $L^{29}{\cdot}Cd(NO_3)_2{\cdot}H_2O{\cdot}EtOH$: front view of two neighboring helices hydrogen bonded to form a sheet and its schematic explanations.[39]

Because the direction of the interhelicate donor–acceptor interactions between the chiral helicates is controlled by spatial affects and intrinsic characters of the interactions themselves, these interactions are likely to be characteristically chiral and run through inheriting the original chirality of the helicates they linked. Thus, the strategy to connect helical chains in a homochiral fashion rests on the potential chiral interactions, despite that some of these interactions are quite weak. As shown in Figure 15, a helical chain is also formed through the coordination of potential atropisomeric chiral ligand $L^{30}$ to the $Zn^{II}$ ions. Neighboring chains are bonded together through π–π interactions between the phenyl groups and the cyclopentadienone units.[40] These supramolecular interactions of exclusively achiral building blocks contribute to the helical chirality of the coordination polymers that arise from spontaneous chiral resolution. The bunches of needle crystals show pronounced (and partially opposite) Cotton effects in their CD spectra, suggesting that one kind of enantiomer is in local excess and even dominant.

C–H···X interactions also have the potential to act as directional interactions in the formation of helical chains and the homochiral aggregation of helicates.[41] With the use of an achiral α,α,′-bis(pyrazolyl)-*m*-xylene ligand ($L^{31}$), Mukherjee and coworkers identified two different handed solids of $Zn^{II}$ coordination polymers.[42] As shown in Figure 16, the chiral pseudotetrahedral coordination environ-

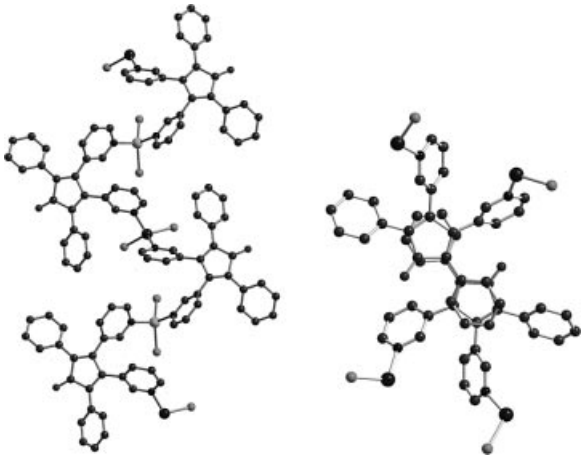

Figure 15. Multiaromatic ring ligand $L^{30}$ (left) and π–π interactions leading to homochiral interactions between helical chains $(ZnCl_2L^{30})_\infty$.[40]

ment around the Zn centers and the twisted conformation of the bidentate ligands bring about the formation of helical chains with the positions of the chlorine atoms fixed. The adjacent parallel helices are held together along the *b* axis primarily by directional C–H···Cl interactions and secondarily by weak π–π interactions between the phenyl rings, leading to the formation of the homochiral 2D sheet. The sheets are again stitched together through the chiral intermolecular C–H···Cl interactions to generate the chiral channels.

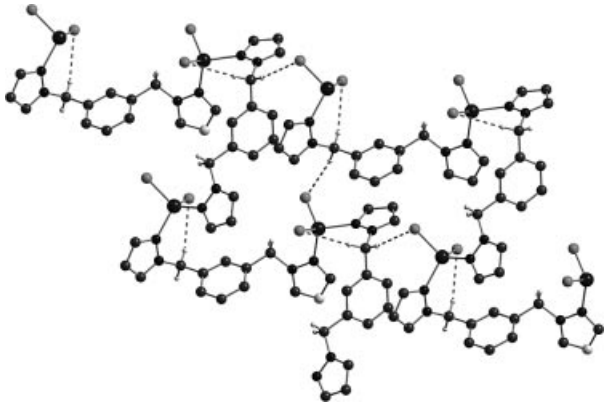

Figure 16. View of the 2D helical sheet $(L^{31}ZnCl_2)_\infty$ formed through C–H···Cl interactions.[42]

The N-positional isomer 2-pyridinyl-3-pyridinylmethanone ($L^{32}$) is another simple ligand that was investigated in terms of chirality transfer.[43,44] Reaction of ligand $L^{32}$ with $Ag(CF_3SO_3)$ in different solvents lead to the generation of a pair of different helical conformational polymorphs. In the racemic crystal A, the ligand winds latitudinally around the helical axis of $2_1$. In the chiral crystal B, the ligand spans longitudinally around a $4_1$helical axis (Figure 17). Spontaneous resolution occurs in the assembly from the helical chains to a homochiral conglomerate $\{[AgL^{32}](CF_3SO_3)\}_\infty$. It seems that the rotation of the pyridyl rings causes the presence of atropisomeric chirality, and the metal centers are bridged to form the homochiral helical chains directly.[44]

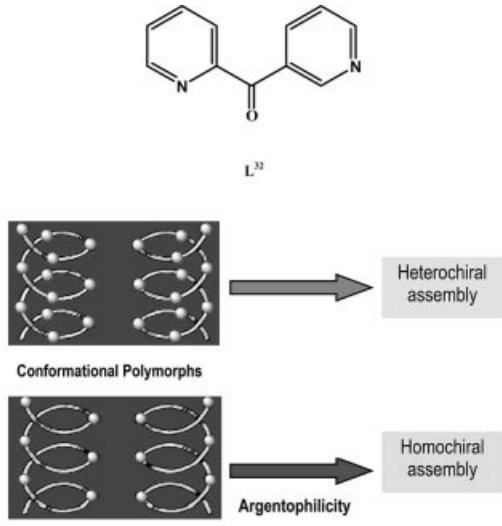

Figure 17. Two kinds of bridging conformations of $L^{32}$ in its coordination complexes. Heterochiral (A, top) and homochiral (B, bottom) assembly of different conformational polymorphs $AgL^{32}$ helical chains by argentophilic interactions.[43,44]

## 5. Homochiral Frameworks – From Achiral Components to Chiral Crystals

Chiral coordination polymers, which possess chiral functionalities such as enantioselective absorption and catalysis, are of great interest. The generation of chiral coordination polymers from achiral ligands without any chiral auxiliary through spontaneous resolution not only provides an easy method for the preparation of chiral functional materials, but also helps the understanding of the chirality origin of life.

Discovered as early as 1846 by Louis Pasteur, spontaneous resolution is still a relatively scarce phenomenon and cannot be predicted a priori because the laws of physics determining the processes are not yet fully understood. The formation of three-dimensional crystal conglomerates is not very frequent (and is even less predictable), reflecting the tremendous preference (more than 90%) for compounds to crystallize in centrosymmetric space groups. However, if there are substantially strong, selective, and directional enough interactions, such as coordination bonds, between neighboring chiral units, the chirality would be able to extend to higher dimensionality, and hence spontaneous resolution would be more likely to occur. Usually, in the preparation of homochiral coordination polymers by spontaneous resolution, two steps are achieved: the generation of the chiral units from the achiral components, and the chirally discriminative interactions may arise from additional intermolecular interactions. Of course, it is quite difficult to isolate the chiral units, always helical chains, from the well-connected network in some case.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

One simple way to construct a homochiral 3D framework is to use the ligands that not only have an atropisomerically chiral bridging mode but also several additional chelating units – some chelators attribute to the formation of helical units, and the others contribute to the extension of the chirality to the whole crystal. Ligand $L^{24}$, *N*,*N*′-bis[1-(pyrazine-2-yl)ethylidene]benzil dihydrazone (Figure 18), falls well into the category of conformational chiral bridging models.[45] As shown in Figure 19, its silver complex comprises a chiral infinite $4_1$ monohelical chain through the two pyrazine–imine bidentate chelating sites. Each ligand adopts a twisted chiral conformation and spans two silver ions to transmit the chirality from one silver center to the other. The metal centers with the same chirality are coordinated by the coupled ligands, leading to the replication of the conformational chirality from one ligand to the other. Such a helical fashion provides an opportunity to modulate the positions and the directions of the additional groups associated with the pyrazine nitrogen atom for interhelicate coordination bonding. Two pyrazine nitrogen atoms from different helical chains coordinate to one silver atom Ag(2) and connect the helical chains together to form a three-dimensional helical network, in which all the fourfold helices are homochiral. Therefore, it is revealed that the chirality of the silver(I) is transmitted through the discriminative helical linkage, or alternatively, the chirality of the helical chain is transmitted through the discriminative bridged units. However, owing to the presence of large voids, the second network with the opposite chirality interpenetrates the former one. The two enantiomeric frames are centrosymmetrically relative, forming a three-dimensional enmeshed "racemate".

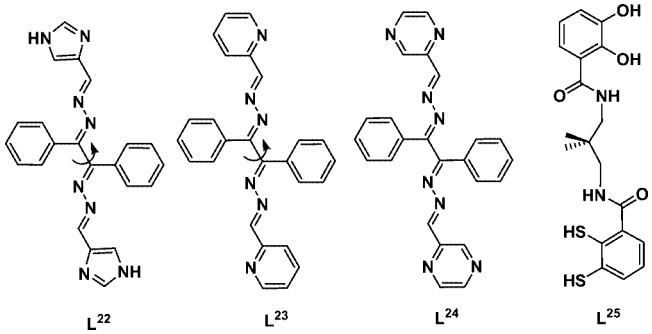

Figure 18. Benzil-based and -related ligands exhibiting a conformationally chiral bridging mode.[33,35,45]

Multicarboxylates with two or more carboxylates connected to aromatic rings are another kind of ligand for the construction of high-dimensional frameworks (Figure 20).[46–50] These species with conformationally chiral coordination modes were also used for homochiral assembly in which the versatile coordination modes of the carboxylate donors make the networks quite complicated.[51] Ligands containing biphenyl groups with more than two carboxylate groups might induce all the metal centers in the network to exhibit the same absolute configuration. 2,2′,3,3′-Oxydiphthalic acid ($L^{33}$) is one such ligand, which was used to build various homochiral 3D features based on

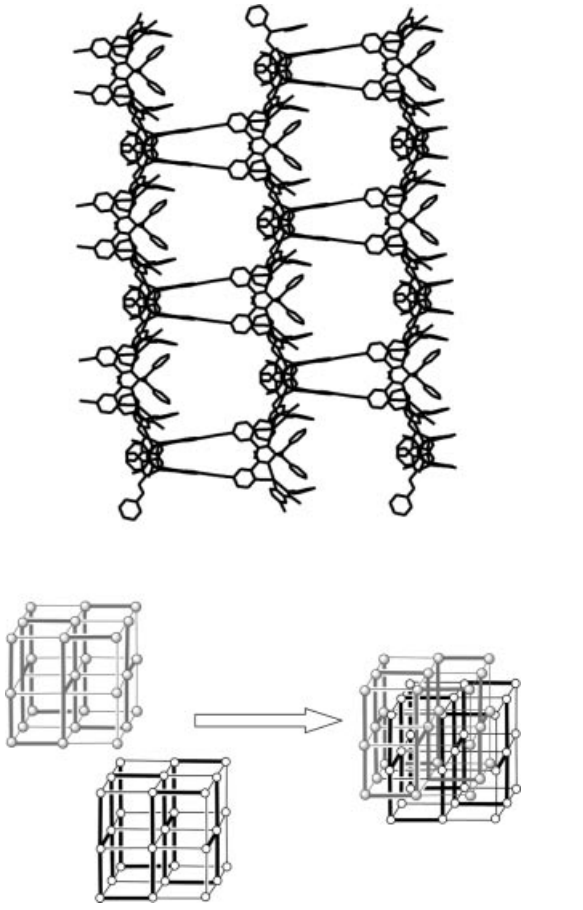

Figure 19. A view of the double interpenetrating nets of $AgL^{24}$ enantiomeric forms of the chiral 3D networks.[45]

helical chains with a suitably bridged bipyridine coligand.[52,53] For example, in the $Zn^{II}$ complex,[52] two kinds of Zn ions are bridged by 2,3- and 2′,3′-carboxylate groups, respectively, to form two similar helical chains from which the chiral puckered herringbones are formed by aligning these helices in parallel (Figure 21). Adjacent layers are interrelated by the $2_1$-screw axis and stack in a slipped *AAA*

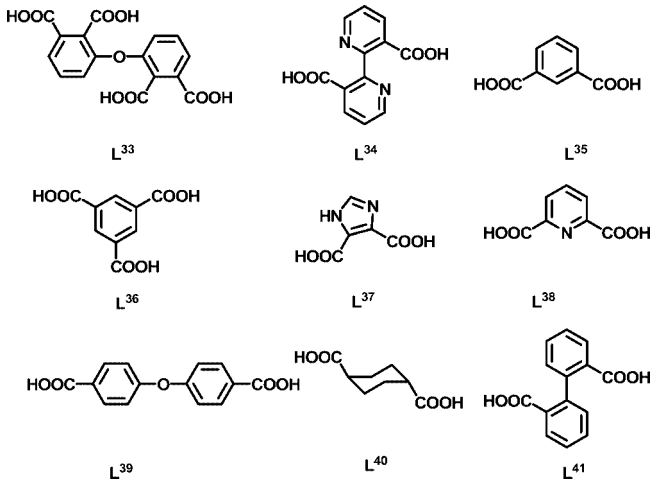

Figure 20. Symmetrical multicarboxylate ligands.[46–50,52,53]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fashion through hydrogen bonds, resulting in a 3D homochiral network. The Cd complex also has two kinds of homochiral helices and chiral 2D sheets, and different from that of the $Zn^{II}$ complex, the chiral layers are parallel and stack through interlayer interactions of coordination bonds (Cd–O) to give a 3D chiral network.

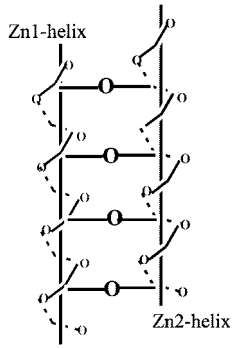

Figure 21. Zn(bpy)$L^{33}$ complexes with homochiral 3D structure assembled from helical chain building units.[52]

Of course, the additional coordinated sites might come from short auxiliary ligands, so that the direction of these interactions could be controlled by the spatial affects of the chiral building units.[54,55] Yan et al. used the simple bis(didentate) pyridylimine ligand containing a –N–N– bond to build a 2D manganese–azido framework.[9] The chirality of the structure unit is induced by the twisted chiral conformation of the coordinated diazine ligands (Figure 2). The constraint of the diazine ligands in the twisted chiral conformation imparts chirality to the triple linkage that consists of two end-on azido bridges plus a –N–N– bridge. This chiral linkage equipped with two chelate sites is chirally discriminative and requires that the two metal coordination spheres have the same absolute configuration. The chirality is preserved when the dimers are interlinked into the 2D network by the homochiral interdimer interactions that arise from the unique bridging topology of the single EE azido bridges. As a result, two kinds of crystals are obtained in the same batch by evaporating the solution of this compound and separating the crystals manually. In both crystals, the homochiral layers extend parallel to the *ab* plane and stack along the *c* direction. In one of these two kinds of crystals, adjacent layers are related by $3_1$ screw axes and stack in an *ABCABC* fashion (*A*, *B*, and *C* represent layers with different orientations but with the same chirality), resulting in a homochiral crystal.

Poeppelmeier et al. reported another interesting complex Zn(pyrazine)($H_2O$) ($MoO_2F_4$),[56] where the *cis*-$MoO_2F_4^{2-}$ anions in the complex are ordered and coordinated to *trans*-$[Zn(pyrazine)_2(H_2O)_2]^{2+}$ cations in an alternating fashion, forming a $3_1$ inorganic helical chain. It is found that when the large organic cations associated with the coordinated donors pack orderly in the solid, the negatively charged $MoO_2F_4^{2-}$ anions are fixed in a special arrangement to fit the helical formation with the two bridged fluoride sites positioned oppositely to the *cis* O atoms. Considering more than six helices interleaved through the Zn–pyrazine–Zn bridges, it is likely that the presence of a short enough linear pyrizine bridging ligand could give rise to the helices packing without introducing any inversion center among them. As illustrated in Figure 22, helices with the same handedness share identical spatial and translational orientations along the Zn–N bridges. When two helices with opposite handedness are bonded together, there are no matching sites for any other helices of either handedness.

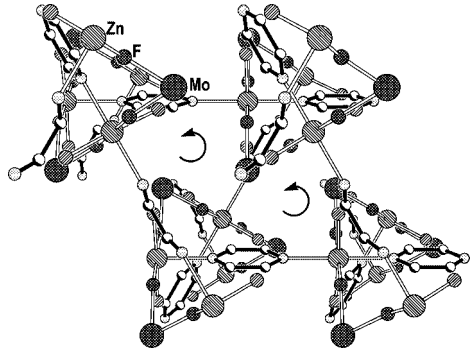

Figure 22. Helix with possible interaction packs with other helices that have the same handedness in compound Zn(pyrazine)($H_2O$)-($MoO_2F_4$).[56]

Another way to construct homochiral 3D frameworks is by using the unsymmetrical ligands as effective connectors to form the polymeric chiral helicates (Figure 23).[57] Lin and his coworkers pointed out that the steric interactions in *cis*-pyridylethenylbenzoate ($L^{42}$) would cause the pyridyl and phenyl groups to be significantly deviated from coplanarity.[58] Such a "skewing" of coordination sites of $L^{42}$ should favor the formation of a helical structure. Hong and coworkers used 4-sulfanylmethyl-4′-phenyl carboxylate pyridine ($L^{43}$)[59] to construct a homochiral $Zn^{II}$ coordination network. As shown in Figure 24, each zinc(II) atom is located in a distorted tetrahedral environment. The chirality transmitting model could be described as that in the former example, in which two kinds of homochiral helices are alternatively assembled along the crystallographic *b* axis. One type of helix is formed by hydroxy-bridging $Zn^{II}$ atoms, and the other is constructed by $L^{43}$-bridging $Zn^{II}$ centers. These distinct homochiral helices are arranged orderly with the zinc(II) atoms acting as hinges, and the novel two-dimensional layers in the *bc* plane stack along the crystallographic *a* axis in an interlocking fashion. The chirality of the [Zn–spcp] helicate should also arise from the $sp^3$ configurations of the C and S atoms in the $–CH_2S–$ spacer, which forces the ligand to be nonlinear and results in the formation of the twisty helical conformation. Because the compound crystallizes in an asymmetric space group $P2_1$, only one kind of tubular helix is involved in the crystal structure.

Another interesting ligand is 2,5-pyridinedicarboxylate $L^{45}$. Its unsymmetricial coordinated mode and the short separation could force the helices to pack together without the introduction of any inversion center.[60] Hong et al. illustrated the dimensional extension of chirality in the helicates based on $\{[NH_2(CH_3)_2]Fe^{III}(L^{45})_2\}_n$. In this complex, the $Fe^{III}$ coordinates to $L^{45}$ in a *cis* mode, forming $2_1$ helical

chains that are arranged parallel or perpendicular to each other with the metal atoms as the connective nodes. This kind of interaction of the helical chains is directional enough to force the 3D network to be homochiral (space group $P4_32_12$), namely the overall structure being chiral. Qiu et al. synthesized the compound $Co(L^{45})(H_2O)_2{\cdot}H_2O$, which crystallized in a space group $P2_12_12_1$.[61] In this compound, there are two types of twofold screw axes along the crystallographic *b* axis, and the helices are interconnected to each other through the cobalt centers to produce an interesting two-dimensional layered structure (Figure 25). Furthermore, the interlayer hydrogen bonds corresponding to the homochiral sheets are directional and strong enough to further pack the 2D undulating layers into a 3D homochiral supramolecular framework. It is notable that the resulting crystals are not racemic as verified by the observation of strong signals in the vibrational circular dichroism (VCD) spectra. The enantiomeric excess might be ascribable to the initial crystals formed as seeds for the handedness of the bulk product, in which the particular handedness of the bulk sample is dependent on what random handedness was formed in the initial crystals.

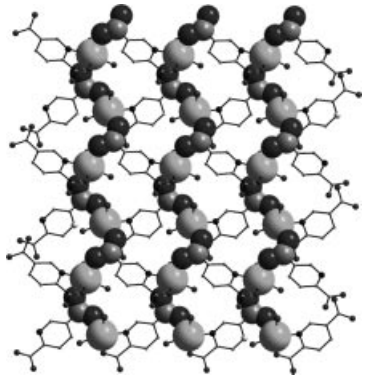

Figure 25. The 2D structure including the right-handed helical chains of –C–O–Co– (the space-filling view) and the left-handed helical chains of –PDC–Co– (the cylindrical view).

## 6. Conclusions

The rational design and construction of chiral materials from achiral sources requires fundamental understanding of the chirality origination and translation. Helicates obtained by self-assembly possess fascinating structures and could act as excellent model systems for studying the extended supramolecular chirality developed from the conformational chirality in classical coordination complexes. In these processes, the coordination bond has become a very useful tool for the construction of large, well-organized, chiral architectures and further chiral aggregations, in the presence of various noncovalent interactions, such as hydrogen bonding, π–π stacking interactions, and van der Waals interactions. Though the structural control and molecular programming in the chiral assembly by using helicates as building intermediates with conformational chiral bridging modes have been significantly explored and improved, the use of achiral ligands to provide self-organized chiral supramolecular species through spontaneous resolution is still in its infancy. The construction and chiral aggregation of helicates will probably suffer from the competition of other fascinating metal-containing achiral assemblies, but they will keep a dominant place if their promising potential applications as molecular and supramolecular functional devices are confirmed and developed. We have no doubt that academic and aesthetic interests will lead to further development in the formation and aggregation of new chiral crystals with helical features. We do think that the enormous potential applications of helical complexes will make it become a considerably attractive field in the near future.

# Highly Luminescent, Neutral, Nine-Coordinate Lanthanide(III) Complexes

Gregg S. Kottas,[a] Marita Mehlstäubl,[a] Roland Fröhlich,[b] and Luisa De Cola*[a]

**Keywords:** Lanthanides / Luminescence / Sensitizers / Energy transfer / Carboxylate ligands

Using a simple ligand design, we have prepared neutral, nine-coordinate lanthanide complexes that exclude water from the inner coordination sphere, thus leading to high emission quantum yields and long excited-state lifetimes. The complexes form in high synthetic yields (49–87 %) by simply mixing the ligand and the lanthanide. Visible luminescence from $Eu^{III}$ ($\Phi$ = 60 %, $\tau$ = 2.2 ms) and $Tb^{III}$ ($\Phi$ = 7 %, $\tau$ = 0.2 ms) and near-infrared luminescence from $Yb^{III}$ ($\Phi$ = 0.7 %), $Nd^{III}$ and $Er^{III}$ were observed in acetonitrile and $CH_2Cl_2$ at room temperature. In addition, the $Gd^{III}$ complex was prepared to gain information about the triplet state of the ligand.

## Introduction

Lanthanide (Ln) complexes[1] that emit in the visible region of the electromagnetic spectrum (Tb, Eu) are important in light-emitting diodes (LEDs),[2] and near-infrared (NIR) emitting $Ln^{III}$ complexes (Yb, Nd, Er) have potential applications in fiber-optic technologies[3] and biomedical imaging.[4] Because $Ln^{III}$ salts have intrinsically low extinction coefficients ($\varepsilon \approx 1–10\ M^{-1}cm^{-1}$),[5] direct excitation is difficult without high intensity sources. The low absorption coefficients are due to intra-4f transitions, which are parity-forbidden. Therefore, it is common to indirectly excite lanthanide ions through an antenna chromophore – a molecule with a high absorption cross section that can readily transfer its energy to the lanthanide ion.[5,6] The advantages of lanthanide luminescence are their narrow emission bands, large Stokes' shifts and long lifetimes (μs to ms). Because the 4f orbitals are shielded by the outer 5s and 5p orbitals, these properties are mostly insensitive to chemical environment. Ln complex emission quantum yields and excited-state lifetimes decrease dramatically upon coordination of solvents (especially water) through vibronic coupling[6c] – a problem compounded for NIR-emitting Ln complexes due to the energy gap law.[7] In addition, lanthanide ions have coordination numbers between 6 and 12, although for bulky ligands it is effectively 8–10,[8] making full coordination somewhat difficult (remaining coordination sites are usually occupied by available solvent). Many lanthanide complexes reported in the literature are charged, rendering them unusable for many applications that require evaporation, such as in the fabrication of small-molecule light-emitting diodes (SMOLEDS).[2,9]

Here we report neutral, nine-coordinate lanthanide complexes with a simple tridentate ligand, which display high emission quantum yields due to the exclusion of solvent molecules from the first coordination sphere.

## Results and Discussion

The syntheses of the complexes are shown in Scheme 1. Dropwise addition of the corresponding $Ln^{III}$ salt, dissolved in water, to a mixture of readily available precursor **1** in EtOH/$H_2O$ at 0 °C gave sparingly soluble complexes **2a**–**2g** in 49–87 % yield (see Supporting Information). After filtration of the resulting precipitated solid, the complexes were crystallized by slow evaporation of $CH_2Cl_2$ from a $CH_2Cl_2$/MeOH solution. All compounds were characterized by elemental analysis and mass spectrometry, and the diamagnetic lanthanum complex **2g** was also characterized by NMR spectroscopy (Figures S4 and S5).

To the best of our knowledge, the only report of similar systems is that of Comby et al.,[10] but these authors investigated the complexation of the ligand **3** with $Ln^{III}$ ions in situ, without isolation of the products (Scheme 1). Ziessel and co-workers have developed a number of macrocyclic ligands based on the bipyridine carboxylate architecture.[11] Multinuclear complexes using a tridentate ligand containing a bipyridine moiety and a carboxylate group have recently been reported by Mamula and co-workers[12] and nonalanthanide cluster based on a derivative of **3** by Comby et al.[13]

The Eu and La complexes **2b** and **2g** formed crystals suitable for X-ray diffraction, and the resulting molecular structure of **2b** is shown in Figure 1 (**2g** is shown in Figure S1).

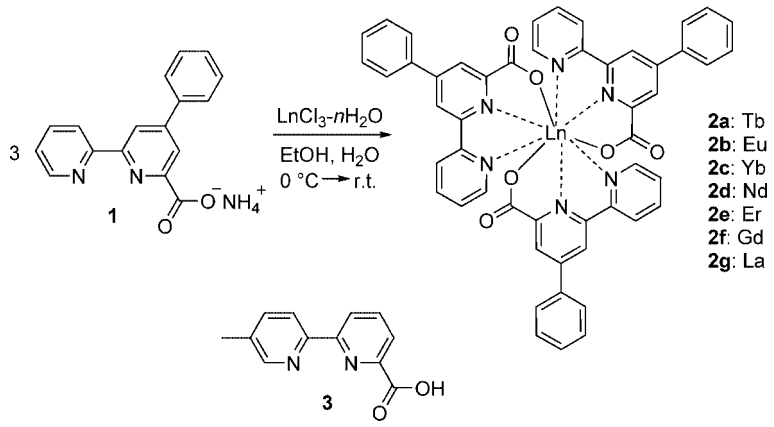

Scheme 1. Synthesis of the lanthanide complexes **2a**–**2g** and previously studied ligand **3**.[10]

The unit cell of **2b** contains one molecule each of MeOH and $CH_2Cl_2$ and that of **2g** contains three molecules of MeOH that are *not coordinated* to the Ln ions (i.e., the ligands fully saturate the inner coordination sphere of the Ln ions).

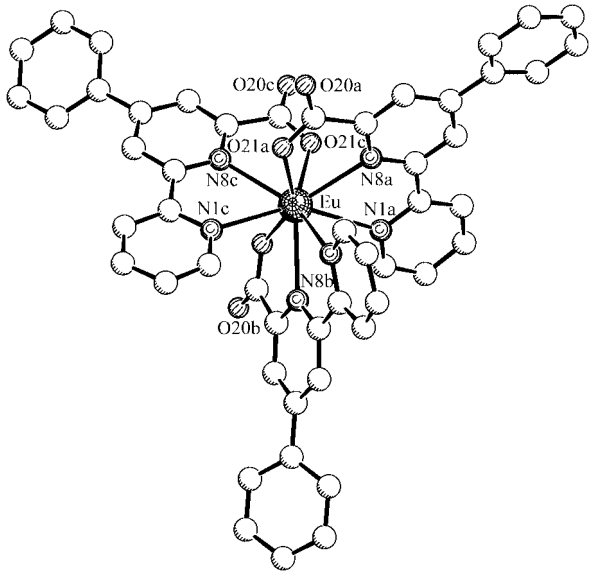

Figure 1. Molecular structure of complex **2b**. The hydrogen atoms and solvent molecules are omitted for clarity.

In **2g**, two La–O bonds have nearly the same length (2.44 Å), while the third is slightly longer (2.47 Å). In addition, the La–N distances range from 2.64 to 2.81 Å, where the longest La–O distance corresponds to the carbonyl group on the pyridine ring containing the longest La–N distance, indicating that there is steric hindrance around the La ion causing one ligand to be slightly crowded out. In **2b**, all distances are slightly shorter, but the same pattern exists: Eu–N distances range from 2.54–2.65 Å for two ligands, while the third has the longest Eu–N bond at 2.72 Å. Likewise, this third ligand has a slightly longer Eu–O distance (2.37 Å) than the other two (2.36 and 2.35 Å). In all cases, the pyridine ring containing the carbonyl group has the shorter of the two Ln–N distances. A table of selected crystal properties is given in the Supporting Information (Table S1).

It should be noted that different isomers of the complexes are possible, based on whether the carboxylate groups are up or down [up-up-up (*fac*) or up-up-down (*mer*)].[14] In the molecular structures isolated, the up-up-down (*mer*) isomer was exclusively observed. However, isomerization in solution is likely as indicated by the broad signals in the NMR spectrum of lanthanum complex **2g** (Figures S4 and S5) and the excited-state lifetime of terbium complex **2a**.[15] We attempted variable-temperature NMR experiments in order to observe the isomerization, but solubility problems prevented us from obtaining reliable measurements.

The complexes do not show absorption bands at energies lower than 340 nm, as can be expected for a simple ligand structure, and the bands can be assigned to π-π* transitions in the ligand with the highest energy transitions localized on the bipyridine units and the shoulder at 320 nm on the carboxylate moieties. Molar extinction coefficient values for the peak maximum at 276 nm are ca. 70000 $M^{-1}cm^{-1}$, and all the complexes show the same features (Figure S2).[16] The transitions in the absorption spectrum of ligand **1** (not shown) are slightly blueshifted vs. those in the complexes, but the features are similar.

The terbium (**2a**) and europium (**2b**) complexes emit brightly at room temperature in acetonitrile and $CH_2Cl_2$ solutions, showing the typical narrow spectra of $Ln^{III}$ cations (Figure 2). For **2a**, excitation of the antenna at 315 nm leads to the characteristic green emission from $Tb^{3+}$ arising from $^5D_4 \rightarrow {}^7F_j$ transitions, with the most intense band at 545 nm corresponding to the $^5D_4 \rightarrow {}^7F_5$ transition. Likewise, for **2b**, excitation of the ligand at 315 nm populates the $Eu^{3+}$ excited state, leading to $^5D_0 \rightarrow {}^7F_j$ transitions, with the most intense at 617 nm ($^5D_0 \rightarrow {}^7F_2$). The nondegenerate $^7F_0$ (579 nm) level is not split, giving evidence that complex **2b** exists as a single (time-averaged) luminescent species in solution.[7b] Due to the exclusion of solvent from the inner coordination sphere of the lanthanide, relatively long excited-state lifetimes (0.2 ms for **2a** and 2.2 ms for **2b**) and high emission quantum yields (7% for **2a**[17] and 60% for **2b**[18]) were found. This is in contrast to the estimated values found by Comby et al.[10] for ligand **3** (7% for $Eu^{III}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complexes and 55% for the $Tb^{III}$ derivatives), but this can be explained by the relative ordering of the energy levels (vide infra).

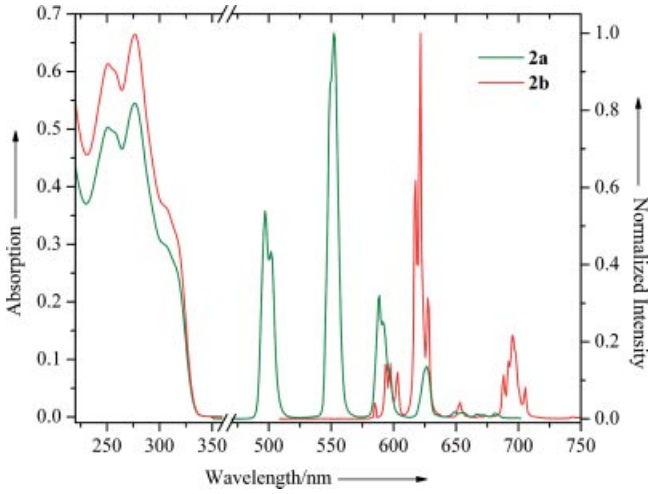

Figure 2. Absorption and normalized emission spectra of complexes **2a** ($1 \times 10^{-5}$ M) and **2b** ($0.8 \times 10^{-5}$ M) in aerated $CH_3CN$ at room temperature ($\lambda_{exc.}$ = 315 nm).

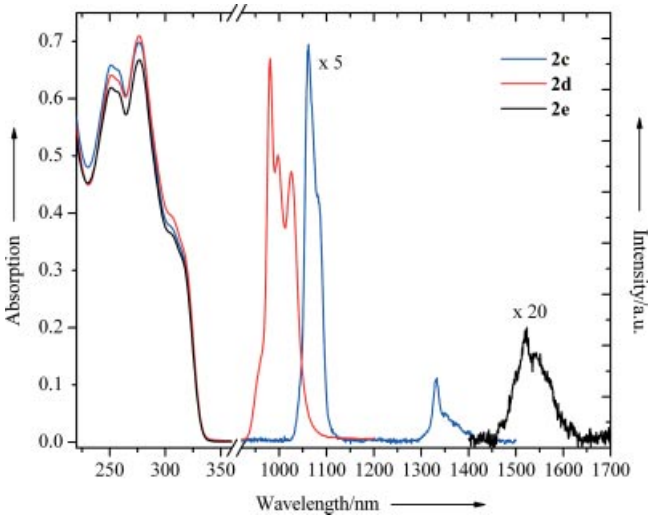

Figure 3. Absorption and emission spectra of complexes **2c**–**2e** in aerated $CH_3CN$ ($1 \times 10^{-5}$ M) at room temperature. The emission spectra were recorded for samples having the same absorption at the excitation wavelength (315 nm) and identical conditions for emission and scaled [**2c** (1×), **2d** (5×), and **2e** (20×)].

The infrared emitters were likewise measured and found to give intense emission in the NIR region. Figure 3 shows the absorption and normalized emission spectra of complexes **2c**–**2e**, where the spectra shown are recorded for samples with identical absorbance values at the excitation wavelength and constant bandpass for emission. Excitation of **2c** at 315 nm led to infrared emission with a maximum at 980 nm, corresponding to the $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition for $Yb^{3+}$. The quantum yield of **2c** was found to be 0.7%,[19] which is quite remarkable for NIR emitters when taking into consideration the energy gap law.[7] Complex **2d** has two emission peaks at 1060 nm ($^4F_{3/2} \rightarrow {}^4I_{11/2}$) and 1333 nm ($^4F_{3/2} \rightarrow {}^4I_{9/2}$) typical of $Nd^{III}$ complexes.[20] Complex **2e** shows the typical broad emission of $Er^{III}$ complexes, with a maximum at 1523 nm corresponding to the $^4I_{13/2} \rightarrow {}^4I_{15/2}$ transition. The spectra shown in Figure 3 are scaled due to the relatively low luminescence of **2d** and **2e** compared to $Yb^{III}$ complex **2c**, showing the dramatic effect of the energy gap law on the emission properties of the complexes.

All complexes showed identical photophysical properties in acetonitrile and $CH_2Cl_2$ solutions.[15,21] In addition to the emitting lanthanides, gadolinium complex **2f** was prepared to ascertain the level of the ligand triplet state ($^3\pi$-$\pi^*$). Because the excited state of $Gd^{III}$ ($^6P_{7/2}$) lies at 32150 $cm^{-1}$ (≈ 311 nm),[7] it is very difficult to populate it through organic excited ligand triplet states. Therefore, $Gd^{III}$ complexes offer the possibility to probe the ligand excited-state properties in systems nearly identical to the luminescent lanthanide complexes, including the enhanced intersystem crossing offered by the heavy gadolinium ion itself.

At room temperature, gadolinium complex **2f** shows a broad emission with a maximum at 350 nm (not shown), which corresponds to fluorescence of the ligand. Upon cooling to 77 K, a small amount of residual singlet emission is observed, but the emission spectrum is dominated by the phosphorescent triplet emission from the ligand (Figure S3). When a delay of 100 μs after the excitation pulse was applied, the singlet emission disappeared. The $^3\pi$-$\pi$ state of the ligand was determined to be 22700 $cm^{-1}$ (2.82 eV) from the 0-0 transition in the phosphorescence spectrum (440 nm) at 77 K. At room temperature, **2f** has a fluorescence lifetime <1 ns, while at 77 K, the lifetime of the phosphorescent triplet state is 5.4 ms.

The emitting levels of $Eu^{III}$ ($^5D_0$) and $Tb^{III}$ ($^5D_4$) lie at 17500 $cm^{-1}$ and 20430 $cm^{-1}$, respectively, and therefore below the triplet state of the ligand (22700 $cm^{-1}$). However, the $^3\pi$-$\pi$ state of the ligand should be sufficiently higher than the emitting level of the lanthanides such that energy transfer is fast and irreversible (i.e., no back energy transfer can occur). Experimental results have previously shown that triplet states of the ligand should be between 2000 $cm^{-1}$[6b] and 3500 $cm^{-1}$[22] above the emitting state of the $Ln^{III}$ ion ($\Delta E$). In the systems reported here, $\Delta E$ is 2270 $cm^{-1}$ for **2a** and 5200 $cm^{-1}$ for **2b**. Although the emission quantum yield of **2a** is still relatively high (5%), it is clear that the $^3\pi$-$\pi$ state of the ligand and the $^5D_4$ state on $Tb^{III}$ are not well matched. Although the $^5D_0$ state of $Eu^{III}$ and the triplet state of the ligand have a high $\Delta E$ value, an emission quantum yield of 60% is obtained. This indicates that $\Delta E$ of 2000 $cm^{-1}$ may allow, for these complexes at room temperature, back energy transfer into the triplet manifold of the ligand in complex **2a**. For the related complexes based on ligand **3**,[10] the quantum yields for the $Eu^{III}$ and $Tb^{III}$ complexes are reversed. Ligand **3** lacks a phenyl ring on the bipyridine ligand and the increased conjugation offered in the ligand reported here would serve to lower the triplet state and improve the energy match between the ligand and the $Eu^{III}$ emitting state. Conversely, ligand **3**, with its higher triplet state, would favor energy matching the $Tb^{III}$ emitting

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

state, which shows the higher emission quantum yield in the previous study.

The gap between the ligand state in **2c** and that of the $Yb^{III}$ $^2F_{5/2}$ state is quite high (ca. 12000 $cm^{-1}$), but still leads to a relatively high emission quantum yield (0.7%). Presumably, this can be increased by better energy matching of the $^3\pi$-$\pi$ state of the ligand and the $^2F_{5/2}$ level of $Yb^{III}$ (i.e., lowering the triplet level of the ligand by redshifting the absorption), although other processes may play a role.[23]

## Conclusions

We have synthesized a series of neutral lanthanide (Ln) complexes based on simple ligand structures that effectively serve as antennae for energy transfer to the $Ln^{III}$ ion, giving the typical narrow emission spectra, large Stokes' shifts and long luminescence lifetimes typical of $Ln^{III}$ ions. In addition, the red- and near-infrared-emitting complexes have high emission quantum yields, which is likely due to the exclusion of vibronically deactivating solvent molecules from the inner coordination sphere of the complex. Another advantage of the present complexes is their neutrality, making them amenable to applications where charged lanthanide complexes are not, such as in the fabrication of SMOLEDs. We are currently investigating the volatility of the complexes.

Furthermore, functionalization of the ligand allows for the synthesis of more soluble derivatives in solvents of different polarity. Finally, more highly conjugated systems will shift the absorption into the visible region, potentially making the complexes more suitable for biological imaging, where ultraviolet excitation light can cause severe damage to biological tissue. The aforementioned derivatives will be presented in a forthcoming full paper.

**Supporting Information** (see footnote on the first page of this article): Synthetic, photophysical and X-ray methods, characterization data for the products, absorption spectra of all complexes, emission spectra of complex **2f**, crystal structure of **2g**, and NMR spectra of **1** and **2g**.

[15] Terbium complex **2a** has a much longer excited state lifetime (1.6 ms) in $CH_2Cl_2$ (vs. 0.2 ms in acetonitrile). We have no concrete explanation for this dramatic change, but experiments are currently underway to understand it. One possible explanation is an isomerization in solution leading to different isomers with different properties, as discussed in the text.
[16] Due to the low solubility of the complexes, we do not feel confident quoting exact molar absorptivity values.

# Synthesis and Characterization of a Gold Complex Containing $[SbPh]^{2-}$ and $[SbPh_2]^-$ Anions as Bridging Ligands

**Dieter Fenske,*[a,b] Alexander Rothenberger,[a,b] and Stephan Wieber[a,b]**

**Keywords:** Bridging ligands / Aurophilicity / Antimony / Gold / Group 15 ligands

The synthesis and structural characterization of the gold antimony complex $[Au_8(SbPh)_2(SbPh_2)_4(PEt_3)_6]$ (**1**) is reported. Complex **1** can be obtained by the reaction of $[AuCl(PEt_3)]$ with a mixture of $PhSb(SiMe_3)_2$ and $Ph_2(SbSiMe_3)$ in presence of the bidentate phosphane ligand dppm [dppm = bis(diphenylphosphanyl)methane]. Complex **1** consists of a distorted heterocubic central $[Au_6Sb_2]$ unit connected to two annulated five-membered rings on two opposite edges. The $Au^I$ ions show weak aurophilic interactions and are bridged by $[SbPh]^{2-}$ and $[SbPh_2]^-$ anions. Despite the high oxidation potential of $Au^I$, the reaction mixtures and crystals are surprisingly stable.

## Introduction

Gold complexes have been the subject of interest over a long period of time and some of the latest investigations focus on the catalytic and pharmaceutical aspects of gold compounds.[1–5] There has also been great interest in the chemistry of gold phosphane complexes and gold chalcogenide clusters.[6–12] However, gold complexes containing heavier group 15 elements are scarce. Recently, Au–As cluster complexes[13,14] were obtained by the synthesis of silylated arsines with $Au^I$ phosphane complexes and a few $Au^I$ complexes with tertiary ligands of the type $ER_3$ (E = Sb, Bi; R = organic group) are known for antimony,[15–17] but none for bismuth.[18] Only recently, the first $Au^I$ and $Cu^I$ complexes $[Au(C_6F_5)_2][Bi\{C_6H_4(2\text{-}CH_2NMe_2)\}_2]$ and $[(PMe_3)_2CuBi(SiMe_3)_2]$ with a M···Bi interaction (M = Cu, Bi) were reported.[19,20] In contrast, there are several copper and silver antimony clusters.[21–24] The copper antimony clusters, for example $[Cu_{20}Sb_{10}(PCy_3)_8]$, $[Cu_{45}Sb_{16}(PEt_2Me)_{16}]$ and $[Cu_{28}Sb_{12}(PEt_3)_{12}\{Sb(SiMe_3)_2\}_2]$ can be obtained by reactions of $Cu^I$ salts with $Sb(SiMe_3)_3$ in the presence of tertiary phosphanes. The concept of oxidation numbers and localised $Cu^I$ and $Cu^{II}$ centres cannot be applied to these CuSb clusters and they are described as molecular alloys. For silver, molecular alloys were not found. Instead reactions between silver nitrate and $PhSb(SiMe_3)_2$ yielded the silver antimony complexes $[Ag_4(Sb_4Ph_4)_2(PiPr_3)_4]$ and $[Ag_4(Sb_6Ph_6)_2(PnBu_3)_4]$ where oxidation of the antimony precursors to anions with Sb–Sb bonds took place.[24]

## Results and Discussion

Here we report the synthesis of the 12-membered Au–Sb ring $[Au_8(SbPh)_2(SbPh_2)_4(PEt_3)_6]$ (**1**)·$16CH_2Cl_2$ by the reaction of $[AuCl(PEt_3)]$ with a mixture of $PhSb(SiMe_3)_2$ and $Ph_2(SbSiMe_3)$ in presence of the bidentate phosphane ligand dppm [dppm = bis(diphenylphosphanyl)methane] (Scheme 1).

$$[AuCl(PEt_3)] + PhSb(SiMe_3)_2/Ph_2Sb(SiMe_3) \xrightarrow{dppm} [Au_8(SbPh)_2(SbPh_2)_4(PEt_3)_6] \quad (1)$$

Scheme 1. Synthesis of $[Au_8(SbPh)_2(SbPh_2)_4(PEt_3)_6]$ (**1**).

Complex **1** crystallizes from $CH_2Cl_2$ as yellow blocks in the triclinic space group $P\bar{1}$ (Figure 1) with one molecule in the unit cell and 16 $CH_2Cl_2$ molecules per unit cell.

The molecular structure of **1** can be described as a 12-membered Au–Sb ring or a distorted heterocubic central $[Au_6Sb_2]$ unit connected to two annulated five-membered rings on two opposite edges. Two gold atoms (Au1, Au1A) are coordinated to a phosphorus atom of triethylphosphane [Au1–P1 2.277(5) Å], whereas the other four gold atoms belong to the nonplanar five-membered rings formed with another four Sb atoms of the $[SbPh_2]^-$ ligands and two further gold atoms [Au4, Au4A]. The bridging angle of the $[SbPh_2]^-$ ligand is about 120° [Au3–Sb3–Au4 118.87(5)°]. Within the peripheral rings the Au4,4A atoms are surrounded by two phosphorus atoms of the phosphane groups and the two antimony atoms of the $[SbPh_2]^-$ ligands in a distorted tetrahedral fashion [P3–Au4–Sb2 108.89(12)°]. Noteworthy structural features are the acute Sb–Au–Sb angle of almost 90° [Sb3–Au4–Sb2 90.50(5)°] and the large P–Au–P angle [P2–Au4–P3 125.25(18)°], which may be the result of steric repulsion of the bulky phosphane ligands. This situation is also reflected in the slightly longer Au–P distance [Au4–P3 2.358(5) Å] relative

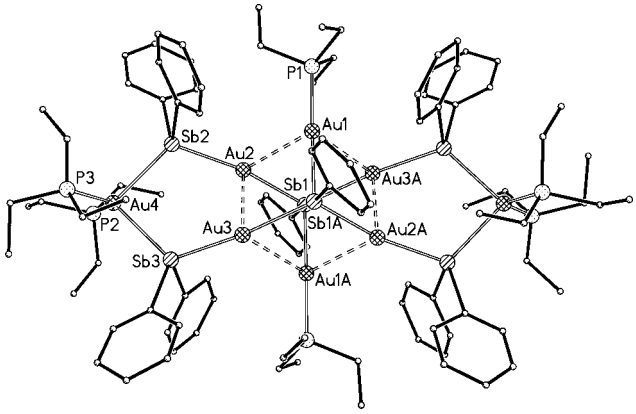

Figure 1. Molecular structure of $[Au_8(SbPh)_2(SbPh_2)_4(PEt_3)_6]$ (**1**) in the solid state [symmetry operation (A) $-x + 1, -y + 1, -z + 1$]. Selected distances [Å] and angles [°]: Au1–Au2 3.0100(10), Au2–Au3 3.0412(17), Au2–Sb2 2.5774(15), Au2–Sb1 2.5883(15), Au3–Sb3 2.5803(12), Au4–Sb3 2.7298(16), Au4–Sb2 2.7350(15), Au1–P1 2.277(5), Au4–P2 2.351(4), Au4–P3 2.358(5), P1–Au1–Sb1A 169.80(11), P1–Au1–Au2 103.92(10), Sb1A–Au1–Au2 83.32(4), P1–Au1–Au3A 102.17(12), Sb1A–Au1–Au3A 84.74(4), Au2–Au1–Au3A 90.48(3), Sb2–Au2–Sb1 167.51(4), Sb2–Au2–Au1 115.45(4), Sb1–Au2–Au1 77.03(3), Sb2–Au2–Au3 93.16(4), Sb1–Au2–Au3 87.47(4), Au1–Au2–Au3 85.21(4), Sb3–Au3–Sb1A 173.68(4), Sb3–Au3–Au2 91.50(4), Sb1A–Au3–Au2 82.56(4), Sb3–Au3–Au1 107.37(4), Sb1A–Au3–Au1A 73.98(3), Au2–Au3–Au1A 81.44(4), P2–Au4–P3 125.25(18), P2–Au4–Sb3 111.05(13), P3–Au4–Sb3 108.74(16), P2–Au4–Sb2 106.81(12), P3–Au4–Sb2 108.89(12), Sb3–Au4–Sb2 90.50(5), Au1A–Sb1–Au2 103.43(5), Au1A–Sb1–Au3A 104.75(5), Au2–Sb1–Au3A 116.13(5), Au2–Sb2–Au4 115.41(5), Au3–Sb3–Au4 118.87(5).

to Au1–P1 with 2.277(5) Å. The same applies to the Au4,4a–Sb bond length, which is the largest observed in **1** [Au4–Sb2 2.7350(15) Å]. Au–Sb bond lengths within the central heterocubic unit are about 0.15 Å shorter [Au2–Sb2 2.5774(15) Å; Sb1–Au3A 2.5903(13) Å]. Au–Sb distances in $Au^I$ stibane complexes are between 2.605 and 2.65 Å.[15–17] If one considers the estimated van der Waals radii of gold (3.6 Å), aurophilic interactions could be expected in compound **1** with Au–Au distances of 3.0100(10) [Au1–Au2] to 3.1773(14) Å [Au3–Au1A].[25] Similar distances are known for other gold compounds, for example the Au–As cluster complexes $[Au_{19}(As\textit{n}Pr)_8(dppe)_6]Cl_3$, $[Au_{10}(As\textit{n}Pr)_4(dppe)_4]Cl_2$ and $[Au_{10}(AsPh)_4(PhAsSiMe_3)_2(P\textit{n}Pr_3)_6]$ or the Au–Se clusters $[Au_{10}Se_4(dpppe)_4]Br_2$ and $[Au_{18}Se_8(dppe)_6]Br_2$ [dppe, dpppe = 1,2-bis(diphenylphosphanyl)ethane or -pentane].[11,13] Aurophilic interactions discussed in the literature for mononuclear gold complexes with Au–Au distances of about 3.05 Å are indicated in **1** by dashed-open bonds (Figure 1).[26] These are longer than Au–Au distances in $Au_2$(g) (2.472 Å) or the Au–Au distance in cubic close packed gold (2.884 Å).[25]

Contrary to copper or silver complexes with stibido ligands, the $Au^I$ ions in **1** adopt a linear coordination with the Sb anions. Despite the high oxidation potential of $Au^I$, the reaction mixture and crystals are surprisingly stable, which is also in marked contrast to the silver antimony cluster complexes that decompose at –40 °C.[24] The added phosphane dppm is not found in the solid-state structure of **1**, but it plays an important role in the reaction. If there is no additional phosphane in the mixture, the reaction turns green immediately, indicating a different reaction pathway that is currently being investigated. However, Au–Sb cluster **1** can also be obtained by the reaction with $PPh_3$ as a stabilizing ligand.

## Conclusions

Despite the high oxidation potential of $Au^I$, the first Au–Sb cluster was described; it was found to exhibit linear coordination of the gold centres to the antimony anions with weak additional aurophilic interactions. The Au–Sb system is surprisingly stable relative to previously described Ag–Sb complexes. With the consideration that gold tends to form Au–Au interactions, further investigations will focus on the synthesis of linked Au–Sb complexes, which may result in novel mixed-metal wires or wires consisting of linked molecular Au–Sb alloys.

## Experimental Section

**General Remarks:** All operations were carried out under an atmosphere of purified nitrogen. $CH_2Cl_2$ was refluxed over $P_2O_5$ and freshly distilled prior to use. The dppm ligand was purchased from Sigma–Aldrich. $[AuCl(PEt_3)]$, $PhSbSiMe_3$ and $Ph_2SbSiMe_3$ were prepared according to published procedures.[27,28] The UV/Vis spectrum was recorded in KBr pellets with a Perkin–Elmer Lambda 900 spectrophotometer. Fourier-transform infrared spectroscopy on KBr pellets was performed with a Bruker IFS 28 FTIR instrument.

**1:** $[AuCl(PEt_3)]$ (0.08 g, 0.228 mmol) was dissolved in $CH_2Cl_2$ (8 mL) and dppm (0.18 g, 0.456 mmol) was then added. The clear, colourless solution was cooled to –78 °C and $PhSbSiMe_3$/$Ph_2SbSiMe$ (1:1.25, 0.03 mL) was added. The yellow reaction mixture was stored at –78 °C overnight, and then it was warmed up to –40 °C and stored over a period of one week. After one week at –40 °C, yellow crystals of **1** could be isolated for crystallographic measurements. UV/Vis (KBr): $\lambda$ = 575 (absorption edge) nm. IR (KBr): $\tilde{\nu}$ = 1584.90 (vw), 1571.11 (m), 1474.54 (m), 1428.29 (s), 1377.15 (vw), 1299.70 (vw), 1260.71 (w), 1180.79 (vw), 1155.11 (vw), 1092.43 (m), 1064.44 (w), 1026.97 (m), 1017.86 (m), 996.89 (w), 802.43 (w), 764.14 (w), 741.80 (m), 727.38 (s), 692.96 (vs), 522.49 (m), 506.21 (m), 458.04 (m), 450.2 (m) $cm^{-1}$.

**X-Ray Crystallographic Study:** Crystallographic data for the compounds were collected with a STOE IPDS II diffractometer by using graphite-monochromatic Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ (all data) using the SHELXTL software package.[29] Hydrogen atoms were placed in calculated positions, non-hydrogen atoms were assigned anisotropic thermal parameters. Disordered components were refined with isotropic thermal parameters. **1**: $C_{104}H_{156}Au_8Cl_{16}P_6Sb_6$: $M_r$ = 4465.54; triclinic, space group $P\bar{1}$, $Z$ = 1; $a$ = 14.270(3), $b$ = 15.365(3), $c$ = 18.851(4) Å; $\alpha$ = 105.47(3), $\beta$ = 90.78(3), $\gamma$ = 113.47(3)°; $V$ = 3620.0(13) $Å^3$; $T$ = 150(2) K; $F(000)$ = 2080; $\rho_{calcd.}$ = 2.048 $g\,cm^{-3}$; reflections measured 22500, of which 13237 were independent ($R_{int}$ = 0.0899); 603 parameters; $wR_2$ = 0.2473 (all data); $R_1$ = 0.0883 [$I > 2\sigma(I)$]; Largest diff. peak and hole 5.289/–3.575 $e\,Å^{-3}$.

# Synthesis and Reactivity of 16-Electron Pentamethylcyclopentadienyl–Ruthenium(II) Complexes with Bis(imidazolin-2-imine) Ligands

**Dejan Petrovic,[a] Thomas Glöge,[a] Thomas Bannenberg,[a] Cristian G. Hrib,[a] Sören Randoll,[a] Peter G. Jones,[a] and Matthias Tamm*[a]**

**Keywords:** Ruthenium / Cyclopentadienyl ligands / N ligands / 16-electron complexes / Coordinative unsaturation

The 1,2-bis(imidazolin-2-imino)ethane ligands $BL^{Me}$ and $BL^{iPr}$ were prepared, in which the ability of the imidazolium moiety to effectively stabilize a positive charge leads to highly basic ligands with a strong electron-donating capacity. This feature is illustrated by the isolation of very stable half-sandwich 16-electron ruthenium complexes of the type $[(\eta^5\text{-}C_5Me_5)Ru(BL^R)]^+$ (**1**, R = Me; **2**, R = *i*Pr), which even resist coordination of the chloride counterion. Their inertness towards hard, π-basic ligands does not prevent these complexes from displaying high reactivity towards soft σ-donor/π-acceptor ligands such as CO and isocyanides, and the complexes $[\mathbf{1}\cdot CO]CF_3SO_3$ and $[\mathbf{1}\cdot CNXy]CF_3SO_3$ (XyNC = 2,6-dimethylphenyl isocyanide) can be isolated. These complexes exhibit CO and CN stretching vibrations at 1886 and 1991 $cm^{-1}$, respectively, which reveals the electron richness and strong π-electron releasing capability of the ruthenium–imine moiety.

## Introduction

Coordinatively unsaturated organometallic complexes play a fundamental role as intermediates in homogeneous transition-metal-catalyzed reactions, and their occurrence is rationalized by the 16- and 18-electron rule proposed by Tolman.[1] Numerous examples have been prepared to date, and their electronic and magnetic properties have been studied.[2] Various factors can be responsible for the stabilization of these species, amongst which the introduction of π-donor ligands such as alkoxides, alkylthiolates, amides, or halides can be successfully employed for the creation of π-stabilized unsaturation.[2,3] Accordingly, the stabilization of 16-electron half-sandwich ruthenium complexes of the type $[(\eta^5\text{-}C_5Me_5)Ru(PR_3)X]$ (X = OR, NHR, Cl, Br, I) can be achieved by electron donation from the heteroatomic anionic ligand.[4] Similarly, ligand π-coordination has been suggested to exist in highly reactive ruthenium–amidinate complexes such as $[(\eta^5\text{-}C_5Me_5)Ru\{i\text{PrNC(Me)N}i\text{Pr}\}]$.[5] In contrast, the cationic 16-electron tmeda complex $[(\eta^5\text{-}C_5Me_5)Ru(Me_2NCH_2CH_2NMe_2)]^+$ can be isolated despite the lack of nitrogen-to-metal π-donation. This complex, however, can only be stabilized by the use of the noncoordinating $[B\{3,5\text{-}C_6H_3(CF_3)_2\}_4]^-$ ($BAr'_4$) counteranion.[6] The same holds true for the rare 16-electron phosphane complexes $[(\eta^5\text{-}C_5Me_5)Ru(PP)]BAr'_4$ [PP = $(PEt_3)_2$, $i\text{Pr}_2\text{PCH}_2\text{CH}_2\text{P}i\text{Pr}_2$].[7]

## Results and Discussion

We present herein the neutral 1,2-bis(imidazolin-2-imino)ethane ligands $BL^{Me}$ and $BL^{iPr}$ and their ability to form 16-electron half-sandwich ruthenium complexes of unprecedented stability. $BL^R$ (R = Me, *i*Pr) are obtained in high yield as air-stable off-white solids from the reaction of the readily available imidazolin-2-imines[8] $Imine^{Me}$ and $Imine^{iPr}$ with 1,2-ethyleneditosylate followed by deprotonation with KO*t*Bu.[9,10] The reaction of $BL^{Me}$ and $BL^{iPr}$ with $[(\eta^5\text{-}C_5Me_5)RuCl]_4$[11] in thf affords the violet-colored complexes $[(\eta^5\text{-}C_5Me_5)Ru(BL^{Me})]Cl$, [**1**]Cl, and $[(\eta^5\text{-}C_5Me_5)Ru(BL^{iPr})]Cl$, [**2**]Cl, in which the chloride counteranions can be easily exchanged for the triflate anion (Scheme 1). Crystals of [**1**]OTf·thf suitable for X-ray diffraction analysis could be obtained from a thf/hexane solution. The unit cell is composed of noninteracting cations **1** and triflate anions, and the shortest Ru–O and Ru–F distances are 5.65 and 6.87 Å, respectively. Any interaction between the cations and the thf solvent molecules can also be excluded as the shortest $Ru\text{–}O_{thf}$ separation is 5.97 Å. In addition, there is no indication of any agostic interaction between the ruthenium center and the C–H bonds of the diimine ligand. The cationic half-sandwich complex exhibits a two-legged piano stool geometry with the $\eta^5\text{-}C_5Me_5$ and the $\eta^2$-diimine ligands adopting a pseudotrigonal planar coordination sphere around the ruthenium atom (Figure 1). The Ct–Ru–N1–N2 dihedral angle (Ct = centroid of the Cp

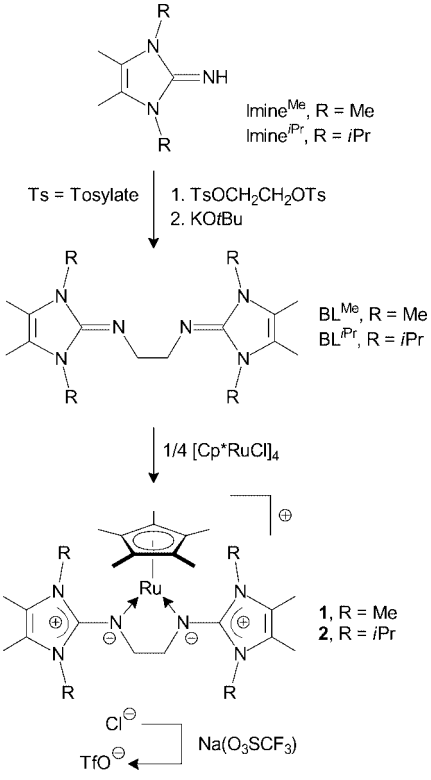
ring) is 179.6°, and the sum of the N1–Ru–N2 angle [76.71(6)°] and the two Ct–Ru–N angles is 360.0°. Accordingly, cation **1** can be regarded as being almost perfectly $C_{2v}$-symmetric.



Scheme 1.

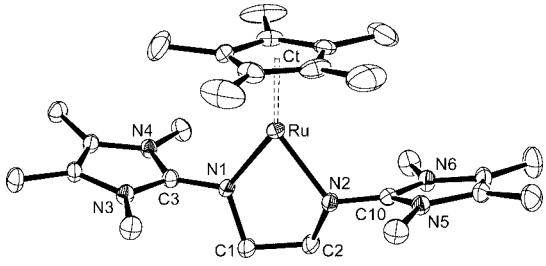


Figure 1. ORTEP diagram of the cation in [**1**]OTf with thermal displacement parameters drawn at 50% probability.[18] The Cp* ligand is disordered over two positions; only one position is shown. Selected bond lengths [Å] and angles [°]: Ru–N1 2.060(2), Ru–N2 2.073(2), Ru–C(Cp*) 2.103(4)–2.194(4), N1–C3 1.349(2), N2–C10 1.345(2); N1–Ru–N2 76.71(6).

The Ru–N distances of 2.060(2) and 2.073(2) Å are significantly shorter than those in the related complex [($\eta^5$-$C_5Me_5$)Ru(tmeda)]BAr′$_4$ [2.183(7), 2.180(6) Å],[6a] and they fall in the same range as the Ru–N bond length observed for the amidinate complex [($\eta^5$-$C_5Me_5$)Ru{iPrNC(Me)-NiPr}] [2.073(3) Å].[5a] Even shorter Ru–N distances are found in neutral bimetallic Cp*Ru complexes containing a highly π-basic diamide ligand.[12] The short Ru–N bonds in **1** are in agreement with a strong electron-releasing capability of the BL$^{Me}$ ligand, which is implied by the ylidic resonance structure shown in Scheme 1. Charge separation in coordinated BL$^{Me}$ can be also clearly deduced from the observation of perpendicularly oriented imidazole moieties with respect to the Ru–N–N coordination plane (dihedral angles = 86.0 and 82.6°). This orientation rules out the possibility of π-interaction between the exocyclic nitrogen atoms and the imidazole rings, leading to elongated C–N distances [N1–C3 = 1.349(2) Å and N2–C10 = 1.345(2) Å], much longer than expected for a N–C($sp^2$) double bond (1.28 Å) and almost in the range of a N–C($sp^2$) single bond (1.38 Å).[13]

The molecular structure of cation **2** in [**2**]OTf·thf, which displays crystallographic mirror symmetry, is shown in Figure 2. Inspection of the crystal packing reveals the absence of any relevant intermolecular contact between the cation and the triflate and the thf molecules. In comparison to **1**, however, the coordination sphere around the ruthenium atom is slightly distorted from a pseudotrigonal planar arrangement. The Ct–Ru–N1–N1a dihedral angle is 168.0°, and the sum of the N1–Ru–N1a angle [77.56(9)°] and the Ct–Ru–N angles is 358.8°. This distortion is associated with a slippage of the $NCH_2CH_2N$ moiety of the diimine ligand to one side of the molecule, opening the opposite side of the ruthenium coordination sphere for two intramolecular C7–H7···Ru contacts of 2.88 Å. This rather long distance excludes the presence of a strong agostic interaction,[7,14] but could imply intramolecular hydrogen bonds of the X–H···M type.[15,16] The Ru–N/N1a bond length in **2** is 2.076(2) Å, which is slightly longer than the corresponding distances found in **1**.

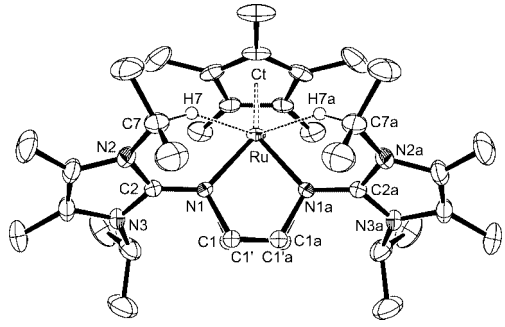

Figure 2. ORTEP diagram of the cation in [**2**]OTf with thermal displacement parameters drawn at 50% probability.[18] The ethylene bridge is disordered. Selected bond lengths [Å] and angles [°]: Ru–N1 2.076(2), Ru–C(Cp*) 2.120(2)–2.156(2), N1–C2 1.340(2); N1–Ru–N1a 77.50(8).

In agreement with the presence of 16-electron species in the solid state, the cations in [**1**]OTf and [**2**]OTf also exhibit $C_{2v}$ symmetry in solution according to their $^1$H and $^{13}$C NMR spectra in [$D_6$]acetone. For instance, the $^1$H NMR spectrum of [**1**]OTf shows one singlet for the $NCH_2CH_2N$ moiety together with three singlets for the three different types of methyl groups. In contrast, two doublets are observed in the $^1$H NMR spectrum of [**2**]OTf for the diastereotopic isopropyl methyl groups, indicating a hindered rotation of the imidazoline moieties around the N1–C2 axis at r.t. on the NMR timescale. Furthermore, the nature of the counterion does not have any impact on the chemical

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

shifts, and the $^1H$ and $^{13}C$ NMR spectra recorded for [**1**]Cl and [**2**]Cl are identical with those observed for the corresponding triflates. Low-temperature NMR spectroscopic studies of the chloride complexes in [$D_6$]acetone solution do not reveal any significant changes, suggesting negligible ruthenium–chloride interaction or a rapid dynamic behavior even at –90 °C (see NMR spectra in the Supporting Information). Low solubility impeded NMR measurements in less polar solvents such as [$D_8$]toluene. Ultimately, the solid-state structure of [**2**]Cl·0.75thf shows an asymmetric unit, which is composed of four independent cations **2**, four chloride anions, and three thf molecules (Figure 3). The shortest Ru–Cl distance is 5.89 Å, excluding any interaction and providing final proof of the stability of these unsaturated 16-electron complexes. The geometries at the ruthenium centers and the Ru–N distances are very similar to the parameters observed in [**2**]OTf·thf with the exception of Ru···H interactions, which were not observed.

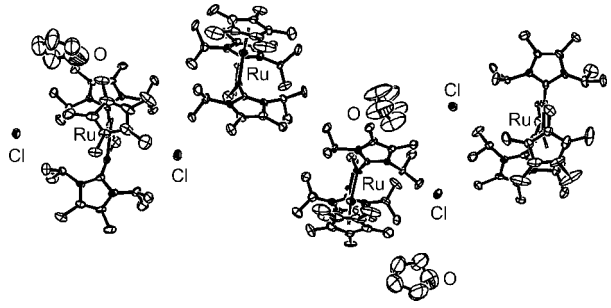

Figure 3. ORTEP diagram of the asymmetric unit of [**2**]Cl·0.75thf with thermal displacement parameters drawn at 50% probability.[18,19]

It should be noted that dynamic behavior in solution was reported for the related complex [($\eta^5$-$C_5Me_5$)RuCl(tmeda)], for which the solid-state structure shows that the chloride atom is attached to the ruthenium center with an unusually long Ru–Cl distance of 2.5116(9) Å.[17] To compare this complex, which contains a hard σ-donor diamine ligand, with our Cp*Ru–diimine complexes, we performed DFT (density functional theory) calculations to determine their heterolytic gas phase Ru–Cl bond dissociation enthalpies.[18] For [**1**]Cl and [**2**]Cl, the enthalpies required to split the chloride ion from the corresponding complex cations are 295.0 and 294.4 kJ/mol, respectively, whereas for the tmeda complex, a significantly higher value of 413.8 kJ/mol was obtained, indicating a much stronger Ru–Cl interaction. These results suggest that the large difference of almost 120 kJ/mol between the gas phase dissociation enthalpies accounts for the observed strong dissociation of the Cp*Ru–diimine complexes in solution, where anion and cation solvation supports straightforward heterolytic Ru–Cl bond cleavage.

On the basis of structural and theoretical results, it can be assumed that the unusual stability of cationic complexes **1** and **2** stems from the strong π-electron releasing capability of the diimine ligands $BL^{Me}$ and $BL^{iPr}$. Indeed, cyclic voltammetric studies on [**1**]OTf and [**2**]OTf in acetonitrile afford very negative redox potentials of $E°$ = –588 mV and $E°$ = –569 mV versus the ferrocene/ferrocenium couple.[20] These potentials are much lower than usually observed for a reversible one-electron $Ru^{II}/Ru^{III}$ oxidation process in cyclopentadienyl–ruthenium complexes.[21] In contrast, it is not surprising that the values reported for *neutral* 16-electron Cp*Ru–amidinate complexes obviously fall in an even more negative range.[5d] The reactivity of [**1**]OTf towards carbon monoxide and 2,6-dimethylphenyl isocyanide (XyNC) gives further evidence for the electron richness of the metal center. Treatment of thf solutions of [**1**]OTf with CO gas or 1 equiv. of XyNC at ambient temperature yields the complexes [**1**·CO]OTf and [**1**·CNXy]OTf as a yellow or red crystalline solid, respectively. In the IR spectra, the CO and CN stretching vibrations are at 1886 and 1991 $cm^{-1}$, which is strongly shifted to lower wavenumbers in comparison to the free, uncoordinated ligands. In general, significantly higher values were reported for other cationic complexes of the type [Cp*Ru(N∩N)CO]$^+$, for examle $\tilde{\nu}_{CO}$ = 1959 and 1963 $cm^{-1}$ for N∩N = RN=CH–CH=NR (R = *i*Pr, Mes),[22] $\tilde{\nu}_{CO}$ = 1963 $cm^{-1}$ for N∩N = bipy,[23] $\tilde{\nu}_{CO}$ = 1948 $cm^{-1}$ for N∩N = phenanthroline,[24] and $\tilde{\nu}_{CO}$ = 1931 $cm^{-1}$ for N∩N = $Me_2NCH_2CH_2NH_2$.[25] Remarkably, the CO stretching frequency in [**1**·CO]OTf is even slightly lower than the values reported for the amidinate complexes [($\eta^5$-$C_5Me_5$)Ru{*i*PrNC(Me)N*i*Pr}CO] ($\tilde{\nu}_{CO}$ = 1901 $cm^{-1}$) and [($\eta^5$-$C_5Me_5$)Ru{*t*BuNC(Ph)N*t*Bu}CO] ($\tilde{\nu}_{CO}$ = 1888 $cm^{-1}$).[5a]

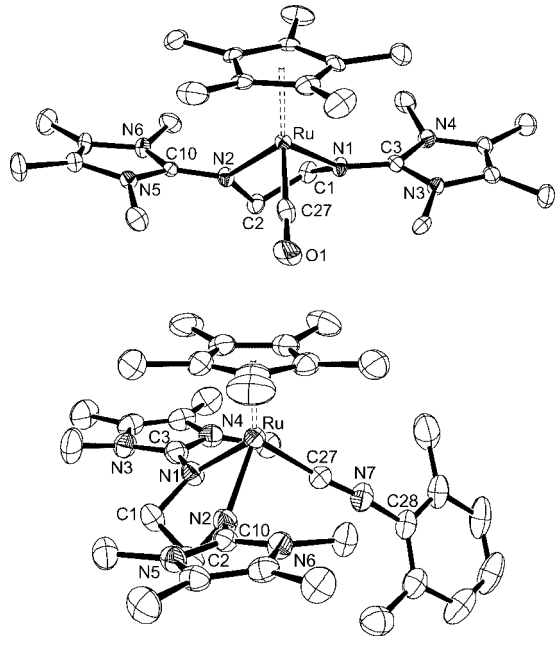

Figure 4. ORTEP diagram of the cations in [**1**·CO]OTf (top) and [**1**·CNXy]OTf (bottom) with thermal displacement parameters drawn at 50% probability.[18] Selected bond lengths [Å] and angles [°] in [**1**·CO]$^+$/[**1**·CNXy]$^+$: Ru–N1 2.165(3)/2.185(3), Ru–N2 2.145(3)/2.153(2), Ru–C27 1.831(4)/1.907(3), Ru–C(Cp*) 2.192(3)–2.272(4)/2.194(3)–2.233(3), N1–C3 1.323(4)/1.331(4), N2–C10 1.319(5)/1.335(4), C27–O1 1.162(5), C27–N7 1.179(4); N1–Ru–N2 77.38(12)/77.94(9), Ru–C27–O1 172.0(4), Ru–C27–N7 175.6(3), C27–N7–C28 174.8(4).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The molecular structures of the cations in [**1**·CO]OTf and [**1**·CNXy]OTf are shown in Figure 4. Both complexes exhibit a three-legged piano stool geometry with elongated Ru–N bonds in comparison to the structure of **1**. The ruthenium–carbon bonds are short [Ru–CO 1.831(4) Å, Ru–CN 1.907(3) Å], confirming strong metal-to-ligand π-back-donation. For instance, the Ru–C distance in [**1**·CO]OTf is significantly shorter than the distances observed for related cationic complexes of the type $[Cp^*Ru(N^{\frown}N)CO]^+$,[26] and it falls in the same range as the bond length observed for the neutral amidinate complex $[(\eta^5\text{-}C_5Me_5)Ru\{t\text{BuNC(Ph)-N}t\text{Bu}\}CO]$.[5a]

## Conclusions

In this contribution, we have presented 16-electron ruthenium half-sandwich complexes of unusual stability, which can be ascribed to the strong π-basic nature of the novel bis(imidazolin-2-imine) ligands $BL^{Me}$ and $BL^{iPr}$, leading to a weak propensity of the Ru atom to coordinate other π-basic ligands such as chloride. In contrast, strong binding of σ-donor/π-acceptor ligands such as CO or isocyanides can be observed. This behavior makes these highly stabilized, yet reactive 16-electron complexes suitable systems for the activation of small molecules such as $N_2$ and $H_2$ and promising candidates for catalytic applications. These investigations are currently in progress in our laboratory.

[19] The crystal of [**2**]Cl was not of high quality. The structure is noncentrosymmetric and contains four independent formula units, but a variety of programs failed to indicate any higher symmetry. All ethylene bridges fail to refine satisfactorily, which may indicate disorder problems. We are attempting to obtain a more reliable dataset, but the current data definitely establish that there is no coordination of chloride to ruthenium.
[20] The potentials were measured at a scan rate of 100 mV/s against a Ag/AgCl reference electrode (3 M KCl). The ferrocene/ferrocenium couple displays a reversible cyclic voltammetric trace with a redox potential $E° = +476$ mV under these conditions; the values given in the text are referenced to $E°(Fc/Fc^+) = 0$ mV.

# An Unusual Carbonyl Chemical Shift in a Carbonylhexairidium Cluster: A Combined Solid-State NMR and DFT Approach

**Michele R. Chierotti,[a] Luigi Garlaschelli,*[b] Roberto Gobetto,*[a] Carlo Nervi,[a] Giulia Peli,[b] Annalisa Sironi,[b] and Roberto Della Pergola[c]**

**Keywords:** NMR spectroscopy / DFT calculations / Carbonyl cluster / Iridium / Chemical shift tensors / Shielding anisotropy

The $^{13}C$ NMR spectrum of $TMBA_2[Ir_6(CO)_{15}]$ [TMBA = $(CH_3)_3N(CH_2C_6H_5)$] shows, at low temperatures, an unprecedented $\mu_2$-bridging carbonyl low-frequency shift, with the resonances of the terminal $\mu_1$-carbonyl ligands placed at higher frequencies. The chemical shift tensors and the shielding anisotropies of the carbonyl ligands, obtained from solid-state NMR analysis, allow us to determine the nature of the M–CO interaction. The results have been compared with the $^{13}C$ MAS data of $Ir_6(CO)_{16}$ where $\mu_3$-CO ligands are present. Further evidence for the assignment and for the peculiar chemical shift value of bridging carbonyl ligands in $TMBA_2[Ir_6(CO)_{15}]$ has been obtained by the DFT calculation of the NMR parameters. The scalar and spin-orbit (SO) relativistic two-component zero-order regular approximation (ZORA) methods were employed in the geometry optimization and NMR chemical shift calculations, respectively. The large SO contribution ($\delta$ = 26.6 ppm) to the $\mu_2$-bridging CO ligand $^{13}C$ chemical shifts accounts for the position of the experimentally observed resonance.

## Introduction

Medium- to high-nuclearity carbonylmetal clusters may present terminal, double-bridging ($\mu_2$) and triple-bridging ($\mu_3$) CO ligands. Thanks to the different M–CO bonding order, it is possible to discriminate the three kinds of ligands by means of spectroscopic techniques such as IR and $^{13}C$ NMR spectroscopy. Increasing the back-bonding in the coordination between metal atom and carbon monoxide ligand results in a higher frequency shift of the CO resonances. Indeed, in most cases CO chemical shifts follow the series:[1] $\delta(M–CO) < \delta(M_2–\mu_2\text{-}CO) < \delta(M_3–\mu_3\text{-}CO)$.

Also within subgroups there is a progressive low-frequency shift as the atomic number increases, for example:[1] $\delta(Co–CO) > \delta(Rh–CO) > \delta(Ir–CO)$.

Stereochemical nonrigidity both in solution and in the solid state is a common feature of carbonylmetal clusters and is well documented in several papers.[2] In many cases, however, solution structures were fully consistent with solid-state X-ray structural determination.

Most carbonyliridium clusters present a complete CO fluxionality at room temperature that yields magnetically equivalent ligands; usually the low-temperature spectrum shows signals between $\delta$ = 160 and 180 ppm for terminal CO ligands, between $\delta$ = 180 and 210 ppm for the edge-bridging ones and between $\delta$ = 220 and 260 ppm for the $\mu_3$-CO ligands.[1]

In this paper we report the NMR characterization of two carbonyliridium clusters, namely $[Ir_6(CO)_{15}]^{2-}$ and $Ir_6(CO)_{16}$. Both compounds have been previously synthesized in 1970 by Malatesta and co-workers,[3] but only in the middle of the 1980s did we manage to determine the cluster's structures. $[Ir_6(CO)_{15}]^{2-}$ shows 12 terminal and three edge-bridging CO ligands,[4] while $Ir_6(CO)_{16}$ has been isolated in two different isomeric forms: a red and a black isomer, the latter being quite unstable.[5]

Our aim is to elucidate and compare the particular spectroscopic properties of the $[Ir_6(CO)_{15}]^{2-}$ and $Ir_6(CO)_{16}$ complexes, using a combined experimental-theoretical approach, employing solid-state NMR and DFT calculations of $^{13}C$ NMR chemical shifts. Within this paper the discussion of only the red isomer of $Ir_6(CO)_{16}$ has been taken into account.

## Results and Discussion

### Spectroscopic Results

The compound $Ir_6(CO)_{16}$ is isostructural with $Rh_6(CO)_{16}$, with four face-bridging and 12 terminal carbonyl

ligands.[5] However, in solution they show very different behaviors. Indeed, $Rh_6(CO)_{16}$ possesses an $O_h$ symmetry and its spectrum, reported by Heaton et al.,[6] is characterized by two resonances, in a 3:1 ratio, at $\delta$ = 180.1 and at 231.5 ppm attributed to the terminal and bridging ($\mu_3$) carbonyl ligands, respectively. On the contrary, the $^{13}C$ NMR solution spectrum of $Ir_6(^{13}CO)_{16}$ in $CD_2Cl_2$ displays a single peak at $\delta$ = 177.60 ppm clearly indicating the presence of chemical exchange among the carbonyl ligands. Even though we used a $^{13}C$-enriched sample, the low solubility of the cluster did not allow us to perform variable-temperature (VT) experiments.

In the solid state $Ir_6(CO)_{16}$ possesses a simple $C_2$ symmetry. Hence, for this reason we expect two distinct signals for the bridging carbonyl ligands and six overlapped peaks for the 12 terminal ligands as already observed for $Rh_6(CO)_{16}$. Indeed, the carbonyl isotropic region of the solid-state spectrum (Figure 1) is characterized by three peaks at $\delta$ = 168.8, 203.9, and 209.2 ppm assigned to the terminal and to the two pairs of equal $\mu_3$-CO ligands, respectively. Because of the overlapping of the signals, instead of six resonances for 12 terminal carbonyl ligands only a single broad asymmetric peak with a shoulder at $\delta \approx$ 166.8 ppm is observed, as has already been seen for the isostructural $Rh_6(CO)_{16}$.[6]

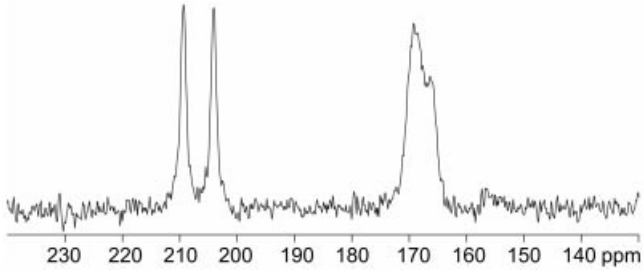

Figure 1. Isotropic region of the solid-state $^{13}C$ MAS NMR spectrum of $Ir_6(^{13}CO)_{16}$ recorded at 68.7 MHz, 25 °C, and at a spinning speed of 5.9 kHz.

We also performed an analysis of the chemical shift tensors $\delta_{11}$, $\delta_{22}$, $\delta_{33}$, where $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, and of the shielding anisotropy (CSA) of the different carbonyl signals, defined as $\Delta\sigma = \sigma_{33} - (\sigma_{11} + \sigma_{22})/2$ with $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$. By recording a spectrum at a low spinning speed (about 3.8 kHz) (Figure 2) it has been possible to calculate the chemical shift tensors by means of the Herzfeld–Berger method.[7] The obtained tensor values, as well as the shielding anisotropy $\Delta\sigma$, are reported in Table 1. Unfortunately, for the $\mu_3$-carbonyl moieties the analysis is slightly approximated due to the small amount of overlapping between the resonances. The terminal CO ligands show a shielding anisotropy value ($\Delta\sigma$ = 385.9 ppm) with pseudo-axial symmetry similar to that observed for the terminal carbonyl ligand of many other organometallic compounds such us $Rh_6(CO)_{16}$, $Os_3(CO)_{12}$, etc., (about 400 ppm).[8] On the other hand, as expected, the bridging ($\mu_3$) carbonyl ligands give rise to a smaller anisotropy of 114.6 ppm. It is worth noting that the chemical shift tensor of the bridging CO sites is axially symmetric due to the threefold rotational symmetry about the C–O axis.

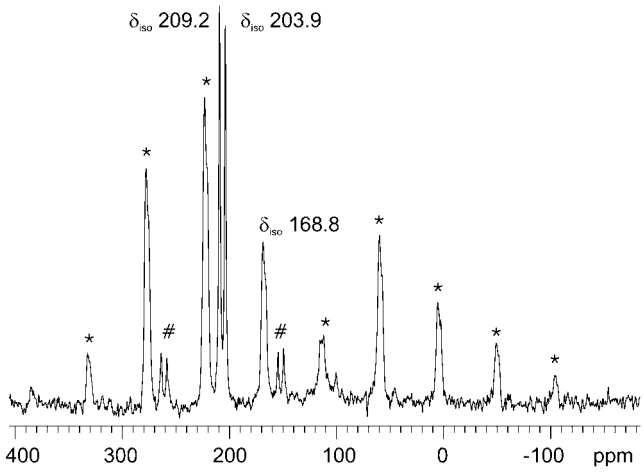

Figure 2. Solid-state $^{13}C$ MAS NMR spectrum of $Ir_6(^{13}CO)_{16}$ recorded at 68.7 MHz, 25 °C, and at a spinning speed of 3.8 kHz. Spinning sidebands marked with * are associated with the peak at $\delta$ = 168.8 ppm, while those marked with # are related to the peaks at $\delta$ = 209.2 and 203.9 ppm.

Table 1. $^{13}C$ chemical shift tensors, shielding anisotropy, and integral values for compound $Ir_6(CO)_{16}$. The shielding anisotropy is defined as $\Delta\sigma = \sigma_{33} - (\sigma_{11} + \sigma_{22})/2$ with $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$ and $\delta_{ii} = -\sigma_{ii}$.

| $\delta_{iso}$ [ppm] | $\delta_{11}$ [ppm] | $\delta_{22}$ [ppm] | $\delta_{33}$ [ppm] | $\Delta\sigma$ [ppm] | Integral value |
|---|---|---|---|---|---|
| 168.8 | 352.7 | 241.9 | –88.6 | 385.9 | 12 |
| 203.9 | 244.8[a] | 244.8[a] | 130.3[a] | 114.6[a] | 4 |
| 209.2 | | | | | |

[a] The spinning sideband analysis was performed by considering a single peak, due to high-resonance overlapping. All these resonances are associated to bridging ligands and then a similar anisotropy is expected.

The structure of $[Ir_6(CO)_{15}]^{2-}$ has been previously reported by Demartin et al.[9] Briefly, it consists of a regular octahedron of stereochemically equivalent iridium atoms connected to 12 terminal and three symmetrically edge-bridging ($\mu_2$) carbonyl ligands. The 12 terminal CO ligands can be divided into two sets, six of them being in an axial and six in an equatorial configuration.

The VT $^{13}C$ NMR experiments of a $^{13}CO$-enriched sample of $TMBA_2[Ir_6(^{13}CO)_{15}]$ dissolved in $[D_8]THF$ are reported in Figure 3. In the range 173–298 K the NMR spectroscopic data clearly show the presence of one or more fluxional processes involving the carbonyl resonances. At room temperature the spectrum is characterized by a single peak at $\delta$ = 191.9 ppm. By decreasing the temperature, the signal broadens and the coalescence temperature is reached at 213 K. By further decreasing the temperature, it is possible to freeze the fluxionality, and three signals appear at $\delta$ = 201.1, 191.2, and 175.2 ppm with relative intensities of 6:6:3, respectively. A careful inspection of the VT spectra reveals that the resonance centered at $\delta$ = 201.1 ppm in the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

temperature range 203–183 K is sharper than the other two resonances; thus, at least two different processes involving the carbonyl ligands determine the fluxional behavior of $TMBA_2[Ir_6(^{13}CO)_{15}]$. The presence of three resonances in the low-temperature limiting spectrum (173 K) agrees with the X-ray structure in which three different types of carbonyl ligands are present (two sets of six terminal CO ligands and one set of three $\mu_2$-CO ligands).

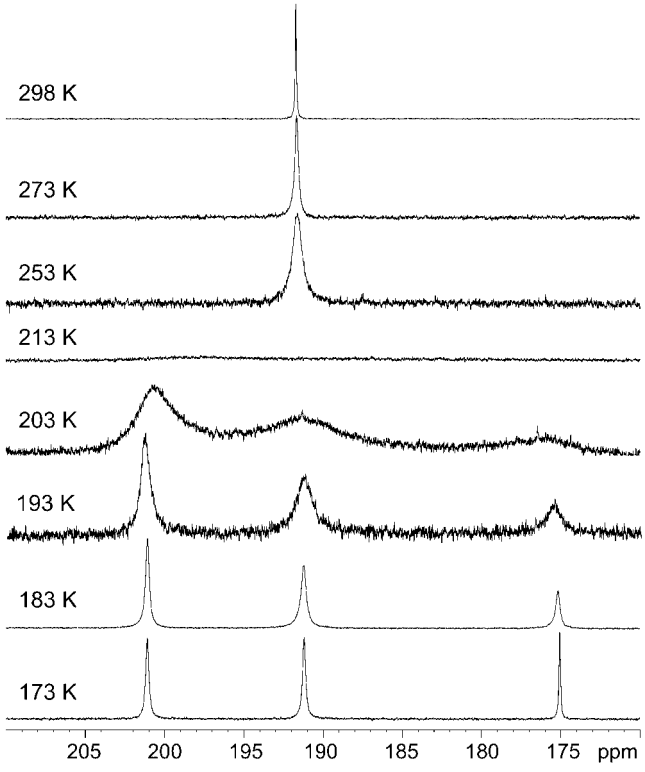

Figure 3. Solution VT $^{13}C$ NMR spectra of $TMBA_2[Ir_6(^{13}CO)_{15}]$ recorded at 151 MHz in the temperature range 173–298 K.

One would expect the bridging carbonyl signals to fall at a higher frequency with respect to the terminal ones, in this case we need to assume an unprecedented low-frequency value for the bridging CO resonance ($\delta$ = 175.2 ppm), and a quite high chemical shift value for the two sets of terminal carbonyl ligands. These results, never reported before, prompted us to find experimental evidence for our assignment. Solid-state NMR is often used as a bridge technique between the solid structure obtained by single crystal X-ray determination and solution NMR spectroscopic data. For this reason we decided to undertake a solid-state NMR investigation of the molecule in order to find NMR parameters corroborating our assignment.

The whole $^{13}C$ MAS spectrum of $TMBA_2[Ir_6(^{13}CO)_{15}]$ is reported in Figure 4. In the carbonyl isotropic region (Figure 5) it is possible to observe 11 isotropic resonances, at $\delta$ = 179.0, 181.5, 184.2, 187.1, 189.5 (sh), 190.5, 193.8, 196.1, 198.3, 202.3, and 205.3 ppm. It is worth noting that the intensities of the signals are quite different and in particular higher integration values are associated with the signals that fall at $\delta$ = 179.0, 184.2, and 196.1 ppm. It is well known that the intensities of the isotropic peaks in solid-state NMR spectra cannot be directly compared without considering the different spinning sideband patterns associated with each resonance (see Figure 4). By careful integration of the isotropic and anisotropic part of the spectrum, we can conclude that all the peaks have the same cumulative intensity except the signals at $\delta$ = 179.0, 196.1, and 205.3 ppm where the relative intensities are 2:3:2 with respect to the other resonances. Thus, the number and the intensities of the peaks are in agreement with the presence of 15 carbonyl ligands.

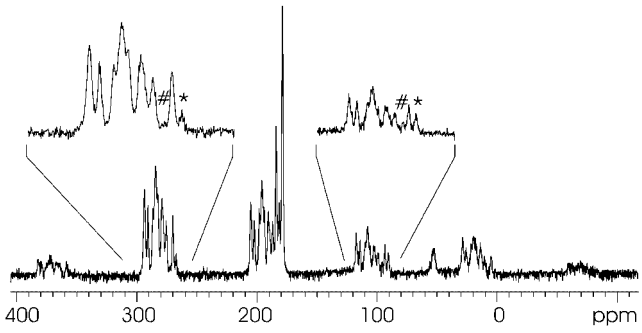

Figure 4. Solid-state $^{13}C$ MAS NMR spectrum of $TMBA_2[Ir_6(^{13}CO)_{15}]$ recorded at 68.7 MHz, 25 °C, and at a spinning speed of 5.9 kHz. Spinning sidebands marked with * are associated with the peak at $\delta$ = 179.0 ppm, while those marked with # are related to the peak at $\delta$ = 184.2 ppm.

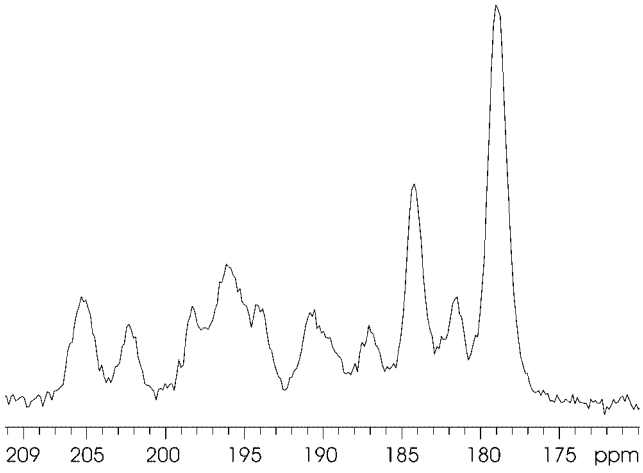

Figure 5. Isotropic region of the solid-state $^{13}C$ MAS NMR spectrum of $TMBA_2[Ir_6(^{13}CO)_{15}]$ recorded at 68.7 MHz, 25 °C, and at a spinning speed of 5.9 kHz.

The chemical shift tensors ($\delta_{11}$, $\delta_{22}$, and $\delta_{33}$) and the shielding anisotropies ($\Delta\sigma$) associated with the different carbonyl signals (see Table 2) afford further information.

From an accurate spectrum analysis it is possible to observe that the spinning sideband manifolds of the peaks centered at $\delta$ = 179.0 and 184.2 ppm are much narrower with respect to the spinning sideband envelopes associated with all other resonances. In particular, the intensities of the first group of the spinning sidebands related to the isotropic peak at $\delta$ = 179.0 ppm (marked with * in Figure 4) drastically decrease as well as those associated with the res-

| 198.3 | | | | | |
| 202.3 | 375.1 | 290.8 | –58.9 | 391.9 | 1 |
| 205.3 | 389.6 | 296.3 | –69.9 | 412.8 | 2 |

[a] The spinning sideband analysis was performed by considering a single peak, due to high-resonance overlapping. All these resonances are associated to terminal ligands and then a similar anisotropy is expected.

onance at $\delta$ = 184.2 ppm (marked with # in Figure 4). Furthermore, we decided to perform the Herzfeld–Berger analysis on the spinning sideband patterns to assert whether terminal and bridging carbonyl ligands give rise to different chemical shift tensor values. The computer simulation of the experimental spinning sideband patterns gave us the tensor and anisotropy values reported in Table 2. By comparing the shielding anisotropies, we can observe that those related to the resonances at $\delta$ = 179.0 and 184.2 ppm ($\Delta\sigma$ = 109.4 and 101.6 ppm, respectively) are about 298 ppm lower than the average anisotropy value of the other signals ($\Delta\sigma$ = 404 ppm); since it is well known that the terminal carbonyl ligands have a CSA value of the order of 400 ppm, whereas bridging carbonyl ligands show smaller values,[10,11] we can assert that the resonances at $\delta$ = 179.0 and 184.2 ppm are associated with the bridging CO ligands.

The counter-intuitive shifts of the bridging carbonyl ligands to lower frequencies with respect to the terminal ones prompted us to try to rationalize by quantum mechanical calculations the observed spectroscopic data and to take advantage of DFT calculations for a full understanding of the system.

## Computational Results

The geometry of $[Ir_6(CO)_{15}]^{2-}$ has been fully optimized by means of the Jaguar program at the B3LYP/LACV3P**++ level, which resulted in a molecular geometry very close to $D_3$ symmetry, even if no symmetry constrains have been imposed. The geometry (Figure 6) shows three types of carbonyl ligands: two groups of terminal ligands each composed of six carbonyl ligands and a single group of three $\mu_2$-bridging carbonyl ligands. The first type of terminal carbonyl ligands points in between the other two $\mu_1$-carbonyl ligands placed on the adjacent Ir atom (t1 in Figure 6), whereas the other group of six terminal carbonyl ligands (type t2, not labelled in Figure 6) are pointing towards each other. The $^{13}C$ NMR chemical shifts calculated at this level by the GIAO method employed by Jaguar are intuitively in agreement with the common chemical experience that predicts bridging CO ligands as being less shielded than terminal ones, but do not correlate with the experimental data, resulting in a complete reversal of the order of the assignment of the resonances (Table 3). Methods that can calculate chemical shifts of main group elements are routinely implemented in most standard quantum chemical packages, but the calculation of NMR shielding constants is particularly challenging in $[Ir_6(CO)_{15}]^{2-}$ because relativistic effects are important even for lighter elements if these elements are bound to heavier metals.[12,13] In these atoms the spin-orbit (SO) coupling induces a non-negligible effect. The calculation of NMR parameters, that take into account the SO coupling, has shown an improved agreement with experimentally determined parameters over previous scalar-relativistic calculations for iodo compounds,[14] mercury halides,[13] and for the $^{13}C$ NMR shifts of 5d transition metal carbonyl complexes.[15] This prompted us to investigate the SO contributions taking advantage of the ADF package.

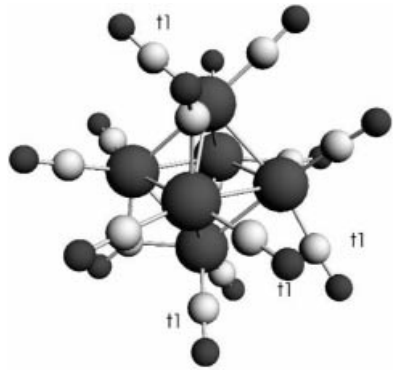

Figure 6. Optimized structure of $[Ir_6(CO)_{15}]^{2-}$, with labels on axial and equatorial terminal carbonyl ligands.

Table 3. Experimental (solution) and calculated[a] $^{13}C$ NMR parameters (ppm) of $[Ir_6(CO)_{15}]^{2-}$. Paramagnetic ($\sigma^{para}$), diamagnetic ($\sigma^{dia}$), and relativistic spin-orbit ($\sigma^{SO}$) contributions to the values of the absolute isotropic shieldings.

| | Exp. | GIAO Jaguar B3LYP/LACV3P**++ | GIAO ADF spin-orbit (and scalar) BP-ZORA/TZ2P | | | |
|---|---|---|---|---|---|---|
| | | $\delta^{iso}$ | $\delta^{iso}$ | $\sigma^{para}$ | $\sigma^{dia}$ | $\sigma^{SO}$ |
| $\mu_2$-CO | 175.2 | 228.4 | 187.7 (212.4) | –274.3 (–272.6) | 242.7 (242.8) | 26.6 |
| $\mu_1$-CO t1 | 191.2 | 211.1 | 198.2 (199.8) | –274.1 (–273.6) | 256.4 (256.4) | 2.3 |
| $\mu_1$-CO t2 | 201.1 | 211.1 | 203.0 (199.2) | –274.0 (–273.7) | 257.1 (257.1) | –3.4 |

[a] The values are the mean of 3 ($\mu_2$) or 6 ($\mu_1$ t1 and $\mu_1$ t2) carbonyl ligands that are nonequivalent because we do not impose the symmetry during calculations. Standard deviations are typically 0.1 ppm and in any case below 0.3 ppm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The geometry optimized using the ADF program with the BP-ZORA/TZ2P method is almost identical to that obtained by Jaguar at the B3LYP/LACV3P**++ level. The results of the ZORA spin-orbit (SO) coupling method reproduce the spectroscopic data of the carbon atoms (Tables 3 and 4). A close inspection of the contributions to the values of the absolute isotropic shielding reveals that the paramagnetic part ($\sigma^{para}$) has almost the same contribution for all three types of carbonyl ligands. The lower contribution of the diamagnetic part ($\sigma^{dia}$) for the bridging $\mu_2$-CO ligands moves the calculated $^{13}C$ chemical shift to higher values, but a much stronger correction of 26.6 ppm with the opposite sign comes from the relativistic spin-orbit part of the shielding ($\sigma^{SO}$). In the case of $[Ir_6(CO)_{15}]^{2-}$, $\sigma^{SO}$ accounts for almost all the observed trend in the chemical shifts. The calculation of $^{13}C$ NMR parameters performed with the scalar BP-ZORA/TZ2P method does not differ substantially from those obtained previously by the Jaguar method (Table 3), pointing out the importance of the SO contribution. This appears to be a case in which the combination of spin-orbit coupling and magnetic field mixes spin triplet states into the ground state, inducing a spin density that then interacts with the nuclei of the carbonylmetal via the Fermi-contact term, as already outlined in the literature.[14,15]

Table 4. Calculated chemical shift tensors ($\delta_{11}$, $\delta_{22}$, $\delta_{33}$) and shielding anisotropy ($\Delta\sigma$) for $[Ir_6(CO)_{15}]^{2-}$ with ADF at spin-orbit BP-ZORA/TZ2P level.

## Conclusions

In this paper we have finally solved the NMR assignment of the CO resonances of $TMBA_2[Ir_6(^{13}CO)_{15}]$ by using a complementary solid-state NMR and computational approach. VT solution NMR studies on a $^{13}C$-enriched sample of $TMBA_2[Ir_6(^{13}CO)_{15}]$ have shown a fluxionality in the behavior of the CO ligands around the metal cluster. Three sets of carbonyl ligands (two terminal and one bridging) have been found in the cluster giving rise to three peaks in the $^{13}C$ NMR solution spectrum at low temperatures. An unusually low-frequency chemical shift for the bridging carbonyl ligand has been observed at 173 K when the CO ligands are almost frozen. Solid-state NMR spinning sideband analysis has given further proof to the right assignment of the bridging carbonyl resonance. Indeed, their signals are associated with a much lower $\Delta\sigma$ than the terminal ligands. This confirms the reliability of solid-state NMR spectroscopy as a bridging technique between crystal structure analysis and solution NMR spectroscopy.

Moreover, we demonstrate by means of ADF with the BP-ZORA/TZ2P method that the low-frequency shift in the bridging carbonyl chemical shift has a significant relativistic spin-orbit contribution that cannot be neglected in a proper assignment of the $^{13}C$ resonances. Therefore, care should also be taken in the evaluation of NMR parameters for lighter elements, in particular when they are bonded to third-row transition metal atoms. The spin-orbit two-component relativistic protocol has been successfully adopted in DFT calculations to evaluate the NMR shielding constants of carbon atoms directly bonded to Ir nuclei. A satisfactory agreement between the calculated and experimental NMR spectroscopic data has been obtained.

## Experimental Section

### General

All operations were carried out under $N_2$ using Schlenk tube techniques. Tetrahydrofuran was distilled from Na/naphthalene; all other analytical-grade solvents were degassed and stored under $N_2$. $[Ir(CO)_4]^-$,[16] $[Ir_4(CO)_{12}]$,[17] $[Ir_6(CO)_{15}]^{2-}$,[18] and $[Ir_6(CO)_{16}]$[19] were prepared according to the published methods; IR spectra were recorded with a Bruker Vector 22 FT-IR spectrophotometer, using 0.1 mm $CaF_2$ cells previously purged with $N_2$.

### Sample Preparation

It has been proved that $[Ir_6(CO)_{15}]^{2-}$ and the closely related neutral cluster $Ir_6(CO)_{16}$ do not exchange their coordinated CO ligands with gaseous $^{13}CO$ and hence they cannot be conveniently enriched for $^{13}C$ NMR studies. Therefore, in order to obtain a $^{13}CO$ enriched sample of both clusters, we had to follow particular synthetic routes, shown in Scheme 1.

$Ir_4(CO)_{12}$ is the key compound for the preparation of the two hexanuclear clusters. However, its direct $^{13}CO$ enrichment is impossible owing to its insolubility in all common organic solvents; therefore, a suitable precursor is necessary which can directly exchange with $^{13}CO$ on the one hand, and on the other hand can be easily transformed back into $Ir_4(CO)_{12}$. This compound is $[Ir_4(CO)_{11}(COOMe)]^-$; in fact it can be obtained by treatment of the parent cluster with sodium methoxide in methanol, it gives a fast exchange with $^{13}CO$ at room temperature and, as already reported,[20] can regenerate $Ir_4(CO)_{12}$ by simple acidification with acetic acid.

The $^{13}CO$-enriched samples of $[Ir_4(CO)_{11}(COOMe)]^-$ (ca. 30%) were obtained by direct exchange at room temperature with the 99% $^{13}CO$ standard, commercially available from Cambridge Isotope Laboratories, by using standard vacuum-line techniques.

The $^{13}C$-enriched tetranuclear cluster then reacts with 2 equiv. of $[Ir(CO)_4]^-$ in refluxing THF to give $^{13}C$-enriched $[Ir_6(CO)_{15}]^{2-}$, which can be isolated as a brown reddish powder by precipitation with an aqueous solution of $[(CH_3)_3N(CH_2C_6H_5)]Cl$ or converted into $Ir_6(^{13}CO)_{16}$ by acidification under $^{13}CO$ (0.051 g, 0.032 mmol, 30% yield).

In a typical preparation, $Ir_4(CO)_{12}$ (1.500 g, 1.359 mmol) was suspended in 60 mL of dry methanol in a 250-mL Schlenk flask and stirred under $^{12}CO$ at room temperature; 10.6 mL of a 0.9 M solution of $NaOCH_3$ in dry methanol (molar ratio $Ir_4(CO)_{12}/NaOCH_3$ = 1:7) was added dropwise to the light yellow suspension; after about 5 h, a clear orange-yellow solution was obtained, due to the formation of the $[Ir_4(CO)_{11}(COOCH_3)]^-$ derivative. After removing the $^{12}CO$ in vacuo, the solution was stirred under $^{13}CO$ (90% v/v) at room temperature for about 4 h. Then an excess of glacial $CH_3COOH$ was added to the solution causing the immediate pre-

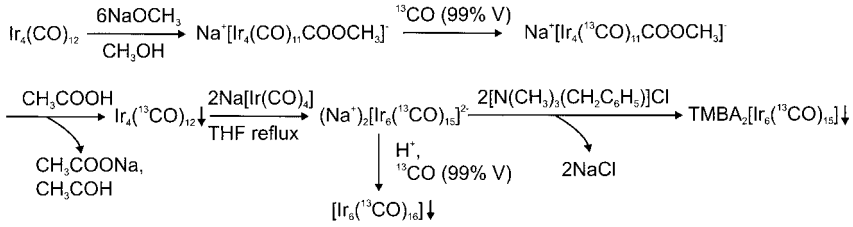

Scheme 1.

cipitation of the light yellow $Ir_4(^{13}CO)_{12}$; the product was filtered, washed several times with water and finally with methanol before being dried in vacuo (1.425 g, 1.291 mmol, 95% yield).

Sodium was added to a suspension of $Ir_4(^{13}CO)_{12}$ (0.429 g, 0.386 mmol) in dry THF (30 mL) and the mixture was vigorously stirred under CO for about 24 h. The FT-IR spectrum of the decanted light yellow liquid showed a typical band of $[Ir(CO)_4]^-$ at 1894 $cm^{-1}$; the brown mixture was filtered and solid $Ir_4(^{13}CO)_{12}$ (0.437 g, 0.396 mmol) was added to the filtrate. The yellow suspension was heated at the reflux temperature under $N_2$ for about 24 h; the FT-IR spectrum of the obtained dark red-brown solution showed an intense band at 1984 $cm^{-1}$, characteristic of the $[Ir_6(^{13}CO)_{15}]^{2-}$ dianion. A solution of $[(CH_3)_3N(CH_2C_6H_5)]Cl$ (0.222 g, 1.193 mmol) in water (60 mL) was then added dropwise to the cluster solution; after removing THF in vacuo, the brown reddish precipitate was collected by filtration, washed with water and finally dried (0.472 g, 0.252 mmol, 64% yield).

### NMR Characterization of $Ir_6(^{13}CO)_{16}$ and $TMBA_2[Ir_6(^{13}CO)_{15}]$

**Solution NMR Measurements:** Solution spectra were recorded with a Bruker Avance 600 spectrometer operating at 150.1 MHz for the $^{13}C$ nucleus. For the VT experiments the compound $TMBA_2[Ir_6(^{13}CO)_{15}]$ was dissolved in $[D_8]$THF and the temperature was varied between 173 and 298 K.

**Solid-State NMR Measurements:** Solid-state data were collected with a Jeol GSX 270 spectrometer equipped with a Doty probe operating at 67.8 MHz for $^{13}C$ and 270 MHz for $^1H$. A standard 90° pulse sequence was used with a pulse duration of 2.5 μs corresponding to a 60° pulse. The recycle delay was 250 s to allow the complete recovery of the magnetization after the pulse; 600–2000 transients were sufficient to obtain a good signal/noise ratio. The spectra were recorded at room temperature at different spinning speeds. Cylindrical 5-mm (o.d.) zirconia rotors with sample volumes of 120 μL were employed. For the sample the magic angle was carefully adjusted from the $^{79}Br$ spectrum of KBr by minimizing the line width of the spinning sideband satellite transitions.

The principal components of the chemical shift tensors were extracted by computer simulation of the spinning sideband patterns obtained at low speed using the HBA program[21] based on the algorithm developed by Herzfeld and Berger.[7] The errors in the evaluation of the chemical shift tensors are less than 4 ppm as evaluated by repetition of the calculation at different spinning speeds. The $^{13}C$ principal tensor components are reported according to the standard convention[10] where $\delta_{11} \geq \delta_{22} \geq \delta_{33}$ and the shielding anisotropy is defined as $\Delta\sigma = \sigma_{33} - (\sigma_{11}+\sigma_{22})/2$ with $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$ and $\delta_{ii} = -\sigma_{ii}$.

### Computational Details

The initial geometry of $[Ir_6(CO)_{15}]^{2-}$ was taken from the literature.[9] Calculations were performed either with Jaguar[22] or with ADF2005.1.[23] In Jaguar we adopted the DFT method based on Becke's three-parameter hybrid functional and Lee–Yang–Parr's gradient-corrected correlation functional (B3LYP), with a triple-ζ basis set LACV3P**++,[24] which also includes the outermost core orbitals and effective core potentials (ECPs). The NMR properties were calculated by the GIAO method used by Jaguar.[25] In the geometry optimization carried out with ADF we used the scalar relativistic two-component zero-order regular approximation (ZORA) method,[26] which requires a specially optimized basis set.[27] The default ZORA doubly polarized triple-ζ (TZ2P) basis set was used. The inner shells were represented by the frozen core approximation (1s for C, O and 1s–4d for Ir were kept frozen). We adopted the generalized gradient approximation (CGA) with Becke (exchange) and Perdew (correlation) gradient corrections (BP). The calculations of the NMR parameters were performed by the ADF NMR property module by means of the scalar and the spin-orbit ZORA methods.[28] In the SO coupling method, which takes into account the interactions between the electron magnetic moments and the magnetic field generated by their own orbital motion, the U1K BEST option was used.[23] The absolute isotropic constant shielding values ($\sigma$) for $^{13}C$ of TMS, used as a reference, were calculated from the optimized structures of TMS with Jaguar ($\sigma^{ref}$ = 184.02 ppm) and with ADF [$\sigma^{ref}$(SO) = 182.71 ppm, $\sigma^{ref}$(scalar) = 182.61 ppm], with the methods and basis sets described above. The $^{13}C$ chemical shift values of the carbonyl ligands were therefore calculated as $\delta = \sigma^{ref} - \sigma^{calcd}$.

# Copper(II) Terpyridine Complexes: Effect of Substituent on DNA Binding and Nuclease Activity

Varadarajan Uma,[a] Munusamy Elango,[a] and Balachandran Unni Nair*[a]

**Keywords:** Copper / Tridentate ligands / DNA binding / Nuclease activity

Mononuclear copper(II) terpyridine complexes, [Cu(ttpy)Cl]Cl (**1**) and [Cu(itpy)Cl]Cl (**2**) (ttpy = tolylterpyridine and itpy = imidazolylterpyridine) were synthesized and characterized. The interaction of the complexes with DNA was studied by electronic and CD spectroscopy, viscosity and gel electrophoresis. Absorption titrations, viscosity and CD experiments reveal an intercalative mode of DNA binding for these complexes. The binding constant values for **1** and **2** are $(5.6 \pm 0.2) \times 10^4$ and $(1.4 \pm 0.2) \times 10^4$ $M^{-1}$, respectively, and suggest moderate binding of these complexes to DNA. From computational studies, it was found that the aromatic π cloud is more uniformly distributed in the case of tolylterpyridine (complex **1**), which possibly leads to better stacking interactions with the DNA bases and hence a higher binding constant value for complex **1**. From the gel electrophoresis experiments, it is inferred that both complex **1** and **2** cleave plasmid DNA in the presence of ascorbic acid and the cleavage efficiency of complex **1** is greater than that of complex **2**.

## Introduction

Small molecules that bind and cleave double-stranded DNA under physiological conditions have found wide applications in the field of medicine, molecular biology and biotechnology.[1–5] Transition-metal complexes characterized by high stability, structural versatility and unique spectroscopic and redox properties are exploited largely in many of these efforts. These metal complexes are capable of binding to DNA by a multitude of interactions and cleave DNA by virtue of their intrinsic chemical, electrochemical and photochemical reactivities.[6–10] In the majority of the complexes studied, the metal ion usually serves as the redox centre and the ligand is responsible for DNA recognition. The modes of recognition are primarily based upon intercalation, groove-binding, hydrogen bonding and electrostatic interactions.

Since the success of platinum complexes as anticancer drugs, studies on the interaction of transition-metal complexes with nucleic acids has been a topic of interest in biochemical and coordination chemical research.[11] Ruthenium(II) polypyridyl complexes have attracted comprehensive attention due to their significance in the development of new therapeutic agents and novel nucleic acid structural probes.[12–14] A number of dinuclear iron complexes are known to exhibit hydrolytic cleavage of duplex DNA.[15–16] Nickel(II) and cobalt(II) macrocyclic complexes have been investigated as potential site-specific DNA modification agents.[17–18] The other metal that has been most widely used in these studies is copper; complexes of copper with different types of ligands have been tested as potential chemical nucleases.[19–22] Among them, 1,10-phenanthroline and its derivatives have attracted great attention due to their high nucleolytic efficiency.[23–26] Studies by Sigman and coworkers have shown that bis(1,10-phenanthroline)copper(I) complex efficiently cleaves DNA through the formation of a sugar hydrogen abstracting active oxygen species.[27–28] They have also been broadly used as foot printing agents of both proteins and DNA,[29] probes of the dimensions of the minor groove of duplex structures,[30] and identifiers of transcription starting sites.[31]

Our laboratory has been focusing on DNA interaction studies of bis-chelated copper(II) complexes with various tridendate terpyridine ligand systems.[32,33] The present work stems from our interest to explore the DNA binding properties and nuclease activity of 1:1 copper(II) complex with these ligand systems and to examine whether they exhibit a significant change in the binding properties as compared to the bis-chelated complexes. In this paper, we report the synthesis and DNA interaction and cleavage studies of copper(II) complexes with two terpyridine derivatives, namely tolyl terpyridine (ttpy), and imidazolyl terpyridine (itpy) ligands, the structures of which are shown in Figure 1. The DNA interaction has been investigated using a host of physical methods like electronic absorption spectroscopy, viscosity measurements, electrochemical methods and circular dichroic studies and the cleavage reactions have been assayed using agarose gel electrophoresis.

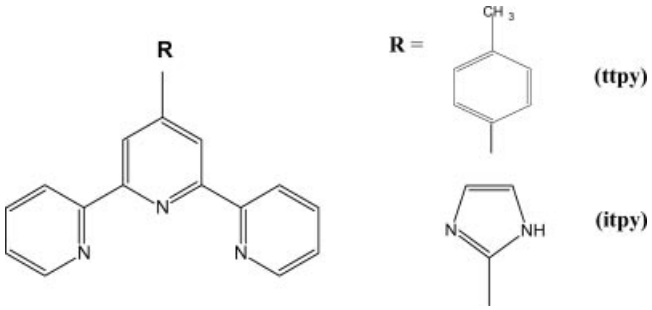

Figure 1. The structures of the ttpy and itpy ligands.

## Results and Discussion

### Synthesis and Spectral Properties

Complexes **1** and **2** could be obtained in good yields and sufficiently pure forms by mixing hot methanolic solutions of copper chloride and the respective terpyridine ligands in equimolar quantities. The authenticity of the complexes was ascertained from mass spectral analysis. The ESI mass spectra of the complexes show base peaks assignable to the parent ion $[Cu{\cdot}L{\cdot}Cl]^+$, where L corresponds to ttpy and itpy for complexes **1** and **2**, respectively.

The electronic spectra of the complexes exhibit intense intraligand bands in the region 280–350 nm and a broad ligand field band in the region 550–800 nm (Table 1). The absorptions in the UV region show a shift to higher wavelengths relative to the unsubstituted terpy complex (228 and 324 nm). This shift is due to the lowering of the LUMO (π*) energy in the ttpy ligand owing to a more extended conjugation relative to the terpy ligand. In the case of copper(II) complexes, three d–d transitions are possible: $d_{xz},d_{yz}\rightarrow d_{x^2-y^2}$, $d_{z^2}\rightarrow d_{x^2-y^2}$, $d_{xy}\rightarrow d_{x^2-y^2}$. However, only a single broad band is observed for both the copper(II) complexes, which indicates the total sum of all the above transitions. The broadness associated with the d–d bands is generally taken as an indication of the geometrical distortion of the complex from perfect planar symmetry.

Table 1. Electronic and EPR (taken at 77 K) spectral parameters for complexes **1** and **2**.

| Complex | Electronic spectra[a] $\lambda$ [nm] ($\varepsilon$, $M^{-1}cm^{-1}$) | $g$ values | $A$ values |
|---|---|---|---|
| Complex **1** | 287 (18,050)<br>318 sh (11,800)<br>690 br (160) | $g_\parallel = 2.36$<br>$g_\perp = 2.06$ | $A_\parallel = 161$ G |
| Complex **2** | 288 (17,765)<br>338 (22,995<br>350 sh (23,595)<br>710 br (153) | $g_\parallel = 2.39$<br>$g_\perp = 2.08$ | $A_\parallel = 165$ G |

[a] br = broad, sh = shoulder.

EPR spectra of complexes **1** and **2** (frozen solutions at 77 K) in DMSO reveal an axial nature with four well-resolved peaks of low intensity in the low-field region and one intense peak in the high-field region. No band corresponding to $M_s = \pm 2$ was observed in the spectra, ruling out any copper–copper interaction. Figure 2 shows the EPR spectrum of complex **1** and the EPR parameters are provided in Table 1. From the observed values for both complex **1** and **2**, it is clear that $g_\parallel > g_\perp$, which indicates that the unpaired electron predominantly lies in the $d_{x^2-y^2}$ orbital.[34] The ratio of $g_\parallel/A_\parallel$ may be considered as a diagnostic parameter of the stereochemistry of the complex, and the range reported for square-planar complexes is 105–135 G.[35] In the present case, this value is higher than 135 G, indicating a considerable tetrahedral distortion around the copper site that could be due to the rigidity of the terpy moiety and the geometrical constraint it imposes on the central metal ion.

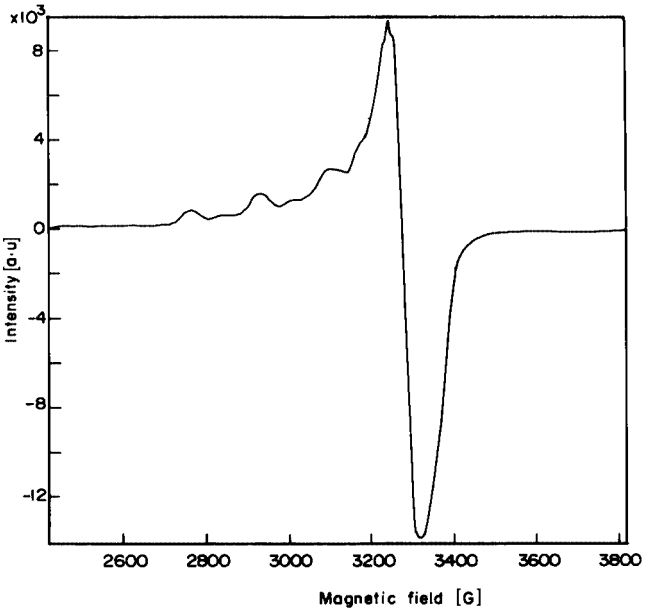

Figure 2. EPR spectrum of a frozen solution of complex **1** at 77 K in DMSO (microwave frequency = 9.5 GHz, power = 3 mW, modulation frequency = 100 kHz, modulation amplitude = 3 G).

Cyclic voltammetric studies to establish the redox behaviour of the copper(II) complexes reveal a non-Nernstian, almost irreversible redox process involving the $Cu^{II}/Cu^{I}$ couple near –0.2 V for both of the complexes (values provided in Table 2). The anodic to cathodic peak current ratio of around 0.2 for both the complexes suggests poor reversibility of the electron transfer process. Figure 3 depicts the cyclic voltammograms of complexes **1** and **2**. The $Cu^{II}/Cu^{I}$ redox potential of complex **1** is slightly more negative relative to **2**, which indicates that the +1 oxidation state is more stabilized in complex **2** than it is in complex **1**.

Table 2. Electrochemical behaviour of complexes **1** and **2**.[a]

| Complexes | $E_{1/2}$ [V] CV | $E_{1/2}$ [V] DPV | $\Delta E_p$ [mV] | $i_{pa}/i_{pc}$ |

### Absorption Titration Experiments

The interaction of the metal complex with DNA causes significant changes in the ligand-centred spectral transitions of the complex and these changes are monitored to calculate the binding constant. In the presence of increasing concentrations of DNA, both **1** and **2** were found to exhibit hypochromism with an almost negligible shift in the absorption maxima. This decrease in the intensity of the spectral band is typical of an intercalative mode of binding wherein the interacting molecule is sandwiched between the DNA base pairs.[36,37] The planarity and extended aromaticity of the terpyridine ligand systems bring about the stacking of the molecule between the DNA bases. The spectral changes on interaction of complex **2** with DNA are shown in Figure 4. The binding constant $K_b$ was estimated to be $(5.6 \pm 0.2) \times 10^4$ and $(1.4 \pm 0.2) \times 10^4$ M$^{-1}$ for complexes **1** and **2**, respectively. The binding constant values for these complexes are of the same order of magnitude as those observed for the corresponding bis-chelate systems reported in our earlier publications.[32] Also, the mode of binding remains intercalative in both cases. This suggests that the major factor influencing the mode and extent of binding could be the large size of the ligand system. The planar terpyridine ring appears to dictate the binding characteristics irrespective of the geometry of the complex (four or six coordinate).

To further explore the influence of substituents on the binding constant values, computational studies were carried out for complexes **1** and **2**. As seen from Figure 1, complexes **1** and **2** differ only in their substituents (R group). Therefore, calculations were carried out by considering only the tolyl and imidazolyl groups (**R1** and **R2**, respectively) as representative of **1** and **2**. Hydrogen atoms were added in the R groups to satisfy the valency (optimized molecular structures shown in Figure 5).

The structures were optimized at the B3LYP/6-31G* level of theory by using the Gaussian 98W suite of programs.[38] Density functional theory (DFT) based descriptors such as chemical hardness ($\eta$) and electrophilicity ($\omega$) were calculated for **R1** and **R2**[39] and the results are presented in Table 3. Nucleus independent chemical shift (NICS) criteria proposed by Schleyer[40] is also calculated at the centre of the rings. All the three parameters, namely, $\eta$, $\omega$ and NICS are measures of reactivity and stability. From the table, it is observed that **R1** is less hard and more reactive than **R2**. This is also implied in the values of $\omega$; the $\omega$ value of **R1** is higher than that of **R2**, indicating the higher reactivity of **R1**. NICS values indicate the degree of aromaticity: the more negative the NICS value, the more aromatic the system and higher the stability. From Table 3, we observe that the NICS value of **R2** is greater than that of **R1**, indicating the higher reactivity and lesser stability of **R1**. Thus, the tolyl-substituted molecule, complex **1**, binds to DNA more strongly [$(5.6 \pm 0.2) \times 10^4$ M$^{-1}$]

Table 3. Chemical hardness ($\eta$), electrophilicity ($\omega$) and nucleus independent chemical shift [NICS(0)] values of R1 and R2 calculated by using the B3LYP/6-31G* level of theory.

| Species | $\eta$ [eV] | $\omega$ [eV] | NICS(0) [ppm] |
|---|---|---|---|
| Toluene | 3.27 | 1.49 | –9.6 |
| Imidazole | 3.51 | 0.97 | –14.4 |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

relative to the imidazole substituted molecule, complex **2** [$(1.4 \pm 0.2) \times 10^4$ M$^{-1}$].

In addition to this, the molecular electrostatic potential map of **R1** and **R2** was calculated at the B3LYP/6-31G* level of theory and is presented in Figure 6. The Gaussview package was used for viewing the map.[41] In the case of **R2**, the π cloud is substantially influenced by the electronegative nitrogen atom of the imidazole ring, but in **R1**, the aromatic π cloud is uniformly distributed above and below the molecular plane, which could bring about favourable stacking interactions with the DNA bases during intercalation (Figure 6). Hence, intercalation in this case would be comparatively more favourable than it is in **R2**. Thus, computational studies clearly show that the tolyl substituent makes complex **1** a better intercalator relative to imidazolyl-substituted complex **2**.

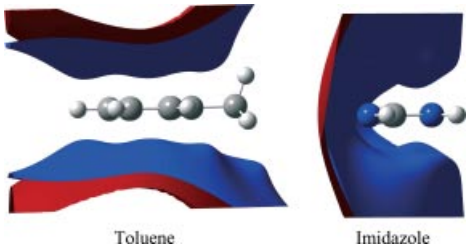

Figure 6. Total electron density map of **R1** and **R2** obtained at 0.003 au surface.

## Viscosity Experiments

Measurement of DNA viscosity is regarded as the least ambiguous and the most critical test of the binding mode of DNA in solution and affords stronger arguments for an intercalative DNA binding mode. The viscosity of DNA is enhanced in a complete or partial intercalative mode of binding where an increase in the length of the polynucleotide occurs as a result of the destacking of the base pairs.[42] A partial nonclassical mode of binding could bend or kink the DNA helix, reduce its effective length and thereby its viscosity. The effect of increasing concentrations of complexes **1** and **2** on the specific relative viscosity of DNA is shown in Figure 7. The relative viscosity of DNA increases steadily with an increase in the concentration of the complex and this result parallels the pronounced absorbance hypochromism that was observed for the complexes and further confirms their intercalative mode of binding. However, the increase in viscosity is less than that observed for proven intercalators.[43] Among the two, the increase in the relative viscosity is more pronounced for complex **1** than for **2**, which parallels the trend in DNA binding studies.

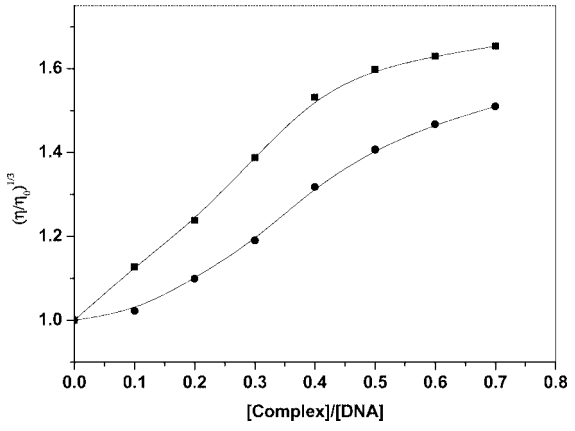

Figure 7. Effect of increasing concentration of complexes **1** (square) and **2** (circle) on the relative viscosity of CT DNA (200 μM).

## Circular Dichroism

Circular dichroic spectral techniques may give us useful information on how the conformation of the DNA chain is influenced by the bound complex. The CD spectrum of CT DNA consists of a positive band at 275 nm that can be due to base stacking and a negative band at 245 nm that can be due to helicity and it is also characteristic of DNA in a right-handed B form.[44] Thus, simple groove binding and electrostatic interaction of small molecules with DNA show less or no perturbations on the base stacking and helicity bands, whereas intercalation enhances the intensities of both the bands stabilizing the right-handed B conformation of CT DNA as observed for classical intercalators.[45] The CD spectrum of CT DNA was monitored in the presence of increasing amounts of complexes **1** and **2**; the changes observed in the case of complex **2** are shown in Figure 8. The positive band showed an enhancement in the molar ellipticity with a slight redshift of the band maxima whereas the negative band showed a decrease in the intensity when the complex concentration was progressively increased. Similar changes were observed in the CD spectrum of DNA in the case of complex **2**. These observations are supportive of the intercalative mode of binding of these complexes, where in the stacking of the complex molecules between the base pairs of DNA leads to an enhancement in the positive band and the partial unwinding of the helix is reflected in the decreased intensity of the negative band. It is also evi-

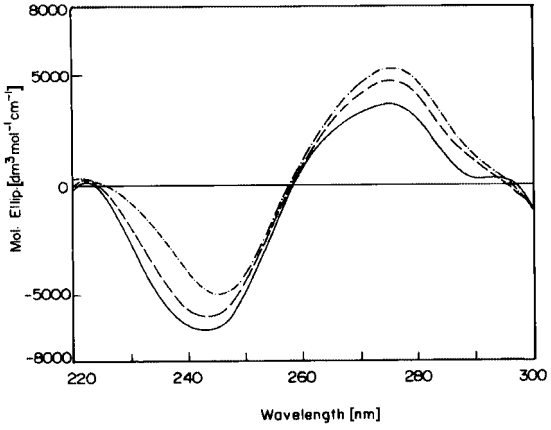

Figure 8. CD spectra of CT DNA (200 μM) in the absence (– – –) and presence of 20 (·-·-·-·-·-) and 40 μM (- - - - - - - -) of complex **1**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dent from the CD spectra that binding of the complex does not lead to any significant change in the conformation of CT DNA.

### Gel Electrophoresis Studies

To determine the ability of the present copper complexes to serve as metallonucleases, DNA cleavage studies were performed on plasmid pBR322 DNA and the results were monitored by gel electrophoresis. The naturally occurring super coiled form (Form I), when nicked, gives rise to an open circular relaxed form (Form II). This upon further cleavage results in the linear form (Form III). When subjected to gel electrophoresis, Form I shows a relatively faster migration than Forms II and III. Form II migrates very slowly owing to its relaxed structure whereas the linear form shows a migration in between Form I and Form II. Figure 9 shows the electrophoretic pattern of plasmid DNA treated with complexes **1** and **2**. Control experiments suggest that untreated DNA and DNA incubated with either complex or ascorbic acid alone does not show any significant DNA cleavage (Figure 9, lanes 1–3) but in the presence of ascorbic acid, the complexes were found to exhibit nuclease activity. In the presence of 25 μM of complex **1** and 75 μM of ascorbic acid, slight cleavage of plasmid DNA occurs as is evident from lane 4 (Figure 9) whereas there is hardly any cleavage in lane 5 (Figure 9), which represents the same concentration of the complex and reductant for **2**. On increasing the concentration of the complex to 50 μM while maintaining the concentration of the reducing agent at 75 μM, the cleavage was found to be much more efficient, as is evident from the increase in Form II (Figure 9, lanes 6 and 7). A further increase in the concentration of the complex to 75 μM and ascorbic acid to 150 μM leads to complete conversion of the supercoiled form to Form II and III (Figure 9, lanes 8 and 9). From Table 4 it is clear that complex **1** exhibits better nuclease activity than **2**.

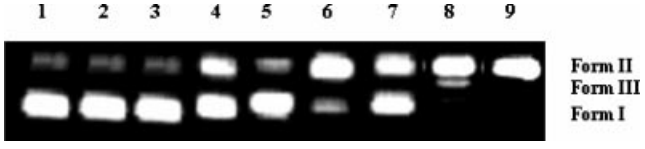

Figure 9. Cleavage of pBR322 DNA by complexes **1** and **2** in the presence of ascorbic acid. DNA (250 ng) was incubated with **1** and **2** for 60 min. in Tris buffer (pH 7.5). Lane 1, DNA control; lane 2, DNA + **1** (75 μM) alone; lane 3, DNA + ascorbic acid (150 μM); lane 4, DNA + **1** (25 μM) + ascorbic acid (75 μM); lane 5, DNA + **2** (25 μM) + ascorbic acid (75 μM); lane 6, DNA + **1** (50 μM) + ascorbic acid (75 μM); lane 7, DNA + **2** (50 μM) + ascorbic acid (75 μM); lane 8, DNA + **1** (75 μM) + ascorbic acid (150 μM); lane 9, DNA + **2** (75 μM) + ascorbic acid (150 μM).

To quantify the nuclease activity of the complexes, rate constants were determined for both complex **1** and **2** by further studying the extent of DNA cleavage in a time dependent manner. The complex concentration was maintained at 75 μM for both **1** and **2** as maximum DNA damage occurs at this particular concentration. The results of gel

Table 4. Extent of DNA cleavage by complexes **1** and **2**.

| Complexes | Concentration of Complex [μM] | %SC | %NC | %L[a] |
|---|---|---|---|---|
| **1** | 25 | 65 | 35 | |
| | 50 | 14 | 86 | |
| | 75 | | 85 | 15 |
| **2** | 25 | 89 | 11 | |
| | 50 | 53 | 47 | |
| | 75 | 2 | 98 | |

[a] SC = supercoiled; NC = nicked circular; L = linear.

electrophoresis were subjected to densitometric quantification and the kinetic parameters were analyzed by assuming a simple pseudofirst-order process for conversion of Form I to Form II. The rate constants determined from the plot of ln(%SC DNA) versus time (shown in Figure 10) were found to be $4.32 \times 10^{-4}$ $s^{-1}$ for complex **1** and $3.14 \times 10^{-4}$ $s^{-1}$ for complex **2**. The higher $k$ value for **1** is clearly indicative of a better nuclease activity of **1** relative to **2**.

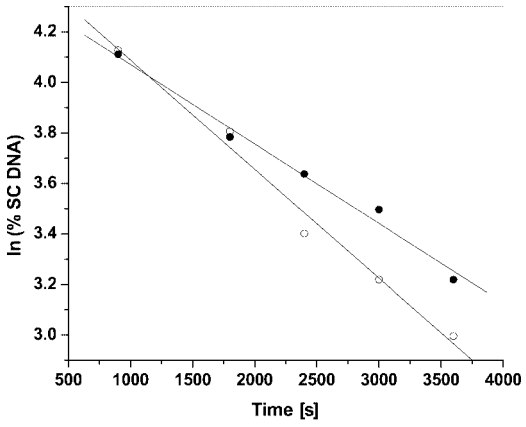

Figure 10. Plot of ln(%SC DNA) versus time for a complex concentration of 75 μM; complex **1** (○), Complex **2** (●).

To explain the cleavage efficiency of **1** being greater than **2** it is essential to look at the probable mechanistic pathway for this process. Because the complexes exhibit nuclease activity only in the presence of ascorbic acid, it is clear that the copper(II) complex in both cases is first reduced to a copper(I) complex, which then reacts with molecular oxygen to produce reactive oxygen species (ROS). A species with a more negative redox potential is always a better reducing agent and would reduce molecular oxygen much more readily thereby causing efficient DNA cleavage. In the present case, because complex **1** has a more negative redox potential than **2**, the former is a better DNA cleaving agent than the latter. Similar observations were also reported by other research groups.[46,47] Moreover, the higher binding affinity of complex **1** towards DNA relative to **2**, could also possibly be another reason for the higher cleavage efficiency of complex **1**. Further studies are under progress to investigate the DNA cleavage in detail.

## Conclusions

The present communication reports the synthesis and characterization of two four-coordinate copper(II) complexes with tridentate terpyridine ligands. On the basis of electronic and EPR spectral studies, the complexes are suggested to have a four-coordinate geometry with considerable tetrahedral distortion in the square plane. The complexes are found to adopt an intercalative mode of binding with moderate binding strengths. The influence of the substituents of the terpyridine ligand was discussed on the basis of computational studies. The tolyl substituent in complex **1** is less hard and more reactive relative to the imidazolyl substituent of complex **2**. Also, the aromatic π cloud almost uniformly lies above and below the molecular plane in complex **1**, which leads to its better intercalative binding with DNA. They exhibit efficient nuclease activity in the presence of ascorbic acid and the differences in their cleavage efficiencies were explained on the basis of spectral and electrochemical results.

## Experimental Section

**General:** 2-Acetyl pyridine, tolualdehyde, *p*-bromobenzaldehyde and imidazole 2-carboxaldehyde were obtained from Sigma Aldrich, USA and used as received. Tris(hydroxymethyl) methylamine (Tris) was obtained from SRL Chemicals. Calf Thymus DNA (CT DNA) was obtained from Fluka Chemicals. All chemicals and reagents used were of analytical grade received from Ranbaxy, Mumbai. Stock solution of DNA was prepared by stirring a sample dissolved in 10 mM (Tris) buffer, (pH 7.2) at 4 °C. The solution was dialyzed exhaustively against the Tris buffer for 48 h and filtered through a membrane filter obtained from Sartorius (45 μM). The filtered DNA solution in the buffer gave a UV absorbance ratio ($A_{260}/A_{280}$) of about 1.8, indicating DNA was sufficiently free from protein.[48] The concentration of DNA was determined by using an extinction coefficient of 6600 $M^{-1}cm^{-1}$ at 260 nm.[49]

**[Cu(ttpy)Cl]Cl (1):** The complex was prepared in good yield from the reaction of $CuCl_2{\cdot}2H_2O$ in methanol with tolyl terpyridine ligand, which was prepared by a procedure reported in the literature.[50] The ligand (0.323 g, 1 mmol) and $CuCl_2{\cdot}2H_2O$ (0.170 g, 1 mmol) were dissolved in methanol individually and the solutions were warmed. The hot solution of the ligand was added slowly with constant stirring to copper chloride when the colour changed to intense green. The solution was cooled to room temperature and the green precipitate of the copper–ttpy complex separated out and was filtered and dried. IR [KBr disc]: $\tilde{\nu}$ = 3069, 1619, 1451, 1098 $cm^{-1}$. MS (ESI): *m*/*z* = 421 $[M - L{\cdot}Cl]^+$. $C_{22}H_{17}Cl_2CuN_3$ (456.5): calcd. C 57.83, H 3.72, N 9.20, Cu 13.91; found: C 57.78, H 3.69, N 9.25, Cu 13.93. The complex is soluble in DMSO and partially soluble in methanol.

**[Cu(itpy)Cl]Cl (2):** The complex was prepared by a similar procedure to that of complex **1**, by taking $CuCl_2{\cdot}2H_2O$ (0.170 g) and itpy (0.299 g) in the mole ratio 1:1; the ligand was prepared by a similar procedure as that of ttpy. IR (KBr disc): $\tilde{\nu}$ = 3068, 1616, 1450, 794 $cm^{-1}$. MS (ESI): *m*/*z* = 397 $[M - L{\cdot}Cl]^+$. $C_{18}H_{13}Cl_2CuN_5$ (432.5): calcd. C 49.94, H 3.00, N 16.18, Cu 14.68; found C 49.87, H 2.94, N 16.09, Cu 14.60. The solubility of the complex is similar to that of **1**.

**Physical Measurements:** ESI mass spectra were recorded with a Finnigan LCQ Advantage mass spectrometer equipped with an electron spray source. Infrared spectra were recorded for the complexes and the ligand by using a Perkin–Elmer RX-1 FTIR spectrometer and the samples were prepared by KBr mull sampling technique. Electronic spectra were recorded with a Perkin–Elmer Lamda35 double beam spectrophotometer. Circular dichroic spectra were recorded with a J-715 spectropolarimeter (Jasco) at 25 °C with a 0.1-cm pathlength cuvette. Cyclic voltammetry was performed on CH-Instruments, electrochemical analyzer, CH-620 B. X-band electron paramagnetic resonance (EPR) spectra at room temperature and liquid nitrogen temperature were recorded with a Bruker EMX 6/1 spectrometer and the field calibration was done by using diphenylpicrylhydrazyl (DPPH).

**DNA Binding and Cleavage Studies – Absorption Titration Experiments:** The electronic spectra of complexes **1** and **2** were monitored in the absence and presence of DNA in the UV region. Absorption titration experiments were conducted by maintaining the metal ion concentration constant (20 μM) and varying the concentration of DNA (0–150 μM). In the reference cell, a DNA blank was placed so as to cancel any absorbance due to DNA at the measured wavelength. From the absorption titration data the binding constant ($K_b$) was determined by using the following equation.

$$[DNA]/(\varepsilon_a - \varepsilon_f) = [DNA]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_b - \varepsilon_f)$$

where $\varepsilon_a$, $\varepsilon_f$ and $\varepsilon_b$ corresponds to $A_{obs}$/[Cu], the extinction coefficient for the free copper complex and the extinction coefficient for the complex in the bound form, respectively. A plot of $[DNA]/(\varepsilon_a - \varepsilon_f)$ versus [DNA] gives $K_b$ as the ratio of the slope to the intercept. Density functional theory calculations were performed to explore the reactivity, stability and electron density parameters of the terpyridine substituents. From the theoretical investigation, the influence of substituent on the magnitude of binding constant is explained.

Viscometric experiments were carried out by using an Ostwald-type viscometer of 2 mL capacity, thermostatted in a water bath maintained at 25 °C. The flow rates for the buffer (10 mM), DNA (200 μM) and DNA in the presence of copper(II) complex at various concentrations (20–140 μM) were measured with a manually operated timer at least three times to agree within 0.2 s. The relative viscosity was calculated according to the relation, $\eta = (t - t_0)/t_0$ where $t_0$ is the flow time of the buffer and $t$ is the observed flow time for DNA, in the presence and absence of the complex. A plot of $(\eta/\eta_0)^{1/3}$ versus $1/R$ ($R$ = [DNA]/[Complex]) was constructed from viscosity measurements.[51]

Voltammetric experiments were carried out by using a standard three-electrode system comprising glassy carbon working electrode with 3 mm diameter, platinum auxillary electrode and saturated calomel reference electrode (SCE). The samples were prepared in DMSO, and the solutions were deoxygenated by purging nitrogen gas for 10 min. prior to the measurements. The experiments were carried out with a complex concentration of $0.2 \times 10^{-3}$ M by using tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte.

Circular dichroic spectrum of DNA in the absence and presence of complexes was recorded with a J-715 spectropolarimeter (Jasco) at 25 °C with a 0.1-cm pathlength cuvette. The spectra were recorded for 200 μM of DNA in the absence and presence of 5–40 μM of the copper(II) complex in the region 220–300 nm.

Cleavage of plasmid DNA was monitored by using agarose gel electrophoresis. Supercoiled pBR322 DNA (180 ng) in tris(hydroxymethyl)methylamine (Tris) buffer was treated with copper(II) complex (25–75 μM) and ascorbic acid (75–150 μM). The samples were incubated for 60 min at 35 °C. A second set of experiments was performed by maintaining the complex concentration at 75 μM and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ascorbic acid at 150 μM and varying the incubation time from 0–60 min. The agarose gel (0.8%) containing 0.5 μg of ethidium bromide was prepared and the electrophoresis of the DNA cleavage products was performed on it. The gels were run at 100 V for 1 h in Tris(boric acid) ethylenediaminetetraacetic acid (TBE) buffer and the bands were identified by placing the stained gel under an illuminated UV lamp. The fragments identified were photographed by using a gel documentation system.

# 1,3-Dipolarophile Character of an Extremely Bulky Phosphaalkyne Mes*C≡P (Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_2$) Leading to the Formation of 1,2,4-Diazaphospholes with Unique Hydrogen Bonding Properties

**Shigekazu Ito,*[a] Hideaki Miyake,[a] and Masaaki Yoshifuji*[a][‡]**

**Keywords:** Heterocycles / Phosphaalkynes / Cycloaddition / Hydrogen bonds / DFT calculations / X-ray crystallography

2-(2,4,6-Tri-*tert*-butylphenyl)-1-phosphaethyne was allowed to react with trimethylsilyldiazomethane derivatives to afford the corresponding 1,2,4-diazaphospholes via [2+3] cycloaddition followed by H/SiMe$_3$ migration, in spite of the steric encumbrance of the substrates. The aromatic character of 1,2,4-diazaphosphole is indicated by the NMR spectroscopic data and the X-ray structure analysis as well as by theoretical calculation to confirm the planar delocalized ring skeleton. The crystal structure of the obtained 1,2,4-diazaphospholes showed remarkable hydrogen bonding character in relation to molecular aggregation due to the presence of bulky aryl groups.

## Introduction

Phosphaalkynes [R–C≡P] are only stable if protected by bulky substituents such as the *tert*-butyl or 2,4,6-tri-*tert*-butylphenyl (Mes*) group. Cycloaddition reactions of such phosphaalkynes have extensively been developed to provide a number of P-heterocyclic compounds which have widely been utilized especially in coordination and organometallic chemistry.[1] Throughout the investigation of phosphaalkynes, *tert*-butylphosphaacetylene [*t*BuC≡P] has played a principal role in the synthesis of P-heterocyclic compounds because of its moderate stability and desirable reactivity,[1,2] and a number of [2+1], [2+2], [2+3], and [2+4] cycloadditions have been observed so far. On the contrary, a phosphaalkyne bearing an extremely bulky Mes* group (**1**, [Mes*C≡P])[3] showed considerably low reactivity in comparison with *t*BuC≡P. Whereas *t*BuC≡P reacts with a diene to afford the corresponding [2+4] adduct,[1] compound **1** gave no six-membered ring compound as a result of Diels–Alder cycloaddition.[4] In addition to the low reactivity and high stability of **1**, the presence of the Mes* group often causes unusual reactions. In the [2+1] cycloaddition with compound **1**, expulsion of the P atom from the initially formed three-membered phosphirene intermediate leads to the formation of the corresponding acetylene derivative **2**,[5,6] probably because of the congestion around the phosphorus, whereas *t*BuC≡P reacts with a carbene (or its heavier congener) to afford the corresponding three-membered phosphirene.[1] Although the presence of bulky substituents in **1** induces such unexpected conversion as to give **3**[6] and **4**[7] in an attempted synthesis of P-heterocyclic compounds, we have utilized **1** for investigations of unique P-heterocyclic diradicals **5**[8] and a monoradical **6**,[8e] which shows the advantage of the introduced Mes* group (Figure 1). Thus, these individual properties of the bulky phosphaalkyne **1** prompted us to explore its unique character, leading to novel findings in the chemistry of P-heterocycles.

In this paper we describe [2+3] additions of compound **1** and trimethylsilyldiazomethane derivatives as dipolar CN$_2$ reagents to demonstrate the ordinary reaction mode of phosphaalkynes[1] leading to important results on novel extremely bulky 1,2,4-diazaphospholes. In these reactions, diazoalkanes overcome the shielding effect of the Mes* group, leading to regioselective cycloaddition for 1,2,4-diazaphospholes, and the formal control of silyl and hydrogen migrations has been accomplished by employing neutral and lithiated trimethylsilyldiazomethanes.[9] Structures of the newly synthesized 1,2,4-diazaphospholes, one of which carries substantial aromatic character,[1,10,11] are discussed in terms of hydrogen-bonding control of molecular aggregation in the presence of the Mes* group. Several 1,2,4-diazaphosphole nucleosides **7** are known, and even the X-ray structures have been reported for **7A** and **7C**. Furthermore, thiocarboxamide **7C** shows antitumor activity against L1210 in vivo,[12] and therefore the newly obtained 1,2,4-diazaphospholes might be available for drug design (Figure 2).

## Results and Discussion

### 1,3-Dipolar Cycloaddition of Mes*C≡P (1) with $Me_3Si(CN_2)H$

Phosphaalkyne **1**, prepared according to our previous reports,[8a,8b] was allowed to react with trimethylsilyldiazomethane in a similar manner to the reported procedures,[13] and 1-trimethylsilyl-1,2,4-diazaphosphole **9** was formed through intermediate **8** almost quantitatively after the solvent was removed (Scheme 1). $^1H$ and $^{13}C$ NMR spectroscopic data of **9** confirm the presence of $NSiMe_3$ and =*C*H groups as well as a 1*H*-1,2,4-diazaphosphole structure. The migration of the silyl group has been observed in previous studies.[13,14] Actually, the total energy of theoretically optimized structures for model compounds **8x**, **9x**, and **9xx** suggested facile conversion from **8** to **9** as well as the migratory aptitude of the silyl group (Figure 3).[15–17] In the $^{13}C$ NMR spectroscopic data of **9**, the H-substituted carbon atom C($sp^2$)-3 has a slightly smaller $^1J_{PC}$ constant ($^1J_{PC}$ = 53.7 Hz, *C*H) than the C-5 ($^1J_{PC}$ = 59.7 Hz, *C*Mes*), which might represent a 5-substituted 1*H*-1,2,4-diazaphosphole.[18–20] The exclusive formation of **9** without a 1,2,3-diazaphosphole isomer indicates that regioselective [2+3] cycloaddition of **1** with the $CN_2$ moiety proceeds under kinetic control by the bulky Mes* group[21] followed by subsequent silyl group migration[13,14,16] to gain higher aromatic stabilization. The N–Si bond in **9** is sensitive to alcohol and moisture, and desilylation took place to afford **10** by addition of ethanol (Scheme 1).[13,22] In the $^1H$ NMR spectrum, the *o-tert*-butyl groups in both **9** and **10** showed a shift to a higher field, because of the aromatic character of the 1,2,4-diazaphosphole ring. A more detailed discussion about structures in relation to aggregation in solution is in progress.

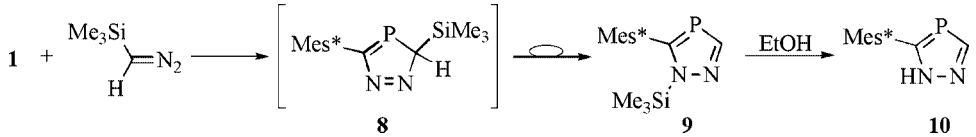
### Molecular and Crystal Structure of a Bulky 1,2,4-Diazaphosphole 10

The structure of **10** was confirmed by X-ray crystallography. Figure 4a shows one of the three independent molecules of **10** (molecule A) in the unit cell. Table 1 shows se-



Scheme 1. Reaction of **1** with trimethylsilyldiazomethane.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lected bond lengths and angles of **10**, indicating that the parameters are similar to the previously reported 1,2,4-diazaphospholes.[12,23–25] The parameters indicate a relatively large contribution of a 5-substituted 1*H*-1,2,4-diazaphosphole structure: the P1–C1 bonds are longer than the P1–C2 distances, and correspondingly the N1–C1 lengths are shorter than the N2–C2 values. Such bonding properties are almost equal to the previously analyzed structures of nonsubstituted or 3,5-disubstituted 1,2,4-diazaphospholes.[23] The diazaphosphole ring is almost planar [$\Theta$(P–C1–N1–N2) = 0.3–0.7°, $\Theta$(P–C2–N1–N2) = 0.6–1.0°], and the Mes* ring is perpendicular to the five-membered ring (dihedral angle: 89.8–90.0°) in order to reduce the steric congestion. As displayed in Figure 4b, three molecules (A, B, and C) form a trimer structure connected by three N–H···N hydrogen bonds (H···N 1.945–1.971 Å; N···N 2.861–2.867 Å). Such a trimer structure of 1,2,4-diazaphospholes has never been reported so far, whereas pyrazoles, a carbon congener of diazaphospholes, show several aggregation modes.[26] The trimer seems to be additionally stabilized by C–H···$\pi_{Mes*}$ interactions, with H···$\pi_{Mes*}$ distances of 2.763, 2.788, and 2.804 Å.[26] Therefore, the first characterized trimer structure[27] of 1,2,4-diazaphosphole **10** in the crystalline state reflects the effect of the Mes* group in determining the position of the atoms as a result of CH–π interaction.[28]

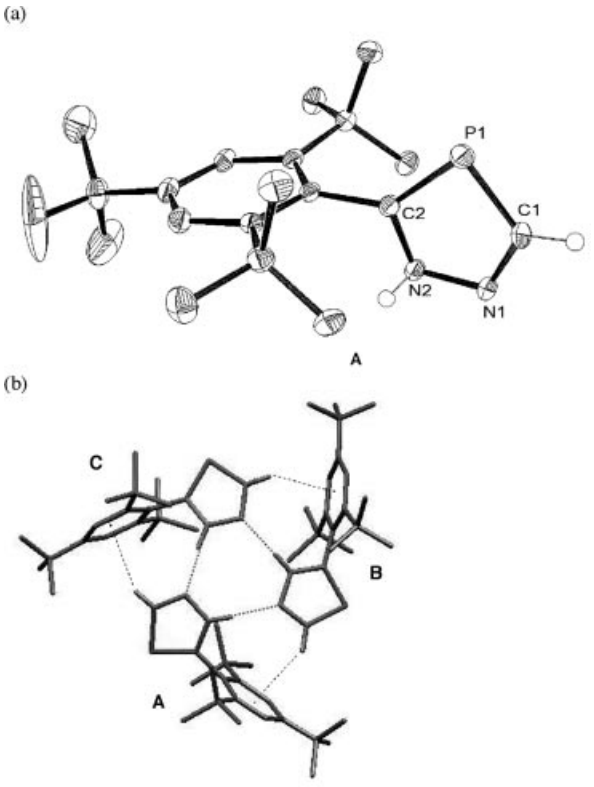


Figure 4. (a) An ORTEP drawing for **10** (50% probability ellipsoids). One of the three independent molecules (**A**) is displayed. Hydrogen atoms in the Mes* group are omitted for clarity. Atom numbering is independent of the nomenclature of 1,2,4-diazaphosphole. (b) Hydrogen-bonded trimer structure of **10** in the crystalline state. ····· NH···N interaction. - - - CH···$\pi_{Mes*}$ interaction.

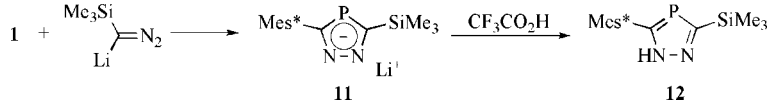
### Preparation and Structure of Bulky 3-Trimethylsilyl-1,2,4-diazaphosphole 12

The reaction of **1** with lithiated trimethylsilyldiazomethane [$Me_3Si(CN_2)Li$] (Scheme 2) gave a different result from that described above. Compound **1** was allowed to react with freshly prepared $Me_3Si(CN_2)Li$ to generate diazaphospholido anion **11**, which was observed by $^{31}P$ NMR ($\delta_P$ = 135.0 ppm), at a value close to that of a fundamental 1,2,4-diazaphospholido anion.[23,29] The anion **11** was then treated with trifluoroacetic acid to afford 3-trimethylsilyl-1,2,4-diazaphosphole **12** in a moderate yield together with a small amount of **10**. The formation of **10** would also have been possible by using nonlithiated trimethylsilyldiazomethane (Scheme 1).

The crystal structure of **12** (Figure 5) is a dimer connected by two N–H···N hydrogen bonds (H···N 2.105 Å; N···N 2.817 Å). A similar dimer structure was known for 3,5-di-*tert*-butyl-1,2,4-diazaphosphole,[23] and the silyl group appears to be effective in constructing the dimer structure of 1,2,4-diazaphosphole. The P–C1 bond is longer than the P–C2 distance, indicating the predominance of the 5-substituted 1*H*-1,2,4-diazaphosphole structure. On the other hand, almost the same bond lengths were observed for N1–C1 and N2–C2, probably because of the π-accepting effect of the silyl group to stabilize the polarized $N^-H^+$ structure.[30] In the $^{13}C$ NMR spectrum, the C($sp^2$) atoms in the five-membered ring did not give sharp signals because of signal broadening, probably indicating effects of



Scheme 2. Reaction of **1** with lithiated trimethylsilyldiazomethane.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the dimer structure of **12** in solution. The five-membered ring is planar [$\Theta$(P–C1–N1–N2) = 0.1(4)°, $\Theta$(P–C2–N1–N2) = 0.3(4)°], and the Mes* ring is perpendicular to the five-membered ring (dihedral angle: 90.0°). Compound **12** is an isomer of **9**, and the silyl- and hydrogen rearrangements of **8** can be formally controlled by the reaction conditions.[9] In contrast to the observed predominant migratory aptitude of the silyl group in the rearrangement from **8** to **9** (Scheme 1), the Si–C bond was tolerant to alcoholysis with wet thf in ethanol.

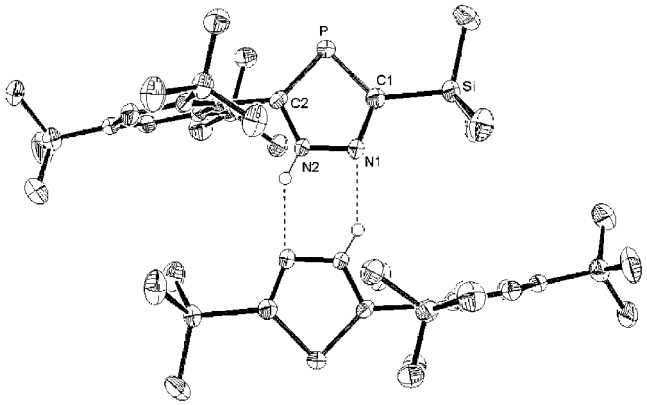


Figure 5. An ORTEP drawing for **12** with dimer structure (50% probability ellipsoids). Hydrogen atoms in the Mes* and the $SiMe_3$ groups are omitted for clarity. Atom numbering is independent from the nomenclature of 1,2,4-diazaphosphole. Typical bond lengths [Å] and angles [°]: P–C1 1.763(4), P–C2 1.744(3), Si–C1 1.886(4), N1–N2 1.349(4), N1–C1 1.340(4), N2–C2 1.337(4), C2–$C_{Mes*}$ 1.500(5), C1–P–C2 87.8(2), N2–N1–C1 109.2(3), N1–N2–C2 118.7(3), P–C1–Si 129.2(2), P–C1–N1 114.4(3), Si–C1–N1 116.4(3), P–C2–N2 109.9(3), P–C2–$C_{Mes*}$ 136.5(3), N2–C2–$C_{Mes*}$ 113.6(3).

## Conclusions

We have demonstrated ordinary [2+3] cycloadditions of phosphaalkyne **1** with diazomethane derivatives affording 1,2,4-diazaphospholes in spite of the presence of an extremely bulky Mes* group. Neutral or lithiated trimethylsilyldiazomethane operated on the structure of the [2+3] adduct to give almost selectively **10** or **12**, respectively. The crystal structure of **10** exhibits the first example of a trimer structure of 1,2,4-diazaphosphole resulting from the presence of the bulky aryl substituent, whereas **12** forms a dimer structure. Although 1,2,4-diazaphosphole is an inherently stable compound and does not require kinetic stabilization, the Mes* group might be effective in discovering novel characteristics of 1,2,4-diazaphospholes which operate molecular assemblies. Attempts to utilize **9**–**12** as unique P-heterocyclic reagents for coordination chemistry are in progress.[1,12,24,31]

## Experimental Section

**General Methods:** All manipulations were carried out under an argon atmosphere by means of standard Schlenk techniques or in a glove box. All solvents employed were dried by appropriate methods. $^1H$, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker Avance 400 spectrometer with $Me_4Si$ ($^1H$, $^{13}C$) and $H_3PO_4$ ($^{31}P$) as internal or external standards. Mass spectra were recorded with a Bruker APEX3 spectrometer. Compound **1** was prepared by the procedures described in the literature.[8a,8b]

**Reaction of 1 with $Me_3Si(CN_2)H$:** To a solution of **1** (91.4 mg, 0.317 mmol) in thf (5 mL) was added trimethylsilyldiazomethane (0.38 mmol, 2.0 M solution in hexane,) at room temperature. After stirring for 30 min, volatiles were removed, and the residual amorphous solid **9** was characterized by NMR spectroscopy. Ethanol (2 mL) was added to **9**, and the volatiles were removed. The residual solid containing **10** was dissolved in chloroform (20 mL), and insoluble materials were filtered off. The chloroform solution was concentrated, and the residue was washed with hexane to obtain **10** as colorless crystals. Compound **10** was purified by silica-gel column chromatography (hexane/EtOAc = 1:1) (total 77.4 mg, 74%). **9**: Colorless amorphous solid: $^{31}P\{^1H\}$ NMR (162 MHz, $C_6D_6$): $\delta$ = 116.6 ppm. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 0.19 (s, 9 H, $SiMe_3$), 1.25 (s, 18 H, *o*-*t*Bu), 1.32 (s, 9 H, *p*-*t*Bu), 7.65 (s, 2 H, Mes*), 8.42 (d, $^2J_{PH}$ = 39.5 Hz, 1 H, CH) ppm. $^{13}C\{^1H\}$ NMR (101 MHz, $C_6D_6$): $\delta$ = –0.63 (s, $SiMe_3$), 31.9 (s, *p*-C*Me*$_3$), 34.2 (d, $^5J_{PC}$ = 3.5 Hz, *o*-C*Me*$_3$), 35.3 (s, *p*-*C*Me$_3$), 38.3 (s, *o*-*C*Me$_3$), 122.6 (s, *m*-Mes*), 133.2 (d, $^2J_{PC}$ = 21.3 Hz, *ipso*-Mes*), 149.3 (s, *p*-Mes*), 149.6 (d, $^3J_{PC}$ = 3.0 Hz, *o*-Mes*), 162.1 (d, $^1J_{PC}$ = 53.7 Hz, *C*H), 182.0 (d, $^1J_{PC}$ = 59.7 Hz, *C*Mes*) ppm. ESI-MS: calcd. for $[M + Na]^+$ ($C_{23}H_{39}N_2PSi$ + Na) 425.2512; found 425.2511. **10**: Colorless prisms (hexane), m.p. 255–256 °C; $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 106.7 ppm. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 1.12 (s, 18 H, *o*-*t*Bu), 1.38 (s, 9 H, *p*-*t*Bu), 7.56 (s, 2 H, Mes*), 8.32 (d, $^2J_{PH}$ = 45.3 Hz, 1 H, CH), 12.0 (brs, 1 H, NH) ppm. $^{13}C\{^1H\}$ NMR (101 MHz, $CDCl_3$): $\delta$ = 31.8 (s, *p*-C*Me*$_3$), 33.4 (d, $^5J_{PC}$ = 3.7 Hz, *o*-C*Me*$_3$), 35.6 (s, *p*-*C*Me$_3$), 38.1 (s, *o*-*C*Me$_3$), 122.7 (s, *m*-Mes*), 127.7 (d, $^2J_{PC}$ = 16.2 Hz, *ipso*-Mes*), 150.7 (d, $^3J_{PC}$ = 3.6 Hz, *o*-Mes*), 151.0 (s, *p*-Mes*), 162.5 (d, $^1J_{PC}$ = 68.5 Hz, *C*Mes*), 174.7 (d, $^1J_{PC}$ = 49.3 Hz, *C*H) ppm. ESI-MS: calcd. for $[M + Na]^+$ ($C_{20}H_{31}N_2P$ + Na) 353.2117, found 353.2116. $C_{20}H_{31}N_2P$ (330.45): calcd. C 72.69, H 9.46, N 8.48; found C 72.52, H 9.46, N 8.50.

**Reaction of 1 with $Me_3Si(CN_2)Li$:** To a solution of trimethylsilyldiazomethane (0.10 mmol) in thf (2 mL) was added butyllithium (0.10 mmol, 1.6 M solution in hexane) at –78 °C and stirred for 5 min. To the mixture was added **1** (30 mg, 0.10 mmol) in thf (1 mL) at –78 °C and stirred for 5 min. The reaction mixture was warmed to room temperature and an aliquot was removed via syringe to observe **11** by $^{31}P$ NMR ($\delta_P$ = 135.0). The mixture was treated with trifluoroacetic acid (0.20 mmol) and volatiles were removed in vacuo. The residual materials were purified by silica-gel column chromatography (hexane/EtOAc = 1:1) to afford **12** (28 mg, 66%) and **10** (3 mg, 9%). Pure **12** was obtained by dissolving in hexane (**10** is less soluble in hexane). **12**: Colorless prisms (hexane), m.p. 251–253 °C; $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 141.2 (br) ppm. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 0.39 (s, 9 H, $SiMe_3$), 1.13 (s, 18 H, *o*-*t*Bu), 1.37 (s, 9 H, *p*-*t*Bu), 7.53 (s, 2 H, Mes*), 11.2 (brs, 1 H, NH) ppm. $^{13}C\{^1H\}$ NMR (101 MHz, $CDCl_3$): $\delta$ = 0.04 (s, $SiMe_3$), 31.8 (s, *p*-C*Me*$_3$), 33.8 (d, $^5J_{PC}$ = 2.9 Hz, *o*-C*Me*$_3$), 35.4 (s, *p*-*C*Me$_3$), 38.1 (s, *o*-*C*Me$_3$), 122.6 (s, *m*-Mes*), 149.7 (s, *p*-Mes*), 149.9 (s, *o*-Mes*, *ipso*-Mes*, 3- and 5-C atoms were unclear) ppm. ESI-MS: calcd. for $[M + Na]^+$ ($C_{23}H_{39}N_2PSi$ + Na) 425.2512; found 425.2513. $C_{23}H_{39}N_2PSi$ (402.63): calcd. C 68.61, H 9.76, N 6.96; found C 68.62, H 9.62, N 7.00.

**X-ray Crystallography:** A Rigaku RAXIS-IV imaging plate detector with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71070 Å) was used. The structure was solved by direct methods

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(SIR92),[32] expanded using Fourier techniques (DIRDIF94).[33] A symmetry-related absorption correction using the program ABSCOR[34] was applied for **10**. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined isotropically. The data were corrected for the Lorentz polarization effect. Structure solution, refinement, and graphical representation were carried out with the teXsan package.[35] The data are summarized in Table 2. CCDC-635494 (**10**) and CCDC-635495 (**12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data request/cif.

Table 2. X-ray data for compounds **10** and **12**.

| Compound | **10** | **12** |
|---|---|---|
| Formula | $C_{20}H_{31}N_2P$ | $C_{23}H_{39}N_2PSi$ |
| Fw /g mol$^{-1}$ | 330.45 | 402.63 |
| Crystal system | triclinic | monoclinic |
| Space group | $P\bar{1}$ (no. 2) | $P2_1/c$ (no. 14) |
| $a$ /Å | 15.3082(2) | 12.583(1) |
| $b$ /Å | 17.4576(3) | 10.1014(9) |
| $c$ /Å | 15.2989(5) | 20.1680(9) |
| $\alpha$ /° | 112.328(2) | 90 |
| $\beta$ /° | 106.479(1) | 90.087(3) |
| $\gamma$ /° | 112.335(2) | 90 |
| $V$ /Å$^3$ | 3029.0(2) | 2563.4(3) |
| $Z$ | 6 | 4 |
| $T$ /K | 140 | 150 |
| $\rho_{calc}$ /g cm$^{-3}$ | 1.087 | 1.043 |
| $\mu$ /mm$^{-1}$ | 0.138 | 0.163 |
| $2\theta_{max}$ /° | 55 | 55 |

[15] Previous theoretical studies on diazaphospholes: L. Nyulászi, P. Várnai, W. Eisfeld, M. Regitz, *J. Comput. Chem.* **1997**, *18*, 609.

[16] Previous theoretical studies on silyl migration: T. J. Barton, J. Lin, S. Ijadi-Maghsoodi, M. D. Power, X. Zhang, Z. Ma, H. Shimizu, M. S. Gordon, *J. Am. Chem. Soc.* **1995**, *117*, 11695.

[17] The STQN process using the optimized structures of 3-silyl-3*H*-1,2,4-diazaphosphole, 1-silyl-1*H*-1,2,4-diazaphosphole, and 5-silyl-1*H*-1,2,4-diazaphosphole estimates activation energies of 7.1 and 30.9 kcal mol$^{-1}$ for the $SiH_3$- and H-migration, respectively [B3LYP/6-31+G(d) level]. The total energy of 3-silyl-1*H*-1,2,4-diazaphosphole is close to that of 5-silyl-1*H*-1,2,4-diazaphosphole. See Supporting Information.

[18] In Scheme 1, the 5-substituted isomer is shown as the structure of **9** although tautomerism might occur between the 5- and 3-substituted forms with trimethylsilyl group shift. Note, however, that 5-methyl-1-trimethylsilyl-1*H*-1,2,4-diazaphosphole (**9meA**) is less stable than the corresponding 3-methyl-1-trimethylsilyl-1*H*-1,2,4-diazaphosphole (**9meB**) by 3.9 kcal mol$^{-1}$ at the B3LYP/6-31+G(d) level of calculation because of the steric repulsion between methyl and trimethylsilyl groups.

[19] 3-Trimethylsilyl-1*H*-1,2,4-diazaphosphole, a tautomeric isomer of **9xx**, possesses lower total energy by 1.4 kcal mol$^{-1}$ at the B3LYP/6-31+G(d) level. See Supporting Information.

# Surface-Assisted Synthesis and Behavior of Dimetallic Mixed-Metal Complexes $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(L)_2]$ (M = Ru, Os; M′ = Fe, Co; L = $CH_3CH_2OH$, $H_2O$)

**Minna Jakonen,[a] Pipsa Hirva,[a] Taina Nivajärvi,[a] Mirja Kallinen,[a] and Matti Haukka*[a]**

**Keywords:** Ruthenium / Osmium / Cobalt / Iron / Synthesis design

The reductive carbonylation of ruthenium and osmium halides in the presence of cobalt and iron surfaces was studied. In these surface-assisted reactions the metal surface plays an active role in releasing metal ions, which can be used for the in situ synthesis of mixed-metal compounds. A linear, dimetallic, chlorido-bridged, trinuclear complex $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ was obtained by the interaction between reducing $RuCl_3$ and the cobalt surface. In the reaction the $RuCl_3$ is reduced with carbon monoxide in the presence of a solid cobalt surface in ethanol solution. During the reduction of the $RuCl_3$ the cobalt surface was simultaneously corroded, releasing cobalt cations. In addition to $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$, the reaction also produced other trinuclear complexes and mononuclear products, such as a bent and linear dimetallic, chlorido-bridged complex with the aqua ligand $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(H_2O)_2]$ and ionic $[RuCl_3(CO)_3]_2[Co(H_2O)_6]$. The carbon monoxide reduction of $RuI_3$ produced the ionic complex $[RuI_3(CO)_3]_2[M'(H_2O)_6]$ (M′ = Fe, Co) in the presence of iron, stainless steel or cobalt. Iodido-bridged trinuclear mixed-metal complexes were not observed. The surface-assisted process proved to be useful with other metal combinations as well. When $RuCl_3$ was replaced with $OsCl_3$, a variety of trinuclear mixed-metal complexes, such as $[Os_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ and ionic $[OsCl_3(CO)_3]_2[M(H_2O)_6]$ (M = Fe, Co), were obtained, depending on the metal surface used. Due the lability of the chlorido-bridged trinuclear complexes, the possible decomposition steps of $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(CH_3CH_2OH)_2]$ (M = Ru, Os; M′ = CO, Fe) were studied computationally, using DFT methods.

## Introduction

Sacrificial anodes, most commonly used in corrosion protection,[1] have a variety of applications in synthetic chemistry[2] and in biochemistry.[3] The sacrificial anode donates metal cations in a reaction solution when current is applied to the anode material by an external power source. These released cations can then be used to form organometallic[4] or inorganic complexes,[5] or inorganic nanomaterial.[6] Nanomaterials prepared by means of sacrificial anodes have been used, for example, in catalytic applications[6a] and as the inhibitors in biochemical applications.[6b] Sacrificial anodes are also useful in the applications of organic chemistry:[7] in the polymerisation of organic monomers,[7c] in the preparation of organic compounds and also in electrocarboxylation reactions.[7d,7e] There also exists an example of the electrosynthesis of the Grignard reagent using sacrificial magnesium.[7g] The typical sacrificial anode materials in electrosynthesis are magnesium, zinc, cadmium and aluminum, but examples involving cobalt, copper, nickel, palladium, silver, tin and iron are also available.[4–7]

Although it is known that solid metal surfaces can also participate in the formation of the products without external current, this phenomenon has not been widely used in the synthesis of organometallic compounds. In fact, carbonylmetal chemistry started to develop via the corrosion products formed under harsh conditions.[8] Mond was the first to report the formation of toxic $Ni(CO)_4$ in nickel pipes carrying carbon monoxide gas.[8] In our earlier study, we suggested that the release of the metal from a metal surface by corrosion, without the use of an externally applied current, could be used for the synthesis of other carbonyl-containing metal complexes. Such an approach was applied in the synthesis of mixed-metal trinuclear Ru-Fe-Ru complexes, which were prepared by reducing $RuCl_3$ with carbon monoxide in the presence of an iron-containing metal surface.[9] In this synthesis method, ruthenium(III) salt and the iron-containing metal surface form a metal pair suitable for redox processing, which releases the less noble metal ions from the surface. The metal cations released can then be used in the in situ synthesis of the trinuclear mixed-metal complexes $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(L)_2]$ (L = $H_2O$, $CH_3CH_2OH$) and a mixture of mononuclear ions $[RuCl_3(CO)_3]_2[Fe(H_2O)_6]$. The potential difference between the metal surface and the reducing metal salt determines the rate of dissolution of the metal cations from the metal surface into the reaction system.

In the current paper we have extended the use of sacrificial metal surfaces from Ru-Fe systems into the other metal combinations. The goal of the study was to examine whether complexes such as $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(L)_2]$, shown in Figure 1, could be synthesized using the metal systems Ru-Co, Os-Fe and Os-Co. In addition, the influence of the halide on the reaction progress was studied using $RuCl_3$ and $RuI_3$ as the reducing components.

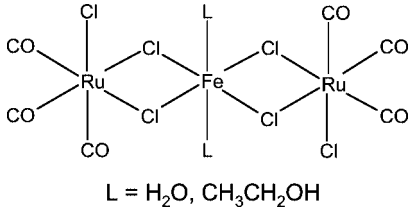

Figure 1. Schematic picture of the chlorido-bridged trinuclear ruthenium-iron complex.[6]

## Results and Discussion

The reductive carbonylation of ruthenium(III) trichloride is typically performed in alcohol solutions either under reflux or in high-pressure carbon monoxide. The reduction produces complexes with partially or fully reduced ruthenium centers.[10–15] Normally, the final reduction product is the zero-valent ruthenium cluster $Ru_3(CO)_{12}$ but several compounds containing carbonyl and halide ligands such as $[RuCl_2(CO)_3]_2$ can also be obtained.[11,14,16] Further exposure to carbon monoxide tends to reduce these species eventually to the highly stable $Ru_3(CO)_{12}$ cluster.[15,17] Like $RuCl_3$, the CO reduction of $OsCl_3$ is commonly carried out in alcohol solutions either under reflux or in a pressurized vessel under elevated CO pressure. Such reactions again produce a variety of halide-containing carbonyl products and, finally, $Os_3(CO)_{12}$.[18–20] A different type of surfaces has been used to assist the reduction process. For example, it has been found that reductive carbonylation of silica-supported $MCl_3$ (M = Ru,Os) produces several halide-containing carbonylmetal(II) compounds as well as the $M_3(CO)_{12}$ cluster.[21]

If metal surfaces are used, this opens up possibilities for synthesizing mixed-metal compounds. For example, if the reductive carbonylation of ruthenium trichloride is carried out in the presence of an iron-containing surface, it acts as a sacrificial source of iron. The active participation of the metal surface permits the formation of mixed-metal products such as trinuclear $[Ru_2Cl_2(\mu\text{-}Cl)_2(CO)_6Fe(L)_2]$ (L = $H_2O$ or $CH_3CH_2OH$) and also the ionic monomeric $[RuCl_3(CO)_3]_2[Fe(H_2O)_6]$,[6] where the cations and anions are bound together by hydrogen bonds. It is believed that during the reduction of $Ru^{3+}$, iron from the surface is simultaneously oxidized and released, which leads to the formation of labile trinuclear dimetallic chlorido-bridged compounds $[Ru_2Cl_2(\mu\text{-}Cl)_2(CO)_6Fe(L)_2]$ (L = $H_2O$ or $CH_3CH_2OH$) with $Ru^{2+}$ and $Fe^{2+}$ centres. The same approach can be applied to other metal combinations using $RuCl_3$ or $OsCl_3$ as the reducing component and iron or cobalt metal as the oxidizing component. The complexes synthesized in this work are summarized in Figure 2.

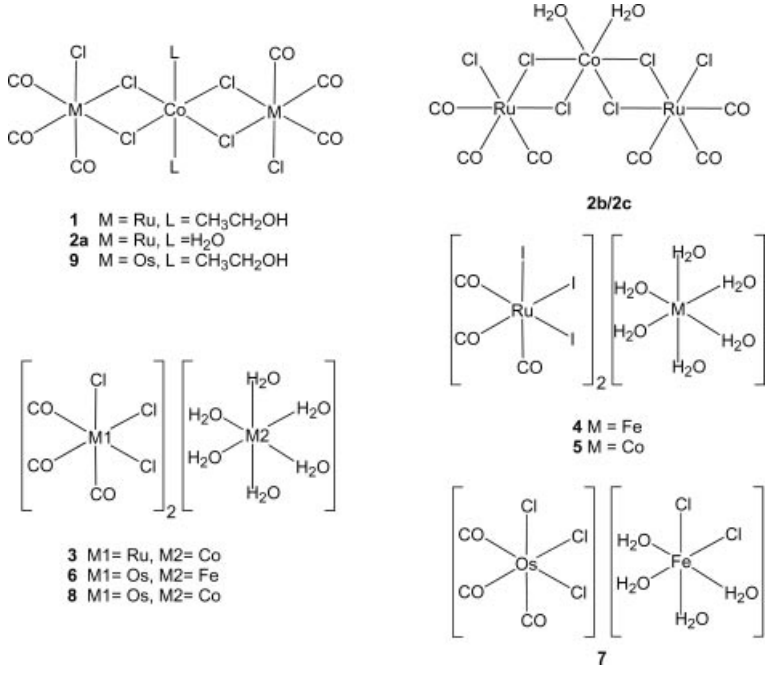

Figure 2. Schematic drawing of the main products involved in the reductive carbonylation reaction of $MX_3$ in the presence of a sacrificial metal surface.

Corrosion of the metal plate could be detected with all of the metals used as an oxidizing surface. Both iron and cobalt surfaces and also stainless steel do corrode. In the reactions with iron or stainless steel, the initially black reaction solution turned greenish-yellow during the carbonylative reduction of $MCl_3$. Green or a greenish color was typical for all reactions involving an iron-containing surface, indicating the release of iron ions. When stainless steel was used as the source of iron ions, the type of corrosion produced was pitting, which is typical of metals and metal alloys with a passive oxide layer on their surface.[22] Fairly uniform corrosion was observed when pure metal, iron or cobalt, was used. In a typical reaction with cobalt surface, the reductive carbonylation of $RuCl_3$ produced a blue solution. Again, the metal surface was clearly worn down. A blue coloration indicates the release of cobalt ions into the reaction solution.

### Formation of Ruthenium-Cobalt Mixed-Metal Complexes

The carbonylative reduction of $RuCl_3$ in the presence of a cobalt plate consistently produced a mixture of various mixed-metal complexes and mononuclear metal complexes with carbonyl and halide ligands. The ratio of the different products varied with each reaction. Because the yields of the individual products were rather low, single-crystal X-ray diffraction was used as the principal method of analysis. In order to crystallize the products, the reaction solutions were concentrated to dryness and the solid products were recrystallized from dichloromethane by means of slow concentration or by adding hexane to the $CH_2Cl_2$ solution. In the case of $RuCl_3$ reduction with a cobalt surface, the crystallization produced a mixture of pale pink crystals and colorless crystals. X-ray analysis of the pink crystals revealed trinuclear $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$, as shown in Figure 3.

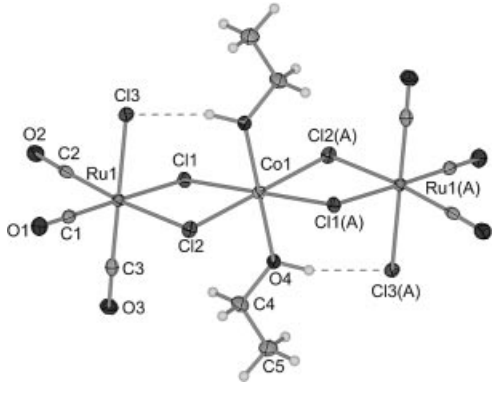

Figure 3. Thermal ellipsoid plot (50% probability level) of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ (**1**). Hydrogen bond [Å, °]: O4–H4O 0.95, H4O···Cl3(A) 2.15, O4···Cl3(A) 3.073(2), O4–H4O···Cl3(A) 164.6. Symmetry transformations used to generate equivalent atoms: (A) $-x + 1, -y, -z + 1$.

Structurally, $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ closely resembles $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(CH_3CH_2OH)_2]$, as reported earlier.[6] The trinuclear structure is supported by hydrogen bonding between the hydroxy hydrogen atom of the ethanol ligand and the terminal chlorido ligand of the ruthenium moiety. The pink crystals of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ could be isolated from the solid product, which was obtained after recrystallization from dichloromethane. The yield of complex **1** was ca. 10–15%. Complex **1** could be obtained both from high-pressure reactions in an autoclave and from low-pressure reactions under reflux. A reasonable yield of the complex **1** permitted further analysis. In order to verify the results, the elemental content of the product was analyzed using both elemental analysis and EDS (Energy Dispersive Spectroscopy). The latter confirmed the presence of cobalt and ruthenium. A pale violet trinuclear complex with aqua ligand, $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(H_2O)_2]$ (**2**), could also be isolated from the product, although the formation of complex **1** seemed to be preferred. The yield of complex **2** remained rather low at ca. 8%. Again, the structural features of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(H_2O)_2]$ were very similar to $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(H_2O)_2]$.[6] Two different structures were found: linear **2a**, presented in Figure 4, and bent **2b**, presented in Figure 5. In both structures the intramolecular hydrogen bonds between the coordinated water molecule and the terminal chlorido ligand further support the trinuclear arrangement of the metal atoms. It was found that the formation of the bent type of isomer **2b** was preferred over linear **2a** when the cobalt plate was replaced by cobalt powder. Such an observation may suggest that the morphology of the surface plays an important role in the formation of trinuclear mixed-metal products.

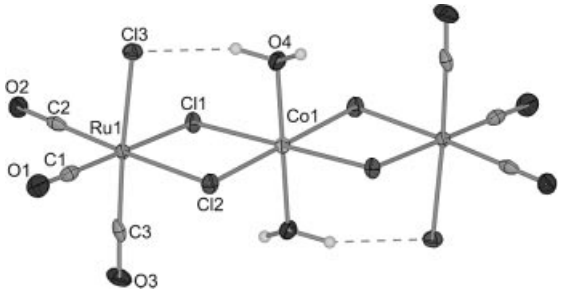

Figure 4. Thermal ellipsoid plot (50% probability level) of $OsCl_2(CO)_3(H_2O)$ (**2a**). Hydrogen bonds [Å, °]: O4–H4 0.98, H4···Cl3 2.30, O4···Cl3 3.242(3), O4–H4···Cl2(A) 161.8.

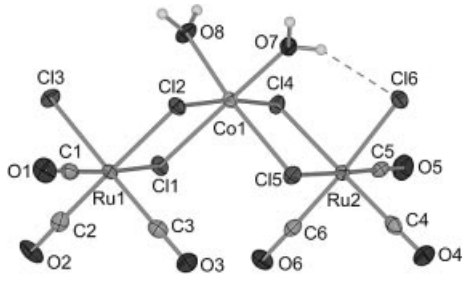

Figure 5. Thermal ellipsoid plot (50% probability level) of the bent $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(H_2O)_2]$ (**2b**), crystallized in the triclinic space group $P\bar{1}$. Hydrogen bond [Å, °]: O7–H7A 0.79, H7A···O2 2.59, O7···O2 3.187(3), O7–H7A···O2 133.2.

The chlorido-bridged trinuclear mixed-metal complexes of types **1** and **2** are labile and sensitive towards moisture. Previous results suggest that the exposure of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(CH_3CH_2OH)_2]$ to moisture leads first to ligand exchange on the central metal atom and then to the formation of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(H_2O)_2]$. Additional exposure to moisture finally breaks down the chlorido bridges and pulls the metal atoms apart, yielding ionic $[Ru(CO)_3Cl_3]_2[Fe(H_2O)_6]$.[6] Similar behavior was also observed with complex **1**. As in the case of the $RuCl_3$/Fe reaction, the $RuCl_3$/Co reaction produced an ionic decomposition product, $[Ru(CO)_3Cl_3]_2[Co(H_2O)_6]$ (**3**), with variable ratios (Figure 6).

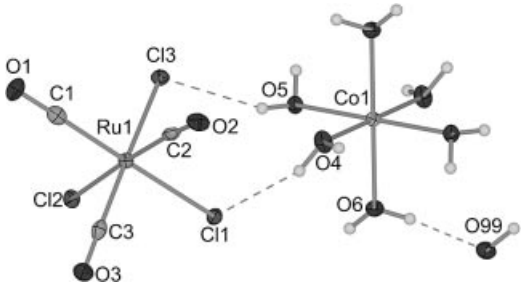

Figure 6. Thermal ellipsoid plot (50% probability level) of $[RuCl_3(CO)_3]_2[Co(H_2O)_6]\cdot 2(H_2O)$ (**3**). The symmetry-related water molecule is not shown. Hydrogen bonds [Å, °]: O4–H4A 0.85, H4A···Cl1 2.36, O4···Cl1 3.140(2), O4–H4A···Cl1 152.8, O5–H5B 0.84, H5B···Cl3 2.44, O5···Cl3 3.220(2), O5–H5B···Cl3 153.8, O6–H6B 0.84, H6B···O99 1.88, O6···O99 2.716(2), O6–H6B···O99 173.3.

Compared to $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(CH_3CH_2OH)_2]$ and $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(H_2O)_2]$, the decomposition of complexes **1** and **2** into the ionic product **3** seems to be slightly slower. For example, complex **1** can be stored in air much longer than the corresponding iron compound without severe decomposition.

In addition to complexes **1**, **2**, and **3**, crystallographic analysis of the reaction products obtained after the reduction of $RuCl_3$ in the presence of cobalt revealed other types of mononuclear products as well such as neutral $RuCl_2(H_2O)(CO)_3$ and $CoCl_2(H_2O)_4$, which could be identified by means of single-crystal X-ray diffraction. This suggests that an alternative decomposition route for trinuclear Ru-Co-Ru may also be possible. The formation of corresponding neutral mononuclear species has been observed in $RuCl_3$/Fe systems earlier, which means that a similar alternative route also exists in the case of $RuCl_3$/Co systems. However, it should be mentioned that, according to the very low yields of the neutral products, this route seems not to be very feasible. Actually, neutral products such as $RuCl_2(H_2O)(CO)_3$ were found only occasionally in some of the reaction products. Each reaction was repeated several times, and the main decomposition product was always found to be ionic $[Ru(CO)_3Cl_3]_2[Co(H_2O)_6]$.

The product distribution of the carbonylative reduction of $RuCl_3$ depends strongly on the reaction conditions. If the reaction is carried out without metal surfaces and if the CO pressure is high enough (> 20 bar) and the reaction time long enough (> 17 h), the dominating carbonylation product is zero-valent, fully carbonylated and reduced $Ru_3(CO)_{12}$. This seems to be true for both reactions, with or without the presence of the solid metal surface. The solvent also has an effect on the progression of the reaction and on the products formed during the reduction. If the alcohol solvent is replaced with water, the final carbonylation product is polymeric $[Ru(CO)_4]_n$.[23] However, the presence of the metal surface tends to favor the partially reduced and carbonylated ruthenium species. If $RuCl_3$ was simply heated under reflux in ethanol and in a CO flow in the presence of an iron or cobalt plate (17 h), $Ru_3(CO)_{12}$ was not detected at all. After 3 h of reaction with 20 bar of CO, the cluster product was still not observable. Increasing the reaction temperature from 125 °C to 150 °C led to the formation of $Ru_3(CO)_{12}$ after only 3 h of reaction with 20 bar of carbon monoxide, but under these conditions $Ru_3(CO)_{12}$ was only a minor product. At 50 bar of CO, ≥ 125 °C and ≥ 3 h reaction times with or without the presence of a metal surface, the principal product was an $Ru_3(CO)_{12}$ cluster. Cluster formation under similar conditions without metal surface is well known and reported by Bruce et al.[24] Nevertheless, it should be noted that partially carbonylated species can still be found even with elevated pressures (50 bar) and long reaction times (17–20 h), where $Ru_3(CO)_{12}$ is already the main product, including in reactions with a metal surface. It seems likely that products with partially reduced ruthenium centres $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6M(L)_2]$, and $[Ru(CO)_3Cl_3]_2[M(H_2O)_6]$ (M = Fe, Co and L = $H_2O$, $CH_3CH_2OH$) are stable enough to interfere with the reduction of ruthenium in the zero-valent state.

From the synthetic point of view, the formation of an unpredictable mixture of products is the main setback, which complicates the use of metal surfaces for synthetic purposes. The yields of the most interesting products, the mixed-metal trinuclear $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(L)_2]$ complexes, consistently remained rather low at around 8–15%. This is mainly due to the lability of the trinuclear compounds in the presence of moisture. However, compared to its Ru-Fe-Ru equivalent, $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(L)_2]$ can certainly be synthesized with better reproducibility and enhanced yields.

The reaction products **1**–**3**, which were obtained with adequate yields, were also analysed using IR spectroscopy. The common feature of all these compounds is that the arrangement of the carbonyl ligands around the ruthenium center is very similar in all of them. The facial arrangement of the CO ligands in each compound gives a ν(CO) pattern with two strong bands: a sharp band at higher wavenumbers around 2140–2145 $cm^{-1}$ and a broad- or double-headed one at lower wavenumbers at ca. 2055–2065 $cm^{-1}$. Two pairs of ν(CO) signals were found at 2143 $cm^{-1}$ and 2077 $cm^{-1}$ in the $CH_2Cl_2$ solution immediately after reaction, when ethanol is evaporated from the Ru-Co reaction solution and the solid material is dissolved in $CH_2Cl_2$. Typically, the higher band was sharp and the lower band much broader. The result closely resembles those found in reactions conducted with iron-containing surfaces, where the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

corresponding signals have been reported to be at 2143 $cm^{-1}$ and 2078 $cm^{-1}$.[6]

ATR-IR (Attenuated Total Reflectance IR) measurements were performed for the chlorido-bridged Ru-Co-Ru complexes **1** and **2**, and for ionic **3**. In the IR measurements of the reaction solutions different complexes could not be assigned, but with the ATR technique the complexes could be identified. In the case of the ATR measurements two bands were detected again, and as with the FTIR spectra the peak at the higher wavenumber was once again strong and rather sharp. The lower peak was double-headed and actually a combination of two peaks. In the spectrum of complex **1** the highest signal is at the wavenumber 2137 $cm^{-1}$, while the lower band has two peaks, at 2075 and 2054 $cm^{-1}$. Similar patterns can be found also in the spectra of the compounds **2** and **3** with the wavenumbers 2135, 2070, and 2054 $cm^{-1}$ for **2** and 2139, 2075, and 2056 $cm^{-1}$ for **3**.

### The Effect of the Halide in the Reducing Salt

In order to study the role of the halide in the reducing salt, the $RuCl_3$ was replaced with $RuI_3$. Otherwise, the reductive carbonylation reaction with cobalt or iron surfaces was carried out under conditions similar to those used for a typical $RuCl_3$ reduction (20 bar of CO, 125 °C, 3 h). Again, the release of iron and cobalt cations was observed in the reaction. The most noticeable feature of these reactions was the absence of halide-bridged trinuclear mixed-metal products. They were detected in reduction reactions with either of the metals (Fe, Co) used. This may indicate that the trinuclear iodido-bridged products are less stable than their chlorido-bridged analogues. The reaction with $RuI_3$ produced variable amounts of $[RuI_3(CO)_3]_2[Fe(H_2O)_6]$ (**4**), $[RuI_3(CO)_3]_2[Co(H_2O)_6]$ (**5**), $[RuI_2(CO)_3]_2$ (**11**) and $Ru(CO)_4I_2$ (**12**), which were characterized by single-crystal X-ray diffraction. Structurally, compounds **4** and **5** are isostructural with the corresponding complex **3** formed in the reduction reactions of $RuCl_3$. The structures of **4**, **11** and **12** are shown in Figures 7, 8, and 9.

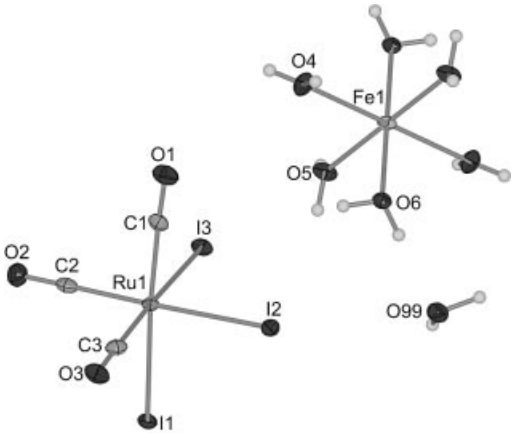

Figure 7. Thermal ellipsoid plot (50% probability level) of $[RuI_3(CO)_3]_2[Fe(H_2O)_6]\cdot 2(H_2O)$ (**4**). The symmetry-related second $[RuI_3(CO)_3]^-$ anion and the solvent water molecule are not shown. Hydrogen bonds [Å, °]: O4–H4A 0.78, H4A···O1 3.14, O4···O1 3.534(6), O4–H4A···O1 114.2, O5–H5A 0.81, H5A···I2 2.83, O5···I2 3.602(4), O5–H5A···I2 159.3, O5–H5B 0.79, H5B···I3 3.32, O5···I3 3.721(4), O5–H5B···I3 176.1, O6–H6A 0.85, H6A···O(99) 1.90, O6···O99 2.752(5), O6–H6A···O99 176.1.

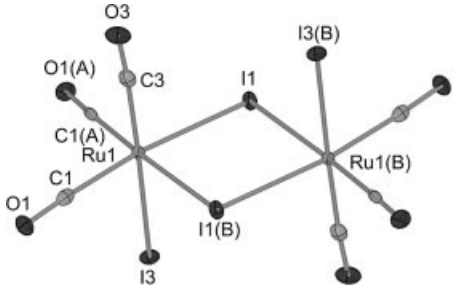

Figure 8. Thermal ellipsoid plot (50% probability level) of $[RuI_2(CO)_3]_2$ (**11**). Symmetry transformations were used to generate equivalent atoms: (A) $x, -y, z$; (B) $-x, -y, -z + 1$.

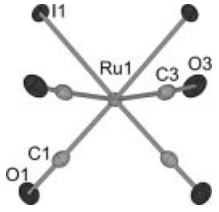

Figure 9. Thermal ellipsoid plot (50% probability level) of $RuI_2(CO)_4$ (**12**).

Another difference between the $RuI_3$ reactions and the reduction reactions of $RuCl_3$ was the strongly decreased formation of $Ru_3(CO)_{12}$. In fact, this was not observed at all even at higher pressures (50 bar) and with long reaction times (20 h). In the reactions under 50 bar pressure of carbon monoxide, the reduction reaction (125 °C, 3–20 h) produced $[RuI_2(CO)_3]_2$ (**11**), presented in Figure 8. The $RuI_2(CO)_4$ (**12**) presented in Figure 9 was found only in the reactions with iodine salt, while no equivalent chloride product was observed in the $RuCl_3$ reactions.

### The Carbon Monoxide Reduction of $OsCl_3$ in the Presence of a Sacrificial Metal Surface

The carbonylative reduction of $OsCl_3$ follows the general lines of the reduction of $RuCl_3$. The final reduction product is the zero-valent cluster $Os_3(CO)_{12}$, especially under high pressures.[18–21] In the current study, the reduction reactions were performed in an alcohol solution either under reflux with a CO stream passing through the reaction solution or in a pressurized autoclave. In both of the reaction setups a sacrificial metal plate (stainless steel, Fe or Co) was added to the system. During the reduction reaction the colour of the solution turned from black to brownish-yellow when an iron-containing plate was used, and greenish-blue when cobalt was used. In all of the osmium reactions, either under reflux or in an autoclave, a dark brown-grey metallic powder was formed. The powder was removed from the solution by filtering prior to crystallization of the carbon-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ylation products. The metallic powder material was characterized with the aid of EDS measurements, which confirmed that the solid material consisted mainly of metallic osmium. The filtrate was analyzed after it had been concentrated and redissolved in dichloromethane. IR analysis revealed two peaks in the ν(CO) region with both Os-Fe and Os-Co systems. In solutions containing Os-Fe, the higher band at 2135 $cm^{-1}$ was again sharp and the lower one at 2058 $cm^{-1}$ was broader. A similar pattern was also found with the Os-Co reaction solution, which produced corresponding peaks at 2135 $cm^{-1}$ and 2054 $cm^{-1}$. In comparison with the Ru-Fe/Co bands, the Os-Fe/Co bands shifted towards lower wavenumbers, but the shape and relative intensities of the bands remained the same in all cases.

The crystallization of the osmium-iron and osmium-cobalt products was much more difficult than that of the ruthenium-iron or, in particular, of the ruthenium-cobalt products. In consequence, the final yields of the separated products remained very low. This also prevented further analysis of the isolated products. Crystallization was performed according to the same procedure as for the ruthenium reactions. Only the mononuclear products could be isolated and characterized from the Os-Fe reactions. Ionic $[OsCl_3(CO)_3]_2[Fe(H_2O)_6]$ (**6**) is the structural equivalent of $[RuCl_3(CO)_3]_2[Co(H_2O)_6]$ (**3**) and another ionic product $[OsCl_3(CO)_3][FeCl_2(H_2O)_4]$ (**7**). In **7**, the osmium atom is in an oxidation state of 2+ and the iron atom is in an oxidation state of 3+. However, this minor product was obtained only from one reaction. The equivalent of complex **7** was observed neither in any of the Ru-Co or Ru-Fe reactions nor in the Os-Co reactions. Another mononuclear reduction product of $OsCl_3$ with no ruthenium counterpart was $OsCl_2(CO)_3(CH_3CH_2OH)$ (**10**). This product was also a minor product found only from one reaction. The solid-state structure of **10** consists of two osmium moieties bound together with a hydrogen bond (Figure 10).

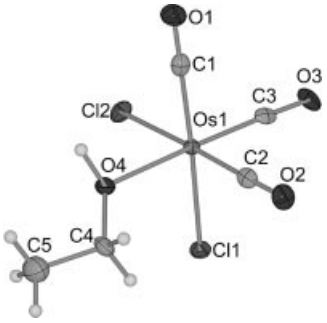

Figure 10. Thermal ellipsoid plot (50% probability level) of $OsCl_2(CO)_3(EtOH)$ (**10**).

From the osmium-cobalt reaction, $[OsCl_3(CO)_3]_2[Co(H_2O)_6]$ (**8**) could be isolated and characterized by means of the single-crystal X-ray diffraction (Figure 11). ATR measurements of the analysed complex **8a** revealed a pattern of signals that was similar to those found by means of the measurements of the Ru-Co complexes **1**, **2** and **3**. The higher band was again sharp at a wavenumber of 2126 $cm^{-1}$, and the lower peak was a combination of two peaks at wavenumbers of 2043 $cm^{-1}$ and 2024 $cm^{-1}$. Compared with the ATR-IR spectra of ruthenium analogues, the signals are shifted to a lower wavenumber, but the shape and intensity of the signals remained the same.

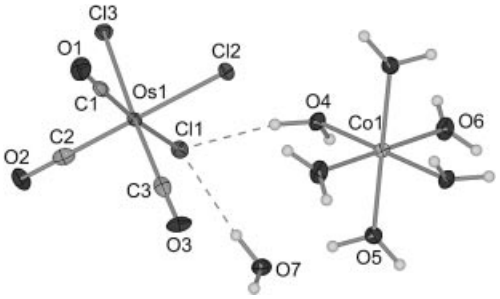

Figure 11. Thermal ellipsoid plot (50% probability level) of $[OsCl_3(CO)_3]_2[Co(H_2O)_6]\cdot 2(H_2O)$ (**8a**). The symmetry-related second $[OsCl_3(CO)_3]^-$ anion and the second water molecule are not shown. Hydrogen bonds [Å, °]: O4–H4B 0.99, H4B···Cl1 2.27, O4···Cl1 3.216(3), O4–H4B···Cl(1) 159.9, O7(A)–H7(A) 0.94, H7(A)···Cl1 2.36, O7(A)···Cl1 3.292(3), O7–H7(A)···Cl1 173.5.

An ethanol-containing trinuclear complex with chlorido bridges, $[Os_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ (**9**), could also be found in the osmium-cobalt reactions. Structurally, **9** is similar to $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6M(CH_3CH_2OH)_2]$ (M = Fe, Co) (Figure 12).

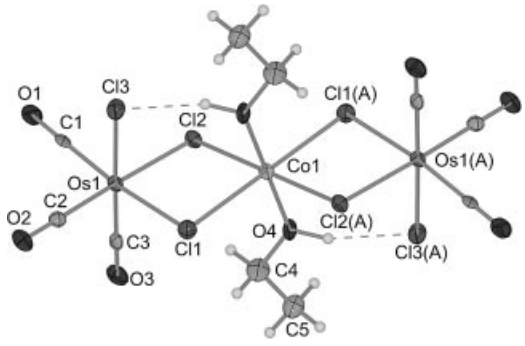

Figure 12. Thermal ellipsoid plot (50% probability level) of $[Os_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ (**9**). Hydrogen bond [Å, °]: O4–H4 0.95, H4···Cl3(A) 2.15, O4···Cl3(A) 3.072(6), O4–H4···Cl3(A) 162.4.

The formation of trinuclear halide-bridged compounds is not as favorable with Os/Fe and Os/Co metal pairs as it is with the Ru/Co pair. Complex **9** was separated in some of the reactions, but significantly more rarely than with the ruthenium analogue **1**. Although Os/Co trinuclear halide-bridged complexes were rare and Os/Fe analogues were not detected during our study, this does not necessarily mean that such a compound cannot be formed at all. Such a product may either be less stable, or the absence of these complexes may simply be due to the fact that the reaction setup as it now exists is unsuitable for osmium reactions. In addition, it can be stated that control of the products in the $OsCl_3$ reactions was undoubtedly more difficult than with $RuCl_3$.

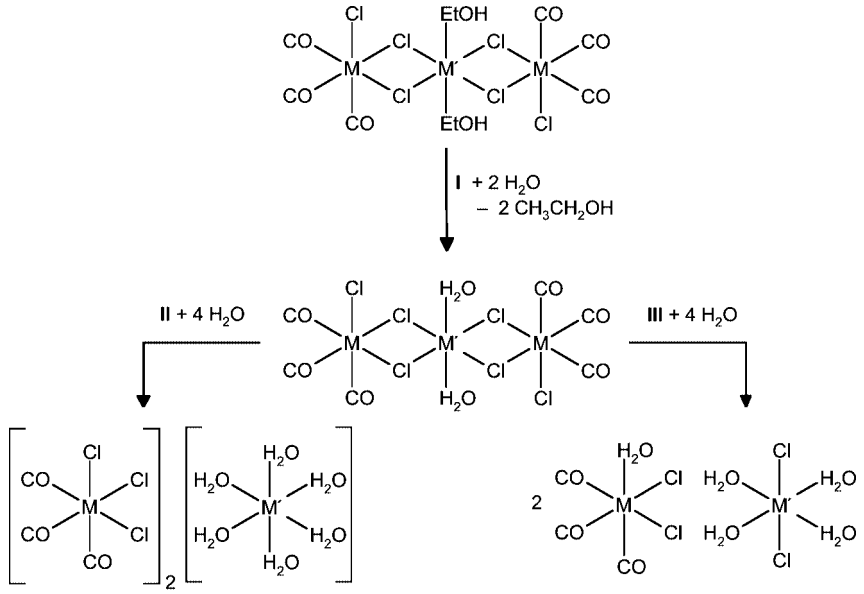

Scheme 1. Decomposition steps of μ-Cl dimetallic trinuclear complexes.

### Stability of the Trinuclear Complexes

Computational work was done to investigate the stability of the complexes by means of their relative energies. In our previous study we investigated[6] the decomposition path of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(CH_3CH_2OH)_2]$. The presence of water launches the decomposition of the halide-bridged trinuclear mixed-metal complexes. The decomposition pathway proceeds by the replacement of the ethanol ligands with water and the formation of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Fe(H_2O)_2]$ and its eventual decomposition into the mononuclear products $[RuCl_3(CO)_3][Fe(H_2O)_6]$, $[RuCl_2(CO)_3(H_2O)]$ and $[FeCl_2(H_2O)_4]$. In the current study we have investigated a similar decomposition route for the Ru/Co, Os/Fe and Os/Co systems by using computational DFT methods. The decomposition steps involved are summarized in Scheme 1 and in Table 1.

Table 1. Calculated DFT energies of the decomposition routes presented in Scheme 1. Values in bold are taken from ref.[9]

| M | M′ | $E_I$ (kJ/mol) | $E_{II}$ (kJ/mol) | $E_{III}$ (kJ/mol) |
|---|---|---|---|---|
| **Ru** | **Fe** | **–34** | **–325** | **67** |
| Ru | Co | –31 | –287 | 68 |
| Os | Fe | –33 | –327 | 92 |
| Os | Co | –29 | –287 | 106 |

The first step in the decomposition of $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(CH_3CH_2OH)_2]$, the replacement of $CH_3CH_2OH$ with $H_2O$ at the bridging metal atom (either Fe or Co), is favourable with all of the metal combinations. The reaction energy of the ligand exchange is around –30 kJ/mol. The two possible structural isomers of $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(H_2O)_2]$, bent and linear, are energetically very similar to each other, which explains the co-existence of both structures. The relative energy between the bent and linear isomers for all the metal combinations is ca. 4 kJ/mol.

The decomposition of $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(H_2O)_2]$ can follow two different main steps (steps **II** and **III** in Scheme 1). The addition of 4 equiv. of $H_2O$ breaks down the chlorido bridges and results in ionic $[MCl_3(CO)_3]_2[M'(H_2O)_6]$ or $[MCl_2(CO)_3(H_2O)]$ and $[M'Cl_2(H_2O)_4]$. According to our calculations, the relative energies of the decomposition products formed along step **II** are around 300 kJ/mol more favourable than for the trinuclear chlorido-bridged complexes. The result agrees well with the experimental results: $[MCl_3(CO)_3]_2[M'(H_2O)_6]$ is the favoured product, although $[MCl_2(CO)_3(H_2O)]$ and $[M'Cl_2(H_2O)_4]$ have been observed from reactions of the ruthenium-cobalt system. It also seems that decomposition step **III** is around 40 kJ/mol more favourable with iron than with cobalt, which is also consistent with experimental observations. According to our calculations, in $M'Cl_2(H_2O)_4$ the most favourable isomer is the *trans*(Cl) structure when the metal atom is iron and the *cis*(Cl) structure when the metal atom is cobalt, although the energy difference between the isomers is less than 5 kJ/mol for both metal chlorides. There are no notable differences in the calculation results between the Ru-Fe, Ru-Co, Os-Fe and Os-Co systems.

## Conclusions

The reductive carbonylation of $MCl_3$ (M = Ru or Os) in the presence of a metal surface (Fe or Co) produces a variety of mixed-metal products, whose components originate from the reducing $MCl_3$ and from the oxidizing surface. The metal ions released from the oxidizing surface can be used for an in situ complex formation. Although this approach produces a mixture of products, it nevertheless provides a useful method for synthesizing trinuclear mixed-metal compounds of the type $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(L)_2]$

(M = Ru, Os; M′ = Fe, Co; L = $CH_3CH_2OH$, $H_2O$). For example, a synthesis of $[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ can be repeated with moderate yields. The main problem in the production of $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(CH_3CH_2OH)_2]$ is that this can be decomposed relatively easily by moisture into mononuclear species such as $[MCl_3(CO)_3]_2[M'(H_2O)_6]$, $[MCl_2(CO)_3(H_2O)]$ and $[M'Cl_2(H_2O)_4]$.

Mechanistically, the reductive carbonylation of $MCl_3$ (M = Ru or Os) in the presence of a metal surface (Fe or Co) follows similar reaction pathways regardless of the reducing metal halide and oxidizing metal surface used. Further, the decomposition of the mixed-metal trinuclear $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(L)_2]$ by moisture is similar in all studied cases. In the case of $[M_2Cl_2(\mu\text{-}Cl)_4(CO)_6M'(CH_3CH_2OH)_2]$, the first step in the decomposition is the replacement of the ethanol ligands by water at the central metal atom (Fe or Co). This is followed by cleavage of the chlorido bridges and the formation of mononuclear products. Energetically, the most favorable decomposition products are ionic compounds of the type $[MCl_3(CO)_3]_2[M'(H_2O)_6]$.

The iodide salt $RuI_3$ can be used instead of $RuCl_3$ in the preparation of ionic products, but no trinuclear compounds of the type $[M_2I_2(\mu\text{-}I)_4(CO)_6M'(L)_2]$ have been obtained so far. This is probably due to the poorer stability of $[M_2I_2(\mu\text{-}I)_4(CO)_6M'(L)_2]$ compared to its chlorido equivalents.

## Experimental Section

**Materials and Measurements:** $RuCl_3{\cdot}x(H_2O)$ (99.9%) was purchased from Alfa Aesar, $OsCl_3{\cdot}x(H_2O)$ from Sigma Aldrich and $RuI_3$ from Strem. The metal plates Co (99.9%, CO000279/3), Fe (99.5%, FE000400/11) and stainless steel were from GoodFellow. The cobalt powder (99.995%) was a product from Aldrich. MeOH (p.a.) and $CH_2Cl_2$ (p.a.) were obtained from Fluka, hexane (p.a.) from Merck, and ethanol (99.5%) from Primalco. The carbon monoxide (98%) used in reactions was purchased from Messer and AGA. The FTIR spectra were measured with a Nicolet Magna IR Spectrometer 750, and ATR-IR measurements were performed using an FTS 7000 Series DIGILAB FTIR spectrometer equipped with a UMA 600 DIGILAB microscope. CE Instruments EA 110 CHNS-O was used in the elemental analyses. Qualitative analyses of cobalt and osmium were conducted using an FE-SEM Hitachi S-4800 Scanning Electron Microscope equipped with a Norman System Six EDS.

**Syntheses**

**High-Pressure Reactions:** Metal trichloride [$RuCl_3{\cdot}x(H_2O)$, $RuI_3$ or $OsCl_3{\cdot}x(H_2O)$] reduction reactions were carried out in a Berghof autoclave equipped with a PTF liner. The solid metals (Co, Fe, stainless steel, $7 \times 7$ mm $\times$ 0.02–0.03 mm or 50 mg of cobalt powder) and 100 mg of metal trichloride reagent were placed in the liner together with 4 mL of ethanol. The autoclave was pressurized with 10, 20 or 50 bar of carbon monoxide (in a typical reaction the CO pressure was 20 bar), quickly heated to 125 °C, and maintained at that temperature for 3 h. After the reaction, the autoclave was cooled in an ice bath. The reaction solution was filtered to remove any possible solid metallic precipitations formed during the reaction. The filtrate was concentrated to dryness and the solid residue dissolved in $CH_2Cl_2$. Crystallization was performed using the $CH_2Cl_2$ solution by slow concentration or by adding hexane to the $CH_2Cl_2$ solution.

**Reactions under Reflux:** Metal trichloride [$RuCl_3{\cdot}n(H_2O)$ or $OsCl_3{\cdot}3(H_2O)$, 250 mg] was placed in a two-necked round-bottom vessel with a metal plate (Co or Fe or stainless steel, $7 \times 7$ mm). $MCl_3$ was diluted in 40 mL of ethanol and the reaction mixture was refluxed in a carbon monoxide stream for 17–20 h, until the reaction solution was yellowish with iron and blue or green with cobalt. Any solid material formed during the reduction was filtered off and the filtrate was placed in a 100 mL round-bottom vessel. The solution was concentrated to dryness and the residue dissolved in $CH_2Cl_2$. The products were crystallized as described above.

All of the reactions produced a mixture of products with variable ratios depending on the reaction time and conditions. In the cases of complexes **1**, **2**, **3**, **8** and **11**, the yields were very low and varied

from reaction to reaction. In these cases the identification of the products was based on single-crystal X-ray analysis.

**Analysis of Separated and Purified Complexes 1–3, 8 and 11**

**$[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(CH_3CH_2OH)_2]$ (1):** $C_{10}H_{12}Cl_6CoO_8Ru_2$ (733.99): calcd. C 16.36, H 1.65; found C 16.24, H 1.69. ATR-IR $\tilde{\nu}$(CO) = 2137 (vs), 2075 (vs), 2054 $cm^{-1}$ (vs). Yield: 10–15%.

**$[Ru_2Cl_2(\mu\text{-}Cl)_4(CO)_6Co(H_2O)_2]\cdot(H_2O)$ (2):** $C_6H_6Cl_6CoO_9Ru_2$ (695.90): calcd. C 10.36, H 0.87; found C 10.11, H 0.97. ATR-IR $\tilde{\nu}$(CO) = 2135 (vs), 2070 (vs), 2054 $cm^{-1}$ (vs). Yield: 8%.

**$[RuCl_3(CO)_3]_2[Co(H_2O)_6]\cdot(H_2O)$ (3):** $C_6H_{14}Cl_6CoO_{13}Ru_2$ (767.96): calcd. C 9.38, H 1.84; found 9.34, H 2.01. ATR-IR $\tilde{\nu}$(CO) = 2139 (vs), 2075 (vs), 2056 $cm^{-1}$ (vs). Yield: 16%.

**$[OsCl_3(CO)_3]_2[Co(H_2O)_6]$ (8):** $C_6H_{12}Cl_6CoO_{12}Os_2$ (928.21): calcd. C 7.76, H 1.30; found C 7.70, H 1.31. ATR-IR $\tilde{\nu}$(CO) = 2126 (vs), 2043 (vs), 2024 $cm^{-1}$ (vs). Yield: 24%.

**$[RuI_2(CO)_3]_2$ (11):** $C_{60}I_4O_6Ru_2$ (877.82): calcd. C 8.21; found C 8.21. IR ($CH_2Cl_2$): $\tilde{\nu}$(CO) = 2118 (s) , 2055 (sh, s) $cm^{-1}$.

**X-ray Crystal Structure Determinations:** The crystals were immersed in cryo-oil, mounted in a Nylon loop and measured at a temperature of 100–150 K. The X-ray diffraction data was collected by means of a Nonius KappaCCD diffractometer using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The Denzo-Scalepack[25] or EvalCCD[26] program packages were used for cell refinements and data reductions. The structures were solved by direct methods or by the heavy-atom method using SHELXS-97,[27] SIR-97,[28] or

SIR2004[29] with a WinGX[30] graphical user interface. An empirical absorption correction was applied to all of the data (XPREP in SHELXTL v.6.14–1[31] or SADABS v.2.10[32]). Structural refinements were carried out using SHELXL-97.[33] In **1**, **2a**, **2c**, **3**, **4**, **5**, **7**, **8a**, **9** and **10** the $H_2O$ and OH hydrogen atoms were located from the difference Fourier map but constrained to ride on their parent atom with $U_{iso}$ = 1.5 $U_{iso}$(parent atom). In **2b** the $H_2O$ hydrogen atoms were also located from the difference Fourier map and refined with fixed coordinates and fixed $U_{iso}$ = 0.05. In **6** and **8b** the idealized positions of the $H_2O$ hydrogen atoms were estimated using the HYDROGEN[34] program and they were constrained to ride on their parent atom by means of $U_{iso}$ = 1.5 $U_{iso}$(parent atom). Other hydrogen atoms were positioned geometrically and were also constrained to ride on their parent atoms by means of C–H 0.98–0.99 Å and $U_{iso}$ = 1.2–1.5 $U_{iso}$(parent atom). The structure of **12** is known and has been previously published in the early 1960s by Dahl and Wampler.[35] The crystallographic details are summarized in Tables 2, 3, 4 and 5. The thermal ellipsoid plots and selected bond lengths and angles for structures **1**, **2a**, **3**, **4**, **8a** and **9**–**12** are given in Figures 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12 and Tables 6 and 7; for the other structures, see the Supporting Information. CCDC-630761 to -630775 (**1**–**12**, respectively) contain the supplementary

Table 7. Selected bond lengths [Å] and bond angles [°] of the complexes **8a** and **9**–**12** presented in Figures 8, 9, 10, 11, and 12.

crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Work:** Full geometry optimization of the complexes was performed using the DFT method with a non-local hybrid functional B3PW91. The Stuttgart-Dresden ECP basis set was used for the metals (Fe, Co, Ru and Os)[36] and 6-31G* for others (C, H, O and Cl). The calculations were made with the Gaussian03 program package.[37]

**Supporting Information** (see footnote on the first page of this article): Figures S1–S5: Thermal ellipsoid plots (at 50% probability level) of **2c**, **5**, **6**, **7**, **8a** and **10**; Figures S6 and S7: ATR-IR spectra of complexes **1**, **2**, **3** and **8**.

## Acknowledgments

Financial support in the form of a grant (grant no. 210265) provided by the Academy of Finland is gratefully acknowledged. The authors would also like to thank Dr. Sari Suvanto for the EDS and ATR measurements, Ritva Romppanen for the elemental analysis measurements, and Dr. Larisa Oresmaa for her valuable comments.

# Precursors for Assembly of Supramolecules Containing Quadruply Bonded $Cr_2^{4+}$ Units: Systematic Preparation of $Cr_2$(formamidinate)$_n$(acetate)$_{4-n}$ ($n$ = 2–4)

**F. Albert Cotton,[a][†] Zhong Li,[a] and Carlos A. Murillo*[a]**

**Keywords:** Metal–metal bonds / Supramolecular chemistry / Chromium / Corner piece precursors

Four quadruply bonded dichromium complexes with mixed-ligand sets, $Cr_2$(formamidinate)$_n$(acetate)$_{4-n}$ ($n$ = 2–4), were synthesized from reactions of anhydrous $Cr_2(O_2CCH_3)_4$ and formamidinate anions. The Cr–Cr bond lengths fall in the range for "supershort" Cr–Cr bonds as they vary from 1.8897(5) Å to 2.012(1) Å. The distance variation depends on the presence or absence of weak axial interactions. Because formamidinate ligands are less labile than acetate groups, these compounds may be useful building blocks for the construction of neutral supramolecules having dichromium units linked by polydentate dianions.

## Introduction

There is emerging interest in the use of metal atoms (or ions) as key elements in the self-assembly of metal-organic supramolecular arrays.[1] Most of these studies have focused on systems with single-metal building blocks of the type $ML_2$, where the L ligands are usually diamine, diphosphane or dicarboxylate and the metal atoms are Pt, Pd, Zn or Cd.[2] These species usually have ions with large charges. The introduction of metal–metal bonded dinuclear units into this field have enriched the diversity of the geometry and properties of the supramolecular systems and allowed the syntheses of neutral molecules.[3] Appropriate selection of the metal containing units and suitable linkers have led to the formation of a variety architectures, including dimers of dimers, loops, triangles, squares, complex polygons and extended 2D and 3D materials.[4]

One of the best strategies for construction of large molecules containing metal–metal bonds has been the use of precursors having subunits containing paddlewheel species with mixed ligands in which some of the paddles are nonlabile formamidinate groups, while the remaining coordination sites are occupied by easily displaceable ligands, such as acetonitrile molecules or carboxylate groups. The labile ligands are then replaced by polydentate linkers to assemble the target supramolecules whose structures depend on the dimensions of the linkers and shape of the corner piece precursors. On the basis of the appropriate choice of subunits and linkers, three basic assembly schemes have been generally employed: (1) Two metal–metal bonded units supported by three formamidinate groups are linked to give dimers of dimers as shown in Scheme 1. Examples are the dimers of dimolybdenum compounds that have been obtained by reactions of $Mo_2(DAniF)_3(CH_3CN_{eq})_2^+$ species (DAniF = *N*,*N*′-di-*p*-anisylformamidinate) with tetraalkylammonium salts of various dicarboxylates.[5] When $Mo_2(DAniF)_3(O_2CCH_3)$ was used as starting material, even the more basic diamidate or the all-nitrogen-donor linker fluoflavinate may be used as linkers and these ligands enable very high intramolecular electronic communication.[6] Compounds having two $Ru_2(DAniF)_3$ units linked by terephthalate anions have also been made by reaction of $(NBu_4)_2O_2CC_6H_4CO_2$ with the building block $Ru_2(DAniF)_3(O_2CCH_3)Cl$[7] and analogous $Ru_2$ compounds with diphenylformamidinate have also been made.[8] (2) Dimetal units with two *cisoid* formamidinate groups with rigid dianions allow the formation of squares, triangles (Scheme 2) and, under some circumstances, loops. Examples are the series of molecular squares assembled by reactions of [*cis*-$M_2(DAniF)_2(CH_3CN_{eq})_4]^{2+}$ (M = Mo, Rh) and dicarboxylate linkers.[9] Sometimes equilibria between triangles and the corresponding squares exist in solution because of entropy-dominated processes.[10] (3) Precursors with structures having *transoid* nonlabile formamidinate groups are expected to give one-dimensional polymers (Scheme 3). Current work in our laboratory involves the synthesis of ladder structures from *trans*-$M_2(DAniF)_2(O_2CCH_3)_2$ compounds. In addition, by utilizing the axial coordination and a combination of these linkage modes, more complex architectures can be made.[11] What is clear from this discussion is that building blocks with mixed-ligand sets of different

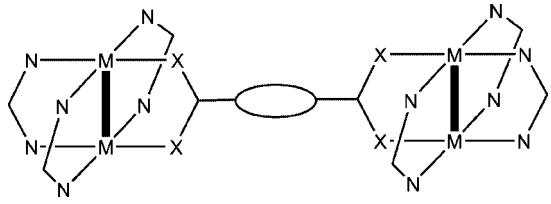
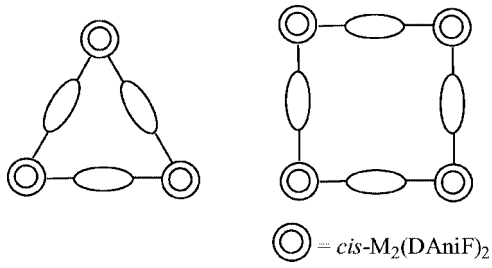
labilities allow selective substitution of the more labile ligands, and preparation of such species is critical for the successful assembly of large molecules.



Scheme 1.



Scheme 2.

An additional advantage of using M–M bonded units in building supramolecules is that a wide selection of transition metal atoms are available and their electronic structures are generally well understood, which allow the introduction of internal spectroscopic probes. Thus far, most of the studies have been limited to dimolybdenum compounds and a handful of molecules containing $W_2$, $Ru_2$ and $Rh_2$ units. Even though the first-row transition metal, chromium, is prone to support metal–metal bonds, and hundreds of compounds with $Cr_2^{4+}$ core have been studied no efforts have been devoted to the methodical construction of appropriate corner pieces.[12] It should be noted that generally chromium compounds are useful in a variety of applications such as catalysts in organic synthetic applications[13] and are also found to be of importance in biosystems.[14] Recently an interesting compound with a Cr-to-Cr bond of order 5 has been reported, in a work that should encourage further exploration of the chemistry of this element.[15]

As a first step in the syntheses of large molecules containing $Cr_2^{4+}$ units, here we report the systematic syntheses of dichromium compounds of the type $Cr_2(formamidinate)_n(acetate)_{4-n}$ ($n$ = 2–4). The compounds are a pair of isomers, namely *cis*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$, **1**, [$DPh^{Cl}F$ = (*o*-$ClC_6H_4N)_2CH$], and *trans*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$ (**2**), as well as $Cr_2(DAniF)_3(O_2CCH_3)$ (**3**) and the parent compound $Cr_2(DAniF)_4$ (**4**). All of these compounds have been characterized structurally and by various spectroscopic techniques.

## Results and Discussion

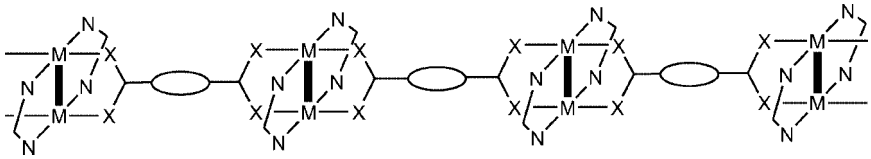
### Syntheses

Reaction of 2 equiv. of $LiDPh^{Cl}F$ with 1 equiv. of anhydrous $Cr_2(O_2CCH_3)_4$ in THF at –70 °C affords **1** and **2** as shown by the isolation of two types of crystals when a benzene solution of the isomer mixture was layered with isomeric hexanes: red acicular crystals of *cis*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$ (**1**) and yellow-orange block crystals of *trans*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$ (**2**). Because of their distinctive shape and color, these isomers can be manually separated in a relatively easy manner and isolated in reasonable yields. It should be mentioned that the appropriate selection of the formamidinate ligands is important as earlier studies had shown that an analogous reaction of $Cr_2(O_2CCH_3)_4$ with 2 equiv. of $LiDPh^{OMe}F$ [$DPh^{OMe}F$ = (*o*-$CH_3OC_6H_4N)_2CH$] gave only the *cis* product,[16] while reaction of the heavier congener $Mo_2(O_2CCH_3)_4$ and 2 equiv. of HDAniF in the presence of $NaOCH_3$ exclusively produced the *trans* species, namely *trans*-$Mo_2(DAniF)_2(O_2CCH_3)$.[17] In the latter study, the *cis* isomer, *cis*-$Mo_2(DAniF)_2(O_2CCH_3)_2$, was obtained from a two-step reaction in which first $Mo_2(DAniF)_4$ and $(Et_3O)BF_4$ in $CH_3CN$ reacted to produce *cis*-$Mo_2(DAniF)_2(CH_3CN_{eq})_4^{2+}$. This reaction was followed by addition of acetate anions which replaced the acetonitrile molecules in the intermediate.

Once **1** and **2** are formed and isolated, these isomers are stable as the $^1H$ NMR spectra of these isomers in $CDCl_3$, which are significantly different from each other, do not change over a period of many hours. The spectra are thus consistent with retention of the geometry in solution.

An analogous reaction between $Cr_2(O_2CCH_3)_4$ but with 3 equiv. of LiDAniF gave complex **3** which has three DAniF groups and one acetate ligand. It should be noted that even when only 2 equiv. of LiDAniF were used, the isolated product was $Cr_2(DAniF)_3(O_2CCH_3)$ and under such conditions no species having the formula $Cr_2(DAniF)_2(O_2CCH_3)_2$ was observed. Furthermore, when traces of water were present in the reaction mixture or whenever an excess of LiDAniF was used, compound **4** was the only isolated species.[18] This compound can also be prepared conveniently and in better yield by reaction of LiDAniF and $CrCl_2$. Compounds **1**–**4** are soluble in common solvents such as THF, dichloromethane, toluene and benzene.

The CVs of **1**–**4** were recorded in $CH_2Cl_2$ using scan rates of 100 mV/s and 0.1 M $Bu_4NPF_6$ as electrolyte. The oxidation processes are irreversible and the potentials ranged from 0.62 V to 1.00 V. This is not unusual for $Cr_2^{4+}$ species which usually decompose upon oxidation. The only $Cr_2^{5+}$ product known so far was produced by oxidation of



Scheme 3.

$Cr_2(DPPC)_4$ (DPPC is the guanidinate-type species *N*,*N*′-diphenyl-1-pyrrolidine carbodiimidate). For $Cr_2(DPPC)_4$ two quasi-reversible waves were observed in the CV having $E_{1/2}$ values of 0.02 and 1.10 V.

### Structural Results

Compounds **1**–**4** have been structurally characterized by single crystal X-ray diffraction and their structures are shown in Figure 1. Compound **1** crystallized in the space group $P2_1/n$ with the molecule residing on a general position. The Cr–Cr bond length of 2.0010(6) Å (Table 1) falls in the range of 1.83–2.60 Å found for Cr–Cr distances in paddlewheel species.[12] For such compounds, the metal–metal distances are affected not only by the identity of the supporting ligand but are very sensitive to the presence or absence of axial interactions. For example, the Cr–Cr distance for the $Cr_2(O_2CCH_3)_4$ molecule in gas phase is 1.97 Å, but this distance increases to 2.369(2) Å when two pyridine molecules coordinate to the axial sites.[19] In **1**, there is no direct axial coordination, however, there are weak axial interactions because the two *cis* formamidinate ligands provide one chlorine atom each at distances of 2.817 and 2.864 Å for Cr(1)···Cl(1) and Cr(2)···Cl(4), respectively. For comparison, in the paddlewheel compound of $Cr_2(DPh^{Cl}F)_4$, [Cr–Cr 2.208(2) Å] the distances between the chlorine and chromium atoms (2.766 Å) are shorter than those in **1**.[20] As a consequence, the Cr–Cr bond length in $Cr_2(DPh^{Cl}F)_4$ [2.208(2) Å] is considerably longer than that in **1** [2.0010(6) Å]. The effect of weak axial interactions on dichromium units has also been documented in compounds with ligands such as 2,6-bis(phenylimino)piperidine, 2,2′-dipyridylamine.[21]

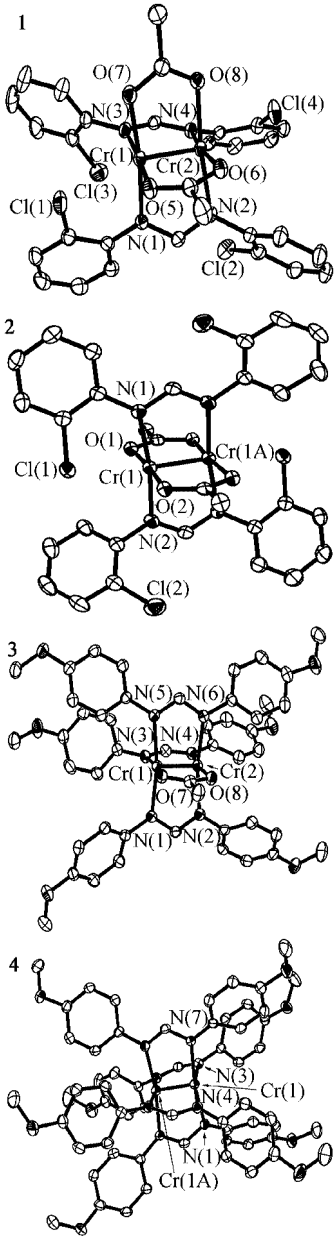

Figure 1. Structures of **1**–**4** with displacement ellipsoids drawn at the 40% probability level. Note the presence of weak Cr···Cl axial interactions in **1** and **2** and the absence of axial interactions in **3** and **4**. The Cr–Cr distances [2.0010(6) and 2.012(1) Å] for **1** and **2**, respectively, are longer than for **3** and **4** [1.8897(5) and 1.924(1) Å, respectively].

Table 1. Selected bond lengths [Å] for **1**–**4**.

| | **1** | **2**·$C_6H_6$ | **3** | **4** |
|---|---|---|---|---|
| Cr(1)–Cr(2) | 2.0010(6) | | 1.8897(5) | |

| Cr(2)–O(2) | | 2.017(3) | | |
| Cr(2)–N(4) | 2.043(2) | | 2.048(2) | 2.054(2) |
| Cr(2)–N(6) | | | 2.033(2) | |
| Cr(2)–O(6) | 1.992(2) | | | |
| Cr(2)–O(8) | 2.015(2) | | 2.025(2) | |

Compound **2**, an isomer of **1**, crystallized in the space group $P\bar{1}$ with the molecule residing on an inversion center. The Cr–Cr bond length of 2.012(1) Å is very similar to that in **1**. Again the two *trans* formamidinate ligands provide one chlorine donor atom capable of interacting with a chromium atom at a distance of 2.793 Å.

For **3**, which crystallized in the space group $P2_1/c$ with $Z$ = 4, the Cr–Cr bond length of 1.8897(5) Å is within the range found in *super-short* quadruply bonded compounds. This is due to the lack of axial coordination by either solvent or other donor atoms in the formamidinate ligand. The bulky formamidinate groups also prevent intermolecular interactions between Cr and O atoms which tend to lengthen the Cr–Cr distances such in the structure of anhydrous $Cr_2(O_2CR)_4$, in which weak intermolecular Cr···O interactions allow the association of $Cr_2(O_2CR)_4$ molecules to form a polymer.[12]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In compound **4**, which crystallized in the space group *C*2/*c* with $Z = 4$, the molecule is located on a general position. The Cr–Cr bond length of 1.924(1) Å resembles that of 1.9178(11) Å in the $Cr_2(DPh^{m\text{–}OMe}F)_4$ analogue[22] and it is consistent for a species without axial interactions. It should be noted that the Cr–Cr distance in the $Cr_2(DPho^{\text{–}OMe}F)_4$ isomer, which has *o*-methoxy groups providing axial interactions, is 2.140(2) Å.[20] This distance is about 0.22 Å longer than that in **4**.

## Concluding Remarks

Systematic syntheses and characterization are reported for a series of dichromium compounds with mixed ligand sets of formamidinate and acetate groups, $Cr_2$(formamidinate)$_n$(acetate)$_{4-n}$ ($n$ = 2–4). The Cr–Cr bond lengths are strongly influenced by the presence or absence of axial interactions. These compounds are expected to serve as precursors for the preparation of supramolecules with different architectures utilizing selective ligand substitution based on the fact that acetate groups are generally more labile than formamidinate groups.

## Experimental Section

**Materials and Methods:** All reactions and manipulations were performed under nitrogen, using either a dry box or standard Schlenk line techniques. Solvents were purified under argon using a Glass Contour solvent purification system or distilled under nitrogen over appropriate drying agents. Anhydrous $Cr_2(O_2CCH_3)_4$[23] and the formamidinate precursors[24] were synthesized following reported procedures; other commercially available chemicals were used as received.

**Analytical and Physical Measurements:** Elemental analyses were performed by Robertson Microlit Laboratories, Madison, New Jersey. Electronic spectra were measured on a Shimadzu UV–2501PC spectrometer in $CH_2Cl_2$ solution. $^1$H NMR spectra were recorded on a Inova–300 NMR spectrometer with chemical shifts ($\delta$, ppm) referenced to residual $CHCl_3$ in $CDCl_3$. Cyclic voltammograms (CVs) were collected on a CH Instruments electrochemical analyzer with Pt working and auxiliary electrodes, Ag/AgCl reference electrode, scan rate of 100 mV/s, and 0.10 M $Bu_4NPF_6$ (in $CH_2Cl_2$) as electrolyte.

**Preparation of *cis*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$ (1) and *trans*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$ (2):** To a solution of $HDPh^{Cl}F$ (265 mg, 1.00 mmol) in THF (20 mL) at –70 °C, methyllithium in diethyl ether (0.32 mL, 1.6 M) was added slowly with stirring. The yellow solution was warmed to 0 °C and then transferred to a suspension of anhydrous chromium acetate (170 mg, 0.500 mmol) in THF (20 mL). The color of the brown suspension turned gradually to orange. After 4 h, the solvent was removed under reduced pressure and the solid residue was extracted with benzene (15 mL). The benzene solution was filtered through a Celite-packed frit, and the filtrate was layered with isomeric hexanes. Two types of crystals formed within 7 d: red acicular crystals of *cis*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$ (**1**) and yellow-orange block crystals of *trans*-$Cr_2(DPh^{Cl}F)_2(O_2CCH_3)_2$ (**2**). These were manually separated.

**For 1:** Yield: 138 mg (37%). $^1$H NMR ($C_6D_6$): 8.62 (s, 2 H, –NC*H*N–), 7.18 (d, 4 H, aromatic C–*H*), 6.80 (m, 8 H, aromatic C–*H*), 6.48 (t, 4 H, aromatic C–*H*), 2.33 (s, 6 H, –C$H_3$). UV-vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}mol^{-1}$) = 400 ($1.5 \times 10^3$) nm. **1**·$2H_2O$: $C_{30}H_{26}Cl_4Cr_2N_4O_5$ (786): calcd. C 45.82, H 3.58, N 7.12; found C 46.02, H 3.96, N 6.92.

**For 2:** Yield: 104 mg (28%). $^1$H NMR ($C_6D_6$): 8.67 (s, 2 H, –NC*H*N–), 7.03 (d, 4 H, aromatic C–*H*), 6.80 (m, 8 H, aromatic C–*H*), 6.55 (t, 4 H, aromatic C–*H*), 2.25 (s, 6 H, –C$H_3$). UV-vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}mol^{-1}$) = 450 ($1.1 \times 10^3$) nm. **2**·$H_2O$: $C_{30}H_{24}Cl_4Cr_2N_4O_4$ (768): calcd. C 46.89, H 3.43, N 7.26; found C 47.08, H 4.07, N 6.87.

**Preparation of $Cr_2(DAniF)_3(O_2CCH_3)$ (3):** A procedure analogous to that described above for **1** and **2** but using HDAniF (383 mg, 1.50 mmol) and $Cr_2(O_2CCH_3)_4$ (170 mg, 0.500 mmol) in THF gave an orange product. Crystals were obtained by layering a benzene solution of **3** with hexanes. Yield: 315 mg (68%). $^1$H NMR ($C_6D_6$): 8.94 (s, 2 H, –NC*H*N–), 8.76 (s, 1 H, –NC*H*N–), 6.68 (d, 16 H, aromatic C–*H*), 6.40 (d, 8 H, aromatic C–*H*), 6.24 (d, 8 H, aromatic C–*H*), 3.22 (s, 12 H, –OC$H_3$), 3.10 (s, 6 H, –C$H_3$ in DAniF). UV-vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}mol^{-1}$) = 410 ($1.3 \times 10^3$) nm. $Cr_2C_{47}H_{48}N_6O_8$ (929): calcd. C 60.77, H 4.62, N 9.05; found C 60.88, H 4.36, N 9.14.

**Preparation of $Cr_2(DAniF)_4$ (4):** To a suspension of anhydrous $CrCl_2$ (130 mg, 1.00 mmol) and HDAniF (510 mg, 2.00 mmol) in THF (30 mL) at –78 °C, a solution of methyllithium in diethyl ether

(0.65 mL, 1.6 M) was added slowly with stirring. The gray suspension changed gradually to a turbid orange dispersion. After 3 h, the solvent was removed under reduced pressure and the residue washed with hexanes (3 × 15 mL). The dry solid was dissolved in benzene (15 mL) and filtered through a Celite-packed frit, and then the filtrate was layered with hexanes. Yield: 420 mg (75%). $^1$H NMR ($\delta$, ppm in $C_6D_6$): 8.69 (s, 4 H, –NC*H*N–), 6.62 (d, 16 H, aromatic C–*H*), 6.38 (d, 16 H, aromatic C–*H*), 3.19 (s, 24 H, –C$H_3$ in DAniF). UV-vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1}$ $mol^{-1}$) = 502 (1.2 × $10^3$) nm. $Cr_2C_{60}H_{60}N_8O_8$ (1125.17): calcd. C 64.05, H 5.37, N 9.96; found C 63.89, H 4.86, N 9.64.

**X-ray Structural Determinations:** Single crystals suitable for X-ray analysis were mounted on the tips of cryoloops attached to a goniometer head. Data for **1**, **2**·$C_6H_6$, **3** and **4** were collected at –60 °C with a Bruker SMART 1000 CCD area detector system. Cell parameters were determined using the program SMART.[25] Data reduction and integration were performed with the software SAINT,[26] while the absorption corrections were applied by using the program SADABS.[27] The structures were solved by direct methods and refined using the SHELXS–97 program.[28] Non-hydrogen atoms, except for those of disordered solvent molecules, were refined with anisotropic displacement parameters. Hydrogen atoms were added in calculated positions. Crystallographic data are given in Table 2 and selected bond lengths in Table 1.

CCDC-641377 to -641380 (for **1**–**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# New Open-Framework Mixed-Valence Chromium(III) Cerium(III)/(IV) Sulfate: $CrCe^{III}_7Ce^{IV}_6(HSO_4)_6(SO_4)_{21}\cdot 75H_2O$

**Barbara M. Casari*[a] and Vratislav Langer[b]**

**Keywords:** Mixed-valent compounds / Lanthanides / Cerium sulfate / X-ray diffraction

The title compound, synthesized from $Cr^{VI}$ and $Ce^{IV}$ species, crystallizes in the space group $P6_3$ with $a$ = 19.3015(2), $c$ = 25.2684(4) Å, and $Z$ = 2. The structural design of the title compound differs essentially from structures of known mixed-valence cerium compounds which all form three-dimensional networks. In the title compound the cerium atoms, interlinked by sulfate groups, extend to form layers held together by hydrogen-bonding contacts. Perpendicular to these layers there are 10 Å wide channels. One third of the channels host solvent water only, while the other two thirds of the channels also host $[Cr(H_2O)_6]^{3+}$ and $[Ce(SO_4)_3(H_2O)_6]^{3-}$ units, blocking each of these channels once per unit cell, resulting in 14 Å long voids.

## Introduction

Currently, there is interest in rare-earth compounds because of their important physical properties and advances achieved in the syntheses of new materials[1] with interesting applications.[2] Rare-earth materials are intriguing due to the complexity of their structural arrangements with high coordination numbers and a variety of coordination geometries. Structural investigations on hydrated rare-earth sulfates are quite numerous[3] and many of these compounds are isomorphic, with the ninefold coordinated rare-earth atoms interlinked by sulfate groups. There is structural information on anhydrous as well as hydrous ternary rare-earth sulfates with all alkaline ions for nearly all of the lanthanide series,[3] but not much work has been done combining transition metals with rare-earth metals to form double salts. Cerium compounds attract research attention owing to their applications as ion conductors, catalysts, magnetic and fluorescence materials. The existence of alterable oxidation states for the cerium ion will result in compounds with new structural frameworks and interesting properties.[4] There are six mixed-valence cerium compounds in the ICSD Database (version 2006-2):[5] $Ce_4O_4S_3$,[6] $Ce_3O_3S_2$,[7] $Ce_{10}(GeO_4)_3(Ge_2O_7)_2(Ge_3O_{10})$,[8] $(H_3O)[Ce_2(SeO_4)_4]$,[9] $KCe_2(SO_4)_4$,[10] and $Ce_{0.968}H_{10.432}O_{12.924}S_2$.[11] Here we present an open-framework structure of a new mixed-valence chromium(III) cerium(III)/(IV) sulfate.

## Results and Discussion

### Synthesis of $CrCe^{III}_7Ce^{IV}_6(HSO_4)_6(SO_4)_{21}\cdot 75H_2O$

The title compound was synthesized from $Cr^{VI}$ and $Ce^{IV}$ species in diluted sulfuric acid. Cerium(IV) in acidic aqueous solutions is metastable with respect to the oxidation of water. The attainment of equilibrium is kinetically controlled, and the reaction is observed only in the presence of a catalyst.[12] Added ions or even the glass vessel may act as the catalytic agent.[12] Thus, in acidic aqueous media cerium(III) will be formed. Cerium(III) is known to inhibit chromium(VI) oxidation of organic compounds, and this effect is attributed to the chromic acid oxidation of the cerium(III) species[13] encountered also in our previous work.[14] The chromium system is able to produce a variety of transient and intermediate species, and several competing redox reactions can take place,[13,14] but the redox equilibria involved in this case can be written as the following total reactions:

$$2\ Ce^{4+} + H_2O \rightarrow 2\ Ce^{3+} + 2\ H^+ + 1/2\ O_2$$

$$[CrO_4]^{2-} + 3\ Ce^{3+} + 8\ H^+ \rightarrow Cr^{3+} + 3\ Ce^{4+} + 4\ H_2O$$

Purbaix diagrams on cerium and chromium species have been revised recently[15] showing that the first reaction occurs in acidic solutions, while the second reaction is dominant in neutral and basic solutions. Hence, in acidic aqueous solutions mixed-valence cerium species as well as mixed-valence chromium species may form.

### Structural Description of $CrCe^{III}_7Ce^{IV}_6(HSO_4)_6(SO_4)_{21}\cdot 75H_2O$

The title compound crystallizes in the space group $P6_3$ with $a$ = 19.3015(2), $c$ = 25.2684(4) Å, and $Z$ = 2. There

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are two atoms, $Cr^{III}$ and $Ce^{III}$, in special positions (on the threefold axis) while the remaining content of the asymmetric unit, two $Ce^{III}$ atoms, two $Ce^{IV}$ atoms, two $HSO_4^-$ groups, seven $SO_4^{2-}$ groups, and approximately 25 water molecules, are in general positions. The structure is noncentrosymmetric mainly due to $Ce1^{III}$ and $Cr^{III}$ atoms that do not respect an additional mirror plane leading to space group $P6_3/m$. The crystal was centrosymmetrically twinned with the twin volume ratio refined to 0.692(10):0.308(10).

The $Cr^{III}$ atom is sixfold coordinated to water molecules, as in known structures of chromium alums.[16] The $Ce^{III}$ atoms are in contact with nine oxygen atoms belonging to three corner-sharing sulfate groups and six water molecules. The $Ce^{III}$ coordination polyhedra are best described as tricapped trigonal prisms for the $Ce^{III}$ atom in a special position and as singly capped tetragonal antiprisms for the two $Ce^{III}$ atoms in general positions. The $Ce^{IV}$ atoms are ninefold coordinated to oxygen atoms belonging to three edge-sharing and three corner-sharing sulfate groups. The $Ce^{VI}$ coordination polyhedra are slightly distorted tricapped trigonal prisms. Coordination numbers such as nine are expected for the large $Ce^{III}$ ion but are rarely encountered for the smaller $Ce^{IV}$ ion.[17] The $Cr^{III}$–O, $Ce^{III}$–O, and $Ce^{IV}$–O distances average to 1.97(1), 2.53(4), and 2.39(9) Å, respectively (Table 1) as in known $Cr^{III}$, $Ce^{III}$, and $Ce^{IV}$ compounds.[16,17] The bond-valence sums for $Cr^{III}$, $Ce1^{III}$, $Ce2^{III}$, $Ce3^{IV}$, $Ce4^{IV}$, and $Ce5^{III}$ are 3.13, 2.85, 2.95, 4.00, 3.98, and 2.95 valence units, respectively (using parameters from Brese and O'Keefe[18] for Cr and Trzesowska et al.[19] for Ce). The S–O distances within the nine sulfate groups average to 1.48(2) Å (Table 1), and as expected, due to the restrained bite angle, the edge-sharing sulfate groups (S6, S7, S8, S12, S13, and S14) show a departure from the ideal tetrahedral symmetry, the angles ranging from 102.4(2) to 111.7(2)°. One of the sulfate groups is partly disordered (S9A, O91A, O92A and S9B, O91B, O92B) occupying 0.563(7) and 0.437(7) of two sets in a general position. All the sulfate groups link two cerium atoms, except for the S3 sulfate unit that is bridging by corner sharing from $Ce1^{III}$ to $Ce3^{IV}$ and $Ce4^{IV}$. It is difficult to distinguish by analyzing the terminal S–O bond length which two of the nine sulfate groups may be protonated to give hydrogen sulfate groups. Hence, the location of these protons may be disordered.

Table 1. Bond lengths [Å].

Symmetry transformations for equivalent atoms: (i): $-x + y + 1$, $-x + 1$, $z$; (ii): $-y + 1$, $x - y$, $z$; (iii): $x + y + 1$, $-x + 2$, $z$; (iv): $-x + y$, $-x + 1$, $z$; (v): $-y + 1$, $x - y + 1$, $z$.

The structural design of the title compound differs from structures of known mixed-valence cerium compounds, all of which form three-dimensional networks.[6–11] In the title compound the cerium atoms, interlinked by sulfate groups, extend to form layers parallel to the *ab* plane (Figure 1a). These layers (ca. 11.5 Å thick) are held together by hydrogen-bonding contacts (Figure 1b). Perpendicular to the layers, in the *c* direction, there are channels (ca. 9.7 Å in diameter), shown in Figure 1a. One of the channels, at (0,0,*z*), hosts solvent water only, while the other two channels, at (1/3,2/3,*z*) and (2/3,1/3,*z*), also host $[Cr(H_2O)_6]^{3+}$ and $[Ce(SO_4)_3(H_2O)_6]^{3-}$ units, blocking each of these channels once per unit cell. Thus, there are voids in the latter two channels, approximately 14 Å long. The $[Cr(H_2O)_6]^{3+}$ cations, located in the channels (Figure 2), are situated between the layers participating in the hydrogen-bonding network that are connecting one layer to an adjacent layer, shown in Figures 1b and 2.

There are four crystallographically different water molecules inside the voids, OW1–OW4. We believe that the OW1 water molecule acts as a hydrogen-bond donor towards O122 (S12 sulfate oxygen atom) and towards O53 (a water molecule attached to Ce5), the OW2 molecule acts as a hydrogen-bond donor towards O72 (S7 sulfate oxygen atom) and towards O11 (a water molecule attached to Ce1), the OW3 water molecule acts as a hydrogen-bond donor towards O12 and O55 (water molecules attached to Ce1 and Ce5, respectively), and that the OW4 water molecule acts

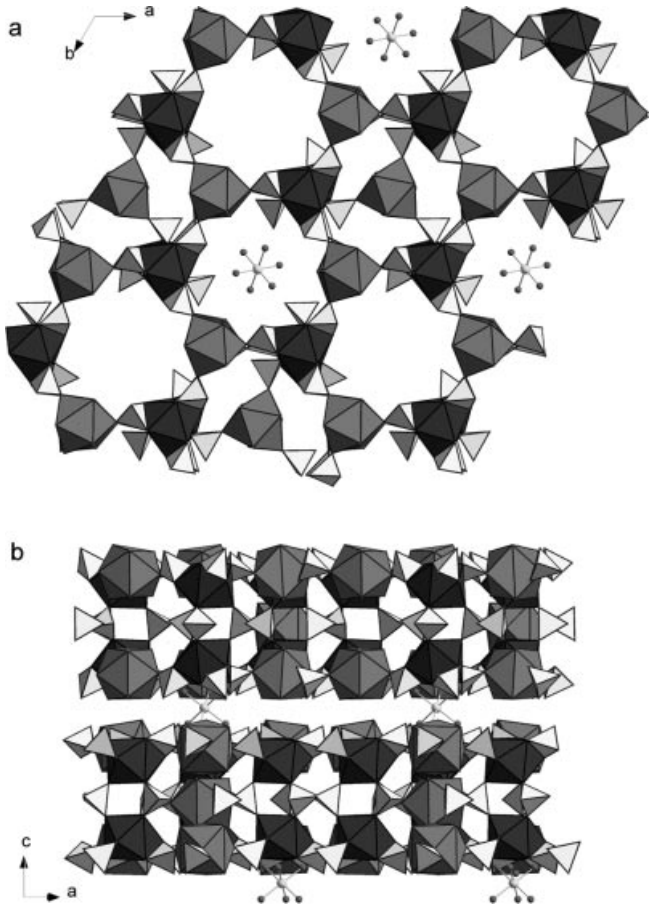

Figure 1. Packing diagrams of the title compound, the $Ce^{III}$ polyhedra are shown in light shades and the $Ce^{IV}$ polyhedra are shown in dark shades. The solvent water molecules are not shown. (a) One single layer extending through sulfate bridges forming channels. (b) There are two layers per unit cell. Adjacent layers are held together by hydrogen-bonding contacts from $[Cr(H_2O)_6]^{3+}$ and from water molecules coordinated to $Ce^{III}$ towards terminal sulfate oxygen atoms.

as a hydrogen-bond donor towards O91 and O103 (oxygen atoms belonging to the S9 and S10 sulfate groups, respectively), in addition, it acts as a hydrogen-bond acceptor from O24 and O53 (water molecules attached to Ce2 and Ce5, respectively). The water molecules coordinated to the $Cr^{III}$ and $Ce^{III}$ ions all participate in the hydrogen-bonding network connecting adjacent layers. Furthermore, there are approximately five additional water molecules that are disordered (see Experimental Section) within the open channel and the two voids, corresponding to 18 water molecules per unit cell in the channel (volume: 861 $Å^3$) plus 12 water molecules per unit cell in the two voids (volume: $2 \times 257$ $Å^3$).

According to the Robin and Day classification,[20] this compound could belong to Class II since the oxidized and reduced cerium ions occupy sites of similar geometry. The structure of the title compound can be regarded as consisting of six $[Ce^{III}(H_2O)_6(SO_4)_{3/2}]$, six $[Ce^{IV}(HSO_4)_{2/2}(SO_4)_{1/3}(SO_4)_{3/2}]^{2/3-}$, $[Ce^{III}(H_2O)_6(SO_4)_{3/3}]^{+}$, $[Cr(H_2O)_6]^{3+}$, and solvent water molecules as the main structural units.

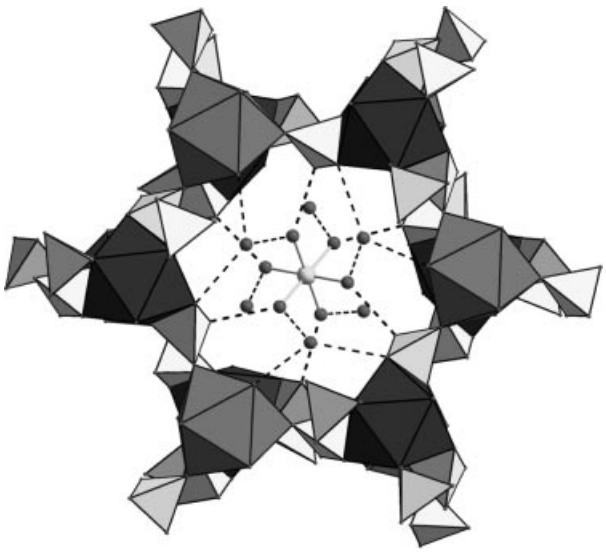

Figure 2. View through one of the channels showing one $[Cr(H_2O)_6]^{3+}$ ion, solvent water molecules, and part of the hydrogen-bonding network. The $Ce^{III}$ polyhedra are shown in light shades and the $Ce^{IV}$ polyhedra are shown in dark shades.

Hence, a possible donor–acceptor couple could be $[Ce^{III}(H_2O)_6(SO_4)_{3/2}]$ and $[Ce^{IV}(HSO_4)_{2/2}(SO_4)_{1/3}(SO_4)_{3/2}]^{2/3-}$ which are linked by one sulfate bridge, $Ce^{III}$–O–S–$O_2$–$Ce^{IV}$. The geometrical distance between the metal sites (>6.5 Å) is sufficiently large to decline direct overlap of the electronic wave functions. Prior to an electron transfer, the nuclear configurations of the reactants and the surrounding medium must adjust to an intermediate configuration with no energy change when the electron moves from the donor to the acceptor.[21] For metal complexes in a polar solvent, the nuclear configuration changes involve adjustments in the metal–ligand bond lengths and angles, and changes in the orientations of the surrounding solvent molecules.[21] Similar adjustments are also required in the stiffer inorganic solid state. Therefore, due to the difference in bond lengths at the donor and acceptor sites, a substantial energy barrier to their interconversion exists, and since electronic coupling with orbitals of appropriate symmetry in the sulfate bridge probably is negligible, this mixed-valence cerium compound presumably is a Class I compound. If there is no electronic interaction between the acceptor and donor sites then the properties of this compound are essentially those of the separate acceptor and donor sites. However, a small portion of Class II character cannot be completely dismissed since the geometry of the donor site, $[Ce^{III}(H_2O)_6(SO_4)_{3/2}]$, is quite flexible due to the coordinated water molecules and further, the oxidizing ability of the acceptor site, $[Ce^{IV}(HSO_4)_{2/2}(SO_4)_{1/3}(SO_4)_{3/2}]^{2/3-}$, may increase if it becomes protonated by the adjacent slightly acidic $[Cr(H_2O)_6]^{3+}$ species. Class II compounds generally possess new optical and electronic properties in addition to those of the separate sites and might be semiconductors or ionic conductors.

There are two structurally related compounds $H_9Nd_7Ce_6(SO_4)_{27}\cdot 72.33H_2O$[22] and $H_9Tb_7Ce_6(SO_4)_{27}\cdot$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$72.2H_2O$.[23] These compounds contain channels and voids of comparable dimensions but they are not mixed-valence compounds and do not contain any hydrated transition-metal ions participating in the hydrogen-bonding network. One compound containing chromium(III) combined with a rare-earth element is samarium chromium silicon oxynitride[24] (space group $P6_3$), but its crystal structure differs from the title compound as it is apatite-like and extends through silicate bridges forming a compact three-dimensional network.

## Experimental Section

**Sample Preparation:** $Ce(SO_4)_2{\cdot}4H_2O$ (0.50 g, 1.27 mmol), $CrO_3$ (0.38 g, 3.8 mmol), and water (5.0 mL) were mixed in a round-bottomed microflask connected to a reflux water condenser. The reaction mixture was refluxed for 24 h until orange crystals of $Ce(CrO_4)_2(H_2O)_2$ were formed. These crystals were dissolved in sulfuric acid (4 M). Concentration at room temperature gave light yellow crystals shaped as hexagonal needles. The title compound may also be produced from $Ce(OH)_4$ and $CrO_3$ in diluted sulfuric acid solution but the best single crystals were achieved with the former description.

**Single Crystal X-ray Analysis:** Data were collected with a Siemens SMART CCD diffractometer equipped with a Siemens LT-2A low-temperature device at –100 °C. A full sphere of the reciprocal space was scanned by 0.3° steps with a crystal-to-detector distance of 3.97 cm and an exposure time per frame of 2 s. A preliminary orientation matrix was obtained using the SMART software.[25] The collected frames were integrated with the orientation matrix which was updated every 100 frames. Final cell parameters were obtained by refinement from 8192 reflections with $I > 10\sigma(I)$ after integration of all the data using the SAINT software.[25] The data were corrected empirically for absorption and other effects using the SADABS software.[26] The structure was solved by direct methods and refined by full-matrix least squares on $F^2$ using the SHELXTL software package.[27] Disordered solvent water molecules (five water molecules in the asymmetric unit) were removed using the PLATON[28] (version 1.10) squeeze instruction. All non-hydrogen atoms were refined anisotropically. Details on data collection and refinement are given in Table 2. Further details of the crystal structures may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-417583. Molecular graphics were drawn with the DIAMOND software package.[29]

# Synthesis, Characterization, and Electrochemical and Electrical Properties of Novel Pentaerythritol-Bridged Cofacial Bismetallophthalocyanines and Their Water-Soluble Derivatives

**Metin Özer,[a] Ahmet Altındal,[b] Ali Rıza Özkaya,[a] Bekir Salih,[c] Mustafa Bulut,[a] and Özer Bekaroğlu*[d]**

**Keywords:** Phthalocyanines / Cofacial configuration / Synthesis / Cyclic voltammetry / Thermopower

Novel cofacial bismetallophthalocyanines and their water-soluble derivatives were prepared. The precursor 4,4′-(2-phenyl-1,3-dioxane-5,5-diyl)bis(methylene)bis(oxy)-diphthalonitrile **3** was obtained by the reaction of [5-(hydroxymethyl)-2-phenyl-1,3-dioxan-5-yl] methanol **1** and 4-nitrophthalonitrile **2** with $K_2CO_3$ in DMF at 50 °C. Cyclotetramerization was achieved by heating the homogenized mixture of the precursor, bisphthalonitrile, and $Zn(OAc)_2{\cdot}2H_2O$ or $Co(OAc)_2{\cdot}4H_2O$ at 300 °C, which was followed by catalytic hydrogenation of the resulting product with Pd/C(10 %) in DMF. The target water-soluble phthalocyanines were acquired from boiling suspensions of the compounds bearing eight OH side groups in aqueous KOH (20 %) solution. The structure of the target compounds was confirmed by elemental analysis, FTIR, UV/Vis, $^1$H NMR, ICP-MS, and MALDI-TOF spectroscopic methods. The electrochemical and spectroelectrochemical measurements suggested the formation of various mixed-valent oxidation and reduction species, as a result of the strong intramolecular interactions between the two cofacial phthalocyanine units in the compounds. Impedance spectroscopy, dc conductivity, and thermopower measurements were performed using spin-coated films of these compounds as a function of temperature (290–440 K) and frequency (40–$10^5$ Hz). Dc conductivity showed typical Arrhenius behavior for all compounds. At low temperatures, a curved line was observed for the complex plane plots of impedance for all phthalocyanines. These curved lines transformed into a full semicircle with increasing temperature. The dependency of frequency exponent *s* on temperature suggested hopping-type conduction. A positive Seebeck coefficient was observed for all compounds, which indicates that the compounds behave as a *p*-type semiconductor.

## Introduction

Phthalocyanine (Pc) dimers and multimers have been the subject of great interest in areas such as electrocatalysis,[1,2] semiconductors,[3] nonlinear optics,[4] electrochromic displays,[5–7] and liquid crystals.[8,9] In this respect, various phthalocyanine,[10–12] porphyrin,[13,14] and mixed phthalocyanine-porphyrin dimers and oligomers[15] having various kinds of linkage have been reported to date. These compounds, especially those with rigid cofacial configurations,[16,17] often show spectroscopic, electrical, and electrochemical properties which differ significantly from the parent monomers. A strong interaction between the face-to-face Pc rings or two metal centers in these types of complexes was usually detected with spectroscopic and electrochemical evidence.[18]

Thin films of organic molecular crystals are promising materials for electronic and optoelectronic devices like solar cells,[19] gas sensors,[20] and light-emitting diodes[21] due to their unique electrical properties. The determination of true fundamental parameters such as the majority carrier type and electronic structure is crucial in order to optimize their potential utility for optical or electronic applications. Optical methods such as ultraviolet photoemission and inverse photoemission spectroscopy are used to determine the electronic structure of phthalocyanine thin films.[22] On the other hand, Hall effect and thermopower measurements are used for the determination of the charge carrier type. The most reliable method to investigate their conduction type is the measurement of thermoelectric power, characterized by the Seebeck coefficient *S*.

The synthesis and properties of cofacial bismetallophthalocyanines with a number of cross-links have been rarely reported in the literature.[23,24] Our interest in the design of novel macrocycles with potential applicability in various technological areas prompted us to synthesize new bridged metallated bisphthalocyanines with four linking

arms between two Pc rings and to investigate their electrochemical and electrical properties.[18,25] Recently, we reported the synthesis, characterization, and electrical and spectroelectrochemical properties of 1,1′-methylenedinaphthalene-bridged cofacial metal-free bisphthalocyanines and bismetallophthalocyanines.[18]

In our continuing efforts, we now report the synthesis and characterization of novel pentaerythritol-bridged cofacial bismetallophthalocyanines and their water-soluble derivatives. The electrochemical and electrical properties of the compounds are also investigated.

## Results and Discussion

### Synthesis

The preparation of the pentaerythritol monoacetal **1** was accomplished by the condensation of pentaerythritol with benzaldehyde in DMF at 25–30 °C according to the given method.[26,27] The original precursor **3** for the synthesis of phthalocyanines was obtained by nitro displacement reaction of **1** and **2** using $K_2CO_3$ as catalyst in DMF with stirring at 50–60 °C. In this work, for the synthesis of the cofacial bismetallophthalocyanines, we developed a solid-phase method in the absence of catalysts. The preparation of phthalocyanine derivatives **4** and **5** was achieved by heating the homogenized mixture of **3** with $Zn(OAc)_2{\cdot}2H_2O$ or $Co(OAc)_2{\cdot}4H_2O$, respectively, in the ratio 1:1 through the cyclotetramerization reaction in a sealed tube at 300 °C for 10 min. The mixtures of Pc **4** or **5** and Pd/C(10%) in DMSO were hydrogenated at room temperature under 1 atm hydrogen pressure for 8 h according to the given procedure.[27] The catalyst was filtered off, and the mixtures were precipitated with the addition of ethanol to give Pc **6** or **7**. Water-soluble Pcs **8** and **9** were achieved by boiling suspensions of **6** or **7**, respectively, in aqueous KOH (20%) solutions (Scheme 1).

The crude Pcs **4**–**7** were dissolved in DMF and precipitated again with a mixture of $CHCl_3$ and ethanol which easily dissolved the starting material and the other impurities. After filtration, each precipitate was washed with boiling acetone and ethanol. The purification of the target Pcs **4**–**7** was achieved with a silica gel column using a THF/DMF gradient system as the eluent. On the other hand, **8**

or **9** were dissolved in water, and they were precipitated again several times in ethanol until the solution was neutral. The precipitates were washed with ethanol and diethyl ether, and then dried in vacuo.

After purification, the compounds were characterized by elemental analysis, FTIR, $^1$H NMR, UV/Vis, MALDI-MS, and ICP-MS spectroscopy. The results of the analyses showed that the compounds were pure enough for the other measurements.

The IR spectra were derived from potassium bromide disks. The existence of C≡N groups appeared at 2231 cm$^{-1}$ as a single peak in the spectrum of **3**. Formation of dinuclear phthalocyanine complexes **4** and **5** starting from the corresponding bisphthalodinitrile derivative was verified by the disappearance of the C≡N stretching vibration band at 2231 cm$^{-1}$. After conversion of **4** and **5** into **6** and **7**, respectively, by the cleavage of the acetal groups, O–H stretching vibrations came out typically around 3402 and 3396 cm$^{-1}$ as strong absorptions.

The UV/Vis spectra of **4**–**7** in DMF display characteristic absorptions around 625 and 680 nm in the Q-band region (Figure 1). The Q-band was attributed to $\pi \rightarrow \pi^*$ transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the Pc ring. The other bands (B) in the UV region at 330–353 nm are observed due to the transitions from the deeper π levels to the LUMO. When aggregation occurs, a band at ca. 630 nm arises in the electronic spectrum as a result of the intramolecular interactions between the Pc units.[18,28] Thus, the band at around 625 nm can be attributed to intramolecular interactions, although the Q-band is not split. The aggregation degree of Pcs is highly affected by the surrounding conditions, one of which is the solvent media. Figures 2 and 3 show the absorption spectra of water-soluble Pcs **8** and **9**, respectively, at different concentrations [$C_8$ = $(5.28\times10^{-6})$–$(4.8\times10^{-7})$ and $C_9$ = $(7.52\times10^{-6})$–$(8.22\times10^{-7})$]. It should be noted that the absorption at around 630 nm, corresponding to aggregation, for **8** and **9** is the main band in water.[29] This observation suggests that aggregation occurs to a greater extent in water as compared with that in organic solvent.[30,31] In addition, although the concentrations of dinuclear water-soluble phthalocyanines **8** and **9** decrease, there is no significant change in the relative intensity of the aggregation band to the Q-band at ca. 685 nm. This situation is consistent with the intramolecular coupling between the rings in dinuclear phthalocyanines.

In addition to these results, the $^1$H NMR ([D$_6$]DMSO) spectra of **3**, **4**, and **6** exhibit the characteristic chemical shifts for the proposed structures as expected. The $^1$H NMR spectrum of **6**, the hydrogenolysis product of **4**, provides supporting evidence for the structure. Removal of the benzylidene acetal in **4** is confirmed by the loss of the singlet proton signal of acetal at $\delta$ = 6.14 ppm in the $^1$H NMR spectrum of **6**. A broad signal at $\delta$ = 11.35 ppm in the $^1$H NMR spectrum of **6** disappeared with $D_2O$ exchange. The $^1$H NMR spectra of **3**, **4**, and **6** exhibit the aromatic protons as multiplets at 7.73–7.21, 8.42–7.03, and 8.31–6.94 ppm, respectively. On the other hand, aliphatic proton signals appeared at 4.88–3.64 ppm for **3**, 4.81–3.57 ppm for **4**, and 4.12–3.13 ppm for **6**.

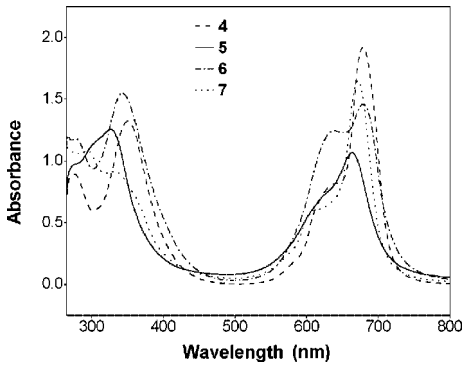

Figure 1. UV/Vis spectra of bis(metallophthalocyanine) derivatives **4**–**7** in DMF.

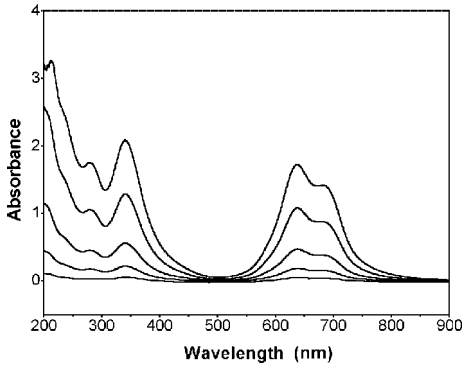

Figure 2. UV/Vis spectra of bis(metallophthalocyanine) derivative **8** in water at different concentrations.

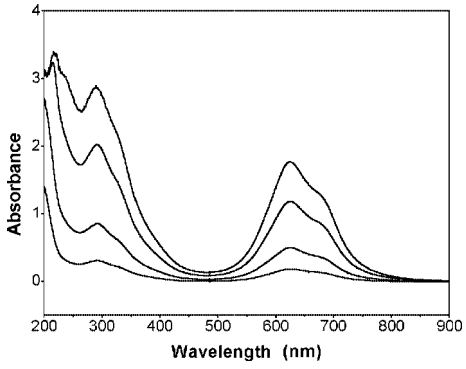

Figure 3. UV/Vis spectra of bis(metallophthalocyanine) derivative **9** in water at different concentrations.

A close investigation of the MALDI-TOF mass spectra of the Pcs confirmed the proposed structures. The protonated molecular ion peaks of **4** and **5** are observed at low intensity, but sodium adduct peaks for both **4** and **5** complexes are found to be dominant intense peaks in the linear mode MALDI-TOF mass spectra using the 3-indoleacrylic acid matrix. Sodium adduct peak stabilities of these complexes were found to be very high in the gas phase compared to the stability (following the intensity of the peaks) of the protonated molecular ion peaks, even if the sodium content in the complexes was lower than 0.1% (data not

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

shown). On the other hand, protonated molecular ion peaks of **6** and **7** complexes are observed at 1685 and 1672 Da, respectively, which exactly overlap with the mass of the protonated complexes calculated from the elemental composition of the compounds. Following the protonated molecular ion peak of **6**, a peak, 88 Da mass lower than the protonated molecular ion peak, is observed at 1596 Da. This peak resulted from the $C_4H_8O_2$ side group elimination from the protonated ion peak of the complex. Also the second $C_4H_8O_2$ side group elimination is observed at low intensity. However, no fragmentation was observed for **7** in the MALDI-TOF mass spectrum. When the MALDI-TOF mass spectra of **6** and **7** were evaluated at low-mass range between 100 and 500 Da, no meaningful intensity peak was observed representing impurities, but mainly matrix species peaks were followed. These results show that either **6** or **7** complexes were very pure. Many different MALDI matrices were tested to obtain highly resolved spectra. The best matrix for **6** and **7** was α-cyano-4-hydroxycinnamic acid for MALDI-MS analyses. Because of the short life time of the protonated complexes **6** and **7** in MALDI-MS, highly resolved spectra could not be obtained in reflectron mode. Beyond the protonated and two fragment ion peaks of **6** and the only protonated ion peak of **7**, MALDI mass spectra of the complexes showed very clear and low fragmentations in MALDI-MS (Figures 4 and 5).

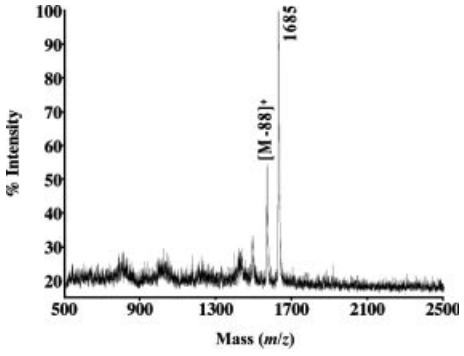

Figure 4. Positive ion mode MALDI-MS spectrum of **6** in α-cyano-4-hydroxycinnamic acid MALDI matrix using nitrogen laser accumulating 50 laser shots.

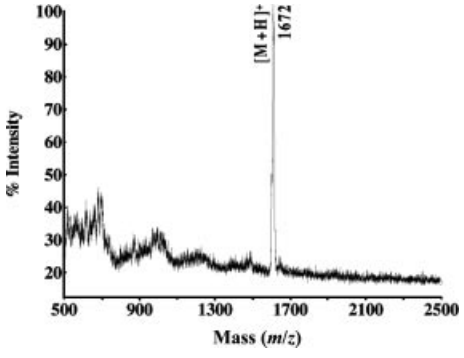

Figure 5. Positive ion mode MALDI-MS spectrum of **7** in α-cyano-4-hydroxycinnamic acid MALDI matrix using nitrogen laser accumulating 50 laser shots.

The ICP-MS measurements were obtained for the determination of the quantities of potassium, zinc, and cobalt atoms in **8** and **9** as described in the literature.[32] The results of ICP-MS analysis provide additional support for the molecular structures of **8** and **9**.

### Electrochemistry and Spectroelectrochemistry

The electrochemical properties of the complexes **4**–**7** were examined by cyclic voltammetry, controlled potential coulometry, and spectroelectrochemistry in DMSO/TBAP. Cyclic voltammetry of each complex displayed four reductions and an oxidation couple. Typical cyclic voltammograms of **4** and **5** in DMSO/TBAP (tetrabutylammonium perchlorate) are shown in Figure 6. The number of electrons transferred for each redox process is determined by the controlled potential electrolysis at the suitable potentials. Coulometric studies of broadly separated voltammetric couples showed that the number of electrons transferred for each redox process ($p$) is approximately equal to unity ($1 > p \geq 0.92$). Thus, the reactions corresponding to all waves in the voltammograms are stepwise one-electron processes of the two cofacial phthalocyanine rings and metal centers. The voltammetric data and the assignment of the redox couples for **4**–**7** are summarized in Table 1. The occurrence of stepwise one-electron processes for these complexes involving two Pc rings and two metal centers, and the comparison of their half-peak potentials with those of monophthalocyanines imply the formation of mixed-valent first- and second-reduced and first-oxidized species during the voltammetric measurements.[33,18] It can be concluded from the results of this study that the binding of two Pc rings at two sides rigidly with four linking arms leads to remarkable intramolecular cofacial coupling and thus to the splitting of the classical monophthalocyanine redox processes. For instance, for complexes **4** and **6**, the Pc(–2)/Pc(–3) redox process is split into the $[Pc(-2)]_2/[Pc(-2)\cdot Pc(-3)]$ and $[Pc(-2)\cdot Pc(-3)]/[Pc(-3)]_2$ processes, forming the mixed-valent $[Pc(-2)\cdot Pc(-3)]$ species. All the redox processes for **4** and **6** should be ligand-based since the $Zn^{II}$ ion is not redox-active in metallophthalocyanines. The difference between the first oxidation and the first reduction potentials for complexes **4** and **6** is remarkably low relative to that of monophthalocyanines (1.34 V for **4**, 1.33 V for **6**, but 1.50–1.70 V for monophthalocyanines). This is in harmony with the cofacial structures of **4** and **6**, leading to the strong electronic coupling and the splitting of molecular orbitals. Previous reports on the electrochemistry of $Co^{II}$ Pcs suggested that both the first reduction and the first oxidation processes in these complexes are metal-based in polar coordinating solvents such as DMSO and DMF.[32] Since complexes **5** and **7** involve two $Co^{II}$ centers, the oxidation and the first two reductions probably correspond to $[Co^{II}Pc(-2)\cdot Co^{III}Pc(-2)]^+/[Co^{II}Pc(-2)]_2$, $[Co^{II}Pc(-2)]_2/[Co^{II}Pc(-2)\cdot Co^{I}Pc(-2)]^-$, and $[Co^{II}Pc(-2)\cdot Co^{I}Pc(-2)]^-/[Co^{I}Pc(-2)]_2^{2-}$ redox processes, respectively. On the other hand, the third and fourth reductions should be related to the splitting of the Pc(–2)/Pc-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(–3) couple and thus ligand-based $[Co^{I}Pc(-2)]_2^{2-}/[Co^{I}Pc(-2)\cdot Co^{I}Pc(-3)]^{3-}$ and $[Co^{I}Pc(-2)\cdot Co^{I}Pc(-3)]^{3-}/[Co^{I}Pc(-3)]_2^{4-}$ redox processes, respectively.

[a] Potentials are reported with respect to the SCE. Half-wave potentials in DMSO vs. $Fc/Fc^{+}$ couple correspond approximately with the given **4**–**7** data minus 0.45 V. $E_{1/2}$ values were measured by cyclic voltammetry [$E_{1/2} = (E_{pa} + E_{pc})/2$]. The peak separation values ($\Delta E_p = E_{pa} - E_{pc}$) are reported at 0.100 V/s. $\Delta E$ is the potential difference between the first oxidation and first reduction potentials. It represents the HOMO–LUMO gap for **4** and **6**, but the charge-transfer transition for **5** and **7** involving redox-active metal centers. $\Delta E_s$ indicates mixed-valent splitting energy for the relevant split redox couple.

The spectroelectrochemical measurements in solution have a vital importance in confirming the assignment of the redox processes in the Pcs, especially in metallo Pcs involving a redox-active metal center. The formation of electrochemically generated species involving a $Co^{I}$ center is confirmed by the appearance of a new intense absorption in the region of 400–500 nm. Figure 7 shows in situ UV/Vis spectral changes during the first and second reductions and the first oxidation of **5** in TBAP/DMSO. Upon the first reduction, a new intense band appears at 488 nm, confirming the formation $Co^{II}\cdot Co^{I}$ mixed-valent species.[34,35] This band can be assigned to metal-to-ligand charge transfer (MLCT) from $Co^{I}$ to the Pc ring. During the second reduction, the absorption of the newly formed MLCT peak continues to increase, forming a quite intense band with a redshift in the Q-band. It is known from the literature[36,37] that both $Co^{II}\cdot Co^{I}$ and $Co^{I}\cdot Co^{I}$ species show Q-band and MLCT absorption (near 500 nm) redshifted relative to less electronically coupled dimers or monophthalocyanines. Thus, the spectral changes observed during the second reduction process indicate the formation of $Co^{I}\cdot Co^{I}$ species. The spectrum of the mixed-valent $Co^{II}\cdot Co^{I}$ species obtained during the first reduction is different from that of the fully reduced $Co^{I}\cdot Co^{I}$ species obtained during the second reduction. The $Co^{II}\cdot Co^{I}$ mixed-valent species has a much weaker MLCT band. This implies that the added first electron may be delocalized over the extended ring system. This type of behavior was observed previously for the (–1)-bridged dinuclear $[CoTRNPc]_2$ (TRN = trineopentoxy).[12] The spectroelectrochemistry of **5** provides additional support for the fact that the reduction of **5** and **7** over the first and second reduction couples proceeds by two distinct one-electron steps, corresponding to the stepwise reduction of each of the cobalt atoms to $Co^{I}$.

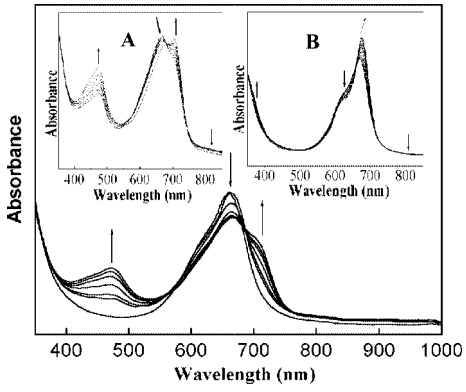

Figure 7. In situ UV/Vis spectral changes during the first reduction, the second reduction (inset A), and the first oxidation (inset B) processes of **5** in TBAP/DMSO.

## Electrical Conductivity and Thermopower Measurements

Dc conductivity of the spin-coated films was determined from the slope of the measured current–voltage (*I*–*V*) measurements by using the following relation:

$$\sigma_{dc} = \frac{I}{V}\cdot\frac{d}{(2n-1)lh}$$

where *I* is the measured current, *V* is the bias voltage, *d* is the electrode spacing, *n* is the number of electrode finger

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pairs, $l$ is the overlap length of the electrode fingers, and $h$ is the thickness of the electrodes. Measurements of $I$–$V$ were carried out in the range of –1 to 1 V. Linear $I$–$V$ behavior was found in this voltage range, indicating no rectifying properties. The variation of the measured dc conductivity with temperature suggests the presence of only one conduction mechanism, assuming that the dominant levels are the conduction and valence bands, in the whole temperature range for the films of **4**–**9**. Arrhenius plots (logarithms of dc conductivity versus inverse temperature) indicated that the compounds are semiconducting in nature. The highest value of conduction activation energy was obtained for the film of **8** and the lowest for **5**. The difference between the electrical conductivity of the films can be attributed to the differences in the stacking arrangements and interplanar spacing.

The frequency-dependent conductivity (ac conductivity) measurements were also performed on thin films of compounds in the frequency range 40–$10^5$ Hz at temperatures between 290 and 440 K. The frequency dependence of the electrical conductivity for a large variety of materials can be expressed as $\sigma = \sigma_0 + \sigma(\omega)$, where $\sigma_0$ is the dc conductivity. The frequency-dependent part of the total conductivity, $\sigma(\omega)$, is given by the power law of the form[38] $\sigma(\omega) = A\omega^s$ where $A$ and $s$ are temperature-dependent parameters. For temperatures above 350 K, frequency-independent conductivity at low frequencies and after a certain characteristic frequency increasing with the power law, was observed. Various models such as tunelling and hopping have been proposed to explain this type of behavior. It is not easy to decide which of these mechanisms is responsible for the observed conduction mechanism. However, the behavior of the exponent $s$ with temperature can help in determining the possible conduction mechanism. The values of $s$ are calculated from the slope of the $\ln\sigma(\omega,T)$ versus $\ln\omega$ graphs and were generally found to decrease with increasing temperature. It was observed that the calculated values of the frequency exponent $s$ are in agreement with the hopping model.

The measured impedance spectra, when plotted in a complex plane plot, appeared in the form of a succession of semicircles representing the contributions to the electrical properties due to bulk material, grain boundry effect, and interfacial polarization phenomena. So, the impedance spectra technique enabled us to separate the effects due to each component. At low temperatures, the impedance spectra consist of a quasivertical line. The existence of semicircular-shaped curves in the Nyquist plot means that the impedance becomes capacitive, even at relatively high frequency. The effect of temperature on the impedance spectra of the films becomes clearly visible with a rise in temperature. On the complex plane plot at high temperatures, only a depressed semicircle with a different radius is observed (Figure 8) for the compounds **4**–**9** at higher temperatures, indicating deviation from the Debye dispersion relation. In the case of a depressed semicircle in the impedance spectra, the relaxation time is considered as a distribution of values, rather than a single relaxation time.

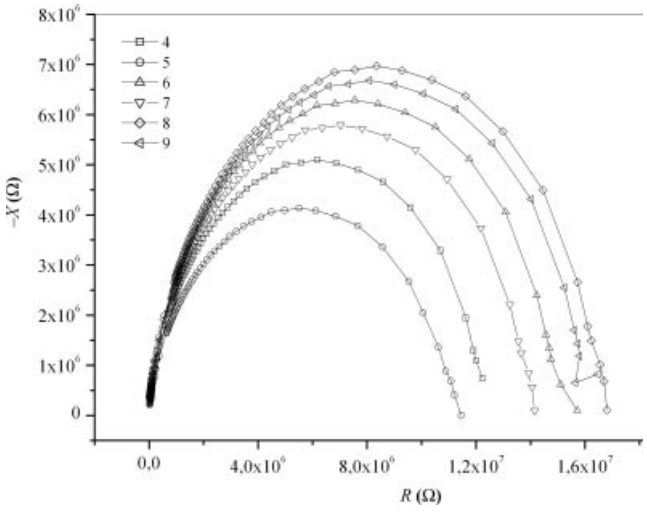

Figure 8. Nyquist plot (imaginary part vs. real part of complex impedance) of the spin-coated films of **4**–**9** at 385 K.

The Seebeck coefficient $S$ provides the transport type by its sign and provides the energetic difference between the Fermi level and transport level by its value. To determine the type of majority carrier, the temperature dependence of the thermoelectric power was also studied for thin films of **4**–**9**. The measured thermopower varied approximately exponentially with temperature for all samples investigated. Figure 9 shows the Seebeck ceefficient $S$ of the samples. Its sign is always positive. Compared to **8**, the absolute value of the thermopower for the film of **5** is larger by nearly a factor of 3. The positive sign of $S$ confirms that the thin films of the compounds behave as a $p$-type semiconductor.

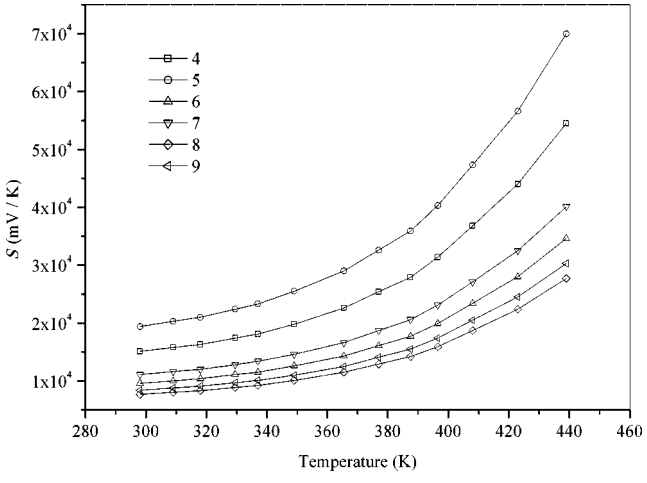

Figure 9. Seebeck coefficient vs. temperature for the films of **4**–**9**.

## Experimental Section

**General:** Compound **1** was synthesized by the methods previously described in the literature.[21,22] 4-Nitrophthalonitrile, pentaerythritol, benzaldehyde, $Zn(AcO)_2{\cdot}2H_2O$, $Co(AcO)_2{\cdot}4H_2O$, and Pd/C(10%) were obtained from commercial suppliers.

Routine IR and UV/Vis spectra were recorded with a Shimadzu FTIR-8300 spectrophotometer as KBr pellets and with a Shimadzu

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

UV-1601 UV/Vis spectrophotometer, respectively. Elemental analyses were performed with the LECO CHNS 932. $^1$H NMR spectra were obtained with a Varian Mercury-Vx 400 MHz spectrometer. Mass spectra were acquired with a Voyager-DE™ PRO MALDI-TOF mass spectrometer (Applied Biosystems, USA) equipped with a nitrogen UV-Laser operating at 337 nm. Spectra were recorded in linear mode with an average of 50 shots. 3-Indole acrylic acid (IAA) (20 mg/mL in acetonitrile) MALDI matrix for **4** and **5**, and α-cyano-4-hydroxycinnamic acid (ACCA) (15 mg/mL in 1:1 water/acetonitrile) MALDI matrix for **6** and **7** were prepared. MALDI samples were prepared by mixing the complex (2 mg/mL in dimethyl sulfoxide) with the matrix solution (1:10, v/v) in a 0.5-mL Eppendorf® microtube. Finally this mixture (1 μL) was deposited on the sample plate, dried at room temp. and then analyzed. The potassium, zinc, and cobalt contents in the digested mixtures were determined using external standards with an Agilent 7500a inductively coupled plasma mass spectrometer (ICP-MS). For the ICP-MS measurements, compounds **8** and **9** (10 mg) were digested by a mixture of acids ($HNO_3$/$HClO_4$/HF, 8:2:2, v/v) at 170 °C for 1 h.

**4,4′-(2-Phenyl-1,3-dioxane-5,5-diyl)bis(methylene)bis(oxy)diphthalonitrile (3):** A mixture of **1** (1.79 g, 8 mmol), **2** (2.77 g, 16 mmol), and $K_2CO_3$ (6.62 g, 48 mmol) in DMF (80 mL) was heated with stirring at 50 °C under argon for 30 h. The cooled reaction mixture was poured into cold water (100 mL) with stirring. The formed precipitate was filtered, washed with water, and dried in vacuo. The separation of the prepared compounds was achieved by column chromatography using silica gel with $CHCl_3$. The white powder product was obtained by evaporation of the solvent. This compound is readily soluble in $CHCl_3$, $CH_2Cl_2$, acetone, and THF. Yield 1.82 g (48%). M.p. 223 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 7.73–7.21 (m, 11 H, arom. CH), 5.51 (s, 1 H, acetal CH), 4.88–3.64 (m, 8 H, aliph. $CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3074–3038 (arom. CH), 2926–2851 (aliph. CH), 2231 (C≡N), 1595 (arom. C=C), 1483, 1390, 1309, 1246 (aliph.–O–arom.), 1165, 1093 cm$^{-1}$. $C_{28}H_{20}N_4O_4$: calcd. C 70.58, H 4.23, N 11.76; found C 70.81, H 4.29, N 11.62.

**2′,10′,16′,24′-[Tetrakis(2-phenyl-1,3-dioxan-5,5-diyl)bis(methylene)bis(oxy)]bis(phthalocyaninato)dizinc(II) (4) and 2′,10′,16′,24′-[Tetrakis(2-phenyl-1,3-dioxan-5,5-diyl)bis(methylene)bis(oxy)]bis(phthalocyaninato)dicobalt(II) (5):** Compound **3** (0.24 g, 0.5 mmol) and $Zn(OAc)_2{\cdot}2H_2O$ (0.22 g, 1 mmol) or $Co(OAc)_2{\cdot}4H_2O$ (0.13 g, 0.5 mmol) were ground in a mortar. Then the mixture was put in a glass tube, and the tube was purged with argon. After being sealed, the mixture was heated at 300 °C for 10 min. After cooling to room temp., the deep turquoise blue **4** or deep blue **5** were powdered by grinding. The crude products were dissolved in DMF (5 mL) and reprecipitated with a mixture of acetone/ethanol (1:1, v/v). After filtration, the precipitates were washed successively with hot water, ethanol, and acetone, and dried in vacuo. Compounds **4** and **5** were isolated using silica gel and a gradient of THF/DMF (10:0.1 to 10:2, v/v) as the eluent. These compounds are soluble in THF, DMSO, DMF, and DMA. Yield (**4**): 58 mg (23%). M.p. >300 °C. UV/Vis (DMF): $\lambda$ (log $\varepsilon$) = 680 (5.29), 638 (4.92), 353 (5.12) nm (Figure 1). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.42–7.03 (m, 44 H, arom. CH), 6.14 (s, 4 H, acetal CH), 4.81–3.57 (m, 32 H, aliph. $CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3067 (arom. CH), 2926 (aliph. CH), 1607 (arom. C=C), 1232 (aliph.–O–arom.), 1090, 1065 cm$^{-1}$. MALDI-TOF MS: $m/z$ = 2038 [M + H]$^+$, 2082 [M – H + 2Na]$^+$. $C_{112}H_{80}N_{16}O_{16}Zn_2$: calcd. C 66.05, H 3.96, N 11.00; found C 65.84, H 3.89, N 11.12. Yield (**5**): 46 mg (18%). M.p. >300 °C. UV/Vis (DMF): $\lambda$ (log $\varepsilon$) = 665 (5.03), 625 (4.88), 330 (5.10), 278 (4.99) nm (Figure 1). IR (KBr): $\tilde{\nu}$ = 3045 (arom. CH), 2941–2850 (aliph. CH), 1603 (arom. C=C), 1265, 1228 (aliph.–O–arom.), 1095, 1057 cm$^{-1}$. MALDI-TOF MS: $m/z$ = 2023 [M + H]$^+$, 2045 [M + Na]$^+$, 2091 [M + 3Na]$^+$. $C_{112}H_{80}Co_2N_{16}O_{16}$: calcd. C 66.47, H 3.98, N 11.07; found C 67.14, H 4.11, N 11.32.

**2′,10′,16′,24′-[Tetrakis(4,4′-2,2-bis(hydroxymethyl)propane-1,3-diyl)bis(oxy)]bis(phthalocyaninato)dizinc(II) (6) and 2′,10′,16′,24′-[Tetrakis(4,4′-2,2-bis(hydroxymethyl)propane-1,3-diyl)bis(oxy)]bis(phthalocyaninato)dicobalt(II) (7):** A suspension of **4** (0.11 g, 0.06 mmol) or **5** (0.12 g, 0.054 mmol) and Pd/C(10%) (30 mg) in DMSO (20 mL) was hydrogenated at room temp. under 1 atm hydrogen pressure for 8 h. The catalyst was filtered off, and the mixture was precipitated with the addition of ethanol to give **6** or **7**. Compounds **6** or **7** were dissolved in DMF (2 mL) and reprecipitated with a mixture of acetone/ethanol (1:1, v/v). After filtration, the precipitates were washed successively with hot acetic acid, water, and alcohol, and dried in vacuo. The purification of **6** and **7** was carried out using silica gel columns with a THF/DMF system changing from 10:0.1 to 10:1 (v/v). These compounds are soluble in THF, DMSO, DMF, and DMA. Yield (**6**): 69 mg (76%). M.p. >300 °C. UV/Vis (DMF): $\lambda$ (log $\varepsilon$) = 680 (5.08), 639 (5.02), 344 (5.11) nm (Figure 1). $^1$H NMR ([D$_6$]DMSO): $\delta$ = 11.35 (br s, 8 H, aliph. OH, disappeared with $D_2O$ exchange), 8.31–6.94 (m, 24 H, arom. CH), 4.12–3.13 (m, 32 H, aliph. $CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3402 (aliph. OH), 3059 (arom. CH), 2926–2851 (aliph. CH), 1603 (arom. C=C), 1466, 1228 (aliph.–O–arom.), 1089, 1045 cm$^{-1}$. MALDI-TOF MS: $m/z$ = 1685 [M + H]$^+$, 1596 [M – 88]$^+$ (Figure 4). $C_{84}H_{64}N_{16}O_{16}Zn_2$: calcd. C 59.90, H 3.83, N 13.31; found C 60.44, H 3.79, N 13.63. Yield (**7**): 62 mg (63%). M.p. >300 °C. UV/Vis (DMF): $\lambda$ (log $\varepsilon$) = 674 (5.13), 610 (4.69), 336 (4.88) nm (Figure 1). IR (KBr): $\tilde{\nu}$ = 3396 (aliph. OH), 3053 (arom. CH), 2933–2874 (aliph. CH), 1603 (arom. C=C), 1468, 1232 (aliph.–O–arom.), 1094, 1056 cm$^{-1}$. MALDI-TOF MS: $m/z$ = 1672 [M + H]$^+$ (Figure 5). $C_{84}H_{64}Co_2N_{16}O_{16}$: calcd. C 60.36, H 3.86, N 13.41; found C 61.01, H 3.80, N 13.11.

**2′,10′,16′,24′-[{Tetrakis(4,4′-2,2-bis(oxidomethyl)propane-1,3-diyl)-bis(oxy)}]bis(phthalocyaninato)dizinc(II)] Octapotassium (8) and 2′,10′,16′,24′-[{Tetrakis(4,4′-2,2-bis(oxidomethyl)propane-1,3-diyl)-bis(oxy)}]bis(phthalocyaninato)dicobalt(II)] Octapotassium (9):** Compound **6** (0.034 g, 0.02 mmol) or **7** (0.017 g, 0.01 mmol) was suspended in aqueous KOH solution (20%, 5 mL) and boiled for 10 min. The solution of the compound **8** or **9** was cooled, and the mixture was poured into ethanol (100 mL). The formed precipitate was filtered off, dissolved in water and reprecipitated in ethanol several times until the solution was neutral. The products were then washed with ethanol and diethyl ether, and dried in vacuo. Both compounds are soluble in water at room temp. Yield (**8**): 0.031 g (77%). M.p. >300 °C. UV/Vis (water): $\lambda$ (log $\varepsilon$) = 687 (4.62), 637 (4.70), 338 (4.53) nm (Figure 2). IR (KBr): $\tilde{\nu}$ = 3061 (arom. CH), 2939–2870 (aliph. CH), 1605 (arom. C=C), 1489, 1226 (aliph.–O–arom.), 1095, 1044 cm$^{-1}$. $C_{84}H_{56}N_{16}O_{16}K_8Zn_2$: calcd. C 50.72, H 2.84, N 11.27; found C 51.08, H 2.79, N 11.31. ICP-MS (Zn, K): Anal. calcd. for $C_{84}H_{56}N_{16}O_{16}K_8Zn_2$: Zn 6.58, K 15.73; found Zn 6.47, K 15.91. Yield (**9**): 0.013 g (65%). M.p. >300 °C. UV/Vis (Water): $\lambda$ (log $\varepsilon$) = 685 (4.36), 623 (4.47), 279 (4.67) nm (Figure 3). IR (KBr): $\tilde{\nu}$ = 3067 (arom. CH), 2931–2865 (aliph. CH), 1601 (arom. C=C), 1482, 1224 (aliph.–O–arom.), 1093, 1047 cm$^{-1}$. $C_{84}H_{56}Co_2N_{16}O_{16}K_8$: calcd. C 51.06, H 2.86, N 11.34; found C 50.81, H 2.79, N 11.18. ICP-MS (Co, K): Anal. calcd. for $C_{84}H_{56}Co_2N_{16}O_{16}K_8$: Co 5.96, K 15.83; found Co 6.07, K 15.79.

**Electrochemistry and Spectroelectrochemistry:** The cyclic voltammetry (CV) and controlled potential coulometry (CPC) measurements were carried out with a Princeton Applied Research Model VersaStat II potentiostat/galvanostat, which was controlled by an external PC and utilized a three-electrode configuration at 25 °C.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The working electrode was a Pt plate with a surface area of 0.10 $cm^2$. The surface of the working electrode was polished with a $H_2O$ suspension of $Al_2O_3$ before each run. The last polishing was done with a particle size of 50 nm. A Pt wire served as the counter electrode. Saturated calomel electrode (SCE) was employed as the reference electrode and was separated from the bulk of the solution by a double bridge. The ferrocene/ferrocenium couple ($Fc/Fc^+$) was also used as an internal standard. Electrochemical grade tetrabutylammonium perchlorate (TBAP) in extra pure DMSO was employed as the supporting electrolyte at a concentration of 0.10 mol/$dm^3$. High purity $N_2$ was used for deoxygenating the solution at least 20 min prior to each run and for maintaining a nitrogen blanket during the measurements. For CPC studies, Pt gauze working electrode (10.5 $cm^2$ surface area), Pt-wire counter electrode separated by a glass bridge, and SCE as a reference electrode were used. The spectroelectrochemical measurements were carried out with an Agilent Model 8453 diode array spectrophotometer equipped with the potentiostat/galvanostat and utilized a three-electrode configuration of thin-layer quartz spectroelectrochemical cell at 25 °C. The working electrode was transparent Pt gauze. Pt-wire counter electrode separated by a glass bridge and a SCE reference electrode separated from the bulk of the solution by a double bridge were used.

**Conductivity and Thermopower Measurements:** The electrodes used in the conductivity and thermopower measurements consisted of an interdigital array of metal electrodes photolithographically patterned on pre-cleaned glass substrate. The films were prepared by spin-coating method. The substrate temperature was kept constant at 290 K during deposition of the materials over the electrodes. Dc conductivity and impedance spectra measurements were performed between 290 and 440 K by using a Keithley 617 electrometer. Ac conductivity and impedance measurements were carried out with a Keithley 3330 LCZ meter in the frequency range 40 to $10^5$ Hz, in the temperature range 290 to 440 K. Both dc and ac conductivity measurements were performed under $10^{-3}$ mbar in the dark. The conductivity data were recorded using an IEEE 488 data acquisition system incorporating a personal computer. The thermopower was determined independently from the electrical conductivity measurements. Thermopower measurements were carried out on the same samples, which were prepared for electrical conductivity measurements. The Seebeck coefficient $S$ was determined by measuring the voltage for a temperature gradient over the samples by using a Keithley 2000 digital multimeter. The temperature difference between the two sides of the film was measured by a Ni/CrNi thermocouple.

# Steric and Electronic Effects in the Dimerization of Wanzlick Carbenes: The Alkyl Effect[‡]

**Michael K. Denk,*[a] Azardokht Hezarkhani,[a] and Feng-Lan Zheng[a]**

**Keywords:** Carbenes / Thiourea / Thermochemistry / Dimerization / Enetetramine / Steric hindrance / DFT calculations / Steric effects / Electronic effects

The steric and electronic influence of *N*-alkyl substituents on the dimerization energies $\Delta G°$ of Wanzlick carbenes (imidazolidin-2-ylidenes) was investigated experimentally and through DFT methods for a series of non-symmetrically substituted Wanzlick carbenes. A series of 3-alkyl-1-*tert*-butylimidazolidin-2-ylidenes with decreasing steric demand of the alkyl substituent (isopropyl, ethyl and methyl) were obtained in four steps from the commercially available *N*-alkylaminoethanol compounds. The carbenes are hydrolytically sensitive, colorless oils that can be distilled without decomposition and show no sign of dimerization to the respective enetetramines, even after prolonged heating. Calculations at the B98/6-31G(d) level confirm that the dimerization of all three carbenes is thermodynamically unfavorable. To separate the steric and electronic stabilization of Wanzlick carbenes by *N*-alkyl substituents, the formation energies of $R,H_3$ mono-alkyl enetetramines were used to derive electronic increments for the *N*-alkyl substituents. The computational data show that all alkyl substituents electronically stabilize Wanzlick carbenes vs. their dimerization products with increments ranging from 2.97 kcal mol$^{-1}$ (*N*-methyl) to as high as 6.28 kcal mol$^{-1}$ (*N*-*tert*-butyl). For combinations of *N*-methyl, *N*-ethyl and *N*-isopropyl substituents, the increments are additive and the dimerization energies were found to be free of noticeably steric effects. Significant steric strain was found for all *t*Bu-substituted carbenes with strain energies of the dimerization products ranging from 6.92 kcal mol$^{-1}$ [formation of (*E*)-$Me_2tBu_2$-enetetramine] to 24.23 kcal mol$^{-1}$ (formation of $tBu_4$ enetetramine). The *tert*-butyl substituent thus assumes a unique position by strongly stabilizing the carbenes electronically as well as sterically.

## 1. Introduction

A limit to the steadily growing number of thermodynamically stable diamino carbenes[1] obtained since the isolation of a imidazol-2-ylidene (**A**, R = 1-adamantyl) in 1991 by Arduengo et al.[2] is their dimerization[3–5] to the respective enetetramines,[6] the very reaction preventing the isolation of 1,3-diphenylimidazolidin-2-ylidene investigated by Wanzlick's group more than 40 years ago.[3] While dimerization of the aromatically stabilized[7] carbenes of type **A** is thermodynamically unfavorable even for small substituents like R = Me, and has only been observed for the special case of the covalently tethered bis-carbene (formation of **B=B**)[8] all other diamino carbenes like **C** and **D** require sterically demanding substituents to be thermodynamically stable towards dimerization.[5–11] A notable exception may be the benzo-annellated carbene **E** that has recently been obtained by Metallinos et al.[12]

The crucial role of steric protection is particularly obvious from the behavior of Wanzlick carbenes **D** which dimerize for R = phenyl, the substituent originally chosen by Wanzlick's group, but are thermodynamically stable towards dimerization for R = *tert*-butyl[4] and mesityl.[13] For alkyl substituents, even a slight relaxation of the steric demand (R = isopropyl, ethyl, or methyl) the Wanzlick carbenes dimerize although the dimerization is slow enough to be observed by NMR methods.[4,5] The slow nature of the dimerization has since been strikingly highlighted by the successful isolation and structural characterization of a series of thermodynamically unstable amino carbenes like the tetramethyl analog of **C**,[10a] the tetraethyl analog of **C**[10b] and even the monoamino carbene **F** (Scheme 1).[10c] Irrespective of the kinetic aspect of the reaction, the presence of bulky substituents remains a prerequisite for the design of thermodynamically stable carbenes. For Wanzlick carbenes bearing identical *N*-substituents, the demarcation line separating stable from unstable carbenes is now established as $tBu_2/iPr_2$[4] and $Mes_2/Ph_2$.[13] Wanzlick carbenes bearing only *one* bulky *N*-alkyl substituent should dimerize to the (E)-enetetramines in which steric repulsion is minimized due to the large-small combination of alkyl substituents facing each other across the double bond (Scheme 2).

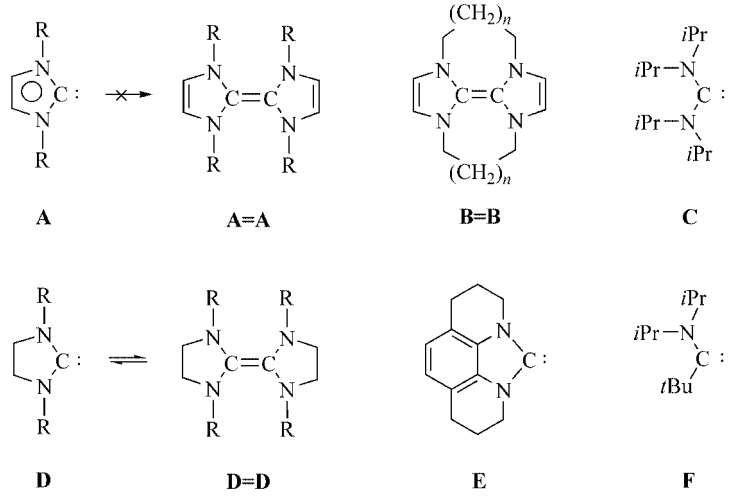
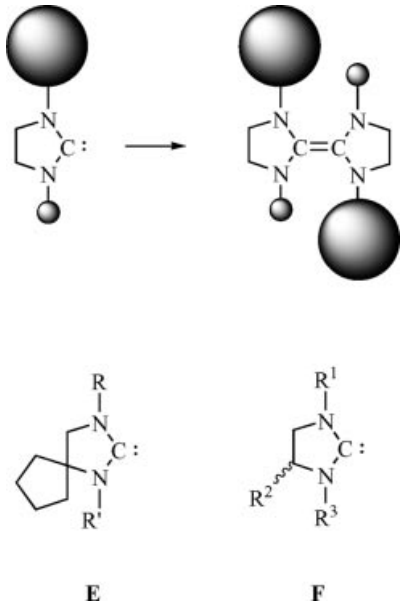


Scheme 1. Dimerization of aminocarbenes.



Scheme 2. Steric matching in non-symmetric Wanzlick carbenes.

To examine this prediction experimentally, we have obtained a series of 3-alkyl-1-*tert*-butylimidazolidin-2-ylidenes with alkyl substituents of decreasing size (R: *i*Pr, Et and Me). Much to our surprise, all three carbenes are perfectly stable and do not show any sign of dimerization even for the smallest substituent (Me). While surprising, the observed lack of dimerization is in good agreement with the behavior of 1,3,4-trisubstituted Wanzlick carbenes **E** and **F** (Scheme 2) which have been obtained via a new elegant synthetic protocol by Hahn's group while this work was in progress.[14]

The observed lack of dimerization is nevertheless hard to rationalize on purely steric grounds so that a more detailed computational examination of the steric and electronic influence of *N*-alkyl groups on the dimerization of Wanzlick carbenes seemed desirable.

## 2. Results and Discussion

The synthesis of Wanzlick carbenes **4** bearing dissimilar substituents R, R′ on the nitrogen atoms is of obvious interest to understand the fine interplay of steric and electronic effects in the Wanzlick equilibrium but is also desirable to broaden the repertoire of N-heterocyclic carbenes used as steering ligands in catalysis. While the symmetrically substituted ethylenediamines RNH-$CH_2CH_2$-NHR′ (R = R′) are commercially available and are also readily accessible from 1,2-dibromoethane and primary amines,[15] ethylenediamines RNH-$CH_2CH_2$-NHR′ bearing dissimilar substituents are less well explored and accessible only through multistep reactions.[16] Except for R, R′ = Me,H the diamines are not commercially available.

Among the number of possible synthetic approaches tested in our group, only the reaction of primary amines with 2-chloroethylamines[17] proved to be the most useful (Scheme 3). Apart from being adaptable to a great variety of substituents R,R′ the reactions are readily scaled up and deliver acceptable yields and purities of the diamines.

The disadvantage of using the rather toxic 2-chloroethylamines is diminished by the fact that the stable and non-volatile hydrochloride salts can be used instead of the volatile free bases.

Reaction of 2-(*tert*-butylamino)ethanol with $SOCl_2$ followed by reaction with the respective primary amine thus gave the *N*-*tert*-butyl-*N*′-(alkyl)ethylenediamines (**1**). To obtain good yields of the respective ethylenediamines, the use of an excess of the primary amine (5 equiv. or more) as well as high reaction temperatures (180 °C) were found to be crucial. Lowering the amount of primary amine lead to the predominant formation of *N*,*N*′-di-*tert*-butylpiperazine through the competing self-condensation of the 2-chloroamine, while lower reaction temperatures were found to be inadequate to achieve complete conversion (detection of the free 2-chloroamine by GC-MS). The synthesis of the respective thioureas from the ethylenediamines turned out to be an additional obstacle. As we noted previously for

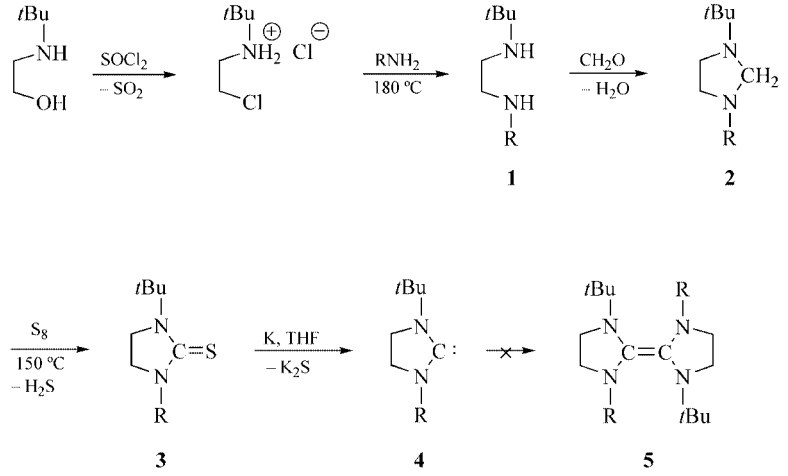
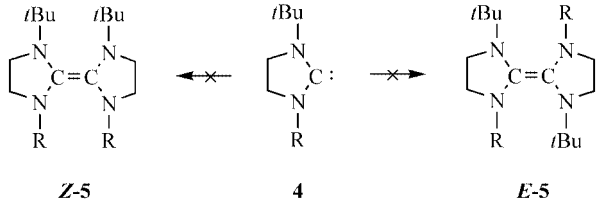


Scheme 3. Synthesis of 3-alkyl-1-*tert*-butylimidazolidin-2-ylidenes from 2-(*tert*-butylamino)ethanol.

ethylenediamines bearing *two* bulky *N*-alkyl substituents, the respective thioureas can only be obtained in poor yields via the textbook $CS_2$ route or its many variations.[18] The reaction of the ethylenediamines **1a**–**1c** with $CS_2$ gave likewise only trace amounts (GC-MS) of the thioureas **3a**–**3c**. The presence of only *one* sterically demanding substituent (*tert*-butyl) is obviously sufficient to block the $CS_2$ route.[18] To circumvent these problems, the thioureas **3a**–**3c** were obtained by oxidation of the respective formaldehyde aminals (imidazolidines) **2a**–**2c** with elemental sulfur, $S_8$, a two-step one-pot approach recently developed in our group to overcome the problems of the $CS_2$ method.[18] Reductive desulfurization of the thioureas with potassium (Kuhn method)[19] gave the respective carbenes in high yields (85–95%).

The carbenes were obtained as spectroscopically pure ($^1$H NMR, $^{13}$C NMR) oils that are readily distilled without decomposition. In line with the previously examined Wanzlick and Arduengo carbenes[20] the carbenes **4a**–**4c** were found to be unreactive towards dry oxygen but readily hydrolyze in air.[21] Most remarkably, the carbenes did not show any sign of dimerization either as such or in $C_6D_6$ at room temperature or at 100 °C even after 12 months. The dimerization of the carbenes **4a**–**4b** can in principle lead to the formation of either the respective (*E*)- or the (*Z*)-enetetramines (Scheme 4).



Scheme 4. Potential formation of enetetramines **5** from carbenes **4a**–**4c**.

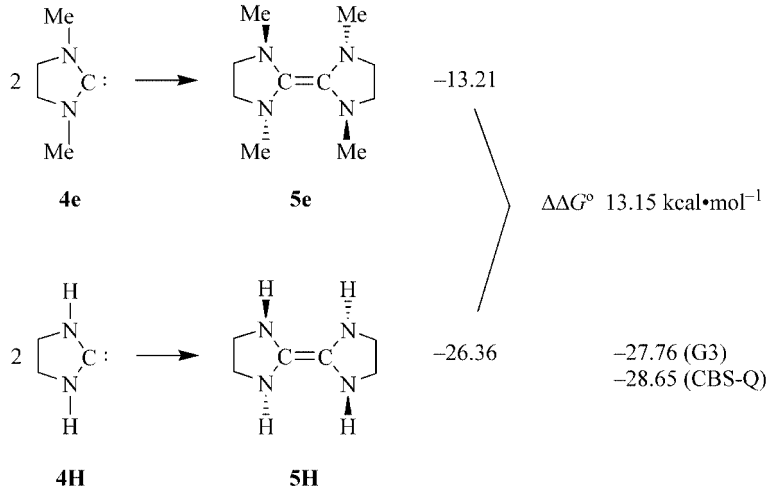
While the (*Z*)-enetetramine is likely to suffer from significant steric front-strain due to the interaction of the *tert*-butyl groups and might be unstable for steric reasons, the argument cannot be applied to the (*E*)-isomer. The fact that neither of the two possible dimerization products could be observed is therefore hard to justify on purely steric grounds and points towards the importance of electronic effects in the stabilization of **4**. To clarify this issue, the steric and electronic influence of different *N*-alkyl substituents on the dimerization energies of Wanzlick carbenes was investigated through DFT calculations.

## Computational Studies

DFT calculations of symmetrically substituted diamino carbenes have already generated significant insight into the nature of the dimerization reaction,[5] and have recently been reviewed by Alder et al.[1a] Of particular importance is the conclusion that calculated dimerization energies $\Delta G°$ are in good qualitative agreement with the experimentally observed dimerization behavior.[1a] The precise balance of steric and electronic effects on the stability of the carbenes towards dimerization on the other hand is less clear. DFT calculations at the B98/6-31G(d) level were carried out to establish if the dimerization of the carbenes **4a**–**4c** has a thermodynamic basis and to quantify steric and electronic effects of the respective *N*-alkyl substituents. The B98 functional was selected because it offers improved thermochemical accuracy over the B3LYP method without adding computational cost.[23] To obtain a benchmark for the accuracy of the DFT calculations, the dimerization energy of the hypothetical unsubstituted carbene **4H** was calculated with the high precision CBS-Q[26] and G3[27] methods. All calculations were carried out with the Gaussian03 suite of programs.[22] Local minima were confirmed through the absence of virtual frequencies. The geometry selected for the enetetramines **5** is that found experimentally for all solid-state structures of *N*-alkyl-substituted enetetramines.[28]

The surprisingly strong effect of *N*-alkyl substituents on the dimerization of Wanzlick carbenes is readily apparent from a comparison of the dimerization energies $\Delta G°$ of *N*,*N*′-dimethylimidazolidin-2-ylidene (**4e**) with that of the unsubstituted carbene **4H** (Scheme 5). The dimerization energies reveal a net stabilizing effect caused by the presence

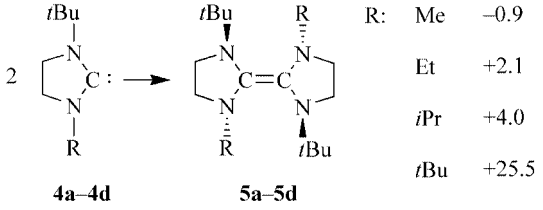
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 5. Influence of *N*-methyl substitution on the dimerization energy of imidazolidin-2-ylidene. Dimerization energies $\Delta G°$ (in kcal mol$^{-1}$) at the B98/6-31G(d), CBS-Q and G3 level.

of four methyl groups ca. 13 kcal mol$^{-1}$. The high accuracy of the B98/6-31G(d) approach can be inferred by the excellent agreement of the dimerization energy of **1H** (–26.4 kcal mol$^{-1}$) with the respective G3 (–27.8 kcal mol$^{-1}$) and CBS-Q data (–28.7 kcal mol$^{-1}$).

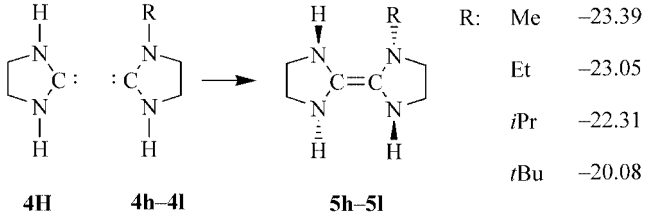
The lack of dimerization observed for the carbenes **4a**–**4c** can in principle have thermodynamic reasons ($\Delta G° > 0$) or kinetic reasons (high $\Delta G^{‡}$). The kinetic stabilization of Wanzlick carbenes bearing only *one* sterically demanding substituent may in fact be expected from the orbital symmetry required non-least-motion pathway.[24] The calculations do however reveal that the dimerization of the carbenes **4a**–**4d** is in fact thermodynamically unfavorable: dimerization is predicted to be thermodynamically unfavorable for **4b** and **4c** and close to thermoneutral for **4a** (Scheme 6). The stable carbene **4d** which was obtained earlier in our group[4] has been included for comparison as the sterically most crowded member of the series.



Scheme 6. Dimerization energies $\Delta G°$ (in kcal mol$^{-1}$) of imidazolidin-2-ylidenes **4a**–**4d** at the B98/6-31G(d) level of theory.

A comparison of the individual reaction energies is instructive. While the dimerization energies $\Delta G°$ show only small incremental changes from **4a**–**4c** a steep rise of ca. 20 kcal mol$^{-1}$ occurs from **4c** to **4d**. While it is tempting to assign this discontinuous change in the dimerization energy to the onset of steric crowding, a rational, quantitative separation of steric and electronic factors is desirable.

To reveal the electronic effects of *N*-alkyl substituents on the dimerization reaction, the formation of the mono-alkyl enetetramines **5h**–**5l** from the respective carbenes were examined (Scheme 7). The presence of only *one* alkyl substituent in the enetetramines **5h**–**5l** eliminates the possibility of steric effects resulting from alkyl–alkyl repulsion. The variation in the dimerization energies will thus reflect the electronic effect of the *N*-alkyl substituent.



Scheme 7. Formation of mono-substituted enetetramines **5h**–**5l** from the respective carbenes **4H**, **4f**–**4i**. Energies $\Delta G°$ at the B98/6-31G(d) level.

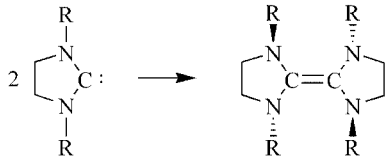
Comparison of the dimerization energies in Scheme 7 with those obtained for the unsubstituted enetetramine **5H** (Scheme 5, $\Delta G° = –26.4$ kcal mol$^{-1}$) leads to electronic increments of the *N*-alkyl substituents as +2.97 kcal mol$^{-1}$ (Me), +3.31 kcal mol$^{-1}$ (Et), +4.04 kcal mol$^{-1}$ (*i*Pr) and +6.28 kcal mol$^{-1}$ (*t*Bu). While all four *N*-alkyl substituents electronically stabilize the carbene vs. the dimer, the effect increases along the series Me < Et < *i*Pr < *t*Bu. Although the electronic influence of the individual alkyl substituents may appear small, it must be born in mind that the overall effect is anything but negligible for the fully substituted enetetramines. The electronic effect of replacing four methyl substituents with four *tert*-butyl substituents amounts to 13 kcal mol$^{-1}$, a large caloric change considering that the dimerization reactions are close to equilibrium.

The electronic increments obtained above can now be used to separate electronic and steric effects of the *N*-alkyl substituents.

Addition of four electronic increments to the base value corresponding to the formation of unsubstituted enetetramine **5H** from the unsubstituted carbene **4H** (–26.36 kcal) will give the strain-free, electronic component $\Delta G_{el}$ of the dimer-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ization energies. Comparison of $\Delta G_{el}$ with the fully optimized values $\Delta G_{FC}$ leads to the quantitative estimate of strain energies $\Delta G_{st}$ according to $\Delta G_{FC} = \Delta G_{el} + \Delta G_{st}$. Scheme 8 shows the results for the symmetrically substituted carbenes.



**4d–4h** **5d–5g**

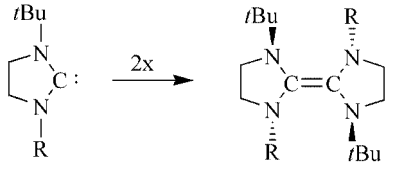
| R | $\Delta G_{fc}$ | $\Delta G_{el}$ | $\Delta G_{st}$ |
|---|---|---|---|
| Me | –13.21 | –14.48 | + 1.27 |
| Et | –12.73 | –13.12 | + 0.39 |
| *i*Pr | –9.65 | –10.20 | + 0.55 |
| *t*Bu | + 25.47 | +1.24 | + 24.23 |

Scheme 8. Dimerization energies $\Delta G°$ (in kcal mol$^{-1}$) of symmetrically substituted Wanzlick carbenes at the B98/6-31G(d) level. Comparison of fully optimized energies ($\Delta G_{FC}$) with those derived from the addition of electronic alkyl increments ($\Delta G_{el}$). Steric contributions $\Delta G_{st}$ derived according to $\Delta G_{FC} = \Delta G_{el} + \Delta G_{st}$.

The dimerization energies obtained from full calculations ($\Delta G_{FC}$) and those obtained through the increment approach ($\Delta G_{el}$) are practically identical for R = Me, Et, and *i*Pr which rules out the presence of significant steric strain for these alkyl substituents. For R = *t*Bu, the pronounced difference between $\Delta G_{FC}$ (+25.47 kcal mol$^{-1}$) and $\Delta G_{el}$ (+1.24 kcal mol$^{-1}$) confirms a strong steric destabilization (+24.23 kcal mol$^{-1}$) of the enetetramine. The same approach can now be used to check if the enetetramines **5a**–**5c** are indeed free from steric strain as the large-small size match of the alkyl substituents (Scheme 2) seems to suggest.

The quantitative analysis (Scheme 9) contradicts this simplistic pictorial prediction by revealing strain energies $\Delta G_{st}$ ranging from +6.92 kcal mol$^{-1}$ (*t*Bu,Me) to +10.25 kcal mol$^{-1}$ (*t*Bu,*i*Pr). Steric strain is in fact a crucial factor for the thermodynamic stability of the carbenes **4a**–**4c** because dimerization would occur otherwise ($\Delta G_{el} < 0$).

The thermodynamic stability of Wanzlick carbenes **4** towards dimerization can in principle be ascribed to an inherent stabilization of the carbenes **4**, a destabilization of the enetetramines **5** or a combination of both. While dimerization energies, experimental or computational, cannot differentiate between these two possibilities, a comparison of other relevant data with the dimerization energies may nevertheless provide some insight. Table 1 compares the influence of the *N*-alkyl substituent on the $^{13}$C NMR shifts and dimerization energies of Wanzlick carbenes **4**, with the calculated length of the carbon–carbon double bond and the associated valence vibrations in the dimers **5** arranged in order of decreasing carbene dimerization energies $\Delta G°$.



**4** **5a–5c**

| R | $\Delta G_{fc}$ | $\Delta G_{el}$ | $\Delta G_{st}$ |
|---|---|---|---|
| Me | –0.94 | –7.86 | +6.92 |
| Et | +2.13 | –7.18 | +9.31 |
| *i*Pr | +4.54 | –5.72 | +10.25 |

Scheme 9. Dimerization energies $\Delta G°$ (in kcal mol$^{-1}$) of non-symmetrically substituted Wanzlick carbenes at the B98/6-31G(d) level. Comparison of fully optimized energies ($\Delta G_{FC}$) with those derived from the addition of electronic alkyl increments. Steric contributions $\Delta G_{st}$ derived according to $\Delta G_{FC} = \Delta G_{el} + \Delta G_{st}$.

Table 1. Dimerization of Wanzlick carbenes: comparison of $^{13}$C NMR shifts and calculated dimerization energies $\Delta G°$ of carbenes **4** with calculated double bond lengths and valence vibrations of the corresponding (*E*)-enetetramines **5**.

| R | | $\delta$ $N_2C$ [ppm] | | $\nu$(C=C) [cm$^{-1}$] | *d*(C=C) [pm] | $\Delta G°$ [kcal mol$^{-1}$] |
|---|---|---|---|---|---|---|
| Me,Me | **4e** | 239.8 | **5e** | 1771 | 135.23 | –13.21 |
| Et,Et | **4f** | 237.7 | **5f** | 1765 | 135.28 | –12.73 |
| *i*Pr,*i*Pr | **4g** | 236.8 | **5g** | 1746 | 135.80 | –9.65 |
| *t*Bu,Me | **4a** | 239.7 | **5a** | 1715 | 136.45 | –0.94 |
| *t*Bu,Et | **4b** | 238.8 | **5b** | 1710 | 136.43 | +2.13 |
| *t*Bu,*i*Pr | **4c** | 237.6 | **5c** | 1704 | 136.70 | +4.54 |
| *t*Bu,*t*Bu | **4d** | 238.3 | **5d** | 1671 | 137.47 | +25.47 |

The increase in double bond lengths and decrease in the C=C stretching frequencies of the enetetramines **5** correlates well with the dimerization energies of **4**. The $^{13}$C NMR shifts ($N_2C$) of the carbenes **4** on the other hand show only a negligible variation regardless of whether the respective carbene dimerizes (**4e**, **4f**, **4g**) or not (**4a**–**4d**). It therefore seems likely, that the variation in dimerization energies is predominantly caused by a progressive destabilization of the enetetramines **5** rather than a stabilization of the carbenes **4**. The thermodynamic stability of Wanzlick carbenes **4** towards dimerization may thus reflect the stability of the dimers **5** rather than those of the carbenes **4**.[25]

A comparable analysis of how the respective activation energies of the dimerization are influenced by steric and electronic factors would be very desirable and will be the subject of future studies.

## 3. Conclusions

The stability of Wanzlick carbenes towards dimerization is the result of a complex interplay between electronic and steric effects of the nitrogen substituents. There is a smooth increase of stability along the series R = Me, Et, *i*Pr, *t*Bu,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the *tert*-butyl substituent occupies a special position by strongly stabilizing the carbenes electronically as well as sterically. A comparison of spectroscopic and computational data suggests that the dimerization energies of Wanzlick carbenes may in fact reflect variations in the stabilities of the enetetramines rather than that of the carbenes themselves.

## 4. Experimental Section

Melting points were recorded in sealed capillaries and are uncorrected. EI-MS spectra were obtained with a Varian CP-3800 GC/Saturn 2000 MS combination at an ionizing voltage of 70 eV and a 30 × 0.25 mm Varian CP 5860 low-bleed phenyl(dimethyl)siloxane column (5% phenyl). Temperature program: 4 min 50 °C; 10 min constant heating rate of 20 °C/min; 6 min 250 °C. NMR spectra were recorded with Bruker 400 MHz ($^1$H) and 500 MHz ($^{13}$C) NMR spectrometers at room temperature. All NMR spectra are referenced vs. tetramethylsilane (internal). 2-(*tert*-Butylamino)ethanol, isopropylamine, ethylamine, methylamine, sulfur, paraformaldehyde and potassium were obtained from Aldrich Inc., thionyl chloride from Johnson Mathey. All operations were carried out under inert gas (99.999% Argon) unless indicated otherwise. [2-(*tert*-butylamino)ethyl chloride] hydrochloride was obtained from 2-(*tert*-butylamino)ethanol and thionyl choride according to ref.[17]

**Synthesis of *N*,*N*′-Disubstituted Ethylenediamines 1a–c:** 2-(*tert*-Butylamino)ethyl chloride hydrochloride (50 g, 0.29 mol), the primary amine (1.45 mol) and water (250 mL) were sealed in a 1-L stainless-steel autoclave and heated to 180 °C for 48 h. After cooling the autoclave to room temperature, water (100 mL) and NaOH pellets (75 g) were added to the autoclave. The resulting biphasic crude solutions were extracted with $Et_2O$ (3 × 100 mL). The combined organic phases were dried by addition of NaOH pellets and decanting from the freshly forming aqueous phase until the NaOH pellets remained undissolved. After removal of the solvent in vacuo, the pure *N*,*N*′-dialkylethylenediamines were obtained by fractional distillation over a 20 cm Vigreux column under normal pressure.

**Synthesis of 3-Alkyl-1-*tert*-butylimidazolidines 2a–c:** A mixture of the respective *N*,*N*′-disubstituted ethylenediamine (**1a**, **1b** or **1c**, 30 mmol), ether (15 mL), and paraformaldehyde (1.2 g, 40 mmol) was stirred at room temperature for 24 h. The resulting turbid solutions were stirred with $MgSO_4$ (ca. 1 g, 24 h) and the imidazolidines isolated by filtration and subsequent evaporation of the solvent in vacuo. Yield quantitative.

**Synthesis of 3-Alkyl-1-*tert*-butylimidazolidine-2-thiones 3a–b:** Elemental sulfur $S_8$ (2.21 g, 8.64 mmol), the respective imidazolidine (34.5 mmol) and ether (15 mL) were sealed in a stainless steel autoclave and heated to 160 °C for 12 h. The cold reaction mixtures were extracted with methanol (3 × 10 mL), filtered, and the thioureas precipitated by dropwise addition of water (ca. 30 mL) to the methanol solution. Crystallization was typically completed after standing at room temperature for 24 h. A second crop of the thioureas could be obtained by cooling the mother liquor to –20 °C. After vacuum drying for 24 h, both fractions were adequate for the subsequent reduction to the carbenes.

**Synthesis of 3-Alkyl-1-*tert*-butylimidazolidin-2-ylidenes 4a–c:** A solution of the respective 3-alkyl-1-*tert*-butylimidazolidine-2-thione (75 mmol) in THF (200 mL) was boiled with potassium (8.80 g, 226 mmol) for 2 h. The slightly yellowish solutions were filtered through a medium-porosity glass frit and the carbenes isolated by removal of the solvent in vacuo.

***N*-*tert*-Butyl-*N*′-methyl-1,2-diaminoethane (1a):** Colorless oil, b.p. 151 °C, 12.9 g (34%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.09 [s, 9 H, C(C$H_3$)$_3$], 2.43 [s, 3 H, C$H_3$], 2.68 [s, 2 H + 2 H, identical shift, NHC$H_2$] ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 29.1 [C(*C*H$_3$)$_3$], 36.4 [N*C*H$_3$], 41.8 [*t*BuN*C*H$_2$], 50.1 [*C*(CH$_3$)$_3$], 52.6 [MeN*C*H$_2$] ppm. # Anomeric Interactions in Pentafluoroethylimidosulfurous Dichloride, $CF_3CF_2N{=}SCl_2$: Structural, Conformational and Configurational Properties in the Gaseous and Condensed Phases

**Norma L. Robles,[a][‡] Rosa M. S. Álvarez,[a][‡‡] Edgardo H. Cutin,[a][‡‡] Carlos O. Della Védova,*[b,c][‡‡] Mauricio F. Erben,[b][‡‡] Roland Boese,[d] Helge Willner,[e] and Rüdiger Mews[f]**

**Keywords:** Imides / Conformation analysis / Structural analysis / Hyperconjugation / Sulfur

The structural, conformational, and configurational properties of pentafluoroethylimidosulfurous dichloride ($CF_3CF_2N{=}SCl_2$) have been studied by vibrational spectroscopy [IR (vapor) and Raman (liquid)] and quantum chemical calculations [HF, B3LYP and MP2 approximations using the 6-311+G(d) and 6-311+G(2df) basis sets]. $CF_3CF_2N{=}SCl_2$ exists in the liquid phase as a single (*Z*) form (C–N bond synperiplanar with respect to the Cl–S–Cl plane; $C_1$ symmetry). The structure was also determined by X-ray diffraction analysis of a single crystal grown in situ at low temperature. The crystalline solid at 159 K (monoclinic, $P2_1/c$, $a$ = 5.2466(10), $b$ = 15.376(3), $c$ = 18.730(3) Å, $\beta$ = 96.391(3)°, $Z$ = 8) consists of two crystallographically inequivalent (*Z*) forms. The results are discussed in terms of both hyperconjugative electronic effects and of natural bond orbital (NBO) calculations.

## Introduction

Theoretical studies performed in the last twenty years have concluded that more than one single effect should be considered in order to understand the factors stabilizing the staggered conformation of ethane. Hyperconjugation, or the anomeric effect, which is a stereoelectronic effect derived from the overlap of σ-bonding orbitals with an adjacent empty or partially filled antibonding orbital, has been proposed as the most significant factor responsible for stabilizing staggered ethane in a definite molecular conformation.[1–3] This concept has also been applied to fluoroethane species,[4] which have recently attracted much attention, and ultrafast carbon–carbon single-bond isomerization of 1-fluoro-2-isocyanatoethane in solution at room-temperature has been analyzed by two-dimensional infrared vibrational echo spectroscopy.[5]

It is well known that conjugation between lone-pair orbitals and π bonds plays an important role in structural chemistry (the resonance effect) and that the conformational preference is strongly influenced by the presence of perfluorinated groups.[6,7] For instance, conjugation in methyl vinyl ether [$CH_3OC(H){=}CH_2$][8–10] results in a sterically unfavorable synperiplanar orientation of the O–C($sp^3$) bond relative to the double bond, whereas the O–C($sp^3$) bond in $CF_3OC(F){=}CF_2$[11] is nearly perpendicular to the plane of the vinyl group [$\phi$(C=C–O–C) = 104(2)°]. An orbital interaction occurs between the oxygen lone-pair orbital and the π*(C=C) antibonding orbital [lpπ(O)→π*(C=C)] in $CH_3OC(H){=}CH_2$, whereas no conjugation is present in the perfluorinated compound.

Structural, configurational, and conformational studies in compounds such as sulfur imides ($R^1NSR^2R^3$)[12] are scarce, and little is known about the factors affecting these properties. In principle, depending on the orientation of the $R^1$–N bond with respect to the $R^2$–S–$R^3$ bisector angle, two forms [(*E*)/(*Z*)] can be expected (Scheme 1).

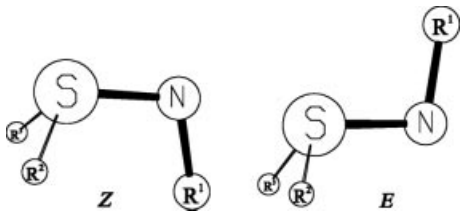


Scheme 1. Representation of the (*Z*) and (*E*) forms of $R^1NSR^2R^3$.

Vibrational spectroscopy, gas electron diffraction, X-ray crystallography, quantum chemical calculations, and other techniques have proved to be powerful tools to understand the structural properties of sulfur imide molecules containing fluorine atoms or fluorinated substituents groups. Thus, the structure and conformational and configurational properties of molecules of the type $R_FN{=}SF_2$ [$R_F$ = $CF_3$,[13–16] FC(O),[17,18] NC,[19] $CF_3C(O)$,[20] and $FSO_2$[21,22]] and $R_FN{=}SCl_2$ [$R_F$ = $CF_3$[23,24] and FC(O)[25]] have been studied, all of which show only a (*Z*) configuration around the putative N=S double bond. It is interesting to note that compounds with different substituents attached at the sulfur atom of the N=S group favor the (*E*) form. Thus, FC(O)N=S(F)$CF_3$[26] and $CF_3C(O)N{=}S(F)CF_3$[27] exist in the vapor as a mixture of (*E*) and (*Z*) forms, with the former predominating.

The question of the nature of the S–N bond in sulfur imides has not yet been resolved, and there is still some controversy as to whether the sulfur imide linkage is a double bond or a semipolar bond.[28] As noted by Protashchuk et al.[29] the relative stabilization of the (*Z*) and (*E*) forms of the simple molecule $HNSH_2$ depends mainly on the effectiveness of the following interactions: (1) the lone pair attached at the nitrogen atom with the σ* antibonding orbitals of the $SH_2$ fragment [lp(N)→σ*(S–H)], (2) the lone pair of the sulfur atom with the σ* antibonding orbital of the NH fragment [lp(S)→σ*(N–H)], and (3) the lone pairs of the nitrogen and sulfur atoms with each other. Both the stabilizing [(1) and (2)] and destabilizing [(3)] interactions are more effective in the (*Z*) than in the (*E*) form, and the destabilizing interaction energy between both lone pairs attached at the nitrogen and sulfur atoms in the (*Z*) form is lower than the stabilizing effects of the negative hyperconjugation, which results in the greater stability of the (*Z*) form for $HNSH_2$. A quantitative evaluation of these effects has been reported recently by Kumar et al.[30] for $HNSH_2$ and also for fluorinated derivatives, by using the NBO population analysis approach.

In order to gain additional experimental and theoretical information about the structural properties of sulfur imides, we report here a study of $CF_3CF_2N{=}SCl_2$ species that draws on its vibrational spectra [IR (vapor) and Raman (liquid)] and single-crystal structure. The presence of the $CF_3CF_2$ group is useful to analyze the effect of a fully fluorinated carbon chain on the molecular structure. Moreover, quantum chemical calculations have been performed in order to assist the interpretation of the experimental data, and Natural Bond Orbital (NBO) population analyses have been applied to rationalize the effect of electronic interactions on the structural, conformational, and configurational properties of $CF_3CF_2N{=}SCl_2$.

## Results and Discussion

### Quantum Chemical Calculations

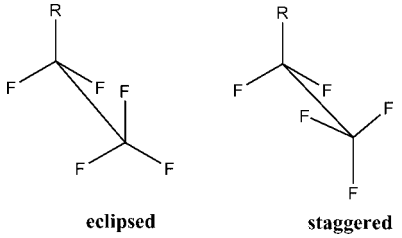
According to the precedents found in the literature for *S*,*S*-dihalo-substituted sulfur imides $R_1N{=}SX_2$ (X = F, Cl; see above), the presence of the (*Z*) form might be expected for $CF_3CF_2N{=}SCl_2$. In order to gain further insight into this molecule, the potential function for internal rotation around the sulfur–imide bond was calculated by geometry optimizations at fixed torsional dihedral angles (steps of 30°) using the HF, B3LYP, and MP2 methods with the 6-311+G(d) basis sets. The derived curves obtained with the HF and MP2 approximations show two minima: a global minimum that corresponds to the (*Z*) structure and a local minimum located about 7.5 kcal mol$^{-1}$ higher in energy which corresponds to the (*E*) form of $CF_3CF_2N{=}SCl_2$ [(*Z*) and (*E*) orientation of the C–N bond with respect to the Cl–S–Cl bisector angle, respectively]. A more complicated picture of the potential energy surface for the mentioned angles was obtained by the hybrid method B3LYP, which shows the same global minimum structure as the former approximations but with a flat region near the local minimum assigned to the (*E*) form. Similar calculations performed by varying the dihedral angle around the C–N bond showed only one minimum at about –150°. Thus, both (*Z*) and (*E*) forms belong to the $C_1$ symmetry point group. Full geometry optimizations and frequency calculations for the two feasible conformers were performed with the more extended 6-311+G(2df) basis sets. The relative energies are summarized in Table 1.

Table 1. Calculated relative energies (corrected for the zero-point energy) in kcal mol$^{-1}$ for stable conformers of $CF_3CF_2N{=}SCl_2$.

| | HF/6-311+G(d) $\Delta E°$[a] | B3LYP/6-311+G(d) $\Delta E°$[a] | MP2/6-311+G(d) $\Delta E°$[a,b] |
|---|---|---|---|
| *syn* | 0.00 | 0.00 | 0.00 |
| *anti* | 5.55 | 7.34 | 7.62 |

[a] Energy differences $\Delta E° = E°_{(E)} - E°_{(Z)}$. [b] Zero-point corrections calculated at the B3LYP/6-311+G(d) level.

Since the perfluoroethyl group ($CF_3CF_2$) can adopt either a staggered or an eclipsed geometry (see Scheme 2),



Scheme 2. Representation of the eclipsed and staggered forms in substituted perfluoroethane molecules.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the potential function for internal rotation around the C–C bond was calculated by full geometry optimization at fixed $\phi$(FC–CN) torsional angles. The staggered form corresponds to the preferred conformation, with $\Delta E$ ($E_{eclipsed} - E_{staggered}$) values of 5.67 and 4.10 kcal mol$^{-1}$ for the HF and B3LYP methods with the 6-311+G* basis set, respectively.

### Vibrational Spectra

Figure 1 shows the IR (vapor) and Raman (liquid) spectra of $CF_3CF_2N{=}SCl_2$. Table 2 lists the experimental frequencies together with the calculated values and a tentative assignment of the 27 expected normal modes of vibration. The vibrational spectra can be interpreted satisfactorily on the basis of the presence of only one form. Assignment of the bands related to the $N{=}SCl_2$ moiety was performed on the basis of the corresponding features for similar *S*,*S*-dichlorosulfur imide derivatives such as $CF_3N{=}SCl_2$,[23] $FC(O)N{=}SCl_2$,[25] and $ClSO_2N{=}SCl_2$.[31] The corresponding *S*,*S*-difluoro derivatives $CF_3N{=}SF_2$,[32] $FC(O)N{=}SF_2$,[23] and $ClSO_2N{=}SF_2$[22] were also taken into account to establish a correlation between the different modes. The fundamental vibrational modes related to the $CF_3CF_2$ moiety were assigned on the basis of calculated frequencies for the title molecule and taking into account the recently reported data for $CF_3CF_2COOH$.[33] All theoretical frequencies show good agreement with the experimental values, which gives confidence to the assignment of the fundamental features.

According to reported data found in the literature for sulfur imide molecules containing a $CF_3$ group as substituent, the region between 1400 and 1100 cm$^{-1}$ shows bands related to the fundamental stretching modes corresponding to both the N=S and the $CF_3$ groups.[23,32] Thus, the presence of several intense and narrow bands in that region in the gas FTIR spectra and weak and broad bands in the liquid Raman spectrum is directly related to those vibrational modes. The frequency of the N=S stretching is directly related to the electron-withdrawing properties of the substituents attached at the nitrogen and sulfur atoms. In fact, an increase in the electron-withdrawing properties of the substituents attached to any of the atoms of the N=S bond increases the bond order of this bond. Taking into account that the band centered at 1314 cm$^{-1}$ in the IR spectrum (1300 cm$^{-1}$, Raman) of $CF_3N{=}SCl_2$[23] was assigned to the N=S stretching, and postulating that the $CF_3$ group is more electronegative than $CF_3CF_2$, the band appearing at 1292 cm$^{-1}$ in the gas FTIR spectrum (1286 cm$^{-1}$ in the liquid Raman spectrum) was assigned to the N=S stretching vibration, in perfect agreement with the theoretical

Table 2. Observed and calculated vibrational data for $CF_3CF_2N{=}SCl_2$ [cm$^{-1}$].

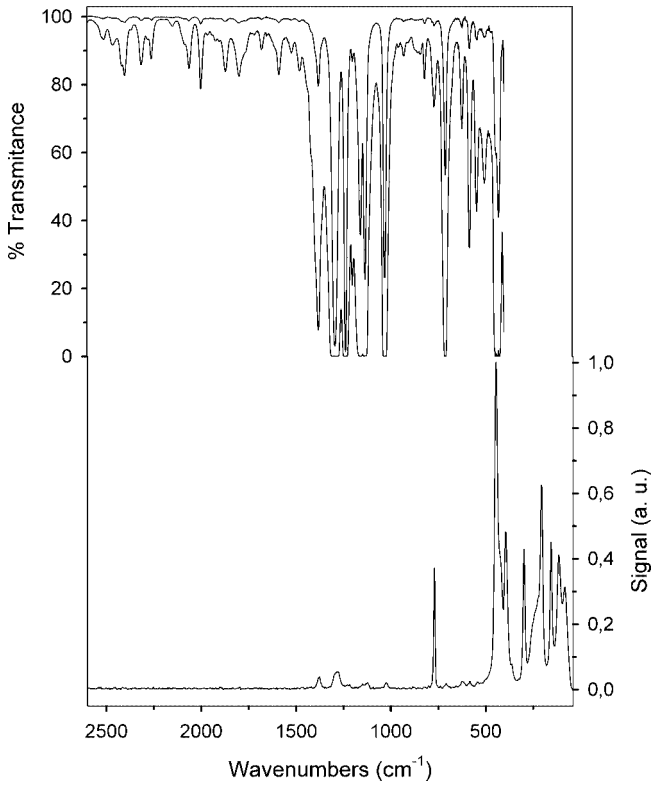

Figure 1. Gas IR (at 15.0 and 1.6 mbar; glass cell with a 200 mm optical path length and 0.5 mm thick Si windows) and liquid Raman spectra for $CF_3CF_2N{=}SCl_2$.

value. Analysis of the IR spectra obtained for seven alkyl esters of pentafluoropropionic acid [$CF_3CF_2C(O)OR$] by Crowder[34] concluded that different R groups do not affect the characteristic stretching and deformation frequency values of the $CF_3CF_2$ group. Thus, taking into account the reported data for $CF_3CF_2COOH$,[33] where the band located at 1334.7 $cm^{-1}$ in the gas FTIR spectrum has been assigned to the C–C stretching mode, the medium intensity feature centered at 1380 $cm^{-1}$ in the IR spectrum (Raman: 1378 $cm^{-1}$) of $CF_3CF_2N{=}SCl_2$ can be assigned to the ν(C–C) stretching mode.

Although theoretical calculations predict a strong coupling between the stretching modes belonging to the $CF_3CF_2$ group, their assignments were performed by considering the $CF_3$ and $CF_2$ groups individually. Only one band is found for the $CF_3$ symmetric and the antisymmetric stretching vibrational normal modes at 1235 and 1218 $cm^{-1}$ in the vapor IR and liquid Raman spectra, respectively. This coincidence in the frequencies of these two modes is also in agreement with our calculations as differences of 6 and 2 $cm^{-1}$ are calculated (HF and B3LYP methods, respectively) for the values of the two normal vibrational modes (Table 2). The second $CF_3$ symmetric stretching appears at 1133 and 1124 $cm^{-1}$ (vapor IR and liquid Raman, respectively). Similarly, the bands centered at 1158 and 1029 $cm^{-1}$ (Raman: 1151 and 1025 $cm^{-1}$) were assigned to the antisymmetric and symmetric stretching modes belonging to the $CF_2$ group, respectively. The medium-intensity bands observed in the IR spectrum at 442 and 429 $cm^{-1}$ (Raman: 445 and 424 $cm^{-1}$) were assigned to the symmetric and antisymmetric stretching modes in the $SCl_2$ group, respectively. This assignment is straightforward because the frequency values as well as the shape of the bands in the vibrational spectra of $CF_3CF_2N{=}SCl_2$ can be directly correlated with the reported features for $CF_3N{=}SCl_2$.[23] Theoretical values also confirm this proposed assignment. The medium-intensity bands found at 770 and 771 $cm^{-1}$ in the IR and Raman spectra, respectively, were assigned to the C–N stretching mode. The theoretical values calculated for this mode (HF: 767 $cm^{-1}$; B3LYP: 766 $cm^{-1}$) again support this assignment.

According to our calculated frequencies, the expected deformation modes related to the $CF_3CF_2$ group are strongly coupled. For this reason, it is not possible to assign the observed features in the vibrational spectra in a straightforward manner. However, by comparison with the assignment reported for $CF_3N{=}SCl_2$,[23] the band located at 709 $cm^{-1}$ in both the IR and Raman spectra could be assigned to the totally symmetric deformation of the $CF_3$ group.

## Crystal Structure

$CF_3CF_2N{=}SCl_2$ crystallizes in the monoclinic space group $P2_1/c$ with eight molecules per unit cell. Table 3 lists the relevant crystal data. In accordance with the theoretical calculations and the spectroscopic investigations, the most stable conformer – the (*Z*) conformer – is observed in the solid state at 159 K (Figure 2). Two nonequivalent molecules are present in the crystal (forms I and II), both of which have similar bond lengths and angles. However, some remarkable differences in the $\phi$(C–C–N=S) torsional angles between both nonequivalent forms are observed. Thus, these values are 146.5° and 160.6° for forms I and II, respectively. In order to illustrate this difference, Figure 3 shows a superimposed picture of both forms.

Table 4 lists the experimental geometrical parameters for $CF_3CF_2N{=}SCl_2$ together with the corresponding values obtained from HF and B3LYP calculations using the 6-311+G(2df) basis set, and the MP2/6-311+G(d) approximation. Contractions of polar bonds are expected on going from the gas to the solid phase. Nevertheless, taking into account the difference in the physical state of the substance, there is good agreement between the theoretical and the experimental data obtained for the (*Z*) conformer of $CF_3CF_2N{=}SCl_2$. The methods reproduce the bond lengths and angles reasonably well in general, except for some values around the sulfur atom. Thus, even with large basis sets (6-311+G(2df)), the B3LYP and MP2 methods predict the S–Cl bond to be too long by up to 0.060 and 0.074 Å, respectively. The theoretical methods used in the current work give similar values for the CN=SCl dihedral angle to those obtained from the X-ray analysis. A staggered conformation for the perfluoroethyl group is found in the crystal, which is well reproduced by the computational methods. However, some differences were observed for the CC–N=S

[a] $w = 1/[\sigma^2(F_o^2) + (0.0313P)^2 + 1.2107P]$, where $P = (F_o^2 + 2F_c^2)/3$.

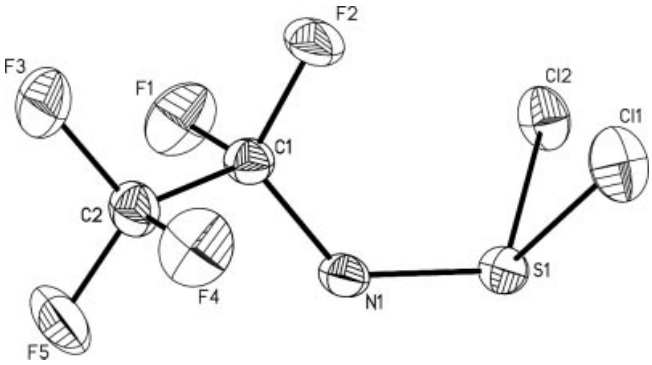

Figure 2. Molecular model, with atom numbering, showing the single-crystal structure of $CF_3CF_2N{=}SCl_2$.

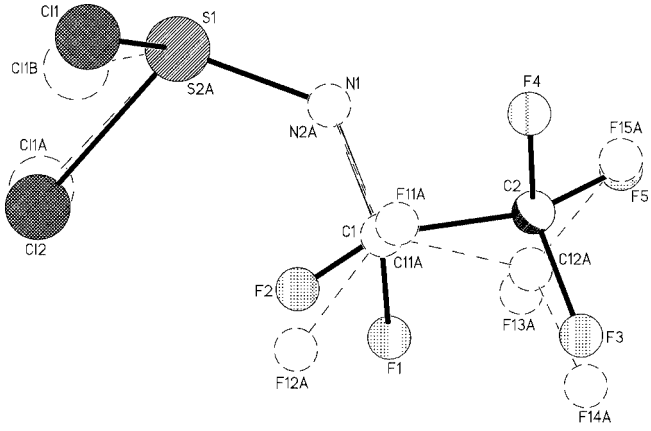

Figure 3. Molecular structures for nonequivalent forms of $CF_3CF_2N{=}SCl_2$ in the crystal.

dihedral angle: the experimental value is –147.0° whereas the computed values are –151.3°, –168.5°, and –123.7° for the HF, B3LYP, and MP2 methods, respectively.

The crystal packing along the *ac* plane is shown in Figure 4. Crystallographic studies on molecules containing halogen–halogen bonds or halogen–halogen contacts have attracted a great deal of attention because they are considered to be one of the important factors that determine the structural features in molecular crystals and may play an important role in crystal engineering as supermolecular synthons.[35–37] The term "halogen bonding" has been defined by Legon to refer to these interactions.[38] Intermolecular interactions dominated by F···F contacts are also common for fluorinated molecules where there is no other choice for stabilizing the packing. According to quantum chemical calculations, F···F contacts in aromatic systems

can contribute up to 14 kcal mol$^{-1}$ of local stabilization energy.[39] The two independent molecules in the crystal of $CF_3CF_2N{=}SCl_2$ are linked to the surrounding molecules by different intermolecular interactions. For example, $CF_3CF_2N{=}SCl_2$ forms chains with short N=S···F–CF nonbonding distances along the *a* axis. These chains formed by molecules in form I show an S1···F1′ distance of 3.168 Å, whereas their analogues in form II (S2···F12′) are slightly longer (3.222 Å). The chains form a parallel array in the *ab* plane. These planes are interconnected with each other in the *c* axis orientation through two distances, an S···N′ electrostatic interaction at 3.315 Å and a Cl···Cl′ nonbonding distance of 3.479 Å (Figure 5).

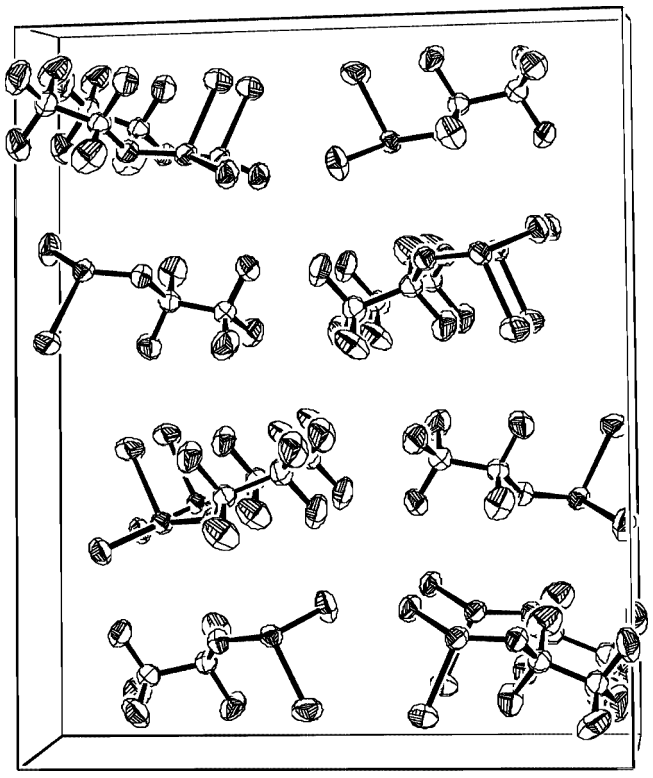

Figure 4. Stereoscopic illustration of the crystal packing of $CF_3CF_2N{=}SCl_2$ at 159 K.

**Natural Bond Orbital Analysis**

NBO analysis for the (*Z*) form of the $CF_3CF_2N{=}SCl_2$ molecule suggests that the formal N=S double bond has only σ-bond character. Indeed, this analysis clearly indicates the presence of two lone-pair orbitals at the nitrogen atom. The nature of these two orbitals is $sp^2$- [lp($Nsp^2$)] and pure p-type [lp(Np)]. Their electron occupancies are low: 1.83 and 1.67 e, respectively, thus indicating the electron-donating capacity of both orbitals, in agreement with the experimental evidence relating the sulfur imide bond order with the electron-withdrawing properties of the substituents attached at the nitrogen and sulfur atoms. Delocalizing interactions evaluated by a second-order perturbation approach reveal that the first lone-pair orbital contributes to a negative hyperconjugative interaction with the S–Cl σ-antibonding orbitals [lp($Nsp^2$)→σ*(S–Cl)], with a stabilizing energy $E^{(2)}$ of 37.71 kcal mol$^{-1}$. The second lone-pair orbital contributes to two stronger lp(Np)→σ*(S–Cl) negative hyperconjugative interactions ($E^{(2)}$ = 97.46 kcal mol$^{-1}$). This interaction corresponds to an electron donation from the formally doubly occupied HOMO to the vacant LUMO in $CF_3CF_2N{=}SCl_2$. Thus, the energy difference between lp(Np)→σ*(S–Cl) and lp($Nsp^2$)→σ*(S–Cl) interactions is mainly related to the different denominator in the expression

$$\Delta E^{(2)}_{\phi\phi^*} = -2\frac{\left\langle \phi \middle| \hat{F} \middle| \phi^* \right\rangle^2}{\varepsilon_{\phi^*} - \varepsilon_{\phi}}$$

in which $\hat{F}$ is the Fock operator, $\phi$ and $\phi^*$ the donating and acceptor orbitals, respectively, and $\varepsilon$ the NBO orbital energy.

This strong electron donation into the σ*(S–Cl) antibonding orbitals is also reflected in the high electronic occupancy of the σ*(S–Cl) orbital of about 0.23 e. The lone-pair orbital at the sulfur atom, on the other hand, donates electron density mainly into the vacant C–N antibonding orbital by a negative hyperconjugation interaction, lp(S)→σ*(C–N), with an $E^{(2)}$ value of 10.82 kcal mol$^{-1}$. All these anomeric interactions decrease on going from the (*Z*)

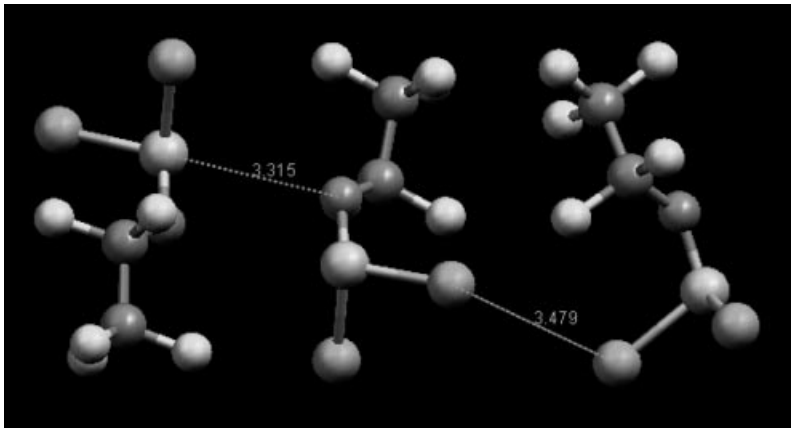

Figure 5. Short nonbonding distances in crystalline $CF_3CF_2N{=}SCl_2$ at 159 K.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to the (*E*) form, similar to the behavior calculated for $H_2SNH$.[30] Thus, the thermodynamic preference of the (*Z*) form for $CF_3CF_2N{=}SCl_2$ can be rationalized as originating from the dominant influence of the stabilizing anomeric interactions.

The atomic charges obtained using the Natural Population Analysis (NPA) approach for (*Z*)-$CF_3CF_2NSCl_2$ reveal that a strong positive charge (+1.25) is located at the sulfur and almost a unit negative charge (–0.99) at the nitrogen atom. These data indicate that, in addition to the negative hyperconjugation, the semipolar character of the S–N bond in sulfur imides can be attributed to this polar attraction rather than to an S–N dπ-pπ orbital interaction. It is known that the S–N rotational barrier in sulfur imide species is expected to be small in comparison with the formal double bonds depicted in their formulae because of the hypervalent nature of the sulfur atom.[40] This value has been estimated to be 8.50 kcal mol$^{-1}$ (after including thermal corrections at the G2 level) for the simple molecule $HNSH_2$.[30] This value increases for the *S*,*S*-disubstituted sulfur imides $HN{-}SX_2$ (X = F, Cl, and Me) mainly due to the fact that the S–N bond strength increases with an enhancement in the electronegativity of the substituent bonded to the sulfur atom. Following this trend, the torsional transition state calculated for $CF_3CF_2NSCl_2$ amounts to 8.45 kcal mol$^{-1}$ [B3LYP/6-311+G(d)], a value which is compatible with the rotational barrier expected for sulfur imides.[41]

## Conclusions

Only the (*Z*) conformer around the sulfur imide bond is observed in both gaseous and condensed $CF_3CF_2N{=}SCl_2$. This structural behavior seems to be a general feature in *S*,*S*-difluoro- and *S*,*S*-dichloro-substituted sulfur imides, whereas for related compounds with two different substituents attached at the sulfur atom the (*E*) conformer is favored. The conformational and configurational properties of these molecules can be rationalized on the basis of the anomeric effect, mainly by invoking electron-donating interactions between the sulfur and nitrogen lone-pair orbitals to opposite σ* orbitals. Thus, the sterically unfavorable (*Z*) orientation is stereoelectronically stabilized mainly by lp(N)→σ*(S–Cl) and, to a minor extent, by lp(S)→σ*(N–C) interactions.

The description of the central sulfur imide bond from the NBO analysis agrees with a semipolar $S^+{-}N^-$ bond with strong hyperconjugative interactions. This analysis indicates a negatively charged nitrogen atom with two lone pairs for the $CF_3CF_2NSCl_2$ molecule, in which the sulfur atom is $sp^3$-hybridized. Thus, valence expansion to more than eight electrons at the sulfur atom can be excluded to explain the bonding. An inspection of the orbital shapes involved in the sulfur imide bond is given in Figure 6, which supports a redistribution of the electronic density from the negatively charged nitrogen atom to the S–N bond. These findings are in agreement with MO calculations on second-row atoms in "hypervalent" molecules. Theoretical studies of $SO_2$, a molecule with the sulfur atom possessing the same formal oxidation state of +IV as in $CF_3CF_2N{=}SCl_2$, show that the S–O bond has a highly ionic character, the octet rule is not violated, and it is not necessary to invoke the term "hypervalency".[42]

## Experimental Section

**Synthesis:** $CF_3CF_2N{=}SCl_2$ was prepared by the reaction between $AlCl_3$ and $CF_3CF_2N{=}SF_2$ according to a literature procedure.[43] The product was purified by several trap-to-trap distillations.

**Vibrational Spectroscopy:** Gas-phase IR spectra were recorded with a resolution of 1 cm$^{-1}$ in the range 4000–400 cm$^{-1}$ with a Bruker IFS 66v FTIR instrument. FT Raman spectra of liquid $CF_3CF_2N{=}SCl_2$ were recorded with a Bruker RFS 100/S FT Raman spectrometer. The sample in a 6-mm (o.d.) glass tube was excited with 150 mW from a 1064-nm Nd:YAG laser (ADLAS, DPY 301, Lübeck, Germany).

**X-ray Diffraction at Low Temperature:** An appropriate crystal of $CF_3CF_2N{=}SCl_2$ about 0.3 mm in diameter was obtained on the diffractometer at a temperature of 159(2) K with a miniature zone-melting procedure using focused infrared laser radiation.[44] The diffraction intensities were measured at low temperature with a Nicolet R3m/V four-circle diffractometer. Intensities were collected with graphite-monochromatized Mo-$K_\alpha$ radiation using the $\omega$-scan technique. The crystallographic data, conditions, and some features of the structure are listed in Table 3. The structure was solved by Patterson syntheses, and refined by the full-matrix least-squares method on *F* with the SHELTXL-Plus program.[45] All atoms were assigned to anisotropic thermal parameters. Atomic coordinates, equivalent isotropic displacement coefficients, and anisotropic displacement parameters ($Å^2 \times 10^3$) for $CF_3CF_2N{=}SCl_2$ have been deposited; further details of the crystal structure investigation may be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstien-Leopoldshafen, Germany (Fax: +49-7247-808-666; E-mail: crysdata@fiz-karlsruhe.de) on quoting the depository number CSD-417110.

**Theoretical Calculations:** All the quantum chemical calculations were performed using the GAUSSIAN03 program.[46] Geometry optimizations were performed with the HF and MP2 approximations and the B3LYP methods using 6-311+G(d) and 6-311+G(2df) basis sets and standard gradient techniques with simultaneous relaxation of all the geometric parameters. Natural population analysis and second-order donor→acceptor interaction energies were estimated at the MP2/6-31+G(d) level by using the NBO analysis[47] as implemented in the GAUSSIAN03 program.

Figure 6. NBO orbitals [MP2/6-31+G(d)] for the sulfur imide bond of $CF_3CF_2N{=}SCl_2$: (a) lp(Np), MO = 57 (HOMO); (b) lp($Nsp^2$), MO = 54; (c) lp(S) MO = 39; (d) σ(N–S) MO = 34.

# Thiodiacetate and Oxydiacetate Cobalt Complexes: Synthesis, Structure and Stereochemical Features

**Abdessamad Grirrane,[a,b] Antonio Pastor,[a] Eleuterio Álvarez,[b] Carlo Mealli,[c] Andrea Ienco,[c] Patrick Rosa,[d,e] and Agustín Galindo*[a]**

**Keywords:** Cobalt / Thiodiacetate / Oxydiacetate / Tridentate Ligands / Coordination modes

A series of cobalt complexes containing the dianionic ligands $X(CH_2COO)_2^{2-}$ (X = S, tda; or X = O, oda) is reported. The complexes [Co(tda)(bipy)($H_2O$)]·4$H_2O$ (**2**), which was characterised by X-ray crystallography, [Co(tda)(phen)($H_2O$)] (**3**), [Co(tda){($MeO)_2$bipy}($H_2O$)]·2$H_2O$ (**4**) and [Co(tda)(dpp)($H_2O$)]·2$H_2O$ (**5**) are obtained by reaction of the precursor complex [Co(tda)($H_2O$)]$_n$ (**1a**) with the bidentate N-donor ligands 2,2′-bipyridine (bipy), *o*-phenanthroline (phen), 4,4′-dimethoxy-2,2′-bipyridine [($MeO)_2$bipy] and 2,3-bis(2-pyridyl)pyrazine (dpp), respectively. The reaction of **1a** with di(2-pyridyl) ketone unexpectedly displaces tda from the coordination sphere and leads to the $Co^{III}$ species [Co{OC(OH)(2-pyridyl)$_2$}$_2$]$^+$[Htda]$^-$·3$H_2O$ (**6**), as confirmed by an X-ray analysis. Three new oxydiacetate complexes of cobalt are also synthesised by treating the known complex [{Co(oda)($H_2O$)$_2$}·$H_2O$]$_n$ with 4,4′-di-*tert*-butyl-2,2′-bipyridine (*t*$Bu_2$bipy), 2,3-bis(2-pyridyl)pyrazine (dpp) and 4,4′-bipyridine (4,4′-bipy). The complexes [Co(oda)(*t*$Bu_2$bipy)($H_2O$)]·1.5$H_2O$ (**7**), [Co(oda)(dpp)($H_2O$)]·2$H_2O$ (**8**) and [{Co(oda)($H_2O$)$_2$}$_2$(μ-4,4′-bipy)]·2$H_2O$ (**9**) are structurally characterised (**8** as a methanol solvate). Complex **9** is binuclear, in contrast to **7** and **8** (mononuclear), and magnetic susceptibility measurements down to 2 K for this complex show high-spin noncorrelated $Co^{II}$ ions with a typical Curie–Weiss behaviour. The Co(oda) fragment in **7**–**9** adopts a planar (*mer*) rather than a folded (*fac*) conformation, the latter of which is common to all the M(tda) complexes but is only occasionally observed in the M(oda) ones. In the final section of the paper, the key geometric parameters that control the stereochemistry of the two ligands are determined from a statistical analysis based on the structurally characterised Co(oda) and Co(tda) complexes.

## Introduction

The thiodiacetate (tda) and oxydiacetate (oda) dianions $X(CH_2COO)_2^{2-}$ (X = S and O, respectively) are versatile ligands that have been widely explored as multidentate and chelating units for one or more metals of a different nature. They contain five atoms that are potential donors, four of which come from two carboxylate groups and one from the thioether or ether function. These ligands can bind a single metal in a tridentate manner, with the two "exo" oxygen donor atoms of the carboxylate groups being capable of additional coordination of another metal or external electrophiles. This permits the formation of homo- and heterometallic extended solids or the formation of stabilizing hydrogen bonds.

The chemistry of thiodiacetate transition metal complexes is comparatively less developed than that of the related oxydiacetate complexes. As a matter of fact, the number of X-ray characterised metal derivatives is smaller for tda than for oda derivatives (160 and 55 hits for the $O(CH_2COO)_2^{2-}$ and $S(CH_2COO)_2^{2-}$ fragments, respectively[1]). Due to our interest in this area of chemistry,[2,3] we started to explore the behaviour of thiodiacetate toward cobalt as no structure of tda-Co complexes had been reported and there were only references in the literature to the solution behaviour of tda-$Co^{II}$ species.[4] The first structural characterisation of a tda-$Co^{II}$ complex was simultaneously presented by us[5] and by Zhu and co-workers[6] (complex [Co(tda)(phen)($H_2O$)]). Some additional examples, namely [Co(tda)(N-N)($H_2O$)]·2$H_2O$ and [Co(tda)($N)_3$]·2$H_2O$, where N and N-N are nitrogen ligands, were published soon afterwards by Xu and co-workers.[7]

In this paper we present a complete report of our studies together with the synthesis and properties of new cobalt

oxydiacetate complexes. The general coordination capabilities of both the tda and oda ligands are compared, with particular emphasis on the structural data now available for cobalt.

## Results and Discussion

### Cobalt Thiodiacetate Complexes

Treatment of aqueous solutions of cobalt dichloride with a 1:1 mixture of $Na_2CO_3$ and thiodiacetic acid, $S(CH_2COOH)_2$, affords, after the appropriate work up, dark pink block-shaped microcrystals of the complex $[Co(tda)(H_2O)]_n$ (**1a**) in good yields. Closely related thiodiacetate complexes of manganese and zinc, $[M(tda)(H_2O)]_n$, could also be synthesised by this route.[3] Complex **1a** is air-stable and soluble in water but not in solvents of low polarity. Its IR spectrum displays a very strong and broad absorption band at about 1589 $cm^{-1}$, which corresponds to the antisymmetric vibrations of the tda carboxylate groups. Another strong band at 1399 $cm^{-1}$ is assigned to the corresponding symmetric vibrations.[8] The IR spectrum is identical to that of the structurally characterised polymeric complexes $[Cd(tda)(H_2O)]_n$[9] and $[Zn(tda)(H_2O)]_n$[3c,10] and, consequently, we proposed a similar crystalline structure for **1a**. During the preparation of **1a**, some dark-pink, needle-shaped crystals were also occasionally observed. The IR spectrum of this second compound, **1b**, shows only minor differences with respect that of **1a**, mainly in the region of coordinated water (see Supporting Information). This spectrum is identical to that of the already reported[11] complex $[Ni(tda)(H_2O)_3]$, therefore taking into account the analytical data, the formula of **1b** is suggested to be $[Co(tda)(H_2O)_3]$.

Complex $[Co(tda)(H_2O)]_n$ (**1a**) exists as $[Co(tda)(H_2O)_3]$ (that is **1b**) in aqueous solution. Two coordinated water molecules can easily be displaced from this species upon reaction with several bidentate N-donor ligands (see Scheme 1). In fact, aqueous solutions of **1a** react with 2,2′-bipyridine (bipy), *o*-phenanthroline (phen), 4,4′-dimethoxy-2,2′-bipyridine [$(MeO)_2$bipy] and 2,3-bis(2-pyridyl)pyrazine (dpp) to give new complexes of general formula $[Co(tda)(N\text{-}N)(H_2O)]$ (N-N = bidentate N-donor ligand). These complexes can be isolated in good yields as crystalline solids containing a variable number of water molecules of hydration {namely, $[Co(tda)(bipy)(H_2O)]\cdot 4H_2O$ (**2**), $[Co(tda)(phen)(H_2O)]$ (**3**), $[Co(tda)\{(MeO)_2bipy\}(H_2O)]\cdot 2H_2O$ (**4**) and $[Co(tda)(dpp)(H_2O)]\cdot 2H_2O$ (**5**)}. All complexes are soluble in water (but not in low polarity solvents) and are air-stable both in solution and in the solid state. Their IR spectra are characterised, besides the absorptions due to the N-donor co-ligands, by two broad absorptions corresponding to the tda carboxylate groups (for instance at 1599 and 1400 $cm^{-1}$ for **2**). The measured effective magnetic moments (in the solid state and at room temperature) are typical of high-spin mononuclear $d^7$-cobalt complexes (4.3–4.9 $\mu_B$).[12]

The crystal structures of complexes $[Co(tda)(bipy)(H_2O)]\cdot 4H_2O$ (**2**) and $[Co(tda)(phen)(H_2O)]$ (**3**) were determined by X-ray diffraction methods. The structure of the latter was published while our work was in progress,[6] therefore some of its features are illustrated here but considered only for comparative purposes (see below). As for complex **2**, the coordination polyhedron around the cobalt atom is a distorted octahedron in which the metal atom is coordinated by the tridentate tda ligand in a typical *fac* arrangement. The coordination sphere is completed by the bidentate bipy ligand and one water molecule, which is bound *trans* to the sulfur donor atom of tda (Figure 1). Complex **2** is isomorphous with the known nickel,[11a] zinc[13] and copper analogues.[14] Selected bond lengths and angles of **2** are collected in Table 1.

Although coordinatively similar (also in terms of Co–O, Co–S and Co–N bond lengths), the pseudo-octahedral complexes **2** and **3** differ in two main aspects: the former features four hydration molecules while the latter has none, and the relative orientation of the N-donor group with respect to the tda ligand is different (Scheme 1). In spite of the similar coordination properties of the bipy and phen bidentate ligands, bipy lies coplanar with the coordinated oxygen donors of tda in **2** (the water ligand lies *trans* to the

| O(1)–Co(1)–N(1) | 92.41(7) | | |

sulfur atom), although the same does not apply to phen, which adopts an upright position in **3**. In other words, it lies coplanar with the S atom while the coordinated water molecule is *trans* to one tda oxygen donor. This situation is similar to that found for the Zn-tda system, for which the bipy[13] and phen[3c] derivatives show different structures.

The crystalline solids **4** and **5** were characterised by analytical and spectroscopic methods as $[Co(tda)\{(MeO)_2\text{-}bipy\}(H_2O)]\cdot 2H_2O$ and $[Co(tda)(dpp)(H_2O)]\cdot 2H_2O$, respectively. The potentially tridentate dpp ligand coordinates in a bidentate fashion in **5**. This also occurs in the oxydiacetate derivative **8**, which has been structurally characterised (see below). The correct structure of **4** and **5** cannot be safely anticipated, however, because two isomers are also possible in this case. Their energies should be rather similar and the adoption of a specific geometry may be caused by subtle factors. For example, the presence or absence of water of crystallisation can clearly affect the final crystal structure since hydrogen bonding is a key feature in oxydiacetate and thiodiacetate metal complexes. Coordinated and solvent water molecules fix the crystal packing of most of these derivatives by interacting with the coordinated or uncoordinated oxygen atoms of tda or oda. In actual fact, complex **2** features a 3D network of hydrogen bonding between the water ligand O1, the water solvent molecules and some oxygen atoms of the carboxylate groups of tda ligand (see Figure S2 in the Supporting Information). Consequently, we propose similar structures for **4** and **5** to that observed for **2** (Scheme 1).

An attempt to obtain an additional cobalt complex with tda was made by treating **1a** with the ligand di(2-pyridyl) ketone. The deep-red crystals obtained after the appropriate work-up have properties that are different to those observed for complexes **2**–**6**. Thus, their diamagnetism suggests the presence of a $Co^{III}$ centre and their analytical data are consistent with a 1:1:2 Co:tda:di(2-pyridyl) ketone ratio. An X-ray structure determination (Figure 2) indicated that the tda ligand is protonated not coordinated, in other words it acts as a counterion. Thus, the species has the unexpected stoichiometry $[Co\{OC(OH)(2\text{-pyridyl})_2\}_2]^+[Htda]^-\cdot 3H_2O$ (**6**). Essentially, two di(2-pyridyl) ketone molecules have been hydrolysed and deprotonated in a process that has already been described (Scheme 2).[15] The latter molecules act as two staggered tridentate *fac* ligands that confer a pseudo-octahedral geometry to the oxidized $Co^{III}$ centre. Selected bond lengths and angles of **6** are collected in Table 2. The

cationic part of **6**, $[Co\{OC(OH)(2\text{-pyridyl})_2\}_2]^+$, has been previously characterised for other cobalt complexes with different counterions.[16] There is good structural consistency among the latter, so their geometrical features do no require further comment.

### Cobalt Oxydiacetate Compounds

The number of structurally characterised cobalt oxydiacetate complexes has grown considerably in the last few years. Some crystallographic reports of Co-oda complexes have appeared,[17] and it is worth mentioning, in particular, that the structure of complex $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$[18] has been re-determined twice.[19] Additionally, Jiang and Wang have pointed out a topological isomerism between this complex and $[\{Co(oda)(H_2O)\}\cdot H_2O]_n$, and discussed their interconversion.[19a] Since our original report on this chemistry,[2a] we have continued our studies of the chemical reactivity of $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ and we can now describe here the synthesis and structural characterisation of three new Co-oda complexes.

The reaction of aqueous solutions of the complex $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ with 4,4′-di-*tert*-butyl-2,2′-bipyridine ($t$Bu$_2$bipy), 2,3-bis(2-pyridyl)pyrazine (dpp) and 4,4′-bipyridine (4,4′-bipy) yields, after the appropriate work-up, crystals of $[Co(oda)(t\text{Bu}_2\text{bipy})(H_2O)]\cdot 1.5H_2O$ (**7**), $[Co(oda)(dpp)(H_2O)]\cdot 2H_2O$ (**8**) and $[\{Co(oda)(H_2O)_2\}_2(\mu\text{-}4,4'\text{-bipy})]\cdot 2H_2O$ (**9**), respectively, with good yields (see Scheme 3). These complexes are air-stable both in solution and in the solid state. They are soluble in water and complex **7** is also soluble in ethanol. The IR spectra show an intense broad absorption around 1600 cm$^{-1}$ due to the antisymmetric vibrations of the coordinated carboxylate groups of oxydiacetate. We have shown in previous work[2a,2d] that the position of the COC stretch of the oxydiacetate ligand (a characteristic sharp and strong absorption) depends on the disposition of the ligand in the coordination sphere. Thus, when the signal appears above 1100 cm$^{-1}$ the oda ligand adopts a planar conformation (*mer*), whereas in other cases the arrangement is non-planar. Bands above the latter limit for complexes **7**–**9** clearly indicate a planar coordination mode (*mer*), and this was validated by the X-ray analyses. Interestingly, while the known Co(oda) fragments can adopt either a *fac* or a *mer* arrangement, the M(tda) analogue is, to date, invariably *fac* for cobalt as well as for all known transition metal complexes (see below).

Complex **7** is monomeric (Figure 3), and selected structural data are reported in Table 3. The coordination geometry of the cobalt atom is distorted octahedral due to the low bite angle of oda [*transoid* O1–Co–O5 angle of 150.42(10)°].

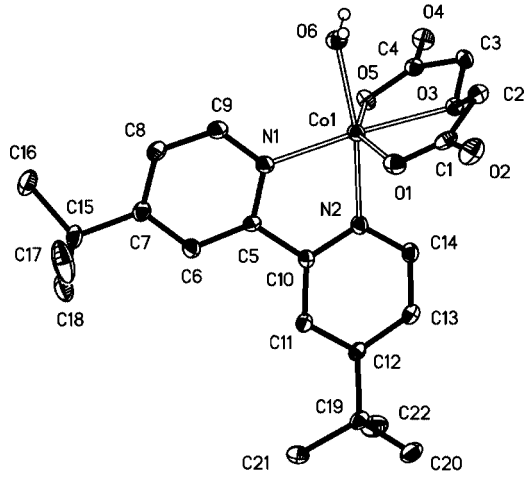

Figure 3. Drawing of one of the two independent molecules in the asymmetric unit of $[Co(oda)(t\text{Bu}_2\text{bipy})(H_2O)]\cdot 1.5H_2O$ (**7**). The hydrogen atoms, except those of the water ligand, and the crystallisation water molecules are not shown.

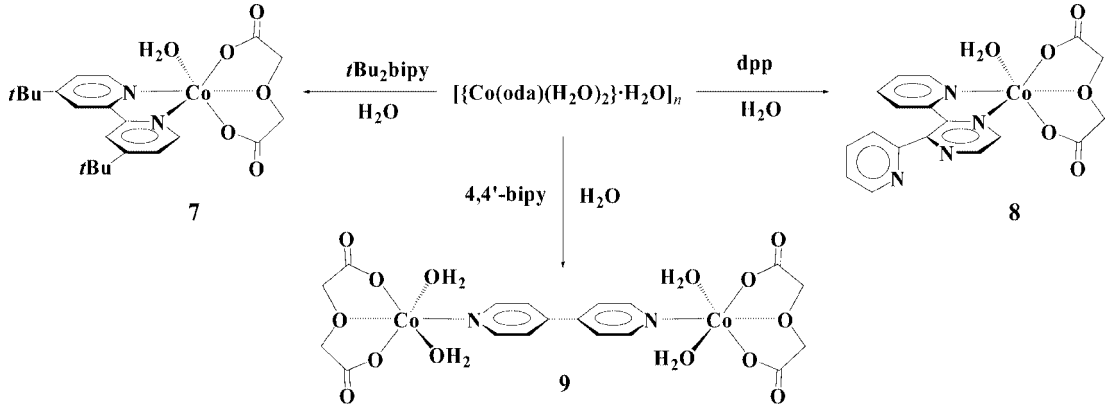

Scheme 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Although the $t$Bu$_2$bipy ligand is common in coordination chemistry (187 hits in the Cambridge Structural Database,[1a] CSD), it appears that complex **7** is the first structure of a cobalt complex with this ligand.

Complex **8** was obtained in the solid state as [Co(oda)(dpp)(H$_2$O)]·2H$_2$O, although the X-ray characterisation was carried out with crystals of the methanol solvate [Co(oda)(dpp)(H$_2$O)]·H$_2$O·1/2MeOH that is formed upon recrystallisation from a MeOH/H$_2$O mixture. Complex **8** is also a monomer, with the cobalt atom octahedrally coordinated by three O atoms of the oda ligand in a quasi-planar arrangement, two N atoms of the 2,3-bis(2-pyridyl)pyrazine molecule and one water molecule (Figure 4). As seen in Table 4, the Co–O bonds range between 2.05 and 2.16 Å and the Co–N bonds are as long as 2.095(3) and 2.131(3) Å. Despite possessing three N donor atoms, the dpp ligand is bidentate in **8** since one of the two pyridyl substituents remains uncoordinated. There is one previous structurally characterised example of a Co-ddp complex[20] in which the dpp ligand bridges two cobalt atoms in a $\mu,\kappa^2,\kappa^2$ coordination mode. Interestingly, all attempts to force coordination of the N atom at the free pyridine ring failed. In fact, further reaction of complex **8** with [{Co(oda)(H$_2$O)$_2$}·H$_2$O]$_n$ or the reaction of two equivalents of the latter starting material with 2,3-bis(2-pyridyl)pyrazine did not produce the expected coordination. The geometry of **8** is related to that of **7** and other complexes of formula [Co(oda)(N-N)(H$_2$O)],[21] therefore no further comment is necessary.

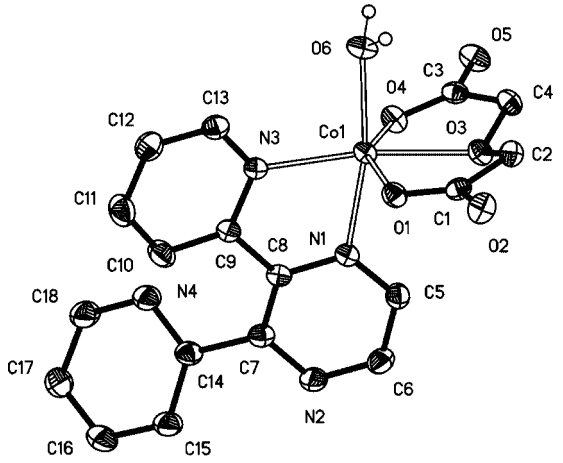

Figure 4. ORTEP drawing of **8** as the methanol solvate [Co(oda)(dpp)(H$_2$O)]·H$_2$O·1/2MeOH. The hydrogen atoms, except those of the water ligand, and the solvent molecules are not shown.

4,4′-Bipyridine was selected as a ligand on the basis of its capacity to afford coordination polymers.[22] However, complex **9** is a binuclear species in which the 4,4′-bipy ligand bridges two cobalt centres (Figure 5). The coordination geometry of each cobalt atom is pseudo-octahedral, with the ethereal oxygen atom of the planar oda ligand O4 occupying a *trans* position with respect to the N-donor atom N1 and the two water ligands mutually *trans*. Selected structural data are collected in Table 5. Complex **9** is isostructural with the zinc analogue [{Zn(oda)(H$_2$O)$_2$}$_2$(μ-4,4′-bipy)]·2H$_2$O.[23] Other cobalt complexes containing a tridentate dianionic ligand may be related to the present species.[24]

The magnetic characterisation of complex **9** was performed with a SQUID susceptometer in the range 1.9–300 K. Magnetisations were measured up to 6 T and showed that loose powder samples have a strong tendency to align with the imposed field, therefore measurements were re-performed with a pellet. The behaviour of both the

susceptibility $\chi_m$ and its product with temperature ($\chi_m T$) are typical of a paramagnetic system, as shown in Figure 6. The $\chi_m T$ value (5.15 emu K mol$^{-1}$ at 300 K) is consistent with two nearly uncorrelated high-spin $Co^{II}$ ions, with corresponding factors of 2.35. On lowering the temperature, $\chi_m T$ starts to decrease significantly below 60 K, while $\chi_m$ rises monotonically without reaching any maximum. A plot of the inverse susceptibility $1/\chi_m$ vs. $T$ gives a Curie–Weiss temperature $\theta$ of +4.4 K above 50 K. High-spin $Co^{II}$ has a $^4T_{1g}$ ground state and, with spin-orbit coupling leaving the orbital moment unquenched, large deviations of $g$ from the free-electron value and large zero-field splittings are expected. The latter, along with possibly some weak exchange interaction between the two cobalt atoms, accounts for the observed decrease of $\chi_m T$ at lower temperatures.

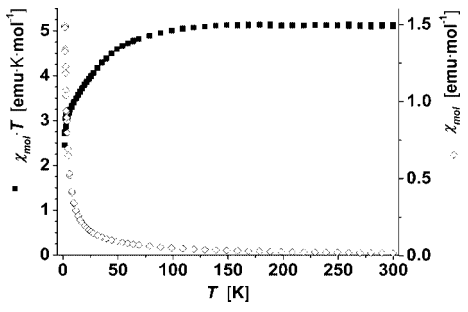

Figure 6. Molar magnetic susceptibility $\chi_m$ (✧, cgs units) and its product with temperature $\chi_m T$ (■, cgs units) of complex **9** between 1.9 and 300 K.

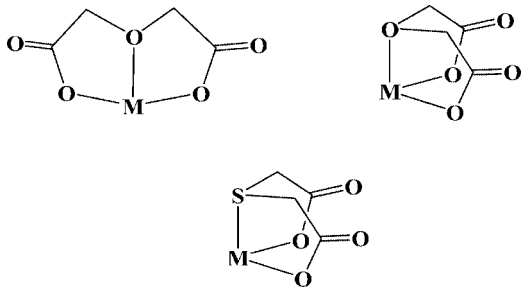
## Factors Governing the Stereochemical Features of the tda and oda Ligands

Although we have published several contributions concerning the coordination chemistry of tda and oda,[2,3,5] this is the first paper in which we address the behaviour of both ligands toward the same metal centre. By exploiting the small but not insignificant number of CSD structures[1a] for all the known cobalt compounds,[25] we have been able to determine the structural parameters that affect the wrapping mode of both types of ligands toward cobalt.

In spite of their similar structures, the presence of a central sulfur or oxygen atom in tda and oda, respectively, has a significant effect on the bonding modes at the metal centres. To date, it has been found that when tda acts as a tridentate ligand it is invariably folded about the M–S vector (*fac* coordination), while oda can adapt to both the folded and planar (*mer*) modes (Scheme 4). We have previously determined the energy differences between the two possible oda conformations in models such as $[Ni(oda)(H_2O)_3]$ and $[VO(oda)(H_2O)_2]$ by DFT calculations[2a,2d] and concluded that there is a small $\Delta E$ value between the two isomers (of the order of 2 kcal mol$^{-1}$ for the Ni compound). Under these circumstances, intermolecular interactions, such as the hydrogen-bond networks involving water crystallisation molecules, probably determine the specific conformation of oxydiacetate.



Scheme 4.

Different sets of geometric parameters are involved in the two possible coordination modes of the ligands. Among these parameters, significant variations are observed for the Co–X (X = O or S) coordination bonds, the $O_{carbox.}$–Co–$O_{carbox.}$ and Co–X–C angles at cobalt and at the heteroatom (C–X–C) and the torsion angles about the X–C and C–C bonds. Thus, it is interesting to determine which parameters exercise most control over the stereochemical features. The Co–S distances fall in the small range 2.508–2.560 Å, with a mean value of 2.52(2) Å (see Figure S3 in the Supporting Information). The corresponding Co–O distances are shorter of course, although their range is wider [2.074–2.269 Å, with a mean value of 2.13(5) Å]. In this case the data refer to both ligand conformations but, in spite of an evident overlap zone, the longer Co–O distances are associated with ligand folding. Beside the Co–X distance, the C–X–C angle is also important since its flexibility is related to the ultimate parameters of folding, in other words the $O_{carbox.}$–Co–$O_{carbox.}$ coordination angle and the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$O_{carbox.}$–Co–X–C torsion angle. The latter parameters should simultaneously approach the limiting values of 90° or 180° for the folded and planar conformations, respectively. Figure 7 shows a quasi-linear interdependence between M–X and C–X–C.

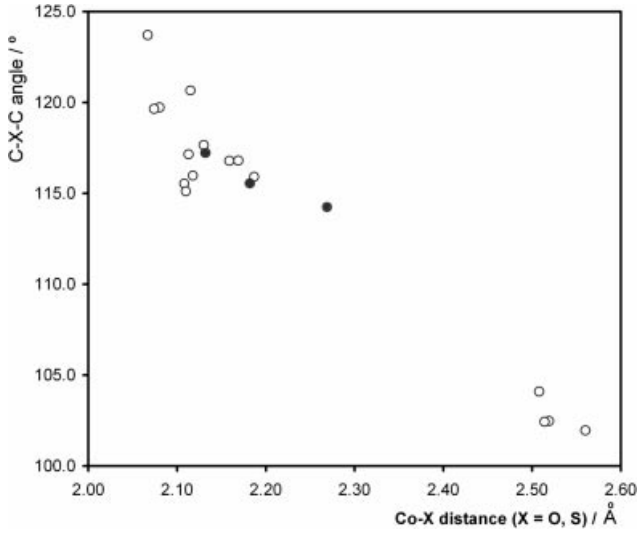


Figure 7. Plot of the Co–X distance [Å] vs. the C–X–C angle [°] showing two separate regions for oda and tda cobalt complexes (black circles are the *fac*-oda compounds).

The question remains, however, as to why the ligand tda never adopts the planar conformation. The average value for the C–O–C angle in uncoordinated ethers is higher than the corresponding C–S–C one in thioethers. Such a difference has a simple theoretical justification based on the different electronegativities of oxygen and sulfur.[26] In the cobalt complexes analysed these angles are within the range 102.0–104.1° for the tda ligand and 114.2–120.7° for the oda ligand. It is evident that ligand folding/unfolding accompanies a significant remodulation of the Co–X and C–X–C parameters, which also depend on electronic constraints (ionic radius, oxidation and spin state of the metal, electronegativity of the X atom, different hard/soft character of the X atom). According to Figure 7, a Co–S distance within the observed range or even shorter should accompany an acute C–S–C angle, which is not yet suitable for conferring the *mer* conformation to tda. This can be verified by considering the correlation diagram between the C–X–C and $O_{carbox.}$–Co–$O_{carbox.}$ angles (Figure 8), from which it becomes evident that there cannot be sufficient opening of the coordination angle at the metal centre for the C–S–C values in question. In conclusion, the planar arrangement (*mer*) is essentially unattainable for Co(tda) complexes, in fact it is impossible to build a model with tolerable distances and angles. Similar graphs to that shown in Figure 8, in which a clear separation of the three coordination modes is observed, can be obtained by plotting the Co–X–$CH_2$ angles against the $O_{carbox.}$–Co–$O_{carbox.}$ angle or against the $O_{carbox.}$–Co–X–C torsion angle (see Supporting Information).

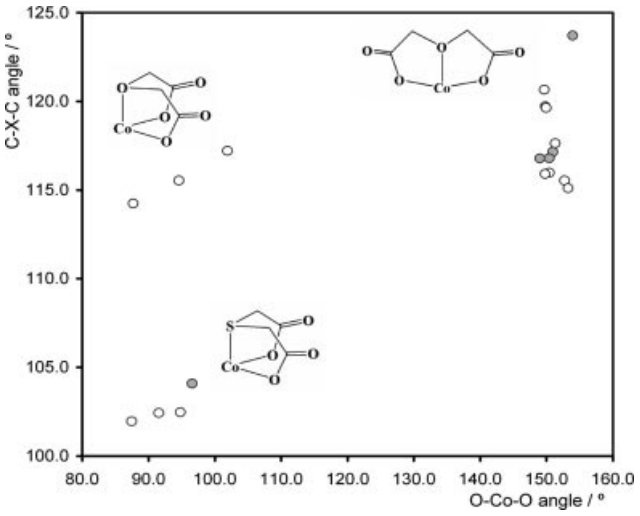

Figure 8. Plot of the C–X–C angle [°] vs. the $O_{carbox.}$–Co–$O_{carbox.}$ angle [°] (shaded circles represent the complexes reported in this paper).

## Experimental Section

**General:** All preparations and other operations were carried out under aerobic conditions. Thiodiacetic acid, oxydiacetic acid and other chemicals were obtained from commercial sources and were used without further purification. $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ was prepared according to the procedure previously reported by us.[2a] Microanalyses (C, H, N) were carried out by the Microanalytical Service of CITIUS. IR spectra were recorded with a Perkin–Elmer Model 883 spectrophotometer (Nujol emulsion in NaCl plates). Magnetic moments were measured in the solid state, at room temperature, with a Sherwood Scientific (Cambridge Research Laboratory) magnetic balance, and between 1.9 and 300 K with a Cryogenic S600 SQUID magnetometer. Molar susceptibilities were corrected using Pascal's constants.[27] For the pellet measurement, the measure had to be corrected for some ferromagnetic impurities. The corrected curve agreed well with a zero-field cooled measurement done on a loose powder sample prior to magnetisation measurements. No significant temperature-independent paramagnetism was found.

**$[Co(tda)(H_2O)]_n$ (1a):** $Na_2CO_3$ (0.63 g, 6 mmol) was added to a solution of $S(CH_2COOH)_2$ (0.90 g, 6 mmol) in water (20 mL). The mixture was stirred until the evolution of $CO_2$ ceased and then added to a solution of $CoCl_2\cdot 6H_2O$ (1.42 g, 6 mmol) in water (15 mL). The resulting solution was stirred for 10 min, then acetone was added and the solution was kept at room temperature overnight. The dark pink crystals of **1a** that formed were filtered off, washed with acetone and diethyl ether and air dried (1.3 g, 96% yield). IR: $\tilde{\nu}$ = 3548–3087 (br), 1637 (vs), 1589 (vs), 1459 (s), 1399 (vs), 1376 (vs), 1243 (m), 1180 (w), 917 (m), 873 (w), 806 (m), 779 (s), 698 (s) $cm^{-1}$. $C_4H_6CoO_5S$ (225.09): calcd. C 21.34, H 2.69; found C 20.86, H 3.00. Small amounts of pink needle crystals of complex $[Co(tda)(H_2O)_3]$ (**1b**) were observed and manually separated in some of the preparations of **1a**. IR: $\tilde{\nu}$ = 3548 (s), 3482–3018 (br), 1635 (vs), 1585 (vs), 1406 (s), 1376 (vs), 1254 (w), 1229 (m), 1204 (w), 1178 (w), 939 (m), 865 (m), 790 (s), 763 (s), 705 (s), 663 (m) $cm^{-1}$. $C_4H_{10}CoO_7S$ (261.12): calcd. C 18.40, H 3.86; found C 18.73, H 3.96.

**$[Co(tda)(bipy)(H_2O)]\cdot 4H_2O$ (2):** Bipy (0.156 g, 1 mmol) was added to a suspension of **1a** (0.261 g, 1 mmol) in water. This mixture,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

which turned deep pink, was heated with stirring until all the solid had dissolved and then concentrated. Complex **2** crystallised upon evaporation of the solvent at room temperature after a few days. The pink crystals were filtered off, washed with water, acetone and diethyl ether and air dried (0.38 g, 84% yield). IR: $\tilde{\nu}$ = 3660–3036 (br), 1599 (vs), 1492 (s), 1462 (s), 1442 (vs), 1400 (s), 1375 (vs), 1338 (s), 1316 (s), 1253 (m), 1233 (m), 1196 (w), 1179 (w), 1157 (w), 1102 (w), 1061 (m), 1043 (w), 1021 (m), 1011 (w), 969 (w), 932 (s), 899 (m), 875 (w), 764 (vs), 735 (s), 698 (s), 648 (s), 626 (m) $cm^{-1}$. $\mu_{eff}$ = 4.5 $\mu_B$ at 25 °C. $C_{14}H_{22}CoN_2O_9S$ (453.33): calcd. C 37.09, H 4.89, N 6.18; found C 37.11, H 4.69, N 6.61.

**[Co(tda)(phen)(H$_2$O)] (3):** A solution of *o*-phen·$H_2O$ (0.198 g, 1 mmol) in 10 mL of methanol was added to a suspension of **1a** (0.230 g, 1 mmol) in 20 mL of water. This mixture, which turned deep pink immediately, was stirred and heated (90 °C) until all the solids had dissolved. It was then concentrated to a volume of about 15 mL. Slow evaporation of the solvent resulted in the formation of crystals of **3**, which were collected by filtration, washed with cold water, acetone and diethyl ether and dried in air (0.38 g, 90%). IR: $\tilde{\nu}$ = 3552–3088 (br), 3063 (w), 1644 (vs), 1584 (vs), 1516 (m), 1494 (w), 1426 (w), 1313 (m), 1213 (m), 1183 (w), 1136 (m), 1101 (m), 988 (w), 933 (m), 918 (m), 868 (m), 846 (s), 788 (m), 773 (m), 758 (m), 723 (s), 665 (m), 640 (m) $cm^{-1}$. $\mu_{eff}$ = 4.3 $\mu_B$ at 25.5 °C. $C_{16}H_{14}CoN_2O_5S$ (405.29): calcd. C 47.42, H 3.48, N 6.91; found C 46.97, H 3.38, N 6.76.

**[Co(tda){(MeO)$_2$bipy}(H$_2$O)]·2H$_2$O (4):** $(MeO)_2$bipy (0.108 g, 0.5 mmol) was added to a suspension of **1a** (0.120 g, 0.5 mmol) in 15 mL of water. This mixture, which turned red, was heated at 90 °C with stirring until all the solid had dissolved and was then poured into a crystallisation dish. Slow evaporation of water resulted in the formation of red crystals of **4**, which were collected by filtration, washed with acetone and diethyl ether and dried in air (0.18 g, 75% yield). IR: $\tilde{\nu}$ = 3669–3951 (br), 1602 (vs), 1496 (s), 1460 (s), 1451 (s), 1413 (s), 1402 (s), 1375 (s), 1339 (s), 1281 (s), 1245 (s), 1224 (s), 1186 (w), 1161 (w), 1130 (w), 1096 (w), 1038 (s), 1004 (m), 921 (m), 865 (m), 838 (s), 793 (m), 766 (m), 732 (m), 694 (m), 665 (m) $cm^{-1}$. $C_{26}H_{30}CoN_4O_{11}S$ (665.53): calcd. C 40.24, H 4.60, N 5.87; found C 40.24, H 4.45, N 5.95.

**[Co(tda)(dpp)(H$_2$O)]·2H$_2$O (5):** This complex was obtained as red crystals (0.11 g, 74% yield) following a similar synthetic procedure as described for **4** but with 2,3-bis(2-pyridyl)pyrazine (0.07 g, 0.3 mmol). IR: $\tilde{\nu}$ = 3601–3039 (br), 1593 (vs), 1529 (m), 1475 (s), 1452 (s), 1394 (vs), 1376 (vs),1298 (m), 1253 (m), 1238 (m), 1215 (m), 1164 (s), 1139 (m), 1121 (m), 1099 (m), 1083 (w), 1059 (w), 1038 (s), 1021 (m), 996 (m), 969 (w), 938 (s), 920 (s), 873 (m), 819 (m), 788 (vs), 761 (s), 752 (s), 705 (s), 662 (m), 647 (m), 624 (s) $cm^{-1}$. $C_{18}H_{20}CoN_4O_7S$ (495.37): calcd. C 43.60, H 4.03, N 11.30; found C 43.95, H 3.90, N 11.70.

**[Co{OC(OH)(2-pyridyl)$_2$}$_2$][Htda]·3H$_2$O (6):** Di(2-pyridyl) ketone (0.184 g, 1 mmol) was added to a suspension of **1a** (0.13 g, 0.5 mmol) in 15 mL of water. This mixture was heated at 90 °C for 0.5 h and then filtered. Slow evaporation of the filtrate resulted in the formation of red crystals of **3**, which were collected by filtration, washed with acetone and diethyl ether and dried in air (0.25 g, 75% yield). IR: $\tilde{\nu}$ = 3666–3080 (br), 1589 (vs), 1443 (vs), 1403 (s), 1376 (s), 1287 (vs), 1235 (vs), 1200 (m), 1164 (s), 1130 (w), 1085 (s), 1059 (w), 1023 (s), 933 (m), 886 (w), 868 (w), 806 (s), 768 (s), 701 (s), 667 (s) $cm^{-1}$. $C_{26}H_{29}CoN_4O_{11}S$ (664.53): calcd. C 46.95, H 4.36, N 8.43; found C 46.83, H 4.48, N 8.33.

**[Co(oda)(*t*Bu$_2$bipy)(H$_2$O)]·1.5H$_2$O (7):** A solution of 4,4′-*t*$Bu_2$bipy (0.147 g, 0.5 mmol) in 10 mL of ethanol was added to a solution of [{Co(oda)$(H_2O)_2$}·$H_2O$]$_n$ (0.122 g, 0.5 mmol) in 15 mL of water. This mixture, which turned deep pink immediately, was stirred and heated (90 °C) until all the solid had dissolved. It was then concentrated to a volume of about 15 mL. Slow evaporation of the solvent resulted in the formation of crystals of **7**, which were washed with cold water, acetone and diethyl ether and dried in air (0.20 g, 72% yield). IR: $\tilde{\nu}$ = 3496–3037 (br), 1613 (vs), 1547 (s), 1408 (vs), 1348 (m), 1305 (s), 1265 (w), 1250 (m), 1200 (m), 1131 (s), 1111 (s), 1038 (w), 1015 (s), 917 (s), 897 (m), 858 (s), 668 (w), 604 (s) $cm^{-1}$. $\mu_{eff}$ = 4.5 $\mu_B$ at 20 °C. $C_{22}H_{33}CoN_2O_{7.5}$ (504.44): calcd. C 52.37, H 6.15, N 5.55; found C 52.03, H 6.47, N 5.68.

**[Co(oda)(dpp)(H$_2$O)]·2H$_2$O (8):** 2,3-Bis(2-pyridyl)pyrazine (0.117 g, 0.5 mmol) was added to an aqueous solution of [{Co(oda)-$(H_2O)_2$}·$H_2O$]$_n$ (0.122 g, 0.5 mmol). This mixture, which turned red immediately, was stirred at 90 °C until the solid had dissolved and was then concentrated. Slow evaporation of water gave red crystals of **8**, which were collected by filtration, washed with cold water, acetone and diethyl ether and dried in air (0.15 g, 63% yield). IR: $\tilde{\nu}$ = 3636–32980 (br), 1605 (vs), 1436 (s), 1422 (s), 1398 (s), 1346 (m), 1305 (s), 1238 (m), 1169 (m), 1122 (s), 1096 (m), 1061 (m), 1038 (m), 1023 (s), 993 (m), 969 (w), 919 (m), 872 (m), 824 (w), 790 (s), 770 (m), 744 (m), 725 (m), 666 (w), 639 (m), 621 (m) $cm^{-1}$. $C_{18}H_{20}CoN_4O_8$ (479.31): calcd. C 45.07, H 4.17, N 11.68; found C 45.09, H 4.14, N 11.90. Good quality crystals of this complex were obtained by recrystallisation from a water/methanol mixture. They were obtained as the methanol solvate [Co(oda)(dpp)$(H_2O)$]·$H_2O$·1/2MeOH and analysed by X-ray crystallography.

**[{Co(oda)(H$_2$O)$_2$}$_2$(μ-4,4′-bipy)]·2H$_2$O (9):** A solution of 4,4′-bipy (0.078 g, 0.5 mmol) in 25 mL of water was added to a solution of [{Co(oda)$(H_2O)_2$}·$H_2O$]$_n$ (0.244 g, 1 mmol) in 25 mL of water. The resulting pink solution was stirred for a few minutes. Complex **9** crystallised upon slow evaporation of the solvent at room temperature. The solid was filtered off, washed with cold water, acetone and diethyl ether and dried in air (0.27 g, 84% yield). Recrystallisation of the product from water resulted in the formation of crystals suitable for an X-ray study. IR: $\tilde{\nu}$ = 3520–3034 (br), 1642 (s), 1600 (vs), 1534 (w), 1492 (m), 1442 (m), 1407 (s), 1346 (w), 1303 (m), 1226 (w), 1132 (s), 1075 (m), 1028 (m), 922 (m), 814 (m), 725 (w), 638 (m) $cm^{-1}$. $\mu_{eff}$ = 4.4 $\mu_B$ at 23 °C. $C_9H_{14}CoNO_8$ (323.14): calcd. C 33.43, H 4.33, N 4.33; found C 33.58, H 4.31, N 4.51.

**X-ray Crystallographic Studies:** A summary of the crystal data of complexes **2** and **6**–**9** is given in Table 6. The X-ray data were collected with three different equipments: an Enraf–Nonius CAD4 diffractometer equipped with a graphite monochromator and Mo-$K_\alpha$ radiation (for **2**, **8** and **9**), a Phillips PW1100 FEBO diffractometer equipped with a graphite monochromator and Cu-$K_\alpha$ radiation (for **6**) and a Bruker–Nonius X8APEX-II CCD diffractometer equipped with a graphite monochromator and Mo-$K_\alpha$ radiation (for **7**). The intensities collected for complexes **2**, **6**, **8** and **9** were corrected for Lorenz and polarisation effects. Three standard reflections were monitored every 2 h during the data collection. The atomic scattering factors are those reported by Cromer and Waber.[28] The structures were solved by direct methods using the SIR97 program.[29] The refinements were made by full-matrix least-squares on all $F^2$ data using SHELXL97.[30] Anisotropic thermal parameters were allotted to all non-hydrogen atoms. The hydrogen atoms of the water bonded to the metal as well as in the free water, when found in the Fourier maps, were refined with an isotropic structure factor, while the other hydrogen atoms were introduced in their calculated positions. The data set for complex **7** was reduced[31] and corrected for Lorentz polarisation effects and absorption by multiscan method applied by SADABS.[32] The structure was solved by direct methods (SIR-2002)[33] and refined

# Ethynyltolan Platinum Complexes with (Arylalkynyl)phosphane Ligands

Ana García,[a] Elena Lalinde,*[a] and M. Teresa Moreno[a]

**Keywords:** Alkyne ligands / Phosphane ligands / Platinum / X-ray diffraction

The ethynyltolan mononuclear complexes *cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(PPh$_2$C≡CR)$_2$] [R = tol (**2**), C$_6$H$_4$C≡CPh (**3**)], which contain (arylalkynyl)phosphane ligands, were prepared, and the X-ray molecular structure of **2** was determined. The reaction of **2** and **3** with *cis*-[Pt(C$_6$F$_5$)$_2$(thf)$_2$] (thf = tetrahydrofuran) in the appropriate molar ratio gave the dinuclear platinum derivatives *cis*-[{Pt(PPh$_2$C≡CR)$_2$(μ-η$^1$:η$^2$-*C*$^α$,*C*$^β$-C≡CC$_6$H$_4$C≡CPh)$_2$}Pt(C$_6$F$_5$)$_2$] [R = tol (**4**), C$_6$H$_4$C≡CPh (**5**)] and the trinuclear derivatives [{Pt(μ-η$^1$:η$^2$-*C*$^α$,*C*$^β$-C≡CC$_6$H$_4$C≡CPh)$_2$(μ-1κ*P*:2η$^2$-*C*$^α$,*C*$^β$-PPh$_2$C≡CR)$_2$}{Pt(C$_6$F$_5$)$_2$}$_2$] [R = tol (**6**), C$_6$H$_4$C≡CPh (**7**)], which are stabilized by a double ethynyltolan bridging system or a mixed ethynyltolan/alkynylphosphane bridging system, respectively.

## Introduction

The ability of alkynylphosphanes (PPh$_2$C≡CR) to bind several metal centres through single P-complexation and/or π-coordination has been well documented.[1–16] Furthermore, these ligands have revealed an interesting reactivity in transition-metal chemistry, such as insertion into reactive M–H or M–C bonds,[17–25] intramolecular coupling reactions[10,26–29] or P–C bond cleavage to afford alkynide (C≡CR) and phosphide (PPh$_2$) fragments,[6,12,30–35] which are often involved in subsequent coupling or insertion reactions.[36–39] In addition, simple P-coordination of alkynylphosphanes polarizes the electron density of the alkyne function by concentrating it on the C$^α$ atom, which favours its interaction with electrophilic and nucleophilic substrates such as water,[40,41] ethanol,[42,43] HX,[44–46] PPh$_2$H[47] or amines.[7,48] PPh$_2$C≡C–X–C≡CR ligands are able to offer higher coordination and reactivity possibilities due to the extension of the delocalised π-system. However, they have only been used as precursors of polymetallic complexes[10,15,49–52] and in P–C bond activation or intramolecular coupling reactions[51,53–55] on a few occasions.

With the aim of exploring the η$^2$-bonding capability of two P-coordinated diphenylphosphane ligands towards a second metal centre as a way of inducing alkyne coupling, we have previously studied the reactivity of *cis*-[MX$_2$(PPh$_2$C≡CR)$_2$] (M = Pd, Pt; X = Cl,[2] C$_6$F$_5$,[4,8,11] C≡CR′;[3] R = Ph, tol, *t*Bu; R′ = Ph, *t*Bu) towards the solvate complex *cis*-[Pt(C$_6$F$_5$)$_2$(thf)$_2$] (thf = tetrahydrofuran). When X is a C$_6$F$_5$ group with a low tendency to form bridges, the η$^2$-alkyne adducts [{Pt(C$_6$F$_5$)$_2$(μ-κ*P*:η$^2$-PPh$_2$C≡CR)$_2$}{Pt(C$_6$F$_5$)$_2$}] (R = Ph, tol), which are generated at low temperature, evolve through an unexpectedly easy sequential insertion of both PPh$_2$C≡CR molecules into a Pt–C$_6$F$_5$ bond to form unusual μ-2,3-bis(diphenylphosphanyl)-1,3-butadien-1-yl dinuclear complexes.[4,8] However, when X is a group with a greater tendency to act as a bridging ligand (X = Cl, C≡CR′) these groups compete with the η$^2$-bonding capacity of the PPh$_2$C≡CR group to coordinate the "Pt(C$_6$F$_5$)$_2$" fragment and only polymetallic species with X or mixed X/PPh$_2$C≡CR bridging systems are obtained.[2,3] In particular, several homo- and heterodimetallic complexes stabilized by double alkynyl bridging systems, such as *cis*-[{Pt(PPh$_2$C≡CR)$_2$(μ-η$^1$:η$^2$-C≡CR′)$_2$}Pt(C$_6$F$_5$)$_2$], and unusual symmetrical *cis*-[{Pt(PPh$_2$C≡C*t*Bu)$_2$(μ$_3$-η$^2$-C≡CPh)$_2$}{Pt(C$_6$F$_5$)$_2$}$_2$] and *cis*-[{Pt(μ-κ*P*:η$^2$-PPh$_2$C≡CR)$_2$(μ-η$^2$-C≡C*t*Bu)$_2$}{Pt(C$_6$F$_5$)$_2$}$_2$] trimetallic species, have been isolated with the mononuclear alkynylplatinum complexes *cis*-[Pt(C≡CR′)$_2$(PPh$_2$C≡CR)$_2$] (R′, R = Ph, *t*Bu) using 1:1 or 1:2 molar ratios, respectively, thereby indicating the following order of bonding capability: C≡CR′ > P-bonded PPh$_2$C≡CR and C≡CPh > C≡C*t*Bu fragments.[3] As an extension of this work to ethynyltolan systems {when referring to ethynyltolan as ligand, its deprotonated anion [(phenylethynyl)phenyl]ethynide is meant}, we report here the preparation and characterisation of the neutral complexes *cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(PPh$_2$C≡CR)$_2$] [R = tol (**2**), C$_6$H$_4$C≡CPh (**3**)], which are stabilized by (arylalkynyl)phosphanes. Furthermore, to gain more insight into the synthetic possibilities of the ethynyltolan and (arylalkynyl)phosphane ligands, especially a comparison of the reactivity of inner and outer alkynyl functions, we have investigated the reactivity of these complexes towards *cis*-[Pt(C$_6$F$_5$)$_2$(thf)$_2$].

## Results and Discussion

The precursor derivative *cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(cod)] (**1**) was obtained using a similar procedure to that used for related *cis*-[Pt(C≡CR)$_2$(cod)] (R = Ph,[56] *t*Bu[57]) derivatives. Thus, the reaction of an ethanolic suspension of [PtCl$_2$(cod)] at low temperature (–30 °C) with HC≡CC$_6$H$_4$C≡CPh (2 equiv.) in a solution of NaOEt (3.7 equiv.), prepared "in situ" from a solution of Na in absolute EtOH, yielded **1** as a white solid in low yield (32%). Treatment of **1** with 2 equiv. of the appropriate (arylalkynyl)phosphane (PPh$_2$C≡Ctol, PPh$_2$C≡CC$_6$H$_4$C≡CPh) easily led to the displacement of the cod ligand and afforded the disubstituted products *cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(PPh$_2$C≡CR)$_2$] [R = tol (**2**), C$_6$H$_4$C≡CPh (**3**); Equation (1)]. These complexes were isolated as orange-brown solids, and their spectroscopic data (see Experimental Section) unequivocally confirmed the P-coordination mode of the PPh$_2$C≡CR ligands.

*cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(cod)] (**1**)
↓ 2 PPh$_2$C≡CR
*cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(PPh$_2$C≡CR)$_2$]
R = tol (**2**), C$_6$H$_4$C≡CPh (**3**) (1)

The IR spectra of **2** and **3** show two strong ν(C≡C) bands: the high-frequency band [2171 cm$^{-1}$ (**2**, **3**)] located at slightly higher wavenumbers than that in the corresponding free (arylalkynyl)phosphane is attributed to the ν(C≡C) stretch of the phosphane ligands, whereas the low-frequency band [2121 (**2**) and 2120 cm$^{-1}$ (**3**)] is assigned to the inner C$^{\alpha}$≡C$^{\beta}$ fragment of the ethynyltolan ligand. According to this assignment, the precursor derivative *cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(cod)] (**1**) shows a medium-intensity band at 2119 cm$^{-1}$. All complexes **1**–**3** also show a very weak high-frequency band (2214 cm$^{-1}$), assigned to the outer C$^5$≡C$^6$ alkyne group of the ethynyltolan ligand [see the Experimental Section (Figure 3) for the labelling scheme]. The phosphorus resonance in complexes **2** and **3** appears as a singlet that is shifted downfield with respect to the corresponding free ligands [$\delta$ = –6.53 (**2**) and –6.27 ppm (**3**) vs. –33.42 (PPh$_2$C≡Ctol) and –33.27 ppm (PPh$_2$C≡CC$_6$H$_4$C≡CPh)], with platinum coupling constants [2350 (**2**) and 2343 Hz (**3**)] comparable to those reported for mononuclear complexes having a tertiary phosphane group *trans* to a terminal alkynide group.[3,58] The $^{13}$C{$^1$H} NMR spectra are particularly significant. The acetylenic carbon resonances for the (arylalkynyl)phosphane ligands of both complexes can clearly be seen and their assignment is mainly based on the $J_{C,P}$ coupling constants observed and also by comparison with the corresponding signals in the starting precursor **1** [$\delta$ = 96.9 (C$^{\alpha}$), 107.8 (C$^{\beta}$), 90.1, 89.4 (C$^{5,6}$) ppm; see Figure 3 for assignments]. The alkynylphosphane C$^{\alpha'}$ resonances are found as an apparent doublet at lower frequencies than those of the C$^{\beta'}$ atoms, which are found as the A part of an AXX′ system [C$^{\alpha'}$: $\delta$ = 80.1 (**2**) and 82.7 ppm (**3**); C$^{\beta'}$: $\delta$ = 108.6 (**2**) and 107.4 ppm (**3**)]. The coupling constants $|^1J_{C\alpha',P} + {}^3J_{C\alpha',P}|$ [103.4 (**2**) and 100.2 Hz (**3**)] and $|^2J_{C\beta',P} + {}^4J_{C\beta',P}|$ [15.1 (**2**) and 14.8 Hz (**3**)] could also be calculated. The C$^{\alpha}$ and C$^{\beta}$ alkynyl resonances also appear as the A part of an AXX′ system, with C$^{\alpha}$ [$\delta$ = 105.2 (**2**) and 104.5 ppm (**3**)] appearing as a doublet of doublets [$|^2J_{C\alpha,Ptrans} + {}^2J_{C\alpha,Pcis}|$ = 155.1 (**2**) and 156.2 Hz (**3**)] and C$^{\beta}$ as a three-line pattern [$\delta$ = 109.3 ($|^3J_{C\beta,Ptrans} + {}^3J_{C\beta,Pcis}|$ = 37.6 Hz; **2**) and 109.4 ($|^3J_{C\beta,Ptrans} + {}^3J_{C\beta,Pcis}|$ = 36.4 Hz; **3**) ppm]. The acetylene carbon atoms of the outer fragments [C$^5$/C$^6$ (**2**) and C$^{5,5'}$/C$^{6,6'}$ (**3**)] appear as sharp singlets [$\delta$ = 89.9, 89.4 (**2**) and 92.2, 89.8, 89.4, 88.3 ppm (**3**)] and were assigned by comparison to these signals in the precursor derivative [$\delta$ = 90.1, 89.4 ppm (**1**)]. The alkynylphosphane C$^{\alpha'}$ resonances are shifted upfield in both complexes with respect to those of free PPh$_2$C≡CR, whereas the C$^{\beta'}$ carbon resonances are very close to those of the free ligands [$\delta$(C$^{\alpha'}$/C$^{\beta'}$) = 84.6/107.9 (PPh$_2$C≡Ctol), 89.2/107.4 (PPh$_2$C≡CC$_6$H$_4$C≡CPh) ppm]. As a consequence, the resulting chemical shift difference ($\Delta$ = $\delta$C$^{\beta'}$ – $\delta$C$^{\alpha'}$), which can be related to the triple-bond polarisation,[9,13,59,60] is similar in both complexes [$\Delta$ = 28.5 (**2**) and 24.7 ppm (**3**)].

An X-ray diffraction study confirmed that **2** (Figure 1) is a slightly distorted square-planar Pt$^{II}$ complex formed by two mutually *cis*-arranged ethynyltolan (C≡CC$_6$H$_4$-C≡CPh) and (tolylethynyl)phosphane (PPh$_2$C≡Ctol) ligands. Selected bond lengths and angles are given in Table 1 and crystallographic data in the Experimental Section. Chemically equivalent Pt–C [2.017(4), 2.007(4) Å] and C≡C {1.196(6) and 1.204(6) Å [(tolylethynyl)phosphane groups]; 1.185(6), 1.198(6) and 1.194(6), 1.195(6) Å (ethynyltolan ligands)} bond lengths are identical within experimental error, while the Pt–P bond lengths differ only slightly [2.2792(11), 2.2919(11) Å]. The inner Pt–C$^{\alpha}$–C$^{\beta}$/C$^{\alpha}$–C$^{\beta}$–C(C$_6$H$_4$) [171.9(4)/176.9(5), 173.0(4)/176.5(5)°] and outer acetylenic fragments C(C$_6$H$_4$)–C$^5$–C$^6$/C$^5$–C$^6$–C(Ph) [175.5(5)/176.9(5), 178.8(6)/177.0(6)°] of the ethynyltolan ligands and the alkynyl moiety in the phosphane fragments P–C$^{\alpha'}$–C$^{\beta'}$/C$^{\alpha'}$–C$^{\beta'}$–C(C$_6$H$_4$) [171.2(4)/175.7(5), 173.6(4)/177.6(5)°] do not deviate significantly from linearity. These values are unexceptional and similar to those found in other X-ray crystallographically characterised mononuclear P-coordinated alkynylphosphane-[8,10,14,15,26,27,61,62] or σ-alkynylplatinum[63–78] complexes. The C$_6$H$_4$ group and the phenyl rings on each ethynyltolan ligand are nearly coplanar [dihedral angles: 2.89(15) and 10.81(17)°], which suggests strong π-delocalisation. However, both ethynyltolan ligands are essentially perpendicular to each other [92.18(17), 91.16(20)°]. The two PPh$_2$C≡Ctol units in this complex exhibit a *cisoidal* arrangement with a dihedral angle between the planes formed by both equivalent Pt–P–C$^{\alpha}$ atoms [Pt(1)–P(1)–C(33) and Pt(1)–P(2)–C(54)] of 51.90(15)°, which leads to a separation between both α-carbon atoms of only 3.1169(72) Å. Carty et al. have suggested a relationship between the ease of intramolecular coupling of the uncoordinated alkyne triple bonds in P-coordinated alkynylphosphane ligands and the proximity of the α-car-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bon atoms of the proximal alkyne units (less than 3.4 Å, twice the van der Waals radius of the carbon atom).[27] In fact, we have recently shown that compounds *cis*-[Pt($C_6F_5$)$_2$($PPh_2C{\equiv}CR$)$_2$] (R = Ph, tol) with "crossed" linear alkynyl moieties and a $C^{\alpha}$–$C^{\alpha}$ separation of 3.20(2) Å (Ph) or 3.34(2) Å (tol) evolve thermally into naphthalene-based bis(diphenylphosphane) complexes[62] *cis*-[Pt($C_6F_5$)$_2$-{$C_{10}H_5$-1-Ph-2,3-κ*PP′*($PPh_2$)$_2$}] and *cis*-[Pt($C_6F_5$)$_2$-{7-$CH_3$-$C_{10}H_4$-1-tol-2,3-κ*PP′*($PPh_2$)$_2$}] by intramolecular [2+2+2] coupling of two adjacent $PPh_2C{\equiv}CR$ ligands, in a similar manner to that previously observed by Carty et al. for related dichloridoplatinum(II) derivatives.[27] Similar naphthalene species can also be generated starting from the diynyl systems *cis*-[Pt($C_6F_5$)$_2$($PPh_2C{\equiv}CC_6H_4C{\equiv}CR$)$_2$] (R = Ph, *t*Bu), but only by photolysis. In contrast, photolysis of the monoalkynyl complexes *cis*-[Pt($C_6F_5$)$_2$($PPh_2C{\equiv}CR$)$_2$] (R = Ph, tol) proceeds with parallel formation of naphthalene species and the new chelating diphosphane complexes *cis*-[Pt($C_6F_5$)$_2${$PPh_2C(Ph){=}C(R)PPh(C{\equiv}CR)$}] (R = Ph, tol).[62] However, in contrast to this behaviour, complex **2**, which exhibits a very short separation between the alkynyl fragments, shows no evidence of coupling either under thermal (4 h at about 225 °C) or photochemical conditions (irradiation of a toluene solution for 90 min at room temperature using a 400-W Hg lamp).

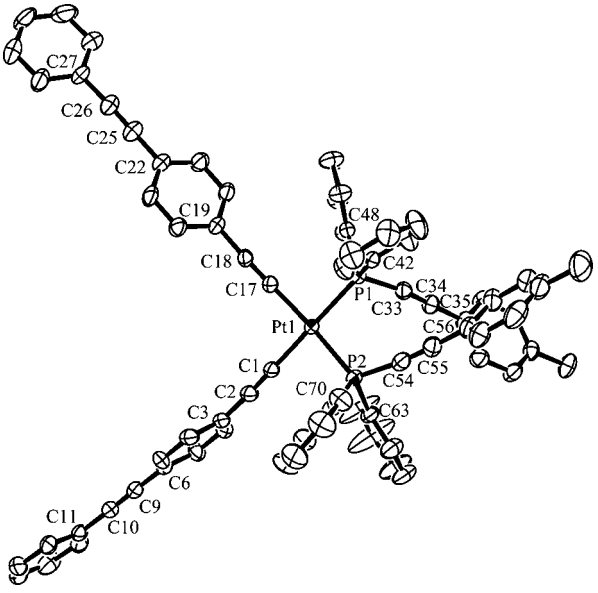

Figure 1. Molecular structure of *cis*-[Pt($C{\equiv}CC_6H_4C{\equiv}CPh$)$_2$-($PPh_2C{\equiv}Ctol$)$_2$] (**2**). Ellipsoids are drawn at the 50% probability level. Hydrogen atoms have been omitted for clarity.

To compare the coordination possibilities of the ethynyltolan ligand and the alkyne function of the P-coordinated (arylalkynyl)phosphane ligands, we studied the reactions of **2** and **3** with *cis*-[Pt($C_6F_5$)$_2$(thf)$_2$]. The results are shown in Scheme 1. Treatment of *cis*-[Pt($C{\equiv}CC_6H_4C{\equiv}CPh$)$_2$-($PPh_2C{\equiv}CR$)$_2$] [R = tol (**2**), $C_6H_4C{\equiv}CPh$ (**3**)] with 1 equiv. of *cis*-[Pt($C_6F_5$)$_2$(thf)$_2$] in $CH_2Cl_2$ at room temperature afforded the corresponding dinuclear derivatives *cis*-[{Pt($PPh_2C{\equiv}CR$)$_2$(μ-$\eta^1$:$\eta^2$-$C^{\alpha}$,$C^{\beta}$-$C{\equiv}CC_6H_4C{\equiv}CPh$)$_2$}Pt-($C_6F_5$)$_2$] [R = tol (**4**), $C_6H_4C{\equiv}CPh$ (**5**)] by $\eta^2$-complexation of the "*cis*-Pt($C_6F_5$)$_2$" fragment with both [*para*-(*para*-phenylethynyl)phenyl]alkynyl ligands. This result was not unexpected and confirms previous observations of the stronger preference of the hard $Pt^{II}$ centre towards platinaalkynyl entities rather than alkynylphosphane groups.[3,11] However, similar reactions of **2** and **3** with 2 equiv. of *cis*-[Pt($C_6F_5$)$_2$-(thf)$_2$] in $CH_2Cl_2$ yielded the trinuclear derivatives *cis*-[{Pt(μ-$\eta^1$:$\eta^2$-$C^{\alpha}$,$C^{\beta}$-$C{\equiv}CC_6H_4C{\equiv}CPh$)$_2$(μ-1κ*P*:2$\eta^2$-$C^{\alpha}$,$C^{\beta}$-$PPh_2C{\equiv}CR$)$_2$}{Pt($C_6F_5$)$_2$}$_2$] [R = tol (**6**), $C_6H_4C{\equiv}CPh$ (**7**)] in which the mononuclear precursors act as symmetrical mixed bis(*cis*-$\eta^2$:κ*P*:$\eta^2$)-chelating tetrahapto ligands of the two "*cis*-Pt($C_6F_5$)$_2$" units by binding through both an ethynyltolan group (μ-$\eta^2$-$C{\equiv}CC_6H_4C{\equiv}CPh$) and the alkyne function of the corresponding (arylethynyl)phosphane ligand (μ-κ*P*:$\eta^2$, inner for **7**).

Table 1. Selected bond lengths [Å] and angles [°] for *cis*-[Pt($C{\equiv}CC_6H_4C{\equiv}CPh$)$_2$($PPh_2C{\equiv}Ctol$)$_2$]·$C_6H_6$ (**2**·$C_6H_6$).

Although all attempts to obtain crystals of complexes **4**–**7** have proved fruitless so far, their spectroscopic data (see Experimental Section) are in accordance with the formulation shown in Scheme 1. Thus, complexes **4** and **5** show one strong ν(C≡C) absorption at 2173 (**4**) and 2172 $cm^{-1}$ (**5**), which confirms that the alkynyl units of the $PPh_2C{\equiv}CR$ ligands remain uncoordinated. The expected ν(C≡C) absorptions at lower frequencies, assignable to the bridging Pt(μ-$C{\equiv}CR)_2$Pt entity, are not observed, although this structural feature has been found previously in other alkynyl-bridged complexes.[57] However, both complexes show an additional very weak ν(C≡C) absorption (2216 $cm^{-1}$) that is clearly due to the outer $C^5{\equiv}C^6$ alkyne entity of these bridging alkynyl groups. The trinuclear derivatives **6** and **7** show two high-frequency bands [one sharp at 2174 (**6**) and 2173 $cm^{-1}$ (**7**) and one very weak at 2214 (**6**) and 2216 $cm^{-1}$ (**7**)] corresponding to uncoordinated alkyne units and weak bands [2019 (**6**) and 2020, 1991 $cm^{-1}$ (**7**)] assignable to the ν(C≡C) moiety of the $\eta^2$-coordinated groups.

The equivalent phosphorus atoms of the terminal alkynylphosphane ligands in the dinuclear derivatives **4** and **5** appear in the $^{31}P\{^1H\}$ NMR spectra at lower frequencies [δ = –11.20 (**4**) and –10.88 ppm (**5**)] than those in the precursors [δ = –6.53 (**2**) and –6.27 ppm (**3**)]. This high-field shift is similar to that previously observed for related dinuclear

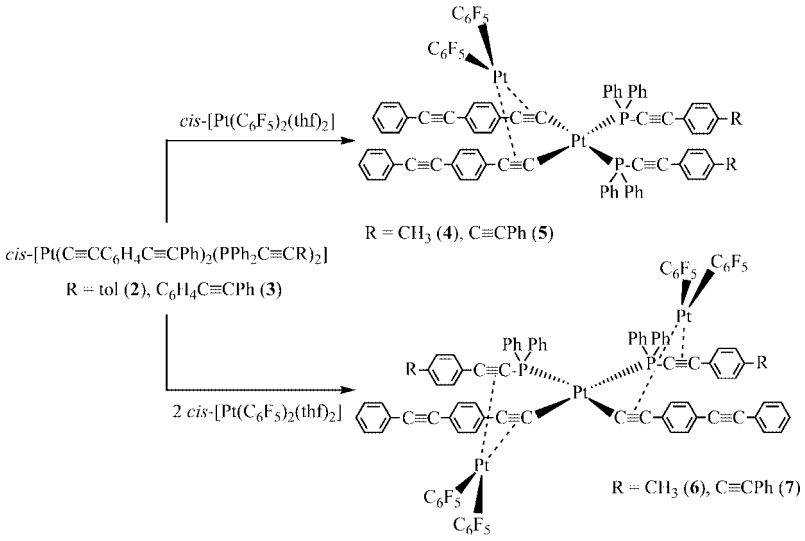

Scheme 1. Synthesis of complexes **4**–**7**.

derivatives *cis*-[{Pt(PPh$_2$C≡CR)$_2$(μ-η$^1$:η$^2$-C≡CR′)$_2$}Pt(C$_6$F$_5$)$_2$][3] and, therefore, is in keeping with the η$^2$-coordination of the "*cis*-Pt(C$_6$F$_5$)$_2$" fragment to the ethynyltolan ligands. The magnitude of $^1J_{P,Pt}$ [2682 (**4**) and 2677 Hz (**5**)] is slightly larger than that in the corresponding mononuclear derivatives with terminal ethynyltolan groups [2350 (**2**) and 2343 Hz (**3**)] due to the smaller *trans* influence of the bridging ethynyltolan ligands. In accordance with the presence of bridging four-electron (arylalkynyl)phosphane (μ-κ*P*:η$^2$) ligands in trinuclear complexes **6** and **7**, both complexes show a considerable downfield shift of the phosphorus resonance [$\delta$ = 0.19 (**6**) and 0.43 ppm (**7**)] with respect to those observed in the mononuclear precursors [$\delta$ = –6.53 (**2**) and –6.27 ppm (**3**)] and even the dinuclear derivatives, in which the PPh$_2$C≡CR molecules act only as P-donor ligands [$\delta$ = –11.20 (**4**) and –10.88 ppm (**5**)]. The platinum-phosphorus coupling constants [2514 (**6**) and 2516 Hz (**7**)] are slightly larger than those observed for the starting precursors [2350 (**2**) and 2343 Hz (**3**)] but somewhat smaller than those of the dinuclear complexes [2682 Hz (**4**) and 2677 Hz (**5**)]. It should be noted that the reaction of *cis*-[Pt(C≡CC$_6$H$_4$C≡CPh)$_2$(PPh$_2$C≡CR)$_2$] [R = tol (**2**), C$_6$H$_4$C≡CPh (**3**)] with 2 equiv. of *cis*-[Pt(C$_6$F$_5$)$_2$(thf)$_2$] could have taken place with formation of *cis*-[{Pt(PPh$_2$C≡CR)$_2$-(μ$_3$-η$^2$-*C*$^\alpha$,*C*$^\beta$-C≡CC$_6$H$_4$C≡CPh)$_2$}{Pt(C$_6$F$_5$)$_2$}$_2$], where the phosphane ligands act as terminal groups and both ethynyltolan fragments act as five-electron μ$_3$-η$^2$ bridging ligands. However, the chemical shift and coupling constant found in the related trinuclear complex *cis*-[{Pt(PPh$_2$C≡C*t*Bu)$_2$(μ$_3$-η$^2$-C≡CPh)$_2$}{Pt(C$_6$F$_5$)$_2$}$_2$] [$\delta$ = –20.55 ppm ($^1J_{P,Pt}$ = 3008 Hz)][3] are clearly different to those observed in the trinuclear derivatives **6** and **7**, with the latter being very close to those found in the symmetric isomers *cis*-[{Pt(μ-η$^1$:η$^2$-C≡C*t*Bu)$_2$(μ-1κ*P*:2η$^2$-PPh$_2$C≡CR)$_2$}{Pt(C$_6$F$_5$)$_2$}$_2$] [$\delta$ = 0.67 to –1.96 ppm ($^1J_{P,Pt}$ = 2488–2501 Hz)].[3] These results indicate that, while the phenylethynyl groups in [Pt](C≡CPh)$_2$ derivatives use both orthogonal π-acetylenic bonds in the formation of {[Pt](μ$_3$-η$^2$-C≡CPh)$_2$}{Pt(C$_6$F$_5$)$_2$}$_2$, the related ethynyltolan fragments in [Pt](C≡CC$_6$H$_4$C≡CPh)$_2$ precursors **2**, **3** only employ one in the formation of complexes **6** and **7**, thereby suggesting the lower bonding capability of these latter groups.

The variable-temperature $^{19}$F NMR spectra of dinuclear complexes **4** and **5** indicate a temperature dependence of the spectral pattern. To illustrate this, the temperature dependence of the $^{19}$F NMR spectrum of **5** in CDCl$_3$ is shown in Figure 2. As can be observed, the limiting low-temperature spectrum is compatible with a static structure. This pattern of five distinct signals (1:1:1:1:1) confirms that both C$_6$F$_5$ groups are rigid on the NMR timescale and equivalent. Upon raising the temperature, the two *o*-F doublets and the two *m*-F multiplets coalesce (above 273 K for *o*-F and 268 K for *m*-F) to only one *o*-F doublet and one *m*-F multiplet resonance. The approximate calculated activation energy is similar for the *ortho*-fluorine ($\Delta G^{\ddagger}_{273K}$ = 50.01 kJ mol$^{-1}$) and for the *meta*-fluorine atoms ($\Delta G^{\ddagger}_{268K}$ = 50.63 kJ mol$^{-1}$). The equivalence of the *o*-F atoms (and the *m*-F ones as well) at high temperature can be explained either by assuming a rapid rotation of the C$_6$F$_5$ groups around the Pt–C bonds, as previously suggested in other systems with "*cis*-Pt(C$_6$F$_5$)$_2$" fragments,[79–83] or by a fast intramolecular exchange of the "*cis*-Pt(C$_6$F$_5$)$_2$" unit below and above the platinum coordination plane. This second possibility has been suggested in related derivatives[3,57,84] stabilized by a double alkynyl bridging system and assumes the existence of a formal inversion of the PtC$_4$Pt central skeleton, which could take place via intermediate species with one or two μ-η$^1$-bonded alkynyl ligands.[85] However, we note that in these complexes (**4**, **5**) an exchange mechanism involving the inner alkynyl moieties of the (arylalkynyl)phosphane ligands cannot be discarded. The trinuclear derivatives **6** and **7** show a pattern that is consistent with two inequivalent C$_6$F$_5$ rings in which both halves are equivalent at room temperature. The two *ortho*-fluorine resonances are broad at this temperature but, unfortunately,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

their extremely low stability in solution, even at low temperature, has prevented us from obtaining the corresponding clean variable-temperature $^{19}F$ NMR spectra.

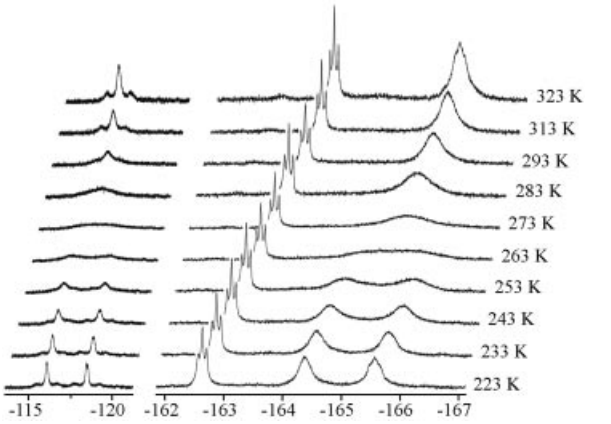

Figure 2. Variable-temperature $^{19}F$ NMR spectra (chemical shifts in ppm) of *cis*-[{Pt($PPh_2C{\equiv}CC_6H_4C{\equiv}CPh)_2$(μ-η$^1$:η$^2$-$C^{\alpha}$,$C^{\beta}$-$C{\equiv}CC_6H_4C{\equiv}CPh)_2$}Pt($C_6F_5)_2$] (**5**) in $CDCl_3$.

## Conclusion

We have reported the formation of novel (μ-$C{\equiv}CC_6H_4C{\equiv}CPh)_2$ (**4**, **5**) and mixed [μ-($C{\equiv}CC_6H_4C{\equiv}CPh$)/μ-($PPh_2C{\equiv}CR$)] (**6**, **7**) bridging di- and triplatinum complexes. In particular, the synthesis of **6** and **7**, which are stabilized by a mixed bridging system, from **2** and **3** with 2 equiv. of *cis*-[Pt($C_6F_5)_2$(thf)$_2$] instead of the isomeric *cis*-[{Pt($PPh_2C{\equiv}CR$)(μ$_3$-η$^2$-$C^{\alpha}$,$C^{\beta}$-$C{\equiv}CC_6H_4C{\equiv}CPh)_2$}{Pt($C_6F_5)_2$}$_2$] is remarkable. We have previously shown[3] that C≡CPh groups are able to act as five-electron donors (μ$_3$-η$^2$-$C^{\alpha}$,$C^{\beta}$-C≡CPh) towards "*cis*-[Pt($C_6F_5)_2$]", thus suggesting that these groups present a stronger η$^2$ capability than the more unsaturated $C{\equiv}CC_6H_4C{\equiv}CPh$ ligands.

## Experimental Section

**General Remarks:** All reactions were carried out under $N_2$ using dried solvents purified by known procedures and distilled prior to use. IR spectra were recorded with a Perkin–Elmer FT-IR 1000 spectrometer as Nujol mulls between polyethylene sheets and NMR spectra were recorded with a Bruker ARX 300 spectrometer. Chemical shifts are reported in ppm relative to external standards ($SiMe_4$, $CFCl_3$ and 85% $H_3PO_4$). Elemental analyses were carried out with a Perkin–Elmer 2400 CHNS/O microanalyzer and mass spectra were recorded with a VG Autospec spectrometer (FAB$^+$) or a Microflex MALDI-TOF Bruker spectrometer operating in the linear and reflector modes using dithranol as the matrix. $HC{\equiv}CC_6H_4C{\equiv}CPh$,[86] $PPh_2C{\equiv}Ctol$,[87] $PPh_2C{\equiv}CC_6H_4C{\equiv}CPh$[13] and *cis*-[Pt($C_6F_5)$(thf)$_2$][88] were prepared according to published procedures. Figure 3 shows the labelling scheme for the carbon atoms in the ethynyltolan ligand and in the (ethynyltolan)diphenylphosphane ligand.

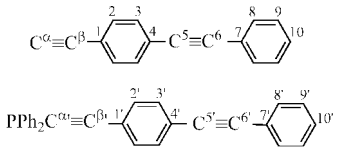

Figure 3. Labelling scheme for the carbon atoms in the ethynyltolan and (ethynyltolan)diphenylphosphane ligand.

**Synthesis of *cis*-[Pt($C{\equiv}CC_6H_4C{\equiv}CPh)_2$(cod)] (1):** A freshly prepared mixture of $HC{\equiv}CC_6H_4C{\equiv}CPh$ (432 mg, 2.138 mmol) and sodium ethoxide (prepared from 84 mg of sodium and 20 mL of ethanol) was added dropwise, with constant stirring, to a suspension of [$PtCl_2$(cod)] (400 mg, 1.069 mmol) in deoxygenated ethanol (10 mL) at –30 °C. After stirring at low temperature for 1 h, the resulting white solid was filtered and washed with successive portions of water (2 × 5 mL) and acetone (2 × 5 mL). Yield: 242 mg (32%). $C_{40}H_{30}Pt$ (705.8): calcd. C 68.07, H 4.28; found C 68.42, H 3.98. IR (Nujol): ṽ = 2214 (vw), 2119 (m) (C≡C) cm$^{-1}$. $^1H$ NMR (300.1 MHz, $CDCl_3$, 20 °C): δ = 7.50 (m), 7.38 (m), 7.32 (m) (18 H, $C_6H_4$, Ph), 5.70 (s, $J_{Pt,H}$ = 43 Hz, 4 H, =C*H*, cod), 2.58 (s, 8 H, C$H_2$, cod) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$, 20 °C): δ = 131.5 (s), 131.2 (s), 130.8 (s), 128.0 (s, $C^{2,3,8,9}$), 127.9 (d, *J* = 16 Hz, $C^{10}$), 126.2 (s), 123.1 (s), 120.8 (s, $C^{1,4,7}$), 107.8 (s, $^2J_{C,Pt} \approx$ 370 Hz, Cβ), 104.3 (s, $J_{C,Pt}$ = 80 Hz, =*C*H, cod), 96.9 (s, Cα), 90.1 (s), 89.4 (s, $C^{5,6}$) ppm. ES (+, ionized with $Na^+$) MS: *m*/*z* (%) = 727 (38) [M$^+$ + Na – H].

**Synthesis of *cis*-[Pt($C{\equiv}CC_6H_4C{\equiv}CPh)_2$($PPh_2C{\equiv}Ctol)_2$] (2):** $PPh_2C{\equiv}Ctol$ (189 mg, 0.630 mmol) was added to a solution of *cis*-[Pt($C{\equiv}CC_6H_4C{\equiv}CPh)_2$(cod)] (**1**; 222 mg, 0.315 mmol) in $CH_2Cl_2$ (10 mL) to give an orange solution. After stirring for 1 h, the resulting solution was concentrated to a small volume, and addition of ethanol (5 mL) gave **2** as an orange-brown solid. Yield: 220 mg (58%). $C_{74}H_{52}P_2Pt$ (1198.27): calcd. C 74.18, H 4.37; found C 73.83, H 3.98. unit. This molecule of benzene was found to be disordered over two positions with two consecutive carbon atoms, C(75) and C(80), in the same position and was modelled adequately. The disordered sets of atoms were refined with a partial occupancy of 0.50 each. Data for **2**·$C_6H_6$ were collected at low temperature (173 K) with a Nonius κ-CCD area-detector diffractometer, using graphite-monochromated Mo-$K_\alpha$ radiation. Data were processed using the DENZO and SCALEPACK suite of programs.[89] The absorption correction was performed using SORTAV.[90] The structure was solved by Patterson and Fourier methods using the DIRDIF92 program,[91] and refined by full-matrix least squares on $F^2$ with SHELXL-97.[92] All non-hydrogen atoms were assigned anisotropic displacement parameters and all hydrogen atoms were constrained to idealised geometries by fixing isotropic displacement parameters at 1.2-times the $U_{iso}$ value of their attached carbon atom for the phenyl hydrogen atoms and 1.5-times for the methyl groups. There are peaks of electron density higher than 1 e Å$^{-3}$ in the final map, but they are located very close to the platinum atoms or in the vicinity of the solvent and have no chemical meaning. CCDC-634038 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request.cif.

# Reactivity of InCp* Towards Transition Metal Carbonyl Clusters: Synthesis and Structural Characterization of the $Rh_6(CO)_{16-x}(InCp^*)_x$ Mixed-Metal Cluster Compounds, $x$ = 1–2

**Elena V. Grachova*[a] and Gerald Linti[b]**

**Keywords:** Rhodium / Indium / Cluster compounds

With $[Rh_6(CO)_{15}(InCp^*)]$, the first example of a transition metal carbonyl cluster with a coordinated InCp* (Cp* = $C_5Me_5$) fragment in the ligand environment is reported. This cluster with direct Rh–In bonds forms in the reaction of the hexanuclear carbonyl rhodium cluster $Rh_6(CO)_{15}(NCMe)$ with InCp* under mild conditions. This is characterized by means of IR and NMR spectroscopy and crystal structure analysis.

## Introduction

Creation of new materials primarily requires chemists to create new compounds with novel and unusual properties. In most cases, unusual properties are the result of the unusual composition and structure of a new compound and the combination of incompatible elements, as for example direct bonds between d- and s,p metals.

Compounds ECp* (E = group 13 metal) are used in organometallic chemistry of transition metals as "building blocks" owing to their capacity to substitute carbonyl ligands and to coordinate directly to a transition metal atom.[1,2] This enables the design of small carbonyl cluster compounds containing direct bonds between transition and non-transition metals.

Recently, we reported the synthesis and structural characterization of a series of mixed-metal rhodium and ruthenium carbonyl cluster complexes containing GaCp* fragments in the coordination environment.[3–5] Extension of these studies to InCp* complexes is directed not only to the creation of novel compounds, but to understand regular trends for the interaction of low nuclear carbonyl cluster compounds with ECp* complexes as well. This understanding is necessary to know how to create the mixed-metal carbonyl cluster compounds with a predetermined, specified relation of transition metal to group 13 metal.

## Results and Discussion

Reactivity of InCp* towards transition metals has been studied and various mixed-metal complexes with InCp* as a ligand were synthesized.[6–11]

We found that the reaction of the labile $[Rh_6(CO)_{15}(NCMe)]$ cluster with a slight excess of InCp* in dry toluene results in the formation of monosubstituted $[Rh_6(\mu_3\text{-}CO)_3(\mu_3\text{-}InCp^*)(CO)_{12}]$ (**1**) and disubstituted $[Rh_6(\mu_3\text{-}CO)_2(\mu_3\text{-}InCp^*)_2(CO)_{12}]$ (**2**) cluster complexes. This is similar to the analogous reaction of the starting cluster with GaCp*.[3,4] The very curious fact is that treatment of the parent $Rh_6(CO)_{16}$ cluster with any amount of InCp* gives no substituted derivatives, which is in contrast to the behaviour of GaCp*. This fact demonstrates the lower coordination ability of $In^I$ derivatives relative to $Ga^I$ organyls.

Clusters **1** and **2** are air-sensitive and are destroyed on silica gel. Single crystals of **1** were obtained and its structure was determined by X-ray analysis. Compound **1** crystallizes

together with one molecule of diethyl ether in the monoclinic crystal system and with the space group $P2_1/n$. An ORTEP view of **1** is shown in Figure 1, selected structural parameters are given in Table 1.

The cluster of **1**, provided that InCp* is a two-electron donor, has 7 skeletal electron pairs that fit the *closo* octahedral rhodium cluster skeleton that is surrounded by 16 ligands as in the parent $Rh_6(CO)_{16}$ cluster. The molecular structure of **1** demonstrates the substitution of one $\mu_3$-CO in the $Rh_6(CO)_{16}$ molecule for an InCp* fragment. As a result, the coordination environment of **1** consists of 12 terminal CO, 3 face-bridging CO and an InCp* fragment, which is coordinated to the metal core in a $\mu_3$ mode.

The InCp* ligand in **1** occupies a nearly symmetrical position over a rhodium triangle. The In–Rh distances fall in the range from 2.7072(10) to 2.7196(9) Å. This fits well with the result found in the only known cluster compound with $\mu_3$-InCp* fragments in the ligand sphere, $[Pd_3(PPh_3)_3(\mu_2\text{-InCp*})(\mu_3\text{-InCp*})_2]$.[10]

The $Cp^*_{centroid}$–In–$Rh_{triangle}$ vector in **1** deviates from linearity (170.27°). This distortion is reflected in the InCp* ligand itself, which is coordinated in a pseudo $\eta^3$ manner [In–$C_{Cp^*}$ contacts, 2.532(12), 2.346(15) Å]. Because there is some rotational disorder in the Cp* ring, which was treated as split positions of the carbon atoms in a 0.67:0.33 ratio, the results must not be overinterpreted. A similar situation was found before in the solid state for the $Rh_6(CO)_{16-x}(\mu_3\text{-GaCp*})_x$ clusters.[3,4] This outward move from the ideal symmetrical position can be formally described as a $\eta^5 \rightarrow \eta^3$ haptotropic shift in the $C_5$ rings of the ECp* fragment, but from our point of view, this phenomenon is essentially caused by steric distortions because of molecule packing in the crystal cell.

The insertion of InCp* in the coordination environment of the carbonyl cluster results in substantial distortions of the parent rhodium octahedron. These distortions are located in the vicinity of the substitution site. Thus, the mean Rh–Rh distance value in the rhodium triangle connected to In in **1** is 2.856(9) Å, whereas the mean Rh–Rh contact for the other metals in the cluster core is 2.746(8) Å (Table 1). Elongation of the Rh–Rh bonds of the indium-capped rhodium triangle looks very similar to the structural effect of weak π-acceptors, which was mentioned earlier for the terminally substituted $Rh_6(CO)_{16}$ derivatives.[12] We found the same effect for the $Rh_6(CO)_{16-x}(\mu_3\text{-GaCp*})_x$ and the $Ru_6C(CO)_{14}(GaCp^*)_3$ clusters, too. This phenomenon provides support to describe the InCp* complex as σ-donor and π-acceptor ligand toward transition metals.[13] However, InCp* is a weaker σ-donor than GaCp*, which is reflected in the lower stability of the $Rh_6(CO)_{16-x}(\mu_3\text{-InCp*})_x$ substituted cluster derivatives relative to $Rh_6(CO)_{16-x}(\mu_3\text{-GaCp*})_x$. Quantum chemical calculations on Pt–GaCp* and Pt–InCp* complexes hint to an analogous interpretation.[8]

The bonding of the face-bridging carbonyl ligands in **1** shows distortion from the highly symmetric coordination mode found in the parent $Rh_6(CO)_{16}$ cluster. This was observed earlier in $Rh_6(CO)_{15}(PR_3)$ compounds.[12] The structural effect of InCp* substitution in this case consists in a shift of all three bridging CO ligands from the idealized position over the centre of the rhodium triangles toward the Rh atoms bonded to In. Thus, one can observe a major contraction of the Rh–$\mu_3$-C bonds on the In–Rh–$\mu_3$-C line and light elongation of the Rh–$\mu_3$-C distances on the $\mu_3$-C–Rh–$\mu_3$-C line, with the average value of the six bond lengths being 2.197(17) Å. That is a little bit longer than the average of 2.186 Å in $Rh_6(CO)_{16}$ (see Table 1).

The structure of **1** as determined in the solid state is evidently maintained in solution. The $^1$H NMR spectrum of **1** displays a singlet signal at $\delta$ = 2.31 ppm, which is typical for symmetrical coordination of the Cp* moiety. This resonance is low-field shifted relative to the corresponding signals of terminally bonded InCp* fragments. This deshielding is typical for the bridging InCp* coordination.[6–11]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The IR spectrum (in $CH_2Cl_2$) of **1** shows peaks in the carbonyl region at 2092 (w), 2075 (sh), 2055 (s) and 2012 (sh) $cm^{-1}$, which correspond to the terminal CO groups, and the middle broad peaks at 1789 and 1778 $cm^{-1}$, which correspond to the bridging carbonyl ligands. The relative positions and intensities of the peaks in the IR spectrum of **1** agree with the spectroscopic results obtained for the $Rh_6(CO)_{15}(\mu_3$-GaCp*) cluster.[3]

We have not yet obtained crystals of **2** that are suitable for X-ray analysis, but its structure was characterized on the basis of spectroscopic data. The FD mass spectrum of **2** displays the signal of the $Rh_6(CO)_{14}(InCp^*)_2$ molecular ion. The observed isotopic distribution pattern fits completely to the calculated one.

The IR spectrum of **2** in the CO region ($CH_2Cl_2$ solution) consists of peaks at 2083 (m), 2049 (s), 2029 (m) and 2010 (w) $cm^{-1}$, which correspond to the terminal CO groups, and the middle broad peak at 1777 $cm^{-1}$, which correspond to the bridging carbonyl ligands. The relative positions and intensities of the signals in the IR spectrum of **2** agree with the spectroscopic results obtained for the $Rh_6(CO)_{14}(\mu_3$-GaCp*)$_2$ cluster, which consists of peaks at 2088 (m), 2052 (s), 2032 (m), 2008 (w) and 1774 (m br.) $cm^{-1}$ ($CHCl_3$ solution). This corroborates that these two cluster compounds comprise identical CO environments. A room temperature $^1H$ NMR spectrum of **2** shows only one signal, a singlet for the methyl groups at $\delta = 2.29$ ppm. This is 0.02 ppm shifted upfield relative to the spectrum of **1**; likewise, this was found for the pair of $Rh_6(CO)_{16-x}$-$(GaCp^*)_x$, $x$ = 1–2 clusters. These spectroscopic data clearly point to substitution of two bridging CO groups in the $Rh_6(CO)_{16}$ cluster environment. Thus, the structure of **2** can be described as a $Rh_6$ octahedron surrounded by 2 face-bridging InCp* fragments, 2 face-bridging CO ligands and 12 terminal carbonyl groups.

## Conclusions

InCp*, similar to GaCp*, is capable of occupying the $\mu_3$-bridging positions of a transition metal core in carbonyl clusters. This results in the formation of cluster compounds with direct bonds between the transition metal and the In atom. The results described above will be used to create mixed-metal cluster compounds with direct bonds between transition and group 13 metals.

## Experimental Section

**General Comments:** All operations were carried out under an atmosphere of dry argon with the use of standard Schlenk techniques. All solvents were distilled under an inert atmosphere over appropriate drying agents prior to use. The starting $Rh_6(CO)_{15}(NCMe)$[14] cluster and the InCp*[15] complex were synthesized according to literature procedures. The purity control of InCp* was carried out by $^1H$ NMR spectroscopy. Infrared spectra were recorded with a Perkin–Elmer 16PC FTIR spectrometer. $^1H$ NMR spectra were measured with a Bruker ARX200 instrument. The chemical shifts were referenced to residual solvent resonances. Microanalysis was carried out in the Microanalytical Laboratory, University of Heidelberg. FAB and FD mass spectra were obtained with a JEOL JMS-700 instrument, Institute of Organic Chemistry, University of Heidelberg.

**Synthesis of 1 and 2:** The chromatographically pure $Rh_6(CO)_{15}$-(NCMe) cluster (68 mg, 0.063 mmol) was dissolved in dry toluene (20 mL), and solid InCp* (30 mg, 0.120 mmol) was added under high stirring. The reaction mixture was kept at room temp. under an atmosphere of argon overnight, wrapped in aluminium foil for light protection. The solvent was then removed in vacuo leaving some brown material. The residue was washed with *n*-hexane (5 mL) and dried in vacuo again. The reaction mixture was extracted with $CH_2Cl_2$ (2 × 5 mL) to yield a red–brown solution with a brown oily precipitate. The solution was diluted with *n*-hexane (5 mL) and filtered through a glass filter giving a dark maroon transparent solution. The solvents were removed in vacuo leaving a dry crystalline material. It was extracted with pentane (2 × 10 mL) by using an ultrasonic bath (2 min) and then passed through a cellulose column (3 × 2 cm) to give a transparent red–brown solution. Removal of the solvent gave brown crystals of $Rh_6(CO)_{15}(InCp^*)$ (**1**); 19 mg were isolated. The residue of the pentane extraction was dissolved in $CH_2Cl_2$ (3 mL), diluted with pentane (5 mL) and passed through a cellulose column giving a transparent brown solution. Removal of the solvents gave a brown crystalline precipitate of $Rh_6(CO)_{14}(InCp^*)_2$ (**2**), 23 mg.

**1:** $^1H$ NMR (200 MHz, $CDCl_3$, ambient temperature): $\delta = 2.31$ (s, $CH_3$). IR ($CH_2Cl_2$, $\nu_{CO}$): $\tilde{\nu} = 2092$ (10), 2075 (sh), 2055 (100), 2012 (sh), 1789 (19), 1778 (21) $cm^{-1}$. IR (n-hexane, $\nu_{CO}$): $\tilde{\nu} = 2098$ (16), 2075 (33), 2064 (100), 2045 (45), 2029 (7), 2010 (6), 1820 (18), 1804 (43) $cm^{-1}$. MS (FD+): $m/z$ = 1092 $[M - 7CO]^+$ $C_{18}H_{15}InO_8Rh_6$. MS (FAB+): $m/z$ = 1148 $[M - 5CO]^+$ $C_{20}H_{15}In_1O_{10}Rh_6$, 1064 $[M - 8CO]^+$ $C_{17}H_{15}InO_7Rh_6$, 1008 $[M - 10CO]^+$ $C_{15}H_{15}InO_5Rh_6$, 952 $[M - 12CO]^+$ $C_{13}H_{15}InO_3Rh_6$, 924 $[M - 13CO]^+$ $C_{12}H_{15}InO_2Rh_6$. $C_{25}H_{15}InO_{15}Rh_6$ (1287.63): calcd. C 23.32, H 1.17; found C 23.82, H 1.88. Single crystals of **1** suitable for X-ray studies were grown from saturated pentane solution under an argon atmosphere at –25 °C.

**2:** $^1H$ NMR (200 MHz, $CDCl_3$, ambient temperature): $\delta = 2.29$ (s, $CH_3$). IR ($CH_2Cl_2$, $\nu_{CO}$): $\tilde{\nu} = 2083$ (17), 2049 (100), 2029 (22), 2010 (9), 1777 (12) $cm^{-1}$. MS (FD+): $m/z$ = 1509 $[M]^+$ $C_{34}H_{30}In_2O_{14}Rh_6$.

**X-ray Crystal Structure Determination:** Intensity data were collected at 100 K with a Bruker AXS Smart CCD diffractometer (Mo-$K_\alpha$ radiation, $\lambda = 0.71073$ Å) and corrected for absorption and other effects. The structure was solved by direct methods and refined by full-matrix least-squares based on $F^2$. All non-hydrogen atoms were given anisotropic displacement parameters. Hydrogen atoms were inserted in calculated positions. Calculations were performed by using the SHELXTL package.[16] $C_{29}H_{15}InO_{16}Rh_6$ (1361.8 $g\,mol^{-1}$), monoclinic, space group $P2_1/n$, $a$ = 12.146(2) Å, $b$ = 22.427(4) Å, $c$ = 14.402(2), $\beta$ = 100.081(3)°, $V$ = 3862(1) Å$^3$, $Z$ = 4, $\phi_{calcd.}$ = 2.342 $g\,cm^{-3}$, $\mu$ = 3.152 $mm^{-1}$, $F(000)$ = 2584, crystal dimensions 0.08 × 0.06 × 0.06 mm$^3$, $2\theta$ range for data collection 2–56°, absorption corrections: ellipsoidal, min/max transmission: 0.714/0.808, 39084 collected reflections, 9620 unique, 4940 observed [$I > 2\sigma(I)$], 508 parameters, GOOF 0.793, weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.0155P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$, $R_1$ = 0.044, $wR_2$ = 0.066 [$I > 2\sigma(I)$], $R_1$ = 0.114, $wR_2$ = 0.076 (all data, 0.129 for unit weights), residual electron density 1.42 e Å$^{-3}$.

CCDC-634755 contains the supplementary crystallographic data for this paper. This data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Repeated Dihydrogen Elimination from Boranes and Gallanes Stabilized by Guanidine-Type Bases: A Quantum Chemical Study Motivated by Recent Experimental Results

**Oxana Ciobanu[a] and Hans-Jörg Himmel*[a]**

**Keywords:** Hydrides / Group 13 elements / Quantum chemical calculations / Hydrogen storage

Monomeric boranes and gallanes stabilized by guanidine derivatives undergo in certain cases $H_2$ elimination reactions leading in a first step to dinuclear E(III) hydrides (E = B or Ga) and in the second step upon elimination of further $H_2$ to dinuclear compounds with the elements in the formal oxidation state +II featuring a direct E–E bond. The thermodynamics for such $H_2$ elimination reactions were calculated applying several methods and basis sets. In addition the calculations provide information about possible mechanisms. Thus the calculations suggest the first step to be an intramolecular $H_2$ elimination followed by a cycloaddition reaction. The second $H_2$ elimination, in which E–E and H–H bonds are formed at the expense of E–H bonds, is almost energy neutral, as anticipated from the small differences in electronegativity between E and H. The reaction barriers are important indicators to answer the question if $H_2$ elimination can be made reversible. Reversible $H_2$ elimination and addition would make this class of compounds in principle interesting for hydrogen storage applications, although obviously the weight percentage of stored dihydrogen is in the special systems presented herein not sufficient for mobile applications. The compounds can also be applied for dehydrocoupling and transfer hydrogenation to deliver a stoichiometric amount of $H_2$ to olefins. Finally, the possibility of elimination of a third $H_2$ leading to a dinuclear E(I) species with an E–E double bond is discussed.

## Introduction

Guanidine derivatives have been widely used as ligands in main group and transition metal complexes.[1] Part of the interest in these compounds stems from their potential applications in catalytic reactions. They either bind as neutral ligands, or after $H^+$ abstraction as negatively charged guanidinate ligands. Two binding modes have been observed for the guanidinate ligand. Thus it can act as a bisdentate chelating ligand to one metal atom or as a bridging ligand to two metal atoms. $Cl_2Al\{(N\mathit{i}Pr)_2CN(CH_3)_2\}$ is an example in which the chelating binding mode is realized.[2] By the use of the guanidinate hpp$^-$ (hppH = 1,3,4,6,7,8-hexahydro-2*H*-pyrimido[1,2-*a*]pyrimidine) the bridging mode can be realized, the dinuclear compound $[(CH_3)_2Al(hpp)]_2$ being one authenticated representative.[2] The hpp ligand has also been proven to be efficient in bringing two transition metals close to another in dinuclear complexes so that they engage in direct and sometimes multiple metal–metal bonding. Examples include the complexes $Nb_2(hpp)_4$ [3] and $M_2(hpp)_4Cl_2$ (e.g. M = Ru,[4] W, Os and Pt [5]).

Recently we have studied the reaction of $H_3Ga{\cdot}NMe_3$ with hppH[6] leading directly to the dinuclear hydride $[H_2Ga(hpp)]_2$ (see Scheme 1). While we were so far not able to grow crystals of $[H_2Ga(hpp)]_2$ with a quality high enough for X-ray diffraction measurements, we obtained a crystal structure for its derivative $[HClGa(hpp)]_2$. The adduct $H_3Ga{\cdot}$hppH, which is likely to be the first intermediate in this reaction, is unstable under the applied reaction conditions, readily eliminates dihydrogen and dimerises. Our experiments show that $[H_2Ga(hpp)]_2$ is also stable only below room temperature and easily loses another molecule of $H_2$ at slightly elevated temperatures to give presumably the compound $[HGa(hpp)]_2$, featuring a Ga–Ga single bond and a *cis*-bent arrangement of the H–Ga–Ga–H fragment (see Scheme 2). The two Ga atoms are thus reduced from the formal oxidation state +III to the formal oxidation state +II. Thermodynamic considerations suggest that the combined Ga–Ga and Ga–H bonds established in the product are almost similar in strength than the combined Ga–H bonds of the reactant, in line with the small difference in electronegativity between Ga and H (1.82 and 2.20 on the Allred–Rochow scale, respectively). This dihydrogen elimination and Ga–Ga bond formation has stirred our interest because we previously have studied in matrix isolation experiments the uptake of dihydrogen by the matrix isolated $Ga_2$ dimer leading to Ga–Ga bond breakage and formation of the hydride $Ga(\mu\text{-}H)_2Ga$ (see Scheme 3).[7] The barrier for this reaction, as estimated experimentally from isotopic (H/D) measurements, amounts to not more than

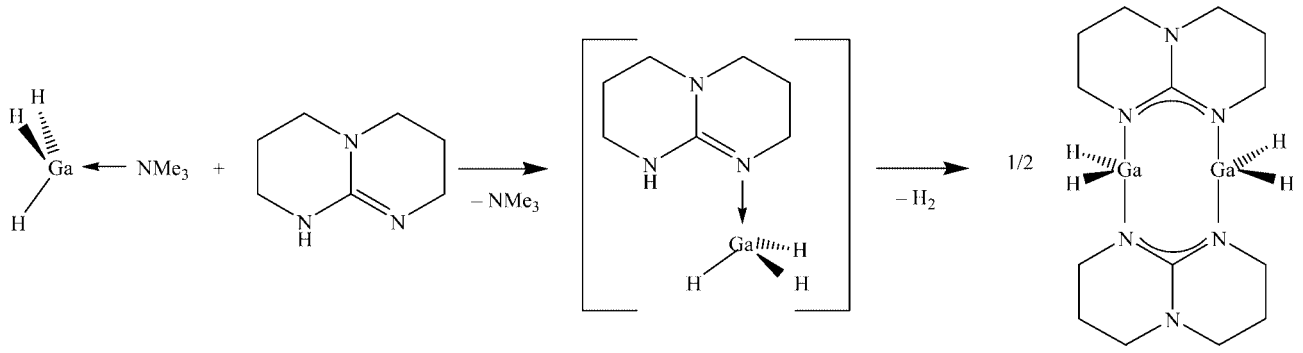

Scheme 1.

40 kJ mol$^{-1}$. The reaction of $Ga_2$ with $H_2$ to give $Ga_2H_2$ was calculated to be exothermic (–96 kJ mol$^{-1}$).[8] Thus, here again, like in the case of $[H_2Ga(hpp)]_2$, the combined Ga–Ga and H–H bonds, being now present in the reactants, are only slightly disfavoured over the two Ga–H–Ga three-center-two-electron bonds established in the product. If the barrier for $H_2$ addition in $[HGa(hpp)]_2$ is comparable with that found for the $Ga_2$ dimer, this class of dinuclear hydrides of group 13 elements is interesting for facile reversible $H_2$ activation. The compounds can certainly be applied for dehydrocoupling reactions and function as a transfer hydrogenation to deliver a stoichiometric amount of $H_2$ to olefins as was recently shown for $H_3B{\cdot}NHMe_2$.[9] Therefore it is highly desirable to get insight into the reaction mechanisms with the aid of quantum chemical calculations. In the following we report our work for B and Ga compounds.

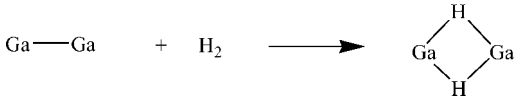


Scheme 3.

## Results and Discussion

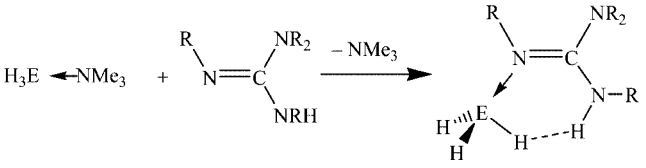
The presentation of the results and their discussion are divided into four sections. The first is concerned with the starting reagent, the adducts of guanidine and some of its derivatives to $EH_3$ (E = B or Ga), and the thermodynamics of their formation. In the second section intramolecular $H_2$ elimination facilitated by intramolecular H···H contacts in the adducts and subsequent dimerization to give dinuclear species is analysed. We will present a detailed mechanism for this important second step on the basis of our quantum chemical calculations. The third section deals with additional $H_2$ elimination to give the dinuclear group 13 element compounds featuring four-coordinate group 13 elements in the formal oxidation state +II and a direct E–E bond. Finally, the fourth section briefly discusses the possibility of further $H_2$ eliminination leading to a compound featuring two directly connected tri-coordinated E atoms in the formal oxidation state +I. Table 1 includes the reaction energies, with and without ZPE (zero-point vibrational energy) corrections, and the changes in the standard Gibbs energy, $\Delta G^0$, for salient reactions discussed herein.

### Step 1. Formation and Structural Characterization of the Adducts of $EH_3$ to Guanidine-Type Bases

Recent experimental work by us has shown that these adducts are either the end-products or reactive intermediates formed in the course of the reaction between $H_3E{\cdot}NMe_3$ and guanidine-type bases (see Scheme 4), depending on the possibilities for intramolecular HH bonding and subsequent $H_2$ elimination.[10] The adducts could generally also be synthesized from $LiGaH_4$ and guanidine·HCl. However, herein only the base-exchange route is discussed which is more straightforward to calculate and was used in most of the experimental work carried out in our group. Table 1 compares the changes in energy and Gibbs energy accompanied by reaction between the model compounds $H_3E{\cdot}NH_3$ (E = B, Ga) and guanidine or its derivatives 1,1,3,3-tetramethylguanidine and hppH. To test the accuracy of our calculational method, we have compared the crystallographically obtained dimensions of the adduct $H_3Ga{\cdot}N(H)C(NMe_2)_2$ [10] with those calculated (see Table 2 and Figure 1). It can be seen that the general level of agreement is pleasing. According to our calculations, the B–N distances in $H_3B{\cdot}NH_3$, $H_3B{\cdot}N(H)C(NH_2)_2$, $H_3B{\cdot}N(H)$-$C(NMe_2)_2$ and $H_3B{\cdot}$hppH measure 165.4, 158.6, 159.2, and 159.0 pm. The Ga–N distances in the corresponding Ga hydrides were calculated to be 218.0, 207.8, 209.1 and 206.8 pm, respectively. The experimentally determined Ga–N bond length for $H_3Ga{\cdot}N(H)C(NH_2)_2$ measures 198.81(19) pm. For comparison, Ga–N distances of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

206.3(4), 208.1(4), 207.9(3), and 204.24(18) pm were measured in $H_3Ga{\cdot}$quinuclidine,[11] $H_3Ga{\cdot}NMe_3$,[12] $H_3Ga{\cdot}NHMe_2$,[13] and $H_3Ga{\cdot}NH_2Me$.[14] Thus the guanidine-type bases lead to relatively short E–N bonds, in agreement to our recent experimental X-ray diffraction results for $H_3Ga{\cdot}N(H)C(NMe_2)_2$ and in line with the stronger basicity of guanidines in comparison to amines.[10] An important structural detail concerning the reactivity of adducts such as $H_3E{\cdot}N(H)C(NH_2)_2$ and $H_3E{\cdot}$hppH is the short H···H contacts established between one or two of the negatively polarised H atoms attached to E and a positively polarised H atom attached to one of the amido groups. Thus in $H_3B{\cdot}N(H)C(NH_2)_2$ and $H_3B{\cdot}$hppH, H···H separations of 175.5 and 162.5 pm are adopted. In the corresponding Ga species, the H···H separations measure 177.1 and 173.7 pm, respectively. These contacts are significantly shorter than the range of 200–240 pm normally prescribed for unconventional dihydrogen bonding of this sort.[15] For comparison, in $[H_2GaNH_2]_3$ [16] and $[H_3AlN(H)Me_2]_2$ [13] intermolecular H···H contacts of 197(2) and 192.5(1.9) pm, respectively, were measured. Particular attention was given to the intermolecular H···H contacts in crystalline $H_3B{\cdot}NH_3$, which were determined in neutron diffraction experiments to be 202 pm.[17] Work on these H···H contacts has been spurred by the search for hydrogen storage materials.[18] The contacts are the reason for the generally lower thermal stability of these compounds in the solid state in comparison to the solution. In adducts such as $H_3E{\cdot}N(H)C(NMe_2)_2$, there is no possibility for intramolecular HH bonding. The analysis of the crystal structure shows, however, that intermolecular HH contacts are established [with shortest H···H contacts of 210(5) pm].[10] Due to the absence of intramolecular H···H interactions, this experimentally verified molecule can be used as reference system to roughly estimate the strength of the H···H contacts in other adducts. As expected, formation of 1,1,3,3-tetramethylguanidine borane and gallane is slightly exothermic [energies of –19 and –18 kJ mol$^{-1}$, respectively, were calculated (see Table 1)]. Formation of $H_3E{\cdot}N(H)C(NH_2)_2$ is significantly more exothermic (reaction energies of –35 and –30 kJ mol$^{-1}$, respectively). The difference in the energy change for reactions to give the adducts of guanidine and 1,1,3,3-tetramethylguanidine should at least partially be caused by the HH bonds which can only be established in the guanidine complex. Thus, as a first estimate, the H···H contacts in $H_3B{\cdot}N(H)C(NH_2)_2$ should be ca. 12–16 kJ mol$^{-1}$ strong. For comparison, the intermolecular H···H bonds in crystalline $H_3B{\cdot}NH_3$ (with a larger bond length of 202 pm [17]) were calculated to be in average ca. 13 kJ mol$^{-1}$ strong.[19] These results demonstrate the importance of intramolecular H···H interactions in the adducts.



Scheme 4.

Table 1. Energy changes (in kJ mol$^{-1}$) without ($\Delta E$) and with ($\Delta E_{ZPE}$) zero-point vibrational energy corrections, and changes in the standard Gibbs energy $\Delta G^0$ (also in kJ mol$^{-1}$) as calculated for important reactions discussed in this work (fmr = four-membered ring).

| Reaction | $\Delta E$ | $\Delta E_{ZPE}$ | $\Delta G^0$ |

### Step 2. Intramolecular $H_2$ Elimination Followed by Dimerization to Give Dinuclear Hydrides

The relatively strong intramolecular H···H interactions in the adducts of hppH and $HNC(NH_2)_2$ to $EH_3$ argue for facile $H_2$ elimination, in full agreement to the body of experimental results accumulated for this class of compounds in our laboratory. The final products of these first $H_2$ elimination reactions are dinuclear species featuring an eight-membered ring in which all four E–N bond lengths are almost equally long (156.9–157.2 and 199.1–199.5 pm in $\{H_2E[HNC(NH_2)NH]\}_2$, 157.8 and 200.3 pm in $[H_2E(hppH)]_2$ (E = B and Ga, respectively). They have also in common an approximately tetrahedral coordination of the group 13 element atoms. E.g. in $[H_2Ga(hpp)]_2$, the H–Ga–H, N–Ga–H and N–Ga–N angles are 123.4°, 101.4°/109.5° and 111.0°, respectively. To test the accuracy of the calculations, the calculated structure for the dimer $[HClGa(hpp)]_2$ was compared to the one determined from X-ray diffraction analysis (see Table 3). From Table 3 comparing the bond lengths it can be seen that the general level of agreement is satisfying. In agreement to our experimental findings, the overall reactions were in all cases calculated to be exothermic (see Table 1). E.g. in the case of $\{H_2B[HNC(NH_2)NH]\}_2$, a reaction energy of –76 without and –113 kJ mol$^{-1}$ with ZPE corrections was calculated. $\Delta G^0$ for this reaction amounts to –113 kJ mol$^{-1}$. The experiments indicate that the barrier for this second step is not very high. What can be said about the exact mechanism for this process?

Table 3. Comparison between calculated and observed bond lengths (in pm) for $[HClGa(hpp)]_2$ (see Figure 1 for the atomic numbering).

| Bond length | Exp.[a] | BP/TZVPP | MP2/TZVPP |

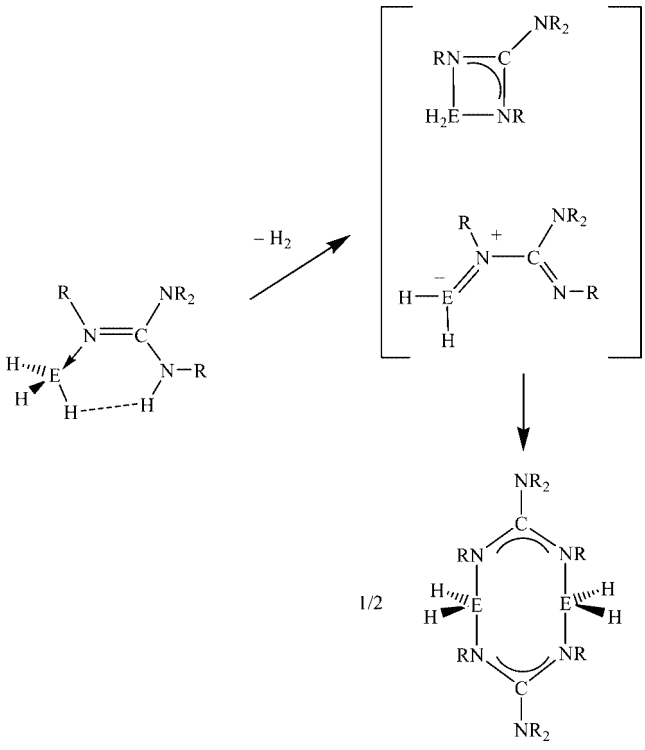
| C6–C7 | 151.2(7) | 152.6 | 153.0 |

[a] From ref.[6] Note that the molecule has a center of inversion.

At least two intermediates have to be considered (see Scheme 5).[20] The first one features a four-membered $EN_2C$ ring and can be described as a guanidinate complex to $EH_2$ in which the guanidinate unit adopts a bidentate chelating coordination mode [e.g. $H_2E(\mu\text{-}NH)_2CNH_2$ for reaction with guanidine]. These intramolecular $H_2$ eliminations represent endothermic processes (see Table 1). However, for the B compounds they are more endothermic than for the Ga homologues. Thus formation of $H_2B(\mu\text{-}NH)_2CNH_2$ is ac-



Scheme 5.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

companied by an energy change of +62 without and +34 kJ mol$^{-1}$ with ZPE corrections. However, with +8 kJ mol$^{-1}$ the $\Delta G^0$ value is very small. In the case of formation of the four-membered ring species $H_2B$(hpp), the energies without and with ZPE are +70 and +46 kJ mol$^{-1}$, and $\Delta G^0$ amounts to not more than +14 kJ mol$^{-1}$. For Ga compounds, formation of the four-membered ring compounds is even associated with a negative $\Delta G^0$ value [–5 kJ mol$^{-1}$ for $H_2Ga(\mu\text{-}NH)_2CNH_2$ and –25 kJ mol$^{-1}$ for $H_2Ga$(hpp)].

For E = B, the four-membered ring is in equilibrium with a diene structure featuring a B=N double bond, e.g. $H_2E{=}N(H)C(NH_2){=}NH$ (E = B or Ga, see reaction Scheme 5). For E = Ga, the diene represents no minimum on the potential energy surface, in line with the lower tendency of Ga to form multiple bonds. The energy of the four-membered ring structure is by not more than 1 kJ mol$^{-1}$ favored over the diene-type intermediate in the case of $H_2B{=}N(H)C(NH_2){=}NH$, and 4 kJ mol$^{-1}$ in the case of $H_2B$(hpp). Figure 2 shows the barrier separating the model diene $H_2B{=}N(H)C(NH_2){=}NH$ from the four-membered ring $H_2B(\mu\text{-}NH)_2CNH_2$. The energy barrier amounts to +56 kJ mol$^{-1}$, and the difference in Gibbs energy between diene and transition state is +57 kJ mol$^{-1}$ under standard conditions. The diene is characterized by B–H and B–N bond lengths of 119.3/120.0 and 141.0 pm; the N–C single bond and the C–N double bond measure 141.8 and 128.0 pm, respectively. The B atom is by 295.9 pm separated from the next N atom. At the transition state, the two shortest B–N distances measure 149.4 and 222.3 pm, and the B–H and B–N bond lengths were calculated to be 119.8/120.3 and 149.4 pm, respectively. With 130.7 and 137.3 pm, the two shortest C–N distances are much closer together. Finally, in the four-membered ring, B–H, B–N, and N–C bond lengths of 121.1, 161.1, and 134.0/133.5 pm are adopted.

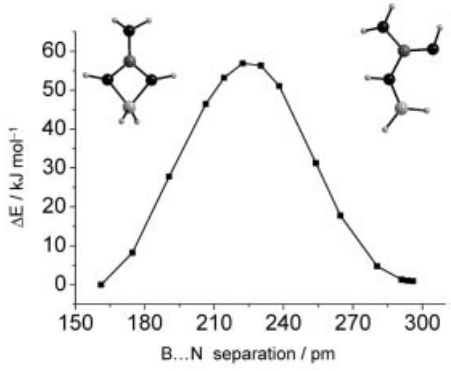


Figure 2. Energy (in kJ mol$^{-1}$) for conversion of the diene structure into the four-membered ring structure relative to that of the diene $H_2BN(H)C(NH_2)NH$ in dependence of the B···N separation.

Figure 3 illustrates the mechanism for intramolecular $H_2$ abstraction starting from the precursor $H_3B{\cdot}N(H){=}C(NH_2)_2$ and leading first to the diene structure. The transition state is reached at an H–H distance between the two eliminated H atoms of 82.0 pm. The B–N distances at this point measure 151.3 and 268.0 pm. The reaction barrier is calculated to be 97 kJ mol$^{-1}$ high. There is an abrupt change in the H–H distance after the transition state has been passed. Abrupt energy changes at the point of formation of a significant H···H interaction are typical for $H_2$ elimination reactions. We observed these abrupt changes also in the case of $H_2$ elimination from the monomeric hydrides $H_2ECl$ (E = Al, Ga or In), which can be generated in matrix isolation experiments from photolytically induced reaction between ECl and $H_2$.[21] The diene afterwards undergoes a [4+4] cycloaddition to give the dinuclear hydride.

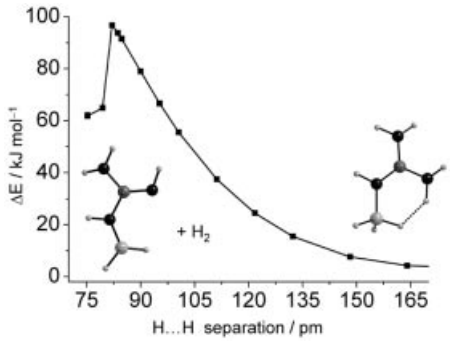

Figure 3. Relative energy (in kJ mol$^{-1}$) for intramolecular $H_2$ elimination from the adduct $H_3B{\cdot}N(H)NC(NH_2)_2$ leading to the diene structure in dependence of the H···H separation.

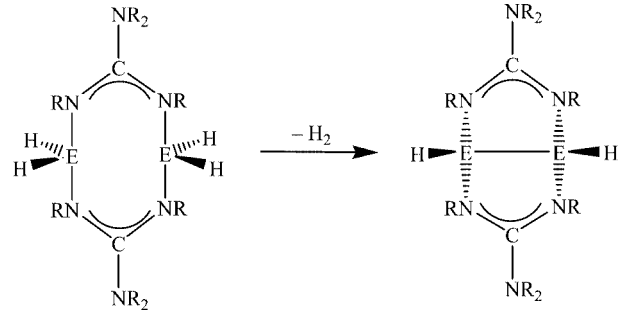
### Step 3. Further $H_2$ Elimination to Give Dinuclear Compounds with the Group 13 Elements in the Formal Oxidation State +II

The body of experimental results accumulated in our group shows that yet another $H_2$ molecule can be eliminated (see Scheme 6). The products of this $H_2$ elimination, $\{HE[HNC(NH_2)(NH)]\}_2$ and $[HE(hpp)]_2$, are dinuclear compounds with group 13 elements in the formal oxidation state +II and a direct E–E bond. The H–E–E–H fragment adopts a *cis*-bent arrangement. The E–E distances were calculated to be 178.1 (E = B) and 242.1 pm (E = Ga) in $HE[HNC(NH_2)NH]\}_2$. In $[HE(hpp)]_2$, E–E distances of 175.3 (E = B) and 237.6 pm (E = Ga) are adopted.



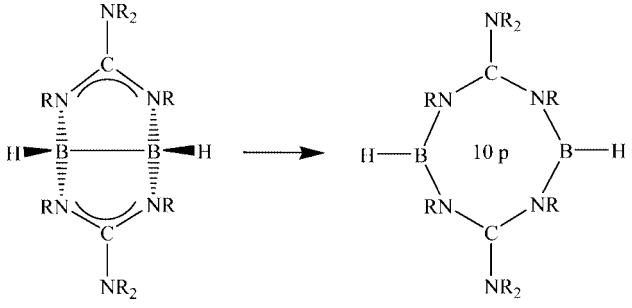
Scheme 6.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Thus the E–E distances lie in a region typical for E–E single bonds (e.g. 172 pm ($B_2F_4$),[22] 170.2 pm ($B_2Cl_2$),[23] 168.9 pm ($B_2Br_4$),[24] and 240.6 pm ($Ga_2Cl_4$·2 dioxane),[25] 252.5 pm $Ga_2(tmp)_4$ (tmp = 2,2,6,6-tetramethylpiperidino).[26] For the E–H distances the calculations returned 121.9 and 157.5 pm in the case of $\{HE[HNC(NH_2)NH]\}_2$, and 122.4–122.8 and 158.0 pm for $[HE(hpp)]_2$. Finally, the E–N distances are 158.0–158.2 (E = B) and 202.7 pm (E = Ga) for $\{HE[HNC(NH_2)NH]\}_2$, and 158.2–158.4 (E = B) and 203.4 pm (E = Ga) for $[HE(hpp)]_2$. Thus the E–N distances are in all cases almost identical to those established in the molecules prior to $H_2$ elimination, although there are some major structural changes.

$H_2$ elimination in all cases comes out to be endothermic, but only very weakly. The small reaction energies are in line with the small differences in electronegativity between B, Ga and H (electronegativity values of 2.01, 1.82 and 2.20, respectively, following the Allred-Rochow scale). As a consequence, $\Delta G^0$ is negative for the formation of $\{HGa[HNC(NH_2)(NH)]\}_2$ and $[HE(hpp)]_2$ (E = B or Ga). Thus for $[H_2Ga(hpp)]_2$, BP/TZVPP calculations predict $H_2$ elimination to be accompanied by an energy change of not more than +5 kJ mol$^{-1}$. With –49 kJ mol$^{-1}$, the $\Delta G^0$ value is significantly negative.

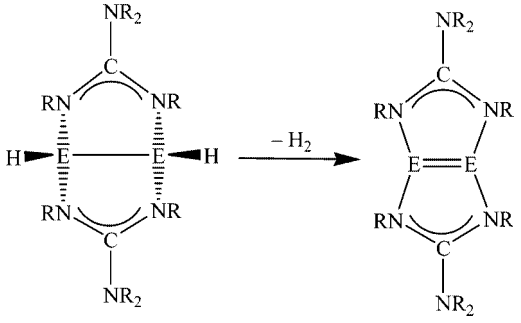
Finally, it is worth mentioning that for $\{HB[HNC(NH_2)NH]\}_2$, the calculations found another energy minimum (exhibiting $C_{2h}$ symmetry) on the potential energy surface. This minimum, with an energy exceeding that of the global minimum by almost 100 kJ mol$^{-1}$ (see Table 1), features a planar, eight-membered ring consisting of four N, two B and two C atoms (see Scheme 7). There are 10 π electrons in the ring, a situation comparable to that in the aromatic $[C_8H_8]^{2-}$ dianion. The planarity indeed argues for at least partial delocalization of the π electrons. The distances within the ring vary (from ca. 136/137 pm for the NC bonds to ca. 144 pm for the BN bonds). In ongoing work we seek to stabilize this energetically disfavoured structure by coordination to a metal fragment.



Scheme 7.

### Step 4. Final $H_2$ Elimination to Give Dinuclear E(I) Molecules

Although so far we have observed no signs of further $H_2$ elimination in our experiments, calculations were carried out for E = B to answer the question if these reactions might be possible. It has been shown previously by other groups that tetra(amino)diboranes(4) such as bis(dimethylamino)bis(pyrrolyl)diborane(4) or bis(dimethylamino)bis(indolyl)diborane(4) can be reduced with lithium powder to give the corresponding dilithium tetra(amino)diborates.[27] These diborates feature short B–B bond lengths [e.g. 158.4(4) pm for dilithium bis(dimethylamino)bis(indolyl)diborate] which can be described as double bonds.[28] The $B_2N_4$ moiety is planar, in line with the double bond description (Scheme 8). The B–B distances in $\{B[HNC(NH_2)NH]\}_2$ and $[B(hpp)]_2$ were calculated to be 159.3 and 158.7 pm, respectively and are thus also significantly shorter than those in $\{HB[HNC(NH_2)NH]\}_2$ and $[HB(hpp)]_2$ (see Figure 4). The angle sum at each of the B atoms is 343°, and the B–N distances measure 148.5 pm. With energy changes of +254 and +90 kJ mol$^{-1}$ for formation of $\{B[HNC(NH_2)NH]\}_2$ and $[B(hpp)]_2$, respectively, the reactions are endothermic, and the $\Delta G^0$ values are positive (see Table 1).



Scheme 8.

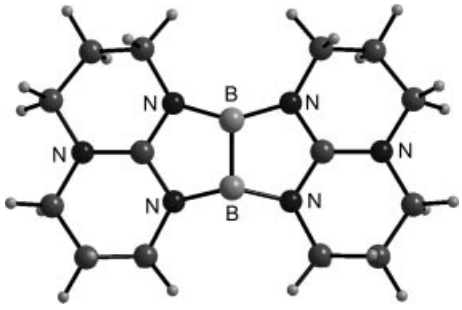


Figure 4. Molecular structure of $[B(hpp)]_2$.

## Conclusions

Quantum chemical calculations were carried out to shed light on the mechanisms of repeated $H_2$ elimination reactions of guanidine-stabilized group 13 element hydrides as recently observed in our laboratory. These repeated $H_2$ eliminations and the possibility of reversibility under mild conditions make this class of compounds attractive for applications in the fields of (i) catalysed dehydrocoupling reactions and transfer hydrogenation for olefins, and (ii) possibly also molecular hydrogen storage materials. The reactions found for this special class of compounds (hydrides

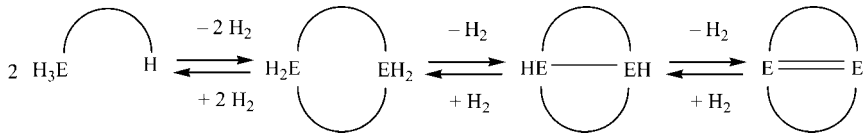

Scheme 9.

stabilized with guanidine-type bases) are examples for more general systems as illustrated in reaction Scheme 9, in the central step of which E–E and H–H bonds are formed at the expense of E–H bonds. If E has an electronegativity close to that of H, the reaction should be thermodynamically favoured. In Figure 5 the reaction sequence starting with $H_3Ga{\cdot}hppH$ is shown.[29] The standard Gibbs energy changes for almost all $H_2$ elimination steps are slightly negative. The bulk of our experimental results accumulated for this class of compounds and to some extent also the quantum chemical calculations presented herein show that the reaction barriers are relatively low ($H_2$ elimination is already observed at temperatures between 25 and 100 °C, depending on the starting adduct).

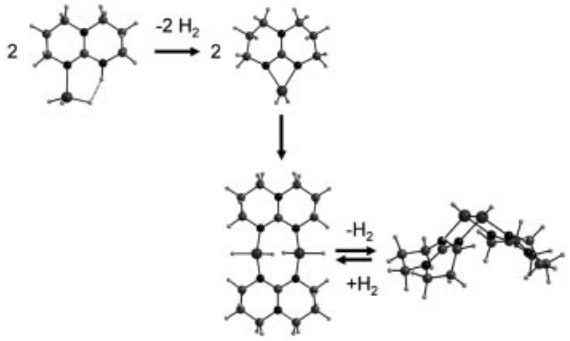

Figure 5. Repeated $H_2$ eliminations starting with the adduct $H_3Ga{\cdot}hppH$.

The calculations provide important details about each of the elimination steps. Relatively strong intramolecular H···H contacts are present in the starting compounds, adducts of the general formula $H_3E{\cdot}N(R)C(NR'R'')(NR'''H)$ (R–R''' being organic groups). These interactions facilitate elimination of a first $H_2$ molecule. Our experimental results agree with the quantum chemical calculations that the product of this $H_2$ elimination is a dinuclear hydride featuring an eight-membered ring. Two possible intermediates were discussed. In the case of boron compounds, a diene intermediate is preferred, which subsequently undergoes a [4+4] cycloaddition. The diene is in equilibrium to a second intermediate, which can be described as a $H_2E$ fragment to which a chelating guanidinate is coordinated, leading to a four-membered ENCN ring. For Ga compounds, the diene structure does not represent an energy minimum on the potential energy surface, but could nevertheless play an important role in the mechanism. The eight-membered ring compounds can eliminate another $H_2$ molecule in a redox-reaction leading to molecules with two fused five-membered rings and direct E–E bonds between E atoms in the formal oxidation state +II. This process is slightly endothermic. However, the negative sign of $\Delta G^0$ calculated for most of these reactions means that these reactions are generally spontaneous. The experimental results accumulated for this class of compounds indicate that the barrier for these $H_2$ elimination reactions is not very high so that the chances for reversibility under mild conditions are high. In a final $H_2$ elimination dinuclear B(I) species with a B–B double bond could be formed. However, $\Delta G^0$ for this process is already positive. We are currently exploring the potential applications of this class of hydrides and similar classes of compounds for dehydrocoupling reactions and hydrogen storage. They certainly can be used highly efficiently for hydrogenation of olefins in the presence of a catalyst.

## Computational Details

Quantum chemical calculations were carried out with the TURBOMOLE program package.[30] The structures and corresponding energies of all molecules were optimized using the DFT functional BP86 (BP is the short notation for Becke–Perdew and is a non-local DFT method employing the Becke exchange and Perdew correlation functionals) in combination with a TZVPP (triple-zeta valence, doubly-polarized) basis set.[31] Table 1 includes the reaction energies with and without zero point vibrational corrections (ZPE, calculated with BP86/SVP) together with the standard Gibbs energy changes, $\Delta G^0$, for all relevant reactions.

# Synthesis, Photophysical and Photochemical Properties of Poly(oxyethylene)-Substituted Phthalocyaninato Oxotitanium(IV) Complexes

**Devrim Atilla,[a] Mahmut Durmuş,[a,b] Özgür Yılmaz,[a] Ayşe Gül Gürek,[a] Vefa Ahsen,[a,c] and Tebello Nyokong*[b]**

**Keywords:** Phthalocyanine / Titanium / Quantum yields / Singlet oxygen / Fluorescence

The synthesis, photophysical and photochemical properties of tetra- and chlorotetrapoly(oxyethylene)-substituted oxotitanium(IV) phthalocyanines are reported for the first time. The new compounds were characterized by elemental analysis, IR, $^1$H and $^{13}$C NMR spectroscopy, electronic spectroscopy and mass spectra. These complexes showed monomeric behaviour in solution. General trends are described for photodegredation, singlet oxygen, triplet state and fluorescence quantum yields, and triplet and fluorescence lifetimes of these compounds in dimethyl sulfoxide (DMSO). Photophysical and photochemical properties of phthalocyanine complexes are very useful for PDT applications. The complexes showed high triplet quantum yields and triplet lifetimes in DMSO. The singlet oxygen quantum yields ($\Phi_\Delta$), which give an indication of the potential of the complexes as photosensitizers in applications where singlet oxygen is required (Type II mechanism), were 0.72 and 0.78 for **3a** and **5a**, respectively. Thus, these complexes show potential as Type II photosensitizers. These complexes were also quenched by benzoquinone for fluorescence quenching studies.

## Introduction

Recently, phthalocyanine (Pc) chemistry has undergone a renaissance because these compounds and many of their derivatives exhibit properties that are interesting for many applications in material science.[1,2] Current research on phthalocyanines (Pcs) has been rapidly expanding into several applied fields including photovoltaics, electrochromism, optical data storage, laser dyes, liquid crystals, chemical sensors and photosensitizers for photodynamic therapy.[3] Because of their properties as semiconductors as well as their large linear and nonlinear optical responses, Pcs are currently of great scientific and technological interest for designing novel electronic and photonic devices. Pcs with highly delocalized cyclic π-electron systems show intense absorptions in the red region (Q band) and these absorptions can be shifted to the near IR region by making relatively small changes in these molecules.[3,4] Fusion of additional aromatic rings (polybenzannulation) has been proposed as a practical method to enhance the conjugation of π-electrons, thus increasing the wavelength of absorbed electromagnetic radiation. However, there is a decrease in the solubility of the products obtained by increased conjugation.[5] The second way to obtain the same effect has been the addition of electron donating groups (e.g. -OR, -SR, etc.) into the periphery of Pcs.[1] The presence of substituents is an additional advantage, as they address the problem of insolubility by making the complexes soluble in most organic solvents as opposed to unsubstituted Pcs that have limited applications. Tetra-substituted Pcs are usually more soluble than the corresponding octa-substituted Pcs due to the formation of constitutional isomers and the high dipole moment that results from the unsymmetrical arrangement of the substituents at the periphery.[6–9] The other method for changing the absorption wavelength is the use of some special metals in the inner core, and $TiO^{2+}$ is one of them.[10] Unsubstituted oxotitanium phthalocyanine (OTiPc), a well-known near-IR-active photoconductive dye used as xerographic photoreceptor in copiers and laser printers,[11–13] was first synthesised by Taube.[14] Also, this material can be used in optical disc information recording. The high third order optical susceptibility values of OTiPc derivatives are well documented.[15] Specific phthalocyanines can thus be tailored such that they consist of certain properties that are required for various applications since the possibility of combining an unlimited number and type of substituents with a great number of central metals is infinite.

Thiol-derivatized metallophthalocyanine complexes show rich spectroscopic and photochemical properties. For example, they are known to absorb at longer wavelengths[16–21] than other metallo phthalocyanine complexes. To the best of our knowledge, titanium phthalocyanines

tetra-substituted with poly(oxyethylene) side chains containing S atoms have not been reported.

Photophysical properties of OTiPc are very useful in applications involving nonlinear optics and optical limiters as these titanyl macrocycles are known to have remarkable properties.[22–28] Herein we report the synthesis of new sterically hindered thia-bridged tetrapoly(oxyethylene)-substituted OTiPc phthalocyanine derivatives (Scheme 1). The influence of the presence of the thia bridges in the poly(oxyethylene) side chains on the photophysical (triplet quantum yields and lifetimes, fluorescence quantum yields and lifetimes) and photochemical (singlet oxygen and photodegradation quantum yields) properties were determined. The quenching of fluorescence by benzoquinone is also discussed.

## Results and Discussion

### Synthesis and Characterization

Treatment of substituted dinitriles **3** and **5** with Ti(OBu)$_4$, urea and DBU in *n*-pentanol led to the formation of corresponding metallo Pcs **3a** and **5a**, respectively (Scheme 1). This method is similar to that reported by Hanack and co-workers.[22] We expect that **3a** and **5a** were prepared as a statistical mixture of four regioisomers due to the various possible positions of the poly(oxyethylene) side chains relative to one another. The four possible isomers of molecular symmetry $D_{4h}$, $C_{4h}$, $C_{2v}$ and $C_s$ and a distribution of 1:1:2:4, respectively, can be obtained.[29] No attempt was made to separate the isomers of complexes **3a** and **5a**.

Thia-bridged tetra- and chlorotetrapoly(oxyethylene)-substituted phthalocyanines **3a** and **5a**, respectively, were purified in each case, by column chromatography (silica gel) and preparative thin-layer chromatography (silica gel) using a mixed solvent system of dichloromethane/methanol as eluent. The waxy products are very soluble in polar and apolar solvents, such as chloroform, benzene, diethyl ether, carbon tetrachloride, *N*,*N*-dimethylformamide, dimethyl sulfoxide (DMSO), ethanol and acetone. They could thus be thoroughly investigated by $^1$H and $^{13}$C NMR in solution. The mass spectra of the phthalocyanine compounds obtained by ESI (electrospray ionisation) showed relatively intense molecular ion peaks.

In the IR spectra characteristic vibrations corresponding to ether groups (C–O–C) at 1120–1100 cm$^{-1}$ and $CH_2$ stretches at ca. 2950–2850 cm$^{-1}$ are common for phthalocyanine compounds **3a** and **5a**. The disappearance of the dinitrile stretches at ca. 2230 cm$^{-1}$ and the presence of Ti=O stretches at ca. 960 cm$^{-1}$ confirmed the formation of MPc.

The $^1$H and $^{13}$C NMR spectra of phthalocyanine compounds **3a** and **5a** in $CDCl_3$ confirmed the proposed structure. The $^1$H NMR spectra of **3a** and **5a** have broad absorptions relative to those of the phthalonitrile derivative. It is likely that broadness is due to both chemical exchange caused by aggregation–disaggregation equilibria and the

fact that the product obtained in this reaction is a mixture of four positional isomers that are expected to show chemical shifts only slightly differing from each other. The poly(oxyethylene)-substituted phthalocyanines were found to be pure by $^1$H NMR spectroscopy with all the substituents and ring protons observed in their respective regions. Pc complexes **3a** and **5a** both showed the phthalocyanine ring protons as unresolved multiplets (most likely due to the presence of isomers), integrating for a total of 12 and 8 protons, respectively. The phthalocyanine ring protons were observed in the range 8.20–9.40 ppm for **3a** and 8.80–9.56 ppm for **5a**. Although the presence of isomers as well as phthalocyanine aggregation at the concentrations used for the NMR measurements may lead to broadening of the aromatic signals, the observed spectra of all the complexes were relatively well-resolved.

## Ground State Electronic Absorption and Fluorescence Spectra

The electronic spectra of phthalocyanine complexes **3a** and **5a** showed intense Q absorption bands around 715 nm (Figure 1). The spectra showed monomeric behaviour as evidenced by a single (narrow) Q band, typical of metallated phthalocyanine complexes for **3a** and **5a** in DMSO.[30] In DMSO, the Q bands were observed at 714 (**3a**) and 716 nm (**5a**), Tables 1 and 2. The B bands are broad due to the superimposition of the $B_1$ and $B_2$ bands in the 350 nm region. The shoulder between 400–500 nm (Figure 1) is tentatively assigned to charge transfer from the electron-rich ring to the electron-poor metal, but it may also be due to intraligand charge transfer between the sulfur groups and the phthalocyanine ring.

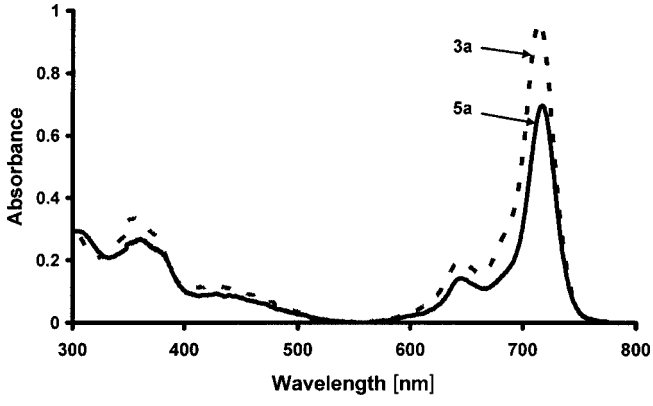

Figure 1. Absorption spectra of substituted oxotitanium phthalocyanines (OTiPc) **3a** and **5a** in DMSO. Concentration = $4\times10^{-6}$ mol dm$^{-3}$.

Aggregation is usually depicted as a coplanar association of rings progressing from monomer to dimer and higher order complexes. It is dependent on the concentration, nature of the solvent, peripheral substituents, complexed metal ions and temperature.[31,32] In the aggregated state, the electronic structure of the complexed phthalocyanine rings is perturbed resulting in alternation of the ground and excited state electronic structure.[33] In this study, the aggregation behaviour of phthalocyanine complexes **3a** and **5a** are investigated in different solvents (*n*-hexane, THF, chloroform, MeOH and DMSO), Figure 2. The complexes did not show aggregation in chloroform, THF or DMSO, whereas they showed aggregation in *n*-hexane and MeOH (Figure 2), as judged by the broadening and blueshifting of the Q band. In DMSO, the Beer–Lambert law was obeyed for all of these compounds in the concentrations ranging from $1.4\times10^{-5}$ to $4\times10^{-6}$ mol dm$^{-3}$, without any distortion of the spectra.

Table 1. UV/Vis spectroscopic data of complexes **3a** and **5a** in different solvents.

| Compound | Solvent | Q band [nm] (log $\varepsilon$) | B band [nm] | N band [nm] |
|---|---|---|---|---|
| **3a** | *n*-Hexane | 705 (4.81) | 343 | – |
| | THF | 710 (5.46) | 352 | – |
| | $CHCl_3$ | 715 (5.52) | 350 | 307 |
| | MeOH | 708 (4.96) | 344 | – |
| | DMSO | 714 (5.34) | 353 | – |
| **5a** | *n*-Hexane | 713 (4.46) | 348 | 307 |
| | THF | 716 (5.24) | 355 | 313 |
| | $CHCl_3$ | 720 (5.27) | 353 | 316 |
| | MeOH | 712 (4.70) | 349 | 314 |
| | DMSO | 716 (5.11) | 361 | 309 |

Table 2. Absorption, excitation and emission spectroscopic data for complexes **3a** and **5a** in DMSO.

| Compound | Q band $\lambda_{max}$ [nm] | log $\varepsilon$ | Excitation $\lambda_{Ex}$ [nm] | Emission $\lambda_{Em}$ [nm] | Stokes shift $\Delta_{Stokes}$ [nm] |
|---|---|---|---|---|---|
| **3a** | 714 | 5.34 | 716 | 724 | 10 |
| **5a** | 716 | 5.11 | 720 | 726 | 10 |

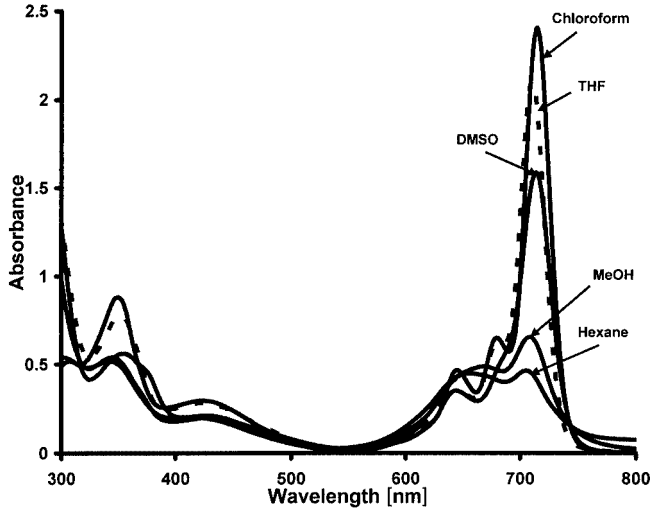

Figure 2. UV/Vis spectrum of **3a** in different solvents. Concentration = $7.20\times10^{-6}$ mol dm$^{-3}$.

Complexes **3a** and **5a** showed similar fluorescence behaviour in DMSO. Figure 3 shows the absorption, fluorescence emission and excitation spectra for complexes **3a** and **5a** in DMSO. Fluorescence emission peaks were observed at 724 nm for **3a** and 726 nm for **5a** in DMSO (Table 2). The

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

excitation spectra were similar to the absorption spectra and both were mirror images of the fluorescent spectra in DMSO (Figure 3). The proximity of the wavelength of each component of the Q band absorption to the Q band maxima of the excitation spectra for all complexes suggests that the nuclear configurations of the ground and excited states are similar and not affected by excitation in DMSO. The observed Stokes shifts (Table 2) were typical of MPc complexes in DMSO.

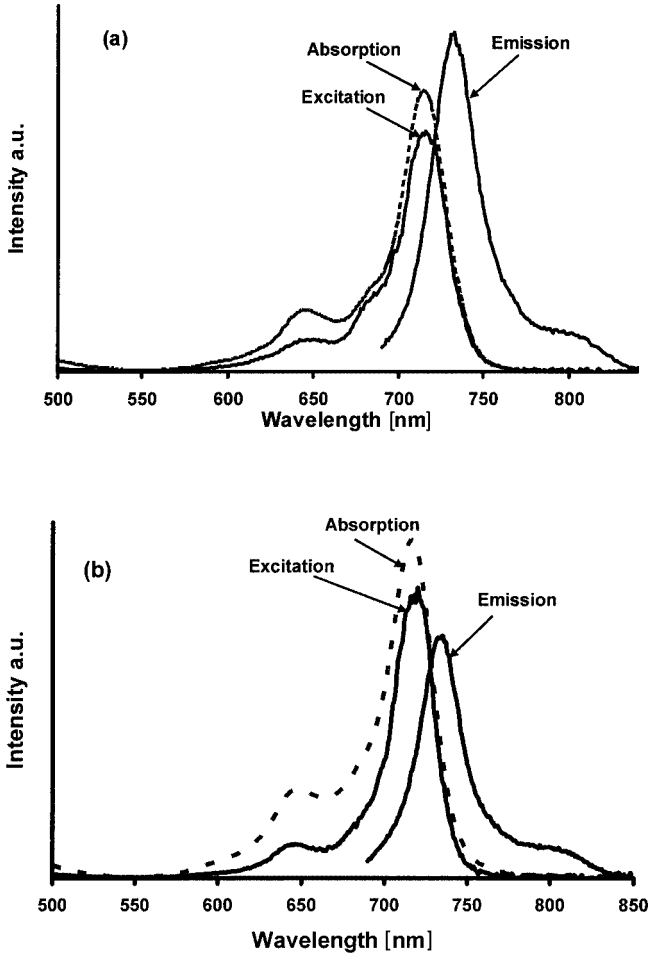

Figure 3. Absorption, excitation and emission spectra of compound **3a** (a), and **5a** (b) in DMSO. Excitation wavelength = 680 nm.

## Photophysical and Photochemical Properties

### *Fluorescence Quantum Yields and Lifetimes*

The fluorescence quantum yields ($\Phi_F$) of the complexes were similar and typical for MPc complexes, Table 3. The $\Phi_F$ value of complex **3a** was larger than that of complex **5a** in DMSO. Complex **5a** contains chlorine ligands, which would enhance intersystem crossing to the triplet state through the heavy atom effect, hence the slightly lower $\Phi_F$ value for **5a** compared to **3a**.

Table 3. Photophysical and photochemical parameters of complexes **3a** and **5a** in DMSO. Triplet absorption wavelength used = 550 nm.

| Compound | $\Phi_F$ | $\tau_T$ [μs] | $\Phi_T$ | $\Phi_{IC}$ | $\Phi_d$ [$\times 10^{-5}$] | $\Phi_\Delta$ | $S_\Delta$ |
|---|---|---|---|---|---|---|---|
| **3a** | 0.16 | 150 | 0.78 | 0.06 | 1.31 | 0.72 | 0.92 |
| **5a** | 0.10 | 220 | 0.85 | 0.05 | 3.35 | 0.78 | 0.92 |

Lifetimes of fluorescence ($\tau_F$) were calculated from the radiative lifetime using the Strickler–Berg equation and fluorescence quantum yields. Using this equation, a good correlation was[34] found for the experimentally determined fluorescence lifetimes and the theoretically determined lifetimes for the unaggregated molecules as is the case in this work. Thus we believe that the values obtained using this equation are a good measure of fluorescence lifetimes. The $\tau_F$ value for **3a** was larger than that of complex **5a** in DMSO, Table 4. The natural radiative lifetime ($\tau_0$) for **3a** was lower than that of complex **5a** in DMSO, Table 4. The rate constant value for fluorescence ($k_F$) of **3a** was larger than complex **5a** in DMSO, Table 4. The heavy atom effect due to the chlorine substituent in **5a** discussed above, will affect both the fluorescence lifetime and rate constant for this complex, hence a lower $\tau_F$ is observed for **5a** compared to **3a**. Complex **3a** showed a lower rate constant ($k_{IC}$) but showed approximately the same quantum yields for internal conversion ($\Phi_{IC}$) in DMSO when compared to complex **5a**, Tables 3 and 4. In addition, complex **3a** showed a lower rate constant for intersystem crossing ($k_{ISC}$) when compared to complex **5a** in DMSO, Table 4.

### *Triplet Lifetimes and Quantum Yields*

The transient spectrum of complex **3a** in DMSO is shown in Figure 4, and shows a maximum at 550 nm; hence the triplet lifetimes and yields were determined at this wavelength for complexes **3a** and **5a**. Figure 5 shows the triplet decay curves of the complexes (using complex **3a** in DMSO as an example). Complexes **3a** and **5a** showed typical triplet lifetimes ($\tau_T$) values for metallophthalocyanines. The triplet lifetime ($\tau_T$) value of complex **5a** was higher than complex **3a** in DMSO, Table 3. This suggests that the triplet state of complex **3a** is quenched more efficiently than that of **5a**.

Table 4. Rate constants for various excited state deactivation processes of complexes **3a** and **5a** in DMSO.

| Compound | $\tau_F$[a] [ns] | $\tau_0$[b] [ns] | $k_F$[c] [$s^{-1}$, $\times 10^8$] | $k_{ISC}$[d] [$s^{-1}$, $\times 10^8$] | $k_{IC}$[e] [$s^{-1}$, $\times 10^7$] | $k_d$[f] [$s^{-1}$, $\times 10^{-2}$] |
|---|---|---|---|---|---|---|
| **3a** | 1.39 | 8.71 | 1.15 | 5.61 | 4.31 | 8.70 |
| **5a** | 1.01 | 10.12 | 0.98 | 8.41 | 4.95 | 15.22 |

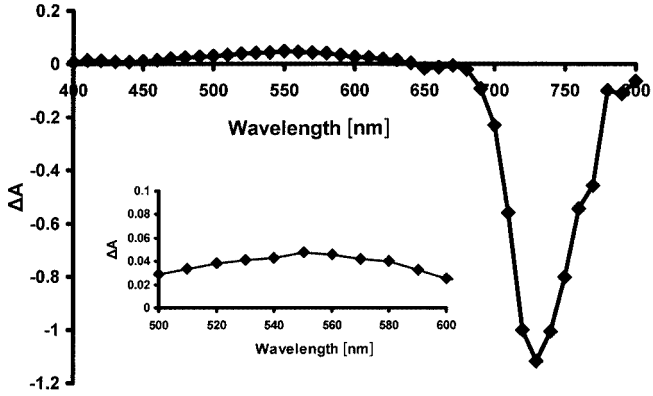

Figure 4. Transient differential spectrum of complex **3a** in DMSO. Excitation wavelength = 714 nm.

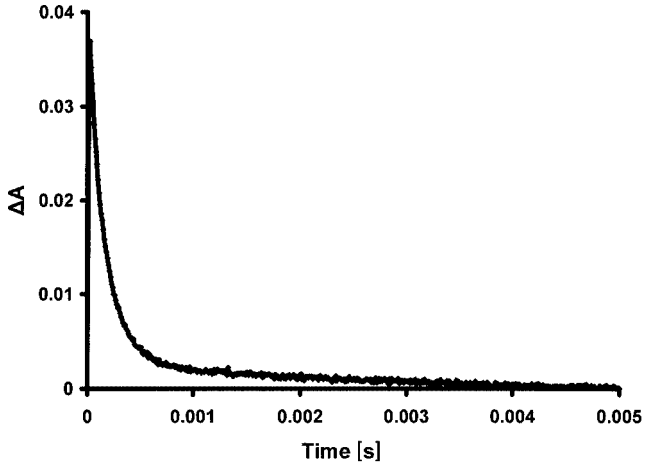

Figure 5. Triplet decay curve of **3a** in DMSO. Excitation wavelength = 714 nm.

The triplet quantum yields ($\Phi_T$) for substituted complexes **3a** and **5a** in DMSO were higher relative to typical[35] metallophthalocyanines in DMSO. For example, ZnPc standard gave $\Phi_T$ value of 0.65[36] when compared to 0.78 and 0.85 obtained in this work. Complex **5a** showed a larger $\Phi_T$ value when compared to complex **3a** in DMSO, Table 3.

### *Singlet Oxygen Quantum Yields*

Singlet oxygen quantum yields ($\Phi_\Delta$) were determined in DMSO using a chemical method [1,3-diphenylisobenzofuran (DPBF)].[37] The disappearance of DPBF was monitored using UV/Vis spectrophotometry. Many factors are responsible for the magnitude of the determined quantum yield of singlet oxygen, including triplet excited state energy, ability of substituents and solvents to quench the singlet oxygen, the triplet excited state lifetime and the efficiency of the energy transfer between the triplet excited state and the ground state of oxygen.

There was no change in the Q band intensity during the $\Phi_\Delta$ determinations, Figure 6, confirming that complexes are not degraded during singlet oxygen studies. The $\Phi_\Delta$ value of complex **3a** was lower when compared to complex **5a** in DMSO, Table 3. The magnitude of $S_\Delta$ ($= \Phi_\Delta/\Phi_T$) represents the efficiency of quenching of the triplet excited state by ground state (triplet) oxygen. Complexes **3a** and **5a** showed $S_\Delta$ of near unity (Table 3), suggesting efficient quenching of the triplet state by triplet molecular oxygen.

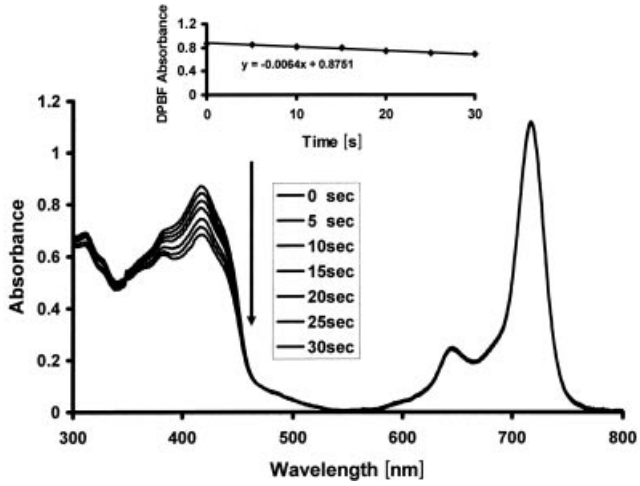

Figure 6. A typical spectrum for the determination of singlet oxygen quantum yield. This determination was for compound **5a** in DMSO at a concentration of $3 \times 10^{-5}$ mol dm$^{-3}$.

### *Photodegradation Studies*

Degradation of the molecules under irradiation can be used to study their stability and this is especially important for those molecules intended for use as photocatalysts. The collapse of the absorption spectra without any distortion of the shape confirms clean photodegradation not associated with phototransformation. The spectral changes observed for complexes **3a** and **5a** during irradiation are as shown in Figure 7 (using complex **3a** as an example in DMSO) and hence confirm that photodegradation occurred without phototransformation to new species which absorb in the Q band region. Table 3 shows that complex **3a** was more stable to degradation compared to complex **5a** in DMSO. The rate constant for photodegradation ($k_d$) of complex **3a** was also lower than that for complex **5a** in DMSO (Table 4).

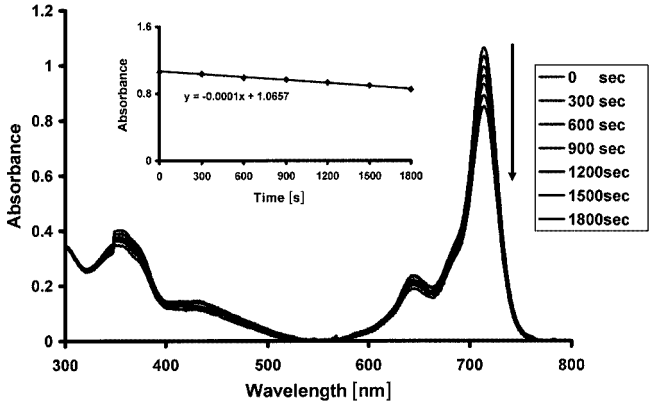

Figure 7. The photodegredation of compound **3a** in DMSO showing the disappearance of the Q band at 5 min intervals.

### Fluorescence Quenching Studies by Benzoquinone

In the presence of benzoquinone (BQ) quencher, a reaction takes place between the excited oxotitanium phthalocyanine complexes and the BQ molecules. The fluorescence quenching of oxotitanium phthalocyanine complexes **3a** and **5a** by BQ in DMSO was found to obey Stern–Volmer kinetics, which is consistent with diffusion-controlled bimolecular reactions. Figure 8 shows the quenching of complex **3a** and BQ in DMSO as an example. This figure shows the quenching behaviour of oxotitanium phthalocyanine complexes **3a** and **5a** typical of the nonaggregated complexes. The slope of the plots shown in Figure 9 gave $K_{SV}$ values. The $K_{SV}$ values for the BQ quenching of oxotitanium phthalocyanine complexes are listed in Table 5 in DMSO. The $K_{SV}$ value of complex **3a** was marginally lower than complex **5a** in DMSO. The bimolecular quenching constant ($k_q$) value of complex **3a** was also lower than complex **5a** in DMSO. Values of $k_q$ near $10^{10}$ M$^{-1}$s$^{-1}$ are in agreement with the theoretical Smoluchowski–Stokes-Einstein approximation at 298 K.[38]

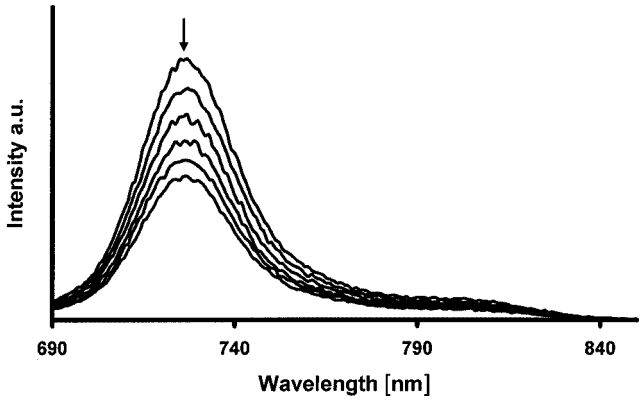

Figure 8. Fluorescence emission spectral changes of **3a** ($1.12\times10^{-5}$ mol dm$^{-3}$) on addition of different concentrations of BQ in DMSO. [BQ] = 0, 0.008, 0.016, 0.024, 0.032, 0.040 mol dm$^{-3}$. Excitation wavelength = 680 nm.

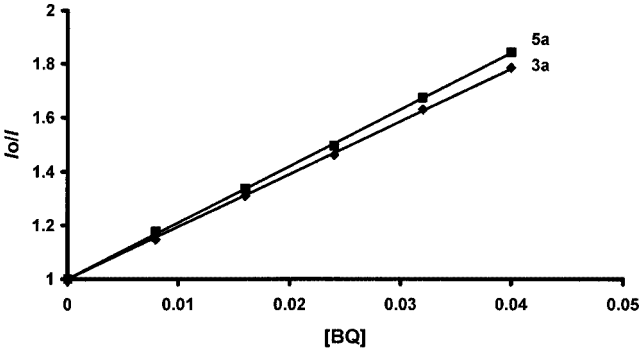

Figure 9. Stern–Volmer plots for BQ quenching of **3a** and **5a**. [MPc] ca. $1.20\times10^{-5}$ mol dm$^{-3}$ in DMSO. [BQ] = 0, 0.008, 0.016, 0.024, 0.032, 0.040 mol dm$^{-3}$. Excitation wavelength = 680 nm.

Table 5. Fluorescence quenching data for complexes **3a** and **5a** in DMSO.

| Compound | $K_{SV}$ [M$^{-1}$] | $k_q$ [dm$^3$ mol$^{-1}$ s$^{-1}$, $\times10^{10}$] |
|---|---|---|
| **3a** | 19.5 | 1.4 |
| **5a** | 21.0 | 2.0 |

## Conclusions

In the present work, the synthesis of new tetra- and chlorotetrathia(polyoxyethylene)-substituted oxotitanium phthalocyanines were described and the compounds were characterized by standard methods ($^1$H and $^{13}$C NMR spectroscopy, elemental analysis, IR and UV/Vis spectroscopy and mass spectrometry). The compounds are soluble in most solvents from *n*-hexane to methanol. In solution, the spectra showed monomeric behaviour evidenced by a single (narrow) Q band, typical of metallated phthalocyanine complexes for **3a** and **5a** in DMSO and the complexes showed charge-transfer bands around 400–500 nm as a shoulder in the UV/Vis spectra. The substituted complexes showed similar and typical fluorescence behaviour in DMSO. The complexes showed higher triplet quantum yields and triplet lifetimes in DMSO than are typical for MPc complexes. Complexes **3a** and **5a** gave high singlet oxygen quantum yields corresponding to high triplet quantum yields. The singlet oxygen quantum yields ($\Phi_\Delta$), which give an indication of the potential of the complexes as photosensitizers in applications where singlet oxygen is required (Type II mechanism), were 0.72 and 0.78 for **3a** and **5a**, respectively. Thus, these complexes show potential as Type II photosensitizers. The stability order among the substituted complexes was **3a** > **5a** in DMSO. The substituted complexes showed similar $K_{sv}$ and $k_q$ values.

## Experimental Section

**Materials:** All solvents were purified as described in Perrin and Armarego.[39] 1,3-Bis[2-(2-ethoxyethoxy)ethoxy]-2-propane-2-thiol (**1**),[40] 4-nitrophthalonitrile (**2**),[41] 4-{2-[2-(2-ethoxyethoxy)ethoxy]-1-[2-(2-ethoxyethoxy)ethoxymethyl]ethylsulfanyl phthalonitrile (**3**),[42] 1,2-dichloro-4,5-dicyanobenzene (**4**)[16] and, 4-chloro-5-{2-[2-(2-ethoxyethoxy)ethoxy]-1-[2-(2-ethoxyethoxy)ethoxymethyl]-ethylsulfanyl}phthalonitrile (**5**)[42] were prepared according to the reported procedures. Zinc phthalocyanine (ZnPc) employed as a standard was obtained from Sigma–Aldrich. All other reagents and solvents were of reagent grade quality and obtained from commercial suppliers.

**Equipment:** Elemental analyses were obtained from Carlo Erba 1106 Instrument. Infrared spectra were recorded with a Bio-Rad FTS 175C FTIR spectrophotometer. Absorption spectra in the UV/Vis region were recorded with an Shimadzu 2001 UV Pc spectrophotometer and a Varian 500 UV/Vis/NIR spectrophotometer. Fluorescence excitation and emission spectra were recorded with a Varian Eclipse spectrofluorometer using 1-cm pathlength cuvettes at room temperature. Mass spectra were recorded with a Thermo LCQ DECA XP-Max spectrometer. $^1$H and $^{13}$C NMR spectra were recorded in $CDCl_3$ solutions with a Varian 500 MHz spectrometer. Photoirradiations were performed with a General electric Quartz line lamp (300 W). A 600 nm glass cut off filter (Schott) and a water filter were used to filter off ultraviolet and infrared radia-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tions. An interference filter (Intor, 700 nm with a band width of 40 nm) was additionally placed in the light path before the sample. Light intensities were measured with a POWER MAX5100 (Molelectron detector incorporated) power meter. Triplet absorption and decay kinetics were recorded with a laser flash photolysis system, the excitation pulses were produced by a Quanta-Ray Nd: YAG laser providing 400 mJ, 90 ns pulses of laser light at 10 Hz, pumping a Lambda-Physik FL3002 dye (Pyridine 1 dye in methanol). Single pulse energy was 2 mJ. The analyzing beam source was from a Thermo Oriel xenon arc lamp, and a photomultiplier tube was used as a detector. Signals were recorded with a two-channel digital real-time oscilloscope (Tektronix TDS 360); the kinetic curves were averaged over 256 laser pulses. Solutions for these studies were degassed with nitrogen for at least 30 min before recording the spectra.

**Photophysical and Photochemical Parameters – Fluorescence Quantum Yields and Lifetimes:** Fluorescence quantum yields ($\Phi_F$) were determined by the comparative method outlined in Equation (1):[34,43]

$$\Phi_F = \Phi_F(\mathrm{Std}) \frac{F \cdot A_{\mathrm{Std}} \cdot \eta^2}{F_{\mathrm{Std}} A \cdot \eta^2_{\mathrm{Std}}} \quad (1)$$

where $F$ and $F_{\mathrm{Std}}$ are the areas under the fluorescence curves of samples **3a** or **5a** and the standard, respectively. $A$ and $A_{\mathrm{Std}}$ are the respective absorbances of the sample and standard at the excitation wavelengths (which was ca. 0.05), and $\eta$ and $\eta_{\mathrm{Std}}$ are the refractive indices of solvents used for the sample and standard, respectively. Unsubstituted ZnPc in DMSO ($\Phi_F = 0.18$)[44] was employed as the standard.

Natural radiative lifetimes ($\tau_0$) were determined using PhotochemCAD Program[45] which uses the Strickler–Berg equation.[46] From $\tau_0$ values, fluorescence lifetimes ($\tau_F$) were determined using Equation (2).

$$\Phi_F = \frac{\tau_F}{\tau_0} \quad (2)$$

**Triplet Quantum Yields and Lifetimes:** The deaerated solutions of the respective tetra-substituted oxotitanium phthalocyanine complexes **3a** and **5a** were introduced into a 1-cm pathlength spectrophotometric cell and irradiated at the Q band maxima with the laser system described above. Triplet quantum yields ($\Phi_T$) were determined by a comparative method using triplet decay,[47] Equation (3):

$$\Phi_T^{\mathrm{Sample}} = \Phi_T^{\mathrm{Std}} \frac{\Delta A_T^{\mathrm{Sample}} \cdot \varepsilon_T^{\mathrm{Std}}}{\Delta A_T^{\mathrm{Std}} \cdot \varepsilon_T^{\mathrm{Sample}}} \quad (3)$$

where $\Delta A_T^{\mathrm{Sample}}$ and $\Delta A_T^{\mathrm{Std}}$ are the changes in the triplet state absorbances of samples **3a** or **5a** and the standard, respectively. $\varepsilon_T^{\mathrm{Sample}}$ and $\varepsilon_T^{\mathrm{Std}}$, the triplet state extinction coefficients for samples **3a** and **5a**, and the standard, respectively. The standard employed was zinc phthalocyanine (ZnPc) in DMSO. The triplet quantum yield is $\Phi_T^{\mathrm{Std}} = 0.65$ for ZnPc[36] in DMSO.

Quantum yields of internal conversion ($\Phi_{IC}$) were obtained from Equation (4), which assumes that only three processes (fluorescence, intersystem crossing and internal conversion) jointly deactivate the excited singlet state of tetra-substituted oxotitanium phthalocyanine complexes.

$$\Phi_{IC} = 1 - (\Phi_F + \Phi_T) \quad (4)$$

Triplet lifetimes were determined by exponential fitting of the kinetic curves using OriginPro 7.5 software.

**Singlet Oxygen and Photodegradation Quantum Yields:** Singlet oxygen ($\Phi_\Delta$) and photodegradation ($\Phi_d$) quantum yield determinations were carried out using the experimental setup described above.[47–49] Typically, a 2 mL portion of the respective tetra-substituted oxotitanium phthalocyanine **3a** or **5a** solutions (absorbance ca. 1 at the irradiation wavelength) containing the singlet oxygen quencher was irradiated in the Q band region with the photoirradiation setup described in refs.[47–49] Values of $\Phi_\Delta$ were determined in air using the relative method with 1,3-diphenylisobenzofuran (DPBF) as singlet oxygen chemical quencher in DMSO [Equation (5)]:

$$\Phi_\Delta = \Phi_\Delta^{\mathrm{Std}} \frac{R \cdot I_{\mathrm{abs}}^{\mathrm{Std}}}{R^{\mathrm{Std}} \cdot I_{\mathrm{abs}}} \quad (5)$$

where $\Phi_\Delta^{\mathrm{Std}}$ is the singlet oxygen quantum yield for the standard ZnPc ($\Phi_\Delta^{\mathrm{Std}} = 0.67$ in DMSO,[50] $R$ and $R^{\mathrm{Std}}$ are the DPBF photobleaching rates in the presence of respective samples **3a** or **5a**, and the standard, respectively. $I_{\mathrm{abs}}$ and $I_{\mathrm{abs}}^{\mathrm{Std}}$ are the rates of light absorption by samples **3a** or **5a** and the standard, respectively. The concentrations of DPBF in the solutions were calculated using the determined values of log $\varepsilon = 4.36$ at 417 nm (DPBF in DMSO). The light intensity used for $\Phi_\Delta$ determinations was found to be $9.51 \times 10^{15}$ photons $s^{-1}$ $cm^{-2}$.

Photodegradation quantum yields were determined using Equation (6):

$$\Phi_d = \frac{(C_0 - C_t) \cdot V \cdot N_A}{I_{\mathrm{abs}} \cdot S \cdot t} \quad (6)$$

where $C_0$ and $C_t$ are the concentrations of samples **3a** or **5a** before and after irradiation, respectively, $V$ is the reaction volume, $N_A$ is Avogadro's constant, $S$ is the irradiated cell area and $t$ is the irradiation time. $I_{\mathrm{abs}}$ is the overlap integral of the radiation source light intensity and the absorption of samples **3a** or **5a**. A light intensity of $3.17 \times 10^{16}$ photons $s^{-1}$ $cm^{-2}$ was employed for $\Phi_d$ determinations.

**Fluorescence Quenching by BQ:** Fluorescence quenching experiments on oxotitanium phthalocyanine complexes **3a** and **5a** were carried out (in air, without degassing) by the addition of different concentrations of BQ to a fixed concentration of the complex, and the concentrations of BQ in the resulting mixtures were 0, 0.008, 0.016, 0.024, 0.032, 0.040 and 0.048 mol $dm^{-3}$. The fluorescence spectra of oxotitanium phthalocyanine complexes **3a** and **5a** at each BQ concentration were recorded, and the changes in fluorescence intensity related to BQ concentration by the Stern–Volmer (S–V) equation [Equation (7)]:[46]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$\frac{I_0}{I} = 1 + K_{SV}[Q] \quad (7)$$

where $I_0$ and $I$ are the fluorescence intensities of fluorophore in the absence and presence of quencher, respectively. [$Q$] is the concentration of the quencher, and $K_{SV}$ is the Stern–Volmer constant; and is the product of the bimolecular quenching constant ($k_q$) and the fluorescence lifetime $\tau_F$ [Equation (8)].

$$K_{SV} = k_q \cdot \tau_F \quad (8)$$

The ratios $\frac{I_0}{I}$ were calculated and plotted against [BQ] according to Equation (7), and $K_{SV}$ was determined from the slope.

**Synthesis**

**Tetrakis{2-[2-(2-ethoxyethoxy)ethoxy]-1-[2-(2-ethoxyethoxy)ethoxymethyl]ethylsulfanylphthalocyaninato}titanium(IV) Oxide (3a):** Under an argon atmosphere, **3** (0.326, 0.7 mmol), urea (18 mg, 0.3 mmol) and three drops of DBU (1,8-diazabicyclo[5.4.0] undec-7-ene) were mixed in *n*-pentanol (3 mL) and heated to 120 °C. At that temperature, $Ti(OBu)_4$ (0.3 mL, 3 mmol) was added, and the reaction mixture was heated at reflux for 6 h at 155 °C. After cooling to room temperature, the mixture was poured into 100 mL hexane and precipitated. The crude product was collected by centrifugation and dried in vacuo. The obtained mixture of metallated and metal-free phthalocyanine was purified by column chromatography on silica gel. Elution with $CH_2Cl_2$/methanol (50:1) gave the metal-free Pc. The main product, oxotitanium Pc, was obtained by changing the eluent to $CH_2Cl_2$/methanol (20:1). Yield: 18 mg (11%). $^1$H NMR (500 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.10 (t, $J$ = 7.1 Hz, 24 H, $CH_3$), 3.39 (m, 4 H, CH), 3.50–3.80 (m, 80 H, $CH_2$), 3.95 (m, 16 H, $CH_2$), 8.20–8.38 (br. m, 4 H, $CH_{ar}$), 8.85–9.40 (br. m, 8 H, $CH_{ar}$) ppm. $^{13}$C NMR (500 MHz, $CDCl_3$, 25 °C, decoupled): $\delta$ = 15.42 ($CH_3$), 48.75 (CH), 66.88 ($CH_2$), 70.14 ($CH_2$), 70.86–71.31 ($CH_2$), 123.27 ($CH_{ar}$), 124.32 ($CH_{ar}$), 125.28 ($CH_{ar}$), 132.94 ($C_{ar}$), 134.96 ($C_{ar}$), 137.62 ($C_{ar}$), 140.87 ($C_{ar}$), 151.43 ($C_{ar}$ *C*=N) ppm. IR (KBr pellet): $\tilde{\nu}$ = 3040, 2980–2850, 1600, 1529, 1450, 1400, 1381, 1350, 1310, 1260, 1240, 1120–1080, 959, 880 cm$^{-1}$. MS (ESI): *m/z* (%) = 1930(100) [M + 1]$^+$. $C_{92}H_{136}N_8TiO_{25}S_4$ (1929): calcd. C 57.20, H 7.10, N 5.81; found C 57.35, H 7.05, N 5.53.

**Tetrakis(2,9,16,23-{2-[2-(2-ethoxyethoxy)ethoxy]-1-[2-(2-ethoxyethoxy)ethoxymethyl]ethylsulfanyl}-3,10,17,24-chlorophthalocyaninato)titanium(IV) Oxide (5a):** Compound **5** (640 mg, 1.27 mmol), urea (36 mg, 0.6 mmol) and three drops of DBU were mixed in *n*-pentanol (5 mL) and heated at 120 °C. At that temperature, $Ti(OBu)_4$ (0.6 mL, 6 mmol) was added, and the reaction mixture was heated at reflux for 6 h at 155 °C. The *n*-pentanol was removed under reduced pressure, and the crude green product was purified by column chromatography (silica gel, $CH_2Cl_2$/methanol, 30:1) and the metallated and metal-free phthalocyanine were obtained from the crude product. Furthermore, the oxotitanium Pc was purified with preparative TLC (silica gel) using $CH_2Cl_2$/MeOH (30:1). Yield: 50 mg (9%). $^1$H NMR (500 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.15 (t, $J$ = 7.2 Hz, 24 H, $CH_3$), 3.20–3.88 (m, 84 H, CH, $CH_2$), 4.12 (m, 16 H, $CH_2$), 8.80–9.56 (br. m, 8 H, $CH_{ar}$) ppm. $^{13}$C NMR (500 MHz, $CDCl_3$, 25 °C, decoupled): $\delta$ = 15.44 ($CH_3$), 49.15 (CH), 66.82 ($CH_2$), 70.08 ($CH_2$), 70.93–71.34 ($CH_2$), 123.27 ($CH_{ar}$), 125.32 ($CH_{ar}$), 126.38 ($C_{ar}$), 134.16 ($C_{ar}$), 135.86 ($C_{ar}$), 137.17 ($C_{ar}$), 141.53 ($C_{ar}$), 151.00 ($C_{ar}$ *C*=N) ppm. IR (KBr pellet): $\tilde{\nu}$ = 3040, 2980–2850, 1600, 1450, 1410, 1380, 1340, 1280, 1240, 1120–1080, 960, 880 cm$^{-1}$. MS (ESI): *m/z* (%) = 2067 (100) [M + 1]$^+$. $C_{92}Cl_4H_{132}N_8TiO_{25}S_4$ (2066): calcd. C 53.43, H 6.43, N 5.42; found C 53.80, H 6.22, N 5.60.

# Localization and Delocalization of Spin Density in Mixed-Valence ($V^{IV}/V^{V}$) $[(V_2O_3)_2(PhPO_3)_4\subset F]^{-n}$ ($n$ = 1, 2): Theoretical and Experimental Studies

**Nguyen Huu Thong,[a] Jabor K. Jabor,[a] Reinhard Stößer,[a] Manfred Meisel,*[a] and Burkhard Ziemer[a]**

**Keywords:** Adsorption / DFT calculation / ESR / Hyperfine structure / Vanadium / Cage compounds

Based on XRD and optimized structures of the cage compound $[(V_2O_3)_2(PhPO_3)_4\subset F]^{-n}$ in singlet ($n$ = 1) and doublet ($n$ = 2) states DFT calculations were carried out to determine the energies and spin density distribution for the symmetries $D_{2d}$, $C_{2v}$ and $C_s$. It turned out, that the cage with $C_s$ symmetry not only represents the energetically more stable doublet system (with respect to $D_{2d}$ and $C_{2v}$-symmetries) but also corresponds to the real compound under study. The SOMO of the $S$ = 1/2 cage represents an antibonding state and the volume of the cage in this state is larger than that in the $S$ = 0 state. The calculated ESR hyperfine coupling constants are in acceptable agreement with those determined by ESR. Experimentally the localization/delocalization of spin density was determined via ESR as a function of temperature and adsorption of the cage on $Al_2O_3$, respectively. A proposal is given for the localization/delocalization of spin density based on thermally driven changes of the cage symmetry in combination with the hopping of the unpaired electron inside the cage.

## Introduction

Vanadium organophosphonates (VOP) represent a large group of organic-inorganic hybrid materials. They have gained increasing research interest not only due to their structural diversity and interesting redox properties but also due to potential applications in different areas, for example catalysis[1] and intercalation.[2] The anions $[(V_2O_3)_2(RPO_3)_4\subset F]^{-n}$ as mentioned in the title of the paper own cage structures and represent interesting model system for (i) spectroscopic and (ii) quantum-chemical investigations.

As a part of our research, we are interested in preparation and study of vanadium organophosphonate cages in the presence of anionic templates. In the past few years several cage structures were prepared in the presence of halide anions, e.g. $F^-$,[3–5] $Cl^-$,[6–8] and $Br^-$.[9] Up to now some questions are still not fully answered: the function of the template anion, the electronic structures including the localization/delocalization of spin density in the cages, the reversibility of the redox reactions and the potential application fields.

In principle, the one-electron reduction of the vanadium cage $[(V_2O_3)_2(RPO_3)_4\subset F]^{-1}$ (R = organic group) should result in the formation of paramagnetic species in a doublet state ($S$ = 1/2). Hardly anything is known about the extent of spin density distribution over the cage. Quantum-chemical calculation and ESR investigation at different temperature in fluid and solid matrices should provide answers to open questions. The unpaired electron in the cage structure can be localized at a single vanadium nucleus or delocalized over 2, 3 or 4 vanadium nuclei. ESR is a powerful tool to detect and monitor such kinds of paramagnetic species. A simple delocalization model will be used to elucidate the phenomena which are observed by ESR. The quantum-chemical calculations (DFT method) start with structures of forced symmetries of the cage covering $D_{2d}$, $C_{2v}$ and $C_s$ and end up with experimentally determined structures (XRD). For comparison the structurally related system $VO(acac)_2$ was investigated by both methods.

The cage compound $[(V_2O_3)_2(PhPO_3)_4\subset F]^{-n}$ in singlet and doublet states represents a suitable model not only for the study of localization/delocalization phenomena of the spin density but also for the reversibility of redox reactions.

It should be mentioned at this point, that the investigation preselected in this paper concerns chemical compounds in different states of aggregation. The quantum-chemical over the gaseous phase, the ESR over the liquid and the XRD the solid phase. But we would like to show that even in the case of the cage compounds, the cage properties will change under the influence of internal and external limiting factors. The cage itself based on its spherical structure is able to preserve most of these unique properties. Therefore, it seems to be justified to perform the investigation as outlined in this paper.

## Results and Discussion

### Calculation Method

The hybrid version of the DFT method with the B3LYP-functional[10] in connection with the basis set 6-311G* of triple zeta quality for V, O and F and with the basis set 4-21G for the organic structure of the cage has been used.[11] All the calculations have been carried out with the quantum chemical code GAUSSIAN 03.[12]

Three types of structures were calculated: (i) The *simplified structures* of forced symmetry and a replacement of the organic rests by H atoms to save computer time, (ii) the *complete structures* like the simplified structures with the real organic rests and (iii) the so-called *"X-ray" structure* using structural parameters obtained from XRD measurements.

The calculations here refer to the cage anions only; the influence of the cations will not be taken into account.

### Simplified Structures with $D_{2d}$ Symmetry

The structures of both the anions $[(V_2O_3)_2(PhPO_3)_4{\subset}F]^{-n}$ in singlet ($n$ = 1) and doublet state ($n$ = 2) have been totally optimized. As displayed in parts a and b of Figure 1 the optimized geometry of the cage in the singlet state leads to an integer network with an $F^-$ anion in the centre of the cage. In contrast, for simplification the doublet structure may be thought to be composed from several fragments: two times $V_2O_3$, four times $HPO_3$ and one $F^-$.

Remarkable is the total delocalization of the additional electron in the doublet structure. Each V atom has the same spin density of 0.39 (the sum of the spin densities is greater than 1 because of the negative spin densities at some O atoms, see Table 5). The comparison between some geometry parameters of the anion cages in the singlet and the doublet state is shown in Table 1. Going from the singlet state to the doublet state both the terminal V–O and the bridging V–O bonds are almost unchanged while the V–OP and V–F distances become larger. That means, an additional electron, delocalized in the cage, causes a larger volume of the cage. This effect can be explained by the analysis of the SOMO of the doublet structure (Figure 2). All V–OP bonds in that orbital own antibonding character, and the occupation of that orbital weakens the bonds between the V atoms in $V_2O_3$ fragments and the O atoms of the $HPO_3$ fragments with the consequence of enlarging the cage. The larger V–F distance in the doublet structure is therefore caused by the enlarging of the cage based on the antibonding character of the bond between the V atoms and the O atoms of $HPO_3$ fragments and not by a weaker bond between the V and F atoms.

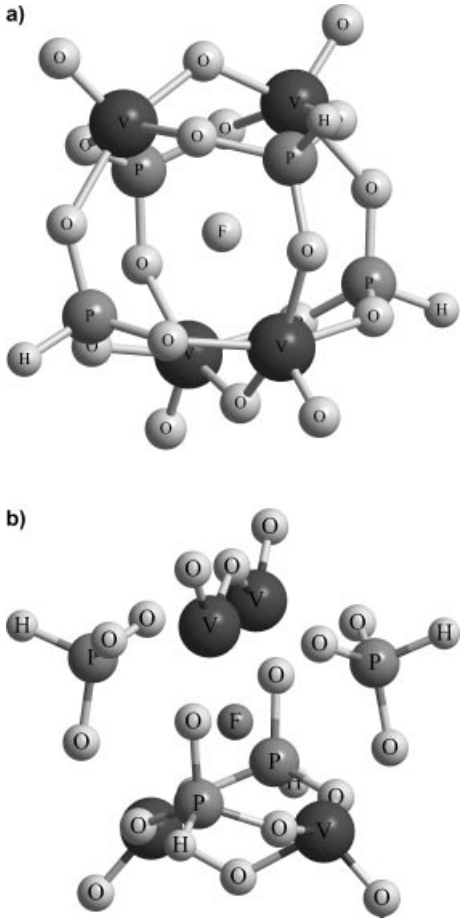

Figure 1. a) Calculated structure of the cage in the $D_{2d}$ singlet state. b) Calculated structure of the cage in the $D_{2d}$ doublet state.

Table 1. Comparison of some geometry parameters of the cage anions with $D_{2d}$ symmetry in the singlet and doublet structure.[a]

| Structural element | Distance [pm] Singlet | Doublet |
|---|---|---|
| V–O(brdg) | 179.1 | 179.0 |
| V–O(term) | 155.8 | 157.0 |
| V–O(–P on plane) | 195.1 | 197.0 |
| V–O(–P out of plane) | 194.3 | 198.0 |
| V–F | 249.0 | 250.4 |
| Energy (au) | –6599.540075 | –6599.547719 |

[a] brdg = bridging; term = terminal; on plane = the bonds on the same plane as the $V_2O_3$ fragment; out of plane = the bonds out of plane which contains the $V_2O_3$ fragment; au = atomic unit = 627.51 kcal/mol.

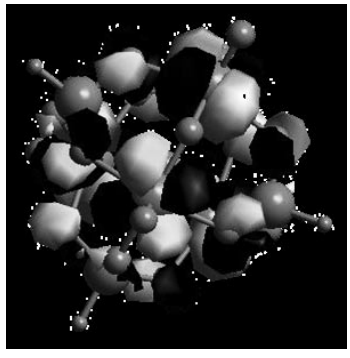

Figure 2. SOMO of the $D_{2d}$ doublet.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The delocalization of the unpaired electron in this model structure follows directly from the symmetry assumed. Under energetic aspects the doublet structure is a bit more stable than the singlet one (see Table 1).

### Simplified Structures with $C_{2v}$ Symmetry

The structures of both the anions $[(V_2O_3)_2(PhPO_3)_4\subset F]^{-n}$ in singlet ($n$ = 1) and doublet state ($n$ = 2) have been totally optimized. The optimized geometry of the cage in the singlet state leads to an integer network with an $F^-$ anion in the centre of the cage similar to the singlet structure in the $D_{2d}$ symmetry (Figure 1, a). While the doublet structure can be regarded as a composite of one $V_2O_3$ fragment, one $F^-$ anion in the centre of the cage and the residue of the cage (Figure 3). The unpaired electron is localized in the $V_2O_3$ fragment with equal spin densities of 0.7 for each of the two V atoms (see Table 5). Each V atom should have the oxidation number of 4.5 in this fragment. As in the case discussed above, the $V^{IV}$–OP and $V^{IV}$–$F^-$ distances are larger than the $V^V$–OP and $V^V$–F distances in the corresponding singlet structure (see Table 2). It should be noted that the $V^V$–F distances in the doublet structure are even smaller than $V^V$–F distances in the singlet structure of the same symmetry (241.0 compared with 247.0 pm). Assuming $C_{2v}$ symmetry, the doublet structure is more stable than the singlet one.

### Structures of $C_s$ Symmetry

#### *Simplified Structures with $C_s$ Symmetry*

The structures of both the anions $[(V_2O_3)_2(PhPO_3)_4\subset F]^{-n}$ with singlet ($n$ = 1) and doublet ($n$ = 2) states have been totally optimized. The optimized geometry of the cage in the singlet state leads to an integer network with an $F^-$ anion in the centre of the cage similar to the singlet structure in the $D_{2d}$ symmetry (Figure 1, a) while the doublet structure formal can be regarded as a composite of one $V_2O_3$ fragment, one $F^-$ anion in the centre of the cage and the residue of the cage (Figure 4). The unpaired electron appears to be localized on the $V_2O_3$ fragment which is positioned in the plane of symmetry. The consequence is, that the two V atoms are no more equivalent: two values for the spin density result: 1.07 and 0.10 (Figure 5, a). That means, the unpaired electron is more or less localized at one V atom with enlarged $V^{IV}$–F distance. The other V atom can be regarded as a "quasi $V^V$ " ion. It stands out, that the $V^{IV}$–O(brdg) and $V^{IV}$–OP distances are enlarged, but the terminal bonds $V^{IV}$–O(term) remain nearly unchanged (see Table 3). Furthermore, the distances of the $V^V$–O(brdg) in the symmetry plane is remarkable shortened (169.0 pm). The SOMO is in general of antibonding character. But there is a bonding pi-character of the bond between the $V^V$ atom and the bridging O atom in the $C_s$ plane (Figure 5, b). Under energetic aspects the doublet structure here also appears to be more stable than the singlet one.

### *The Complete and X-ray Doublet Structures with $C_s$ Symmetry*

The cages in the complete doublet structure with $C_s$ symmetry and the so-called X-ray doublet structure have been calculated. This has been done in order to find out what kind of influences can be expected by the organic rests of the cage. As the results of the calculation show, there is no essential influence of the phenyl substituents on the localization of the unpaired electron or on the geometry of the cage (column 2 and 3 of Table 4). The optimized parameters of the complete structure are in a good agreement with those of the XRD experiments. The calculated $C_s$ symmetry of the cage anion is compatible with that in the crystal (for related compounds see ref.[3]). But one has to note, that the spin localization at one V atom in the X-ray structure is not so strong as in the gaseous phase and that the V–F distances in the symmetry plane, determined by XRD, are remarkable shorter and more asymmetric than those in the complete structure calculated for the gaseous phase (Table 4). The most probable reason for this finding should be the packing effect in the solid state, which results in deformation of the cages and the fragments $V_2O_3$ and $HPO_3$ come closer together (see also the ESR spectra from solutions of the cage with $S = 1/2$).

### Comparison of the Simplified Doublet Structures Having Different Symmetries

Table 5 shows the energies, the spin densities and the Fermi contact coupling constants of the simplified doublet structures in regarded symmetries. A B3LYP calculation of $VO(acac)_2$ (acac = acetylacetonate) in $C_2$ symmetry has also been carried out for comparison (the last line of Table 5). First there is a tendency of delocalization of the additional electron in the higher symmetries. Second, the cage anion

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

seems energetically to prefer the less symmetric geometry $C_s$. Third, the Fermi contact coupling constants depend strongly of the forced symmetries. Fourth, both the spin densities and the Fermi contact coupling constants of the cage in $C_s$ symmetry and $VO(acac)_2$ in $C_2$ are very similar. This fact reflects the similar electronic structure of the VO groups and the similar {4+1} coordination of the V atoms in both.

Table 5. Comparison of the energies, the spin densities and the Fermi contact coupling constants between simplified doublet structures with different symmetries.

## The Experimental Findings of ESR Spectroscopy

As mentioned above, from theoretical and experimental point of view it was of interest to have a simple model system to compare the obtained results for the cage structure with those of the model. For structural reasons $VO(acac)_2$ was selected because this system has several advantages. It is well known for a long time, it bears a similar structural unit ($VO_5$), and in dilute solutions there is no doubt that only one $^{51}V$ centre is present in the molecular unit with $S = 1/2$.[13,14] The corresponding experimental and simulated ESR spectra are collected in Figure 6 and Figure 7, respectively. The spectra displayed in Figure 6 represent the resonances of $V^{IV}$ species in fluid (Figure 6, a and c) and frozen (Figure 6, b and d) solutions. The shape of the spectra in the fluid solution is characterized by an incomplete averaging out of the anisotropic hyperfine splitting by molecular motion (tumbling). It means, beside higher order hyperfine effects the typical dependence of the line width of the individual hyperfine-lines on the nuclear spin quantum number $m_I$ results.[15] The spectra could be reproduced by simulation taking into account the line width effects mentioned above together with third order effects of hyperfine splitting (Figure 7). Note that the different patterns of the spectra (Figure 6, a and c) are caused by the different viscosity and polarity of the solvents used and are manifested in the pa-

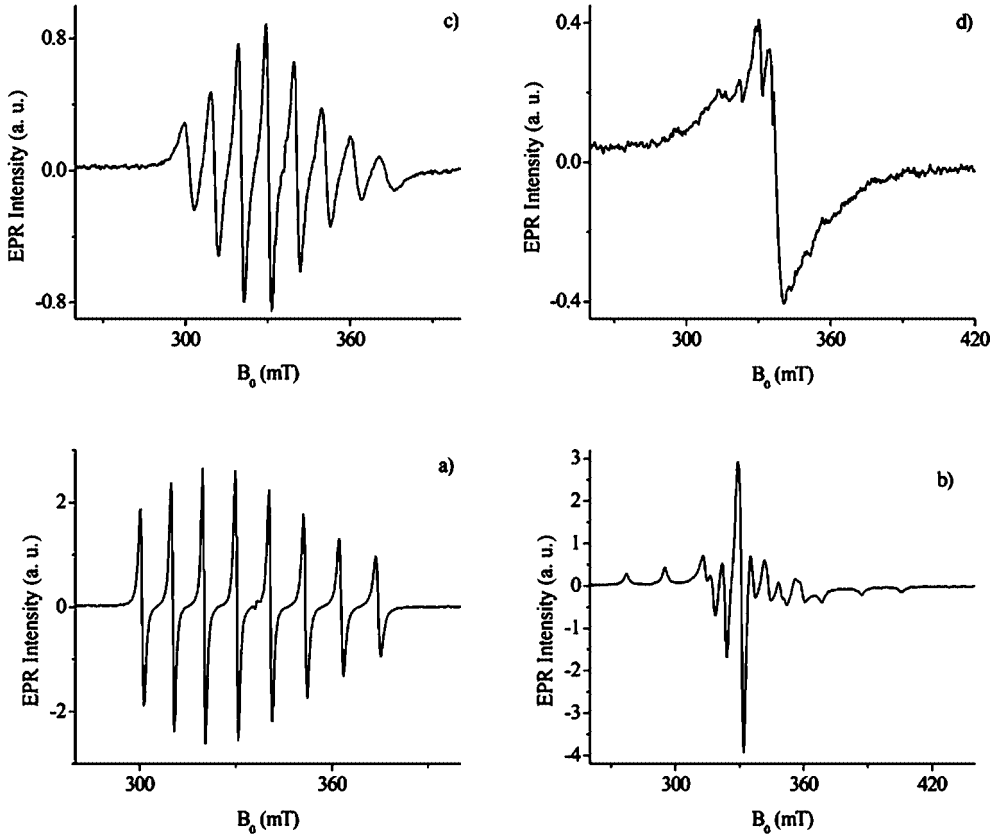

Figure 6. ESR spectra of $VO(acac)_2$, a) $CH_3CN$ solution at 293 K, b) $CH_3CN$ solution at 77 K; c) DMSO solution at 293 K; d) DMSO solution at 77 K.

rameters {$\alpha$, $\beta$, and $\gamma$} of the simulation[16] (see caption of Figure 7). The result of the quantum-mechanical calculations of this model system is already given in Table 5.

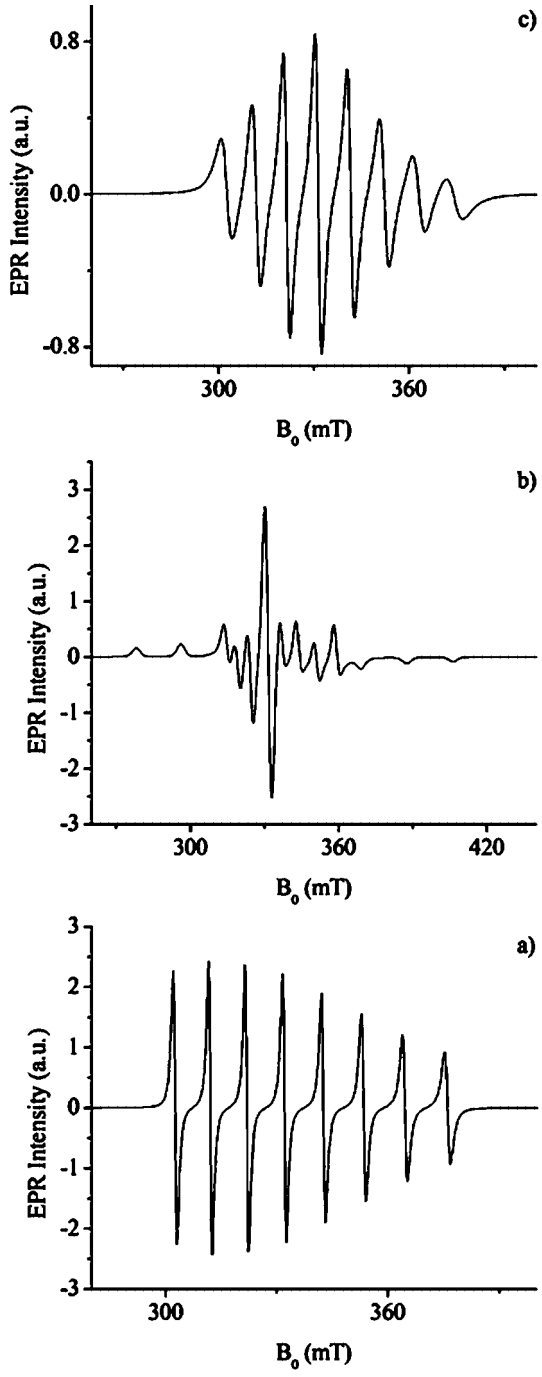

Figure 7. Simulated ESR spectra of $VO(acac)_2$, a) $CH_3CN$ solution at 293 K ($g_{iso}$ = 1.971, $A_{iso}$ = 105 G, $\alpha$ = 10.31, $\beta$ = –0.79, $\gamma$ = 0.19); b) $CH_3CN$ solution at 77 K ($g_{\|}$ = 1.956, $A_{\|}$ = 183.5 G, $g_{\perp}$ = 1.986, $A_{\perp}$ = 62.5 G); c) DMSO solution at 293 K ($g_{iso}$ = 1.969, $A_{iso}$ = 102.3 G, $\alpha$ = 21.60, $\beta$ = –2.76, $\gamma$ = 2.0).

The reduction of $[Ph_3PCH_2CH_3][(V_2O_3)_2(PhPO_3)_4 \subset F]$ with $I^-$ in $CH_3CN$ at room temperature results in the formation of paramagnetic species in a doublet state ($S$ = 1/2). The ESR spectrum of the paramagnetic species (Figure 8, a) exhibits an isotropic 29-line pattern with $g_{iso}$ = 1.964 and $A_{iso}$ = 28.6 G, due to the symmetrical interaction of the unpaired electron with 4 vanadium nuclei in the cage.[4,5,17,18] Generally, the spin density can be delocalized homogeneously, if the cage is surrounded by a symmetrical solvation shell. The consequence of that is the observation of equal values of the hyperfine coupling constant for the four vanadium nuclei ($^{51}V$, $I$ = 7/2) in the cage. A further condition for this observation is a fast reorientation of the cage ($\tau_R \approx 10$ ns) which averages out a possible residue of anisotropy of the hyperfine patterns. Under these conditions one can observe a 29 line spectrum. So, any process which will change the tumbling rate of the cage and/or make it asymmetrical should be responsible for to the change of the ESR spectra. One way to do so is to measure the ESR spectra at lower temperature. The ESR spectrum of frozen $CH_3CN$ solution (77 K) exhibits an 8 line pattern (Figure 8, b) which reflects also a large portion of anisotropic interactions. These effects are manifested in the known dependency of the intensity on the nuclear spin quantum number $m_I$.[15] It is noteworthy that the spectral change between fluid and frozen solutions is reversible.

Another way to make the cage asymmetrical is to adsorb it on the surface of e.g. alumina. The symmetry of the cage should be changed due to specific interactions between the cage and the active sites of the $Al_2O_3$ with a tendency to localize of the unpaired electron at one or two vanadium atoms assisted by the geometrical shape of the cage. The scale of these specific interactions[13,14] is of essential influence on the localization/delocalization of the spin density of the doublet state. The ESR spectrum (Figure 8, c) of $Al_2O_3$ after contact with the paramagnetic $CH_3CN$ solution shows an axial anisotropic eight-line spectrum inclusive some degree of broadening due to coupling of the unpaired electron to a single $^{51}V$ nucleus ($I$ = 7/2). The spectrum represents in its essential feature the envelope of adsorbed and aggregated cages. Broadening of the ESR signals may be attributed to the presence of a spin-spin exchange between the aggregated paramagnetic species in the solid. Lowering the temperature to 77 K yields the spectrum as displayed in Figure 8 (d).

Removing the aggregated species from the system by washing with $CH_3CN$ results in a nearly complete anisotropic 8-line spectrum (Figure 8, e) with an axial feature, $g_{\|}$ = 1.935, $A_{\|}$ = 195 G, $g_{\perp}$ = 1.986 and $A\perp$ = 72 G (compare also with the spectra displayed in Figure 6). In this case the spin density must be "fully" localized at one $^{51}V$-nucleus in the cage. Obviously, the immobilization of the cages at the surface of $Al_2O_3$ is sufficiently strong. It is evidenced by the ESR spectrum taken at 77 K (Figure 8, f) which gave no essential differences with respect to that obtained at 293 K. Furthermore these facts not only confirm the process of adsorption[13,14,19] of the cage but also the adsorption-induced localization of spin density in the cage. The solution of the cage ($S$ = 1/2) coexisting with the {adsorbence/adsorbate} yield, when separately measured at 293 K, a

## On the Localization/Delocalization of Spin Density in the Cage with $S$ = 1/2

### *Comparison Between Experiment and Theory*

The simulation[16] of the spectra obtained for the solution of $VO(acac)_2$ in $CH_3CN$ at 293 K yields the following coupling constants: $A_0$ = 105. Because the quantum-chemical calculations refer to "free" molecules, the influence of polar or nonpolar solvents on the paramagnetic species in the experiments must be taken into account. The literature offers for $VO(acac)_2$ several values for the isotropic coupling constant in the range of 100 G.[13,14] Based on these values one can estimate a solvent-depending interval of ± 5 G for the isotropic coupling constant. Keeping in mind the general difficulties of the calculation of spin densities, there is an acceptable correspondence to the calculated value of 85 G (Table 5).

Inspecting the hyperfine coupling pattern of the solution of the cage $S$ = 1/2 in $CH_3CN$ at 293 K (Figure 8, a) the value of $A_o$ = 28.6 G reflects the delocalization of the spin

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

density in the cage because this $A$ value must be lower than ca. 100 G for a localization on one $^{51}V$ centre by factor of 1/4. But it must be taken into account that there is a negative spin density at the O atoms and small ones at the P atoms. Therefore, the experimental spectrum is governed by the splitting of the $^{51}V$. Note that a splitting by the O atom is negligible because the natural abundance of the $^{17}O$ isotope is very small.

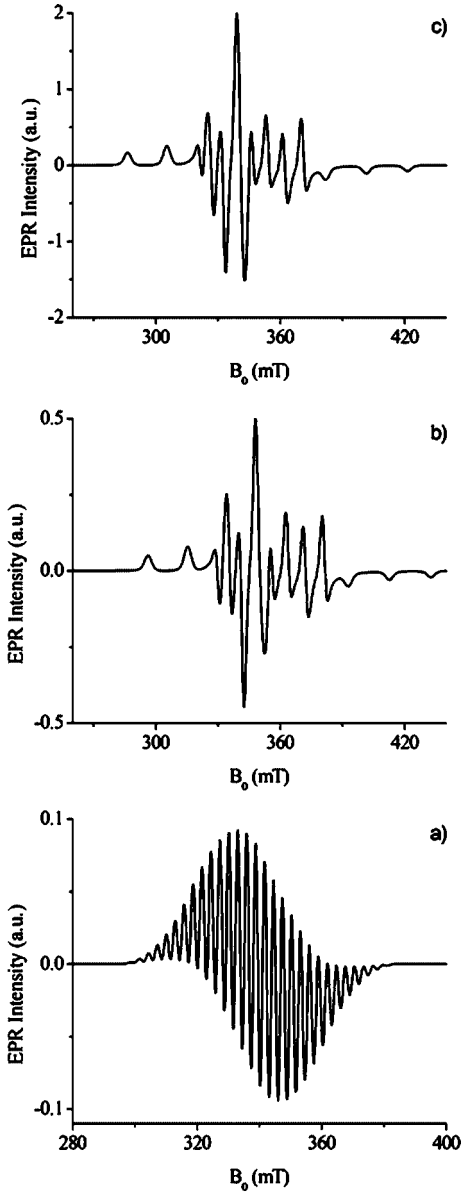

Figure 9. Simulated ESR spectra of $[(V_2O_3)_2(PhPO_3)_4\subset F]^{2-}$ a) $CH_3CN$ solution at 293 K ($g_{iso}$ = 1.964, $A_{iso}$ = 28.6 G); b) in contact with $Al_2O_3$ and washing with $CH_3CN$ at 293 K ($g_{\|}$ = 1.935, $A_{\|}$ = 195 G, $g_{\perp}$ = 1.986, $A_{\perp}$ = 72 G); c) in contact with $Al_2O_3$ and washing with $CH_3CN$ at 77 K ($g_{\|}$ = 1.934, $A_{\|}$ = 69.6 G, $g_{\perp}$ = 1.982, $A_{\perp}$ = 192.8 G).Under structural aspects ESR investigation can be performed successfully if the hyperfine structure is only less disturbed by magnetic dipole–dipole and exchange interactions. This is best realized by the use of diamagnetically diluted systems, e.g. diluted solution or diluted single complexes respectively. The latter ones bear in principle the highest content of information but there are some experimental difficulties to prepare homogeneously diluted diamagnetic solids. For the title compound it was therefore easier to make use of the advantage of the solubility of $[Ph_3PCH_2CH_3][(V_2O_3)_2(PhPO_3)_4\subset F]$ in organic solvents.

Upon cooling, the ESR spectrum became gradually broad and no coalescence temperature could be distinct even below the freezing point of $CH_3CN$ (230 K). The broad and unresolved line may due to the presence of different delocalization states i.e. 29, 21, and/or 15 lines (caused by the coupling with 4, 3 or 2 $^{51}V$ nuclei) which give the envelope of the hyperfine structure. The broad line was only found in the temperature range between the localized and fully delocalized states. However, the ESR of frozen solution (77 K) exhibits an 8 lines pattern (Figure 8, b) with a large degree of line broadening due to the anisotropy caused by the localization of the unpaired electron at one $^{51}V$ nucleus. The broad lines may indicate either that the hopping of the unpaired electron is still taking place to a small extend even at 77 K or that the electron becomes trapped on one vanadium atom with a partial spin density delocalization to other vanadium atoms in the cage (either through V–O–V and/or V–O–P–O–V). This for sure will give rise to more hyperfine lines which will contribute to the envelope. It is noteworthy that the spectral change between fluid and frozen solution is reversible which indicates that the cage compound retains its structure at these temperatures. A selection of simulated ESR spectra is given in Figure 9 together with the corresponding comments.

### *Simple Model Representation for the Delocalization of Spin Density in the Reduced Cage (S = 1/2)*

At low temperatures "packing effects" are of influence on the cage geometry and electron distribution resulting in anisotropic ESR spectra exhibiting an eight-line pattern. This implies the localization of spin density at one $^{51}V$ nucleus. The result corresponds to that of the quantum-chemical calculations forcing the cage to $C_s$ symmetry (Table 5). This configuration of the cage is represented by an energetically minimum at the potential surface which also leads to an essential localization of the spin density. The $C_s$ symmetry of the cage could be also deduced from the results of XRD. The XRD could be performed on the cage system with $S$ = 0 as well as with $S$ = 1/2. The last one bears a high concentration of unpaired electrons in the solid sample which leads to an additional effect of spin-density delocalization. The spin exchange between the cages yields a single exchange narrowed ESR line which gives no direct information about the delocalization in the individual cages of the magnetically undiluted sample.

Rising the temperature of the frozen solution of the cage in the $S$ = 1/2 state, the bond lengths and angles tend to fluctuate around temperature dependent (equilibrium) mean values. These mean values correspond to higher symmetries like $C_{2v}$ or $D_{2d}$ (see for example Table 5). In other words: driven by the thermal fluctuations these cage configurations of higher symmetry will be generated with a certain probability. The action of thermal energy induces a shift of the geometrical mean values and the bond lengths (Table 3) will be larger. It should be noted, that such states

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the cage must not represent minima at the potential surface. As a consequence of the admixture of such states at higher temperature (taking into account the actual solvent properties like dielectric constant, viscosity, polarity, etc.) a progressive delocalization of spin density appears in the cages. If the fluctuating $D_{2d}$ symmetry reaches a large statistical weight, the delocalization is nearly complete. This is possible, because the fluctuations of the cage geometry are followed directly by fluctuations of the spin density.

Based on a rather classical aspect the process of spin density delocalization can be regarded as a "hopping process" of the unpaired electron inside the cage with $S = 1/2$. By this hopping, transition states can be reached in the time average which are in formal correspondence to the states obtained by the quantum chemical calculations using $C_{2v}$ and $D_{2d}$ symmetries.

The patterns of the ESR spectra of the mixed-valence system $[(V_2O_3)_2(PhPO_3)_4 \subset F]^{2-}$ measured in solution at room temperature are governed at least by three processes:

i) The hopping of the unpaired electron between the $^{51}V$ atoms present in the cage.

ii) The tumbling rate of the cage: the cage possess no spherical symmetry (maximal $D_{2d}$) even at fast hopping rate[20] a tumbling rate of ca. $10^{10}$ $s^{-1}$ appears to be necessary to produce an isotropic and therefore optimal resolved ESR spectrum. This is approximately the case for the solution of the cage in the doublet state in acetonitrile ($\eta CH_3CN = 0.345$ mPas) (Figure 8, a) at 293 K.

iii) Fluctuation of the cage geometry likewise induced by thermal energy of the environment. But these fluctuations are limited by the template central $F^-$ ion which tends to preserve the cage geometry.

In solution of higher viscosity, e.g. DMSO ($\eta$ = 2.473 mPas), see also part c of Figure 6, spectral resolution of the ESR spectra will be achieved at higher temperature (e.g. 80 °C) where the tumbling of the cage is fast enough to resolve the 29-line spectrum [i.e. the coupling of the unpaired electron with 4 approximately equivalent $^{51}V$ nuclei ($I = 7/2$)].

At room temperature (Figure 8, a), the hopping is fast enough for the X-band ESR to detect the coupling with 4 equivalent $^{51}V$ nuclei. The rest anisotropy of the cage ($D_{2d}$ symmetry or lower) prevents at lower tumbling rates a high spectral resolution because the individual hyperfine lines are too broad with respect to the values of the hyperfine constant of 28.5 G.

Obviously, the hopping rate at low-temperatures is much slower (e.g. $\approx 10^8$ $s^{-1}$). Therefore the frozen solution of the cage exhibits at 77 K an eight line spectrum (Figure 8, b) with evidences the localization of the unpaired electron at one $^{51}V$ nuclei. The broad lines result from less effective hopping at 77 K, producing additional but small hyperfine splitting.

Rising the temperature (up to ≈ 150 K) the eight-line spectrum with the relatively broad lines is more or less preserved. Above ca. 150 K the hopping process will be more effective, contributing more and more to the delocalization of the unpaired electrons and the eight-line spectrum is transformed to the envelope of the 29 line spectrum. The envelope results, because at this temperature there is no real tumbling which could average out the rest of the anisotropic hyperfine coupling. Increasing the temperature even more, up to the fluid system at 293 K, the combined effect of fast hopping and fast tumbling makes the spectral resolution as displayed in Figure 8 (a) possible.

### The X-ray Structure

As shown in Figure 10 the structure of [Ag(1-methylimidazole)$_2$]$_2$[$(V_2O_3)_2(PhPO_3)_4 \subset F$] is constructed from the anionic cage fragment $[(V_2O_3)_2(PhPO_3)_4 \subset F]^{2-}$ which is already described in literature[3,4] and from two cationic [Ag(1-methylimidazole)$_2$] fragments. In each cationic frag-

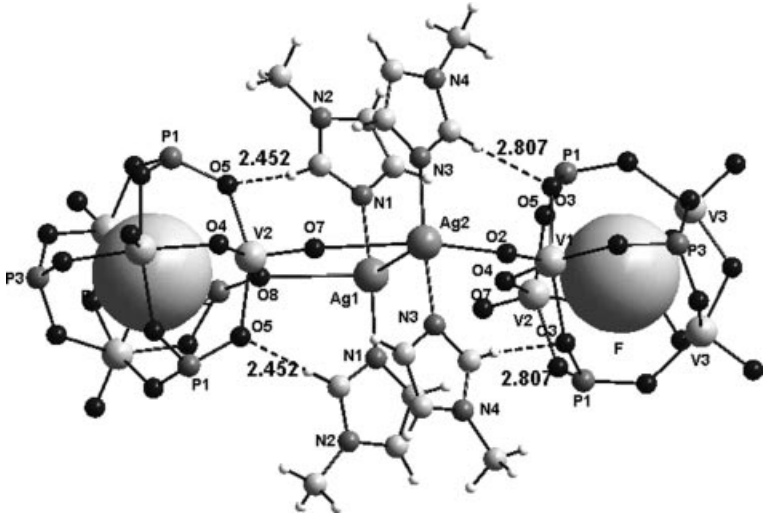

Figure 10. X-ray structure of part of 1D-chain compound [Ag(1-methylimidazole)$_2$]$_2$[$(V_2O_3)_2(PhPO_3)_4 \subset F$] showing the fluoride anion (with van der Waals radii) in the centre of the cage, hydrogen bonds between Ag(1-methylimidazole)$_2$ fragments and the O atoms of the cage and the Ag–Ag bond. Phenyl rings of the cage fragments were omitted for clarity.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ment, the Ag ion is coordinated by two nitrogen atoms of different 1-methylimidazole groups to make a nearly linear bond angles between N(1)–Ag(1)–N(1) (171.45°) and N(3)–Ag(2)–N(3) (173.04°). The Ag(1)–N(1) and Ag(2)–N(3) distances are 2.060 and 2.118 Å, respectively. The cationic parts are connected together through π-π stacking interactions between the methylimidazole moieties and through Ag(1)–Ag(2) bond (3.091 Å) which is shorter than the van der Waals contact distance (3.40 Å)[21] and slightly larger than Ag–Ag metallic bond (2.89 Å).[22]

The methylimidazole groups which are connected to the Ag(2) are laying in one plane while the 1-methylimidazole groups which are connected to the Ag(1) are lying in different planes (the angle between the methylimidazole planes is 24.046°). The cationic and anionic fragments are holding together through Ag–O bonds and through intermolecular hydrogen bonds to make 1D chain running along *x* axis. The Ag(2) ion is bonded to two cages through the vanadyl oxygen atoms, namely through the O(2) of one cage and through O(7) of another [Ag(2)–O(2) 2.659 Å, Ag(2)–O(7) 2.701 Å], which means that the cage acts as a ligand toward $Ag^+$ ions to create a 1D chain. Also, the cage is bonded to Ag(1) through O(8) [Ag(1)–O(8) 2.834 Å]. There are week intermolecular hydrogen bonds between the methylimidazole groups and oxygen atoms of the cage [H(19) with O(5) and H(23) with O(3)] and between hydrogen atom H(10) on the phosphonate phenyl group with Ag(2) [Ag(2)–H(10) 2.746 Å].

For Crystal data and structure refinement for [Ag(1-methylimidazole)$_2$]$_2$[$(V_2O_3)_2(PhPO_3)_4$⊂F] see Table 6. Selected bond lengths and angles are collected in Tables 7 and 8, respectively.

## Conclusions

For all symmetries examined in this paper it has been shown that the doublet structures are more stable than the singlet ones. The geometries of the doublet structures depend essentially on the SOMO of the additional electron. From a purely empirical point of view without referring to quantum-mechanical calculations there is no definite statement about the residence of the additional electron possible. The hybrid DFT method, at least in the B3LYP version, is able to differentiate between delocalization and localization in mixed-valence vanadium organophosphonates. It should be noted that the amount of Hartree–Fock exchange[23,24] of the DFT functional is of special influence on the values calculated for the spin density. 20% of Hartree–Fock exchange seems to be a good choice for the calculation of delocalized spin densities. Generally, it could be stated that the tendency of delocalization of spin density rises with lowering of the amount of Hartree–Fock exchange. Reduc-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing the Hartree–Fock exchange to 15% the localization of the additional electron was not realized (calculated by self-defined B3LYP functional in the frame of GAUSSIAN 03).

Comparison of the experimental and calculated hyperfine coupling constants (for doublet structure with $D_{2d}$ symmetry) shows good agreement: ca. 28.6 and 27.5 G. Obviously, the stronger tendency of delocalization of spin density yields a better agreement between the results of the theoretical calculations and the experimental ones.

Lowering of the temperature down to 77 K causes localization of spin density which is announced by the eight line ESR spectrum resulting mainly from the interaction of the unpaired electron with one $^{51}$V nucleus. At least two reasons can be quoted for this behaviour: (i) states generated in freezing process deform the cage via specific interaction and can end up in $C_s$ symmetry; (ii) assuming the process of hopping for the spin-density delocalization, a lowering of the temperature diminished the rate (or the efficiency of the hopping of the unpaired electron) and the localization of spin density is favoured.

Further support for the localization results from the comparison of the spectrum with that of $VO(acac)_2$. This molecule is anisotropic (suffering from an axial perturbation) but the symmetrical cage cannot be deformed in such a way. Furthermore, one has to assume that some electron hopping occurs even at 77 K takes place in a restricted manner. This is of influence on the actual spectral pattern characterized by line widths and intensities, but they are able to change the averaged localization of spin density to a small extent.

It can be stated that the hyperfine coupling constant for the localized spin density ($A_{iso}$ = 113 G) in the cages is in acceptable corresponds to the value calculated for the cage in $C_s$ symmetry (85.3 G). No further discrete effects of the spin density localization (e.g. splitting from two or three $^{51}$V nuclei) could be observed by ESR in the temperature range between 77 and 293 K. Therefore different probabilities should result to find the unpaired electron on 4, 3, 2, or 1 $^{51}$V atom of the cage. The superposition of these probabilities yield a broad ESR line which represent the envelope of the hyperfine patterns resulting from splitting by 4, 3, 2, and 1 $^{51}$V nucleus. Lowering of the temperature starting from 293 K to the range of ca. 200 K and below more and more increases the probability to find the unpaired electron at one $^{51}$V nucleus.

## Experimental Section

The synthesis of the cage compounds was carried out by a new route of synthesis using KF as a source of the fluoride anion.[5] All chemicals were of analytical grade.

**X-ray:** Data collection was carried out on an IPDS diffractometer (Stoe & Cie) at 180 K using graphite-monochromated Mo-$K_\alpha$ radiation and a cryostream cooler (Oxford Cryosystems). The data set was collected in steps of $\Delta\phi$ = 1.1° up to 198°. The measured intensities were corrected for background, Lorentz polarization, absorption and crystal decay effects. The structure was solved[25] and refined[26] with the SHELX 97 program.

**ESR Spectroscopy:** ESR spectra (X-band) were recorded using the spectrometer ERS 300 (ZWG/Magnettech., Berlin-Adlershof, Germany). The spectra were simulated using the programs Simfonia.[16] The temperature control unit E-257/WL-257 (Varian, USA) was applied for the variation of the temperature of the samples inside the cavity. Because of the lower limit of the temperature range was of interest ($T \geq 77$ K) which bears some difficulties with respect to the stability, a simple alternative to the gas-flow apparatus E-257 was used: a Dewar flask was filled with liquid nitrogen to cool the sample down to 77 K. Afterwards the liquid nitrogen was removed and the Dewar flask was closed. The temperature was raised with a flat exponential curve caused by the transport of the heat from the environment into the sample. The temperature was monitored using a thermocouple positioned inside the sample. In the same time, the ESR spectra were measured continually in a time interval of small temperature changes.

The following experiments were performed to transform the cage into the doublet state ($S$ = 1/2) as well as to change the spatial distribution of the spin density inclusive the possible changes of the cage geometry:

i) By reaction of the cage compound $Ph_3PCH_2CH_3[(V_2O_3)_2(PhPO_3)_4F]$ with $(n\text{Bu})_4NI$ in $CH_3CN$ one electron was transferred to the cage and the system persisted in the doublet state ($S$ = 1/2). Then ESR spectra were measured at 293 and 77 K in a capillary tube (inner diameter, 1 mm).

ii) The paramagnetic solution (i) was treated with $Al_2O_3$ (Aldrich), then the solvent was removed and the ESR spectra of the solid (adsorbents/adsorbate) were measured at 293 and 77 K.

iii) The solid part of (ii) was washed with $CH_3CN$, and then the ESR spectra were measured at 293 and 77 K of both the solid and the solution.

CCDC-640689 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

The Deutscher Akademischer Austausch Dienst (DAAD) is acknowledged for financial support of Jabor K. Jabor. Dr. W. Hermann and Dr. A. Zehl are kindly acknowledged for supporting parts of the experimental works. Furthermore we thank Th. Ritschel for supporting the calculations.

## COVER PICTURE

**The cover picture shows** the schematic structures of a 2,5-dithienylphosphole and a dithieno[3,2-*b*:2′,3′-*d*]-phosphole, as well as the fluorescence properties of materials based on the latter system. These scaffolds are two of the most promising organophosphorus-based building blocks for organic electronics to date. Extensive investigations of their structure−property relationships has laid ground for a variety of applications such as sensing or as an active component in electronic devices. Details on the syntheses, their systematic modifications, as well as the resulting (opto)-electronic properties of the materials are presented in the Microreview by M. G. Hobbs and T. Baumgartner on p. 3611ff.

Phosphane and Phosphite Unsymmetrically Disubstituted Diiron Complexes Related to the Fe-Only Hydrogenase Active Site

**Keywords:** Bioinorganic chemistry / Carbonyl displacement / Diiron complexes / Fe-only hydrogenase / P ligands

## Antitumour Agents

Platinum(II) and palladium(II) complexes with 4-(2-hydroxybenzoyl)-2-(pyridin-2-yl)-1*H*-pyrazol-3-ol ($HL^1$) have been synthesised as potential anticancer compounds. Protonation constants of the ligand and solid-state structures of the complexes are reported. The cytotoxic evaluation revealed that $Pt^{II}$ and $Pd^{II}$ complexes were active in the micromolar concentration range. Color code of ORTEP drawing: blue = N; green = Cl, red = O; yellow = Pt.

# Recent Developments in Phosphole-Containing Oligo- and Polythiophene Materials

**Matthew G. Hobbs[a] and Thomas Baumgartner*[a]**

**Keywords:** Phosphole / Thiophene / Conjugated materials / Organic electronics / Fluorescence

The introduction of phosphorus-containing moieties into π-conjugated thiophene materials has been found to provide materials with strongly optimized and highly tunable optoelectronic features compared to their native thiophene counterparts. 2,5-Diaryl- and 2,5-bis(heteroaryl)phospholes as well as fused tricyclic dithieno[3,2-*b*:2′,3′-*d*]phospholes represent two very valuable building blocks for organic electronics as their intriguing features can be altered systematically by several, in part unique, methodologies. The potential scope of these modifications has been determined by comprehensive investigations of their structure–property relationships via suitable molecular model compounds. On several occasions, these observations could successfully be transposed to corresponding polymers that are often difficult to characterize independently. The same is true for the first organic light-emitting diodes (OLEDs) based on a phosphole scaffold, whose properties could also be predicted successfully.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Organic π-conjugated polymers and oligomers have commanded a significant amount of attention as a result of the conducting (upon doping), or semiconducting properties that they exhibit.[1] Consequently, these materials have great potential for use in electronic devices such as organic or polymer-based light-emitting diodes (OLEDs/PLEDs),[2] photovoltaic cells,[3] field-effect transistors (FETs),[4] nonlinear optical (NLO) devices and polymeric sensors.[5] The development of these systems, and the optimization of their optoelectronic properties often requires the use of model systems. Well-defined model systems allow for the elucidation of important structure–property relationships through the systematic variation of the model's chemical structure, and supramolecular organization. By taking advantage of established structure–property relationships, the properties of materials may be engineered at the molecular level to suit those required by specific applications.[1]

Varying the composition of the π-conjugated backbone in such materials has proven to be a particularly "fruitful" approach to tailoring the properties of organic π-conju-

gated materials. Heterocyclopentadienes (pyrrole, furan, silole, and thiophene) have been used extensively to this end.[1] Poly- and oligothiophenes have proven to be particularly useful, and consequently form one of the most studied classes of π-conjugated polymers.[6] The ease with which thiophenes can be functionalized allows entire families of thiophene materials, displaying unique properties to be prepared. These families may be used to establish important structure-property relationships. Thiophene materials are often light emitting in the red-orange region of the visible spectrum, consistent with their ca. 2.0 eV bandgap.[6] This red emission is often difficult to obtain using other π-conjugated polymers, and implies that polythiophenes may be highly useful in LED applications. Unfortunately, the emission of polythiophenes is often quenched due to their tendency to form aggregates in the solid state, and the heavy-atom effect of sulfur. As a result, polythiophene materials display significantly lower emission efficiencies than those based on other more established π-conjugated scaffolds such as poly(fluorenes) (PFs), and poly(phenylenevinylenes) (PPVs).[6] The incorporation of other conjugated units into oligo- and polythiophenes has proven to be a reliable method to improve emission efficiency, and the performance of the light-emitting devices derived from these materials.[6]

Theoretical studies have implied that the phosphorus analog of pyrrole (phosphole) may be an excellent building block for the construction of π-conjugated materials.[7] Organophosphorus materials have received relatively little attention despite the fact that the incorporation of $\sigma^3,\lambda^3$-phosphorus centers allows for a number of facile, nearly quantitative chemical modifications to be performed. Trivalent phosphorus centers display a versatile reactivity, allowing for the preparation of entire families of materials exhibiting unique properties from a single precursor.[8] Reaction with oxidizing agents results in the formation of $\sigma^4,\lambda^5$-phosphorus centers, while the Lewis basicity of the $\sigma^3,\lambda^3$-phosphorus center allows for complexation with Lewis acids, and transition metals. The reaction of trivalent phosphorus centers with methylating agents results in the formation of a cationic $\lambda^4$-phosphorus species. Most importantly, all of these facile chemical modifications result in significant changes to the properties of the involved materials. The use of chemical modifications to tune the properties of a material is not possible in this simplicity with genuine organic systems.

The phosphole moiety **A** (Figure 1) in particular, displays a high potential for use in π-conjugated organic materials. Phosphorus centers do not readily form sp hybrids, therefore the phosphorus atom in phospholes is highly pyramidalized, and the lone pair displays a high degree of s character.[9] This prevents an efficient endocyclic interaction between the phosphorus lone pair and the phosphole's butadiene moiety. In fact, the small degree of aromaticity displayed by phospholes (an NICS value of –5.3 has been determined theoretically)[10] is actually due to a hyperconjugative overlap of the compound's butadiene system with the exocyclic P–R σ bond, and not the phosphorus lone pair.[11] This makes phosphole an ideal choice for the construction of π-conjugated materials because exocyclic delocalization along the polymer chain is favored in species exhibiting low resonance energies.[7]

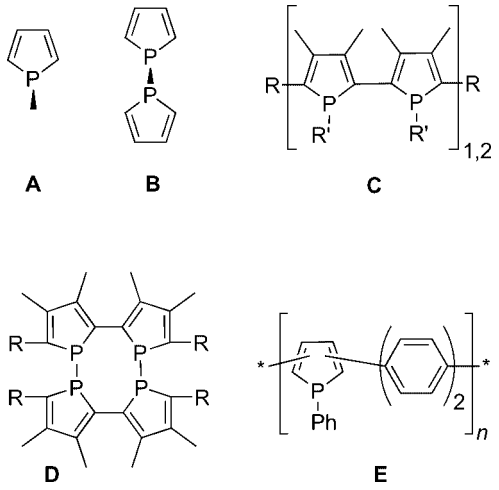

Figure 1. Phosphole-containing oligomers and polymers.

Additionally, σ–π conjugation ("through-bond" delocalization) is possible in 1,1′-biphospholes **B**, as a result of the low σ–σ* energy gap, and the high polarizability of the P–P linkage.[9] The interaction between the two phosphole π systems through the P–P σ bond in **B** may result in fascinating electronic properties that may be exploited in materials science. Although the chemistry of phospholes is well developed,[9] the incorporation of these phosphacyclopentadienes into π-conjugated materials has only been investigated quite recently. Tetrameric phosphole oligomers **C** ($n$ = 2) and **D** have been prepared from α,α′-biphospholes **C** ($n$ = 1),[12,13] however the first polymeric system to incorporate phosphole moieties **E**, was not reported until 1997 (Figure 1).[14,15] X-ray structural analyses revealed that the rings in compounds **C** were significantly twisted with respect to one another, preventing an effective overlap of the conjugated π system.[12,16]

Recently, phospholes have successfully been substituted for thiophene moieties in several well-defined oligo- and polythiophene systems. These systems display fascinating optoelectronic properties, and in some cases, unprecedented luminescence efficiencies. As a result, functional OLEDs and sensory materials have already been developed using these materials. Phosphaorganic materials have recently been comprehensively reviewed,[8] therefore the purpose of this microreview will be to provide a more detailed overview of the recent developments of the 2,5-dithienylphosphole, and the dithieno[3,2-*b*:2′,3′-*d*]phosphole systems. Related 2,5-diarylphosphole systems will also be discussed where relevant. The substitution at both the thiophene, and the phosphole moieties of these well-defined model systems may be altered, in addition to the possibility of facile chemical modifications involving the trivalent phosphorus center. Comparisons and contrasts between the properties of the obtained materials are highly dependant on the nature of the diarylphospholes or dithienophosphole based systems.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Consequently, structure-property relationships have been extensively investigated, and the properties of the systems have been tuned to suit potential applications.

## 2. 2,5-Diaryl- and 2,5-Bis(heteroaryl)phospholes

The incorporation of heteroaryl substituents at the α positions (2,5-positions) of a phosphole moiety provides materials displaying promising optoelectronic properties, as a result of exocyclic π conjugation present between the phosphole and the α-substituted aryl groups. Theoretical calculations have demonstrated this exocyclic π conjugation, by showing that the delocalization over the phosphole's 1,3-butadiene moiety increases [as determined using the Julg Index (JI)] upon introduction of heteroaryl substituents at the α positions of the phosphole ring.[17] This substitution was also shown to result in a concurrent reduction of the aromaticity (endocyclic π conjugation) of the phosphole ring (as measured by its calculated NICS values), demonstrating the fine balance between exocyclic and endocyclic delocalization in π-conjugated materials.[7] The 2,5-diarylphosphole system **1** developed by Réau and co-workers is a versatile model system for the development of π-conjugated materials (Figure 2).[18] It is possible to modify the chemical structure of **1** in a number of different manners, allowing for a full elucidation of the structure–property relationships displayed by the model system. Possible structural variations include the nature of the exocyclic phosphorus substituent, the size of the fused carbocycle present on the phosphole backbone, the aromatic groups present at the 2- and 5-positions of the phosphole moiety, and functionalization of the phosphorus center by facile chemical modifications (oxidation, complexation, methylation etc.). Structure–property relationships involving the 2,5-diarylphosphole system **1** have been established by examining the effects of these modifications on the system's interesting optoelectronic, and electrochemical properties. Where necessary, these effects have been rationalized theoretically.

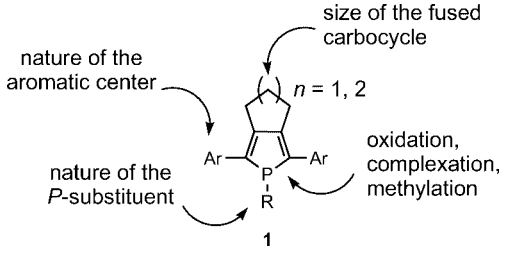

Figure 2. The π-conjugated phosphole system developed by Réau et al.

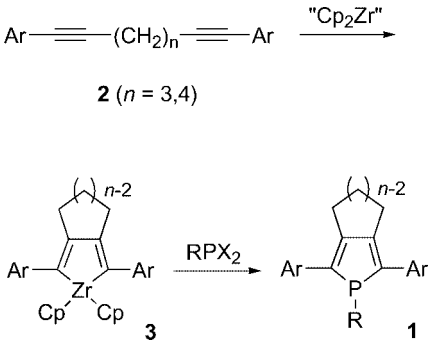
### 2.1 Modification of the π-Conjugated Framework

Compounds of type **1** are prepared using the Fagan–Nugent route,[18] a versatile method for the preparation of heteroles (Scheme 1).[19] They can be obtained by an intramolecular oxidative coupling between "zirconocene" and diynes in which the alkyne moieties are linked by a $(CH_2)_3$ or a $(CH_2)_4$ spacer. This spacer is required to promote the desired 2,5-substitution pattern.[18c] Subsequent reaction of the zirconacyclopentadienes **3** with dihalophosphanes produces the desired 2,5-diarylphospholes **1** in nearly quantitative yields. The use of different dihalophosphanes in the synthesis described above allows for the introduction of different substituents at the phosphorus center of 2,5-diarylphospholes **1**.[9] As a result of their stability in air, and their more favorable optoelectronic properties, *P*-phenyl-substituted phospholes dominate this family of 2,5-diarylphospholes, and the subsequent discussion of derivatives of **1** will focus on *P*-phenyl-substituted phospholes.

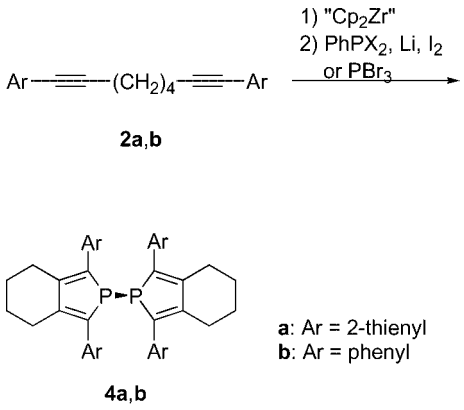


Scheme 1. Synthesis of 2,5-diaryl- and 2,5-diheteroarylphospholes.

The interaction between π chromophores in organic materials is not limited to assemblies connected by π-conjugated linkers. Indeed, the interaction of nearby π chromophores through σ linkers may occur with linkers that display high polarizabilities, and low σ–σ* gaps.[20] The electronic properties of materials displaying this form of σ–π hyperconjugation are often unique. The exocyclic P–R σ bond in phospholes is known to participate in a hyperconjugative interaction with the compound's butadiene moiety.[11] It has been suggested that P–P σ bonds display the requisite features (high polarizability and low σ-σ* gaps) to allow for an efficient interaction of the π-chromophores via a P–P σ bridge.[9] The 1,1′-biphospholes **B** (Figure 1) are a well-known family of compounds[9] that display the potential for an interaction of the phosphole π systems through the P–P σ link. The extended biphospholes **4a**,**b** were prepared according to the classical route for the preparation of 1,1′-biphospholes.[21] This route involves the reductive cleavage of the P–Ph bond in *P*-phenyl phospholes to generate intermediate phospholyl anions. Subsequent oxidation of the phospholyl anions results in the formation of the targeted 1,1′-biphospholes. The targeted biphospholes can also be prepared using an efficient "one-pot" synthesis starting from the 1,7-diyne precursors **2** (Scheme 2).[18f]

The structural parameters of **4a** suggest that the exocyclic conjugation observed between the composite heterocycles in the *P*-phenylphosphole precursor, remains in the 1,1′-biphosphole product, and the two π chromophores adopt a *gauche* conformation relative to one another (Figure 3).[18f] The absorption properties of the 1,1′-biphospholes, as determined by UV/Vis spectroscopy differ markedly from those of the corresponding phospholes. The individual 2,5-diarylphospholes display relatively simple ab-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Preparation of conjugated P–P biphospholes.

sorption spectra with a single band in the 400 nm range due to the π–π* transition. On the other hand, the 1,1′-biphospholes **4a**,**b** display rather complex absorption spectra, with multiple bands, including one remarkably red-shifted absorption (broad shoulder between 440–560 nm for **4a**). Quantum chemical calculations revealed that an interaction of the π chromophores through the P–P linkage results in the splitting of the HOMO and LUMO levels of the parent phospholes.[18f] The optical properties, and the presence of a P–P-mediated through-bond interaction suggest that biphosphole materials, particularly those bearing thienyl substituents, may be useful in the development of novel materials. Additionally, it was demonstrated that the optical properties of the biphospholes could still be tuned by chemical functionalization (oxidation and coordination to AuCl were investigated) of the phosphorus centers.[18f]

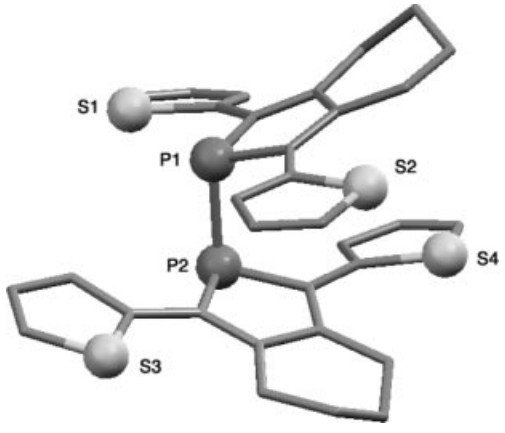


Figure 3. Molecular structure of **4a** in the solid state. Picture generated from the CSD-database file (code: BEWQAW).

Up until this point we have not been concerned with the nature of the aromatic substituents at the α positions of the phosphole moieties in Réau's 2,5-diarylphospholes **1**. In fact, a variety of aryl and heteroaryl groups have been incorporated into this system, and they display a profound influence on the optoelectronic and electrochemical properties of the system.[18] The nature of the aromatic groups can be varied by using an appropriately substituted diyne **2** in the first step of the Fagan–Nugent synthesis of the 2,5-diarylphospholes **5**–**7** (Figure 4).

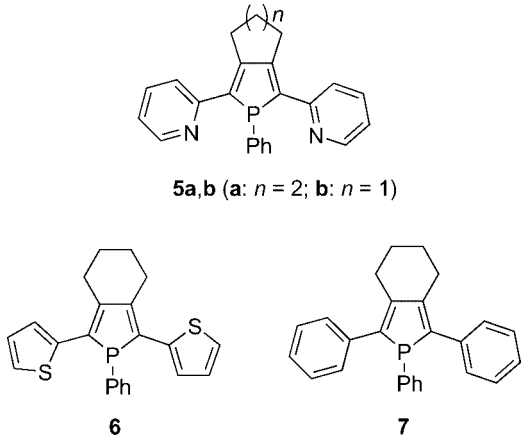

Figure 4. Variations of the aryl-/heteroaryl substituent.

2-Pyridyl groups were originally incorporated into these positions with the aim of preparing alternating electron-deficient/-rich (with the phosphole ring being considered as electron-rich heterocyclopentadiene)[22] species capable of exhibiting charge-transfer structures.[18a] It was anticipated that these charge-transfer structures would result in a more coplanar structure of the three heterocyclic rings, increasing the potential for conjugation between their π electron systems, potentially reducing the bandgaps of the corresponding materials.[23] Indeed, X-ray structural analysis of the 2,5-bis(2′-pyridyl)phosphole **5a** revealed that the twist angles between the heterocyclic rings were relatively small, and that the C–C bond lengths between the heterocyclic rings were intermediary between those expected of single and double bonds, implying an extensive π conjugation between the 2-pyridyl substituents and the central phosphole ring (Figure 5, top).[18a] Moreover, the phosphorus center in **5a** is highly pyramidalized, and the structural data indicate a rather small degree of endocyclic π conjugation, illustrating the balance between exocyclic, and endocyclic (aromatic) conjugation in these species. The oligothiophene analog **6**, in which a single thiophene ring is replaced by a phosphole ring, was prepared by Réau and co-workers shortly following their report of the preparation of **5a**.[18b] In addition to allowing for a comparison between the effects of substitution with an electron-poor heteroaromatic species (pyridine), and an electron-rich species (thiophene), the preparation of the 2,5-bis(2′-thienyl)phosphole **6** also provided an excellent model to study the effects resulting from the replacement of the central heteroatom in polythiophene with a heteroatom displaying remarkably different properties. As was observed with the 2,5-bis(2′-pyridyl)-phosphole **5a**, the structural features of **6** are consistent with an extended delocalization path incorporating the dienic moiety of the phosphole ring, and the thienyl substituents (Figure 5, bottom).[18c]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

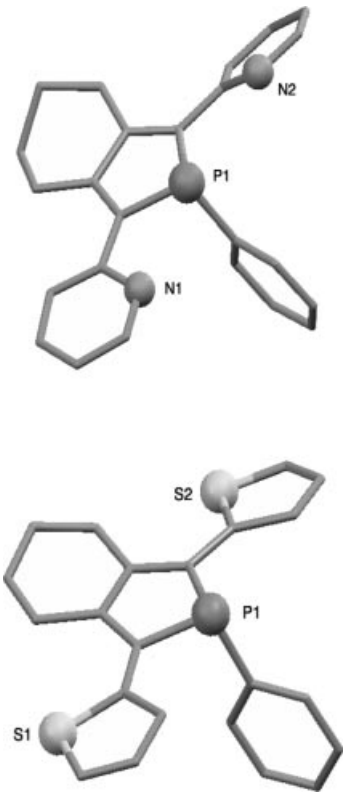

Figure 5. Molecular structures of the phospholes **5a** (top), and **6** (bottom) in the solid state. Pictures generated from the CSD-database files [codes: JOQFUQ (**5a**), MEKZEH (**6**)].

The absorbance properties of the 2,5-dithienylphosphole **6** display an even larger red shift relative to the 2,5-diphenylphosphole **7** ($\Delta\lambda_{max}$ = 58 nm, $\Delta\lambda_{onset}$ = 38 nm) than was observed with the 2,5-dipyridylphosphole **5a** ($\Delta\lambda_{max}$ = 45 nm, $\Delta\lambda_{onset}$ = 18 nm), indicating a significantly lowered HOMO–LUMO (π–π*) gap in the thienyl-substituted system. As a result, the incorporation of phosphole moieties into polythiophene materials may result in a significant optimization of the material's bandgap. Moreover, the emission of the dithienylphosphole **6** ($\lambda_{em}$ = 501 nm) is also significantly red-shifted relative to that of both the diphenyl- and the dipyridylphospholes which displayed emissions at similar wavelengths (**5a**: $\lambda_{em}$ = 463 nm; **7**: $\lambda_{em}$ = 466 nm).[18a–18c] It is important to note that the presence of terminal thiophene units in these oligomers allows for the potential preparation of dithienylphosphole polymers by electropolymerization. Importantly, the electrochemical oxidation potential of the diarylphosphole is related directly to the electron-rich or -deficient nature of the aryl substituents.[18a–18c] In summary, the optoelectronic properties of the 2,5-diarylphospholes display increasing red shifts upon substitution of pyridyl groups for phenyl substituents, and a further red shift upon introduction of thienyl substituents.

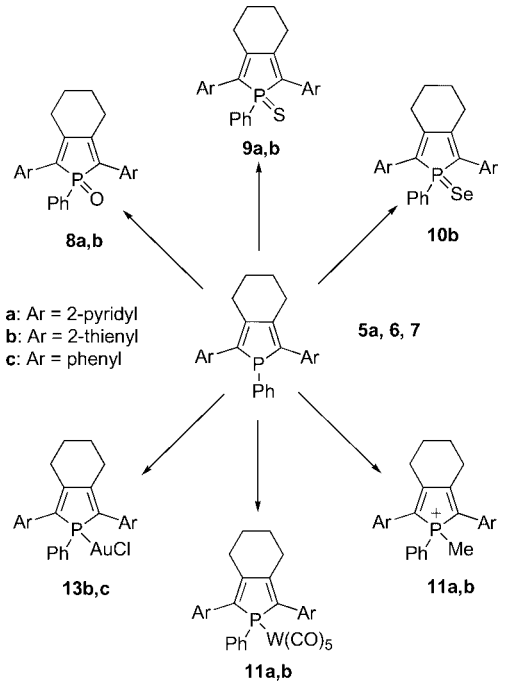
The valence π-MOs of these compounds are formed by a combination of the π-MOs of the constituent heterocycles (phosphole and either pyridine or thiophene).[17] The HOMO of 2,5-bis(2′-thienyl)phospholes arises from an antibonding combination of the thiophene, and the phosphole HOMOs, which have very nearly the same energies (the energy of the MOs differs by only 0.2 eV). In the case of the 2,5-dipyridylphospholes, however, the HOMO of the pyridine moiety is relatively high in energy. As a result, the HOMO of the phosphole moiety experiences a more efficient interaction with the HOMO-1 of the pyridine ring (the energies of these two MOs differ by 0.8 eV). Owing to the greater energy difference between the pyridine HOMO-1, and the phosphole HOMO, they experience a less-efficient interaction, and the resulting HOMO in the dipyridylphosphole is only moderately raised. The near match of the HOMO energies of thiophene and phosphole, on the other hand, result in a very efficient interaction. The resulting HOMO of the dithienylphosphole system is much more significantly raised in energy than that of the dipyridylphosphole. The same calculations predict that the LUMOs of the 2,5-bis(2′-thienyl)phosphole, and the 2,5-bis(2′-pyridyl)phosphole have very similar energies. Consequently, the observed red shift in the absorption (π–π* transition) spectrum of the dithienylphosphole relative to the dipyridylphospholes may be rationalized on the basis of its destabilized HOMO, and the resulting decreased HOMO–LUMO gap. Comparison of the experimentally obtained absorption values for the 2,5-bis(2′-thienyl)phosphole **6** ($\lambda_{max}$ = 412 nm)[18b,18c] with that the analogous oligothiophene ($\lambda_{max}$ = 353 nm)[24] reveals a significant optimization of the HOMO–LUMO gap upon substitution of the central heteroatom in the terthiophene by phosphorus.

### 2.2 Modification of the Phosphorus Center

As discussed earlier, the incorporation of phosphole moieties into materials is desirable because it may allow for the preparation of entire families of compounds from a single precursor, by taking advantage of the versatile reactivity displayed by the $\sigma^3,\lambda^3$-phosphorus center. Indeed, the phosphorus center in Réau's 2,5-dipyridylphosphole **5a**, 2,5-dithienylphosphole **6**, and 2,5-diphenylphosphole **7** has been functionalized in a number of different ways (oxidation, complexation etc.) to yield new compounds displaying significantly different optoelectronic and electrochemical properties (Scheme 3).[18,25]

The bis(heteroaryl)phosphole oxides **8** can be prepared by the quantitative reaction of the bis(heteroaryl)phosphole with trimethylsilyl peroxide. Similarly, reaction of the phosphole species with other elemental chalcogens (sulfur and selenium) results in the quantitative formation of the corresponding bis(heteroaryl)phosphole sulfides **9**, and selenides **10**.[18] This oxidative functionalization of the phosphorus center in the 2,5-bis(2-thienyl)phosphole system results in a significant red shift of both the absorption ($\Delta\lambda_{max}$ = 11–22 nm) and emission wavelengths ($\Delta\lambda_{em}$ = 46–55 nm) of these compounds.[18a–18e,18g,18h] The oxidized compounds all display a single peak in their absorption and emission spectra in both solution, and the solid state.[18g,18d] Examination of the absorption and emission data of the chalcogen series **8b**, **9b**, and **10b**, reveals that the magnitude of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Chemical modifications of the $\sigma^3,\lambda^3$-phosphorus center in 2,5-bis(heteroaryl)phospholes.

observed red shifts increases with the increasing electronegativity (O >> S > Se) of the chalcogen used.[18c] This trend has been rationalized formally on the basis of the stabilities of the ylide forms of the P=E bond ($\leftrightarrow P^+–E^–$).[26] The ylide forms, featuring a positively charged phosphorus center, are of course more stabilized for more electronegative chalcogens E. The introduction of a formal positive charge at the phosphorus center of a phosphole ring results in a shift in the aromaticity of the ring from slightly aromatic, to slightly antiaromatic. The increased antiaromatic character of the $\sigma^4$-phospholes results in a destabilization of the compound's bonding MOs, and a stabilization of the compound's antibonding MOs.[26] As a result the HOMO–LUMO gap is decreased in the less aromatic $\sigma^4$-phosphole species. DFT calculations[17] also revealed that oxidation of the phosphorus center results in a stabilization of the energy levels of both the HOMO and the LUMO of the oxidized bis(heteroaryl)phospholes, with the stabilization of the LUMO being more significant.[18b,18c] In summary, oxidation may prove to be a reliable method to reduce the bandgap of dithienylphosphole materials. It should be noted that the fluorescence efficiency, and the decomposition temperature of the 2,5-bis(2-thienyl)phosphole sulfide **9b** were reasonably high ($\phi_{PL}$ = 4.6%, $T_d$ = 254 °C),[18c] suggesting that thioxo-2,5-dithienylphospholes may be well-suited to incorporation into functional OLEDs.

Methylation of the trivalent phosphorus center in the bis(heteroaryl)phospholes to generate phospholium salts **11** proved to be another facile, and nearly quantitative means of altering the properties of the bis(heteroaryl)phosphole system (Scheme 3).[18b,18c] The functionalization resulted in relatively small red shifts in the excitation wavelengths ($\Delta\lambda_{max}$ **11a** = 4 nm; **11b** = 30 nm), and significantly larger red shifts in the emission wavelengths ($\Delta\lambda_{em}$ **11a** = 47 nm; **11b** = 92 nm) of the phospholium products. In fact, the red shifts observed upon methylation of the dithienylphosphole system are larger than those observed as a result of any other functionalization (oxidation, coordination etc.) of the phosphole's phosphorus center.[18] As discussed earlier for the dithienylphosphole chalcogenides, the presence of a positive charge at the phosphorus center in the phosphole ring reduces the aromatic stabilization of the compound, resulting in decreased HOMO–LUMO gaps.[26] The ionic nature, and the significant reduction of the HOMO–LUMO gap of the obtained phospholium products makes this modification potentially useful towards the development of functional phospholium materials.

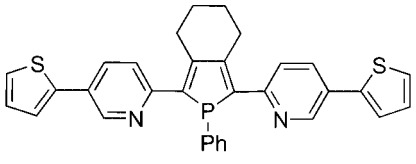
Trivalent $\sigma^3,\lambda^3$-phosphanes are among the most versatile classes of organometallic ligands. Phospholes typically display similar coordination chemistry. Consequently, a large family of complexes can be prepared from a single phosphole precursor. The coordination chemistry of the dithienylphosphole ligand, however, has to this point been limited to its inclusion in tungsten and gold complexes **12** and **13**, respectively (Scheme 3).[18c,18d,18g] Coordination to the octahedral tungsten unit seems to have relatively little effect on the properties exhibited by the dithienylphosphole ligand.[18c] In contrast, coordination to gold produces a complex displaying dramatically different properties than those reported for the free ligand.[18d,18g] Significant red shifts in the absorption ($\Delta\lambda_{max}$ = 16 nm), and the emission wavelengths ($\Delta\lambda_{em}$ = 43 nm) are observed upon coordination to AuCl, and the fluorescence efficiency of **13b** improves to 14.0% compared to 5.0% in the free ligand. The gold complex displays a relatively high thermal decomposition temperature ($T_d$ = 218 °C), allowing thin films to be obtained upon vacuum sublimation. While the excitation properties of the complex are similar in solution and in the thin film (a small red shift of 12 nm is observed in the thin film), the emission properties of the thin film are unique,[18d,18g] displaying two broad emission bands of similar intensity. The first emission is only marginally red-shifted relative to that observed in solution ($\Delta\lambda_{em}$ = 6 nm), however the second is remarkably red-shifted ($\Delta\lambda_{em}$ = 146 nm). When the gold complexes are dispersed in a polymethacrylate matrix, the low-energy emission disappears.[18g] This observation suggests that the first emission is due to the metal-perturbed intraligand π–π* transition, while the second, remarkably red-shifted emission, is probably due to the formation of aggregates. The above observations suggest that dithienylphosphole AuCl complexes are a promising material for incorporation into OLEDs. In particular, materials displaying broad emissions may be suitable for the development of white organic light-emitting diodes (WOLEDs).[27]

### 2.3 Bis(thienyl)phosphole Oligomers and Polymers

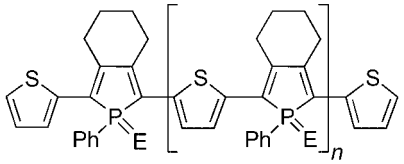
The evolution of optoelectronic and electrochemical properties with increasing chain length is of great interest

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

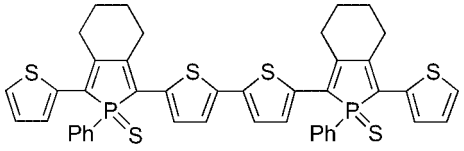
in the chemistry of π-conjugated organic materials.[1] The effect of increasing chain length in the π-conjugated 2,5-dithienylphospholes has been studied through the preparation of several well-defined oligomers.[18b,18c,18e] The mixed oligomer **14** (Figure 6), containing alternating donor and acceptor units, was prepared using an appropriately substituted diyne.[18b] As with the 2,5-bis(2-pyridyl)phospholes **5b** prepared earlier, this oligomer was expected to display increased conjugation as a result of intramolecular charge transfers. Indeed, the observed wavelength of excitation ($\lambda_{max}$ = 427 nm) is red-shifted relative to either the 2,5-dipyridylphosphole **5b** or the 2,5-dithienylphosphole **6**. The emission of the mixed oligomer **15** is even more significantly red-shifted ($\Delta\lambda_{em}$ = 107 nm relative to the 2,5-dipyridylphosphole **5b**).



**14**



**15a** (*n* = 1), **15b** (*n* = 2)



**16**

Figure 6. Well-defined 2,5-bis(heteroaryl)phosphole oligomers.

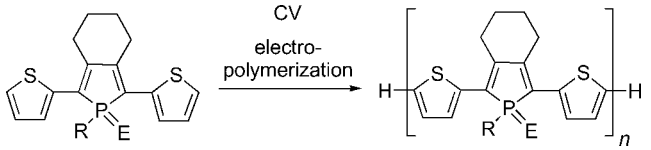
The oligo(α,α′-thiophene-phospholes) **15** (Figure 6) and their derivatives were prepared by the Fagan–Nugent route, using suitable bis- and tris(diynes).[18e] The three reported oligo(α,α′-thiophenephospholes) all display one broad band in their absorption spectra, assignable to the π–π* transitions of the thiophene-phosphole system. The excitation wavelength of the thiophene-phosphole dimer **15a** ($\lambda_{max}$ = 490 nm) is significantly red-shifted relative to that of the corresponding monomeric 2,5-dithienylphosphole **6** ($\lambda_{max}$ = 412 nm), demonstrating the successful extension of the conjugated π system in this oligomer. Sulfurization of the shorter oligomer leads to an additional red shift in the excitation wavelength. The magnitude of the red shift that occurs upon functionalization of the phosphorus centers with sulfur is similar for both the monomeric 2,5-dithienylphosphole **6**, and the bis(α,α′-thiophenephosphole) **15a** ($\Delta\lambda_{max} \approx$ 20 nm). Red shifts of similar magnitude are observed in the emission of both bis(α,α′-thiophenephospholes) **15a** and **15b**, resulting in emission in the red-orange region of the visible spectrum. Inspection of the UV/Vis spectrum of the larger tris(α,α′-thiophenephosphole) **15b** oligomer reveals an additional red shift relative to the bis-(α,α′-thiophenephosphole) **15a** ($\Delta\lambda_{max}$ = 42 nm). This red shift reveals a further extension of the conjugated π system by the coherently smaller bandgap in the longer oligomer. The bis(α,α′-thiophenephospholes) **15** were subjected to further study by CV. This study supported the extended conjugation upon chain extension, by demonstrating that oxidation and reduction potentials were decreased, and increased respectively in the longer oligomers.[18e]

Polythiophenes are often prepared by electropolymerization of thiophene monomers and oligomers.[6] The presence of terminal thiophene functionalities in the 2,5-dithienylphospholes, and their derivatives is thus interesting, because they may allow for the preparation of polymers from this well-developed family of π-conjugated oligomers. It is well known that α,α′ coupling is the major route involved in the electropolymerization of thiophenes,[6,28] therefore the "dimer" **16** (Figure 6), the product of one such coupling was prepared to examine the effects of α,α′ coupling in the 2,5-dithienylphosphole system **6**. The "dimer" was prepared using the Fagan–Nugent method with an appropriately substituted bis(diyne),[29] and was isolated as the sulfurized phosphole derivative.[18c] Absorption spectroscopy of **16** revealed significant red shifts in the excitation wavelengths relative to those displayed by the corresponding monomer **9b** ($\Delta\lambda_{max}$ = 100 nm, $\Delta\lambda_{onset}$ = 132 nm). These bathochromic shifts suggest an effective extension of the conjugated system, and imply that polymers generated electrochemically from 2,5-dithienylphosphole derivatives may display highly favorable properties, particularly with respect to bandgap.

During the electrochemical CV analyses of many of the 2,5-bis(2-thienyl)phosphole derivatives, the deposition of insoluble films was observed on the working electrode surfaces (Scheme 4).[18b,18c,18f] Repeated cycling resulted in a regular increase of the oxidation and reduction peak currents, consistent with the formation of an electroactive material on the surface of the electrode. By this method, polymeric films were obtained for the parent $\sigma^3$-dithienylphosphole **6** (E = lone pair),[18c] the $\sigma^3$-dithienyl-1,1′-biphosphole **4a**,[18f] and a large number of $\sigma^4$-dithienylphospholes,[18b,18c] including oxidized (**8**, E = O), methylated (**11**, E = $Me^+$), and transition-metal-coordinated species **13** (E = AuCl). The poor solubility of these films prevented the full characterization of most of the obtained polymers, however the optical properties of all the polymers were probed through their thin-film absorption spectra. The film obtained from the parent 2,5-bis(2-thienyl)phosphole **poly(6)** (E = lone pair) displayed two unresolved absorptions, both red-shifted relative to the corresponding monomer **6** ($\Delta\lambda_{max}$ = 51 nm, 155 nm). The absorption spectra of the functionalized dithienylphospholes all displayed red shifts relative to the appropriate monomers as well, illustrating the extension of the conjugated π system upon polymerization. The functionalized nature of the phosphorus centers in these polymers often resulted in an additional red shift in their $\lambda_{max}$ values relative to that of the parent $\sigma^3$-dithienylphos-

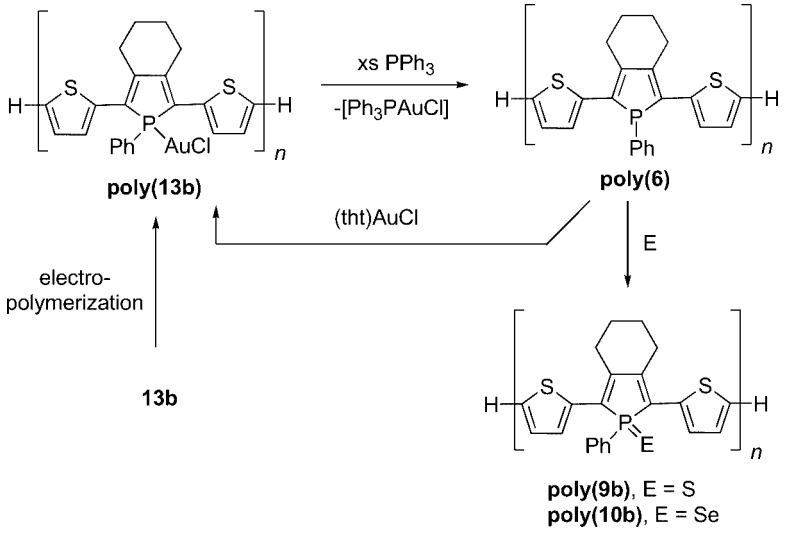
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phole polymer **poly(6)**. The general trends observed for the monomers with respect to the red shift resulting from a specific functionalization of the phosphorus center were preserved in the polymers. For example, the largest red shift in both the polymer and the monomer series is observed upon methylation of the phosphorus center. Comparison between the properties displayed by the well-defined α,α′-coupled dimer **16**, and the analogous polymer suggest that the polymers obtained are in fact, longer α,α′-coupled oligomers.[18c] In summary, these results demonstrate the utility of incorporating a reactive heteroatom such as phosphorus into electroactive polythiophene materials. In addition to allowing the bandgaps of the resulting polythiophene-like materials to be tuned via facile chemical modifications of the monomeric precursors, the incorporation of the phosphorus center may result in a bandgap that is already optimized relative to that displayed by analogous, purely thiophene-containing oligomers.[17]



Scheme 4. Electropolymerization of 2,5-dithienylphospholes.

The presence of reactive, Lewis basic $\sigma^3,\lambda^3$-phosphorus centers in polythiophene materials such as those described above should allow for a variety of postfunctionalizations to be performed with the polymeric materials such as **poly(6)**. Functionalized dithienylphosphole polymers have been shown to display different properties than their non-functionalized analogs, therefore postfunctionalization of trivalent phosphorus-containing polythiophenes should allow them to be used as effective chemosensors.[5] In order to investigate the utility of the phosphole-modified polythiophenes as molecular sensors, the preparation of a corresponding 2,5-dithienyl-$\sigma^3,\lambda^3$-phosphole polymer film was required. This non-protonated polymer film[30] **poly(6)** was obtained using a *P*-protection/electropolymerization/deprotection sequence (Scheme 5).[18h] Protection of the phosphorus center by coordination to AuCl (**13b**), followed by electropolymerization resulted in the formation of the insoluble AuCl-coordinated dithienylphosphole polymer film **poly(13b)**. Deprotection was achieved in the presence of excess triphenylphosphane, affording [AuCl($PPh_3$)] and the deprotected polymer **poly(6)**. The $\sigma^3$-phosphole-containing polymer displayed a blue shift in its absorption band ($\Delta\lambda_{onset}$ = 41 nm), and a significant negative shift in its oxidation current offset ($\Delta E_{pa}$ = 0.26 V), consistent with the shifts observed at the molecular level for this system.[18d,18g] The polymer **poly(6)** could be treated with a AuCl solution to regenerate the protected polymer **poly(13b)**. This result effectively demonstrated that the chemistry displayed by phospholes at the molecular level could be extended to the macromolecular level, a prerequisite for the development of chemosensors from the phosphorus-modified polythiophenes. The possibility that further postfunctionalizations of the deprotected polymer might result in property shifts similar to those displayed at the molecular level, led to the investigation of the $\sigma^3$-phosphorus-containing polythiophene's reactions with chalcogens. Immersion of Pt electrode, modified with a film of the deprotected polymer **poly(6)** into a solution containing elemental sulfur resulted in the nearly quantitative sulfurization of the polymer.[18h] The polymer **poly(9b)** displayed a red shift in its absorption ($\Delta\lambda_{onset}$ = 38 nm), and an anodic shift in its oxidation current ($\Delta E_{pa}$ = 0.23 V) upon exposure to elemental sulfur. The $\sigma^3$-phosphole-modified polythiophene also displayed an anodic shift ($\Delta E_{pa}$ = 0.11 V) in the presence of elemental selenium. When the anodic shifts of the $\sigma^3$-phosphole-modified polythiophene **poly(6)** were monitored as a function of time in a sulfur-containing solution, a collective response was observed, and the degree of sulfurization could be monitored by observing the gradual shifts in the electro-



Scheme 5. Postfunctionalization of poly(2,5-thienylphospholes).

chemical properties of the material. This $\sigma^3,\lambda^3$-phosphorus-containing polythiophene is the first reported conjugated polymer capable of detecting chalcogens.

### 2.4 Phosphole-Based OLEDs

The development of functional OLEDs requires materials displaying several requisite features.[2] The materials must display high thermal stabilities, so that homogeneous thin films may be deposited upon vacuum sublimation. Good luminescence efficiencies are also required if a material is to be incorporated into OLEDs. Additionally, it is essential that the materials display favorable hole and electron injection, and transportation properties. It has been demonstrated that materials based on the 2,5-bis(2′-thienyl)-phosphole **6** and its derivatives display remarkable properties, with the potential for tuning by simple chemical modifications of the material's phosphorus center.[18] It is possible to tune the emission properties, the ionization potentials, and the electron affinities of these materials, allowing the color of the emission to be varied, and a good match to be obtained between the HOMO and LUMO levels of the material, and the cathode and anode (respectively) of the device. Moreover, a number of dithienylphosphole derivatives display high thermal stabilities (the thioxo- and AuCl-coordinated species **9b** and **13b** for example). These characteristics suggest that dithienylphosphole materials may be particularly well suited for incorporation into functional OLEDs. Indeed the incorporation of thioxo-dithienylphosphole, and AuCl-coordinated dithienylphosphole into functional OLEDs represented the first examples of OLEDs based on organophosphorus materials.[18d,18g] These compounds were both incorporated into single-layer OLEDs having an ITO/PEDOT:PSS/**phosphole**/Mg:Al/Ag configuration [ITO = indium-tin oxide; PEDOT = poly(3,4-ethylenedioxythiophene); PSS = polystyrene sulfonate]. The OLEDs incorporating the AuCl-functionalized phospholes displayed unique emission properties, similar to those observed for the same materials in the solid state.[18g] The long-wavelength emission of the AuCl-functionalized 2,5-diphenylphosphole **13c** was dominant, resulting in a saturated red emission from the device. This is of interest because non-doped red-emitting OLEDs are relatively rare.[31] The emission of the AuCl-coordinated dithienylphosphole **13b** on the other hand, uniformly covers a broad range ($\lambda_{EL}$ = 500–800 nm), suggesting its potential for use in WOLED applications. The performance of a number of other single-layer devices having the same configuration but incorporating other diarylphospholes were also evaluated.[18g] Importantly, the electroluminescence of these devices matched those displayed by the emissive materials in the solid state, suggesting that the luminescence mechanisms involved are similar. This result implies that the structure–property relationships established for the diarylphosphole materials, can be extended to luminescent devices, offering a predictable means of tuning the emission color of the devices. The device based on the thioxo-2,5-dithienylphosphole **9b** outshone the other devices (including those based on the AuCl-coordinated diarylphospholes **13b**) in all respects.[18g] This device displayed the lowest turn-on voltage (2.0 V), the greatest brightness (3613 cd m$^{-2}$), and the best external electroluminescence quantum efficiency (EEQE) (0.16%). Unfortunately, the EEQE values of the single-layer devices, including that based on the thioxo-dithienylphosphole **9b** were rather modest. This often occurs in single-layer devices as a result of unbalanced charge carrier injection and transport. With the aim of improving device performances, multilayer devices were prepared for all the emissive phosphole materials examined, by sandwiching the emissive layer between a hole-transporting layer (HTL), *N*,*N*′-diphenyl-*N*,*N*′-bis(1-naphthyl)-1,1′-biphenyl-4,4"-diamine (α-NPD), and an electron-transporting layer (ETL), tris(8-hydroxyquinoline)aluminum ($Alq_3$). The resulting devices displayed turn-on voltages, and emissions similar to those observed in the corresponding single-layer devices. It was therefore concluded that the diarylphospholes remained the source of emission, and not the newly introduced ETL or HTLs. The performance of the multi-layer devices were dramatically improved with respect to brightness, and EEQE, often displaying improvements of over one order of magnitude. Once again, the best performance in all aspects was obtained with the thioxo-2,5-bis(2-thienyl)phosphole **9b** based device. This device displayed a low turn-on voltage (2.2 V), and dramatically improved brightness (37830 cd m$^{-2}$), and EEQE (0.80%). As a result of the outstanding performance of the thioxo-, and the intriguing emission of the AuCl-functionalized dithienylphospholes **9b** and **13b**, these materials were evaluated as potential hosts for dopant fluorescent dyes. The problem of obtaining red emission is often solved by incorporation of a dopant such as 2-*tert*-butyl-4-(dicyanomethylene)-6-(1,1,7,7-tetramethyljulolidyl-9-enyl)-4*H*-pyran (DCJTB) into an emissive host matrix.[31] Both doped multilayer devices displayed red emission arising from the DCJTB dopant ($\lambda_{EL}$ = 617–623 nm), and not the dithienylphosphole host. Moreover, the performance of both devices was similarly exceptional. Low turn-on voltages (2.2–2.4 V), and exceptional brightness (36538 cd m$^{-2}$), and EEQEs (1.22 and 1.83%) were observed for the doped devices. These observations suggest an efficient resonant energy transfer from the dithienylphosphole emissive matrices to the DCJTB dopant. These results demonstrate that efficient luminescent devices can be prepared from phosphole-containing oligothiophenes, offering the additional ability to fine-tune the properties of the system by taking advantage of the reactive phosphorus heteroatom.

## 3. Fused Tricyclic Dithieno[3,2-*b*:2′,3′-*d*]-phospholes

Open-chain organic π-conjugated materials consisting of aromatic, or heteroaromatic rings often display a significant degree of twisting between adjacent subunits in the solid state. Because the orbital overlap of the conjugated π sys-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tem varies approximately with the cosine of the twist angle, this rotational disorder in open-chain systems results in a significant decrease in the degree of π conjugation displayed by oligomers and polymers of this type.[6] Annelated ring systems have the advantage of forcing the constituent rings to adopt a coplanar geometry, maximizing the overlap of the π systems of the constituent subunits. Moreover, the fused nature of the ring system in annelated materials limits the possibility of non-radiative decay processes, potentially allowing for extremely efficient emission from materials of this type. Theoretical calculations have suggested that fused polythiophene materials may display favorable bandgaps relative to their open-chain analogs.[32] Moreover, fused dithienothiophenes have recently been shown to display remarkably efficient emission.[33] Because emission is favored relative to internal conversion in the fused polythiophene system, the observed emissions of an annelated system were found to be blue-shifted relative to those of its α-coupled, open-chain polythiophene analogs. The 2,5-dithienylphospholes **1** developed by Réau et al., demonstrated that the incorporation of a phosphole moiety into the backbone of an oligothiophene results in the formation of materials displaying a number of highly favorable optoelectronic properties. Furthermore, the presence of a reactive heteroatom in these systems allows their properties to be tuned in a predictable manner following the establishment of structure–property relationships.[18,25] These results prompted Baumgartner and co-workers to develop the dithieno[3,2-*b*:2′,3′-*d*]phosphole system **17**.[34] As was seen in the 2,5-dithienylphosphole system **1**, it is possible to systematically modify the structure of **17** in a number of different ways, allowing for the establishment of structure–property relationships (Figure 7).[34] Modification of the substitution at both the phosphorus center, and the 2- and 6-positions of the dithieno unit generates a wide variety of dithienophospholes with unique properties. Moreover, the versatile reactivity of the $\sigma^3,\lambda^3$-phosphorus center allows for a number of chemically facile functionalizations (oxidation, complexation etc.) to be performed. Specific attention will be paid to the dithienophosphole's optoelectronic properties since their extraordinary nature makes this system a promising candidate for the development of materials to be used in optoelectronic applications (e.g. OLEDs, PLEDs, OFETs as well as photovoltaic cells).

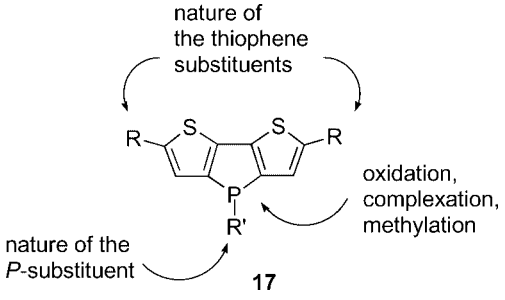

Figure 7. The dithieno[3,2-*b*:2′,3′-*d*]phosphole system developed by Baumgartner et al.

Many of the intriguing properties displayed by the dithieno[3,2-*b*:2′,3′-*d*]phosphole system can be rationalized by examining the molecule's frontier orbitals. Quantum chemical calculations revealed that both the HOMO and the LUMO of the parent dithieno[3,2-*b*:2′,3′-*d*]phosphole **17** can be easily derived from the frontier orbitals of the individual composite heterocycles, providing evidence that the π system is well-delocalized over the entire molecule (Figure 8).[34b] The HOMO of **17** is an antibonding combination of the HOMOs of the individual thiophene rings, resembling the phosphole's HOMO. The LUMO of **17** also resembles the phosphole ring's LUMO, and is comprised mainly of a bonding combination of the thiophene rings' LUMOs. It is important to note that the HOMO contains a nodal plane at the phosphorus center, while the LUMO contains a contribution from the $\sigma^*_{P-R}$ MO. As a result, chemical modifications of the phosphorus center will significantly affect the compound's LUMO. This feature will prove essential to the eventual tuning of the optoelectronic properties of dithienophosphole materials through modifications of the compound's phosphorus center.

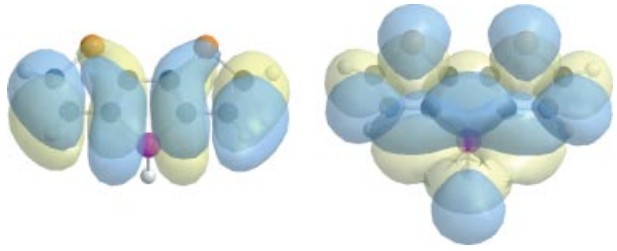

Figure 8. Frontier orbitals of the dithieno[3,2-*b*:2′,3′-*d*]phosphole (B3LYP/6-31G* level): HOMO (left), LUMO (right); P (purple), S (orange), C (black).

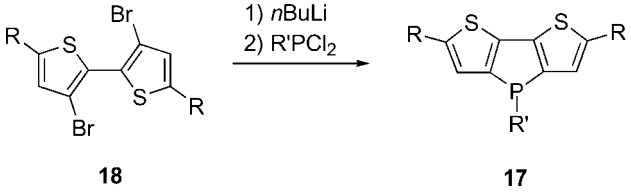
The dithieno[3,2-*b*:2′,3′-*d*]phospholes **17** can be accessed synthetically by lithiation of 3,3′-dibromo-2,2′-bithiophenes **18**, followed by reaction with an appropriately substituted dichlorophosphane (Scheme 6).[34] The resulting dithienophospholes display strong photoluminescence, typically in the blue region of the visible spectrum. The photoluminescence quantum yields are unprecedentedly high, ranging from 47 to 88%,[34] providing evidence that emission in these annelated systems is indeed favored relative to internal conversion.



Scheme 6. Synthesis of dithieno[3,2-*b*:2′,3′-*d*]phospholes **17**.

The rigid tricyclic system of the *P*-phenyl compound **19a** is planar, and displays a high degree of π conjugation, as evidenced by the shortened C–C single bonds, and the elongated C=C double bonds present in the fused ring system (Figure 9).[34a] The observed bond shortening/elongation is significantly more pronounced in the fused tricyclic system

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

than in Réau's 2,5-dithienylphospholes. The phosphorus center is significantly pyramidalized, and the endocyclic P–C bonds are similar in length to the exocyclic P–C bond, implying a minimal involvement of the phosphorus lone pair in the molecule's delocalized π system. These observations support the reduced aromatic character of the phosphole moiety in **19a**, and the resulting increased exocyclic π conjugation within the molecule, once again illustrating the balance between endocyclic (aromaticity), and exocyclic conjugation. As a result of this feature, materials derived from the dithieno[3,2-*b*:2′,3′-*d*]phosphole scaffold display highly desirable optoelectronic properties.[34]

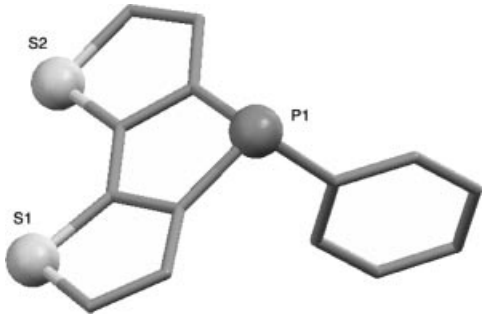


Figure 9. Molecular structure of **19a** in the solid state. Picture generated from the CSD-database file (code: FEHQAL).

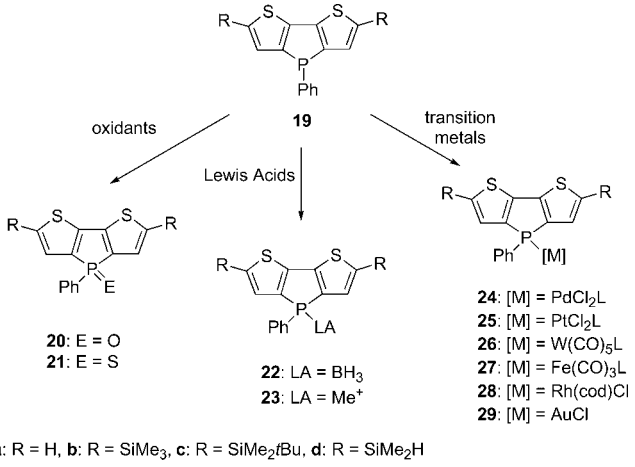
### 3.1 Modification of the Phosphorus Center

The use of different dichlorophosphanes allows for the introduction of different substituents at the phosphorus center. Aromatic substituents at the phosphorus center typically result in more stable compounds than alkyl substituents due to the propensity for oxidation displayed by the latter.[9,34a] The subsequent discussion of derivatives of **17** will therefore focus on *P*-phenyl-substituted phospholes. The presence of a reactive phosphorus heteroatom in the dithieno[3,2-*b*:2′,3′-*d*]phosphole system allows the system to be tuned by taking advantage of these synthetically facile chemical modifications (Scheme 7).[34] The optoelectronic properties of the dithienophospholes **19** are particularly sensitive to such modifications as a result of the phosphorus center's contribution to the molecule's LUMO. Reaction of the Lewis basic phosphorus center in the dithieno[3,2-*b*:2′,3′-*d*]phosphole system with a Lewis acidic borane results in the formation of the phosphane–borane adducts **22** in almost quantitative yield.[34a,34b,34e]

As observed with Réau's system **1**, the phosphorus center in the dithieno[3,2-*b*:2′,3′-*d*]phosphole system may also be oxidized using a variety of oxidizing agents. The reactions are very general, and proceed in almost quantitative yields regardless of differences in the substitution at the thiophene rings. Reaction with peroxides ($H_2O_2$ or *t*BuOOH) results in the formation of $\sigma^4,\lambda^5$-dithienophosphole oxides **20**, while $\sigma^4,\lambda^5$-dithienophosphole sulfides **21** may be prepared by reaction with elemental sulfur.[34a,34b,34d,34e] Both the borane adducts, and the oxidized $\sigma^4$-dithienophospholes **22** and **20** display red-shifted excitation and emission wavelengths. The magnitude of this red shift is greater for the oxidized species than for the dithienophosphole–borane adducts ($\Delta\lambda_{max}$ = 8 nm, $\Delta\lambda_{em}$ = 9 nm). The phosphole oxides **20** and sulfides **21** display identical red shifts as a result of their similar nature, however the intensity in the observed fluorescence is significantly stronger for the dithienophosphole oxide than for the sulfide as a result of sulfur's increased quenching ability.[34b] These red shifts are larger in both the excitation ($\Delta\lambda_{max}$ = 28 nm) and emission wavelengths ($\Delta\lambda_{em}$ = 38 nm) than those observed for the corresponding borane adducts **22** as a result of the oxidized phosphorus center's increased electron-accepting ability. It should be noted that in the presence of electron-withdrawing substituents on the thiophene rings (vide infra), a cumulative effect is observed in both the excitation and emission wavelengths, resulting in larger red shifts for both the borane adducts **22**, and the oxidized $\sigma^4,\lambda^5$-dithienophospholes **20**, **21**. Quantum chemical calculations show that the oxidation of the phosphorus center in the dithieno[3,2-*b*:2′,3′-*d*]phosphole system results in a significant lowering of the LUMO energy level.[34b] Because the HOMO of the dithienophospholes **17** contains no contribution from the phosphorus center, this lowering of the LUMO's energy accounts for the observed red shifts. The experimentally observed band maxima are in good agreement with those calculated by TD-DFT means, implying that such computations may be helpful in predicting the optoelectronic properties of yet unknown dithienophospholes.[34b]



Scheme 7. Functionalization of the $\sigma^3,\lambda^3$-phosphorus center in dithienophospholes **19**.

Recently, cationic phospholium compounds **23**, based on the dithieno[3,2-*b*:2′,3′-*d*]phosphole system have been prepared by methylation of the phosphorus center (Figure 10).[34f] Treatment of the dithienophosphole with methyl triflate resulted in the formation of the cationic phospholium salt **23a** (Scheme 7). The fluorescence of the cationic dithienophosphole exhibits a pronounced red shift, emitting in the green region of the visible spectrum [$\lambda_{max}(\pi$–$\pi^*)$ = 376 nm, $\lambda_{em}$ = 467 nm].[34f] This is the largest red shift observed, due exclusively to the functionalization of the phosphorus center, and not due to a cumulative effect re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sulting from functionalization of both the phosphorus and the thiophene rings in the dithieno[3,2-*b*:2′,3′-*d*]phosphole system (vide infra). The magnitude of this red shift highlights the potential utility of this simple chemical modification in terms of significantly tuning the optoelectronic properties of dithienophospholes. It should be noted in this context that the methylation of the phosphorus center provides access to species that are also water soluble.[34f]

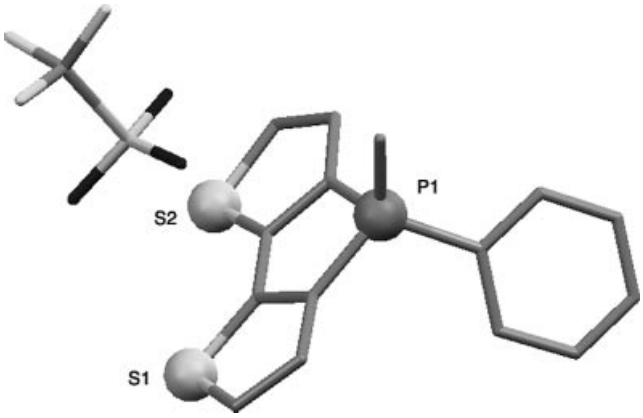


Figure 10. Molecular structure of **23a(OTf⁻)** in the solid state. Picture generated from the CIF-file.[34f]

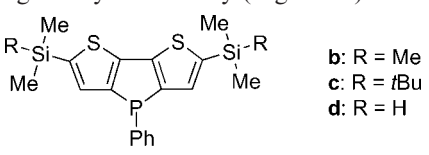
Dibenzophospholes are known to coordinate to a variety of metal centers, behaving similarly to diphenylphosphanes.[9] The rigid tricyclic dithieno[3,2-*b*:2′,3′-*d*]phospholes **19** behave in a similar manner (Scheme 7).[34b,34c] The coordination of the dithieno-phospholes to transition metals results in an increase in the acceptor character of the dithienophosphole's phosphorus center. X-ray structure analyses of several complexes based on Pd, Pt, W, and Au revealed that the structural properties of the coordinated dithienophosphole ligands are similar to those of the free ligands. This result is in line with the poor delocalization of the phosphorus lone pair in the dithienophosphole system **17**.[9] Similarly to the free ligands, the fluorescence observed in the transition-metal complexes is due to intra-ligand π–π* transitions. As a result of the increased acceptor capacity of the phosphorus center however, red shifts in the absorption and emission wavelengths of the dithienophosphole–metal complexes relative to the free ligands are typically observed. The magnitude of these shifts is dependant on a number of factors that are not always predictable, including the nature of the metal, the substitution of the dithienophosphole ligand, and the geometry of the resulting complexes.[34c] The earlier work of Réau and co-workers had demonstrated that phosphole AuCl complexes display very promising optoelectronic properties. In fact, the complexes have been incorporated into functional OLEDs.[18d,18g] Consequently, the gold(I) complexes **29** of the dithieno[3,2-*b*:2′,3′-*d*]phosphole system were also prepared (Scheme 7). Reaction of the dithienophospholes **19** with AuCl(tht) (tht = tetrahydrothiophene) resulted in quantitative formation of the desired AuCl complexes **29**. The gold center displays a linear geometry, and shows no evidence of aurophilic interactions in the solid state (closest Au–Au distance ca. 5.639 Å) as determined by X-ray crystallography.[34c] While the optoelectronic properties of the transition metal–dithienophosphole complexes examined earlier were relatively insensitive to the nature of the metal (emission at ca. 460 nm for Pt, W, Fe, and Rh complexes **25**, **26**, **27**, and **28**), the AuCl complexes **29** display intriguing optoelectronic properties, including unique absorption and emission wavelengths.[34c] The gold complexes display two absorptions. The red-shifted absorptions have been assigned to the intraligand π–π* transition, whereas the blue-shifted absorptions observed ($\lambda_{max}$ **29b**: 375 nm; **29c**: 405 nm) are likely due to $\sigma_{AuP}$–π* transitions, although a ligand-to-metal charge transfer (LMCT) process cannot be ruled out. Typically bands in the absorption spectra of dithienophospholes are broad and poorly resolved. This is indeed the case with gold complex **29b**.[34c] The absorption spectrum of complex **29c** however, displays relatively narrow, well-resolved bands. This feature may arise as a result of poorer intermolecular interactions between the complexes in solution due to the added steric bulk of the *tert*-butyl group present in the silyl substituents on the thiophene rings of **29c**. The AuCl complex **29c** also displays a strong emission at 445 nm in the solid state, identical to that observed in solution, providing evidence that the complex does not aggregate in the solid state. The unique absorbance properties displayed by **29c** suggest that variation of the silyl functionality may allow the selective optoelectronic properties displayed by this system to be controlled. As a result, AuCl-coordinated dithienophosholes may be well-suited for the development of functional materials and devices.

### 3.2 Modification of the Dithieno-Framework

A number of different substituents may also be introduced at the 2- and 6-positions of the thiophene rings in dithieno[3,2-*b*:2′,3′-*d*]phospholes. The introduction of electron-accepting groups on the thiophene rings results in red shifts for both the excitation and emission wavelengths relative to those observed for the non-functionalized dithienophosphole **19a**.[34] This observation is in line with the further extension of the delocalized π system, and concurrent reduction in the molecule's optical HOMO–LUMO gap induced by the electron-accepting centers. This extension of the delocalized π system is further supported by spectroscopic data. Silyl groups have been used extensively to this end,[34a,34b,34c,34e] including trimethylsilyl (**19b**), *tert*-butyldimethylsilyl (**19c**), and dimethylsilyl (**19d**) groups that have been investigated systematically (Figure 11).



**19b,c,d**

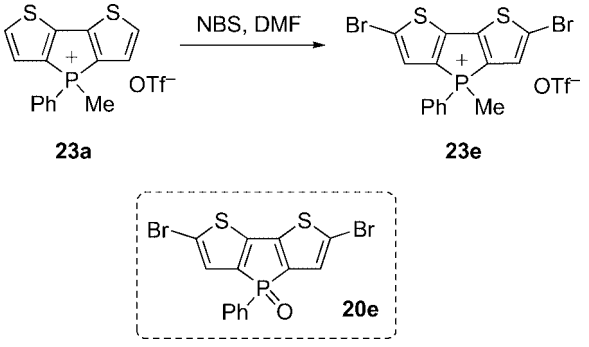
Figure 11. Silyl-functionalized dithienophospholes.

All of these silyl-substituted dithienophospholes display similar emission wavelengths ($\lambda_{em}$ = 420–422 nm), however

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the nature of the silyl groups has a significant effect on the excitation wavelengths.[34b,34e] The red shifts observed (R = *t*Bu: $\Delta\lambda_{max}$ = 20 nm; R = H: $\Delta\lambda_{max}$ = 22 nm) are consistent with the relative inductive effects expected for methyl, *tert*-butyl, and hydrogen (Me < *t*Bu < H) substituents at the silyl centers. The fact that the emission wavelength in these molecules is not significantly affected by the changes to the silyl centers, while the excitation wavelength is sensitive to them, allows the Stokes shifts of these dithienophospholes to be tuned in a predictable manner. Additionally, the use of the dimethylsilyl-substituted dithieno[3,2-*b*:2′,3′-*d*]phospholes **19d** allowed access to polymeric systems through hydrosilation and dehydrogenative coupling reactions (vide infra).

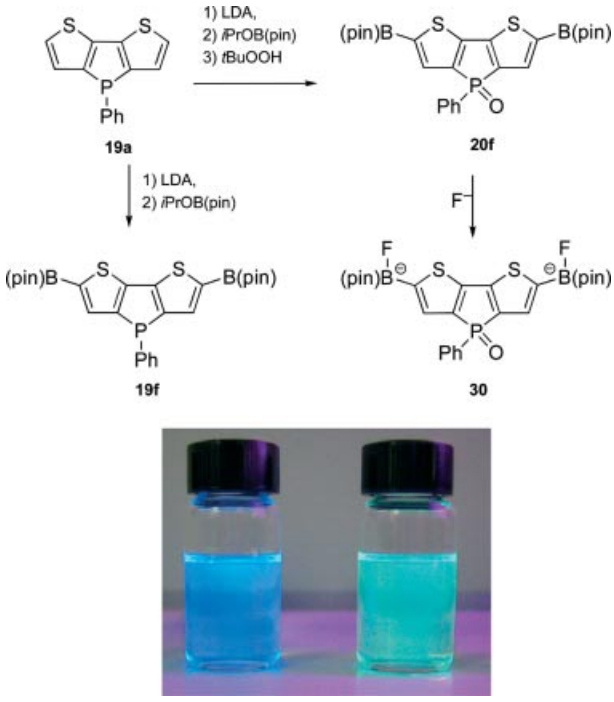
The introduction of bromo substituents at the 2- and 6-positions, to provide the dithienophospholium salt **23e**, can be achieved by treatment of the dithienophospholium salt **23a** with NBS in DMF (Scheme 8).[34f] As with other electron-accepting substituents, the presence of the bromo substituents results in a decrease in the compound's optical HOMO–LUMO gap. This feature becomes obvious when examining the extraordinarily red-shifted values obtained for both the absorption [$\lambda_{max}(\pi–\pi^*)$ = 411 nm] and the emission ($\lambda_{em}$ = 495 nm) wavelengths of the dibrominated dithienophosphole **23e**.



Scheme 8. Introduction of bromo functionalities to the dithienophosphole.

It should be noted that the large magnitude of the observed red shift in this compound arises as the result of the cumulative effect of the electron-accepting cationic phosphorus center, and the electron-accepting substituents on the thiophene moieties. This observation highlights the fact that considerable optimizations of the dithienophosphole system's optoelectronic properties are possible through these simple chemical modifications, or combinations of simple chemical modifications. This method has recently been extended to provide access to 2,6-dibromo-dithienophospholes oxides **20e** (Scheme 8) as well.[34g] Most importantly, in terms of the potential for the use of this system in future optoelectronic materials, is the fact that the bromo functionalities allowed for the incorporation of the dithieno-phosphole system into polymeric materials,[34f] and well-defined oligomers through palladium-catalyzed cross-coupling reactions (vide infra).[34g]

The introduction of Lewis acidic boron centers to the thiophene rings of the dithienophosphole system was possible using a different strategy. Lithiation of the 2- and 6-positions of the unsubstituted dithienophosphole **19a** with LDA, followed by addition of two equivalents of isopropoxy(pinacol)borane resulted in the formation of the boryl-functionalized dithienophosphole **19f** (Scheme 9).[34d] Similarly to other dithienophospholes, boryl-substituted compound **19f** displays blue luminescence, and the emission wavelength ($\lambda_{em}$ = 419 nm) is not significantly different from those displayed by dithienophospholes bearing electron-accepting silyl groups on the thiophene rings ($\lambda_{em}$ = 420–422 nm).[34a,34b,34e]



Scheme 9. Boryl-functionalized dithienophospholes – sensory materials (bottom left: **20f** - without fluoride, bottom right: **30** - with fluoride).

As a result of the high affinity of Lewis acidic boron centers for fluoride anions, the development of an effective sensory material based on the dithienophosphole system was possible.[34d] The fluorescence spectrum of the oxidized, air and moisture stable compound **20f** displays the expected red shifts in both the absorption and emission wavelengths ($\Delta\lambda_{max}$ = 22 nm, $\Delta\lambda_{em}$ = 33 nm) consistent with the increased electron-acceptor character of the phosphorus center upon oxidation. Treatment of **20f** with $Bu_4NF$ results in the formation of the ionic borate-functionalized dithienophosphole **30** (Scheme 9).[34d] The ionic borate species **30** displays significantly red-shifted absorption ($\lambda_{max}$ = 415 nm) and emission wavelengths ($\lambda_{em}$ = 485 nm) relative to its neutral borane-functionalized precursor **20f**. In fact, the emission of the compound now occurs in the blue-green region of the visible spectrum, allowing for naked-eye detection of fluoride ions under UV light. These changes in the fluorescence spectrum upon addition of fluoride can be detected at the ppm scale. Addition of $Bu_4NCl$, $Bu_4NBr$, or $Bu_4NI$ however, results in no change to the fluorescence

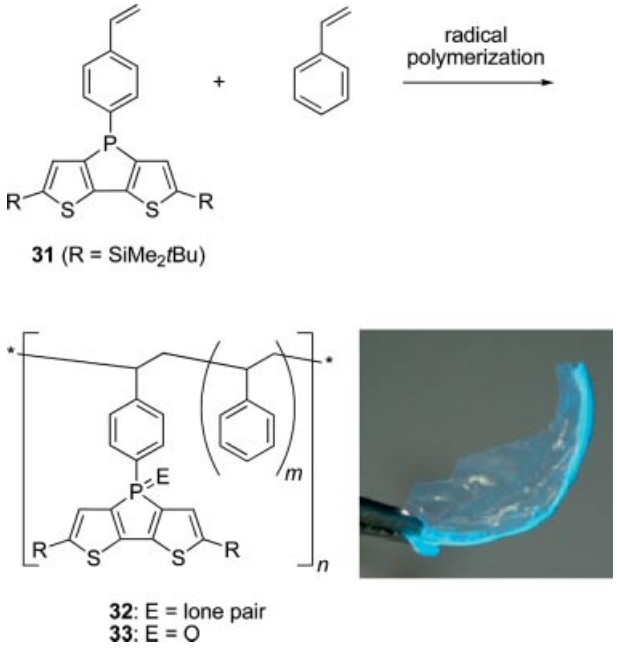
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

properties of the borane-functionalized dithienophosphole **20f**, consistent with the high selectivity of the boron centers for fluoride ions. As a result, the borane-functionalized dithienophospholes **19f** and **20f** function as useful, selective, and potentially quantitative sensory materials for fluoride ions.[34d]

### 3.3 Dithienophosphole Polymers

Polymeric materials based on the dithieno[3,2-*b*:2′,3′-*d*]-phosphole scaffold have been prepared with the aim of combining the favorable optoelectronic properties displayed by the monomers, with the desirable properties, such as processability (e.g. as thin films) displayed by macromolecular systems.[1] Additionally, oligomers and polymers incorporating the dithienophosphole moiety directly into the conjugated backbone may display additional delocalization between π-conjugated subunits, resulting in optimization of the material's bandgap and further tuning of the material's optoelectronic properties.

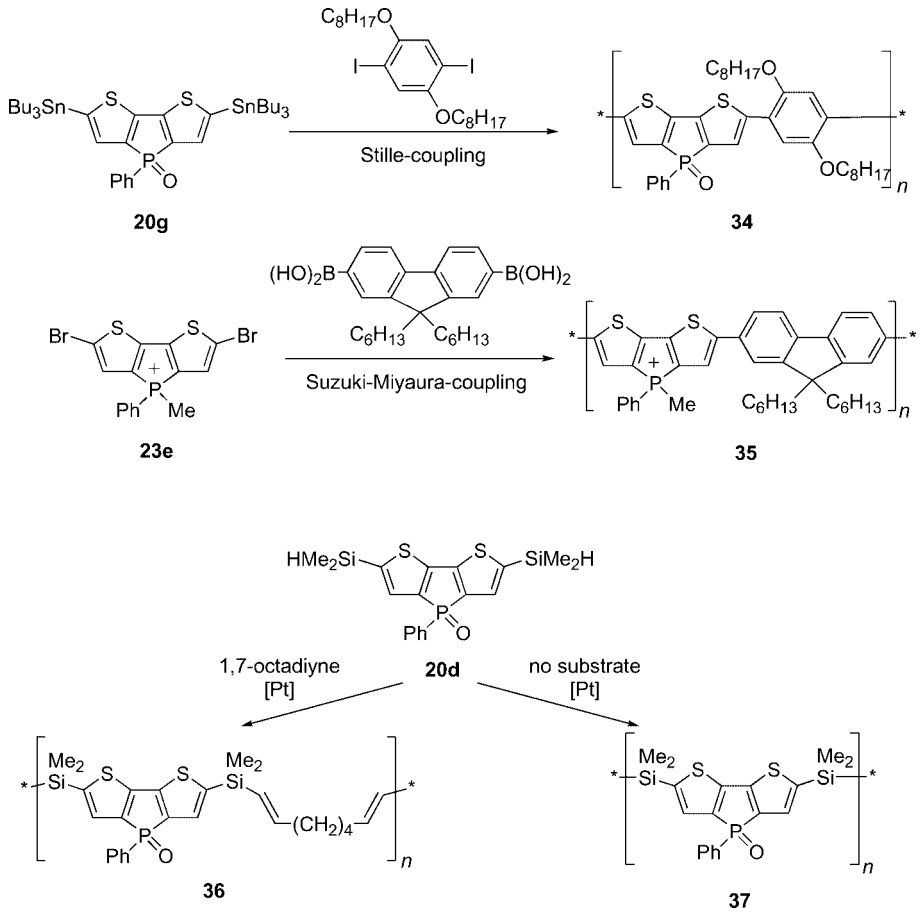
The introduction of a 4-vinylphenyl substituent at the phosphorus center of **31** allowed for the incorporation of the dithienophosphole scaffold into a polymeric system as a side-chain functionality.[34a] Radical polymerization of **31** in the presence of styrene in varying ratios provided polymers such as **32** as white amorphous solids (Scheme 10). Gel permeation chromatography (GPC) revealed a high molecular weight of $M_n$ = 147650 g mol$^{-1}$, and a polydispersity (PDI) of 2.46 for a copolymer with a 1:30 (**31**/styrene) ratio. Differential scanning calorimetry (DSC) analysis of the copolymer **32** revealed other favorable properties of the material, such as a glass transition temperature $T_g$ = 114.2 °C superior to that of polystyrene, and a high thermal decomposition temperature of $T_d$ = 428.2 °C. As expected the favorable optoelectronic properties of the dithienophosphole monomers were preserved in the copolymer **33**, which displayed absorption and emission wavelengths ($\lambda_{max}$ = 352 nm, $\lambda_{em}$ = 424 nm) nearly identical to those of the monomeric dithienophosphole **31** ($\lambda_{max}$ = 352 nm, $\lambda_{em}$ = 422 nm). Additionally, the exceptional photoluminescence efficiency of the monomers was preserved with the copolymer displaying a high photoluminescence quantum yield ($\phi_{PL}$ = 74.3%). Oxidation of the phosphorus centers is accomplished by reaction of **32** with $H_2O_2$. As was observed with the dithienophosphole monomers, oxidation of the phosphorus center results in a significant red shift in the optical spectra of the air-stable oxidized polymer **33** ($\Delta\lambda_{max}$ = 22 nm, $\Delta\lambda_{em}$ = 34 nm) relative to their $\sigma^3$-phosphole-containing analogs **32**. In order to probe the potential of the obtained copolymers as PLED materials, thin films of the copolymers were prepared. The thin film of the $\sigma^3,\lambda^3$-dithienophosphole copolymer **32** displayed red shifts in both its excitation and emission wavelengths ($\lambda_{max}$ = 374 nm, $\lambda_{em}$ = 452 nm), while surprisingly the $\sigma^4,\lambda^5$-dithienophosphole copolymer **33** displayed a slightly blue-shifted absorption ($\Delta\lambda_{max}$ = –2 nm), and a significantly blue-shifted emission ($\Delta\lambda_{max}$ = –22 nm). Both the oxidized and the non-oxidized copolymers displayed good light stability, with decreases in emission intensity of less than 5% following two hours irradiation. As a result of these favorable properties, the incorporation of the obtained copolymer into functional optoelectronic devices may be possible.



Scheme 10. Incorporation of the dithienophosphole system into polystyrene as a side-chain functionalization; right: thin film of the polymer **32**.

Recently, several copolymers containing the dithieno[3,2-*b*:2′,3′-*d*]phosphole moiety in the polymer backbone have also been prepared (Scheme 11).[34b,34e,34f] Consequently, conjugation between monomers, or comonomers may be possible, resulting in further optimization of the optoelectronic properties of the resulting dithienophosphole materials. The ability to introduce a variety of functionalities at the 2- and 6-positions of the thiophene rings of the dithienophosphole system has allowed for the preparation of a variety of copolymers using different coupling protocols. The incorporation of stannyl groups on the thiophene rings allowed for the preparation of a copolymer using Stille cross-coupling methods.[34b] Stille coupling of the oxidized stannyl-substituted dithienophosphole **20g** with 1,4-diiodo-2,5-bis(octyloxy)benzene as the aryl halide component resulted in the formation of a reddish-brown, poorly soluble material **34**. Suzuki–Miyaura coupling was used to obtain a copolymer from dithienophospholium monomers bearing bromo functionalities (**23e**) and a suitable fluorene-bis(boronic) acid.[34f] The obtained yellow copolymer was sufficiently soluble to allow for its analysis using GPC. This analysis revealed a molecular weight $M_w$ = 9800 g mol$^{-1}$, and a *PDI* of 1.70. A dibromo-functionalized dithienophosphole oxide has recently been subjected to similar reaction conditions, resulting in the formation of an insoluble dithienophosphole-fluorene copolymer.[34g] The insolubility of this material prevented a full characterization, however, the red shifts observed in its optoelectronic properties relative

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 11. Preparation of polymers containing the dithienophosphole system in the polymer backbone.

to those of the dibrominated precursor supported the successful copolymerization. The introduction of borane ester substituents in dithienophosphole **20f** should also allow for the copolymerization of this compound using Suzuki–Miyaura protocols, however to date, attempts to do so have resulted in the regeneration of the parent dithienophosphole **20a**.[34g]

Platinum-catalyzed hydrosilation has also been used to obtain copolymers from an α,ω-bis(alkyne) (1,7-octadiyne) and oxidized dimethylsilyl-substituted dithienophospholes **20d**.[34e] The use of PtDVDS ("Karstedt catalyst") resulted in conversion to the polymeric material **36**. GPC analysis of the obtained oily **36** revealed molecular weights up to $M_w$ = 8000 g mol$^{-1}$. When a similar hydrosilation reaction was attempted using an alkene (cf. alkyne) substrate with the same catalyst system, a surprising result was obtained. Instead of the expected 1,2-addition of silicon and hydrogen to the alkene, dehydrogenative homocoupling of the dimethylsilyl groups was observed, producing a polymer **37** in which the dithienophosphole moieties are linked directly by disilanylene groups.[34e] The formation of this product was also observed in the absence of alkene substrates confirming that the alkenes were not involved in its generation. The disappearance of the Si–H signal and the presence of two sets of $^{29}$Si satellites in the methyl proton signal ($^2J_{Si-H}$ = 25.4 Hz, $^3J_{Si-H}$ = 17.2 Hz) of the product's $^1$H NMR spectrum were particularly supportive of such a dehydrogenative Si–Si homocoupling. GPC analysis of the obtained polymer **37** revealed molecular weights up to $M_w$ = 10000 g mol$^{-1}$. This quantitative dehydrocoupling of a tertiary silane is unprecedented to date. The optoelectronic properties of the copolymer **36** ($\lambda_{max}$ = 378 nm, $\lambda_{em}$ = 460 nm) are not significantly different from those displayed by the corresponding monomer **20d** ($\lambda_{max}$ = 383 nm, $\lambda_{em}$ = 457 nm), indicating that the conjugated π system of the dithienophosphole is not significantly extended as a result of copolymerization. Similarly, the emission of the homopolymer **37** ($\lambda_{em}$ = 459 nm) is almost identical to that of the monomer, while the absorption experiences a slight red shift ($\Delta\lambda$ = 10 nm) relative to the dithienophosphole monomer **20d**. These observations are in line with the earlier observation that modification of the silyl substituents in dithienophospholes results in slight changes to the compound's absorption properties, but not to its emission wavelength.[34b] Both silicon-containing dithienophosphole polymers **36** and **37** display good emission intensities, and photoluminescence quantum yields of ca. 56%,[34e] in line with the preservation of the favorable optoelectronic properties of the monomers in the macromolecular systems.

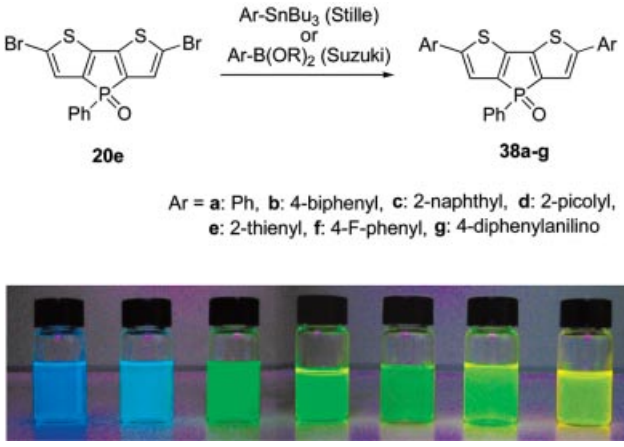
In contrast to the silicon-containing dithienophosphole polymers **36** and **37**, those obtained through coupling reactions of the dithienophospholes and suitable aryl copoly-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mers **34** and **35** display optoelectronic properties, with emissions and absorptions that are significantly different from those of the corresponding monomers.[34b,34f] These polymers contain an exclusively π-conjugated backbone, containing the dithienophosphole moiety. As a result, narrowing of the polymer's optical HOMO–LUMO gap and a corresponding red shift in the absorption and emission wavelengths of the macromolecular systems relative to the monomeric compounds was anticipated. Indeed, the emission of the polymer **35** obtained by Suzuki–Miyaura coupling with a fluorene copolymer displays a visibly red-shifted emission, now appearing in the yellow-green region ($\lambda_{em}$ = 509 nm) of the visible spectrum (cf. the blue emission at $\lambda_{em}$ = 467 nm of the corresponding monomer **23e**).[34f] The absorption wavelength of the polymer ($\lambda_{max}$ = 485 nm) is also significantly red-shifted relative to that of the monomer ($\lambda_{max}$ = 376 nm). The photoluminescence quantum yield of polymer **35** ($\phi_{PL}$ = 47.0%) is in the same range as those reported for the dithienophosphole monomers.[34f] Although poor solubility prevented a full characterization of the copolymer **34** obtained by Stille coupling of the stannyl-functionalized dithienophosphole **20g** with an aryl halide,[34b] the obtained product displayed significantly red-shifted optoelectronic properties. The yellow emission of compound **34** at $\lambda_{em}$ = 555 nm is the most strongly red-shifted emission reported to date for polymeric materials derived from the dithieno[3,2-*b*:2,3-*d*]phosphole system. A red shift of similar magnitude is also observed in the excitation wavelength of polymer **34** ($\Delta\lambda_{max}$ = 123 nm). These results are indicative of a strongly extended π conjugation in both of the polymers discussed. As a result, dithienophosphole polymers **34** and **35**, containing exclusively π-conjugated backbones display highly intriguing optoelectronic properties, making them promising materials for future optoelectronic applications. The ionic nature of the methylated dithienophosphole fluorene copolymer **35** in particular, makes this material appealing for potential applications as a conjugated polyelectrolyte (CPE).[1]

### 3.4 Extended Dithienophosphole Molecules

To date, the emission of molecular dithieno[3,2-*b*:2′,3′-*d*]-phosphole systems has been largely limited to the blue region of the visible spectrum ($\lambda_{em}$ = 408–495 nm).[34] As was seen with Réau's system, the extension of the conjugated π system in well-defined oligomers, allows for further optimization of the bandgaps in the resulting materials. In principle, this strategy should allow access to well-defined species capable of displaying emission over a much larger range, depending on the π-conjugated system's degree of extension. Very recently, the use of 2,6-dibromodithienophosphole oxide **20e**, allowed for the incorporation of a wide variety of aryl substituents at the 2- and 6-positions of the dithienophosphole via palladium-catalyzed C–C coupling processes (Scheme 12).[34g] Stille and Suzuki–Miyaura cross-coupling protocols allowed for the preparation of a number of 2,6-diaryl-substituted dithienophospholes **38a**–**g**, displaying significantly extended π-conjugated systems (Scheme 12). Indeed the visible shift from blue-green to yellow-orange fluorescence emission could be observed in the cross-coupling reaction mixtures over the course of the reactions. The complete results of this study will be presented in a forthcoming publication.[34g] The effect of extended π conjugation on the optoelectronic properties of the resulting materials was investigated by incorporating aryl substituents displaying increasing conjugated paths. In line with the conclusion that extension of the conjugated path results in decreased HOMO–LUMO gaps, increasing red shifts in the optoelectronic properties of the products were observed with increasing conjugated path length in the aryl substituents. The effect of electron-rich, and electron-deficient aryl and heteroaryl substitution was also examined. The incorporation of thienyl groups (**38e**) was once again demonstrated to result in more favorable optoelectronic properties in the resulting materials, in line with the prediction that thienyl substituents are subject to a more favorable orbital interaction with phosphole moieties, resulting in decreased HOMO–LUMO gaps in the corresponding materials.[17]



Scheme 12. Synthesis of well-defined, extended dithienophospholes with different emission colors.

The most significant red shift in the optoelectronic properties of the dithieno[3,2-*b*:2′,3′-*d*]phosphole system observed to date arises as a result of the incorporation of 4-diphenylanilino substituents at the 2- and 6-positions of the thiophene rings (**38g**). This compound displays a bright orange emission ($\lambda_{em}$ = 566 nm), and a remarkably red-shifted absorption ($\lambda_{max}$ = 527 nm). When compared with the blue emission of the parent dithienophosphole **19a** ($\lambda_{em}$ = 415 nm), this observation illustrates the versatile nature of the dithienophosphole system, and as a result the wide range of properties accessible through this system.

## 4. Conclusions

The incorporation of phosphole moieties into π-conjugated oligo- and polythiophenes has resulted in the development of new materials displaying fascinating properties. Both the 2,5-bis(2′-thienyl)phosphole, and the dithieno[3,2-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*b*:2′,3′-*d*]phosphole systems have proven to be versatile scaffolds as a result of the various manners in which their frameworks may be modified. Firstly, the nature of the exocyclic phosphorus substituents has profound effects on the stabilities of the obtained materials in both scaffolds. The properties of the obtained materials were also shown to be highly dependant on the nature of the 2,5-aryl substituents in Réau's diarylphosphole system, and the nature of the substituents at the 2- and 6-positions of Baumgartner's dithienophosphole system. In many respects diarylphospholes bearing thienyl substituents displayed superior properties relative to phospholes bearing alternative aryl, or heteroaryl substituents. Well-defined oligomers displaying additional π conjugation relative to the corresponding monomers have been prepared for both systems, potentially serving as useful models for larger macromolecular systems. Both families of compounds have been incorporated into such macromolecular systems, either as side-chain functionalities, or as subunits within the conjugated path. Of paramount importance in both scaffolds, the presence of a reactive trivalent phosphorus center allows for a variety of facile, quantitative chemical modifications (oxidation, complexation, methylation) to be performed. These modifications often result in significant changes to the properties of the obtained materials. As a result, large families of compounds, displaying novel properties may be prepared from single precursors. These modifications have been extended from the molecular level to the macromolecular level, allowing for a variety of postfunctionalizations of the obtained polymeric materials. Due to their intriguing properties, both phosphole-containing oligothiophene systems serve various functions in different applications: chemosensors for fluoride anions have been prepared using molecular dithienophospholes, while polymeric 2,5-dithienylphospholes were used in the development of the first polymeric chalcogen sensor. Recently, the fascinating emissive properties of the 2,5-dithienylphosphole system allowed for its incorporation in the first functional OLEDs based on organophosphorus materials. Although it is acknowledged that the study of organophosphorus π-conjugated materials such as the 2,5-diarylphosphole, and the dithieno-phosphole systems examined remains in its infancy, these promising systems represent key developments towards maturity in this field, and the development of new functional devices based on organophosphorus π-conjugated materials.

# Activated Aryl Chlorides: Useful Partners for the Coupling with 2-Substituted Thiazoles in the Palladium-Catalysed C-H Activation/Functionalisation Reaction

**Aditya L. Gottumukkala[a] and Henri Doucet*[a]**

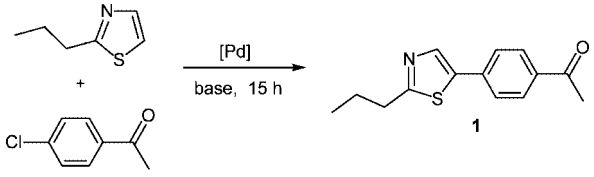
**Keywords:** Aryl chlorides / Catalysis / C-H activation / Palladium / Thiazoles

Aryl chlorides are noticeably uncommon partners in coupling reactions with heteroaromatics through C-H activation. We report herein that as little as 1 mol-% of the air-stable PdCl(dppb)($C_3H_5$) complex catalyses the direct coupling of electron-deficient aryl chlorides with 2-substituted thiazole derivatives. A range of functionalities on the aryl chloride such as acetyl, formyl, ester, nitro, nitrile or trifluoromethyl is tolerated.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Arylthiazole derivatives are important building blocks in organic synthesis.[1] Palladium catalysed Suzuki, Stille or Negishi cross-coupling reactions are probably the most important methods for the synthesis of such compounds.[1–4] However, these reactions require the preparation of an organometallic derivative and they provide an organometallic salt (MX) as a byproduct.

Over the last few years, very interesting results for the coupling of aryl bromides or iodides with thiazole derivatives by C-H activation have been reported and provide an economically and environmentally attractive procedure for the preparation of such compounds.[5] So far, most of the results described for this reaction were obtained with reactive, but expensive aryl bromides[6] or iodides.[7] The use of chloride substrates for cross-coupling reactions with thiazoles by C–H bond activation (Scheme 1) would be a considerable advantage for sustainable development because of their lower cost, lower mass and the wider diversity of available compounds.[8–11] However, for this coupling, aryl chlorides are noticeably uncommon partners. This is due to the fact that chlorides were generally found to be unreactive under the experimental conditions employed to activate iodide and bromide analogues. In most cases, for Suzuki, Heck or Sonogashira reactions aryl chlorides were activated using electron-rich, sterically hindered, monodentate phosphane ligands associated to palladium.[11a] Moreover, in most cases, the direct coupling of aryl chlorides with heteroaromatics such as pyridines, thiophenes or thiazoles were performed with the use of relatively large amounts of palladium or ruthenium catalysts (2.5–10 mol-%).[7–10,12] Therefore, the discovery of more effective conditions, with the use of a lower catalyst loading for the coupling of thiazoles with these challenging substrates is still subject to significant improvement.



Scheme 1.

Monophosphane ligands associated to palladium were successfully used for the direct coupling of thiazoles derivatives with aryl bromides or iodides,[5] but the efficiency of bidentate phosphane ligands for such a coupling reaction has attracted less attention.[7c] In the literature, most of the couplings of heteroaryl derivatives with aryl halides were performed at elevated temperatures (140–150 °C).[5] At these temperatures, fast decomposition of the palladium complexes associated to monophosphane ligands generally occurs. In some cases, the use of polydentate ligands seems to increase the stability and longevity of the catalyst, so we could expect better conversions of aryl chlorides by using bidentate ligands.[13]

## Results and Discussion

First, we examined the efficiency of $[PdCl(C_3H_5)]_2$ associated to mono- or bidentate ligands on the yield of the direct coupling of 4-chloroacetophenone with 2-*n*-propylthiazole (Scheme 1, Table 1). $[PdCl(C_3H_5)]_2$ associated to

[a] Yield in parenthesis is isolated yield. [b] The formation of side products was also observed. [c] Reaction performed in an autoclave.

the dppe or 1,1′-dppf ligands led to low conversions of 41 and 10%, respectively (Table 1, Entries 1 and 2). On the other hand, we observed that with $PdCl(C_3H_5)(dppb)$[14] as the catalyst, dmac as the solvent, AcONa as the base and heated 150 °C, 5-(4-acetylphenyl)-2-propyl-thiazole (**1**) was obtained with 72% conversion (Table 1, Entry 3). The dppb ligand is known to give sterically more hindered complexes than those of 1,1′-dppf or dppe. By using $PPh_3$ as the ligand, the formation of **1** was observed in 58% conversion together with the formation of a side product (Table 1, Entry 4). The palladium source also has a large influence on the yield. The use of $Pd(OAc)_2$ led to reactions with lower yields than those with $[PdCl(C_3H_5)]_2$ (Table 1, Entries 7 and 8). Pd/C or $Pd(OH)_2/C$ was found to be almost completely ineffective for this coupling (Table 1, Entries 5 and 6). Then, the influence of several parameters such as the base, solvent and temperature with the use of $PdCl(C_3H_5)(dppb)$ as the catalyst was examined. AcOK also led to a high yield of **1** (Table 1, Entry 9). By using carbonates or KF as bases, lower conversions were obtained (Table 1, Entries 10–12). The influence of a few other solvents such as dmf, dmso, nmp, dioxane or xylene was also examined, but in all cases, low conversions were observed (Table 1, Entries 13–17). An elevated reaction temperature (150 °C) was necessary to obtain a high yield of the product. At 130 °C, a lower conversion of 32% was obtained. On the other hand, a very high reaction temperature led to a very low conversion of 6%. This is probably due to faster decomposition of the catalyst (Table 1, Entries 18 and 19).

Then, the scope and limitations of this reaction by using $PdCl(dppb)(C_3H_5)$ in dmac with AcOK or AcONa as bases at 150 °C was investigated (Scheme 2, Table 2). The reaction

Table 2. Palladium catalysed cross-coupling with thiazole derivatives (Scheme 2). Conditions: $PdCl(dppb)(C_3H_5)$ see ref.[14], ArCl (1 equiv.), thiazole derivative (2 equiv.), AcOK or AcONa (4 equiv.), dmac, 150 °C, 15 h, GC and NMR yields.

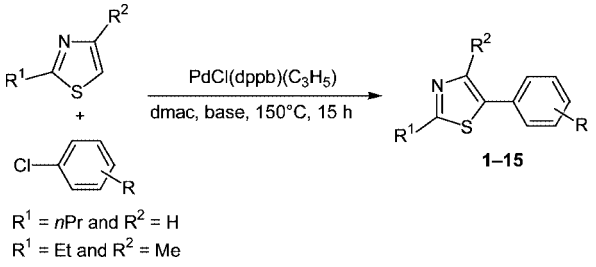
proceeds nicely with several *para*-substituted aryl chlorides. Electron-withdrawing groups in the aryl chlorides are favourable, whereas an electron-donation group is unfavourable. For example, the coupling with 4-chlorobenzaldehyde, methyl 4-chlorobenzoate, 4-chlorobenzonitrile or 4-chloronitrobenzene gave the corresponding 5-aryl-2-*n*-propylthiazoles **2**–**6** in good yields (Table 2, Entries 1–6). On the other hand, poorly activated 4-chlorofluorobenzene was recovered unreacted (Table 2, Entry 7). This result seems to indicate that with this catalyst the oxidative addition of the aryl chloride to palladium is the rate-limiting step of the catalytic cycle. As expected, quite similar reactivity was obtained by using *meta*-substituted 3-chlorobenzonitrile (Table 2, Entry 8). Sterically congested *ortho*-substituted aryl chlorides gave low-to-high yields of **8**–**10**, depending on the substituents (Table 2, Entries 9–12).



Scheme 2.

Finally, the coupling in the presence of the sterically more-hindered 2-ethyl-4-methylthiazole was studied. 2-Ethyl-5-aryl-4-methylthiazole derivatives **11**–**15** were obtained selectively in moderate-to-high yields (Table 2, Entries 13–17).

## Conclusions

In the presence 1 mol-% of the air-stable PdCl(dppb)($C_3H_5$) complex, the direct arylation of 2-substituted thiazole derivatives with the use of aryl chlorides proceeds in moderate-to-high yields. The structure of the ligand, palladium source and reaction conditions have a large influence on the yields. With this system, only electron-deficient aryl chlorides gave satisfactory results. However, it should be noted that a wide range of functionalities such as acetyl, formyl, ester, nitro, nitrile or trifluoromethyl on the aryl chloride is tolerated. This procedure is very simple, economically attractive and uses commercially available ligand and catalyst precursors. The air-stability of the catalyst and ligand make this procedure more convenient than those using bulky electron-rich phosphanes that are often employed to activate aryl chlorides in palladium-catalysed reactions.[11]

## Experimental Section

As a typical experiment, a mixture of 4-chloroacetophenone (0.154 g, 1 mmol), 2-*n*-propylthiazole (0.254 g, 2 mmol) and AcOK (0.392 g, 4 mmol) was heated at 150 °C for 15 h in dry dmac (5 mL) in the presence of PdCl(dppb)($C_3H_5$)[14] (6.1 mg, 0.01 mmol) under an atmosphere of argon. After extraction with dichloromethane, evaporation and filtration through silica gel (pentane/ether) corresponding product **1** was obtained in 53% (0.129 g) isolated yield as an oil. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 7.96 (d, $J$ = 8.5 Hz, 2 H), 7.92 (s, 1 H), 7.60 (d, $J$ = 8.5 Hz, 2 H), 2.99 (t, $J$ = 7.4 Hz, 2 H), 2.60 (s, 3 H), 1.85 (sext., $J$ = 7.4 Hz, 2 H), 1.03 (t, $J$ = 7.4 Hz, 3 H) ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 197.1, 172.1, 138.9, 137.1, 136.2, 136.1, 129.1, 126.3, 35.6, 26.6, 23.3, 13.6 ppm. $C_{11}H_9NOS$ (203.12): C 65.00, H 4.46; found C 64.75, H 4.76.

# Synthesis and Crystal Structure of a Heptanuclear and an Octanuclear Copper(II) Complex Derived from α-D-Glucofuranoses

**Michael Gottschaldt,*[a] Rainer Wegner,[b] Helmar Görls,[b] Ernst-G. Jäger,[a][†] and Dieter Klemm[a]**

**Keywords:** Carbohydrates / Copper complexes / Cluster compounds

$Cu^{II}$ complexes of different 6-(β-keto-enamino)-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranoses **3a–f** have a high tendency to build up oligonuclear clusters. Two new oligonuclear copper(II) complexes could be synthesised, crystallised and their structures determined. The complex **Cu(3a)** was found to consist of a heptanuclear cluster in which two β-cubane like substructures share one copper ion. The structure is highly asymmetric and in the cluster every $Cu^{II}$ ion has a different coordination geometry. Variation of the residues of the β-ketoenaminic unit leads to the formation of the octanuclear copper(II) complex **Cu(3e)**. Similarly, this has two β-cubane subunits consisting of a heptanuclear structure with an additionally attached copper ion. In the crystal, two $Cu_8$ cluster molecules are found differing in their geometries due to intermolecular interactions responsible for the formation of a supramolecular network.

## Introduction

While there are a number of structurally characterised octanuclear copper clusters, examples of heptanuclear species rarely feature in the literature although recently a few compounds were synthesised and their properties determined. By complexation of 2,4,6-triallyloxy-1,3,5-triazin with CuCl or $CuCl_2$, $Cu_7$ and $Cu_8$ clusters could be isolated.[1] A dimeric tetradecanuclear copper macrocyclic complex with a heptanuclear core structure derived from 2,6-diaminomethyl-4-methylphenol and copper acetate could be synthesised and structurally characterised.[2] Heptanuclear copper subunits have been found in metal-organic frameworks comprised of 1,2,4-triazoles.[3] Addition of ethylenediamine to a D-mannopyranose containing Fehling's solution leads to a heptanuclear $Cu^{II}$ complex.[4] Further, linear "tritopic" ligands have been found to assemble copper complexes with higher orders of oligomerisation[5] such as ferromagnetic $Cu_8$ pinwheel clusters.[6] Copper(II) salts form with *N*-(2-pyridylmethyl)acetamide,[7] *N*-propyamine[8] or dipyridyl ketone and 2-hydroxypyridine[9] $Cu_8$-clusters. Octanuclear metallamacrocyclic complexes have been synthesised from the pentadentate trianionic Schiff base ligand *N*,*N*′-(2-hydroxypropane-1,3-diyl)bis(salicylaldimine)[10] or ditopic thiocarbohydrazones.[11] Efficient cleavage of supercoiled DNA in the presence of $H_2O_2$ was observed for an octanuclear copper(II) complex.[12] Derived from cytidine,[13] dithiocarbamates,[14] bis(diphenylphosphanyl)amide and

$(Me_3Si)_2Se$[15] and methylsiloxane[16] different supramolecular arrangements of $Cu_8$ clusters have been be obtained. As a building block for the synthesis of heterobimetallic complexes, an octanuclear cubic copper(I) complex, exhibiting six free peripheral coordinating sites, was synthesised from 4,5-diazafluorene.[17]

Our attempts to build up oligonuclear copper complexes of β-ketoenaminic ligands based on amino carbohydrates led to very effective catalysts for the oxidation of 3,5-di-*tert*-butylcatechol.[18] Depending on the amino carbohydrate used, different types of oligomerisation could be observed. Compounds derived from 6-amino-6-deoxy-1,2,3-tri-*O*-methyl-α-D-glucopyranosides **1a**–**f** form trinuclear copper(II) complexes[19] and with 5-amino-5-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranoses of type **2a**–**f** as the sugar backbone very stable dinuclear complexes could be obtained.[20] However, simply changing the position of the amino group starting from 6-amino-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranoses **3a**–**f** lead to the formation of oligonuclear $Cu^{II}$ complexes (Scheme 1). The structures of these complexes from **3a**–**f** were very difficult to assign because of their size and their lack of suitability for NMR spectroscopy. They differ depending on the residues $R^1$ and $R^2$, the copper(II) salt used for complexation and the reaction conditions.

## Results and Discussion

By variation of the reaction conditions and after continual attempts at crystallisation, we were able to obtain crystals of the $Cu^{II}$ complexes derived from the ligands **3a** and **3e** which were suitable for single crystal X-ray structure analysis (Figure 1).

### Synthesis and Crystal Structure of Cu(3a)

Reaction of **3a** with $Cu(OAc)_2$ in a toluene/methanol mixture with an excess of triethylamine leads to the formation of **Cu(3a)**. The dark green powder obtained could be crystallised from benzene/methanol to give green crystals suitable for single-crystal X-ray structure analysis (Table 1). In the heptanuclear complex, two doubly deprotonated ligand molecules one of which acts as a tridentate ligand (D), one as a tetradentate ligand (A) and three triply deprotonated ligand molecules acting as tetradentate ligands (B, C, E) are enclosed (Figure 1, a). The Cu atom labeled Cuc is further coordinated by a 2,4-pentandionate ion which is formed from a ligand molecule during synthesis. The composition of the compound is therefore $[Cu_7(\eta^4\text{-}\mathbf{3a})_3(\eta^4\text{-}H\mathbf{3a})(\eta^3\text{-}H\mathbf{3a})(acac)]$. The elemental unit contains additional solvent molecules. The structure can be described as consisting of two β-type cubane-like cluster which share the copper atom labeled Cug. The bridging ligand atoms between the copper centres are the alkoxido oxygen atoms O2a–O2e, O6b, O6c and O6e. The triply deprotonated ligands B, C and E are coordinated to the copper atoms Cub, Cud and Cuf, while the doubly deprotonated ligands A and

D are coordinated to the copper atoms Cua and Cue (Figure 2). The central copper atom Cug is surrounded by the alkoxido oxygen atoms in the 3-position of the tetradentate ligands and the corresponding alkoxido groups in the 5-position. The coordination geometry is therefore octahedral. Cuc bears the acetylacetonate ligand and is incorporated into the cubane structure by the oxygen atoms O2a (5-position of ligand A), O6c and O6e (3-position of ligands C and E). Its distorted octahedral coordination sphere is completed by the hydroxido oxygen atom O6a (3-position of ligand A). All other copper atoms are five-coordinate. Cua, Cub, Cud and Cue are surrounded by the carbonyl (O1) and 5-alkoxido oxygen (O2) atoms and the enaminic nitrogen atom of their own ligands (A, B, C and D). The fourth coordination position in the plane of the square-pyramidal geometry is occupied by one of the 3-alkoxido oxygen atoms belonging to one of the tetradentate ligands in the neighbouring cubane subunit (Cua–O6e; Cub–O6c; CuD–O6b, Cue–O6b). The 5-alkoxido oxygen atom of the neighbouring ligand in the same cubane subunit is located in the axial position. The last copper atom Cuf bears the 5-alkoxido oxygen atom O2d instead of the 3-alkoxido oxygen atom. Its coordination geometry is much more distorted than the coordination spheres of the other five-coordinate copper atoms and can be described both as distorted square-pyramidal and trigonal-bipyramidal. Preliminary studies to determine the magnetic properties of **Cu(3a)** are included in the electronic supporting information.

### Synthesis and Crystal Structure of Cu(3e)

Heating ligand **3e** to reflux together with $Cu(OAc)_2$ and an excess of triethylamine in a mixture of toluene and hexane for several hours gives **Cu(3e)** as a dark green powder. The product was crystallised from acetone/diethyl ether to give crystals suitable for X-ray structure analysis. The compound crystallises in an orthorhombic space group and, besides several solvent molecules, the asymmetric unit of the unit cell contains two chemically identical clusters with the formula $[Cu_8(\eta^4\text{-}\mathbf{3e})_4(\eta^3\text{-H}\mathbf{3e})(OAc)(\mu\text{-}OAc)(H_2O)]$ shown in part b of Figure 1. There are only small differences in bond lengths and angles between the two cluster molecules (Table 2) so that the following copper atoms (and their ligand molecules) can be regarded as equivalent for the discussion of the structure: Cua–Cug, Cub–Cui, Cuc–Cuh, Cud–Cuj, Cue–Cuk, Cuf–Cul, Cu1–Cu2a and Cu2–Cu1a.

Seven of the eight copper atoms show similar arrangements to that of **Cu(3a)**. They form two heterocubane ($Cu_4O_4$) subunits which share one corner (Cu2). In contrast to this is the additional copper atom (Cua) which is bound to one of the cubane subunits by a bridging acetate ligand and by the second alkoxido oxygen atom (O3a) of its ligand molecule which binds to three copper atoms of the cubane subunit [O3a–Cu1 1.973(4) Å, O3a–Cub 2.399(4) Å, O3a–Cuc 2.066(4) Å]. The water oxygen atom occupies the axial position with a Cua–O9a bond length of 2.338(5) Å. Five copper atoms of the cluster carry their own ligand molecules (A–E) and the other three copper atoms (Cu1, Cu2

and Cuf) are surrounded by the bridging alkoxido groups of the ligands and by an acetate oxygen atom. Except for the central copper atom (Cu2) which has a distorted octahedral environment, each copper atom has five binding partners in a more or less distorted square-planar geometry. Cub and Cuc are bound directly to each other by the alkoxido oxygen atom O2b which occupies the axial position in the environment of Cuc with a (for this position) remarkably short bond length of 2.285(4) Å. The fourth equatorial position in the ligand sphere of Cuc is occupied by one alkoxido group (O3d) of the ligand D from the other cubane subunit. The same position can be found for this atom in the ligand sphere of Cub, whereas the axial position is occupied by O3a. Cu1 is one of the atoms without its own ligand molecule. It is surrounded by the oxygen of the bridging acetate ion (O11a) and four alkoxido oxygen atoms, O3a, O3d, O2c and O2b with each pair being in the 3- and in 5-positons of their ligands. The axial ligand is the alkoxido oxygen O2c [2.549(4) Å] which makes the cubane subunit of the so-called β-type with two parallel longer Cu–O bonds perpendicular to each other. The central copper atom Cu2 is surrounded by the six alkoxido oxygen atoms of the ligands B, C and D. In the second subunit of the cluster there are two copper atoms, Cud and Cue, with their own ligands. As for Cub and Cuc, the Cu–ligand monomers are bridged by the alkoxido atom O2e which originates from the axial ligand of Cud at a relatively short distance of 2.293(5) Å. The ligand sphere of Cuc is completed by the alkoxido oxygen atoms in the 3-positions of the ligands B and C from the other subunit, with O3c in the axial position [2.526(5) Å]. O3b is the last binding partner of Cud in the fourth equatorial position. The last copper atom of the cluster Cuf is surrounded by the two alkoxido groups in the 5-positons of the neighbouring ligand molecules D and E, O3c from ligand C of the other subunit and by the oxygen atom O3e of the neighbouring ligand E. This is the only hydroxido group which is not deprotonated in the complex since it is the only one not acting as a bridging ligand and forming a hydrogen bond with the carbohydrate ring oxygen atom O4e [O···O distance 2.883(5) Å].

The copper-bound water molecule containing O9a forms a hydrogen bond with the carboxylate oxygen atom O7k of the other octanuclear cluster [O9a···O7k 2.784(5) Å; $x$, $y + 1$, $z - 1$] and the diethyl ether oxygen atom O1 [O9a···O1 2.773(6) Å; $x$, $y + 1$, $z$]. The water molecule of the other cluster (O9g) forms a corresponding hydrogen bond with the next neighbouring complex [O9g···O7e 2.827(6) Å; $x$, $y - 1$, $z$] and one ethanol oxygen atom [O9g···O4 2.827 Å; $x$, $y - 1$, $z$]. These hydrogen bonds establish chains. The next step towards a 3D network results from the water molecule containing O6 which is found at a distance of 2.896(8) Å from O9g and the next symmetry equivalent O9g at $-x - 1$, $-y - z$, $z$.

Though the bond lengths and angles in the two cluster molecules are very similar (Table 2), least-squares plane calculations on the coordinate planes show further differences – not so much in the mean deviation from planarity and in the copper distance from the plane but in the angles between them. It is striking that the highest differences between the two cluster molecules is found for the Cuc and Cuh coordinate planes [angles with Cu1 and Cu2a 33.0(2)° and 78.6(2)°, Cua/Cug 21.2(2)° and 28.2(2)°, Cud/Cuj 111.5(2)° and 80.2(2)°, Cue/Cuk 26.4(2)° and 37.2(2)° and Cuf/Cul 112.2(2)° and 98.8(2)°, respectively]. This is coincidental with the fact that the peripheral carboxylate oxygen atom of the ligand of Cuh is involved in hydrogen bonding, whereas the corresponding oxygen atom belonging to the ligand of Cuc shows no intermolecular interaction. The angles between the two cubane subunits in each cluster, at 103.8(2)° and 105.8(2)°, differ from the ideal 90(2)° but much less so than in **Cu(3a)**.

## Conclusions

In summary, the use of β-ketoenaminic ligands derived from 6-amino-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose provides access to polynuclear copper(II) complexes with highly asymmetric structures. Complexation of 6-[(2,2-diacetylvinyl)amino]-6-deoxy-1,2-*O*-isopropylidene-α-D-glu-

cofuranose (**3a**) gives a heptanuclear cluster whereas 6-[(2-ethoxycarbonyl-2-phenylcarbonylvinyl)amino]-6-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranose (**3e**) leads to the formation of an octanuclear compound. The resultant structures provide insight into the coordination behaviour of this class of carbohydrate-based ligand.

## Experimental Section

**General Remarks:** All reagents and solvents were purchased from commercial sources and used as received. Electronic spectra were recorded with a Varian Cary 1 or Cary 5E spectrophotometer at room temperature. IR spectra were recorded on a Perkin–Elmer 2000 spectrometer; NMR spectra on a Bruker AC-200 instrument and mass spectra on a Finnigan MAT SSQ 710 or a Finnigan MAT 95XL TRAP machine. Elemental analyses were performed on a Leco CHNS 932.

**Heptacopper(II) Complex Cu(3a):** The ligand **3a** (0.5 mmol) and triethylamine (2 mmol) were heated to reflux together with copper(II) acetate monohydrate (0.6 mmol) in a 4:1 mixture of toluene/methanol (50 mL) for 4 h. The solution was filtered and the solvent evaporated. The residue was recrystallised from benzene/methanol to give dark green crystals suitable for X-ray structure analysis. IR (ATR): $\tilde{\nu}$ = 3372 (w), 2985 (w), 2936 (w), 2881 (w), 2845 (vw), 1645 (w), 1596 (vs), 1521 (s), 1442 (s), 1384 (vs), 1280 (s), 1214 (s), 1164 (w), 1066 (s), 1010 (s), 940 (s), 872 (s), 793 (w), 646 (s), 615 (w) cm$^{-1}$. UV/Vis (methanol): $\lambda_{max}$ = 269 (lg$\varepsilon$ = 4.8063), 304 (lg$\varepsilon$ = 4.5201), 654 nm (lg$\varepsilon$ = 2.8552). MS (ESI in methanol): *m*/*z* (%) = 2100 (3), [7 Cu] [$Cu_7L_5$ + Na]$^+$, 1648 (15), [5 Cu] [$Cu_5L_4$ + Na]$^+$, 1256 (100), [4 Cu] [$Cu_4L_3$ + Na]$^+$. $C_{80}H_{111}Cu_7N_5O_{37}$ [$Cu_7L_5$Acac] (2174.20): calcd. C 44.19, H 5.15, N 3.22; found C 44.26, H 5.54, N 3.39.

**Octacopper(II) Complex Cu(3e):** Ligand **3e** (290 mg, 0.69 mmol) together with $Cu(OAc)_2$ (125 mg, 0.69 mmol) and triethylamine (200 μL, 2.76 mmol) in 50 mL toluene/hexane, 4:1 were refluxed for 5 h. After cooling to room temperature the mixture was filtered, the solvent evaporated and the dark green powder dried. After several attempts the product could be crystallised from acetone/ether to give 105 mg (32%) of dark green crystals suitable for X-ray structure analysis. IR (ATR): $\tilde{\nu}$ = 3429 (vw), 2982 (w), 2937 (w), 1708 (vw), 1669 (s), 1620 (vs), 1568 (vs), 1554 (s), 1449 (s), 1415 (vs), 1382 (s), 1283 (s), 1262 (s), 1213 (s), 1164 (w), 1068 (s), 1010 (s), 732 (w), 699 (w), 642 (w), 617 (vw) cm$^{-1}$. UV/Vis (toluene): $\lambda_{max}$ = 299 (lg$\varepsilon$ = 4.4810), 320 (lg$\varepsilon$ = 4.4517), 615 nm (lg$\varepsilon$ = 2.6894). MS (ESI in Methanol): *m*/*z* (%) = 2618 (0.5) [8 Cu] [$Cu_8L_5$ + Na]$^+$, 2499 (1) [6 Cu] [$Cu_6L_5$ + Na]$^+$, 1994 (3) [5 Cu] [$Cu_5L_4$]$^+$, 1532 (20) [4 Cu] [$Cu_4L_3$ + Na]$^+$, 444 (100) [0 Cu] [L + Na]$^+$. $C_{109}H_{126}Cu_8N_5O_{44}$ [$Cu_8L_5(OAc)_2$] (2718.59): calcd. C 48.16, H 4.67, N 2.58; found C, 48.54; H 4.69; N, 2.64.

**X-ray Crystallographic Study:** The intensity data for the compounds were collected on a Nonius KappaCCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz and polarisation effects but not for absorption.[21,22] The structures were solved by direct methods (SHELXS[23]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELXL-97[24]). The hydrogen atoms of the structures were included in calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[16] XP (SIEMENS Analytical X-ray Instruments, Inc.) or ORTEP was used for structure representations.

CCDC-188438 (for **Cu(3a)**) and -188437 (for **Cu(3e)**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal Data for Cu(3a):** $C_{94}H_{129}Cu_7N_5O_{39}$, $M_r$ = 2397.80 g mol$^{-1}$, pink prisms, size 0.12 × 0.10 × 0.10 mm, orthorhombic, space group $P2_12_12_1$, $a$ = 19.12230(10), $b$ = 23.912(2), $c$ = 28.021(2) Å, $V$ = 12812.7(14) Å$^3$, $T$ = –90 °C, $Z$ = 4, $\rho_{calcd.}$ = 1.243 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 12.11 cm$^{-1}$, $F$(000) = 4972, 20404 reflections in $h$(–17/22), $k$(–24/24), $l$(–32/31), measured in the range 1.29° ≤ $\theta$ ≤ 24.44°, completeness $\theta_{max}$ = 72.1% (due to crystal decomposition), 13374 independent reflections, $R_{int}$ = 0.0707, 8979 reflections with $F_o > 4\sigma(F_o)$, 1232 parameters, 0 restraints, $R_{1obs}$ = 0.0854, $wR_{2obs}$ = 0.2178, $R_{1all}$ = 0.1184, $wR_{2all}$ = 0.2376, GOOF = 1.010, Flack parameter 0.02(2), largest difference peak and hole: 1.051 / –0.745 e Å$^{-3}$.

**Crystal Data for Cu(3e):** $C_{114.75}H_{144.5}Cu_8N_5O_{47.5}$, $M_r$ = 2862.17 g mol$^{-1}$, blue prisms, size 0.12 × 0.10 × 0.10 mm, orthorhombic, space group $P2_12_12$, $a$ = 28.205(6), $b$ = 45.281(9), $c$ = 21.342(4) Å, $V$ = 27257(9) Å$^3$, $T$ = –90 °C, $Z$ = 8, $\rho_{calcd.}$ = 1.395 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 13.06 cm$^{-1}$, $F$(000) = 11840, 70163 reflections in $h$(–36/33), $k$(–58/20), $l$(–25/24), measured in the range 1.31° ≤ $\theta$ ≤ 27.47°, completeness $\theta_{max}$ = 89.7%, 47879 independent reflections, $R_{int}$ = 0.0347, 37010 reflections with $F_o > 4\sigma(F_o)$, 3152 parameters, 0 restraints, $R_{1obs}$ = 0.0593, $wR_{2obs}$ = 0.1437, $R_{1all}$ = 0.0870, $wR_{2all}$ = 0.1610, GOOF = 1.048, Flack parameter 0.006(8), largest difference peak and hole: 1.049/–0.514 e Å$^{-3}$.

**Supporting Information** (see also the footnote on the first page of this article): Analytical data of **3a**, **3e**, selected crystal data for copper complexes, preliminary results of magnetic measurements for **Cu(3a)**.

# Kinetics of the Formation of $[Ln(DOTAM)]^{3+}$ Complexes

**Zsolt Baranyai,[a] István Bányai,[b] Ernő Brücher,*[a] Róbert Király,[a] and Enzo Terreno[c]**

**Keywords:** Macrocyclic ligands / Lanthanides / Kinetics / Reaction mechanisms

The kinetics of the formation of lanthanide(III) complexes of the neutral ligand DOTAM differ considerably from those of DOTA and its derivatives, which contain negatively charged pendant groups. Formation of the complexes $[Ln(DOTAM)]^{3+}$ occurs upon direct encounter of the $Ln^{3+}$ ions and the fully deprotonated ligand in the pH range 4.7–5.8. The formation of a protonated intermediate, which is characteristic of the complexation of DOTA and its derivatives, was not detected. General base catalysis is not valid in the formation reactions of $[Ln(DOTAM)]^{3+}$, which also indicates the absence of protonated intermediates. The rates of the proton-exchange reactions for the ligand species $H_2DOTAM^{2+}$ and $HDOTAM^{+}$ have been studied by $^1H$ NMR spectroscopy. Proton exchange was found to be a general base-catalysed process, therefore it cannot play an important role in the formation of these complexes. The second-order rate constants, $k_L$, which characterize the formation of the complexes $[Ln(DOTAM)]^{3+}$, are lower than the analogous rate constants reported for the $Ln^{3+}$ complexes of open-chain multidentate ligands by three to four orders of magnitude. These low $k_L$ values can be interpreted by assuming an early rate-determining step (probably the second or third $Ln^{3+}$–amide bond formation) in the reaction sequence that leads to the $[Ln(DOTAM)]^{3+}$ complex.

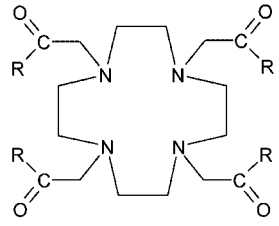
## Introduction

Lanthanide(III) complexes of the different tetraamide derivatives of DOTA (Scheme 1) have attracted considerable interest in recent years because of their promising applications in different fields of biological chemistry. Positively charged complexes {e.g. $[La(DOTAM)]^{3+}$}, for example, promote or catalyse rapid RNA cleavage and hydrolysis of some biopolymers (e.g. phosphate esters),[1–3] and complexes of $Eu^{3+}$ and $Yb^{3+}$ with DOTAGly, DOTAGly-Et and other DOTA tetraamide derivatives, have been proposed as chemical exchange saturation transfer (CEST) agents in magnetic resonance imaging.[4–8] Another possible field of application for the tetraamide derivatives is the development of luminescent sensors.[9,10]

The structure of the lanthanide(III) ($Ln^{3+}$) complexes formed with the DOTA tetraamide derivatives was found to be similar to that of $[Ln(DOTA)(H_2O)]^-$,[11] with the $Ln^{3+}$ ion occupying a position in the coordination cage formed by the four ring nitrogen atoms and four amide oxygen atoms, which form a square antiprism. A water molecule is coordinated to the $Ln^{3+}$ ion in a capping position.[1,2,12–16]



Scheme 1. Molecular structures of the ligands discussed.

The solution structure of the $Ln^{3+}$–DOTA tetraamide complexes has been studied by $^1H$, $^{13}C$ and $^{17}O$ NMR spectroscopy, and the lifetime of the inner-sphere water was found to be significantly higher than that of the complexes $[Ln(DOTA)(H_2O)]^-$.[12,16–19] The stability constants ($\log K_{ML}$) of the $Ln^{III}$ complexes formed with the DOTA tetraamide derivatives are about 10–15 orders of magnitude lower than the $\log K_{ML}$ values of the DOTA complexes.[2,15,20,21] However, the rates of the $Cu^{2+}$- and proton-assisted dissociation of the complexes $[Eu(DOTAM)]^{3+}$, $[Eu(DTMA)]^{3+}$ and $[Eu^{III}DOTTA]^{3+}$ are significantly lower than that of $[Eu(DOTA)]^-$.[1,12] The fairly large stability constants and the unusually high kinetic inertness of the complexes formed with the neutral DOTA tetraamide ligands is quite unexpected since $Ln^{3+}$ ions prefer ligands containing oxygen donor atoms with a negative charge. The moderate stability and high kinetic inertness of these complexes is probably the result of the good match between the size of the $Ln^{3+}$ ions and the preformed cavity of the neutral

ligands. The high thermodynamic and kinetic stabilities displayed by the $Ln^{3+}$ complexes of $DOTA^{4-}$ and its negatively charged derivatives can be accounted for not only in terms of the size matching between the $Ln^{3+}$ ions and the ligands but also the important role played by the electrostatic interactions. Thus, the study of the behavior of the DOTA tetraamide ligand DOTAM may give some new information about the kinetics and mechanisms of the reactions taking place between $Ln^{3+}$ ions and neutral macrocyclic ligands possessing a preformed cavity.

The formation of $Ln^{3+}$ complexes with DOTA tetraamide ligands takes place very slowly in aqueous solutions and, because of these slow reactions, the complexes in the solid state are often prepared in non-aqueous solution.[1,12–14] The kinetics of formation of the tetraamide complexes $[Ln(DOTAGly)]^-$ are very similar to those of $[Ln(DOTA)]^-$, as we have reported previously.[21] This similarity is probably due to the presence of four negatively charged functional groups in both $DOTA^{4-}$ and $DOTAGly^{4-}$, which can coordinate to $Ln^{3+}$ in the first step of the reaction and form mono- and diprotonated intermediates. The protons protonate the ring nitrogen atoms, while the $Ln^{3+}$ ion is still outside of the coordination cage. The rate-determining step of the formation of $[Ln(DOTA)]^-$ and $[Ln(DOTAGly)]^-$ is the deprotonation of the monoprotonated intermediate in a first-order reaction.[21–26] Because they isolated the diprotonated compound $[Gd(H_2DOTAM)(H_2O)_4](ClO_4)_5$ in the solid state, Parker et al. have assumed that the formation of $Gd(DOTAM)^{3+}$ occurs by a similar pathway.[27] However, as our preliminary studies have indicated, the formation of $Ln^{3+}$ complexes of the ligand DOTAM occurs by a completely different pathway as their rates of formation are directly proportional to the concentration of both $Ln^{3+}$ and DOTAM. A detailed study of the rates of the reaction shown in Equation (1) between $Ln^{3+}$ ions ($Ln^{3+}$ = $Ce^{3+}$, $Eu^{3+}$, $Gd^{3+}$, $Er^{3+}$ and $Yb^{3+}$) and DOTAM may provide new information about the role of the charged and uncharged functional groups in the reactions of a preorganized macrocyclic ligand.

$$Ln^{3+} + H_nL^{n+} \rightleftharpoons LnL^{3+} + nH^+ \ (n = 1, 2) \quad (1)$$

## Results and Discussion

### Kinetics of Complex Formation

The rates of complex formation were studied in the pH range 4.7–5.8, where the ligand species $H_2DOTAM^{2+}$ and $HDOTAM^+$ predominate [the protonation constants were found to be 6.05 and 9.07 by pH-metric titrations]. The protons presumably protonate two diagonal ring nitrogen atoms, as has been observed for $H_2DOTA^{2-}$.[28]

In the presence of an excess of $Ln^{3+}$ ions, the rate of complex formation is given by Equation (2), where $k_{obs}$ is a pseudo-first-order rate constant and $[L]_t$ and $[LnL]_t$ are the total concentrations of ligand and metal complex, respectively.

$$\frac{d[LnL]_t}{dt} = k_{obs}[L]_t \quad (2)$$

The $k_{obs}$ values obtained for the formation reactions of $Ce(DOTAM)^{3+}$ and $Eu(DOTAM)^{3+}$ are shown in Figures 1 and 2, respectively.

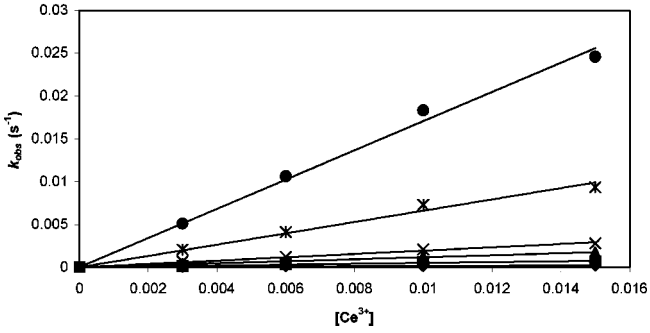

Figure 1. Rates of formation of $[Ce(DOTAM)]^{3+}$ at 25 °C in 1.0 M KCl. [DOTAM] = $3.0 \times 10^{-4}$ M, [NMP] = 0.05 M. The pH values are 4.80 (◆), 5.01 (■), 5.16 (▲), 5.30 (x), 5.53 (∗) and 5.77 (●).

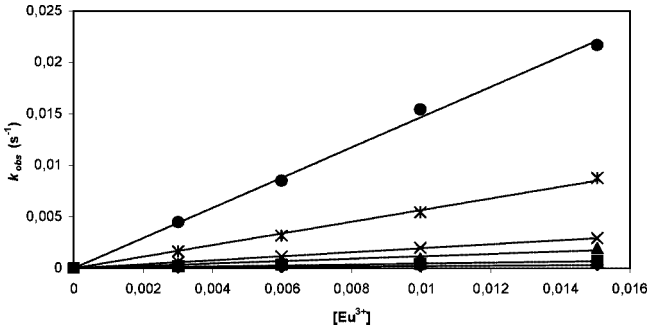

Figure 2. Rates of formation of $[Eu(DOTAM)]^{3+}$ at 25 °C in 1.0 M KCl. [DOTAM] = $3.0 \times 10^{-4}$ M, [NMP] = 0.05 M. The pH values are 4.78 (◆), 5.01 (■), 5.17 (▲), 5.30 (×), 5.56 (∗), and 5.76 (●).

As seen in Figures 1 and 2, the $k_{obs}$ values are directly proportional to the concentration of $Ce^{3+}$ and $Eu^{3+}$ over a broad concentration range. This observation differs considerably from the results obtained for the formation of DOTA and DOTA derivative complexes of $Ln^{3+}$, where similar $k_{obs}$ vs. $[Ln^{3+}]$ plots gave saturation curves, thus indicating the formation of a reaction intermediate.[21–26] The intermediates in the formation of $Ce(DOTA)^-$ and $Eu(DOTA)^-$ were detected by spectrophotometry and luminescence spectroscopy even at similar concentrations of $Ln^{3+}$ and ligand.[22,24] The absence of any intermediate in the formation of Ln(DOTAM) is particularly interesting because the diprotonated complex $[Gd(H_2DOTAM)(H_2O)_4](ClO_4)_5$, which can be regarded as an intermediate, has recently been observed in the solid state by Parker et al.[27] The X-ray crystal structure of this complex shows that the $Gd^{3+}$ion is located outside the coordination cage of the diprotonated ligand, where four amide oxygen atoms and four water molecules are coordinated to the metal ion. The authors assume that the formation of the complex [Gd-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(DOTAM)]$^{3+}$ could occur by deprotonation of the intermediate assisted by water as a base.[27]

The formation of an intermediate does not imply that the reaction product is formed by transformation of the intermediate. Thus, the formation of an intermediate in the complexation of DOTA with some divalent metal ions has been detected by Kasprzyk and Wilkins, although they assumed that the intermediate was not on the reaction pathway (it acted as a "dead-end" complex) and that complex formation occurred according to a simple second-order reaction.[29]

The 4f–5d UV absorption bands of $Ce^{3+}$ are suitable for detecting the formation of an intermediate in the reactions of $Ce^{3+}$ with DOTA and its derivatives.[21,23] However, the formation of an intermediate in the reaction of $Ce^{3+}$ with DOTAM could not be detected by spectrophotometry even if a 100-fold excess of $Ce^{3+}$ was used (Figure 3). The absorption of the excess $Ce^{3+}$ was compensated, but the spectrum obtained after 4 min is somewhat distorted, probably because of the imperfect compensation of one of the absorption bands of 0.05 M $Ce^{3+}$(aq), which appears at about 295 nm.

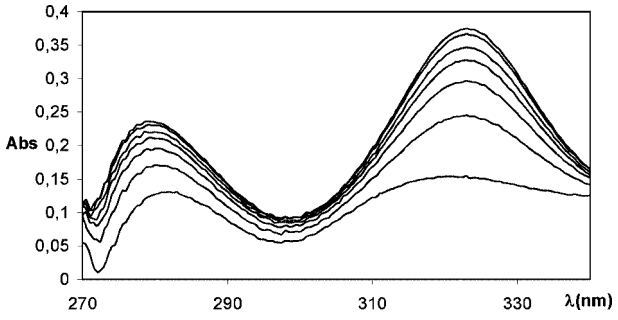

Figure 3. Absorption spectra of a $5 \times 10^{-4}$ M solution of DOTAM containing 0.05 M $Ce^{3+}$ at pH = 4.58 in the presence of 0.05 M NMP buffer 4, 8, 16, 20, 24, 28 and 32 min (in ascending order) after mixing the components (25 °C and 1.0 M KCl).

On the basis of the data presented in Figures 1 and 2, the pseudo-first-order rate constants can be expressed as $k_{obs} = k_f[Ln^{3+}]$, and the rate of formation can be given as Equation (3).

$$\frac{d[LnL]_t}{dt} = k_f[Ln^{3+}][L]_t \quad (3)$$

These findings show that the complexes Ln(DOTAM)$^{3+}$ are formed by direct encounter between the $Ln^{3+}$ ion and the ligand in a second-order reaction. In the pH range studied the ligand DOTAM is present in the form of $HL^+$ and $H_2L^{2+}$ species, and the concentration of the non-protonated species L is very low. However, it is expected that the neutral form of the ligand is the most reactive species because the $Ln^{3+}$ ion and the positive charge of the protonated species $HL^+$ and $H_2L^{2+}$ hinder the reaction.[30] However, if we assume that the reaction can take place with all ligand species, the formation rate can be expressed as Equation (4).

$$\frac{d[LnL]_t}{dt} = k_L[Ln^{3+}][L] + k_{HL}[Ln^{3+}][HL] + k_{H_2L}[Ln^{3+}][H_2L] \quad (4)$$

On the basis of Equations (3) and (4), and taking into account the protonation constants of the ligand ($K_1^H$ = [HL]/[L][H$^+$] and $K_2^H$ = [$H_2$L]/[L][H$^+$]), the second-order rate constant $k_f$ can be calculated from Equation (5), which takes into account all the possible reaction pathways, although some experimental data indicate that the reaction occurs only by encounter of the $Ln^{3+}$ ions and the neutral species L.

$$k_f = \frac{k_L + k_{HL}K_1^H[H^-] + k_{H_2L}K_1^H K_2^H[H^+]^2}{1 + K_1^H[H^-] + K_1^H K_2^H[H^+]^2} \quad (5)$$

The formation rates of the complexes [Ce(DOTAM)]$^{3+}$ and [Eu(DOTAM)]$^{3+}$ are directly proportional to the concentration of the neutral ligand L since the plots of $k_f$ vs. [L] give straight lines. In this case, according to Equation (5), $k_f = k_L/a_L$, where $a_L = 1 + K_1^H[H^+] + K_1^H K_2^H [H^+]^2$. A plot of $\log k_f$ against $\log \alpha_L$ gives a straight line with a slope of –1, which also indicates the predominance of the reaction between the neutral ligand L and the $Ln^{3+}$ ions.[22,29]

The rates of formation were also studied for the complexes of $Gd^{3+}$, $Er^{3+}$ and $Yb^{3+}$ at different pH values and at two $Ln^{3+}$concentrations. The $k_{obs}$ values obtained are presented in Table 1.

Table 1. Pseudo-first-order rate constants ($k_{obs}$, $s^{-1}$) obtained for the formation of $Gd^{3+}$, $Er^{3+}$ and $Yb^{3+}$ complexes of DOTAM ([L]$_t$ = $3 \times 10^{-4}$ M, 1.0 M KCl, 25 °C).

| | | $10^3 \times k_{obs}$ [$s^{-1}$] | |
|---|---|---|---|
| $Ln^{3+}$ | pH | $6 \times 10^{-3}$ M | $1.0 \times 10^{-2}$ M |
| $Gd^{3+}$ | 5.01 | 0.58 | 1.11 |
| | 5.35 | 1.91 | 2.81 |
| | 5.46 | 3.45 | 6.99 |
| | 5.54 | 4.78 | 10.7 |
| | 5.68 | 9.55 | 22.5 |
| $Er^{3+}$ | 5.20 | 0.13 | 0.26 |
| | 5.56 | 0.72 | 1.29 |
| | 5.71 | 1.77 | 2.63 |
| | 5.90 | 3.85 | 6.54 |
| $Yb^{3+}$ | 5.19 | 0.15 | 0.25 |
| | 5.44 | 0.49 | 0.66 |
| | 5.54 | 1.22 | 1.98 |
| | 5.66 | 2.55 | 3.69 |

The rate constants $k_L$ were calculated for the formation reactions by fitting the $k_f$ data (calculated from the $k_{obs}$ values) to the equation $k_f = k_L/a_L$. The obtained rate constants $k_L$ are presented in Table 2. The $k_f$ data were also fitted to Equation (5) when the $k_{HL}$ values obtained for the formation reaction of [Ce(DOTAM)]$^{3+}$ and [Eu(DOTAM)]$^{3+}$ were low and had a negative sign, although the $k_{H_2L}$values were also low and so the contribution of the third term of the numerator of Equation (5) to the $k_f$ values is not significant.

Table 2. Rate constants $k_L$ ($M^{-1}s^{-1}$) characterising the formation of $[Ln(DOTAM)]^{3+}$ complexes (25 °C, 1.0 M KCl).

| $Ln^{3+}$ | $k_L$ ($M^{-1}s^{-1}$) |
|---|---|
| $Ce^{3+}$ | $(7.7\pm0.3)\times10^3$ |
| $Eu^{3+}$ | $(2.7\pm0.1)\times10^4$ |
| $Gd^{3+}$ | $(4.0\pm0.5)\times10^4$ |
| $Er^{3+}$ | $(5.6\pm0.3)\times10^3$ |
| $Yb^{3+}$ | $(6.6\pm1.0)\times10^3$ |

The rate constants $k_L$, determined for the reactions of the $Ln^{3+}$ ions with DOTAM, are about three to four orders of magnitude lower than those reported for the complexation reactions with monodentate or open-chain multidentate ligands.[31–33] The observed reaction rates are particularly low because of the extremely low concentration (ca. $10^{-8}$ M) of the deprotonated ligand L in the pH range investigated.

To obtain further evidence that protonated intermediates do not play any role in the formation of complexes $[Ln(DOTAM)]^{3+}$, we studied the effect of changing the concentration of the buffer, *N*-methylpiperazine (NMP), on the rates of formation of $[Ce(DOTAM)]^{3+}$ and $[Eu(DOTAM)]^{3+}$. If protonated intermediates were formed and the rate-determining step of the complexation were the deprotonation of the intermediates, then an increase in the concentration of a general base like NMP ($pK_1$ = 4.83) would cause an increase in the rate of complex formation.[26,27] The rate constants $k_{obs}$ obtained for the formation of $[Ce(DOTAM)]^{3+}$ and $[Eu(DOTAM)]^{3+}$ do not show any change with an increase in the concentration of the buffer (Figure 4). These findings confirm that the formation of complexes $[Ln(DOTAM)]^{3+}$ occurs without the involvement of protonated intermediates.

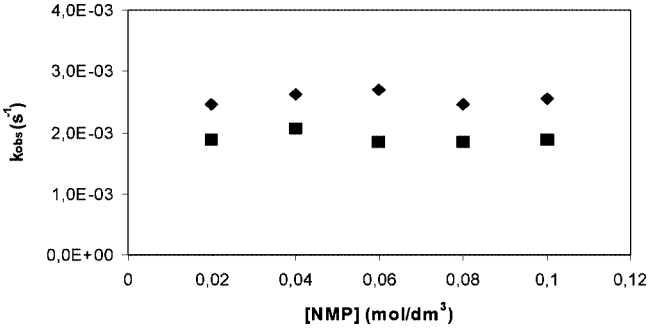

Figure 4. Rates of formation of $[Ce(DOTAM)]^{3+}$ (◆; pH = 5.32) and $[Eu(DOTAM)]^{3+}$ (■; pH = 5.2). The concentration of DOTAM and $Ln^{3+}$ ions was $3\times10^{-4}$ M and $6\times10^{-3}$ M, respectively (25 °C and 1.0 M KCl).

### Proton-Exchange Rates of the DOTAM Ligand

The $^1H$ NMR spectra of the DOTAM ligand (Figures 5 and 6) indicate that the rate of proton exchange in the species $H_2DOTAM^{2+}$ and $HDOTAM^+$ is relatively low, which could play some role in the slow formation of the $[Ln(DOTAM)]^{3+}$ complexes.

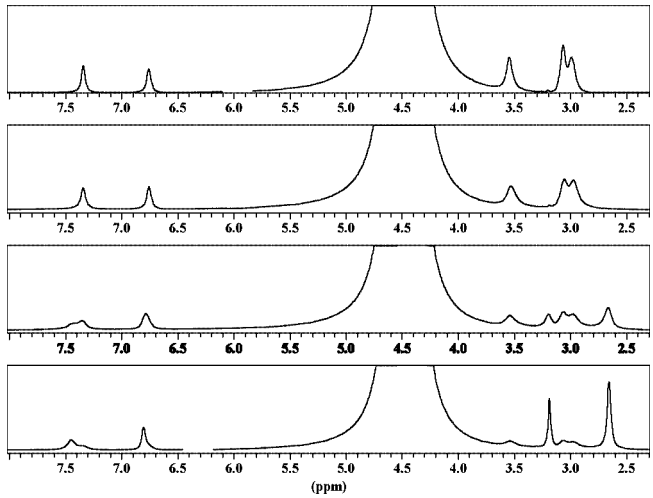

Figure 5. $^1H$ NMR spectra of the ligand DOTAM. The pH values from top to bottom are: 4.04, 5.03, 5.94 and 6.48.

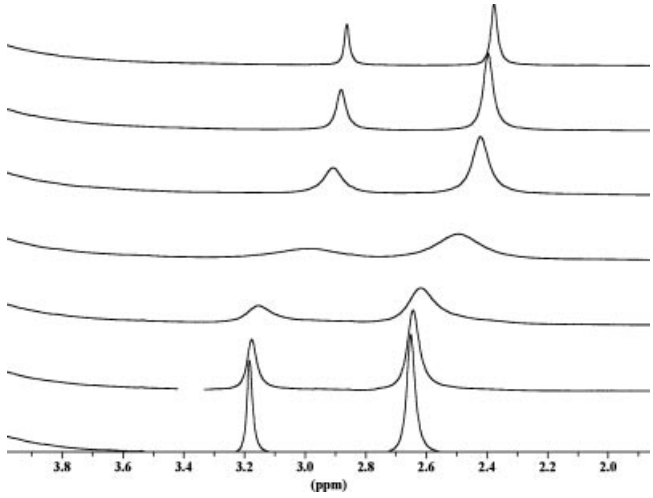

Figure 6. Variation of the $^1H$ NMR spectrum of DOTAM with pH. The pH values from top to bottom are: 7.45, 7.99, 8.53, 9.04, 9.55, 9.83 and 10.22.

At pH ≈ 4, where the species $H_2DOTAM^{2+}$ predominates, there are three broad signals in the $CH_2$ region in a 1:1:1 ratio. Two of these are assignable to the ring protons ($\delta$ = 2.98 and 3.16 ppm), while the third belongs to the amide $CH_2$ group ($\delta$ = 3.54 ppm). The signals observed between $\delta$ = 6.6 and 7.5 ppm are due to the $NH_2$ protons of the amide group. The chemical shift of the ring protons is not affected by the pH. Interestingly, the ligand $HDOTAM^+$, which predominates at pH > 7, has only two peaks in the $CH_2$ region, probably due to some fluxional motion of the molecule that averages the two signals of the ring methylene protons. Figure 6 shows that both the chemical shifts and the line widths of these signals change considerably with increasing pH. It is likely that these spectral variations are related to the proton-exchange process that occurs for the species $HDOTAM^+$ and DOTAM. Analysis

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the pH dependence of the proton chemical shifts allowed the determination of the $\log K_1^H$ value ($9.01 \pm 0.07$), which is in good agreement with the value obtained by pH-metry.

Exchange between the monoprotonated and nonprotonated forms of DOTAM was analysed using the simplified analytical equation reported by Piette and Anderson.[34] The exchange rate constant ($k_{ex}$) can be determined from the nonexchange linewidth and the chemical shifts of the signals in the absence of exchange. These data were obtained from the spectra, and the first-order rate constants were calculated in the pH range 8–10.[34] The proton-exchange rate is linearly proportional to the $OH^-$ concentration, as expressed by Equation (6), where the rate constant $k_0 = (1.2 \pm 0.3) \times 10^3\ s^{-1}$ refers to the rate of spontaneous deprotonation of $HDOTAM^+$, which probably takes place with the help of $H_2O$ molecules.

$$k_{ex} = k_0 + k_1[OH^-] \quad (6)$$

The rate constant $k_1 = (5.3 \pm 0.5) \times 10^8\ M^{-1}s^{-1}$ corresponds to the rate of the $OH^-$-assisted deprotonation of the species $HDOTAM^+$. The rate of proton exchange is relatively low, probably because the proton is attached to the ring nitrogen atom in the coordination cage. For the proton exchange to occur, the ligand must have a special conformation where it can donate the proton to an $H_2O$ molecule or an $OH^-$ ion. This conformation is formed by some fluxional motion of the ligand, although the experimental data are not good enough to be able to separate the contribution of fluxionality. The role of the $OH^-$-assisted deprotonation is negligible in the pH range 4.7–5.8, and the spontaneous deprotonation of $HDOTAM^+$ is much faster than complex formation, which means that this deprotonation cannot control the rate of complexation.

The $^1H$ NMR signals of the DOTAM ligand are broad because of the slow proton exchange and fluxional processes. However, the widths of the signals decrease in the presence of a general base. Thus, an increase in the concentration of sodium acetate to 0.3 M at pH = 9.0 results in a decrease of 18 and 35 Hz in the linewidths of the ring and amide methylene protons, respectively. The two ring proton signals merge into one broad signal at pH = 4.1 when the concentration of sodium formate is increased to 0.25 M. These findings indicate that the proton-exchange reactions of the species $H_2DOTAM^{2+}$ and $HDOTAM^+$ are general base catalysed processes. However, general base catalysis is not valid for the formation of $[Ln(DOTAM)]^{3+}$ (Figure 4), therefore we can conclude that the rate of proton exchange of the free ligand does not play a role in the slow complex formation.

### Mechanism of Complex Formation

The kinetic data obtained for the formation of the $[Ln(DOTAM)]^{3+}$ complexes show that the complexation occurs through a direct reaction between the $Ln^{3+}$ ions and the deprotonated ligand DOTAM that follows second-order kinetics. On this basis, since the only species formed is $[Ln(DOTAM)]^{3+}$, the rate of formation can be expressed on the basis of Equation (3) as Equation (7).

$$\frac{d[LnL]}{dt} = k_L[Ln^{3+}][L] \quad (7)$$

A low reactivity of the protonated ligands is known even for the reactions of open-chain aminocarboxylate ligands, where the ratio of the rate constants $k_L/k_{HL}$ is often as large as $10^5$–$10^6$.[30] In the case of the macrocyclic DOTA and its derivatives, the metal ion cannot enter directly into the coordination cage formed by the four ring nitrogen atoms and four oxygen donors, thus maintaining the four negatively charged pendant arms. This is due to the electrostatic repulsion caused by the presence of the protonated nitrogen atoms. Complex formation requires that this proton is shifted to another donor atom, such as the pendant carboxylate group in the case of DOTA. In the complexation of DOTAM, the proton cannot be transferred to the carboxamide moiety because it can be protonated only in very strongly acidic solutions. On this basis, the formation of complexes of DOTAM does not take place via a protonated intermediate, thus it must occur only with the participation of the fully deprotonated ligand DOTAM.

The rate constants $k_L$ reported in Table 2, are three to four orders of magnitude lower than the second-order rate constants determined for the formation of $Ln^{3+}$ complexes with murexide, oxalate or anthranilate ligands. The rate-determining step for these reactions was assumed to be the second bond formation, in other words the chelation step.[31–33]

In metal complex formation with macrocyclic ligands, formation of the first metal–ligand bond is followed by several subsequent steps in which new metal–ligand bonds are formed sequentially as the coordinated water molecules are released. Unfortunately, it is very difficult to determine which is the rate-determining step in such multi-step processes.

The very slow formation of the complexes $[Ln(DOTAM)]^{3+}$ may be tentatively interpreted in terms of the knowledge obtained for the reactions of multidentate ligands.[30] The first step of the complexation is the formation of an outer-sphere complex between the DOTAM ligand and the $[Ln(H_2O)_n]^{3+}$ ion ($n = 9$ for the ions between $La^{3+}$ and $Nd^{3+}$, $n = 8$ for the ions from $Gd^{3+}$ to $Lu^{3+}$; $n$ is between 8 and 9 for $Sm^{3+}$ and $Eu^{3+}$).[33,35] By defining the tetraamide ligand as $A_4$, this outer-sphere complex can be formulated as $Ln(H_2O)_n{\cdot}A\text{-}A_3$, which is characterized by the stability constant $K_{os}$. The subsequent steps of the formation of $[Ln(DOTAM)]^{3+}$ complexes are shown in Scheme 2, where $k_{jk}$ are first-order rate constants.

$$Ln(H_2O)_n \cdot A - A_3 \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} (A_3 - A)Ln(H_2O)_{n-1} \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} (A_2 - A_2)Ln(H_2O)_{n-2} \rightleftharpoons$$
$$\ldots \rightleftharpoons (A_4)Ln(H_2O)_{n-4} \xrightarrow{fast} Ln(H_2O)(DOTAM)$$

Scheme 2. The subsequent steps of the formation of $[Ln(DOTAM)]^{3+}$ complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

If the second bond formation were the rate-controlling step, then the expression for the second-order rate constant $k_L$ would be as shown in Equation (8).[30]

$$k_L = \frac{k_{23}k_{34}K_{os}}{k_{32} + k_{34}} \quad (8)$$

Since dissociation of the intermediate $(A_3\text{-}A)Ln(H_2O)_{n-1}$ is probably much faster than the formation of $(A_2\text{-}A_2)\text{-}Ln(H_2O)_{n-2}$, that is $k_{32} >> k_{34}$ and $k_{23} \approx k_{H_2O}$ ($k_{H_2O}$ is the water exchange rate), Equation (8) can be simplified to Equation (9).

$$k_L = k_{H_2O}K_{os}\frac{k_{34}}{k_{32}} \quad (9)$$

To obtain $k_L$ values of around $10^3$–$10^4$, the $K_{os}$ and $k_{34}/k_{32}$ values must be low, since the value of $k_{H_2O}$ is about $10^7$–$10^8$ $s^{-1}$.[31–33] The value of $K_{os}$ for an $Ln^{3+}$ ion and a neutral ligand can be estimated to be 0.3 M on the basis of the Fuoss equation.[36,37] The ratio $k_{34}/k_{32}$ must be low, and if these values were about $10^{-3}$ for the different $Ln^{3+}$ ions then the $k_L$ values would be approximately $10^3$–$10^4$, as was found experimentally. These considerations indicate that the rate-determining step for the formation of $[Ln(DOTAM)]^{3+}$ complexes must be quite early in the sequence shown in Scheme 2 (second or third bond formation) because the ratios analogous to $k_{34}/k_{32}$ are presumably lower for the later intermediates in the sequence.

The formation rate constants $k_L$ show a maximum at $Gd^{3+}$ in the series of lanthanides. Similar phenomena have often been observed for the formation of lanthanide complexes of mono- and multidentate ligands.[32,33] Since the water exchange rates of the $Ln^{3+}$(aq) ions decrease from $Gd^{3+}$ to $Yb^{3+}$, and probably also to the lighter elements, interpretation of the trend of the complexation rates is based on the assumption that the water exchange rates may influence the rates of complex formation, as expressed by Equation (9).[31–33]

## Conclusions

The complexation properties of DOTAM, which contains four uncharged acetamide functional groups, differ considerably from those of the parent ligand DOTA, which possesses four negatively charged pendant groups. The mechanisms of formation of $[Ln(DOTAM)]^{3+}$ and $[Ln(DOTA)]^-$ complexes are therefore also different. Thus, during the formation of the latter complexes, the acetate groups of the diprotonated ligand coordinate to the $Ln^{3+}$ ion to form a stable intermediate, which then undergoes transfer of the ring NH protons to the donor atoms of the pendant groups followed by entry of the metal ion into the macrocyclic cage. The complexes with DOTAM cannot be formed via protonated intermediates of this type, however, because the ring protons cannot be transferred to the amide oxygen atom. The formation of $[Ln(DOTAM)]^{3+}$ complexes therefore does not involve the formation of protonated intermediates.

The kinetic data indicate that the formation of $[Ln(DOTAM)]^{3+}$ complexes occurs in a direct reaction between the fully deprotonated DOTAM ligand and the $Ln^{3+}$ ion in a second-order reaction. Although the proton-exchange reactions of the protonated species $H_2DOTAM^{2+}$ and $HDOTAM^+$ are relatively slow on the NMR timescale, they have no effect on the rate of complex formation.

The second-order rate constants $k_L$, which characterize the formation of the $[Ln(DOTAM)]^{3+}$ complexes, are three to four orders of magnitude lower than the rate constants reported for the reactions of open-chain multidentate ligands. However, the trend of the $k_L$ values in the series of lanthanides is somewhat similar to that of the rates of complexation with some monodentate and multidentate ligands.

The formation of $[Ln(DOTAM)]^{3+}$ complexes occurs by successive replacement of the coordinated water molecules of the $Ln(H_2O)_n^{3+}$ ion. The low $k_L$ values observed can be interpreted by assuming that the rate-determining $Ln^{3+}$–amide bond formation probably occurs quite early in the reaction sequence, probably being in the second or third step of the complex formation.

The preformed coordination cage of the ligand plays an important role in determining the moderate stability constants and extremely low proton-assisted dissociation rates of the $Ln^{3+}$ complexes formed with the neutral ligand DOTAM. The neutrality of the acetamide pendant groups of the ligand has a major influence on the kinetics and mechanisms of the formation reactions; however, the rates are also influenced by the water exchange rates of the $Ln^{3+}$(aq) ions.

## Experimental Section

The chemicals used in the experiments were of the highest analytical grade. The $CeCl_3$ solution was prepared from $CeCl_3 \cdot 7H_2O$ (Aldrich, 99.9%). For the preparation of the other $LnCl_3$ solutions, $Ln_2O_3$ (Fluka, 99.9%) was dissolved in 6.0 M HCl and the excess of acid evaporated. The concentration of the $LnCl_3$ solutions was determined by complexometric titration with standardized $Na_2H_2EDTA$ and xylenol orange as indicator. The ligand DOTAM was prepared as described previously.[1] The concentration of the solution of DOTAM was determined by pH-metric titrations in the presence and absence of a large excess of $CaCl_2$. The protonation constants of DOTAM were also determined by pH-metry at 25 °C in 1.0 M KCl. The method proposed by Irving et al. was used to calculate $[H^+]$ from the measured pH values.[38] A Radiometer PHM93 pH meter, an ABU 80 autoburette and a Metrohm 6.0234.100 combined electrode were used for the pH measurements and titration. The pH-meter was calibrated with potassium hydrogen phthalate (pH = 4.005) and borax (pH = 9.180) buffers. The protonation constants were calculated with the program PSEQUAD.[39] The rates of formation of $[Ce(DOTAM)]^{3+}$ and $[Eu(DOTAM)]^{3+}$ were studied by spectrophotometry (Cary E1 spectrophotometer) at 320 and 250 nm, respectively. To study the formation of the $Gd^{3+}$, $Er^{3+}$ and $Y^{3+}$ complexes, the release of $H^+$ from the ligand was monitored by spectrophotometry at 616 nm in weakly buffered solutions with bromocresol green as indicator.[29] The decrease in pH was about 0.07–0.1 pH units in the presence of *N*-methylpiperazine (NMP) buffer. The formation of complexes was studied in the presence of a 5- to 50-fold $Ln^{3+}$ excess in order to maintain pseudo-first-order conditions. The concentration of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

DOTAM was varied between $1 \times 10^{-4}$ and $5 \times 10^{-4}$ M. The pseudo-first-order rate constants were calculated by fitting the absorbance values to Equation (10), where $A_0$, $A_e$ and $A_t$ are the absorbance values at the start, at equilibrium and at time $t$ of the reaction.

The rates of formation [Equation (1)] were studied in the pH range 4.7–5.8 (25 °C, 1.0 M KCl). The $^1H$ NMR spectra were recorded

$$A_t = (A_0 - A_e)e^{-k_{obs}t} + A_e \quad (10)$$

with a Bruker Avance 600 spectrometer in $H_2O$ solution with a capillary containing $D_2O$ as lock and reference.

# Proton Affinities in Water of Maingroup-Element Hydrides – Effects of Hydration and Methyl Substitution

Marcel Swart,[a][‡] Ernst Rösler,[a] and F. Matthias Bickelhaupt*[a]

**Keywords:** Acidity / Basicity / Density functional calculations / Periodic table / Proton affinities / Thermochemistry / Solvent effects

We have computed the proton affinities in water of archetypal anionic and neutral bases across the periodic table using the generalized gradient approximation (GGA) of density functional theory (DFT) at BP86/QZ4P//BP86/TZ2P. The main purpose of this work is to provide an intrinsically consistent set of values of the 298-K proton affinities in aqueous solution of all anionic ($XH_{n-1}^-$) and neutral bases ($XH_n$) constituted by maingroup-element hydrides of groups 14–17 and the noble gases (i.e., group 18) along the periods 1–6. Hydration has little effect on the trends in PA values, especially in the case of the neutral bases. However, in the case of the anionic bases, hydration drastically reduces the magnitude of the PA values. Finally, we have studied how proton affinities in water are affected by methyl substitution at the protophilic center.

## 1. Introduction

Designing new (and optimizing existing) approaches and routes in chemical synthesis requires knowledge of the thermochemistry involved in the targeted reactions. In this context, the proton affinity (PA) of a reactant or intermediate species B often plays an important role. This thermochemical quantity is defined as the enthalpy change associated with dissociation of the conjugate acid [Equation (1)].[1–8]

$$BH^+ \rightarrow B + H^+;\ \Delta H = PA \qquad (1)$$

Overall reaction enthalpies and reaction barriers (and thus reaction rates) are related to the PA, as soon as proton transfer occurs somewhere along the cascade of elementary steps of a reaction mechanism. This is often the case, as proton transfer is ubiquitous in chemical reaction mechanisms, either as simple proton transfer (PT) or as part of a more complex chemical transformation, for example, base-induced elimination reactions that may compete with nucleophilic substitution.[9–13] And, as chemical reactions are usually carried out in the condensed phase, knowledge of the *condensed-phase* PA values is vital for the understanding and prediction of (competing) reaction mechanisms.

Previously, we have studied the *gas-phase* proton affinities and trends therein of anionic and neutral maingroup-element hydrides and noble gases.[14,15] Gas-phase proton affinities are obviously directly applicable to gas-phase chemistry[3–6] but they are also relevant for chemistry occurring in the condensed phase.[1,16] On one hand, they reveal the intrinsic basicity of the protophilic species involved and, thus, they shed light on how this property is affected by the solvent. On the other hand, they can serve as a universal, solvent-independent framework of reference, from which the actual basicity of a species in solution might be obtained through correcting for the particular solvent under consideration.[17–19]

Here, we focus on the proton affinities in water and how the presence of the solvent changes the basicity of the protophilic species. The solvent environment may be taken into account using different approximations, e.g., through empirical corrections (Born, Onsager), or by including explicit solvent molecules, or through placing the solute in a dielectric continuum (COSMO[20,21]). The empirical corrections give only a rough estimate for the solvation process, while the inclusion of explicit solvent molecules necessitates sampling of the solvents' degrees of freedom in molecular simulations[22,23] (Monte Carlo, molecular dynamics). We choose the dielectric continuum (COSMO[20,21]) model as a reasonable compromise between accuracy and feasibility.

The present study has three objectives. First, we aim at setting up a complete description at BP86/QZ4P//BP86/TZ2P of the proton affinities (PA = $\Delta_{acid}H_{298}$ of reaction 1) in aqueous solution for the anionic (B = $XH_{n-1}^-$) and neutral (B = $XH_n$) maingroup-element hydrides of groups 14–17 and the noble gases, i.e. group 18, and periods 1–6.

In addition to the PA values of all bases ($\Delta_{acid}H_{298}$), we also report the corresponding 298 K reaction entropies ($\Delta_{acid}S_{298}$, provided as $-T\Delta_{acid}S_{298}$ values), and 298 K reaction free energies ($\Delta_{acid}G_{298}$). We have previously shown that this level of density functional theory (DFT)[24–32] performs well for computing gas-phase PA values.[14,15] Second, we wish to evaluate directly the effect of hydration on the PA values by comparing the condensed-phase values to the previously obtained[14,15] gas-phase values. Third, we examine the influence of stepwise methylation of the protophilic center X in species $Me_mXH_{n-m-1}^-$ and $Me_mXH_{n-m}$ (for periods 2 and 3), for example, $PH_3$, $MePH_2$, $Me_2PH$, $Me_3P$.

To the best of our knowledge, our series of in total 65 bases has never before been studied consistently with one and the same method over its full range, either experimentally or theoretically. The very consistency in the values of the present study makes our data particularly suitable for inferring accurate *trends* in condensed-phase basicity across the periodic table.

## 2. Results and Discussion

### 2.1. Effect of Hydration on Proton Affinities

bases are collected in Table 1 and 2 and the trends are visualized in Figure 1. The effect of solvation on the PA values is summarized in Table 3, Table 4 shows the separate contributions from solvation of the base, the proton and the conjugate acid. Before proceeding, we stress that various species for which we compute the proton affinity in water are not stable in water. For example, any anionic base with a higher PA than that of water (e.g., $NH_2^-$) will immediately abstract a proton from the latter. Access to the PA value of such in water transient species is interesting both, for the fundamental reason of having a complete trend, but also for the very practical reason to know if such a species remains intact in solution or if it directly abstracts a proton.

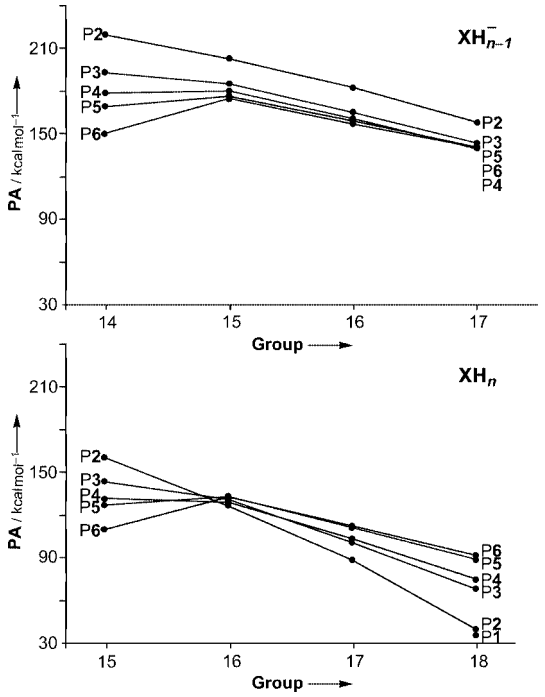

Figure 1. Proton affinities PA in water (at 298 K) of anionic bases $XH_{n-1}^-$ (upper) and neutral bases $XH_n$ (lower) constituted by the element hydrides of groups 14–18 and periods 1–6 (P1–P6), computed at BP86/QZ4P//BP86/TZ2P.

[a] Computed at BP86/QZ4P//BP86/TZ2P. [b] See Equation (2). $\Delta H_{solv}(H^+)$ = –119.93 kcal/mol.

Two general observations can be made for the present PA values in aqueous solution by comparison with the corresponding PA values in the gas phase.[14,15] First, hydration reduces especially the PA values of the anionic bases and somewhat less so the PA values of the neutral bases (see Table 3). Second, the trends in PA values for either the anionic and neutral bases are only little affected by hydration, as follows from comparison of Figure 1 in the present study with that in ref.[15] (see however also the more detailed discussion in Sections 2.2 and 2.3).

The fact that the neutral bases are much less affected by hydration is easily understood if one considers that the

[a] $\Delta\Delta H$ is the change in PA due to solvation, i.e., $\Delta PA_{solv}$, as defined in Equation (2). [b] Computed at BP86/QZ4P//BP86/TZ2P for the reactions $Me_mH_{n-m-1}XH \rightarrow H^+ + Me_mH_{n-m-1}X^-$ with $n$ = 3, 2, 1 and 0 for groups 14, 15, 16 and 17, and $Me_mH_{n-m}XH^+ \rightarrow H^+ + Me_mH_{n-m}X$ with $n$ = 3, 2, 1 and 0 for groups 15, 16, 17 and 18, respectively.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

main effect of solvation stems from the ionic species. The change in PA due to solvation, $\Delta PA_{solv}$, is given by Equation (2).

$$\Delta PA_{solv} = \Delta H_{solv}(base) + \Delta H_{solv}(H^+) - \Delta H_{solv}(conj.acid) \quad (2)$$

The change in enthalpy of solvation of the proton $\Delta H_{solv}(H^+)$ is large (–119.93 kcal/mol). For the neutral bases, this term is largely compensated by the strong enthalpy of solvation of their *positively charged conjugate acid*, $\Delta H_{solv}$(conj.acid). The latter ranges from –81 to –106 kcal/mol (see Table 4). Consequently, the change in proton affinity due to solvation $\Delta PA_{solv}$ is relatively small for neutral bases (see Tables 3 and 4).

The situation is different for the anionic bases. In the gas phase, they have significantly larger PA values than the neutral bases because of the charge separation, and the associated loss in Coulombic attraction, that goes with dissociating the neutral conjugate acid into the negatively charged base and the positively charge proton.[14,15] On the other hand, in solution, both the base and the proton (but not the conjugate acid) are heavily stabilized as they both carry one elementary charge. Thus, according to Equation (2), there is not a compensation but an amplification of the stabilizing effect of hydration through the terms $\Delta H_{solv}(base) + \Delta H_{solv}(H^+)$. Consequently, the reduction in proton affinity due to solvation $\Delta PA_{solv}$ is large for anionic bases (see Tables 3 and 4).

Eventually, hydration makes the PA values of the anionic bases come closer to those of the neutral bases but they remain somewhat higher than the latter (see Figure 1 and Tables 1 and 2). For instance, the difference in PA between $NH_2^-$ and $NH_3$, which is 200 kcal/mol in the gas phase, is reduced to 42 kcal/mol in water (see Tables 1 and 2). This is mainly due to the PA of the *anionic* base ($NH_2^-$) that decreases by 201 kcal/mol, while that of the *neutral* base ($NH_3$) decreases by only 42 kcal/mol (see Table 3).

### 2.2. Trends in Proton Affinities in Water

The *trends* in PA values for either the anionic and neutral bases are, as pointed out above, much less affected by hydration than the absolute values. Yet there are small but not negligible effects which are discussed in the present section. Furthermore, we note that hydration effects on trends in PA values are only small in the case of the simple element hydrides. Later on, in Section 2.3, we will see that trends can in fact be qualitatively changed by hydration in the case of the methyl-substituted bases.

First, we examine the trends in PA values in water as such before we consider the changes relative to the gas phase. For the anionic bases, we obtain the well-known trend of a decreasing basicity along the second period as the PA falls from 221 to 203 to 183 to 158 kcal/mol along $CH_3^-$, $NH_2^-$, $OH^-$ and $F^-$ (see Table 1 and Figure 1). The PA values also decrease down each group: for instance, for group 15, the PA decreases from 203 to 185 to 180 to 177 to 175 kcal/mol along $NH_2^-$, $PH_2^-$, $AsH_2^-$, $SbH_2^-$ and $BiH_2^-$. However, the changes in descending group 14 are significantly larger than those in groups 15–17. Thus, as can be seen in Figure 1, upper, the trend for monotonic decrease in PA along the second (P2) and third (P3) periods changes into a trend where the PA first increases from group 14 to group 15 and then decreases again along groups 15, 16 and 17. The corresponding reaction entropies yield a relatively small (but not entirely constant) contribution $-T\,\Delta_{acid}S_{298}$ of –5 to –9 kcal/mol for 298 K. As a consequence, the Gibbs free energies $\Delta_{acid}G_{298}$ show the same trends as the corresponding PA values (see Table 1).

For the neutral bases, we also obtain the well-known trend of decreasing basicity along the second period, just as for the anionic bases. Thus, the PA falls from 161 to 127 to 89 to 40 for $NH_3$, $OH_2$, FH, Ne. A striking change occurs from group 15 to groups 17 and 18. Descending group 15, the PA *decreases* but descending groups 17 and 18, the PA *increases* (see Table 2). Group 16 is an intermediate case with relatively constant PA values that do not show a pronounced trend. Thus, the trend of monotonic decrease of PA along the second (P2), third (P3), and fourth (P4) period changes into a trend, along the fifth (P5) and sixth (P6) period, of an initial increase of the PA from group 15 to group 16 followed by a decrease along groups 16–18 (see Figure 1, lower).

There is an interesting common feature in the trends of both anionic and neutral bases. This feature is the kink in the PA trend along a period that always occurs after the step from the tricoordinate to the dicoordinate base, that is, at group 15 for the anionic $XH_{n-1}^-$ and at group 16 for the neutral $XH_n$ (see Figure 1). The effect is most pronounced for bases with a more heavy protophilic center in which the valence *ns* AO is inactive. This suggests that the effect, that is, the sudden increase in PA from a tricoordinate to a dicoordinate base is associated with an active n*p*-type lone pair which becomes available in the latter.

The above trends of PA values in water are very similar to those in the gas phase. But, as announced above, there are differences which manifest themselves in particular in the case of the anionic bases. In the first place, the *magnitude of the hydration effect* ($\Delta PA$) on the PA values of the anionic bases $XH_{n-1}^-$ strongly *decreases down each group* (see Table 3). The largest change occurs from period 2 to period 3. This causes the PA values of $XH_{n-1}^-$ from different periods to shift closer together. The decrease in the hydration effect $\Delta PA$ on the proton affinities if one descends the periodic Table can be easily understood with the classical electrostatic Born model of a spherical ion in a dielectric continuum [Equation (3), in a.u.].[17,33]

$$\Delta E_{solv} = -\frac{q^2}{2a}\left(1-\frac{1}{\varepsilon_r}\right) \quad (3)$$

In this equation, $\varepsilon_r$ is the relative dielectric constant of the solvent (i.e. 78.4 for water). The charge $q$ is –1 for the $XH_{n-1}^-$ ion. The appearance of the effective radius $a$ of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ion in the denominator leads to smaller solvation energies for larger ions. Thus, as the atomic radius of the protophilic center X (and therefore of the base $XH_{n-1}^-$) increases down a group, the stabilization due to solvation of the anionic base $\Delta\Delta H_{solv}$(base) diminishes and so does, according to Equation (2), the hydration effect ΔPA on the proton affinity.

The same simple model (i.e. Equations 2 and 3) predicts that, in the case of the neutral bases, the hydration effect increases down the periodic Table. This is indeed what happens although the effect is somewhat less pronounced than that for the anionic bases (see Table 3). Similar size effects can also be observed along a period. For example, the hydration-induced reduction of the proton affinity, ΔPA, increases from –194 to –201 to –207 to –215 kcal/mol along $CH_3^-$, $NH_2^-$, $OH^-$ and $F^-$ (see Table 3). In fact, the value of –214.6 kcal/mol for $F^-$ is the largest hydration effect on a PA value in this study. The trend in ΔPA along the second period anionic bases can again be understood in terms of the solvation stabilization becoming more effective as the anionic protophilic center becomes smaller (see equations 2 and 3).

### 2.3. Methyl Substituent Effects

Finally, we have studied the effect on the PA in water of stepwise replacing all hydrogen atoms in second- and third-period anionic bases $XH_{n-1}^-$ and neutral bases $XH_n$ by methyl substituents, for which the results are collected in Tables 1, 2 and 5 and visualized in Figures 2 and 3. Methyl substitution increases the basicity in aqueous solution as reflected by the PA in all cases, that is, for both second- and third-period anionic *and* neutral bases. For example, along $OH_2$, MeOH and $Me_2O$, the PA increases from 127 to 130 to 131 kcal/mol, and along $SH_2$, MeSH and $Me_2S$, the PA increases from 131 to 137 to 142 kcal/mol (see Table 2). In three cases the trend comes practically to a hold along the step in which the last possible methyl group is introduced, namely, from $Me_2CH^-$ to $Me_3C^-$, from $MeNH^-$ to $Me_2N^-$ and from $Me_2NH$ to $Me_3N$ (see Tables 1 and 2).

This similarity in PA trends between second- and third-period bases in water contrasts with the situation for the anionic bases in the gas phase.[14,15] In the case of the latter, methyl substitution also increases the PA of third-period bases $XH_{n-1}^-$ but it *decreases* the PA of the second-period bases $XH_{n-1}^-$. It was shown that the reduction in basicity of the second-period anionic bases is *not* the result of a stabilization of the protophilic center by methyl groups.[14] In fact, the introduction methyl groups *destabilizes in all cases* both the base and the conjugate acid. The opposite trends in the effect of methyl substitution on the gas-phase PA of second- and third-period anionic bases $XH_{n-1}^-$ originate from the fact that a *second-period base is destabilized less by introducing a methyl group* than its corresponding conjugate acid whereas a *third-period base is destabilized more* than its conjugate acid.

This difference between methyl-substituent effects on the PA of second- and third-period anionic bases obviously disappears in aqueous solution. Our analyses show that this is associated with the loss in solute–solvent interaction that goes with methyl substitution. The anionic second-period bases are particularly strongly solvated [due to the small size of their charged protophilic center, see Equation (3)], significantly more so than their neutral conjugate acid.

Table 5. Analysis of the methyl-substituent effect on PA energies $\Delta_{acid}E$ in water in terms of the partial reaction schemes in Figure 2 and Figure 3.[a]

| Base | $\Delta E_{N/C}$ | $\Delta E_{A/N'}$ | $\Delta_{acid}E$ | Base | $\Delta E_C$ | $\Delta E_{N'}$ | $\Delta_{acid}E$ |
|---|---|---|---|---|---|---|---|
| $C^{\cdots-}$ | | | 158.02 | $Si^{\cdots-}$ | | | 147.17 |

Therefore, these bases also suffer most from the shielding of the charged protophilic center from the solvent by the methyl substituents. Consequently, in water, methyl-substitution destabilizes the base more than it destabilizes the conjugate acid also in the case of the anionic second-period bases.

This leads to the well-known reversal, from gas phase to condensed phase, of the trend in basicity along a series of increasingly methyl-substituted second-period bases. For example, in the gas phase, the basicity decreases along $OH^- > MeO^-$ and along $NH_2^- > MeNH^- > Me_2N^-$. But in water, the basicity decreases in the opposite order, namely, along $MeO^- > OH^-$ and along $Me_2N^-$, $MeNH^- > NH_2^-$ (see Table 1 and ref.[14]).

Our analyses that lead to the above conclusion consist of a decomposition of the proton-affinity energies $\Delta_{acid}E$ [i.e., only the electronic-energy part, $\Delta E$, of the proton affinity, see Equation (6) in methodological section], associated with acid dissociation of the conjugate acids, into three partial reactions, as shown in the thermochemical cycles in the top panels of Figures 2 and 3. This decomposition is now explained for the anionic bases [see Equation (4)] but the situation is of course completely equivalent for the neutral bases [see Equation (5)]. The first step, which is associated with an energy change $-\Delta E_N(m)$, is dissociation of all substituents (but not the acidic proton) of the conjugate acid $Me_mH_{n-m-1}XH$ to form the radical $XH^{(n-1)\cdot}$ (see Figure 2). The energy $\Delta E_N(m)$ is the stabilization of the protophilic center X in the neutral conjugate acid $Me_mH_{n-m-1}XH$ by all substituents, i.e., the interaction with $m$ methyl groups (Me) and $n$-$m$-1 hydrogen atoms (H). Next, the unsubstituted acid $XH^{(n-1)\cdot}$ is dissociated into $X^{-(n-1)\cdot} + H^+$ (see Figure 2). The corresponding reaction energy is the proton-affinity energy $\Delta_{acid}E$ of the anionic base $X^{-(n-1)\cdot}$. The third and last step, which is associated with an energy change $\Delta E_A(m)$, is addition of all substituents to the protophilic center $X^{-(n-1)\cdot}$ to form the base $Me_mH_{n-m-1}X^-$ (see Figure 2; $m$ = number of methyl substituents). The energy $\Delta E_A(m)$ is the stabilization of the protophilic center X in the anionic base $Me_mH_{n-m-1}X^-$ by all substituents, i.e., the interaction with $m$ methyl groups (Me) and $n$-$m$-1 hydrogen atoms (H). The computed proton-affinity energies $\Delta_{acid}E$, $\Delta E_N$ and

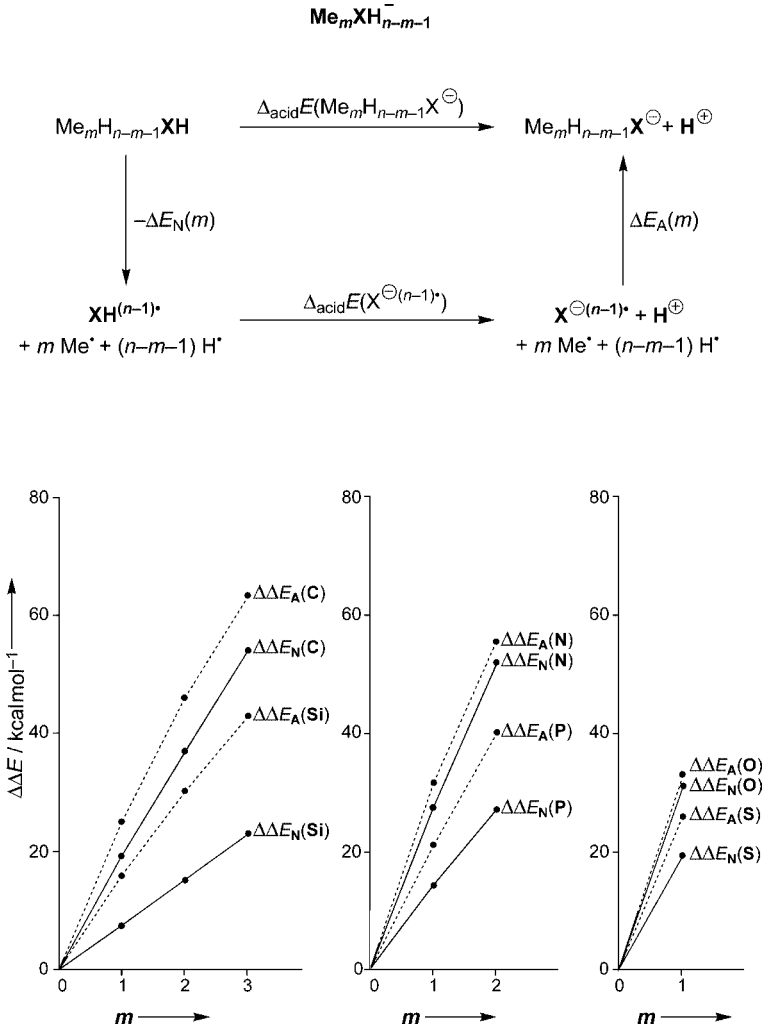

Figure 2. Effect of methyl substitution on the energies $\Delta E_N(X)$ and $\Delta E_A(X)$ of the anionic $XH_{n-1}^-$ and corresponding neutral conjugate acids $XH_n$ in water, computed at BP86/QZ4P//BP86/TZ2P [see Equation (4) and Table 5].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

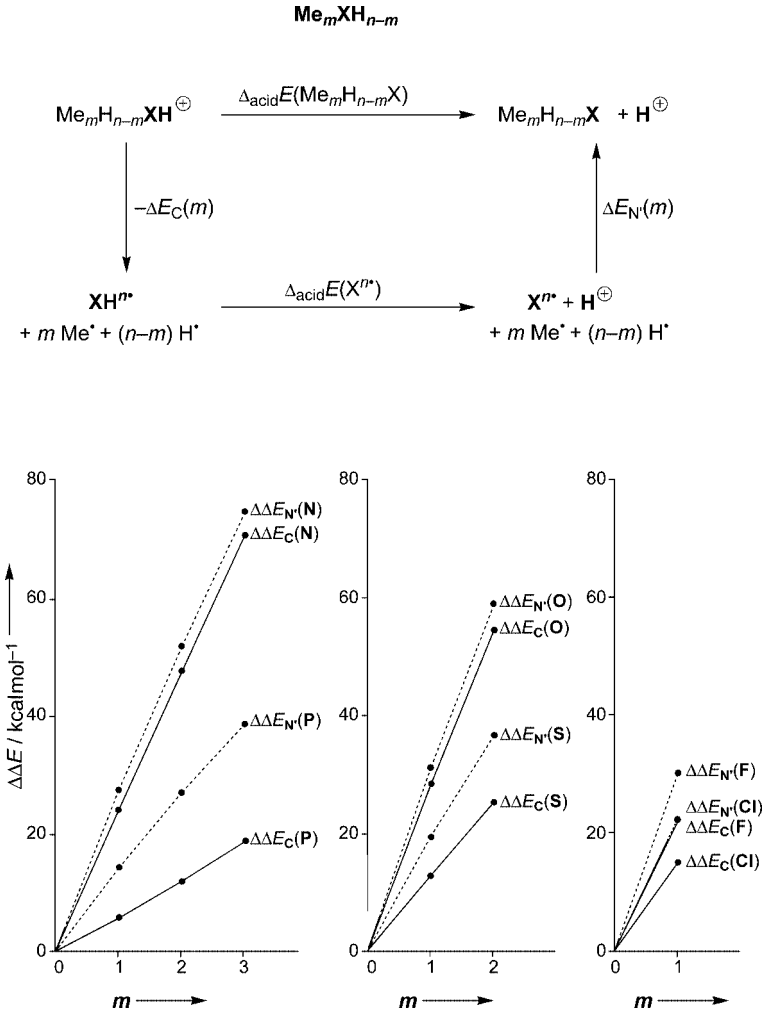

Figure 3. Effect of methyl substitution on the energies $\Delta E_C(X)$ and $\Delta E_{N'}(X)$ of the neutral $XH_n$ and corresponding cationic conjugate acids $XH_{n+1}^+$ in water, computed at BP86/QZ4P//BP86/TZ2P [see Equation (5) and Table 5].

$\Delta E_A$ of the *anionic* bases are collected in Table 5, together with corresponding energy terms $\Delta_{acid}E$, $\Delta E_C$ and $\Delta E_{N'}$ for the *neutral* bases.

The relationship between the proton-affinity energy $\Delta_{acid}E$ and the other energy terms of the thermochemical cycles shown in Figures 2 and 3 is summarized in Equations (4) and (5) ($m$ = number of methyl substituents) for the anionic ($Me_mH_{n-m-1}X^-$) and the neutral bases ($Me_mH_{n-m}X$).

$$\Delta_{acid}E(Me_mH_{n-m-1}X^-) = \Delta_{acid}E(X^{-(n-1)\bullet}) + \Delta E_A(m) - \Delta E_N(m) \quad (4)$$

$$\Delta_{acid}E(Me_mH_{n-m}X) = \Delta_{acid}E(X^{n\bullet}) + \Delta E_{N'}(m) - \Delta E_C(m) \quad (5)$$

Thus, according to Equation (4), the proton-affinity energy $\Delta_{acid}E(Me_mH_{n-m-1}X^-)$ of the base $Me_mH_{n-m-1}X^-$ is determined by the proton-affinity energy $\Delta_{acid}E(X^{-(n-1)\bullet})$ of the unsubstituted and deprotonated protophilic center $X^{-(n-1)\bullet}$ plus the *difference* in stabilization $\Delta E_A(m)$ of $X^{-(n-1)\bullet}$ in the base $Me_mH_{n-m-1}X^-$ and the stabilization $\Delta E_N(m)$ of $XH^{(n-1)\bullet}$ in $Me_mH_{n-m-1}XH$ by $m$ methyl (Me) and $n$-$m$-1 hydrogen substituents. The methyl-substituent effect on the proton-affinity energy, i.e., the change $\Delta\Delta_{acid}E(m)$ in this value if one goes from 0 to $m$ methyl substituents, therefore depends not only on the change $\Delta E_A(m) - \Delta E_A(0)$ in stabilization of the anionic base *but also on the change* $\Delta E_N(m) - \Delta E_N(0)$ *in stabilization of the neutral conjugate acid*. And, the same holds, *mutatis mutandis*, for the neutral bases, see Equation (5).

In Figure 2, lower panel, we have plotted the changes in stabilization by the substituents $\Delta\Delta E_A = \Delta E_A(m) - \Delta E_A(0)$ and $\Delta\Delta E_N = E_N(m) - \Delta E_N(0)$ for the anionic second- and third-period bases $Me_mH_{n-m-1}X^-$ and their conjugate acids $Me_mH_{n-m-1}XH$. In the lower panel of Figure 3, the corresponding plots for the neutral bases are depicted. Now it is clear that introducing a methyl substituent, i.e., replacing a hydrogen by the sterically more demanding and solvent-shielding methyl group, leads consistently in all cases to a destabilization of the system. And, contrasting the situation for the anionic bases in the gas-phase,[14] a methyl group

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*destabilizes* the anionic base *more* than its corresponding neutral conjugate acid also for the second period and not only the third period.

## 3. Conclusions

The proton affinities (PA) in water of simple anionic bases $XH_{n-1}^-$ and neutral bases $XH_n$ (derived from or constituted by maingroup-element hydrides $XH_n$) show qualitatively similar trends along a period or down a group in the periodic table as the corresponding PA values in the gas phase, namely: a monotonic decrease along the second and third period which starting at the fourth (for $XH_{n-1}^-$) or fifth period (for $XH_n$) turns into a peak-shaped trend with an initial increase from the tri- to the dicoordinate base (e.g. from $GeH_3^-$ to $AsH_2^-$) followed again by a monotonic decrease along the rest of the period.

In the gas phase, the anionic bases $XH_{n-1}^-$ have a significantly higher PA than the neutral bases $XH_n$. Hydration however drastically reduces the PA of the anionic bases, i.e., much more so than that of the neutral bases. This causes the PA values of anionic and neutral bases to differ much less in aqueous solution than in the gas phase.

In water, methyl substitution increases practically always the PA of both the anionic bases $Me_mXH_{n-m-1}^-$ and the neutral bases $Me_mXH_{n-m}$. In the gas phase, methyl substitution has the same effect with one important exception: in the case of the anionic second-period bases $Me_mXH_{n-m-1}^-$, the gas-phase PA decreases if methyl groups are introduced. Thus, for example, $OH^-$ is more basic than $MeO^-$ in the gas phase but, in water, $MeO^-$ is more basic than $OH^-$. We have analyzed in detail why this is so.

## 4. Methods

### 4.1. Basis Sets

All calculations were performed with the Amsterdam Density Functional (ADF) program.[34,35] Molecular orbitals (MOs) were expanded using two different large, uncontracted sets of Slater-type orbitals: TZ2P and QZ4P.[36] The TZ2P basis is of triple-ζ quality, augmented by two sets of polarization functions (2*p* and 3*d* on H; *d* and *f* on heavy atoms). The QZ4P basis, which contains additional diffuse functions, is of quadruple-ζ quality, augmented by four sets of polarization functions (two 2*p* and two 3*d* sets on H; two *d* and two *f* sets on heavy atoms). Core electrons (e.g. 1*s* for 2nd period, 1*s*2*s*2*p* for 3rd period, 1*s*2*s*2*p*3*s*3*p* for 4th period, 1*s*2*s*2*p*3*s*3*p*3*d*4*s*4*p* for 5th period, 1*s*2*s*2*p*3*s*3*p*3*d*4*s*4*p*4*d* for 6th period) were treated by the frozen core (FC) approximation.[35] An auxiliary set of *s*, *p*, *d*, *f*, and *g* STOs was used to fit the molecular density and to represent the Coulomb and exchange potentials accurately in each SCF cycle. Scalar relativistic corrections were included self-consistently using the Zeroth Order Regular Approximation (ZORA).[37]

### 4.2. Density Functional

Energies and gradients were calculated using the local density approximation (LDA; Slater exchange and VWN[38] correlation) with gradient corrections[31,32] due to Becke (exchange) and Perdew (correlation) added self-consistently. This is the BP86 density functional, which is one of the three best DFT functionals for the accuracy of geometries,[39] with an estimated unsigned error of 0.009 Å in combination with the TZ2P basis set. In a previous study[14] on the proton affinity of anionic species, we compared the energies of a range of other DFT functionals, to estimate the influence of the choice of DFT functional. These functionals included the Local Density Approximation (LDA), Generalized Gradient Approximations (GGAs), *meta*-GGA and hybrid functionals. The BP86 functional emerged as one of the best functionals. The restricted and unrestricted formalisms were used for closed-shell and open-shell species, respectively. In the present study, all geometry optimizations and vibrational analyses have been done at BP86/TZ2P. Energies have been computed in a single-point fashion, on top of the BP86/TZ2P geometries, using the BP86/QZ4P level of theory. Overall, this leads to a BP86/QZ4P// BP86/TZ2P approach.

### 4.3. Solvent Effects and Thermochemistry

Solvent effects were taken into account in all calculations using the COSMO model,[20,21] used explicitly both within the solving of the SCF equations and the optimization of the geometry. The solvent radius ($R_s$) for water was taken from experimental data for the macroscopic density ($\rho$) and molecular mass ($M_m$) with the formula $R_s^3 = 2.6752 \cdot M_m/\rho$,[40] leading to a $R_s$ value of 1.9 Å for water; a value of 78.4 was used for the dielectric constant of water. Atomic radii values were taken from the MM3 van der Waals radii,[41] which are available for almost the whole periodic system, and scaled by 0.8333 (the MM3 radii are 20% larger than the normal van der Waals radii due to the specific form for the van der Waals energy within the MM3 force field). The surface charges at the GEPOL93 solvent-excluding surface[42–44] were corrected for outlying charges. This setup provides a "non-empirical" approach to including solvent effects with a dielectric continuum, and works well for solvation processes.[1] The file needed for including this setup in a COSMO computation with the ADF program (including all values of the above-mentioned atomic radii) is provided as Table S1 in the electronic supporting information.

Geometries were optimized using analytical gradient techniques until the maximum gradient component was less than $1.0 \times 10^{-4}$ atomic units (see Table S2 in the electronic supporting information). Vibrational frequencies were obtained through numerical differentiation of the analytical gradients,[35] where for most of the systems the GEPOL93 surface was recreated at each displaced geometry.

For three systems (i.e., $Me_3N$, $Me_3NH^+$ and $Me_3PH^+$), these standard settings resulted in one large imaginary frequency (in the range from –2300 to –24000 $cm^{-1}$) which, however, proved to have a positive value (of around 1200 and 2000 $cm^{-1}$) in the more accurate (automatic) PES scan afterwards. This imaginary frequency is related to the numerical differentiation in combination with the GEPOL93 surface. Thus, by creating the GEPOL93 surface in the case of the three problematic systems *only* for the initial geometry and keeping this surface (geometrically) fixed for all displaced geometries, the large imaginary frequencies do not occur. Moreover, for well-behaved systems, keeping the GEPOL93 surface fixed or recreating them at every displaced geometry has a negligible effect on the enthalpy (<0.1 kcal/mol). Thus, for the problematic cases of $Me_3N$, $Me_3NH^+$ and $Me_3PH^+$, we used the thermodynamic data from the calculations where the GEPOL93 surface was fixed.

Reaction enthalpies at 298.15 K and 1 atm ($\Delta H_{298}$) were calculated from the corresponding changes in electronic energy ($\Delta E$) according to Equation (6), assuming an ideal gas.[33]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$\Delta H_{298} = \Delta E + \Delta E_{trans,298} + \Delta E_{rot,298} + \Delta E_{vib,0} + \Delta(\Delta E_{vib})_{298} + \Delta(pV) \quad (6)$$

Here, $\Delta E_{trans,298}$, $\Delta E_{rot,298}$ and $\Delta E_{vib,0}$ are the differences between products and reactants in translational, rotational and zero point vibrational energy, respectively; $\Delta(\Delta E_{vib})_{298}$ is the change in the vibrational energy difference as one goes from 0 to 298.15 K. The vibrational energy corrections are based on our frequency calculations. The molar work term for the gas-phase process, $\Delta(pV)$, is taken to be $(\Delta n)RT$; $\Delta n = +1$ for one reactant $BH^+$ dissociating into two products $B + H^+$. Thermal corrections for the electronic energy are neglected.

**Supporting Information** (see also the footnote on the first page of this article): Figures S1–S3 in color, input file (including atomic radii) for "non-empirical" COSMO solvation computations with ADF, and Cartesian coordinates of all species occurring in this study.

# Vanadium(IV) and Oxidovanadium(IV) and -(V) Complexes with Soft Thioether Coordination – Synthesis, Spectroscopic and Structural Studies

**Andrew L. Hector,[a] William Levason,[a] Annie J. Middleton,[a] Gillian Reid,*[a] and Michael Webster[a]**

**Keywords:** Vanadium / Thioether / Structural studies

$VOCl_3$ reacts with the thioethers $RS(CH_2)_2SR$ (R = Me, Et or *i*Pr) and 1,4-dithiane to form the first examples of $V^V$ thioether complexes, the highly reactive, intensely coloured $[VOCl_3(dithioether)]$ which have been characterised by $^1H$ and $^{51}V$ NMR, IR and UV/Vis spectroscopy. Combining $VOCl_3$ with $[9]aneS_3$ gives $[VOCl_3(\kappa^2\text{-}[9]aneS_3)]$ which, upon treatment with $SbCl_5$ gives $[VOCl_2(\kappa^3\text{-}[9]aneS_3)][SbCl_6]$. Vanadium *K*-edge extended X-ray absorption fine structure (EXAFS) studies on three examples provided partial structural analyses for these very unstable compounds. Reaction of $VCl_4$ with $O(SiMe_3)_2$ in $CH_2Cl_2$/MeCN followed by addition of $RS(CH_2)_2SR$ (R = Me or Et) produced $[VOCl_2\{RS(CH_2)_2SR\}]$. The crystal structure of $[\{VOCl_2(MeSCH_2CH_2SMe)\}_4]$ reveals a unique tetrameric $V_4O_4$ core with each vanadium also coordinated to a chelating dithioether and two Cl ligands to complete the distorted octahedral geometry. Under rigorously anhydrous conditions $VCl_4$ reacts with $RS(CH_2)_2SR$ (R = Me, Et, *i*Pr, Ph), 1,4-dithiane or $[9]aneS_3$ to form $[VCl_4(thioether)]$ which are assigned as six-coordinate distorted octahedral species on the basis of their spectroscopic characterisation. In some cases trace hydrolysis of these compounds provides an alternative route to the $[VOCl_2(dithioether)]$ complexes.

## Introduction

Vanadium has a very rich coordination chemistry owing in part to the accessibility of a range of oxidation states. However, the ease with which vanadium can undergo a redox switch between oxidation states, combined with its lability, leads to significant synthetic challenges in preparing pure materials, especially in the +4 and +5 oxidation states. These higher oxidation states of vanadium are dominated by oxido species and the majority of neutral ligand complexes known are with hard O- or N-donor ligands.[1–3] Examples of high oxidation state vanadium complexes with softer, neutral σ-donor ligands such as thio- or selenoethers are extremely rare – no $V^V$ derivatives are known and the only structurally characterised example with $V^{IV}$ is the distorted octahedral vanadyl species $[VOCl_2([9]aneS_3)]$.[4,5] The lower oxidation state $V^{III}$ and $V^{II}$ thioether complexes are well established,[5–8] but reports of $V^{IV}$ thioethers contain very limited data.[9,10] We note that much early work on phosphane complexes of $VCl_4$ is now known to be erroneous (see for example ref.[11] for a thorough discussion of the problems) due to the failure to recognise the ease of reduction to $V^{III}$ or the hydrolysis to $VOCl_2$ adducts, and the over-reliance on qualitative EPR spectra from incompletely characterised samples. In a recent paper concerned with $VOCl_3$ adducts with neutral N- or O-donor ligands,[3] we briefly noted that in dry $CH_2Cl_2$ solution $VOCl_3$ is reduced by $SR_2$ (R = Me, Et, *n*Bu or Ph), $PhSCH_2CH_2SPh$, $Me_2Se$ or $MeSeCH_2CH_2SeMe$. In an effort to investigate more fully the chemistry of $V^{IV}$ and $V^V$ precursors with soft thioether ligands and to establish whether the ligand structure is important in determining the course of the reactions, we have conducted a systematic study of $VOCl_3$, $VOCl_2$ and $VCl_4$ with the dithioethers $RSCH_2CH_2SR$ (R = Me, Et, *i*Pr), 1,4-dithiane and the macrocyclic $[9]aneS_3$ and $[18]aneS_6$. We report here the results of this investigation including the IR, UV/Vis and NMR (for $V^V$) spectroscopic characterisation of the resulting complexes, structural studies via vanadium *K*-edge EXAFS measurements, and a crystal structure of an extremely unusual metallocyclic vanadyl(IV) species, $[\{VOCl_2(MeSCH_2CH_2SMe)\}_4]\cdot CH_2Cl_2$.

## Results and Discussion

**$VOCl_3$ Complexes:** $VOCl_3$ and 2,5-dithiahexane react in anhydrous $CH_2Cl_2$ to give a dark red-brown solution from which $[VOCl_3(MeSCH_2CH_2SMe)]$ was obtained as a red-black powder by precipitation with *n*-hexane (Scheme 1). The freshly prepared complex is very soluble in chlorocarbons and extremely moisture-sensitive (turning into a blue oil in air), and decomposes even in the dark in ca. 48 h, becoming dull purple and completely insoluble in chlorocarbons. The red-black $[VOCl_3(RSCH_2CH_2SR)]$ (R = Et or

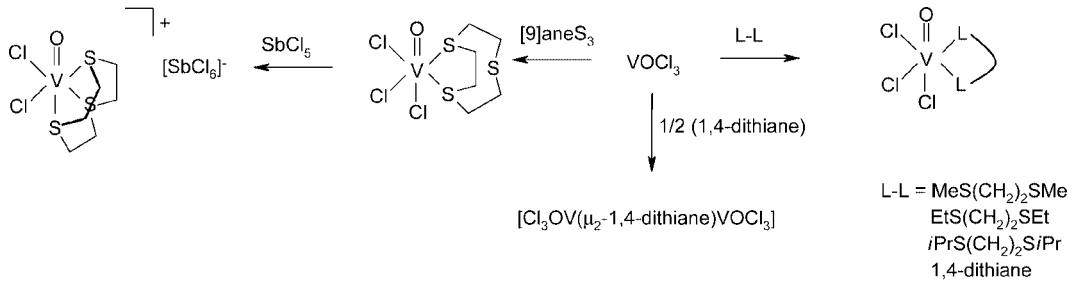

Scheme 1.

*i*Pr) are obtained similarly, although they are even less stable and decompose in a few hours, which prevented microanalytical data being obtained, but are spectroscopically very similar to the dithiahexane complex. In contrast, $VOCl_3$ in $CH_2Cl_2$ solution was immediately reduced by $PhSCH_2CH_2SPh$, *cis*-MeSCH=CHSMe or $MeS(CH_2)_3SMe$ to pinkish $V^{III}$-containing products (based upon their UV/Vis spectra). The red-black [$VOCl_3$(1,4-dithiane)] was obtained by treating a solution of 1,4-dithiane with a stoichiometric amount of $VOCl_3$ and precipitation with *n*-hexane, but using an excess of $VOCl_3$ gave the brown dinuclear [$(VOCl_3)_2$(1,4-dithiane)]. The reaction of thiacrowns with $VOCl_3$ is also very dependent on the ligand used. Both [9]aneS$_3$ and [18]aneS$_6$ react with excess $VOCl_3$ in $CH_2Cl_2$ to precipitate dark red-brown solids of composition [$VOCl_3$([9]aneS$_3$)] and [$(VOCl_3)_2$([18]aneS$_6$)] respectively, but [12]aneS$_4$ or [14]aneS$_4$ afford pale purple powders which lack any VO features in the IR spectra and their UV/Vis spectra suggest six-coordinate [$VCl_3$(thiacrown)], similar to complexes made directly from [$VCl_3(thf)_3$].[8] The [$VOCl_3$([9]aneS$_3$)] complex is stable for some weeks in the dark and the dry solid can be handled quickly in air, although it slowly turns blue in moist air (ca. 5 min) – the hydrolysis product was identified by IR and UV/Vis spectroscopy as [$VOCl_2$([9]aneS$_3$)].[4,5] Attempts to abstract chloride from [$VOCl_3$([9]aneS$_3$)] using $FeCl_3$ were unsuccessful, but when this reaction was repeated using $SbCl_5$, which is a much stronger Lewis acid, the brown-purple [$VOCl_2$([9]aneS$_3$)][$SbCl_6$] was formed in good yield. The complexes of the thiacrowns are very poorly soluble in chlorocarbons, which prevented solution spectroscopic studies.

The IR spectra of [$VOCl_3(RSCH_2CH_2SR)$] (Table 1) exhibit strong bands at ca. 970–1000 cm$^{-1}$ assigned as ν(VO), and strong features at 400–300 cm$^{-1}$ due to ν(VCl), which are similar to those observed in six-coordinate $V^V$ complexes of N- and O-donor ligands.[3] The UV/Vis spectra of the solid compounds are dominated by intense L→V charge-transfer transitions above ca. 19000 cm$^{-1}$ (usually with weak shoulders to lower energy), generally similar in band energies to those reported for N- or O-donor ligands,[3] suggesting that π(Cl)→V transitions are mainly responsible for the strong features. The insoluble materials produced by decomposition of the solids exhibited intense, poorly defined features across the visible region, presumably indicating mixed-valence materials. In anhydrous $CH_2Cl_2$ solution all three complexes exhibit single, quite sharp $^{51}$V NMR resonances with chemical shifts only slightly (5–15 ppm) to low frequency of $VOCl_3$, and the spectra are unchanged on cooling the samples to 190 K. These values compare with much more negative resonances found for complexes with N- or O-donors[3,12] and are consistent with soft V–S coordination in these complexes. Hydrolysis in solution leads to the production of $[VOCl_4]^-$ and $[VO_2Cl_2]^-$, readily identified by their $^{51}$V NMR resonances at $\delta$ +48 and –362 ppm respectively.[12] The $^1$H NMR spectrum of [$VOCl_3(MeSCH_2CH_2SMe)$] at 295 K in $CD_2Cl_2$ shows single δ(Me) and δ($CH_2$) resonances due to coordinated dithioether, to high frequency of those of the uncomplexed ligand, and the single δ(Me) and δ($CH_2$) resonances indicate a single geometric isomer with the sulfur donor atoms *trans* to Cl, giving *fac* chlorines (Scheme 1). On cooling the solution to 190 K, pyramidal inversion at the sulfur

slows and four coordinated δ(Me) resonances and a complex pattern of overlapping δ($CH_2$) signals are present, consistent with three invertomers (*meso-1, meso-2* and *DL*) in a complex lacking axial symmetry. In the presence of added ligand, separate resonances for "free" and coordinated dithioether are seen, showing ligand exchange is slow on the NMR timescale at ambient temperatures. The $^1$H NMR spectra of the [$VOCl_3$(RS$CH_2CH_2$SR)] (R = Et or *i*Pr) exhibit generally similar behaviour, although even at the lowest temperatures studied (190 K) the $^3J_{HH}$ couplings within the Et and *i*Pr groups are not resolved, only broad singlets are observed for the different protons – this broadening may be due to the proximity to the quadrupolar $^{51}$V nucleus.

The dark red [$VOCl_3$(1,4-dithiane)] has similar physical and spectroscopic properties to the acyclic dithioether complexes, and is assigned a similar six-coordinate geometry, probably with chelating dithiane. The spectroscopic properties of the dark brown [($VOCl_3$)$_2$(1,4-dithiane)] are rather different, notably υ(VO) is at 1020 cm$^{-1}$, in the range observed for five-coordinate $VOCl_3$ adducts.[3] 1,4-Dithiane often favours a bridging coordination mode[13] and this may account for the formation of a 2:1 complex uniquely with this ligand.

The [$VOCl_3$([9]ane$S_3$)] complex is very poorly soluble in chlorocarbons, $MeNO_2$ or MeCN and decomposed by strong donor solvents such dmf, which has prevented solution spectroscopic studies. Three possible structures for this complex are the seven-coordinate [$VOCl_3$(κ$^3$-[9]ane$S_3$)], six-coordinate [$VOCl_3$(κ$^2$-[9]ane$S_3$)] or [$VOCl_2$(κ$^3$-[9]ane$S_3$)]Cl. The spectroscopic properties are similar to those of [$VOCl_3$(RS$CH_2CH_2$SR)], and the EXAFS data (below) are consistent with [$VOCl_3$(κ$^2$-[9]ane$S_3$)]. The failure of the complex to react with $FeCl_3$ (to form [$VOCl_2$(κ$^3$-[9]ane$S_3$)][$FeCl_4$]) rules out the cationic formulation, and whilst seven-coordination is known for a very small number of $V^V$ compounds, all seem to contain small bite-angle ligands such as κ$^2$-$NO_3$ or κ$^2$-$S_2CNR_2$[1] and it seems highly unlikely here. Hence the data support a [$VOCl_3$(κ$^2$-[9]ane$S_3$)] formulation. The 2:1 [18]ane$S_6$ complex probably has a similar vanadium core. The dark brown-purple [$VOCl_2$([9]ane$S_3$)][$SbCl_6$] formed by reaction of $VOCl_3$, $SbCl_5$ and [9]ane$S_3$ in anhydrous $CH_2Cl_2$ has υ(VO) at 1020 cm$^{-1}$, higher than that in the neutral [$VOCl_3$([9]ane$S_3$)] (974 cm$^{-1}$) and a very strong, broad band at 343 cm$^{-1}$ assigned as the $T_{1u}$ mode of the $[SbCl_6]^-$ ion.

The instability of the [$VOCl_3$(RS$CH_2CH_2$SR)] in solution and the insolubility of the macrocyclic complexes prevented all attempts to obtain crystals for X-ray structure determination. We therefore collected vanadium *K*-edge EXAFS data on three examples. Data were collected in transmission mode from freshly prepared (within 24 h) samples of [$VOCl_3$(MeS$CH_2CH_2$SMe)], [$VOCl_3$([9]ane$S_3$)] and [$VOCl_3$(1,4-dithiane)] diluted with BN (Experimental section). The data were all fitted to a four-shell model of 1 × O, 2 × Cl (*trans* S), 1 × Cl (*trans* O), and 2 × S, corresponding to a six-coordinate environment with the thioether sulfur atoms *trans* to Cl (see Experimental Section for details). The results are summarised in Table 2. Figure 1 shows a typical example of the background subtracted EXAFS data and the Fourier transform. The data on the three complexes are in excellent agreement. Few complexes of $VOCl_3$ have been structurally characterised but the *d*(V–O) of ca. 1.6 Å in the thioether complexes compares well with those in $[VO_2Cl_2]^-$ (1.58 (av) Å),[14] [$VOCl_2$([9]ane$S_3$)] (1.579(4) Å)[4] and [$VOCl_3${(2-nitrophenyl)pyridine-2-

carboxamide}] (1.572(1) Å).[14] For comparison *d*(V–O) in solid molecular $VOCl_3$ (133 K) is 1.562(7) Å and *d*(V–Cl) 2.125(3) and 2.124(2) Å.[15] Two V–Cl shells were refined, the slightly shorter distances corresponding to the two chlorines *trans* to S, and the longer distance due to the one chlorine *trans* to V=O. The V–S distances at ca. 2.66–2.69 Å are significantly longer than V–$S_{trans Cl}$ in both $[\{VOCl_2(MeSCH_2CH_2SMe)\}_4]$ (2.48 Å) (Table 3) and $[VOCl_2([9]aneS_3)]$ (2.47 Å). The Ti–$S_{trans–Cl}$ distances in $[TiCl_4(dithioether)]$ are 2.60–2.65 Å.[16] The similarity of the distances within the three $V^V$ complexes and the best fit statistical data also support the six-coordinate $S_2Cl_3O$ donor sets for $[VOCl_3([9]aneS_3)]$ and $[VOCl_3(1,4\text{-dithiane})]$ proposed above based upon the spectroscopic data.

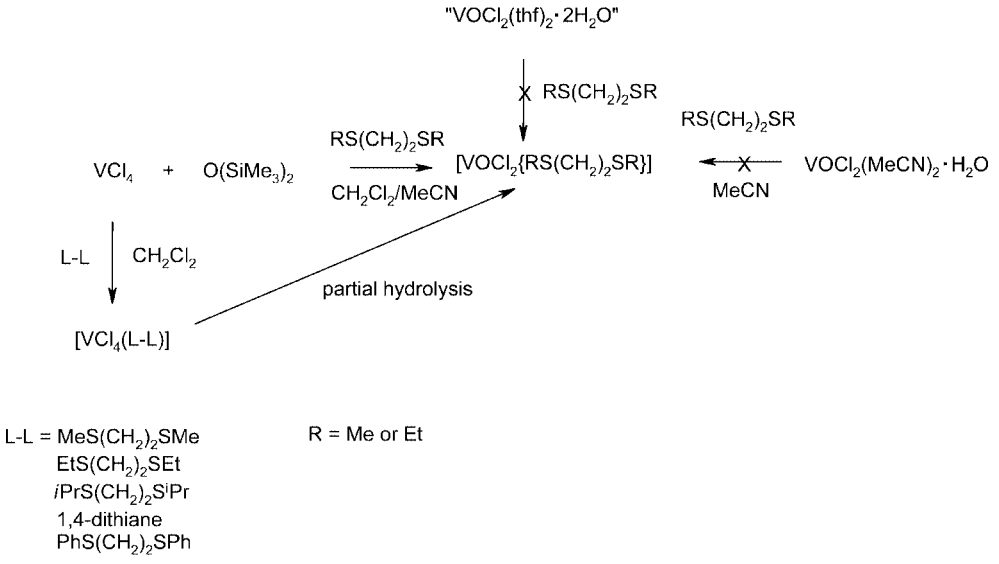
**$VOCl_2$ Complexes:** Red-brown crystals of $[\{VOCl_2(MeSCH_2CH_2SMe)\}_4]$ were initially obtained by storing a dilute $CH_2Cl_2$ solution of $VCl_4$ and $MeSCH_2CH_2SMe$ in a freezer for a few days, and were found to have the unique tetranuclear structure described below. The crystals clearly form by hydrolysis and red-brown powders of $[\{VOCl_2(RSCH_2CH_2SR)\}_4]$ (R = Me or Et) can be isolated in modest yield by storing dilute $CH_2Cl_2$ solutions of $VCl_4$ and $RSCH_2CH_2SR$ (after removal of precipitated $[VCl_4(RSCH_2CH_2SR)]$ by filtration) in a freezer for 1–2 weeks (Scheme 2). Hydrolysis does not stop at these species and after several months blue oils form. The robust (blue) $[VOCl_2([9]aneS_3)]$ can be made by hydrolytic oxidation of $[VCl_3([9]aneS_3)]$,[4] or by decomposition of $[VOCl_3([9]aneS_3)]$ (above), but these routes are not viable for the acyclic dithioethers. However, reaction of $VCl_4$ with one molequiv. of $O(SiMe_3)_2$ in anhydrous $CH_2Cl_2$ containing a small amount of MeCN, followed by addition of $RSCH_2CH_2SR$ produced the $[\{VOCl_2(RSCH_2CH_2SR)\}_4]$ in good yield. The MeCN presumably stabilises the $VOCl_2$ intermediate, since the reaction in neat $CH_2Cl_2$ does not work. Excess MeCN should be avoided since it reduces $VCl_4$ to $V^{III}$.[17] The $[\{VOCl_2(RSCH_2CH_2SR)\}_4]$ are readily hydrolysed in solution and decomposed by alcohols or acetone, but the pure, dry solids can be handled quickly in air. They are paramagnetic with $\mu_{eff}$ = 1.8 $\mu_B$ and exhibit ν(V=O) at 975, 837 (R = Me) or 985, 830 (R = Et) $cm^{-1}$ (Table 1) consistent with the V–O···V bridged structure (below).

Many vanadyl compounds are known; the majority are blue or green, discrete five-coordinate square pyramids or distorted octahedra (5 + 1 coordination), or sometimes chain polymers with *trans* O=V···O=V··· links.[1,2] A limited number of orange-brown polymers with polydentate Schiff bases are also known.[1,18] The structure of $[\{VOCl_2(MeSCH_2CH_2SMe)\}_4]$ is quite different (Table 3, Figure 2) and has a tetranuclear $V_4O_4$ core. The structure can either be described as based upon square pyramidal $VOCl_2(MeSCH_2CH_2SMe)$ units with apical chlorine, linked through asymmetric *cis* oxygen bridges into a tetramer, or as a puckered square with vanadium at the corners and asymmetric [V–O 1.640(3), 2.004(3) Å], non-linear [V–O–V 168.6(2)°] oxygen bridges along the edges. The coordination about each vanadium is completed by two terminal chlorines and a chelating dithioether [S–V–S angle 80.85(5) °]



Scheme 2.

which has the *DL* configuration. In addition to the disparate V–O distances (the differences are 0.4 Å), the bond lengths around the vanadium centres reveal that the *trans* influence of the ligands on this hard metal is O > Cl > S. Thus V–$S_{transO}$ 2.662(1) Å, whilst V–$S_{transCl}$ 2.482(2) Å and V–$Cl_{transO}$ 2.311(1) Å, V–$Cl_{transS}$ 2.288(1) Å. For comparison, the bond lengths in the six-coordinate (5 + 1) [$VOCl_2$([9]ane$S_3$)] are V–O 1.579(4), V–Cl 2.295(5), and V–S 2.634(5), 2.470(5) Å.[4] A search of the CCDB revealed that the structure of the [{VO(SNNS)}$_4$] [SNNS = the dianion of *N*,*N*′-bis(*o*-mercaptophenyl)ethylendiamine] also contains a $V_4O_4$ core, but with a boat conformation.[19] The closest analogue to the structure of [{$VOCl_2$-($MeSCH_2CH_2SMe$)}$_4$] appears to be [{$TiOCl_2$([15]crown-5)}$_4$], a hydrolysis product of [$TiCl_4$([15]crown-5)], which contains a planar $Ti_4O_4$ ring with coordination at each Ti completed by two terminal chlorines and a $\kappa^2$-crown ether.[20]

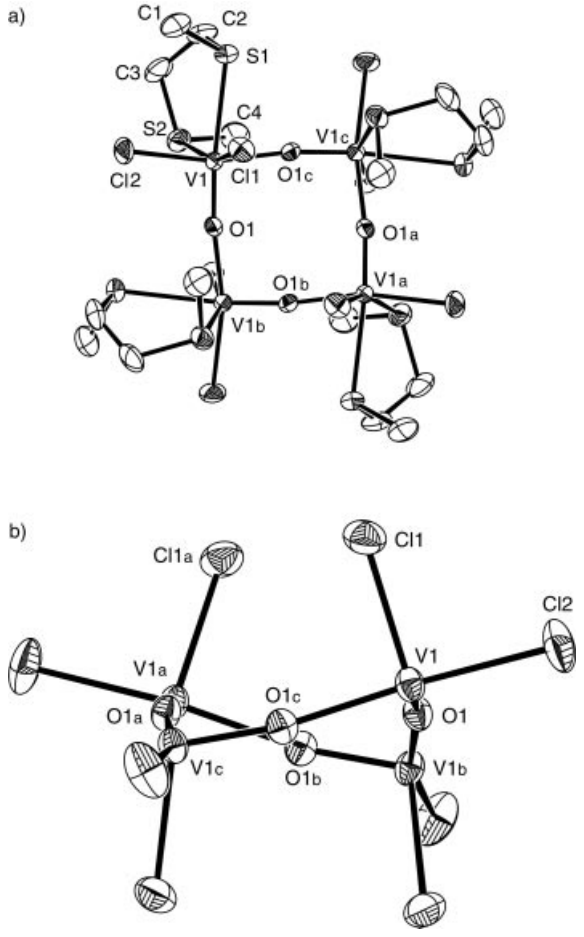

Figure 2. (a) Structure of the tetrameric molecule [{$VOCl_2$($MeSCH_2CH_2SMe$)}$_4$]·$CH_2Cl_2$. Thermal ellipsoids are drawn at the 50% probability level and H atoms are omitted for clarity. Symmetry operations: $a$ = –$x$, –$y$, $z$; $b$ = $y$, –$x$, 2 – $z$; $c$ = –$y$, $x$, 2 – $z$; (b) edge view of the $V_4O_4$ core within the tetramer.

**$VCl_4$ Complexes:** The reactions of the dithioethers $RSCH_2CH_2SR$ (R = Me, Et, *i*Pr), 1,4-dithiane and $MeS(CH_2)_3SMe$ in a 1:1 mol. ratio in rigorously anhydrous $CH_2Cl_2$ solution at or below ambient temperatures formed dark violet [$VCl_4$(dithioether)], which precipitated from the solutions. Using excess dithioether, addition of neat ligand to concentrated solutions of $VCl_4$ (which generates considerable heat) or gently heating $CH_2Cl_2$ solutions, produced lighter coloured materials, which contained substantial amounts of $V^{III}$. Gentle reflux of the $CH_2Cl_2$ preparative solutions in the presence of excess ligand produced complete reduction to pale lilac six-coordinate $V^{III}$ complexes. Using the weaker donor $PhSCH_2CH_2SPh$ produced an unstable dark purple solid [$VCl_4$($PhSCH_2CH_2SPh$)], but the related ligand $PhS(CH_2)_3SPh$ does not form a $V^{IV}$ complex; under similar reaction conditions it produced a pale lilac powder with the UV/Vis spectrum of a $V^{III}$ complex ($E_{max}$ 11970, 18500, 28570 $cm^{-1}$).[21] The reaction of $VCl_4$ with [9]ane$S_3$ in $CH_2Cl_2$ precipitates the purple solid [$VCl_4$([9]ane$S_3$)] which is insoluble in common solvents and when dry may be handled quickly in air without visible decomposition. Refluxing a mixture of $VCl_4$ with [9]ane$S_3$ in $CH_2Cl_2$ results in the known bright pink complex [$VCl_3$([9]-ane$S_3$)].[5] Repeated attempts to isolate [$VCl_4(SR_2)_2$] (R = Me, Et, *n*Bu or Ph) by reaction of $VCl_4$ with $SR_2$ in a 1:≤2 molar ratio in anhydrous $CH_2Cl_2$ solution failed. Excess thioether brings about immediate reduction to $V^{III}$, as described previously.[7,22,23]

The solid [$VCl_4$(dithioether)] are extremely moisture-sensitive, evolving yellow fumes in air and turning green-blue. However, in contrast to the $V^V$ [$VOCl_3$(dithioether)] complexes, they are stable in the dry box for several weeks. The complexes are very poorly soluble in chlorocarbons (cf. [$TiCl_4$(dithioether)])[16] and decomposed by acetone, alcohols or thf. The complexes are paramagnetic with magnetic moments $\mu_{eff}$ = 1.7–1.9 $\mu_B$, consistent with $d^1$ $V^{IV}$. The diffuse reflectance spectra show broad features at ca. 19000–20000 $cm^{-1}$ with a weaker shoulder to low energy (ca. 17000 $cm^{-1}$). The original work on these complexes assigned these features as d–d transitions and ascribed the splitting to the low symmetry ($C_{2v}$).[9] However, a d–d assignment seems at odds with the very intense colours and we propose that these bands are charge transfer π(Cl)→V (main band) and π(S)→V (shoulder), respectively. These assignments are supported by approximate calculations based upon the optical electronegativity model.[21,24,25] The spectrum of $[VCl_6]^{2-}$ contains the $^2T_{2g} \rightarrow {}^2E_g$ transition at 15500 $cm^{-1}$ and the lowest charge-transfer band, π(Cl)→V($t_{2g}$) at 20500 $cm^{-1}$.[24] The lowest energy charge-transfer band ($E_{max}$) for a $d^1$ complex in octahedral symmetry is predicted by the Equation (1):

$$E_{max}/cm^{-1} = 30000\{\chi_{opt}(L) - \chi_{opt}(M)\} - (14/3)B \quad (1)$$

Using the normal Pauling electronegativities for Cl and S, and estimating the Racah parameter ($B$) for Cl = 650 $cm^{-1}$, leads to a prediction of π(Cl)→V($t_{2g}$) ca. 20000 $cm^{-1}$ and π(S)→V($t_{2g}$) ca. 17000 $cm^{-1}$. The very significant low energy shift in the charge-transfer bands between [$TiCl_4$(dithioether)][16] and [$VCl_4$(dithioether)] is also consistent with the much greater ease of reduction of the vanadium complexes.

## Conclusions

The results reported here constitute the first detailed characterisation of a series of soft, neutral thioether ligand complexes of $V^{IV}$ and $V^{V}$. The architecture of the thioether ligands plays a significant role in governing the vanadium oxidation state produced and the relative stabilities of the complexes. Soft donor ligand complexes of $V^{V}$ are extremely unusual (phosphanes, arsanes, selenoethers and some thioethers bring about immediate reduction to $V^{IV}$ and/or $V^{III}$).[3,7,10] The tetrameric structure observed for $[\{VOCl_2(MeSCH_2CH_2SMe)\}_4]$ is a new structure type for vanadyl(IV), and contrasts with the discrete distorted octahedral geometry in the (coordinatively saturated) $[VOCl_2([9]aneS_3)]$. The successful isolation of these complexes indicate that under appropriate conditions and with judicious choice of ligand architecture, it may be possible to obtain limited examples of analogues with other soft donor ligands (e.g. selenoethers or arsanes).

## Experimental Section

All reactions were conducted under anhydrous conditions and under dry dinitrogen using standard vacuum line Schlenk and glovebox techniques. $VOCl_3$ and $VCl_4$ (Aldrich) were used as received. Solvents were dried by distillation from $CaH_2$ ($CH_2Cl_2$) or Na/benzophenone ketyl (hexane and diethyl ether). The thioethers $RSCH_2CH_2SR$ (R = Me, Et, *i*Pr, Ph) and $MeS(CH_2)_3SMe$ were made by literature methods[26] and dried and stored over molecular sieves. 1,4-dithiane, [9]aneS$_3$ and [18]aneS$_6$ were obtained from Aldrich and were dried by melting in vacuo immediately before use. Physical measurements were made as described previously[3] and microanalytical data were obtained from the microanalytical laboratory of Strathclyde University. All measurements were made on freshly prepared samples and the samples of the majority of the compounds were prepared several times and checked for consistency of the spectroscopic data.

**$[VOCl_3(MeSCH_2CH_2SMe)]$:** A solution of $VOCl_3$ (0.23 g, 1.3 mmol) in dry $CH_2Cl_2$ (5 mL) was added to a solution of 2,5-dithiahexane (0.16 g, 1.3 mmol) in dry $CH_2Cl_2$ (20 mL). The dark red solution was concentrated to ca. 5 mL in vacuo, dry *n*-hexane (5 mL) added and the red-black solid isolated by filtration, and dried in vacuo. Yield 0.18 g, 46%. $C_4H_{10}Cl_3OS_2V$ (295.5): calcd. C 16.3, H 3.4; found C 16.1, H 3.6. $^1$H NMR (300 MHz, $CD_2Cl_2$, 300 K): $\delta$ = 2.5 (s, 3 H, $CH_3$), 3.0 (s, 2 H, $CH_2$); (193 K): $\delta$ = 2.36, 2.39, 2.47, 2.60 (s, $CH_3$), 3.15–3.33 (br. m, $CH_2$) ppm. $^{51}$V NMR ($CH_2Cl_2$, 300 K): $\delta$ = –14 ($w_{1/2}$ = 800 Hz, sharpens on cooling but shift unchanged) ppm. UV/Vis ($CH_2Cl_2$): $E_{max}$ ($\varepsilon_{mol}$, $cm^{-1}\,dm^3\,mol^{-1}$) = 17120 (sh), 20160 (930), 21050 (1150), 25600 (1500), 31050 (sh), 33330 (2700) $cm^{-1}$.

**$[VOCl_3(EtSCH_2CH_2SEt)]$:** This compound was best made by adding excess $VOCl_3$ to the ligand in $CH_2Cl_2$ and pumping to dryness in vacuo in the dark. Yield 65%. As made it is a red-black powder, very soluble in chlorocarbons. Even in the dark in the glove box the complex decomposes in less than 24 h becoming insoluble in chlorocarbons. $^1$H NMR (300 MHz, $CD_2Cl_2$, 300 K): $\delta$ = 1.46 (br. s, 3 H, $CH_3$), 2.96 (br. s, 2 H, $CH_2$), 3.20 (br. s, 2 H, $CH_2$) ppm. $^{51}$V NMR ($CH_2Cl_2$, 300 K): $\delta$ = –7.1 ($w_{1/2}$ = 850 Hz); (223 K): $\delta$ = –7.5 ($w_{1/2}$ = 700 Hz) ppm.

**$[VOCl_3(i PrSCH_2CH_2S i Pr)]$:** This complex was made similarly to the one above, obtained as a red-black powder, yield 62%. $^1$H NMR (300 MHz, $CD_2Cl_2$, 300 K): $\delta$ = 1.2 (br., 6 H, $CH_3$), 1.40 (br., H, CH), 3.0 (br. s, 2 H, $CH_2$); (190 K): $\delta$ = 1.17, 1.18 (sh), 1.31, 1.39, 2.95, 3.08 (all broad and with no couplings resolved) ppm. $^{51}$V NMR ($CH_2Cl_2$, 300 K): $\delta$ = –5.4 ($w_{1/2}$ = 700 Hz); (213 K): $\delta$ = –6.1 ($w_{1/2}$ = 700 Hz) ppm. UV/Vis ($CH_2Cl_2$): $E_{max}$ = 15300 (sh), 20960, 28600, 30500 $cm^{-1}$.

**$[VOCl_3(1,4\text{-dithiane})]$:** A solution of $VOCl_3$ (0.23 g, 1.3 mmol) in dry $CH_2Cl_2$ (5 mL) was added to a solution of freshly sublimed 1,4-dithiane (0.16 g, 1.3 mmol) in dry $CH_2Cl_2$ (20 mL). The dark red solution was concentrated to ca. 5 mL in vacuo, dry *n*-hexane (5 mL) added and the red-black solid isolated by filtration, and dried in vacuo. Yield 0.22 g, 58%. $C_4H_8Cl_3OS_2V$ (293.5): calcd. C 16.4, H 2.8; found C 16.3, H 3.2. $^1$H NMR (300 MHz, $CD_2Cl_2$, 300 K): $\delta$ = 3.34 (br., $CH_2$); (190 K): $\delta$ = 3.63 (br., 2 H), 3.05 (br., 2 H) ppm. $^{51}$V NMR ($CH_2Cl_2$, 300 K): $\delta$ = +18 ($w_{1/2}$ = 300 Hz); (213 K): $\delta$ = +38. UV/Vis ($CH_2Cl_2$): $E_{max}$ = 16000 (sh), 18100, 21200, 26000 $cm^{-1}$.

**$[(VOCl_3)_2(1,4\text{-dithane})]$:** 1,4-Dithiane (0.12 g, 1.0 mmol) was freshly sublimed in vacuo and then dissolved in dry $CH_2Cl_2$ (15 mL) and added to a solution of $VOCl_3$ (0.36 g, 2.0 mmol) in dry $CH_2Cl_2$ (10 mL). The very dark brown solution was stirred for 1 h at room temperature and then concentrated in vacuo to ca. 5 mL. Dry *n*-hexane (5 mL) was added by cannula and the dark brown powder which separated was filtered off and dried in vacuo. Yield 0.32 g, 67%. $C_4H_8Cl_6O_2S_2V_2$ (466.8): calcd. C 10.3, H 1.7; found C 10.3, H 1.1. $^1$H NMR (300 MHz, $CD_2Cl_2$, 300 K): $\delta$ = 3.1 (s, $CH_2$) ppm. $^{51}$V NMR ($CH_2Cl_2$, 300 K): $\delta$ = +10.5 ($w_{1/2}$ = 100 Hz), little changed on cooling ppm. UV/Vis ($CH_2Cl_2$): $E_{max}$ = 18200 (sh), 21370, 27170 $cm^{-1}$.

**$[VOCl_3([9]aneS_3)]$:** [9]aneS$_3$ (0.09 g, 0.5 mmol) was dissolved in dry $CH_2Cl_2$ (15 mL) and added to a solution of $VOCl_3$ (0.09 g, 0.5 mmol) in dry $CH_2Cl_2$ (10 mL). A dark red-brown solid separated immediately. The dark suspension was concentrated to ca. 5 mL in vacuo, and the red-brown solid filtered off, rinsed with dry *n*-hexane (5 mL) and dried in vacuo. Yield 0.17 g, 94%. $C_6H_{12}Cl_3OS_3V$ (353.6): calcd. C 20.4, H 3.4; found C 20.5, H 3.7. {When the dry solid is exposed to air it turns pale green-blue in ca. 5 min and this product was identified as $[VOCl_2([9]aneS_3)]$. IR (Nujol): $\tilde{\nu}$ = 960 $cm^{-1}$ (VO), 344, 307 (sh) (VCl) $cm^{-1}$. UV/Vis (*dr* in $BaSO_4$): $E_{max}$ = 14450, 25000 sh, 30120 $cm^{-1}$.}

**$[VOCl_2([9]aneS_3)][SbCl_6]$:** $VOCl_3$ (0.09 g, 0.5 mmol) and $SbCl_5$ (0.15 g, 0.5 mmol) were dissolved in dry $CH_2Cl_2$ (15 mL), and stirred for 10 min, after which a solution of [9]aneS$_3$ (0.09 g, 0.5 mmol) in $CH_2Cl_2$ (10 mL) was added by syringe. The mixture slowly became brown and then deep purple in colour and after about 30 min contained a deep purple-brown precipitate in a pale yellow solution. The solid was filtered off, rinsed with $CH_2Cl_2$ (5 mL) and dried in vacuo. Yield 0.30 g, 91%. $C_6H_{12}Cl_8OS_3SbV$ (652.7): calcd. C 11.0, H 1.9; found C 10.7, H 2.2. IR (Nujol): $\tilde{\nu}$ = 1020 $\nu$(VO), 418 (VCl), 343 $\nu(SbCl_6)$ $cm^{-1}$.

**$[(VOCl_3)_2([18]aneS_6)]$:** Was made similarly to the [9]aneS$_3$ complex above using a 2.5:1 ratio of $VOCl_3$:[18]aneS$_6$ giving a dark red-brown powder. Yield 75%. $C_{12}H_{24}Cl_6O_2S_6V_2$ (707.3): calcd. C 20.4, H 3.4; found C 20.5, H 3.7.

**$[\{VOCl_2(MeSCH_2CH_2SMe)\}_4]$. Method 1:** $VCl_4$ (0.19 g, 1.0 mmol) was dissolved in a mixture of anhydrous $CH_2Cl_2$ (20 mL) and MeCN (0.5 mL), $Si(OMe_3)_2$ (0.18 g, 1.0 mmol) added, and the solution stirred for 15 min. $MeSCH_2CH_2SMe$ (0.12 g, 1.0 mmol) was then added, the solution stirred for 1 h and then concentrated in vacuo to ca. 5 mL. The brown solid was separated by filtration and dried in vacuo. Yield 0.15 g, 45%.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Method 2:** $VCl_4$ (0.38 g, 2.0 mmol) was dissolved in anhydrous $CH_2Cl_2$ (15 mL) and $MeSCH_2CH_2SMe$ (0.24 g, 2.0 mmol) in $CH_2Cl_2$ (10 mL) added producing a very dark solution and some precipitate. The solid was filtered off and the solution stirred at room temperature under nitrogen for 24 h, and then refrigerated for 1 week. The brown solid formed was filtered off and dried in vacuo. Yields variable – typically 10–15%. $C_4H_{10}Cl_2OS_2V{\cdot}CH_2Cl_2$ (345.2): calcd. C 17.4, H 3.5; found C 17.2, H 3.7. $\mu_{eff}$ (298 K) = 1.81 $\mu_B$.

**[$VOCl_2$(EtSCH$_2$CH$_2$SEt)]:** Was made similarly by Method 1 above. Yield 55%. $C_6H_{14}Cl_2OS_2V$ (288.0): calcd. C 25.0, H 4.9; found C 24.6, H 5.3. $\mu_{eff}$ (298 K) = 1.80 $\mu_B$.

**[$VCl_4$(MeSCH$_2$CH$_2$SMe)]:** $VCl_4$ (0.38 g, 2.0 mmol) was dissolved in anhydrous $CH_2Cl_2$ (15 mL) and $MeSCH_2CH_2SMe$ (0.24 g, 2.0 mmol) in $CH_2Cl_2$ (10 mL) added producing a very dark solution and some precipitate. Concentration in vacuo to ca. 5 mL, followed by filtration produced a dark solid which became a purple-black powder on drying in vacuo. Yield 0.50 g, 80%. $C_4H_{10}Cl_4S_2V$ (315.0): calcd. C 15.2, H 3.2; found C 14.8, H 3.8. IR (Nujol): $\tilde{\nu}$ = 379 (sh), 362 (br), 316 (sh) (VCl) $cm^{-1}$. UV/Vis (*dr* in $BaSO_4$): $E_{max}$ = 17240 (sh), 19500, 29400, 38500 $cm^{-1}$. $\mu_{eff}$ (298 K) = 1.70 $\mu_B$.

**[$VCl_4$(EtSCH$_2$CH$_2$SEt)]:** Dark purple powder made similarly to the above. Yield 85%. $C_6H_{14}Cl_4S_2V$ (343.1): calcd. C 21.0, H 4.1; found C 21.4, H 4.3. IR (Nujol): $\tilde{\nu}$ = 365 (br), 346, 295 (sh) (VCl) $cm^{-1}$. UV/Vis (*dr* in $BaSO_4$): $E_{max}$ = 17000 (sh), 19650, 28400, 37750 $cm^{-1}$. $\mu_{eff}$ (298 K) = 1.68 $\mu_B$.

**[$VCl_4$(*i*PrSCH$_2$CH$_2$S*i*Pr)]:** Dark purple powder made similarly. Yield 70%. $C_8H_{18}Cl_4S_2V{\cdot}CH_2Cl_2$ (456.0): calcd. C 23.7, H 4.4; found C 22.9, H 4.0. IR (Nujol): $\tilde{\nu}$ = 389, 344 (br), 290 (VCl) $cm^{-1}$. UV/Vis (*dr* in $BaSO_4$): $E_{max}$ = 17850 (sh), 19600, 29400, 39525 $cm^{-1}$. $\mu_{eff}$ (298 K) = 1.70 $\mu_B$.

**[$VCl_4$(1,4-dithiane)]:** Dark red-black powder was made similarly. Yield 55%. $C_4H_8Cl_4S_2V$ (313.0): calcd. C 15.4, H 2.6; found C 15.3, H 2.9. IR (Nujol): $\tilde{\nu}$ = 384, 351, 312 (VCl) $cm^{-1}$. UV/Vis (*dr* in $BaSO_4$): $E_{max}$ = 17600 (sh), 20000, 28250 $cm^{-1}$. $\mu_{eff}$ (298 K) = 1.73 $\mu_B$.

**[$VCl_4${MeS(CH$_2$)$_3$SMe}]:** Dark purple powder. Yield 85%. $C_5H_{12}Cl_4S_2V$ (329.0): calcd. C 18.3, H 3.7; found C 18.3, H 3.9. IR (Nujol): $\tilde{\nu}$ = 368 (br) 330 (br) (VCl) $cm^{-1}$. UV/Vis (*dr* in $BaSO_4$): $E_{max}$ = 17000 (sh), 20100, 29100, 39600 $cm^{-1}$.

**[$VCl_4$(PhSCH$_2$CH$_2$SPh)]:** A cold solution of $VCl_4$ (0.19 g, 1.0 mmol) in $CH_2Cl_2$ (30 mL) was added slowly to a solution of $PhSCH_2CH_2SPh$ (0.25 g, 1.0 mmol) in $CH_2Cl_2$ (10 mL) with vigorous stirring. An intensely purple solution was produced, which was immediately concentrated to 10 mL in vacuo, and the dark solid which precipitated isolated by filtration, and dried in vacuo. Yield 0.28 g, 63%. If the solution is stirred for 1 h before work-up significant amounts of $V^{III}$ (UV/Vis evidence) are present. $C_{14}H_{14}Cl_4S_2V{\cdot}CH_2Cl_2$ (524.1): calcd. C 34.4, H 3.5; found C 34.5, H 3.5. IR (Nujol): $\tilde{\nu}$ = 372, 344 (br), 304 (VCl) $cm^{-1}$. UV/Vis (*dr* in $BaSO_4$): $E_{max}$ = 17250 (sh), 19200, 29400 $cm^{-1}$.

**X-ray Crystallography:** Crystals of [{$VOCl_2$(MeSCH$_2$CH$_2$SMe)}$_4$]·$CH_2Cl_2$ were obtained from a $CH_2Cl_2$ solution by cooling to about –20 °C for several days (see text). Data collection used a Nonius Kappa CCD diffractometer with confocal mirror monochromated Mo-$K_\alpha$ X-radiation ($\lambda$ = 0.71073 Å) and with the crystal held at 120 K in a cooled nitrogen gas stream. Structure solution was straightforward[27–29] with H atoms introduced into the model in calculated positions except for the dichloromethane solvate where no H atoms were included. The inclusion of the TWIN/BASF[28] commands made a small improvement to the data fit. Selected bond lengths and angles are given in Table 3 with crystallographic data in Table 4.

Table 4. Crystallographic data for [{$VOCl_2$(MeSCH$_2$CH$_2$SMe)}$_4$]·$CH_2Cl_2$.

**EXAFS Data Collection and Treatment:** Vanadium *K*-edge EXAFS data were collected at ambient temperature on station 7.1 of the Daresbury SRS fitted with a silicon 110 monochromator and operating in transmission mode. Data were recorded from samples prepared <24 h previously, sealed in foil-wrapped flasks under $N_2$ and stored in the cold. Samples of the complexes were diluted ca. 1:3 with dry, powdered BN and pressed between Kapton windows in 1 mm thick cells. Two or three data sets were collected from each sample and then averaged. Background subtraction was performed with the PAXAS[30] package and the $k^3$-weighted EXAFS were fitted using Excurve.[31] The [$VOCl_3${MeS(CH$_2$)$_2$SMe}], [$VOCl_3$(1,4-dithiane)] and [$VOCl_3$($\kappa^2$-[9]ane$S_3$)] EXAFS were modelled with a cluster of $C_s$ symmetry with oxygen and one Cl on the mirror plane and an overall geometry close to octahedral. The models were tested for both five- and six-coordination, the best fit statistical data supporting six-coordination with $S_2Cl_3O$ donor sets.

## Acknowledgments

We thank the Engineering and Physical Sciences Research Council (EPSRC) for support (EP/C001176/1) and the Director of the Daresbury Laboratory for provision of facilities for EXAFS studies under award ref. 47036. We also thank Dr S. G. Fiddy for help with the EXAFS data collection and Charlotte D. Beard for some preliminary studies.

# Chlorido-Bridged $Mn^{II}$ Schiff-Base Complex with Ferromagnetic Exchange Interactions

**Chuan-Min Qi,[a] Xu-Xia Sun,[a] Song Gao,[b] Shu-Lan Ma,*[a] Da-Qiang Yuan,[c] Cui-Hong Fan,[a] Hai-Bo Huang,[a] and Wen-Xiang Zhu[a]**

**Keywords:** Manganese / Schiff bases / Magnetic properties

The preparation, crystal structure, and magnetic properties of the μ-Cl-bridged dinuclear complex $[Mn(HL)(\mu\text{-}Cl)Cl]_2$ (**1**) with the Schiff-base ligand HL, 2-methyl-6-[(pyridine-2-yl-methylene)amino]phenol, is reported. Structural studies show that **1** is binuclear with a pair of chlorine atoms bridging the manganese atoms in a central $Mn_2Cl_2$ plane, the intramolecular Mn···Mn separation being 3.694 Å. Each manganese atom in **1** is six-coordinate with two nitrogen atoms (one imine nitrogen and one pyridine nitrogen) and one phenolic oxygen from the neutral tridentate ligand, and three chlorine atoms (one terminal and two bridging) building an elongated octahedral environment. The two octahedra adopt the unique geometry sharing an equatorial-to-axial edge with parallel equatorial planes. The hydrogen bonds between the coordinated $Cl^-$ anions and hydroxy groups connect the dimeric coordinated units together forming a one-dimensional chain. Variable temperature susceptibility measurements in the temperature range of 2.0–300 K reveal a ferromagnetic coupling ($J$ = +0.94 $cm^{-1}$) in the dimer via the double chlorido bridge, and a weak antiferromagnetic coupling ($zJ'$ = –0.036 $cm^{-1}$) between the dimers through the intermolecular hydrogen bonding. A comparison of the magnetic coupling of **1** with other structurally similar $Mn(\mu\text{-}Cl)_2$-Mn compounds is discussed in detail. Complex **1** may provide useful information for the magneto-structural correlations of this kind of compounds.

## Introduction

The preparation and magnetic properties of discrete polynuclear molecules and coordination polymers of paramagnetic metal complexes are of considerable interest to the field of molecular magnetism.[1] In particular, the coordination chemistry of manganese has received a great deal of attention because of the variable structures of manganese complexes and the possibility of magnetic coupling interaction.[2] The magnetic behavior of $Mn^{II}$ polymers is dependent on the bridging and terminal ligands. Most magnetic studies on these $Mn^{II}$ polymers are relative to those with bridging ligands, such as azide,[3] dicyanamide,[4] and carboxylate.[5] Ferromagnetic exchange coupling among these $Mn^{II}$ compounds is rather unusual. This kind of magnetic interaction has been found in $Mn^{II}$ dinuclear complexes and polymers with end on bridging azido,[3,6] $Mn^{II}$ dinuclear complexes with diazine and some phenoxido bridging ligands.[7] Magnetically active chlorido-bridged systems are well-known in general, but relatively few investigations of the structure and magnetic properties of chlorido-bridged compounds have been carried out.[8] The angular dependence of the strength and nature of the magnetic coupling in M(μ-X)M systems was studied in detail for $Cu^{II}$ and $Cr^{III}$ systems,[1a,9] but the paucity of magneto-structural studies with dichlorido-bridged $Mn^{II}$ dimers precludes us to go further. In order to check the correlation between the angle at the bridging chlorine atom and the nature and value of magnetic coupling in $Mn^{II}$ compounds as well as to investigate the influence of additional structural factors, many more examples are needed. In this paper, we report the structural and magnetic study of the new dichlorido-bridged $Mn^{II}$ dinuclear complex $[Mn(HL)(\mu\text{-}Cl)Cl]_2$ (**1**) with the tridentate Schiff-base ligand. We will see that this six-coordinate $Mn^{II}$ dimer presents unusual ferromagnetic interactions. To establish magneto/structural correlations of $Mn^{II}$ compounds with bis(μ-chlorido) bridges, the magnetic properties of **1** were also compared to those of four structurally similar dimers, $[MnCl(\mu\text{-}Cl)(bpea)]_2$ (**2**), $[Mn(biz)_2(\mu\text{-}Cl)]_2Cl_2$ (**3**), $[Mn(mpbpa)Cl(\mu\text{-}Cl)]_2$ (**4**) and $[Mn(dpp)Cl(\mu\text{-}Cl)(H_2O)]_2$ (**5**),[8] and two one-dimensional bis(μ-chlorido) $Mn^{II}$ complexes $[Mn(\mu\text{-}Cl)_2(bpy)]_n$ (**6**) and $[Mn(\mu\text{-}Cl)_2(mppma)]_n$ (**7**).[10]

## Results and Discussion

### IR and UV/Vis Spectroscopy

The IR Spectra of Schiff-base ligand HL and complex **1** provide information about the metal–ligand bonding. The strong absorption band at 1624 $cm^{-1}$ in ligand HL is assigned to the azomethine group, $\nu$(C=N).[11] The band is shifted to lower wavenumbers at 1594 $cm^{-1}$ in the complex, which can be attributed to the coordination of the C=N nitrogen atom to metal ions. In addition, the absorption band at 1582 $cm^{-1}$ assigned to the pyridine group of the ligand is shifted to 1562 $cm^{-1}$, suggesting that the coordination of the pyridine nitrogen atom group to metal ions.[12]

The UV-visible spectroscopic data for ligand HL and the complex were studied in MeOH. Schiff-base molecule HL exhibits three maxima centered at 289, 361, and 442 nm. Complex **1** exhibits three maxima centered at 240, 349, and 474 nm. The absorption bands at 200–400 nm in the complex may correspond to ligand-centered (LC) π–π* transitions, while the strong band in the range greater than 400 nm can be ascribed to the ligand-to-metal charge transfer (LMCT) transitions.[13]

### Description of the Structure

Selected bond lengths and angles of **1** are summarized in Table 1. The crystal structure of **1** consists of centrosymmetric double chlorido-bridged $[Mn(HL)(\mu\text{-}Cl)Cl]_2$ dimeric units (Figure 1). One phenolic oxygen O1, one imine nitrogen N1, one pyridine nitrogen N2 from the tridentate neutral ligand, one terminal Cl1, and two bridging $Cl^-$ anions Cl2 and Cl2A (–*x* + 1, –*y* + 1, –*z*) are coordinated to one $Mn^{II}$ ion in an elongated octahedral geometry. The best equatorial plane in the octahedron is defined by O1, N1, N2, and Cl2A set of atoms with the mean deviation of 0.0085 Å, the manganese atom being 0.1168 Å out of this mean plane. The terminal Cl1 atom occupies an axial position *trans* to the Cl2 bridge with a largest bond angle of 175.01° for Cl1–Mn1–Cl2, and a significant axial elongation (2.482 Å for Mn1–Cl1 and 2.606 Å for Mn1–Cl2) are also observed. The two small bite angles subtended at the manganese atom by the chelating ligand (69.94° for O1–Mn1–N1 and 72.92° for N1–Mn1–N2) may be considered the main reason for the distortion of the metal coordination sphere.

The Mn–$N_{imine}$, Mn–$N_{py}$ (py = pyridine), and Mn–$O_{phenol}$ distances are 2.239, 2.279, and 2.313 Å, respectively. The distance of Mn–$N_{imine}$ is close to those noted for other $Mn^{II}$ Schiff-base complexes.[14] The M–$N_{py}$ distance is longer than M–$N_{imine}$, which is comparable to other $Mn^{II}$ Schiff-base complexes.[14c,15]

The bridging $Mn_2Cl_2$ unit is constrained to be planar by the presence of the crystallographic inversion center. This $Mn_2Cl_2$ plane is practically orthogonal with the above equatorial plane O1/N1/N2/Cl2A in the octahedron, the value of the dihedral angle between both planes being 86.6°. The Mn–Cl–Mn angle of 93.80° and the different Mn–Cl distances of 2.451 and 2.606 Å show that the $Mn_2Cl_2$ core is considerably distorted from an ideal square. The two Mn–Cl bonds within the $Mn_2Cl_2$ core lie within the typical range for bridged $Mn^{II}$ chloride atoms (2.31–2.61 Å),[8c,8d,16] being longer than those terminal $Mn^{II}$–chlorido bonds (2.27–2.37 Å)[17] observed in other complexes. The two Mn–$Cl_{bridge}$ bonds in **1** are significantly different, and the terminal Mn–Cl bond (2.482 Å), essentially coplanar with the $Mn_2Cl_2$ core, is between the Mn–$Cl_{bridge}$ bonds, which is divergent from other di-μ-chlorido $Mn^{II}$ complexes containing longer Mn–$Cl_{bridge}$ bonds than Mn–$Cl_{terminal}$ bonds.[8a,18] The intramolecular Mn–Mn distance of 3.694 Å in **1** is shorter than other hexacoordinate dinuclear $Mn^{II}$ compounds with chlorido and nitrogen ligands (3.74–3.85 Å),[8a,8c,8d,18a] which points to a strong effect of the chlorido bridges in **1**. The whole Schiff-base molecule (N1/N2/O1/C1–C13) is merely an approximate plane with a deviation of 0.0695 Å. This distortion from planarity may be due to intermolecular hydrogen bonding interactions. There exist intermolecular hydrogen bonds in **1**. The hydroxy group O1–H1 of the dimer is hydrogen bonded to the Cl1B anion (–*x*, –*y* + 1, –*z*) of one adjacent dimer and forms O1–H1···Cl1B (O1···ClB 3.004 Å, H1···ClB 2.198 Å, and the O1–H1···Cl1B 157.83°), and the Cl1 anion of the

present dimer forms a hydrogen bond Cl1···H1B–O1B (–*x*, –*y* + 1, –z) with the hydroxy group of the adjacent unit. The hydroxy group O1A–H1A of the present dimer is again hydrogen-bonded to Cl1D (*x* + 1, *y*, *z*) of another adjacent dimer and forms O1A–H1A···Cl1D, and at the same time the Cl1A anion forms a hydrogen bond Cl1A···H1C–O1C (*x* + 1, *y*, *z*) with the hydroxy of the adjacent unit. As a result, the hydrogen bonds between coordinated $Cl^-$ anions and hydroxy groups tie the coordinated dimeric units together forming a one-dimensional zig–zag chain (Figure 2). In the chain, the shortest interdimer manganese–manganese distance is 5.523 Å for Mn1–Mn1B (–*x*, –*y* + 1, –*z*).

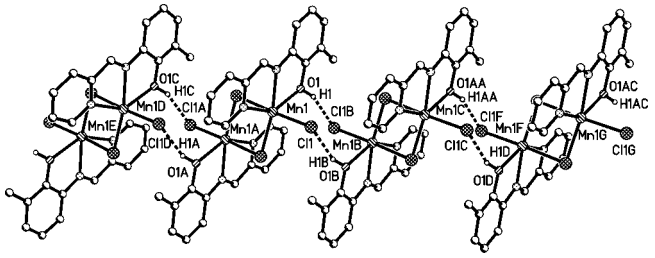

Figure 2. The one-dimensional hydrogen bond chain extending along the *a* axis of **1** (some hydrogen atoms are omitted for clarity).

## Magnetic Properties

Variable temperature magnetic susceptibility on **1** was measured in the range 2.0–300 K (Figure 3). At room temperature, the $\chi_m T$ value for the dinuclear unity is 8.73 $cm^3 mol^{-1} K$, a value which is as expected for two independent spins $S$ = 5/2 (8.75 $cm^3 mol^{-1} K$). Upon cooling from room temperature, $\chi_m T$ increases smoothly at first until around 80 K, below this temperature it increases sharply to reach a maximum of 11.24 $cm^3 mol^{-1} K$ at 6.0 K and then decreases rapidly to 9.70 $cm^3 mol^{-1} K$ at 2.0 K. The $\chi_m^{-1}$ versus $T$ plot is essentially linear, and least-squares fitting of the data to the Curie–Weiss law gave $C$ = 8.72 $cm^3 mol^{-1} K$ and $\theta$ = +1.74 K. The increase in $\chi_m T$ upon cooling and the positive Weiss constant indicates that there exists a ferromagnetic coupling between two $Mn^{II}$ centers in the dimer. The rapid decrease in $\chi_m T$ at lower temperatures is probably due to the weak antiferromagnetic interdimer interaction.[19] This latter contribution is also supported by the field dependence of the magnetization recorded at 2 K (Figure 4) with a magnetization which tends to a saturation value of 9.46 N$\beta$, slightly below the expected saturation value of 10.0 N$\beta$ for two $S$ = 5/2 spins without interactions.[20]

Keeping in mind the structure of **1**, the magnetic data were fitted through Equation (1),[8b,21] which considers both the intradimer and interdimer interactions. The additional coupling parameter, $zJ'$, was added to take into account the magnetic behavior at low temperature as a molecular field approximation.[22]

The best fitting of the data in the temperature range 2–300 K leads to the parameters $g$ = 1.98, $J$ = +0.94 $cm^{-1}$, $zJ'$ = –0.036 $cm^{-1}$. The reliability factor $R$, defined as $R(\chi_m T)$ = $\Sigma(\chi_m T_{obs} - \chi_m T_{calc})^2 / \Sigma(\chi_m T_{obs})^2$, is equal to $9.97 \times 10^{-6}$. The calculated data curve (solid line in Figure 3) matches the experimental magnetic data very well. The results indicate magnetic exchange interactions should mainly pass through the double μ-Cl bridge pathway, which exhibits a ferromagnetic coupling interaction via the double chlorido bridges. The smaller negative $zJ'$ value shows that there exists a weak antiferromagnetic interaction between the $Mn^{II}$ dimers through the intermolecular hydrogen bonding.

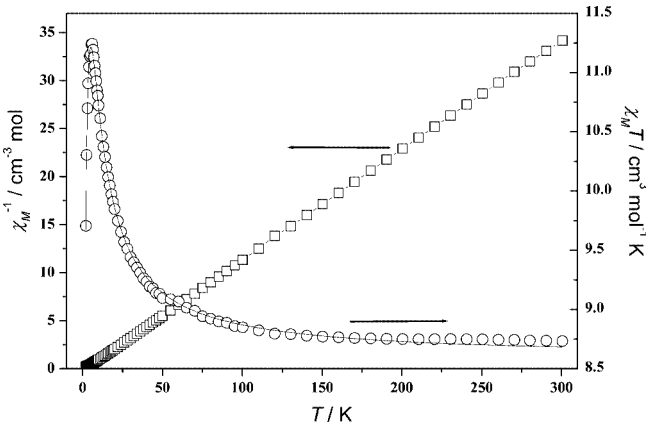

Figure 3. The plot of temperature dependence of $\chi_m^{-1}$ (□) and $\chi_m T$ (○) of **1** measured at 1000 Oe. The solid line represents the best fit of the experimental data as discussed in the text.

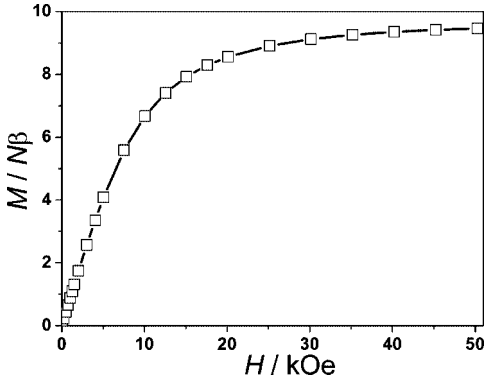

Figure 4. Magnetization vs. field up to $H$ = 50 kOe at 2.0 K. (The solid line is only a guide for the eye and does not indicate fitting).

$$\chi_M = \frac{\chi_t}{1-(2zJ'/Ng^2\beta^2)\chi_t} \quad (1)$$

*where*

$$\chi_t = \frac{2Ng^2\beta^2}{kT} \times \frac{55+30\exp(5x)+14\exp(9x)+5\exp(12x)+\exp(14x)}{11+9\exp(5x)+7\exp(9x)+5\exp(12x)+3\exp(14x)+\exp(15x)}$$

*with* $x = -J/kT$

Ferromagnetic interactions between two $S$ = 5/2 $Mn^{II}$ centers via chlorido bridges is precedented but has not been studied in detail. A spin dimer of $S$ = 5/2 $Mn^{II}$ is expected to exhibit $J$ coupling of at least 25 times less than a spin dimer of $S$ = 1/2 $Cu^{II}$,[23] and thus the values of $J$ of the dichlorido-bridged manganese(II) complexes are usually small as listed in Table 2.

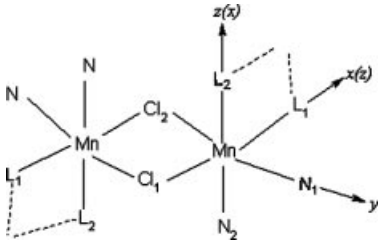
[b] See Scheme 1. [c] Average values of the angles and the distances in the two nonequivalent $[Mn_2(\mu\text{-}Cl)_2]^{2+}$.

Many one-dimensional six-coordinate bis(μ-chlorido)-$Mn^{II}$ polymers are reported and most of them show antiferromagnetic coupling.[10b,24] There are few bis(μ-chlorido)-$Mn^{II}$ dinuclear complexes reported and they exhibit ferromagnetic coupling[8] or antiferromagnetic interaction.[25] Table 2 summarizes some structural parameters and magnetic coupling constants for the dinuclear and one-dimensional dichlorido-bridged complexes with similar structures of **1**. With the aim to compare the magnetic properties of these compounds, the one-dimensional systems have been considered as dinuclear complexes (Scheme 1). In all cases, a rectangular core is observed with two distinct Mn–Cl distances. In a *trans* disposition to one chlorido bridge (with the short Mn–Cl distance), there is a N-ligand, while *trans* to the other chlorido bridge (with long Mn–Cl distance) the L1 ligand could be Cl (for **1**, **5**, **6**, and **7**) or N (for **2**, **3**, and **4**) (Scheme 1). The other two positions of the octahedron are occupied by a N-ligand and by an L2 ligand. For compounds **2**, **4**, **6**, and **7** this ligand (L2) is Cl, while for **3** it is an N-ligand, and for **1** and **5** it is an O-ligand. The different kinds of ligands around the $Mn^{II}$ ions give rise to different distortions in the coordination polyhedron.



Scheme 1.

There are two types of geometries that have been characterized in the literatures: geometry I has two octahedra sharing an equatorial-to-axial edge with parallel equatorial planes, and geometry II has two octahedra sharing an equatorial edge with coplanar equatorial planes. For compounds **1**, **5**, and **6** with well-differentiated $Mn–Cl_{bridge}$ distances (Table 2), geometry I is often observed, while for compounds as **2**, **3**, **4**, and **7** containing near $Mn–Cl_{bridge}$ values, geometry II is formed. Extended Hückel calculations with the CACAO program for the six complexes (**2**–**7**) showed that for axially elongated compound **6**, the $d_{x^2-y^2}$ orbital of the manganese ions is perpendicular to the $Mn_2Cl_2$ plane and points to one chlorido bridge while the $d_{z^2}$ orbital points to the other bridge. For other compounds with smaller distortion on the octahedron the $d_{x^2-y^2}$ orbitals are in the $Mn_2Cl_2$ plane, and the magnetic interaction may be sensitive to the Mn–Cl–Mn angle.[10a] The different magnetic interaction for the two one-dimensional complexes **6** and **7** with similar structure could be attributed to the major axial elongation on the octahedron present in **6**. Important elongation of the octahedron in our complex **1** is also observed as **6**, and the two $d_{x^2-y^2}$ orbitals of the $Mn^{II}$ ions of **1** may be parallel as in **6**. The $d_{x^2-y^2} \pm d_{x^2-y^2}$ could be quite degenerated, and thus the antiferromagnetic contribution, depending on $\Delta_i$ gaps and the overlap through the bridging ligands, as being shown $J_{AF} \propto \sum\Delta_i^2$, may be smaller, which agrees with the ferromagnetic behavior observed in this case ($J$ = +0.94 $cm^{-1}$). From Table 2 we can see that for the complexes with geometry I, the values of $\sum\Delta_i^2$ are minor, and for those with geometry II, major values of $\sum\Delta_i^2$ are often shown.[10a] There should be certain correlation among the coordination geometry, the disposition of $d_{x^2-y^2}$ orbital of the metal ions, the value of $\sum\Delta_i^2$, and the magnetic interaction.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Another complex **5**[8b] also adopts geometry I, but no important elongation on the octahedron is observed as **6**, and the different disposition of $d_{x^2-y^2}$ orbitals may result in its small positive value of *J*.

The sign and magnitude of the coupling constant for $Cu(\mu\text{-}Cl)_2Cu$ dimers depend mainly on the Cu–Cl–Cu bridging angle, the Cu–Cl distance, the nature of the terminal ligands, and the coordination geometry.[26] An important result of the DFT study is that the presence of N-donor terminal ligands seems to favor the ferromagnetic coupling, whereas replacement by halide anions results in the antiferromagnetic behavior.[26b] These results could also explain the magnetic interaction of these chlorido-bridged $Mn^{II}$ complexes. A major value of $\sum\Delta_i^2$ was found for **3** relative to its structurally similar complexes **2** and **4**, and a minor ferromagnetic interaction should be attended. Nevertheless, the major number of N-terminal ligands and the minor Mn–Cl–Mn angle of **3** relative to other compounds may contribute its not small, positive *J* value.

Complex **1** contains quite more differentiated Mn–$Cl_{bridge}$ distances and an obvious axial elongation on the octahedron, which induce the rare octahedral geometry I with parallel equatorial planes and determine the unique disposition of $d_{x^2-y^2}$ orbital of the two $Mn^{II}$ ions. The peculiar geometry and the smallest Mn–Cl–Mn angle and shorter Mn–Mn distance of **1** compared with other compounds may induce its strongest ferromagnetic behavior.

The interesting structure and the novel ferromagnetic behavior of complex **1** might provide useful information for the magneto-structural correlations for dichlorido-bridged $Mn^{II}$ systems in the future. With continued research efforts designed to improve theoretical models and to obtain a greater number of experimental examples, the nature of the relationship between the structural properties and the exchange-coupling constant for these systems can be refined.

## Conclusions

We prepared and characterized dichlorido-bridged $Mn^{II}$ complex **1** with ferromagnetic exchange interactions. Complex **1** is binuclear with a pair of chlorine atoms bridging the manganese atoms in a central $Mn_2Cl_2$ plane, the intramolecular Mn···Mn separation being 3.694 Å. The hydrogen bonds between the coordinated $Cl^-$ anions and hydroxy groups tie the dimeric units together forming a one-dimensional chain. There are two well-differentiated Mn–$Cl_{bridge}$ bonds in the $Mn_2Cl_2$ core and obvious axial elongation on the octahedron of the metal $Mn^{II}$ ion. These structural features induce the geometry I of two octahedra sharing an equatorial-to-axial edge with parallel equatorial planes. This unique geometry may cause a parallel disposition of $d_{x^2-y^2}$ orbitals (and the $d_{z^2}$ orbitals) of the $Mn^{II}$ ions, and minor values of the antiferromagnetic contribution $\sum\Delta_i^2$ could be attended, and thus a ferromagnetic interaction is observed. The smallest Mn–Cl–Mn angle and the shorter Mn–Mn distance of **1** may also induce its maximum *J* value.

## Experimental Section

**General:** All commercially available chemicals were of analytical grade and used as received. C, H, and N analyses were determined with an Elementar vario EL elemental analyzer. UV-visible spectra were measured with a GBC Cintra 10e UV/Vis spectrophotometer in MeOH solution. The IR spectra were recorded with a Nicolet-AVATAR 360 FTIR spectrometer using KBr pellets in the 4000–400 $cm^{-1}$ regions. Variable-temperature magnetic susceptibility data for the crystalline sample of complex **1** was obtained in an external field of 1000 G with an Oxford Maglab 2000 system magnetometer in the 2–300 K temperature range. The susceptibilities were corrected for diamagnetism with Pascal's constants for all the constituent atoms.

**Ligand HL:** A mixture of pyridine-2-carbaldehyde (0.107 g, 1 mmol) and 2-amino-6-methylphenol (0.123 g, 1 mmol) was heated at reflux in anhydrous ethanol (20 mL) for 2 h. After the solvent was removed under reduced pressure, *n*-hexane (20 mL) was then added, and the mixture was heated at reflux for another 0.5 h. The reaction mixture was filtered and left to stand at room temperature and brown crystals were obtained from the filtrate after 15 min. Yield: 0.172 g, 81%. M.p. 95–96 °C. $^1H$ NMR (500 MHz, DMSO): $\delta$ = 8.76 (s, 1 H, phenol-OH), 8.74 (s, 1 H, imide-H), 8.70 (d, *J* = 4.2 Hz, 1 H, pyridine-H), 8.58 (d, *J* = 7.9 Hz, 1 H, pyridine-H), 7.96 (t, *J* = 7.6 Hz, 1 H, pyridine-H), 7.50 (t, *J* = 6.3 Hz, 1 H, pyridine-H), 7.28 (d, *J* = 7.9 Hz, 1 H, Ar-H), 7.08 (d, *J* = 7.3 Hz, 1 H, Ar-H), 6.78 (t, *J* = 7.7 Hz, 1 H, Ar-H), 2.22 (s, 3 H, -$CH_3$) ppm. IR (KBr pellet): $\tilde{\nu}$ = 3402, 3046, 2921, 1624, 1600, 1582, 1566, 1476, 1433, 1344, 1235, 1163, 1082, 1013, 991, 944, 834, 783, 742, 733, 598 $cm^{-1}$. UV/Vis (MeOH): $\lambda$ ($\varepsilon$, $10^4$ $M^{-1}cm^{-1}$) = 289(4.25), 361(4.92), 442(1.50) nm. $C_{13}H_{12}N_2O$ (212.10): calcd. C 73.56, H 5.70, N 13.20; found C 73.57, H 5.92, N 13.22.

**$[Mn(HL)(\mu\text{-}Cl)Cl]_2$ (1):** To a yellow solution of HL (0.011 g, 0.05 mmol) in $CH_2Cl_2$ (5 mL) was added a solution of $MnCl_2{\cdot}4H_2O$ (0.010 g, 0.05 mmol) in $CH_3CH_3OH$ (5 mL) dropwise with stirring for 1 h. The reaction mixture was filtered and left to stand at room temperature. On slow evaporation of the solution for several days, the deep red crystals of **1** suitable for X-ray analysis were collected. IR (KBr pellet): $\tilde{\nu}$ = 3420, 3052, 1594, 1562, 1481, 1373, 1324, 1272, 1209, 1173, 1112, 988, 894, 781, 748, 637,

547 $cm^{-1}$. UV/Vis (MeOH): $\lambda$ ($\varepsilon$, $10^3$ $M^{-1}cm^{-1}$) = 240(11.75), 349(7.73), 474(3.36) nm. $C_{26}H_{24}Cl_4Mn_2N_4O_2$ (676.17): calcd. C 46.14, H 3.55, N 8.28; found C 46.28, H 3.45, N 8.20.

**X-ray Crystallographic Study:** The crystal with dimensions $0.20 \times 0.12 \times 0.08$ mm of **1** was selected for X-ray diffraction experiments. The measurements were performed with a Bruker SMART 1000 CCD diffractometer at room temperature (293 K) with graphite monochromatized *Mo-K*$_\alpha$ radiation ($\lambda$ = 0.71073 Å). Semiempirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXS-97 and SHELXL-97 programs.[27] All non-hydrogen atoms were refined with anisotropic displacement parameters and the hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinements. A summary of the crystallographic data and details of the structure refinements are listed in Table 3. CCDC-298016 contains the crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis, Stability Constant Determination, and Structural Study of Some Complexes of a Zinc Triad Containing Pyridyl-amine-quinoline and Pyridyl-thio-quinoline

**Luciano Canovese,*[a] Fabiano Visentin,[a] Gavino Chessa,[a] Carlo Levi,[a] and Alessandro Dolmella[b]**

**Keywords:** Zinc / Quinoline-based ligands / Fluorescence / Formation constants

The potentially fluorescent and terdentate ligands containing nitrogen or sulfur as coordinating atom were synthesized and used in the formation of perchlorate or chloride complexes of the metals of the Zn triad. The reaction of the ligands with metal perchlorate salts yields the corresponding bis-chelate derivatives, whereas the same ligands react with metal chloride salts to give monochelate complexes. All of these complexes undergo NMR-scale fast fluxional rearrangement in solution. Some structural X-ray diffractometric studies were also performed and the ensuing data confirm the surmised structures and the solution rearrangement in the case of monochelate substrates and of one Hg derivative, respectively. The equilibrium constants of formation in the case of monochelate derivatives were also determined in water by means of spectrophotometric titration of the studied ligand with the metal ions. The values of the equilibrium constants were confirmed by supplementary determination taking into account the exchange between two different metals and/or dissociation equilibria. The fluorescence activity of ligands and complexes was eventually studied and notably one fluorescent silent ligand gives rise to fluorescent zinc derivatives.

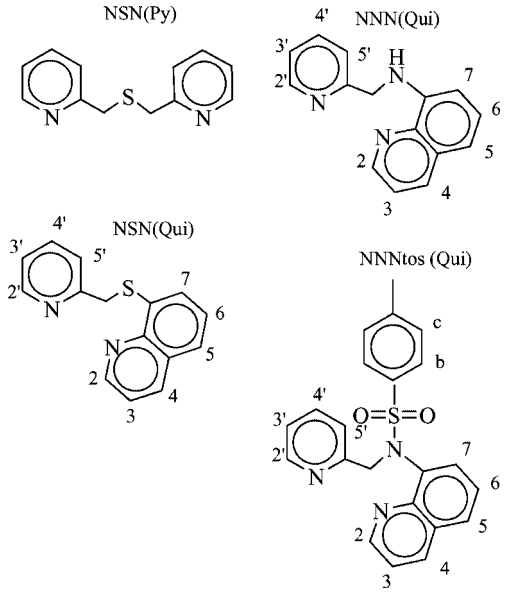
## Introduction

The bioactivity of group-12 metal ions is well known, the toxic effects of mercury and cadmium on living organisms being widely recognized.[1] On the contrary zinc is present in traces in many enzymes and consequently it must be considered a bio-compatible metal at least when its concentration is confined within the millimolar range.[2] High concentrations of zinc could, however, entail pollution problems when industrial or human wastes in restricted areas are involved.

In this respect, the synthesis of new ligands with remarkable coordinating capabilities represents an important step for the development of chemical devices for the field monitoring of several metal ions.[3–10] For this reason, we decided to synthesize a series of new polydentate ligands and test their versatility in the identification of the group-12 metals when present in different concentrations and situations.

The synthesized ligands are reported in Scheme 1. We chose to analyze the coordinating capability of the ligands toward proton and metals in distilled water and in the presence of chloride ions since we aim at using these substrates directly in marine or lagoon waters.



Scheme 1.

It is well known that quinoline displays remarkable properties as a photophysical fluorescent chromophore[11] and as a coordinating agent towards many transition-metal ions.

Therefore, the synthesis of polydentate ligands bearing quinoline together with other potentially coordinating atoms could represent an important target in a strategy aiming at low cost and easy identification of several analytes.

## Results and Discussion

### General Remarks

Owing to the low solubility of the ligands and related complexes in water, all determinations of equilibrium constants were performed without ionic strength control since any addition of inert salt induces massive precipitation under our experimental conditions (i.e. the solubility of the Hg complexes in 0.01 M $NaClO_4$ dramatically drops to about $1 \times 10^{-6}$ mol dm$^{-3}$). For this reason we have determined the complex formation equilibrium constants by means of the UV/Vis technique, any potentiometric approach being inadequate. We therefore chose to privilege the use of water as solvent instead of controlling the ionic strength in mixed solvents since we expect that the ligands we synthesized should be used as metal probes in natural and waste waters.

### Synthesis of the Ligands

The ligands NSN(Py) {NSN(Py) = 2-[(2-pyridylmethyl)-thio]pyridine},[12a] NNNtos(Qui) [NNNtos(Qui) = 8-*N*-tosyl-*N*-(2-pyridylmethyl)quinoline] and NSN(Qui) [NSN-(Qui) = 8-[(2-pyridylmethyl)thio]quinoline], were synthesized according to published procedures;[12b] the ligand NNN(Qui) {NNN(Qui) = 8-[(2-pyridylmethyl) amino]-quinoline} was obtained by removing the tosyl group from the NNNtos(Qui) moiety by acid hydrolysis with concentrated $H_2SO_4$ at 110 °C.

### Synthesis of the Complexes

#### *Bis-Chelate Complexes*

Addition of the perchlorate salt $M(ClO_4)_2$ (M = Zn, Cd, Hg) to the ligand LL′L′′ [LL′L′′ = NNN(Qui), NNNtos-(Qui), NSN(Qui)] in acetonitrile or methanol yields the corresponding complex of general formula $[M(LL'L'')_2](ClO_4)_2$.

The complexes of Hg and Cd with the ligand NSN are characterized by the down-field shift of the $CH_2S$ protons and the concomitant high-field shift of the aromatic protons $H^2$ and $H^{2'}$. This phenomenon had already been observed,[13] and was traced back to the interactions occurring between the ring currents of the opposite rings of the bis coordinated ligand. A down-field shift of the aromatic protons would be otherwise observed upon ligand coordination. Moreover, in these complexes the $CH_2S$ protons resonate as a singlet and no ($^{199}Hg^1H$) and ($^{111/113}Cd^1H$) coupling even at the lowest temperature achievable (233 K) was observed. The lack of any observable coupling constants could be traced back to the small value of the constant itself or to the rapid exchange of the ligand among complexes. The authors, however, on the basis of their own experience with these kinds of ligands and according to previous observations,[14] are inclined to believe that the ligands in these cases are not firmly bound to the central metal and that a fluxional rearrangement affects these complexes in solution. As a matter of fact, the solid-state structure of the complex $[Hg(NSN)_2(OClO_3)]ClO_4$ was clearly produced by the displacement of one terminus of the potentially terdentate ligand (the quinoline nitrogen) by the oxygen of a perchlorate ion. Usually, the solid-state structure of a species cannot be considered as a warranty of its solution behavior. However, in this case the displacement of a nitrogen terminus must be definitely promoted by the rearrangement of the complex itself in solution. Furthermore, the lack of diastereotopicity of the $CH_2S$ protons indicates that the rate of sulfur absolute configuration inversion is fast with respect to the NMR time scale. The NNN(Qui) derivatives behave very similarly to those of the NSN ligand. Also in these cases no coupling between Hg, Cd, and protons is observed, the aromatic protons $H^2$ and $H^{2'}$ resonate at higher field with respect to the free ligand in both the complexes; no diastereotopicity was observed for $CH_2N$ protons which, however, resonate at field values very similar to those of the free ligand. The complexes $[Zn(LL'L)_2](ClO_4)_2$ [LL′L = NSN(Qui), NNN(Qui)] behave similarly. However, the $H^2$ and $H^{2'}$ protons of the complex $[Zn[NSN(Qui)]_2](ClO_4)_2$ resonate down field with respect to the free ligand, apparently no interference between the ring currents being operative in this case.

The most prominent features of the bis-chelate derivatives of the ligand NNNtos(Qui) are the diastereotopicity of the $CH_2N$ protons and the signals due to the $H^2$ and $H^{2'}$ protons which resonate downfield with respect to the free ligand. The tosyl group in planar tetra-coordinated complexes was shown to lie almost perpendicular to the main complex coordination plane thereby inducing an asymmetry in the $sp^3$ $CH_2N$ protons which give rise to an AB system when the rearrangement movement is slow in the NMR time scale.[12] All the $^1H$ NMR spectra of complexes $[M\{NNNtos(Qui)\}](ClO_4)_2$ (M = Hg, Cd, Zn) display for the $CH_2N$ protons an AB system indicating a slow rearrangement of the tosyl wing around the metal center. The down-field resonance of the aromatic $H^2$ and $H^{2'}$ protons is also detected in the case of Hg and Cd complexes with NNNtos(Qui) but, probably because of the compensating effect of the tosyl fragment which is orthogonal to the complex main plane, no interactions between ring currents are observable.

Moreover, in the cases of the Hg and Cd derivatives, the $^1H$ NMR low-temperature spectra display the $^{199}Hg^1H$ and $^{111/113}Cd^1H$ coupling for the signals due to the $CH_2N$ and $H^2$ and $H^{2'}$ protons.

### *Monochelate Dichloro Complexes*

Addition of the ligand LL′L′′ [LL′L′′ = NSN(Qui), NNN(Qui), NNNtos(Qui)] to $MCl_2$ (M = Hg, Cd, Zn) in methanol yields the corresponding monochelate dichloro complexes of general formula $[M(LL'L'')Cl_2]$. In any case a general down-field shift of the ligand signals of the $CH_2S$, $CH_2N$, and aromatic protons is observed upon coordination. The $CH_2N$ shift for both the NNN ligands is less pronounced being almost isochronous with that of the free ligand. The lack of a high-field shift of the $H^2$ and $H^{2'}$ aromatic protons induced by the currents of the opposite rings represents a useful clue to monochelation.

### X-ray Crystal Structure

The ORTEP[15] representations of the complexes $[Hg\{NSN(Qui)\}Cl_2]$ (**1**), $[Hg\{NSN(Qui)\}_2(OClO_3)](ClO_4)$ (**2**), and $[Zn\{NNN(Qui)\}Cl_2]$ (**3**) together with the employed numbering schemes are shown in Figures 1, 2, and 3, respectively. Complexes **1** and **3** are neutral and five-coordinate; complex **2** is cationic and six-coordinate.

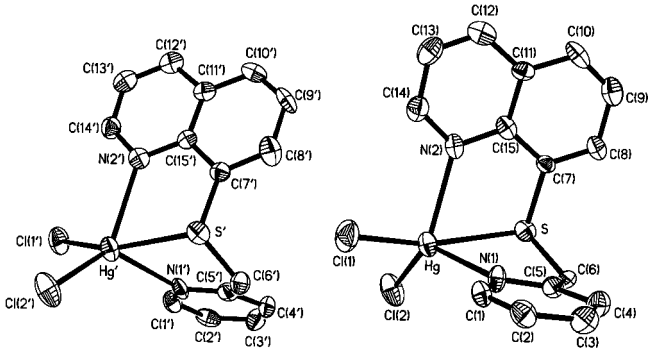

Figure 1. Anisotropic ellipsoid representation of the *TBPY*-5-12-*C* (right) and *TBPY*-5-12-*A* (left) units of complex **1**. The thermal ellipsoids are drawn at the 40% probability level. Hydrogen atoms have been omitted.

Five-coordinate complexes **1** and **3**: In complexes **1** and **3** the environment of the metal is given by a tridentate [NSN(Qui) or NNN(Qui)] ligand and by two chloride ions. Notably, in the unit cell of **1** there are two crystallographically independent complexes that are mirror images without forming, however, an enantiomeric pair (see below). The coordination geometry of both units appears intermediate between square pyramidal (*sp*) and trigonal bipyramidal (*tbp*), while it is square pyramidal in **3**. The $\tau$ angular structural index[16] (ideal values: 0 for *sp* and 1 for *tbp* geometry) was used to measure the deviation from either one of the ideal arrangements in **1** and **3**. In the two units of **1** $\tau$ = 0.59 and $\tau$ = 0.45 (average 0.52), whereas $\tau$ = 0.01 in **3**. Accordingly, we considered the two units of **1** like distorted *tbp* complexes. In this description, the apical positions around Hg are taken by the Cl(1) chloride and by the S atom of the chelate ligand, while the equatorial plane is filled by the Cl(2), N(1), and N(2) atoms. In **3**, the Cl(1) chloride takes the apical position above Zn and the basal plane is filled by the Cl(2), N(1), N(2), and N(3) atoms.

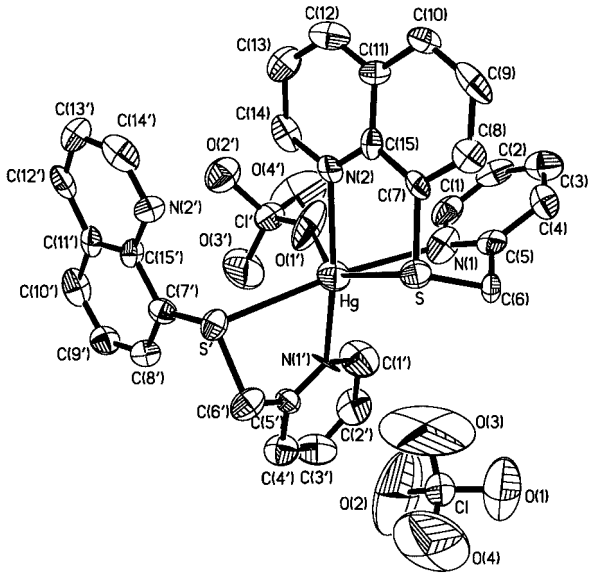

Figure 2. Anisotropic ellipsoid representation of complex **2**. The thermal ellipsoids are drawn at the 40% probability level. Hydrogen atoms have been omitted.

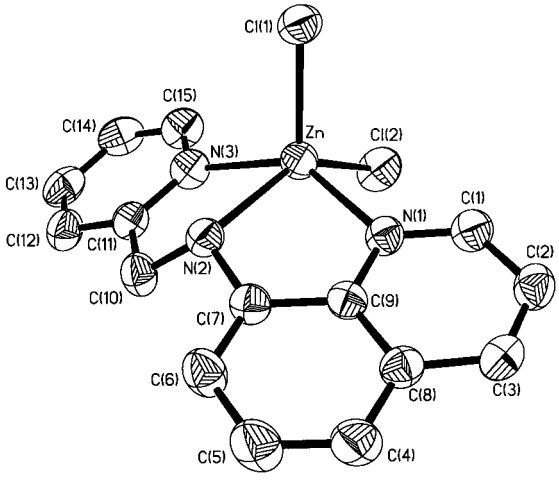

Figure 3. Anisotropic ellipsoid representation of complex **3**. The thermal ellipsoids are drawn at the 40% probability level. Hydrogen atoms have been omitted.

For the sake of clarity, in the remaining part of the discussion the two units of **1** will be named *TBPY*-5-12-*C* and *TBPY*-5-12-*A*, following the IUPAC[17] recommendations for determining the absolute configuration in inorganic compounds and the CIP (Cahn, Ingold, and Prelog) priority rules.[18] As noticed above, the two units are not alike and the difference becomes clear by comparing the angles Cl(1)–Hg–S, N(1)–Hg–N(2) (imposed by chelation), N(1)–Hg–Cl(1), N(2)–Hg–Cl(1), and S–Hg–Cl(2), whose values are 163.1(1), 95.2(3), 97.5(3), 94.6(3), and 90.8(1)° in *TBPY*-5-12-*C* and 156.5(1), 97.2(4), 93.8(3), 89.4(3), and 97.1(1)° in *TBPY*-5-12-*A*, respectively. The Hg atom also deviates from the equatorial plane by 0.42 Å in *TBPY*-5-12-*C* and 0.31 Å in *TBPY*-5-12-*A*. In **3**, the departure of the Zn atom

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

from the basal plane is even larger (0.66 Å) and such deviation implies that all the Cl(1)–Zn–equatorial donor angles are well above 90° (from 104.8 to 111.9°).

Our findings were compared with data taken from the Cambridge Crystallographic Database (CCD).[19] We searched the repository looking for (a) five-coordinate monomeric $Hg^{II}$ complexes containing a thioether ligand, (b) five-coordinate monomeric $Hg^{II}$ complexes containing at least two pyridine-like ligands, (c) five-coordinate $Zn^{II}$ complexes containing at least two pyridine-like ligands and an $N_3Cl_2$ coordination set. Search (a) returned nine entries. In these structures, the $Hg^{II}$–S(thioether) distances vary from 2.491[20] to 2.822[21] Å. The values found in *TBPY*-5-12-*C* and *TBPY*-5-12-*A* [2.759(4) and 2.748(3) Å, respectively] fit in the range and are close to those of the cations described in the literature[21,22] (2.731 and 2.727 Å, respectively).

Search (b) yielded 13 entries, in which the reported $Hg^{II}$–N(pyridyl) distances vary from 2.235[23] to 2.619[24]Å. The values found in *TBPY*-5-12-*C* and *TBPY*-5-12-*A* are 2.350(9), 2.44(1) Å and 2.38(1), 2.44(1) Å, respectively [the longer $Hg^{II}$–N bond always involving N(2)], again within the experimental range, and are similar to those found in the cation reported in ref.[25] (2.363, 2.401 Å) and in the neutral complexes reported in ref.[26] (2.373, 2.400 Å) and ref.[27] (2.372, 2.429 Å). The Hg–Cl distances are 2.455(4), 2.450(3) Å in *TBPY*-5-12-*C* and 2.494(4), 2.428(4) Å in *TBPY*-5-12-*A*. The longer Hg–Cl bond always involves the Cl(1) *trans* to S. These data agree with CCD values for 35 five-coordinate complexes (2.238–3.029 Å).

It is worth noting that complexes in which a five-coordinate $Hg^{II}$ is surrounded at the same time by pyridyl and thioether ligands are rather uncommon.[22,25] Recently, Bebout and co-workers[14] described some zinc triad complexes (with c.n. = 4, 5, or 6) of a symmetric N,S mixed ligand (L) closely related to NSN(Qui). The Hg–N, Hg–S distances found in **1** fit reasonably well with the values quoted by Bebout for six-coordinate $Hg^{II}$ complexes with pyridyl (2.352–2.557 Å) or crown-thioether ligands (2.458–2.751 Å), whereas the Hg–Cl terminal bonds are somewhat longer than those reported for either four-coordinate $Hg(L)Cl_2$ [2.4049(8), 2.4099(8) Å] or five-coordinate $Hg_2(L)Cl_4$ [2.336(2), 2.395(2) Å].[14]

Search (c) returned about 20 entries, but only 11 of these show an aliphatic amine donor atom like **3**. In the reported structures, the Zn–$N_{py}$, Zn–$N_{ali}$ ($N_{py}$ = pyridine nitrogen, $N_{ali}$ = aliphatic amine nitrogen), and Zn–Cl distances vary, respectively, in the ranges 2.039[28]–2.511,[28] 2.129[29]–2.464,[30] and 2.220[30]–2.345[29]Å. In **3**, the Zn–$N_{py}$ bonds are 2.124(3), 2.156(3) Å, Zn–$N_{ali}$ is 2.234(3) Å, and the Zn–Cl distances are 2.252(1) and 2.343(1) Å, respectively. The longer Zn–Cl bond involving the Cl(2) chloride *trans* to the aliphatic amine N(2) appears to be the second longest reported so far after 2.345 Å in ref.[29]. An overall arrangement about Zn similar to that of **3** is found in the complexes described in ref.[31,32] and to a lesser degree in those reported in refs.[29,33]

The chloride ligands of **1** and **3** are involved in a network of nonbonding interactions, which appears to be more extended in **1**. The intermolecular contacts are listed in detail in Table 2SI of the Supporting Information. The packing diagram of **1** also reveals that the quinoline rings of adjacent molecules are stacked in the solid state. The stacking occurs along the crystallographic *a* axis, in a head-to-tail arrangement. The separation between the planes is 3.47 Å as compared to 3.40 Å in graphite.

Six-coordinate complex **2**: In this cation (Figure 2) one of the two NSN(Qui) donors acts as tridentate and the other one as bidentate. The coordination position that is not occupied by the quinolyl N atom is taken by a perchlorate anion. This situation is unusual, and to the best of our knowledge, in the CCD there is no structure of general formula $[M(LL'L)_2]$ (M = six-coordinate metal, L, L′ = N, S or O, LL′L = tridentate ligand forming with the metal two adjacent five-membered rings) showing a similar arrangement. The uncommon coordinating behavior shown by one NSN donor might be due, at the first glance, to somewhat greater steric demand of the perchlorate anion, compared to the chloride one in **1**. However, we also suspect that the expected $[Hg\{NSN(Qui)\}_2](ClO_4)_2$ was represented by the colorless specimen of **2** that we could not characterize by X-ray diffraction (see Experimental Section). We will try to clarify this issue in future investigations.

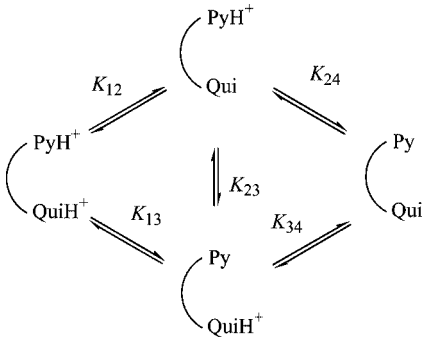
The coordination environment around Hg is distorted octahedral. The dihedral angle formed by the face N(1), N(2), S with the triangle opposed to it is 30.5° (ideal value = 0°). The base plane is defined by the N(1), N(2), N(1′) and S′ atoms. The largest deviation from this plane is shown by N(1′) (–0.15 Å), while Hg itself deviates by +0.20 Å. The severe distortion of the octahedron is mainly due to the narrow S–Hg–O(1′) angle [144.1(3)°] and to the variability in Hg–N distances. In fact, in the tridentate NSN(Qui) Hg–N(1) 2.63(1) Å, Hg–N(2) 2.28(1) Å, while in the bidentate NSN(Qui) Hg–N(1′) 2.23(1) Å. Likewise, in the tridentate donor, the Hg–S–C(6) and Hg–S–C(7) angles are 97.1 and 96.1°, respectively, while the Hg–S′–C(6′) and Hg–S′–C(7′) angles in the bidentate unit are 87.7 and 113.1°, respectively.

A comparison with existing data was made searching the CCD repository for (a) six-coordinate monomeric $Hg^{II}$ complexes containing a thioether ligand, (b) six-coordinate monomeric $Hg^{II}$ complexes with the metal surrounded by at least four pyridyl ligands. Search (a) returned ten entries, in which the $Hg^{II}$–S(thioether) distance varies between 2.458[34] and 3.050[34]Å. In **2**, there is a shorter and a longer Hg–S bond [2.621(4) Å and 2.749(5) Å], a situation already found by Bebout[14] [bonds of 2.654(1) and 2.671(1) Å] and also quite similar to what was observed in the complexes described in ref.[35] (bonds of 2.654, 2.735, 2.639, 2.751 Å) and ref.[36] (distances of 2.728, 2.638, and 2.712 Å).

Search (b) returned eight entries, with $Hg^{II}$–N(pyridyl) distances ranging from 2.271[37] to 2.685[38]Å. The shorter and longer Hg–N distances found in **2** [2.23(1), 2.28(1), 2.63(1) Å] again fit into the experimental range, with the shorter bond being in fact the shortest Hg–N(pyridyl) bond so far reported, about 0.04 Å shorter than the one reported

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in ref.[37] (2.271 Å), and the longer one being the second longest after the one found in ref.[38] (2.685 Å). A similar situation with shorter and longer Hg–N distances has been reported by Bebout[14] [2.382(4), 2.409(4) Å, 2.501(4), 2.511(4) Å] as well as in the cation described in ref.[39] (2.351, 2.418, 2.413 Å). Taken all together, these data suggest that the asymmetry of the ligand and the steric requirements of the quinolyl moiety are responsible for the NSN(Qui) donor failing to bind mercury in a bis-tridentate fashion as well as for the variation in the Hg–S, Hg–N bond lengths (Scheme 2).



Scheme 2.

It is also worth noting that the perchlorate ligand is rather unusual in $Hg^{II}$ complexes. A search in the CCD returned only five structures, in which the Hg–O distance ranges between 2.569 and 2.932 Å. The only six-coordinate Hg complex reported[13] shows Hg–O distances of 2.569 and 2.650 Å, comparing well with our value of 2.60(1) Å. Like in **1** above, the oxygen atoms of the two perchlorate residues and the quinolyl N atom of the bidentate NSN(Qui) donor are involved in a network of nonbonding interactions. The intermolecular contacts are detailed in Table 2SI.

## Determination of the Acid Dissociation Constants

The determination of the acid dissociation constants of the ligands was performed by potentiometric titration with NaOH (0.1 M) of the conjugated acids of the ligand [NNN(Qui)·3HCl; NSN(Qui)·2HCl; NSN(Py)·2HCl] produced in situ by addition of the stoichiometric amount of HCl (0.1 M) in degassed water at controlled ionic strength (0.1 M, NaCl) under $N_2$ stream. The pH vs. titrant volume data were elaborated by means of routines appropriately written in the SCIENTIST™ environment. The macroconstant and microconstant sets are referred for each ligands to the following general schemes and are reported in Tables 1 and 2, respectively (see Supporting Information).

$LL'L''H_3^{3+} + H_2O \rightleftharpoons LL'LH_2^{2+} + H_3O^+$
$pK_{a3}$ [LL′L″ ⇌ NNN(Qui)]

$LL'L''H_2^{2+} + H_2O \rightleftharpoons LL'LH^+ + H_3O^+$
$pK_{a2}$ [LL′L″ ⇌ NNN(Qui), NSN(Qui), NSN(Py)]

$LL'L''H^+ + H_2O \rightleftharpoons LL'L + H_3O^+$
$pK_{a1}$ [LL′L″ ⇌ NNN(Qui), NSN(Qui), NSN(Py)]

Table 1. Macroconstant set determined by titration with NaOH (0.1 M) of the acid LLL·*n*HCl ($n$ = 2, 3) in degassed water ($I$ = 0.1) at 25 °C.

| LL′L″·*n*HCl | p$Ka_3$ | p$Ka_2$ | p$Ka_1$ |
|---|---|---|---|
| NSN(Py)·2HCl | / | 3.33 ± 0.04 | 5.23 ± 0.02 |
| NSN(Qui)·2HCl | / | 2.98 ± 0.14 | 4.83 ± 0.03 |
| NNN(Qui)·3HCl | <2 | 2.80 ± 0.13 | 4.84 ± 0.02 |

## Determination of the Formation Equilibrium Constants

### *Hg*

The spectrophotometric titration of the ligand NNN(Qui) with $HgCl_2$ was performed in water and resolved by means of the HYPERQUAD™ 2003 program[40] according to the model:

$$Hg^{2+} + 2Cl^- \rightleftharpoons HgCl_2 \quad (1)$$
$\log K_1 = 13.22 \pm 0.2$[41]

$$Hg^{2+} + 2Cl^- + NNN(Qui) \rightleftharpoons [Hg\{NNN(Qui)\}Cl_2] \quad (2)$$
$\log K_2 = 18.56 \pm 0.01$

$$Hg^{2+} + 2Cl^- + 2NNN(Qui) \rightleftharpoons [Hg\{NNN(Qui)\}_2Cl_2] \quad (3)$$
$\log K_3 = 23.52 \pm 0.02$

It is apparent that the formation of the species in solution is influenced by the ligand/Hg ratio and by the equilibrium constants, equilibrium (3) being the most favored at high NNN(Qui)/Hg ratios. The formulation of the complex $[Hg\{NNN(Qui)\}_2Cl_2]$ does not imply any structural preference since several attempts to produce crystals suitable for X-ray collection were unsuccessful and a mixture of uncharacterized products was always obtained. According to the structure of $[Hg\{NSN(Qui)\}_2(OClO_3)](ClO_4)$ (**2**) and to the chloride coordinating characteristics, we suggest that this species could be represented as a neutral six-coordinate octahedral complex bearing two partially coordinated NNN(Qui) fragments and two chlorides. The pH of the unbuffered solution hardly deviates from 6.5 and therefore no protonation equilibrium of the ligand occurs (see Supporting Information) and no formation of mercury hydroxide is observed. Moreover, owing to the stability of the $HgCl_2$ species the equilibrium constants are better described as shown in equations 4 and 5.

Table 2. Microconstant set determined by titration with NaOH (0.1 M) of the acid LL′L″·*n*HCl ($n$ = 2, 3).

| In degassed water ($I$ = 0.1) at 25 °C | p$K_{12}$ | p$K_{13}$ | p$K_{24}$ | p$K_{34}$ | p$K_{23}$ |
|---|---|---|---|---|---|
| NSN(Py)·2HCl | 3.63 ± 0.16 | 3.63 ± 0.16 | 4.93 ± 0.02 | 4.93 ± 0.02 | 0.00 ± 0.03 |
| NSN(Qui)·2HCl | 3.09 ± 0.02 | 3.63 ± 0.04 | 4.72 ± 0.19 | 4.18 ± 0.21 | 0.54 ± 0.06 |
| NNN(Qui)·3HCl | 2.87 ± 0.02 | 3.63 ± 0.04 | 4.77 ± 0.17 | 4.01 ± 0.19 | 0.76 ± 0.06 |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$HgCl_2 + NNN(Qui) \rightleftharpoons [\{HgNNN(Qui)\}Cl_2]$ (4)
$\log K_4 = 5.34 \pm 0.21$ ($\log K_4 = \log K_2 - \log K_1$)

$HgCl_2 + 2NNN(Qui) \rightleftharpoons [Hg\{NNN(Qui)\}_2Cl_2]$ (5)
$\log K_5 = 10.30 \pm 0.22$ ($\log K_5 = \log K_3 - \log K_1$)

As a matter of fact the complex $[Hg\{NNN(Qui)\}Cl_2]$ in solution dissociates according to step (4) but at variance with zinc (vide infra) the dissociation constant (ca. $6 \times 10^{-6}$) is badly determined owing to the unfavorable change of absorbance as a function of concentration.

The equilibrium constants between mercury and the NSN ligands were also determined in a similar way and a summary of the results is reported in the following Table 3.

Table 3. Log $K_2$, log $K_3$, log $K_4$, and log $K_5$ for the reaction of $HgCl_2$ with terdentate NNN or NSN ligands in $H_2O$ at 25 °C.

| Ligand | $\log K_2$ | $\log K_3$ | $\log K_4$ | $\log K_5$ |
|---|---|---|---|---|
| NNN(Qui) | $18.56 \pm 0.01$ | $23.52 \pm 0.02$ | $5.34 \pm 0.21$ | $10.30 \pm 0.22$ |
| NSN(Qui) | $18.84 \pm 0.04$ | $23.52 \pm 0.04$ | $5.62 \pm 0.24$ | $10.30 \pm 0.24$ |
| NSN(Py) | $18.60 \pm 0.07$ | $22.95 \pm 0.13$ | $5.38 \pm 0.27$ | $9.73 \pm 0.33$ |

As can be seen the equilibrium constant values are hardly influenced by the nature of the chelating ligands. However, only some complexes of the ligands NNNtos(Qui) and NNN(Qui) display fluorescence activity, the latter being the more soluble species; for this reason we decided to extend our investigation on zinc and cadmium using NNN(Qui) as the complexing agent.

### *Zn*

Analogously to the Hg case the values of the equilibrium constants were determined by direct titration of a ca. $1 \times 10^{-4}$ mol dm$^{-3}$ solution of the ligand NNN(Qui) with $ZnCl_2$. The model fitted by means of the HYPERQUAD™ 2003 program[40] was as shown in equations 1* to 3*.

$Zn^{2+} + 2Cl^- \rightleftharpoons ZnCl_2$ (1*)
$\log K_1^* = 1$[41]

$Zn^{2+} + NNN(Qui) \rightleftharpoons [Zn\{NNN(Qui)\}]^{2+}$ (2*)
$\log K_2^* = 4.58 \pm 0.02$

$Zn^{2+} + 2NNN(Qui) \rightleftharpoons [Zn\{NNN(Qui)\}_2]^{2+}$ (3*)
$\log K_3^* = 8.50 \pm 0.04$

As can be seen, chloride does not compete efficiently with oxygenated ligands ($H_2O$), thus the zinc complexes were written with vacant coordination sites which might be occupied by $H_2O$, $Cl^-$, and $OH^-$, the latter being the less probable since $pK_a\ Zn(H_2O)_x^{2+} \approx 9$.

At variance with mercury, reaction 2* can be checked by studying the dissociation of the complex $[Zn\{NNN(Qui)\}]^{2+}$ taking place upon dilution. In this case the favorable absorbance change allows the determination of $1/K_2^* = 1 \times 10^{-5}$ ($\log K_2^* = 5 \pm 0.5$) which is in substantial agreement with the value of $\log K_2^* = 4.58$ previously determined.

Moreover, it is possible to study the direct exchange between the Hg complex and $Zn(ClO_4)_2$ according to the reaction 4*.

$[Hg\{NNN(Qui)\}Cl_2] + Zn^{2+} \rightleftharpoons [Zn\{NNN(Qui)\}]^{2+} + HgCl_2$ (4*)
$\log K_4^* = -0.92 \pm 0.03$

From reactions 4 and 4* the value of $\log K_2^* = 4.42 \pm 0.24$ is obtained.

It is apparent that an internal consistency among the $K_2^*$ values is achieved. Thus, according to the previous choice the value of $\log K_2^* = 4.58 \pm 0.02$ is assumed.

### *Cd*

The direct exchange between the species $[Zn\{NNN(Qui)\}]^{2+}$ and $Cd^{2+}$ according to the model described below. Reaction 1** can be treated as a combination of 2* and 3**.

$[Zn\{NNN(Qui)\}]^{2+} + Cd^{2+} \rightleftharpoons [Cd\{NNN(Qui)\}]^{2+} + Zn^{2+}$ (1**)

$Zn^{2+} + NNN(Qui) \rightleftharpoons [Zn\{NNN(Qui)\}]^{2+}$ (2*)
$\log K_2^* = 4.58 \pm 0.02$

$Cd^{2+} + NNN(Qui) \rightleftharpoons [Cd\{NNN(Qui)\}]^{2+}$ (3**)
$\log K_3^{**} = 2.99 \pm 0.01$

In this respect from the titration of a dechlorinated solution of $[Zn\{NNN(Qui)\}]^{2+}$ (from $[Zn(NNN(Qui))Cl_2]$ treated with $AgClO_4$) with $Cd(ClO_4)_2$ it is possible to obtain the logarithm of the formation constant $K_3^{**}$ as the refined parameter, the formation constant for zinc $K_2^*$ being held constant ($4.58 \pm 0.02$) throughout the fitting process. The chloride ions were removed from the solution in order to avoid formation of cadmium complexes containing chloride bridges which might complicate the resolution of the system. Moreover, no precipitation problems arise under these conditions.

As an internal check of consistency the direct titration of $Cd^{2+}$ $\{Cd(ClO_4)_2\}$ with NNN(Qui) ligand was also performed and the value of $2.89 \pm 0.01$ for $\log K_3^{***}$ was determined by means of the customary HYPERQUAD™ 2003 program.[40] In the presence of an excess of NNN(Qui) ligand a further equilibrium takes place.

$Cd^{2+} + 2NNN(Qui) \rightleftharpoons [Cd\{NNN(Qui)\}_2]^{2+}$ (4**)
$\log K_4^{**} = 6.31 \pm 0.08$

The independently determined values for $K_3^{***}$ are in good agreement with each other, this fact confirming the model reliability and the consistency of the different approaches.

The equilibrium constants measured in the cases of $Zn^{2+}$ and $Cd^{2+}$ complexes lie among the values reported in the literature when di(2-pyridyl)amine and bis[(2-pyridyl)-methyl]amine are used as ligands.[42] The case of $Hg^{2+}$ complexes turns out to be more difficult to compare since the data in the literature are referred to complexes without chloride. The $\log K_3$ value ($23.52 \pm 0.02$), however, is in substantial agreement with that found by other authors when $Hg(NO_3)_2$ is reacting with bis[(2-pyridyl)methyl]amine.[42] In this respect it is noteworthy that the ionic strength control in the titration of the ligand with $HgCl_2$ is irrelevant since only neutral molecules are involved.

The titration spectra and the values of the extinction coefficients are reported in the Supporting Information (Table 3SI).

### Spectroscopic Properties of the Ligands

The spectral features of the ligands NNN(Qui) and NSN(Qui) in different solvents are summarized in Table 4.

Table 4. Absorption and emission ($\lambda_{exc}$ = 320 nm) maxima and fluorescence quantum yields of the ligands NNN(Qui) and NSN(Qui) in different solvents.

| Ligand | Solvent | $\lambda_{abs}$ [nm] | $\lambda_{em}$ [nm] | $\Phi$ |
|---|---|---|---|---|
| NNN(Qui) | *n*-hexane | 260<br>365 | 426 | <0.001 |
| | $CH_3CN$ | 258<br>360 | 489 | 0.020 ± 0.002 |
| | $H_2O$ | 252<br>337 | – | – |
| NSN(Qui) | *n*-hexane | 253<br>340 | 380 | 0.010 ± 0.001 |
| | $CH_3CN$ | 251<br>332 | 420 | 0.020 ± 0.002 |
| | $H_2O$ | 248<br>317 | 453 | 0.10 ± 0.01 |

The most prominent spectral changes observed at increasing solvent polarity for both ligands are the following: *i*) a marked blue shift of the first ππ* absorption band, *ii*) a red shift of the fluorescence emission with a concomitant increase of the Stokes shift, and *iii*) an increase of fluorescence quantum yields. These changes are consistent with a stabilization of both the ground and the first excited singlet state by polar solvents.[43] NNN(Qui) is fluorimetrically silent in $H_2O$; this could be attributed to the occurrence of a bimolecular quenching induced by the formation of an H-bond with the central amine nitrogen.

The water-insoluble NNNtos(Qui) does not show any fluorescence signal in organic solvents, probably because of an intramolecular quenching due to rotation of the tosyl moiety around the N–S bond.

### Fluorescence Properties of the Complexes

Both the complexes [Zn{NNN(Qui)}$Cl_2$] and [Zn{NNNtos(Qui)}$Cl_2$] are soluble and fluorescent in $H_2O$. Probably, metal coordination to the aliphatic nitrogen in [Zn{NNN(Qui)}$Cl_2$] prevents its interaction with the protic solvent;[44] the fluorescence quantum yield, however, is very low ($\Phi < 0.001$). On the contrary, a relatively high quantum yield $\Phi$ is observed for [Zn{NNNtos(Qui)}$Cl_2$], both in $H_2O$ [$\lambda^{max}_{em}$ (nm) = 440; $\Phi$ = 0.050 ± 0.005] and $CH_3CN$ [$\lambda^{max}_{em}$ (nm) = 375; $\Phi$ = 0.020 ± 0.002]. A plausible explanation for this behavior is that steric constraint due to metal–N chelation limits the rotational freedom of the tosyl group, thereby preventing the fluorescence quenching observed for the free ligand.

The fluorescent behavior of the ligand NNN(Qui) has also been studied with $Cd^{2+}$. A mild increase (twofold) of the fluorescent signal at $\lambda_{em}$ = 520 nm has been observed for a Cd/NNN(Qui) ratio of 2000/1. This is probably due to the high spin/orbit coupling constant of $Cd^{2+}$. For the sake of completeness a Table summarizing the photochemical properties of several complexes bearing similar ligands and the related references is reported in the Supporting Information (Table 4SI).

## Conclusions

From the present study it may be deduced that:

a) Bis-chelate complexes of the zinc triad with terdentate and potentially fluorescent ligands of the type NNN or NSN are easily obtained when perchlorate salts of the metals are used in the coordination reaction.

b) Monochelate complexes of the zinc triad with the above-mentioned ligands are easily obtained when chloride salts of the metals are used.

c) Among the X-ray determinations the structure of the complex [Hg{NSN(Qui)}$OClO_3$]$ClO_4$, which is quite unusual, bears witness to the flexibility in solution of this sort of ligand when coordinated to $d^{10}$ metals.

d) The macroscopic and microscopic set of acid dissociation constants for the terdentate NSN and NNN ligands has been determined.

e) The fluorescence of the ligands and of the corresponding metal complexes has been studied. In the case of the fluorescent silent ligands NNN(Qui) and NNNtos(Qui) the corresponding complexes with Zn were shown to be fluorescent.

## Experimental Section

**Solvents and Reagents:** $CH_3CN$, $CH_3OH$, and $H_2SO_4$ were commercial-grade chemicals and were used without further purification. HCl (0.1 M) and NaOH (0.1 M) were prepared by appropriate dilution of NORMEX solutions (Carlo Erba Reagents). $Hg(ClO_4)_2 \cdot 6H_2O$, $Cd(ClO_4)_2 \cdot 6H_2O$ (Alfa-Aesar), $Zn(ClO_4)_2 \cdot 6H_2O$, $AgNO_3$, $HgCl_2$, $CdCl_2 \cdot H_2O$, $ZnCl_2$ (Sigma–Aldrich), and $CD_3CN$ and $CD_3OD$ were commercial-grade reagents and used without further purification.

**IR, NMR, UV/Vis, and Fluorescence Measurements:** IR and $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Perkin–Elmer Spectrum One spectrophotometer and a Bruker Avance 300 spectrometer, respectively. The proton and carbon assignment was performed by $^1H$-$^{13}C$-HMQC and HMBC techniques in the case of the bis-chelate complexes $[ML_2](ClO_4)_2$ [M = Zn, Cd, Hg; L = NSN(Qui), NNN(Qui)]. The proton assignment for the chlorinated complexes $[MCl_2]$ [M = Zn, Cd, Hg; L = NSN(Qui), NNN(Qui)] and for all complexes with NNNtos(Qui) as ancillary ligand was achieved by $^1H$-$^1H$-COSY experiment because of their low solubility. UV/Vis spectra were taken with a Perkin–Elmer Lambda 40 spectrophotometer equipped with a Perkin–Elmer PTP6 (Peltier temperature programmer) apparatus. All fluorescence spectra were recorded with a Perkin–Elmer luminescence spectrometer LS 50 ($T$ = 298 K) and fluorescence quantum yields $\Phi_X$ were measured relative to quinine sulfate in $H_2SO_4$ (0.5 M) as a standard and calculated according to the following formula:

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$\Phi_X = \Phi_{ST} \frac{S_X}{S_{ST}} \cdot \frac{A_{ST}}{A_X} \cdot \frac{n_X^2}{n_{ST}^2}$$

where $S$ represents the area of the corrected emission fluorescence spectra ($\lambda_{exc}$ = 320 nm), $A$ is the optical density at 320 nm, and $n$ the refractive index of the solvent used.

**Synthesis of Ligands:** The synthesis of the ligands NSN(Py), NSN(Qui), and NNNtos(Qui) was carried out according to the published procedure.[12]

**8-[(Pyridylmethyl)amino]-quinoline NNN(Qui):** To concentrated $H_2SO_4$ (7.5 mL) 8-*N*-tosyl-*N*-(2-pyridylmethyl)quinoline [NNNtos-(Qui)] (2.358 g, 6.05 mmol) was added and the solution was stirred for 2 h at 110 °C. To the resulting mixture a saturated aqueous solution of NaCl (10 mL) and NaOH (6 M, 60 mL) was added. The neutral residue was extracted with $CH_2Cl_2$ and washed with a saturated aqueous solution of NaCl. The organic phase was eventually dried under vacuum. The crude product was purified by flash chromatography through a silica column with a 1:1 $CH_2Cl_2/Et_2O$ mixture as eluent. Concentration under vacuum of the eluate yields 1.088 g (4.62 mmol) of the title compound as a yellow/green oil. Yield 76%. $^1$H NMR ($CD_3CN$, $T$ = 298 K): $\delta$ = aminomethyl protons, 4.66 (d, $J_{CH2-NH}$ = 5.92 Hz, 2 H, pyr-$CH_2$N), amine protons 7.25 (br. s, 1 H, pyr-NH), pyridine and quinoline protons 6.67 (dd, 1 H, 7-$H_{qui}$), 7.11 (dd, $J$ = 7.93 Hz and $J$ = 1.15 Hz, 1 H, 5-$H_{qui}$), 7.27 (dd, $J$ = 4.83 Hz, 1 H, 3′-$H_{pyr}$), 7.36 (t, 1 H, 6-$H_{qui}$), 7.41 (d, 1 H, 5′-$H_{pyr}$), 7.48 (dd, 1 H, 3-$H_{qui}$), 7.72 (td, $J$ = 8.00 and $J$ = 1.75 Hz, 1 H, 4′-$H_{pyr}$), 8.18 (dd, $J$ = 8.33 and $J$ = 1.75 Hz, 1 H, 4-$H_{qui}$), 8.62 (d, 1 H, 2′-$H_{pyr}$), 8.79 (dd, $J$ = 4.17 Hz, 1 H, 2-$H_{qui}$) ppm. $^{13}$C NMR ($CD_3CN$, $T$ = 298 K): $\delta$ = thiomethyl carbon, 48.03 (pyr-$CH_2$N), pyridine C atoms 121.34, 121.59, 122.04 (C-5′$_{pyr}$, C-3′$_{pyr}$, C-3$_{qui}$), 136.54 (C-4′$_{pyr}$), 149.00 (C-2′$_{pyr}$), 158.50 (C-6′$_{pyr}$), quinoline C atoms 104.91 (C-5$_{qui}$), 113.90 (C-7$_{qui}$), 127.63 (C-6$_{qui}$), 128.56 (C-4a$_{qui}$), 138.05 (C-8$_{qui}$), 138.83 (C-4$_{qui}$), 144.36 (C-8a$_{qui}$), 147.14 (C-2$_{qui}$) ppm. $^1$H NMR ($CDCl_3$, $T$ = 298 K): $\delta$ = aminomethyl protons, 4.73 (d, $J$ = 5.8 Hz, 2 H, pyr-$CH_2$N), amine protons 7.03 (br. s, 1 H, pyr-NH), pyridine and quinoline protons 7.09 (dd, $J$ = 8.1 and 1.1 Hz, 1 H, 5-$H_{qui}$), 7.20 (dd, $J$ = 4.7 and = 7.6 Hz, 2 H, 3′-$H_{pyr}$), 7.34 (t, $J$ = 7.5 Hz, 1 H, 6-$H_{qui}$), 7.41 (m, 2 H, 3-$H_{qui}$, 5′-$H_{pyr}$), 7.63 (td, $J$ = 7.6 and 1.8 Hz, 1 H, 4′-$H_{pyr}$), 8.09 (dd, $J$ = 8.3 and 1.7 Hz, 1 H, 4-$H_{qui}$), 8.65 (d, 1 H, 2′-$H_{pyr}$), 8.79 (dd, $J$ = 4.2 Hz, 1 H, 2-$H_{qui}$) ppm. $^{13}$C NMR ($CDCl_3$, $T$ = 298 K): $\delta$ = thiomethyl carbon, 49.1 (pyr-$CH_2$N), pyridine C atoms 121.0, 121.4, 121.9 (C-5′$_{pyr}$, C-3′$_{pyr}$, C-3$_{qui}$), 136.6 (C-4′$_{pyr}$), 149.3 (C-2′$_{pyr}$), 158.9 (C-6′$_{pyr}$), quinoline C atoms 105.2 (C-5$_{qui}$), 114.3 (C-7$_{qui}$), 127.6 (C-6$_{qui}$), 128.6 (C-10$_{qui}$), 138.3 (C-4$_{qui}$), 144.3 (C-9$_{qui}$), 147.0 (C-2$_{qui}$) ppm.

**Synthesis of Bis-Chelate Complexes**

**[Hg[NNN(Qui)]$_2$](ClO$_4$)$_2$:** A solution of $Hg(ClO_4)_2 \cdot 6H_2O$ (0.0861 g, 0.18 mmol) in acetonitrile (4 mL) was added slowly to a stirred solution of NNN(Qui) (0.09 g, 0.38 mmol) in acetonitrile (2 mL). The resulting solution was diluted 1:1 with toluene at 0 °C. The solution was concentrated under reduced pressure and the complex precipitated. The complex was filtered off, washed with toluene, pentane, and dried under vacuum. Cream microcrystals were obtained (0.1224 g, 0.14 mmol). Yield 80%. IR (KBr): $\tilde{\nu}$ = $\nu_{N-H}$ 3289.4, $\nu_{C-H}$ 3048.0, 2920.7, $\nu_{C=N}$ 1613.4, $\nu_{C=C}$ 1512.8, 1445.8, $\nu_{ClO4^-}$ 1090.5 cm$^{-1}$. $^1$H NMR ($CD_3CN$, $T$ = 298 K): $\delta$ = aminomethyl protons, 4.69 (s, 4 H, pyr-*N*-$CH_2$), amine protons, 6.14 (br. s, 2 H, pyr-NH), pyridine and quinoline protons 7.39 (d, $J$ = 8.2 and 4.5 Hz, 2 H, 3-$H_{qui}$), 7.58 (m, 6 H, 6-$H_{qui}$, 7-$H_{qui}$, 3′-$H_{pyr}$), 7.69 (dd, $J$ = 7.35 and 2.3 Hz, 2 H, 5-$H_{qui}$), 7.75 (d, $J$ = 7.9 Hz, 2 H, 5′-$H_{pyr}$), 8.14 (td, $J$ = 7.7 and 1.7 Hz, 2 H, 4′-$H_{pyr}$), 8.25 (m, 4 H, 4-$H_{qui}$, 2-$H_{qui}$), 8.42 (d, $J$ = 4.8 Hz, 2 H, 2′-$H_{pyr}$) ppm. $^{13}$C NMR ($CD_3CN$, $T$ = 298 K): $\delta$ = aminomethyl C atoms, 51.7 (pyr-N-$CH_2$), quinoline C atoms 122.0 (C-3$_{qui}$), 125.2, 125.8 (C-5$_{qui}$, C-7$_{qui}$), 127.39 (C-6$_{qui}$), 128.2 (C-8$_{qui}$), 128.8 (C-10$_{qui}$), 138.9 (C-4$_{qui}$), 139.0 (C-9$_{qui}$), 150.3 (C-2$_{qui}$); pyridine C atoms 122.4 (C-3′$_{pyr}$), 125.8 (C-5′$_{pyr}$), 141.2 (C-4′$_{pyr}$), 149.1 (C-2′$_{pyr}$), 154.6 (C-6′$_{pyr}$) ppm. $C_{30}H_{26}Cl_2HgN_6O_8$: calcd. C 41.41, H 3.01, N 9.66; found C 41.25, H 2.97, N 9.51.

The following complexes were synthesized in an analogous way using the appropriate perchlorate salts.

**[Cd{NNN(Qui)}$_2$](ClO$_4$)$_2$:** Yield 85% (white microcrystals). IR (KBr): $\tilde{\nu}$ = $\nu_{N-H}$ 3251.4, $\nu_{C-H}$ 3078.6, 2931.4, $\nu_{C=N}$ 1613.3, $\nu_{C=C}$ 1511.0, 1440.6, $\nu_{ClO4^-}$ 1107.9 cm$^{-1}$. $^1$H NMR ($CD_3CN$, $T$ = 298 K): $\delta$ = aminomethyl protons, 4.61 (s, 4 H, pyr-N-$CH_2$), amine protons, 5.70 (br. s, 2 H, pyr-NH), pyridine and quinoline protons 7.48 (m, 4 H, 3-$H_{qui}$, 3′-$H_{pyr}$), 7.65 (d, $J$ = 7.7 Hz, 2 H, 5′-$H_{pyr}$), 7.72 (t, 2 H, 6-$H_{qui}$), 7.85 (dd, $J$ = 6.2 Hz, 2 H, 7-$H_{qui}$), 7.90 (dd, $J$ = 8.3 and 1.1 Hz, 2 H, 5-$H_{qui}$), 8.08 (td, $J$ = 7.7 Hz, 2 H, 4′-$H_{pyr}$), 8.20 (dd, $J$ = 4.6 Hz, 2 H, 4-$H_{qui}$), 8.28 (d, $J$ = 4.7 Hz, 2 H, 2′-$H_{pyr}$), 8.45 (dd, $J$ = 8.3 and 1.6 Hz, 2 H, 2-$H_{qui}$) ppm. $^{13}$C NMR ($CD_3CN$, $T$ = 298 K): $\delta$ = aminomethyl C atoms, 53.9 (pyr-N-$CH_2$), quinoline C atoms 122.6 (C-3$_{qui}$), 124.9 (C-7$_{qui}$), 126.4 (C-5$_{qui}$), 127.7 (C-6$_{qui}$), 129.2 (C-10$_{qui}$), 139.6 (C-2$_{qui}$), 139.7 (C-8$_{qui}$), 140.5 (C-9$_{qui}$), 150.3 (C-4$_{qui}$); pyridine C atoms 124.7 (C-5′$_{pyr}$), 125.0 (C-3′$_{pyr}$), 140.6 (C-4′$_{pyr}$), 148.5 (C-2′$_{pyr}$), 155.8 (C-6′$_{pyr}$). $C_{30}H_{26}CdCl_2N_6O_8$: calcd. C 50.26, H 3.64, N 7.99; found C 50.32, H 3.73, N 8.05.

**Potentiometric Titrations and Calculations:** The potentiometric determinations were carried out by a Metrohm 654 pH-meter equipped with a Metrohm glass electrode calibrated at 25 °C by means of standard Metrohm buffer solutions (pH 4 and 7). All the measurements were carried out under $N_2$ stream in a thermostatted potentiometric cell.

The appropriate quantity of the ligands NSN(Py), NSN(Qui), and NNN(Qui) were poured into volumetric flasks (250 mL) and the appropriate volumes of HCl (0.1 M) were added to obtain NSN(Py)·2HCl, NSN(Qui)·2HCl, and NNN(Qui)·3HCl, respectively. Addition of NaCl (0.1 M) in water yielded the solutions at pre-determined concentration and ionic strength ([Ligand·$n$HCl] = $1 \times 10^{-3}$ M; $I$ = 0.1 M).

An aliquot (50 mL) of the solution under study was then titrated with NaOH (0.1 M, $I$ = 0.1 M). Evaluation of acid/base constants from the pH values vs. volume of NaOH added, was obtained by routines written using the SCIENTIST™ program. For calculation details see the Supporting Information.

**Spectrophotometric Determination of the Complex Formation Constants:** All the experiments were carried out in water (degassed under $N_2$ stream; pH ≈ 6.5) and in thermostatted (25 °C) flasks. A standard stock of solutions (50 mL; $3 \times 10^{-4}$ M) of the ligands [NNN(Qui), NSN(Qui), and NSN(Py)] was prepared by dissolving a weighted amount of the appropriate ligand in a volumetric flask and diluting to the mark with $H_2O$. The ligand solutions ($7–9 \times 10^{-5}$ M) used in the experiment were then prepared by dilution of the stock solution. The ligand solution was titrated by adding microaliquots of a standard solution of $MCl_2$ (M = Hg, Zn; [$MCl_2$] = 0.01 M) and $Cd(ClO_4)_2$ ([$Cd(ClO_4)_2$] = 0.5 M) by means of a micropipette. The ensuing absorbance values at different wavelengths were recorded at 25 °C and the evaluation of stepwise stability constants from the absorbance vs. volume of $MCl_2$ mL data was achieved by the speculative use of the program HYPERQUAD™.[40] The expected total absorbance value ($A_T$) for each solution is given as $A_T = \Sigma_i \varepsilon_i c_i$, where $\varepsilon_i$ and $c_i$ are the molar extinction coefficient and the concentration of the involved species, respectively. The iterative adjustment of calculated values of $\varepsilon_{ML}$ and $\varepsilon_{ML2}$ and subsequent refinement of the parameters was continued until the correlation matrix was minimized. The values of refined $\varepsilon_L$ are in good agreement with the values measured by the Lambert–Beer experiment. UV/Vis titration spectra are reported in the Supporting Information.

The metal exchange spectrophotometric titrations were performed by addition of a weighted amount of $Zn(ClO_4)_2 \cdot 6H_2O$ ($1 \times 10^{-4} \leq$ [$Zn(ClO_4)_2$] $\leq 1 \times 10^{-2}$ M) or of microaliquots of a standard stock solution (0.01 M) of $Cd(ClO_4)_2 \cdot 6H_2O$ to solutions of [Hg{NNN(Qui)}$Cl_2$] or [Zn{NNN(Qui)}]$^{2+}$ ($1 \times 10^{-4}$ M), respectively. The absorbance values were taken at $\lambda$ = 250 nm. The exchange constants from the absorbance vs. [$M(ClO_4)_2$] values were obtained by routines written using the SCIENTIST™ program. For calculation details see the Supporting Information.

**X-ray Structural Determination:** Well-formed crystals of the complexes [Hg{NSN(Qui)}$Cl_2$] (**1**), [Hg{NSN(Qui)}$_2${$OClO_3$}]($ClO_4$) (**2**), and [Zn{NNN(Qui)}$Cl_2$] (**3**) suitable for X-ray analysis, were mounted on the top of a glass fiber and transferred to either a STADI4 diffractometer equipped with a CCD camera (**1**, **2**) or to a Nonius DIP-1030H system (**3**). The latter was generously made available by colleagues at the Department of Chemical Sciences of the University of Trieste, Italy. During the crystallization process,

complex **2** forms crystals that are either colorless or ruby-red. The data presented here refer to the ruby-red specimen, as the colorless crystals proved inadequate for the X-ray experiment.

The X-ray diffraction data were collected at room temperature using graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and corrected for Lorentz and polarization effects (**1**–**3**) and for absorption (**1**, **2**). For **3**, a total of 36 frames were collected, each with a rotation of 6° about $\phi$, an exposure time of 20 min, and the detector position at 90 mm from the crystal, whereas data reduction and cell refinement were carried out using the programs DENZO and SCALEPACK.[45] The structures were solved by means of the heavy-atom methods (**1**, **2**) or the direct methods (**3**), using the SHELXTL-NT package,[46] and were refined by full-matrix least-squares procedure on $F^2$ with the SHELXL-97[47] program. Scattering factors incorporated in SHELXL-97 were used; no empirical extinction corrections were applied.

In the last cycles of refinement of **1** and **3**, all the non-H atoms were allowed to vibrate anisotropically. In **2** the ratio between the number of observed reflections and the number of parameters was unsatisfactory. Accordingly, the atoms belonging to the inner coordination core were refined anisotropically, while the remaining non-H atoms were refined isotropically. As for H atoms, in **1** and **2** they were placed in idealized positions and refined with the "riding model." In both structures the $U_{iso}$ values of hydrogen atoms were set at 1.2 times $U_{eq}$ of the appropriate carrier atom. In **3**, the H atoms were refined isotropically. The crystal data and refinement parameters of the three complexes are summarized in the Supporting Information (Table 1SI); none of the structures revealed any anomalous feature. Selected interatomic distances and angles are shown in Table 5.

CCDC-642237 to -642239 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Details on acidity macro- and micro-constant and stability constant determination, UV/Vis spectra of the spectrophotometric titrations, X-ray crystallographic data.

## Acknowledgments

The authors gratefully acknowledge the Colleagues of the Dipartimento di Scienze Chimiche of the University of Trieste (Italy), Profs. L. Randaccio, E. Zangrando, and S. Geremia, for kindly allowing access to their instrumentation for the X-ray diffraction data collection of complex **3**. We also thank Dr. F. Ricchelli of the Dipartimento di Scienze Biologiche of the University of Padova (Italy) and Dr. Peter Nikolai of the Bulgarian Academy of Sciences for the helpful discussion and suggestions about the photochemical properties of the ligands and complexes.

# Iron(III) Exchange Process between Hexadentate Tripodal Ligands: Models for the Ternary Complexes

Guy Serratrice,*[a] Frédéric Biaso,[a] Jean-Louis Pierre,[a] Sylvie Blanc,[b] and Anne-Marie Albrecht-Gary[c]

**Keywords:** Mixed ligands / Iron / Exchange interactions / Siderophores / Tripodal ligands

Using tripodal ligands as tools, the kinetics of iron removal from ferric complexes of the tripodal tris(hydroxyquinoline) ligands O-TRENSOX and of tris(catechol) TRENCAMS was investigated. Two hexadentate heterotripodal ligands were also examined (TRENSOX2CAMS with two hydroxyquinoline and one catechol subunits and TRENSOXCAMS2 with two catechol and one hydroxyquinoline subunits) as possible models of the ternary complexes involved in the iron exchange process. The main result of this kinetic study is the pertinence of the iron complexes of the mixed ligands as models for the transient and successive ternary complexes occurring in the iron exchange, which proceeds "arm-by-arm" between a homotopic ligand and the iron complex of another homotopic ligand.

## Introduction

Microbial iron bioavailability is driven by the coordination chemistry of siderophores, which are iron-chelating agents that are excreted by microorganisms to render iron soluble in the environment and favor the uptake of this metal. Iron chelation by some natural or synthetic chelators can be applied to human diseases characterized by iron overload, and water-soluble iron complexes can be used to alleviate iron deficiency in plants, preventing and even reversing iron chlorosis. The coordination chemistry of a great number of water-soluble natural or synthetic iron chelators was recently reviewed, and it is usually considered that $Fe^{III}$ removal from ferrisiderophore or from other biological complexes (transferrin carriers or storage complexes, receptor proteins, citrate, and low molecular-weight chelates) involves the formation of a ternary complex.[1] The dynamic of Fe removal from various $Fe^{III}$ complexes was studied and the formation of the ternary complex is often consistent with the kinetic data.[2–4] Nevertheless, a molecular description of the "so-called ternary" complex was never discussed to the best of our knowledge. Recently, Crumbliss et al. described the formation of a ternary complex in a redox mechanism for iron release from a siderophore.[5]

Using tripodal ligands as tools and starting from the hypothesis of a step-by-step ("arm-by-arm") exchange, we investigated the kinetics of the iron removal from the ferric complexes of the tripodal tris(hydroxyquinoline) ligands O-TRENSOX ($\mathbf{L^0}$),[6] and $\mathbf{L'^0}$,[7] where $\mathbf{L^0}$ is anchored to a tertiary amine and $\mathbf{L'^0}$ to a tertiary carbon (Figure 1), and a tris(catechol) analogue built from a tertiary amine[8] TRENCAMS ($\mathbf{L^3}$). Two hexadentate heterotripodal ligands were also examined, TRENSOX2CAMS ($\mathbf{L^1}$) with two hydroxyquinoline units and one catechol[9] unit and TRENSOXCAMS2 ($\mathbf{L^2}$) with two catechol moieties and one hydroxyquinoline[9] building block (Figure 1). Our aim was to gain insight into the step-by-step ligand exchange processes via kinetic intermediates called "ternary complexes". In addition, kinetic experiments on the iron removal from EDTA by these tripodal ligands were carried out. All the collected results allow the analysis of the influence of the structure of the ligand and of the nature of the chelating groups on the kinetic parameters.

## Results

We monitored the iron exchange reactions between two ligands using different competing ligand concentrations in pseudo first-order conditions. The global reaction of a ligand-exchange type is expressed by Equation (1) (charges omitted for clarity).

$$FeL + L' \rightarrow FeL' + L \quad (1)$$

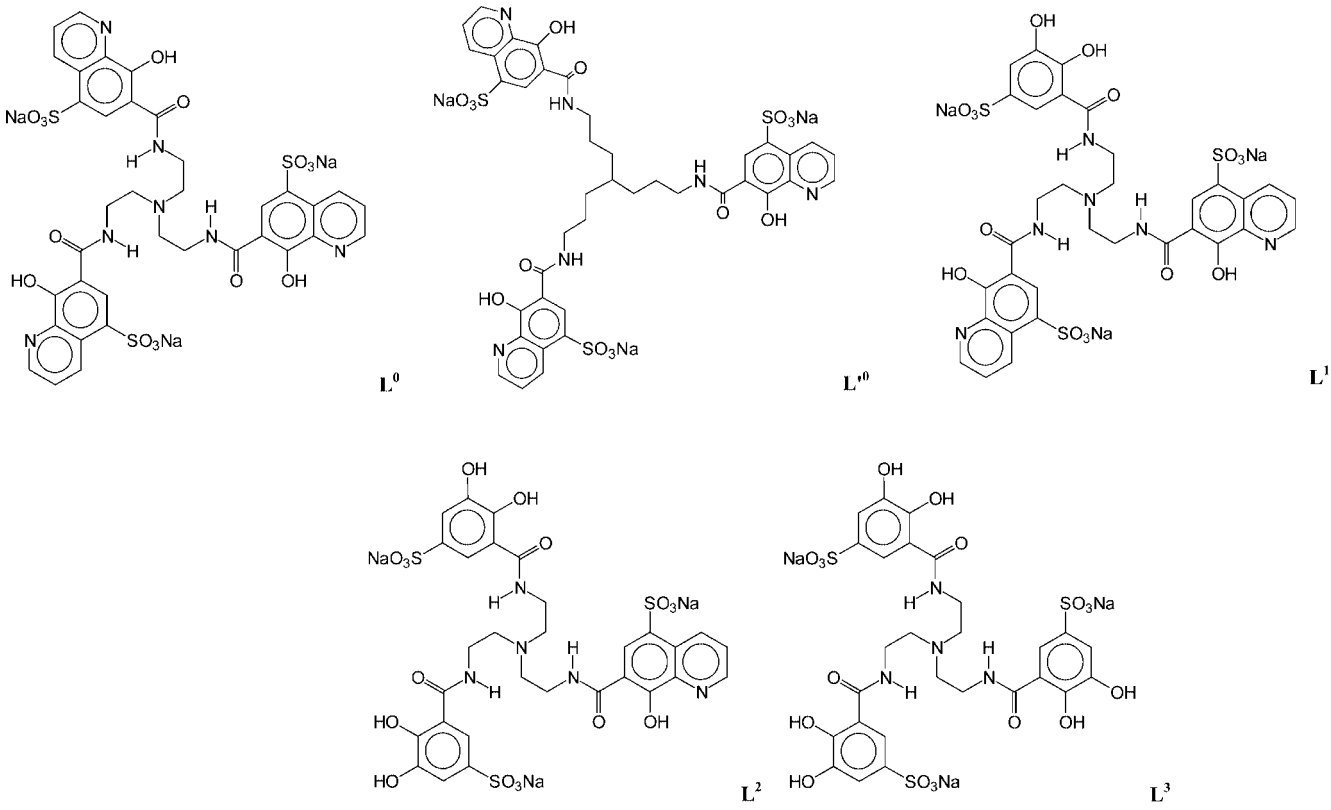

Figure 1. Chemical formulae of tripodal ligands $\mathbf{L}^n$ ($n$ refers to the number of catechol groups in the tripodal ligand).

Three FeL complexes were studied: Fe-EDTA, Fe$\mathbf{L}^0$, and Fe$\mathbf{L}^3$; L′ was $\mathbf{L}^0$, $\mathbf{L}'^0$, $\mathbf{L}^1$, $\mathbf{L}^2$, and/or $\mathbf{L}^3$. In particular, this series of exchanges allows the study of the kinetics of adding a catechol or an 8-hydroxyquinoline arm into the iron coordination sphere and the effect of the structure of the tripodal ligand (i.e. homopodal or heteropodal, anchor group). During the exchange reaction, monoexponential growth of absorbance was observed in all cases at the selected wavelength of the FeL′ complex, indicating that the reaction proceeds via a single rate-limiting step. No variation in the amplitude of the absorbance was observed during the mixing time for all the studied systems, indicating that a fast step, involving a change in the coordination sphere around $Fe^{III}$ does not occur before the first detectable step. The UV/Vis spectra were recorded as a function of the time and at the end of the kinetics. The structure of the final complex was supported by its absorption spectrum on the basis of our previous studies, particularly for the mixed coordination around $Fe^{III}$[9] related to one catechol and two 8-hydroxyquinoline groups as in Fe$\mathbf{L}^1$ or two catechol and one 8-hydroxyquinoline groups as in Fe$\mathbf{L}^2$ (see the $\lambda_{max}$ and $\varepsilon$ values in the Experimental Section).

### Iron Exchange from Fe-EDTA

The reaction was monitored with $\mathbf{L}^0$, $\mathbf{L}'^0$, $\mathbf{L}^1$, $\mathbf{L}^2$, and $\mathbf{L}^3$. The reaction was found to be complete and to occur in one distinguishable step. A linear dependence of the observed pseudo first-order rate constant $k^{obs}$ on [L′] with negligible intercept was observed [Equation (2)]. The values of $k_1$ are collected in Table 1.

$$k^{obs} = k_1 [L']_{tot} \quad (2)$$

Table 1. Kinetic data ($k_1$ values in $M^{-1}s^{-1}$) for the first step of the iron exchange reaction between FeL and L′.[a]

| Competing | Ferric complex | | |
|---|---|---|---|
| ligand | [Fe-EDTA]$^-$ | [Fe$\mathbf{L}^0$]$^{3-}$ | [Fe$\mathbf{L}^3$]$^{6-}$ |
| $\mathbf{L}^0$ | 4.0 ± 0.5 | – | 1.9 ± 0.1 |
| $\mathbf{L}^1$ | 14.2 ± 1.5 | 23 ± 1 | 5.5 ± 0.8 |
| $\mathbf{L}^2$ | 97 ± 2 | 77 ± 4 | 1.1 ± 0.15 |
| $\mathbf{L}^3$ | 145 ± 3 | 81 ± 4[b] | – |
| $\mathbf{L}'^0$ | 5.1 ± 0.4 | – | – |

[a] In aqueous 50 mM MOPS buffer, pH = 7.4, $I$ = 0.1 M ($NaClO_4$) and at temperature $T$ = 25.0 °C. [b] Intercept = $(6.6 \pm 0.6) \times 10^{-2}$ $s^{-1}$.

### Iron Exchange from Fe-O-TRENSOX

The reaction was monitored with $\mathbf{L}^1$, $\mathbf{L}^2$, and $\mathbf{L}^3$ and was found to proceed in one distinguishable step. The UV/Vis spectra recorded as the reaction proceeded exhibited isosbestic points indicating that no intermediary species were formed during the reaction. For Fe$\mathbf{L}^0$ + $\mathbf{L}^3$, the reaction was complete (see Figure S1 in the Supporting Information). For Fe$\mathbf{L}^0$/$\mathbf{L}^1$, the spectrum recorded at the equilibrium was found to be similar to that of the Fe$\mathbf{L}^1$ complex,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

indicating the substitution of an 8-hydroxyquinoline group by a catechol group. However, the substitution by the two 8-hydroxyquinoline groups of $\mathbf{L^1}$ does not change the spectrum and cannot be detected. For Fe$\mathbf{L^0/L^2}$ the spectrum recorded at the end of the first step is similar to the spectrum of the Fe$\mathbf{L^2}$ complex, indicating the substitution of two 8-hydroxyquinoline groups by two catechol groups. Figure 2 shows the UV/Vis spectra recorded as the reaction proceeds.

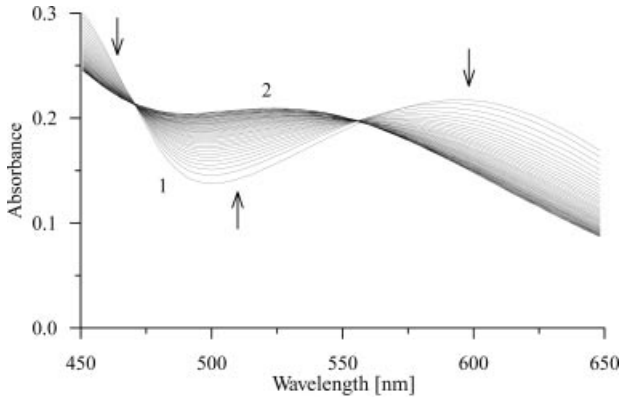

Figure 2. UV/Vis spectra recorded as a function of time for the exchange Fe$\mathbf{L^0/L^2}$; experimental conditions: [Fe$\mathbf{L^0}$] = 0.04 mM, [$\mathbf{L^2}$] = 0.4 mM, pH = 7.4 (50 mM MOPS buffer), $I$ = 0.1 M ($NaClO_4$), $T$ = 25 °C. (1) $t$ = 0 s, (2) 260 s; the arrows indicate the direction of change as the reaction proceeds.

The plots of $k^{obs}$ versus the ligand concentration show a linear dependence with a negligible intercept except for Fe$\mathbf{L^0/L^2}$. The values of $k_1$ are reported in Table 1.

### Iron Exchange from TRENCAMS

The spectrum recorded at the end of the reaction of Fe$\mathbf{L^3}$ with $\mathbf{L^1}$ or $\mathbf{L^2}$ is similar to the spectrum of the $\mathbf{FeL^2}$ complex, indicating the substitution of a catechol group by an 8-hydroxyquinoline group (see Figure S1 in the Supporting Information). The reaction was found to proceed in one detectable step. The plot of $k^{obs}$ versus the ligand concentration shows a linear dependence with negligible intercept. The values of $k_1$ are reported in Table 1.

For the reaction of Fe$\mathbf{L^3}$ with $\mathbf{L^0}$, two steps were observed as deduced from the two-exponential growth of absorbance measured at 600 nm. The spectrum recorded at the end of the first step is similar to the spectrum of the Fe$\mathbf{L^2}$ complex, indicating the substitution of a catechol group by an 8-hydroxyquinoline group (species noted $\mathbf{L^0}$Fe$\mathbf{L^3}$), and the spectrum recorded at the equilibrium after the second step is similar to the spectrum of the Fe$\mathbf{L^1}$ complex, which indicates that the substitution of a second catechol group by an 8-hydroxyquinoline group (species noted $\mathbf{L^0}$Fe$\mathbf{L^3}$*). The plot of $k_1^{obs}$ (first step) versus the ligand concentration shows a linear dependence with a nonzero intercept while $k_2^{obs}$ was found to be independent of the ligand concentration. This is consistent with the reactions according to Equations (3) and (4) and the rate law according to Equation (5) by considering the two reactions occur independently since $k_1^{obs} >> k_2^{obs}$.

$$\mathrm{Fe}\mathbf{L^3} + \mathbf{L^0} \rightleftharpoons \mathbf{L^0}\mathrm{Fe}\mathbf{L^3}\ k_1, k_{-1} \quad (3)$$

$$\mathbf{L^0}\mathrm{Fe}\mathbf{L^3} \rightarrow \mathbf{L^0}\mathrm{Fe}\mathbf{L^3}^*\ k_2 \quad (4)$$

$$k_1^{obs} = k_1[L^0] + k_{-1} \quad (5)$$

Thus, the values $k_1 = 1.9 \pm 0.1\ M^{-1}s^{-1}$, $k_{-1} = (2.1 \pm 0.2) \times 10^{-4}\ s^{-1}$, and $k_2 = (2.3 \pm 0.3) \times 10^{-5}\ s^{-1}$ were obtained.

## Discussion

The general feature resulting from the kinetic studies is that the iron exchange reactions proceed in one detectable step except for the exchange Fe$\mathbf{L^3/L^0}$ (two detectable steps). Hence, the formation of an intermediate ternary complex was only shown for this last case. In a previous investigation on the acid dissociation kinetics of the $Fe^{III}$ complexes with these tripodal ligands, we observed a very fast dissociation of one arm of the ligand which is maintained in proximity to the first coordination sphere of $Fe^{III}$.[10] This indicates that the complex has one labile arm thus favoring the formation of the precursor complex and then the substitution by one arm of the competing ligand. So, it is reasonable to propose that the kinetic rate constant $k_1$ represents the substitution rate of one arm of the initial complex by one arm of the competing ligand. In addition, this study clearly reveals the effect of the nature of the entering group, catechol or an 8-hydroxyquinoline group, on the ligand substitution rate constants.

### Iron Exchange with Homotopic Ligands $\mathbf{L^0}$, $\mathbf{L'^0}$, and $\mathbf{L^3}$

For the iron exchange from the EDTA complex, the final spectrum indicates that the reaction is complete. The same result is obtained with the heterotopic ligands. It is proposed that when the first arm of the incoming ligand is attached, EDTA dissociates rapidly and next two arms quickly coordinate to $Fe^{III}$ via catechol or the 8-hydroxyquinoline groups. The values of $k_1$ shows that the substitution rate of the catechol group ($145\ M^{-1}s^{-1}$) is about one order of magnitude faster than that of the 8-hydroxyquinoline (4.0 and $5.1\ M^{-1}s^{-1}$). Similar values for $k_1$ were obtained for the iron exchanges between Fe$\mathbf{L^0}$ and $\mathbf{L^3}$ ($81\ M^{-1}s^{-1}$) or between Fe$\mathbf{L^3}$ and $\mathbf{L^0}$ ($1.9\ M^{-1}s^{-1}$ for the first step).

### Iron Exchange with Heterotopic Ligands $\mathbf{L^1}$ and $\mathbf{L^2}$

For the exchanges Fe$\mathbf{L^0/L^1}$ and Fe$\mathbf{L^0/L^2}$, the nature of the entering group was clearly identified as a catechol group on the basis of the spectrum change. In a previous paper,[9] we determined the UV/Vis parameters for the ferric complexes with a mixed catechol/8-hydroxyquinoline coordina-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion sphere. In addition, the values of $k_1$ (23 and 77 $M^{-1}s^{-1}$ for Fe**L**$^0$/**L**$^1$ and Fe**L**$^0$/**L**$^2$, respectively) are of the same order of magnitude as those for the exchanges Fe**L**$^0$/**L**$^3$ (81 $M^{-1}s^{-1}$) and Fe-EDTA/**L**$^3$ (145 $M^{-1}s^{-1}$), which correspond to the substitution by a catechol arm. For the exchanges Fe**L**$^3$/**L**$^1$ and Fe**L**$^3$/**L**$^2$, the entering group was identified as an 8-hydroxyquinoline unit according to the spectral change. The values of $k_1$ (5.5 and 1.1 $M^{-1}s^{-1}$ for Fe**L**$^3$/**L**$^1$ and Fe**L**$^3$/**L**$^2$, respectively) are of the same order of magnitude as those for the exchanges Fe**L**$^3$/**L**$^0$ (1.9 $M^{-1}s^{-1}$), Fe-EDTA/**L**$^0$ (4.0 $M^{-1}s^{-1}$), or Fe-EDTA/**L**$'^0$ (5.1 $M^{-1}s^{-1}$), which correspond to the substitution by an 8-hydroxyquinoline arm. All these results indicate that the substitution rate is mainly controlled by the nature of the entering group. Accordingly, the iron exchange rates from Fe-EDTA with **L**$^1$ and **L**$^2$, 14.2 and 97 $M^{-1}s^{-1}$, respectively, can be attributed to the substitution by the catechol arm. Table 2 summarizes the values of $k_1$ for the three series of iron exchange collected according to the nature of the chelating group that enters in the iron coordination sphere.

The fact that close $k_1$ values are obtained for one type of entering group (catechol or 8-hydroxyquinoline) in the different exchange systems suggests that the step is the substitution of one arm of the initial complex by one arm of the competing ligand, leading to the formation of an intermediate ternary complex before the substitution of the two other arms. The higher substitution rate measured for the catechol group can be attributed to its greater electron donor ability and to its lower bulkiness relative to the 8-hydroxyquinoline group. This might be also attributed to the charge of the incoming chelating group that depends on the protonation state of the ortho hydroxy groups. Indeed, a negative deprotonated hydroxy is assumed to be more reactive than the protonated one. For the catechol groups in **L**$^1$, **L**$^2$, and **L**$^3$ the lower p$K_a$ is 5.62,[9] 5.55,[9] and 5.57,[8] respectively, indicating that the hydroxy group of one arm is deprotonated at pH 7.4, whereas for the 8-hydroxyquinoline groups the lower p$K_a$ is 7.44[6] for **L**$^0$ and 6.68[7] for **L**$'^0$. For the sake of comparison, the numbers of deprotonated OH groups in the catechol and 8-hydroxyquinoline moieties are reported in Table 2. Analysis of the data shows that $k_1$ cannot be directly related to the protonation state of the OH group. It is thus suggested that the negative charge of the incoming group is not a decisive factor for the rate constant.

It should be pointed out that the substitution rate by the catechol group is decreasing as the number of 8-hydroxyquinoline groups increases (or inversely as the number of catechol groups decreases) in the competing ligand: 81, 77, or 23 $M^{-1}s^{-1}$ for Fe**L**$^0$/**L**$^3$, **L**$^2$, or **L**$^1$, respectively, and 145, 97, or 14.2 $M^{-1}s^{-1}$ for Fe-EDTA/**L**$^3$, **L**$^2$, or **L**$^1$, respectively. In contrast, the same trend is not observed for the substitution rate by the 8-hydroxyquinoline group (substitution of Fe**L**$^3$ by **L**$^0$, **L**$^1$, or **L**$^2$; 1.9, 5.5, or 1.1 $M^{-1}s^{-1}$, respectively). This indicates that steric factors rather than statistical factors occur: the 8-hydroxyquinoline group is assumed to slow down the entering of the tripodal ligand in the iron coordination sphere.

Our results suggest that iron exchange occurs step-by-step, each arm of the incoming tripodal ligand substitutes successively the leaving ligand as the coordination bonds are broken. This is clearly evidenced for the iron exchange between Fe**L**$^3$ and **L**$^0$ since the formation of an intermediate ternary complex having a mixed coordination 8-hydroxyquinolinate/catecholate could be identified from the UV/Vis spectra as previously published.[9] A probable mechanism is depicted in Figure 3. The same process is assumed to occur for the exchange between Fe**L**$^0$ and **L**$^3$, but the coordination of the second and the third catechol groups is fast relative to the first one. This can be inferred by the labilizing effect of strong electron pair donors as catechol ligands, which increases the electron density of the metal, weakening the bonds with the coordinated donor atoms. Replacement of a coordinated group by a catechol group in the first coordination shell enhances the ligand exchange of the remaining arms. In contrast, in the case of the reaction between Fe**L**$^3$ and **L**$^0$, the substitution of the second arm of the tripodal ligand is very slow ($k_2$ = 2.3 $10^{-5}$ $s^{-1}$). It is suggested that the substitution of catechol groups by poorer electron pair donors as 8-hydroxyquinoline groups diminishes the electron density at the iron center, slowing down the exchange of the remaining coordinating arms. In addition, this effect is enhanced by the steric effect of the incoming 8-hydroxyquinoline group. The sensitivity of the rate constant to the nature of the bidentate group of the incoming ligand indicates a rather associative character of the mechanism for

Table 2. Kinetic data ($k_1$ values in $M^{-1}s^{-1}$) for the first step of the iron exchange reaction between FeL and L′[a]collected according to the entering group.

| Competing ligand | Catechol as an entering group | | | 8-Hydroxyquinoline as an entering group | | |
|---|---|---|---|---|---|---|
| | [Fe**L**$^0$]$^{6-}$ | [Fe-EDTA]$^-$ | Number of OH deprotonated[b] | [Fe**L**$^3$]$^{6-}$ | [Fe-EDTA]$^-$ | Number of OH deprotonated[b] |
| **L**$^0$ | | | | 1.9 | 4.0 | 0.5 |
| **L**$^1$ | 23 | 14.2 | 1 | 5.5 | | 0 |

these series of iron exchange. In summary, the exchange rate constants of the first step depend on the nature of the entering arm (catechol or 8-hydroxyquinoline) and on the nature of second and third arm of the incoming tripodal ligand (homotripodal or heterotripodal; Figure 3).

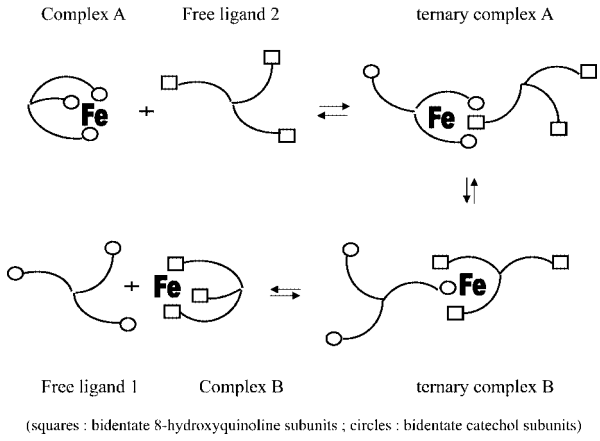

Figure 3. Successive steps for the ligand exchange at the iron center via ternary complexes.

## Conclusions

The main result of this study is the pertinence of the Fe**L**$^{1}$ and Fe**L**$^{2}$ complexes as models for the transient and successive ternary complexes occurring in the iron exchange processes between Fe**L**$^{0}$ and **L**$^{3}$ and between Fe**L**$^{3}$ and **L**$^{0}$. The results allow the first molecular description of the ternary complex formed during the iron exchange between two abiotic siderophores. Generally, ligand exchanges are slow, but they are facilitated by the formation of the so-called ternary ferric complexes with the two ligands bound to Fe$^{III}$. Our study supports this concept.

## Experimental Section

**Materials:** All commercial reagents were of the highest purity grade and used without further purification. Iron(III) stock solutions were prepared by dissolving the appropriate amount of ferric perchlorate hydrate (Aldrich) in standardized $HClO_4$ solution. The solutions were standardized for ferric ion concentration spectrophotomerically by using a molar extinction coefficient of 4160 $M^{-1}\,cm^{-1}$ at 240 nm.[11] The ligands were synthesized according to procedures previously described (**L**$^{0}$,[6] **L′**$^{0}$,[12] **L**$^{1}$,[9] **L**$^{2}$,[9] and **L**$^{3}$[8]).

**Kinetics Studies:** Iron(III) exchange kinetics between Fe**L**$^{0}$ and **L**$^{1}$, **L**$^{2}$, or **L**$^{3}$, between Fe**L**$^{3}$ and **L**$^{0}$, **L**$^{1}$, or **L**$^{2}$, and between Fe-EDTA and **L**$^{0}$, **L**$^{1}$, **L**$^{2}$, **L**$^{3}$, or **L**$^{4}$ were studied in aqueous 50 mM MOPS buffer, pH = 7.4, $I$ = 0.1 M ($NaClO_4$), and at temperature $T$ = (25.0 ± 0.2) °C. The kinetics were studied under pseudo first order conditions by using a large excess of the entering ligand over the complex. Initial concentration of the FeL complex was $2.0\times10^{-5}$ mol $L^{-1}$, initial concentration of ligand L′ was varied in a range from $2\times10^{-4}$ to $1.2\times10^{-3}$ mol $L^{-1}$. Fast kinetic measurements were performed with a KINSPEC UV (BIO-LOGIC Company, Claix, France) stopped-flow spectrophotometer equipped with a diode array detector (J & M) and connected to a microcomputer; slow kinetic measurements were performed with a Perkin–Elmer Lambda2 or Varian Cary 50 UV/Vis spectrophotometer. The kinetic data were treated on line with the commercial BIO-KINE program (BIO-LOGIC Company, Claix, France). In each run, equal volumes of solutions of the complex and of the ligand were mixed. The absorbance changes with time were recorded at the maximum of the charge-transfer band of the complex that is formed, specifically, $\lambda_{max}$ = 490, 525, and 550 nm for Fe**L**$^{3}$,[8] Fe**L**$^{2}$,[9] and Fe**L**$^{1}$,[9] respectively, and 595 nm for Fe**L**$^{0}$[6] and Fe**L′**$^{0}$.[7] Some visible spectra from 400 to 650 nm were recorded in time by using a diode array detector.

**Supporting Information** (see footnote on the first page of this article)**:** Figures S1 and S2: UV/Vis spectra recorded as a function of time for the exchanges Fe**L**$^{0}$/**L**$^{3}$ and Fe**L**$^{3}$/**L**$^{2}$. Tables S1 to S8: rate constants values for the different exchanges FeL/L′.

# Synthesis and Characterization of $Cu^{II}$ Complexes with Amino Acid Substituted Di(2-pyridyl)amine Ligands

**Srećko I. Kirin,[a] Hemant P. Yennawar,[a] and Mary Elizabeth Williams*[a]**

**Keywords:** Bioconjugates / Bioinorganic chemistry / Copper complexes / Di(2-pyridyl)amine

The two-step syntheses of the substituted di(2-pyridyl)-amine ligands (dpa), dpa-$CH_2CO_2H$ (**1**) and dpa-$PhCO_2H$ (**2**), are described. Ligands **1** and **2** are successfully coupled to the amino acid phenylalanine, yielding the derivatives **4** and **6**, respectively. Four $Cu^{II}(dpa)_2$ complexes, [Cu(dpa-$CH_2CO_2tBu)_2(NO_3)_2$] (**$3_{Cu}$**), [Cu(dpa-$CH_2CO$-$PheOMe)_2$-$(H_2O)_2](NO_3)_2$·2MeOH (**$4_{Cu}$**), [Cu(dpa-$PhCO_2Me)_2$ $(MeOH)_2$]-$(ClO_4)_2$ (**$5_{Cu}$**) and [Cu(dpa-PhCO-$PheOMe)_2(ClO_4)_2$] (**$6_{Cu}$**) have been prepared and characterized, including their single crystal X-ray structures. Fluorescence emission at UV (for **3** and **4**) or blue (for **5** and **6**) wavelengths of the free ligands is preserved in the corresponding Cu complexes, although with lower intensity. X-band EPR spectra of **$4_{Cu}$** and **$6_{Cu}$** both revealed one axial $Cu^{II}$ signal with hyperfine and superhyperfine splittings. Complexes **$4_{Cu}$** and **$6_{Cu}$** are chiral inorganic complexes with amino acid bioconjugates that may serve as nucleoside analogs in modified peptide nucleic acids (PNA).

## Introduction

Inorganic nucleic acid derivatives and structural mimics have received increased attention in recent years[1] in view of their potential applications in biological and material sciences. Electrostatic attraction has been used to coat the exterior of nucleic acids with metals,[1a] and metal complexes have been inserted into double-stranded DNA (dsDNA) duplexes by intercalation and threading.[2] In contrast, metal ions have been incorporated *inside* the core of the nucleic acid duplex by replacing hydrogen bonds with metals that covalently link the nucleobases. Inclusion of metals in this manner changes the properties of the dsDNA duplex. For example, Lee et al. abstracted protons from the nucleobases of a DNA duplex at high pH, and replaced some of these H atoms with Zn cations.[3] The resulting duplex had improved electrical conductivity that was attributed to the metal-linked base pairs. Analogously, two thymine nucleobases have been shown to form a neutral complex upon complexation of a $Hg^{II}$ ion.[4] Using this coordination chemistry, dsDNA duplex formation by metal coordination of multiple $Hg^{II}$ ions along the oligonucleotide has been demonstrated. Nucleobases have also been replaced by synthetic ligands to adjust the binding affinity of metal ions. A number of common metal binding ligands and a variety of metal ions and oligomeric backbones (i.e. sugar phosphate and pseudo-peptide) have also been reported.[5–18]

Di(2-pyridyl)amine (dpa) is a well-known ligand for a range of transition metals, and structural studies on these complexes have been reported.[19] Metal dpa complexes have been used as homogeneous or heterogeneous catalysts in a number of chemical transformations including hydrolytic or oxidative DNA cleavage,[20] hydrolytic cleavage of amino acid esters,[21] oxidation of alcohols,[22] ring-opening metathesis polymerization,[23] Heck reactions,[24] and various asymmetric reactions.[25] Dpa based luminescence has been utilized for the development of new materials.[26] Given these properties of metal dpa complexes, development of methods for incorporation of the ligand into synthetically modified nucleic acids, nucleobases analogs, or bioconjugates will lead to broad applications in bioinorganic systems.

We have recently described heterocyclic ligand-containing aminoethyl glycine (aeg) oligomers,[5b,14] chains that are charge-neutral mimics of the sugar phosphate backbone of DNA. Our aeg oligomers crosslink by coordination of transition-metal ions and are synthetic inorganic structural analogs of dsDNA in which all hydrogen-bonded base pairs are replaced by metal coordination bonds. In previous studies, the aeg backbone has been successfully substituted with the acetic acid derivatives of the py,[5b,14a–5e] bpy,[14a,14c,14e] tpy,[14e] phtpy[14g] or hq[14f] ligands shown in Figure 1. Herein we extend this chemistry by introducing the fluorescent dpa ligands **1** and **2** and attach the ligands to an amino acid. Two of these ligands are crosslinked by coordination

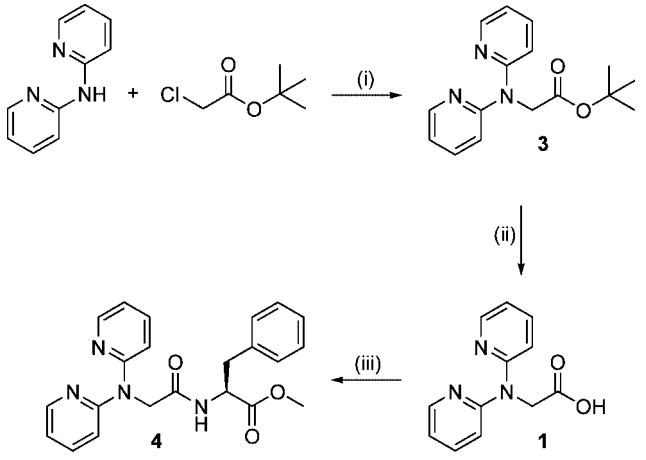
## Results and Discussion

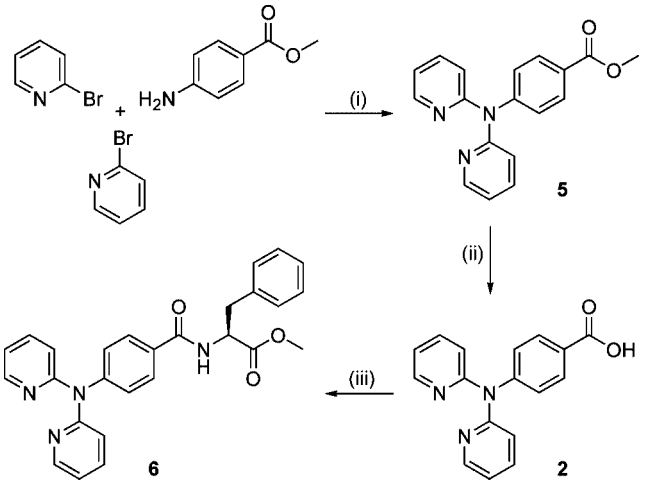
### Dpa Ligands and Amino Acid Conjugates

In contrast to the other ligands shown in Figure 1, dpa has not yet been used extensively in the synthesis of nucleoside analogs or bioconjugates. This is likely due to the difficult derivatization of the central amine atom. In the literature two different routes are frequently used for the synthesis of the aromatic amines like **1** and **2**: the Pd-catalyzed Buchwald–Hartwig amination[28,29] and the Ullmann condensation,[30,31] often catalyzed by $Cu^{II}$ salts. The Buchwald–Hartwig amination is strongly affected by electron-withdrawing substituents [like the *p*-methoxycarbonyl group in Scheme 2, reaction (i)],[32] while the Ullmann condensation needs aggressive conditions (high temperatures and extended reaction times), to produce only moderate yields.[30]

The Ullmann condensation was used to prepare key intermediates **3** and **5** according to Scheme 1 and Scheme 2, respectively. The ester **3** was synthesized by substitution of the commercially available dpa with *tert*-butyl bromoacetate in DMSO with KOH and catalytic KI to give the purified ester **3** in 47% yield. Deprotection of the ester proceeded smoothly to give the free acid **1** (91% yield). The synthesis of ester **5** included the construction of the dpa framework by condensation of *p*-aminobenzoic acid with two equivalents of 2-bromopyridine, $K_2CO_3$, and co-catalysts KI, $Cu(SO_4)_2$ and phenanthroline, to give the pure compound in 52% yield. Ester **5** was deprotected in standard conditions to yield the free acid **2** (89%).



Scheme 1. Synthesis of the aliphatic side chain dpa derivatives **1**, **3** and **4**: (i) KOH, KI (cat.), DMSO/2 h, room temp. (47%); (ii) TFA, TIS, DCM/10 h, room temp. (91%); (iii) HBTU, HOBt, H-Phe-OMe·HCl, DIPEA/20 h, 0 °C→room temp. (51%).



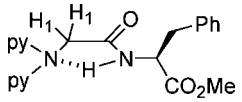
Scheme 2. Synthesis of the aromatic side chain dpa derivatives **2**, **5** and **6**: (i) $K_2CO_3$, KI (cat.), $Cu(SO_4)_2{\cdot}5H_2O$ (cat.) phen (cat.), neat/7 h, 200 °C (52%); (ii) 1 M NaOH/16 h, room temp. (89%); (iii) HBTU, HOBt, H-Phe-OMe·HCl, DIPEA/20 h, 0 °C→room temp. (56%).

The ability of the ligands **1** and **2** to react in amide condensations was tested by reaction with the primary amine group of acid-protected phenylalanine according to Scheme 1 and Scheme 2. The corresponding products **4** and **6** were obtained, strongly indicating the viability of **1** and **2**, respectively, for the construction of dpa-substituted aeg oligomers.

Interestingly, the $^1H$ NMR ($CDCl_3$) spectra of the phenylalanine conjugates **4** and **6** contain different features. The amide proton in **6** is found below 7 ppm, as expected for an amide proton not involved in H-bonding. In contrast the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

amide proton in **4** is shifted above 7 ppm, which is indicative of H-bonding that likely is a result of the formation of the cyclic conformation of **4** in Figure 2. A hydrogen bond between the amide proton and the central dpa nitrogen atom causes the formation of a five-membered ring. This cyclic conformation is not possible for the rigid conjugate **6**.

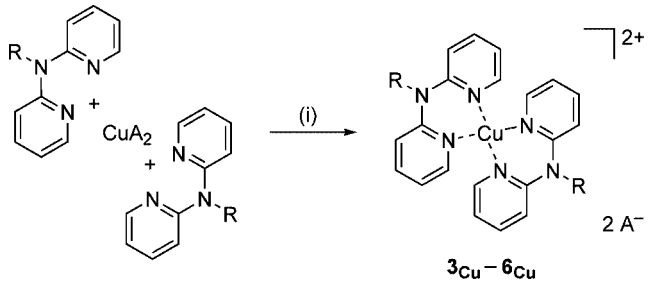


**4**

Figure 2. The cyclic conformation of dpa - amino acid conjugate **4** in $CDCl_3$ solution.

## Dpa Metal Complexes

The complexes $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$ have been obtained in moderate to good yields (50–75%) by mixing methanolic solutions of ligands **3** or **4** with $Cu^{II}$ nitrate and ligands **5** or **6** with $Cu^{II}$ perchlorate as shown in Scheme 3. Time of flight positive ion electrospray (TOF-ES+) mass spectra of $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$ contain the molecular ion peaks for the $[CuL_2]^+$ complex, where L is the corresponding ligand **3**–**6**.



$\mathbf{3_{Cu}}$ – $\mathbf{6_{Cu}}$

$\mathbf{3_{Cu}}$, R = -$CH_2CO_2t$Bu, A = $NO_3^-$
$\mathbf{4_{Cu}}$, R = -$CH_2$CO-PheOMe, A = $NO_3^-$
$\mathbf{5_{Cu}}$, R = -*p*-$C_6H_4CO_2$Me, A = $ClO_4^-$
$\mathbf{6_{Cu}}$, R = -*p*-$C_6H_4$CO-PheOMe, A = $ClO_4^-$

Scheme 3. Synthesis of the $[Cu(dpa)_2]$ complexes $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$: (i) MeOH, Δ (50–75%).

Optical absorbance and emission spectroscopy were also used to characterize the Cu complexes. The UV/Vis absorbance and fluorescence spectroscopic data of complexes $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$ are compared to those of the free ligands **3**–**6** in Table 1. Absorption spectra of the ligands and the Cu complexes contain characteristic peaks at high energy that are due to the π–π* transition of the aryl groups ($\lambda < 320$ nm). Additional peaks in the spectra of $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$ are found at 375–390 nm and above 600 nm. Both the ligands and the metal complexes are emissive; the UV (for **3** and **4**) or blue (for **5** and **6**) fluorescent emission of the free ligands is attributed to π*–π relaxation in the dpa ligand.[32] The red shift of the emission bands in the aromatic side chain ligands **5** and **6** is a result of the conjugation with the adjacent phenyl ring. In contrast, the emission bands are preserved in the Cu complexes, but are weaker in intensity than in the corresponding free ligands, as has been reported for other $[Cu(dpa)_2]^{2+}$ complexes.[33]

Table 1. Compilation of spectroscopic data.

| | $\lambda_{max}$/nm[a] | | |
|---|---|---|---|
| | $\lambda_{abs}$ | $\lambda_{ex}$ | $\lambda_{em}$ |
| **3** | 228, 306 | 296 | 360 |
| **4** | 228, 303[b] | 278 | 304 |
| **5** | 223, 311 | 324 | 432 |
| **6** | 225,[b] 311 | 318 | 414 |
| $\mathbf{3_{Cu}}$ | 296, 379,[c] 621[c] | 280 | 305 |
| $\mathbf{4_{Cu}}$ | 296, 376,[c] 594[c] | 279 | 304 |
| $\mathbf{5_{Cu}}$ | 315, 390,[c,b] 679[c,d] | 324 | 434 |
| $\mathbf{6_{Cu}}$ | 309, 391,[c] 678[c,d] | 317 | 415 |

[a] The maxima ($\lambda_{max}$) of absorption ($\lambda_{abs}$), excitation ($\lambda_{ex}$) and emission ($\lambda_{em}$) were measured in methanol. [b] Shoulder. [c] These signals were measured in methanol/water = 1:1 solvent mixture due to low solubility in methanol. [d] very broad peak.

X-band EPR spectra of $\mathbf{4_{Cu}}$ and $\mathbf{6_{Cu}}$ (0.5 mM in frozen solution of a 1:1 water/methanol mixture) both show a well-resolved axial $Cu^{II}$ signal with large separation of $g_{\|}$ and $g_{\perp}$ (Figures S9 and S10 and quantitative details in the supporting information; for supporting information see also the footnote on the first page of this paper). This observation is expected for a compound containing electronically identical $Cu^{II}$ atoms separated by a distance of at least 6 Å[14a,34a] and is consistent with the geometry found by X-ray crystallography, see below. In addition, the EPR spectra show hyperfine splitting due to coupling of the unpaired electron with the copper nucleus ($I$ = 3/2 for $^{63}$Cu and $^{65}$Cu) and superhyperfine splitting due to coupling with the directly coordinated nitrogen nuclei ($I$ = 1 for $^{14}$N and $I$ = 1/2 $^{15}$N).[34b,34c]

## X-ray Crystallography

Single crystals suitable for X-ray analysis could be obtained for all four complexes in this study. Precipitation from a methanol solution was successful for $\mathbf{5_{Cu}}$, diffusion of diethyl ether in the methanol solution of the complex was used for $\mathbf{3_{Cu}}$, while slow evaporation from methanol solution was applied for $\mathbf{4_{Cu}}$ and $\mathbf{6_{Cu}}$.[35] Single crystals of the complexes were grown directly from the reaction mix-

[a] See Figure 7 for explanation.

The crystal structures of $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$ share a number of common features that for clarity are described using $\mathbf{3_{Cu}}$ as the example (Figure 3). The structure unambiguously confirms

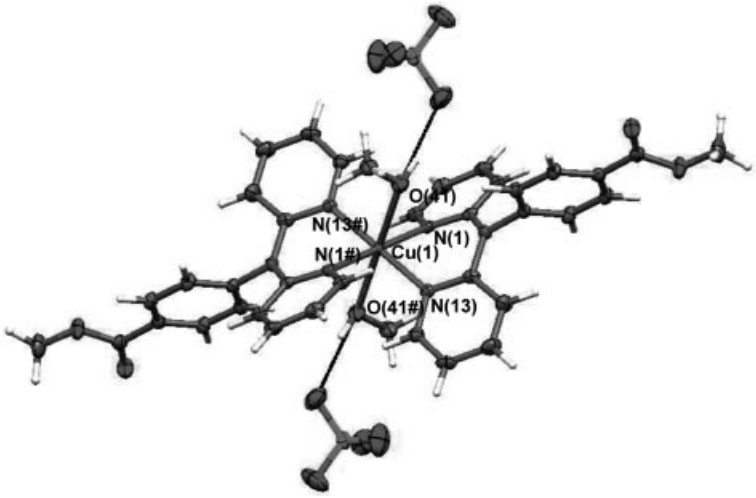

Figure 5. X-ray single crystal structure of $\mathbf{5_{Cu}}$ (thermal ellipsoids at 50% probability).

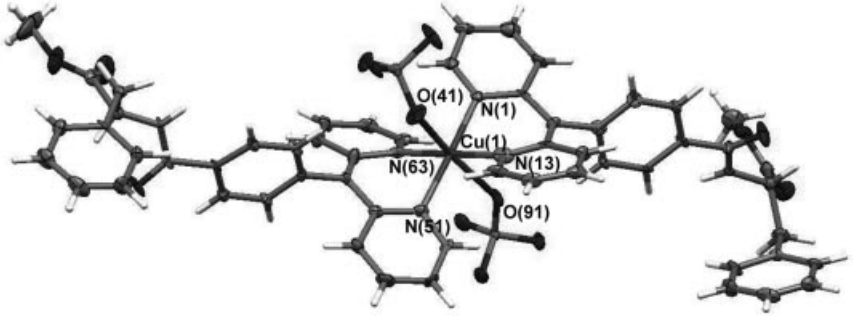

Figure 6. X-ray single crystal structure of $\mathbf{6_{Cu}}$ (thermal ellipsoids at 50% probability).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the [Cu(dpa)$_2$] stoichiometry as well as the bidentate nature of the dpa ligand, in which only the py nitrogen atoms coordinate to the Cu and the central dpa amine atom is not involved in metal chelation. The $N_4O_2$ coordination polyhedron is Jahn–Teller distorted square pyramidal. Four N atoms from the two dpa ligands coordinate to the Cu in the equatorial plane, *d*(Cu–N) = 1.99 and 2.01 Å, while nitrate counterions occupy the apical positions, *d*(Cu–O) = 2.47 Å. The bite angle of the dpa ligand (85.1°) indicates that there is only minimal strain in the six-membered chelate ring. Because the counterions or solvent molecules occupy apical positions, differences exist in the structures: these are nitrates in $\mathbf{3_{Cu}}$, perchlorates in $\mathbf{6_{Cu}}$, water in $\mathbf{4_{Cu}}$, and methanol in $\mathbf{5_{Cu}}$.

Selected geometrical parameters are summarized in Figure 7. The dpa moiety in $\mathbf{3_{Cu}}$ is not planar, and the angle $\alpha$ between the py rings is found to be 43.6°. In addition the central dpa chelate ring B is not coplanar with the coordination plane C and the angle between B and C is 38.1°. The conformation of the phenyl side chain with respect to the dpa moiety defined by the $\chi$ angle, specific to $\mathbf{5_{Cu}}$ and $\mathbf{6_{Cu}}$, is shown in Figure 7.[36] In both $\mathbf{5_{Cu}}$ and $\mathbf{6_{Cu}}$ $\chi$ is rather large, >70°, resulting in a "twisted" conformation in these complexes.

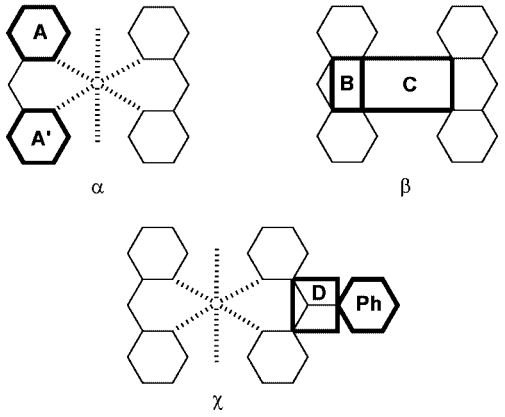

Figure 7. Selected geometrical parameters in [Cu(dpa)$_2$] complexes are defined as $\alpha$ (angle between the planes A and A′), $\beta$ (angle between B and C), and $\chi$ (angle between the planes H and Ph).

In $\mathbf{3_{Cu}}$ and $\mathbf{5_{Cu}}$ no significant intermolecular contacts are found, except the hydrogen bond between the coordinated methanol and a perchlorate counterion in $\mathbf{5_{Cu}}$. The inorganic nucleoside pair analogs $\mathbf{4_{Cu}}$ and $\mathbf{6_{Cu}}$ have more interesting intermolecular interactions. In $\mathbf{4_{Cu}}$ the amide oxygen atom of the dpa ligand coordinates to the water molecule in the apical position by hydrogen bonding. In addition, π-stacking is found between dpa ligands from neighboring molecules, which causes chains to form along the *a* crystallographic axis (Figure S11 in the electronic supporting information). Dpa π-stacking allows the Cu atoms of neighboring complexes to come as close as 8.2 Å. In $\mathbf{6_{Cu}}$, short contacts include hydrogen bonding between the coordinated perchlorate counterion of one molecule and the phenylalanine amide proton of the neighboring molecule. There is also weak π-stacking between the py substituent from one molecule with the phenyl substituent of Phe from its neighbor. These contacts cause the formation of chains along the *c* axis in the crystal of $\mathbf{6_{Cu}}$ (Figure S12 in the electronic supporting information). As a result, the Cu–Cu separation in these chains is 12.1 Å. The large separation of the copper centers in $\mathbf{4_{Cu}}$ and $\mathbf{6_{Cu}}$ is in accordance with the EPR spectra discussed above.

## Conclusions

The two new bidentate heterocyclic nitrogen ligands **3** and **5** have been prepared using the Ullmann reaction in at least 47% yield. The ester groups in **3** and **5** have been hydrolyzed in standard conditions to give the acids **1** and **2**, respectively. Ligands **1** and **2** have a carboxylic functional group that allows their use in conjugation with biological molecules. To confirm this, the bioconjugates **4** and **6** with the amino acid H-Phe-OMe have been prepared following Scheme 1 and Scheme 2.

The Cu complexes $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$ have been synthesized and fully characterized, including their X-ray single crystal structures. In addition to confirming the 1:2 metal to ligand stoichiometry, the X-ray structures reveal square bipyramidal geometries for all four complexes in this study. Both the free ligands and their corresponding Cu complexes are fluorescent.

Conjugates of metal complexes with amino acids or peptides have a number of biological applications,[37,38] including artificial catalysts or enzymes for biochemical reactions.[39] In this paper, we present complexes with an 1:2 metal/ligand stoichiometry that can serve as inorganic analogs of nucleic acids.[5b,14] Our current efforts are focused on the development of chiral inorganic nucleic acid models based on the aeg-oligoamide chemistry.

## Experimental Section

**General Remarks:** Chemicals were used without further purification except where indicated. UV/Vis absorption spectra were measured in 1-cm quartz cuvettes in a double-beam spectrophotometer (Varian Cary 500). Excitation and emission spectra were recorded with a Photon Technologies International fluorimeter. Positive-ion time of flight electrospray mass spectrometry (TOF ES+) was performed using a Mariner mass spectrometer (Perseptive Biosystems). For fragments containing copper only the isotopomer of the highest intensity was described. NMR spectra were collected with a 360-MHz spectrometer (Bruker AV 360). Chemical shifts, $\delta$/ppm, indicate a downfield shift from tetramethylsilane, TMS, the internal standard. Coupling constants, *J*, are given in Hz. X-band EPR spectra were obtained using a 9.5-GHz Bruker eleXsys 500 spectrometer equipped with a liquid helium cryostat. The experiments were performed in a frozen solution (0.5 mM in methanol/water = 1:1) at 20 K, with a modulation frequency of 100 kHz and a modulation amplitude of 5 G. The *g* factors were calculated as $g = 714.484\ \nu/B_0$, were $\nu$ is the microwave frequency in GHz and $B_0$ the magnetic field in gauss.

**Dpa-$CH_2CO_2t$Bu (3):** KOH (3.0 g, 53.6 mmol, 4.6 equiv.) was added to the solution of dpa (2.0 g, 11.7 mmol) in dimethyl sulfox-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ide (DMSO, 40 mL) and the resulting suspension was stirred overnight at room temperature. KI (200 mg, 1.2 mmol, 0.1 equiv.) and *tert*-butyl chloroacetate (4 × 0.5 mL, 14.0 mmol, 1.2 equiv.) were added. The reaction was stirred for additional 2 h and the resulting mixture was extracted with diethyl ether (3 × 50 mL). The organic extracts were dried with $Na_2SO_4$, filtered and the ether removed under reduced pressure to give a brown oil. The crude product was purified by column chromatography (silica, hexane/ethyl acetate = 8:2). Yield: 1.56 g (47%), pale yellow oil. $M_r$ (calcd. for $C_{16}H_{19}N_3O_2$) = 285.34, MS (TOF ES+): *m*/*z* = 324.5 $[M + K]^+$, 308.5 $[M + Na]^+$, 286.5 $[M + H]^+$, 230 $[M - OtBu]^+$. HR MS (TOF ES+): exp. 286.1549 and calcd. 286.1556 for $[C_{17}H_{12}N_3O_2]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.32 (ddd, $^3J_{HH}$ = 1.0, 2.0 and 5.0 Hz, 2 H, $H_{py\text{-}6}$), 7.53 (ddd, $^3J_{HH}$ = 2.0, 7.2 and 8.4 Hz, 2 H, $H_{py\text{-}4}$), 7.22 (dt, $^3J_{HH}$ = 1.0 and 8.4 Hz, 2 H, $H_{py\text{-}3}$), 6.87 (ddd, $^3J_{HH}$ = 1.0, 5.0 and 7.2 Hz, 2 H, $H_{py\text{-}5}$), 4.83 (s, 2 H, $H_1$), 1.42 (s, 9 H, $H_{OtBu}$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 175.26 (C=O), 156.75 ($C_{py\text{-}2}$), 148.24 ($C_{py\text{-}6}$), 137.14 ($C_{py\text{-}4}$), 117.24 ($C_{py\text{-}5}$), 113.87 ($C_{py\text{-}3}$), 80.93 ($C_{q\text{-}tBu}$), 50.63 ($C_1$), 28.03 ($C_{Me}$) ppm.

**Dpa-$CH_2CO_2H$ (1):** Dpa-Ac-O*t*Bu (**3**, 1.5 g, 5.26 mmol) was dissolved in a mixture of dichloromethane (DCM, 12 mL), TIS (0.6 mL) and TFA (12 mL), stirred at room temperature and the reaction monitored by TLC (silica, hexane/ethyl acetate = 8:2). After the disappearance of the starting material (10 h), the DCM was evaporated under reduced pressure and cold ether (–20 °C) was added to the residue. After 1 h at –20 °C, the precipitate was collected by filtration. Yield: 1.10 g (91%) of an off-white solid. $M_r$ (calcd. for $C_{12}H_{11}N_3O_2$) = 229.23. MS (TOF ES+): *m*/*z* = 230.1 $[M + H]^+$, 252.1 $[M + Na]^+$. HR MS (TOF ES+): exp. 230.0921 and calcd. 230.0930 for $[C_{17}H_{12}N_3O_2]^+$. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 8.30 (ddd, $^3J_{HH}$ = 0.8 and 5.0 Hz, 2 H, $H_{py\text{-}6}$), 7.72 (dq, $^3J_{HH}$ = 2.0 and 8.5 Hz, 2 H, $H_{py\text{-}4}$), 7.29 (dt, $^3J_{HH}$ = 0.8 and 8.5 Hz, 2 H, $H_{py\text{-}3}$), 7.02 (dq, $^3J_{HH}$ = 0.8 and 5.0 Hz, 2 H, $H_{py\text{-}5}$), 4.82 (s, 2 H, $H_1$) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 170.96 (C=O), 155.22 ($C_{py\text{-}2}$), 146.83 ($C_{py\text{-}6}$), 137.99 ($C_{py\text{-}4}$), 117.33 ($C_{py\text{-}5}$), 113.70 ($C_{py\text{-}3}$), 48.91 ($C_1$) ppm.

**Dpa-$CH_2$CO-PheOMe (4):** Dpa acetic acid (**1**, 229 mg, 1 mmol), was suspended in acetonitrile (30 mL) and cooled to 0 °C with an ice bath. HBTU (379 mg, 1 mmol) and diisopropylethylamine (DIPEA, 875 μL, 5 mmol) were added. After the clear solution was stirred for 1 h at 0 °C, H-Phe-OMe·HCl (216 mg, 1 mmol) was added. The reaction mixture was allowed to reach room temperature and the stirring was continued for 20 h. After that period, the reaction mixture was concentrated under reduced pressure. The residue was dissolved in DCM (50 mL), washed with sodium hydrogen carbonate (satd. aq., 3 × 50 mL) and the organic extract was dried with sodium sulfate, filtered and evaporated under reduced pressure. The crude product was subjected to column chromatography (silica, hexane/ethyl acetate = 2:8) to yield a colorless oil (200 mg, 51%). $M_r$ (calcd. for $C_{22}H_{22}N_4O_3$) = 390.44, MS (TOF ES+): *m*/*z* = 391.2 $[M + H]^+$, 413.2 $[M + Na]^+$. HR MS (TOF ES+): exp. 391.1802 and calcd. 391.1770 for $[C_{22}H_{23}N_4O_3]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.32 (ddd, $^3J_{HH}$ = 1.0, 2.0 and 5.0 Hz, 2 H, $H_{py\text{-}6}$), 7.85 (d, $^3J_{HH}$ = 8.0 Hz, 1 H, $NH_{amide}$), 7.58 (ddd, $^3J_{HH}$ = 2.0, 7.5 and 9.5 Hz, 2 H, $H_{py\text{-}4}$), 7.14–7.07 (m, 5 H, 2 $H_{Ph\text{-}m}$, 1 $H_{Ph\text{-}p}$ and 2 $H_{py\text{-}3}$), 6.96–6.91 (m, 4 H, 2 $H_{Ph\text{-}o}$ and 2 $H_{Py\text{-}5}$), 4.90 (td, $^3J_{HH}$ = 6.0 and 8.0 Hz, 1 H, $H_{Phe\text{-}a}$), 4.84 (d, $^3J_{HH}$ = 16.5 Hz, 1 H, $H_{1a}$), 4.71 (d, $^3J_{HH}$ = 16.5 Hz, 1 H, $H_{1b}$), 3.63 (s, 3 H, $H_{OMe}$), 3.11–2.99 (m, 2 H, $H_{Phe\text{-}\beta}$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 171.65 ($C_{ester}$), 170.57 ($C_{amide}$), 156.33 ($C_{py\text{-}2}$), 148.32 ($C_{py\text{-}6}$), 137.59 ($C_{ph\text{-}i}$), 135.89 ($C_{py\text{-}4}$), 129.22 ($C_{phe\text{-}m}$), 128.21 ($C_{phe\text{-}o}$), 126.78 ($C_{phe\text{-}p}$), 117.92 ($C_{py\text{-}5}$), 114.42 ($C_{py\text{-}3}$), 53.07 ($C_1$), 52.71 ($C_{OMe}$), 52.09 ($C_{Phe\text{-}\alpha}$), 37.85 ($C_{Phe\text{-}\beta}$) ppm.

**Dpa-$PhCO_2$Me (5):** Methyl *p*-aminobenzoic acid (2 g, 13.23 mmol), 2-bromopyridine (2.5 mL, 26.11 mmol), potassium carbonate (2 g), potassium iodide (200 mg), copper(II) sulfate pentahydrate (200 mg) and phenanthroline (200 mg) were mixed in a 100-mL round-bottomed flask and heated at 200 °C for 7 h. After the reaction mixture was cooled down to room temperature, it was partitioned between water (150 mL) and ethyl acetate (150 mL). The water layer was further extracted with ethyl acetate (2 × 150 mL). The combined organic extracts were dried with sodium sulfate, filtered and evaporated at reduced pressure. The crude product was subjected to column chromatography (Ø 2.5 cm, silica, 75 g), a hexane/ethyl acetate gradient (5:5 → 2:8) was used as eluent. Yield: 2.0 g (52%), pale yellow oil. $M_r$ (calcd. for $C_{18}H_{15}N_3O_2$) = 305.33. MS (TOF ES+): *m*/*z* = 306.1 $[M + H]^+$. HR MS (TOF ES+): exp. 306.1261 and calcd. 306.1243 for $[C_{18}H_{16}N_3O_2]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.36 (ddd, $^3J_{HH}$ = 1.0, 2.0 and 5.0 Hz, 2 H, $H_{Py\text{-}6}$), 7.79 (d, $^3J_{HH}$ = 9.0 Hz, 2 H, $H_{Ph\text{-}3,5}$), 7.60 (ddd, $^3J_{HH}$ = 2.0, 7.5 and 8.5 Hz, 2 H, $H_{py\text{-}4}$), 7.16 (d, $^3J_{HH}$ = 9.0 Hz, 2 H, $H_{Ph\text{-}2,6}$), 6.99–7.04 (m, 4 H, $H_{py\text{-}5}$ and $H_{py\text{-}3}$), 3.89 (s, 3 H, $H_{OMe}$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 166.14 (C=O), 157.68 ($C_{py\text{-}2}$), 149.30 ($C_{Ph\text{-}1}$), 148.90 ($C_{Py\text{-}6}$), 137.86 ($C_{Py\text{-}4}$), 130.96 ($C_{Ph\text{-}3,5}$), 125.83 ($C_{Ph\text{-}2,6}$), 124.98 ($C_{Ph\text{-}4}$), 119.14 ($C_{Py\text{-}5}$), 117.88 ($C_{Py\text{-}3}$), 52.61 ($C_{OMe}$) ppm.

**Dpa-$PhCO_2$H (2):** Ligand **5** (2.0 g, 6.55 mmol) was dissolved in methanol (20 mL), 1 M NaOH (aq., 1.6 g in 20 mL) was stirred room temperature added and monitored by TLC (silica, hexane/ethyl acetate = 3:7). After the disappearance of the starting material (16 h), the reaction mixture was neutralized with HCl and the solvents evaporated to dryness. The residue was partitioned between water (150 mL) and ethyl acetate (150 mL), and the aqueous layer was further extracted with ethyl acetate (2 × 150 mL), dried with sodium sulfate, filtered and evaporated at reduced pressure. Yield: 1.63 g (89%), off white solid. The crude product was used without further purification. $M_r$ ($C_{17}H_{13}N_3O_2$) = 291.30. MS (TOF ES+): *m*/*z* = 292.1 $[M + H]^+$, 314.1 $[M + Na]^+$. HR MS (TOF ES+): exp. 292.1100 and calcd. 292.1086 for $[C_{17}H_{14}N_3O_2]^+$. $^1H$ NMR ([D$_6$]-DMSO): $\delta$ = 8.22 (m, 2 H, $H_{py\text{-}6}$), 8.85 (d, $^3J_{HH}$ = 8.5 Hz, 2 H, $H_{Ph\text{-}3,5}$), 7.66 (ddd, $^3J_{HH}$ = 2.0 Hz, 2 H, $H_{py\text{-}4}$, 7.5 and 8.5), 7.03–6.92 (m, 6 H, $H_{Ph\text{-}2,6}$, $H_{Ph\text{-}2,6}$ and $H_{py\text{-}5}$) ppm. $^{13}C$ NMR ([D$_6$]-DMSO): $\delta$ = 167.32 (C=O), 157.28 ($C_{py\text{-}2}$), 148.61 ($C_{Ph\text{-}1}$), 148.41 ($C_{Py\text{-}6}$), 138.23 ($C_{Py\text{-}4}$), 130.58 ($C_{Ph\text{-}3,5}$), 127.30 ($C_{Ph\text{-}4}$), 124.89 ($C_{Ph\text{-}2,6}$), 119.19 ($C_{Py\text{-}5}$), 117.63 ($C_{Py\text{-}3}$) ppm.

**Dpa-PhCO-Phe-OMe (6):** Dpa *p*-benzoic acid (**2**, 220 mg, 0.75 mmol), was suspended in DCM (30 mL) and cooled to 0 °C with an ice bath. HBTU (284 mg, 0.75 mmol), HOBt (125 mg, 0.75 mmol) and DIPEA (700 μL, 4 mmol) were added. After the clear solution was stirred for 1 h at 0 °C, H-Phe-OMe·HCl (165 mg, 0.75 mmol) was added. The reaction mixture was allowed to reach room temperature and the stirring was continued for 20 h. After that period, the reaction mixture was washed with sodium hydrogen carbonate (satd. aq., 3 × 50 mL) and the extracts was dried with sodium sulfate, filtered and evaporated under reduced pressure. The crude product was subjected to column chromatography (silica, hexane/ethyl acetate = 2:8) to yield an off-white solid (190 mg, 56%). $M_r$ (calcd. for $C_{27}H_{24}N_4O_3$) = 452.50. MS (TOF ES+): *m*/*z* = 453.2 $[M + H]^+$, 475.2 $[M + Na]^+$. HR MS (TOF ES+): exp. 453.1932 and calcd. 453.1940 for $[C_{27}H_{25}N_4O_3]^+$. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.33 (ddd, $^3J_{HH}$ = 1.0, 2.0 and 5.0 Hz, 2 H, $H_{py\text{-}6}$), 7.68 (d, $^3J_{HH}$ = 9.0 Hz, 2 H, $H_{Ph\text{-}3,5}$), 7.58 (ddd, $^3J_{HH}$ = 2.0, 7.5 and 9.5 Hz, 2 H, $H_{py\text{-}4}$), 7.31–7.06 (m, 7 H, $H_{Ph\text{-}3,5}$, $H_{Ph\text{-}m}$, $H_{Ph\text{-}p}$ and $H_{py\text{-}3}$), 7.01–6.95 (m, 4 H, $H_{Ph\text{-}o}$ and $H_{Py\text{-}5}$), 6.49 (d, $^3J_{HH}$ = 7.5 Hz, 1 H, $NH_{amide}$), 4.90 (td, $^3J_{HH}$ = 5.5 and 7.5 Hz, 1 H, $H_{Phe\text{-}\alpha}$), 3.75 (s, 3 H, $H_{OMe}$), 3.27 (dd, $^3J_{HH}$ = 5.5 and 14.0 Hz, 1 H, $H_{Phe\text{-}\beta1}$), 3.27 (dd, $^3J_{HH}$ = 5.5 and 14.0 Hz, 1 H, $H_{Phe\text{-}\beta2}$) ppm.

$^{13}$C NMR ($CDCl_3$): $\delta$ = 171.95 ($C_{ester}$), 166.18 ($C_{amide}$), 157.62 ($C_{py\text{-}2}$), 148.76 ($C_{Ph\text{-}1}$), 148.23 ($C_{py\text{-}6}$), 137.80 ($C_{Ph\text{-}i}$), 135.78 ($C_{py\text{-}4}$), 129.78 ($C_{Ph\text{-}4}$), 129.25 ($C_{phe\text{-}m}$), 128.56 ($C_{Ph\text{-}3,5}$), 128.37 ($C_{phe\text{-}o}$), 127.10 ($C_{phe\text{-}p}$), 125.58 ($C_{Ph\text{-}2,6}$), 118.95 ($C_{py\text{-}5}$), 117.62 ($C_{py\text{-}3}$), 53.33 ($C_{OMe}$), 52.29 ($C_{Phe\text{-}\alpha}$), 37.73 ($C_{Phe\text{-}\beta}$) ppm.

***Caution:*** *Perchlorate salts are potentially explosive and should be handled with great care!*

**Cu Complexes, General Procedure:** Solutions containing the corresponding ligand or Cu salt were briefly heated to boiling before adding the Cu salt solution to the ligand solution reaction mixture was filtered hot and cooled to room temperature. If precipitation was observed, the vial was closed and left at room temperature for the indicated period (method 1). If no precipitation occurred, the vial was placed in a container with diethyl ether (10 mL), closed, and left at room temperature for the indicated period (method 2), or the vial was left open for slow evaporation of the solvent (method 3). In all cases the product was isolated by filtration and dried in air.

**[Cu(dpa-$CH_2CO_2t$Bu)$_2$(NO$_3$)$_2$] ($\mathbf{3_{Cu}}$):** Ligand **3** (62.7 mg, 0.22 mmol), $Cu(NO_3)_2{\cdot}2.5H_2O$ (23 mg, 0.10 mmol) and methanol (10 + 5 mL) were used, method 2. After standing for 7 d, the product was collected by filtration. Yield: 38 mg (50%) of dark brown crystals, X-ray quality. $M_r$ (calcd. for $C_{32}H_{38}N_8O_{10}Cu$) = 758.24. MS (TOF ES+): *m*/*z* = 286 [ligand **3** + H]$^+$, 317 [M – 2NO$_3$]$^{2+}$, 410 [M – NO$_3$ – ligand **3**]$^+$, 633 [M – 2NO$_3$]$^+$. HR MS (TOF ES+): *m*/*z* = exp. 633.2210 and calcd. 633.2251 for [$C_{32}H_{38}N_6O_4{}^{63}Cu$]$^+$.

**[Cu(dpa-$CH_2$CO-PheOMe)$_2$(H$_2$O)$_2$](NO$_3$)$_2{\cdot}$2MeOH ($\mathbf{4_{Cu}}$):** Ligand **4** (39 mg, 0.11 mmol), $Cu(NO_3)_2{\cdot}2.5H_2O$ (12 mg, 0.05 mmol) and methanol (10 + 5 mL) were used, method 3. After standing for 5 d, the product was collected by filtration. Yield: 40 mg (75%) of violet-blue crystals, X-ray quality. $M_r$ (calcd. for $C_{46}H_{56}N_{10}O_{16}Cu$) = 1068.54; M (TOF ES+): 391.2 [ligand **4** + H]$^+$, 413.2 [ligand **4** + Na]$^+$, 453.1 [M – 2NO$_3$ – ligand **4**]$^+$, 843.3 [M – 2NO$_3$]$^+$, 866.4 [M – 2NO$_3$ + Na]$^+$. HR MS (TOF ES+): exp. 843.2717 and calcd. 843.2680 for [$C_{44}H_{44}N_8O_6{}^{63}Cu$]$^+$; X-band EPR (9.370 GHz): $g_\parallel$ = 2.17, $A_\parallel = 189\times10^{-4}$ cm$^{-1}$, $g_\perp$ = 2.05.

**[Cu(dpa-PhCO$_2$Me)$_2$(MeOH)$_2$](ClO$_4$)$_2$ ($\mathbf{5_{Cu}}$):** Ligand **5** (33.6 mg, 0.11 mmol), $Cu(ClO_4)_2{\cdot}6H_2O$ (18.5 mg, 0.05 mmol) and methanol (5 + 5 mL) were used, method 1. After standing for 1 d, the product was collected by filtration. Yield: 35 mg (75%) of dark brown crystals, X-ray quality. $M_r$ (calcd. for $C_{36}H_{30}Cl_2N_6O_{12}Cu$) = 873.11; M (TOF ES+): 306.1 [ligand **5** + H]$^+$, 328.1 [ligand **5** + Na]$^+$, 369.2 [M – 2 ClO$_4$ – ligand **5**], 673.2 [M – 2 ClO$_4$]$^+$. HR MS (TOF ES+): exp. 673.1627 and calcd. 673.1625 for [$C_{36}H_{30}N_6O_4{}^{63}Cu$]$^+$.

**[Cu(dpa-PhCO-PheOMe)$_2$(ClO$_4$)$_2$] ($\mathbf{6_{Cu}}$):** Ligand **6** (37.3 mg, 0.0825 mmol), $Cu(ClO_4)_2{\cdot}6H_2O$ (13.9 mg, 0.0375 mmol) and methanol (10 + 5 mL) were used, method 3. After standing for 7 d, the product was collected by filtration. Yield: 27 mg (62%) of green-brown crystals, X-ray quality. $M_r$ (calcd. for $C_{54}H_{48}Cl_2N_8O_{14}Cu$) = 1167.46. MS (TOF ES+): *m*/*z* = 453.2 [ligand **6** + H]$^+$, 475.2 [ligand **6** + Na]$^+$, 967.3 [M – 2 ClO$_4$]$^+$. HR MS (TOF ES+): exp. 967.2982 and calcd. 967.2993 for [$C_{54}H_{48}N_8O_6{}^{63}Cu$]$^+$; X-band EPR (9.370 GHz): $g_\parallel$ = 2.24, $A_\parallel = 160\times10^{-4}$ cm$^{-1}$, $g_\perp$ = 2.07.

**X-ray Crystallographic Data Collection and Refinement:** A dark blue single crystal of $\mathbf{3_{Cu}}$, a blue crystal of $\mathbf{4_{Cu}}$ and dark green specimens of $\mathbf{5_{Cu}}$ and $\mathbf{6_{Cu}}$ were coated with paratone freezing oil, picked up with nylon loops and mounted in the nitrogen cold stream of the diffractometer. Intensity data were collected using a Bruker AXS APEX diffractometer equipped with a Mo-target rotating anode X-ray source and a graphite monochromator (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å). Data reduction (including intensity integration, background, Lorentz and polarization corrections) was performed by use of the Bruker software package. The structure was solved by direct methods (SHELXS)[40] and refined by the full-matrix, least-squares method based on $F^2$ against all reflections (SHELXL).[41] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed geometrically and were refined by use of the riding model. Crystallographic data of $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$ are listed in Table 3.

Table 3. Crystallographic data for $\mathbf{3_{Cu}}$–$\mathbf{6_{Cu}}$.

# A Hexadecanuclear Copper(I)–Copper(II) Mixed-Valence Compound: Structure, Magnetic Properties, Intervalence Charge Transfer, EPR, and NMR

**Senjuti De,[a] Shubhamoy Chowdhury,[a] Jnan P. Naskar,[a] Michael G. B. Drew,[b] Rodolphe Clérac,[c] and Dipankar Datta*[a]**

**Keywords:** Copper / High-nuclearity complexes / Aggregates / Mixed-valent compounds / Charge transfer / N,O ligands

Hexadecanuclear copper mixed-valence complex **2** containing 10 $Cu^{II}$ centers and 6 $Cu^{I}$ centers was isolated with N,O donor ligands. From the X-ray crystal structure, **2** was found to contain a centrosymmetric dimeric cation – each monomeric unit composed of eight copper centers. It displays a very broad and weak intervalence charge-transfer band around 1100 nm at room temperature in the solid state. Variable-temperature magnetic susceptibility measurements indicate an $S = 1/2$ ground state for half of **2**, explicitly, each $Cu_8$ moiety has a $g$ value around 2.26. Complex **2** was examined by NMR spectroscopy at room temperature in solution and by EPR at low temperature; the data indicates that the valence is delocalized in **2** at room temperature but localized at low temperature.

## Introduction

High-nuclearity ($n > 10$) metal complexes are of much current interest as these may have applications in catalysis, bio- and nanotechnology, material science, and molecular magnetism. The most impressive example is possibly $[Mn_{84}O_{72}(CH_3COO)_{78}(CH_3O)_{24}(CH_3OH)_{12}(OH)_6(H_2O)_{42}]\cdot x H_2O\cdot y CHCl_3$, which is a single molecule magnet of nano dimension.[1] The highest nuclearity $n$ has so far been achieved in the case of Mo ($n$ = 368).[2] This $n$ may depend on the oxidation state of the metal. For example, the highest $n$ reported to date for $Cu^{I}$ is 146,[3] whereas it is 44 in the case of $Cu^{II}$.[4] Further, the situation might change in mixed-valence compounds. The highest $n$ reported so far for $Cu^{I}$–$Cu^{II}$ mixed-valence compounds is 38; this complex is made up of 36 $Cu^{II}$ centers and 2 $Cu^{I}$ centers.[5] A somewhat old review on high nuclearity $Cu^{I}$–$Cu^{II}$ mixed-valence complexes is available.[6] A general interesting feature of the mixed-valence complexes is the appearance of an intervalence charge-transfer (ICT) band in the electronic spectra.[7–9] However, such a band was not observed so far in any $Cu^{I}$–$Cu^{II}$ mixed-valence complex with $n > 3$. Herein we describe an air stable $Cu^{I}$–$Cu^{II}$ mixed-valence complex with $n$ = 16 that displays the rare ICT band.

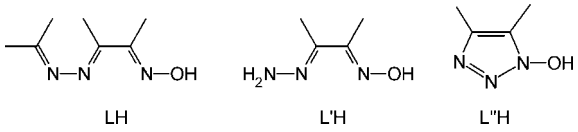
Previously we reported[10] a hexanuclear $Cu^{II}$ complex of LH (H: dissociable proton; Scheme 1), the acetone condensate of L′H (3-hydrazono-butan-2-one oxime; Scheme 1), of the formulation $Cu_6L_6(O)(OH)(ClO_4)_3$ (**1**). Its X-ray crystal structure was also reported. It is a H-bonded, centrosymmetric dimer of a centrally $\mu_3$-oxido bridging $Cu_3$ complex cation $[Cu_3L_3(O)]^{2+}$ having peripheral oximato bridges. We have now found that if the crystallization of **1** is delayed in its synthesis, **1** is transformed into unique hexadecanuclear mixed-valence $Cu^{I}$–$Cu^{II}$ complex **2**. Its X-ray crystal structure, spectroscopic (electronic and magnetic resonance), and magnetic properties are described here.



Scheme 1. Some ligands involved in the present work; H: dissociable proton.

## Results and Discussion

The unit cell of **2** contains a centrosymmetric dimer of formula $[Cu_{16}L_2L'_2L''_{16}(H_2O)_2]^{6+}$ together with 6 discrete perchlorate anions and 10 solvent water molecules. Thus, the molecular formula of **2** is $[Cu_{16}L_2L'_2L''_{16}(H_2O)_2](ClO_4)_6\cdot 10H_2O$. The cation shown in Figure 1 contains eight independent copper atoms, all with different environments; Cu1, Cu6, and Cu7 are tetrahedral, Cu2 is four-coordinate square planar, Cu3 and Cu4 are five-coordinate square pyramidal, Cu5 is two-coordinate linear, and Cu8 is three-coordinate trigonal. The numbering scheme is such that the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligands are numbered 1–10 inclusive with each atom numbered by the ligand number first and then the position of the atom in the ligand; L′′ is numbered 1–8 inclusive, with L′ numbered 9 and L numbered 10. In ligand L′′, three atoms, namely N*n*1, N*n*2 and O*n*5 are found to bind to copper atoms. The acyclic ligands L and L′ both chelate to one copper atom but also bind to other copper atoms through their other available donor atoms.

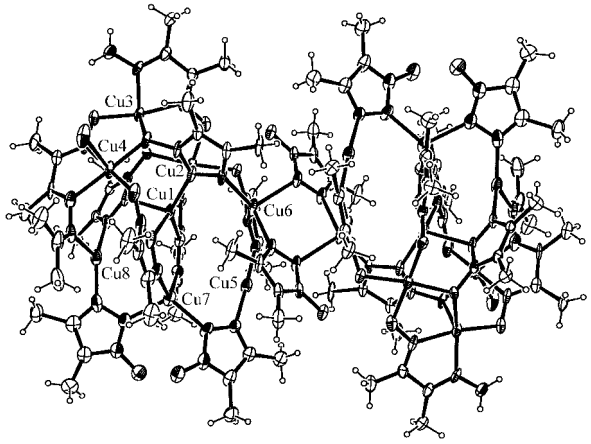


Figure 1. The structure of the centrosymmetric, dimeric cation in **2** with ellipsoids at 10% probability.

The environment of Cu1, shown in Figure 2; it is four-coordinate tetrahedral in which the metal atom is bound to four ligands through their central nitrogen atom N*n*1, where *n* is 1, 2, 7, and 8. The environment of Cu2 by contrast is four-coordinate square planar in which the metal atom is bonded to four ligands through the terminal oxygen atom O*n*5 where *n* is 5, 7, 8, and 9 (Figure 3). There is, in addition, a weak interaction with a perchlorate oxygen atom O21 at 2.53(1) Å. The environment of Cu3 is a five-coordinate square pyramid with O15 in an axial position and O105 and O85 together with the two nitrogen atoms N95 and N92 from the bidentate ligand L′ in the equatorial plane (Figure 4). Cu4 also has a five-coordinate square pyramidal geometry, but here a water molecule is in an axial position with O15 and O25 as well as two nitrogen atoms N105 and N102 from the bidentate L (Figure 5). The Cu5 atom is two-coordinate linear (Figure 6) and is bonded to N42 and N52 at 1.878(11) and 1.886(11) Å. The N42–Cu5–N52 angle is 173.4(5)°. There are no other bonding interactions for Cu5. The Cu6 atom has a tetrahedral environment but unlike Cu1 it is bonded to two N*n*1 atoms and two N*n*2 atoms. The Cu6 atom is involved in the centrosymmetric bridge as shown in Figure 7. The Cu7 atom is also tetrahedral and similar to Cu6, which is bonded to a combination of N*n*1 and N*n*2 atoms as shown in Figure 8. The Cu8 atom is three-coordinate trigonal and is bonded to N32, N82, and N101 as shown in Figure 9. Overall, the closest Cu···Cu distance in the cation $[Cu_{16}L_2L'_2L''_{16}(H_2O)_2]^{6+}$ is 3.114 Å between Cu1 and Cu2, indicating that there are no significant bonding interactions between copper atoms.

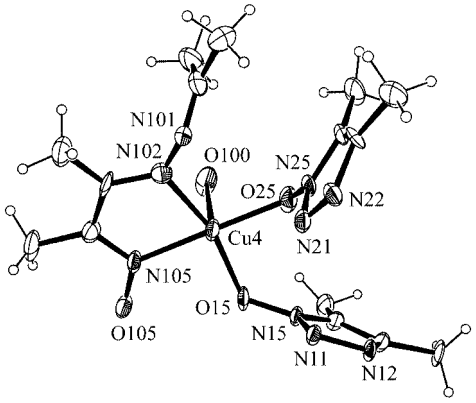

Figure 5. The environment of Cu4 with ellipsoids at 25% probability. O100 belongs to a water molecule. Selected bond lengths [Å] and angles [°]: Cu4–O25 1.914(10), Cu4–O15 1.950(10), Cu4–N105 2.007(10), Cu4–N102 2.014(13), Cu4–O100 2.313(10), O25–Cu4–O15 91.0(4), O25–Cu4–N105 179.2(5), O15–Cu4–N105 88.3(4), O25–Cu4–N102 102.5(5), O15–Cu4–N102 162.6(4), N105–Cu4–N102 78.3(5), O25–Cu4–O100 90.6(4), O15–Cu4–O100 95.8(4), N105–Cu4–O100 89.0(4), N102–Cu4–O100 94.9(4).

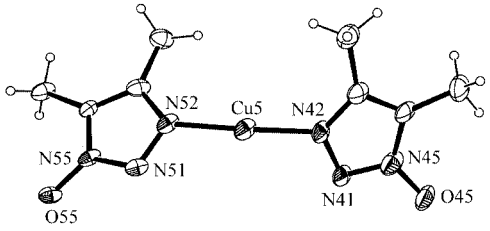

Figure 6. The environment of Cu5 with ellipsoids at 25% probability. Selected bond lengths [Å] and angles [°]: Cu5–N42 1.878(11), Cu5–N52 1.886(11), N42–Cu5–N52 173.4(5).

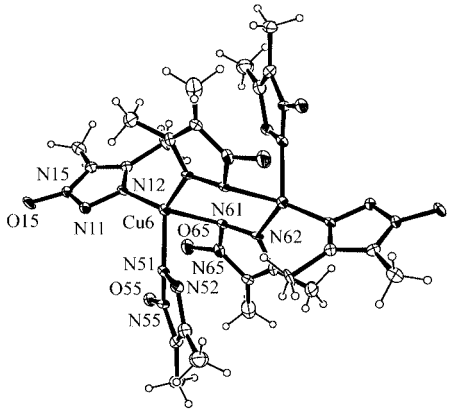

Figure 7. The environment of Cu6 with ellipsoids at 25% probability. The centrosymmetric bridge in the dimer is shown. Selected bond lengths [Å] and angles [°]: Cu6–N12 1.978(10), Cu6–N62$1 2.000(10), Cu6–N51 2.054(9), Cu6–N61 2.245(10), N12–Cu6–N62$1 125.6(4), N12–Cu6–N51 120.0(4), N62$1–Cu6–N51 105.0(4), N12–Cu6–N61 106.3(5), N62$1–Cu6–N61 102.8(4), N51–Cu6–N61 89.4(4).

We now discuss the binding nature of the three ligands occurring in **2** (Scheme 1). Of the three ligands, L and L′ are acyclic whereas L′′ is cyclic. The two acyclic ligands, L′ and L, chelate to one metal, N92 and N95 to Cu3, and

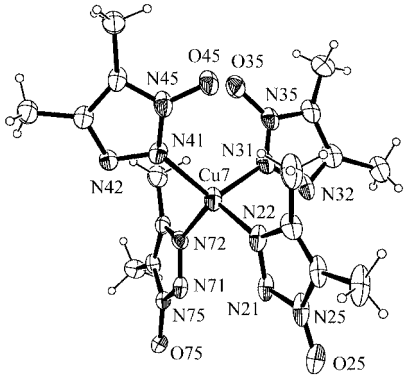

Figure 8. The environment of Cu7 with ellipsoids at 25% probability. Selected bond lengths [Å] and angles [°]: Cu7–N22 1.985(12), Cu7–N41 2.023(11), Cu7–N72 2.042(11), Cu7–N31 2.138(14), N22–Cu7–N41 122.1(5), N22–Cu7–N72 114.1(5), N41–Cu7–N72 104.1(4), N22–Cu7–N31 100.8(5), N41–Cu7–N31 113.1(5), N72–Cu7–N31 100.9(4).

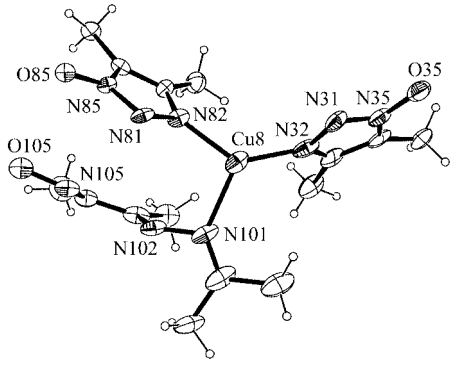

Figure 9. The environment of Cu8 with ellipsoids at 25% probability. Selected bond lengths [Å] and angles [°]: Cu8–N32 1.915(15), Cu8–N82 1.979(11), Cu8–N101 2.096(13), N32–Cu8–N82 130.3(5), N32–Cu8–N101 124.8(5), N82–Cu8–N101 102.8(5).

N102 and N105 to Cu4. In addition, O95 is bound to Cu2 within L′, N101 to Cu8, and O105 to Cu3 within L. There are eight types of L′′. Type 1 is bonded to four different metals: Cu1 through N11, Cu6 through N12, and Cu3 and Cu4 through O15. Type 2 is bonded to three copper atoms: Cu1 through N21, Cu7 through N22, and Cu4 through O25. Type 3 is bonded to two copper atoms: Cu7 through N31 and Cu8 through N32. Instead of bonding to a copper atom, O35 forms a strong hydrogen bond of 2.80 Å to solvent water O50. Type 4 is bonded to Cu7 through N41 and Cu5 through N42 but O45 remains unbonded. Type 5 is bonded to Cu6 through N51, Cu5 through N52, and Cu2 through O55. Type 6, which is adjacent to the center of symmetry, binds Cu6 through N61 and Cu61 through N62 (see Figure 7). Type 7 is bonded to Cu1 through N71, Cu7 through N72, and Cu2 through O75. Type 8 is bonded to Cu1 through N81, Cu8 through N82, and Cu2 and Cu3 through O85. Thus, for L′′, it can be concluded that its N*n*1 and N*n*2 are bound to different copper atoms, whereas its O*n*5 is bonded to two, one, or no copper atoms.

The formulation of complex **2** indicates that it consists of 10 $Cu^{II}$ and 6 $Cu^{I}$ centers. To assign the oxidations states

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of various copper centers in **2**, we take recourse to the bond valence sum (BVS) model. BVS relates the bond lengths around a metal center to its oxidation state. In this method, originally introduced by Pauling and developed later by Brown and coworkers,[11–13] the valence $v_{ij}$ of a bond between two atoms $i$ and $j$ is given empirically by Equation (1), where $r_{ij}$ is the length (expressed in Å) and $r_0$ a parameter characteristic of the bond.

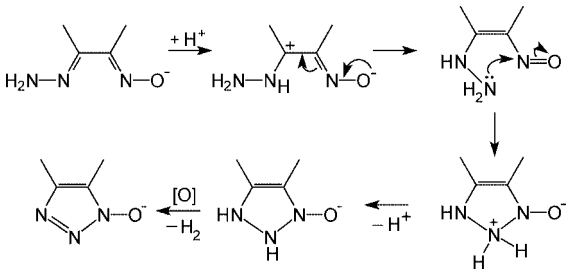
$$v_{ij} = \exp[(r_0 - r_{ij})/0.37] \quad (1)$$

The oxidation number $V_i$ of an atom $i$ is a simple algebraic sum of the $v$ values of all the bonds formed by the atom [Equation (2)]; it is also known as BVS.

$$V_i = \sum_j v_{ij} = \sum_j \exp[(r_0 - r_{ij})/0.37] \quad (2)$$

Thus, if $r_0$ is known for a particular bond type the BVS can be calculated from the crystallographically determined $r_{ij}$ values. The $r_0$ values for $Cu^{II}$–N and $Cu^{II}$–O bonds, as refined by us,[12] are 1.719 and 1.679 Å, respectively. Previously, we found[12] that with these $r_0$ values, the BVS values calculated for a number of $Cu^{II}$ complexes of N and O donor ligands are found to lie in the range of $2.00 \pm 0.35$ valence units, specifically, the oxidation number of copper in these complexes are reproduced within $\pm 0.35$ valence units. When we apply this method to **2**, we obtain the following BVS values for the eight types of copper atoms: Cu1, 1.73; Cu2, 1.95; Cu3, 2.26; Cu4, 2.10; Cu5, 1.29; Cu6, 1.61; Cu7, 1.67; and Cu8, 1.44. Thus our BVS calculations show that in the cases of Cu5, Cu6, and Cu8, the errors in the calculated oxidation states by assuming an oxidation state of II for all the copper atoms, exceed our stipulated error limit of $\pm 0.35$ valence units. Consequently, an oxidation state of I is assigned to Cu5, Cu6, and Cu8 and an oxidation state of II to other five copper centers, namely Cu1, Cu2, Cu3, Cu4, and Cu7.

In the synthesis of complex **2** from complex **1**, L is transformed to L′ and L′′. L′ is generated from L by simple hydrolysis of the acetone azine bond. Ligand L′ is then subsequently transformed into L′′. A tentative mechanism for this transformation in methanol (a protic solvent) is suggested in Scheme 2. It involves a two-electron oxidation in the last step. We believe this oxidation is brought about by two $Cu^{II}$ centers because the reaction **1**→**2** occurs under a $N_2$ atmosphere as well, and thereby some of the $Cu^{II}$ centers are reduced to $Cu^{I}$, which leads to the formation of a mixed-valence species. Interestingly, in the synthesis of [1,2,3]triazol-1-ol (the basic skeleton in L′′H) from glyoxal, proposed by Begtrup, a similar oxidation by $Cu^{2+}$ occurs in the last step.[14] X-ray crystal structures of a few of its derivatives are available. However, metal complexes of [1,2,3]triazol-1-ol are so far not known in the literature. Complex **2** illustrates the hitherto unexplored coordination behavior of [1,2,3]triazole-1-ol.



Scheme 2. A proposed mechanism for the chemical transformation of L′ into L′′ in a protic solvent.

Variable-temperature magnetic susceptibility ($\chi$) of **2** was measured and is shown in Figure 10 as a $\chi T$ versus $T$ plot. At room temperature, $\chi T$ is 0.89 $cm^3 \cdot K \cdot mol^{-1}$ and slowly decreases to 0.85 $cm^3 \cdot K \cdot mol^{-1}$ at 210 K. The value of $\chi T$ is found to be roughly constant in the temperature range 210–100 K. Then it again decreases down to an asymptotic value of 0.48 $cm^3 \cdot K \cdot mol^{-1}$ at 1.85 K. On the basis of the molecular structure of complex **2** (Figure 1), we tried to simplify the topology of the $Cu_{16}$ aggregate in order to analyze the magnetic behavior theoretically. The centrally located four diamagnetic $Cu^{I}$ centers magnetically isolate the $Cu^{II}$ ions into two distinct $Cu^{II}_5$ units (see the inset in Figure 10). In each such unit, at least four different types of magnetic interactions are present and were considered to model the magnetic property in the framework of Heisenberg's theory. However, all our attempts in this regard were unsuccessful due to the incapacity to evaluate the strong antiferromagnetic interaction between $S = 1/2$ $Cu^{II}$ metal ions present in a part of the $Cu^{II}_5$ units (likely through direct oxygen bridges). Unfortunately, the limited available temperature range between 210 and 300 K did not allow an accurate estimation of these strong interactions. The decrease in the $\chi T$ product below 100 K reveals that there are additional and weaker antiferromagnetic interactions in the $Cu^{II}_5$ units. Even if the amplitude of these interactions is not possible to determine, the asymptotic $\chi T$ value of 0.48 $cm^3 \cdot K \cdot mol^{-1}$ observed at 1.85 K suggests an $S = 1/2$ ground state for a $Cu_8$ unit with a $g$ value around 2.26.

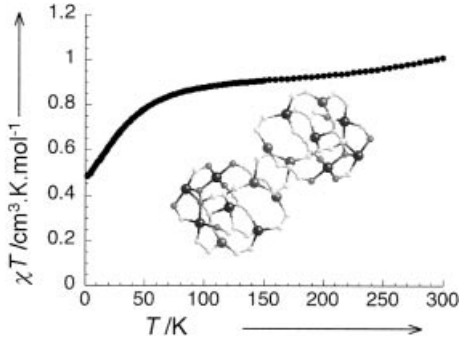


Figure 10. Temperature dependence of the $\chi T$ product at 1000 Oe (where $\chi = M/H$) for half of $[Cu_{16}L_2L'_2L''_{16}(H_2O)_2](ClO_4)_6 \cdot 10H_2O$ (**2**) shown schematically in the inset.

Complex **2** displays a very broad and weak band around 1100 nm in the solid state at room temperature (Figure 11). This band could not be observed in methanol solution at

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

room temperature. However, relative to the intensity of the 650 nm band (Figure 11), which is very well observed in methanol solution, it appears that the intensity of the 1100 nm band is much less than 2900 $M^{-1}\cdot cm^{-1}$. No copper(II) or copper(I) complex is known in the literature that displays an absorption band at such a long wavelength. We ascribe this band to an intervalence charge transfer in **2**. It is difficult to specify how many copper centers are actually involved in the intervalence charge transfer. It is possible that two-coordinate Cu5 and three-coordinate Cu8 are not involved in the intervalence charge transfer process because of geometric reasons. One of the criteria for facile intervalence charge transfer is that the coordination environments (geometries and the binding atoms) of metal centers in the two oxidation states should be close to each other.[7–9] The four-coordinate copper(I) center Cu6 is directly bridged to two four-coordinate copper(II) centers Cu1 and Cu2. Of these two, Cu1 has a distorted tetrahedral $N_4$ and Cu2 ha a square planar $O_4$ coordination sphere. Thus, geometrywise and in terms of the nature of the binding atoms, the copper(I) center Cu6 seems to be compatible only with the copper(II) center Cu1 for the involvement in the ICT process. Previously in a binuclear mixed-valence $Cu^{I}$–$Cu^{II}$ complex where both the copper centers have $N_2O_2$ coordination sphere, Long and Hendrickson[15] have observed a broad ICT band at 950 nm with an intensity of 400 $M^{-1}\cdot cm^{-1}$ in solution at room temperature.

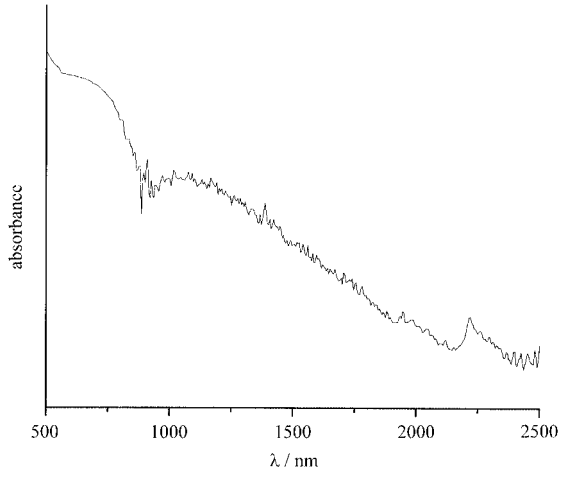

Figure 11. A portion of the absorption spectrum of **2** in nujol at room temperature.

The extensive valence delocalization in the complex of Long and Hendrickson at room temperature was established by the observation of a seven-line EPR spectrum in solution. Interestingly, their complex gives an EPR spectrum characteristic of a mononuclear copper(II) center at 100 K, to be exact, with the lowering of temperature valence gets localized.[15] In our case, valence delocalization renders the EPR signal so broad that we do not see any EPR spectrum at room temperature either in the solid state (Figure 12) or in solution. However, at low temperature (5 K) **2** displays an unsymmetrical spectrum with a *g* value of ca. 2.12. Thus in complex **2** valence is also delocalized at room temperature and localized at low temperature. The nonobservance of an EPR spectrum for **2** in methanol solution at room temperature despite being paramagnetic is supported by the observation of its $^1H$ NMR spectrum in $CD_3OD$ at room temperature (Figure 13). Resonances due to the various methyl and $NH_2$ groups and water molecules present in **2** appear within the range –5 to 15 ppm. As expected, the $^1H$ signals are somewhat broad (Figure 13).

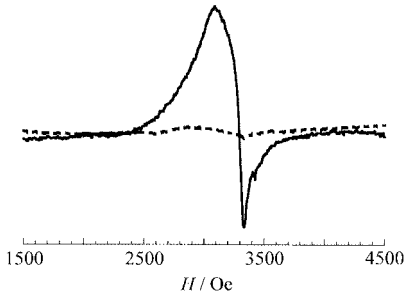

Figure 12. X-band EPR spectrum of **2** in solid state at 300 (dashed line) and 5 (full line) K.

## Concluding Remarks

Here we have described a unique, self-assembled, paramagnetic cluster containing copper(I) and copper(II) that displays NMR in solution at room temperature and EPR at low temperature. Such magnetic resonance behavior only suggests that valence is delocalized in complex **2** at room temperature but localized at lower temperatures. This sort of valence localization–delocalization is expected intuitively. On reaching sufficiently low temperatures, a delocalized (ambient-temperature) system gets *trapped in a valence-localized state*.[16,17] Accordingly, an intervalence charge-transfer band is also observed for **2** at room temperature at a low energy (1100 nm). In Hush theory,[18,19] for a class II (valence localized) system the observed bandwidth should be close to $(2310 \times \tilde{\nu}_{max})^{1/2}$ $cm^{-1}$; when the experimental bandwidth is much lower than the calculated one, the system becomes class III (complete valence delocalization). With $\lambda_{max}$ = 1100 nm, the half-width is calculated to be 4600 $cm^{-1}$. Unfortunately, because of an intense neighboring band in the absorption spectrum of **2**, we cannot ascertain the exact half-width of the 1100 nm band experimentally, thus preventing us to categorize mixed valence complex **2** in terms of Hush theory. Self-assembly, which is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

an important phenomenon in nature, has been a matter of extensive research in recent times.[20,21] Here it has assumed a different dimension.

## Experimental Section

**General:** Microanalyses were performed with a Perkin–Elmer 2400II elemental analyzer. FTIR spectra (KBr disc) were recorded with a Shimadzu FTIR-8400S spectrophotometer, UV/Vis/NIR spectra with a Perkin–Elmer Lambda 950 spectrophotometer, and NMR spectra with a Bruker DPX300 spectrometer. The magnetic susceptibility measurements were obtained with the use of a Quantum Design SQUID magnetometer MPMS-XL. This magnetometer works between 1.8 and 400 K for dc applied fields ranging from –7 to 7 T. Measurements were performed on finely ground crystalline samples of 31.36 mg. $M$ vs. $H$ measurements were performed at 100 K to check for the presence of ferromagnetic impurities that were found to be absent. The magnetic data were corrected for the sample holder and the diamagnetic contribution.

**Synthesis of 1:** Prepared by modifying the previously published procedure[10] in the following manner. $Cu(ClO_4)_2{\cdot}6H_2O$ (1.86 g, 5 mmol) dissolved in methanol (10 mL) was added dropwise to LH (0.77 g, 5 mmol) and anhydrous sodium acetate (0.41 g, 5 mmol), dissolved in methanol (20 mL), with stirring. A dark green compound started precipitating immediately. Stirring was continued for only 2 min. Then the compound was filtered, washed with cold methanol (5 mL) and dried in air. Yield: 0.4 g (30%).

**Synthesis of 2:** Complex **1** (0.53 g, 0.32 mmol) was dissolved in methanol (100 mL) in a conical flask to obtain a clear green solution and layered with diethyl ether (300 mL), stoppered, and left undisturbed. After three weeks, the precipitated green crystalline compound was filtered and washed with diethyl ether (single crystals suitable for X-ray crystallography were found at the upper portion). It was dried under vacuum over fused $CaCl_2$. Yield: 0.35 g (65%). $\Lambda_M$ (MeOH): 591 $\Omega^{-1}{\cdot}cm^2{\cdot}mol^{-1}$. FTIR (KBr): $\tilde{\nu}$ = 3447 (vb) $\nu$(OH), 1117 (vs), 629 (s) $\nu(ClO_4)$ $cm^{-1}$. UV/Vis/NIR (MeOH): $\lambda$ ($\varepsilon$, $M^{-1}{\cdot}cm^{-1}$) = 203 ($10.5\times10^5$), 263 ($14.3\times10^4$), 322 ($10.9\times10^4$), 642 ($2.9\times10^3$) nm. $C_{86}H_{160}Cl_6Cu_{16}N_{60}O_{56}$ (4160.01): calcd. C 24.81, H 3.88, N 20.20; found C 24.70, H 3.96, N 20.03.

***Caution!*** Though we have not met with any incident during our studies, care should be taken in handling these compounds as perchlorate salts are potentially explosive. These should not be prepared and stored in larger amounts.

**X-ray Crystallography:** Data for **2** were collected at 150 K with a Bruker SMART APEX CCD diffractometer using graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data reduction was performed with SAINT+[22] and absorption corrections applied using SADABS.[23] The structure was solved by direct methods[24] and refined[25] on $F^2$ using SHELX97. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were refined isotropically using a riding model. Of the three perchlorate anions in the asymmetric unit, two were refined with distance constraints. Five independent water molecules were located but their hydrogen atoms could not be located. Crystal Data: $C_{43}H_{80}Cl_3Cu_8N_{30}O_{28}$; $M_r$ = 2080.04; triclinic; space group $P\bar{1}$; $a$ = 13.898(4), $b$ = 16.328(5), $c$ = 18.642(6) Å; $\alpha$ = 82.144(6), $\beta$ = 72.186(5), $\gamma$ = 80.408(5)°; $V$ = 3955(2) Å$^3$; $Z$ = 2; $D_{calcd.}$ = 1.747 g·cm$^{-3}$. 18127 independent reflections were measured and were refined to $R_1$ 0.1178, $wR_2$ 0.2818 for 7300 reflections with $I>2\sigma(I)$. CCDC-600589 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

# Tripodal Trimanganese(III) Complexes of New Unsymmetrical Pentadentate Ligands Derived from 2-(Salicylideneamino)phenol: Syntheses, Crystal Structures and Properties

**Masahiro Muto,[a] Naoya Hatae,[a] Yumi Tamekuni,[a] Yasunori Yamada,[a] Masayuki Koikawa,*[a] and Tadashi Tokii*[a]**

**Keywords:** Bridging ligands / Ligand design / Manganese / X-ray structures / Magnetic properties / Redox chemistry

Trinuclear manganese(III) complexes of new unsymmetrical pentadentate ligands, 6-hydroxy-2-(2-hydroxyphenyl)-5-(salicylideneamino)benzoxazole ($H_3L^1$) and 5-(5,6-benzosalicylideneamino)-6-hydroxy-2-(2-hydroxynaphthyl)benzoxazole ($H_3L^2$), $[Mn_3(L^1)_3(CH_3OH)_3]$ (**1**) and $[Mn_3(L^2)_3(dmf)(CH_3OH)(H_2O)]$ (**2**) (dmf = *N*,*N*-dimethylformamide), have been prepared. The structures of the ligands $H_3L^1$, $H_3L^2$ and complex **1** were determined by X-ray crystallography, which revealed that the ligands have two distant chelating sites. The molecular structure of **1** is regarded as a tripodal pyramid with a cavity of about 3 Å diameter. Each $Mn^{III}$ ion is coordinated by *ONO* atoms from a tridentate Schiff base site and *ON* atoms from a benzoxazole site of two respective $H_3L^1$ ligands. The intramolecular Mn···Mn distances for **1** are in the range 8.0683–8.1791 Å, and the nearest intermolecular Mn···Mn distance, 5.7824(15) Å, is shorter than the intramolecular values. Magnetic measurements of **1** indicate that weak antiferromagnetic interactions ($J = -0.2\ cm^{-1}$, $g = 2.0$) are dominant in the trinuclear manganese(III) core. Cyclic voltammogram of **1** in dmf showed obscure redox couples assigned to two single-electron transfer processes.

## Introduction

The development of nanoscale molecular architectures such as macrocyclic metal ion arrays is of considerable interest in materials science and supramolecular chemistry because these complexes often have characteristic redox, magnetic and mechanical functions and host–guest chemistry.[1–3] Moreover, the discrete macrocyclic structures can be used as secondary building units for higher-order constructions such as two- or three-dimensional network structures.[4,5] In any case, ligands that have appropriate bridging abilities and directions are used. For example, most macrocyclic metal complexes have been organised by small anions based on acetate and hydroxy anions. In this case, μ-acetato or μ-hydroxido bridges are slanted at small bending angles to the metal-to-metal direction. According to the extent of these angles, various sizes of macrocyclic metal arrangements are prepared. However, because the preparations of such complexes depend on contingency, it is rather difficult to strategically develop scientific research. Therefore, it is important that ligands that have multiple separate coordination sites, are carefully designed to obtain such nanomolecular architectures by self-assembly.

It is known that 2-(salicylideneamino)phenol ($H_2sap$)[6–11] and many other similar *ONO*-tridentate ligands form stable metal complexes.[12–20] We prepared modified ligands [$H_3L^1$: 6-hydroxy-2-(2-hydroxyphenyl)-5-(salicylideneamino)benzoxazole; $H_3L^2$: 5-(5,6-benzosalicylideneamino)-6-hydroxy-2-(2-hydroxynaphthyl)benzoxazole; $H_4L'$: 4,6-bis(salicylideneamino)benzene-1,3-diol] and introduced *ON*-bidentate or *ONO*-tridentate coordination sites into $H_2sap$ (Scheme 1). The newly designed ligands, $H_3L^1$ and $H_3L^2$, have unsymmetrical structures, and it is expected that $H_3L^n$ will lead to polynuclear complexes that have a complicated structure because the two coordination sites face different directions. These unsymmetrical multidentate ligands can generally arrange metal ions suitable for the property of each coordination site. It is possible to apply the syntheses of functional models for metalloenzymes in the field of bioinorganic chemistry.[21–23] On the other hand, the symmetrical ligand $H_4L'$, which has been known for a long time and was reported in detail in 1970,[24,25] is expected to lead to geometrically regularly structured complexes because it adapts *mer* coordination. Such symmetrical ligands are often used in studies of magnetism or electroconductivities, which require structural regularity.[25,26]

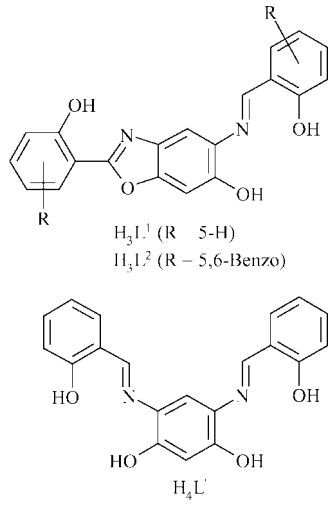


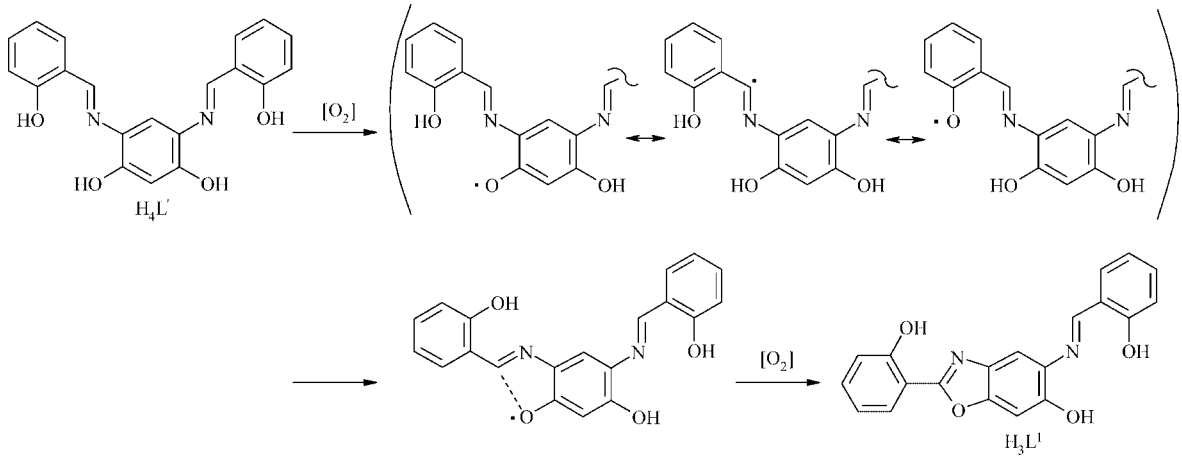
Scheme 1. Structure of the ligands.

In this study, we prepared new trinuclear manganese(III) complexes of these ligands with novel tripodal geometry. We describe here the syntheses, X-ray structural characterisation and magnetic and electrochemical properties of these newly obtained ligands and complexes.

## Results and Discussion

The ligands $H_3L^n$ and $H_4L'$ were identified by elemental analysis, FTIR, $^1$H NMR, FAB mass spectrometry and X-ray crystal structural analysis. The symmetrical ligand $H_4L'$ was temporarily obtained as the monohydrochloride, $H_4L'$·HCl, from a simple reaction of 4,6-diaminoresorcinol dihydrochloride with 2-hydroxybenzaldehyde. This ligand showed characteristic IR bands assigned to $\nu$(C=N) vibrations based on the Schiff base at 1622–1651 cm$^{-1}$ and $\nu$(OH) vibrations at 3070 and 3355 cm$^{-1}$. In the FAB mass spectrum, an intense molecular ion peak was observed at 349.1, and was assigned to the free ligand $H_4L'$. The free ligand $H_4L'$ without HCl could be isolated when two equivalents of triethylamine were used in the synthetic process. These ligands, $H_4L'$ and $H_4L'$·HCl, had similar $^1$H NMR spectra. It is considered that both ligands have a comparable structure in solution. The unsymmetrical ligand $H_3L^1$ was prepared from the filtrate obtained in the synthetic process for free $H_4L'$. On the other hand, the homologous symmetrical ligand obtained using 2-hydroxy-1-naphthaldehyde was not isolated by a similar synthetic method for $H_4L'$. The unsymmetrical ligand $H_3L^2$ was obtained as a green product under basic reaction conditions with triethylamine. The starting material, 4,6-diaminoresorcinol, can be simply oxidised to *p*-quinone imine or *p*-semiquinone imine species. In fact, the intensity of an ESR signal related to the radical in crude 4,6-diaminoresorcinol gradually increases in air. It is supposed that symmetrical Schiff base ligands, the same as $H_4L'$, are initially formed and that oxidation to a semiquinone imine form by molecular oxygen might have proceeded under such basic reaction conditions. Scheme 2 shows a reaction pathway for $H_3L^1$ formation. It is known that such radical species are stabilised by π conjugation as illustrated in Scheme 2. Consequently, the active radical species might lead to ring formation to yield benzoxazole derivatives. The free ligands $H_3L^1$ and $H_3L^2$ have characteristic IR bands assigned to $\nu$(C=N) vibrations based on Schiff base and benzoxazoline components at 1615–1634 cm$^{-1}$, and $\nu$(OH) vibrations at 3202 cm$^{-1}$ for $H_3L^1$ and at 3051 cm$^{-1}$ for $H_3L^2$. In the FAB mass spectra, intense molecular ion peaks were observed at 347.2 and 447.2.

The reaction of $H_4L'$·HCl and $H_3L^2$ with manganese(II) acetate tetrahydrate yielded trinuclear manganese(III) complexes **1** and **2**, respectively. Elemental analytical data of the complexes gave a 1:1 metal/ligand ratio. The $\nu$(C=N) vibrations observed in free ligands shifted to about 1600 cm$^{-1}$. It is suggested that both binding sites act as tridentate and bidentate chelates. At ambient conditions the manganese(III) species are produced regardless of whether manganese(II) or manganese(III) is used as the manganese source. The formation of phenoxyl radicals as shown in Scheme 2 might be accelerated by the existence of manganese(III) species. As a result, it is supposed that $H_4L'$ undergoes more facile oxidation to $H_3L1$ in these reactions. All attempts to obtain complex **1** by using $H_3L^1$ instead of



Scheme 2. Reaction pathway for the five-membered ring formation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$H_4L'$ were unsuccessful. One of the reasons was considered to be the low solubility of $H_3L^1$ in organic solvents.

### X-ray Crystal Structures

Single crystals of $H_4L'$, $H_3L^1$ and $H_3L^2$, suitable for X-ray crystallography, were obtained by recrystallisation from mixed dmf solution layered with methanol or acetonitrile. All the obtained crystals were thin and fragile needles. Although the structure refinements were insufficient, the obtained results clearly revealed the ligand structures. ORTEP drawings of these are shown in Figure 1. For ligand $H_4L'$, both salicylaldehyde molecules formed Schiff base *ONO*-coordination sites such as 2-(salicylideneamino)phenol ($H_2$sap). On the other hand, $H_3L^1$ and $H_3L^2$ had *ON*-bidentate coordination sites comprising the benzoxazole substructure in addition to *ONO*-tridentate sites. The C(14)–N(2) bond length in $H_3L^1$ is 1.283(6) Å, and deviation of the five-membered ring, C(11)–C(12)–N(2)–C(14)–O(3), from planarity is very small (0.0060 Å). These data reveal the existence of a C=N double bond and the formation of a benzoxazole moiety, and prove that the ligand $H_4L'$ can undergo facile oxidation in air. The molecular structures of $H_3L^1$ and $H_3L^2$ differ in planarity from $H_2$sap frameworks. As for the dihedral angles defined by two phenyl rings binding O(1) and O(2), the angles are 10.2(2)° ($H_3L^1$) and 4.9(4)° ($H_3L^2$). It is assumed that the $H_2$sap framework in $H_3L^2$ is much more delocalised than that in $H_3L^1$. In any case, *ON*- and *ONO*-coordination sites face opposite directions. Therefore, the ligand frameworks can be regarded to have an S-shape conformation (Table 1).

Table 1. Selected bond lengths and angles of **1**.

| Bond lengths [Å] | | Angles [°] | |
|---|---|---|---|
| Mn(1)–O(1) | 1.895(5) | O(1)–Mn(1)–O(8) | 91.3(2) |

Table 2. Electrochemical data of **1** and **2**.[a]

| Complex | $Mn_3$(II,III,III)/$Mn_3$(II,II,III) | | | $Mn_3$(III,III,III)/$Mn_3$(II,III,III) | | | $\Delta E$[c] |
|---|---|---|---|---|---|---|---|
| | $E_{pa}$ | $E_{pc}$ | $E_{1/2}(1)$[b] | $E_{pa}$ | $E_{pc}$ | $E_{1/2}(2)$[b] | |
| **1** | –0.68 | –0.77 | –0.73 | –0.548 | –0.64 | –0.59 | 0.14 |
| **2** | –0.70 | –0.80 | –0.75 | –0.546 | –0.71 | –0.63 | 0.12 |

[a] In V vs. $Ag/Ag^+$, scan rate 100 $mV s^{-1}$. Determined on a GC electrode in dmf. [b] $E_{1/2} = (E_{pc} + E_{pa})/2$. [c] $\Delta E = |E_{1/2}(1) - E_{1/2}(2)|$.

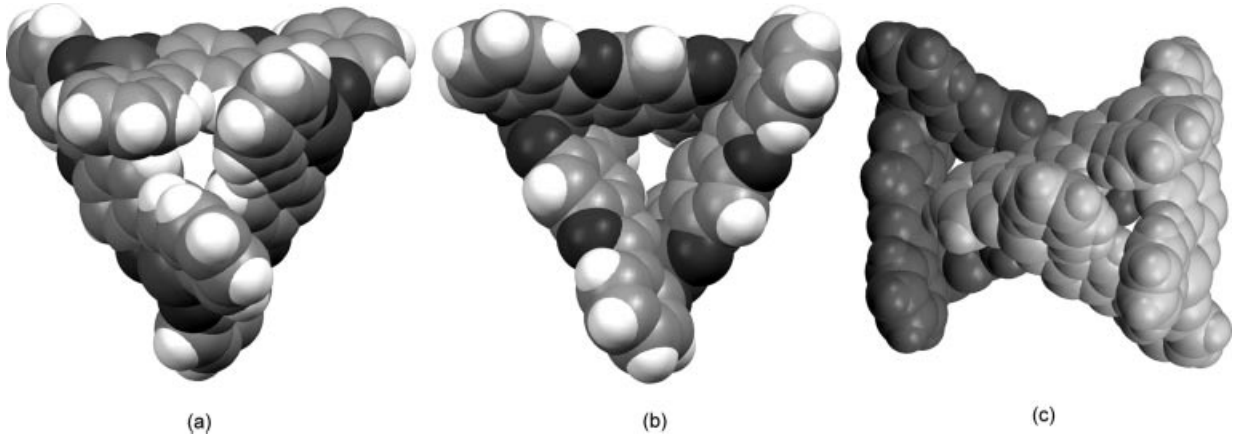

Figure 3. CPK models of **1**. Coordinating solvents are omitted for clarity; (a) view from the apex of the tripodal pyramid, (b) view from the cavity side and (c) enantiomer pairs in crystal packing; symmetry codes: ($x$, $y$, $z$) and ($1 - x$, $-y$, $1 - z$).

ions and coordinating solvents. CPK models of the $[Mn_3(L^1)_3]$ unit without the coordinating methanol molecules are shown in Figure 3. The entire molecular structure of **1** is regarded as a tripodal pyramid with a cavity. The coordination environments of the three manganese ions are very similar. Each manganese(III) ion forms a six-coordination geometry by three sets of donor components. The most effective donor set is the *ONO* one from the tridentate Schiff base binding site of $(L^1)^{3-}$. The N=C bond lengths (1.277–1.303 Å) in the Schiff base site are close to the value for standard $N(sp^2)=C(sp^2)$ double bonds. The sum of bond angles around N(1), N(3) and N(5) are 359.6, 359.3 and 359.8°, respectively. These data imply that the ligands are present in the Schiff base form, and not in the benzoxazine form. This coordination behaviour is very similar to that of 2-(salicylideneamino)phenol. The second one is the *ON* donor set from the bidentate benzoxazole site of a ligand different from the *ONO* donor. The phenolic oxygen atom coordinates to an identical plane, and the *ONO* Schiff base forms an equatorial plane. The nitrogen atom of the oxazole moiety is located in an axial position. The remaining sixth position of the manganese ion is occupied by a methanol molecule to form an $N_{oxazole}$–Mn–$O_{methanol}$ elongated axis. This axis corresponds to the Jahn–Teller axis for normal six-coordinate manganese(III) complexes. In complex **1**, the Jahn–Teller axes are defined as N(4)–Mn(1)–O(13) [Mn(1)–N(4) 2.304(6), Mn(1)–O(13) 2.250(8) Å], N(6)–Mn(2)–O(14) [Mn(2)–N(6) 2.241(6), Mn(2)–O(14) 2.264(4) Å] and N(2)–Mn(3)–O(15) [Mn(3)–N(2) 2.250(6), Mn(3)–O(15) 2.241(8) Å]. Equatorial planes comprise O(1)–N(1)–O(2)–O(8) for Mn(1) (av. 1.921 Å), O(5)–N(3)–O(6)–O(12) for Mn(2) (av. 1.924 Å) and O(9)–N(5)–O(10)–O(4) for Mn(3) (av. 1.921 Å). The bond lengths around the manganese(III) ions fall within the range observed for the manganese(III) complexes with Schiff base ligands.[16,27–31] In addition, coordination environments are very similar to that of [Mn(sap)L] [HL: 2-(2-hydroxyphenyl)benzoxazole], with a five-coordinate square-pyramidal structure, except for a coordinating methanol molecule.[17] It is well known that tridentate $H_2$sap derivatives usually form phenoxo-bridged dinuclear metal complexes.[6–9,18,20] However, when bidentate ligands such as phenanthroline are available, ternary mononuclear complexes such as [Mn(sap)L] are often reported.[11,19] In the present case, the reaction of $H_3L^1$ with manganese ions corresponds to the latter because $H_3L^1$ has both (sap) and bidentate coordination sites. As a result, $H_3L^1$ acts as an S-shaped hook to the manganese atom and locks each manganese atom to stabilise the tight triangular structure.

As for the characteristic structural properties, it is worth noting that these complexes have a cavity. The present complexes have long Mn···Mn distances arising from the unique ligand structure. The distances for **1** are 8.1791(16), 8.1081(15) and 8.0683(16) Å. Considering the van der Waals radius, a small molecule with an external diameter of about 3 Å can be held in the cavities. In fact, as shown in Figure 3, pairs of enantiomers are loosely aggregated in crystal lattices. In this pair, phenyl rings of the complexes are mutually intercalated in each cavity accompanied by π–π stacking [C(8)···$C(17)^i$ 3.411(10) Å]. It is suggested that these complexes can be expected in an application in host–guest chemistry. In the crystal packing, several intermolecular hydrogen bonds between coordinating solvents and neighbouring molecules are recognised. The distance be-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tween the O(14) atom of the coordinating methanol molecule and the O(8)$^{j}$ atom of $(L^1)^{3-}$ in the neighbouring molecule is 2.949(7) Å, which is regarded as a typical hydrogen bond (symmetry code j: $1 - x$, $-1/2 - y$, $1/2 - z$). As a result, the nearest intermolecular Mn···Mn distance [Mn(2)···Mn(1)$^{j}$ 5.7824(15) Å] is shorter than intramolecular Mn···Mn distances.

For complex **2**, X-ray reflection data and analytical results were insufficient for discussing structural details, because the crystals obtained were efflorescent. An identified molecular structure of **2** is very similar to that of **1** except for the coordinating solvent molecules. The estimated structure of **2** is consistent with the molecular formula suggested by the elemental analysis.

## Magnetic Properties

Powder samples of the complexes showed two ESR signals at $g \approx 9.0$ (strong) and 2.0 (weak) at room temperature. The spectra of **1** and **2** are shown in Figure 4. Generally, observation of ESR signals of mononuclear six-coordinate manganese(III) complexes are often difficult because of the fast spin relaxation and large zero-field splitting.[32] However, when the coordination geometries around the manganese(III) ion are strongly distorted, the signals can be observed as anisotropic signals. In the present complexes, the geometries of manganese(III) ions have strong axial distortion along with weakly coordinated solvent molecules. In consequence, it is assumed that these strong anisotropic signals were observed at an apparent $g$ value of about 9.0.[33] The weak signals at $g \approx 2.0$ might have arisen from manganese(II) impurities.

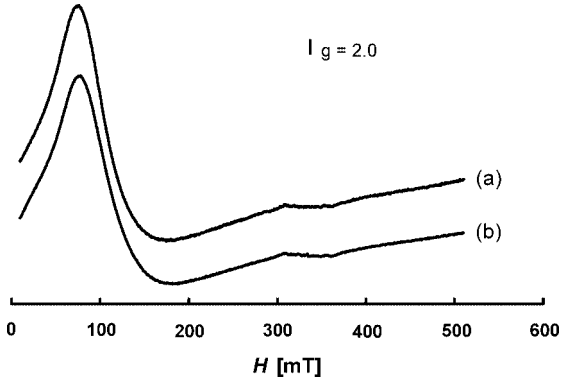

Figure 4. X-band polycrystalline ESR spectra of **1** (a) and **2** (b) at room temperature. The bar indicates the position of the weak resonance.

The magnetic moments per Mn atom of the complexes at room temperature are 4.90 (for **1**) and 4.83 (for **2**) B.M., which are close to the spin-only values (4.90) for four unpaired spins ($S = 2$). Magnetic susceptibility measurements for **1** were performed in the temperature range 2–300 K. The $\chi_A$ and $\mu_{eff}$ versus $T$ plots are shown in Figure 5. The $\mu_{eff}$ values are virtually constant from 300 K to 50 K, and then rapidly decrease with decreasing temperature and reach 3.96 B.M. at 2 K. This behaviour indicates the presence of a very weak antiferromagnetic interaction between manganese(III) ions. The magnetic property was simulated by means of the triangular spin model for $S = 2$ (Scheme 3).

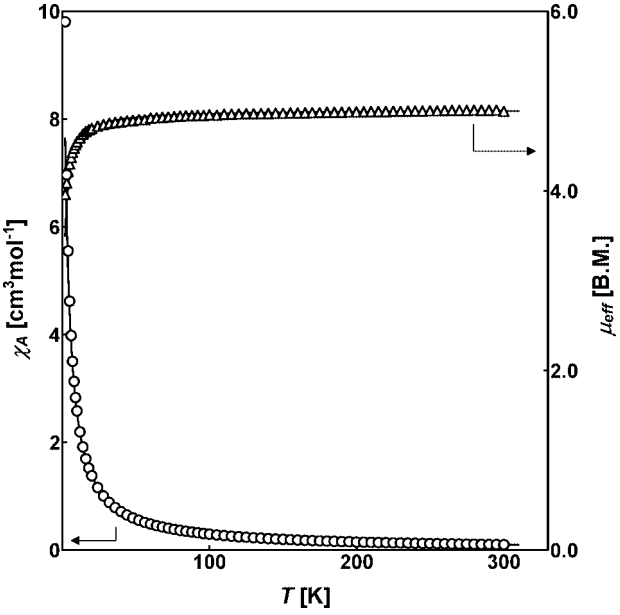

Figure 5. Temperature dependence of the magnetic susceptibilities for **1**. The solid curves were obtained as described in the text.

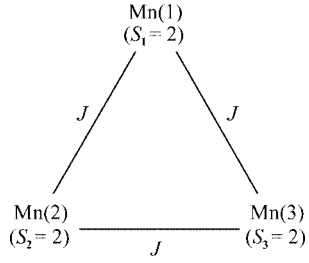

Scheme 3. Triangular spin model for **1**.

The Hamiltonian is written as in Equation (1).

$$H = -J(S_1S_2 + S_2S_3 + S_3S_1) \quad (1)$$

Magnetic susceptibilities are given by Equation (2), where $\chi_A$ is the magnetic susceptibility per manganese ion, and other symbols have their usual meanings.

$$\chi_A = \{Ng^2\beta^2/3k(T-\theta)\}\mathbf{A}/\mathbf{B} + N\alpha$$
$$\mathbf{A} = 182 + 220\exp(-12J/kT) + 180\exp(-22J/kT) + 112\exp(-30J/kT) + 50\exp(-36J/kT) + 6\exp(-40J/kT)$$
$$\mathbf{B} = 13 + 22\exp(-12J/kT) + 27\exp(-22J/kT) + 28\exp(-30J/kT) + 25\exp(-36J/kT) + 9\exp(-40J/kT) + \exp(-42J/kT) \quad (2)$$

The best fitting parameters are $J = -0.2$ cm$^{-1}$, $g = 2.00$, $N\alpha = 0$ and $\theta = -1.5$ K. For triangular complexes, spin-frustration behaviour was often observed. In the present complex **1**, the obtained $J$ value suggests that the weak antiferromagnetic interactions are dominant. However, the absolute $J$ value is too small to dispute the essence of magnetic interaction owing to the long Mn–Mn distances (av. 8.119 Å).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

A notable result is the contribution of the $\theta$ value, which suggests that overall antiferromagnetic interactions are several times larger than the $J$ value. As shown in the crystal packing diagram, **1** has a high-order structure linked through hydrogen bonds established between the coordinated methanol and the phenolic oxygen atom of neighbouring complex molecules. Such connections are known to mediate intermolecular magnetic interactions.[34–36] In addition, because the distance between the nearest intermolecular manganese ions, 5.7824(15) Å, is shorter than the intramolecular distances (av. 8.119 Å), it is assumed that the intermolecular antiferromagnetic interaction is larger than the intramolecular interaction.

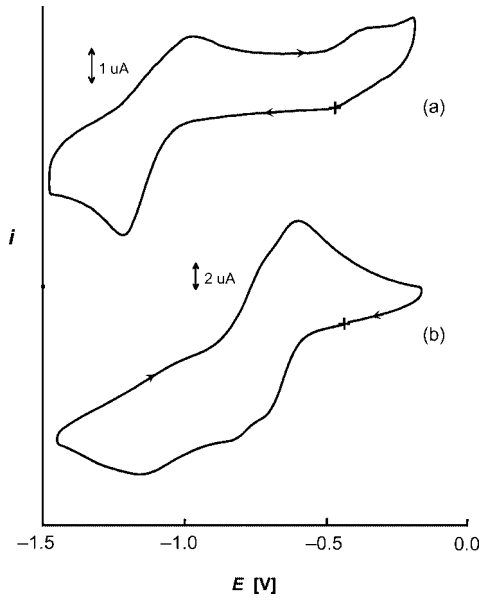

Figure 6. Cyclic voltammograms of $H_3L^1$ (a) and **1** (b); glassy-carbon electrode, scan rate 100 mV s$^{-1}$, concentration $1 \times 10^{-3}$ M, in dmf.

### Electrochemistry

Electrochemical properties of the present complexes were examined by cyclic voltammetry (CV) in dmf containing tbap (0.1 M) as the supporting electrolyte. The cyclic voltammograms of $H_3L^1$ and **1** are shown in Figure 6. When measurements were performed in the range from –0.1 to –1.4 V, three irreversible redox couples were observed at about –0.6, –0.7 and –1.0 V. The redox couples at about –1.0 V can be assigned to the reduction of the benzoxazole moiety, because the voltammogram of $H_3L^1$ also showed similar waves. In the positive range, both present complexes showed no wave except for the irreversible oxidation of phenolic oxygen atoms originating in the ligands. The electrochemical data of **1** and **2** are summarised in Table 3.

Although the first and second reduction waves are not so clear, it is assumed that they can be assigned to metal-centred one-electron transfer processes $Mn_3$(III,III,III)/$Mn_3$(II,III,III) and $Mn_3$(II,III,III)/$Mn_3$(II,II,III), respectively. The redox process of $Mn_3$(II,II,III)/$Mn_3$(II,II,II) could not be observed in the present measurements, even though we performed CV under various measurement conditions. It is considered that the effect of the ligand reduction process makes the voltammogram obscure. The potential differences ($\Delta E$) between two metal-centred redox couples are higher than 36 mV, which is expected for a purely statistical treatment in the two-electron process.[37] In multinuclear complexes, $\Delta E$ values often increase when an electronic repulsion effect exists between the redox centres. In complex **1**, the bridging ligands forming long metal-to-metal distances are expected to yield small $\Delta E$ close to the statistical case. However, the ligands have a π-conjugation system that is expected to enhance the electronic communication between manganese ions. As a result, it is assumed that the electronic repulsion effect is enhanced in **1**; large $\Delta E$ values were observed in these complexes. Such a phenomenon was also observed in other macrocyclic complexes having long metal-to-metal distances like **1**.[1,38,39]

## Conclusions

In the present study, it was demonstrated that the newly obtained unsymmetrical pentadentate ligands $H_3L^1$ and $H_3L^2$ support the formation of trinuclear manganese(III) complexes described as $[Mn_3(L^n)_3(solvent)_3]$. In the present complexes, the manganese atoms have six-coordinate geometries with elongated octahedral distortion. The molecular structures of the complexes are regarded as tripodal pyramids with a small cavity. The cavity is used for π–π stacking between enantiomer pairs. The magnetic interactions among trinuclear metal cores are very weak because of the long metal-to-metal distances. It is interesting that the obtained complexes are not phenoxo-bridged dinuclear complexes but trinuclear complexes. The result suggests that the present ligands can provide new applications for obtaining trinuclear macrocyclic complexes and can develop the understanding of self-assembly.

## Experimental Section

**Materials:** All ordinary reagents and solvents were purchased and used as received, unless otherwise noted. Methanol was purified by distillation from magnesium turnings.

### Preparations

**$H_4L'$·HCl:** A solution of 2-hydroxybenzaldehyde (0.976 g, 8 mmol) in dry methanol (10 mL) was added dropwise to a solution of 4,6-diaminoresorcinol dihydrochloride (0.852 g, 4 mmol) in dry methanol (40 mL) with stirring. The solution became a bright red suspension. The resulting precipitate was filtered off, washed with dry methanol and dried in vacuo. Yield of $H_4L'$·HCl·2$H_2O$: 1.36 g, 81%. $C_{20}H_{21}ClN_2O_6$ (420.85): calcd. C 57.08, H 5.03 N, 6.66; found C 56.76, H 5.04, N 6.77. IR (KBr): $\tilde{\nu}$ = 3355 and 3070 (OH), 1622–1651 (C=N), 860 and 758 (phenyl) $cm^{-1}$. $^1H$ NMR (300 MHz, dmso, tms): $\delta$ = 9.12 (s, 2 H), 7.80 (s, 1 H), 7.62 (d, 2 H), 7.45–7.39 (t, 2 H), 7.02–6.92 (m, 4 H), 6.72 (s, 1 H) ppm. FAB-MS: *m*/*z* = 349.1 [($H_4L'$)$H^+$].

**$H_4L'$:** A solution of 2-hydroxybenzaldehyde (0.976 g, 8 mmol) in dry methanol (10 mL) was added dropwise to a solution of 4,6-diaminoresorcinol dihydrochloride (0.852 g, 4 mmol) in dry methanol (40 mL) with stirring. The solution became a bright red suspension. A solution of triethylamine (0.808 g, 8 mmol) in dry methanol (5 mL) was added slowly, and the mixture was stirred at room temperature for 1 h. The resulting orange precipitate was filtered off, washed with dry methanol and dried in vacuo. Single crystals suitable for X-ray crystallography were obtained by recrystallisation from dmf solution layered with methanol. Yield of $H_4L'$·1/2MeOH·1/2$H_2O$: 1.143 g, 77%. $C_{20.5}H_{19}N_2O_5$ (373.39): calcd. C 65.94, H 5.13, N 7.50; found C 65.66, H 5.19, N 7.45. IR (KBr): $\tilde{\nu}$ = 1615–1634 (C=N), 859 and 756 (phenyl) $cm^{-1}$. $^1H$ NMR (300 MHz, dmso, tms): $\delta$ = 9.03 (s, 2 H), 7.65 (s, 1 H), 7.60 (d, 2 H), 7.35 (t, 2 H), 6.97–6.91 (m, 4 H), 6.65 (s, 1 H) ppm.

**$H_3L^1$:** The next day, ligand $H_3L^1$ precipitated from the orange solution from which the ligand $H_4L'$ had been filtered off. Single crystals suitable for X-ray crystallography were obtained by recrystallisation from dmf solution layered with acetonitrile. Yield of $H_3L^1$·4$H_2O$: 0.013 g, 0.8%. $C_{20}H_{22}N_2O_8$ (418.40): calcd. C 57.41, H 5.30, N 6.70; found C 57.27, H 5.19, N 6.78. IR (KBr): $\tilde{\nu}$ = 3202 (OH), 1615–1634 (C=N), 765 and 750 (phenyl) $cm^{-1}$. $^1H$ NMR (300 MHz, dmso, tms): $\delta$ = 9.07 (s, 1 H), 7.99 (d, 1 H), 7.91 (s, 1 H), 7.64 (d, 1 H), 7.51 (t, 1 H), 7.41 (t, 1 H), 7.34 (s, 1 H), 7.12 (d, 1 H), 7.07 (d, 1 H), 6.98 (t, 2 H) ppm. FAB-MS: *m*/*z* = 347.2 [($H_3L^1$)$H^+$].

**$H_3L^2$:** A solution of triethylamine (0.808 g, 8 mmol) in dry 1,4-dioxane (10 mL) was added dropwise to a solution of 4,6-diaminoresorcinol dihydrochloride (0.852 g, 4 mmol) and 2-hydroxy-1-naphthaldehyde (1.376 g, 8 mmol) in dry 1,4-dioxane (30 mL) with stirring. The dark green slurry was stirred at room temperature for 3 h. The resulting precipitate was filtered off and washed with dry 1,4-dioxane. Upon recrystallisation from a mixed solution of dmf/methanol, $H_3L^2$ precipitated as orange needles, was filtered off, and dried in vacuo. Single crystals suitable for X-ray crystallography were obtained by recrystallisation from dmf solution layered with methanol. Yield of $H_3L^2$·1/2$H_2O$: 0.27 g, 14.8%. $C_{28}H_{19}N_2O_{4.5}$ (455.47): calcd. C 73.84, H 4.20, N 6.15; found C 73.46, H 4.54, N 6.47. IR (KBr): $\tilde{\nu}$ = 3238 (OH), 1615–1622 (C=N), 746 (phenyl) $cm^{-1}$. $^1H$ NMR (300 MHz, dmso, tms): $\delta$ = 9.67 (s, 1 H), 8.58–8.51 (m, 3 H), 8.08 (d, 1 H), 7.96 (d, 1 H), 7.84 (d, 1 H), 7.71 (d, 1 H), 7.64 (t, 1 H), 7.54–7.44 (m, 3 H), 7.37 (d, 1 H), 7.30 (t, 1 H), 6.84 (d, 1 H) ppm. FAB-MS: *m*/*z* = 447.2 [($H_3L^2$)$H^+$].

**$[Mn_3(L^1)_3(CH_3OH)_3]$ (1):** A methanol solution (5 mL) of triethylamine (0.020 g, 0.2 mmol) was added to an orange suspension of $H_4L'$·HCl (0.077 g, 0.2 mmol) in methanol (15 mL) with stirring. A solution of manganese(II) acetate tetrahydrate (0.049 g, 0.2 mmol) in dry methanol (20 mL) was added to the resulting light brown solution, and the mixture was stirred for 10 min. The obtained dark brown solution was filtered, and the filtrate was allowed to stand at room temperature for 1 d to give dark brown crystals suitable for X-ray crystallography. Yield of **1**: 0.039 g, 45.3%. $C_{63}H_{45}Mn_3N_6O_{15}$ (1290.90): calcd. C 58.62, H 3.51, Mn 12.77, N 6.51; found C 58.47, H 3.10, Mn 13.07, N 6.74. IR (KBr): $\tilde{\nu}$ = 1606 (C=N), 1146 (C–O), 752 (phenyl) $cm^{-1}$. UV (dmf): $\lambda$ ($\varepsilon$) = 373 (37200), 503 (22900) and 800 sh (500 $dm^3 mol^{-1} cm^{-1}$) nm. $\Lambda_m$ (dmf) = 2.60 $S cm^{-2} mol^{-1}$.

**$[Mn_3(L^2)_3(dmf)(CH_3OH)(H_2O)]$ (2):** A solution of manganese(II) acetate tetrahydrate (0.025 g, 0.1 mmol) in dry methanol (10 mL) was added to an orange suspension of $H_3L^2$ (0.045 g, 0.1 mmol) in dmf (10 mL). The resulting dark brown mixture was stirred for 3 h and then filtered to remove insoluble materials. Triethylamine (0.02 g, 0.2 mmol) was added to the filtrate, and the solution was allowed to stand at room temperature for 3 d to give dark brown crystals suitable for X-ray crystallography. Yield of **2**·2dmf·$CH_3OH$: 0.029 g, 48.4%. $C_{95}H_{76}Mn_3N_9O_{18}$ (1796.51): calcd. C 63.51. H 4.26, Mn 9.17, N 7.02; found C 63.21, H 3.94, Mn 8.80, N 6.96. IR (KBr): $\tilde{\nu}$ = 1616, 1600 (C=N), 1144 (C–O), 828 and 756 (phenyl) $cm^{-1}$. UV (dmf): $\lambda$ ($\varepsilon$) = 410 sh (31600), 465 sh (20000), 526 sh (19900), 769 sh (1000) and 870 sh (500 $dm^3 mol^{-1} cm^{-1}$) nm. $\Lambda_m$ (dmf) = 1.90 $S cm^{-2} mol^{-1}$.

**Physical Measurements:** Elemental analyses for C, H and N were obtained at the Elemental Analysis Service Center, Kyushu University. Manganese was determined with a Perkin–Elmer A Analyst 100 atomic absorption spectrometer. Nuclear magnetic resonance spectra were recorded with a JNM-AL300 spectrometer in [$D_6$]-dmso using tetramethylsilane as the internal standard. FAB mass spectra for $H_3L^n$ and $H_4L'$ were recorded with a JMS-GC mate II. Infrared spectra and electronic spectra were recorded with a Perkin–Elmer Spectrum 2000 FTIR spectrometer on KBr disks and a Perkin–Elmer Lambda 19 UV/Vis/NIR spectrophotometer, respectively, at the Instrumental Analysis Center, Saga University. X-band ESR spectra were recorded with a JEOL JES-TE300 ESR spectrometer at room temperature. Magnetic susceptibilities in the temperature range 2–300 K were measured with a Quantum Design

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

MPMS XL SQUID susceptometer under an applied magnetic field of 500 G. The susceptibilities at room temperature were determined by the Gouy method with a Sherwood Scientific Magnetic Susceptibility Balance. These were corrected for the diamagnetism of the constituent atoms using Pascal's constant.[40] The effective magnetic moments were calculated from the equation $\mu_{eff} = 2.828[(\chi_A - N\alpha)T]^{1/2}$, where $\chi_\alpha$ is the atomic magnetic susceptibility and $N\alpha$ is the temperature-independent paramagnetism. Molar conductances were determined in dmf at 25 °C with a TOA EC METER CM-30G. Cyclic voltammograms (CVs) were obtained with a BAS 100B electrochemical voltammetric analyser. The CV measurements were carried out in dmf containing 0.1 M tetrabutylammonium perchlorate (tbap) as supporting electrolyte. (***Caution:*** tbap is explosive and should be handled with great care!) The three-electrode cell that was used was equipped with a glassy carbon ($\phi$ = 3 mm) working electrode, a platinum wire counter electrode, and an $Ag/Ag^+$ electrode as the reference.

**X-ray Crystal Structure Determinations:** The diffraction data were measured with a Rigaku AFC5S automated four-circle diffractometer having graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71069 Å) radiation. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections for complexes **1**, 24 reflections for $H_3L^1$ and $H_4L'$, and 6 reflections for $H_3L^2$. The data were collected using the $\omega$-scan technique to a maximum $2\theta$ value of 55.1° for $H_3L^1$, 55.0° for $H_4L'$ and **1**, and the $\omega$-$2\theta$-scan technique to a maximum $2\theta$ value of 45.0° for $H_3L^2$. The weak reflections [$I < 10\sigma(I)$] were rescanned (maximum 5 rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of the peak counting time was 2:1. The intensities of three representative reflections were measured after every 150 reflections. Over the course of data collections, the standards decreased by 0.7% for **1**. Polynomial correction factors were applied to the data to account for this phenomenon. Empirical absorption corrections, based on azimuthal scans of several reflections, were applied. The data were corrected for Lorentz and polarisation effects. The crystallographic data and collection details are summarised in Table 3. The structures were solved by direct methods (SIR92) and expanded using Fourier techniques.[41,42] All hydrogen atoms were located in the calculated positions and refined using the riding model. The final cycle of full-matrix least-squares refinement on $F$ using SHELXL-97 was based on observed reflections and variable parameters, and converged with unweighted and weighted agreement factors of $R$ and $R_w$.[43,44] Neutral atom scattering factors were taken from Cromer and Waber.[45] Anomalous dispersion effects were included in $F_c$;[46] the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley.[47,48] All calculations were performed using the Rigaku CrystalStructure crystallographic software package, except for refinement, which was performed using SHELXL-97.[49] CCDC-625063 to -625066 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# New Reactivity of 4-Amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole: Synthesis and Structure of a Mononuclear Species, a Dinuclear Species, and a Novel Tetranuclear Nickel(II) Rectangle Box, and Magnetic Properties of the Dinuclear and Tetranuclear Complexes

**Ming-Liang Tong,*[a] Chao-Gang Hong,[a] Ling-Ling Zheng,[a] Meng-Xia Peng,[a,b] A. Gaita-Ariño,[c] and Juan Modesto Clemente Juan*[c]**

**Keywords:** Nickel / Polynuclear / Azides / Magnetic properties

Reactions of $Ni(O_2CMe)_2·4H_2O$ or $NiCl_2·6H_2O$, 4-amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole (abpt) and $NaN_3$ or KSCN in different molar ratios heated under reflux or hydrothermal conditions generate a mononuclear species with dimorphous phases, a dinuclear species incorporating an in situ deaminated [bpt-H]$^-$ ligand and a tetranuclear rectangle box incorporating an unprecedented $\mu:\eta^1:\eta^2:\eta^1$ coordination mode of the deprotonated [abpt-H]$^-$ ligand. Structural analysis reveals that a pair of $[Ni_2(\mu_{1,1}\text{-}N_3)(\mu\text{-}OAc)]$ motifs in $[Ni_4(abpt)_2(abpt\text{-}H)(N_3)_5(O_2CMe)_2]·5H_2O$ (**1**) are bridged by two abpt and one [abpt-H]$^-$ units into a rectangle box. $[Ni_2(bpt\text{-}H)_2(SCN)_2(H_2O)_2]·2H_2O$ (**2**) is a neutral centrosymmetric dinuclear $Ni^{II}$ complex doubly bridged by abpt ligands. The complex $[Ni(abpt)_2(N_3)_2]$ (**3**) is a neutral centrosymmetric mononuclear $Ni^{II}$ complex and crystallizes in polymorphous phases, showing an interesting example of temperature-induced polymorphism. Variable-temperature magnetic susceptibility measurements reveal that the ferromagnetic interaction via the $(\mu_{1,1}\text{-}N_3)_2(\mu\text{-}OAc)$ and $(\mu_{1,1}\text{-}N_3)(\mu_{1,1}\text{-}NH_{abpt-H})(\mu\text{-}OAc)$ bridges slightly dominates over the antiferromagnetic interaction via the abpt bridges, therefore indicative of an overall ferromagnetic coupling between $Ni^{II}$ centers in **1**, and a moderate antiferromagnetic interaction occurs in **2**.

## Introduction

Magnetic multimetal-centered complexes or metal clusters have attracted much attention over the past decades.[1,2] 4-Amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole (abpt) is a potential multitopic ligand and its coordination chemistry has been investigating since the mid 1980s.[3] In particular, the spin-crossover system $[Fe(abpt)_2(X)_2]$ (where X = $SCN^-$, $SeCN^-$ or $N(CN)_2^-$, $TCNQ^-$) has been structurally and magnetically characterized.[4] So far, many coordination compounds of adpt have been synthesized.[5a,5b] However, most of them are mononuclear, particularly, only two examples of dinuclear nickel and copper complexes have been structurally characterized before our work,[3,5c] which indicate that the majority of these coordination compounds have relatively poor crystallization behavior in common solvents. This urged us to pursue its chemical reactivity under relatively unconventional conditions. We have recently been investigating a few in situ metal–organic reactions targeting a magnetic cluster system and furnished an interesting sandwich-type high-spin heterometallic $Ni_{12}K_4$ cluster from the reaction of di-2-pyridyl ketone with nickel acetate and azide in the presence of potassium *tert*-butoxide as a catalytic base.[6] Herein we report a tetranuclear rectangle box, a dinuclear complex and a mononuclear complex in polymorphous phases, which are synthesized by reflux and hydrothermal methods, respectively. They are $[Ni_4(abpt)_2(abpt\text{-}H)(N_3)_5(O_2CMe)_2]·5H_2O$ (**1**), $[Ni_2(bpt\text{-}H)_2(SCN)_2(H_2O)_2]·2H_2O$ (**2**) (bpt-H = 3,5-di-2-pyridyl-1,2,4-triazolate), α-$[Ni(abpt)_2(N_3)_2]$ (**3α**), and β-$[Ni(abpt)_2(N_3)_2]$ (**3β**). The [abpt-H]$^-$ in **1** resulted from the deprotonation of abpt during the reflux conditions and [bpt-H]$^-$ in **2** was formed from the deamination of abpt under solvothermal conditions.

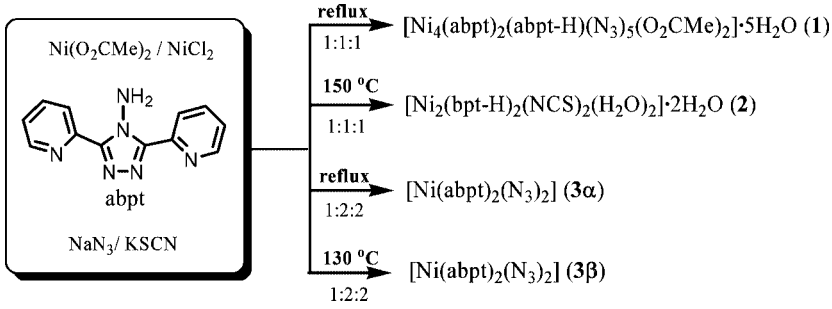
## Results and Discussion

### Synthesis and Characterization

In the reported metal complexes of the abpt ligand,[5a] the azide anion has not been chosen as the counterions, the azide salt is, therefore, introduced into the reaction system.



Scheme 1. Synthesis of **1**, **2**, **3α**, and **3β**.

The reaction of $Ni(O_2CMe)_2·4H_2O$, $NaN_3$ and abpt in a 1:1:1 molar ratio heated at reflux generated tetranuclear complex **1** (Scheme 1). When $NaN_3$ was replaced by KNCS, the solvothermal reaction of $NiCl_2·6H_2O$, KNCS and abpt in a 1:1:1 molar ratio led to dinuclear complex **2**. Remarkable is the deamination of abpt into bpt during the reaction probably related to the extreme conditions of the solvothermal reaction, which was also observed in the hydrothermal reaction of $[Co(abpt)_2(SCN)_2]$[3d] with $CoCl_2$. Furthermore, reactions of $NiCl_2·6H_2O$, $NaN_3$ and abpt in a 1:2:2 molar ratio heated at reflux or under solvothermal conditions led to the polymorphous mononuclear complexes of **3α** and **3β**, respectively, demonstrating that the factor of reaction temperature notably affects the final products. It should be noted that **3α** and **3β** are the first examples of ternary metal–abpt–azide complexes.

In addition to the bands of the abpt and $[abpt\text{-}H]^-$ ligands, the points of interest in the IR spectrum of the four complexes lie mainly in the bands due to the $N_3^-$ or $SCN^-$ groups. For **1**, the asymmetrical stretch $\nu_{as}(N_3)$ appears as strong bands at ca. 2070 and 2041 $cm^{-1}$, which is in good agreement with the existence of terminal and EO bridging azides in **1**; bands of weak intensity at about 1301 and 1284 $cm^{-1}$ can be ascribed to the azide symmetric stretch $\nu_s(N_3)$. Very strong bands corresponding to the characteristic $\nu_{as}$ of the azido ligands appeared at 2034 $cm^{-1}$ for **3α** and at 2053 $cm^{-1}$ for **3β**. For **2**, the stretching vibration of the $SCN^-$ group appears as a doublet at 2108 and 2058 $cm^{-1}$.

## Crystal Structure

Single-crystal X-ray structure analysis revealed that **1** is a neutral tetranuclear $Ni^{II}$ complex. A perspective view of the core part of **1** with the atom-labeling scheme is shown in Figure 1. Selected metric parameters associated with the nickel(II) center in **1** are given in Table 1. Each asymmetric unit of **1** contains four $Ni^{II}$ atoms, two abpt ligands, one anionic $[abpt\text{-}H]^-$ ligand, five $N_3^-$ ligands, two acetate ligands, and five lattice water molecules. Each $Ni^{II}$ atom is in a distorted octahedral $[NiN_5O]$ environment, of which the coordination sphere for Ni1 or Ni2 is formed by two pyridyl N atoms, one triazole N atom, one azide N atom, one amine N atom, and one acetate O atom [Ni–N = 2.001(3)–2.166(3), Ni–O = 2.050(3) and 2.052(2) Å, *cis* N–Ni–N/O = 77.53(12)–103.06(12)°, *trans* N–Ni–N/O = 166.59(12)–176.55(13)°], while the coordination sphere for Ni3 or Ni4 is formed by one pyridyl N atom, one triazole N atom, three azide N atoms, and one acetate O atom [Ni–N = 2.062(4)–2.179(3), Ni–O = 2.047(3) and 2.053(3) Å, *cis* N–Ni–N/O = 76.55(12)–105.20(12)°, *trans* N–Ni–N/O = 167.27(12)–173.10(13)°]. The Ni1 and Ni2 are triply bridged by one μ-amino [Ni–$N_{amino}$–Ni = 97.74(14)°], one $\mu_{1,1}$-azide [Ni–$N_{azide}$–Ni = 88.92(12)°], and one μ-carboxylate-O,O′ with the Ni···Ni distance of 3.0253(8) Å and the Ni3 and Ni4 are triply bridged by two $\mu_{1,1}$-azides [Ni–$N_{azide}$–Ni = 95.74(13) and 98.39(15)°] and one μ-carboxylate-O,O′ with the Ni···Ni distance of 3.138(1) Å. The Ni1 and Ni4/Ni2 and Ni3 are each singly triazole-bridged with the Ni···Ni

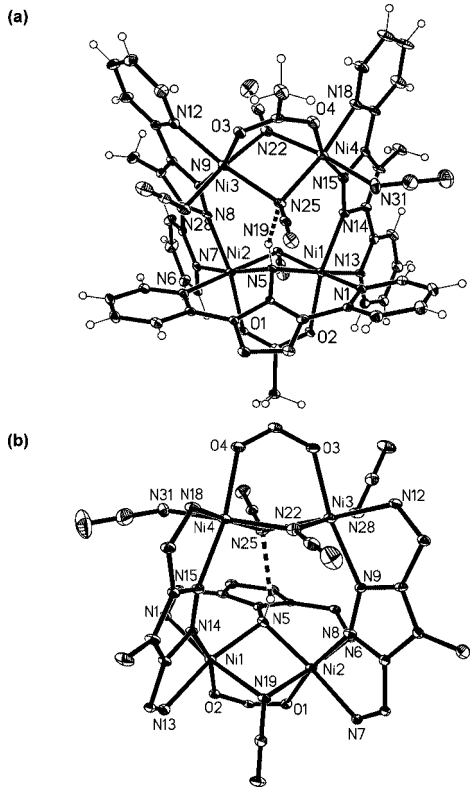


Figure 1. ORTEP plots of the molecular structure (a) and the connectivity pattern (b) in **1**. The methyl group and some of the carbon atoms of the pyridyl groups are omitted for clarity. 50% thermal ellipsoids are shown.

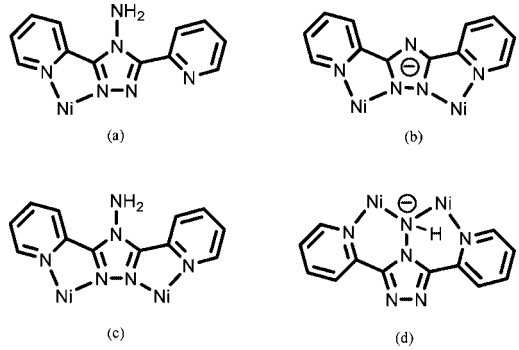
separations of 4.578(1) and 4.6680(9) Å, respectively. A rectangle box is formed through these bridges. It is noteworthy that the dihedral angles between the coordinated pyridyl groups and the triazolato ring for the abpt and [abpt-H]$^-$ motifs are quite different. They are 24.5 and 25.2° for the anionic noncoplanar [abpt-H]$^-$ ligand, 2.3 and 22.1° for one half coplanar abpt ligand, and 6.1 and 7.0 ° for another coplanar abpt ligand, implying that there are different magnetic exchanges via the coplanar abpt, half-coplanar abpt and noncoplanar [abpt-H]$^-$ bridges. A recently reported example related to **1** was found in a tetranuclear nickel(II) rectangle box in which the long edges are spanned by the pyrazolate and each short edge is spanned by an acetate and a $\mu_{1,1}$ azide. The resulting rectangle was further capped by a $\mu_{1,1,3,3}$ bridging ligand.[7]

It is noteworthy that **1** is the first structurally characterized polynuclear cluster of the anionic [abpt-H]$^-$ ligand, in which the deprotonated 4-amino group, rather than N1 of the triazole ring, is coordinated to the Ni$^{II}$ ion, and the deprotonated amino group of the [abpt-H]$^-$ acts as a μ-bridge, and the resulting anionic [abpt-H]$^-$ ligand adopts an unprecedented $\mu:\eta^1:\eta^2:\eta^1$ coordination mode (Scheme 2d). Although the anionic [abpt-H]$^-$ form was previously found in [Rh$^I$(abpt-H)(diolefin)] (diolefin = 1,5-cyclooctadiene, 2,3-(tetrafluorobenzo)bicyclo[2.2.2]octatriene, or bicyclo-[2.2.1]heptadiene) based mainly on spectroscopic data[8a] and recently structurally characterized in [Rh(phen)$_2$(abpt-H)](PF$_6$)$_2$,[8b] it only plays a chelating role via the imine nitrogen and a pyridine nitrogen. The deprotonated amino group is also stabilized by a moderate N–H···N$_{azide}$ hydrogen bond [N···N = 2.871(4) Å, N–H···N$_{azide}$ = 148(3)°].



Scheme 2. Coordination modes of abpt (*a*, *c*), bpt-H (*b*), and abpt-H (*d*) in **1**, **2**, **3α**, and **3β**.

Compound **2** is a neutral centrosymmetric dinuclear Ni$^{II}$ complex (Figure 2a). Each asymmetric unit of **2** contains one Ni$^{II}$ atom, one anionic [bpt-H]$^-$ ligand, one SCN$^-$ ligand, one aqua ligand, and one lattice water molecule. The Ni$^{II}$ atom is in a distorted octahedral [NiN$_5$O] environment. The four basal nitrogen atoms coordinated to the Ni$^{II}$ atom belong to the pyridyl [N1 and N4a] and triazole [N2 and N3a] groups of two [bpt-H]$^-$ ligands. The Ni–N$_{pyridyl}$ distances are 2.220(2) and 2.193(2) Å (Table 2), respectively, which is slightly longer than those found in **1**; the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Ni–$N_{triazole}$ distances are 2.014(2) and 2.018(2) Å, respectively, which is shorter than those [2.110(3)–2.179(3) Å] found in **1**. The axial positions are occupied by one monodentate coordinating $SCN^-$ anion [Ni–N6 = 2.044(3) Å] and one aqua ligand (Ni–O1w = 2.062(2) Å]. The dihedral angles between the coordinated pyridyl groups and the triazolato ring are 3.0 and 4.8°, respectively. It is noteworthy to mention that recently most of the discrete and polymeric metal complexes of $[bpt\text{-}H]^-$ have been structurally characterized,[9] which probably contributes to the fact that the hydro(solvo)thermal method was widely adopted in the preparations of new metal–organic frameworks in the past decade.[10] It is also interesting that the aqua ligands and the lattice water molecules form hydrogen-bonded cyclic water tetramers [O···O = 2.729(3) and 2.755(3) Å; O–H···O = 158(4) and 169(3)°], $(H_2O)_4$ with graph set notation of $R_4^2(8)$. Theoretical studies on the basis of ab initio electronic structure calculations predicted that the cyclic $(H_2O)_4$ clusters have several configurations, $R_4^4(8)$-types of $D_{2h}$, $C_4$, or $S_4$ symmetry and $R_4^3(8)$-type of $C_s$ symmetry and most of them have widely been found in metal–organic frameworks and organic hosts.[11a,11b] The rare $R_4^2(8)$-type cyclic $(H_2O)_4$ tetramer was very recently found in an organic host.[11c] Each $(H_2O)_4$ tetramer in **2** is surrounded by four dinuclear species and each dinuclear species is surrounded accordingly by four $(H_2O)_4$ tetramers via the Ni–O coordination and O–H···N hydrogen-bonding interactions (Figure 2b).

Both **3α** and **3β** are neutral centrosymmetric mononuclear $Ni^{II}$ complexes. Their coordination geometries are quite similar. Each asymmetric unit of **3α** and **3β** contains one-half of a $Ni^{II}$ atom, which lies on an inversion center, one abpt ligand, and one $N_3^-$ ligand. The $Ni^{II}$ atom is coordinated in a distorted octahedral $[NiN_6]$ environment. The four equatorial nitrogen atoms coordinated to the $Ni^{II}$ atom belong to the pyridyl [N1 and N1a] and triazole [N2 and N2a] groups of two abpt ligands. The Ni–$N_{pyridyl}$ distance is 2.101(2) and 2.101(3) Å for **3α** and **3β**, respectively (Tables 3 and 4), which is slightly longer than those found in **1**; the Ni–$N_{triazole}$ distances are 2.039(2) and 2.053(3) Å for **3α** and **3β**, respectively, which is shorter than those [2.110(3)–2.179(3) Å] found in **1**. The remaining two *trans*

positions are occupied by symmetry-related monodentate $N_3^-$ anions [Ni–N7 2.126(2) and 2.126(3) Å for **3α** and **3β**, respectively]. The dihedral angles between the coordinated pyridyl groups and the triazolato rings are 5.2(4) and 6.7(5)° for **3α** and **3β**, respectively, while those between the noncoordinating pyridyl groups and the triazolate rings are 7.1(4) and 10.2(5) ° for **3α** and **3β**, respectively. There exists intramolecular moderate N–H···N hydrogen bonding interactions between the amine groups and the noncoordinating pyridyl groups [for **3α**: N6···N4 = 2.848(2) Å; N6–H6a···N4 = 141(2)°; for **3β**: N6···N4 = 2.863(5) Å; N6–H4a···N4 = 122(7)°]. What interested us was that the orientations of the linear azide motifs in **3α** and **3β** are quite different, as shown in Figures 3a and 4a. In **3α**, the linear azide motifs run approximately parallel to the long sides of the abpt ligands, while in **3β** the linear azide motifs are approximately perpendicular to the long side of the abpt ligands. Although adjacent monoclinic $[Ni(abpt)_2(N_3)_2]$ motifs are extended via the N–H···$N_{azide}$ [N6···N9$^i$ = 2.966(3) Å, N6–H6b···N9$^i$ = 170(2)° for **3α**; N6···N9$^j$ = 3.095(7) Å, N6–H6b···N9$^j$ = 153(6)° for **3β**; symmetry codes: $i = x, y - 1, z$; $j = x, y, z - 1$] into 1D supramolecular double-stranded chains (Figures 3b and 4b), the dimensions of the cavities in 1D hydrogen-bonded chains of **3α** and **3β** are different. Particularly, the 1D chains are further extended by the nonclassical C–H···N hydrogen bonding (for **3α**: C···N = 3.442 Å and C–H···N = 150.3°; for **3β**: C···N = 3.508 Å and C–H···N = 142.5°) and offset π–π interactions (3.426–3.467 Å) into different 2D molecular layers in **3α** and **3β** (Figure 3c and 4c), and finally resulting in different 3D molecular packings in two polymorphous species. It should be noted that **3α** and **3β** represent a new interesting example showing temperature-induced polymorphism, which was observed in the case of molecular crystals of organic compounds, hydrogen bonded frameworks, and metal complexes such as L-glutamic acid, terpyridine, and $[Cu(Ph_2SNH)_4][PF_6]_2$.[12]

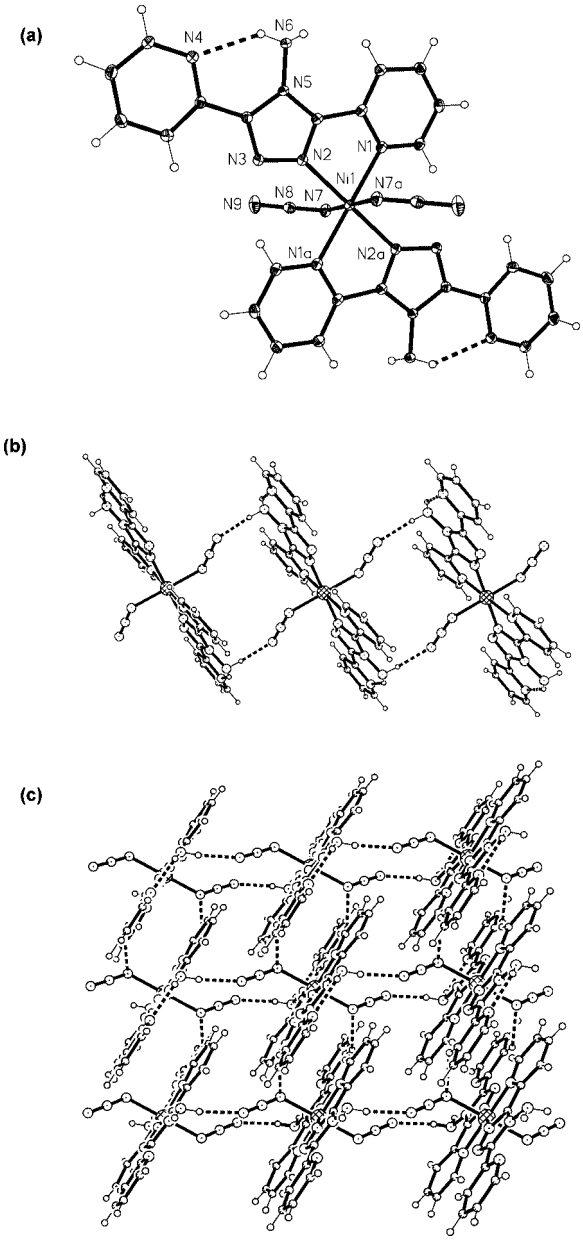

Figure 3. ORTEP plot of the coordination geometry of **3α** (a), the 1D hydrogen-bonded chain (b), and the extension of the 1D chains into 2D molecular layer by interchain π–π and C–H···N interactions in **3α**. 50% thermal ellipsoids are shown.

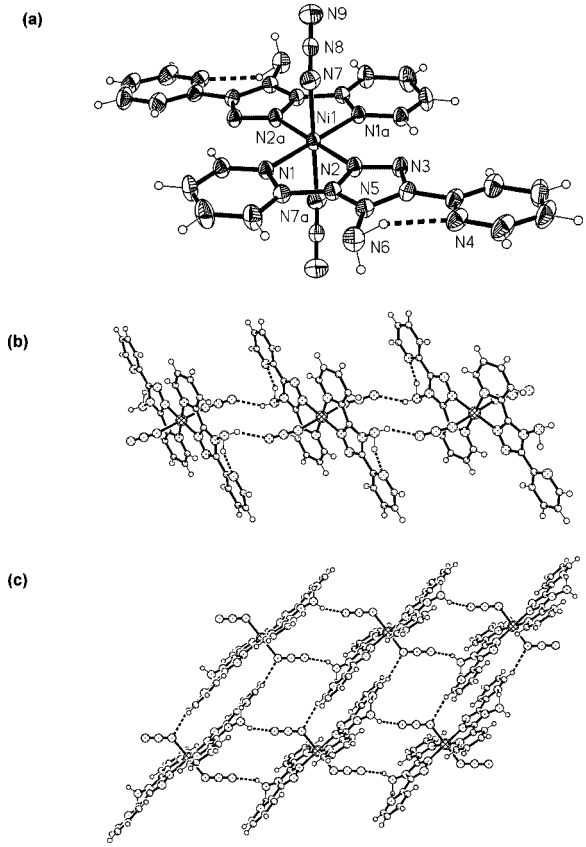

Figure 4. ORTEP plot of the coordination geometry of **3β** (a), the 1D hydrogen-bonded chain (b), and the extension of the 1D chains into 2D molecular layer by interchain π–π and C–H···N interactions in **3β**. 50% thermal ellipsoids are shown.

### Magnetic Properties

Magnetic susceptibility data were measured with polycrystalline samples of **1** and **2** in 1.0 KG field over the temperature range of 2–300 K.

For **1**, from room temperature down to 35 K, the $\chi_m T$ product increases continuously and reaches a maximum with 6.56 emu K mol$^{-1}$ (Figure 5). This behavior is indicative of an overall ferromagnetic coupling between the Ni$^{II}$ centers and the low temperature decrease is due to a strong zero-field splitting (ZFS) and/or the presence of a single antiferromagnetic interaction between two of the four Ni$^{II}$ centers. The magnetic data were analyzed with the spin Hamiltonian in Equation (1).

$$\hat{H} = -2J_1\hat{S}_1\hat{S}_2 - 2J_2\hat{S}_2\hat{S}_3 - 2J_3\hat{S}_3\hat{S}_4 - 2J_4\hat{S}_1\hat{S}_4 + D\left(\hat{S}_{z1}^2 + \hat{S}_{z2}^2 + \hat{S}_{z3}^2 + \hat{S}_{z4}^2\right) \quad (1)$$

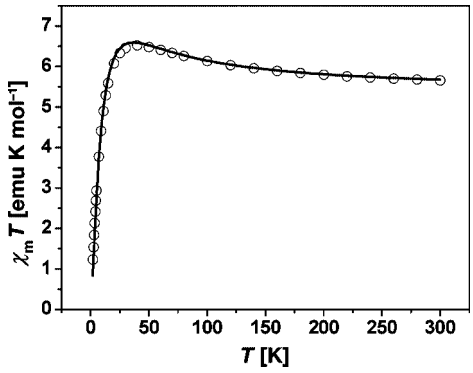

Figure 5. Plot of $\chi_M T$ vs. $T$ for **1**. Solid lines represent the best fit with the parameters given in the text.

Calculations were performed with the magnetism package MAGPACK.[13] The first best fit that was obtained from a least-squares analysis of the $\chi_m T$ implies a very big $D$ value ($D$ = 23.8 cm$^{-1}$) and unrealistic exchange parameters are $J_1$ = 2.37 cm$^{-1}$, $J_2$ = 4.84 cm$^{-1}$, $J_3$ = 15.7 cm$^{-1}$, $J_4$ = –3.95 cm$^{-1}$, and $g$ = 2.31 ($R = 7.5 \times 10^{-4}$). This solution was discarded. In order to reduce the number of parameters, we assumed that the two exchange parameters associated to the azide bridge were equal ($J_1 = J_3$) and the other two exchange parameters associated to the abpt bridge were also equal ($J_3 = J_4$). The best fit implies a zero ZFS and the parameters are $J_1 = J_3$ = 15.3 cm$^{-1}$, $J_2 = J_4$ = –2.2 cm$^{-1}$, and $g$ = 2.32. According to this calculation it is found that the ground state is $S$ = 0. Compared with those reported in our recently reported hexanuclear Ni$_6$ circle and other related species,[6] the ferromagnetic interactions ($J_1$ and $J_3$) can be assigned to the exchange pathway through the ($\mu_{1,1}$-N$_3$)$_2$(μ-OAc) and ($\mu_{1,1}$-N$_3$)($\mu_{1,1}$-N$_{abpt-H}$)(μ-OAc) bridges. The other two antiferromagnetic interactions can be assigned to the remaining exchange pathways indifferently, which is consistent with the results of X-ray structural analysis. In the future, more compounds of closely related, but significantly different, structures will be needed together with detailed magnetic studies and independent information (ab initio calculations) for a better understanding of magnetic superexchange in this type of compound.

For **2**, the magnetic data (Figure 6) were analyzed with the following spin Hamiltonian: $H = -2JS_1S_2$ ($S_1 = S_2$ = 1). From this Hamiltonian, the equation of magnetic susceptibility can be derived as $\chi = (Ng^2\beta^2/kT)[(5 + e^{4x})/(5 + 3e^{4x} + e^{6x})]$,[3a] in which $N$, β, and $k$ are fundamental constants, $g$ and $J$ are adjustable parameter, and $x = -J/kT$. The obtained parameters were fitted to be $J$ = –17.62 cm$^{-1}$ and $g$ = 2.19 ($R = 5.1 \times 10^{-4}$). The sign of $J$ in **2** is consistent with the antiferromagnetic $J_2$ and $J_4$ coupling via the abpt bridge in **1**.

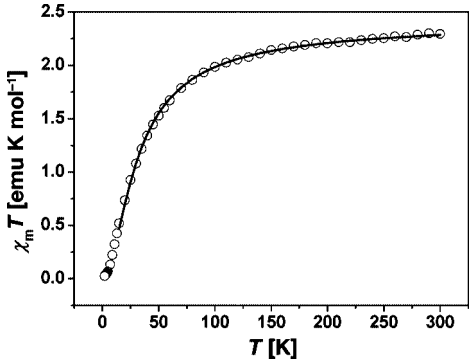

Figure 6. Plot of $\chi_M T$ vs. $T$ for **2**. Solid lines represent the best fit with the parameters given in the text.

## Conclusions

In this study, we present new reactivity of 4-amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole to generate a novel tetranuclear nickel(II) rectangle box, a neutral dinuclear species, and a mononuclear species with two polymorphous phases. The μ:η$^1$:η$^2$:η$^1$ coordination mode of the deprotonated [abpt-H]$^-$ ligand in the tetranuclear nickel(II) rectangle box is for the first time observed; the anionic ligand (bpt-H) in the dinuclear nickel(II) complex was generated in situ and resulted from Ni$^{II}$-assisted deamination. The mononuclear complex represents a new interesting example showing temperature-induced polymorphism. Temperature-dependent magnetic studies revealed the presence of moderate antiferromagnetic coupling via the double μ-abpt bridges in dinuclear complex and the presence of both weak antiferromagnetic coupling via the single μ-abpt bridges and ferromagnetic coupling through the ($\mu_{1,1}$-N$_3$)$_2$(μ-OAc) and ($\mu_{1,1}$-N$_3$)($\mu_{1,1}$-N$_{abpt-H}$)(μ-OAc) bridges, all of which gives an overall ferromagnetic coupling in the tetranuclear complex.

## Experimental Section

**General Remarks:** All reagents were obtained from commercial sources and used as received, unless stated otherwise. 4-Amino-3,5-bis(pyridin-2-yl)-1,2,4-triazole (abpt) was synthesized according to the literature procedure.[14] All preparations and manipulations were performed under aerobic conditions. The C and H microanalyses were carried out with a Various EL elemental analyzer.

The FTIR spectra were recorded from KBr pellets in the range 4000–400 cm$^{-1}$ with a Bruker-EQUINOX 55 FTIR spectrometer. Variable-temperature magnetic susceptibility data were obtained from a Quantum Design SQUID MPMS XL-7 magnetometer. The diamagnetism of the sample and sample holder were taken into account and its contributions to the susceptibility were corrected using Pascal's constants. The effective molar magnetic moments were calculated with the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$.

**$[Ni_4(abpt)_2(abpt\text{-}H)(N_3)_5(O_2CMe)_2]\cdot 5H_2O$ (1):** To a methanolic solution (20 mL) of $Ni(O_2CMe)_2\cdot 4H_2O$ (0.120 g, 0.5 mmol) was added a solution of abpt (0.119 g, 0.5 mmol) in the same solvent (20 mL) with magnetic stirring. Once the materials were dissolved, $NaN_3$ (0.036 mg, 0.5 mmol) was slowly added. The resultant mixture was heated at reflux for 5 h and then filtered. The resulting green solution was then maintained undisturbed at ambient temperature. After 7 d, deep green crystals were collected (yield ca. 52% based on abpt). IR (KBr): $\tilde{\nu}$ = 3449 (s), (br), 3070 (m), 2070 (s), 2041 (vs), 1562 (s), 1493 (s), 1463 (s), 1430 (s), 1342 (w), 1301 (w), 1284 (w), 1258 (m), 1159 (w), 1102 (w), 1056 (w), 1015 (m), 799 (s), 751 (m), 695 (m), 641 (m), 607 (w), 467 (w) cm$^{-1}$. $C_{40}H_{45}N_{33}Ni_4O_9$ (1366.85): calcd. C 35.25, H 3.32, N 33.82; found C 35.02, H 3.25, N 33.69.

**$[Ni_2(bpt\text{-}H)_2(SCN)_2(H_2O)_2]\cdot 2H_2O$ (2):** A mixture of abpt (0.056 g, 0.25 mmol) and KNCS (0.186 g, 1.0 mmol) were added to a water/ethanol solution (1:1, 15.0 mL) of $NiCl_2\cdot 6H_2O$ (0.082 g, 0.33 mmol) and stirred. The resultant mixture was heated in a stainless steel reactor with a Teflon liner at 150 °C for 72 h. After a period of approximately 14 h cooling to room temp., green block-like crystals were obtained, isolated simultaneously by filtration, and washed with water (yield: 29%). IR (KBr): $\tilde{\nu}$ = 3745 (m), 3343 (w), 3071 (m), 2934 (m), 2358 (m), 2108 (m), 2058 (s), 1608 (s), 147 (m), 1415 (m), 1267 (m), 1152 (s), 1050 (m), 777 (s), 731 (m), 633 (s) cm$^{-1}$. $C_{26}H_{24}N_{12}Ni_2O_4S_2$: calcd. C 41.64, H 3.23, N 22.41; found C 41.25, H 3.10, N 22.32.

**α-$[Ni(abpt)_2(N_3)_2]$ (3α):** The synthetic method was similar to that of **1** by using 1:2:2 molar ratio of $Ni^{2+}$/abpt/$N_3^-$ (yield 65%). IR (KBr): $\tilde{\nu}$ = 3331 (m), 3204 (s), 3116 (m), 2034 (s), 1639 (s), 1605 (s), 1590 (s), 1569 (s), 1491 (s), 1456 (s), 1426 (s), 1302 (s), 1254 (s), 1167 (s), 1047 (m), 1015 (s), 976 (s), 785 (s), 745 (s), 697 (s) cm$^{-1}$. $C_{24}H_{20}N_{18}Ni$: calcd. C 46.55, H 3.26, N 40.71; found C 46.42, H 3.20, N 40.53.

**β-$[Ni(abpt)_2(N_3)_2]$ (3β):** A mixture of abpt (0.120 g, 0.5 mmol) and $NaN_3$ (0.036 g, 0.5 mmol) were added to an aqueous solution (15.0 mL) of $Ni(O_2CMe)_2\cdot 4H_2O$ (0.060 g, 0.25 mmol) and stirred. The resultant mixture was heated in a stainless steel reactor with a Teflon liner at 130 °C for 72 h. After a period of approximately 14 h cooling to room temp., green block-like crystals were obtained (yield: 21%). IR (KBr): $\tilde{\nu}$ = 3337 (m), 3223 (s), 3128 (m), 2053 (s), 1638 (s), 1613 (s), 1578 (s), 1557 (s), 1487 (s), 1498 (s), 1426 (s), 1302 (s), 1258 (s), 1188 (s), 1060 (m), 1025 (s), 998 (s), 774 (s), 765 (s), 666 (s), 601 (s), 426 (s) cm$^{-1}$. $C_{24}H_{20}N_{18}Ni$: calcd. C 46.55, H 3.26, N 40.71; found C 46.47, H 3.22, N 40.36.

***Safety Note:*** *Azide salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared and these should be handled with great caution.*

**X-ray Crystallographic Study:** Diffraction intensities of **1**, **2**, **3α**, and **3β** were collected with a Bruker Apex CCD area-detector diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). For data reduction the "Bruker Saint Plus" program was used.[15] Data were corrected for Lorentz and polarization effects; empirical absorption correction was applied by using multiscan program SADABS.[16] The structures were solved with direct methods and refined with a full-matrix least-squares technique with the SHELXTL programs.[17] Non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms for the carbon atoms were calculated assuming ideal geometries, while those for the amino, imino groups, and water molecules are located from the difference Fourier map and refined with isotropic temperature factors. A summary of the data collection and structure refinement information is provided in Table 5. Drawings were produced with SHELXTL.[18]

CCDC-285539 (for **1**), -285540 (for **2**), -294286 (for **3α**), and -294287 (for **3β**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Phosphane and Phosphite Unsymmetrically Disubstituted Diiron Complexes Related to the Fe-Only Hydrogenase Active Site

**Ping Li,[a] Mei Wang,*[a] Chengjiang He,[a] Xiaoyang Liu,[a,b] Kun Jin,[a] and Licheng Sun*[a,c]**

**Keywords:** Bioinorganic chemistry / Carbonyl displacement / Diiron complexes / Fe-only hydrogenase / P ligands

A series of unsymmetrically disubstituted diiron complexes [(μ-pdt){$Fe(CO)_2L^1$}{$Fe(CO)_2L^2$}] [pdt = 1,3-propanedithiolato; $L^1 = PMe_3$, $L^2 = PMe_2Ph$, **4**; $PPh_3$, **5**; $PCy_3$, **6**; $P(OEt)_3$, **7**; $L^1 = PMe_2Ph$, $L^2 = PPh_3$, **8**; $P(OEt)_3$, **9**; $L^1 = P(OEt)_3$, $L^2 = PPh_3$, **10**; $PCy_3$, **11**] and [(μ-edt){$Fe(CO)_2PMe_3$}{$Fe(CO)_2PPh_3$}] (edt = 1,2-ethanedithiolato, **12**) were prepared by means of stepwise CO displacements of [(μ-pdt)$Fe_2(CO)_6$] and [(μ-edt)-$Fe_2(CO)_6$] by different tertiary phosphane and phosphite ligands. The interconversion of the irondithiacyclohexane ring and the rotation of the [$Fe(CO)_2PR_3$] subunit were studied using by variable-temperature $^{31}P\{^1H\}$ NMR spectroscopy of **4**, **6** and **12** in solution. The molecular structures of **4**–**6**, **8**–**10** and **12** show that complexes **4**–**6**, **8**, **9** and **12** possess an apical/basal coordination mode and complex **10** has an apical/apical conformation. The X-ray analyses indicate that the $PMe_2Ph$ ligand in the apical position of the starting complex [(μ-pdt){$Fe(CO)_3$}{$FeCO_2(PMe_2Ph)$}] rotates to the basal position on conversion to the products **8** and **9**. Cyclic voltammograms of **4**–**11** were studied both under argon and CO. The influences of the phosphane and phosphite ligands on the redox properties of the unsymmetrically disubstituted diiron complexes are discussed.

## Introduction

Iron-only hydrogenases with popular metals and simple diatom ligands in their active sites can catalyse the proton reduction to molecular hydrogen more efficiently than other types of hydrogenases. In recent years, synthesis of structural and functional models of the Fe-only hydrogenase active site has been a hot topic in bioinorganic and organometallic chemistry. The well-studied organometallic diiron complex [(μ-pdt)$Fe_2(CO)_6$] (pdt = 1,3-propanedithiolato) serves as a synthetic model of the Fe-only hydrogenase active site in terms of the structure revealed by X-ray crystallographic studies.[1,2] Various good donor ligands, such as $CN^-$,[3–9] $PR_3$,[8–17] CNR[18,19] and NHC (N-heterocyclic carbene)[20,21] have been successfully introduced to the model complexes by CO displacement in order to investigate the electrochemistry and protonation properties of the derivatives. Tertiary phosphane ligands, which can avoid the intricacy of the protonation process on the cyanide nitrogen atom, are widely used in many model complexes of the Fe-only hydrogenase, especially for hydridodiiron dithiolate complexes.[22–24] Although the CO displacement of [(μ-$SR)_2$-$Fe_2(CO)_6$] (R = Me, Et, Ph), [(μ-edt)$Fe_2(CO)_6$] (edt = 1,2-ethanedithiolato), [(μ-pdt)$Fe_2(CO)_6$] and [(μ-adt)$Fe_2(CO)_6$] (adt = 2-azapropane-1,3-dithiolato) by tertiary phosphanes has been extensively studied,[10–17] to the best of our knowledge the model complexes in the form of [(μ-pdt){$Fe(CO)_2$-$L^1$}{$Fe(CO)_2L^2$}] with two different π ligands have been scarcely reported.[10] To continue a systematic study of the influence of phosphane and phosphite ligands on the coordination structures, the reactivity and the redox properties of the iron centres,[15] a series of unsymmetrically disubstituted model complexes [(μ-pdt){$Fe(CO)_2L^1$}{$Fe(CO)_2L^2$}] [$L^1 = PMe_3$, $L^2 = PMe_2Ph$, **4**; $PPh_3$, **5**; $PCy_3$, **6**; $P(OEt)_3$, **7**; $L^1 = PMe_2Ph$, $L^2 = PPh_3$, **8**; $P(OEt)_3$, **9**; $L^1 = P(OEt)_3$, $L^2 = PPh_3$, **10**; $PCy_3$, **11**] and [(μ-edt){$Fe(CO)_2PMe_3$}{$Fe(CO)_2$-$PPh_3$}] (**12**) with two different tertiary phosphane and phosphite ligands were prepared and among them **4**–**6**, **8**–**10** and **12** were crystallographically characterised. Here we describe the preparation, variable-temperature $^{31}P\{^1H\}$ NMR spectra, molecular structures and cyclic voltammograms of diiron complexes unsymmetrically disubstituted by phosphane and phosphite ligands.

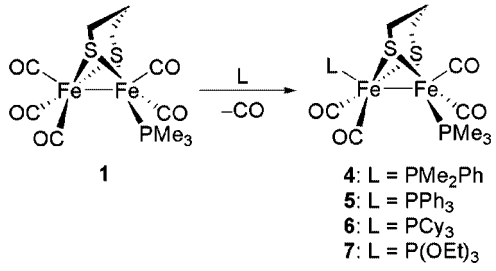
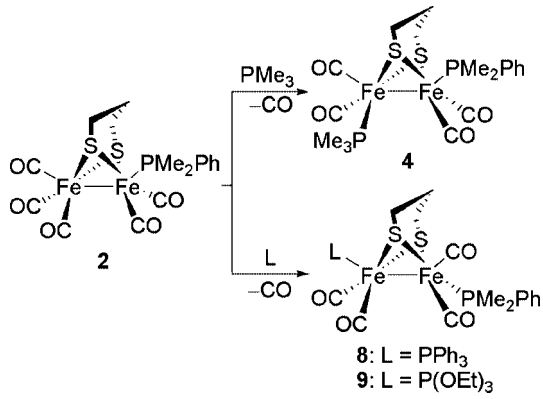
## Results and Discussion

### Preparation and Spectroscopic Characterisation of Complexes 4–12

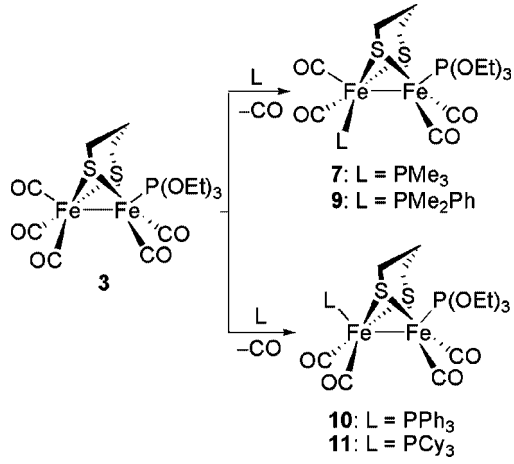
The monosubstituted complexes $[(\mu\text{-pdt})Fe_2(CO)_5L^1]$ [$L^1$ = $PMe_3$, **1**; $PMe_2Ph$, **2**; $P(OEt)_3$, **3**] were prepared in moderate yields according to the previous report.[15] Treatment of **1** with $PMe_2Ph$, $PPh_3$ and $P(OEt)_3$ in toluene at reflux afforded products **4**, **5** and **7**, respectively, in good yields (Scheme 1). Complex **6** could be obtained from **1**, in a moderate yield, in the presence of 1 equiv. of $PCy_3$ using $Me_3NO$ as a CO-removing reagent. The disubstituted complexes **4**, **8** and **9** were obtained in yields of 40–70% by the replacement of CO in **2** with 1 equiv. of the corresponding tertiary phosphane or phosphite ligand in toluene at reflux (Scheme 2). Complexes **7** and **9** could also be prepared by treatment of **3** with a slight excess of $PMe_3$ and $PMe_2Ph$ under the same conditions (Scheme 3). The reaction of complex **3** with 1 equiv. or an excess of $PPh_3$ in toluene at reflux did not afford complex **10**, presumably due to the high activation energy caused by the large bulk and weak donating capability of the $PPh_3$ ligand. Consequently, $Me_3NO$ was used as CO removing reagent to prepare complex **10** (Scheme 3). Although the volume of $PCy_3$ is larger than that of $PPh_3$, complex **11** could be obtained in a good yield from a solution of **3** and 1 equiv. of $PCy_3$ in toluene at reflux. The stronger donating capability of $PCy_3$ benefits the $PCy_3$/CO displacement. Complex **12** was prepared according to a similar procedure used for **5**. The unsymmetrically disubstituted diiron dithiolate complexes **4**–**12** are relatively thermally and air-stable in the solid state.



Scheme 1.



Scheme 2.



Scheme 3.

The products **4**–**12** were characterised by ESI- or APCI-MS, IR, $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy as well as elemental analysis. The results of the elemental analyses for all products are in good agreement with the proposed compositions. The $[M + H]^+$ peaks of all the diiron dithiolates were detected in the mass spectra in ESI- or APCI-positive mode. The disubstituted complexes **4**–**11** each display three $\nu$(CO) bands in the region of 1900–2000 $cm^{-1}$. The IR data of $\nu$(CO) for **4**–**11** are listed in Table 1 together with the

Table 1. A comparison of $\nu$(CO) bands of **1**–**11** and the all-CO parent complex in $CH_3CN$.

| Complex | $L^1$, $L^2$ | $\nu$(CO)/$cm^{-1}$ | $\Delta\nu(CO)_{av}$/$cm^{-1}$[a] |
|---|---|---|---|
| All-CO complex | – | 2074 (m), 2036 (s), 1995 (s) | – |
| **1** | $PMe_3$, – | 2037 (s), 1980 (s), 1919 (m) | 56 |
| **2** | $PMe_2Ph$, – | 2040 (s), 1980 (s), 1921 (m) | 55 |
| **3** | $P(OEt)_3$, – | 2046 (s), 1989 (s), 1936 (m) | 45 |
| **4** | $PMe_3$, $PMe_2Ph$ | 1981 (m), 1943 (s), 1908 (m) | 91 |
| **5** | $PMe_3$, $PPh_3$ | 1985 (s), 1946 (s), 1905 (s) | 90 |

[a] $\Delta\nu(CO)_{av} = [\Sigma\nu(CO)_{all\text{-}CO} - \Sigma\nu(CO)]/3$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$\nu$(CO) data of complexes **1**–**3** and the all-CO complex.[15,25] A comparison of the $\nu$(CO) bands for the three subsets (**1** vs. **4**–**7**, **2** vs. **4**, **8** and **9**, and **3** vs. **7** and **9**–**11**) of complexes **4**–**11** shows that the introduction of the second phosphane and phosphite ligand has a considerable effect on the $\nu$(CO) bands of the diiron complexes. The variation of the $\nu$(CO) bands implies the influence of different tertiary phosphane and phosphite ligands on the electron density of the Fe centres. Compared with the all-carbonyl complex, the average values of the three strong $\nu$(CO) bands are red-shifted by 73–97 $cm^{-1}$ for **4**–**11**. The shift values [$\Delta\nu(CO)_{av}$] are consistent with the electron-donating capabilities of different phosphane and phosphite ligands.

### Variable-Temperature $^{31}P\{^1H\}$ NMR Spectra of Complexes 4, 6 and 12

The variable-temperature $^{31}P\{^1H\}$ NMR spectra of **4**, **6** and the edt-bridged analogue **12** are shown in Figures 1 and 2. Complexes **4** and **6** each display two signals at $\delta$ = 25.5 and 29.6 ppm for **4**, and $\delta$ = 23.3 and 68.1 ppm for **6**, in the $^{31}P\{^1H\}$ NMR spectra at room temperature [Figure 1(a) and (b)]. On lowering the temperature, each $^{31}P\{^1H\}$ NMR signal of complex **4** splits into two resonances ($\delta$ = 26.5, 26.8 for $PMe_3$ and $\delta$ = 32.5, 33.3 ppm for $PMe_2Ph$) at –80 °C [Figure 1(a′) and the inset]. Two resonances for the $PMe_3$ ligand and two broad signals for the $PCy_3$ ligand can be observed for complex **6** at –80 °C [Figure 1(b′)]. The broad resonance of the $PCy_3$ ligand may result from the slow rotation of the bulky $PCy_3$ ligand. The splitting of the $^{31}P\{^1H\}$ NMR signals at low temperature can be attributed to the slowing down of the interconversion of the $FeS_2C_3$ six-membered rings in complexes **4** and **6**. The resonance difference for the $PMe_3$ ligand of **6** ($\delta$ = 2.4 ppm) is apparently larger than that for the splitting of the $PMe_3$ ligand of **4** ($\delta$ = 0.3 ppm), presumably due to the large interaction between the propanedithiolato group and the bulky $PCy_3$ ligands. A similar interconversion of the irondithiacyclohexane rings in the symmetrically $PR_3$-disubstituted diiron complexes has been previously reported by Darensbourg and co-workers.[13,26]

To explore the rotation flexibility of phosphane ligands of the $[Fe(CO)_2PR_3]$ subunit and to avoid the interconversion of the S-to-S bridge, an edt-bridged analogue [(μ-edt){$Fe(CO)_2PMe_3$}{$Fe(CO)_2PPh_3$}] (**12**) was prepared for study by variable-temperature $^{31}P\{^1H\}$ NMR spectroscopy. Complex **12** displays two $^{31}P$ resonances at $\delta$ = 22.7 ppm for $PMe_3$ and $\delta$ = 60.3 ppm for $PPh_3$ at room temperature [Figure 2(top)]. When the measuring temperature was lowered to –80 °C, four $^{31}P$ signals were observed for the edt-bridged diiron complex **12** [Figure 2(bottom)], two strong signals at $\delta$ = 27.3 ppm for $PMe_3$, $\delta$ = 60.7 ppm for $PPh_3$ and two weak signals at $\delta$ = 17.0 ppm for $PMe_3$ and $\delta$ = 59.9 ppm for $PPh_3$. It is noticeable that the large resonance difference (10.3 ppm) between the two $^{31}P$ signals for the $PMe_3$ ligand of **12** can be observed, while the difference for the $PPh_3$ ligand is only 0.8 ppm. A rational explanation for the obtained variable-temperature $^{31}P\{^1H\}$ NMR spectra of **12** is that the splitting of the $^{31}P$ resonances at low temperature is caused by the slowing down of the rotation of the subunit $[Fe(CO)_2PMe_3]$,[13] and the subunit $[Fe(CO)_2PPh_3]$ does not rotate in solution within the range between –80 and 25 °C but maintains its apical position as in the crystalline state. Accordingly, the two strong signals can be attributed to the major apical ($PPh_3$)/basal ($PMe_3$) isomer of **12** and the two weak signals to the ap/ap isomer. The $^{31}P\{^1H\}$ NMR spectra of **12** suggest that the coordination

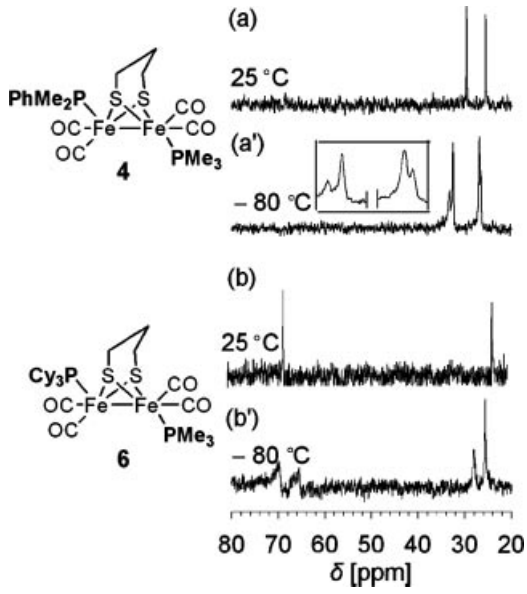

Figure 1. Variable-temperature $^{31}P\{^1H\}$ NMR spectra of **4** and **6** in $CDCl_3$.

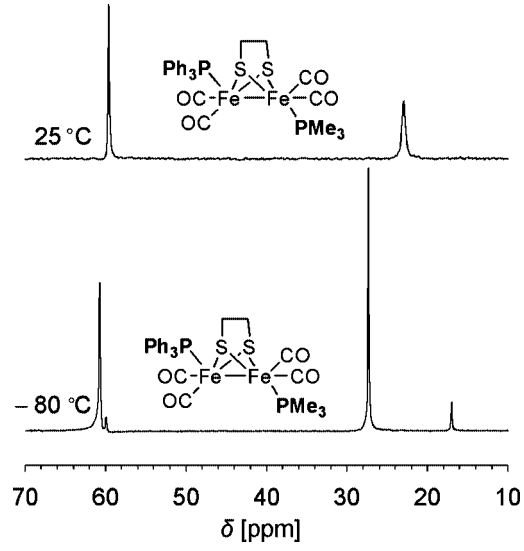

Figure 2. $^{31}P\{^1H\}$ NMR spectra of **12** at variable temperature in $CDCl_3$.

orientation of the $PMe_3$ ligand in the $[Fe(CO)_2PMe_3]$ subunit does not exhibit an apparent effect on the chemical shift of the $PPh_3$ ligand attached to the vicinal iron atom.

### Molecular Structures of Complexes 4–6, 8–10 and 12

Single-crystal X-ray diffraction studies were carried out on complexes **4**–**6**, **8**–**10** and **12** to determine the coordination conformations of the phosphane and phosphite ligands in the diiron complexes. The molecular structures of **4**–**6**, **8**–**10** and **12** are presented in Figure 3 and selected bond lengths and angles are listed in Table 2. The central 2Fe2S cores of complexes **4**–**6**, **8**–**10** and **12** are all in butterfly conformation as for previously reported model complexes[10–15] and each iron atom is coordinated with a distorted square-pyramidal geometry. The vertex carbon atoms of the $FeS_2C_3$ six-membered rings all orient to the phenyl-containing phosphane ligands, either in apical (**4**, **5** and **10**) or in basal (**9**) positions. In contrast, the ellipsoid of the vertex carbon atom C(14) is disordered in the crystalline state of **8** with two phenyl-containing phosphane ligands attached to two iron atoms. The distances of the Fe–Fe bonds in **4**–**6**, **8** and **9** are quite similar (2.534–2.544 Å), while the Fe–Fe bond of **10** [2.5077(5) Å] with an ap/ap conformation is apparently shorter than that of its analogous ap/ba isomers **4**–**6**, **8** and **9**. The Fe–Fe bond [2.5553(4) Å] of the edt-bridged diiron complex **12** is longer than those of the pdt-bridged complexes. The dihedral angle, defined by the S(1)Fe(1)Fe(2) and S(2)Fe(1)Fe(2) planes, increases to 73.30(2)° for **10** featuring two bulky ligands as compared to 70.89(3)° for **4** bearing two small ligands and it increases to 77.72(2)° when the pdt-bridge is replaced by the edt-bridge. The dihedral angle is affected by the steric interactions between the phosphane or phosphite ligand and the S-to-S linker.

The X-ray diffraction analyses clearly show that the conformations of the two coordinating phosphane and phosphite ligands in complexes **4**–**6**, **8**, **9** and **12** are predominantly determined by the relative sizes of the ligands. Complexes **4**–**6**, **8**, **9** and **12** feature an ap/ba conformation in the crystalline state which is a common conformation for double-CO displacement by two non-carbonyl ligands on each iron atom of $[(\mu\text{-pdt})Fe_2(CO)_6]$.[4,9,20] The size of the second phosphane or phosphite ligand determines the orientation of the $PMe_2Ph$ group in complexes **4**, **8** and **9**, which is in the apical position of **4** with $PMe_3$ as its counterpart and in the basal positions of **8** and **9** with $PPh_3$ or $P(OEt)_3$ on the other iron atom. Complex **10** containing two bulky ligands possesses an ap/ap conformation which, to the best of our knowledge, is the first structurally characterised unsymmetrically disubstituted diiron dithiolate complex of the ap/ap conformation except for the symmetrically $PMe_2Ph$-, $PPh_2(BrC_6H_4)$- and CN-*t*-Bu-disubstituted analogues.[15,19,27] Our previous crystallographic studies clarified that the ligand $PMe_2Ph$ in the starting complex **2** is in an apical orientation.[15] The basal position of the $PMe_2Ph$ ligand in **8** and **9** clearly verifies the conformational mobility of the $[Fe(CO)_2PMe_2Ph]$ subunit of the diiron dithiolate model complex in solution.

### Cyclic Voltammograms of Complexes 4–11

The cyclic voltammograms (CVs) of complexes **4**–**11** were studied to evaluate the effects of different phosphane ligands on the redox properties of the iron atoms. Except for **6** and **11**, the CV measurements were carried out in $CH_3CN$ for all complexes. The CVs of complexes **6** and **11** were recorded in toluene/$CH_3CN$ (1:3, v/v) because of the poor solubility of **6** and **11** in $CH_3CN$.

Under argon, complexes **5**, **8** and **10** containing a $PPh_3$ ligand each display two reduction peaks in the range of –1.98 to –2.26 V (vs $Ag/Ag^+$, 0.01 M $AgNO_3$) in their CVs

[Figure 4(a) for **5**] and the other complexes **4**, **6**, **7**, **9** and **11** without $PPh_3$ ligands each show a broad peak including two overlapping reduction events from –2.09 to –2.28 V [Figure 4(b) for **9**]. Considering the small potential differences of the two reduction peaks for each complex, the second reduction peak cannot be attributed to the further reduction process of $Fe^IFe^0$ to $Fe^0Fe^0$. In order to assign the reduction peaks, CVs of **4**–**11** were performed under CO in a CO-saturated $CH_3CN$ solution. As the two sub-groups display similar CVs under CO (complexes with a $PPh_3$ ligand and those without $PPh_3$ ligand), we chose complexes **5** and **9** as examples for comparison of the CVs recorded under argon and under CO (Figure 4). The CVs of other complexes (**4**, **6**–**8**, **10** and **11**) under argon and under CO are given in the Supporting Information.

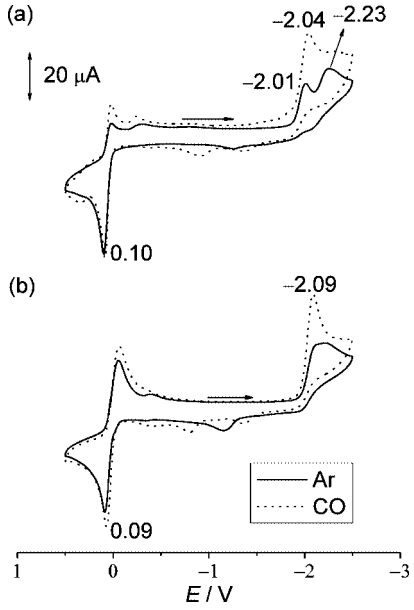

Figure 4. Cyclic voltammograms of complexes **5** (a) and **9** (b) under argon and under CO; 1.0 mM diiron complex, 0.05 M $nBu_4NPF_6$ in $CH_3CN$, scan rate 0.1 V $s^{-1}$.

The current of the first reduction peak at –2.01 V in the CV of **5**, which has been assigned to the $Fe^IFe^I/Fe^IFe^0$ process, increases under CO relative to that detected under argon. In the meantime the current height of the second reduction peak at –2.23 V apparently decreases when compared with that detected under argon. Similarly, the broad reduction peak in the range of –2.0 to –2.5 V for complex **9** under argon changes to a sharp reduction peak at –2.09 V under CO and the more cathodic overlapping peak disappears. The peak at –2.09 V can be attributed to the $Fe^IFe^I/Fe^IFe^0$ process. The different CVs recorded under argon and under CO reminded us of similar changes in the CVs reported for $PMe_2Ph$- and pta- (1,3,5-triaza-7-phosphaadamantane) -monosubstituted complexes[14,15] in which the second peaks detected under argon or $N_2$ may be attributed to a solvent-substituted species resulting from the 19-electron radical anion formed at the first reduction process. Furthermore, it was found that the current height ratio [*i*(I)/*i*(II)] of the two reduction peaks under argon varies with the scan rate. The *i*(I)/*i*(II) ratio increases when the CV is recorded at a higher scan rate. As shown in Figure 5, the values of the *i*(I)/*i*(II) ratios are ca. 1.0, 2.0 and 3.3 at scan rates of 0.1, 0.4 and 1.0 V $s^{-1}$, respectively. The CVs of multiple scans for complex **5** at a scan rate of 4.0 V $s^{-1}$ show that the current height of the second reduction peak apparently increases in the second scan cycle accompanied by a decrease in the height of the first reduction peak (see Supporting Information). After three scan cycles, the current height ratio of the two reduction peaks does not exhibit any observable change. In view of the results of the CO control experiments, the variable scan rate measurements and the CVs of multiple scans, the second reduction peak detected under argon, either as a separated peak for the complex with a $PPh_3$ ligand or as an overlapping peak for the complex without $PPh_3$, is most likely due to the reduction of a new complex, presumably generated by a quick chemical reaction following the first reduction of the diiron(I,I) complex. In comparison, the reported symmetrically disubstituted diiron analogues $[(\mu\text{-pdt})\{Fe(CO)_2L\}_2]$ [L = $PMe_3$, $PMe_2Ph$, $P(OEt)_3$, pta] each exhibit only one reduction peak in the $Fe^IFe^I/Fe^IFe^0$ region of the CVs.[14,15,27] It seems that the reductive $[Fe^IFe^0]$ intermediates formed by the unsymmetrically disubstituted diiron complexes, especially the complexes containing a $PPh_3$ ligand, are less stable than those derived from the symmetrically disubstituted diiron analogues.

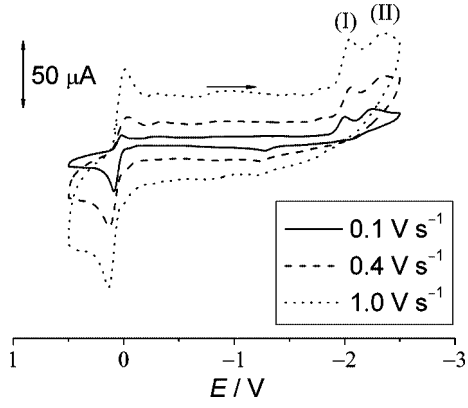

Figure 5. Cyclic voltammograms of complex **5** (1.0 mM) under argon; scan rate 0.1 [*i*(I)/*i*(II) = 1.0], 0.4 [*i*(I)/*i*(II) = 2.0] and 1.0 V $s^{-1}$ [*i*(I)/*i*(II) = 3.3].

The redox potentials under CO for complexes **4**–**11** are listed in Table 3. The anodic peaks at –0.02 to +0.21 V have been assigned to the first oxidation process of $Fe^IFe^I$ to $Fe^{II}Fe^I$ as described in the literature.[28] Complexes **6**, **7** and **9**–**11** exhibit quasi-reversible oxidation peaks, while **4**, **5** and **8** display irreversible peaks for the first oxidation process. It is interesting to notice that the $P(OEt)_3$ and $PCy_3$ ligands show a certain capability to stabilise the $Fe^{II}Fe^I$ species formed in the first oxidation process. This phenomenon was also observed in the CVs of the previously prepared

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$P(OEt)_3$ and $PMe_2Ph$ symmetrically disubstituted complexes.[15] The $Fe^IFe^I$ to $Fe^{II}Fe^I$ oxidative peak was quasi-reversible for $[(\mu\text{-pdt})\{Fe(CO)_2P(OEt)_3\}_2]$ and totally irreversible for $[(\mu\text{-pdt})\{Fe(CO)_2PMe_2Ph\}_2]$. The redox potentials of **4**–**11** are consistent with the electron-donating capabilities of the phosphane and phosphite ligands. Complex **6** containing $PMe_3$ and $PCy_3$ displays the most negative redox potentials, –0.02 V for the oxidation process of $Fe^IFe^I$ to $Fe^{II}Fe^I$ and –2.15 V for the $Fe^IFe^I$ to $Fe^IFe^0$ process. In contrast, complex **10** featuring $P(OEt)_3$ and $PPh_3$ shows the most positive redox potentials, +0.21 V for the oxidation process of $Fe^IFe^I$ to $Fe^{II}Fe^I$ and –1.98 V for the $Fe^IFe^I$ to $Fe^IFe^0$ process. In general, the variations in the redox potentials by changing phosphane and phosphite ligands are ca. 230 mV for the first oxidation process and ca. 170 mV for the first reduction process.

Table 3. Redox potentials of complexes **4**–**11**.[a]

| Complex | $L^1$, $L^2$ | $E_{pa}$/V $Fe^IFe^I/Fe^{II}Fe^I$ | $E_{pc}$/V $Fe^IFe^I/Fe^IFe^0$ |

| **9** | $PMe_2Ph$, $P(OEt)_3$ | +0.09 | –2.09 |
| **10** | $P(OEt)_3$, $PPh_3$ | +0.21 | –1.98 |
| **11**[b] | $P(OEt)_3$, $PCy_3$ | +0.14 | –2.14 |

[a] $nBu_4NPF_6$ (0.05 M) in a CO-saturated $CH_3CN$ solution under CO; scan rate: 0.1 $V s^{-1}$; working electrode: glassy carbon electrode of diameter 3 mm; reference electrode: non-aqueous $Ag/Ag^+$ electrode (0.01 M $AgNO_3$ in $CH_3CN$); counter electrode: platinum wire. [b] Data collected in CO-saturated toluene/$CH_3CN$ (1:3, v/v) mixture.

## Conclusions

Nine unsymmetrically disubstituted diiron dithiolate complexes **4**–**12** with various phosphane and phosphite ligands were prepared and well characterised. The rotation of the $[Fe(CO)_2PMe_3]$ subunit can be detected by the variable-temperature $^{31}P\{^1H\}$ NMR spectra of **12**, which also suggest that the $[Fe(CO)_2PPh_3]$ subunit does not rotate in solution in the range between –80 and 25 °C. In the substitution reactions of $[(\mu\text{-pdt})\{Fe(CO)_3\}\{Fe(CO)_2PMe_2Ph\}]$ (**2**) by $PPh_3$ and $P(OEt)_3$, the $PMe_2Ph$ ligand in the apical position of **2** moves to the basal position on formation of the products **8** and **9** and this provides clear evidence for the conformational flexibility of the $[Fe(CO)_2PMe_2Ph]$ subunit in solution. The CVs of complexes **4**–**11** under argon and under CO show that the reductive $[Fe^IFe^0]$ intermediates formed by the unsymmetrically disubstituted diiron complexes are not stable under argon. A considerable part of the $[Fe^IFe^0]$ intermediate is converted to a new complex by a quick chemical reaction which can be suppressed when the CV measurement is carried out under CO. The redox potentials of $PR_3$-disubstituted diiron dithiolate complexes can be adjusted in a range of ca. 200 mV.

## Experimental Section

**General Procedures:** All reactions and operations related to organometallic complexes were carried out under dry oxygen-free dinitrogen using standard Schlenk techniques. Solvents were dried and distilled prior to use according to the standard methods. Commercially available chemicals, 1,3-propanedithol, $Fe(CO)_5$ and all tertiary phosphanes and phosphite compounds were reagent grade and used as received. Compounds $[(\mu\text{-pdt})Fe_2(CO)_5L]$ [L = $PMe_3$, **1**; $PMe_2Ph$, **2** and $P(OEt)_3$, **3**] and $[(\mu\text{-edt})Fe_2(CO)_5PMe_3]$ were prepared according to previously reported procedures.[15,25] Infrared spectra were recorded in $CH_3CN$ solutions with a JASCO FT/IR 430 spectrophotometer. $^1H$ and $^{31}P\{^1H\}$ NMR spectra were recorded with a Varian INOVA 400 NMR spectrometer. Elemental analyses were performed with a Thermoquest-Flash EA 1112 elemental analyser and the mass spectra of the iron complexes were recorded with an HP1100 MSD instrument.

**Synthesis of $[(\mu\text{-pdt})\{Fe(CO)_2PMe_3\}\{Fe(CO)_2L\}]$ [L = $PMe_2Ph$ (4), $PPh_3$ (5), $P(OEt)_3$ (7)]:** Complex **1** (0.43 g, 1.0 mmol) was treated with $PMe_2Ph$ (0.14 g, 1.0 mmol) in toluene (40 mL) at reflux for 5 h. Complex **4** was obtained by column chromatography on neutral alumina with hexane and $CH_2Cl_2$ as gradient eluents. Yield: 0.11 g (40%). $C_{18}H_{26}Fe_2O_4P_2S_2$ (544.2): calcd. C 39.73, H 4.82; found C 39.77, H 4.87. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.68, 7.42 (2 s, 5 H, Ph), 1.87 (s, 6 H, the $CH_3$ of $PMe_2Ph$), 1.67–1.56 (br. m, 6 H, $CH_2CH_2CH_2$), 1.45 (s, 9 H, $PMe_3$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 30.99 ($PMe_2Ph$), 25.89 ($PMe_3$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1981, 1943, 1907 $cm^{-1}$. APCI-MS: $m/z$ = 544.8 $[M + H]^+$. Complex **5** was prepared according to a procedure similar to that of **4**, with $PPh_3$ (0.26 g, 1.0 mmol) as the ligand. Yield: 0.40 g (60%). $C_{28}H_{30}Fe_2O_4P_2S_2$ (668.3): calcd. C 50.32, H 4.52; found C 50.24, H 4.63. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.75, 7.33 (2 s, 15 H, Ph), 1.47 (d, 9 H, $PMe_3$), 1.66–1.12 (br. m, 6 H, $CH_2CH_2CH_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 62.81 ($PPh_3$), 25.66 ($PMe_3$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1985, 1946, 1905 $cm^{-1}$. APCI-MS: $m/z$ = 669.0 $[M + H]^+$. Complex **7** was prepared according to a similar procedure used for **4** but with $P(OEt)_3$ (0.17 g, 1.0 mmol) as the ligand. Yield: 0.36 g (62%). $C_{16}H_{30}Fe_2O_7P_2S_2$ (572.2): calcd. C 33.59, H 5.28; found C 33.71, H 5.18. $^1H$ NMR ($CDCl_3$): $\delta$ = 4.16 (s, 6 H, $OCH_2$), 1.46 (d, 9 H, $PMe_3$), 1.37 [s, 9 H, the $CH_3$ of $P(OEt)_3$], 1.61–1.21 (br. m, 6 H, $CH_2CH_2CH_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 175.38 [$P(OEt)_3$], 27.10 ($PMe_3$) ppm. IR ($CH_3CN$): $\tilde{\nu}$ = CO = 1991, 1949, 1907 $cm^{-1}$. APCI-MS: $m/z$ = 572.8 $[M + H]^+$.

**Synthesis of $[(\mu\text{-pdt})\{Fe(CO)_2PMe_3\}\{Fe(CO)_2PCy_3\}]$ (6):** Complex **6** can be obtained by using $Me_3NO$ as a CO-removing reagent. A solution of complex **1** (0.43 g, 1.0 mmol) in $CH_3CN$ (10 mL) was treated with $Me_3NO{\cdot}2H_2O$ (0.11 g, 1.0 mmol) at 50 °C for 30 min and $PCy_3$ (0.28 g, 1.0 mmol) was then added to the solution. The mixture was stirred for 1 h and the resultant solution concentrated to dryness under vacuum. The crude product was purified by flash column chromatography on neutral alumina with hexane/$CH_2Cl_2$ (1:1) as eluent. Yield: 0.15 g (22%). $C_{28}H_{48}Fe_2O_4P_2S_2$ (686.42): calcd. C 48.99, H 7.05; found C 48.93, H 6.94. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.47 (s, 9 H, $PMe_3$), 2.12–1.29 (br. m, 39 H, $CH_2CH_2CH_2$ and $PCy_3$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 68.54 ($PCy_3$), 23.49 ($PMe_3$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1976, 1937, 1901 $cm^{-1}$. ESI-MS: $m/z$ = 687.0 $[M + H]^+$.

**Synthesis of $[(\mu\text{-pdt})\{Fe(CO)_2(PMe_2Ph)\}\{Fe(CO)_2L\}]$ [L = $PPh_3$ (8), $P(OEt)_3$ (9)]:** Triphenylphosphane (0.26 g, 1.0 mmol) was added to a solution of complex $[(\mu\text{-pdt})Fe_2(CO)_5(PMe_2Ph)]$ (**2**) (0.50 g, 1.0 mmol) in toluene (40 mL). The solution was heated to reflux with stirring for 5 h, and the colour turned deep red. After the solution was concentrated by solvent evaporation under vac-

uum, the crude product was purified by column chromatography on neutral alumina with hexane/$CH_2Cl_2$ (2:1) as eluent. Product **8** was obtained by cooling the concentrated hexane/$CH_2Cl_2$ solution to –20 °C. Yield: 0.51 g (69%). $C_{33}H_{32}Fe_2O_4P_2S_2$ (730.4): calcd. C 54.27, H 4.42; found C 54.20, H 4.45. $^1$H NMR ($CDCl_3$): $\delta$ = 7.72, 7.39 (2 br. s, 20 H, Ph), 1.79 (d, 6 H, the $CH_3$ of $PMe_2Ph$), 1.48–1.26 (br. m, 6 H, $CH_2CH_2CH_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 62.95 ($PPh_3$), 32.98 ($PMe_2Ph$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1982, 1946, 1913 cm$^{-1}$. APCI-MS: *m*/*z* = 731.0 [M + H]$^+$. Complex **9** was prepared according to a similar procedure used for **8** or by using complex **2** as a starting compound. The reaction of **2** (0.50 g, 1.0 mmol) with $P(OEt)_3$ (0.17 g, 1.0 mmol) was carried out in toluene. Yield: 0.40 g (64%). $C_{21}H_{32}Fe_2O_7P_2S_2$ (634.2): calcd. C 39.77, H 5.09; found C 39.77, H 5.15. $^1$H NMR ($CDCl_3$): $\delta$ = 7.62, 7.38 (2 s, 5 H, Ph), 4.10 (s, 6 H, $OCH_2$), 1.77 (s, 6 H, the $CH_3$ of $PMe_2Ph$), 1.32 [s, 9 H, the $CH_3$ of $P(OEt)_3$], 1.52–1.20 (br. m, 6 H, $CH_2CH_2CH_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 175.15 [$P(OEt)_3$], 34.38 ($PMe_2Ph$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1991, 1952, 1922 cm$^{-1}$. ESI-MS: *m*/*z* = 634.8 [M + H]$^+$.

**Synthesis of [(μ-pdt){Fe(CO)$_2$P(OEt)$_3$}{Fe(CO)$_2$L}] [L = PPh$_3$ (10), PCy$_3$ (11)]:** A solution of [(μ-pdt)$Fe_2(CO)_5P(OEt)_3$] (**3**) (0.52 g, 1.0 mmol) in $CH_3CN$ (15 mL) was treated with $Me_3NO{\cdot}2H_2O$ (0.11 g, 1.0 mmol) at room temperature. The red solution was stirred for 15 min and turned dark red. Triphenylphosphane (0.26 g, 1.0 mmol) was added to the mixture in one portion with stirring. The reaction mixture was stirred for 20 min, and the resultant solution was concentrated to dryness under vacuum. The crude product was purified by flash column chromatography on neutral alumina with hexane/$CH_2Cl_2$ (1:1) as eluent. Product **10** was obtained by cooling the concentrated hexane/$CH_2Cl_2$ solution to –20 °C. Yield: 0.54 g (72%). $C_{31}H_{36}Fe_2O_7P_2S_2$ (758.4): calcd. C 49.10, H 4.78; found C 49.12, H 4.89. $^1$H NMR ($CDCl_3$): $\delta$ = 7.74, 7.41 (2 s, 15 H, Ph), 4.15 (s, 6 H, $OCH_2$), 1.55 (br. s, 6 H, $CH_2CH_2CH_2$), 1.35 [s, 9 H, $CH_3$ of $P(OEt)_3$] ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 175.00 [$P(OEt)_3$], 64.19 ($PPh_3$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1997, 1955, 1934 cm$^{-1}$. ESI-MS: *m*/*z* = 759.1 [M + H]$^+$. Complex **3** (0.52 g, 1.0 mmol) was treated with $PCy_3$ (0.14 g, 1.0 mmol) in toluene (40 mL) at reflux for 6 h. Complex **11** was obtained by column chromatography on neutral alumina with hexane and $CH_2Cl_2$ as gradient eluents. Yield: 0.51 g (65%). $C_{31}H_{54}Fe_2O_7P_2S_2$ (776.5): calcd. C 47.95, H 7.01; found C 47.68, H 6.94. $^1$H NMR ($CDCl_3$): $\delta$ = 4.18 (s, 6 H, $OCH_2$), 1.38 [s, 9 H, $CH_3$ of $P(OEt)_3$], 2.12–1.29 (br. m, 39 H, $CH_2CH_2CH_2$ and $PCy_3$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 174.77 [$P(OEt)_3$], 69.97 ($PCy_3$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1993, 1943, 1933 cm$^{-1}$. ESI-MS: *m*/*z* = 777.2 [M + H]$^+$.

**Synthesis of [(μ-edt){Fe(CO)$_2$PMe$_3$}{Fe(CO)$_2$PPh$_3$}] (12):** Complex [(μ-edt){$Fe(CO)_2PMe_3$}{$Fe(CO)_3$}] (0.42 g, 1.0 mmol) was treated with $PPh_3$ (0.26 g, 1.0 mmol) in toluene (40 mL) at reflux for 5 h. The workup of complex **12** was similar to that for **5**. Yield: 0.42 g (64%). $C_{27}H_{28}Fe_2O_4P_2S_2$ (654.3): calcd. C 49.56, H 4.31; found C 49.78, H 4.54. $^1$H NMR ($CD_3COCD_3$): $\delta$ = 7.65 (m, 9 H, Ph), 7.50 (s, 6 H, Ph), 1.81 (d, 2 H, $CH_2$), 1.53 (d, 9 H, $PMe_3$), 1.06 (d, 2 H, $CH_2$) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 60.31 ($PPh_3$), 22.68 ($PMe_3$) ppm. IR ($CH_3CN$): $\tilde{\nu}$CO = 1982, 1945, 1907 cm$^{-1}$. APCI-MS: *m*/*z* = 654.9 [M + H]$^+$.

**X-ray Structure Determination of Complexes 4–6, 8–10 and 12:** The single-crystal X-ray diffraction data were collected with an AFE5R Rigaku diffractometer for **4**, **8** and **9** and a Siemens SMART CCD diffractometer for **5**, **6**, **10** and **12**, with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.071073 Å) at 293 K using the $\omega$-2$\theta$ scan mode. Data processing was accomplished with the SAINT processing program.[29] Intensity data for **4**–**6** and **8**–**10** were corrected for absorption using the SADABS program.[30] All structures were solved by direct methods and refined on $F^2$ against full-matrix least-squares methods by using the SHELXTL97 program package.[31] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located by geometrical calculation. Details of crystal data, data collections and structure refinements are summarised in Tables 4 and 5. CCDC-627499 (**4**), -627500 (**5**), -627501 (**6**), -627502 (**8**), -627503 (**9**), -627504 (**10**) and -630623 (**12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrochemical Studies of Complexes 4–11:** Cyclic voltammograms were obtained in a three-electrode cell under argon using a BAS 100B electrochemical workstation. The working electrode was a glassy carbon disk (0.071 cm$^2$) polished with 3 and 1 μm diamond pastes and sonicated for 10 min prior to use. The reference electrode was a non-aqueous Ag/Ag$^+$ (0.01 M $AgNO_3$ in $CH_3CN$) electrode and the counter electrode was a platinum wire. A solution of 0.05 M $n$Bu$_4$NPF$_6$ (Fluka, electrochemical grade) in $CH_3CN$ was used as the supporting electrolyte for complexes **4**, **5** and **7**–**10**. A mixed solution of 0.05 M $n$Bu$_4$NPF$_6$ (Fluka, electrochemical grade) in toluene and acetonitrile (1:3, v/v) was used as supporting electrolyte for complexes **6** and **11** due to its poor solubility in pure $CH_3CN$. Acetonitrile (Aldrich, spectroscopic grade) used for electrochemical measurements was freshly distilled from $CaH_2$ under $N_2$.

**Supporting Information** (see footnote on the first page of this article): Cyclic voltammograms of complexes **4**, **6**–**8**, **10** and **11** under argon and CO, as well as the multiple scans for complex **5** at a scan rate of 4.0 V s$^{-1}$ are included.

# Synthesis, Structure, Protolytic Properties, Alkylating and Cytotoxic Activity of Novel Platinum(II) and Palladium(II) Complexes with Pyrazole-Derived Ligands

**Elzbieta Budzisz,*[a] Magdalena Malecka,[b] Bernhard K. Keppler,[c] Vladimir B. Arion,[c] Grzegorz Andrijewski,[d] Urszula Krajewska,[e] and Marek Rozalski[e]**

**Keywords:** Metal complexes / Platinum / Palladium / Pyrazole ligands / Antitumor agents / Alkylating and cytotoxic activity

Novel platinum(II) and palladium(II) complexes $[PtCl_2(HL^1)]$ (**3a**), $[NH_2(CH_3)_2][PtCl_2(L^1)]$ (**3b**), $[PdCl_2(HL^1)]$ (**4a**), $[NH_2(CH_3)_2][PdCl_2(L^1)]$ (**4b**) and $[PdCl(CH_3CN)(L^1)]$ (**4c**), where $HL^1$ = 4-(2-hydroxybenzoyl)-2-(pyridin-2-yl)-1*H*-pyrazol-3-ol, have been synthesised as potential anticancer compounds. Protonation constants of the ligand were determined by pH-metric titration ($\log K_1 = 7.74 \pm 0.03$; $\log K_2 = 2.85 \pm 0.05$). The solid-state structures of complexes **3b** and **4c** have been determined by X-ray diffraction, showing square-planar coordination geometry of $Pt^{II}$ and $Pd^{II}$ ions. In addition, the compounds have been characterised by IR, $^1H$ NMR and FAB mass spectrometry. The results of preliminary studies on the cytotoxic activity in vitro against HL-60 and NALM-6 leukaemia cell lines are also reported and the $IC_{50}$ values compared with those of the metal-free ligand and cisplatin. Cytotoxic evaluation revealed that $Pt^{II}$ and $Pd^{II}$ complexes were active in the micromolar concentration range.

## Introduction

Cisplatin [diamminedichloroplatinum, *cis*-$PtCl_2(NH_3)_2$] is known as a DNA-modifying agent with strong anticancer potency.[1–3] Despite its wide clinical application, cisplatin causes many serious side effects, such as nephrotoxicity, ototoxicity, peripheral neuropathy and allergy.[4] In addition, the therapeutic efficacy of cisplatin is limited by inherent or treatment-induced resistance of tumour cell subpopulations.[5] Therefore, various platinum(II) and palladium(II) complexes with nitrogen-containing ligands were evaluated in the search for less toxic and more selective anticancer drugs.[6] Simple structural analogues of cisplatin were found to possess no advantages because of similar mechanism of action, structure of DNA adducts, toxicity profile, adverse effects and tumour cross-resistance.[7] Recently, attention has been focused on inert, nonleaving ligands, whose steric and electronic features may affect the mechanism of substitution at the metal centre, DNA binding and drug metabolism. It is believed that complexes containing bulky ligands are kinetically and thermodynamically more stable than simple cisplatin analogues.[8] Taking into account the structural analogy between $Pt^{II}$ and $Pd^{II}$ complexes, a variety of studies on $Pd^{II}$ complexes have been performed, including on their cytotoxicity[9] and antitumour activity.[10–12] Palladium complexes with β-carboline alkaloids,[13–15] pyrazoles[16] and DMSO[17] were tested against solid tumour cell lines, and in some cases exhibited remarkable activity. It was suggested that their biological activity depends on the nature of the ligand, the type of counterion used and the configuration of the complex.[18]

For many years the research in our laboratory has been directed towards the synthesis of chromone (benzo-γ-pyrone) and coumarin (benzo-α-pyrone) derivatives and the study of their reactivity towards nucleophilic reagents containing nitrogen, oxygen, sulfur and carbon.[19] In particular, in protolytic solvents at room temperature chromones have been converted efficiently into enamine-type compounds with a typical lemon-yellow colour.[20,21] The chromones and coumarins react with hydrazines to afford pyr-

azole derivatives.[22] A class of pyrazole-containing palladium(II) complexes has been reported to possess antibacterial,[23] antidepressant,[24] monoamine oxidase inhibiting[25] and antitumour activity.[26,27]

In addition, both type of compounds (chromones and coumarins) exhibit interesting biological properties,[28,29] including anticonvulsant,[30] antimicrobial,[31] spasmolytic,[32] antioxidant[33] and antitumour activities.[34] The metal complexes with coumarin as a ligand reveal anticoagulant action[35,36] and possess antiproliferative activity.[37,38] Notably, complexes with cerium(III), zirconium(IV), copper(II), zinc(II), bismuth(III) and cadmium(II) show pronounced cytotoxic activity in vitro.[39,40] The rare earth metal complexes of coumarin derivatives endowed with anticoagulant and anti-HIV activity were also documented.[41–43] Current efforts are focused on developing metal-based drugs with improved clinical effectiveness, reduced general toxicity and a broader spectrum of activity.

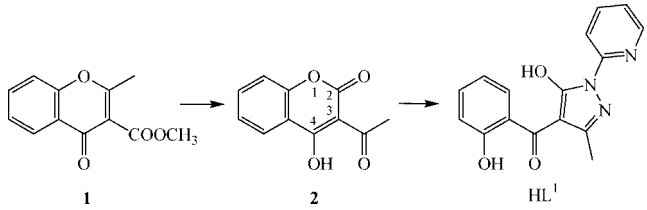
Herein we report the synthesis of a novel pyrazole ligand $HL^1$ by the reaction of coumarin with 2-hydrazinopyridine. Protonation constants of the ligand were determined by pH-metric titration. This ligand, as will be shown below, forms *cis* complexes with platinum(II) and palladium(II), which are often more cytotoxic than the *trans* isomers.[44] The structures of two $Pt^{II}$ and $Pd^{II}$ complexes determined by X-ray diffraction are reported. The results of preliminary studies on the alkylating and in vitro cytotoxic activity against HL-60 and NALM-6 leukaemia cell lines are also discussed.

## Results and Discussion

### Preparation of the Ligands

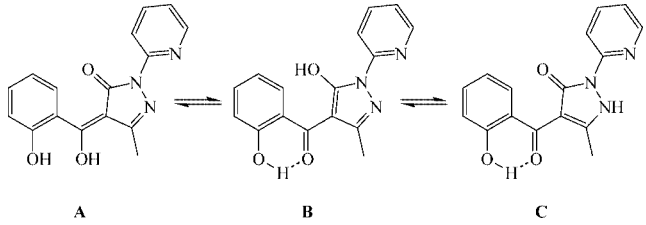
Pyrazole-based chelating ligands have attracted our attention, because of their ability to form *cis*-configured complexes. The anticancer activity of a metal complex depends not only on the metal itself, but also on its oxidation state, on the number and type of bound ligands, and the coordination geometry of the complex.[45]

By reaction of 3-acetyl-4-hydroxycoumarin (**2**), which was obtained from methyl ester **1**, with 2-hydrazinopyridine in a 1:1 molar ratio in refluxing methanol, we obtained 4-(2-hydroxybenzoyl)-2-(pyridin-2-yl)-1*H*-pyrazol-3-ol ($HL^1$) in 62% yield (Scheme 1).

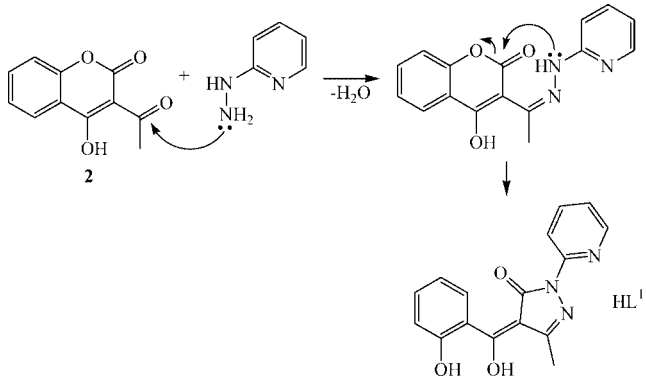


Scheme 1. Synthesis of the ligand $HL^1$.

Three different tautomeric forms (A, B and C) can be envisaged for $HL^1$ (Scheme 2). Of these, B and C are stabilised by intramolecular hydrogen bonding. The formation of $HL^1$ presumably proceeds by an attack of 2-hydrazinopyridine on the carbonyl group (C-3 position in coumarin), followed by the nucleophilic attack of the hydrazine nitrogen on the carbonyl atom at C-2 position (Scheme 3).



Scheme 2. Possible tautomeric forms of the ligand $HL^1$.



Scheme 3. Stepwise formation of $HL^1$.

The ligand has been characterised by elemental analysis, IR spectroscopy, $^1H$ and $^{13}C$ NMR spectroscopy and mass spectrometry (see Experimental Section).

### Synthesis of Complexes

The synthesised ligand $HL^1$ behaves as a strong bidentate chelating agent forming a five-membered metallocycle through coordination of the pyrazole and the pyridine nitrogen atoms to the corresponding metal ion. A review of the coordination chemistry of acylpyrazolone derivatives has been recently published.[46]

Complexes $[M^{II}Cl_2(HL^1)]$, where M = Pt (**3a**) and Pd (**4a**) (Scheme 4), were prepared at room temperature by mixing equimolar amounts of $HL^1$ and potassium tetrachloroplatinate(II) or potassium tetrachloropalladate(II), respectively, in water/methanol. Reactions of $K_2[PtCl_4]$ or $K_2[PdCl_4]$ with $HL^1$ in 1:1 molar ratio in dimethylformamide (DMF) produced (after two weeks) the complexes $[NH_2(CH_3)_2][MCl_2(L^1)]$, where M = Pt (**3b**) and Pd (**4b**). The cation $[NH_2(CH_3)_2]^+$ has been presumably formed by light-induced decomposition of DMF and protonation of the arising dimethylamine.[47] The complex $[PdCl(CH_3CN)(L^1)]$ (**4c**) resulted from the reaction of $[PdCl_2(C_6H_5CN)_2]$ with $HL^1$ in 1:1 molar ratio in chloroform/methanol (2:1), followed by recrystallisation from acetonitrile/diethyl ether.

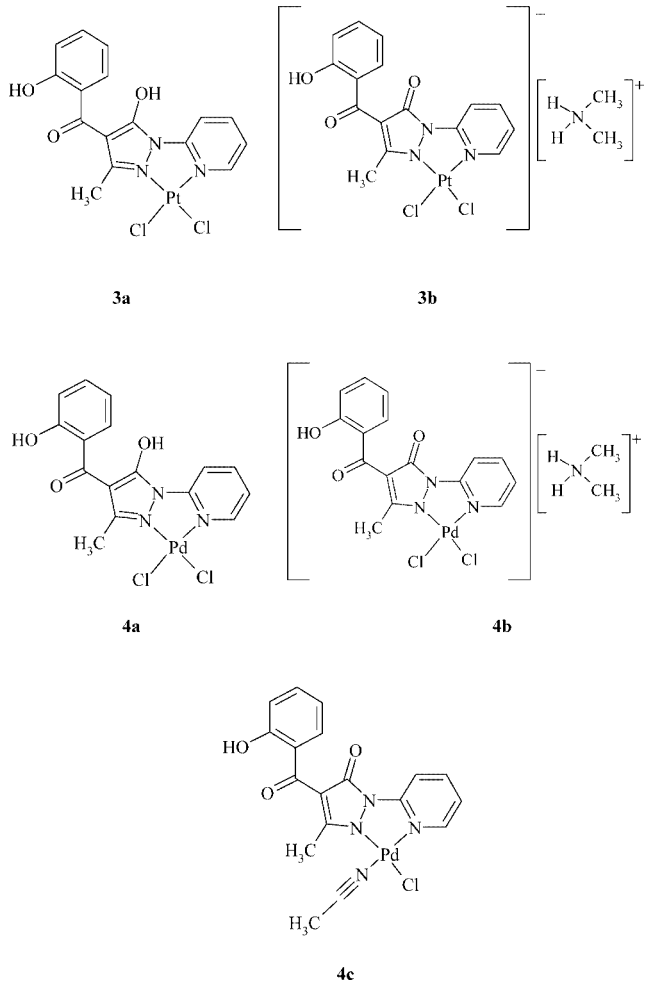

Scheme 4. The library of novel complexes prepared.

The synthesised complexes **3a** and **4a** are sparingly soluble in water, acetone and ethanol, but well soluble in DMSO and DMF.

The composition and the structure of the complexes prepared were confirmed by elemental analyses, IR spectra, $^1$H NMR spectra, mass spectrometry measurements and X-ray diffraction for compounds **3b** and **4c**. Some characteristic IR vibrations for these complexes are given in Table S1 (see Supporting Information). Significant differences in the IR spectra of complexes **3** and **4** were observed in comparison with that of ligand $HL^1$. The latter shows a strong band at 1660 cm$^{-1}$ due to $\nu$(C=O). This band is shifted by 14–32 cm$^{-1}$ to lower frequencies in the spectra of metal complexes. Moderately strong bands at 355, 334 and 328 cm$^{-1}$ can be attributed to $\nu$(M–Cl) of the complexes. Stretching vibrations of the M–N bonds were observed at 420 cm$^{-1}$. The FAB mass spectrum of **3a** recorded in positive-ion mode contains a peak at *m*/*z* 563 due to the $[M + H]^+$ ion and a strong peak at *m*/*z* 528 attributed to $[M - Cl]^+$. Analogously, the spectrum of **4a** shows two peaks at *m*/*z* 473 and 438, which were assigned to $[M + H]^+$ and $[M - Cl]^+$, correspondingly. For complex **4c** we have observed a peak at *m*/z 478 due to $[M + H]^+$. The purity of complexes **3b** and **4b** was confirmed by elemental analysis.

## The Protonation Constants of the Ligand $HL^1$

The potentiometric measurements performed within the pH range 2.5–11.0 showed that under titration with KOH, the ligand $HL^1$ acts as a weak acid with a protonation constant of about $10^8$. These acidic properties can be attributed to the hydroxy group attached to the aromatic ring. Its acidity, slightly higher than that observed for phenols, is probably enhanced by the vicinity of the carbonyl group. In the presence of a strong acid the ligand $HL^1$ acts as a weak base. However, its basicity is small and, within accessible range of concentrations, it was possible to determine potentiometrically only one additional protonation constant. Supposedly, it refers to the equilibrium of protonation of the pyridine nitrogen atom, which is expected to have a higher affinity for the proton than the pyrazole nitrogen atom.

Thus, the stepwise protonation constants of $\log K_1 = 7.74 \pm 0.03$ and $\log K_2 = 2.85 \pm 0.05$ were calculated from titration curves. This implies that, under physiological conditions, the nitrogen atoms of the ligand present in solution are unprotonated.

## X-ray Crystallography

Single crystal X-ray diffraction studies of compound **3b** were undertaken to elucidate the coordination sphere of platinum(II) and the tautomeric form of the ligand. The molecular structure of **3b** with the atom numbering scheme is shown in Figure 1. Selected bond lengths and angles are given in Table 1. The asymmetric unit consists of one $[PtCl_2(L^1)]^-$ anion and one $[NH_2(CH_3)_2]^+$ cation. The coordination environment of $Pt^{II}$ atom is planar, formed by two nitrogen atoms and two chloride ligands. The $PtN_2Cl_2$ "square" adopts a *cis* configuration. The geometry about the Pt atom deviates from the ideal square plane: the atoms N1, N3 and Cl1, Cl2 form angles smaller than 90° with the Pt atom, and consequently the N3–Pt–Cl2 and N1–Pt–Cl1 angles are larger than 90°. The distribution of electron density over the ligand backbone and the presence of a countercation indicate that $HL^1$ acts as a monodeprotonated ligand and adopts the tautomeric form C (Scheme 2).

The crystal lattice is stabilised by a net of intermolecular and intramolecular hydrogen bonds. The atom O1 participates in two O–H···O hydrogen bonds: intramolecular O1–H5···O2, which closes an extra six-membered ring, and intermolecular O5–H5···O1$^{(i)}$. In addition, N4–H16···O3 interaction is of note. The atom N4 is also involved in hydrogen bonds to the Cl atoms (see Table S2).

The packing of the molecules in the crystal lattice is stabilised by C–H···π interactions. Atom C11 is involved in a weak C–H···π intermolecular interaction with the centroid of the ring 3 (N3/C12/C13/C14/C15) [symmetry code (ii): $2 - x$, $1 - y$, $-z$] and C18 interacts with Cg4, where Cg4 is the centroid of ring C1–C6 (more details in Table S3). A number of π–π stacking interactions are observed in the crystal lattice (see Figure S2).

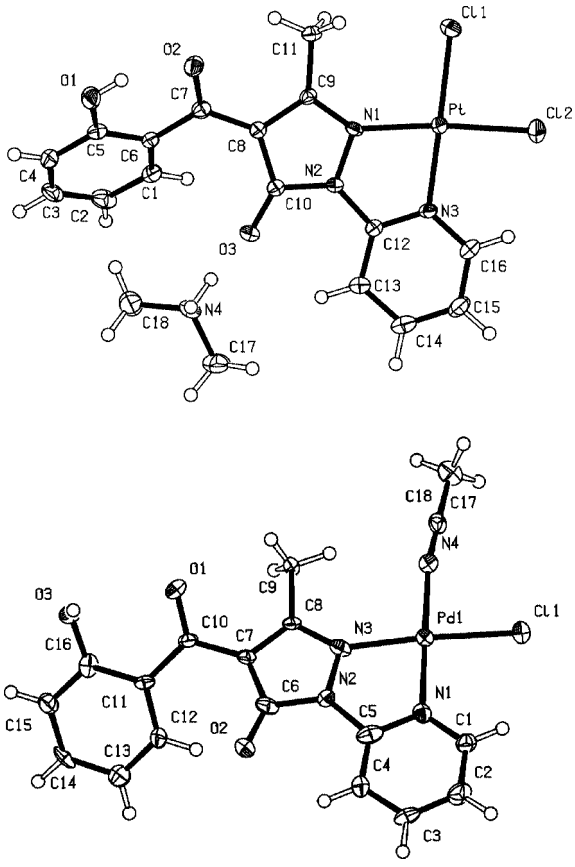

Figure 1. ORTEP drawing of **3b** (top) and of the first independent molecule of **4c** (bottom) with thermal ellipsoids depicted at 50% probability level.

Compound **4c** crystallised in the orthorhombic space group $Pca2_1$ with four crystallographically independent molecules of $[PdCl(CH_3CN)(L^1)]$ in the unit cell. In all four molecules the organic species acts as a monodeprotonated bidentate ligand coordinating to the Pd ion through two nitrogen atoms with formation of a five-membered metallocycle. The square-planar coordination geometry of each $Pd^{II}$ ion is completed by one chlorido ligand and one $CH_3CN$ molecule. The bond lengths in the coordination polyhedron of all four independent molecules are given for comparison in Table 1. The bond lengths C6–O2 of 1.243(13), C10–O1 of 1.240(12) and C16–O3 of 1.343(13) Å clearly indicate the stabilisation of tautomer C in the complex (Scheme 2). The same tendency in bond length distribution is observed in three other crystallographically independent molecules (Table 1).

## Biological Characterisation

### *Alkylating Activity*

Alkylating agents belong to the first class of cytostatics used for chemotherapy.[48] Under in vivo conditions they alkylate nucleophilic centres of nucleobases and amino acids, resulting either in cleavage or cross-linking of double-stranded DNA molecules or proteins. Such cleavage destroys DNA, while covalent cross-links prevent unwinding of nucleic acids, which is functionally important in replication and transcription processes.[49] Cisplatin and carboplatin are the nonclassical alkylating agents. These drugs interact with cellular DNA according to the same mechanism[50,51] by metallation of nucleobases of both DNA strands.

An effective drug concentration for carboplatin is 4–7-fold higher as compared to cisplatin, and the former is also less toxic.[52] The "alkylating" activities of the ligand $HL^1$ and of the complexes **3a** and **4a** were determined by the Preussmann test.[53] The level of "alkylation" of 4-(4-nitrobenzyl)pyridine (NBP) was quantified spectrophotometrically at 560 nm. The molar absorbances (A) for complexes **3a** and **4a** were 0.303 and 0.069, respectively, compared with 0.047 for $HL^1$ (Table 2). Interestingly, cisplatin in this test shows $A = 0.300$[54] and carboplatin alkylates NBP giving $A = 0.231$. According to the Preussmann scale (see footnote to Table 2), the complex **3a** and both reference compounds cisplatin and carboplatin exhibit moderate alkylating activity in this test.

Table 2. Alkylating activity of substituted pyrazoles and their $Pt^{II}$ and $Pd^{II}$ complexes.

| Compound | $\varepsilon$ [$M^{-1}cm^{-1}$] | Absorbance[a] $\lambda_{max}$ = 560 nm | Alkylation activity[b] |
|---|---|---|---|
| $HL^1$ | 47.3 | 0.0473 | – |
| **3a** | 303.4 | 0.3034 | ++ |
| **4a** | 69.0 | 0.0690 | + |

| Carboplatin | 231.2 | 0.2312 | ++ |

[a] Means from 3 determinations. [b] According to ref.[53]: (–) $A <$ 0.05, (+) $A$ = 0.05–0.1, (++) $A$ = 0.1–0.5, (+++) $A > 0.5$. [c] According to ref.[54].

## Cytotoxicity Assay

Cytotoxicity assays for complexes **3a** and **4a** were performed on human acute leukaemia HL-60 and NALM-6 cell lines (Figure 2). Cisplatin and carboplatin were used as

Table 1. Selected bond lengths [Å] for compounds **3b** and **4c**.

| Structure **3b** | | Structure **4c** | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | Molecule 1A | | Molecule 1B | | Molecule 1C | | Molecule 1D | |
| Pt–N1 | 2.019(4) | Pd1–N1 | 2.022(9) | Pd2–N5 | 2.001(10) | Pd3–N9 | 2.019(10) | Pd4–N13 | 2.003(10) |
| Pt–N3 | 2.033(3) | Pd1–N3 | 2.022(9) | Pd2–N7 | 2.007(10) | Pd3–N11 | 2.024(9) | Pd4–N15 | 2.007(10) |
| Pt–Cl2 | 2.302(2) | Pd1–N4 | 2.014(10) | Pd2–N8 | 1.989(10) | Pd3–N12 | 1.972(11) | Pd4–N16 | 1.979(10) |
| Pt–Cl1 | 2.303(2) | Pd1–Cl1 | 2.297(3) | Pd2–Cl2 | 2.286(3) | Pd3–Cl3 | 2.285(3) | Pd4–Cl4 | 2.294(3) |

the reference compounds. Both metal complexes exhibited relatively high cytotoxic activity with the $IC_{50}$ values in the micromolar range. Their cytotoxic effectiveness was nearly the same as that for carboplatin and only 5 (**3a**) or 10 (**4a**) times lower in comparison to cisplatin, a well-established therapeutic agent used for the treatment of leukaemia (Table 3). The most potent was the platinum(II) complex **3a**, with an $IC_{50}$ of 4.7 and 3.9 μM for HL-60 and NALM-6 cells, respectively, in line with alkylating activity towards NBP.

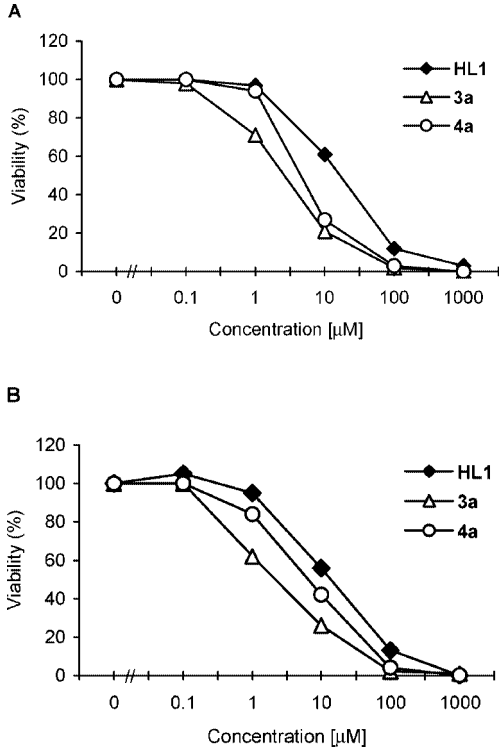

Figure 2. A: Survival curves for HL-60 and B: NALM-6 leukaemia cells exposed for 48 h to tested compounds $HL^1$, **3a** and **4a**. Each point represents the mean of four independent determinations. Standard deviations are excluded for clarity and do not exceed 20% of the mean value for each point.

Table 3. $IC_{50}$ values [μM] for $HL^1$ and complexes **3a** and **4a**.

| Compound | $IC_{50}$[a] HL-60 | NALM-6 |
|---|---|---|
| $HL^1$ | 29.9 ± 8.3 | 30.0 ± 5.3 |
| **3a** | 4.7 ± 0.6 | 3.9 ± 0.6 |
| **4a** | 7.0 ± 0.5 | 8.3 ± 0.3 |
| Cisplatin | 0.8 ± 0.1 | 0.7 ± 0.3 |
| Carboplatin | 4.3 ± 1.3 | 0.7 ± 0.2 |

[a] $IC_{50}$ – concentration of a tested compound required to reduce the fraction of surviving cells to 50% of that observed in the control, nontreated cells. Mean values of $IC_{50}$ (in μM) ± S.D. from four experiments are presented.

Comparison of the data in Table 3 clearly shows that the in vitro antiproliferative activity of complexes **3a** and **4a** exceeds that of uncomplexed ligand $HL^1$. This strongly supports the view that cytotoxicity can be quite safely ascribed to the presence of the metal centre.

## Conclusions

In this paper we have described the synthesis of a new chelating pyrazole ligand $HL^1$, which is characterised by two protonation constants determined by pH-metric titration ($\log K_1 = 7.74 \pm 0.03$; $\log K_2 = 2.85 \pm 0.05$). The ligand forms neutral complexes of the type $[MCl_2(HL^1)]$, where M = Pt (**3a**) and Pd (**4a**) in aqueous methanol. In DMF solutions the ionic species $[NH_2(CH_3)_2][PtCl_2(L^1)]$ with M = Pt (**3b**) and Pd (**4b**) have been isolated. Starting from $[PdCl_2(C_6H_5CN)_2]$ and $HL^1$, and using acetonitrile for recrystallisation, the complex $[PdCl(CH_3CN)(L^1)]$ (**4c**) has been prepared. X-ray diffraction studies of **3b** and **4c** showed that the ligand in both square-planar complexes acts as a monodeprotonated one, adopting the tautomeric form C.

Complexes **3a** and **4a** exhibit in vitro antiproliferative activity in HL-60 and NALM-6 leukaemia cells, with the cytotoxicity $IC_{50}$ values similar to those for carboplatin. The sequence in activity against HL-60 and NALM-6 leukaemia cells is as follows **3a** > **4a** > $HL^1$. The alkylating activity of the platinum compound **3a** was comparable with those of cisplatin and carboplatin.

## Experimental Section

**Materials:** All substances were used without further purification. Potassium tetrachloroplatinate(II) and potassium tetrachloropalladate(II) were purchased from Aldrich. $CDCl_3$ and $[D_6]$DMSO solvents for NMR spectroscopy were obtained from Dr. Glaser AG, Basel, Switzerland. Solvents for synthesis (toluene, methanol, dimethylformamide, acetone) were reagent-grade or better and were dried according to standard protocols.[55] The melting points were determined using an Electrothermal 1A9100 apparatus and they are uncorrected. The IR spectra were recorded with a Pye-Unicam 200G Spectrophotometer in KBr or CsI pellets. The $^1$H NMR spectra were registered at 300 MHz on a Varian Mercury spectrometer. The MS data were obtained on a LKB 2091 mass spectrometer (70 eV ionisation energy). The FAB mass spectra were recorded with a Finnigan Matt 95 mass spectrometer (NBA, $Cs^+$ gun operating at 13 keV). For the new compounds satisfactory elemental analyses (±0.3% of the calculated values) were obtained using a Perkin–Elmer PE 2400 CHNS analyser. Methyl 2-methyl-4-oxo-4*H*-chromene-3-carboxylate (**1**)[56] and 3-acetyl-4-hydroxychromen-2-one (**2**)[57,58] were prepared as described in the literature.

**4-(2-Hydroxybenzoyl)-2-pyridin-2-yl-1*H*-pyrazol-3-ol ($HL^1$):** 2-Hydrazinopyridine (0.13 g, 1.15 mmol) in methanol (5 mL) was added to a solution of **2** (0.24 g, 1.15 mmol) in methanol (15 mL) and the mixture was refluxed for 1 h. The solid crude product formed was filtered off, dried in air and recrystallised from ethanol as a white solid. Yield 0.21 g (62%); m.p. 197–198 °C, $R_f$ = 0.78 (methanol/chloroform, v/v 1:1). IR (KBr): $\tilde{\nu}$ = 3428 (OH), 1735 (C=O), 1630, 1589 (C=N), 1458 (C=C) cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.47 (s, 3 H, $CH_3$), 6.88 (t, $J$ = 6.15 Hz, 1 H), 6.99 (d, $J$ = 2 Hz, 1 H), 7.22–7.26 (m, 2 H), 7.46–7.49 (m, 1 H), 7.86 (t, $J$ = 6.35 Hz, 1 H), 7.96 (d, $J$ = 3.4 Hz, 1 H), 8.26 (dt, 1 H, Ar) ppm (see Figure S1a, Supporting Information). $^{13}$C NMR (75.4 MHz, $[D_6]$DMSO, 25 °C): $\delta$ = 14.45, 103.18, 112.22, 116.25, 117.89, 119.79, 123.23, 131.33, 133.17, 141.71, 143.67 153.66, 158.77, 160.91, 190.92 ppm (Figure S1b). EI-MS: *m*/*z* (%) = 295 (51) [M$^+$],

175 (100%), 79 (7%). $C_{16}H_{13}N_3O_3 \cdot 1/3H_2O$ (301.29): calcd. C 63.78, H 4.57, N 13.94; found C 63.93, H 4.33, N 13.60.

**Pt Complex 3a:** A solution of $K_2PtCl_4$ (0.04 g, 0.10 mmol) in water (5 mL) was added dropwise to a solution of HL[1] (0.03 g, 0.10 mmol) in methanol (5 mL). The reaction mixture was stirred at room temperature for 48 h. The solvent was removed under reduced pressure at room temperature to half of the initial volume. After 3 h the precipitated yellow solid was filtered off, washed with methanol/water, 1:1 and dried under reduced pressure over $CaCl_2$. Yield 38.2 mg (68%); m.p. 315–317 °C. IR spectrum in CsI, selected bands: $\tilde{\nu}$ = 3428 *ν*(OH); 1631 (C=O), 1593 (C=N), 1460 (C=C), 420 (Pt–N), 384 (Pt–Cl) $cm^{-1}$. $^1H$ NMR (300 MHz, [$D_6$]-DMSO, 25 °C): $\delta$ = 2.71 (s, 3 H, $CH_3$), 6.79–6.86 (m, 2 H), 7.22 (t, 1 H), 7.34 (t, 1 H), 7.82 (d, 1 H), 8.02 (t, 1 H), 8.42 (d, 1 H), 8.78 (d, 1 H) ppm. FAB-MS: *m*/*z* (%) = 563. $C_{16}H_{13}Cl_2N_3O_3Pt$ (561.26): calcd. C 34.24, H 2.33, N 7.48; found C 34.43, H 2.16, N 7.46.

**Pt Complex 3b:** A solution of $K_2[PtCl_4]$ (0.04 g, 0.10 mmol) in DMF (10 mL) was added dropwise to a solution of HL[1] (0.03 g, 0.10 mmol) in DMF (10 mL). The mixture was stirred at room temperature for 24 h. The KCl formed was removed by filtration and the diethyl ether was allowed to diffuse into a DMF solution of the complex. After two weeks the yellow solid was filtered off, washed with diethyl ether and dried in air. The single crystals suitable for X-ray analyses were obtained directly from the synthesis. Yield 27.28 mg (45%); m.p. 251–253 °C. $C_{18}H_{20}Cl_2N_4O_3Pt$ (606.34): calcd. C 35.65, H 3.32, N 9.24; found C 35.72, H 3.41, N 9.23.

**Pd Complex 4a:** A solution of $K_2[PdCl_4]$ (0.09 g, 0.27 mmol) in water (3 mL) was added dropwise to a stirred solution of HL[1] (0.08 g, 0.27 mmol) in methanol (15 mL). A yellow solid formed immediately; the suspension was stirred for a further 30 min, then the solid was filtered off, washed with cold water, cold methanol and diethyl ether, and dried in air. Yield 93.15 mg (73%); m.p. 284–285 °C. IR spectrum in CsI, selected bands: $\tilde{\nu}$ = 3457 (OH); 1654 (C=O), 1593 (C=N), 1475(C=C), 420 (Pd–N), 338 (Pd–Cl) $cm^{-1}$. $^1H$ NMR (300 MHz, [$D_6$]DMSO, 25 °C): $\delta$ = 2.41 (s, 3 H, $CH_3$), 6.77–6.87 (m, 2 H), 7.20 (t, 1 H), 7.34 (t, 1 H), 7.81 (d, 1 H), 8.02 (t, 1 H), 8.42 (d, 1 H), 8.73 (d, 1 H) ppm (Figure S1c). FAB-MS: *m*/*z* (%) 473. $C_{16}H_{13}Cl_2N_3O_3Pd \cdot H_2O$ (490.626): calcd. C 39.16, H 3.08, N 8.56; found C 38.96, H 3.11, N 8.63.

**Pd Complex 4b:** A solution of $K_2[PdCl_4]$ (0.03 g, 0.10 mmol) in DMF (10 mL) was added dropwise to a solution of HL[1] (0.03 g, 0.10 mmol) in DMF (10 mL). The mixture was stirred at room temperature for 48 h. The KCl formed was removed by filtration and the diethyl ether was allowed to diffuse into a DMF solution of the complex. After two weeks the yellow solid was filtered off, washed with diethyl ether and dried in air. Yield 27.3 mg (45%); m.p. 253–254 °C. $C_{18}H_{20}Cl_2N_4O_3Pd$ (606.34) calcd. C 35.65, H 3.32, N 9.24; found C 35.72, H 3.41, N 9.23.

**Pd Complex 4c:** A suspension of $[Pd(C_6H_5CN)_2Cl_2]$ (0.10 g, 0.25 mmol) in chloroform (5 mL) was added to a stirred solution of HL[1] (0.074 g, 0.25 mmol) in methanol/chloroform (1:1) (5 mL). The product precipitated immediately from the reaction mixture. Stirring was continued for 30 min and the complex was filtered off, washed with cold water, cold methanol and diethyl ether, and dried in air. Recrystallisation from acetonitrile/diethyl ether (1:1) afforded a red crystalline product **4c**. Yield 53.7 mg (45%); m.p. 276.4–278.0 °C. FAB-MS: *m*/*z* (%) 478. $C_{18}H_{15}ClN_4O_3Pd$ (477.198): calcd. C 45.30, H 3.17, N 11.74; found C 45.35, H 2.98, N 11.83.

**Potentiometric Measurements:** The protonation constants of HL[1] were determined by pH-metric titrations of five identical 10-mL samples at (25.0 ± 0.1) °C. The total ligand concentration in each sample was 2.859 mmol $dm^{-3}$. The samples contained also 3 mmol $dm^{-3}$ $HClO_4$ and 0.05 mol $dm^{-3}$ $NaClO_4$. Owing to very low solubility in pure water, a mixed 70% (v/v) ethanol/water solvent was used. The titrations were carried out with carbonate-free KOH solutions of known concentration (1 mol $dm^{-3}$) using an autoburette. The drop volume during these titrations was 1 μL. The experimental value of $pK_w$ = 15.50 ± 0.03 was obtained from our acid–base calibration in the mixed solvent. The pH was measured with a combined glass electrode ESAgP-301 WM (Eurosensor) connected to computer-aided universal electrochemical meter EMU0,[59] produced by the Technical University of Wrocław, Poland. The same equipment was also used to control the autoburette, as well as for the data acquisition and their introductory treatment. The electrode was calibrated by titration of 0.01 M HCl (in 70% ethanol) with 1 M KOH at (25 ± 0.1) °C. Stepwise protonation constants were calculated with our own program based on algorithm PKAS.[60,61]

**X-ray Crystallographic Data:** X-ray diffraction data for yellow and red single crystals of **3b** and **4c**, respectively, were collected at 193 K on a STOE IPDS diffractometer and at 120 K on a Nonius Kappa CCD diffractometer. The unit cell parameters were determined from all reflection data in $\theta$ ranges 2.26–28.08° and 2.71–24.73°. 11713 and 11440 intensities were collected using graphite-monochromated Mo-$K_\alpha$ radiation. 4316 and 11440 independent reflections were measured in the ranges $-9 \le h \le 9$, $-13 \le k \le 13$, $-18 \le l \le 18$, and $-51 \le h \le 51$, $-8 \le k \le 8$, $-24 \le l \le 24$, respectively for **3b** and **4c**. In the data-reduction step, intensities were corrected for Lorentz and polarisation effect[62] for **3b** and using Denzo-SMN software[63] for **4c**. The structure was solved by direct methods using the SHELXS86[64] program and refined by full-matrix least-squares calculation on $F^2$ using SHELXL97.[65] Non-hydrogen atoms were refined with anisotropic displacement parameters. The H atoms were placed in calculated positions and allowed to ride. The molecular geometry was calculated by PLATON.[66] The drawings were made by PLATON and are presented in Figure 1. The crystal data and details of data collection for both compounds are given in Table 4.

CCDC-622068 (for **3b**) and -622067 (for **4c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Biological Measurements**

**Determination of Alkylating Properties:** The test compound (0.005 mmol) was dissolved in 2-methoxyethanol (1 mL) and a solution of 4-(4-nitrobenzyl)pyridine (NBP) in 2-methoxyethanol (5% solution, 1 mL) was added. The sample was heated at (100 ± 0.5) °C for 1 h and then quickly cooled to 20 °C. 2-Methoxyethanol (2.5 mL) and piperidine (0.5 mL) were added to the sample to give a total volume of 5 mL. The final concentration of the test compound was $1 \times 10^{-3}$ M. After 90 s the absorbance was measured at $\lambda_{560}$ nm in a glass cell (1 cm). 2-Methoxyethanol was used as a reference solvent.

**Cell and Cytotoxicity Assay:** The cytotoxicity was determined in the human leukaemia promyelocytic HL-60 and lymphoblastic NALM-6 cell lines. Cells were cultured in RPMI 1640 medium supplemented with 10% foetal calf serum and antibiotics (penicillin (100 U/mL) and streptomycin (100 μg/mL) in 5% $CO_2$/95% air. Exponentially growing cells were seeded at $3 \times 10^5$ per well of a 24-well plate (Nunc), and cells were then exposed to the compounds for 48 h. Stock solutions were prepared freshly in DMSO, then dilutions from $10^{-3}$ to $10^{-7}$ M in complete culture medium were

made. The number of viable cells was counted in a Bürker haemocytometer using trypan-blue exclusion assay.[67] The values of $IC_{50}$ (the concentration of test compounds required to reduce the cell survival fraction to 50% of the control) were calculated from concentration–response curves (as illustrated in Figure 2) and used as a measure of cellular sensitivity to a given treatment. All data were expressed as means ± SD.

**Supporting Information** (see also the footnote on the first page of this article): IR data (Table S1), $^1$H NMR, $^{13}$C NMR spectra (Figure S1, a–c), crystallographic data (Tables S2 and S3, and Figure S2).

## Acknowledgments

Financial support from the Medical University of Łódź (grant nos. 502-13-629 and 503-3066-2 to E. B. and 503-315-2 to the Department of Pharmaceutical Biochemistry) is gratefully acknowledged. The authors thank Professor Werner Massa and his group for providing the instrument for data collection at the Philipps University.

# Cleavage of CO by Mo[N(R)Ar]$_3$ Complexes

Gemma Christian,[a] Robert Stranger,*[a] Brian F. Yates,[b] and Christopher C. Cummins[c]

**Keywords:** C–O activation / Molybdenum / Three-coordinate complexes / Density functional calculations / Bond cleavage

The reaction of $MoL_3$ [L = $NH_2$ and N(*t*Bu)Ar] with CO was explored using DFT in order to rationalize why CO cleavage is not observed experimentally for this system in contrast to the corresponding $N_2$ reaction which results in spontaneous cleavage of the N–N bond. The binding of CO to $MoL_3$ was found to be both kinetically and thermodynamically favored over the binding of $N_2$, with the formation of the encounter complex, $L_3Mo$–CO, calculated to be without barrier and exothermic. While the overall reaction to form the C–$MoL_3$ and O–$MoL_3$ products was calculated to be energetically favorable, both the encounter complex and intermediate dimer, $L_3Mo$–CO–$MoL_3$, were found to be lower in energy than the products, with the final C–O cleavage step calculated to be endothermic by 169 kJ mol$^{-1}$ and 163 kJ mol$^{-1}$ for L = $NH_2$ and N(*t*Bu)Ar, respectively. The unfavorable CO cleavage step can be attributed to the fact that Mo does not possess the optimum d-electron configuration to sufficiently stabilise the carbide and oxide products relative to the CO-bridged intermediate dimer.

## Introduction

One of the most significant discoveries in dinitrogen chemistry is the cleavage of $N_2$ by Mo[N(*t*Bu)Ar]$_3$ under mild conditions.[1,2] $N_2$ reacts with Mo[N(*t*Bu)Ar]$_3$ to form the intermediate dimer, [Ar(*t*Bu)N]$_3$Mo–$N_2$–Mo[N(*t*Bu)Ar]$_3$, with $N_2$ bridging the metal centers end-on, followed by N–N bond cleavage to form the nitride product N–Mo[N(*t*Bu)Ar]$_3$.[3–5] The reaction proceeds under mild conditions (1 atm of pressure and between –33 and 25 °C) compared with the extreme conditions of 200 atm and 500 °C required in the industrial Haber–Bosch process for nitrogen fixation. In addition to $N_2$ cleavage, Mo[N(*t*Bu)Ar]$_3$ is also known experimentally to cleave the stronger N–N bond in $N_2O$ to form the nitride, N–Mo[N(*t*Bu)Ar]$_3$, and nitrosyl, [Ar(*t*Bu)N]$_3$Mo–NO, products.[6,7]

Following the success of $N_2$ and $N_2O$ cleavage by Mo[N(R)Ar]$_3$ complexes under mild conditions, attention was turned to other small multiply bonded molecules such as CO and $CN^-$. Although CO and $CN^-$ are isoelectronic with $N_2$, and therefore in principle Mo[N(R)Ar]$_3$ complexes are able to provide the necessary number of electrons to reductively cleave these small molecules, to date neither C–O or C–N bond cleavage has been observed.[8–10] The carbide complex [C–Mo[N(*t*Bu)Ar]$_3$]$^-$ has been synthesized from the encounter complex, [Ar(*t*Bu)N]$_3$Mo–CO, the latter easily formed by the reaction of Mo[N(*t*Bu)Ar]$_3$ with CO.[8] However, despite the ready formation of the encounter complex, neither the intermediate dimer or C–O cleavage is observed and instead, the O atom in the [Ar(*t*Bu)N]$_3$Mo–CO complex is removed through conversion to the related methylidene complex, [HC–Mo[N(*t*Bu)Ar]$_3$], which is then deprotonated to form [C–Mo[N(*t*Bu)Ar]$_3$]$^-$.[8,9]

The resistance of CO to cleavage by Mo[N(R)Ar]$_3$ complexes may well be a consequence of the fact that the bond dissociation energy for CO is approximately 100 kJ mol$^{-1}$ greater than that for $N_2$. However, an alternative view is that the metals used to form the intermediate dimer, in this case only Mo, are not tuned to optimise the thermodynamics of the cleavage reaction. This aspect is particularly pertinent since a recent theoretical study[11] has shown that CO cleavage is predicted to be spontaneous under mild conditions when two different three-coordinate complexes Re[N(R)Ar]$_3$ and Ta[N(R)Ar]$_3$ are used. In this reaction, an intermediate dimer is formed with Re[N(R)Ar]$_3$ and Ta[N(R)Ar]$_3$ binding to the C and O atoms, respectively, and cleavage of CO proceeds without barrier.

The reaction steps of [Ar(*t*Bu)N]$_3$Mo with CO are shown in Scheme 1, assuming the cleavage of CO proceeds by a mechanism analogous to the $N_2$ cleavage reaction. The first step involves the binding of CO to form the encounter complex, [Ar(*t*Bu)N]$_3$Mo–CO, followed by binding of a second Mo[N(*t*Bu)Ar]$_3$ unit to form [Ar(*t*Bu)N]$_3$Mo–CO–Mo[N(*t*Bu)Ar]$_3$, and finally C–O bond cleavage to give the products C–Mo[N(*t*Bu)Ar]$_3$ and O–Mo[N(*t*Bu)Ar]$_3$.

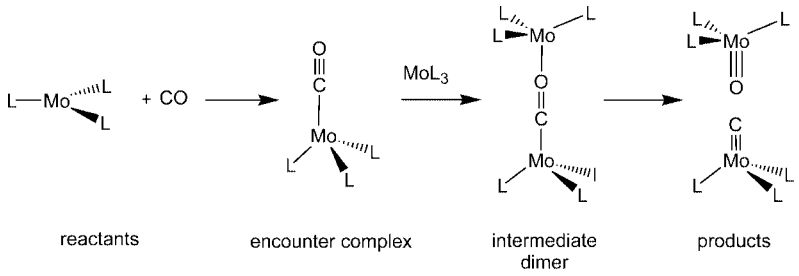

Scheme 1. The reaction of CO with $MoL_3$, L = $NH_2$ or N(*t*Bu)Ar.

In this study, the reaction mechanism shown in Scheme 1 is explored using density functional theory (DFT) for both the model, L = $NH_2$, and experimental, L = N(*t*Bu)Ar, systems in order to rationalise the experimental results. Earlier work on the analogous $N_2$ cleavage reaction by us and other groups[5,12–14] has shown that DFT methods give results in good agreement with experiment.

## Results and Discussion

### 1.1 Calculated Structures

For the model system (L = $NH_2$), calculations were carried out on the encounter complex, $[H_2N]_3Mo–CO$ and intermediate dimer, $[H_2N]_3Mo–CO–Mo[NH_2]_3$. The energies and structures of the remaining species, namely the reactant, $[H_2N]_3Mo$, and products, $[H_2N]_3Mo–C$ and $[H_2N]_3Mo–O$, have been reported in earlier studies.[13,15] In the case of the experimental system [L = N(*t*Bu)Ar], QM/MM calculations were carried out for the reactant, encounter complex, intermediate dimer and products. The optimized model and QM/MM structures are shown in Figure 1 and selected structural data from these calculations are shown in Table 1.

For the model system, the reaction of $[H_2N]_3Mo$ with CO gives rise to two possible encounter complexes, $[H_2N]_3Mo–CO$ [structure (c)] and $[H_2N]_3Mo–OC$. Both complexes have doublet ground states with approximately $C_s$ symmetry with one amide ligand rotated by 90° around the metal–ligand axis. The Mo–C–O angle of 177° indicates that the Mo–CO fragment is slightly distorted from linear geometry. Similar ligand rotation has been found for the analogous dinitrogen complex $[H_2N]_3Mo–N_2$.[13,16] The model and QM/MM structures of the CO encounter complex [structures (c) and (d)] have very similar core structures and bond lengths. Because the formation of the O-bound encounter complex was calculated to be endothermic, it is not considered further.

For the model system, the optimized $C_s$ structure of the intermediate dimer [structure (e)] has a bent Mo–C–O–Mo core with a C–O–Mo bond angle of 126° in the triplet spin state. In the QM/MM system [structure (f)], bending of the core is also observed but the larger size of the N(*t*Bu)Ar ligands restricts the C–O–Mo bond angle to 163°. Analogous to the $N_2$-bridged intermediate dimer,[13,16] ligand rotation around the metal–N(amide) axis is also observed for the CO-bridged intermediate dimer. However, while ligand rotation is observed at only one metal center for the model

[a] Data has been included for the model intermediate dimer $[H_2N]_3Mo$–CO–$Mo[NH_2]_3$ even though the optimized structure is not a true minimum.

system, it occurs at both metal centers for the QM/MM system. This difference between the model and QM/MM structures is a consequence of the fact that rotation of the bulky N(tBu)Ar ligands has been shown to reduce steric crowding.[16]

The $[Ar(tBu)N]_3Mo$–C product [structure (h)] has approximately trigonal symmetry, unlike $[H_2N]_3Mo$–C, $[H_2N]_3$-Mo–O and $[Ar(tBu)N]_3Mo$–O [structures (g), (i) and (j)] which all show rotation of one or more of the amide ligands. However, the QM/MM structure for $[Ar(tBu)N]_3$-Mo–C with one ligand rotated lies only 11 kJ mol$^{-1}$ higher in energy. In general, the metal–amide distances are greater for L = N(*t*Bu)Ar than L = $NH_2$, consistent with the increased steric crowding for the former ligand. The C–O bond lengths of 1.278 and 1.276 Å in the lowest energy model and QM/MM intermediate dimer structures, respectively, indicate moderate activation compared to free CO (cf. 1.128 Å).

### 1.2 Overall Reaction Profile

The relative energies of species along the reaction pathway for the cleavage of CO by $MoL_3$ are summarized in Table 2 for both the model and QM/MM systems. The corresponding energies of species in the analogous $N_2$ cleavage reaction are also included for comparison. Overall, the CO cleavage reaction is exothermic for the model and experimental systems but the encounter complex and intermediate dimer are lower in energy than the products in both systems. Cleavage of the C–O bond to form $L_3Mo$–C and $L_3Mo$–O is highly unfavorable, and is calculated to be endothermic by 169 and 163 kJ mol$^{-1}$ for the model and experimental systems, respectively. In general, when L = N(*t*Bu)Ar, the reaction of $MoL_3$ with CO is less exothermic and the species along the reaction pathway are less stable relative to reactants than when L = $NH_2$. This is consistent with the results for the $N_2$ cleavage reaction where a similar decrease in exothermicity was found when L = N(*t*Bu)Ar due to increased steric crowding.

Table 2. Calculated energies of the encounter complex, dimer and products relative to reactants for the reaction of CO and $N_2$ with $MoL_3$ for L = $NH_2$ and N(*t*Bu)Ar.[13]

| Reaction | L | Encounter complex | Dimer | Product |
|---|---|---|---|---|
| CO | $NH_2$ | –152 | –248 | –79 |
| | N(*t*Bu)Ar | –142 | –222 | –59 |
| $N_2$ | $NH_2$ | –71 | –241 | –335 |
| | N(*t*Bu)Ar | –43 | –238 | –293 |

From the data in Table 2, the intermediate dimer is calculated to be the lowest energy species on the reaction pathway, and is 96 and 80 kJ mol$^{-1}$ lower in energy than the encounter complex for L = $NH_2$ and L = N(*t*Bu)Ar, respectively. However, under the reported experimental conditions, the intermediate dimer is not isolated, and instead the reaction is observed to cease with the formation of the encounter complex $[Ar(tBu)N]_3Mo$–CO.[8,9] Although formation of the dimer is entropically unfavorable, $\Delta S$ is calculated to be 218 J mol$^{-1}$·$T^{-1}$ which is not enough to offset $\Delta H$, even at room temperature.

### 1.3 Formation of the Encounter Complex and Intermediate Dimer

Because the calculations indicate that the intermediate dimer, $L_3Mo$–CO–$MoL_3$, should be thermodynamically stable, then it is pertinent to examine the kinetic barriers that may prevent its formation. Accordingly, the formation of both the $L_3Mo$–CO encounter complex and intermediate dimer, $L_3Mo$–CO–$MoL_3$, for L = $NH_2$ and N(*t*Bu)Ar, were investigated via linear transits, the results of which are shown in Figure 2.

The formation of the encounter complex, $L_3Mo$–CO, begins on the spin quartet surface but the spin doublet crosses below the quartet surface to become the minimum at an Mo–C distance of around 1.9 Å. There is no barrier to formation in either spin state for the model or QM/MM systems and the reaction is exothermic by 152 and 142 kJ mol$^{-1}$ for L = $NH_2$ and N(*t*Bu)Ar, respectively. To put these re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

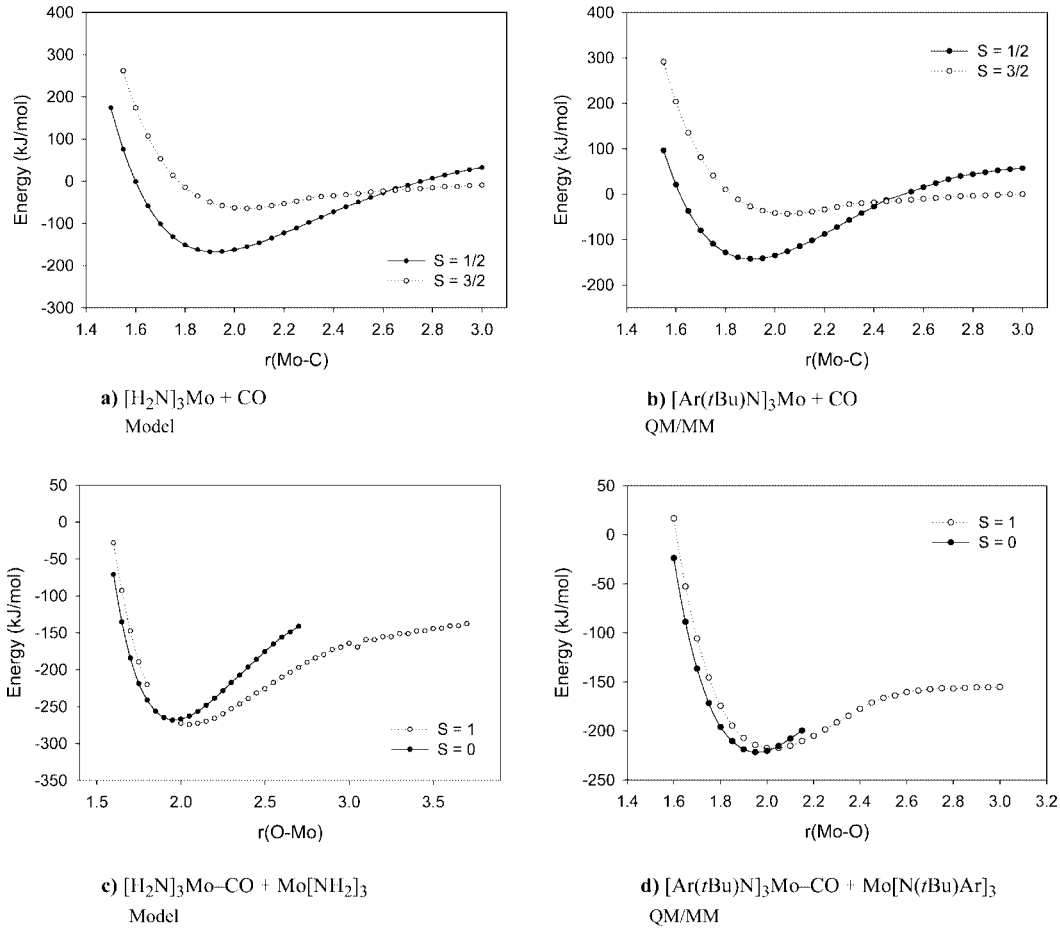

Figure 2. Linear transit results for the formation of (a) $[H_2N]_3Mo–CO$, (b) $[Ar(tBu)N]_3Mo–CO$, (c) $[H_2N]_3Mo–CO–Mo[NH_2]_3$ and (d) $[Ar(tBu)N]_3Mo–CO–Mo[N(tBu)Ar]_3$.

sults in context, the formation of the analogous $N_2$ encounter complex, $[Ar(tBu)N]_3Mo–N_2$, is exothermic by only 43 kJ mol$^{-1}$ and in addition, has a barrier of approximately 18 kJ mol$^{-1}$. The uptake of CO by $Mo[N(tBu)Ar]_3$ is therefore both kinetically and thermodynamically much more favorable than the uptake of $N_2$, consistent with experimental observations in that, while $[Ar(R)N]_3Mo–CO$ has been isolated, $[Ar(R)N]_3Mo–N_2$ has not been observed.[4,17]

Dimer formation for both $[H_2N]_3Mo–CO$ and $[Ar(tBu)N]_3Mo–CO$ through binding of a second $MoL_3$ complex end-on to O, occurs initially on the spin triplet surface. For L = N(*t*Bu)Ar, the spin singlet state crosses below the triplet when the Mo–O distance is approximately 2.0 Å with the minimum lying at approximately 1.9 Å. For the model system, the spin singlet surface also crosses the triplet around 1.9 Å, but lies higher in energy at the minimum distance of approximately 2.0 Å. As is apparent from Figure 2, there is no barrier to dimer formation for either the model or experimental system.

It is possible that the absence of dimer formation experimentally may be linked to the reaction conditions used. There are two differences in the reported reactions of $Mo[N(tBu)Ar]_3$ with $N_2$ and CO. Firstly, the solvent used in the CO reaction was tetrahydrofuran (THF) whereas non-polar solvents were used in the reaction with $N_2$. Secondly, CO, which is bound more easily than $N_2$, was in excess.

Solvent effects on the reaction energetics were investigated by performing calculations on the model system which allowed binding of THF directly to the reactant, $Mo[NH_2]_3$, encounter complex, $OC–Mo[NH_2]_3$, and the intermediate dimer, $[H_2N]_3Mo–CO–Mo[NH_2]_3$. In the case of the encounter complex, binding of THF to either the Mo or CO was explored. The results are summarized in Table 3.

Table 3. Calculated energies for the binding of THF to $Mo[NH_2]_3$, $[H_2N]_3Mo–CO$ and $[H_2N]_3Mo–CO–Mo[NH_2]_3$.

| | $\Delta E$ [kJ mol$^{-1}$] |
|---|---|
| $[H_2N]_3Mo–THF$ | –2 |
| $[H_2N]_3Mo–CO–THF$ | ca. 4 |
| THF–$[H_2N]_3Mo–CO$ (*trans*) | –37 |
| $[THF][H_2N]_3Mo–CO–Mo[NH_2]_3$ | –13 |
| $[H_2N]_3Mo–CO–Mo[NH_2]_3[THF]$ | –38 |
| $[THF][H_2N]_3Mo–CO–Mo[NH_2]_3[THF]$ | –59 |

Binding of THF to the reactant or directly to CO in the encounter complex is predicted to be weak, but binding of THF to Mo (*trans* to CO) in the encounter complex is exothermic by 37 kJ mol$^{-1}$. Binding of THF to the intermediate dimer is also favorable, particularly when THF is bound at both ends. Although binding of solvent molecules is ex-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pected to be weaker for the experimental system due to ligand crowding, based on these results, the intermediate dimer should be even more stable relative to reactants and encounter complex in the presence of THF. In addition to calculations involving the explicit binding of THF, the effect of the bulk properties of the solvent on the reaction pathway was also studied using the COSMO model. However, the relative energies changed by at most 10 kJ mol$^{-1}$ compared to the unsolvated calculations, and the formation of the dimer is still calculated to be exothermic.

Because the above calculations indicate that solvent effects do not favor formation of the encounter complex over the intermediate dimer, the other main difference in the reaction conditions, namely the presence of excess CO, must be significant. For the $N_2$ cleavage reaction, binding of $N_2$ to form the intermediate dimer is known to be slow experimentally,[4] and therefore there is an excess of Mo[N(*t*Bu)Ar]$_3$ available to react with the encounter complex to form the intermediate dimer. Binding of CO to form the encounter complex, [Ar(*t*Bu)N]$_3$Mo–CO, however, is fast and calculated to be more exothermic than the formation of the intermediate dimer. When CO is in excess, the rapid uptake of CO by Mo[N(*t*Bu)Ar]$_3$ will leave little remaining Mo[N(*t*Bu)Ar]$_3$ for dimer formation. However, under different reaction conditions, namely controlling the CO concentration so that it is never in excess, the formation of the [Ar(*t*Bu)N]$_3$Mo–CO–Mo[N(*t*Bu)Ar]$_3$ dimer may be possible.

## Conclusions

Calculations were carried out on the reaction of $MoL_3$ with CO for the model (L = $NH_2$) and experimental [L = N(*t*Bu)Ar] ligand systems. On the basis of these calculations, the formation of the encounter complex and intermediate dimer are predicted to be thermodynamically favorable and without barrier. Despite the overall cleavage reaction being exothermic, both the encounter complex and intermediate dimer are predicted to be more stable than the O–$MoL_3$ and C–$MoL_3$ products and therefore the final C–O cleavage step is unfavorable, being endothermic by 169 and 163 kJ mol$^{-1}$ for the model and experimental systems, respectively. The endothermic CO cleavage step can be rationalized on the basis of the electronic properties of the metal. An earlier study examining M–L bond energies in model [$NH_2$]$_3$M–L (L = N, C, O) complexes showed that the strongest M–O, M–N and M–C bonds occurred for $d^2$, $d^3$ and $d^4$ metal configurations, respectively.[15] Therefore, in the $L_3$Mo + CO system, $Mo^{III}$ does not possess the optimum d-electron configuration to sufficiently stabilise the carbide and oxide products relative to the intermediate dimer.

The intermediate dimer, $L_3$Mo–CO–$MoL_3$, is calculated to be the lowest energy species along the reaction pathway, and from both a thermodynamic and kinetic perspective, the calculations indicate that its formation is more favorable than the analogous $N_2$-bound dimer which is observed experimentally in the reaction of Mo[N(*t*Bu)Ar]$_3$ with dinitrogen. Thus, the absence of the CO-bridged intermediate dimer experimentally is attributed to the different reaction conditions employed compared to its $N_2$ counterpart, namely the use of a polar solvent and the presence of excess CO. Since calculations which investigated solvent effects were shown to favor formation of the CO-bridged intermediate dimer, it is concluded that this species is not observed experimentally due to the presence of excess CO and the ability of Mo[N(*t*Bu)Ar]$_3$ to rapidly bind CO. This conclusion is also consistent with the observation that, while [Ar(*t*Bu)]$_3$Mo–CO has been isolated, [Ar(*t*Bu)]$_3$Mo–$N_2$ has not been observed experimentally.

## Computational Section

The calculations carried out in this work were performed with the Amsterdam Density Functional (ADF)[18–20] program running on either Linux-based Pentium IV computers or the Australian National University Supercomputing Facility. All calculations used the local density approximation (LDA) to the exchange potential, the correlation potential of Vosko, Wilk and Nusair (VWN),[21] the Becke[22] and Perdew[23] corrections for non-local exchange and correlation, and the numerical integration scheme of te Velde and co-workers.[24] Geometry optimizations were performed using the gradient algorithm of Versluis and Ziegler.[25] All electron, triple-ζ Slater-type orbital basis sets (TZP) with polarization functions were used for all atoms. Relativistic effects were incorporated using the zero-order relativistic approximation (ZORA)[26–28] functionality in ADF. Frequency calculations were used to confirm that the optimized model structures of lowest energy were true minima and were computed by numerical differentiation of energy gradients in slightly displaced geometries.[29,30] Solvent-corrected calculations were carried out using the COSMO method[31] to accommodate the bulk effects of the tetrahydrofuran solvent used in the experimental work. For these calculations the solvent dielectric constant was set at 7.58 and the radius (rigid sphere) at 3.18 Å. All calculations were carried out in a spin-unrestricted manner. Optimized structures for the model system were corrected for zero-point vibrational energy. The convergence criteria for geometry optimizations were $10^{-3}$ Hartrees for energy and $10^{-2}$ Hartrees/Ångstrom for gradient. SCF convergence was set at $10^{-6}$. The integration parameter, accint, was set to 4.0 for geometry optimizations and to 6.0 for frequency calculations. For the experimental M[N(R)Ar]$_3$ system, the QM/MM[32] method implemented in ADF was used. For these calculations, the system under study was partitioned into two regions one of which was treated with DFT and the other with force field methods. The electronically important parts of the molecule were included in the QM region. Accordingly, $N_2$, CO, the N donors from the amide ligands, and Mo were treated with DFT while the *t*Bu and 3,5-$C_6H_3Me_2$ substituents were treated with molecular mechanics using the Sybyl[33] force field available in ADF. UFF van der Waals parameters[34] were used for Mo and all other parameters involving the metal atoms were set to zero. The bonds that cross the QM/MM partition, known as link bonds, were "capped" by H for the QM region. The ratio of the link bond to the length of the capping bond was kept constant throughout the calculations corresponding to the link bond parameters being fixed at values of $\alpha_{[N–C(R)]}$ = 1.489 and $\alpha_{[N–C(Ar)]}$ = 1.412. All QM/MM calculations on the experimental systems were undertaken in $C_1$ symmetry.

# Methyllead(IV) Derivatives Stabilized by $DAPTSC^{2-}$: Synthesis and Structures of New Diorganolead(IV) Complexes

**José S. Casas,*[a] Eduardo E. Castellano,[b] Javier Ellena,[b] María S. García-Tasende,[a] Facundo Namor,[a] Agustín Sánchez,[a] José Sordo,[a] and María J. Vidarte[a]**

*Dedicated to Professor Joachim Strähle on the occasion of his 70th birthday*

**Keywords:** Lead / Diorganolead(IV) complexes / Metallation

The reaction of the bis(thiosemicarbazone) of dimethyl pyridine-2,6-diyl diketone, $H_2DAPTSC$, with $PbMe_2(OAc)_2$, $PbMePh(OAc)_2$ or $PbPh_2(OAc)_2$ in MeOH afforded the complexes $[PbMe_2(DAPTSC)]$, $[PbMePh(DAPTSC)]$ or $[PbPh_2(DAPTSC)]$ (in the first two cases together with $[Pb(DAPTSC)]$). X-ray crystallography of the Pb(IV) complexes showed that the metal has a pentagonal bipyramidal coordination sphere. The $N_3,S_2$-bound $DAPTSC^{2-}$ anion occupied the equatorial plane and the organic groups were in the apical positions. These compounds retain the same coordination mode in DMSO solution. $DAPTSC^{2-}$ is also $N_3,S_2$-bound in $[Pb(DAPTSC)]$, a complex with a stereochemically active $Pb^{II}$ lone pair. The reaction of $PbPh_2Cl_2$ with $H_2DAPTSC$, also in methanol at room temperature, afforded $[PbPh_2(H_2DAPTSC)]_2[PbPh_2Cl_4]Cl_2{\cdot}6CH_3OH$. X-ray crystallography of this centrosymmetric complex showed it to consist of two $[PbPh_2(H_2DAPTSC)]^{2+}$ cations of similar structure to the neutral $[PbR_2(DAPTSC)]$ complexes, together with a *trans*-octahedral $[PbPh_2Cl_4]^{2-}$ anion and two $Cl^-$ anions. This compound decomposes in DMSO solution, probably evolving to $H_2DAPTSC$ and $PbPh_2Cl_2(DMSO)_n$. In order to evaluate the changes undergone by $H_2DAPTSC$ under metallation, the X-ray structure of the free molecule was also determined.

## Introduction

Structural information on methyllead(IV) coordination compounds is rather scarce. Apart from a small number of compounds with lead–metal bonds or with relatively simple anions (tetramethyllead,[1] trimethyllead chloride,[2] trimethyllead iodide,[3] trimethyllead acetate,[4] trimethyllead 2-furate,[5] trimethyllead diphenylphosphinate[6] or trimethyllead methylthiolato[7]), the only such structure in the CSD[8] is that of the complex bis(tetraphenylimidodiphosphanato)dimethyllead(IV), which was obtained in the recrystallization of the corresponding trimethyllead compound.[6] This paucity of information is probably related to the intrinsic instability of methyllead(IV) compounds, which are more unstable than the corresponding phenyl derivatives.

According to the classic papers of Huber et al.,[9] the decomposition of dimethyllead(IV) compounds occurs through redistribution of the methyl groups as shown in Equation (1).

$$2\ PbMe_2X_2 \rightarrow PbMe_3X + PbMeX_3 \quad (1)$$

This is followed by a reduction-elimination step carried out by the monomethyl derivative, see Equation (2).

$$PbMeX_3 \rightarrow MeX + PbX_2 \quad (2)$$

This evolution seems to be stimulated by the presence of Lewis bases such as DMSO, possibly because these bases stabilize the decomposition products.

As the redistribution process probably involves short distance between the lead centres,[10] we speculated that the starting organolead compound might be more stable, the bulkier the ligand X. We have investigated this idea using the potentially pentadentate bis(thiosemicarbazone) ligand ($H_2DAPTSC$, Figure 1) as $X_2$. This Schiff base coordinates well, in both neutral and deprotonated forms, to a variety of metal and organometal ions.[11] Coordination usually occurs through N(3), N(4), N(5), S(1) and S(2), and results in the occupation of a significant part of the volume around the metal centre.

Herein we describe the synthesis and structures of new complexes obtained using this strategy, including the first methylphenyllead(IV) and only the second dimethyllead(IV) coordination compounds to have been studied by X-ray diffractometry.

## Results and Discussion

### Synthesis

$H_2$DAPTSC was combined in methanol with $PbMe_2(OAc)_2$, $PbMePh(OAc)_2$, $PbPh_2(OAc)_2$, $PbPh_3(OAc)$ and $PbPh_2Cl_2$. The reaction of the diacetates evolved as expected: the bis(thiosemicarbazone) replaced the acetate anions, the basicity of which favoured the observed deprotonation of the incoming ligand.

$$PbR_2(OAc)_2 + H_2DAPTSC \rightarrow [PbR_2(DAPTSC)] + 2\ HOAc$$

However, the additional isolation of [Pb(DAPTSC)] when the organometallic moiety had methyl groups showed that hindrance of the redistribution reaction, Equation (1), was not complete. $[PbPh_2(DAPTSC)]$ was also the product of the reaction between $H_2$DAPTSC and $PbPh_3(OAc)$, probably through a protodephenylation (acidic decomposition) reaction. Reaction of $H_2$DAPTSC with $PbPh_2Cl_2$ gave a product, the stoichiometry of which suggested that the bis(thiosemicarbazone) ligand was neutral and only replaced the chloride ligands of two-thirds of the $PbPh_2Cl_2$ molecules, the remaining third accepting half of the displaced $Cl^-$ anions, see Equation (3).

$$3\ PbPh_2Cl_2 + 2\ H_2DAPTSC \rightarrow 2\ [PbPh_2(H_2DAPTSC)]^{2+} + [PbPh_2Cl_4]^{2-} + 2\ Cl^- \quad (3)$$

This explains why unreacted $H_2$DAPTSC was recovered in spite of the reaction having being carried out in a 1:1 mol ratio. A somewhat related process has been observed[12] when $PbPh_2Cl_2$ was combined with certain monothiosemicarbazones (HTSCs), although in these cases only one chloride ligand was displaced from the coordination sphere of the metal, giving $[PbPh_2Cl(HTSC)]^+$.

### Solid-State Structures

Figure 1 shows the molecular structure of $H_2$DAPTSC·MeOH, which, unlike those of certain similar compounds (see paragraph below),[13] has not hitherto been determined by X-ray crystallography. Although the diffraction data were not of high quality, the conformations and relative orientations of the thiosemicarbazide chains are unquestionable, and this information is relevant to the analysis of the changes that occur upon deprotonation and coordination. The bond lengths and angles in these chains (Table 1) are unexceptional.[14] The chain bearing S(1) is roughly parallel to the line through C5 and N4 (named the "closed-arm" orientation in this article), and places the methyl group $C(10)H_3$ *trans* to N(4). By contrast, the chain bearing S(2) is roughly orthogonal to the line C5–N4 (the "open-arm" orientation), and places the methyl group $C(11)H_3$ *cis* to N(4). These orientations, together with the (*Z*) configuration about C(2)=N(3) in the closed arm, the (*E*) configuration about C(8)=N(5) in the open arm, and the mutually *trans* orientations of the N–N and C=S bonds in both chains, allow the stabilization of the molecule by three intramolecular hydrogen bonds (Figure 1 and Table 2). That the same structure has been observed in the dimethylthallium(III) complex $[TlMe_2(HDAPTSC)]$[15] suggests that it holds in methanol solutions of $H_2$DAPTSC as well as in the solid state.

Interestingly, the above structure differs from the structures of the three N1- or N2-substituted bis(thiosemicarbazones) derived from dimethyl pyridine-2,6-diyl diketone that were studied previously by X-ray diffractometry, namely the bis(3-hexamethyleneiminylthiosemicarbazone) ($H_2L^1$·$H_2O$),[13a] the bis(1-ethylthiosemicarbazone) ($H_2L^2$)[13b] and the bis(1-methylthiosemicarbazone) ($H_2L^3$),[13c] although these compounds differ compositionally only concerning the substituents at N(1) and N(7) ($H_2L^1$ and $H_2L^1$) or N(2) and N(5) ($H_2L^3$). Note that the lattices of $H_2L^2$ and $H_2L^3$ contain only the bis(thiosemicarbazone) molecules, whereas those of $H_2L^1$·$H_2O$ and $H_2$DAPTSC·MeOH also feature molecules of solvent. Although there is a thiosemicarbazide chain with open-arm orientation in all four molecules, the other arm is open in $H_2L^2$ and $H_2L^3$, closed in $H_2$DAPTSC·MeOH and "semi-closed" in $H_2L^1$·$H_2O$ (Scheme 1). Such variety is not unexpected given the flexibility of thiosemicarbazide chains, which readily adapt their conformations to minimize weak intra- and intermolecular forces. Together with the differences in composition and in the number and nature of intermolecular hydrogen bonds, it leads to these compounds

having very different supramolecular structures: dimers in $H_2L^1$·$H_2O$ and $H_2L^3$, chains in $H_2L^2$ and two-dimensional sheets in $H_2$DAPTSC·MeOH.

The molecular structure of [$PbMe_2$(DAPTSC)] is shown, together with its numbering scheme, in Figure 2. The dideprotonated ligand coordinates to the dimethyllead(IV) unit through S1, S(1)$^i$, N(3), N(3)$^i$ and N(4) (i = $-x$, $y$, $z$). The two chains bind the lead atom symmetrically, and together with the nitrogen atom of the pyridine ring occupy the equatorial plane of a pentagonal bipyramidal coordination polyhedron in which the two methyl groups of the almost linear $PbMe_2^{2+}$ unit [C–Pb–C 172.9(5)°] are apical. The resulting [$PbC_2N_3S_2$] kernel has not hitherto been observed. The strongest Pb–N interaction is with the pyridine nitro-

gen [Pb–N(4) 2.509(9)], although this bond is longer than the sum of the covalent radii, 2.35 Å.[16] The identical thiosemicarbazone chains adopt *E* conformation around C(2)–N(3) and *Z* around C(1)–N(2). The conformational changes with respect to free $H_2$DAPTSC are summarized in Scheme 2. The C–S bond is longer in the complex [1.725(7) Å] than in $H_2$DAPTSC [1.674(4) and 1.694(4) Å], showing the expected thione-to-thiol evolution upon metallation. Two hydrogen bonds involving the N(1)$H_2$ groups and the S and N(2) atoms of neighbouring molecules (see Table 2) give rise to a 2D network in the *xz* plane.

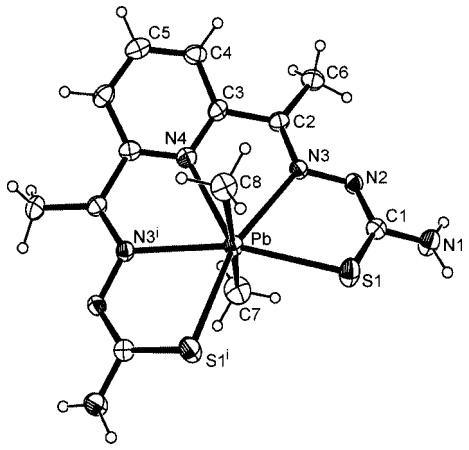

Figure 2. Molecular structure of [$PbMe_2$(DAPTSC)]. Ellipsoids are drawn at the 50% probability level.

That DAPTSC$^{2-}$, as expected, embraces the organometallic moiety, and must hamper intermolecular approach, but the observed formation of [Pb(DAPTSC)] shows that it is still possible to approach the Pb centre from above or below the equatorial coordination plane. We are currently investigating whether more enveloping ligands provide better stabilization of their methyllead(IV) complexes, so reducing the formation of lead(II) derivatives.

The structures of [PbPhMe(DAPTSC)]·0.45$H_2O$ (Figure 3) and [$PbPh_2$(DAPTSC)]·MeOH (see Figure S1 in the electronic supplementary information) are similar to that of [$PbMe_2$(DAPTSC)], showing only minor differences in certain bond lengths and angles and the expected packing differences deriving from their solvent molecules. Analysis of these small structural differences is difficult, because the esd values are not always similar and because the intermolecular forces can influence the intramolecular ones. For example, the Pb–S bonds of [$PbMe_2$(DAPTSC)] are slightly longer than those of [$PbPh_2$(DAPTSC)]·MeOH (see Table 1), but this could be due either to an intrinsically smaller acceptor capacity of the $Me_2Pb^{2+}$ moiety or to the lessening of the donor ability of the sulfur as a consequence of its intermolecular N(1)–H(1)···S bond. Also, in the diphenyllead(IV) complex the two arms of the ligand are no longer equivalent, showing small differences in the Pb–N and Pb–S bond lengths.

Figure 4 shows the molecular structure and numbering scheme of [$PbPh_2$($H_2$DAPTSC)]$_2$[$PbPh_2Cl_4$]$Cl_2$·6$CH_3OH$. This complex is centrosymmetric, consisting of two [$PbPh_2$($H_2$DAPTSC)]$^{2+}$ cations, a [$PbPh_2Cl_4$]$^{2-}$ anion and the two chloride anions. As in the [$PbR_2$(DAPTSC)] complexes (see also ref.[11c,17–20]), in the cation [$PbPh_2$($H_2$DAPTSC)]$^{2+}$ the thiosemicarbazone ligand binds to the diphenyllead(IV) fragment through its two sulfur and three nitrogen atoms. However, there are two major differences with respect to [$PbPh_2$(DAPTSC)]·MeOH: i) all the metal–ligand bonds are longer, and ii) both the C–S bond lengths suggest scant evolution of the ligand to the thiol form. Both these differences reflect weaker interaction with the organometallic cation.

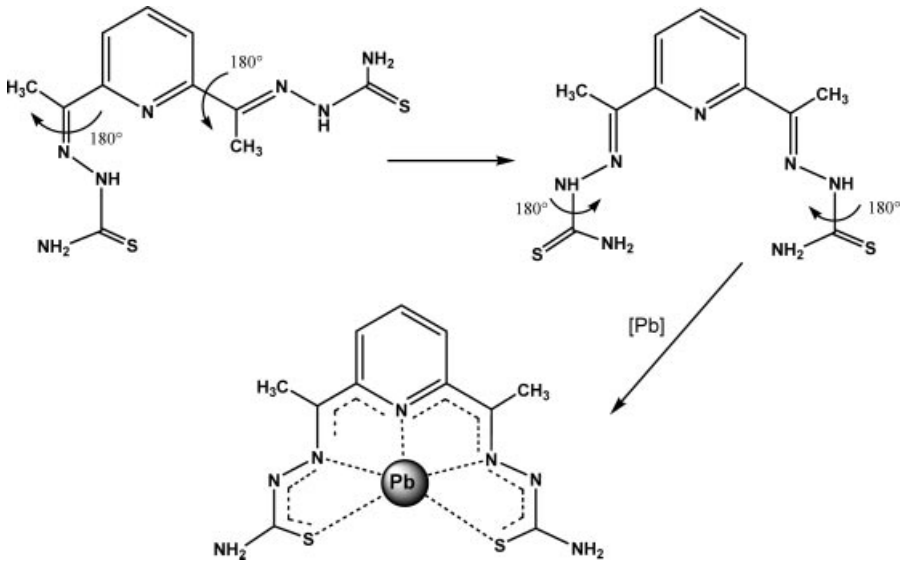

Scheme 2.

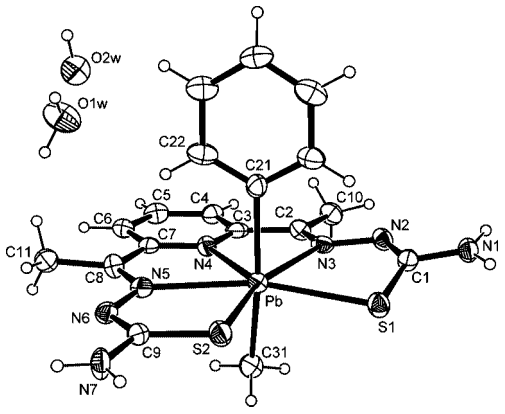

Figure 3. Molecular structure of [PbPhMe(DAPTSC)]·0.45$H_2O$. Ellipsoids are drawn at the 50% probability level.

In the anion $[PbPh_2Cl_4]^{2-}$, the Pb(2) atom is octahedrally coordinated. This fragment was previously found in $[\{PbPh_2(BPyTSC)\}_2(PbPh_2Cl_4)]$·2MeOH,[12] although in that case it interacted with the $[PbPh_2(BPyTSC)]$ moiety through chloro bridges, while in the present case it is only linked to the $[PbPh_2(H_2DAPTSC)]^{2+}$ cation by the hydrogen bonds N(6)–H(6)···Cl(1) and N(7)–H(7A)···Cl(1) (see Table 2). In keeping with this, the Pb(2)–Cl(2) bond in the present compound is shorter than any of the Pb–Cl bonds in the BPyTSC complex, in which both Cl atoms are bridges and one takes part in a hydrogen bond. By contrast, the Pb(2)–Cl(1) bond is longer than any of the Pb–Cl bonds in $[\{PbPh_2(BPyTSC)\}_2(PbPh_2Cl_4)]$·2MeOH, probably because of the two hydrogen bonds of Cl(1). These interactions, together with others involving the isolated chloride ion Cl(3) and the solvent molecules (Table 2), give rise to a complicated two-dimensional network.

Figure 5 shows the molecular structure of [Pb(DAPTSC)]. In this case, the five donor atoms of the ligand define the base of a pentagonal pyramid, and the $Pb^{II}$ cation is 1.1 Å from this plane. The location of all the metal–ligand interactions on the same side of the metal centre suggests the presence of a stereochemically active lone-

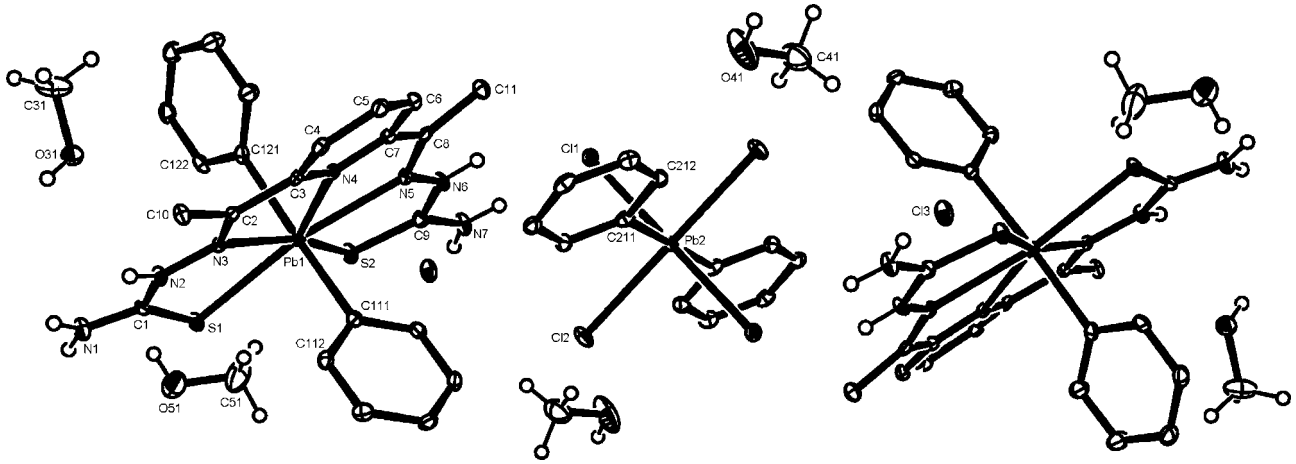

Figure 4. Crystal structure of $[PbPh_2(H_2DAPTSC)]_2[PbPh_2Cl_4]Cl_2$·6$CH_3OH$. All hydrogen atoms, except those on MeOH, and N atoms have been omitted for clarity. Ellipsoids are drawn at the 30% probability level.

pair on the other side. Except for minor differences in bond lengths, this is the same molecular structure as when the ligand is N(1),N(7)-dimethylated,[21] but the crystal packing is different. In the lattice of [Pb(DAPTSC)] the molecules stack along the *x* axis, each Pb centre increasing its coordination number to 7 by means of two weak Pb···S$^{i}$ interactions with the neighbouring molecule on the side opposite its own ligand (i = 1 + *x*, *y*, *z*) and giving rise to a polymeric chain (Figure 6). These polymeric chains interact by N–H···N hydrogen bonds (see Table 2) to form two-dimensional networks in the *xz* plane. In the N(1),N(7)-dimethylated complex[21] no secondary interactions are observed, and each monomer links to another two through π–π interactions between their pyridine rings and the resulting polymeric chains are linked in 2D networks by NH···S hydrogen bonds.

## Solution Studies

The $^{1}$H, $^{13}$C and $^{207}$Pb NMR spectroscopic data for the complexes are included in the Experimental Section. Only $^{1}$H spectra could be obtained for [$PbMe_2$(DAPTSC)] (because of the small amount of solid isolated) and [Pb(DAPTSC)] (because of its poor solubility). The $^{207}$Pb NMR signal was only located for [$PbPh_2$($H_2$DAPTSC)]$_2$[$PbPh_2Cl_4$]$Cl_2$·6$CH_3OH$ and [$PbPh_2$(DAPTSC)]. $^{1}$H and $^{13}$C NMR spectra were interpreted by comparison with those of the ligand.[11a]

The $^{1}$H and $^{13}$C NMR spectra of [$PbPh_2$($H_2$DAPTSC)]$_2$[$PbPh_2Cl_4$]$Cl_2$·6$CH_3OH$ show signals in positions similar to those found in the spectra of the free ligand and $PbPh_2Cl_2$ in [$D_6$]DMSO. This suggests that Equation (3) has been shifted to the left, possibly because $PbPh_2Cl_2$ forms adducts with the solvent DMSO.[22] The $^{207}$Pb chemical shift and $^{3}J$($^{13}$C-$^{207}$Pb) coupling constant support this conclusion, their values being the same as those obtained for $PbPh_2Cl_2$ in DMSO solution.[12] The value of the molar conductivity in DMSO, 8.0 S·cm$^2$·mol$^{-1}$ ($10^{-3}$ M), rules out any ionic behaviour,[23] and is likewise in accordance with the proposed evolution.

The $^{1}$H spectra of [$PbMe_2$(DAPTSC)], [$PbPh_2$-(DAPTSC)], [PbMePh(DAPTSC)] and [Pb(DAPTSC)] are all similar. With respect to the spectrum of the free ligand, the signals corresponding to the N(2,6)H protons disappear because of the formation of DAPTSC$^{2-}$ in the complexes; the signals of the N(1,7)$H_2$ groups shift to higher fields and merge to form just one signal; the C(5)H protons become slightly deshielded and C(4,6)H is shielded. The $^{13}$C NMR spectra of [$PbPh_2$(DAPTSC)] and [PbPhMe(DAPTSC)] are also similar: in both complexes, C(1,9), C(2,8) and C(3,7) are all more shielded than in the free ligand, while C(4,6), C(5) and C(10,11) become deshielded. The shielding of C(1,9) by about 3 ppm is in accordance with evolution of the C=S group to the thiol form when S coordinates to the metal. The shielding of C(2,8) and deshielding of C(10,11) testify to the persistence of Pb–N(3) and Pb–N(5) interactions when the complexes are dissolved in DMSO, while the deshielding of the pyridine ring carbons C(4,6) and C(5) suggests that the Pb–N(4) interaction also perdures. This behaviour is similar to that of the analogous dimethyl and diphenyltin(IV) complexes, [$SnR_2$(DAPTSC)],[11a] which in the solid state show the same coordination scheme as in the lead complexes.

The above conclusions are also supported by the available NMR spectroscopic data for the diorganolead(IV) moieties. For [$PbPh_2$(DAPTSC)], a coordination of at least seven is suggested by the fact that the $^{3}J$ and $^{4}J$($^{1}$H-$^{207}$Pb) coupling constants are larger than in compounds with a coordination number of six;[24] and although the chemical shift of $^{207}$Pb for this compound, –608.9 ppm, is very close to those found in the spectra of certain diaryllead(IV) acetates, for which a coordination number of six has been postulated,[25] this chemical shift is probably not at odds with heptacoordination to C, N and S atoms, as N and S atoms exert a smaller shielding effect than O atoms.

Similarly, the $^{2}J$($^{1}$H-$^{207}$Pb) value for [$PbMe_2$(DAPTSC)], 190.0 Hz, is close to those found for other dimethyllead(IV) complexes[26] with a coordination number of seven in DMSO solution, and the $^{2}J$ value for [PbPhMe(DAPTSC)], 209.2 Hz, is even larger. To the best of our knowledge, the only previously reported $^{2}J$ value for a methylphenyllead(IV) complex is that of $PbPhMeCl_2$, 105.4 Hz, for which a coordination number of five was assumed.[27]

## Conclusions

The reactions of the diorganolead(IV) derivatives $PbMe_2(OAc)_2$ and $PbPhMe(OAc)_2$ with $H_2DAPTSC$ each afford two products: the corresponding dimethyllead(IV) or methylphenyllead(IV) complex, and the lead(II) compound [Pb(DAPTSC)]. Isolation of the former confirms that this bis(thiosemicarbazone) ligand can impede, albeit only partially, the decomposition of methyllead(IV) compounds to "inorganic" lead(II) derivatives. The reaction of $H_2DAPTSC$ with $PbPh_2(OAc)_2$ proceeds without any appreciable decomposition of the organometallic moiety to form $[PbPh_2(DAPTSC)]_2$, which can also be prepared by reacting $H_2DAPTSC$ with $PbPh_3(OAc)$ (probably through a protodephenylation process).

The deprotonation of the incoming ligand in the above processes is attributable to the basicity of the outgoing acetate groups. When $H_2DAPTSC$ reacts with $PbPh_2Cl_2$ it remains neutral and is only able to displace chloride from part of the substrate molecules, competing unsuccessfully with the displaced $Cl^-$ ions for the remainder. The resulting ionic compound, $[PbPh_2(H_2DAPTSC)]_2[PbPh_2Cl_4]Cl_2$, comprises $[PbPh_2(H_2DAPTSC)]^{2+}$ cations and $[PbPh_2Cl_4]^{2-}$ and $Cl^-$ anions.

The above complexes were studied by X-ray diffraction in the solid state, and by $^1H$, $^{13}C$ and $^{207}Pb$ NMR spectroscopy in DMSO solution. In the solid state, both neutral $H_2DAPTSC$ and dianionic $DAPTSC^{2-}$ behave as pentadentate ligands, although the former establishes longer, weaker bonds with the metal. The weaker donor capacity of $H_2DAPTSC$ is corroborated by its displacement by the solvent when $[PbPh_2(H_2DAPTSC)]_2[PbPh_2Cl_4]Cl_2$ is dissolved in dimethyl sulfoxide.

## Experimental Section

**Chemicals:** 2,6-Diacetylpyridine (Aldrich), thiosemicarbazide (Merck), dichlorodiphenyllead (Panreac), chlorotriphenyllead (Aldrich), lead iodide (Aldrich), methyl iodide (Aldrich) and methyllithium (Aldrich), all of reagent grade, were used without further purification.

**Physical Measurements:** Elemental analyses for C, H, N and S were performed with a Fisons 1108 microanalyzer. Melting points were determined with a Gallenkamp electrically heated apparatus. NMR spectra were recorded in DMSO using a Bruker AMX 300 spectrometer for $^1H$ spectra (at 300.14 MHz) and $^{13}C$ spectra (75.4 MHz) (these are referred to TMS through the solvent signals: $^1H$, 2.50 ppm; $^{13}C$, 39.50 ppm), and a Bruker AMX 500 at 104.58 MHz for $^{205}Pb$ spectra [using a saturated solution of $PbPh_4$ in $CDCl_3$ ($\delta$ = 178.0 ppm) ppm as external reference]. Conductance measurements ($S{\cdot}cm^2{\cdot}mol^{-1}$) were performed at room temperature using a Crison MicroMC 2202 conductivity meter and $10^{-3}$ M samples prepared in dry DMSO (Aldrich) under $N_2$ in a glovebox. Elemental analyses and spectroscopic measurements were carried out in the RIAIDT services of the University of Santiago de Compostela. X-ray data were collected at the RIAIDT services of the University of Santiago de Compostela and at the São Carlos Institute of Physics of the University of São Paulo.

**Synthesis of the Ligands and the Starting Organolead(IV) Compounds:** $H_2DAPTSC$ was prepared as described previously[28] from 2,6-diacetylpyridine and thiosemicarbazide. Crystals appropriate for X-ray study were obtained by recrystallization from MeOH. $PbMe_2Br_2$ was prepared using a published method,[29] by reaction of $PbI_2$ with IMe and LiMe in ether, and subsequent reaction of the tetramethyllead formed with $Br_2$. $C_2H_6Br_2Pb$ (397.1): calcd. C 6.05, H 1.52; found C 5.3, H 1.5. $PbPhMeCl_2$ was prepared[27] by reacting MeMgI and MeI with $PbPh_3Cl$. The $PbPh_3Me$ thus formed was dissolved in chloroform and this solution was treated with a stream of HCl(g) until a solid formed. $C_7H_8Cl_2Pb$ (370.25): calcd. C 22.71, H 2.18; found C 21.8, H 2.1. $PbR_2(OAc)_2$ (R = Me, Ph), $PbPhMe(OAc)_2$ and $PbPh_3(OAc)$ were prepared by reaction of the corresponding dihalides or monohalide with AgOAc in 1:2 or 1:1 mol ratio in methanol. The AgX formed was filtered out and the solution containing the organolead(IV) acetate was used immediately in the preparation of the complexes.

**Synthesis of the Complexes:** The complexes were prepared by reacting $H_2DAPTSC$ with $PbMe_2(OAc)_2$, $PbPhMe(OAc)_2$ $PbPh_2Cl_2$, $PbPh_2(OAc)_2$ or $PbPh_3(OAc)$ in methanol.

***Caution!*** Lead is a highly toxic cumulative poison. Lead compounds should be handled carefully.[30]

**[$PbMe_2$(DAPTSC)]:** A freshly prepared solution of $PbMe_2(OAc)_2$ (0.22 g, 0.62 mmol) in MeOH (20 mL) was slowly stirred into a yellow suspension of $H_2DAPTSC$ (0.156 g, 0.503 mmol) in the same solvent (20 mL). The orange suspension obtained was stirred for 1 h at room temperature, and the yellow-orange solid formed was filtered out. The $^1H$ NMR spectrum of this solid suggests a mixture consisting of the complex [Pb(DAPTSC)] [also formed when the ligand reacts with $PbMePh(OAc)_2$, vide infra] together with a small amount of the free ligand. A few monocrystals of [$PbMe_2$(DAPTSC)] that were suitable for X-ray study were obtained from the mother liquor after slow evaporation of the solvent. M.p. 227 °C. $^1H$ NMR ([$D_6$]DMSO): $\delta$ = 6.9 [br. s, 2 H, N(1,7)$H_2$], 7.8 [d, 2 H, C(4,6)H], 8.14 [t, 1 H, C(5)H], 2.50 [s, C(10,11)$H_3$, overlaps with solvent signal], 1.65 [s, $^2J(^1H\text{-}^{207}Pb)$ = 190.2 Hz, 6 H, $CH_3$–Pb] ppm.

**[PbPhMe(DAPTSC)]·0.45$H_2O$ and [Pb(DAPTSC)]:** A solution of freshly prepared $PbPhMe(OAc)_2$ (0.10 g, 0.24 mmol) was slowly added to a suspension of $H_2DAPTSC$ (0.07 g, 0.24 mmol) in the same solvent (10 mL). The orange suspension obtained was stirred for 12 h at room temperature. The orange solid formed was filtered out and vacuum-dried. The $^1H$ NMR spectrum of this solid indicated a mixture of [Pb(DAPTSC)] and [PbPhMe(DAPTSC)]. Evaporation of the mother liquor gave crystals of these two complexes that were suitable for X-ray diffractometry. [PbPhMe(DAPTSC)]·0.45$H_2O$. $C_{18}H_{21.9}N_7O_{0.45}PbS_2$ (614.8): calcd. C 35.13, H 3.59, N 15.95, S 10.43; found C 34.90, H 3.51, N 16.25, S 10.57. $^1H$ NMR ([$D_6$]DMSO): $\delta$ = 7.02 [br. s, 4 H, N(1,7)$H_2$], 7.78 [d, 2 H, C(4,6)*H*], 8.06 [t, 1 H, C(5)*H*], 2.50 [s, C(10,11)$H_3$, overlaps with the solvent signal], 7.51 [d, 2 H, $H_o$(Ph-Pb)], 7.20 [t, 3 H, $H_{m,p}$(Ph-Pb)], 1.79 [s, $^2J(^1H\text{-}^{207}Pb)$ = 209.2 Hz, 3 H, C$H_3$-Pb] ppm. $^{13}C$ NMR ([$D_6$]DMSO): $\delta$ = 176.8 [C(1,9)], 150.7 [C(3,7)], 146.9 [C(2,8)], 122.1 [C(4,6)], 140.3[C(5)], 14.2 [C(10,11)], 130.7 [$C_o$(Ph-Pb)], 129.1 [$C_m$(Ph-Pb)], 127.8 [$C_p$(Ph-Pb)] ppm. The signal for Me-Pb has not been located. [Pb(DAPTSC)]. M.p. 270 °C. $C_{11}H_{14}N_7PbS_2$ (515.60): calcd. C 25.62, H 2.74, N 19.02, S 12.44; found C 26.20, H 2.63, N 18.76, S 12.33. $^1H$ NMR ([$D_6$]DMSO): $\delta$ = 7.02 [br. s, 4 H, N(1,7)$H_2$], 7.83 [d, 2 H, C(4,6)*H*], 8.18 [t, 1 H, C(5)*H*], 2.50 [s, C(10,11)$H_3$, overlaps with solvent signal] ppm.

**[$PbPh_2$(DAPTSC)]:** A freshly prepared solution of $PbPh_2(OAc)_2$ (0.36 g, 0.758 mmol) in MeOH (20 mL) was slowly stirred into a suspension of $H_2DAPTSC$ (0.18 g, 0.578 mmol) in the same solvent (20 mL). The mixture was stirred for 1 h at room temperature and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the orange solid formed was filtered out. M.p. 230 °C. $C_{23}H_{23}N_7PbS_2$ (668.8): calcd. C 41.31, H 3.47, N 14.66, S 9.59; found C 40.48, H 3.90, N 14.02, S 9.74. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 7.14 [br. s, 4 H, N(1,7)$H_2$], 7.72 [d, 2 H, C(4,6)$H$], 7.98 [t, 1 H, C(5)$H$], 2.51 [s, C(10,11)$H_3$], 7.56 [d, $^3J$($^1$H-$^{207}$Pb) = 228.2 Hz, 4 H, $H_o$(Ph-Pb)], 7.20 [t, $^4J$($^1$H-$^{207}$Pb) = 83.0 Hz, 4 H, $H_m$(Ph-Pb)], 7.13 [t, 2 H, $H_p$(Ph-Pb)] ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 176.8 [C(1,9)], 150.3 [C(3,7)], 147.2 [C(2,8)], 122.3 [C(4,6)], 40.3 [C(5)], 14.4 [C(10,11)], 173.0 [$C_{ipso}$(Ph-Pb)], 130.7 [$^2J$($^{13}$C-$^{207}$Pb) = 117.7 Hz, $C_o$(Ph-Pb)], 129.1 [$^3J$($^{13}$C-$^{207}$Pb) = 217.0 Hz, $C_m$(Ph-Pb)], 127.8 [$^4J$($^{13}$C-$^{207}$Pb) = 36.3 Hz, $C_p$(Ph-Pb)] ppm. $^{207}$Pb NMR ([D$_6$]-DMSO): $\delta$ = –608.7 ppm.

[PbPh$_2$(DAPTSC)] was also obtained by reaction of H$_2$DAPTSC with PbPh$_3$(OAc), as follows: a solution of PbPh$_3$(OAc) (0.2 g, 0.42 mmol) in MeOH (20 mL) was added to a yellow suspension of H$_2$DAPTSC (0.13 g, 0.42 mmol) in the same solvent (20 mL). The orange solution obtained was stirred overnight at room temperature and filtered to remove a small amount of H$_2$DAPTSC in suspension. Slow concentration of the filtrate afforded orange crystals of [PbPh$_2$(DAPTSC)]·MeOH that were suitable for X-ray study.

**[PbPh$_2$(H$_2$DAPTSC)]$_2$[PbPh$_2$Cl$_4$]Cl$_2$·6CH$_3$OH:** A suspension of PbPh$_2$Cl$_2$ (0.1 g, 0.23 mmol) in MeOH (10 mL) was stirred into a yellow suspension of H$_2$DAPTSC (0.071 g, 0.23 mmol) in the same solvent (10 mL). The deep yellow suspension obtained was stirred for 4 h at room temperature, after which the yellow solid in suspension was filtered out and discarded (its $^1$H NMR spectrum and elemental analysis corresponded to H$_2$DAPTSC). Slow concentration of the mother liquor afforded a yellow-green crystalline solid that was suitable for X-ray study. M.p. 197 °C. $C_{64}H_{84}Cl_6N_{14}O_6Pb_3S_4$ (2108.02): calcd. C 36.47, H 4.02, N 9.30, S 6.08; found C 35.80, H 3.90, N 10.03, S 6.94. $\Lambda_m$ (DMSO, $10^{-3}$ M) = 8.0 S·cm$^2$·mol$^{-1}$. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 8.40 s, 8.13 [s, 4H N(1,7)$H_2$], 10.30 [s, 2 H, N(2,6)$H$], 8.41 [d, 2 H, C(4,6)$H$], 7.76 [t, 1 H, C(5)H], 2.43 [s, C(10,11)$H_3$], 8.12 [d, 8 H, $H_o$(Ph-Pb)], 7.60 [t, 8 H, $H_m$(Ph-Pb)], 7.43 [t, 4 H, $H_p$(Ph-Pb)] ppm. $^{13}$C NMR ([D$_6$]-DMSO): $\delta$ = 179.0 [C(1,9)], 153.4 [C(3,7)], 148.0 [C(2,8)], 120.4 [C(4,6)], 136.6 [C(5)], 12.0 [C(10,11)], 170.5 [$C_{ipso}$(Ph-Pb)], 133.5 [$C_o$(Ph-Pb)], 129.6 [$^3J$($^{13}$C-$^{207}$Pb) ≈ 200, $C_m$(Ph-Pb)], 129.5 [$C_p$(Ph-Pb)] ppm. $^{207}$Pb NMR ([D$_6$]DMSO): $\delta$ = –507.3 ppm.

**X-ray Crystallography:** Crystal data were collected at room temperature ([PbMe$_2$(DAPTSC)]) or low temperature (all others) on

a CCD-2000 Bruker-Nonius (RIAIDT, University of Santiago de Compostela) or on an Enraf-Nonius CAD4 or Enraf-Nonius Kappa CCD (São Carlos Institute of Physics, University of São Paulo). The data were corrected for absorption by numerical[31] [$PbMe_2$(DAPTSC)], empirical[32] ($H_2$DAPTSC) or semi-empirical[33] (all others) methods. Structures were solved by direct methods for the ligand and the Patterson method for the complexes, followed by normal difference Fourier techniques. Hydrogen atoms were included in idealized positions and refined with isotropic displacement parameters, except that the H bound to the oxygen atom in $H_2$DAPTSC·MeOH was located on the density map and refined isotropically. The program used was SHELX97.[34]

Although the data for the ligand and the $Pb^{II}$ complex were not of very good quality, successive refinements allowed the full resolution of both structures. In [PbPhMe(DAPTSC)]·0.45$H_2O$ the water molecules are disordered, their O atoms occupying two positions, O1W and O2W, with occupancy factors 3.5 and 0.1, respectively. O2W was not refined anisotropically.

Molecular graphics were obtained with ORTEP[35] and PLATON.[36] Crystal data, experimental details and refinement parameters are listed in Table 3.

CCDC-634589 (for $H_2$DAPTSC·MeOH), -634590 (for [$PbMe_2$(DAPTSC)]), -634591 (for [PbPhMe(DAPTSC)]·0.45$H_2O$), -634592 (for [$PbPh_2$(DAPTSC)]·MeOH), -634593 (for [$PbPh_2$($H_2$DAPTSC)]$_2$[$PbPh_2Cl_4$]$Cl_2$·6MeOH) and -634594 (for [Pb(DAPTSC)]) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Figure S1 shows the molecular structure of [$PbPh_2$(DAPTSC)]·MeOH.

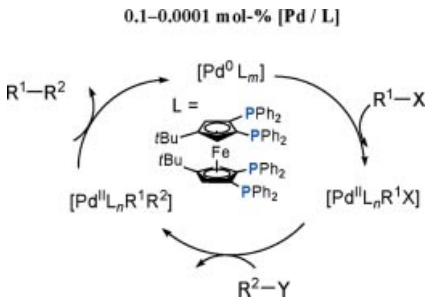
## MICROREVIEW

### C−C Cross-Coupling Reactions

**J.-C. Hierso,* M. Beaupérin, P. Meunier ..... 3767−3780**

Ultra-Low Catalyst Loading as a Concept in Economical and Sustainable Modern Chemistry: The Contribution of Ferrocenylpolyphosphane Ligands

**Keywords:** Sustainable chemistry / Homogeneous catalysis / P ligands / Ferrocenylphosphanes / Cross-coupling / Multidentate ligands



The search for catalytic longevity and ultra-low catalyst loadings on the basis of multidentarity effects and robustness of new ferrocenylphosphane ligands were focused on high-value palladium-catalyzed C−C cross-coupling reactions. Low-loading catalysis was also explored with success for C−N cross-coupling in the allylic amination of achiral substrates.

## SHORT COMMUNICATIONS

### Mo Poly(methimazolyl)borates

**A. F. Hill,* N. Tshabang, A. C. Willis ..... 3781−3785**

Poly(methimazolyl)borate Alkyne Complexes of Molybdenum and Tungsten

**Keywords:** Alkyne / Molybdenum / Tungsten / Methimazolylborates / Scorpionates

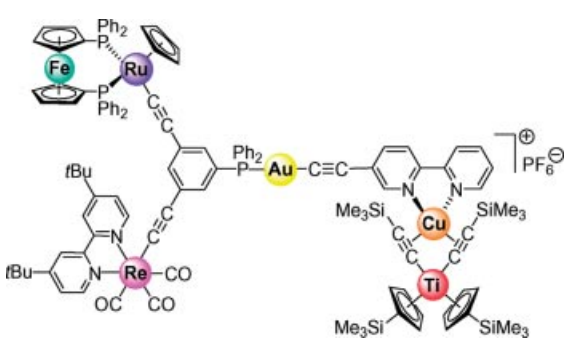
Synthetic routes are reported for the complexes [MI(alkyne)(CO){H$_n$B(mt)$_{4-n}$}] (mt = methimazolyl; $n$ = 1, 2; M = Mo, W). The reaction of [MoI(PhC≡CPh)(CO){HB(mt)$_3$}] with Na[HB(mt)$_3$] provides [Mo(PhC≡CPh)(CO){HB(mt)$_3$}$_2$] which features both κ$^3$-*S*,*S*′,*S*″ (mauve) and κ$^1$-*S* (cyan) coordination modes.

### Heteromultimetallic Complexes

**R. Packheiser, H. Lang* ..... 3786−3788**

The First Heterohexametallic Transition-Metal Complex

**Keywords:** Heteromultimetallic / Transition metal / Acetylides / Organometallic π-tweezers / Transmetallation / Mass spectrometry



The synthesis of a heterohexanuclear Fe-Ru-Re-Au-Cu-Ti metal complex and its characterisation by $^1$H, $^{31}$P{$^1$H} NMR and IR spectroscopy, elemental analysis and ESI mass spectrometry are reported.

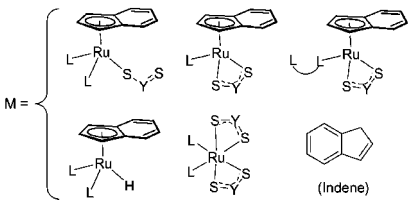
## Ruthenium Complexes

**S. Y. Ng, J. Tan, W. Y. Fan, W. K. Leong, L. Y. Goh,* R. D. Webster ..... 3827–3840**

Synthetic, X-ray Diffraction, Electrochemical, and Density Functional Theoretical Studies of (Indenyl)ruthenium Complexes Containing Dithiolate Ligands

**Keywords:** Ruthenium complexes / Dithiolates / Cyclic voltammetry / Density functional calculations



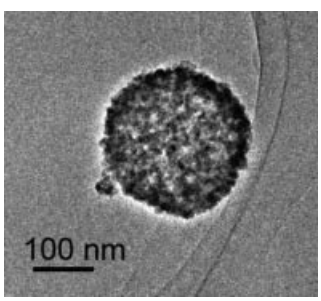
Halide substitution of the complexes [(Ind)Ru($L_2$)X] [($L_2$) = dppf, X = Cl; ($L_2$) = dppm, X = Cl; and ($L_2$) = $(CO)_2$, X = I] with the 1,1-dithiolates $^{-}S_2Y$ (Y = $CNR_2$, COR, $PR_2$) gives rise to a product mixture (M) dependent on the nature of $L_2$, $S_2Y$, and the solvent.

## Hollow Nanospheres

**M. Yang, Y. Zhang, G. Pang,* S. Feng ..... 3841–3844**

Preparation of $Cu_2O$ Hollow Nanospheres under Reflux Conditions

**Keywords:** Cuprous oxide / Nanospheres / Reflux conditions



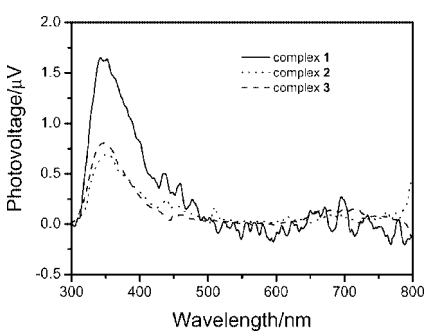
Cuprous oxide hollow nanospheres with diameters of 100–200 nm were prepared by heating a solution of copper acetate and hydrazine as a reductant in 2-propanol at reflux. The UV/Vis diffuse reflectance spectrum indicates that the optical absorption edge of the hollow $Cu_2O$ nanospheres is redshifted relative to their solid counterparts.

## $Mn^{II}$ Supramolecules

**L.-P. Sun, S.-Y. Niu,* J. Jin, L. Zhang ..... 3845–3852**

Crystal Structure and Surface Photovoltage Properties of $Mn^{II}$ Coordination Supramolecules

**Keywords:** Manganese / Hydrogen bonds / Surface photovoltage spectroscopy



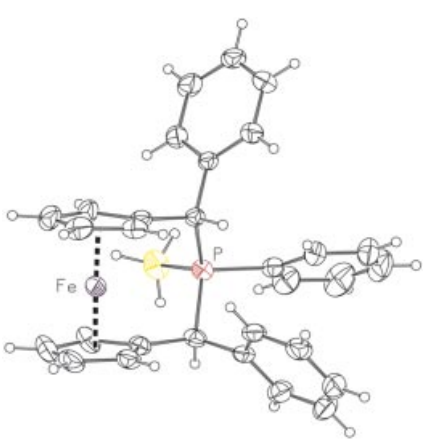
Three $Mn^{II}$ coordination supramolecules were hydrothermally synthesized and characterized by crystallography and SPS techniques. Complexes **1**–**3** exhibit positive SPV response in the range of 300–800 nm; the differences in intensities are attributable to differences in the structures of the complexes. They also possess *p*-type semiconductor characteristics.

## Ferrocenophane-Based Phosphanes

**N. Fleury-Brégeot, A. Panossian, A. Chiaroni, A. Marinetti* .... 3853–3862**

Stereospecific Synthesis, Structural Characterisation and Resolution of 2-Phospha-[3]ferrocenophane Derivatives – a New Chiral Scaffold

**Keywords:** Phosphane ligands / Ferrocenophane / Chiral resolution / Palladium



A stereospecific synthetic approach gives access to 2-phospha[3]ferrocenophane derivatives containing stereogenic carbon atoms in the three-atom bridge. The first chiral phosphane of this series has been obtained in enantiomerically pure form by resolution with a chiral cyclopalladate complex.

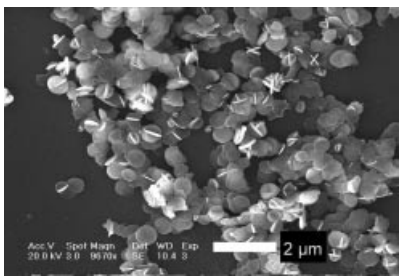
## Europium-Doped Nanodisks

Singly crystalline $LaF_3:Eu^{3+}$ nanodisks with a hexagonal structure were synthesized by a simple method. The mechanism of formation of the nanodisks was explored; furthermore, the size of the disks can be simply moderated by varying the concentration of the initial reactants.



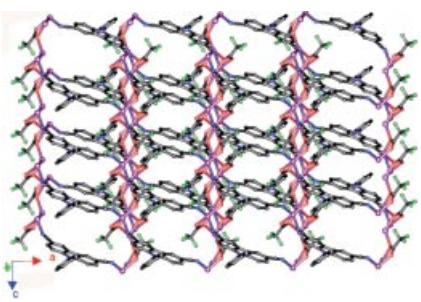
**L. Zhu, J. Meng, X. Cao* ..... 3863–3867**

Facile Synthesis and Photoluminescence of Europium Ion Doped $LaF_3$ Nanodisks

**Keywords:** Materials science / Crystal growth / Rare earths / Fluorescence

## Silver Coordination Polymers

One rigid bent bridging ligand with highly planar π-conjugated spacers, 3,6-dicyano-9-phenylcarbazole (dcphcz), was designed and synthesized. The coordination of the ligand dcphcz with a series of $Ag^I$ salts with different counterions has been investigated. Four new Ag-containing coordination polymers with different polymeric motifs, $\{[Ag(dcphcz)]BF_4\}_n$, $\{[Ag(dcphcz)]ClO_4\}_n$, $\{[Ag(dcphcz)][Ag_2(dcphcz)(H_2O)_2](SO_3CF_3)_3{\cdot}C_6H_6{\cdot}(H_2O)_2\}_n$, and $[Ag_2(dcphcz)(CF_3COO)_2]_n$, were obtained.



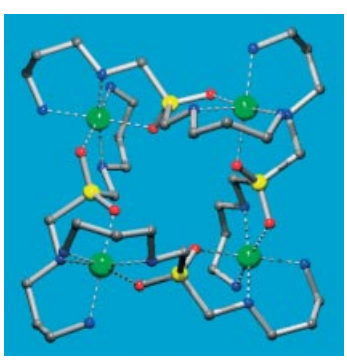
**K.-J. Wei, J. Ni, J. Gao, Y. Liu,* Q.-L. Liu* ..... 3868–3880**

Self-Assembly of Silver(I) Coordination Polymers from AgX (X = $BF_4^-$, $ClO_4^-$, $CF_3COO^-$, and $SO_3CF_3^-$) and a Rigid Bent 3,6-Dicyano-9-phenylcarbazole Ligand: The Templating Effect of Anions

**Keywords:** Silver / N ligands / Supramolecular chemistry / Luminescence / Coordination polymers / Metal-organic frameworks

## Aminophosphinic Acids

The acid–base properties of two tetraaminophosphinic acid ligands and their complexation with $Cu^{2+}$, $Ni^{2+}$, and $Zn^{2+}$ ions were studied by potentiometry. Both ligands behave similarly to linear tetraamines. The phosphinic acid moiety shows weak coordination ability. In the solid state, nitrogen atoms coordinate the metal ions mostly in a square-planar fashion.



**V. Kubíček,* I. Řehoř, J. Havlíčková, J. Kotek, I. Císařová, P. Hermann, I. Lukeš ..... 3881–3891**

Synthesis and Coordination Behavior of Symmetrical Tetraamine Phosphinic Acids

**Keywords:** Aminophosphinates / Complexes / Stability constants / Potentiometry

## Hydrogen-Bonded Helices

Three metal–organic coordination polymers were synthesized under hydrothermal conditions. The bptc ligand takes part in three different coordination modes, and compound **1** exhibits a 3D network with 1D open channels that contain free solvent water molecules. Two kinds of chiral, helical, hydrogen-bonded chains exist in the neighboring holes.

# Ultra-Low Catalyst Loading as a Concept in Economical and Sustainable Modern Chemistry: The Contribution of Ferrocenylpolyphosphane Ligands

**Jean-Cyrille Hierso,*[a] Matthieu Beaupérin,[a] and Philippe Meunier[a]**

**Keywords:** Sustainable chemistry / Homogeneous catalysis / P ligands / Ferrocenylphosphanes / Cross-coupling / Multidentate ligands

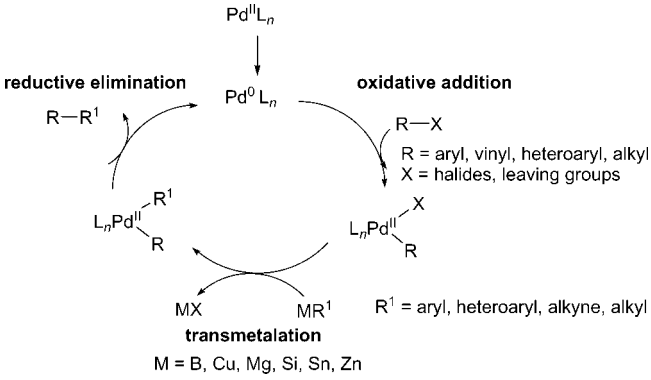
The challenge of sustainability in modern chemistry will be met with new technologies and processes provided significant progress is made in several key research areas, such as the expansion of chemistry from renewable feedstock, the design of environmentally benign chemicals and solvents, the minimization of depletive resources, and the development of high-performance catalysis. In this prospect, ligand chemistry is a pivotal science that links modern-organic, -inorganic, -organometallic, and -coordination chemistry through a vast number of valuable applications, precisely associated to catalysis. We review in this article our recent work on catalysis promoted by original ferrocenyl tetra-, tri-, and diphosphane ligands. New concepts, taking advantages of this family of branched multidentate ligands, have led to progress in homogeneous catalysis. The search for catalyst longevity and ultra-low catalyst loadings (high turnover numbers), on the basis of multidentarity effects and robustness of the ferrocenyl backbone were focused on high-value palladium-catalyzed C–C cross-couplings, such as Heck, Suzuki, and Sonogashira reactions. Low catalyst loading was also explored for C–N cross-coupling in the allylic amination of achiral substrates. The advantages of this newly born family of ligands in the class of multidentate compounds are discussed in light of the valuable information gathered up to now on their reactivity, structure, and mechanistic behavior.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction and Scope

Sustainable chemistry is expected, at the beginning of this new century, to solve many of the global environmental challenges we must face. This major societal and economic matter is now a priority of the scientific research programs in many industrialized nations,[1] and a guidance for chemists on this multiparameter question is summarized by the twelve principles of green chemistry.[2] One of these principles, which concerns explicitly catalytic chemistry, states: "Catalytic reagents (as selective as possible) are superior to stoichiometric reagents". The underlying idea of this principle is that, owing to catalysis, the minimization of the resources consumed and the economy of atoms is effective. However, a practical overview of the huge field covered by the term "catalysis" shows that the so-called "catalyst amount" ranges from substoichiometric amounts (30 mol-%) to amazingly low quantities down to $10^{-6}$ mol-%.[3,4]

Among the most fertile and innovative fields in "catalysis" for the last three decades is the formation of carbon–carbon bonds by employing active transition metals (Scheme 1). In this prospect, palladium catalysts emerged as powerful tools in reactions aimed at the coupling of organic halides with organometallic substrates that are based mainly on boron- (Suzuki–Miyaura reaction), tin- (Stille reaction), zinc- (Negishi reaction), silicon- (Hiyama reaction), or magnesium reagents (Kumada–Corriu reaction).[5]



Scheme 1.

From an economic and financial point of view,[6] the catalyst turnover number (TON)[7] is a key parameter for industrial applications. Relevant recent reviews by Farina[8] and by Corbet and Mignani[5] illustrated that the efficient use of a catalytic system at less than $10^{-1}$ mol-% (TON ≥ 1000) can avoid its recovery and thus its recycling. Convergent benefits are found between industrial and sustainable development with the use of such kind of high-efficiency catalytic systems. As a consequence, in the last

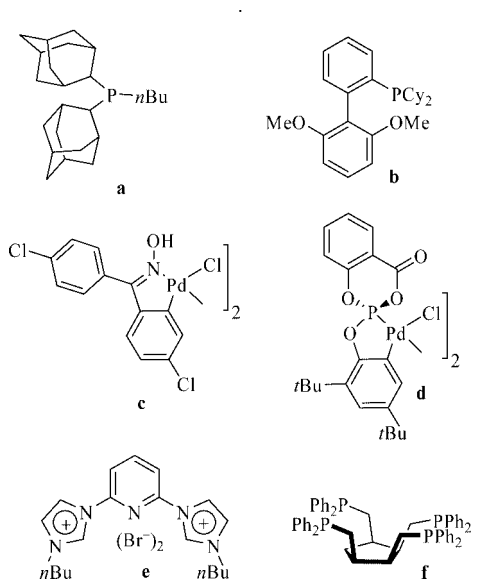
decade the progress on ligand chemistry became a major goal in the community of the organic chemist, and creativity partnered with a better understanding of the mechanistic necessities led to the emergence of several families of useful ligands for high-turnover palladium catalytic systems. For instance, and nonexhaustively: bulky electron-rich trialkylmonophosphanes,[9] (biaryl)dialkylphosphanes,[10] di- and tridentate pincers,[11] heterostructures at the origin of various palladacycles,[12,13] carbenes,[14] or multidentate polyphosphanes (Scheme 2) were found to be very efficient catalytic auxiliaries.[15]

On this basis and ongoing since the mid 1990s we developed the design, synthesis, and characterization of original di-, tri-, and tetraphosphanes built on the ferrocenyl backbone (some representative examples of the library of ligands developed are depicted in Scheme 3). Catalytic applications of a selection of these ligands with palladium in the formation of C–C and C–N bonds are reviewed herein. The reactions explored, namely Suzuki, Heck, and Sonogashira cross-couplings, as well as the amination of allylic acetates, led either to high TONs or high turnover frequencies (TOFs) depending on the reaction and on the ligands. The general advantages of this newly born family of ligands, in the class of multidentate species, are detailed and discussed in light of the gathered structural and mechanistic information. Finally, some of the trends and properties identified could serve as a privileged starting point for the further development of the promising concepts of catalyst *longevity* and ultra-low catalyst loading.



Scheme 2.

## Milestones in Ultra-Low Catalyst Loadings

In 1995 Herrmann and coworkers reported "...new, structurally defined, easy-to-handle palladium complexes, that surpass all previously known catalysts of the Heck reaction as regards stability and lifetime."[16] The authors observed from kinetic measurements that standard catalytic systems combining 1 mol-% $Pd(OAc)_2$ with 2–6 mol-% of

*Dr. Jean-Cyrille Hierso completed his Ph.D. in 1997 at the Université P. Sabatier and the National School of Engineer of Toulouse under the supervision of Prof. Ph. Kalck, after an M.S. degree with Drs. B. Chaudret and C. Amiens. He worked as a postdoctoral fellow first with Prof. M. Etienne (LCC-CNRS) then in the group of Prof. J. Reedijk (Leiden University, The Netherlands). In 2001, he was appointed Maître de Conférences at the Université de Dijon, and was awarded his Habilitation in 2006. He has coauthored about 40 papers in the fields of chemical vapor deposition, organometallic chemistry, hetero- and homogeneous catalysis, metalloligand synthesis, and coordination chemistry.*

*Matthieu Beaupérin was born in 1982 in Saint-Malo (France). In 2006, he graduated from the Graduate School of Chemistry and Chemical Engineering of Clermont-Ferrand (ENSCCF) specializing in organic chemistry. He is currently a Ph.D. student in the group of Prof. P. Meunier, where he is working under the supervision of J.-C. Hierso on the synthesis of ferrocenylphosphanes and their use in catalyzed cross-coupling reactions.*

*Prof. Philippe Meunier was born in Auxerre (France) in 1946. He obtained his Ph.D. (1979) in heterocyclic chemistry from the Université de Bourgogne after a long period of work in photoelectron spectroscopy and theoretical chemistry at the University of Pau. He then joined the group of organometallic chemistry at Dijon and began to work in group 4 organometallic chemistry. He became a full professor in 1992, and he is currently head of a research group in the Institute of Molecular Chemistry of the Université de Bourgogne (ICMUB-CNRS 5260). His research interests concern group 4 organometallic chemistry for synthesis and group 10 coordination chemistry for catalysis applications.*

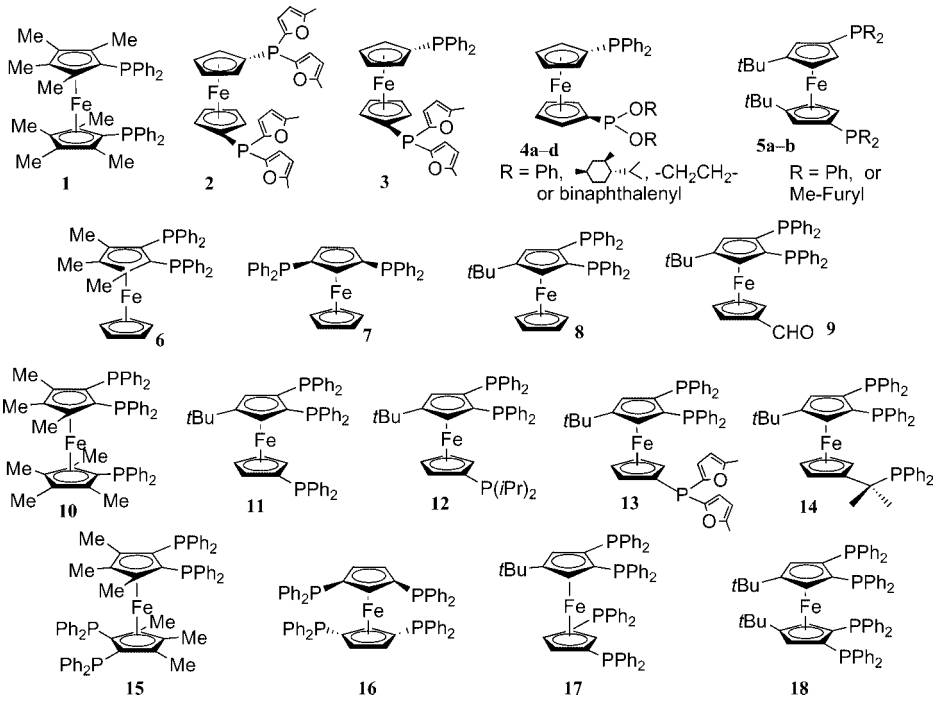
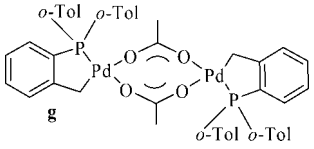


Scheme 3.

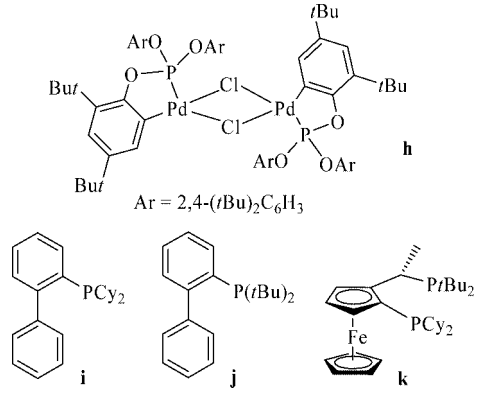
the triarylphosphane $PPh_3$ are rapidly deactivated in the Heck reaction between 4-bromoanisole and *n*-butyl acrylate above 120 °C; a temperature useful for the activation of demanding organic halides such as deactivated bromides and chlorides. The decomposition of the ligand ($P–C_{aryl}$ bond cleavage), as well as its oxidation [$P(O)Ph_3$ formation] were proposed to be responsible for the deposition of catalytically inactive palladium black. From the treatment of palladium(II) acetate with tris(*o*-tolyl)phosphane in toluene, cyclometalation afforded efficient palladacycle pre-catalyst **g** (Scheme 4).[16] In the Heck reaction of the activated 4-bromobenzaldehyde to *n*-butyl acrylate a TON of 200000 was obtained in a quantitative coupling achieved at 135 °C for 12 h ($5 \times 10^{-4}$ mol-% cat.).



Scheme 4.

This study can be considered as a starting point in the explicit recognition of the concepts of long-term stability and increased lifetimes of the catalysts in palladium-catalyzed cross-coupling-type reactions. The mechanistic involvement of palladacycles in cross-couplings is subject of severe controversy:[8] whether palladacycles upon catalysis remain quasiunchanged and react in $Pd^{II}/Pd^{IV}$ processes, or only constitute slow-delivery reservoirs of active naked palladium, the result was a focus of the community on the ultra-low catalyst loading in C–C cross-coupling reactions.

After this work, the group of Beller[17] followed by Bedford[18] both confirmed the efficiency of palladacycles in the activation of aryl bromides for biaryl formation (in Suzuki coupling) under conditions of low catalyst loading. Palladacycle **g**, depicted in Scheme 4, allowed the coupling of phenylboronic acid to the electronically activated 4-bromoacetophenone with a TON of 74000 (yield 74%, in the presence of $10^{-3}$ mol-% cat. at 130 °C for 16 h) and to the electronically deactivated 4-bromoanisole with a TON of 7600 (yield 76%, in the presence of $10^{-2}$ mol-% cat.).[17] Orthopalladated triarylphosphite complex **h** (Scheme 5) was employed for the coupling of phenylboronic acid to 4-bromoacetophenone and 4-bromoanisole and resulted in the formation of coupling products with TONs of, respectively, 1000000 (yield 100%, in the presence of $10^{-4}$ mol-% cat. at 110 °C for 2 h) and 30000 (yield 30%, $10^{-3}$ mol-% cat. at 130 °C for 15 h).[18] The same phosphite palladacycle pre-catalyst allowed the Heck coupling of 4-bromoacetophenone to styrene, and 4-bromoanisole to *n*-butyl acrylate, with, respectively, TONs of 5700000 (yield 57%, $10^{-5}$ mol-% cat. at 180 °C for 69 h) and 9800 ($10^{-2}$ mol-% cat. at 160 °C for 65 h).[19]



Scheme 5.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In 1999, Buchwald and coworkers disclosed a new family of ligands able to promote ultra-low loading catalysis with aryl bromides and chlorides.[20,21] (Biaryl)dialkylphosphanes **i** and **j** (Scheme 5) were the first of this class to be employed: the coupling of phenylboronic acid to the electronically activated 4-bromoacetophenone and the electronically deactivated 4-(*tert*-butyl)bromobenzene was effective with TONs of, respectively, 91000000 (yield 91%, $10^{-6}$ mol-% [Pd/2·**j**] at 100 °C for 24 h) and 18600 (yield 93%, $5 \times 10^{-3}$ mol-% [Pd/2·**i**] at 100 °C for 16 h). In addition, phenylboronic acid was successfully coupled to the electronically activated 4-chloroacetophenone with a TON of 4600 (yield 92%, $2 \times 10^{-2}$ mol-% [Pd/2·**j**] at 100 °C for 23 h), and to the electronically deactivated 4-chlorotoluene with a TON of 1860 (yield 93%, $5 \times 10^{-2}$ mol-% [Pd/2·**i**] at 100 °C for 25 h). These results well-illustrate the difficulties encountered when organic chlorides are preferred to bromides for cross-coupling. Interestingly, Buchwald indicated also at that time that the coupling of the electronically activated 4-bromoacetophenone was possible with $Pd(OA_C)_2$ in the absence of a ligand with a TON of 100000 (yield 100%, $10^{-3}$ mol-% Pd at 100 °C for 19 h) while "...under these conditions, Suzuki coupling reactions of other substrates give little or no products in the absence of phosphane ligands.";[21] anticipating, therefore, the future studies on ligand-free palladium low loading catalyst (see below).

After 2000, a blooming of the high-turnover palladium catalysts for the reactions of Heck, Suzuki, Stille, and Sonogashira occurred in the literature, with systems based on, for instance, ligands such as trialkylmonophosphanes,[9] modified (biaryl)dialkylphosphanes,[10] oxime palladacycles,[12] strongly π-acidic orthopalladated diarylphosphite palladacycles,[13] or carbenes[14] (respectively, **a**, **b**, **c**, **d**, and **e** in Scheme 2). The use of ferrocenyl diphosphanes, such as the electron-rich josiphos (**k**; Scheme 5) was also successful in some other low catalyst loading cross-couplings,[22] following the seminal works published by Hayashi et al. for the Kumada–Corriu reaction.[23] The high performances of the aforementioned systems were thoroughly reviewed in many recent articles,[8,24–28] and their portrayal fall out of the scope of the present review; however, two important points appeared to us as conceptual landmarks: the efficiency and scope of the multidentate diarylalkylphosphane named tedicyp (**f**; Scheme 2), and the so-called "homeopathic" ligand-free catalysis.

At the end of 2000, the first study by Doucet and Santelli appeared on the catalytic activity of the tetradentate polyphosphane ligand *cis*,*cis*,*cis*-1,2,3,4-tetrakis(diphenylphosphanylmethyl)cyclopentane (tedicyp) in C–N cross-coupling reactions.[15,29] By employing this original ligand in the palladium-catalyzed amination of allyl acetates, a TON of 680000 was obtained for the coupling of dipropylamine to allylacetate (yield 68%, $10^{-4}$mol-% cat. at 25 °C for 136 h). The authors intensively explored the catalytic performances of this multidentate ligand that is based on a cyclopentane alkyl backbone in the pallado-catalyzed reactions of allylic amination, Heck, Suzuki, and Sonogashira. This chemistry was reviewed recently,[4] nevertheless it is worthy of note that, in the reported corpus of more than 50 papers devoted to the activity of Pd/tedicyp in C–C and C–N cross-coupling, was described: (1) the coupling of phenylboronic acid to 4-bromoacetophenone and to 4-bromoanisole with TONs of, respectively, 96000000 (yield 96%, $10^{-6}$ mol-% cat. at 130 °C for 135 h) and 93000 (yield 93%, $10^{-3}$ mol-% cat. at 130 °C for 24 h);[30] (2) the Heck coupling of activated 3,5-bis(trifluoromethyl)bromobenzene to *n*-butyl acrylate with a remarkable TON of 210000000 (yield 21%, $10^{-7}$ mol-% cat. at 130 °C for 72 h) or with a TON of 78000000 and a better yield of 78% ($10^{-6}$ mol-% cat. at 130 °C for 40 h), and the coupling of deactivated 4-bromoanisole to *n*-butyl acrylate with a TON of 82000 (yield 82%, $10^{-3}$ mol-% cat. at 130 °C for 72 h);[31] (3) the Sonogashira cross-coupling of phenylacetylene to 4-bromoacetophenone and 4-bromoanisole with TONs of, respectively, 700000 (yield 70%, $10^{-4}$ mol-% cat. at 140 °C for 20 h) and 3800 (yield 38%, $10^{-2}$ mol-% cat. at 140 °C for 20 h).[32] The scope and performances of tedicyp shed light on the interest of examining the activity of multidentate phosphanes for the development of ultra-low loading catalytic processes.

The term of "homeopathic" catalyst loading has been related to the ligand-free palladium-catalyzed Heck reaction and biaryl formation.[33] Whereas this expression is objectively inappropriate for several reasons,[34] the ligand-free catalysis results that are associated with it are interesting from an economic and environmental point of view. Ligand-free $Pd(OAc)_2$ can be used as a catalyst in the Heck reaction of aryl bromides as long as the amount of catalyst is kept between $10^{-1}$ to $10^{-2}$ mol-% (TONs ranging from 1000 to 10000). For instance, in the coupling of the activated 4-bromobenzaldehyde to *n*-butyl acrylate a TON of 2000 was obtained with a quantitative coupling achieved at 135 °C in only 1 h ($5 \times 10^{-2}$ mol-% cat.). As expected, the coupling of deactivated 4-bromoanisole to *n*-butyl acrylate was more difficult, leading to a TON of 1800 in 5 h at 135 °C (yield 91%, $5 \times 10^{-2}$ mol-% cat.).[3] The authors believe that the corresponding concentration of palladium is low enough to preclude deactivation by palladium-black formation; conversely, a catalyst/substrate ratio lower than $10^{-2}$ mol-% lead to a conversion too slow to be practical. The limits of this interesting concept were found for couplings such as Negishi- (with zinc organometallics) and Kumada–Corriu reactions (with Grignard reagents), whereas the Suzuki reaction could be carried out with aryl bromides in the presence of $5 \times 10^{-1}$ to $2 \times 10^{-2}$ mol-% of $Pd(OAc)_2$: for instance, the coupling of phenylboronic acid to activated 4-bromoacetophenone was achieved with a TON of 4800 (yield 95%, $2.5 \times 10^{-2}$ mol-% cat., at 90 °C in 4 h). These results illustrate that to reach the lowest catalyst loadings (below $10^{-2}$ mol-% cat.) the stabilization and steric/electronic activation provided by the ligand chemistry remain up to now unavoidable. Table 1 summarizes the short historical perspective given above through the example of the Suzuki reactions under ultra-low catalyst loading conditions.

Finally, to develop our projects on sustainable chemistry and ultra-low catalyst loading we were inspired by a study

reported in 2002 by Bedford on "...the importance of catalyst longevity".[13] The difficulties encountered in the coupling of halides other than iodides has often been ascribed to their reluctance to perform the oxidative addition to palladium. Improved catalytic activities were detected from systems that combine palladium to hindered strongly σ-electron-donating ligands (such as trialkylphosphanes); in addition, the success of bulky ligands has been suggested to be derived from the ability of these ligands to promote geometrically driven coordinative unsaturation important to the transmetalation and reductive elimination steps. The perspective of Bedford and coworkers was different when they attributed the spectacular TONs they observed (with poor σ-donor phosphonite ligand **d**; Scheme 2) not to a specific high activity of their catalyst but more to an outstanding *catalyst longevity*. This concept of catalyst longevity, and consequently the stability of the catalytic species under the reaction conditions, appeared primordial to us for sustainable chemistry and led us to employ the robust ferrocenyl backbone as a platform with a tunable flexibility to build new active ligands.

## Performances of Ferrocenylphosphanes in Heck and Suzuki Reactions

### Structural Considerations for Tetraphosphane Ferrocenic Ligands

The ferrocenyl backbone, owing to its peculiar sandwich structure, displays a number of different conformations that have to be elucidated for ferrocenyl derivatives both in the solid-state and in solution. We were specifically interested in the mutual positions adopted by the different phosphorus atoms. For instance, tetraphosphanes **15** and **18** [1,1′,2,2′-tetrakis(diphenylphosphanyl)-3,3′-4,4′,5,5′-hexamethylferrocene and 1,1′,2,2′-tetrakis(diphenylphosphanyl)-4,4′-di-*tert*-butylferrocene; Scheme 3] revealed very different geometrical features. As shown by the molecular structures in Figure 1, in the solid state the favored conformation for **15** (Figure 1, left) shows the two chelating pairs of phosphorus atoms that face opposite directions (staggered conformation).

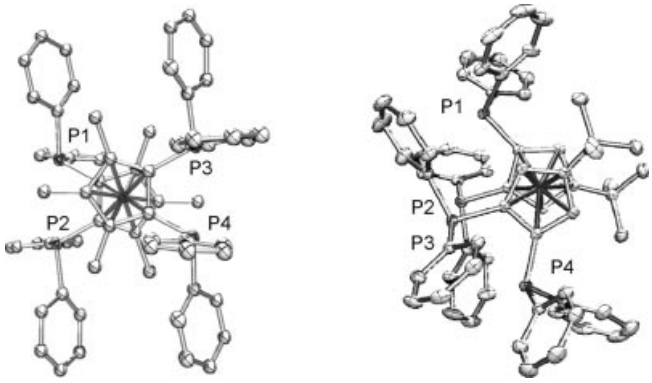

Figure 1. Molecular structures of **15** and **18** from X-ray diffraction studies (Povray illustration).

Conversely, in the favored conformation found for **18** (Figure 1, right) the four phosphorus atoms point towards the same half-space as a result of steric factors attributed to the hindering *tert*-butyl groups; the phenyl groups are also interlocked (P2 and P3 are in the eclipsed conformation).[35] In solution, NMR spectroscopic experiments indicated that the conformation of **18** is restricted, similarly to the solid state, exhibiting an AA′BB′ spin-system pattern. *The cisoid conformation for the tert-butylated tetraphosphane was conserved in solution above 90 °C, as attested by $^{31}P$ NMR spectroscopy in [$D_8$]toluene.* Therefore, in the multidentate ferrocenylphosphanes the coordination properties not only depend on the chelating possibilities of phosphorus (1,1′- or 1,2-P bonding) but also on the rotational features of the ferrocenic backbone, a rather unexploited facet prior to these studies.

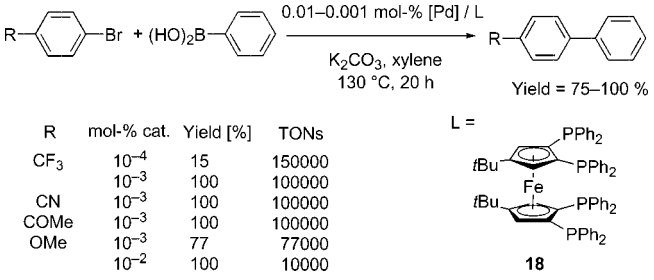
### Suzuki C–C Cross-coupling and Heck Vinylation with a Ferrocenyltetraphosphane

As detailed above, in the last decade much progress in metal-catalyzed cross-coupling reactions was accomplished in the synthesis and recognition of efficient auxiliary ligands. Regarding the organic substrates now, significant advances have been reported on the activation of the relatively inert aryl bromides and chlorides relative to their iodide analogues; indeed, the relative reactivity of the aryl halides is well-established as Ar–I (65 kcal mol$^{-1}$ of bond dissoci-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ation energies) >> Ar–Br (81 kcal mol$^{-1}$) > Ar–Cl (96 kcal mol$^{-1}$).[36] As a consequence, we focused our efforts in the coupling of bromides and chlorides more than iodides. We verified, however, that concerning the coupling of activated or deactivated iodides all the catalytic systems described herein shows an enhancement in the activity of one or two orders of magnitude relative to bromides.

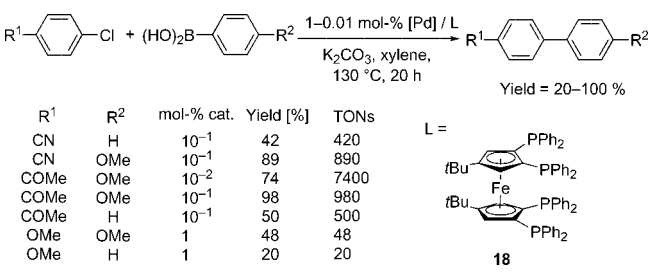
The first reaction we explored under conditions of ultra-low catalyst loading was the arylation of aryl halides with boronic acids (Scheme 6).[37] With the view to deliver more economical catalytic systems, we tested in priority nickel catalysts [$NiCl_2$, $Ni(cod)_2$, cod = 1,5-cyclooctadiene] with multidentate tetraphosphane **18** (Scheme 3), under various conditions, with unsuccessful results. Conversely, the results obtained by employing the system $[Pd(\eta^3\text{-}C_3H_5)Cl]_2$ combined with **18** were very interesting. High reaction rates were obtained with aryl bromides. TONs around 100000 were found for the coupling of phenylboronic acid to the activated 4-bromoacetophenone and 4-cyanobromobenzene (up to 150000 with 4-trifluoromethylbromobenzene) and a very good TON of 77000 was reached with deactivated 4-bromoanisole.



| R | mol-% cat. | Yield [%] | TONs |
|---|---|---|---|
| $CF_3$ | $10^{-4}$ | 15 | 150000 |
| | $10^{-3}$ | 100 | 100000 |
| CN | $10^{-3}$ | 100 | 100000 |
| COMe | $10^{-3}$ | 100 | 100000 |
| OMe | $10^{-3}$ | 77 | 77000 |
| | $10^{-2}$ | 100 | 10000 |

Scheme 6.

The coupling of chlorides, although successful for electronically activated substrates, did not allow reach high TONs (Scheme 7); the catalytic activity of the system, nevertheless, compared favorably to the activity of classical ligands such as $PPh_3$ or dppe [1,2-bis(diphenylphosphanyl)-ethane].[37] In the coupling of phenylboronic acid to electronically activated 4-chloroacetophenone, the systems combining [Pd/4 $PPh_3$] and [Pd/2 dppe] were found useless at low loadings of 0.1 mol-% cat. as less than 2% and only 22% yield, respectively, of the coupling products were obtained in 20 h. The catalyst [Pd/**18**] reached, under these conditions, a TON of 500 (yield 50%).

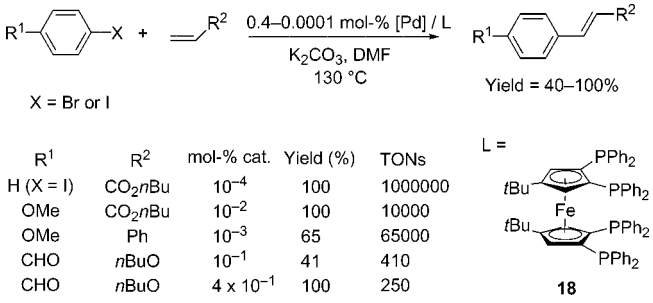


| $R^1$ | $R^2$ | mol-% cat. | Yield [%] | TONs |
|---|---|---|---|---|
| CN | H | $10^{-1}$ | 42 | 420 |
| CN | OMe | $10^{-1}$ | 89 | 890 |
| COMe | OMe | $10^{-2}$ | 74 | 7400 |
| COMe | OMe | $10^{-1}$ | 98 | 980 |
| COMe | H | $10^{-1}$ | 50 | 500 |
| OMe | OMe | 1 | 48 | 48 |
| OMe | H | 1 | 20 | 20 |

Scheme 7.

The highest TON of 7400 was obtained for the coupling of 4-methoxybenzeneboronic acid with 4-chloroacetophenone (yield 74%, $10^{-2}$ mol-%, 130 °C, 20 h). The substrate 4-cyanochlorobenzene was also efficiently coupled to 4-methoxybenzeneboronic acid with a TON of 890 (yield 89%, $10^{-1}$ mol-%). Lower TONs were obtained for the couplings with electronically deactivated 4-chloroanisole, showing the limit of the ligand, which remains nevertheless among the most active phosphanes in the class of the ligands incorporating exclusively aryl groups on the phosphorus atom (poor electron donor relative to alkyl substituents).

With the same catalytic system employed for Suzuki coupling, the Heck vinylation of aryl iodides and bromides with *n*-butyl acrylate, styrene, and *n*-butyl vinyl ether were investigated under conditions of very low catalyst loading (Scheme 8).[37] In the coupling of unactivated iodobenzene to *n*-butylacrylate, a very high TON of 1000000 was obtained (yield 100%, $10^{-4}$ mol-%, 130 °C, 48 h). With electronically deactivated 4-bromoanisole, the coupling to *n*-butyl acrylate and to styrene proceeded with high TONs of 10000 (yield 100%, $10^{-2}$ mol-%, 130 °C, 48 h) and 65000 (yield 65%, $10^{-3}$ mol-%, 130 °C, 20 h), respectively. Even the strongly deactivated electron-rich alkene *n*-butyl vinyl ether led to the corresponding adducts in the presence of 0.1 mol-% catalyst with TONs ranging from 250 to 400.



| $R^1$ | $R^2$ | mol-% cat. | Yield (%) | TONs |
|---|---|---|---|---|
| H (X = I) | $CO_2n$Bu | $10^{-4}$ | 100 | 1000000 |
| OMe | $CO_2n$Bu | $10^{-2}$ | 100 | 10000 |
| OMe | Ph | $10^{-3}$ | 65 | 65000 |
| CHO | *n*BuO | $10^{-1}$ | 41 | 410 |
| CHO | *n*BuO | $4 \times 10^{-1}$ | 100 | 250 |

Scheme 8.

The characterization of the complexes involved in the catalytic cycles is important to understand the origin of their activities under conditions of ultra-low catalyst loading. The palladium precatalyst complexes formed under the conditions employed for the Heck and Suzuki reactions in chlorinated solvents (P/Pd = 4) were identified as being ex-

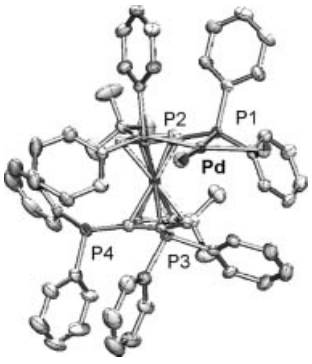


Figure 2. Molecular structure of [$PdCl_2$·**18**] from X-ray diffraction studies.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

clusively 1,2-chelating P-bonded either mononuclear ([$PdCl_2$·**18**], see Figure 2, formed in majority above 90%) or dinuclear palladium chloride (<10%).[37]

NMR characterization in solution confirmed the solid-state X-ray analysis of the complexes, and clearly indicated that the phosphorus P3 atom is strongly oriented towards the (P1/Pd/P2) area of coordination (and especially its lone pair of electrons). The fine analysis of the unprecedented "through-space" coupling constants found between the phosphorus atoms was detailed,[38] and a theoretical model was proposed for nuclear spin transmitting.

In the course of the precatalyst characterization studies, an intriguing phenomenon was identified and investigated by variable-temperature $^{31}P$ NMR spectroscopy.[37] Under the starting conditions used for Heck and Suzuki catalysis (P/Pd = 4) was observed the occurrence of dynamic behavior at the scale rate of NMR spectroscopy. Two signals were detected between 0 and 10 ppm, an unusual range of chemical shift for the –$PPh_2$ groups (A in Figure 3).[39]

We envisioned that the four phosphorus atoms could be alternatively bonded and released from the palladium center, leading to large signals of average chemical shift. Upon cooling, the characteristic behavior of the labile compounds was confirmed with a coalescence and decoalescence (B in Figure 3) of the spin system. The dynamic phenomenon was reversible, and the labile species were stable up to 370 K. At this temperature the biligated mononuclear com-

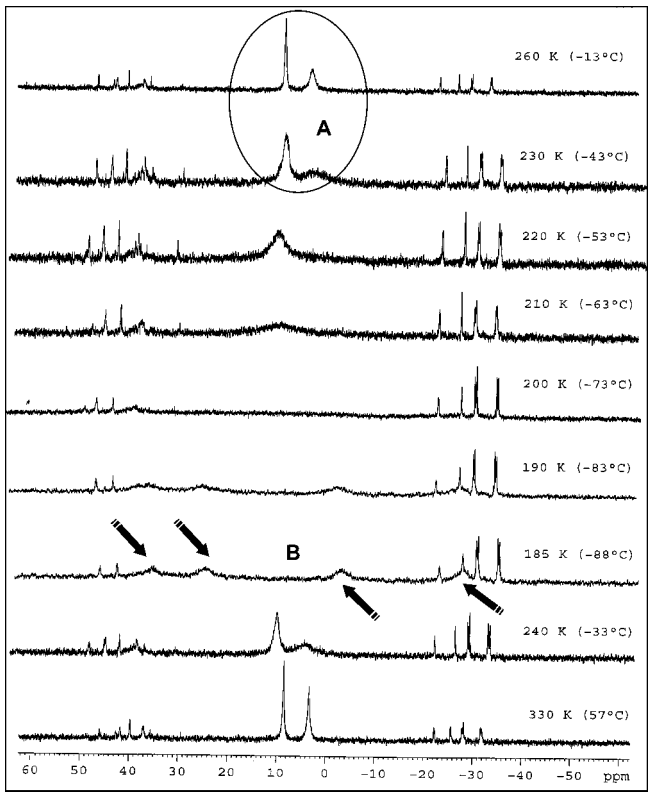

Figure 3. VT $^{31}P$ NMR spectrum of the [Pd/**18**] (1:1) catalytic system.

plex [$PdCl_2$·**18**] (Scheme 9) is quantitatively formed. Scheme 10 gives a summarized picture of the observed phenomena, which involves the chlorinated solvent.[37]

The most reasonable explanation, taking into account the ratio P/Pd, is that the palladium center "travels" between the four phosphorus donors at a high exchange rate. This constitutes a unique observation in the chemistry of multidentate compounds and the first proof of the possibility for the catalytic palladium species to be further stabilized by the close vicinity of several coordinating atoms during the successive catalytic steps. This would statistically decrease de facto the deactivation of catalysts by palladium-black formation. In addition, as postulated by Doucet and Santelli for their tetraphosphane, the "coordination pressure" around the metal center might accelerate some determining steps in cross-couplings such as the reductive elimination.[4] This "active" multidentate behavior would partly explain why, contrary to more fragile systems, polyphosphane ligands can be efficiently combined with palladium in low concentrations such as $10^{-2}$ to $10^{-4}$ mol-%.

### Performances of a Bulky π-Acidic Ferrocenyldiphosphane in Suzuki and Heck Reactions

As mentioned above, bulky phosphane ligands with high σ-donor abilities emerged as powerful ligands. Their efficiency was initially surprising since strong σ-donor ligands would not be expected to facilitate the transmetalation and reductive elimination steps. These performances revealed the importance of oxidative addition steps, particularly with substrates containing strong carbon–halide bonds. Additionally, the success of bulky phosphanes was suggested to be derived from the ability of these ligands to promote *geometrically driven* coordinative unsaturation and palladium reactivity. These geometric features appear to be important to the transmetalation and reductive elimination steps when utilizing strongly electron-donating ligands. Conversely, high activity in the cross-coupling reactions of aryl bromides and chlorides has been reported in some cases with palladium complexes incorporating various strongly electron-withdrawing phosphite ligands.[40] As a consequence of the complexity in the prediction of a rate-limiting step, it did not appear unreasonable to us to test, in more depth, a range of cross-coupling reactions using a comparatively "forgotten" π-acidic bulky ferrocenylphosphane ligand. We choose to build a weakly σ-donor phosphane on the ferrocenic backbone with phosphorus bearing heterocyclic substituents, which are notably less developed than the corresponding ferrocenyldiphosphanes bearing aryl or alkyl substituents. The new ligand 1,1′-bis[bis(5-methyl-2-furyl)phosphanyl]ferrocene (**2**; Figure 4), is obtained in 80% isolated yield from reaction of lithiated ferrocene with bis(5-methyl-2-furyl)bromophosphane (see below, amination).[41] Ligand **2** was isolated in pure form on a 10-g scale, as a crystalline orange powder, insensitive to air and moisture (Scheme 10).

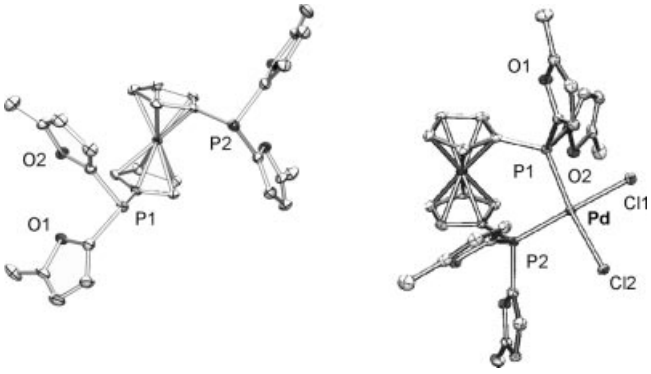

Figure 4. Molecular structures of **2** and [$PdCl_2$·**2**] from X-ray diffraction studies.

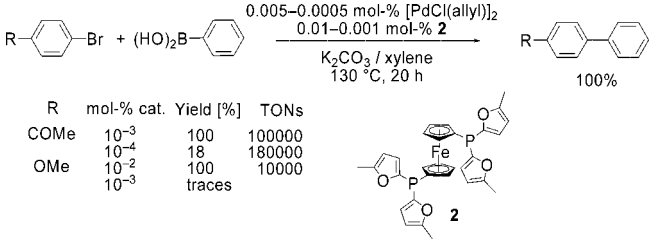
Suzuki cross-coupling with the use of activated substrate 4-bromoacetophenone with phenylboronic acid afforded the corresponding product in the presence of the in-situ-formed [$PdCl_2$·**2**] precatalyst and $K_2CO_3$ (Scheme 11).[41] Surprisingly, regarding the low basicity of phosphorus atoms, a high TON of 100000 with complete conversion was obtained in the presence of $10^{-3}$ mol-% catalyst: a result equivalent to that obtained with more electron-rich tetraphosphane **18** under identical conditions (Scheme 6). A TON of 180000 was obtained after 20 h (yield 18%, $10^{-4}$ mol-% cat. at 130 °C). Deactivated and electron-rich 4-bromoanisole gave a complete conversion with a TON of 10000 ($10^{-2}$ mol-% catalyst), but disappointingly a lower concentration did not yield any product. Under identical conditions tetraphosphane **18** facilitated a TON of 77000, in the presence of $10^{-3}$ mol-% catalyst. The preliminary experiments on the Heck reaction were conducted by using 4-bromoanisole with *n*-butyl acrylate *without* the addition of tetraalkylammonium salts, which are often used to delay palladium black formation. Here, excellent conversions were obtained in the presence of $10^{-2}$ mol-% catalyst (TON 10000), but again lowering the concentration of one order of magnitude completely inhibited the reaction.



Scheme 11.

Except for the robustness of the ferrocenyl backbone, phosphane ligand **2** is very different from **18**, and obviously in this case no "multidentarity" effect was expected. To the best of our knowledge, only a few reports exist on the use of highly-efficient catalysts incorporating very poor σ-donating phosphane ligands in cross-coupling reactions.[40] One of our goals was to demonstrate the possibility of variation in the phosphorus substituents, and to explore its effects. Subtle changes in the rate-determining step *depending*

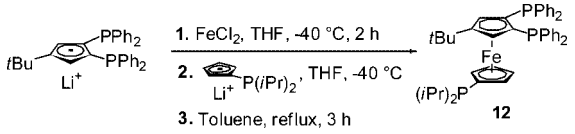
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*on the substrate* are probably at the origin of the results obtained. For more demanding substrates, the oxidative addition is rate-determining (and disfavored by poor σ-donating ligands such **2**). In contrast, for strongly activated substrates (aryl iodides and activated bromides) where the oxidative addition is comparatively facile, the same ligands would multiply the rates of transmetalation and reductive elimination. These results led us to exploit ligand **2** in other reactions for which its π-acidic character would reveal to be more useful (see below, C–N coupling).

## Performances of Ferrocenylphosphanes in Sonogashira–Heck Alkynylations

### Structural Considerations for Triphosphane Ferrocenic Ligands

We anticipated that "geometrically simpler" ferrocenyl-*tri*phosphanes (relative to tetraphosphanes **15** or **18**) might lead, as well, to highly active systems in palladium-catalyzed C–C coupling. We developed therefore a methodology for the preparation of dissymmetric achiral trisubstituted ferrocenes (**11**–**14**; Scheme 3) from two different Cp salts: the process is efficient and complete in two simple steps.[42,43] With the view to additionally improve the performance of a ligand, we chose to electronically enrich one of the phosphorus atoms and to provide the ferrocenyl backbone with better flexibility by unblocked axial rotation. This strategy prompted us to design and synthesize ferrocenyl aryl/alkyl triphosphane **12**, 1,2-bis(diphenylphosphanyl)-1′-(diisopropylphosphanyl)-4-*tert*-butylferrocene (Scheme 12).



Scheme 12.

The X-ray structural characterization (Figure 5) and the solution NMR spectroscopic study revealed that,[42] as expected, the rotational flexibility of **12** was greater than that of the tetraphosphane parents; in the preferred conformation the three phosphorus atoms are not pointing in the same direction. The palladium coordination complexes were found to be preferentially 1,2-P bonded.

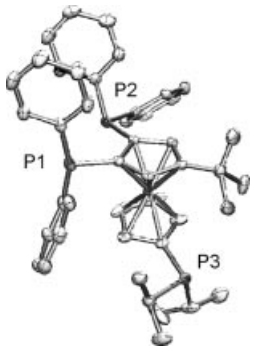


Figure 5. Molecular structure of **12** from X-ray diffraction studies.

Similar to its parent ligands, **12** is stored under air without any precaution and appeared insensitive to moisture and elevated temperatures in solution [the P(*i*Pr)$_2$ atom is not sensitive to oxidation].

### Alkynylations with a Ferrocenyltriphosphane

The examination of Suzuki cross-coupling reactions with the use of **12** was not as promising as we expected. For instance, a TON of only 10000 was obtained in the coupling of electron-poor 4-bromoacetophenone with phenylboronic acid, whereas tetraphosphane **18** gave a TON of 77000 under similar conditions (Scheme 6). We then tested the performances of the triphosphane in the more demanding reaction of aryl alkynylation in the presence of palladium and copper (Sonogashira cross-coupling).[44] The scope and

limitations of tridentate ferrocenylphosphane ligand **12** for the alkynylation of a variety of aryl bromides with alkynes is described in Scheme 13.

A very high TON of 95000 was obtained for the reaction of iodobenzene with phenylacetylene (yield 95%, $10^{-3}$ mol-% cat.).[44] In the presence of activating groups on the aryl bromide, high reaction rates were observed as well: the coupling of 4-bromoacetophenone, 4-bromobenzonitrile, and 4-fluorobromobenzene with phenylacetylene in the presence of $10^{-3}$ to $10^{-4}$ mol-% of [Pd/**12**] led to the coupling products in 94 to 20% yields (the highest TONs obtained were of 250000, 46000, and 20000, respectively). We determined the influence on the reaction of the presence of *ortho* substituents on the aryl bromide: with electronically activated 2-trifluoromethylbromobenzene: a good TON of 9300 was obtained with high conversion (yield 93%, $10^{-2}$ mol-% cat.). A lower TON of 900 was observed by using sterically congested 9-bromoanthracene (yield 90%, $10^{-1}$ mol-% cat.). The quantitative conversion of strongly deactivated 4-bromoanisole required a higher catalyst loading (0.4 mol-% cat.), consequently lower TONs of 230 to 520 were obtained. We also performed a few reactions with activated aryl chlorides such as 4-chlorobenzonitrile and 4-chloroacetophenone that were also converted in excellent yields with *less than 1 mol-%* of catalyst and in the absence of copper iodide (TONs of 540 and 205, respectively).[44] Finally, we extended the scope of the catalytic reaction to other alkynes such as dec-1-yne and but-1-yn-4-ol. With these alkynes, TONs of 620 and 460, respectively, were obtained with 4-bromoacetophenone. Consequently, this novel mixed ferrocenyl aryl/alkyl triphosphane was found thermally stable, insensitive to air and moisture, and its robustness allowed aryl alkynylation at $10^{-1}$ to $10^{-4}$ mol-% catalysts loading with iodides, bromides, and activated chlorides. Copper-free coupling with the use of phenylacetylene was also accessible in good yield. In the case of this ligand we must underline that no evidence of multidentarity (such as observed for **18**) was collected to date; nevertheless, only few multidentate ligands (tri-, tetradentate or more) have been tested for Sonogashira–Heck-type alkynylations. This is all the more surprising that, most of the time, threefold or more excess of monodentate ligands are used under the reported conditions. The emerging chemistry of multidentate ligands could be of high interest in the future development of catalyzed cross-coupling alkynylations.

### Performances of a Bulky π-Acidic Ferrocenyldiphosphane in Sonogashira Alkynylation

To our surprise, the system based on diphosphane ligand **2** also efficiently catalyzed the arylation of phenylacetylene with activated and deactivated substrates.[41] By using 4-bromoacetophenone in the presence of $10^{-4}$ mol-% catalyst a TON of 920000 *among the highest reported* with bromides was obtained. 4-Bromoanisole was quantitatively converted with a lower TON of 1000, consistently with the results observed in Suzuki/Heck reactions.[41] We found in parallel that **2** could be also a useful ligand under mild reaction conditions in allylic amination reactions (see below).

## Performances of Ferrocenylphosphanes in Allylic Amination Reactions

### Allylic Amination from Allylacetates with π-Acidic Ferrocenyldiphosphanes

Palladium-catalyzed amination of allyl acetates is recognized as being a powerful tool to form allylamine blocks. To test more efficient catalytic systems in terms of atom economy we employed the 1,1′-bis[bis(5-methyl-2-furyl)-phosphanyl]ferrocene (**2**) ligand in this reaction as well as related dissymmetric compound **3** (Scheme 10) and their coordination complexes.[45,46] Nucleophilic amination of allylic acetate was performed at r.t. with unprecedented turnover frequencies (Scheme 14, Table 2).

As seen in Table 2 (Entries 1–5): in the presence of $10^{-2}$ mol-% catalyst [Pd/**2**] the coupling of aniline to allyl acetate occurred at a high TOF of 10000 $h^{-1}$ with complete conversion and 96% selectivity in monoallylamine; under identical conditions of temperature and concentration, 60% conversion was obtained after 40 h with the more electron-rich parent ligand 1,1′-bis[diphenylphosphanyl]ferrocene (150 $h^{-1}$ TOF), the monophosphanes $PPh_3$ and $PCy_3$ were ineffective. Excellent conversions of 98 to 100% were achieved from the cyclic secondary amines pyrrolidine (TOF 4900 $h^{-1}$) and piperidine (TOF 5000 $h^{-1}$). Only a slightly decreased 85% conversion was obtained with less nucleophilic cyclic morpholine (TOF 4250 $h^{-1}$). The coupling of the primary amine benzylamine appeared more difficult and less selective (TOF 1825 $h^{-1}$ for a 75% selectivity in monoallylation product). In addition to primary amines and cyclic secondary amines, more delicate aliphatic secondary amines were efficiently coupled (Table 2, Entries 6–8). Complete conversion of the sterically demanding diisopropylamine was obtained at 80 °C in the presence of 0.1 mol-% catalyst in 2 h (TOF 480 $h^{-1}$) and of the long alkyl chain bearing dioctylamine at r.t. after 20 h (best TOF 225 $h^{-1}$). These good results prompted us to investigate the allylic amination reaction employing a much more demanding substrate, the monoterpene derivative geranyl acetate (Table 2, Entries 9–11). At r.t., 75% conversion in geranylaniline was obtained after 20 h with total selectivity. Morpholine reacted with geranyl acetate in the presence of 1 mol-% catalyst to give a 60% conversion in 1 h at r.t. and 98% after 20 h. A TOF of 333 $h^{-1}$ was obtained at 80 °C with 98% of geranylamine formed in 3 h.

This catalytic system was also found to be remarkably active and selective for the amination of substituted allylic acetates. The coupling reaction to amines of 3-phenylallyl acetate (Table 2, Entries 12–17) and (*E*)-hex-2-en-1-yl acetate (Table 2, Entries 18–22) was carried out at 0.1 and 0.01 mol-% [Pd/**2**]. 3-Phenylallyl acetate reacted with diethylamine, pyrrolidine, or morpholine to give complete con-

[a] Total selectivity is always in linear monoallylamine (mono = linear monoallylamine, di = diallylamine, lin = linear isomer, brch = branched isomer).

version with 0.1 mol-% catalyst. Lowering the catalyst loading to 0.01 mol-% resulted in TONs of 7600, 2600, and 4800, respectively. In each case, good regioselectivity was observed for the linear product (93–94%) The selectivity was found to be higher in linear monoallylamine for the coupling of $HNEt_2$ to (*E*)-hex-2-en-1-yl acetate (99%). Coupling reactions with cyclic secondary amines proceeded in more than 90% yield by employing 0.1 mol-% catalyst (94% selectivity in linear product). Only in the course of the addition of dioctylamine were lower TONs and TOFs observed because 0.4 mol-% catalyst was required to reach 60% conversion in 20 h at 50 °C. The results obtained are certainly due to an accelerating effect on the nucleophilic substitution induced by the electron-withdrawing furyl groups on the phosphorus atoms of the ligands; we have provided a more detailed discussion on this topic.[41] The performance of the [Pd/**3**] system was found to be similar or slightly inferior to that of [Pd/**2**].[45] Finally, we have recently shown that multidentate ferrocenylphosphanes can also be useful in allylic substitution reactions.[47]

## Trends and Perspectives in Rationally Designed Ferrocenylpolyphosphane Ligands for Low Loading Catalysis

The ferrocenylphosphane species we developed present several features that are profitable to the rational design of a large number of new metalloligands. Figure 6 summarizes some of these useful points to produce adaptable systems of high-efficiency in catalytic reactions. We briefly discuss the expected effects on catalysis of the possible structural modifications (a more detailed discussion on ferrocenylpolyphosphane structural effects in catalysis was reported else-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

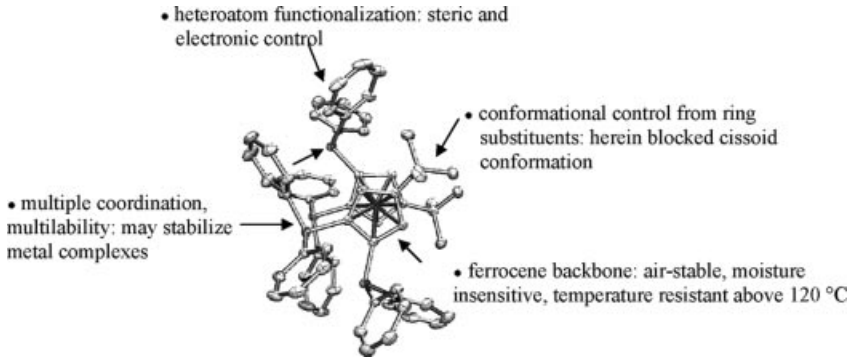

Figure 6. General features of adaptable ferrocenylphosphane ligands for high-performance catalytic reactions.

where[48]): (1) The first advantage in catalysis of these ferrocenylphosphane ligands is the robustness of the ferrocenyl backbone, which allows their handling and storage under air for years without any particular precaution. Non-glovebox conditions and temperatures above 120 °C can be used in long-term reactions without deactivation. (2) The advantage of having three or more phosphanyl groups on the ferrocene backbone is an important question. First from a practical point of view, a recent review of the use of dppf and derivatives showed that, up to now, no results matching the ultra-low loading catalysis presented herein were obtained with these diphosphanes.[48] Several reported studies from our group and others,[30–32,37,45] clearly established that classical ligands [such as $PPh_3$, dppe, dppb = 1,2-bis(diphenylphosphanyl)butane, or dppf] led to less stable catalytic systems under the conditions of low catalyst concentrations that we investigated. The ligand behavior of tetradentate phosphane **18** is expected to furnish to the $Pd^0$ species multiple coordination, as described above for $Pd^{II}$, which stabilizes the catalytic systems and therefore leads to efficient catalysis in the presence of only low loadings of the precious metal. More positions for substitution on phosphorus (or other donor atoms) are available on the ferrocenyl backbone. Therefore, polyphosphanes of higher-rank such as penta- or hexaphosphanes (or more) should be reachable. We believe that such a kind of "*enhanced multidentarity*" would permit one to pursue the effort for stabilizing catalytic systems, and promoting their longevity under ultra-low concentrations. (3) The substituents on the cyclopentadienyl rings allow the conformation of the ferrocene to be controlled, and therefore can induce a more-or-less important rigidity to the ligand as a function of their hindrance. Therefore, when a specific conformation is required, such as the orientation of several donor atoms in the same direction of space (this was shown with phosphorus atoms, but it could probably be extended to other donors, such as nitrogen atoms, etc.) very hindering substrates such as *tert*-butyl groups could be used. We envision the use of more hindered substituents (such as trityl groups, $CPh_3$) with the view to determine their influence on the conformation. Additionally, positive or negative electronic effects can be expected, as well, from the noncoordinating substituents on the Cp rings and should be worthy of further investigations. (4) We showed that the substituents on the phosphorus atoms can be modified to either more electron-donating (e.g. *i*Pr) or more electron-withdrawing groups (e.g. furyl), or to have increased bulkiness. This is a very important point as the use of modified ligands containing either electron-rich $PCy_2$ or $PtBu_2$ moieties are well-known for having induced impressive results in cross-coupling reactions (by facilitating the oxidative addition step of the catalytic cycles, see first section).

Following these trends, a number of new ligands are currently being developed in our laboratory, that incorporate other substituents on the Cp ring and on phosphorus atoms, as well as unique conformations: their features and performances are under investigation and will be reported in due time.

## Conclusions

Multidentate[49] ferrocenylphosphane ligands offer some of the highest TONs observed in Heck, Suzuki, and Sonogashira cross-coupling reactions. Demanding substrates such as aryl bromides and activated aryl chlorides were coupled with fairly good to excellent TONs from different ferrocenylpolyphosphane auxiliaries. In the achiral version of the palladium-catalyzed allylic acetate amination reaction, the modification of dppf with π-acidic furyl heterocycles provided ferrocenyldiphosphane catalysts for which high TONs were obtained together with several of the best TOFs reported to date. To obtain high TONs (>10000), relatively elevated reaction temperatures are often required for cross-coupling; under these conditions, the use of ferrocenylphosphane ligands certainly help to stabilize the catalytic species. In addition, these ligands with regard to their bulkiness would also have a positive influence as accelerators in the reductive elimination step of the cross-coupling catalytic cycle by inducing steric pressure on the active palladium center. Further mechanistic studies are absolutely necessary and in the future will certainly provide keys for the development of multidentate ligands resource-economic catalysts.

[34] First, the dilution factor 30 C (or 30 CH) commonly employed in medical homeopathy corresponds to a $10^{-60}$ volume dilution of the active substance. In addition, in the Heck reaction and C–C or C–N cross-couplings the highest catalyst dilutions reach $10^{-6}$ to $10^{-7}$ mol-% cat. and were carried out *with the assistance of phosphane ligands* (see for instance refs.[4,20] and references cited therein). Therefore, the expression "homeopathic palladium" has the advantage to strike the mind, but in our opinion should be avoided for catalyst loadings only down to $10^{-1}$ to $10^{-2}$ mol-%, *low catalyst loadings* being more acceptable; *ultra-low loading* catalysts should be reserved for loadings below $10^{-4}$ mol-% (corresponding to maximum TONs of 1000000).

# Poly(methimazolyl)borate Alkyne Complexes of Molybdenum and Tungsten

**Anthony F. Hill,*[a] Never Tshabang,[a] and Anthony C. Willis[a]**

**Keywords:** Alkyne / Molybdenum / Tungsten / Methimazolylborates / Scorpionates

Synthetic routes are reported to complexes of the form [MI(alkyne)(CO){$H_nB(mt)_{4-n}$}] (mt = methimazolyl; $n$ = 1, 2; M = Mo, W) through the reactions of alkyne complexes $[WI_2(HC{\equiv}CSiMe_3)_2(CO)_2]$ or $[MI_2(RC{\equiv}CR)_2(NCMe)(CO)]$ (M = Mo, W; R = Me, Ph) with the salts $Na[H_nB(mt)_{4-n}]$. The derivative [MoI(PhC≡CPh)(CO){$HB(mt)_3$}] reacts with $Na[HB(mt)_3]$ to provide the complex [Mo(PhC≡CPh)(CO){$HB(mt)_3$}$_2$] in which the two $HB(mt)_3$ ligands adopt different non-interconverting coordination modes, $\kappa^3$-*S*,*S*′,*S*′′ and $\kappa^1$-*S*.

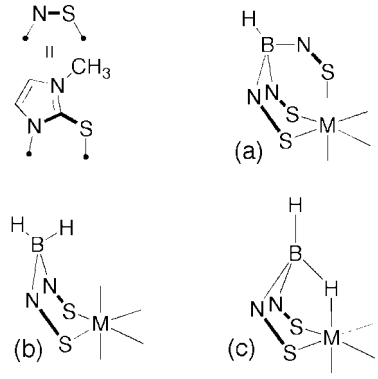
## Introduction

Alkyne complexes of divalent molybdenum or tungsten[1] in which the metal centres are either ligated by dithiocarbamato[2] or tris(pyrazolyl)borato ligands,[3] display a rich chemistry that has been extensively developed by Templeton and co-workers. Tris- and bis(methimazolyl)borate ligands, discovered respectively by Reglinski[4] and Parkin[5] (Scheme 1), might be superficially considered as hybrids of these two classes of more familiar ligand, being anionic and presenting either three or two sulfur donors. Accordingly, a similarly rich chemistry might also be anticipated for alkyne complexes of $Mo^{II}$ and $W^{II}$ bearing these ligands. In passing one might also note that alkynes are recognised substrates for the molybdenum site of nitrogenase,[6] generating interest in the nature of alkyne binding to molydbenum complexes that feature a sulfur-rich coordination sphere. It is, however, increasingly found to be the case that methimazolylborato ligands may demonstrate quite unique coordination features distinct from those offered by dithiocarbamates or poly(pyrazolyl)borates. Whilst the $HB(mt)_3$ ligand displays geometrical flexibility associated with the intrinsically chiral but readily invertible $C_3$-[3.3.3]bicyclo $HB(mt)_3M$ cage,[7] the $H_2B(mt)_2$ chelate has an emerging propensity for 3-centre, 2-electron B–H–metal interactions ($\kappa^3$-*H*,*S*,*S*′ coordination),[8–11] behaviour that has on occasion also been demonstrated by the $HB(mt)_3$ ligand.[11b,12–15] Both of these features are manifest in the chemistry to be described, which concerns the synthesis of the first alkyne complexes ligated by poly(methimazolyl)borates.



Scheme 1. Poly(methimazolyl)borato coordination. (a) $\kappa^3$-*S*,*S*′,*S*′′; (b) $\kappa^2$-*S*,*S*′; (c) $\kappa^3$-*H*,*S*′,*S*′′.

## Results and Discussion

Baker's versatile complexes $[MI_2(PhC{\equiv}CPh)_2(NCMe)(CO)_2]$ [M = Mo (**1a**), W (**1b**)] which arise from the facile reactions of tolane with $[MI_2(NCMe)_2(CO)_3]$[1b,16] appeared to be suitable substrates for the introduction of poly(methimazolyl)borate ligands (Scheme 2). However, we find that in attempting to extend this protocol to the synthesis of a tungsten complex of ethynyltrimethylsilane, nitrile substitution occurs exclusively to provide the dicarbonyl complex $[WI_2(HC{\equiv}CSiMe_3)_2(CO)_2]$ (**2**). The formulation followed from spectroscopic data and was confirmed by a crystallographic study, the results of which are summarised in Figure 1. Considering each alkyne as a single ligand, the geometry at tungsten (which lies on a crystallographic twofold axis that bisects I1–W1–I1′; symmetry generated atoms in grey), may be described as pseudo-octahedral. The geometry adopted is optimal for satisfying the π-acidic character of the carbonyl ligands and both the π-acid and π-donor functions of the alkynes. The two carbonyl ligands are bent

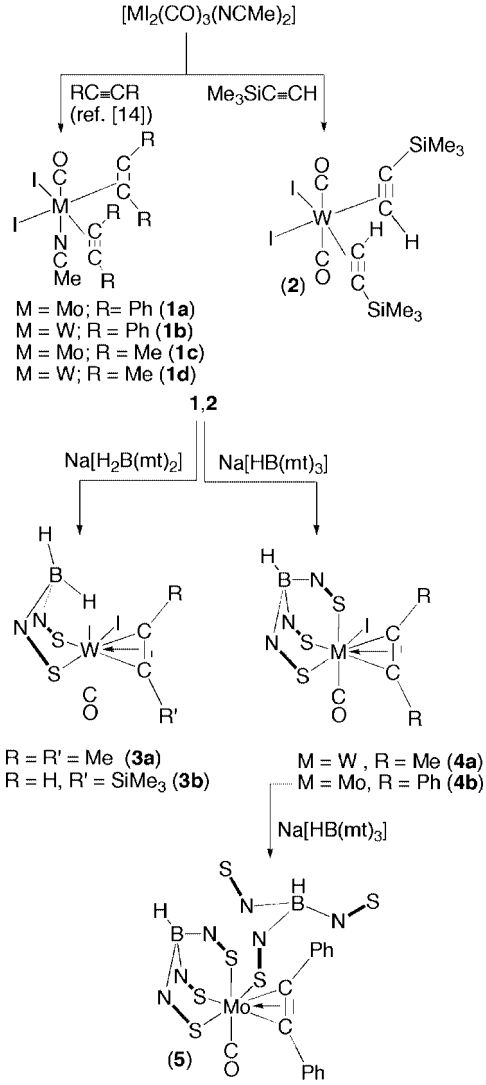
away from the alkyne ligands towards the π-basic iodide ligands [C1–W1–C1′ 162.5(3)°, C1–W1–I1 82.6(2), 84.3(2) °], however, if we loosely denote this as the *z*-axis ($d^4 = d^0_{xy}d^2_{xz}d^2_{yz}$) then each of the occupied $d_{xz}$ and $d_{yz}$ orbitals are able to retrodatively interact with both carbonyls and *one* π* orbital from each alkyne. This leaves the $d_{xy}$ orbital vacant for donation from an occupied π-orbital of each alkyne.[1] Accordingly, the tungsten-alkyne bond lengths indicate a degree of W–C multiple bonding although these are significantly different (10σ), presumably due to the relative steric requirements of the silyl and hydrogen alkyne substituents.



Scheme 2. Synthesis of alkyne poly(methimazolyl)borate complexes.

The complexes **1d** and **2** react with the salt Na[$H_2B$-(mt)$_2$][8a] to provide the monoalkyne complexes [WI(RC≡CR′)(CO){$H_2B$(mt)$_2$}] [R = R′ = Me (**3a**); R = H, R′ = $SiMe_3$ (**3b**)]. Simple 18-electron rule arguments require that the $H_2B$(mt)$_2$ anion (charged formalism) provide a minimum of 6 valence electrons were the alkyne to provide the maximum 4 valence electrons on offer. Thus a 3-centre 2-electron B–H–W interaction must be invoked and its occurrence is substantiated both by $^1$H NMR and IR spectroscopy: For **3b**, a high field resonance at $\delta_H$ = –5.10 ppm in the $^1$H NMR spectrum and an infrared absorption at 2261 cm$^{-1}$ ($CH_2Cl_2$) provide spectroscopic signatures for B–H–W interactions and may be compared with values of $\delta_H$ = –5.05 ppm and 2306 cm$^{-1}$ for the structurally characterised complex [Mo(η$^2$-SCNMe$_2$)(CO)$_2${κ$^3$-*H*,*S*,*S*′-$H_2B$(mt)$_2$}].[8a] The complex [W(CO){$H_2B$(mt)$_2$}$_2$] which features both bidentate (κ$^2$-*S*,*S*′) and tridentate (κ$^3$-*H*,*S*,*S*′) coordinated $H_2B$(mt)$_2$ ligands[8b] has $\delta_H$ = –3.58 ppm and $\nu_{BHW}$ = 2246 cm$^{-1}$ for the latter mode of coordination. For **3a** only one mt environment is observed on the $^1$H and $^{13}$C NMR timescales consistent with a stereochemically non-rigid molecule. For **3b**, however, whilst fluxionality is suggested by the $^1$H NMR spectrum (300 MHz), distinct "mt" environments are resolved in the $^{13}$C{$^1$H} NMR spectrum (75 MHz) at room temperature. Presumably, hemilability on the part of the B–H–W interaction allows access to a five coordinate stereochemically non-rigid intermediate.[7]

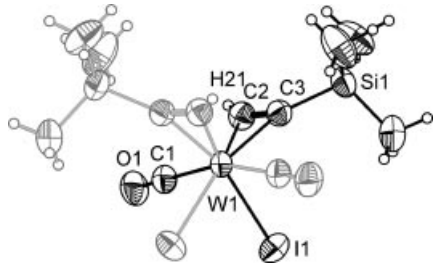


Figure 1. Geometry of **2** in a crystal of **2**·$(CH_3OH)_2$ (50% displacement ellipsoids; a rotation axis bisects I1–W–I1′; symmetry-generated atoms in grey). Selected bond lengths [Å] and angles (deg.): W1–I1 2.8547(4), W1–C1 2.081(5), W1–C2 2.099(6), W1–C3 2.148(5), Si1–C3 1.874(5), C2–C3 1.271(8), C3–W1–I1 88.43(14), C3–W1–C2 34.8(2), I1–W1–C2 89.74(15), C3–W1–C1 111.5(2), I1–W1–C1 84.33(15), C2–W1–C1 77.0(2).

In a similar manner to the syntheses of **3** a smooth reaction occurs between Na[HB(mt)$_3$] and **1d** to provide the complex [WI(CO)(MeC≡CMe){HB(mt)$_3$}] (**4a**) in moderate yields. The $^1$H NMR spectroscopic data for **4a** suggest that there is only one species present in solution and since the complex has two stereogenic components, i.e., the chiral δ/λ $C_3$-HB(mt)$_3$Mo cage and *R*/*S*-MoI(CO)(PhCCPh) pyramid, it may be assumed that a racemate of enantiomers (δ*R*/λ*S* or δ*S*/λ*R*) arises through facile inversion of the HB(mt)$_3$W cage. Similarly facile inversion has been noted for the alkylidyne complexes [W(≡CR)(CO)$_2${HB(mt)$_3$}] (R = $C_6H_4$Me-4, N*i*Pr$_2$), and purported to proceed via a dissociative (mt) mechanism.[7] The alkyne ligand in **4a** gives rise to two $^{13}$C resonances ($\delta_C$ 207.4, 206.9 ppm) (restricted rotation on the $^{13}$C NMR timescale) in the region characteristic of 4-electron (σ+π) donor alkyne coordination.[1]

Although the corresponding molybdenum tolane complex [MoI(CO)(PhC≡CPh){HB(mt)$_3$}] (**4b**) could be similarly prepared by employing a 1:1 stoichiometry of **1a** and Na[HB(mt)$_3$], invariably a small amount of poorly soluble

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

material was formed as a side product. The yield of this could be maximised by the use of two equivalents of $Na[HB(mt)_3]$ or, alternatively, the reaction of $Na[HB(mt)_3]$ with isolated **4b**. The poor solubility of the side product compromised the acquisition of spectroscopic data other than from FAB-MS and IR spectra. Mass spectrometry indicated the gross composition $[Mo(CO)(\eta\text{-}PhC{\equiv}CPh)\{HB(mt)_3\}_2]$ (**5**) but gave no indication of the connectivity of this apparently 20–22 electron complex. The geometry was eventually established by crystallographic analysis, the results of which are summarised in Figure 2. The molecular geometry of the mononuclear complex is based on a pseudo-octahedral molybdenum centre that bears one $HB(mt)_3$ ligand coordinated in a conventional tridentate manner ($\kappa^3$-*S*,*S*′,*S*′′), whilst the second binds to molybdenum through a single sulfur donor ($\kappa^3$-*S*). Monodentate $HB(mt)_3$ coordination is unprecedented in transition metal chemistry, however we have previously identifed this mode of coordination in the tin derivative $Ph_3Sn\{HB(mt)_3\}$.[17] Copious structural data exist for molybdenum alkyne complexes,[18] however consideration of the parameters of **5** with those for the exemplary complexes $[Mo(PhC{\equiv}CPh)(\eta\text{-}C_5H_5)_2]$ (a 2-electron alkyne),[19] $[Mo(MeC{\equiv}CMe)_2(S_2Cpyr)_2]$ (a homoleptic sulfur donor set)[20] and $\{Mo(PhC{\equiv}CPh)(CO)_2[HB(pz')_3]\}^{n+}$ ($n$ = 0, 1; pz′ = 3,5-dimethylpyrazol-1-yl, a redox pair),[21] reveals that the alkyne has particularly short Mo–C separations coupled with a long C–C bond. Such geometric features are typically associated with alkynes acting as "4-electron" σ+π donors to an octahedral $d^4$-metal centre. However, it is noteworthy that the $\nu_{CO}$ value for **5** (1790 $cm^{-1}$) is remarkably low and indicative of an exceptionally π-basic molybdenum centre. This contrasts dramatically with the value of 1960 $cm^{-1}$ for the alkyne complex $[W(\eta\text{-}HC{\equiv}CH)(CO)(S_2CNEt_2)_2]$.[22] In a similar manner the neutral cyclopentadienone and vinyl ketene complexes $[W(CO)(S_2CNEt_2)_2(L)]$ (L = O=C-$(C_8H_{12})_2$,[23] $H_2C{=}CHCH{=}CO$[24]) have $\nu_{CO}$ = 1921 and 1960 $cm^{-1}$, whilst even the anionic complex $[W(CO)(SPh)(\kappa^2\text{-}S_2C_2Me_2)_2]^-$ has $\nu_{CO}$ = 1933 $cm^{-1}$ although the oxidation state of the tungsten in this sulfur rich complex is open to debate.[25] Thus the very low $\nu_{CO}$ value for **5** is quite exceptional such that the geometric features of the alkyne may be as much to do with conventional retrodonation into the alkyne π* orbital as with depletion of the C≡C π-bonding orbitals.

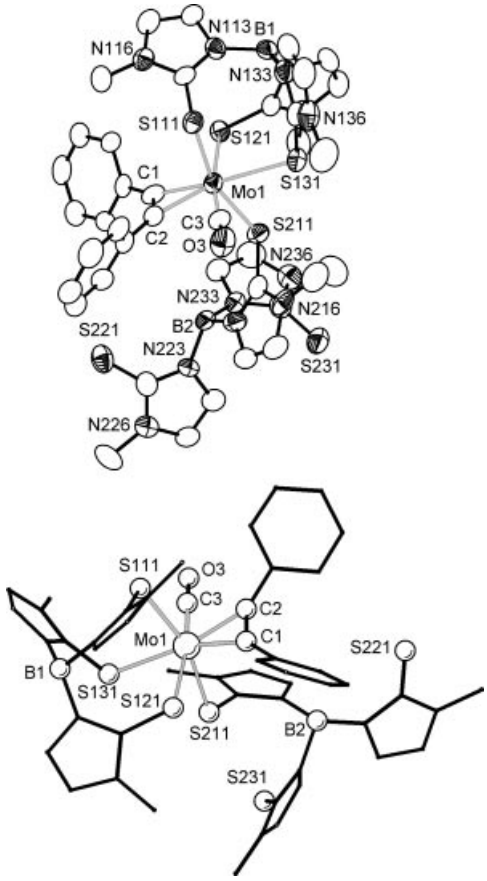

Figure 2. Top: Molecular geometry of **5**·$(CH_2Cl_2)_2$ (40% displacement ellipsoids, hydrogen atoms bound to carbon omitted). Bottom: Alternative simplified view. Selected bond lengths [Å] and angles (deg.) Mo1–S111 2.440(2), Mo1–S121 2.602(2), Mo1–S131 2.637(2), Mo1–S211 2.464(2), Mo1–C1 2.052(8), Mo1–C2 2.051(7), C1–C2 1.306(10), S111–Mo1–S121 93.74(6), S111–Mo1–S131 85.59(7), S121–Mo1–S131 85.39(6) S121–Mo1–S211 82.25(6), S131–Mo1–S211 75.97(7), C1–Mo1–C2 37.1(3), Mo1–S111–C112 107.0(2), Mo1–S121–C122 110.0(3), Mo1–S131–C132 107.7(2), Mo1–S211–C212 109.7(3), Mo1–C1–C11 148.7(6), Mo1–C2–C21 145.7(6).

## Conclusions

Synthetic routes to lead compounds for the study of alkyne derivatives of molybdenum and tungsten ligated by methimazolylborate ligands $H_nB(mt)_{4-n}$ ($n$ = 1,2) have been developed. In the case of dihydrobis(methimazolyl)borate derivatives, the propensity for 3c–2e B–H–metal interactions is manifest. In this respect, the behaviour of the $H_2B(mt)_2$ ligand is reminiscent of that first noted by Trofimenko, Kosky and Cotton[26] for the corresponding $H_2B(pzMe_2)_2$ ligand ($pzMe_2$ = 3,5-dimethylpyrazol-1-yl). However the inclusion of an extra atom in each of the arms of the $H_2B(mt)_2$ ligand (cf $pzMe_2$) results in an increased propensity for such 3c–2e B–H–metal interactions. In all cases, the alkyne coordination may be described as "4-electron," even for complex **5**, which has two alternative appended potential donors.

## Experimental Section

All manipulations of air-sensitive compounds were carried out under dry and oxygen-free nitrogen using standard Schlenk and vacuum line techniques, with dried and degassed solvents. NMR spectra were obtained at 25 °C with a Varian Gemini spectrometer 300BB ($^1H$ at 300.75 MHz, $^{13}C$ at 75.4 MHz, $^{11}B$ at 96.2 MHz). Mass Spectra were obtained with a ZAB-SEQ4F spectrometer (FAB, ACPI or ESI techniques) using matrices of either 3-nitrobenzyl alcohol (NBA) or acetonitrile and methanol (ESI). The elemental microanalysis was carried out by the microanalytical service of the Australian National University. The compounds $Na[H_2B$-

$(mt)_2]$,[8a] Na[HB(mt)$_3$],[27] $[MI_2(CO)_3(NCMe)_2]$[16a] and $[MoI_2(CO)(NCMe)(\eta^2\text{-PhC}{\equiv}\text{CPh})_2]$[16b] were prepared according to the indicated published procedures. Other reagents were used as received from commercial sources.

**Synthesis of $[WI_2(CO)_2(\eta^2\text{-HC}{\equiv}\text{CSiMe}_3)_2]$ (2):** Two equivalents of cold ethynyltrimethylsilane (0.70 g, 3.88 mmol) were added to a solution of $[WI_2(CO)_3(NCMe)_2]$ (1.50 g, 2.91 mmol) in $CH_2Cl_2$ (30 mL) at 0 °C in a foil-covered Schlenk tube. The reaction was warmed to room temperature, and left to stir for a further 12 h, after which time the colour had changed from brown to orange. The solvent was removed to dryness and diethyl ether (20 mL) was added and then the reaction flask was triturated for 20 min in an ultrasonic bath to provide an orange precipitate. The product was filtered and washed with diethyl ether (2 × 5 mL) and dried. The product was recrystallised from $CH_2Cl_2$ and petroleum ether (b.p. 40–60 °C). X-ray quality crystals of a methanol bis(solvate) were obtained by recrystallisation from a concentrated solution of methanol at –16 °C. Yield 1.34 g (78%). IR ($CH_2Cl_2$): $\tilde{\nu}_{CO}$ = 2089, 2070 cm$^{-1}$. (Nujol): $\tilde{\nu}_{CO}$ = 2099, 2075 cm$^{-1}$. $^1$H NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 0.38 (s, 18 H, $CH_3$), 11.1 (s, 2 H, C≡CH) ppm. $^{13}$C{$^1$H}NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 208.8 (CO), 195.3 (H*C*≡CSi), 173.5 (HC≡*C*Si), 0.33 ($SiCH_3$) ppm. $C_{12}H_{20}I_2O_2Si_2W$ (690.12): calcd. C 20.89, H 2.92, N 0.00; found C 21.07, H 3.05, N 0.00.

**Crystal Data:** $C_{12}H_{20}I_2O_2Si_2W{\cdot}(CH_3OH)_2$; $M_W$ = 754.20, monoclinic, *C*2/*c*, *a* = 17.1441(4), *b* = 12.1896(3), *c* = 12.8038(5) Å, $\beta$ = 97.6004(11)°, *V* = 2652.23(12) Å$^3$, *Z* = 4, $D_c$ = 1.889 Mg m$^{-3}$, $\mu$(Mo-$K_\alpha$) = 6.785 mm$^{-1}$, *T* = 200(2) K, yellow plate 0.35 × 0.28 × 0.05 mm; 3054 independent measured reflections, *F* refinement, $R_1$ = 0.027, $wR_2$ = 0.030; 2144 independent observed absorption corrected reflections [$I > 3\sigma(I)$, $2\theta \leq 55°$], 106 parameters, CCDC-284294.

**Synthesis of $[WI\{H_2B(mt)_2\}(CO)(\eta^2\text{-HC}{\equiv}\text{CSiMe}_3)]$ (3b):** A mixture of $[WI_2(CO)_2(\eta^2\text{-HC}{\equiv}\text{CSiMe}_3)_2]$ (**2**: 0.50 g, 0.72 mmol) and Na[$H_2B(mt)_2$] (0.19 g, 0.72 mmol) was stirred in $CH_2Cl_2$ (20 mL) at room temperature under nitrogen for 3 h, after which time the color of the mixture had changed from orange to green. The suspension was filtered through diatomaceous earth to remove NaI. The green filtrate was reduced to a minimum and petroleum ether (b.p. 40–60 °C) (15 mL) added resulting in the formation of a green precipitate. The product was filtered and washed with diethyl ether (2 × 5 mL) and dried. The green product was recrystallised from $CH_2Cl_2$/$Et_2O$. Yield 0.28 g (54%). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1923 ($\nu_{CO}$), 2265 ($\nu_{BHW}$), 2445 ($\nu_{BH}$) cm$^{-1}$. IR (Nujol): $\tilde{\nu}$ = 1927 ($\nu_{CO}$), 2263 ($\nu_{BHW}$), 2420 ($\nu_{BH}$) cm$^{-1}$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = –0.43 (br., 1 H, BHW), 0.24 (s, 9 H, $SiCH_3$), 3.44 (s, 6 H, $NCH_3$), 6.98, 7.06 (d × 2, $^3J_{HH}$ = 1.8 Hz, 2 H, NHC=CHN), 13.1 (s, 1 H, HC≡C) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = 229.5 (WCO), 203.2, 190.5 (C≡C), 161.4, (C=S), 123.6, 122.8 (NHC=CHN), 35.2 ($NCH_3$), 0.49 ($SiCH_3$) ppm. $^{11}$B{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = –2.53 ppm. $C_{14}H_{22}BIN_4OS_2SiW$ (676.13): calcd. C 25.59, H 3.15, N 7.96; found C 25.56, H 3.54, N 7.99. MS (ESI): *m*/*z* (%) = 549.1 (65) [M – I]$^+$.

**Synthesis of $[MoI\{HB(mt)_3\}(CO)(\eta^2\text{-PhC}{\equiv}\text{CPh})]$ (4b):** A mixture of $[MoI_2(CO)(NCMe)(\eta^2\text{-PhC}{\equiv}\text{CPh})_2]$ (**1a**: 0.50 g, 0.65 mmol) and Na[HB(mt)$_3$] (0.24 g, 0.65 mmol) was stirred in $CH_2Cl_2$ (20 mL) at room temperature under $N_2$ for 3 h, after which time the color had changed from brown to a light green. Sodium iodide was removed by filtration through diatomaceous earth and the green filtrate was then concentrated to ca 2 mL. Dilution with petroleum spirit (b.p. 40–60 °C) (15 mL) precipitated the crude product, which was then recrystallised from $CH_2Cl_2$ and diethyl ether. Yield 0.28 g (56%). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1933 ($\nu_{CO}$), 2456 ($\nu_{BH}$) cm$^{-1}$. IR (Nujol): $\tilde{\nu}$ = 1938 ($\nu_{CO}$), 2404 ($\nu_{BH}$) cm$^{-1}$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 3.05, 3.87, 4.02 (3s, 3 × 3 H, $NCH_3$), 6.85, 6.92, 7.02 (3d, $^3J_{HH}$ = 1.8 Hz, 3 × 2 H, NHC=CHN), 7.36–7.72 (m, 10, $C_6H_5$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = 237.4 (MoCO), 207.4, 206.9 (C≡C), 162.6, 160.5, 159.8, (C=S), 126.5–129.0 ($C_6H_5$), 124.7, 123.0, 122.4, 121.2, 120.6, 120.1 (NHC=CHN), 36.4, 35.0, 34.5 ($NCH_3$) ppm. $^{11}$B{$^1$H} NMR ([$D_6$]DMSO): $\delta$ = 0.71 ppm. ESI-MS: *m*/*z* (%) = 781.9 (5) [M – $CH_3$]$^+$, 655.1 (15) [M – I]$^+$. $C_{27}H_{26}BIMoN_6OS_3$ (780.38): calcd. C 41.56, H 3.36, N 10.77; found C 41.92, H 3.66, N 10.14.

**Synthesis of $[Mo\{HB(mt)_3\}_2(CO)(\eta^2\text{-PhC}{\equiv}\text{CPh})]$ (5):** One equivalent of Na[HB(mt)$_3$] (0.25 g, 0.33 mmol) was added to a solution of $[MoI\{HB(mt)_3\}(CO)(\eta^2\text{-PhC}_2\text{Ph})]$ (**4b**: 0.12 g, 0.33 mmol) in $CH_2Cl_2$ (20 mL) and the mixture stirred at room temperature for 12 h resulting in the formation of an orange precipitate. The supernatant was then decanted and the orange product was washed with cold ethanol (20 mL) followed by cold diethyl ether (10 mL) and then dried in vacuo. N.B.: The product is poorly soluble in common organic solvents, compromising the acquisition of elemental and solution spectroscopic data. Yield 0.19 g (59%). IR (DMSO): $\tilde{\nu}$ = 1797 ($\nu_{CO}$), 2449, 2407 ($\nu_{BH}$) cm$^{-1}$. IR (Nujol): $\tilde{\nu}$ = 1790 ($\nu_{CO}$), 2433, 2406 ($\nu_{BH}$) cm$^{-1}$. APCI-MS: *m*/*z* (%) = 1029 (30) [M + Na]$^+$, 975 (25) [M – CO]$^+$. $^{11}$B{$^1$H} NMR (96.2 MHz, [$D_6$]DMSO): $\delta$ = 2.00 ppm. Storage of a dilute solution of **5** in dichloromethane at –20 °C provided crystals of a dichloromethane bis-solvate. Satisfactory elemental microanalytical data not obtained due to partial desolvation.

**Crystal Data:** $C_{39}H_{42}B_2MoN_{12}OS_6{\cdot}(CH_2Cl_2)_2$, $M_w$ = 1174.67, monoclinic, $P2_1/n$, *a* = 14.6842(3), *b* = 18.7132(6), *c* = 19.7601(6) Å, $\beta$ = 107.6683(16)°, *V* = 5173.7(3) Å$^3$, *Z* = 4, $D_c$ = 1.508 Mg m$^{-3}$, $\mu$(Mo-$K_\alpha$) = 0.749 mm$^{-1}$, *T* = 200(2) K, 9074 independent measured reflections, *F* refinement, $R_1$ = 0.064, $wR_2$ = 0.056; 4681 independent observed absorption corrected reflections [$I > 3\sigma(I)$, $2\theta \leq 50°$], 604 parameters.

CCDC-289494 and -289495 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The First Heterohexametallic Transition-Metal Complex

Rico Packheiser[a] and Heinrich Lang*[a]

**Keywords:** Heteromultimetallic / Transition metal / Acetylides / Organometallic π-tweezers / Transmetallation / Mass spectrometry

The synthesis and characterisation of a first heteromultimetallic transition metal complex with six different metal atoms (Fe, Ru, Re, Au, Cu and Ti), connected through carbon-rich bridging units, are reported. Complex {1-[($\eta^2$-dppf)($\eta^5$-$C_5H_5$)RuC≡C]-3-[(bipy•)$(CO)_3$ReC≡C]-5-[$PPh_2$AuC≡C-bipy({[Ti](μ-σ,π-C≡$CSiMe_3$)$_2$}Cu)]$C_6H_3$}$PF_6$ is accessible in a consecutive reaction sequence by applying building blocks from a ligand and coordination complex library.

## Introduction

The linking of modular constructed transition-metal building blocks by carbon-rich bridging units to generate heteromultimetallic assemblies has increasingly gained interest during the last years.[1] A straightforward method to prepare such complexes is given by using the principle of the molecular "tinkertoy" approach.[2–4] This generally requires the prior preparation of multifunctional organic, coordination and/or organometallic molecules, which allow the stepwise synthesis of multitopic transition-metal-containing species. In particular, as different binding sites of the connecting units reactive groups, such as acetylides, phosphanes and N,N-donor systems (N,N = bi- or tridentate Lewis bases) can be used to control the synthesis of (hetero)multimetallic complexes. In context with this background, heteromultimetallic complexes with up to four different transition metals were synthesised, a hitherto scarcely explored class of compounds in transition-metal chemistry.[5] Very recently we reported the successful preparation of a heteromultimetallic species in which five different transition metals (Fe-Ru-Au-Cu-Ti) are spanned by carbon-rich organic units.[6] Extending this idea, we describe here for the first time the synthesis of an even heterohexanuclear transition-metal complex supported by applying the precoordinated multitopic organometallic building block 1-[($\eta^2$-dppf)($\eta^5$-$C_5H_5$)RuC≡C]-3-[(bipy*)$(CO)_3$ReC≡C]-5-($PPh_2$)-$C_6H_3$.

## Results and Discussion

The heterohexanuclear complex prepared was of the type {1-[($\eta^2$-dppf)($\eta^5$-$C_5H_5$)RuC≡C]-3-[(bipy*)$(CO)_3$ReC≡C]-5-[$PPh_2$AuC≡C-bipy({[Ti](μ-σ,π-C≡$CSiMe_3$)$_2$}Cu)]$C_6H_3$}-$PF_6$ (**5**) by using the versatile starting material 1-[($\eta^2$-dppf)-($\eta^5$-$C_5H_5$)RuC≡C]-3-[(bipy*)$(CO)_3$ReC≡C]-5-($PPh_2$)$C_6H_3$ (**1**) {dppf = 1,1′-bis(diphenylphosphanyl)ferrocene; bipy = 2,2′-bipyridine-5-yl; bipy* = 4,4′-di-*tert*-butyl-2,2′-bipyridine; [Ti] = ($\eta^5$-$C_5H_4SiMe_3$)$_2$Ti} and the relevant organometallic fragments. The newly synthesised transition-metal complexes and the overall synthetic methodology employed are depicted in Scheme 1.

Molecule **1** was prepared as described earlier by starting from 1,3,5-tribromobenzene.[7] Treatment of **1** with (tht)-AuC≡C-bipy (**2**), in situ generated from (tht)AuCl and 5-ethynyl-2,2′-bipyridine (tht = tetrahydrothiophene)[7] gave by replacement of the S-donor ligand tetrahydrothiophene by tertiary phosphane **1** coordination complex 1-[($\eta^2$-dppf)($\eta^5$-$C_5H_5$)RuC≡C]-3-[(bipy*)$(CO)_3$ReC≡C]-5-($PPh_2$-AuC≡C-bipy)$C_6H_3$ (**3**) (Scheme 1). After appropriate workup, compound **3** could be isolated as a yellow powder in moderate yield.

When we attempted to crystallise complex **3** by diffusion of *n*-hexane into a dichloromethane solution containing **3**, it was discovered that this complex is not stable because it decomposes to produce (bipy*)$(CO)_3$ReC≡C-bipy along with an insoluble yellow precipitate that does not dissolve in common organic solvents. This observation underlies an unexpected transmetallation reaction between the Re and Au alkynyls. The insoluble precipitate probably evinces a polymeric structure formed by the remaining phosphane gold(I) acetylide building block. Nevertheless, complex **3** with its four different transition-metal atoms is a key starting material for the synthesis of organometallic assemblies of higher nuclearity owing to the presence of a pendant 2,2′-bipyridine entity as a further N-ligating site.

{1-[($\eta^2$-dppf)($\eta^5$-$C_5H_5$)RuC≡C]-3-[(bipy*)$(CO)_3$ReC≡C]-5-[$PPh_2$AuC≡C-bipy({[Ti](μ-σ,π-C≡$CSiMe_3$)$_2$}-Cu)]$C_6H_3$}$PF_6$ (**5**) is formed in a straightforward manner when **3** is treated with the organometallic π-tweezer

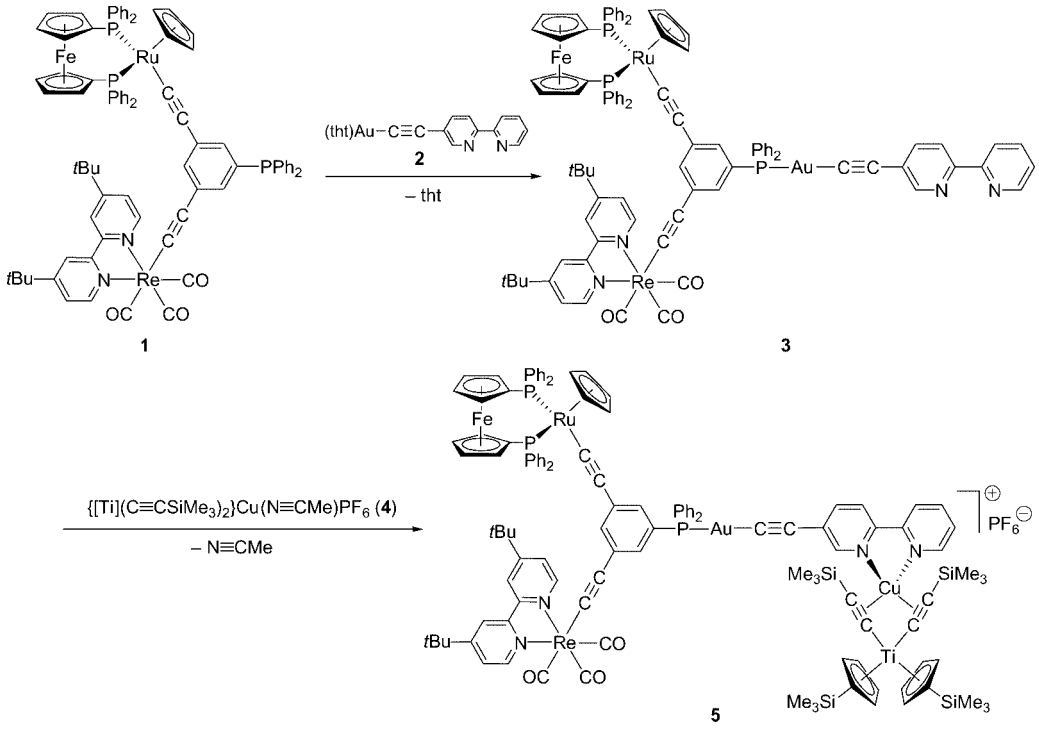

Scheme 1. Synthesis of heterotetrametallic **3** and heterohexanuclear **5** {[Ti] = ($\eta^5$-$C_5H_4SiMe_3)_2$Ti}.

[{[Ti](μ-σ,π-C≡CSiMe$_3$)$_2$}Cu(N≡CMe)]PF$_6$ (**4**), whereby the acetonitrile ligand in **4** is substituted by the bipyridine entity of **3**. Within this reaction, the coordination number at copper(I) changes from three (planar) to four (pseudo-tetrahedral).

Orange **5** is only soluble in polar solvents such as tetrahydrofuran or chloroform as a result of its ionic character. This complex is stable in the solid state, that is, no intramolecular redox processes are observed. However, it should be mentioned that all efforts to produce X-ray quality crystals of **5** failed owing to the instability of this complex in solution over prolonged periods. In **5** the appropriate transition metals Ti, Re, Fe, Ru, Cu and Au are connected by carbon-rich organic bridging units.

The synthetic protocol developed to prepare heteromutlinuclear **3** and **5** is directed to the use of modular-shaped organometallic building blocks (vide supra). In this respect, IR and NMR ($^1$H, $^{31}$P{$^1$H}) spectroscopy allow the progress of the reactions to be monitored, and thus the structure and composition of the final assemblies can be verified. In addition, ESI-TOF mass spectrometric studies were carried out with **3** and **5**.

Most characteristic in the IR spectra of **3** and **5** is the appearance of $\nu_{C\equiv C}$ and $\nu_{CO}$ vibrations typical for the individual σ alkynyl organometallic transition-metal fragments, which are diagnostic and represent a useful monitoring tool. The introduction of the gold acetylide building block at the phosphane is evidenced by the respective $\nu_{C\equiv C}$ absorption at 2117 cm$^{-1}$ (AuC≡C), which is typical for phosphane-stabilised gold(I) acetylides and also found in **5**.[8]

The $^{31}$P{$^1$H} NMR spectra of **3** and **5** show the expected resonance signals. In all complexes, a signal at $\delta \approx 54$ ppm is observed for the dppf entity. Owing to the coordination of the phosphane to gold(I), a representative shift to lower field from –5.4 (**1**) to 41.2 (**3**) ppm is observed which is, however, not influenced by further metal coordination as given in **5**.[8]

The $^1$H NMR spectroscopic properties of **3** and **5** nicely correlate with their formulations as heteromultinuclear assemblies based on the 1,3-diethynyl-5-diphenylphosphanylbenzene core, and the spectra show the respective resonance signal patterns for the organic units. Most distinctive for the formation of **5** is the chemical shift of the bipyridine protons H6/H6′ (**3**: H6′, 8.66; H6, 8.79 ppm; **5**: H6/H6′, (m) 8.49–8.58 ppm). Furthermore, as a result of the coordination of the bipyridine unit to the organometallic π-tweezer-stabilised copper(I) centre in **5**, a highfield shift of the Me$_3$SiC≡C protons is observed relative to **4**,[9] which can be explained by the ring current of the bipyridine ligand.

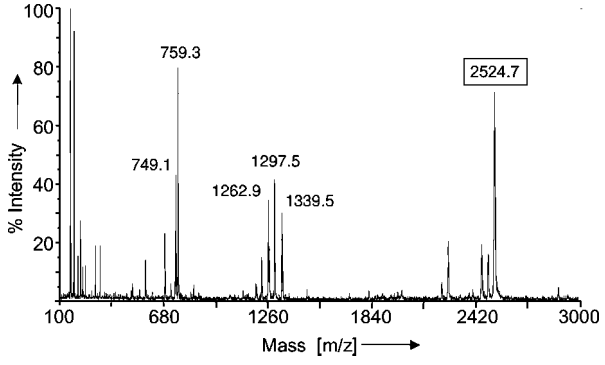

Figure 1. ESI-MS spectra of heterohexanuclear **5**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The identity of heterotetranuclear **3** and heterohexametallic **5** was additionally evidenced from mass spectrometric investigations. The electrospray ionisation mass spectrum (ESI-MS) of **3** shows an ion peak at *m*/*z* = 1944.7, which corresponds to $[\mathbf{3} + H]^+$. The spectrum of **5** (Figure 1) exhibits a prominent ion peak at *m*/*z* = 2524.7, whose mass and isotope distribution pattern comply to $[\mathbf{5} - PF_6]^+$ and confirm the elemental composition and charge state.

## Conclusions

This report pertaining to the first synthesis of an organometallic complex in which a total of six different early and late transition metals, such as titanium, rhenium, iron, ruthenium, copper and gold, are connected by carbon-rich π-conjugated bridging units demonstrates that such large heteronuclear assemblies can be synthesised in a straightforward manner by combining different organic and/or organometallic building blocks of lower nuclearity from a ligand and coordination complex library that was particularly built for this purpose. This procedure allows the composition and structure of such novel molecules to be controlled, but it also should be mentioned that unexpected reactions can occur that make this field of chemistry even more challenging than initially anticipated. Similar to racing cars, from which we learn experience for everyday vehicles, the chemistry described above will surely provide the impetus for future detailed investigations in this field of chemistry, including spectroelectrochemical studies and material properties.

## Experimental Section

**Starting Materials, Reaction Conditions and Instrumentation:** All manipulations were carried out under anhydrous and anaerobic conditions by using standard Schlenk techniques. Tetrahydrofuran and *n*-hexane were purified by distillation from sodium/benzophenone. $[\{[Ti](\mu\text{-}\sigma,\pi\text{-}C{\equiv}CSiMe_3)_2\}Cu(N{\equiv}CMe)]PF_6$[9a] was prepared according to a published procedure. Infrared spectra were recorded with a Perkin–Elmer FTIR spectrometer Spectrum 1000. NMR spectra were recorded with a Bruker Avance 250 spectrometer; chemical shifts are given in $\delta$ units (parts per million) and are referenced to residual solvent resonances ($^1$H NMR: $CDCl_3$, $\delta$ = 7.26) or an external 85% $H_3PO_4$ standard ($^{31}P\{^1H\}$).

**5:** To $[\{[Ti](\mu\text{-}\sigma,\pi\text{-}C{\equiv}CSiMe_3)_2\}Cu(N{\equiv}CMe)]PF_6$ (**4**) (25 mg, 0.033 mmol) dissolved in tetrahydrofuran (25 mL) was added in a single portion 1-[($\eta^2$-dppf)($\eta^5$-$C_5H_5$)RuC≡C]-3-[(bipy*)$(CO)_3$ReC≡C]-5-($PPh_2$AuC≡C-bipy)$C_6H_3$ (**3**) (60 mg, 0.031 mmol). The resulting reaction mixture was stirred for 2 h at 25 °C, whereby the colour of the solution changed from orange to red. The solvent was reduced in volume, and the product was precipitated by the addition of *n*-hexane, washed twice with *n*-hexane and dried under vacuum to afford an orange-red solid. Yield: 70 mg (0.026 mmol, 85%). $^1$H NMR (250 MHz, $CDCl_3$, 25 °C, TMS): $\delta$ = –0.50 (s, 18 H, Si*Me*$_3$), 0.27 (br. s, 18 H, Si*Me*$_3$), 1.41 (s, 18 H, *t*Bu), 3.93 (dpt, $J_{HP}$ = 1 Hz, $J_{HH}$ = 2.4 Hz, 2 H, $C_5H_4$), 4.02 (br. s, 2 H, $C_5H_4$), 4.20 (s, 5 H, $C_5H_5$), 4.25 (br. s, 2 H, $C_5H_4$), 5.00 (br. s, 2 H, $C_5H_4$), 6.23–6.30 (m, 8 H, $C_5H_4$/$C_5H_4SiMe_3$), 6.83 (dpt, $J_{HP}$ = 12.8 Hz, $J_{HH}$ = 1.5 Hz, 1 H, $C_6H_3$), 7.00 (dpt, $J_{HP}$ = 15 Hz, $J_{HH}$ = 1.5 Hz, 1 H, $C_6H_3$), 7.06–7.53 [m, 26 H ($C_6H_5$) + 1 H ($C_6H_3$) + 2 H (*H5*/bipy*)], 7.62–7.75 [m, 4 H ($C_6H_5$) + 1 H (*H5′*/bipy)], 8.12 (dd, $^3J_{H4H3}$ = 8.4 Hz, $^4J_{H4H6}$ = 2.0 Hz, *H4*/bipy), 8.18–8.27 (m, 3 H, *H3*/bipy* + *H4′*/bipy), 8.42 (d, $^3J_{H3H4}$ = 8.4 Hz, 1 H, *H3*/bipy), 8.49–8.58 (m, 3 H, *H3′*,*H6*,*H6′*/bipy), 8.97 (d, $^3J_{H6H5}$ = 6.0 Hz, 2 H, *H6*/bipy*) ppm. $^{31}P\{^1H\}$ NMR (101.25 MHz, $CDCl_3$, 25 °C, $H_3PO_4$): $\delta$ = –145.1 (septuplet, $J_{PF}$ = 713 Hz, $PF_6$), 40.8 (Au*P*$Ph_2$), 53.7 (dppf) ppm. IR (KBr): $\tilde{\nu}$ = 1893, 1904, 2003 (s, CO), 2060 (m, *C*≡*C*Ru), 2117 (w, *C*≡*C*Au) $cm^{-1}$. MS (ESI-TOF): *m*/*z* (%) = 2524.7 (70) $[M - PF_6]^+$. $C_{120}H_{121}AuCuF_6FeN_4O_3P_4ReRuSi_4Ti$ (2669.03): calcd. C 54.00, H 4.57, N 2.10; found C 54.76, H 4.80, N 2.04.

# Self-Assembly of Dimeric $Mn^{III}$–Schiff-Base Complexes Tuned by Perchlorate Anions

**Manuel R. Bermejo,[a] M. Isabel Fernández,*[b] Esther Gómez-Fórneas,[b] Ana González-Noya,[b] Marcelino Maneiro,*[b] Rosa Pedrido,[a] and M. Jesús Rodríguez[b]**

**Keywords:** Manganese / Self-assembly / Anions / Schiff bases / Peroxidase

The synthesis and structural and spectroscopic characterisation of 12 manganese(III)–Schiff-base complexes of the formula $[MnL^n(H_2O/CH_3OH)_2](ClO_4)(mH_2O)$ ($m$ = 0, 1) are described. The multidentate $H_2L^n$ and $H_4L^n$ Schiff-base ligands were obtained by condensation of different diamines (1,2-diaminoethane, 1,2-diamino-2-methylethane, 1,2-diamino-2,2-dimethylethane, 1,3-diamino-2,2-dimethylpropane) and 2,3-dihydroxybenzaldehyde, 3-methoxy-2-hydroxybenzaldehyde or 3-ethoxy-2-hydroxybenzaldehyde. The crystal structures of $H_2L^3$ and $H_4L^{10}$ ligands were solved by X-ray crystallography, revealing their ability to bind metal centres. Recrystallisation of complexes **2** and **8** from methanol yielded single crystals of $[MnL^2(H_2O)_2](ClO_4)$ and $[MnL^8(H_2O)_2](ClO_4)$. Their X-ray characterisation shows a tetragonally elongated octahedral geometry for the manganese coordination sphere, formed by the chelation of the $N_2O_2$ donor set of the inner compartment of the Schiff base to the equatorial plane of the octahedron and by the binding of two water molecules in the axial positions. The octahedron entities are linked in pairs by μ-aquo bridges between neighbouring axial water molecules and also by π–π stacking interactions, establishing dimeric structures. Perchlorate anions are accommodated in the cavities of the framework and form hydrogen bonds with the aqua ligands, leading to infinite spirals of the complexes generated by a screw axis along $a$. Moreover, the peroxidase activity of the crystallographically solved complexes **2** and **8**, studied in the presence of the water-soluble trap ABTS, agrees with the predicted rate according to the activity/rhombicity correlation.

## Introduction

Crystal engineering of supramolecular architectures sustained by noncovalent intermolecular forces represents a rapidly expanding field that offers potential for the development of new types of functional solids.[1,2] The self-assembly of metal-organic frameworks is highly influenced by factors such as the geometric requirements of metal ions,[3,4] the ligand design,[5,6] the solvents used for crystallisation[7] or the selection of the counteranions.[8] Understanding the role of these factors may extend our knowledge of the relevant structural types and establishes proper synthetic strategies that lead to the desired species with predictable structures and properties.

In recent times one of our research goals constitutes the study of supramolecular chemistry of manganese(III).[9–11] The coordination chemistry of this species has been extensively studied[12,13] due to its rich redox behaviour, where manganese(III) complexes are the active sites of numerous enzymes,[14] but studies focusing on their multidimensional arrangements are less abundant. This paper presents new results from our intention of studying in depth the multidimensional arrangements of manganese(III) chemistry.

We have already shown how the introduction of chloride anions may induce the self-assembly of $Mn^{III}$ complexes, through a hydrogen-bonding net, to give 2D supramolecular architectures[10] when the ligand has hydroxy functional groups in adequate positions. We are now exploring the use of weakly coordinating anions such as perchlorates, nitrates, etc., to construct $Mn^{III}$ polymer networks.[15–18] The ability of these anions for establishing hydrogen bonds would allow new supramolecular architectures to be obtained and would also lead to systems of interest for the selective recognition between anions and receptors.[19,20]

Herein we report a series of $Mn^{III}$–Schiff-base complexes associated by perchlorate counteranions, using ligands with adequate OH groups. The selected Schiff-base ligands, $H_4L^n$ and $H_2L^n$ (see Scheme 1), contain six and four potential donor atoms, respectively. They have in common an inner compartment with two imine nitrogen atoms and two phenol oxygen atoms, but $H_4L^n$ ligands have an extra couple of outer phenol groups, while $H_2L^n$ ligands present two outer methoxy or ethoxy groups.

## Results and Discussion

### Synthesis and Spectroscopic Studies

The Schiff-base ligands were obtained in almost quantitative yield by the well-known experimental procedure, and afterwards they were characterised by elemental analysis, electrospray, IR, $^1$H- and $^{13}$C NMR spectroscopy, as well as the measurements of their melting points. Additionally, $H_2L^3$ and $H_4L^{10}$ gave crystals suitable for their characterisation by X-ray crystallography.

The manganese complexes were prepared following a variation of the Boucher method reported by us previously.[21] The manganese compounds obtained by this synthetic route, in high yield, are sparingly soluble in water and common organic solvents, but are quite soluble in MeOH, DMF and DMSO. Elemental analyses establish their general formula as $[MnL^n(H_2O/CH_3OH)_2](ClO_4)$-$(mH_2O)$ ($m$ = 0, 1).

All these complexes show similar IR spectral features (Table 1), exhibiting a strong band between 1621–1610 cm$^{-1}$ attributable to $\nu$(C=$N_{imine}$), which is shifted 7–22 cm$^{-1}$ lower than that in the free ligand. An up-frequency shift of the $\nu$($CO_{phenol}$) band to higher frequency (6–21 cm$^{-1}$) is also observed. These data suggest the coordination of the Schiff base in its dianionic form to the metal through the inner phenol oxygen and the imine nitrogen atoms.

The IR spectra also show broad unsplit bands ca. 1100 cm$^{-1}$, together with bands at 630 cm$^{-1}$, indicative of the presence of the uncoordinated perchlorate anion.

The presence of a broad band at about 3400 cm$^{-1}$ is associated with coordinated and/or solvated water/methanol molecules, but unfortunately it interferes with the observation of uncoordinated hydroxy groups.[22]

The ES mass spectra exhibit peaks relating to fragments $[MnL]^+$, which thus further corroborate coordination of the ligand to the manganese ion. The appearance of minor peaks in some complexes that could be assigned to the $[Mn_2L_2]^+$ dimeric entity (see Table 1) suggests their tendency to dimerise, although this spectroscopic technique is not sensitive enough to unambiguously detect either these dimers or the coordinated water molecules in every case.

The room temperature magnetic moments of the complexes are listed in Table 1. They exhibit values close to the spin-only value of 4.9 BM, as expected for a high-spin magnetically diluted d$^4$ manganese(III) ion, indicating little or no antiferromagnetic interaction.

The electronic spectroscopic data recorded are very similar for all compounds **1**–**12**, indicating that the $Mn^{III}$ complexes are behaving as high-spin octahedral d$^4$ systems, probably suffering a significant Jahn–Teller distortion which affects the spectra and complicates its interpretation. The characteristic UV broad band obtained at 480–490 nm ($\varepsilon$ = 2600–3300 L mol$^{-1}$ cm$^{-1}$) corresponds to the $^5E_g \leftarrow {}^5T_{2g}$ transition, and the peak appearing around 300 nm ($\varepsilon$ = 21000–23000 L mol$^{-1}$ cm$^{-1}$) can be attributed to the Schiff-base ligand → $Mn^{III}$ LMCT band.

Furthermore, the conductivity measurements in DMF give $\Lambda_M$ values of 90–60 μS cm$^{-1}$, indicating a behaviour attributable to 1:1 electrolytes.[23]

Paramagnetic $^1$H NMR spectroscopic studies of these $Mn^{III}$ complexes were undertaken using [$D_6$]dmso as the solvent. The data are presented in Table 1. The interpretation of the data was based on previous findings for manganese(III) complexes with related Schiff-base ligands.[9,24] The spectra contain proton resonances that lie outside the diamagnetic region ($\delta$ = 0–14 ppm) due to the well-known isotropically shifting of the ligand protons for high-spin $Mn^{III}$ complexes in an octahedral field. In this sense, the

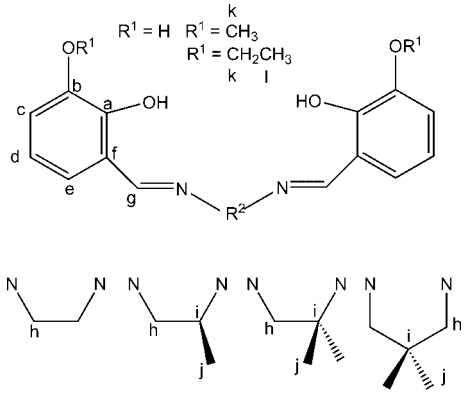
data obtained from these NMR spectroscopic studies serve to corroborate the formation of the manganese(III) complexes since two sets of upfield sharp peaks corresponding to the H4 and H5 protons of the aromatic rings (Scheme 2) are observed. Clearly the upfield signals (ranging from –20.10 to –34.15 ppm) arise from H4 protons, while the downfield resonances (–14.50 to –21.99 ppm) arise from H5 protons. Our experience shows that signals in *ortho* positions to donor atoms are not observable for these kinds of complexes by paramagnetic $^1H$ NMR spectroscopy. Since H4 signals are discernible for all complexes, including **1**, **4**, **7** and **10**, with external hydroxy groups in the aromatic rings of the Schiff bases, the NMR spectra suggest no coordination through these groups to the metal ion.



Scheme 2.

### Crystallographic Studies of Ligands $H_2L^3$ and $H_4L^{10}$

Crystals of $H_4L^{10}$ suitable for X-ray studies were obtained by slow evaporation of a methanol solution of the ligand. The crystal structure, with the numbering scheme, is shown in Figure 1. Selected bond lengths and angles are given in Table 2.

The crystal structure is made up of $H_4L^{10}$ discrete molecules. The C7–N8 and N12–C13 distances of 1.276(2) and 1.290(2) Å, respectively, are consistent with N=C double bonding. One of the four oxygen atoms, O22, lacks a hydrogen atom, appearing in the carbonyl form, which is corroborated by the C19–O22 distance of 1.2928(18) Å, in accordance with a C=O double bond. The other three oxygen

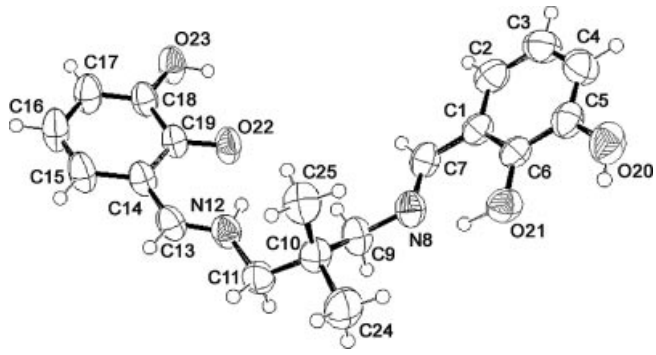


Figure 1. Molecular structure of $H_4L^{10}$ showing the atomic numbering scheme.

atoms form phenol groups, and they present longer C–O distances [C5–O20 1.365(2) Å, C6–O21 1.347(2) Å, C18–O23 1.361(2) Å], corresponding to the expected single bonds.

The study of these distances reveals the transfer of one proton from a hydroxy group of each molecule to the neighbouring nitrogen atom N12. This process is favoured by the so-called "proton-sponge" effect,[25] which consists of the increase in the basicity of the imine nitrogen atoms due to the spatial nearness of their lone pairs. The instability of a situation of proximity of these two lone pairs is then solved by the attraction of one phenol hydrogen atom by one of the nitrogen atoms. This leads to the formation of a relatively strong $[N–H\cdots O]^+$ intramolecular bond [H22···O22 1.75(2) Å, N12···O22 2.5914(19) Å and N12–H22···O22 145.2°]. Despite the symmetry of the compound, a second proton transfer to the other imine nitrogen atom does not occur since it would mean a very unfavourable situation, involving the formation of two neighbouring $[N–H]^+$ groups and preventing the $[N–H\cdots O]^+$ intramolecular hydrogen bond.

An additional intramolecular hydrogen bond exists between the N8 imine nitrogen atom and the neighbouring phenol oxygen atom [H21···N8 1.55(3) Å, O21···N8 2.5767(19) Å and O21–H21···N8 146.2°]. These intramolecular hydrogen bonds are typical of Schiff bases derived from salicylaldehydes.[26] Besides, intermolecular interactions by hydrogen bonds can also be observed between the phenol oxygen atoms of neighbouring molecules.

According to this crystal structure study, the rather planar conformation of the set N8–N12–O21–O22 suggests that this ligand should easily act as tetradentate donor in the equatorial plane about an octahedral metal centre. However, we cannot predict the role of the outer phenol oxygen atoms of each aldehyde residue during complexation as they could coordinate, for instance, to the metal centre by an axial position, but also their role could be limited to intermolecular hydrogen-bond interactions.

Slow evaporation of a methanol solution of ligand $H_2L^3$ gives crystals, suitable for X-ray diffraction studies, of $C_{20}H_{24}N_2O_4$. The crystal structure is displayed in Figure 2 with the atom numbering scheme adopted. Selected bond lengths and angles are in Table 2.

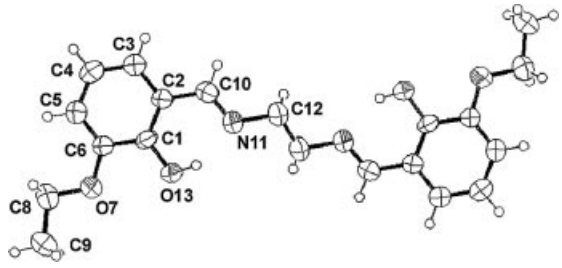

Figure 2. Molecular structure of $H_2L^3$ showing the atomic numbering scheme.

The crystal structure reveals that $H_2L^3$ exists as discrete molecules, and it is composed of two identical 3-methoxy-2-hydroxybenzylimine moieties connected by the flexible C12–C12B methylene chain (so-called spacer in supramolecular chemistry), so we will only discuss one of them. The C10–N11 distance of 1.272(5) Å is consistent with C=N double bonding. Both imine groups are fully localised in the molecule. The angle of 120.2(4)° around the N11 atom confirms its $sp^2$ character.

The disposition adopted by the free ligand in the solid state is conditioned by two strong intramolecular hydrogen-bond interactions which form two six-membered rings. These interactions arise from the contact between the hydroxy and the imine groups. In this case and contrary to the situation described for $H_4L^{10}$, both hydroxy oxygen atoms retain their hydrogen atoms. As expected, the O13–H13···N11 [H13···N11 1.59(7) Å, O13···N11 2.555(5) Å and O13–H13···N11 154(6)°] hydrogen bonding establishes an almost planar N11–C10–C2–C1–O13–H13 ring.

This kind of Schiff-base ligand, with a flexible spacer, produces this type of "open" structure as we have previously found in similar ligands.[27,28] These and other similar ligands present adequate conditions to be useful in the synthesis of octahedral complexes, occupying the equatorial positions around the metal centre.

### Crystallographic Studies of Complexes 2 and 8

Recrystallisation of $[MnL^2(H_2O)_2](ClO_4)$ (**2**) and $[MnL^8(H_2O)_2](ClO_4)$ (**8**) from methanol solutions by slow evaporation afforded brown crystals from which we determined their molecular structures. Both crystal structures show similar features; thereby, they will be discussed together. An ORTEP view of **8** with the atomic numbering scheme is shown in Figure 3. Experimental details are given in Table 5. Main bond lengths and angles are listed in Table 3.

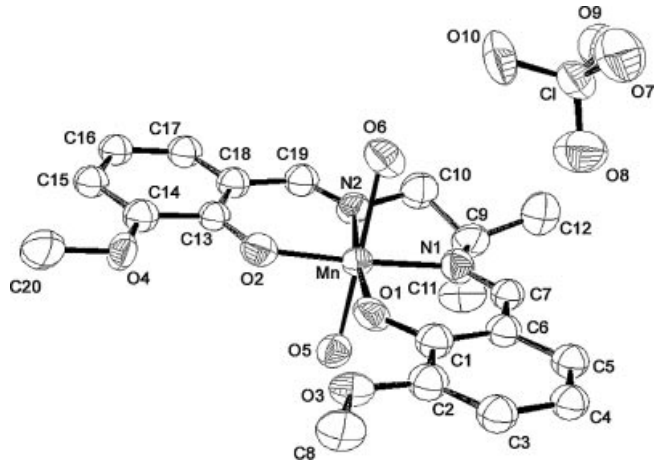

Figure 3. Molecular structure of **8** showing the atomic numbering scheme.

Table 3. Selected bond lengths [Å] and angles [°] for complexes **2** and **8**.

The crystallographic analyses show $[MnL^n(H_2O)_2]^+$ mononuclear cationic complexes, where the geometry around each manganese(III) ion can be described as distorted octahedral. The structure of these cations comprises the planar Schiff-base ligand tightly bound to the manganese(III) ion through the inner $N_2O_2$ compartment by the $N_{imine}$ and $O_{phenol}$ atoms (Mn–$N_{imine}$ bond lengths of 1.95–1.97 Å and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Mn–O_{phenol}$ of 1.84–1.87 Å are typical of such complexes and corroborate the bisdeprotonation of the ligands),[9,10,29] occupying the equatorial positions and giving rise to two six-membered chelate rings (which are nearly planar) and an additional five-membered chelate ring. The coordination sphere around each manganese centre is then completed by capping water molecules. The axial Mn–O distances (ranging from 2.23 to 2.36 Å) are considerably longer than the equatorial Mn–O bond lengths quoted earlier, indicating that the Jahn–Teller elongation expected for a high-spin $d^4$ manganese(III) ion is present among these complexes. The deviation from an ideal octahedral geometry is also revealed by the range of angles observed around the metal centre (from 81.83° to 93.84°), as well as by the interaxial angle OW–Mn–OW of 177.95° for **2** and 176.97° for **8**.

From the viewpoint of supramolecular chemistry, complexes **2** and **8** exhibit a topology constructed by hydrogen bonds, which help to stabilise the packing and induce the assembly of the mononuclear cationic complexes.

The superstructure of the complexes involves associations through a combination of π-aryl interactions and hydrogen bonds between capping water and outer phenoxy and axial water oxygen atoms of the neighbouring Schiff-base ligand. This results in Mn···Mn distances of about 4.90 Å, which are short for monomeric compounds; these types of $[MnL(H_2O)_2]_2^{2+}$ systems have been reported by us previously[30,31] as μ-aquo dimers (Figure 4). However, these Mn···Mn distances are too long to establish intermetallic interactions between neighbouring manganese ions, in accordance with the non-antiferromagnetic behaviour shown by the magnetic studies.

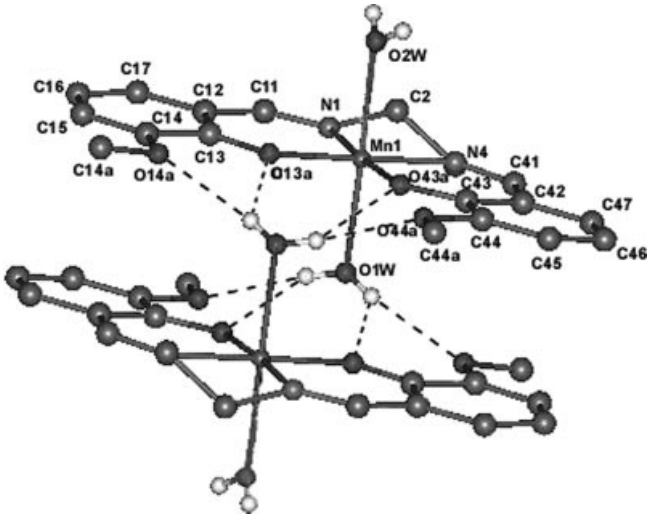

Figure 4. Ball-and-stick diagram of the μ-aqua dimer formed for **2** through hydrogen bonds.

Moreover, the μ-aquo dimers are interconnected by hydrogen bonding involving the perchlorate counterions. In this way, pairs of neighbouring μ-aquo dimers are linked by two perchlorate anions. The hydrogen-bonding interactions involving perchlorate anions with their symmetry codes for compounds **2** and **8** are given in Table 4. This hydrogen-bonding scheme arises from the interactions of two perchlorate ions which establish two pairs of hydrogen bonds to two adjacent μ-aquo dimers. Each pair is directed from the perchlorate anions to the external capping water molecule of each dimeric building unit (see Figure 5). These multiple intermolecular interactions are extended into the solid to form infinite spirals generated by a screw axis along *a*. The 1D network of manganese dimers generates a kind of tunnel along the *c* axis. Perchlorate anions are accommodated in such cavities of the framework.

Table 4. Hydrogen-bonding scheme (distances and angles) involving perchlorate counterions for complexes **2** and **8**.

| D–H···A [Å] | D–H [Å] | H···A [Å] | D···A [Å] | D–H···A [°] |

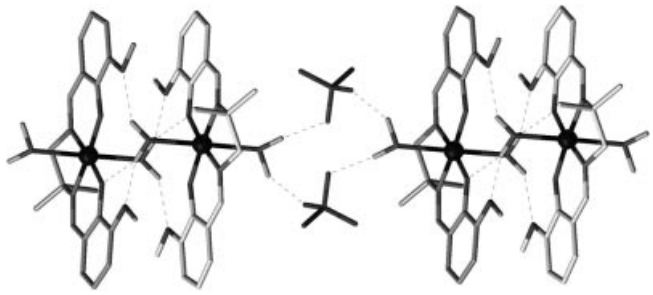

Figure 5. Stick diagram for **8** showing the hydrogen bonding between adjacent $[MnL^8(H_2O)_2]_2^{2+}$ dimeric units through perchlorate anions.

A comparison between the role of perchlorate and chloride counterions as multiple hydrogen-bond acceptors for similar manganese(III) complexes derived from $H_4L$ Schiff bases may be established. We have previously reported how each chloride ion could be involved in four O–H···Cl bonds, connecting three neighbouring cationic complexes and assembling them to constitute a 2D network.[10] In the present work, we find each perchlorate anion is only able to form two hydrogen bonds. This behaviour implies preference is given to one direction and provokes a decrease in the dimensionality of the network.

### Redox Properties and Peroxidase Essays

The electrochemical behaviour of some of the complexes (**2**, **3**, **5**, **7**, **8** and **12**) was studied by cyclic voltammetry. In all cases this technique exhibits a one-electron reduction-oxidation peak system in the 0 to –0.1 V potential range. The difference between the anodic and cathodic potentials indicates a redox reversible character. Moreover, these negative potentials belong to the range which would favour the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

catalytic activity, as we have previously reported for other $Mn^{III}$–Schiff-base systems.[31,32]

The peroxidase-like activity of the cited complexes was followed by the oxidation of the diammonium salt of 2,2′-azinobis(3-ethylbenzothiazoline)-6-sulfonic acid (ABTS) at pH 6.8. The reaction of ABTS with $H_2O_2$ in the presence of the complexes generates $ABTS^{\cdot+}$, which can be clearly identified by its characteristic absorption bands (415, 650, 735 and 815 nm) and measured quantitatively at $\lambda$ = 650 nm since $\varepsilon$ = 12000 $M^{-1}cm^{-1}$ has been determined. The rate of formation of $ABTS^{\cdot+}$ ranges from 30–40% with respect to the initial ABTS. This shows an important capacity of hydrogen peroxide decomposition by the studied complexes. The activity is comparable to that of a previous series of Mn–Schiff-base complexes, reported by us, incorporating carboxylate ligands,[31] but is much higher than an earlier Mn–Schiff-base series with the chloride counterion.[10] Recently, we have tried to establish a correlation between peroxidase activity and the structural motifs of the complexes.[31] We have postulated what seems to be an easy approach to predict the capacity of $H_2O_2$ decomposition by these types of complexes as a finction of the tetragonal elongation of the octahedral geometry in the crystal structure. An axial water molecule in this class of distorted geometries constitutes a quite labile ligand, which would generate a vacant position in the coordination sphere to accommodate the substrate molecule.

In order to quantify the tetragonal elongation we have employed the "rhombicity" of the structure as the ratio between their manganese–axial-oxygen distances and their manganese–equatorial-oxygen distances. This correlation is also valid for the data taken for complexes **2** and **8** of this work. Their Mn–Ow/Mn–Oeq ratios of 1.24 and 1.27, respectively, are compatible with their peroxidase activity.

## Conclusions

We can conclude that these types of manganese(III) complexes, formed from Schiff bases with inner and outer O–X (X = H, $CH_3$, $CH_2CH_3$) groups, constitute suitable building units for establishing rich hydrogen-bonding networks. In the present work, the selection of the proper spacer in the Schiff-base ligand allows formation of $[MnL]_2^{2+}$ dimeric units, which can be connected through perchlorate counterions to form 1D chains. The lower dimensionality of the network with respect to the case of a chloride counterion (2D → 1D) can be interpreted in terms of the lower symmetry of the perchlorate (tetrahedral) than that of the chloride (spherical), involving a higher directionality of the network. The ability of these types of complexes to accommodate different anions in the vacancies of the framework becomes an interesting research field for selective recognition between anions and receptors, beyond their worthwhile redox behaviour.

## Experimental Section

**Physical Measurements:** Elemental analyses were performed with a Carlo Erba model 1108 CHNS-O elemental analyser. The IR spectra were recorded as KBr discs with a Bruker IFS-66V FTIR spectrophotometer and UV–Vis spectra with a Varian Cary IE. $^1$H- and $^{13}$C NMR spectra were recorded with a Bruker WH 300 MHz spectrometer using DMSO as the solvent and $SiMe_4$ as an internal reference. ES mass spectra were recorded with a Hewlett-Packard LC-MSD Series 1100a spectrometer. Conductivities of $10^{-3}$ M solutions in DMF were measured with a Crison Micro CM 2200 conductivimeter. Room-temperature magnetic susceptibilities were measured using a Faraday balance MSB-MKI by Evans; $HgCo(NCS)_4$ was employed as a susceptibility standard.

Electrochemical measurements were performed with an EG&G PAR model 273 potentiostat, controlled by EG&G PAR model 270 software. A Metrohm model 6.1204.000 graphite disc coupled to a Metrohm model 628–10 rotating electrolyte device was used as a working electrode. A saturated calomel electrode was used as a reference, and a platinum wire was used as an auxiliary electrode. All measurements were made with ca. $10^{-3}$ mol dm$^{-3}$ solutions of the complexes in dimethylformamide using 0.2 mol dm$^{-3}$ $NBu_4PF_6$ as a supporting electrode. Cyclic voltammetry measurements were performed with a static graphite electrode.

**Materials:** 2,3-Dihydroxybenzaldehyde (Sigma–Aldrich), 3-methoxy-2-hydroxybenzaldehyde (Fluka Chemika), 3-ethoxy-2-hydroxybenzaldehyde (Fluka Chemika), diamines [1,2-diaminoethane, 1,2-diamino-2-methylethane, 1,2-diamino-2,2-dimethylethane, 1,3-diamino-2,2-dimethylpropane] (Aldrich) and manganese(II) perchlorate hexahydrate (Fluka) were used as received without further purification.

**Preparation of the Ligands:** The hexadentate Schiff bases, $H_xL^n$, used in this study were prepared by condensation of the appropriate diamine with 2,3-dihydroxybenzaldehyde, 3-methoxy-2-hydroxybenzaldehyde or 3-ethoxy-2-hydroxybenzaldehyde in methanol.[33,34] They were isolated in virtually quantitative yield and satisfactorily characterised by elemental analysis, $^1$H- and $^{13}$C NMR spectroscopy, ES mass spectroscopy and IR spectroscopy. This can be typified by the following preparation of $H_4L^1$.

**$H_4L^1$:** To a methanol solution (120 mL) of 2,3-dihydroxybenzaldehyde (4.00 g, 28.96 mmol) was added 1,2-diaminoethane (0.97 mL, 14.48 mmol). This mixture was heated at reflux in a round-bottomed flask fitted with a Dean Stark trap to remove the water produced during the reaction. After heating for 3 h, the solution was concentrated to yield a yellow solid. The product was collected by filtration, washed with diethyl ether and dried in air. $C_{16}H_{16}N_2O_4$ (300.30): calcd. C 63.9, H 5.4, N 9.3; found C 63.3, H 5.6, N 9.4. $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 8.54 (s, 2 H), 6.65–6.85 (m, 6 H), 3.93 (s, 4 H) ppm. $^{13}$C NMR (75 MHz, [D$_6$]-DMSO): $\delta$ = 167.1 ($C_g$), 151.0 ($C_a$), 145.8 ($C_b$), 118.1 ($C_f$), 58.0 ($C_h$) ppm. ES-MS: *m*/*z* = 301.2. IR: $\tilde{\nu}$ = $\nu$(O–H) 3258, $\nu$(C=N) 1633, $\nu$(C–O) 1246 cm$^{-1}$. M.p. 240 °C.

**$H_2L^2$:** 3-Methoxy-2-hydroxybenzaldehyde (2.00 g, 13.15 mmol) and 1,2-diaminoethane (0.41 mL, 6.57 mmol). $C_{18}H_{20}N_2O_4$ (328.37): calcd. C 65.8, H 6.2, N 8.5; found C 65.7, H 6.2, N 8.6. $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 13.42 (br.), 8.56 (s, 2 H), 6.79–7.01 (t, d, d, 6 H), 3.92 (s, 4 H), 3.76 (s, 6 H) ppm. $^{13}$C NMR (75 MHz, [D$_6$]DMSO): $\delta$ = 167.7 ($C_g$), 152.3 ($C_a$), 148.7 ($C_b$), 59.0 ($C_h$), 56.5 ($C_k$) ppm. ES-MS: *m*/*z* = 329.3. IR: $\tilde{\nu}$ = $\nu$(O–H) 3087, $\nu$(C=N) 1633, $\nu$(C–O) 1249 cm$^{-1}$. M.p. 165 °C.

**$H_2L^3$:** 3-Ethoxy-2-hydroxybenzaldehyde (2.00 g, 12.04 mmol) and 1,2-diaminoethane (0.40 mL, 6.02 mmol). $C_{20}H_{24}N_2O_4$ (356.42): calcd. C 67.4, H 6.7, N 7.9; found C 66.9, H 6.8, N 7.1. $^1$H NMR (300 MHz, [D$_6$]DMSO): $\delta$ = 8.54 (s, 2 H), 6.72–6.99 (d, d, t, 6 H), 4.00 (q, 4 H), 3.97 (s, 4 H), 1.31 (t, 6 H) ppm. $^{13}$C NMR (75 MHz,

**Preparation of the Complexes:** All the complexes were synthesised by air oxidation of the solution made up from $Mn(ClO_4)_2 \cdot 6H_2O$ and the Schiff base.[21] A typical preparation of these complexes is outlined.

**$[Mn(H_2L^4)(H_2O)(CH_3OH)](ClO_4)$ (4):** $H_4L^4$ (0.30 g, 0.95 mmol) was dissolved in methanol (40 mL), and then a solution of NaOH (1.90 mmol, 4 M) in methanol (0.48 mL) was added. After stirring for 10 min, a solution of $Mn(ClO_4)_2 \cdot 6H_2O$ (0.35 g, 0.95 mmol) in methanol (10 mL) was added, and the solution turned brown. (**Caution**: Although no problems were encountered in this work, perchlorates are potentially explosive and should be handled in only small quantities and with care!) The progress of the reaction was followed by TLC for 3 d, and the mixture was then filtered. The complex was obtained from the filtrate as a brown solid after crystallisation. It was isolated by filtration and washed with diethyl ether and dried in air. Yield: 0.37 g (75%). $C_{18}H_{22}ClMnN_2O_{10}$ (516.77): calcd. C 41.8, H 4.3, N 5.4; found C 42.0, H 4.1, N 5.6.

**$[Mn(H_2L^1)(H_2O)_2](ClO_4)(H_2O)$ (1):** $H_4L^1$ (0.50 g, 1.66 mmol), $Mn(ClO_4)_2 \cdot 6H_2O$ (0.60 g, 1.66 mmol) and NaOH (0.83 mL, 3.32 mmol). Yield: 0.76 g (90%). $C_{16}H_{20}ClMnN_2O_{11}$ (506.73): calcd. C 37.9, H 4.0, N 5.5; found C 38.0, H 3.9, N 5.8.

**$[Mn(L^2)(H_2O)_2](ClO_4)(H_2O)$ (2):** $H_2L^2$ (0.33 g, 1.00 mmol), $Mn(ClO_4)_2 \cdot 6H_2O$ (0.36 g, 1.00 mmol) and NaOH (0.50 mL, 2.00 mmol). Yield: 0.35 g (65%). $C_{18}H_{24}ClMnN_2O_{11}$ (534.78): calcd. C 40.4, H 4.5, N 5.2; found C 40.1, H 4.3, N 5.2. Complex **2** was recrystallised from methanol solution, affording brown crystals adequate for X-ray diffraction studies.

**$[Mn(L^3)(H_2O)_2](ClO_4)(H_2O)$ (3):** $H_2L^3$ (0.20 g, 0.56 mmol), $Mn(ClO_4)_2 \cdot 6H_2O$ (0.20 g, 0.56 mmol) and NaOH (0.28 mL, 1.12 mmol). Yield: 0.10 g (32%). $C_{20}H_{28}ClMnN_2O_{11}$ (562.84): calcd. C 42.7, H 5.0, N 5.0; found C 42.0, H 4.9, N 4.8.

**$[Mn(L^5)(H_2O)_2](ClO_4)(H_2O)$ (5):** $H_2L^5$ (0.39 g, 1.00 mmol), $Mn(ClO_4)_2 \cdot 6H_2O$ (0.36 g, 1.00 mmol) and NaOH (0.50 mL, 2.00 mmol). Yield: 0.35 g (65%). $C_{19}H_{26}ClMnN_2O_{11}$ (548.81): calcd. C 41.6, H 4.8, N 5.1; found C 41.4, H 4.6, N 5.1.

**$[Mn(L^6)(H_2O)_2](ClO_4)(H_2O)$ (6):** $H_2L^6$ (0.20 g, 0.54 mmol), $Mn(ClO_4)_2 \cdot 6H_2O$ (0.19 g, 0.54 mmol) and NaOH (0.27 mL,

1.08 mmol). Yield: 0.21 g (68%). $C_{21}H_{31}ClMnN_2O_{11}$ (577.87): calcd. C 43.7, H 5.2, N 4.9; found C 44.0, H 5.0, N 4.7.

**[Mn($H_2L^7$)($H_2O$)($CH_3OH$)]($ClO_4$) (7):** $H_4L^7$ (0.30 g, 0.91 mmol), $Mn(ClO_4)_2·6H_2O$ (0.33 g, 0.91 mmol) and NaOH (0.46 mL, 1.82 mmol). Yield: 0.29 g (60%). $C_{19}H_{24}ClMnN_2O_{10}$ (530.79): calcd. C 43.0, H 4.6, N 5.3; found C 42.7, H 4.3, N 5.3.

**[Mn($L^8$)($H_2O$)$_2$]($ClO_4$) (8):** $H_2L^8$ (0.36 g, 1.00 mmol), $Mn(ClO_4)_2·6H_2O$ (0.36 g, 1.00 mmol) and NaOH (0.50 mL, 2.00 mmol). Yield: 0.35 g (65%). $C_{20}H_{26}ClMnN_2O_{10}$ (544.82): calcd. C 44.1, H 4.8, N 5.1; found C 43.8, H 4.7, N 5.0. Single brown crystals, useful for X-ray diffraction studies, were obtained from slow evaporation of a methanol solution of complex **8**.

**[Mn($L^9$)($H_2O$)$_2$]($ClO_4$) (9):** $H_2L^9$ (0.20 g, 0.52 mmol), $Mn(ClO_4)_2·6H_2O$ (0.18 g, 0.52 mmol) and NaOH (0.26 mL, 1.04 mmol). Yield: 0.25 g (83%). $C_{22}H_{30}ClMnN_2O_{10}$ (572.87): calcd. C 46.1, H 5.2, N 4.9; found C 46.4, H 5.1, N 4.6.

**[Mn($H_2L^{10}$)($H_2O$)($CH_3OH$)]($ClO_4$) (10):** $H_4L^{10}$ (0.30 g, 0.88 mmol), $Mn(ClO_4)_2·6H_2O$ (0.32 g, 0.88 mmol) and NaOH (0.44 mL, 1.76 mmol). Yield: 0.34 g (70%). $C_{19}H_{26}ClMnN_2O_{10}$ (532.81): calcd. C 44.1, H 4.8, N 5.1; found C 44.3, H 4.6, N 5.0.

**[Mn($L^{11}$)($H_2O$)$_2$]($ClO_4$)($H_2O$) (11):** $H_2L^{11}$ (0.20 g, 0.68 mmol), $Mn(ClO_4)_2·6H_2O$ (0.20 g, 0.68 mmol) and NaOH (0.34 mL, 1.35 mmol). Yield: 0.10 g (30%). $C_{21}H_{30}ClMnN_2O_{11}$ (576.86): calcd. C 43.7, H 5.2, N 4.9; found C 43.3, H 5.0, N 4.7.

**[Mn($L^{12}$)($H_2O$)$_2$]($ClO_4$) (12):** $H_2L^{12}$ (0.20 g, 0.50 mmol), $Mn(ClO_4)_2·6H_2O$ (0.18 g, 0.50 mmol) and NaOH (0.25 mL, 1.00 mmol). Yield: 0.22 g (75%). $C_{23}H_{32}ClMnN_2O_{10}$ (586.90): calcd. C 47.1, H 5.5, N 4.8; found C 48.0, H 5.4, N 4.6.

**Peroxidase Probes:** Oxidation of 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) with $H_2O_2$ in the presence of the complexes was tested. An aqueous solution of ABTS (50 μL, 0.009 M, $4.5 \times 10^{-7}$ mol) and a methanol solution of the complex (10 μL, $10^{-3}$ M, $10^{-8}$ mol) were added to water (3 mL). The oxidation of ABTS started immediately after addition of an aqueous solution of $H_2O_2$ (50 μL, 10 M, $5 \times 10^{-4}$ mol).

**X-ray Crystallographic Studies:** Crystals of $H_2L^3$, $H_4L^{10}$, **2** and **8** suitable for X-ray diffraction studies were obtained by slow evaporation of methanol solutions of the cited solids. Data for $H_4L^{10}$ and **2** were collected with a Smart CCD-1000 Bruker diffractometer employing graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation. Data for **8** were collected with a Nonius FR591-kappa CCD2000 diffractometer using graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation. Data for $H_2L^3$ were collected with a Nonius Mach3 diffractometer employing graphite-monochromated Cu-$K_\alpha$ ($\lambda$ = 1.54180 Å) radiation. The structures were solved by direct methods[35] and finally refined by full-matrix least-squares based on $F^2$. An empirical absorption correction was applied using SADABS.[36] All non-hydrogen atoms were anisotropically refined, and all hydrogen atoms were included in the model at geometrically calculated positions. Detailed data collection and refinement of the compounds are summarised in Table 5. CCDC-636345 ($H_2L^3$), -636346 ($H_4L^{10}$), -636347 (**2**) and -636348 (**8**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis of Carbon and Silica Hollow Spheres with Mesoporous Shells using Polyethylene Oxide/Phenol Formaldehyde Polymer Blend

Chun-Yi Chang-Chien,[a] Chun-Han Hsu,[a] Tsung-Ying Lee,[a] Che-Wei Liu,[a] Sheng-Ho Wu,[a] Hong-Ping Lin,*[a,b] Chih-Yuan Tang,[c] and Chin-Yen Lin[c]

**Keywords:** Polymer blends / Mesoporous materials / Metal oxides / Organic templates

Polyethylene oxide/phenol formaldehyde silica composite hollow spheres were obtained from a fast silicification of a polymer blend, containing polyethylene oxide (PEO) as silica gelator and phenol formaldehyde (PF) polymer as carbon source, in a highly diluted silica solution at pH ≈ 5.0–6.0. The PF–PEO/silica hollow spheres can be feasibly converted to mesoporous silica hollow spheres by hydrothermal treatment and calcination, and to mesoporous carbon hollow spheres after pyrolysis under a nitrogen atmosphere and silica etching. Because the formation of the hollow spheres is kinetically controlled, the diameter of the hollow spheres is dependent on the molecular weight of the PEO polymer, pH value of the silica solution, and the PF content, and the size can be tuned within a range of a few micrometers to tens of nanometers. These mesoporous hollow spheres have high surface areas and large pore sizes and volumes. In practice, the mesoporous carbon hollow spheres with an interconnected mesostructure were used as a solid template to prepare different metal oxide hollow spheres. After impregnation of the proper metal oxide precursors and calcination, the $\gamma$-$Al_2O_3$, *anatase*-$TiO_2$, $\alpha$-$Fe_2O_3$, $ZrO_2$, MgO, and $CeO_2$ hollow spheres composed of nanoparticles were readily synthesize.

## Introduction

Since the discovery of mesoporous silicas by Mobil researchers and Kuroda,[1] the construction of organic templates to synthesize advanced materials has become a significant area of scientific and technological interest.[2,3] Because of potential applications in drug storage and release, confined-space catalysis, thermal and electrical insulators, separation, and biomolecule release, the fabrication of functional porous materials with hollow interiors has attracted much attention.[4–10] Typically, hollow spheres of various diameters and wall thicknesses were synthesized by using polymer or silica beads,[5,6] gold nanoparticles,[7] emulsion drops,[8–9] or multi-layers vesicles[10] as interior templates. However, a removable expensive polymer bead, silica, or a Au nanoparticle is energy-consuming and uneconomic. Moreover, fine tuning for the chemical composites and synthetic conditions (i.e. temperature, stirring rate, pH value, etc.) to prepare stable emulsions or vesicles as the morphological templates of the inorganic materials is a sophisticated approach. In addition to creating the hollow interior, introduction of porosity to the shell is also crucially important for controlling accessibility and permeability of the void interior space to the environment.[11] Up to now, the development of a convenient synthetic method and the use of cost-effective precursors to generate the materials with hollow interiors and porous shell is still of much interest.

In polymer chemistry,[12] it is well-known that thermosetting phenol formaldehyde polymers (PF) have been widely used as carbon precursors in industry and that nature-friendly polyethylene oxide (PEO) homopolymers have a high affinity to aggregate with silica species through hydrogen bonding between the ether and silanol groups. From analysis of the molecular structures of the PEO polymer and PF polymers, it can be seen that the ether groups (i.e. –O– : hydrogen-bonding acceptor) of the PEO polymers and the methylene hydroxide and phenol groups (i.e. $–CH_2OH$ and $C_6H_6–OH$: hydrogen-bonding donor) of the PF polymers have a high degree of hydrogen-bonding complementarity. Therefore, PEO and PF polymers could construct a homogeneously miscible PF–PEO polymer blend. On the basis of these concepts, in this study we used the PF–PEO polymer blend in a water/ethanol solution as the morphological and mesostructural template of the silica. When combined with a stock sodium silicate solution at pH ≈ 5.0–6.0, PF–PEO/silica hollow spheres were quickly generated. Because the synergistic PF–PEO/silica hollow spheres contain carbonizable PF polymer and silica, hollow

carbon spheres with mesoporous shells were prepared after pyrolysis and silica removal. Alternatively, hollow silica spheres with porous shells were obtained from hydrothermal treatment and calcination in air.

## Results and Discussion

Figure 1 shows the representative SEM image of the as-synthesized PF–PEO6000/silica composite. It can be clearly seen that the morphology of the particle is spherical and that the diameter of the sphere ranges from 1.0 to 0.5 μm. Some broken spheres reveal that the spheres are hollow and the wall thickness is around 0.1–0.2 μm. The inner cavities of the spheres were clearly identified by TEM contrast imaging (Figure 1B). Clearly, the spheres are almost hollow (>90%). The TGA curve of the PF–PEO6000/silica composite is intermediate between the TGA curves of the PEO/silica and PF polymer (Figure 1C), which demonstrates a homogeneous blending between PEO6000 and PF polymers. This average in combustion temperature occurs commonly in homogeneous organic or polymer blends.

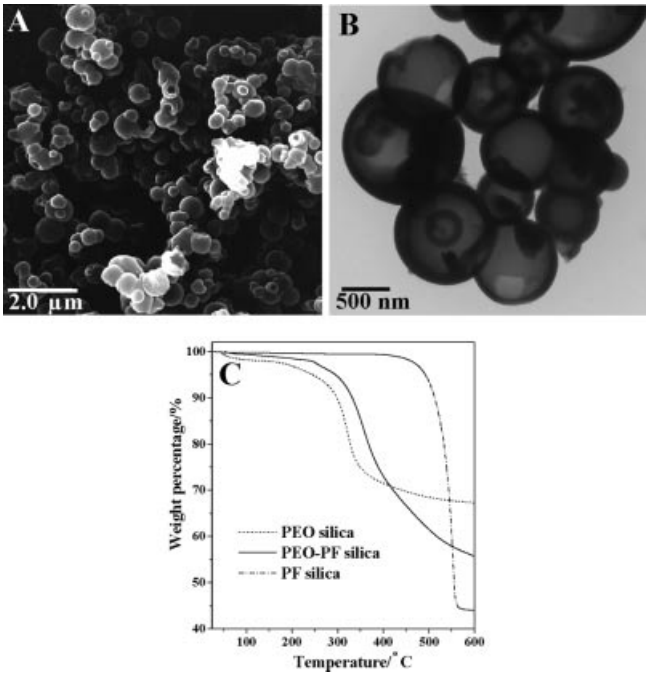

Figure 1. SEM (A) and TEM (B) images of the PF–PEO6000/silica hollow spheres prepared by using a synthetic component of PF/PEO6000/sodium silicate/$H_2O$ = 2.0: 2.0: 8.0: 315.0 g. (C). TGA curves of the PEO6000/silica, PF–PEO/silica, and PF/silica composites.

Because the PF–PEO/silica composite hollow spheres contain the carbonizable PF polymer, the mesoporous carbon hollow spheres can thus be easily obtained from high-temperature pyrolysis and silica removal by HF etching. The resulting mesoporous carbon retains the spherical morphology (Figure 2A). Some broken or folded hollow spheres reveal that the mesoporous carbon spheres are hollow.[13] The hollow interiors of the carbon spheres can be more clearly shown in a TEM image (Figure 2B). The shell thickness of the hollow mesoporous carbon spheres is around 0.1 μm. The preservation of the hollow-sphere morphology indicates that the thermosetting PF polymers disperse homogeneously within the shell, and then form a stable cross-linked framework to keep the hollow-sphere morphology. The high-magnification TEM image clearly shows that the mesostructure of the hollow sphere's shell is wormhole-like (i.e. interconnected), and the pore size is around a few nanometers (inset of Figure 2B). In parallel to the TEM observations, the hollow mesoporous carbon spheres exhibit a type IV $N_2$ adsorption–desorption isotherm with a capillary condensation occurring at $P/P_0$ = 0.3 to 0.4 (Figure 2C). By analyzing the adsorption isotherm, the mesoporous carbon hollow spheres have a high Brunauer–Emmett–Teller surface area (≈1500 $m^2 g^{-1}$), large Barrett–Joyner–Halenda pore size (≈2.6 nm), and pore volume (≈0.93 $cm^3 g^{-1}$), as do the mesoporous carbons obtained from the mesoporous silica-templating method.[4]

To obtain information about the thermal stability and carbon phase of the hollow mesoporous carbon spheres, TGA, Raman spectroscopy, and XRD investigations were performed.[14,15] The hollow mesoporous carbon spheres exhibit significant weight loss in a narrow temperature range between 600 and 650 °C (Supporting Information, Figure S1). Thus, the porous carbon of high thermal stability can be easily produced from the PF–PEO6000/silica composite. The silica residue in the porous carbon is less than 2.0 wt.-%, indicating that the silica was almost entirely removed by HF etching. The mesoporous carbon hollow spheres show two broad XRD peaks that can be indexed to (002) and (100) diffraction peaks for the amorphous carbons (Figure 2D). In addition, the Raman spectrum of the sample displays two broad vibration bands (inset of Figure 2D). One band is around 1580 $cm^{-1}$ (G-band; the interplane $sp^2$ C–C stretching) and the other band is located around 1340 $cm^{-1}$ (D-band; the defects within the carbon), which also indicate the amorphous carbon structure.[16]

In addition to producing mesoporous carbon hollow spheres, mesoporous silica hollow spheres also can be generated from the PF–PEO6000/silica composite after hydrothermal treatment at 100 °C and calcination at 560 °C in air. The microtome TEM image shows that the mesostructure of the shell of the hollow silica spheres is disordered and that the pore size is around a few nanometers (Figure 2E). Therefore, the mesoporous silica hollow sphere displays type IV $N_2$ adsorption–desorption isotherms with an apparent capillary condensation occurring at $P/P_0$ = 0.6–0.7 (Figure 2F). The mesoporous silica hollow spheres have Brunauer–Emmett–Teller surface area of 520 $m^2 g^{-1}$, a mean Barrett–Joyner–Halenda pore size of 6.2 nm, and a pore volume of 0.75 $cm^3 g^{-1}$. Consequently, the high-quality mesoporous carbon and silica hollow spheres can be conveniently obtained from the calcination and (carbonization + silica removal) of the PF–PEO/silica composite hollow spheres, respectively.

When using other PEO homopolymers of different molecular weights to blend with the same amount of PF polymer, the TEM images revealed that the prepared mesoporous carbon samples consisted of hollow spheres (yield > 90%) with different diameters (Figure 3). By comparing the diameters of these mesoporous carbon hollow spheres, it is clear that the average diameters and the shell thickness decrease with an increase in the PEO polymer molecular weight. According to these current results, the use of the PEO100000 or PEO300000 polymers gave hollow spheres in tens of nanometers (Figure 3B, C), and submicro- to micrometer hollow sphere were obtained with PEO10000 or PEO6000 (Figures 3A and 2B). Like the hollow mesoporous carbon spheres synthesized with PEO6000, other hollow mesoporous carbon spheres have high surface area, mesoporosity, and large pore volume (Supporting Information, Figure S2). Clearly, the mesoporous silica hollow spheres with various diameters (tens of nanometers to micrometers) were also obtained from the hydrothermal treatment and organic template removal (Supporting Information, Figure S3). To the best of our knowledge, this is the first time that the mesoporous carbon and silica hollow spheres with various diameters have been synthesize by using the commercially attractive PF–PEO polymer blend and sodium silicate.

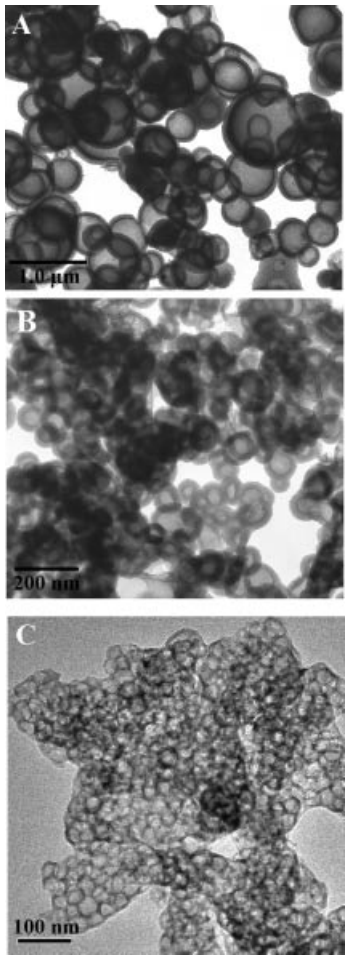

Figure 3. TEM images of the mesoporous carbon hollow spheres synthesized with PF–PEO*n* polymer blend as template. (A) $n$ = 10000; (B) $n$ = 100000; (C) $n$ = 300000. The synthetic compositions are: PF/PEO*n*/sodium silicate/$H_2O$ = 2.0: 2.0: 8.0: 315.0 g.

To understand the driving force of the formation of the hollow spheres, we poured the ethanol/water solution of the PF–PEO polymer blend into water and found that an opaque solution (i.e. PF–PEO emulsion solution) was formed at the beginning and then the hydrophobic PF polymers gradually underwent phase separation and precipitation from the aqueous phase. In contrast, when the PF–PEO polymer blend solution was added to a sodium silicate solution, a light yellow gel solution was formed in a few seconds without phase-separation and precipitation of the free PF polymers. This is because the silicate species can quickly assemble with the PEO parts in the PF–PEO polymer blend at pH around 5.0–6.0 to solidify the hydrother-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mally unstable PF–PEO emulsions and prohibit the self-precipitation of the hydrophobic PF polymer. Although the phase-separation approach is typically used to prepare hollow latex particles,[15] this is the first time that it was employed to synthesize porous materials.

On the basis of all the above observations, a simple plausible mechanism was proposed addressing the formation of the hollow spheres. As shown in Scheme 1, when the PF–PEO solution was added into a highly diluted sodium silicate aqueous solution, the hydrophobic PF polymers induced the formation of PF–PEO emulsions. At the same time, the silica species, which assemble with the PEO polymers, attach onto the outer surface of the PF–PEO emulsions. After fast further silica condensation, the PF–PEO emulsions were solidified prior to the PF phase-separation, and then the hollow PF–PEO/silica hollow spheres were generated. Therefore, with careful control of the condensation rate of the silica species on the PF–PEO emulsions and the coalescence rate of the PF–PEO emulsions induced by the hydrophobic PF polymer, a capsule-shaped PF–PEO/silica composite was obtained. Because the PEO homopolymer of higher molecular weight can assemble faster with the silica species than the lower molecular weight polymers, the average diameter of the trapped PF–PEO/silica hollow spheres becomes smaller (Figure 3).

According to silica chemistry, it is well-known that the silica condensation rate depends on the pH value.[17] Figure 4 exhibits the mesoporous carbon samples prepared at different pH values. It is clear that the pH value of the silicate solution must be tuned in the range of 5.0–6.0 to get the hollow spheres, where matching interaction between PEO and silica species (i.e. hydrogen bonding between $-CH_2CH_2O^{\delta-}$ of the PEO polymer and the silanol group –SiOH of the silica species) and fast silica condensation rate could prevent the self-precipitation of the PF polymers.[18] In this pH value range, the silica condensation rate increases with the pH value,[17] and thus the average diameter of the hollow spheres decreases as the pH value increases (Figures 2B, 4B, and 4D). However, outside of this pH range, the hollow spheres were no longer obtained. At pH values $<5.0$, the slow silica condensation rate led to the generation of micrometer-sized solid spheres or particles (Figure 4A). However, at pH values $>7.0$, mismatching interactions between the negatively charged silicate species and the partially negative PEO polymer resulted in the separation of the silica and the PF–PEO polymer blend, which led to the precipitation of the PF polymers.

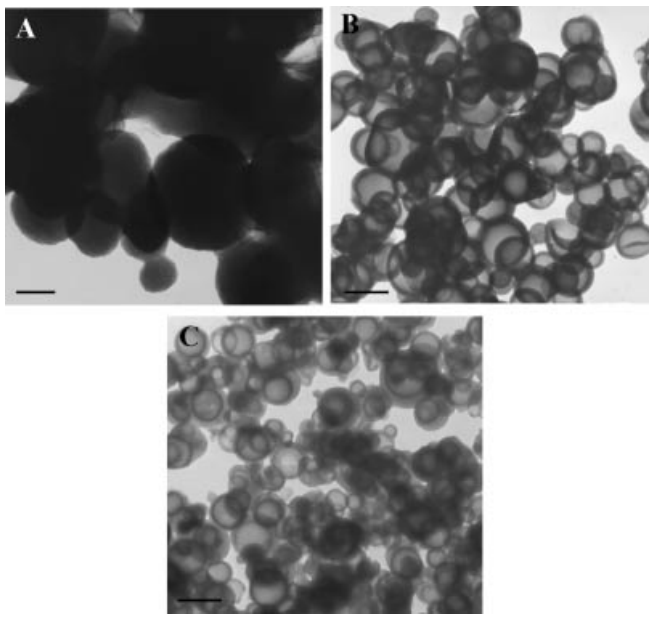

Figure 4. TEM micrographs of the mesoporous carbon hollow spheres synthesized in silica solutions at different pH value (PF/PEO6000 weight ratio = 2.0). (A) pH = 4.0; (B) pH = 5.5; (C) pH = 6.0. Scale bar = 500 nm.

In addition to studying the effect of the silica condensation rate on the diameter of the hollow spheres, we also changed the content of the PF polymer to control the coalescence rate of the PF–PEO emulsions. As expected, we found that the average diameter of the mesoporous carbon hollow spheres increased with an increase in the PF polymer content (Figure 5). When the PF/PEO6000 weight ratio is higher than 1.5, the PF polymer precipitation rate is relatively too fast to be completely trapped and some PF polymer precipitates. Moreover, it must be mentioned that the yield of the carbon is determined by the PF content. At low PF/PEO6000 weight ratios ($<0.5$), the carbon yield is very low. Consequently, the appropriate PF/PEO6000 weight ratio to obtain carbon hollow spheres in a suitable yield ranges form 0.8 to 1.5. To reduce the dispersion in the diameter of the hollow spheres, considerably kinetic and thermodynamic principles behind the formation of the hollow spheres will be further studied.

It is known that there are advantages to use mesoporous carbon as solid templates:[4,19–21] (1) The high stability of the carbon framework can stand for cruel synthetic conditions. (2) The amorphous carbon should be easily removed
