The thermochemical values calculated for the gas phase indicate that the enthalpy of reaction and the Gibbs free energy (at 298 K) are –27.0 and –13.2 kcal mol$^{-1}$, respectively, which means that the reaction is exothermic, as would be expected in view of the better metal saturation in the [Ti(Me-DAD)$_3$] species. This result is compatible with some experimental findings. For example, tom Dieck and co-workers have reported that the addition of *i*Pr-DAD to [Ti(*i*Pr-DAD)$_2$] yields the complex [Ti(*i*Pr-DAD)$_3$],[65] and Scholz and co-workers have described that the reduction of [$TiCl_4$(thf)$_2$] in the presence of magnesium gives [Ti(DAD)$_2$] in the presence of two equivalents of DAD or [Ti(DAD)$_3$] with an excess of ligand.[59] As for the reverse reaction, the expulsion of one ligand from [M(DAD)$_3$] introduces significant metal unsaturation, which the system generally compensates for by ligand folding. In this regard, the nature of the substituents attached to the nitrogen centers can play a decisive role, as described previously. Two recent contributions with metals other than those of group 4 have demonstrated the decisive influence of the substituents. Thus, substitution of the *t*Bu groups with $C_6F_5$ ones in a diazabutadiene ligand induces a variation in the oxidation state of europium,[66] and the selection of alkyl or aryl substituents in α-diimino ligands coordinated to iron affects the spin state of the metal, which is correlated with a specific catalytic activity.[67]

## 9. Conclusions

We have extensively reviewed the known complexes formed by a metal of the group 4 and at least one α-diimino ligand. The latter, due to its *noninnocent* character, can also be described as a dianionic enediamido species. We have focused our attention on the electronic aspects of the metal–DAD bonding and on geometric effects, which are triggered depending on the ligand's electronic and steric properties and the number of co-ligands as well as the oxidation state of the metal. In particular, the frontier MOs are strongly affected by the folding of the metallacycles, which permits a greater electron donation ability from the ligand. In general, com-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plexes with a higher coordination number (pseudo-octahedral), including the homoleptic $[M(DAD)_3]$ class, feature planar metallacycles, which contrasts with the folding of the metallacycles observed in $[L_2M(DAD)]$, CpLn, and $[M(DAD)_2]$ complexes, where the metal is less saturated (higher oxidation state). Notable exceptions have been highlighted. The various cases have been analyzed in terms of DFT calculations and qualitative MO arguments. When the findings are ambiguous (where the DFT response does not allow for discerning the structural preferences) the QTAIM method has been adopted to extract useful information about the distribution of the electron density within the models. In particular, we have found that for a given stereochemistry, unpredicted C–H···N hydrogen bonding can contribute to the stability for specific types of planar metallacycles. Finally, we have analyzed the energetics behind the interconversion between $[M(DAD)_2]$ and $[M(DAD)_3]$ complexes, which has been found to be exclusive to group 4 metals.

**Supporting Information** (see also the footnote on the first page of this article): Seven tables (labeled S1–S7) with selected structural data (bond lengths and angles), relative energies, and optimized stuctures for calculated and experimental complexes. Five tables with optimized coordinates for compounds **7a**–**d**. Additional information regarding the QTAIM analyses is also provided.

## Acknowledgments

Financial support from the Secretaría de Estado de Educación y Universidades (sabbatical stay at ICCOM, A. G.) and the Ministerio de Educación y Ciencia (CTQ2004-00084) is gratefully acknowledged. The quantum-chemical calculations were carried out with the High Performance Systems of the Centro di Calcolo Interuniversitario CINECA (CNR-CINECA agreement) and the facilities of SIC (University of Seville).

# Superoxide Reductases

**Alice S. Pereira,[a] Pedro Tavares,[a] Filipe Folgosa,[a] Rui M. Almeida,[a] Isabel Moura,*[a] and José J. G. Moura[a]**

**Keywords:** Bioinorganic chemistry / Nonheme iron centres / Superoxide / Structure-activity relationships

Reactive oxygen species (ROS), when in excess, are among the most deleterious species an organism can deal with. The physiological effects of ROS include amino acid chain cleavage, DNA degradation and lipid oxidation, among others. They can be formed in the cytoplasm in a variety of ways, including autooxidation reactions (FMN- and FAD-containing enzymes) and Fenton reactions as a result of the cytoplasmatic pool of iron ions. The superoxide anion ($O_2^{\cdot-}$), despite its short half-life in solution, is particularly pernicious as it can form other reactive ROS (such as the strong oxidant peroxynitrite) or oxidize and/or reduce cellular components. For strict anaerobic or microaerophilic bacteria it is of particular importance to be able to dispose of ROS in a controlled manner, especially if these organisms are temporarily exposed to air. This review aims to describe the structural characteristics of superoxide reductases (SORs) and mechanistic aspects of biological superoxide anion reduction. SORs can be considered the main class of enzymes behind the oxygen detoxification pathway of anaerobic and microaerophilic bacteria. The geometry of the active site (three classes have been described), the possible electron donors in vivo and the current hypothesis for the catalytic mechanism will be discussed. Some phylogenetic considerations are presented, regarding the primary structure of SORs currently available in genome databases.

## Introduction

Reactive oxygen species have been implicated in different metabolic pathways. ROS can be divided into radical (superoxide, hydroxyl, peroxyl, alkoxyl and hydroperoxyl) and nonradical (hydrogen peroxide, ozone, singlet oxygen, peroxynitrite and hypochlorous acid) entities. At higher concentrations they present problems to the normal cellular functions by, for example, oxidizing lipids, reducing sugars and amino acids or causing a large number of purine and pyrimidine modifications.[1–3] Reactions with proteins can lead to protein cleavage, cross-linkage or the loss of structural and/or catalytic function. Cellular protein degradation systems may, or may not, recognize these abnormal proteins. When not recognized, abnormal proteins will accumulate and, over time, will cause harmful effects in the cells or organisms. Although it is usual to think of ROS species as byproducts of cell metabolism, at physiological levels ROS can serve other purposes, for example, being involved in cell signalling and other important functions. At this level, ROS can be valuable or even required for a particular physiological reaction. More than 30 years ago, it was shown that the superoxide anion stimulated the formation of cGMP.[4] Interestingly, a recent study unveiled one beneficial role of ROS.[5] According to the authors, ROS are implicated in otoconia (small calcium carbonate crystals present in the inner ears of mammals) formation and could be required for interactions between otoconial components. As a result, ROS seem crucial to the mechanism by which vertebrates are able to sense gravity and maintain balance. For all the above reasons, understanding enzymes that can control ROS concentration is extremely important.

One significant ROS is the superoxide anion ($O_2^{\cdot-}$). The superoxide anion is generated by a one-electron reduction of molecular oxygen.[6–12] Some of the known sources of superoxide are: (1) Electron leakage, which can promote the reduction of $O_2$ to $O_2^{\cdot-}$. For example, it is known that several components of the mitochondrial electron transport chain (*b*-type cytochromes, coenzyme Q) can leak electrons. Also, in fatty acid desaturation, electron donors of the desaturase enzyme (flavoproteins and cytochrome $b_5$) can produce $O_2^{\cdot-}$. (2) Heme-containing proteins, namely hemoglobin and myoglobin, will produce $O_2^{\cdot-}$ by conversion of the oxy form into the met form of the protein. (3) Uncoupling of P450 oxidase activity with concomitant production of $H_2O_2/O_2^{\cdot-}$. (4) Enzymatic production of $O_2^{\cdot-}$ by xanthine oxidase, peroxidases and other oxidases. (5) The so-called autooxidation reactions where several molecules (reduced forms of FMN and FAD, adrenalin, thiol-containing mole-

cules and others) can slowly reduce $O_2$ to $O_2^{\cdot-}$, most probably in the presence of catalytic amounts of metal ions. (6) Fenton reactions where the products (ferric ions, hydroxyl radical) can react with hydrogen peroxide to produce $O_2^{\cdot-}$. (7) Iron(II) oxidation by ferritin produces $H_2O_2$ as a secondary product. (8) Intentional production of $O_2^{\cdot-}$, for example in the plasma membrane of macrophages by an enzymatic complex (containing FAD and *b*-type cytochrome) that uses NADPH as the reducing agent.

How long-lived is the superoxide anion after its generation? In aqueous solutions, the superoxide anion readily dismutates into hydrogen peroxide and molecular oxygen. This is a pH-dependent phenomenon, which probably occurs by protonation of at least one superoxide anion. It was calculated that, at pH 7.0, the dismutation reaction has an approximate rate constant of $5 \times 10^5$ M$^{-1}$ s$^{-1}$, which means that superoxide will only subsist for a few microseconds. Nevertheless, during that time superoxide can react with some cellular components to give rise to other potentially toxic species. Chemically, the superoxide anion can act as an oxidizing or a reducing agent. At low levels, the superoxide anion will not react with proteins unless there are accessible thiol groups. In such a case, the thiol groups are oxidized, and thiol-rich or-containing enzymes can be targeted and their functionalities modified. The superoxide anion can also be involved in enzyme reduction such as cytochrome *c* or ferritins. One of the most striking examples of superoxide damage is the oxidation of the [4Fe-4S] cluster of aconitase, a Krebs' cycle enzyme, with concomitant inactivation of the enzyme and release of reactive iron.[13] Other small molecules can also react with superoxide. For instance, NO reacts with superoxide to give rise to peroxynitrite, which is recognized as a potent oxidizing agent. These reactions have deleterious effects and will sequester the superoxide anion from solution and prevent the dismutation reaction.[14,15] For a complete panorama on superoxide, and ROS in general, the reader is advised to consult the excellent book on the matter by Halliwell and Gutteridge.[16]

To avoid the pernicious effects described above and, in a controlled manner, to dispose of intracellular superoxide anions, organisms possess one (or in rare cases, both) of two different enzymatic systems: superoxide dismutases and superoxide reductases. Under optimal conditions these enzymes will sequester the superoxide anion prior to dismutation or its reaction with other cellular components.[17]

In this review we aim to provide a concise, yet all-embracing, focused review on superoxide reductases. Hopefully, we will be able to communicate to the reader the his-

*Alice S. Pereira (front row, 2nd from left) received her Ph.D. from Universidade Nova de Lisboa in 1995 and worked on the purification and characterization of iron–sulfur proteins from sulfate-reducing bacteria and was a Postdoctoral Fellow at U.S.F (1995) and at Emory University (1995–1997). From October 1997 to March 2000 she was part of the Centro de Química Física e Biotecnologia in the Department of Chemistry of the Universidade Nova de Lisboa as a Postdoctoral Fellow. She has been a faculty member in the Department of Chemistry of the Universidade Nova de Lisboa since 2000. Her research is focused on the study of metalloenzymes involved in iron metabolism and oxygen activation.*

*Pedro Tavares (front row, left) received his Ph.D. from Universidade Nova de Lisboa in 1994. In 1995, he joined the Physics Department of Emory University as a postdoctoral research fellow. Since 1999, he has been a faculty member in the Department of Chemistry of the Universidade Nova de Lisboa. His current research interests are centred on the study of catalytic mechanisms of iron-containing enzymes implicated in detoxification mechanisms and oxygen activation.*

*Filipe Folgosa (back row, left) was born in Lisbon, Portugal. He received a Bachelor of Science degree in Biochemistry from Universidade de Lisboa in 2004 and joined the Department of Chemistry at Faculdade de Ciências e Tecnologia – Universidade Nova de Lisboa as a PhD student. He works with Professor Pedro Tavares and his scientific interests are focused on non-heme iron proteins, such as superoxide reductases, using fast kinetics techniques to study them.*

*Rui M. Almeida (back row, right) was born in Lagos, Portugal. He received a Bachelor of Science degree in Biochemistry from Universidade de Lisboa in 2004, and the following year he joined the Department of Chemistry at Faculdade de Ciências e Tecnologia – Universidade Nova de Lisboa as a PhD student. He works in Professor José Moura's group and studies the interactions of superoxide reductases with its physiological partners through the use of NMR spectroscopy and in silico molecular docking studies.*

*Isabel Moura (front row, 2nd from right) received her Ph.D. from Universidade Nova de Lisboa, in Biochemistry, in 1981. She has served as a Professor of Chemistry in the Department of Chemistry, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa (FCT-UNL) since 1999. From 1979 to 1981 she was a researcher at the Fresh Water Biological Institute, University of Minnesota, USA. During the period of 1984–2000 she acted as an Adjunct Professor at the University of Georgia, Athens, GA, USA, and in 2003 she was the President of the Chemistry Department at FCT-UNL. Research topics are focused in the field of bioinorganic chemistry, mainly related to the characterization of enzymes of the S- and N-biocycles. Structure–function relationships and the role of metal ions in biology are also areas of interest. She has authored circa 280 publications.*

*José J. G. Moura (front row, right) received his Ph.D. from Universidade Nova de Lisboa, in Bioiniorganic Chemistry, in 1979. Since 1994 he has acted as a Professor of Chemistry in the Department of Chemistry, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa (FCT-UNL). Other duties include being a Research Specialist at the Fresh Water Biological Institute, University of Minnesota, USA from 1979 to 1981, an Adjunct Professor at the University of Georgia, Athens, GA, USA from 1984 to 2000, a member of the Research Panels in NATO, INTAS, COST and EC Councils from 1991 to 1994, the President of the Chemistry Department (FCT-UNL) from 1997 to 2000, the President of the Scientific Council (FCT-UNL) from 2003 to 2006 and the Director of FCT-UNL Library in 1996. Research topics are focused in the field of bioinorganic chemistry; the role of metal ions in biology, bioelectrochemistry and protein–protein interactions are areas of interest, and he has circa 320 publications.*

torical aspects of this interesting class of enzymes and at the same time provide the information needed to build an up-to-date knowledge in this research area.

The reader should note that throughout this article we will refer to SORs by the initial, "historical" names given to the enzymes before their enzymatic activity was characterized; hence, desulfoferrodoxin (Dfx) refers to class I SORs and neelaredoxin (Nlr) to class II SORs. Class III SORs have no official historical name, although they are frequently also called neelaredoxins owing to the UV/Vis spectrum similarities to class II SORs. These enzymes were also once called rubredoxin oxidoreductases (Rbo), when it was discovered that rubredoxin (Rd) could provide electrons to SORs, although this terminology is scarcely used anymore, except to denominate their coding gene (see below).

Furthermore, the reader is advised that in this review residue numbering is always quoted with regard to the numbering established in the work being cited. For the convenience of the readers, Table 1 and Appendix I (in Supporting Information) contain the number of homologous residues in different protein sequences

## Desulfoferrodoxin – Class I SOR

In 1990, the purification and characterization of a protein containing a new type of nonheme iron from crude extracts of the sulfate and nitrate reducer *Desulfovibrio (D.) desulfuricans* ATCC 27774 as well as from extracts of *D. vulgaris* Hildenborough was reported.[18] Currently, five Dfx proteins were isolated and characterized from *D. desulfuricans* ATCC 27774, *D. vulgaris* Hildenborough, *D. baarsii*, *Archaeoglobus (A.) fulgidus* and *Methanobacterium (M.) thermoautotrophicum* (Table 2).

The protein from *D. desulfuricans* ATCC 27774 was subjected to extensive biochemical and spectroscopic characterization. This dimeric protein ($2 \times 14$ kDa) contained two iron atoms per monomer, and the as-isolated form showed a visible spectrum dominated by maxima at 495, 368 and 279 nm, thus exhibiting a pink colour. The EPR spectrum of this form showed a set of resonances ($g$ = 7.7, 5.7, 4.1 and 1.8) characteristic of a high-spin ferric ion ($S$ = 5/2) with an E/D value of 0.08. Mössbauer spectroscopy clearly indicated the presence of two high-spin iron centres, one being ferric and the other ferrous. All these spectroscopic data pointed to the fact that this protein contained one iron centre (centre I) of the $FeS_4$ type, closely resembling the one found in desulforedoxin (Dx) from *D. gigas*,[19–22] and a second ferrous centre (centre II). Owing to the unusual combination of iron centres, the protein was denominated desulfoferrodoxin. Although initially purified in a semireduced state, named pink form, it was also possible to isolate the fully oxidized state of the protein.[23] In this form, named gray form according to its colour, the UV/Vis spectrum shows additional bands at 335 and 635 nm, the EPR spectrum has additional resonances at $g$ = 4.3 and 9.6 and the Mössbauer spectral component attributed to centre II is characteristic of a high-spin ferric ion with E/D of approximately 1/3. Potentiometric redox titrations of Dfx showed that centre II has a rather high midpoint redox potential (ca. +240 mV at pH 7.6) that is in agreement with the fact that the protein could be aerobically isolated in the semireduced state.

The primary structure of Dfx determined by automated Edman degradation and mass spectrometry of the composing peptides confirmed not only the expected homology with Dx but also revealed a high homology to another iron-containing protein from *D. gigas* named neelaredoxin, which possesses one iron centre similar to centre II of Dfx, but no centre I (described in detail in the next section).[24] In conjunction with Mössbauer and Resonance Raman spectroscopic data, the sequence data indicated that centre

II should have only one cysteinyl S ligand in an octahedral coordination of nitrogen and/or oxygen ligands. Sequence comparison also revealed that Dfx from *D. desulfuricans* ATCC 27774 was highly homologous with the product of the *D. vulgaris* Hildenborough *rbo* gene that encodes for Dfx,[25] whereas the N-terminal sequence of the *D. vulgaris* Hildenborough Dfx was identical to the deduced amino acid sequence. It was also found that a single transcript contained both *rub* and *rbo* genes (enconding for rubredoxin and Dfx, respectively), pointing to the fact that Rd could be a redox partner of Dfx. The origin of the Dfx coding gene, *rbo*, was also questioned.[26] It was shown that in *D. vulgaris* the *rbo* gene is expressed as a 14 kDa protein whereas in *D. gigas* the *dsr* gene coding for Dx and the gene coding for Nlr are expressed independently. Thus, Dx is not formed by post-translational modification of Dfx, but most probably the *rbo* gene originated from a gene-fusion event between the genes coding for the Dx and Nlr proteins. So, the Dfx monomer can be described as a 14 kDa polypeptide chain with an approximately 4 kDa N-terminus similar to Dx and a C-terminal region of ca. 10 kDa homologous to Nlr. In fact, two constructs were engineered where either the N-terminal or the C-terminal region was cloned and expressed separately in *Escherichia (E.) coli*.[27] The N-terminal variant consisted of a DNA fragment encoding the first 39 amino acids from *D. vulgaris* Hildenborough Dfx (DfxN), sharing approximately 50% sequence identity with *D. gigas* Dx. The C-terminal domain consisted of a DNA fragment encoding the last 92 amino acids of *D. vulgaris* Hildenborough Dfx (DfxC). Both recombinant fragments were able to bind iron. Biochemical and spectroscopic characterization showed that DfxN and DfxC exhibited properties similar to Dx and Nlr, respectively.

The first crystallographic structure of a superoxide reductase was obtained for *D. desulfuricans* ATCC 27774 Dfx.[28,29] The structure was solved by MAD phasing, using the iron centres present in the protein as anomalous scatterers, up to 1.9 Å resolution (see Figures 1 and 2). The crystallographic model showed the expected two domains: spherical domain I is notably similar to that of Dx (rms deviation of 0.59 Å for the backbone atoms), and the larger domain II harbours an iron site with square-pyramidal coordination to four histidine equatorial ligands and one cysteine axial ligand. The coordination geometry is such that three histidine ligands (His48, His68 and His74) coordinate to the iron ion through their N2 atom, with the exception of His118, which bonds through Nδ1. Cys115 binds in the axial position. A possible sixth ligand was not found, and an axial position is easily accessible to the solvent, which is thus available for substrate binding. Another important feature is that several β-sheets extend from monomer to monomer, which supports the existence of a functional dimer. Domain I and II are linked by a region of polypeptide chain (residues 34–39), which creates an elongated cavity with an approximate volume of 430 $Å^3$. A calcium ion was also found at the dimer interface coordinated by eight oxygen atoms (Ser87, Thr89 from both monomers and two water molecules). The dimeric nature of *D. desulfuricans*

ATCC 27774 Dfx was also probed in equilibrium unfolding experiments.[30] By using the concentration dependence of aromatic residue emission, the dissociation constant of Dfx was determined to be ca. 1 μM. With the use of guanidine hydrochloride as a denaturating agent and with short incubation times, it was possible to observe one reversible transition (without loss of secondary structure) independent of the Dfx concentration. Only at longer incubation times was complete irreversible unfolding, with iron centre dissociation, observed. On the basis of these studies, a model was proposed where the equilibrium unfolding involves a monomeric intermediate with a native-like secondary structure. Such a finding is in agreement with the observation that mass spectroscopy and gel filtration results of *D. desulfuricans* ATCC 27774 protein are not consistent with a dimeric form.[18,24] However, in the case of the recombinant Dfx of *M. thermoautotrophicum*, more than two oligomeric species exist, with the smallest stable form being the dimeric one.[31]

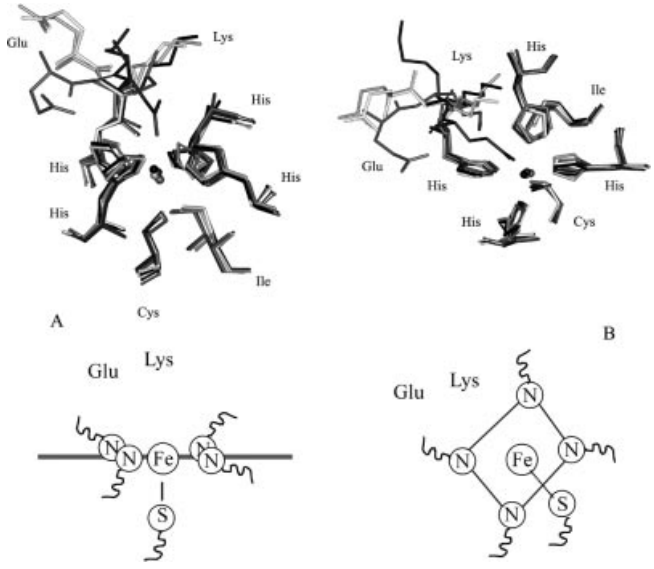

Figure 2. SOR active site showing the iron ligands and other functionally important/conserved residues. Overlapping of five different structures (aligned on the basis of the iron atom) obtained for *D. desulfuricans* ATCC 27774 (white), *T. pallidum* (light grey), *T. maritima* (grey), *P. furiosus* (dark grey), and *D. baarsii* (black). Cartoons below each set of structures intent to explain the view angle: (A) histidine ligands plane oriented transversal to the plane of the paper; (B) histidine ligands plane coincident with plane of the paper.

The accessibility of centre II towards external molecules was also evident by the characterization of a stable cyano-bridged dinuclear iron cluster.[32–34] This adduct is formed upon oxidation of ferrous centre II with potassium ferricyanide to afford the mixed-valence cyano-bridged [$Fe^{III}$–NC–$Fe^{II}(CN)_5$] complex. As proven by spectroscopic and crystallographic studies, this cyano-bridged diiron complex adopts a bent geometry. In the case of the enzyme of *D. baarsii*, the determined crystallographic structure of the complex shows both electrostatic and steric complementarities between the active site and the ferricyanide anion.

Two different types of studies showed the possibility of structural changes in centre II. In one particular work, the redox-induced structural changes were monitored by using FTIR coupled to electrochemical techniques.[35] The use of both the wild type and mutant proteins led to the proposal that centre II can bind a sixth ligand, namely a glutamate, in its ferric state [supporting the different coordination states observed in the crystallographic structure of *Pyrococcus (P.) furiosus* enzyme, see below]. The same study ruled out any relevant role, other than electrostatic interaction with substrate molecules, of a nearby lysine residue. In a different type of study, with the use of variable temperature UV/Vis, MCD, CD and EPR spectroscopy, it was shown that major electronic–vibrational changes in both centres result from the conversion of the all-ferric, grey form, to the semireduced, pink form.[36] It is suggested that an extended environmental reorganization of the region between centre I and centre II controls the electron transfer. Nonetheless, up to the moment this review was written, no direct proof of such a transfer existed, and its viability is always hindered by the large iron-to-iron distance (ca. 22 Å).

## Neelaredoxin – Class II SOR

In 1994, Chen and coworkers reported the isolation, from extracts of *D. gigas*, of an iron-containing blue protein that was named neelaredoxin.[37] Since then, this protein was also purified from other organisms, including *P. furiosus*, and extensive spectroscopic studies were performed.[38] The crystallographic structures were also determined for the oxidized and reduced states (at resolutions of 1.7 and 2.0 Å, respectively).[39] The primary structures of *D. gigas* and *P. furiosus* Nlrs have ca. 50% identity, and both are highly homologous to the C-terminal domain of Dfx proteins. As expected, the observed spectroscopic properties are similar to those obtained for Dfx centre II. In practice, one can consider Nlr to be a short Dfx, only containing the equivalent of the Dfx domain II (see Figure 1).

*P. furiosus* Nlr is a homotetrameric protein with a subunit molecular mass of about 14 kDa. Each subunit contains one mononuclear iron centre that is similar to the Dfx centre II. The 3D structure of the protein in the reduced state [Protein Data Bank (PDB) entry 1DQK] shows that the ferrous iron centre is coordinated to the imidazole nitrogen atoms from four histidine ligands that occupy the equatorial positions and a cysteine ligand that occupies the axial position. This square-pyramidal coordination leaves a sixth position that is vacant or occupied by a solvent molecule. However, in two subunits of the oxidized Nlr structure (ferric state) a carboxylate group from a nearby glutamate becomes the sixth ligand (see Figure 2). This finding implies that the glutamate residue might have an important role in catalysis. A possible explanation is that the glutamate residue regulates the accessibility of the substrate to the active site. The vacant sixth position in the reduced state would allow substrate binding to centre II with concomitant substrate reduction and release. However, in the ferric state the coordinated glutamate would either slow down or even pre-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vent substrate binding and enzymatic catalysis. Although this is an important finding, one should be aware that this is the only structure available that shows fully occupied coordination of the iron centre and that some mutant studies challenged the proposed gating mechanism (see below). The presence of a glutamate residue as the sixth ligand was shown to be pH-dependent. Despite Resonance Raman spectra not showing it clearly, UV/Vis spectroscopic data present significant changes, which strongly suggest that at higher pH levels or in the E14A mutant protein the glutamate can be substituted for a hydroxide functionality or by Lys15.[40]

Also important is that a potential Rd binding site is found in the vicinity of the solvent-exposed residues that are close to the iron centre. The proposed site contains iron ligands (Glu14, His47 and His114) in addition to adjacent residues (Trp11, Ile39, Pro40, Pro42, Thr44 and Ile113). Binding at this site will result in an iron-to-iron distance of approximately 8 Å.

Possible electron-transfer pathways were identified in a Resonance Raman study of the *P. furiosus* enzyme.[40] In this work, an analogy was made with type 1 copper proteins and an almost-conserved Tyr-Cys-X-X-His motif in class I and II SORs. This hypothesis is especially attractive to class I enzymes where the Tyr residue lays between domains I and II, in a direct path between iron centres. However, the *P. furiosus* structural data shows that the proposed Tyr residue is not responsible for mediating the electron transfer from Rd to Nlr because in this case the residue is located at a subunit interface of the homotetramer and buried inside the protein.

It is noteworthy to mention that in class I and III enzymes [*D. baarsii* and *Treponema (T.) pallidum*, respectively], a high-spin ferric hydroxide species in the active site was identified at basic pH values.[41] This hydroxide species is postulated to occur at the end of the catalytic process and in a pH-dependent equilibrium with the glutamate-coordinated species. Small molecules such as cyanide or nitric oxide can also bind to the Nlr active site. Nitric oxide was used as a substrate analogue to probe the structural and electronic environment of the active site.[42] It was shown that NO binds reversibly to the ferrous centre. The NO adduct is hexacoordinate, with NO binding in a bent mode *trans* to the cysteinyl S ligand, which gives rise to an EPR signal that is characteristic of a near-axial ($S$ = 3/2) spin system ($E/D$ = 0.06). Such a system was rationalized to result from the antiferromagnetic coupling between a high-spin ferric iron ($S$ = 5/2) and a $NO^-$ ion ($S$ = 1). The addition of $CN^-$ to class I and II enzymes in the oxidized form results in the conversion of the native high-spin ferric state ($S$ = 5/2) into a heterogeneous low-spin ferric state ($S$ = 1/2).[43] Combined spectroscopic data (Resonance Raman, FTIR and ENDOR) showed that the bound cyanide adopts three distinct conformations and that this heterogeneity is observed at room temperature. Also, the heterogeneity is not present in ferrous class II enzyme adducts, where a homogeneous near-linear conformation is observed. The use of mutant proteins with the replacement of either glutamate or lysine residues (present in the vicinity of the substrate binding site) by alanine did not reveal any significant spectroscopic difference. Thus, the mutated residues do not interact with the bound cyanide and therefore most probably do not play a role in the orientation and/or protonation of ferric reaction intermediates.

It is also curious to note that it was possible to express the *P. furiosus* enzyme in plant cells, in which case the survival at high temperatures is enhanced.[44] Such experiments are useful to demonstrate that the Nlr gene can produce functional recombinant proteins in plants, altering the eukaryotic metabolism.

## Class III SOR

Class I and II enzymes were found in anaerobic bacteria (or, at the most, microaerotolerant). Interestingly, a third class of SOR was found in a microaerophilic obligate pathogen of humans. *T. pallidum* is the agent responsible for venereal syphilis and during infection disseminates hematogenously to invade several tissue types. Throughout this process the bacteria must tolerate significant oxidative stress.[45] An analysis of *T. pallidum* genome does not show the presence of enzymes typically needed to deal with ROS, such as superoxide dismutases, catalases or peroxidases. However, it is possible to find a gene highly homologous to Dfx, the expression of which was shown through reverse transcriptase–polymerase chain reaction.[46,47] Gene sequence analysis showed that the gene product should be a ca. 14 kDa protein containing two domains homologous to Dfx domain I and II. In this case, domain I lacked three of the four cysteine residues responsible for centre I iron binding. The gene was cloned and expressed in *E. coli*, and the gene product was subjected to biochemical and spectroscopic characterization. The protein was found to be a homodimer containing a sole iron site per monomer. This iron site had almost equal visible, EPR and Mössbauer spectra to those of Dfx centre II, and exhibited a midpoint redox potential of approximately +210 mV (pH 7.8).

Enzymatic studies revealed that the protein was able to catalyze superoxide reduction to hydrogen peroxide and that the rubredoxin of the same organism is capable of functioning as an electron donor in this catalytic reaction.[46–48]

The crystal structure of *T. pallidum* SOR was recently obtained (Figures 1 and 2).[49,50] The enzyme shows a structure similar to Dfx, with two domains. As expected, the N-terminal domain does not contain an iron centre, but it is able to maintain the β-barrel topology in an overall arrangement that is very similar to the one found in Dfx. It is noted that the absence of cysteine residues does cause a decrease in the cohesion of the domain and that in the region corresponding to the one where centre I is present in Dfx some disorder is observed. The C-terminal region contains a pentacoordinate iron atom with four histidine and one cysteine residues in a square-pyramidal geometry. This iron centre is highly exposed to the solvent. The axial posi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion *trans* to the cysteine residue is vacant, with a water molecule located at approximately 4.3 Å from the iron centre. However, in one of the molecules present in the asymmetric unit it was found that the same water molecule was located closer to the iron atom (2.6 Å), similar to what was found in the *P. furiosus* enzyme for the reduced iron centre. In contrast to what was found for Dfx, calcium does not seem to be essential for dimerization.

## Discovery of New Enzymatic Activity – Superoxide Anion Reduction

The function of these proteins was partially unveiled in 1996 when Touati and coworkers reported that Dfx from sulfate-reducing bacterium *D. baarsii* could suppress all deleterious effects caused by superoxide dismutase (SOD) deficiency in *E. coli*.[51] The authors were trying to isolate the superoxide dismutase gene from *D. baarsii* when they noticed that a DNA fragment containing two open reading frames with homologous sequences to the *rbo* and *rub* genes of *D. vulgaris* Hildenborough functionally complemented an *E. coli* mutant deficient in cytoplasmic SODs. The experiments proved that the *E. coli* mutant regains the ability to grow on minimal medium (without the addition of branched amino acids), and that its growth on gluconate and succinate as the sole carbon sources was no longer impaired. It was also observed that iron–sulfur cluster containing enzymes were protected from inactivation and that oxygen-dependent spontaneous mutagenesis returned to values closed to those observed in the wild type strain. It was possible to ascertain that Dfx centre II was in fact the responsible agent for this effect as neither Rd nor Dx, when expressed independently, were able to significantly raise the aerobic survival of the *E. coli* mutant. In contrast, expression of Dfx would allow complete avoidance of superoxide stress. Subsequently, Liochev and Fridovich proposed that Dfx would be involved in a "direct" or "indirect" mechanism of $O_2^{\cdot-}$ scavenging,[52] but without exhibiting significant SOD activity. Similar to the previous study, these authors were able to confirm that overexpression of Dfx complemented the SOD defects, preventing inactivation of iron–sulfur-containing fumarases.

Additional evidence that Dfx was involved in an oxygen defense mechanism was reported by Voordouw and Voordouw.[53] In this work, the *rbo* gene was deleted from the *D. vulgaris* Hildenborough genome and the resultant mutant was able to grow normally under anaerobic conditions, but it clearly became more sensitive to oxygen inactivation (with 100-fold drop in CFU by exposure to air for 24 hours, when compared to the wild type strain).

The definitive identification of the enzymatic activity of Nlr and Dfx was reported in 1999.[54,55] In an attempt to purify a putative superoxide dismutase from cell-free extracts of *P. furiosus*, Adams and coworkers isolated, for the first time, the above-described *P. furiosus* Nlr. This protein exhibited high activity in the standard SOD assay (values comparable to bovine SOD). In this assay, a constant flux of $O_2^{\cdot-}$ was produced by using a mixture of xanthine and xanthine oxidase under aerobic conditions. This mixture also contained horse heart cytochrome *c*, which could be directly reduced by $O_2^{\cdot-}$, and the reduction rate of cytochrome *c* would thus be representative of $O_2^{\cdot-}$ production (ca. 14 μM $min^{-1}$).[56,57] The addition of SOD to the reaction mixture would decrease the cytochrome *c* reduction rate as a result of the competition towards $O_2^{\cdot-}$. Excess SOD would completely avoid cytochrome *c* reduction. Replacement of SOD by *P. furiosus* Nlr would have a similar effect, except that for excess amounts of enzyme cytochrome *c* oxidation was observed. Such a fact can only be explained if Nlr can use cytochrome *c* as an electron donor for a redox reaction that involves $O_2^{\cdot-}$ as the substrate. It was then proposed that this reaction would be the direct reduction of $O_2^{\cdot-}$ to peroxide:

$$O_2^{\cdot-} + 2H^+ + D_{red} \rightarrow H_2O_2 + D_{ox}$$

where $D_{red}$ and $D_{ox}$ represent the reduced and oxidized forms of an electron donor. The activity was designated by cytochrome *c* superoxide oxidoreductase or SOR activity. Additionally, it was observed that Rd from the same organism was able to replace cytochrome *c* as the electron donor. This distinct catalytic reaction was further confirmed by testing the SOD activity of Nlr in assays with different superoxide detection methods where no Nlr electron donor was present (pyrogallol, epinephrine or nitroblue tetrazolium oxidation and acetylated cytochrome *c* reduction). In this case, SOR activity was reduced by at least 95% relative to that of SOD. Subsequent works confirmed that Dfx, as well as other Nlr proteins, possessed SOR activity,[46,58,59] that Rd is the putative physiologic electron donor in this reaction[48,57,60] and that the electron transfer between Rd and SOR was in fact the rate-limiting step of the overall reaction in the case of *D. vulgaris* Hildenborough, as shown in an in vitro study by Kurtz and coworkers.[17] These studies definitively pointed to the fact that SOR enzymes are deeply involved in oxygen detoxification systems of either strict anaerobic, microaerotolerant or microaerophilic bacteria. Other work with *D. vulgaris* Hildenborough mutant strains also showed that SOR plays a key role in oxygen defense when this organism is subjected to fully aerobic conditions and for superoxide anions generated in the cytoplasm.[61,62] For microaerophilic conditions, SOD seems to be important for protection of periplasmic components.[63] It was also found that overproduction of Dfx might interfere with the reducing pathway that keeps SoxR in its active form.[64] SoxR is a [2Fe-2S]-containing transcription factor that is oxidized as a response to oxidative stress and that activates global response to oxidative stress.[65–67] However, Wildschut and coworkers reported that rubredoxin:oxygen oxidoreductase (ROO) is also an important component of this system as it can enhance the survival of *D. vulgaris* Hildenborough by itself under microaerophilic conditions.[68]

It was also pointed out that SOR is engineered to perform one reaction (superoxide reduction) whereas SOD can perform both superoxide reduction and oxidation, effec-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tively becoming a superoxide dismutase.[69] Interestingly, it was also proposed that *A. fulgidus* Nlr can be a bifunctional enzyme, and the possibility of ferric Nlr being reduced by the superoxide anion was put forward.[70]

Recently, it was reported that *D. baarsii* Dfx cyano-bridged [$Fe^{III}$–NC–$Fe^{II}(CN)_5$] complex could react with the superoxide anion.[71] In this case, the authors proposed that superoxide suffers a one-electron reduction with concomitant oxidation of an organic substrate to form alkyl peroxide and a water molecule, and that this catalysis was carried out by the ferrocyanide moiety of the complex.

## The Catalytic Mechanism of Superoxide Anion Reduction

How do SORs reduce $O_2^{\cdot-}$? To address this question several researchers tried to identify catalytic intermediates of the reduction process. Several studies based on pulse radiolysis were able to identify different intermediates[70,72–77] and some characterization was done with the aid of UV/Vis, EPR, Resonance Raman and Mössbauer spectroscopy.[41,75,78–81] In these studies, relevant mutants were used, in particular point mutations in glutamate (*D. baarsii* E47A) and lysine (*D. baarsii* K48I) residues located at the active site. While the emergent picture is still not complete (with some discrepancies in the number and nature of the intermediates that depend on the source of the enzyme under study), it is reasonable to describe the catalysis in the following way. The active enzyme (Figure 3, form a) is in the ferrous, pentacoordinate state, which is in redox equilibrium (pH dependent) with the hexacoordinate resting ferric state. As described previously, the active iron centre can have either a hydroxide (Figure 3, form f) or a glutamate (Figure 3, form h) as the sixth ligand. This coordination is pH dependent, with the hydroxide ligand being favoured at higher pH values ($pK_a \approx 9.0$). Catalysis proceeds with substrate binding to the ferrous site. The superoxide anion might be attracted, owing to electrostatic interaction, by a lysine residue (*D. vulgaris* Hildenborough K48 homologue). The first intermediate formed seems to be a ferric–peroxo species that forms with a rate constant $k_1 = 10^9\ M^{-1}\,s^{-1}$ and a characteristic maximum at 600 nm (Figure 3, form b). A

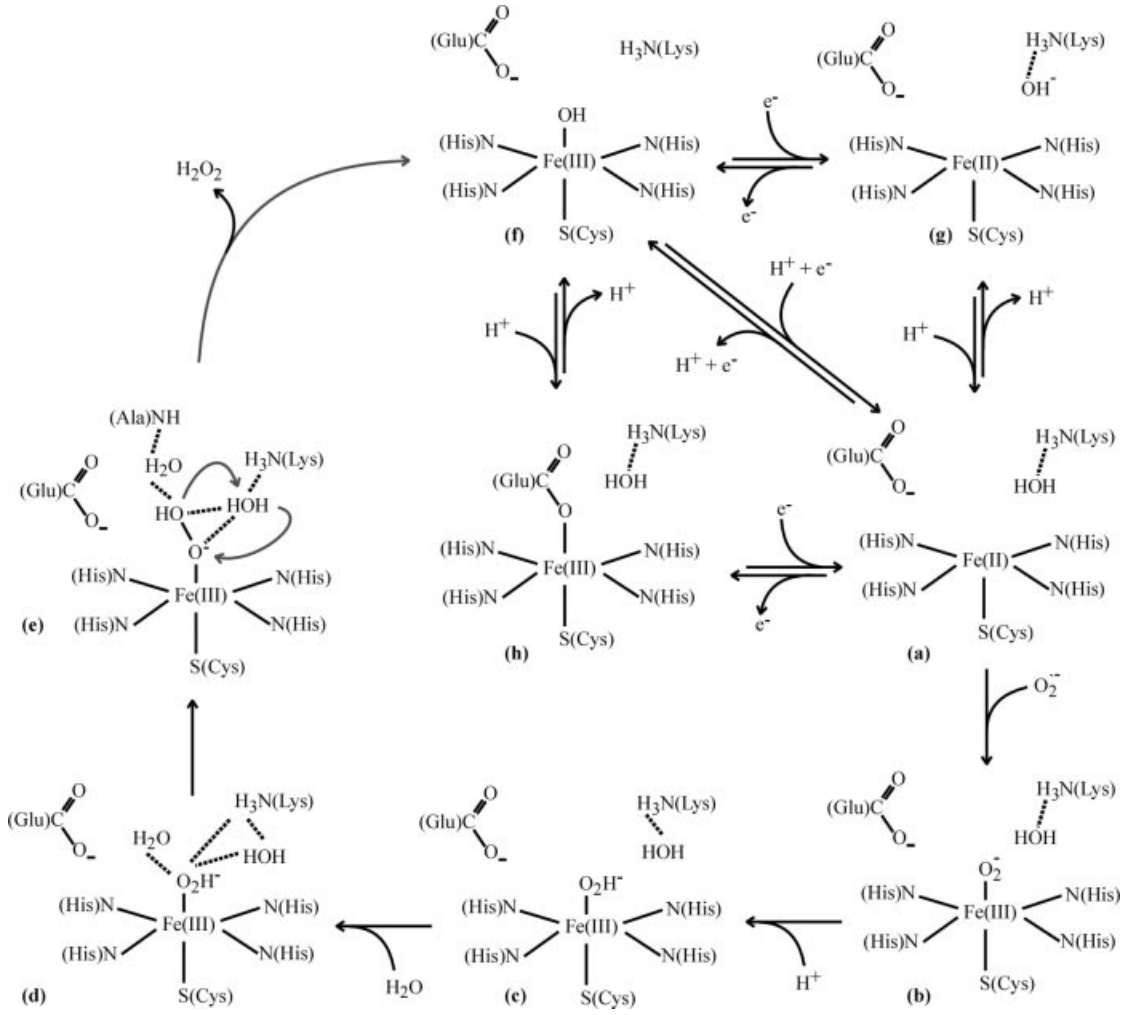

Figure 3. Catalytic scheme of superoxide anion reduction. The following enzyme forms were considered: (a) ferrous active state; (b) ferric peroxo intermediate; (c) ferric hydroperoxo intermediate; (d) an extra water molecule is recruited; (e) rearrangement leading to protonation; (f) ferric hydroxyl-bound resting state and (h) ferric carboxylate-bound resting state.

probable analogue of this intermediate can be obtained by reacting a mutant protein (*D. vulgaris* Hildenborough E47A homologue) with excess $H_2O_2$. The absence of the glutamate residue does not affect the natural substrate binding, but does stabilize a ferric–peroxo species. This species was characterized by Resonance Raman and Mössbauer spectroscopy and is best described as a high-spin $Fe^{3+}$-$\eta^2$-peroxo derivative. Although some authors claim that in the *D. vulgaris* Hildenborough and *A. fulgidus* enzymes this first intermediate undergoes direct protonation to yield the final products,[75] there is enough evidence (collected for *D. baarsii* and *T. pallidum* SORs) that a second intermediate is formed (Figure 3, form c).[73,74,76] The second intermediate has a characteristic peak at 625 nm and, contrary to the first intermediate, the rate constant for its formation is proportional to the proton concentration of the solvent ($k_2 = k_1 \cdot [H^+]$), which indicates that the protonation process occurs directly from the solvent.[76] As a result of this fact, proton transfer seems to be the rate-limiting step, and thus it is fair to assume that this second intermediate is a ferric hydroperoxo species. Subsequently, protonation of the second intermediate leads to $H_2O_2$ release. It was proposed that the proton donor could be a water molecule that is hydrogen-bonded to a nearby lysine residue, which would result in a high-spin ferric hydroxide species. Lysine interaction can lower the apparent p$K_a$ of water molecules, which makes it a suitable proton donor to the ferric hydroperoxo intermediate. Experimental evidence supports this conclusion. In the crystallographic structure of *T. pallidum*, it was possible to model a H-bonding network through water molecules that interact with the conserved lysine residue,[50] and, in *D. baarsii*, Resonance Raman studies showed the formation, at basic pH, of a ferric hydroxide species. At more acidic pH values, the conserved glutamate residue replaces the hydroxide moiety. Very recently, a study by Katona et al. was published[82] in which an elegant methodology combining Resonance Raman spectroscopy and kinetic crystallography was used to study *D. baarsii* SOR crystals soaked with $H_2O_2$. This study revealed that in a E114A mutant (known to stabilize ferric peroxide complexes) the superoxide anion binds in a side-on mode ($\eta^1$) and is subsequently reduced by the iron atom. The authors further proposed that upon protonation and coordination to two water molecules, which were recruited and activated by nearby lysine and alanine residues, a second protonation step yields hydrogen peroxide which is then released, leaving the iron centre coordinated to a hydroxy group. This work clearly identifies the role of the water molecules that are present in the active site, whose action avoids the formation of an oxo–ferryl species by enabling the protonation of the proximal oxygen atom (Figure 3, forms d and e).

Computational studies were conducted in an effort to explain this $O_2^{\cdot-}$ reduction mechanism.[83] In this work the use of DFT and ZINDO/S-CI results support the existence of a peroxo or hydroperoxo intermediate and point to the importance of the protonation of this intermediate in the production of $H_2O_2$, in contrast to possible cleavage of the O–O bond found in heme enzymes.

For purposes of clarity, we did not include in the above discussion the oxidation state of Dfx centre I. The electrons necessary for $O_2^{\cdot-}$ reduction can be donated by Rd either directly to the active site or through centre I, and under physiological conditions it might be possible that this donation will prevent the formation of the glutamate-coordinated species because reduction can occur rapidly after $H_2O_2$ release, as observed in pulse radiolysis experiments where excess reductant was used.[77] One curious observation is that in a *D. vulgaris* Hildenborough Dfx mutant where one cysteine residue, which was responsible for the iron binding in the Dx-like centre I, was replaced by a serine residue, the resulting protein lacked centre I but possessed a normal centre II and its catalytic properties were almost identical to those of the wild type protein.[84] Thus, this *D. vulgaris* Hildenborough Dfx variant functions in a similar manner to class III SOR. Electron transfer studies, in the absence or presence of substrate, between Rd and the different classes of SOR showed that there is a trend in the specificity for the electron donor and acceptor from the same organism.[48,57] One interesting result was that in *D. gigas*, Dx was able to transfer electrons to SOR more efficiently (with an apparent three times greater rate constant) than Rd. Clearly more studies need to be performed to unveil the role of centre I in catalysis as well as to understand the interaction between redox partners.

In *P. furiosus*, it was possible to reconstitute, in vitro, the reduction pathway.[85] In this case it was shown that Rd is reduced by NAD(P)H by an NAD(P)H rubredoxin oxidoreductase (NROR) and that the reconstitution of the full

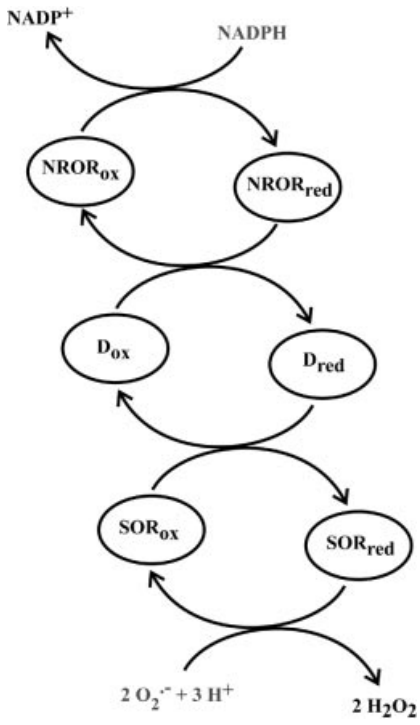

Figure 4. Proposed electron-transfer pathway in superoxide anion reduction. NROR–NADPH: rubredoxin oxidoreductase; D–Rd or Dx; SOR–Dfx, Nlr or class III SOR.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pathway allowed the reduction of the superoxide anion to hydrogen peroxide by using NAD(P)H as the electron donor (Figure 4).

## Phylogenetic Considerations

Searching the microbial genomic databases yields a total of 50 SOR analogues, with approximately 12% of the sequenced genomes containing at least one gene coding for this enzyme. A comparison of all 50 amino acid sequences can be found in Appendix I and the phylogenetic relationships among SOR enzymes are displayed in Figure 5. From the 50 different sequences, it was possible to identify 23 Dfx, 20 Nlr and 6 class III enzymes. One sequence (*Geobacter sp.* FRC-32) showed a high homology to the C-terminal part of Dfx proteins but completely lacked the N-terminal part, and so it can be described as a short Nlr protein (please note that for this case the genome is not completely sequenced). Comparison of all sequences reveals that only seven amino acids are completely conserved. These are the five ligands of the active site (four histidine and one cysteine residues), one proline and one isoleucine, both located near the active site and, so far, with no direct implication on the catalytic mechanism. Both the lysine and glutamate residues were judged necessary for catalysis and are highly conserved. In one instance the lysine residue

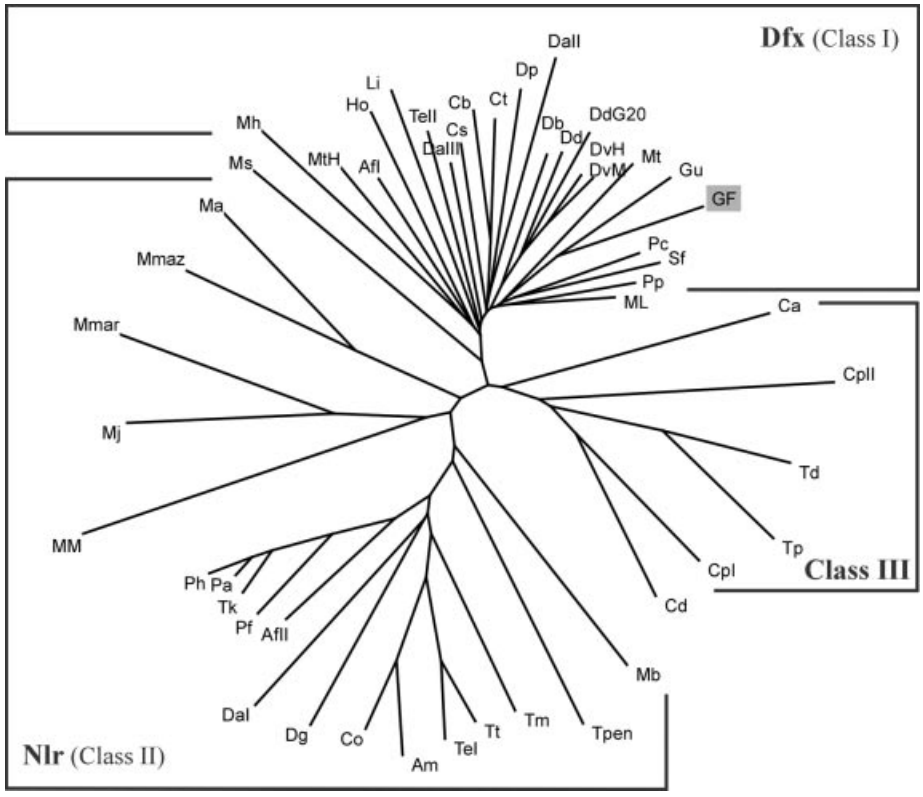

Figure 5. Phylogenetic relationship among SOR enzymes considering the three classes described in the text. Sequences were obtained in the integrated microbial genomes, DOE Joint Genome Institute (http://img.jgi.doe.gov/cgi-bin/pub/main.cgi), The Institute for Genomic Research (http://www.tigr.org/), RCSB PDB database (http://www.rcsb.org/pdb/home/home.do) or through the NCBI website (http://www.ncbi.nlm.nih.gov/). Sequence alignment and tree construction were performed with ClustalX[94] and the tree displayed with TreeView (http://taxonomy.zoology.gla.ac.uk/rod/treeview.html). The grey box denotes the special case of class I SORs, *Geobacter sp.* FRC-32. The following abbreviations were used: **AfI**, *Archaeoglobus fulgidus* DSM4304; **AfII**, *Archaeoglobus fulgidus*; **Am**, *Alkaliphilus metalliredigens* QYMF; **Ca**, *Clostridium acetobutylicum* ATCC 824; **Cb**, *Clostridium beijerinckii* NCIMB 8052; **Cd**, *Clostridium difficile* 630; **Co**, *Clostridium sp.* OhILAs; **CpI**, *Clostridium phytofermentans* ISDg; **CpII**, *Clostridium phytofermentans* ISDg; **Cs**, *Caldicellulosiruptor saccharolyticus* DSM 8903; **Ct**, *Clostridium tetani* E88; **DaI**, *Desulfuromonas acetoxidans* DSM 684; **DaII**, *Desulfuromonas acetoxidans* DSM 684; **DaIII**, *Desulfuromonas acetoxidans* DSM 684; **Db**, *Desulfovibrio baarsii*; **Dd**, *Desulfovibrio desulfuricans* ATCC 27774; *Desulfovibrio desulfuricans* G20; **Dg**, *Desulfovibrio gigas*; **Dp**, *Desulfotalea psychrophila* LSv54; **DdG20**, *Desulfovibrio desulfuricans* G20; **DvH**, *Desulfovibrio vulgaris subsp. vulgaris* str. seemed to be replaced by an arginine residue whereas glutamate can be either located one residue further away from the active site (primary sequence wise) or be replaced by an aspartate residue (in one case). They are, however, highly conserved as one would expect from the mechanistic studies referred above. It is noteworthy that some organisms contain more than one gene coding for different SOR enzymes, such as the case of *Clostridium phytofermentans* where two different class III putative SOR enzymes exist and *Desulfuromonas acetoxidans* with three putative SOR coding genes. In the case of *A. fulgidus*, *Desulfuromonas acetoxidans* and *Thermoanaerobacter ethanolicus* it is even possible to find genes coding for both Dfx and Nlr enzymes. In the case of *A. fulgidus*, both gene products were already isolated.[70,86]

Another striking feature is that genes coding for Dx, one of the possible redox partners of SOR enzymes, could be found in *D. gigas*, where it was originally identified, but also in *Methanosarcina mazei* and *Methanospirillum hungatei*. Whereas the first two organisms contain genes coding for Nlr enzymes, the last one only seems to contain a gene for the Dfx enzyme.

Another striking example is the one found for *P. horikoshii*, where it was not possible to find any Rd or Dx coding gene. In this case, it will be necessary to consider a different electron donor.

## Outlook

SORs are now structurally well-characterized proteins, with a considerable amount of biochemical, spectroscopic and crystallographic data on all three classes of enzymes. The mechanism of superoxide anion reduction is, however, still under evaluation. It is not yet completely understood why some enzymes of the same class will have two reaction intermediates (peroxo and hydroperoxo species) whereas others (of different classes) seem to have a single intermediate that undergoes direct protonation with concomitant $H_2O_2$ release.

The importance of Dfx centre I in catalysis is also elusive. Is this centre the primary recipient of electrons, delivering them to the active site in a regulated manner? This is apparently not the case because in Dfx mutants, where centre I was destroyed, activity remained similar to that of the wild type proteins.[84]Also, class III enzymes show a similar overall quaternary structure and are able to function without centre I. Nevertheless, almost half the genes found are ascribed to Dfx-type enzymes, which means that evolution decided to maintain centre I regardless of its apparent lack of function. It was suggested that centre I might have a catalytic role such as reducing molecular oxygen to superoxide that, consequently, could be further reduced in Dfx centre II.[84] While this is certainly an attractive proposal because organisms could in a single enzyme cope with oxygen and superoxide tolerance, no proof of such a catalysis exists.

Could the role of centre I be related to the nature of the physiologic electron donor? Up until now, both Rd and Dx were identified as possible electron donors. Dx was thought to be present only in *D. gigas* and was shown to be able to conduct superoxide-mediated electron transfer to *D. gigas* Nlr and *T. pallidum* SOR. It was now found that a putative Dx gene exists in *Methanospirillum hungatei* that also contains a putative Dfx coding gene. Therefore, it would be interesting to know if Dx could also act as an electron donor for Dfx enzymes.

Finally, the reader should be aware that during the past years some authors have addressed the biological function of superoxide reductase[87–92] as well as the use of biomimetic models to understand the catalytic mechanism.[93]

**Supporting Information** (see footnote on the first page of this article)**:** Sequence alignment of all SOR and putative SOR proteins found done with ClustalX.[94] Figure was prepared using the ESPript program.[97]

# Alternating and Non-Alternating Pd-Catalysed Co- and Terpolymerisation of Carbon Monoxide and Alkenes

**Eduardo J. García Suárez,[a] Cyril Godard,[a] Aurora Ruiz,[a] and Carmen Claver*[a]**

**Keywords:** Polymerisation / Polyketones / Palladium / Carbon monoxide / Alkenes

The co- and terpolymerisation of carbon monoxide and alkenes are usually catalysed by palladium complexes, and the properties of the produced polyketones can be finely tuned by an appropriate choice of catalyst and olefinic monomer. After a general overview of the topic, selected recent advances in this field are described. The use of palladium systems containing modified diphosphane and/or new phosphorus-based ligands, and the results obtained using a series of modular N and S ligands, including chiral ligands, in CO/styrene co- and terpolymerisations are reported. The use of new P-O ligands in non-alternating CO/ethene copolymerisation is also described.

## Introduction

The industrial interest in polyketones obtained by the catalytic copolymerisation of carbon monoxide with one or more alkene monomers has increased relentlessly over the last few decades. These materials represent a class of low-cost thermoplastics whose synthesis, properties and applications are still the object of intense fundamental and applied research. At least two of these CO/olefins polymers are produced industrially, namely Carilon® by Shell[1] and Ketonex® by BP.[2]

Polyketones provide a unique web of chemical and physical properties, which include photo- and biodegradability, good chemical resistance to acids, bases and solvents, impermeability to hydrocarbons and strong rigidity and impact strength.[3,4] These properties can be both modified and improved by changing the number or nature of the comonomers and tuning the structure of the metal catalyst. The diversity of their properties makes polyketones superior to polyolefins, polyamides and polyacetals.[5]

With this review, we wish to present a concise overview of relevant advances in Pd-catalysed CO/olefin co- and ter-

*Cyril Godard (left) was born in Saint-Rémy, France, in 1974. He was awarded a Ph.D. from the University of York in 2004 (with Prof. R. N. Perutz and Dr. S. B. Duckett). After postdoctoral work on mechanistic studies using Para-Hydrogen Induced Polarisation techniques, he joined the Universtat Rovira i Virgili in Tarragona where he is currently a Juan de la Cierva research fellow and is working on nanocatalysis. His research interests lie in the areas of organometallic chemistry, enantioselective processes and mechanisms in metal-catalysed catalysis.*

*Carmen Claver (second from left) is Professor of Inorganic Chemistry at the University Rovira i Virgili (URV) in Tarragona, Spain, a position she has held since 1991. She received her PhD in 1978 from the University of Zaragoza, Spain, working in the field of organometallic chemistry and homogeneous catalysis. Her research is aimed at the development of advanced transition metal catalysis and covers the synthesis of ligands and complexes and the characterisation of intermediates, focusing mainly on their application in enantioselective catalysis and polymerisation processes. She has co-authored scientific contributions in this field and has participated in the edition and publication of several books. She has received several scientific awards, and was recognised in 2003 as a Distinguished Researcher by the Catalan Government.*

*Eduardo J. García Suárez (second from right) was born in 1973 in Gijón, Spain. He completed his undergraduate studies in 2002 at the Universidad de Oviedo. In 2003, he was awarded a Marie Curie training fellowship at the Istituto di Chimica dei Composti Organometallici in Florence, Italy. He is currently working towards his PhD under the supervision of Prof. Carmen Claver and Dr. Claudio Bianchini at the Universitat Rovira i Virgili in Tarragona, Spain.*

*Aurora Ruiz (right) completed her undergraduate studies in chemistry at the Universitat de Barcelona (UB) and was awarded a PhD from the same university in 1983. She is now Professor of Inorganic Chemistry at the Faculty of Chemistry of the Universitat Rovira i Virgili (URV) in Tarragona. Her current research field is homogeneous catalysis covering aspects of synthesis, characterisation of chiral organometallic complexes and their application in asymmetric catalysis.*

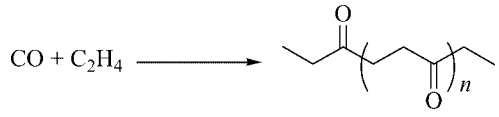
polymerisation. As the first developments have already been reviewed,[6] particular focus will be given to recent advances in this field, including contributions from our research group.

### Perfectly Alternating CO/Ethene Copolymerisation

The simplest polyketone is the CO/ethene copolymer (Scheme 1).



Scheme 1. Polyketone formation by alternating CO/ethene copolymerisation.

Perfectly alternating CO/ethene copolymerisation is efficiently carried out in methanol at moderate temperatures (about 80 °C) in the presence of a catalyst system that contains a $Pd^{II}$ salt with a weakly coordinating counterion and a chelating diphosphane as essential components (Figure 1).[6]

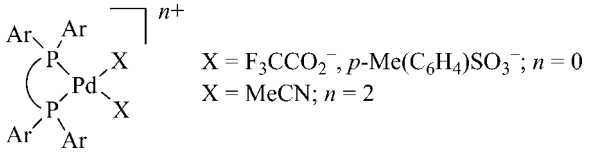


Figure 1. Usual pre-catalysts for perfectly alternating CO/ethene copolymerisation.

1,3-Bis(diphenylphosphanyl)propane (dppp) was the ligand that opened the way to the efficient synthesis of polyketones.[7] Pressures between 30 and 60 bar of CO/ethene are usually employed. When all the CO has been consumed, the catalyst promotes the dimerisation of ethene into butenes. Polyketones with different combinations of end groups such as diketone, keto-ester and diester groups can be obtained.

The optimal reaction conditions in methanol require the presence of both a strong oxidant ($E^0 \geq 0$) and a protic acid ($pK_a \leq 4$) whose conjugate base must have a low binding affinity to $Pd^{II}$. 1,4-Benzoquinone (BQ) and *p*-toluenesulfonic acid (TsOH) are two examples that fulfil these requirements and are the stabilising compounds for the most productive catalytic systems. Productivities as high as 11000 g CP (g Pd h)$^{-1}$ (CP = copolymer) can be obtained under these experimental conditions.[6]

The role of the 1,4-benzoquinone is to oxidise the $Pd^0$ or $Pd^I$ species that are formed in the catalytic process to $Pd^{II}$, and the main role of the protic acid is to prevent the deactivation of the palladium(II) catalyst into inactive (P-P)$Pd^0$ by protonating the latter species to reform the catalytically active species [(P-P)PdH]$^+$.

### Ligand Systems Used in CO/Ethene Copolymerisation

One of the advantages of catalytic systems bearing phosphorus-based ligands is the structural diversity and the ease of modification of this type of ligand. Drent et al.[6a,7b] were the first to investigate the influence of the structure of the diphosphane ligand on the activity of the $Pd^{II}$ catalyst. This study found a strong dependence of the catalytic activity on the chain length of the carbon backbone between the two phosphorus atoms, with dppp giving the highest productivity.

Since the discovery of the efficiency of the Pd-dppp catalyst by Shell Research in 1984, various dppp-like ligands have been designed and successfully employed to catalyse CO/ethene copolymerisation in combination with $Pd^{II}$ salts. Most ligand variations have involved substitutions in both phenyl groups and/or the carbon backbone, and a considerable increase in the productivity (ca. 50%) was obtained when alkyl groups were introduced in both the 1- and 3-positions of the dppp backbone to yield *meso*-2,4-bis(diphenylphosphanyl)pentane (bdpp). Both electronic and steric factors have been suggested to explain the remarkable activity of these catalysts, and it was proposed that the increased activity of Pd(*meso*-bdpp) could be due to the more facile re-oxidation of the one-electron-reduced species by both 1,4-benzoquinone or $H^+$, which would result in a larger number of active Pd centres in the catalytic mixture.

In terms of productivity and catalyst stability, the introduction of *ortho*-methoxy groups at each phenyl unit of the dppp ligand has also been shown to have a beneficial influence (Figure 2).[8]

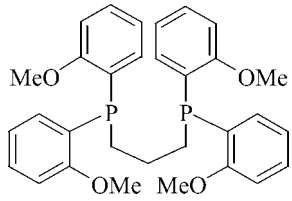

Figure 2. *o*-MeO-dppp used in CO/ethene copolymerisation.

A water-soluble version of *o*-MeO-dppp containing *m*-sodium sulfonatophenyl groups has also been used, which shows that the *ortho*-methoxy moiety can exert both a steric and an electronic influence on the palladium centre.[8b]

Modifications of the ligand backbone of dppe-based ligands have also been investigated and it was found that the backbone rigidity and the overall steric crowding at the Pd centre play a crucial role in determining the catalytic activity.[9] Thus, $Pd^{II}$ catalysts bearing the *cyclo*-tetraphos ligand (Figure 3) are 10-times more efficient than those with dppe.

The beneficial effect of the ligand rigidity for copolymerisation reactions has also been confirmed using bis-phospholyl-substituted carbon backbones.[10]

Experimental evidence has also shown that four-membered ring systems with isopropyl-substituted phenyl rings can also exhibit high catalytic activity (Figure 4).[11]

Phosphorus-metallocene based ligands have also been tested recently for the copolymerisation of CO/ethene.[12] Relatively low molecular weight copolymers were obtained and both the catalytic activity and the chemoselectivity of the copolymerisation reaction were shown to depend on the

sandwiched metal centre, the substituents on the cyclopentadienido ring and on the substituents bonded to the phosphorus donor atoms.

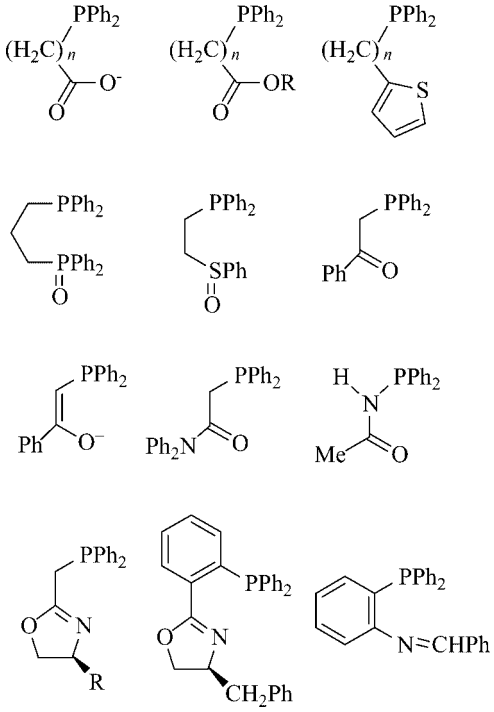

Figure 5. Hemilabile P-O, P-N and P-S ligands.

Another class of ligands used for CO/ethene copolymerisation corresponds to hemilabile phosphane ligands containing oxygen, nitrogen or sulfur donor atoms,[13] although their catalytic activity is lower than that of dinitrogen and diphosphane ligands. Some of the P-O, P-N and P-S ligands that have been studied with the aim of forming efficient catalysts for CO/ethene copolymerisation are presented in Figure 5.

Sterically rigid dinitrogen ligands such as bipyridine (bipy), phenanthroline (phen) and their alkyl-substituted derivatives form efficient catalysts for alternating CO/ethene copolymerisation under both homogeneous and heterogeneous conditions.[14]

## CO/Styrene Copolymerisation

Unlike aliphatic olefins, the copolymerisation of styrene and its derivatives with CO requires the use of $Pd^{II}$ catalysts with chelating dinitrogen ligands[3,6a,15,16] – the use of Pd catalysts bearing diphosphane ligands gives only low molecular weight oligomers.[6a,16c,16f,17] It is commonly agreed that termination by β-H elimination is favoured over propagation of the polymer due to the higher electron density on the palladium centre in phosphane-modified catalysts,[6,16–18] and it has also been suggested that the (diphosphane)Pd–styryl intermediates formed in the initial steps of the CO/styrene copolymerisation are so strongly stabilised by π-benzylic coordination that this inhibits CO insertion. Termination by β-H elimination thus becomes favoured and oligoketones are formed instead of polyketones.[17]

Copolymers of the general formula $[CH(Ar)CH_2CO]_n$ show regio- and stereoisomerism due to the presence of truly stereogenic centres in the polymer backbone.[19] Depending on the regioselectivity of the monomer insertion, either primary (1,2-mode) or secondary (2,1-mode), into the polymer chain, three different arrangements are possible during the polymerisation: tail-to-tail, head-to-tail and head-to-head. With dinitrogen ligands styrene insertion into the Pd–acyl bond takes place exclusively in a 2,1-fashion and leads only to head-to-tail units. However, a mechanistic study using a phosphane-phosphite ligand showed that 1,2-insertion of styrene can occur and that in this case β-H elimination occurs from the 2,1-complex rather than the 1,2-complex.[17c]

Syndiotactic and isotactic alternating copolymers present very low and high optical activities, respectively, and control of the regio- and enantioselectivities of styrene insertion, ultimately leading to stereoregular polyketones, can be achieved by a suitable choice of bidentate ligands.

Copolymerisation catalysts usually contain achiral ligands that lead to the formation of products of head-to-tail regioselectivity and syndiotactic stereoselectivity. The stereoselectivity is a result of chain control, with the enantioface of the incoming styrene being directed by the stereogenic centre of the last incorporated styrene unit, taking into account that styrene inserts exclusively in a 2,1-mode.[16b,16d]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Typical catalysts used for perfectly alternating copolymerisation of CO and styrene for the production of syndiotactic copolymers contain a $Pd^{II}$ salt and a chelating dinitrogen ligand such as bipy or phen. This reaction requires the presence of a Brønsted acid (e.g. TsOH) and a large excess of a strong oxidant such as BQ with respect to Pd. The production of copolymer is strongly decreased in the absence of oxidant, although the molecular weight of the copolymer is inversely proportional to the concentration of BQ.[3,6,15,16] The solvent of choice is usually methanol, although a striking effect has been observed on the stability of the catalytic systems with 2,2,2-trifluoroethanol (TFE) as solvent.[20] This effect was attributed to the higher stability of Pd-acyl intermediates in TFE than in methanol. For instance, the lower nucleophilicity of TFE could inhibit the chain end by alcoholysis. The palladium(II) complex $[Pd(bipy)_2][PF_6]_2$ has been found to still be active in TFE after 48 h of reaction and to yield high molecular weight copolymers with a productivity of 360 g CP (g Pd h)$^{-1}$, and high yields and high molecular weight copolymers are obtained even in the absence of oxidant.[21]

The influence of various counterions has also been investigated, with the result that the catalytic activity decreases in the order B[3,5-$(CF_3)_2C_6H_3]_4$ (BArF) > $SbF_6/PF_6$> $BF_4$ > OTf >> $BPh_4$ (OTf = triflate). The strength of the interionic interactions has been shown to have a negative effect on the productivity of the catalysts.[22]

The production of syndiotactic copolymers of 4-methylstyrene and CO has been achieved at 0 °C at 1 atm of CO with the Pd complex **1** (Figure 6), which was also used as a precursor in studies of the first steps of the polymer chain-growth, as catalyst.

It has been demonstrated that when a catalyst bearing ligands that contain one or several stereogenic centres is used, the enantioface discrimination is directed by the ligand and not the chain end control. Brookhart and coworkers, for example, have reported the first enantioselective copolymerisation of CO and styrene using a Pd(bisoxazoline) system (complex **2**, Figure 6). The reaction was performed under 1 atm of CO at room temperature with 4-*tert*-butylstyrene as both solvent and substrate and yielded copolymers with both a highly isotactic microstructure and high optical activity as a result of enantiomorphic site control.[23] The orientation of the incoming styrene was shown to be strongly controlled by the presence of substituents in the 4-positions of the oxazoline ring. However, the use of palladium systems bearing oxazolinyl-pyridine ligands (complex **3**, Figure 6) leads to the production of mainly syndiotactic copolymers, which indicates that chain control predominates.

The production of chiral alternating CO/styrene copolymers has also been reported, although with a lower stereoregularity, with a pyridine-imine system (complex **4**, Figure 6),[24] and Carfagna et al. have reported the production of highly isotactic optically active copolymers of CO and styrene or 4-methylstyrene with a bisoxazoline catalytic system (complex **5**, Figure 6). They obtained only low yields, however, and attributed this to the weak coordinating properties of this ligand which result in a destabilisation of the catalyst under these reaction conditions.[25] Productivities as high as 21 g CP (g Pd h)$^{-1}$ for average molecular weight copolymers have been obtained at room temperature under a constant CO pressure of 1 bar with palladium complexes bearing chiral diketimines or dialdimines.[26]

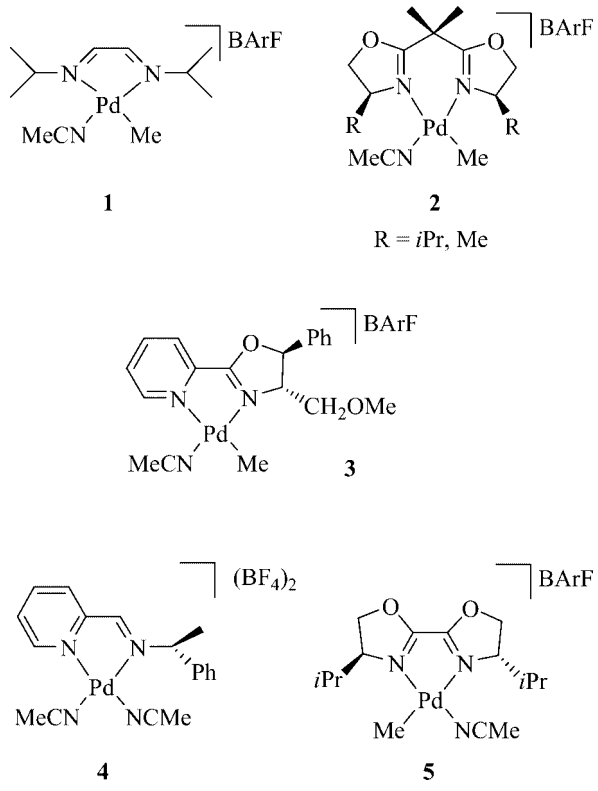

Figure 6. Some systems used in Pd-catalysed CO/styrene copolymerisation.

Brookhart et al., in a particularly inventive strategy, have achieved the production of stereoblock polyketones by exchanging ligands during the catalytic reaction. Thus, an isotactic segment is produced in a first step using the bisoxazoline system **2** (Figure 6), then addition of bipyridine to the reaction medium results in the elongation of the copolymer in a syndiotactic way.[27]

## CO/Olefins Terpolymerisation

Despite the fact that the two polyketones that have been commercialised are terpolymers of CO/ethene/propene,[1,2] terpolymerisation reactions have been much less studied than copolymerisations. Similarly to the copolymerisation catalysts, the terpolymerisation of CO with aliphatic olefins is usually performed using complexes bearing phosphorus-based ligands,[28] and the only reported example of terpolymerisation of CO with two vinylarenes is promoted by Pd(phen) complexes.[13h,29] The terpolymerisation of CO with one aliphatic and one aromatic olefin is somewhat more versatile and various types of ligand systems have been successfully used, such as P-P,[30] P-OP,[31] P-N[13h,32] and N-N[15,16d,22,30,33–35] (Figure 7).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

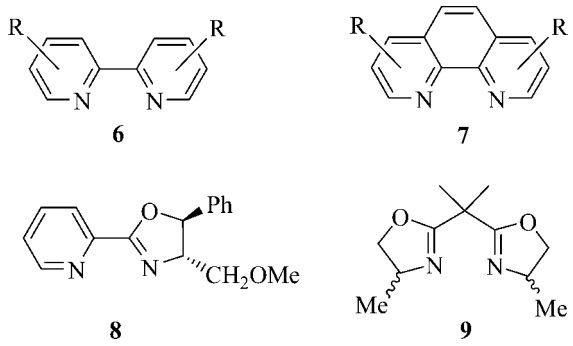

Figure 7. N-N ligands used for the Pd-catalysed terpolymerisation of CO with one aliphatic and one aromatic olefin.

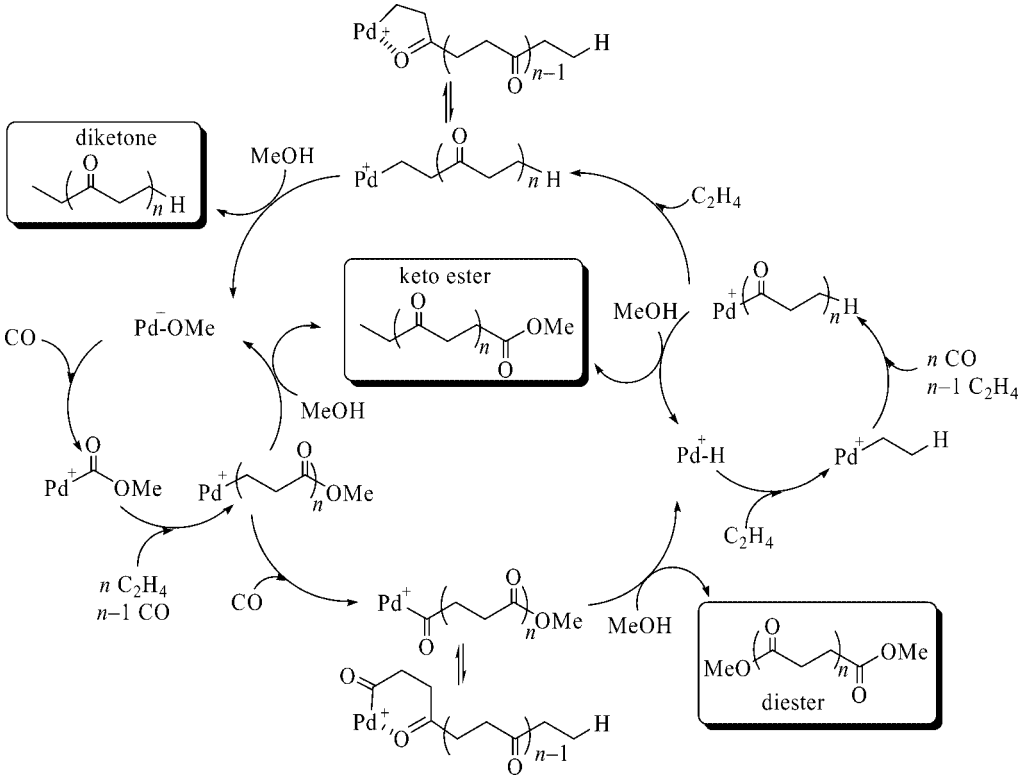
The propagation step of this reaction is based on alternating migratory insertion of CO into a Pd–alkyl bond and of one of the olefins into a Pd–acyl bond. Depending on the characteristics of both the olefins and the catalyst, the resulting terpolymers can have a distinct composition and thus distinct properties.

The dinitrogen systems used for this reaction are essentially derived from planar bipy and phen systems (**6** and **7** in Figure 7), although Brookhart and Consiglio have reported that the use of chiral ligands (**8** and **9**, Figure 7) in this reaction produces optically active terpolymers.

### Mechanism

The first detailed mechanistic study of the Pd-catalysed perfectly alternating CO/ethene copolymerisation was reported by Drent et al. in 1991, and since then a large number of studies from both an experimental and theoretical viewpoint have been reported and have contributed to a better understanding of each step of the catalytic reaction. These studies have also helped to identify, and obtain information about, the active species and resting states in the reaction. Most of these studies have been reviewed before therefore only a brief description of the catalytic cycle will be given here.[6,3,36]

As shown in Scheme 2, two competing cycles that are connected by cross terminating steps and whose prevalence depends on the reaction conditions participate in the production of polyketones. One cycle initiates with a Pd–H species and is favoured by traces of water in the solvent (methanol) via the Water Gas Shift reaction.[37] Rapid insertion of ethene gives an alkyl species that reacts reversibly with CO to yield an acyl complex, which then irreversibly inserts a second ethene molecule. The propagation thus occurs through alternating CO and ethene insertions. Keto esters and diketones can be produced from this cycle, depending on the termination path: the methanolysis of an acyl species yields a keto ester whereas protonolysis of an alkyl complex yields a diketone. The second cycle initiates with a Pd-methoxy species that reacts with CO to form a methoxycarbonyl-Pd complex. Keto esters are also produced during this cycle, together with copolymers with a diester structure that are produced by methanolysis of a acyl-Pd. The palladium hydride species is the most probable initiator in the presence of organic oxidants, and methanolysis is therefore the main termination mechanism. Kinetic studies have shown that ethene insertion is the rate-limiting step of the reaction.[6]



Scheme 2. Proposed mechanism for CO/ethene copolymerisation by diphosphanepalladium catalysts.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Two competing chain-transfer mechanisms have been proposed for the alternating copolymerisation of CO and ethene. One involves termination by an unexpected isomerisation into the enolate followed by protonation with methanol and subsequent initiation by insertion of CO into the methoxypalladium species, and the second one involves termination by methanolysis of the acylpalladium species and subsequent initiation by insertion of ethene into the palladium–hydride bond.[38]

The main features of the catalytic cycle for CO/styrene copolymerisation are similar to those of CO/ethene copolymerisation. The propagation step, in particular, is identical, with alternating insertions of CO into Pd–alkyl bonds and of styrene into Pd–acyl bonds. However, the initiation and termination steps are distinct and depend on the nature of the olefinic substrate.[6] The termination pathway that prevails in methanol involves fast β-hydrogen elimination from alkyl species and thus yields a Pd–H complex at the end of the cycle.

We will now focus on selected recent advances in this field. We describe the use of palladium systems containing modified diphosphane and/or new phosphorus ligands, and the results obtained using a series of modular N and S ligands, including chiral ligands, in CO/styrene co- and terpolymerisation. The use of new P-O ligands in non-alternating CO/ethene copolymerisation is also described.

## Ligand Tuning: Modified Diphosphane and Related P-P Ligands

As mentioned in the introduction, $Pd^{II}$ catalysts based on diphosphane ligands have been shown to be the most suitable catalyst systems for the alternating copolymerisation of carbon monoxide and ethene.[6a] Many attempts have been carried out to improve this catalytic system by modifying the diphosphane moiety.[8b] The introduction of methoxy groups in the *ortho* positions in the phenyl rings attached to the phosphorus atoms, for example, has been shown to have a beneficial effect on the copolymerisation in terms of productivity and average molecular weight of the resulting polyketones.[39,40]

Two new chelating diphosphanes ligands have been synthesised and tested in the alternating copolymerisation reaction of carbon monoxide and ethene (Figure 8).[41] The aim of this study was to compare the diphosphane ligand **10** with the neutral and less rigid $C_3$-bridged diphosphane ligand **11** in the copolymerisation reaction. Ligand **10** is the first example of a diphosphonium ligand for the copolymerisation of carbon monoxide and ethene. The square-planar complexes [$PdCl_2$(P-P)] and [$Pd(OAc)_2$(P-P)] (P-P = **10**, **11**) were used as catalyst precursors for the CO/ethene copolymerisation reaction and showed high activity and remarkable control of the molecular weight of the alternating polyketone products.

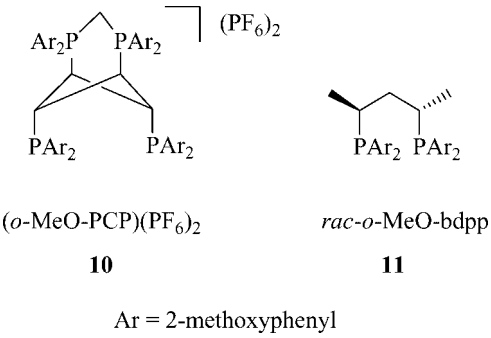


Figure 8. New chelating ligands used in CO/ethene copolymerisation.

[$PdX_2$(P-P)] (P-P = **10**, **11**) complexes (X = Cl or OAc) were then used to generate very active Pd species in water/AcOH mixtures or in MeOH in the presence of *p*-TsOH. The dichloride complexes were tested in mixtures of water and AcOH under standard experimental conditions (40 bar, CO:ethene = 1:1, 85 °C). Perfectly alternating polyketones were obtained in all cases, with only ketone end-groups.

The mechanism of CO/ethene copolymerisation catalysed by [$PdCl_2$(P-P)] complexes in acidic aqueous media is well known, and the chain transfer and propagation steps have been studied in some detail.[6,42] It is usually accepted that neutral $Pd^{II}$–H complexes are generated from the dichloride precursors by the a Water Gas Shift (WGS) reaction.[43]

[$Pd(OAc)_2$(P-P)] complexes were found to be good precursors for the copolymerisation reaction in MeOH in the presence of 2 and 20 equivalents of *p*-TsOH. The acid was used both as a scavenger of the acetate ion and as oxidising agent to form $Pd^{II}$ species from $Pd^0$.[6,42] With both catalyst precursors, the copolymer product contained keto and ester end-groups in a 1:1 ratio. Both catalysts gave polymers with larger $M_n$ (number-average molecular weights) values than the polymers obtained in water/AcOH. It was therefore concluded that the chain-transfer step is slower in MeOH than in water/AcOH. In contrast with the trend usually observed for CO/ethene copolymerisation in MeOH catalysed by $Pd^{II}$–diphosphane complexes,[6,40b] an inverse dependence of the productivity on the acid concentration was found for the reactions catalysed by [$Pd(OAc)_2$(**11**)].

The polyketones obtained with the diphosphonium-diphosphane catalysts showed $M_n$ values up to five times lower than those obtained with the less rigid $C_3$ diphosphane catalysts. These results can be explained by a faster chain-transfer due to the electronic and steric properties of the diphosphonium-diphosphane ligand.

In order to gain an understanding on the beneficial effect of the *ortho*-methoxy group on the alternating copolymerisation of carbon monoxide and ethene,[42,44] neutral and dicationic palladium(II) complexes bearing *o*-MeO-dppe, *o*-MeO-dppp and their analogous precursors with dppe and dppp were synthesised. The catalytic activities were compared in various reaction media (MeOH, $CH_2Cl_2$, TFE, toluene and $H_2O$/AcOH). In addition, in situ and in operando HP-NMR experiments were performed in order to provide

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

valuable information on catalysis resting states and intermediates. Independently of the reaction media, higher catalyst productivities and polyketone molecular weights were achieved using the modified ligands, except in TFE, in which both productivities and molecular weights were lower. This unexpected behaviour in TFE was suggested to be due to the formation of an effective web of hydrogen-bonding interactions between solvent molecules and the *o*-methoxy oxygen atoms of either *o*-MeO-dppp or *o*-MeO-dppe. A slower diffusion of the monomers would take place as a result of the increased congestion at the metal centre, thus lowering the propagation rate. Although this hypothesis was not supported by experimental evidence, such interactions have previously been reported for related palladium systems.[45] The differences observed in productivity between modified and unmodified ligands for the different reaction media can be attributed to both steric and electronic factors related to the *o*-methoxy groups, which would induce a lower tendency to form inactive bis-chelates and dimers, reduced phosphane oxidation,[46] an increased basicity of the metal centre,[40b] and a reduced stability of catalyst resting states such as β-keto alkyl chelates.[42]

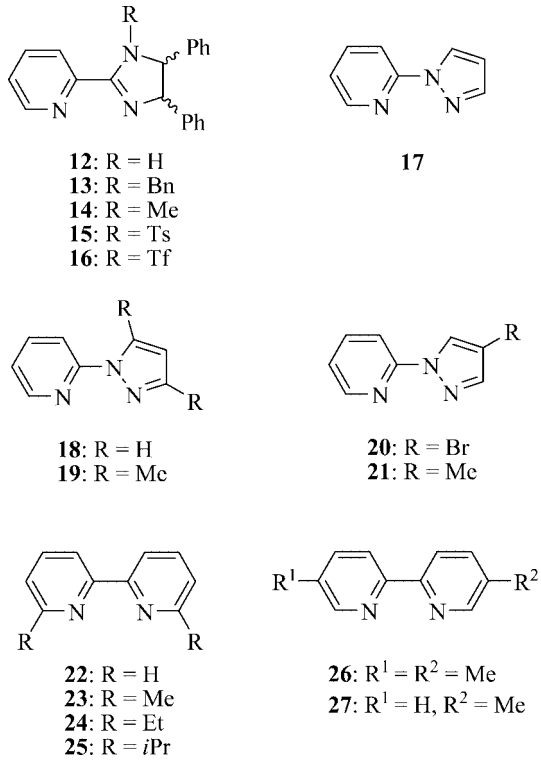

Figure 9. N-N′ ligands used in our group for CO/TBS copolymerisation.

### Modular N-N′ Ligands for the Copolymerisation of CO and Styrene

As discussed above, the Pd-catalysed copolymerisation of CO and vinyl arenes has been reported to be more efficient with nitrogen donor ligands than with phosphorus-based ligands.[3,6a,15,16] In contrast with CO/ethene copolymerisation, a stereogenic centre is created in each -(COCHRCH$_2$)- unit, therefore the use of a chiral ligand is of interest. The alternating CO/4-*tert*-butylstyrene (TBS) copolymerisation reaction has been investigated in our research group using various systems containing chelating asymmetric dinitrogen ligands (Figure 9).

When modular imidazolyl-pyridine ligands **12**–**16** were used, the stereochemistry of the corresponding palladium complexes [PdMe(NCMe)(N-N′)][BArF] was found to be influenced by the electronic properties of the R substituents of the imidazole moieties.[47,48] Indeed, in the case of ligands **12**–**14** the imidazole unit was always found to be *cis* to the methyl group bonded to Pd whereas in the case of ligands **15** and **16**, which contain electron-withdrawing substituents, a mixture of *cis* and *trans* isomers was obtained. This correlation between the relative stability of the *cis* and *trans* isomers of these cationic complexes and the nature of the R substituents was also confirmed by density functional theory calculations.[48] In terms of catalysis, productivities between about 2 and 30 g CP (g Pd h)$^{-1}$ were achieved, with molecular weights of between 17000 and about 80000 under mild conditions ($P_{CO}$ = 1 bar, room temp., TBS/Pd = 620). The nature of the substituents was found to influence both the productivity of the catalyst and the stereoregularity of the polymer but had no effect on the molecular weight of the polyketones. The catalysts bearing the less basic imidazole moieties **15** and **16** were found to be the most active, probably because they favour the coordination of the styrene substrate. They were also shown to favour the production of *u* diads, giving highly syndiotactic copolymers. The microstructure of the polyketones obtained with the (*R*,*S*)-4′,5′-imidazolines was found to depend on the electronic properties of the ligands, whereas only syndiotactic polyketones were obtained when the (*R*,*R*) diastereoisomers were used. This result indicates that chain-end control is more effective than enantiosite control. A comparison of the structures of the complexes containing (*R*,*R*)- and (*R*,*S*)-4′,5′ imidazoline moieties showed that the presence of the (*R*,*R*) diastereoisomers leads to a lower degree of distortion that stabilises the complexes during catalysis, although no direct trend with the productivity of the catalyst could be determined.

When the imidazole moiety was replaced by a pyrazole unit (ligand **17**), the productivity of the catalyst and the molecular weight of the polyketone produced were both found to be moderate under the same conditions (ca. 20 g CP (g Pd h)$^{-1}$ and 30000, respectively).[49]

In the case of pyrimidine-pyrazole ligands, the coordination to the palladium centre to give [PdMe(NCMe)-(N-N′)]$^+$ complexes was found to be directed by the steric bulk of the pyrazole moiety.[49,50] Indeed, when ligand **18** was used, the pyrazole moiety was found to be in a *cis* position to the PdMe group. However, when methyl substituents were introduced in positions 3 and 5 of the pyrazole unit (ligand **19**), the pyrimidine moiety was found to be *cis* to the methyl group. The corresponding polyketones were obtained in high yield with a molecular weight of up to 82000

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and polydispersities ranging between 1.3 and 1.7, which are close to the best values reported for planar $C_s$-symmetric dinitrogen ligands with styrene derivatives. The high yield is due to the stability of the active species when the reaction is carried out in TFE. Similarly, the enhanced growth of the polymeric chain, as a result of competition between the propagation and the termination steps, is due to the greatly enhanced stability of the acyl- and/or alkylpalladium intermediate in TFE with respect to $CH_2Cl_2$ or chlorobenzene, which causes a remarkable increase in the catalyst lifetime. Optimisation of the amount of trifluoroethanol required for the copolymerisation reaction was performed with bipyridyl ligands and was shown to have a direct effect on the productivity of the catalyst.[51] This effect is shown in Figure 10 using $[Pd(bipy)_2][BArF]_2$ as catalyst precursor.

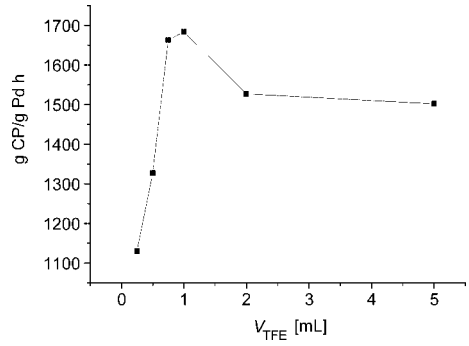

Figure 10. Optimisation of the amount of trifluoroethanol required for CO/TBS copolymerisation ($T$ = 60 °C, $V_{TBS}$ = 10 mL, nPd = $5.1 \times 10^{-4}$ mmol; nBQ = $5.1 \times 10^{-3}$ mmol).

The cationic palladium systems [PdMe(NCMe)(N-N′)][BArF] containing imidazolyl-pyridine ligands *cis*-**12**, *cis*-**13**, *cis*- and *trans*-**15** and pyrazolyl-pyridines **18**, **20** and **21** have also been used for the terpolymerisation of CO/TBS/ethene.[50,52] It was found that the choice of the olefin preferentially inserted into the terpolymer is strictly related to the nature of the nitrogen ligand present in the catalyst and not only to the kind of ligand. Thus, a slight modification in the chelating N ligands coordinated to palladium terpolymerisation catalysts leads to unexpected results in the composition of the terpolymers. For example, the catalysts containing imidazolyl-pyridines **12**, **13** and **15** readily insert ethylene, even at low pressures, and terpolymers with a perfectly controlled composition are obtained if the ethylene/styrene ratio is varied. However, complexes with ligands **18**, **20** and **21** show less versatility towards ethylene pressure and give terpolymers with similar amounts of both olefins. Differences are also encountered in activity/stability: while catalysts bearing ligands *trans*-**15**, **18** and **21** are highly active, those with ligands **12**, **13** and *cis*-**15** decompose quickly. Upon comparing the planar ligands **18** and **21** with the bulkier chiral ones **12**, **13** and **15**, it seems that the chiral imidazolyl-pyridines interfere more with the coordination/insertion of the olefin, which is the rate-determining step of the reaction. This would explain why the systems containing planar ligands **18** and **21** are more active than the system containing *trans*-**15**. The similarity between ligands *cis*-**15** and *trans*-**15**, which only differ in the configuration of one asymmetric carbon atom, and their disparate productivities show that it is more probable that a steric rather than an electronic, effect is responsible for these results. In fact, X-ray analysis of the complex $[Pd(Cl)_2$(*trans*-**15**)] shows that this ligand presents a unique distortion in the imidazoline plane, which may account for the high reactivity observed with this ligand. Comparison with the CO/TBS results shows that the size of the polymer chain is lower when the chain contains ethylene, which favours β-H elimination. Circular dichroism (CD) analysis of the terpolymer obtained with the enantiomerically pure ligand **15** shows that it is optically active. Since this ligand is not able to induce chirality in the CO/TBS copolymerisation (syndiotactic copolymers were obtained), it is clear that the presence of ethylene in the growing polymer chain decreases the probability of chain-end control exerted by the last inserted styrene unit and makes enantiomorphic site control possible.

The effect of the counterion on the copolymerisation reaction has also been studied.[51] Comparison between the known $[Pd(bipy)_2][PF_6]_2$ system and its BArF analogue showed that the use of the latter system increases the catalyst activity considerably. Important differences were also observed in the X-ray structures of the two complexes. However, the introduction of substituents in the 6-position of the dipyridyl ligands **23**–**25** was found to completely inhibit the catalytic reaction when $[Pd(bipy^R)_2][BArF]_2$ complexes were used as catalyst precursors. Catalyst precursors with mixed ligands such as $[Pd(bipy^R)(bipy)][BArF]_2$ gave copolymers of higher molecular weight than with $[Pd(bipy)_2][BArF]_2$, although the catalyst activity was greatly reduced. However, the introduction of one or two methyl substituents in the 5-position of the pyridyl rings (ligands **26** and **27**) was found to have a positive effect on the productivity of the catalysts, although no effect was observed on the molecular weight and tacticity of the polymers produced.

### Modular S-S Ligands in CO/Styrene Copolymerisation

Sulfur-containing ligands have rarely been used in copolymerisation reactions although bis(alkyl)thioether systems have been shown to be active in the copolymerisation of CO/styrene, even though a loss of stereocontrol occurred.[6a,53] We have reported the synthesis and use of thioether ligands in various catalytic processes and we therefore thought that these ligands could provide interesting results in the Pd-catalysed copolymerisation of CO and 4-*tert*-butylstyrene. In 2002, we reported the use of the thioether ligands **28**–**30** for this reaction (Figure 11).[54]

The palladium complexes [PdMe(NCMe)(**28**–**30**)][BArF] were synthesised and used as catalyst precursors. The catalytic results obtained were similar to those reported using chiral P-OP, N-N, and P-N ligands in terms of activity and molecular weights.[23,55,56] However, it should be noted that these results were obtained under mild conditions (1 atm

CO and room temperature). Nevertheless, the activities and molecular weights of the polymers obtained were much lower than those achieved with planar N–N ligands such as bipyridine. The rather high polydispersity values and the non-linear relationship between time and molecular weights indicated that these systems are not living.[16d] Although the productivity of the catalyst bearing ligand **28** was found to increase when the CO pressure was increased from 1 to 5 atm, these systems were found to decompose with time under these reaction conditions and long reaction times resulted in a decrease of the catalyst productivities. These systems were, however, stabilised by large excesses of olefinic substrates under 1 atm of CO. Furthermore, although it was suggested that the atactic nature of the copolymers produced using thioether ligands is due to the flexibility of the donor atom structure,[6a] the system bearing ligand **30** yielded polymers with prevailing isotacticity, which therefore indicates that control of the stereoregularity can be achieved using this type of ligand.

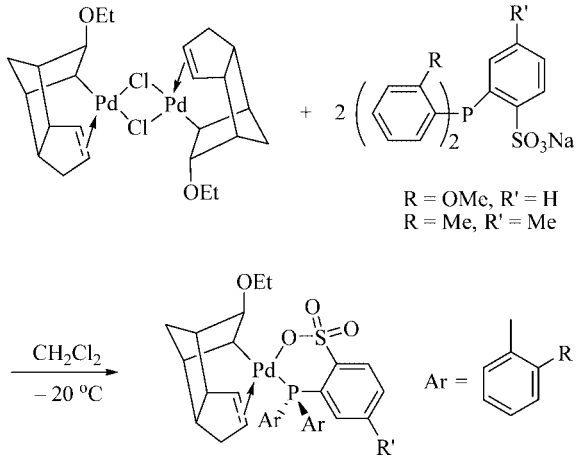
### P-O Ligands in Non-Alternating CO/Ethene Copolymerisation

In previous sections we have dealt with the palladium-catalysed perfectly alternating copolymerisation of ethene and carbon monoxide and its mechanism. It is well known that the double insertion of carbon monoxide in this reaction does not occur for thermodynamic reasons, whereas the double insertion of ethene is kinetically disfavoured. The formation of a stable five-membered cationic palladium metallacycle (see **A**, Figure 12) by an electrostatic interaction between the oxygen of the carbonyl and the cationic palladium centre, known as "back-biting", kinetically favours the insertion of carbon monoxide over ethene insertion.[17b,57] In over two decades of research in the area of late transition metal catalysed polymerisation of carbon monoxide and ethene, no extra insertions of ethene or carbon monoxide have ever been reported; even high ethene/carbon monoxide ratios produce exclusively error-free polyketone until all the carbon monoxide has been consumed.[7b,58] Nevertheless, the double insertion of ethene should be possible, as the same cationic palladium species that is used for the copolymerisation is known to efficiently dimerise ethene into butenes.[59]

The development of novel late transition metal catalysts for the synthesis of new copolymers containing a non-polar backbone and a controlled amount of a polar monomer is of considerable interest to both academia and industry.[59] However, the design of metal catalysts for such copolymerisation reactions is not a trivial task and, despite the many attempts that have been made in this area so far, only a very few new materials have been obtained.[60] The production of non-perfectly alternating carbon monoxide and ethene copolymers is one of the main aims in polyketone research in order to obtain new materials with desirable properties and which can be further functionalised.

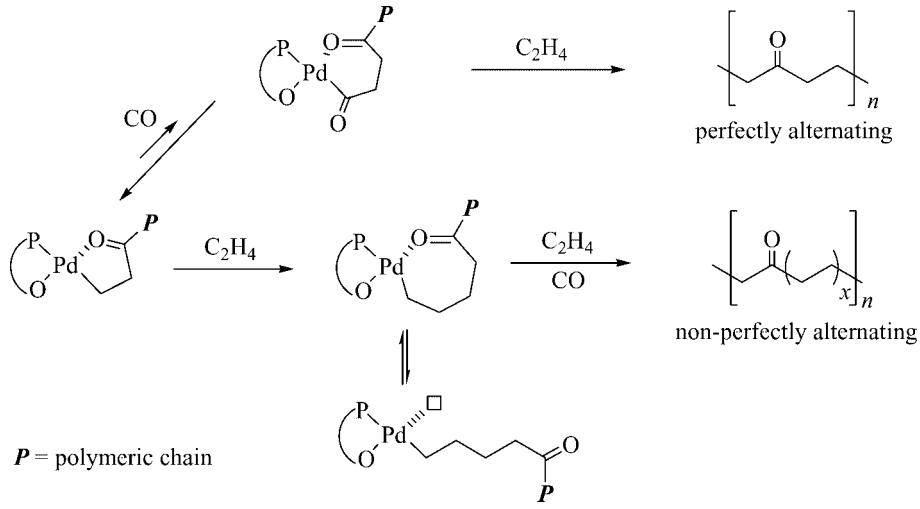
In 2002, Drent et al. reported the first example of a palladium-catalysed non-perfectly alternating copolymerisation of carbon monoxide and ethene. The Pd-containing catalyst precursors bearing alkoxy-arylphosphane ligands containing sulfonic acid groups were formed in situ by mixing palladium acetate and the ligand in a near stoichiometric ratio. Double, triple and quadruple insertions of ethene into the growing polyketone chain were observed. The production of extra insertions of ethene was attributed to the destabilisation of the neutral chelate (**B**; Figure 12) to the extent that ethene effectively competes with carbon monoxide for the next insertion.[61]

More recently, Rieger et al. have reported the first examples of neutral $Pd^{II}$ complexes bearing sulfonated phosphane ligands (Scheme 3). Higher activities as well as higher insertion of extra amounts of ethene (up to 30%) into the copolymer chain were achieved[62] when compared to the previously reported in situ copolymerisation reactions.[61]



Scheme 3. $Pd^{II}$ complexes bearing sulfonated phosphane ligands.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4. Mechanism for non-perfectly alternating CO/ethene copolymerisation (□ = vacant site).

The mechanism of the perfectly alternating copolymerisation of carbon monoxide and ethene by $Pd^{II}$ catalysts based on diphosphane ligands has been extensively studied and is now well known.[6] However, only a few studies on the mechanism of the non-alternating copolymerisation of carbon monoxide and ethene have been published.[61–63] Rieger et al. have proposed that this new polymerisation proceeds via two intertwined pathways (Scheme 4), where the same active species may switch between the production of alternating and non-alternating blocks in the same polymer chain.[62] Multiple ethene insertions are suggested to be facilitated by a stereoelectronic destabilisation of the neutral chelate to an extent that enables ethene to effectively compete with carbon monoxide for the next insertion, as previously proposed by Drent et al.[61]

Based on this report, it was assumed that the neutral nature of the CO-inserted 6-membered chelate could lead to a decarbonylation reaction yielding the five-membered ring complex that could then react with ethene to form a seven-membered chelate, which is proposed to open more easily and therefore facilitates the incorporation of further ethylene units. Furthermore, increasing the pressure of ethene and employing high CO/ethene gas blend ratios (1:20) statistically provides a higher probability of ethene insertion over carbon monoxide insertion.

Ziegler and co-workers have reported work based on Drent's ligands that explains the formation of a non-perfectly alternating copolymer based on the decarbonylation of the acylpalladium complexes formed during the catalytic process.[63] This is possible if the acylpalladium complex with sulfonated phosphane ligands does not form a Pd–O chelate bond between the metal and a carbonyl group on the polyketone chain, thus favouring the decarbonylation.

## Conclusions

Although co- and terpolymerisation of carbon monoxide and olefins has been the subject of numerous investigations, the demand from industry for new types of material makes this area still challenging and offers new possibilities.

The modification of diphosphane ligands by introducing methoxy groups yields more efficient systems, although the presence of TFE decreases the productivity of the catalysts. Chiral N-N′ and S-S ligands can be used in CO/styrene copolymerisation systems to control the stereochemistry of the catalysts and the stereoregularity of the resulting copolymers. Finally, non-alternating CO/ethene copolymerisation, which can provide new materials with interesting properties, is now possible with Pd/P-O systems. Research in this area is still at a very early stage, however, and therefore represents a new challenge in the field of CO/ethene copolymerisation.

## Acknowledgments

The authors are grateful to all the co-workers who participated in the polymerisation studies and especially to Amaia Bastero, whose contribution was essential to the studies mentioned in this review. We also wish to thank the Spanish Ministerio de Educación y Ciencia (CTQ2004-04412/BQU, Consolider Ingenio 2010 CSD2006-0003 and a Juan de la Cierva fellowship to C. Godard), the Generalitat de Catalunya (2005SGR007777 and Distinction for Research Promotion, 2003 C. C.) and the European Commission (EC) (HPRN-CT-2002-00196) for financial support.

# NMR Studies of Paramagnetic Metallocarbaporphyrinoids

**Ewa Pacholska-Dudziak[a] and Lechosław Latos-Grażyński*[a]**

**Keywords:** Carbaporphyrinoids / Porphyrinoids / NMR spectroscopy / Organometallic chemistry

Carbaporphyrinoids provide a suitable macrocyclic platform for organometallic investigations that provide unique opportunities for modifying a macrocyclic structure. Alteration of a coordination core is a route of choice for stabilizing unusual metal ion oxidation states and coordination geometries. This microreview presents the general characteristic of paramagnetic metallocarbaporphyrinoids, with a focus on NMR studies. NMR spectroscopy of paramagnetic molecules can be considered as a powerful probe of several intriguing aspects of the molecular and electronic structures, structural rearrangements, and reactivity, including oxidation and oxygenation, of this fascinating class of compounds. The chosen examples address paramagnetic organometallic nickel(II) and nickel(III) complexes of *N*-confused porphyrins, the reactions of nickel(II) dimethylated *N*-confused porphyrins with organometallic reagents, the stabilization of rare organocopper(II) species, the investigation of weak intramolecular metal–arene interactions, and the conformational flexibility of nickel(II) benziporphyrin and vacataporphyrin. Particular emphasis is placed on NMR studies as an efficient way of detecting intermediate species formed in the course of oxidation and oxygenation of iron(*n*) carbaporphyrinoids.

## Introduction

$^1$H NMR spectroscopy has been extensively applied to paramagnetic molecules including a variety of paramagnetic metalloproteins. The fundamental theoretical description of the electron–nucleus interaction, as reflected by the NMR parameters, illustrated by appropriate examples of applications has been presented in several monographic works.[1–10] In particular, the amount of NMR information provided by the contact shift and dipolar shift, and their temperature dependency, have been addressed. Relaxation phenomena related to the presence of unpaired electrons have also been a topic of some interest. Amongst others, the following subjects have been investigated: spin density delocalization correlated to the electronic structure, structural and electronic equilibria, the dynamics of intramolecular rearrangements, stereochemistry, solvation, and the structure of the second coordination sphere.

$^1$H NMR spectroscopy has been found to be a particularly useful method for detecting and characterizing iron complexes of porphyrins,[7] *N*-substituted porphyrins,[11–15] heteroporphyrins,[16–19] and hemoproteins in different coor-

*Ewa Dudziak (née Pacholska) was born in Wrocław, Poland, in 1969. She completed her PhD in 2000 under the supervision of Prof. Latos-Grażyński at the University of Wrocław, where she also obtained her BSc in 1993. She was a postdoctoral researcher in Dijon with Prof. Roger Guilard at the University of Burgundy, France. She is now working in Prof. Latos-Grażyński's group at the University of Wrocław on complexes of core-modified porphyrins with a flexible skeleton involved in organometallic coordination.*

*Professor Latos-Grażyński (the corresponding member of the Polish Academy of Sciences) is the Polish representative on the Editorial Board of this journal. Prof. Latos-Grażyński's involvement in porphyrin chemistry stems from his interest in the NMR of paramagnetic systems. Thus, much of his research has been devoted to the electronic structure and reactivity of paramagnetic metalloporphyrins, especially hemes. He has investigated model systems for heme enzymes, heme degradation, the activation of dioxygen by metalloporphyrins, the reactivity of metalloporphyrin π-radicals, and the properties of unusually oxidized systems, for example organocopper(II) species. The attention of Prof. Latos-Grażyński and his group is currently focused on the synthesis of novel porphyrinoids that have at least one of the regular pyrroles replaced by a carbo- or heterocyclic moiety. The organometallic species that can be made from carbaporphyrinoids are of special interest.*

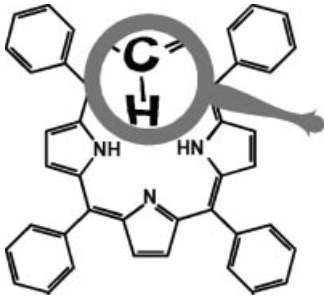
dination/oxidation states.[8,20] These studies have yielded an insight into the mechanisms of spin-density transfer in paramagnetic metalloporphyrins. In particular, it has been found that this technique is extremely sensitive toward fine structural effects such as substitution, electronic asymmetry, axial ligation (steric hindrance and basicity), or puckering of an equatorial macrocycle. Exchange and rotation of the molecular fragments have also been a subject of interest, and the intermediate iron porphyrin species that act in dioxygen activation or oxygen-atom transfer have been "trapped" by NMR spectroscopy.[21–23] Recently, octaethylporphyrin degradation (coupled oxidation) has been explored in order to establish the reactivity of iron complexes in various stages of heme degradation.[24–35] For instance, the paramagnetic shift patterns for the model iron octaethylbiliverdin-related radical complexes present several useful probes for detecting analogous species in hemoproteins by $^1$H NMR spectroscopy.[35]

Recent progress in the $^1$H NMR spectroscopic characterization of paramagnetic hemoproteins is related to the search for suitable spectroscopic models that involve the synthesis of fine-tuned iron porphyrins. These models mimic the spectroscopic properties encountered in hemoproteins for a given electronic state.[7] The application of two-dimensional techniques initially afforded an unambiguous assignment of resonances related to the active hemoprotein site and eventually yielded three-dimensional hemoprotein structures in solution.[8,20]

In light of the format of a microreview, here we intend to present an overview centered on our most recent efforts in the field of paramagnetic metallocarbaporphyrinoids, with a focus on the application of $^1$H NMR spectroscopy to this unique class of compounds. Thus, variations of the porphyrin core involving the introduction of a hydrocarbon unit in place of one of pyrrolic nitrogens have led to a new class of macrocycles − carbaporphyrinoids (Scheme 1) − that have interesting properties both in terms of their aromatic character and their potential ability to bind metal ions.[36,37]



Scheme 1. A carbaporphyrinoid.

Such a replacement preserves three regular pyrrole moieties while the ($C_n$NNN) core determines the monocarbaporphyrinoid structure.[38–45] The internal carbon atom(s) belong(s) to the carbo- or heterocycles that replace(s) the original pyrrole ring of the porphyrin. In general, carbaporphyrinoids provide a unique molecular platform that is suitable for exploring organometallic chemistry in a peculiar macrocyclic environment and forcing an unusual coordination geometry and/or oxidation state of the metal ions.[39–41,44,45] Systematic, comprehensive summaries of the current state-of-the-art in carbaporphyrinoid chemistry are contained in several review articles.[38–46]

## Carbaporphyrinoids

The synthesis of 2-aza-21-carba-5,10,15,20-tetraarylporphyrin ("inverted porphyrin", "*N*-confused porphyrin", "mutant porphyrin", "carbaporphyrin") was seminal for the field of cabaporphyrinoids.[36,37] An inverted porphyrin is a constitutional isomer of a porphyrin which preserves its general structural framework.[46,47] The synthesis of this molecule prompted intense synthetic work to generate a whole class of carbaporphyrinoids.[36–40,43–45,48–50]

Here, we have gathered together the representative structures of two tautomers of this *N*-confused porphyrin, namely (CP*H*)H$_2$ and (*H*CP*H*)H,[36,37] and the alkylated *N*-confused porphyrins (*R*CP*H*)H, (CP*R*)H$_2$ and (*R*CP*R*$_1$)-H,[44,51–55] *m*-benziporphyrin (*m*BP*H*)H,[56] *m*-benziporphodimethene (*m*BDM*H*)H,[57] *p*-benziporphyrin (*p*BP*H*$_2$)H,[57] vacataporphyrin (VP*H*$_2$)H,[58] and *N*-confused pyriporphyrin (*N*PyP*H*)H (3-aza-*m*-benziporphyrin)[59] that have been used in our laboratory to synthesize paramagnetic compounds for subsequent NMR investigation (Scheme 2).

We will use the symbol CP to denote the trianion obtained from the inverted porphyrin by abstraction of all pyrrolic NH protons and the *C*-bound H(21) hydrogen. The groups attached to the N(2) atom are indicated by a prefix in italics and the group attached to C(21) as a suffix in italics. A similar method is used to form acronyms for other carbaporphynoids, as shown above.

## Paramagnetic Organometallic Nickel(II) *N*-Confused Porphyrin Derivatives

Methylation of a diamagnetic nickel(II) complex of [(*H*CP)Ni$^{II}$] with methyl iodide yields stable organonickel-(II) complexes (Scheme 3), namely diamagnetic [(CP*Me*)-Ni$^{II}$] and the two paramagnetic species [(*H*CP*Me*)Ni$^{II}$X] (X = Cl, I) and [(*Me*CP*Me*)Ni$^{II}$I].[52]

The mechanism of this methylation involves oxidative addition of the methyl cation to the carbaporphyrin C(21), which is activated due to Ni–C coordination. The concerted reversible addition of HX converts diamagnetic [(CP*Me*)-Ni$^{II}$] into paramagnetic [(*H*CP*Me*)Ni$^{II}$X]. The axial coordination step is accompanied by protonation of the peripheral nitrogen. The $^1$H and $^2$H NMR spectra of paramagnetic [(*H*CP*Me*)Ni$^{II}$X] and [(*Me*CP*Me*)Ni$^{II}$I] were analyzed by considering their $C_1$ symmetry (Figure 1). There are seven distinct pyrrole C-H positions for [(*H*CP*Me*)Ni$^{II}$X], an NH(2) position analogous to the CH(2) of the regular porphyrin, and four inequivalent *meso*-aryl rings. The resonances were assigned by making use of selective deuteration and 2D COSY experiments. Thus, the characteristic pattern of six downfield-shifted pyrrole resonances accompanied by

upfield-shifted H(3) and NH(2) resonances is diagnostic of *C*-methylation. The most characteristic feature, namely the broad downfield resonance (linewidth: 1320 Hz) at $\delta$ = 109.7 ppm, was assigned to the 21-Me group.

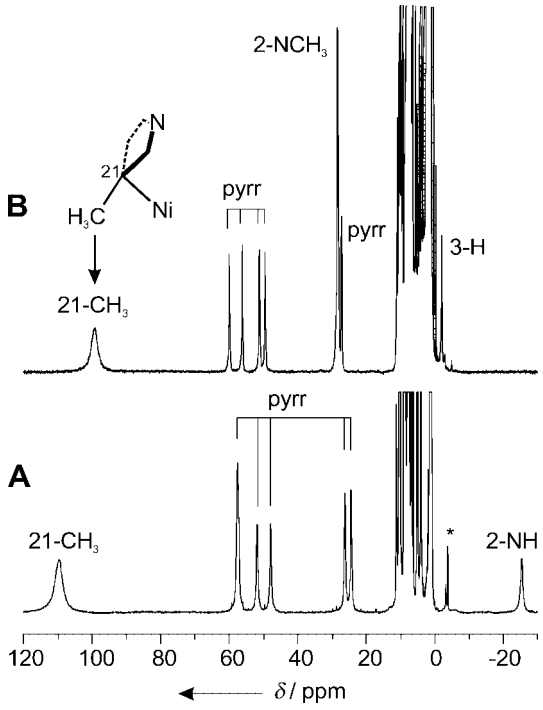

Figure 1. $^1$H NMR spectra ($CDCl_3$, 293 K) of paramagnetic mono- and dimethylated nickel(II) carbaporphyrins [(*H*CP*Me*)Ni$^{II}$Cl] (A) and [(*Me*CP*Me*)Ni$^{II}$I] (B). The peak labels follow systematic numbering of the porphyrin ring or denote proton groups; pyrr: regular pyrrole ring protons. Reproduced, with permission, from ref.[52] Copyright 1996 American Chemical Society.

As in the case of methylation, the reaction of [(*H*CP)-Ni$^{II}$] with haloalkanes in the presence of proton scavengers yielded the C(21)-alkylated complexes [(CP*CH$_2$R*)Ni$^{II}$]. Protonation of the external nitrogen of the inverted pyrrole during HX addition (X = Cl, I) combines with coordination of the apical ligand and leads to paramagnetic nickel(II) complexes. A very strong differentiation of the isotropic shift for the diastereotopic methylene protons was observed in the $^1$H NMR spectra of the protonated paramagnetic species [(*H*CP*CH$_2$*R)Ni$^{II}$X].[54]

The downfield shift of the pyrrolic and *C*-methyl resonances of [(*Me*CP*Me*)Ni$^{II}$X] indicates a σ-delocalization of the spin density. This is consistent with the ground state of Ni$^{II}$, which has two unpaired electrons in the σ-symmetry orbitals $(d_{x^2-y^2})^1(d_{z^2})^1$. The large differences in β-H contact shifts result from the π-spin density delocalized into the porphyrin framework, which originates from the peculiar spin-density transfer within the inverted pyrrole ring. The isotropic shift of the inverted *C*-methylated pyrrole ring is of significance with respect to the nature of the Ni–inverted pyrrole interaction in this paramagnetic organonickel(II) complex. The considerable downfield C(21)-$CH_3$ shift can be accounted for by direct σ-delocalization over three single bonds in the Ni–C(21)–$C_{(methyl)}$–H fragment. The tilt of the inverted *C*-methylated ring changes the geometry of the spin-density delocalization path as compared to regular pyrrole rings. The unpaired spin density is localized on the molecular orbital dominated by the $p_z$ component, which can transfer the σ-spin density but simultaneously contributes to π-orbitals of the inverted pyrrole ring. Such an overlap within the inverted ring will permit direct transfer of the unpaired spin density of the C(21) $p_z$ into the π system without any π M–L bonding.

## Organometallic Ni$^{III}$ Complexes

The one-electron oxidation of [(*H*CP)Ni$^{II}$] and [(*Me*CP)-Ni$^{II}$] results in the formation of extremely rare organonickel(III) derivatives.[60] The EPR spectral patterns of the one-electron-oxidized species depend on the axial ligand introduced by the oxidant or by metathesis. In each case the spin-Hamiltonian parameters [$g_{av} > 2.1$ (77 K) or $g_{iso} > 2.1$ (298 K)] reveal a metal-centered oxidation rather than formation of a radical cation ($g_{iso} \approx 2.002$). The localization of the one-electron oxidation on the nickel ion was supported by analysis of the observed $^{61}$Ni hyperfine splitting. $^2$H NMR spectroscopy was used as an independent probe to determine the electronic structure of the nickel(III). Such an approach can be complementary to the EPR studies and allows a direct observation of the spin-density delocalization on the macrocycle.

In light of the EPR results two representative species, namely [($D_7$-*H*CP)Ni$^{III}$Br] and [($D_7$-*H*CP)Ni$^{III}$($NO_3$)] were selected for $^2$H NMR investigation [($D_7$-*H*CP)H has all β-positions substituted with deuterium]. The well-resolved EPR spectra of this complex suggest that its $^1$H NMR resonances could be beyond detection due to the relatively long electron spin-lattice relaxation time $T_{1e}$.[9] Line widths for deuterium resonances are theoretically predicted to be 42 times smaller than the corresponding proton resonances due to the different electron-nuclear dipolar relaxation.[61] This narrowing has been observed experimentally for many paramagnetic species and renders $^2$H NMR spectroscopy particularly useful in detecting those paramagnetically broadened resonances that are visible in the $^1$H NMR spectrum.

In the case of [($D_7$-*H*CP)Ni$^{III}$Br], all resonance peaks assigned to the pyrrole deuterons are located within the region $\delta$ = 2–8 ppm that is consistent with the $(d_{z^2})^1$ formulation of the electronic ground state (Figure 2, trace A). No spin density is present in the β-pyrrole positions since there is no overlap of the metal out-of-plane orbital with the ligand orbital. On the contrary, all but one pyrrole resonances of [($D_7$-*H*CP)Ni$^{III}$($NO_3$)] are shifted downfield and are widely spread, covering the $\delta$ = 0–50 ppm region (Figure 2, trace B). This downfield shift of the pyrrole resonances is indicative of σ-delocalization of the spin density and requires a considerable $d_{x^2-y^2}$ metal orbital contribution to the SOMO, as determined previously by EPR spectroscopy.

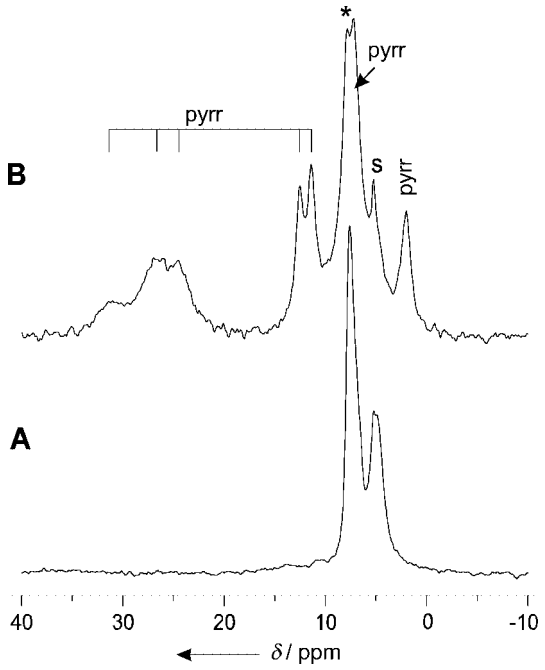

Figure 2. $^2$H NMR spectra (298 K in $CH_2Cl_2$) of [($D_7$-*H*CP)-$Ni^{III}$Br] (A) and [($D_7$-*H*CP)$Ni^{III}(NO_3)$] (B); s: solvent. Reproduced, with permission, from ref.[60] Copyright 1997 American Chemical Society.

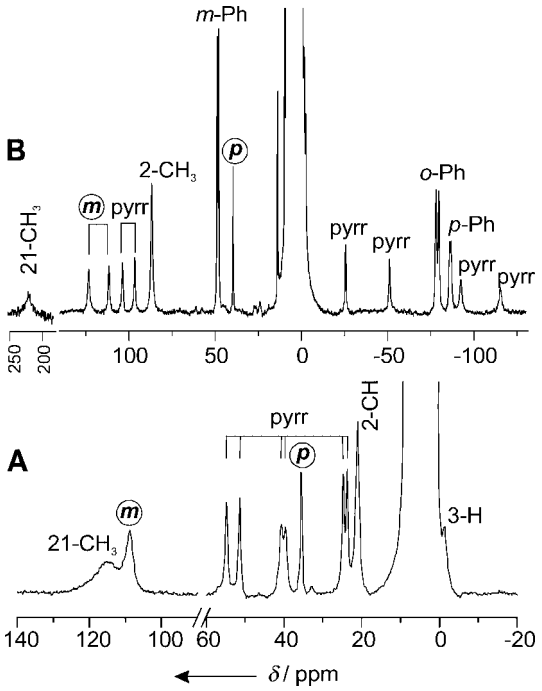

Figure 3. $^1$H NMR spectra of [(*Me*CP*Me*)$Ni^{II}$Ph] (A; 293 K, $C_7D_8$) and [(*Me*CP*Me*)$Ni^{II}$Ph]$^-$ (B; $C_7D_8$, 253 K) formed by treating [(*Me*CP*Me*)$Ni^{II}$Cl] with phenyllithium in toluene at 203 K. The peaks of the Ni-coordinated phenyl group are marked by circles. Reproduced, with permission, from ref.[62] Copyright 2000 American Chemical Society.

## Reactions of [(*Me*CP*Me*)$Ni^{II}$Cl] with Organometallic Reagents

Addition of phenylmagnesium iodide to a toluene solution of the nickel(II) chloride complex of dimethylated inverted porphyrin [(*Me*CP*Me*)$Ni^{II}$Cl] at 203 K results in the formation of a rare paramagnetic σ-phenylnickel(II) species [(*Me*CP*Me*)$Ni^{II}$Ph], which contains both equatorial and apical $Ni^{II}$–C bonds.[62] The coordination of the σ-phenyl group was determined by the unique pattern of three σ-phenyl resonances (*ortho*: $\delta$ = 361.3 ppm; *meta*: $\delta$ = 103.2 ppm; *para*: $\delta$ = 34.8 ppm at 273 K) in the $^1$H and $^2$H NMR spectra (Figure 3).

Predictably, the first step in the titration with phenyllithium results in the formation of [(*Me*CP*Me*)$Ni^{II}$Ph] and the subsequent one-electron reduction with excess PhLi yields [(*Me*CP*Me*)$Ni^{II}$Ph]$^-$, which can also be generated by an independent route, namely by reduction of [(*Me*CP*Me*)-$Ni^{II}$Ph] with lithium triethylborohydride or tetrabutylammonium borohydride. The spectroscopic data (Figure 3, trace B) indicate that [(*Me*CP*Me*)$Ni^{II}$Ph] undergoes a one-electron reduction without a substantial disruption of the molecular geometry. The presence of two paramagnetic centers in [(*Me*CP*Me*)$Ni^{II}$Ph]$^-$, namely the high-spin nickel(II) and the carbaporphyrin radical anion, produces a remarkable variation in the spectral pattern, such as upfield and downfield positions of the pyrrole resonances and a sign alternation of the *meso*-phenyl resonances.

A single species was detected in the $^1$H NMR titration of [(*Me*CP*Me*)$Ni^{II}$Cl] with *n*-butyllithium. The formation of the one- or two-electron-reduced species {[(*Me*CP*Me*)-$Ni^{II}$Bu]$^-$ or [(*Me*CP*Me*)$Ni^{II}$Bu]$^{2-}$, respectively} can be considered to account for the peculiar spectroscopic properties [pyrrole: $\delta$ = 17.33, 15.45, –5.79, –7.74, –14.62, –58.14 ppm; $CH_3$(21): $\delta$ = 3 ppm at 203 K]. The temperature dependencies of the hyperfine shifts demonstrate the pronounced anti-Curie behavior, which was interpreted in terms of a temperature-dependent spin equilibrium.

## Organocopper(II) *N*-Confused Porphyrin and Its Methylated Derivatives

The inverted porphyrin and its methylated derivatives stabilize the rare organocopper(II) complexes [(*H*CP)$Cu^{II}$], [(*Me*CP)$Cu^{II}$], [(*H*CP*H*)$Cu^{II}$X], [(*Me*CP*H*)$Cu^{II}$X] (X = $Cl^-$, $CF_3CO_2^-$), and [(*Me*CP*Me*)$Cu^{II}$Cl].[63] The EPR spectra of these complexes reveal typical features that are diagnostic of the copper(II) electronic structure.[63] In particular, the superhyperfine coupling pattern indicates the presence of three nitrogen donors in the first coordination sphere.[63,64] Addition of an acid (HX) to [(*H*CP)$Cu^{II}$] and [(*Me*CP)$Cu^{II}$] yields [(*H*CP*H*)$Cu^{II}$X] and [(*Me*CP*H*)$Cu^{II}$X], respectively. The mechanism of this reaction includes protonation of the inner C(21) accompanied by an axial coordination of the anion. The $^2$H NMR investigations (Figure 4) carried out for the pyrrole deuterated derivatives [($D_7$-CP)$Cu^{II}$] and [($D_7$-*Me*CP*Me*)$Cu^{II}$Cl] and the methyl deuterated complex

## Nickel(II) Complexes of Benziporphyrins – A Study of Weak Intramolecular Metal–Arene Interactions

Owing to the nonplanar coordination geometry of the metal ion the nickel complexes [(*m*BP*H*)$Ni^{II}$Cl] and [(*p*BP$H_2$)$Ni^{II}$Cl] are all paramagnetic, with $S = 1$.[65] The $^1$H NMR spectra shown in Figure 5 correspond to effective $C_s$ symmetry of the molecules. The observed pattern of chemical shifts is typical for high-spin $Ni^{II}$ complexes of porphyrins and porphyrin analogues, with most of the β-H pyrrole resonances in the downfield region ($\delta$ = 10–60 ppm) and the *meso*-aryl peaks in the range $\delta$ = 0–10 ppm.[39] A similar spectroscopic pattern has been observed for [(*m*BP*OAc*)$Ni^{II}$Cl].[66] Almost complete assignment of these signals was achieved from the 2D COSY spectrum.

The shifts of the *m*-phenylene protons of [(*m*BP*H*)$Ni^{II}$Cl] are of special interest. The signals for H(2,4) and H(3) show evident sign alteration ($\delta$ = 22.5 and –40.8 ppm at 298 K, respectively). The broadened signal, which is shifted to $\delta$ = 386 ppm in the spectrum of [(*m*BP*H*)$Ni^{II}$Cl] (298 K), is assigned to the inner H(22). This is easily verified by acidifying a solution of ([*m*BP)$Ni^{II}$] with DCl rather than HCl. The resulting species, [(*m*BP*D*)$Ni^{II}$Cl], is selectively deuterated at position 22 and no low-field signal is observed. The above assignment also relied on the significant broadening of the H(22) signal relative to H(2,4), which is caused by the proximity of the paramagnetic $Ni^{II}$ center. This argument was reinforced by a quantitative analysis of relaxation times, which yielded approximate distances between the nickel ion and certain protons in the molecule (Figure 6).[2,5,65] The $^1$H NMR spectrum of [(*p*BP$H_2$)$Ni^{II}$Cl] appears to be similar to the preceding spectrum of [(*m*BP*H*)-$Ni^{II}$Cl] except that the *p*-phenylene resonances H(2,3) and H(21,22) are located at $\delta$ = –10.5 and 0.0 ppm, respectively (298 K), rather than in the far downfield region.

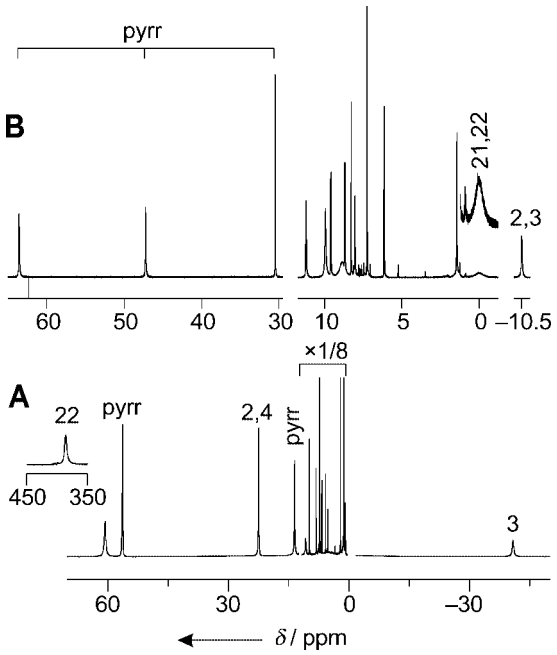

Figure 5. $^1$H NMR spectra ($CDCl_3$, 298 K) of [(*m*BP*H*)$Ni^{II}$Cl] (A) and [(*p*BP$H_2$)$Ni^{II}$Cl] (B). Reproduced, with permission, from ref.[65] Copyright 2004 American Chemical Society.

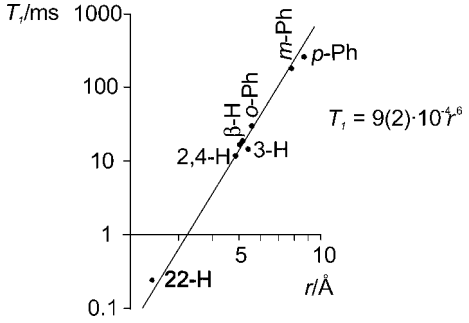

Figure 6. Relaxation plots for [(*m*BP*H*)$Ni^{II}$Cl]. The dependence between $T_1$ ($CDCl_3$, 298 K) and *r* (crystal structure averages) is linear in bilogarithmic axes.[65] Reproduced, with permission, from ref.[65] Copyright 2004 American Chemical Society.

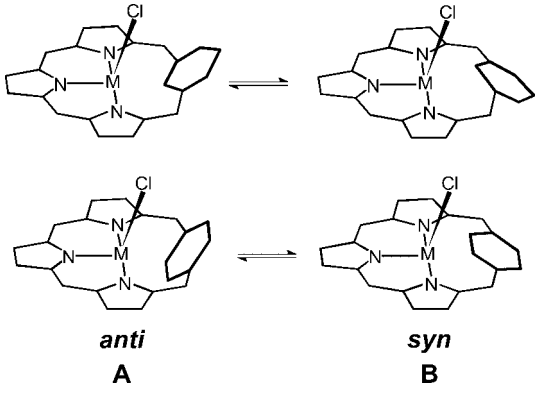
X-ray studies performed on [(*m*BP*H*)$Ni^{II}$Cl] show that the arene fragment approaches the metal ion at a distance much shorter than the sum of the van der Waals radii, which corresponds to the formation of a weak agostic bond. Consequently, an agostic mechanism of spin-density transfer was proposed to explain the enormous H(22) shift as a result of electron donation from the CH bond to the metal. To account for the shifts of protons H(2,4) and H(3) it is necessary to assume π delocalization into the arene ring, which may result either from direct interaction with the metal center or from σ-π polarization.

## Conformational Flexibility of Nickel(II) Benziporphyrins

The linewidths of certain signals for [(*m*BP*H*)$Ni^{II}$Cl] and [(*p*BP$H_2$)$Ni^{II}$Cl] exhibit an unusual temperature depen-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dence that is characteristic of a dynamic process.[67] This was interpreted in terms of an equilibrium wherein one of the forms is present at a very small concentration and cannot be observed directly. The two exchanging forms are only present at comparable concentrations, and therefore yield separate signals in the slow exchange limit, for the nickel(II) benziporphodimethene complex [(*m*BDM*H*)-Ni$^{II}$Cl]. A mechanism involving motion of the phenylene moiety was proposed to account for the observed exchange process (Scheme 4).



Scheme 4. Conformational equilibria in [(*m*BDM*H*)Ni$^{II}$Cl].

The temperature-dependence of the linewidths in the $^1$H NMR spectrum of [(*m*BP*H*)Ni$^{II}$Cl] is shown in Figure 7 for the *m*-phenylene H(2,4) signal. The logarithm of $\nu_{1/2}$ is plotted against $T^{-1}$ as this has often been found to yield a linear plot for a paramagnetic species in the absence of chemical exchange.[68,69]

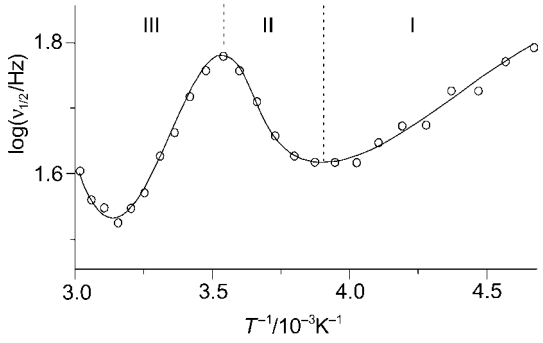


Figure 7. Temperature dependence of the linewidths in the $^1$H NMR spectrum for H(2,4) of [(*m*BP*H*)Ni$^{II}$Cl] ($CDCl_3$, 213–333 K). The continuous line is for illustrative purposes only. Reproduced, with permission, from ref.[67] Copyright 2004 American Chemical Society.

The temperature profile (regions I–III) corresponds to an exchange process between two paramagnetic species A and B, one of which is significantly less populated ($P_A >> P_B$) and thus impossible to observe directly.[5,61,68] The dynamic process is slow in region I and the observed dependence may therefore be attributed solely to paramagnetic broadening and extrapolated into regions II and III.[68] The analysis concentrated on region II, which corresponds to the slow-exchange limit between A and B. The pre-exchange lifetime for A ($\tau_A$) was obtained experimentally by determining line widths, $\nu_{1/2,A,i}$, over a wide temperature range, and an Eyring plot of the [(*m*BP*H*)Ni$^{II}$Cl] data for region II collected in deuterated chloroform yielded the activation parameters. The values $\Delta H^{\ddagger}$ = 63 kJ mol$^{-1}$ and $\Delta S^{\ddagger}$ = 20 J/mol K yield a $\Delta G^{\ddagger}$ of 57 kJ mol$^{-1}$ (298 K). These values are in the range found for various dynamic processes observed in porphyrins, including rotation of *meso*-aryl substituents and macrocycle inversion.[70–72]

Benziporphyrin macrocycles are generally more flexible than regular porphyrins, as can be judged from the puckered structures observed in the solid state for free bases and their complexes.[56,57,65,66] This is a result of the loss (or decrease) of macrocyclic aromaticity combined with the steric constraints generated by the introduction of a phenylene ring into the macrocyclic structure. Conformational dynamics involves puckering of the benziporphyrin macrocycle, rotation of *meso*-aryl rings, or both. The preferred conformation of the macrocycle in the metal complexes [(*m*BP*H*)-Ni$^{II}$Cl] and [(*p*BP$H_2$)Ni$^{II}$Cl] has the phenylene ring tilted away from the metal center with the inner CH bonds and the axial MX bond in an *anti* orientation (Scheme 4), as confirmed by their respective X-ray structures.[57,65] However, it is possible that minute amounts of *syn* conformers may be present in solution and rapidly equilibrate with the respective *anti* forms. Actually the DFT modeling, carried out for benziporphyrin complexes of zinc(II) and cadmium(II), indicates that the postulated *syn* conformers are thermally accessible.

## Two Coordination Modes of Vacataporphyrin

5,10,15,20-Tetraaryl-21-vacataporphyrin (butadieneporphyrin, annulene-porphyrin hybrid),[58] which contains a vacant space instead of a heteroatomic bridge, forms paramagnetic nickel(II) complexes where a metal ion is bound in the macrocyclic cavity by three pyrrolic nitrogens.[73] Coordination imposes a steric constraint on the geometry of the ligand and leads to two directly detectable stereoisomers with the butadiene fragment oriented towards [(VP$H_2$)-Ni$^{II}$Cl-*i*] or away from [(VP$H_2$)Ni$^{II}$Cl-*o*] the macrocyclic center (Scheme 5).

The specific assignment of two sets of resonances to [(VP$H_2$)Ni$^{II}$Cl-*o*] and [(VP$H_2$)Ni$^{II}$Cl-*i*] (Figure 8) was based on the notion that the butadiene fragment in the folded conformation of [(VP$H_2$)Ni$^{II}$Cl-*i*] blocks the coordination of the second axial ligand, which contrasts with the behavior of [(VP$H_2$)Ni$^{II}$Cl-*o*].

The H(2,3) signals of [(VP$H_2$)Ni$^{II}$Cl-*o*] or [(VP$H_2$)-Ni$^{II}$Cl-*i*] have chemical shifts that are typical for the β-H pyrrolic positions of nickel(II) 21-heteroporphyrins in spite of the vacancy.[39] The extremely broad H(1,4) signal of [(VPH$_2$)Ni$^{II}$Cl-*o*] was detected by $^2$H NMR spectroscopy at $\delta$ = –3.5 ppm (298 K).

A plot of $\log \nu_{1/2}$ against $T^{-1}$ yields a straight line for [(VP$H_2$)Ni$^{II}$Cl-*i*], which suggests the absence of any chemical exchange.[18,19,39,52,67–69,74] On the other hand, the line widths of certain signals of [(VP$H_2$)Ni$^{II}$Cl-*o*] exhibit an un-

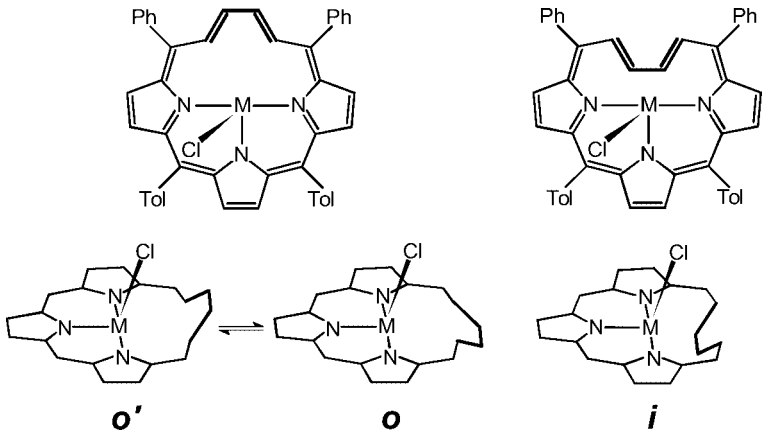

Scheme 5. Stereoisomers of [(VP$H_2$)Ni$^{II}$Cl]. Reproduced, with permission, from ref.[73] Copyright 2005 American Chemical Society.

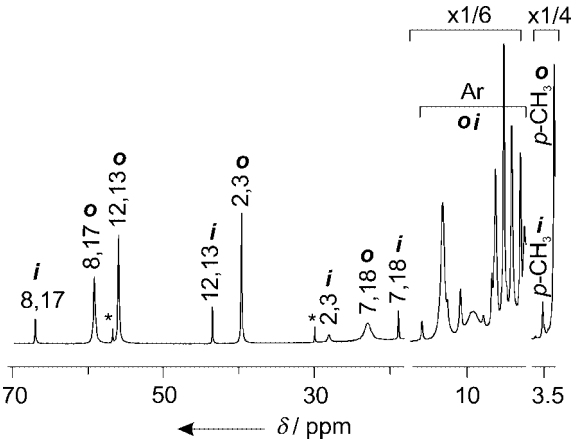

Figure 8. $^1$H NMR spectra of [(VP$H_2$)Ni$^{II}$Cl] ($CDCl_3$, 298 K). The resonances of the different stereoisomers are marked. Reproduced, with permission, from ref.[73] Copyright 2005 American Chemical Society.

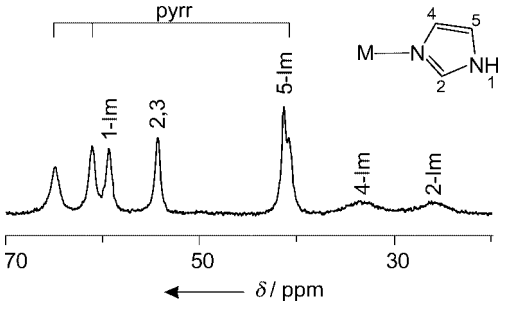

Figure 9. $^1$H NMR ($CDCl_3$, 298 K) spectra of [(VP$H_2$)Ni$^{II}$Cl] in the presence of imidazole. The molar ratio (VP$H_2$)Ni$^{II}$Cl/imidazole is 1:2.5. Reproduced, with permission, from ref.[73] Copyright 2005 American Chemical Society.

usual temperature dependence that is characteristic of a dynamic process.[67–69] This behavior can be interpreted in terms of a conformational equilibrium in which one of the forms is present at a very low concentration.[5,61,68] The conformational equilibrium presented in Scheme 5 may contribute to this mechanism providing that the concentration of [(VP$H_2$)Ni$^{II}$Cl-*o*] is much greater than that of [(VP$H_2$)Ni$^{II}$Cl-*o′*] and that the process is in the slow-exchange limit. Thus, two co-existing stereoisomers reveal a different conformational flexibility in the same solution.

The markedly different spectra of [(VP$H_2$)Ni$^{II}$Cl-*i*] in [$D_4$]MeOH or [$D_3$]acetonitrile as compared to chlorinated solvents are attributed to an axial coordination of two solvent molecules and formation of a single species, namely [(VP$H_2$)Ni$^{II}$($CD_3OD$)$_2$]$^+$ or [(VP$H_2$)Ni$^{II}$($CD_3CN$)$_2$]$^+$. Similarly, the addition of two equivalents of imidazole converts [(VP$H_2$)Ni$^{II}$Cl-*o*] and [(VP$H_2$)Ni$^{II}$Cl-*i*] into [(VP$H_2$)-Ni$^{II}$(Im)$_2$]$^+$ (Figure 9). All resonances of the coordinated imidazole are clearly discernible and have been assigned by line width analysis and selective deuteration. Their positions are similar to those determined for other imidazole adducts of nickel(II) heteroporphyrins.[75]

## Iron(II) Complexes of Benziporphyrins

The molecular structure of [(*m*BP*H*)Fe$^{II}$Br] resembles that of [(*m*BP*H*)Ni$^{II}$Cl].[65,76] The distances between iron and the pyrrolic nitrogens are in the range for high-spin Fe$^{II}$ porphyrin complexes and the tripyrrolic fragment arranges in a dome-shaped geometry. The distances from iron to the inner C atom [C(22)] and inner hydrogen [H(22)] are 2.579(4) and 2.439(36) Å, respectively. Nevertheless, these values are small compared to the van der Waals contact and suggest the formation of a weak agostic bond.

The β-pyrrolic signals in the $^1$H NMR spectrum of [(*m*BP*H*)Fe$^{II}$Br] (Figure 10) are located at $\delta$ = 49.4, 21.1, and 6.5 ppm at 298 K, as shown by $^2$H NMR spectroscopy for [($D_6$-*m*BP*H*)Fe$^{II}$Br].[76] These values are close to those reported for the high-spin nickel(II) complexes [(*m*BP*OAc*)-Ni$^{II}$Cl] and [(*m*BP*H*)Ni$^{II}$Cl].[65,66] The hydrogens on the *m*-phenylene ring were identified at $\delta$ = 440 [H(22)], 65.8 [H(2,4)], and –33.2 [H(3)] ppm (298 K). An agostic mechanism of spin-density transfer, as described previously for [(*m*BP*H*)Ni$^{II}$Cl], explains the shifts of [(*m*BP*H*)Fe$^{II}$Br] as resulting from electron donation from the C–H bond to the metal.

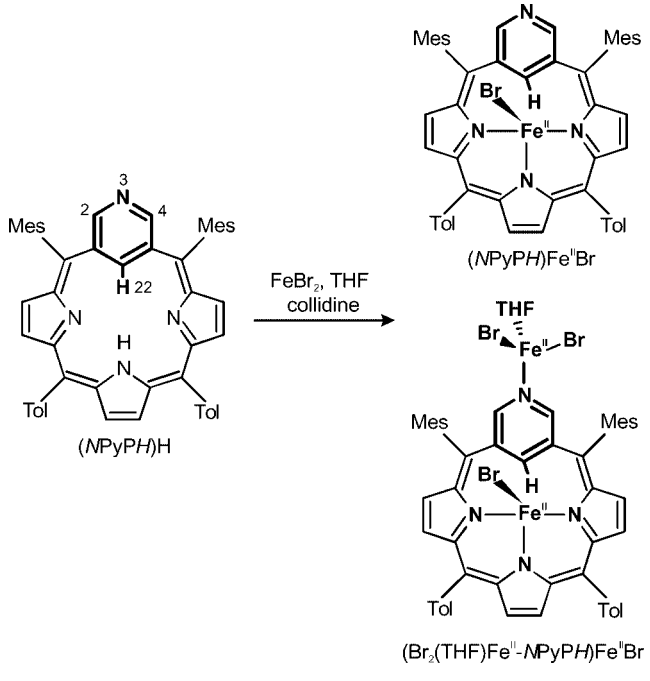
## High-Spin Iron Complexes of *N*-Confused Pyriporphyrin

Insertion of iron(II) into *N*-confused pyriporphyrin, which is the simplest homologue of *N*-confused 5,10,15,20-tetraarylporphyrin, yields the high-spin iron(II) complex [(*N*PyP*H*)Fe$^{II}$Br] and the diiron species [(Br$_2$LFe$^{II}$-*N*PyP*H*)Fe$^{II}$Br] (L = coordinating solvent) where the second iron(II) coordinates to the perimeter nitrogen atom (Scheme 6).[77]



Scheme 6. Synthesis of iron(II) *N*-confused pyriporphyrin complexes. Reproduced, with permission, from ref.[77] Copyright 2006 American Chemical Society.

The characteristic patterns of the pyrrole and pyridine resonances in the $^1$H NMR spectra were found to be diagnostic of the ground electronic state of iron and the donor properties of C(22)–H and N(3) centers (Figure 11). The downfield H(22) resonances, which are found for iron(II) *N*-confused pyriporphyrin in a very unusual spectroscopic window ($\delta$ = 350–800 ppm) for a range of axial ligands, can be considered as a diagnostic sign of an agostic Fe$^{II}$–{C(22)-H} interaction.[76]

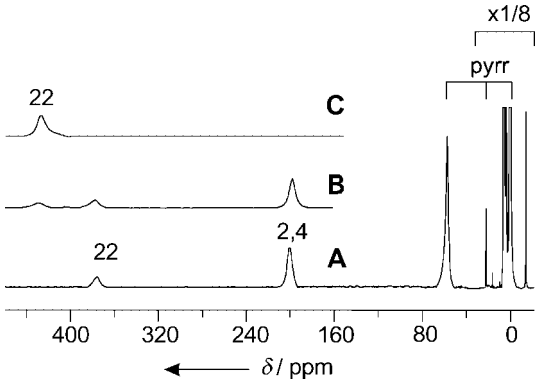


Figure 11. (A) $^1$H NMR spectrum of [(Br$_2$LFe$^{II}$-*N*PyP*H*)Fe$^{II}$Br]; (B) conversion of [(Br$_2$LFe$^{II}$-*N*PyP)Fe$^{II}$Br] into [(*N*PyP)Fe$^{II}$Br] during titration with Br$_2$; (C) [(*N*PyP)Fe$^{II}$Br]. All spectra were recorded in $CD_2Cl_2$ at 298 K; L = thf. Reproduced, with permission, from ref.[77] Copyright 2006 American Chemical Society.

To probe the ability of the perimeter nitrogen to bind iron(II) a systematic titration of [(*N*PyP*H*)Fe$^{II}$Cl] in [D$_3$]-acetonitrile or [D$_8$]THF was carried out. Smooth changes of the chemical shifts of the pyridine moiety directly engaged in coordination were observed during the course of the titration of [(*N*PyP*H*)Fe$^{II}$Cl] with Fe$^{II}$Cl$_2$, which was explained by an equilibrium involving a diiron species.

The spectroscopic pattern of [(Br$_2$LFe$^{II}$-*N*PyP*H*)Fe$^{II}$Br] in non-coordinating solvents resembles that of the monoiron species [(*N*PyP*H*)Fe$^{II}$Br], although the H(2,4) resonance is remarkably shifted to $\delta$ = 201 ppm (298 K; Figure 11). [(Br$_2$LFe$^{II}$-*N*PyP)Fe$^{II}$Br] can be easily converted into [(*N*PyP)Fe$^{II}$Br] by addition of competing ligands (pyridine) or by an external iron(II)-directed oxidation, which promotes dissociation. In spite of the enormous line widths the far downfield shifted resonances provide an analytically valuable pattern that is unique for the *N*-confused diiron species. The downfield position of the H(2,4) resonance for [(Br$_2$LFe$^{II}$-*N*PyP)Fe$^{II}$Br] is consistent with coordination to the high-spin iron(II) assuming that the spin-delocalization pathways are identical to that determined for nickel(II) thiaporphyrin.[78]

Addition of Br$_2$ to a solution of [(*N*PyP*H*)Fe$^{II}$Br] in the absence of dioxygen results in a one-electron oxidation that yields the high-spin iron(III) *N*-confused pyriporpyrin [(*N*PyP*H*)Fe$^{III}$Br]$^+$ (Scheme 7). The high-spin complex preserves the side-on interaction between the inverted pyridine ring and iron(III) as in [(*N*PyP*H*)Fe$^{II}$Br]. The characteristic set of three pyrrole resonances at $\delta$ = 122.4, 79.6 and 70.4 ppm ([D$_2$]dichloromethane, 298 K) can be readily assigned to [(*N*PyP)Fe$^{III}$Br]$^+$. The reaction of [(*N*PyP*H*)-Fe$^{II}$Br] with dioxygen results in the formation of five-coordinate [(*N*PyPO)Fe$^{III}$Br] [(*N*PyPO*H*)H = 3-aza-22-hydroxy-*m*-benziporphyrin; Scheme 7].

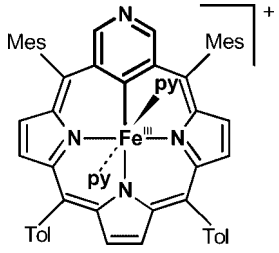
## Low-Spin Organoiron(III) *N*-Confused Pyriporphyrin

The one-electron oxidation of [(*N*PyPH)Fe$^{II}$Br] with dioxygen in pyridine, which is accompanied by deprotonation of a C(22)H fragment and formation of an Fe–C(22) bond, produces the low-spin, six-coordinate iron(III) complex [(*N*PyP)Fe$^{III}$(py)$_2$]$^+$ (Scheme 8), as confirmed by a combination of $^1$H NMR, EPR and structural data.[79]



Scheme 8. [(*N*PyP)Fe$^{III}$(py)$_2$]$^+$.

The cationic complex involves a six-coordinate iron atom bound to the *N*-confused pyriporphyrin through its three pyrrolic nitrogens and the trigonal pyridyl C(22) atom. The porphyrin is strongly ruffled, defining two deep grooves along the $C_{meso}$–$C_{meso}$ axes that are at right angles to each other. The $^1$H NMR spectrum of [(PyP)Fe$^{III}$(D$_5$-py)$_2$]$^+$ is clearly distinct from that of any known low-spin iron(III) porphyrin [β-H: $\delta$ = 21.3, 16.2, and 4.1 ppm ($CD_2Cl_2$, 298 K)]. In fact, only the recently described low-spin iron(III) complex of the "true" pyriporphyrin reveals a similar $^1$H NMR spectrum.[80] Still, the spectroscopic pattern of the pyrrole and *meso*-aryl resonances is consistent with the features assigned to the less common $(d_{xz}d_{yz})^4(d_{xy})^1$ low-spin ground electronic state.[7,81–83] This unique spectroscopic feature can be related to the extensive ruffling of the macrocycle,[82,84–86] equatorial C-coordination, and/or axial pyridine coordination.[7] A conformational rearrangement process was detected which involves two structures differentiated by macrocyclic ruffling.

## Remarkable Paramagnetically Shifted $^1$H and $^2$H NMR Spectra of Iron(II) 2-Aza-21-carbaporphyrin

An uncommon type of metal ion–inverted pyrrole ring interaction detected in the solid-state structure of iron(II) 2-aza-21-carbaporphyrin [(*H*CP*H*)Fe$^{II}$Br] has raised the question of its impact on the $^1$H NMR spectroscopic features.[87,88] [(*H*CP*H*)Fe$^{II}$Br] has a conformation where the iron is side-on with respect to the inverted pyrrole plane[87] and the inverted pyrrole ring is sharply bent from the porphyrin plane. The Fe···C(21) distance (2.361 Å) is longer than a regular Fe–C bond but shorter than the sum of the van der Waals radii.

The solid-state geometry of the Fe$^{II}$···{C(21)–H(21)} fragment in [(*H*CP*H*)Fe$^{II}$Br] is within the range of an agostic interaction [Fe···H(21) = 1.971 Å].[87] The $^1$H NMR spectrum of [(*H*CP*H*)Fe$^{II}$Br] is substantially similar to the spectra of high-spin iron(II) core-modified porphyrins.[14,16,89] Five pyrrole resonances of [(*H*CP*H*)Fe$^{II}$Br] are spread over the low-field region from $\delta$ = 30 to 50 ppm, and two other β-H resonances occur at $\delta$ = 8.4 and 0.78 ppm. The resonance at $\delta$ = –8.0 ppm (293 K) was assigned to the N(2)H hydrogen. The most characteristic $^1$H NMR ($^2$H NMR) feature of [(*H*CP*H*)Fe$^{II}$Br], namely the downfield shifted resonance at $\delta$ = 812 ppm (linewidth of 6200 Hz at 293 K in [D$_2$]dichloromethane), was unambiguously assigned to the internal H(21) hydrogen.[88] The $^2$H NMR spectrum of [(D$_7$-*H*CP*D*)Fe$^{II}$Br], which stretches over a window of almost 900 ppm, shows the remarkably large paramagnetic shift of C(21)D, as the $^2$H NMR spectrum

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

combines simultaneously all pyrrole resonances, including the C(21)D one (Figure 12). Variable-temperature NMR measurements for the C(21)H resonance of [(*H*CP*H*)Fe$^{II}$Br] revealed remarkable changes of the chemical shifts, which fall in a window of 1244 ppm at 208 K. Addition of 2-methylimidazole to a [$D_2$]dichloromethane solution of [(*H*CP*H*)Fe$^{II}$Br] results in the formation of the high-spin five-coordinate species [(*H*CP*H*)Fe$^{II}$(2-MeIm)]$^+$, which was identified by the unique chemical shift of the C(21)H resonance ($\delta$ = 1090 ppm). To the best of our knowledge these are the largest chemical shifts reported thus far for iron porphyrins or iron porphyrin derivatives[7,90,91] and are even larger than the extreme chemical shifts determined for paramagnetic compounds, including σ-aryl complexes of nickel(II) heteroporphyrins (e.g. *ortho*-H: $\delta$ = 568 ppm at 203 K).[6,39,78,92] Extreme contact shifts have been reported for the β-$CH_2$ hydrogens of cysteines that ligate iron in oxidized ruberodoxin ($\delta$ = 300–900 ppm, 303 K)[93] and copper(II) in azurin ($\delta$ = 800, 850 ppm at 278 K).[94]

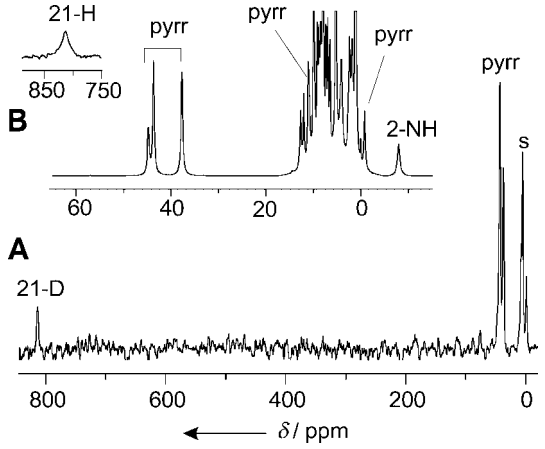


Figure 12. (A) $^2$H NMR spectrum of [($D_7$-*H*CP*D*)Fe$^{II}$Br] ($CH_2Cl_2$, 298 K). (B) $^1$H NMR spectrum of [(*H*CP*H*)Fe$^{II}$Br] ($CD_2Cl_2$, 298 K); s: solvent. The inset in (B) shows the H(21) resonance. Reproduced, with permission, from ref.[88] Copyright 2003 American Chemical Society.

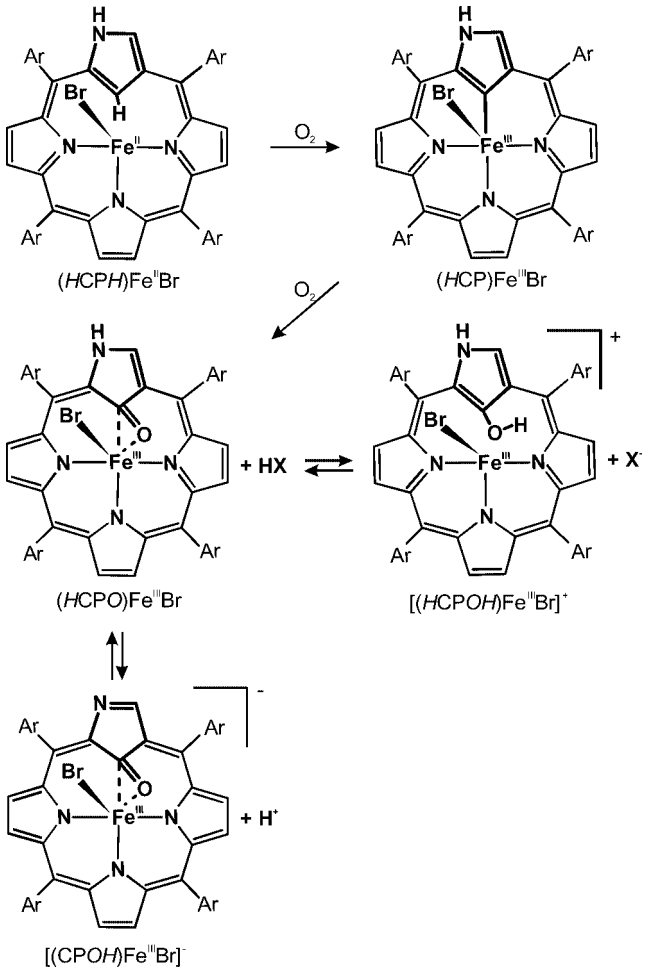
The $^1$H NMR spectra of iron(II) 2-aza-21-carbaporphyrins display the spread of regular β-H resonances, which is markedly larger than for their more symmetrical counterparts.[11,89,95] The paramagnetic shifts of [(*H*CP*H*)Fe$^{II}$Br] can be explained by a model that is typically applied to high-spin iron(II) porphyrins and iron(II) *N*-substituted porphyrins. In the case of a high-spin iron(II) center [$(d_{xy})^2(d_{xz}d_{yz})^2(d_{z^2})^1(d_{x^2-y^2})^1$] both σ and π routes of spin density delocalization can operate. The contact shift predominates for the regular pyrrole resonances, which determines their downfield positions.[7,14,16] The typical delocalization pathways involve delocalization through a σ-framework by way of σ-donation to the half occupied $d_{x^2-y^2}$ iron(II) orbital.[14] Actually, the variation of the β-H positions in the $^1$H NMR spectrum may be accounted for by specific π-delocalization mechanisms that have been discussed in detail for iron(III) porphyrins.[96,97] One pyrrole 3-H and the 2-NH resonance are evidently different from the other six and show upfield shifts. Thus, the side-on location of the iron(II) with respect to the pyrrole ring primarily affects spin transfer to the modified pyrrole ring. An analogous effect has been observed for paramagnetic nickel(II) 2-aza-21-carbaporphyrin and metalloheteroporphyrins.[39,52] Significantly, the peculiar metal ion–inverted pyrrole ring interaction detected in the solid-state structure of [(*H*CP*H*)Fe$^{II}$Br] is clearly reflected by an unprecedented isotropic shift of the H(21) atom that is involved in an agostic interaction [Fe$^{II}$–C(21)H] in solution.

## Oxidation and Oxygenation of Iron(II) 2-Aza-21-carbaporphyrin

Dioxygen reacts cleanly with iron(II) 2-aza-21-carbaporphyrin to form the corresponding five-coordinate intermediate-spin iron(III) complexes and, eventually, the 2-aza-21-carbaporphyrin gains an oxo functionality.[98] Generally speaking insertion of an oxygen atom into an M–C bond (a carbon atom built into the aromatic moiety) is quite rare,[99–109] and no direct evidence for the formation of intermediates in the oxygenation process has been found.



Scheme 9. Reaction of [(*H*CP*H*)Fe$^{II}$Br] with dioxygen. Reproduced, with permission, from ref.[98] Copyright 2004 American Chemical Society.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The oxidation and oxygenation of [(*H*CP*H*)$Fe^{II}$Br] have been followed by $^1$H and $^2$H NMR spectroscopy.[98] Thus, addition of dioxygen to [(*H*CP*H*)$Fe^{II}$Br] in dichloromethane yields a series of iron(III) complexes in consecutive reactions (Scheme 9).

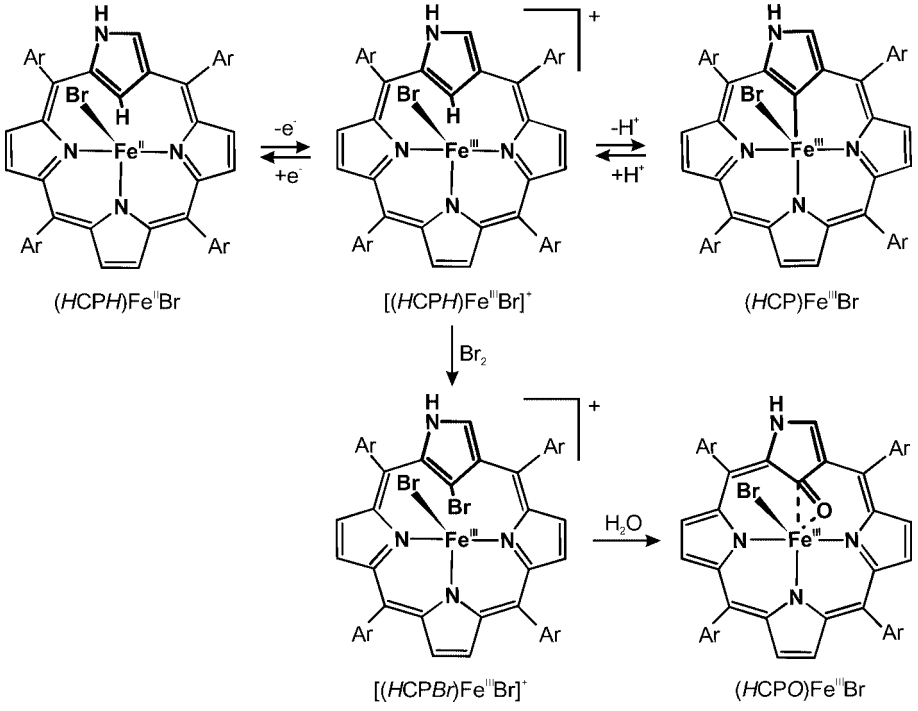
One-electron oxidation with dioxygen, which is accompanied by deprotonation of a C(21)H fragment and formation of an Fe–C(21) bond, produces the intermediate-spin, five-coordinate iron(III) complex [(*H*CP)$Fe^{III}$Br] (Scheme 10). Insertion of an oxygen atom into the preformed $Fe^{III}$–C(21) bond in the subsequent step yields [(*H*CP*O*)$Fe^{III}$Br]. Protonation at the oxygen atom then affords [(*H*CP*OH*)$Fe^{III}Br]^+$. The considered mechanism of [(*H*CP)$Fe^{III}$Br] oxygenation involves the insertion of dioxygen into the Fe–C bond. The O–O bond of the transient species cleaves rapidly and 2-aza-carbaporphyrin acquires an oxo functionality [C(21)O] in the coordination core.

Addition of $I_2$ or $Br_2$ to a solution of [(*H*CP*H*)$Fe^{II}$Br] in the absence of dioxygen results in a one-electron oxidation that yields [(*H*CP*H*)$Fe^{III}Br]^+$. This iron(III) compound has also been obtained by titration of [(*H*CP)$Fe^{III}$Br] with acids due to protonation at C(21). Addition of $Br_2$ to a solution containing [(*H*CP)$Fe^{III}$Br] or [(*H*CP*H*)$Fe^{III}Br]^+$ results in bromination at C(21) to yield [(*H*CP*Br*)$Fe^{III}Br]^+$, in agreement with the typical reactivity of inverted porphyrins.[51,110] Subsequent reaction with water results finally in formation of the C=O fragment in [(*H*CP*O*)$Fe^{III}$Br]. This complex contains a ligand which is a 2-aza-21-carbaporphyrin derivative with the oxygen atom located on the inner carbon, in other words *N*-confused porphyrin *C*-oxide. Such a ligand was first detected in the dimeric product of [{(CP*H*)$Fe^{II}$}$_2$] oxygenation, although in a different tautomeric form,[111] and in the oxidation of [(*H*CPH)$Ni^{II}$] with $OsO_4$.[112]

Selected spectra that emphasize the utility of $^1$H NMR spectroscopy for observing oxidation/oxygenation transformations of [(*H*CP*H*)$Fe^{II}$Br] are presented in Figure 13. The characteristic patterns of pyrrole and N(2)H resonances are diagnostic of the ground electronic state of iron and the donor character of C(21).

The average chemical shift of the perimeter resonances ($\delta_{av}$) at 298 K was considered here as a suitable parameter for characterizing the ground electronic/spin state of iron(*n*) inverted porphyrins. Thus, the value of $\delta_{av}$ for six regular pyrroles was examined for [(*H*CP*H*)$Fe^{II}$Br], [(*H*CP*H*)-$Fe^{III}Br]^+$, and [(*H*CP*Br*)$Fe^{III}Br]^+$, where a side-on location of the metal ion with respect to the *N*-confused pyrrole ring has been determined. The values of $\delta_{av}$ for [(*H*CP*O*)-$Fe^{III}$Br], [(*H*CP*OH*)$Fe^{III}Br]^+$, [(*H*CP*H*)$Fe^{III}Br]^+$, and [(*H*CP*Br*)$Fe^{III}Br]^+$ approach those found for high-spin iron(III) tetraarylporphyrins,[7] iron(III) β-substituted tetraarylporphyrin,[96] and iron(III) *N*-methyltetraarylporphyrin ($\delta_{av}$ for regular pyrrole rings),[13] and the average chemical shift of [(*H*CP*H*)$Fe^{II}$Br] is consistent with that found for high-spin iron(II) tetraarylporphyrins, iron(II) *N*-methyltetraarylporphyrin, and iron(II) 21-thiatetraarylporphyrin.[7,14,89] Finally, the upfield β-H positions seen for [(*H*CP)$Fe^{III}$Br] and [(*H*CP)$Fe^{III}$(1-MeIm)]$_2^+$ are clearly consistent with intermediate- and low-spin states, respectively, considering the asymmetric iron(III) porphyrins as reference molecules.[7,11,95,113,114]

The isotropic shift pattern for the β-H pyrrole of [(*H*CP)-$Fe^{III}$Br] and [(*H*CP)$Fe^{III}$(1-MeIm)]$_2^+$ reflects the extensive spin delocalization into the π molecular orbitals of the in-



Scheme 10. Oxidation of [(*H*CP*H*)$Fe^{II}$Br]. Reproduced, with permission, from ref.[98] Copyright 2004 American Chemical Society.

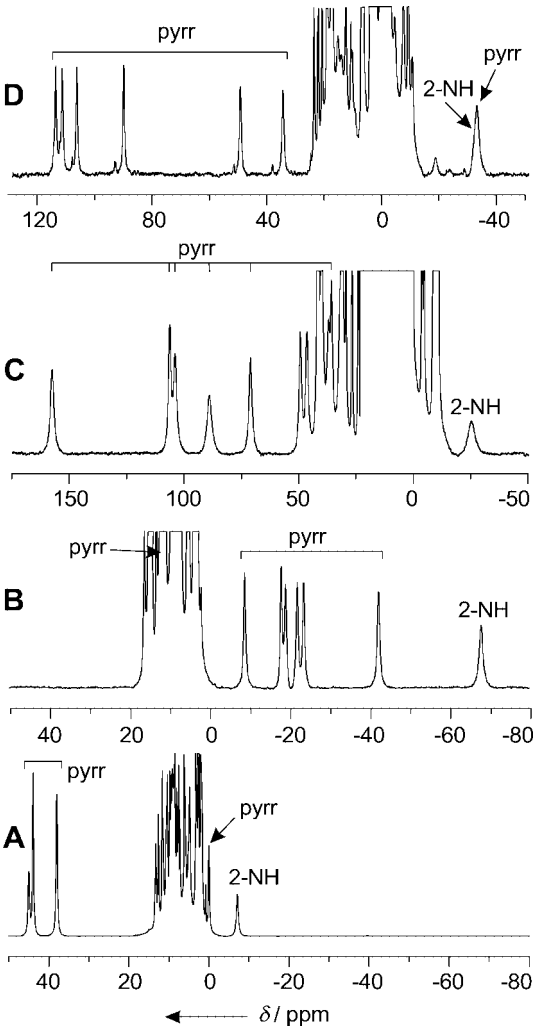

Figure 13. Oxidation and oxygenation of iron inverted porphyrins as followed by $^1$H NMR spectroscopy ($CD_2Cl_2$, 298 K): (A) [(*H*CP*H*)Fe$^{II}$Br]; (B) [(*H*CP)Fe$^{III}$Br]; (C) ([*H*CP*O*)Fe$^{III}$Br]; (D) [(*H*CP*H*)Fe$^{III}$Br]$^+$. Reproduced, with permission, from ref.[98] Copyright 2004, American Chemical Society.

verted porphyrin. The dominance of the π-spin transfer mechanism has been taken as direct evidence that $d_{x^2-y^2}$ is not populated in [(*H*CP)Fe$^{III}$Br] and [(*H*CP)Fe$^{III}$-(1-MeIm)]$_2^+$. Thus, the ground state can be related to the following models of the electronic configuration: intermediate-spin $(d_{xy})^2(d_{xz})^1(d_{yz})^1(d_{z^2})^1(d_{x^2-y^2})^0$ for [(*H*CP)Fe$^{III}$Br] and low-spin $(d_{xy})^2(d_{xz}d_{yz})^3(d_{z^2})^0(d_{x^2-y^2})^0$ for [(*H*CP)Fe$^{III}$-(1-MeIm)]$_2^+$. The β-H shifts of [(*H*CP)Fe$^{III}$Br] are larger as there are two π-symmetry unpaired electrons in the $S$ = 3/2 state in comparison to one π electron in [(*H*CP)Fe$^{III}$-(1-MeIm)]$_2^+$ ($S$ = 1/2).[113]

An extension of these investigations to *N*- and *C*-methylated iron porphyrins allowed the similarities of iron(*n*) *N*-confused and *C*- and *N*-methylated *N*-confused porphyrin complexes for a given oxidation/spin state to be established.[115] There are considerable similarities in the $^1$H NMR properties within each of these pairs. The analytically useful hyperfine shift patterns determined previously for iron(II) and iron(III) *N*-confused porphyrin provided useful and potentially unique probes for detecting the analogous species by $^1$H NMR spectroscopy. This spectroscopic means of identification has gained an additional advantage, namely the characteristic large downfield C-*Me* contact shift provides a well-defined signal in a unique window ($\delta$ = 420–520 ppm) for iron(III) *C*-methylated *N*-confused porphyrins, which contrasts with the relatively small values for iron(II) *C*-methylated derivatives ($\delta$ = 50–80 ppm). The most characteristic $^1$H NMR features of [(*H*CP*Me*)-Fe$^{III}$Br]$^+$ and [(*Me*CP*Me*)Fe$^{III}$Br]$^+$, namely the broad resonances at $\delta$ = 498 or 432 ppm, can be assigned to the internal C-*Me* groups. The directions and magnitudes of these shifts resemble those reported for the N-*Me* group of the [(*Me*TPP)Fe$^{III}$Cl]$^+$ complex.[13]

Dioxygen reacts cleanly with the carbaporphyrin complex [(*Me*CP*H*)Fe$^{II}$Br] to form the corresponding five-coordinate intermediate-spin iron(III) complex [(*Me*CP)Fe$^{III}$Br] although, contrary to 2-aza-21-carbaporphyrin, the *N*-methylated derivative does not acquire an oxo functionality. Similarly, the C-*Me* group, which is positioned near the center of the carbaporphyrin, presents a serious steric barrier that plays an essential role in governing the reactivity of this iron *C*-methylated *N*-confused porphyrin. For instance, [(*Me*CP*Me*)Fe$^{II}$Br] undergoes only one-electron oxidation. Further investigations of the iron carbaporphyrinoid complexes are expected to afford a unique insight into the reactivity of a metal–C bond as specifically tuned carbaporphyrins can be expected to influence feasible pathways of oxygenation processes.

## Conclusions

In a sense, in this microreview we have intended to remind the community of inorganic chemists that NMR of paramagnetic molecules can be considered as a powerful spectroscopic probe of intriguing aspects of molecular and electronic structures, structural rearrangements, and reactivity. The chosen examples address the chemistry of a new class of carbaporphyrinoid complexes that has recently been explored in our laboratory. As presented, the entrapment of metal ions in the coordination core of carbaporphyrinoids creates a very efficient protection of the metal–C bond and allows the stabilization of extremely rare or virtually unknown oxidation/electronic states of metal ions in an organometallic environment, such as copper(II),[63,116,117] silver(III),[118,119] iron(III),[98] or paramagnetic nickel(II).[44,52] Extensive studies on the NMR of paramagnetic metallocarbaporphyrinoids (reviewed above) have established a general relationship between the isotropic shift pattern of these porphyrin-like macrocycles and their electronic and molecular structures. In particular, we have found that the restraints introduced by incorporating the carbocyclic moiety into an appropriately sized carbaporphyrinoid allow the creation of a geometry that affords metal–carbocyclic ring distances that can be classified as intermediate between a regular chemical bond and a van der Waals interaction.[57,65,67,76] The proximity of a dia-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

magnetic metal ion and an arene gives rise to observable $^{1}$H-M and $^{13}$C-M scalar couplings in the NMR spectra (M = NMR-active metal ion). Such couplings are usually classified as "through-space" or "nonbonding" because their magnitude cannot be rationalized in terms of the network of regular bonds in the molecule.[57,65,120] The metal–arene interactions of nickel(II), iron(II), and iron(III) have been probed in complementary investigations using their paramagnetically shifted $^{1}$H NMR spectra.[52,65,76,88,98] NMR spectroscopy provides a uniquely useful probe for studying this type of interaction. Apart from purely structural considerations, the understanding of such a "borderline" M···C–H interaction is fundamental for the exploration of transient states that might be active in organometallic catalysis.

# Growth of Metal Nanoparticles in a Sol-Gel Silica Thin Film

**Miroslava Malenovska,[a] Sandra Martinez,[a][‡] Marie-Alexandra Neouze,[a] and Ulrich Schubert*[a]**

**Keywords:** Thin films / Nanostructures / Inorganic-organic hybrid materials / Nanocomposites

Silica films on glass substrates with homogeneously dispersed platinum, gold or silver nanoparticles were prepared by sol-gel processing mixtures of tetraethoxysilane and {3-[(2-aminoethyl)amino]propyl}triethoxysilane complexes of the corresponding metal ions, followed by dip-coating and hydrogen treatment of the films at elevated temperatures.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Numerous work has been published on the synthesis of metal oxide or metal nanoparticles[1] in polymeric,[2] inorganic,[3] or hybrid organic-inorganic matrices.[4] Independent of the type of matrix material, the principles of introducing the nanoparticles are rather similar. Thus, the matrix can be formed around pre-formed (stabilized) nanoparticles, the particles can be generated in the pre-formed matrix, or matrix and nanoparticles can be synthesized concomitantly. All methods, when properly controlled, can lead to homogeneously dispersed materials.

We have previously developed a sol-gel method by which nanometer-sized metal oxide or metal particles with narrow size distributions are generated within a silica matrix.[5–7] The nanoparticles prepared by this method are not agglomerated and are homogeneously distributed in the $SiO_2$ matrix, even in materials with high metal loading. The high metal dispersion in the nanocomposites was achieved by tethering metal ions to the matrix generated during sol-gel processing. To this end, trialkoxysilyl-substituted metal complexes of the type $[(RO)_3Si(CH_2)_nA]_nMX_m$, formed in situ by reaction of a metal salt ($MX_m$) with alkoxysilanes $(RO)_3Si(CH_2)_nA$ (A = a coordinating group), were used as precursors for sol-gel processing. Metal coordination is retained during gel formation, and the metal complexes are tethered to the gel network through the $(CH_2)_nSiO_{3/2}$ groups. The metal loading can be adjusted by using $Si(OR)_4$ as a co-precursor. The resulting gels with the idealized composition $[O_{3/2}Si(CH_2)_nA]_nMX_m{\cdot}xSiO_2$ had the typical color of the corresponding metal complexes. When the metal complex containing gels were subsequently heated in air, all organic moieties were oxidized and/or pyrolyzed, i.e. carbon-free materials were obtained, and nanosized metal oxide particles [i.e., the nanocomposites $MO_y{\cdot}(x+n)SiO_2$] were formed in the silica matrix. In the final step, the oxide particles were reduced by hydrogen, resulting in metal/silica nanocomposites, $M{\cdot}(x+n)SiO_2$. Since the nanoparticles are formed during the *oxidation* step, the reaction conditions during this step, including the nature of the organic groups (counterion, tethering groups) being burnt, determine the size of the obtained metal oxide nanoparticles.[7] The particle size is not changed significantly during the subsequent reduction step.

This procedure results in nanocomposite *powders*, due to the removal of the organic groups. Although we have previously shown that the synthesis of metal/silica nanocomposite powders by the coordination/oxidation/reduction protocol can also be applied to the coating of porous silica pellets with Pt nanoparticle-containing gels,[6] this synthesis protocol is not suitable to prepare coherent nanoparticle-containing *films*. Such sol-gel films are interesting for a variety of applications.

It was recently shown for aerogels that metal nanoparticles are also formed by direct reduction of tethered metal complexes without prior removal of the organic groups.[8] Since removal of the organic groups is detrimental to good film properties, this modification of the synthesis protocol may also allow to obtain metal nanoparticle containing films. However, this is not at all a straightforward modification of the existing procedure, because the *metal* particles will not be formed by reduction of existing metal oxide particles, but instead by nucleation and growth during the reduction step. Since nucleation and growth of the nanoparticles occurs under completely different conditions, one cannot assume that the modified approach necessarily also results in nearly monodisperse, highly dispersed metal particles as were obtained by the described coordination/oxidation/reduction route.

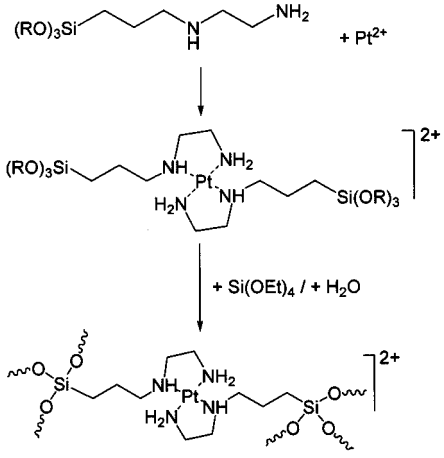
We now show that metal particle containing sol-gel films can be prepared by exposing the films to hydrogen at elevated temperatures without prior calcination. Gold/silver alloy particles with diameters of 2.5–7 nm in a silica film were already obtained by UV irradiation of sol-gel films.[9] The work reported in this contribution has proof-of-concept character, without optimization of the reaction conditions, the metal particle sizes or the properties of the silica matrix.

## Results and Discussion

The metal nanoparticle containing sol-gel films were synthesized in three successive steps. In the first step (Scheme 1 for $Pt^{2+}$), metal complexes substituted by {3-[(2-aminoethyl)amino]propyl}triethoxysilane (AEAPTS), a trialkoxysilyl-substituted derivative of ethylenediamine, were prepared in situ. In the second step (Scheme 1), a sol was formed by hydrolytic polycondensation of the (AEAPTS) metal complex and $Si(OEt)_4$. This sol was dip-coated on glass slides resulting in thin, transparent films of the metal complex containing inorganic-organic hybrid material. In the final step, the metal ions in the sol-gel film were reduced by exposure to hydrogen at elevated temperatures, resulting in the formation of metal nanoparticles.



Scheme 1.

The advantage of this approach is that films can be prepared by standard coating technologies. The presence of the organic groups not only renders possible an atomic dispersion of the metal component during film formation, but also allows, in principle, to adjust the properties of the coating sol in the same way as for other well-known applications of alkoxysilane mixtures.

The reduction of the metal was followed by X-ray diffraction (Figure 1), which confirms the "postsynthesis reduction" in the last synthesis step, i.e. after formation of the silica film. Only a broad bump corresponding to amorphous silica was observed before the films were exposed to hydrogen and after the films were heated in hydrogen up to 200 °C. Only when the reduction temperature was increased to 400 °C, did reflections of elemental Pt emerge additionally. An average diameter of 6.8 nm was calculated by Scherrer's equation from the half-height widths of the reflections. When the reduction temperature was raised to 500 °C, the reflections became sharper, as expected, and the average particle diameter increased to 22 nm.

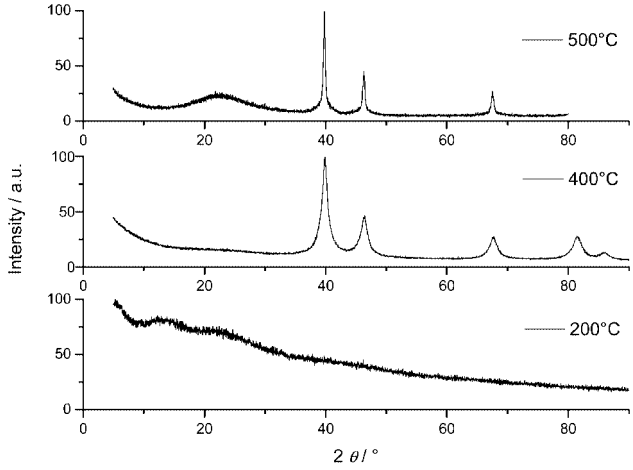


Figure 1. Temperature-dependent XRD on the reduction of platinum in the sol-gel films. The films were kept at each temperature in hydrogen for 2 h before the diffractogram was taken.

Silica films containing gold or silver nanoparticles were similarly prepared. The diffraction patterns (Figure 2) showed both the broad bump for amorphous silica and the characteristic reflections of the reduced gold or silver particles. An average diameter of 7.9 nm was calculated for the Au particles by Scherrer's equation, and of 13.1 nm for the silver particles.

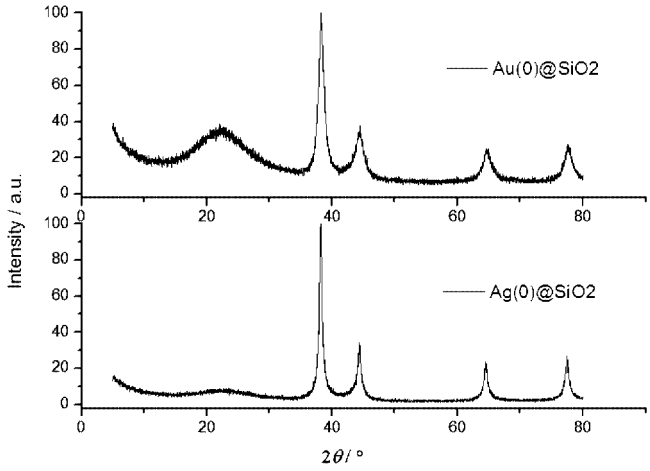

Figure 2. XRD of silica films containing gold or silver nanoparticles after reduction at 500 °C.

As a consequence of the tethering of the metal complexes, the metal ions are perfectly dispersed in the film before being reduced. During reduction of the metal ions, growth of the resulting metal particles is limited by the sur-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rounding silica matrix. This leads to a homogeneous dispersion of the metal nanoparticles. Figure 3 shows the TEM of the silica film with platinum nanoparticles in the range 10–100 nm (average ca. 30 nm). The metal particle size is of course also dependent on the reduction temperature, and larger average particle sizes were consequently obtained when the temperature was increased.

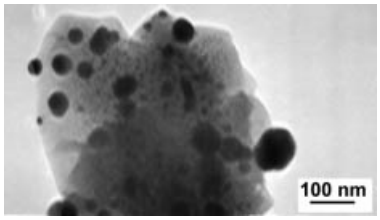

Figure 3. TEM of $Pt^0$ nanoparticles dispersed in the silica film after reduction at 500 °C.

A key issue in this work was also the film properties. Even after hydrogen treatment at 500 °C for 2 h, the film remained transparent. Adhesion of the film after reduction was as good as before, and the films were crack-free.

## Conclusions

The present work shows the feasibility of preparing silica *films* with dispersed noble metal nanoparticles by sol-gel processing. Reduction is performed after coating, i.e. in the deposited sol-gel film, in which the metal cations are chelated by the amino groups and thus linked to the silica network. Contrary to synthesis protocols for carbon-free nanocomposite *powders*, the organic tethers and the counterions of the employed metal salts were not oxidatively removed prior to reduction. This had a beneficial influence on the quality of the final coating.

The metal nanoparticles obtained are highly dispersed in the silica film. However, the obtained metal particles have a much broader particle size distribution than those prepared by the coordination/oxidation/reduction protocol. This may be due to different nucleation and growths mechanisms in the reduction step and/or the influence of the substrate. This will be subject to further work.

The possibility to generate metal nanoparticles without completely destroying the organic groups of the gel opens the possibility of optimizing the properties of the coatings, e.g. adhesion to substrates or compliance of the films, by using organically substituted trialkoxysilanes $R'Si(OR)_3$ as co-reactants.

The goal of the work reported here was a proof of principle. We have neither optimized the reduction conditions nor the film or particle properties. Future work also needs to address the fate of the organic groups during hydrogen reduction at elevated temperatures and their influence on the particle growth and the film properties.

## Experimental Section

**General:** {3-[(2-aminoethyl)amino]propyl}triethoxysilane (AEAPTS) and ethanol were distilled before use and kept under inert gas. Ethanol was kept over molecular sieves under an inert gas.

**Preparation of the Coating Solutions:** An amount of 0.1 mmol of $AgNO_3$, $HAuCl_4$, or $Pt(acac)_2$ (acac = acetylacetonate), was dissolved in 10 mL of freshly distilled, dried ethanol. An amount of AEAPTS was added to the solution of the metal salt which corresponded to a metal/AEAPTS molar ratio of 1:2, 1:3, and 1:4 for silver, gold and platinum, respectively. The mixture was stirred at room temperature until the color of the solution did not change any more, which indicated the formation of the metal complexes $[Ag(AEAPTS)_2]^+$, $[Au(AEAPTS)_2]^{3+}$, or $[Pt(AEAPTS)_2]^{2+}$.[5,7] An amount of 0.2 mmol of tetraethoxysilane (TEOS) was added to the metal complex solution and sol-gel reactions were started by addition of 40 mL of 0.2 N aqueous $NH_4OH$. The resulting colloidal suspensions, which had the typical color of the corresponding metal complexes, were heated to 70 °C for 72 h.

**Dip-Coating:** Glass sides were cleaned by treatment with a concentrated sodium hydroxide solution followed by successive rinsing with ethanol and deionised water and then coated by dip-coating with a withdrawal speed of 24 $cm\,min^{-1}$.

**Metal Reduction:** The coated glass plates were put in an oven flushed with hydrogen. The temperature was then raised to 500 °C at 10 $°C \cdot min^{-1}$ and kept at this temperature under hydrogen for 2 h.

**Characterization:** The obtained films were characterized by transmission electron microscopy (TEM) with a JEOL 200CX. X-ray analyses were carried out with a Philips X'Pert diffractometer using Cu-$K_\alpha$ radiation. For both investigations, the films were scraped off from the glass slides.

# Dinuclear Nickel–Ruthenium Complexes as Functional Bio-Inspired Models of [NiFe] Hydrogenases

**Yohan Oudart,[a] Vincent Artero,*[a] Jacques Pécaut,[b] Colette Lebrun,[b] and Marc Fontecave[a]**

**Keywords:** Nickel / Ruthenium / Hydrogen / Electrocatalysis / Biomimetic chemistry / Hydrogenases

Three new dinuclear nickel ruthenium complexes, namely $[Ni(xbsms)Ru(p\text{-cymene})Cl]^+$, $[Ni(emi)Ru(CO)_2Cl_2]^{2-}$ and $[Ni(emi)Ru(p\text{-cymene})Cl]^-$ [$H_2$xbsms = 1,2-bis(4-mercapto-3,3-dimethyl-2-thiabutyl)benzene, $H_2$emi = *N*,*N*′-ethylenebis(2-mercaptoisobutyramide], have been synthesized and fully characterized as models of the active site of [NiFe] hydrogenases. The three-dimensional structure of $[Ni(xbsms)Ru(p\text{-cymene})Cl]^+$ reveals a nickel center in a square-planar dithioether-dithiolate environment that is connected to a ruthenium moiety via a $Ni(\mu\text{-}SR)_2Ru$ bridge. These complexes catalyze hydrogen evolution by electroreduction of the weakly acidic $Et_3NH^+$ ions in dimethylformamide and are therefore among the first bio-inspired functional models of [NiFe] hydrogenases. The catalytic activity of these new complexes is explained by the existence of a cooperative effect between the metal centers and is further related to their electronic properties.

## Introduction

Hydrogenase enzymes catalyze the reversible formation/oxidation of dihydrogen and can be divided into two main classes, depending on their metal content.[1] In addition to classical Fe/S clusters, Fe-only hydrogenases display a hexanuclear active site (H-cluster) constituted by a [4Fe-4S] cluster bound through a cysteine-derived sulfur bridge to the $[Fe_2(\mu_2\eta^4\text{-}SRS)(CO)_3(CN)_2L]$ sub-site (R is proposed to be -$CH_2NHCH_2$-, L = $H_2O$, $H_2$ or $H^-$; Figure 1). By contrast, [NiFe] hydrogenases contain a dinuclear nickel-iron active center.[2] In the reduced active state the nickel ion is only coordinated by four cysteinate residues, two of which also bridge an organometallic {Fe(CO)$(CN)_2$} moiety (Figure 1). The [NiFe] hydrogenase from *Allochromatium vinosum* displays a Nernstian catalytic behavior for hydrogen oxidation when immobilized on a pyrolytic graphite "edge" electrode.[8] As unique molecular catalysts for $H_2/H^+$ interconversion, hydrogenases are thus competitive with platinum metal, which has prompted the synthesis, pioneered by Darensbourg et al., of a great variety of biomimetic complexes[9–11] with the aim of both better understanding the catalytic mechanism of native [NiFe] hydrogenases at the molecular level and developing new electrocatalysts to be used in fuel-cells for hydrogen uptake or in electrolytic/photosynthetic cells for hydrogen production. The most accurate of these structural mimics are $[(bdt)Ni(\mu_2\text{-}"S_3")Fe(CO)(PMe_3)_2]$ [$H_2$"$S_3$" = bis(2-mercaptophenyl)sulfide; $H_2$bdt = 1,2-benzenedithiol],[12] $[Ni(xbsms)Fe(CO)_2I_2]$ [$H_2$xbsms = 1,2-bis(4-mercapto-3,3-dimethyl-2-thiabutyl)-benzene],[13] and $[(dedtc)Ni(pdt)Fe(CO)_2(CN)_2]^-$ (dedtc$^-$ = diethyldithiocarbamato anion; $H_2$pdt = propanedithiol),[14] all of which have a nickel ion in an $S_4$ environment and CO ligands bound to iron (Figure 2). However, no catalytic activity has been reported so far for dinuclear nickel-iron complexes, and hydrogen evolution activity has only been demonstrated with trinuclear biomimetic complexes: $[(bdt)\{Ni(PMe_3)\}_2(bdt)_2Fe(CO)]$[15] stoichiometrically reduces $HBF_4$ to $H_2$ and $[Ni(L)Fe_2(CO)_6]$ [L = *S*,*S*′-bis(2-mercapto-5-methylphenyl)-1,4-dithiabutane] electrocatalyzes the reduction of $CF_3COOH$ to $H_2$ at –1.64 V vs. Fc/$Fc^+$ in $CH_2Cl_2$.[16] In a bio-inspired approach, we recently

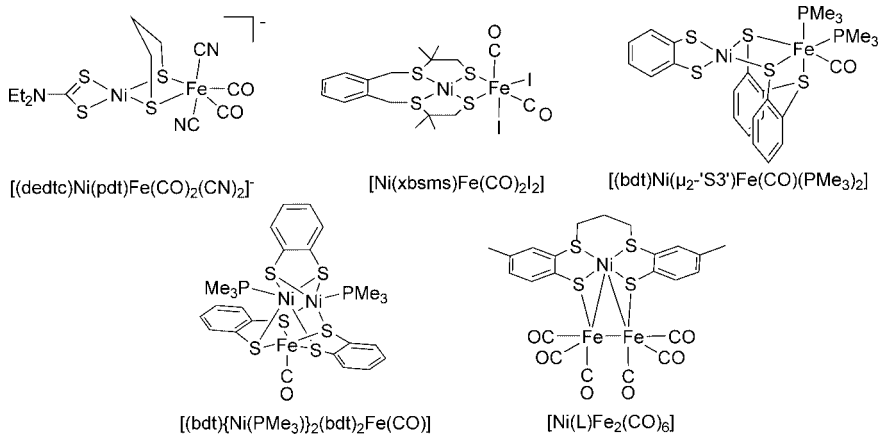

Figure 2. Selected structural models for [NiFe] hydrogenases from the literature (references are given in the text).

reported the catalytic activity of a dinuclear nickel-ruthenium complex in which an electron-rich organometallic moiety is introduced as a surrogate for the {Fe(CO)(CN)$_2$} fragment.[17] In order to shed light on the structure-function relationships in this class of catalysts, and to gain more insight into the reaction mechanism, we have prepared three new compounds that vary in both the tetradentate ligand around the nickel ion and the organometallic ligand set of the ruthenium center. Their catalytic activity for $Et_3NH^+$ reduction in dimethylformamide is investigated, and further comparison with the activity of structurally related mononuclear complexes of nickel and ruthenium provides evidence for a synergic effect between the metal centers in these dinuclear catalysts.

## Results

### Syntheses

Treatment of [Ni(xbsms)][18] with half an equivalent of [RuCl$_2$(*p*-cymene)$_2$]$_2$ in $CH_2Cl_2$ under argon afforded [Ni(xbsms)Ru(*p*-cymene)Cl]Cl (**1**Cl, Figure 3) in high yield, chromatographic purification of which yielded an analytically pure compound. Subsequent treatment with one equivalent of $AgBF_4$ in $CH_2Cl_2$ yielded **1**$BF_4$. This synthesis is very similar to that used previously for the preparation of [Ni(xbsms)Ru(CO)$_2$Cl$_2$] (**2**).[17]

Similarly, treatment of (NEt$_4$)$_2$[Ni(emi)] [H$_2$emi = *N*,*N*′-ethylenebis(2-mercaptoisobutyramide)][19] with half an equivalent of [RuCl$_2$(*p*-cymene)$_2$]$_2$ in $CH_2Cl_2$ under argon afforded (NEt$_4$)[Ni(emi)Ru(*p*-cymene)Cl] [(NEt$_4$)**3**, Figure 3]. (NEt$_4$)**3** can be purified by precipitation upon addition of pentane to a tetrahydrofuran solution even though samples proved to be systematically contaminated with $Et_4NCl$ salt. The compound (NEt$_4$)$_2$[Ni(emi)Ru(CO)$_2$Cl$_2$] [(NEt$_4$)$_2$**4**, Figure 3] was obtained from the stoichiometric reaction of (NEt$_4$)$_2$[Ni(emi)] with [Ru(CO)$_2$Cl$_2$]$_n$ although it proved difficult to purify, the major impurities being $Et_4NCl$ and (NEt$_4$)[Ni(emi)Ru(CO)$_3$Cl]. The latter arises from the reaction of (NEt$_4$)$_2$[Ni(emi)] with [Ru(CO)$_3$Cl$_2$], which often contaminates samples of [Ru(CO)$_2$Cl$_2$].

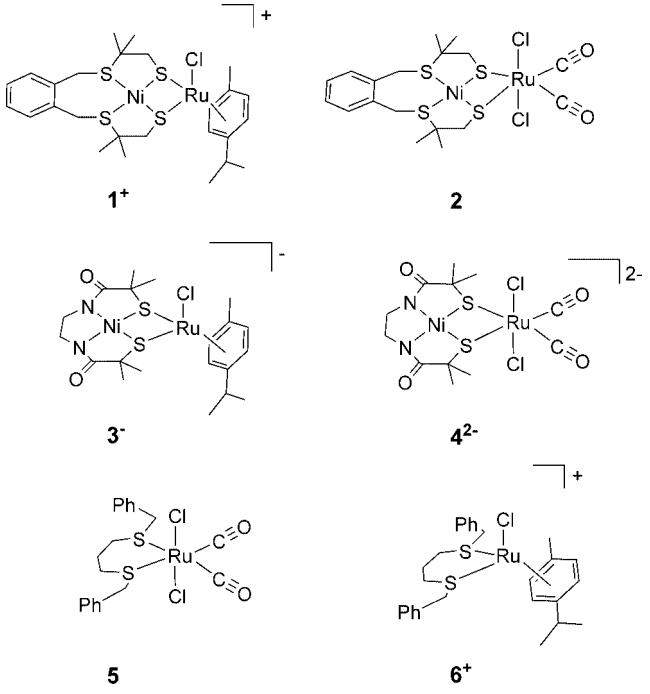

Figure 3. Molecular structures of the dinuclear nickel-ruthenium and mononuclear ruthenium complexes.

Two mononuclear ruthenium compounds, namely [("$C_3S_2$")Ru(CO)$_2$Cl$_2$] (**5**, Figure 3) and [("$C_3S_2$")RuCl(*p*-cymene)$_2$]Cl (**6**Cl, Figure 3) were also prepared by reaction of [Ru(CO)$_2$Cl$_2$]$_n$ and [RuCl$_2$(*p*-cymene)$_2$]$_2$ with 1,7-diphenyl-2,6-dithiaheptane ("$C_3S_2$"),[20] a bidentate ligand bearing two dithioether functions, in order to compare the dinuclear catalysts with mononuclear compounds having the same coordination sphere. Both complexes were purified by silica gel column chromatography to afford analytically pure powders.

### *Structures of [Ni(xbsms)Ru(p-cymene)Cl]$BF_4$ and [("$C_3S_2$")Ru(p-cymene)Cl]$BF_4$*

The structure of the dinuclear cation **1**$^+$ in **1**$BF_4$ (Figure 4) is very similar to that of **2**,[17] with the *p*-cymene ligand replacing both the CO ligands and one chloride. Com-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plex $\mathbf{1}^+$ is furthermore structurally related to $[Ni(S_2N_2)Ru(arene)Cl]^+$ {arene = *p*-cymene or $C_6Me_6$; $S_2N_2^{2-}$ = $[S(CH_2)_2NMe(CH_2)]_2^{2-}$}, which was recently described by Rauchfuss et al.[21] The nickel atom is in a square-planar environment formed by the four sulfur atoms and the sulfur atoms of the thiolate groups are involved in two bridges with the ruthenium atom. Due to steric interactions with the axial methyl groups of the {Ni(xbsms)} fragment, the ruthenium moiety is located *trans* to the axial methyl groups and therefore *cis* to the aromatic cycle of the xbsms ligand.[22] A chloride ligand bound to ruthenium is directed towards, but does not interact with, the nickel atom [$d$(Cl···Ni) = 3.20 Å]. The ruthenium is in an octahedral environment and the nickel–ruthenium distance (3.29 Å) is longer than that in complex **2**, although both Ni–S [2.1692(15) and 2.1858(14) Å] and Ru–S [2.4020(14) and 2.4210(14) Å] bonds are only 0.02 Å shorter. This could be the consequence of a less-pronounced bending of the $Ni(\mu\text{-}S)_2Ru$ core (hinge angle 129.8° as compared to 124.1° in **2**). Significant distortion in the equatorial plane of the ruthenium octahedra arises from the acute S1–Ru–S4 angle [71.10(5)°] due to bridging constraints.

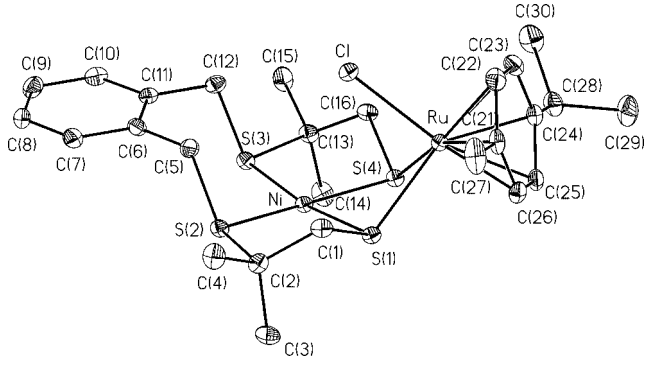

Figure 4. Structure of the cation $\mathbf{1}^+$ in $\mathbf{1}BF_4$ (30% probability thermal ellipsoids).

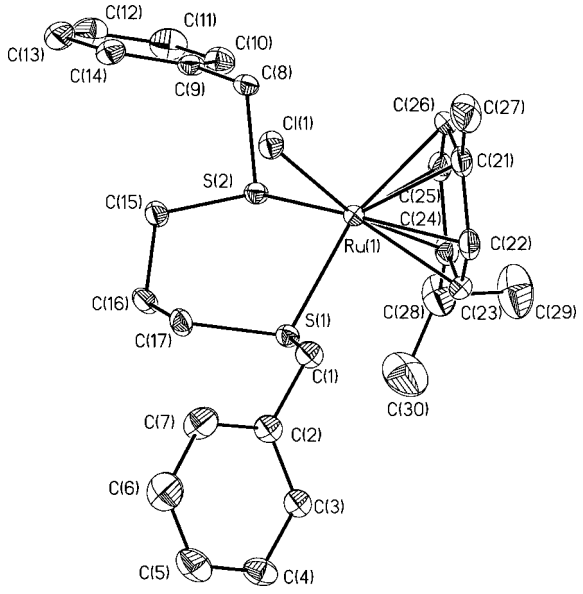

Figure 5. Structure of the cation $\mathbf{6}^+$ in $\mathbf{6}Cl{\cdot}2CH_2Cl_2$ (30% probability thermal ellipsoids).

The structure of complex $\mathbf{6}^+$ is shown in Figure 5. The ruthenium atom is in a pseudo-octahedral environment formed by the aromatic ligand, two thioether groups, and a chloride anion. The sulfur–ruthenium bonds [2.3737(11) and 2.3825(10) Å] are only slightly shorter than the ruthenium-thiolate bonds in $\mathbf{1}^+$, which means that $\mathbf{6}^+$ can thus be considered as a good comparative model for the ruthenium coordination sphere in $\mathbf{1}^+$.

## Spectroscopic Characterization

### *Infrared Spectroscopy*

The infrared spectra of **2**, $\mathbf{4}^{2-}$, and **5**, which have the same ruthenium moiety, display two $\nu_{CO}$ bands of equal intensity, in agreement with a *cis* arrangement of the carbonyl ligands at the ruthenium center ($A_1$ and $B_1$ stretching modes in $C_{2v}$ symmetry). Extraction of the force constants $k_{CO}$ (Figure 14) was done using the secular equations in the $C_{2v}$ symmetry group.[23] As the C≡O force constant is directly related to the intensity of the metal-to-ligand π-backbonding, we were able to order all three compounds with regard to the electron richness of the ruthenium center and thus the electronic properties of their ligands. As expected, the dithioether ligand in complex **5** is less electron-donating than [Ni(xbsms)], which coordinates to ruthenium through its thiolate groups in complex **2**. $[Ni(emi)]^{2-}$ is the most electron-donating ligand in this series, probably due to its negative charge.

### *NMR Spectroscopy*

The $^1H$ and $^{13}C$ NMR spectra of $\mathbf{1}^+$ indicate a $C_s$ symmetry with heterotopic faces for the xbsms ligand. As 2D NMR correlation experiments correlate with crystallographic distances, the solid-state molecular structure is probably retained in solution, as previously reported for **2**.[17] The observation of two doublets ($^3J$ = 5.7 and 6 Hz) for the aromatic protons of the *p*-cymene moiety in $\mathbf{1}^+$ and $\mathbf{3}^-$ indicates a free rotation around the ruthenium-arene bond. The $^1H$ NMR spectra of $(NEt_4)\mathbf{3}$ and $(NEt_4)_2\mathbf{4}$ display two singlets for the methyl and methylene groups of the $emi^{2-}$ ligand, with chemical shifts different from the corresponding ones in the parent $[Ni(emi)]^{2-}$ complex. This suggests a symmetrical coupling of the nickel and ruthenium moieties. One singlet is masked by the signals of the $Et_4N^+$ cation but is clearly seen in the 2D $^1H$-$^{13}C$ spectra. Integration measurements are nevertheless in good agreement with the proposed charges of the complexes. A comparison of the chemical shifts for the aromatic protons in the organometallic moieties of $\mathbf{1}^+$, $\mathbf{3}^-$, and $\mathbf{6}^+$ establishes the same order as established above for the different ligands of ruthenium regarding their electron-donating properties.

### *Electrochemistry*

The cyclic voltammograms recorded at a scan rate of 100 mV s$^{-1}$ for complexes **5** and $\mathbf{6}^+$ in dimethylformamide

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

display one irreversible reduction wave at –1.29 V and –0.97 V vs. Ag/AgCl, respectively (see Supporting Information). Coulometry during bulk electrolysis experiments revealed that these waves represent a one-electron process and can thus be assigned to the reduction of $Ru^{II}$ to $Ru^{I}$. Complex **5** is more difficult to reduce than $\mathbf{6}^{+}$ and thus the metal in the $\{Ru(CO)_2Cl_2\}$ moiety is more electron-rich than in $\{Ru(p\text{-cymene})Cl\}^{+}$.

The cyclic voltammogram of **1**Cl (Figure 6, trace a) in dimethylformamide shows a reversible electron-transfer process at +0.60 V vs. Ag/AgCl. This process has not yet been definitely assigned but we have evidence that the oxidation concerns the whole $\{Ni(\mu\text{-}S)_2Ru\}$ moiety. In addition, as in $[Ru(p\text{-cymene})Cl_2]_2$, the ruthenium center in **1**Cl displays a chemically irreversible one-electron reduction peak at –0.82 V with the corresponding anodic peak at –0.15 V. These features are consistent with an ECE mechanism (E = electron-transfer step; C = chemical step) involving the irreversible loss of a chloride ligand to yield a coordinatively unsaturated $Ru^{I}$ species. Such a mechanism, although bielectronic, has previously been observed for *trans*(Cl)-$[Ru(bipy)(CO)_2Cl_2]$.[24] Furthermore, an irreversible one-electron process is observed at –1.42 V. This can be tentatively assigned to a nickel-centered reduction by comparison with the cyclic voltammogram of [Ni(xbsms)], which shows an irreversible cathodic peak at –1.45 V vs. Ag/AgCl in dimethylformamide (see trace a in Figure 9).

The cyclic voltammograms of $(NEt_4)$**3** (Figure 7, trace a) and $(NEt_4)_2$**4** (Figure 8, trace a) display a reversible wave at 0.24 V and 0.39 V vs. Ag/AgCl, respectively. The cyclic

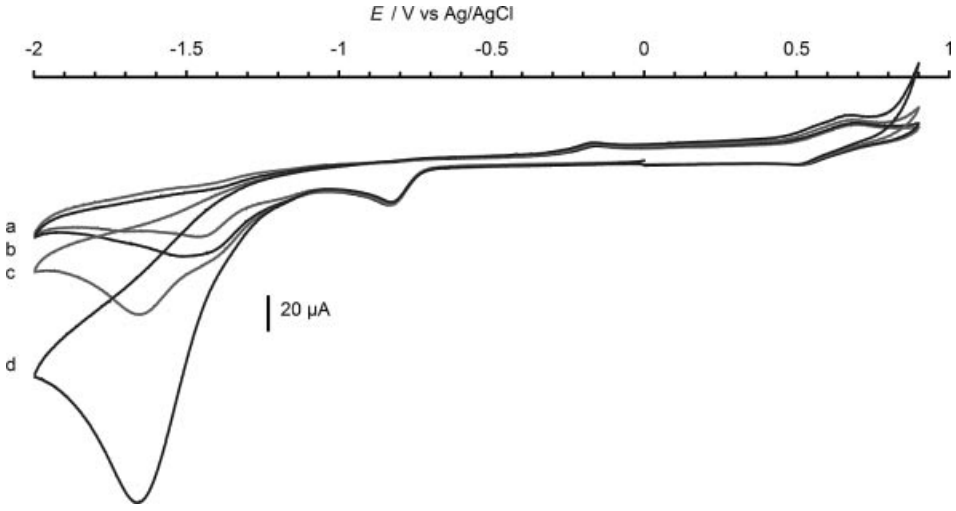

Figure 6. Cyclic voltammograms of **1**Cl (1.0 mM) in the presence of various amounts of $Et_3NHCl$ recorded in a dimethylformamide solution of $n Bu_4NBF_4$ (0.1 M) on a glassy carbon electrode at 100 mV $s^{-1}$: a) 0 equiv.; b) 1.5 equiv.; c) 3.0 equiv.; d) 10 equiv.

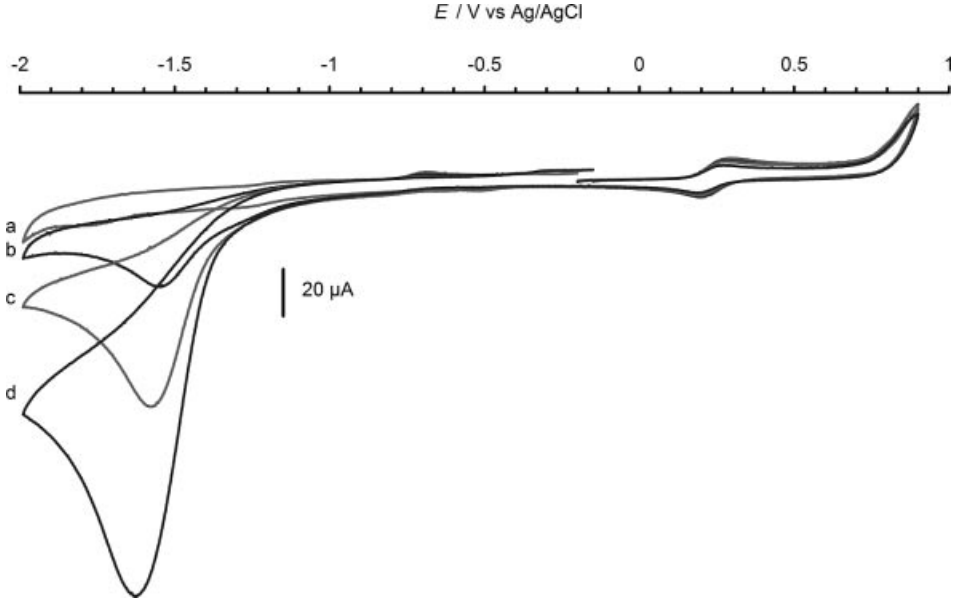

Figure 7. Cyclic voltammograms of $(NEt_4)$**3** (1.0 mM) in the presence of various amounts of $Et_3NHCl$ recorded in a dimethylformamide solution of $n Bu_4NBF_4$ (0.1 M) on a glassy carbon electrode at 100 mV $s^{-1}$: a) 0 equiv.; b) 1.5 equiv.; c) 3.0 equiv.; d) 10 equiv.

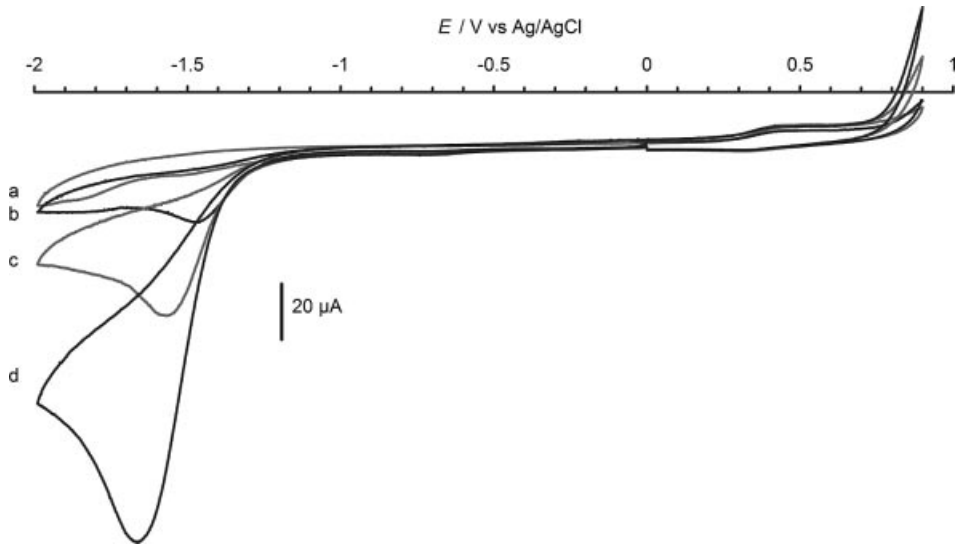

Figure 8. Cyclic voltammograms of $(NEt_4)_2$**4** (1.0 mM) in the presence of various amounts of $Et_3NHCl$ recorded in a dimethylformamide solution of $nBu_4NBF_4$ (0.1 M) on a glassy carbon electrode at 100 mV $s^{-1}$: a) 0 equiv.; b) 1.5 equiv.; c) 3.0 equiv.; d) 10 equiv.

voltammogram of $(NEt_4)$**3** exhibits two cathodic irreversible and flattened waves at –1.30 and –1.85 V vs. Ag/AgCl, which were shown to be monoelectronic by coulometric experiments. An irreversible anodic peak is seen at –0.66 V vs. Ag/AgCl on the reverse scan. As for **1**Cl, an ECE mechanism involving loss of a chloride ligand from the ruthenium center can be proposed. $(NEt_4)_2$**4** is also monoelectronically and irreversibly reduced at –1.54 V vs. Ag/AgCl, although no anodic peak can be observed in the reverse scan.

## Proton Reduction Electrocatalysis

### *Cyclic Voltammetry*

Addition of increasing amounts of $Et_3NHCl$ to dimethylformamide solutions of **1**Cl (Figure 6), $(NEt_4)$**3** (Figure 7), or $(NEt_4)_2$**4** (Figure 8) leads to the appearance of an electrocatalytic wave corresponding to hydrogen evolution, which increases in height and shifts to lower potentials. The peak potentials of the electrocatalytic waves as a function of the number of equivalents of acid added, which range from –1.46 to –1.57 V vs. Ag/AgCl, are listed in Table 1. The appearance of this electrocatalytic wave is the only observed modification of the cyclic voltammogram upon addition of acid, which suggests that these complexes are not prone to protonation in the $Ni^{II}$-$Ru^{II}$ state. In the cases of **1**Cl and $(NEt_4)$**3**, the electrocatalytic wave is a new cathodic process that occurs after an irreversible reduction step. A similar behavior has already been observed for **2**.[17] As far as $(NEt_4)_2$**4** is concerned, the electrocatalytic wave develops on the irreversible cathodic process observed at –1.54 V vs. Ag/AgCl in the absence of acid.

The nickel precursor [Ni(xbsms)] also catalyzes the hydrogen evolution reaction from $Et_3NHCl$ at –1.45 V vs. Ag/AgCl in dimethylformamide (Figure 9). The electrocatalytic behavior in this case consists of the appearance of a new wave at –1.35 V vs. Ag/AgCl upon addition of one equivalent of $Et_3NH^+$. This wave increases in height and shifts to lower potential upon further addition of acid.

$(NEt_4)_2$[Ni(emi)] is not stable in the presence of $Et_3NHCl$ in dimethylformamide, as revealed by the formation of a black precipitate. We suspect that a disproportionation reaction takes place after protonation of $[Ni^{II}(emi)]^{2-}$ to produce a $Ni^{III}$ species together with elemental nickel. The resulting mixture catalyzes $Et_3NHCl$ electroreduction, poss-

Table 1. Electrocatalytic properties of **1**Cl, **2**, $(NEt_4)$**3**, $(NEt_4)_2$**4**, [Ni(xbsms)], and $(NEt_4)_2$[Ni(emi)]. Electrocatalytic peak potentials ($E_{her}$, V) were determined by cyclic voltammetry at 100 m V $s^{-1}$ in a dimethylformamide solution of $nBu_4NBF_4$ (0.1 M) on a glassy carbon electrode. TOF and total TON were determined by bulk electrolysis experiments at –1.60 V of a dimethylformamide solution (6 mL) of $nBu_4NBF_4$ (0.1 M) and $Et_3NHCl$ (0.5 mmol) at a mercury pool (1.23 $cm^2$) in the presence of millimolar concentrations of catalyst. All potentials are quoted with respect to Ag/AgCl.

| | **1**Cl | **2** | $(Et_4N)$**3** | $(Et_4N)_2$**4** | [Ni(xbsms)] | $(Et_4N)_2$[Ni(emi)] |
|---|---|---|---|---|---|---|
| $E_{her}$ with 1.5 equiv. of $Et_3NHCl$ | –1.57 | –1.59 | –1.55 | –1.46 | –1.45 | – |
| $E_{her}$ with 3 equiv. of $Et_3NHCl$ | –1.65 | –1.66 | –1.60 | –1.57 | –1.46 | – |
| $E_{her}$ with 10 equiv. of $Et_3NHCl$ | –1.66 | –1.78 | –1.64 | –1.67 | –1.52 | – |
| Total TON after 4.5 h | 28.9 | 12.4 | 26.5 | 6.8 | 6.4 | 5.5 |
| TOF [$h^{-1}$] | 6.4 | 2.75 | 5.9 | 1.5 | 1.4 | 1.2 |

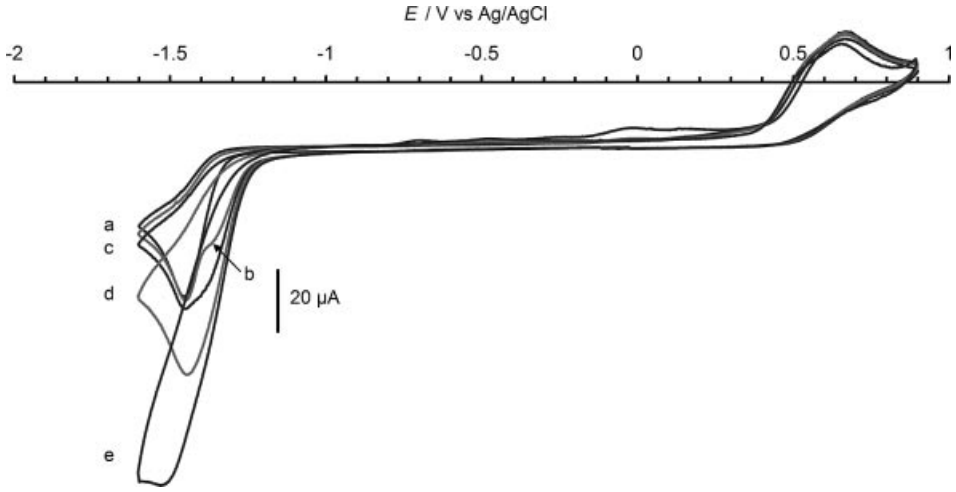

Figure 9. Cyclic voltammograms of [Ni(xbsms)] (1.0 mM) in the presence of various amounts of $Et_3NHCl$ recorded in a dimethylformamide solution of $nBu_4NBF_4$ (0.1 M) on a glassy carbon electrode at 100 mV $s^{-1}$: a) 0 equiv.; b) 1.0 equiv.; c) 1.5 equiv.; d) 3.0 equiv.; e) 10 equiv.

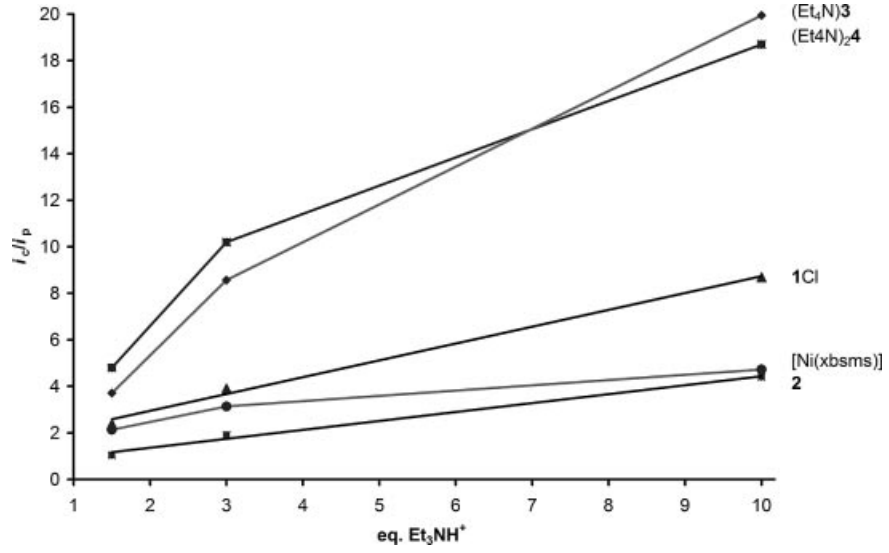

Figure 10. Evolution of the $i_c/i_p$ ratio between the catalytic peak current and the current of a monoelectronic wave as a function of the number of equivalents of acid added for **1**Cl, **2**, $(NEt_4)$**3**, $(NEt_4)_2$**4**, and [Ni(xbsms)].

ibly due to heterogeneous catalysis by elemental nickel, as shown by the appearance of an electrocatalytic wave with peak maxima below –1.7 V vs. Ag/AgCl in the cyclic voltammograms (see Supporting Information).

In contrast, the mononuclear ruthenium complex **6**Cl does not exhibit electrocatalytic activities. As far as complex **5** is concerned, some electrocatalytical activity is observed at potentials below –1.8 V vs. Ag/AgCl. Thus, for millimolar solutions of **5** in the presence of 10 equivalents of $Et_3NHCl$, the reduction current between –1.8 and –2.0 V vs. Ag/AgCl is higher than that observed by direct reduction at the electrode in the absence of catalyst (see Supporting Information).

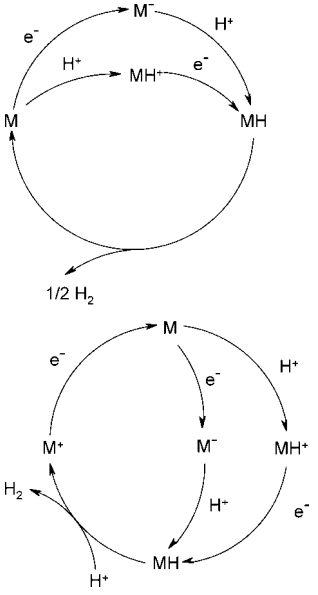
Figure 10 shows the evolution of the $i_c/i_p$ ratio, where $i_c$ is the catalytic peak current and $i_p$ the peak current of a monoelectronic wave, as a function of the number of equivalents of acid added. It is clear that the {Ni(emi)}-based catalysts have much higher catalytic peak intensities than the {Ni(xbsms)}-based catalysts. This reveals that the {Ni(emi)} moiety enhances the catalytic rate. It also appears that the evolution of the catalytic peak current for **1**Cl and **2** is proportional to the number of equivalents of added acid, which could indicate that the rate-determining step is a protonation.

### *Modeling Cyclic Voltammograms*

In order to characterize the mechanisms for hydrogen production, we modeled the cyclic voltammograms for the electroreduction of $Et_3NH^+$ catalyzed by **2** and $(NEt_4)_2$**4** in dimethylformamide using the DigiElch software.[25–30] Proton reduction yields dihydrogen following two general pathways depending on whether the H–H bond is formed in a homolytic or a heterolytic step.[31] The general mechanistic schemes are given in Scheme 1. Both pathways include pro-

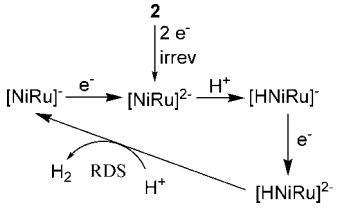
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tonation of the metal center to give a metal hydride complex. In the homolytic mechanism, $H_2$ evolution results from a reductive elimination reaction from two metal hydride moieties, whereas in the heterolytic pathway the metal hydride species is subjected to proton attack, which results in hydrogen production. We were unable to model the experimental cyclic voltammograms, namely to reproduce high $i_c/i_p$ ratios, using the homolytic hydrogen formation mechanism. This could be due to the fact that the rate of a step which is second-order with regard to the catalyst is necessarily slow and thus makes the homolytic pathway less kinetically favorable than the heterolytic one. In the following we will therefore only consider the heterolytic pathway.



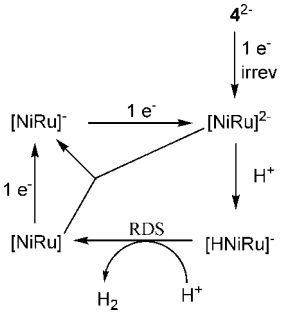
Scheme 1. Homolytic (top) and heterolytic (bottom) pathways for proton reduction catalyzed by a coordination compound.

The relative order of the two one-electron transfer and two protonation steps in the mechanism can be immediately determined by a simple examination of the voltammograms. In the cases of **1**Cl, **2**, and $(NEt_4)$**3**, the electrocatalytic wave develops at potentials more negative than the reduction potential of the catalyst; this implies that the hydride moiety formed by protonation after reduction of the catalyst needs to be activated by further reduction. The ECEC mechanism used for simulation of the electrocatalytic behavior of **2** is shown in Scheme 2. By contrast, the development of an electrocatalytic wave on a reduction wave of the catalyst, as



Scheme 2. Catalytic ECEC mechanism used for modeling the electrocatalytic behavior of **2** (RDS indicates the rate-determining step).

in the case of $(NEt_4)_2$**4**, suggests that the two one-reduction steps occur before the two protonation steps. Scheme 3 shows the suggested ECCE mechanism for this complex.



Scheme 3. Catalytic ECCE mechanism used for modeling the electrocatalytic behavior of $(NEt_4)_2$**4** (RDS indicates the rate-determining step).

The charge-transfer parameters ($E^0$, $a$, $k_s$) and diffusion coefficients describing the redox properties of the catalysts were determined from voltammograms obtained in the absence of acid and then used as such for simulation in the presence of acid. Heterogeneous charge-transfer processes are relatively slow, with rate constants $k_s$ ranging from $10^{-3}$ to $10^{-2}$ cm s$^{-1}$. Total and fast chemical reactions were introduced into the model to account for the irreversibility of the electrochemical processes.

By including the catalytic steps shown in Schemes 2 and 3 we succeeded in modeling the experimental cyclic voltammograms (Figures 11 and 12) and were able to reproduce the experimental data recorded at variable scan rates in the presence of a 1/1.5-, 3-, and 10-fold molar excess of $Et_3NHCl$ with one set of thermodynamic and kinetic constants for each compound. We chose the height, position, and shape of the catalytic wave as relevant criteria for the evaluation of the simulations. As can be seen in Figures 11 and 12, the major difference between simulated and experimental values concerns the reverse scan. In the case of $(NEt_4)_2$**4**, a disproportionation reaction was introduced to better reproduce the reverse scan of the electrocatalytic wave. Its equilibrium constant was calculated from the standard potentials of the corresponding redox couples and the scan rate was set as being diffusion-controlled.

The second protonation step was found to be the rate-determining step in both cases since the value of its rate constant [$10^3$ mol$^{-1}$ L s$^{-1}$ for **2** and $10^4$ mol$^{-1}$ L s$^{-1}$ for $(NEt_4)_2$**4**] determines the height of the electrocatalytic wave.

### *Bulk Electrolysis Experiments*

As for **2**, hydrogen evolution was detected and quantified by gas chromatography and volumetry during bulk electrolysis experiments of $Et_3NHCl$ on a mercury pool at –1.60 V vs. Ag/AgCl in dimethylformamide with **1**Cl, $(NEt_4)$**3**, $(NEt_4)_2$**4**, and [Ni(xbsms)] as electrocatalysts. As an example, Figure 13 shows the evolution of the charge passed during the bulk electrolysis of 0.5 mmol of $Et_3NHCl$ in the presence of 5 μmol of **1**Cl. The correlation between the charge and volume of evolved hydrogen is shown in the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

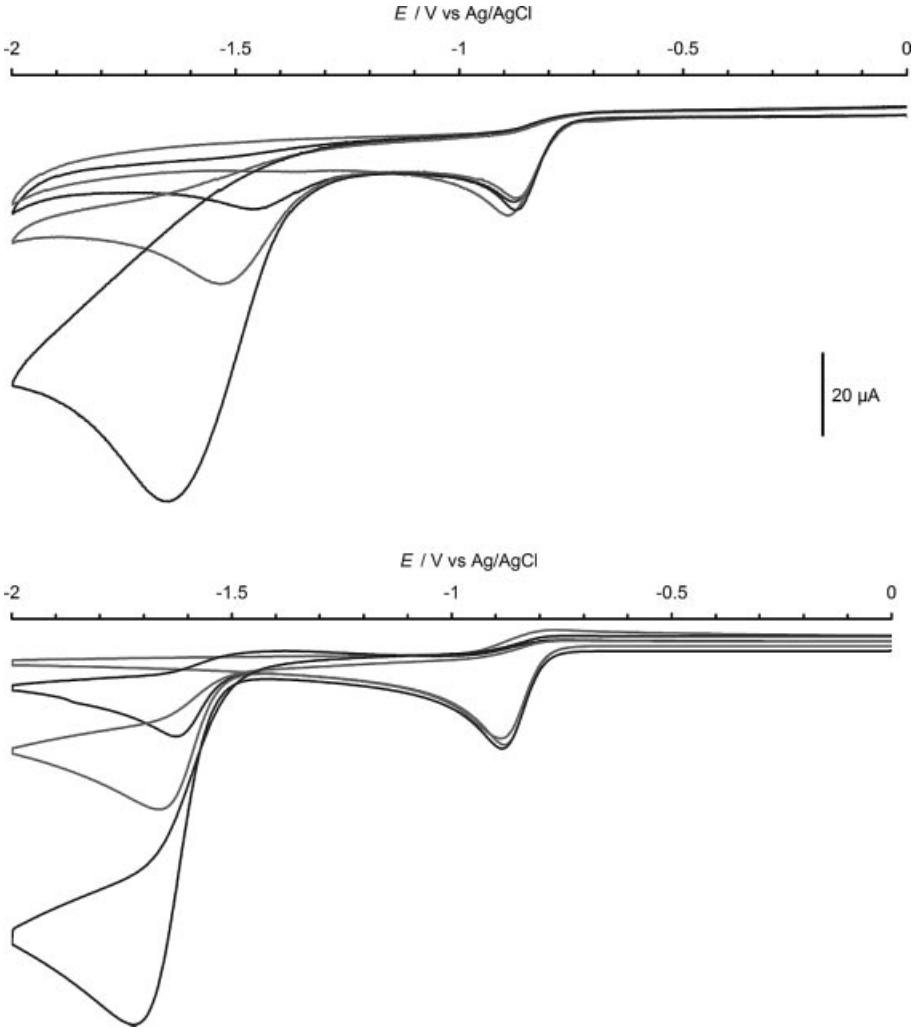


Figure 11. Experimental (top) and simulated (bottom) cyclic voltammograms of **2** (1.0 mM) recorded in a dimethylformamide solution of $n$Bu$_4$NBF$_4$ (0.1 mM) at a glassy carbon electrode in the presence of Et$_3$NHCl (1.0, 3.0, and 10 equiv.). Scan rate: 100 mV s$^{-1}$.

inset. The faradaic yield reaches 98%. Et$_3$NHCl is quantitatively converted to $H_2$ (50 turnovers) in 4 h [maximum turnover frequency ($TOF_{max}$) of 22 h$^{-1}$]. Addition of a further 0.5 mmol of Et$_3$NHCl allowed a second electrolytic run, with comparable yield and slightly lower rate, thereby indicating the chemical stability of the catalyst.

Table 1 summarizes the catalytic parameters of the various compounds, including complex **2**, determined under the same conditions and in the same electrolysis cell with a mercury pool of smaller but reproducible area. All of the dinuclear complexes catalyze Et$_3$NHCl reduction faster than their corresponding nickel precursor and all except (NEt$_4$)$_2$**4** are more active than [Ni(xbsms)]. The {Ru(*p*-cymene)Cl}$^+$ derivatives **1**Cl and (NEt$_4$)**3** are clearly the most efficient catalysts during bulk electrolysis experiments. Complexes **5** and **6**Cl are totally inactive under these conditions at –1.6 V vs. Ag/AgCl.

Finally, in order to compare the catalysts in terms of their chemical stability during cycling, we recorded cyclic voltammograms and/or steady-state rotating-disk-electrode voltammograms for the oxidative process before and after catalysis. Whereas the anodic wave disappears completely after 15 turnovers for catalysts **1**Cl and **2**, complexes (NEt$_4$)**3** and (NEt$_4$)$_2$**4** are quite stable under the catalytic conditions since the oxidative process appears quite unaffected after 29 and 27 turnovers, respectively (see Supporting Information).

## Discussion

The rational synthesis of heterodinuclear complexes that model the active sites of [NiFe] hydrogenases is a promising but challenging approach to the design of new catalysts for $H_2$ production or activation.[31] As far as nickel thiolate complexes are concerned, the main difficulty resides in the control of the nuclearity of the synthetic compound. The use of chelating ligands serves to avoid the formation of homometallic nickel clusters and a careful design of the precursor for the second metal site is required to avoid the formation of heterometallic oligomers. In particular, this implies that only a few labile ligands can be present on this

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

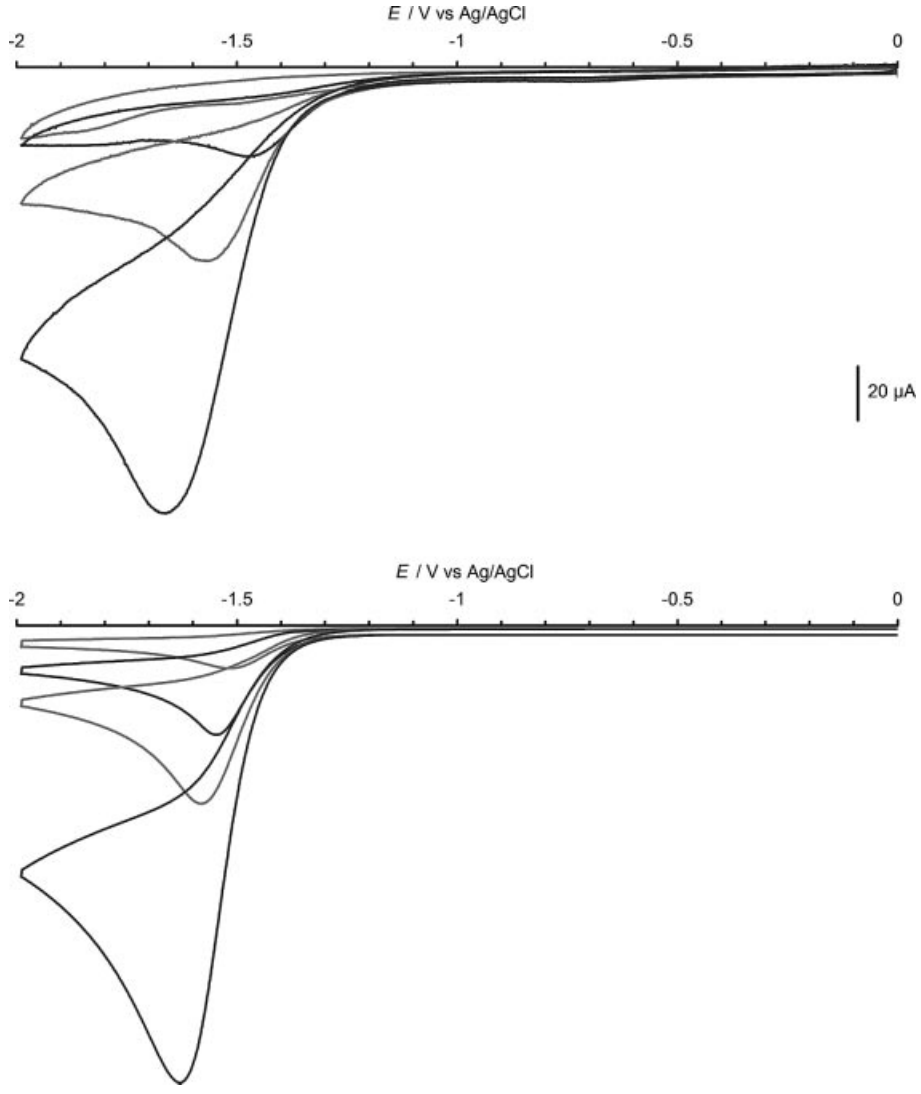

Figure 12. Experimental (top) and simulated (bottom) cyclic voltammograms of $(NEt_4)_2$**4** (1.0 mM) recorded in a dimethylformamide solution of $n$Bu$_4$NBF$_4$ (0.1 M) at a glassy carbon electrode in the presence of Et$_3$NHCl (1.5, 3.0, and 10 equiv.)). Scan rate: 100 mV s$^{-1}$.

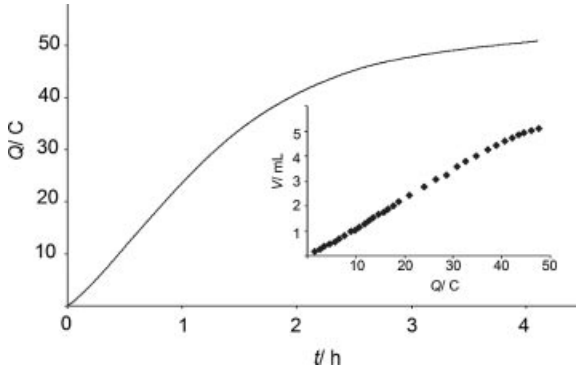

Figure 13. Coulometry for bulk electrolysis at –1.60 V vs. Ag/AgCl of a dimethylformamide solution (10 mL) of Et$_3$NHCl (0.05 M) and $n$Bu$_4$NBF$_4$ (0.1 M) at a mercury pool (approx. 3 cm$^2$) in the presence of **1**Cl (0.5 mM). The volume of hydrogen evolved as a function of charge is represented in the inset.

precursor. However, as a consequence, most of the reported models display a coordinatively saturated coordination sphere around the iron center with consequent low reactivity. Exceptions for nickel-iron assemblies are found for [Ni(xbsms)Fe(CO)$_2$I$_2$],[13] which contains labile iodide ligands, and [Ni(S{(CH$_2$)$_2$NMe(CH$_2$)$_2$S}$_2$)FeCp]$^+$,[32] which displays a vacant coordination site at the iron center. Unfortunately, no reactivity study regarding proton reduction or hydrogen oxidation has been reported either for these two complexes or for the other dinuclear nickel-iron complexes described to date. This may be due to some inherent instability of these complexes upon redox switching during catalysis. We thus decided to substitute iron for the heavier metal ruthenium with the aim of isolating species stable enough for the observation of electrochemical catalysis of hydrogen production. This approach initially allowed the preparation of **2** and we report here the synthesis and characterization of three novel nickel-ruthenium heterodinu-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

clear complexes carrying labile chloride ligands at the ruthenium metal center. In each case, the desired complex is the sole product of the reaction and separation from the salts is the sole purification step required. All four complexes contain the $\{Ni(\mu\text{-}SR)_2Ru\}$ fragment with bidentate coordination of the nickel complex to the ruthenium center. The hinge angles in **2** and $\mathbf{1}^+$ are in the range usually found in naturally occurring hydrogenases,[32] and the nickel–ruthenium distances are similar to the longer Ni–Fe distances observed in enzymes by X-ray crystallography: most of the nickel–iron distances determined for hydrogenases lie between 2.53 and 2.97 Å, which indicates some direct electronic interaction between the two metal centers, although, as an exception, a Ni–Fe distance of 3.23 Å was observed for the [NiFe] hydrogenase from *Desulfovibrio desulfuricans*.[33] However, computational modeling predicts large variations of this bond length in the active site depending on the redox state of the enzyme.[34]

### *Activation Potential*

All three new nickel-ruthenium compounds synthesized exhibit electrocatalytic activity for hydrogen production with overvoltages (also called activation potential: the difference between the electrocatalytic potential and the equilibrium potential of the $H^+/H_2$ couple under the same conditions) of 0.8–1.0 V, as estimated from the tabulated value of –1.31 V vs. $Fc/Fc^+$ for the $Et_3NH^+/H_2$ couple in dimethylformamide.[35] There is no net benefit in substituting either arene for CO ligands on ruthenium or $emi^{2-}$ for $xbsms^{2-}$ around the nickel ion as regards overvoltage.

For comparison, a variety of square-planar nickel complexes are known to catalyze proton electroreduction, most of which have an $N_4$ coordination sphere with mixed amino, imino, or pyridine ligands assembled in a macrocycle.[36–39] Except for $[Ni(L_{N4})]^+$ $\{L_{N4}^- = 2,6\text{-}HN[(CH_2)_3N{=}C(CH_3)]_2\text{-}C_5H_3N^-\}$, which is active at –1.1 V vs. SCE in acidic (pH 2) aqueous solution,[38] all of these catalysts are active at –1.5 to –1.6 V vs. SCE towards relatively weak acids or in neutral aqueous solutions. Two functional bio-inspired catalysts, namely $[(bdt)\{Ni(PMe_3)\}_2Fe(CO)(bdt)_2]$,[15] which stoichiometrically reduces $HBF_4$ into $H_2$, and $[Ni(L)\text{-}Fe_2(CO)_6]$ $[L = (CH_3C_6H_3S_2)_2(CH_2)_3]$, which electrocatalyzes the reduction of $CF_3COOH$ into $H_2$ at –1.64 V vs. $Fc/Fc^+$ in $CH_2Cl_2$, were described recently.[16] All these complexes catalyze proton electroreduction with an activation potential of 0.8 to 1.2 V. Very recently, DuBois et al. have described a series of nickel bis(diphosphane) complexes that are very competitive, as regards electrocatalytic potential, as electrocatalysts for both proton reduction and hydrogen oxidation.[40,41] However, the unique catalytic properties of these new catalysts are due to the presence of pendant basic sites and are not directly related to the nature of the coordination sphere around nickel [amino residues located on the ligands play the role of proton relays and greatly enhance the activity relative to classical noncatalytic nickel bis(diphosphane) complexes].

### *Catalytic Rate and Stability*

As seen in Figure 10, both $(NEt_4)$**3** and $(NEt_4)_2$**4** show high catalytic peak current enhancement relative to **1**Cl and **2**. Even though no direct analytical relationship between the catalytic peak current measured by cyclic voltammetry and turnover frequency exists, a comparison of the cyclic voltammograms recorded under the same conditions shows that the catalytic rate is greatly enhanced by the introduction of the $emi^{2-}$ anion as a ligand in place of $xbsms^{2-}$.

The same considerations based on $i_c/i_p$ values lead to the conclusion that the presence of an arene ligand rather than carbonyl ligands on the ruthenium center improves the efficiency of the catalyst. This is further confirmed by bulk electrolysis experiments: thus, when substituting $\{(p\text{-cymene})RuCl\}^+$ for $\{Ru(CO)_2Cl_2\}$ the rate of hydrogen production in both the {Ni(emi)} and {Ni(xbsms)} series is improved (Table 1).

Catalysis always takes place on or after an irreversible wave so that the isolated and structurally characterized dinuclear species are likely to be pre-catalysts rather than active catalysts. The exact nature of the chemical reaction following reduction is unknown. Loss of chloride ligand from the ruthenium center is likely, although radical reactions involving hydrogen atoms in the β-position with regards to the nickel center, as identified in mononuclear nickel thiolate complexes,[42] cannot be ruled out. Furthermore, no evidence for any breakdown of the dinuclear species could be obtained, and we could demonstrate that $\mathbf{3}^-$ and $\mathbf{4}^{2-}$ do not decompose during catalysis.

### *Cooperativity Between Metal Centers*

The electrocatalytic properties of dinuclear complexes for hydrogen production clearly denote the existence of a cooperative effect between nickel and ruthenium. Thus, while $(NEt_4)_2$[Ni(emi)] and **5** or $\mathbf{6}^+$ display no or only weak catalytic activity (e.g. at potentials below –1.8 V vs. Ag/AgCl and with low turnover frequencies) the dinuclear catalysts $(NEt_4)$**3** and $(NEt_4)_2$**4** readily catalyze $Et_3NHCl$ reduction near –1.6 V vs. Ag/AgCl, and hydrogen evolution during bulk electrolysis experiments at –1.6 V vs. Ag/AgCl is five times faster in the presence of $(NEt_4)$**3** than in the presence of $(NEt_4)_2$[Ni(emi)]. As for the [Ni(xbsms)] derivatives, coupling with ruthenium moieties results in an enhancement of the rate of hydrogen evolution by a factor of two (complex **2**) or five (complex **1**Cl). However, this is at the expense of the electrocatalytic potential, which is about 200 mV more negative than the electrocatalytic potential of [Ni(xbsms)] under the same conditions. Such a cooperative effect has been suggested to account for the higher activity of $[Ni_2(bis\text{-}cyclam)]^{4+}$ compared to $[Ni(cyclam)]^{2+}$ for proton reduction[37] and for the high activity in photoelectrochemical production of hydrogen catalyzed by bis(metallocene)s such as [1.1]ferrocenophane.[43]

Figure 14 shows the inverse correlation between the electrocatalytic potential and the C≡O force constant as a probe of the electron density on the metal centers for the three CO-containing compounds in this study. The nickel-iron hydrogenase from *D. gigas* nicely fits in this correlation

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

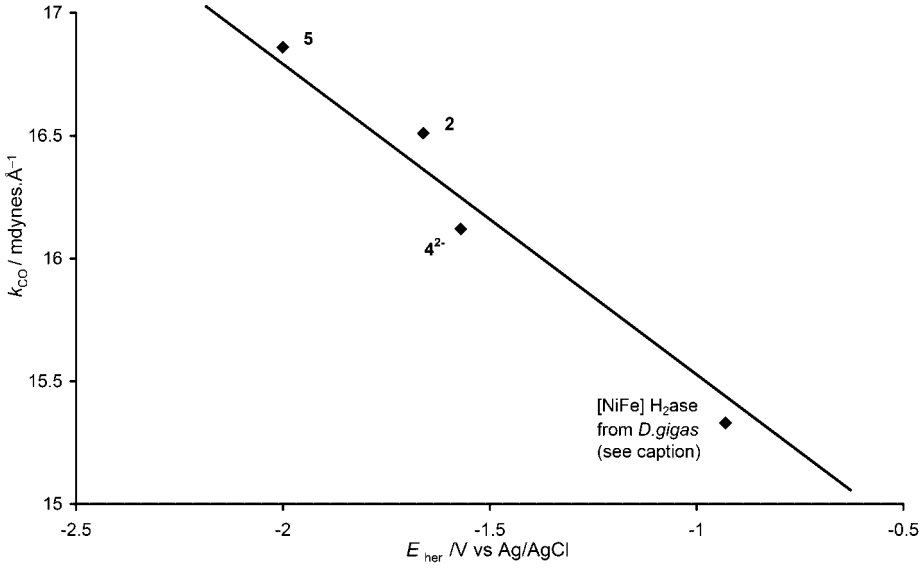

Figure 14. Correlation between the C≡O force constant ($k_{CO}$) and the electrocatalytic potential ($E_{her}$) for compounds **2**, $(NEt_4)_2$**4**, and **5**. Data have been extrapolated for [NiFe] hydrogenase from *D. gigas* in dimethylformamide solution using the measured $\nu_{CO}$ frequency for native enzyme in water and the experimental potential for reduction of $Et_3NHCl$ on a platinum electrode in dimethylformamide.[35]

when extrapolating the redox potential measured in water to dimethylformamide solution. We can conclude from this correlation that the more electron-rich the metal center the better the catalyst as far as overvoltage is concerned. This implies that the rate-determining step has a nucleophilic nature and may involve a protonation. This is further supported, in the case of **1**Cl and **2**, by the relative linearity of the $i_c/i_p$ ratio as a function of the number of equivalents of added acid and by modeling studies of the cyclic voltammograms of **2** and $(NEt_4)_2$**4**.

Modeling of the voltammograms was possible with classical catalytic mechanisms involving metal hydride species[44] resulting from the interaction of protons with the reduced dinuclear complexes. Two distinct mechanisms have been identified: $\mathbf{1}^+$, **2**, and $\mathbf{3}^-$ catalyze proton reduction by an ECEC mechanism similar to that (Scheme 3) proposed for proton electroreduction catalyzed by a rhodium porphyrin[45] and the $\{BF_2\}$-bridged cobaloxime $[Co(dmgBF_2)_2L_2]$ (L = $H_2O$, $CH_3CN$, dmf).[46] In contrast, $\mathbf{4}^{2-}$-catalyzed hydrogen evolution proceeds by an ECCE pathway similar to the catalytic mechanism for hydrogen evolution determined for iron porphyrin[47] or cobaloxime complexes.[48] The rate-determining step was found to be protonation of the hydride intermediate in both cases, as previously reported for iron porphyrin[47] or cobaloxime complexes.[48]

## Conclusions

We have synthesized a series of novel bio-inspired dinuclear nickel-ruthenium complexes that are efficient catalysts for proton reduction under quite neutral conditions in dimethylformamide and have found evidence for a cooperative effect between the metal centers which enhances the catalytic rate, whereas high electron density at the metal centers favors low overvoltages. The catalysts are more stable when no hydrogen atom is present in the β-position with regard to the nickel center. These general trends may help in the synthesis of new catalysts with a lower overvoltage and higher stability.

## Experimental Section

**Materials:** All reactions were carried out under argon using standard Schlenk techniques. Solvents were distilled under argon. NMR solvents were deoxygenated by three freeze-pump-thaw cycles and stored over molecular sieves. Commercial dimethylformamide and acetonitrile for electrochemistry were degassed by bubbling nitrogen through them. $(NEt_4)_2$[Ni(emi)],[19] [Ru(*p*-cymene)$Cl_2]_2$,[49,50] $[Ru(CO)_2Cl_2]_n$,[51,52] [Ni(xbsms)],[18] and 1,7-diphenyl-2,6-dithiaheptane ("$C_3S_2$")[20] were prepared according to reported procedures. The supporting electrolyte ($n$Bu$_4$N)$BF_4$ was prepared from ($n$Bu$_4$N)$HSO_4$ (Aldrich) and $NaBF_4$ (Aldrich) and dried overnight at 80 °C under vacuum. Triethylammonium chloride (Acros) was used as received.

**Methods and Instrumentation:** $^1$H NMR spectra were recorded at room temperature in 5-mm tubes with a Bruker AC300 spectrometer equipped with a QNP probehead. $^1$H NMR signals were assigned by NOE difference experiments performed using standard pulse sequences. IR spectra were recorded with a Bruker Vector 22 spectrophotometer (400–4000 cm$^{-1}$, Class 3A laser). The spectra were recorded in solution, using a KBr cell. UV/Vis spectra were recorded with a Carry Bio1 (Varian) spectrophotometer in quartz Schlenk cells. ESI mass spectra were recorded with a Finnigan LCQ thermoquest ion-trap. Elemental analyses were performed by the Service Central d'Analyse of the CNRS (Vernaison, France). All electrochemical measurements were carried out under nitrogen in a thermostatted cell at 20 °C. A standard three-electrode configuration was used consisting of a glassy carbon (3 mm in diameter) or platinum (2 mm in diameter) disk as the working electrode, an auxiliary platinum wire and an Ag/AgCl/aqueous $AgCl_{sat}$ + KCl

3 M (named Ag/AgCl through this text) reference electrode closed by a Vycor frit and dipped directly into the solution. In order to take into account the liquid junction potential between aqueous and non-aqueous solution, this electrode was calibrated with the internal reference system $Fc^+/Fc$, which was found at 0.46 V vs. Ag/AgCl in $CH_3CN$ (0.53 V in dimethylformamide). The $Fc^+/Fc$ couple ($E^0$ = 0.400 V vs. SHE)[53] can be used to quote potentials relative to an SHE, when needed.

Cyclic voltammograms were recorded with a EG&G PAR 273A instrument. Solution concentrations were approx. 1 mM for the catalyst and 0.1 M for the supporting electrolyte ($n$-$Bu_4N$)$BF_4$. Electrodes were polished with an MD-Nap polishing pad with 1-μm monocrystalline diamond DP suspension and DP lubricant blue (Struers). Additions of $Et_3NHCl$ were made by syringe as a 50 mM solution in dimethylformamide.

Bulk electrolysis experiments and coulometry were carried out on an EG&G PAR 273A instrument in dimethylformamide, using a mercury pool cathode. The platinum-grid + carbon-foam counter electrode was placed in a separate compartment connected by a glass-frit and filled with a 0.1 M solution of ($n$$Bu_4N$)$BF_4$ in degassed dimethylformamide. A made-to-measure electrolysis cell with a cylindrical reservoir was used. The mercury pool surface was therefore identical from one experiment to another. The mercury surface was measured as 1.23 $cm^2$. The electrolysis cell constant was determined to be $2.34 \times 10^{-4}$ $s^{-1}$ by performing bulk electrolysis of methylviologen hexafluorophosphate.[54]

The following procedure was followed for catalytic acid reduction bulk electrolysis: A degassed dimethylformamide solution (6–10 mL) containing 0.1 M ($n$$Bu_4N$)$BF_4$ was first electrolyzed at –1.60 V vs. Ag/AgCl until the current reached 1% of its initial value. The catalyst was then added and electrolysis was also performed at –1.60 V vs. Ag/AgCl until the current reached 1% of its initial value. $Et_3NHCl$ was then added and electrolysis was still performed at –1.60 V vs. Ag/AgCl. The faradaic yield was estimated from a periodic volumetric measurement of the amount of evolved gas. Hydrogen was tested for purity using a Delsi Nermag DN200 GC chromatograph equipped with a 3 m Porapack column and a thermal conductivity detector (TCD). Except when using $(Et_4N)_2$[Ni(emi)] as the catalyst, the electrolytic solutions remained clear after catalysis. We checked that neither the mercury pool nor the graphite electrode exhibit catalytic activity when washed after electrochemical experiments and replaced under the same conditions in the absence of catalyst. We can thus rule out the formation of any heterogeneous catalysis (coating or amalgam).

Cyclic voltammograms were simulated using the DigiElch software.[25–30] A first simulation and best-fitting was performed for **2** and $(NEt_4)_2$**4** in dimethylformamide in the absence of added acid. Parameters were refined until voltammograms recorded at 20, 50, and 100 mV $s^{-1}$ could be simulated using the same set of values. The resulting parameters were kept unchanged for simulation of voltammograms recorded in the presence of acid. The model was then modified to include the catalytic steps and the new parameters refined until one set of values provided correct simulation of the voltammograms recorded in the presence of various amounts of added acid (1, 1.5, 3, and 10 equiv.) at different scan rates (20, 50, and 100 mV $s^{-1}$).

**Crystal Structure Analysis:** Crystallographic data are summarized in Table 2. Data collection was performed at 298 K with a Bruker SMART diffractometer with a CCD area detector, with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Empirical absorption correction (Sadabs) was performed. Molecular structures were solved by direct methods and refined on $F^2$ by full-matrix least-squares techniques with the SHELXTL package,[55] with anisotropic thermal parameters. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were generally found and refined isotropically. The hydrogen atoms of the methyl and isopropyl groups of the $p$-cymene ligands and the solvent molecules were placed in ideal positions and refined as riding atoms with individual isotopic displacement parameters.

Table 2. Crystallographic data for **6**Cl·2$CHCl_3$ and **1**$BF_4$.

| | **6**Cl·2$CH_2Cl_2$ | **1**$BF_4$ |
|---|---|---|
| Formula | $C_{29}H_{38}Cl_6RuS_2$ | $C_{26}H_{38}BClF_4NiRuS_4$ |
| Molecular mass | 764.53 | 760.84 |
| Color | orange | red |
| Crystal size [$mm^3$] | $0.50 \times 0.20 \times 0.20$ | $0.30 \times 0.10 \times 0.05$ |
| Crystal system | triclinic | monoclinic |
| Space group | $P\bar{1}$ | $P2_1/n$ |
| $a$ [Å] | 13.900 (6) | 13.823(4) |
| $b$ [Å] | 14.225(6) | 11.843(3) |
| $c$ [Å] | 17.531(7) | 18.598(5) |
| $\alpha$ [°] | 96.280(8) | 90 |
| $\beta$ [°] | 92.949(7) | 97.029(6) |
| $\gamma$ [°] | 98.191(8) | 90 |
| $V$ [$Å^3$] | 3402(2) | 3021.7(14) |
| $Z$ | 4 | 4 |
| $\rho_{calcd}$ [mg $m^{-3}$] | 1.492 | 1.672 |
| $\mu$ [$cm^{-1}$] | 10.73 | 15.29 |
| Reflections measured | 21319 | 8075 |
| Unique reflections ($R_{int}$) | 15538 ($R$int = 0.0127) | 4189 ($R$int = 0.0251) |
| Refined parameters | 913 | 514 |
| Observed reflections [$I > 2\sigma(I)$] | 13084 | 3596 |
| $R$ indices (all data) | $R_1$[a] = 0.0581, $wR_2$[b] = 0.1001 | $R_1$ = 0. 0592, $wR_2$ = 0.1471 |
| Goodness of fit ($S$) | 1.12 | 1.03 |
| $\Delta\rho$ (max/min) [e $Å^{-3}$] | 1.081/–1.077 | 1.993/–1.711 |

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$, $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ where $P = [2F_c^2 + \max.(F_o^2, 0)]/3$ (see CIF file for values of $a$ and $b$).

Crystals of **1**$BF_4$ were grown from a filtered solution of equimolar amounts of **1**Cl and $AgBF_4$ in chloroform with added pentane at 4 °C. The asymmetric unit contains one $\mathbf{1}^+$ cation and one $BF_4^-$ anion disordered over two positions around the boron atom.

Crystals of **6**Cl·2$CH_2Cl_2$ suitable for X-ray diffraction were grown from a dichloromethane/pentane solution of **6**Cl at 4 °C. The asymmetric unit contains two $\mathbf{6}^+$ cations, two chloride anions, and four molecules of $CH_2Cl_2$, one of which is disordered over two positions.

CCDC-281929 (for **1**BF4) and -631503 (for **6**Cl·2$CHCl_3$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Center via ww.ccdc.cam.ac.uk/datarequest/cif.

**[Ni(xbsms)Ru(*p*-cymene)Cl]Cl (1Cl):** [Ru(*p*-cymene)$Cl_2$]$_2$ (101 mg, 0.160 mmol) and [Ni(xbsms)] (128 mg, 0.318 mmol) were dissolved in dichloromethane (5 mL). After 30 min stirring at room temperature, the mixture was evaporated to dryness. The product was passed through a silica gel column using an acetonitrile/methanol (10:1, v/v) mixture as eluent. The first fraction was dried under vacuum to yield pure **1**Cl·0.5$CH_2Cl_2$·2.5$H_2O$ as a red powder (158 mg, 74%). $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 7.28 (s, 4 H, Ar), 5.73 (d, $J$ = 5.7 Hz, 2 H, Ru-Ar), 5.54 (d, $J$ = 5.7 Hz, 2 H, Ru-Ar), 5.33 (d, $J_{A,B}$ = 12 Hz, 2 H, ArC$H_{ax}$$H_{eq}$S), 3.87 (d, $J_{A,B}$ = 12 Hz, 2 H, ArC$H_{eq}$$H_{ax}$S), 3.02 [d, $J_{A,B}$ = 12 Hz, 2 H, $(CH_3)_2$CC$H_{eq}$$H_{ax}$], 2.51 [sept, $J$ = 6.9 Hz, 1 H, $(CH_3)_2$C$H$Ar], 2.50 [d, $J_{A,B}$ = 12 Hz, 2 H, $(CH_3)_2$CC$H_{eq}$$H_{ax}$], 2.12 (s, 3 H, Ru-ArC$H_3$), 1.72 (s, 6 H, $Me_{ax}$),1.45 (s, 6 H, $Me_{eq}$), 1.21 [d, $J$ = 6.9 Hz, 6 H, $(CH_3)_2$CHAr] ppm. ESI-MS: *m*/*z* (%) 675 (100) [M]. $C_{26.5}H_{44}Cl_3NiO_{2.5}RuS_4$ (797.02): calcd. C 39.93, H 5.56, Cl 13.83, Ni 7.36, Ru 12.68, S 16.09; found C 40.19, H 5.34, Cl 12.56, Ni 7.32, Ru 11.66, S 13.21. UV/Vis: $\lambda_{max}$ ($\varepsilon$) = 453 nm (706 $M^{-1}cm^{-1}$), 337.

**(NEt$_4$)[Ni(emi)Ru(*p*-cymene)Cl] [(NEt$_4$)3]:** [Ru(*p*-cymene)$Cl_2$]$_2$ (37.5 mg, 0.118 mmol) and $[NEt_4]_2$[Ni(emi)] (69 mg, 0.119 mmol) were dissolved in dichloromethane (5 mL). After 30 min stirring at room temperature, the mixture was evaporated to dryness. The product was extracted twice with tetrahydrofuran then pentane was added to the combined filtrates. Crystallization of this solution occurred at 4 °C. The resultant small red crystals were separated by filtration with a 71% yield (60 mg). $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 5.49 (d, $J$ = 6 Hz, 2 H, Ru-Ar), 5.44 (d, $J$ = 6 Hz, 2 H, Ru-Ar), 3.35 [m, 8 H, N(C$H_2$$CH_3$)$_4^+$], 2.78 [sept, $J$ = 7.2 Hz, 1 H, $(CH_3)_2$C$H$Ar], 2.11 (s, 3 H, Ru-ArC$H_3$), 1.57 (s, 4 H, NC$H_2$), 1.3 [m, 24 H, $(CH_3)_2$CS and N($CH_2$C$H_3$)$_4^+$], 1.12 [d, $J$ = 7.2 Hz, 6 H, $(CH_3)_2$CHAr] ppm. $^{13}$C NMR (76 MHz, $CD_3OD$): $\delta$ = 85.98, 82.53 (Ar), 52.78, 52.74, 52.69 [N($CH_2$$CH_3$)$_4^+$], 32.16 or 30.57 [$(CH_3)_2$CS], 28.60 (N$CH_2$), 21.73 [$(CH_3)_2$CHAr], 17.56 [$(CH_3)_2$CHAr], 7.05 [N($CH_2$$CH_3$)$_4^+$] ppm. UV/Vis: $\lambda_{max}$ ($\varepsilon$) = 523 nm (198 $M^{-1}cm^{-1}$), 430 (263), 353, 240.

**(NEt$_4$)$_2$[Ni(emi)Ru(CO)$_2$Cl$_2$] [(NEt$_4$)$_2$4]:** [Ru(CO)$_2$Cl$_2$]$_n$ (12.4 mg, 0.054 mmol) and $[NEt_4]_2$[Ni(emi)] (30 mg, 0.052 mmol) were dissolved in dichloromethane (5 mL). After 5 min stirring at room temperature, the mixture was evaporated to dryness to give a red solid. $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 3.47 [m, 16 H, N(C$H_2$$CH_3$)$_4^+$], 3.16 (s, 4 H, NC$H_2$), 1.62 [m, 12 H, $(CH_3)_2$CS], 1.38 [m, 24 H, N($CH_2$C$H_3$)$_4^+$] ppm. IR: ($CH_2Cl_2$): $\nu_{CO}$ = 2037 (s), 1958 (s) $cm^{-1}$. UV/Vis: $\lambda_{max}$ ($\varepsilon$) = 517 nm (185 $M^{-1}cm^{-1}$), 390–410.

**[("$C_3S_2$")Ru(CO)$_2$Cl$_2$] (5):** [Ru(CO)$_2$Cl$_2$]$_n$ (219 mg, 0.961 mmol) and 1,7-diphenyl-2,6-dithiaheptane ("$C_3S_2$"; 274 mg, 0.951 mmol) were dissolved in methanol (5 mL). After stirring for 1 h at room temperature, the mixture was filtered and the filtrate evaporated to dryness. The product was passed through a silica gel column using dichloromethane as eluent. The first pale-yellow fraction was dried under vacuum to yield [("$C_3S_2$")Ru(CO)$_2$Cl$_2$]·0.5$CH_2Cl_2$·0.9$CH_3CN$ as a red powder (132 mg, 26.7%). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.37 (m, 10 H, Ar), 4.23 (s, 4 H, PhC$H_2$S), 2.83 (m, 4 H, $CH_2$C$H_2$S), 2.13 (m, 2 H, C$H_2$$CH_2$S) ppm. $^{13}$C NMR (76 MHz, $CDCl_3$): $\delta$ = 191.93 (CO), 130.42, 130.00, 129.72, 129.54, 129.39 (Ar), 41.77 (Ph$CH_2$S), 28.49 ($CH_2$$CH_2$S), 24.19 ($CH_2$$CH_2$S) ppm. IR ($CH_2Cl_2$): $\nu_{CO}$ = 2074 (s), 2007 (s) $cm^{-1}$. $C_{21.3}H_{23.2}Cl_{2.5}N_{0.9}O_2RuS_2$ (577.66): calcd. C 44.28, H 4.04, Cl 15.34, Ru 17.49, S 11.10; found C 43.83, H 4.13, Cl 13.77, Ru 17.66, S 11.44. UV/Vis: $\lambda_{max}$ ($\varepsilon$) = 381 nm (295 $M^{-1}cm^{-1}$).

**[("$C_3S_2$")Ru(*p*-cymene)Cl]Cl (6Cl):** [Ru(*p*-cymene)$Cl_2$]$_2$ (166 mg, 0.524 mmol) and "$C_3S_2$" (151 mg, 0.524 mmol) were dissolved in dichloromethane (5 mL). After 30 min stirring at room temperature, the mixture was evaporated to dryness. The product was then passed through a silica gel column using methanol as eluent. The first red fraction was dried under vacuum to yield [("$C_3S_2$")Ru(*p*-cymene)Cl]Cl·2$CH_2Cl_2$ (187 mg, 48%) as a red powder. $^1$H NMR (300 MHz, $CD_3OD$): $\delta$ = 7.47 (m, 10 H, Ar), 5.87 (d, $J$ = 6 Hz, 2 H, Ru-Ar), 5.71 (d, $J$ = 6 Hz, 2 H, Ru-Ar), 4.32 (dd, $J_{A,B}$ = 12.9 Hz, $\nu_A$ = 5.36, $\nu_B$ = 5.29, 4 H, PhC$H_2$S), 2.8 (m, 4 H, SC$H_2$$CH_2$), 2.77 [sept, 1 H, $(CH_3)_2$C$H$Ar], 2.32 (m, 2 H, $SCH_2$C$H_2$), 2.26 (s, 3 H, Ru-Ar$CH_3$), 1.35 [d, $J$ = 7.2 Hz, 6 H, $(CH_3)_2$CHAr] ppm. $^{13}$C NMR (76 MHz, $CD_3OD$): $\delta$ = 134.77, 130.64, 129.72, 129.43, 129.20 (Ar), 88.29, 87.86 (Ru-Ar), 47–50 ($PhCH_2$S), 31.55, 30.39, 30.24, 29.70 [$(CH_3)_2$CHAr, S$CH_2$$CH_2$, $SCH_2$$CH_2$], 22.06 [$(CH_3)_2$CHAr], 17.86 (Ru-Ar$CH_3$) ppm. ESI-MS: *m*/*z* (%) 596 (100) [M]$^+$. $C_{29}H_{38}Cl_6RuS_2$ (764.53): calcd. C 45.56, H 5.01, Cl 27.82, Ru 13.22, S 8.39; found C 42.25, H 4.41, Cl 24.56, Ru 11.37, S 7.86. UV/Vis: $\lambda_{max}$ ($\varepsilon$) = 351 nm (886 $M^{-1}cm^{-1}$), 429.

**Supporting Information** (see also the footnote on the first page of this article): Cyclic voltammograms of **5**, **6**Cl, and $Et_3NHCl$ in dimethylformamide solution; cyclic voltammograms of $(Et_4N)_2$[Ni(emi)] in the presence of various amounts of $Et_3NHCl$ in dimethylformamide solution; cyclic voltammograms and steady-state rotating-disk-electrode voltammograms recorded for (NEt$_4$)**3** and (NEt$_4$)**4** before and after catalysis and parameters used to simulate cyclic voltammograms using the mechanisms described in Schemes 2 and 3 using DigiElch 2.0.

**Note Added in Proof** (May 2, 2007): During correction of the proofs, the synthesis and full characterization of the bridging hydride derivative of a dinuclear complex [(L)Ni(μ-H)Ru($C_6Me_6$)]$^+$ was reported by Ogo et al.[56] This species was obtained from the hydrogen reduction of a nickel-ruthenium compound very similar to $\mathbf{1}^+$ and $\mathbf{3}^-$. As this reaction corresponds to the addition of two electrons and one proton to the $Ni^{II}$-$Ru^{II}$ state, this new compound is a stable analogue of the reactive intermediates proposed here in the catalytic mechanisms for hydrogen electro-production.

# Inter- and Intramolecular Electron Transfer in Modified Azurin Dimers

Thyra E. de Jongh,[a] Maren Hoffmann,[b] Oliver Einsle,[b] Davide Cavazzini,[c] Gian-Luigi Rossi,[c] Marcellus Ubbink,[a] and Gerard W. Canters*[a]

**Keywords:** Metalloproteins / Protein structures / Copper protein / Electronic coupling / Hydrophobic patch

A dimer of N42C azurin (*P. aeruginosa*), formed by intermolecular disulfide bond formation between the introduced surface-exposed cysteine residues, was previously shown to exhibit low rates of intramolecular electron self-exchange. The work presented here aims to render the construct sensitive to pH by the introduction of an additional surface mutation (M64E). The structural and mechanistic effects of ionisable residues in the hydrophobic patch were analysed as a function of pH. A crystal structure of the dimer at pH = 3.1, solved to 2.3 Å resolution, displays an orientation distinct from other known azurin complexes. The dimer exhibits slow intramolecular self-exchange at pH* = 4.5 ($k_{ese}^{intra} \approx 25\ s^{-1}$), in line with the Cu–Cu distance of 20.5 Å observed in the crystal structure of the dimer. The intermolecular electron self-exchange rate constant amounts to $k_{inter} = (1.8 \pm 0.1) \times 10^4\ M^{-1}s^{-1}$. Thus, at protein concentrations less than 1 mM, the intramolecular process dominates the electron self-exchange. A change from low to high pH results in a slowing down of the electron-exchange processes. A partitioning between intra- and intermolecular exchange proved impossible at low pH due to the limited precision of the experimental data.

## Introduction

Abbreviations: 1,5-dip: 1,5-bis(imidazol-1-yl)pentane; 1,6-dih: 1,6-bis(imidazol-1-yl)hexane; wt: wild type; Azu: azurin; BMME: bis(maleimidomethyl) ether.

Among the physico-chemical processes that constitute the basis of life, the formation of protein–protein complexes occupies a prominent place. An example of this kind is provided by the metabolic processes in the living cell. They are mediated by protein–protein complexes that promote interprotein electron transfer (ET). These complexes have a transient nature. Their lifetimes reflect the rate at which metabolic processes take place in the cell and generally lie within the range of from 1 to 1000 ms. It is precisely their fleeting existence which makes these transient complexes difficult to study by conventional means such as crystallography. Two main alternative routes of research have been explored in the recent past. One technique relies on the use of NMR which is a form of spectroscopy that is eminently suited for the study of dynamic processes and short-lived structures.[1–4] The other is to freeze the complexes by covalently linking them as soon as they have formed in the hope that the covalently linked complex preserves the active conformation. The cross-linked complex can then be studied in detail.

Previous research has focused on complexes in which two monomers of the electron-transfer protein azurin (Azu) have been linked.[5,6] The rationale for studying these complexes is twofold. First, the covalent linking of the partners in an encounter complex may lead to a configuration that is different from the active configuration, i.e. the configuration that leads to protein–protein ET. For this reason it is important to study how the linking may affect the structure of the complex and how small changes in the contact surface may influence the details of this structure. Secondly, it is of interest to know how the structure of the complex and thereby the ET process may be modified by applying changes in the surface of the contact area. This may be relevant for the technological implementation of proteins in electronic devices such as sensors, actuating elements and fuel cells etc.

Azurin from *Pseudomonas aeruginosa* is a so-called blue copper protein of 14 kDa, in which a single Cu ion is immobilized in the protein structure through bonds to two histidines, a cysteine and a methionine. The backbone carbonyl oxygen atom of a glycine completes the coordination shell through a weak coordinate bond. The electron self-exchange (ese) rate of the protein is high ($1 \times 10^6\ M^{-1}s^{-1}$, at room temperature) and insensitive to pH.[7] The crystal

structure of Azu provides a clue as to why the ese rate is so high.[8] The Azu molecules pack with their so-called hydrophobic patches positioning the His117 ligands of the Cu atoms in the monomers directly opposite each other.[8] This configuration optimises the electronic coupling between the Cu centres in the two monomers. The coupling is further enhanced by the presence of two water molecules that form an H-bonded pathway between the $N^{\varepsilon}$ atoms of the two histidines.[8,9]

Confirmation that this is a favoured orientation for two Azu molecules in an ET-active complex came from studies of complexes in which two Azu molecules were covalently linked. By introducing a cysteine at position 42 (Asn42Cys mutation) and incubating the mutated protein with bis(maleimidomethyl) ether (BMME), a covalently linked dimer of Azu was obtained in which the hydrophobic patches face each other.[5] A high intramolecular ese rate was observed ($>10^4\ s^{-1}$) while the intermolecular rate (i.e. between two different dimers) was too slow to be measurable.[5] The latter observation confirmed that the packing of the Azu moieties in the dimer blocks the hydrophobic patch, thereby rendering intermolecular ET virtually impossible. Leaving out the BMME linker and connecting the two Azu molecules directly by the Cys42–Cys42 disulfide bridge resulted in a complex in which the two Azu molecules had rotated around the Cys42 –Cys42 link, apparently to relieve a slight steric hindrance. As a result intra-ese stopped. Inter-ese was only slightly slower than observed for wild-type (wt) Azu.[5,6]

Earlier evidence for the involvement of the hydrophobic patch in the ese reaction of (monomeric) azurin had been obtained from studies of azurin variants in which charges had been introduced in the hydrophobic patch. The Met44-Lys mutation, for instance, was found to diminish the ese rate by two orders of magnitude in the pH range in which the Lys side chain is protonated and therefore charged, while the ese rate returns to its wt value at high pH, at which the Lys side chain becomes deprotonated and therefore uncharged.[10–12] Likewise, the Met64Glu mutation caused a slowing down of the ese reaction at high pH where the Glu side chain becomes charged.[13]

The present study deals with Azu dimers that are linked directly through a Cys–Cys link at position 42. In addition, a charge was introduced in the hydrophobic patch by the mutation M64E. The effect of pH on the inter- and intra-dimer electron self-exchange was studied. The expectation was that the inter-dimer ese rate would be affected by pH while, by analogy with earlier results on the Cys42–Cys42-coupled dimer, the intra-protein rate would be too slow to be measurable and independent of pH. Contrary to this expectation, the latter rate appeared to be clearly non-zero. Also, the structure of the complex as determined by X-ray diffraction shows that the two Azu moieties are in an orientation that differs from both the BMME- and the disulfide-linked dimers of the N42C Azu variant. NMR spectroscopic studies substantiate the absence of significant structural variations in time, as well as the absence of significant perturbations of the interface between the two monomers. The observed rates can be rationalised with the help of current models of ET on the basis of the observed structure of the complex. The results show that our present understanding of the parameters that determine the structure of an association complex is insufficient to predict structural variations on the basis of simple intuitive arguments.

## Results

Electron self-exchange rates were determined by monitoring the resolved NMR signal of the $H^{\gamma 2}$ methyl group of Val31. In oxidised wt Azu, this signal occurs at $\delta$ = –0.77 ppm at room temperature and pH = 8.5, while it occurs at $\delta$ = –0.69 ppm in reduced Azu. In a partly reduced/partly oxidised solution of Azu, two signals can therefore be observed at –0.77 and –0.69 ppm, which coalesce in the case when there is fast electron self-exchange between reduced and oxidized Azu, while only broadening of the individual signals is seen when the ese is slow. By analysing the shape of the Val31 γ2-methyl signal the ese rate can be extracted. Repeating the measurements at a series of different pH values gives the pH dependence of the ese rate.

For wt Azu, the position of the Val31 signal is pH-dependent.[12] At low pH the signal occurs at $\delta$ = –0.670 and –0.720 ppm for reduced and oxidised Azu, respectively, while at high pH these positions are $\delta$ = –0.690 and –0.770 ppm, respectively. At intermediate pH values the peaks of both the high- and the low-pH forms can be seen simultaneously, their relative intensities varying with pH. This is illustrated in Figure 1A. Apparently, the protein is involved in a protonation/deprotonation equilibrium with slow exchange kinetics. It is known that the residue involved is His35.[11,12,14] The pH dependence of the Val31 signals, with different $pK_a$ values for the oxidised and reduced forms (Figure 1B), complicates the analysis of the electron self-exchange data considerably. Therefore, His35 was eliminated by replacing it with phenylalanine. This is one of a series of His35 mutations which are known only to marginally affect the structure of the Azu and its ET kinetics.[11,15] It was checked that the H35F mutation eliminated the pH dependence of the Val31 resonances (Figure 1A).

For the next experiments, Azu was prepared in which the following mutations had been applied: His35Phe, Asn42Cys and Met64Glu. Subsequently, dimers were constructed in which the Azu moieties were connected through the C42–C42 S–S bridge. In solutions of partly reduced/oxidised dimers broadening but no coalescence of the Val31 γ2-methyl signals was observed when compared with signals from the fully reduced or oxidised solutions (Figure 2). Qualitatively it can be concluded that the exchange is in the slow regime.

To distinguish the contributions to the line broadening that derive from inter-dimer and intra-dimer electron self-exchange, the Val31 γ2-methyl signals were measured as a function of total concentration of the dimer. One would expect the *intra*-dimer contribution to be constant and the *inter*-dimer contribution to diminish at lower concentrations. The signals measured at pH* = 4.5 and 295 K (Fig-

Solid lines represent fits to the Henderson–Hasselbalch equation from which $pK_{a,ox}$ and $pK_{a,red}$ were determined at 6.3 and 7.0, respectively.

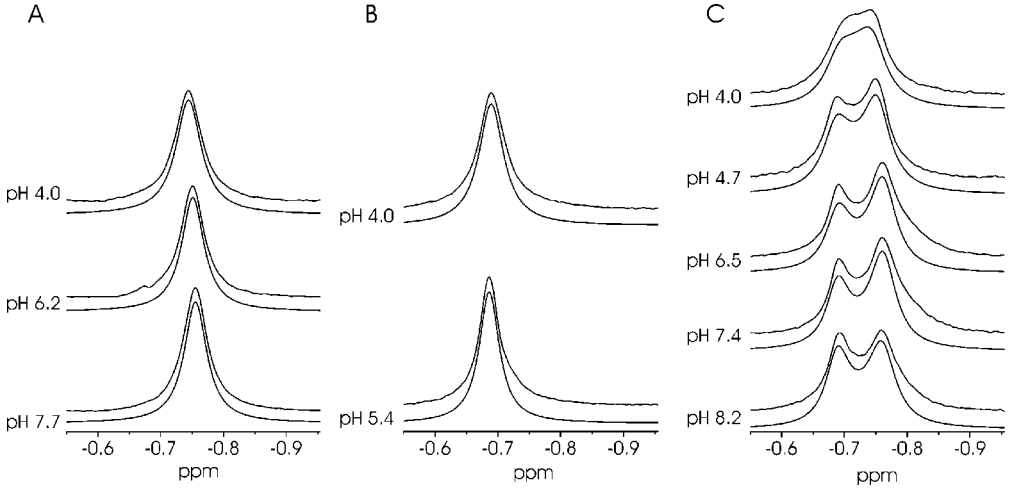

Figure 2. Val31 γ2-methyl resonance in the $^1$H NMR spectrum of H35F/N42C/M64E disulfide azurin at (A) 100%, (B) 0% and (C) 50–60% oxidation (1 mM of dimer protein in 25 mM potassium phosphate, $T$ = 295 K). The upper traces represent the experimental data, while the simulated spectra generated using the MEX software program are shown in the lower traces. The experimental spectra have been corrected for the presence of a small (≈ 5%) amount of redox-inactive azurin with a resonance at δ ≈ –0.69 ppm.

ure 3A) were simulated with the MEX/MEXICO software.[16] The input parameters consisted of the line widths and positions of the signals measured at the highest and lowest dilution for the 100% *ox* and 100% *red* solutions. The inter- and intramolecular electron self-exchange rates were varied until the best fit with experiment was obtained.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The fits are reproduced in Figure 3A and the observed rates as a function of dimer concentration are shown in Figure 3B. The intra-dimer contribution is constant, as expected, and corresponds to an intra-dimer ese rate of $k_{intra}$ = 25 $s^{-1}$. The inter-dimer contribution is proportional to the concentration. The slope yields the second-order rate constant which amounts to $k_{inter} = (1.8 \pm 0.1) \times 10^4$ $M^{-1} s^{-1}$.

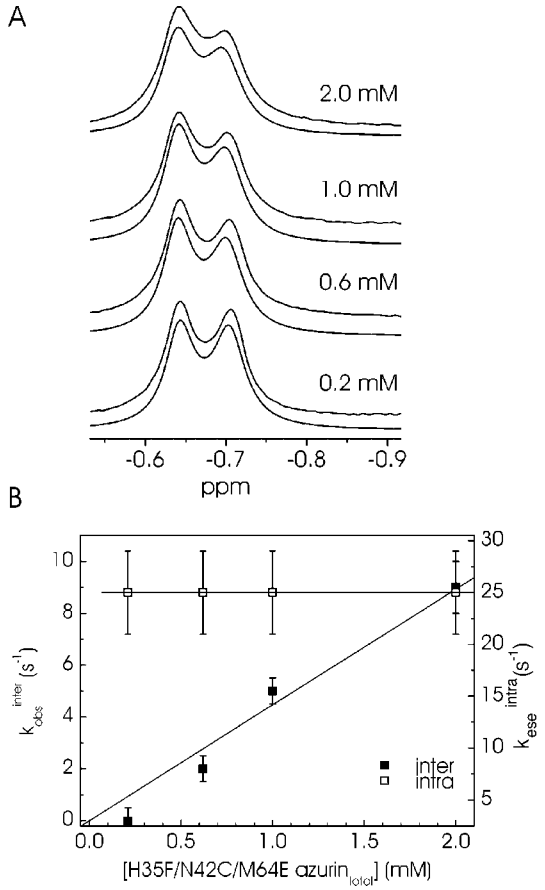

Figure 3. A. Upfield region of the $^1$H NMR spectrum of H35F/N42C/M64E disulfide azurin at (50 ± 3) % oxidation at several dilutions. The upper traces show the experimental data, the MEX-simulated spectra are shown in the lower traces ($T$ = 295 K, 25 mM potassium phosphate, pH* = 4.5). B. $k_{obs}^{inter}$ (filled squares) and $k_{ese}^{intra}$ (open squares) values for H35F/N42C/M64E disulfide azurin that correspond to the simulated traces shown in panel A vs. the protein dimer concentration. The lines indicate least-squares linear fits.

The next question to be addressed deals with the pH dependence of the line broadening. It is clear from Figure 2C that the broadening becomes less at high pH, indicating that the electron self-exchange processes slow down in a similar way to that observed for the monomeric species in solution.[13] Simulation with the MEX software shows that the combined contributions from the intra- and inter-electron self-exchange processes decrease by a factor of 3 when going from pH = 4.0 to 8.2. The partitioning between these two processes was not possible. This was because of insufficient precision of the data resulting from the difficulty in keeping the degree of oxidation/reduction of the solution precisely fixed during the pH titration.

To aid in the interpretation of the data, the structure of the N42C/M64E azurin S–S dimer at pH = 3.1 was determined to 2.3 Å resolution by X-ray diffraction. The results are presented in Table 1. Crystals obtained at high pH did not diffract well enough for structure analysis. The structure of the dimer is shown in Figure 4B. For comparison the packing of the monomers in the crystal of wt Azu is shown in Figure 4A.[8] In Figure 4C the C42–C42-connected dimer of Azu is depicted in which no other than the N42C mutation had been applied.[5] It is clear that in Figure 4C the two halves of the dimer have rotated around the Cys–Cys link when compared with Figure 4A. Remarkably, the structure in Figure 4B is intermediate.

[a] Molecules seen as monomeric azurin subunits.

Comparison of each of the subunits of the N42C/M64E azurin dimer with the structure of reduced wt azurin at pH = 5.5 (PDB access code 1E5Y) shows that they are largely unaffected by the introduction of the mutations. The overall backbone atom root-mean-square difference between the wt structure and each of the monomers in the N42C/M64E dimers amounts to 0.6 Å, excluding the N- and C-terminal residues. The regions directly around the sites of the mutation are relatively unperturbed. The two subunits share a contact surface, with the contacts between the two surfaces consisting mainly of weak hydrophobic interactions in a manner that is clearly distinct from the classical hydrophobic packing in crystals of wt azurin.[8] In the dimer interface, two water molecules can be found that form several hydrogen bonds with the protein (Figure 5). A hydrogen-bonding network across the interface is formed which stabilises the conformation of the dimer by forming hydrogen bonds between each of the water molecules to Glu64 $O^{\varepsilon}$ or the backbone oxygen atoms of Cys42 on both protein chains. The shortest Cu–Cu distance observed is the intramolecular distance of 20.5 Å. All Cu–Cu distances between dimers in adjacent asymmetric units within the crystal exceed 25 Å. These intermolecular interactions can therefore be considered irrelevant for the electron self-exchange analysis.

To probe the dynamic aspects of the dimer structure, HSQC NMR spectra were obtained for the $^{15}$N-labelled dimer and compared with those of the $^{15}$N-labelled monomer. The spectra were measured at a number of pH values (Supporting Information: Figure S2). The dimer spectra are al-

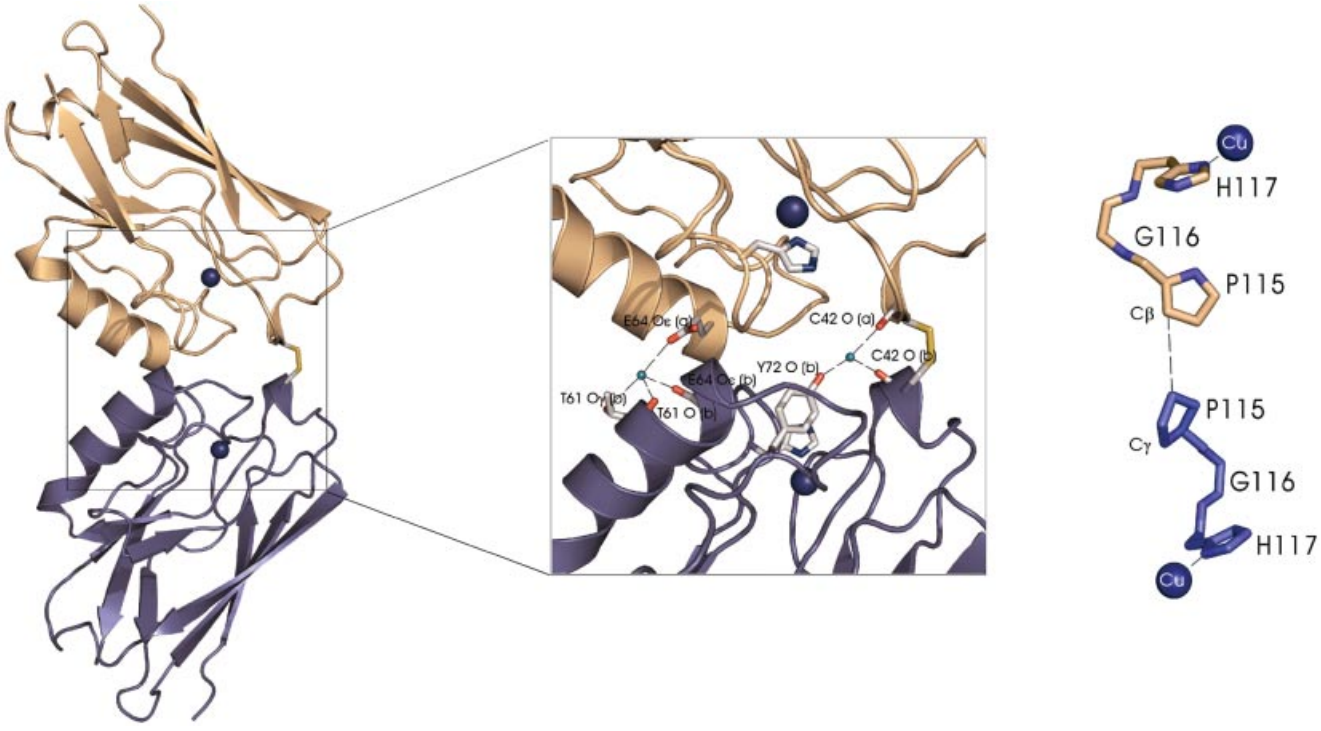

Figure 5. Left: Crystal structure of the N42C/M64E azurin disulfide-bridged dimer at pH = 3.1. The copper centres are depicted as dark-blue spheres. Close-up: Interface of the dimer showing the ordered water molecules (small light-blue spheres). All residues involved in hydrogen bonding with these water molecules are shown (sticks) and labelled. The hydrogen bonds are shown as dashed lines. The letters within parentheses indicate the individual protein chains (a and b). Also shown are the Cu ligands H117 (sticks). Right: Tunnelling pathway between the copper centres of the N42C/M64E disulfide-bridged dimer of azurin as calculated with the programme HARLEM.[22] The through-space jump between Pro115(A) C-β and Pro115(B) C-γ is indicated by a dashed line.

most identical to those of the monomer except for a few residues in the hydrophobic patch, viz. C42, V43 and M44. When increasing the pH from 4.4 to 8.4 the cross peaks corresponding to these residues move to slightly different positions (Figure S2). The transition occurs at a somewhat lower pH for the dimer. There is no evidence for strong interactions between the subunits since, overall, no severe perturbations of the resonance patterns can be observed.

## Discussion

The aim of the work presented here was to construct a protein complex with pH-dependent structural and ET properties. To this end, a covalently cross-linked homodimer of the blue copper protein azurin was created by intermolecular disulfide bond formation between engineered surface-exposed cysteines. The pH dependence was introduced by substitution of the interfacial M64 by an ionisable Glu residue. Analysis of the ET rate as a function of pH required additional replacement of the protonatable H35 residue by Phe. It was shown that over the entire pH range studied, the complex exhibited slow electron self-exchange. Although no unambiguous distinction could be made between the inter- and intramolecular contributions to the ese process from the pH-dependent data, the concentration dependence of the observed ese rate identifies intramolecular exchange as the dominant process (see Figure 3).

Despite the presence of several ionisable groups in the interface, the electron self-exchange behaviour of the complex shows only moderate pH dependence. The low exchange rates observed for the H35F/N42C/M64E dimer ($1.8 \times 10^4$ M$^{-1}$ s$^{-1}$) contrast with what is observed for the N42C azurin dimer for which a roughly ten times higher $k_{ese}^{inter}$ was determined ($2.8 \times 10^5$ M$^{-1}$ s$^{-1}$). It is tempting to relate this difference to the clear difference between the crystallographically determined structures of the two complexes. Whereas the N42C dimer adopts a rather "open" dimer conformation [interfaces are $a = (1.8 \times 10^2)$ Å$^2$] with an intramolecular Cu–Cu distance >25 Å, the N42C/M64E dimer at pH = 3.1 forms a much more closed conformation [interfaces are $a = (7.0 \times 10^2)$ Å$^2$] in which the straight intramolecular Cu–Cu distance is only 20.5 Å. Although this distance is still rather large, it is within the limits that allow for intramolecular e.s.e., albeit with low rates. The alternative explanation that in the H35F/N42C/M64E dimer the Glu64 unit in the interface is deprotonated and therefore intermolecular association is slowed down, is less likely since at the employed pH* of 4.5 the ese rate of the monomer is not yet affected by deprotonation of Glu64.[13]

According to Dutton et al., the rate of ET, $k_{ET}$, between two redox centres separated by a homogeneous medium is given by Equation (1),[17,18] in which $\rho$ denotes the packing density, $d$ the distance separating the donor and acceptor sites, $\lambda$ the reorganization energy and $\Delta G^0$ the standard free energy of the reaction (energies are in eV).

$$\log k_{ET} = 13.0 - (1.2 - 0.8\rho)(d - 3.6) - (\Delta G^0 + \lambda)^2/\lambda \quad (1)$$

For the N42C azurin dimer, these parameters are $\lambda$ = 0.7 eV, $\rho$ = 0.75 and $\Delta G^0$ = 0 eV (e.s.e.).[5] Based on these parameters and a Cu–Cu distance of 20.5 Å, a value of $k_{ese}^{intra} \approx 1.4 \times 10^2$ s$^{-1}$ can be predicted, in reasonable agreement with the experimentally determined rate.

Alternatively, ET can be viewed as proceeding along defined tunnelling pathways (TPs).[19–22] In the crystal structure of the N42C/M64E dimer a path can be identified that involves residues H117, G116 and P115 on both chains and a large through-space jump of 4.0 Å between the C-β and C-γ atoms of Pro115 on either chain, respectively (Figure 5). The coupling efficiency of this pathway is extremely low ($\Pi_\varepsilon < 10^{-8}$) and is, in fact, too low for ET to occur at a discernible rate. The pathway algorithm, however, calculates couplings in static structures with fixed distances between atoms. In reality, protein motions may temporarily shorten through-space distances, increasing the coupling strength. Also, although in the crystal structure no ordered water molecules were observed within hydrogen-bonding distances of the P115 residues, in solution solvent molecules may temporarily contribute to the electronic coupling and enhance the electron self-exchange.

## Conclusions

Chemical shift perturbation analysis of the dimer indicates that the dimer interface is not strongly perturbed by the covalent linking of the monomers throughout the investigated pH range. Also, contrary to expectation, the neutralisation of the Glu64 side chain has little effect on the conformation of the dimer. The crystal structure of the dimer at low pH shows, again contrary to expectation, that the two Azu moieties in the dimer move less far apart (through a rotation around the Cys42–Cys42 link) than in the dimer without the M64E mutation.

The observed ese rates are in accordance with the structural features. The intermolecular rate is lower than in the C42–C42 dimer without the M64E mutation, in agreement with the smaller surface accessible area in the hydrophobic patch. The intramolecular ese rate on the other hand is larger, in line with the smaller Cu–Cu distance.

The phenomenological model of Dutton et al. gives a value for the ese rate that is in accordance with observation whereas the pathway model of Beratan, Betts and Onuchic predicts a rate that is orders of magnitude too small because there is a gap in the pathway that has to be bridged. It means that the structure may have dynamic features, by which the gap is closed some of the time; although, on a millisecond time scale, the NMR spectroscopic data provide no indication for time-dependent features of the dimer structure within the investigated pH range. Alternatively, water molecules may bridge the gap as seen in several other dimer-like structures of Azu. No water molecules could be observed in the structure suggesting that there are no ordered water molecules in the interface. However, this does not necessarily mean that in the course of time they cannot provide effective electronic coupling.

The overall conclusion is that the ET rates and the structural data produce a consistent picture of the Azu (N42C/M64E) dimer that is clearly different from simple intuition. Why the N42C/M64E Azu dimer behaves counter-intuitively remains open to further experimentation.

## Experimental Section

**Mutagenesis:** The secondary mutation M64E was introduced into the N42C azurin gene by splice overlap extension (SOE) site-directed mutagenesis for which two partially complementary oligo-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nucleotides were designed. The forward primer (i.e. extending in the coding direction) 5′-*GGGCGTGCTCAC*CGACGGC**GA**-GGCTTCCG encodes for the replacement of methionine-64 by a glutamate. The reverse primer 5′-*GTGACCACGCCC*-TGCATGTC**T**GC**A**GCGGTGCT includes two silent mutations that encode a *Pst*I restriction site for screening purposes. The section in *italics* shows the complimentary regions in the two primers, the mutation sites are shown in bold. As a template, the N42C azu containing plasmid pIA02, derived from pUC18, was used.[6] The presence of the N42C/M64E azurin gene in the newly created plasmid pTJ01 was confirmed by sequence analysis and the obtained plasmid was then used as a template for the one-step synthesis of the H35F/N42C/M64E azurin gene in a procedure based on the Stratagene's ExSite® PCR-Based Site-Directed Mutagenesis Kit. Two fully complementary 32 base-pair-long oligonucleotides encoding the His35Phe mutation were used as primers: (forward primer) 5′-CCGTCAACCTGTCC**TTC**CCCGG*G*AACC-TGCCG. The mutated codon for the H35F substitution is indicated in bold and an additional silent mutation that was introduced for screening by *Xma*I digestion is in *italics.* Sequence analysis confirmed the presence of all desired mutations in the resultant pTJ02 plasmid. The H35F/N42C/M64E azurin gene was subcloned into a pET28a vector for cytoplasmic expression by removal of the signal sequence. Gene amplification was performed using primers for *N*-terminal signal peptide removal (5′-GGTCAGCG*CCATGG*CCGAGTGC TCGGTGG (*Nco*I site is in *italics*) and addition of a *C*-terminal *Bam*HI/*Bst*YI recognition site (in *italics*) (5′-CCGA*GGATCC*GCATCACTTCAGGG). Insertion into a pET28a vector was accomplished by digestion of the gene fragment using the restriction enzymes *Bst*YI and *Nco*I. The vector was digested by the enzymes *Bam*HI and *Nco*I, after which the gene and vector fragments were ligated resulting in the plasmid named pTJ13.

**Protein Expression and Purification:** Wild-type and H35F azurin were expressed and produced as described previously.[11,23] Non-isotopically labelled N42C/M64E azurin and H35F/N42C/M64E azurin were produced in the periplasmic space of *E. coli* JM109 cells transformed with plasmids pTJ01 or pTJ02, respectively. Cells were cultured on an LB medium at 37 °C/250 rpm to an $OD_{600}$ of 0.6 before induction by addition of 100 μM IPTG. Cells were harvested by centrifugation typically about 5 h after induction. Both mutants were isolated and purified from the medium as described for N42C azurin with yields of 10–15 mg/L.[6] Up to 50% of the purified azurin was found to contain zinc in the metal-binding site and was thus redox-inactive. Uniformly $^{15}$N-labelled H35F/N42C/M64E azurin was produced in the cytoplasm of BL21 *E. coli* cells transformed with pTJ13 and grown on isotopically labelled OD2-N medium (Silantes GmbH) supplemented with 50 μM kanamycin at 30 °C/200 rpm. Once an $OD_{600}$ of 0.5 was obtained, the temperature was lowered to 25 °C followed by induction with 1 mM IPTG after 30 min. Due to lower growth rates, cells grown on the OD2-N medium were not harvested until 15 h after induction. The cytoplasmically produced protein was released from the cells by resuspension in 20 mM MES, 100 mM NaCl, pH = 6.5 and disruption of the cells in a French Press cell in the presence of phenylmethylsulfonyl fluoride (PMSF) (1 mM) and DNase I (50 mg mL$^{-1}$). After centrifugation, the protein was isolated from the resultant supernatant following a protocol similar to that used for periplasmically expressed azurin. The protein was initially purified in the apo form and reconstituted with copper before further purification on a DEAE ion exchange column.

**Cross Linking:** Disulfide-linked dimers of N42C/M64E and H35F/N42C/M64E holo-azurin were spontaneously formed upon addition of a slight molar excess of $Cu(NO_3)_2$ and an approximately five-fold excess of $K_3Fe(CN)_6$. Excess $Cu(NO_3)_2$ and $K_3Fe(CN)_6$ were subsequently removed by repeated rounds of dilution and concentration using a Centricon concentration device (Molecular weight cut-off: 10 kDa). Analysis of the protein sample by SDS-PAGE under non-reducing conditions showed near complete dimerization.

**NMR Sample Preparation:** Fully reduced samples were obtained by incubation with 2 mM ascorbate at room temp. until the sample had turned completely colourless. Ascorbate was then removed from the sample by washing with deaerated 25 mM potassium phosphate ($KP_i$) at pH = 7.0. All NMR samples of unlabelled protein were prepared in 25 mM $KP_i$ at pH* = 7.0 (* uncorrected for deuterium isotope effect), 99.9% $D_2O$ and concentrated to 1–2 mM of protein. For experiments in which the protein concentration had to be varied, the sample was stepwise diluted with 25 mM $KP_i$ at pH* = 7.0 until dilution by a factor of 10 was reached. The pH of the samples was adjusted to the desired value by addition of small amounts of NaOD or DCl. Partially oxidised samples were attained by mixing of fully oxidised and fully reduced protein in the required ratios. The degree of oxidation of the samples was determined by measuring the absorbance at 628 nm relative to a fully oxidised sample of the same concentration. UV/Vis spectra were recorded with a Perkin–Elmer lambda 800 spectrophotometer using a special sample holder for NMR tubes equipped with fibre-optic light guides (Hellma). A sample of fully reduced, monomeric $^{15}$N-H35F/N42C/M64E azurin was prepared in 25 mM $KP_i$ at pH = 5.7, 5 mM dithiotreitol (DTT) supplemented with 6% $D_2O$ and concentrated to 2 mM. The pH of the sample was adjusted by addition of small amounts of NaOH or HCl. After recording the NMR spectra, DTT was removed by repeated rounds of concentration and dilution with 25 mM $KP_i$. Dimerisation of the protein was accomplished by addition of a catalytic amount of $Cu(NO_3)_2$ and an approximately ten-fold molar excess of $K_3Fe(CN)_6$. Once fully dimerised, as confirmed by SDS-PAGE analysis, the protein was transferred to a solution containing 25 mM $KP_i$ at pH = 4.3. Selective reduction to $Cu^I$ azurin without disruption of the intermolecular disulfide bond was performed by addition of 2 mM ascorbate. Titration to the desired pH was achieved by addition of small amounts of either NaOH or HCl.

**NMR Spectroscopy:** All $^1$H NMR experiments were performed at 295 K with a Bruker Avance DMX 600 MHz spectrometer. Spectra were calibrated against an internal reference of 200 μM 3-(trimethylsilyl)propionate-$d_4$ (TSP). As the chemical shift of TSP ($\delta$) is sensitive to pH ($pK_a$ = 5.0), its reference position was corrected for pH according to Equation (2).[24]

$$\delta = 0.003 - 0.019 \times (1 + 10^{(5.0-pH)})^{-1} \quad (2)$$

In addition to the Val31 $^1$H signal of the oxidised protein, the spectra of the fully oxidised samples indicated the presence of a small amount (≈ 5%) of an additional species for which a low-intensity resonance was observed at δ ≈ –0.69 ppm at all pH values. This feature is commonly encountered in samples of azurin and can be attributed to the presence of a small amount of redox-inactive azurin. This resonance was subtracted from the experimental spectra shown in Figure 2. Multi-dimensional NMR experiments were performed at 302 K. Data sets were processed in the AZARA program suite (available at http://www.bio.cam.ac.uk) and analysed with ANSIG for WINDOWS 1.0.[25,26] Backbone assignments were obtained through standard sequential assignment procedures using the [$^{15}$N,$^1$H] HSQC, NOESY-HSQC and TOCSY-HSQC spectra on the basis of assignments available for wild-type azurin.[27]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Electron Self-Exchange Rate Determination:** The ese rates were determined by simulation of the line shape of the Val31 methyl $^1$H NMR resonance using the MEX/MEXICO program suite developed by Bain and Duns.[16] All possible intermolecular and intramolecular exchange processes were taken into account (see Supporting Information). The chemical shifts and linewidths of the fully oxidised and fully reduced protein were given as input parameters whilst both the inter- and intramolecular ese rates were manually iterated until simulations were obtained that resembled the experimental traces best, as judged by visual inspection.

**Crystallisation and Structure Solution:** The disulfide-linked dimer of N42C/M64E azurin was crystallised by sitting drop vapour diffusion using a reservoir solution containing 30% (w/v) polyethylene glycol 4000 and 0.1 M sodium citrate buffer at pH = 3.1. The protein was concentrated to 8 mg mL$^{-1}$ and mixed in a 1:1 ratio with the reservoir solution. Rod-shaped crystals grew within 2 d. Due to the high content of PEG 4000, the mother liquor turned out to be sufficiently cryoprotective for direct flash-cooling of the crystals in liquid nitrogen without formation of ice. Data were collected with a Rigaku MicroMax 007 rotating-anode X-ray generator with a mar345dtb image plate detector. For structure solution, the model of the native azurin from *P. aeruginosa* was used with the program MOLREP. Two monomers were found in the asymmetric unit, clearly connected through a disulfide bridge between residues 42. The N42C and M64E mutations were modelled with O,[28] and refinement was carried out with REFMAC5.[29] The coordinates and structure factors have been deposited in the Protein Data Bank under accession code 2OJ1. Figures 4 and 5 were generated using PyMOL 0.98.[30]

**Solvent Accessibility and Interface Areas:** The solvent-accessible surface area (ASA) was calculated using the program NACCESS 2.1.1 with a probe radius of 1.4 Å. The interface area was defined as the sum of the ASAs of the individual proteins minus the ASA of the complex. The interface in disulfide-bridged dimers of N42C azurin was defined as the average of the two dimers in the asymmetric unit of the structure deposited in the protein data bank with accession code 1JVO.[6]

**Supporting Information** (see footnote on the first page of this article): This material contains, first, a description of the model used as a basis for the lineshape simulations. The simulations were used to determine the electron self-exchange rates for the azurin dimer. Second, it contains the 2D-NMR data as a function of pH obtained on the H35F/N42C/M64E azurin monomers and the H35F/N42C/M64E azurin dimers.

# Coordination Versatility of 5(3)-(2-Hydroxyphenyl)-3(5)-methylpyrazole: Synthesis, Crystal Structure and Properties of $Co^{III}$, $Ni^{II}$ and $Cu^{II}$ Complexes

**Marta Viciano-Chumillas,[a] Stefania Tanase,[a] Guillem Aromí,[b] Jan M. M. Smits,[c] René de Gelder,[c] Xavier Solans,[d] Elisabeth Bouwman,[a] and Jan Reedijk*[a]**

**Keywords:** Cobalt / Nickel / Copper / Pyrazoles / Phenols / Crystal structures

New complexes with 5(3)-(2-hydroxyphenyl)-3(5)-methylpyrazole ($H_2$phpz), $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]\cdot 3CH_3CN$ (**1**), $[Ni(Hphpz)_2]$ (**2**) and $[Cu(Hphpz)_2]$ (**3**), were synthesized and structurally characterized. The ligand coordinates in the form of 3-(2-hydroxyphenyl)-5-methylpyrazole in all cases, except for one ligand in the $Co^{III}$ complex, where it coordinates in the 5-(2-hydroxyphenyl)-3-methylpyrazole mode. Crystallographic analysis revealed that **1** contains two chemically and crystallographically distinct cobalt(III) ions triply bridged by one phenoxide and two pyrazolate groups, giving rise to a $[Co_2(N\text{-}N)_2O]$ core with a Co···Co distance of 3.154 Å. Additionally, the $H_2$phpz ligand shows four different coordination modes with the metal ions, demonstrating its versatility. The dinuclear unit of **1** is stabilized by strong intramolecular N–H···O hydrogen-bonding interactions involving the phenol oxygen atom of the $H_2$phpz ligand and the N–H functionality of the pyrazole ring. The crystal structure of the isomorphous complexes **2** and **3** reveals the presence of centrosymmetric mononuclear units with the $MN_2O_2$ [M = $Ni^{II}$ (**2**), $Cu^{II}$ (**3**)] chromophore displaying a slightly distorted square-planar geometry. The mononuclear structures of **2** and **3** are further stabilized by intramolecular hydrogen bonds established between the acid N–H group as donor and the phenoxide group of the $H_2$phpz ligand as acceptor. Spectroscopic studies, ESI-MS and cyclic voltammetry were performed, supporting the crystallographic analysis.

## Introduction

Pyrazole-based ligands have received a great deal of attention over the last decades because of their interesting coordination chemistry, unusual structural features, and remarkable physical and chemical properties.[1,2] The incorporation of pyrazole groups in the design of new ligands allows the study of their structural properties to serve specific stereochemical requirements for a particular metal-binding site. In addition to its remarkable capacity to coordinate to a variety of metal ions, the pyrazole entity also has the ability to bring two metal centres into close proximity and provide an intramolecular pathway for spin-exchange interactions.[3] Although a significant number of coordination compounds containing pyrazole ligands have been obtained to date, the design and synthesis of novel pyrazole-containing complexes by employing more versatile ligands or by varying the nature of the reactants and synthetic conditions are still under investigation. We have recently reported that the ligand 5(3)-(2-hydroxyphenyl)-3(5)-methylpyrazole ($H_2$phpz) exhibits a variety of coordination abilities and tends to form large metal cluster aggregates.[4,5] The amount of base or the type of solvent are paramount in controlling the different coordination modes, thereby providing a rich versatility to the ligand.

In the present study we extended our investigations to the coordination of this ligand with cobalt, nickel and copper ions, and we report the synthesis, characterization and crystal structure of a quite unusual dinuclear cobalt(III) complex, $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]\cdot 3CH_3CN$ (**1**), triply bridged by one phenoxide and two pyrazolate groups, as well as two new isomorphous mononuclear complexes $[Ni(Hphpz)_2]$ (**2**) and $[Cu(Hphpz)_2]$ (**3**), and a dopant of $Cu^{II}$ in **2**. To the best of our knowledge, **1** is the first example of a dinuclear cobalt(III) complex bridged by both pyrazolate and phenoxide groups. A remarkable feature of this compound is the observed binding versatility of the $H_2$phpz ligand, which is coordinated in four different modes to the two cobalt(III) ions (Scheme 1).

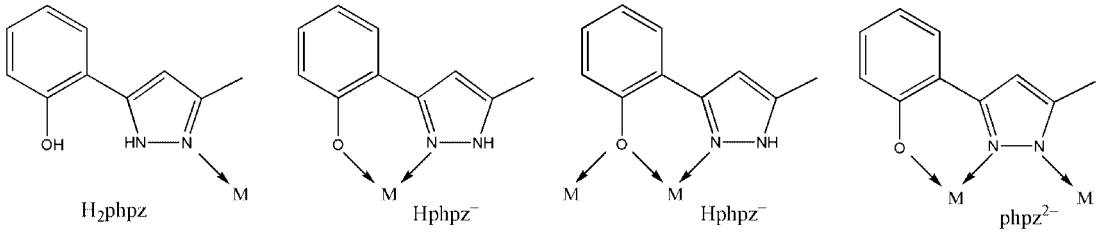

Scheme 1. Four different coordination modes of the 5(3)-(2-hydroxyphenyl)-3(5)-methylpyrazole ligand in complex **1**.

## Results and Discussion

### Synthesis and Spectroscopic Properties

The reaction of 5(3)-(2-hydroxyphenyl)-3(5)-methylpyrazole ($H_2$phpz) with $Co(ClO_4)_2·6H_2O$ in the ratio 2:1 in the presence of 2 equiv. triethylamine yielded the diamagnetic cobalt(III) complex $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]·3CH_3CN$ (**1**) as a purple solid. After filtration, slow evaporation of the solution afforded dark-brown crystals suitable for X-ray crystallography. The presence of base as well as the aerobic conditions are responsible for the oxidation of cobalt(II) to cobalt(III). The infrared spectrum of **1** suggests the coordination of the ligand to the cobalt(III) ion, as indicated by the shift of the $\nu_{C-O}$ stretching vibration from 1636 $cm^{-1}$ in the free ligand to 1596 $cm^{-1}$ in the complex and the $\nu_{C=N}$ stretching vibration from 1576 $cm^{-1}$ in the free ligand to 1558 $cm^{-1}$ in the complex. The peak observed at 3425 $cm^{-1}$ can be assigned to the phenol hydrogen atom of the $H_2$phpz ligand that remains neutral by coordination to cobalt(III). The band due to $\nu_{N-H}$ stretching vibration is observed at 3280 $cm^{-1}$ and is less broad than that of the free ligand because of the coordination of the ligands in the complex.[6] The ligand field spectrum of **1** in the solid state exhibits a broad absorption band at 576 nm that is characteristic of octahedral cobalt(III) complexes. The band at 335 nm can be assigned based on its intensity to a $p_\pi \rightarrow d_\sigma^*$ transition, whilst the band at 271 nm arises from a $\pi$-$\pi^*$ ligand transition.[7]

The reaction of $Ni(ClO_4)_2·6H_2O$, $H_2$phpz and $Bu_4NOH$ in a 1:1:2 ratio in methanol yielded a green compound that upon dissolution in dichloromethane followed by slow diffusion of diethyl ether afforded complex **2** as dark-green crystals. The infrared spectrum of **2** displays a strong band assignable to the $\nu_{N-H}$ stretching vibration at 3299 $cm^{-1}$. Several sharp weak bands observed in the range 2900–3150 $cm^{-1}$ are likely to be caused by the $\nu_{C-H}$ stretches of the methyl group. As the free $H_2$phpz ligand displays the $\nu_{C-O}$ stretching vibration at 1636 $cm^{-1}$, the shift of this band to 1600 $cm^{-1}$ in complex **2** suggests the coordination of the phenol oxygen atom. The ligand field spectrum of **2** displays two broad bands at 490 and 622 nm assigned to d-d transitions for the low-spin $Ni^{II}$ compound; the absorption band at 622 nm is assigned to a $d_{x^2-y^2} \rightarrow d_{zy}$ transition, whilst the absorption band at 490 nm is attributed to the $d_{z^2} \rightarrow d_{zy}$ transition.[8] The absorptions observed in the range 420 to 270 nm are likely to be caused by the metal-to-ligand and inter- or intra-ligand charge-transfer transitions. The solid compound turned out to be diamagnetic as expected for square-planar $Ni^{II}$, thereby allowing the study of a solid solution (dopant) of the isomorphous $Cu^{II}$ compound.

Complex **3** was obtained by reaction of $Cu(ClO_4)_2·6H_2O$ and $H_2$phpz in a 1:1 ratio and in the presence of 2 equiv. sodium methoxide as base. The reaction of $H_2$phpz with $Ni(OAc)_2$ and $Cu(OAc)_2$ in acetonitrile and in the absence of base afforded **2** and **3**, respectively, as polycrystalline samples with yields up to 76% for **2** and 72% for **3**. The infrared spectrum of complex **3** is very similar to that of complex **2**, and it exhibits the bands expected for the monoanionic Hphpz$^-$ ligand. Notably, the stretching vibrations $\nu_{C-O}$ at 1599 $cm^{-1}$ and $\nu_{C=N}$ at 1548 $cm^{-1}$ are observed at lower energies compared with the IR spectrum of the pure ligand. The ligand field spectrum shows a broad asymmetric band at 660 nm attributed to d-d transitions of copper(II) complexes with square-planar geometry; the absorption bands in the range 455–350 nm are a result of Cu–O and Cu–N charge-transfer transitions.

### Description of the Crystal Structures

A single-crystal X-ray analysis of **1** revealed the identity of the product as $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]·3CH_3CN$. Selected bond lengths and angles for **1** are given in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] for the complex $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]·3CH_3CN$ (**1**).

| Bond lengths | | | |
|---|---|---|---|
| Co1–O21 | 1.865(4) | Co2–N11 | 1.929(5) |
| Co1–N12 | 1.875(5) | Co2–O41 | 1.879(4) |
| Co1–N31 | 1.925(6) | Co2–N32 | 1.875(6) |
| Co1–O81 | 1.919(4) | Co2–O61 | 1.916(4) |
| Co1–N72 | 1.914(5) | Co2–N52 | 1.893(5) |
| Co1–N91 | 1.969(6) | Co2–O81 | 2.002(4) |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As shown in Figure 1, the molecular structure of **1** consists of a highly asymmetric dinuclear unit with two cobalt(III) ions bridged by two pyrazolate groups and one phenoxide group with a Co···Co separation of 3.154 Å. This distance is slightly longer than those observed for other triply bridged dinuclear cobalt(III) complexes.[9] Most remarkably, the $H_2$phpz ligand shows four different coordination modes in the molecular structure of **1**: (i) quite unusual, the $H_2$phpz ligand remains neutral and is N-monodentate bound to Co2, with the ligand present in the 5-(2-hydroxyphenyl)-3-methylpyrazole mode; (ii) a uninegative Hphpz$^-$ ligand is NO-chelating to Co1; (iii) a second uninegative Hphpz$^-$ molecule acts as a NO-bidentate chelating ligand, and it links the two cobalt(III) ions through a phenoxido bridge; and (iv) two ligand molecules are doubly deprotonated, and these phpz$^{2-}$ ligands coordinate in a $N_2O$-tridentate manner to link the two cobalt(III) ions by a double pyrazolato bridge. In the last three modes the ligand is present in the 3-(2-hydroxyphenyl)-5-methylpyrazole conformation. As a result, both cobalt(III) ions have a distorted octahedral geometry and are in quite different coordination environments. The Co1 ion has a $CoN_4O_2$ donor set in a *trans* octahedral geometry, whilst the Co2 ion has a $CoN_3O_3$ donor set in a *mer* octahedral geometry. The cobalt(III) to oxygen and cobalt(III) to nitrogen bond lengths are in the ranges of 1.865–2.002 Å and 1.875–1.969 Å, respectively, as expected for low-spin cobalt(III) complexes.[10] The largest deviation from the octahedral geometry is observed for the *trans* angle which is O81–Co2–O41 174.90(17)°. The Co–O–Co angle is 107.09°, and it is slightly smaller than the angle normally observed for phenoxido-bridged dinuclear cobalt(III) complexes.[11,12] The least-squares plane of the aromatic ring of the $N_2O$-tridentate phpz$^{2-}$ ligand and the plane defined by Co1, Co2 and O81 have a dihedral angle of 38.11°. The bending angle of the bridging pyrazole least-squares planes to the Co1–N12–N11–Co2 and Co1–N31–N32–Co2 coordination planes is 5.36° and 5.64°, respectively. The dihedral angle between the planes of the two bridging pyrazole rings is 79.91°, whilst the dihedral angle between the $CoN_{pz}N_{pz}Co$ planes is 75.98°.

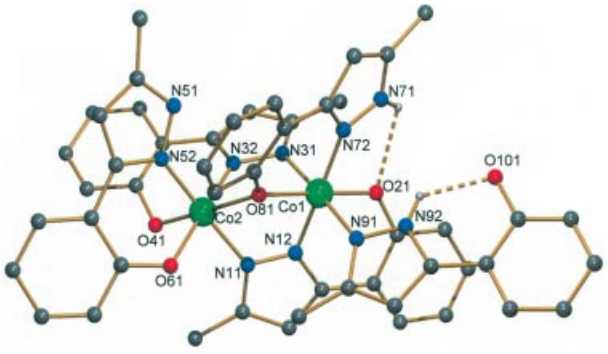

Figure 1. Pluton projection of the neutral complex $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]\cdot 3CH_3CN$ (**1**) showing the intramolecular hydrogen-bonding interactions. Hydrogen atoms that are not involved in hydrogen bonds and the acetonitrile molecules have been omitted for clarity.

The ligands adopt conformations that vary from nearly planar to considerably twisted with the dihedral angle between the phenyl and pyrazole ring planes ranging from 1.34° to 23.37°. These conformations are determined by the presence of strong intramolecular and intermolecular hydrogen bonds involving the O(phenol)–H and N(pz)–H moieties, as well as acetonitrile lattice molecules. The strongest intramolecular hydrogen bond involves the N–H group of the N-monodentate ligand bound to Co1 (N92–H92···O101 2.624 Å); the distance N71–H71···O21 of 2.756 Å would also suggest hydrogen bonding, but the angle of 107.9° is rather small. In addition, the O–H group of O101 participates in an intermolecular donor hydrogen-bonding interaction with a lattice acetonitrile molecule (O101–H101···N3 2.800 Å). The other two acetonitrile lattice molecules are at longer hydrogen-bond lengths (from N51 and N71). The acetonitrile molecules are kept rather weakly bound in the lattice, as is also seen from the elemental analyses (C, H and N), and some acetonitrile molecules might be replaced by atmospheric water. Table 2 gives some details of the hydrogen-bonding patterns.

Table 2. Hydrogen-bond details (distances [Å] and angles [°]) for $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]\cdot 3CH_3CN$ (**1**).

| Donor–H···Acceptor | D–H | H···A | D···A | D–H···A |
|---|---|---|---|---|
| N71–H71···O21 | 0.87 | 2.36 | 2.756(8) | 107.9 |
| N92–H92···O101 | 0.87 | 2.03 | 2.624(8) | 124.6 |
| O101–H101···N3 | 0.83 | 2.01 | 2.800(9) | 159.8 |
| N51–H51···N6 | 0.87 | 2.17 | 2.996(9) | 157.9 |
| N71–H71···N9 | 0.87 | 2.49 | 3.271(12) | 149.8 |

Complexes **2** and **3** are isostructural, and they crystallize in the space group $P2_1/n$. In both cases, the asymmetric unit contains half of a centrosymmetric mononuclear unit. The metal ion has a *trans*-$MN_2O_2$ environment formed by two Hphpz$^-$ ligand molecules that bind in a NO-bidentate chelating manner in the 3-(2-hydroxyphenyl)-5-methylpyrazole mode. The molecular structure of **2** is shown in Figure 2. The structure of **3** is presented in the electronic supporting information. The coordination geometry of the $NiN_2O_2$ chromophore is slightly distorted square-planar [N1–Ni–O1 91.90°, O1–Ni–N1a 88.10(8)°]. The Ni–N [1.862(2) Å] and Ni–O1 [1.868(2) Å] bond lengths agree well with the values expected for a low-spin $Ni^{II}$ ion in a square-planar environment.[13] The dihedral angle between the phenyl and pyrazole ring planes within the ligand is 4.62°. Examination of the crystallographic data (Supporting Information) reveals that the $Cu^{II}$ coordination environment of complex **3** is somewhat more distorted than that of the $Ni^{II}$ ion in **2**. As shown in Figure 2, there are two strong intramolecular hydrogen bonds with the acid N–H group as donor and the phenoxide group as acceptor [N2···O1a 2.612(3) Å, N2–H2···O1a 111°]. The crystal lattice is further stabilized by very weak π-π interactions involving the pyrazole rings; the shortest distance between the pyrazole planes is 3.919 Å. The closest Ni···Ni separation is 5.735 Å. Details for the $Cu^{II}$ compound are given in the electronic supporting information.

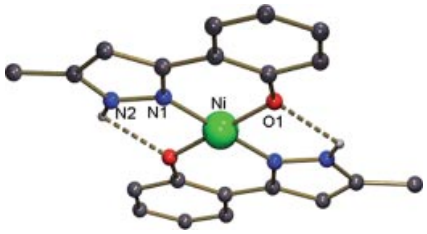

Figure 2. Pluton projection of the molecular structure of [Ni(Hphpz)$_2$] (**2**) showing the intramolecular hydrogen-bonding interactions. Hydrogen atoms that are not involved in hydrogen bonds have been omitted for clarity.

### EPR and Magnetic Susceptibility

Complexes **1** and **2** display no EPR signal, neither in the solid state nor in $CH_2Cl_2$ solution, at room temperature or at 77 K. These results strongly indicate that **1** and **2** are diamagnetic ($S = 0$), as expected for low-spin $d^6$ octahedral $Co^{III}$ complexes and low-spin $d^8$ square-planar $Ni^{II}$ complexes.

The polycrystalline powder EPR spectrum of **3** recorded at room temperature and 77 K shows a broad spectrum ($g = 2.06$), and no resolved hyperfine splitting was observed (Figure 3). When $Cu^{II}$ ions were separated by dilution as a 2% dopant in the diamagnetic host lattice of **2**, both hyperfine and superhyperfine splitting were observed (Figure 3). The superhyperfine structure is observed in the perpendicular region of the spectrum, arising from the interaction of the $Cu^{II}$ unpaired electron with the two nitrogen donor atoms of two ligand molecules that results in a five line splitting ($A_N = 10$ G). The magnitude of $g_\parallel$ and $A_\parallel$ (2.25 and 200 G, respectively) and the five superhyperfine lines indicate that the $Cu^{II}$ ion has an axial coordination geometry with two nitrogen donors in the equatorial plane,[14] in agreement with the X-ray crystal structure. The spectrum shows an unusual transition in the perpendicular region. This transition is caused by overshoot features which result in overlap of the perpendicular and the parallel transitions.[15]

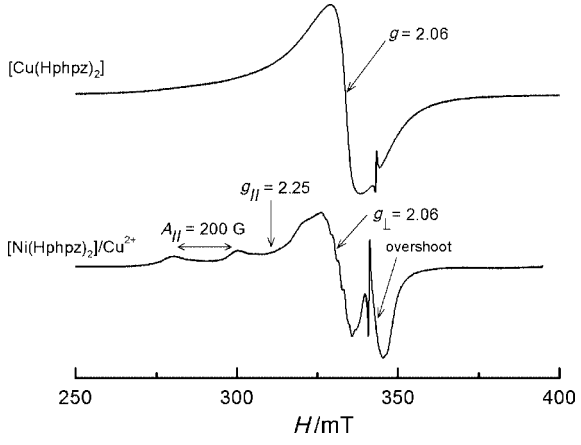

Figure 3. EPR spectra recorded at room temperature of [Cu(Hphpz)$_2$] (top) and [Ni(Hphpz)$_2$]/$Cu^{2+}$ (bottom), with the radical DPPH marker at $g = 2.00$.

The temperature-dependent magnetic susceptibility of **3** in the range 2–300 K shows paramagnetic behaviour which results from the absence of effective exchange magnetic interactions between the mononuclear units. At 300 K, the $\chi_M T$ value is equal to 0.35 $cm^3 K mol^{-1}$ which is close to the theoretical value of 0.375 $cm^3 K mol^{-1}$ expected for a single noncoupled $Cu^{II}$ centre ($S = 1/2$). The Ni compound was found to be diamagnetic.

### Solution Chemistry

The positive-ion mass spectrum of **1** in methanol solution exhibits prominent signals at $m/z = 983$ and 810 that can be assigned to the molecular ion $\{[Co_2(H_2phpz)(Hphpz)_2(phpz)_2] + H\}^+$ and the fragment $\{[Co_2(Hphpz)_2(phpz)_2] + H\}^+$. These results suggest that complex **1** retains its dinuclear structure in solution. Therefore, the redox behaviour of **1** was studied in acetonitrile solution within the potential range –1.8 to 1.5 V vs. a Ag/AgCl electrode at ambient temperature (300 K). The cyclic voltammogram of complex **1** shows one irreversible wave at +1.2 V that could be assigned to the oxidation of the ligand on the electrode surface. No cathodic peak was observed, in agreement with the high stability of the dinuclear cobalt(III) core in solution.

The NMR spectroscopic analysis of **1** shows a complicated spectrum due to the low symmetry of the complex. The peaks could not be assigned because of the splitting of multiple peaks in the aromatic region of the complex as compared with the five peaks of the free ligand. Nevertheless, the integration of the aromatic peaks is in agreement with the different coordination modes of the ligand in the complex.

The study of the electrochemical behaviour of the $Ni^{II}$ and $Cu^{II}$ complexes was carried out in $CH_2Cl_2$ solution in the range +1.2 to –1 V. For both **2** and **3**, a quasireversible ligand oxidation at 0.9 V was observed in the positive range. No other redox processes were observed for **2**. For **3**, the additional anodic process observed at 0.62 V can be assigned to a quasireversible one-electron oxidation of $Cu^{II}$ to $Cu^{III}$, and no cathodic process was observed. This result is not surprising given the preference of $Cu^{I}$ for nonplanar coordination geometry and the anionic nature of the ligand.

## Conclusions

In this study, the synthesis, crystal structure and spectroscopic characterization of an unusual dinuclear cobalt(III) complex and two new mononuclear $Ni^{II}$ and $Cu^{II}$ complexes have been presented. The reaction of the ligand 5(3)-(2-hydroxyphenyl)-3(5)-methylpyrazole with cobalt provided access to a new dinuclear complex, in which the versatility of the ligand showing four different coordination modes is beautifully illustrated. This dinuclear cobalt complex is unique, as it is triply bridged by two pyrazolate moieties and one phenoxide moiety with a Co···Co distance of 3.154 Å. This compound is stabilized through N–H···O in-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tramolecular hydrogen interactions. Also, N–H···N intermolecular hydrogen interactions are present with acetonitrile lattice molecules. ESI-MS and cyclic voltammetry studies showed that the dinuclear complex is highly stable in solution. Additionally, the reaction of the ligand with $Ni^{II}$ and $Cu^{II}$ ions readily afforded mononuclear species of type $[M(Hphpz)_2]$, in which the ligand appears to be strong enough to generate the low-spin $Ni^{II}$ cation. The EPR spectrum of the $Cu^{II}$ dopant in this lattice confirmed the geometry and chromophore. Further work aimed at the synthesis of higher nuclearity species is in progress.

## Experimental Section

**General Remarks, Analysis and Spectroscopy:** Starting materials were purchased from Aldrich, and all manipulations were performed using materials as received. The $H_2$phpz ligand was synthesized according to the reported procedure.[16] Elemental analyses (C, H and N) were performed with a Perkin–Elmer 2400 series II analyser. Infrared spectra (4000–300 $cm^{-1}$) were recorded with a Perkin–Elmer Paragon 1000 FTIR spectrometer equipped with a Golden Gate ATR device, using the reflectance technique. Ligand field spectra were obtained with a Perkin–Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. The electrochemical measurements were performed with an Autolab PGstat10 potentiostat controlled by GPES4 software. A three-electrode system was used, consisting of a platinum working electrode, a platinum auxiliary electrode and a Ag/AgCl reference electrode. The experiments were carried out at room temp. under argon with tetrabutylammonium hexafluorophosphate as supporting electrolyte. All potentials are reported relative to Ag/AgCl. Electrospray mass spectra in acetonitrile/water (80:20) were recorded with a Thermo Finnigan AQA apparatus. X-band powder EPR spectra were obtained with a JEOL RE2x electron-spin resonance spectrometer using DPPH ($g$ = 2.0036) as a standard. Magnetic susceptibility measurements (2–300 K) were carried out at 0.1 T using a Quantum Design MPMS-5 5 T SQUID magnetometer.

**Synthesis of $[Co_2(H_2phpz)(Hphpz)_2(phpz)_2]\cdot 3CH_3CN$ (1):** A solution of 5(3)-(2-hydroxyphenyl)-3(5)-methylpyrazole (61 mg, 0.35 mmol) and triethylamine (67 mg, 0.66 mmol) in acetonitrile (7 mL) was slowly added to a solution of $Co(ClO_4)_2\cdot 6H_2O$ (66 mg, 0.18 mmol) in acetonitrile (2 mL). The resulting purple solution was stirred for 5 min to give a purple precipitate. The purple solid was collected by filtration, washed with acetonitrile and ether and dried in air. Yield: 26.03 mg (34%). Crystals suitable for X-ray diffraction were obtained by slow evaporation of the filtrate. $C_{56}H_{53}Co_2N_{13}O_5$ (1105.97): calcd. C 60.82, H 4.83, N 16.46; found C 58.13, H 5.00, N 15.08. Loss of some lattice acetonitrile molecules may result in lower C, H and N analyses as the acetonitrile molecules are weakly held in the lattice; replacement of one acetonitrile molecule by three molecules of water would generate a more accurate C,H,N analysis [complex·$2CH_3CN\cdot 3H_2O$, $C_{54}H_{56}Co_2N_{12}O_8$ (1118.98): calcd. C 57.96, H 5.04, N 15.02]. IR: $\tilde{\nu}$ = 3425 (w), 3280 (w), 1596 (m), 1558 (s), 1463 (s), 1456 (s), 1299 (m), 1229 (s), 1188 (w), 1116 (m), 1038 (w), 986 (s), 850 (s), 772 (m), 752 (m), 744 (m), 641 (m), 602 (m), 584 (s), 436 (m), 418 (s) $cm^{-1}$. UV/Vis: $\lambda_{max}$ = 576, 335, 271 nm.

**Synthesis of $[Ni(Hphpz)_2]$ (2):** The ligand $H_2$phpz (161 mg, 0.92 mmol) and 1 M methanol solution of $Bu_4NOH$ (2 mL, 2 mmol) were dissolved in methanol (10 mL). To this solution was added a solution of $Ni(ClO_4)_2\cdot 6H_2O$ (367 mg, 1 mmol) in methanol (10 mL), and the mixture was then stirred. A green microcrystalline precipitate formed immediately. After a few minutes, the solid (230 mg) was collected by filtration and dissolved in $CH_2Cl_2$ (20 mL). The dark-green solution was layered with $Et_2O$ in various sealed tubes. After a few days, large dark-green crystals suitable for X-ray crystallography were collected. Yield: 27.53 mg (15%). $C_{20}H_{18}NiN_4O_2$ (405.09): calcd. C 53.16, H 4.19, N 11.95 (The calculated values given here are for the complex **2**·$0.75CH_2Cl_2$. The presence of $CH_2Cl_2$ is not unexpected as the complex was crystallized from this solvent); found C 53.87, H 4.36, N 12.42. IR: $\tilde{\nu}$ = 3299 (s), 1600 (s), 1553 (s), 1471 (s), 1412 (s), 1314 (s), 1249 (s), 1197 (m), 1121 (m), 1039 (m), 1117 (m), 864 (s), 788 (s), 738 (m), 668 (m), 645 (m), 587 (s), 475 (m), 384 (s) $cm^{-1}$. UV/Vis: $\lambda_{max}$ =

622, 490, 415, 360, 268 nm. The reaction of 2 equiv. $H_2$phpz with 1 equiv. $Ni(OAc)_2$ in acetonitrile and in the absence of base afforded **2** as a polycrystalline sample with a yield of 76%. The $Cu^{II}$-doped $Ni^{II}$ compound was prepared using this method but using a Ni/Cu ratio of 100:2.

**Synthesis of [Cu(Hphpz)$_2$] (3):** A solution of $H_2$phpz (35 mg, 0.20 mmol) and sodium methoxide (22 mg, 0.40 mmol) in methanol (5 mL) was slowly added to a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (76 mg, 0.20 mmol) in methanol (2 mL). The resulting green solution was stirred for 5 min to give a green precipitate. The solid was removed by filtration, and slow evaporation of the filtrate gave large dark-brown-red needles suitable for X-ray crystallography. Yield: 23.78 mg (58%). $C_{20}H_{18}CuN_4O_2$ (409.93): calcd. C 58.60, H 4.43, N 13.67; found C 58.43, H 4.30, N 13.76. IR: $\tilde{\nu}$ = 3311 (s), 1599 (m), 1548 (s), 1464 (s), 1316 (s), 1247 (m), 1196 (w), 1121 (m), 1065 (m), 1039 (w), 1018 (m), 857 (s), 791 (m), 739 (m), 668 (m), 641 (m), 618 (m), 593 (s), 575 (s), 470 (m), 371 (s) $cm^{-1}$. UV/Vis: $\lambda_{max}$ = 660, 455, 380, 350, 263 nm. The reaction of 2 equiv. $H_2$phpz with 1 equiv. $Cu(OAc)_2$ in acetonitrile and in the absence of base afforded **3** as a polycrystalline sample with a yield of 72%.

**X-ray Crystallographic Study:** Intensity data for single crystals were collected using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) with a Nonius KappaCCD diffractometer. Crystal and refinement data are shown in Table 3 for **1**, **2** and **3**. The intensity data were corrected for Lorentz and polarization effects, and for absorption (multiscan absorption correction[17]). The structures were solved by Patterson methods.[18] The programs EvalCCD, DIRDIF96 and SHELXL-97 were used for data reduction, structure solution, refinement and evaluation.[19–22] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed at calculated positions and were refined riding on the parent atoms. Geometric calculations and molecular graphics were performed with the PLATON package.[23]

CCDC-628568, -639396 and -641268 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Table S1 summarizes the selected bond lengths [Å] and angles [°] for the complexes [Ni(Hphpz)$_2$] (**2**) and [Cu(Hphpz)$_2$] (**3**), and Figure S1 shows the crystal structure of [Cu(Hphpz)$_2$] (**3**).

# Structures of the b- and d-Acid Derivatives of Vitamin $B_{12}$ and Their Complexes with $[M(CO)_3]^+$ (M = $^{99m}$Tc, Re)

**Bernhard Spingler,[a] Stefan Mundwiler,[a] Pilar Ruiz-Sánchez,[a] Dave R. van Staveren,[a] and Roger Alberto*[a]**

**Keywords:** Vitamins / X-ray diffraction / Rhenium / Technetium / Labelling

The acid hydrolysis of natural vitamin $B_{12}$ yields several products in which the acetamide or propionamide side chains on the corrin framework are converted into the corresponding acids. These acids can be derivatised with further functionalities. We have separated in particular the b- and the d-acid derivatives **1** and **2**, respectively, since functionalisation at these positions of the corrin ring generally keeps the affinity for vitamin $B_{12}$ transport proteins intact. Although the authenticity of **1** and **2** seemed evident from $^1$H NMR investigations, it has not been supported by X-ray structure analysis. The coupling of ethyl *N*-(3-aminopropyl)-*N*-(pyridin-2-ylmethyl)glycinate (**3**) to the carboxylate groups in **1** and **2** by peptide synthetic methods gave the vitamin $B_{12}$ derivatives **4** and **5**, respectively. The structures of **4** and **5** could be characterised by X-ray analysis, which unambiguously confirmed the presence of the b- and d-acid in **1** and **2**, respectively. The reaction of **4** and **5** with the complex $[Re(OH_2)_3(CO)_3]^+$ in water gave the corresponding vitamin $B_{12}$ derivatives **8** and **9**, and the aqueous reaction of **4** and **5** with the complex $[^{99m}Tc(OH_2)_3(CO)_3]^+$ afforded the $^{99m}$Tc homologues **10** and **11**, respectively.

## Introduction

Cyanocobalamin or vitamin $B_{12}$ (abbreviated as $B_{12}$ in the following) is, like most of the vitamins, not synthesised by mammals but by a few bacteria only. However, essentially all higher organisms are $B_{12}$ dependent, and the human body in particular has developed a highly complex system for the uptake and biochemical conversion of $B_{12}$ into the two coenzymes methyl- and adenosylcobalamin. Excellent and comprehensive reviews appeared recently covering all aspects of $B_{12}$ chemistry, biochemistry and physiology.[1–3] $B_{12}$ has been proposed as a Trojan horse for cyto- or radiotoxic compounds, since it is essential for the human body. Vitamin-mediated drug uptake by rapidly growing and dividing aggressive tumours having a high density of transcobalamin receptors seems to be an attractive strategy.[4] Covalent conjugation of bioactive molecules to the $B_{12}$ molecule can be performed at several functional sites. The 5′-OH group of the α-ribofuranoside in the backloop would be such a versatile site according to structure–activity relationships. However, little functionalisation has been reported, because of the complexity of site-specific derivatisation.[5] Furthermore, the b- and d-acid sites are attractive positions for conjugation of functionalities or metal complexes. It could be shown by Hogenkamp et al. that covalent binding of a spacer with DTPA and subsequent labelling with $^{111}$In led to a good uptake in the tumour cells, but the uptake was also high in the kidneys.[6,7] We have chosen the b- and d-acids for derivatisation. Although it is known that the affinity of such derivatives for transcobalamin proteins decreases, it is still strong enough for binding and transportation.[8–10] In our previous work, we attached histidine derivatives at the b- or d-acids of $B_{12}$.[11,12] Preliminary studies with $^{99m}$Tc-labelled $B_{12}$ derivatives led to very promising results in vitro and in vivo. Biologically active molecules have also been introduced by direct coordination to the $Co^{III}$ atom in $B_{12}$ or through the cyano group bound to it. Grissom et al. coupled fluorescing molecules by a Co–C bond to $B_{12}$ and used this derivative for lymphatic mapping.[13,14] We bound several rhenium, technetium and platinum complexes to the cyano group and could confirm the authenticity of the products by X-ray structure analysis.[15,16]

The preferred site for derivatisation are the three propionamide and the two acetamide groups bound to the periphery of the corrin ring, which is, like the backloop, bound to three propionamide and two acetamide groups. Scheme 1 gives an overview of the structure of $B_{12}$ and the relative positions of the respective groups.

Characterisation of $B_{12}$ derivatives is mainly performed with NMR spectroscopy. NMR-restrained molecular mechanics/molecular dynamics methods have successfully been used to structurally characterise $B_{12}$ derivatives.[17] Nevertheless, X-ray structure analysis would be preferable, but

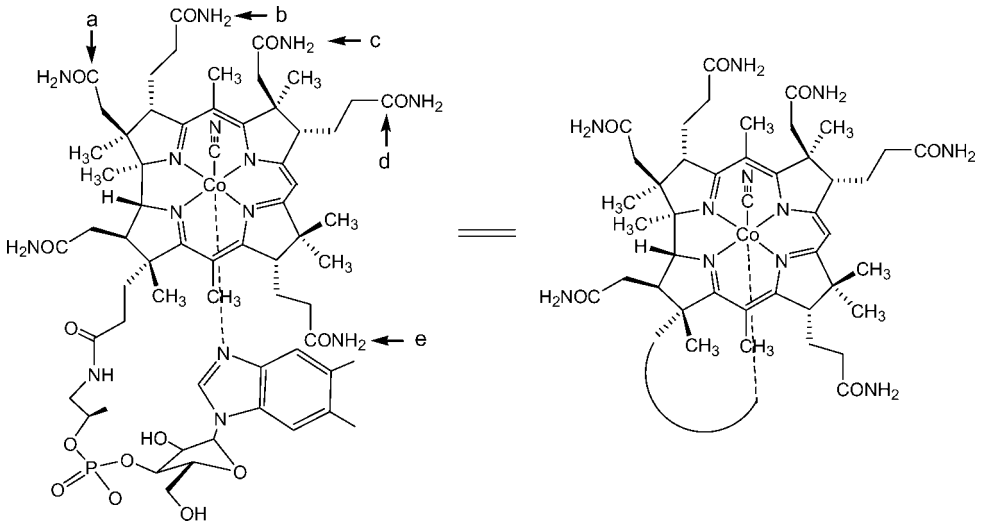


Scheme 1. Assignment of the side chains on the periphery of the corrin ring in $B_{12}$.

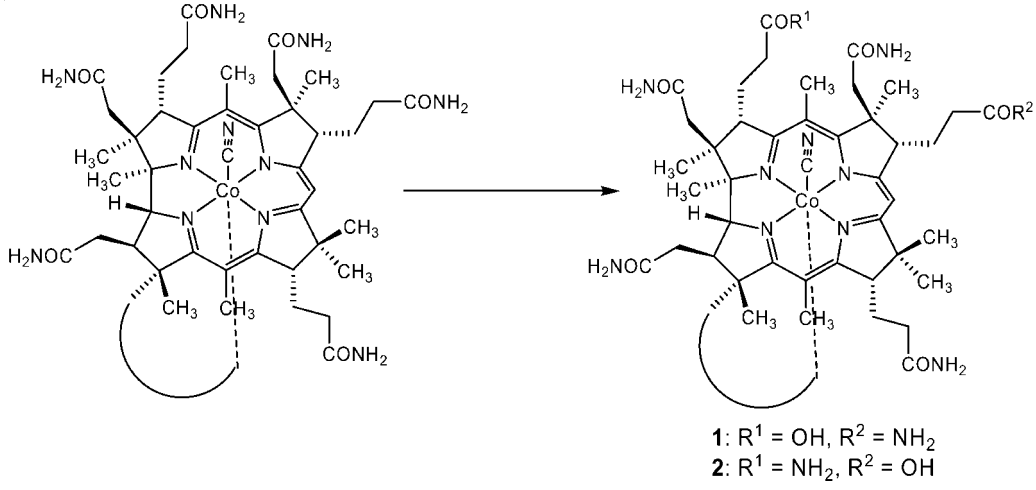
some $B_{12}$ derivatives are very difficult to crystallise. Milestones in $B_{12}$ structure analysis were certainly the elucidation of the structure of native $B_{12}$ by Hodgkin et al.,[18] and those of methylcobalamin and finally adenosylcobalamin (coenzyme $B_{12}$).[19,20] X-ray crystallography of $B_{12}$ and its derivatives has recently been reviewed extensively.[21–23] These reviews reveal the surprising fact that no X-ray analysis of a $B_{12}$ derivative in which one of the amide side chains has been functionalised is available. To the best of our knowledge, the only available X-ray structure of the product of a derivatisation at the corrin ring is that of one in which the C10-H has been replaced by a chlorine atom.[24] We present in this study the synthesis and the first X-ray structures of $B_{12}$ molecules that were derivatised at either the b- or the d-acid with a ligand for binding to transition metals. In a second step, these $B_{12}$ derivatives were labelled with the *fac*-$[M(CO)_3]^+$ (M = Re, $^{99m}$Tc) moiety.

## Results and Discussion

### Syntheses

Mild acid hydrolysis of the amide side chains in $B_{12}$ yields a mixture of monocarboxylic b-, d- and e-acids. These can be separated and obtained in pure form by sequential ion-exchange chromatography and RP-HPLC methods.[8,25–27] With a slightly modified method (see Experimental Section) we obtained 280 mg (15%) of the b-acid **1** and 132 mg (7%) of the d-acid **2**, starting with 1.9 g of vitamin $B_{12}$ (Scheme 2). These yields are consistent with the literature. However, we isolated only 94 mg (5%) of the e-acid.

The determination of the exact structures of the products of hydrolysis turned out to be difficult. Initially, the main product, compound **1**, was thought to be the e-acid because



Scheme 2. Mild hydrolysis of $B_{12}$ yields the b- and d-acids **1** and **2**.[8,25–27]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of its ability to hydrolyse the backloop and from the results of X-ray and neutron diffraction studies.[26,28] Subsequent neutron diffraction studies indicated that it could be the b-acid, an assumption that was later confirmed by sophisticated multi-dimensional NMR measurements.[29–32] The similar diffraction power of the OH and $NH_2$ groups was the problem in X-ray analysis. Cobalamin crystals were rarely obtained in the quality required for an unambiguous differentiation between these two groups. An X-ray structure analysis of respective derivatives such as esters or alkylamides would solve this problem (see later). However, initially all attempts failed, because the conjugated groups prevented crystallisation or were disordered.[23,33]

Since we are interested in the introduction of coordinating ligands rather than simple organic groups, we selected the tridentate chelate *N*-(pyridin-2-ylmethyl)glycine. This basic ligand structure is known to form strong complexes with the *fac*-$[M(CO)_3]^+$ moiety that are stable in vivo.[34] To enable the conjugation of the basic ligand framework to the biomolecule, an alkyl chain with a terminal functionality was introduced to the secondary amine by adaptation of known synthetic pathways.[35] In this case, the 3-aminopropyl chain bound to the secondary amine group in the basic ligand structure gave compound **3**, which then comprised the tridentate chelate (after de-esterification) and an additional primary amine for coupling with the b- and d-carboxylic acids (Scheme 3).

The reaction of **1** and **2** in the presence of ligand **3** and coupling reagents gave the corresponding derivatives **4** (b-acid) and **5** (d-acid), respectively, after HPLC purification, in about 30% yield. In order to obtain the free tridentate ligand, the ester functionality can be removed from the ligand by alkaline hydrolysis. It turned out, however, that the hydrolysis in advance was not required, since coordination to the *fac*-$[M(CO)_3]^+$ moiety catalysed this reaction and led to immediate hydrolysis during the coordination process.

X-ray-quality crystals could be grown by very slow vapour diffusion of either acetone or acetonitrile into an aqueous solution of **4** or **5**, respectively. The crystals of **4** were of exceptional quality for $B_{12}$ crystals, which is shown by the $R_1$ value of 5.9% for the strong reflections. Furthermore, more than 92% of all reflections with a resolution better than 0.75 Å had an intensity higher than 2 sigma. On the other hand, the diffraction of the crystals of **5** was not strong enough on our Mo home source; therefore, we collected synchrotron data on the F1 beamline at HASYLAB/DESY to a resolution of 0.99 Å. Both structures crystallised in the "typical" $B_{12}$ space group $P2_12_12_1$. In the literature, the family of $B_{12}$ crystal structures with the $P2_12_12_1$ space group is subdivided into four clusters on the basis of the ratio of the cell axes *b*/*a* and *c*/*a*.[21] Introduction of the rather large unit of **3** into the $B_{12}$ framework apparently did not distort the normal $B_{12}$ crystal packing. The corresponding ratios for the crystal structures of **4** and **5** are 1.40 and 1.39 for *b*/*a* and 1.61 and 1.61 for *c*/*a*, respectively. These values place **4** and **5** clearly into cluster II. Furthermore, an overlay of the two structures reveals an almost identical conformation of all substituted as well as unsubstituted amide side chains (Figure 1). The ORTEP plots of **4** and **5** are shown in Figure 2 and Figure 3, respectively. It should be noted that both ligand structures include the ethyl ester as the pendent since the coupling was performed directly with compound **3**. This was confirmed by the mass spectra of both compounds. Because of the disorder in the structure of **5**, we were only able to localise the terminal $CH_3$ group in **4** but not that in **5**; hence, it does not appear in the line drawings or the ORTEP drawings.

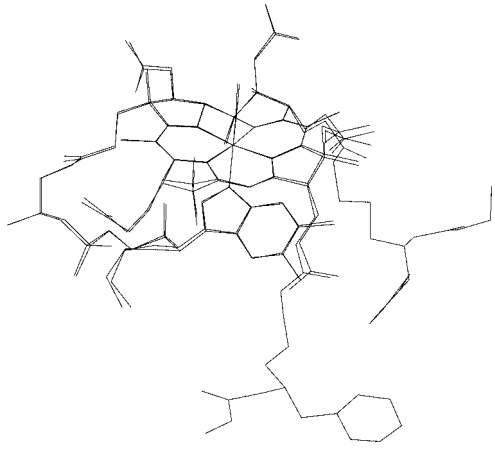


Figure 1. Overlay of the X-ray structures of **4** and **5**.

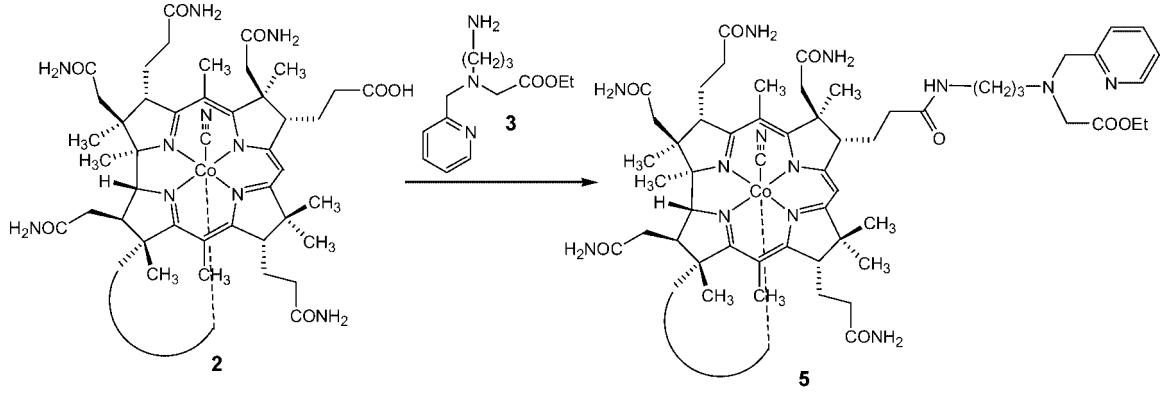

Scheme 3. Derivatisation of $B_{12}$ d-acid **2** with ligand **3** to yield compound **5**.

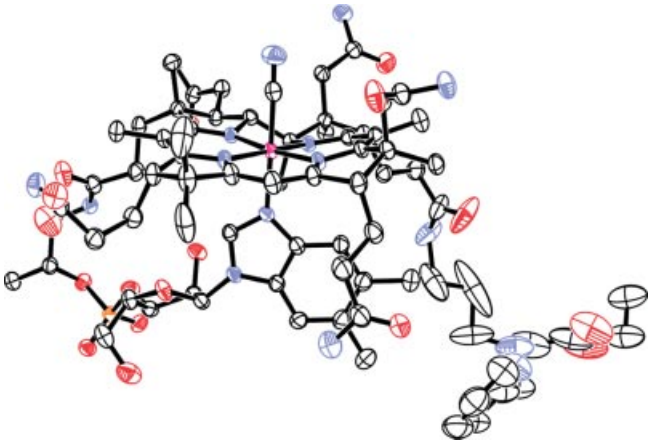

Figure 2. ORTEP plot of **4**. Hydrogen atoms and some water molecules were omitted for clarity.

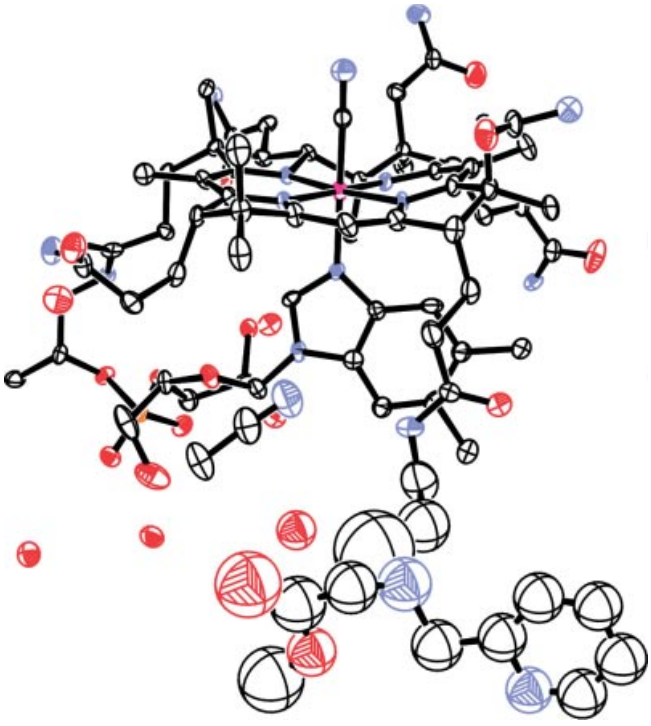

Figure 3. ORTEP plot of **5**. Hydrogen atoms and some water molecules were omitted for clarity.

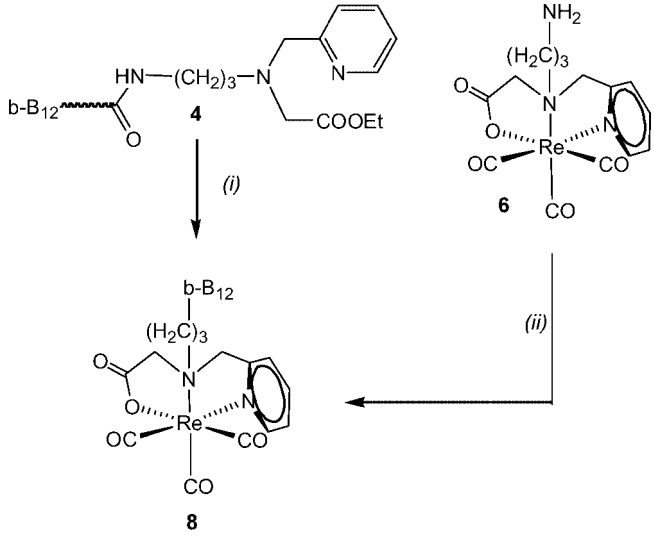
The nitrogen atom of the pyridine group in **4** is hydrogen-bonded to a five-membered cluster of water molecules with extensive contact between three $B_{12}$ molecules. The nitrogen atom of the pyridine group in **5** has two hydrogen bonds with symmetry-generated neighbouring molecules in a Y-shaped alignment of three water molecules (Table 1).

### Complexation with $[Re(OH_2)_3(CO)_3]^+$ and Labelling with $[^{99m}Tc(OH_2)_3(CO)_3]^+$

In compounds **4** and **5**, the carboxylate group is still protected by an ester functionality. Mild alkaline hydrolysis of the ethyl ester over an extended period would convert the ester into the acid and render all three coordination sites available; however, decomposition products were observed during this process, presumably as a result of c-lactam formation. The formation of the c-lactam of $B_{12}$ in alkaline media is a known reaction.[36,37] During the reaction of **4** and **5** with $[Re(OH_2)_3(CO)_3]^+$ in water, we observed that ester cleavage was catalysed by the presence of the metal complex, probably after initial coordination to one or two of the nitrogen donors. A similar observation was made with histidine complexes, in which an ester function was also converted quantitatively to the carboxylate during coordination.[12] After the reaction was completed, we found a mixture of two complexes, one of which was the desired product **8** (for the b-derivative). The highest yield for a single product, however, was obtained by an indirect pathway. The formation of the complex **6** from **3** and $[Re(OH_2)_3(CO)_3]^+$ is quantitative. Complex **6** was then coupled to acid **1** and afforded complex **8** directly in very good yield without byproducts (Scheme 4). The second strategy, as described before, refers to the prelabelling of biomolecules with $^{99m}Tc$. Since yields are usually far from quantitative, prelabelling is not the method of choice for technetium. We had observed previously that ester bonds are much more efficiently cleaved in the presence of technetium than in the presence of rhenium. This observation was confirmed by treating $[^{99m}Tc(OH_2)_3(CO)_3]^+$ with **4** or **5** at moderate temperature. We observed the exclusive formation of the desired products **10** and **11** without any byproducts, even though byproducts had been observed in the corresponding reactions with $[Re(OH_2)_3(CO)_3]^+$. Comparison of the retention times of **10** and **11** with **8** and **9** confirmed the identity of the corresponding homologues. These technetium complexes are stable in human serum albumin for at least 24 h without reoxidation to $[^{99m}TcO_4]^-$. Compounds **10** and **11** therefore represent excellent radiotracers for uptake studies in cancer cells or microbial infections.



Scheme 4. Reaction pathways to **8**, (*i*) direct reaction of **4** with $[Re(OH_2)_3(CO)_3]^+$ to give **8** (postlabelling) or (*ii*) conjugation of preformed **6** to **1** (prelabelling).

## Conclusions

We have synthesised two $B_{12}$ derivatives that comprise tridentate chelators attached to the corrin periphery. For the first time, an X-ray structure analysis of a $B_{12}$ compound with corrin side-chain derivatisation could be elucidated confirming the assignments of earlier NMR investigations. The derivatives are coordinated to $[Re(OH_2)_3(CO)_3]^+$ and to $[^{99m}Tc(OH_2)_3(CO)_3]^+$, thus representing useful radiolabelled $B_{12}$ compounds for in vitro and in vivo studies.

## Experimental Section

**General Remarks:** Reagent grade chemicals were obtained from Merck, Dietikon (CH), Aldrich, Fluka or Buchs (CH) and were used without further purification. HPLC analyses were performed with a Merck-Hitachi L-7000 system equipped with a EG&G Berthold LB 508 radiometric detector, using Waters XTerra RP8 columns (5-μm particle size, $1 \times 100$ mm) and a flow rate of 1 mL min$^{-1}$. Chromatograms were recorded at 250 and 360 nm. Sodium acetate buffer A1 was prepared by mixing acetic acid (2.9 mL) and sodium hydroxide (4.55 mL, 2 M) in water (900 mL) and methanol (100 mL). Tris buffer A2 was prepared by dissolving 2-amino-2-(hydroxymethyl)propane-1,3-diol (605 mg) in water, adding HCl (2 M) to reach a pH of 8.2, adjusting the volume to 1000 mL and adding acetonitrile (10 mL). Eluent B was always methanol. Preparative HPLC separations were performed with a Varian Prostar system equipped with two Prostar 215 pumps and a Prostar 320 UV/Vis detector using Waters XTerra Prep RP8 columns (5-μm particle size, $3 \times 100$ mm and $30 \times 100$ mm). Flow rates were 4 mL min$^{-1}$ for the $3 \times 100$-mm column and 30 mL min$^{-1}$ for the $30 \times 100$-mm column. UV/Vis spectra were recorded with a Varian Cary 50 spectrometer, IR spectra were recorded with a Bio-Rad FTS-45 spectrometer in KBr. ESI-MS were recorded with a Merck Hitachi M-8000 spectrometer. The values of the $^{187}Re$ isotope are reported for Re compounds. NMR spectra were recorded with a Bruker DRX 500 MHz spectrometer.

Cobalamin derivatives were desalted by applying an aqueous solution of the compound to a Chromafix RP18ce cartridge and then thoroughly rinsing with water. The desalted product was then eluted with methanol, the solvent was removed, and the resulting product was dried in high vacuum.

The ethyl ester of *N*-(3-aminopropyl)-*N*-(pyridin-2-ylmethyl)glycinate, compound **3**, was prepared as described for its pentyl analogue.[35] Cyclisation of the compound was observed under basic conditions; therefore, the Boc-protected precursor was stored and deprotected with TFA just prior to further functionalisation. [Re({*N*-(3-aminopropyl)*N*-pyridin-2-ylmethylamino}acetato)$(CO)_3$] (**6**) was prepared by treating the fully deprotected [*N*-(3-aminopropyl)-*N*-pyridin-2-ylmethylamino]acetic acid with $(Et_4N)_2[Re(Br)_3(CO)_3]$ in water (see below). The syntheses of the b- and d-acids **1** and **2** of $B_{12}$ were performed according to the literature but with some slight modifications in the purification process as described below.[8]

**X-ray Crystallography:** Suitable crystals were covered with Paratone N oil, the mother liquor was removed, and the crystals were finally mounted with the help of the magnetic loops. Single-crystal diffraction data for **4** were collected with a Stoe IPDS diffractometer at 183(2) K by using graphite-monochromated Mo radiation (0.71073 Å). Data were corrected for Lorentz and polarisation effects as well as for absorption. Single-crystal diffraction data of **5** were collected at the F1 beamline at HASYLAB/DESY with a Huber Kappa diffractometer at 100(2) K, by using $\lambda = 0.7500$ Å radiation and a MarCCD 165 detector. Integration of intensities was performed with the XDS program.[38] A series of 190 frames with a 1.0-degree phi rotation and an exposure time of 90 s was collected. The XDS program compensated for the beam intensity loss between two refills. Both structures were solved with direct methods by using SIR97[39] and refined by full-matrix least-squares methods on $F^2$ with SHELXL-97.[40] Appropriate restraints had to be used to constrain the geometry of the highly flexible ligand part in **5**. The terminal carbon atom of the ethyl ester in **5** could not be localised in the electron density map. ORTEP plots were generated by the ORTEP32 software and are drawn at 30% probability. The crystal data and refinement parameters of **4** and **5** are summarised in Table 1. CCDC-630989 and CCDC-630990 contain the supple-

mentary crystallographic data for this paper. They can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Vitamin $B_{12}$ b- and d-Acids 1 and 2:** Vitamin $B_{12}$ (1.88 g, 1.39 mmol) was hydrolysed in HCl (0.1 M, 190 mL) as described in literature.[8] The purification was modified in the following way. After desalting the crude reaction mixture by phenol extractions, three fractions were isolated on a Dowex column. The first fraction contained exclusively **2**, the second one a mixture of **1** and **2**, and the third one contained **2** and the e-acid. The second fraction (mixture of **1** and **2**) was separated by preparative HPLC (column: Waters XTerra Prep RP8, 5 μm, 30 × 100 mm; buffer A1; gradient: 0.5%min$^{-1}$ starting from 100% A1). The mixture of **2** and the e-acid was separated on the same system but using the buffer A2. Compound **1** was isolated in a yield of 280.6 mg (14.9%), compound **2** in a yield of 131.5 mg (7.0%), and the e-acid was obtained in a yield of 94.26 mg (5.0%). Assignment of the isomers was carried out by comparison with the HPLC retention order given in literature.

**Synthesis of 4:** A solution of freshly prepared **3** (361 μmol) in water (1 mL) was added to **1** (65.0 mg, 48.1 μmol). EDC (46.1 mg, 240 μmol) was added, and the pH was adjusted to 5.5 with NaOH (0.1 M). After the mixture was stirred at room temperature for 15 h, HPLC analysis exhibited about 50% of product **4**. More EDC (46.1 mg, 240 μmol) was added, but even extended stirring at room temperature did not lead to a significant amount of formation of more **4**. The solvent was removed in vacuo, and the residue was purified by preparative HPLC (buffer A1, gradient: 0.5%min$^{-1}$ starting from 100% A1). The main fraction was collected, the solvent was removed in vacuo, and the product was desalted to give **4** in a yield of 25.8 mg (16.2 μmol, 33.3%). $R_t$ = 13.1 min (gradient A1/B). $^1$H NMR (500 MHz, $CD_3OD$, 300 K): $\delta$ = 8.43 (d, $J$ = 4.9 Hz, 1 H, L12), 7.77 (t, $J$ = 7.7 Hz, 1 H, L10), 7.58 (d, $J$ = 7.8 Hz, 1 H, L9), 7.28 (t, $J$ = 6.9 Hz, 1 H, L11), 7.25 (s, 1 H, B7), 7.12 (s, 1 H, B2), 6.56 (s, 1 H, B4), 6.27 (d, $J$ = 3.0 Hz, 1 H, R1), 6.04 (s, 1 H, C10) ppm. $^{13}$C NMR (125.8 MHz, $CD_3OD$, 293 K): $\delta$ = 181.65, 180.20, 177.67, 176.73, 175.65, 175.58, 175.43, 174.72, 174.48, 174.34, 173.19, 167.22, 166.98, 160.49, 160.44, 149.67, 143.55, 138.86, 138.34, 135.72, 133.88, 131.56, 125.07, 124.04, 117.92, 112.65, 108.77, 105.21, 95.76, 88.05, 86.50, 83.74 (d, $J_{C,P}$ = 5.6 Hz), 76.40, 75.55, 73.69 (d, $J_{C,P}$ = 6.1 Hz), 71.66, 70.80, 70.56, 62.74, 61.79, 60.85, 60.45, 57.75, 56.97, 55.91, 55.67, 55.13, 53.31, 52.64, 50–49 (1 C below solvent), 46.91, 43.99, 43.16, 40.22, 38.88, 37.06, 35.43, 33.58, 33.09, 33.06, 32.42, 29.74, 28.01, 27.96, 27.52, 21.07, 20.61, 20.43, 20.26 (d, $J_{C,P}$ = 3.8 Hz), 20.02, 17.67, 17.16, 16.51, 16.21, 14.71 ppm. ESI-MS: $m/z$ = 806.5 $[M + H + Na]^{2+}$, 795.6 $[M + 2 H]^{2+}$. UV/Vis (methanol): $\lambda$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 278.0 (8500), 361.1 (26500), 549.1 (8000) nm. A full $^1$H NMR spectrum is shown in the Supporting Information. The ester can be hydrolysed to the acid. Because of self-catalysed cleavage processes (see above) this compound has to be labelled immediately. Labelling can be performed directly with **4** without the need for prior deesterification. $R_t$ = 10.8 min.

**Synthesis of 5:** The procedure is similar to the preparation of **4**. Compound **2** (9.3 mg, 6.9 μmol) was treated with **3** (7 μmol) and EDC (6.6 mg, 34 μmol) as described for the synthesis of **4**. After HPLC purification, the product **5** was isolated in a yield of 3.6 mg (33%). $R_t$ = 15.5 min (gradient A1/B). $^1$H NMR (500 MHz, $CD_3OD$, 300 K): $\delta$ = 8.41 (d, $J$ = 4.9 Hz, 1 H, L12), 7.79 (t, $J$ = 7.7 Hz, 1 H, L10), 7.56 (d, $J$ = 7.8 Hz, 1 H, L9), 7.30 (t, $J$ = 5.6 Hz, 1 H, L11), 7.25 (s, 1 H, B7), 7.12 (s, 1 H, B2), 6.56 (s, 1 H, B4), 6.27 (d, $J$ = 3.0 Hz, 1 H, R1), 6.05 (s, 1 H, C10) ppm. $^{13}$C NMR (125.8 MHz, $CD_3OD$, 293 K): $\delta$ = 181.72, 180.27, 177.77, 177.64, 177.50, 175.86, 175.69, 175.47, 174.72, 174.36, 173.84, 173.05, 167.25, 167.05, 160.65, 149.63, 143.58, 138.90, 138.43, 135.60, 134.00, 131.59, 125.10, 124.06, 118.02, 112.62, 108.82, 105.24, 95.76, 88.11, 86.56, 83.84 (d, $J_{C,P}$ = 5.6 Hz), 76.49, 75.65, 73.77 (d, $J_{C,P}$ = 6.1 Hz), 70.85, 62.84, 61.75, 60.86, 60.51, 57.79, 57.02, 55.73, 55.15, 53.10, 52.62, 46.95, 44.02, 43.19, 40.25, 38.59, 36.37, 35.45, 33.78, 33.63, 33.13, 32.52, 32.45, 29.79, 28.21, 27.78, 27.57, 21.09, 20.60, 20.51, 20.33 (d, $J_{C,P}$ = 3.8 Hz), 20.09, 17.65, 17.24, 16.53, 16.25, 14.77 ppm. $^{31}$P NMR (300 MHz, $CD_3OD$, 300 K): $\delta$ = 1.373 ppm. ESI-MS: $m/z$ = 1612 $[M + Na]^+$, 1590 $[M + H]^+$, 806 $[M + H + Na]^{2+}$, 795.1 $[M + 2 H]^{2+}$. UV/Vis (methanol): $\lambda$ ($\varepsilon$, L mol$^{-1}$ cm$^{-1}$) = 279.0 (13400), 361.1 (23300), 549.1 (7200) nm. Free acid $R_t$ = 10.6 min (A1/B). Full $^1$H and $^{13}$C NMR spectra are shown in the Supporting Information.

**Synthesis of 6:** Complex $[NEt_4]_2[ReBr_3(CO)_3]$ (75 mg, 0.09 mmol) was dissolved in water (10 mL), and a solution of fully deprotected **3** (36 mg, 0.13 mmol) in methanol was added. The solution was heated to 70–80 °C for 2 h. The proceeding of the reaction was monitored by HPLC: the peak with $R_t$ = 6.2 min ($[Re(OH_2)_3(CO)_3]^+$) disappeared, and a new peak (product **6**) with $R_t$ = 15.1 min appeared. After 2 h, the conversion was complete. When the reaction mixture was cooled, a white powder precipitated from solution. This precipitate was filtered, washed with small amounts of cold water and dried in vacuo. Yield: 32 mg (72%); the rest remained in the filtrate. It is important to apply temperatures above 70 °C in order to ensure ester hydrolysis during complexation. $^1$H NMR (300 MHz, $CD_3OD$, 300 K): $\delta$ = 8.83 (d, $J$ = 5.7 Hz, 1 H), 8.11 (t, $J$ = 7.8 Hz, 1 H), 7.74 (d, $J$ = 8.1 Hz, 1 H), 7.56 (t, 1 H, $J$ = 6.9 Hz), 4.78 (d, 1 H, $J$ = 15.6 Hz), 4.55 (d, 1 H, $J$ = 15.9 Hz), 3.90 (d, 1 H, $J$ = 17.1 Hz), 3.70 (m, 2 H), 3.53 (d, $J$ = 16.8 Hz, 1 H), 3.04 (t, $J$ = 7.5 Hz, 2 H), 2.18 (m, 2 H) ppm. ESI-MS: $m/z$ = 493.80 $[M + H]^+$. $C_{12}H_{18}F_3N_3O_7Re$ (6·TFA): calcd. C 25.76, H 3.24, N 7.51; found C 25.23, H 3.21, N 7.33.

**Synthesis of 8:** Two synthetic procedures are possible. The direct reaction of **4** with $[Re(OH_2)_3(CO)_3]^+$ in water gives compound **8** in good yield. Alternatively, the complex **6** can be preformed by the reaction of fully deprotected **3** and $[Re(OH_2)_3(CO)_3]^+$ followed by coupling to **1** as described in the following part. Compound **1** (26.7 mg, 19.8 μmol), complex **6** (29.2 mg, 60 μmol), EDC (11.5 mg, 60 μmol) and *N*-hydroxysuccinimide (6.9 mg, 60 μmol) were dissolved in a mixture of water (5 mL) and DMSO (0.5 mL), and the pH was adjusted to 5.5. After 5 h at room temperature, HPLC analysis exhibited about 33% of product **8**. More EDC and *N*-hydroxysuccinimide were added and the stirring was continued for 3 d with addition of EDC and *N*-hydroxysuccinimide in 24-h intervals. The water was removed in vacuo, and the product was precipitated by adding diethyl ether. The oily suspension was centrifuged and decanted. Washing with diethyl ether was repeated twice (5 mL each time) until a fine precipitate formed. The crude product was dried at high vacuum, purified by preparative HPLC (A1, gradient 1%min$^{-1}$ starting from 100% A1) and desalted to give **8** in a yield of 9.1 mg (23%). $R_t$ = 14.2 min (gradient A1/B). IR (KBr): $\tilde{\nu}$ = 2927, 2134, 2024, 1913, 1897, 1662 cm$^{-1}$. $^1$H NMR (500 MHz, $CD_3OD$, 300 K): $\delta$ = 8.1 (d, $J$ = 4.5 Hz, 1 H, L12), 8.10 (t, $J$ = 8 Hz, 1 H, L10), 7.73 (m, 1 H, L9), 7.54 (m, 1 H, L11), 7.26 (s, 1 H, B7), 7.14 (s, 1 H, B2), 6.59 (m, 1 H, B4), 6.27 (s, 1 H, R1), 6.05 (s, 1 H, C10) ppm. $^{13}$C NMR (125.8 MHz, $CD_3OD$, 300 K): $\delta$ = 198.39, 198.24, 197.46, 183.33, 181.75, 180.28, 177.72, 177.68, 176.77, 175.74, 175.69, 175.46 (2 C), 174.90, 174.76, 174.36, 167.27 (2 C), 160.90, 153.72, 143.63, 141.85, 138.39, 135.77, 133.97, 131.63, 127.20, 125.19, 117.99, 112.65, 105.25, 102.57, 95.74, 88.13, 86.59, 83.83 (d, $J_{C,P}$ = 4.5 Hz), 76.52, 75.74, 73.72 (d, $J_{C,P}$ =

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

5.4 Hz), 70.89, 69.44, 68.87, 62.90, 62.04, 60.55, 55.27, 55.77, 49–50 (1C below solvent), 46.93, 44.35, 43.04, 40.29, 38.01, 36.44, 35.51 (2 C), 33.66, 33.11 (2 C), 32.45 (2 C), 29.74, 27.60, 26.46, 21.13, 20.64, 20.47, 20.31 (d, $J_{C,P}$ = 3.2 Hz), 20.09, 17.65, 17.25, 16.69, 16.24 ppm. ESI-MS: $m/z$ = 1831.7 $[M + H]^+$, 916.1 $[M + H]^{2+}$. UV/Vis (methanol): $\lambda$ = 278.0, 361.1, 519.9, 551.1 nm. A full $^1$H NMR spectrum is shown in the Supporting Information.

**Synthesis of 9:** Compound **9** was prepared following one of the procedures described for **8**. Full $^1$H and $^{13}$C NMR spectra are shown in the Supporting Information.

**Labelling of 3 and 4 with $[^{99m}Tc(OH_2)_3(CO)_3]^+$ (10 and 11):** Solutions of the precursor $[^{99m}Tc(OH_2)_3(CO)_3]^+$ were prepared from $[^{99m}TcO_4]^-$ as described in the literature or by using the Isolink® kits as commercially available from Mallinckrodt Med. B.V. Petten NL.[41] Labelling of **4** and **5** was performed in a 10-mL glass vial with a rubber stopper which was flushed with $N_2$ for 10 min. In this vial, a solution of the respective $B_{12}$ derivative (20 μL, 0.001 M in water), MES buffer pH 6.2 (20 μL or 40 μL, final conc. 0.1 M) and a $[^{99m}Tc(OH_2)_3(CO)_3]^+$ solution (160 or 1940 μL) were mixed, and the reaction mixture was kept at 75 °C for 1–2 h. The final $B_{12}$ concentration was $10^{-4}$ to $10^{-5}$ M. HPLC analysis with γ-detection was performed to verify full conversion of the $^{99m}$Tc precursor. Under these conditions, the ester protecting groups of the chelators were cleaved to enable tridentate complexation. Comparison with the retention times of the corresponding rhenium complexes confirmed the authenticity of the labelled compounds. $R_t$ (**8**) = 15.1 min, $R_t$ (**9**) = 17.9 min. The delay is a result of the two separate detectors. Both compounds labelled with $^{99m}$Tc were stable in human serum albumin for at least 24 h at 37 °C.

**Supporting Information** (see footnote on the first page of this article): $^1$H NMR spectra for compounds **4**, **8**, **5** and **9** and $^{13}$C NMR spectra for compounds **5** and **9**.

# *ortho*- and *para*-Thioquinonoid π-Complexes: First Synthesis, Reactivity, and Crystal Structure Determination

**Jamal Moussa,[a] Marie Noelle Rager,[b] Kamal Boubekeur,[a] and Hani Amouri*[a]**

**Keywords:** Reactive intermediates / Coordination modes / Sulfur / Thioquinones / Iridium

Overcoming a long-standing challenge, the *o*- and *p*-dithiobenzoquinone iridium complexes [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) and [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) were rationally synthesized and fully characterized for the first time including the X-ray molecular structure of [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**). Our strategic approach involves the preparation of the halogenated 1,2- and 1,4-dichloro arene π complexes [Cp*Ir-*o*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**4**) and [Cp*Ir-*p*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**5**), which are the key molecules for **6** and **7**. Subsequent treatment of **4** and **5** with NaSH and halogen displacement provides the target thioquinonoid π complexes **6** and **7** in 88 % and 95 % yields respectively. Further, the coordination chemistry of the *o*-dithiobenzoquinone iridium complex [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) was studied by treating **6** with [(bpy)$PtCl_2$] in the presence of AgOTf, which provided the novel platinum complex [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}][OTf]$_2$ (**10**) in 91 % yield. The X-ray molecular structure of **10** is reported and shows as outstanding features the formation of 1D supramolecular assembly, which results from π–π ($d$ = 3.484 Å; $d$ = 3.669 Å) and Pt···Pt ($d$ = 3.574 Å) interactions between individual subunits.

## Introduction

Although the chemistry of *o*- and *p*-benzoquinone is well documented,[1] very little is known about the related *o*- and *p*-dithiobenzoquinone (**1**, **2**) (Figure 1). Unlike benzoquinones, the sulfur analogues are highly reactive owing to their instability, making their handling and isolation in pure form a difficult task. Thus examples of isolated thioquinones are scarce and in fact *p*-dithiobenzoquinone (**2**) has been generated and characterized spectroscopically only at low temperature (10 K) in an argon matrix because it is extremely reactive and was observed to decompose in an unknown manner on moderate warming of the matrix.[2] Recently Oda and co-workers reported the synthesis of 2,6-di-*tert*-butyl-1-thio-1,4-benzoquinone, where the presence of two *tert*-butyl groups at the 2- and 6-positions offers steric protection and increases the stability of the mono-thiobenzoquinone.[3] More recently, Cava and co-workers reported the synthesis of dithioanthraquinone analogue in 16% yield by several steps: first annelation of thiophene rings to benzoquinone produced the anthraquinone analogue, and subsequent treatment with Lawesson's reagent and/or Davy reagent methyl for 18 h produced the mono- and dithio-anthraquinone analogues.[4] However, none of the previous attempts allowed the isolation of *p*-dithiobenzoquinone (**2**).

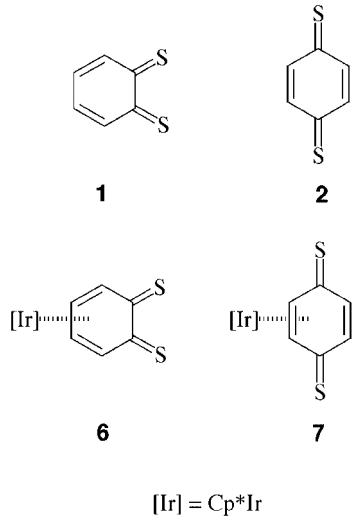

Figure 1. *o*- and *p*-dithiobenzoquiones complexes.

The isomeric *o*-dithiobenzoquinone (**1**) has proven to be even more elusive. Three attempts to generate this compound have been recorded. (i) The matrix-isolated product from pyrolysis of 1,3-benzodithiol-2-one showed an ultraviolet spectrum suggestive of the transient benzodithiete rather than that expected of *o*-dithiobenzoquinone (**1**).[5] (ii) The photolysis of the same starting material 1,3-benzodi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thiol-2-one also did not afford **1** as an isolable product but its transient generation was proven by trapping it with dimethyl acetylenedicarboxylate to give dimethyl 1,4-benzodithiin-2,3-dicarboxylate in moderate yield.[6] (iii) Finally, Perkin and Green's diaminodithioquinone approach did not yield the monomeric elusive dithione (**1**) either; instead a polymeric species featuring disulfide bonds was proposed.[7] All these procedures illustrate the difficulty in isolating and stabilizing *o*- and *p*-dithiobenzoquinones (**1**, **2**).

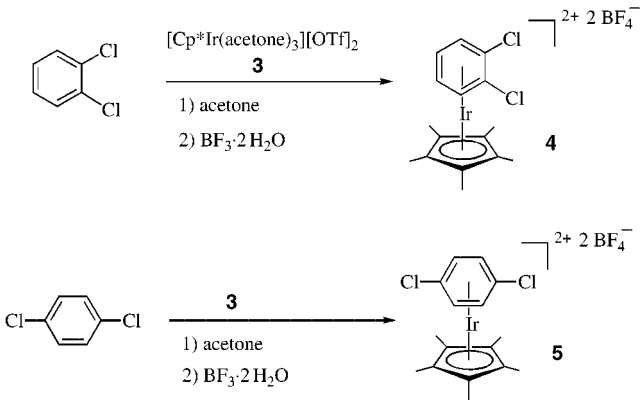
In contrast, here we report a rational synthetic procedure to isolate and fully characterize the first stable $\eta^4$-dithio-*o*- and -*p*-benzoquinone complexes (**6**, **7**) (Figure 1). The parent compounds were obtained as iridium complexes [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) and [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) and were fully characterized including the first X-ray molecular structure of the dithio-*p*-benzoquinone as a metal complex **7**.

In a previous work we reported the first example of metal-stabilized *o*-quinone methide, and showed that the Cp*Ir can stabilize this highly reactive intermediate through $\eta^4$-coordination to the internal diene moiety of the simple quinone methide.[8] Pursuing our research in this area, that is, stabilization of reactive intermediates,[9] we discovered that Cp*Ir can also stabilize the elusive *o*- and *p*-dithiobenzoquinone intermediates; a previous communication on the stabilization of **2** has recently been published.[10] Our synthetic approach is completely different to that reported for the quinone methide. It involves the synthesis of halogenated 1,2- and 1,4-dichloroarene π complexes [Cp*Ir-*o*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**4**) and [Cp*Ir-*p*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**5**), which are the key molecules for **6** and **7**. Subsequent substitution of the chlorides by ($HS^-$) provided the title compounds [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) and [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) in high yields (Figure 1).

## Results and Discussion

### Synthesis and Characterization of the Halogenated Arene π Complexes 4, 5 and Their Related *o*- and *p*-$\eta^4$-Dithiobenzoquinones 6, 7

We recently discovered that the π complexing ability of the $Cp^*Ir^{2+}$ moiety is dramatically enhanced towards electron-poor halogenated arenes when the reaction is conducted in $BF_3{\cdot}2H_2O$ solution. These experimental conditions allow a smooth and efficient complexation of highly electron-deficient aromatics. Thus treatment of an excess of *o*- and/or *p*-dichlorobenzene with the solvated iridium complex [Cp*Ir(acetone)$_3$][OTf]$_2$ (**3**) in $BF_3{\cdot}2H_2O$ solution gave the iridium complexes [Cp*Ir-*o*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**4**) and [Cp*Ir-*p*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**5**) quantitatively as white microcrystalline complexes (Scheme 1). These air- and moisture-sensitive compounds were completely characterized. The $^1$H NMR spectra recorded for **4** and **5** in $CD_3NO_2$ were similar, for instance, to the *ortho* complex **4**, which showed the presence of two doublets of doublets at $\delta$ = 7.52 and 7.83 ppm attributed to the aromatic protons and another singlet at $\delta$ = 2.35 ppm attributed to the methyl protons of Cp*Ir. In a similar fashion the *para* isomer **5** gave a singlet at $\delta$ = 7.82 ppm assigned to the ring protons and at $\delta$ = 2.48 ppm attributed to the methyl protons of Cp*Ir. The $^{19}$F NMR spectra of both complexes showed a singlet at –152.7 ppm for **4** and at –153.6 ppm for **5** designated to the free $BF_4$ anion.[11] Further, the infrared spectra also showed a large band at 1083 cm$^{-1}$ attributed to $BF_4$ anions. The $^{13}$C NMR spectrum is in agreement with the proposed formula (see Experimental Section). As mentioned before, compounds **4** and **5** were very air- and moisture-sensitive and hence were kept under argon at low temperature because of the lability of the C–Cl bond of the coordinated arenes.



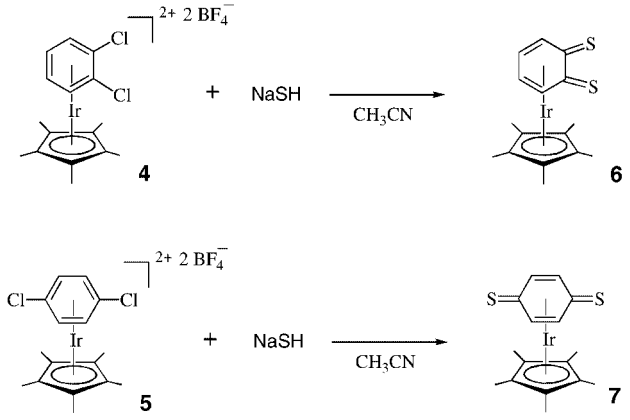
Scheme 1.

We then treated the white powder complexes **4** and **5** with an excess of dried NaSH in $CH_3CN$ for 20 min. Reaction workup provided the neutral *o*- and *p*-$\eta^4$-dithiobenzoquinone complexes [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) and [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**). Compounds **6** and **7** were obtained as red and orange microcrystalline materials, analytically pure and stable under argon. For instance, the infrared spectrum of **6** recorded in KBr discs displayed a sharp band at 1085 cm$^{-1}$, while that of **7** gave a band at 1096 cm$^{-1}$, which we attribute to C=S vibration. This thiocarbonyl stretching frequency is lower than that of the free monothio-1,4-benzoquinone (1141 cm$^{-1}$).[3] Such a trend has been observed for the C=O vibration in the related free and metallated 1,4-benzoquinone.[12] It is worth mentioning that infrared data for *o*- and *p*-dithiobenzoquinone complexes have not been reported before. All attempts to obtain crystals of *o*-dithiobenzoquinone metal complex **6** for an X-ray study were not successful, however we were able to obtain crystals of the *p*-isomer [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) and the structure was determined (vide infra).

The structure of the *p*-dithiobenzoquinone [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) was confirmed by a single-crystal X-ray diffraction study (Scheme 2). Crystals of **7** were grown by vapor diffusion of diethyl ether into a solution of the complex in $CH_2Cl_2$. Complex **7** crystallizes in the monoclinic unit cell with space group $P2_1/m$ with $Z$ = 2. The asymmetric unit consists of three half complexes (I, II, and III), which are totally generated by crystallographic mirror planes and one molecule of $CH_2Cl_2$ with 25% occupation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Molecules I and II show π–π interactions between (a) the $\eta^5$-Cp*Ir moiety of molecule I and the $\eta^4$-(S–$C_6H_4$–S) unit of another thioquinone metal complex (II) with $d$ = 3.565(4) Å and $\alpha$ = 21.30(12)° and (b) the $\eta^5$-Cp*Ir moiety of molecule II and the $\eta^4$-(S–$C_6H_4$–S) unit of another thioquinone metal complex (I) with $d$ = 3.631(3) Å and $\alpha$ = 17.69(15)°, providing a one-dimensional supramolecular chain (Figure 2, a).



Scheme 2. X-ray molecular structures of *p*-dithiobenzoquinone [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) and [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}]-[OTf]$_2$ (**10**).

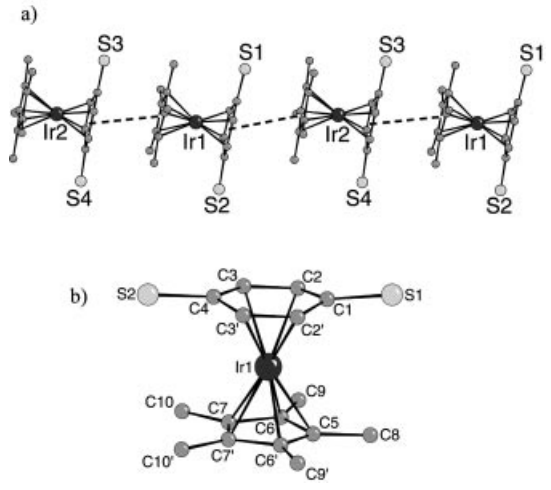


Figure 2. X-ray molecular structure of *p*-dithiobenzoquinone complex [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**). (a) 1D supramolecular chain formed through π–π contacts between molecules I and II. (b) Selected bond lengths [Å] and angles [°] for **7** molecule I: Ir1···C1 2.353(8), Ir1···C2 2.210(6), Ir1···C3 2.219(5), Ir1···C4 2.346(7), C1···S1 1.726(10), C4···S2 1.713(9), C2–C1–C2′ 114.2(9), C3–C4–C3′ 115.0(8).

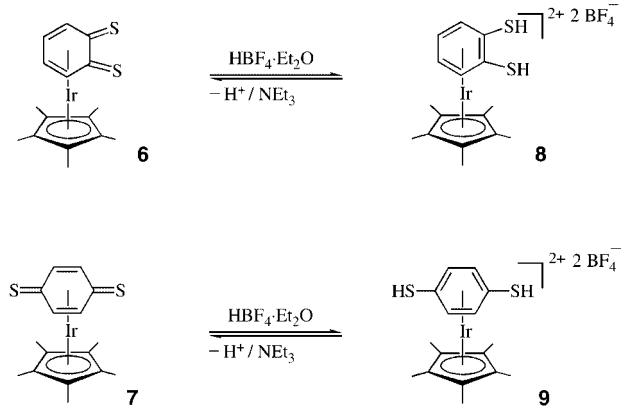
The distance between the closest sulfur atoms of two independent molecules II and III is 4.23 Å, suggesting the absence of an interatomic contact (sum of van der Waals radii of sulfur is 3.7 Å).[13] A view of complex **7** with selected bond lengths and angles is shown in Figure 2b. The structure of **7** clearly shows the Cp*Ir moiety is coordinated to only four diene carbons of the π-thioquinone ligand. For instance the average values of the Ir–C distances are 2.367, 2.358 Å longer than those of the diene subunit (average bond lengths of 2.206, 2.214 Å) in molecules I, II and III. Further, the $\eta^4$-thioquinone ligand acquires a boat-like conformation with the thioquinoid carbons bent out of the diene plane by $\theta$ = 8.22(0.7)° and $\theta$ = 8.21(0.4)° in molecule I, while in molecule II the two dihedral angles are $\theta$ = 8.49(0.6)°, $\theta$ = 7.69(0.3)°, and $\theta$ = 12.94 (0.8) and $\theta$ = 10.04(1.1) in molecule III. These angle values are smaller than those reported for the analogous iridium benzoquinone complex ($\theta$ = 16°).[12a] The C–S bond lengths for the three independent molecules (I, II, III) are 1.719, 1.705, and 1.710 Å, which on average is 1.711 Å and characteristic of a partial double bond character (vide infra). This bond length is shorter than the simple C–S bond of 1.796 Å reported for 1,4-benzenedithiol[14] and 1.766 Å for 4,4′-biphenyldithiol,[15] but comparable to C=S bond lengths of 1.674–1.702 Å reported for several thiourea compounds.[16] To the best of our knowledge this is the first X-ray structure of the parent thioquinone complex reported in the literature.

Protonation of a suspension of either [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) or [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) in $CH_3CN$ by $HBF_4{\cdot}Et_2O$ provided a rapid color change, giving rise to a red solution for **6** and yellow solution for **7**. Reaction work-up allowed the isolation of the related dithiophenol complexes [Cp*Ir-*o*-($\eta^6$-HS–$C_6H_4$–SH)][$BF_4$]$_2$ (**8**) or [Cp*Ir-*p*-($\eta^6$-HS–$C_6H_4$–SH)][$BF_4$]$_2$ (**9**) in 95% and 93% yields respectively as red and pale yellow microcrystalline solids (Scheme 3).



Scheme 3.

Compound **9** was characterized by spectroscopic data ($^1$H, IR). For instance the $^1$H NMR of **9** recorded in $CD_3CN$ showed the presence of a singlet at $\delta$ = 1.98 ppm attributed to the methyl protons of $\eta^5$-Cp*Ir and another singlet at $\delta$ = 7.15 ppm assigned to the aromatic protons that integrate to four protons. In a similar way complex **8** showed one singlet at $\delta$ = 2.10 ppm and two doublet of doublets at $\delta$ = 6.83 and 7.70 ppm, respectively. Upon treatment of the NMR tube sample of **9** in $CD_3CN$ with $NEt_3$, the starting material [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) was recovered. A similar behavior was also observed to the *o*-dithiophenol complex **8**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In a previous work[10] we investigated, by an ab initio computational approach employing the hybrid density functional B3LYP method, the role of the metal in stabilizing the elusive intermediate *p*-dithiobenzoquinone in **7**. Computational analyses using density functional theory confirm a net transfer of about 0.8 units of electron density to the π* ligand LUMO. This additional electron density is largely localized around the thiocarbonyl bonds, resulting in a reduction in C=S bond order as well as the anticipated decrease in C=C bond order. This provides further confirmation of the versatility of the "Cp*Ir" metal fragment in stabilizing reactive π systems. Having these thioquinoid complexes in hand for the first time, we investigated the reactivity of the *o*-thioquinoid metal complex [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) towards electrophilic platinum adduct "(bpy)-$Pt(OTf)_2$".

When the *o*-dithiobenzoquinone metal complex [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) was treated with [(bpy)$PtCl_2$] in $CH_3CN$ in the presence AgOTf, a new compound was obtained, which was fully characterized as [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}][OTf]$_2$ (**10**) (see Experimental Section); further, the X-ray molecular structure of **10** was determined. The $^1$H NMR of **10** recorded in $CD_3CN$ shows the presence of two doublets of doublets at $\delta$ = 6.68 ppm and at $\delta$ = 7.07 ppm attributed to the metallated *o*-thioquinone and a singlet at $\delta$ = 1.98 ppm assigned to the Cp*Ir moiety. Further, we note the presence of four multiplets assigned to the "(bpy)Pt" fragment. Red crystals of **10** were obtained from nitromethane/ether solution. Complex **10** crystallizes in the monoclinic unit cell, space group $P2_1/c$. A view of the cationic part of the complex and selected bond lengths and angles are shown in Figure 3. The structure of **10** shows indeed that the *o*-thioquinone iridium complex chelates the "(bpy)Pt" fragment through the two sulfur centers such that the coordination geometry around the Pt becomes square planar. Because of this coordination mode, the aromatic ring of the *o*-thioquinone is planar and symmetrically bound ($\eta^6$-) to the Cp*Ir moiety.

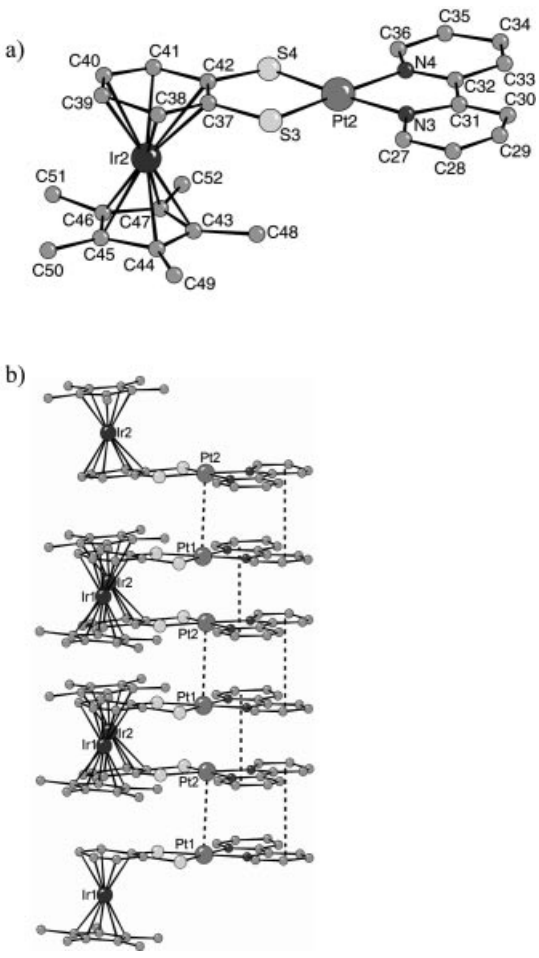


Figure 3. (a) View of the cationic part of complex **10**. Selected bond lengths [Å] and angles [°] for **10**: Ir2···C37 2.382(5), Ir2···C38 2.350(1), Ir2···C39 2.290(3), Ir2···C40 2.215(7), Ir2···C41 2.252(5), Ir2···C42 2.341(5), C42···S4 1.748(5), C37···S3 1.709(0), Pt2···S4 2.283(2), Pt2···S3 2.301(8), Pt2···N4 2.093(7), Pt2···N3 2.098(1), S4–Pt2–S3 89.51(1), S4–Pt2–N4 96.07(2), S3–Pt2–N3 94.99(2), N4–Pt2–N3 79.40(1). (b) 1D supramolecular chain formed through π–π and Pt···Pt contacts between individual molecules.

Further examination of the crystal packing of **10** reveals important information such as: the molecules are stacked in a head-to-tail orientation with several π–π interactions between adjacent bipyridyl ligands with $d$ = 3.484 Å and $d$ = 3.669 Å and also show the presence of a Pt1···Pt2 interaction at $d$ = 3.574 Å. These Pt···Pt/π–π interactions occur in an alternate fashion among the individual molecules of [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}]$^{2+}$, describing a 1D supramolecular chain. In this supramolecular assembly each square planar Pt(bpy) subunit is rotated by 38.54° relative to the adjacent molecule. Other platinum(II) polypyridyl complexes have shown similar extended linear chain packing.[17] Our results, in which we describe the structure of a *o*-thioquinone metal complex for the first time and also its coordination chemistry, are unprecedented.

## Concluding Remarks

In this paper we have reported the first synthesis and full characterization of *o*- and *p*-thiobenzoquinone metal complexes [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**) and [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**). The key molecules to their synthesis are the halogenated arene π complexes [Cp*Ir-*o*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**4**) and [Cp*Ir-*p*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**5**), which we prepared following a novel synthetic procedure. The structure of **7** was also reported and shows the "Cp*Ir" moiety is coordinated in a $\eta^4$-fashion to the *p*-thiobenzoquinone. This illustrates the role of the "Cp*Ir" fragment in stabilizing such reactive intermediates. The *o*-thiobenzoquinone iridium complex can be used as an *organometallic linker* and chelates the electrophilic "(bpy)$Pt(OTf)_2$" adduct, which provides a 1D supramolecular assembly [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}][OTf]$_2$ (**10**). Our future objectives are directed towards the use of these first thioquinoid complexes **6** and **7** as *organometallic linkers* in a similar way to the related benzoquinone metal complex[18] in order to construct novel supramolecular coordination polymers exhibiting short Pt···Pt contacts and also to study their photoluminescence properties.

## Experimental Section

All experimental manipulations were carried out under argon using Schlenk tube techniques. The $^1H$, $^{13}C$, and $^{19}F$ NMR spectra were recorded in $CD_2Cl_2$, $CD_3CN$, and $CD_3NO_2$ using a Bruker Avance 400 NMR spectrometer at 400.13, 100.61, and 376.45 MHz, respectively. Infrared spectra were recorded from KBr discs on a Bio-Rad FTIR spectrometer FTS 165.

**Synthesis of [Cp*Ir-*o*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (4):** A solution of $AgCF_3SO_3$ (260 mg, 1.0 mmol) in acetone (10 mL) was added to [Cp*Ir(μ-Cl)Cl]$_2$ (200 mg, 0.25 mmol) in acetone (5 mL) to rapidly give a white precipitate of AgCl. The reaction mixture was stirred for 15 min then the resulting yellow solution of [Cp*Ir(acetone)$_3$][OTf]$_2$ (**3**) was filtered under argon into a dry Schlenk tube containing 1,2-dichlorobenzene (0.6 mL, 5.0 mmol) and the solvent was removed under vacuum. $BF_3{\cdot}2H_2O$ (1 mL) was added to the yellow residue, which immediately decolorized. The mixture was stirred for 30 min at room temperature, then diethyl ether (60 mL) was added. Complex **4** precipitated out as a white microcrystalline air-sensitive powder that was filtered and washed several times with diethyl ether (20 mL) and dried under vacuum (300 mg, 0.47 mmol). Yield: 94%. This complex is highly air- and moisture-sensitive and hence accurate elemental analysis could not be obtained. $C_{16}H_{19}B_2Cl_2F_8Ir$ (648 g mol$^{-1}$): calcd. C 29.65, H 2.96; found C 28.40, H 2.87. $^1H$ NMR (400 MHz, $CD_3NO_2$): $\delta$ = 2.35 (s, 15 H, Cp*), 7.52 (dd, 2 H, aromatic, $^3J_{H,H}$ = 4.7, $^4J_{H,H}$ = 2.7 Hz), 7.83 (dd, 2 H, aromatic, $^3J_{H,H}$ = 4.7, $^4J_{H,H}$ = 2.7 Hz) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CD_3NO_2$): $\delta$ = 9.4 (s, –$CH_3$, Cp*), 109.3 (s, C=C, Cp*), 99.1 (s, C–H, aromatic), 100.3 (s, C–H, aromatic), 117.3 (s, C–Cl, aromatic) ppm. $^{19}F$ NMR (376 MHz, $CD_3NO_2$): $\delta$ = –152.7 (s, $BF_4$) ppm. IR (KBr disk): $\tilde{\nu}$(B–F) = 1083 cm$^{-1}$.

**Synthesis of [Cp*Ir-*p*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (5):** This complex was prepared in a similar way to that of [Cp*Ir-*o*-($\eta^6$-$C_6H_4Cl_2$)][$BF_4$]$_2$ (**4**), using $AgCF_3SO_3$ (520 mg, 2 mmol), [Cp*Ir(μ-Cl)Cl]$_2$ (400 mg, 0.5 mmol) and $BF_3{\cdot}2H_2O$ (1 mL). Yield: 80% (515 mg, 0.8 mmol). This complex is highly air- and moisture-sensitive and hence accurate elemental analysis could not be obtained. $C_{16}H_{19}B_2Cl_2F_8Ir$ (648 g mol$^{-1}$): calcd. C 29.65, H 2.96; found C 27.39, H 2.96. $^1H$ NMR (400 MHz, $CD_3NO_2$): $\delta$ = 2.48 (s, 15 H, Cp*), 7.82 (s, 4 H, aromatic) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CD_3NO_2$): $\delta$ = 8.3 (s, –$CH_3$, Cp*), 108.5 (s, C=C, Cp*), 99.4 (s, C–H, aromatic), 114.9 (s, C–Cl, aromatic) ppm. $^{19}F$ NMR (376 MHz, $CD_3NO_2$): $\delta$ = –153.6 (s, $BF_4$) ppm. IR (KBr disk): $\tilde{\nu}$(B–F) = 1083 cm$^{-1}$.

**Synthesis of [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (6):** A solution of **3** (340 mg, 0.52 mmol) in $CH_3CN$ (10 mL) was added to a suspension of dried HSNa (360 mg, 6.0 mmol) in $CH_3CN$ (5 mL) and the mixture was stirred for 20 min at room temperature, then the solvent was removed by evaporation under vacuum. The residue was extracted by $CH_2Cl_2$ (20 mL) and filtered through Celite. After filtration through Celite, $CH_2Cl_2$ was evaporated under vacuum. Complex **6** was obtained as an orange microcrystalline powder (238 mg, 0.49 mmol). Yield: 88%. M.p. 185 °C (dec.) $C_{16}H_{19}IrS_2{\cdot}3H_2O$ (522 g mol$^{-1}$): calcd. C 36.73, H 4.30, S 12.39; found C 36.84, H 4.83, S 12.29. $^1H$ NMR (300 MHz, $CD_2Cl_2$): $\delta$ = 1.87 (s, 15 H, Cp*), 5.90 (dd, 2 H, diene, $^3J_{H,H}$ = 7.37, $^4J_{H,H}$ = 1.77 Hz), 6.44 (dd, 2 H, diene, $^3J_{H,H}$ = 7.37, $^4J_{H,H}$ = 1.77 Hz) ppm. IR (KBr disk): $\tilde{\nu}$(C=S) = 1085 cm$^{-1}$.

**Synthesis of [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (7):** This complex was prepared in a similar way to that of Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (**6**), using HSNa (360 mg, 6.0 mmol) and **3** (340 mg, 0.52 mmol). Complex **7** was obtained as an orange microcrystalline powder (238 mg, 0.49 mmol). Yield: 95%. M.p. 160 °C (dec.) $C_{16}H_{19}IrS_2{\cdot}H_2O$ (486 g mol$^{-1}$): calcd. C 39.57, H 4.36, S 13.20; found C 38.96, H 4.32, S 13.24. $^1H$ NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.91 (s, 15 H, Cp*), 5.96 (s, 4 H, aromatic) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CD_2Cl_2$): $\delta$ = 7.1 (s, –$CH_3$, Cp*), 96.25 (s, C=C, Cp*), 91.8 (s, C–H, aromatic), 148.1 (s, C=S, aromatic) ppm. IR (KBr disk): $\tilde{\nu}$(C=S) = 1096 cm$^{-1}$.

**Synthesis of [Cp*Ir-*o*-($\eta^6$-HS–$C_6H_4$-SH)][$BF_4$]$_2$ (8):** $HBF_4{\cdot}Et_2O$ (1 mL) was added to a solution of [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (50 mg, 0.1 mmol) in $CH_3CN$ (3 mL), causing the purple solution to rapidly turn red. The reaction was left to proceed for 10 min. Addition of $Et_2O$ (50 mL) provided a red oil-like substance (61 mg, 0.095 mmol). Yield: 95%. This compound is unstable, hence elemental analysis could not be performed. $^1H$ NMR (300 MHz, $CD_3CN$): $\delta$ = 2.10 (s, 15 H, Cp*), 6.83 (dd, 2 H, diene, $^3J_{H,H}$ = 7.37, $^4J_{H,H}$ = 1.77 Hz), 7.70 (dd, 2 H, diene, $^3J_{H,H}$ = 7.37, $^4J_{H,H}$ = 1.77 Hz) ppm. IR (KBr disk): $\tilde{\nu}$(B–F) = 1083 (s, br) cm$^{-1}$.

**Synthesis of [Cp*Ir-*p*-($\eta^6$-HS–$C_6H_4$-SH)][$BF_4$]$_2$ (9):** This compound was prepared in a similar way to that of **8**. Complex **9** was obtained as a yellow microcrystalline substance. Yield: 93%. This compound is unstable, hence elemental analysis could not be performed. $^1H$ NMR (300 MHz, $CD_3CN$): $\delta$ = 1.98 (s, 15 H, Cp*), 7.15 (s, 4 H, diene) ppm. IR (KBr disk): $\tilde{\nu}$(B–F) = 1083 (s, br) cm$^{-1}$.

**Synthesis of [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}][OTf]$_2$ (10):** A solution of AgOTf (52 mg, 0.20 mmol) in $CH_3CN$ (10 mL) was added to a suspension of [(bpy)$PtCl_2$][19] (42 mg, 0.10 mmol) in $CH_3CN$ (10 mL) and the mixture was stirred for 4 h at room temperature and then filtered through Celite. [Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)] (53 mg, 0.11 mmol) in $CH_3CN$ (10 mL) was added to the pale yellow filtrate solution (60 mL); after one hour at room temperature, the solvent was removed under vacuum and the orange powder obtained was washed twice with acetone (5 mL) and $CH_2Cl_2$ (5 mL). Complex **10** was obtained as an orange microcrystalline powder (101 mg, 0.09 mmol). Yield: 91%. $C_{28}H_{27}F_6IrN_2O_6PtS_4{\cdot}CH_2Cl_2$ (1200.95 g mol$^{-1}$): calcd. C 28.98, H 2.43, N 2.33, S 10.67; found C 28.96, H 2.33, N 2.45, S 11.32. $^1H$ NMR (300 MHz, $CD_3CN$): $\delta$ = 1.98 (s, 15 H, Cp*), 6.68 (dd, 2 H, aromatic, $^3J_{H,H}$ = 4.63, $^4J_{H,H}$ = 2.41 Hz), 7.07 (dd, 2 H, aromatic, $^3J_{H,H}$ = 4.63, $^4J_{H,H}$ = 2.41 Hz), 7.74 (ddd, 2 H, bpy, $^3J_{H,H}$ = 7.42 Hz, $^3J_{H,H}$ = 5.65, $^4J_{H,H}$ = 1.69 Hz), 8.34 (m, 2 H, bpy), 8.39 (m, 2 H, bpy), 8.84 (dd, bpy, 2 H, $^3J_{H,H}$ = 5.73, $^4J_{H,H}$ = 1.53, $^5J_{H,H}$ = 0.69 Hz) ppm. IR (KBr disk): $\tilde{\nu}$($CF_3SO_3^-$) = 1031; 1260 cm$^{-1}$.

**X-ray Molecular Structures of 7 and 10:** Suitable crystals of [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) or [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}][OTf]$_2$ (**10**) were obtained using slow diffusion techniques from $CH_2Cl_2$/diethyl ether solution for **7** and from $CH_3NO_2$/diethyl ether for **10**. The selected crystal of the very moisture-sensitive **7** or **10** was rapidly selected, mounted onto a glass fiber, and transferred in a cold nitrogen gas stream. Orange crystals of **7**: $C_{48}H_{57}Ir_3S_6{\cdot}1/2CH_2Cl_2$, monoclinic, $P2_1/m$, $a$ = 14.5450(5), $b$ = 9.2730(11), $c$ = 20.6380(3) Å, $\beta$ = 94.271(4)°, $V$ = 2775.8(5) Å$^3$, $Z$ = 2, $T$ = 250(2) K, $\mu$ = 7.476 mm$^{-1}$, 33263 reflections measured, 8342 independent ($R_{int}$ = 0.0413), 6364 observed [$I \geq 2\sigma(I)$], 321 parameters, final $R$ indices $R_1$ [$I \geq 2\sigma(I)$] = 0.0335 and $wR_2$ (all data) = 0.0956, gof on $F^2$ = 1.027, max./min. residual electron density = 1.31/–1.34 e Å$^{-3}$. Red crystals (**10**): $(C_{26}H_{27}IrN_2PtS_2)_2(CF_3O_3S)_4{\cdot}CH_3NO_2$, monoclinic, $P2_1/c$, $a$ = 8.793(3), $b$ = 34.296(9), $c$ = 25.208(6) Å, $\beta$ = 91.621(9)°, $V$ = 7599(4) Å$^3$, $Z$ = 4, $T$ = 200(2) K, $\mu$ = 7.471 mm$^{-1}$, 65719 reflections measured, 22256 independent ($R_{int}$ = 0.0615), 9023 observed [$I > 2\sigma(I)$], 848 parameters, final $R$ indices $R_1$ [$I > 2\sigma(I)$] = 0.0832 and $wR_2$ (all data) = 0.1928, gof on $F^2$ = 1.033, max./min. residual electron density = 3.33/–3.29 e Å$^{-3}$. Intensity data were collected with a Bruker-Nonius Kappa-CCD with graphite-mono-

# Tris(dibenzo[*a*,*d*]cycloheptenyl)phosphane: A Bulky Monodentate or Tetrapodal Ligand

**Urs Fischbach,[a] Heinz Rüegger,[a] and Hansjörg Grützmacher*[a]**

**Keywords:** Alkene ligands / Gold / Iridium / Palladium / Phosphane ligands / Rhodium / Silver / Tetradentate ligands / Solid-state NMR spectroscopy

The tetradendate phosphane tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)phosphane ($trop_3P$, **1**) was synthesized from tris(trimethylsilyl)phosphane and 5-chloro-5*H*-dibenzo[*a*,*d*]cycloheptene. Sulfurization of **1** with elemental sulfur led to $trop_3P$=S. Complexes of **1** with $Ag^I$, $Au^I$, $Rh^I$, $Ir^I$, and $Pd^{II}$ were prepared. The structures of $trop_3P$ (**1**), $trop_3P$=S (**2**), [AgCl($trop_3P$)] (**3**), [Au($trop_3P$)(MeCN)]$PF_6$ (**5**), [RhCl($trop_3P$)] (**6**) and [Pd($trop_3P$)($H_2O$)]$(OTf)_2$ (**9**) were determined by X-ray diffraction studies. In the coinage metal complexes, **1** serves as monodentate extremely bulky $\kappa^1$-phosphane ligand (cone angle ca. 250°). In the $Rh^I$, $Ir^I$, and $Pd^{II}$ complexes, **1** acts as tetradendate ligand. CP MAS NMR spectroscopy shows that the span of the chemical shift tensor increases in **7**, **6**, and **9** in this order ($\Omega$ = 310 ppm, 410 ppm, 465 ppm) and contains two strongly deshielded components, which are responsible for the unusual high frequency isotropic shift of the $^{31}P$ resonances. This property correlates inversely with the metal to olefin backbonding (M→C=$C_{trop}$) and $\delta(^{31}P)$ decreases with increasing M→C=$C_{trop}$ in the order **9** ($\delta$ = 260 ppm) > **7** ($\delta$ = 196 ppm) > **6** ($\delta$ = 135 ppm) > **3** ($\delta$ = –30.9 ppm).

## Introduction

Both phosphanes and alkenes look back on a history of more than one and a half centuries as ligands in metal coordination chemistry.[1] Metal complexes with these ligands have undergone constant development ever since their discovery. The combination of both types of binding sites in one molecule generates bi- or polydentate ligands and was achieved in the group of Nyholm in the mid-sixties with the synthesis of the first chelating phosphane–alkene ligands.[2] The most prominent feature of these chelating ligands is their hemilabile character: while the phosphane moiety usually binds quite strongly to a metal center, the olefin is less tightly attached and thus often prone to dissociation. Many different potentially chelating phosphane–olefin ligands have been prepared in the past forty years. Scheme 1 shows selected examples.

Acyclic alkenylphosphanes are the most obvious type of chelating phosphane–alkene ligands and mono, di- and trialkenylphosphanes (**I**, **II** and **III**) have been synthesized and characterized some decades ago.[3] Their coordination behaviour towards $Mo^0$,[4] $W^0$,[5] $Pd^{II}$,[6] $Pt^{II}$[7] and $Rh^I$[8] was investigated. Depending on the size of the resulting chelate ring, alkenylphosphanes act either as monodentate phosphanes or as multidentate chelating ligands, specifically with short chains ($n < 2$) the alkenyl group remains uncoordinated. Chemical transformations of the alkenyl group (hydrogenation, nucleophilic attack) were observed. Dialkenylphosphanes **II** often bind with one alkenyl group only to the metal center, i.e. they do not serve as tripodal ligands in the electronic ground state structures of the complexes. A large number of *ortho*-alkenylphenylphosphanes (**IV**, **V**) have been prepared[9] and $V^0$,[10] $Cr^0$, $Mo^0$ and $W^0$,[11] $Mn^I$ and $Re^I$,[12] $Fe^0$ and $Ru^0$,[13] $Rh^I$,[14] $Pd^{II}$,[15] and $Pt^{II}$,[16] $Cu^I$ and $Ag^I$[17] complexes were prepared and structurally characterized. Bidentate coordination of the ligands **IV** was established in all complexes. The ligands were prone to addition and isomerization reactions, e.g. hydrogenation or migration of the double bond.

Difurylphosphanes **VI** were applied in the cobalt-catalyzed homologation of methanol and conversions of up to 70% and ethanol selectivities of up to 50% were achieved.[18] The mixed anhydrides of diphenylphosphinous acid and acrylic acids **VII** may coordinate via the acrylic double bond (observed with $Rh^I$[19]) or via the oxygen atom of the carbonyl group (observed with $Ru^{II}$[20]). Binding of the double bond in $Rh^I$ complexes is weak and degradation occurred.[21] A ligand of type **VII** was found to be active in the $Rh^I$-catalyzed hydrogenation of acrylic acids.[22] The bidentate phosphane–alkene ligand **VIII** obtained from the condensation of chlorodiphenylphosphane with diallylamine was reported recently. The ligand coordinates to $W^0$, $Ru^{II}$, $Rh^I$, $Pd^{II}$ and $Pt^{II}$ and both, $\kappa^1$:$\eta^2$- and $\kappa^1$-coordination, were observed.[23]

For $Rh^I$ complexes with type **I**, **III**, **IV** and **V** ligands, trigonal bipyramidal (TBP) structures were observed.[24]

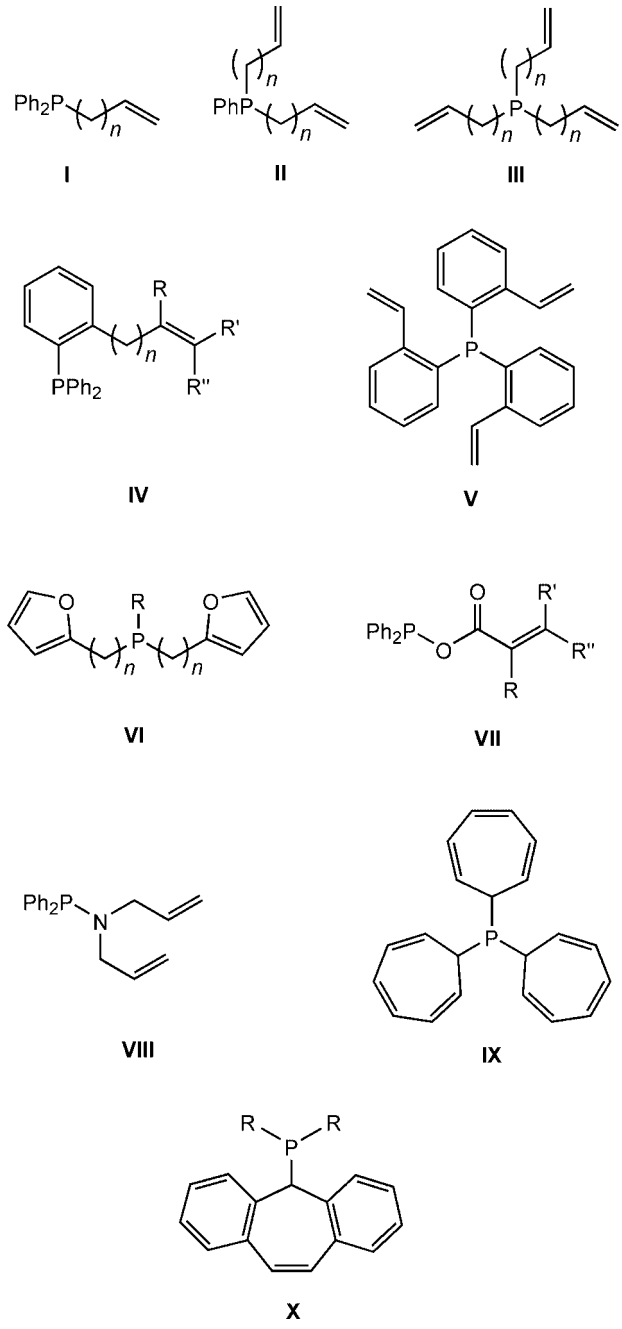


Scheme 1. Mono-, di- and triolefin phosphanes.

This form should be especially favoured by tetradentate tris(alkenyl)phosphanes like **III** and **V**. While X-ray diffraction studies show that $Rh^{I}$ complexes have the P-donor in the axial and the three C=C donors in the equatorial plane, NMR spectroscopic studies revealed that the latter are fluxional on the NMR time scale and likely dissociate.[25]

The phosphane $cht_3P$ **IX** (cht = cycloheptatrienyl) was synthesized by Herberhold and co-workers in 1994.[26] Due to the boat conformation of the seven-membered cht rings, this phosphane is preorganized for binding to a transition metal center by the P-donor and the opposite C=C bonds and stabilization of TBP structures can be expected. However, rotation around the P–C bonds, facile inversion of the boat conformation of the cht ring, and additional coordination of metals through the C=C bonds adjacent to the P-atom make the ligand fluxional and complicate its coordination chemistry. Indeed a variety of coordination modes are observed in complexes which do not show a special preference for TBP structures, such as $V^{0}$[27] ($\kappa^1$), $Cr^0$, $Mo^0$, $W^0$,[28] $Mn^{I}$,[29] $Fe^0$ and $Ru^{0}$[30] complexes ($\kappa^1$-, $\kappa^1$:$\eta^2$- and $\kappa^1$:$\eta^4$-coordination). With $Rh^{I}$ and $Ir^{I}$ the expected trigonal bipyramidal complexes were isolated and these are quite stable, indeed, and it needed other polydentate ligands to displace $cht_3P$ **IX**.[31] A bidentate coordination mode is observed for **IX** in fluxional $Pd^{II}$ and $Pt^{II}$ dichloride complexes,[32] but the abstraction of one chloride leads to cationic $[MX(cht_3P)]^+$ complexes with TBP structures.[33] In complexes with $Cu^{I}$ and $Ag^{I}$, ligand **IX** binds via the P-atom and small but detectable interactions with the opposite C=C bonds of the cht rings were discussed on the basis of solid-state structure data (distances of the metal center to the centroids of the coordinated C=C double bonds in the range of 2.6–3.0 Å were observed[34,35]).

In parallel to the work of Herberhold et al., we started about 10 years ago the investigation of (5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)phosphanes **X** as ligands, which we named tropp (from dibenzo**trop**ylidenyl**p**hosphane). The trivial name dibenzotropylidenyl (= trop) will be used throughout this paper instead of 5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl.[36] The annelated benzo groups make these compounds especially rigid with the phosphanyl substituent in 5-position residing in the energetically preferred *endo*-conformation. A concave binding site results, which is perfectly pre-organized for transition metal binding. A large number of structurally different ligands based on the trop platform[37] and a variety of complexes with $Rh^{I}$ and $Ir^{I}$,[38] $Pd^{II}$, $Pd^0$, $Pt^{II}$, $Pt^0$,[37a–37c,37g] $Cu^{I}$, $Ag^{I}$ and $Au^{I}$[39] as metal centers were prepared. Noteworthy is the ability of the tropp-type ligands to stabilize complexes with transition metal centers in formally low oxidation states, that is the first stable paramagnetic $Rh^0$ and $Ir^0$ complexes could be isolated.[40]

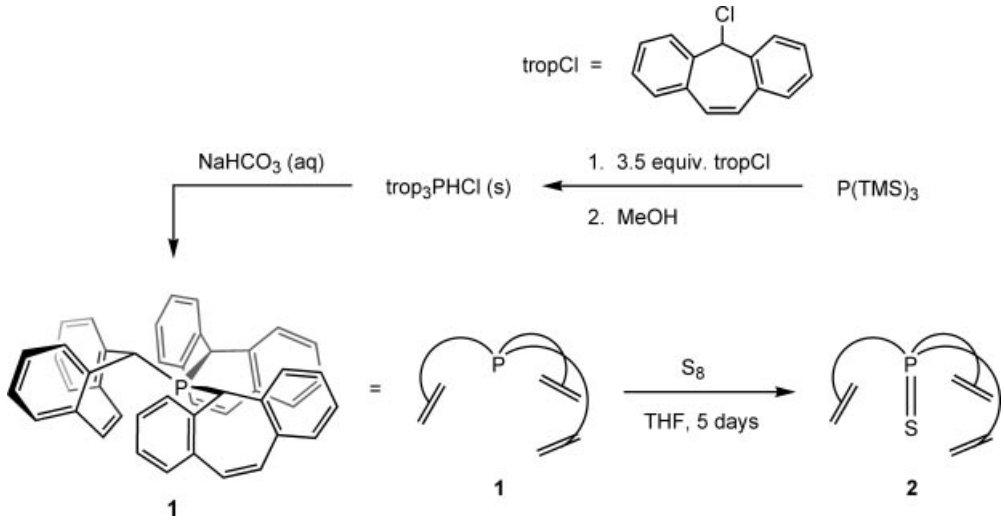
In the continuation of our work, we report here the synthesis of the ligand tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)-phosphane ($trop_3P$, **1**) and the synthesis of various transition metal complexes. The coinage metals only exert weak (if any) interactions with the olefinic double bonds, while with $Rh^{I}$, $Ir^{I}$ and $Pd^{II}$ trigonal bipyramidal complexes are obtained in which the $C{=}C_{trop}$ groups are tightly bound and $trop_3P$ acts as tetrapodal ligand.

## Results and Discussion

### Synthesis and Structural Characterization of $trop_3P$ (1)

The phosphane $trop_3P$ was obtained by treating tris(trimethylsilyl)phosphane with 3.5 equiv. of tropCl. The product precipitated from the solution as its hydrochloride salt after the addition of methanol to the reaction mixture and was easily isolated. Further work-up under standard conditions led to the final product (Scheme 2). $Trop_3P$ can be stored without special precautions on air for at least two

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2. Synthesis of $trop_3P$ (**1**) and $trop_3P{=}S$ (**2**).

years and in substance is not oxygenated by 1 atm of $O_2$ at room temperature. The structure of **1** was determined by X-ray diffraction. Figure 1 and Figure 2 show the molecule from two different angles; selected bond lengths and angles are given in the Figure caption, pertinent crystal data are given in Table 4. The threefold symmetry axis of the cubic unit cell coincides with the $C_3$ molcular symmetry axis. There are no mirror planes in the crystal due to the slight twist of the trop moieties and the space group is chiral ($P\bar{4}3n$), that is the crystals exist in two enantiomorphic forms. The prominent structural feature of **1** is the *endo-endo-endo* conformation of the $trop_2P$ substituents at each individual seven-membered ring, which all have a boat conformation. NMR spectra indicate that this highly symmetric structure is also present in solution. Hence, **1** is a highly pre-organized rigid ligand for tetradentate binding in TBP structures with a typical sum of bond angles at the P-atom, $\Sigma°(P) = 295.5°$.

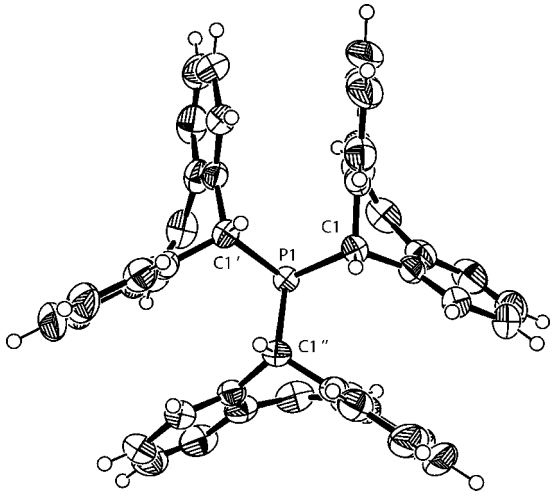


Figure 1. ORTEP plot of $trop_3P$ (**1**) (thermal ellipsoids at 50% probability). View along the threefold symmetry axis of both the molecule and the crystal. Sum of bond angles at P1: 295.5°.

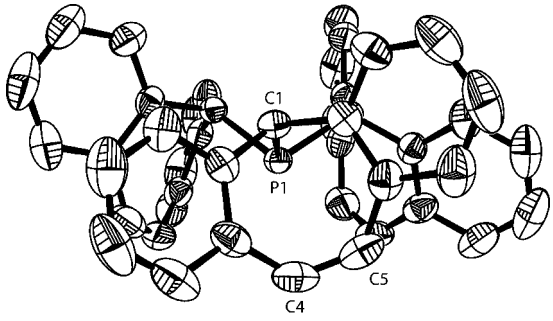

Figure 2. ORTEP plot of $trop_3P$ (**1**) (thermal ellipsoids at 50% probability, hydrogen atoms omitted for clarity). View perpendicular to the threefold symmetry axis. Selected bond lengths [Å] and angles [°]: P1–C1: 1.9015(22); C4–C5: 1.330(4); C1–P1–C1′: 98.50(9). Torsion angles [°]: C1′–P1–C1–C7: 45.14(21); C31–P1–C1–C2: 89.98(20).

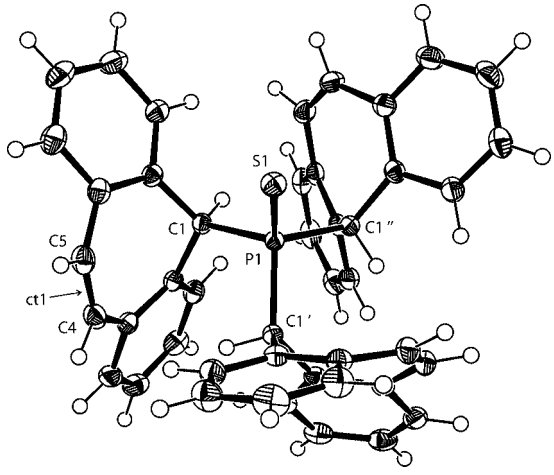

Figure 3. ORTEP plot of $trop_3P{=}S$ (**2**) (thermal ellipsoids at 50% probability, solvent molecules omitted for clarity). Selected bond lenghts [Å] and angles [°]: P1–S1: 1.9409(9); P1–C1: 1.9181(14); mean C=C (double bond): 1.333(2); S1–P1–C1: 112.42(5); C1–P1–C1′: 106.37(5). Sum of bond angles of the three carbon substituents at P1: 319°. Torsion angle $\varphi$(S1–P1–C1–ct1): 73.2°.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

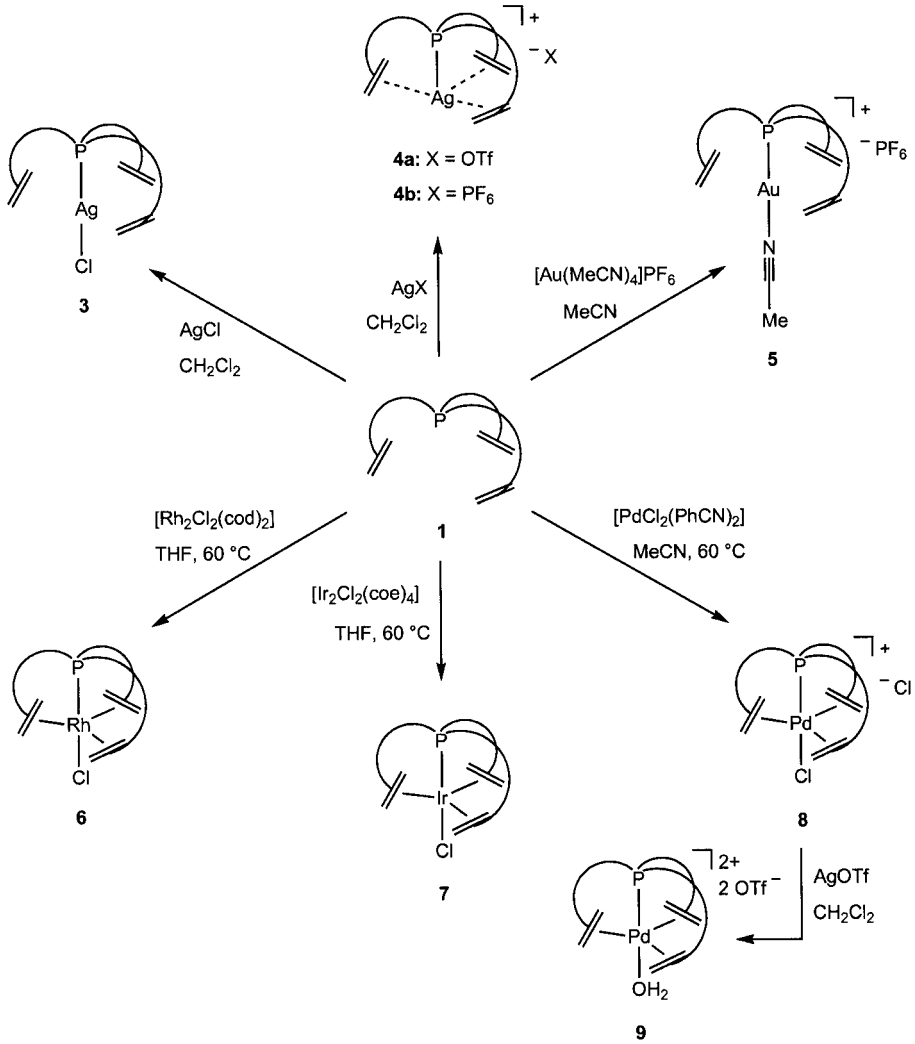
In order to test whether the phosphorus atom can be involved in a chemical reaction, **1** was treated with $S_8$ (Scheme 2). After stirring in THF at 60 °C for about five days, $trop_3P{=}S$ (**2**) precipitated and could be isolated (higher reaction temperatures led to decomposition). A plot of the structure obtained by X-ray diffraction is shown in Figure 3 (selected bond lengths and angles are given in the Figure caption, pertinent crystal data are given in Table 4). In contrast to **1**, the trop substituents in **2** are considerably more twisted. This is indicated by the torsion angle $\varphi$ = X–P1–C1–ct1 = 73.2° in **2** vs. $\varphi$ = 23.0° in **1** where X stands for the phosphorus lone pair or a substituent and ct for the centroid of the $C{=}C_{trop}$ unit (ideally $C_{3v}$ with $\varphi$ = 0°, that is the $C{=}C_{trop}$ group is orthogonal to the P–X vector). As expected, the sum of the C–P–C angles at the phosphorus atom increases to 319° upon sulfurization. Noteworthy is the slight lengthening of the P–C bonds in **2** [1.918(1) Å] with respect to **1** [1.902(2) Å] while usually a shortening is observed upon increasing the formal oxidation state at the phosphorus center to $P^V$.

### Metal Complexes of $trop_3P$

The coordination chemistry of $trop_3P$ (**1**) was investigated through the synthesis of complexes containing the $d^{10}$ noble metal ions, $Ag^I$ and $Au^I$, and the $d^8$ valence electron configured metal ions, $Rh^I$, $Ir^I$ and $Pd^{II}$. The first two metal ions are expected to bind weakly, the latter strongly to the $C{=}C_{trop}$ units. The coordination to the $C{=}C_{trop}$ bonds can be evaluated by NMR spectroscopic data and inspection of the molecular structures. Low-frequency $^{13}C$ NMR resonances for the significantly shielded $C{=}C_{trop}$ carbon nuclei and torsion angles $\varphi$ close to 0° are expected when the olefinic units are tightly bound.

### Silver and Gold

Despite its low solubility, AgCl is dissolved completely when stirred in a $CH_2Cl_2$ solution of phosphane **1** at room temperature. After about 20 h [AgCl($trop_3P$)] (**3**) is quantitatively obtained (Scheme 3). The silver salts AgOTf and



Scheme 3. Synthesis of $trop_3P$ transition metal complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[Ag(MeCN)_4]PF_6$ reacted rapidly with **1** to give the complexes $[Ag(trop_3P)]OTf$ (**4a**) and $[Ag(trop_3P)]PF_6$ (**4b**), respectively. Crystals of the compounds **3**, **4a** and **4b** were grown and investigated by X-ray diffraction. We were unable to refine the data sets of compounds **4a**, **4b** likely because of severe disorder of the $OTf^-$ and $PF_6^-$ anions. The structure of **3** was solved and a plot of the structure is shown in Figure 4 (see the Figure caption for selected bond lengths and angles and Table 4 for pertinent crystal data). As expected, P1 and Cl1 coordinate to the Ag center in an almost linear fashion (P1–Ag1–Cl1: 173.1°). The structural data give no indications for coordination of the $C{=}C_{trop}$ bonds. The mean distance between the Ag atom and the double bond centroids, ct, is approximately 3.2 Å, the $C{=}C_{trop}$ bonds are not elongated in **3** [$C{=}C_{trop}$ 1.328(1) Å] with respect to the free phosphane **1** [$C{=}C_{trop}$ 1.330(4) Å], and the torsion angle $\varphi$ (Ag1–P1–C1–ct1) = 27(7)° remains large.

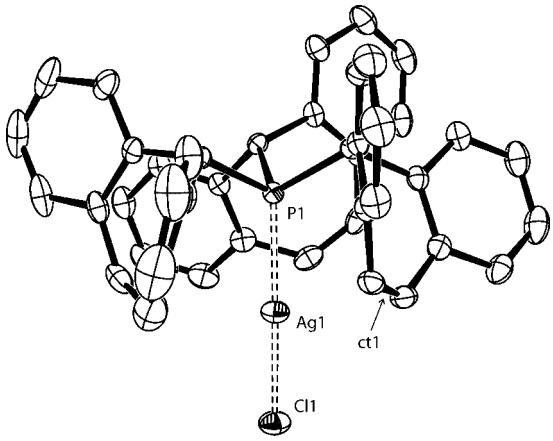


Figure 4. ORTEP plot of $[AgCl(trop_3P)]$ (**3**) (thermal ellipsoids at 30% probability, hydrogen atoms and solvent molecules omitted for clarity, only one of two independent molecules shown). Selected bond lenghts [Å] and angles [°]: Ag1–P1: 2.3677(21); Ag1–Cl1: 2.3528(23); mean Ag1–ct: 3.16(12); mean C=C (double bond): 1.328(12); P1–Ag1–Cl1: 173.10(3). Sum of bond angles of the three carbon substituents at P1: 305°. Mean torsion angle $\varphi$(Ag1–P1–C1–ct1): 27(7)°.

These conclusions are supported by NMR spectroscopy. The element silver consists of two NMR-active isotopes, $^{107}Ag$ (51.84%) and $^{109}Ag$ (48.16%) with $I$ = 1/2. Due to weak coordination and rapid exchange processes, $^{31}P$ NMR spectra of silver phosphane complexes often display a single broad resonance signal at room temperature, which sometimes can be resolved at low temperatures. The silver complex **3** is persistent even at room temperature and the two couplings $^1J(^{107}Ag,^{31}P)$ and $^1J(^{109}Ag,^{31}P)$ are clearly resolved in the $^{31}P$ NMR spectrum (Figure 5).

A $^1H,^{109}Ag$ HMQC spectrum was measured in order to search for indications of Ag–($CH{=}CH_{trop}$) interactions (Figure 6). The sizeable Ag–H coupling of 9.0 Hz to the benzylic protons (easily observed in the standard $^1H$ NMR spectrum) gives rise to strong cross peaks in the two-dimensional spectrum. None of the other protons couple strongly enough to generate cross peaks that are detectable above

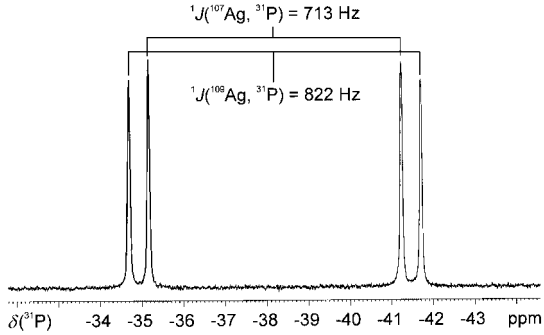

Figure 5. $^{31}P$ NMR spectrum of $[Ag(trop_3P)]OTf$ (**4a**) at room temperature. Coupling to the two almost equally abundant silver isotopes $^{107}Ag$ and $^{109}Ag$ is clearly resolved.

the noise level. In a second experiment, the Ag–H coupling constants were measured by means of a $^{31}P$, $^1H$ HMQC spectrum (Figure 7). Additional nuclei besides $^{31}P$ and $^1H$ in the spin system will cause a doubling of the resonances in the 2D spectrum. Furthermore, a diagonal displacement of the cross peaks will be observed, which corresponds to the coupling with the additional nuclei. This is clearly visible for the benzylic hydrogen atoms, which do couple with the $^{107}Ag$ and $^{109}Ag$ nuclei and give eight diagonally displaced cross peaks. Note that from this spectrum individual $^3J(^{109}Ag,^1H)$ and $^3J(^{107}Ag,^1H)$ coupling constants can be obtained as a consequence of the resolution in the $^{31}P$ domain. Furthermore, the signs of $^3J_{Ag,H}$ and $^1J_{Ag,P}$ are the same. For the olefinic protons, only four cross peaks can be

recorded, but there is in fact a tiny shift of –0.5 Hz in the $^1$H NMR dimension. To the best of our knowledge this is the second coupling constant between a silver nucleus and an olefinic proton that could be measured.[39] Its small magnitude indicates a very weak and likely dynamic interaction between the C=$C_{trop}$ double bonds and the Ag atom. We note that although the unlike signs of $^2J$(Ag,$H_{olefinic}$) and $^3J$(Ag,$H_{benzylic}$) are in agreement with such an explanation, we cannot exclude a coupling mechanism involving just the olefinic proton and extended lone pairs on silver, similar to the ones often encountered in fluorine chemistry. In any case, our data give no indications of metal-to-olefin, Ag→C=$C_{trop}$, π-back-donation and if there were a silver–olefin interaction, this would consists in an olefin to metal, C=$C_{trop}$→Ag, σ-donation within the Dewar–Chatt–Duncanson terminology. This view is fully supported by inspection of the $^{13}$C NMR spectroscopic data of the C=$C_{trop}$ carbon nuclei (see Table 2 and the discussion below).

We were especially interested in the synthesis of a monophosphane gold complex, possibly with an additional labile ligand. Therefore we reacted $trop_3P$ (**1**) with [$Au^I(MeCN)_4$]-$PF_6$, which was obtained by electrolysis of a gold wire in an acetonitrile solution containing the $PF_6^-$ anion.[41,42] Upon mixing a suspension of **1** in MeCN with a MeCN solution of [$Au^I(MeCN)_4$]$PF_6$, immediate dissolution of **1** was observed. The product [Au($trop_3P$)(MeCN)]$PF_6$ (**5**) was subsequently precipitated by adding toluene (Scheme 3). The structure of **5** is displayed in Figure 8 (see the Figure caption for selected bond lengths and angles and Table 4 for pertinent crystal data obtained by X-ray diffraction). The gold center is coordinated by the phosphorus atom of the $trop_3P$ ligand and a nitrogen atom of the MeCN ligand in a linear coordination sphere (P1–Au1–N1 176.3°). The

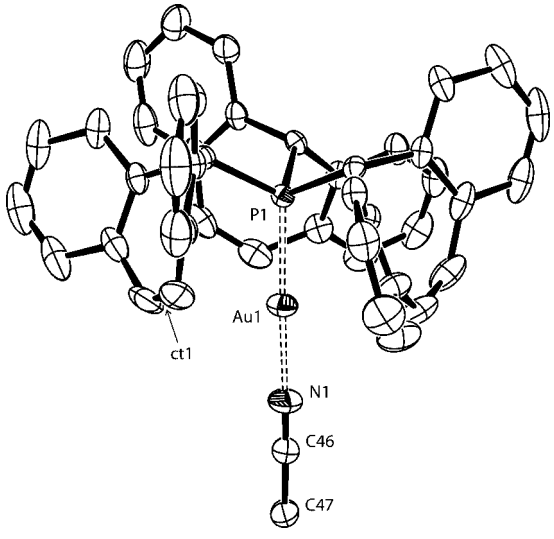

Figure 8. ORTEP plot of [Au($trop_3P$)(MeCN)]$PF_6$ (**5**) (thermal ellipsoids at 30% probability, hydrogen atoms and counteranion omitted for clarity). Selected bond lenghts [Å] and angles [°]: Au1–P1: 2.2343(9); Au1–N1: 2.043(4); mean Au1–ct: 3.14(6); mean C=C (double bond): 1.33(3); P1–Au1–N1: 176.30(13); Au1–N1–C46: 175.5(5). Sum of bond angles of the three carbon substituents at P1: 309°. Mean torsion angle φ(Au1–P1–C1–ct1): 24(7)°.

Au1–P1 and the Au1–N1 distances are in good accordance with reported bond lengths.[43] The long distances between the gold atom and surrounding C=$C_{trop}$ groups (average 3.139 Å) and the twist of the C=$C_{trop}$ units (average φ = 24.4°) exclude any significant interaction. This is also corroborated by the $^{13}$C NMR shifts of the C=$C_{trop}$ units, which again show high frequency shifts upon coordination (see Table 2 below).

Thus, in $d^{10}$ valence electron configured silver and gold complexes, **1** behaves as extremely bulky monodentate phosphane ligand (cone angle approx. 250°)[44] and the resulting complexes are kinetically inert.

### Rhodium, Iridium, and Palladium

When [$Rh_2(\mu\text{-}Cl)_2(cod)_2$] was treated with **1** in THF at 60 °C, quantitative conversion to the desired product [RhCl($trop_3P$)] (**6**) was observed after 30 h (Scheme 3). Complex **6** precipitated directly from the reaction solution and was isolated as yellow powder by simple filtration. Concentrations higher than 0.03 M should be avoided, because partial decomposition of the ligand with formation of bi(dibenzo[*a*,*d*]cyclohepten-5-yl), $trop_2$, was observed. The structure of **6** was determined by X-ray diffraction. Figure 9 shows a plot, selected bond lengths and angles are listed in the Figure caption, and in Table 4 pertinent crystal data are given. Complex **6** has an almost perfect trigonal bipyramidal structure with the P- and Cl-atoms in the apical and the three C=$C_{trop}$ units in the equatorial positions; the P1–Rh1–Cl1 angle is 179° and the ct–Rh–ct angles vary between 119.2° and 121.4°. Clearly, the C=$C_{trop}$ double bonds are coordinated: The averaged Rh–ct distances are short (2.15 Å), the C=C bonds are elongated to 1.40 Å, and the torsion angles φ are smaller than 10°. This leads to an almost perfect parallel stacking of the benzo rings of neighbouring trop groups at distances of about 3.2 Å. The structural data of **6** very closely match the ones reported for the complex [RhCl($cht_3P$)] by Herberhold et al.,[45] only the Rh–C distances are marginally shorter by about 1%. Table 1 gives a compilation of selected structure parameters for both compounds.

The iridium complex [IrCl($trop_3P$)] (**7**) was prepared in about 70% yield when **1** was treated with [$Ir_2(\mu\text{-}Cl_2)(coe)_4$] for 3 d at 60 °C in THF. The reaction is somewhat more sluggish than in the case of the synthesis of **6** but after removal of impurities, **7** is obtained as bright white powder (Scheme 3). Crystals of **7** showed merohedral twinning and we were unable to refine the structure satisfactorily. However, the gross structural features were determined and show that **7** has as expected, a structure analogous to the rhodium complex **6**.

[$PdCl_2(PhCN)_2$] reacted with **1** in $CH_2Cl_2$ at room temperature to form an $\eta^2$ complex, likely [$PdCl_2$-($trop_3P$)(PhCN)] with only one double bond of one trop substituent coordinated, while the phosphorus center and the other two C=$C_{trop}$ bonds remain uncoordinated, which is indicated by the rather low-frequency $^{31}$P NMR reso-

| | 2.254(3) Å | 2.287(2) Å |
| P–Rh–Cl | 179.06(3)° | 178.9(1)° |

[a] Data from ref.[45]. [b] Standard deviation.

nance at $\delta$ = –48.1 ppm. Performing the reaction in THF or acetonitrile as solvent and heating the reaction mixture to 60 °C for 24 h caused vanishing of the initial yellow color and a red solid started to precipitate. This compound showed a $^{31}$P NMR shift at $\delta$ = 263.8 ppm and was identified as [Pd(trop$_3$P)Cl]Cl (**8**) (Scheme 3). Exchange of the chlorides by triflate anions using AgOTf was a straightforward reaction and gave an intense ruby red solution ($\lambda_{max}$ = 497 nm). From this solution, very dark crystals of the composition [Pd(trop$_3$P)(H$_2$O)](OTf)$_2$ (**9**) were obtained which were subjected to a X-ray diffraction study. The dication [Pd(trop$_3$P)(H$_2$O)]$^{2+}$ has a TBP structure with the P-atom of the trop$_3$P ligand and an oxygen atom of a water molecule in the axial positions (Figure 10, see the Figure caption for selected bond lengths and angles and Table 4 for pertinent crystal data). The three C=C$_{trop}$ units are bound in the equatorial positions at about 2.3 Å. This distance is significantly longer (ca. 0.13 Å) than the one in the Rh$^{I}$ complex **6**. The less pronounced Pd→C=C$_{trop}$ π-backbonding also leads to shorter C=C$_{trop}$ bonds (average 1.383 Å) when compared to the Rh$^{I}$ complex **6**. The averaged torsion angle $\varphi$ is again smaller than 10°. The Pd1–O1 bond length [2.142(4) Å] is very similar to Pd–O distances found in structures of tetracoordinate planar Pd$^{II}$ aqua complexes, while **9** seems to be the first structurally characterized pentacoordinate Pd$^{II}$ aqua complex.

## NMR Spectroscopy

Selected $^{31}$P, $^{1}$H, and $^{13}$C solution NMR spectroscopic data of trop$_3$P (**1**), [AgCl(trop$_3$P)] (**3**), [Au(trop$_3$P)(MeCN)]-PF$_6$ (**5**), [RhCl(trop$_3$P)] (**6**), [IrCl(trop$_3$P)] (**7**), and [Pd-(trop$_3$P)(H$_2$O)](OTf)$_2$ (**9**) are listed in entries 1–6 in Table 2.

For comparison we also list the corresponding data for analogous cht$_3$P complexes (entries 7–12). The proton and $^{13}$C NMR spectroscopic data are remarkably similar in both series. The proton in β-position (denoted as H$_{benz}$) is little influenced by metal coordination to the P-atom as long as the complex remains neutral (especially in the rhodium and iridium complexes, **6** and **7**, respectively). Metal charge has an influence, that is an increasingly positive charge of the complex shifts the H$_{benz}$ resonance to higher frequencies (by 1.63 ppm in the dication **9**, by 0.76 ppm in the mono-cation **5**). Metal to C=C$_{trop}$ π-backbonding, M→C=C$_{trop}$, is reflected in the chemical shifts of the $^{13}$C$_{olef}$ and $^{13}$C$_{benz}$ and to a certain extent in the $^{1}$H$_{olef}$ nuclei. Increasing π-backbonding causes a low-frequency shift (shielding) of the $^{13}$C$_{olef}$ resonances of the C=C$_{trop}$ units. The data clearly show that M→C=C$_{trop}$ backbonding in the silver and gold complexes is negligible as already stated above, the coordination shifts $\Delta\delta$ = ($\delta_{complex}$ – $\delta_{free\ ligand}$) are even positive (+7 and +5 ppm for **3** and **5**, respectively) while negative $\Delta\delta$ are expected when π-backdonation is significant. This is the case in the Pd$^{II}$ complex **9** ($\Delta\delta$ = –15.4), Rh$^{I}$ complex **6** ($\Delta\delta$ = –45.6), and Ir$^{I}$ complex **7** ($\Delta\delta$ = –59.4) and backbonding increases in this order. The increasing slight shift to lower frequency of the $^{13}$C$_{benz}$ resonance in the same order is a consequence of the increasing bending of the central seven-membered ring upon shortening of the metal C=C$_{trop}$ distances. This effect causes a slight decrease of the sum of the two P–C$_{benz}$–C and the C–C$_{benz}$–C angle (336.0° in the free phosphane **1**; 334° in **9**, and 331° in **6**). The $^{1}$H$_{olef}$ resonances are also increasingly shifted to low frequency (by 0.3 ppm in **6**, 0.9 ppm in **7**) upon increasing the metal to olefin backbonding, but this effect is counterbalanced by the formal charge at the metal center and in

[a] Table includes only chemical shift data; multiplicities and coupling constants are omitted for simplicity. [b] Data from ref.[35]. [c] Data from ref.[33].

the $Pd^{II}$ complex **9** $H_{olef}$ is even deshielded by 1.1 ppm. The same trends are observed in the $cht_3P$ complexes (see entries 7–12).

A remarkable feature of the $M(trop_3P)$ and $M(cht_3P)$ complexes with $M{\rightarrow}C{=}C_{trop}$ backbonding are the unusual high frequency shifts of the $^{31}P$ resonances. Especially in the $Pd^{II}$ complexes, the $^{31}P$ coordination chemical shifts are almost 300 ppm for **9** and approx. 450 ppm for $[Pd(cht_3P)Cl]^+$, which shows likely the least shielded $^{31}P$ nucleus for a seemingly "ordinary" phosphane complex.[34] Interestingly, this unusual shift to high frequencies becomes smaller when the $M{\rightarrow}C{=}C_{trop}$ backbonding increases, that is in the order Pd > Rh > Ir the $^{31}P$ resonance frequencies decrease. On the contrary, for the $d^{10}$-metal complexes, especially for the silver complexes, small coordination shifts of the $^{31}P$ resonance are observed.

In order to gain some insight into these unusual $^{31}P$ NMR shifts, we recorded CP MAS spectra of **1**, **3**, **6**, **7**, and **9**. The top of Figure 11 shows the spectra obtained for **1** and **3** at a spinning frequency of 8 and 7 kHz, respectively. On the bottom of Figure 11, the spectra on static powder samples are displayed. A single sharp resonance with very small side bands is observed for $trop_3P$ (**1**). The spectrum obtained with a non-rotating sample is indicative for an axial chemical shift tensor in complete accordance with the high symmetry determined in the X-ray diffraction study. The anisotropy of the chemical shift tensor, expressed in its span $\Omega$, is about 19 ppm, which is within the expected range for free phosphanes. The $^{31}P$ CP MAS spectrum of $[AgCl(trop_3P)]$ (**3**) at 7 kHz shows a sharp doublet, that is the one bond coupling to silver is resolved under these conditions, but not to the individual $^{109}Ag$ and $^{107}Ag$ isotopes (cf. Figure 5). A non-spinning probe showed a typical rhombic signal of moderate band width with $\Omega \approx 24$ ppm close to the one of the free phosphane **1**.

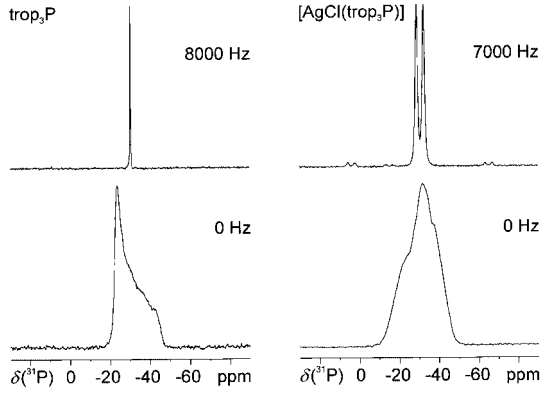

Figure 11. 202 MHz $^{31}P\{^1H\}$ CP MAS spectra of $trop_3P$ (**1**) and $[AgCl(trop_3P)]$ (**3**) at 8/7 kHz and 0 Hz spinning frequency, respectively.

Figure 12 shows the experimental spectra of $[RhCl(trop_3P)]$ (**6**), $[IrCl(trop_3P)]$ (**7**) and $[Pd(trop_3P)(H_2O)]^{2+}$ (**9**). At 3 kHz rotation frequency of the samples, the spectra observed for **6** and **7** are not significantly different from the axial type (skew $\kappa > 0.9$), but a rhombic spectrum is seen for **9** ($\kappa = 0.87$). In all cases two components of the chemical shift tensor, $\delta_{11}$ and $\delta_{22}$, were recorded at frequencies typical of weak shielding while the remaining, $\delta_{33}$, was observed at negative values rather similar for all investigated compounds **1**–**9**. The largest anisotropy $\Omega \approx 460$ ppm is obtained for the $Pd^{II}$ complex **9**. Clearly, the components $\delta_{11}$ and $\delta_{22}$ are responsible for the isotropic high-frequency shift

[c] Values determined by analysis of the experimental MAS spectrum and then fitting a simulation.

recorded in solution. Simulation of the spectra led to the chemical shift tensor elements listed in Table 3. The axial spectra of **6** and **7** allow to conclude that the $\delta_{33}$ element is aligned with the M–P vector and $\delta_{11}$ and $\delta_{22}$ are consequently orthogonal to M–P and parallel to the equatorial coordination plane with the metal C=$C_{trop}$ arrangement.[46] As Table 3 shows, the deshielding of $\delta_{11}$ and $\delta_{22}$ decreases in the order **9** < **6** < **7** as the M→C=$C_{trop}$ backbonding increases.

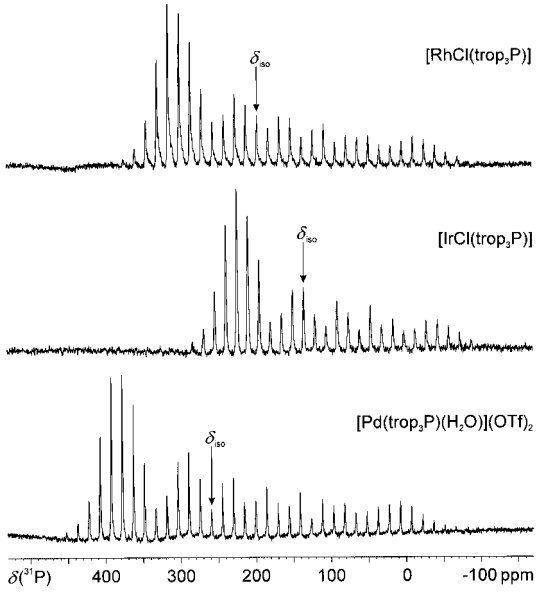

Figure 12. 202 MHz $^{31}P\{^1H\}$ CP MAS spectra of [RhCl($trop_3P$)] (**6**) (top), [IrCl($trop_3P$)] (**7**) (middle) and [Pd($trop_3P$)($H_2O$)]($OTf)_2$ (**9**) (bottom) at 3 kHz rotation frequency.

## Conclusions

The new phosphane $trop_3P$ was synthesized in an unexpected simple manner from $P(SiMe_3)_3$ and 5-chlorodibenzo[*a*,*d*]cycloheptene, tropCl. The structure of $trop_3P$ is very rigid and the phosphorus atom is deeply embedded in a concave pocket formed by the three trop substituents. This makes the phosphane infinitely stable against oxidation on air and long reaction times are needed for converting $trop_3P$ into the corresponding thiophosphorane, $trop_3P$=S, or to bind transition metals into the pocket. In complexes with $d^{10}$ valence electron configured metal complexes, $trop_3P$ behaves as an extremely bulky monodenate ligand with a cone angle of approx. 250°. Consequently, complexes of $Ag^I$ and $Au^I$ are kinetically stabilized and the isolation of a rare stable cationic monophosphane acetonitrile complex [Au($trop_3P$)(MeCN)]$^+$ (**5**) was achieved.[47] Although questionless a silver–olefin interaction exists in compounds like $[Ag(C_2H_4)_3]^+$ $Al[OC(CF_3)_3]_4^-$,[48] our data do not support the idea that any significant interaction (in the sense of a chemical bond formed by orbital overlap) exists in linearly coordinated $ML_2$ complexes where M = $Ag^+$ or $Au^+$, which have additional olefinic moieties in close proximity. In complexes with $d^8$ valence electron configured transition metals, $trop_3P$ serves as tetradentate ligand and trigonal pyramidal [M($trop_3P$)] fragments were observed[49] with M = $Rh^I$, $Ir^I$, and $Pd^{II}$ to which a fifth ligand X = $Cl^-$, $H_2O$ binds in the remaining axial position. Structural and NMR spectroscopic data suggest that π-backbonding from filled d-orbitals at the transition metal center to the π* orbitals of the coordinated C=C double bonds increases as expected in the order $Pd^{II}$ < $Rh^I$ < $Ir^I$. Remarkably, the $^{31}P$ NMR shifts react most sensitively to this effect and a decrease in M→C=$C_{trop}$ backbonding causes a strong deshielding, that is shifts to higher frequencies. $^{31}P$ CP MAS NMR spectroscopy allowed the chemical shift tensor to be determined and shows that the unusual deshielding of the $^{31}P$ nuclei in the [MX($trop_3P$)] complexes is caused by large positive $\delta_{11}$ and $\delta_{22}$ components, which are in plane with the three coordinated C=$C_{trop}$ units and the metal center M = $Pd^{II}$, $Rh^I$, $Ir^I$. The third component, $\delta_{33}$, is aligned with the M–P bond and has similar negative values for all complexes. Under the assumption that the $^{31}P$ NMR shift is dominated by the paramagnetic shift term, excitations into unoccupied orbitals are likely responsible for this phenomenon. We suggest that these relevant unoccupied orbitals are those which correspond to an antibonding interaction between a filled d-orbital at the metal center and the π*-orbital of the C=$C_{trop}$ bond. A strong M→C=$C_{trop}$ backbonding will stabilize the bonding d(M)–π*(C=C) interaction at low energies but lift the antibonding d(M)–π*(C=C) interaction to high energies. Inversely, a weak M→C=$C_{trop}$ backbonding will create an energetically low lying antibonding d(M)–π*(C=C) interaction and excitations into this orbital are made responsible for the exceptional coordination shifts leading to unusally high-frequency-shifted $^{31}P$ resonances in the $Pd^{II}$ complexes {$\delta(^{31}P)$ = 270.6 ppm in [Pd($trop_3P$)($H_2O$)]$^{2+}$}; [$\delta(^{31}P)$ = 435.9 ppm in [Pd($cht_3P$)(Cl)]$^+$]. For

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a detailed explanation of this phenomenon, an in-depth quantum chemical analysis is needed, which however was beyond the scope of this study.

## Experimental Section

**General Procedures:** All manipulations of air- or moisture-sensitive compounds were performed on a standard vacuum line in flame-dried flasks under an atmosphere of argon. Solvents were distilled under argon from Na (toluene), Na/benzophenone (THF, diethyl ether), Na/benzophenone/tetraglyme (*n*-hexane), $CaH_2$ ($CH_2Cl_2$, chloroform, acetonitrile), $P_2O_5$ (acetonitrile). Air-sensitive compounds were stored and weighed in gloveboxes. Basic chemicals were ordered from commercial suppliers and used as received. The following organic compounds and metal precursors were prepared according to literature methods: tropCl,[50] $(TMS)_3P$,[51] $[Ir_2(COE)_4(\mu\text{-}Cl)_2]$.[52] IR spectra were recorded on a Perkin–Elmer Spectrum 2000 FT-IR-Raman spectrometer with the ATR technique. Mass spectra of organic compounds were recorded on a Finnigan MAT SSQ 7000 mass spectrometer using electron ionization. Melting points were determined with a Büchi melting point apparatus and are not corrected. UV/Vis spectra were recorded on a UV/Vis/NIR lambda 19 spectrometer in 5-mm quartz cuvettes (200–1000 nm). Solution NMR spectra were recorded on Bruker Avance 400, 300, 250 and 200 spectrometers. Chemical shifts ($\delta$) are measured and referenced according to IUPAC[53] and expressed in ppm. $^{31}P$ CP MAS solid state NMR spectra were acquired at room temperature on a Bruker Avance instrument operating at a $^1H$ Larmor frequency of 500 MHz. Conventional cross-polarization and magic-angle-spinning techniques were implemented by using 4-mm rotors with which rotational frequencies of at least 11 kHz were achieved. The strength of the magnetic field was adjusted such that the $^{13}C$ carboxylate resonance of α-glycine appeared at $\delta$ = 176.0 ppm. In consequence referencing of all isotopes could be achieved as for the solution NMR using the unified $\Xi$ scale.[53] Chemical shifts are expressed relative to $H_3PO_4$. CP MAS spectra were simulated by using the SIMPSON program package.[54]

**Preparation of Tris(5*H*-dibenzo[*a*,*d*]cycloheptен-5-yl)phosphane (1):** TropCl (13.4 g, 59 mmol) was placed under argon in a 500-mL round-bottom Schlenk flask. It was dissolved in 250 mL freshly distilled, dry THF. $P(SiMe_3)_3$ (4.5 mL, 3.9 g, 16 mmol) was added dropwise to this solution. The resulting mixture was stirred at room temperature for several days and the reaction was monitored by $^{31}P$ NMR spectroscopy. The first substitution leading to $trop(SiMe_3)_2P$ [$\delta(^{31}P)$ = –148.2 ppm] is quite fast, the second step to $trop_2(SiMe_3)P$ [$\delta(^{31}P)$ = –70.3 ppm] and third step to **1** proceed more slowly. When the $^{31}P$ NMR spectrum showed almost complete conversion to $trop_3P$ **1** (after 4 to 6 d), MeOH (2.5 mL, 2.0 g, 62 mmol) was added and stirring was continued for another 12 h. During this time a white precipitate formed in the reaction mixture ($trop_3P{\cdot}HCl$) [$\delta(^{31}P)$ = –45.5 ($^1J_{P,H}$ = 480 Hz) ppm]. This precipitate was collected by filtration and washed with THF. The product was obtained by suspending ($trop_3P{\cdot}HCl$) in a concentrated $NaHCO_3$ solution and extracting the resulting mixture twice with $CH_2Cl_2$. The combined organic phases were dried with $Na_2SO_4$ and concentrated to dryness. The product was dried in high vacuum giving a fine white powder of high purity. If necessary, **1** can be further purified by recrystallization from toluene. Yield: 7.54 g (80%). M.p. 247 °C. $C_{45}H_{33}P$ (604.72): calcd. C 89.38, H 5.50, P 5.12; found C 89.12, H 5.66. IR (ATR): $\tilde{\nu}$ = 3013 (w, $\nu_{CH}$), 1592 (w), 1488 (m), 1453 (m), 1432 (m), 1329 (m), 1287 (m), 796 (s), 781 (s), 728 (s), 633 (s) $cm^{-1}$. MS (EI): *m*/*z* 603 ($M^+$), 191 ($C_{15}H_{11}^+$). $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 4.16 (d, $^2J_{P,H}$ = 1.8 Hz, 3 H, $H_{benz}$), 6.30 (s, 6 H, $H_{olef}$), 6.44–6.51 (m, 6 H, $H_{aryl}$), 6.81–6.87 (m, 6 H, $H_{aryl}$), 6.97–7.06 (m, 12 H, $H_{aryl}$) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 55.6 (d, $^1J_{P,C}$ = 36.3 Hz, 3 C, $C_{benz}$), 125.0 (d, $J_{P,C}$ = 0.7 Hz, 6 C, $C_{olef}$), 128.3 (s, 6 C, $C_{aryl}$), 128.6 (s, 6 C, $C_{aryl}$), 128.6 (d, $J_{P,C}$ = 3.1 Hz, 6 C, $C_{aryl}$), 131.6 (d, $J_{P,C}$ = 5.7 Hz, 6 C, $C_{aryl}$), 135.4 (d, $J_{P,C}$ = 3.5 Hz, 6 C, $C_{aryl}$), 139.3 (d, $J_{P,C}$ = 9.0 Hz, 6 C, $C_{aryl}$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CDCl_3$, 25 °C): $\delta$ = –22.7 (s) ppm.

**Preparation of Tris(5*H*-dibenzo[*a*,*d*]cycloheptен-5-yl)phosphane Sulfide (2):** In a Schlenk flask, $trop_3P$ (240 mg, 0.40 mmol) and $S_8$ (14 mg, 0.44 mmol) were suspended in THF (20 mL). This mixture was heated to 60 °C and stirred for several days. Conversion was about 20% after 17 h and about 40% after 40 h. After five days, a white precipitate had formed, which was collected by filtration and washed with THF. The filtrate still contained about 50% starting material. The collected product was dried in high vacuum to give a microcrystalline white solid. Yield: 35 mg (14%). M.p. 212 °C. $C_{45}H_{33}PS$ (636.78): calcd. C 84.88, H 5.22, P 4.86; found C 84.43, H 4.91. IR (ATR): $\tilde{\nu}$ = 3017 (w, $\nu_{CH}$), 2972 (w, $\nu_{CH}$), 2852 (w, $\nu_{CH}$), 1494 (m), 1456 (m), 1432 (m), 1160 (m), 1065 (m), 803 (s), 779 (s), 769 (s), 726 (s), 687 (s), 615 (m). $^1H$ NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 5.39 (d, $^2J_{P,H}$ = 16 Hz, 3 H, $H_{benz}$), 6.34 (br. s, 6 H, $H_{olef}$), 7.10–7.25 (m, 12 H, $H_{aryl}$), 7.25–7.40 (m, 6 H, $H_{aryl}$), 7.40–7.50 (m, 12 H, $H_{aryl}$) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 59.5 (d, $^1J_{P,C}$ = 23.5 Hz, 3 C, $C_{benz}$), 127.3 (s, 6 C, $C_{olef}$), 128.8 (s, 6 C, $C_{aryl}$), 129.9 (s, 6 C, $C_{aryl}$), 131.7 (d, $J_{P,C}$ = 6.5 Hz, 6 C, $C_{aryl}$), 133.2 (s, 6 C, $C_{aryl}$), 135.8 (s, 6 C, $C_{aryl,quat}$), 136.0 (s, 6 C, $C_{aryl,quat}$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 79.5 (s) ppm.

**Preparation of Chloro[tris(5*H*-dibenzo[*a*,*d*]cycloheptен-5-yl)phosphane]silver(I) (3):** Aqueous solutions of $AgNO_3$ (2.0 g, 12 mmol) and $NH_4Cl$ (1.0 g, 19 mmol) were aggregated to precipitate AgCl. This precipitate was collected by filtration, washed with water, ethanol and diethyl ether and dried on air. $trop_3P$ **1** (158 mg, 0.26 mmol) and an excess of the freshly precipitated AgCl (123 mg, 0.86 mmol) were combined in $CH_2Cl_2$ (20 mL). This mixture was stirred for 16 h. The remaining AgCl was removed by filtration and washed with $CH_2Cl_2$. The filtrate was concentrated to dryness. Then the product was washed with small amounts of pentane and dried in high vacuum. The product was obtained as a bright white microcrystalline solid. Yield: 135 mg (69%). M.p. 251–260 °C (decomposition). $C_{45}H_{33}AgClP$ (748.04): calcd. C 72.25, H 4.45, P 4.14; found C 71.98, H 4.58. IR (ATR): $\tilde{\nu}$ = 3017 (w, $\nu_{CH}$), 1594 (w), 1486 (m), 1455 (m), 1434 (m), 1334 (m), 1296 (m), 798 (s), 785 (s), 729 (s), 637 (s) $cm^{-1}$. $^1H$ NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 4.46 (dd, $^2J_{P,H}$ = 12 Hz, $^3J_{Ag,H}$ = 7.8 Hz, 3 H, $H_{benz}$), 6.54 (s, 6 H, $H_{olef}$), 6.56 (d br, $^3J_{H,H}$ = 7.2 Hz, 6 H, $H_{aryl}$), 7.01 (dd, $^3J_{H,H}$ = 7.2 Hz, $^4J_{H,H}$ = 1.8 Hz, 6 H, $H_{aryl}$), 7.16 (ddd, $^3J_{H,H}$ = 7.2 Hz, 7.2 Hz; $^4J_{H,H}$ = 1.8 Hz, 6 H, $H_{aryl}$), 7.20 (dd br, $^3J_{H,H}$ = 7.2 Hz, 7.2 Hz; 6 H, $H_{aryl}$) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 54.4 (dd, $^1J_{P,C}$ = 5.7 Hz, $^2J_{Ag,C}$ = 1.5 Hz, 3 C, $C_{benz}$), 126.7 (d, $J_{P,C}$ = 1.7 Hz, 6 C, $C_{aryl}$), 129.2 (s, 6 C, $C_{aryl}$), 129.4 (d, $^3J_{P,C}$ = 4.6 Hz, 6 C, $C_{aryl}$), 129.5 (d, $J_{P,C}$ = 1.7 Hz, 6 C, $C_{aryl}$), 132.0 (dd, $^4J_{P,C}$ = 5.3 Hz, $^1J_{Ag,C}$ = 2.0 Hz, 6 C, $C_{olef}$), 135.0 (d, $J_{P,C}$ = 4.6 Hz, 6 C, $C_{aryl,quat}$), 136.0 (d, $J_{P,C}$ = 3.3 Hz, 6 C, $C_{aryl,quat}$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = –27.7 (d, $^1J_{107Ag,P}$ = 669 Hz, $^1J_{109Ag,P}$ = 771 Hz) ppm.

**Preparation of [Tris(5*H*-dibenzo[*a*,*d*]cycloheptен-5-yl)phosphane]silver(I) Trifluoromethanesulfonate (4a):** In a Schlenk flask, $trop_3P$ **1** (480 mg, 0.79 mmol) was dissolved in THF. AgOTf (204 mg,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.79 mmol) was added to this solution and the resulting mixture was stirred for three days. Any precipitates were removed by filtration through celite. The filtrate was concentrated to about one third of its volume and left at –20 °C for crystallization. The precipitated product was collected by filtration and dried in high vacuum. The product was an off-white powder. Yield: 360 mg (53%). M.p. 223–228 °C (decomposition). Due to the light sensitivity of the compound, we were not able to obtain reliable elemental analytical data. IR (ATR): $\tilde{\nu}$ = 3362(br., $\nu_{H2O}$), 3020 (w, $\nu_{CH}$), 1594 (w), 1489 (m), 1455 (m), 1434 (m), 1330 (m), 1265 (s), 1234 (s), 1156 (s), 1027 (s), 802 (s), 788 (s), 763 (s) 732 (s), 635 (s) cm$^{-1}$. $^1$H NMR (300 MHz, $CD_3CN$, 25 °C): $\delta$ = 4.78 (dd, $^2J_{P,H}$ = 13 Hz, $^3J_{Ag,H}$ = 9.0 Hz, 3 H, $H_{benz}$), 6.56 (s, 6 H, $H_{olef}$), 6.71–6.78 (m, 6 H, $H_{aryl}$), 6.92–6.99 (m, 6 H, $H_{aryl}$), 7.10–7.19 (m, 12 H, $H_{aryl}$) ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $CD_3CN$, 25 °C): $\delta$ = 52.9 (dd, $^1J_{P,C}$ = 5.6 Hz, $^2J_{Ag,C}$ = 3.6 Hz, 3 C, $C_{benz}$), 126.6 (d, $^5J_{P,C}$ = 1.5 Hz, 6 C, $C_g$), 129.2 (d, $^4J_{P,C}$ = 1.7 Hz, 6 C, $C_h$), 129.6 (d, $^3J_{P,C}$ = 4.6 Hz, 6 C, $C_e$),129.9 (s, 6 C, $C_f$), 131.2 (dd, $^4J_{P,C}$ = 6.0 Hz, $^1J_{Ag,C}$ = 1.7 Hz, 6 C, $C_{olef}$), 134.1 (d, $^3J_{P,C}$ = 4.5 Hz, 6 C, $C_c$), 135.6 (d, $^2J_{P,C}$ = 2.7 Hz, 6 C, $C_b$) ppm. $^{19}$F{$^1$H} NMR (188.3 MHz, $CD_3CN$, 25 °C): $\delta$ = –79.2 (s) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CD_3CN$, 25 °C): $\delta$ = –38.3 (d, $^1J_{107Ag,P}$ = 713 Hz, $^1J_{109Ag,P}$ = 822 Hz) ppm. $^{109}$Ag{$^1$H} NMR (13.4 MHz, $CD_3CN$, 25 °C): $\delta$ = 717 (d, $^1J_{Ag,P}$ = 822 Hz) ppm.

**Preparation of [Tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)phosphane]silver(I) Hexafluorophosphate (4b):** A solution of trop$_3$P **1** (195 mg, 0.33 mmol) in THF was added dropwise to a solution of [Ag(MeCN)$_2$]$PF_6$ (110 mg, 0.33 mmol) in THF. The reaction mixture was left overnight under strict exclusion of light for crystallization. The precipitated product was collected by filtration and dissolved in acetonitrile. Impurities were removed by filtration and the filtrate was concentrated to dryness. Recrystallization from THF and drying in high vacuum yielded the product as a slightly off-white microcrystalline powder. Yield: 131 mg (47%). M.p. 198–202 °C (decomposition). Due to the light sensitivity of the compound, we were not able to obtain reliable elemental analytical data. IR (ATR): $\tilde{\nu}$ = 3057 (w, $\nu_{CH}$), 1595 (w), 1490 (w), 1455 (w), 1434 (w), 1330 (w), 1295 (w), 834 (s), 803 (s), 788 (m), 765 (m), 734 (m), 637 (m) cm$^{-1}$. $^1$H NMR (300.1 MHz, $CD_3CN$, 25 °C): $\delta$ = 4.76 (dd, $^2J_{P,H}$ = 12.9 Hz, $^3J_{Ag,H}$ = 9.0 Hz, 3 H, $H_{benz}$), 6.55 (s, 6 H, $H_{olef}$), 6.71–6.78 (m, 6 H, $H_{aryl}$), 6.92–6.99 (m, 6 H, $H_{aryl}$), 7.12–7.21 (m, 12 H, $H_{aryl}$) ppm. $^{19}$F{$^1$H} NMR (188.3 MHz, $CD_3CN$, 25 °C): $\delta$ = –72.8 (d, $^1J_{P,F}$ = 706 Hz) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CD_3CN$, 25 °C): $\delta$ = –37.9 (d, $^1J_{107Ag,P}$ = 715 Hz, $^1J_{109Ag,P}$ = 825 Hz, trop$_3$*P*), –144.5 (hept, $^1J_{P,F}$ = 706 Hz, *P*$F_6$) ppm.

**Preparation of (Acetonitrile)[tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)-phosphane]gold(I) Hexafluorophosphate (5):** Due to the strong oxidizing potential of Au$^I$ this synthesis was carried out under inert conditions. The precursor complex [Au(MeCN)$_4$]$PF_6$ was synthesized using a slightly modified published procedure.[41] [Au(MeCN)$_4$]$^+$ is generated by oxidation of a gold wire in an electrolysis apparatus. The anode consisted of a coiled gold wire, whereas for the cathode a coiled silver wire was used. The three compartments were separated by two anion-selective membranes. [Ag(MeCN)$_2$]$PF_6$ (1.67 g, 4.99 mmol) and $Me_4NPF_6$ (1.29 g, 5.9 mmol) were dissolved in acetonitrile (50 mL) and transferred into the cathodic compartment. The bridge compartment was filled with $Me_4NPF_6$ (1.33 g, 6.1 mmol) dissolved in acetonitrile (30 mL). To neat acetonitrile (50 mL) in the anodic compartment, 0.5 mL of a solution of $Et_4NI$ ($6\cdot10^{-4}$ M, $3\cdot10^{-4}$ mmol) were added (the resulting solution was $6\cdot10^{-6}$ M in $Et_4NI$). The iodide catalytically activated the surface of the gold wire. After the electrolysis the product solution in the anodic compartment was separated by cannula filtration from colloidal Au$^0$ precipitates and used immediately afterwards. Separately, trop$_3$P **1** (0.19 g, 0.31 mmol) was suspended in freshly distilled acetonitrile (50 mL). Then the decanted solution of [Au(MeCN)$_4$]$PF_6$ in acetonitrile was added dropwise until the reaction mixture became clear (about 15 mL). Toluene was added until some precipitate started to form. Leaving the mixture at room temperature overnight gave cubic shaped crystals suitable for X-ray diffraction (50 mg, 16%). Further product was obtained by concentration of the solution and was collected by filtration. The slightly yellow micro-crystalline powder was washed with toluene and dried in high vacuum. Yield: 236 mg (76%). M.p. 208–212 °C (decomposition). IR (ATR): $\tilde{\nu}$ = 3021 (w, $\nu_{CH}$), 1491 (m), 1455 (m), 1433 (m), 1334 (m), 1301 (m), 834 (s), 797 (s), 763 (s), 734 (s), 641 (m) cm$^{-1}$. $^1$H NMR (300 MHz, $CD_3CN$, 25 °C): $\delta$ = 4.92 (d, $^2J_{P,H}$ = 15 Hz, 3 H, $H_{benz}$), 6.48 (s, 6 H, $H_{olef}$), 6.67–6.73 (m, 6 H, $H_{aryl}$), 7.02–7.07 (m, 6 H, $H_{aryl}$), 7.18–7.30 (m, 12 H, $H_{aryl}$) ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $CD_3CN$, 25 °C): $\delta$ = 54.2 (d, $^1J_{P,C}$ = 25 Hz, 3 C, $C_{benz}$), 127.3 (d, $J_{P,C}$ = 2.0 Hz, 6 C, $C_{aryl}$), 129.3 (d, $J_{P,C}$ = 2.1 Hz, 6 C, $C_{aryl}$), 129.5 (s, 6 C, $C_{aryl}$), 130.3 (d, $^4J_{P,C}$ = 6.4 Hz, 6 C, $C_{olef}$), 131.7 (d, $J_{P,C}$ = 2.2 Hz, 6 C, $C_{aryl}$), 134.5 (s, 6 C, $C_{aryl,quat}$), 135.1 (d, $J_{P,C}$ = 4.5 Hz, 6 C, $C_{aryl,quat}$) ppm. $^{19}$F{$^1$H} NMR (188.3 MHz, $CD_3CN$, 25 °C): $\delta$ = –72.8 (d, $^1J_{P,F}$ = 706 Hz, P$F_6$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CD_3CN$, 25 °C): $\delta$ = 0.7 (s, trop$_3$*P*), –144.5 (hept, $^1J_{P,F}$ = 706 Hz, *P*$F_6$) ppm.

**Preparation of (Chloro)[tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)phosphane]rhodium(I) (6):** In a Schlenk flask [Rh$_2$(μ-Cl)$_2$(COD)$_2$] (201 mg, 0.41 mmol) and trop$_3$P **1** (493 mg, 0.82 mmol) were suspended in THF (12 mL). This orange suspension was stirred at 60 °C. Upon heating, all solids dissolved. After 30 h of stirring at 60 °C, a pale yellow precipitate had formed and the $^{31}$P NMR spectrum showed almost complete conversion. The mixture was left at –20 °C overnight in order to complete crystallization. The precipitate was collected by filtration, washed with THF (5 mL), and dried in high vacuum. The product was a light yellow powder. Yield: 424 mg (70%). M.p. 320 °C (starting decomposition). $C_{45}H_{33}ClPRh$ (743.08): calcd. C 72.74, H 4.48, P 4.17; found C 72.64, H 4.74. IR (ATR): $\tilde{\nu}$ = 3017 (w, $\nu_{CH}$), 1937 (w), 1599 (w), 1574 (w), 1483 (m), 1451 (m), 1417 (m), 1325 (w), 1286 (m), 743 (s), 731 (s), 643 (m) cm$^{-1}$. MS (EI): *m*/*z* 742 ($M^+$), 191 ($C_{15}H_{11}^+$). $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 3.97 (d, $^2J_{P,H}$ = 13 Hz, 3 H, $H_{benz}$), 5.93 (s, 6 H, $H_{olef}$), 6.50 (d, $^3J_{H,H}$ = 7.2 Hz, 6 H, $H_{aryl}$), 6.77 (dd, $^3J_{H,H}$ = 7.2 Hz, 7.2 Hz; 6 H, $H_{aryl}$), 6.86 (dd, $^3J_{H,H}$ = 7.2 Hz, 7.2 Hz; 6 H, $H_{aryl}$), 7.02 (d, $^3J_{H,H}$ = 7.2 Hz, 6 H, $H_{aryl}$) ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 48.4 (d, $^1J_{P,C}$ = 21.7 Hz, 3 C, $C_{benz}$), 79.4 (d, $^2J_{P,C}$ = 6.3 Hz, 6 C, $C_{olef}$), 126.7 (s, 6 C, $C_{aryl}$), 127.1 (d, $J_{P,C}$ = 7.2 Hz, 6 C, $C_{aryl}$), 127.5 (s, 6 C, $C_{aryl}$), 130.5 (s, 6 C, $C_{aryl}$), 133.7 (d, $J_{P,C}$ = 5.1 Hz, 6 C, $C_{aryl}$), 135.6 (s, 6 C, $C_{aryl}$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 191.7 (d, $^1J_{Rh,P}$ = 147.5 Hz) ppm.

**Preparation of (Chloro)[tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)phosphane]iridium(I) (7):** Because [Ir$_2$(μ-Cl)$_2$(coe)$_4$] is very air- and moisture-sensitive, the reaction was carried out under strictly inert conditions. In a Schlenk flask [Ir$_2$(μ-Cl)$_2$(coe)$_4$] (232 mg, 0.26 mmol) and **1** (314 mg, 0.52 mmol) were suspended in THF (18 mL). This orange suspension was stirred at 60 °C. Upon heating, all the solids dissolved and the color darkened. After 70 h of stirring at 60 °C the solution was dark brown and the $^{31}$P NMR spectrum showed about 70% conversion to the product. The reaction mixture was filtered over Celite and the filtrate was concentrated. Leaving the sample at –20 °C overnight allowed to crystallize the product in form of fine white needles. These were collected by filtration. To remove residual iridium metal, the product was dissolved in $CH_2Cl_2$ and filtered over a short silica gel column

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

($R_f$ = 0.3). The product was precipitated with *n*-hexane and dried in high vacuum to give a white microcrystalline powder. Yield: 115 mg (53%). M.p. 340 °C (starting slight decomposition). $C_{45}H_{33}ClIrP$ (832.39): calcd. C 64.93, H 4.00, P 3.72; found C 64.72, H 4.03. IR (ATR): $\tilde{\nu}$ = 3014 (w, $\nu_{CH}$), 1600 (w), 1575 (w), 1483 (m), 1403 (w), 1286 (m), 746 (s), 732 (s), 644 (m) $cm^{-1}$. MS (EI): *m*/*z* 832 ($M^+$), 191 ($C_{15}H_{11}^+$). $^1H$ NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 4.15 (d, $^2J_{P,H}$ = 13 Hz, 3 H, $H_{benz}$), 5.40 (s, 6 H, $H_{olef}$), 6.46 (d, $^3J_{H,H}$ = 6.9 Hz, 6 H, $H_{aryl}$), 6.70–6.84 (m, 12 H, $H_{aryl}$), 7.02 (d, $^3J_{H,H}$ = 6.9 Hz, 6 H, $H_{aryl}$) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 44.8 (d, $^1J_{P,C}$ = 21.7 Hz, 3 C, $C_{benz}$), 65.6 (s, 6 C, $C_{olef}$), 126.4 (s, 6 C, $C_{aryl}$), 127.6 (d, $J_{P,C}$ = 7.5 Hz, 6 C, $C_{aryl}$), 127.8 (d, $J_{P,C}$ = 1.2 Hz, 6 C, $C_{aryl}$), 131.7 (d, $J_{P,C}$ = 1.6 Hz, 6 C, $C_{aryl}$), 133.4 (d, $J_{P,C}$ = 5.1 Hz, 6 C, $C_{aryl}$), 135.7 (s, 6 C, $C_{aryl}$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 134.1 (s) ppm.

**Preparation of (Aqua)[tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)phosphane]palladium(II) Trifluoromethanesulfonate (9):** In a Schlenk flask, $[PdCl_2(MeCN)_2]$ (166 mg, 0.43 mmol) and **1** (262 mg, 0.43 mmol) were suspended in acetonitrile (12 mL). This orange suspension was stirred at 60 °C. Upon heating, the suspension became red. After 24 h of stirring at 60 °C a dark red precipitate had formed and the $^{31}P$ NMR spectrum showed complete conversion. The mixture was left at –20 °C overnight in order to complete crystallization. The precipitate was collected by filtration and dried in high vacuum. The filtrate was evaporated to dryness and the residue dissolved in THF. A further crop of product was precipitated with *n*-hexane, collected by filtration, and subsequently dried in high vacuum for 24 h. $^{31}P$ NMR spectroscopy showed that this material consisted in majority of $[PdCl(trop_3P)]Cl$ [$\delta(^{31}P)$ = 263.8 ppm] and some $[Pd(trop_3P)(MeCN)]Cl_2$ [$\delta(^{31}P)$ = 256.1 ppm]. Subsequently, this product mixture (134 mg, 0.17 mmol) was dissolved in $CH_2Cl_2$ (15 mL) and AgOTf (133 mg, 0.52 mmol) was added. The resulting suspension was stirred for 16 h. The color changed from dark red to dark ruby red. The suspension was filtered through Celite, concentrated, and the product was precipitated with *n*-hexane. After washing with pentane, the dark ruby powder was dried in high vacuum. Yield: 162 mg (92%). M.p. 166–171 °C (decomposition). $C_{47}H_{35}F_6O_7PPdS_2$ (1027.29): calcd. C 54.95, H 3.43, P 3.02; found C 54.71, H 3.65. IR (ATR): $\tilde{\nu}$ = 3048 (w, $\nu_{CH}$), 1599 (w), 1507 (w), 1457 (m), 1431 (w), 1221 (s), 1159 (s), 1025 (s) 747 (s), 632 (s) $cm^{-1}$. UV ($CH_2Cl_2$): $\lambda_{max}$ = 497 nm. $^1H$ NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 5.79 (d, $^2J_{P,H}$ = 11 Hz, 3 H, $H_{benz}$), 6.96–7.03 (m, 6 H, $H_{aryl}$), 7.05–7.13 (m, 12 H, $H_{aryl}$), 7.16–7.22 (m, 6 H, $H_{aryl}$), 7.40 (s, 6 H, $H_{olef}$) ppm. $^{13}C\{^1H\}$ NMR (75.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 51.9 (d, $^1J_{P,C}$ = 16.0 Hz, 3 C, $C_{benz}$), 109.6 (s, 6 C, $C_{olef}$), 128.5 (d, $J_{P,C}$ = 1.4 Hz, 6 C, $C_{aryl}$), 128.7 (d, $J_{P,C}$ = 8.6 Hz, 6 C, $C_{aryl}$), 129.4 (d, $J_{P,C}$ = 5.1 Hz, 6 C, $C_{aryl}$), 129.6 (d, $J_{P,C}$ = 1.5 Hz, 6 C, $C_{aryl}$), 131.3 (s, 6 C, $C_{aryl}$), 135.6 (d, $J_{P,C}$ = 1.1 Hz, 6 C, $C_{aryl}$) ppm. $^{19}F$ NMR (188.3 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = –78.1 (br. s, 3 F), –77.9 (s, 3 F) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 270.6 (s) ppm.

**X-ray Crystallography:** Crystals of **1** were grown from a THF solution that was layered with hexane. Crystals of **2** were obtained by slow cooling of a saturated toluene solution. Crystals of **3** grew from a reaction mixture of **4a** and $nBu_4NCl$ in acetonitrile. Crystals of **5** were obtained by layering an acetonitrile solution of the compound with toluene. Crystals of **6** and **9** were grown by slow evaporation of THF and $CH_2Cl_2$ solutions, respectively. Data collection for the X-ray structure determinations were performed on Bruker SMART 1 K and SMART APEX platforms with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The reflex intensities were measured by CCD area detectors. The collected frames were processed with the proprietary software SAINT[55] and an absorption correction was applied (SADABS[56]). Solution and refinement of the structures was performed with SHELXS-97[57] and SHELXL-97[58] respectively. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were placed in their idealized positions and allowed to ride on the respective carbon atoms. Associated crystallographic data and other experimental details are summarized in Table 4.

Table 4. Crystal data and refinement for compounds **1**, **2**, **3**, **5**, **6** and **9**.

# Spin Canting and Topological Ferrimagnetism in Two Manganese(II) Coordination Polymers Generated by In Situ Solvothermal Ligand Reactions

Lin Cheng,[a] Wei-Xiong Zhang,[a] Bao-Hui Ye,*[a] Jian-Bin Lin,[a] and Xiao-Ming Chen*[a]

**Keywords:** Solvothermal ligand reaction / Coordination polymers / Spin canting / Topological ferrimagnetism

Two manganese(II) coordination polymers, $[Mn_2(bpt)(pa)_2(N_3)]_n$ [**1**; Hpa = picolinic acid, Hbpt = 3,5-bis(2-pyridyl)-4*H*-1,2,4-triazole] and $[Mn_3(ina)_2(pa)_2(N_3)_2]_n$ (**2**; Hina = isonicotinic acid), have been synthesized by solvothermal treatment, in which the ligands bpt and pa were generated in situ by cyclocondensation and hydrolysis of 2-pyridylamidrazone, respectively. In **1**, each binuclear subunit $[Mn_2(bpt)(N_3)]$ bridged by bpt and $N_3^-$ ligands is interlinked to four adjacent subunits via four tridentate pa ligands into a diamondoid 3D network, which shows spin-canting magnetism arising from the lack of inversion centers between the interacting spin centers. In **2**, the $Mn^{II}$ ions are alternately connected by double $\mu_{1,3}$-carboxylate/$\mu_{1,1}$-azide and double $\mu_{1,1}$-carboxylate bridges into a 1D magnetic chain, which exhibits a topological ferrimagnetic behavior in an antiferromagnetic-antiferromagnetic-ferromagnetic sequence. These chains are further interlinked via ina ligands into a 2D network.

## Introduction

Recent years have witnessed an explosion of interest in molecular-based magnetic materials, since such materials can help in understanding magneto-structural correlations and some fundamental phenomena of magnetism, and may have potential applications.[1–4] A basic design route for this kind of magnetic materials is to appropriately organize the paramagnetic ions into ordered polynuclear architectures by use of bridging ligands that can efficiently transmit magnetic superexchange. In addition to the nature of the metal centers, the bulk magnetic properties mainly depend on the bridging modes and bridging geometries of the bridging ligands. This fact provides an opportunity to produce new molecule-based magnetic materials by crystal engineering, although so far the pursuit of designing polynuclear complexes and extended networks with predictable magnetic properties is still a challenge, because the structural factors governing the exchange coupling between paramagnetic centers are complex and elusive. Azide was widely used to connect metal ions, and the correlation between the structure and magnetic properties of the end-on (EO), or $\mu_{1,1}$-azide, and end-to-end (EE), or $\mu_{1,3}$-azide, coordination modes was observed, generally giving ferro- (F) and antiferromagnetic (AF) interactions, respectively. The interactions also depend highly on the M–N–M angle;[5,6] however, these angles are mutable and difficult to predict and control in the uniquely azide-bridged complexes. Therefore, the introduction of a second bridging ligand to control the exchange angle between the metal ions may provide a feasible approach to the construction of bulk magnetic materials. Furthermore, multidentate ligands containing a carboxylate and a pyridyl group, such as nicotinate (na), isonicotinate (ina), and picolinate (pa), have been frequently used in the preparation of magnetic materials, because the various coordination modes adopted by the carboxylate group can transmit the magnetic coupling in different degrees, and the coordination of the pyridyl and carboxylate groups in these ligands may result in extended frameworks.[7] Unfortunately, the examples of higher dimensional (2D and 3D) molecule-based magnetic materials in which bridging azide and carboxylate groups coexist are relatively rare so far.[8]

Meanwhile, the hydro(solvo)thermal technique has been successfully applied to synthesize inorganic materials,[9] inorganic–organic hybrid materials, and coordination polymers.[10] It facilitates not only the assembly and crystallization of functional metal coordination polymers that can not be directly assembled from the organic ligands and metal ions,[10] but also some important in situ ligand reactions,[11–13] leading to the formation of in situ generated mixed-ligand coordination polymers that can not be easily obtained otherwise.[13f]

During our study of the reaction mechanisms of different organonitriles with hydrazine hydrate,[14] two new mixed-ligand polymeric manganese(II) complexes, $[Mn_2(bpt)(pa)_2(N_3)]_n$ [**1**; Hpa = picolinic acid, Hbpt = 3,5-bis(2-pyridyl)-4*H*-1,2,4-triazole] and $[Mn_3(ina)_2(pa)_2(N_3)_2]_n$ (**2**; Hina =

isonicotinic acid), containing azide and carboxylate bridges, have been synthesized and characterized by single-crystal X-ray diffraction and low-temperature magnetic studies.

## Results and Discussion

### Synthesis

Compound **1** was synthesized under solvothermal conditions with 2-pyridylamidrazone and azide anion in the presence of $Mn^{II}$ salt, in which both bpt and pa ligands were generated in situ (Scheme 1). Interestingly, bpt was obtained by the cyclocondensation reaction of 2-pyridylamidrazone in the presence of $Mn^{II}$ ion.[14] Meanwhile, the hydrolysis reaction was also observed. It is not surprising to observe the hydrolysis reaction of 2-pyridylamidrazone to pa at high temperature and pressure, since amidrazone groups can be hydrolyzed to carboxylate groups under common reaction conditions.[15] Presumably, $Mn^{II}$ ions promote the hydrolysis of 2-pyridylamidrazone.[16] When $Mn(ina)_2$ salt was used in place of $MnC_2O_4{\cdot}3H_2O$, **2** was produced, and only the hydrolysis but not the cyclocondensation reaction was observed. This fact may be attributed to the different $Mn^{II}$ sources, as the structure of the 3D $Mn(ina)_2{\cdot}0.5EtOH{\cdot}0.5H_2O$ is more stable than that of the 1D $MnC_2O_4{\cdot}3H_2O$.[17,18] Obviously, it is more difficult to release $Mn^{II}$ ions, which can facilitate cyclocondensation reactions, from the more stable $Mn^{II}$ salt.

### Description of the Crystal Structures

#### *[Mn$_2$(bpt)(pa)$_2$(N$_3$)]$_n$ (1)*

Compound **1** crystallizes in the acentric *Fdd*2 space group. Each bpt ligand binds to two $Mn^{II}$ ions [Mn1–N1 2.301(4) and Mn1–N2 2.222(4) Å] in a *cis* bis(chelate) mode. A pair of $Mn^{II}$ ions are additionally bridged by an azide ligand in the EE mode [Mn1–N5 2.198(4) Å] and further coordinated by four pa ligands derived from the hydrolysis of 2-pyridylamidrazone to furnish a dinuclear secondary building unit (SBU) (Figure 1a). The intradimer distance Mn1···Mn1A is 4.665 Å, much shorter than that in the dinuclear $Mn^{II}$ complexes double bridged by EE azide (5.166–5.485 Å).[5c,19] Furthermore, each SBU connects four adjacent SBUs via the μ-carboxylate bridges of four pa ligands into a 3D coordination polymer (Figure 1b), in which each pa acts as a tridentate ligand and each carboxylate group bridges two SBUs in a *syn-anti* coordination mode (Mn···Mn 6.080 Å). From the topological point of view, each SBU can be considered as a four-connecting node, which is connected by four bridging pa ligands as two-connecting linkers. Consequently, the 3D network can be regarded as a diamondoid structure, as shown in Figure 1c.

#### *[Mn$_3$(ina)$_2$(pa)$_2$(N$_3$)$_2$]$_n$ (2)*

Compound **2** is a 2D coordination polymer constructed by trinuclear SBUs with the bridging ligands ina, pa, and $N_3^-$. There are two crystallographically independent $Mn^{II}$ ions in each SBU (Figure 2a), in which Mn1 is located at a crystallographic inversion center and displays a slightly distorted octahedral geometry, being surrounded by four oxygen atoms [Mn1–O4 2.125(2) and Mn1–O2A 2.207(1) Å] from two pa and two ina ligands as well as by two nitrogen atoms [Mn1–N3 2.227(2) Å] from two $N_3^-$. On the other hand, the Mn2 atom adopts an $N_3O_3$ geometry, being coordinated by a chelating pa ligand [Mn2–N1 2.257(2), Mn2–O1 2.216(2) Å], one bridging oxygen atom from another pa, and a nitrogen atom of one EO azide [Mn2–N3 2.134(2) Å] ligand, as well as one oxygen and one nitrogen atom from two ina ligands [Mn2–N2d 2.357(2), Mn2–O3 2.168(1) Å]. The coordination modes of ina, pa, and azide in **2** are depicted in Figure 3. The Mn1 and Mn2 atoms are bridged by two *syn-syn* μ-1,3-carboxylate groups of the ina and pa ligands as well as by an EO azide ligand. Furthermore, the SBUs are interlinked to each other via two single oxygen bridges to form a chain. The Mn1···Mn2 distance is 3.569 Å, being markedly shorter than that of a mixed-ligand $Mn^{II}$ complex featuring a *syn-syn* carboxylate and an EO azide (3.861 Å) ligand.[8c] The Mn1–N3–Mn2 angle [109.86(8)°] is significantly larger than the crossover angle between AF and F interactions on the EO coordination mode of azide[5a] and the experimental observations (100.5–104.1°),[5c,19] but much smaller than that reported in $[Mn_3(N_3)_2(na)_4(H_2O)_2]$ (118.6°).[8c] The Mn2···Mn2A distance is 3.512 Å, comparable with those in carboxylate-bridged trinuclear $Mn^{II}$ complexes,[20] and the Mn2–O1–Mn2A angle is 105.56(6)°. The adjacent chains are further linked by tridentate ina ligands (Figure 3a) into a 2D network. The interchain Mn···Mn distances across the ina ligands are 9.073 and 9.527 Å.

### Magnetic Properties

#### *Magnetic Properties of 1*

The magnetic susceptibility of powder **1** was investigated in the temperature range 2–300 K at an applied field of 500 G, and the plots of $\chi_M$ and $\chi_M T$ vs. $T$ are shown in Figure 4. When the sample is cooled from 300 K, the $\chi_M$ per $Mn^{II}$ exhibits a smooth increase to a rounded maximum of 0.038 emu mol$^{-1}$ at ca. 25 K, then decreases slightly to 0.037 emu mol$^{-1}$ at 7.8 K, and thereafter increases rapidly to 0.110 emu mol$^{-1}$ at 2 K. Meanwhile, the $\chi_M T$ per $Mn^{II}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

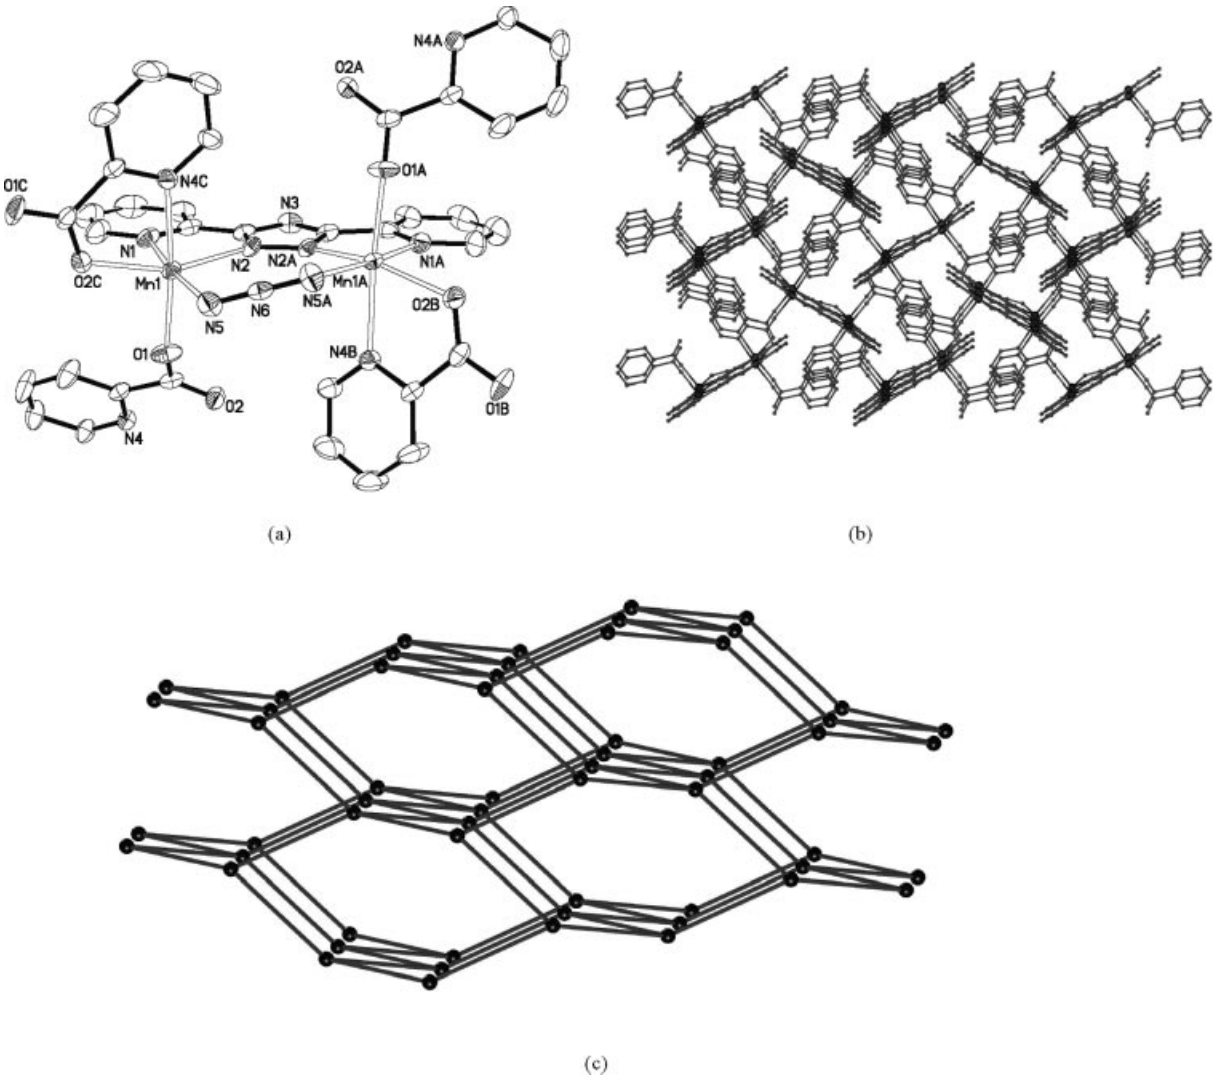

Figure 1. Views of the dinuclear SBU (a) (symmetry codes, A: $-x$, $1-y$, $z$; B: $-1/4-x$, $1/4+y$, $-1/4+z$; C: $1/4+x$, $3/4-y$, $-1/4+z$), the 3D structure (b), and the topology (each ball represents a $Mn_2$ SBU) (c) of **1**.

displays a sharp decrease upon cooling to a minimum of 0.27 emu K mol$^{-1}$ at 7.2 K, and then a slight increase to a maximum of 0.51 emu K mol$^{-1}$ at 5.7 K, finally decreasing again upon further cooling to 2 K.

The $\chi_M T$ value per $Mn^{II}$ of ca. 3.82 emu K mol$^{-1}$ at 300 K is slightly lower than the calculated value of 4.38 emu K mol$^{-1}$ for magnetically isolated high-spin $Mn^{II}$ ions ($S = 5/2$, $g = 2.0$). The temperature dependence of magnetic susceptibility above 100 K obeys the Curie–Weiss law $\chi_M = C/(T - \theta)$ with a Weiss constant $\theta = -70.0(6)$ K and a Curie constant $C = 4.73(1)$ cm$^3$ mol$^{-1}$ K, indicating a dominant AF interaction between the metal centers (Figure 4, inset). Therefore, we can assume an AF coupling between the dimetallic centers via the EE-azide and *cis*-bpt bridges, probably together with a weak AF coupling between the dimeric SBUs in the 3D structure via the *syn-anti* carboxylate bridge. These are in agreement with the observation of AF interactions for $Mn^{II}$ complexes connected via EE-azide, *cis*-bpt,[21] or *syn-anti* carboxylate bridges.[22] The magnetic exchange between the $Mn^{II}$ ions follows two pathways: intradimeric via EE-azide and *cis*-bpt, as well as interdimeric via *syn-anti* carboxylate bridges. The intradimeric interaction ($J$) can be expressed as: $\hat{H}_{ex} = -2J\hat{S}_1\hat{S}_2$. The susceptibility per $Mn_2$ ($\chi'_{dimer}$) can be given as shown in Equation (1).[23]

$$\chi'_{dimer} = \frac{2N\beta^2 g^2}{kT}\left[\frac{55e^{30x} + 30e^{20x} + 14e^{12x} + 5e^{6x} + e^{2x}}{11e^{30x} + 9e^{20x} + 7e^{12x} + 5e^{6x} + 3e^{2x} + 1}\right] \quad (1)$$

Taking into consideration the possibility of the interactions between the dinuclear SBUs in the crystal lattice, a correction for the molecular field is made [Equation (2)].

$$\chi_M = \frac{\chi'_{dimer}}{1 - 2zJ'\chi'_{dimer}/N\beta^2 g^2} \quad (2)$$

Where $N$ is the Avogadro number, $\beta$ is the Bohr magneton, $k$ is the Boltzmann constant, $x = J/kT$, $J$ is the intra-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

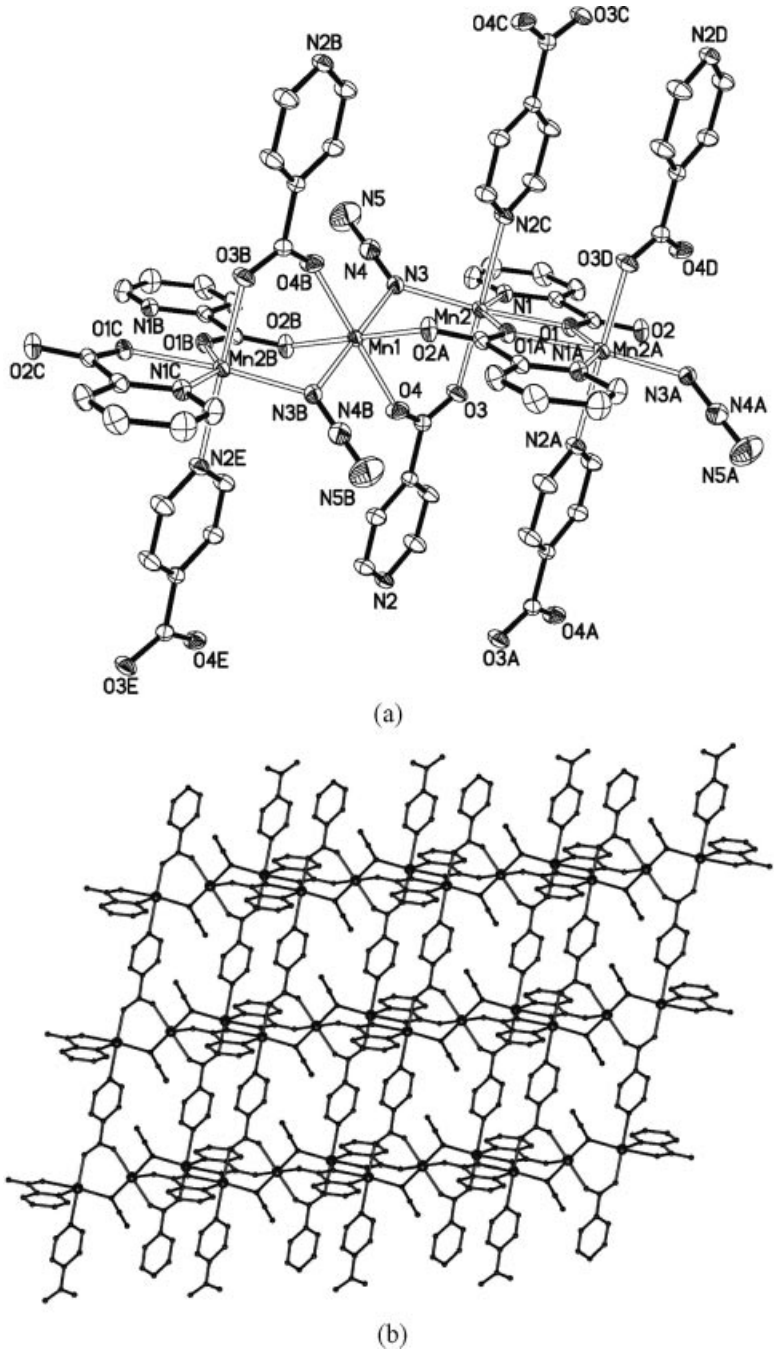

Figure 2. Views of the SBU (a) (symmetry codes, A: $-x, -y, -z$; B: $1-x, -y, -z$; C: $1+x, y, z$; D: $x, 1+y, z$; E: $-x, -1-y, -z$; F: $1-x, -1-y, -z$) and the 2D structure viewed along the $c$ axis (b) in **2**.

dimer coupling constant, $J'$ is the interdimer exchange interaction, and $z$ is the number of nearest neighbors of the dimer. The best fitting of the experimental magnetic data above 40 K to Equation 2 gives the following parameters: $g = 2.04(1)$, $J = -3.71(2)\ cm^{-1}$, $zJ' = -1.35(3)\ cm^{-1}$ and $R = 6.95\times10^{-7}$, where $R = \Sigma[(\chi_M T)_{obs} - (\chi_M T)_{calcd}]^2/\Sigma[(\chi_M T)_{obs}]^2$. The results are in good agreement with those reported for 2D $Mn^{II}$ complexes containing EE azide bridging networks [19,24] and confirm that the interactions mediated via the EE-azide and *cis*-bpt, and *syn-anti* carboxylate bridges are all AF interactions. However, it should be noted that the fitted values for $J$ and $zJ'$ are only qualitatively valid, because their comparability in magnitude does not meet the requirement of the molecular field approximation that $zJ'$ should be much smaller than $J$.[24]

The magnetic properties of **1** in the low-temperature region are more complicated: the susceptibility exhibits first an increase, then a decrease, and finally a rapid increase. Though the intradimer and interdimer AF interactions tend to align the $Mn^{II}$ spins in a compensated way to give a zero

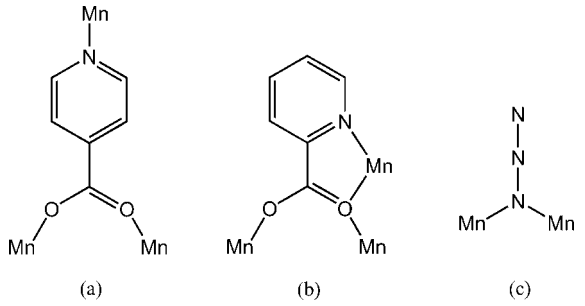

Figure 3. Coordination modes of ina (a), pa (b), and azide (c) in **2**.

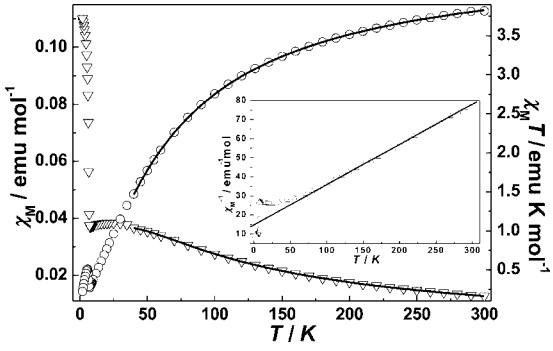

Figure 4. Temperature dependence of $\chi_M$ (▽) and $\chi_M T$ (○) for **1**. The dots are experimental values and the solid lines represent the best fits. Inset: temperature dependence of $\chi_M^{-1}$ (Δ) for **1**; the solid line represents the best fit of the Curie–Weiss law $\chi_M = C/(T - \theta)$.

residual moment, the low-temperature magnetic behavior of **1**, in which both $\chi_M$ and $\chi_M T$ increase sharply, suggests the existence of uncompensated residual spin moments and the occurrence of long-range weak F ordering.[25] The weak ferromagnetism may come from spin canting: the antiferromagnetically coupled local spins are not perfectly antiparallel but canted to each other, resulting in uncompensated residual spins.[19,24] The correlation between the residual spins may lead to long-range ordering. In **1**, the $\chi_M T$ values increase rapidly upon cooling below 7 K, indicating an F-like correlation. To further observe the magnetic transition at low temperature, FC (field-cooled) and ZFC (zero-field-cooled) magnetization measurements were carried out at 100 G below 30 K. As depicted in Figure 5a, compound **1** displays weak spontaneous magnetization that can be attributed to the onset of long-range ordering of the canted spins. The divergence of the ZFC and FC data below $T_c$ = 6.5 K indicates irreversibility arising from the formation of an ordered magnetic state. To confirm this phenomenon, FC magnetizations at different fields were applied, as the magnetic behavior of a weak ferromagnetism arising from spin canting is rather field-dependent. As expected, the field dependence of the FC magnetization was really observed (Figure 5b). The increase in the $\chi_M$ and $\chi_M T$ values become imperceptible at higher fields at the measured temperature, and these curves show no rise anymore at a magnetic field of 20 kG or above, indicating that the weak 3D AF interaction is overcome by the external field to result in an ordered F phase.

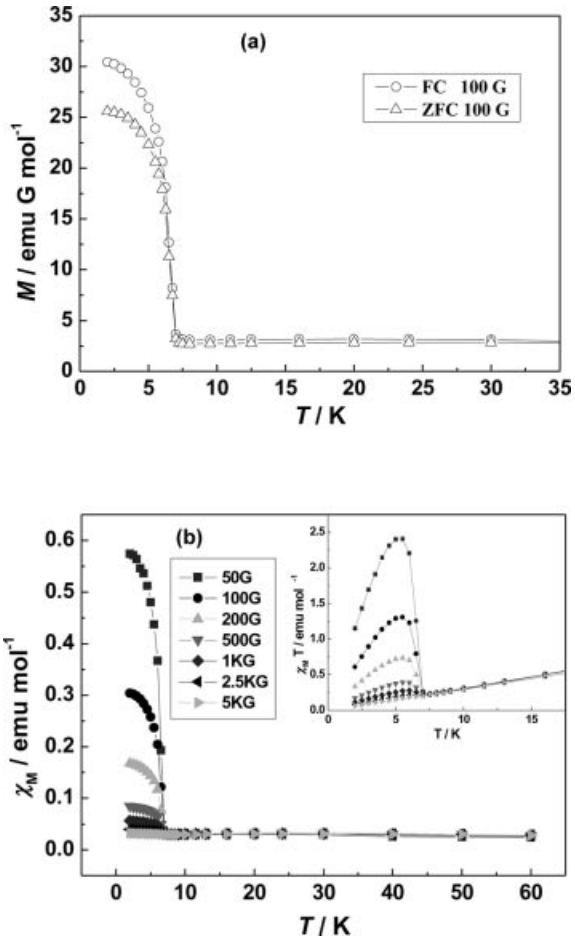

Figure 5. FC and ZFC magnetization plots at 100 G (a) and FC magnetizations in the forms of $\chi_M$ and $\chi_M T$ (inset) vs. $T$ plots at different fields (b) for **1**.

Further experimental evidence for the spin-canted weak ferromagnetism in **1** comes from field-dependent isothermal magnetization measurements at 2 K (Figure 6). In the high-field region ($H > 15$ kG), the magnetization increases linearly with the field, and the magnetization value (0.364 N$\beta$) at the highest field (70 kG) is far below the saturation value (5 N$\beta$) expected for $Mn^{II}$ species ($S$ = 5/2). This behavior is consistent with weak ferromagnetism due to spin canting.[25] A hysteresis loop was observed at 2 K with a remnant magnetization ($M_r$) of 0.005 N$\beta$ and a coercive field ($H_c$) of 820 G (Figure 6, inset), confirming the weak F ordering at low temperature.

It is well-known that spin canting may arise from single-ion magnetic anisotropy and/or antisymmetric exchange (Dzyaloshinsky–Moriya interaction).[26,27] Considering the isotropic character of the $Mn^{II}$ ion, it has been often suggested that the Dzyaloshinsky–Moriya interaction is the main source of spin canting in $Mn^{II}$ compounds,[27,28] which is consistent with the acentric *Fdd2* space group of **1**. This may suggest that spin canting has a significant contribution from acentric symmetry between the interacting spin centers.

### *Magnetic Properties of 2*

The $\chi_M T$ vs. $T$ plot for compound **2** is shown in Figure 7. The $\chi_M T$ value (4.01 emu K mol$^{-1}$) per $Mn^{II}$ at 300 K is somewhat lower than that expected for a high-spin $Mn^{II}$ ion (4.38 emu K mol$^{-1}$). The magnetic susceptibility above 50 K obeys the Curie–Weiss law with a Weiss constant, $\theta$ = –45.1(3) K, and a Curie constant, $C$ = 4.63(1) cm$^3$ mol$^{-1}$ K, indicating the presence of a dominant AF interaction (Figure 7, inset). On cooling, $\chi_M T$ falls to 1.67 emu K mol$^{-1}$ at 14 K and then rises at lower temperatures to reach a maximum value of 3.49 emu K mol$^{-1}$ at 2 K. This behavior is the typical of ferrimagnetism.

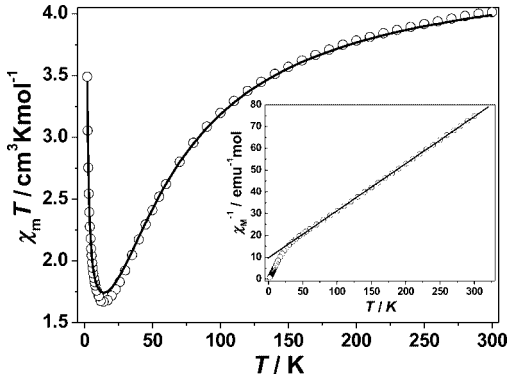

Figure 7. Plot of $\chi_M T$ vs. $T$ for **2**; the solid line represents the best fit of the data according to the theoretical model. Inset: temperature dependence of $\chi_M^{-1}$ for **2**; the solid line represents the best fit of the Curie–Weiss law $\chi_M = C/(T - \theta)$.

The ferrimagnetic behavior of **2** can be suggested to arise from intrachain magnetic interactions due to the fact that the $Mn^{II}$ chains are well separated by the ina bridges, in agreement with the absence of peaks in the real parts, $\chi'$, above 2 K in the curves of ac susceptibility (Figure S1). There are two kinds of magnetic exchange pathways in compound **2** with a $J_1J_1J_2$ repeating sequence according to the chain topology: one consists of two *syn-syn* $\mu_2$-1,3-carboxylate bridges and an EO azide bridge; the other consists of two $\mu_{1,1}$-O bridges from two $\mu_3$-carboxylate groups (Figure 8a). Due to noncompensation in spin moments within such a chain, the magnetic exchange through the former kind of bridges should be AF and that through the latter must be F. The exchanges alternate according to an AF-AF-F repeating sequence to produce the spin topology that corresponds to a (5, 5/2) ferromagnetic chain (Figure 8b). The field-dependent magnetization curve at 2 K indicates that the saturation magnetization per $Mn^{II}$ atom, achieved at 70 kG, is ca. 1.73 N$\beta$ (Figure 9). This value is consistent with an $S$ = 5/2 spin state per $[Mn_3(ina)_2(pa)_2(N_3)_2]$ basic unit, indicating that the $Mn^{II}$ chain is a typical (5, 5/2) topological ferrimagnetic chain with alternating AF-AF-F interaction.[25,29–31]

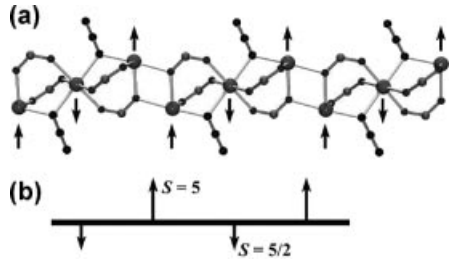

Figure 8. Bridging chain (a) and spin topology of the (5, 5/2) ferrimagnetic chain (b) in **2**.

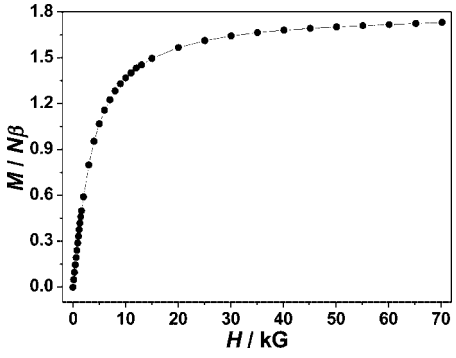

Figure 9. The field-dependent magnetization curve of **2** at 2 K.

To evaluate the exchanges, a nonlinear least-squares fitting of the theoretical expression proposed by Escuer et al.[31a,31b] to the experimental data has been performed by varying $g$, $J_1$, $J_2$ and minimizing the residual $R = [\Sigma(\chi_{obs}T - \chi_{calc}T)^2/\Sigma(\chi_{obs}T)^2]$. The best fit to the data above 2 K is achieved with $g$ = 2.02(1), $J_1$ = –6.21(8) cm$^{-1}$, $J_2$ = 0.22(1) cm$^{-1}$, $R = 1.10 \times 10^{-4}$. The $J_1$ value is associated with the AF exchange through the mixed carboxylate/azide (EO) bridges, in agreement with the previous observations in $Mn^{II}$ complexes,[8c,32] whereas the double $\mu_{1,1}$-O bridges mediate a ferromagnetic ($J_2$) interaction, which may arise from accidental orthogonality between magnetic orbitals around the metal ions.[29,33] Relative to the 3D complex of trinuclear SBUs $[Mn_3(4\text{-aba})_6]_n$ ($J_1$ = –4.5 cm$^{-1}$, $J_2$ = 0.38 cm$^{-1}$),[29] the AF is slightly stronger, while the F is slightly weaker, which may be attributed to the fact that $\mu_{1,1}$-azide bridges transmit stronger AF interactions with a large Mn1–N3–Mn2 angle [109.86(8)°], while $\mu_{1,1}$-O bridges transmit a weaker F exchange as the Mn2–O1–Mn2A angle [105.56(6)°] is larger than that in $[Mn_3(4\text{-aba})_6]_n$ (97.10°).

## Conclusions

Two manganese(II) coordination polymers, $[Mn_2(bpt)(pa)_2(N_3)]_n$ (**1**) and $[Mn_3(ina)_2(pa)_2(N_3)_2]_n$ (**2**), have been synthesized under solvothermal conditions. The bpt and pa ligands were generated in situ by cyclocondensation and hydrolysis of 2-pyridylamidrazone, respectively. Magnetic studies show that **1**, featuring a diamondoid network, exhibits spin-canting magnetism due to the lack of inversion centers between the interacting spin centers, while **2** shows a topological ferrimagnetic behavior in an AF-AF-F sequence, in which the magnetic exchanges through the mixed $\mu_{1,3}$-carboxylate/$\mu_{1,1}$-azide bridges and the double $\mu_{1,1}$-carboxylate bridges are AF and F, respectively.

## Experimental Section

**General Remarks:** The reagents and solvents employed were commercially available and used as received without further purification. The C, H, and N microanalyses were carried out with a Vario EL elemental analyzer. The FTIR spectra were recorded from KBr pellets in the range 400–4000 $cm^{-1}$ with a Bruker TENSOR 27 FTIR spectrometer. Magnetic susceptibility data of powder samples were collected in the temperature range 2–300 K with the use of a Quantum Design MPMS XL-7 SQUID magnetometer. The diamagnetic corrections were estimated from the Pascal's constants. 2-Pyridylamidrazone,[34] $MnC_2O_4{\cdot}3H_2O$,[17] and $Mn(ina)_2{\cdot}0.5EtOH{\cdot}0.5H_2O$[18] were synthesized according to the published procedures, and their identities were confirmed with NMR spectra or elemental analysis.

**Synthesis of $[Mn_2(bpt)(pa)_2(N_3)]_n$ (1):** A mixture of 2-pyridylamidrazone (0.272 g, 2 mmol), $MnC_2O_4{\cdot}3H_2O$ (0.197 g, 1 mmol), $NaN_3$ (0.130 g, 2 mmol), and 95% $C_2H_5OH$ (4 mL) was heated in a 15-mL Teflon-lined autoclave at 120 °C for 3 d, followed by slow cooling (5 °C $h^{-1}$) to room temperature. After the mixture was filtered and washed with 95% ethanol, yellow block crystals were collected and dried in air (0.247 g, yield ca. 80% based on Mn). $C_{24}H_{16}Mn_2N_{10}O_4$ (618.34): C 46.62, H 2.61, N 22.65; found C 46.62, H 2.65, N 22.66. FTIR: $\tilde{\nu}$ = 3852 (w), 3745 (w), 3387 (vs), 3077 (w), 2061 (s), 1575 (s), 1463 (m), 1389 (vs), 1145 (m), 1092 (m), 1043 (m), 848 (w), 806 (w), 759 (m), 700 (m), 637 (m), 528 (m) $cm^{-1}$.

**Synthesis of $[Mn_3(ina)_2(pa)_2(N_3)_2]_n$ (2):** The reaction was carried out by a method similar to that for **1**, using $Mn(ina)_2{\cdot}0.5EtOH{\cdot}0.5H_2O$ (0.331 g, 1 mmol) instead of $MnC_2O_4{\cdot}3H_2O$. After the mixture was filtered and washed with 95% ethanol, yellow block crystals were collected and dried in air (0.181 g, yield ca. 74% based on Mn). $C_{24}H_{16}Mn_3N_{10}O_8$ (737.28): C 39.10, H 2.19, N 19.00; found C 39.07, H 2.21, N 18.86. FTIR: $\tilde{\nu}$ = 3745 (w), 3393 (m), 3348 (m), 3068 (w), 2979 (w), 2622 (w), 2001 (s), 1620 (s), 1550 (vs), 1475 (m), 1395 (s), 1336 (m), 1292 (m), 1171 (w), 1092 (w), 1050 (m), 1010 (m), 850 (m), 770 (m), 698 (vs), 648 (w), 603 (w), 556 (w), 451 (m) $cm^{-1}$.

**X-ray Crystallographic Study:** Diffraction intensities for the compounds were collected at 293(2) K with a Bruker Apex CCD area-detector diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). Absorption corrections were applied by using the multiscan program SADABS.[35] The structures were solved with direct methods and refined with the full-matrix least-squares technique using the SHELXTL program package.[36] Anisotropic thermal parameters were applied to all the non-hydrogen atoms. The organic hydrogen atoms were generated geometrically (C–H: 0.96 Å). The absolute structure of **1** has been determined with a Flack parameter of 0.01(3).[37] Crystal data as well as details of data collection and refinement for the com-

# N–H Group Transfer and Oxidative Addition Chemistry Promoted by Isolable Bis(cyclopentadienyl)titanium Sandwich Complexes

**Tamara E. Hanna,[a] Emil Lobkovsky,[a] and Paul J. Chirik*[a]**

**Keywords:** Titanium / Oxidative addition / Cyclopentadienyl / Group transfer / Nitrogen

Addition of propylenimine (2-methylaziridine) to the bis(cyclopentadienyl)titanium sandwich complexes, $(\eta^5\text{-}C_5Me_4R)_2$-Ti (R = *i*Pr, $SiMe_3$), resulted in rapid [NH] group transfer followed by C–H activation of a cyclopentadienyl methyl group to yield the corresponding cyclometalated titanocene amido compounds. Exposure of these molecules to 4 atm of $H_2$ at 55 °C resulted in hydrogenolysis of the metal–carbon bond to form the titanium amido hydride compounds, $(\eta^5\text{-}C_5Me_4R)_2$-$Ti(NH_2)H$. Deuteriolysis with DCl gas confirmed exclusive cyclometalation from the positions adjacent to the isopropyl and trimethylsilyl substituent. Oxidative addition of the N–H bonds of amines has also been observed. Addition of $NH_3$ to either $(\eta^5\text{-}C_5Me_4SiMe_3)_2Ti$ or $(\eta^5\text{-}C_5Me_4iPr)_2Ti$ yielded the corresponding titanocene amido hydrides along with the titanocene(III) amides, $(\eta^5\text{-}C_5Me_4R)_2TiNH_2$, arising from formal deprotonation by unreacted sandwich from the putative titanocene ammonia complex.

## Introduction

The synthesis of isolable, thermally stable bis(cyclopentadienyl)titanium sandwich complexes by introduction of sterically demanding ring substituents has offered the rare opportunity to explore the fundamental coordination chemistry of a well-defined divalent titanium center.[1,2] Our laboratory has discovered that several complexes of the general formula, $(\eta^5\text{-}C_5Me_4R)_2Ti$ (R = *i*Pr, *t*Bu, $SiMe_3$, $SiMe_2Ph$) coordinate dinitrogen upon cooling in solution (Figure 1).[3] Both the maximum temperature of dinitrogen coordination[3] and the number of $N_2$ ligands[4] are sensitive to the nature of the ring substituents, where smaller, electron-withdrawing groups increase the azophilicity of the titanium. Unusual examples of titanocene monocarbonyl complexes have also been prepared by careful addition of CO to the

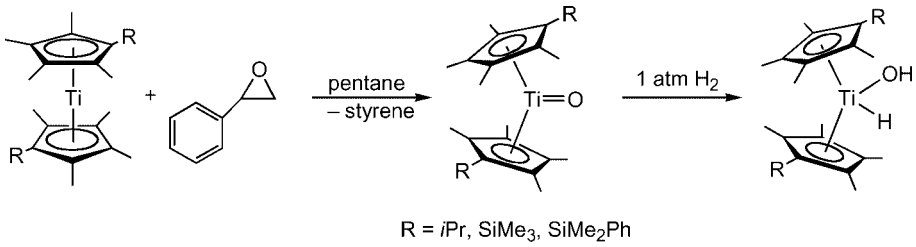

Figure 2. Synthesis and hydrogenation of bis(cyclopentadienyl)titanium oxo complexes.

corresponding sandwich (Figure 1).[4] At low temperature, these molecules coordinate $N_2$ to yield mixed carbonyl-dinitrogen compounds.[4]

Subsequent studies have focused on the oxidation of the isolable bis(cyclopentadienyl)titanium sandwiches with the goal of generating titanium ligand multiple bonds that do not require stabilization by coordination of additional base. Our initial studies have focused on the preparation of monomeric, base-free titanocene oxo complexes. Treatment of $(\eta^5\text{-}C_5Me_4R)_2Ti$ [R = *i*Pr (**1**), $SiMe_3$ (**2**), $SiMe_2Ph$ (**3**)] with styrene oxide induced oxygen atom abstraction affording the desired terminal oxo complexes, $(\eta^5\text{-}C_5Me_4R)_2Ti{=}O$, and free olefin (Figure 2).[5] While the isopropyl-substituted variant **1=O** is only stable in [$D_6$]benzene for hours at 23 °C, the silylated compounds **2=O** and **3=O** were isolated in the solid state and in the case of **3=O** characterized by X-ray diffraction. The relative thermal stability of these compounds contrasts $(\eta^5\text{-}C_5Me_5)_2Ti{=}O$, which requires the presence of a Lewis base such as 4-phenylpyridine for observation and isolation.[6,7]

Exposure of each of the monomeric, base-free titanocene oxo complexes to $H_2$ results in rapid hydrogenation of the Ti=O bond to furnish the corresponding hydroxy hydride derivatives, $(\eta^5\text{-}C_5Me_4R)_2Ti(OH)H$. This behavior highlights the benefits of the base-free species as addition of dihydrogen to $(\eta^5\text{-}C_5Me_5)_2Ti(O)L$ (L = pyridine) yields a mixture of products from which $(\eta^5\text{-}C_5Me_5)_2Ti(OH)_2$ and $(\eta^5\text{-}C_5Me_5)_2Ti(OH)H$ were identified.[8] The pressure dependence on the rate of hydrogenation of **2=O** established a first order dependence on $H_2$.[5] This rate law, in combination with the measurement of a normal, primary kinetic isotope effect of 2.7(3) at 23 °C, supports a 1,2-addition pathway for hydrogenation of the Ti=O bond. Similar results were obtained for hydrosilylation of **2=O** to yield the corresponding hydrido titanocene siloxide. In contrast, C–H bonds of saturated and unsaturated hydrocarbons have proven unreactive, most likely a result of the strong Ti=O π-bond.

Inspired by these observations, the synthesis of the corresponding "parent imido" complexes, $(\eta^5\text{-}C_5Me_4R)_2Ti{=}NH$, was targeted. Many isolable titanium imides have been reported and their chemistry extensively studied,[9] especially with respect to C–H activation.[10] Most of these compounds contain sterically demanding nitrogen substituents (e.g. *t*Bu, aryl, $SiMe_3$), which impart stability. Parent imido derivatives, $L_nTi{=}NH$, are by comparison relatively rare[11] despite their potential intermediacy in the preparation of titanium nitride thin films.[12] In this contribution, we describe our efforts to prepare parent titanocene imido derivatives by [NH] group transfer and also explore N–H oxidative addition of amines. The stability of the transient parent imides is also compared with isolable titanocene oxo compounds.

## Results and Discussion

Our synthetic approach for the preparation of $(\eta^5\text{-}C_5Me_4R)_2Ti{=}NH$ compounds was inspired by the [O]-atom transfer chemistry used to prepare the corresponding oxo derivatives. Treatment of a [$D_6$]benzene solution of **1** with a stoichiometric quantity of propylenimine yielded one equivalent of propylene and an initial equimolar mixture of two new $C_1$-symmetric titanium products, inconsistent with formation of the desired imido compound.

Over the course of one week at 23 °C, the mixture of diastereomers (vide infra) converts to a single thermodynamic product. The major isomer exhibits two doublets centered at $\delta$ = 1.78 and 2.90 ppm, indicating cyclometalation of one of the cyclopentadienyl methyl groups. Similar resonances centered at $\delta$ = 1.94 and 2.82 ppm are observed for the minor thermodynamic isomer. In addition, both compounds exhibit N–H resonances that integrate to two protons, consistent with formation of two diastereomers of the cyclometalated amide complex **1-CM-NH$_2$** [Equation (1)].

A similar outcome was observed with the silylated titanium sandwich, **2**. Addition of one equivalent of propylenimine again resulted in rapid evolution of one equivalent of propylene and formation of two $C_1$-symmetric titanocene compounds. In this case, a 3:1 mixture of diastereomers of the cyclometalated titanium amide complex **2-CM-NH$_2$** was formed [Equation (1)]. No change in the ratio of the mixture of isomers was observed after standing for one week at 23 °C. Thermolysis at 65 °C over the course of days resulted in gradual decomposition.

The assignment of the stereochemistry of the observed diastereomers of **1-CM-NH$_2$** and **2-CM-NH$_2$** was accomplished by a combination of two-dimensional (NOESY, HSQC, HMBC) NMR experiments. Complete details are reported in the Supporting Information. Observation of cyclometalated titanocene amide complexes following addition of propylenimine suggests that the desired parent imido compounds, $(\eta^5\text{-}C_5Me_4R)_2Ti{=}NH$, are formed transiently but undergo rapid 1,2-addition of a C–H bond from

(1)

the diastereotopic cyclopentadienyl methyl groups adjacent to the isopropyl or trimethylsilyl substituent. The conversion of the kinetic mixture of diastereomers of **1-CM-NH$_2$** to a sole thermodynamic isomer demonstrates that the C–H activation reaction is reversible. In the case of **2-CM-NH$_2$** where the ratio of diastereomers remains constant, we are unable to distinguish between the kinetic and thermodynamic preferences for methyl group cyclometalation.

To determine whether bis(cyclopentadienyl)titanium imido complexes bearing larger nitrogen substituents would exhibit improved thermal stability, ($\eta^5$-$C_5Me_4SiMe_3$)$_2$-Ti=NSiMe$_3$ (**2=NSiMe$_3$**) was prepared by addition of $Me_3SiN_3$ to **2** [Equation (2)]. As was observed with [$\eta^5$-$C_5H_3$-1,3-($SiMe_3$)$_2$]$_2$Ti=NSiMe$_3$,[13] the [D$_6$]benzene $^1$H and $^{13}$C NMR spectra of **2=NSiMe$_3$** exhibit the number of resonances expected for a $C_2$-symmetric imide complex. It should be noted that in the solid state, [$\eta^5$-$C_5H_3$-1,3-($SiMe_3$)$_2$]$_2$Ti=NSiMe$_3$ contains a near linear Ti=N–Si linkage.[13]

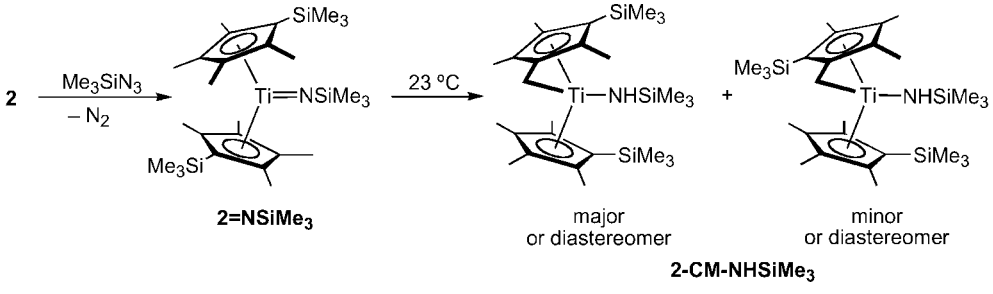
Allowing [D$_6$]benzene solutions of **2=NSiMe$_3$** to stand at 23 °C for days resulted in cyclometalation of the cyclopentadienyl methyl groups both adjacent and distal to the [SiMe$_3$] substituent. All four diastereomers were detected by NMR spectroscopy, but only two formed in appreciable quantities. The major isomer was identified as one of the diastereomers arising from distal methyl group cyclometalation while the other is one of the diastereomers from adjacent methyl group C–H activation. The two minor diastereomers account for less than 10% of the mixture. Because the presence of four isomeric $C_1$-symmetric titanocene compounds produces complex NMR spectra with considerable peak overlap, the stereochemistry of each diastereomer could not be reliably assigned.

Confirmation of the regiochemistry of cyclometalation was provided by treating the mixture of products with DCl. Analysis of the resulting isotopomers of **2-Cl$_2$** established deuterium incorporation into both methyl positions. Importantly, no deuterium incorporation into the [SiMe$_3$] substituents was observed, confirming that these positions do not undergo C–H activation.

The reactivity of **1-CM-NH$_2$** and **2-CM-NH$_2$** was also explored. Exposure of the kinetic mixture of diastereomers of **1-CM-NH$_2$** to 4 atm of $H_2$ resulted in slow hydrogenation to give the hydrido titanocene amido complex ($\eta^5$-$C_5Me_4iPr$)$_2$Ti($NH_2$)H [**1-(NH$_2$)H**] upon heating to 55 °C for three days. Performing the experiment with $D_2$ gas yielded the deuterated isotopologue with the isotopic labels incorporated into the appropriate cyclopentadienyl methyl groups and the titanium-hydride (deuteride). Incorporation of the isotopic label was also observed in the N–H position, consistent with reversible 1,2-addition and elimination sequences. Similar hydrogenation chemistry was observed with **2-CM-NH$_2$** to yield ($\eta^5$-$C_5Me_4SiMe_3$)$_2$Ti($NH_2$)H [**2-(NH$_2$)H**] (Figure 3).

Intramolecular hydrogen exchange was explored with **2-(NH$_2$)H** by EXSY NMR spectroscopy. No crosspeaks indicative of exchange were observed up to temperatures of 90 °C with mixing times of 700 ms. Intermolecular exchange was probed by addition of four atmospheres of $D_2$ gas to a [D$_6$]benzene solution of **2-(NH$_2$)H** and no isotopic incorporation was observed over the course of days at 23 °C. The failure to observe isotopic exchange at ambient temperature demonstrates that the barrier for 1,2-elimination of $H_2$ is higher for **2-(NH$_2$)H** than **2-(OH)H**.[5]

The isolation of the thermally stable bis(cyclopentadienyl)titanium amido hydrides **1-(NH$_2$)H** and **2-(NH$_2$)H** suggested that these compounds could also be prepared by N–H oxidative addition of ammonia.[14,15] Addition of one equivalent of $NH_3$ gas to a [D$_6$]benzene solution of **1** yielded only small amounts (about 10%) of the desired amido hydride **1-(NH$_2$)H** (Figure 4). The major product



(2)

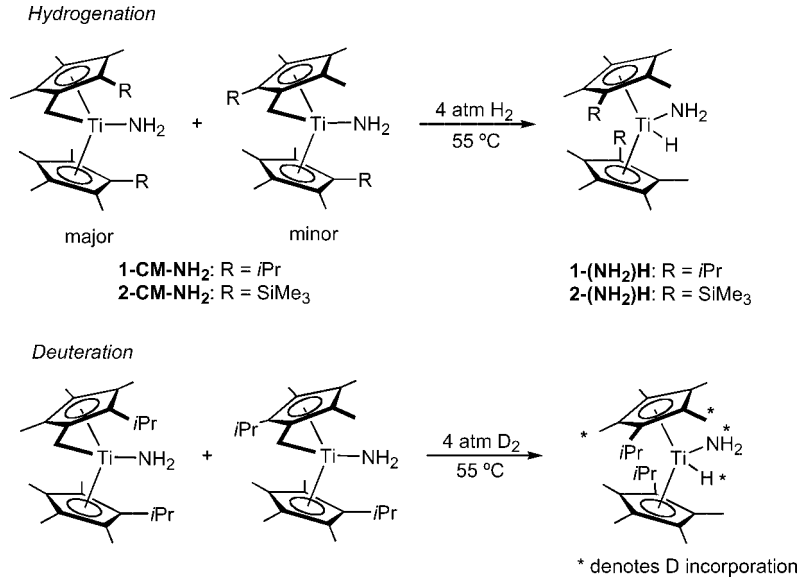

Figure 3. Hydrogenation and deuteration of bis(cyclopentadienyl)titanium cyclometalated amide complexes.

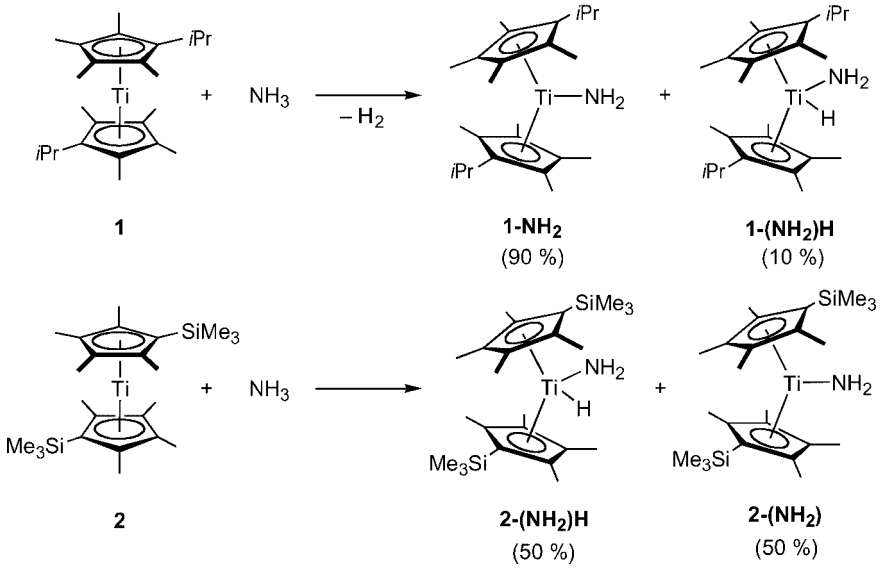

Figure 4. Ammonia addition to **1** and **2**.

was identified as the paramagnetic titanium(III) amido complex, $(\eta^5\text{-}C_5Me_4iPr)_2Ti(NH_2)$ (**1-NH$_2$**).[16]

For the silylated sandwich **2**, ammonia addition yielded approximately 50% of **2-(NH$_2$)H** along with an NMR-silent titanium compound, assigned as **2-NH$_2$**. This mixture was formed reproducibly and was unchanged when either an excess or stoichiometric quantity of $NH_3$ was added. The identity of **2-NH$_2$** was established by treatment with PhSSPh to yield diamagnetic $(\eta^5\text{-}C_5Me_4SiMe_3)_2Ti(NH_2)$-(SPh) [**2-(NH$_2$)(SPh)**].

Several additional experiments were performed to elucidate the origin of **1-NH$_2$**. Inverting the order of addition whereby **1** was added to a saturated [$D_6$]benzene solution of ammonia increased the amount of **1-(NH$_2$)H** formed. Treatment of **1** with a slightly larger amine, $MeNH_2$, produced only the oxidative addition product, $(\eta^5\text{-}C_5Me_4iPr)_2$-Ti(NHMe)H [**1-(NHMe)H**] (Figure 5). No reaction was observed upon addition of $tBuNH_2$, $PhNH_2$ or $Me_2NH$.

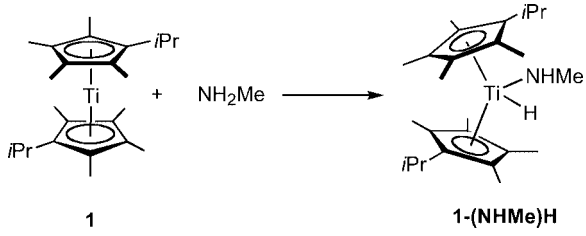

Figure 5. Methylamine addition to **1**.

Based on the experimental data, a mechanism for the formation of **1-NH$_2$** was proposed and is presented in Figure 6. Addition of ammonia to the sandwich forms the transient ammonia complex **1-NH$_3$**, which in the presence

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

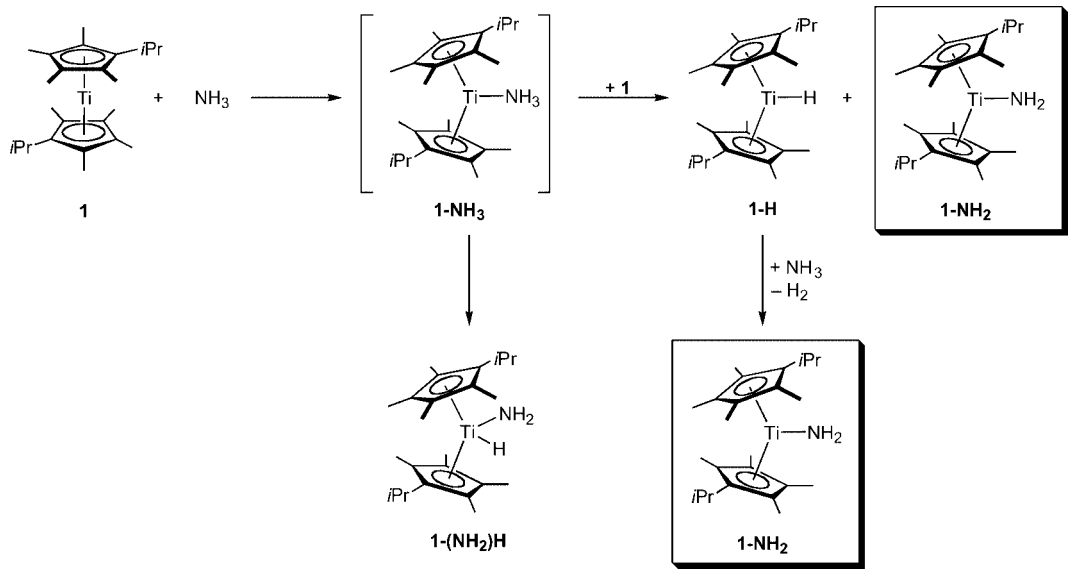

Figure 6. Proposed mechanism for the formation of **1-NH$_2$** from $NH_3$ addition to **1**.

of unreacted **1** undergoes formal deprotonation to yield **1-NH$_2$** and the titanium(III) hydride **1-H**. Increased amounts of the N–H oxidative addition product **1-(NH$_2$)H** from the inverse addition experiment support this initial pathway. Furthermore, the observation of sole N–H oxidative addition chemistry upon $MeNH_2$ addition to **1** is also consistent with this proposal, as bimolecular reactions are less likely with a more hindered amine. Addition of ammonia to **1-H** liberates dihydrogen (experimentally observed) and yields additional **1-NH$_2$** (Figure 6). The feasibility of this reaction has been confirmed experimentally by treatment of isolated **1-H** (vide infra) with ammonia.[16]

The proposed intermediacy of **1-H** during formation of **1-NH$_2$** prompted exploration of the hydrogenation chemistry of **1**. Addition of four atmospheres of $H_2$ to **1** forms a bright orange [$D_6$]benzene solution signaling formation of diamagnetic **1-H$_2$**. The $^1$H NMR spectrum of **1-H$_2$** suggests a dynamic process involving the cyclopentadienyl methyl groups in solution as these resonances are broadened while those for the isopropyl substituents remain sharp. Monitoring the addition of $D_2$ gas to **1** by $^2$H NMR spectroscopy revealed rapid incorporation of the isotopic label into both methyl positions of **1-D$_2$** (Figure 7), consistent with reversible cyclometalation on the NMR time scale. Much like ($\eta^5$-$C_5Me_5)_2TiH_2$,[17] removal of the dihydrogen atmosphere from **1-H$_2$** resulted in rapid conversion to the titanium(III) monohydride **1-H**, demonstrating that the introduction of the isopropyl substituent into the cyclopentadienyl rings offers little increased stability for the corresponding titanocene dihydride.

The reactivity of the titanium sandwich **1** with heterocycles was also explored. Our laboratory has previously demonstrated that the $\eta^9$,$\eta^5$-bis(indenyl)zirconium sandwich complex, [$\eta^9$-$C_9H_5$-1,3-$(SiMe_3)_2$][$\eta^5$-$C_9H_5$-1,3-$(SiMe_3)_2$]Zr, promotes the C–H activation of 4-(dimethylamino)pyridine

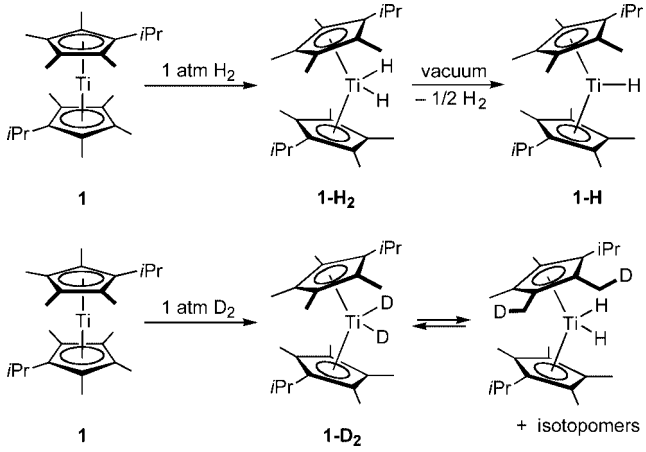

Figure 7. Addition of dihydrogen and dideuterium to **1**.

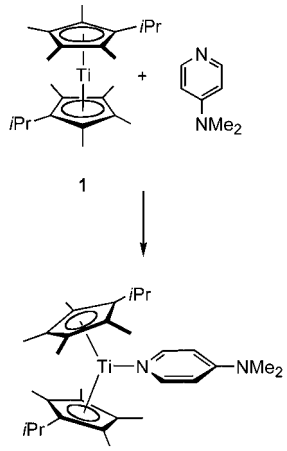
(DMAP) to yield the corresponding zirconium aryl hydride compound.[18] We were curious if the less reducing first row transition metal was sufficiently potent to promote C–H activation or if a stable titanium(II) ligand complex would form. If the later scenario was favored, the spin state ($S$ = 0 or 1) of the resulting bent titanocene derivative was of interest. With the exception of dicarbonyl and dinitrogen derivatives, bis(cyclopentadienyl)titanium(II) ligand complexes are relatively rare. Examples include ($\eta^5$-$C_5R_5)_2$Ti(bipy) (R = H, Me; bipy = bipyridine),[19] ($\eta^5$-$C_5H_5)_2$Ti(pyrrole)$_2$,[20] ($\eta^5$-$C_5H_5)_2$Ti$(PMe_3)_2$[21] and ($\eta^5$-$C_5H_5)_2$Ti$(PF_3)_2$.[22] As expected for coordinatively saturated complexes, all of these compounds, with the exception of ($\eta^5$-$C_5Me_5)_2$Ti(bipy), are diamagnetic.

Stirring a diethyl ether solution of **1** with a stoichiometric quantity of DMAP followed by recrystallization at –35 °C furnished red rods identified as the paramagnetic DMAP complex **1-DMAP** [Equation (3)]. A solid state magnetic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

moment of 2.7 $\mu_B$ was determined by magnetic susceptibility balance at 23 °C and is consistent with the spin only value for two unpaired electrons. A slightly lower value of 2.3 $\mu_B$ was measured by Evans method in [$D_6$]benzene solution but is also consistent with an $S = 1$ titanium(II) center.



(3)

The solid-state structure of **1-DMAP** was determined by X-ray diffraction and a representation is presented in Figure 8. The overall molecular geometry is typical for a group 4 bent metallocene derivative with an idealized $C_2$ axis of molecular symmetry defined by the Ti(1)–N(1) bond. The plane of the DMAP ring lies in the titanocene wedge and is nearly coplanar with the dimethylamino group. The metrical parameters for the coordinated heterocycle are similar to free DMAP,[23] indicating little reduction by the titanium center. Attempts to induce C–H activation by thermolysis of **1-DMAP** have been unsuccessful. Warming [$D_6$]benzene solutions of the compound to 95 °C for 3 d produced no observable change by $^1$H NMR spectroscopy.

### Comparison of Ti=E Species to Promote 1,2-Addition Chemistry

Our laboratory has synthesized a family of substituted bis(cyclopentadienyl)titanium oxo,[5] imido, and transient alkylidene compounds.[13] The propensity of each class of Ti=E (E = O, NR, $CR_2$) linkage to promote the C–H activation of the cyclopentadienyl methyl groups provides insights into the relative stability of each type of titanium element (or group) multiple bond. Within the series of imides, the nitrogen substituent influences the rate of 1,2-addition as the more sterically protected [Ti=N$SiMe_3$] and [Ti=N*Ar*] (*Ar* = substituted aryl) linkages are isolable[13] while [Ti=NH] species have yet to be observed directly.

The identity of the titanium–ligand multiple bond also dictates the rate of C–H activation by 1,2-addition. Whereas the transient alkylidene, [[$\eta^5$-$C_5H_3$-1,3-($SiMe_3$)$_2$]$_2$-Ti=CH($SiMe_3$)], has proven too reactive to observe, similar imide complexes have been isolated and shown to promote C–H activation.[13] In contrast, the titanocene oxo derivatives are reluctant to activate C–H bonds. These differences are most likely a result of the strength of the Ti=E π-bond, where the Ti=O fragment is expected to be the strongest and Ti=$CR_2$ the weakest. Simply comparing O–H and C–H bond strengths of small molecules such as water and $Ph_2CH_2$ and assuming the overall entropy change in the 1,2-addition reaction is approximately –30 eu, the Ti=O π bond strength can be estimated as approximately 30 kcal/mol stronger than that for Ti=$CR_2$. Using the N–H bond strength of ammonia in a similar approximation places the Ti=NH π bond strength only 10 kcal/mol weaker than the oxo and accounts for the stability of certain variants of these compounds but also the ability to undergo intramolecular 1,2-addition of C–H bonds.

## Concluding Remarks

Treatment of isolable bis(cyclopentadienyl)titanium sandwich complexes with propylenimine resulted in [NH] group transfer followed by rapid C–H activation of a cyclopentadienyl methyl group to yield cyclometalated titanocene amido compounds. These observations suggest that the relative strength of the Ti=E π bond (E = O > NR > $CR_2$) determines the propensity of the titanium compound to participate in 1,2-addition of C–H bonds. Exposure of the resulting cyclometalated titanocene amido compounds to dihydrogen at 55 °C yielded the corresponding amido hydride complexes. For the silylated derivative, ($\eta^5$-$C_5Me_4SiMe_3$)$_2$Ti($NH_2$)H, this compound was also prepared by oxidative addition of an N–H bond of ammonia along with ($\eta^5$-$C_5Me_4SiMe_3$)$_2$Ti$NH_2$. Similar chemistry was observed with the more open titanocene sandwich, ($\eta^5$-$C_5Me_4$*i*Pr)$_2$Ti, as significant quantities of the titanium(III) amide complex, ($\eta^5$-$C_5Me_4$*i*Pr)$_2$Ti$NH_2$, were obtained upon addition of $NH_3$. Subsequent experiments changing the order of addition and the size of the amine support a pathway involving deprotonation from coordinated ammonia by free bis(cyclopentadienyl)titanium sandwich.

## Experimental Section

**General Considerations:** All air- and moisture-sensitive manipulations were carried out using standard high vacuum line, Schlenk or cannula techniques or in an M. Braun inert atmosphere drybox containing purified nitrogen. The Braun drybox was equipped with a cold well designed for freezing samples in liquid nitrogen. Solvents for air- and moisture-sensitive manipulations were dried and deoxygenated using literature procedures.[24] Toluene, benzene, pentane and heptane were further dried by distillation from "titanocene".[25] Deuterated solvents for NMR spectroscopy were distilled from sodium metal under an atmosphere of argon and stored over 4-Å molecular sieves. Argon and hydrogen gas were purchased from Airgas Incorporated and passed through a column containing manganese oxide on vermiculite and 4-Å molecular sieves before admission to the high vacuum line. DMAP was recrystallized from pentane and dried under vacuum. Propylenimine was initially dried with 4-Å molecular sieves and distilled immediately before use. The compounds ($\eta^5$-$C_5Me_4$*i*Pr)$_2$Ti($N_2$)$_2$ [**1-($N_2$)$_2$**],[3] ($\eta^5$-$C_5Me_4SiMe_3$)$_2$-Ti (**2**)[2] and ($\eta^5$-$C_5Me_4SiMe_2Ph$)$_2$Ti($N_2$) [**3-($N_2$)**][4] were prepared according to literature procedures.

$^1$H NMR spectra were recorded on a Varian Inova 400 Spectrometer operating at 399.860 MHz. All chemical shifts are reported relative to $SiMe_4$ using $^1$H (residual) chemical shifts of the solvent as a secondary standard. $^2$H and $^{13}$C NMR spectra were recorded on a Varian Inova 500 Spectrometer operating at 76.848 and 125.716 MHz, respectively. $^2$H and $^{13}$C chemical shifts are reported relative to $SiMe_4$ using chemical shifts of the solvent as a secondary standard.

Single crystals suitable for X-ray diffraction were coated with polyisobutylene oil in a drybox, transferred to a nylon loop and then quickly transferred to the goniometer head of a Bruker X8 APEX2 diffractometer equipped with a molybdenum X-ray tube ($\lambda$ = 0.71073 Å). Preliminary data revealed the crystal system. A hemisphere routine was used for data collection and determination of lattice constants. The space group was identified and the data were processed using the Bruker SAINT+ program and corrected for absorption using SADABS. The structures were solved by direct methods (SHELXS) completed by subsequent Fourier synthesis and refined by full-matrix least-squares procedures. CCDC-628974 (for **1-DMAP**) contains supplementary crystallographic data. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Elemental analyses were performed at Robertson Microlit Laboratories, Inc., in Madison, NJ.

**Preparation of ($\eta^5$-$C_5Me_4$iPr)($\eta^5$-$C_5Me_3$-$\eta^1$-2-$CH_2$-$CHMe_2$)Ti-$NH_2$ (1-CM-$NH_2$):** A J. Young NMR tube was charged with 0.033 g (0.077 mmol) of **1-($N_2$)$_2$** and approximately 0.5 mL of [$D_6$]-benzene were added. On the high vacuum line, the tube was degassed at liquid nitrogen temperature and 45 Torr of propylenimine (0.077 mmol) were added with a 31.6 mL calibrated gas bulb. The tube was shaken and thawed, resulting in an immediate colour change from dark red to bright red. The solvent was removed to yield **1-CM-$NH_2$** as a red oil. $^1$H NMR ([$D_6$]benzene, major thermodynamic isomer): $\delta$ = 1.18 (d, *J* = 6 Hz, 3 H, $C_5Me_3$-$\eta^1$-2-$CH_2$-CH*$Me_2$*), 1.22 (d, *J* = 6 Hz, 3 H, $C_5Me_3$-$\eta^1$-2-$CH_2$-CH*$Me_2$*), 1.22 (d, *J* = 6 Hz, 6 H, $C_5Me_4$CH*$Me_2$*), 1.46 (s, 3 H, $C_5$*$Me_3$*-$\eta^1$-2-$CH_2$-$CHMe_2$), 1.66 (s, 3 H, $C_5$*$Me_3$*-$\eta^1$-2-$CH_2$-$CHMe_2$), 1.67 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 1.74 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 1.78 (d, *J* = 3 Hz, 1 H, $C_5Me_3$-$\eta^1$-2-C*$H_2$*-$CHMe_2$), 1.82 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 1.91 (s, 3 H, $C_5$*$Me_3$*-$\eta^1$-2-$CH_2$-$CHMe_2$), 2.04 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 2.50 (m, 1 H, $C_5Me_3$-$\eta^1$-2-$CH_2$-C*H*$Me_2$), 2.66 (m, 1 H, $C_5Me_4$C*H*$Me_2$), 2.90 (d, *J* = 3 Hz, 1 H, $C_5Me_3$-$\eta^1$-2-C*$H_2$*-$CHMe_2$), 4.90 (br. s, 2 H, N*$H_2$*) ppm. $^1$H NMR ([$D_6$]benzene, minor thermodynamic isomer): $\delta$ = 1.12 (d, *J* = 6 Hz, 3 H, $C_5Me_3$-$\eta^1$-2-$CH_2$-CH*$Me_2$*), 1.13 (d, *J* = 6 Hz, 3 H, $C_5Me_3$-$\eta^1$-2-$CH_2$-CH*$Me_2$*), 1.24 (d, *J* = 6 Hz, 6 H, $C_5Me_4$CH*$Me_2$*), 1.63 (s, 3 H, $C_5$*$Me_3$*-$\eta^1$-2-$CH_2$-$CHMe_2$), 1.73 (s, 3 H, $C_5$*$Me_3$*-$\eta^1$-2-$CH_2$-$CHMe_2$), 1.75 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 1.78 (s, 3 H, $C_5$*$Me_3$*-$\eta^1$-2-$CH_2$-$CHMe_2$), 1.80 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 1.85 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 1.94 (d, *J* = 3 Hz, 1 H, $C_5Me_3$-$\eta^1$-2-C*$H_2$*-$CHMe_2$), 2.10 (s, 3 H, $C_5$*$Me_4$*$CHMe_2$), 2.55 (m, 1 H, $C_5Me_3$-$\eta^1$-2-$CH_2$-C*H*$Me_2$), 2.67 (m, 1 H, $C_5Me_4$C*H*$Me_2$), 2.82 (d, *J* = 3 Hz, 1 H, $C_5Me_3$-$\eta^1$-2-C*$H_2$*-$CHMe_2$), 4.85 (br. s, 2 H, N*$H_2$*) ppm. $^{13}$C NMR ([$D_6$]benzene): $\delta$ = 11.16, 11.21, 11.69, 11.84, 11.96, 12.06, 12.09, 12.14, 12.18, 12.26, 12.88, 13.64, 13.90 (Me), 21.01, 22.22, 23.14, 23.22, 23.26, 23.43, 26.33, 27.31, 27.37, 27.55, 27.87, 30.48 (*C*$HMe_2$/CH*$Me_2$*), 69.56, 70.05 (*C*$H_2$), 110.67, 111.25, 114.84, 115.18, 116.07, 117.42, 117.90, 117.98, 118.17, 118.42, 118.91, 119.04, 120.78, 121.24, 122.32, 123.35, 123.55, 128.45, 132.21, 137.51 (Cp) ppm. H, $C_5Me_3$-η$^1$-2-C$H_2$-SiMe$_3$), 1.87 (s, 3 H, $C_5Me_4$SiMe$_3$), 1.90 (s, 3 H, $C_5Me_4$SiMe$_3$), 1.94 (s, 3 H, $C_5Me_3$-η$^1$-2-CH$_2$-SiMe$_3$), 2.06 (s, 3 H, $C_5Me_4$SiMe$_3$), 2.81 (d, $J$ = 3 Hz, 1 H, $C_5Me_3$-η$^1$-2-C$H_2$-SiMe$_3$), 4.79 (br. s, 2 H, N$H_2$) ppm. $^{13}$C NMR ([D$_6$]benzene): $\delta$ = 2.05, 2.49, 3.18 (Si$Me_3$), 10.94, 11.08, 11.18, 11.39, 11.57, 12.40, 12.52, 12.73, 14.25, 14.56, 14.78, 14.96, 15.06, 15.35 (Me), 69.89, 70.04 ($CH_2$), 107.11, 109.03, 114.57, 117.27, 118.50, 120.31, 120.66, 123.37, 123.93, 124.33, 125.17, 125.42, 127.62, 128.24, 128.63, 128.96, 130.29, 130.77, 131.25, 135.26 (Cp) ppm. IR (KBr): $\tilde{\nu}$ = 3377, 3453 (NH$_2$) cm$^{-1}$.

**Preparation of (η$^5$-C$_5$Me$_4$iPr)$_2$Ti(NH$_2$)(H) [1-(NH$_2$)(H)]:** A J. Young NMR tube was charged with 0.033 g (0.077 mmol) of **1-CM-NH$_2$** and approximately 0.5 mL of [D$_6$]benzene were added. On the high vacuum line, the tube was degassed at –196 °C and 1 atm of $H_2$ was added. The tube was then heated to 55 °C for three days resulting in a colour change to orange. The solvent was removed in vacuo to yield 0.029 g (96.7%) of **1-(NH$_2$)(H)** as an orange solid. $^1$H NMR ([D$_6$]benzene): $\delta$ = 1.32 (d, $J$ = 3 Hz, 6 H, $C_5Me_4CH$$Me_2$), 1.34 (d, $J$ = 3 Hz, 6 H, $C_5Me_4CH$$Me_2$), 1.78 (s, 6 H, $C_5$$Me_4$CHMe$_2$), 1.89 (s, 6 H, $C_5$$Me_4$CHMe$_2$), 1.91 (s, 6 H, $C_5$$Me_4$CHMe$_2$), 1.92 (s, 6 H, $C_5$$Me_4$CHMe$_2$), 2.13 (s, 1 H, Ti-$H$), 2.88 (m, 2 H, $C_5Me_4C$$H$Me$_2$), 5.88 (br. s, 2 H, N$H_2$) ppm. $^{13}$C NMR ([D$_6$]benzene): $\delta$ = 11.36, 12.05, 12.38, 12.58 (Me), 23.15, 23.31, 28.29 ($C$HMe$_2$/CH$Me_2$), 113.24, 114.21, 114.28, 115.34, 126.71 (Cp) ppm. IR (KBr): $\tilde{\nu}$ = 1644 (Ti–H), 3361, 3435 (NH$_2$) cm$^{-1}$.

**Preparation of (η$^5$-C$_5$Me$_4$SiMe$_3$)$_2$Ti(NH$_2$)(H) [2-(NH$_2$)(H)]:** This molecule was prepared in an identical manner to **1-(NH$_2$)(H)** with 0.027 g (0.0621 mmol) of **2-CM-NH$_2$**, approximately 0.5 mL of [D$_6$]benzene and one atmosphere of dihydrogen to afford **2-(NH$_2$)-(H)** as an orange solid after 3 d of heating. $C_{24}H_{45}NSi_2Ti$ (451.63): calcd. C 63.82, H 10.04, N 3.10; found C 63.72, H 9.88, N 3.24. $^1$H NMR ([D$_6$]benzene): $\delta$ = 0.42 (s, 18 H, $C_5Me_4Si$$Me_3$), 1.71 (s, 6 H, $C_5$$Me_4$SiMe$_3$), 1.73 (s, 6 H, $C_5$$Me_4$SiMe$_3$), 1.83 (s, 6 H, $C_5$$Me_4$-SiMe$_3$), 1.94 (s, 6 H, $C_5$$Me_4$SiMe$_3$), 2.08 (s, 1 H, Ti-$H$), 5.96 (br. s, 2 H, N$H_2$) ppm. $^{13}$C NMR ([D$_6$]benzene): $\delta$ = 2.56 (SiMe$_3$), 10.94, 11.58, 14.35, 14.82 (Me), 110.07, 117.04, 118.65, 119.59, 125.43 (Cp) ppm. IR (KBr): $\tilde{\nu}$ = 1610 (Ti–H), 3373, 3444 (NH$_2$) cm$^{-1}$.

**Preparation of (η$^5$-C$_5$Me$_4$iPr)$_2$Ti(NHMe)(H) [1-(NHMe)(H)]:** A J. Young NMR tube was charged with 0.036 g (0.0836 mmol) of **1-(N$_2$)$_2$** and approximately 0.5 mL of [D$_6$]benzene were added. On the high vacuum line, the tube was degassed at –196 °C and methylamine was admitted with a 31.6 mL gas bulb (0.0836 mmol, 49 Torr). Upon thawing, a colour change from red to bright red was observed. The solvent was removed in vacuo to yield 0.032 g (94.1%) of **1-(NHMe)(H)** as a red solid. $C_{25}H_{43}NTi$ (405.46): calcd. C 74.05, H 10.69, N 3.45; found C 73.86, H 10.86, N 3.79. $^1$H NMR ([D$_6$]benzene): $\delta$ = 1.32 (d, $J$ = 8 Hz, 12 H, $C_5Me_4CH$$Me_2$), 1.81 (s, 6 H, $C_5$$Me_4$CHMe$_2$), 1.96 (s, 18 H, $C_5$$Me_4$CHMe$_2$), 2.13 (s, 1 H, Ti-$H$), 2.86 (m, 2 H, $C_5Me_4C$$H$Me$_2$), 3.19 (d, $J$ = 8 Hz, 3 H, NH$Me$), 6.71 (br. s, 1 H, N$H$Me) ppm. $^{13}$C NMR ([D$_6$]benzene): $\delta$ = 11.90, 12.61, 12.79, 13.37 (Me), 23.08, 23.21, 27.82 ($C$HMe$_2$/CH$Me_2$), 43.71 (NH$Me$), 113.52, 114.24, 115.78, 116.67, 125.52 (Cp) ppm. IR (KBr): $\tilde{\nu}$ = 1626 (Ti–H), 3381, 3414 (N–H) cm$^{-1}$.

**Preparation of (η$^5$-C$_5$Me$_4$SiMe$_3$)$_2$Ti=NSiMe$_3$ (2=NSiMe$_3$):** A 20 mL scintillation vial was charged with 0.052 g (0.1196 mmol) of **2** and approximately 5 mL pentane were added. Azidotrimethylsilane (16.1 μL, 0.1196 mmol) was added by syringe and the solution was stirred for 10 min. An immediate colour change from red to bright red was observed, signaling formation of **2=NSiMe$_3$**. The solvent was removed in vacuo to yield a red oil which was then dissolved in benzene and lyophilized to yield 0.042 g (67.7%) of **2=NSiMe$_3$** as a red solid. $C_{27}H_{51}NSi_3Ti$ (521.80): calcd. C 62.14, H 9.85, N 2.68; found C 61.77, H 9.87, N 2.28. $^1$H NMR ([D$_6$]-benzene): $\delta$ = 0.17 (s, 18 H, $C_5Me_4Si$$Me_3$), 0.37 (s, 9 H, NSi$Me_3$), 1.80 (s, 12 H, $C_5$$Me_4$SiMe$_3$), 2.52 (s, 12 H, $C_5$$Me_4$SiMe$_3$) ppm. $^{13}$C NMR ([D$_6$]benzene): $\delta$ = 1.95 (SiMe$_3$), 6.08 (NSi$Me_3$), 12.36, 17.66 (Me), 121.06, 125.28, 137.13 (Cp) ppm.

**Preparation of (η$^5$-C$_5$Me$_4$SiMe$_3$)(η$^5$-C$_5$Me$_3$-η$^1$-3-CH$_2$-SiMe$_3$)Ti-NHSiMe$_3$ and (η$^5$-C$_5$Me$_4$SiMe$_3$)(η$^5$-C$_5$Me$_3$-η$^1$-2-CH$_2$-SiMe$_3$)Ti-NHSiMe$_3$ (2-CM-NHSiMe$_3$):** A J. Young NMR tube was charged with 0.030 g (0.057 mmol) of **2=NSiMe$_3$** and approximately 0.5 mL of [D$_6$]benzene were added. The solution was heated to 45 °C over the course of one week, resulting in a colour change from red to dark red/brown. The solvent was removed in vacuo to yield a dark oil. $^1$H NMR ([D$_6$]benzene, major isomer): $\delta$ = 0.22 (s, 9 H, NHSi$Me_3$), 0.31 (s, 9 H, $C_5Me_4Si$$Me_3$), 0.34 (s, 9 H, $C_5Me_3$-η$^1$-3-CH$_2$-Si$Me_3$), 1.30 (s, 3 H, $C_5Me_3$-η$^1$-3-CH$_2$-SiMe$_3$), 1.58 (s, 3 H, $C_5$$Me_4$SiMe$_3$), 1.66 (s, 3 H, $C_5$$Me_4$SiMe$_3$), 1.93 (s, 3 H, $C_5Me_3$-η$^1$-3-CH$_2$-SiMe$_3$), 1.97 (s, 3 H, $C_5Me_3$-η$^1$-3-CH$_2$-CHMe$_2$), 1.99 (d, $J$ = 5 Hz, 1 H, $C_5Me_3$-η$^1$-3-C$H_2$-SiMe$_3$), 2.10 (s, 3 H, $C_5$$Me_4$SiMe$_3$), 2.33 (s, 3 H, $C_5$$Me_4$SiMe$_3$), 2.56 (d, $J$ = 5 Hz, 1 H, $C_5Me_3$-η$^1$-3-C$H_2$-SiMe$_3$), 3.70 (br. s, 1 H, N$H$SiMe$_3$) ppm. $^1$H NMR ([D$_6$]benzene, minor isomer): $\delta$ = 0.19 (s, 9 H, NHSi$Me_3$), 0.22 (s, 9 H, $C_5Me_3$-η$^1$-2-CH$_2$-Si$Me_3$), 0.31 (s, 9 H, $C_5Me_4Si$$Me_3$), 1.65 (s, 3 H, $C_5$$Me_4$SiMe$_3$), 1.85 (s, 3 H, $C_5$$Me_4$SiMe$_3$), 1.87 (d, $J$ = 5 Hz, 1 H, $C_5Me_3$-η$^1$-2-C$H_2$-SiMe$_3$), 1.88 (s, 3 H, $C_5Me_3$-η$^1$-2-CH$_2$-SiMe$_3$), 1.90 (s, 3 H, $C_5Me_3$-η$^1$-2-CH$_2$-SiMe$_3$), 1.95 (s, 3 H, $C_5Me_3$-η$^1$-2-CH$_2$-CHMe$_2$), 1.95 (s, 3 H, $C_5$$Me_4$SiMe$_3$), 2.11 (s, 3 H, $C_5$$Me_4$-SiMe$_3$), 2.82 (d, $J$ = 5 Hz, 1 H, $C_5Me_3$-η$^1$-2-C$H_2$-SiMe$_3$), 3.10 (br. s, 1 H, N$H$SiMe$_3$) ppm. $^{13}$C NMR ([D$_6$]benzene): $\delta$ = 2.17, 2.47, 2.92, 3.49, 6.45, 6.84 (Si$Me_3$), 11.72, 12.35, 12.42, 12.73, 12.91, 13.05, 14.53, 15.29, 15.43, 16.91, 17.33, 18.02, 18.33 (Me), 71.05, 74.93 ($CH_2$), 104.68, 108.42, 117.71, 118.88, 119.44, 120.83, 122.89, 123.67, 124.46, 127.24, 129.14, 129.19, 130.72, 130.68, 131.61, 131.82, 132.54, 136.16, 139.68, 140.57 (Cp) ppm.

**Generation of (η$^5$-C$_5$Me$_4$iPr)$_2$TiH$_2$ (1-H$_2$):** A J. Young NMR tube was charged with 0.016 g (0.037 mmol) of **1-(N$_2$)$_2$** and approximately 0.5 mL [D$_8$]toluene were added. On the high vacuum line, the tube was cooled to –196 °C, degassed and one atmosphere of dihydrogen was added. Upon thawing, the colour changed from red to bright orange. Cooling the solution to –75 °C under an atmosphere of dihydrogen revealed formation of **1-H$_2$**. $^1$H NMR ([D$_8$]toluene, –75 °C): $\delta$ = 1.32 (d, $J$ = 7 Hz, 12 H, $C_5Me_4CH$$Me_2$), 1.52 (s, 12 H, $C_5$$Me_4$CHMe$_2$), 2.08 (s, 12 H, $C_5$$Me_4$CHMe$_2$), 3.25 (s, 2 H, Ti-$H$), 3.41 (m, 2 H, $C_5Me_4C$$H$Me$_2$) ppm. $^{13}$C NMR ([D$_8$]-toluene, –75 °C): $\delta$ = 11.73, 14.25 (Me), 24.10, 30.47 ($C$HMe$_2$/CH$Me_2$), 118.00, 119.42, 134.69 (Cp) ppm.

**Preparation of (η$^5$-C$_5$Me$_4$iPr)$_2$Ti(DMAP) (1-DMAP):** A 20 mL scintillation vial was charged with 0.102 g (0.237 mmol) of **1-(N$_2$)$_2$**, 0.029 g (0.237 mmol) of 4-(dimethylamino)pyridine (DMAP) and approximately 5 mL diethyl ether. The reaction was stirred for one hour at ambient temperature and the solvent was removed in vacuo, yielding a red/brown solid. The compound was washed with pentane and recrystallized from diethyl ether at –35 °C to yield 0.084 g (71.2%) of **1-DMAP** as red rods. $C_{31}H_{48}N_2Ti$ (496.56): calcd. C 74.98, H 9.74, N 5.64; found C 74.93, H 9.23, N 5.17. $^1$H NMR ([D$_6$]benzene): $\delta$ = 3.74 ($\Delta\nu_{1/2}$ = 129 Hz). $\mu_{eff}$ = 2.7 $\mu_B$ (solid state), 2.3 $\mu_B$ (Evans) ppm.

**Observation of (η$^5$-C$_5$Me$_4$SiMe$_3$)$_2$Ti(NH$_2$)(SPh) [2-(NH$_2$)(SPh)]:** A J. Young NMR tube was charged with 0.018 g (0.040 mmol) of **2-NH$_2$**, 0.005 g (0.040 mmol) of $Ph_2S_2$ and approximately 0.5 mL [D$_6$]benzene. The tube was placed in a 45 °C oil bath for approximately 18 h, leading to a colour change from orange to bright red.

# The First Copper Complexes Bearing the 1,3,5-Triaza-7-phosphaadamantane (PTA) Ligand

**Alexander M. Kirillov,[a] Piotr Smoleński,[a] M. Fátima C. Guedes da Silva,[a] and Armando J. L. Pombeiro*[a]**

**Keywords:** Copper / N,P ligands / Structure elucidation / Phosphane ligands

The $Cu^{I}$ compound $[Cu(PTAH)_4](NO_3)_5$ (**1**) {PTAH = *N*-protonated form of 1,3,5-triaza-7-phosphaadamantane (PTA)} was easily prepared by reacting hydrated $Cu(NO_3)_2$ and PTA in aqueous acidic solution at room temperature. Further treatment of **1** with sodium hydroxide in water led to an unprotonated PTA derivative $[Cu(PTA)_4](NO_3)$ (**2**). Both compounds are water-soluble and air-stable, and were characterized by IR, $^{1}H$-, $^{13}C\{^{1}H\}$-, $^{31}P\{^{1}H\}$- and $^{63}Cu$ NMR spectroscopy, FAB-MS(+), elemental and single-crystal X-ray diffraction structural analyses. They exhibit a nearly regular tetrahedral coordination environment about each copper centre filled by the phosphorus atoms of the four PTAH/PTA moieties, which show distinct and unusual geometrical arrangements if viewed along the P–Cu bonds. The $^{31}P\{^{1}H\}$- and $^{63}Cu$ NMR spectra of **2** in $D_2O$ solution show spin coupling between the $^{31}P$ and $^{63}Cu$ nuclei at room temperature. These compounds represent the first examples of Cu complexes bearing PTA or any derived ligand with a cagelike PTA core and expand the restricted family of aqua-soluble copper phosphane complexes.

## Introduction

The coordination chemistry of the aqua-soluble phosphane 1,3,5-triaza-7-phosphaadamantane (PTA) and derived species has received increased attention in recent years.[1] This is mainly due to the good solubility of transition-metal PTA complexes in water, thus making possible their efficient application in aqueous phase catalysis,[2] as water-soluble antitumor agents[1,3] and as photoluminescent materials.[1,4] In particular, one of us has reported that Rh and Ru complexes with PTA or its *N*-alkylated derivatives are catalysts for the hydrogenation, hydroformylation and isomerization of alkenes.[5]

However, although a large variety of copper phosphane complexes has been reported,[6] known water-soluble examples remain rather scarce and include compounds with, for example, tris(*m*-sulfonatophenyl)phosphane,[7a] tris(hydroxymethyl)phosphane,[7b] tris(*m*-tolyl)phosphane[7c] and tris(*p*-fluorophenyl)phosphane[7c] [the aqua solubility of the last two examples should arise from the other ligands such as dihydrobis(3-nitro-1,2,4-triazol-1-yl)borate]. Moreover, the Cu–PTA chemistry is virtually unknown;[1] only one study reported the formation of $[Cu_nS_m(PTA)]^-$ ($n$ = 1, 2, 4 and 5; $m$ = 2–4) species in the gas phase under the Fourier transform ion cyclotron resonance (FTICR) mass spectrometry conditions,[8] whereas there are no examples of *isolated* copper complexes with PTA or its derivatives. In contrast, more than 100 complexes with a cagelike PTA core and with other transition metals have already been synthesized[1,3–5,9] and structurally characterized.[6]

By extending PTA coordination chemistry to our recent studies on the synthesis of water-soluble Cu complexes with other ligands (which catalyze the mild functionalization of alkanes),[10] we now report the easy synthesis of the new aqua-soluble $Cu^{I}$–PTA compounds $[Cu(PTAH)_4](NO_3)_5$ (**1**) and $[Cu(PTA)_4](NO_3)$ (**2**). They constitute, as far as we are aware of, the first isolated examples of copper complexes bearing PTA or any derived ligand with a cagelike PTA core. They were characterized by IR, $^{1}H$-, $^{13}C\{^{1}H\}$-, $^{31}P\{^{1}H\}$- and $^{63}Cu$ NMR spectroscopy, FAB-MS(+), elemental and single-crystal X-ray diffraction structural analyses.

## Results and Discussion

### Synthesis and Spectroscopic Characterization

Addition of an excess of PTA to an acidic aqueous solution of $Cu^{II}$ nitrate provided the formation, at room temperature and in air, of the cationic $Cu^{I}$ complex $[Cu(PTAH)_4](NO_3)_5$ (**1**) by a redox process resulting in the reduction of $Cu^{II}$ to $Cu^{I}$ and partial oxidation of PTA to the corresponding phosphane oxide (Scheme 1, **a**), which was identified by $^{31}P\{^{1}H\}$ NMR spectroscopic data of the reaction mixture and by the unit-cell parameters of isolated single crystals measured by X-ray diffraction which are in

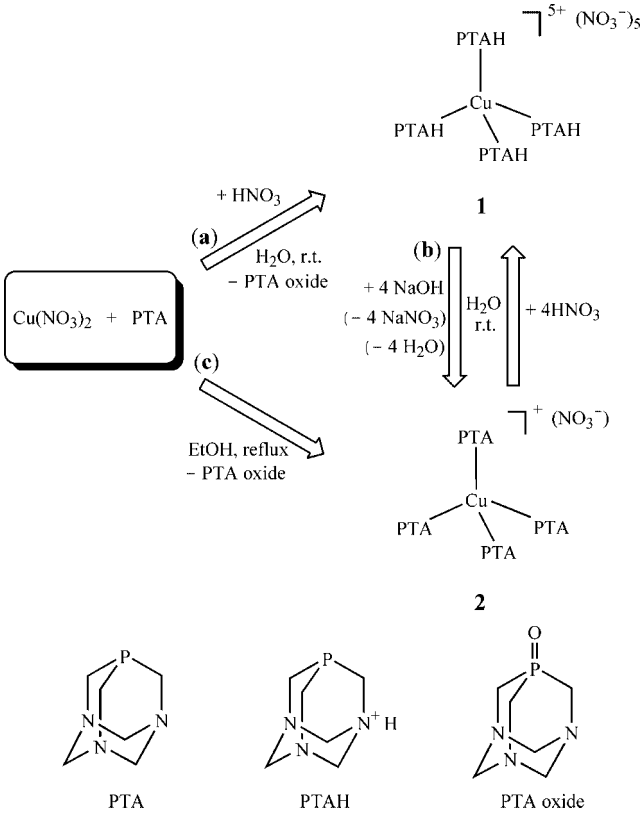
agreement with those already reported.[11] This correlates with the previously described[12] ability of PTA to act as a reductant and to stabilize low-oxidation metal states, thus leading to the synthesis of, for example, $Pt^0$, $Pd^0$, $Ni^0$ and $Ru^{II}$ PTA complexes starting from the corresponding metal(II/III) chlorides.[5a,12] Compound **1** was further precipitated by addition of EtOH to the reaction mixture, and it was isolated as a white microcrystalline solid in 92% yield, based on $Cu^{II}$ nitrate. Further treatment of **1** with 4 equiv. sodium hydroxide in water at room temperature (Scheme 1, **b**) led to the formation of the unprotonated derivative $[Cu(PTA)_4](NO_3)$ (**2**), which was isolated, upon recrystallization from MeOH, in 57% yield as a white microcrystalline solid. Compound **2** was also obtained directly (83% yield) from $Cu^{II}$ nitrate upon reaction with an excess of PTA in refluxing EtOH (Scheme 1, **c**). Moreover, protonation of **2** led to **1**, thus showing the reversibility of their interconversion. Both compounds **1** and **2** are air-stable solids, which are soluble and stable in water ($S_{25\,°C} \approx 6$ and 64 mg mL$^{-1}$, respectively) and in DMSO solutions.



Scheme 1.

The IR spectra of **1** and **2** (KBr pellet) show a set of vibrations typical of coordinated PTAH/PTA, as well as broad and strong bands (1382 and 1363 cm$^{-1}$, respectively) due to the nitrate ions. The complex molecular ion with four unprotonated PTA ligands, $[Cu(PTA)_4]^+$, is clearly observed at $m/z$ = 691 with the expected isotopic pattern in the FAB-MS(+) spectra of both compounds **1** and **2**, whereas the heaviest detected fragment ($m/z$ = 816) $[Cu(PTA)_4 + 2Cu – 3H]^+$ results from coupling of the molecular ion with two copper ions. Other typical peaks correspond to the stepwise fragmentations by loss of one to four PTA ligands, followed in **1** by the recombination of obtained species with $Cu^+$.

The $^1$H NMR spectra of both compounds, recorded in $D_2O$ solution, show two types of methylene protons. Hence, the PC$H_2$N protons occur as a doublet at $\delta$ = 4.2 ppm ($^2J_{P–H}$ = 4.8 Hz) and as a broad singlet at $\delta$ = 4.1 ppm in **1** and **2**, respectively, while the AB spin system due to the NC$H_{ax}$N and NC$H_{eq}$N protons[13] is centred at $\delta \approx 4.8$ ppm ($^2J_{AB}$ = 7.0 Hz) (for **1**) and 4.6 ppm ($^2J_{AB}$ = 13.5 Hz) (for **2**). Their $^{13}$C{$^1$H} NMR spectra are similar, presenting two broad singlets at $\delta$ ca. 74 and 53 ppm, assigned to the N$CH_2$N and P$CH_2$N carbon nuclei, respectively. The $^{31}$P{$^1$H} NMR spectrum of **1**, in $D_2O$, exhibits a broad singlet at $\delta$ = –82.5 ppm (Figure 1, **a**) which, on addition of an excess of free PTA or PTAH, shifts upfield (see parts **a** and **c**, respectively, in Figure 1) without observing a distinct resonance of the free phosphane ligand, which is consistent with fast exchange of coordinated and free phosphane ligands.

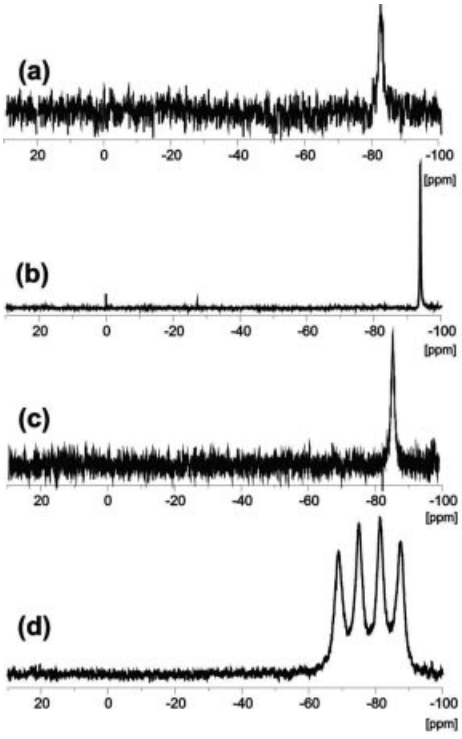


Figure 1. $^{31}$P{$^1$H} NMR spectra of **1** in $D_2O$ solution: (a) standard spectrum; (b, c) with an excess of added PTA (b) or PTAH (c); (d) at pH = 8.0 (after addition of NaOH, with formation of **2**).

The $^{31}$P{$^1$H} NMR spectrum of **2** displays a 1:1:1:1 quartet at $\delta$ = –78.2 ppm ($^1J_{P–Cu}$ = 761 Hz) (Figure 1, **d**) which, in contrast to **1**, does not show appreciable change upon addition of an excess of free PTA; the spectrum is maintained with the appearance of the singlet of free PTA at $\delta$ = –95.0 ppm. This indicates that the mentioned fast phosphane exchange is not detected in the case of **2**, and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the $^{31}P$–$^{63}Cu$ spin coupling ($^{63}Cu$ and $^{65}Cu$, $I = 3/2$) is observed. In agreement, the $^{63}Cu$ NMR spectrum of **2** (Figure 2) shows a 1:4:6:4:1 quintet, with the same $^{1}J_{P–Cu}$ at $\delta$ = 181.5 ppm (relative to $[Cu(MeCN)_4][PF_6]$), although no $^{63}Cu$ resonance was detected in the case of **1**, even upon long acquisition time.

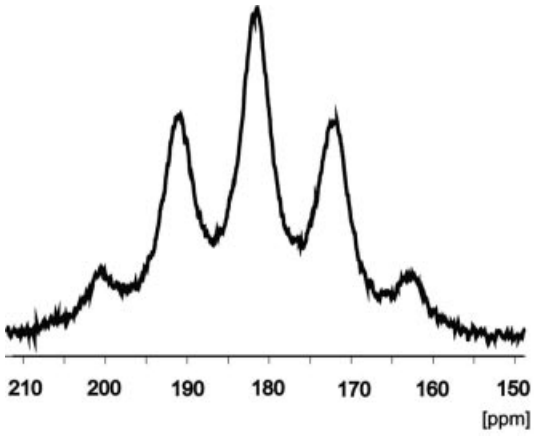

Figure 2. $^{63}Cu$ NMR spectrum of **2** in $D_2O$ (or **1** after addition of NaOH).

Hence in our systems, protonation of PTA appears to have a marked effect on the rate of that dynamic process in solution and/or on the quadrupolar relaxation of the Cu nuclei in the $^{63}Cu$ NMR spectroscopy.[14] The significance of distortion from the regular tetrahedral geometry in the solid state[14–16] cannot be ascribed in our case, namely in view of the fluxional behaviour in solution. The effect of the phosphane Tolman cone angle also cannot be recognized in our study since PTA and PTAH are expected to have similar values of the cone angle (103° for PTA[1,17] is a relatively small value in comparison with those of common organophosphane ligands). This differs from other systems for which the type of $^{31}P\{^{1}H\}$ NMR spectrum was associated with the Tolman angle. For example, as for complex **1** (in spite of its small PTAH cone angle), a broad singlet was observed in the $^{31}P\{^{1}H\}$ NMR spectrum (without reporting any $^{63}Cu$ NMR signal) of $[Cu(PPh_3)_4][BF_4]$[15] bearing a phosphane ligand with a cone angle higher than 136°. However, for $[CuL_4][PF_6]$ (L = $PMe_3$, $PMe_2Ph$, $PPh_2H$, $PPhH_2$)[15] and $[Cu\{P(CH_2OH)_3\}_3\{P(CH_2OH)_2(CH_2O^-)\}]$,[7b] which also have a distorted geometry of the metal centres but bear phosphane ligands with the Tolman cone angle lower than 136° (as in complex **1**), the characteristic quartet due to the coupling with copper (as in complex **2** but not in **1**) was detected. The chemical shift ($\delta$ = 181.5 ppm) observed in the $^{63}Cu$ NMR spectrum of **2** is comparable to those reported for other tetrahedral $Cu^{I}$ complexes, for example, $[Cu(PMePh_2)_4][BF_4]$ ($\delta$ = 192 ppm),[15] while $^{1}J_{P–Cu}$ (761 Hz) is also close to the values of 796 and 785 Hz found for $[Cu(PMe_3)_4][PF_6]$ and $[Cu(PMe_2Ph)_4][PF_6]$, respectively, although at different chemical shifts (i.e., $\delta$ = 287 and 265 ppm, respectively).[15]

Interestingly, upon changing the pH of the aqueous solution of **1** to a slightly basic value (i.e., pH ≈ 8 after addition of NaOH), one observes in the $^{31}P\{^{1}H\}$ NMR spectrum the conversion of the singlet (Figure 1, **a**) to the 1:1:1:1 quartet of **2** (Figure 1, **d**), in agreement with the deprotonation of **1** to afford **2** (Scheme 1, **b**). A corresponding feature is revealed by the $^{63}Cu$ NMR spectrum (Figure 2) which shows the appearance of the 1:4:6:4:1 quintet of **2**. The conversion of **1** into **2** can also be monitored by $^{1}H$ NMR spectroscopy which displays an upfield shift of the $NCH_2N$ protons.

Elemental analyses agree with the proposed formulations of **1** and **2** which are authenticated by single-crystal X-ray diffraction studies, as discussed now.

## X-ray Crystal Structures

The asymmetric unit of **1** consists of the $[Cu(PTAH)_4]^{5+}$ cation bearing a +5 charge (due to the protonated character of all the phosphane ligands), which is balanced by five nitrate ions. A thermal ellipsoid plot of the cationic part of **1** is depicted in part (**a**) of Figure 3. The nearly tetrahedral coordination environment about the copper centre is filled by four phosphorus atoms with the corresponding P–Cu–P

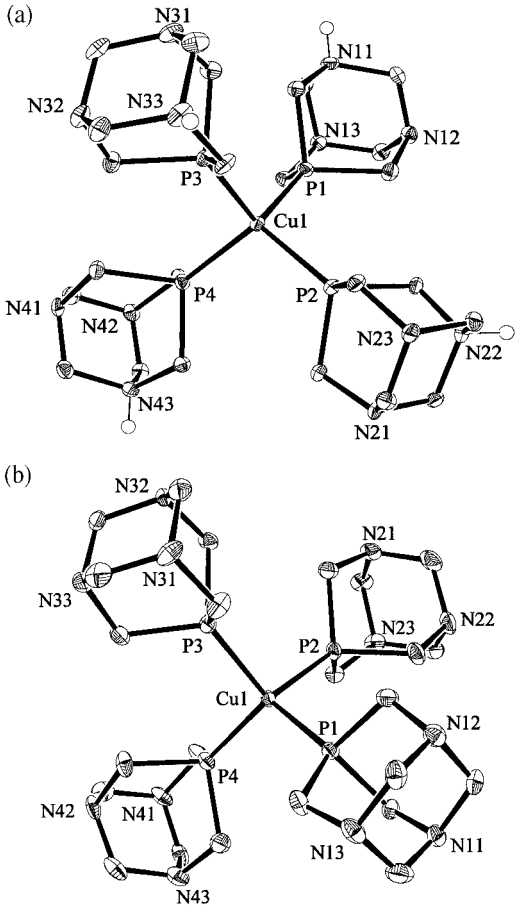

Figure 3. Thermal ellipsoid plots of the cationic parts of **1** (**a**) and **2** (**b**) with a partial labelling scheme. The methylene hydrogen atoms are omitted for clarity. Displacement ellipsoids are drawn at the 50% probability level. Hydrogen atoms are represented by circles of arbitrary radii.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

angles ranging from 108.14(3) to 111.21(3)° [the average value of 109.46(3)° is very close to that of a regular tetrahedron], with an average P···P separation of ca. 3.752 Å. The Cu–P bonds display almost equal, within 3σ, distances [i.e., 2.298(1) Å, average value] (Table 1) which correlate with those reported for other $Cu^{I}$ complexes bearing four monodentate phosphane ligands, for example, $[Cu\{P(CH_2OH)_3\}_3\{P(CH_2OH)_2(CH_2O^-)\}]$,[7b] $[Cu(PMe_3)_4]X$ {X = Cl,[18] Br,[18] I,[18] $[CuCl_2]^-$[19] or $[CuMe_2]^-$[20]} and $[Cu\{PH_2(mes)\}_4][PF_6]$ (mes = mesityl).[21] In **1**, all the 1,3,5-triaza-7-phosphaadamantane ligands possess a similar geometry and are protonated at one of the nitrogen atoms (i.e., N11, N22, N33 and N43) of each PTAH moiety (Figure 3, **a**), thus resulting in a slight elongation of the (H)N–C bonds [1.519(4) Å, average value] relative to other N–C distances [1.463(4) Å, average value] concerning the unprotonated nitrogen atoms (Table 1). Similar features of the (H)N–C bond elongation were reported for other transition-metal complexes with PTAH ligands.[22] Each NH proton of **1** is further involved in two hydrogen-bonding contacts with nitrate ions, with N···O distances ranging from 2.795(3) to 3.103(3) Å [2.940(3) Å, average value] and N–H···O angles from 122(2) to 177(2)° [142(3)°, average value] (Figure 4). In general, most of the bonding parameters do not significantly differ from the expected values found for related tetrahedral-type transition-metal PTAH/PTA complexes, for example, $[M(PTAH)]Cl_4$ (M = Pt, Pd, Ni),[22a] $[Pt(PTA)_2(PTAH)_2][BF_4]$,[12] $[Pt(PTA)_3(PTAH)]Cl$,[12] $[Au(PTA)(PTAH)_3][PF_6]_4$[22b] and $[Au(PTA)_4]X$ (X = Cl,[22b,23] $PF_6$[22b]).

[a] Average distance calculated from 12 bonds. [b] Average distance calculated from 24 bonds. [c] Average distance calculated from 36 bonds.

The crystal structure of **2** bears the $[Cu(PTA)_4]^+$ cation (Figure 3, **b**) with all the phosphane ligands being unprotonated and one nitrate anion balancing the overall charge. The tetrahedral environment around the copper atom is slightly more distorted than that of **1**, exhibiting higher deviations from the idealized geometry, with the minimal and maximal P–Cu–P angles of 105.90(6) and 113.57(6)°, respectively (Table 1). Although the structure of **2**, with mostly similar bonding parameters, resembles that of **1** and

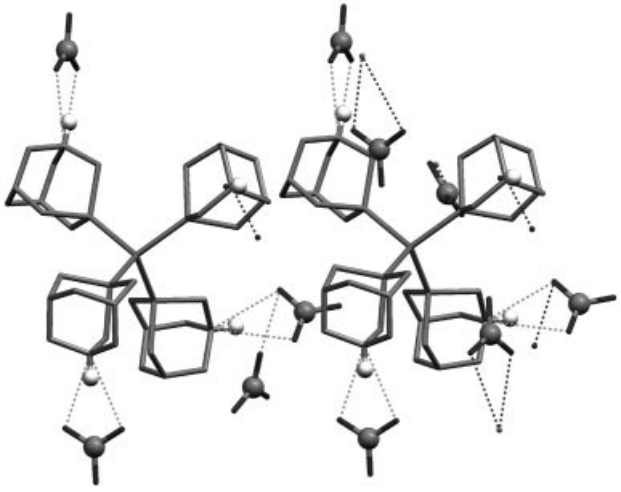

Figure 4. Fragment of the crystal packing diagram of **1** showing the N–H···O hydrogen bonds (dashed lines). NH hydrogen atoms and nitrate nitrogen atoms are shown as white and grey balls, respectively. The methylene hydrogen atoms are omitted for clarity.

therefore is not discussed in detail, it is noteworthy to mention the different geometric arrangements of the phosphane ligands in these compounds (Figure 3).

Hence, in **1** all the PTAH ligands show nearly equivalent arrangements if viewed along the P–Cu bond (Figure 5, **a**), where the three nitrogen atoms of each PTAH ligand are oriented similarly in relation to the other phosphane ligands forming coplanar P∩N,P sets. In contrast, in compound **2** the PTA ligands are not geometrically equivalent and are arranged in different ways (see parts **b** and **c** in Figure 5) from that in **1** (Figure 5, **a**). Thus, two of the phosphane ligands in **2**, that is, P1 and P4, if viewed down the P–Cu bond are ca. 45° (Figure 5, **b**) and 15° (Figure 5, **c**) rotated, respectively, relative to the orientation of PTAH ligands in **1** (Figure 5, **a**), whereas the other two phosphane ligands (i.e., P2 and P3) are less rotated (ca. 5–8°) approaching the arrangement depicted in part **a** of Figure 5. The analysis of previously reported X-ray crystal structures[6] of a dozen compounds with the $[M(L)_4]$ (L = PTA, PTAH or *N*-methyl-1,3,5-triaza-7-phosphaadamantane) unit reveals that the most common phosphane arrangement is that depicted in part **b** of Figure 5 (i.e., observed in 11 compounds, 3 of them also having 1 phosphane moiety arranged as in

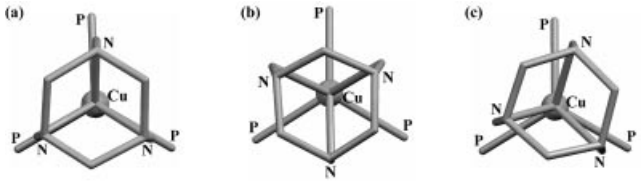

Figure 5. Ball-and-stick partial representation of the X-ray crystal structures of **1** (a) and **2** (b, c) down the P3–Cu1 (a), P1–Cu1 (b) and P4–Cu1 (c) bonds, showing the perspective arrangement of one PTAH/PTA ligand (to which belong the three represented nitrogen atoms) relative to the copper centre and the other phosphane ligands (only the Cu–P bonds are shown). Hydrogen atoms are omitted for clarity.

Figure 5, **c**). Only one compound, $[Au(PTA)(PTAH)_3][PF_6]_4$,[22b] possesses a phosphane arrangement similar to **1** (Figure 5, **a**), whereas there are no examples (apart from **2**) of compounds exhibiting the combination of three types of geometries close to those depicted in parts **a**–**c** of Figure 5.

## Conclusions

We have found a simple route to new $Cu^I$ complexes with 1,3,5-triaza-7-phosphaadamantane ligands based on a redox reaction of a $Cu^{II}$ salt with free PTA in aqueous solution at room temperature, thus showing that the reducing ability of PTA[12] can be also extended to copper(II) centres.

Protonation of ligated PTA promotes the ligand exchange and has a drastic effect on both the $^{31}P\{^1H\}$- and $^{63}Cu$ NMR spectra, with loss of the detection of $^1J_{P-Cu}$ coupling. The recognition of this NMR dependence on the solution pH is of significance towards the NMR characterization of further $Cu^I$–PTA complexes. The lack of a NMR resonance in spectra of samples obtained in acidic medium could have been a difficulty encountered by others, preventing the characterization and report of Cu complexes with such phosphane ligands, prior to the current study.

The enhanced lability of the PTA ligand upon protonation can be of synthetic value and deserves to be further explored for the preparation of derived complexes.

The obtained $Cu^I$ compounds **1** and **2** show, in the solid state, unusual relative orientations of the PTA (or PTAH) ligands.

The study also shows that it is possible to conveniently prepare Cu complexes bearing PTA (or its protonated form) ligands, allowing the expansion of the still limited group of water-soluble copper phosphane complexes, which encourages the search for their possible applications in aqueous media.

The extension of the work towards the synthesis of Cu compounds with *N*-alkylated PTA derivatives as well as the catalytic activity tests of Cu–PTA species in aqueous medium are currently in progress and will be reported elsewhere.

## Experimental Section

**General Materials and Experimental Procedures:** All chemicals were obtained from commercial sources and used as received. 1,3,5-Triaza-7-phosphaadamantane (PTA) was prepared by a published method.[24] C, H and N elemental analyses were carried out by the Microanalytical Service of the Instituto Superior Técnico. Melting points were determined with a Kofler Table. The FAB-MS(+) spectra were obtained with a Trio 2000 instrument by bombarding 3-nitrobenzyl alcohol (*m*-NBA) matrices of the samples with 8 keV (ca. $1.18 \times 10^{15}$ J) Xe atoms. Mass calibration for data system acquisition was achieved using CsI. Infrared spectra (4000–400 $cm^{-1}$) were recorded with a BIO-RAD FTS 3000MX instrument in KBr pellets. $^1H$-, $^{13}C\{^1H\}$-, $^{31}P\{^1H\}$- and $^{63}Cu$ NMR spectra were measured with a Varian UNITY 300 spectrometer at ambient temp. The $^{31}P$ and $^{63}Cu$ chemical shifts are relative to an external 85% $H_3PO_4$ aqueous solution and an $[D_3]MeCN$ solution of $[Cu(MeCN)_4][PF_6]$,[14] respectively.

**$[Cu(PTAH)_4](NO_3)_5$ (1):** To an aqueous solution (10.0 mL) of $Cu(NO_3)_2 \cdot 2.5H_2O$ (232 mg, 1.00 mmol) were added concentrated $HNO_3$ (65% in $H_2O$, 277 μL, 4.00 mmol) and an excess of an aqueous solution (5.00 mL) of PTA (786 mg, 5.00 mmol) with continuous stirring at room temp. The resulting white suspension was stirred for 1 h, followed by the addition of EtOH (15.0 mL) to provide further precipitation of the product. This was filtered off, washed with EtOH ($3 \times 10$ mL) and dried in vacuo to afford complex **1** as a white microcrystalline solid. Yield: 92% (926 mg), based on copper nitrate. Complex **1** is slightly soluble in $H_2O$ ($S_{25\,°C} \approx 6\ mg\,mL^{-1}$) and $Me_2CO$, is soluble in DMSO and is insoluble in EtOH, MeOH, $C_6H_6$, $CHCl_3$, $CH_2Cl_2$ and MeCN. M.p. ca. 215 °C. $C_{24}H_{52}CuN_{17}O_{15}P_4$ (1006.2): calcd. C 28.65, H 5.21, N 23.66; found C 28.64, H 5.59, N 23.35. FAB-MS(+) (*m*-NBA): *m*/*z* = 816 $[Cu(PTA)_4 + 2Cu - 3H]^+$, 691 $[Cu(PTA)_4]^+$, 659 $[Cu(PTA)_3 + 2Cu - 3H]^+$, 597 $[Cu(PTA)_3 + Cu]^+$, 534 $[Cu(PTA)_3]^+$, 502 $[Cu(PTA)_2 + 2Cu - 3H]^+$, 440 $[Cu(PTA)_2 + Cu]^+$, 377 $[Cu(PTA)_2]^+$, 220 $[Cu(PTA)]^+$, 63 $[Cu]^+$. IR (KBr): $\tilde{\nu}$ = 2984 (br. s) ν(NH + CH), 1382 (br. vs) $\nu(NO_3)$, 1120 (m), 1131 (s), 988 (s), 955 (s), 854 (m), 813 (m), 774 (s), 708 (w), 648 (w), 611 (w), 560 (s), 482 (w) and 449 (m) (PTA bands) $cm^{-1}$. $^1H$ NMR (300 MHz, $D_2O$, $Me_4Si$): $\delta$ = 4.74 $H^A$ and 4.87 $H^B$ ($^2J_{AB}$ = 7.0 Hz, 24 H, $NCH^AH^BN^+$ and $NCH^AH^BN$), 4.18 (br. d, $^2J_{P-H}$ = 4.8 Hz, 24 H, $PCH_2N$) ppm. $^1H$ NMR (300 MHz, $[D_6]$dmso, $Me_4Si$): $\delta$ = 4.79 (br. s, 24 H, $NCH_2N$), 4.11 (br. s, 24 H, $PCH_2N$) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $D_2O$, $Me_4Si$): $\delta$ = 73.8 (br. s, $NCH_2N$), 53.1 (br. s, $PCH_2N$) ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz, $D_2O$, 85% $H_3PO_4$): $\delta$ = –82.5 (br. s) ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz, $[D_6]$dmso, 85% $H_3PO_4$): $\delta$ = –82.6 (br. s) ppm. X-ray-quality single crystals were grown by slow evaporation, in air at room temp., of the reaction filtrate or $H_2O$ solution of **1**.

**$[Cu(PTA)_4](NO_3)\cdot 2H_2O$ ($2\cdot 2H_2O$). Method 1:** An aqueous cloudy solution (20 mL) of **1** (211 mg, 0.210 mmol) was neutralized by an aqueous 0.168 M NaOH solution (5.0 mL, 0.840 mmol) for 10 min, followed by evaporation of the obtained clear colourless solution in vacuo. The resulting white solid was treated with hot MeOH (ca. 40 mL) to produce a cloudy solution, which was filtered off. The obtained colourless filtrate was left in a fridge at ca. 5 °C for 2 d to afford compound $\mathbf{2}\cdot 2H_2O$ as a white crystalline solid, which was isolated by filtration. Yield: 57% (95 mg), based on **1**. Complex **2** is soluble in $H_2O$ ($S_{25\,°C} \approx 64\ mg\,mL^{-1}$), DMSO, MeOH and EtOH, is sparingly soluble in THF and $Me_2CO$ and is insoluble in nonpolar solvents. M.p. ca. 245 °C. $C_{24}H_{52}CuN_{13}O_5P_4$ (790.20): calcd. C 36.48, H 6.63, N 23.04; found C 36.55, H 6.80, N 22.42. FAB-MS(+) (*m*-NBA): *m*/*z* = 816 $[Cu(PTA)_4 + 2Cu - 3H]^+$, 691 $[Cu(PTA)_4]^+$, 534 $[Cu(PTA)_3]^+$, 377 $[Cu(PTA)_2]^+$, 220 $[Cu(PTA)]^+$. IR (KBr): $\tilde{\nu}$ = 3400 (br. s) and 3233 (br. s) $\nu(H_2O)$, 2902 (br. s) ν(CH), 1363 (br. s) $\nu(NO_3)$, 1243 (m), 1105 (m), 1014 (s), 974 (s), 807 (m) (PTA bands) $cm^{-1}$. $^1H$ NMR (300 MHz, $D_2O$, $Me_4Si$): $\delta$ = 4.61 $H^A$ and 4.58 $H^B$ ($^2J_{AB}$ = 13.5 Hz, 24 H, $NCH^AH^BN^+$ and $NCH^AH^BN$), 4.14 (br. s, 24 H, $PCH_2N$) ppm. $^{13}C\{^1H\}$ NMR (75.4 MHz, $D_2O$, $Me_4Si$): $\delta$ = 73.8 (br. s, $NCH_2N$), 53.1 (br. s, $PCH_2N$) ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz, $D_2O$, 85% $H_3PO_4$): $\delta$ = –78.2 (br. q, $^1J_{^{63}Cu-^{31}P}$ = 761 Hz) ppm. $^{63}Cu$ NMR (79.5 MHz, $D_2O$, $[Cu(MeCN)_4][PF_6]$): $\delta$ = 181.5 (br. quint, $^1J_{^{63}Cu-^{31}P}$ = 761 Hz) ppm. X-ray-quality crystals of $\mathbf{2}\cdot 2MeOH$ were grown by slow evaporation of the filtrate (left after isolation of **2**) in conical tubes in air for several days.

**Method 2:** To the blue ethanol solution (30.0 mL) of $Cu(NO_3)_2 \cdot 2.5H_2O$ (79 mg, 0.34 mmol) was added an excess of solid PTA (321 mg, 2.04 mmol). The obtained mixture was refluxed for 1 h under dinitrogen, leading to a pale-green suspension. The solid was filtered off, washed with cold EtOH ($2 \times 30$ mL) and $CHCl_3$

(2 × 15 mL) (to remove the excess phosphane and the formed phosphane oxide) and dried in vacuo to afford complex **2** as a white powder. Yield: 83% (209 mg), based on copper nitrate.

**Refinement Details for the X-ray Crystal Structure Analysis of 1 and 2:** Intensity data were collected using a Bruker AXS-KAPPA APEX II diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation. Data were collected at 150 K using omega scans of 0.5° per frame, and a full sphere of data was obtained. Cell parameters were retrieved using Bruker SMART software and refined using Bruker SAINT on all the observed reflections. Absorption corrections were applied using SADABS. Structures were solved by direct methods by using the SHELXS-97 package[25] and refined with SHELXL-97[26] with the WinGX graphical user interface.[27] All hydrogen atoms were inserted in calculated positions. Least square refinement with anisotropic thermal motion parameters for all the non-hydrogen atoms (except for C2 in a methanol molecule in **2** which was refined isotropically) and isotropic for the remaining atoms gave $R_1$ = 0.0357 (for **1**) and 0.0569 (for **2**). In **2**, the maximum and minimum peaks in the final difference electron density map are 1.704 and –0.933 e Å$^{-3}$, respectively, close to one of the methanol molecules of crystallization (C2–O2) possibly indicating a disorder which, however, could not be modulated. The selected bonding parameters for **1** and **2** are given in Table 1, and the crystallographic data is summarized in Table 2.

Table 2. Crystal data and structure refinement details for **1** and **2**.

| | **1** | **2**·2MeOH |
|---|---|---|

# Coupling Reactions of an Allenylcarbene Complex with Alkynes and Styrene

**Ting Bin Wen,[a] Wai Yiu Hung,[a] Herman H.-Y. Sung,[a] Zhongyuan Zhou,[b] Ian D. Williams,[a] and Guochen Jia*[a]**

**Keywords:** Osmium / Fulvenes / Carbenes / Alkynes / Alkenes

The allenylcarbene complex $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ undergoes coupling reactions with $HC\equiv CSiMe_3$ and $PhC\equiv CC\equiv CPh$ to produce the fulvene complexes $[OsCl_2\{\eta^6\text{-}C_5H_2(Ph)(SiMe_3)(=CHPh)\}(PPh_3)]$ and $[OsCl_2\{\eta^6\text{-}C_5H(Ph)_2(C\equiv CPh)(=CHPh)\}(PPh_3)]$, respectively. A similar coupling reaction also occurs between $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ and styrene.

## Introduction

The [2+2+2] cyclotrimerization of alkynes to give six-membered aromatic rings is one of the most common reactions promoted by transition metal complexes and has been utilized in the synthesis of many useful natural products and novel organic materials.[1–3] In sharp contrast, examples of metal-mediated [2+2+1] cyclotrimerization of alkynes to give thermodynamically less stable isomeric fulvene derivatives are limited to only a few scattered reports.

The stoichiometric formation of fulvene metal complexes from formal [2+2+1] cyclotrimerizations of alkynes has been reported for the reaction of rhodium,[4] iridium,[5] and palladium[6] complexes with alkynes. Reported catalytic cyclotrimerization reactions of alkynes to give fulvenes include the titanium aryloxide/LiC≡C*t*Bu-catalyzed cyclotrimerization of *tert*-butylacetylene[7] and the $[(\eta^3\text{-}C_3H_5)PdCl]_2$/dppf-catalyzed cyclotrimerization of aliphatic alkynes.[8] Fulvene or fulvenyl intermediates may also be involved in the reactions of terminal alkynes with transition metal complexes to give complexes with ligands derived from the oligomerization of alkynes.[9–15]

There are several possible pathways that can lead to the formation of fulvenes from the [2+2+1] cyclotrimerization of alkynes; these are illustrated in Scheme 1. Fulvenes may be formed via a metallacyclopentadiene route, which involves oxidative coupling of two molecules of alkynes at the metal to give a metallacyclopentadiene intermediate, isomerization of another molecule of alkyne to a vinylidene ligand, and reductive cyclization to a fulvene product by coupling of the vinylidene ligand and the metallacyclopentadiene ring (Scheme 1, path a). Reactions of preformed iridiacyclopentadiene compounds with terminal alkynes have been shown to produce fulvene complexes.[5] In the reaction involving a base (Scheme 1, path b), for example the titanium aryloxide/LiC≡C*t*Bu-catalyzed cyclotrimerization of *tert*-butylacetylene, a metallacyclopentadiene-acetylide intermediate has been proposed. This intermediate undergoes reductive coupling followed by an insertion to give the fulvenyl complex, which reacts with alkyne to give fulvene and regenerate the metallacyclopentadiene-acetylide intermediate.[7] In principle, fulvenes could also be formed via metallacyclobutene intermediates (Scheme 1, path c). This reaction has been proposed for the formation of a fulvene complex from the reaction of $[RhCl(COD)]_2$ (COD = cycloocta-1,5-diene) with HC≡C*t*Bu in the presence of $AgPF_6$.[4] In this regard, it would be interesting to demonstrate that preformed metallacyclobutene complexes could react with alkynes to give fulvene complexes.

We have recently reported the synthesis of the $\eta^2$-allenylcarbene complex $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ (**1**),[16,17] which can be regarded as an isomer of an osmacyclobutene, from the reaction of PhC≡CH with the vinylidene complex $[OsCl_2(=C=CHPh)(PPh_3)_2]$ or $[OsCl_2(PPh_3)_3]$. In this work, we will describe its coupling reactions with alkynes. Its reaction with styrene has also been investigated for comparison.

## Results and Discussion

### Coupling Reaction of $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ (1) with Alkynes

Treatment of **1** with $HC\equiv CSiMe_3$ in dichloromethane produced the $\eta^6$-fulvene complex $[OsCl_2\{\eta^6\text{-}C_5H_2(Ph)(SiMe_3)(=CHPh)\}(PPh_3)]$ (**2**), which was isolated as a green solid in 81% yield (Scheme 2). The NMR spectroscopic

data (in $CD_2Cl_2$) of the isolated solid suggest the presence of two isomers (**2a** and **2b**) in a ratio of 4.5:1 in solution (Scheme 2).

The structure of **2a** was determined by X-ray diffraction analysis of a single crystal grown from a $CH_2Cl_2$ solution of **2** layered with hexane. Selected bond lengths and angles are shown in Table 1. The structure shown in Figure 1 clearly reveals that coupling of $HC{\equiv}CSiMe_3$ with the allenylcarbene ligand has occurred to give the $\eta^6$-4,6-diphenyl-2-(trimethylsilyl)fulvene complex **2**.

The interaction of osmium and the exocyclic double bond in complex **2a** is indicated by the inclination of the C(1)–C(6) bond toward osmium, with an angle of 26.9° from the fulvene ring plane. The displacement of C(6) from the fulvene ring plane is 0.625 Å. However, this interaction is weak, as reflected by the rather long Os–C(6) separation [2.632(4) Å] and the relatively short exocyclic double bond [the C(1)–C(6) distance being 1.380(5) Å]. Three extreme canonical forms (see Scheme 3), namely an $\eta^6$-triene (**2**), an $\eta^5$-cyclopentadienido-σ-alkyl ("tucked-in", **2′**), and a zwit-

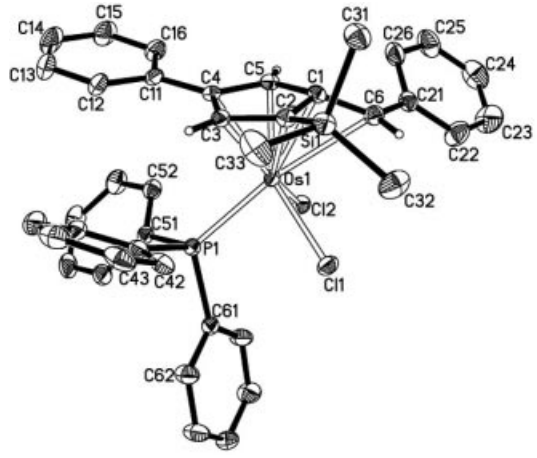

Figure 1. Molecular structure of [$OsCl_2$\{$\eta^6$-$C_5H_2$(Ph)($SiMe_3$)-(=CHPh)\}($PPh_3$)] (**2a**).

terionic form (**2"**), can be considered for the fulvene complex.[18] The structural data of **2a** suggest that the fulvene ligand in **2a** can be regarded as being bound to the osmium in an $\eta^6$-triene fashion. As shown in Table 2, the Os–C(exocyclic) bond lengths in the structurally characterized osmium fulvene complexes [($\eta^5$-$C_5Me_5$)Os\{$\eta^6$-$C_5Me_4$-(=$CPh_2$)\}]($PF_6$),[19] [($\eta^5$-$C_5Me_5$)Os\{$\eta^6$-$C_5Me_4$(=$CH_2$)\}]-($BPh_4$),[20] and [($\eta^5$-$C_5Me_5$)Os\{$\eta^6$-$C_5Me_4$(=$CHC_6F_5$)\}]-($PF_6$)[21] are significantly shorter and the exocyclic C–C bond lengths significantly longer than those in complex **2a**, which is indicative of a "tucked-in" bonding type in these complexes. As expected, the inclination angles in these complexes are also significantly larger (35.6–41.8°) than that in **2a** (26.9°).

The $^{31}P\{^1H\}$ NMR spectrum of **2** in $C_6D_6$ at room temperature displays two singlets at $\delta$ = –0.3 (major) and –7.8 ppm (minor), thereby indicating the presence of two isomers in solution. In the $^1H$ NMR spectrum, the major isomer displays a singlet at $\delta$ = 6.51 ppm and two doublets at $\delta$ = 5.00 and 7.83 ppm for the three fulvene protons. The splitting of the signals at $\delta$ = 5.00 and 7.83 ppm is due to coupling with the $^{31}P$ nuclei, as suggested by $^1H\{^{31}P\}$ NMR experiments. The $^1H$ NMR spectrum of the minor isomer exhibits three singlets in the $^1H$ NMR spectrum at $\delta$ = 5.49, 6.31, and 6.80 ppm for the fulvene protons. Fulvene complexes such as [$Re(C_6F_5)$\{($\eta^6$-$C_5Me_4$(=$CH_2$)\}$(CO)_2$][18a,18b] and [$RuCl_2$(py)\{($\eta^6$-$C_5Me_4$(=$CPh_2$)\}][22] also exist as two isomers in solution. This isomerism has been attributed to the presence of conformational isomers due to restricted rotation about the metal-fulvene bond. A similar isomerism can be proposed for **2**. Scheme 4 shows three possible conformers of **2**. On the basis of steric reasons, one would expect the stability of these three conformers to be in the order **2a** > **2b** > **2c**.

The two isomers observed in solution by NMR spectroscopy can be attributed to **2a** and **2b**. The major isomer can be assigned to the conformer revealed by the X-ray structure (**2a**), in which the exocyclic double bond is *trans* to $PPh_3$. In agreement with the structure, the $^1H$ NMR spectrum shows two signals at $\delta$ = 7.83 ($J_{P,H}$ = 5.8 Hz) and 5.00 ppm ($J_{P,H}$ = 4.0 Hz) assignable to C(6)H and C(5)H, respectively, and a singlet at $\delta$ = 6.51 ppm assignable to C(3)H. The minor isomer observed in solution may correspond to conformer **2b** in which the exocyclic double bond is *cis* to $PPh_3$. The three fulvene signals at $\delta$ = 5.49, 6.31, and 6.80 ppm observed for the minor isomer can be assigned to C(5)H, C(3)H, and C(6)H, respectively.

Scheme 5 shows a plausible mechanism for the formation of **2** from the coupling reaction. Complex **1** could rearrange

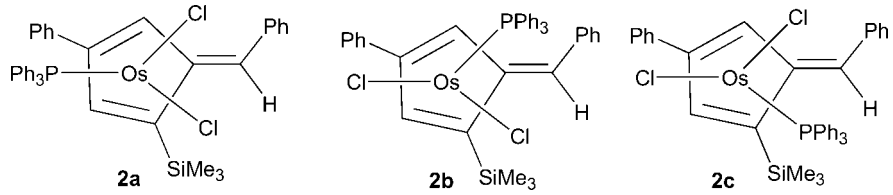
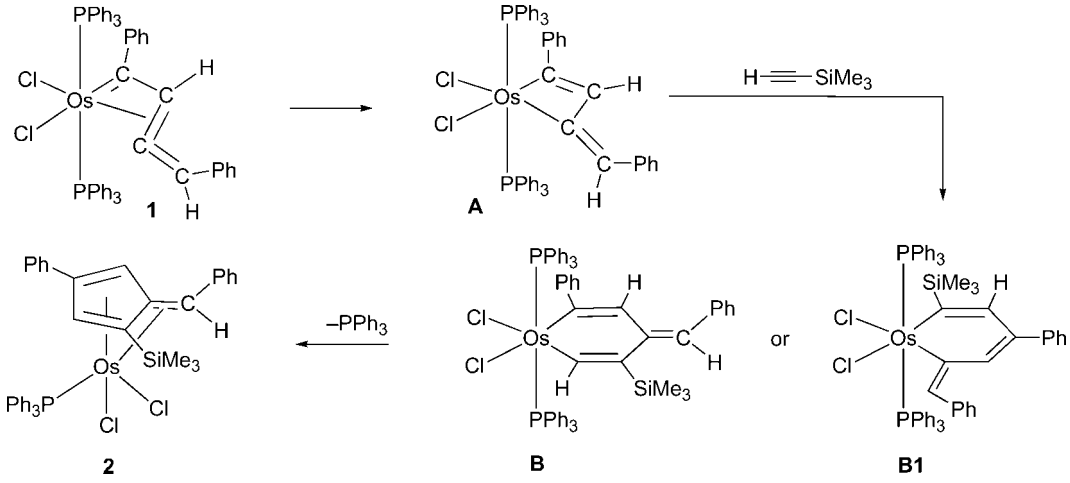


Scheme 4.

to metallacyclobutene **A**, which undergoes cycloaddition with $HC{\equiv}CSiMe_3$ to give the metallacyclohexadiene intermediate **B** or **B1**. Complex **B** or **B1** could then undergo reductive elimination, followed by coordination of the fulvene to osmium and loss of one $PPh_3$ ligand to give **2**. A similar mechanism has been proposed previously.[4,9]



Scheme 5.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The reaction of **1** with PhC≡C–C≡CPh produced the analogous fulvene complex **3** (Scheme 1), although the reaction is slow in dichloromethane at room temperature. When a mixture of **1** and PhC≡C–C≡CPh in benzene was refluxed for 1 h, a brown solution containing **3** along with small amounts of unreacted **1** and an unidentified species with a $^{31}P$ chemical shift of $\delta$ = –16.0 ppm was produced. Complex **3** was isolated in 43% yield from the reaction mixture. Attempts to isolate and identify the unknown species with a $^{31}P$ chemical shift of $\delta$ = –16.0 ppm failed. The structure of **3** was also confirmed by a single-crystal X-ray diffraction study. A view of the molecular structure is shown in Figure 2 and selected bond lengths and angles are listed in Table 3.

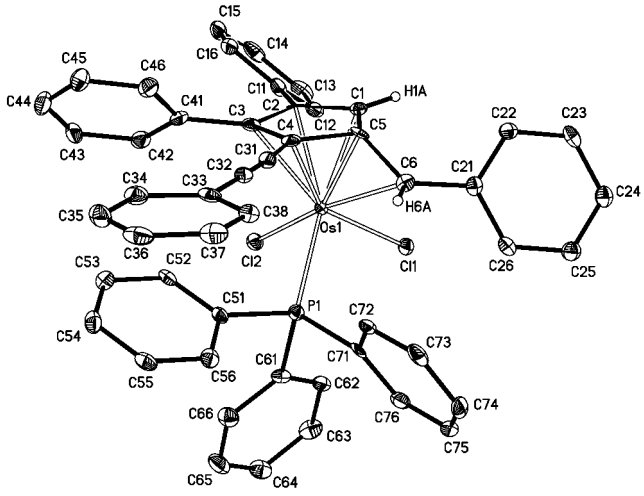


Figure 2. Molecular structure of $[OsCl_2\{\eta^6\text{-}C_5H(C{\equiv}CPh)(Ph)_2(=CHPh)\}(PPh_3)]$ (**3**).

Like complex **2**, the fulvene ligand in **3** is also $\eta^6$-coordinated to osmium. However, the interaction between the exocyclic double bond and the osmium center is stronger for **3**. Thus, the Os–C(6) bond length is 2.392(4) Å and the exocyclic C–C double bond [C(5)–C(6)] bond length is 1.424(6) Å. For comparison, the Os–C(exocyclic) bond length is 2.632(4) Å and the exocyclic C–C bond length is 1.380(5) Å in complex **2a**. The inclination angle of **3** (38.2°) is also significantly larger than that of **2a** (26.9°). The structural features associated with the Os($\eta^6$-fulvene) moiety in **3** are similar to those of the previously reported osmium fulvene complexes $[(\eta^5\text{-}C_5Me_5)Os\{\eta^6\text{-}C_5Me_4(=CPh_2)\}](PF_6)$,[19] $[(\eta^5\text{-}C_5Me_5)Os\{\eta^6\text{-}C_5Me_4(=CH_2)\}](BPh_4)$,[20] and $[(\eta^5\text{-}C_5Me_5)Os\{\eta^6\text{-}C_5Me_4(=CHC_6F_5)\}](PF_6)$[21] (see Table 2).

Consistent with the solid-state structure, the $^1H$ NMR spectrum displays two signals at $\delta$ = 6.00 and 6.62 ppm assignable to the ring proton and the exocyclic =CH proton, respectively. The $^{31}P\{^1H\}$ NMR spectrum shows a singlet at $\delta$ = –8.0 ppm (in $CD_2Cl_2$). It is interesting to note that two isomers are observed for **2** in solution but only one isomer is observed for **3**. Complex **3** can, in principle, also exhibit conformational isomerism in solution, and the exact reason why only one conformer is observed for **3** is not clear. The possibility that the fulvene ring is rotating very rapidly in **3** was excluded as additional $^{31}P$ signals were not observed for a $CD_2Cl_2$ solution of **3** at low temperature (220 K). Since in situ $^{31}P$ NMR spectroscopy showed a minor $^{31}P$ signal along with that of **3** (see above), we tentatively assume that another conformer of **3** may also be produced in the reaction, although we were not able to isolate or identify it. We note that two isomers have been observed for $[RuCl_2(py)\{(\eta^6\text{-}C_5Me_4(=CPh_2)\}]$ whereas only one isomer was observed for the closely related complex $[RuCl_2(dmso)\{(\eta^6\text{-}C_5Me_4(=CPh_2)\}]$.[22]

Table 3. Selected bond lengths [Å] and angles [°] for $[OsCl_2\{\eta^6\text{-}C_5H(C{\equiv}CPh)(Ph)_2(=CHPh)\}(PPh_3)]\cdot 3C_6D_6$ (**3**·$3C_6D_6$).

It is interesting to note that complexes **2a** and **3** adopt different conformations in the solid state. This difference could be related to the relative bulkiness of $SiMe_3$, Ph, and C≡CPh. One might expect that the steric effects of these groups are in the order $SiMe_3$ > Ph > C≡CPh, therefore the bulky $PPh_3$ ligand tends to be in a position close to C≡CPh rather than Ph in **3**, but close to Ph rather than $SiMe_3$ in **2a**.

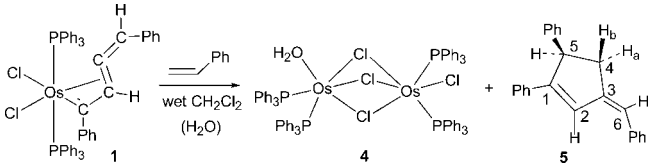
We also studied the reaction of **1** with $SiMe_3C{\equiv}C–C{\equiv}CSiMe_3$. However, the reaction produced many unidentified phosphorus-containing species which proved difficult to separate and identify.

### Coupling Reaction of $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ (1) with Styrene

The easy formation of fulvene complexes from the reaction of $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ (**1**) with alkynes promoted us to investigate the reaction of **1** with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

styrene. Treatment of complex **1** with an excess of styrene in wet $CH_2Cl_2$ leads to the formation of the bimetallic complex $[(PPh_3)_2ClOs(\mu\text{-}Cl)_3Os(H_2O)(PPh_3)_2]$ (**4**) as the only phosphorus-containing product (Scheme 6).



Scheme 6.

Complex **4** was isolated as a light-brown solid in 75% yield and was characterized by elemental analysis, NMR spectroscopy, and mass spectrometry. The $^{31}P\{^1H\}$ NMR spectrum of **4** in $C_6D_6$ displays four sets of doublets of equal intensity at $\delta$ = –6.5, –7.8 ($J_{P,P}$ = 11.4 Hz), –16.4, and –17.4 ppm ($J_{P,P}$ = 16.7 Hz), thereby indicating the presence of four inequivalent phosphorus nuclei. This pattern is closely analogous to that of the dinuclear complex $[(PPh_3)_2ClOs(\mu\text{-}Cl)_3Os\{=C=CH[C(OH)Ph_2]\}(PPh_3)_2]$[23] and suggests the formation of a bimetallic complex of the type $[(PPh_3)_2ClOs(\mu\text{-}Cl)_3Os(L)(PPh_3)_2]$.

Definite proof of the structure came from a single-crystal X-ray structure analysis. Crystals suitable for X-ray diffraction were grown from a $CH_2Cl_2$ solution of **4** layered with hexane. Selected bond lengths and angles are given in Table 4 and a view of the molecular geometry of **4** is shown in Figure 3. The structure of **4** is similar to that of $[(PPh_3)_2ClOs(\mu\text{-}Cl)_3Os\{=C=CH[C(OH)Ph_2]\}(PPh_3)_2]$,[23] with replacement of the vinylidene ligand in the latter complex by an aqua ligand, and deserves no further comments.

Table 4. Selected bond lengths [Å] and angles [°] for $[(PPh_3)_2ClOs(\mu\text{-}Cl)_3Os(H_2O)(PPh_3)_2]\cdot CH_2Cl_2$ (**4**·$CH_2Cl_2$).

Obviously, the hydrocarbon ligand of **1** has been eliminated from the metal center in the reaction. The $^1H$ NMR spectrum of the reaction mixture shows the formation of several organic products, among which compound **5** is the most dominant (ca. 78%). A sample of compound **5** could be isolated as an oil by column chromatography on silica gel using hexane as the eluent, and its structure was readily deduced from spectroscopic data. Thus, the FAB mass spectrum shows an ion peak at *m*/*z* 308.1, indicating that it is composed of a molecule of styrene and the original allenylcarbene unit of **1**. The $^1H$ NMR spectrum ($C_6D_6$) shows two multiplets at $\delta$ = 2.98 and 3.29 ppm, which could be assigned to the two diastereotopic C$H_2$ ring protons C(4)$H_a$ and C(4)$H_b$, respectively (see Scheme 6 for labelling). The $^1H$ and $^1H$-$^1H$ COSY NMR spectra clearly indicate that the $CH_2$ group is adjacent to a CH group, which has its $^1H$ NMR signal at $\delta$ = 4.16 ppm and is assignable to the signal of C(5)H. The presence of the stereogenic center at C5 is responsible for the different environments around C(4)$H_a$ and C(4)$H_b$. The coupling constant between C(4)$H_a$ and C(4)$H_b$ is 17.3 Hz, while the coupling constants between C(5)H and C(4)Hs are 3.7 and 8.3 Hz for C(4)$H_a$ and C(4)$H_b$, respectively, consistent with the assignment that the latter is formally *trans* to C(5)H. In the $^1H$ NMR spectrum, the signal of the C(2)H ring proton appears at $\delta$ = 6.32 ppm and the signal of the exocyclic C*H*Ph proton [C(6)H] appears as a triplet at $\delta$ = 7.51 ppm due to coupling with the protons of the $CH_2$ group.

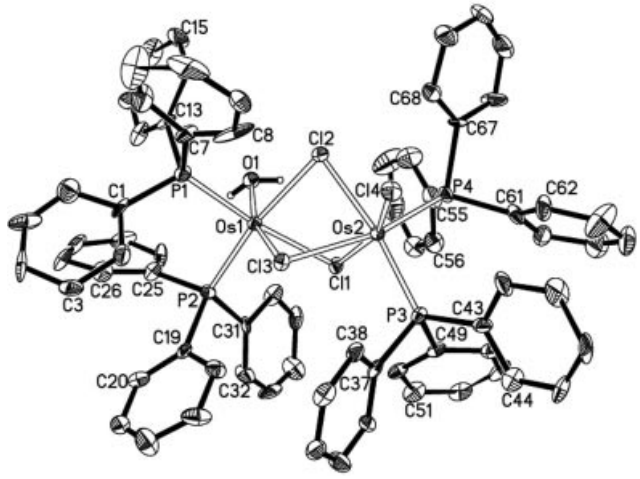

Figure 3. Molecular structure of $[(PPh_3)_2ClOs(\mu\text{-}Cl)_3Os(H_2O)(PPh_3)_2]$ (**4**).

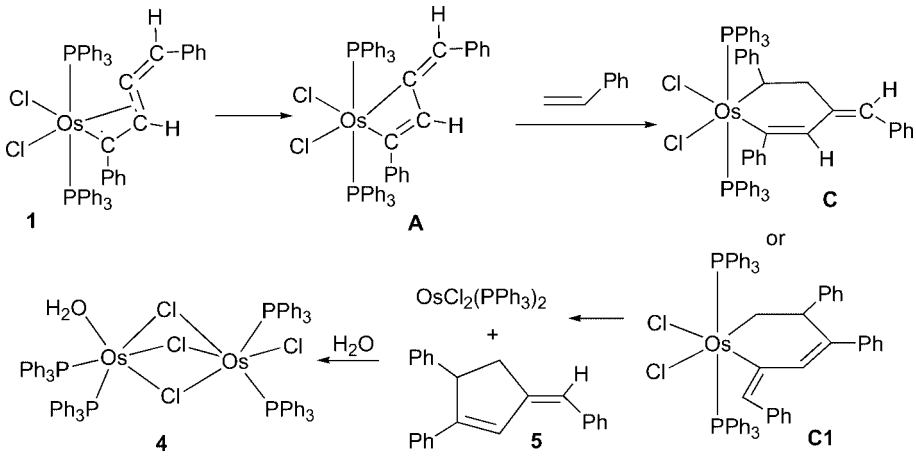
Scheme 7 shows a plausible mechanism for the formation of **4** and **5** from the reaction of **1** with styrene. Complex **1** can rearrange to metallacyclobutene **A**, which can undergo cycloaddition with styrene to give the metallacyclic intermediate **C** or **C1**. Subsequent reductive elimination of **C** or **C1** would give **5** and the transient $OsCl_2(PPh_3)_2$ fragment, which reacts with water in solution to give **4**. Although we have no direct evidence for intermediates **C** and **C1**, they are closely related to intermediates **B** and **B1**.

The allenylcarbene complex **1** was originally derived from the coupling of two molecules of phenylacetylene. Thus, the net transformation involving formation of **1** and the coupling of **1** with styrene represenst a rare example of a [2+2+1] co-cyclotrimerization of alkynes and alkenes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 7.

While many examples of [2+2+2] co-cyclotrimerization of alkynes and alkenes to give cyclohexadienes are known,[24] the related [2+2+1] co-cyclotrimerization of alkynes and alkenes, to the best of our knowledge, is still unknown.

In summary, we have demonstrated that the allenylcarbene complex $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ (**1**), which is originally derived from the coupling of two molecules of phenylacetylene at osmium, can undergo coupling reactions with alkynes to give fulvene complexes. The reactions reported here support a previously proposed mechanism that [2+2+1] cyclotrimerization of alkynes could occur via metallacyclobutene intermediates. We have also shown that complex **1** can undergo a similar coupling reaction with styrene. This result is interesting as it represents a rare example of metal-mediated [2+2+1] co-cyclotrimerization of alkynes and alkenes.

## Experimental Section

All manipulations were carried out under nitrogen using standard Schlenk techniques unless otherwise stated. Solvents were distilled under nitrogen from sodium benzophenone (hexane, diethyl ether, thf), sodium (benzene), or calcium hydride ($CH_2Cl_2$). $[Os\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$[16] was prepared according to the literature method. All other reagents were used as received from Aldrich Chemical Co. USA.

Microanalyses were performed by M-H-W Laboratories (Phoenix, AZ). $^1H$, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded with a JEOL EX-400 spectrometer (400 MHz) or a Bruker ARX-300 spectrometer (300 MHz). $^1H$ and $^{13}C$ NMR shifts are quoted relative to TMS, and $^{31}P$ chemical shifts relative to 85% $H_3PO_4$. Mass spectra were recorded with a Finnigan TSQ7000 spectrometer.

**$[OsCl_2\{\eta^6\text{-}C_5H_2(Ph)(SiMe_3)(=CHPh)\}(PPh_3)]$ (2):** $HC{\equiv}CSiMe_3$ (0.43 mL, 3.0 mmol) was added to a solution of $[OsCl_2(=CPh\text{-}CH=C=CPh)(PPh_3)_2]$ (0.50 g, 0.50 mmol) in $CH_2Cl_2$ (50 mL) and the reaction mixture was stirred at room temperature for 72 h to give a brown solution. The volume of the mixture was reduced to about 1 mL, then diethyl ether (20 mL) was added slowly with stirring and the mixture was filtered to remove a small amount of dark brown precipitate. The filtrate was evacuated to dryness under vacuum and the residue was extracted with 1 mL of benzene to give a brown solution. Addition of hexane (30 mL) to the benzene extract produced a green precipitate, which was collected by filtration, washed with hexane (2 × 30 mL), and dried under vacuum overnight. The $^{31}P\{^1H\}$ and $^1H$ NMR spectra indicate the presence of two isomers in a ratio of about 1:4.5. Yield: 0.34 g (81%). FAB-MS (NBA): *m/z* 826 [$M^+$]. $C_{39}H_{37}Cl_2OsP_2Si$: calcd. C 56.72, H 4.52; found C 56.68, H 4.61.

**2a** ($PPh_3$ is *trans* to the exocyclic double bond): $^1H$ NMR (300.13 MHz, $CD_2Cl_2$, see Scheme 1 for labels): $\delta$ = 0.45 (s, 9 H, $SiMe_3$), 5.00 [d, $J_{P,H}$ = 4.0 Hz, 1 H, C(5)-H], 6.51 [s, 1 H, C(3)-H], 7.06–7.65 (m, $C_6H_5$, $PPh_3$, mixed with those of **2b**), 7.83 [d, $J_{P,H}$ = 5.8 Hz, 1 H, C(6)-H] ppm. $^{13}C\{^1H\}$ NMR (100.4 MHz, $CD_2Cl_2$): $\delta$ = 0.5 (s, $SiMe_3$), 73.3 (s, C-3), 82.00 (s, C-5), 83.4 (d, $J_{P,C}$ = 2.6 Hz, C-2), 98.1 (s, C-1), 108.1 (s, C-4), 108.5 (d, $J_{P,C}$ = 16.4 Hz, C-6), 127.6–135.9 (m, $C_6H_5$, $PPh_3$, mixed with those of **2b**) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $C_6D_6$): $\delta$ = –0.3 (s) ppm.

**2b** ($PPh_3$ is *cis* to the exocyclic double bond): $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 0.50 (s, 9 H, $SiMe_3$), 5.49 [s, 1 H, C(5)-H], 6.31 [s, 1 H, C(3)-H], 6.80 [s, 1 H, C(6)-H], 7.06–7.65 (m, $C_6H_5$, $PPh_3$, mixed with those of **2a**) ppm. $^{13}C\{^1H\}$ NMR (100.4 MHz, $CD_2Cl_2$): $\delta$ = –0.1 (s, $SiMe_3$), 79.2 (s, C-5), 82.6 (s, C-6), 94.5 (s, C-4), 97.5 (s, C-1), 100.4 (d, $J_{P,C}$ = 10.3 Hz, C-2), 111.5 (d, $J_{P,C}$ = 8.9 Hz, C-3), 127.9–137.1 (m, $C_6H_5$, $PPh_3$, mixed with those of **2a**) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $C_6D_6$): $\delta$ = –7.8 (s) ppm.

**$[OsCl_2\{\eta^6\text{-}C_5H(C{\equiv}CPh)(Ph)_2(=CHPh)\}(PPh_3)]$ (3):** A mixture of $[Os\{=CPh(\eta^2\text{-}CH=C=CHPh)Cl_2(PPh_3)_2]$ (0.20 g, 0.20 mmol) and $PhC{\equiv}C\text{–}C{\equiv}CPh$ (0.20 g, 0.99 mmol) in benzene (15 mL) was refluxed for 1 h. Unreacted $[OsCl_2\{=CPh(CH=C=CPh)(PPh_3)_2]$ was then removed by filtration and residue was washed with benzene (2 × 5 mL). The solvent was removed from the brown filtrate under vacuum and the residue dissolved in $CH_2Cl_2$ (2 mL). Addition of diethyl ether (8 mL) to the residue gave a greenish brown precipitate, which was collected by filtration, washed with diethyl ether (3 × 2 mL), and dried under vacuum. The residue was recrystallized from benzene to give a red precipitate, which was collected by filtration, washed with benzene (2 mL) and diethyl ether (2 × 3 mL), and dried under vacuum. Yield: 80 mg (43%). $C_{50}H_{37}Cl_2OsP{\cdot}0.25CH_2Cl_2$: calcd. C 63.45, H 3.97; found C 63.70, H 4.20. $^1H$ NMR (300.13 MHz, $CD_2Cl_2$): $\delta$ = 6.00 (d, $J_{P,H}$ = 2.1 Hz, 1 H, =CH), 6.62 (d, $J_{P,H}$ = 5.1 Hz, 1 H, =C*H*Ph), 6.30–7.74 (m, 35 H, $C_6H_5$, $PPh_3$) ppm. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CD_2Cl_2$): $\delta$ = –8.0 (s) ppm.

**$[(PPh_3)_2ClOs(\mu\text{-}Cl)_3Os(H_2O)(PPh_3)_2]$ (4) and 5:** Styrene (0.18 mL, 1.6 mmol) was added to a solution of $[OsCl_2\{=CPh\text{-}$

(CH=C=CPh)($PPh_3$)$_2$] (0.32 g, 0.32 mmol) in $CH_2Cl_2$ (20 mL) and the reaction mixture was stirred at room temperature for 24 h to give a light-brown solution. The volume of the reaction solution was reduced to about 1 mL and hexane (30 mL) was then added slowly with stirring to produce a light-brown precipitate. The mixture was further stirred for 10 min and then filtered. The solid was collected by filtration, washed with diethyl ether (2 × 15 mL) and hexane (15 mL), and dried under vacuum to give **4**. Yield: 0.19 g (75%). $C_{72}H_{62}Cl_4P_4Os_2$: calcd. C 54.41, H 3.93; found C 54.52, H 4.12. FAB-MS (NBA): $m/z$ 1570.8 [M – $H_2O$]$^+$. $^1$H NMR (300.13 MHz, $C_6D_6$): $\delta$ = 7.00–7.16 (m, 22 H), 7.26–7.35 (m, 26 H), 7.80–8.03 (m, 12 H), ($PPh_3$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$): $\delta$ = –6.5 (d), –7.8 (d), ($J_{P,P}$ = 11.4 Hz), –16.4 (d), –17.4 (d) ($J_{P,P}$ = 16.7 Hz) ppm. The filtrate and the washing solution obtained above were collected together and the solvent was pumped off. The residue was extracted with 1 mL of benzene and loaded onto a silica gel column. The column was eluted with hexane to give the organic compound **5** along with a small amount of other unidentified organic species as a yellow solution, which was evaporated to dryness on a rotary evaporator and dried under vacuum to give a yellow oil. FAB-MS (NBA): $m/z$ 308.1 [M$^+$]. $^1$H NMR (300.13 MHz, $C_6D_6$, see Scheme 6 for labels): $\delta$ = 2.98 [m, $^2J_{C(4)\text{-}H_a,C(4)\text{-}H_b}$ = 17.3, $^3J_{C(4)\text{-}H_a,C(5)\text{-}H}$ = 3.7, $^4J_{C(4)\text{-}H_a,C(6)\text{-}H} \approx$ 1.8, $^4J_{C(4)\text{-}H_a,C(2)\text{-}H} \approx$ 0.9 Hz, 1 H, C(4)-$H_a$], 3.29 [m, $^2J_{C(4)\text{-}H_a,C(4)\text{-}H_b}$ = 17.3, $^3J_{C(4)\text{-}H,C(5)\text{-}H}$ = 8.3, $^4J_{C(4)\text{-}H_b,C(6)\text{-}H} \approx$ 2.0, $^4J_{C(4)\text{-}H_b,C(2)\text{-}H} \approx$ 0.9 Hz, 1 H, C(4)-$H_b$], 4.16 [ddd, $^3J_{C(4)\text{-}H_b,C(5)\text{-}H}$ = 8.3, $^3J_{C(4)\text{-}H_a,C(5)\text{-}H}$ = 3.7, $^4J_{C(2)\text{-}H,C(5)\text{-}H}$ = 2.5 Hz, 1 H, C(5)-H], 6.32 [br. s, $W_{1/2}$ = 4.5 Hz, 1 H, C(2)-H], 7.51 [br. t, $^4J_{C(4)\text{-}H,\ C(6)\text{-}H}$ = 1.8 Hz, 1 H, C(6)-H], 6.77–7.77 (m, 15 H, Ph) ppm.

**Crystallographic Details for 2a, 3, and 4:** Crystals of **2** and **4** suitable for X-ray diffraction were grown from $CH_2Cl_2$ solutions of **2** and **4** layered with hexane, and crystals of **3** were grown from a $CH_2Cl_2$ solution layered with benzene. Data collections were performed with a Bruker AXS diffractometer equipped with a SMART APEX CCD area detector. Intensity data were collected using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature for **2** and **4**, and at 100 K for **3**. Data reduction and absorption correction were performed using SAINT v.6.26 and SADABS v.2.03, respectively. Structure solution and refinement were performed using the SHELXTL v.6.10 software package. All three structures were solved by direct methods, expanded by difference Fourier syntheses, and refined by full-matrix least-squares on $F^2$. Non-hydrogen atoms were refined anisotropically, except for the $CH_2Cl_2$ solvent in **4**. This was found to be severely disordered and its atoms were given split occupancies and refined isotropically using C–Cl bond length restraints. Some phenyl rings of the $PPh_3$ ligands in **4** also exhibited extensive disorder and were refined with ideal C–C distances and planarity restraints. All hydrogen atoms were placed in geometrical positions and with riding parameters. Further crystallographic details are given in Table 5.

CCDC-631969 (for **2a**), -631970 (for **3**), and -631971 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Unraveling the *o*-Methoxy Effect in the CO/Ethene Copolymerization Reaction by Diphosphanepalladium(II) Catalysis

**Claudio Bianchini,*[a] Andrea Meli,[a] Werner Oberhauser,*[a] Carmen Claver,[b] and Eduardo J. Garcia Suarez[b]**

**Keywords:** Polyketones / Palladium / Diphosphane ligands / Catalysis / Copolymerization / Kinetics

Relevant steps in the CO/ethene copolymerization reaction, namely the migratory insertion of $[Pd(Me)(CO)(P\text{-}P)]BAr'_4$ and the carbonylation of the β-keto chelates $[Pd(CH_2CH_2C(O)Me)(P\text{-}P)]BAr'_4$ have been studied by in situ high-pressure NMR spectroscopy in $CH_2Cl_2$; P-P = 1,2-bis[bis(2-methoxyphenyl)phosphanyl]ethane or 1,3-bis[bis(2-methoxyphenyl)phosphanyl]propane. This study, backed by batch catalytic reactions in the same solvent, has contributed to rationalizing the higher catalytic activity of $Pd^{II}$ catalysts modified with *o*-methoxy-substituted diphosphane ligands as compared to analogous $Pd^{II}$ catalysts with 1,2-bis(diphenylphosphanyl)ethane (dppe) and 1,3-bis(diphenylphosphanyl)propane (dppp) ligands. It was found that *o*-MeO substituents on the phosphorus aryl rings ease the opening of the β-chelate ring by CO and affect the kinetics of the overall CO/ethene copolymerization. Indeed, unlike the catalysts with the dppe and dppp ligands, the rate of carbonylation of the *o*-MeO-modified β-keto chelates is limited by the Pd(alkyl)(CO) migratory insertion, which makes the overall copolymerization process independent of the CO pressure.

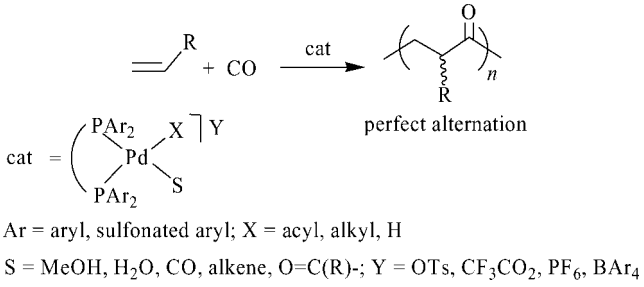
## Introduction

Perfectly alternating polyketones are high-performance thermoplastics obtainable by copolymerization of carbon monoxide and alkenes, generally ethene, in the presence of $Pd^{II}$ catalysts modified with chelating diphosphanes (Scheme 1).[1] The copolymerization reactions are commonly performed in protic solvents (alcohols, preferentially methanol), yet aprotic solvents such as $CH_2Cl_2$ are used in reactions catalyzed by $Pd^{II}$ alkyl precursors as well as in model mechanistic studies.[2]



Scheme 1. Copolymerization reaction with $Pd^{II}(P\text{-}P)$ complexes.

The introduction of one *o*-methoxy substituent on each phosphorus aryl ring of the ligand greatly enhances the productivity as compared to reactions promoted by catalysts with unsubstituted diphosphanes.[2d,3]

Both steric and electronic factors have been invoked to account for the positive effect of the *o*-methoxy groups on the catalyst activity, yet no clear-cut explanation has been put forward so far. Indeed, most of the previous hypotheses are based on indirect observations such as the decreased formation of catalytically inactive bis-chelates or binuclear species;[4] the reduced tendency towards phosphane oxidation;[5a] the increased basicity of the metal center;[5b] and the reduced stability of catalyst resting states.[5c]

Intrigued by the possibility of elucidating the *ortho-methoxy effect*, we decided to look at two well-known reactions occurring during the propagation step of the alternating $CO/C_2H_4$ copolymerization: (i) the migratory insertion of $[Pd(Me)(CO)(P\text{-}P)]^+$ complexes and (ii) the carbonylation of the β-keto chelates $[Pd(CH_2CH_2C(O)Me)(P\text{-}P)]^+$ (Scheme 2).[5b,5c]

To this purpose, complexes stabilized by the two couples of ligands shown in Scheme 3 were employed as model compounds.[5b,5c]

In situ high-pressure NMR (HPNMR) and IR techniques have been employed to determine kinetic and thermodynamic parameters, while batch catalytic reactions under different experimental conditions have provided information on the dependence of the reaction rate on CO and ethene pressures. Incorporation of the results obtained

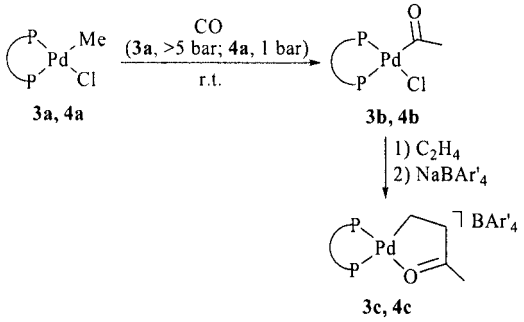
unambiguously show that the *o*-methoxy groups can interact with the metal center, leading to a mechanism where the opening of the β-keto chelates and the overall copolymerization rate as well are zero-order with respect to the CO pressure.

## Results and Discussion

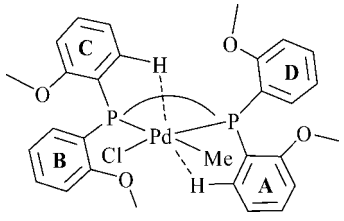
### Generation of the β-Keto Chelates [Pd($CH_2CH_2C(O)Me$)(P-P)]$BAr'_4$

The synthetic procedure for the β-keto chelate complexes [Pd($CH_2CH_2C(O)Me$)(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3c**; *o*-MeO-dppp, **4c**; Ar′ = 3,5-$(CF_3)_2$-$C_6H_3$) is illustrated in Scheme 4.



Scheme 4. In situ synthesis of the $Pd^{II}$ β-keto chelates **3c** and **4c**.

The chlorido-methyl precursors [PdCl(Me)(P-P)] (P-P = *o*-MeO-dppe, **3a**; *o*-MeO-dppp, **4a**) were conveniently prepared by the plain reaction of PdCl(Me)(COD) (COD = cycloocta-1,5-diene) with the appropriate diphosphane and isolated as off-white crystalline solids in 78 and 67% yield, respectively.[2d] Unambiguous characterization of **3a** and **4a** in solution was achieved by variable-temperature $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy in $CD_2Cl_2$. Complexes **3a** and **4a** exhibit fluxional behavior on the NMR time-scale due to the exchange of equatorial and axial aryl groups. The $^1H$ NMR spectrum at 21 °C of either complex displayed one set of resonances for the aryl hydrogen atoms ($\delta$ = 6.87–7.91 and 6.87–7.58 ppm, respectively) and two singlets for the methoxy groups ($\delta$ = 3.59/3.60 and 3.66/3.76 ppm, respectively), which is consistent with the presence of two couples of equivalent aryl groups in the *o*-MeO-ligands. Decreasing the temperature led to a progressive broadening of all resonances. At –70 °C, the $^1H$ NMR spectra of **3a** and **4a** showed four singlets for the methoxy groups at $\delta$ = 3.42, 3.44, 3.75, and 3.76 ppm and $\delta$ = 3.56, 3.67, 3.69, and 3.72 ppm, respectively. This pattern can be safely attributed to the formation of equatorially and axially oriented methoxy groups as illustrated in the sketch reported in Scheme 5.[2d,6]



Scheme 5. Low temperature conformation of **3a** and **4a**.

The $^1H$ NMR spectra at –70 °C showed also a significant downfield shift of the resonances of two aryl hydrogen atoms ($\delta$ = 8.45/8.61 and 8.55/8.74 ppm, respectively), which, on the basis of $^1H$-$^{31}P$ COSY experiments, can be assigned to the *o*-H atoms of the axial aryl rings **A** and **C** interacting with the metal center. Analogous fluxional behavior has been previously reported for the X-ray authenticated complexes $PdCl_2$(P-P) (P-P = *o*-MeO-dppe, *o*-MeO-dppp).[2d] Further spectroscopic evidence in support of the conformation proposed in Scheme 5 was provided by a $^1H$ ROESY experiment at –70 °C of **3a**, indicating two significant correlations between the hydrogen atoms of the Pd methyl group and the *o*-H atoms of the aryl rings **A** and **C**.

A single-crystal X-ray analysis of **3a**·$CHCl_3$ has confirmed the structure proposed in solution. Suitable crystals were obtained by slow diffusion of toluene into a $CHCl_3$ solution of **3a**. An ORTEP drawing of **3a**·$CHCl_3$ is shown in Figure 1, while selected distances and angles are reported in Table 1.

The crystal structure shows a square-planar palladium center coordinated by *cis* phosphorus atoms. The Pd–P bond lengths of 2.221(2) Å (*trans* to chloride) and 2.343(2) Å (*trans* to methyl) are in line with the greater *trans*-influence of the methyl group as compared to chlo-

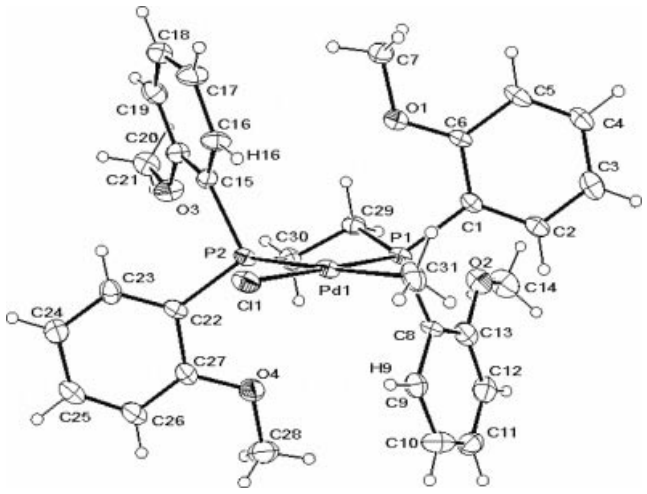

Figure 1. ORTEP plot of **3a**·$CHCl_3$. The solvent molecule was omitted for clarity. Thermal ellipsoids are shown at the 30% probability level.

Table 1. Selected bond lengths and bond angles for **3a·CHCl$_3$**.

| Bond lengths [Å] and bond angles [°] | |
|---|---|
| Pd(1)–P(1) | 2.221(2) |
| Pd(1)–P(2) | 2.343(2) |
| Pd(1)–Cl(1) | 2.389(2) |
| Pd(1)–C(31) | 2.095(8) |
| P(1)–Pd(1)–P(2) | 86.27(9) |
| C(31)–Pd(1)–Cl(1) | 89.30(20) |
| **Intramolecular distances [Å]** | |
| Pd(1)–O(1) | 3.573(6) |
| Pd(1)–O(2) | 5.181(6) |
| Pd(1)–O(3) | 5.271(7) |
| Pd(1)–O(4) | 3.870(6) |
| Pd(1)–H(9) | 2.809 |
| Pd(1)–H(16) | 2.855 |

ride. The four *o*-methoxy oxygen atoms are disposed around the palladium center in such a way that two of them, O(1) and O(4), point to the metal center occupying a pseudo-apical position (Pd···O distances of 3.573(6) and 3.870(6) Å], while the other two, O(2) and O(3), are close to pseudo-equatorial positions (Pd···O distances of 5.181(6) and 5.271(7) Å]. All of these Pd···O distances are too large for an effective electrostatic interaction between palladium and the *o*-methoxy groups. In contrast, the *o*-H atoms H(9) and H(16) show short intramolecular Pd···H distances of 2.809 and 2.855 Å, respectively, which are comparable to those found in the crystal structure of $PdCl_2$(*o*-MeO-dppe).[2d]

Pressurizing a $CH_2Cl_2$ solution of **3a** with >5 bar CO in a 10-mm-OD HPNMR tube at room temperature led to the immediate formation of the acetyl complex PdCl(COMe)(*o*-MeO-dppe) (**3b**). In contrast, the formation of the complex PdCl(COMe)(*o*-MeO-dppp) (**4b**) from **4a** required no pressurization as it was quantitatively obtained by bubbling CO into a $CH_2Cl_2$ solution of the methyl complex at room temperature (Scheme 4). Once formed, the acetyl complexes were stable in solution even in the absence of CO.

Ethene bubbling into $CH_2Cl_2$ solutions of the acyl complexes **3b** and **4b** for 2 min, followed by the addition of stoichiometric $NaBAr'_4$, gave the β-keto chelates **3c** and **4c** (Scheme 4). Compounds **3b**, **3c**, **4b**, and **4c** have been unambiguously characterized by variable-temperature $^{31}P\{^1H\}$ and $^1H$ NMR spectroscopy. Selected NMR spectroscopic data are reported in Table 2 and Table 3, respectively.

Like the chlorido-methyl precursors **3a** and **4a**, the β-keto chelates **3c** and **4c** exhibit fluxional behavior in $CD_2Cl_2$ solution at room temperature, due to the exchange of equatorial and axial aryl groups. At –70 °C both compounds adopt the conformation shown in Scheme 6.

The $^1H$ NMR spectra of **3c** and **4c** at –70 °C showed a multiplet at $\delta$ = 8.48 and 8.28 ppm, respectively, which, on the basis of $^1H$-$^{31}P$ COSY experiments, was assigned to the

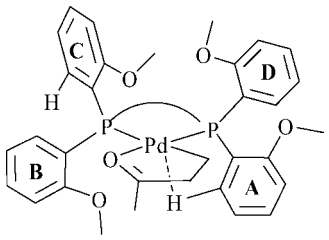

Scheme 6. Low temperature conformation of **3c** and **4c**.

*o*-H atom of ring **A**. At the same temperature, a $^1$H-ROESY experiment of **3c** revealed the existence of significant correlations between the Pd-$CH_2$ unit and the *o*-H atoms of the aryl rings **A** and **D** and between the *o*-methoxy hydrogen atoms from the equatorial aryl ring **B** and the hydrogen atoms of the COMe unit. The stereochemical position of the aryl ring **C** could not be unambiguously determined, yet, due to the lack of the downfield-shifted multiplet of the *o*-H atom of ring **C** in the $^1$H NMR spectrum, it is likely that ring **C** is turned around in such a way that the corresponding *o*-methoxy group points towards the metal center.

The β-keto chelates **3c** and **4c** and the corresponding derivatives with dppe (**1c**) and dppp (**2c**) were also characterized by in-situ IR spectroscopy in $CH_2Cl_2$ at room temperature (Table 4). The spectra were scarcely informative except for showing a blue shift of ca. 6 $cm^{-1}$ of the C=O stretching band for the *o*-methoxy-susbstituted complexes, which is consistent with the higher σ-donor ability of *o*-MeO-dppe and *o*-MeO-dppp as compared to dppe and dppp.

Table 4. Selected IR absorption bands in $CH_2Cl_2$ of selected complexes.

| | [Pd($CH_2CH_2C$(O)Me)-(P-P)]BAr′$_4$ ν(C=O) [$cm^{-1}$] | [Pd(CO)(COMe)-(P-P)]BAr′$_4$ ν(CO)/ν(C=O) [$cm^{-1}$] |

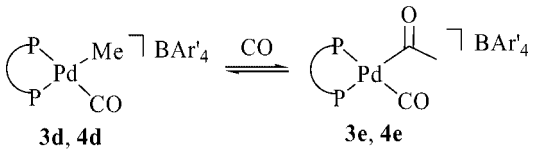
## Generation and Migratory Insertion Barriers of [PdMe(CO)(P-P)]BAr′$_4$

The carbonyl-methyl complexes [PdMe(CO)(P-P)]BAr′$_4$ (P-P = *o*-MeO-dppe, **3d**; *o*-MeO-dppp, **4d**) were selectively generated in situ by bubbling CO into a HPNMR tube containing a $CD_2Cl_2$ solution of the corresponding chloridomethyl complex at –120 °C.

The kinetics of conversion of the carbonyl-methyl complexes to the (acetyl)carbonyl products [Pd(CO)(COMe)-(P-P)]BAr′$_4$ (P-P = *o*-MeO-dppe, **3e**; *o*-MeO-dppp, **4e**) (Scheme 7) were conveniently followed by variable-temperature $^{31}P\{^1H\}$ NMR spectroscopy in $CD_2Cl_2$. $^{31}P\{^1H\}$ and $^1$H NMR spectroscopic data for **3d**–**4e** are given in Table 5 and Table 6, respectively.



Scheme 7. Migratory insertion of **3d** and **4d**.

Table 5. $^{31}P\{^1H\}$ NMR chemical shifts in ppm, multiplicities in parentheses, and PP coupling constants (Hz) in square brackets for the palladium complexes [Pd(X)(Y)(P-P)]BAr′$_4$ in $CD_2Cl_2$ solutions at temperatures (°C) given in curly brackets.

| P-P | X = Me,Y = CO | X = COMe, Y = CO |
|---|---|---|
| *o*-MeO-dppe | 57.59 (d) [31.0] | 35.75 (d) [48.7] |
| | 24.34 (d) {–50} | 16.55 (d) {–40} |
| *o*-MeO-dppp | 22.40 (d) [62.8] | 8.00 (d) [88.7] |
| | –29.9 (br. s) {–90} | –28.5 (d) {–40} |

Table 6. $^1$H NMR chemical shifts in ppm and multiplicities in parentheses for the palladium complexes [Pd(X)(Y)(P-P)]BAr′$_4$ in $CD_2Cl_2$ solutions at temperatures (°C) given in curly brackets.

| P-P | X = Me, Y = CO | X = COMe, Y = CO |
|---|---|---|
| *o*-MeO-dppe | 0.43 (m) {–50} | 1.65 (s) {–40} |
| *o*-MeO-dppp | 0.08 (m) {–90} | 1.88 (s) {–40} |

Consistent with the greater σ-donor ability of *o*-MeO-dppe and *o*-MeO-dppp vs. dppe and dppp, the IR spectra of the (acetyl)carbonyl complexes **3e** and **4e** in $CH_2Cl_2$ (Table 4) showed a blue shift of the COMe absorption band (3–6 $cm^{-1}$) and a red shift of the CO absorption band (7–8 $cm^{-1}$) as compared to the analogue derivatives [Pd(CO)-(COMe)(P-P)]BAr′$_4$ with dppe (**1e**) and dppp (**2e**).[2b,2c]

The study of the migratory insertion of the methyl(carbonyl) complexes was carried out at different CO pressures (5–20 bar), showing the reaction rate to be independent of the CO concentration. According to first-order kinetics, the free energy of activation for the migration insertion process was calculated applying the equation: $\Delta G^{\ddagger} = RT(\ln kT/h -$

Table 7. Experimental activation barriers and temperatures for the migratory insertions of (alkyl)carbonyl complexes and for the carbonylation of β-chelates.

| P-P | [Pd(Me)(CO)(P-P)]$^+$ | | | [Pd($CH_2CH_2C$(O)Me)(P-P)]$^+$ | | | [Pd($CH_2CH_2C$(O)Me)(CO)(P-P)]$^+$ | | |
|---|---|---|---|---|---|---|---|---|---|
| | $T$ [°C] | $t_{1/2}$ [min] | $\Delta G^{\ddagger}$ [kcal/mol] | $T$ [°C] | $t_{1/2}$ [min] | $p$(CO) [bar] | $T$ [°C] | $t_{1/2}$ [min] | $\Delta G^{\ddagger}$ [kcal/mol] |
| *o*-MeO-dppe | –40 | 52 | 17.4(1) | –60 | 25 | 20 | –40 | 100 | 17.7(1) |
| dppe[2b] | –40 | 12 | 16.9(1) | –20 | 15 | 20 | | | |
| *o*-MeO-dppp | –80 | 105 | 14.6(1) | –90 | 6 | 20 | –60 | 10 | 15.2(1) |
| dppp[2c] | –60 | 10 | 15.2(1) | –70 | 84 | 20 | | | |

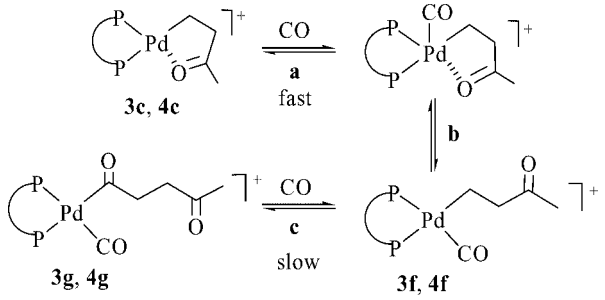
$\ln k_r$) with $k_r = \ln 2/t_{1/2}$ ($T$ = temperature during the conversion; $t_{1/2}$ = half-life time in seconds).[2b,2c] The values of the activation energies for the migratory insertion in **3d** and **4d** are given in Table 7 that also reports data previously reported for the dppe and dppp analogues [PdMe(CO)(P-P)]-$BAr'_4$ (P-P = dppe, **1d**; dppp, **2d**).[2b,2c]

The results obtained showed the migratory insertion of PdMe(CO) to be a low-energy process for all complexes; in addition it was lower for the dppp complexes than for the dppe ones and, in particular, for the *o*-MeO-dppp complex **4d**, which is known to generate the most active catalysts in several reaction media.[2d]

### Carbonylation Reactions of the β-Keto Chelates

The reactions of the β-keto chelates **3c** and **4c** with 20 bar CO in $CD_2Cl_2$ were studied in situ by $^1H$ and $^{31}P\{^1H\}$ HPNMR spectroscopy at low temperature. HPNMR tubes containing $CD_2Cl_2$ solutions of these complexes under nitrogen were cooled to ca. –120 °C, pressurized with 20 bar CO, and then inserted into the NMR probe-head pre-cooled to –90 °C. The conversion of the β-keto chelates into the (acyl)carbonyl complexes [Pd(CO)-$(COCH_2CH_2C(O)Me)$(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3g**; *o*-MeO-dppp, **4g**) was found to involve (alkyl)carbonyl intermediates of the formula [Pd(CO)$(CH_2CH_2C(O)Me)$-(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3f**; *o*-MeO-dppp, **4f**) (Scheme 8). Selected $^{31}P\{^1H\}$ and $^1H$ NMR spectroscopic data of the final products and intermediates are reported in Table 2 and Table 3, respectively, while sequences of $^{31}P\{^1H\}$ NMR spectra acquired during the carbonylation of either **3c** or **4c** with 20 bar CO are reported in Figure 2 and Figure 3, respectively.



Scheme 8. Carbonylation of **3c** and **4c**.

Compound **3c** started to convert into the (alkyl)carbonyl complex **3f** at –60 °C with a $t_{1/2}$ value of 25 min (Figure 2, trace b). Increasing the temperature to –40° led to the quantitative formation of **3f** already after recording the first $^{31}P\{^1H\}$ NMR spectrum (trace c). At this temperature, **3f** slowly converted into the (acyl)carbonyl complex **3g** (trace d), which was the only phosphorus-containing species at room temperature (trace e).

In an analogous experiment, **4c** was found to convert already at –90 °C into the (alkyl)carbonyl complex **4f** (Figure 3, trace b), which, in turn, started to transform into the final (acyl)carbonyl product **4g** at –80 °C. Because of the slow conversion rate at this temperature, the migratory insertion of **4f** was more conveniently evaluated at –60 °C (trace d).

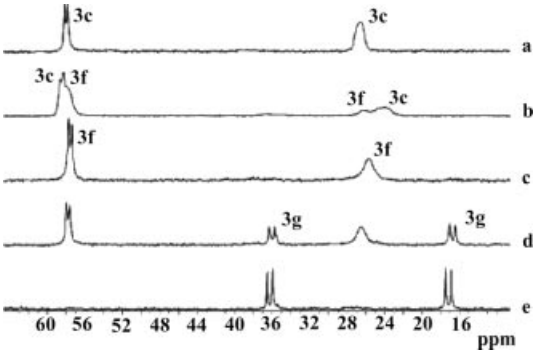


Figure 2. Variable-temperature $^{31}P\{^1H\}$ NMR study (sapphire tube, $CD_2Cl_2$, 81.01 MHz) of the carbonylation reaction of **3c**: (a) under nitrogen at –90 °C; (b) under CO (20 bar) after 40 min at –60 °C; (c) after 5 min at –40 °C; (d) after 80 min at –40 °C; (e) at room temperature.

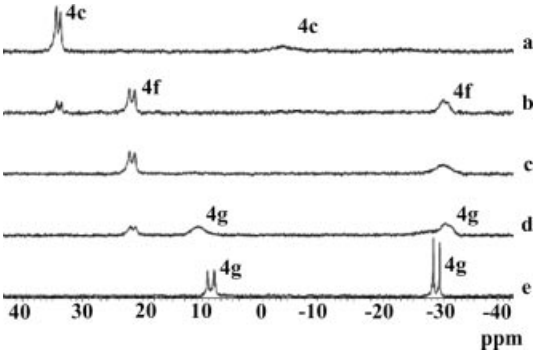

Figure 3. Variable-temperature $^{31}P\{^1H\}$ NMR study (sapphire tube, $CD_2Cl_2$, 81.01 MHz) of the carbonylation reaction of **4c**: (a) under nitrogen at –90 °C; (b) under CO (20 bar) after 30 min at –90 °C; (c) after 30 min at –80 °C; (d) after 10 min at –60 °C; (e) at room temperature.

To the best of our knowledge, (alkyl)carbonyl compounds such as **3f** and **4f** have never been intercepted along the carbonylation of diphosphane-modified palladium alkyl complexes. Like all the other new products obtained in situ, the characterization of the (alkyl)carbonyl complexes was achieved by NMR spectroscopy as well as by comparison with the spectra of similar or related complexes (i.e., γ-keto acyl chelates)[7] described in the literature (Table 2 and Table 3). Experimental evidence supporting the (alkyl)carbonyl structure of **3f** and **4f** was provided by the $^{31}P$ chemical shifts and the $^2J_{PP}$ coupling constants that were practically identical to those of the carbonyl-methyl complexes **3d** and **4d**. Moreover, the $^1H$ NMR shifts of the $PdCH_2CH_2C(O)Me$ units were significantly upfield shifted with respect to the values observed for the β-keto chelates (**3c** vs. **3f**: C(O)Me, $\delta$ = 2.40 vs. 2.10 ppm; $PdCH_2$, $\delta$ = 0.82 vs. 0.30 ppm; **4c** vs. **4f**: C(O)Me, $\delta$ = 2.17 vs. 1.51 ppm;

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$PdCH_2$, $\delta$ = 0.84 vs. 0.37 ppm). In particular, the high-field shift of the C(O)Me singlets agrees well with the de-coordination of the carbonyl-oxygen atom from the metal center.[7g]

Temperatures and $t_{1/2}$ values for the conversion of the β-chelates **3c** and **4c** into the corresponding (alkyl)carbonyl product and the activation energies of the migratory insertions of the latter compounds are reported in Table 7. The opening of the β-chelate ring by CO is apparently easier for the *o*-MeO-susbstituted complexes than for the $PPh_2$-ones, which might well account for the greater catalytic activity of the former complexes in batch reactions.[2d,3–5]

In the light of the kinetic and thermodynamic data relative to the opening of the β-chelate ring by CO and to the alkyl migration to CO (Table 7), one may safely conclude that the latter process (step **c** of Scheme 8) limits the overall rate of the transformation of **3c** and **4c** into the (acyl)carbonyl products **3g** and **4g**, which is a relevant step in the propagation mechanism of the CO/ethene copolymerization by $Pd^{II}$-diphosphane catalysis.[1] Accordingly, since the Pd(CO)alkyl migratory insertion is independent of the CO pressure (vide infra), the overall copolymerization process would be independent of the CO pressure, at least under a gas pressure of 20 bar. This result dramatically differs from the previously reported studies of CO/ethene copolymerization by the $PPh_2$-precursors **1c** and **2c** where the actual copolymerization rate depends on both CO and $C_2H_4$ pressure[8] and the opening of the β-chelates by CO is the rate-limiting step in the propagation step involving CO insertion (Table 7).[2b,2c]

### Catalytic CO/Ethene Copolymerization Reactions

In an attempt to determine the dependence of the copolymerization rate on CO and ethene pressures under actual catalytic conditions, several batch reactions were carried out using either the *o*-MeO-modified chlorido-methyl complex **4a** or the analogous dppp derivative **2a** in $CH_2Cl_2$ at 50 °C.[2d] The results of this study are summarized in Table 8 which also reports data obtained in MeOH with the known catalyst $[Pd(H_2O)_2(o\text{-MeO-dppp})](OTs)_2$ (**4h**).[2d] In excellent accord with the present kinetic study, the catalytic activity of **4a** did not vary with the CO pressure in the range from 5 to 30 bar (entries 1, 2, 4), whereas an increase in activity occurred on increasing the $C_2H_4$ pressure (entry 3 vs. 2). In contrast, the productivity of the dppp precursor **2a** showed a clear dependence on the CO pressure (entries 5–6), which is in agreement with a previous kinetic study by Toniolo and Chaudhary for reactions carried out in MeOH.[8] The latter solvent was therefore used in reactions catalyzed by the *o*-MeO-dppp precursor **4h** (entries 7–9) which showed no dependence on the CO pressure above 10 bar, thus confirming and generalizing the results of the present kinetic study in $CH_2Cl_2$. Noteworthy, a zero-order dependence on the CO pressure has also been reported for the CO/ethene/propene terpolymerization catalyzed by the water-soluble system Pd acetate/sulfonated *o*-MeO-dppp.[3d]

Table 8. Ethene/CO copolymerization reactions catalyzed by diphosphanepalladium precursors in different solvents.

| Entry[a] | Precursor | P(CO) [bar] | $P(C_2H_4)$ [bar] | Productivity[b] |
|---|---|---|---|---|
| 1 | PdCl(Me)(*o*-MeO-dppp) | 5 | 20 | 5.0 |
| 2 | PdCl(Me)(*o*-MeO-dppp) | 20 | 20 | 5.1 |
| 3 | PdCl(Me)(*o*-MeO-dppp) | 20 | 40 | 7.4 |
| 4 | PdCl(Me)(*o*-MeO-dppp) | 30 | 20 | 4.9 |
| 5 | PdCl(Me)(dppp) | 5 | 20 | 0.6 |
| 6 | PdCl(Me)(dppp) | 20 | 20 | 2.8 |
| 7[c] | $[Pd(H_2O)_2(o\text{-MeO-dppp})](OTs)_2$ | 10 | 20 | 17.0 |
| 8[c] | $[Pd(H_2O)_2(o\text{-MeO-dppp})](OTs)_2$ | 15 | 20 | 16.8 |
| 9[c] | $[Pd(H_2O)_2(o\text{-MeO-dppp})](OTs)_2$ | 20 | 20 | 18.1 |

[a] Reaction conditions: precursor (0.010 mmol), $CH_2Cl_2$ (75 mL), $NaBAr'_4$ (1.5 equiv.), BQ (80 equiv.), 20 min, 50 °C, 1200 rpm. [b] Productivity: kilograms of alt-E-CO (g Pd × h)$^{-1}$. [c] Reaction conditions: precursor (0.0024 mmol), MeOH (100 mL), 1 h, 85 °C, 1200 rpm.

## Conclusions

The present study confirms that *o*-MeO substituents on the P-aryl rings of chelating diphosphanes exert a beneficial effect on the activity of $Pd^{II}$ catalysts for the alternating CO/ethene copolymerization. Electronic effects, related to the ability of the methoxy oxygen atoms to interact with the metal center, seem to play a major role in driving the catalytic activity. Indeed, even though no direct evidence for the coordination of the *o*-MeO group to palladium has been observed in the course of either migratory insertion or carbonylation reactions, NMR spectroscopy has shown the aryl rings to adopt a conformation which favors the interaction between the *o*-MeO oxygen atoms and the metal center.

High-pressure NMR studies supported by batch catalytic reactions have unambiguously shown that the presence of *o*-MeO substituents on the P-aryl rings affects the kinetics of the CO/ethene copolymerization by $Pd^{II}$-chelating diphosphane catalysis. Unlike analogous catalysts without *o*-methoxy-substituted ligands, the rate of carbonylation of the β-keto chelates is limited by the Pd(alkyl)(CO) migratory insertion, which makes the overall copolymerization process independent of the CO pressure, at least in the range of the partial CO pressures investigated (5–30 bar).

## Experimental Section

**General Procedures:** All reactions and manipulations were carried out under nitrogen using Schlenk-type techniques. The solvents were generally distilled from dehydrating reagents and were deoxygenated before use. The reagents were used as purchased from Aldrich or Fluka, unless stated otherwise. PdCl(Me)(COD)[9] (COD = cycloocta-1,5-diene), $[Pd(CH_2CH_2C(O)Me)(dppe)]BAr'_4$ (**1c**),[2b] $[Pd(CH_2CH_2C(O)Me)(dppp)]BAr'_4$ (**2c**),[2c] [Pd(CO)(C(O)Me)-(dppe)]$BAr'_4$ (**1e**),[2b] [Pd(CO)(C(O)Me)(dppp)]$BAr'_4$ (**2e**),[2c] and $NaBAr'_4$[10] were prepared according to literature methods. All the isolated solid samples were collected on sintered-glass frits and washed with appropriate solvents before being dried under a stream of nitrogen. Copolymerization reactions were performed with a 250-mL stainless steel autoclave, constructed at the ICCOM-CNR

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(Florence, Italy), equipped with a magnetic drive stirrer and a Parr 4842 temperature and pressure controller. The autoclave was connected to a gas reservoir to maintain a constant pressure during the catalytic reactions. GC/MS analyses of the solutions were performed on a Shimadzu QP2100S apparatus equipped with a SPB-1 Supelco fused silica capillary column (30 m, 0.25 mm i.d., 0.25 μm film thickness). Deuterated solvents for routine NMR measurements were dried with molecular sieves. $^{1}H$, $^{13}C\{^{1}H\}$, $^{31}P\{^{1}H\}$ NMR spectra were obtained with either a Bruker ACP 200 (200.13, 50.32 and 81.01 MHz, respectively) or a Bruker Avance DRX-400 spectrometer (400.13, 100.62 and 161.98 MHz), respectively. Chemical shifts are reported in ppm ($\delta$) relative to TMS, referenced to the chemical shifts of residual solvent resonances ($^{1}H$ and $^{13}C$ NMR) or 85% $H_3PO_4$ ($^{31}P$ NMR). $^{1}H$-$^{31}P$ COSY spectra and $^{1}H$ ROESY were recorded with a Bruker Avance DRX-400 spectrometer. High-pressure NMR experiments were carried out on the Bruker ACP 200 using a 10-mm sapphire NMR tube, which was purchased from Saphikon (Milford, NH), while the titanium high-pressure charging head was constructed at the ISSECC-CNR (Florence, Italy).[11] Elemental analyses were performed using a Carlo Erba Model 1106 elemental analyzer. Infrared spectra were recorded on a FT-IR Spectrum GX instrument (Perkin–Elmer).

***S*ynthesis of the Methyl-chlorido Complexes PdCl(Me)(P-P):**[2d] A solid sample of PdCl(Me)(COD) (0.20 mmol, 52.99 mg) was added to a stirred solution of the appropriate diphosphane ligand (0.20 mmol) in $CH_2Cl_2$ (20 mL) at room temperature. After 1 h, the resulting colorless solution was concentrated to ca. 5 mL under reduced pressure. Addition of *n*-pentane/diethyl ether (1:1, v/v; 20 mL) led to the precipitation of [PdCl(Me)(P-P)] (P-P = *o*-MeO-dppe, **3a**; *o*-MeO-dppp, **4a**) as an off-white solid, which was filtered off, washed with *n*-pentane, and dried under a stream of nitrogen.

**3a:** Yield 78%, 105.31 mg. $C_{31}H_{35}ClO_4P_2Pd$ (675.11): calcd. C 55.13, H 5.22; found C 55.09, H 5.24. $^{31}P\{^{1}H\}$ NMR (81.1 MHz, $CDCl_3$, 21 °C): $\delta$ = 61.09 (d, $^{2}J_{P,P}$ = 22.0 Hz, $P_A$), 39.07 (d, $P_M$) ppm. $^{1}H$ NMR (200.13 MHz, $CDCl_3$, 21 °C): $\delta$ = 0.40 (dd, $^{3}J_{H,PM}$ = 8.0 Hz, $^{3}J_{H,PA}$ = 3.2 Hz, 3 H, PdMe), 2.19–2.93 (m, 4 H, $PCH_2$), 3.59 (s, 6 H, OMe), 3.60 (s, 6 H, OMe), 6.87–7.91 (m, 16 H, Ar) ppm. $^{31}P\{^{1}H\}$ NMR (161.98 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = 60.70 (d, $^{2}J_{P,P}$ = 23.2 Hz, $P_A$), 38.32 (d, $P_M$) ppm. $^{1}H$ NMR (400.16 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = 0.40 (dd, $^{3}J_{H,PM}$ = 8.0 Hz, $^{3}J_{H,PA}$ = 3.0 Hz, 3 H, PdMe), 2.08 (m, 1 H, PCH*H*), 2.38 (m, 1 H, P′CH*H*), 2.91 (dt, $^{2}J_{H,P}$ = 56.0 Hz, $^{3}J_{H,H}$ = 13.6 Hz, 1 H, PC*H*H), 3.08 (dt, $^{2}J_{H,P}$ = 56.0 Hz, $^{3}J_{H,H}$ = 13.6 Hz, 1 H, P′C*H*H), 3.42 (s, 3 H, OMe), 3.44 (s, 3 H, OMe), 3.76 (s, 6 H, OMe), 6.72–7.73 (m, 14 H, Ar), 8.45 (dd, $^{2}J_{H,P}$ = 15.9 Hz, $^{3}J_{H,H}$ = 7.3 Hz, 1 H, *o*-H-$Ar_{ax.}$(A), 8.61 (dd, $^{2}J_{H,P}$ = 15.1 Hz, $^{3}J_{H,H}$ = 7.5 Hz, 1 H, *o*-H-$Ar_{ax.}$(C)) ppm.

**4a:** Yield 67%, 91.92 mg. $C_{32}H_{37}ClO_4P_2Pd$ (689.11): calcd. C 55.75, H 5.41; found C 55.74, H 5.43. $^{31}P\{^{1}H\}$ NMR (81.01 MHz, $CDCl_3$, 21 °C): $\delta$ = 30.80 (d, $^{2}J_{P,P}$ = 52.5 Hz, $P_A$), –0.56 (d, $P_M$) ppm. $^{1}H$ NMR (200.13 MHz, $CDCl_3$, 21 °C): $\delta$ = 0.32 (dd, $^{3}J_{H,PM}$ = 7.9 Hz, $^{3}J_{H,PA}$ = 3.5 Hz, PdMe), 1.92 (m, 2 H, $CH_2$), 2.43 (m, 2 H, $PCH_2$), 2.57 (m, 2 H, $PCH_2$), 3.66 (s, 6 H, OMe), 3.75 (s, 3 H, OMe), 3.76 (s, 3 H, OMe), 6.87–7.58 (m, 16 H, Ar) ppm. $^{31}P\{^{1}H\}$ NMR (161.98 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = 30.88 (d, $^{2}J_{P,P}$ = 51.4 Hz, $P_A$), –2.42 (d, $P_M$) ppm. $^{1}H$ NMR (400.16 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = –0.89 (dd, $^{3}J_{H,PM}$ = 7.7 Hz, $^{3}J_{HPA}$ = 3.2 Hz, PdMe), 1.70 (m, 1 H, CH*H*)), 1.92 (m, 1 H, C*H*H), 2.20 (m, 1 H, PCH*H*), 2.30 (m, 1 H, P′CH*H*), 2.48 (m, 1 H, PC*H*H), 2.79 (m, 1 H, P′C*H*H), 3.56 (s, 3 H, OMe), 3.67 (s, 3 H, OMe), 3.69 (s, 3 H, OMe), 3.72 (s, 3 H, OMe), 6.67–7.71 (m, 14 H, Ar), 8.55 (dd, $^{2}J_{H,P}$ = 16.4 Hz, $^{3}J_{H,H}$ = 7.3 Hz, 1 H, *o*-H-$Ar_{ax.}$(A)), 8.74 (dd, $^{2}J_{H,P}$ = 14.7 Hz, $^{3}J_{H,H}$ = 7.1 Hz, 1 H, *o*-H-$Ar_{ax.}$(C)) ppm.

**In Situ Synthesis of the (Acetyl)Chloride Complexes PdCl(COMe)-(P-P):** In a typical experiment, a solid sample of the methyl-chlorido complex PdCl(Me)(P-P) (0.03 mmol) was dissolved in a Schlenk tube containing $CD_2Cl_2$ (2 mL) under nitrogen at room temperature. The resulting solution was first transferred into a 10-mm sapphire tube and then pressurized to >5 bar of CO at room temperature. Irrespective of the diphosphane the quantitative formation of the corresponding (acetyl)chloride complex PdCl(CO-Me)(P-P) (P-P = *o*-MeO-dppe, **3b**; *o*-MeO-dppp, **4b**) occurred at room temperature. The most relevant $^{31}P\{^{1}H\}$ and $^{1}H$ NMR chemical shifts and coupling constants for **3b** and **4b** are reported in Tables 2 and 3, respectively. The excess CO was released and nitrogen was gently bubbled through the solution previously cooled to –30 °C for 2 min to eliminate any trace of CO. Both complexes were found to be stable also in the absence of CO. Unlike **3b**, **4b** was generated even by bubbling CO through **4a** solutions for 5 min at room temperature. A procedure analogous to that described above was applied to prepare $CH_2Cl_2$ solutions of **3b** and **4b** for the IR characterization: ν(C=O) 1669 (**3b**), 1674 (**4b**) $cm^{-1}$.

**In Situ Synthesis of the β-Keto Chelates [Pd($CH_2CH_2C$(O)Me)-(P-P)]$BAr'_4$:** In a typical experiment, a solution of PdCl(COMe)-(P-P) (0.03 mmol) in $CD_2Cl_2$ (2 mL) was prepared as above in a Schlenk tube at –30 °C under nitrogen. Ethene was bubbled through the solution maintained at –30 °C for 2 min and then a solid sample of $NaBAr'_4$ (0.03 mmol) was added to the solution to scavenge the chloride ligand from Pd. The resulting solution was transferred into a 10-mm sapphire tube. $^{31}P\{^{1}H\}$ and $^{1}H$ NMR spectra were acquired in the temperature range from 20 to –90 °C. Irrespective of the diphosphane ligand, the $^{31}P\{^{1}H\}$ and $^{1}H$ NMR spectra of this sample showed the quantitative conversion of the (acyl)chloride complex into the corresponding β-chelate complex [Pd($CH_2CH_2C$(O)Me)(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3c**; *o*-MeO-dppp, **4c**). IR spectra of **3c** and **4c** were acquired from $CH_2Cl_2$ solutions of these compounds prepared by applying the same synthetic protocol as described above, using $CH_2Cl_2$ instead of $CD_2Cl_2$. The IR values of the CO stretching frequencies are reported in Table 4.

**3c:** $^{31}P\{^{1}H\}$ NMR (161.98 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = 57.36 (d, $^{2}J_{P,P}$ = 26.9 Hz, $P_A$), 25.43 (br., $P_M$) ppm. $^{1}H$ NMR (400.13 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = 0.82 (m, 1 H, PdCH*H*), 1.21 (m, 1 H, PdC*H*H), 2.05 (m, 2 H, $PCH_2$), 2.42 (m, 3 H, COMe), 2.58 (m, 2 H, P′$CH_2$), 2.80 (m, 1 H, COCH*H*), 3.08 (m, 4 H, COC*H*H + OMe), 3.51 (s, 3 H, OMe), 3.80 (s, 3 H, OMe), 3.83 (s, 3 H, OMe), 6.72–7.82 (m, 27 H, Ar), 8.48 [dd, $^{2}J_{H,P}$ = 17.0 Hz, $^{3}J_{H,H}$ = 7.3 Hz, 1 H, *o*-H-$Ar_{ax.}$(A)] ppm.

**4c:** $^{31}P\{^{1}H\}$ NMR (161.98 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = 33.51 (d, $^{2}J_{PP}$ = 57.9 Hz, $P_A$), –12.4 (br., $P_M$) ppm. $^{1}H$ NMR (400.13 MHz, $CD_2Cl_2$, –70 °C): $\delta$ = 0.95 (m, 2 H, $PdCH_2$), 2.21 (s, 3 H, COMe), 2.31 (m, 3 H, PC*H*H + C$H_2$), 2.51 (m, 2 H, PCH*H* + P′CH*H*), 2.92 (m, 3 H, $COCH_2$ + P′C*H*H), 3.59 (s, 3 H, OMe), 3.70 (s, 3 H, OMe), 3.83 (s, 3 H, OMe), 3.86 (s, 3 H, OMe), 6.62–7.83 (m, 27 H, Ar), 8.28 [dd, $^{2}J_{H,P}$ = 17.0 Hz, $^{3}J_{H,H}$ = 7.1 Hz, 1 H, *o*-H-$Ar_{ax.}$(A)] ppm.

**In Situ Generation and Migratory Insertion Barriers of [PdMe(CO)-(P-P)]$BAr'_4$. HPNMR Experiments:** In a typical experiment, the methyl-chlorido complex [PdCl(Me)(P-P)] (0.03 mmol) was dissolved in deoxygenated $CD_2Cl_2$ (2 mL) and the resulting solution was then transferred into a 10-mm sapphire tube, which was cooled to –120 °C by means of an ethanol/liquid nitrogen bath. CO was bubbled through this solution for 2 min at this temperature, fol-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lowed by the addition of $NaBAr'_4$ (0.03 mmol). The CO pressure was adjusted to the desired value (5–20 bar). The solution was shaken for 2 min at –120 °C, followed by the introduction of the sapphire tube into the probe-head previously cooled to –90 °C. Irrespective of the diphosphane ligand, the $^{31}P\{^1H\}$ and $^1H$ NMR spectra showed the quantitative conversion of the starting methyl-chlorido complex into the corresponding carbonyl-methyl complexes [PdMe(CO)(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3d**; *o*-MeO-dppp, **4d**) (selected $^{31}P\{^1H\}$ and $^1H$ NMR spectroscopic data of the carbonyl-methyl complexes are reported in Tables 5 and 6, respectively). Afterwards the probe temperature was gradually increased and $^{31}P\{^1H\}$ and $^1H$ NMR spectra were recorded at each intermediate temperature. Increasing the temperature converted each carbonyl-methyl complex into the corresponding (acetyl)carbonyl derivative [Pd(COMe)(CO)(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3e**; *o*-MeO-dppp, **4e**) (selected $^{31}P\{^1H\}$ and $^1H$ NMR spectroscopic data of the (acetyl)carbonyl complexes are reported in Tables 5 and 6, respectively). At the conversion temperature, the decrease in concentration of the carbonyl-methyl complex was followed by $^{31}P\{^1H\}$ NMR spectroscopy. Spectra were taken at intervals of 5–10 min, depending on conditions. The reaction was followed for 2–3 half-lives. IR spectra of **3e** and **4e** were acquired from $CH_2Cl_2$ solutions of these compounds prepared by applying the same synthetic protocol as described above, using $CH_2Cl_2$ instead of $CD_2Cl_2$. The IR values of the CO stretching frequencies are reported in Table 4.

**Carbonylation of the β-Keto Chelates [Pd($CH_2CH_2C(O)Me$)(P-P)]$BAr'_4$. HPNMR Experiments:** $CD_2Cl_2$ (2 mL) solutions of the β-keto chelates [Pd($CH_2CH_2C(O)Me$)(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3c**; *o*-MeO-dppp, **4c**) (0.03 mmol) were synthesized in situ in a Schlenk tube at –30 °C, as described above. Nitrogen was bubbled through the solution to eliminate any trace of ethene. The solutions were transferred into a 10-mm sapphire tube at room temperature. Then the sapphire tube was introduced in a pre-cooled NMR probe (–90 °C) and $^{31}P\{^1H\}$ and $^1H$ NMR spectra were acquired at this temperature. The sapphire tube was then removed from the probe and immersed in an ethanol/liquid nitrogen thermostat bath (ca. –120 °C) before to be charged with CO (5–20 bar). Afterwards the sapphire tube was introduced again into the NMR probe head at –90 °C. $^{31}P\{^1H\}$ and $^1H$ NMR spectra showed that the β-chelate complexes were still present. Afterwards the probe temperature was gradually increased and $^{31}P\{^1H\}$ and $^1H$ NMR spectra were recorded at each intermediate temperature. Increasing the temperature caused the conversion of the β-chelate complex into the corresponding (acyl)carbonyl derivative [Pd(CO)($COCH_2CH_2C(O)Me$)(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3g**; *o*-MeO-dppp, **4g**) via the (alkyl)carbonyl complexes [Pd(CO)($CH_2CH_2C(O)Me$)(P-P)]$BAr'_4$ (P-P = *o*-MeO-dppe, **3f**; *o*-MeO-dppp, **4f**). Selected high-pressure $^{31}P\{^1H\}$ NMR spectra of the carbonylation of either **3c** or **4c** under 20 bar of CO are shown in Figures 2 and 3, respectively. Selected $^{31}P\{^1H\}$ and $^1H$ NMR spectroscopic data of the complexes **3f**, **4f**, **3g**, and **4g** are reported in Tables 2 and 3, respectively. At the conversion temperature the decrease in concentration of the β-keto chelates was followed by $^{31}P\{^1H\}$ NMR spectroscopy. Spectra were taken at intervals of 5–10 min, depending on conditions. The reaction was followed for 2–3 half-lives.

**[Pd($CH_2CH_2C(O)Me$)(P-P)]$BAr'_4$/[Pd($COCH_2CH_2C(O)Me$)(CO)(P-P)]$BAr'_4$ Equilibria:** Solutions of the (acyl)carbonyl complexes **3g** and **4g**, prepared as reported above in HPNMR tubes, were immersed in a thermostat bath at –20 °C. CO was released and then couples of vacuum-nitrogen cycles were applied. $^{31}P\{^1H\}$ and $^1H$ NMR spectra of these samples acquired at –20 °C allowed us to follow the transformation of the (acyl)carbonyl complexes into the corresponding β-chelates **3c** and **4c**.

**Catalytic Copolymerization Reactions in $CH_2Cl_2$:** $CH_2Cl_2$ (75 mL), saturated with CO at room temperature, was introduced by suction into an autoclave (250 mL), previously evacuated by a vacuum pump, containing the catalyst precursor (0.010 mmol) and $NaBAr'_4$ (0.012 mmol). The autoclave was charged with the required pressures of CO and $C_2H_4$ at room temperature and then heated. As soon as the temperature reached 50 °C, stirring (1200 rpm) was started and the catalytic reaction was conducted under constant pressure. After 20 min, the autoclave was cooled by means of an ice-water bath and the unreacted gases were released. The insoluble copolymer was filtered off, washed with $CH_2Cl_2$, and dried under vacuum at 60 °C to constant weight.

**Catalytic Copolymerization Reactions in MeOH:** Typically, MeOH (100 mL), was introduced by suction into an autoclave (250 mL), previously evacuated by a vacuum pump, containing the catalyst precursor (0.0024 mmol) and 1,4-benzoquinone (BQ, 0.192 mmol). The autoclave was charged with the desired pressure of CO and $C_2H_4$ at room temperature and then heated. As soon as the temperature reached 85 °C, stirring (1200 rpm) was started and the catalytic reaction was conducted under constant pressure for 1 h. Afterwards the autoclave was cooled by means of an ice-water bath and the unreacted gases were released. The insoluble copolymer was filtered off, washed with MeOH, and dried under vacuum at 60 °C to constant weight.

**Crystal Structure Determination of 3a·$CHCl_3$:** Several crystallization attempts with different solvents were performed and only the diffusion of toluene into a $CHCl_3$ solution of **3a** gave a single crystal, although of poor quality. Crystal data and structure refinement details for **3a·$CHCl_3$** are reported in Table 9.

Table 9. Crystal data and structure refinement details for **3a·$CHCl_3$**.

X-ray diffraction intensity data were collected at 223 K with an Oxford Diffraction CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) using ω-scans. Cell refinement, data reduction, and empirical absorption correction were

carried out with the Oxford diffraction software and SADABS.[12a] All structure determination calculations were performed with the WINGX package[12b] with SIR-97,[12c] SHELXL-97,[12d] and ORTEP-3 programs.[12e] Final refinements based on $F^2$ were carried out with anisotropic thermal parameters for all non-hydrogen atoms, which were included using a riding model with isotropic $U$ values depending on the $U_{eq}$ of the adjacent carbon atoms.

CCDC-632065 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The Synthesis of Iridabenzenes by the Coupling of Iridacyclopentadienes and Olefins

**Margarita Paneque,*[a] Manuel L. Poveda,*[a] Nuria Rendón,[a] Eleuterio Álvarez,[a] and Ernesto Carmona[a]**

**Keywords:** Metallacycles / Olefins / Insertion / Isomerisation / Alkylidenes

The iridacyclopentadiene [(Tp$^{Me2}$)Ir{C$^1$(R)=C(R)C(R)=C$^4$(R)}(H$_2$O)(*Ir–C$^4$*)] (**1**; R = CO$_2$Me) reacts with propene at 60 °C to give the iridabenzene [(Tp$^{Me2}$)Ir{C$^1$(Et)C(R)C(R)C(R)C$^5$(R)}(H)(*Ir–C$^5$*)] (**6**), which also contains a hydride ligand, as the main product, accompanied by complexes **7** and **8** derived from the insertion of propene into the Ir–C bonds of **1**. In contrast, the closely related metallacycle [(Tp$^{Me2}$)Ir{C$^1$(R)=C(H)C(R)=C$^4$(R)}(H$_2$O)(*Ir–C$^4$*)] (**1-H**) gives the iridabenzene [(Tp$^{Me2}$)Ir{C$^1$(Me)C(R)C(H)C(R)C$^5$(R)}(Me)(*Ir–C$^5$*)] (**13**), which contains an iridium-bonded methyl group, upon treatment with propene at 20 °C. The proposed mechanism for the formation of metallabenzenes **6** and **13** postulates Ir–propene → Ir=CHEt or Ir–propene → Ir=CMe$_2$ isomerisations, followed by insertion of the alkylidene ligand into an Ir–C(R) bond (regioselective for **1-H**) and α-H or α-Me elimination from the resulting alkyliridium moiety. At 25 °C, neat acetonitrile induces stereoselective hydride migration onto both the Ir=C bonds of **6** to give a kinetic mixture (6:1 ratio) of the isomeric adducts [(Tp$^{Me2}$)Ir{C$^1$H(Et)C(R)=C(R)C(R)=C$^5$(R)}(MeCN)(*Ir–C$^5$*)] (**9**) and [(Tp$^{Me2}$)Ir{C$^1$H(R)C(R)=C(R)C(R)=C$^5$(Et)}(MeCN)(*Ir–C$^5$*)] (**10**), with the latter being the thermodynamically preferred product. In contrast, complex **13** is stable in acetonitrile up to 100 °C, where it mainly experiences ring fragmentation to give the iridacyclopentadiene **1-H** as its MeCN adduct. All new compounds have been fully characterised by microanalysis and spectroscopy. Additionally, the solid-state structures of **5**, **6** and **13** have been determined by X-ray crystallography.

## Introduction

We have recently reported on the reaction of the iridacyclopentadiene [(Tp$^{Me2}$)Ir{C$^1$(R)=C(R)C(R)=C$^4$(R)}(H$_2$O)(*Ir–C$^4$*)] [**1**; Tp$^{Me2}$ = hydrotris(3,5-dimethylpyrazolyl)borate, R = CO$_2$Me] with ethylene (Scheme 1).[1] The first species formed is the iridacycloheptadiene **2** as the result of the insertion of C$_2$H$_4$ into one of the two identical Ir–C bonds. This species rearranges readily at room temperature to the hydride-alkenyl derivative **3** by extrusion of H$_2$O and β-H elimination, whereas upon heating at 40–60 °C the alkyl-allyl complex **4** is obtained by means of a stereoselective hydride migration. In a parallel study we have observed that (Scheme 1) the iridacyclopentadiene [(Tp$^{Me2}$)Ir{C$^1$(R)=C(H)C(R)=C$^4$(R)}(H$_2$O)(*Ir–C$^4$*)] (**1-H**) gives rise to related species (**3-H** and **4-H**, respectively) under similar conditions, thereby implying that ethylene inserts regioselectively into the Ir–C bond close to the C–H functionality. In this paper we describe the different and unusual chemistry observed when **1** and **1-H** are treated with propene and 1-butene. Part of the findings reported herein have been briefly communicated.[2]

## Results and Discussion

### Reaction of Complex 1 with Propene

Bubbling propene through a solution of complex **1** in CH$_2$Cl$_2$ at room temperature leads to partial conversion to the metallacycloheptadiene **5**, as deduced from the NMR spectra of the reaction mixture [Equation (1)], in a spectroscopic yield of about 50%. The yield does not improve upon extending the reaction time. Complex **5** is closely related to species **2**, which forms in the reaction of **1** with ethylene, and is probably formed by the same mechanism, namely temporary displacement of the water ligand by a molecule of propene followed by insertion of the olefin into one of the equivalent Ir–C bonds and subsequent coordination of H$_2$O.[1] Interestingly, this insertion process is highly selective as only one of the four possible stereoisomers is observed.

Complex **5** can be isolated as a pale-yellow, microcrystalline solid by column chromatography on silica gel. The most characteristic $^1$H NMR signals of this compound are those corresponding to the two diastereotopic protons of the methylene group bonded to the metal, which appear at $\delta$ = 3.46 and 2.84 ppm (doublet of doublets and triplet, respectively), while the corresponding carbon atom resonates at $\delta$ = 6.5 ppm ($^1J_{C,H}$ = 126 Hz) in the $^{13}$C{$^1$H} NMR spectrum. The MeCH group of the metallacycle gives rise

to $^1$H NMR resonances at $\delta$ = 3.22 (m, CH) and 1.25 ppm (d, *Me*CH) and to $^{13}$C{$^1$H} NMR signals at $\delta$ = 38.5 (*C*HMe) and 19.4 ppm (CH*Me*). The configuration of the CHMe group was derived from an X-ray study, the results of which are shown in Figure 1. The corresponding crystallographic data are collected in the Experimental Section, while selected bond lengths and angles for complex **5** are shown in Table 1. As expected, the Ir–C(sp$^3$) bond (2.08 Å) is somewhat longer than the Ir–C(sp$^2$) one (2.02 Å).[3] It should also be noted that, of the three Ir–N bonds, that *trans* to water is appreciably shorter (2.03 Å) than the other two (2.16 Å av.),[1] which are *trans* to the two different Ir–C σ bonds and the Ir–C(sp$^3$) and the Ir–C(sp$^2$) bonds (Ir–C16 and Ir–C28, respectively).

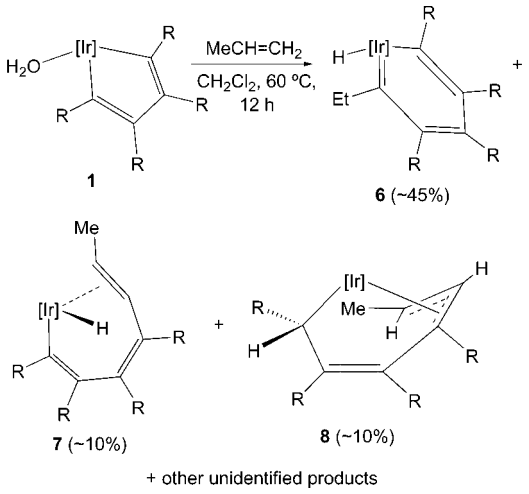
Interestingly, the rearrangement of **1** to **5** shown in Equation (1) does not proceed when thf is used as the reaction solvent, possibly because thf coordination prevents binding of the alkene. We have also found that propene insertion is reversible, at least in $CDCl_3$ and $C_6D_6$. Thus, upon standing at room temperature for several hours, solutions of **5** in these deuterated solvents revert to **1** and free propene. This occurs even in the presence of added propene, although in these cases the back reaction is naturally slower. In contrast, solutions of **5** in hexane/diethyl ether mixtures remain unchanged for at least 48 h.

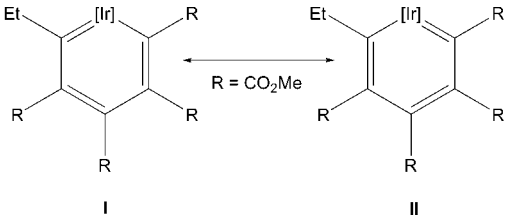
Different results are observed when compound **1** is treated with propene in $CH_2Cl_2$ at 60 °C; this reaction gives the mixture of compounds **6**–**8** shown in Equation (2). Complexes **6** and **7** were isolated as green and dark-yellow microcrystalline solids, respectively, by column chromatography on silica gel, although characterisation of **8** required its direct preparation from **7** (see below). The analytical and spectroscopic data for **6**–**8** support its proposed formulation, which for **6** was confirmed by an X-ray structure determination.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



(2)

Compound **6**, which is the major product of Equation (2), has an iridabenzene structure. Its formation from **1** and propene, that is, by coupling of an alkene with a metallacyclopentadiene, constitutes a novel synthetic procedure for this kind of aromatic metallacycle.[4] Its hydride ligand resonates at $\delta$ = –21.41 ppm in the $^1$H NMR spectrum, while the low field resonances at $\delta$ = 274.2 and 202.1 ppm found in the $^{13}C\{^1H\}$NMR spectrum are due to the Ir–*C*(Et) and Ir–*C*($CO_2$Me) carbon nuclei, respectively. Both these values suggest a partial double-bond character of the Ir–C bonds,[4] with a higher carbene character for the carbon atom bonded to the stronger electron-donating alkyl group. In other words, the electronic structure of **6** may be thought of as being intermediate between those of **I** and **II** below, with a larger contribution of the former.



This assumption was reinforced by the solid-state structural data obtained by X-ray crystallography[2] (Figure 2 and Table 2). Even though the two Ir–C bond lengths are similar, the Ir–C(Et) bond [1.922(4) Å] is shorter than the Ir–C($CO_2$Me) bond [1.979(4) Å]. The iridium atom in **6** deviates appreciably from the mean plane defined by the five ring-carbon atoms (0.57 Å), this deviation being intermediate between values found in the iridabenzene [($Tp^{Me2}$)-Ir{$C^1$(R)C(R)C(R)C(R)$C^5$(R)}(OCOR)(*Ir*–$C^5$)], which contains bulkier substituents (0.74 Å),[4f] and in the less congested species [($Tp^{Me2}$)Ir{$C^1$(H)C(Me)C(Me)C(H)$C^5$-(Me)}(H)(*Ir*–$C^5$)][3] (0.50 Å).

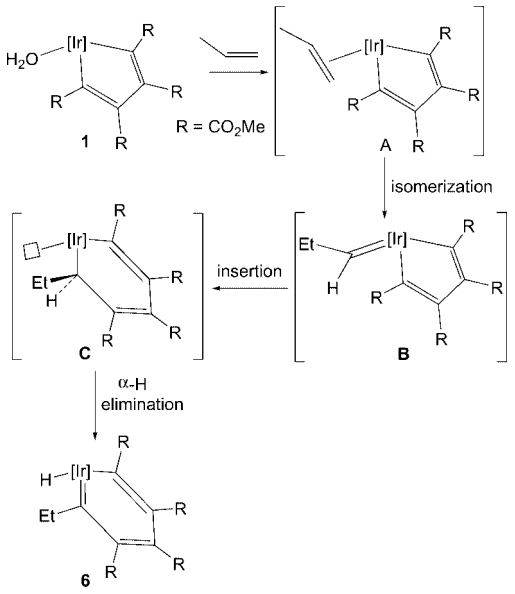
A plausible mechanism for the formation of complex **6** is shown in Scheme 2. Coordination of the olefin after displacement of the molecule of $H_2O$ gives intermediate **A**, which is proposed to undergo alkene isomerisation into a propylidene (to give **B**) and then a stereoselective migratory carbene insertion into one of the Ir–C bonds of the metallacycle. The resulting species **C** converts into the observed iridabenzene by means of an α-hydride elimination. An alkene-to-alkylidene rearrangement is an uncommon process, although there is literature precedent.[5] The migratory insertion of alkylidenes into M–C bonds[6] and the α-hydride elimination are well-known elementary steps.[7] Other mechanistic (also highly speculative) pathways for the formation of **6** can, however, also be envisaged.[8]

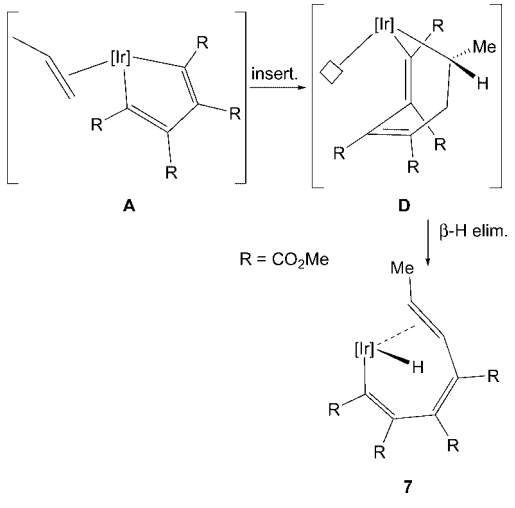
The hydride ligand of complex **7** gives rise to a high-field resonance at $\delta$ = –16.93 ppm in the $^1$H NMR spectrum, while the π-coordinated alkene terminus exhibits resonances at $\delta$ = 6.01 (d), 4.34 (m) and 1.15 ppm (d) for the C*H*=CHMe, CH=C*H*Me and CH=CH*Me* protons, respectively. The *trans* disposition of the olefinic protons was de-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



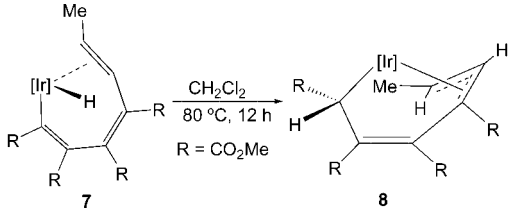
Scheme 2. Proposed mechanism for the formation of **6**.

duced from their $^3J_{H,H}$ coupling constant (11 Hz). The $^{13}C$ NMR spectroscopic data as well as two-dimensional experiments are also in agreement with the structure proposed. In particular, the NOESY spectrum confirmed the *trans* configuration of the coordinated olefin and also its coordination to the metal through the face displayed in Equation (2). The hydride-alkenyl **7** is related to **3** (see Introduction) and it is important to highlight that only the represented stereoisomer is observed. It probably forms from intermediate **D** by a β-H elimination process (Scheme 3), while, in turn, **D** forms from **A** by an olefin insertion reaction that has a stereoselectivity different to that leading to **5** (note that the configuration of the CHMe group of this complex cannot yield a vinyl compound by β-H elimination).



Scheme 3. Proposed mechanism for the formation of **7**.

Compound **3** is stable in solution for only a short period of time at room temperature as it transforms slowly into the allyl derivative **4**.[1] In contrast, **7** is stable under these conditions, although, upon heating, it also gives rise to an allyl species (**8**) due to the stereospecific transfer of the hydride to the α-carbon atom of the alkenyl ligand of **7** [Equation (3)]. Compound **8** exhibits $^1H$ NMR resonances due to the π-coordinated allyl moiety at $\delta$ = 7.11 (d, CH), 3.61 (m, C*H*Me) and 1.47 ppm (d, CH*Me*), while the carbon nuclei of this fragment produce $^{13}C$ NMR resonances at $\delta$ = 93.7 (CH), 38.5 (*C*HMe) and 68.2 ppm ($C_q$), with these values being similar to those found for the related species **3**.[1] It is interesting to note that **8** contains a catenated $\eta^1$-allyl-$\eta^3$-allyl ligand which, in principle, can isomerize by concomitant change of the hapticity of the two allyl moieties. However, as for **4**,[1] only the species with the $CO_2Me$ group on the $sp^3$ carbon bonded to the metal is observed.



(3)

### Reaction of the Iridabenzene 6 with MeCN

As represented in Scheme 4, iridabenzene **6** reacts with neat MeCN at 20 °C to give a 6:1 kinetic mixture of the isomeric metallacyclohexadienes[4c,4h,9] **9** and **10**, which are the products of the stereospecific migration of the hydride ligand onto the two different Ir–C bonds followed by coordination of MeCN. Both complexes can be cleanly separated by chromatography and have been fully characterised by spectroscopic methods. The aliphatic carbon bonded to iridium in complex **9** resonates at $\delta$ = 4.8 ppm in the $^{13}C\{^1H\}$ NMR while the corresponding nucleus of **10** appears at $\delta$ = 4.6 ppm. The latter species is the thermodynamic product of the reaction, as **9** transforms cleanly and almost quantitatively into **10** in $C_6D_6$ at 90 °C ($t_{1/2}$ = 4 h). Interestingly, the kinetic ratio of **9** to **10** in neat MeCN was found to vary with temperature (5 at 30 °C, 4.2 at 40 °C, 2.8 at 60 °C and 2.1 at 80 °C) and a graphic representation of ln[**9**]/[**10**] vs. $1/T$ gives a straight line (Figure 3) from which the values of $\Delta\Delta H^{\neq}$ = 3.75 kcal mol$^{-1}$ and $\Delta\Delta S^{\neq}$ = 5 cal mol$^{-1}$ K$^{-1}$ can be computed (the latter favours the formation of **10** at high temperatures).

The proposed mechanism[9] for the formation of these adducts is also shown in Scheme 4 and implies the competitive transformation of complex **6** into the unsaturated intermediates **C** and **E**, which are then trapped by MeCN. As commented above, complex **9** transforms into the thermodynamically more stable isomer **10** when heated at 90 °C in $C_6D_6$. In principle, this reaction could be the result of a direct 1,5-suprafacial shift of the hydrogen atom between the two Cα positions.[9] However, several indications appear to be more in agreement with a mechanism in which iridabenzene **6** is a true intermediate of this rearrangement,

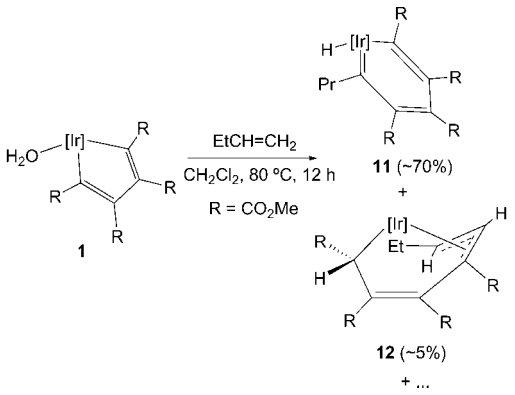
which means that, as shown in Scheme 4, all reaction steps are reversible. Thus, under the above conditions ($C_6D_6$, 90 °C) it is observed that: (i) NMR monitoring of the **9** → **10** rearrangement reveals the formation of observable concentrations of iridabenzene **6**, which is not detected when the reaction is effected in the presence of around 10 equivalents of MeCN or [$D_3$]MeCN; (ii) the rate of disappearance of **9** does not vary in the presence of 10 equivalents of MeCN (or [$D_3$]MeCN); (iii) in the presence of [$D_3$]-MeCN (10 equiv.), **10** contains [$D_3$]MeCN almost exclusively at 50% conversion whereas **9** is only partially deuterated (50%); (iv) **10** exchanges MeCN for [$D_3$]MeCN (10 equiv. [$D_3$]MeCN), although the exchange rate is appreciably slower than the transformation of **9** into **10** (around 50% incorporation after 16 h). All these observations are in agreement with the transformation of **9** into **10** proceeding via iridabenzene **6** (Scheme 4), with the rate-determining step being the dissociation of the acetonitrile ligand of **9** ($k_{-3}$).

### Reaction of Complex 1 with 1-Butene

To complete our study of the reactivity of **1** towards olefins, its reaction with 1-butene was also investigated. As expected, the results are similar to those previously discussed for propene, with a mixture of compounds **11** and **12** [Equation (4)] being obtained at 80 °C. Column chromatography of the crude reaction mixture allowed isolation of **11**, and even though the allyl species **12** could not be isolated as a pure solid we were able to characterise it by NMR spectroscopy. Spectroscopic data for these two compounds can be found in the Experimental Section and do not warrant further discussion.



(4)

### Reaction of Complex 1-H with Propene

An unexpected redistribution reaction occurs when propene is bubbled through a solution of complex **1-H** in $CH_2Cl_2$ (25 or 60 °C). Equation (5) shows the nature of the resulting product (iridabenzene **13**), which, quite surprisingly, has a metal-bound methyl group instead of a hydride ligand. This methyl group must proceed from the olefin. Additionally, it is important to note that the coupling process that gives rise to the metallacycle is highly selective, since only the iridabenzene that bears the hydrogen substituent in the *para* position is obtained. Compound **13** was fully characterised by NMR spectroscopy and also by X-ray diffraction studies. Once more, the resonance due to the carbon atom bonded to iridium which supports the Me group, Ir–*C*(Me), appears at lower field than the related Ir–*C*($CO_2$Me) ($\delta$ = 272.7 and 217.6 ppm, respectively). Another characteristic $^{13}C\{^1H\}$ NMR signal is that of the methyl group bonded to iridium, which appears at high field ($\delta$ = –17.6 ppm). The $^1H$ NMR spectrum shows two singlets at $\delta$ = 1.98 and 0.91 ppm for the Me group in the α-position of the metallacycle and for the Me group bonded to iridium, respectively, while the CH of the iridabenzene ring resonates at $\delta$ = 9.15 ppm.

(5)

Figure 4 shows an ORTEP view of the molecule of **13**[2] while Table 3 contains selected bond lengths and angles. The Ir atom in this iridacycle deviates by 0.70 Å from the plane defined by the five carbon atoms of the metallacycle. The two Ir–C(ring) distances are different, showing once more the unsymmetrical electronic delocalisation: the Ir–C(Me) bond [1.936(2) Å] is slightly shorter than the Ir–C($CO_2$Me) [1.957(2) Å].

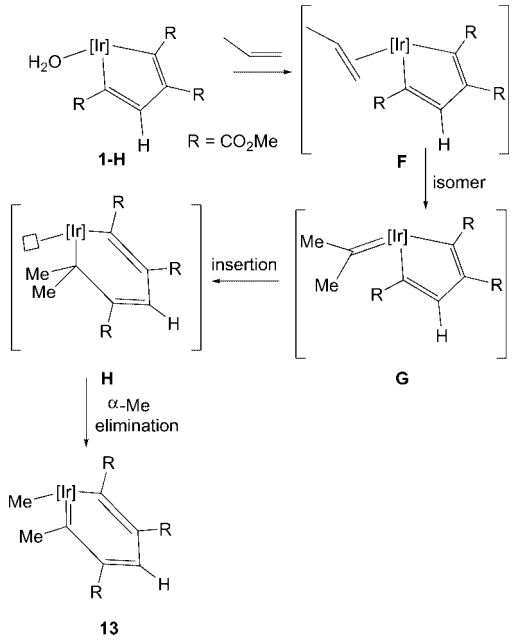
Scheme 5 shows a possible mechanism for the formation of **13**. Once again, it is proposed that an alkylidene, **G**, resulting from the isomerisation of the propene ligand in **F** is a key intermediate, although for reasons that are difficult to explain a dimethylcarbene unit, $=CMe_2$, appears to be favoured over the linear propylidene, =C(H)Et. This isomerisation would be followed by a regioselective migration of the alkenyl carbon atom adjacent to the CH group onto the alkylidene, to give **H**, and finally by an α-Me elimination. This last process, namely the α-elimination of alkyl or aryl groups, is unusual, although some examples are known.[10] Clearly other mechanistic possibilities can be envisaged for the formation of complex **13** but, once again, they include highly speculative assumptions.[8]



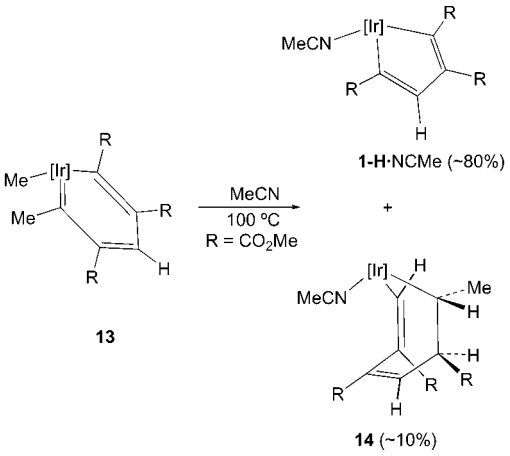
Scheme 5. Proposed mechanism for the formation of **13**.

## Reaction of the Iridabenzene 13 with MeCN

Preliminary studies on the reactivity of the iridabenzene **13** reveal interesting differences with respect to the behaviour observed for **6**. Thus, **13** does not react with neat acetonitrile at 20 °C, and at 100 °C it mainly reverts to iridacycle **1-H**, which was isolated in the form of the known MeCN adduct **1-H·MeCN** [Equation (6)], a complex that has already been reported as resulting from the reaction of **1-H** with MeCN.[1] This clearly demonstrates that, despite requiring C–C bond formation and cleavage, the reaction of **1-H** with propene is a reversible process. Furthermore, Equation (6) represents an unusual fragmentation of a metallabenzene species.

Compound **1-H·MeCN** is not the only compound formed in the reaction of **13** and MeCN at 100 °C (approx. 80% spectroscopic yield) as the $^1$H NMR spectrum of the crude product mixture shows the presence of a second species − the new compound **14** (approx. 10% spectroscopic yield, separated by column chromatography) − for which the structure shown in Equation (6) can be tentatively suggested on the basis of NMR spectroscopic studies. It is pro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

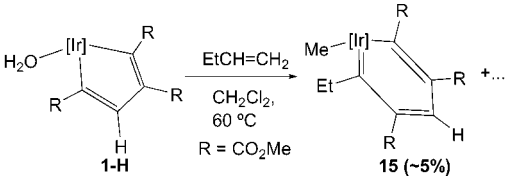


(6)

posed that the three carbon atoms of the original molecule of propene become incorporated into the metallacycle skeleton of **14**, although the complexity of the structure and the absence of mechanistic information advise against a discussion of possible reaction routes, which at this stage would be highly speculative.

### Reaction of Complex 1-H with 1-Butene

Finally, reaction of **1** with $EtCH{=}CH_2$ at 60 °C takes place with formation of a complex reaction mixture from which only complex **15** (approx. 5% spectroscopic yield, separated by column chromatography) has been unequivocally identified [Equation (7)]. The major product (approx. 20% spectroscopic yield) is an isolable compound following chromatographic procedures but an unambiguous formulation cannot be proposed with the available data. It seems clear, however, that it is structurally related to other compounds that are generated in very small amounts during the reactions of **1** and **1-H** with propene and 1-butene.



(7)

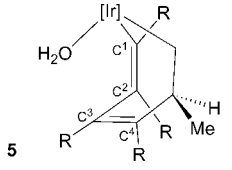
## Conclusions

Iridabenzene complexes that also contain metal-bound hydride or methyl groups have been obtained by a new synthetic method that consists of the coupling of iridacyclopentadienes with olefins in a process that is proposed to occur by an olefin-to-alkylidene isomerisation in the metal coordination sphere. Interestingly, the reaction outcome depends strongly on the substitution pattern of the five-membered metallacycle and the nature of the olefin (propene being very efficient as a metallabenzene generator while ethylene gives only products derived from the insertion of the olefin into the Ir–C bonds). The reactivity of these iridabenzenes with acetonitrile has been studied and it has been found that the hydride ligand migrates easily and reversibly onto the Ir–C bonds of the metallacycle. Finally, a very unusual thermal fragmentation of a metallabenzene has also been observed.

## Experimental Section

**General Procedures:** Microanalyses were performed by the Microanalytical Service of the Instituto de Investigaciones Químicas (Sevilla). Infrared spectra were obtained with Perkin–Elmer 577 and 684 spectrometers. NMR spectra were recorded with Bruker DRX-500, DRX-400 and DPX-300 spectrometers. Spectra are referenced to external $SiMe_4$ ($\delta$ = 0 ppm) using the residual protio solvent peaks ($^1$H NMR experiments) or the characteristic resonances of the solvent nuclei ($^{13}$C NMR experiments) as internal standards. Spectral assignments were made by means of routine one- and two-dimensional NMR experiments where appropriate. Manipulations were performed either in air or under oxygen-free dinitrogen, following conventional Schlenk techniques. The complexes [($Tp^{Me2}$)-Ir{$C^1$(R)=C(R)C(R)=$C^4$(R)}($H_2O$)(*Ir–C*$^4$)] (**1**) and [($Tp^{Me2}$)-Ir{$C^1$(R)=C(H)C(R)=$C^4$(R)}($H_2O$)(*Ir–C*$^4$)] (**1-H**) were obtained by published procedures.[1]

**Complex 5:** $MeCH{=}CH_2$ was bubbled through a solution of **1** in $CH_2Cl_2$ (0.2 g, 0.25 mmol; 7 mL) for 7 min. The resulting mixture was stirred under propene in a sealed vessel at room temperature for 12 h, and the solvent was then removed under reduced pressure. The $^1$H NMR spectrum of the residue showed it to consist of a mixture of **1** and **5** in a 1:1 ratio. Complex **1** was isolated by column chromatography on silica gel, with a mixture of hexane and $Et_2O$ (1:1) as eluent, in 32% yield. An analytically pure sample was obtained by crystallisation from a mixture of hexane and $Et_2O$ (1:1) at –20 °C (pale-yellow crystals). $R_f$ = 0.18 [silica gel, hexane/$Et_2O$ (1:5)]. IR (Nujol): $\nu$(OH) = 3381 cm$^{-1}$ (br). $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 5.77, 5.71, 5.66 (s, 1 H each, 3 $CH_{pz}$), 3.95, 3.65, 3.58, 3.05 (s, 3 H each, 4 $CO_2$Me), 3.46, 2.84 (dd+t, $^2J_{H,H}$ = 12.4, $^3J_{H,H}$ = 3.7 Hz, 1 H each, $IrCH_2$), 3.22 (m, 1 H, C*H*Me), 2.37, 2.36, 2.36, 2.31, 2.16, 2.13 (s, 3 H each, 6 $Me_{pz}$), 1.25 (d, $^3J_{H,H}$ = 6.8 Hz, 3 H, CH*Me*) ppm; the coordinated molecule of $H_2O$ could not be located. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 178.2, 175.8, 169.9, 164.9 (*C*$O_2$Me), 164.0 ($C^1$), 153.6, 151.2, 149.9, 144.2, 143.6, 142.3 ($C_{qpz}$), 145.6 ($C^4$), 132.1, 129.2 ($C^3$, $C^4$), 108.4, 107.8, 106.5 ($CH_{pz}$), 52.8, 52.0, 51.2, 50.4 ($CO_2$*Me*), 38.5 ($^1J_{C,H}$ = 133 Hz, *C*HMe), 19.4 (CH*Me*), 14.8, 14.2, 13.4, 12.9, 12.6, 12.4 ($Me_{pz}$), 6.5 ($^1J_{C,H}$ = 126 Hz, $CH_2$) ppm. $C_{30}H_{42}BIrN_6O_9{\cdot}0.5Et_2O$ (870.03): calcd. C 44.2, H 5.4, N 9.6; found C 44.4, H 5.4, N 9.2.

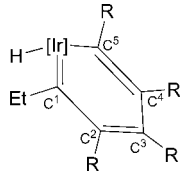


**Complexes 6–8:** Compound **1** was dissolved in $CH_2Cl_2$ (0.5 g, 0.63 mmol; 12 mL), then $MeCH{=}CH_2$ was bubbled through the solution for 7 min and the stirring was continued under propene, in a closed vessel, for 12 h at 60 °C. After this period the solvent

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

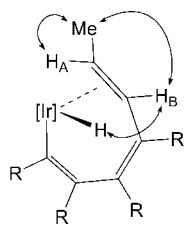
was removed under reduced pressure and the formation of a mixture of complexes **6** (approx. 45%), **7** (approx. 10%) and **8** (approx. 10%), along with other by-products, was ascertained by $^1$H NMR spectroscopy. Complexes **6**–**8** were separated by column chromatography (silica gel) with hexane/$Et_2O$ (1:1) as eluent. Complex **6** (34% yield) was purified by crystallisation from a mixture of pentane and $CH_2Cl_2$ (1:1) at –20 °C (dark-green crystals). Complex **7** (10% yield) was obtained analytically pure by crystallisation from a mixture of hexane and $CH_2Cl_2$ (1:1) at –20 °C (dark-yellow solid). Complex **8** could not be obtained as a pure solid by this method, but it could be alternatively and satisfactorily obtained as follows: Compound **7** was dissolved in $CH_2Cl_2$ (0.020 g, 0.02 mmol; 2 mL) and the solution stirred at 80 °C for 12 h. After this period of time the solvent was removed under vacuum and $^1$H NMR monitoring of the crude reaction showed quantitative transformation of **7** into **8**. This compound could be purified by crystallisation from a mixture of hexane and $CH_2Cl_2$ (1:1) at –20 °C (yellow solid).

**6:** $R_f$ = 0.47 [silica gel, hexane/$Et_2O$ (1:3)]. IR (Nujol): ν(Ir–H) = 2162 cm$^{-1}$. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 5.80, 5.72, 5.69 (s, 1 H each, 3 $CH_{pz}$), 3.85, 3.80, 3.70, 3.18 (s, 3 H each, 4 $CO_2Me$), 3.13, 2.38 (dq, $^2J_{H,H}$ = 15.8, $^3J_{H,H}$ = 7.7 Hz, 1 H each, $CH_3CH_2$), 2.47, 2.42, 2.37, 2.06, 2.03, 1.17 (s, 3 H each, 6 $Me_{pz}$), 0.74 (t, 3 H, $CH_3CH_2$), –21.41 (s, 1 H, Ir-H) ppm; the signal at $\delta$ = 2.38 ppm is obscured by the resonances of the $Me_{pz}$ and was detected in the COSY spectrum. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 274.2 ($C^1$), 202.1 ($C^5$), 179.0, 170.8, 168.2, 167.0 ($CO_2$Me), 154.0, 152.0, 150.3, 146.1, 145.4, 143.2 ($C_{qpz}$), 151.7 ($C^3$), 140.1 ($C^2$), 131.1 ($C^4$), 106.6, 106.5, 105.3 ($CH_{pz}$), 52.9, 52.7, 52.6, 51.2 ($CO_2Me$), 51.3 ($^1J_{C,H}$ = 130 Hz, $CH_3CH_2$), 16.3, 16.2, 13.9, 13.0, 12.9 (1:1:1:2:1, $Me_{pz}$), 11.4 ($CH_3CH_2$) ppm. $C_{30}H_{40}BIrN_6O_8$ (815.03): calcd. C 44.2, H 4.9, N 10.3; found C 43.9, H 4.8, N 10.0.

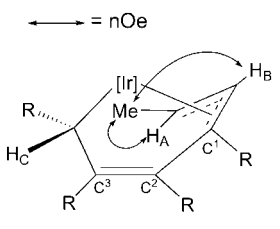


**6**

**7:** $R_f$ = 0.39 [silica gel, hexane/$Et_2O$ (1:8)]. IR (Nujol): ν(Ir–H) = 2194 cm$^{-1}$. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 6.01 (d, $^3J_{B,A}$ = 11 Hz, 1 H, $H_B$), 5.92, 5.76, 5.62 (s, 1 H each, 3 $CH_{pz}$), 4.34 (m, 1 H, $H_A$), 3.83, 3.75, 3.52, 3.06 (s, 3 H each, 4 $CO_2Me$), 2.43, 2.30, 2.29, 2.28, 2.26, 2.18 (s, 3 H each, 6 $Me_{pz}$), 1.15 (d, $^3J_{H,H}$ = 6.0 Hz, 3 H, $CH_AMe$), –16.93 (s, 1 H, Ir-H) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 174.6, 169.5, 167.6, 166.9 ($CO_2$Me), 152.4, 152.3, 150.5, 144.8, 143.5, 143.5 ($C_{qpz}$), 138.3, 133.8, 128.8, 126.7 ($CCO_2$Me), 108.5, 107.9, 106.1 ($CH_{pz}$), 61.1 ($CH_B$), 56.4 ($CH_A$), 52.5, 52.3, 51.8, 50.7 ($CO_2Me$), 17.8 ($CH_AMe$), 16.5, 16.5, 15.9, 12.9, 12.9, 12.7 ($Me_{pz}$) ppm. $C_{30}H_{40}BIrN_6O_8$·1.25$CH_2Cl_2$ (921.28): calcd. C 40.7, H 4.6, N 9.1; found C 40.7, H 4.8, N 8.6.



**7**



**8**

**8:** $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 7.11 (d, $^3J_{B,A}$ = 10.3 Hz, 1 H, $H_B$), 5.86, 5.80, 5.59 (s, 1 H each, 3 $CH_{pz}$), 5.06 (s, 1 H, $H_C$), 3.72, 3.64, 3.45, 3.35 (br) (s, 3 H each, 4 $CO_2$Me), 3.61 (m, 1 H, $H_A$), 2.70, 2.41, 2.36, 2.28, 2.24, 2.17 (s, 3 H each, 6 $Me_{pz}$), 1.47 (d, $^3J_{H,H}$ = 5.7 Hz, 3 H, $CH_AMe$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 175.0, 166.8 (2:2, $CO_2$Me), 152.5, 151.8, 144.5, 143.4 (1:2:1:2, $C_{qpz}$), 130.9, 128.8 ($C^2$, $C^3$), 110.6, 108.7, 107.2 ($CH_{pz}$), 93.7 ($^1J_{C,H}$ = 161 Hz, $CH_B$), 68.2 ($C^1$), 52.2, 51.9, 51.6, 50.9 ($CO_2Me$), 38.5 ($CH_A$), 19.2 ($CH_AMe$), 17.8, 15.7, 13.6, 13.5, 13.1, 12.8 ($Me_{pz}$), 9.9 ($^1J_{C,H}$ = 134 Hz, $CH_C$) ppm. $C_{30}H_{40}BIrN_6O_8$ (815.03): calcd. tion for 5 min. The resulting solution was stirred under 1-butene in a closed vessel for 12 h at 80 °C. After this period of time the solvent was removed under vacuum and the formation of a mixture of complexes **11** (approx. 70%) and **12** (approx. 5%), along with other by-products, was ascertained by $^1$H NMR spectroscopy. Complexes **11** and **12** were separated by column chromatography (silica gel) with hexane/$Et_2O$ (1:1) as eluent. Complex **11** (38% yield) could be purified by crystallisation from a mixture of pentane and $CH_2Cl_2$ (1:1) at –20 °C (pale brown crystals). Complex **12** could not be separated by column chromatography and was characterised by NMR spectroscopy of the crude mixture.

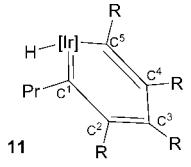
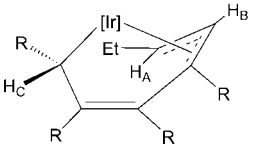
**11:** $R_f$ = 0.38 [silica gel, hexane/$Et_2O$ (1:3)]. IR (Nujol): ν(Ir–H) = 2157 cm$^{-1}$. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 5.79, 5.72, 5.68 (s, 1 H each, 3 $CH_{pz}$), 3.84, 3.80, 3.69, 3.17 (s, 3 H each, 4 $CO_2Me$), 3.04, 2.34 (dt + m, $^2J_{H,H}$ = 13.5, $^3J_{H,H}$ = 5 Hz, $CH_3CH_2CH_2$, 1 H each), 2.48, 2.42, 2.37, 2.06, 2.03, 1.16 (s, 3 H each, 6 $Me_{pz}$), 1.33, 1.12 (m, m, 1 H each, $CH_3CH_2CH_2$), 0.61 (t, $^3J_{H,H}$ = 7.3 Hz, 3 H, $CH_3CH_2CH_2$), –21.41 (s, 1 H, Ir-H) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 272.8 ($C^1$), 201.5 ($C^5$), 178.8, 170.5, 168.0, 166.8 ($CO_2Me$), 153.8, 151.7, 150.0, 145.8, 145.1, 143.0 ($C_{qpz}$), 151.1 ($C^3$), 140.3 ($C^2$), 130.8 ($C^4$), 106.3, 106.3, 105.0 ($CH_{pz}$), 60.6 ($CH_3CH_2CH_2$), 52.6, 52.4, 52.3, 50.9 ($CO_2Me$), 20.5 ($CH_3CH_2CH_2$), 16.0, 16.0, 13.6, 12.8, 12.7, 12.7 ($Me_{pz}$), 15.0 ($CH_3CH_2CH_2$) ppm. $C_{31}H_{42}BIrN_6O_8$ (829.74): calcd. C 44.9, H 5.1, N 10.1; found C 44.5, H 5.2, N 9.8.



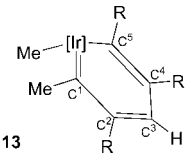
11



12

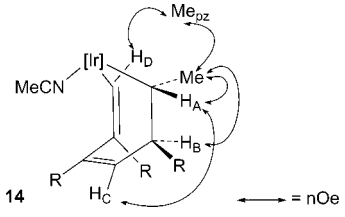
**12:** $R_f$ = 0.30 [silica gel, hexane/$Et_2O$ (1:3)]. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 7.05 (d, $^3J_{B,A}$ = 10.0 Hz, 1 H, $H_B$), 5.86, 5.79, 5.59 (s, 1 H each, 3 $CH_{pz}$), 5.09 (s, 1 H, $H_C$), 3.74, 3.72, 3.45, 2.69 (s, 3 H each, 4 $CO_2Me$), 3.58 (this signal is obscured by the $CO_2Me$ resonances and was detected by a COSY spectrum, 1 H, $H_A$), 2.40, 2.35, 2.27, 2.25, 2.18, 1.41 (s, 3 H each, 6 $Me_{pz}$), 1.90, 1.54 (signals detected by a COSY spectrum, 1 H each, $CH_2CH_3$), 1.27 (t, $^3J_{H,H}$ = 7.2 Hz, 3 H, $CH_2CH_3$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 92.8 ($^1J_{C,H}$ = 162 Hz, $CH_B$), 46.9 ($^1J_{C,H}$ = 166 Hz, $CH_A$), 26.9 ($^1J_{C,H}$ = 126 Hz, $CH_2CH_3$), 9.4 ($^1J_{C,H}$ = 135 Hz, $CH_C$) ppm.

**Complex 13:** MeCH=$CH_2$ was bubbled through a solution of **1-H** in $CH_2Cl_2$ (0.32 g, 0.44 mmol; 10 mL) for 5 min. The resulting mixture was stirred under propene at room temperature for 15 h, and after this period of time the solution had turned from dark yellow to green. The solvent was removed under reduced pressure and formation of compound **13** in 80% spectroscopic yield was determined by $^1$H NMR spectroscopy. Complex **13** could be purified by column chromatography on silica gel with a mixture of hexane and $Et_2O$ (2:1) as eluent (54% yield). It could be crystallised from a mixture of hexane and $Et_2O$ (2:1) at –20 °C as thin, dark-green needles. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 9.15 (s, 1 H, $C^3$H), 5.84, 5.80, 5.65 (s, 1 H each, 3 $CH_{pz}$), 3.87, 3.79, 3.25 (s, 3 H each, 3 $CO_2Me$), 2.43, 2.41, 2.19, 2.07, 0.99 (s, 2:1:1:1:1, 6 $Me_{pz}$), 1.98 (s, 3 H, $C^1$Me), 0.91 (s, 3 H, IrMe) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 272.7 ($C^1$), 217.6 ($C^5$), 179.9, 166.0, 165.4 ($CO_2Me$), 154.5, 151.8, 148.8, 144.6, 144.5, 142.5 ($C_{qpz}$), 153.7 ($^1J_{C,H}$ = 158 Hz, $C^3$), 139.5 ($C^2$), 132.0 ($C^4$), 108.1, 107.9, 105.5 ($CH_{pz}$), 52.1, 51.9, 50.7 ($CO_2Me$), 44.9 ($^1J_{C,H}$ = 128 Hz, $C^1Me$), 15.4, 14.9, 13.1, 13.0, 12.9, 12.6 ($Me_{pz}$), –17.6 ($^1J_{C,H}$ = 130 Hz, IrMe) ppm. $C_{28}H_{38}BIrN_6O_6\cdot Et_2O$ (831.03): calcd. C 46.2, H 5.8, N 10.1; found C 46.0, H 5.6, N 10.3.



13

**Complex 14:** Two or three drops of MeCN were added to a solution of compound **13** in cyclohexane (0.03 g, 0.04 mmol; 2 mL) and the mixture was stirred at 100 °C for 15 h. After this period of time the solvent was removed under reduced pressure and the $^1$H NMR spectrum of the crude reaction mixture showed the presence of complex **14** in 12% spectroscopic yield. It could be isolated by column chromatography on silica gel, with a mixture of hexane and $Et_2O$ (1:3) as eluent, in 7% yield (dark yellow crystals). $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 10.76 (s, 1 H, $H_D$), 6.87 (d, $^3J_{H,H}$ = 7.1 Hz, 1 H, $H_C$), 5.76, 5.71, 5.69 (s, 1 H each, 3 $CH_{pz}$), 3.72, 3.65, 3.63 (s, 3 H each, 3 $CO_2Me$), 3.46 (m, 1 H, $H_B$), 3.39 (m, 1 H, $H_A$), 2.38, 2.36, 2.32, 2.14, 2.09 (s, 1:1:2:1:1, 6 $Me_{pz}$), 0.40 (d, $^3J_{H,H}$ = 7.1 Hz, 3 H, $CH_AMe$), 2.29 (s, 3 H, MeCN) ppm. In $C_6D_6$ $H_C$ resonates at $\delta$ = 7.47 ppm (d, $^3J_{C,B}$ = 8.1 Hz) while $H_B$ appears at $\delta$ = 3.99 ppm (dd, $^3J_{B,A}$ = 11.6 Hz) and $H_A$ at $\delta$ = 3.80 ppm (dq, $^3J_{A,Me}$ = 7.3 Hz). The NOESY connections shown above were obtained in this solvent. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 176.8, 170.4, 166.4 ($CO_2Me$), 163.1 ($^1J_{C,H}$ = 139 Hz, $CH_D$), 151.5, 150.3, 150.2, 143.8, 143.4, 143.0 ($C_{qpz}$), 137.1 ($^1J_{C,H}$ = 161 Hz, $CH_C$), 134.1, 128.9 ($C_qCO_2Me$), 116.8 (Me$CN$), 108.2, 108.0, 106.8 ($CH_{pz}$), 55.5 ($^1J_{C,H}$ = 136 Hz, $CH_B$), 51.5, 51.0, 50.9 ($CO_2Me$), 21.6 ($CH_AMe$), 15.8, 14.0, 13.4, 12.7, 12.4 (1:1:1:2:1, $Me_{pz}$), 9.1 ($^1J_{C,H}$ = 128 Hz, $CH_A$), 3.5 ($Me$CN) ppm. $C_{30}H_{41}BIrN_7O_6$ (798.03): calcd. C 45.1, H 5.2, N 12.3; found C 44.6, H 5.8, N 12.2.



14

**Complex 15:** EtCH=$CH_2$ was bubbled through a solution of **1-H** in $CH_2Cl_2$ (0.4 g, 0.54 mmol; 12 mL) for 5 min. The resulting mixture was stirred under 1-butene at 60 °C for 15 h, and after this period of time the solvent was removed under reduced pressure. The $^1$H NMR spectrum of the crude reaction mixture showed the formation of compound **15** (6%) along with other by-products. It was separated by column chromatography on silica gel, with a mixture of hexane and $Et_2O$ (5:1) as eluent, in 5% yield (dark-green crystals). $R_f$ = 0.23 [silica gel, hexane/$Et_2O$ (1:1)]. $^1$H NMR ($CDCl_3$, 25 °C): $\delta$ = 8.95 (s, 1 H, $C^3$H), 5.82, 5.76, 5.65 (s, 1 H each, 3 $CH_{pz}$), 3.87, 3.78, 3.25 (s, 3 H each, 3 $CO_2Me$), 2.95, 2.15 (m, 1 H each, $CH_2CH_3$), 2.44, 2.43, 2.39, 2.17, 2.13, 1.09 (s, 3 H each, 6 $Me_{pz}$), 0.90 (s, 3 H, IrMe), 0.81 (t, $^3J_{H,H}$ = 7.3 Hz, 3 H, $CH_2CH_3$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$, 25 °C): $\delta$ = 283.4 ($C^1$), 210.7 ($C^5$), 179.2, 166.5, 165.5 ($CO_2Me$), 154.2, 151.7, 149.4, 144.8, 144.3, 142.4 ($C_{qpz}$), 152.8 ($^1J_{C,H}$ = 159 Hz, $C^3$), 139.9 ($C^2$), 131.0 ($C^4$), 108.1, 107.9, 105.3 ($CH_{pz}$), 52.1, 52.0, 50.8 ($CO_2Me$), 50.8 ($CH_2CH_3$), 15.1, 13.7, 13.0, 12.8, 12.6 (2:1:2:1:1, $Me_{pz}$, $CH_2CH_3$), –18.4 ($^1J_{C,H}$ = 128 Hz, IrMe) ppm. $C_{29}H_{40}BIrN_6O_6\cdot Et_2O$ (845.03): calcd. C 46.9, H 5.9, N 9.9; found C 46.6, H 5.9, N 9.8.

**X-ray Crystallography:** The X-ray structures of complexes **6** and **13** were reported in a preliminary communication.[2] Data for compound **5** were collected with a Bruker-Nonius X8APEX-II CCD diffractometer by using ω and ϕ scans with a scan width of 0.3° (in the range $5.60° < 2\theta < 61.16°$) and a 20-s exposure time with a crystal-to-detector distance of 37.5 mm. The data were reduced (SAINT)[11] and corrected for Lorentz polarisation effects and absorption by a multiscan method with SADABS.[12] The structure was solved by direct methods (SIR-2002)[13] and refined against all $F^2$ data by full-matrix least-squares techniques (SHELXTL-6.12).[14] All the non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were included in calculated positions and refined as riding on their respective carbon atoms with isotropic displacement parameters. $C_{35}H_{54}BIrN_6O_9$ [$C_{30}H_{54}BIrN_6O_9{\cdot}C_5H_{12}$], $M_r$ = 905.85, yellow prism crystal ($0.24 \times 0.22 \times 0.19$ mm) from pentane/diethyl ether; triclinic, space group $P\bar{1}$ (no. 2), $a$ = 10.7973(3), $b$ = 11.2238(3), $c$ = 16.5423(4) Å, $\alpha$ = 102.7200(10)°, $\beta$ = 90.3650(10)°, $\gamma$ = 101.6970(10)°, $V$ = 1912.16(9) Å$^3$, $Z$ = 2, $\rho_{calcd.}$ = 1.573 g cm$^{-3}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å, $F$(000) = 920, $\mu$ = 3.551 mm$^{-1}$, $T$ = 100(2) K. 39188 Measured reflections, of which 11594 were unique ($R_{int}$ = 0.0257); 469 refined parameters, final $R_1$ = 0.0226 for reflections with $I > 2\sigma(I)$, $wR_2$ = 0.0619 (all data), GOF = 1.095.

CCDC-631538 (for **5**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[8] As suggested by a referee of our preliminary communication,[2] intermediate **C** may be reached by a sequence of olefin insertion and H transposition via the metal centre. However, it is difficult to understand in this case why the involved hydride intermediate does not transform into an allyl species as described in Scheme 1 and ref.[1] The same reasoning applies to intermediate **H** in Scheme 5.

# Cyanometalate Cages with Exchangeable Terminal Ligands

**Julie L. Boyer,[a] Haijun Yao,[a] Matthew L. Kuhlman,[a] Thomas B. Rauchfuss,*[a] and Scott Wilson[a]**

**Keywords:** Cyanide / Ruthenium / Hydrogen bonds / Cage compounds / Heterometallic complexes

The coordination chemistry of the unusual metallo-ligand $Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_3$ ($Cs\subset Co_4Ru_3$) is described with attention to the behavior of the ligand itself, its binding to Lewis-acidic metal cations, and its ability to stabilize catalytically relevant Ru–$PPh_3$ fragments. A series of tests demonstrate that the "rim" $[CpCo(CN)_3]^-$ groups in $Cs\subset Co_4Ru_3$ are exchangeable. Upon treatment with $[(MeC_5H_4)Co(CN)_3]^-$ (Co′) $Cs\subset Co_4Ru_3$ undergoes vertex exchange to give $Cs\subset Co_{4-x}Co'_xRu_3$. Similarly the cage is degraded by CO. Most convincing, $Cs\subset Co_4Ru_3$ reacts with $PhNH_3OTf$ to precipitate the polymer $PhNH_3CpCo(CN)_3$ and form the molecular box $[Cs\subset Co_4Ru_4]^+$. Treatment of $Cs\subset Co_4Ru_3$ with $[M(NCMe)_x]PF_6$ (M = Cu, Ag) gave the Lewis acidic cages $\{Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_3M(NCMe)\}PF_6$, which reacted with tertiary phosphane ligands to give adducts $[Cs\subset Co_4Ru_3M(PPh_3)]PF_6$. Lewis acidic octahedral vertices were installed using Fe, Ni, and Ru reagents. The boxes $[Cs\subset Co_4Ru_3M(NCMe)_3]^{2+}$ (M = Ni, Fe) formed readily from the reaction $Cs\subset Co_4Ru_3$ with $[Ni(NCMe)_6](BF_4)_2$ and $[Fe(NCMe)_6](PF_6)_2$. Displacement of the MeCN ligands gives $[Cs\subset Co_4Ru_3Ni(9\text{-ane-}S3)](BF_4)_2$. A series of boxes were prepared by the reaction of $Cs\subset Co_4Ru_3$ and $RuCl_2(PPh_3)_3$, $RuHCl(PPh_3)_3$, and $[(C_6H_6)Ru(NCMe)_3](PF_6)_2$. The derivative of the hydride, $[Cs\subset Co_4Ru_3Ru(NCMe)(PPh_3)_2](PF_6)_2$, was characterized crystallographically.

## Introduction

The centuries old field of metal cyanide chemistry[1] has experienced a renaissance due the zeolitic,[2,3] magnetic,[4] and electronic properties[5] of cyanometalate materials. Parallel to these application-driven studies, we have focused on synthetic methodologies leading to discrete molecular architectures that can be characterized in solution. In recent years we have developed families of molecular cyanometalate ensembles that are synthesized analogously to Prussian Blue (PB), except that our molecular building blocks are tricyanometalates.[6] Half of the coordination sphere of these tricyanometalates is occupied by a strongly coordinating, non-displaceable co-ligand such as $C_5H_5^-$. The face-capping co-ligand inhibits the formation of polymers, by minimizing cross-linking, but still allows the formation of three-dimensional structures, which resemble subunits of PB.[7,8]

Our first attempt at molecular cyanometalate cages afforded the cationic cage $[CpCo(CN)_3]_4[Cp^*Rh]_4^{4+}$.[7] Replacing the dicationic tritopic Lewis acid with a monocationic analog results in charge-neutral ionophilic molecular cages.[9] Specifically, the reaction $[CpCo(CN)_3]^-$, $[Cp^*Ru(NCMe)_3]^+$, and CsOTf at the ratio of 4:4:1 produces the molecular box $\{Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_4\}^+$ ($Cs\subset Co_4Ru_4^+$).[10] By changing the ratio of the reactants to 4:3:1, one obtains instead the violet-colored "defect" box $Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_3$ ($Cs\subset Co_4Ru_3$).[10] Aside from its novel structure, an exciting aspect of $Cs\subset Co_4Ru_3$ is its potential as a well-defined building block for the assembly of novel molecular cages via $Cs\subset Co_4Ru_3 + ML_n^z \rightarrow Cs\subset Co_4Ru_3ML_n^z$, a box-completion process. Proof-of-concept was provided by the finding that $Cs\subset Co_4Ru_3$ reacts with one equiv. of $[Cp^*M(NCMe)_3](PF_6)_n$ to give the completed box $Cs\subset Co_4Ru_3M^z$ (M = Cp*Ru, Cp*Rh, $z$ = 1, 2) in high yield.[10]

All previously synthesized cyanometalate boxes and defect boxes possessed non-displaceable ligands such as Cp and Cp*. Isolable cyanometalate cages with *displaceable* ligands L, e.g. $Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_3ML_n^z$ (L = MeCN, $n$ = 1, 3), represent intriguing targets, which would enable the generation of ensembles of greater complexity and enhanced reactivity. For example, one could envision a modular approach to the preparation of "boxes-of-boxes." Few cyanometalates of nuclearity >8 have been well-characterized *in solution*.[11] We previously described the "double boxes" $\{[Cs\subset Co_4Ru_3]_2M\}^z$, and we anticipate that still higher nuclearity cages can be achieved. The construction of such oligo-cages will require boxes with one or more vertices that contain labile terminal ligands. This paper outlines our initial efforts toward this goal (Scheme 1).

## Results and Discussion

### Solution Properties of the $Cs\subset Co_4Ru_3$ Metallo-Ligand

Prior to examining the complexation properties of $Cs\subset Co_4Ru_3$, we conducted experiments aimed at elucidating the solution behavior of this "defect box." Four isomers are possible, depending on the relative stereochemistry of the three $CpCo(CN)_3$ units situated on the "rim" (Scheme 2). Two $C_s$ isomers are observed by $^1H$ NMR spectroscopy.[10] The interconversion of these two $C_s$ isomers is hypothesized to occur through the scission of one Ru–N bond, rotation of the unidentate $[CpCo(CN)_3]^-$ subunit, and reformation of the Ru–N bond to a different cyano group of the same $[CpCo(CN)_3]^-$ subunit (Scheme 2).

The stereochemical nonrigidity of the rim $[CpCo(CN)_3]^-$ groups is indicated by the effect of solvent on the *endo*$_2$*exo*$_1$/*endo*$_1$*exo*$_2$ isomer ratio. In THF solution, the ratio is 3:1, whereas addition of 10% MeCN shifts this ratio to 9:1 (Figure 1). The presence of MeCN favors the $C_s$ isomer with two *endo* $CN_t$ ligands (see Scheme 2). Furthermore, small amount of MeCN cause the chemical shifts of the Cp signals to shift downfield, possibly due an apparent interaction of the Cp protons with the triple bond of the MeCN. The interaction between the MeCN protons and the cyanide linkers of the cage framework was previously indicated with the solid-state structure of $Cs\subset Co_4Ru_3$.[2]

Labeling studies provided further evidence that the $Cs\subset Co_4Ru_3$ cage undergoes partial disassembly in solution. Two Ru–N bonds must break to dissociate a "rim" $CpCo(CN)_3^-$ subunit. As monitored by ESI-MS, $Cs\subset Co_4Ru_3$ was shown to exchange with $K[(MeC_5H_4)Co(CN)_3]$ (Co′) to give $Cs\subset Co_{4-x}Co'_xRu_3$ over the course of days. Altering the amount of Co′ from one to four equiv. did not increase the rate vertex exchange, suggesting that vertex exchange is dissociative, being dependent only on $[Cs\subset Co_4Ru_3]$. In a similar experiment, we found that the

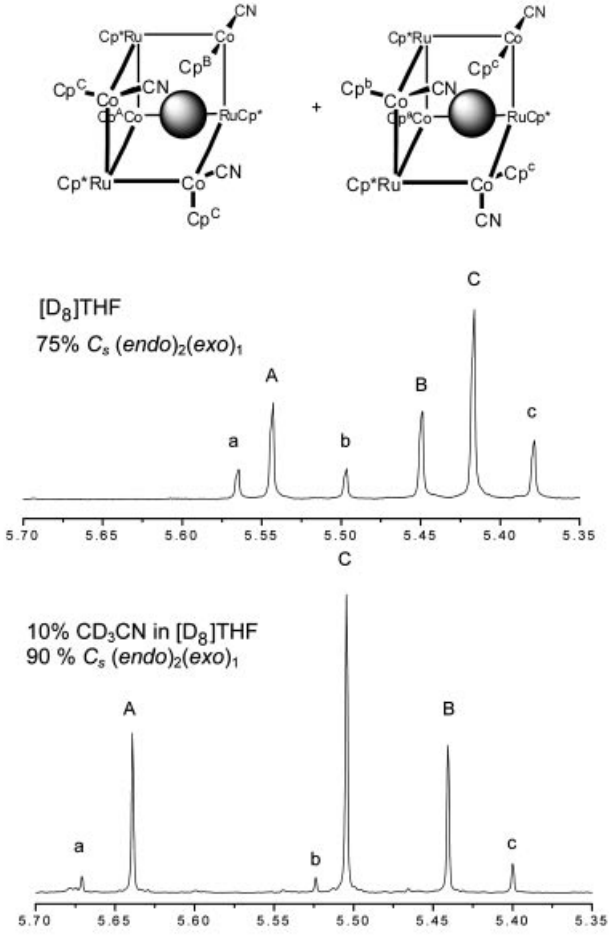

Figure 1. Schematic of the two detected isomers of $Cs\subset Co_4Ru_3$ (top), $^1H$ NMR spectra of $Cs\subset Co_4Ru_3$ in various solvents (bottom).

defect box $[CpCo(CN)_3]_4[Cp^*Rh]_3^{2+}$ ($Co_4Rh_3^{2+}$) underwent rapid exchange with Co′ to give $Co_{4-x}Co'_xRh_3^{2+}$ in under 5 h.

Treatment of a solution of $Cs\subset Co_4Ru_3$ with CO resulted in rapid degradation as indicated by the appearance of a $\nu_{CO}$ band at 1943 $cm^{-1}$. ESI-MS of the reaction mixture featured peaks corresponding to $\{[CpCo(CN)_3]_2[Cp^*Ru(CO)]_3\}^+$. We propose $\{[CpCo(CN)_3]_2[Cp^*Ru(CO)]_3\}^+$ is a trigonal-bipyramidal cage, other examples of which are known in cyanometalate chemistry.[12]

Further evidence for the mobility of the $CpCo(CN)_3^-$ vertices in $Cs\subset Co_4Ru_3$ came from vertex extraction reactions involving ammonium ions. Thus treatment of this cage with $PhNH_3OTf$ afforded the coordination polymer $PhNH_3CpCo(CN)_3$ [Equation (1)].

$$4\ Cs\subset Co_4Ru_3 + 4\ PhNH_3^+ \rightarrow 4\ PhNH_3CpCo(CN)_3 + 3\ [Cs\subset Co_4Ru_4]^+ + Cs^+ \quad (1)$$

This polymeric species was independently synthesized by treating an MeCN solution of $PPN[CpCo(CN)_3]$ with $PhNH_3OTf$ ($PPN^+ = Ph_3PNPPh_3^+$). The yellow solid was soluble only in polar solvents, i.e. those expected to compete for hydrogen bonds. The polymer adopts a "folded tape" motif, constructed from strong hydrogen bonds connecting the acidic protons and the basic cyanide ligands (Figure 2). The ammonium cyanide distances (*N*···*N*C–Co) range from 2.747 to 2.999 Å indicating strong hydrogen bonds.[13]

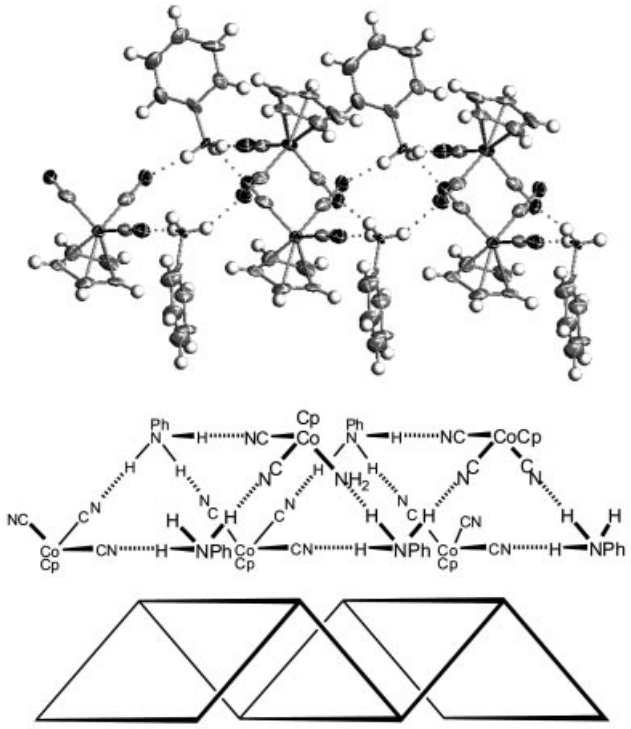

Figure 2. Structure of the hydrogen-bonded polymer $PhNH_3CpCo(CN)_3$ (top). Schematic illustrating the bonding in the tape polymer (bottom).

Although the defect box $Cs\subset Co_4Ru_3$ does undergo partial disassembly in solution, it displayed greater stability than the analogous $Co_4Rh_3^{2+}$, which lacks a centrally "gluing" $Cs^+$ center. The $Co_4Rh_3^{2+} + [Cp^*Ru(NCMe)_3]^+$ reaction afforded a mixture of $Co_4Rh_4^{4+}$, $Co_4Rh_3Ru^{3+}$, and $Co_4Rh_2Ru_2^{2+}$. These products, especially $Co_4Rh_4^{4+}$, indicate that the starting $Co_4Rh_3^{2+}$ disassembles followed by reassembly of $[Cp^*Rh(NCMe)_3]^{2+}$, $[Cp^*Ru(NCMe)_3]^+$, and $[CpCo(CN)_3]^-$ in a nearly statistical manner. Slightly different products are obtained when the $Co_4Rh_3^{2+} + [Cp^*Ru(NCMe)_3]^+$ reaction was conducted in the presence of $Cs^+$. Again, the main products are $Co_4Rh_4^{4+}$ and $Co_4Rh_3Ru^{3+}$, but we also obtained small amounts of $Cs\subset Co_4Rh_2Ru_2^{3+}$ and $Cs\subset Co_4Rh_3Ru^{4+}$. These latter two species are unprecedented examples of cationic receptors binding $Cs^+$. In contrast to the behavior of the Cs-free cages, $Cs\subset Co_4Ru_3$ remained intact upon complexation to $[Cp^*Rh(NCMe)_3]^{2+}$ to produce $Cs\subset Co_4Ru_3Rh^{2+}$ quantitatively.

### Boxes with Lewis-Acidic Tetrahedral Vertices: Copper(I) and Silver(I)

Treatment of a MeCN solution of $[Cu(NCMe)_4]PF_6$ with a THF solution of $Cs\subset Co_4Ru_3$ at 0 °C gave red

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$\{Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_3Cu(NCMe)\}PF_6$ ($[Cs\subset Co_4Ru_3Cu(NCMe)]PF_6$). The $^1H$ NMR spectrum confirmed the $C_{3v}$ symmetry with two Cp resonances in a 3:1 ratio and single resonance for Cp*. The IR spectrum of $[Cs\subset Co_4Ru_3Cu(NCMe)]PF_6$ featured a single broad $\nu_{CN}$ band at 2144 $cm^{-1}$, which is higher in energy vs. $\nu_{CN}$ for the terminal cyanides of $Cs\subset Co_4Ru_3$ (2129 $cm^{-1}$). The ESI-MS of the product solution supported the formulation. The red-colored silver derivative $[Cs\subset Co_4Ru_3Ag(NCMe)]^+$ was prepared analogously from $AgPF_6$ and $Cs\subset Co_4Ru_3$.

The MeCN ligands in $[Cs\subset Co_4Ru_3M(NCMe)]^+$ (M = Ag, Cu) exchange readily. Treatment of these cages with $PPh_3$ yielded the expected adducts $[Cs\subset Co_4Ru_3MPPh_3]PF_6$, which were characterized spectroscopically. We attempted to generate higher nuclearity cyanometalates by exploiting the Lewis acidities of $[Cs\subset Co_4Ru_3M(NCMe)]^+$ by their condensation with (18-crown-6 K)$_3[Co(CN)_6]$ or $Et_4NCN$. Such reactions only regenerated $Cs\subset Co_4Ru_3$, suggesting that the metallo-ligand $Cs\subset Co_4Ru_3$ is only weakly bound to the coinage metal.

### Boxes with Lewis-Acidic Octahedral Vertices: Nickel

Condensation of $Cs\subset Co_4Ru_3$ with $[Ni(NCMe)_6](BF_4)_2$ gave the trimetallic cage $\{Cs[CpCo(CN)_3]_4[Cp^*Ru]_3Ni(NCMe)_3\}^{2+}$ ($[Cs\subset Co_4Ru_3Ni(NCMe)_3]^{2+}$). To prevent the generation of the $\{\{Cs[CpCo(CN)_3]_4[Cp^*Ru]_3\}_2Ni\}^{2+}$ byproduct, the $Cs\subset Co_4Ru_3$ cage was added as an MeCN slurry to a concentrated solution of $[Ni(NCMe)_6](BF_4)_2$. The $^1H$ NMR spectrum of the red product indicated $C_{3v}$ symmetry. The signals, especially those of the "rim" CpCo centers, are broadened due to their adjacency to the paramagnetic octahedral $Ni^{II}$ center. The IR spectrum of $[Cs\subset Co_4Ru_3Ni(NCMe)_3](BF_4)_2$ featured a single broad $\nu_{CN}$ band at 2170 $cm^{-1}$; absent was the $\nu_{CNt}$ band at 2129 $cm^{-1}$ for $Cs\subset Co_4Ru_3$. The ESI-MS of the product solution supported the formation of $[Cs\subset Co_4Ru_3Ni(NCMe)_3]^{2+}$ ($m/z$ = 855); signals corresponding to $\{(Cs\subset Co_4Ru_3)_2Ni\}^{2+}$ were not detected. The metalation route enjoys some generality: a slurry of $Cs\subset Co_4Ru_3$ was found to react with $[Fe(NCMe)_6](PF_6)_2$ to afford $[Cs\subset Co_4Ru_3Fe(NCMe)_3](PF_6)_2$, which was identified by ESI-MS.

The MeCN ligands of $[Cs\subset Co_4Ru_3Ni(NCMe)_3]^{2+}$ exchange with a variety of Lewis bases. Qualitative tests using ESI-MS showed that 9-ane-S3 formed adducts (9-ane-S3 is 1,4,7-trithiacyclononane). Preparative-scale reaction gave the red crystalline species $[Cs\subset Co_4Ru_3Ni(9\text{-ane-}S3)](BF_4)_2$, which was characterized crystallographically (see below).

Attempts were made to generate higher nuclearity cages by exploiting the Lewis acidity of $[Cs\subset Co_4Ru_3Ni(NCMe)_3]^{2+}$. Treatment of these cages, however, with $K[(C_5R_5)M(CN)_3]$ [$(C_5R_5)$M = Cp*Rh, CpCo] or $Et_4NCN$ generated the double box $\{(Cs\subset Co_4Ru_3)_2Ni\}^{2+}$, as indicated by ESI-MS analysis. Apparently, scission of the Ni–N(cage) bonds is facile. A sample $\{[Cs\subset Co_4Ru_3]_2Ni\}(BF_4)_2$ was generated independently by treatment of $Cs\subset Co_4Ru_3$ with 0.5 equiv. of $[Ni(NCMe)_6](BF_4)_2$ and characterized by $^1H$ NMR and IR spectroscopy, as well as ESI-MS.

### Boxes Completed with Lewis-Acidic Octahedral Vertices: Ruthenium

The metallo-ligand $Cs\subset Co_4Ru_3$ was shown to bind a variety of ruthenium $PPh_3$ complexes. Thus, $RuCl_2(PPh_3)_3$ and $RuHCl(PPh_3)_3$ afforded the corresponding eight-vertex cages (Scheme 1). The $^1H$ NMR spectra of $[Cs\subset Co_4Ru_3Ru(PPh_3)_2Cl]Cl$ and $[Cs\subset Co_4Ru_3Ru(PPh_3)_2H]Cl$ are consistent with $C_s$ symmetry (Figure 3). Treatment of $[Cs\subset Co_4Ru_3Ru(PPh_3)_2H]Cl$ with an MeCN solution of $AgPF_6$ gave $[Cs\subset Co_4Ru_3Ru(PPh_3)_2(NCMe)](PF_6)_2$, concomitant with formation of Ag. This MeCN-containing product was characterized by proton NMR spectroscopy and X-ray crystallography.

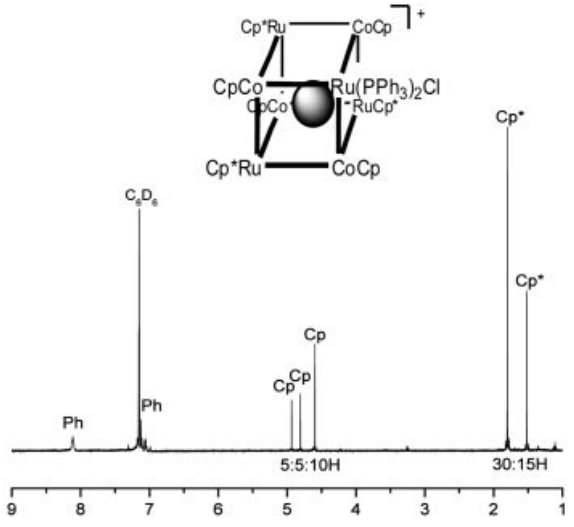

Figure 3. $^1H$ NMR spectrum of $\{Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_3[Ru(PPh_3)_2Cl]\}Cl$ in $C_6D_6$ solution.

A cage containing one $Ru(C_6H_6)^{2+}$ vertex was prepared from the reaction of $Cs\subset Co_4Ru_3$ and $[(C_6H_6)Ru(NCMe)_3](PF_6)_2$. Photolysis of $[Cs\subset Co_4Ru_3Ru(C_6H_6)](PF_6)_2$ was anticipated to afford the corresponding $[Ru(NCMe)_3]$ derivative, which would be promising building block. Unfortunately, photolysis of $[Cs\subset Co_4Ru_3Ru(C_6H_6)](PF_6)_2$ was a slow process. Only 30% conversion to $[Cs\subset Co_4Ru_3Ru(NCMe)_3](PF_6)_2$ was observed after four days.[14]

### X-ray Crystallographic Results on New Molecular Boxes

Single crystal X-ray structure of $[Cs\subset Co_4Ru_3Ni(9\text{-ane-}S_3)](BF_4)_2$ confirmed the structure of the completed box. The $Cs\subset Co_4Ru_3$ subunit remains intact and binds the Ni(9-ane-S3) subunit in a tridentate fashion forming the trimetallic cube framework, analogous to previously reported completed boxes (Figure 4).[15] In the case of $[Cs\subset Co_4Ru_3Ru(PPh_3)_2(NCMe)](PF_6)_2$, the dicationic cage consists of a $Co_4Ru_4(\mu\text{-}CN)_{12}$ cube with a $Ru(PPh_3)_2(NCMe)^{2+}$ vertex and three Cp*Ru vertices. The cyanide linkages in both the

[Cs⊂Co$_4$Ru$_3$Ni(9-ane-S$_3$)](BF$_4$)$_2$ and [Cs⊂Co$_4$Ru$_3$Ru(PPh$_3$)$_2$(NCMe)](PF$_6$)$_2$ cages are ordered, as indicated by characteristically short Co-C distances. The cage frameworks conform well to the geometry of a cube with ca. 90° N–M–N and C–M–C angles (Table 1 and Table 2).

## Conclusions

The cage Cs⊂Co$_4$Ru$_3$ is a versatile metallo-ligand, despite its stereochemical complications. Neither of the two isomers of this cage are poised to serve as a tridentate ligand: reorientation of the terminal cyanide ligands is required. Metalation of Cs⊂Co$_4$Ru$_3$ is complete upon addition of the electrophile. The isomerization of the terminal cyanides would appear to require the scission of at least one intra-cage Ru–NC–Co linkage, which allows it to exchange sites with the terminal cyanide ligand. Various chemical tests – cage degradation with CO and PhNH$_3^+$, as well as quasi-degenerate exchange reactions – show that vertex exchange occurs, however, more slowly than complexation.

The metallo-ligand Cs⊂Co$_4$Ru$_3$ exhibits exceptional affinity for binding to diverse metal centers. This work substantially extends this range to include a range of metal centers that bear reactive ligands. We show that these site-differentiated cages can undergo selective substitution reactions without disruption of the M$_8$(μ-CN)$_{12}$ framework. It appears that this first generation of reactive cages are insufficiently robust, so further work is merited on the design of new cyanometalate cage-ligands. The Cs⊂Co$_4$Ru$_3$ ligand functions as a facially capping tridentate ligand akin to tris(pyrazolyl)borate (Tp) and triazacyclononane (TACN). Complexes of the type Tp$_2$M$^z$ and (TACN)$_2$M$^z$ are common, whereas the half-sandwich complexes are rarer.[16]

## Experimental Section

Reactions and manipulations were performed under nitrogen, using standard Schlenk-line techniques. Solvents were dried and deoxygenated prior to use K(MeC$_5$H$_4$)Co(CN)$_3$,[17] [Cu(NCMe)$_4$]PF$_6$,[18] [Ni(NCMe)$_6$](BF$_4$)$_2$,[19] [Fe(NCMe)$_6$](PF$_6$)$_2$,[20] Ru(PPh$_3$)$_3$Cl$_2$,[21] [(C$_6$H$_6$)Ru(NCMe)$_3$](PF$_6$)$_2$[22] and {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$}[10] were prepared according to literature methods. Elemental analyses were conducted by the School of Chemical Sciences Microanalytical Laboratory. $^1$H and $^{31}$P NMR spectra were acquired with Varian Unity 400 and 500. Electrospray ionization-mass spectra (ESI-MS) and MS-MS measurements were acquired with a Micromass Quattro QHQ quadrupole-hexapole-quadrupole instrument. Infrared spectra were obtained with a Mattson Galaxy Series FT-IR 3000 on pressed KBr pellets.

**Crystallography:** Crystals were mounted to a thin glass fiber using oil (Paratone-N, Exxon). Data were filtered to remove statistical outliers. The integration software (SAINT) was used to test for crystal decay as a bilinear function of X-ray exposure time and sine ($\theta$). Data were collected with a Siemens Platform/CCD automated diffractometer. Crystal and refinement details are given in supplementary material. The structures were solved using SHELXTL by direct methods; correct atomic positions were deduced from an E map or by an unweighted difference Fourier synthesis. H atom $U$ values were assigned as 1.2 times the $U_{eq}$ values of adjacent C

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms. Non-H atoms were refined with anisotropic thermal coefficients. Successful convergence of the full-matrix least-squares refinement of $F^2$ was indicated by the maximum shift/error for the last cycle.

CCDC-632474 for {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ni(9-ane-S3)}-(BF$_4$)$_2$, -632475 for PhNH$_3$CpCo(CN)$_3$, and -632476 for {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ru(NCMe)(PPh$_3$)$_2$}(PF$_6$)$_2$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre at www.ccdc.cam.ac.uk/data_request/cif.

The solvent was then removed in vacuo and the red residue was extracted into MeCN and $CH_2Cl_2$ and analyzed by mass spectrometry and IR spectroscopy, respectively ESI-MS: (*m*/*z*) = 1198 [{[CpCo(CN)$_3$]$_2$[Cp*RuCO]$_3$}$^+$]. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1947 ($\nu_{CO}$), 2165 ($\nu_{CN}$), 2126 cm$^{-1}$.

**Degradation with PhNH$_3^+$. Generation of PhNH$_3$CpCo(CN)$_3$:** A THF stock solution of PhNH$_3$OTf (1 mL, 0.004 M) was added to 7.4 mg (0.004 mmol) of Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$. After 7 d, a yellow-colored precipitate, PhNH$_3$[CpCo(CN)$_3$], formed. This species was independently prepared by addition of a solution of PhNH$_3$OTf (97.2 mg, 0.4 mmol) in MeCN (50 mL) to a solution of PPN[CpCo(CN)$_3$] (294.7 mg, 0.4 mmol) in MeCN (20 mL) to afford yellow microcrystals. Yield: 0.0761 g (64%). IR (KBr): $\tilde{\nu}$ = 2129 ($\nu_{CN}$) cm$^{-1}$, 2603 ($\nu_{NH}$) cm$^{-1}$. C$_{14}$H$_{13}$CoN$_4$ (296.05): calcd. C 56.75, H 4.43, N 18.92; found C 56.38, H 4.36, N 18.53. The salt was insoluble in acetone, $CH_2Cl_2$, THF, MeCN but dissolved in EtOH and DMSO. Single crystals were grown by vapor diffusion of Et$_2$O into an EtOH solution.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$[Cu(NCMe)]}PF$_6$, [Cs⊂Co$_4$Ru$_3$Cu-(NCMe)]PF$_6$:** A solution of Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$ (413 mg, 0.25 mmol) in THF (30 mL) was added dropwise to a stirred solution of [Cu(MeCN)$_4$]PF$_6$ (93 mg, 0.25 mmol) in MeCN (15 mL) at 0 °C over 1 h. The resulting dark red solution was stirred for 5 h, and the solvent was removed under vacuum. Yield: 394 mg (83%). $^1$H NMR (CD$_3$CN): $\delta$ = 1.68 (s, 45 H, Cp*), 5.53 (s, 15 H, Cp), 5.60 (s, 5 H, Cp) ppm. ESI-MS: *m*/*z* = 1714 [M$^+$ – MeCN]. IR (KBr): $\tilde{\nu}$ = 2144 ($\nu_{CN}$) cm$^{-1}$. C$_{64}$H$_{68}$Co$_4$CsCuF$_6$N$_{13}$PRu$_3$ (1898.94): calcd. C 40.46, H 3.61, N 9.59; found C 40.93, H 3.75, N 10.07.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Cu(PPh$_3$)}PF$_6$, [CsCo$_4$Ru$_3$Cu(PPh$_3$)]-PF$_6$:** An MeCN stock solution of PPh$_3$ (1 mL, 0.0012 M) was added dropwise to a stirred solution of [Cs⊂Co$_4$Ru$_3$Cu(NCMe)]PF$_6$ (2.2 mg, 0.0012 mmol) in MeCN (5 mL). $^1$H NMR (CD$_3$CN): $\delta$ = 1.68 (s, 45 H), 5.51 (s, 15 H), 5.61 (s, 5 H), 7.55 (m, 15 H) ppm. $^{31}$P NMR (CD$_3$CN): $\delta$ = 21.89 ppm. ESI-MS: *m*/*z* = 1977 [{Cs[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$[CuPPh$_3$]}$^+$].

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ag(NCMe)}PF$_6$, [Cs⊂Co$_4$Ru$_3$Ag-(NCMe)]PF$_6$:** A solution of AgPF$_6$ (33.4 mg, 0.13 mmol) in MeCN (10 mL) was added dropwise to a slurry of Cs⊂Co$_4$Ru$_3$ (218 mg, 0.13 mmol) in MeCN (15 mL) at 0 °C. The deep red solution was warmed to room temperature. After stirring for 1 h, the solvent was evaporated. Yield: 87% (220 mg). $^1$H NMR (CD$_3$CN): $\delta$ = 1.68 (s, 45 H, Cp*), 1.96 (s, 3 H, MeCN), 5.54 (s, 15 H, Cp), 5.62 (s, 5 H, Cp) ppm. ESI-MS: *m*/*z* = 1758 [{Cs[CpCo(CN)$_3$]$_4$-[Cp*Ru]$_3$Ag}$^+$]. IR (KBr): $\tilde{\nu}$ = 2141 ($\nu_{CN}$) cm$^{-1}$. C$_{64}$H$_{68}$AgCo$_4$CsN$_{13}$F$_6$PRu$_3$ (1943.26): calcd. C 39.52, H 3.53, N 9.37; found C 39.13, H 3.55, N 9.60.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ag(PPh$_3$)}PF$_6$, [Cs⊂Co$_4$Ru$_3$Ag(PPh$_3$)]-PF$_6$:** A solution of PPh$_3$ (12.8 mg, 0.05 mmol) in MeCN (10 mL) was added dropwise to a stirred solution of [Cs⊂Co$_4$Ru$_3$-Ag(NCMe)]PF$_6$ (95.2 mg, 0.05 mmol) in MeCN (20 mL). The solvent was removed under vacuum. $^1$H NMR (CD$_3$CN): $\delta$ = 1.68 (s, 45 H, Cp*), 5.51 (s, 15 H, Cp), 5.62 (s, 5 H, Cp), 7.54–7.53 (m, 15 H, Ph) ppm. $^{31}$P NMR (CD$_3$CN): $\delta$ = 10.7 [d, $^1J$(P, $^{107}$Ag) = 577 Hz], 10.70 [d, $^1J$(P, $^{109}$Ag) = 651.9 Hz] ppm. ESI-MS: *m*/*z* = 2021 [{Cs[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$AgPPh$_3$}$^+$].

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ni(NCMe)$_3$}(BF$_4$)$_2$, [Cs⊂Co$_4$Ru$_3$Ni-(NCMe)$_3$](BF$_4$)$_2$:** A slurry of Cs⊂Co$_4$Ru$_3$ (224 mg, 0.14 mmol) in MeCN (90 mL) was added dropwise to a solution of [Ni(NCMe)$_6$]-(BF$_4$)$_2$ (65.2 mg, 0.14 mmol) in MeCN (10 mL) at 0 °C. The deep red solution was warmed to room temperature. After stirring for 1 h, the solvent was removed in vacuo. Yield: 227 mg (85%). $^1$H NMR (CD$_3$CN): $\delta$ = 1.70 (s, 45 H, Cp*), 1.96 (s, 9 H, MeCN), 4.99 (br. s, 15 H, Cp), 5.63 (s, 5 H, Cp) ppm. IR (KBr): $\tilde{\nu}$ = 2170 ($\nu_{CN}$) cm$^{-1}$. ESI-MS: *m*/*z* = 855 [{Cs[CpCo(CN)$_3$]$_4$-[Cp*Ru]$_3$Ni}$^{2+}$], 1796 [{Cs[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ni}BF$_4^+$]. C$_{68}$H$_{74}$B$_2$Co$_4$CsF$_8$N$_{15}$NiRu$_3$ (2005.16): calcd. C 40.69, H 3.72, N 10.48; found C 41.05, H 3.96, N 10.77.

**[{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$}$_2$Ni](BF$_4$)$_2$:** A solution of Cs⊂Co$_4$Ru$_3$ (197.1 mg, 0.12 mmol) in $CH_2Cl_2$/MeCN (40 mL, 1:1) was treated with a solution of [Ni(NCMe)$_6$](BF$_4$)$_2$ (28.6 mg, 0.06 mmol) in MeCN (10 mL). The solvent was removed in vacuo. Yield: 169 mg (80%). $^1$H NMR (CD$_3$CN): $\delta$ = 1.68 (s, 90 H, Cp*), 5.09 (br. s, 30 H, Cp), 5.62 (s, 10 H, Cp) ppm. ESI-MS: *m*/*z* = 1680 [[{Cs[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$}$_2$Ni]$^{2+}$]. C$_{124}$H$_{130}$B$_2$Co$_{88}$Cs$_2$N$_{24}$NiRu$_6$ (3531.48): calcd. C 42.14, H 3.71, N, 9.52; found C 42.56, H 3.74, N 9.80.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Fe(NCMe)$_3$}(PF$_6$)$_2$:** A slurry of Cs⊂Co$_4$Ru$_3$ (168.5 mg, 0.1 mmol) in MeCN (70 mL) was added

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dropwise to a stirred solution of $[Fe(NCMe)_6](PF_6)_2$ (60.5 mg, 0.1 mmol) in MeCN (8 mL) at 0 °C. The deep red solution was warmed to room temperature. After a further 1 h, the solvent was removed in vacuo. Yield: 170 mg (80%). IR (KBr): $\tilde{\nu}$ = 2153 ($\nu_{CN}$) $cm^{-1}$. ESI-MS: *m*/*z* = 854 [{Cs[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Fe}$^{2+}$]. $C_{68}H_{74}Co_4CsF_{12}FeN_{15}P_2Ru_3$ (2118.26): calcd. C 38.52, H, 3.52, N, 9.92; found C 39.03, H 3.56, N 9.81.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ni(9-ane-S3)}(BF$_4$)$_2$, [CsCo$_4$Ru$_3$Ni(9-ane-S3)](BF$_4$)$_2$:** A solution of 9-ane-S3 (7.3 mg, 0.04 mmol) in MeCN (10 mL) was added to a solution of $[Cs{\subset}Co_4Ru_3Ni(NCMe)_3](BF_4)_2$ (81.5 mg, 0.04 mmol) in of MeCN (10 mL). The red solution was stirred for 1 h, and the solvent was removed in vacuo. ESI-MS: *m*/*z* = 945 [{Cs[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ni(9-ane-S3)}$^{2+}$]. Single crystals were grown by vapor diffusion of $Et_2O$ into a $CH_2Cl_2$/acetone solution of $[Cs{\subset}Co_4Ru_3Ni(9\text{-ane-S3})](BF_4)_2$.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$RuCl(PPh$_3$)$_2$}Cl:** A solution of $Cs{\subset}Co_4Ru_3$ (440 mg, 0.266 mmol) in THF (40 mL) was added dropwise to a stirred solution of $RuCl_2(PPh_3)_3$ (256 mg, 0.266 mmol) in THF (40 mL) at 0 °C over the course of 1 h. After stirring the resulting dark red solution for 16 h, the solvent was removed under vacuum. The residue was extracted with $Et_2O$ (60 mL), and this extract was concentrated under vacuum. Addition of hexane gave a dark red solid. Yield: 390 mg (63%). $^1$H NMR ([D$_8$]THF): $\delta$ = 1.69 (s, 15 H, Cp*), 1.73 (s, 30 H, Cp*), 4.83 (s, 5 H, Cp), 4.96 (s, 10 H, Cp), 5.54 (s, 5 H, Cp), 7.08 (m, 12 H, Ph), 7.45 (m, 6 H, Ph), 7.73 (m, 12 H, Ph) ppm. ESI-MS: *m*/*z* = 2312 [M$^+$, (Cs⊂{[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$RuCl(PPh$_3$)$_2$}$)^+$]. $C_{98}H_{95}Cl_2Co_4CsN_{12}P_2Ru_4$ (2345.56): calcd. C 50.16, H 4.08, N 7.16; found C 50.33, H 3.21, N 7.27.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$RuH(PPh$_3$)$_2$}Cl:** A solution of $Cs{\subset}Co_4Ru_3$ (330 mg, 0.2 mmol) in THF (30 mL) was added dropwise to a stirred solution of $RuHCl(PPh_3)_3$ (185 mg, 0.2 mmol) in THF (30 mL) at 0 °C over the course of 1 h. After stirring the dark red solution for 16 h, it was concentrated under vacuum to ca. 10 mL. Addition of 50 mL of hexane gave a dark red precipitate, which was washed with hexane, dried under vacuum to give a dark red solid. Yield: 348 mg (75%). $^1$H NMR ($CD_3CN$): $\delta$ = –15.24 (t, $J_{Ru\text{-}H}$ = 27 Hz, 1 H, Ru-H), 1.68 (s, 15 H, Cp*), 1.73 (s, 30 H, Cp*), 4.83 (s, 10 H, Cp), 5.01 (s, 5 H, Cp), 5.60 (s, 5 H, Cp), 7.20 (m, $J_{H\text{-}H}$ = 7 Hz, 12 H, Ph), 7.27 (m, $J_{H\text{-}H}$ = 7 Hz, 6 H, Ph), 7.52 (m, $J_{H\text{-}H}$ = 7 Hz, 12 H, Ph) ppm. ESI-MS: *m*/*z* = 2278 [M$^+$, (Cs⊂{[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$RuH(PPh$_3$)$_2$}$)^+$]. $C_{98}H_{96}ClCo_4CsN_{12}P_2Ru_4$ (2311.12): calcd. C 50.91, H, 4.18, N, 7.27; found C 51.03, H 4.23, N 8.62.

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ru(NCMe)(PPh$_3$)$_2$}(PF$_6$)$_2$:** A mixture of {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$RuH(PPh$_3$)$_2$}Cl (46 mg, 0.02 mmol) and $AgPF_6$ (5 mg, 0.0.02 mmol) in THF (5 mL) was stirred overnight. After the solvent was removed under vacuum, the residue was extracted with MeCN (5 mL), which was concentrated to ca. 1 mL. Dilution of this extract with $Et_2O$ (5 mL ) gave a red-colored solid. The product was crystallized by dissolution in MeCN followed by the slow addition of $Et_2O$. Crystals were grown by liquid diffusion of diethyl ether into acetonitrile solution. ESI-MS: *m*/*z* = 1139 [M$^+$, {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ru(NCMe)(PPh$_3$)$_2$}$^{2+}$].

**{Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ru(C$_6$H$_6$)}(PF$_6$)$_2$:** A solution of $Cs{\subset}Co_4Ru_3$ (330 mg, 0.2 mmol) in THF (15 mL) was added dropwise to a solution of $[(C_6H_6)Ru(NCMe)_3](PF_6)_2$ (119 mg, 0.2 mmol) in MeCN (25 mL) at 0 °C over 1 h. After stirring for 16 h, the resulting dark red solution was evaporated. Yield: 340 mg (80%). $^1$H NMR ($CD_3CN$): $\delta$ = 1.66 (s, 45 H, Cp*), 5.58 (s, 5 H, Cp), 5.73 (s, 15 H, Cp), 6.17 (s, 6 H, $C_6H_6$) ppm. ESI-MS: *m*/*z* = 915 [M$^{2+}$, {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ru(C$_6$H$_6$)}$^{2+}$]. $C_{98}H_{96}ClCo_4CsN_{12}P_2Ru_4{\cdot}CH_3CN{\cdot}Et_2O$: calcd. C 39.78, H 3.79, N 8.15; found C 40.42, H 3.64, N 8.36. A solution of {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ru(C$_6$H$_6$)}(PF$_6$)$_2$ (9 mg) in $CD_3CN$ (0.7 mL) in a NMR tube was subjected to photolysis using a mercury lamp. After 96 h, the ESI-MS and NMR spectra of the reaction mixture showed a 30% conversion to {Cs⊂[CpCo(CN)$_3$]$_4$[Cp*Ru]$_3$Ru(NCCD$_3$)$_3$}(PF$_6$)$_2$.

# Synthesis and Catalytic Activity of $\eta^1$-Allyl and $\eta^3$-Allyl, Ethyl, and Hydrido Complexes of Ruthenium–Pentamethyl[60]fullerene

**Yutaka Matsuo,[a] Takashi Uematsu,[b] and Eiichi Nakamura*[a,b]**

**Keywords:** Ruthenium / Fullerenes / Allyl complexes / Hydrido complexes / Isomerization

$\eta^1$-Allyl and $\eta^3$-allyl, ethyl, and hydrido ruthenium complexes of pentamethyl[60]fullerene, $Ru(\eta^5\text{-}C_{60}Me_5)R(CO)_2$ (R = $\eta^1$-allyl, Et, H) and $Ru(\eta^5\text{-}C_{60}Me_5)(\eta^3\text{-allyl})(CO)$ were synthesized by the reaction of a chlorido complex $Ru(\eta^5\text{-}C_{60}Me_5)Cl(CO)_2$ with an allyl and an ethyl Grignard reagent or lithium aluminum hydride. Conversion of the $\eta^1$-allyl complex to the corresponding $\eta^3$-allyl complex and the catalytic performance of the hydrido and the chlorido complexes in the isomerization reaction of 1-decene to internal decenes are described.

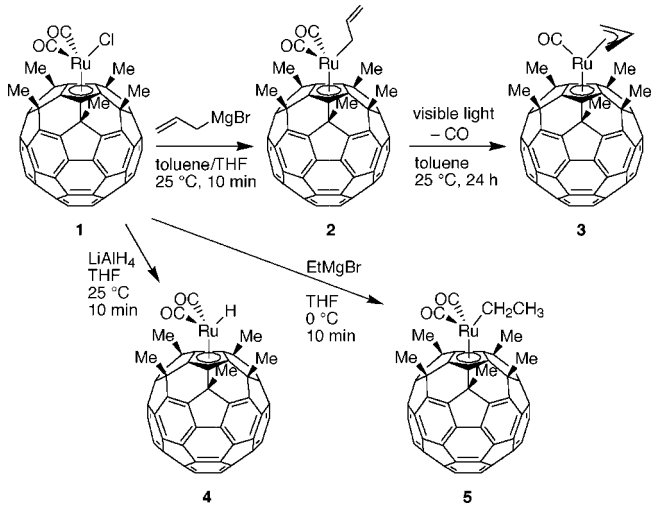
## Introduction

Cooperative effects of fullerene conjugated systems and transition metal atoms have attracted the interest of inorganic and organometallic chemists[1] because of the possible dπ-conjugative synergy that may create new properties unavailable from individual systems.[2] We have employed pentaorgano[60]fullerenes[3] as $\eta^5$-fullerene ligands and synthesized various metal–fullerene complexes involving Re,[4] Fe,[5] Ru,[6] Rh,[7] Ir,[8] Ni,[9] Pd,[9] and Pt[9] atoms. Among them, many ruthenium(II) complexes are particularly interesting because of stable facial coordination of the pentaorgano[60]fullerene ligands to the $d^6$ metal center with the octahedral geometry.[6a] Indeed, ruthenium complex $Ru(\eta^5\text{-}C_{60}Me_5)Cl(CO)_2$ was obtained in high yield on a large scale and was used as a useful starting material for the study of the organometallic chemistry of the metal–fullerene complexes.[6a] As an extension of our work in this area, we have investigated further derivatization of the ruthenium complex and obtained various ruthenium–pentamethyl[60]fullerene complexes. Herein we report the synthesis and catalytic activity of $\eta^1$- and $\eta^3$-allyl, ethyl, and hydrido ruthenium complexes of pentamethyl[60]fullerene (Scheme 1).



Scheme 1. Syntheses of allyl, ethyl, and hydrido complexes.

## Results and Discussion

### Synthesis of $\eta^1$- and $\eta^3$-Allyl Ruthenium Complexes of Pentamethyl[60]fullerene

Treatment of a solution of $Ru(\eta^5\text{-}C_{60}Me_5)Cl(CO)_2$ (**1**)[6a] in toluene with a solution of allylmagnesium bromide in thf at 25 °C led to a ligand exchange reaction to afford $\eta^1$-allyl complex **2**, $Ru(\eta^5\text{-}C_{60}Me_5)(\eta^1\text{-allyl})(CO)_2$, in quantitative yield (Scheme 1). Product **2** was purified by neutral alumina chromatography to remove magnesium salts. Decomposition of **2** through loss of the ruthenium metal was observed upon silica gel column chromatography, which resulted in the formation of an oxidized compound of pentamethyl[60]fullerene, $C_{60}Me_5O_2OH$.[10] This product was identified by MS (APCI–) (*m*/*z* = 844 $[M]^-$). Compound **2** was isolated as an orange powder and was stable in air as a solid for over one month. Characterization of **2** was performed by $^1H$ and $^{13}C$ NMR, IR, and UV/Vis spectroscopic measurements, and combustion analysis. In the $^1H$ NMR spectrum, a set of three signals due to the olefinic protons was observed in lower field at $\delta$ = 4.86, 5.14, and 6.51 ppm, which indicates that the complex is a σ-allyl complex. The IR spectrum exhibited asymmetric and symmetric stretch-

ing vibrations of the carbonyl groups at 2016 and 1960 $cm^{-1}$, which suggests two carbonyl ligands remain on the ruthenium center.

We next investigated conversion of $\eta^1$-allyl complex **2** into an $\eta^3$-allyl complex through decarbonylation. Compound **2** did not react at all in $C_6D_6$ at 25 °C for 24 h. However, when the $C_6D_6$ solution of **2** was irradiated by visible light with 60 W incandescent light at 25 °C for 14 h, $\eta^3$-allyl compound **3**, Ru($\eta^5$-$C_{60}Me_5$)($\eta^3$-allyl)(CO), formed. According to the ligand field theory, such as light-induced decarbonylation process involves electron transition to antibonding orbital of the metal–carbonyl bond. The effect of the strongly light-absorbing fullerene part is therefore apparent. The progress of the reaction was monitored by analysis of the $^1H$ NMR spectra (Figure 1). After three hours of irradiation, the $\eta^1$- and $\eta^3$-allyl complexes were observed in a 1:1 ratio. Irradiation for 14 h completed this conversion. On heating the reaction mixture to 110 °C in $C_6D_6$ for 24 h in a sealed tube, instead of the light irradiation, $\eta^3$-allyl compound **3** slowly formed (only with ca. 10% conversion). It is known that an $\eta^5$-cyclopentadienyl-$\eta^3$-allyl metal complex exists in two isomeric forms: *exo* and *endo* isomers (Figure 2).[11] In contrast, the present reaction produced only an *exo* isomer (see below). If a pathway of *endo–exo* interconversion exists (which may involve pseudorotation of the $\eta^3$-allyl group about the allyl–metal bond axis or an equilibrium that goes through an $\eta^1$-allyl intermediate), the experimental observation would suggest that the *exo* isomer is thermodynamically much more stable than the *endo* isomer. It must then be the steric bulk of the pentamethyl[60]fullerene ligand that is responsible for the *exo* preference. Such a tendency, though less pronounced, in the stability of the *exo* isomer has also been observed in usual $\eta^5$-cyclopentadienyl-$\eta^3$-allyl ruthenium systems.[12]

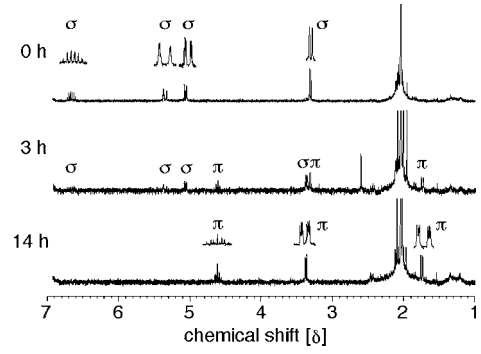

Figure 1. Conversion of **2** to **3** as monitored with $^1H$ NMR spectroscopic measurements.

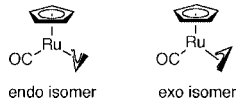

Figure 2. The *endo* and *exo* isomers of $\eta^5$-Cp-$\eta^3$-allyl ruthenium carbonyl complex.

$\eta^3$-Allyl complex **3** was isolated in 49% yield by preparative HPLC. Side products were the oxidized pentamethyl[60]fullerene and unidentified insoluble products. Identification of the *exo* form of **3** was achieved by $^1H$ and $^{13}C$ NMR, IR, and UV/Vis spectroscopic measurements, and combustion analysis as well as an X-ray crystallographic study (Figure 3). The $^1H$ NMR spectrum displayed a signal pattern typical for an $\eta^3$-allyl group. Signals due to the *syn* and *anti* protons on the terminal carbon atoms and one proton on the center carbon atom were observed at $\delta$ = 3.38, 1.75, and 4.61, respectively. The IR spectrum showed one strong CO absorption at 1943 $cm^{-1}$. The X-ray analysis clearly showed the *exo* form of the $\eta^3$-allyl ligand. As shown in the top view, the carbonyl ligand are located in the space among two methyl groups of the pentamethyl-[60]fullerene ligand and the $\eta^3$-allyl ligand. The side view indicates roughly parallel coordination of the $\eta^3$-allyl ligand to the $\eta^5$-cyclopentadienyl part of the pentamethyl[60]-fullerene moiety. The angle between a least-squares plane consisting of the three carbon atoms of the $\eta^3$-allyl and that of the five carbon atoms of the $\eta^5$-cyclopentadienyl part is 11.24(2)°. Although some ruthenium $\eta^3$-allyl complexes have been used in catalysis,[13] complex **3** was too stable to show catalytic activity.

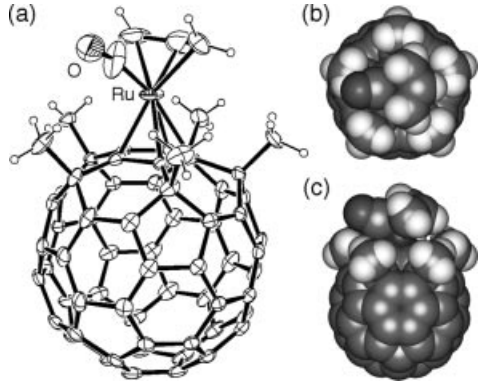

Figure 3. X-ray crystal structure of **3**·$CS_2$. Solvent molecules are omitted for clarity. (a) ORTEP drawing with 30% probability level ellipsoids. (b) CPK model, top view. (c) CPK model, side view.

### Synthesis of Hydrido Ruthenium Complexes of Pentamethyl[60]fullerene

Synthesis of hydrido complex **4**, Ru($\eta^5$-$C_{60}Me_5$)$H(CO)_2$, was performed next. We used three hydrogenation reagents: lithium aluminum hydride (LAH), diisobutylaluminum hydride (DIBAL), and sodium borohydride ($NaBH_4$). Target compound **4** was obtained in 76% isolated yield by the reaction of chlorido complex **1** with LAH in thf at 25 °C (Scheme 1). Treatment of **1** with DIBAL in thf afforded **4** in 42% yield. The reaction of **1** with $NaBH_4$ did not yield the desired hydrido complex but gave several unidentified complexes. This may be due to hydroboration taking place on the fullerene moiety of **1**. Characterization of **4** was performed by $^1H$, $^{13}C$ NMR, IR, and UV/Vis spectroscopic measurements and combustion analysis. In the $^1H$ NMR spectrum, a proton signal characteristic of the hydride group was observed at $\delta$ = –10.07 ppm. The IR spectrum exhibited asymmetric and symmetric vibration absorptions

Table 1. Isomerization of 1-decene to internal alkenes catalyzed by ruthenium–pentamethyl[60]fullerene complexes.

| Entry | Catalyst | 1-Decene [equiv.] | Temp. [°]C | Time [h] | Conversion [%] | Yield [%] 2-Decene (*E*/*Z*) | Other internal alkenes |
|---|---|---|---|---|---|---|---|
| 1 | **4** | 10000 | 140 | 6 | 95 | 49 (2.0) | 46 |
| 2 | **4** | 2600 | 100 | 16 | 24 | 14 (1.8) | 10 |
| 3 | **4** | 2600 | 60 | 16 | 0 | – | – |
| 4 | **3** | 2600 | 100 | 16 | 0 | – | – |
| 5 | **1** | 2600 | 140 | 18 | 96 | 56 (1.8) | 40 |
| 6 | **1** | 2600 | 100 | 16 | 12 | ND | ND |

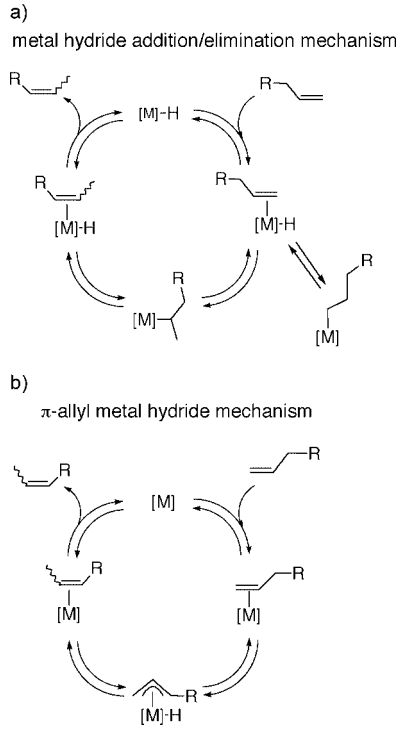
at 2062 and 2024 $cm^{-1}$ that are due to the two carbonyl ligands.

We then examined the catalytic activity of the pentamethyl[60]fullerene ruthenium complexes in alkene isomerization reactions from terminal alkenes to internal alkenes. Many active catalysts using transition metal complexes, such as Fe, Pd, Rh, Pt, Ni, Ir, Ru, Cr, Ti, and Zr complexes, have been used in isomerization reactions of alkenes.[14] In general, two reaction pathways have been considered. One is a metal hydride addition/elimination mechanism (Scheme 2a), and the other is a π-allyl metal hydride mechanism (Scheme 2b). Motivated by the former reaction mechanism, we used hydrido complex **4** in the isomerization reaction of 1-octene. Complex **4** was found to be catalytically active at high temperature. The reaction with the use of 0.01 mol-% of **4** for 6 h at 140 °C took place with 95% conversion to give 49% of 2-decene in an *E*/*Z* ratio of 2.0 and 46% of other internal alkenes (Table 1, Entry 1). When the reaction was heated to 100 °C with 0.083 mol-% of **4** for 18 h, only 24% conversion with a similar product distribution (Table 1, Entry 2) was observed, whereas the reaction heated at 25 or 60 °C did not afford any isomerization products at all (Table 1, Entry 3).

In this reaction, high temperature was essential, which could be due to the high activation energy for decarbonylation of catalyst precursor **4** to the catalytically active monocarbonyl complex. We therefore attempted this alkene isomerization reaction at 25 °C with visible light irradiation which was effective for the conversion of **2** into **3**, but the isomerized products were not obtained. This may then be due to decomposition of the intermediates by further loss of the carbonyl ligand.

Allyl complex **3** did not show any catalytic activity in the alkene isomerization reaction even at 100 °C, whereas chlorido complex **1** gave the isomerized products in 96% conversion at 140 °C, and in 12% conversion at 100 °C. The latter result can be attributed to the formation of **4** from **1** in the presence of alkenes or to a catalytic cycle involving the π-allyl metal hydride (Scheme 2b).

Although ruthenium alkyl complexes having no β-hydrogen such as Ru($\eta^5$-$C_{60}Me_5$)Me$(CO)_2$ and Ru($\eta^5$-$C_{60}Me_5$)-$(CH_2SiMe_3)(CO)_2$[6a] have been synthesized, syntheses of ruthenium alkyl complexes having β-hydrogen atoms are still scarce.[15] In the present fullerene complex series, we could synthesize a stable ruthenium ethyl complex Ru($\eta^5$-$C_{60}Me_5$)Et$(CO)_2$ (**5**) by the reaction of **1** with ethylmagnesium bromide in thf at 0 °C in 48% yield. This complex was perfectly stable and did not show any tendency of β-hydride



Scheme 2. Two possible mechanisms for transition-metal-catalyzed alkene isomerization.

elimination under light irradiation and under heating. We considered that the elimination reaction was inhibited because of either conformational or electronic effects of the $\eta^5$-$C_{60}Me_5$ moiety. One may recall the strong stabilization effect of this fullerene ligand in $\eta^3$-allylnickel chemistry.[9a]

## Conclusion

We have synthesized $\eta^1$-allyl and $\eta^3$-allyl, ethyl, and hydrido ruthenium complexes of pentamethyl[60]fullerene and showed that the hydrido complex catalyzes the 1-decene isomerization reaction. The present set of experiments suggests new opportunities for the exploration of reactivities of the ruthenium–carbon and –hydrogen bonds, especially under excitation of the fullerene ligand by light irradiation.

## Experimental Section

**General Procedure:** All manipulations involving air- and moisture-sensitive compounds were carried out under an atmosphere of argon by using standard Schlenk techniques. Toluene and thf were

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

distilled from Na/K alloy and thoroughly degassed by trap-to-trap distillation before use. Ru($\eta^5$-$C_{60}Me_5$)Cl(CO)$_2$ was prepared according to the literature.[6a] Solutions of *t*BuOK in thf and allylmagnesium bromide in thf were purchased from Sigma–Aldrich Co. and used as received. Other commercial reagents were used without purification. HPLC analyses were performed with a Shimadzu LC-10A system equipped with a SPD-M10A diode array detector and a Cosmosil-Buckyprep column (4.6 × 250 mm, Nacalai Tesque Co.). Preparative HPLC separations were performed by the use of a preparative scale Buckyprep column (20 mm × 250 mm). The $^1$H and $^{13}$C NMR spectra were recorded with a JEOL EX 400 spectrometer. The $^1$H NMR spectra are reported in parts per million from internal tetramethylsilane and in the $^{13}$C NMR spectra from 77.0 ppm ($CDCl_3$) or from 128.0 ppm ($C_6D_6$). Other spectra were recorded with the use of the following instruments: IR, ReactIR 1000; UV/Vis, JASCO V-570; mass spectra, Waters ZQ2000. Elemental analyses were performed at organic elemental analysis laboratory in the Department of Chemistry, University of Tokyo.

**Ru($\eta^5$-$C_{60}Me_5$)($\eta^1$-allyl)(CO)$_2$ (2):** A solution of allylmagnesium bromide (0.090 mmol) in thf (0.090 mL) was added to a solution of **1** (30 mg, 0.030 mmol) in toluene (6 mL) under an atmosphere of argon at room temperature. After stirring for 10 min, a small amount of ethanol was added to the resulting brown solution. The solution was passed through a pad of neutral alumina, and the red-colored filtrate was dried under vacuum to obtain **2** (30 mg, 99% yield) as an orange powder. M.p. 215–220 °C (dec.). $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 6.51 (ddt, $^3J_{H-H}$ = 16.6 (*trans*), 9.8 (*cis*), 8.4 Hz, 1 H, Ru-$CH_2$-C*H*), 5.14 (dd, $^3J_{H-H}$ = 16.6 Hz (*trans*), $^2J_{H-H}$ = 1.9 Hz (*gem*), 1 H, Ru-$CH_2$-CH=C$H_2$), 4.86 (dd, $^3J_{H-H}$ = 9.8 Hz (*cis*), $^2J_{H-H}$ = 1.9 Hz (*gem*), 1 H, Ru-$CH_2$-CH=C$H_2$), 3.32 (d, $^3J_{H-H}$ = 8.4, 2 H, Ru-C$H_2$), 2.41 (s, 15 H, $C_{60}Me_5$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 29.79 (1 C, Ru-*C*$H_2$CH=$CH_2$), 30.43 (5 C, $C_{60}Me_5$), 51.11 [5 C, $C_{60}(sp^3)$], 108.48 (1 C, Ru-$CH_2$CH=*C*$H_2$), 111.82 [5 C, $C_{60}$(Cp)], 143.56 (10 C, $C_{60}$), 143.85 (10 C, $C_{60}$), 146.78 (1 C, Ru-$CH_2$*C*H=$CH_2$), 147.64 (5 C, $C_{60}$), 148.02 (10 C, $C_{60}$), 148.40 (5 C, $C_{60}$), 152.56 (10 C, $C_{60}$), 201.50 (2 C, CO) ppm. UV/Vis (toluene/2-propanol, 7:3): $\lambda$ = 287, 355 (sh), 395 nm. IR (diamond probe): $\tilde{\nu}$1960 (s) (CO), 2016 (s). MS (APCI–): *m*/*z* = 993 [M]$^-$, 952 [M – allyl]$^-$. HPLC (toluene/2-propanol, 7:3; flow rate: 1 mL min$^{-1}$): $t_R$ = 8.2 min. $C_{70}H_{20}O_2Ru$ (994.00): calcd. C 84.58, H 2.03; found C 84.38, H 2.00.

**Ru($\eta^5$-$C_{60}Me_5$)($\eta^3$-allyl)(CO) (3):** Compound **2** (30 mg, 0.030 mmol) was dissolved in toluene (12 mL) under an atmosphere of argon. This solution was stirred vigorously and irradiated with 60 W incandescent light at room temperature. After 24 h, the resulting red-colored solution was purified by preparative HPLC (toluene/2-propanol, 7:3; flow rate: 20 mL min$^{-1}$). The fractions containing **3** were collected, and the solvents were evaporated to dryness to obtain **3** (14 mg, 49% yield) as orange microcrystals. M.p. 240–245 °C (dec.). $^1$H NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 4.61 (m, 1 H, $H_{center}$), 3.38 (dt, $^3J_{H(center)-H(syn)}$ = 6.8 Hz, 2 H, $H_{syn}$), 2.05 (s, 15 H, $C_{60}Me_5$), 1.75 (dt, $^3J_{H(center)-H(anti)}$ = 11.2 Hz, 2 H, $H_{anti}$) ppm. $^{13}$C NMR (100 MHz; $CDCl_3/CS_2$, 1:1; 25 °C): $\delta$ = 30.45 (5 C, $C_{60}Me_5$), 33.69 (2 C, $C_3H_5$), 50.73 [5 C, $C_{60}(sp^3)$], 69.61 (1 C, $C_3H_5$), 106.77 [5 C, $C_{60}$(Cp)], 143.28 (10 C, $C_{60}$), 143.77 (10 C, $C_{60}$), 146.65 (5 C, $C_{60}$), 147.73 (10 C, $C_{60}$), 148.14 (5 C, $C_{60}$), 153.05 (10 C, $C_{60}$), 192.50 (1 C, CO) ppm. UV/Vis (toluene/2-propanol, 7:3): $\lambda$ = 291, 348 (sh), 394 nm. IR(diamond probe): $\tilde{\nu}$1943 (s) (CO). MS (APCI–): *m*/*z* = 965 [M]$^-$. HPLC (toluene/2-propanol, 7:3; flow rate: 1 mL min$^{-1}$): $t_R$ = 7.39 min. $C_{69}H_{20}ORu$ (965.99): calcd. C 85.79, H 2.09; found C 84.68, H 2.01.

**Synthesis of Ru($\eta^5$-$C_{60}Me_5$)H(CO)$_2$ (4):** To a solution of **1** (10 mg, 0.050 mmol) in thf (1.7 mL) was added powdered $LiAlH_4$ (0.38 mg, 0.050 mmol) at 25 °C. After stirring for 10 min, the color of the solution changed from red to brown. After the reaction was quenched with a small amount of ethanol, the solution was evaporated to dryness. The residue was dissolved in toluene (10 mL), and the supernatant was separated from the insoluble salts by filtration. The filtrate was evaporated to dryness and dried under vacuum for 5 h to obtain the title compound (7.2 mg, 0.38 mmol, 76% yield). M.p. 180–190 °C (dec.). $^1$H NMR (400 MHz; $CDCl_3/CS_2$, 1:1; 25 °C): $\delta$ = –10.07 (s, 1 H, Ru-*H*), 2.30 (s, 15 H, $C_{60}Me_5$) ppm. $^{13}$C NMR (100 MHz; $CDCl_3/CS_2$, 1:1; 25 °C): $\delta$ = 32.16 (5 C, $C_{60}Me_5$), 49.88 [5 C, $C_{60}(sp^3)$], 110.70 [5 C, $C_{60}$(Cp)], 143.41 (10 C, $C_{60}$), 143.82 (10 C, $C_{60}$), 146.55 (5 C, $C_{60}$), 147.63 (10 C, $C_{60}$), 148.19 (5 C, $C_{60}$), 152.34 (10 C, $C_{60}$), 199.73 (2 C, CO) ppm. UV/Vis (toluene/2-propanol, 7:3): $\lambda$ = 287, 349 (sh), 396 nm. IR (diamond probe): $\tilde{\nu}$ 1962 (s) (CO), 2024 (s). MS (APCI–): *m*/*z* = 954 [M]$^-$. HPLC (toluene/2-propanol, 7:3; flow rate: 1 mL min$^{-1}$): $t_R$ = 8.02 min. $C_{67}H_{16}O_2Ru$ (953.93): calcd. C 84.36, H 1.69; found C 84.01, H 1.41.

**Ru($\eta^5$-$C_{60}Me_5$)Et(CO)$_2$ (5):** A solution of EtMgBr (0.075 mmol) in thf (0.083 mL) was added to a solution of **1** (50 mg, 0.050 mmol) in toluene (16 mL)under an atmosphere of argon at 0 °C. After stirring for 10 min, the resulting brown suspension was quenched with a small amount of ethanol and passed through a pad of silica gel. This eluent was purified by HPLC (toluene/2-propanol, 7:3; flow rate: 20 mL min$^{-1}$). The fractions containing the title compound were collected, and the solvents were evaporated to dryness. The solid was then dissolved again in a small amount of $CS_2$, and this solution was dried under vacuum to obtain the title compound (23 mg, 0.025 mmol, 48% yield). M.p. 210–215 °C (dec.). $^1$H NMR (400 MHz; $CDCl_3/CS_2$, 1:1; 25 °C): $\delta$ = 2.63 (q, $^3J_{H-H}$ = 7.6 Hz, 2 H, Ru-C$H_2$CH$_3$), 2.40 (s, 15 H, $C_{60}Me_5$), 1.75 (t, $^3J_{H-H}$ = 7.6 Hz, 3 H, Ru-$CH_2$C$H_3$) ppm. $^{13}$C NMR (100 MHz; $CDCl_3/CS_2$, 1:1; 25 °C): $\delta$ = –8.31 (1 C, Ru-*C*$H_2$CH$_3$), 23.19 (1 C, Ru-$CH_2$*C*H$_3$), 30.07 (5 C, $C_{60}Me_5$), 50.79 [5 C, $C_{60}(sp^3)$], 111.68 [5 C, $C_{60}$(Cp)], 143.36 (10 C, $C_{60}$), 143.62 (10 C, $C_{60}$), 146.46 (5 C, $C_{60}$), 147.63 (10 C, $C_{60}$), 148.12 (5 C, $C_{60}$), 152.34 (10 C, $C_{60}$), 201.88 (2 C, CO) ppm. UV/Vis (toluene/2-propanol, 7:3): $\lambda$ = 285, 355 (sh), 395 nm. IR(diamond probe): $\tilde{\nu}$ 2008 (s) (CO), 1950 (s). MS (APCI–): *m*/*z* = 981 [M]$^-$. HPLC (toluene/2-propanol, 7:3; flow rate: 1 mL min$^{-1}$): $t_R$ = 7.67 min. $C_{69}H_{20}O_2Ru$ (981.99): calcd. C 84.40, H 2.05; found C 84.11, H 1.80.

**NMR-Monitoring of Conversion from 2 to 3:** Compound **2** was placed in an NMR tube connected to a vacuum system and $C_6D_6$ (0.6 mL) was transferred into it by trap-to-trap distillation. The NMR tube was sealed by flame and subjected to the reaction conditions: light irradiation with 60 W incandescent light or heating at 110 °C. Conversion of **3** into **2** was monitored by $^1$H NMR spectroscopy.

**Isomerization of 1-Decene**: Compound **4** and 10000 equiv. of 1-decene were placed in a Schlenk tube and heated at 140 °C. After stirring at this temperature for 6 h, the solution was passed through a cotton plug and subjected to the $^1$H NMR and GC measurements to estimate the product distributions. In the $^1$H NMR spectrum, terminal and internal olefin protons were observed at $\delta$ = 4.9 ppm and $\delta$ = 5.4 ppm, respectively.

**X-ray Crystallographic Analysis:** Single crystals of **3** suitable for X-ray diffraction studies were grown and subjected to data collection. The data sets were collected with a MacScience DIP2030 Imaging Plate diffractometer by using Mo-$K_\alpha$ (graphite monochromated, $\lambda$ = 0.71069 Å) radiation. The structure of **3** was solved by direct methods (SIR97).[16] The positional and thermal parameters of non-hydrogen atoms were refined anisotropically on $F^2$ by the full-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

matrix least-squares method by using SHELXL-97.[17] Hydrogen atoms were placed at calculated positions and refined with riding mode on their corresponding carbon atoms. In the subsequent refinement, the function $\Sigma\omega(F_o^2 - F_c^2)^2$ was minimized, where $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes, respectively. The agreement indices are defined as $R_1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$ and $wR_2 = [\Sigma\omega (F_o^2 - F_c^2)^2/\Sigma (\omega F_o^4)]^{1/2}$. CCDC-632009 contains the supplementary crystallographic information for **3**. This data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Photophysical Properties of Bis-Cyclometallated Iridium(III)–Styryl Complexes and Their Saturated Analogues

**Marc Lepeltier,[a] Terence Kwok-Ming Lee,[b] Kenneth Kam-Wing Lo,*[b] Loic Toupet,[c] Hubert Le Bozec,[a] and Véronique Guerchais*[a]**

**Keywords:** Iridium / Luminescence / Bis-cyclometallated complexes

This manuscript reports the synthesis and photophysical investigation of a series of $Ir^{III}$ complexes $Ir(C^{\wedge}N)_2(O^{\wedge}O)$ which are functionalized in the *para* position of the pyridine ring by styryl groups substituted with electron-donor and -acceptor end groups. The saturated derivative $Ir(C^{\wedge}N$-ppy-4-$CH_2CH_2C_6H_4OMe)_2(O^{\wedge}O$-acac) (**4a**-$H_2$) was formed from $[Ir(C^{\wedge}N$-ppy-4-$CH{=}CHC_6H_4OMe)_2]_2(\mu\text{-}Cl)_2$ (**3a**) at 140 °C, whereas at 80 °C the parent unsaturated complexes $Ir(C^{\wedge}N$-ppy-4-$CH{=}CHC_6H_4R)_2(O^{\wedge}O)$ [$O^{\wedge}O$ = acac, R = OMe (**4a**), $NEt_2$ (**4b**), H (**4c**), $NO_2$ (**4d**); $O^{\wedge}O$ = dpm, R = OMe (**5a**), $NEt_2$ (**5b**)] were isolated. The saturated complex **4a**-$H_2$ exhibits intense green emission with a 36 % quantum yield at 298 K. The styryl complexes **4a**–**4d**, **5a** and **5b** are very weakly emissive at 298 K, but show intense red luminescence in alcohol glass at 77 K. The amino- and nitro-substituted complexes **4b** and **4d** give low-energy emission ($\lambda_{em}$ = 651 and 647 nm, respectively). The emissive states of these complexes are believed to possess predominant triplet intra-ligand charge-transfer ($^3$ILCT) and metal-to-ligand charge-transfer ($^3$MLCT) character, respectively.

## Introduction

There is a growing interest in the study and design of luminescent heavy-transition-metal complexes for their potential applications in optoelectronic devices such as light-emitting diodes (OLEDs) and luminescent probes for biomolecules.[1–3] Iridium complexes, homoleptic and heteroleptic, featuring cyclometallated phenylpyridine (ppy) ligands and relative derivatives have been extensively studied in recent years. The emission is believed to arise from a strong mixing between the MLCT and LC excited states. The colour of the emission depends highly on the choice of the cyclometallating ligand, and efforts are focused on the design and synthesis of new ligands for optimization of the luminescence properties.[4,5] In this context, we have started a research program on the luminescence properties of functionalized styryl Ir complexes in order to study the influence of the ligand modification on the photophysical properties of the resulting complexes. The synthesis of tris-chelate iridium(III) complexes is, in fact, very versatile; this requires drastic conditions and depends on the nature of the cyclometallating ligands used.[6] In a recent attempt to prepare tris-cyclometallated iridium(III)–styryl complexes *fac*-$Ir(C^{\wedge}N$-ppy-4-$CH{=}CHC_6H_4R)_3$ [R = OMe (**2a**), $NEt_2$ (**2b**)] by the classical route, that is, from the corresponding bis-cyclometallated chloro-bridged dimers **3a**,**3b** and 4-(donor-substituted-styryl)-2-phenylpyridines **1a**,**1b** in refluxing glycerol, we observed the unexpected formation of the fully saturated complexes **2**-$H_2$.[7a] To overcome this problem, an alternative smooth procedure was developed by direct functionalization of the tris-chelate-methyl complex *fac*-$Ir(C^{\wedge}N$-ppy-4-$Me)_3$. However, this very attractive "chemistry-on-the-complex" procedure was restricted to only donor-substituted styryl derivatives and did not allow the introduction of acceptor end groups.

We showed that extension of the ligand π-conjugation induces a strong redshift of the emission band of more than 100 nm relative to the unsubstituted complex $Ir(C^{\wedge}N$-ppy$)_3$ (in 77 K glass, **2a**-$H_2$ and **2a** emit at 496 and 616 nm, respectively). Moreover, the presence of a donor-acceptor D–A interaction by introducing a diethylamino group instead of a methoxy group leads to an additional redshift of 35 nm ($\lambda_{em}$ = 651 nm for **2b** in 77 K glass). In order to rationalize the electronic effects of the styryl end group, we have directed our studies towards the corresponding neutral heteroleptic bis-cyclometallated complexes $Ir(C^{\wedge}N$-ppy-4-$CH{=}CHC_6H_4R)_2(O^{\wedge}O)$ containing different end groups from strong donors to strong acceptors (R = $NEt_2$, OMe, H, $NO_2$). Bis-cyclometallated species, where the third ligand $O^{\wedge}O$ is an anionic acetylacetonate (acac) or dipyvaloylme-

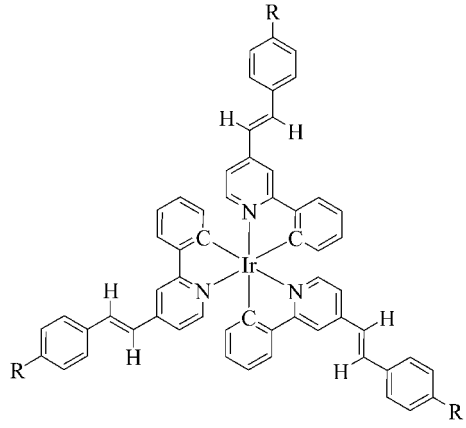
**2a**-$H_2$: R = OMe, **2b**-$H_2$: R = $NEt_2$



**2a**: R = OMe, **2b**: R = $NEt_2$

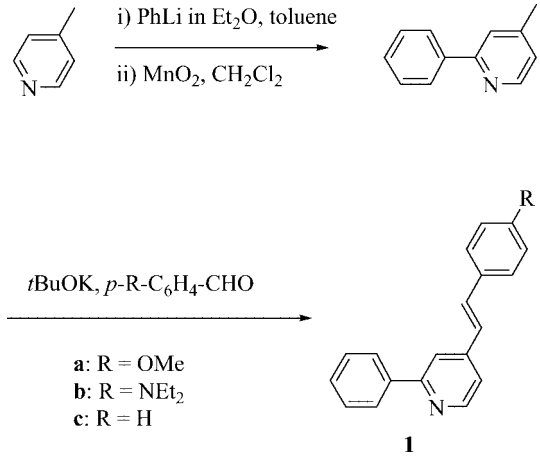
thane (dpm) ligand, are easily accessible whatever the nature of R. The photophysical properties of these neutral Ir(*C*^*N*-ppy)$_2$(*O*^*O*) derivatives have been shown to be very similar to those of the corresponding tris-cyclometallated species.[4] The hydrogenation reaction of the styryl C=C double bond observed during the course of the synthesis of tris-cyclometallated complexes is inhibited in this case, simply by lowering the reaction temperature.

We report here the synthesis and spectroscopic characterization of a new family of bis-cyclometallated iridium–styryl complexes and the saturated complex Ir(*C*^*N*-ppy-4-$CH_2CH_2C_6H_4OMe)_2$(*O*^*O*-acac) (**4a**-$H_2$); the effects of the styryl substituent R on their photophysical properties will be discussed. The synthesis and X-ray crystal structures of the free ligands will also be described.

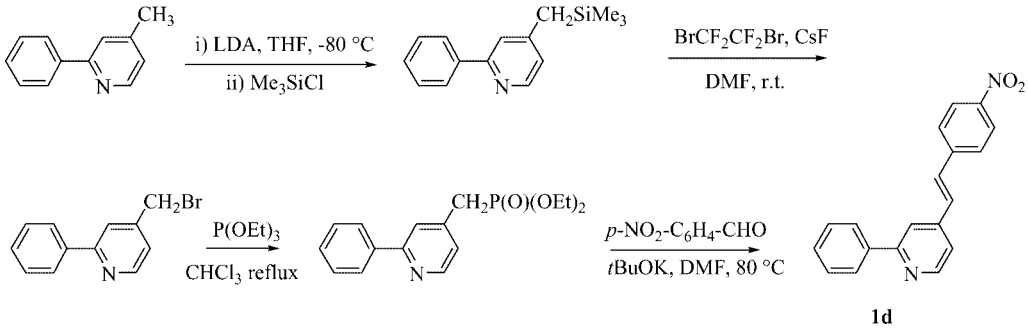
## Results and Discussion

### Synthesis of the Ligands

The donor-substituted phenylpyridine derivatives, the methoxy-, diethylamino- and non-substituted 4-styryl-2-phenylpyridine derivatives (ppy-4-CH=$CHC_6H_4$R) [R = OMe (**1a**), $NEt_2$ (**1b**), H (**1c**)], were obtained from 4-picoline in a two-step procedure. The first step was the phenylation at the α position, upon addition of PhLi followed by oxidation with $MnO_2$.[8] Then deprotonation of the methyl group with *t*BuOK and condensation with the appropriate aldehyde *p*-R-$C_6H_4$-CHO (R = OMe, $NEt_2$, H) afforded, by in situ dehydration, the expected unsaturated derivatives **1** (Scheme 1). Compounds **1a**–**1c** were purified by crystallization from a mixture of toluene/pentane and were isolated in 86, 96 and 34% yield, respectively, from ppy-4-Me (4-methyl-2-phenylpyridine). In all cases, the *E* configuration of the C=C double bond was confirmed by the presence of an AB system with a characteristic $^3J_{H–H}$ coupling of 16 Hz. We did not observe any photoisomerization process $E \rightarrow Z$ in acidic medium or under sunlight (vide infra).



Scheme 1.



Scheme 2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The described procedure cannot be applied to benzaldehyde featuring an electron-withdrawing group.[9] The nitro derivative **1d** was prepared by a different procedure (Scheme 2). This synthesis involved a Wadsworth–Emmons reaction between the (diethylphosphoryl)methyl-2-phenylpyridine and *p*-nitrobenzaldehyde. The phosphonate derivative was prepared in a two-step procedure, following the method described for 2,2′-bipyridines.[10–12] The first step was the deprotonation of the methyl precursor ppy-4-Me and subsequent addition of TMSCl to give 4-(trimethylsilylmethyl)-2-phenylpyridine; the latter was then converted into the 4-(bromomethyl)-2-phenylpyridine, and eventually the phosphonate derivative was formed by means of an Arbuzov reaction. Compound **1d** was isolated in an overall yield of 33%. The *E* configuration was ascertained by the presence of the AB system which appears at $\delta$ = 7.42 ($^3J$ = 16 Hz) and 7.28 ppm.

### X-ray Crystal Studies of 1a, 1b and 1d

The styryl derivatives **1a**, **1b** and **1d** were characterized by X-ray diffraction studies (Figures 1, 2 and 3, respectively). Crystals were obtained by slow diffusion of pentane in toluene solutions of **1a**, **1b** and **1d**. Selected distances and angles are listed in Table 1. Derivatives **1a**, **1b** and **1d** crystallized as dimers. The two molecules are almost identical, except in the case of **1b** for which the conformation about the C12–C9 bond is different; *s-cis* and *s-trans* isomers (C12–C13 and C9–C10) are observed. In all compounds, the *E* configuration of the C=C double bond of the styryl group is confirmed; the C12–C13 bond length in **1a** and **1d** is characteristic of a double bond and compares well with that of the bipyridine analogues.[9] In contrast, the C12–C13 distance in **1b** is significantly shorter, probably because of the crystal packing. In the *s-trans* isomer, the

phenyl group is tilted relative to the adjacent pyridine ring (dihedral angle N1–C7–C6–C1 –25.35°), whereas the planarity is better for the *s-cis* isomer (dihedral angle 3.63°). The styryl group is almost coplanar with the nitrogen ring in the former isomer, whereas the deviation is about 20° in the latter isomer.

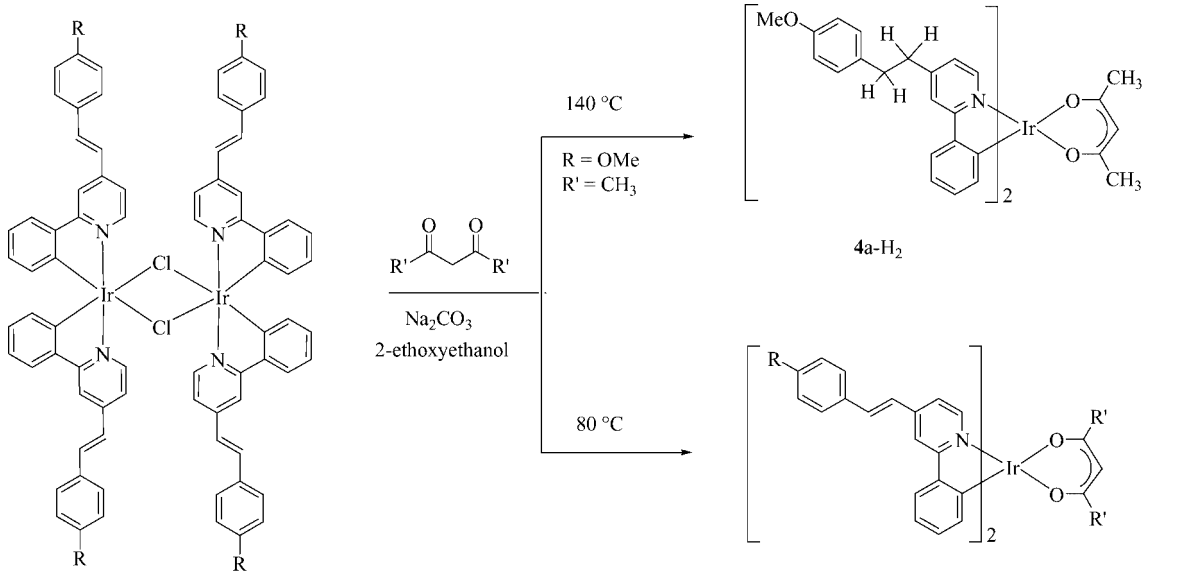
## Synthesis of the Metal Complexes

The precursor dimers $[Ir(C^{\wedge}N\text{-ppy-4-CH=CHC}_6H_4R)_2]_2(\mu\text{-Cl})_2$ [R = OMe (**3a**), $NEt_2$ (**3b**), H (**3c**), $NO_2$ (**3d**)] were prepared following classical procedures starting from $IrCl_3{\cdot}nH_2O$ (140 °C).[13,14] For comparison, we also prepared the methyl complex $[Ir(C^{\wedge}N\text{-ppy-4-Me})_2]_2(\mu\text{-Cl})_2$ (**3e**).[15] Compounds **3a**–**3d** were isolated as orange powders and **3e** as a yellow powder. They are sparingly soluble in $CH_2Cl_2$. The $NO_2$-derivative **3d** is too insoluble in $CD_2Cl_2$ to be characterized by $^1H$ NMR spectroscopy, but dissolution in DMSO gives rise to the formation of the DMSO adduct $[Ir(C^{\wedge}N\text{-ppy-4-CH=CHC}_6H_4NO_2)_2(DMSO)(Cl)]$ (**3d**-DMSO). Such solvation by strong coordinating solvents ($H_2O$, $CH_3CN$, DMF) has been already reported; the reaction products were not isolated because of re-formation of the corresponding chloro-bridged dimer.[16] The $^1H$ NMR spectrum of the DMSO adduct **3d**-DMSO shows two different sets of signals for the magnetically nonequivalent C^N ligands. For instance, two pyridine signals ($py^6$) are observed at low field at $\delta$ = 9.82 and 9.50 ppm. The $^1H$ NMR spectra of crude **3a**–**3c** show the presence of only one set of signals which is attributed to the racemic mixture ($\Delta\Delta/\Lambda\Lambda$) as indicated by a characteristic low-field doublet at $\delta$ = 9.15 ppm (**3a**) for the pyridine proton in the 6-position. The *E* ($^3J_{H-H}$ = 16 Hz) configuration of the double bond of the styryl group of **3** was maintained during the synthesis. Exposure of the $CD_2Cl_2$ solutions of **3a**–**3c** to sunlight for a few hours, however, resulted in the appearance of new aromatic signals. Several doublets from $\delta$ = 9.28 ppm to $\delta$ = 9.04 ppm were then observed for the proton $H^6$ of the pyridine ring of **3a**. We assume that *trans*/*cis* isomerization of the C=C double bond occurs under these conditions (vide infra).

Dimers were then converted upon cleavage of the chloro bridges with bidentate ligands, such as 1,3-diketonates, into mononuclear complexes. We used acetylacetone (acacH) and dipivaloylmethane (dpmH). Treatment of **3a** with acacH and $Na_2CO_3$ in 2-ethoxyethanol at 140 °C led to the formation of the bis-cyclometallated complex **4a**-$H_2$, in which the C=C double bonds of the styryl groups were hydrogenated (Scheme 3). Moreover, the free hydrogenated ligand $HC^{\wedge}N\text{-}H_2$ **1a**-$H_2$ was also isolated. Compound **4a**-$H_2$ was obtained as a yellow powder, and its structure was confirmed by $^1H$- and $^{13}C$ NMR spectroscopy and elemental analysis. The methylene protons appear as multiplets at



Scheme 3. Synthesis of the bis-cyclometallated complexes: influence of the reaction temperature.

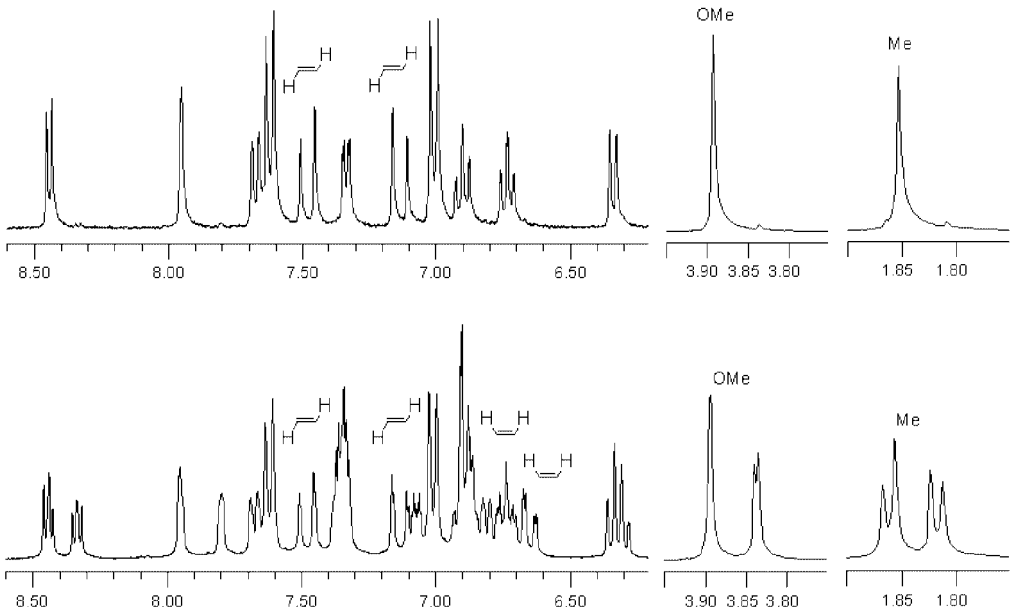

Figure 4. NMR spectra (δ values given in ppm) of **4a**: before (top) and after (bottom) exposure for one hour in the sunlight.

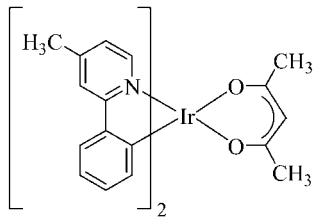
$\delta$ = 3.14 ppm ($\delta$ = $^{13}$C 37.5 ppm) and 3.07 ppm ($\delta$ = $^{13}$C 35.7 ppm). Such a hydrogenation reaction could be mediated by Ir species which are known to catalyse hydrogen transfer reductions.[17] This feature was also observed in the attempted synthesis of the parent tris-cyclometallated styryl species **2**. Since the saturated derivative Ir(*C*^*N*-ppy-$CH_2CH_2C_6H_4OMe)_3$ was formed, an alternative synthesis involving functionalization after complexation was developed.[7a] It is likely that the drastic conditions used for the synthesis of Ir complexes, the presence of an alcohol (hydrogen donor) and a base all favour this process. It is noteworthy that the dimers **3** were not hydrogenated since no base was present in the reaction medium.

Concerning the bis-cyclometallated mononuclear species (the oxygenated derivatives **4** and **5**), side hydrogenation reactions could be avoided by performing the syntheses at lower temperature, namely 80 °C instead of 140 °C. Selective formation of the styryl complexes Ir(*C*^*N*-ppy-4-$CH=CHC_6H_4R)_2$(*O*^*O*) [O^O = acac, R = OMe (**4a**), $NEt_2$ (**4b**), H (**4c**), $NO_2$ (**4d**); O^O = dpm, R = OMe (**5a**), $NEt_2$ (**5b**)] can occur at this reaction temperature (Scheme 3). Compounds were isolated in excellent yield (ca. 90%) as red-brown powders. Similarly, the saturated complex Ir(*C*^*N*-ppy-4-Me)$_2$(*O*^*O*-acac) (**4e**) was isolated as a yellow compound. The cleavage of the dimers occurred with retention of the configuration, that is, the resulting products **4a**–**4d**, **5a** and **5b** have $C_2$ symmetry.

We note that the aromatic regions of the $^1$H NMR spectra of **4** and **5** are similar to those of dimers **3**; the aromatic signals appear in the same order. For example, the lowest field signal ($\delta \approx$ 8.30 ppm) is assigned to the proton in the α position of the nitrogen atom of the pyridine ring as a characteristic signature, in contrast to that of the tris-chelate species, which is due to the pyridine proton H$^3$. Upon exposure of $CH_2Cl_2$ solutions to sunlight, the complexes



**4e**

**4a**–**4c**, **5a** and **5b**, like the dimer precursors, undergo partial isomerization of the C=C double bond leading to the formation of three isomers (*E*/*E*, *E*/*Z*, *Z*/*Z*). For instance, the $^1$H NMR spectra display two sets of signals for vinylic protons of the *cis*-alkenyl group of the *E*/*Z* and *Z*/*Z* isomers of **4a**; one signal is located at $\delta$ = 6.65 ppm ($^3J_{H-H}$ = 12 Hz, the second doublet is masked), and the second set is found at $\delta$ = 7.49 and 7.14 ppm, as the result of the splitting of the former AB system of the *E*/*E* isomer (Figure 4). It is noteworthy that the $NO_2$ derivative **4d** was not prone to isomerization under such conditions; no change was observed by $^1$H NMR spectroscopy.

## Absorption and Emission Properties of the Ligands and Complexes

The photophysical data of the free ligands **1a**–**1d** in $CH_2Cl_2$ solutions at 298 K are presented in Table 2. Compounds **1a**, **1c** and **1d** display an intense absorption band between 290–390 nm that is assigned to a ligand-centred ($^1$LC) ($\pi \rightarrow \pi^*$) transition (Figure 5). The strong absorption bands of compounds **1c** and **1d** are comparable to those of their non-phenylated counterparts, namely styrylpyridine and (*p*-nitrostyryl)pyridine [292 nm (31300 $M^{-1}cm^{-1}$) and

| | R | $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$cm$^{-1}$) | $\lambda_{em}$/nm | $\Phi$[a] |
|---|---|---|---|---|
| **1a** | OMe | 264 (16000), 309 sh (23000), 310 sh (23000), 327 (29000) | 404 | 0.008 |
| **1b** | $NEt_2$ | 251 (27000), 277 sh (18000), 335 (9400), 382 (17000) | 487 | 0.078 |
| **1c** | H | 262 (24000), 312 (33000), 328 sh (20000) | 364 | – |
| **1d** | $NO_2$ | 257 (25000), 335 (33000) | – | – |

[a] Emission quantum yields were determined using quinine sulfate as the standard.

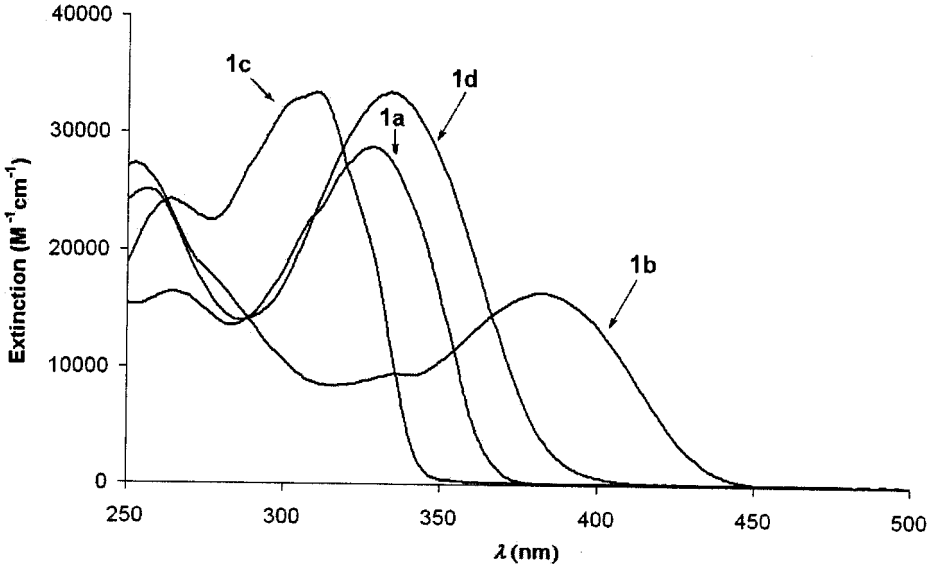

Figure 5. Absorption spectra of ppy-4-CH=CHC$_6$H$_4$R **1a**–**d** in $CH_2Cl_2$ solutions at 298 K.

332 nm (30875 M$^{-1}$cm$^{-1}$) in $CH_3CN$, respectively].[18] Interestingly, the absorption spectrum of the amino-styryl ligand **1b** shows a strong band at 382 nm (17000 M$^{-1}$cm$^{-1}$) which can be assigned to an intra-ligand charge-transfer ($^1$ILCT) transition from the electron-donating amino group to the electron-accepting pyridine ring via the π-linker styryl group. This intense and structureless band is typical for "push-pull" molecules and compares well with that found for the related bipyridine derivative bpy-4-styryl-$NEt_2$, for which absorption maximum occurs at 394 nm in $CH_3CN$.[19]

Compounds **1a**–**1c** are fluorescent upon photoexcitation. The emission colour of the compounds in $CH_2Cl_2$ at 298 K ranges from blue to green (Figure 6), depending on the identity of the substituent R. The emission energy decreases in the order **1c** (364 nm) > **1a** (404 nm) > **1b** (487 nm),

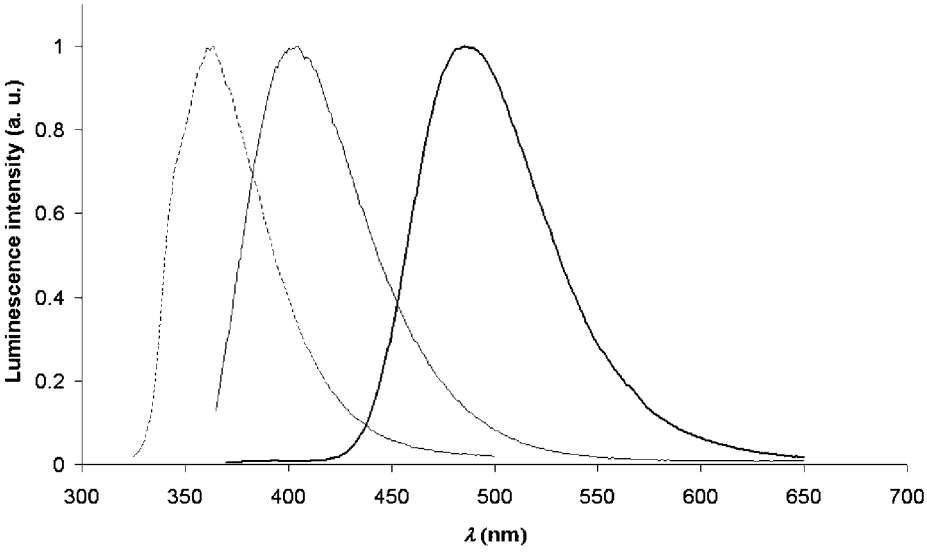

Figure 6. Normalized emission spectra of ppy-4-CH=CHC$_6$H$_4$R **1a** (−), **1b** (−) and **1c** (---) in $CH_2Cl_2$ solutions at 298 K.

which is consistent with the electron-donating ability of the substituent R. Compound **1d** is non-emissive. The observation of a positive solvatochromic shift on the emission band of **1b** in solvents ranging from toluene to DMSO, is in agreement with a charge-transfer emissive state (Table 3, Figure 7). The emission quantum yields for **1a** and **1b** are comparable to those reported for the bpy-styryl-4-R derivatives (R = $NBu_2$, 3.6%;[19] R = OOct, 1%).[9]

Table 3. Absorption and emission wavelengths of **1b** in various solvents at 298 K.

| Solvent | $\lambda_{abs}$/nm | $\lambda_{em}$/nm |
|---|---|---|
| Toluene | 383 | 457 |
| Acetone | 384 | 495 |
| $CH_2Cl_2$ | 382 | 488 |
| Ethanol | 386 | 510 |
| DMSO | 395 | 517 |

The absorption spectra of the dimers **3a**–**3d** show intense bands between 250–350 nm (Table 4), which are assigned to $^1$LC ($\pi\rightarrow\pi^*$) transitions of the cyclometallated ligands. The characteristic $^1$ILCT absorption band of **3b** occurs at 431 nm. The redshift of 48 nm compared to the absorption band of the free ligand is ascribed to the increased electron-accepting properties of the pyridine ring after its coordination to the iridium(III) centre. A similar shift was observed for related $[M(bpy\text{-}4\text{-}CH{=}CHC_6H_4R)_3]^{2+}$ complexes.[20] Moderately intense bands are present in the lower energy region (450–550 nm). The absorption bands of **3c** at 467 nm and **3d** at 500 nm are tentatively assigned to an admixture of $^1$MLCT/$^3$MLCT transitions. The nitro group of **3d** significantly shifts the MLCT absorption band to lower energy (500 nm), compared with that of the styryl derivative **3c** (467 nm). The shift is attributed to the strong electron-accepting properties of the nitro substituent, which substantially lower the LUMO of the complex.[7b] The MLCT transition of **3b** is not clearly resolved and is probably embedded in the intense and broad ILCT band.

The absorption spectra of the bis-cyclometallated acac (**4a**–**4d**) and dpm (**5a** and **5b**) complexes closely resemble those of the corresponding dimers. The absorption features originate mainly from the $Ir(C^{\wedge}N)_2$ moieties (Figure 8,

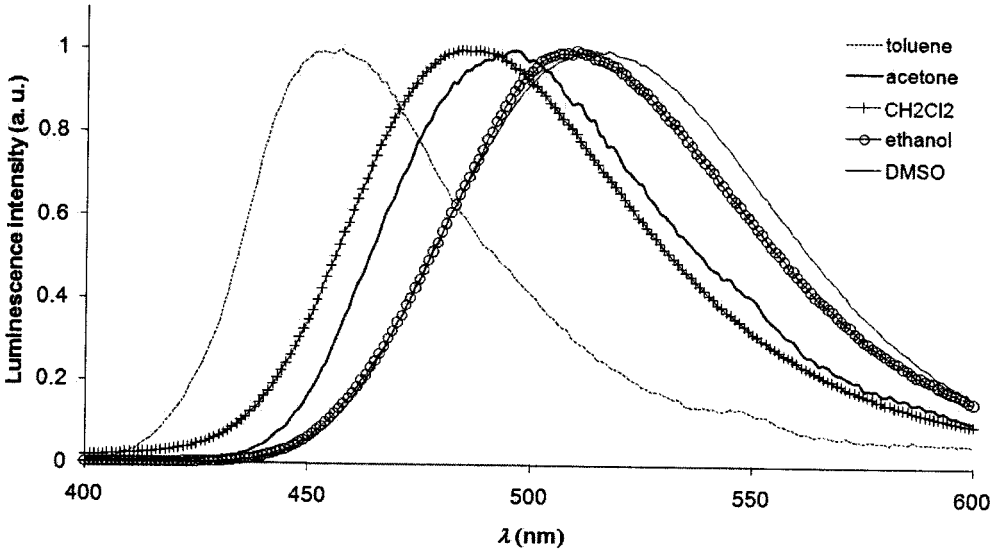

Figure 7. Emission spectra of ppy-4-CH=$CHC_6H_4NEt_2$ (**1b**) in different solvents in fluid solutions at 298 K.

found at 412, 460 and 490 nm, respectively. Thus, addition of the alkyl group $CH_2CH_2C_6H_4OMe$ to the ppy ligand causes no significant changes.[4a]

Upon excitation, complex **4a**-$H_2$ in $CH_2Cl_2$ solution at 298 K shows strong green emission (Figure 9, Table 5). The emission properties of this complex are very similar to those of the dimethyl complexes $Ir(dmppy)_3$[15] and $Ir(dmppy)_2(acac)$[21] [Hdmppy = 4-methyl-2-(4-methylphenyl)pyridine]. The presence of a methyl or an alkyl group such as $CH_2CH_2$-$C_6H_4OMe$ in the *para* position of the pyridine ring brings no significant effects to the photophysical properties of these types of complexes. The emission of **4a**-$H_2$ is assigned to a state of an admixture of $^3$MLCT and $^3$LC character.[4a,22]

The emission data for complexes **3a**–**3d**, **4a**–**4d**, **5a** and **5b** are summarized in Table 4. All the styryl complexes show very weak emission in fluid solutions at room temperature (Figure 10).[7] In alcohol glass at 77 K, they become strongly emissive. The emission bands of the complexes show rich vibronic structures with progressional spacings of ca. 1400 $cm^{-1}$, typical of C=C aromatic stretching. The emission behaviour of the complexes depends strongly on the cyclometallating ligands, whereas the ancillary ligands acac and dpm O^O or the chloro bridge play a minor role. For these reasons, only the emission properties of the acac complexes **4a**–**4d** are discussed.

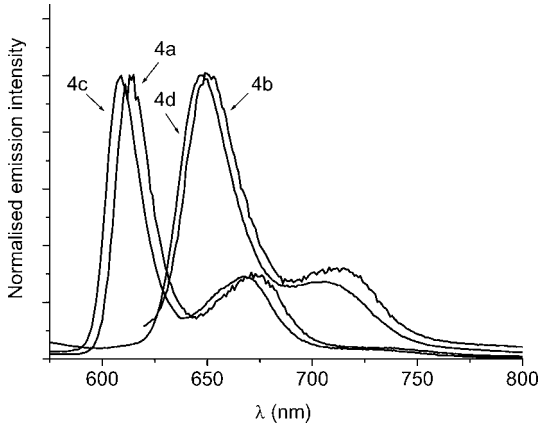

Figure 10. Emission spectra of complexes **4a**–**4d** in $CH_2Cl_2$/EtOH/MeOH (1:4:1, v/v/v) at 77 K.

At 77 K, complexes **4a**–**4d** emit in the red region from 609 to 788 nm with a lifetime in the microsecond timescale. As expected, increasing the π-conjugation of the C^N ligand induces a bathochromic shift of the emission band; for example, the emission of $Ir(C^N\text{-ppy})_2(O^O\text{-acac})$ shifts from 516 to 548 nm when benzoquinoline is used as the C^N ligand.[4a,4b] In this work, a shift from green to red emission is observed after the addition of a styryl group to the ppy ligand. The emission energy difference is significant [$Ir(C^N\text{-ppy})_2(O^O\text{-acac})$ in 77 K glass, $\lambda_{em}$ = 492 nm; for **4c**, $\lambda_{em}$ = 609 nm]. This is also in line with the data observed for the saturated complex **4a**-$H_2$; breaking the conjugation of the styryl group gives rise to green emission. Substitution of the hydrogen atom in **4c** by a methoxy end group has no marked effects on the emission maximum. In both cases, the emission is believed to arise from an admixture of $^3$MLCT and $^3$IL states. In contrast, substitution by an amino group induces a redshift to 651 nm in **4b**. It is likely that the presence of an amino group results in $^3$ILCT character in the emissive states of **4b** and **5b**. The nitro-derivative **4d** also gives low-energy emission ($\lambda_{em}$ = 647 nm). Owing to the strong electron-accepting properties of the nitro substituent, the emissive state of complex **4d** should possess predominantly $^3$MLCT character, resulting from the stabilization of the π*-acceptor orbitals of the C^N ligand.[7]

## Conclusions

A new family of bis-cyclometallated iridium(III)–styryl complexes were prepared. Reduction of the C=C double bond can be avoided by performing the synthesis under mild reaction conditions. Low-temperature glass of all the styryl complexes **4a**–**4d**, **5a** and **5b** gives intense red emission upon photoexcitation. Compared with the unmodified $[Ir(C^N\text{-ppy})_2(O^O)]$ complexes, large bathochromic shifts in emission energy were achieved by adding a conjugated styryl group to the ppy ligand and by introducing a strong electron-withdrawing nitro group. Incorporation of a diethylamino substituent into the cyclometallating ligand leads to a switch of emissive-state character from $^3$MLCT to $^3$ILCT, resulting in increased emission lifetimes. We anticipate that these luminescent iridium(III) complexes can act as interesting building blocks for luminescent macromolecular architectures.

## Experimental Section

All manipulations were performed using Schlenk techniques under argon. All solvents were dried and purified by standard procedures. All starting materials were used as received. NMR spectra were recorded with Bruker DPX-200, AV 300 or AV 500 MHz spectrometers. $^1$H and $^{13}$C chemical shifts are given versus $SiMe_4$ and were determined by reference to residual $^1$H and $^{13}$C solvent signals. $^{31}$P chemical shifts are given versus ext. $H_3PO_4$ (85%). Attribution of carbon atoms was based on HMBC, HMQC and COSY experiments. UV/Vis absorption spectra were recorded using a UVIKON 9413 spectrophotometer, and emission spectra were measured with a PTI C 60 fluorescence spectrophotometer. High resolution mass spectra (HRMS) were performed using a MS/MS ZABSpec TOF at the CRMPO (Centre de Mesures Physiques de l'Ouest) in Rennes. Elemental analyses were performed by the Service central d'analyse du CNRS at Vernaison. Cyclic voltammograms were recorded using a PAR model 273 Autolab. The working electrode was polished Pt, the counter electrode was a Pt wire, and a saturated calomel electrode (SCE) was used as the reference electrode. The $Cp_2Fe/Cp_2Fe^+$ redox couple was used as a secondary internal reference.

Luminescence quantum yields were measured by the optically dilute method[23] using an aerated aqueous solution of $[Ru(bpy)_3]Cl_2$ ($\Phi_{em}$ = 0.028) or quinine sulfate in 1 N $H_2SO_4$ as the standard solutions.[24] Low-temperature (77 K) glass photophysical measurements were performed with the sample loaded in a quartz tube inside a quartz-walled Dewar flask filled with liquid nitrogen. The

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

excitation source for emission lifetime measurements was the 355 nm output (third harmonic) of a Quanta-Ray Q-switched GCR-150–10 pulsed Nd-YAG laser. Luminescence decay signals from a Hamamatsu R928 photomultiplier tube were converted to potential changes by a 50 Ω load resistor and then recorded with a Tektronix Model TDS 620A digital oscilloscope.

**Synthesis of 4-Methyl-2-phenylpyridine:** To a solution of 4-methylpyridine (5 g, 53.8 mmol) in toluene (70 mL) was added a freshly prepared solution of PhLi in $Et_2O$ (70 mL) [from PhBr (22.6 mL, 215 mmol) and Li metal (2.98 g, 430 mmol)]. After 24 h of stirring, the solution was hydrolysed with water (150 mL), and the compound was extracted with $CH_2Cl_2$ (3 × 200 mL). The organic phase was dried with $MgSO_4$, and $MnO_2$ (56 g, 645 mmol) was added. The solution was stirred for 3 h, filtered and the solvent was evaporated. Chromatography on silica gel using heptane/ethyl acetate (90:10) gave ppy-4-Me as orange crystals. Yield 4.57 g (50%). $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 8.55 (d, $^3J$ = 4.8 Hz, 1 H, py$^6$), 7.98 (m, 2 H, Ph *ortho*), 7.55 (d, $^4J$ = 1 Hz, 1 H, py$^3$), 7.43 (m, 3 H, Ph *meta* and *para*), 7.05 (dd, $^3J$ = 4.8 Hz, $^4J$ = 1 Hz, 1 H, py$^5$), 2.41 (s, 3 H, $CH_3$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$): $\delta$ = 157.2 (C$^4$-py), 149.4 (C$^6$-py), 147.7 (C$^2$-py), 139.5 (Ph *ipso*), 128.8 (Ph *para*), 128.7 (Ph *meta*), 126.9 (Ph *ortho*), 123.1 (C$^5$-py), 121.1 (C$^3$-py), 21.1 ($CH_3$) ppm. HRMS: calcd. for $C_{12}H_{11}N$ [M]$^+$ 169.0892; found 169.0885.

**Synthesis of Pyridines 1a–1c:** 4-Methyl-2-phenylpyridine (0.5 g, 2.96 mmol), the appropriate aldehyde [4-methoxybenzaldehyde, 4-(diethylamino)benzaldehyde or benzaldehyde (3.5 mmol)] and *t*BuOK (0.4 g, 3.5 mmol) were dissolved in DMF (20 mL). The reaction mixture was refluxed for 3 h, and then $CH_2Cl_2$ (150 mL) was added. The organic phase was washed with water and an aqueous solution of 1 M KOH, and dried with $MgSO_4$. The product was crystallized from a toluene/pentane mixture.

**4-(4-Methoxystyryl)-2-phenylpyridine (1a):** White powder. Yield 0.73 g (86%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 8.66 (d, $^3J$ = 5 Hz, 1 H, py$^6$), 8.07 (m, 2 H, Ph *ortho*), 7.77 (s, 1 H, py$^3$), 7.53 (m, 4 H, $C_6H_4$ and Ph *meta*), 7.47 (m, 1 H, Ph *para*), 7.31 (m, 2 H, =CH and py$^5$), 6.96 (m, 3 H, =CH and $C_6H_4$), 3.85 (s, 3 H, $OCH_3$) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CDCl_3$): $\delta$ = 160.2 (C$^1$-$C_6H_4$), 158.0 (C$^2$-py), 150.0 (C$^6$-py), 145.8 (C$^4$-py), 139.6 (Ph *ipso*), 132.6 (=CH), 129.0 (Ph *para*, C$^4$-$C_6H_4$), 128.8 (Ph *meta*), 128.5 (C$^3$-$C_6H_4$), 127.0 (Ph *ortho*), 124.0 (=CH), 119.0 (C$^5$-py), 117.9 (C$^3$-py), 114.3 (C$^2$-$C_6H_4$), 55.4 ($OCH_3$) ppm. HRMS: calcd. for $C_{20}H_{17}NO$ [M]$^+$ 287.1310; found 287.1307. $C_{20}H_{17}NO$ (287.36): calcd. C 83.60, H 5.96, N 4.87, O 5.57; found C 83.22, H 5.85, N 4.87, O 5.76.

**4-[*p*-(Diethylamino)styryl]-2-phenylpyridine (1b):** Yellow powder. Yield 0.93 g (96%). $^1$H NMR (500 MHz, $CD_2Cl_2$): $\delta$ = 8.64 (d, $^3J$ = 5.1 Hz, 1 H, py$^6$), 8.09 (m, 2 H, Ph *ortho*), 7.78 (s, 1 H, py$^3$), 7.54 (m, 2 H, Ph *meta*), 7.48 (m, 3 H, $C_6H_4$ and Ph *para*), 7.33 (d, $^3J$ = 16.2 Hz, 1 H, =CH), 7.30 (d, $^3J$ = 5.1 Hz, 1 H, py$^5$), 6.89 (d, $^3J$ = 16.2 Hz, 1 H, =CH), 6.71 (d, $^3J$ = 8.8 Hz, 2 H, $C_6H_4$), 3.42 (q, $^3J$ = 7.1 Hz, 4 H, $CH_2$), 1.23 (t, $^3J$ = 7.1 Hz, 6 H, $CH_3$) ppm. $^{13}$C{$^1$H} NMR (125 MHz, $CD_2Cl_2$): $\delta$ = 157.5 (C$^2$-py), 149.8 (C$^6$-py), 148.3 (C$^1$-$C_6H_4$), 146.5 (C$^4$-py), 139.8 (Ph *ipso*), 133.4 (=CH), 128.8 (Ph *para*), 128.7 (Ph *meta*, C$^3$-$C_6H_4$), 126.9 (Ph *ortho*), 123.2 (C$^4$-$C_6H_4$), 120.5 (=CH), 118.7 (C$^5$-py), 117.3 (C$^3$-py), 111.5 (C$^2$-$C_6H_4$), 44.4 ($CH_2$), 12.7 ($CH_3$) ppm. Yield 0.26 g (34%). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.69 (d, $^3J$ = 5 Hz, 1 H, py$^6$), 8.07 (m, 2 H, Ph *ortho*), 7.81 (s, 1 H, py$^3$), 7.60 (m, 2 H, Ph* *ortho*), 7.53 (m, 3 H, Ph *para* and *meta*), 7.49 (m, 3 H, Ph* *para* and *meta*), 7.39 (m, 1 H, =CH), 7.35 (m, 1 H, py$^5$), 7.12 (d, $^3J$ = 16 Hz, 1 H, =CH) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$): $\delta$ = 158.1 (C$^2$-py), 150.0 (C$^6$-py), 145.4 (C$^4$-py), 139.5 (Ph *ipso*), 136.2 (Ph* *ipso*), 133.1 (=CH), 129.0 (Ph/Ph* *para*), 128.9 (Ph/Ph* *meta*), 128.8 (Ph/Ph* *para* and *meta*), 127.1 (Ph* *ortho*), 127.0 (Ph *ortho*), 126.3 (=CH), 119.2 (C$^5$-py), 118.1 (C$^3$-py) ppm. HRMS: calcd. for $C_{19}H_{15}N$ [M]$^+$ 257.1205; found 257.1214. $C_{19}H_{15}N$ (257.34): calcd. C 88.68, H 5.88, N 5.44; found C 88.86, H 5.98, N 5.29.

**Synthesis of 2-Phenyl-4-[(trimethylsilyl)methyl]pyridine:** Lithium diisopropylamine, freshly prepared from diisopropylamine (6.9 mL, 47 mmol) and *n*BuLi (1.6 M in hexane, 29.6 mL, 47.3 mmol), in THF (50 mL) at –80 °C was added to a solution of 4-methyl-2-phenylpyridine (2.05 g, 12.3 mmol) in THF (15 mL) at –80 °C. The reaction mixture was stirred at –80 °C for 0.5 h and then at –10 °C for an additional 0.5 h. At –80 °C, TMSCl (1.53 mL, 17.8 mmol) was added. The reaction was quenched after 2 min of stirring by the addition of absolute ethanol (20 mL), followed by a saturated aqueous solution of $NaHCO_3$ (20 mL). Ethyl acetate (100 mL) was added, and the organic phase was washed with water (100 mL) and a saturated aqueous solution of NaCl (100 mL). The organic phase was dried with $MgSO_4$, and the solvent was evaporated to give an orange oil. Yield 2.78 g (98%). $^1$H NMR (200 MHz, [D$_6$]acetone): $\delta$ = 8.47 (d, $^3J$ = 5 Hz, 1 H, py$^6$), 8.12 (m, 2 H, Ph *ortho*), 7.62 (s, 1 H, py$^3$), 7.47 (m, 3 H, Ph *meta* and *para*), 7.01 (d, $^3J$ = 5 Hz, 1 H, py$^5$), 2.29 (s, 2 H, $CH_2$), 0.07 (s, 9 H, $SiMe_3$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, [D$_6$]acetone): $\delta$ = 156.4 (C$^2$-py), 150.9 (C$^4$-py), 149.2 (C$^6$-py), 139.7 (Ph *ipso*), 128.7 (Ph *para*), 128.5 (Ph *meta*), 126.7 (Ph *ortho*), 122.2 (py), 119.7 (py), 26.7 ($CH_2$), –2.7 ($SiMe_3$) ppm. HRMS: calcd. for $C_{15}H_{19}NSi$ [M]$^+$ 241.1313; found 241.1287.

**Synthesis of 4-(Bromomethyl)-2-phenylpyridine:** 2-Phenyl-4-[(trimethylsilyl)methyl]pyridine (0.66 g, 2.73 mmol) was dissolved in DMF (15 mL), and 1,2-dibromotetrafluoroethane (2.84 g, 10.9 mmol) and cesium fluoride (1.66 g, 10.9 mmol) were added. The reaction mixture was stirred at room temp. for 2 h. Ethyl acetate (50 mL) was added, and the organic phase was washed with water (3 × 50 mL). The organic phase was dried with $MgSO_4$, and the solvent was evaporated. The product was purified by column chromatography over silica [heptane/ethyl acetate (80:20)] to give a brown oil. Yield 0.55 g (81%). $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 8.68 (d, $^3J$ = 5 Hz, 1 H, py$^6$), 8.02 (m, 2 H, Ph *ortho*), 7.74 (s, 1 H, py$^3$), 7.50 (m, 3 H, Ph *meta* and *para*), 7.25 (d, $^3J$ = 5 Hz, 1 H, py$^5$), 4.45 (s, 2 H, $CH_2$) ppm. $^{13}$C{$^1$H} NMR (50 MHz, $CDCl_3$): $\delta$ = 158.5 (C$^2$-py), 150.6 (C$^6$-py), 147.3 (Ph *ipso*), 139.3 (C$^4$-py), 129.7 (Ph *para*), 129.3 (Ph *ortho*), 127.4 (Ph *meta*), 122.4 (C$^3$-py), 120.8 (C$^5$-py), 31.4 ($CH_2$) ppm.

**Synthesis of 4-[(Diethoxyphosphoryl)methyl]-2-phenylpyridine:** To a solution of 4-(bromomethyl)-2-phenylpyridine (1.85 g, 7.46 mmol) in $CHCl_3$ (10 mL) was added triethylphosphite (10.2 mL, 9.89 g, 59.6 mmol). The reaction mixture was refluxed for 3 h. The solvent was evaporated, and the residue was washed with pentane and then dried under vacuum to give a black oil. Yield 1 g (45%). $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 8.66 (d, $^3J_{H-H}$ = 5 Hz, 1 H, py$^6$), 8.01 (m, 2 H, Ph *ortho*), 7.76 (s, 1 H, py$^3$), 7.47 (m, 3 H, Ph *meta* and *para*), 7.21 (m, 1 H, py$^5$), 4.09 (dq, $^3J_{H-P}$ = $^3J_{H-H}$ = 7 Hz, 4 H, Et), 3.21 (d, $^2J_{H-P}$ = 22 Hz, 2 H, $CH_2P$), 1.29 (t, $^3J_{H-H}$ = 7 Hz, 6 H, Et) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$): $\delta$ = 157.6 (C$^6$-py), 149.7 (d, $^4J_{C-P}$ = 2.6 Hz, C$^2$-py), 141.9 (d, $^2J_{C-P}$ = 8.5 Hz, C$^4$-py), 139.1 (Ph *ipso*), 129.1 (Ph *para*), 128.7 (Ph *meta*), 127.0 (Ph *ortho*), 123.4 (d, $^3J_{C-P}$ = 6 Hz, C$^3$-py), 121.9 (d, $^3J_{C-P}$ = 6.3 Hz, C$^5$-py), 62.4 (d, $^1J_{C-P}$ = 6.8 Hz, $CH_2$), 33.7 (d, $^2J_{C-P}$ = 137.3 Hz, OEt), 16.4 (d, $^3J_{C-P}$ = 6 Hz, OEt) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $CDCl_3$): $\delta$ = 25.7 [P(O)(OEt)$_2$] ppm.

**X-ray Crystallography:** Single crystals for X-ray diffraction studies were grown by slow diffusion of pentane in a toluene solution of complexes **1a**, **1b** and **1d** at 20 °C. The samples **1a** and **1d** were studied with an NONIUS Kappa CCD and **1b** with a Bruker AXS X8-APEX II with graphite-monochromatized Mo-$K_\alpha$ radiation. The data collection and refinement parameters are presented in Table 6. The structures were solved with SIR-97[25] which reveals the non-hydrogen atoms of the molecules. The whole structures were refined by full-matrix least-square techniques on $F^2$, with hydrogen atoms refined using the Riding mode. Structures were solved by Patterson or direct methods. The structures were completed by subsequent difference Fourier techniques and refined by full-matrix least-squares on $F^2$ (SHELXL-97) with initial isotropic parameters.[26a] Atomic scattering factors from International Tables for X-ray Crystallography. ORTEP views were realized with PLATON.[26b]

CCDC-272375 (for **1a**), -257689 (for **1b**) and -275435 (for **1d**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Absorption and emission spectra of **3a** and **3d**. Comparison of the absorption and emission spectra of the acac **4a** and dpm adduct **5a**.

## Acknowledgments

We acknowledge the award of a grant by the Centre National de la Recherche Scientifique (CNRS)/Research Grants Council (RGC) (F-HK02/04T) under the PROCORE, France–Hong Kong Joint Research Scheme. M. L. thanks the Région Bretagne for a grant. Muriel Escadeillas is gratefully acknowledged for her help. We thank Prof. Vivian W. W. Yam of The University of Hong Kong for access to equipment for photophysical measurements.

# Reactions of 1,2,4-Trithiolane, 1,2,5-Trithiepane, 1,2,5-Trithiocane and 1,2,6-Trithionane with Nonacarbonyldiiron: Structural Determination and Electrochemical Investigation

**Jochen Windhager,[a] Manfred Rudolph,*[a] Silvio Bräutigam,[a] Helmar Görls,[a] and Wolfgang Weigand*[a]**

*Dedicated to Prof. Wolfgang Beck on the occasion of his 75th birthday*

**Keywords:** Iron / Cluster compounds / S ligands / Hydrogenase / Electrocatalysis / Dihydrogen

The reactions of 1,2,4-trithiolane (**1**), 1,2,5-trithiepane (**6**), 1,2,5-trithiocane (**12**) and 1,2,6-trithionane (**10**) with nonacarbonyldiiron (**2**) have been investigated. A novel diiron model complex, which can serve as a model complex of the active site of [Fe-only]-hydrogenase, was formed from the reaction with **1**. In contrast, the reaction of **6** with **2** afforded the trinuclear iron cluster **7**. Interestingly, the diiron compound **11** was obtained with 1,2,6-trithionane (**10**), which can be attributed to the more flexible dithiolato ligand **10**. Furthermore, the reaction with 1,2,5-trithiocane (**12**) yielded the trinuclear cluster **13**. X-ray structure analyses were performed on compounds **3**, **7**, **10**, **11** and **13**. The reactions of the reduced iron species **3** with pivalic acid (HP) were studied electrochemically. The most significant features of the experimental cyclic voltammograms (CVs) could be reproduced by digital simulation on the basis of a reaction scheme that includes both the coordination of HP as well as the catalytic generation of hydrogen.

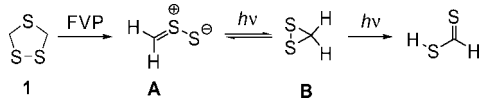
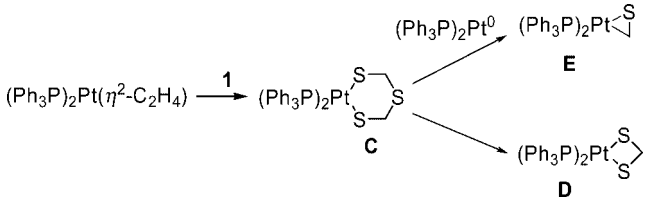
## Introduction

The recent generation of thiosulfine **A** and the first dithiirane **B** by flash vacuum pyrolysis (FVP) of 1,2,4-trithiolane (**1**), in argon matrices at 10 K, was monitored by both IR and UV/Vis spectroscopy (Scheme 1).[1] In 1993, Nakayama and Ishii et al. reported the first synthesis of stable dithiirane.[2] We have shown that platinum(0) complexes, for instance $Pt(\eta^2\text{-}C_2H_4)(Ph_3P)_2$, react with 1,2,4-trithiolane (**1**) by insertion along the S–S bond. When two equivalents of the platinum(0) complex were used, dithiolatoplatinum(II) **C** was obtained (Scheme 2). This complex decomposed to give the –platinum complex **E** and the methylenedithiolato complex **D**.[3]



Scheme 1. Flash vacuum pyrolysis (FVP) of 1,2,4-trithiolane **1**.



Scheme 2. Treatment of 2 equiv. $Pt(\eta^2\text{-}C_2H_4)(Ph_3P)_2$ with 1,2,4-trithiolane (**1**) to give a 1:1 mixture of methylenedithiolato complex **D** and thioformaldehyde complex **E**.

The oxidative addition of low-valent metal complexes to cyclic disulfides has received significant attention in recent years.[4] As an extension of previous work, reaction of **1** with nonacarbonyldiiron (**2**) was conducted to investigate whether **2** would insert into the S–S bond with the formation of a novel type of dithiolato-bridged diiron complex, which can serve as a model for the active site of [Fe-only]-hydrogenases. Since the first X-ray structure determination of [Fe-only]-hydrogenase was reported,[5] several research groups have prepared simple dinuclear iron complexes that have structural, spectroscopic and functional properties similar to those of the active site of [Fe-only]-hydrogenase.[6] Moreover, the two iron atoms in the active site are bridged by a three-atom-linked dithiolato ligand $SCH_2XCH_2S$;

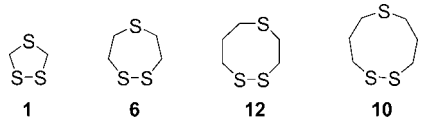
however, the nature of the X group remains unclear. Nevertheless, it has been postulated that X is an NH unit that is hydrogen bonded to a nearby cysteine-SH unit.[5a]

In order to elucidate the influence of the X group on the hydrogenase activity, we set out to prepare model complexes with X = S by reaction of **1** with **2**. We also tested the reactivity of 1,2,5-trithiepane (**6**), 1,2,5-trithiocane (**13**) and 1,2,6-trithionane (**10**) towards **2** to determine the role of the length of the dithiolate linker in the model complexes (Scheme 3). Very recently, Darensbourg and Hall et al. performed theoretical calculations to determine the influence of the nature of X and the lengthening of the dithiolato bridge on the conformational structure of the model complexes.[7]

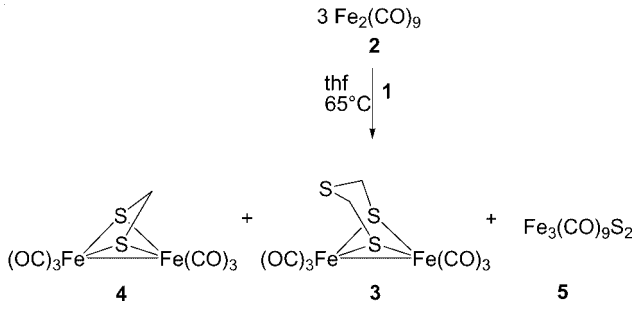


Scheme 3. The sulfur heterocycles **1**, **6**, **10** and **12**.

## Results and Discussion

### Reaction of $Fe_2(CO)_9$ (2) with 1,2,4-Trithiolane (1)

Treatment of 3 equiv. $Fe_2(CO)_9$ (**2**) with 1 equiv. 1,2,4-trithiolane (**1**) in thf for 15 min at 65 °C afforded a mixture of three compounds **3**–**5**, which were separated and isolated by using column chromatography (Scheme 4).



Scheme 4. Reaction of 3 equiv. $Fe_2(CO)_9$ (**2**) with 1 equiv. 1,2,4-trithiolane (**1**).

The $^1$H NMR spectra of **3** and **4** shows one singlet each at $\delta$ = 3.21 and 4.61 ppm, respectively. On the basis of the $^1$H and $^{13}$C NMR spectroscopic data, compound **4** was identified as the known methylenedithiolato-bridged compound.[8] The crystal data of product **5** confirms the presence of a trinuclear complex $Fe_3S_2(CO)_9$.[9] MS analysis shows the stepwise fragmentation of six CO groups and the molecular peak at *m*/*z* = 404 for product **3**, which suggests the presence of a diiron hexacarbonyl complex fragment coordinated to the sulfurdithiolato ligand (SDT). Single-crystal X-ray analysis reveals the proposed structure of **3** (Figure 1); the iron coordination geometry in **3** is rather similar to that in its oxadithiolate (ODT) analogue $Fe_2(\mu\text{-}SCH_2OCH_2S\text{-}\mu)(CO)_6$.[6i] The Fe–Fe bond length in **3** is 2.5120(5) Å, a value very similar to those in the propanedithiolate (PDT) analogue [2.5103(11) Å][6a–6d] and in the ODT analogue [2.5113(13) Å],[6i,6l] but slightly longer (0.02 Å) than that in the azadithiolato (ADT) complex [2.4924(7) Å].[6e–6g] The Fe–Fe bond in **3** is slightly shorter than those reported for the oxidised state diiron subsite (2.62 and 2.60 Å) and that in the reduced state diiron subsite of the enzyme structure (2.55 Å).[5a] Similar to the ODT complex, the bridgehead sulfur atom is disordered (50%).

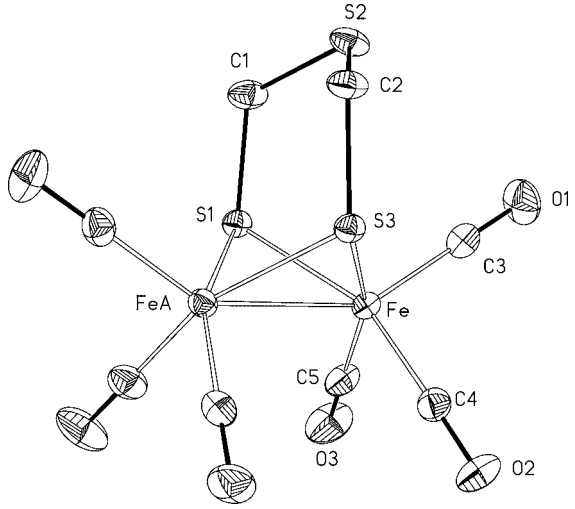


Figure 1. Structure of $Fe_2(SDT)(CO)_6$ (**3**) with thermal ellipsoids set at the 50% probability level (hydrogen atoms are omitted for clarity). Selected distances [Å] and angles [°]: Fe–FeA 2.5120(5), Fe–C3 1.800(9), Fe–C4 1.794(5), Fe–C5 1.800(8), Fe–S1 2.2514(5), Fe–S3 2.2557(7); Fe–S1–FeA 67.672(19), Fe–S3–FeA 67.82(2).

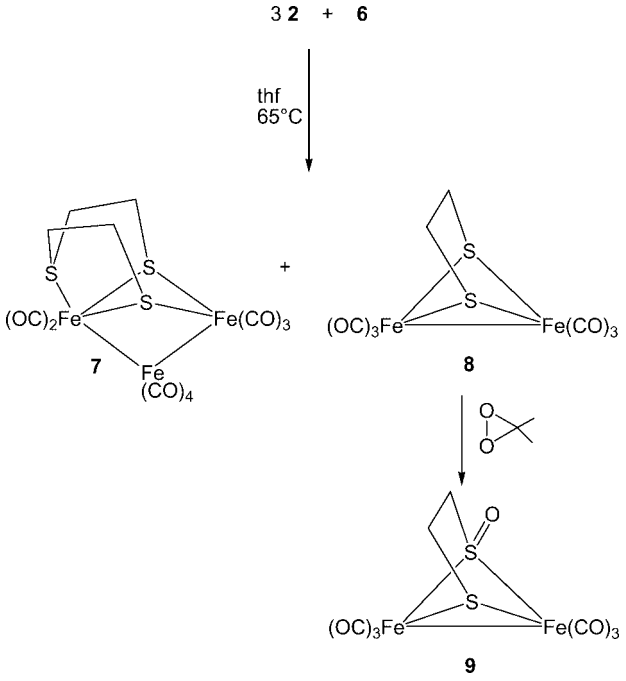
### Reaction of $Fe_2(CO)_9$ (2) with 1,2,5-Trithiepane (6)

By analogy with 1,2,4-trithiolane (**1**), the reaction of 1,2,5-trithiepane (**6**) with **2** was carried out in thf for 15 min at 65 °C. The crude mixture was separated by using column chromatography. Products **7** and **8** were isolated as analytically pure orange and green solids, respectively. For compound **8**, the $^1$H NMR analysis reveals one singlet at $\delta$ = 2.34 ppm. Oxidation of **8** with excess dimethyldioxirane (DMD) quantitatively afforded complex **9**, which was subsequently analysed by X-ray diffraction analysis (Scheme 5). Compounds **8** and **9** have been mentioned previously in the literature.[10]

$^1$H-$^1$H COSY and $^1$H-$^{13}$C HSQC spectra of **7** reveal four groups of $^1$H resonances in a 1:1:1:1 ratio as well as two $^{13}$C signals at $\delta$ = 39.68 and 45.59 ppm. DEI-MS shows the $[M]^+$ ion at *m*/*z* = 572, with the stepwise fragmentation of nine CO groups. On the basis of spectroscopic data, it is suggested that **7** consists of more than two $Fe(CO)_3$ moieties, a result that is further confirmed by the X-ray structure analysis as a trinuclear cluster. The isostructural ruthenium cluster was synthesised by the reaction of $Ru_3(CO)_{12}$ and 1,4,7-trithiacyclononane (9S3) in thf.[11] Alternatively, when the complex $Ru_3(CO)_7(\mu\text{-}CO)_2(1,1,1\text{-}\eta^3\text{-}9S3)$ is heated at reflux for 16 h, an analogous ruthenium cluster is obtained.[12]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 5. Reaction of 1,2,5-trithiepane (**6**) with **2**.

As shown in Figure 2, all iron atoms display a distorted octahedral coordination geometry. The Fe1 and Fe2 centres are $\mu^2$-bridged by the bis(thiolatoethylene sulfide) ligand (BTES). Because of the two additional methylene groups in the BTES ligand relative to that in **3**, the thioether S atom coordinates to Fe1. A similar motif was also observed in the complex $[(ON)Ni(\mu\text{-BTES})Fe(NO)_2]$.[13]

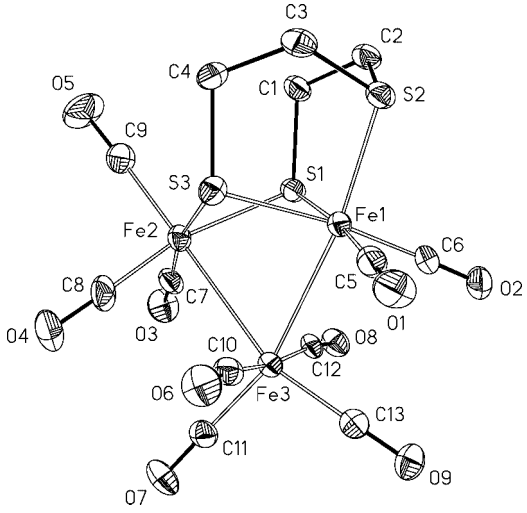


Figure 2. Structure of $Fe_3(\mu\text{-BTES})(CO)_9$ (**7**) with thermal ellipsoids set at the 50% probability level (hydrogen atoms are omitted for clarity). Selected distances [Å] and angles [°]: Fe1–Fe3 2.7355(13), Fe2–Fe3 2.7622(14), Fe1–S1 2.314(2), Fe1–S3 2.302(2), Fe2–S1 2.317(2), Fe2–S3 2.318(2), Fe2–S2 2.250(2); Fe1–S1–Fe2 81.92(6), Fe1–S3–Fe2 82.18(7).

The Fe–S bond lengths for the bridging sulfur atoms in **7** are 2.312 Å (mean), but the Fe1–S2 bond is remarkably shorter [2.250(2) Å]. The Fe1–S1/S3–Fe2 angles of 81.92(6)° and 82.18(7)° differ significantly from the corresponding angles in **3**, 67.82(2)° and 67.67(2)°, respectively. Accordingly, the Fe1···Fe2 distance in **7** (3.036 Å) is significantly longer than that in **3** [2.5120(5) Å]. As a consequence, a $Fe(CO)_4$ fragment inserts into the Fe1 and Fe2 bond, leading to cluster species **7**, a cluster with a total electron count of 50, which is classified as hypho according to the Wade–Mingos rules.

### Reactions of $Fe_2(CO)_9$ (2) with 1,2,6-Trithionane (10)

1,2,6-Trithionane (**10**) was conveniently obtained by a reported procedure.[14] Colourless needles that were suitable for X-ray diffraction analysis were obtained by recrystallising **10** from hexane at –25 °C. The nine-membered ring shows a nonplanar structure (Figure 3) with a for C3–S3–S4–C4 torsion angle of 60.62(15)°. The S3–S4 bond is 1.993(3) Å and is slightly shorter than the corresponding bond in $\alpha\text{-}S_8$ (2.05 Å).[15]

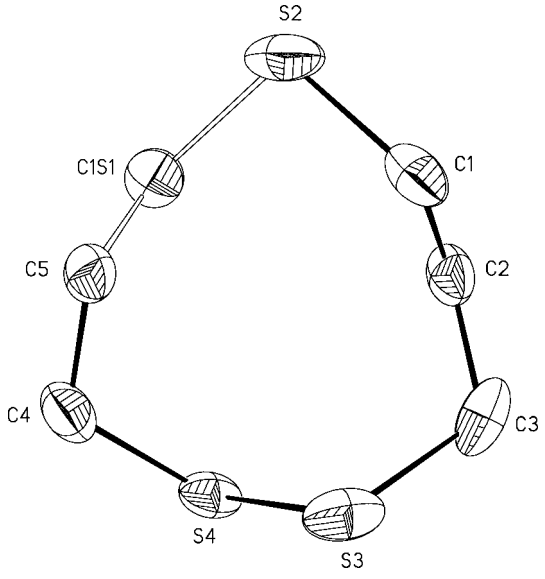

Figure 3. Structure of 1,2,6-trithionane (**10**) with thermal ellipsoids set at the 50% probability level (hydrogen atoms are omitted for clarity). Selected distances [Å] and angles [°]: S3–S4 1.993(3); C3–S3–S4–C4 60.62(15)°.

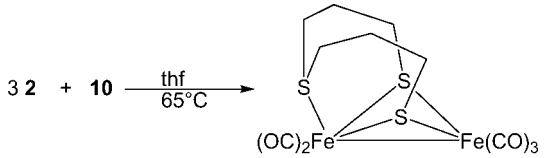
When **10** was treated with 3 equiv. **2** in thf at 65 °C, a red-brown solution was obtained. After 15 min, the reaction was complete, and compound **11** was isolated after workup as a brown solid by column chromatography (Scheme 6).



Scheme 6. Reaction of 1,2,6-trithionane (**10**) with **2**.

$^1H$-$^1H$ COSY and $^1H$-$^{13}C$ HSQC analysis of **11** allowed the assignment of the $^{13}C$ resonances at $\delta$ = 18.90 and 27.01 ppm to the C5 and C2 atoms, respectively; the reso-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nances at 28.41 and 28.47 ppm are assigned to the C1 and C6 atoms and those at 36.72 and 37.56 ppm to the C3 and C4 atoms, respectively. The latter 4 carbon atoms are directly connected to the thiolato groups and thioether group, respectively. All signals in the $^1$H NMR spectrum are assigned to the 12 diastereotopic protons. DEI-MS reveals the $[M]^+$ ion at $m/z$ = 432 and a stepwise fragmentation of five CO groups. These results indicate the formation of a diiron complex with both $Fe(CO)_2$ and $Fe(CO)_3$ moieties.

This structural motif was confirmed by X-ray diffraction (Figure 4). Red-brown crystals of **11** were obtained from hexane at –25 °C. The crystals were stable in air for weeks at room temperature, but decomposed in solution under argon above 0 °C within one day to form an insoluble brown solid. Complex **11** displays two five-coordinate iron centres with square-pyramidal geometry and an Fe–Fe bond length of 2.5016(5) Å, which is slightly shorter than that in **3**. Complex **11** may be compared with $[Fe_2\{MeSCH_2C(Me)(CH_2S)_2\}(CO)_5]$, showing a similar Fe–Fe distance [2.5086(9) Å].[16]

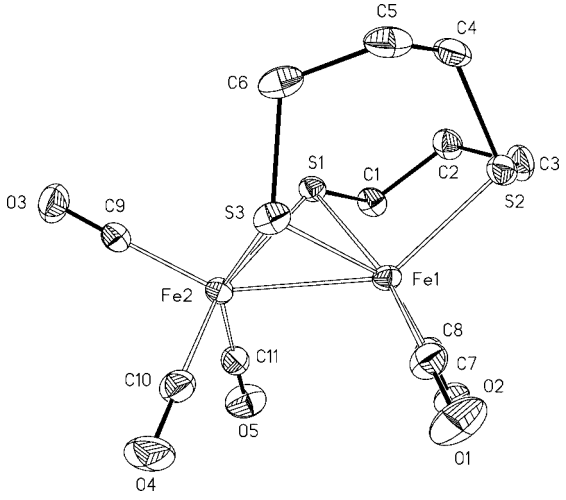


Figure 4. Structure of $Fe_2(\mu$-BTPS$)(CO)_5$ (**11**) with thermal ellipsoids set at the 50% probability level (hydrogen atoms are omitted for clarity). Selected distances [Å] and angles [°]: Fe1–Fe2 2.5016(5), Fe1–S1 2.2568(7), Fe1–S3 2.2448(8), Fe2–S1 2.2481(7), Fe2–S3 2.3040(8), Fe1–S2 2.2449(7); Fe1–S1–Fe2 67.46(2), Fe1–S3–Fe2 66.71(2).

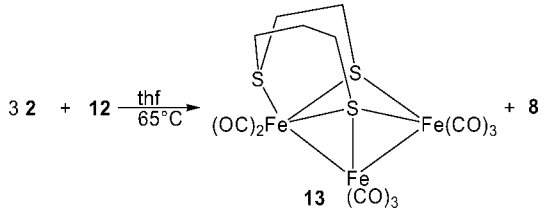
The thiolato sulfur atoms S1 and S3 are $\mu^2$-coordinated to Fe1 and Fe2. In addition, the thioether atom (S2) is connected to Fe1. The angles Fe1–S1–Fe2 [67.46(2)°] and Fe1–S3–Fe2 [66.71(2)°] compare well to those in **3** [67.82(2)° and 67.67(2)°], but in contrast to **3**, **11** does not contain a mirror plane. The presence of the extra methylene groups in **11** relative to **7** reduces steric strain and thus provides the BTPS ligand with more flexibility, which enables the coordination of the thioether S2 atom to Fe1 with the formation of a Fe–Fe bond. With the exception of the Fe2–S3 bond length [2.3040(8) Å], the remaining Fe–S distances are quite similar [2.2448(8), 2.2449(7), 2.2481(7), 2.2568(7) Å].

### Reactions of $Fe_2(CO)_9$ (2) with 1,2,5-Trithiocane (12)

In order to elucidate the influence of the size of the dithiolato thioethers on the structure of the iron complexes, we also treated **12** with **2** at 65 °C in thf. After workup, compounds **8** and **13** were isolated by column chromatography (Scheme 7). Additionally, two green side-fractions were obtained, but unfortunately, we have not been able to characterise them yet. The fraction containing **13** was dissolved in chloroform. After diffusion of pentane into the concentrated solution, red-brown crystals were afforded after 2 d at 0 °C.



Scheme 7. Reaction of 1,2,5-trithiocane (**12**) with **2**.

The $^1$H-$^1$H COSY spectrum of **13** shows ten groups of resonance signals, which were assigned to the ten diastereotopic protons. According to the $^1$H-$^1$H COSY and $^1$H-$^{13}$C HSQC spectra of **13**, the $^{13}$C resonances at $\delta$ = 34.54 and 34.75 ppm are attributed to the carbon atoms of the ethylene group [C1 and C2] and the signals at 25.41, 31.71 and 36.92 ppm to the C4, C5 and C3 atoms, respectively. DEI-MS reveals the $[M]^+$ ion at $m/z$ = 558 and a stepwise fragmentation of eight CO groups.

As shown in Figure 5, complex **13** has a distorted "non-closed" square-pyramidal $Fe_3S_2$ core with Fe1–Fe2, Fe2–Fe3 and Fe2–S3 distances of 2.7352(9), 2.6888(9) and 2.1173(12) Å, respectively. As in the molecular structure of **7**, all iron atoms have a distorted octahedral coordination geometry. The geometry of Fe1–S1–Fe3–S3 is almost square planar, with a mean deviation from planarity of 0.0941 Å. The Fe1–S1–Fe3 angle of 93.65(4)° and Fe1–S3–Fe3 angle of 100.56(4)° are significantly larger than the corresponding angles in **7** [81.92(6)° and 82.18(7)°]. As a result, the Fe1···Fe3 distance is considerably longer (3.376 Å) than the corresponding distance in **7**. The 3-(2-thiolatoethylthio)-propane-1-thiolato ligand is coordinated to the Fe1 and Fe3 atoms, but the S3 atom is $\mu^3$-coordinated to the three iron atoms as a result of the almost planar geometry of the Fe1–S1–Fe3–S3 moiety, which is remarkably different from that observed in **7**. Therefore, instead of an $Fe(CO)_4$ unit as in **7**, an $Fe(CO)_3$ complex fragment coordinates in **13**, which leads to an arachno cluster. In contrast to compound **7**, the Fe–S distances are quite different from each other. The Fe1–S1 [2.3255(12) Å] and Fe3–S1 [2.3042(12) Å] bonds are significantly longer than the Fe1–S3 [2.2040(12) Å] and Fe3–S3 [2.1854(12) Å] bonds, which can be attributed to the larger strain caused by the ethylenethiolato group than that caused by the propylenethiolato group.

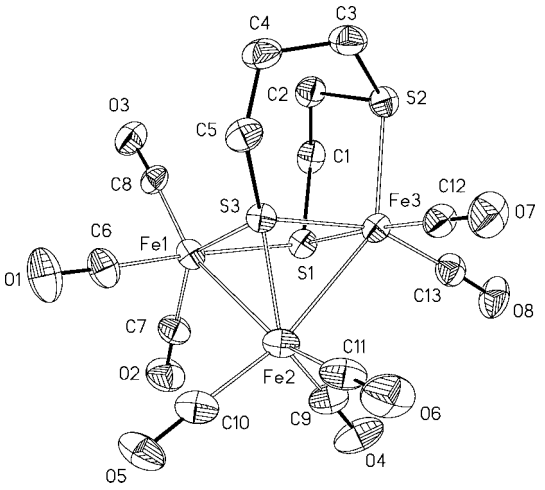

Figure 5. Structure of $Fe_3(S(CH_2)_2S(CH_2)_3S)(CO)_8$ (**13**) with thermal ellipsoids set at the 50% probability level (hydrogen atoms are omitted for clarity). Selected distances [Å] and angles [°]: Fe1–Fe2 2.7352(9), Fe2–Fe3 2.6888(9), Fe1–S1 2.3255(12), Fe1–S3 2.2040(12), Fe3–S1 2.3042(12), Fe3–S3 2.1854(12), Fe2–S3 2.1173(12), Fe3–S2 2.2545(13); Fe1–S1–Fe3 93.65(4), Fe1–S3–Fe3 100.56(4).

## Electrochemical Investigations

The electrochemical behaviour of **3** was studied in the aprotic solvent acetonitrile by varying the concentration of pivalic acid (denoted as HP). This Brønsted acid is electrochemically inactive in the required potential range so that site effects originating from the steady-state concentration of electrochemically produced radicals can be excluded. Moreover, the use of pivalic acid in anhydrous acetonitrile leads to the favourable situation in which catalytic hydrogen generation does not occur in the potential range where the two-electron reduction of the iron species proceeds. Unlike the processes reported, for instance, by Best, Pickett et al.[17] or those for the system denoted as **1-P** by Darensbourg et al.[18c] and Rauchfuss et al.[18a,18b] in which the overall current is dominated by the catalytic reactions as soon as acid is present, the interaction between reduced iron species and pivalic acid that occurs prior to the catalytic cycle can be studied independently in a well-separated potential range. A similar situation was observed for the model system 1 of the above-mentioned articles by Darensbourg and Rauchfuss et al.[18]

### Electrochemistry of 3 in the Absence of Pivalic Acid

The solid lines in Figure 6 show the cyclic voltammetric reduction of **3** in acetonitrile measured by varying the scan rate from 5 to 200 V $s^{-1}$. The open-circle traces show theoretical CVs simulated on the basis of the following reaction scheme (**3** is denoted as Fe–Fe).

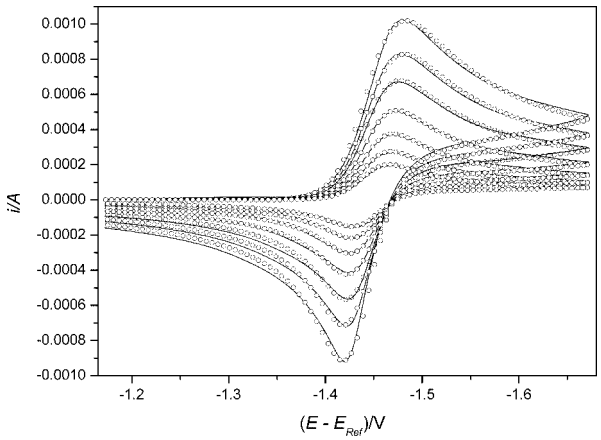

Figure 6. Experimental (solid lines) and simulated (open circles) CVs for the reduction of 2.46 mM **3** in acetonitrile with scan rates of 5, 10, 20, 40, 80, 125 and 200 V $s^{-1}$. The simulated curves refer to the mechanism postulated in (R1)–(R3).

The reduction proceeds in a stepwise manner with two one-electron steps; the second step occurs at more positive potentials than the first and is so fast that only a lower limit can be estimated for $k_s^0$ in (R2).

$$\mathrm{Fe{-}Fe} + e \leftrightarrow {}^{-}\mathrm{Fe{-}Fe} \quad \left(U_1^0 = -1.505\ \mathrm{V};\ k_1^0 \approx 0.65\ \mathrm{cm/s}\right) \quad \text{(R1)}$$

$${}^{-}\mathrm{Fe{-}Fe} + e \leftrightarrow {}^{-}\mathrm{Fe{-}Fe}^{-} \quad \left(U_2^0 = -1.39\ \mathrm{V};\ k_2^0 > 1\ \mathrm{cm/s}\right) \quad \text{(R2)}$$

$${}^{-}\mathrm{Fe{-}Fe}^{-} \rightarrow Q \quad \left(k_{f3} \approx 1\ \mathrm{s}^{-1};\ k_{b3} \ll k_{f3}\right) \quad \text{(R3)}$$

The fact that the electron transfer results in a cleavage of the iron–iron bond is not considered in the above reaction scheme[21] because this information cannot unambiguously be extracted from the experimental CVs. There are only some indirect indications that a bond cleavage in (R1) could account for the higher energy and the slower rate constant associated with this reaction. It would also explain why the reoxidation of the reduced iron species does not proceed in a fully reversible manner. By convoluting the experimental CVs with $t^{-1/2}$ (a procedure called "semi-integration" in the electrochemical literature[21]) as shown in Figure S1[22] (see Supporting Information), it is revealed that the electrons consumed in the forward scan are almost completely regained in the backward scan, but about 3% of the iron species is reoxidised at a slightly more positive potential. This is an indication of the existence of an unknown decomposition product postulated in (R3). However, the effect was too small to examine the reoxidation process via the unknown product.

### Electrochemistry of 3 in the Presence of Pivalic Acid

Figure 7 presents the CVs of **3** in acetonitrile (solid line) at different concentrations of pivalic acid. By looking at the semi-integrated curves shown in Figure S2[22], it is revealed that the overall number of electrons consumed in the forward scan up to about –1.55 V is independent of HP concentration. Consequently, the reduced iron species are not yet able to produce hydrogen from pivalic acid by homogeneous electron transfer in the potential range in which the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(heterogeneous) two-electron reduction proceeds. Moreover, the electrons consumed in the reduction process are completely regained in the backward scan irrespective of the HP concentration [except for a small difference that corresponds roughly to the amount assigned to the unknown product *Q* in reaction (R3)], but the overall reoxidation occurs in four processes (indicated by P2–P5 in Figure 7) if the acid is present.

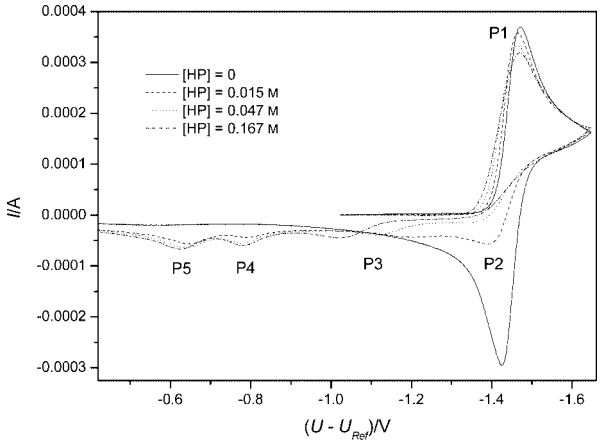

Figure 7. Cyclic voltammograms of 2.46 mM **3** in the absence and presence of pivalic acid. The scan rate is $v = 20\ V\,s^{-1}$.

Further reduction is observed when the potential scan is extended to negative potentials beyond –1.6 V, as can be seen in Figure 8a,b. The additional reduction process P6 at about –2.2 V is not observed in the absence of pivalic acid, and the current of this peak grows with increasing HP concentration. The most likely explanation for this observation is the catalytic reduction of pivalic acid to hydrogen, mediated by the iron complex. The importance of understanding the electrochemistry of the processes leading to the catalytic formation of hydrogen is revealed when **3** is considered as a model complex for the active site of [Fe-only]-hydrogenase.

Figure 7 makes it clear that the peaks associated with processes P2–P5 exhibit very different potential shifts as a function of the HP concentration. While P4 is rather independent of the HP concentration, a tenfold increase in [HP] results in a shift in P5 to more positive potentials by about 59/2 mV. The strongest dependence is observed for P3, where the potential shift is about three Nernst factors. The last observation could be explained by assuming that the charge-transfer reaction in P3 occurs in the form of a preceding chemical reaction caused by the dissociation of three HP molecules. Indeed, the current curve referring to [HP] = 0.015 M in Figure 7 shows the plateau shape expected for a preceding chemical reaction, but as the HP concentration increases, the curve becomes increasingly peak-shaped. It is therefore more likely that P3 represents a ladder scheme or that the equilibrium concentration of the species that is reoxidised is not negligibly small at higher HP concentrations.

In this paper we have mostly focussed on the reactions leading to P1, P2 and P3 in Figure 7 and to P6 in Figure 8. On looking at Figure 9, it can be seen that P1–P3 can be reproduced very well by adding the reactions to (R1)–(R2).

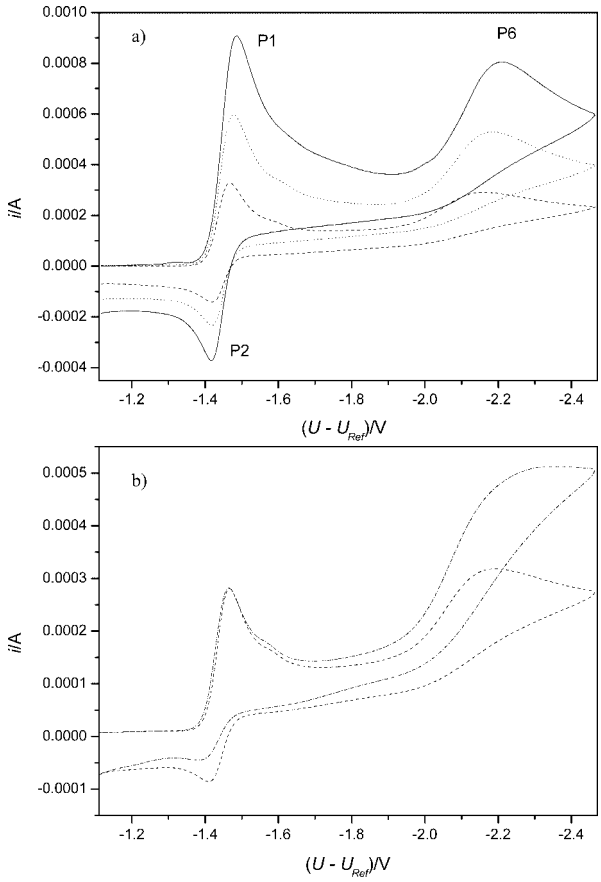

Figure 8. Cyclic voltammograms of **3** in the presence of pivalic acid. (a) 2.2 mM **3** and 10 mM HP, scan rate 20 $V\,s^{-1}$ (dashed line), 77 $V\,s^{-1}$ (dotted line) and 200 $V\,s^{-1}$ (solid line). (b) 2.0 mM **3** and 10 mM (dashed line) or 20 mM (dotted and dashed line) HP, scan rate 20 $V\,s^{-1}$.

It is important to emphasise that parameter couplings prevent the determination of some parameters in the above reaction scheme. This means that virtually the same standard deviation is obtained with different parameter combinations. Despite this uncertainty, the signature of the above reaction scheme is that it may serve as a basis for interpreting (at least qualitatively) the pathway leading to the catalytic generation of hydrogen shown in the CVs in Figure 8.

The reaction of the reduced iron species **3** in the presence of pivalic acid starts with the formation of 1:1 and 1:2 complexes. In the case of the monoanion, only the 1:1 complex needs to be considered because the equilibrium for reaction (R8) seems to lie far to the left. Actually, electrochemical methods such as cyclic voltammetry are not able to distinguish whether undissociated HP molecules are hydrogen-bonded in (R4)–(R7) and (R10) or if a proton transfer occurs as formulated here for (R4).

However, the fact that the ratio of the peak currents associated with P1 and P2 exhibits virtually no scan-rate dependence even when using only a relatively small excess of pivalic acid (see Figure 9a) can be explained only if the complex formation in (R4)–(R6) proceeds as an irreversible process where the effect of the dissociation reaction remains

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

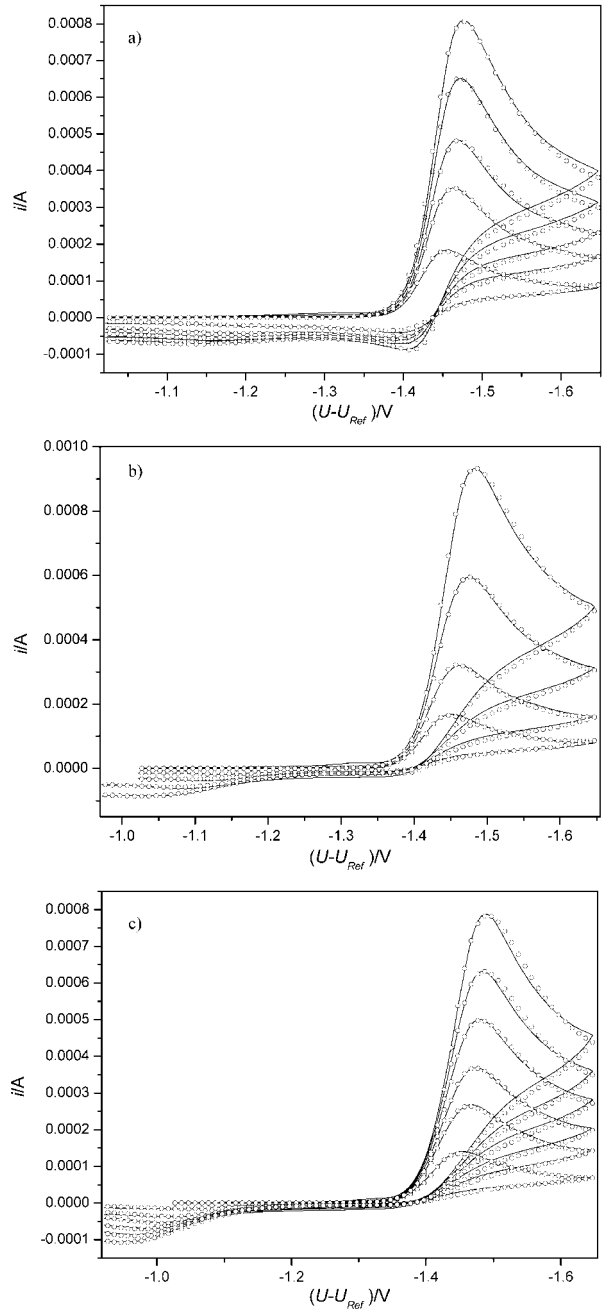

Figure 9. Experimental (solid lines) and simulated (open circles) CVs for the reduction of 2.46 mM **3** in the presence of pivalic acid. (a) [HP] = 0.015 mol L$^{-1}$; $v$ = 5, 20, 40, 77, 125 V s$^{-1}$. (b) [HP] = 0.047 mol L$^{-1}$; $v$ = 5, 20, 77, 200 V s$^{-1}$. (c) [HP] = 0.167 mol L$^{-1}$; $v$ = 5, 20, 40, 77, 125, 200 V s$^{-1}$. The simulated curves refer to the mechanism postulated in (R4)–(R11), with $n$ = 3 in (R7).

$$^{-}Fe-Fe + HP \rightarrow {}^{-}Fe-Fe(HP) \quad (K_4 >> 1; k_{f4} \approx 10^5\,M^{-1}s^{-1}) \quad (R4)$$

$$Fe-Fe + HP \rightarrow Fe-Fe(HP) \quad (K_5; k_{f5} \approx 10^5\,M^{-1}s^{-1}) \quad (R5)$$

$$^{-}Fe-Fe^{-}(HP) + HP \rightarrow {}^{-}Fe-Fe^{-}(HP)_2 \quad (K_5K_6 >> 1; k_{f6} >> k_{b5}) \quad (R6)$$

$$^{-}Fe-Fe^{-}(HP)_2 + nHP \leftrightarrow {}^{-}Fe-Fe^{-}(HP)_2[HP]_n \quad (K_7 \approx 55; k_{f7} \approx 3\times10^6\,M^{-1}s^{-1}) \quad (R7)$$

$$^{-}Fe-Fe(HP) + e \leftrightarrow {}^{-}Fe-Fe^{-}(HP) \quad (U_8^0 \approx -1.6\,V; k_8^0 \approx 0.3\,s^{-1}) \quad (R8)$$

$$^{-}Fe-Fe(HP)_2 + e \leftrightarrow {}^{-}Fe-Fe^{-}(HP)_2 \quad (U_9^0 \approx -1.09\,V; k_9^0 \approx 0.3\,s^{-1}) \quad (R9)$$

$$^{-}Fe-Fe(HP) + HP \leftarrow {}^{-}Fe-Fe(HP)_2 \quad (K_{10} << 1; k_{b10} >> 1) \quad (R10)$$

$$^{-}Fe-Fe^{-}(HP)_2[HP]_n \rightarrow Q^{*} \quad (k_{f11} \approx 4; k_{b11} << k_{f11}) \quad (R11)$$

$$^{-}Fe-Fe + HP \rightarrow Fe-Fe(H) + P^{-} \quad (R12)$$

negligibly small. The latter effect may rather be expected for the formation of a protonated species where the opposite charge of the ions counteracts the dissociation reaction. On the other hand, HP is a very weak acid in acetonitrile and is not dissociated. The p$K_a$ value of acetic acid (which is rather a stronger acid) in anhydrous acetonitrile is only 22.3.[23] However, one should keep in mind that the basicity of the anions of **3** could be increased in the same way that the acidity of pivalic acid is decreased under anhydrous conditions. Nevertheless, it is unlikely that more protons are coordinated than that required to compensate for the negative charge of the reduced iron species, and it remains even questionable whether the dianion of **3** is a strong enough base for the deprotonation of two molecules of pivalic acid. For this reason, we prefer a neutral formulation Fe–Fe(HP), where (HP) in parenthesis represents either a strongly hydrogen-bonded HP molecule or a proton. This type of $H^+$/HP-bonding must be clearly distinguished from the weak and labile bonding of HP molecules postulated in (R7), for which square brackets are used.

Unfortunately, the number $n$ of HP molecules coordinated in this step [R(7)] could not unambiguously be determined. The numbers reported in (R7) refer to $n$ = 1. The problem is that the effect of reaction (R7) is mostly visible in P3, but the average height of the plateau current can be satisfactorily well reproduced with the values $1 \leq n \leq 3$. Thus, for instance, a standard deviation of $s$ = 0.013 was obtained by fitting the experimental data based on reactions (R1), (R2) and (R4)–(R11) with $n$ = 1, while a minimum of $s$ = 0.012 was found for $n$ = 3. This finding is not very significant. However, inspection of all simulated and experimental curves in the potential range associated with P3 reveals that the correct shift for the (half) peak potential of the plateau current as a function of HP concentration is attained only for $n$ = 3, which is in agreement with the potential shift of about three Nernst factors mentioned above. It should be emphasised that we were not able to simulate the experimental data when only (R7) was used with $n$ = 3 and (R5) and (R6) were omitted. We assumed a strong irreversible coordination in the first step and a weaker and labile coordination in the follow-up reaction.

The weak hydrogen bonding of three additional HP molecules could occur, for instance, at the sulfur centres of the molecule provided that the species postulated in (R7) is really a di- or at least a monoanion. Arguments supporting such an assumption can be found in the literature. For example, hydrogen bonding of three undissociated acid molecules at a radical monoanion was postulated in the reduction pathway of 3,5-di-*tert*-butyl-1,2-benzoquinone in the presence of 2,2,2-trifluoroethanol.[24]

Finally it should be mentioned that reaction (R11) plays a similar role to that of process P3 in the absence of pivalic acid. A somewhat larger rate constant was used for (R11), which is in agreement with the results from semi-integration shown in Figures S1 and S2[22].

We will now deal with the most critical question arising from the above reaction scheme: where do the additional processes P4 and P5 in Figure 7 come from? The most

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

straightforward explanation is that $n$ in (R7) really equals 3 and that the three peaks represent the reoxidation processes associated with $n = 1$, 2 and 3 for the corresponding species not yet consumed in the dissociative pathway. Of course, this situation cannot be simulated on the basis of the above reaction scheme that takes only the gross reaction but not the successive complex formation steps into account. The description of more detailed investigations that focus particularly on these processes is beyond the scope of this paper. These findings will be published separately; a detailed knowledge of these processes does not seem to be necessary for the understanding of the pathway that leads to the catalytic current (P6) in Figure 8.

As a first step, this process was analysed by determining the number of electrons additionally consumed in the presence of pivalic acid in the potential range between –1.6 and –2.5 V. The latter was accomplished by semi-integrating the experimental CVs measured with a small excess of pivalic acid. Figure S3 (Supporting Information) shows the number of electrons, $z$, determined in this way as a function of the scan rate. It can be concluded that two additional electrons are consumed in this potential range in the limiting case $v \rightarrow \infty$, where the contributions of the catalytic reactions become negligibly small.

A more detailed analysis reveals that a catalytic process is still not detectable when only one more electron is transferred to the doubly reduced iron species (at least when working with a small excess of pivalic acid).

P6 is governed equally by heterogeneous and homogeneous charge-transfer reactions when as little as a fivefold excess and scan rates between 20 and 200 $V s^{-1}$ are used. Moreover, the formulation of feasible follow-up reactions is simplified by the fact that $^{-}$Fe–Fe$^{-}$(HP)$_2$ is the dominating species in the postulated reaction scheme. Hence, only two further reduction steps of this species were taken into consideration. On looking at Figure 8, it can be seen that the curve remains peak-shaped and no reoxidation process is visible in the potential range associated with P6, independent of the scan rate. Thus, at least the first reduction step (apparently not yet involved in a catalytic process) must be slow and fully irreversible. This could be explained by assuming that further reduction of the HP complexes proceeds as a concerted proton and electron transfer (CPET) reaction in which electron transfer from the electrode to the complex occurs simultaneously with proton transfer from a hydrogen-bonded HP molecule within the complex. CPET reactions have also been invoked for the electrochemical reduction of superoxide,[25] the oxidation of an amino phenol[26] and the oxidation of 1,4-hydrobenzoquinone-2,5-dicarboxylate.[27] Arguments supporting the CPET designation, rather than the possible two-step pathways, have been fully developed for each case.

Because of the perfect coupling between the heterogeneous rate constants and the standard potential for an irreversible charge-transfer process, the heterogeneous rate constants were set to more or less arbitrary values and the standard potential was then adjusted together with the charge-transfer coefficient to simulate the shape of the current curve, at least qualitatively. The following values were used: $U^0_{15} = -1.475$ V, $k^0_{15} = 10^{-3}$ cm $s^{-1}$, $\alpha_{15} \approx 0.25$; $U^0_{16} = -1.77$ V, $k^0_{16} = 1.2 \times 10^{-3}$ cm $s^{-1}$, $\alpha_{16} \approx 0.35$.

The assumption that the catalytic cycle is obtained by a reaction of type (R15), which forms a product that can then be directly re-reduced according to the pathway (R1), (R2), (R5), (R6), (R13) and (R14), is not in agreement with the experimental results.

$$^{-}Fe - Fe^{-}(HP)_2 + e \rightarrow {}^{-}H - Fe - Fe^{-}(HP) + P^{-} \quad (R13)$$

$$^{-}H - Fe - Fe^{-}(HP) + e \rightarrow {}^{-}H - Fe - Fe - H^{-} + P^{-} \quad (R14)$$

$$^{-}H - Fe - Fe - H^{-} + 2HP \rightarrow Fe - Fe + H_2 + 2P^{-} \quad (R15)$$

The assumption mentioned above inevitably leads to the situation in which the current curve does not remain peak-shaped for each scan rate. It becomes increasingly plateau-shaped, as expected for a first-order catalytic mechanism when the scan rate is reduced. Therefore, the shape of the peak for P6 in Figure 8 cannot result from a second-order catalytic reaction in which the depletion of HP accounts for the decay in the catalytic current after a maximum value is reached. A reasonable agreement between simulation and experiment could be obtained only by assuming that the species produced in the first catalytic step [R(16)] does not only undergo a catalytic regeneration reaction according to reactions R(17) or R(18), but also a deactivation reaction in the form of a slow irreversible charge-transfer step [R(19)] that results in the formation of a species that does not participate in the catalytic cycle. It is very possible that this species, simply denoted as $^{-}$H–Fe–Fe$^{-}$, is stabilised by hydrogen-bonded HP molecules or through follow-up reactions.

$$^{-}H - Fe - Fe - H^{-} + HP \xrightarrow{k_{f18}} {}^{-}H - Fe - Fe + H_2 + P^{-} \quad (R16)$$

$$^{-}H - Fe - Fe + HP \xrightarrow{k_{f19}} {}^{-}H - Fe - Fe(HP)$$

$$\xrightarrow{e} {}^{-}H - Fe - Fe^{-}(HP) \quad (R17)$$

$$^{-}H - Fe - Fe + 2HP \rightarrow {}^{-}Fe - Fe(HP)_2 + H \quad (R18)$$

$$^{-}H - Fe - Fe + e \rightarrow {}^{-}H - Fe - Fe^{-} \quad (R19)$$

This leads to the following situation: if the HP concentration is low, the current for the process P6 is governed by reactions (R16) and (R17), while the catalytic cycle [going from (R17) or (R18) back to (R13) or (R10), respectively] has a relatively small effect. The forward scan of the experimental CVs shown in Figure 8 can be reproduced very well for this limiting case by using $k_{f18} \approx 5 \times 10^6$ $M^{-1} s^{-1}$, $k_{f19} \leq 10^4$ $M^{-1} s^{-1}$ and the following charge transfer parameters for (R17) and (R19): $U^0 = -1.82$ V, $k^0 = 10^{-3}$ cm $s^{-1}$, $\alpha \approx 0.5$. However, because of the irreversibility of the reduction steps postulated in the catalytic cycle, the height of the curve for P2 is much smaller than that in the experimental CVs. Very good agreement for both scan segments can be attained if the product on the right-hand side of the last equation [R(19)] is reoxidised in two steps to **3**. As $^{-}$H–Fe–Fe$^{-}$ is formally a triply reduced iron species, a follow-up

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

reaction (maybe with the release of hydrogen) has to occur before, after or in a concerted way with the charge transfer. The standard potential(s) and the heterogeneous rate constant(s) for the two reoxidation steps are not critical as long as this pathway remains much faster (in the potential range associated with P2) than the return of the species into the catalytic cycle by reactions (R13) and (R14). The CVs simulated for this limiting case (under the same experimental conditions as those for Figure 8a) are shown in Figure 10.

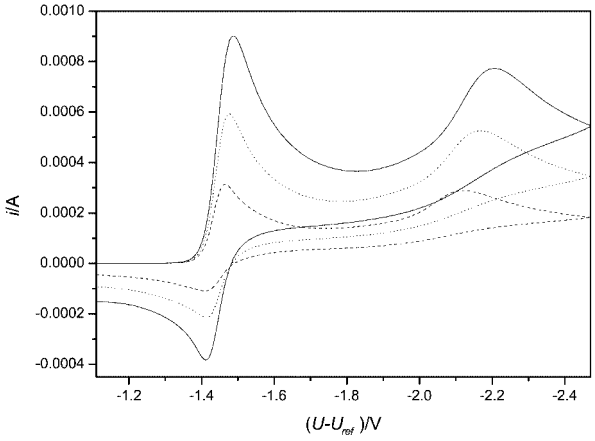

Figure 10. CVs simulated on the basis of (R13), (R14), (R17), (R18) and (R20) by using the same experimental conditions as those given for Figure 8 (a) and the kinetic parameters mentioned in the text.

By increasing the HP concentration, reactions (R17) or (R18) should be favoured, at the expense of reaction (R19). Consequently, the current for the process P6 should grow, while that for P2 becomes smaller. This exact result is observed in the experimental CVs shown in Figure 8 b. This effect and the fact that the height of the peak for P6 not only increases but also broadens when the HP concentration is doubled could be reproduced well in the simulated CVs shown in Figure 11.

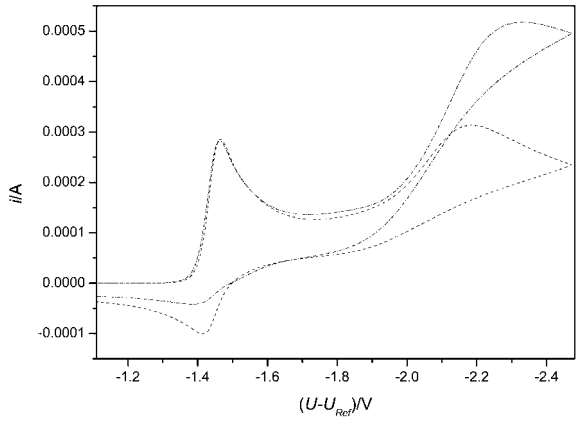

Figure 11. CVs simulated on the basis of (R13), (R14), (R17), (R18) and (R20) by using the same experimental conditions as those given for Figure 8b. Note, however, that different values for $k_{f18}$ and $k_{f19}$ were used in both curves to reproduce the most characteristic features of the experimental CVs.

However, the characteristic changes in the experimental CVs mentioned above could not be attained by repeating the simulations with twice the HP concentration with the same kinetic parameters as those for Figure 10. When the HP concentration is doubled, a simulated CV that matches the experimental CV was obtained with the parameters $k_{f18} \approx 10^5\ M^{-1}\,s^{-1}$ and $k_{f19} \approx 8 \times 10^6\ M^{-1}\,s^{-1}$ and by shifting the $U^0_{15}$ value in a positive direction by about 0.1 V (a similar effect can also be achieved by analogously shifting the $U^0_{21}$ value instead of varying $k_{f19}$).

In principle, this result is not surprising because only products derived from the 1:2 complex were considered to participate in the catalytic cycle. This means that the rate constants optimised in this way describe the overall effect of all HP complexes that can be activated in the catalytic cycle by reduction steps that are analogous to reactions (R13) and (R14). In the best case, such an approach applies to one particular HP concentration. Other more subtle effects may also play a role. For instance, the conditional standard potential for CPET reactions such as (R13) and (R14) is not independent of the HP concentration if the anions on both sides of the reaction are stabilised in different ways by hydrogen bonding to HP molecules. The results obtained on the basis of the simplified reaction scheme in this paper are therefore a promising first step worth pursuing in further studies.

## Conclusions

The present study shows that the heterocyclic compounds **1**, **6**, **10** and **13** react with $Fe_2(CO)_9$ (**2**) by insertion along the S–S bond to provide novel model complexes for [Fe-only]-hydrogenase. The structures of the resulting products are dependent on the ring size of the heterocycles: the reaction with 1,2,4-trithiolane (**1**) yields the diiron complex **3** that adopts a structure quite similar to $Fe_2(PDT)(CO)_6$, $Fe_2(ADT)(CO)_6$ and $Fe_2(ODT)(CO)_6$.[6a–6g,6i,6l] The seven- and eight-membered heterocycles **6** and **13** lead to the three-iron clusters **7** and **13** with intramolecular coordination of the thioether moiety. Furthermore, we have demonstrated that the nine-membered ring compound **10** delivers a diiron complex containing the coordinating thioether. The structures can be attributed to the different flexibilities of the heterocycles **1**, **6**, **10** and **13**.

The electrochemical reduction of **3** proceeds through two reversible, one-electron steps. The second step is faster and has a more positive standard potential than the first. The chemical reversibility of these processes is lost after a weak Brønsted acid is added. In the case of pivalic acid, the experimental CVs can be explained by assuming that either two undissociated HP molecules are strongly coordinated to the dianion by hydrogen bonds or a neutral species is formed by proton transfer. Additionally, up to three HP molecules may be weakly coordinated by hydrogen bonds, but no catalytic hydrogen generation is observed in the potential range in which the two-electron reduction occurs.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Hydride species (usually considered as the catalytically active species in the literature) are generated in two further one-electron reduction steps. However, unlike most of the systems reported in the literature,[28] the hydrides of **3** are produced in slow and irreversible charge-transfer processes, which result in a well-separated current peak at a distinctly more negative potential. The latter may be attributed to the particularly low acidity of pivalic acid in acetonitrile under anhydrous conditions. The shape of this peak and the scan rate dependence of its height are not in agreement with the postulation of a catalytic cycle in which the direct regeneration of the electrocatalytically active species is the rate-determining step. The experimental curves could be reproduced sufficiently well by assuming that a deactivation reaction in the form of an irreversible charge-transfer reaction proceeds simultaneously with the regeneration of the electrocatalytically active species.

## Experimental Section

**General:** The $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker DRX 200 or DRX 400 spectrometer by using the solvent as a standard. 2D NMR spectra were recorded with the DRX 400 spectrometer. The mass spectra were recorded with a FINNIGAN MAT SSQ 710 instrument. The IR spectra (KBr pellet technique) were recorded with a Thermoelectron Nicolet AVATAR 30070 DTGS or with a Biorad FTF 25 apparatus (ATR cuvettes for neat samples). 1,2,4-Trithiolane (**1**),[29] 1,2,5-trithiepane (**6**), 1,2,6-trithionane (**10**) and 1,2,5-trithiocane (**13**)[14] were prepared according to literature protocols. Elemental analyses were performed with a LECO CHNS-932 apparatus. Solvents and $Fe_2(CO)_9$ (**2**) were purchased from Sigma–Aldrich. Tetrahydrofuran (thf) was dried with sodium/benzophenone before use. Reported yields refer to the amount of purified products. For column chromatography Merck Silica gel 60 (0.015–0.040 mm) was used. Merck TLC aluminium sheets silica gel 60 $F_{254}$ were used for TLC.

**$Fe_2(SDT)(CO)_6$ (3):** Nonacarbonyldiiron (**2**) (2 g, 5.5 mmol) and 1,2,4-trithiolane (**1**) (227 mg, 1.83 mmol) were dissolved in thf (20 mL) and stirred at 65 °C for 15 min under argon. The colour of the light orange solution became deep red, and a brown solid (inorganic iron sulfides) precipitated. The reaction mixture was cooled to room temperature, and the solvent was removed under reduced pressure. The crude product was purified by column chromatography by using hexane as eluent. The orange fraction ($R_f$ = 0.5) was collected, and the solvent was removed. The product was obtained as a red-orange solid. Crystals suitable for X-ray diffraction analysis were obtained by slow evaporation of a concentrated pentane solution of **3** into hexane at 0 °C. Product **3** was also crystallised from a solution of hexane at –25 °C. Yield 279 mg (37.8%). $C_8H_4Fe_2O_6S_3$ (404): calcd. C 23.78, H 0.99, S 23.81; found C 23.81, H 1.26, S 23.48. $^1H$ NMR (200 MHz, $CDCl_3$, 25 °C): $\delta$ = 3.21 (s, 4 H, C$H_2$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): $\delta$ = 27.7 (*C*$H_2$), 206.79 (*C*O) ppm. FTIR (KBr): $\tilde{\nu}$ = 2075 (s), 2027 (s), 1999 (vs, $\nu$CO, terminal) $cm^{-1}$. MS (DEI = 70 eV): *m*/*z* (%) = 404 (16) [$M^+$], 376 (100) [$M^+$ – 28; CO], 348 (70) [$M^+$ – 56; 2 CO], 320 (46) [$M^+$ – 84; 3 CO], 292 (17) [$M^+$ – 112; 4 CO], 264 (42) [$M^+$ – 140; 5 CO], 236 (58) [$M^+$ – 168; 6 CO], 208 (58) [264 – 56; Fe], 176 (26) [208 – 32; S], 144 (68) [176 – 32; S], 122 (12) [144 – 32; S], 78 (8) [$CH_2S_2$], 56 (26), 45 (12) [CHS].

**$Fe_3(BTES)(CO)_9$ (7):** Nonacarbonyldiiron (**2**) (1.49 g, 4.08 mmol) and 1,2,5-trithiepane (**6**) (207 mg, 1.36 mmol) in thf (15 mL) were stirred at 65 °C for 15 min under argon. The colour of the light orange solution became deep green, and a brown solid (mixture of inorganic iron sulfides) precipitated. The reaction mixture was cooled to room temperature, and the solvent removed under reduced pressure. The crude brown product was purified by column chromatography with diethyl ether as eluent. The dark green fraction ($R_f$ = 0.5) was collected, and the solvent removed. The product was obtained as a dark green solid. Crystals suitable for X-ray diffraction analysis were obtained by slow evaporation of a concentrated ether solution of **7** into hexane at 0 °C. Yield 327 mg (41.4%). $C_{13}H_8Fe_3O_9S_3$ (571.93): calcd. C 27.30, H 1.41, S 16.82; found C 27.26, H 1.65, S 16.65. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.69 (ddd, $^2J_{AB}$ = 13.4, $^3J_{AC}$ = 19.6, $^3J_{AD}$ = 5.2 Hz, 2 H, $H_BH_ACSCH_AH_B$), 2.34 (ddd, $^2J_{CD}$ = 13.7, $^3J_{CA}$ = 19.6, $^3J_{CB}$ = 6.9 Hz, 2 H, $SCH_CH_D$), 3.13 (dd, $^2J_{AB}$ = 13.4, $^3J_{BC}$ = 6.9 Hz, 2 H, $H_BH_ACSCH_AH_B$), 3.27 (dd, $^2J_{CD}$ = 13.7, $^3J_{DA}$ = 5.2 Hz, 2 H, $SCH_CH_D$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): $\delta$ = 39.7 ($CH_2SCH_2$), 45.6 ($SCH_2CH_2$), 202.5, 208.6, 211.1, 211.8, 213.7 (*C*O) ppm. FTIR (KBr): $\tilde{\nu}$ = 2073 (s), 2033 (vs), 1958 (vs, $\nu$CO, terminal) $cm^{-1}$. FTIR (ATR cuvette): $\tilde{\nu}$ = 2071 (s), 2034 (m), 2021 (m), 2001 (s), 1974 (s), 1968 (s), 1953 (s), 1939 (s, $\nu$CO, terminal) $cm^{-1}$. MS (DEI = 70 eV): *m*/*z* (%) = 572 (2) [$M^+$], 544 (1) [$M^+$ – 28; CO], 516 (3) [$M^+$ – 56; 2 CO], 488 (2) [$M^+$ – 84; 3 CO], 460 (2) [$M^+$ – 112; 4CO], 432 (2) [$M^+$ – 140; 5CO], 404 (5) [$M^+$ – 168; 6 CO], 376 (12) [$M^+$ – 196; 7 CO], 348 (12) [$M^+$ – 224; 8 CO], 316 (10) [$M^+$ – 252; 9 CO].

**$Fe_2(BTPS)(CO)_5$ (11):** Nonacarbonyldiiron (**2**) (1.01 g, 2.77 mmol) and 1,2,6-trithionane (**10**) (166 mg, 0.92 mmol) in thf (15 mL) were stirred for 15 min at 65 °C under argon. The colour of the light orange solution became red-brown, and a brown solid (inorganic iron sulfides) precipitated. The reaction mixture was cooled to room temperature, and the solvent removed under reduced pressure. The crude brown product was purified by column chromatography with diethyl ether as eluent. The red-brown fraction ($R_f$ = 0.6) was collected, and the solvent removed. Product **11** was a brown solid, which was crystallised from a solution of hexane at –25 °C. Yield 56 mg (14.1%). $C_{11}H_{12}Fe_2O_5S_3$ (432.09): calcd. C 30.58, H 2.80, S 22.26; found C 31.03, H 3.15, S 22.02. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.32 [m, 1 H, $H_BH_AC(6)SCH_AH_B$], 2.12 [ddd, $^2J$ = 15.5, $^3J$ = 10.1, $^3J$ = 4.5 Hz, 1 H, $H_BH_AC(6)SCH_AH_B$], 2.23 [t, $^2J$ = 11.8 Hz, 1 H, $CH_2C(5)H_CH_DCH_2$], 2.33–2.40 [m, 2 H, $CH_2C(5)H_CH_DCH_2$ and $SC(4)H_EH_F$], 2.44 [ddd, $^2J$ = 12.3, $^3J$ = 7.9, $^3J$ = 3.7 Hz, 2 H, $H_BH_AC(1)SCH_AH_B$], 2.76–2.87 [m, 3 H, $CH_2C(2)H_CH_DCH_2$ and $SC(3)H_EH_F$], 2.96 [ddd, $^2J$ = 11.8, $^3J$ = 7.4, $^3J$ = 3.7 Hz, 1 H, $SC(3)H_EH_F$], 3.19 [ddd, $^2J$ = 14.3, $^3J$ = 5.6, $^3J$ = 2.8 Hz, 1 H, $H_BH_AC(4)SCH_AH_B$] ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): $\delta$ = 18.9 [*C*(5)], 27.0 [*C*(2)], 28.41, 28.47 [*C*(1), *C*(6)], 36.7 [*C*(3)], 37.6 [*C*(4)], 209.7, 211.9, 213.9 (*C*O) ppm. FTIR (ATR cuvette): $\tilde{\nu}$ = 2040 (s), 1952 (vs), 1906 (vs, $\nu$CO, terminal) $cm^{-1}$. MS (DEI = 70 eV): *m*/*z* (%) = 432 (10) [$M^+$], 404 (18) [$M^+$ – 28; CO], 376 (28) [$M^+$ – 56; 2 CO], 348 (46) [$M^+$ – 84; 3 CO], 320 (52) [$M^+$ – 112; 4 CO], 292 (97) [$M^+$ – 140; 5 CO].

**$Fe_3(S(CH_2)_2S(CH_2)_3S)(CO)_8$ (13):** Nonacarbonyldiiron (**2**) (1.315 g, 3.6 mmol) and 1,2,5-trithiocane (**12**) (200 mg, 1.2 mmol) in thf (20 mL) were stirred for 15 min at 65 °C under argon. The colour of the light orange solution became red-brown, and a brown solid (inorganic iron sulfides) precipitated. The reaction mixture was cooled to room temperature, and the solvent was removed under reduced pressure. The crude red-brown product was purified by column chromatography using diethyl ether as eluent. The main orange fraction ($R_f$ = 0.9) was identified as complex **8** (yield:

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

154 mg, 34.5%), and the yield of the nonidentified green fractions was 57 mg. The red-brown fraction ($R_f$ = 0.13) was collected, the solvent was removed and compound **13** was obtained as a red-brown solid. Crystals suitable for X-ray diffraction analysis were obtained by slow evaporation of pentane into a concentrated solution of **13** in chloroform at 0 °C. Yield 46 mg (6.8%). $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.64 [m, 1 H, $H_BH_AC(2)SCH_AH_B$], 2.48 [m, $^2J$ = 15.5, $^3J$ = 10.1, $^3J$ = 4.5 Hz, 1 H, $H_BH_AC(2)$-$SCH_AH_B$], 2.83–2.95 [m, 2 H, $CH_2C(4)H_CH_DCH_2$ and $H_BH_AC(3)$-$SCH_AH_B$], 3.10 [m, 1 H, $SC(5)H_EH_F$], 3.24 [m, 1 H, $H_BH_AC(4)$-$SCH_AH_B$], 3.44 [m, 1 H, $SC(5)H_EH_F$], 3.59 [m, 1 H, $SC(1)H_CH_D$], 3.68 [m, 1 H, $H_BH_AC(3)SCH_AH_B$], 3.88 [m, 1 H, $SC(1)H_CH_D$] ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): $\delta$ = 25.4 [C(4)], 31.7 [C(3)], 34.5 [C(2)], 34.7 [C(3)], 36.9 [C(5)], 214.8 (*C*O) ppm. FTIR (ATR cuvette): $\tilde{\nu}$ = 2053 (s), 1982 (vs), 1962 (vs), 1938 (vs), 1920 (vs, $\nu$CO, terminal) cm$^{-1}$. MS (DEI = 70 eV): *m*/*z* (%) = 558 (2) [M$^+$], 530 (9) [M$^+$ – 28; CO], 502 (15) [M$^+$ – 56; 2 CO], 474 (5) [M$^+$ – 84; 3 CO], 446 (15) [M$^+$ – 112; 4 CO], 418 (48) [M$^+$ – 140; 5 CO].

**Electrochemistry – Instrumentation and Procedures:** Cyclic voltammetric measurements were conducted using a three-electrode technique with a home-built computer-controlled device based on a PCI 6110-E data acquisition board (National Instruments). The measurements were performed in acetonitrile (containing 0.25 M tetra-*n*-butylammonium perchlorate) under a blanket of solvent-saturated argon. The ohmic resistance, which had to be compensated for, was determined by measuring the impedance of the system at potentials where the faradaic current was negligibly small. Background correction was accomplished by subtracting the CVs of the blank electrolyte (containing the same concentration of supporting electrolyte) from the experimental CVs. The reference electrode was an Ag|AgCl electrode in acetonitrile containing 0.25 M tetra-*n*-butylammonium chloride. As recommended by IUPAC,[19] all data reported in this paper were referenced to the ferrocenium/ferrocene couple; the measurements were taken at the end of the experiments. The working electrode was a hanging mercury drop (*m* = 2.79 mg) produced by a CGME instrument (Bioanalytical Systems, Inc., West Lafayette, USA).

Theoretical CVs were simulated by using the DigiElch simulation package (www.DigiElch.de). The simulation algorithm used in this program has been described previously.[20]

Unless otherwise stated, all charge-transfer coefficients were assumed to be 0.5, and the diffusion coefficients of all iron species postulated in the reaction schemes were set to $(1.02 \pm 0.03) \times 10^{-5}$ cm$^2$ s$^{-1}$. This is the value determined for **3**. The diffusion coefficient of pivalic acid was estimated to be $2.5 \times 10^{-5}$ cm$^2$ s$^{-1}$.

In a typical series of experiments, about 0.002 mol L$^{-1}$ of the complex was employed for the measurements consisting of seven scan rates ranging from 5 to 200 V s$^{-1}$ and six different HP concentrations ranging from 0.01 to 0.2 mol L$^{-1}$. All experimental curves were then used for finding a suitable mechanism by making use of DigiElch's nonlinear regression procedure. The standard deviation between simulated and experimental CVs was normalised with respect to the maximum peak current found in the experimental CV. Hence, an overall standard deviation of $s$ = 0.01 means that the average difference between the simulated and experimental CVs is 1% of the (average) peak current.

**Crystal Structure Determination:** The intensity data for the compounds were collected with a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz and polarisation effects, but not for absorption effects.[30,31] The structures were solved by direct methods (SHELXS[32]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELXL-97[33]). For compound **10**, the hydrogen atoms were located by difference Fourier synthesis and refined isotropically. For other compounds, the hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[32] The XP software (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

**Crystal Data for 3:** $C_8H_4Fe_2O_6S_3$, $M_r$ = 403.99 g mol$^{-1}$, red-brown prism, size 0.03 × 0.03 × 0.02 mm, monoclinic, space group $P2_1/m$, $a$ = 6.8211(3), $b$ = 13.3393(7), $c$ = 7.8888(3) Å, $\beta$ = 107.898(3)°, $V$ = 683.05(5) Å$^3$, $T$ = –90 °C, $Z$ = 2, $\rho_{calcd.}$ = 1.964 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 25.96 cm$^{-1}$, $F$(000) = 400, 4305 reflections in $h$(–8/7), $k$(–17/16), $l$(–9/10), measured in the range 2.71° ≤ $\Theta$ ≤ 27.46°, completeness $\Theta_{max}$ = 99.8%, 1630 independent reflections, $R_{int}$ = 0.033, 1389 reflections with $F_o > 4\sigma(F_o)$, 83 parameters, 0 restraints, $R1_{obs}$ = 0.025, $wR_{2obs}$ = 0.060, $R1_{all}$ = 0.034, $wR_{2all}$ = 0.063, GOF = 1.029, largest difference peak and hole: 0.352/–0.541 e Å$^{-3}$.

**Crystal Data for 7:** $C_{13}H_8Fe_3O_9S_3$, $M_r$ = 571.92 g mol$^{-1}$, black prism, size 0.03 × 0.03 × 0.01 mm, orthorhombic, space group $P2_12_12_1$, $a$ = 8.5561(3), $b$ = 13.8497(7), $c$ = 16.5594(6) Å, $V$ = 1962.28(14) Å$^3$, $T$ = –90 °C, $Z$ = 4, $\rho_{calcd.}$ = 1.936 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 25.51 cm$^{-1}$, $F$(000) = 1136, 13746 reflections in $h$(–11/10), $k$(–16/17), $l$(–21/21), measured in the range 1.92° ≤ $\Theta$ ≤ 27.48°, completeness $\Theta_{max}$ = 99.8%, 4485 independent reflections, $R_{int}$ = 0.123, 3575 reflections with $F_o > 4\sigma(F_o)$, 253 parameters, 0 restraints, $R1_{obs}$ = 0.063, $wR_{2obs}$ = 0.150, $R1_{all}$ = 0.085, $wR_{2all}$ = 0.164, GOF = 1.049, Flack-parameter –0.01(3), largest difference peak and hole: 1.417/–1.033 e Å$^{-3}$.

**Crystal Data for 10:** $C_6H_{10}S_3$, $M_r$ = 178.32 g mol$^{-1}$, colourless prism, size 0.10 × 0.10 × 0.06 mm, monoclinic, space group $P2_1/c$, $a$ = 9.4696(6), $b$ = 12.4325(9), $c$ = 7.8849(3) Å, $\beta$ = 113.932(3)°, $V$ = 848.49(9) Å$^3$, $T$ = –90 °C, $Z$ = 4, $\rho_{calcd.}$ = 1.396 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 7.88 cm$^{-1}$, $F$(000) = 376, 5708 reflections in $h$(–12/11), $k$(–14/16), $l$(–9/10), measured in the range 2.35° ≤ $\Theta$ ≤ 27.49°, completeness $\Theta_{max}$ = 99.1%, 1937 independent reflections, $R_{int}$ = 0.045, 1346 reflections with $F_o > 4\sigma(F_o)$, 91 parameters, 0 restraints, $R1_{obs}$ = 0.041, $wR_{2obs}$ = 0.097, $R1_{all}$ = 0.072, $wR_{2all}$ = 0.112, GOF = 1.040, largest difference peak and hole: 0.272/–0.374 e Å$^{-3}$.

**Crystal Data for 11:** $C_{11}H_{12}Fe_2O_5S_3$, $M_r$ = 432.09 g mol$^{-1}$, red-brown prism, size 0.06 × 0.06 × 0.05 mm, monoclinic, space group $P2_1/c$, $a$ = 10.2933(5), $b$ = 9.3713(4), $c$ = 16.2889(6) Å, $\beta$ = 90.898(3)°, $V$ = 1571.06(12) Å$^3$, $T$ = –90 °C, $Z$ = 4, $\rho_{calcd.}$ = 1.827 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 22.59 cm$^{-1}$, $F$(000) = 872, 10241 reflections in $h$(–13/12), $k$(–12/10), $l$(–20/20), measured in the range 1.98° ≤ $\Theta$ ≤ 27.48°, completeness $\Theta_{max}$ = 99.2%, 3567 independent reflections, $R_{int}$ = 0.047, 2681 reflections with $F_o > 4\sigma(F_o)$, 190 parameters, 0 restraints, $R1_{obs}$ = 0.033, $wR_{2obs}$ = 0.069, $R1_{all}$ = 0.0560, $wR_{2all}$ = 0.078, GOF = 0.967, largest difference peak and hole: 0.361/–0.445 e Å$^{-3}$.

**Crystal Data for 13:** $C_{13}H_{10}Fe_3O_8S_3$, $M_r$ = 557.94 g mol$^{-1}$, red-brown prism, size 0.05 × 0.05 × 0.05 mm, monoclinic, space group $P2_1/c$, $a$ = 13.8117(6), $b$ = 9.5857(4), $c$ = 14.9198(7) Å, $\beta$ = 100.243(4)°, $V$ = 1943.82(15) Å$^3$, $T$ = –90 °C, $Z$ = 4, $\rho_{calcd.}$ = 1.907 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 25.68 cm$^{-1}$, $F$(000) = 1112, 12736 reflections in $h$(–16/17), $k$(–11/12), $l$(–19/17), measured in the range 3.07° ≤ $\Theta$ ≤ 27.49°, completeness $\Theta_{max}$ = 99.1%, 4422 independent reflections, $R_{int}$ = 0.052, 3214 reflections with $F_o > 4\sigma(F_o)$, 244 parameters, 0 restraints, $R1_{obs}$ = 0.046, $wR_{2obs}$ = 0.101, $R1_{all}$ = 0.076, $wR_{2all}$ = 0.112, GOF = 1.021, largest difference peak and hole: 1.084/–0.638 e Å$^{-3}$.

# Use of the Sulfato Ligand in 3d-Metal Cluster Chemistry: A Family of Hexanuclear Nickel(II) Complexes with 2-Pyridyl-Substituted Oxime Ligands

**Constantina Papatriantafyllopoulou,[a] Guillem Aromi,[b] Anastasios J. Tasiopoulos,[c] Vassilios Nastopoulos,[a] Catherine P. Raptopoulou,[d] Simon J. Teat,*[e] Albert Escuer,*[b] and Spyros P. Perlepes*[a]**

**Keywords:** Nickel(II) clusters / Magnetic properties / Sulfato complexes / Oxime complexes

The initial use of 2-pyridyl-substituted oximes [(py)C(R)-NOH; R = Me, Ph]/sulfate blend in nickel(II) chemistry has yielded a family of hexanuclear clusters. The syntheses, structures and magnetic properties are reported of $[Ni_6(SO_4)_4(OH)\{(py)C(Me)NO\}_3\{(py)C(Me)NOH\}_3(MeOH)_2(H_2O)]$ (**1**), $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(MeOH)_3]$ (**2**) and $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(H_2O)_3]$ (**3**), where (py)C(Me)NOH is methyl 2-pyridyl ketone oxime and (py)C(ph)NOH is phenyl 2-pyridyl ketone oxime. The hexanuclear molecules present in the three complexes have similar structures which contain the $[Ni_6(\mu_3\text{-}OH)(\mu_3\text{-}SO_4)_3(\mu_3\text{-}ONR)_3]^{2+}$ core. The core consists of six $Ni^{II}$ ions arranged as two parallel equilateral triangular subunits, one small (Ni···Ni ca. 3.3 Å) and the other larger (Ni···Ni ca. 6.0 Å). Characteristic IR bands are discussed in terms of the known structures of **1**–**3**. The magnetic properties of **1** and **2** have been studied by variable-temperature dc magnetic susceptibility techniques which indicate antiferromagnetic interactions. A simple 2-*J* model was found to be adequate to describe the similar thermal variation of the molar magnetic susceptibilities of **1** and **2**.

## Introduction

There continues to be a great interest in the synthesis and physicochemical study of polynuclear metal complexes (clusters) containing paramagnetic metal ions. Among the reasons for this is the search for various nuclearity oxido-bridged metal clusters to model $M_x$ sites in biomolecules.[1] In addition, 3d-metal clusters often display interesting and sometimes novel magnetic properties, including high ground state spin values, currently up to $S = 83/2$,[2] and single-molecule magnetism (SMM) behavior.[3] Crucial to such efforts and others is the continuing development of new synthetic procedures to polynuclear species. However, there is no obvious and guaranteed route to such species.[4] The lack of control has led to the neologism "self-assembly" being introduced.

In recent years several groups have been introducing an element of design into the assembly process by choosing rigid ligands with predictable and controllable binding modes.[5–7] Other researchers use a complementary approach named "serendipitous assembly",[8] where the variables in the reaction system are modified following certain rationales to influence the product found, rather than to control or design the target molecule. Since it is clear that inorganic chemists cannot simply trust to luck in preparing metal clusters, there has to be considerable forethought in the ligands, metals and conditions used for any significant progress to be made.[9]

With the points mentioned above in mind, and in the context of "serendipitous assembly",[8] our group[10] and others[11] have been exploring "ligand blend" reactions involving the monoanions $(py)C(R)NO^-$ of various 2-pyridyl-substituted oximes[12] [Figure 1; R can be a non-donor group or a group containing an extra donor site, i.e. a second 2-pyridyl group in the particular case of di-2-pyridyl ketone oximate $(py)_2CNO^-$] *and* carboxylates, *with* or *without* additional inorganic monoanions ($Cl^-$, $Br^-$, $NO_3^-$, $N_3^-$, $SCN^-$), with the belief that they might foster formation of transition-metal clusters. The immense structural diversity displayed by the complexes reported stems in part from the ability of $(py)C(R)NO^-$ to exhibit many distinct bridging coordination modes. Employment of additional inorganic monoanions with a good coordination capacity gives an ex-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

traordinary structural versatility in the *ternary* ligand systems. Thus, the (py)C(R)NO$^-$/R′CO$_2^-$ (R = H, Me, Ph, py; R′ = H, Me, Et, Ph) "blends", without or with additional inorganic anions (Cl$^-$, Br$^-$, NO$_3^-$, N$_3^-$, SCN$^-$) have led to a variety of Cr, Mn, Fe, Co, Ni and Cu clusters[10–12] with nuclearities ranging from 3 to 12 and with interesting magnetic properties, including SMM behavior.[10h,10n]

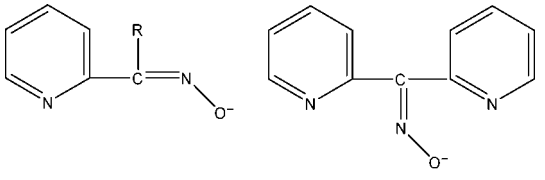

Figure 1. The structural formulae and abbreviations of the ligands discussed in the text.

Very recently we decided to begin a program which can be considered as a modification of the above *binary* ligand system approach. We have been exploring the use of the sulfato ligand, $SO_4^{2-}$, instead of the carboxylato ligand, R′CO$_2^-$. The great coordinative flexibility and versatility of the (py)C(R)NO$^-$ ligands, as well as the $\mu_2$, $\mu_3$, $\mu_4$, $\mu_5$ or $\mu_6$ potential of $SO_4^{2-}$ (Figure 2),[13] prompted as to combine the 2-pyridyl oximates with the sulfate ligand to aim for new types of clusters. Our belief was that the simultaneous employment of the two ligand types in 3d-metal chemistry would give structural flexibility in the (py)C(R)NO$^-$/$SO_4^{2-}$ "blends". The possible advantages of using $SO_4^{2-}$ instead of R′CO$_2^-$ include (i) the possibility of triggering aggregation of preformed smaller cationic species[14] containing *only* (py)C(R)NO$^-$ into new, higher-nuclearity products, and (ii) the possible diversion of known reaction systems developed using *mono*anionic carboxylates to new species as a result of the higher charge and higher denticity/bridging capability of sulfates.

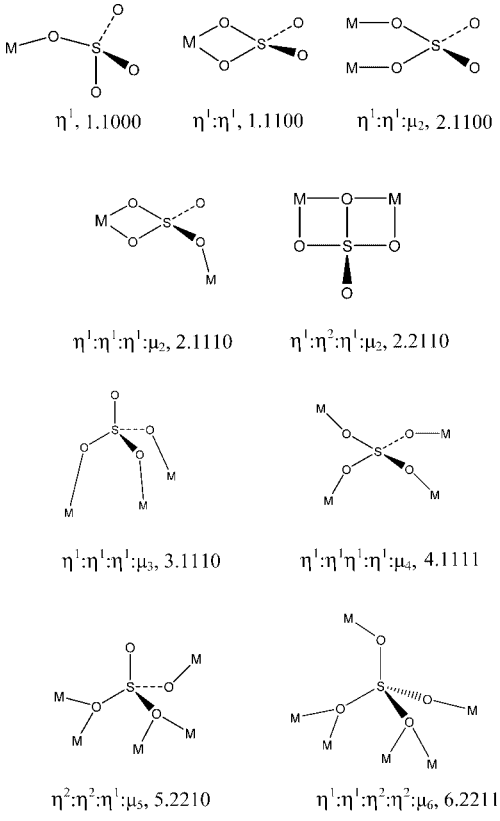

Figure 2. The up to now crystallographically established coordination modes of the sulfato ligand, and the η/μ and Harris[21] notations which describe these modes. The novel $\eta^1$:$\eta^2$:$\mu_3$ (3.2100) ligation mode that appears in the clusters described here is not included (see Figure 4).

The sulfate ion is currently a ligand of intense interest.[13,15] Somewhat to our surprise, the sulfato ligand has not been used in transition-metal cluster chemistry. On the other hand, there is currently a renewed interest in the coordination chemistry of oximes.[16] 2-Pyridyl-substituted oximes are a subclass of oxime ligands, currently very popular in several aspects of coordination chemistry.[12,16c,17]

We herein report the first use of $SO_4^{2-}$ in 3d-metal/2-pyridyloximate chemistry. We describe synthetic procedures to a family of novel hexanuclear Ni$^{II}$/$SO_4^{2-}$/(py)C(R)NO$^-$ (R = Me, Ph) complexes, which have been characterized by single-crystal X-ray crystallography and IR spectroscopy; the magnetic properties of two representative complexes are also described and analyzed. With one exception,[18] the prepared compounds are the first Ni$^{II}$/$SO_4^{2-}$ clusters that appear in the literature. Moreover, they allow the initial assessment of ligation tendencies of the $SO_4^{2-}$ ion in the coordination chemistry of 2-pyridyl-substituted oximes.

## Results and Discussion

### Synthesis and IR Characterization

The original aim of this synthetic program was to explore the versatile bridging potential of the binary (py)C(R)NO$^-$/$SO_4^{2-}$ system for the assembly of Ni$^{II}$ ions into clusters with novel structures and magnetic properties. Our general synthetic approach for the isolation of heteroleptic Ni$^{II}$ clusters was to treat an excess of the metal sulfate with (py)C(R)NOH (R = Me, Ph) and a base in MeOH. The addition of base is necessary for the deprotonation of the organic ligand. Note that reactions in the absence of base lead to complexes [Ni(SO$_4$){(py)C(Me)NOH}(H$_2$O)$_3$], [Ni(SO$_4$)-{(py)C(Me)NOH}$_2$(H$_2$O)], [Ni$_2$(SO$_4$)$_2${(py)C(ph)NOH}$_4$] and [Ni{(py)C(ph)NOH}$_3$](SO$_4$)[19] that contain the neutral ligands.

Treatment of NiSO$_4$·6H$_2$O with one equivalent of (py)C(Me)NOH and one equivalent of NaOMe in MeOH gave a green solution from which the hexanuclear cluster [Ni$_6$(SO$_4$)$_4$(OH){(py)C(Me)NO}$_3${(py)C(Me)NOH}$_3$(MeOH)$_2$(H$_2$O)] (**1**) was obtained in 65% yield. The methoxide ions act as proton acceptors to facilitate formation of OH$^-$ and (py)C(Me)NO$^-$ ligands. Reactions with small variations in the Ni$^{II}$/(py)C(Me)NOH ratio gave the same Ni$_6$ compound **1**. As expected, the nature of the base is not crucial for the identity of the product; we were able to isolate

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**1** by using a plethora of bases such as $NEt_3$, $NMe_4OH$, $NEt_4OH$, $LiOH·H_2O$ etc. (see Method B in the Experimental Section). Because cluster **1** has a $Ni^{II}$/organic ligand ratio of 1:1, we wondered whether the hexanuclear complex could be prepared by the reaction of $[Ni(SO_4)\{(py)C(Me)NOH\}(H_2O)_3]$ with the appropriate amount of the base. The conversion of the mononuclear to the hexanuclear complex can be accomplished easily by treatment of the former with the stoichiometric amount of $LiOH·H_2O$ in MeOH at 35–40 °C.

We initially came across complexes $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(MeOH)_3]$ (**2**) and $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(H_2O)_3]$ (**3**) when we tried to prepare the $(py)C(ph)NO^-$/(py)C(ph)NOH analog of complex **1**. The 1:1:1 $NiSO_4·6H_2O$/(py)C(ph)NOH/NaOMe reaction mixture in MeOH gave an orange solution, which upon layering with $Et_2O$ yielded crystals that were obviously a mixture of two products. Microscopic examination showed both greenish-yellow prisms and yellow plates to be present in a visual ratio of roughly 1:1. Their not-too-dissimilar solubility prevented chemical separation; however, the differences in color and crystal shape allowed easy manual separation of the two materials. The prismatic and plate-like crystals were crystallographically identified as complexes **2**·3.2 MeOH·1.5 $H_2O$ and **3**·3 $H_2O$, respectively.

With the identities of **2** and **3** established, convenient syntheses of pure materials were sought under alternative reaction conditions. This was not possible for **2**. Thus, the manual separation of the prismatic crystals from their above-described mixture with **3** remains the only source of complex **2** to date for further measurements. Complex **3** has $H_2O$ molecules as the only solvate ligands; thus attempts to obtain pure **3** were made by adding $H_2O$ in the reaction mixture. Working with an 8:2 (v/v) MeOH/$H_2O$ solvent mixture, we were lucky enough to isolate the yellow plates of **3** as the only product. It is likely that factors such as

relatively solubility, lattice energy, crystallization kinetics and nature of the cation of the base, amongst others, determine the identity of the isolated product.

Two features of the reactions deserve comments. First, the reaction mixtures which lead to **1**–**3** should be filtered before crystallization to remove $Na_2SO_4$ or $Li_2SO_4$ which are insoluble in MeOH; the filtration is not necessary for the preparation of pure **3**. The products also need to be washed with a small amount of $H_2O$ to ensure complete removal of the alkali sulfate. Second, the addition of counter anions such as $ClO_4^-$ and $PF_6^-$ (for the isolation of potentially existing cationic species) and the crystallization method have no influence on the identity of the products.

The IR spectra of air-dried samples of complexes **1**, **2** and **3** exhibit a shoulder at 3430–3400 $cm^{-1}$ and one broad band of medium intensity at 3410–3255 $cm^{-1}$ assignable to ν(OH) vibrations of $OH^-$, (py)C(R)NOH, $H_2O$ and/or MeOH. Complexes **1**–**3** have $C_1$ symmetry at their sulfato ligands. The bands at about 1180–1150, 1130 and 1030 $cm^{-1}$ are therefore attributed[20] to the $\nu_3$ modes, while the bands at about 690, 630 and 590 $cm^{-1}$ are assigned[20] to the $\nu_4$ modes with the higher wavenumber band being superimposed by ligands' vibrations. The band at 1652 (**1**) and ca. 1600 (**2**, **3**) is assigned to the oximate ν(C=N) vibrational mode;[9d] in **2** and **3** this band may also have an aromatic stretch character. The appearance of many bands in the 1200–1000 $cm^{-1}$ region and possible overlap with the sulfato stretching vibration renders exact assignments of the two expected[14c] ν(N–O) modes difficult; a strong band at 1070 (**1**) and ca. 1050 (**2**, **3**) $cm^{-1}$ is a serious candidate for this vibration.[14a,14b]

## Description of Structures

Partially labelled plots of the hexanuclear molecules present in **1**·2.53 MeOH·1.60 $H_2O$, **2**·3.2 MeOH·1.5 $H_2O$ and **3**·3 $H_2O$ are shown in Figures 3, 7 and 8, respectively. Selected interatomic distances and angles are listed in Tables 1, 2 and 3. Tables 4, 5 and 6 summarize intracluster hydrogen bonding data for the three complexes. The molecu-

Table 2. Selected interatomic distances [Å] and angles [°] for $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(MeOH)_3]$·3.2 MeOH·1.5 $H_2O$ (**2**·3.2 MeOH·1.5 $H_2O$).

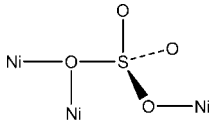
In the following the binding modes of the various ligands will be often described using Harris notation.[21] Occasionally we shall use the widely approved notation based on the Greek letters μ and η.

Complex **1**·2.53 MeOH·1.60 $H_2O$ crystallizes in the monoclinic space group $P2_1/n$. Its structure consists of hexanuclear $[Ni_6(SO_4)_4(OH)\{(py)C(Me)NO\}_3\{(py)C(Me)NOH\}_3(MeOH)_2(H_2O)]$ molecules, and MeOH and $H_2O$ solvate molecules; the latter two will not be further discussed. If we assume that the nitrogen atoms of the $\mu_3$ oximate groups and the terminal oxygen atoms of the 3.2100 sulfato ligands (Figure 4) contribute to the core formation, the molecule of **1** contains the $[Ni_6(\mu_3\text{-}OH)(\mu_3\text{-}SO_4)_3(\mu_3\text{-}ONR)_3]^{2+}$ core; an alternative description of the core (using only the bridging oxygen atoms) is $[Ni_6(\mu_3\text{-}OH)(\mu\text{-}OR')_3(\mu\text{-}OR'')_3]^{2+}$, where R′ = $SO_3$ and R″ = NC(py)(Me). The topology of the core consists of six $Ni^{II}$ ions arranged as two parallel (Figure 5), near-equilateral triangular subunits, one "small" and the other "large". The metal ions in the small triangle [defined by Ni(1), Ni(2) and Ni(3)] are held together by the $\mu_3$-$OH^-$ ligand [O(23)] and one $\eta^1{:}\eta^1{:}\eta^1{:}\mu_3$ (or 3.1110,[21] Figure 2) sulfato group. Each $Ni_2$ edge is additionally bridged by one diatomic oximate group from one 3.211 (py)C(Me)$NO^-$ ligand (Figure 6). Each $Ni_2$ edge of the large triangle [defined by Ni(4), Ni(5) and Ni(6)] is bridged by two oxygen atoms of one $\eta^1{:}\eta^2{:}\mu_3$ (or 3.2100, Figure 4) sulfato ligand. Each apex of the small triangular unit is linked to an apex of the large triangular unit by two monoatomic oxygen bridges from one 3.2100 $SO_4^{2-}$ ion and one 3.211 (py)C(Me)$NO^-$ ligand, and to another apex of the large triangle by the diatomic oximate group of one 3.211 pyridyloximate ligand already used to bridge a $Ni_2$ edge of the small triangle. One bidentate chelating (py)-C(Me)NOH molecule (1.011, Figure 6) and one terminal solvate ligand [MeOH at Ni(5) and Ni(6), $H_2O$ at Ni(4)] complete six-coordination at each metal center of the large triangle.



$\eta^1{:}\eta^2{:}\mu_3$, 3.2100

Figure 4. The new $\eta^1{:}\eta^2{:}\mu_3$ (3.2100) coordination mode of the $SO_4^{2-}$ ion which has been crystallographically identified in complexes **1**–**3**.

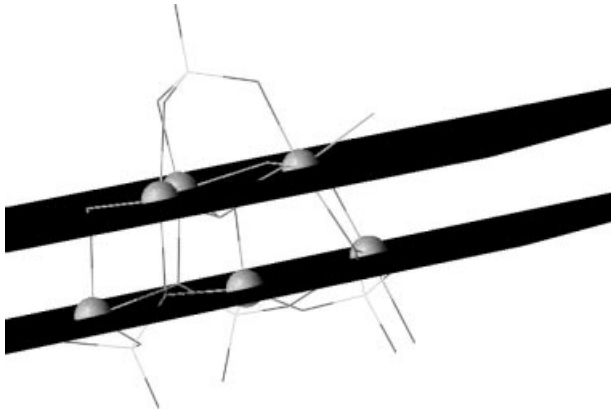


Figure 5. A view of **1** emphasizing the parallel $Ni_3$ planes.

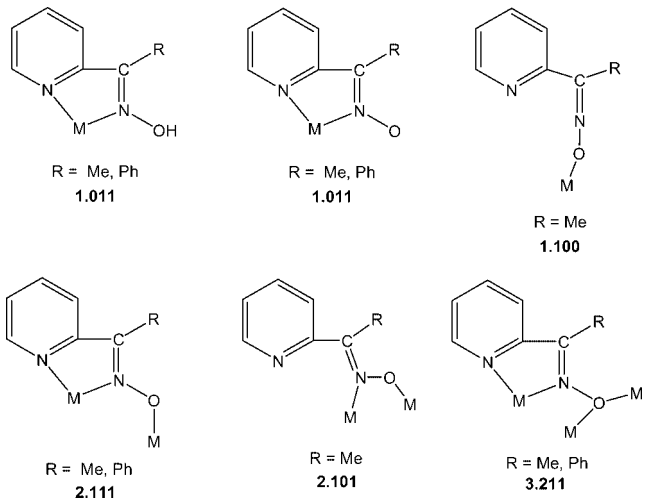

Figure 6. The up to now crystallographically established coordination modes of the ligands (py)C(ph)NOH, (py)C(ph)$NO^-$, (py)-C(Me)NOH and (py)C(Me)$NO^-$, and the Harris notation[21] that describes these modes. The 3.211 ligation mode of (py)C(Me)$NO^-$ is new and has identified for the first time in complex **1**.

Using the perspective view of Figure 5, the $\mu_3$-OH oxygen atom O(23) is 0.633 Å below the $Ni_3$ plane that it bridges [Ni(1)Ni(2)Ni(3)], i.e. the hydroxido ligand is between the almost parallel planes (dihedral angle: 0.6°) defined by the two triangular subunits. The distance between the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

planes is 2.182 Å. The small triangle can be viewed as an inverse 9-metallacrown-3 subunit.[9i]

The $Ni^{II}\cdots Ni^{II}$ separations within the small triangular unit are in the narrow 3.293(4)–3.304(4) Å range; those within the large one are in the 5.947(4)–6.000(4) Å range. A distorted octahedral environment is created about each metal center. The Ni–$O_{sulfato}$ bond lengths are typical.[15c,18,22] The Ni–O bond lengths for the bridging sulfate oxygen atoms are longer than the Ni–O distance exhibited by the terminal oxygen atom from the same sulfato ligand.

There is a large amount of hydrogen bonding in **1**·2.53 MeOH·1.60 $H_2O$. We will briefly comment on the intramolecular hydrogen bonds, see Table 4. Each (py)C(Me)NOH oxime group is strongly intramolecularly hydrogen-bonded to an uncoordinated O atom from an 3.2100 sulfato ligand. The other uncoordinated O atom of each 3.2100 sulfato ligand also acts as acceptor; the donors for these hydrogen bonds are the MeOH and $H_2O$ ligands. The sulfato O(13) atom participates in two hydrogen bonds; of interest is also the fact that the lattice water oxygen atom OW(31) acts both as a donor and as an acceptor.

The structures of the hexanuclear molecules present in complexes **2**·3.2 MeOH·1.5 $H_2O$ (Figure 7) and **3**·3 $H_2O$ (Figure 8) are very similar to the structure of **1** except that: (i) The (py)C(Me)NOH/(py)C(Me)$NO^-$ ligands of **1** are replaced by (py)C(ph)NOH/(py)C(ph)$NO^-$ ligands in **2** and **3**, and (ii) the peripheral MeOH and $H_2O$ ligands of **1** are replaced by three terminal MeOH ligands in **2** and three terminal $H_2O$ ligands in **3**. Note that there are two crystallographically independent hexanuclear molecules in **3**·3 $H_2O$, but their bond lengths and angles differ only marginally. The three compounds also differ in the lattice solvate molecules that are present.

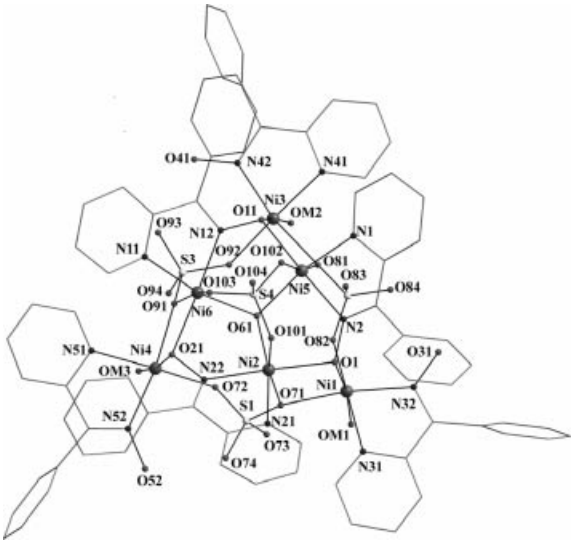

Figure 7. Partially labelled plot of the hexanuclear molecule present in complex **2**·3.2 MeOH·1.5 $H_2O$. The hydrogen atoms have been omitted for clarity.

The ligands (py)C(Me)NOH, (py)C(Me)$NO^-$, (py)C(ph)NOH and (py)C(ph)$NO^-$ have been observed in numerous ligation modes over the years.[12] Because most of their

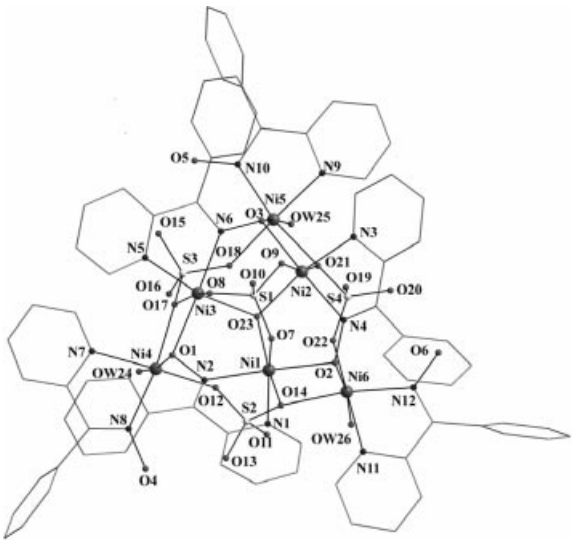

Figure 8. Partially labelled plot of one of the two, crystallographically independent hexanuclear molecules present in complex **3**·3 $H_2O$. The hydrogen atoms have been omitted for clarity.

complexes were reported only recently, we felt it timely to collect the structurally characterized non-organometallic, metal complexes of these ligands in Tables 7 and 8, together with the cores of the polynuclear complexes and the coordination modes of (py)C(R)NOH/(py)C(R)$NO^-$ (R = Me, Ph). Inspection of Tables 7 and 8 clearly shows that: (i) the complexes **1**–**3** are amongst the highest-nuclearity clusters of any metal identified with the (py)C(R)$NO^-$ ligands, (ii) the 2.111 coordination mode is the most common for the bridging (py)C(R)$NO^-$ ligands, and (iii) the 3.211 mode of (py)C(Me)$NO^-$ observed in **1** is new, i.e. it has not been characterized before, while this mode is rare in the complexes containing bridging (py)C(ph)$NO^-$ ligands.

Complexes **1**–**3** join a rather small, but growing family of $Ni^{II}_6$ complexes bearing N- and/or O-donors and possessing the metal ions in various topologies, such as hexagons, Chinese-lantern-like objects and face-shared distorted dicubanes in which one of the corners of each cubane is missing.[24] Complexes **1**–**3** are the highest-nuclearity sulfato nickel(II) clusters which have been structurally characterized.

## Magnetic Studies

Solid-state dc magnetic susceptibility measurements were performed on polycrystalline samples of the representative complexes **1** and **2**, under a constant field of 0.04 T in the temperature range 2.0–300 K. The $\chi_M T$ vs. $T$ plots for the two complexes are shown in Figure 9. The complexes exhibit a very similar magnetic behavior. The $\chi_M T$ values at room temperature are 7.39 $cm^3 mol^{-1}$ K for **1** and 7.50 $cm^3 mol^{-1}$ K for **2**, close to the expected value of 7.59 $cm^3 mol^{-1}$ K for six non-interacting $S = 1$ centers assuming $g = 2.25$. As the temperature is lowered, the $\chi_M T$ product for both compounds experiences a slight decrease in the 300 to ca. 75 K range, followed by a sharper decline

at lower temperatures and reaching the values of 2.37 (**1**) and 3.14 (**2**) $cm^3\,mol^{-1}\,K$ at 2.0 K. The data indicate an overall antiferromagnetic behavior. Magnetization experiments performed at 2.0 K (Figure 10) show a continuous increase of $M$ as the field increases, reaching a non-saturated value close to five electrons under an external field of 5 T.

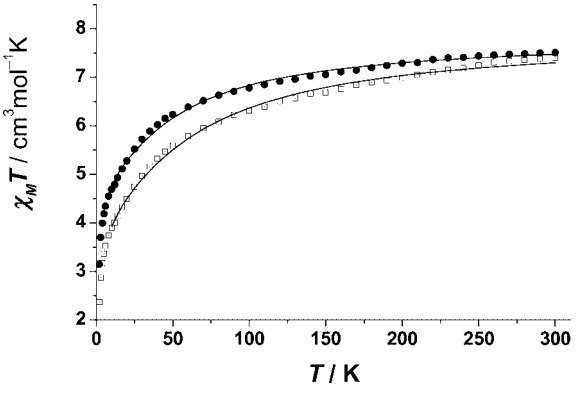

Figure 9. $\chi_M T$ vs. $T$ plots for complexes **1** (open squares) and **2** (open circles). The solid lines represent the best fit to the data as described in the text.

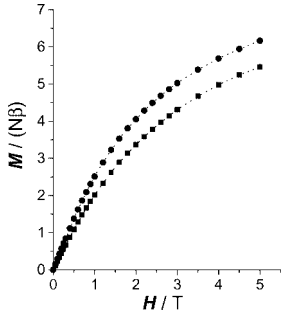

Figure 10. Magnetization plots for compounds **1** (filled squares) and **2** (filled circles) at 2 K. The dashed lines are guides for the eye.

Close inspection of the very similar molecular structures reveals that there are four different superexchange pathways and thus four different kinds of $J$ values: $J_1$ is associated (from now onwards the numbering scheme that will be used

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

is the same with that used in the real structure of **1**, see Figure 3) with the Ni(1)···Ni(2), Ni(2)···Ni(3) and Ni(1)···Ni(3) interactions through the central hydroxido bridge, a triatomic part of the 3.1110 sulfato ligand and one diatomic oximate group from a 3.211 (py)C(Me)NO$^-$ ligand; $J_2$ is associated with the Ni(1)···Ni(6), Ni(2)···Ni(5) and Ni(3)···Ni(4) interactions, each through a double ($\mu$-$O_{sulfato}$)/($\mu$-$O_{oximate}$) pathway; $J_3$ is associated with the Ni(1)···Ni(4), Ni(2)···Ni(6) and Ni(3)···Ni(5) interactions, each through one diatomic oximate group from a 3.211 (py)C(Me)NO$^-$ ligand (the Ni–O–N–Ni torsion angles are close to 90°); and finally $J_4$ is associated with the Ni(4)···Ni(5), Ni(5)···Ni(6) and Ni(4)···Ni(6) interactions, each through a single triatomic part of one 3.2100 sulfato ligand. If we consider that the six Ni$^{II}$ ions occupy the apices of a very distorted octahedron, the superexchange pathways are along the twelve edges. The spin Hamiltonian for such a system is given by Equation (1).

$$H = -J_1(S_1\cdot S_2 + S_1\cdot S_3 + S_2\cdot S_3) - J_2(S_1\cdot S_6 + S_2\cdot S_5 + S_3\cdot S_4) - J_3(S_1\cdot S_4 + S_2\cdot S_6 + S_3\cdot S_5) \quad (1)$$

$$H = -J_4(S_4\cdot S_5 + S_4\cdot S_6 + S_5\cdot S_6)$$

To avoid a vast parameterization, we decided to attempt to fit the susceptibility data using a simpler 2-$J$ model. In order to decide the best way to reduce the number of the coupling constants, we have performed the following analysis of the above mentioned "octahedral" model. It is known that the superexchange Ni–O–X–O–Ni interactions mediated by tetrahedral anions with electronegative central atoms, e.g. $SO_4^-$, $ClO_4^-$, $PO_4^{3-}$, are negligible.[18] Assuming $J_4 = 0$, the spin Hamiltonian can be expressed in the form of Equation (2) and the resulting new, simpler interaction scheme is shown in Figure 11. In Figure 12 we show some selected simulations of the magnetic response of the "octahedral" model, performed by means of the program CLUMAG.[25]

$$H = -J_1(S_1\cdot S_2 + S_1\cdot S_3 + S_2\cdot S_3) - J_2(S_1\cdot S_6 + S_2\cdot S_5 + S_3\cdot S_4) - J_3(S_1\cdot S_4 + S_2\cdot S_6 + S_3\cdot S_5) \quad (2)$$

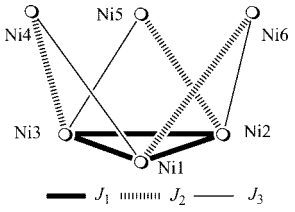

Figure 11. A 3-$J$ exchange-interaction pattern corresponding to the Hamiltonian of Equation (2) for the hexanuclear clusters reported in this work. The Hamiltonian of Equation (3) follows the same scheme assuming $J_2 = J_3$. The exchange pathways corresponding to $J_1$, $J_2$ and $J_3$ are described in the text. The numbering scheme used for the Ni$^{II}$ ions is the same with that used in the solution of the structure of **1**·2.53 MeOH·1.60 $H_2O$. Atoms Ni(1), Ni(2), Ni(3), Ni(4), Ni(5) and Ni(6) of the shown interaction scheme correspond to atoms Ni(2), Ni(5), Ni(6), Ni(4), Ni(3) and Ni(1), respectively, of the structure of **2**·3.2 MeOH·1.5 $H_2O$ (Figure 7).

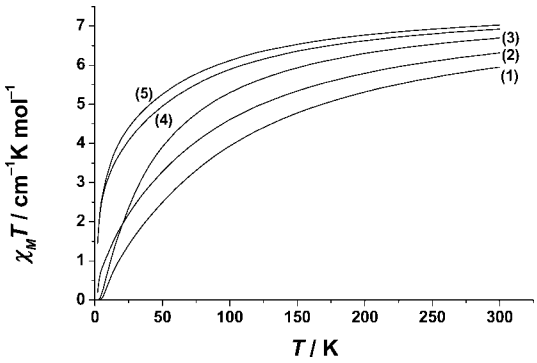

Figure 12. Calculated $\chi_M T$ vs. $T$ curves for a spin system similar to that of **1**–**3** and for various sets of the $J$ constants. A detailed description of the curves (1)–(5) is given in the text.

Curve (1) represents the behavior of a system on the basis of the Hamiltonian of Equation (1) in the case of $J_1 = J_2 = J_3 = J_4 = -20$ cm$^{-1}$ and $g = 2.25$. This system has a well-defined $S = 0$ ground state as can be seen in Figure 13. Removing the interaction in one of the octahedral faces, i.e. $J_4 = 0$, with $J_1 = J_2 = J_3 = -20$ cm$^{-1}$ and $g = 2.25$, and applying the Hamiltonian of Equation (2), we obtained curve (2); the system has a new $S = 0$ ground state (Figure 13). Curve (3) of Figure 12 is the result of the calculation with the parameters $J_1 = -20$ cm$^{-1}$, $J_2 = -10$ cm$^{-1}$, $J_3 = -5$ cm$^{-1}$ and $g = 2.25$. Again the system has an $S = 0$ ground state (Figure 13). As it is clearly evident in Figure 12, in these three cases the $\chi_M T$ value tends to zero at low temperatures by contrast with the experimental behavior of **1** and **2**, see Figure 9. More interesting are plots/curves (4) and (5) of Figure 12, obtained applying the sets $J_1 = -20$ cm$^{-1}$, $J_2 = -5$ cm$^{-1}$, $J_3 = -5$ cm$^{-1}$ and $J_1 = -20$ cm$^{-1}$, $J_2 = -5$ cm$^{-1}$, $J_3 = 0$ cm$^{-1}$, respectively. For these simulations in which $J_1 >> J_2$, $J_3$, the $\chi_M T$ product does not strongly tend to zero at low temperatures (in agreement with the experimental data, see Figure 9); this is a consequence of the close "distances" of the $S = 0$, 1, 2, 3 states in the energy spectrum, see Figure 13 for the $J_1 = -20$ cm$^{-1}$, $J_2 = -5$ cm$^{-1}$, $J_3 = -5$ cm$^{-1}$ case, plot (4). It is important to realize that the relative values of $J_2$ and $J_3$ become poorly relevant and it is not reliable to try to fit separately these two coupling constants. It should be mentioned at this point that any calculation assuming $J_1 << J_2$, $J_3$ gives $\chi_M T$ products that clearly tend to a value close to zero, and such a situation can not be assumed for **1** and **2**.

On the basis of the above calculations, we decided to apply the spin Hamiltonian of Equation (3), where $J_1$ is the coupling constant for the interactions within the small triangle [defined by Ni(1), Ni(2) and Ni(3) in **1**] and $J_2$ is a common coupling constant associated with the six interactions between the small triangle and the three peripheral Ni$^{II}$ ions [Ni(4), Ni(5) and Ni(6) in **1**]. The best-fit parameters are $J_1 = -20.5$ cm$^{-1}$, $J_2 = -2.3$ cm$^{-1}$, $g = 2.29$ for **1** and $J_1 = -17.0$ cm$^{-1}$, $J_2 = -1.9$ cm$^{-1}$, $g = 2.30$ for **2**. The agreement factor, defined as $R = \Sigma[(\chi_M)_{calcd.} - (\chi_M)_{obsd.}]^2/\Sigma[(\chi_M)_{obsd.}]^2$ was $1.1 \times 10^{-4}$ and $8.1 \times 10^{-5}$ for **1** and **2**, respectively, see Figure 9. Looking at the energy of the $S =$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

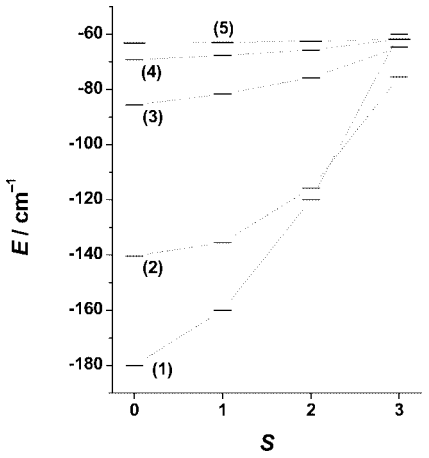

Figure 13. Energy levels for the $S = 0, 1, 2, 3$ states in the following cases: Plot (1) refers to $J_1 = J_2 = J_3 = J_4 = 20\ cm^{-1}$; plot (2) refers to $J_1 = J_2 = J_3 = -20\ cm^{-1}$; plot (3) refers to $J_1 = -20\ cm^{-1}$, $J_2 = -10\ cm^{-1}$, $J_3 = -5\ cm^{-1}$; plot (4) refers to $J_1 = -20\ cm^{-1}$, $J_2 = -5\ cm^{-1}$, $J_3 = -5\ cm^{-1}$; plot (5) refers to $J_1 = -20.5\ cm^{-1}$, $J_2 = J_3 = -2.3\ cm^{-1}$, $g = 2.29$, set of parameters resulting from the fitting procedure for **1** based on the Hamiltonian of Equation (3).

0, 1, 2, 3 levels [plot (5) in Figure 13], we realize that these spin levels are very close, i.e. with a very narrow range of less than $1.5\ cm^{-1}$, in good agreement with the magnetization data (Figure 10). Upon increasing the external field, the close non-zero spin levels give a non-saturated magnetization at 2 K as a result of the partial population of levels up to $S = 3$. The next lower $S = 4$ level is $26\ cm^{-1}$ higher in energy, excluding a magnetization corresponding to more than six unpaired electrons, as it is experimentally observed.

$$H = -J_1(S_1 \cdot S_2 + S_1 \cdot S_3 + S_2 \cdot S_3) - J_2(S_1 \cdot S_6 + S_2 \cdot S_5 + S_3 \cdot S_4 + S_1 \cdot S_4 + S_2 \cdot S_6 + S_3 \cdot S_5) \quad (3)$$

The bridging =N–O$^-$ group is known to be very efficient in mediating a strong antiferromagnetic interaction, which is provided by an orbital exchange pathway essentially of σ nature.[14c] The antiferromagnetic $J_1$ coupling is consistent with its mediation mainly by two types of bridges, a single-atom $\mu_3$-OH$^-$ group with a Ni–O(H)–Ni angle of ca. 110° and a diatomic =N–O$^-$ linkage. The non-planarity of the Ni–O–N–Ni moiety (noticeable torsion angle) reduces the antiferromagnetism, giving rise to moderate antiferromagnetic coupling.[24b] The sign of $J_2$ seems logical owing to its mediation by a $(\mu\text{-O})_2$ pathway with an average Ni–O–Ni angle of ca. 101° and one diatomic, non-planar =N–O$^-$ linkage; however, its magnitude can not be easily rationalized in the simple 2-$J$ model adopted.

## Conclusions and Perspectives

The initial use of the sulfate ligand in nickel(II)/2-pyridyl oximes chemistry, i.e. the study of the coordination chemistry of the *binary* $SO_4^{2-}$/(py)C(R)NOH (R = Me, Ph) "ligand blends" with nickel(II), has provided access to three hexanuclear clusters with interesting structures and magnetic features. The magnetic properties of two representative clusters have been interpreted using two exchange interactions in a simplified model.

Analogues of **1**–**3** with 2-pyridinecarbaldehyde oxime [(py)C(H)NOH] or di-2-pyridyl ketone oxime [$(py)_2$-CNOH], see Figure 1, are not known, until to date, and it is currently not evident whether the preparation and stability of such hexanuclear complexes are dependent on the particular nature of the R substituent on the oxime/oximate carbon. Clearly the $Ni^{II}/SO_4^{2-}$/(py)C(R)NOH chemistry warrants further study and expansion to other 3d-metals. Synthetic efforts are also in progress to realize a higher bridging behavior of the $SO_4^{2-}$ ion, e.g. $\mu_4$-$\mu_6$ (Figure 2) in 3d-metal/(py)C(R)NOH chemistry. Because the $\mu_3$-OH$^-$ ligand propagates antiferromagnetic exchange interactions in the small $Ni_3$ triangular unit of **1**–**2**, we are intensively pursuing our efforts to substitute the hydroxido bridge by an end-on triply bridging azido ligand ($\eta^1$:$\mu_3$ or 3.100), according to our well-developed synthetic strategy,[26] in order to introduce specifically ferromagnetic components in the superexchange Scheme. Work at the time of writing shows that most of the just mentioned perspectives are realizable.

## Experimental Section

**Materials and Physical Measurements:** All manipulations were performed under aerobic conditions using materials and solvents (Merck, Aldrich) as received. Complex $[Ni(SO_4)\{(py)C(Me)NOH\}(H_2O)_3]$ was prepared as described elsewhere.[19] Methyl 2-pyridyl ketone oxime, (py)C(Me)NOH, was synthesized by the reaction of equimolar quantities of 1-pyridin-2-ylethanone (2-acetylpyridine), (py)C(Me)O, $H_2NOH{\cdot}HCl$ and NaOEt in EtOH.[27] Elemental analyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Laboratory with an EA 1108 Carlo–Erba analyzer. IR spectra (4000–400 $cm^{-1}$) were recorded with a Perkin–Elmer 16 PC FT-spectrometer with samples prepared as KBr pellets. Magnetic susceptibility measurements in the 1.9–300 K range under a field of 0.5 T were performed with a Quantum Design SQUID magnetometer at the Magnetochemistry Service of the University of Barcelona. All measurements were carried out on polycrystalline samples. Data were corrected for diamagnetic contributions using Pascal's constants.

**$[Ni_6(SO_4)_4(OH)\{(py)C(Me)NO\}_3\{(py)C(Me)NOH\}_3(MeOH)_2(H_2O)]{\cdot}2.53\,MeOH{\cdot}1.60\,H_2O$ ($1{\cdot}2.53\,MeOH{\cdot}1.60\,H_2O$). Method A:** Solid NaOMe (0.033 g, 0.60 mmol) was added to a colorless solution of (py)C(Me)NOH (0.082 g, 0.60 mmol) in MeOH (25 mL); the solid soon dissolved. Solid $NiSO_4{\cdot}6H_2O$ (0.158 g, 0.60 mmol) was then added and the resultant solution was stirred for 1 h at room temperature. A small quantity of undissolved material was removed by filtration and the green filtrate layered with $Et_2O$ (50 mL). Slow mixing gave X-ray quality green crystals of the product. The crystals were collected by filtration, washed with cold $H_2O$ (1 mL), cold MeOH (2 mL) and ice-cold $Et_2O$ ($2 \times 3$ mL), and dried in air. Yield: 0.114 g (65%). The air-dried solid analyzed satisfactorily as MeOH-free ($1{\cdot}1.60\,H_2O$). $C_{44}H_{59.20}N_{12}Ni_6O_{27.60}S_4$ (1678.34): calcd. C 31.79, H 3.59, N 10.11; found C 31.45, H 3.72, N 9.98. IR data (KBr pellet): $\tilde{\nu}$ = 3430 (sh), 3406 (m, broad), 1652 (m), 1602 (s), 1562 (w), 1476 (m), 1440 (w), 1376 (w), 1334 (w), 1148 (s), 1126 (s), 1070 (s), 1036 (s), 984 (m), 782 (m), 690 (m), 628 (m), 592 (w), 484 (w), 430 (w) $cm^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Method B:** A colorless solution of (py)C(Me)NOH (0.136 g, 1.00 mmol) in MeOH (10 mL) was slowly added to a slurry of $LiOH·H_2O$ (0.042 g, 1.00 mmol) in MeOH (5 mL); the hydroxide soon dissolved. The solution was then added to a slurry of $NiSO_4·6H_2O$ (0.263 g, 1.00 mmol) in MeOH (10 mL) and the resulting green solution was stirred for 1 h at room temperature. A small quantity of undissolved material was removed by filtration. The filtrate was allowed to stand undisturbed in a closed flask for a period of 4–5 d. Green crystals appeared which were collected by filtration, washed with cold $H_2O$ (1 mL), cold MeOH (1 mL) and ice-cold $Et_2O$ (2 mL), and dried in air. Yield: 0.123 g (42%). The dried solid was analyzed satisfactorily as **1**·1·60 $H_2O$. The identity of the product was further confirmed by IR spectroscopic comparison with the authentic sample prepared by method A.

**Method C:** A suspension of compound $[Ni(SO_4)\{(py)C(Me)NOH\}(H_2O)_3]$ (0.080 g, 0.22 mmol) in warm MeOH (25 mL) was treated with solid $LiOH·H_2O$ (0.006 g, 0.15 mmol). The mixture was stirred overnight at 30 °C, filtered to remove a few quantity of undissolved starting material, and the green solution was then allowed to stand undisturbed in a closed vial at room temperature. Green prismatic crystals formed within 12–14 h, and these were collected by filtration, washed with cold MeOH (2 × 2 mL) and dried in the air. Yield (based on the mononuclear complex): 0.026 g (40%). The product was identified by microanalyses and IR comparison with material from method A.

**$[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(MeOH)_3]$·3.2 MeOH·1.5 $H_2O$ (2·3.2 MeOH·1.5 $H_2O$) and $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(H_2O)_3]$·3 $H_2O$ (3·3 $H_2O$) as a Mixture:** Solid NaOMe (0.033 g, 0.60 mmol) was added to a colorless solution of (py)C(ph)NOH (0.119 g, 0.60 mmol) in MeOH (25 mL); the solid soon dissolved. Solid $NiSO_4·6H_2O$ (0.158 g, 0.60 mmol) was then added and the resulting solution was stirred for 1 h at room temperature. A small quantity of undissolved material was removed by filtration and the orange filtrate layered with $Et_2O$ (50 mL). Slow mixing gave an approximately 1:1 mixture of greenish yellow prisms and yellow plates. The crystals were carefully collected by filtration, washed with cold $H_2O$ (0.5 mL), cold MeOH (1 mL) and ice-cold $Et_2O$ (2 × 3 mL), and dried in air. The two products were readily separable manually, and the yellow prisms and yellow plates proved by single-crystal X-ray crystallography to be complexes **2**·3.2 MeOH·1.5 $H_2O$ and **3**·3 $H_2O$, respectively. Batches of the different samples were used for analyses and characterization. Yield for **2**·3.2 MeOH·1.5 $H_2O$: 0.065 g (30%). The air-dried solid was analyzed satisfactorily as MeOH-free (**2**·1.5 $H_2O$). $C_{75}H_{73}N_{12}Ni_6O_{27.5}S_4$ (2059.96): calcd. C 43.67, H 3.57, N 8.15; found C 43.23, H 3.72, N 7.91. IR data (KBr pellet)

Table 9. Crystal data and structure refinement for $[Ni_6(SO_4)_4(OH)\{(py)C(Me)NO\}_3\{(py)C(Me)NOH\}_3(MeOH)_2(H_2O)]$·2.53 MeOH·1.60 $H_2O$ (**1**·2.53 MeOH·1.60 $H_2O$), $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(MeOH)_3]$·3.2 MeOH·1.5 $H_2O$ (**2**·3.2 MeOH·1.5 $H_2O$) and $[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(H_2O)_3]$·3 $H_2O$ (**3**·3 $H_2O$).

for **2**·1.5 $H_2O$: $\tilde{\nu}$ = 3415 (sh), 3396 (m, broad), 1599 (m), 1470 (m), 1442 (m), 1341 (w), 1180 (s), 1129 (s), 1051 (s), 1028 (s), 965 (m), 792 (m), 745 (m), 706 (m), 628 (m), 595 (w), 474 (w), 432 (w) $cm^{-1}$. Yield for **3**·3 $H_2O$: 0.073 g (35%). $C_{72}H_{70}N_{12}Ni_6O_{29}S_4$ (2047.90): calcd. C 43.37, H 3.24, N 8.43; found C 43.45, H 3.14, N 8.50. IR data (KBr pellet) for **3**·3 $H_2O$: $\tilde{\nu}$ = 3401 (sh), 3255 (m, broad), 1604 (m), 1466 (m), 1442 (m), 1337 (w), 1175 (s), 1125 (s), 1048 (s), 1028 (s), 971 (m), 788 (m), 746 (m), 704 (m), 627 (m), 598 (w), 468 (m), 429 (w) $cm^{-1}$.

**$[Ni_6(SO_4)_4(OH)\{(py)C(ph)NO\}_3\{(py)C(ph)NOH\}_3(H_2O)_3]$·3 $H_2O$ (3·3 $H_2O$):** This complex was prepared pure in the form of yellow plates in a manner analogous to the above mentioned mixture, but using $LiOH·H_2O$ (0.017 g, 0.40 mmol) in place of NaOMe and $MeOH/H_2O$ (25 mL, 8:2, v/v) instead of MeOH. The yield was 0.001 g (60%). The air-dried solid analyzed satisfactorily as **3**·3 $H_2O$. The identity of the product was further confirmed by unit cell determinations of three crystals. The three individual determinations revealed a unit cell with dimensions identical to those found for the yellow plates, which resulted from the above described procedure that led to the mixture of **2**·3.2 MeOH·1.5 $H_2O$ and **3**·3 $H_2O$.

**X-ray Crystallographic Studies:** Crystals of **1**·2.53 MeOH·1.60 $H_2O$ were mounted in Paratone-N oil, crystals of **2**·3.2 MeOH·1.5 $H_2O$ in capillary filled with drops of mother liquor and crystals of **3**·3 $H_2O$ were mounted in air at low temperature. Diffraction measurements for **1**·2.53 MeOH·1.60 $H_2O$ were made with an Oxford Diffraction CCD instrument using graphite-monochromated Mo radiation. The X-ray data set for **2**·3.2 MeOH·1.5 $H_2O$ was collected with a $P2_1$ Nicolet diffractometer upgraded by Crystal Logic using graphite-monochromated Cu-$K_\alpha$ radiation, while diffraction measurements for **3**·3 $H_2O$ were made with a Bruker Platinum 200 CCD diffractometer on Station 11.3.1[28a] of the Advanced Light Source at Lawrence Berkeley National Laboratory, with wavelength on 0.77490 Å from a Silicon 111 monochromator. Complete crystal data and parameters for data collection and refinement are listed in Table 9. Unit cell dimensions were determined and refined by using 10130 (for **1**·2.53 MeOH·1.60 $H_2O$ at 100 K), 25 (for **2**·3.2 MeOH·1.5 $H_2O$ at 298 K) and 8475 (for **3**·3 $H_2O$ at 193 K) reflections in the ranges $10.44 < 2\theta < 55.66°$, $22 < 2\theta < 54°$ and $5.10 < 2\theta < 67.30°$, respectively. The crystals of **2**·3.2 MeOH·1.5 $H_2O$ had poor diffraction ability (despite their sufficient size) and the data were collected in increasing $2\theta$ shells. The data collection was terminated when about 50% of the collected shell data were unobserved. The structures were solved by direct methods using SIR92[28b] (**1**·2.53 MeOH·1.60 $H_2O$), SHELXS-86[28c] (**2**·3.2 MeOH·1.5 $H_2O$) and Bruker SHELXTL[28d] (**3**·3 $H_2O$), and refined by full-matrix least-squares techniques on $F^2$ with SHELXL-97[28e] (for **1**·2.53 MeOH·1.60 $H_2O$ and **2**·3.2 MeOH·1.5 $H_2O$) and Bruker SHELXTL[28d] (for **3**·3 $H_2O$). For all the structures the fully occupied non-hydrogen atoms were refined anisotropically. In the case of **1**·2.53 MeOH·1.60 $H_2O$ all lattice solvent molecules were refined with partial occupation factors, while in the case of **2**·3.2 MeOH·1.5 $H_2O$ the solvate molecules were refined isotropically. For the three structures, the hydrogen atoms attached to carbon atoms were placed at calculated positions. In **1**·2.53 MeOH·1.60 $H_2O$ most other hydrogen atoms were located from $\Delta F$ maps and refined isotropically. In **2**·3.2 MeOH·1.5 $H_2O$, the hydroxy hydrogen atoms of the coordinated MeOH molecules and the hydrogen atom of the bridging hydroxido ligand were located by difference maps and refined isotropically. In the structure of **3**·3 $H_2O$, the bridging hydroxido hydrogen atom was found in the difference map, while hydrogen atoms could neither be found or placed for the $H_2O$ molecules and were therefore omitted from the refinement.

CCDC-633009 (**1**·2.53 MeOH·1.60 $H_2O$), -633010 (**2**·3.2 MeOH·1.5 $H_2O$) and -633011 (**3**·3 $H_2O$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

S. P. P. thanks the European Social Fund (ESF) [Operational Program for Educational and Vocational Training II (EPEAEK II) and particularly the program PYTHAGORAS (grant no. 365.037)] for funding the above work. # Conformational Analysis of One-Dimensional Coordination Polymers Based on $[Cp_2Cr_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ by Solid-State Multinuclear NMR Spectroscopy and Density Functional Calculations

**Manfred Scheer,*[a] Laurence J. Gregoriades,[a] Manfred Zabel,[a] Marek Sierka,[b] Long Zhang,[c] and Hellmut Eckert*[c]**

*Dedicated to Professor Joachim Heinicke on the occasion of his 60th birthday*

**Keywords:** Chromium / Copper / Halides / Density functional calculations / NMR spectroscopy / Phosphorus

Reaction of the complex $[Cp_2Cr_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ (**2**) with copper(I) halides leads to the quantitative formation of the new one-dimensional (1D) linear polymers $[CuX\{Cp_2Cr_2(CO)_4(\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}P_2)\}]_n$ [X = Cl (**3**), Br (**4**), I (**5**)]. Polymers **3**–**5** are the first examples of supramolecular aggregates incorporating **2** as a connecting moiety. The solid-state structures of **3**–**5** are compared and their remarkable influence on the respective solid-state $^{31}P$ magic angle spinning (MAS) NMR spectra is interpreted with the help of density functional theory (DFT) calculations, which suggest that the $^{31}P$ chemical shifts are extremely sensitive to the position of the phosphorus atoms with respect to the cones of anisotropy of the carbonyl ligands.

## Introduction

The construction of well-defined supramolecular assemblies from discrete units is a field of considerable interest in contemporary chemical research.[1] Typically, different metal centres are connected by suitable N-, O- and/or S-donor-containing organic ligands as linkers. In our research group, however, we utilise organometallic $P_n$- and $As_n$-ligand complexes as connecting moieties.[2] The tetrahedrane complex $[Cp_2Mo_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ (**1**),[3] for example, has proven to be a particularly versatile supramolecular building block and forms the basis of several oligomers and one-dimensional (1D) polymers isolated in our group.[2a,2d] In view of the versatility of complex **1** as a linker, we decided to investigate the coordination potential of its chromium analogue $[Cp_2Cr_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ (**2**),[4] particularly due to the fact that it is less stable than **1** and readily undergoes fragmentation reactions,[5] and could thus lead to the formation of novel compounds with unusual $P_n$-ligand arrangements. We report herein the synthesis, characterisation and solid-state $^{31}P$ magic angle spinning (MAS) NMR spectral features of the new 1D polymers $[CuX\{Cp_2Cr_2(CO)_4(\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}P_2)\}]_n$ [X = Cl (**3**), Br (**4**), I (**5**)], which are the first examples of supramolecular aggregates containing **2** as a linking unit. The MAS NMR spectra are interpreted with the help of density functional theory (DFT) calculations on the compounds **3**–**5** and the results obtained in a previous $^{31}P$ MAS NMR study on the analogous 1D polymers $[CuX\{Cp_2Mo_2(CO)_4(\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}P_2)\}]_n$ [X = Cl (**6**), Br (**7**), I (**8**)].[2d]

## Results and Discussion

### Synthesis of the Products

Treatment of **2** with CuX (X = Cl, Br, I) in a mixture of $CH_3CN$ and $CH_2Cl_2$ at room temperature leads to the formation of the 1D polymers **3**–**5** [Equation (1)] as air-sensitive, moss-green microcrystalline powders. The polymers can be stored indefinitely at ambient conditions under an inert atmosphere and are insoluble in most common solvents. They are, however, soluble in trace amounts in polar solvents such as $CH_3CN$, but then apparently dissociate completely into the starting materials, as evidenced by $^{31}P$ NMR spectroscopy.

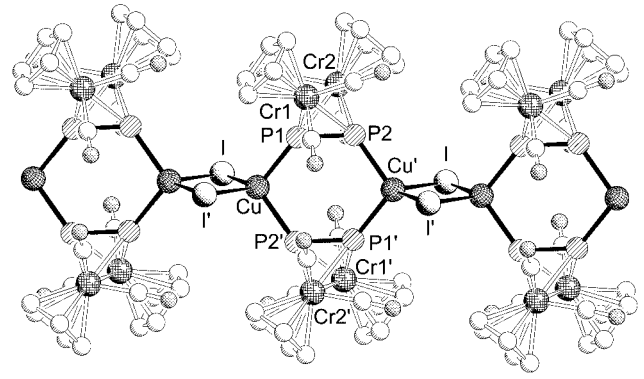
**4**



**5**

Figure 1. Portions of the structures of polymers **3**–**5** (hydrogen atoms have been omitted for clarity). See Table 1 for selected bond lengths and angles.

### X-ray Crystallographic Characterisation of the Products

Compounds **3**–**5** were characterised by X-ray crystallography; the measurement details are summarised in the Experimental Section. Their structures display a polymeric core (Figure 1) reminiscent of that in the molybdenum analogues $[CuX\{Cp_2Mo_2(CO)_4(\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}P_2)\}]_n$ [X = Cl (**6**), Br (**7**), I (**8**)].[2a,2d] The $Cu^I$ centres in **3**–**5** are found in a distorted tetrahedral coordination mode and are bridged by the phosphorus atoms of **2** and the halogen atoms. As a result, structures consisting of an alternating arrangement of planar four-membered $Cu_2X_2$ rings and six-membered $Cu_2P_4$ rings in a slight chair-like conformation are formed, which are nearly orthogonal to each other. Compounds **4** and **5** and their molybdenum analogues **7** and **8** are structurally similar, whereas polymers **3** and **6** are different. Unlike the molybdenum derivative **6**, the $Cu_2P_4$ rings in the chromium analogue **3** possess an inversion centre situated at the centre of these rings.

Selected structural details for compounds **3**–**5** are listed in Table 1. The P–P bond lengths of the $Cr_2P_2$ moieties in **3** and **4** are unchanged compared to uncoordinated **2** [2.060(1) Å],[4a] whereas those in **5** are marginally longer. Although the Cu–P bond lengths are generally longer than those found in complexes of the type $[Cu_2X_2(PPh_3)_3]$[6] (X = Cl:[6a] 2.183(4)–2.245(5) Å; Br:[6b] 2.190(3)–2.260(3) Å; I:[6c] 2.219(3)–2.267(3) Å], the Cu–X bond lengths are within the ranges found in these compounds (X = Cl:[6a] 2.298(4)–2.454(4) Å; Br:[6b] 2.370(2)–2.610(2) Å; I:[6c] 2.500(2)–2.819(1) Å].

Table 1. Comparison of selected bond lengths [Å] and angles [°] in compounds **3**–**5**.

| | **3** (X = Cl) | **4** (X = Br) | **5** (X = I) |
|---|---|---|---|
| P–P | 2.061(1) | 2.061(1) | 2.073(2) |
| Cu–P | 2.289(1) | 2.297(1) | 2.323(2) |
| | 2.296(1) | 2.305(1) | 2.333(2) |
| Cu–X | 2.344(1) | 2.467(4) | 2.611(1) |
| | 2.363(1) | 2.479(4) | 2.675(1) |
| P–Cu–P | 103.17(2) | 104.07(2) | 104.95(7) |
| P1–Cu–X | 111.41(2) | 111.97(2) | 106.77(6) |
| | 114.53(2) | 112.84(2) | 116.81(6) |
| P2–Cu–X | 112.02(2) | 110.77(2) | 106.42(6) |
| | 115.58(2) | 113.81(2) | 113.17(6) |
| X–Cu–X | 100.49(2) | 103.62(2) | 108.10(4) |
| Cu–X–Cu | 79.51(2) | 76.38(1) | 71.90(3) |
| Cu···Cu···Cu | 174.86(1) | 176.48(2) | 170.50(1) |

A further interesting structural feature observed in all three polymers is that the copper atoms are alternately distributed along two parallel lines, as illustrated by the Cu···Cu···Cu angles given in Table 1 and the representation

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the polymers in Figure 2. Moreover, the folding angle of the $Cu_2P_4$ rings (dihedral angle between CuP1P2′ and P1P2P1′P2′ planes for **3** and **5**; dihedral angle between CuP1′P2 and P1P2P1′P2′ planes for **4**) decreases as the size of the halogen atom increases (**3**: 3.81(1)°; **4**: 2.48(1)°; **5**: 0.97(1)°].

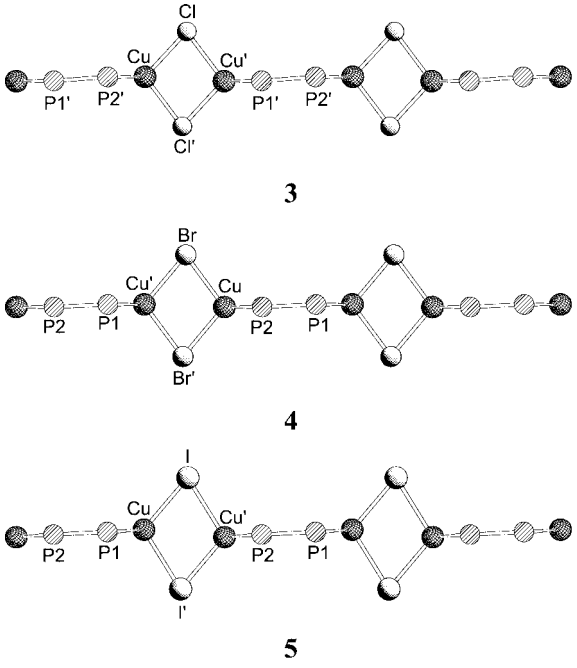


Figure 2. View of the structures of **3**–**5** perpendicular to the faces of the $Cu_2X_2$ rings, demonstrating that the copper atoms in the polymers are alternately distributed along two parallel lines (chromium atoms and their supporting ligands have been omitted for clarity).

### Spectroscopic Characterisation of the Products

Complexes **3**–**5** are soluble in $CH_3CN$ in trace amounts although they apparently dissociate completely into the starting materials according to $^{31}P$ NMR measurements. However, the fragments detected in the positive-ion ESI mass spectra of the compounds in $CH_3CN$ at room temperature (Table 2) suggest that oligomeric species are most likely also present in solution.

Table 2. Selected fragments [*m*/*z* (relative abundance in %)] detected in the positive-ion ESI mass spectra of compounds **3**–**5** in $CH_3CN$ and the proposed cations for these fragments.

| 3 (X = Cl) | 4 (X = Br) | 5 (X = I) | Proposed Cation |
|---|---|---|---|
| 1076.7(3) | 1166.6(9) | 1260.7(12) | $[(Cu_3X_2)\{Cp_2Cr_2(CO)_4P_2\}_2]^+$ |
| 1022.6(2) | 1110.5(4) | 1204.6(7) | $[(Cu_3X_2)\{Cp_2Cr_2(CO)_3P_2\}_2]^+$ |
| 978.7(16) | 1022.7(18) | 1070.6(10) | $[(Cu_2X)\{Cp_2Cr_2(CO)_4P_2\}_2]^+$ |
| 922.7(8) | 966.6(11) | 1014.6(10) | $[(Cu_2X)\{Cp_2Cr_2(CO)_3P_2\}_2]^+$ |

Solid-state $^{31}P$ MAS NMR measurements were performed for polymers **3**–**5** at room temperature; the spectra obtained are depicted in Figure 3. The chloride and bromide derivatives exhibit identical spectra and display two multiplets near $\delta$ = –100 and 80 ppm, whereas the iodide derivative displays one broad signal at $\delta$ = 46.3 ppm with

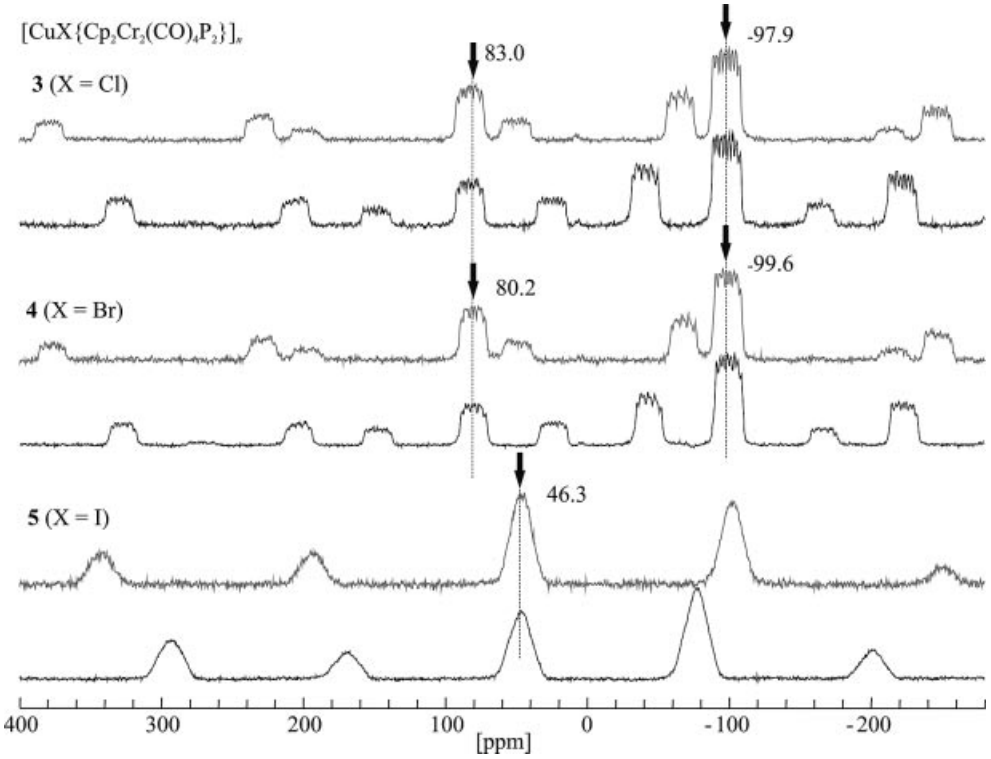

Figure 3. Solid-state $^{31}P$ MAS NMR spectra of polymers **3**–**5** [X = Cl (**3**), Br (**4**), I (**5**)], recorded with a spinning rate of 25 (bottom) and 30 kHz (top). The peaks marked with arrows are the MAS centre-bands whereas the unmarked peaks are the spinning side-bands.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

no analysable fine structure. These spectra may seem puzzling at first sight considering the solid-state structures of polymers **3**–**5** (Figure 1) as all three polymers contain two sets of crystallographically distinct phosphorus atoms (P1 and P2), which nevertheless appear to be chemically similar. Accordingly, the severely broadened $^{31}$P NMR spectrum of the iodide derivative **5** can be interpreted in terms of two unresolved signal components. In contrast, the spectra observed for the chloride and bromide derivatives **3** and **4**, respectively, both of which exhibit two signals separated by about 180 ppm, are initially most surprising. As discussed previously,[2d] we can interpret this observation as a result of the deshielding effect exercised by the cones of anisotropy of the carbonyl ligands. A detailed examination of the structures reveals that the orientation of the P1 and P2 atoms with respect to these ligands differs and, furthermore, the average interatomic distance between the P1 atoms and the carbonyl carbon atoms of the corresponding $Cr_2P_2$ moieties in **3** and **4** [**3**: 3.128(1) Å; **4**: 3.129(1) Å] is shorter than that of the P2 atoms [**3**: 3.286(1) Å; **4**: 3.279(1) Å]. The corresponding average interatomic distances in **5** are 3.065(1) and 3.079(1) Å. Thus, in analogy to the situation previously described for the molybdenum compounds **6**–**8**,[2d] the environments of the P1 and P2 atoms in **3** and **4** are somewhat different while those of the P1 and P2 atoms in **5** are essentially identical, as suggested by the $^{31}$P MAS NMR spectra. While the spectra of **3**–**5** are astonishingly similar to those of the molybdenum analogues **6**–**8**, a satisfactory simulation of the spectrum of **3** (Figure 4) could only be obtained by including the additional effect of $^2J_{P,P}$ coupling; this coupling also manifests itself by broadening effects in the spectrum of **4** (Figure 4).

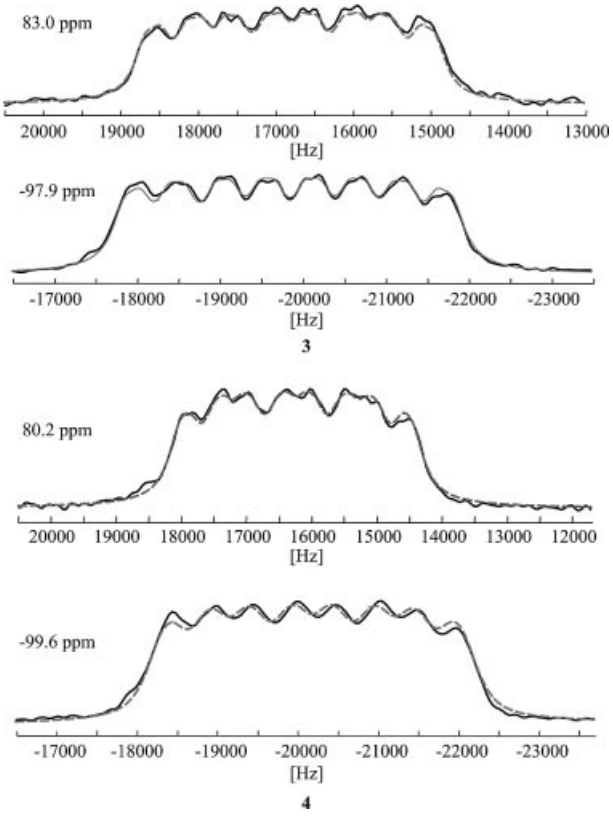

Figure 4. Comparison of the experimental (solid curve) and simulated (dashed curve) solid-state $^{31}$P MAS NMR spectra of polymers **3** and **4** (**3**: $\delta$ = 83.0 ($^1J_{Cu,P}$ = 1004, $^1J_{P,P}$ = 532, $^2J_{P,P}$ = 200 Hz, P1) and –97.9 ppm ($^1J_{Cu,P}$ = 1079, $^1J_{P,P}$ = 533, $^2J_{P,P}$ = 199 Hz, P2); **4**: $\delta$ = 80.2 ($^1J_{Cu,P}$ = 962, $^1J_{P,P}$ = 531, $^2J_{P,P}$ = 195 Hz, P1) and –99.6 ppm ($^1J_{Cu,P}$ = 1024, $^1J_{P,P}$ = 531, $^2J_{P,P}$ = 175 Hz, P2).

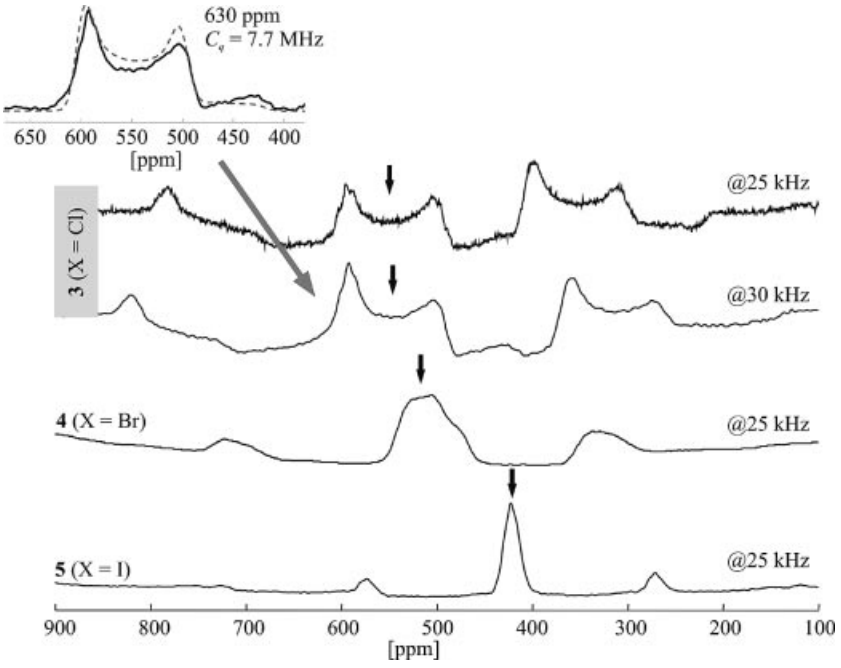

Figure 5. $^{63}$Cu MAS NMR spectra of compounds **3** (two different spinning frequencies), **4** and **5**. MAS centre-bands are labelled with black arrows. The inset compares the MAS centre-band (solid curve) to a simulated second-order quadrupolar powder pattern lineshape (dashed curve; $\eta$ = 0).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The low-field signals in the spectra of **3** and **4** are assigned to the P1 atoms since they are closer, on average, to the carbonyl ligands than are the P2 atoms, and therefore experience greater deshielding.

The $^{63}$Cu MAS NMR spectra of compounds **3**–**5** are presented in Figure 5. The spectrum of **5** exhibits a sharp line centred near $\delta$ = 422 ppm vs. crystalline CuI, while the MAS NMR spectra for **3** and **4** are strongly broadened by second-order quadrupolar perturbations. The $^{63}$Cu MAS NMR spectrum of **3** could be simulated with an isotropic chemical shift of $\delta$ = 630 ppm, a nuclear electric quadrupolar coupling constant of 7.7 MHz and a zero asymmetry parameter by using the dmfit routine. For **4**, the simulation of the experimental spectra yielded an isotropic chemical shift of $\delta$ = 550 ppm, and nuclear electric quadrupolar coupling constants of 5.2 and 4.8 MHz for $^{63}$Cu and $^{65}$Cu, respectively. Since the spectra of **4** were rather poorly resolved, no reliable value could be determined for the asymmetry parameter. The isotropic chemical shifts measured for the copper nuclei within the distorted $CuP_2X_2$ tetrahedral environments are consistent with those previously measured for the analogous molybdenum-based compounds[2d] and show a monotonic trend along the I → Br → Cl series. Furthermore, inspection of Table 1 reveals that the $CuX_2P_2$ tetrahedra become increasingly distorted along this series (note the significant trend of the X–Cu–X angles in particular), thereby offering a good structural rationale for the large changes observed in the $C_q$ values measured for the copper nuclei.

### Theoretical Calculations

Density functional theory (DFT) calculations were carried out on complexes **3**–**5** to support the $^{31}$P MAS NMR assignments proposed above. Full structure optimisations of the crystal structures were performed and the most important calculated structural parameters, which are in very good agreement with the experimental data (Table 1), are presented in Table 3. The calculated $^{31}$P NMR chemical shifts (Table 4) are also in very good agreement with the experimental data. For the chloride and bromide derivatives, the calculated chemical shifts of the P1 and P2 atoms are separated by about 200 ppm, whereas in the iodide derivative these shifts differ by 2 ppm. The results of the calculations thus support the deductions inferred.

Table 3. Comparison of selected calculated bond lengths [Å] and angles [°] in compounds **3**–**5**.

| | **3** (X = Cl) | **4** (X = Br) | **5** (X = I) |

## Conclusions

The $P_2$-ligand complex **2** reacts with copper(I) halides to yield the new 1D polymers **3**–**5**. Thus, in contrast to the reactivity of complex **2** towards organometallic Lewis-acidic complexes,[5] the tetrahedrane structure of **2** remains intact upon reaction with copper(I) halides. The cores of **3**–**5** consist of an alternating arrangement of six-membered $Cu_2P_4$ and four-membered $Cu_2X_2$ [X = Cl (**3**), Br (**4**), I (**5**)] rings that are nearly orthogonal to each other. This structural motif is reminiscent of that of the 1D polymers **6**–**8**,[2a,2d] which are the molybdenum analogues of compounds **3**–**5**. Polymers **3**–**5** are the first extended assemblies incorporating **2** as a ligand and thus demonstrate the potential of **2** as a supramolecular building block.

Solid-state $^{31}$P MAS NMR measurements have been performed on the polymers **3**–**5**. The spectra of **3** and **4** display two well-separated signals, whereas only one broad signal is observed in the spectrum of **5**. Each polymer contains two sets of crystallographically distinct phosphorus atoms (P1 and P2), which, at first sight, appear chemically similar. However, inspection of the average interatomic distances between the phosphorus atoms and the carbonyl carbon atoms of the respective units of **2** has revealed that the P1 and P2 atoms in **3** and **4** are shielded to different degrees by the carbonyl ligands, while the P1 and P2 atoms in **5** are shielded to virtually the same extent. Thus, as already demonstrated for the molybdenum analogues **6**–**8**, the chemical shift of the phosphorus atoms in polymers **3**–**5** appears to be exceedingly sensitive to the position of the phosphorus atoms with respect to the cones of anisotropy of the carbonyl ligands, and this has been confirmed by DFT calculations on these compounds.

## Experimental Section

**General Remarks:** All manipulations were performed under an atmosphere of dry nitrogen using standard glove-box and Schlenk techniques. All solvents were freshly distilled from appropriate drying agents immediately prior to use. IR spectra were recorded with a Varian FTS 2000 spectrometer. Solution NMR spectra were acquired with a Bruker Avance 400 MHz spectrometer. ESI mass spectra were recorded with a Finnigan Thermoquest TSQ 7000 mass spectrometer.

**Reagents:** $[Cp_2Cr_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ (**2**) was prepared according to the literature procedure.[4b] CuCl (Strem) and CuBr (Strem) were

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

purified before use, under a nitrogen atmosphere, by washing with the appropriate aqueous hydrohalic acid (half-concentrated), followed by $H_2O$, EtOH and $Et_2O$. The resulting solids were then dried at room temperature under high vacuum and stored in a dry box. CuI (Aldrich) was purified and stored in a similar manner, the only difference being that a mixture of aqueous HCl (half-concentrated) and KI was used as the first washing medium.

**Crystal Structure Analysis:** Data were collected with a STOE IPDS diffractometer. The structures were solved using SIR-97[7] and refined using SHELXL-97[8] with anisotropic displacements for non-hydrogen atoms. Hydrogen atoms were located in idealised positions and refined isotropically according to the riding model. Further details are given in Table 5.

CCDC-633372 to -633374 (for **3**–**5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Solid-State MAS NMR Spectroscopy:** $^{31}P$, $^{63}Cu$ and $^{65}Cu$ MAS NMR spectra were recorded at resonance frequencies of 202.5, 132.6 and 142.1 MHz, respectively, on a Bruker DSX-500 spectrometer equipped with a 2.5-mm NMR probe operating at MAS rotation frequencies of 25–30 kHz. Typical acquisition parameters for single-pulse measurements: pulse length: 3.0 μs (90° flip angle) for $^{31}P$ and 0.7 μs (30° flip angle) for $^{63,65}Cu$; recycle delay: 150 s for $^{31}P$ and 1 s for $^{63,65}Cu$; 256–512 scans for $^{31}P$ and 10000 scans for $^{63,65}Cu$. $^{31}P$ and $^{63,65}Cu$ NMR chemical shifts are referenced to 85% $H_3PO_4$ and crystalline CuI, respectively.

**Theoretical Calculations:** The following procedure was used to calculate the $^{31}P$ NMR chemical shifts. Starting from the experimental crystal structures, compounds **3**–**5** were fully optimised at the density functional theory (DFT) level using the Vienna Ab initio Simulation Package (VASP)[9,10] along with the Perdew–Wang (PW91)[11] exchange-correlation functional. The electron–ion interactions were described by the projector augmented wave (PAW) method[12] as used by Kresse and Joubert.[13] A plane-wave basis set with an energy cutoff of 300 eV along with appropriate PAW potentials was used. For the integration of the Brillouin zone, a $(1\times2\times1)$ Monkhorst–Pack grid[14] was used for **3** and **4** and a $(2\times1\times1)$ grid for **5**. Next, molecular fragments containing three $[CuX\{Cp_2Cr_2(CO)_4(\mu,\eta^2{:}\eta^1{:}\eta^1\text{-}P_2)\}]$ (X = Cl, Br, I) units terminated with single X atoms were cut out from the optimised structures. The $^{31}P$ chemical shifts were calculated for the fragments within the GIAO approach,[15] using the BP86 exchange-correlation functional,[16] SVP basis sets[17] and the Gaussian 03 program package.[18] Relativistic effective core potentials were used for iodine.[19] The $^{31}P$ chemical shifts relative to 85% $H_3PO_4$ were calculated from absolute shielding constants, $\sigma$, by using $PO(CH_3)_3$ as an internal secondary standard ($\sigma$ = 188.1) with an experimental $^{31}P$ chemical shift[20] of $\delta$ = 140 ppm relative to 85% $H_3PO_4$.

**Synthesis of 3:** A solution of CuCl (49 mg, 0.49 mmol) in $CH_3CN$ (10 mL) was carefully layered over a solution of **2** (100 mg, 0.25 mmol) in $CH_2Cl_2$ (10 mL) at room temperature. The vessel was left at room temperature in the dark and moss-green needles of **3** were deposited within a month. These were filtered, washed with $CH_3CN$ ($2\times3$ mL) and pentane ($2\times3$ mL), in that order, and dried under vacuum. Yield: 100 mg (80%); m.p. 167 °C (decomp.). $^{31}P$ MAS NMR (202.5 MHz, room temp.): $\delta$ = –97.9 (m), 83.0 ppm (m). $^{63}Cu$ MAS NMR (132.6 MHz, room temp.): $\delta$ = 630 ppm (br). Positive-ion ESI MS ($CH_3CN$, room temp.): *m/z* (%) 1076.7 (3) $[Cu_3Cl_2\{Cp_2Cr_2(CO)_4P_2\}_2]^+$, 1022.6 (2) $[Cu_3Cl_2\{Cp_2Cr_2(CO)_3P_2\}_2]^+$, 978.7 (16) $[Cu_2Cl\{Cp_2Cr_2(CO)_4P_2\}_2]^+$, 922.7 (8) $[Cu_2Cl\{Cp_2Cr_2(CO)_3P_2\}_2]^+$, 878.8 (33) $[Cu\{Cp_2Cr_2(CO)_4P_2\}_2]^+$, 864.7 (2) $[Cu_2Cl\{Cp_2Cr_2(CO)_2P_2\}_2]^+$, 822.8 (43) $[Cu\{Cp_2Cr_2(CO)_3P_2\}_2]^+$, 794.8 (1) $[Cu\{Cp_2Cr_2(CO)_{2.5}P_2\}_2]^+$, 766.8 (22) $[Cu\{Cp_2Cr_2(CO)_2P_2\}_2]^+$, 712.7 (1) $[Cu\{Cp_2Cr_2(CO)P_2\}_2]^+$, 751.8 (1) $[Cu_2Cl\{Cp_2Cr_2(CO)P_2\}_2]^+$, 695.9 (1) $[Cu_2Cl\{Cp_2Cr_2P_2\}_2]^+$, 654.7 (1) $[Cu\{Cp_2Cr_2P_2\}_2]^+$, 511.8 (60) $[Cu\{Cp_2Cr_2(CO)_4P_2\}(NCCH_3)]^+$,

# Tagging (Arene)ruthenium(II) Anticancer Complexes with Fluorescent Labels

**Fabio Zobi,[a] Beeta Balali Mood,[a] Peter A. Wood,[a] Francesca P. A. Fabbiani,[a] Simon Parsons,[a] and Peter J. Sadler*[a]**

**Keywords:** Anticancer agents / Organometallic compounds / Fluorescence / Ruthenium / Hydrolysis

Fluorescent (arene)ruthenium(II) complexes have been prepared by tagging a small fluorogenic reporter onto the chelating ligand of complexes of the type $[(\eta^6\text{-arene})RuCl(Z)]^+$ (Z = chelating ligand). Complexes $[(\eta^6\text{-}p\text{-cym})RuCl(NNO)](Cl)$ (**2**), $[(\eta^6\text{-}p\text{-cym})RuCl(\mathbf{L3})](Cl)$ (**3**) and $[(\eta^6\text{-}p\text{-cym})RuCl(\mathbf{L4})](Cl)$ (**4**) {*p*-cym = *p*-cymene, NNO = 2-[(2-aminoethyl)amino]ethanol, **L3** = 2-[(2-aminoethyl)amino]ethyl-2-(methylamino)benzoate and **L4** = *N*-{2-[(2-aminoethyl)-amino]ethyl}-2-(methylamino)benzamide} were obtained in good yield from the reaction of the Ru dimer $[(\eta^6\text{-}p\text{-cym})RuCl_2]_2$ (**1**) and the corresponding ligand. The compounds have been fully characterized and their X-ray crystal structures are reported. Compounds **3** and **4** show a photoluminescence response centered at 435 nm with partial fluorescence quenching of the fluorogenic reporters **L3** and **L4** upon coordination to the metal center. Species **2**–**4** show good solubility both in water and organic solvents. In water, **2**–**4** readily hydrolyze to form the aqua complexes. These are stable at acidic pH forming 10–15 % of the corresponding hydroxido complexes in buffered solution (25 mM HEPES) as the pH is raised to a physiological value (pH = 7.44). Under these conditions, **4** (but not **2** or **3**) undergoes a fast pH-dependent reversible intramolecular rearrangement. Experimental data and semiempirical calculations indicate that the major species arising from this transformation is a complex with a tridentate chelating ligand following deprotonation at the nitrogen atom of the amide group. Esterase-catalyzed hydrolysis of **3** liberates isatoic acid (**MIAH**) and generates **2** indicating that the complex is a substrate for the enzyme. Complexes similar to **3** may have potential for esterase-activated Ru-based prodrug delivery systems.

## Introduction

Organometallic ruthenium(II) complexes of the type $[(\eta^6\text{-arene})RuCl(X)(Y)]$ (where X, Y are monodentate or chelating ligands) comprise a relatively new group of anticancer compounds which are cytotoxic to cancer cells, including cisplatin-resistant cell lines.[1,2] The geometry of the complexes is generally described as pseudo-octahedral "three-legged piano-stool" in which a π-bonded arene ligand provides the seat supported by a σ-bonded chlorido and a chelating ligand which form the three legs of the stool. The arene ligand is strongly bound and stabilizes the ruthenium(II) oxidation state. It resists hydrolysis and provides a lipophilic side to the complex.[3,4] Most of the halide compounds, however, are ionic and exhibit good aqueous solubility and appear to undergo rapid aquation (substitution of bound Cl by $H_2O$).[4] Thus, while $\eta^6$-arene–$Ru^{II}$ bonds are inert toward hydrolysis, the monofunctional complexes $[(\eta^6\text{-arene})Ru^{II}(en)(Cl)]^+$ (en = ethylenediamine) readily lose their chlorido ligand and transform into the corresponding, more reactive, aquated species.[4–6]

This type of compound has continued to attract attention since it was reported by Morris et al. in 2001 that $[(\eta^6\text{-biphenyl})Ru(en)Cl][PF_6]$ is as cytotoxic to cancer cells as carboplatin.[1] Although the cellular target for (arene)ruthenium compounds and the mechanism underlying their biological effects are not yet known, much of the research has focused on the interaction of these complexes with DNA bases and oligonucleotides.[1,5–10] In the same report Morris et al. described strong and selective binding to G bases on DNA, while no inhibition of topoisomerase I or II was detected. Subsequently, Chen et al. showed that $[(\eta^6\text{-arene})Ru(en)]^{2+}$ complexes exhibit a remarkably high preference for binding to guanine N7.[5,6] Such binding is stabilized by H-bonding between the O6 of G and NH of the en ligand and strong arene–nucleobase stacking when the arene is extended, suggesting a potential DNA-binding mode, involving simultaneous arene intercalation and $Ru^{II}$ coordination.[5,6] Hydrophobic interactions were described both in solution and in the solid state, and it was suggested that it is the flexibility of the arene ligand that allows for simultaneous arene–base stacking and N7-covalent binding. The remarkable site selectivity of the complexes was further demonstrated by Novakova et al. who showed by transcription mapping experiments that in cell-free media the interaction of $[(\eta^6\text{-arene})Ru(en)]^{2+}$ complexes with DNA occurs at G N7.[11] In the same report noncovalent, hydrophobic interaction between the arene ligand and DNA was demonstrated by competitive ethidium displacement.

Reactions of the (arene)chlorido(ethylenediamine)$Ru^{II}$ complexes with nucleotides appear to involve initial aquation of the arene complexes, and reactions of the aqua complexes with cyclic guanosine monophosphate are faster than those of the chlorido complexes.[4–6] Wang et al. showed that rates of aquation of these (arene)ruthenium anticancer agents are >20× faster than that of cisplatin. The aqua complexes behave as weak acids with p$K_a$ values for the aqua adducts ranging from 7.7 to 8.[4]

In contrast to *cis*-[$PtCl_2(NH_3)_2$], cisplatin, [($\eta^6$-arene)-Ru(en)]$^{2+}$ complexes show little binding to adenine. This is attributable to repulsive interactions between the exocyclic amino group of the base and (en)Ru $NH_2$ groups.[5,6] Replacing the neutral en by anionic acetyl acetonate as the chelating ligand changes the nucleobase specificity, and the overall affinity for adenosine was demonstrated to be greater than for guanosine.[7] The cytotoxicity of the complexes increases with the size of the arene ring system in the series arene = benzene < *p*-cymene < biphenyl < dihydroanthracene < tetrahydroanthracene which further supports a potential DNA-binding mode, involving simultaneous arene intercalation and $Ru^{II}$ coordination.[2]

Other cytotoxic (arene)Ru complexes of general formula [($\eta^6$-arene)$RuCl_2$(X)] (X = monodentate ligand) have also recently been reported, including 1,3,5-triaza-7-phosphaadamantane (PTA) and imidazole compounds described by Dyson et al.[12–16] These complexes show activity towards the TS/A mouse adenocarcinoma cancer cell line and no apparent cytotoxicity towards HBL-100 human mammary (non-tumor) cell line.[13,14] The cellular target and the mechanism underlying the biological effects for these (arene)ruthenium compounds are also not yet known. The molecules, however, exhibit a pH-dependent DNA damage such that at pH values typical of hypoxic cells DNA is damaged, whereas at pH values characteristic of healthy cells little or no damage is detected.[13,14] The complexes described by Dyson and co-workers may act by a different mechanism from those of general formula [($\eta^6$-arene)-RuCl(X)(Y)]. Loss of the arene is observed in the former complexes, and it has been suggested that single-stranded DNA may wrap around the metal center with formation of multiple coordinative N-donor bonds.[12]

In view of the importance of understanding the biological distribution of (arene)ruthenium compounds, and thus elucidating their mechanism of action, we have tagged them with a small fluorescent probe. Fluorescence microscopy has been widely used to study cellular distribution of organic drugs,[17–19] and recently it has been applied successfully to platinum complexes.[20–24] In the latter case, fluorogenic reporters of different size have been used. These range from large carboxyfluorescein diacetate,[20–22] to medium-size diaminoanthracene[23,24] to small dinitrophenyl derivatives.[20–22] Cellular uptake of labeled compounds is affected by large fluorophores, and it has been suggested that fluorescein-labeled compounds diffuse in and out of the cells and intracellular compartments at a greater rate than the parent compounds.[25]

Owing to these considerations, we have synthesized methylisatoic anhydride (**MIA**) based fluorescent derivatives of (arene)ruthenium complexes and studied their properties. The **MIA** probe was chosen for its relatively small size, a feature that we anticipated might not alter significantly the properties of the complexes. The probe has found wide applications in biochemistry, and it has been used to label a variety of biological substrates ranging from RNA and Ras-like low-molecular-weight GTP-binding proteins to relatively large enzymes like kinases and ATPases.[26–30] We report here the synthesis and characterization of **MIA**-based fluorescent derivatives of (arene)ruthenium complexes (Scheme 1). We have also studied the interaction of complexes **3** and **4** (Scheme 1) with porcine liver esterase (PLE), and we show that esterase-catalyzed hydrolysis reactions can liberate methylisatoic acid (**MIAH**) from complex **3** suggesting a possible use of similar derivatives in esterase-activated Ru-based prodrug delivery systems.

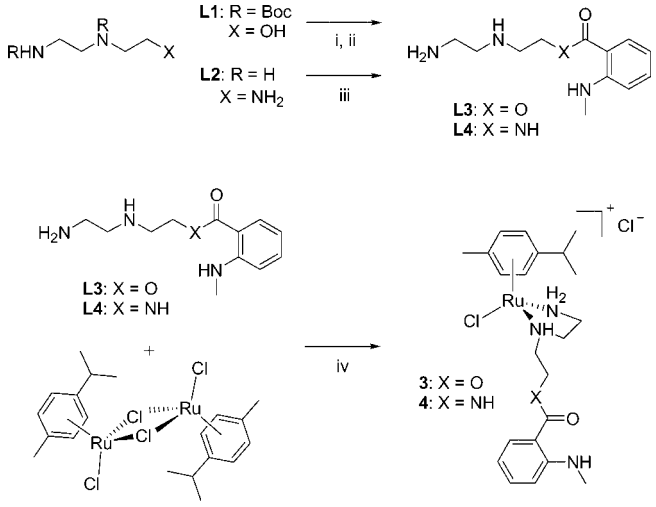
## Results and Discussion

### Synthetic Aspects and General Considerations

Reaction of the dimer [($\eta^6$-*p*-cym)$RuCl_2$]$_2$ (**1**) with 2.2 mol-equiv. of the corresponding ligand afforded the complexes [($\eta^6$-*p*-cym)RuCl(NNO)](Cl) (**2**), [($\eta^6$-*p*-cym)-RuCl(**L3**)](Cl) (**3**) and [($\eta^6$-*p*-cym)RuCl(**L4**)](Cl) (**4**) in good yields (Scheme 2). Complex **2** was first prepared for a direct conjugation reaction with **MIA**. This strategy, however, proved unsuccessful, and we were able to detect only small amounts of **3** by this route. We then proceeded by the organic synthesis of ligands (Scheme 2), and we used **2** as a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

standard for comparison with species **3** and **4**. The compounds were characterized by $^1$H NMR spectroscopy and electrospray ionization mass spectrometry (ESI-MS). The ESI mass spectra of **2**–**4** in water, methanol or $CH_3CN$ provided parent peaks corresponding to the cations. Depending on the cone voltage, peaks corresponding to further loss of HCl were also observed. All spectra confirmed the presence of the expected products.



Scheme 2. Synthesis of **MIA**-related ligands and complexes. Conditions: i: **MIA**, $CH_3CN$, $K_2CO_3$, room temp. ii: TFA, $CH_2Cl_2$, room temp. iii: **MIA**, $CHCl_3$, $K_2CO_3$, room temp. iv: $CHCl_3$, room temp.

Complexes **2**–**4** showed good solubility both in water and organic solvents. The NMR spectra of compounds **3** and **4** in deuteriated chloroform contain peaks between δ = 6.5 and 8.1 ppm that correspond to the aromatic protons of the 2-(methylamino)benzoate/benzamide fragment; aliphatic proton signals are observed between δ = 2.5 and 4.7 ppm. Peaks for arene ligand protons are observed between δ = 5.4 and 5.9 ppm, with the C*H*$(CH_3)_2$ proton displaying a characteristic septet between δ = 1.7 and 2 ppm. Methyl group signals appear at δ ≈ 1.3 ppm. In water, the compounds readily form the corresponding aqua complexes. These are stable at acidic pH*, and no hydroxido species could be detected under these conditions. The p$K_a$ values of the aqua complexes also lie above 7 in agreement with values reported for similar arene species.[4,7] As the pH is raised to within the physiological range (buffered solutions, pH = 7.44) the complexes behave as weak acids forming about 10–15% of the corresponding hydroxido species. Complexes **2** and **3** are stable under these conditions for hours, but **4** slowly undergoes an intramolecular rearrangement following deprotonation at the amide nitrogen atom. This process is described in detail in the following sections. Attempts to obtain X-ray quality crystals of the aqua and hydroxido complexes were unsuccessful, but the chlorido adducts were readily crystallized from organic solvents.

## X-ray Crystallography

Crystallographic data are listed in Table 4 and selected bond lengths and angles in Table 1. The structures of the complexes **2**, **4** and **3** are shown in Figures 1, 2 and 3, respectively. All complexes have the familiar pseudo-octahedral "three-legged pianostool" geometry as described previously. Complex **2** crystallizes in space group $P\bar{1}$ with one solvent molecule of methanol and shows disorder in the methyl groups of the isopropyl substituent of *p*-cym. The disorder was modelled by allowing ½ occupancy for each of the four carbon atoms involved. The $Cl^-$ counter anion bridges the hydroxy groups of the solvent molecule and the pendent arm of the chelating ligand through two hydrogen bonds.

Table 1. Selected bond lengths [Å] and angles [°] for cations of **2**, **3** and **4**.[a]

| | **2** | **3** | **4** |
|---|---|---|---|
| Ru–Cl | 2.4257(10) | 2.4148(8) | 2.4149(18) |
| Ru–N′ | 2.125(4) | 2.132(3) | 2.115(6) |
| Ru–N′′ | 2.168(3) | 2.159(3) | 2.142(6) |
| N′–Ru–N′′ | 79.48(14) | 80.32(10) | 79.7(2) |
| N′–Ru–Cl | 83.89(10) | 82.71(8) | 85.13(17) |
| N′′–Ru–Cl | 86.92(9) | 86.88(8) | 87.83(17) |

[a] N′ and N′′ refer to the primary and secondary amine, respectively, of the chelate ligand.

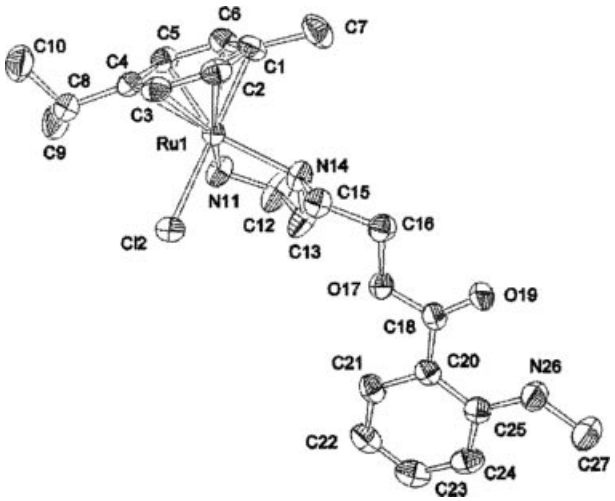

Figure 3. ORTEP diagram and atom numbering scheme for the cation of **3** (50% probability ellipsoids). The H atoms have been omitted for clarity.

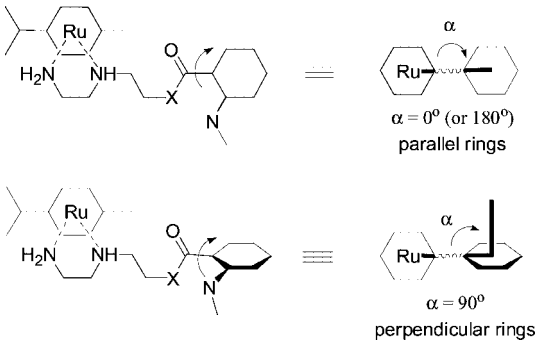

Figure 4. Schematic representation and definition of the angle $\alpha$.

Complex **4** also crystallized in space group $P\bar{1}$ with two independent molecules in the asymmetric unit. These differ by the relative orientation of the 2-(methylamino)benzamide ring with respect to the aromatic arene ring (see Figure 4). In one molecule the plane defined by the six carbon atoms of the 2-(methylamino)benzamide ring forms an angle $\alpha$ of 28° with the plane of *p*-cym, while in the other molecule the benzamide ring is rotated with an angle $\alpha$ of 47°. Three solvent molecules of chloroform co-crystallize with the complex with two $Cl^-$ counterions completing the content of the asymmetric unit. The counterions form H-bonds with NH and $NH_2$ groups of the chelating ligand.

In order to obtain crystals of **3**, the $Cl^-$ counterion had to be removed by addition of $AgClO_4$. Thus, complex **3**, as a $ClO_4^-$ salt, crystallized in space group $P2_1/n$. No solvent molecules are present in the asymmetric unit. The $ClO_4^-$ counterion shows disorder in one oxygen atom. In this case also the disorder was modelled by allowing ½ occupancy for each oxygen atom. In this structure the plane defined by the 2-(methylamino)benzoate ring is almost perpendicular to that of the *p*-cym ring ($\alpha$ = 88°, Figure 4).

For structures of the cations of **2**, **3** and **4**, metal–nitrogen and metal–chlorido bonds all fall within normal values (Table 1).[1–7] Bond lengths and distances around the metal coordination sphere are similar (within 3σ) in all three structures indicating that addition of 2-(methylamino)benzoate/benzamide has little effect on the overall coordination of the bidentate chelate. In the crystal structure of the $ClO_4^-$ salt of **3**, short van der Waals contacts are found between *p*-cym hydrogen atoms and the carbonyl oxygen atom and the $CH_3NH$ group of the 2-(methylamino)benzoate fragment of adjacent molecules. These are shown in Figure 5. Such short contacts involving coordinated arenes are becoming increasingly recognized.[31] They have also been observed in [($\eta^6$-*p*-cym)M(acac)Cl] (M = Ru or Os) complexes,[7] and it has been suggested that the weak polarization of arene ring C–H bonds may lead to interactions be-

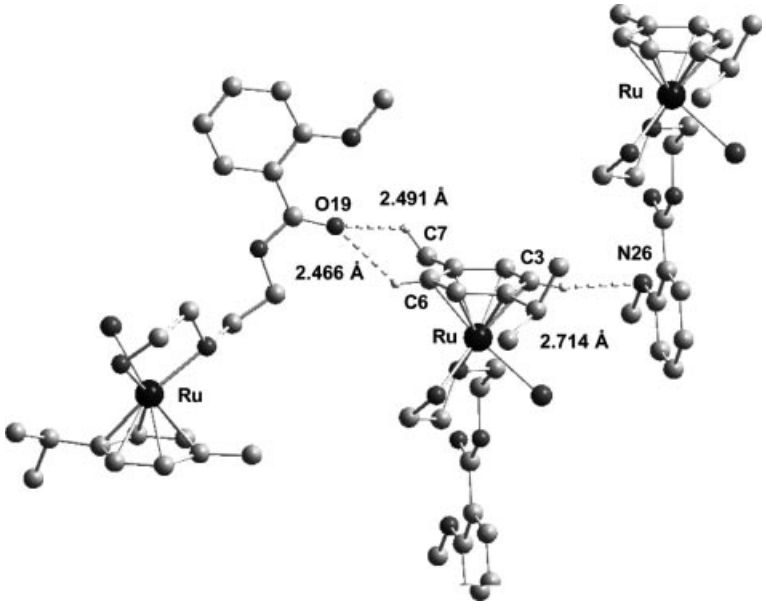

Figure 5. Short contacts involving arene hydrogen atoms of the cation in the crystal structure of **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tween the coordinated arene and H-bond acceptors in biological target sites such as DNA or RNA.[32] It is worth noting that we found no evidence of π-stacking interactions in any of the reported structures.

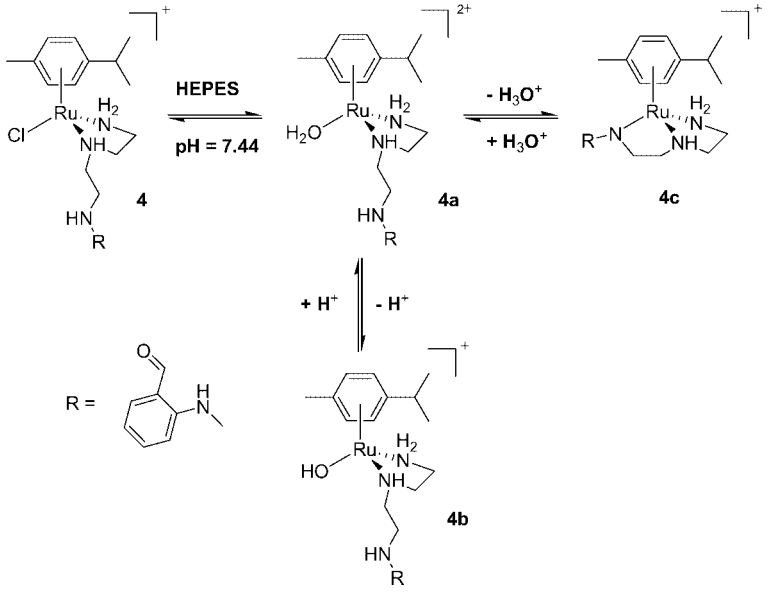
Complexes **3** and **4** are the first examples of metal complexes with a pendent 2-(methylamino)benzoate/benzamide ring, thus restricting structural comparisons with similar compounds. To the best of our knowledge, the only other instance in which the same fragments have been used in coordination chemistry is in the preparation of Bosnich's type of ligands in complexes investigated for cooperative dimetallic redox reactivity. In those complexes, however, the fragment is part of a larger dinucleating ligand framework.[33–38]

### Stability in Aqueous Buffered Solutions

In water the compounds readily form the corresponding aqua complexes which are stable at acidic pH. In a buffered solution (25 mM HEPES, pH = 7.44) the complexes behave as weak acids forming about 10–15% of the corresponding hydroxido species. Complexes **2** and **3** are stable under these conditions for hours, while **4** slowly undergoes an intramolecular rearrangement following deprotonation at the amide nitrogen atom as shown in Scheme 3.

The $^1$H NMR spectrum of **4** in the buffered solution is shown in Figure 6. After ca. 15 min, three sets of *p*-cym signals were visible in the spectrum of the complex (Figure 6a). The major species is the aqua complex **4a** with *p*-cym resonances at $\delta$ = 5.52, 5.67 and 5.72 ppm. The corresponding resonances of the hydroxido species **4b** are shifted upfield to $\delta$ = 5.18 and 5.38 ppm. A third set of *p*-cym signals assigned to **4c** appears at $\delta$ = 5.15 and 5.30 ppm. Formation of **4c** was clearly evident from the time-dependent evolution of the NMR spectrum. The reaction was complete within 3 h, and the mixture thus obtained was stable for hours under these conditions. Formation of **4c** is accompanied by the appearance of a fourth species (**4d** in Figure 6). The relative integrated intensity of the signals corresponding to **4d** account for about 2% of the total *p*-cym resonances compared to 9% of the hydroxido species **4b** and 89% of **4c**. We tentatively assign these **4d** resonances to an HEPES complex of **4**. Although sulfonates are weak ligands, the assignment is reasonable given the relatively high concentration of the buffer. Moreover, it has been shown that under similar conditions, reactions of (arene)-ruthenium species with nucleotides produce ca. 1.5% of stable phosphate-bound complexes.[6] It is worth noting that the relative concentration of the hydroxido species **4b** remains unchanged during the course of the transformation indicating that the aqua complex **4a** is the reactive species.

Relative to peaks for **4a**, the NHu proton signals suffer a dramatic downfield shift for **4c**. This indicates either a strong interaction of these hydrogen atoms with nucleophilic atoms or a strong deshielding influence of the aromatic ring current of the benzamide fragment; or a combination of both. Related [($\eta^6$-arene)Ru(en)guanine]$^+$ complexes, for example, show stereospecific en NHd bonding with guanine O6, and these species in solution show a downfield shift of the chelate en NHd hydrogen signals of up to 1 ppm compared to the parent aqua complex.[5,6] It is unlikely that the observed shifts result from a partial overlap or π–π stacking of the aromatic rings, but it is possible that the shifts are also a consequence of the ring current generated by the orientation of the benzamide ring. Proton signals of the benzamide fragment show an unusual behaviour. The four non-equivalent resonances collapse into two signals, which might suggest an increased symmetry of the ring. This, however, is not possible as it would imply a complete rearrangement of the ring substituents. Therefore, we assign this to a coincidental overlap of resonances.



Scheme 3. Hydrolysis of **4** in buffered solution (25 mM HEPES, pH = 7.44).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

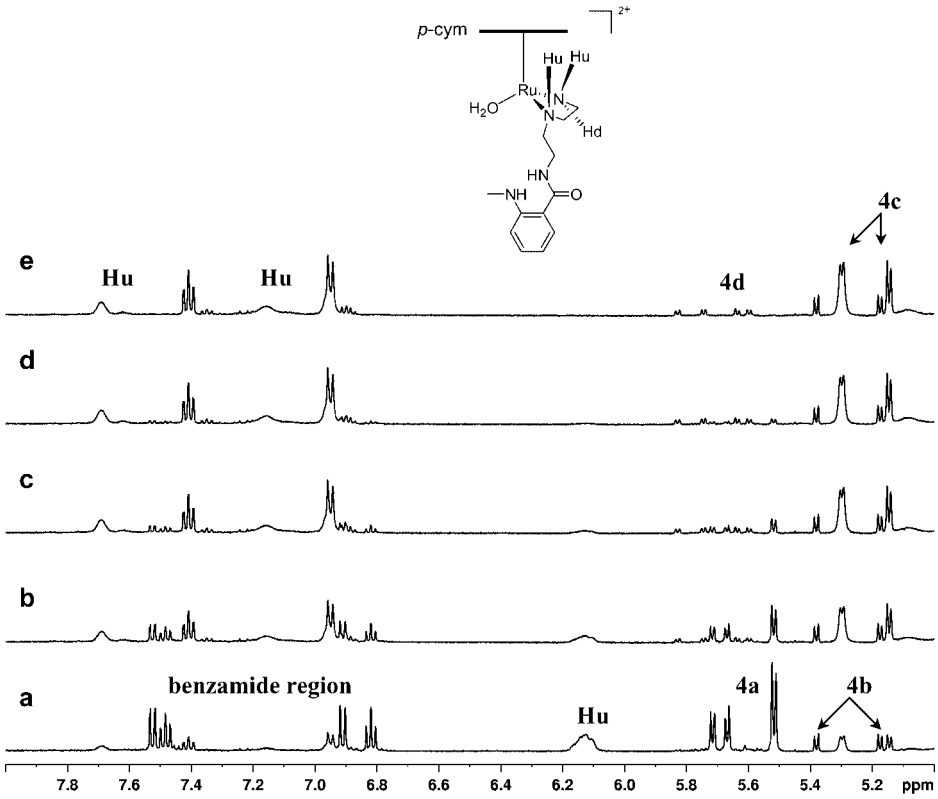


Figure 6. $^1$H NMR spectrum ($\delta$ = 5.1–7.9 ppm) of a 3 mM solution of [($\eta^6$-*p*-cym)Ru(**L4**)Cl]Cl (**4**) in HEPES buffer (25 mM, pH = 7.44). (a) After ca. 15 min; (b–d) 30-min time intervals; (e) after 3 h.

Substitution reactions of the aquated species **4a** are likely to follow the associative interchange mechanism previously described for related complexes. Wang et al. showed that aquation and anation substitution reactions of (arene)Ru species are influenced by steric hindrance of the arene ligand and that the rates of aquation of the halide complexes follow the order Cl ≈ Br > I, consistent with an associative mechanism.[4] Substituents on the *p*-cym ligand exert only minor steric effects when compared to the complexes studied by Wang et al.; however, as a π-acid ligand, *p*-cym depletes electron density on the metal center making it more electropositive. As demonstrated for [($\eta^6$-$C_6H_6$)-$Ru(H_2O)_3]^{2+}$, this electronic effect makes $Ru^{II}$ behave like an $Ru^{III}$ center in arene species,[39] thus making substitution reactions appear to occur by associative interchange mechanisms.

Changes observed in the NMR spectrum are accompanied by a transition in the UV/Vis spectrum as shown in Figure 7. Soon after dissolution of **4** in the buffer solution (pH = 7.44), the UV/Vis spectrum showed a broad d-d transition between 300 and 360 nm. Within 2 h, a relatively sharp peak at 294 nm replaced this absorption indicating that $H_2O$ is replaced by a ligand which causes a greater splitting of the metal d-orbitals. The intramolecular

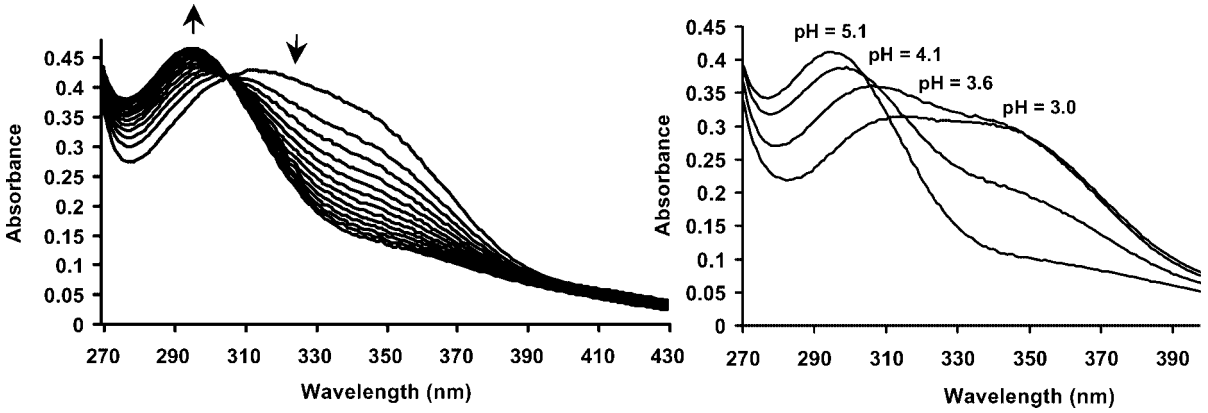

Figure 7. Left: Time evolution of the UV/Vis spectrum of a 0.5 mM solution of **4** (270–430 nm, 25 mM HEPES buffer, pH = 7.44, 5-min time intervals). Right: UV/Vis spectra of **4** at fixed pH values.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rearrangement of **4a** is a pH-dependent reversible process (Figure 7). Aliquots of a stock solution of **4** in water were added to 25 mM HEPES solutions, and the pH was adjusted to different values by addition of HCl. The mixtures were allowed to equilibrate at room temperature for 24 h, and their UV/Vis and ESI-MS spectra were recorded. UV/Vis analysis indicated that **4a** is stable at pH $< 3$ (Figure 7). Species **4c** began to form at pH $\approx 3.5$ and became the predominant species at higher pH values.

ESI-MS analysis confirmed this observation (Supporting Information: Figure S1). At pH $< 3.5$ only the parent peak corresponding to the cation of **4** is observed ($C_{22}H_{34}ClN_4ORu$: $m/z$ = 507.15, matching the predicted isotope pattern). At higher pH values a second peak corresponding to loss of HCl from the parent cation of **4** was also observed. This peak became the predominant signal at pH $> 4$.

### Geometry Optimization and INDO/S Analysis and Electronic Spectra

The molecular structure of **4c** was also confirmed by theoretical calculations. Molecular structures **B** and **C** were initially modeled from the crystal structure of the cation of **4** (structure **A**) and were optimized at the semiempirical level using default Hyperchem 7.5 INDO/1 functional and basis set. Structures are shown in Figure 8 and selected bond lengths are listed in Table 2. Structure **B** was chosen as a model of **4c**, while **C** (as a **4d** model) was optimized for comparison reasons. The tridentate chelate in **B** is stabilized by hydrogen bonds involving the 2-(methylamino)-benzamide ring and the Hd proton of the primary amine coordinated to the metal center. Compared to **A**, Ru–N distances increase slightly in **B** upon coordination of the deprotonated amide nitrogen atom. These results reflect an increased electron density at the metal center that weakens the σ-donor bonds of the chelate. The opposite effect is calculated for **C**, where Ru–N distances decrease (on average by 0.14 Å) by allowing HEPES to enter the Ru coordination sphere and occupy a coordination site through the sulfonate oxygen atom.

Table 2. Summary of selected INDO/1-optimized bond lengths [pm].

| | Ru–$NH_2$ | Ru–NH | Ru–X[a] |
|---|---|---|---|
| Structure **A** | 213 | 215 | 241 |
| Structure **B** | 216 | 220 | 199 |
| Structure **C** | 200 | 199 | 194 |

[a] X refers to the atom occupying the exchangeable coordination site. Thus, for structure **A**, X = Cl; for structure **B**, X = N; for structure **C**, X = O.

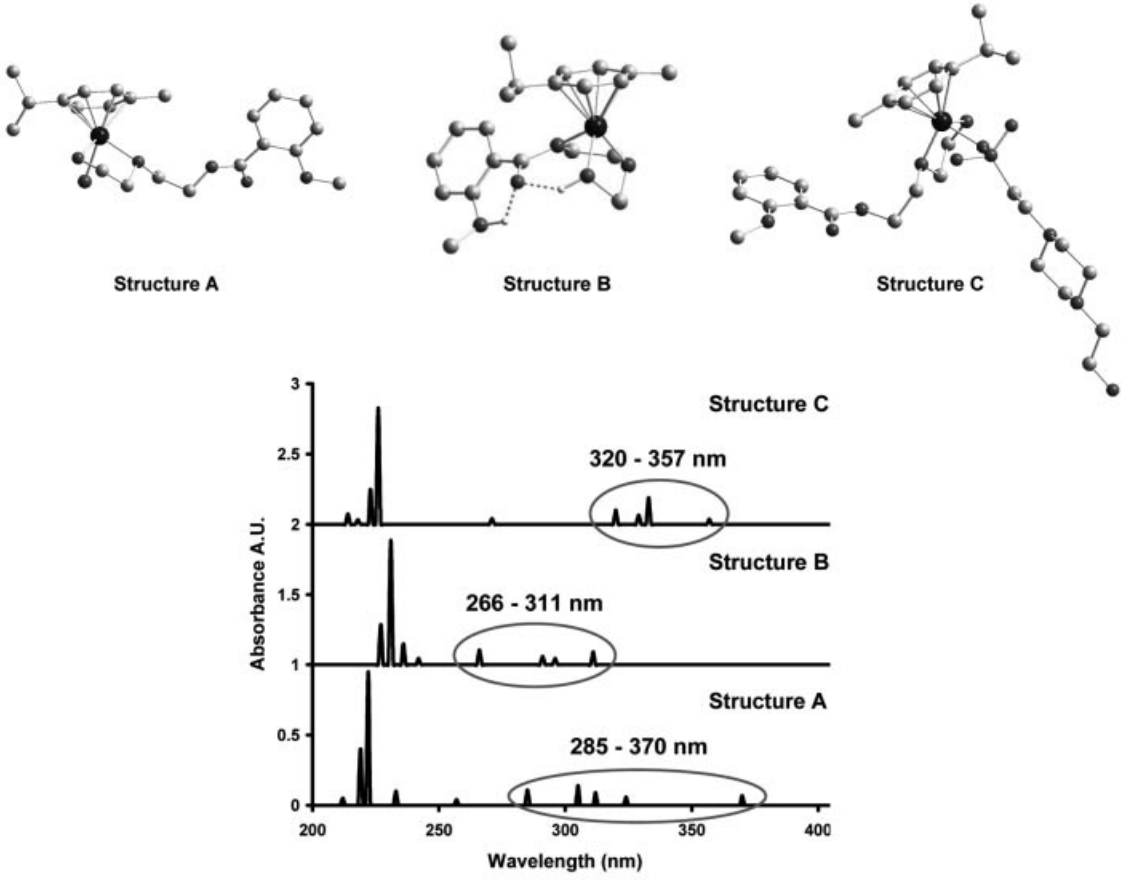

Figure 8. INDO/1-optimized geometry of structure **A** (**4**), **B** and **C** and relative predicted (gas-phase, INDO/S) spectra. Vertical bars are the predicted oscillator strengths and locations of individual computed transitions.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In both **B** and **C** the planarity of the arene ligand is somewhat lost compared to **A**. Both the methyl and the isopropyl group of *p*-cymene are slightly bent out of the plane defined by the six carbon atoms of the *p*-cym aromatic ring. The distortion of the arene is uniform and relatively contained in **C** with both methyl and isopropyl groups deviating from planarity by about 0.06 Å. In **B** the distortion is more pronounced and uneven with the methyl and the isopropyl substituents out of the benzene plane by 0.14 and 0.06 Å, respectively. In **A** the observed deviation is on average 0.04 Å. The net effect of these distortions is clearly visible in the predicted electronic spectra of the complexes discussed below.

Predicted absorptions of structures **A**, **B** and **C** are listed in Table 3, and spectra are shown in Figure 8. Calculations for the electronic spectra are essentially gas-phase, but the Zerner INDO parameters were obtained from solution-phase experimental data and are more likely to predict spectra where the solvent may play an important role.[40–43] In all cases calculated spectra show relatively strong transitions in the 220–235 nm region and a series of peaks of lesser intensity at longer wavelength. Overall the spectra compare well with experimental data. Complexes of the type [($\eta^6$-arene)M(X)(Y)] (M = $Ru^{II}$ or $Os^{II}$; X, Y = simple σ-donors, monodentate or chelating ligands) show a first band at 300–400 nm which is assigned to a metal d-d transition. A second band appears at around 250 nm with a shoulder at about 225 nm, and these are assigned to a d(M)→π*(X/Y) and to an arene π→π* transition, respectively.[44] The calculated spectra replicate well these features.

The loss of planarity of the arene ligand in **B** and **C** is reflected by a bathochromic shift of the π→π* transition relative to **A** (Figure 8). The degree of shift in energy can be related to the degree of arene distortion in the predicted structures. The shift is more pronounced in **B** (Δ = +9 nm) then in **C** (Δ = +5 nm). These predictions are reasonable because, while most steric effects in organic compounds cause steric inhibition of resonance which determines hypsochromic displacements in the electronic spectrum, geometry distortion tend to cause the opposite effect.[45,46] Distortion of an aromatic system raises the energy of both ground and excited states of the molecule. However, due to the greater antibonding character of the excited states their energies are less affected by distortion. Consequently, it is expected that the UV spectra would show their bands shifted bathochromically with respect to the normal, unstrained compounds of comparable structure and degree of substitution.

With respect to the d-d transition, the experimental UV/Vis spectrum of **4a** at pH = 3 (Figure 7) shows a broad absorption spanning from about 300 to 360 nm. As the pH is raised to 5.1, the transition is blueshifted with $\lambda_{max} \approx$ 294 nm. The predicted spectrum of structure **A** shows five peaks ranging from 285 to 370 nm in close agreement with the experimental spectrum of **4a** at low pH. The same d-d transition suffers two opposite shifts in the calculated spectra of **B** and **C**. A hypsochromic shift in the absorption is predicted for **B** (peaks in the range of 266–311 nm) which is consistent with the replacement of $H_2O$ or $Cl^-$ by the deprotonated amide group with stronger σ-donor character. For **C**, a bathochromic shift is predicted (peaks in the range of 320–357 nm). Of the two optimized structures, **B** shows the closest similarity to the UV/Vis spectrum of **4a** at pH = 5.1 (see Figures 8 and 9). Therefore, in agreement with experimental data, we argue that in 25 mM HEPES at pH = 7.44, **4a** undergoes deprotonation at the nitrogen atom of

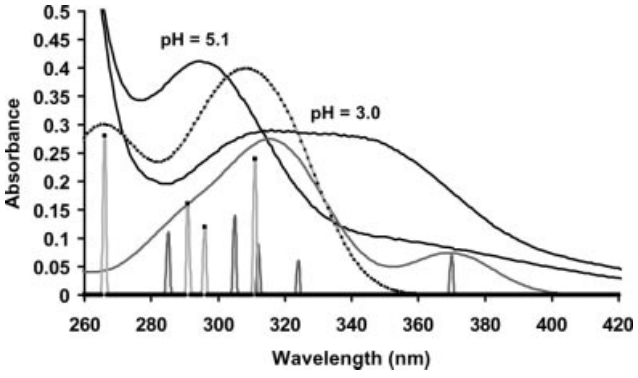

Figure 9. Experimental (black) and predicted (gas-phase, INDO/S) spectra of **4** (dark grey) and of structure **B** (light grey with squares). The vertical bars are the predicted oscillator strengths and locations of individual computed transitions. The oscillator strengths are arbitrarily scaled to match the overall spectra; they retain their correct relative intensity.

the amide group generating a complex with a tridentate chelate encompassing the $Ru^{II}$ center as depicted by structure **B**.

### Fluorescence Spectroscopy and PLE-Catalyzed Hydrolysis

In aqueous solutions (pH < 7) compounds **3** and **4** show a photoluminescence response upon excitation at 325 nm. The emission spectra of both compounds show a broad peak centered at around 435 nm. As expected, quenching of fluorescence is observed in the spectra of **3** and **4** compared to the spectra of methylisatoic acid (**MIAH**) and the corresponding free ligands **L3** and **L4** (Figure 10; Supporting Information: Figures S2 and S3). This is due to an internal heavy-atom effect. The quenching of fluorescence by heavy atoms is a phenomenon first identified as "physical quenching" by F. Perrin,[47,48] and it has been the subject of many studies.[49] Heavy atoms in the fluorophore, or in close contact with it, increase the rate of intersystem crossing (ISC) by strengthening spin-orbit coupling,[50,51] as for electronic transitions of heavy atoms. Thus, the decrease of fluorescence yield (radiative transition $S_1 \rightarrow S_0$) is explained by an increase in the probability of the competing $S_1 \rightarrow T_n$ radiationless transition of the fluorophore.

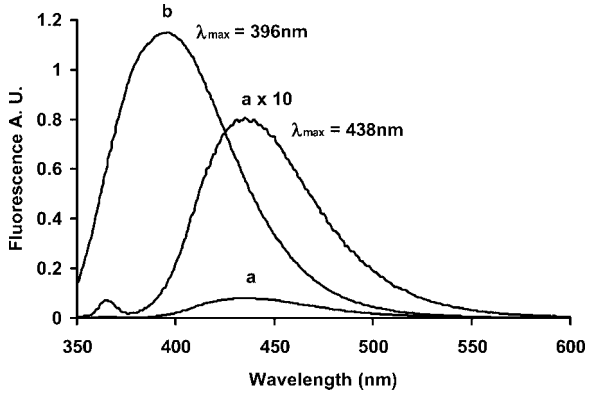

Figure 10. Fluorescence responses ($\lambda_{ex}$ = 325 nm) of a 7 μM aqueous solution of **4** (a), and of **MIAH** (b).

Complexes **3** and **4** show pH-dependent fluorescence responses (Figure 11) with maxima centered at around neutral pH. Complex **3** shows a local photoluminescence maximum at pH = 6; however, the fluorescence of the sample increases exponentially at pH > 8 due to base-catalyzed hydrolysis of the **L3** ester bond. Under these conditions, the conjugate base of **MIAH** is liberated, and the overall fluorescence of the sample increases. This observation prompted us to study the interaction of compounds **3** and **4** with porcine liver esterase (PLE) in order to determine if the complexes are substrates for this enzyme.

Ester hydrolysis by cytosolic esterases is a common strategy employed to trap photoluminescent organic sensors (most often fluorescein-type sensors) within the cell or to activate organic-based progrugs. Recently, the same strategy has being considered for possible esterase-activated metal-based prodrug delivery systems.[52] Experiments were performed in 25 mM HEPES-buffered solutions at pH = 7.44. Samples of the metal complexes were prepared in the buffer and allowed to equilibrate at room temperature for 5 h. Under these conditions, **3** hydrolyses to form the corresponding aqua (**3a**), hydroxido (**3b**) and HEPES (**3d**) complexes with relative percentage abundances of ca. 84, 14 and 2%, respectively. Complex **4**, on the other hand, is mainly present as the tridentate chelate **4c** following deprotonation at the amide nitrogen atom as described above. After the equilibration period, the enzyme was added and the interactions monitored by $^1H$ NMR and fluorescence spectroscopy.

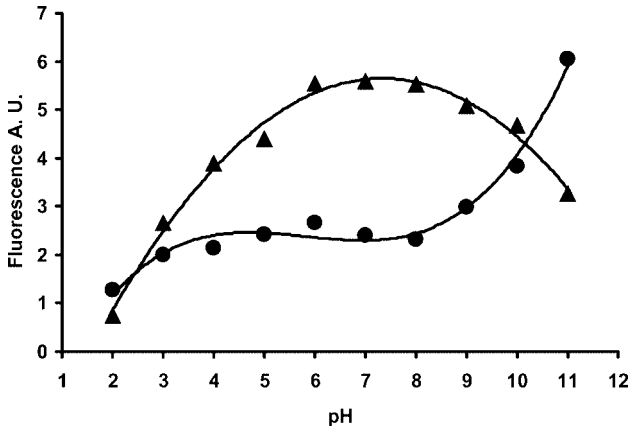

Figure 11. pH-dependent fluorescence responses ($\lambda_{ex}$ = 325 nm, $\lambda_{em}$ = 438 nm) of a 7 μM unbuffered aqueous solution of **3** (circles) and of **4** (triangles).

Treatment of **3** with PLE led to an increase in the photoluminescence intensity in its emission spectrum accompanied by a blue shift in the $\lambda_{em}$ maximum from 438 to 398 nm as shown in Figure 12. The reaction was complete after ca. 150 h of incubation, when no further spectral change could be detected. The hypsochromic shift clearly indicates hydrolysis of the **L3** ester bond and release of free **MIAH**. No change was observed in the fluorescence spectrum of **4** over the same time period. Under our experimen-

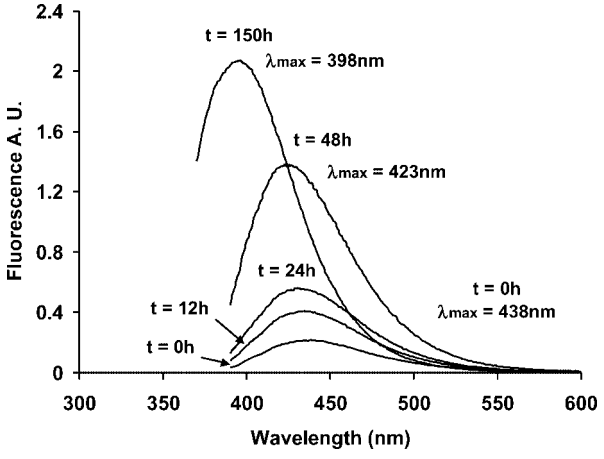

Figure 12. Fluorescence responses ($\lambda_{ex}$ = 325 nm) of a 10 μM solution of **3** (25 mM HEPES, pH = 7.44) after addition of PLE (7.5 U, incubation at 298 K).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

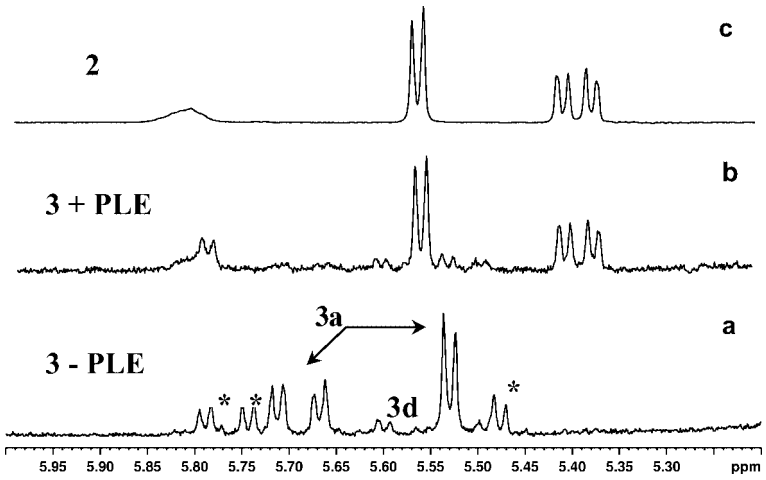

Figure 13. Low-field *p*-cym region of the $^1$H NMR spectra of a 2 mM solution of **3** in HEPES buffer (25 mM, pH = 7.44); (a) 5 h after dissolution at 298 K, (b) after 1 week incubation with PLE (15 U) at 298 K, (c) *p*-cym peaks of **2** in HEPES buffer (15 min). Asterisks indicate overlapping resonances of **3b** and **3d**.

tal conditions, PLE-catalyzed hydrolysis of the ester bond in **3** appears to be slow ($t_{1/2} \approx 40$ h) when compared to fluorophore-bearing organic molecules.[53] However, we are not aware of comparable examples involving inorganic complexes of the type we have investigated. Platinum complexes prepared by Reedijk and co-workers are all derivatized with fluorogenic reporters through amide bonds.[20–24] Their chemistry has been concentrated on reactions with guanine for comparison with the parent compounds, and they have been studied almost exclusively to elucidate their cellular distribution. Their interactions with cytosolic esterases do not appear to have been investigated.

In order to determine the fate of the ruthenium complex in the PLE-catalyzed hydrolysis of **3**, a millimolar sample of the compound was incubated with the enzyme (HEPES buffer, $D_2O$ solution, pH = 7.44) for 7 d. At the end of the incubation period, a white precipitate was detected and later identified as a 2-(methylamino)benzoate salt. The $^1$H NMR spectrum of the remaining solution was recorded and compared to the spectra of **2** and **3** in the same buffer. These are shown in Figure 13. The spectrum of **3** in the buffer revealed the presence of three species: the aqua complex (**3a**) as the major adduct, together with the hydroxido (**3b**) and HEPES (**3d**) adducts with overlapping resonances. The species distribution remained unaltered over a period of 5 h. After 1 week, a new single major set of signals was visible (Figure 13b). The peaks show the same resonances ($\delta$ = 5.38, 5.41 and 5.56 ppm) as for the *p*-cym peaks of **2** in HEPES (Figure 13c). The experimental evidence clearly indicates that esterase-catalyzed hydrolysis of **3** liberates **MIAH** and generates complex **2**. Thus, although the hydrolysis reaction appears to be slow, the results indicate that **3** is a substrate for the enzyme.

## Conclusions

We have synthesized and characterized fluorescent (arene)Ru$^{II}$ complexes of the type [($\eta^6$-arene)RuCl(Z)] (Z = chelating ligand). The compounds show interesting photoluminescent properties and may find some application in fluorescence microscopy studies aimed at elucidation of their cellular trafficking and thus provide new insights into the mechanism of action of this new class of anticancer compounds. Our results show that a fluorogenic reporter may be tagged onto these complexes either through an ester or an amide bond. If the fluorophore is linked through an ester bond, the resulting compounds may be substrates for cytosolic esterases. In this case, esterase-catalyzed hydrolysis of the reporter could potentially alter the fluorescent profile and consequently the resulting (apparent) cellular distribution of the compounds. Derivatization of the compounds through an ester bond, however, might prove useful in the design of esterase-activated Ru-based prodrug delivery systems. This is a common strategy in medicinal chemistry, as it is the case, for example, with capecitabine, an orally available prodrug of 5-deoxy-5-fluorouridine, which has recently come into clinical use for the treatment of breast and colorectal cancers.[54–57] A similar approach focussed on platinum drugs was recently suggested by Lippard.[49] Finally, tagging a reporter (or a prodrug) to (arene)Ru$^{II}$ complexes through an amide linkage is also promising; however, a spacer of proper length (> –[$CH_2$]$_2$–) must be employed. Our study indicates that if a spacer of only two carbon atoms is used, then the amide nitrogen atom readily undergoes deprotonation under physiological conditions, promoting the formation of a stable five-membered chelate ring.

## Experimental Section

**Materials:** Reagents were purchased from Aldrich and used without further purification. A porcine liver esterase (PLE) suspension was purchased from Fluka and used as supplied. [($\eta^6$-*p*-cym)-$RuCl_2$]$_2$ (**1**) was prepared according to a published procedure.[58,59]

**X-ray Crystallography:** All diffraction data were collected using a Bruker Smart Apex CCD diffractometer equipped with an Oxford

Cryosystems low-temperature device operating at 150 K (Table 4). Absorption corrections for all data sets were performed with the multiscan procedure SADABS.[60] Structures were solved by direct methods (SHELXS or SIR92).[61,62] Complexes were refined against $F^2$ using CRYSTALS (**2** and **3**)[63] or SHELXL (**4**).[61] H-atoms were placed in idealised positions. In **2** the *i*Pr group is rotationally disordered about the pivot carbon atom (C82), and in **3** one O-atom of the perchlorate anion was modelled over two sites. The crystal of **4** was twinned. The diffraction pattern was indexed with two orientation matrices related by a twofold rotation about the (0 1 –1) reciprocal lattice direction (CELL_NOW);[64] reflections from both domains were integrated simultaneously (SAINT)[65] and used in the refinement. The twin scale factor was 0.2811(13). CCDC-634687 (**2**), -634689 (**3**) and -634688 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**NMR Spectroscopy:** $^1$H NMR spectra were acquired with Bruker DMX 500 ($^1$H, 500 MHz) or DPX 360 ($^1$H, 360 MHz) spectrometers using TBI probe-heads equipped with *z*-field gradients. Typically, $^1$H NMR spectra in $D_2O$ were acquired with water suppression by Shaka's method or with presaturation. $^1$H NMR chemical shifts were referenced internally to 1,4-dioxane ($\delta$ =3.75 ppm) for aqueous solutions, and $CHCl_3$ ($\delta$ =7.26 ppm) for [D]chloroform solutions. All data processing was carried out using XWIN-NMR version 2.0 (Bruker U.K. Ltd.).

**Mass Spectrometry:** Electrospray ionization mass spectra (ESIMS) were obtained with a Micromass Platform II mass spectrometer, and solutions were infused directly. The capillary voltage was 3.5 V, and the cone voltage was varied between 10 and 45 V, depending on sensitivity. The source temperature was 353 K. Mass spectra were recorded in a scan range of $m/z$ = 200–1200 for positive ions.

**pH Measurements:** pH measurements were carried out using a Corning 240 pH meter equipped with an Aldrich micro-combination electrode calibrated with Aldrich standard buffer solutions of pH = 4, 7, and 10. For NMR samples prepared in $D_2O$, no correction has been applied for the effect of deuterium on the glass electrode.

**Spectroscopic Measurements and Fluorometric Determinations:** All glassware was washed sequentially with 20% $HNO_3$, deionised water, and ethanol before use. Purified water was obtained from a Millipore Milli-Q water purification system. Stock solutions of reagents in water were made up to concentrations of 2 mM and kept at 4 °C in 500-μL aliquots. Portions were diluted to the required concentrations immediately prior to each experiment. Fluorescence and absorption data were measured in water and in HEPES buffer (25 mM, pH = 7.4), prepared with Millipore water. Solutions were stored in clean, dry propylene containers and were filtered before data acquisition. Fluorescence spectra were recorded from 350 to 600 nm. All measurements were performed in triplicate. Fluorescence spectroscopy measurements were performed with Perkin–Elmer LS50B or Edinburgh Instruments FS900 Fluororimeters. Excitation was set to 325 nm and emission was collected through a 350-nm cut-off filter.

**Computational Methods:** Molecular structures were initially modelled from the crystal structure of the cation of **4** and were optimized at the semiempirical INDO/1 level. A tight self-consistent-field convergence criterion ($10^{-6}$ hartree) was employed in all calculations. The electronic spectra of the complexes were calculated with the INDO/S method in the Zerner implementation[40–42,66] using the Hyperchem (version 7.5) software.[43] The ruthenium and nitrogen atomic parameters of Krogh-Jespersen et al. were used.[67] The overlap weighting factors, $f\sigma$ and $f\pi$, for INDO/S calculations were set at 1.267 and 0.585, respectively, and the number of CISs in the CIS calculations was 1250 (25 occupied and 25 unoccupied orbitals). The optical spectra of these ruthenium complexes were calculated using the SWizard program.[68,69] Half-bandwidths $\Delta_{1/2}$ were assumed to be equal to 3000 cm$^{-1}$, which is a typical half-bandwidth value for octahedral ruthenium complexes.[70]

### Synthetic Procedures

**[($\eta^6$-*p*-cym)RuCl(NNO)](Cl) (2):** [($\eta^6$-*p*-cym)$RuCl_2$]$_2$ (**1**) (100 mg, 0.16 mmol) was dissolved in $CHCl_3$ (5 mL). To this solution 2.2 mol-equiv. of 2-[(2-aminoethyl)amino]ethanol (**NNO**) was added and the mixture stirred for 12 h. A change in colour of the solution from deep red to pale yellow was observed within 10 s of addition of the ligand to **1**. The yellow precipitate was then collected by filtration, washed with ice-cold $CHCl_3$ and then three times with 5 mL of ice-cold diethyl ether. Yield: quantitative. $C_{14}H_{26}Cl_2N_2ORu$ (410.75): calcd. C 40.98, H 6.39, N 6.83; found C 40.82, H 6.09, N 6.57. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.56

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(d, 6 H, cymene), 2.43 (s, 3 H, cymene), 2.08 (sept, 1 H, cymene), 2.99 (t, 2 H, $CH_2$), 3.18 (t, 2 H, $CH_2$), 3.49 (t, 2 H, $CH_2$), 3.56 (br., 1 H, $NH_2$), 4.06 (t, 2 H, $CH_2$), 5.04 (br., 1 H, $NH_2$), 6.63 (br., 1 H, OH), 7.33 (br., 1 H,NH) ppm. ESI MS (+ve): $m/z$ = 375 $[M]^+$. Crystals suitable for X-ray diffraction were obtained by slow diffusion of diethyl ether into a methanolic solution of the complex (typically, 5 mg of complex in 250 μL of solvent; diffusion occurred at 4 °C).

***N*,*N*′-Bis(*tert*-butoxycarbonyl)-2-[(2-aminoethyl)amino]ethanol (L1):**[71] To a solution of 2-[(2-aminoethyl)amino]ethanol (50 mmol) in THF/$H_2O$ (1:1) (300 mL), $KHCO_3$ (150 mmol) and *tert*-butoxycarbonyl anhydride ($Boc_2O$) (120 mmol) were added consecutively at 0 °C. After the reaction mixture had reached room temp., the solution was stirred overnight. The mixture was then acidified to pH = 4 by careful addition of acetic acid at 0 °C and then extracted with $CH_2Cl_2$ (4 × 200 mL). The combined organic phases were dried ($Na_2SO_4$) and concentrated under reduced pressure to give **L1** as a viscous colourless oil which crystallized on standing. **L1** was used for the next step without further purification. Yield: 6 g (60%). $^1$H NMR (360 MHz, $CDCl_3$): $\delta$ = 1.44 (s, 9 H, $CH_3$), 1.47 (s, 9 H, $CH_3$), 3.32 (m, 2 H, $CH_2$), 3.37 (m, 4 H, $CH_2$), 3.74 (m, 2 H, $CH_2$) ppm. ESI MS (+ve): $m/z$ = 343.37 $[M + K^+]$.

***N*,*N*′-Bis(*tert*-butoxycarbonyl)-2-[(2-aminoethyl)amino]ethyl-2-(methylamino)benzoate (L1′):** Boc-protected 2-[(2-aminoethyl)-amino]ethanol (0.4 g, 1.39 mmol) was dissolved in dried $CH_3CN$ (20 mL). *N*-Methylisatoic anhydride (**MIA**) (0.37 g, 2.08 mmol) was added to this solution. An excess amount of $K_2CO_3$ (2 g, 27.8 mmol) was added to the above mixture. The mixture was stirred at room temp. for 48 h, during which the reaction progress was monitored by TLC. The desired product was separated from the other possible byproducts and impurities by silica column chromatography using a solvent system of ($CH_3OH/CH_2Cl_2$, 12:88). The column was eluted with a total of 300 mL of eluent. The fractions obtained were analyzed by $^1$H NMR spectroscopy, and those containing the desired product were combined. The solvents ($CH_3OH/CH_2Cl_2$) were removed by rotary evaporation, and the resulting yellow oil was stored at 4 °C for 18 h. During storage, the product spontaneously crystallized into a light yellow solid. Yield: 277 mg (45%). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.40 (s, 18 H, $CH_3$), 2.86 (s, 3 H, $CH_3$), 3.26 (t, 2 H, $CH_2$), 3.37 (t, 2 H, $CH_2$), 3.58 (t, 2 H, $CH_2$), 4.31 (t, 2 H, $CH_2$), 4.92 (br., 1 H, NH), 5.15 (br., 1 H, NH), 6.58 (t, 1 H, aromatic), 6.63 (d, 1 H, aromatic), 7.36 (t, 1 H, aromatic), 7.48 (d, 1 H, aromatic) ppm. ESI MS (+ve): $m/z$ = 439.1 $[M]^+$, 338.1 $[M - C_5H_{10}O_2]^+$.

**2-[(2-Aminoethyl)amino]ethyl-2-(methylamino)benzoate (L3):** Boc deprotection of **L1′** was attained by dropwise addition of 15 mol-equiv. of TFA (1.28 mL, 3.45 mmol) to a solution of **L1′** (0.1 g, 0.23 mmol) in distilled $CH_2Cl_2$ (10 mL). The mixture was stirred at room temp. for 48 h and was monitored by TLC. The solvents were then removed by rotary evaporation. The crude product was re-dissolved in methanol and purified with the aid of preparative thin layer chromatography (TLC). The desired product was then extracted from preparative TLC silica by re-dissolution in methanol and stirring at room temp. for 18 h. This solution was then filtered under gravity, and all the solvents were removed from the filtrate under vacuum. The product was a dark yellow oil. Yield: 28 mg (51%). $C_{12}H_{19}N_3O_2$ (237.30): calcd. C 60.74, H 8.07, N 17.71; found C 61.03, H 8.04, N 17.38. $^1$H NMR (500 MHz, $D_2O$): $\delta$ = 2.06 (s, 1 H, $CH_3$), 3.43 (t, 2 H, $CH_2$), 3.53 (t, 2 H, $CH_2$), 3.61 (t, 2 H, $CH_2$), 4.58 (t, 2 H, $CH_2$), 6.98 (t, 1 H, aromatic), 7.09 (d, 1 H, aromatic), 7.63 (t, 1 H, aromatic), 8.07 (d, 1 H, aromatic) ppm. ESI MS (+ve): $m/z$ = 238 $[M - H]^+$.

***N*-{2-[(2-Aminoethyl)amino]ethyl}-2-(methylamino)benzamide (L4):** Typically, *N*-(2-aminoethyl)ethane-1,2-diamine (100 mg) was dissolved in $CHCl_3$ (2 mL). To this solution, **MIA** (100 mg) in $CHCl_3$ (2 mL) was added in 0.25-mL portions. Immediately after the addition of **MIA**, a white precipitate appeared. The reaction was allowed to proceed for 2 h. The white precipitate was filtered off, while the $CHCl_3$-soluble fraction was concentrated to about 3 mL and then loaded onto a preparative TLC plate. With 15% $CH_3OH$ in $CH_2Cl_2$, all the impurities contained in the starting material moved with the front, molecules derivatized with two or three **MIA** moved to the middle of the plate, while **L4** moved only a few cm from the base line. Yield: 38 mg (32%). $C_{12}H_{20}N_4O$ (236.31): calcd. C 60.99, H 8.53, N 23.71; found C 60.23, H 8.40, N 23.69. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.75 (br., $NH_2$), 2.68 (m, 2 H, $CH_2$), 2.79 (m, 2 H, $CH_2$), 2.83 (m, 5 H, $CH_2$ + $CH_3$), 3.47 (m, 2 H, $CH_2$), 6.56 (t, 1 H, aromatic), 6.64 (d, 1 H, aromatic), 6.82 (br., NH), 7.30 (t, 1 H, aromatic), 7.36 (2, 1 H, aromatic), 7.47 (br., NH) ppm. ESI MS (+ve): $m/z$ = 259.15 $[M + Na^+]$.

**[($\eta^6$-*p*-cym)RuCl(L3)](Cl) (3):** Ligand **L3**, (0.032 g, 0.13 mmol), was dissolved in $CH_3OH/CHCl_3$ (20:80) (2.4 mL). This was added dropwise to a solution of $[(\eta^6\text{-}p\text{-cym})RuCl_2]_2$ (**1**) (0.036 g, 0.059 mmol) in $CHCl_3$ (2.8 mL) to prevent any initial precipitation of the ligand. The colour of dimer solution changed from deep red to orange once all of **L3** was added. The mixture was stirred at room temp. for 40 h. During this time, a yellow precipitate developed on the sides of reaction flask, while the colour of the reaction mixture remained unchanged. Further precipitation was obtained by addition of diethyl ether (10 mL). The yellow precipitate was dried under vacuum. Yield: 22 mg (30%). $C_{22}H_{33}Cl_2N_3O_2Ru$ (543.49): calcd. C 48.62, H 6.12, N 7.73; found C 47.98, H 6.07, N 7.91. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.38 (d, 6 H, *p*-cymene), 1.74 (sept, 1 H, *p*-cymene), 2.46 (s, 3 H, *p*-cymene), 2.85–3.20 (m, 4 H, $CH_2$), 3.21 (t, 2 H, $CH_2$), 4.06 (t, 2 H, $CH_2$), 4.72 (br., 1 H, $NH_2$), 5.67–5.78 (dd, 4 H, *p*-cymene), 6.14 (br., 1 H, $NH_2$), 6.23 (br., 1 H, NH), 6.82 (t, 1 H, aromatic), 6.96 (d, 1 H, aromatic), 7.31 (br., 1 H, OH), 7.53 (t, 1 H, aromatic), 8.04 (d, 1 H, aromatic) ppm. ESI MS (+ve): $m/z$ = 508 $[M]^+$. Crystals suitable for X-ray diffraction were obtained by slow diffusion of pentane into a $CHCl_3$ solution of the complex (5 mg of complex + 2 mg of $NaClO_4$ in 250 μL of solvent; diffusion occurred at room temp.).

**[($\eta^6$-*p*-cym)RuCl(L4)](Cl) (4):** **1** (44 mg) was dissolved in $CHCl_3$ (3 mL). To this solution 2.2 mol-equiv. of **L4** (38 mg) in $CHCl_3$ (1 mL) was added and the mixture stirred for 48 h. The colour of the solution changed within 1 h from red to orange to olive-green. The reaction was monitored by $^1$H NMR spectroscopy and stopped when no further change could be observed. Diethyl ether was added to the solution depositing a yellow precipitate which was then collected by filtration and washed with diethyl ether. Yield: 68 mg (78%). $C_{22}H_{34}Cl_2N_4ORu$ (542.51): calcd. C 48.71, H 6.32, N 10.33; found C 48.08, H 5.97, N 9.98. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.22 (d, 6 H, $CH_3$, *p*-cymene), 2.08 (sept, 1 H, *p*-cymene), 2.24, (s, 3 H, $CH_3$, *p*-cymene), 2.85, (s, 3 H, $CH_3$), 3.7–2.6, (m, 8 H, $CH_2$), 5.44 (d, 1 H, *p*-cymene), 5.60 (d, 1 H, *p*-cymene), 5.65 (d, 1 H, *p*-cymene), 5.91 (d, 1 H, *p*-cymene), 6.53 (t, 1 H, aromatic), 6.59 (d, 1 H, aromatic), 7.29 (t, 1 H, aromatic), 7.99 (d, 1 H, aromatic) ppm. ESI MS (+ve): $m/z$ = 507.1 $[M]^+$. Crystals of **4** suitable for X-ray diffraction were obtained by slow diffusion of pentane into a $CHCl_3$ solution of the complex.

**Supporting Information** (see footnote on the first page of this article). Positive-ion ESI-MS spectra of a solution of **4** in 25 mM HEPES at different pH values; fluorescence response of **L3** and **L4** upon titration of 1.2 mol-equiv. of **1** (Figures S1–S3); ZINDO1/S

# Hafnium Oxide Doped Mesostructured Silica Films

**Ralf Supplit,[a] Nicola Hüsing,*[b] Silvia Gross,[c] Sigrid Bernstorff,[d] and Michael Puchberger[a]**

**Keywords:** Mesostructured films / Ligand-assisted templating / Self-assembly / Surfactants

Hafnium oxide doped silica films with ordered mesostructures were produced with hafnium:silicon ratios between 1:60 and 1:6. A surfactant–hafnium alkoxide complex was synthesized and used as a template in a sol–gel dip-coating process. Face-centred orthorhombic, 2D centred rectangular and lamellar films were formed by evaporation-induced self-assembly (EISA). The influence of subsequent heat treatment was studied by GISAXS and TEM. The surface and in-depth molecular composition of the films was studied by XPS.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Hafnium dioxide is a ceramic material characterized by high thermal and chemical stability, high dielectric constant, good mechanical strength, catalytic properties and low electrical conductivity.[1–3] Stable porous mesostructured hafnium oxide was successfully synthesized by the groups of Sayari and Stucky by applying a surfactant templating approach[4,5] and, recently, the first mesoporous and even mesostructured thin films of crystalline hafnia were reported by using large nonionic block-copolymer templates as the structure-directing agent.[6,7]

The incorporation of hafnia in silica can lead to a noticeable improvement in the properties of $SiO_2$, for example for catalytic applications, and at the same time the problems related to the use of pure hafnium dioxide, such as high cost and low specific surface area, can be overcome. Furthermore, the binary $HfO_2$–$SiO_2$ system is appealing for the development of high-κ film to overcome limitations in the fabrication of integrated circuits.[8–10] In the past, hafnia–silica systems were developed by using conventional sol–gel processing; however a homogeneous distribution of the Hf- and Si-centres in the matrix is difficult to achieve owing to the different reaction rates of the corresponding alkoxide precursors that often result in phase separation. It is well-known that the reactivity of alkoxide precursors towards hydrolysis and condensation increases dramatically with an increase in the atomic number of the elements with the same valence: for example, silicon alkoxides < titanium alkoxides < hafnium alkoxides. Several strategies were developed to overcome the problems related to these different reactions rates, such as a modified sol–gel process based on the reaction of organically modified hafnium oxoclusters with organofunctional silanes,[11] the pyrolytic conversion of single-source precursors[12] and a chemical solution deposition approach.[13]

Highly porous, mesostructured binary $HfO_2$–$SiO_2$ films have – at least to the best of our knowledge – not been reported so far. The aim of this study is to present a synthetic strategy that allows not only precise control over the evolution of the final periodically arranged solid structure in the mixed oxide ($HfO_2$–$SiO_2$) thin film, but also a homogeneous distribution of Hf in the silica matrix even for high Hf:Si ratios. Our approach is based on a combination of ligand-assisted templating methods in which the faster reacting alkoxide (Hf-alkoxide) is coordinated to the structure-directing agent – a nonionic surfactant – in combination with a solvent evaporation-induced self-assembly approach for rapid film formation by dip-coating.

## Results and Discussion

Hafnium alkoxide/surfactant complexes were formed by the equimolar reaction of hafnium *n*-butoxide with the terminal hydroxyl group of the surfactant Brij-56 ($C_{16}EO_{10}$, decaethyleneglycol hexadecyl ether) (Scheme 1). The resulting complex (Hf–Brij) was analyzed by 2D-NMR spectroscopy.

Figure 1 shows the HSQC spectra of the product (a) compared with the unmodified surfactant (b) and with the pure hafnium butoxide (c). The dotted circle in Figure 1 (a-5) highlights a new peak at $\delta$ = 4.20 ppm ($^1$H)/69.2 ppm

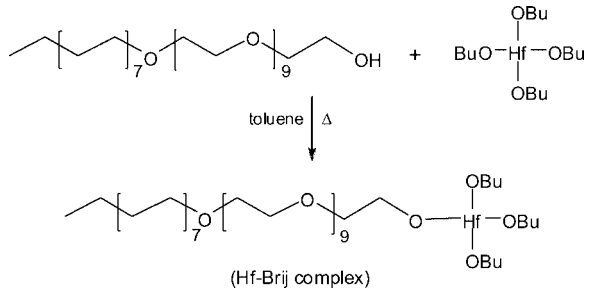

Scheme 1. Synthesis of the Hf–Brij coordination compound.

($^{13}$C) that appeared after the reaction of hafnium butoxide with Brij-56, whereas the signal at $\delta$ = 4.05 ppm ($^{1}$H)/ 69.3 ppm ($^{13}$C) [Figure 1 (a-4)], which was assigned to O-*CH*$_2$ of the butoxy groups, stayed unchanged. The new peak was assigned to the $CH_2$ group of the surfactant chain that is coordinated to the hafnium through an oxygen bridge. The TOCSY spectrum further shows that this signal correlates only to the $CH_2$ signal at $\delta$ = 3.57 ppm of the surfactant, whereas the signal at $\delta$ = 4.05 ppm correlates to signals at $\delta$ = 1.55, 1.36 and 0.95 ppm and can therefore be clearly assigned to a butoxy group.

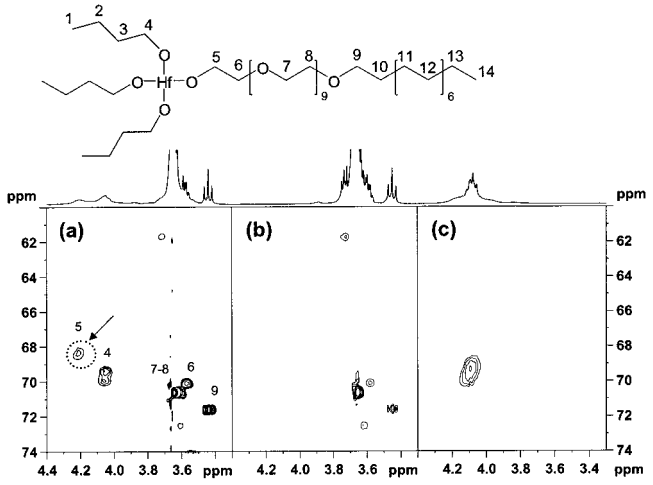

Figure 1. 2D NMR (HSQC) spectra of (a) Hf–Brij-56, (b) Brij-56 and (c) Hf(OBu)$_4$.

The Hf–Brij complex was used as the structure-directing agent in an evaporation-induced self-assembly process (EISA) to form mesostructured thin films (Figure 2).[14] The modified surfactant was added to a prehydrolyzed solution of tetraethoxysilane to form an opalescent sol. Direct addition of hafnium butoxide to such a sol would result in immediate precipitation of hafnia. This shows that the surfactant does not only serve as a structure-directing agent but also acts as an agent to control and slow down the hydrolysis and condensation rate of the alkoxide. Films were prepared by dip-coating from solutions containing different molar ratios (*M*) of the modified surfactant/tetraethoxysilane in otherwise constant composition. The resultant films were labelled Hf–Brij (*M*).

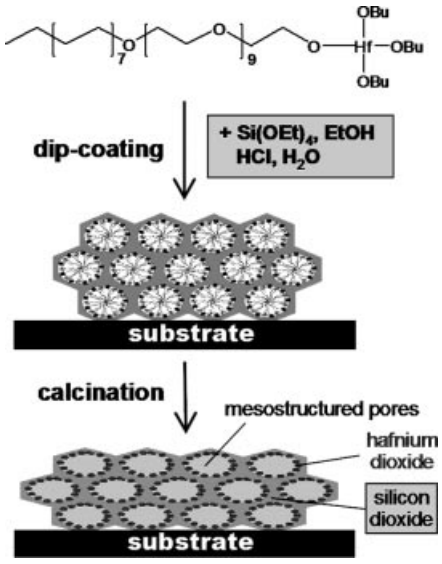

Figure 2. Schematic description of the synthetic strategy towards mesostructured hafnium oxide doped silica films.

The phase diagram of the surfactant Brij-56 shows cubic-spherical micellar, hexagonal, cubic-bicontinuous, lamellar and reversed-cubic-bicontinuous mesophases in surfactant/water mixtures with increasing concentrations of the amphiphile.[15] During the sol–gel process, the silica species replace the position of the water molecules in the hydrophilic regions of the mesophases and the volume fraction ratio of silica to amphiphile can be used to roughly predict the arising mesophases.[16] However, the systems become more complicated when mixed oxide precursors are in use, and the phase diagrams can only be used as a first guideline for the prediction of the accessible structures. When the modified surfactant is removed by calcination, it leaves the transition-metal oxide in the matrix. In this way, a silica film doped with hafnium oxide in periodically arranged mesopores is produced (Figure 2). EXAFS analysis in previous studies showed that this approach yields a molecular dispersion of the transition-metal oxide (titanium or iron) within the silica matrix without the agglomeration to nanoparticles.[17]

In the present study, a sequence of Hf oxide doped films that were prepared with different ratios (*M*) of Hf–Brij/tetraethoxysilane was analyzed by GISAXS (Figure 3). The predominant feature of the diffraction patterns is the formation of diffraction spots rather than rings, which indicates that the films are highly textured. Evaporation-induced self-assembly usually results in films with the densest crystallographic plane of the mesostructure aligned parallel to the substrate.[18] From the phase diagram of Brij-56, micellar cubic and hexagonal mesostructures are expected at low concentrations of the surfactant. During the drying and calcination processes of the films, shrinkage occurred preferentially along the direction normal to the surface plane. Because the mesostructure is aligned with respect to the substrate, this shrinkage is anisotropic and results in distortion of the mesostructure. Body-centred cubic (*Im*3*m*) struc-

tures transform to face-centred orthorhombic (*Fmmm*) and 2D-hexagonal (*P6m*) to 2D centred rectangular mesostructures (*C2mm*).[19–21] In agreement to that, the GISAXS analysis showed that with increasing surfactant concentrations, face-centred orthorhombic ($0.03 < M < 0.06$), 2D-centered rectangular ($M = 0.10$) and lamellar films ($M = 0.17$) were obtained. At a ratio $M = 0.12$, a biphasic film was obtained that consists of 2D-centered rectangular and lamellar mesostructures. We also found biphasic films consisting of face-centred orthorhombic as well as 2D-centered rectangular domains in the concentration range $0.06 < M < 0.10$. The existence of two phases in the same film can be attributed to a concentration gradient and inhomogeneity during EISA or to the presence of two interfaces: solid–liquid and liquid–air.

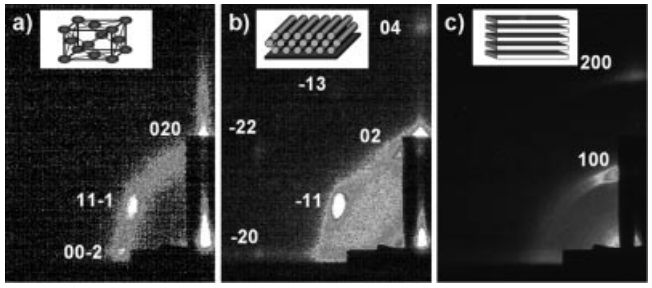

Figure 3. GISAXS pattern for Hf–Brij(0.034), Hf–Brij(0.102), Hf–Brij(0.12) and Hf–Brij(0.17) in the as-deposited state.

No structures that are derived from a bicontinuous cubic mesophase were obtained. Under certain reaction conditions (i.e. aging temperature of 45 °C), the formation of films with this mesostructure was described in the literature.[22]

In contrast, films that were prepared under the same conditions with unmodified Brij-56 did not result in the formation of an orthorhombic mesostructure. The obtained films were disordered ($M < 0.05$), 2D-centered rectangular ($0.05 < M < 0.21$) and lamellar ($0.21 < M < 0.42$). The fact that an additional mesostructure was formed under the same conditions with the hafnium alkoxide/Brij-56 complex can be explained by the larger head group volume of the modified surfactant, which increases the stability of mesostructures with a higher curvature.

The films were successively heat-treated at different temperatures and a GISAXS pattern was recorded after each step (Figure 4). The orthorhombic mesostructure had unit cell parameters of $a = 9.1$, $b = 10.2$ and $c = 12.8$ nm in the as-deposited state. After calcination at 700 °C, shrinkage was observed exclusively along the $b$ direction of the unit cell (perpendicular to the substrate) to give $a = 9.1$, $b = 6.9$ and $c = 12.9$ nm.

TEM analysis (Figure 5) of the calcined (500 °C) sample of Hf–Brij(0.034) confirmed the face-centred orthorhombic mesostructure.

The 2D-centered rectangular GISAXS pattern of Hf–Brij(0.10) (Figure 6) showed unit cell parameters of $a = 6.9$ and $b = 9.6$ nm at 25 °C. After heat treatment to 500 °C, the unit cell parameters are $a = 6.7$ and $b = 6.5$. The shrinkage (30%) occurred as expected and almost exclusively along the direction perpendicular to the substrate plane. Further heat treatment to 700 °C resulted in the destruction of the mesostructure as indicated by a strong decrease in the intensity of the 02 diffraction spot and the disappearance of the –11 and –20 spots, respectively.

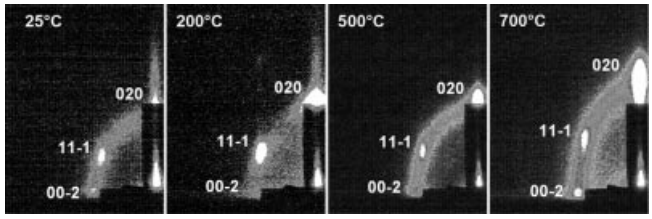

Figure 4. GISAXS series of Hf–Brij(0.034) as-deposited and successively calcined at the indicated temperatures.

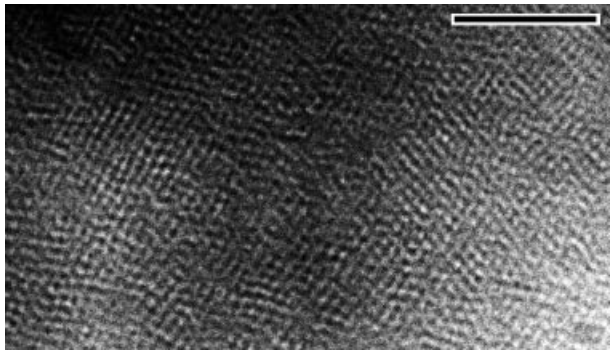

Figure 5. TEM analysis of Hf-Brij(0.034) after calcination at 450 °C; scale bar = 100 nm.

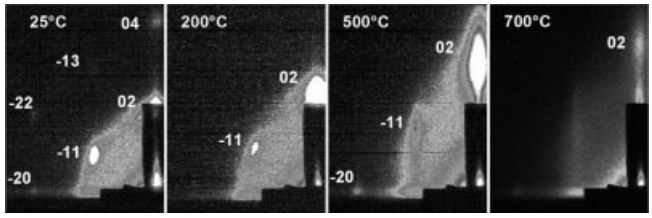

Figure 6. GISAXS series of Hf–Brij(0.10) successively calcined at the indicated temperatures.

TEM analysis of Hf–Brij(0.10) after calcination at 500 °C shows the cylindrical pores of the 2D-centered rectangular mesostructure (Figure 7).

Wide angle XRD (Figure 8) shows an amorphous network below 900 °C. Above that temperature crystallization of tetragonal hafnia occurred and the crystallite size reached approximately 10 nm at 1200 °C.[12]

The surface and in-depth composition of the Hf–Brij(0.12) sample after calcination at 450 °C was analyzed by XPS. The atomic percentages of the different elements of interest (O, Hf, C, Si) were evaluated as a function of the sputtering time, which can in turn be related to the depth of the sample.

In Figure 9 the survey spectra of the Hf–Brij(0.12) samples at the outer surface (a) and after 60 min sputtering (b) are superimposed. As it can be seen, on the surface the

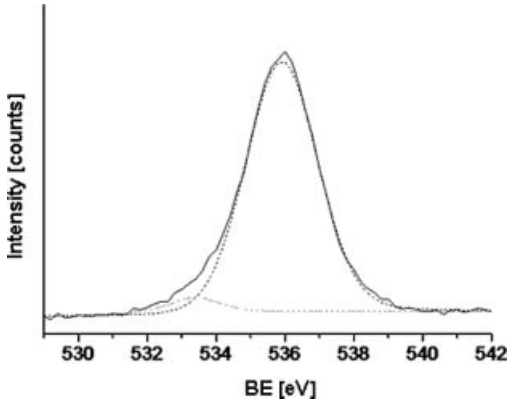

Figure 10. Deconvoluted O1s peak after 20 min sputtering.

peaks corresponding to silicon, carbon and oxygen are distinctly evident, whereas after sputtering the peaks of hafnium could also be detected. Additionally, upon sputtering, a noticeable reduction in the carbon contamination was detected, but carbon was also still present in the inner layers of the film. In addition to the survey spectra, selected spectra of the regions of interest were also acquired. The binding energies (BE) in the annealed samples were corrected for charging effects by assuming for the C1s transition a value typical for adventitious carbon (284.6 eV).[23] As it can be seen in Figure 10, the O1s peak is asymmetric and consists of two components, which could be evidenced after deconvolution. The major contribution whose value is, after charge correction, 532.9 eV, was ascribed to silica, whereas a further component at 530.6 eV (after charge correction), could be ascribed to hafnia, in agreement with the value reported in the literature.[23] Accordingly, the area intensity ratio of the two components is about 11, which is also the detected Si/Hf molar ratio.

As far as the Hf4f peak is concerned, the detected values range in the interval 17.6–18.0 and are higher than the value reported for bulk hafnia (16.7).[23] This finding is in agreement with the data reported in literature, which accounts for the shift to a higher binding energy for hafnium in a Hf–O–Si environment with respect to pure $HfO_2$.[24] Accordingly, the values detected for the $Hf4d_{5/2}$ peak, in the range 214.0–214.6 eV, are also higher than the value reported in literature (213.2 eV).[11,24]

The in-depth composition of the films, performed by sputtering analysis cycles, reveals an even distribution of the hafnium guest species in the silica host matrix. As shown in Figure 11, where the Si/Hf atomic ratios are plotted versus the sputtering time, the hafnium signal displays a uniform profile along the investigated thickness. In the outer layers, an enrichment of silicon was detected, whereas after about 20 min of sputtering the amount of hafnium gradually started to increase and the experimental Si/Hf atomic ratio ranged from 5 to 9.5, with a mean value of about 8, which is in good agreement with the nominal ratio in the starting solution (7.2). After 480 min of sputtering, the boundary between the film and the silicon substrate was reached, as the silicon peak displays two fully distinguishable components: the first at 103.9 eV, which is ascribable to the silica film, and the second at about 99.5 eV, which is attributable to the metallic silicon of the wafer substrate.

From the carbon signal, a considerable reduction in the contamination was observed after sputtering, but a significant presence of carbon (about 10% atomic) was detected along the whole film thickness, which can be ascribed to incomplete decomposition of organics upon annealing.

## Conclusions

We demonstrated an effective, direct synthetic method for the preparation of mesostructured hafnium oxide doped silica films by the use of a decaethyleneglycol hexadecyl ether/hafnium butoxide complex as a structure-directing agent. By variation of the ratio between the modified surfactant:silica precursor, face-centred orthorhombic, 2D-centered rectangular and lamellar films were obtained. The influence of heat treatment on the mesostructure was investigated by GISAXS and TEM measurements. The face-centred orthorhombic mesostructure was stable at temperatures above 700 °C. The 2D-centered rectangular structure showed a somewhat lower heat stability and was already affected at that temperature. The lamellar structure was destroyed at 300 °C. The in-depth chemical composition of the film was analyzed by XPS. The measurements showed that there is a uniform distribution of the hafnium species in the silica host matrix with a concentration close to the nominal value in the starting solution.

## Experimental Section

**Materials:** Hafnium *n*-butoxide was supplied from Aldrich and used without further purification. Tetraethyl orthosilicate and Brij-56 ($C_{16}EO_{10}$) were purchased from Fluka and used as received. Toluene (99%) was obtained from Merck and distilled from calcium hydride prior to use. Ethanol (96%) was supplied by Merck.

**Methods:** The composition of the films at the surface and in the bulk was investigated by XPS. Photoelectron spectra were obtained with a Perkin–Elmer Φ5600ci spectrometer by using nonmonochromatized Al-$K_\alpha$ radiation (1486.6 eV). The spectrometer was calibrated by assuming the binding energy (BE) of the Au4f7/2 line at 83.9 with respect to the Fermi level. The standard deviation for the BE values was 0.15. The reported BE were corrected for charging effects by assigning the BE value of 284.6 eV to the C1s line of carbon. Survey scans (187.85 pass energy, 1/step, 25 ms/step) were obtained in the 0–1300 range. Detailed scans (58.7 pass energy, 0.2 eV/step, 50 ms/step) were recorded for the O1s, C1s, Hf4f, Hf4d and Si2p regions. The atomic percentages of the different species were determined by using the C1s, O1s, Hf4f and Si2p regions. In particular, after each sputtering cycle, the determination of the four atomic percentages was performed as a function of the increasing sputtering time, which was used to obtain the in-depth profiles of the various species. The atomic composition, after a Shirley-type background subtraction was evaluated by using sensitivity factors supplied by Perkin–Elmer.[23,25] Depth profiles were carried out by $Ar^+$ sputtering at 3 keV with an argon partial pressure of $5 \times 10^{-6}$ Pa. A specimen area of $2 \times 2$ mm$^2$ was sputtered. Samples were introduced directly by a fast entry lock system into the XPS analytical chamber. The assignment of the peaks was carried out by using the values reported.[23,24,26] Room-temperature grazing incidence GISAXS experiments were performed at the Austrian high-flux SAXS beam line at the synchrotron radiation centre Elettra, Trieste, Italy.[27] Films deposited on single-side polished silicon wafer substrates and subsequently calcined at different temperatures were measured at a photon energy of 8 keV and with a grazing angle $\alpha$ below 2° between the beam and the film surface. 2D-diffraction patterns were recorded with a CCD detector (Photonic Science) with a distance ($L$) of 107 cm from the sample. The recorded area is indicated by the dotted rectangle in Figure 12. The $d$ spacing was determined from the diffraction spots by analysis of the CCD images with the FIT2D program (A. P. Hammersley/ESRF). TEM images were recorded with a JEOL JEM-100CX analytical transmission electron microscope. For film samples, the surface of the film was scratched and the powder was attached to Formvar copper grids. XRD patterns were recorded with a Philips X'Pert diffractometer with a Philips PW 3040/60 (mppx) generator and a Philips PW 3050/60 goniometer. NMR spectra were recorded with a Bruker Avance 300 spectrometer equipped with a 5 mm broadband probe head and a $z$ gradient unit. 2D spectra, COSY (correlated spectroscopy), TOCSY [totally correlated spectroscopy, $T$(mix) = 120 ms] and HSQC (heteronuclear single quantum correlation), were measured with Bruker standard pulse sequences. $CDCl_3$ (99.8% euriso-top) was employed as the solvent.

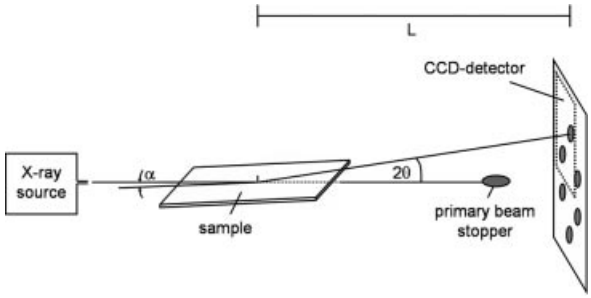

Figure 12.Setup of the GISAXS measurements.

**Synthesis of Hf-Brij56:** The reaction was carried out in a three-necked round-bottomed flask equipped with a reflux condenser and a distillation apparatus under an argon atmosphere. To remove residual water, the surfactant Pluronic-P123 was dissolved in toluene and heated to 100 °C for approximately 4 h. During that time, the toluene/water azeotrope was distilled off. The dried surfactant was then dissolved again in fresh absolute toluene. $Hf(OBu)_4$ was also dissolved in absolute toluene and added dropwise to the above prepared solution with a transition metal/surfactant molar ratio of 1:1. The mixture was stirred at 110 °C overnight. Toluene and the formed alcohol were removed by distillation and the metal-coordinated surfactants were obtained as slightly yellow or white pastes in 95% yield. $^1$H NMR (300.13 MHz, $CDCl_3$): $\delta$ = 0.82–0.95 (m, 12 H, 1-H, 14-H), 1.22–1.4 (m, 32 H, 2-H, 11-H, 12-H, 13-H), 1.55 (m, 8 H, 10-H, 3-H), 3.42 (t, $J$ = 6.8 Hz, 2 H, 9-H), 3.61 (m, 38 H, 6-H, 7-H, 8-H), 4.05 (m, 6 H, 4-H), 4.20 (m, 2 H, 5-H) ppm. $^{13}$C NMR (75.47 MHz, $CDCl_3$): $\delta$ = 14.2 (C-1, C-14), 19.1 (C-2), 22.8 (C-13), 26–32 (C-11, C-12), 29.5 (C-10), 36.8 (C-3), 69.3 (C-4), 69.2 (C-5), 70.0 (C-6), 71.7 (C-9), 70–71 (C-7, C-8) ppm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Film Preparation:** TEOS (61 mL) was prehydrolyzed in a solution containing water (4.87 mL), dilute hydrochloric acid (0.07 N, 2 mL) and ethanol (61 mL) at 60° for 90 min. This "stock" solution (8 mL) was mixed with ethanol (7 mL), HCl (0.07 N, 0.4 mL), water (0.4 mL) and different amounts of the metal-coordinated surfactant resulting in a molar ratio of Hf–Brij/TEOS/EtOH/$H_2O$/HCl = *x*:1:42:15:0.0052. Films were prepared within one hour on single-sided polished silicon wafers by dip-coating with a holding time of 30 s, a withdrawal speed of 4 mm/s at a relative humidity of 35–50%. The films were aged for at least 24 h prior to calcination. Powder samples for XRD analysis were scratched from coated glass plates after drying for 24 h at room temperature.

## Acknowledgments

The financial support of the European community for the ELETTRA synchrotron measurements is greatly acknowledged. We thank the USTEM at the Vienna University of Technology for allowing access to their TEM facilities and Berthold Stäüger from the Division of Structural Chemistry of the Institute of Chemical Technologies and Analytics, Vienna University of Technology for the XRD measurements.

# DNA Interactions Mediated by Cyclopentadienidoruthenium(II) Complexes Containing Water-Soluble Phosphanes

**Antonio Romerosa,*[a] Mustapha Saoud,[a] Tatiana Campos-Malpartida,[a] Chaker Lidrissi,[a] Manuel Serrano-Ruiz,[a] Maurizio Peruzzini,[b] Jose Antonio Garrido,[c] and Federico García-Maroto[c]**

**Keywords:** Ruthenium / Cyclopentadienyl ligands / Phosphanes / DNA / Bioinorganic chemistry

The water-soluble ruthenium(II) complexes $Na_2[RuCpX(mTPPMS)_2]$ [X = Cl (**1**), I (**2**)] and $Na_x[RuCp(mTPPMS)(PR^1{}_3)(PR^2{}_3)](OTf)_y$ [$PR^1{}_3 = PR^2{}_3 = PPh_3$ (**3**), PTA (**4**), x = y = 0; $PR^1{}_3$ = mTPPMS, $PR^2{}_3$ = PTA (**5**), x = 1, y = 0; $PR^1{}_3$ = mTPPMS, $PR^2{}_3$ = mPTA (**6**), x = y = 0; $PR^1{}_3 = PR^2{}_3$ = mTPPMS (**7**), x = 2, y = 0; $PR^1{}_3 = PPh_3$, $PR^2{}_3$ = PTA (**8**), x = y = 0; $PR^1{}_3$ = mPTA, $PR^2{}_3 = PPh_3$ (**9**), x = 0, y = 1; mTPPMS = $Ph_2P(3\text{-}OSO_2C_6H_4)^-$; PTA = 1,3,5-triaza-7-phosphaadamantane; mPTA = *N*-methyl-1,3,5-triaza-7-phosphaadamantane] have been synthesized and characterised by elemental analysis, NMR and IR spectroscopy and crystallographic methods. The X-ray crystal structure determination of $[RuCp(mTPPMS)(PPh_3)(PTA)]\cdot 2H_2O$ (**8**·$2H_2O$), which is the first half-sandwich ruthenium complex bearing three different phosphanes, has also been determined. The binding properties of these new water-soluble ruthenium complexes towards DNA and the interaction of free mTPPMS with the nucleic acid have been studied using the mobility shift assay, which has shown that both the activity of the ruthenium complexes and the possible mechanism governing the interaction with DNA are strictly dependent on the composition of the complexes.

## Introduction

Coordination and organometallic complexes of transition metals offer a great potential for use as anticancer agents due to their widely diverse structures and bonding modes. Change in the structural requirements and electronic properties of the metal complexes may be finely tuned to optimize the metal interaction with nucleic acid nucleobases. Ruthenium complexes have shown important biological activity and are becoming increasingly important in both bioinorganic chemistry and anticancer chemotherapy.[1–5] The water solubility of ruthenium compounds has been greatly increased by using dialkyl sulfoxide derivatives such as in [*trans*-$RuCl_4$(DMSO)Im][ImH] (NAMI-A) and [*trans*-$RuCl_4$(DMSO)dmtp][Hdmtp] (KP1019), which have recently successfully completed phase-one clinical trials,[5–12] and by the use of water-soluble phosphanes.[13,14] Work by Sadler and co-workers on the antitumor properties of organometallic piano-stool compounds[15] has shown that these complexes are effective antitumour agents and has contributed to understanding the effective mechanism ruling the interaction between the target biomolecule and the ruthenium complex.

Recently, we have reported the synthesis of the piano-stool complexes $[RuCpX(PR^1{}_3)(PR^2{}_3)]^{n+}$ (X = Cl, I; $PR^1{}_3 = PPh_3$, $PR^2{}_3$ = PTA, mPTA; $PR^1{}_3 = PR^2{}_3$ = PTA, mPTA; PTA = 1,3,5-triaza-7-phosphaadamantane; mPTA = *N*-methyl-1,3,5-triaza-7-phosphaadamantane)[16] and their interaction with DNA, which suggests a non-innocent role for the ancillary chloride ligand as the analogous germane iodide complexes are inactive towards DNA. Indeed, replacement of the chloride by a DNA fragment in the coordination sphere of the metal may result in a covalent bond between the metal and a DNA base, thus accounting for the cytotoxicity of organoruthenium species.[16b] The DNA activity of this family of complexes is further dependent on the water-soluble phosphane coordinated to the metal (PTA or mPTA), thereby suggesting that an improved interaction of the reactive {$CpRuCl(PR^1{}_3)$} fragment with DNA could be achieved by an adequate choice of the water-soluble phosphane bonded to the metal.

In order to verify this hypothesis further and to expand the number of half-sandwich $CpRu^{II}$ species bearing water-soluble phosphane ligands, we turned our attention to mTPPMS [mTPPMS = $Ph_2P(3\text{-}OSO_2C_6H_4)^-$]. This sulfonated phosphane, in spite of being one of the most popular

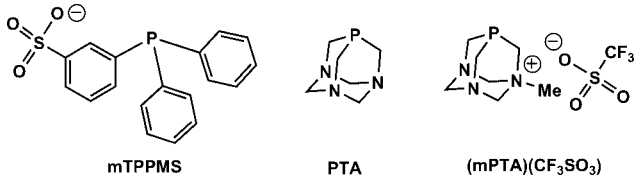
water-soluble phosphanes for catalytic hydrogenations,[17] hydroformylations[17] and ring-opening cyclo-alkene metathesis[18] under water-containing biphasic conditions, has never been used as a water-soluble synthon of potentially bioactive organometallic or inorganic ruthenium-based complexes.

Herein, we report our recent efforts in this area and describe the synthesis and characterization of a large class of new water-soluble half-sandwich ruthenium(II) complexes supported by one, two or three mTPPMS ligands in combination with halide and/or other hydrophilic (PTA and mPTA) and hydrophobic ($PPh_3$) phosphane co-ligands [PTA = 1,3,5-triaza-7-phosphaadamantane; mPTA = *N*-methyl-1,3,5-triaza-7-phosphaadamantane; see Scheme 1]. Additionally, we have performed DNA activity studies for these complexes and compare the results with other water-soluble {CpRu} species. The results of this study show a clear dependence of the reactivity towards DNA on the kind of phosphane bonded to the metal.

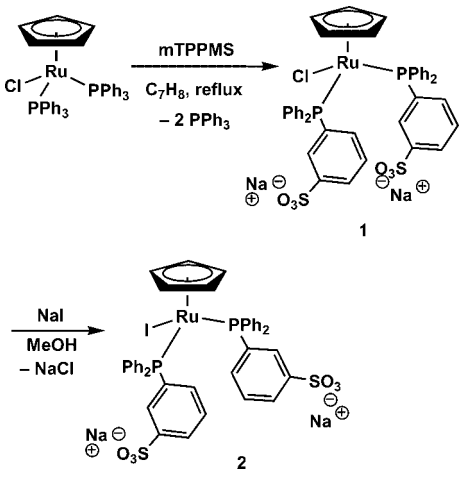


Scheme 1.

## Results and Discussion

### Synthesis and Characterization of Ruthenium Complexes 1 and 2

Complex **1** was straightforwardly obtained by substitution of the two $PPh_3$ ligands in the parent compound $[RuClCp(PPh_3)_2]$ with mTPPMS in refluxing toluene. This procedure gives **1** in much higher yield than the one described previously[19] by Suárez et al. from the direct reaction of freshly distilled CpH with $RuCl_3{\cdot}3H_2O$ and mTPPMS in refluxing ethanol. The compound obtained shows good solubility in water (41 mg mL$^{-1}$, $4.41 \times 10^{-2}$ M) as a consequence of the two mTPPMS ligands, whose presence is supported by elemental analysis and a spectroscopic investigation (see Experimental Section). Reaction of **1** with NaI or KI in MeOH at room temperature gives the quantitative formation of **2**, where the chloride ligand has been replaced by iodide (Scheme 2). Complex **2** is noticeably more stable than **1** towards oxidation and is less soluble in water, in agreement with the behaviour found for the complexes $[RuCp(PR^1{}_3)(PR^2{}_3)X]^{n+}$ (X = Cl, I; $PR^1{}_3$ = $PPh_3$, $PR^2{}_3$ = PTA, mPTA; $PR^1{}_3$ = $PR^2{}_3$ = PTA, mPTA; $n$ = 0, 1), where the iodine derivatives are always less water-soluble than the corresponding chlorides.[16] The spectroscopic properties of **2** match those of **1** and do not deserve additional comments.



Scheme 2.

### Synthesis and Characterization of the mTPPMS Tris-Phosphane Ruthenium Complexes $Na_x[RuCp(mTPPMS)(PR^1{}_3)(PR^2{}_3)]$ [$PR^1{}_3$ = $PR^2{}_3$ = $PPh_3$ (3), PTA (4), $x$ = 0; $PR^1{}_3$ = mTPPMS, $PR^2{}_3$ = PTA (5), $x$ = 1; $PR^1{}_3$ = mTPPMS, $PR^2{}_3$ = mPTA (6), $x$ = 0; $PR^1{}_3$ = $PR^2{}_3$ = mTPPMS (7), $x$ = 2]

The reaction of $[RuCpCl(PPh_3)_2]$ with Na(mTPPMS) and $NaBF_4$, which aids chloride abstraction, in MeOH at reflux led to the substitution of the chloride ligand by mTPPMS and yielded the tris-phosphane complex $[RuCp(mTPPMS)(PPh_3)_2]$ (**3**). Similarly, the reaction of mTPPMS in MeOH with the bis-PTA derivative $[RuCpCl(PTA)_2]$ afforded the related complex $[RuCp(mTPPMS)(PTA)_2]$ (**4**) after substitution of the chloride by an mTPPMS ligand (Scheme 3). Complexes **3** and **4** were characterised by elemental analysis and conventional NMR spectroscopy. In keeping with the proposed formulation, the two complexes exhibit an $AM_2$ splitting pattern which, for **3**, results in a second-order multiplet centred at around $\delta$ = 39.6 ppm due to a fortuitous coincidence of the chemical shifts for the phosphorus atoms of both $PPh_3$ and mTPPMS which was not possible to simulate accurately. The $AM_2$ spin system is clearly visible in the spectrum of **4**, where the doublet at $\delta$ = –34.43 ppm is assigned to the two equivalent PTA P atoms while the low-field shifted triplet ($\delta$ = 49.57 ppm) is assigned to the single mTPPMS P atom.

Half-sandwich cyclopentadienidoruthenium complexes featuring three phosphane co-ligands like **3** and **4** are extremely rare and, to the best of our knowledge, are limited to the recently described complex $[RuCp(PPh_3)_2(PH_3)]Y$ (Y = $CF_3SO_3$, $PF_6$).[20] With the aim of preparing new {CpRu} complexes incorporating three tertiary phosphane co-ligands, we investigated the reaction of the bis(mTPPMS) complex **1** with additional water-soluble tertiary phosphanes. Thus, we studied the reaction of **1** with PTA, $mPTA(CF_3SO_3)$ and mTPPMS in refluxing MeOH containing $NaBF_4$. After usual workup, the new complexes $Na[RuCp(mTPPMS)_2(PTA)]$ (**5**), [RuCp(mPTA)-

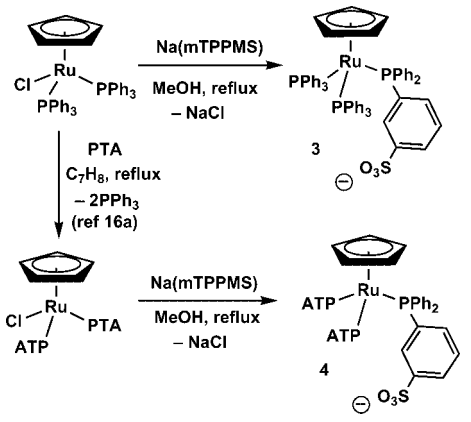
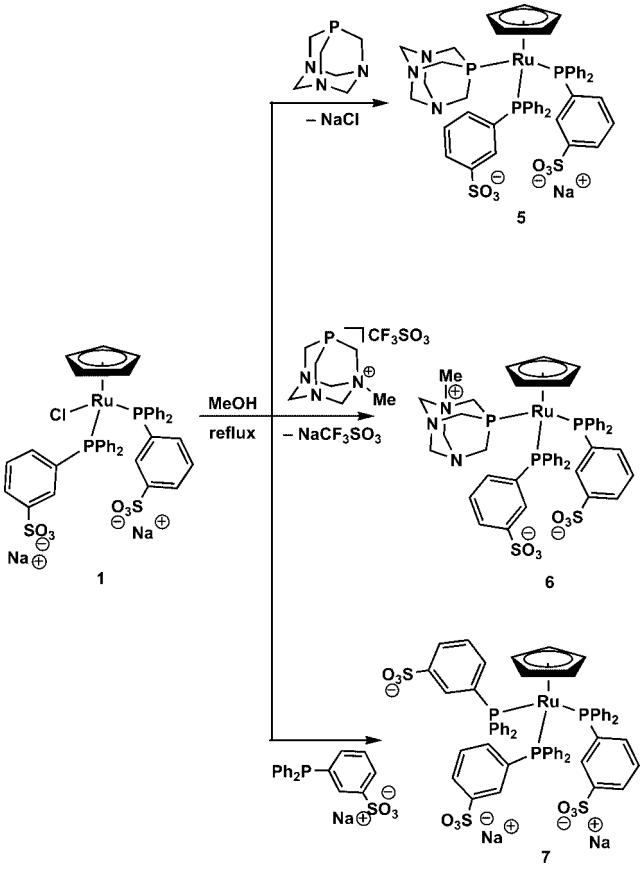


Scheme 3.

$(mTPPMS)_2$] (**6**) and $Na_2$[RuCp(mTPPMS)$_3$] (**7**) were obtained as a result of chloride substitution by PTA, mPTA and mTPPMS, respectively (Scheme 4).[21]



Scheme 4.

Complexes **5**–**7** were characterized by standard spectroscopic techniques. In the $^1$H NMR spectrum of **5**, the singlet due to the five Cp protons is found at $\delta$ = 4.73 ppm, which is in agreement with the chemical shift observed for complexes containing PTA.[16] A triplet at $\delta$ = –44.54 ppm (1 P) and a doublet for mTPPMS at $\delta$ = 42.22 (2 P) in the $^{31}$P{$^1$H} NMR spectrum unequivocally point to the formation of a triphosphane derivative.

Similar NMR properties were observed for **6** and **7**, which again are in agreement with the proposed formulas. Complex **6** is only moderately soluble in [D$_6$]DMSO, in which its $^{31}$P{$^1$H} NMR exhibits two broad signals for mTPPMS each corresponding to one P atom and a broad resonance integrating for one P atom with a chemical shift that is distinctive for ruthenium-bonded mPTA ($\delta$ = –29.66 ppm).[19] Steric crowding around ruthenium can be invoked to account for the magnetic inequivalency of the two mTPPMS ligands, but unfortunately the low solubility of **6** in solvents other than DMSO prevented us from performing a complete NMR investigation at low temperature, where the appearance of a distinct AMQ spin system could be anticipated.

The $^{31}$P NMR spectrum of **7**, which is the first homoleptic {CpRu} phosphane complex, is much simpler as it shows only a broad singlet at $\delta$ = 40.68 ppm with a chemical shift similar to that found for the other mTPPMS phosphane bonded to ruthenium. In the $^1$H NMR spectrum, the Cp signal for **6** falls at $\delta$ = 4.91 ppm which does not differ too much from that of **5**. In contrast, **7** shows the Cp singlet at $\delta$ = 3.96 ppm, close to that found for **3**, which only contains $PPh_3$ and mTPPMS.

### Synthesis and Characterization of the Heteroleptic Tris-Phosphane Ruthenium Complexes [RuCp(mTPPMS)(PR$^1_3$)-(PR$^2_3$)](OTf)$_x$ [PR$^1_3$ = PPh$_3$, PR$^2_3$ = PTA (8), $x$ = 0; PR$^1_3$ = mPTA, PR$^2_3$ = PPh$_3$ (9), $x$ = 1]

The reaction of [RuClCp(PPh$_3$)(PTA)][16b] with mTPPMS in refluxing MeOH led, after the usual workup, to chloride substitution and formation of [RuCp(mTPPMS)(PTA)(PPh$_3$)] (**8**). In a similar procedure, the reaction of [RuClCp(PPh$_3$)(mPTA)](CF$_3$SO$_3$) with mTPPMS gave [RuCp(mTPPMS)(PPh$_3$)(mPTA)](CF$_3$SO$_3$) (**9**; Scheme 5). Complexes **8** and **9** are the first examples of half-sandwich {CpRu} complexes containing three different phosphanes and represent a unique type of water-soluble metal complex containing two different water-soluble phosphanes along with a hydrophobic PPh$_3$ ligand. The strategy adopted here of replacing the chloride ligand in [RuClCp(PPh$_3$)(PR$_3$)]$^{n+}$ (PR$_3$ = PTA, mPTA, mTPPMS) with different water-soluble phosphanes could provide a wide range of water-soluble ruthenium complexes that share the same structural and geometric properties but may be different enough to result in a completely different interaction toward bio-molecules, particularly DNA.

The presence of three different phosphanes in **8** is clearly shown by the appearance of an AXX′ spin system in the $^{31}$P{$^1$H} NMR spectrum (Figure 1). The three doublets of doublets arise at $\delta$ = –49.30 ($^2J_{PTA,mTPPMS}$ = 41.8, $^2J_{PTA,PPh_3}$ = 38.8 Hz, PTA), 41.56 ($^2J_{PPh_3,mTPPMS}$ = 32.0, $^2J_{PPh_3,PTA}$ = 38.8 Hz, PPh$_3$) and 43.65 ppm )$^2J_{mTPPMS,PPh_3}$ = 32.0, $^2J_{mTPPMS,PTA}$ = 41.8 Hz, mTPPMS). The chemical shift of the PTA ligand in **8** is closer to that in **5** ($\delta$ = –44.54 ppm) than in **4** ($\delta$ = –34.43 ppm), which suggests that the PTA chemical shift for complexes [RuCp(PTA)(PR$^1_3$)(PR$^2_3$)]$^{n+}$

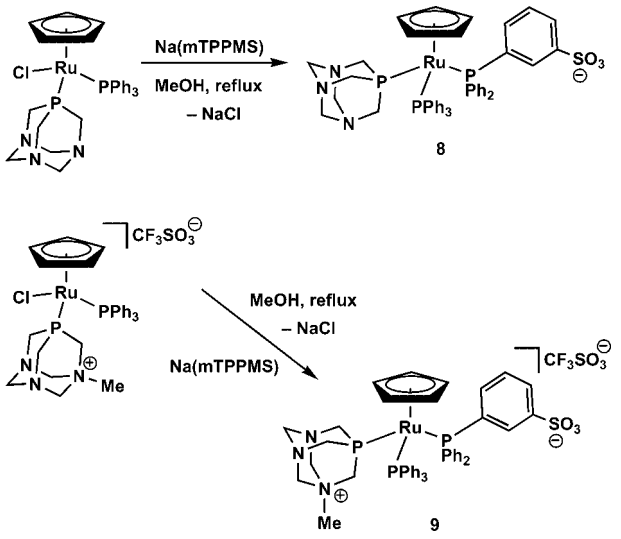

Scheme 5.

($PR^1_3$ = $PR^1_3$ = $PPh_3$, mTPPMS, PTA; $n$ = 0, 1) moves to high field as the number of mTPPMS ligands coordinated to the metal increases. The $^{31}P\{^1H\}$ NMR spectrum of **9** in $CD_3OD$, which differs from **8** by the presence of one cationic mPTA ligand instead of a neutral PTA, agrees with the proposed formula. A broad triplet at $\delta$ = –26.58 ppm is ascribed to the mPTA ligand while the fortuitous coincidence of the $PPh_3$ and mTPPMS signals is responsible for the broad resonance (two P atoms) at $\delta$ = 40.48 ppm which does not show any fine structure at –60 °C.

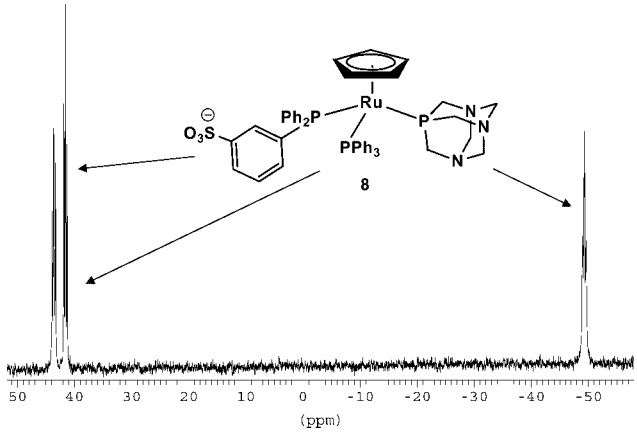

Figure 1. $^{31}P\{^1H\}$ NMR spectrum of **8** in $CDCl_3$ at 20 °C.

The $^1H$ NMR spectra of both **8** and **9** show the expected signals for both the coordinated phosphanes and the Cp ligand with the correct integral ratio. The chemical shift of the Cp group in **8** ($\delta$ = 4.86 ppm), which is shifted to low field in comparison with **1** ($\delta$ = 4.21 ppm), **2** ($\delta$ = 4.27 ppm), **3** ($\delta$ = 3.99 ppm) and **7** ($\delta$ = 3.96 ppm) but similar to that for **4** ($\delta$ = 5.00 ppm), **5** ($\delta$ = 4.73 ppm), **6** ($\delta$ = 4.91 ppm) and **9** ($\delta$ = 4.93 ppm), is worth noting. These data suggests that the resonance for the Cp protons appears at about $\delta$ = 5 ppm when PTA and/or mPTA are coordinated to the {CpRu} unit whereas it moves to high field (to around $\delta$ = 4 ppm) when mTPPMS and/or $PPh_3$ are bound to the metal.

In order to get more information on these complexes and to confirm their putative structures, we decided to undertake an X-ray diffraction study of one illustrative example of these tris-phosphane {CpRu} complexes. Crystals of **8**·$2H_2O$ were grown from a cold dilute MeOH solution and were found to be suitable for a crystallographic study. In keeping with the presence of a trio of different phosphanes coordinated to ruthenium, the asymmetric unit contains two enantiomeric ruthenium complexes and two disordered water molecules. The ruthenium atom in each enantiomer is pentahapto bonded to a cyclopentadienido ring, one $PPh_3$ and to two different water-soluble phosphanes (mTPPMS and PTA), which are coordinated to ruthenium through the apical phosphorus atom (Figure 2).[22] Remarkably, a search in the Cambridge Crystallographic Database did not find any X-ray authenticated ruthenium complexes with mTPPMS or other sulfonated phosphanes, which is quite surprising in view of the intense recent research activity aimed at preparing and studying water-soluble complexes of sulfonated phosphane ligands.

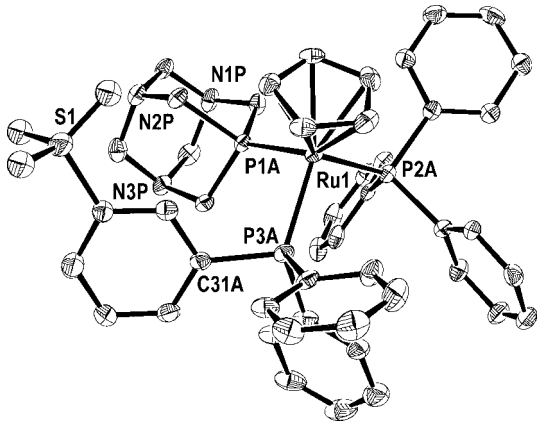

Figure 2. ORTEP view and atom numbering of compound **8**·$2H_2O$. Hydrogen atoms have been omitted for clarity.

The overall geometry of the two enantiomers of **8** is very similar to that observed for three-legged piano-stool complexes of the type $[MCpL_2X]$ and to the structures of $[RuCp(PPh_3)_2(PH_3)]PF_6$[20] and $[Ru\{\eta^5\text{-}C_5H_4C(CH_3)_2CH(PPh_2)C_5H_4N\}\{PPh_2(OCH_2CH_3)\}PPh_3]PF_6$,[23] which are the only reported examples of a {CpRu} moiety bonded to three tertiary phosphane ligands, although neither are soluble in water. The Cp rings in the pair of enantiomers are essentially planar, with the biggest deviations from the average Cp plane being 0.0084 (C1M; Ru1) and 0.0024 Å (C5N; Ru2), respectively. The $Ru–Cp_{(centroid)}$ distances are quite similar for the two enantiomeric molecules [Ru1–$Cp_{(centroid)}$ 1.883, Ru2–$Cp_{(centroid)}$ 1.886 Å] and somewhat longer than those found in $[RuClCp(PTA)_2]$ [$Ru–Cp_{(centroid)}$ 1.844 Å],[24] $[RuClCp(PPh_3)(PTA)]$ [Ru1–$Cp_{(centroid)}$ 1.845,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Ru2–$Cp_{(centroid)}$ 1.837 Å].[16b] The Ru–$P_{(PTA)}$ separation [Ru1–P1A 2.324(2), Ru2–P1B 2.306(3) Å] is similar to those found in other X-ray authenticated Ru–PTA derivatives,[16,22,23] while the Ru–$PPh_3$ distances [Ru1–P2A 2.370(3), Ru2–P2B 2.354(3) Å] are longer than those found in [RuClCp($PPh_3$)(PTA)] [Ru1–P1 2.302(2), Ru2–P2 2.298(3) Å].[16b]

The coordination polyhedron of each of the two enantiomers shows a distorted pseudo-octahedral geometry [P2A–Ru–P3A 101.78(10)°, P2B–Ru–P3B 101.46(9)°, P1A–Ru–P2A 94.32(10), P1A–Ru–P3A 95.12(10), P1B–Ru–P2B 93.22(9), P1B–Ru–P3B 97.46(9)], probably due to the high degree of steric repulsion between the three phosphanes.

The arrangement of enantiomeric pairs along the asymmetric unit of **8**·2$H_2O$ is supported by an evident network of hydrogen bonds. These form zigzag chains involving two disordered double water bridges that connect two oxygen atoms of the same pendent sulfonate group to a pair of N atoms (N3P, N3T) belonging to two PTA ligands from neighbouring complex molecules (Figure 3).

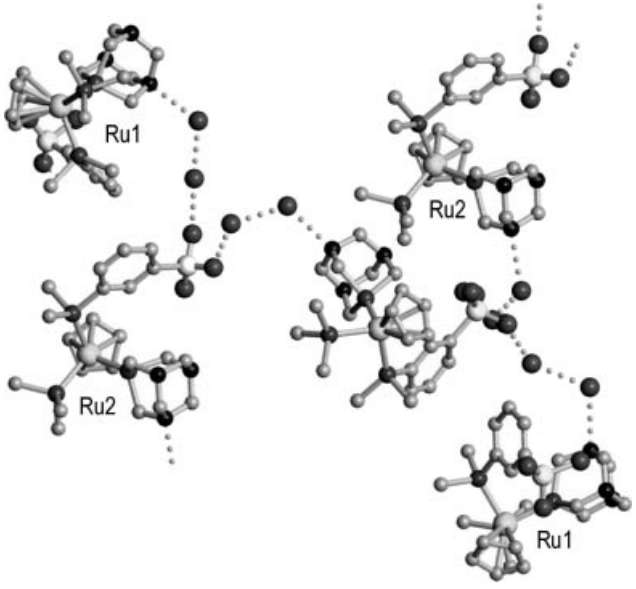

Figure 3. View of the hydrogen-bonding network of **8**·2$H_2O$. Only the *ipso* carbons of the phenyl rings of $PPh_3$ are shown, and hydrogen atoms have been omitted for clarity.

### Water Solubility and Reactivity Towards $D_2O$, $O_2$ and CO

The solubility of the new {CpRu}/mTPPMS complexes in water is summarized in Table 1 together with their stability towards hydrolysis and air. The solubility of these complexes in water may be anticipated from the presence of one, two or three water-soluble phosphanes bonded to the {CpRu} unit. However, this solubility spans a wide range of values from 0.60 mg mL$^{-1}$ for **8** and **9** to 41 mg mL$^{-1}$ for **1**. Interestingly, we did not find a direct dependence of the complex solubility on the number of water-soluble phosphanes bonded to the metal, which is puzzling. The solubility of complexes **1**, **2** and **7**, which contain only mTPPMS ligands, in water is greater than that of **3**, **4**, **5** and **6**, where mTPPMS is accompanied by $PPh_3$, PTA and mPTA, in different combinations. Furthermore, complexes **8** and **9**, which bear three different phosphanes, two of which are water-soluble, are practically insoluble in water. Although this behaviour defies any simple explanation, it is intriguing that the three more water-soluble derivatives (**1**, **2** and **7**) are the organoruthenium species that exhibit a double negative charge that is balanced by two sodium cations. The water solubility drops by one order of magnitude in **5** [$S(H_2O)_{25°C}$ = 2.5 mg mL$^{-1}$], which is a monoanion/monocation complex, and reduces slightly more in the neutral complexes **3**, **6** and **8** [$S(H_2O)_{25°C}$ < 1.0 mg mL$^{-1}$). The modest water solubility of the ionic complex **9** escapes from this rationale but is in agreement with the fact that its neutral zwitterionic character provides low solubility in water. As a general rule, the presence of $PPh_3$ in the trio of phosphanes coordinated to the {CpRu} moiety causes a severe reduction of the water solubility (see complexes **3**, **8** and **9**), although completely water-soluble combinations, such as those in **5** or **6**, are not mandatory to assure a good solubility of the related {CpRu} complexes in water, irrespective of whether they are neutral (**6**) or ionic (**5**). An interaction between oppositely charged ligands in complexes containing both mTPPMS and mPTA could lead to a lower than expected water solubility. As previously observed for other [RuCpX($PR^1_3$)($PR^2_3$)] derivatives, the water solubility of the iodide species **2** is lower than that of the chloride analogue **1**.[16,25]

Most of the complexes are stable to air in aqueous solution and can be recovered unchanged after being exposed

Table 1. Stability of complexes **1**–**9** in $D_2O$ under $O_2$ and solubility in water at 25 °C.

| Complex | Time [days] | $S(H_2O)_{25°C}$ [mg mL$^{-1}$] |
|---|---|---|
| $Na_2$[RuCpCl(mTPPMS)$_2$] (**1**) | 0.25 | 41 ($4.41\times10^{-2}$ M) |
| $Na_2$[RuCpI(mTPPMS)$_2$] (**2**) | >4[a] | 15 ($1.47\times10^{-2}$ M) |
| [RuCp(mTPPMS)($PPh_3$)$_2$] (**3**) | 0.18 | 0.9 ($8.7\times10^{-4}$ M) |
| [RuCp(mTPPMS)(PTA)$_2$] (**4**) | >4[a] | 10 ($1.2\times10^{-2}$ M) |
| Na[RuCp(mTPPMS)$_2$(PTA)] (**5**) | >4[a] | 2.5 ($2.4\times10^{-3}$ M) |
| [RuCp(mPTA)(mTPPMS)$_2$] (**6**) | >4[a] | 1.3 ($1.3\times10^{-3}$ M) |
| $Na_2$[RuCp(mTPPMS)$_3$] (**7**) | ca. 2 | 20.0 ($1.6\times10^{-3}$ M) |
| [RuCp(mTPPMS)($PPh_3$)(PTA)] (**8**) | >4[a] | 0.6 ($6.2\times10^{-4}$ M) |
| [RuCp(mTPPMS)(mPTA)($PPh_3$)]($CF_3SO_3$) (**9**) | >4[a] | 0.6 ($5.6\times10^{-4}$ M) |

to visible light for more than four days at 40 °C in $D_2O$ (vide infra). In spite of the crowding at ruthenium caused by the presence of three phosphanes in a piano-stool structure, these complexes are thermally robust and do not dissociate a phosphane when refluxed in the presence of KI in EtOH or when saturated with carbon monoxide in $CDCl_3$ or $CD_3OD$ and kept at 40 °C for several hours (NMR tube experiment). Complete reaction with KI was observed only with **1** and, partially, with **7**, which gives a partial conversion to the iodide complex **2**. No reaction was observed with CO in $CD_3OD$ at 40 °C.

### Interaction of the {CpRu(mTPPMS)} Complexes with DNA

Previous studies on Pt and Ru complexes[26] have shown that modification of the electrophoretic mobility of plasmid DNA on agarose gels is commonly taken as confirmation of the presence of a direct DNA–metal interaction. The alteration of the DNA structure leads to the unwinding of the plasmid molecule holding up the migration of supercoiled DNA (SC) and slightly increasing the mobility of the open circular DNA (OC) to a point (coalescence point, CP) where both forms co-migrate. We have investigated the interaction of the new water-soluble ruthenium complexes with SC DNA using the shift mobility assay. Reactions between the ruthenium complexes and SC plasmid DNA were performed in water buffered with phosphate at pH 7.0 for 14 h at 37 °C and then samples were analyzed by electrophoresis on agarose-TAE gels. The reaction was performed in the dark even though no photochemical activation of the present ruthenium complexes has been observed, in contrast to other ruthenium complexes.[27,28]

Delay of SC DNA was observed for complexes **1**, **2**, **3** and **7**. In addition, a modest increase in the amount of OC DNA was observed, relative to untreated DNA, which indicates that some DNA cleavage may also occur. The highest activity was observed for **1** and **7** (CP at an Ri value of 6 and 5; Ri = Ru/base molar ratio) while the iodide complex **2** and complex **3**, which contains $PPh_3$, showed a lower activity against DNA (CP at Ri values of 16 and 15). No unwinding was observed with compounds containing the PTA ligands **4** and **5** at Ri values (up to 15) where the others ruthenium complexes were active (Figure 4).

The interaction of ruthenium complexes **8** and **9** with plasmidic DNA was also investigated. Although delay of SC-DNA was repeatedly observed only for **8**, a precise quantification of its activity was not possible due to the limited water solubility of this compound. Nevertheless, this result is in agreement with the DNA activity observed for other previously investigated ruthenium complexes containing mPTA which is significantly higher than that found for related species containing PTA, as observed for $[RuClCp(mPTA)(PPh_3)]^+$ vs. $[RuClCp(PTA)(PPh_3)]$.[16]

The activity of the ligand Na(mTPPMS) was also studied in a blank experiment. Interestingly, when plasmid DNA was incubated with increasing amounts of this water-soluble phosphane an increase of the relaxed form of the plasmid (OC) was obtained that was found to correlate inversely with the amount of the supercoiled form (SC). This indicates that a direct conversion of the SC into the OC form is taking place and, therefore, that mTPPMS itself is able to cleave DNA.

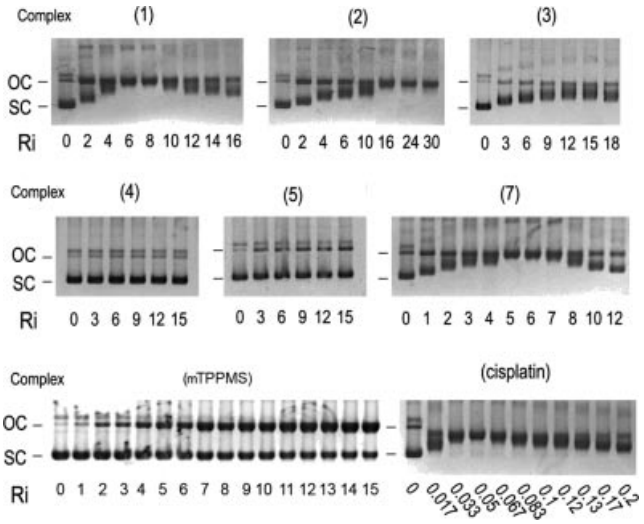

Figure 4. DNA mobility shift assay of the ruthenium complexes. Plasmid DNA was incubated with complexes $Na_2$-$[RuClCp(mTPPMS)_2]$ (**1**), $Na_2[RuCp(I)(mTPPMS)_2]$ (**2**), $[RuCp(mTPPMS)(PPh_3)_2]$ (**3**), $[RuCp(mTPPMS)(PTA)_2]$ (**4**), Na-$[RuCp(mTPPMS)_2(PTA)]$ (**5**), $Na_2[RuCp(mTPPMS)_3]$ (**7**) and the Na(mTPPMS). Ri values (Ri = Ru/base molar ratio) shown above as indicated in the Experimental Section. *cis*-$[PtCl_2(NH_3)_2]$ (cisplatin) was used as a control under the same experimental conditions.

As briefly mentioned above, only complexes **1**, **3** (less than 4 h) and **7** (ca. 2 days) react with water, probably by substitution of one ligand by a water molecule. The other ruthenium complexes (**2**, **4**, **5**, **6**, **8** and **9**) are stable in water for more than two days at 40 °C in diffuse daylight, thus suggesting that the species that interact with DNA are the unchanged ruthenium complexes. In keeping with the robustness of the $Na_x[RuCp(mTPPMS)(PR^1_3)(PR^2_3)](OTf)_y$ complexes with respect to phosphane dissociation, it is likely possible that the metal center in these complexes cannot interact directly with DNA N-nucleophiles. Many known ruthenium derivatives do not selectively interact with nucleobases and behave as intra- or interstrand cross-linking agents.[29] The interesting activity exhibited by the mTPPMS ligand towards DNA suggests that ruthenium complexes containing this ligand may be active agents for modifying DNA by a mechanism different from that usually accepted, which entails direct bonding to DNA nucleobases. Two diverse complex/DNA interaction processes can therefore be proposed for the present {CpRu(mTPPMS)} complexes. In the first mechanism an easy ligand substitution at ruthenium would allow for the interaction with DNA, whereas in the second mechanism the interaction between the metal complex and the DNA molecule might occur through a ruthenium-coordinated mTPPMS moiety without ligand dissociation. These two possible processes could act either separately or cooperatively with or without

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a synergic effect. In the chloride complex **1**, it is conceivable that chloride, most likely exchanged with a water molecule, could be substituted by a purine base, probably coordinated through the imidazole N7 atom, as has been proposed for the related ruthenium complexes $[RuCp(L)(L')X]^{n+}$ (X = Cl, I; L = $PPh_3$, L′ = PTA, mPTA; L = L′ = PTA, mPTA).[16b] This hypothesis is supported by the lower reactivity of the iodide **2**. This complex, however, is still more active than [RuCpI(L)(L′)] (L = $PPh_3$, L′ = PTA, mPTA; L = L′ = PTA, mPTA), which do not contain mTPPMS ligands.[16b] Complex **2** might therefore also interact with DNA through a mechanism that does not involve ligand substitution at ruthenium. The two proposed DNA interaction routes could take place cooperatively for complex **7**, which displays a DNA activity similar to **1**. Complex **7** contains three mTPPMS ligands bonded to the {CpRu} unit and one phosphane is labile enough to be partially replaced by iodide through mTPPMS dissociation/water coordination. As a matter of fact, an in situ $^{31}P$ NMR experiment in $D_2O$ at 40 °C shows the appearance, together with the singlet due to unchanged **7**, of additional resonances that could be assigned to aquo complexes formed from the starting complex by water substitution of the ligands originally bonded to the metal.

Complexes **3**–**6**, **8** and **9**, which contain phosphanes that are recalcitrant to substitution, display DNA activity that is much lower than **1**, **2** and **7**. This reduced DNA activity, however, is not a consequence of their lower water solubility. For example, $S(H_2O)_{25°C}$ for the biologically active complex **3** is 0.9 mg mL$^{-1}$ whereas that for the inactive species **4** is 10 mg mL$^{-1}$. A negative influence of both PTA and mPTA on the DNA activity of mTPPMS ruthenium complexes could be hypothesized if one considers the lack of activity shown by **4** (PTA) and **5** (mPTA) with respect to the highly active **3**. Nevertheless, it is not possible to rule out that traces of free mTPPMS could be produced by a small scale dissociation of the complex. Some of the DNA modification observed may therefore be a consequence of the direct interaction of free ligand with DNA; this dissociation could also lead to a direct Ru–DNA interaction. This effect is not likely to be very significant but may be responsible for the observed single-strand break, as observed for cisplatin.

## Conclusions

A large family of new water-soluble {CpRu(mTPPMS)} complexes, namely $Na_2[RuCp(mTPPMS)_2X]$ [X = Cl (**1**), I (**2**)] and $Na_x[RuCp(mTPPMS)(PR^1_3)(PR^2_3)](OTf)_y$ [$PR^1_3$ = $PR^2_3$ = $PPh_3$ (**3**), PTA (**4**), $x = y = 0$; $PR^1_3$ = mTPPMS, $PR^2_3$ = PTA (**5**), $x = 1$, $y = 0$; $PR^1_3$ = mTPPMS, $PR^2_3$ = mPTA (**6**), $x = y = 0$; $PR^1_3$ = $PR^2_3$ = mTPPMS (**7**), $x = 2$, $y = 0$; $PR^1_3$ = $PPh_3$, $PR^2_3$ = PTA (**8**), $x = y = 0$; $PR^1_3$ = mPTA, $PR^2_3$ = $PPh_3$ (**9**), $x = 0$, $y = 1$], that contain different combinations of water-soluble (PTA, mPTA, mTPPMS) or hydrophobic ($PPh_3$) phosphanes has been synthesized and characterized. Complex **8**·2$H_2O$, which has been characterized in the solid state by X-ray diffraction analysis, is the first example of an X-ray authenticated ruthenium complex bearing three different phosphane ligands.

DNA activity tests have shown that only complexes **1**, **2**, **3** and **7** actively destabilize the duplex SC DNA structure in the dark while the rest of the tris-phosphane complexes are inactive. The ligand mTPPMS itself shows DNA activity and control experiments have indicated that a direct conversion of the SC into the OC form takes place by DNA cleavage. These results suggest that ruthenium complexes containing mTPPMS might be active agents towards DNA by a *non-dissociative mechanism* that differs from the direct bonding to DNA. Two diverse mechanisms may therefore be proposed to explain the high DNA activity of mTPPMS–Ru complexes. Besides direct DNA interaction by ligand substitution at the metal, a second process may take place by interaction between the ruthenium-coordinated mTPPMS and DNA *without ligand dissociation*. Work is in progress to obtain more extensive and precise information about the effect of the water-soluble phosphane mTPPMS on the DNA activity of this class of water-soluble ruthenium complexes.

In light of these results it may be possible to design highly DNA-active water-soluble ruthenium complexes by the appropriate combination of water-soluble phosphanes and suitable organometallic platforms, including the potentially useful {CpRu} synthon. Studies in this direction are underway in our laboratory.

## Experimental Section

**General Procedures:** All chemicals were reagent grade and were used as received from commercial suppliers, unless otherwise stated. Solvents were distilled under nitrogen from the appropriate drying agent (sodium/benzophenone for thf, sodium for toluene) prior to use. Water was doubly distilled and deoxygenated before use. All reactions and manipulations were routinely performed under a dry nitrogen atmosphere by using standard Schlenk-tube techniques. The ligands PTA, mPTA($CF_3SO_3$), Na(mTPPMS) and the complexes $[RuCpCl(PPh_3)_2]$, $[RuCpCl(PPh_3)(PTA)]$ and $[RuCpCl(PPh_3)(mPTA)](CF_3SO_3)$ were prepared as described in the literature.[16,17,30] Deuterated solvents ($CD_3OD$, [D$_6$]DMSO and $CDCl_3$) for NMR measurements (Cortec-Euriso-top) were dried with molecular sieves (0.4 nm). $^1H$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker DRX300 spectrometer operating at 300.13 ($^1H$) or 75.47 MHz ($^{13}C$). Peak positions are quoted relative to tetramethylsilane and were calibrated against the residual solvent resonance ($^1H$) or the deuterated solvent multiplet ($^{13}C$). $^{31}P\{^1H\}$ spectra was recorded on the same instrument operating at 121.49 MHz and chemical shifts are quoted relative to external 85% $H_3PO_4$ with downfield values taken as positive. IR spectra were recorded for KBr discs using an IR-ATI Mattson Infinity Series spectrophotometer. Elemental analyses (C,H,N,S) were performed with a Fisons Instruments EA 1108 elemental analyser.

**Synthesis of $Na_2[RuCpCl(mTPPMS)_2]$ (1):** The sodium salt of the ligand Na(mTPPMS) (1.00 g, 2.74 mmol) was slowly added to a rapidly stirring solution of $[RuCpCl(PPh_3)_2]$ (1.00 g, 1.37 mmol) in 30 mL of toluene. After two hours refluxing, the yellow powder which separated was filtered, washed with $Et_2O$ (2 × 3 mL) and vacuum dried. The resulting compound is hygroscopic and

was stored under inert atmosphere. Powder, yield 1.09 g (85%). $S(H_2O)_{25°C}$ = 41 mg mL$^{-1}$ ($4.41 \times 10^{-2}$ M). $C_{41}H_{33}ClNa_2O_6P_2RuS_2$ (930.29): calcd. C 52.94, H 3.58, S 6.89; found C 52.70, H 3.72, S 6.50. IR (KBr): $\tilde{\nu}$ = 1188 cm$^{-1}$ [s, br; $\nu(SO_3)$]. $^1$H NMR (20 °C, $CD_3OD$): $\delta$ = 4.21 (s, 5 H, Cp), 7.14–8.12 (m, 28 H, $PPh_3$) ppm. $^{13}C\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = 81.21 (s, Cp), 126.24–144.00 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = 40.09 (br. s) ppm.

**Synthesis of $Na_2$[RuCpI(mTPPMS)$_2$] (2):** $Na_2$[RuClCp(mTPPMS)$_2$] (**1**) (0.1 g, 0.11 mmol) in 5 mL of MeOH was added slowly, with stirring, to a solution of NaI (0.016 g, 0.11 mmol) in 5 mL of MeOH. The resulting yellow solution was stirred for a further hour at room temperature and then its volume reduced to 1 mL under vacuum. Addition of 5 mL of $Et_2O$ gave a pale-yellow precipitate, which was filtered, washed with $Et_2O$ (2 × 2 mL) and vacuum dried. Powder, yield 0.101 g (95%). $S(H_2O)_{25°C}$ = 15 mg mL$^{-1}$ ($1.47 \times 10^{-2}$ M). $C_{41}H_{33}INa_2O_6P_2RuS_2$ (1021.9): calcd. C 48.15, H 3.25, S 6.26; found C 47.70, H 3.72, S 5.82. IR (KBr): $\tilde{\nu}$ = 1186 cm$^{-1}$ [s, br; $\nu(SO_3)$]. $^1$H NMR (20 °C, $CD_3OD$): $\delta$ = 4.27 (s, 5 H, Cp), 7.15–8.04 (m, 28 H, $PPh_3$) ppm. $^{13}C\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = 81.17 (s, Cp), 125.25–143.70 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = 38.03 (br. s) ppm.

**Synthesis of [RuCp(mTPPMS)(PPh$_3$)$_2$] (3):** Solid [RuClCp($PPh_3$)$_2$] (0.10 g, 0.14 mmol) was added to a solution of $NaBF_4$ (0.015 g, 0.138 mmol) in 50 mL of MeOH whilst stirring. After 15 min, Na(mTPPMS) (0.052 g, 0.14 mmol) was added and the mixture was heated to reflux for 1 h. The resulting yellow solution was filtered through a plug of celite and the solvent completely removed to leave a yellow solid, which was dissolved in 5 mL of $CH_2Cl_2$. This solution was filtered through a sintered glass frit and concentrated to 0.5 mL. Addition of 10 mL of $Et_2O$ yielded a yellow precipitate, which was filtered, washed with $Et_2O$ (2 × 2 mL) and vacuum dried. Powder, yield 0.12 g (83%). $S(H_2O)_{25°C}$ = 0.9 mg mL$^{-1}$ ($8.7 \times 10^{-4}$ M). $C_{59}H_{48}O_3P_3RuS$ (1031.2): calcd. C 68.66, H 4.69, S 3.10; found C 68.22, H 4.82, S 2.75. IR (KBr): $\tilde{\nu}$ = 1196 cm$^{-1}$ $\nu(SO_3)$. $^1$H NMR (20 °C, $CD_3OD$): $\delta$ = 3.99 (s, 5 H, Cp), 6.98–8.08 (m, 44 H, $PPh_3$, mTPPMS) ppm. $^{13}C\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = 81.04 (s, Cp), 125.98–138.05 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = 39.58 (br. m, $PPh_3$, mTPPMS) ppm.

**Synthesis of [RuCp(mTPPMS)(PTA)$_2$] (4):** A solution of [RuClCp(PTA)$_2$] (0.10 g, 0.19 mmol) in MeOH (15 mL) was added to solid Na(mTPPMS) (0.07 g, 0.19 mmol) and the resulting suspension refluxed for 5 h. The white precipitate that separated out was filtered while hot, washed with MeOH (3 × 5 mL) and $Et_2O$ (2 × 5 mL), and vacuum dried. Powder, yield 0.090 g (57%). $S(H_2O)_{25°C}$ = 10 mg mL$^{-1}$ ($1.2 \times 10^{-2}$ M). $C_{35}H_{43}N_6O_3P_3RuS$ (822.14): calcd. C 51.09, H 5.27, N 10.22, S 3.89; found C 50.61, H 5.42, N 9.78, S 3.35. IR (KBr): $\tilde{\nu}$ = 1197 cm$^{-1}$ $\nu(SO_3)$. $^1$H NMR (20 °C, $D_2O$): $\delta$ = 3.65–3.81 [m, 12 H, $CH_2P_{(PTA)}$], 4.27–4.38 [m, 12 H, $CH_2N_{(PTA)}$], 5.00 (s, 5 H, Cp), 7.18–7.91 (m, 14 H, aromatic) ppm. $^{13}C\{^1H\}$ NMR (20 °C, $D_2O$): $\delta$ = 55.66 [br. s, $CH_2P_{(PTA)}$], 70.29 [s, $CH_2N_{(PTA)}$], 83.78 (s, Cp), 127–136 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $D_2O$): $\delta$ = –34.43 (d, $^2J_{PTA,mTPPMS}$ = 34.5 Hz, 2 P, PTA), 49.57 (t, $^2J_{mTPPMS,PTA}$ = 34.5 Hz, 1 P, mTPPMS) ppm.

**Synthesis of Na[RuCp(mTPPMS)$_2$(PTA)] (5):** [RuCpCl(mTPPMS)$_2$] (**1**; 0.10 g, 0.11 mmol) and $NaBF_4$ (0.012 g, 0.11 mmol) were dissolved in 10 mL of MeOH and stirred at room temperature for 30 min before PTA (0.017 g, 0.11 mmol) was added. The suspension was refluxed for 30 min and then cooled to room temperature. Removal of the solvent under vacuum left a yellowish solid, which was mixed with 5 mL of $CH_2Cl_2$ to give a yellow suspension which was filtered and evaporated to 1 mL. Addition of $Et_2O$ (2 mL) gave a pale-yellow precipitate which was collected by filtration, washed with 2 mL of $Et_2O$ and vacuum dried. Powder, yield 0.082 g (72%). $S(H_2O)_{25°C}$ = 2.5 mg mL$^{-1}$ ($2.4 \times 10^{-3}$ M). $C_{47}H_{45}N_3NaO_6P_3RuS_2$ (1029.1): calcd. C 54.81, H 4.41, N 4.08, S 6.21; found C 54.53, H 4.52, N 3.81, S 5.83. IR (KBr): $\tilde{\nu}$ = 1194 cm$^{-1}$ $\nu(SO_3)$. $^1$H NMR (20 °C, $D_2O$): $\delta$ = 4.57–4.67 [m, 6 H, $CH_2P_{(PTA)}$], 5.23–5.31 [m, 6 H, $CH_2N_{(PTA)}$], 4.73 (s, 5 H, Cp), 7.23–8.43 (m, 15 H, aromatic) ppm. $^1$H NMR (20 °C, $CD_3OD$): $\delta$ = 4.10–4.30 [m, 6 H, $CH_2P_{(PTA)}$], 4.81–4.82 [m, 6 H, $CH_2N_{(PTA)}$], 4.35 (s, 5 H, Cp), 6.80–8.20 (m, 28 H, aromatic) ppm. $^{13}C\{^1H\}$ NMR (20 °C, DMSO): $\delta$ = 54.14 [br. s, $CH_2P_{(PTA)}$], 73.30 [s, $CH_2N_{(PTA)}$], 76.83 (s, Cp), 126–138 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $D_2O$): $\delta$ = –44.54 (t, $^2J_{PTA,mTPPMS}$ = 39.9 Hz, 1 P, PTA), 42.22 (d, $^2J_{mTPPMS,PTA}$ = 39.9 Hz, 2 P, mTPPMS) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = –49.63 (t, $^2J_{PTA,mTPPMS}$ = 38.8 Hz, 1 P, PTA), 42.80 (d, $^2J_{mTPPMS,PTA}$ = 37.0 Hz, 2 P, mTPPMS) ppm.

**Synthesis of [RuCp(mPTA)(mTPPMS)$_2$] (6):** Complex **6** was prepared following the procedure described above for **5** but replacing PTA with mPTA($CF_3SO_3$) (0.04 g, 0.11 mmol). Powder, yield 0.104 g (95%). $S(H_2O)_{25°C}$ = 1.35 mg mL$^{-1}$ ($1.3 \times 10^{-3}$ M). $C_{48}H_{47}N_3O_6P_3RuS_2$ (1020.1): calcd. C 56.46, H 4.64, N 4.12, S 6.27; found C 56.30, H 4.72, N 3.84, S 6.02. IR (KBr): $\tilde{\nu}$ = 1196, 1218 cm$^{-1}$ $\nu(SO_3)$. $^1$H NMR (20 °C, [$D_6$]DMSO): $\delta$ = 2.81 [br. s, 3 H, $CH_3N_{(mPTA)}$], 4.17 [br. m, 6 H, $CH_2P_{(mPTA)}$], 5.10 [br. m, 6 H, $CH_2N_{(mPTA)}$], 4.91 (s, 5 H, Cp), 6.74–7.82 (m, 28 H, aromatic) ppm. $^{13}C\{^1H\}$ NMR (20 °C, [$D_6$]DMSO): $\delta$ = 48.72 [s, $CH_3N_{(mPTA)}$], 51.84 [br. s, $NCH_2P_{(mPTA)}$], 59.33 [br. s, $CH_3NCH_2P_{(mPTA)}$], 68.06 [s, $NCH_2N_{(mPTA)}$], 79.11 [s, $CH_3NCH_2P_{(mPTA)}$], 86.34 (s, Cp), 128.38–148.65 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, [$D_6$]DMSO): $\delta$ = –29.33 (br. s, 1 P, mPTA), 39.96 (br. s, 1 P, mTPPMS), 46.29 (br. s, 1 P, mTPPMS) ppm.

**Synthesis of $Na_2$[RuCp(mTPPMS)$_3$] (7):** Complex **1** (0.10 g, 0.11 mmol) and $NaBF_4$ (0.012 g, 0.11 mmol) were dissolved in MeOH (10 mL). The mixture was stirred for 15 min and then solid Na(mTPPMS) (0.04 g, 0.11 mmol) was added. The solution was then refluxed for 30 min. During this time a white precipitate formed, and this was subsequently filtered off to afford a yellow solution. Evaporation of the solvent gave a yellow powder, which was dissolved in 5 mL of $CH_2Cl_2$ and the mixture filtered and concentrated to 0.5 mL. Addition of $Et_2O$ (10 mL) gave a pale-yellow precipitate, which was filtered, washed with $Et_2O$ (2 × 2 mL) and vacuum dried. Powder, yield 0.16 g (88%). $S(H_2O)_{25°C}$ = 20.0 mg mL$^{-1}$ ($1.6 \times 10^{-3}$ M). $C_{59}H_{47}Na_2O_9P_3RuS_3$ (1236.0): calcd. C 57.28, H 3.83, S 7.76, found C 57.02, H 4.01, S 7.45. IR (KBr): $\tilde{\nu}$ = 1193 cm$^{-1}$ [s br., $\nu(SO_3)$]. $^1$H NMR (20 °C, $D_2O$): $\delta$ = 3.96 (s, 5 H, Cp), 6.66–7.70 (m, 42 H, aromatic) ppm. $^{13}C\{^1H\}$ (20 °C, $D_2O$): $\delta$ = 76.45 (s, Cp), 123.05–134.56 (all singlets, aromatic) ppm; $^{31}P\{^1H\}$ NMR (20 °C, $D_2O$): $\delta$ = 40.68 (br. s, mTPPMS) ppm.

**Synthesis of [RuCp(mTPPMS)(PPh$_3$)(PTA)]·2H$_2$O (8·2H$_2$O):** A suspension of [RuClCp($PPh_3$)(PTA)] (0.17 g, 0.25 mmol) and Na(mTPPMS) (0.10 g, 0.27 mmol) in 20 mL of methanol was heated to reflux. The mixture slowly turned pale yellow and after 1 h it was cooled to 8 °C. The crystals that separated out were filtered and dried in air. Crystals, yield 0.203 g (84%). $S(H_2O)_{25°C}$ = 0.60 mg mL$^{-1}$ [$6.2 \times 10^{-4}$ M]. $C_{47}H_{45}N_3O_3P_3RuS{\cdot}2H_2O$ (962.165): calcd. C 58.62, H 5.13, N 4.37, S 3.32; found C 58.52, H 5.22, N 4.22, S 3.10. IR (KBr): $\tilde{\nu}$ = 1197 cm$^{-1}$ $\nu(SO_3)$. $^1$H NMR (20 °C, $CDCl_3$): $\delta$ = 3.78, 3.95 [AB system, $^2J_{H_AH_B}$ = 14.0 Hz, 6 H, $CH_2P_{(PTA)}$], 4.14, 4.23 [AB system, $^2J_{H_AH_B}$ = 12.6 Hz, 6 H, $CH_2N_{(PTA)}$], 4.86 (s, 5 H, Cp), 6.97–8.60 (m, 29 H, aromatic) ppm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$^{13}C\{^1H\}$ NMR (20 °C, [D$_6$]DMSO): $\delta$ = 79.12 [d, $^1J_{C,P}$ = 33.0 Hz, $CP_{(PTA)}$], 79.78 [s, $CN_{(PTA)}$], 85.33 (s, Cp), 128.67–133.55 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $CDCl_3$): $\delta$ = –49.30 (dd, AXX′ system, $^2J_{PTA,mTPPMS}$ = 41.8, $^2J_{PTA,PPh_3}$ = 38.8 Hz, PTA), 41.56 (dd, AXX′ system, $^2J_{PPh_3,mTPPMS}$ = 32.0, $^2J_{PPh_3,PTA}$ = 38.8 Hz, $PPh_3$), 43.65 (dd, AXX′ system, $^2J_{mTPPMS,PPh_3}$ = 32.0, $^2J_{mTPPMS,PTA}$ = 41.8 Hz, mTPPMS) ppm.

**Synthesis of [RuCp(mTPPMS)(mPTA)(PPh$_3$)](CF$_3$SO$_3$) (9):** [RuClCp($PPh_3$)(mPTA)]($CF_3SO_3$) (0.18 g, 0.23 mmol) and Na(mTPPMS) (0.1 g, 0.27 mmol) were dissolved in MeOH (30 mL) and the mixture refluxed for 12 h. The resulting yellow suspension was filtered through sintered glass and the solvent evaporated to dryness under vacuum to leave a yellow solid, which was washed and triturated with $Et_2O$ (2 × 5 mL) before being dried under vacuum. Powder, yield 0.23 g (92%). $S(H_2O)_{25°C}$ = 0.60 mg mL$^{-1}$ (5.6 × 10$^{-4}$ M). $C_{49}H_{49}F_3N_3O_6P_3RuS_2$ (1091.1): calcd. C 53.89, H 4.53, N 3.85, S 5.86; found C 53.10, H 4.72, N 5.32, S 5.52. IR (KBr): $\tilde{\nu}$ = 1194 cm$^{-1}$ $\nu(SO_3)$. $^1H$ NMR (20 °C, $CD_3OD$): $\delta$ = 3.05 [s, 3 H, $CH_3N_{(mPTA)}$], 3.37–4.61 [m, 6 H, $CH_2P_{(mPTA)}$], 4.87–5.57 [m, 6 H, $CH_2N_{(mPTA)}$], 4.93 (s, 5 H, Cp), 6.58–7.55 (m, 29 H, aromatic) ppm. $^{13}C\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = 51.24 [s, $CH_3N_{(mPTA)}$], 60.33 [br., $NCH_2P_{(mPTA)}$], 68.37 [br., $CH_3NCH_2P_{(mPTA)}$], 79.26 [s, $CH_3NCH_2N_{(mPTA)}$], 79.74 [s, $NCH_2N_{(mPTA)}$], 85.8 (s, Cp), 120.28 (q, $^1J_{C,F}$ = 320.4 Hz, $OSO_2CF_3$), 128.43–138.09 (all singlets, aromatic) ppm. $^{31}P\{^1H\}$ NMR (20 °C, $CD_3OD$): $\delta$ = –26.58 (br. t, $^2J_{mPTA,mTPPMS,PPh_3}$ = 37.9 Hz, mPTA), 40.48 (br. d, $^2J_{mTPPMS,PPh_3,mPTA}$ = 33.3 Hz, $PPh_3$, mTPPMS) ppm.

**Reactions of 3–9 with KI:** In a typical procedure, a solution of the appropriate ruthenium complex **3**–**9** (approx. 0.10 mmol) dissolved in 15 mL of MeOH was treated with a slight excess of KI (0.022 g, 0.13 mmol) and brought to reflux. After 5 h, the solution was cooled and the solvents evaporated to dryness. In all cases, except **7**, the $^{31}P\{^1H\}$ NMR spectra of the crude reaction mixture confirmed that no reaction had occurred. In the case of **7**, the product obtained was a mixture of the starting material **7** (85%) and **2** (15%), which likely forms by partial replacement of one mTPPMS in **7** with iodide.

**Reactions of 3–9 with CO:** In a typical procedure, a 5-mm NMR tube was charged with about 0.10 mmol of the appropriate solid ruthenium complex **1**–**9** and around 0.5 mL of $CDCl_3$ (or $CD_3OD$ for **1**, **2** and **7**). The resulting solution was then cooled to 0 °C and dry CO was slowly bubbled through it for 2 min. The $^{31}P\{^1H\}$ NMR spectra showed no change either after one day at room temperature or one day at 40 °C.

**Stability Tests for the Ruthenium Complexes 1–9 Towards D$_2$O and O$_2$:** In a standard procedure, a 5-mm NMR tube was charged in the air with 10 mg of the appropriate ruthenium complex **1**–**9** and $D_2O$ (1.0 mL). The solution was then cooled to about 0 °C and $O_2$ was slowly bubbled through it for 2 min through a long syringe needle and then kept at 40 °C. $^{31}P\{^1H\}$ NMR monitoring showed extensive decomposition within four days only for **1**, **3** and, partially, for **7**, as indicated by the disappearance of the NMR signals and by the appearance of singlet signals that could not assigned to any known complexes apart from free mTPPMS (see also Table 1).

**DNA Mobility Shift Assay:** pBluescript KSII plasmid (3Kbp, from Stratagene; 1 μg) was added to 20 μL of 10 mM phosphate buffer solution at pH 7.0 and diluted with the appropriate amount of a freshly prepared water solution of the ruthenium complex **1**–**9** to achieve the desired stoichiometry between the nucleobase and the ruthenium complex. The reaction mixtures were then incubated for 14 h at 37 °C in the dark and 10 μL sample-aliquots were withdrawn and analysed by electrophoresis in 1% agarose-TAE gels. DNA bands were visualised by staining with ethidium bromide and photographed under UV light. The Ri value (metal to base molar ratio at the onset of the incubation) at which complete transformation of the supercoiled to relaxed form of the plasmid was registered for each active compound.

**X-ray Analysis of 8·2H$_2$O:** Crystals suitable for an X-ray diffraction study were obtained directly from the reaction mixture used to synthesize **8**. The crystals obtained were filtered off and dried in air. Data were collected at 293 K on a Bruker APEX CCD diffractometer (XDIFRACT service of the University of Almeria) using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å). The unit cell parameters were obtained from least-squares refinement of 3975 reflections (4.334° < $\theta$ < 36.673°). The data were corrected for Lorentz and polarization effects. Details of crystal data and relevant information are summarized in Table 2.

Table 2. Summary of crystal data for **8**·2H$_2$O.

The structure was solved using the Sir97 program.[31] Final refinement and the graphical representation were performed with SHELX-TL.[32] Refinement was done by full-matrix least-squares calculations, initially with isotropic thermal parameters. All non-hydrogen atoms and water oxygen atoms were refined anisotropically, whereas hydrogen atoms were placed at calculated positions and then refined isotropically. All of the phenyl rings were treated as rigid bodies with $D_{6h}$ symmetry and C–C distances fixed at

# Solvent Control in the Protonation of [Cp*Mo(dppe)$H_3$] by $CF_3COOH$

**Pavel A. Dub,[a,b] Miguel Baya,[a] Jennifer Houghton,[a] Natalia V. Belkova,[b] Jean-Claude Daran,[a] Rinaldo Poli,*[a] Lina M. Epstein,[b] and Elena S. Shubina*[b]**

**Keywords:** Molybdenum / Hydrido ligand / Trifluoroacetato ligand / Proton transfer / Dihydrogen bonding

The outcome of the reaction between [Cp*Mo(dppe)$H_3$] [dppe = 1,2-bis(diphenylphosphanyl)ethane] and trifluoroacetic acid (TFA) is highly dependent on the solvent and the TFA/Mo ratio. The dihydride compound [Cp*Mo(dppe)$H_2$($O_2CCF_3$)] is obtained selectively when the reaction is carried out in aromatic hydrocarbons (benzene, toluene) when using less than one equivalent of TFA. The dihydride is also the end product when THF or MeCN are used as solvent, independent of the TFA/Mo ratio. In benzene/toluene the use of excess acid has a profound effect, resulting in the formation of the tetrahydrido complex [Cp*Mo(dppe)$H_4$]$^+$, which did not further evolve into the dihydrido product. Monitoring of the reaction by NMR and IR spectroscopy under different conditions (solvent, temperature, TFA/Mo ratio) reveals the rapid establishment of an equilibrium between the dihydrogen-bonded adduct, [Cp*Mo(dppe)$H_3$]···$HO_2CCF_3$, the ion-paired proton-transfer product, [Cp*Mo(dppe)$H_4$]$^+$···$^-O_2CCF_3$, and the separated ions, followed by a slower irreversible transformation to the final dihydride product with $H_2$ evolution. The activation parameters of the $H_2$ evolution and M–OR product formation were determined. Excess TFA in low-polarity solvents stabilizes the separated charged species by forming the homoconjugate anion [$CF_3COO(CF_3COOH)_n$]$^-$. The effect of the solvent on the course of the reaction can be interpreted in terms of the different polarity, H-bonding ability, and coordinating power of the various solvent molecules.

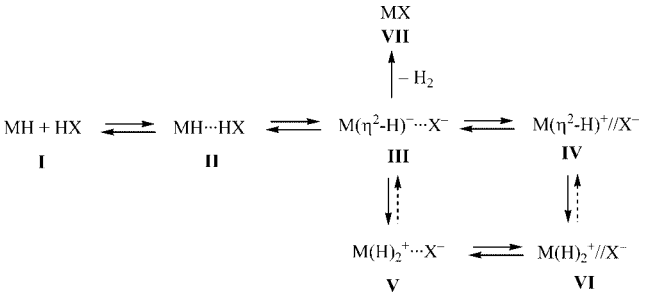
## Introduction

It is now well established that a common proton-transfer pathway from a proton donor HX to a transition-metal hydride complex involves the initial attack of HX on the hydride ligand with formation of a dihydrogen-bonded adduct, MH···HX, followed by proton transfer and production of a nonclassical dihydride (dihydrogen complex) product, M($\eta^2$-$H_2$)$^+$. The establishment of a hydrogen-bonded ion pair between the nonclassical cation and its counteranion increases the stability of the M($\eta^2$-$H_2$)$^+$ complex and retards its transformation into a classical polyhydride or organyloxo (X = OR) species (Scheme 1).[1]

The formation of M($\eta^2$-$H_2$)$^+$···$X^-$ ion pairs (**III**, $X^-$ = $CF_3COO^-$, $ArO^-$, $R^FO^-$), stabilized by hydrogen bonds between the dihydrogen ligand and counteranions, was detected for [CpRuH(CO)($PCy_3$)],[2,3] $PP_3MH_2$ {$PP_3$ = $P(CH_2CH_2PPh_2)_3$},[4] and [Cp*MH(dppe)] (M = Fe,[5] Ru[6]) complexes by IR and UV/Vis spectroscopy. The ion-pair stability increases with the proton-accepting ability of the anion.[3]



Scheme 1.

Proton transfer may also be assisted by a second molecule of the proton donor HX, depending on the acid strength. In this case, the conjugate base $X^-$ in species **III**–**VI** may be present in the form of the homoconjugate anion, $XHX^-$. We have recently shown that the irreversible isomerization of [Cp*M($\eta^2$-$H_2$)(dppe)]$^+$ complexes (M = Fe,[5] Ru[6]) into classical *trans*-dihydride species occurs upon dissociation of the M($\eta^2$-$H_2$)$^+$···$XHX^-$ ion pair (i.e., **III** to **IV**). This is indicated by the difference in temperature at which the M($\eta^2$-$H_2$)$^+$ → M$(H)_2^+$ isomerization process can occur depending on the counteranion; higher temperatures are necessary to induce isomerization in the presence of more basic anions (greater ion-pair stability). Additionally,

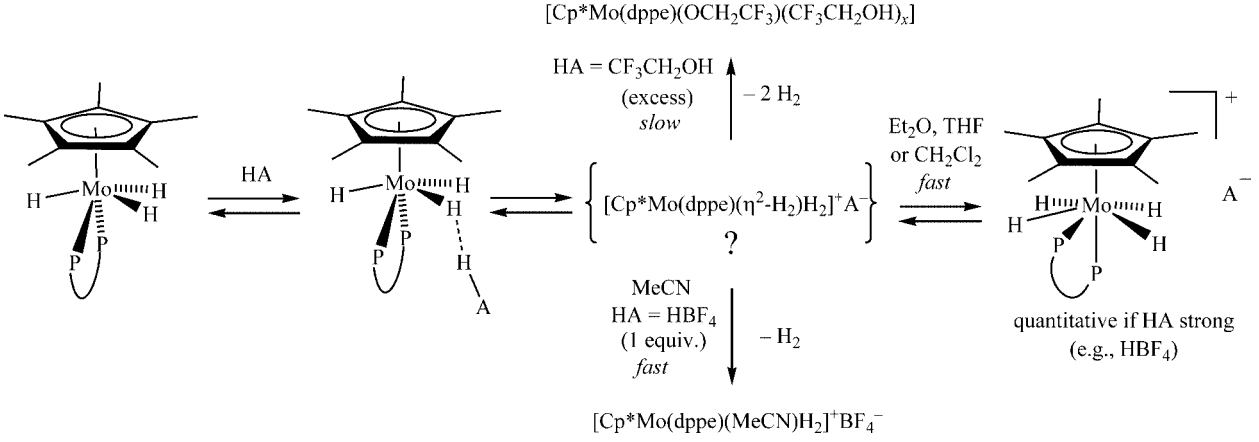
the isomerization rate constant does not depend on the anion nature.[7,8] In some cases, the nonclassical to classical rearrangement (**III** to **V**, or **IV** to **VI**) is a reversible process.[9]

In many cases, however, basic anions ($X^-$ = $RO^-$, $RCOO^-$) tend to displace $H_2$ from the transition-metal coordination sphere, yielding organyloxo products (i.e., **VII**). This is the case for the protonation of [(triphos)ReH$(CO)_2$],[10] [$Re(CO)H_2(NO)(PR_3)_2$],[11] and the previously mentioned [CpRuH(CO)$(PCy_3)$],[2] for which corresponding $M(\eta^2\text{-}H_2)^+X^-$ complexes could be isolated as $BF_4^-$ salts. These evolved into MX species in the presence of fluorinated alcohols or carboxylic acids. This reaction proceeds intramolecularly without the hydrogen-bonded ion-pair dissociation.[2] Most of the M–OR complexes were only characterized in solution; two examples of isolated compounds are [$ReH(OC_6H_4NO_2)(CO)(NO)(PMe_3)_2$][11] and [(triphos)$Re(CO)_2(OCOCH_2Cl)$].[10] In addition to the counteranion nature, temperature and solvent polarity could be used to control the stability of the $M(\eta^2\text{-}H_2)^+$ species and the proton-transfer equilibrium position. For example, the substantial increase in the dielectric constant of the Freon mixture ($CDCl_2F/CDF_3$, 2:1) at low temperatures was reported to assist the proton transfer to [Cp*$RuH_3(PCy_3)$], yielding [Cp*$Ru(H)_2(\eta^2\text{-}H_2)(PCy_3)]^+$-$OR^-$.[12] However, the influence of the medium on the $H_2$ release process was not studied in detail.

In contrast to all of the described systems, the protonation of the trihydridomolybdenum complex [Cp*Mo(dppe)$H_3$] gave, via the intermediate formation of a dihydrogen-bonded complex, the cationic classical tetrahydride complex [Cp*Mo(dppe)$H_4]^+$ (**V/VI**), without the detection of a nonclassical isomer, [Cp*Mo(dppe)$(\eta^2\text{-}H_2)$-$H_2]^+$ (**III/IV**). Theoretical calculations, however, located the latter complex on the proton-transfer potential energy surface, with a very low energy barrier for the intramolecular rearrangement.[13] Facile access to a nonclassical isomer is evidenced by the evolution of $H_2$ from [Cp*Mo(dppe)$H_4]^+$ at ambiet temperature. We now report new results on the protonation of [Cp*Mo(dppe)$H_3$] using trifluoroacetic acid (TFA) in various solvents of different coordinating (in particular H-bonding) ability and polarity: benzene, toluene, THF, $CH_2Cl_2$, and MeCN. These reactions led to the formation of a new hydride product with a coordinated trifluoroacetate anion. We will show how subtle changes in the protonation medium may drastically affect the reactivity of [Cp*Mo(dppe)$H_3$] and the stability of its protonation product.

## Results

Since the results of previous investigations into the protonation of [Cp*Mo(dppe)$H_3$][13–15] serve as a basis for the new findings described in this paper, we summarize here the salient points that emerge from those studies. (i) The trihydride complex has a high basicity factor ($E_j$ = $1.42 \pm 0.02$), placing it in the category of the most hydridic complexes known. (ii) As mentioned in the Introduction, the interaction with $HBF_4$ in noncoordinating or weakly coordinating solvents (diethyl ether, THF) leads directly to the tetrahydride complex [Cp*Mo(dppe)$H_4]^+$, without the detection of a nonclassical intermediate, although its presence is suggested by the theoretical calculations. (iii) [Cp*Mo(dppe)$H_4]^+BF_4^-$ is unstable and rapidly loses dihydrogen; in MeCN, this process leads to the formation of the solvent-stabilized complex [Cp*Mo(dppe)$H_2$(MeCN)]$^+$. (iv) The interaction with weaker proton donors [the fluorinated alcohols $CH_2FCH_2OH$, $CF_3CH_2OH$, and $(CF_3)_2CHOH$] in low-polarity solvents (e.g., THF, $CH_2Cl_2$) at low temperatures leads to the observation of intermediate hydrogen-bonded adducts. Infrared spectral analysis, in combination with theoretical calculations, indicates that one of the hydride ligands of [Cp*Mo(dppe)$H_3$] takes part in hydrogen bonding. (v) Proton transfer from the dihydrogen-bonded adduct yields, without the observable intervention of a second HA molecule in the rate-determining step, the tetrahydride product as a 1:1 ion-pair stabilized by a hydrogen bond between the cation and the anion, [Cp*Mo(dppe)-$H_4]^+\cdots A^-$, as established for HA = *p*-nitrophenol and $CF_3CH_2OH$. The proton-transfer reaction is equilibrated for these weaker proton donors. (vi) On a longer timescale,



Scheme 2.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the tetrahydride product $[Cp^*Mo(dppe)H_4]^+$, obtained using HA = $CF_3CH_2OH$, evolves at ambient temperature by release of two $H_2$ molecules to form the hydride-free product $[Cp^*Mo(dppe)(OCH_2CF_3)]$, probably stabilized by coordination of a second alcohol molecule, $[Cp^*Mo(dppe)(OCH_2CF_3)(CF_3CH_2OH)]$. These observations are summarized in Scheme 2.

### Protonation in Benzene/Toluene: Formation of Compound $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$

The room-temperature reaction between $[Cp^*Mo(dppe)H_3]$ and *strictly* 1 equiv. TFA in toluene led selectively to a new dihydride complex, $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$, as seen in Equation (1). The parallel formation of free $H_2$ was confirmed by $^1H$ NMR spectroscopic monitoring (characteristic resonance at $\delta$ = 4.58 ppm). The new hydride compound was isolated and fully characterized. It is quite stable in aromatic solvents, decomposing very slowly with generation of free dppe (identified by its $^{31}P$ resonance at –12.9 ppm) and other unidentified products that do not contain hydride ligands. Ca. 13% of the product decomposed after 22 hours at room temperature.

$$[Cp^*Mo(dppe)H_3] + TFA \rightarrow [Cp^*Mo(dppe)H_2(O_2CCF_3)] + H_2 \quad (1)$$

The compound is characterized by a hydride resonance centered at –5.09 ppm, with a relative intensity corresponding to two protons, only slightly displaced relative to the hydride resonance of $[Cp^*Mo(dppe)H_3]$ at –5.16 ppm. The $^{31}P\{^1H\}$ NMR spectrum shows a resonance at 76.9 ppm, which becomes a triplet when selectively decoupled from the dppe proton resonance, confirming the presence of two hydride ligands. The shape of the hydride resonance suggests the occurrence of a dynamic process. A variable-temperature NMR investigation gave further information about this process and also provided longitudinal relaxation times for the hydride resonances. The shape of the $^1H$ resonances in the hydride region as a function of temperature is shown in Figure 1 (a). Cooling resulted in broadening and eventual decoalescence (225 K), yielding two broad resonances in a 1:1 ratio at –4.19 and –6.24 ppm. The more upfield resonance starts to resolve into a doublet at the lowest temperature, indicating coupling ($J \approx 72$ Hz) to another $I$ = 1/2 nucleus, probably one of the two phosphorus donor atoms that therefore appear to be inequivalent. This inequivalence was demonstrated by the variable-temperature $^{31}P\{^1H\}$ NMR investigation (see part b of Figure 1); decoalescence was observed at $T < 233$ K to yield two resonances in an approximate ratio of 1:1. No P–P coupling can be discerned from the spectra. The $^{31}P$ NMR data were used in a lineshape analysis, from which the activation parameters of $\Delta H^{\ddagger} = (6.4 \pm 0.4)$ kcal mol$^{-1}$ and $\Delta S^{\ddagger} = (10 \pm 2)$ cal K$^{-1}$ mol$^{-1}$ were calculated using an Eyring analysis (see electronic Supporting Information). The lineshape analysis of the $^1H$ resonance was complicated by the lack of knowledge of $J_{HP}$ data due to broadness in the low-temperature spectra, but a simulation using the rate constant obtained from the $^{31}P$ NMR spectrum and a reasonable guess for the $J_{HP}$ values gave a reasonable fit above coalescence, suggesting that the same mechanism is responsible for both H and P exchange processes. A possibility for this mechanism is illustrated in Scheme 3. The $T_1$ value for the hydride resonance remains rather high throughout the temperature range (see Supporting Information), characteristic of a classical dihydride, with a minimum of 510 ms before decoalescence. For comparison, the $T_{1min}$ of complex $[Cp^*Mo(dppe)H_4]^+$ is 174 ms for the $BF_4^-$ salt and 191 ms when obtained by proton transfer from TFE (these measurements were carried out at 400 MHz).[13]

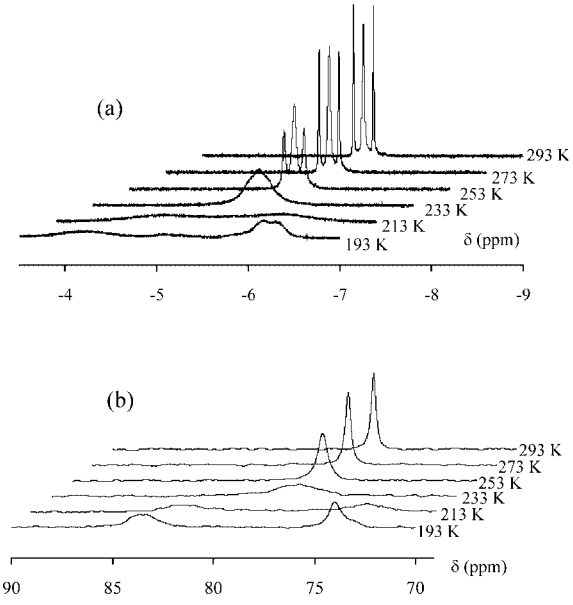


Figure 1. Variable-temperature spectra for compound $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$ in $C_6D_5CD_3$: (a) $^1H$ NMR (500 MHz); (b) $^{31}P\{^1H\}$ NMR (202 MHz).

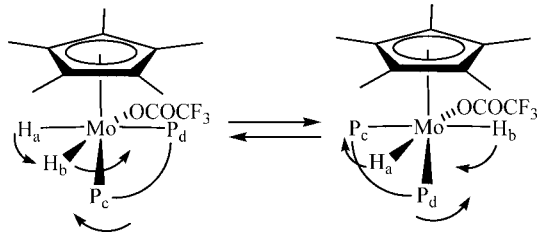

Scheme 3.

The chemical composition of the product was confirmed by single-crystal X-ray analysis. The coordination geometry, shown in Figure 2, corresponds to a rather severely distorted octahedron if the Cp* ligand is considered to occupy a single coordination position at the ring centroid. This distortion is caused by steric repulsion between the Cp* and dppe ligands and by the small size of the two hydride ligands, which force the pseudoaxial (*trans* to the Cp* ligand) phosphorus donor to move up into the wedge of the two Mo–H bonds. The CNT–Mo1–P1 angle [122.648(13)°] is greater than the CNT–Mo1–O1, CNT–Mo1–H1, and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

CNT–Mo1–H2 angles [119.74(4)°, 98.5(10)°, and 96.9(9)°, respectively], whereas the CNT–Mo1–P2 angle [144.369(14)°] is much smaller than 180°. A similar distortion was observed in the structure of the related $[Cp^*Mo(dppe)H(MeCN)_2]^{2+}$ complex.[14] The other notable feature is the monodentate coordination of the trifluoroacetate ligand, which occupies a pseudoequatorial position *cis* to the P1 and H1 donors and *trans* to H2. The Mo1–O1 bond length [2.2008(15) Å] is unexpectedly longer than those found in other Mo monodentate carboxylate derivatives in the same or lower oxidation state, for example, 2.167(4) Å found in $[Cp^*Mo^{II}(CO)(PMe_3)_2(O_2CMe)]$,[16] 2.102(3) and 2.092(3) Å found in $[CpMo^{III}(\eta^4\text{-}C_4H_6)(O_2CCF_3)_2]$,[17] and 2.113(4) and 2.102(4) Å found in $[Cp_2Mo^{IV}(O_2CPh)_2]$.[18] Another interesting feature is the similar C8–O1 [1.249(3) Å] and C8–O2 [1.221(3) Å] distances (bond difference Δ = 0.028 Å). These are not quite as long or short, respectively, as expected for localized single and double bonds. For instance, the recently determined structure of $Ph_3CCH_2COOH$ shows clearly defined C–O [1.304(3) Å] and C=O [1.203(3) Å] bonds (Δ = 0.101 Å) with no obvious sign of hydrogen atom disorder.[19] The monodentate carboxylate C–O distances in the mentioned examples show larger differences between C=O and C–O bond lengths, although not quite as large as those found in free carboxylic acids, namely 1.277(8) Å compared with 1.212(8) Å (Δ = 0.065 Å) for $[Cp^*Mo^{II}(CO)(PMe_3)_2(O_2CMe)]$,[16] 1.276(5) and 1.255(5) Å compared with 1.200(5) and 1.192(6) Å (Δ = 0.076 and 0.063 Å, respectively) for $[CpMo^{III}(\eta^4\text{-}C_4H_6)(O_2CCF_3)_2]$,[17] and 1.281(8) and 1.300(8) Å compared with 1.208(8) and 1.210(8) Å (Δ = 0.073 and 0.090 Å, respectively) for $[Cp_2Mo^{IV}(O_2CPh)_2]$.[18] This combined evidence indicates a significant ionic contribution to the bond between the Mo center and the monodentate anion, which then continues to promote some electronic delocalization between the two C–O bonds. Other relevant structural parameters are listed in Table 1.

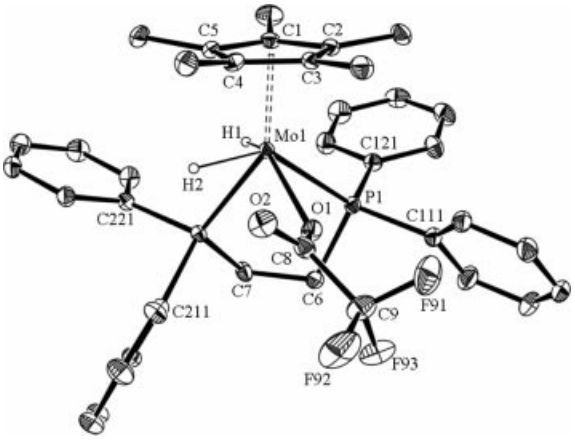

Figure 2. ORTEP view of compound $[Cp^*Mo(dppe)H_2(OCOCF_3)]$. Hydrogen atoms, except for the two hydride ligands, are omitted for clarity. The thermal ellipsoids are drawn at the 30% probability level.

Compound $[Cp^*Mo(dppe)H_2(OCOCF_3)]$ exhibits two intense overlapping $\nu^{as}_{OCO}$ bands in the IR spectrum; the frequencies and relative intensities of which are solvent dependent (see Table 2). As the solvent polarity increases, $A_{low}/A_{high}$ decreases and $\Delta\nu = (\nu_{high} - \nu_{low})$ increases. The same behavior was observed previously for $[CpM(CO)_2(OCOR)]$ complexes (M = Fe, Ru)[20] and was explained by the presence of a Fermi resonance between the fundamental $\nu^{as}_{OCO}$ stretching vibration and an overtone or combination band of very close frequency. The larger intensity ratio observed in $CH_2Cl_2$ could be explained by the different nature of the solute–solvent interaction, since this solvent could act as a proton donor and form hydrogen bonds with the carboxyl group coordinated to the metal.

Table 2. Characteristics of the $\nu^{as}_{OCO}$ band of $[Cp^*Mo(dppe)H_2(OCOCF_3)]$ in the solid state and in solution.

| Solvent | $\nu^{as}_{OCO}$ /cm$^{-1}$ | Δν | Intensity ratio ($A_{low}/A_{high}$) |
|---|---|---|---|
| Solid (KBr) | 1700 sh, 1685 s | 15 | 1.8 |
| $C_6H_6$ | 1700 sh, 1690 | 10 | 1.2 |
| $C_6D_5CD_3$ | 1700 sh, 1690 | 10 | 1.1 |
| THF | 1702, 1690 | 12 | 1.0 |
| $CH_2Cl_2$ | 1706 sh, 1688 | 18 | 2.2 |

### Protonation in Benzene/Toluene: Evolution with Time

The $^1$H NMR spectroscopic monitoring of the $[Cp^*Mo(dppe)H_3]$–TFA reaction in $C_6D_6$ at different TFA/Mo ratios at room temperature was most enlightening. Figure 3 (a) shows the spectrum of the starting material before TFA addition.[21]

When using a 10-fold excess of TFA, the tetrahydrido complex $[Cp^*Mo(dppe)H_4]^+$ was the only observed product, see Figure 3 (b). This is characterized by a hydride triplet resonance at –3.57 ppm ($J_{HP}$ = 37.9 Hz) in the $^1$H NMR spectrum and by a $^{31}$P resonance at 72.3 ppm in $C_6D_6$, quite close to the values previously reported for the $BF_4^-$ salt in $CDFCl_2$ at –60 °C.[14] In agreement with the literature, decomposition takes place at room temperature (90% after

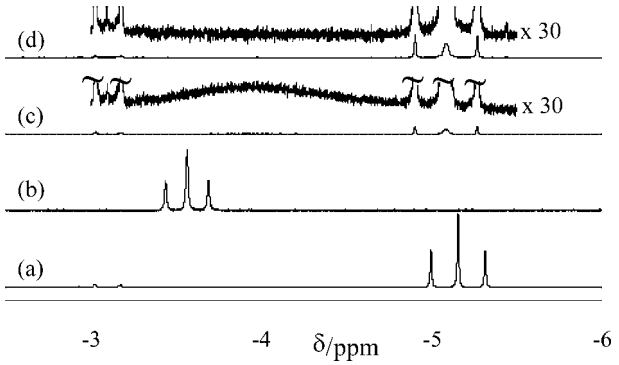

Figure 3. $^1$H NMR (300 MHz) spectroscopic monitoring of the reaction between [Cp*Mo(dppe)$H_3$] and TFA in $C_6D_6$ (290 K): (a) starting material before the TFA addition; (b) immediately after the TFA addition (10 equiv.); (c) immediately after the TFA addition (1 equiv.); (d) after 3.5 h from spectrum (c).

ca. 25 minutes), without yielding any hydride-containing product. This decomposition was not investigated in any further detail.

For the 1:1 reaction, a broad resonance was initially present in the hydride region at an intermediate position between those of the trihydride and tetrahydride complexes, in addition to the final product resonance (Figure 3, c). The position and shape of the broad resonance depends on the TFA/Mo ratio and on the temperature (vide infra). The $^{31}$P{$^1$H} NMR spectrum at room temperature exhibits two small and broadened resonances at the characteristic positions of the trihydride complex ($\delta$ = 91.4 ppm) and the tetrahydride protonation product ($\delta$ = 72.3 ppm),[22] in addition to the sharp resonance of the [Cp*Mo(dppe)$H_2$($O_2CCF_3$)] product at 76.9 ppm and a minor contaminant resonance.[21] This suggests that the broad $^1$H resonance results from a rapid degenerate exchange between the starting complex [Cp*Mo(dppe)$H_3$], which is not completely consumed, and its protonation product, [Cp*Mo(dppe)$H_4$]$^+$. This exchange will be addressed in further detail in the next section. Given the larger chemical shift difference between the $^{31}$P resonances, the shape of the $^{31}$P NMR spectrum is much closer to the slow exchange limit than that of the $^1$H NMR spectrum. After a few hours at room temperature (or upon brief warming to ca. 40 °C), the broad band disappears and the resonance corresponding to [Cp*Mo(dppe)$H_2$($OCOCF_3$)] increases in intensity (Figure 3, d). These observations reveal the presence of an equilibrium between the tetrahydride complex and the starting trihydride complex, followed by a slow irreversible conversion to the final product by $H_2$ loss.

A variable-temperature study of the reaction mixture in $C_6D_5CD_3$, carried out immediately after mixing the reagents in a 1:1 ratio, confirmed the earlier assignments. The hydride resonance of the dihydride product evolved as discussed previously (Figure 1, a), whereas the broad resonance at –3.63 ppm decoalesced at $T < 270$ K to yield two resonances at the expected positions of [Cp*Mo(dppe)$H_3$] and [Cp*Mo(dppe)$H_4$]$^+$. The incomplete protonation in the presence of a stoichiometric amount of TFA shows that the protonation process is at equilibrium using this particular proton donor. Both complexes exhibit sharp resonances when alone and also when mixed together with [Cp*Mo(dppe)$H_2$($OCOCF_3$)]. Interestingly, the hydride resonance of [Cp*Mo(dppe)$H_4$]$^+$ broadens again at $T <$ 240 K, but does not decoalesce. On the other hand, the $BF_4^-$ salt of this complex was previously reported to retain sharp lines in the $^1$H- and $^{31}$P NMR spectra down to –90 °C, indicating rapid equilibration between the inequivalent H sites.[14] This suggests that the hydride scrambling process is slowed down by hydrogen bonding between [Cp*Mo(dppe)$H_4$]$^+$ and $CF_3COO^-$.

The reaction with 3 equiv. TFA resulted in the observation of a sharp resonance at the chemical shift of the tetrahydride complex (indicating essentially complete disappearance of the starting trihydride reagent) and no significant amount of the dihydride product. The subsequent addition of 2 equiv. $Et_2NH$ to this solution led to the formation of complex [Cp*Mo(dppe)$H_2$($OCOCF_3$)] cleanly and quantitatively. When using 1.5 equiv. TFA, rather sharp resonances for the tetrahydrido complex and the final dihydrido product were initially observed by $^1$H NMR spectroscopic monitoring, but the latter was once again the only observable species remaining at the end of the reaction (ca. 30 minutes at 290 K). When using only 0.5 equiv. TFA, on the other hand, a broad resonance was again initially present, but its chemical shift was closer to that of the starting hydride complex (see Figure 4). This is as expected because the equilibrium mixture of the rapidly exchanging [Cp*Mo(dppe)$H_3$] and [Cp*Mo(dppe)$H_4$]$^+$ complexes is now richer in the former. The formation of the final dihydride product was slower (equilibrium was attained in ca. two hours at 290 K), and ca. 50% of the initial trihydride remained unreacted. As [Cp*Mo(dppe)$H_4$]$^+$ reacted to yield [Cp*Mo(dppe)$H_2$($OCOCF_3$)], the resonance corresponding to [Cp*Mo(dppe)$H_3$] sharpened. The addition of excess TFA to a solution containing [Cp*Mo(dppe)$H_2$-($OCOCF_3$)] did not lead to any reaction, in particular no tetrahydride resonance was observed under these conditions.

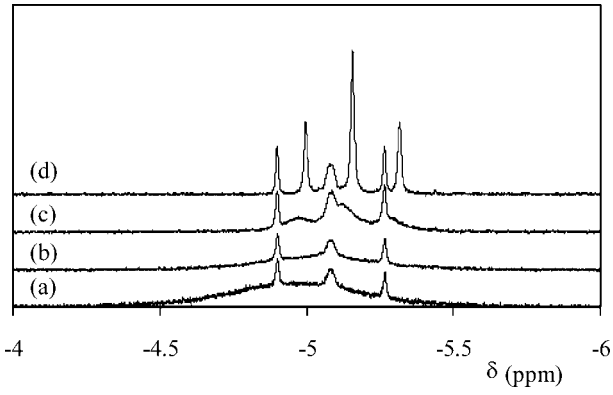

Figure 4. $^1$H NMR (300 MHz) spectroscopic monitoring of the reaction between [Cp*Mo(dppe)$H_3$] and TFA (1:0.5 ratio) in $C_6D_6$ (290 K): (a) recorded immediately; (b) after 7 min; (c) 28 min; (d) 155 min.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

We also investigated the reaction between [Cp*Mo(dppe)$H_3$] and $CF_3COOD$ (1 equiv.) by $^1H$ NMR spectroscopy in $C_6D_5CD_3$. The reaction progressed in an essentially identical manner to that when $CF_3COOH$ was used: immediate observation of the virtual triplet at –5.25 ppm due to the final product and a broad resonance centered at ca. –3.6 ppm. The latter disappears upon brief warming to ca. 40 °C. However, the NMR spectrum shows the formation of $H_2$ and HD in ca. 3:1 ratio. This is not surprising since all hydride positions in the tetrahydride complex are readily scrambled, therefore the elimination of $H_2$ from the [Cp*Mo(dppe)$H_3$D]$^+$ cation will be statistically favored. The molybdenum product resulting from this reaction should therefore contain both H and D. The hydride resonance does not show evidence for the presence of isotopomers, probably because the isotope shift is too small. The formation of deuterated product(s), [Cp*Mo(dppe)-HD($O_2CCF_3$)] and/or [Cp*Mo(dppe)$D_2$($O_2CCF_3$)], however, was confirmed by a $^2H$ NMR-spectroscopic study, which revealed a binomial triplet resonance at –5.9 ppm with $J_{PD}$ = 7.7 Hz.

### Protonation in Other Solvents: NMR-Spectroscopic Study

The solvent has a significant effect on the course of the protonation reaction. The behavior in [$D_8$]thf is similar but not identical to that in aromatic hydrocarbons (see Figure 5); use of a (sub)stoichiometric amount of the acid initially yields a broad hydride resonance (Figure 5, b). Time evolution at these ratios leads to sharpening of the signals as the irreversible $H_2$ elimination and [Cp*Mo(dppe)-$H_2$($O_2CCF_3$)] formation takes place: a similar process to that shown in Figure 4 for the benzene solution. When the sample corresponding to Figure 5 (b) was treated with additional TFA (total 1.5 equiv.), quantitative formation of the dihydride product occurred (Figure 5, c). Use of a large excess (10 equiv.) of $CF_3COOH$ affords a sharp triplet corresponding to the tetrahydrido cation and a strong resonance for the [Cp*Mo(dppe)$H_2$($O_2CCF_3$)] product (Figure 5, d). As in $C_6D_6$ or $C_6D_5CD_3$, a broad resonance is not obtained at this ratio. However, with time, the tetrahydride resonance disappears and the dihydride resonance increases in [$D_8$]thf (Figure 5, e), whereas in the analogous benzene solution decomposition occurs without formation of the dihydride product, as stated earlier.

THF was found to be a suitable solvent in which to probe the nature of the degenerate exchange between [CpMo(dppe)$H_3$] and [Cp*Mo(dppe)$H_4$]$^+$, by repeating the protonation in the presence of $HBF_4$ instead of $CF_3COOH$ (the $BF_4^-$ salt of the tetrahydride product is soluble in THF, but precipitates from toluene or benzene). If the exchange takes place bimolecularly via a symmetrical [Cp*(dppe)-$H_3$Mo···H···Mo$H_3$(dppe)Cp*]$^+$ transition state, the lineshape of the signal will not depend on the nature of the acid. On the other hand, a unimolecular pathway involving the conjugate base of the proton donor should yield a slower exchange rate for the $BF_4^-$ sample, because this is a much weaker base than $CF_3COO^-$. The NMR-spectroscopic

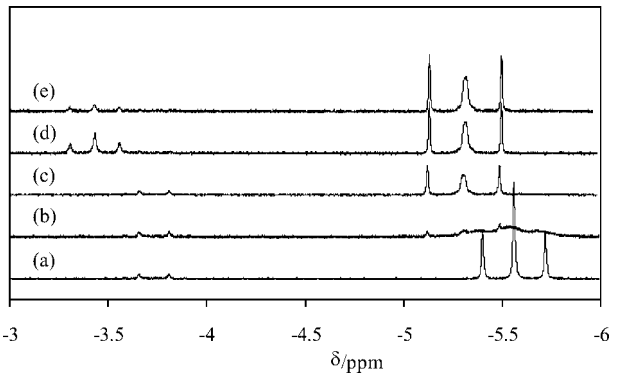

Figure 5. $^1H$ NMR (300 MHz) spectroscopic monitoring of the reaction between [Cp*Mo(dppe)$H_3$] and TFA in [$D_8$]thf (290 K): (a) before the TFA addition; (b) TFA/Mo = 0.5, 8 min; (c) further addition of 1 equiv. to sample (b): TFA/Mo = 1.5, 30 min; (d) TFA/Mo = 10, immediately after the addition; (e) after 13 min from spectrum (d). The doublet resonance at $\delta$ = –3.73 ppm belongs to the [Cp*Mo($\kappa^1$-dppe)$H_5$] contaminant.[14]

study of a 2:1 [Cp*Mo(dppe)$H_3$]/$HBF_4$ mixture provides evidence in favor of the unimolecular pathway. As seen in Figure 6, addition of 0.5 equiv. $HBF_4$ results in a decrease in the [Cp*Mo(dppe)$H_3$] resonance and the appearance of the [Cp*Mo(dppe)$H_4$]$^+$ resonance, plus a weak triplet resonance at –5.65 ppm ($J_{HP}$ = 53.5 Hz), whilst the doublet resonance of the [Cp*Mo($\kappa^1$-dppe)$H_5$] contaminant remains unchanged. The trihydride and tetrahydride complexes give separated sharp resonances, contrary to the same situation in the presence of trifluoroacetate anion in the same solvent (Figure 5, b). This clearly demonstrates that the anion determines the rate of degenerate exchange. This exchange process therefore involves the hydrogen-bonded ion pair [Cp*Mo(dppe)$H_4$]$^+$···$^-O_2CCF_3$ and the dihydrogen-bonded trihydride [Cp*Mo(dppe)$H_3$]···$HO_2CCF_3$, the latter being in further rapid equilibration with free trihydride and TFA. Analogous broadening phenomena for hydride signals as a consequence of dihydrogen bonding and equilibrated proton transfer were noted previously in other cases, although the broadening effect was limited to a few Hz in most cases.[2,23]

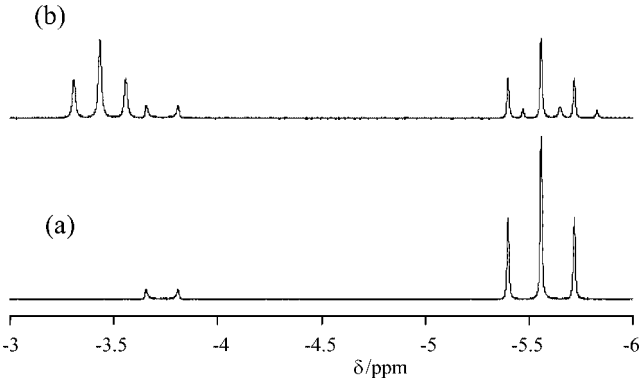

Figure 6. $^1H$ NMR-spectroscopic study of a [Cp*Mo(dppe)$H_3$]/$HBF_4$ mixture in [$D_8$]thf: (a) starting compound; (b) 21 min after the addition of 0.5 equiv. $HBF_4$. The doublet resonance at $\delta$ = –3.73 ppm belongs to the [Cp*Mo($\kappa^1$-dppe)$H_5$] contaminant.[14]

The new triplet resonance at –5.65 ppm in Figure 6 is assigned to complex $[Cp^*Mo(dppe)H_2(THF)]^+$. It is associated with a new $^{31}P\{^1H\}$ resonance at 70.7 ppm. For comparison, the related $[Cp^*Mo(dppe)H_2(MeCN)]^+$ complex, obtained from the protonation of $[Cp^*Mo(dppe)H_3]$ by $HBF_4$ in MeCN,[14] displays a proton resonance at –5.50 ppm ($J_{P1}$ = 51 Hz, $J_{P2}$ = 52 Hz) and a phosphorus resonance at 78.1 ppm. NMR spectroscopic monitoring shows that this resonance grows while the resonance of the tetrahydride product simultaneously decreases. Interesting features to note are (i) this cationic THF adduct is not observed in the protonation experiment with $CF_3COOH$; (ii) the rate of disappearance of the tetrahydride complex is much slower in the presence of the $BF_4^-$ anion than in the presence of the $CF_3COO^-$ anion (cf. Figure 6 with Figure 5); and (iii) conversion to the THF solvent adduct appears to be much slower than the analogous reaction in MeCN, which was reported to lead to vigorous gas evolution and quantitative production of the MeCN complex within 60 minutes.[14]

When using $CH_2Cl_2$ as the solvent, the initially formed tetrahydride complex displayed a sharper resonance, even when as little as 0.5 equiv. of the acid was used. The formation of minor amounts of $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$ was also detected (ca. 10% for the 1 equiv. experiment). In this solvent, however, the interpretation of the data is difficult because of the instability of the starting material, the cationic tetrahydride intermediate, and the product (24% decomposition within one hour at room temperature).

Finally, the results of the protonation with TFA (0.5 and 1 equiv.) in $[D_3]$MeCN at room temperature are shown in Figure 7. In both cases, the immediate formation of $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$ and $[Cp^*Mo(dppe)H_4]^+$ was observed. When using 0.5 equiv., the resonances corresponding to the tetrahydride complex and trihydride residual starting compound are separate and relatively sharp (see Figure 7, a): a similar situation to that seen in $CD_2Cl_2$ using TFA as the proton donor or in $[D_8]$thf using $HBF_4$. This indicates that the degenerate exchange is slow under these conditions contrary to the situations in $[D_8]$thf and $C_6D_6$ using TFA as the proton donor. In turn, this suggests that weak ion pairing occurs, if any, between the tetrahydrido cation and the trifluoroacetate anion in $[D_3]$MeCN. The conversion of the tetrahydride complex to $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$ was relatively fast and quantitative, see parts b–d in Figure 7. As already noted, when the reaction was carried out in THF the final product was the trifluoroacetate compound rather than the solvent adduct $[Cp^*Mo(dppe)H_2(MeCN)]^+$ (previously shown to result from the interaction with $HBF_4$), implying that the ligand exchange shown in Equation (2) (S = THF, MeCN) is completely displaced towards the right.

A first comparison of the behavior of $[Cp^*Mo(dppe)H_4]^+$ in noncoordinating solvents confirms the complex instability, as previously shown for the $BF_4^-$ salt, leading to hydride-free decomposition products.[14] However, in the presence of either coordinating solvents or the $CF_3COO^-$ anion, efficient trapping of the 16-electron product of $H_2$ dissociation, $[Cp^*Mo(dppe)H_2]^+$, is achieved. The coordinating $CF_3COO^-$ anion is an even better trap than THF and MeCN. The nature of the solvent has a dramatic effect on two related features: (i) the ability of the $CF_3COO^-$ anion to attack the cationic complex and yield the neutral dihydride-trifluoroacetate product and (ii) the rate of degenerate exchange between $[Cp^*Mo(dppe)H_3]$ and $[Cp^*Mo(dppe)H_4]^+$. The way in which these two processes are affected by the solvent properties will be addressed in more detail in a later section.

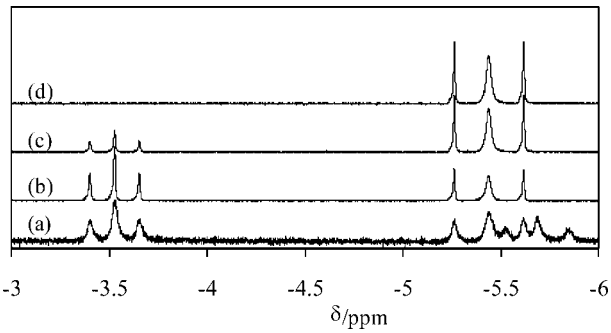

Figure 7. $^1H$ NMR-spectroscopic study of the $[Cp^*Mo(dppe)H_3]$–TFA reaction in $[D_3]$MeCN at room temperature: (a) 0.5 equiv. TFA, recorded immediately; (b) 1 equiv. TFA, recorded immediately; (c) after 9 min from spectrum (b); (d) 40 min after spectrum (b).

## IR Studies

As equilibrium positions and reaction rates are expected to strongly depend on the solvent's ability to influence hydrogen bonding and ion pairing equilibria, we considered that additional useful information could be gathered from infrared investigations, especially at low temperature where ion pairing and hydrogen bonding are favored. The dielectric permittivity, $\varepsilon$, increases at ambient temperature in the order toluene (2.4) < THF (7.8) < $CH_2Cl_2$ (8.3) << MeCN (35.9).[24] It increases substantially upon cooling for some solvents, for example, values of 15.5 for $CH_2Cl_2$[25,26] and 11.9 for THF[27,28] are recorded at 200 K, but not for others, for example, 2.47 at 240 K and 2.71 at 180 K for toluene.[26] On the other hand, these solvents have different coordinating and acid/base properties. THF is quite an efficient hydrogen-bond acceptor ($E_j$ = 1.04), better than MeCN ($E_j$ = 0.75),[29] although the latter is generally a better ligand for transition metals. Benzene and toluene are much weaker bases ($E_j$ = 0.4),[29] whereas $CH_2Cl_2$ tends to behave more like a weak proton donor than as a proton acceptor.[24] We start by presenting the spectral features of the TFA proton donor in the $\nu_{CO}$ region in various solvents, since the TFA/solvent interaction certainly plays an important role in the proton-transfer equilibria involving the hydride complex. The relevant spectra are shown in Figure 8. Two bands at similar frequencies are observed in $CH_2Cl_2$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and toluene (1804 and 1785 $cm^{-1}$ for the former, 1803 and 1788 $cm^{-1}$ for the latter). The higher frequency band is due to the acid monomer, whereas the lower frequency one is typically assigned to the corresponding dimer.[30] Note that the equilibrium is shifted towards the dimer in toluene, as is evident from the different relative intensities. In THF the wide, asymmetric $\nu_{CO}$ band of the acid monomer is greatly redshifted to 1780 $cm^{-1}$ because of the formation of stronger hydrogen bonds to solvent molecules. The shoulder at 1762 $cm^{-1}$ (which becomes a distinct band at 200 K) is assigned to the $CF_3COOH$ dimer. The low-frequency asymmetry of the acid bands in all solvents suggests the presence of higher order TFA associates. Thus THF can form hydrogen bonds with $CF_3COOH$, lowering the activity of the acid, which is one of the reasons for the evolution of $[Cp^*Mo(dppe)H_4]^+CF_3COO^-$ into the final dihydride product in this solvent, as will be shown later.

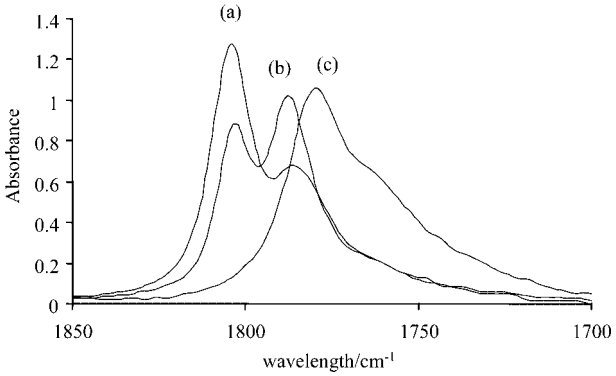

Figure 8. IR spectra of trifluoroacetic acid solutions (0.027 M, pathlength 0.04 mm) in various solvents at 290 K: (a) $CH_2Cl_2$; (b) toluene; (c) THF.

### *In Dichloromethane*

Although the starting material and products are unstable in dichloromethane at room temperature, they do not decompose at low temperatures and this solvent has many advantages for infrared studies (it is not a strong proton acceptor, therefore it does not compete with the basic hydride complexes for hydrogen bonding, and it has good solvent properties for ionic compounds). An IR spectroscopic monitoring at 200 K in the acid $\nu_{CO}$ and conjugated anion $\nu^{as}{}_{OCO}$ vibration region yielded the results shown in Figure 9. At this temperature the dihydride complex $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$, which has a $\nu^{as}{}_{OCO}$ at 1692 $cm^{-1}$ (vide infra), did not form.

A tentative assignment of all observed bands is possible on the basis of previous IR studies into the interaction between $CF_3COOH$ and various bases,[30–32] in combination with the results shown in the previous section. At 200 K the acid self-association equilibrium is shifted to the dimer, exhibiting a strong band at 1780 $cm^{-1}$ with a shoulder at 1800 $cm^{-1}$ (Figure 9, b). The spectrum recorded for the solution with a $MoH_3$/TFA ratio of 1:0.5 (Figure 9, c) shows a prominent band at 1686 $cm^{-1}$ due to the $\nu^{as}{}_{OCO}$ vibration of the trifluoroacetate anion. Its relatively sharp nature and almost negligible high frequency shift relative to

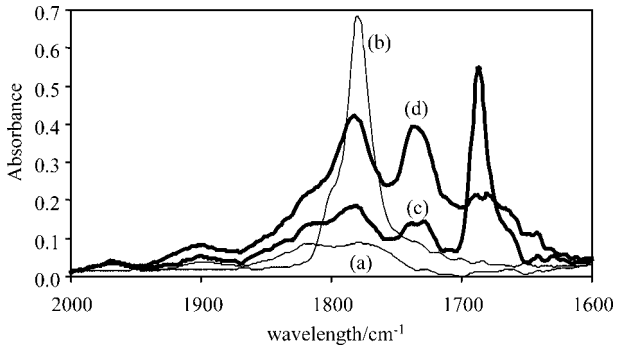

Figure 9. Low-temperature (200 K) IR spectra for the reaction between $[Cp^*Mo(dppe)H_3]$ and TFA in $CH_2Cl_2$: (a) $[Cp^*Mo(dppe)H_3]$ (0.028 M); (b) TFA (0.014 M); (c) mixture of $[Cp^*Mo(dppe)H_3]$ (0.028 M) and TFA (0.014 M); (d) mixture of $[Cp^*Mo(dppe)H_3]$ (0.028 M) and TFA (0.028 M).

the position of the free $CF_3COO^-$ anion[31,32] indicates the formation of either a weakly H-bonded contact ion pair or a solvent-separated ion pair, consistent with the relatively high polarity of $CH_2Cl_2$ at low temperatures and the poor proton-donor ability of the $[Cp^*Mo(dppe)H_4]^+$ cation. In reference to Scheme 1, this means that species **V** is extensively dissociated to **VI** or that the interaction is loose under these solvent and temperature conditions. There is no significant intensity in the region characteristic for the free homoconjugate anion, $[CF_3COO(CF_3COOH)_n]^-$. According to the literature, this species should display a low intensity, broad band with a maximum at 1630–1620 $cm^{-1}$.[33] Given the presence of an excess of the trihydride complex, most of the acid is presumably consumed and little is left to yield the homoconjugate anion. The relative intensity of the 1686 $cm^{-1}$ band indicates that the proton-transfer equilibrium is highly shifted to the tetrahydride product, and the presence of the unreacted trihydride complex is indicated by the shoulder at 1816 $cm^{-1}$ {cf. the starting spectrum of free $[Cp^*Mo(dppe)H_3]$ in Figure 9, a}. There are two additional weak bands in this spectrum. The first one at 1782 $cm^{-1}$ could be assigned to free $CH_3COOH$, but it is also consistent with a H-bonded adduct where the acid acts as a proton donor (a $CF_3COO$–H···B interaction does not significantly perturb the CO normal mode). The second band at 1736 $cm^{-1}$ indicates the presence of a H-bonded adduct where the acid acts as a proton acceptor [the $CF_3C(OH)O$···HA interaction significantly redshifts the CO normal mode].[34,35] Thus, these bands constitute evidence for the presence of a 2:1 H-bonded adduct, $[Cp^*Mo(dppe)H_3]$···$HO_2CCF_3$···$HO_2CCF_3$. The simultaneous presence of a 1:1 adduct, $[Cp^*Mo(dppe)H_3]$···$HO_2CCF_3$, cannot be established because it would also afford a band at ca. 1780 $cm^{-1}$. A general picture of the proton-transfer process can be drawn as shown in Scheme 4.

An increase in the $CF_3COOH/MoH_3$ ratio is expected to shift the hydrogen-bonding equilibrium position towards the 2:1 adduct. At the same time, equilibria involving the anionic species (either hydrogen bonded or free) are expected to shift towards the homoconjugate anion (equilibria

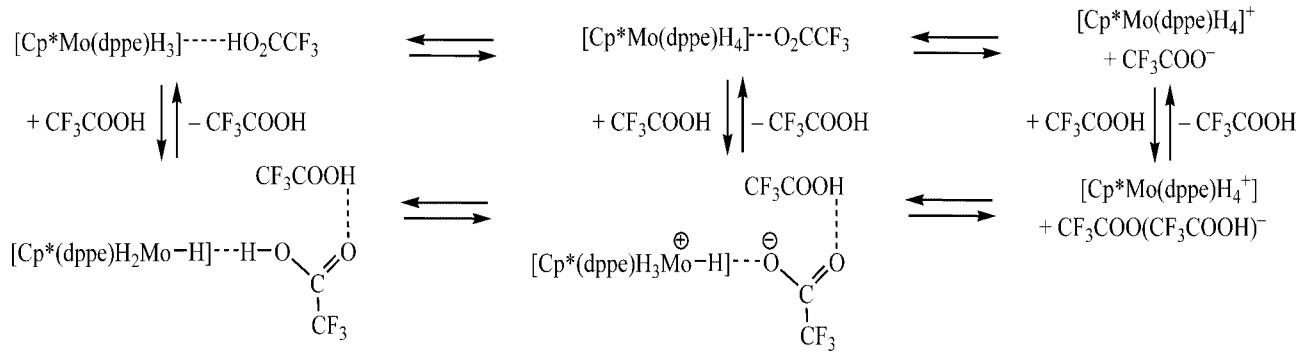

Scheme 4.

drawn vertically in Scheme 4). On the other hand, an increase in the $CF_3COOH/MoH_3$ ratio will not affect the equilibria shown horizontally in Scheme 4. Indeed, upon addition of a second 0.5 equiv. TFA (final $MoH_3$/TFA ratio of 1:1), see Figure 9d, the IR spectrum reveals a significant increase in intensity for the bands assigned to the neutral 2:1 adduct and a dramatic decrease for that assigned to the free anion. The growth of a broad shoulder at lower frequencies signals the formation of anionic aggregates, as expected.

### *In [D8]Toluene*

The low-temperature IR spectral picture in [$D_8$]toluene in the presence of a stoichiometric amount of TFA is similar to that shown in dichloromethane, see Figure 10. The band at 1742 $cm^{-1}$ observed for the 1:1 mixture (Figure 10c) is assigned to the $\nu_{CO}$ of the hydrogen-bonded complex (cf. 1736 $cm^{-1}$ in $CH_2Cl_2$), whereas the bands at 1690 and 1674 $cm^{-1}$ are assigned to the $CF_3COO^-$ anion ($\nu^{as}_{OCO}$, cf. 1686 $cm^{-1}$ in $CH_2Cl_2$). The complex pattern attained for this absorption is possibly related to the presence of different hydrogen-bonded species (hydrogen bonding should be favored more in low-polarity toluene). The anion band did not show a significant increase in intensity at greater $MoH_3$/TFA ratios (1:0.5 or 1:0.2), indicating that the proton-transfer equilibrium is shifted further towards the neutral hydrogen-bonded species in this solvent in comparison with $CH_2Cl_2$. This agrees with the results of the NMR investigation. Upon warming above 270 K, the bands corresponding to the [Cp*Mo(dppe)$H_2(O_2CCF_3)$] product at 1702 and 1690 $cm^{-1}$ quickly grow, while the shoulder at 1674 $cm^{-1}$ disappears. The final spectrum is shown in part d of Figure 10. Monitoring the growth of this band for the 1:1 reaction in $C_6H_6$ at 298 K (see Figure S3 in the Supporting Information) yielded a first-order rate constant of $(1.8 \pm 0.1)\times10^{-3}$ $s^{-1}$. In the presence of a 3–5-fold excess of acid, the broad, low intensity $\nu^{as}_{OCO}$ band of the homoconjugated anion was observed at ca. 1640 $cm^{-1}$. No formation of [Cp*Mo(dppe)$H_2(O_2CCF_3)$] was observed under these conditions, in agreement with the NMR spectroscopic data.

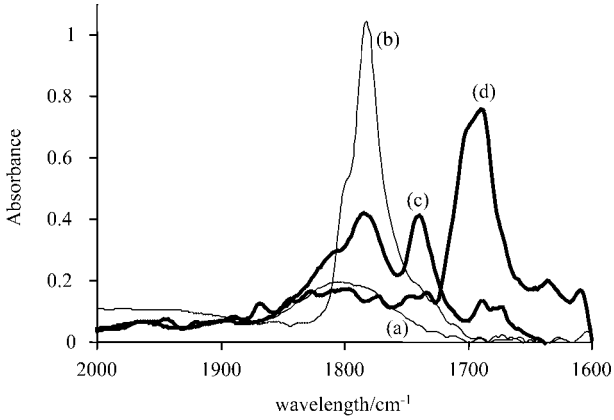

Figure 10. IR spectra for the reaction between [Cp*Mo(dppe)$H_3$] and TFA in [$D_8$]toluene: (a) [Cp*Mo(dppe)$H_3$] (0.027 M) at 200 K; (b) TFA (0.027 M) at 200 K; (c) 1:1 mixture (0.027 M) at 200 K; (d) same mixture as (c), after complete conversion at room temperature.

### *In THF*

At low temperature in this solvent and in the presence of 1 equiv. TFA, the dominant species were the neutral hydrogen-bonded complexes, as indicated by the major bands at 1784 and 1744 $cm^{-1}$ (see Figure 11, c). No significant amounts of the $CF_3COO^-$ ion were seen. This implies that proton transfer occurs to a smaller degree than in toluene. No homoconjugated anion band was observed upon raising the TFA excess to 5 equiv., in contrast to the results in aromatic hydrocarbon solution. Upon warming, the spectral changes were similar to those observed in toluene (see previous section), yielding [Cp*Mo(dppe)$H_2(O_2CCF_3)$], see Figure 11 (d). We also investigated the reverse proton-transfer reaction by mixing together [Cp*Mo(dppe)$H_4$]$^+BF_4^-$ {generated in situ at 200 K from [Cp*Mo(dppe)$H_3$] and $HBF_4$} and $CF_3COONa$ at 200 K in THF. This experiment confirms the reversible nature of the proton-transfer process and the position of equilibrium. The essentially complete disappearance of the trifluoroacetate anion $\nu^{as}_{OCO}$ bands at 1702 and 1690 $cm^{-1}$ and the growth of the $\nu_{CO}$ band at 1752 $cm^{-1}$ corresponding to the H-bonded adduct[36] were observed at 200 K in the presence of either 1

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

or 2 equiv. $[Cp^*Mo(dppe)H_4]^+BF_4^-$. Subsequent warming to 290 K led once again to $[Cp^*Mo(dppe)H_2(OCOCF_3)]$ formation.

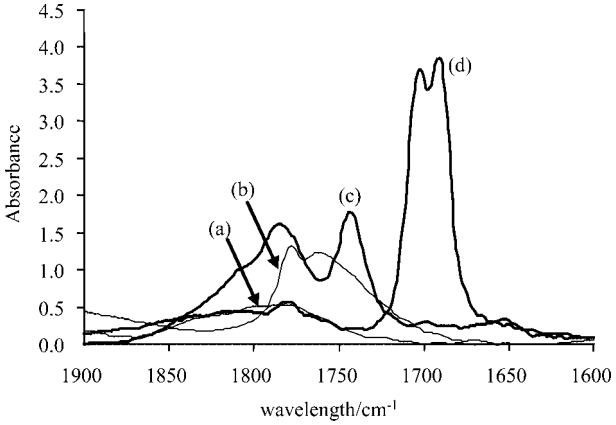

Figure 11. Low-temperature (200 K) IR spectra for the reaction of $[Cp^*Mo(dppe)H_3]$ with TFA in THF: (a) $[Cp^*Mo(dppe)H_3]$ (0.07 M); (b) TFA (0.07 M); (c) 1:1 mixture (0.07 M) at 200 K; (d) same mixture as (c), after complete conversion at room temperature.

Since the NMR-spectroscopic study shows that this conversion also occurs in the presence of excess acid, a kinetics investigation was carried out at 298 K using different TFA/Mo ratios. The reaction was found to be zero order with respect to the acid (see Table 3). Interestingly, the rate constant in THF is identical to that measured in benzene (vide supra) within experimental error. The study was also extended to different temperatures (using a TFA/Mo ratio of 1:1), with the subsequent Eyring analysis (see Supporting Information) giving the following activation parameters: $\Delta H^{\ddagger} = (31.8 \pm 0.5)$ kcal mol$^{-1}$ and $\Delta S^{\ddagger} = (36 \pm 2)$ e.u. The large positive activation entropy suggests that the transition state is dissociative in nature. At low temperatures, the rearrangement becomes too slow; for instance, reaction rate constants of $5.2 \times 10^{-8}$ and $5.8 \times 10^{-15}$ s$^{-1}$ are calculated at 250 and 200 K, respectively.

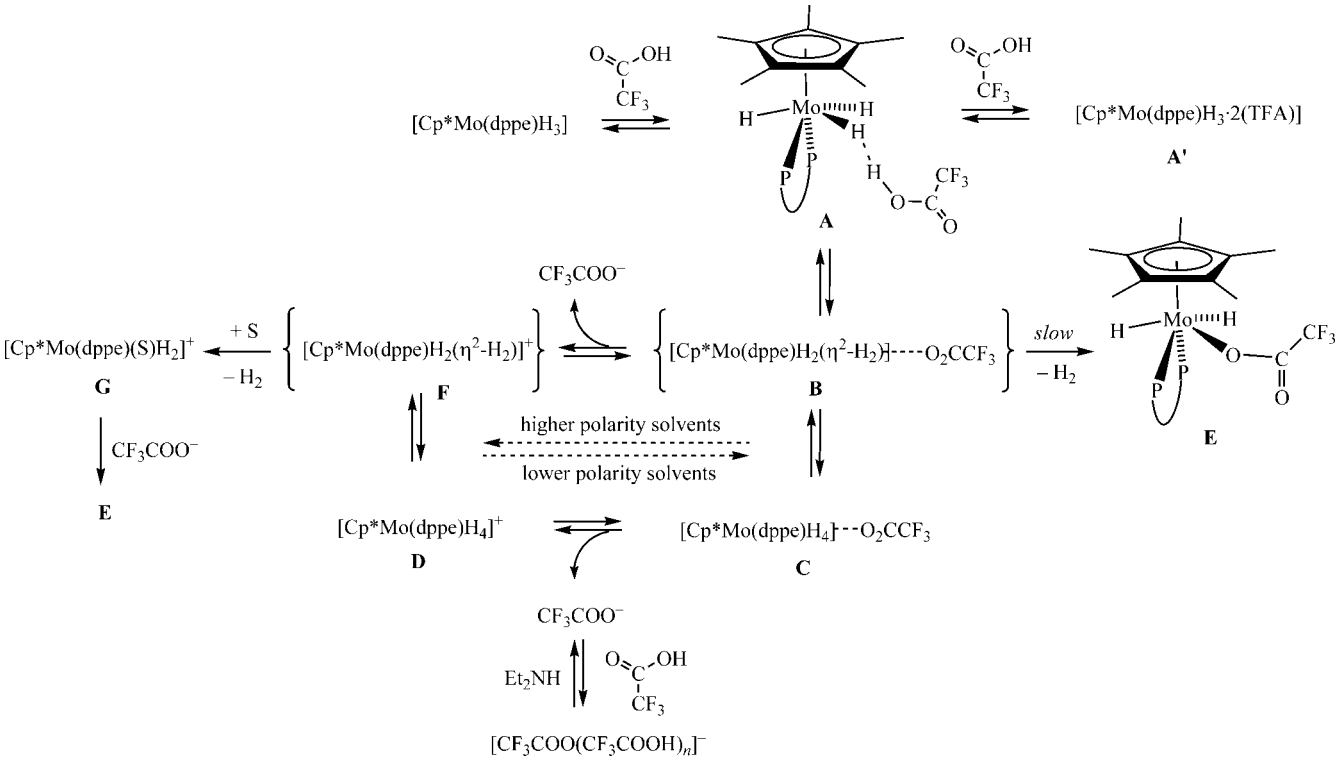
Table 3. Rate constants for the $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$ formation reaction in THF; $[MoH_3] = 0.025$ M.

| $T$ /K | TFA/Mo | $k$ /10$^{-3}$ s$^{-1}$ |
|---|---|---|
| 280 | 1 | $0.064 \pm 0.0015$ |
| 290 | 1 | $0.63 \pm 0.01$ |
| 298 | 0.5 | $1.7 \pm 0.1$ |
| 298 | 1 | $1.8 \pm 0.1$ |
| 298 | 3 | $1.9 \pm 0.1$ |
| 298 | 5 | $1.80 \pm 0.05$ |
| 308 | 1 | $13.7 \pm 0.2$ |

## Discussion

The collective observations that will be detailed now are summarized in Scheme 5.

Proton transfer to $[Cp^*Mo(dppe)H_3]$, via the H-bonded adduct **A** to yield the classical tetrahydride complex, $[Cp^*Mo(dppe)H_4]^+$, **C**/**D**, is the only reaction that may occur at low temperatures. The formation of the 2:1 H-bonded adduct **A′** was also evidenced by low-temperature IR spectroscopy, but one molecule of TFA is sufficient for proton transfer to occur, as also indicated by previous ki-



Scheme 5.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

netics studies.[13] The proton transfer probably proceeds via a nonclassical intermediate (species **B** in Scheme 5), although we have not found any direct experimental evidence to support this proposition. Our recently reported theoretical calculations[13] indicate that the nonclassical complex lies in a very shallow minimum with a low barrier for conversion to the classical tetrahydride product, with the isomerization taking place without counteranion dissociation. The competitive dihydrogen evolution yielding [Cp*Mo(dppe)$H_2$($O_2CCF_3$)] occurs only above 250 K and is possible (in noncoordinating solvents) by the reverse reaction between **D** and $CF_3COO^-$. This forms the ion pair **C** which subsequently isomerizes to the nonclassical species **B**.

The formation of [Cp*Mo(dppe)$H_4$]$^+$ is reversible below 250 K in contrast to the irreversible formation of *trans*-Cp*$MH_2$(dppe)$^+$ (M = Fe, Ru).[6,8] One important difference between these systems is the reversibility of the nonclassical/classical isomerization for [Cp*Mo(dppe)$H_4$]$^+$ (according to the DFT calculations), whereas this process is irreversible for [Cp*M(dppe)$H_2$]$^+$ (M = Fe, Ru). However, proton transfer to the hydride ligand is less thermodynamically favorable for [Cp*Mo(dppe)$H_3$] than for [Cp*Fe(dppe)H]; a significant amount of TFA remained unreacted (in the H-bonded form) for a TFA/Mo ratio of 0.5 in $CH_2Cl_2$ at 200 K (see Figure 9), whereas it was completely consumed under the same solvent, temperature, and stoichiometry conditions in the presence of [Cp*Fe(dppe)H].[5] These results contrast with the higher basicity factor of [Cp*Mo(dppe)$H_3$] ($E_j$ = 1.42 ± 0.02)[13] relative to [Cp*Fe(dppe)H] ($E_j$ = 1.36 ± 0.02).[7] The corresponding proton transfer to [Cp*Ru(dppe)H] ($E_j$ = 1.39), however, is also an equilibrium process.[6] The basicity factor correlates with the strength of the hydrogen bond (formation enthalpy), whereas the protonation equilibrium is determined by the free energy of the proton-transfer process. Obviously, the two parameters do not necessarily correlate quantitatively.

Both the **A** ⇄ **C**/**D** equilibrium position and rate of the irreversible [Cp*Mo(dppe)$H_2$($O_2CCF_3$)] formation depend on the temperature, the solvent, and the $MoH_3$/TFA ratio. Polar solvents (e.g., dichloromethane at low temperatures, acetonitrile) weaken the hydrogen bond in **C** and lead to the formation of a solvent-separated ion pair (species **D** in Scheme 5), which stabilizes the tetrahydrido complex against the $H_2$ loss. The proton-transfer equilibrium is shifted to species **D** in $CH_2Cl_2$ even in the presence of stoichiometric amounts of the acid. Low-polarity solvents (e.g., toluene) provide less stabilization for the charged species, thus the proton-transfer equilibrium is shifted to the left when near stoichiometric amounts of the acid are used. The tetrahydride product exists as an ion pair stabilized by hydrogen bonding to the $CF_3COO^-$ anion (species **C** in Scheme 5), as reflected for instance in a reduced rate of hydride site exchange measured by $^1$H NMR spectroscopy below 240 K. The formation of hydrogen-bonded ion pairs of 1:1 composition was also confirmed for weaker proton donors.[13] At room temperature and above, the competitive irreversible $H_2$ elimination process eventually leads to the quantitative formation of the final product **E**. However, excess acid favors ion-pair dissociation through formation of the thermodynamically more stable homoconjugate anion, thereby stabilizing the proton-transfer product **D** and precluding the $H_2$ evolution.

In solvents with proton-accepting ability (THF, MeCN) the activity of the acid is reduced by hydrogen bonding with solvent molecules, formation of the homoconjugated anion is not observed, and the reaction yields **E** even in the presence of excess acid. The attainment of the same formation rate constant in THF and in benzene and the zero-order dependence on TFA agree with the proposed unimolecular generation of **E** from the same intermediate **B**. Furthermore, the large positive activation entropy is consistent with a dissociative mechanism (i.e., $H_2$ must leave before the trifluoroacetate anion can coordinate), as may be expected from the electronically saturated nature of system **B**. The rate of formation in MeCN was not determined with accuracy, but the NMR spectroscopic data in Figure 7 allow us to estimate a rate constant of ca. $2 \times 10^{-3}$ s$^{-1}$, that is, close to that determined in THF and benzene (see Table 3), if we assume a first-order decay process is in operation. The high polarity of MeCN favors proton transfer and ion-pair dissociation through the stabilization of the charge-separated species, but the instability of [Cp*Mo(dppe)$H_4$]$^+$ leads to its ultimate decomposition by $H_2$ elimination. In this case, the process may be solvent-assisted, leading to the solvent adduct **G**, as previously established by the protonation with $HBF_4$.[14] This phenomenon also occurs in THF as verified by using $HBF_4$. However, the $CF_3COO^-$ anion has a stronger coordinating power than both THF and MeCN, and the ultimate product is once again **E**.

Species **A** and **C**/**D** exhibit a dynamic exchange process, as revealed by a broad $^1$H resonance at room temperature which decoalesces at 270 K in $C_6D_5CD_3$ for the mixture containing 1 equiv. TFA. This results from the fast and direct unimolecular proton transfer involving the dihydrogen-bonded complex **A** and the H-bonded ion pair **C**. It is not possible, unfortunately, to use this information to derive an accurate value for the proton-transfer rate constant because of the complexity of the coupled equilibria and the irreversible transformation to product **E**. Assuming, however, that only species **A** and **C** are present in an approximately equimolar ratio, an activation barrier $\Delta G^{\ddagger}$ of 11.7 kcal mol$^{-1}$ may be estimated for the proton transfer in $C_6D_5CD_3$ at 270 K, from the coalescence temperature and the chemical shift difference.[37] This activation barrier is lower than that of the proton transfer by HFIP in toluene ($\Delta G^{\ddagger}_{293\,K}$ = 15.8 kcal mol$^{-1}$),[13] in agreement with the higher proton-donating ability of TFA. It is also lower than $\Delta G^{\ddagger}_{270\,K}$ for the proton transfer from HFIP to [Cp*Fe(dppe)H] in $CH_2Cl_2$ (14.7 kcal mol$^{-1}$) or from PFTB to [CpRuH(CO)($PCy_3$)] in hexane (16.1 kcal mol$^{-1}$), calculated for 270 K using the published activation parameters.[3,5] IR kinetic data (vide supra) give $\Delta G^{\ddagger}_{270\,K}$ = 22.1 kcal mol$^{-1}$ for the dihydrido-trifluoroacetate formation. The irreversibility of the $H_2$ evolution process renders [Cp*Mo(dppe)$H_2$($O_2CCF_3$)] the sole end product.

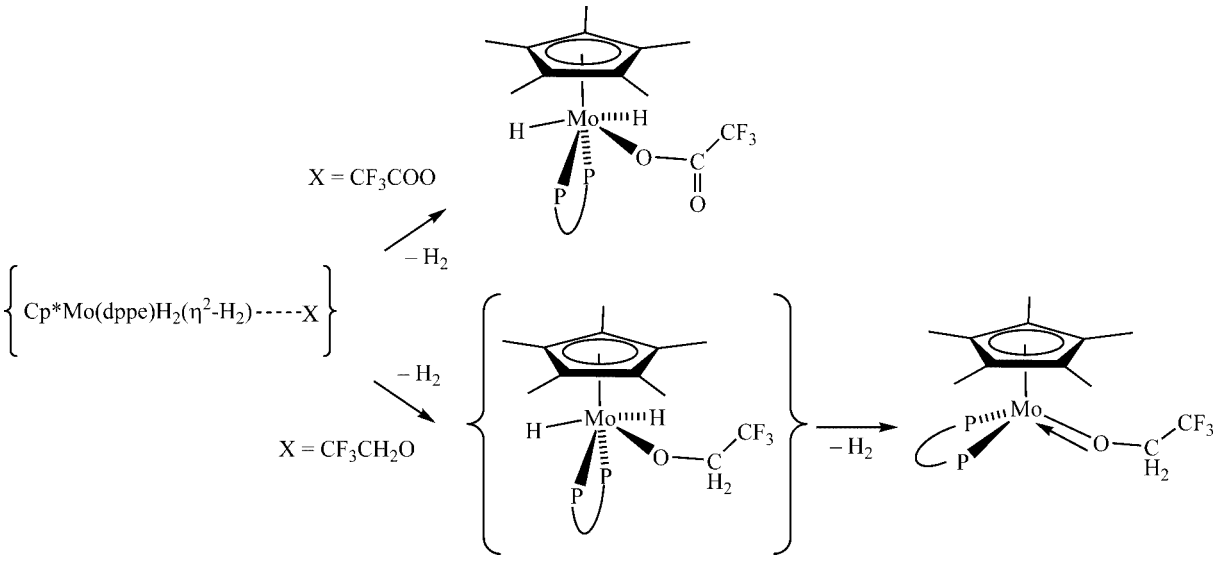

Scheme 6.

A final point of interest is a comparison between the results shown here and those reported previously for the decomposition of the proton-transfer product obtained with TFE, which led to a diamagnetic hydride-free decomposition product, $[Cp^*Mo(dppe)(OCH_2CF_3)(TFE)_x]$ ($x$ = 0 or 1). The mechanism is likely to be the same for both systems, leading to a first $H_2$ elimination assisted by the coordination of the alkoxide ligand (see Scheme 6). Why does $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$ show no tendency to expel a second $H_2$ molecule and form the hypothetical compound $[Cp^*Mo(dppe)(O_2CCF_3)]$, in which the trifluoroacetate ligand would bind in a chelating fashion, whereas $[Cp^*Mo(dppe)H_4]^+(^-OCH_2CF_3)$ leads to a hydride-free product without the observation of even trace amounts of a dihydride intermediate? A possible rationalization is that the stronger π-donating ability of the oxygen lone pairs in the fluorinated alkoxide ligand may assist the elimination of the second $H_2$ molecule by stabilizing the resulting 16-electron half-sandwich $Mo^{II}$ product. By contrast, the lone pair of the trifluoroacetate oxygen donor atom is not sufficiently basic and the second oxygen atom is presumably not capable of assisting the $H_2$ elimination process, because of either thermodynamic or kinetic reasons.

## Conclusions

We explored the protonation of $[Cp^*Mo(dppe)H_3]$ by trifluoroacetic acid in various solvents which display different proton-accepting ability, polarity, and coordinating power toward transition metals: dichloromethane, benzene/toluene, THF, and MeCN. The nature of the solvent and the amount of excess acid determined the nature of the product by delicately controlling the position of the proton transfer and ion pairing equilibria. In agreement with previous investigations, the classical tetrahydrido cation was produced following the initial formation of a dihydrogen-bonded intermediate without the observation of a nonclassical tautomer (dihydrogen complex); it is stable at low temperatures and can exist as solvent-separated or contact ion pair. However, the use of suitable conditions of solvent, temperature, and hydride/acid ratio led to the selective formation of a new product, the dihydrido complex $[Cp^*Mo(dppe)H_2(O_2CCF_3)]$. The trifluoroacetate anion is a sufficiently strong ligand to coordinate to the cationic complex and saturate its coordination sphere after loss of $H_2$, even in the presence of coordinating solvent molecules such as MeCN or THF. However, it remains coordinated in a monodentate fashion and, contrary to the $CF_3CH_2O^-$ anion, is not capable of inducing the elimination of the residual hydride ligands as $H_2$ to form a hydride-free product.

## Experimental Section

**General:** All manipulations were performed under argon by standard Schlenk techniques. All solvents were dried with an appropriate drying agent (Na/benzophenone for benzene, toluene or THF; Na for pentane; $CaH_2$ for $CH_2Cl_2$) and were freshly distilled under argon prior to use. $C_6D_6$, $C_6D_5CD_3$, [$D_8$]thf, $CD_3CN$, and $CD_2Cl_2$ (Euriso-Top) for NMR spectroscopic experiments and $C_6D_5CD_3$ (Aldrich) for IR spectroscopic experiments were degassed by three freeze-pump-thaw cycles, and then purified by vacuum transfer at room temp. $[Cp^*Mo(dppe)H_3]$ was synthesized according to the literature.[14]

### Spectroscopic Studies

**NMR Investigations:** Samples of $[Cp^*Mo(dppe)H_3]$ in each solvent were prepared under argon in 5-mm NMR tubes. The $^1H$- and $^{31}P\{^1H\}$ NMR data were collected with Bruker AMX300 and Bruker AV500 spectrometers, operating at 300.1 or 500.3 MHz and 121.5 or 202.5 MHz, respectively. The temperature was calibrated using a methanol chemical-shift thermometer; the accuracy and stability was ±1 K. All samples were allowed to equilibrate at every temperature for at least 3 min. The spectra were calibrated with the residual solvent resonance ($^1H$) and with external 85% $H_3PO_4$ ($^{31}P$). The conventional inversion-recovery method (180–$\tau$–90) was

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

used to determine the variable-temperature longitudinal relaxation time $T_1$. Standard Bruker software was used for the calculation of the longitudinal relaxation time.

**IR-Spectroscopic Investigations:** The IR measurements were performed with the "Infralum 801" FTIR spectrometer using $CaF_2$ cells of 0.04-cm path length. All IR measurements were carried out by the use of a home-modified cryostat (Carl Zeiss Jena) in the 190–290 K temperature range. The cryostat modification allowed operation under an inert atmosphere and the transfer of the reagents (premixed either at low or room temp.) directly into the cell precooled to the required temperature. The accuracy of the temperature adjustment was ±1 K. This setup was used both for the variable-temperature studies and for the kinetics investigations.

**Synthesis of [Cp*Mo(dppe)H$_2$(O$_2$CCF$_3$)]:** A $CF_3COOH$ solution (9.5 μL, 0.13 mmol) in THF (3 mL) was slowly added to a solution of [Cp*Mo(dppe)$H_3$] (80 mg, 0.13 mmol) in THF (15 mL). The reaction mixture was stirred at room temp. for ca. 1.5 h. The solvent was evaporated, and the resulting solid was recrystallized from pentane. Yield: 75 mg (78%). $^1$H NMR (300.13 MHz, $C_6D_6$, 290 K): $\delta$ = –5.09 (Mo–$H_2$), 1.79 (s, 15 H, Cp*), 3.2–2.5 (m, 4 H, –$CH_2$–$CH_2$–), 7.10–7.77 (m, 20 H, Ph) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$, 290 K): $\delta$ = 76.9 (s) ppm. The $^1$H hydride and the $^{31}$P resonances decoalesce at low temperatures (see Results section). IR (KBr): $\tilde{\nu}$ = 1682 and 1702 (sh) ($\nu^{as}_{OCO}$), 1818 and 1850 (Mo–$H_2$) cm$^{-1}$. $C_{38}H_{41}F_3MoO_2P_2$ (744.6): calcd. C 61.29, H 5.56; found C 61.26, H 5.54. Crystals were grown by slow diffusion of a pentane layer into a saturated solution of the mixture containing [Cp*Mo(dppe)$H_3$] and ca. 1 equiv. of TFA in toluene.

**Kinetics of the [Cp*Mo(dppe)H$_2$(O$_2$CCF$_3$)] Formation:** The reagents were mixed at low temperature (ca. 270 K), and the solution was transferred into the cryostat. The kinetics data were obtained by following the increase of the band at 1692 cm$^{-1}$ corresponding to the [Cp*Mo(dppe)H$_2$(O$_2$CCF$_3$)] complex at the desired temperature. The first-order rates were obtained by plotting $\ln(A_\infty - A_t)$ versus time $t$.

**X-ray Analysis of Compound [Cp*Mo(dppe)H$_2$(O$_2$CCF$_3$)]:** A single crystal was mounted under inert perfluoropolyether on the tip of a glass fiber and cooled in the cryostream of the Oxford-Diffraction XCALIBUR CCD diffractometer. Data were collected using the monochromatic Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073). The structure was solved by direct methods (SIR97)[38] and refined by least-squares procedures on $F^2$ using SHELXL-97.[39] All hydrogen atoms attached to carbon were introduced in the calculation in idealized positions and treated as riding models. The two hydride ligands were located in difference Fourier syntheses, and they were freely refined with isotropic thermal parameters. The molecule was drawn with the help of ORTEP32.[40] Crystal data and refinement parameters are shown in Table 4.

CCDC-632317 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Table of longitudinal relaxation times at different temperatures for the hydride resonance of [Cp*Mo(dppe)H$_2$(O$_2$CCF$_3$)] and figures showing IR spectra of this compound in various solvents, the IR-spectroscopic study of its formation kinetics in toluene, and an Eyring plot of the rate constants in THF.

[21] The starting material contains a minor amount of the [Cp*Mo($\kappa^1$-dppe)$H_5$] contaminant, which is characterized by a doublet resonance at –3.09 ppm in the $^1$H NMR spectrum and by a singlet at 57.2 ppm in the $^{31}P\{^1H\}$ NMR spectrum. This is the typical by-product of the [Cp*Mo(dppe)$H_3$] synthesis[13] and is present in variable amounts in different samples. It is rather difficult to completely remove this impurity, but its presence does not interfere with the observed transformations since it is less basic than the trihydride complex (thus is not consumed when using substoichiometric amounts of TFA), whereas it is transformed into the trihydride complex with $H_2$ evolution by an excess amount of the acid.
[22] These two resonances are sufficiently sharp for detection only on a high-field instrument ($^{31}$P resonance at 202 MHz).

# Synthesis, Characterization and Stability of Spirodiene Complexes of Molybdenum(II): New Route to *ansa*-Molybdenocene and Ring-Functionalized Molybdenocene Compounds

**Jan Honzíček,[a] Filipe A. Almeida Paz,[b] and Carlos C. Romão*[a]**

**Keywords:** Metallocenes / Molybdenum / Spiro compounds / Functionalized cyclopentadienes / X-ray diffraction

The reactions of $[Mo(CO)_2(Cp)(NCCH_3)_2][BF_4]$ (**1**) with spiro[2.4]hepta-4,6-diene and spiro[4.4]nona-1,3-diene give the complexes $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_2\}(CO)_2(Cp)][BF_4]$ (**3**) and $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_4\}(CO)_2(Cp)][BF_4]$ (**4**), respectively. $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_2\}(CO)_2(Cp)][BF_4]$ (**3**) is stable towards ring opening at room temperature, but its formation is accompanied by small amounts of ring-opening products $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)(CO)(Cp)][BF_4]$ (**5**) and $[Mo\{\eta^5\text{-}C_5H_4(CH_2)_2\text{-}\eta^1\text{-}CO\}(CO)(Cp)][BF_4]$ (**6**). With 1,1-dimethylspiro[2.4]hepta-4,6-diene, two isomers with the formula $[Mo\{\eta^4\text{-}C_5H_4CH_2C(CH_3)_2\}(CO)_2(Cp)][BF_4]$ are formed (**7** and **8**). While the *endo*-isomer **7** is stable towards ring opening, the *exo*-isomer **8** slowly rearranges to the ring-opened product $[Mo\{\eta^5\text{-}C_5H_4C(CH_3)_2CH_2\text{-}\eta^1\text{-}CO\}(CO)(Cp)][BF_4]$ (**9**). The reaction of $[Mo(CO)_2(Ind)(NCCH_3)_2][BF_4]$ (**2**) with spiro[4.4]nona-1,3-diene also gives the diene coordinated species $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_4\}(CO)_2(Ind)][BF_4]$ (**11**), which is the first example of a structurally characterized, coordinated, unsubstituted spirodiene. In contrast, reaction of **2** with spiro[2.4]hepta-4,6-diene leads directly to the *ansa*-cyclopentadienyl complex $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)(CO)(Ind)][BF_4]$ (**12**). Reaction of **12** with bromine or iodine leads to the formation of Cp-substituted molybdenocene derivatives $[Mo\{\eta^5\text{-}C_5H_4(CH_2)_2X\}(CO)(Ind)X][BF_4]$ (**13**: X = Br, **14**: X = I). The compounds $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)(CO)(Ind)][BF_4]$ (**12**) and $[MoBr\{\eta^5\text{-}C_5H_4(CH_2)_2Br\}(CO)(Ind)][Br]\cdot 0.5H_2O$ (**13a**) were structurally characterized, and they open the way to new functionalized molybdenocene complexes that have biological applications.

## Introduction

Bent metallocene complexes of the type $[M(Cp)_2X_2]$ (M = Ti, V, Nb, Mo; X = halide) have been investigated for their use in biological applications ever since their antitumor activity was discovered by Köpf and Köpf-Maier.[1] Because of the particular requirements of such applications, which include aqueous solubility and biocompatibility, considerable attention has been given in the last few years to the synthesis of modified and functionalized variants of such complexes. Substitution of halide ligands gives compounds with modified physical and chemical properties. This approach leaves the "$M(Cp)_2$" moiety unchanged, and properly chosen substituents can help in overcoming problems, such as low water solubility[2] or biological incompatibility,[3] that complicate the use of the parent compounds. Furthermore, substitution can protect the "$M(Cp)_2$" moiety during transport into the tumor cells. The active species is then generated in close proximity of or directly in the tumor cell.[4]

However, modification of the Cp rings seems to be a more promising approach towards solving of the abovementioned problems, as shown by the many results obtained in the field of bioorganometallic radiopharmaceuticals.[5] Such a modification could enable the fine tuning of cytostatic properties as was recently shown by the titanocene compounds.[6] Moreover, it allows the introduction of reactive groups that offer an anchor on which to append biologically active molecules capable of directing the final complex to the target receptors or diseased tissues.[7] This is a central issue in chemotherapy, because the treatment then becomes more effective at low doses and the damage to non-targeted and/or healthy tissues is minimized.

In the case of group IV metallocenes, a variety of ring-substituted compounds containing functional groups on one or both cyclopentadienyl rings is known,[8] thus supporting a wider range of in vitro[9] and in vivo biological tests.[10] For group V and VI metals, the quest for suitable synthetic routes is still on-going. Following our long-standing interest in the chemistry of the highly stable molybdenocene fragment, and the fact that the dichloride $[MoCl_2(Cp)_2]$ is currently under comprehensive scrutiny because of its mechanism towards antitumor action,[11] we decided to

explore a new suitable approach towards achieving functionalization of its rings. The introduction of alkyl substituents in one[12] or both rings has been documented.[13]

Compounds with $\eta^5$:$\eta^1$-cyclopentadienidoethyl ligands, which are derived from C–C cleavage of spirodiene compounds by the $Mo^0$ species, are potent precursors for ring-functionalized group VI metallocenes.[14] When Mo atoms are used for this purpose, the resulting *ansa* complex $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)_2]$ enables the introduction of various substituents containing functional groups onto the cyclopentadienyl rings.[15] The resulting products are functionalized equally on both rings. The problem of functionalizing only one of cyclopentadienyl rings could probably be solved by the use of the *ansa* compound $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)(\eta^4\text{-}C_5H_6)(CO)]$[16] that was previously synthesized from $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)(CO)_3]$[17] and cyclopentadiene through a photochemical route. Unfortunately, none of these routes is very practical in the absence of metal vapor synthesis equipment or sound control of the photochemical reactions. In the present work, we propose another approach starting from the readily available $Mo^{II}$ allyl complexes $[Mo(\eta^3\text{-}C_3H_5)(CO)_2(Cp')]$ (Cp′ = Cp, Ind). These compounds, activated by $HBF_4$, as well as their stabilized counterparts $[M(CO)_2(Cp')(NCCH_3)_2][BF_4]$ (**1**: Cp′ = Cp, **2**: Cp′ = Ind) are known as strong dienophiles that could be capable of coordinating spiro[2.4]hepta-4,6-diene and spiro[4.4]nona-1,3-diene to give the $\eta^4$-diene complexes.[18] The question to be answered involved the possibility that such a coordination could activate the spirodiene ligands towards C–C cleavage and aromatization of the cyclopentadienyl ring, even in spite of the fact that the Mo center is in the +2 oxidation state; this issue was probed before, not only for Mo, but also for W, Fe, Co and Ni.[19] The following work gives an affirmative answer to this question and provides a new route to differentially substituted molybdenocene derivatives.

## Results

### Cyclopentadienyl Complexes

$[Mo(CO)_2(Cp)(NCCH_3)_2][BF_4]$ (**1**) reacts with spiro[2.4]-hepta-4,6-diene and spiro[4.4]nona-1,3-diene in $CH_2Cl_2$ at room temperature to give compounds $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_2\}(CO)_2(Cp)][BF_4]$ (**3**) and $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_4\}(CO)_2(Cp)][BF_4]$ (**4**), respectively. While **4** was the only product detected in its reaction mixture, for the reaction leading to **3**, two other ring-opening products were detected in the crude product. The sample collected before recrystallization contained approximately 86% of compound **3**, 7% of $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)(CO)(Cp)][BF_4]$ (**5**) and 7% of $[Mo\{\eta^5\text{-}C_5H_4(CH_2)_2\text{-}\eta^1\text{-}CO\}(CO)(Cp)][BF_4]$ (**6**), as determined by $^1H$ NMR spectroscopy (see Scheme 1).

Both **3** and **4** are stable complexes in solution in the absence of strong light, and they can be recrystallized from $CH_2Cl_2/Et_2O$. This means that compounds **5** and **6** are not formed directly by decomposition of **3** but result from unclear events occurring in the initial reaction mixture. The infrared spectra of compounds **3** and **4** show two CO stretching vibrations each in the typical region for similar cationic compounds with terminal carbonyl groups (**3**: 2019, 1960 $cm^{-1}$; **4**: 2020, 1964 $cm^{-1}$).[19] $^1$NMR and $^{13}C\{^1H\}$ NMR spectra of these compounds are consistent with the $\eta^4$-coordination of the appropriate spirodiene. The resonances for the protons of the diene system are shifted to higher field upon coordination, relative to the resonances for the free ligands. Furthermore, coordination results in nonequivalent methylene groups. In the NMR spectrum of compound **3**, the signals for the protons of both methylene groups are also shifted to higher field. Nevertheless, this shift is much smaller than that recently reported for the iron(0) complex $[Fe\{\eta^4\text{-}C_5H_4(CH_2)_2\}(CO)_3]$[20] (see Table 1). We assign the resonance at higher field to the methylene protons on the external face of the coordinated spiro[2.4]hepta-4,6-diene, in accord with reported literature observations for coordinated cyclopentadienes. In fact, $[M(\eta^4\text{-}5R,5R'\text{-}C_5H_4)L_n]$ complexes, where R, R′ = $CH_2X$, systematically reveal higher field resonances for the $CH_2X$ substituent on the diene face opposite to the metal.[21] This effect is also observed in the very similar complexes $[M\{\eta^4\text{-}C_5(CH_3)_5H\}(CO)_2(Cp)]^+$ (M = Mo, W).[12a]

In compound **4**, only the protons of the methylene groups that are in neighborhood of the *ipso* carbon atom are affected by the coordination. The signals that are shifted to higher field are assigned to the methylene protons on the external face, while the signals at lower field to those on

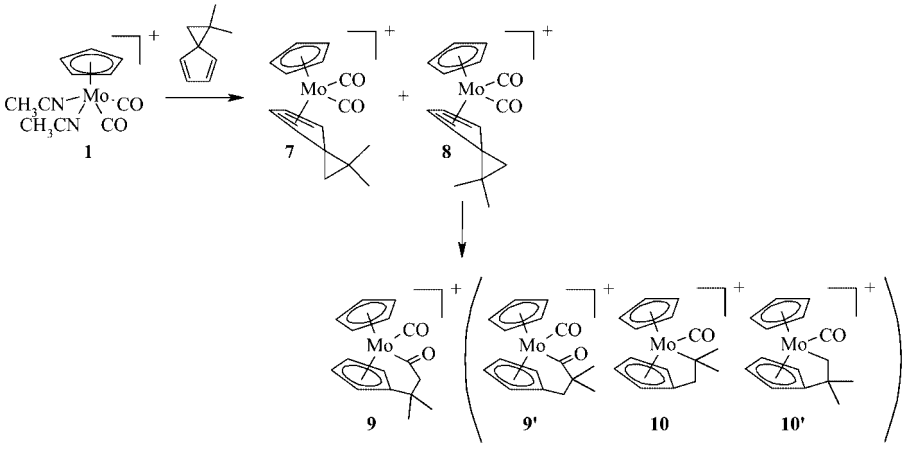
[a] Internal face. [b] External face. [c] Not observed.

the internal face. The connectivity between the methylene groups was established by selective irradiation experiments. $^{13}C\{^1H\}$ NMR spectra of compounds **3** and **4** show that the signals for the diene carbon atoms are shifted to higher field, while the signals for the *ipso* carbon atoms and for the neighboring methylene groups appear at lower field (see Table 1). The methylene carbon atoms on the external face have resonances that are upfield relative to those for the carbon atoms on the internal face.

The ring-opening products **5** and **6** were not possible to isolate and identify separately. They were identified by NMR spectroscopy, performed on the reaction mixture containing **5** and **6** together with **3**, and their identification was based on the diastereotopic protons of the methylene groups. The connectivity between the assigned multiplets of these minor compounds was established by selective irradiation experiments (for appropriate spectra see the Supporting Information). For compound **5**, these resonances were found at $\delta$ = 2.82, 2.62, –0.41 and –0.89 ppm. The last two high field signals were assigned to the methylene group bonded to molybdenum as depicted in Scheme 1. They are in agreement with those reported for similar *ansa* alkyls such as $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)_2]$.[14a] Compound **6** exhibits multiplets in its NMR spectrum at $\delta$ = 3.57–3.37 ppm (10 lines) and $\delta$ = 2.48–2.28 ppm (10 lines). These values are very similar to those reported for the compound that results from the ring opening of $[Fe\{\eta^4\text{-}C_5H_4(CH_2)_2\}(CO)_3]$ to form $[Fe(\eta^5\text{-}C_5H_4CH_2CH_2\text{-}\eta^1\text{-}CO)(CO)_2]$, which has the same kind of metal–acyl ligation proposed for **6**: $\delta$ = 3.40 (t); 2.15 ppm (t).[20] The presence of the acyl ligand could not be unequivocally established by solution IR spectroscopy because of the interference from moisture-derived absorptions and because of the low concentration of the compound. In KBr pellets, the mixture decomposed quickly.

The effect of the presence of substituents on the $sp^3$ carbon atoms of the spirodiene was studied by using 1,1-dimethyl-spiro[2.4]hepta-4,6-diene. This diene reacts with compound **1** in $CH_2Cl_2$ at room temperature (16 h) to give a 1:1:1 mixture of the *endo* **7** and *exo* isomers **8** of $[Mo\{\eta^4\text{-}C_5H_4CH_2C(CH_3)_2\}(CO)_2(Cp)][BF_4]$ and a ring-opened product (Scheme 2). The $^1H$ NMR spectra of **7** and **8** show signals for the protons in the Cp and spirodiene rings with chemical shifts similar to those found for compound **3**. Relative to the uncoordinated ligand, the resonances for the methyl protons of the *exo* isomer (**8**) and the methylene protons of the *endo* isomer (**7**) appear at higher field (**8**: $\delta$ = 0.90 ppm; **7**: $\delta$ = 0.48 ppm), which leads to the structural



Scheme 2. Reaction of compound **1** with 1,1-dimethyl-spiro[2.4]hepta-4,6-diene.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

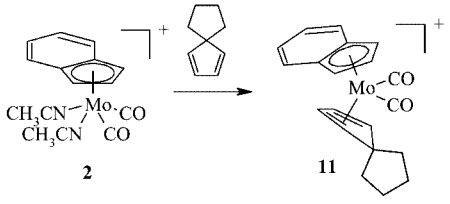
assignment in Scheme 2.[21] The methyl groups of compound **7**, which are on the internal face, are not affected by coordination.

$^1$H NMR measurements of the 1:1:1 mixture in $CD_2Cl_2$, after 12 and 24 h, show exclusive activation of the *exo* isomer **8** towards ring opening (see Scheme 2). In fact, at room temperature, the resonances belonging to **7** remain unaffected, while **8** converts into a new compound, which may have one of the structures **9**, **9′**, **10**, or **10′**, as depicted in Scheme 2. The mixture of compounds **7** and the new compound, which was obtained after stirring for 24 h in $CH_2Cl_2$, is stable at room temperature, and the relative abundance of both components remains unchanged. No evidence for the formation of a second ring-opening product was observed. We were unable to isolate this new compound from the reaction mixture. Therefore, its tentative characterization relies upon the NMR spectroscopic data since solution IR spectroscopy could not conclusively identify an acyl function.

In agreement with the proposed strained *ansa* structure that would be expected from the chemistry of coordinatively activated spirodienes already exemplified by compounds **5** and **6**, the $^1$H NMR spectrum of the new compound shows diastereotopic methylene and methyl groups. The chemical shift for the methylene protons ($\delta$ = 2.22–2.12 ppm) rules out structure **10′**, since the Mo–C$H_2$ signal should appear at a much higher field. Structure **10** is not clearly compatible with the available $^1$H NMR spectroscopic data for related compounds. In fact, the C$H_2$ group at the Cp ring appears at ca. 2.5 ppm in compounds such as [Mo($\eta^5$-$C_5H_4CH_2$-$\eta^1$-$CH_2$)$_2$][15] or in **12** (see below). The more open, alternative acyl-bridged structures present the resonances for $C_5H_4$–$CH_2$ at $\delta > 3$ ppm in well-established compounds such as [Fe($\eta^5$-$C_5H_4CH_2CH_2$-$\eta^1$-CO)(CO)$_2$] (ca. 3.4 ppm)[20] or the related [Mo($\eta^5$-$C_5H_4CH_2CH_2X)_2X_2$] (X = Cl, Br, I, SPh; ca. 3.5 ppm).[15] Such chemical shift values are in agreement with those in compound **6**, which has two methylene resonances at $\delta$ = 2.22–2.12 ppm and $\delta$ = 3.57–3.37 ppm. However, since the new compound does not have any resonances in the $\delta$ = 3.5 ppm region, the formation of structure **9′** is most unlikely. Therefore, the NMR spectroscopic data is most compatible with structure **9**, although no definitive assignment is possible at present. This structure corresponds to the opening of the unhindered face of the spirodiene $C_3$ ring, which is facing the metal.

### Indenyl Compounds

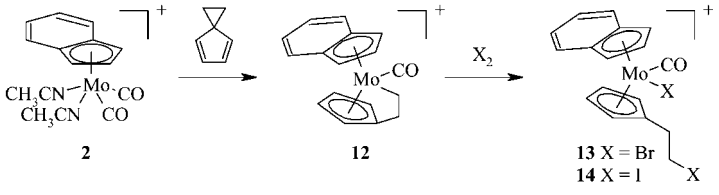
[Mo(CO)$_2$(Ind)(NCCH$_3$)$_2$][BF$_4$] (**2**) was used as a starting material for the synthesis of mixed–ring molybdenocenes containing indenyl rings. Its reaction with spiro[4.4]-nona-1,3-diene gave [Mo{$\eta^4$-$C_5H_4(CH_2)_4$}(CO)$_2$(Ind)][BF$_4$] (**11**) in high yield (Scheme 3). The IR and NMR spectra of **11** are similar to those of its cyclopentadienyl counterpart **4**. In the NMR spectra of compound **11**, the signals for the spiro[4.4]nona-1,3-diene protons and carbon atoms are shifted to a higher field than those of **4**, which is in according with the higher electrophilicity of the Mo$^{II}$ center. The CO stretching vibrations of **11** occur at 2005 and 1950 cm$^{-1}$. These values are lower than those of the cyclopentadienyl counterpart **4**. The structure of **11** was confirmed by X-ray diffraction crystallography, as discussed below.



Scheme 3. Synthesis of compound **11**.

In contrast to the latter reaction, the ring-opened *ansa* compound [Mo($\eta^5$-$C_5H_4CH_2$-$\eta^1$-$CH_2$)(CO)(Ind)][BF$_4$] (**12**) was found to be the sole product of the reaction between **2** and spiro[2.4]hepta-4,6-diene (Scheme 4). The IR spectrum of this compound shows only one band in range for CO vibrations (1991 cm$^{-1}$). The $^1$H NMR spectrum shows four multiplets that are assigned to the substituted cyclopentadienyl ring, seven multiplets for the indenyl ring, and four multiplets for the ethylene bridge. The nonequivalence of the cyclopentadienyl and indenyl protons, which is caused by the low symmetry of complex **12**, is also observed in the $^{13}$C{$^1$H} NMR spectrum. The methylene protons were found to be diastereotopic, which is similar to that found for the cyclopentadienyl analog **5**. The abnormally high-field signal in the $^1$H NMR ($\delta$ = –0.07 ppm and –3.21 ppm) and $^{13}$C{$^1$H} NMR ($\delta$ = –39.3 ppm) spectra provide evidence for the bonding of the methylene group to the metal. The structural assignment of **12** was confirmed by X-ray crystallography, as discussed below.

Compound **12** is a suitable starting material for the preparation of ring-substituted compounds. Indeed, according to Scheme 4, its reactions with halogens give the compounds [Mo{$\eta^5$-$C_5H_4(CH_2)_2X$}(CO)(Ind)X][BF$_4$] (**13**: X = Br, **14**: X = I) in high yield. These compounds provide NMR spectra that are expected for compounds with $\eta^5$-bonded indenyl and substituted $\eta^5$-cyclopentadienyl rings. In compound **13**, the protons of the methylene group bonded to the cyclopentadienyl ring are diastereotopic and



Scheme 4. Reaction of compound **2** with spiro[2.4]hepta-4,6-diene.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thus give rise to a six-line multiplet at $\delta$ = 3.54 ppm. In the case of compound **14**, this effect was observed for both methylene groups. The six-line multiplets are found at $\delta$ = 3.37 and 2.84 ppm. This effect is probably caused by the larger steric hindrance of iodine. The IR spectra of compounds **13** and **14** show CO stretching vibrations at 2055 and 2049 $cm^{-1}$. These values correspond to those found for analogous compounds without substituents on the cyclopentadienyl ring.[12a] These structural assignments are supported by the X-ray diffraction crystal structure obtained for compound **13**, as discussed below.

### Mass Spectrometry

Compounds **3**, **4**, **11**, **12**, **13**, and **14** were characterized by positive-ion ESI mass spectrometry. These compounds have common features and give the peaks for the parent cation $[M - BF_4]^+$ and for $[M - BF_4 - CO]^+$. As expected, the peaks for $[M - BF_4 - 2(CO)]^+$ were observed for compounds containing two carbonyl ligands (**3**, **11**). The mass spectra for the spirodiene compounds **3** and **11** and the *ansa* compound **12** contain peaks that are formed from dehydrogenation. Compounds **3** and **12** exhibit the peaks assigned to $[M - BF_4 - 2(CO) - H_2]^+$ and $[M - BF_4 - CO - H_2]^+$ in their spectra, respectively. The peaks for $[M - BF_4 - 2(CO) - H_2]^+$ and $[M - BF_4 - 2(CO) - 2H_2]^+$, which were found in the case of compound **11**, suggest the possibility of single and double dehydrogenation for the compounds that contain a chain of four methylene groups.

### X-ray Analyses of Compounds 11, 12, and 13a

The structures of $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_4\}(CO)_2(Ind)][BF_4]$ (**11**), $[Mo(\eta^5\text{-}C_5H_4CH_2\text{-}\eta^1\text{-}CH_2)(CO)(Ind)][BF_4]$ (**12**), and $[MoBr\{\eta^5\text{-}C_5H_4(CH_2)_2Br\}(CO)(Ind)][Br]\cdot 0.5H_2O$ (**13a**) were determined in the solid state at 100(2) K (**11**) or at 150(2) K (**12**, **13a**) by single-crystal X-ray diffraction. Figures 1, 2, and 3 depict the crystallographically independent cationic complexes present in the crystal structures of **11**, **12**, and **13a**, respectively. Tables 2, 3, and 4 summarize the most relevant and structurally significant geometrical parameters associated with these structures. The asymmetric units of **12** and **13a** each comprise two crystallographically independent molybdenum complexes (Figures 2 and 3).

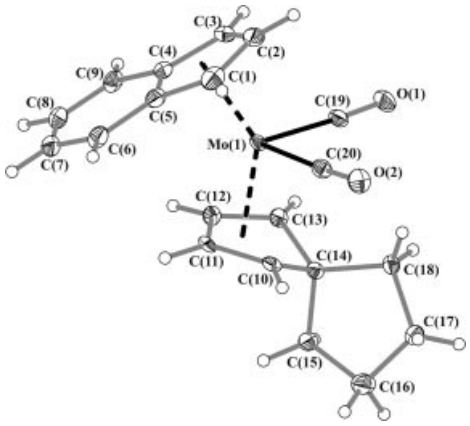


Figure 1. Schematic representation of the cationic complex $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_4\}(CO)_2(Ind)]^+$ present in the crystal structure of **11**; the labeling scheme for all non-hydrogen atoms is shown. Thermal ellipsoids are drawn at the 30% probability level, and hydrogen atoms are represented as small spheres with arbitrary radii. Mo–C bonds to the $\eta^5$-indenyl and $\eta^4\text{-}C_5H_4(CH_2)_4$ organic ligands are shown as black-filled dashed bonds to the corresponding centers of gravity ($C_{g,Ind}$ and $C_{g,diene}$, respectively).

The Mo–C bonds observed for the indenyl ligands [found in the ranges 2.301(5)–2.413(4) Å, 2.254(4)–2.460(3) Å, and 2.264(3)–2.454(3) Å for structures **11**, **12**, and **13a**, respectively] are well within the range found for similar structures (38 entries in the CSD, with Mo···C interatomic distances in the range 2.24–2.50 Å; median 2.31 Å).[22] The significant spread of the interatomic Mo···C distances (magnitude of 0.26 Å for the expected range) is typical for $\eta^5$-Ind coordination. Likewise, the distances to the center of gravity, Mo···$C_{g,Ind}$, are in perfect agreement with known values for $\eta^5$-hapticity (38 entries; 1.95–2.19 Å with a median of

2.03 Å). The values of the fold angle $\psi$ (3.79° for **11**, 4.41° and 4.63° for **12**, and 5.66° and 6.17° for **13a**) are also in line with this coordination mode (typically in the range 0.25–9.63° with a median of 4.40°).[23]

To the best of our knowledge, complex **11** represents the first reported crystal structure of a complex with an unsubstituted spirocyclic cyclopentadiene group. Spiro[4.4]nona-1,3-diene is coordinated in a typical $\eta^4$-coordination fashion (Figure 1), with all Mo···C distances in the range 2.276(4)–2.448(4) Å (Table 2). The corresponding four carbon atoms [C(10) to C(13)] lie almost on the same plane (maximum deviation 0.004(5) Å). This plane is perpendicular to the metal–diene centroid vector [{Mo(1)–$C_{g,diene}$}–$P_{diene}$ = 89.8(3)°; $P_{diene}$ is the diene plane]. The C–C bond lengths of the diene system [C(10)–C(11) = 1.402(7) Å; C(11)–C(12) = 1.424(6) Å; C(12)–C(13) = 1.396(7) Å] correspond to a butadiene fragment. The distance between the centroid of the diene system and molybdenum [$C_{g,diene}$–Mo(1)] is 2.062(5) Å. The spiro carbon atom [C(14)] is found to lie 0.496(4) Å out of the diene plane. The angle

between the diene plane and the plane defined by atoms C10, C13 and C14 [29.3(4)°] is smaller than that previously reported for the spirocyclic isodicyclopentadiene complex of iron(0) [36.2(3)°].[24]

The $\eta^4$-bonded spiro[4.4]nona-1,3-diene ligand is found in the less common (*exo*) conformation. So far, nine other structures (from 35 entries available in the CSD) that present the "M(Cp′)($\eta^4$-diene)LL′" (Cp′ = Cp, Cp*, Ind; M = transition metal) moiety display a similar conformation.[22]

By taking into consideration the centers of gravity of the carbon atoms connected to the molybdenum atom in **11** ($C_{g,Ind}$ and $C_{g,diene}$ for the $\eta^5$-indenyl and $\eta^4$-spiro[4.4]nona-1,3-diene molecules, respectively), we note that the Mo coordination resembles a highly distorted tetrahedron (Figure 1) in which the tetrahedral angles are significantly distorted from the ideal values and range from 84.96(18)° to 137.03(5)° (Table 2). The large angle is subtended between the centers of gravity of the C1–C5 and C10–C13 rings. The two Mo–C≡O bonds form a rather small tetrahedral angle of 84.96(18)°.

A peculiar feature of the structures of both **12** and **13a** is the presence of two crystallographically independent cationic complexes composing the asymmetric unit. As depicted in Figures 2 and 3, the two single complexes belonging to each structure are almost mirror images of each other, with only subtle differences. The slightly distinct bond lengths and angles for each pair of identical complexes are, presumably, a consequence of distinct interactions arising from the crystal packing. When viewed from above (schematic representations on the sides of Figures 2 and 3), the spatial distribution of the aromatic five-membered rings (substituted Cp versus indenyl) is not exactly identical for each pair: while in the one complex the rings are almost eclipsed (dihedral angles of about 3.9° and 1.7° for **12** and **13a**, respectively), in the other complex the substituted cyclopentadienyl ring is slightly rotated towards a staggered conformation (dihedral angles of about 14.3° and 7.5° for **12** and **13a**, respectively).

On the other hand, differences within each pair of identical complexes also arise from the intrinsic conformational flexibility associated with the aliphatic chains. This feature is particularly evident for structure **13a**, in which the two pendant arms of the substituted $\eta^5$-$C_5H_4$ rings have markedly distinct conformations and the angles between the planes containing the two aromatic rings are statistically distinct (ca. 42.0° and 44.1° for the complexes on the left and right, respectively; see Figure 3).

The two substituted cyclopentadienyl ligands of structures **12** and **13a** interact in different manners with the molybdenum centers, basically as a result of their distinct pendant arms. However, both are connected to the metallic center through the cyclopentadienyl ring, which exhibits a typical $\eta^5$-coordination fashion. The Mo···C distances for **12** and **13a** are in the ranges 2.284(4)–2.303(4) Å and 2.283(3)–2.379(3) Å, respectively, (Tables 3 and 4), which is in accord with those found from a systematic search in the CSD[22] (1628 entries for $\eta^5$-Cp: Mo–C bonds in the range 2.12–2.65 Å with median of 2.33 Å). The cyclopentadienidoethyl ($C_5H_4$–$CH_2$–$CH_2$) ligand is connected to the metallic center in **12** through the $\eta^5$-$C_5H_4$ ring and through the terminal $\eta^1$-$CH_2$ to form a *pseudo*-five-membered chelate ring (Figure 2) with an average bite angle of about 91.7° (Table 3). This value is in good agreement with those reported for the only other two related structures that contain this organic moiety found in the literature (average bite angle of 91.3°).[25] The (2-bromoethyl)cyclopentadienide ($C_5H_4$–$CH_2$–$CH_2$–Br) ligand in **13a** is exclusively bound to the molybdenum center through the $\eta^5$-$C_5H_4$ aromatic ring. A literature search reveals only one other structure that has a ligand of the type $C_5H_4$–$CH_2$–$CH_2$–X (where "X" is a halogen) bound to molybdenum: [Mo($\eta^5$-$C_5H_4CH_2CH_2I)_2$-$I_2$].[25a]

Interestingly, each crystallographically independent molybdenum center in **12** and **13a** can also be envisaged as being coordinated to four distinct moieties, which renders it as a chiral crystallographic center: in Figure 2 (structure **12**), the depicted complexes have *R* and *S* configurations (left and right, respectively), while in Figure 3 (structure **13a**), the configurations are instead *S* and *R* (left and right, respectively). It is also important to emphasize that these two crystal structures are not ideal crystal racemates, because the two geometrical isomers are not exact mirror images as previously described. Relative to **11**, the tetrahedral coordination geometries of the molybdenum centers in **12** and **13a** are significantly more distorted; while for **12**, the tetrahedral bond lengths and angles are within the ranges 1.944(1)–2.273(4) Å and 88.51(14)–145.46(2)°, respectively, for **13a**, the values are instead in the ranges 1.985(1)–2.6147(4) Å and 84.59(11)–136.79(2)°. Noteworthy is the fact that the larger tetrahedral angles for **13a** (correspond-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

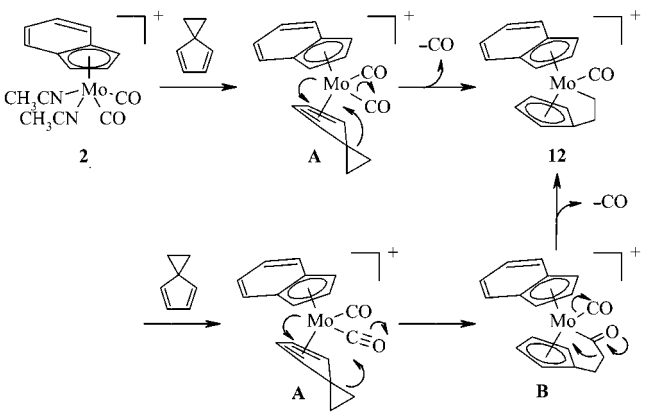
ing to the angle between the two centers of gravity of the organic moieties) are comparable to those of **11**; on the other hand, the angles that are >145° for structure **12** (see Table 3) essentially arise as a result of the geometrical constraints imposed by the five-membered chelate rings of the $\eta^5$:$\eta^1$-cyclopentadienidoethyl ligand.

The crystal packing arrangements of **12** and **13a** are essentially mediated by a considerable number of weak C–H···(O,F,Br) hydrogen bonds (not shown). In structure **13a**, and similarly to that in **11**, π–π interactions between $\eta^5$-indenyl organic ligands that belong to neighboring complexes also occur, and the water molecule of crystallization present in the crystal structure is further engaged in two strong and rather liner O–H···Br hydrogen-bonding interactions with two neighboring bromide anions (not shown): O(1 W)–H(1A)···Br(6) with $d_{D\cdots A}$ = 3.292(3) Å and ∠(DHA) = 170(3)°; O(1 W)–H(1B)···Br(5) with $d_{D\cdots A}$ = 3.268(3) Å and ∠(DHA) = 169(4)°.

## Discussion

Earlier reports on the reactivity of $Mo^0$ compounds towards spirodienes include both very reactive Mo atoms[14a] and $Mo(CO)_3(NCCH_3)_3$.[17] In both cases, the only products observed result from the opening of the cycloalkane ring and concomitant formation of one $\eta^5$-$C_5H_4$–Mo and one $\eta^1$-C–Mo bond. Similar reactivity was observed for hexamethylcyclopentadiene $C_5(CH_3)_6$, which reacts with molybdenum metal in the gas phase to give $Mo(CH_3)_2(Cp^*)_2$.[26] This formal C–C oxidative addition reaction is supported by the aromatization of the $C_5$ ring.

In the present case, the cationic $Mo^{II}$ compounds **1** and **2** are more discriminate in their reactions towards the opening of coordinated spirodienes. The less-strained spiro[4.4]-nona-1,3-diene does not undergo ring opening upon coordination to $[Mo(CO)_2(Cp')]^+$ (Cp′ = Cp, Ind), and the spirodiene complexes **4** and **11** are formed in good yield. These species are stable, and no signs of ring opening were observed. The breaking of the C–C bond takes effect only in the case of the more-strained cyclopropane ring of spiro[2.4]hepta-4,6-diene coordinated to both $[Mo(CO)_2(Cp')]^+$ fragments, but under different circumstances. Reaction of **1** with spiro[2.4]hepta-4,6-diene gives the $\eta^4$-diene compound **3** and the *ansa* compounds **5** and **6**. The last two compounds were obtained in a 1:1 molar ratio and result from ring opening of the $C_3$ ring. Each one represents a type of ring-opening product already described in the literature. In **5**, one CO group is lost and a new C–Mo bond is formed, while in **6**, the broken ring binds to a coordinated CO group instead, which results in an acyl complex. However, **5** and **6** are not formed directly from **3**. In fact, in $CH_2Cl_2$ solution and under normal laboratory light, **3** remains unchanged for at least 24 h, which is longer than the reaction time for the formation of **3**, **5**, and **6** from **1** and the spirodiene. Irradiation of a clean solution of **3** does not lead to **5**, **6**, or any tractable product. Therefore, the ring opening reaction leading to **5** and **6** takes place through pathways that are not yet clear. In contrast, the indenyl compound **2** does not form a stable or observable diene complex with spiro[2.4]hepta-4,6-diene and gives the *ansa* compound **12** selectively. Our interpretation of the above findings is depicted in Scheme 5.



Scheme 5. Proposed pathways to compound **12** (intermediates **A** and **B** were not observed).

In both cases, a diene species should be obtained by substitution of the labile $CH_3CN$ ligands. The dienophilic character of the fragment $[Mo(CO)_2(Cp')]^+$ supports this reasoning. However, once formed, such diene complexes may have a different reactivity, which depends on the Cp′ ring present. In the case where Cp′ = Cp, complex **3** remains stable. In the case where Cp′ = Ind, the putative intermediate **A** (not observed) is expected to be much more labile towards CO loss than **3**. This is in line with the reported higher lability of $[Mo(\eta^4\text{-}C_5H_6)(CO)_2(Ind)]^+$ towards CO loss and formation of $[Mo(CO)(Cp)H(Ind)]^+$ relative to its Cp counterpart.[12a] Therefore, when intermediate **A** loses CO, the facing C–C bond of the $C_3$ ring adds across to form **12**. The alternative hypothesis that **A** undergoes C–C bond addition to CO to form **B** (not observed), which then looses CO and undergoes CO deinsertion from the acyl to lead to **12** also needs to be considered.[27] These insertion/deinsertion reactions are usually slow at the $Cp_2Mo$ fragment, but they might be favored by the indenyl over the cyclopentadienyl counterpart.

It is interesting to also note the comparison between the reactivity of spiro[2.4]hepta-4,6-diene and 1,1-dimethylspiro[2.4]hepta-4,6-diene towards the fragment $[Mo(CO)_2(Cp)]^+$. The effects of such substituents have been investigated both in coordination-assisted ring opening[28] and in the reduction of the free spiro[2.4]hepta-4,6-dienes.[29] Both substituted and unsubstituted spiro[2.4]hepta-4,6-dienes form $\eta^4$ complexes with $[Mo(CO)_2(Cp)]^+$, namely **3**, **7** and **8**. However, while **3** and **7** are stable towards subsequent ring opening, **8** slowly rearranges to a new compound. Although we have not yet been able to identify the structure of this compound, the fact that **8** reacts must mean that the substituted spirodiene is more reactive than its unsubstituted counterpart. In addition, its coordination mode also determines its reactivity, as **7** does not evolve into any ring-opening product. Since **8** has the less-hindered C–C bond

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

facing the metal, steric factors would favor the formation of **9** (or **10′** for that matter), as is most likely according to the NMR spectroscopic data available. With this view, **10′** would also have been a favorable outcome, but it was not observed. This stereochemical line of reasoning was first encountered for the reaction of 1,1-dimethyl-spiro[2.4]-hepta-4,6-diene[28] and 1-phenyl-spiro[2.4]hepta-4,6-diene[30] with $[Mo(CO)_3(NCCH_3)_3]$, which always led to the opening of the unsubstituted $C_{ipso}$–$CH_2$ bond of the $C_3$ ring. This was interpreted as the result of the preferred coordination of the substituted spirodienes having the substituents on the face opposite to the $Mo(CO)_3$ fragment, as found in **8**.[28] However, the same report reveals that for $Fe_2(CO)_9$ no such clear regioselectivity was observed, which implies that electronic factors may overrule steric considerations, as observed in the chemistry of free spirodienes. Moreover, this stereochemical argument cannot explain the selectivity that prevents the formation of **10′**. Further experimental studies supported by DFT calculations, aiming at the full characterization of the product **9** (or **10**), and the study of the activation of 1,1-dimethyl-spiro[2.4]hepta-4,6-diene by the more reactive $[Mo(CO)_2(Ind)]^+$ fragment are currently underway in our laboratories to try to understand these mechanistic details.

Regardless of the mechanistic questions, the results described mark an important step in our development of ring-functionalized molybdenocene complexes. The transformation of **12** into **13** and **14** follows the pattern previously shown by the groups of Green[14a] and Royo.[14b] The pendant bromo- and iodoalkyl substituents allow the introduction of a wide variety of functions and of bioactive molecules, as ample literature precedent has already shown. A related manipulation starting from **9** (or any of its congeners in Scheme 2) can be envisaged, thus extending the range of compounds to the bis(cyclopentadienyl)molybdenum fragment.

## Conclusions and Outlook

Spiro[2,4]hepta-4,6-dienes and spiro[2,4]nona-4,6-diene coordinate readily, to form the products in high yields, to the $[Mo(CO)_2(Cp')]^+$ fragment (Cp′ = Cp, Ind). For the Cp derivatives, ring opening only takes place with the 1,1-dimethyl-spiro[2,4]hepta-4,6-diene. In contrast, the indenyl containing fragment induces a high-yield ring opening of the unsubstituted spiro[2,4]hepta-4,6-diene, but not of spiro[2,4]nona-4,6-diene, to produce the *ansa* compound **12** from which haloalkyl-functionalized fragments are introduced onto a molybdenocene structural framework, as in compounds **13** and **14**. These are among the few examples of ring-functionalized molybdenocene derivatives capable of being manipulated for conjugation with bioactive molecules for biological and medical applications and are the first to contain differentially substituted rings. The preparation of such conjugates is presently underway and is directed towards their use as antitumor drugs.

## Experimental Section

**Methods and Materials:** All operations were performed under nitrogen by using conventional Schlenk-line techniques. The solvents were purified and dried by standard methods.[31] Spiro[2.4]hepta-4,6-diene,[14b] spiro[4.4]nona-1,3-diene,[32] 1,1-dimethyl-spiro[2.4]-hepta-4,6-diene,[33] $[Mo(CO)_2(Cp)(NCCH_3)_2][BF_4]$ (**1**),[34] and $[Mo(CO)_2(Ind)(NCCH_3)_2][BF_4]$ (**2**)[12a] were prepared according to literature procedures. Bromine and iodine (Aldrich) were used as obtained without further purification.

**Measurements:** Positive-ion electrospray ionization (ESI) mass spectra were recorded with API-ION TRAP (PO 03 MS). Samples were measured in $CH_2Cl_2$ solution. The molybdenum-containing ions had a clearly visible metal isotope pattern, which arises from the distribution: $^{92}$Mo 14.84%, $^{94}$Mo 9.25%, $^{95}$Mo 15.92%, $^{96}$Mo 16.68%, $^{97}$Mo 9.55%, $^{98}$Mo 24.13%, $^{100}$Mo 9.63%.[35] Spectra obtained were computer simulated (WSearch32 2005). Mass peaks listed refer to fragments with the isotopes $^1$H, $^{12}$C, $^{16}$O, $^{79}$Br, $^{98}$Mo, and $^{127}$I. $^1$H and $^{13}$C{$^1$H} NMR spectra were recorded in solutions at room temperature with Bruker AMX-300 spectrometer. $CDCl_3$, $CD_2Cl_2$, and [D$_6$]acetone were used as obtained (Cambridge Isotope Laboratories) without further purification. Chemical shifts are given in ppm relative to tms. IR spectra were recorded in the 4000–440 cm$^{-1}$ region (step 2 cm$^{-1}$) on a Mattson 7000 FT-IR spectrometer with KBr pellets. Spectra for compounds **3** and **4** were measured in $CH_2Cl_2$ solution with ZnS cuvettes.

**Synthesis of $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_2\}(CO)_2(Cp)][BF_4]$ (3):** A solution of **1** (0.20 g, 0.52 mmol) in $CH_2Cl_2$ (25 mL) was treated with excess spiro[2.4]hepta-4,6-diene (0.14 g, 1.52 mmol). After stirring the reaction mixture for 16 h, it was concentrated in vacuo to ca. 3 mL. By adding $Et_2O$, a yellow powder precipitated (**3**). The crude product was recrystallized from $CH_2Cl_2/Et_2O$ and then from $CHCl_3/Et_2O$. Yield: 0.11 g (0.28 mmol, 54%). Positive-ion MS: *m*/*z* (%) = 311 $[M - BF_4]^+$, 283 $[M - BF_4 - CO]^+$, 255 $[M - BF_4 - 2(CO)]^+$, 253 (100) $[M - BF_4 - 2(CO) - H_2]^+$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 6.37 (t, 2 H, $C_5H_4$), 5.81 (s, 5 H, $C_5H_5$), 4.80 (t, 2 H, $C_5H_4$), 1.35 (t, $^3J_{H,H}$ = 9 Hz, 2 H, $CH_2$), 0.68 (t, $^3J_{H,H}$ = 9 Hz, 2 H, $CH_2$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = 225.1 (2 C, *C*O), 96.8 (2 C, $C_5H_4$), 94.3 (5 C, $C_5H_5$), 88.7 (2 C, $C_5H_4$), 28.6, 14.3 (2 C, $CH_2$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2019 (s) [($\nu_a$(CO)], 1960 (s) [$\nu_s$(CO)] cm$^{-1}$.

**Synthesis of $[Mo\{\eta^4\text{-}C_5H_4(CH_2)_4\}(CO)_2(Cp)][BF_4]$ (4):** The reaction was carried out as that described for compound **3**, but with spiro[4.4]nona-1,3-diene (0.18 g, 1.50 mmol). Recrystallization of the crude product was carried out with $CH_2Cl_2/Et_2O$. Yield: 0.19 g (0.45 mmol, 86%). Positive-ion MS: *m*/*z* (%) = 339 (100) $[M - BF_4]^+$, 311 $[M - BF_4 - CO]^+$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 6.13 (t, 2 H, $C_5H_4$), 5.80 (s, 5 H, $C_5H_5$), 5.09 (t, 2 H, $C_5H_4$), 2.09 (t, $^3J_{H,H}$ = 7 Hz, 2 H, $CH_2$), 1.70 (quint, 2 H, $CH_2$), 1.60 (quint, 2 H, $CH_2$), 1.31 (t, $^3J_{H,H}$ = 7 Hz, 2 H, $CH_2$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = 227.3 (2 C, *C*O), 96.4 (2 C, $C_5H_4$), 94.5 (5 C, $C_5H_5$), 85.7 (2 C, $C_5H_4$), 72.4 ($C_{ipso}$, $C_5H_4$) 52.3, 37.8, 25.3, 25.0 (4 C, $CH_2$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2020 (s) [$\nu_a$(CO)], 1964 (s) [$\nu_s$(CO)] cm$^{-1}$.

**Reaction of $[Mo(CO)_2(Cp)(NCCH_3)_2][BF_4]$ (1) with 1,1-Dimethyl-spiro[2.4]hepta-4,6-diene:** A solution of **1** (0.20 g, 0.52 mmol) in $CH_2Cl_2$ (25 mL) was treated with excess 1,1-dimethyl-spiro[2.4]-hepta-4,6-diene (0.18 g, 1.50 mmol). After stirring the reaction mixture for 16 h, it was concentrated in vacuo to ca. 3 mL. By adding $Et_2O$, 0.14 g of an orange powder precipitated. The NMR spectrum of this product measured immediately after dissolving the product in $CD_2Cl_2$ shows a 1:1:1 mixture of $[Mo\{endo\text{-}\eta^4\text{-}C_5H_4CH_2C(CH_3)_2\}(CO)_2(Cp)][BF_4]$ (**7**), $[Mo\{exo\text{-}\eta^4\text{-}C_5H_4CH_2C(CH_3)_2\}(CO)_2(Cp)][BF_4]$ (**8**), and $[Mo\{\eta^5\text{-}C_5H_4C(CH_3)_2\text{-}$

$CH_2$-$\eta^1$-CO}(CO)(Cp)][$BF_4$] (**9**). The same sample measured after 12 and 24 h shows 1:2 mixture compounds **7** and **9**. **7:** $^1$H NMR ($CD_2Cl_2$): $\delta$ = 6.33 (t, 2 H, $C_5H_4$), 5.82 (s, 5 H, $C_5H_5$), 4.86 (t, 2 H, $C_5H_4$), 1.17 (s, 2 H, $CH_2$), 0.90 (s, 6 H, $CH_3$). **8:** $^1$H NMR ($CD_2Cl_2$): 6.36 (t, 2 H, $C_5H_4$), 5.77 (s, 5 H, $C_5H_5$), 4.89 (t, 2 H, $C_5H_4$), 1.28 (s, 6 H, $CH_3$), 0.48 (s, 2 H, $CH_2$). **9:** $^1$H NMR ($CD_2Cl_2$): 6.30 (t, 2 H, $C_5H_4$), 5.71 (s, 5 H, $C_5H_5$), 5.52 (t, 2 H, $C_5H_4$), 2.24–2.12 (4-line m, 2 H, $CH_2$), 1.12 (s, 3 H, $CH_3$), 1.05 (s, 3 H, $CH_3$) ppm.

**Synthesis of [Mo{$\eta^4$-$C_5H_4(CH_2)_4$}$(CO)_2$(Ind)][$BF_4$] (11):** The reaction was carried out as that described for compound **4**, but with a solution of **2** (0.25 g, 0.57 mmol) instead of **1** in $CH_2Cl_2$. Recrystallization of the crude product was carried out with $CH_2Cl_2$/$Et_2O$. Yield: 0.22 g (0.53 mmol, 92%). Positive-ion MS: *m*/*z* (%) = 389 [M – $BF_4$]$^+$, 361 [M – $BF_4$ – CO]$^+$, 333 [M – $BF_4$ – 2(CO)]$^+$, 331 (100) [M – $BF_4$ – 2(CO) – $H_2$]$^+$, 329 [M – $BF_4$ – 2(CO) – 2$H_2$]$^+$. $^1$H NMR ($CDCl_3$): $\delta$ = 7.78–7.75 (m, 2 H, $C_9H_7$), 7.41–7.37 (m, 2 H, $C_9H_7$), 6.37 (d, 2 H, $C_9H_7$), 5.74 (t, 1 H, $C_9H_7$), 5.30 (t, 2 H, $C_5H_4$), 4.85 (t, 2 H, $C_5H_4$), 1.83 (t, $^3J_{H,H}$ = 7 Hz, 2 H, $CH_2$), 1.57 (quint, 2 H, $CH_2$), 1.44 (quint, 2 H, $CH_2$), 1.10 (t, $^3J_{H,H}$ = 7 Hz, 2 H, $CH_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 227.4 (2 C, *C*O), 130.1 (2 C, $C_9H_7$), 125.8 (2 C, $C_9H_7$), 111.9 (2$C_{ipso}$, $C_9H_7$), 95.8 (2 C, $C_9H_7$), 93.2 (2 C, $C_5H_4$), 92.4 ($C_9H_7$), 85.2 (2 C, $C_5H_4$), 71.6 ($C_{ipso}$, $C_5H_4$), 51.9, 37.1, 24.9, 24.7 (4 C, $CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3102 (m), 2969 (m), 2878 (m), 2005 (vs) [$\nu_a$(CO)], 1950 (vs) [$\nu_s$(CO)], 1072 (br., vs) [$\nu$(BF)] cm$^{-1}$. Crystals suitable for X-ray structural analysis were prepared by carefully layering the dichloromethane solution of compound **11** with a double volume of hexane.

**Synthesis of [Mo($\eta^5$-$C_5H_4CH_2$-$\eta^1$-$CH_2$)(CO)(Ind)][$BF_4$] (12):** A solution of **2** (0.25 g, 0.57 mmol) in $CH_2Cl_2$ (25 mL) was treated with excess spiro[2.4]hepta-4,6-diene (0.14 g, 1.52 mmol). After stirring the reaction mixture for 16 h, it was concentrated in vacuo to ca. 3 mL. By adding $Et_2O$, an orange powder precipitated (**12**). The crude product was recrystallized from $CH_2Cl_2$/$Et_2O$. Yield: 0.23 g (0.55 mmol, 96%). Positive-ion MS: *m*/*z* (%) = 333 [M – $BF_4$]$^+$, 305 [M – $BF_4$ – CO]$^+$, 303 (100) [M – $BF_4$ – CO – $H_2$]$^+$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 7.79 (d, 1 H, $C_9H_7$), 7.54 (t, 1 H, $C_9H_7$), 7.42 (t, 1 H, $C_9H_7$), 7.33 (d, 1 H, $C_9H_7$), 6.31 (d, 1 H, $C_5H_4$), 6.24, 6.12 (2 × s, 2 H, $C_9H_7$), 5.45 (t, 1 H, $C_9H_7$), 5.39, 4.85, 4.82 (3 × s, 3 H, $C_5H_4$), 2.55 (6-line m, 1 H, $C_5H_4CH_2CH_2$Mo), 2.39 (6-line m, 1 H, $C_5H_4CH_2CH_2$Mo), –0.07 (5-line m, 1 H, $C_5H_4CH_2CH_2$Mo), –3.21 (7-line m, 1 H, $C_5H_4CH_2CH_2$Mo) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = 226.4 (*C*O), 132.5, 131.6, 126.6, 124.7 (4 C, $C_9H_7$), 114.0, 107.9 (2$C_{ipso}$, $C_9H_7$), 97.5, 93.3, 90.7, 86.8, 86.7, 84.1, 83.3 (7 C, $C_5H_4$ and $C_9H_7$), 80.9 ($C_{ipso}$, $C_5H_4$), 19.0 ($C_5H_4CH_2CH_2$Mo), –39.3 ($C_5H_4CH_2CH_2$Mo) ppm. IR (KBr): $\tilde{\nu}$ = 3098 (m), 2947 (m), 1991 (vs) [$\nu$(CO)], 1061 (vs) [$\nu$(BF)] cm$^{-1}$. Crystals suitable for X-ray structural analysis were prepared by carefully layering the dichloromethane solution of compound **12** with a double volume of hexane.

**Synthesis of [MoBr{$\eta^5$-$C_5H_4(CH_2)_2Br$}(CO)(Cp)][$BF_4$] (13):** A solution of **12** (0.10 g, 0.24 mmol) in $CH_2Cl_2$ (15 mL) was cooled to –78 °C and then treated with excess bromine (0.10 g, 0.63 mmol). After stirring the mixture for 30 min at –78 °C, the volatiles were evaporated in vacuo. The crude product was recrystallized from $CH_2Cl_2$/$Et_2O$ to obtain **13** as a purple powder. Yield: 0.13 g (0.22 mmol, 94%). Positive-ion MS: *m*/*z* (%) = 493 [M – $BF_4$]$^+$, 465 (100) [M – $BF_4$ – CO]$^+$, 384 [M – $BF_4$ – CO – Br]$^+$. $^1$H NMR ([$D_6$]-acetone): $\delta$ = 8.02 (d, 1 H, $C_9H_7$), 7.84–7.76 (m, 2 H, $C_9H_7$), 7.60 (d, 1 H, $C_9H_7$), 6.69 (t, 1 H, $C_9H_7$), 6.47 (d, 2 H, $C_9H_7$), 6.35 (t, 1 H, $C_5H_4$), 6.27 (t, 1 H, $C_5H_4$), 6.22 (q, 1 H, $C_5H_4$), 6.03 (q, 1 H, $C_5H_4$), 3.54 (6-line m, 2 H, $C_5H_4CH_2CH_2$Br), 2.76 (t, 2 H, $C_5H_4CH_2CH_2$Br) ppm. $^{13}$C NMR ([$D_6$]acetone): $\delta$ = 218.3 (*C*O), 135.7, 135.6, 130.9, 128.7 (4 C, $C_9H_7$), 121.6, 121.5 (2$C_{ipso}$, $C_9H_7$), 112.8 ($C_{ipso}$, $C_5H_4$), 106.2, 102.3, 99.2, 94.4, 91.1, 91.0, 87.3 (7 C, $C_5H_4$ and $C_9H_7$), 33.3, 32.9 (2 C, $CH_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3138 (m), 3109 (m), 3097 (m), 3063 (m), 2055 (vs) [$\nu$(CO)], 1062 (vs) [$\nu$(BF)] cm$^{-1}$.

**Synthesis of [MoBr{$\eta^5$-$C_5H_4(CH_2)_2Br$}(CO)(Ind)][Br]·0.5$H_2O$ (13a):** The reaction was carried out as that described for compound **13**, but at room temperature. The crude product was recrystallized several times from $CH_2Cl_2$/ether and acetone/ether. Crystals suitable for X-ray structural analysis were prepared by carefully layering the dichloromethane solution of compound **13a** with a double volume of hexane.

**Synthesis of [Mo{$\eta^5$-$C_5H_4(CH_2)_2I$}(CO)(Cp)I][$BF_4$] (14):** A solution of **12** (0.10 g, 0.24 mmol) in $CH_2Cl_2$ (15 mL) was cooled to –78 °C and then treated with excess iodine (0.14 g, 0.59 mmol). After stirring the mixture for 30 min at –78 °C, the volatiles were evaporated in vacuo. The crude product was washed with $Et_2O$ and then recrystallized from $CH_2Cl_2$/$Et_2O$ to obtain **14** as a purple powder. Yield: 0.15 g (0.22 mmol, 93%). Positive-ion MS: *m*/*z* (%) = 587 (100) [M – $BF_4$]$^+$, 559 [M – $BF_4$ – CO]$^+$. $^1$H NMR ([$D_6$]-acetone): $\delta$ = 7.94–7.89 (m, 2 H, $C_9H_7$), 7.76 (d, 1 H, $C_9H_7$), 7.63 (t, 1 H, $C_9H_7$), 6.68 (s, 2 H, $C_9H_7$), 6.63 (s, 2 H, $C_9H_7$), 6.44 (t, 1 H, $C_9H_7$), 6.37 (s, 1 H, $C_5H_4$), 6.28 (s, 1 H, $C_5H_4$), 6.23 (s, 1 H, $C_5H_4$), 6.13 (s, 1 H, $C_5H_4$), 3.37 (6-line m, 2 H, $C_5H_4CH_2CH_2$I), 2.84 (6-line m, 2 H, $C_5H_4CH_2CH_2$I) ppm. $^{13}$C NMR ([$D_6$]acetone): $\delta$ = 219.3 (*C*O), 135.4, 135.1, 132.4, 128.3 (4 C, $C_9H_7$), 117.9, 117.0 (2$C_{ipso}$, $C_9H_7$), 112.4 ($C_{ipso}$, $C_5H_4$), 103.3, 101.7, 98.1, 96.4, 91.0, 90.0, 86.9 (7 C, $C_5H_4$ and $C_9H_7$), 34.5 ($C_5H_4CH_2CH_2$I), 4.7 ($C_5H_4CH_2CH_2$I) ppm. IR (KBr): $\tilde{\nu}$ = 3127 (m), 3086 (m), 2049 (vs) [$\nu$(CO)], 1057 (vs) [$\nu$(BF)] cm$^{-1}$.

**X-ray Crystallography:** Suitable single-crystals of **11**, **12**, and **13a** were manually harvested from the crystallization vials and mounted on a Hampton Research CryoLoops by using FOMBLIN Y perfluoropolyether vacuum oil (LVAC 25/6) purchased from Aldrich,[36] with the help of a Stemi 2000 stereomicroscope equipped with Carl Zeiss lenses. Data were collected on a Bruker X8 Kappa APEX II charge-coupled device (CCD) area-detector diffractometer (Mo-$K_\alpha$ graphite-monochromated radiation, $\lambda$ = 0.7107 Å) controlled by the APEX2 software package[37] and equipped with an Oxford Cryosystems Series 700 cryostream that is monitored remotely by the software interface Cryopad.[38] Images were processed by using the software package SAINT+,[39] and data were corrected for absorption by the multiscan, semi-empirical method implemented in SADABS.[40] The structures were solved by using Patterson synthesis with SHELXS-97,[41] which allowed the immediate location of the central molybdenum metallic center for each complex and the Br atoms in compound **13a**. All the remaining non-hydrogen atoms were directly located with difference Fourier maps calculated from successive full-matrix, least-squares refinement cycles on $F^2$ by using SHELXL-97.[42] All non-hydrogen atoms were successfully refined by using anisotropic displacement parameters. Hydrogen atoms attached to carbon were located at their idealized positions with appropriate *HFIX* instructions in SHELXL: *43* for the aromatic hydrogen atoms associated with the Cp-substituted rings and indenyl molecules; *13* and *23* for the hydrogen atoms associated with the conjugated diene of spiro[4.4]-nona-1,3-diene and the –$CH_2$– chains, respectively. These hydrogen atoms were included in subsequent refinement cycles in riding-motion approximation with isotropic thermal displacements parameters ($U_{iso}$) fixed at 1.2 times $U_{eq}$ of the carbon atom to which they are attached.

| Largest diff. peak and hole [e Å$^{-3}$] | 2.462, –1.140 | 4.016, –1.414 | 1.070, –0.713 |

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. [c] $w = 1/[\sigma^2(F_o^2) + (mP)^2 + nP]$ where $P = (F_o^2 + 2F_c^2)/3$.

In structure **12**, the two $BF_4^-$ anions were found to be statistically disordered over two distinct crystallographic positions. This statistical disorder was modeled for the two anions over a central and common to the two positions B–F bond with fixed rates of occupancy of 0.80:0.20 and 0.70:0.30. Moreover, in order to ensure chemically reasonable geometries for these moieties, the B–F and F···F distances of all moieties were restrained to common (but refinable) values, which ultimately refined to 1.356(1) and 2.210(1) Å, respectively.

In structure **13a**, the two hydrogen atoms associated with the water molecule of crystallization were markedly visible from the last difference Fourier map synthesis, and were included in the final structural model, with the O–H and H···H distances restrained to 0.95(1) and 1.55(1) Å (in order to ensure a chemically reasonable geometry for this moiety) and by using a riding model with an isotropic displacement parameter fixed at *1.5* times $U_{eq}$ of the oxygen atom to which they are attached.

The last difference Fourier map synthesis showed, for **11**, the highest peak (2.462 e Å$^{-3}$) and deepest hole (–1.140 e Å$^{-3}$) located at 1.77 Å from F(2) and 0.74 Å from Mo(1), respectively; for **12**, the highest peak (4.016 e Å$^{-3}$) and deepest hole (–1.414 e Å$^{-3}$) are located at 0.70 Å from Mo(1) and 0.61 Å from Mo(2), respectively; for **13a**, the highest peak (1.070 e Å$^{-3}$) and deepest hole (–0.713 e Å$^{-3}$) are instead located at 0.94 Å from Br(6) and 0.89 Å from Mo(2), respectively. Crystallographic data and structure refinement details are summarized in Table 5.

CCDC-634114, CCDC-634115 and CCDC-634116 (for **11**, **12** and **13a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): The composition of the compounds prepared was checked by mass spectrometry and NMR spectroscopy. Positive-ion electrospray ionization (ESI) mass spectra and $^{13}C\{^1H\}$ NMR spectra are included.

## Acknowledgments

We are grateful to *Fundação para a Ciência e Tecnologia* (FCT, Portugal) for supporting the postdoctoral project SFRH/BPD/24889/2005 and for funding the purchase of the single-crystal diffractometer. We wish to acknowledge Ana Varela Coelho for providing data from the Mass Spectrometry Service at the Instituto de Tecnologia Química e Biológica, Universidade Nova de Lisboa, Oeiras, Portugal.

# Activation of Aromatic, Aliphatic, and Olefinic Carbon–Fluorine Bonds Using $Cp^*_2HfH_2$

**Ryan D. Rieth,[a] William W. Brennessel,[a] and William D. Jones*[a]**

**Keywords:** Metallocenes / Hydrides / Reduction / Fluorocarbons

The hafnium hydride $Cp^*_2HfH_2$ is reacted with a series of fluorocarbons to examine the scope of C–F bond activation. Aromatic, vinylic, and aliphatic C–F bonds all show some degree of reactivity, and possible mechanisms are discussed.

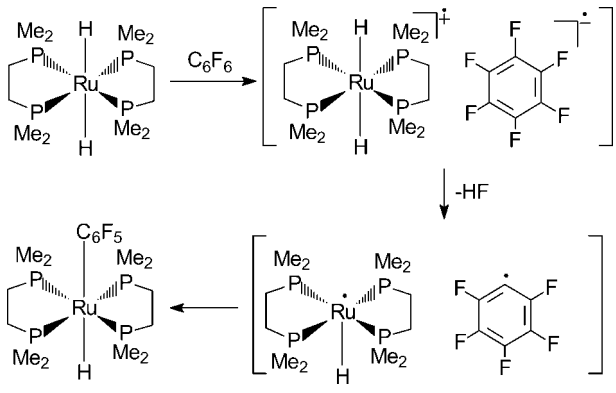
## Introduction

Organometallic chemists have long been interested in the activation of typically inert C–F bonds using transition-metal complexes. The advantages of promoting C–F bond cleavage are both academic and practical. In one sense, the selective and predictable disruption of these interactions may result in greater synthetic utility of readily available fluorocarbons. In addition, such knowledge could have environmental ramifications, eventually leading to the destruction of harmful chlorofluorocarbons (CFCs) in the upper atmosphere. While both stoichiometric[1] and catalytic[2] C–F activation reactions have been reported using transition metals, significant efforts continue to be made to improve known methodologies and to discover new ways to cleave these strong bonds selectively with an important goal being an understanding of the mechanisms by which these transformations take place.

To date, a variety of mechanisms for C–F bond activation by transition metals have been suggested. Some of the more notable strategies involve electron transfer, electrophilic pathways, homolytic cleavage, oxidative addition, and nucleophilic routes.[3–4] While many of these mechanisms feature intermolecular interactions, several examples involve intramolecular activation,[5–6] which is oftentimes accompanied by the liberation of a small molecule such as HF.

As an example of the electron-transfer mechanism, Perutz and co-workers have suggested that an electron-rich dihydride, $Ru(dmpe)_2H_2$ (dmpe = $Me_2PCH_2CH_2PMe_2$), is capable of donating an electron to a heavily fluorinated aromatic compound, eventually leading to the formation of the observed product by the route depicted in Equation (1).[7] Similar considerations have been implicated in reactions involving Ni and Rh.[8–9]



(1)

Electrophilic C–F bond activation has been suggested to occur by fluoride transfer, especially when strong Lewis acids are employed. For example, fluoride transfer from an aromatic fluorocarbon to an open coordination site in $[L_2TiMe]^+$ systems has recently been proposed by Ziegler and co-workers.[10] Rosenthal et al. have shown that cationic zirconocene complexes can abstract fluoride from perfluorophenyl groups to give Zr–F species.[11] In most cases where suggested, fluoride transfer is thought to likely occur through a cyclic transition state [Equation (2)]. Furthermore, olefinic fluorocarbons have been shown to participate in β-fluoride elimination following insertion into metal-hydride bonds, leading to the generation of a new fluorocarbon or small fluorine-containing molecule.[12–15] For perfluoroalkyl–metal complexes, α-fluoride elimination has been shown to be operative in several systems, many of which feature the use of Group 9 metals.[16] A titanium perfluoromethyl complex has also been reported, indicating that such species can be stable.[17]

(2)

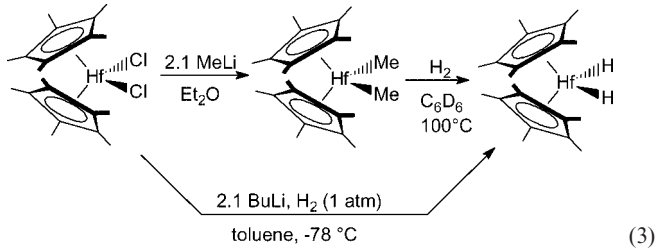
In addition to mechanisms involving the transfer of electrons or fluoride, other mechanisms that have been identified include the involvement of radical-based species in the C–F bond cleavage reactions of aliphatic fluorocarbons using $Cp^*_2ZrH_2$,[18] the oxidative addition of an aromatic C–F bond to phosphane $Ni^0$ complexes,[9,19] and the nucleophilic aromatic substitution on fluorinated aromatic species using early transition-metal complexes.[1(d),6]

As an addition to the variety of metal-based systems known to cleave C–F bonds,[3,20] the following account summarizes C–F bond activation research done using bis(pentamethylcyclopentadienyl)hafnium dihydride, $Cp^*_2HfH_2$ (**1**). The substrate scope includes aromatic, aliphatic, and olefinic compounds featuring varying steric properties and degrees of fluorination. Heterocyclic substrates are also briefly considered, and mechanistic insight into the reaction of **1** with several fluorinated alkenes is presented.

## Results and Discussion

### Synthesis of $Cp^*_2HfH_2$ and its Fluoro Derivatives

The synthesis of **1** was achieved by conversion of commercially available $Cp^*_2HfCl_2$ to $Cp^*_2HfMe_2$[21] followed by reaction with hydrogen at elevated temperature [Equation (3)]. Comparison of $^1H$ NMR spectroscopic data to known literature values for **1** confirmed that it was indeed the expected product.[22]



(3)

The long reaction time required for a reasonable degree of conversion can be avoided using the method reported by Bercaw, in which **1** was made directly from $Cp^*_2HfCl_2$ using *n*-butyllithium under hydrogen, a process that afforded the dried, isolated product in roughly 3 d.[22] Due to the sensitive nature of the starting hafnium complex,[23] great care was taken to prevent air and moisture from being present in any reaction using **1** as a starting material. To this end, all solvents must first be dried with purple sodium/benzophenone ketyl and then over green titanocene, formed from the reaction of $Cp_2TiCl_2$ and zinc dust in the solvent of interest.[24]

In order to obtain a general idea of how **1** reacts with fluorinated organic compounds, the starting hafnium complex was treated with several substrates, including fluorinated aromatics and olefinic compounds, aliphatic C–F bonds, and fluorinated heterocycles.

In most of the reactions, two primary metal-based products formed, $Cp^*_2HfHF$ (**2**) and $Cp^*_2HfF_2$ (**3**), as a result of either mono- or di-hydrodefluorination, respectively. Their presence in the reaction mixtures was determined by

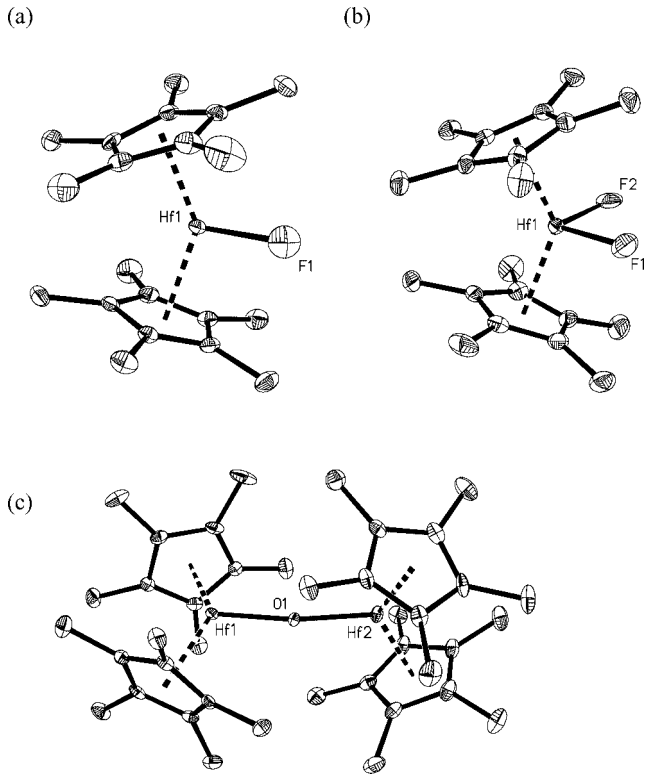


Figure 1. ORTEP diagrams of: a) **2**; b) **3**; and c) **4**. Ellipsoids are drawn at the 50% probability level. Hydrogen atoms are omitted for clarity. The fluoride ligand in **2** is disordered over two sites.

Table 1. Selected X-ray data for **2**, **3**, and **4**.

| | $Cp^*_2HfHF$ (**2**) | $Cp^*_2HfF_2$ (**3**) | $[Cp^*_2Hf]_2O$ (**4**) |

their characteristic NMR spectroscopic data. Characterization of **2** was accomplished by $^1$H and $^{19}$F NMR, as well as by $^1$H-$^{19}$F heteronuclear correlation spectroscopy. The structure of **2** was confirmed by X-ray crystallography (Figure 1).[25] Complex **3** was characterized by $^{19}$F NMR spectroscopic data, which was later confirmed through independent synthesis of the complex.[26] Further characterization was achieved through $^1$H NMR spectroscopic data[26] and X-ray crystallography (Figure 1).[25] An additional hafnium complex, $(Cp^*_2HfH)_2O$ (**4**), was isolated from a crystallization attempt of **1** and was characterized by X-ray crystallography (Figure 1) and $^1$H NMR spectroscopic data.[23,27] This compound likely arises from side reaction with adventitious water. Selected distances and angles for complexes **2**, **3**, and **4** are summarized in Table 1. Selected crystallographic data are compared in Table 2.

### Reactions of 1 with Fluoroaromatics and Fluoroaliphatics

The compounds 2- and 3-fluoropyridine both were observed to react with **1** at room temperature over the course of several hours. NMR analysis of the reaction mixtures revealed the presence of **2** and small amounts of **3** in both reactions but no free pyridine in either. In both reactions, **2** forms prior to the formation of **3**, indicating a sequential reaction of the Hf–H bond. In addition, pyridine was not observed by GC-MS analysis of the volatile materials from the reactions, suggesting that it forms strong adducts with hafnium-containing moieties in the reaction mixture. While 2-fluoropyridine reacts within a few hours, 3-fluoropyridine reacts relatively sluggishly over the course of several days.

Additional reactions using monofluorinated aromatic compounds were briefly pursued, but these experiments did not reveal the expected evidence of C–F bond cleavage. Specifically, 2- and 4-fluorobiphenyl were allowed to react with **1** for over 3 d at 120 °C without displaying C–F reactivity. In addition to reactions with monofluorinated aromatic substrates, the activation of aliphatic C–F bonds was studied using 1-fluorohexane. Initial conversion of **1** to **2** was not observed by $^{19}$F NMR until the reaction mixture was monitored after being heated to 60 °C for 44 h. The reaction was nearly complete after 20 d at 120 °C. Furthermore, hexane was also detected by $^1$H NMR spectroscopy[18] with the observed ratio of **2**:hexane being 0.4:1.0. Small amounts of **3** (5%) were also observed.

Several polyfluorinated aromatic compounds were examined. Highly symmetric substrates 1,2,4,5-tetrafluorobenzene and 2,2′,3,3′,5,5′,6,6′-octafluorobiphenyl did not participate in C–F bond cleavage after days at 120 °C. However, heating for 120 h at 100 °C produced traces of **2** or **3** in reactions involving 1,2,3,4-tetrafluorobenzene and 2,3,4,5,6-pentafluoro(allylbenzene), respectively. While longer reaction times at elevated temperatures reduced the amount of substrate relative to metal-based products, the products generated do not display NMR spectroscopic data that matches that of the expected organic products.[29]

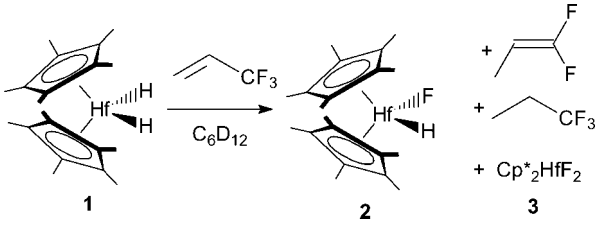
Several perfluorinated aromatic compounds were also examined: hexafluorobenzene, octafluoronaphthalene, and decafluorobiphenyl. NMR analysis of the reactions showed that each reaction generated **2** upon heating, but that weeks at 100–120 °C are required. The observed $^{19}$F NMR chemical shift values of the organic products match known values

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

for pentafluorobenzene, 2H-heptafluoronaphthalene, and 4H-nonafluorobiphenyl.[1(d)] Additionally, 2H-heptafluoronaphthalene was observed by GC-MS analysis of the volatile materials from its respective reaction and the potential presence of 2H-nonafluorobiphenyl as the major product from its respective reaction was discounted based on previously published NMR spectroscopic data.[30] Note that $C_6F_6$ is substantially less reactive than the other perfluoroarenes.

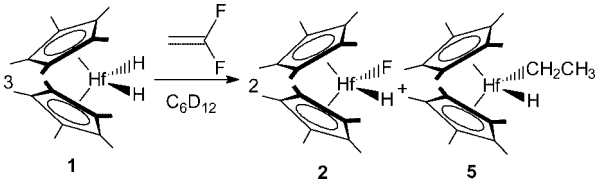
### Reactions of 1 with Fluoroolefins

Partially fluorinated olefins investigated include 3,3,3-trifluoropropene, 1,1-difluoroethylene, hexafluoroisobutene, 3,4,4,4-tetrafluoro-3-trifluoromethyl-1-butene, α-(trifluoromethyl)styrene, and difluoromethylenecyclohexane. Reaction with 3,3,3-trifluoropropene produced **2**, **3**, 1,1-difluoropropene, and 1,1,1-trifluoropropane in a 3.7:0.5:3.4:1.0 ratio after 43 h at room temperature [Equation (4)]. However, the bulk of the conversion was observed to have occurred by $^{19}F$ NMR spectroscopy after roughly 3 min had elapsed. NMR spectroscopic data from 1,1-difluoropropene and 1,1,1-trifluoropropane match previously reported data[14] and 1,1-difluoropropene was identified by analyzing the volatile materials from the reaction by GC-MS.



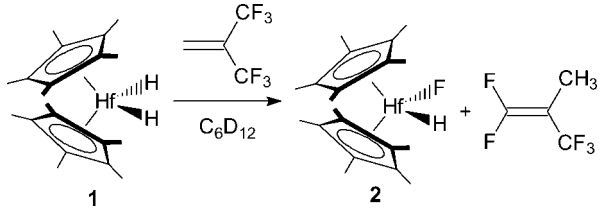
(4)

Reaction of **1** with 1,1-difluoroethylene produced **2** and a species assigned as $Cp^*_2Hf(CH_2CH_3)H$ (**5**) after 20 min at room temperature [Equation (5)]. The diagnostic $^1H$ NMR signals for **5** [$\delta$ = 11.95 (s, Hf–*H*), 0.32 (t, $-CH_2CH_3$), –0.22 (q, $-CH_2CH_3$)] are close to those reported for this complex in $C_6D_6$.[22] Furthermore, because 1-fluoroethylene[31] and free ethylene[32] were not observed, the formation of this complex can be rationalized by subsequent insertions and eliminations of 1,1-difluoroethylene and fluoroethylene into a Hf–H bond, a sequence of transformations which ultimately result in ethylene formation. This ethylene then undergoes Hf–H insertion to finally arrive at **5**.



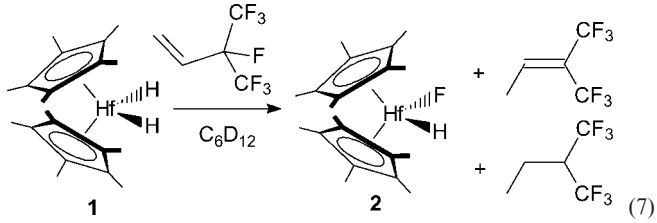
(5)

In order to alter the steric profile of the studied olefins, bulkier alkenes were then used to contrast their reactivity with that of the smaller compounds. The reaction of **1** and hexafluoroisobutene produced 1,1,3,3,3-pentafluoro-2-methyl-1-propene[14] after 50 h at room temperature [Equation (6)]. The final ratio of **2**:1,1,3,3,3-pentafluoro-2-methyl-1-propene was 1.7:1.0, according to $^{19}F$ NMR spectroscopic data.



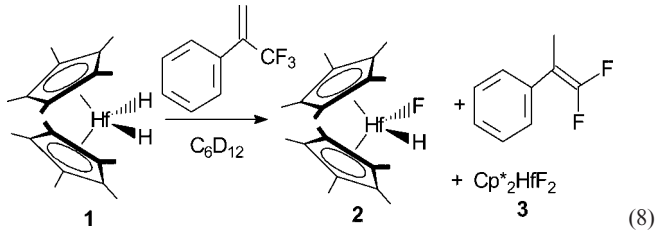
(6)

The analogous reaction using 3,4,4,4-tetrafluoro-3-trifluoromethyl-1-butene produced 1,1,1-trifluoro-2-trifluoromethyl-2-butene and 1,1,1-trifluoro-2-trifluoromethyl-2-butane, both of which could be confirmed by literature precedent [Equation (7)].[14] The reaction was allowed to proceed for 146 h at room temperature, although this time was not sufficient to completely consume **1**. The final ratio of **2**:1,1-trifluoro-2-trifluoromethyl-2-butene: 1,1,1-trifluoro-2-trifluoromethyl-2-butane obtained from $^{19}F$ NMR spectroscopic data was 11.3:7.9:1.0. The olefinic organic product was also identified by GC-MS.



(7)

The reaction of **1** with α-(trifluoromethyl)styrene produced β,β-difluoro-α-methylstyrene, the presence of which was confirmed from previous NMR spectroscopic data [Equation (8)].[33] First evidence of the formation of **2** was observed after heating the reaction mixture for 18 h at 80 °C. **3** was first observed following 92 h of heating at 80 °C. The reaction was terminated after 163.5 h at 160 °C. On the basis of $^{19}F$ NMR spectroscopic data, the final ratio of **2**:**3**: β,β-difluoro-α-methylstyrene was 0.8:1.0: 1.5.

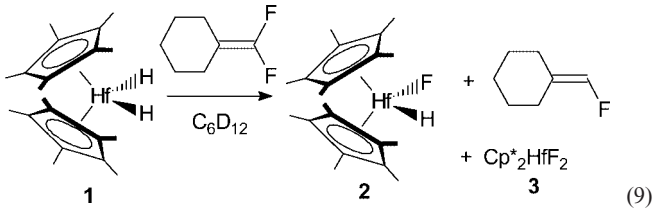


(8)

The reaction involving difluoromethylenecyclohexane was carried out in the same manner, producing **2**, **3**, and fluoromethylenecyclohexane in a 12.8:1.0: 38.0 ratio (by $^{19}F$ NMR) after 93 h of reaction at 160 °C [Equation (9)]. Initial formation of **2** was not observed until after 22 h had

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

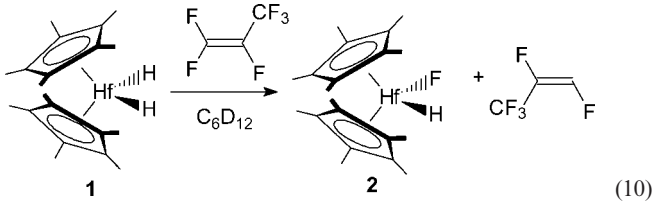
elapsed at 120 °C. Literature values[14] were used to match obtained NMR spectroscopic data with the corresponding organic product.



(9)

**Reactions of 1 with Perfluoroolefins**

Following the set of reactions using polyfluorinated alkenes, the perfluorinated olefins perfluoropropene and octafluorocyclopentene were used in reactions with **1**. The perfluoropropene reaction proceeded at room temperature and yielded **2** and (*E*)-1,2,3,3,3-pentafluoropropene in a 1.8:1.2 ratio (using $^{19}$F NMR spectroscopic data) after 41.5 h [Equation (10)]. The identity of the organic product was determined from previous NMR spectroscopic data[15] and conflicted with the data available for the *Z* isomer.[34]



(10)

On the basis of $^{19}$F NMR spectroscopic data, the analogous reaction using octafluorocyclopentene produced a mixture of **2**, **3**, and 1H-heptafluorocyclopentene in a 41:1.0:27.4 ratio after 47 h at room temperature. Identity of the organic product was confirmed by previously obtained NMR spectroscopic data[34] and by GC-MS data obtained from the volatile materials from the reaction. Full consumption of **1** was achieved.

In an effort to understand the hydrodefluorination of octafluorocyclopentene in more detail, a stepwise C–F activation experiment was performed as follows: equimolar amounts of **1** and octafluorocyclopentene were reacted at room temperature, after which the volatile organic product (1H-heptafluorocyclopentene) was vacuum-transferred onto an additional equivalent of **1**. The first step of this reaction essentially proceeded as before, with the exception being that a small amount of a second product isomer, 4H-heptafluorocyclopentene, was observed by $^{19}$F NMR after 30 min of reaction at room temperature. The ratio of the major (expected) product to the new, minor product was 5.5:1.0. After 20 h of reaction, **1** was no longer present in the reaction mixture, and the volatile materials were vacuum-transferred to a second equivalent of **1**. The reaction was then periodically monitored by NMR spectroscopy over the course of several months (Figure 2). The reaction at room temperature afforded 1H,2H-hexafluoro-cyclopentene as the initial major organic product. However, after an extended amount of time at room temperature, 1H,2H,3H-pentafluorocyclopentene could be observed. The identity of both fluorocyclopentene products was confirmed through comparison to available NMR spectroscopic data.[34]

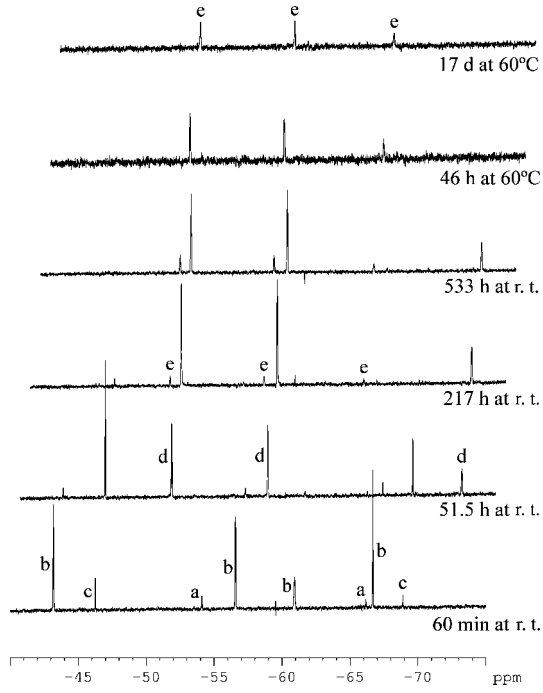


Figure 2. $^{19}$F NMR spectroscopic data for the stepwise hydrodefluorination of perfluorocyclopentene. Temperatures (°C) and allowed reaction times for the various spectra are listed in the right margin. (a = octafluorocyclopentene; b = 1H-heptafluorocyclopentene; c = 1H,2H-hexafluorocyclopentene; d = 1H,2H,3H-pentafluorocyclopentene; e = **6**).

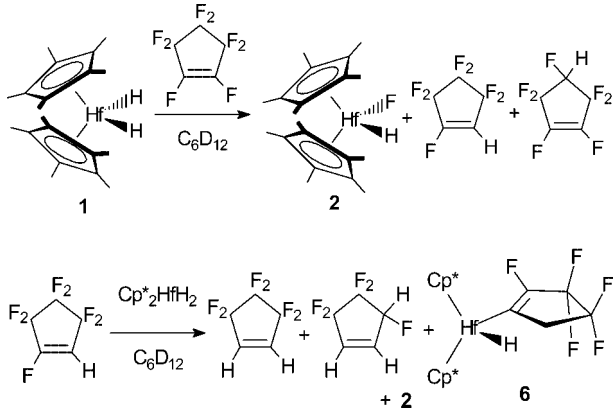
Following a period of decreased activity, the reaction mixture was heated first to 60 °C and then to 100 °C. The relatively high temperature drastically altered the observed product distribution and even resulted in the formation of a species tentatively assigned as **6** (Scheme 1). The assignment of **6** is based largely on NMR integration values and previous observation of a similar complex involving Zr.[34]

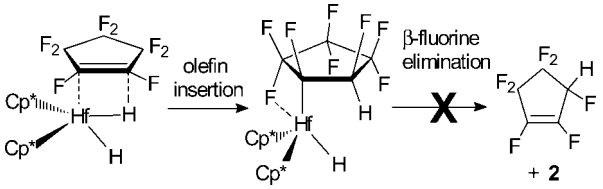


Scheme 1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

There appeared to be no evidence of other fluorinated cyclopentene derivatives following prolonged heating at 100 °C.[35] GC-MS analysis of the volatile materials from the reaction revealed the presence of 1H,2H,3H-pentafluorocyclopentene.

While the stepwise reaction of octafluorocyclopentene shows a preference for vinylic C–F activation over cleavage of neighboring C–F bonds, the mechanism by which the organic products are generated remains unclear. While an olefin insertion prior to β-fluoride elimination mechanism seems to be operative for other non-cyclic olefins,[4,12–15] such a process cannot be responsible for the formation of observed products in this case, because the product predicted by the mechanism is not observed [Equation (11)]. Consequently, a new mechanism must be postulated for this facile olefinic hydrogenolysis. At this point, preliminary calculations suggest a 4-center metathesis pathway between the Hf–H and C–F bond for the reaction.



(11)

## Low-Temperature Studies

Low-temperature NMR spectroscopy was used to look for intermediates that might provide mechanistic insight into the reaction of fluorinated olefins with **1**. In particular, reactions of **1** with 3,3,3-trifluoropropene, 1,1-difluoroethylene, and 1,1-difluoropropene were studied at low temperature. Reactions were initiated at –110 °C and samples monitored in the NMR probe as they warmed to room temperature. Of the substrates examined, the reactions involving 3,3,3-trifluoropropene provided the most insight. Figure 3 shows some of the $^{19}$F NMR spectroscopic data obtained from this reaction.

The most striking aspect of the data presented in Figure 3 is the fact that some of the species observed, specifically the compounds corresponding to the peaks labeled **c** and **e**, seem to be present at low temperature but gradually vanish as the temperature is increased. One way to rationalize these observations is summarized in Equation (12) below. Assuming that insertion of the olefin into the metal-hydride bond of **1** is the initial step in the reaction, one could expect two different species – one with a branched fluoroalkyl ligand **7** and one featuring a straight-chain fluoroalkyl moiety **8** – to form. Because the NMR spectra taken from roughly –110 °C to –60 °C display only starting olefin, **1**, and two unidentified species, it seems reasonable to argue that the unassigned species may be the two insertion products, **7** and **8**. Strengthening that assertion is the fact that the signal assigned to **8** is a sharp triplet, as would be expected.

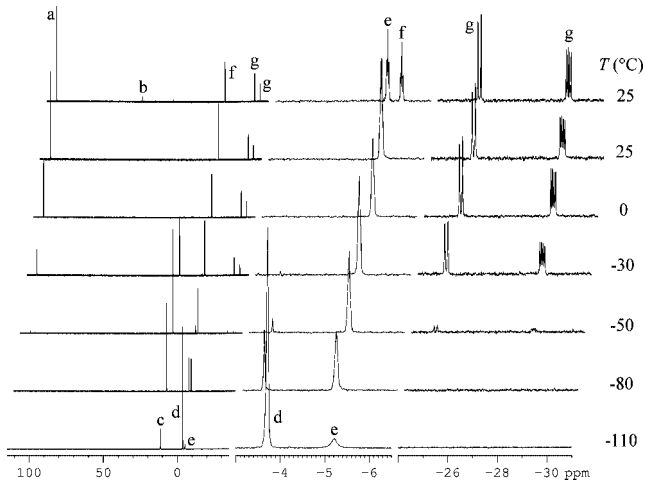


Figure 3. Variable-temperature $^{19}$F NMR spectroscopic data for the reaction of 3,3,3-trifluoropropene with **1**. The temperatures (°C) corresponding to the various spectra are given in the right margin. Regions of interest are expanded for clarity. (a = **2**, b = **3**, c = **7**, d = 3,3,3-trifluoropropene, e = **8**, f = 1,1,1-trifluoropropane, g = 1,1-difluoropropene).

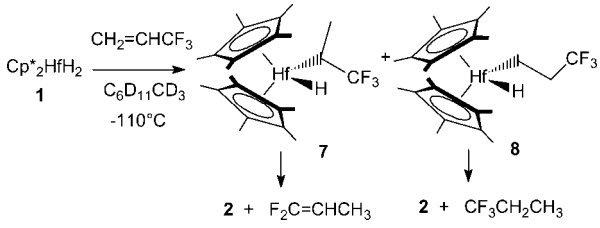

(12)

Subsequent warming of the reaction mixture results in relatively rapid disappearance of the NMR signal tentatively assigned to **7** accompanied by an appreciable increase in the signals corresponding to **2** and 1,1-difluoropropene. The β-fluoride elimination from the trifluoromethyl group is consistent with these observations. Moreover, prolonged storage of the reaction mixture at room temperature promotes the growth of the signal previously assigned to 1,1,1-trifluoropropane. Because the hydrogenated olefin signal intensity approaches that of the resonance assigned to **8**, it appears as though complex **8** may be the source of 1,1,1-trifluoropropane.

The low-temperature experiment using 3,3,3-trifluoropropene was monitored by $^{1}$H NMR in a separate trial and showed similar behavior to that observed by $^{19}$F NMR spectroscopy. Specifically, two previously unobserved signals appeared between 12–14 ppm and were tentatively assigned as the Hf–H signals from **7** ($\delta$ = 13.80 ppm) and **8** ($\delta$ = 12.90 ppm). As expected, the signal from **7** decreased quickly upon warming and was completely absent by the time the reaction was warmed to –10 °C. In addition, another resonance at $\delta$ = 0.50 ppm exhibited the same behavior and was assigned as the methyl group of **7** based on integration. The Hf–H signal from **8** along with an additional signal at –0.03 ppm (assigned to the metal-bound

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methylene of **8** based on integration) expectedly lingered at room temperature.

While the reaction of 3,3,3-trifluoropropene with **1** appeared to successfully demonstrate that the insertion/elimination mechanism accounts for the formation of observed products, the same could not be said for the reactions of 1,1-difluoroethylene and 1,1-difluoropropene with **1**. At the current time, it appears as though the reaction involving 1,1-difluoroethylene proceeds too rapidly at low temperature to observe intermediates. In contrast, the reaction of 1,1-difluoropropene has not provided results suitable for discussion of its mechanism of reaction.

### Comparison with Reactions of Zirconium Dihydride

A comparison can be made here with the related reactivity of the zirconium analog $Cp^*_2ZrH_2$. This complex has been reported to reduce aliphatic,[36] aromatic,[1d–18] and olefinic[14–15] C–F bonds under mild conditions. It can also undergo β-fluoride elimination in fluorophenyl derivatives to generate benzyne intermediates.[37] In addition, reduction of $sp^3$ $CF_2H$–R has been reported to occur slowly with this compound. The reaction mechanisms proposed vary from free radical chain for aliphatic C–F, to nucleophilic attack for monofluoroaromatics, to insertion/β-fluoride elimination for fluoroolefins.[4] Additionally, other electrophilic titanocene[38] and zirconocene[39] complexes have been seen to cleave C–F bonds in perfluoropyridine. In general, the reactivity patterns seen with $Cp^*_2HfH_2$ mimic those of $Cp^*_2ZrH_2$, except that the hafnium complex is less reactive. Reactions proceed to give similar products either slowly, or not at all. While fewer mechanistic studies have been undertaken with hafnium, it is likely that the substrates react by similar mechanisms as in the zirconium cases.

## Experimental Section

All substrates were used as delivered without purification. Products have been characterized and unreacted starting materials have been identified primarily by comparing known $^{19}F$ NMR chemical shift values to those obtained during a given experiment (using external α,α,α-trifluorotoluene in [$D_{12}$]cyclohexane as a reference). Reported NMR spectroscopic data not referenced to external α,α,α-trifluorotoluene in [$D_{12}$]cyclohexane were converted accordingly. In some cases, $^1H$ NMR and GC-MS data were used to further confirm the identity of the organic products. NMR spectra were recorded with Bruker Avance instruments (400 or 500 MHz). GCMS data were recorded with a Shimadzu model QP2010 spectrometer. A Siemens SMART CCD area detector diffractometer equipped with an LT-2 low-temperature unit was used for X-ray crystal structure determination.

**Preparation of $Cp^*_2HfH_2$:** From dimethyl complex: $Cp^*_2HfCl_2$ (3.85 mmol; Strem) was dissolved in roughly 40 mL of diethyl ether (previously vacuum-transferred from purple sodium/benzophenone ketyl) in a nitrogen glovebox. On a Schlenk line, 2.1 equiv. of methyllithium (8.09 mmol; 1.4 M in $Et_2O$ from Aldrich) were added to the reaction mixture by syringe under positive nitrogen pressure. The reaction mixture was stirred under static nitrogen for roughly 25 h before ca. 1 mL of ACS-grade methanol was added under positive nitrogen pressure to quench the reaction. The volatile materials were removed by vacuum. Isolation of the final product was achieved by filtering a hexane mixture of crude product through celite, cooling the filtrate to –78 °C to induce crystallization, removing the mother liquor/washing the crystals with cold hexane via cannula transfer, and drying in vacuo (3.06 mmol, 80%). The second step involved placing a $C_6D_6$ solution of $Cp^*_2HfMe_2$ (0.06 mmol) under 15 psi of UHP-grade hydrogen gas (Airgas) at 100 °C. The reaction was periodically monitored by $^1H$ NMR over the course of 6 weeks, with the hydrogen being replaced many times with fresh hydrogen following several freeze-pump-thaw degassing cycles (≈ 97% final conversion to **1**). The reaction was repeated on a preparative scale with the remaining $Cp^*_2HfMe_2$. **1** was also prepared in 33% yield from the reaction of $Cp^*_2HfCl_2$ and BuLi, as described in ref.[22]. $^1H$ NMR ($C_6D_6$): $Cp^*_2HfCl_2$, $\delta$ = 1.91, s. $Cp^*_2HfMe_2$, $\delta$ = 1.80, (s, 30 H), –0.70 (s, 6 H) $Cp^*_2HfH_2$ (**1**), $\delta$ = 2.05, (s, 30 H), 15.63 (s, 2 H) ppm. $^1H$ NMR ($C_6D_{12}$): $Cp^*_2HfH_2$ (**1**), $\delta$ = 2.03, (s, 30 H), 15.37 (s, 2 H) ppm.

**Isolation of 2 and 3:** Samples of **2** and **3** were obtained from the non-volatile organometallic residue of the fluorocarbon reduction reactions. X-ray quality crystals were grown by allowing a pentane solution of the hafnium complex to evaporate into a small quantity of toluene at –30 °C in a nitrogen glovebox. X-ray quality crystals of **4** were obtained by allowing pentane vapor to diffuse into a concentrated $CH_2Cl_2$ solution of **4** at room temperature in a nitrogen glovebox. For **2**, $^1H$ NMR ($C_6D_{12}$): $\delta$ = 1.95 (s, 30 H), 10.90 (d, $J$ = 4.8 Hz, 1 H) ppm. $^{19}F$ NMR: $\delta$ = 107.8 (s) ppm. For **3**, $^1H$ NMR ($C_6D_{12}$): $\delta$ = 1.89 (s) ppm. $^{19}F$ NMR: $\delta$ = 49.7 (s) ppm. For **4**, $^1H$ NMR ($C_6D_{12}$): $\delta$ = 2.00 (s, 30 H), 2.08 (s, 30 H), 9.79 (s, 2 H) ppm.

**Reactions of 1 with Fluorocarbons:** All experiments were run in NMR tubes fitted with a Teflon™ stopper using equimolar amounts of **1** and substrate. Unless otherwise noted, twice-dried [$D_{12}$]cyclohexane was used as solvent to dissolve mixtures of the starting hafnium complex and solid substrates in a nitrogen glovebox. In reactions involving liquid substrates, ca. 10 mg of **1** was first dissolved using $C_6D_{12}$ in a nitrogen glovebox and the previously-degassed liquid substrate was added via syringe. Gaseous compounds were condensed into chilled reaction vessels using high vacuum techniques.

For reactions of 2- and 3-fluoropyridine, $^{19}F$ data[40] showed the loss of fluorocarbon reactant and the formation of **2** and small amounts of **3** (2–4%) over the course of a week at room temperature. Pyridine was not seen by $^1H$ NMR spectroscopy.[41] For reactions of 2- and 4-fluorobiphenyl, no reaction was observed at 120 °C by $^{19}F$ NMR spectroscopy.[42] Polyfluorinated aromatics showed only traces of reaction if any reaction at all after extended heating at 120 °C, as determined by monitoring the $^{19}F$ NMR spectra of these reactions. Substrates examined were 1,2,4,5-tetrafluorobenzene,[1(d)] 2,2′,3,3′,5,5′,6,6′-octafluorobiphenyl,[43] 1,2,3,4-tetrafluorobenzene,[1(d)] and 2,3,4,5,6-pentafluoro(allylbenzene).[44] In contrast, perfluorinated aromatics showed some evidence for slow reaction. $^{19}F$ NMR spectroscopic examination of reactions of hexafluorobenzene,[45] octafluoronaphthalene,[46] and decafluorobiphenyl[47] showed reduction to produce **2** after several days at 100–120 °C. Reaction of **1** with 1-fluorohexane[48] commenced only upon heating to 60 °C, and approached completion after 20 d at 120 °C.

$^{19}F$ NMR spectroscopy was used to monitor reactivity of the partially fluorinated olefins 3,3,3-trifluoropropene,[49] 1,1-difluoroethylene,[50] hexafluoroisobutene,[51] 3-trifluoromethyl-3,4,4,4-tetrafluoro-1-butene, α-(trifluoromethyl)styrene,[52] and difluoromethyl-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

enecyclohexane,[53] as described in the text. Reactions of **1** with the perfluorinated olefins perfluoropropene[54] and octafluorocyclopentene[55] were also examined by $^{19}F$ NMR spectroscopy, but now reaction occurred quickly at room temp.

**Low-Temperature Reaction of 1 with Fluorocarbons:** Compound **1** was dissolved in [$D_{14}$]methylcyclohexane in a nitrogen glovebox. The substrate of choice was measured by achieving the appropriate pressure in a pre-calibrated glass bulb. The substrate was then condensed into the reaction vessel following degassing of the solution of **1**. Special effort was directed at keeping the NMR tube cold following transfer of the substrate, which was achieved by thawing the frozen solution of **1** in a liquid nitrogen/ethanol slush bath (–116 °C). In most instances, the NMR probe was pre-cooled to –110 °C.

1,1-Difluoropropene was obtained through the previously mentioned reaction of **1** with 3,3,3-trifluoropropene, with the exception being that the reaction was run in $C_6D_{11}CD_3$ in instances where 1,1-difluoropropene was designed to serve as a starting material in a subsequent low-temperature experiment. The volatile materials from the reaction (primarily 1,1-difluoropropene, 1,1,1-trifluoropropane, and solvent) were vacuum-transferred from this reaction onto another equivalent of **1** before thawing the reaction mixture at –116 °C. Detailed descriptions of these reactions are given in the text.

**X-ray Structure Determinations:** Single crystals of **1**, **2**, and **3** were mounted under Exxon Paratone-8277™ on glass fibers and immediately placed in a cold nitrogen stream at 100 K on the X-ray diffractometer. The X-ray intensity data (1.3 hemispheres) were collected over 6 h with a standard Siemens SMART APEX II CCD Area Detector System equipped with a normal focus molybdenum-target X-ray tube operated at 2.0 kW (50 kV, 40 mA).[56] Data were corrected for absorption using the program SADABS.[57] Space group assignments were made on the basis of systematic absences and intensity statistics by using the XPREP program (Siemens, SHELXTL 97). The structures were solved by using direct methods and refined by full-matrix least-squares on $F^2$.[58] For all of the structures, the non-hydrogen atoms were refined with anisotropic thermal parameters except for the fluoride ligand in **2**, which was disordered over two sites and refined isotropically. The Hf-bound hydride in **2** was not included in the final refinement model. There was nothing unusual about the solution or refinement of any of the structures, although the fluoride and hydride ligands in **2** were disordered (76/24 and 60/40). Compound **4** refined with a Flack parameter of 0.055(8). Further experimental details of the X-ray diffraction studies are provided in Table 2. CIF files for the structures **2**–**4** have been deposited with the CCDC.[59]

# The Effect of Catalyst Loading in Copper-Catalyzed Cyclohexane Functionalization by Carbene Insertion

**Ana Caballero,[a] M. Mar Díaz-Requejo,[a] Swiatoslaw Trofimenko,[b] Tomás R. Belderraín,*[a] and Pedro J. Pérez*[a]**

**Keywords:** Copper / C–H activation / Homogeneous catalysis / Carbenes / N ligands

A study of the variables that affect the insertion of the :$CHCO_2Et$ group (formed from ethyl diazocetate, EDA) into the C–H bonds of cyclohexane in the presence of a $Tp^xCu$ complex as the catalyst ($Tp^x$ = trispyrazolylborate ligand) has demonstrated an anomalous effect of the catalyst loading. The use of low concentrations of catalyst produces an increase in the yield of the C–H activation product ethyl cyclohexaneacetate. This effect has also been found in the case of other less elaborated catalysts such as $[Bp^{Br3}Cu]$ or $[(bipy)_2Cu][I]$.

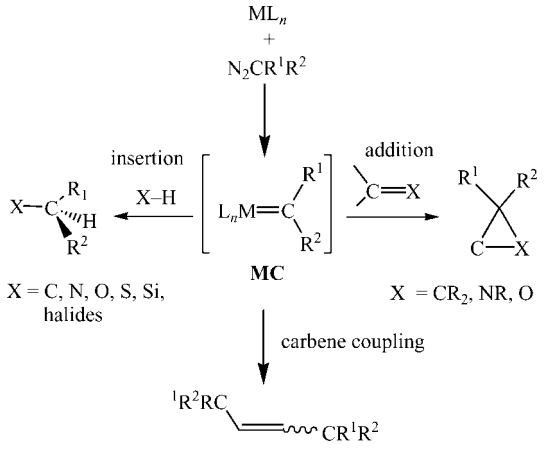
## Introduction

Diazo reagents have been employed extensively as a carbene source, initially under thermal or photochemical conditions and in the last decades with the aid of transition-metal complexes as catalysts for several transformations[1] for the transfer of the carbene unit to many saturated and unsaturated substrates (Scheme 1). Besides the desired addition or insertion products, the undesired carbene coupling side-reaction has usually been observed in the vast majority of reported systems.

It is well established that the transformations depicted in Scheme 1 take place through the intermediacy of a metallocarbene species $L_nM{=}CR^1R^2$, which is generated from the direct reaction of the catalyst $ML_n$ and the diazo compound,[1] and that this constitutes the rate-determining step of the overall process.[2,3] The transient metallocarbenoid species (MC) usually displays an electrophilic behavior,[4] which explains its reactivity towards the nucleophiles available in solution − the diazo compound or the target substrate to be functionalized. Due to its high reactivity, there are few reports in the literature in which these intermediates have been detected or isolated. In the case of copper, the first observation of one of these species under catalytic conditions is due to Straub and Hofmann.[5] Later, Warren and Dai described the preparation and structural characterization of the copper carbene complex $[(N–N)Cu{=}CPh_2]$ from the reaction of a diketiminatocopper(I) complex and $Ph_2CN_2$.[6]



Scheme 1. Transition-metal-catalyzed carbene transfer from diazo compounds.

In recent years we have described the potential of a family of complexes of general formula $[Tp^xCu(NCMe)]$ ($Tp^x$ = homoscorpionate ligand) toward the two processes mentioned above: the addition of :$CHCO_2Et$ from ethyl diazoacetate (EDA) to multiple carbon–carbon bonds (alkenes,[7] alkynes,[8] aromatics[9]) or its insertion into single X–H bonds (alkanes,[10] amines,[11] alcohols[12]). All these transformations are accompanied by the copper-catalyzed carbene coupling reaction, which leads to the formation of diethyl fumarate and maleate in variable yields [Equation (1)]. In this contribution, we present the results obtained during the course of our investigations focused on the study of the variables that could affect the formation of these undesired by-products with the aim of its decrease or suppression. We

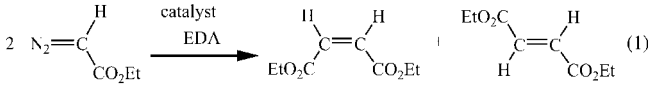
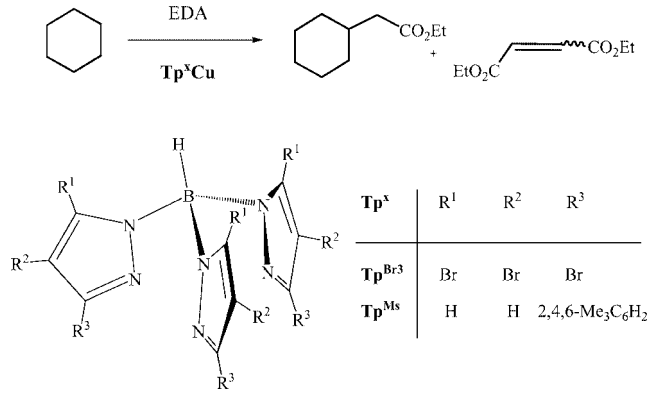
have found an unexpected effect of the catalyst loading that affects the chemoselectivity of these transformations not only in the case of the [Tp$^x$Cu(NCMe)] catalysts but also with other less elaborated catalysts. This knowledge has allowed the enhancement of the yields of the desired products.



## Results and Discussion

We have previously reported[10] that the complexes [Tp$^{Br3}$Cu(NCMe)] (**1**) and [Tp$^{Ms}$Cu] (**2**) catalyze the insertion of EDA into the C–H bonds of cyclohexane (Scheme 2), leading to the formation of ethyl cyclohexaneacetate as well as diethyl fumarate (DEF) and maleate (DEM). Under the same conditions (1:20:2000 for [catalyst]:[EDA]:[$C_6H_{12}$], 0.05 mmol of catalyst) **1** and **2** gave 90 and 54% yield of ethyl cyclohexaneacetate, respectively, with DEF and DEM accounting for the remaining EDA. In order to diminish such amounts of non-desired products, we studied the effect of the following variables that could affect the chemoselectivity induced by a given catalyst: (a) the addition rate of EDA, (b) the concentration of EDA, and (c) the catalyst loading.



Scheme 2. [Tp$^x$Cu]-catalyzed cyclohexane functionalization by EDA insertion.

### Effect of EDA Concentration and Addition Time

The traditional experimental methodology in metal-catalyzed diazo compound decomposition usually employs a large excess of substrate with respect to the diazo compound, as well as slow addition devices to add the latter to the solution containing the catalyst and the substrate.[1,13] With this experimental design, the [diazo compound]/[catalyst] ratio in the reaction mixture can be maintained at low values, thereby minimizing the formation of DEF and DEM. To verify this common behavior, we have run a series of five experiments for the reaction of cyclohexane and EDA in the presence of **1** or **2** in which only the time employed for the addition of EDA was varied. Figure 1 (left) shows the conversion into ethyl cyclohexaneacetate obtained at the end of each experiment (determined from the NMR spectra of the crude reaction mixture). Those carried out at $t$ = 0 h were performed by adding the diazo compound in one portion, whereas the others were run with the aid of a syringe pump programmed to add the EDA (1 mmol dissolved in 10 mL of cyclohexane) over 1, 3, 6 and 12 h. An increase in the yields of the desired product was observed upon lengthening the addition time, although for the Tp$^{Ms}$-containing catalyst this increase was not as high as with the Tp$^{Br3}$ catalyst. The use of the latter in a series of experiments in which only the concentration of EDA in the feed solution was varied gave the results shown on the right-hand side in Figure 1: the lower the value of [EDA], the higher the yield of the desired product. Overall, both sets of experiments are in agreement with the mentioned effect of the [EDA]:[catalyst] ratio in the reaction mixture: a low value of this ratio enhances the yield of the desired product and decreases the yields of DEF and DEM.

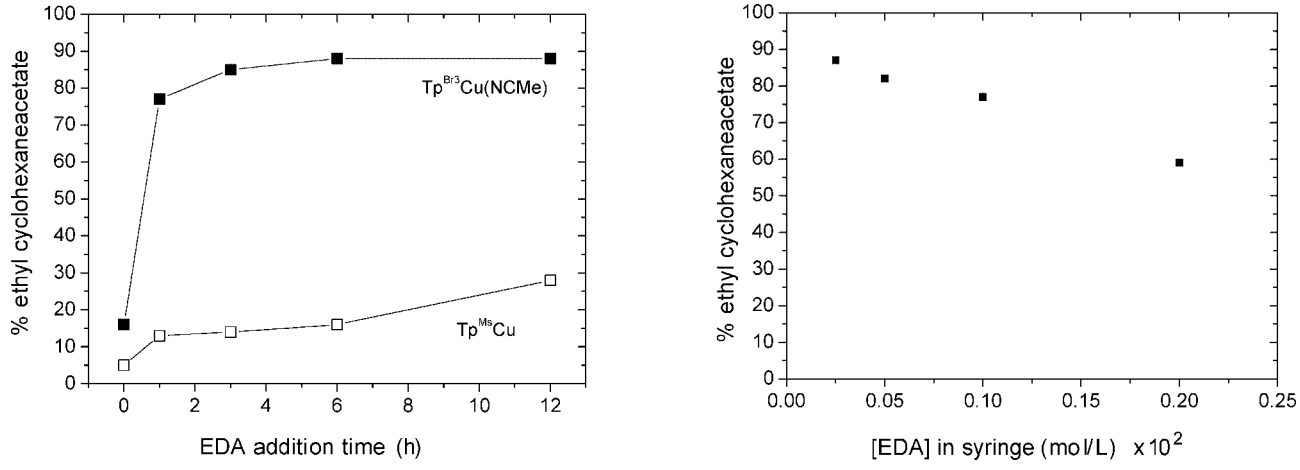


Figure 1. Variation of the yield of ethyl cyclohexaneacetate with EDA addition time (left) and the EDA concentration added from the syringe pump {[Tp$^{Br3}$Cu(NCMe)] as the catalyst}.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### Effect of the Catalyst Loading

Another approach to ensure the above conditions, i.e., a low [EDA]:[catalyst] ratio is to employ a higher catalyst loading at a fixed EDA concentration and addition time (6 h). Surprisingly, when we employed a fivefold amount of the catalyst (0.25 mmol instead of the 0.05 mmol in the previous experiments), we did not observe any increase in the yields of ethyl cyclohexaneacetate *but the opposite effect*. As shown in Figure 2, a certain decrease occurred with **1** (from 88 to 70%) as the catalyst, whereas no response to this variable was obtained from the experiment with **2** and the same catalyst loading (ca. 16% in both cases). We then explored the use of different catalyst loadings in the range 0.002 to 0.25 mmol, with the results displayed in Figure 2. An unexpected increase in the degree of conversion of cyclohexane and EDA into ethyl cyclohexaneacetate took place when the catalyst concentration was decreased in both cases. No EDA was detected by GC shortly after the addition was completed, which is an indication of the ease with which catalysts **1** and **2** consume the diazo compound. The main yield enhancement in the case of the $Tp^{Ms}Cu$ catalyst appeared on going from 0.01 to 0.002 mmol as the catalyst loading, which corresponds to an increase of nearly 45% (from 25 to 70%). This is a completely unexpected behavior since such an increase takes place in the direction in which the [EDA]:[catalyst] also increases, which is exactly the contrary to that found above when EDA addition time or EDA concentration were studied. It is also worth mentioning that this anomalous effect is not observed with styrene as the substrate. In this case, a similar study was carried out but no effect of the catalyst loading was observed. This is in good agreement with the fact that styrene is much more reactive than a cyclohexane C–H bond, and there is no real competition between cyclopropanation and the EDA decomposition toward diethyl fumarate and maleate.

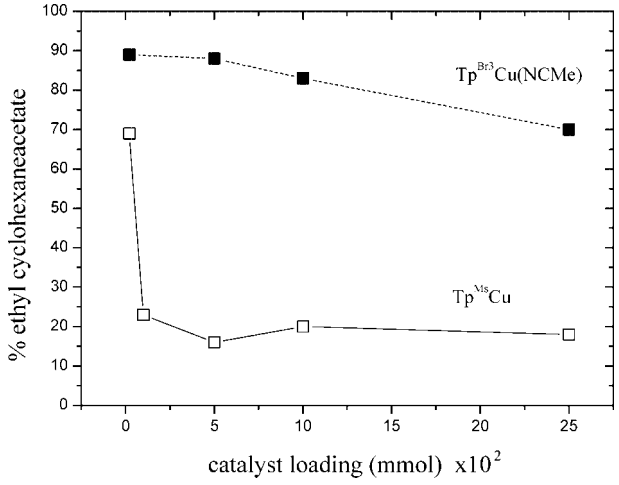

Figure 2. Effect of the catalyst loading on the yields in ethyl cyclohexaneacetate.

### Scope of this Methodology

We have not been able to find a reasonable explanation for this behavior[14] as our experimental methodology, which is based on the use of slow addition devices for EDA, prevents us from carrying out reliable kinetic studies. However, the importance of the discovery of the effect of the catalyst loading in this transformation, which gives a noticeable enhancement in the yields simply by decreasing the amount of catalyst, should be pointed out. At this point, we wondered about the extension of this proposal to other copper-based catalysts. The number of catalytic systems based on copper for the intermolecular insertion of diazo compounds into C–H bonds is very limited,[15] the highest conversions thus far being obtained with our $Tp^xCu$ system.[10] In contrast, there are more examples for the intramolecular version, including chiral catalysts that have led to moderate to high degrees of enantioselectivity.[16] The ligands bound to the copper center in these cases were preferentially bis-oxazolines and bis-imines, i.e., ligands with two nitrogen donor atoms. However, there are no reports of the use of these catalysts for the intermolecular, asymmetric insertion of diazo compounds into C–H bonds. In the search for model complexes for the above chiral systems, we decided to study the catalytic properties of the complex $[Bp^{Br3}Cu]$ (**4**), which is similar to the $[Bp^xCu]$ complexes already reported by other authors.[17] Table 1 shows the results obtained for the reaction of EDA and cyclohexane in the presence of **4**. In one-portion addition reactions, only an 8% yield of ethyl cyclohexaneacetate was observed with a 0.05 mmol catalyst loading. This yield was improved up to 13% when performing the slow addition of EDA over 3 h (entry 2). Although modest, it is worth pointing out that these data compare well with those shown in Figure 1 for **2** as the catalyst under the same conditions. Following the strategy learnt from the previous sections, we used a lower catalyst loading (0.002 mmol) of **4** and observed the desired effect: the yields were enhanced up to 36 and 49% with EDA addition times of 4 and 17 h, respectively. We find these results quite remarkable in two ways: first, they demonstrate the catalytic capability of a copper complex with a bidentate, not tridentate, $Bp^x$ ligand, with yields similar to those obtained with **2**, and secondly, they demonstrate that the steric protection assumed for the $Tp^xCu$ system seems not to be as crucial as initially supposed, and that other factors, such as the electron-withdrawing nature of the ligand and catalyst loading, could be very important at this point.

Complex **4** could be a good model for anionic chiral ligands (semicorrines, some bisoxazolines), but many others, including those referred to above, are neutral in nature. In order to check the validity of our proposal, we ran a few experiments using $[(bipy)_2Cu][I]$ (**5**) as the catalyst for the insertion of EDA into the C–H bonds of cyclohexane. We anticipated a very low catalytic activity for this complex in this reaction since (a) no electron-withdrawing groups are bonded to the metal center and (b) it appears to be coordinatively and electronically saturated. However, previous studies with this complex for the cyclopropanation of styrene have shown that bipy de-coordination takes place easily.[3a] Under our standard conditions (0.05 mmol of **5**, 1 mmol of EDA, one portion addition of the diazo ester),

Table 1. Use of [$Bp^{Br3}$Cu] (**4**) and [$(bipy)_2$Cu][I] (**5**) as catalysts for the reaction of ethyl diazoacetate and cyclohexane.[a]

| Catalyst loading [mmol] | EDA addition time [h] | [$Bp^{Br3}$Cu][b] | [$(bipy)_2$Cu][I][b] |
|---|---|---|---|
| 0.05 | one portion | 8 | nd |
| 0.05 | 3 | 13 | – |
| 0.002 | 4 | 36 | 10 |
| 0.002 | 12 | – | 18 |
| 0.002 | 17 | 49 | – |

[a] See Experimental Section. [b] Yields calculated by NMR spectroscopy, with DEF and DEM formation accounting for 100% of EDA.

no ethyl cyclohexaneacetate was observed, with only DEF and DEM being detected at the end of the reaction. This could be enough to discard **5** (or any other complex) as a potential catalyst. However, based on our proposal, we ran two experiments with a lower catalyst loading and, with the aid of a syringe pump, with a total addition time of 4 and 12 h, the yields of the desired product increased up to 10 and 18%, respectively. Again, these results indicate that, even for very low activity and non-elaborated catalysts, the catalyst loading affects the chemoselectivity of the reaction.

## Conclusions

We have discovered that the formation of diethyl fumarate and maleate in the presence of [$Tp^x$Cu] is influenced by the catalyst loading in the opposite sense that would normally be expected. The use of very low concentrations of the [$Tp^x$Cu] catalysts causes a decrease in the formation of DEF and DEM and a concomitant increase in the yields of the desired C–H-functionalized product. These findings have been extended to copper complexes with bidentate ligands as models for other already known catalysts. We believe that these results could be extended to many already known systems for the copper-catalyzed carbene transfer from diazo compounds, thereby opening up a new perspective in the copper-catalyzed insertion of diazo compounds into C–H bonds.

## Experimental Section

**General:** $^1$H NMR spectra were run at 400 MHz and $^{13}$C NMR at 100 MHz, with $CDCl_3$ as solvent. Mass spectra were recorded with a Varian Saturn 2100T. GC analysis was performed with a Varian CP-3800. Solvents were dried and degassed before use. All reagents were purchased from Aldrich and employed without any further purification. The synthesis of the copper catalysts[7–10] was carried out as reported previously.

**General Catalytic Experiment:** [$Tp^x$Cu] (0.05 mmol) was dissolved in a mixture of $CH_2Cl_2$ (10 mL) and cyclohexane (10 mL). A solution of EDA (1 mmol) in cyclohexane (10 mL) was slowly added during the programmed time with the aid of a syringe pump, at room temperature. No EDA was detected at the end of the reaction by GC, only ethyl cyclohexaneacetate and diethyl fumarate and maleate. Other experiments were performed by adding the pure diazo compound in one portion. For those experiments carried out without cyclohexane, dichloromethane were employed as the sole solvent.

The reported yields correspond to an average of at least of two runs, and were determined in the following manner. After removal of volatiles, the crude product was investigated by $^1$H NMR spectroscopy, with a standard compound being added (tosyl chloride or styrene) to ensure that all the initial EDA was converted in the observed products. The observed ratios were compared to those from GC analysis in order to establish the response factors, which were later employed in the subsequent experiments to determine the yields. The products were identified by comparison with commercial samples (ethyl cyclohexaneacetate, diethyl fumarate and maleate) or with data already reported.

## Acknowledgments

We thank the Ministerio de Educación y Ciencia for funding (Proyecto CTQ2005-00324BQU) and reserach fellowship (A. C.). The Ramón y Cajal Programme is also thanked (M. M. D. R.).

# A PCP-Pincer $Ru^{II}$–Terpyridine Building Block as a Potential "Antenna Unit" for Intramolecular Sensitization

**Marcella Gagliardo,[a] Fabio Rizzo,[b,c] Martin Lutz,[d] Anthony L. Spek,[d] Gerard P. M. van Klink,[a] André E. Merbach,[e] Luisa De Cola,[c] and Gerard van Koten*[a]**

**Keywords:** Ruthenium / Lanthanides / Pincer ligands / Luminescence

The redox- and photoactive mononuclear complex [Ru(PCP)-(tpy–DTTANa$_4$)]Cl {PCP = [$C_6H_3(CH_2PPh_2)_2$-2,6]$^-$; tpy–DTTA$^{4-}$ = 4′-(2,2′:6′,2′′-terpyridine)-diethylenetriamine-*N*,*N*,*N*′′,*N*′′-tetraacetate} possesses an externally directed, vacant $N_3O_4$ polyaminocarboxylate-type binding site that coordinates to lanthanide(III) ions to give the neutral heterodinuclear $Ru^{II}$–$Ln^{III}$ complexes [Ru(PCP)(tpy–DTTA)Ln($H_2O$)$_2$] (Ln = $Gd^{3+}$, $Eu^{3+}$). The photophysical properties of solutions of the mononuclear complex [Ru(PCP)(tpy–DTTANa$_4$)]Cl were investigated in MeOH/EtOH (1:4) and compared to those of the solutions of heterodinuclear complexes [Ru(PCP)-(tpy–DTTA)Ln($H_2O$)$_2$] (Ln = $Gd^{3+}$, $Eu^{3+}$). Rigid matrix excitation at 77 K of the ππ* level of the ruthenium chromophore in the [Ru(PCP)(tpy–DTTA)Eu($H_2O$)$_2$] complex results in a weak europium(III) emission pointing to a transfer of energy from Ru→Eu as a result of the metal-to-ligand charge-transfer (MLCT) excited state of the ruthenium component to the luminescent lanthanide ion. The excited state lifetime of the europium complex is 0.2 ms in methanol solution. In deuterated solvents, the lifetime increases to 0.4 ms, which indicates that the process is solvent-dependent as a result of the strongly coordinated molecules of water that are responsible for the quenching in nondeuterated solvents.

## Introduction

Luminescence exerted by lanthanides is a subject that attracts considerable interest because of their potential use as components,[1] luminescent probes[2] and sensors for light amplification and frequency conversion.[3] In particular, research efforts were devoted to the design of fluorophores containing the most emissive $Eu^{III}$ and $Tb^{III}$ ions. Their long-lived emission (up to ms) in the visible spectral region, positioned away from most intrinsic fluorescence of organic or biological molecules, found a wide range of applications such as probes for clinical use (e.g. fluoroimmuno assay agents) and sensors for time-resolved microscopy.[4]

The in-principal spin-forbidden luminescence of the lanthanide ions originates from transitions within the partially filled 4f orbitals.[5] Lanthanide ions with completely filled ($Lu^{III}$) or completely unfilled ($Y^{III}$ and $La^{III}$) 4f orbitals do not show any luminescence. Characteristics of the luminescence displayed by the other ions are the line-like emission, long excited state lifetimes and the fact that the low energy of the emission is hardly affected by the environment of the ions, as the filled 5s and 5p orbitals shield the electrons in the 4f levels. In other words, the effect of the ligand field is rather small. The biggest drawback of all the lanthanide ions is their low molar absorption coefficient. A way to circumvent this problem is to use chelating ligands that are able to efficiently absorb UV and/or visible light. Upon excitation, the allowed π→π* transitions lead to the population of their excited states, which can undergo efficient energy transfer to the excited states of the lanthanide ions. Such an energy transfer in most cases occurs from the triplet-excited level of the ligands. The process is often referred to as the "antenna-effect".

Several UV-absorbing aromatic chromophores containing nitrogen and/or oxygen donor atoms (e.g. β-diketonates,[6] phenantridine,[7] bipyridine,[8] terpyridine,[9] calix[4]-arenes and *m*-terphenyl moieties[10]) as well as fluorescent dyes possessing low ππ* transitions (e.g. fluorenone dyes[11] or tetrazine[12]) were used as light-harvesting units in lanthanide complexes.

Most recently, it was demonstrated that intramolecular sensitization of lanthanide(III) ions can be achieved by

coupling a lanthanide ion to a redox-active d block fragment that possesses broad d-d and intense charge-transfer (CT) transitions in the visible spectral region to efficiently collect photonic energy.[13] Intersystem crossing (ISC), followed by a multipolar d→4f energy transfer, leads to the sensitization of the lanthanides. One of the advantages of this approach relies on the multiplicity of the lowest excited state of the metal complexes (often the triplet states) and to the long-lived excited state lifetimes (ns versus hundreds of ns or several μs) of the metal complexes. The long-lived excited states of the donor d block allow for energy transfer processes that can be rather slow relative to the systems containing organic donor chromophores. Another interesting characteristic displayed by metal complexes is the presence of CT states in the visible region that can be selectively excited to produce sensitization of the lanthanide ions. Importantly, the energy of these states depends on the energy gap between the d and π* orbitals, for a MLCT state, and they can be modulated by choosing an appropriate metal ion, by changing the chelating ligand or by fine tuning the donating properties of the hosting ligands by introduction of electron-withdrawing or -releasing substituents (i.e. changing the HOMO and LUMO energies). However, an efficient electronic energy transfer in such polymetallic edifices requires orbital overlap between the d block excited LUMO and the 4f orbitals of the lanthanides.[14] Thus, the distance between the d and f units must be short and the linker must maximize the electronic interactions. This condition is difficult to realize because the preparation of suitable bridging ligands, as well as the introduction of two different metals, often represents a chemical challenge.

The field of heterodinuclear d/f block assemblies and the properties that can arise from metal–metal interactions is extensively reviewed.[13] Most of the systems reported to date contain low-spin $d^6$ pseudooctahedral chromophores ($Ru^{II}$, $Re^{I}$, $Ir^{III}$ and $Os^{II}$) or square-planar $Pt^{II}$ fragments that are connected to lanthanide ions by short heteroditopic bridging ligands (Scheme 1). The high-energy triplet level required for the sensitization of the europium(III) ions hampered the applicability of transition-metal-based antennae for photoexcitation of this lanthanide ion. However, recently De Cola and coworkers demonstrated the innovative use of cyclometallated $[Ir^{III}C_2N_4]$ chromophores to act as donors for the sensitization of a luminophoric $Eu^{III}$ ion.[15]

Scheme 1. Synthesis of the [Ru(PCP)(tpy–$NMe_2$)]Cl complex.

With the aim to study the potential applicability of stable, redox and photoactive bis(ortho)cyclometallated PCP-pincer $Ru^{II}$–terpyridine complexes as photosensitizers for $Eu^{III}$ ions, the synthesis of a new building block, [Ru(PCP)(tpy–DTTA$Na_4$)]Cl (vide infra; **5**, Scheme 2), was undertaken. Complex **5** contains the monoanionic, tridentate coordinating bisphosphanylaryl ligand $[C_6H_3(CH_2PPh_2)_2\text{-}2,6]^-$ (PCP) and the bifunctional chelator ligand [tpy–DTTA]$Na_4$ {tpy–$DTTA^{4-}$ = 4′-(2,2′:6′,2′′-terpyridine)diethylenetriamine-*N*,*N*,*N*′′,*N*′′-tetraacetate}. The rigid, chelating tpy–DTTA ligand with a $N_3O_4$ donor atom

set was employed by Merbach and coworkers in the synthesis of heterometallic complexes $[M(tpy–DTTA)_2Gd_2(H_2O)_2]$ (M = $Fe^{2+}$, $Ru^{2+}$) that were investigated as MRI contrast agents.[16,17] It is of special interest to this work to demonstrate that the organometallic [Ru(PCP)(tpy–$DTTANa_4$)]Cl building block is well-suited for anchoring trivalent ions such as $Gd^{III}$ and $Eu^{III}$ to give novel heterodinuclear complexes [Ru(PCP)(tpy–DTTA)Ln$(H_2O)_2$] {Ln = $Gd^{3+}$ (**6**), $Eu^{3+}$ (**7**)}. The luminescence properties of the prepared complexes are presented and discussed.

## Results and Discussion

### Synthesis of the Monomeric Complex [Ru(PCP)(tpy–$DTTANa_4$)]Cl (5)

The ligand tpy–DTTA was prepared following the four step reaction reported by Ruloff et al.[17] Reaction[18] of [RuCl(PCP)($PPh_3$)] (**1**, Scheme 1) with an equimolar quantity of tpy–DTTA (**3**, Scheme 2) in MeOH heated at reflux afforded the desired product [Ru(PCP)(tpy–DTTA)]Cl only in low yield (< 10%). Preparation of complex [Ru(PCP)(tpy–$NMe_2$)]Cl (**2**, 63%, Scheme 1), performed under the same experimental conditions, proved unambiguously that coordination of the tpy–DTTA ligand is not hampered by the electron-donating properties of the amino substituent at the 4′-position of the tpy moiety. Synthesis of **5** involving the use of the tpy–DTTA tetrasodium salt instead of the free tetraacid was successful, which underlies the influence of the pH on the coordination properties of the tpy unit. Thus, treatment of **1** with an equimolar amount of [tpy–DTTA]$Na_4$ (**4**, Scheme 2) in refluxing methanol gave complex **5** as a dark red solid in good yield (55%). Complex **5** is stable to air and moisture and is highly soluble in water and polar solvents. The NMR spectroscopic data for **2** and **5** were as expected for their proposed six-coordinate geometry about the ruthenium centres and are similar to those of the analogous [Ru(PCP)(tpy)]Cl complex.[18]

Single-crystals of **5** suitable for X-ray analysis could not be obtained. Instead, the molecular structure of **2** was determined, which provides information concerning the effects of a 4′-$NMe_2$ substituent on both the Ru–tpy bond distances and angles.

Suitable crystals of **2** were obtained from a $CH_2Cl_2$ solution to which *n*-hexane was slowly diffused. Figure 1 depicts the molecular structure of **2** (a selection of bond lengths and angles are given in Table 1). In the solid state of **2**, a ruthenium centre, the monoanionic *P,C,P*-coordinated bisphosphanylaryl ligand and the tridentate-coordinated tpy–$NMe_2$ ligand are present. The Ru1 atom adopts a distorted octahedral coordination environment and both the PCP-pincer and tpy–$NMe_2$ ligands are coordinated in a meridional fashion. The Ru1–C1 bond length of the PCP-pincer ligand is 2.120(2) Å, whereas the two Ru–P distances are 2.3189(6) and 2.3330(5) Å, respectively.

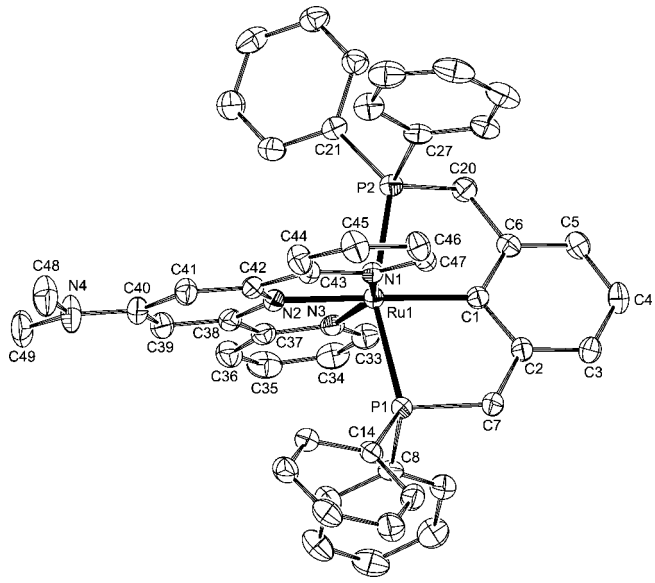

Figure 1. Displacement ellipsoid plot of **2**, drawn at the 50% probability level. Hydrogen atoms, uncoordinated chloride anions and disordered solvent molecules are omitted for clarity.

Table 1. Selected bond lengths [Å], bond angles [°] and torsion angles [°] for **2**.

| Bond Lengths [Å] | | | |
|---|---|---|---|
| Ru1–N1 | 2.0886(17) | Ru1–N2 | 2.0292(17) |
| Ru1–N3 | 2.0899(17) | Ru1–C1 | 2.120(2) |
| Ru1–P1 | 2.3189(6) | Ru1–P2 | 2.3330(5) |
| N4–C40 | 1.361(3) | N4–C48 | 1.454(3) |
| N4–C49 | 1.454(3) | | |
| **Bond Angles [°]** | | | |
| N1–Ru1–N3 | 155.85(7) | N2–Ru1–C1 | 178.40(7) |
| P1–Ru1–P2 | 157.35(2) | N1–Ru1–N2 | 78.01(6) |
| N2–Ru1–N3 | 77.86(7) | N3–Ru1–C1 | 101.25(7) |
| C1–Ru1–N1 | 102.84(7) | P1–Ru1–N1 | 89.70(5) |
| P1–Ru1–N2 | 99.37(5) | P1–Ru1–N3 | 93.16(5) |
| P1–Ru1–C1 | 79.32(6) | P2–Ru1–N1 | 91.96(5) |
| P2–Ru1–N2 | 103.07(5) | P2–Ru1–N3 | 94.49(5) |
| P2–Ru1–C1 | 78.29(6) | | |
| **Torsion Angles [°]** | | | |
| N1–C43–C42–N2 | 0.0(3) | N2–C38–C37–N3 | 0.4(3) |
| C1–C2–C7–P1 | 23.6(2) | C1–C6–C20–P2 | 24.2(2) |
| C39–C40–N4–C48 | –177.2(2) | C41–C40–N4–C49 | 175.8(2) |

The three pyridyl groups of the tpy–$NMe_2$ ligand are almost coplanar. The N1–Ru–N3 bond angle [155.85(7)°] is slightly smaller than those observed in other $Ru^{II}$–tpy complexes, which show values in the range of 156.9(5) to 159.8(1)°.[19] As commonly observed for other $Ru^{II}$–tpy complexes, geometrical constraints of the tpy backbone makes the central Ru–N2 distance [2.0292(17) Å] shorter than those of Ru–N1 [2.0886(17) Å] and Ru–N3 [2.0899(17) Å]. Analogous to what was reported for $[Ru(tpy–NMe_2)_2](PF_6)_2$,[19b] the 4′-$NMe_2$ group is approximately coplanar with the central pyridine ring of the tpy moiety [torsion angle C39–C40–N4–C48 is –177.2(2)°], which points to a planar geometry of the nitrogen atom and a high degree of π-conjugation between the $sp^2$-hybridized

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atom of the $NMe_2$ group and with the pyridine ring. This is also apparent from the short N4–C40 distance of 1.361(3) Å and both the N4–C48 and N4–C49 bonds are 1.454(3) Å in length. Comparison of these data obtained for **2** with those reported for $[Ru(tpy\text{-}NMe_2)_2](PF_6)_2$ [$C_{tpy}$–$NMe_2$ = 1.352(14) Å; cf. 1.366(5) Å for the free tpy–$NMe_2$ ligand] reveals that in **2** the conjugation between the dimethylamino group and the central pyridine ring is slightly lower. This may indicate that the σ-donor capability of the cyclometallating PCP-pincer ligand in **2** is lower than that of the terpyridine ligands in $[Ru(tpy\text{–}NMe_2)_2](PF_6)_2$.[18]

### Synthesis of the Heteronuclear Complexes [Ru(PCP)(tpy–DTTA)Ln($H_2O$)$_2$] {Ln = $Gd^{3+}$ (6), $Eu^{3+}$ (7)}

The preparation of the lanthanide(III) complexes was straightforward. Reaction of stoichiometric amounts of **5** with the corresponding $LnCl_3{\cdot}6H_2O$ salt in a MeOH/$H_2O$ mixture afforded the NaCl-free complexes [Ru(PCP)(tpy–DTTA)Ln($H_2O$)$_2$] {Ln = $Gd^{3+}$ (**6**), $Eu^{3+}$ (**7**)} as red coloured solids in good yields after several washings with cold water. Both complexes, characterized by elemental analysis, are soluble in MeOH and DMSO and insoluble in THF, chlorinated solvents, aliphatic and aromatic solvents. In agreement with the results obtained with the analogous complex $[Ru(tpy\text{–}DTTA)_2Gd(H_2O)_2]$,[16] the solubility of **6** and **7** in water is very low. In water, **6** and **7** precipitate as light orange flocculent solids that can be recovered by centrifugation and redissolved in MeOH. A straightforward explanation for their low solubility is that the lipophilic phenyl substituents on the phosphorus centres of the PCP-pincer ligand may favour the formation of aggregates that resemble those of reverse micelle-type architectures in which the {PCP–Ru–tpy} units are at the core and the {DTTA–Gd} units are at the periphery. At the periphery of these aggregates, one carboxyl group of a $[DTTA]^{4-}$ unit may bridge a second lanthanide ion of another molecule forming an oligomeric/polymeric insoluble material. The coordinated water molecules complete the coordination sphere around each lanthanide ion leading to a nine-coordinate metal centre. Importantly, the X-ray structure of the complex $[\{C(NH_2)_3\}_3Gd(TTAHA)]{\cdot}9H_2O$ {$H_6$TTAHA = [*N*-tris(2-aminoethyl)amine-*N*′,*N*′,*N*′′,*N*′′,*N*′′′,*N*′′′-hexaacetate]}[20] revealed that two pendant arms of the tripod $[TTAHA]^{6-}$ ligand and the N-donor atoms are coordinated by the donor set $N_3O_4$ to $Gd^{3+}$. The eighth and ninth coordination sites are occupied by carboxylate oxygens belonging to the "free" pendant arm of a neighbouring complex.[20] They can be replaced by two water molecules when the complex is dissolved in water.[20]

Because the NaCl containing complexes are soluble in water, it is clear that in the presence of salt such aggregates are not formed. Coordination of the $Cl^-$ ion may compete with the coordination of the carboxyl groups (Scheme 2). Owing to the negative charge on the oxygen centres, the $N_3O_4$ pocket is able to bind the $Na^+$ cation, which results in the breakdown of the insoluble aggregates. This cooperative ion–cation bonding can be a result of the "excess" coordinating ability of the DTTA unit. Recently, Merbach and coworkers discovered that gadofullurene aggregates, whose formation may be ascribed to hydrophobic forces, can be disgregated by the addition of NaCl in aqueous solutions of $Gd@C_{60}[C(COOH)_2]_{10}$ and $Gd@C_{60}(OH)_x$ ($x \approx 27$).[21] Intercalation of the salt results in the separation of the molecules and inhibits the interactions.[21]

Interestingly, the solubility of the aggregates in water could not be improved by adding excess NaCl to aqueous solutions of NaCl-free **6** and **7**. More detailed studies are required to understand the factors that determine the solubility properties of these complexes.

Coordination of the lanthanide ions to the $[DTTA]^{4-}$ unit in **6** and **7** was investigated by infrared (IR) spectroscopy in KBr matrix. Table 2 reports the data for the bands that are most sensitive to the coordination of the lanthanide ions to the polyaminocarboxylate pendant arms of the $DTTA^{4-}$ unit. The IR spectroscopic data indicate that $O_4$-chelation of the $[DTTA]^{4-}$ unit occurs in both complexes. The asymmetric vibration mode, $\nu_{as}$(CO), of the carboxylato groups is shifted to a higher wavenumber by ca. 30 $cm^{-1}$ upon lanthanide coordination relative to the $\nu_{as}$(CO) vibration mode in parent complex **5**, which demonstrates that the carboxylato oxygens in **6** and **7** are coordinated to the lanthanide ion.[22] The symmetric vibration mode, $\nu_s$(CO), also shifts to higher wavenumbers upon coordination relative to that of **5**.

### UV/Vis Absorption Spectroscopy

The electronic spectra of mononuclear **5** and heterodinuclear **6** and **7** were recorded in MeOH at room temperature (Figure 2). Absorption maxima ($\lambda_{max}$) and molar absorption coefficients ($\varepsilon_{max}$) are summarized in Table 2. Data for complexes **2** and [Ru(PCP)(tpy)]Cl[18] are included for comparison. The UV/Vis spectra of all complexes exhibit bands

Table 2. Infrared spectral and absorption data.

| Compound | $\nu_{as}$(CO)[b] [$cm^{-1}$] | $\nu_s$(CO)[b] [$cm^{-1}$] | $\lambda_{max}$[c] [nm] ($\varepsilon_{max} \times 10^{-4}$ [$M^{-1}\,cm^{-1}$]) |

in the UV region characteristic of the π→π* transition of the chelating ligands.[23] In the visible region, less intense, broad absorption bands are observed, which are assigned to singlet metal-to-ligand charge-transfer ($^1$MLCT) transitions from the dπ(Ru) orbitals to the π* orbitals of the tpy ligand.[23] The electronic spectra of **6** and **7** show only minor changes relative to **5**, which proves that the lanthanide ions do not substantially affect the electronic properties of the {(PCP)Ru(tpy)} moiety. The UV/Vis spectra of **5**–**7** recorded in water display similar spectroscopic features, but it must be noted that they tend to precipitate because of their low solubility in aqueous media. $^1$H NMR spectroscopic analysis in $CD_3OD$ of the precipitated solid obtained from an aqueous solution containing **7** proved, however, that the collected Ru–Eu complex is indeed **7**.

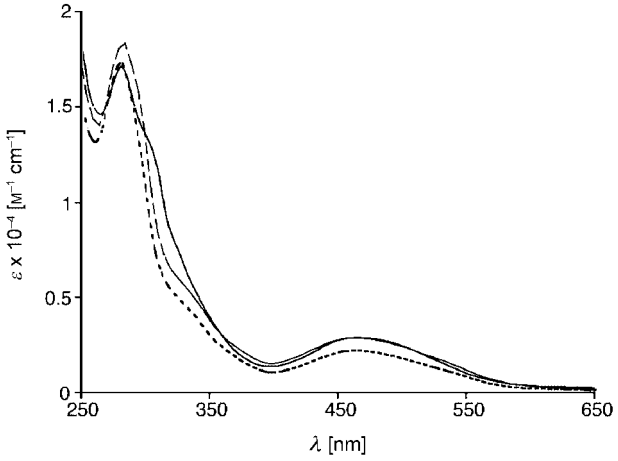

Figure 2. UV/Vis absorption spectra of mononuclear complex **5** (-----) and heterodimetallic complexes **6** (– – –) and **7** (——) measured in MeOH at 298 K.

## Emission Properties

The emissive properties of **5**–**7** were investigated in MeOH/EtOH (1:4) both at room temperature and in rigid matrix at 77 K. Emission and lifetime data recorded at 77 K are summarized in Table 3. Similar to that observed for [Ru(PCP)(tpy)]Cl and other $Ru^{II}$–tpy complexes,[24] **5** does not show emission at room temperature. This is not surprising as it is well-established that for $Ru^{II}$–tpy complexes at room temperature, a fast and efficient excited-state deactivation by nonradiative processes occurs, which is related to the population of the nonemitting metal-centred ($^3$MC) state that results from the low energy gap between the luminescent $^3$MLCT level and this state. However, **5** does not emit even at 77 K. Such a lack of emission at low temperature, contrary to what was observed for Ru–tpy analogues, could be due to the functionalization of the central pyridine ring of the tpy ligand in **5** with a tertiary amino group bearing the chelating polyaminocarboxylate units. In fact, the 4′-amino substituent is an excellent electron donor and could act as an efficient quencher both at room and low temperatures. This effect is reduced, however, once the polyaminocarboxylate unit coordinates to a lanthanide cation because the lone pair of electrons on the nitrogen atom could be involved in the coordination. In fact, at both room and low temperature, complexes **6** and **7** exhibit ruthenium-based $^3$MLCT emission at 650 and 670 nm, respectively, which is independent of the excitation wavelength. These results indicate that the coordination of the lanthanide ions indeed also involves the nitrogen atom of the amino group, which removes any possible quenching pathway. However, it cannot be excluded that some contribution to the intensity of the ruthenium-based emission also comes from the rigidification of the structure upon lanthanide ion complexation. The emission spectrum of $Ru^{II}$–$Gd^{III}$ complex **6** recorded at room temperature and at 77 K shows, aside from the ruthenium-based component, a structureless band at 440 nm (2.8 ns) and at 560 nm (200 μs). These bands were assigned on the basis of their excited lifetime to the fluorescence and phosphorescence of the ligand, respectively. It is well-known that $Gd^{III}$ promotes intersystem crossing from the singlet excited state to the corresponding triplet state (by large spin-orbit coupling induced by the heavy atom effect) and that there are no energy levels of the lanthanide ion (the energy of the lowest excited states of $Gd^{III}$ is at 32 200 $cm^{-1}$) that can accept energy from the triplet state of the ligand or from the {(PCP)Ru(tpy–DTTA)} unit. The excitation energy of the ligand-centred ππ* triplet excited state ($^3$LC) of **6**, found at 17 857 $cm^{-1}$, is still energetically suitably placed to act as a sensitizer for the luminescent $^5D_0$ of $Eu^{III}$ (17 000 $cm^{-1}$) (Figure 3, top), which allows a thermodynamically favoured energy transfer from the antenna chromophore to the lanthanide. As a result, upon excitation at 270 nm the spectrum of **7** exhibits straight lines of modest intensity that are due to transitions between the first excited state $^5D_0$ and the ground state multiplet $^7F_{1-2}$ of the $Eu^{3+}$ ion (Figure 4).

Analogously, excitation of $Ru^{II}$–$Eu^{III}$ complex **7** into the $^1$MLCT transition of the {(PCP)Ru(tpy–DTTA)} unit at 460 nm (21 739 $cm^{-1}$) produces emission from the $^5D_0$ excited state of $Eu^{III}$ (17 000 $cm^{-1}$) and from the ruthenium $^3$MLCT. The latter state, located around 14 925 $cm^{-1}$, is well below the $^5D_0$ level of europium. Thus, it can be excluded that the europium-based emission is due to an energy transfer from this state. These findings suggest that the europium emission may partly be quenched by a Eu→Ru back-energy transfer. The most likely mechanism for the sensitization of the europium ion is a partial energy transfer from the $^1$MLCT state. This mechanism would involve the direct population (upon excitation at 460 nm) of the $^1$MLCT state, fast intersystem crossing to the triplet state of the ligand, which from the Ru–Gd complex was estimated to lie between the ruthenium $^1$MLCT and the $^5D_0$ state of the europium and finally, energy transfer to the emitting lanthanide ion (Figure 3, bottom). It is interesting to note that the two excitation wavelengths (270 and 460 nm) lead to a different emission ratio between the ruthenium and the europium centres. A detailed analysis of the emissions suggests that despite the direct excitation into the ruthenium $^1$MLCT (460 nm), the ruthenium versus europium intensity is lower

| | $\lambda_{em.}$ [cm$^{-1}$][a] | $\tau$ [μs][c] | $\lambda_{em.}$ [cm$^{-1}$][a,b] | $\tau$ [ns][d] | $\lambda_{em.}$ [cm$^{-1}$][a,b] | $\tau$ [ms][e] | $\tau$ [ms][f] |
| **6** | 560(200) | | 650 (23.5) | | – | – | – |
| **7** | – | | 670 (34.1) | | 612 | 0.2 | 0.4 |

[a] Emission data recorded in MeOH/EtOH (1:4); $\lambda_{exc.}$ = 270 nm. [b] Emission data recorded in MeOH/EtOH (1:4); $\lambda_{exc.}$ = 460 nm. [c] Lifetime data recorded in MeOH/EtOH (1:4); $\lambda_{exc.}$ = 270 nm. [d] Lifetime data recorded in MeOH/EtOH (1:4); $\lambda_{exc.}$ = 460 nm. [e] Measurement performed in MeOH; $\lambda_{exc.}$ = 611 nm. [f] Measurement performed in dry $CD_3OD$; $\lambda_{exc.}$ = 611 nm. LC = ligand centred.

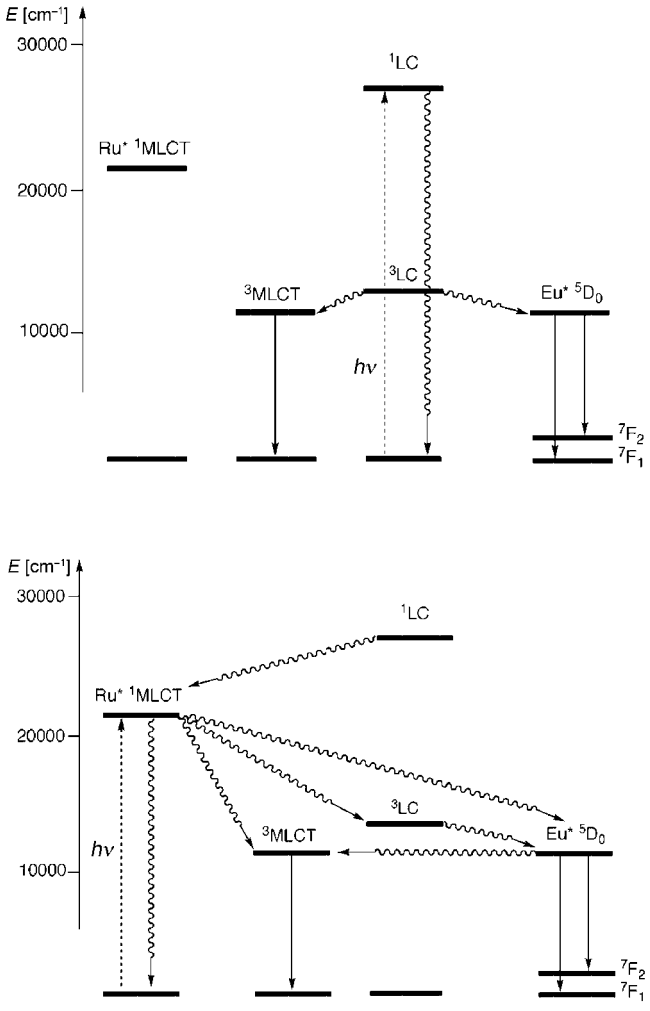

Figure 3. Energy diagram that accounts for the most important pathway for excited state deactivation of $Ru^{II}$–$Eu^{III}$ complex **7**. Top: excitation at 270 nm. Bottom: excitation at 460 nm. All radiative processes are represented with solid lines whereas the nonradiative ones are wavy.

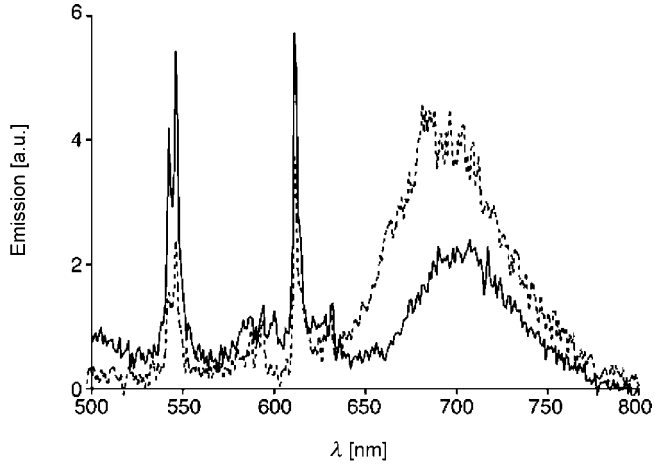

Figure 4. Emission spectral profile of $Ru^{II}$–$Eu^{III}$ complex **7** measured in MeOH/EtOH (1:4) at 77 K at $\lambda_{exc.}$ = 270 nm (– – –) and at $\lambda_{exc.}$ = 460 nm (——).

than upon excitation into the ligand-centred singlet state (270 nm). These results agree with the hypothesis that upon population of the singlet $^1$MLCT (or even of the $^3$MLCT) state, energy transfer to the $^5D_0$ of the europium is favoured more than from the ligand-localized excited states. Further support of sensitization, most likely from the $^1$MLCT, comes from the excitation spectra at low temperature. The excitation spectrum of **7** in MeOH/EtOH (1:4) at 77 K almost matches its absorption spectrum. The observed shift of the $^1$MLCT band from 460 to 400 nm is attributed to the rigid matrix, which prevents relaxation of the excited state observed at room temperature in polar solvents.

To gain more information about the quenching of the $Eu^{III}$ luminescence by its chemical environment, the lifetimes in MeOH and dry $CD_3OD$ were measured (Table 3). Monoexponential decay of the europium emission was observed in both cases. The lifetime of europium determined at 611 nm in MeOH ($\tau$ = 0.2 ms) doubled by a factor of two when the measurements were performed in dry $CD_3OD$ ($\tau$ = 0.4 ms). This solvent effect indicates that the emission intensity of the $Eu^{III}$ ion is sensitive to the number of coordinated water molecules and points to a slow exchange between the solvent and the strongly bound water molecules. The number of water molecules coordinated to the europium centre was calculated with the use of the empiric Horrocks equation[25] ($q = A\,[1/\tau(H_2O) - 1/\tau(D_2O)]$; A = 1.05 ms; uncertainty of ±0.5), which takes into account the quenching by the OH oscillators in the second coordination sphere. The estimated value of 2.5 molecules is in very good agreement with the structure of complex **7** depicted in Scheme 2, which is based on elemental analysis results. The water molecules coordinated to the lanthanide ion may exert a quenching effect on the lifetime of the $Eu^{3+}$ emission.

The Ru- and Eu-centred quantum yields ($\Phi$) for both complexes were rather low and hardly measurable, with reference to commonly used standards.

## Conclusions

The present work demonstrates that the inert organometallic building block [Ru(PCP)(tpy–DTTA$Na_4$)]Cl is able to coordinate gadolinium(III) and europium(III) ions to give the heterodimetallic complexes [Ru(PCP)(tpy–DTTA)-Ln($H_2O$)$_2$] (Ln = $Gd^{3+}$, $Eu^{3+}$) in good yield. Study of the photophysical properties shows that coordination of the $Gd^{III}$ cation to the mononuclear [Ru(PCP)(tpy–DTTA)]$^{3-}$ anion is accompanied by population of the triplet-excited state of the ligand and by an increase in the intensity of the ruthenium-based emission from the $^3$MLCT state. It was shown that the Ru–Eu complex exhibits sensitized visible emission upon excitation of the ππ* level and the {(PCP)-Ru(tpy–DTTA)} chromophoric unit at 470 nm, though only in rigid matrix at 77 K. The efficiency of energy transfer from $Ru^{II}$ to $Eu^{III}$ upon excitation into the $^3$LC and $^1$MLCT states was not determined because of the low intensity of the signals. However, emission lifetimes of the $Eu^{III}$ luminescence, measured in $CH_3OH$ and dry $CD_3OD$ solutions were found to be 0.2 and 0.4 ms, respectively, which confirms the presence of water coordinated to the metal ion.

The short lifetime of the $Eu^{III}$ luminescence was rationalized on the basis of a nonefficient d→f energy transfer and quenching by the coordinated water molecules. Sensitization of the $Eu^{III}$ luminescence combined with the stability of the organometallic {(PCP)Ru(tpy–DTTA)} unit in polar solvents and water encourage studies directed at the optimization of the properties (e.g. water solubility and thermodynamic stability under physiological conditions) of this class of complexes in order to produce efficient systems with properties suitable for practical applications, for example in bioassays. Notably, the complexes presented in this work are neutral. This is an important factor to take into account because positively or negatively charged molecules may lead to nonspecific binding in biological media.

## Experimental Section

**General:** All the experiments were carried out under a dry nitrogen atmosphere by using standard Schlenk techniques. Pentane and $Et_2O$ were distilled from sodium with benzophenone as an indicator. $CH_2Cl_2$ was dried with $CaH_2$. MeOH was dried with magnesium and used freshly distilled. Compounds **1**,[26] 4′-dimethylamino-2,2′:6′,2″-terpyridine,[19b] and **3**[17] were prepared according to literature procedures. All other reagents that were used are commercially available. $^1$H, $^{13}$C and $^{31}$P{$^1$H} NMR spectra were recorded at 298 K with a Varian AC200 or Varian Inova 300 spectrometer. Chemical shifts are reported relative to the residual solvent signal ($^1$H and $^{13}$C NMR spectra) or are externally referenced to 85% $H_3PO_4$ solution in water ($^{31}$P NMR spectra). Elemental microanalysis of mononuclear complexes **2** and **5** were performed by Dornis und Kolbe, Mikroanalytisches Laboratorium, Müllheim a. d. Ruhr, Germany. Elemental microanalysis of heterodinuclear complexes **6** and **7** were performed by Prof. Dr. H. Malissa and G. Reuter GmbH, Analytische Laboratorien, Lindlar, Germany.

**Electronic Spectroscopic Measurements:** UV/Vis absorption spectra were obtained with a Varian Cary 5000 spectrophotometer. Steady-state luminescence was measured in EtOH/MeOH (4:1) and in deuterated methanol at 77 K by using a Jobin Yvon Horiba Fluorolog 3 spectrofluorometer equipped with a Xe arc light source, a Spex R928P photomultiplier tube detector and double excitation and emission monochromators. Emission spectra were corrected for source intensity and detector response by using standard correction curves. For nanosecond time resolved lifetime measurements, a NanoLED-17 laser (sets at 295 nm) working with a maximum repletion rate of 1 MHz and a pulse <750 ps was used as an excitation source. The TBX Picosecond Photon Detection Module was used as the detector. Estimated errors are as follows: band maxima, ±2 nm; relative luminescence intensity, ±20%; lifetimes, ±10%.

**X-ray Crystal Structure Determination of 2:** $[C_{49}H_{43}N_4P_2Ru]Cl$ + disordered solvent, $Fw$ = 886.33 (Derived values do not contain the contribution of the disordered solvent molecules), red plate, $0.36 \times 0.21 \times 0.09$ mm$^3$, monoclinic, $C2/c$ (no. 15), $a$ = 34.5027(3), $b$ = 10.6866(1), $c$ = 24.4514(3) Å, $\beta$ = 93.4702(4)°, $V$ = 8999.10(16) Å$^3$, $Z$ = 8, $D_x$ = 1.308 g/cm$^3$ (Derived values do not contain the contribution of the disordered solvent molecules), $\mu$ = 0.52 mm$^{-1}$ (Derived values do not contain the contribution of the disordered solvent molecules). 67258 Reflections were measured with a Nonius Kappa CCD diffractometer with rotating anode (graphite monochromator, $\lambda$ = 0.71073 Å) up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.65 Å$^{-1}$ at a temperature of 150 K. An absorption correction based on multiple measured reflections was applied (0.77–0.95 correction range). Number of unique reflections: 10287 ($R_{int}$ = 0.0717). The structure was solved with automated Patterson Methods[27] and refined with SHELXL-97[28] against $F^2$ of all reflections. Non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were introduced in geometrically idealized positions and refined with a riding model. The crystal structure contains large voids (907.4 Å$^3$/unit cell) filled with disordered solvent molecules. Their contribution to the structure factors was secured by back-Fourier transformation by using the SQUEEZE routine of the PLATON program,[29] which resulted in 328 electrons/unit cell. 516 parameters were refined with no restraints. $R1/wR2$ [$I > 2\sigma(I)$]: 0.0332/0.0809. $R1/wR2$ [all refl.]: 0.0508/0.0874. $S$ = 1.081. Residual electron density between –0.65 and 0.51 e Å$^{-3}$. Geometry calculations and checking for higher symmetry was performed with the PLATON program.[29] CCDC-634988 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**[Ru(PCP)(tpy-$NMe_2$)](Cl) (2):** A solution of **1** (0.46 g, 0.5 mmol) in MeOH (15 mL) was added to a solution of 4′-$NMe_2$-2,2′:6′,2″-terpyridine (0.14 g, 0.5 mmol) in MeOH (5 mL). The reaction mixture was heated at reflux for 2 d. Subsequently, the solvent was evaporated in vacuo to give a red solid residue, stable to air and moisture, which was dissolved in $CH_2Cl_2$ (5 mL). Addition of pentane/$Et_2O$ (1:5) caused the precipitation of **2** as a red powder that was collected by filtration, washed with hexane and dried in vacuo. Yield: 0.29 g, 63%. $^1$H NMR (300.1 MHz, $CD_2Cl_2$): $\delta$ = 8.25 [d, $J_{H,H}$ = 7.0 Hz, 2 H, tpy(3, 3″)], 7.88 [s, 2 H, tpy(3′, 5′)], 7.47 [m, 2 H, tpy(4, 4″)], 7.21 [d, $J_{H,H}$ = 6.0 Hz, 2 H, tpy(6, 6″)], 7.13 (m, 3 H, ArH), 7.08 (vt, $J_{H,H}$ = 7.65 Hz, 4 H, *para*-H $PPh_2$), 6.93 (vt, $J_{H,H}$ = 7.8 Hz, 8 H, *ortho*-H $PPh_2$), 6.60 (m, 8 H, *meta*-H $PPh_2$), 6.42 [t, $J_{H,H}$ = 6.0 Hz, 2 H, tpy(5, 5″)], 3.98 (vt, $J_{H,P}$ = 4.0 Hz, 4 H, $CH_2$-P), 3.5 (s, 6 H, N-$CH_3$) ppm. $^{13}$C NMR (75.5 MHz, $CD_2Cl_2$): $\delta$ = 182.2 (d, $^3J_{C,P}$ = 17.2 Hz, $C_{ipso}$), 158.44, 154.3, 154.0, 153.1, 147.6 (vt, $J_{C,P}$ = 9.1 Hz, C-2,6), 134.4, 133.6 (vt, *ortho*-C $PPh_2$), 133.5 (vt, *meta*-C $PPh_2$), 130.6, 129.4 (dvt, $^1J_{C,P}$ = 74.8 Hz, $^{vt}J$ = 4.5 Hz, $C_{quat.}$ $PPh_2$), 129.2 (s, *para*-C $PPh_2$), 125.9, 122.7,

# Chelating $\eta^6$-Arene-$\eta^1$-carbene Ligands in Ruthenium Complexes

Ismail Özdemir,*[a] Serpil Demir,[a] Bekir Çetinkaya,[b] Loïc Toupet,[c] Ricardo Castarlenas,[d] Cédric Fischmeister,[d] and Pierre H. Dixneuf*[d]

**Keywords:** Ruthenium–arene / NHCs / Imidazolinylidene / Metathesis / ROMP / Polymerization

N-Heterocyclic carbene (NHC) ruthenium complexes containing a chelating NHC-$\eta^6$-arene ligand have been prepared and evaluated as precursors for ring opening metathesis polymerization (ROMP). The reaction of $[RuCl_2(p\text{-cymene})]_2$ with electron-rich olefins of the bis(imidazolinylidene) type containing at least one arylmethyl-*N* chain (aryl: 2,4,6-trimethylphenyl, 3,4,5-trimethoxyphenyl) selectively leads, upon heating, to ruthenium(II) complexes **2** containing a chelating bridged carbene $\eta^6$-arene ligand. The reaction of complexes containing an additional $ROCH_2CH_2N$ group with AgOTf leads to ionic complexes **5** with a tridentate trifunctional carbene/arene/ether ligand. The X-ray structure of $[RuCl_2\{\eta^1\text{-}CN(CH_2\{\eta^6\text{-}C_6H_2Me_3\text{-}2,4,6\})CH_2CH_2N(CH_2\{C_6H_2(OMe)_3\text{-}3,4,5\})\}]$ (**2c**) and that of the ionic ruthenium complex containing a trifunctional carbene/arene/ether ligand that provides ten electrons, $[RuCl\{\eta^1\text{-}CN(CH_2\{\eta^6\text{-}C_6H_2Me_3\text{-}2,4,6\})CH_2CH_2N(CH_2CH_2OCH_3)\}][CF_3SO_3]$ (**5e**), have been determined. The precursors **2** in the presence of AgOTf and propargyl alcohol, in order to produce an allenylidene initiator, and complexes **5** in the presence of propargyl alcohol lead to ROMP of norbornene. It is shown that initial chloride abstraction is required and that the catalyst activity is increased by using mesityl–ruthenium precursors and coordinated branched ether complexes.

## Introduction

Electron-releasing heterocyclic carbenes have been identified in the early days of their coordination chemistry as phosphane ligand equivalents.[1] Recently, sterically hindered N-heterocyclic carbenes (NHCs) of the 1,3-imidazolylidene and 1,3-imidazolinylidene type have been used to stabilize novel organometallic structures[2] and to generate new catalyst precursors especially in the field of C–C bond formation[3–5] and in alkene metathesis.[6] Their success in catalysis is largely due to their ability to increase the electron density at the metal site and to protect coordinatively unsaturated active metal species by their high steric hindering effect.

It is expected that when the NHC orientation is perturbed in space, the catalytic activity of the linked metal site should be largely modified. This influence has lead to the design of new chelating NHCs. Examples of bis(NHC)s,[7] mixed pyridine-carbene[8] and oxazoline-carbene[9] complexes have already been reported. We have recently shown the route to metal complexes containing mixed arene and carbene ligands providing eight electrons to the metal, and have demonstrated that the natural orientation of the carbene in these complexes is significantly modified.[10]

We now present new eight-electron bridged ($\eta^6$-arene-$\eta^1$-carbene)ruthenium complexes from related electron-rich bis(1,3-imidazolin-2-ylidene) olefins containing at least one arylmethylene group linked to a nitrogen atom. We also show that the resulting ($\eta^6$-arene-$\eta^1$-carbene)$RuCl_2$ complexes can be used to generate intermediates of the type [($\eta^6$-arene-$\eta^1$-carbene)RuCl]OTf and that these are catalyst precursors, associated to propargyl alcohol, for the polymerization of cyclic olefins by the ring opening metathesis polymerization (ROMP) process. The X-ray structure of the neutral complex $[RuCl_2\{\eta^1\text{-}CN(CH_2\{\eta^6\text{-}C_6H_2Me_3\text{-}2,4,6\})CH_2CH_2N(CH_2\{C_6H_2(OMe)_3\text{-}3,4,5\})\}]$ and those of two ionic ruthenium complexes containing di- or tridentate NHC ligands are also reported.

## Results and Discussion

The electron-rich olefins that contain one (**1a**–**1b**) or two (**1c**–**1d**) arylmethylene group(s) attached to a nitrogen atom[11] were treated with the ruthenium source $[RuCl_2(p\text{-cymene})]_2$[12] in toluene at 100 °C for 4 h in order to bring about complete conversion of $[RuCl_2(p\text{-cymene})]_2$ and substitution of the *p*-cymene ligand. The ruthenium complexes containing the bridged carbene-arene ligand were isolated as brown solids: **2a** (90%), **2b** (93%), **2c** (89%), **2d** (82%) (Scheme 1).

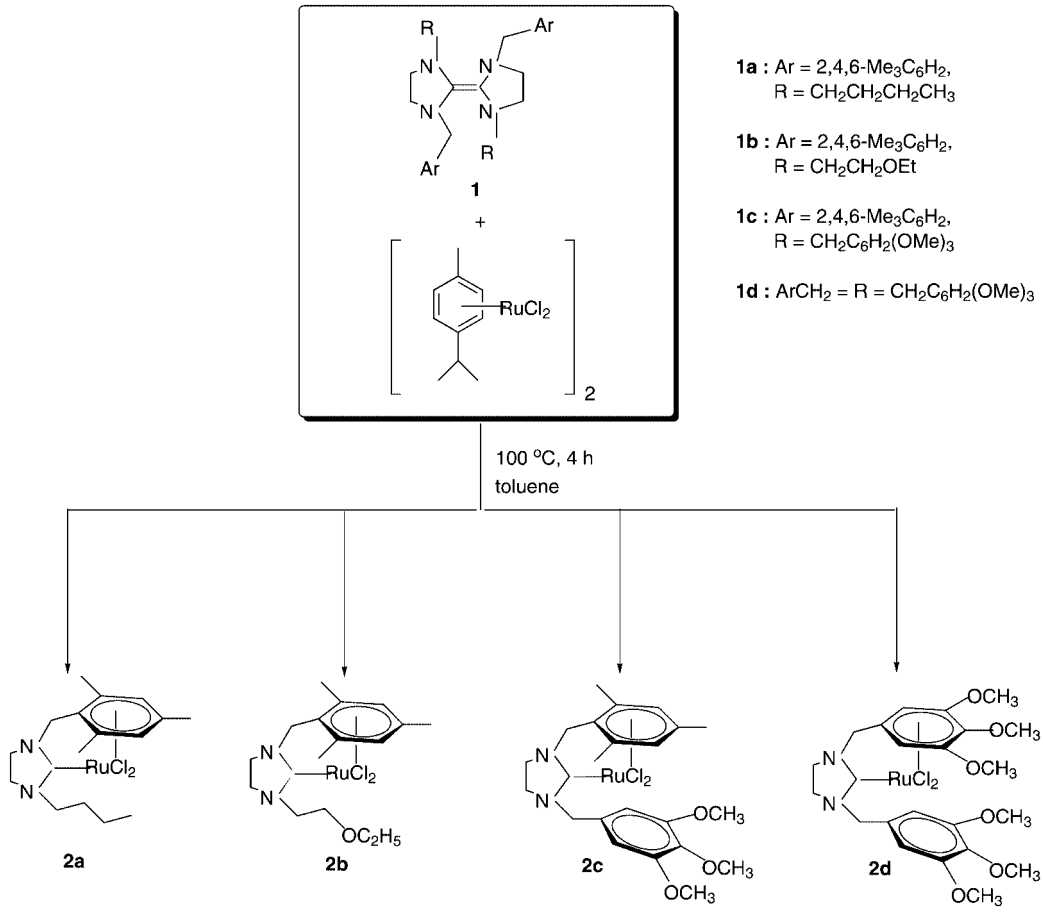

Scheme 1. Preparation of (η⁶-arene-η¹-carbene)$RuCl_2$ complexes.

The $^1H$ NMR spectra show the absence of the *p*-cymene ligand and the presence of a coordinated mesityl group in **2a**–**c** with equivalent ortho methyl groups and equivalent high-field aryl CH proton resonances at $\delta$ = 5.36–5.43 ppm (cf. $\delta$ = 6.7 ppm for **1a**–**1c**). Complex **2d** shows a coordinated aryl CH proton signal at $\delta$ = 4.78 ppm and noncoordinated aryl proton signals at $\delta$ = 6.79 ppm, whereas the aryl proton signal appears at $\delta$ = 6.90 ppm in the related olefin precursor **1d**. The coordination of the carbene carbon is evidenced by a low-field singlet in the $^{13}C$ NMR spectrum at $\delta$ = 200–201.5 ppm for **2a**–**2d**.

These syntheses show that the intramolecular displacement of the *p*-cymene ligand by the mesityl group is quantitative and rather easy. They also show (**2c**) that the coordination of the mesityl group is favoured over that of the 3,4,5-$(MeO)_3C_6H_2$ group likely because of steric repulsion between the methoxy group and the chloride ligands. The complexes **2** that do not contain an alkene-metathesis-initiating carbene are inert as catalysts for the ROMP of cyclic olefins. In order to change them into active catalysts for alkene metathesis, attempts were made to transform them into related allenylidene–ruthenium complexes according to Equation (1).[12]

$$\mathrm{LnRuCl_2} \xrightarrow[-\mathrm{AgCl}]{\mathrm{Ag^+}} \mathrm{LnRuCl}^+ \xrightarrow{\mathrm{HC{\equiv}CC(OH)Ph_2}} \mathrm{LnRuCl(=C=C=CPh_2)}^+ \quad (1)$$

Indeed, the [Ru=C=C=$CPh_2$(Cl)($PCy_3$)(*p*-cymene)]X[13] complexes were shown to be active precursors for ROMP on either thermal[14] or acid-promoted[15] transformations into indenylidene–ruthenium derivatives. The indenylidene carbene plays the role of alkene metathesis initiator in these catalyst precursors. Attempts to isolate the 16-electron ruthenium intermediates were made by the abstraction of one chloride ion from complexes **2**, before attempting allenylidene–ruthenium complex formation by addition of propargylic alcohol.

Complex **2b** and complexes **3** and **4**, analogous to **2b** and **2d**, were treated with one equivalent of AgOTf in dichloromethane at room temperature for 3 h, and the ionic complexes **5b**, **5e**, **6** were isolated in 78–85% yields (Scheme 2). The $^1H$ and $^{13}C$ NMR spectra show that the arene group remains coordinated to the metal, the (Ru=C) carbene carbon ($\delta$ = 197 ppm) is only slightly shielded relative to that in complexes **2** ($\delta$ = 200 ppm). In their $^1H$ NMR spectra at

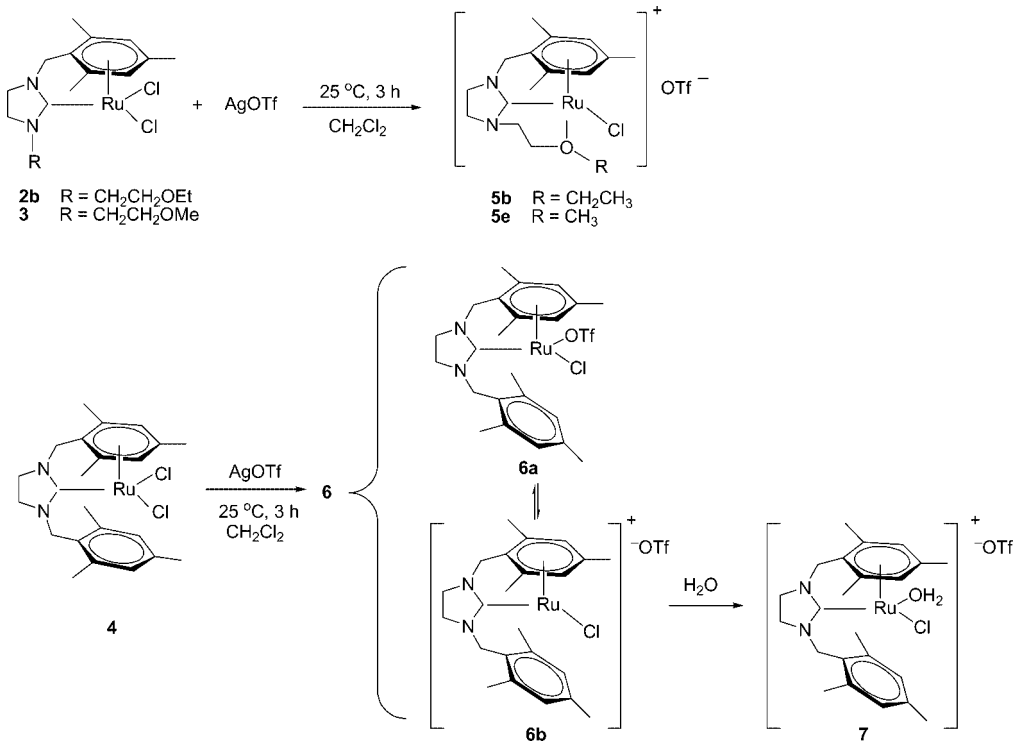

Scheme 2. Preparation of ionic mixed arene carbene ruthenium complexes **5**, **6** and **7**.

room temperature, complexes **5** show nonequivalent coordinated mesityl CH protons, which is consistent with a chiral ruthenium centre. Complex **6** is an orange solid that reacts with wet solvents to give the aquo complex **7** for which an X-ray structure has been determined (Figure 1, Table 1).[16] The nature of **6** can be understood as an 18-electron complex **6a** with a weak Ru–OTf bond in equilibrium with a 16-electron complex **6b**. The latter reacts with water in the same way that the intermediates obtained from the reaction between **2b** or **3** and AgOTf react with the ether branch to give complexes **5b** and **5e**.

## X-ray Diffraction Study of 2c and 5e

In order to evaluate the ligand modification brought about by the abstraction of one chloride ion from complexes **2**, structural studies were carried out on a neutral complex **2c**[17] and an ionic complex **5e**[18] containing a coordinating chain.

Molecular structures of **2c** and **5e** with selected data are presented in Figure 2 with Table 2, and Figure 3 with Table 3, respectively. The structure of **2c** confirms that one of the mesityl groups is coordinated to the ruthenium atom. The structure of **5e** shows that formally a chlorine atom has been displaced by the methoxy oxygen atom and that the ligand is tricoordinate, donating ten electrons to the ruthenium atom. The mesityl–ruthenium bond length is not sig-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nificantly modified: the Ru–arene distance is 1.690 Å in **2c** and 1.693 Å in **5e**. By contrast, we can observe a slightly shorter carbene C–Ru bond when the NHC is tricoordinate: 1.996(3) Å in **5e** and 2.050(2) Å in **2c**.

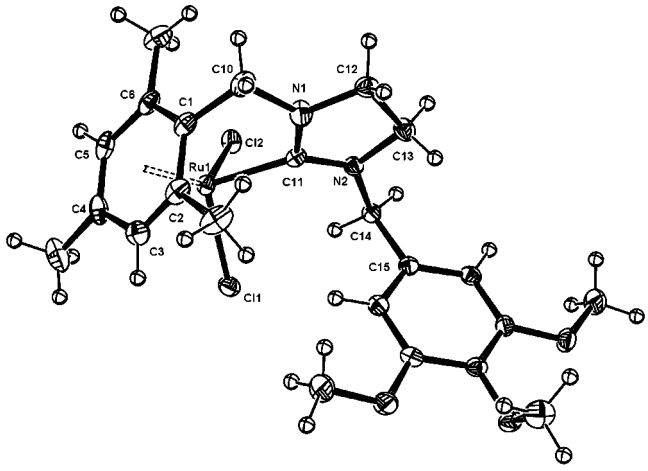

Figure 2. Molecular structure of **2c** showing 50% ellipsoid probability. A dichloromethane molecule is omitted for clarity.

## ROMP Promoted by Complexes 2 and 5

ROMP of norbornene was studied under two sets of conditions by taking into account that complexes **2** do not react with norbornene in the absence or presence of propargylic alcohol. Thus, the catalysts were generated directly from the precursors **2** by in situ treatment first with AgOTf in PhCl followed by the addition of propargylic alcohol, without isolation of the intermediate of type **5**. The resulting allenylidene or indenylidene intermediate could not be isolated, consequently the ROMP reaction was performed in situ as soon as the propargylic alcohol was added to complexes **5**, and chlorobenzene was used as solvent (conditions [a], Table 4). An analogously successful approach for the in situ generation of alkene metathesis catalysts was used for the ring closing metathesis (RCM) of dienes.[10] Another polymerization procedure was used by combining the isolated ionic complexes **5** and propargylic alcohol, $HC{\equiv}CCPh_2OH$, in order to generate the allenylidene intermediate and then the indenylidene initiator in situ

Table 4. ROMP of norbornene in PhCl catalyzed by various N-heterocyclic carbene-ruthenium intermediates in situ generated from **2** and **5**.

| Catalyst precursor | Conditions | Yield [%] | $10^{-3} \times M_n$[d] | PDI[e] | *cis* [%][f] |

(conditions [b], Table 4). Precursor **2a**, under conditions [a], led to similar yields at 80 °C and room temperature, but higher molecular mass was obtained at room temperature. This indicates that a lower number of active initiators are produced at room temperature. Precursor **2b**, in the absence of AgOTf and propargylic alcohol, leads to very low activity, thus showing that the initial halide abstraction from complexes **2** is required to trigger efficient polymerization. Precursor **2c** gives a higher yield (94%) after 15 min at 80 °C, but with a broad polydispersity. Complexes **2a** and **2d** afford similar yields and polydispersity at 80 °C. However, at room temperature, precursors **2a** and **2c** with a coordinated mesityl group are much more active than **2d** with the coordinated trimethoxybenzyl group, thus showing the influence of the nature of the coordinated arene.

The ROMP, performed directly with ionic complexes **5b** and **5e**, shows that the most efficient precursor is **5b** both at room temperature and at 80 °C with high yield (>95%) and good polydispersity (PDI = 1.5). The comparison of this result to that obtained from **2b** alone indicates that the preliminary chloride ion abstraction by silver salt treatment is essential to obtain high yield and low polydispersity. The nature of the coordinated OR group, e.g. OEt or OMe, has a strong influence. The precursor **5b** (OEt) exhibits a much higher activity than **5e** (OMe).

## Conclusions

The above results show that bis(imidazolinylidene) olefins containing an arylmethyl-*N* group always displace the *p*-cymene to give ($\eta^1$-carbene-$\eta^6$-arene)$RuCl_2$ complexes upon reaction with $[RuCl_2(p\text{-cymene})]_2$. Upon chloride abstraction, these complexes containing an additional $ROCH_2CH_2$–N group lead to the tridentate carbene/arene/ether ionic complexes **5b** and **5e**. The mixed arene-NHC precursors **2** are ROMP initiators after chloride abstraction and reaction with propargylic alcohol to initially produce allenylidenes. The most active precursors **2a**, **2b** and **5b**, operate at room temperature.

## Experimental Section

Syntheses were carried out by using standard Schlenk techniques under an inert argon atmosphere with previously dried solvents. The starting complex $[RuCl_2(p\text{-cymene})]_2$ was prepared by known methods.[12] Electron-rich olefins **1** were prepared according to Lappert's procedure.[11] Infrared spectra were recorded by using KBr pellets in the range 400–4000 $cm^{-1}$ with an ATI UNICAM 2000 spectrometer. $^1H$ NMR (300 MHz) and $^{13}C$ NMR (75.5 MHz) spectra were recorded with a Bruker AM 300 WB FT spectrometer, and the chemical shifts were referenced to $CDCl_3$. Microanalyses were performed by the TÜBITAK analysis centre in Ankara.

A**[$RuCl_2${$\eta^1$-CN($CH_2${$\eta^6$-$C_6H_2Me_3$-2,4,6})$CH_2CH_2N(CH_2CH_2CH_2CH_3)$}] (2a):** A solution of the electron-rich olefin **1a** (284 mg, 0.55 mmol) and the ruthenium complex $[RuCl_2(p\text{-cymene})]_2$ (306 mg, 0.5 mmol) in degassed toluene (15 mL) was heated at 100 °C for 4 h to give **2a** in 90% yield (387 mg), after extraction into and crystallization from dichloromethane/hexane (5:20). $^1H$ NMR (300.13 MHz, $CDCl_3$): $\delta$ = 0.81 (t, $J$ = 7.4 Hz, 3 H, $CH_2CH_2CH_2CH_3$), 1.21 (hex., $J$ = 7.4 Hz, 2 H, $CH_2CH_2CH_2CH_3$), 1.42 (m, 2 H, $CH_2CH_2CH_2CH_3$), 2.11 (s, 6 H, 2 $CH_3$ Mes), 2.23 (s, 3 H, $CH_3$ Mes), 3.53 (t, $J$ = 7.6 Hz, 2 H, $CH_2CH_2CH_2CH_3$), 3.75 (s, 4 H, $NCH_2CH_2N$), 4.07 (s, 2 H, $NCH_2$ Mes), 5.38 (s, 2 H, CH Mes) ppm. $^{13}C$ NMR (75.47 MHz, $CDCl_3$): $\delta$ = 14.5 ($CH_2CH_2CH_2CH_3$), 17.2 (2 $CH_3$ Mes), 17.7 ($CH_2CH_2CH_2CH_3$), 20.1 ($CH_3$ Mes), 31.2 ($CH_2CH_2CH_2CH_3$), 47.4 ($CH_2CH_2CH_2CH_3$), 48.3 and 49.5 ($NCH_2CH_2N$), 50.0 ($NCH_2$ Mes), 88.8, 94.2, 99.4 and 100.6 ($CH_2C_6H_2Me_3$-2,4,6), 200.1 (Ru=C) ppm. $C_{17}H_{26}Cl_2N_2Ru$ (430.08): calcd. C 47.44, H 6.09, N 6.51; found C 47.47, H 6.02, N 6.39. M.p. 256–257 °C.

**[$RuCl_2${$\eta^1$-CN($CH_2${$\eta^6$-$C_6H_2Me_3$-2,4,6})$CH_2CH_2N(CH_2CH_2OCH_2CH_3)$}] (2b):** A solution of the electron-rich olefin **1b** (302 mg, 0.55 mmol) and the ruthenium complex $[RuCl_2(p\text{-cymene})]_2$ (306 mg, 0.5 mmol) in degassed toluene (15 mL) was heated at 100 °C for 4 h to give **2b** in 93% yield (415 mg) after extraction into and crystallization from dichloromethane/hexane (5:20). $^1H$ NMR (300.13 MHz, $CDCl_3$): $\delta$ = 1.07 (t, $J$ = 6.36 Hz, 3 H, $CH_2CH_2OCH_2CH_3$), 2.07 (s, 6 H, 2 $CH_3$ Mes), 2.21 (s, 3 H, $CH_3$ Mes), 3.35 (q, $J$ = 6.20 Hz, 2 H, $CH_2CH_2OCH_2CH_3$), 3.49 and 3.73 (s, 4 H, $NCH_2CH_2N$), 3.76 (m, 2 H, $CH_2CH_2OCH_2CH_3$), 3.94 (t, $J$ = 4.76 Hz, 2 H, $CH_2CH_2OCH_2CH_3$), 4.07 (s, 2 H, $NCH_2$ Mes), 5.36 (s, 2 H, CH Mes) ppm. $^{13}C$ NMR (75.47 MHz, $CDCl_3$): $\delta$ = 17.1 (2 $CH_3$ Mes), 15.7 ($CH_3$ Mes), 17.7 ($CH_2CH_2OCH_2CH_3$), 47.4 and 49.7 ($NCH_2CH_2N$), 48.6 ($NCH_2$ Mes), 52.3 ($CH_2CH_2OCH_2CH_3$), 66.4 ($CH_2CH_2OCH_2CH_3$), 72.8 ($CH_2CH_2OCH_2CH_3$), 88.8, 94.2, 99.3 and 100.8 ($CH_2C_6H_2Me_3$-2,4,6), 200.5 (Ru=C) ppm. $C_{17}H_{26}Cl_2N_2ORu$ (446.38): calcd. C 45.74, H 5.87, N 6.27; found C 45.71, H 5.90, N 6.25. M.p. 213–214 °C.

**[$RuCl_2${$\eta^1$-CN($CH_2${$\eta^6$-$C_6H_2Me_3$-2,4,6})$CH_2CH_2N(CH_2{C_6H_2(OMe)_3-3,4,5})$}] (2c):** A solution of the electron-rich olefin **1c** (420 mg, 0.55 mmol) and the ruthenium complex $[RuCl_2(p\text{-cymene})]_2$ (306 mg, 0.5 mmol) in degassed toluene (15 mL) was heated at 100 °C for 4 h to give **2c** in 89% yield (493 mg) after extraction into and crystallization from dichloromethane/hexane (5:20). $^1H$ NMR (300.13 MHz, $CDCl_3$): $\delta$ = 2.10 (s, 6 H, 2 $CH_3$ Mes), 2.26 (s, 3 H, $CH_3$ Mes), 3.52 (t, $J$ = 10.38 Hz, 2 H, $NCH_2CH_2N$), 3.67 (t, $J$ = 10.37 Hz, 2 H, $NCH_2CH_2N$), 3.74 [s, 3 H, $NCH_2C_6H_2(OMe)_3$-3,4,5], 3.76 [s, 6 H, $NCH_2C_6H_2(OMe)_3$-3,4,5], 4.05 (s, 2 H, $NCH_2$ Mes), 4.66 [s, 2 H, $NCH_2C_6H_2(OMe)_3$-3,4,5], 5.43 (s, 2 H, CH Mes), 6.67 [s, 2 H, $NCH_2C_6H_2(OMe)_3$-3,4,5] ppm. $^{13}C$ NMR (75.47 MHz, $CDCl_3$): $\delta$ = 17.3 (2 $CH_3$ Mes), 17.9 ($CH_3$ Mes), 47.6 and 49.9 ($NCH_2CH_2N$), 48.5 ($NCH_2$ Mes), 54.2 [$NCH_2C_6H_2(OMe)_3$-3,4,5], 56.9 [$NCH_2C_6H_2(OMe)_3$-3,4,5], 61.5 [$NCH_2C_6H_2(OMe)_3$-3,4,5], 89.5, 94.8, 99.9 and 101.5 ($CH_2C_6H_2Me_3$-2,4,6), 107.7, 133.3, 138.4 and 154.2 [$NCH_2C_6H_2(OMe)_3$-3,4,5], 200.9 (Ru=C) ppm. $C_{23}H_{30}Cl_2N_2O_3Ru$ (554.47): calcd. C 46.49, H 4.87, N 4.52, S 5.17; found C 46.54, H 4.79, N 4.58, S 5.20. M.p. 242–243 °C.

**Polymerization of Norbornene by [(Arene)(NHC)RuCl$_2$)] 2:** Ruthenium complex **2** ($1.5\times10^{-5}$ mol), AgOTf ($1.5\times10^{-5}$ mol), HC≡C-CPh$_2$(OH) ($1.7\times10^{-5}$ mol), and norbornene ($4.5\times10^{-3}$ mol) were mixed in dry chlorobenzene (5 mL) under an argon atmosphere. The suspension was stirred at the desired temperature for the required time. After reaction, the resulting viscous mixture was dissolved in $CHCl_3$ (20 mL) containing 2,6-di-*tert*-butyl-4-methylphenol (BHT) (0.1%) as a radical scavenger and ethyl vinyl ether (0.3 mL). The solution was poured into methanol (300 mL) to precipitate the polymer, which was collected by filtration, dried under vacuum, and characterized by $^1$H and $^{13}$C NMR spectroscopy. Average molecular weights were determined by using GPC calibrated with polystyrene standards.

**Polymerization of Norbornene by [(Arene)(NHC)RuCl)]OTf 5:** Ruthenium complex, **5** ($1.5\times10^{-5}$ mol), HC≡C–CPh$_2$(OH) ($1.7\times10^{-5}$ mol), and norbornene ($4.5\times10^{-3}$ mol) were mixed in dry chlorobenzene (5 mL) under an argon atmosphere. The suspension was stirred at the desired temperature for the required time. After reaction, the resulting viscous mixture was treated as for polymerization with complexes **2**.

[16] A few crystals suitable for X-ray structure determination were taken out of an NMR solution. Crystal data for compound **7**: $RuClC_{23}H_{32}ON_2$, $CF_3SO_3$, $CHCl_3$, $M_r$ = 757.46, triclinic, $P\bar{1}$, $a$ = 8.9960(4), $b$ = 12.9478(5), $c$ = 14.1936(6) Å, $\alpha$ = 95.034(3), $\beta$ = 89.390(3), $\gamma$ = 111.241(3)°, $V$ = 1534.6(1) Å$^3$, $Z$ = 2, $D_X$ = 1.639 Mg m$^{-3}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å, $\mu$ = 9.80 cm$^{-1}$, $F$(000) = 768, $T$ = 120(1) K. The sample (0.21 × 0.16 × 0.14 mm) was studied with an Oxford Diffraction Xcalibur Saphir 3 diffractometer with graphite monochromatized Mo-$K_\alpha$ radiation. The data collection[19] ($2\theta_{max}$ = 54°, omega scan frames via 0.75° omega rotation and 20 s per frame, index ranges: $0 \le h \le 11$, $-16 \le k \le 16$, $-18 \le l \le 18$) gives 11443 reflections. The data leads to 6541 independent reflections, 5524 of which with $I > 2.0\sigma(I)$. The structure was solved with SIR-97,[20] which reveals the non-hydrogen atoms of the molecule. After anisotropic refinement, many hydrogen atoms may be found with a Fourier Difference. The whole structure was refined with SHELXL97[21] by the full-matrix least-squares techniques (use of $F$ square magnitude; x, $y$, $z$, $\beta_{ij}$ for Ru, Cl, C, O, S, F and N atoms, $x$, $y$, $z$ in riding mode for H atoms; 361 variables and 5524 observations with $I > 2.0\sigma(I)$; calcd. $w = 1/[\sigma^2(F_o^2) + (0.064P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$ with the resulting $R$ = 0.032, $R_w$ = 0.098 and $S_w$ = 1.137, $\Delta\rho < 0.8$ e. Å$^{-3}$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[22] CCDC-290024 contains the supplementary crystallographic data of compound **7** for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[17] Crystal data for compound **2c**, CCDC : $C_{23}H_{30}N_2O_3Cl_2Ru$, $CH_2Cl_2$, $M_r$ = 639.39, orthorhombic, *Pbca*, $a$ = 15.1773(1), $b$ = 14.9059(1), $c$ = 23.7686(3) Å, $V$ = 5377.2(1) Å$^3$, $Z$ = 8, $D_X$ = 1.580 Mg m$^{-3}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å, $\mu$ = 10.09 cm$^{-1}$, $F$(000) = 2608, $T$ = 110 K. The crystal (0.32 × 0.22 × 0.20 mm) was studied with a NONIUS Kappa CCD with graphite monochromatized Mo-$K_\alpha$ radiation. The cell parameters are obtained with Denzo and Scalepack[23] with 10 frames (psi rotation: 1° per frame). The data collection[24] ($2\theta_{max}$ = 54°, 297 frames via 1.5° omega rotation and 22 s per frame, index ranges: $0 \le h \le 19$, $0 \le k \le 19$, $0 \le l \le 30$) gave 52555 reflections. The data reduction with Denzo and Scalepack[23] led to 6170 independent reflections [5345 with $I > 2.0\sigma(I)$]. The structure was solved with SIR-97,[20] which revealed the non-hydrogen atoms of the structure. After anisotropic refinement, many hydrogen atoms may be found with a Fourier Difference. The whole structure was refined with SHELXL97[21] by the full-matrix least-squares techniques (use of $F$ square magnitude; x, $y$, $z$, $\beta_{ij}$ for Ru, Cl, O, N and C atoms, x, $y$, $z$ in riding mode for H atoms; 307 variables and 5345 observations with $I > 2.0\sigma(I)$; calcd. $w = 1/[\sigma^2(F_o^2) + (0.044P)^2 + 7.15P]$ where $P = (F_o^2 + 2F_c^2)/3$ with the resulting $R$ = 0.032, $R_w$ = 0.082 and $S_w$ = 1.053, $\Delta\rho < 0.70$ e Å$^{-3}$. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[22] CCDC-249335 contains the supplementary crystallographic data of compound **2c** for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Ruthenium(II) Complexes of Thiosemicarbazones: The First Water-Soluble Complex with pH-Dependent Antiproliferative Activity

**Sanja Grguric-Sipka,[a][‡] Christian R. Kowol,[a] Seied-Mojtaba Valiahdi,[a] Rene Eichinger,[a] Michael A. Jakupec,[a] Alexander Roller,[a] Sergiu Shova,[a][‡‡] Vladimir B. Arion,*[a] and Bernhard K. Keppler*[a]**

**Keywords:** Antitumour agents / Ruthenium / N,S ligands / X-ray diffraction

Two ruthenium(II) complexes of 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone ($HL^1$) and phenanthrenequinone thiosemicarbazone ($HL^2$), namely $[Ru^{II}Cl(L^1)(PPh_3)_2]$ (**1**) and $[Ru^{II}Cl(L^2)(PPh_3)_2]$ (**2**), have been synthesised and characterised by IR, UV/Vis and NMR spectroscopy, electrospray mass spectrometry, cyclic voltammetry and X-ray crystallography. In addition, the X-ray crystal structure of $[Ru^{III}Cl_2(L^2)PPh_3]$·dmso·$1.25H_2O$ (**3**·dmso·$1.25H_2O$) is reported. The reaction of $[Ru^{II}Cl_2(dmso)_4]$ with $HL^1$ and 1,3,5-triaza-7-phosphaadamantane (PTA) gives the highly water-soluble complex $[Ru^{II}Cl(L^1)(HPTA)_2]Cl_2$·$C_2H_5OH$·$H_2O$ (**4**·$C_2H_5OH$·$H_2O$) ($S_{25°C} \geq 250$ mg/mL), which has been fully characterised. Complex **4** shows strong antiproliferative effects in low micromolar concentrations in the ovarian carcinoma cell line 41M ($IC_{50}$ = 0.87 μM) and more moderate activity in the breast cancer cell line SK-BR-3 ($IC_{50}$ = 39 μM). The activity of the compound is 6.5- and 5.4-times higher at pH = 6.0 than at pH = 7.4 in the non-small cell lung cancer cell line A549 and the colon carcinoma cell line HT-29 ($GI_{50}$ = 24 and 8.0 μM at pH = 6.0 for A549 and HT-29, respectively).

## Introduction

Thiosemicarbazones form a class of mixed hard-soft oxygen/nitrogen-sulfur chelating ligands that show a variety of coordination modes in metal complexes. The thiosemicarbazone can act as a monodentate ligand that binds to the metal ion through the sulfur atom[1] or as a bidentate ligand that coordinates to the metal ion through the sulfur atom and one of the nitrogen atoms of the hydrazine moiety to form a four- or a five-membered metallacycle.[2,3] The coordination capacity of thiosemicarbazones can be increased by using for their preparation aldehydes or ketones containing additional functional group(s) in position(s) suitable for chelation.[4] Beside their interesting coordination chemistry, thiosemicarbazones have a wide pharmacological spectrum of activity; their potential has been recognised to include antitumour, antiviral, antibacterial, antifungal and antimalarial properties.[5] The enzyme ribonucleotide reductase has been identified as a principal target, and thiosemicarbazones are among the most potent known inhibitors of this enzyme.[6,7] The inhibition of ribonucleotide reductase prevents the conversion of ribonucleotides into deoxyribonucleotides, which results in the impairment of DNA synthesis and repair.[8] The applicability of thiosemicarbazones as antitumour agents has been explored for over half a century,[9] the first compound of this class to enter phase II clinical trials as an antineoplastic agent being 3-aminopyridine-2-carboxaldehyde thiosemicarbazone (3-AP, triapine).[10,11] The effect of certain metals on the biological activity of thiosemicarbazones has been receiving considerable attention recently.[12–14] Although a large number of reports are available on the chemistry and biological activity of copper(II), cobalt(III), gallium(III), iron(III), platinum(II) or palladium(II) thiosemicarbazonates,[15–18] there are only a few reports on antitumour activity of the corresponding ruthenium complexes.[19,20] Interest in ruthenium was stimulated by phase I clinical trials of two ruthenium complexes, namely $(H_2im)$[*trans*-$Ru^{III}Cl_4$(Him)(dmso)] (NAMI-A; Him = imidazole) and $(H_2ind)$[*trans*-$Ru^{III}Cl_4(Hind)_2$] (KP1019; Hind = indazole), the first as an antimetastatic drug and the second as an anticancer agent against primary tumours and metastases, and in particular colon carcinomas.[21,22]

The very high cytotoxicity of our recently synthesised gallium(III) and iron(III) complexes with $N^4$-substituted α-N-heterocyclic thiosemicarbazones[23] in vitro together with the above-mentioned interest in ruthenium chemistry prompted us to synthesise novel ruthenium complexes of

thiosemicarbazones. We chose two ligands, 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone ($HL^1$), which shows very high cytotoxicity in the low nanomolar range and the ability to destroy the tyrosyl radical of mouse ribonucleotide reductase R2 protein,[23] and phenanthrenequinone thiosemicarbazone ($HL^2$), which is known to have antiproliferative activity in the low micromolar range.[24] The presence of the phenanthrene moiety in $HL^2$ renders this ligand capable of DNA intercalation in addition to its potential ribonucleotide reductase inhibiting properties.

Ruthenium(II) complexes with two monoanionic tridentate thiosemicarbazones are neutral species that are sparingly soluble or even insoluble in aqueous media.[25] Water solubility is required to assay the cytotoxicity in vitro, therefore we focused on the synthesis of complexes with a 1:1 metal/ligand stoichiometry. A literature survey showed that phosphorus-containing species and, in particular, triphenylphosphane often serve as ancillary ligands to complete the coordination sphere of ruthenium upon coordination of a thiosemicarbazone.[26–28] This prompted us to consider 1,3,5-triaza-7-phosphaadamantane (PTA) as a co-ligand as it is known to endow metal complexes with aqueous solubility and solubility in polar organic solvents.[29a–29e,30] The (PTA)ruthenium compounds reported so far that show antiproliferative activity are organometallic compounds derived from [Ru($\eta^6$-*p*-cymene)$Cl_2$(PTA)],[29a] some of which have been found to cause pH-dependent DNA damage.

Herein we report on the synthesis, spectroscopic characterisation and X-ray diffraction structures of three novel complexes and the pH-dependent in vitro antiproliferative activity of the first thiosemicarbazone/PTA mixed ruthenium(II) complex with high aqueous solubility.

## Results and Discussion

The reaction of [$Ru^{II}Cl_2(PPh_3)_3$] with either 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone ($HL^1$) in dry dichloromethane or phenanthrenequinone thiosemicarbazone ($HL^2$) in absolute ethanol afforded the complexes *trans*-[$Ru^{II}Cl(L^1)(PPh_3)_2$] (**1**) and *trans*-[$Ru^{II}Cl(L^2)(PPh_3)_2$] (**2**) in 41 and 80% yield, respectively. In one case the synthesis of **2** was accompanied by marginal formation of a side product, a few red crystals of which separated first on crystallisation from dimethyl sulfoxide. An X-ray diffraction study (see Supporting Information) showed that this minor species has the composition [$Ru^{III}Cl_2(L^2)PPh_3$] (**3**). Repeated crystallisation of **2** from dimethyl sulfoxide did not produce any significant amounts of **3**, thereby preventing its full characterisation. The complex *trans*-[$Ru^{II}Cl(L^1)(HPTA)_2$]$Cl_2$ (**4**) was prepared by the reaction of 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone and PTA with [$Ru^{II}Cl_2(dmso)_4$] in absolute ethanol (Figure 1). Complex **4** appears to be the first reported ruthenium(II) complex that contains a thiosemicarbazone and 1,3,5-triaza-7-phosphaadamantane (PTA) as ligands. Complexes **1** and **2** are well soluble in $CHCl_3$ but sparingly soluble in ethanol and methanol and insoluble in water, whereas complex **4** is very soluble in water ($S_{25°C} \geq 250$ mg/mL), dmso, ethanol and methanol.

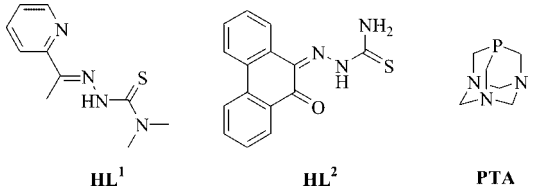

Figure 1. Structures of the ligands used.

### Spectroscopic Characterisation

Complexes **1** and **4** show two well-resolved MLCT transitions in their electronic absorption spectra. The bands at 476 (**1**) and 450 nm (**4**) can be attributed to an Ru(4dπ)→π*(py) MLCT transition, whereas the bands at 379 (**1**) and 378 nm (**4**) can be assigned to an Ru(4dπ)→π*(imine) transition.[25] The strong absorptions at 597 and 470 nm in complex **2** are assignable to a combination of MLCT bands and $Ru^{II}$ d–d bands, and the high-energy absorptions in the ultraviolet region for **1**, **2** and **4** can be attributed to intraligand π–π* transitions.

The ESI mass spectrum of complex **1** recorded in the positive mode contains a strong peak at *m*/*z* = 847 attributed to the $[M - Cl]^+$ ion and a second remarkable signal at *m*/*z* = 585 assigned to $[M - Cl - PPh_3]^+$. Complex **2** shows a low intensity peak at *m*/*z* = 942 due to the $[M + H]^+$ ion and more intense peaks at *m*/*z* = 964 and 980 attributed to $[M + Na]^+$ and $[M + K]^+$ ions, respectively. An intense signal at *m*/*z* = 906 corresponds to $[M - Cl]^+$, while that at *m*/*z* = 644 corresponds to $[M - Cl - PPh_3]^+$. The ESI mass spectrum of complex **4** contains peaks at *m*/*z* = 673 and 695, which were assigned to $[M - H]^+$ and $[M - 2H + Na]^+$, respectively. A signal at *m*/*z* = 637 is due to $[M - Cl]^+$, while that at *m*/*z* = 538 is due to $[M - H - HPTA + Na]^+$. The observed isotopic patterns fit well with the theoretical isotopic distributions.

The $^1H$ NMR spectrum of complex **1** in $CDCl_3$ shows signals attributable to the pyridine ring protons of coordinated thiosemicarbazone at $\delta$ = 8.62, 7.36, 6.86 and 6.47 ppm. The lack of any NH signal indicates the deprotonation of the ligand. Proton resonances due to the $PPh_3$ ligand are found between $\delta$ = 7.54 and 7.14 ppm. The $^{31}P$ NMR spectrum shows one resonance at $\delta$ = 30.42 ppm, thus indicating the equivalence of the two $PPh_3$ ligands in **1**. This signal is shifted only slightly downfield from that for *trans*-[RuCl(pabh)$(PPh_3)_2$] (Hpabh is a Schiff base derived from 2-pyridinecarbaldehyde and benzoylhydrazine) at $\delta$ = 27.62 ppm ($CDCl_3$).[31] Complex **2** in [$D_6$]dmso shows aromatic proton signals for the phenanthrenequinone moiety between $\delta$ = 7.19 and 8.89 ppm. The signal integrations and multiplicities are in agreement with the proposed formula, although exact assignment is not possible due to extensive overlap with resonances originating from the triphenylphosphane ligands. A singlet that can be assigned to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the $NH_2$ group was found at $\delta$ = 8.13 ppm. The hydrazinic NNH proton signal at $\delta$ = 14.42 ppm present in the $^1H$ NMR spectrum of the metal-free thiosemicarbazone is absent in the spectrum of the complex, thus indicating the deprotonation of the thiosemicarbazone ligand upon complexation. As for **1**, the $^{31}P$ NMR spectrum of **2** is very simple, displaying one resonance at $\delta$ = 27.36 ppm due to the equivalence of the two $PPh_3$ ligands.

Complex **4** in [$D_6$]dmso shows a signal at $\delta$ = 9.87 ppm that can be assigned to the protons of the two quaternary nitrogen atoms in the PTA ligands. As for **1**, the absence of a further NH resonance indicates the presence of a monoanionic thiosemicarbazone ligand in **4**. The pyridine ring protons occur as multiplets at $\delta$ = 8.77, 7.85, 7.67 and 7.33 ppm. The singlet due to the $N(CH_3)_2$ group is found at $\delta$ = 3.33 ppm together with the water signal. The proton resonances of the methylene groups bridging the nitrogen atoms in PTA appear as a singlet at $\delta$ = 4.62 ppm, while the resonances due to the $PCH_2N$ protons are observed as a multiplet at $\delta$ = 3.71 ppm. The $^{31}P$ NMR spectrum of **4** exhibits one singlet resonance at $\delta$ = –38.13 ppm for the two equivalent PTA ligands {cf. $\delta$ = –33.45 ppm for the two equivalent phosphorus atoms in $[RuCl(PTA)_2([9]aneS_3)]$-$CF_3SO_3$}.[29e]

The electrochemical properties of complexes **1**, **2** and **4** have been studied by cyclic voltammetry in dmso solution (0.2 M [$n$Bu$_4$N][$BF_4$]) using a glassy carbon working electrode. The cyclic voltammograms of all complexes show a single one-electron oxidation wave at $E_{1/2}$ = 0.59, 0.71 and 0.73 V vs. NHE for **1**, **2** and **4**, respectively, which can be assigned to $Ru^{II}/Ru^{III}$ electron transfer. The peak-to-peak separation ($\Delta E_p$) of 70–90 mV in complexes **1** and **2** is almost independent of the scan rate. In addition, the equality of the anodic peak current ($i_{pa}$) and the cathodic peak current ($i_{pc}$) indicates a reversible electron-transfer. The $Ru^{II}/Ru^{III}$ oxidation wave in complex **4** shows $\Delta E_p$ values of 110–130 mV in the range of scan rates from 50 to 1000 mV s$^{-1}$ and $i_{pa}/i_{pc}$ ratios close to 1. Deviations from the ideal Nernstian value of 59 mV are well documented for this type of complexes.[26] Complex **2** shows two additional irreversible reduction waves with $E_{p/2}$ values of –0.78 and –1.27 V which can be ascribed to the reduction of the thiosemicarbazone ligand. The more positive oxidation response (+140 mV) in **4** in comparison to that in **1** is in line with the poorer electron-donating ability of PTA compared to $PPh_3$.[32]

## Crystal Structures

The thiosemicarbazone ligand in **1** acts as a monoanion $(L^1)^-$ and occupies a meridional plane about the ruthenium ion, coordinating to it through pyridine nitrogen atom N1, imine nitrogen atom N2 and the thiolate sulfur atom S (Figure 2). A Cl ligand completes the square plane around the ruthenium ion. The thiosemicarbazone ligand is planar. All non-hydrogen atoms of $(L^1)^-$ lie in the crystallographic symmetry plane together with the central metal ion and the chlorido ligand. Two *trans*-positioned triphenylphosphane ligands in **1** complete the octahedron. A comparison of the bond lengths in the coordination polyhedron of **1** with those in $[Ru(HL)(PPh_3)_2Cl]^+$ [HL = 2-acetylpyridine 4-(4-tolyl)thiosemicarbazone][26] shows that the Ru–Cl bond in **1** [2.4812(13) Å] is significantly longer than in $[Ru(HL)(PPh_3)_2Cl]^+$ [2.459(2) Å]. The interatomic Ru–N1 and Ru–N2 distances of 2.092(4) and 1.976(4) Å, respectively, are similar to those in $[Ru(HL)(PPh_3)_2Cl]^+$ [2.085(5) and 1.984(5) Å, respectively], whereas the Ru–S and Ru–P bonds are shorter in **1** {2.3725(13) and 2.3747(8) Å compared to 2.386(2) and 2.399(1) Å in $[Ru(HL)(PPh_3)_2Cl]^+$}. The distribution of electron density over the thiosemicarbazide moiety in the compared complexes is different, thereby indicating the prevailing double-bond character of C8–S in $[Ru(HL)(PPh_3)_2Cl]^+$ [1.707(6) Å vs. 1.751(5) Å in **1**]. The N3–C8 bond length in **1** [1.335(7) Å] is equal within 3σ to that in $[Ru(HL)(PPh_3)_2Cl]^+$ [1.359(7) Å]. The molecules of **1** interact weakly with each other through C–H···Cl contacts, as shown in Figure S1 (Supporting Information).

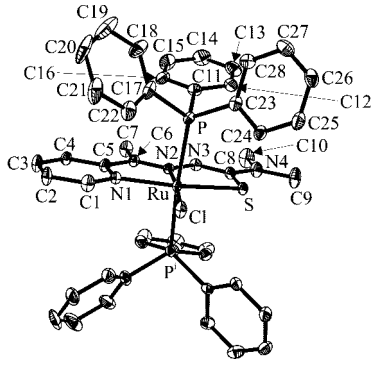

Figure 2. Perspective view of the molecule of $[Ru^{II}(L^1)(PPh_3)_2Cl]$ (**1**) with atom labelling scheme. Thermal ellipsoids are drawn at the 50% probability level, and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru–N1 2.092(4), Ru–N2 1.976(4), Ru–S 2.3725(13), Ru–Cl 2.4812(13), Ru–P1 2.3747(8), S–C8 1.751(5), C8–N3 1.335(7) Å; P1–Ru–P1$^i$ 175.08(6). Symmetry code: $^i$: $-x$, $y$ + 1, $z$.

The ruthenium(II) ion in **2** is coordinated by the thiosemicarbazone anion $(L^2)^-$ through carbonyl oxygen atom O, imine nitrogen atom N1 and thiolate sulfur atom S and by the chlorido ligand in the equatorial plane. In addition, two triphenylphosphane ligands are bound in axial positions (Figure 3). Relevant bond lengths and angles are given in the legend to Figure 3. A comparison of the bond lengths of the thiosemicarbazone moiety in complex **2** with those of the metal-free thiosemicarbazone[24] shows that the S–C15 bond [1.707(4) Å] in **2** is longer than in $HL^2{\cdot}CH_3CN$ [1.681(2) Å], whereas the C15–N2 bond [1.348(9) Å] in **2** is similar to that in $HL^2{\cdot}CH_3CN$ [1.365(3) Å]. The coordination of $HL^1$ and $HL^2$ (Figure 1) to the ruthenium(II) ion in their deprotonated forms in **1** and **2**, respectively, is also indicated by the absence of counterions. The ligand in **2** has also undergone a configurational change from the (*E*) configuration found in the metal-free state[24] to a (*Z*) configuration relative to the C15–N2 bond. The phenanthrene

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

moieties in the crystal structure of **2** are stacked pairwise in an offset manner with an interplanar separation between the benzene rings (C9–C14) and (C9–C14)′ of around 3.32 Å; the distance between their centroids (X···X′) is 3.857 Å (Figure S2). The hydrogen bond between N3 as proton donor and the Cl atom of the neighbouring molecule as proton acceptor, with an N3···Cl contact of 3.490 Å, is also worthy of note.

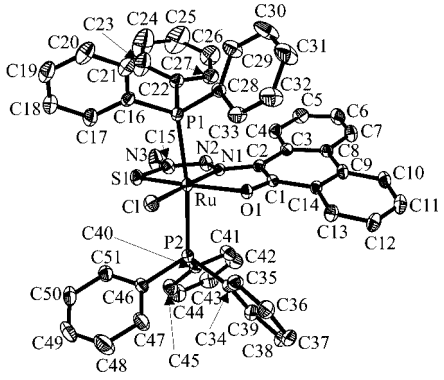

Figure 3. Perspective view of the molecule of $[Ru^{II}(L^2)(PPh_3)Cl]$ (**2**) with atom numbering scheme. Thermal ellipsoids are drawn at the 30% probability level, and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru–O 2.096(2), Ru–N1 1.936(3), Ru–S 2.3608(14), Ru–P1 2.3932(10), Ru–P2 2.3824(10), Ru–Cl 2.4528(9), S–C15 1.707(4), C15–N2 1.348(9) Å; P1–Ru1–P2 170.36(3), O–Ru–S 160.96(6), N1–Ru–Cl 171.31(8).

The structure of complex **4** is shown in Figure 4. The coordination polyhedron of the ruthenium ion can be described as a distorted octahedron. As in **1**, the metal ion is coordinated in the equatorial plane by the thiosemicarbazone monoanion through pyridine nitrogen atom N1, imine nitrogen atom N2 and the thiolate sulfur atom S, and by the chlorido ligand Cl1. Both axial positions are occupied by two PTA ligands, which are bound to the ruthenium ion through phosphorus atoms P1 and P2. The Ru–$P_{(PTA)}$ separations [Ru–P1 2.3019(19), Ru–P2 2.2958(19) Å] are in the range expected for Ru–PTA complexes.[30,33] The Ru–Cl1 bond [2.4571(16) Å] is normal for Ru–PTA complexes containing chlorido co-ligands.[34] In addition, the two PTA ligands are protonated at N5 and N8, respectively, and form hydrogen bonds to Cl2 and Cl3. The S–C8 bond [1.771(6) Å] is longer than the C–S bond found in 2-acetylpyridine *N*-pyrrolidinylthiosemicarbazone [1.692(4) Å][35] and also longer than in $HL^1$ [1.720(2) Å].[36] The lengthening of this bond in **4**, along with the N2–N3 and N3–C8 bonds, indicates a significant electron delocalisation over the thiosemicarbazide moiety.[37] The Ru–N2 distance [1.979(5) Å] is slightly shorter than the Ru–N1 distance [2.081(5) Å], presumably because of steric reasons. The association of a proton with N5 of one PTA and of another one with N8 of the second PTA ligand makes the corresponding atoms good proton donors, and they are consequently involved in hydrogen bonding to the two chloride anions Cl2 and Cl3, respectively (see Figure 4).

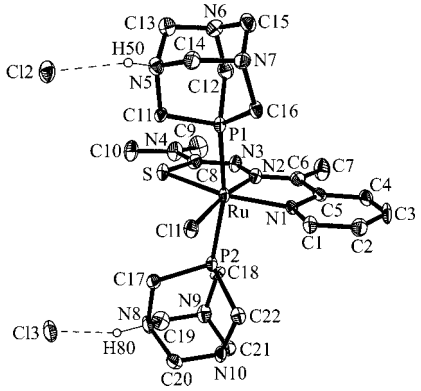

Figure 4. Perspective view of the complex $[Ru^{II}(L^1)(HPTA)_2Cl]Cl_2$ (**4**) with atom numbering scheme. Thermal ellipsoids are drawn at the 50% probability level, and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru–N1 2.081(5), Ru–N2 1.979(5), Ru–S 2.3707(17), Ru–Cl1 2.4571(16), Ru–P1 2.3019(19), Ru–P2 2.2958(19), S–C8 1.771(6), C8–N3 1.303(8); P1–Ru–P2 166.05(5).

### Determination of the p$K_a$ Value

The pH of a 0.005 M aqueous solution of $[Ru^{II}Cl(L^1)(HPTA)_2]Cl_2$ (**4**) is about 3. $^{31}P$ NMR spectra of an aqueous ($D_2O$) solution of **4** were recorded at different pH* (= pD) values (from 2.11 to 11.40). We suppose that the complex exists predominantly in the monoprotonated form ($\delta$ = –37.03 ppm) at pH* = 2.11, whereas the signal of the neutral complex (with unprotonated PTA ligands) is found at $\delta$ = –48.45 ppm at pH* = 11.40 (see Figure S4, Supporting Information). At pH = 3.82 the main signal is shifted to $\delta$ = –40.02 ppm and a second, minor (< 4%) $^{31}P$ signal emerges at $\delta$ = –41.30 ppm, which increases gradually in intensity and shifts to higher frequency more sluggishly than the first peak (Figure S4). At the end of the titration (pH* = 11.40) the intensity of the second signal is 50% of the main signal. Moreover, the intensity of this second resonance increases with time. The appearance of this second $^{31}P$ resonance can be suppressed by addition of an excess of NaCl to a solution of **4** in $D_2O$. Repeated titration of a 0.15 M NaCl solution of **4** in $D_2O$ with NaOD from pH* = 3.29 to 10.30 showed that the second peak now appears first at pH = 5.16 and remains of very low intensity (< 5%) until the end of the titration (pH = 10.30). These results show that a solution of complex **4** in $D_2O$ in the pH range indicated above undergoes both protolytic reactions and hydrolysis of the $Ru^{II}$–Cl bond.

A p$K_a$ value of 4.46 for one of the axially coordinated PTA ligands in **4** was obtained from a $^{31}P$ NMR pH* titration curve in $D_2O$ (Figure 5). This value is higher than that (3.13) found from $^{31}P$ NMR titration of the coordinated PTA in $[RuCl_2(PTA)(\eta^6\text{-}p\text{-cymene})]$,[38] but lower than those reported for metal-free PTA (5.63[29c] and 6.0[39]).

The evolution of the absorption spectrum of **4** in 0.15 M NaCl aqueous solution on increasing the pH from 2.88 to 9.30 is given as Supporting Information (Figure S5) and is characterised by an isosbestic point at 445 nm.

### Antiproliferative Activity in Cancer Cell Lines

The antiproliferative effects of compound **4** were first examined in the human cancer cell lines 41M and SK-BR-3 by means of a colourimetric microculture assay (MTT assay) with continuous exposure at pH = 7.4 for 96 h. Concentration-effect curves are presented in Figure 6A. The compound exerts strong antiproliferative effects in low micromolar concentrations in the ovarian carcinoma cell line 41M ($IC_{50}$ = 0.87 μM), while the breast cancer cell line SK-BR-3 is much less sensitive ($IC_{50}$ = 39 μM). The $IC_{50}$ values obtained in the non-small cell lung cancer cell line A549 and the colon carcinoma cell line HT-29 (Table 1) suggest that these cells are rather insensitive, but a direct comparison with the other two cell lines is not appropriate because of the different exposure times. However, experiments on the pH dependency of the antiproliferative effects, with exposure at either pH = 6.0 or 7.4 for 24 h, followed by incubation in a drug-free medium (pH = 7.4) for a further 72 h revealed that the activity of the compound is 6.5- and 5.4-times higher under slightly acidic conditions in A549 and HT-29 cells, respectively, with $IC_{50}$ values shifted towards lower micromolar concentrations (Figure 6B, Table 1). The extent of this activation clearly exceeds that of cisplatin (3.2- and 2.2-fold in A549 and HT-29 cells, respectively), while the effects of oxaliplatin are independent of the pH under the same experimental conditions.[40]

This pronounced pH dependency suggests that compound **4** may be activated preferentially in a slightly acidic environment. Such acidic conditions occur in the extracellular fluid of solid tumours as a consequence of constitutive upregulation of glycolysis (independent of oxygen supply), which is a hallmark of malignant progression that confers a growth advantage to tumour cells under the conditions of intermittent hypoxia resulting from hypovascularisation.[41,42] The altered pH gradients across cell membranes in acidic tumour regions affect the cellular drug accumulation and cytotoxicity of weakly basic chemotherapeutics such as anthracyclines, vinca alkaloids or mitoxantrone and

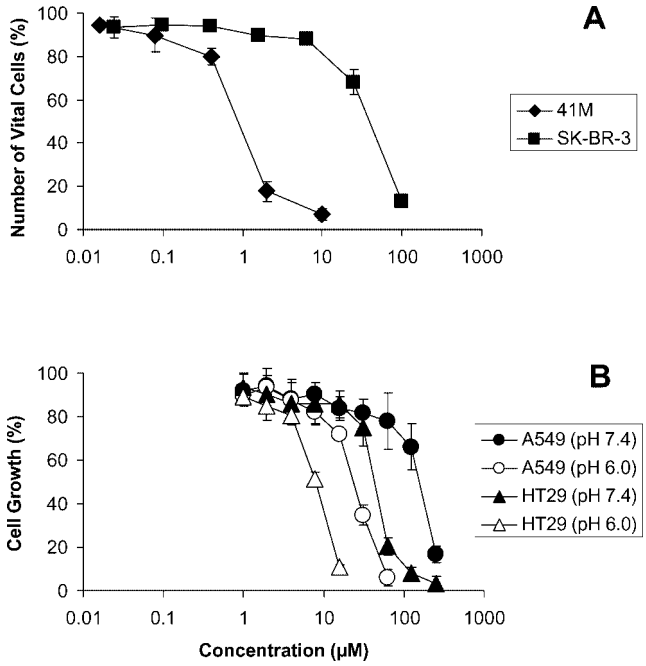

Figure 6. Antiproliferative effects of compound **4**, as determined by an MTT assay. A) Concentration-effect curves in 41M and SK-BR-3 cells (continuous exposure for 96 h). B) Concentration-effect curves (corrected for differences in growth kinetics of the corresponding controls) in A549 and HT-29 cells at pH = 7.4 and 6.0 (24 h exposure), indicating enhanced cytostatic effects in a slightly acidic medium.

Table 1. Antiproliferative effects of compound **4** in four human cancer cell lines and the pH dependency in two of these cell lines.

| Cell line | Exposure time [h] | $IC_{50}$ [μM][a] pH = 7.4 | $GI_{50}$ [μM][b] pH = 7.4 | pH = 6.0 | $GI_{50}$ ratio |
|---|---|---|---|---|---|
| 41M (ovary) | 96 | 0.87±0.09 | | | |
| SK-BR-3 (breast) | 96 | 39±5 | | | |
| A549 (lung) | 24 | 186±16 | 156±18 | 24±1 | 6.5 |
| HT29 (colon) | 24 | 47±4 | 43±4 | 8.0±0.4 | 5.4 |

[a] 50% inhibitory concentrations in the MTT assay. [b] 50% growth inhibition (corrected for differences in growth kinetics of the corresponding controls) after exposure for 24 h in the MTT assay. All values are the means with standard deviations obtained from at least three independent experiments.

may therefore contribute to the reduced chemosensitivity of acidic tumours.[43–45] On the other hand, weakly acidic drugs such as chlorambucil are more cytotoxic when the extracellular pH is slightly acidic.[44,46] These observations are consistent with ion trapping, according to which weak electrolytes that are not transported actively concentrate in the compartment where their ionised fraction is larger. Ion trapping has also been discussed as a possible explanation for the pH-dependent cellular uptake and cytotoxicity of the metal complex cisplatin, the hydrolysis products of which are in a pH-dependent equilibrium.[47] Therefore, the importance of appropriate $pK_a$ values for the design of antitumour drugs has been emphasised.[48] Furthermore, the development of prodrugs that are selectively activated in an acidic environment is being pursued as a strategy to in-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

crease the therapeutic index by effectively killing tumour cells without impairing normal tissues.[49]

Some (PTA)ruthenium(II) complexes related to the compounds presented here have been found to induce DNA damage in isolated bacterial plasmids only at pH values less than about 7.0[50] and to exert a stronger cytotoxicity in breast cancer cells than in a non-malignant mammary gland cell line, while analogues containing methylated PTA, which is not protonated in acidic solution, do not show this kind of selectivity.[38] PTA has therefore attracted attention as a ligand that apparently confers tumour selectivity to (arene)ruthenium(II) compounds, which has been tentatively attributed to activation by protonation (assuming that the protonated form is actually the active species). While it has not been reported whether the cytotoxicity of arene–$Ru^{II}$–PTA complexes is pH-dependent, our findings with compound **4**, which exerts stronger antiproliferative effects at pH values encountered in solid tumours (6.0) than at pH values prevailing in normal tissues (7.4), support this notion. The presence of two PTA ligands in compound **4** may be favourable from this point of view and may constitute a basis for further attempts to increase tumour-selective activity. However, the pronounced decrease of p$K_a$ (from 5.6 to 3.0–3.3) resulting from the coordination of PTA to ruthenium(II) in arene–$Ru^{II}$–PTA complexes renders the possibility that ion trapping accounts for any pH-dependent cytotoxicity of this type of compounds rather unlikely[38] and raises the need for other explanations that might be completely different from previous assumptions.

In contrast to arene–$Ru^{II}$–PTA complexes, the presence of the biologically active thiosemicarbazone ligand may play a role in the activity of complex **4** even though this ligand is tightly bound to the metal centre in a tridentate manner. However, even a partial release of 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone should result in a tremendous increase in cytotoxicity because its $IC_{50}$ values of 0.22 and 2.7 nM in 41M and SK-BR-3 cells, respectively,[23] are three to four orders of magnitude below those of complex **4**. If a release of the thiosemicarbazone ligand accounts for the effects of compound **4**, it must be assumed to occur only to a very small degree.

## Conclusions

Following a known approach based on using P-containing derivatives as co-ligands, a novel highly water-soluble ruthenium(II) thiosemicarbazonate complex, namely $[Ru^{II}(L^1)(HPTA)_2Cl]Cl_2$, has been prepared. This, to the best of our knowledge, is the first ruthenium(II) complex with mixed thiosemicarbazone/PTA ligands to be isolated and characterised by X-ray crystallography. The complex shows pH-dependent antiproliferative activity in vitro in micromolar concentrations against the non-small cell lung cancer cell line A549 and the colon carcinoma cell line HT29.

## Experimental Section

**General:** All chemicals were obtained from commercial suppliers and were used without further purification. Phenanthrenequinone thiosemicarbazone,[24] 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone,[51] 1,3,5-triaza-7-phosphaadamantane (PTA)[52] and *cis*-$[RuCl_2(dmso)_4]$[53] were prepared according to published procedures. Elemental analyses were carried out at the Institute of Physical Chemistry of the University of Vienna with a Carlo Erba microanalyser. Infrared spectra were recorded with a Bruker Vertex 70 FTIR spectrometer as KBr pellets (4000–400 $cm^{-1}$). Electronic spectra were obtained with a Perkin–Elmer Lambda 650 UV/Vis spectrophotometer. Electrospray ionisation mass spectrometry was carried out in methanol with a Bruker Esquire 3000 instrument (Bruker Daltonics, Bremen, Germany). Expected and experimental isotope distributions were compared. The NMR spectra were recorded with a Bruker DPX 400 instrument using standard Bruker pulse programs. Chemical shifts for $^1H$ NMR spectra were referenced to the residual $^1H$ present in deuterated dmso and $CHCl_3$, respectively, and $^{31}P$ NMR to external $H_3{}^{31}PO_4$ in $D_2O$. Cyclic voltammograms were measured in a three-electrode cell using a 0.2-mm-diameter glassy carbon working electrode, a platinum auxiliary electrode and an $Ag|Ag^+$ reference electrode containing 0.1 M $AgNO_3$, the potential of which was corrected using an internal standard redox couple of ferrocenium/ferrocene. Measurements were performed at room temperature using an EG & G PARC 273A potentiostat/galvanostat. Deaeration of solutions was accomplished by passing a stream of argon through the solution for 5 min prior to the measurements and then maintaining a blanket of argon over the solution during the measurement. The potentials were measured in 0.2 M $[nBu_4N][BF_4]$/dmso, with $[Fe(\eta^5\text{-}C_2H_5)_2]$ ($E_{1/2}{}^{ox}$ = +0.68 V vs. NHE)[54] as internal standard, and are quoted relative to NHE.

**$[RuL^1Cl(PPh_3)_2]$ (1):** A suspension of 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone (22.3 mg, 0.1 mmol) in dry dichloromethane (5 mL) was added to a solution of $[RuCl_2(PPh_3)_3]$ (95.8 mg, 0.1 mmol) in dry dichloromethane (5 mL) and the resulting mixture was refluxed under argon for 4 h. The solution was concentrated to about 5 mL, and allowed to stand at +4 °C overnight. The product was obtained as green-brown crystals, which were filtered off, washed with *n*-hexane and dried in vacuo. Yield: 36 mg (41%). $C_{46}H_{43}ClN_4P_2RuS\cdot0.5CH_2Cl_2$ (924.86): calcd. C 60.39, H 4.80, N 6.06, S 3.47; found C 60.61, H 4.80, N 6.30, S 3.57. ESI-MS: *m*/*z* = 847 $[M - Cl^-]^+$, 585 $[M - Cl^- - PPh_3]^+$. (s), 1434 (s), 1190 (s), 743 (m), 694 (s) and 519 (s, $\nu_{[Ru(PPh_3)_2]}$) $cm^{-1}$. $^1H$ NMR (400.13 MHz, [D$_6$]dmso): $\delta$ = 8.88 (dd, $^3J_{H,H}$ = 8.3, $^4J_{H,H}$ = 1.8 Hz, 1 H, phq), 8.43 (dd, $^3J_{H,H}$ = 7.8, $^4J_{H,H}$ = 1.0 Hz, 1 H, phq), 8.35 (d, $^3J_{H,H}$ = 8.6 Hz, 1 H, phq), 8.26 (m, 1 H, phq), 8.13 (s, 2 H, $NH_2$), 7.65 (m, 1 H, phq), 7.52–7.49 (m, 12 H, $PPh_3$), 7.26–7.19 (m, 9 H, $PPh_3$ and phq), 7.14–7.11 (m, 12 H, $PPh_3$) ppm. $^{31}P\{^1H\}$ (162.00 MHz, [D$_6$]dmso): $\delta$ = 27.36 [s, 2 P, $(PPh_3)_2$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 597 nm (9080) , 470 (14580), 320 (13600), 268 (49330 $M^{-1}cm^{-1}$) nm. **Method b). [RuL$^2$Cl(PPh$_3$)$_2$]:** Phenanthrenequinone thiosemicarbazone (28.2 mg, 0.1 mmol) in dry ethanol (5 mL) and triphenylphosphane 76.0 mg (0.29 mmol) in dry ethanol (5 mL) were added to [$RuCl_2$(dmso)$_4$] (48.0 mg, 0.1 mmol) in dry ethanol (5 mL) and the mixture refluxed under argon for 5 h. The black solid was filtered off, washed with absolute ethanol and *n*-hexane and dried in vacuo. Yield: 79 mg (80%). $C_{51}H_{40}ClN_3OP_2RuS$ (941.42): calcd. C 65.07, H 4.28, N 4.46; found C 64.78, H 4.43, N 4.38. Single crystals suitable for X-ray data collection were obtained from a chloroform solution of **2** saturated with *n*-hexane.

**[RuL$^1$Cl(HPTA)$_2$]Cl$_2$·C$_2$H$_5$OH·H$_2$O (4·C$_2$H$_5$OH·H$_2$O):** A solution of 2-acetylpyridine $N^4$,$N^4$-dimethylthiosemicarbazone (22.3 mg, 0.1 mmol) in dry ethanol (5 mL) was added to a suspension of *cis*-[$RuCl_2$(dmso)$_4$] (44.8 mg, 0.1 mmol) in dry ethanol (5 mL), and the resulting mixture was heated at 65 °C under argon for 1 h to yield a red solution. PTA (31.6 mg, 0.2 mmol) was then added and heating was continued for a further 4 h. The green-yellow side product was separated by filtration and the red solution concentrated to about 1 mL and allowed to stand at +4 °C overnight. The red crystals formed were filtered off, washed with cold dry ethanol and dried in vacuo. Yield: 7 mg (10%). $C_{22}H_{39}Cl_3N_{10}P_2RuS{\cdot}C_2H_5OH{\cdot}H_2O$ (809.14): calcd. C 35.63, H 5.85, N 17.31, S 3.96; found C 35.09, H 5.40, N 17.49, S 4.07. ESI-MS: *m*/*z* = 673 [M – $H^+$]$^+$, 695 [M – 2 $H^+$ + $Na^+$]$^+$, 637 [M – 2 $H^+$ – $Cl^-$]$^+$, 538 [M – 2 $H^+$ – PTA + $Na^+$]$^+$. IR: $\tilde{\nu}$ = 1531 [w, $\nu_{(C=N)}$], 1503 (w), 1397 (s), 1315 (s), 768 (m), 566 (m) $cm^{-1}$. $^1H$ NMR (400.13 MHz, [D$_6$]dmso): $\delta$ = 9.87 (s, 2 H, NH), 8.77 (d, $^3J_{H,H}$ = 5.3 Hz, 1 H, py), 7.85 (m, 1 H, py), 7.67 (d, $^3J_{H,H}$ = 8.1 Hz, 1 H, py), 7.33 (m, 1 H, py), 4.62 (s, 12 H, $NCH_2N$), 3.78–3.67 (m, $^3J_{H,P}$ = 10.6 Hz, 12 H, $NCH_2P$), 3.33 [s, 6 H, $N(CH_3)_3$, below the water signal], 2.42 (s, 3 H, $CH_3$) ppm. $^{31}P\{^1H\}$ (162.00 MHz, [D$_6$]dmso): $\delta$ = –38.13 [s, 2 P, $(HPTA)_2$]. UV/Vis ($H_2O$): $\lambda_{max}$ ($\varepsilon$) = 522 sh (870), 450 (5460), 378 sh (18320), 355 (25910), 280 sh (9220), 222 sh (38930 $M^{-1}cm^{-1}$) nm. Red crystals of composition **4**·2$H_2O$ of X-ray diffraction quality were obtained by recrystallisation from ethanol.

**Determination of the p$K_a$ Values:** The pH* titration experiment was carried out in $D_2O$ at 298 K using an Ecoscan pH 6 (Eutech) pH meter equipped with a micro-combination pH electrode (Orion) for NMR tubes calibrated with buffer solution at pH = 4, 7 and 10. The pH* values were adjusted with diluted DCl and NaOD. The p$K_a$ value of the coordinated PTAs in **4** was determined by plotting the change in chemical shift of the $^{31}P$ signal against pH* and fitting the curve to the modified Henderson–Hasselbalch equation[55] ($\delta_{obs}$, $\delta_{HA}$ and $\delta_A$ are the chemical shifts for the observed, protonated and deprotonated species, respectively), by using the program KALEIDAGRAPH,[56] with the assumption that the observed values are weighted averages according to the populations of the protonated and deprotonated species.

$$\delta_{obs} = \frac{\delta_{HA} + \delta_A \cdot 10^{(pH-pK_a)}}{1+10^{(pH-pK_a)}}$$

The p$K_a$* value determined from the titration curve in Figure 5 was corrected by using the equation p$K_a$ = 0.929 p$K_a$* + 0.42 suggested by Krezel and Bal,[57] (with p$K_a$* as the p$K_a$ value determined in $D_2O$) for conversion of protonation constants, measured in $D_2O$ into constants valid for $H_2O$ solutions. The error is estimated as ±0.04 pK units for two $^{31}P$ resonances, and the mean value was taken.

**X-ray Crystallography:** X-ray diffraction measurements were performed with an X8 APEXII CCD diffractometer. Single crystals of **1**–**4** were positioned at 40, 40, 40 and 37.5 mm from the detector, respectively, and 1187, 1438, 1328 and 1320 frames were measured each for 70, 120, 50 and 10 s with a 1° scan-width. The data were processed using the SAINT software package.[58] The structures were solved by direct methods and refined by full-matrix least-squares techniques. Non-hydrogen atoms were refined with anisotropic displacement parameters. H atoms were inserted in geometrically calculated positions and refined with a riding model. The following computer programs were used: structure solution: SHELXS-97;[59] refinement: SHELXL-97;[60] molecular diagrams: ORTEP;[61] computer CPU: Pentium IV; scattering factors were taken from the literature.[62] Crystal data, data collection parameters, and structure refinement details are given in Table 2. CCDC-630689 (**1**·3$CH_2Cl_2$), -630686 (**2**), -630687 (**3**·dmso·1.25$H_2O$) and -630688 (**4**·2$H_2O$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Cell Lines and Culture Conditions:** Human 41M (ovarian carcinoma) and SK-BR-3 (mammary carcinoma) cells were kindly provided by Lloyd R. Kelland (CRC Centre for Cancer Therapeutics, Institute of Cancer Research, Sutton, UK) and Evelyn Dittrich (General Hospital, Medical University of Vienna, Austria), respectively. Human A549 (non-small cell lung cancer) and HT29 (colon carcinoma) cells were kindly provided by Brigitte Marian (Institute of Cancer Research, Medical University of Vienna, Austria). Cells were grown in 75-$cm^2$ culture flasks (Iwaki/Asahi Technoglass, Gyouda, Japan) as adherent monolayer cultures in complete culture medium [Minimal Essential Medium (MEM) supplemented with 10% heat-inactivated fetal bovine serum, 1 mM sodium pyruvate, 4 mM L-glutamine and 1% non-essential amino acids (100×) (all purchased from Sigma–Aldrich, Vienna, Austria)]. Cultures were maintained at 37 °C in a humidified atmosphere containing 5% $CO_2$.

**Antiproliferative Activity in Cancer Cell Lines:** Antiproliferative effects were determined by means of a colourimetric microculture assay [MTT assay; MTT = 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2*H*-tetrazolium bromide]. Cells were harvested from the culture flasks by trypsinisation and seeded into 96-well microculture plates (Iwaki/Asahi Technoglass, Gyouda, Japan) in cell densities of $4 \times 10^3$ (except HT-29: $3 \times 10^3$ cells/well), in order to ensure exponential growth throughout drug exposure. After pre-incubation for 24 h, 41M and SK-BR-3 cells were exposed to serial dilutions of the test compound in 200 μL/well complete culture medium for 96 h under an atmosphere containing 5% $CO_2$. For pH-dependency experiments in A549 and HT-29 cells, the test compound was dissolved in Dulbecco's Modified Eagles Medium (DMEM) (w/o sodium hydrogencarbonate) supplemented with 10% heat-inactivated fetal bovine serum, 1 mM sodium pyruvate, 4 mM L-glutamine, 1% non-essential amino acids (100×) and sodium hydrogencarbonate in either 8.8 mM (pH = 6.0) or 39.6 mM (pH = 7.4) concentration (all purchased from Sigma–Aldrich, Vienna, Austria), and cells were exposed under an atmosphere containing 8% $CO_2$ for 24 h, followed by incubation in 200 μL/well drug-free DMEM (pH = 7.4) for a further 72 h. At the end of

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. [c] GOF = $\{\Sigma[w(F_o^2 - F_c^2)^2]/(n - p)\}^{1/2}$, where $n$ is the number of reflections and $p$ is the total number of parameters refined.

incubation, all media were replaced by 150 μL/well RPMI 1640 medium (supplemented with 10% heat-inactivated fetal bovine serum and 2 mM L-glutamine) plus 20 μL/well MTT solution in phosphate-buffered saline (5 mg/mL). After incubation for 4 h, the medium/MTT mixtures were removed and the formazan crystals formed by the mitochondrial dehydrogenase activity of vital cells were dissolved in 150 μL of dmso per well. Optical densities at 550 nm were measured with a microplate reader (Tecan Spectra Classic), using a reference wavelength of 690 nm to correct for unspecific absorption. The quantity of vital cells was expressed in terms of T/C values by comparison with untreated control microcultures, and 50% inhibitory concentrations ($IC_{50}$) were calculated from concentration-effect curves by interpolation. In order to correct for differences in growth kinetics in the pH-dependency experiments, concentration-effect curves were transformed by taking the optical densities of separate MTT-stained control microcultures at the beginning of drug exposure as zero values, and $GI_{50}$ concentrations were calculated instead of $IC_{50}$ values. Evaluation is based on the mean of at least three independent experiments, each comprising at least six microcultures per concentration level.

**Supporting Information** (see footnote on the first page of this article): Crystal packing of complexes **1** and **2**, the molecular structure of **3**, $^{31}$P NMR spectra of **4**, UV/Vis spectra of **4** at different pH values and IR spectra of **1**, **2** and **4**.

## Acknowledgments

The authors would like to thank the Austrian Science Fund (FWF), the Austrian Council for Research and Technology Development, the Austrian Research Promotion Agency (FFG), the European Cooperation in the Field of Scientific and Technical Research (COST) and the Faustus Forschung Austria Translational Drug Development AG, Vienna, Austria for financial support. We also thank Dr. Hanspeter Kählig for NMR titrations and Mag. Raffael Schuecker for helpful discussions, as well as Mag. Michael Grössl for ESI-MS measurements.

# The Role of Water in the Stereoselective Hydrogenation of 1,2-Diphenylacetylene Catalyzed by the Water-Soluble [{$RuCl_2$(*m*tppms)$_2$}$_2$]

**Gábor Kovács,[a–c] Gregori Ujaque,[a] Agustí Lledós,*[a] and Ferenc Joó*[b,c]**

**Keywords:** Alkynes / Biphasic catalysis / Density functional calculations / Hydrogenation / Reaction mechanisms

Density functional theory with dielectric continuum models was applied to describe the reaction mechanism of the stereoselective hydrogenation of phenyl-substituted alkynes with the water-soluble ruthenium complex [{$RuCl_2$(*m*tppms)$_2$}$_2$] *m*tppms [(*meta*-sulfonatophenyl)diphenylphosphane] in acidic aqueous solutions. The water solvent is modelled by the inclusion of a small cluster of three water molecules in addition to a continuum model. The possible reaction mechanisms leading to the formation of the different (*Z* and *E*) stereoisomers are computationally evaluated. It was shown that the reaction takes place in two steps; one hydrogen comes from the hydrido complex, whereas the second hydrogen is transferred from the hydroxonium ions present in the solution. The formation of the different stereoisomers is determined by the order of the two hydrogenation steps, and the analysis suggests that the formation of the (*Z*)-isomer is more favourable, which is consistent with the experimental results.

## Introduction

Chemo- and stereoselective reduction of carbon–carbon multiple bonds plays an important role in organic synthetic processes, both in the laboratory and in processes of industrial scale.[1] The complete hydrogenation of either double or triple carbon–carbon bonds occurs on almost all hydrogenation catalysts; however, semihydrogenation of alkyne derivatives (especially if stereoselectivity is desired) requires more sophisticated catalysts and reaction conditions.[2]

There are many examples of heterogeneous catalysts that are suitable for the conversion of alkynes into (*Z*)-alkenes, such as the Lindlar catalyst[2a] or the "P2Ni" catalytic system.[2b] Recently, Pd nanoparticles[3] and Pd catalysts supported on mesostructured silica[4] were developed as highly active and selective catalysts for partial alkyne hydrogenation. Numerous homogeneous catalytic systems are also known; however, the number of the catalysts that are selective towards the alkyne functionality in the presence of other reducible functionalities in the same molecule is more limited. Some good examples are the $Pd^0$ complexes of asymmetric bidentate nitrogen ligands,[5] cationic rhodium complexes of chelating phosphanes[6] and Cr(arene)$(CO)_3$ complexes.[7]

Aqueous and especially aqueous–organic biphasic systems have provided new prospects in organometallic catalysis,[8] since one major problem of homogeneous catalysis, that is, the separation of the catalyst from the products, can be easily solved.[8a,8b] Moreover, since the reaction in these systems takes place in the aqueous phase (the catalyst has to be water-soluble) these processes are more economical and environmentally friendly than those carried out in regular organic solvents.[8c,8d]

One of the most frequently described families of water-soluble complexes catalyzing different hydrogenation reactions are rhodium and ruthenium complexes prepared with sulfonated aromatic phosphane ligands.[1c,1d,8a] The ruthenium complex of *m*tppms [(*meta*-sulfonatophenyl)diphenylphosphane], that is [{$RuCl_2$(*m*tppms)$_2$}$_2$], was used effectively by Joó and co-workers for the selective reduction of the C=O or C=C functionalities of cinnamaldehyde in water/chlorobenzene two-phase systems, depending on reaction conditions,[9] and it has recently been reported that the aforementioned complex catalyzes the stereoselective hydrogenation of disubstituted alkynes.[10] It was found that the stereoselectivity of the reaction is mainly influenced by the pH of the aqueous solutions. In acidic solutions, the major product of the reaction is the (*Z*)-alkene, whereas under basic reaction conditions the (*E*)-isomer of the alkenes is formed in higher quantity; furthermore, a significant overreduction to the corresponding alkane was also observed.[10]

When chemo- or stereoselectivity found during aqueous-phase catalytic processes is to be explained, the unique characteristics of water have to be considered. In contrast with nonpolar organic solvents, water commonly plays the

role of not only the solvent but that of the reactant in the catalytic cycle.[11] Water can alter the reaction pathway by interacting with the metal complex as a coordinating ligand, as a species taking part in proton-transfer reactions and, additionally, water molecules can stabilize reaction intermediates by forming hydrogen and dihydrogen bonds with different parts of the various complexes.[12] Another important feature of aqueous solutions is that the pH of the solution can be an important factor in determining chemical reactivity or selectivity.[9a,13] The pH of the solution influences both the formation of the different catalytically active species[9a] and the concentration of the reactive ions ($H_3O^+$ and $OH^-$).

Recently we published a series of papers in which, we intended to describe aqueous-phase organometallic catalytic processes by means of theoretical methods.[14,15] As a continuation of the aforementioned works, in the present study, the mechanism of the hydrogenation of 1,2-diphenylacetylene is analyzed by means of theoretical methods, with the intention of exploring the origin of the observed stereoselectivity.

## Computational Details

Complexes $[RuHCl(PH_3)_3]$ and $[RuHCl(H_2O)(PH_3)_2]$ were adopted as models for the catalytically active hydrido species. The formation of these hydrido species in aqueous solutions was already discussed when the mechanism of the selective hydrogenation of C=C functionalities in α,β-unsaturated aldehydes with the same catalytic system ($[\{RuCl_2(m\text{tppms})_2\}_2]$ catalyst in acidic aqueous solution) was considered.[15] Hence, the results regarding the formation of the appropriate catalytically active species are only summarized briefly in this paper.

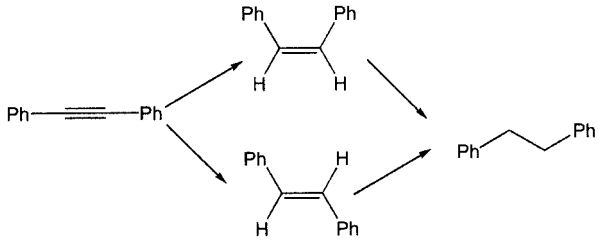
We first carried out density functional theory calculations to identify the structures of the reaction intermediates of the catalytic process. In some cases, we also located the transition states corresponding to different steps of the reaction. Normal coordinate analysis has been used to verify the nature of these stationary points, and for each transition structure we calculated the intrinsic reaction coordinate (IRC) routes towards the corresponding minima. If the IRC calculations failed to reach the energy minima on the potential energy surface, we performed geometry optimizations from the final phase of the IRC path. All geometries that are presented in the article are the geometry-optimized structures of the corresponding complexes.

All DFT calculations were performed with the program package Gaussian03[16] and the B3LYP[17] combination of functionals. The LANL2DZ[18] pseudopotential was employed for the ruthenium centre, and the standard 6-31G(d) basis set was used for the other atoms.[19] For all the optimized structures, we estimated the effect of the bulk aqueous medium ($\varepsilon = 78.4$) by the application of the polarizable continuum model (PCM)[20] as implemented in Gaussian 03, thus all energies given in the text correspond to the energies taking into consideration the effect of the bulk solvent.

When solvent molecules participated in the reaction, the solvent environment was represented by a cluster of three water molecules connected by hydrogen bonds. A single water molecule is not enough to give a realistic description of the medium, since proton exchange processes that take place during the catalytic process imply transfer of charges with formation of highly reactive ions. Thus, reacting water molecules were represented by a $[(H_2O)_3]$ cluster, whereas hydroxonium ions, which are present in aqueous acidic solutions at reasonable concentration, were represented by $[(H_3O)(H_2O)_2]^+$. On the basis of earlier systematic investigations by Kovács et al.,[14,15] it can be concluded that a cluster of three water molecules represents a good compromise between a realistic description, the system size and related proportional computational time.

## Results and Discussion

As it was stated in the introduction, hydrogenation of 1,2-diphenylacetylene (Scheme 1) catalyzed by $[\{RuCl_2(m\text{tppms})_2\}_2]$ in acidic aqueous solutions always resulted in (*Z*)-stilbene [(*Z*)-1,2-diphenylethene)] with only traces of (*E*)-stilbene, and only slight overreduction to the corresponding alkane was observed.[10]



Scheme 1. Formation of products during the hydrogenation of 1,2-diphenylacetylene.

In the work to be presented, theoretical methods were applied to provide a possible mechanistic description for the formation of both (*Z*)- and (*E*)-stilbene during the hydrogenation of 1,2-diphenylacetylene in the current catalytic system and furthermore to account for the significant (*Z*)- vs. (*E*)-selectivity observed.

### The Catalytically Active Species

The formation of the catalytically active species was described in detail in one of our earlier publications, in which the mechanism of the regioselective C=C hydrogenation of α,β-unsaturated aldehydes was considered.[15] In the following section we often refer to those results, since the reaction for which a mechanism is presented proceeds in the same catalytic system.

Under acidic conditions $[RuHCl(m\text{tppms})_3]$ was detected by NMR spectroscopy to be the major species.[9] However, the spectroscopically detected complex cannot be the reactive species, since it only has a vacant position *trans* to the hydrido ligand. Thus, on the basis of QM/MM calculations

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(in which $PPh_3$ ligands were used as models for the *m*tppms ligands) and experimental considerations, it was concluded that there were two possible pathways for the formation of a catalytically active species.[15a] One is the rearrangement of the complex to create a vacancy in the *cis* position to the hydrido ligand, and the other pathway involves the coordination of a water molecule and subsequent dissociation of a phosphane ligand. Both pathways were found to be feasible, thus the catalytic cycle was described by both possible active catalysts.[15a]

On the basis of the aforementioned considerations, the same two catalytically active species were considered in the current reaction. The models, $[RuHCl(PH_3)_3]$ (**1**) and $[RuHCl(H_2O)(PH_3)_2]$ (**1′**) for the assumed catalytically active species are shown in Figure 1.

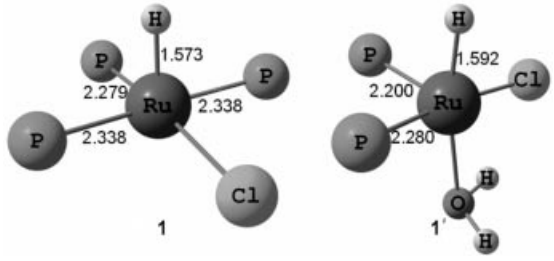


Figure 1. Optimized structures for $[RuHCl(PH_3)_3]$ (**1**) and $[RuHCl(H_2O)(PH_3)_2]$ (**1′**); the hydrogen atoms of the $PH_3$ ligands are omitted for clarity.

### Description of the Possible Reaction Mechanisms

We have calculated the possible reaction paths starting from both complex **1** and complex **1′**. Since no significant difference was found between the reaction mechanisms and energy profiles obtained for the two catalytically active species, we suppose it is enough to present the results starting from **1**. Nevertheless, the structures and energies of all stationary points obtained are available in the Supporting Information.

For the alkyne hydrogenation in the current catalytic system, three different reaction mechanisms were considered. The first step of all of them is the coordination of 1,2-diphenylacetylene to the catalytically active species and the formation of complex **2** (Figure 2). The total energy of the coordination is –3.9 kcal/mol (it has to be mentioned that this energy takes into account the fact that, prior to the coordination of the substrate, **1** has to rearrange in order to have the coordination vacancy in the *cis* position to the hydrido ligand).

Three mechanistic pathways for the semireduction of the carbon–carbon triple bond was considered:

I. Initial hydrido ligand transfer to the adjacent carbon atom with subsequent protonation of the other carbon atom by the participation of the solvent molecules (the *cis* product is formed).

II. Proton transfer from the solvent and subsequent transfer of the hydrido ligand to the other carbon atom of the triple bond (the *trans* product is formed).

III. Classical mechanism with no solvent participation (the *cis* product is formed).

#### Mechanism I

The first step of the reduction is the insertion of the carbon atom (in the *cis* position to the hydrido ligand) into the Ru–H bond, which takes place through the formation of $\mathbf{TS_{2-3}}$ (Figure 2), which lies 7.2 kcal/mol above the initial complex **2**. The product of this reaction is the intermediate **3** (lying 1.9 kcal/mol above complex **2**), in which an agostic bond is formed [*d*(C–H) = 1.16 Å, *d*(Ru–H) = 2.00 Å].

In aqueous solution, this complex can be stabilized by the coordination of a water molecule on the agostic site with an energy change of –21.4 kcal/mol. (Another mechanistic possibility is the coordination of a $H_2$ molecule instead of a $H_2O$ molecule to **3**, which will be discussed later as Mechanism III.) Considering the orientation of the phenyl groups in structure **4**, it can be seen that starting from this complex only the (*Z*)-isomer can be formed (Figure 3).

Since complex **4** does not contain either another hydrido ligand or an empty coordination site, the only possibility for the completion of the hydrogenation is the protonation of the Ru-bound carbon atom. Protonation of reasonably strong metal–carbon bonds require stronger acids, and in an aqueous phase, solvated hydroxonium ions can play that role. It was shown earlier[14a] that application of a single $H_3O^+$ as a protonating agent in the calculations represents a poor description of the real solvent environment. However, as it was mentioned in the introduction, previous studies[14,15] show that using a cluster of $[H_3O(H_2O)_2]^+$ as a representation of acidic aqueous solutions provides a good compromise between a realistic description, the system size and related proportional computational time. Hence, complex **4** and $[H_3O(H_2O)_2]^+$ were put together, and structure **5** was optimized as a minimum in the potential energy hypersurface (Figure 4), in which the acidic hydrogen of $H_3O^+$ points towards the carbon atom in order to be protonated. The transition state $\mathbf{TS_{5-6}}$ was also located as a stationary point on the potential energy surface, and it was found to lie only 1.6 kcal/mol above structure **5** in energy (Figure 4).

As a result of the protonation, (*Z*)-stilbene is formed, which remains loosely coordinated to the metal centre. The structure obtained as a result of IRC calculations and subsequent geometry optimization starting from $\mathbf{TS_{5-6}}$ is shown as structure **6** (Figure 4). The total energy change for the process **5** → **6** is hard to estimate correctly (it was calculated to be –37.9 kcal/mol), since rearrangement of the water cluster leads to the formation of a new hydrogen bond between $(H_2O)_3$ and the coordinated water molecule, the exergonicity of this step is thus surely overestimated.

The product of the protonation reaction was optimized without the water clusters (**7**), and it is shown in Figure 5. In this complex, the product (*Z*)-stilbene is still weakly co-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

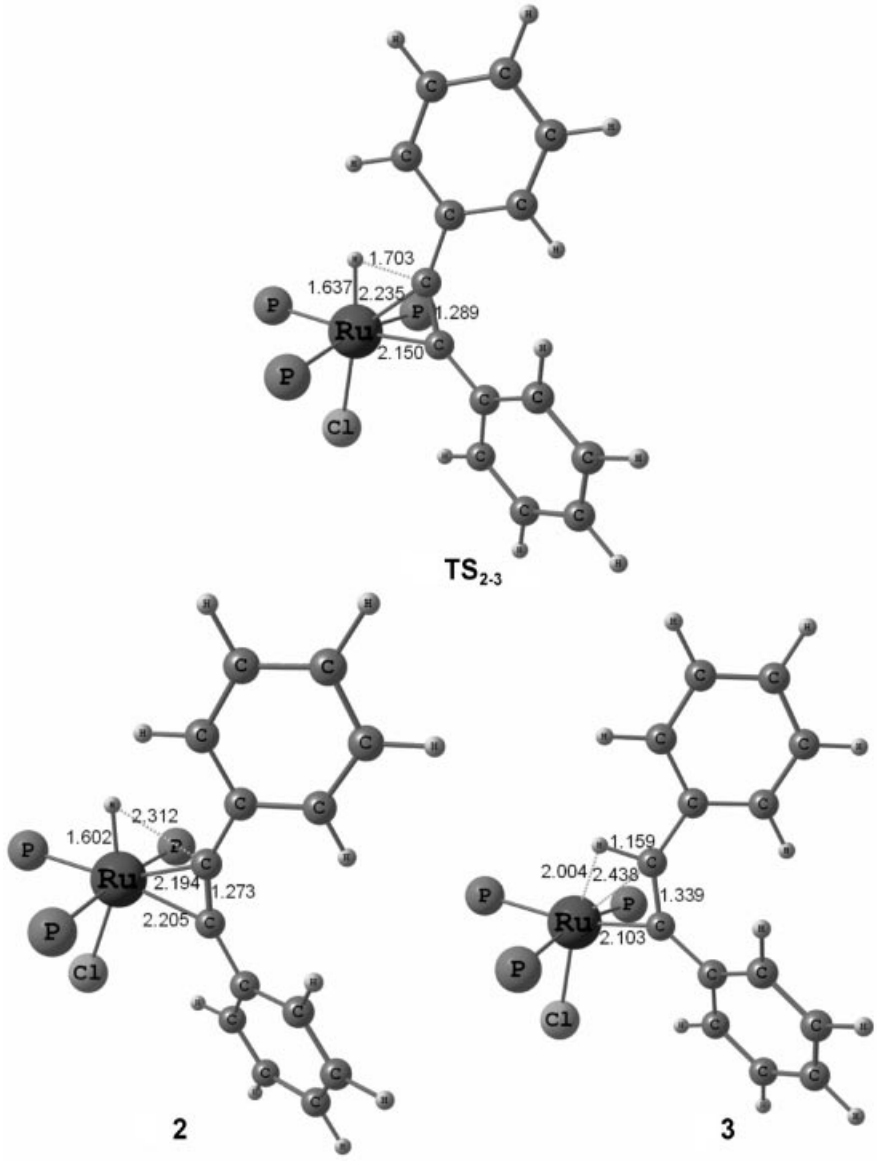

Figure 2. Optimized structures with selected bond lengths representing carbon insertion into the Ru–H bond in complex **2** (Mechanism I).

ordinated [*d*(Ru–C) = 2.65 and 2.63 Å, respectively] to the ruthenium centre. Complete decoordination of the product from **7** leads to the formation of **8** (Figure 5), with an energy change of 9.3 kcal/mol, generating an empty coordination site.

The final step of the reaction regenerates the catalytically active hydrido species. In aqueous solution, the most obvious way for this step to occur is the coordination and subsequent deprotonation of a $H_2$ molecule. It was shown in earlier studies that regeneration of the (hydrido)ruthenium is an energetically favourable reaction, since coordination of the $H_2$ molecule is an exergonic process, and the deprotonation of the coordinated $H_2$ molecule with water molecules occurs through low energy barriers.[15a]

In this case, coordination of hydrogen to complex **8** leads to complex **9** (Figure 5). The energy change for the coordination is –9.1 kcal/mol. On the basis of previous studies,[14,15] it is reasonable to assume that the deprotonation takes place by proton transfer from the dihydrogen ligand to the surrounding water molecules. In order to describe this step, we carried out calculations for a model that involves the interaction of complex **9** with a cluster of three water molecules and also for the corresponding hydrido species where the proton is transferred to the water (see structures **10** and **11** in Figure 6). The transition state for the deprotonation reaction could not be identified in these calculations because of the flat nature of the potential energy surface corresponding to structure **10**. In fact, the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

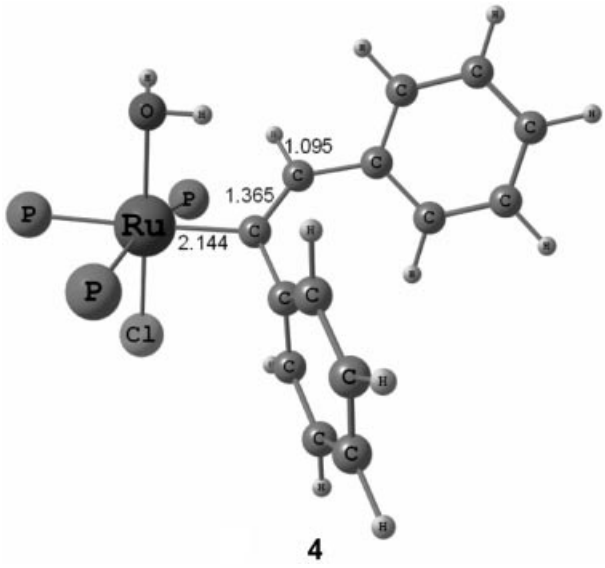

Figure 3. Optimized structure for complex **4**.

geometry optimization procedure initiated from the **9**···$(H_2O)_3$ species converged to **11** after leaving the flat part of the surface. The estimated energy difference between **10** and **11** is reasonably low (–6.2 kcal/mol) and shows that the deprotonation of the coordinated hydrogen ligand is thermodynamically favourable. It is expected that these kinds of computational difficulties could be avoided if much larger water clusters were used to represent the bulk water medium; however, larger clusters are at present computationally prohibitive.

The dissociation of a $H_2O$ molecule from the deprotonated complex and rearrangement to the most stable isomer leads to the regeneration of complex **1**, thus closing the catalytic cycle. The energy change for the last process is 3.7 kcal/mol. The reaction mechanism is summarized in Scheme 2.

### Mechanism II

Another possibility for the reduction to take place is that, after the coordination of 1,2-diphenylacetylene and formation of complex **2**, the first step of the reduction is the protonation of one carbon atom of the triple bond by the solvent environment. To explore this possible reaction pathway, $[H_3O(H_2O)_2]^+$ was used as the model for the protonating agent in aqueous solutions as in Mechanism I and in earlier projects.

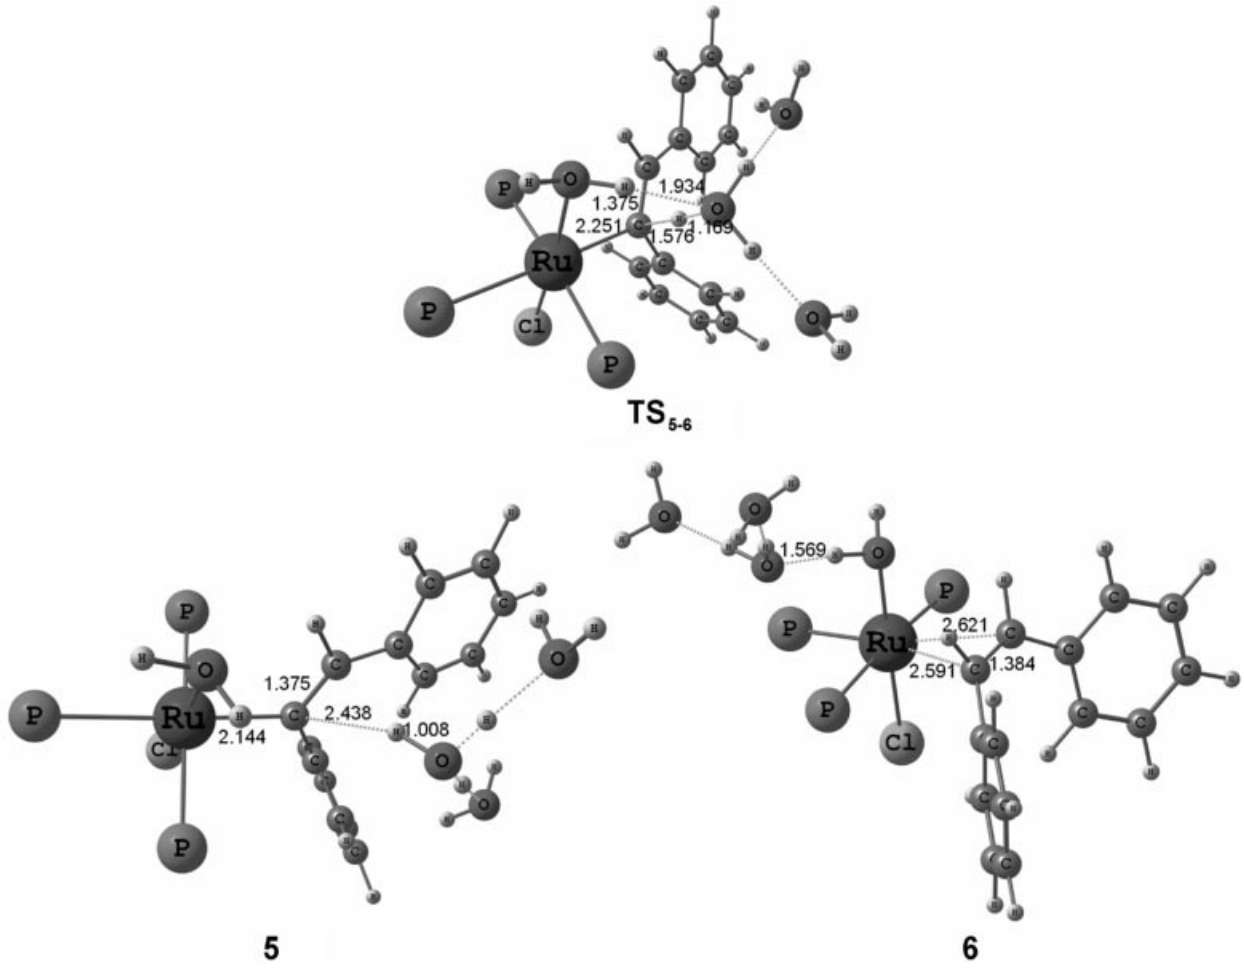

Figure 4. Optimized structures with selected bond lengths representing the protonation of the carbon atom (Mechanism I).

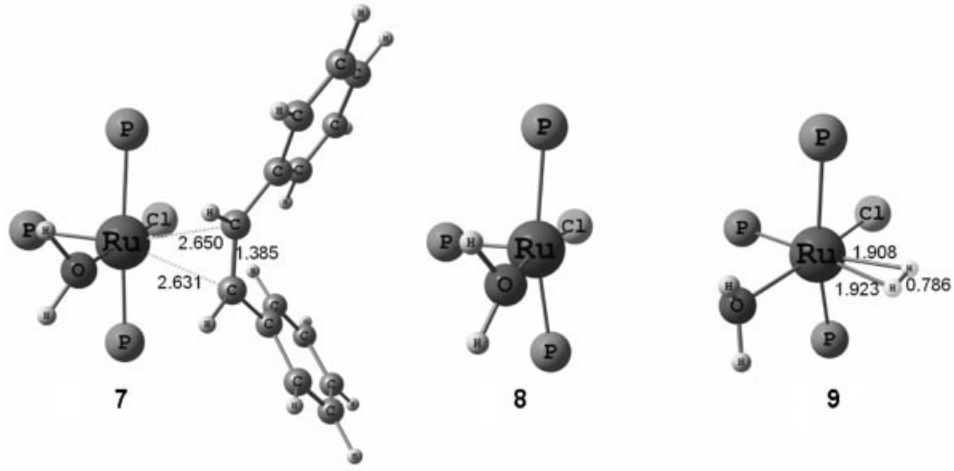

Figure 5. Optimized structures with selected bond lengths representing the decoordination of the product and subsequent coordination of a $H_2$ molecule.

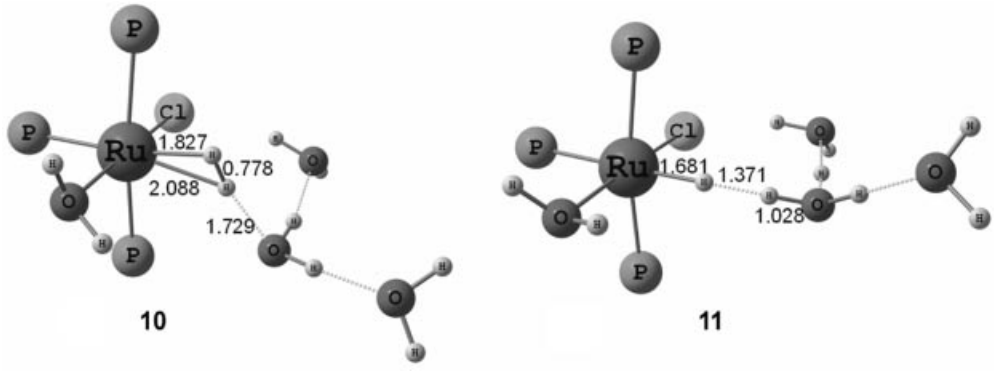

Figure 6. Optimized structures with selected bond lengths representing the deprotonation of the coordinated $H_2$ molecule.

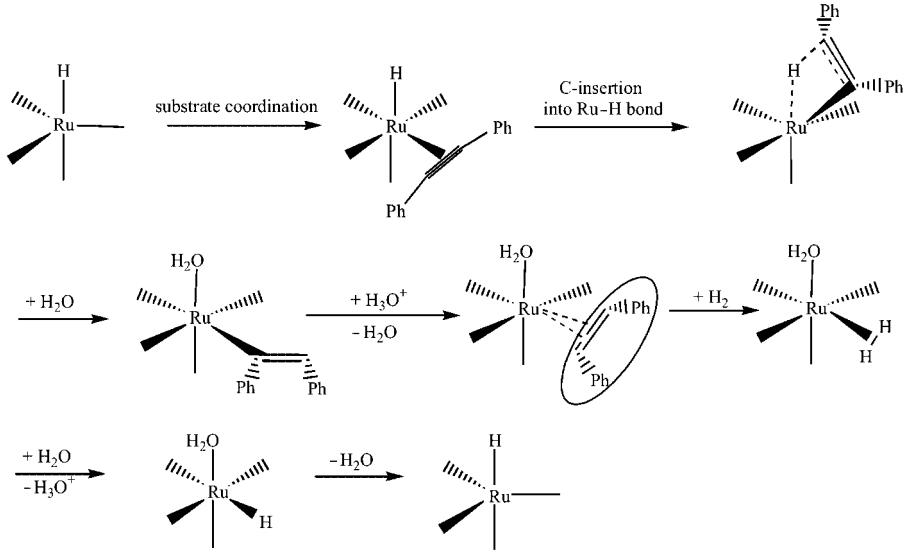

Scheme 2. Mechanism I for the reduction of 1,2-diphenylacetylene catalyzed by [{$RuCl_2$(*m*tppms)$_2$}$_2$] in acidic aqueous solutions.

Hence, $[H_3O(H_2O)_2]^+$ and complex **2** were put together in a way that the acidic hydrogen of the cluster points to the carbon atom, which is intended to be protonated, and structure **12** was optimized as a minimum (Figure 7). The transition state (**TS$_{12–13}$**) corresponding to proton transfer from $[H_3O(H_2O)_2]^+$ to the metal complex was also located as a stationary point on the potential energy surface, and the barrier for the protonation was found to be 9.6 kcal/

mol (Figure 7). The product of the protonation is structure **13**, which lies 1.5 kcal/mol lower in energy than structure **12** (Figure 7).

The completion of the reduction can be facilitated in this case by the transfer of the hydrido ligand to the other carbon atom. One would also think about the protonation of the other carbon, but protonation of a positively charged complex is considered to be very unfavourable. To obtain the stationary points relevant to this hydrido transfer, structure **13** was reoptimized in the absence of the water molecules, and structure **14** was optimized as the corresponding minimum (Figure 8). The transition state $\mathbf{TS_{14–15}}$ corresponding to the hydrido transfer was located on the potential energy surface, and the process can be characterized by a barrier of 9.1 kcal/mol. The steric position of the phenyl rings in structure **14** clearly indicates that in this reaction pathway only the (*E*)-isomer can be formed.

The product of the process, structure **15**, calculated from the IRC calculations contains coordinated (*E*)-stilbene (the energy change for the hydrido transfer is –31.4 kcal/mol), but in the presence of water molecules, this intermediate is converted into structure **16** (Figure 9). This complex, which contains a water molecule and (*E*)-stilbene loosely coordinated and has a similar structure to that of complex **7**, is formed from structure **15** with an energy change of –7.2 kcal/mol.

Further steps of the reaction mechanism, that is, regeneration of the catalytically active species, are the same as those in Mechanism I: decoordination of (*E*)-stilbene is followed by the coordination and subsequent deprotonation of a $H_2$ molecule. Then, decoordination of the $H_2O$ molecule regenerates the empty coordination site, which makes the coordination of another substrate molecule possible. The energy changes for these steps are the following: product dissociation: 8.4 kcal/mol, hydrogen coordination: –9.1 kcal/mol, deprotonation of $H_2$: –6.2 kcal/mol and $H_2O$ decoordination: 3.7 kcal/mol. The reaction mechanism is summarized in Scheme 3.

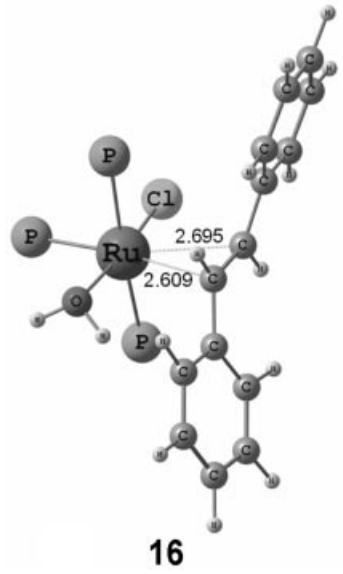

Figure 9. Optimized structure for complex **16**.

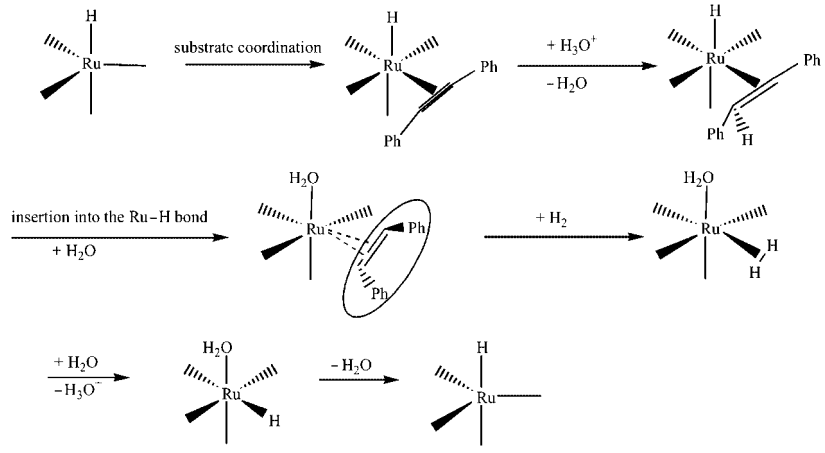
### Mechanism III

The third possible mechanism considered for the hydrogenation of 1,2-diphenylacetylene with the aforementioned Ru complex is connected to Mechanism I. As it was mentioned, complex **3**, formed by carbon insertion into the Ru–H bond, can be stabilized by the coordination of either a $H_2O$ or a $H_2$ molecule.

The coordination of a water molecule and the following reaction steps were discussed as Mechanism I. Another possibility is the coordination of a $H_2$ molecule to the complex and σ-bond metathesis between the $\eta^2$-coordinated $H_2$ and the alkyl moiety. Complex **17**, formed by the coordination of a hydrogen molecule to complex **3**, is shown in Figure 10. The energy change for the coordination is –16.0 kcal/mol. In this case the second hydrogen can come from the coordinated $H_2$ molecule. The transition state $\mathbf{TS_{17–18}}$ and the



Scheme 3. Mechanism II for the reduction of 1,2-diphenylacetylene catalyzed by [{$RuCl_2$(*m*tppms)$_2$}$_2$] in acidic aqueous solutions.

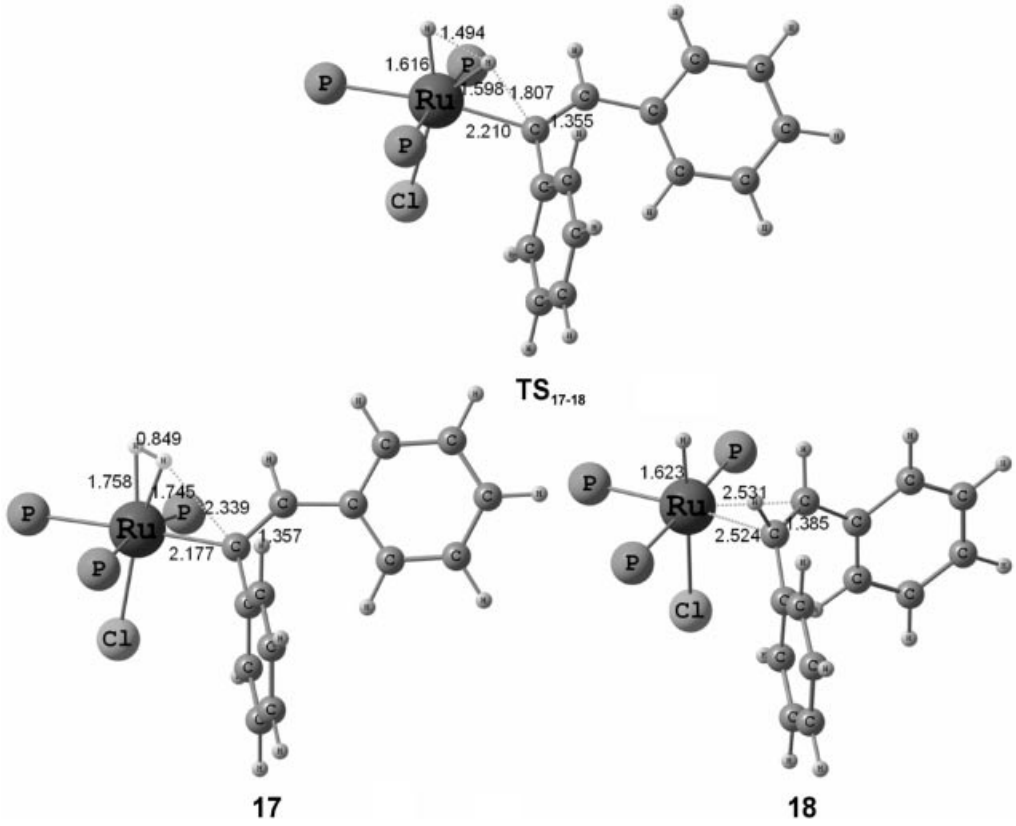

Figure 10. Optimized structures with selected bond lengths representing σ-bond metathesis in structure **17** (Mechanism III).

product of this reaction step, structure **18** (Figure 10), were obtained as stationary points. The calculated reaction barrier is 3.7 kcal/mol, whereas the energy change is –27.8 kcal/mol.

This mechanism would also facilitate the formation of the (*Z*)-product. Although the global barrier for this process is really similar to that of Mechanism I, we believe that this pathway does not play an important role in the process. The reason for this is not only that the coordination of $H_2$ to complex **2** is energetically less favourable than that of water (–21.4 vs. –16.0 kcal/mol), but also that the concentration of $H_2$ molecules in acidic aqueous solutions is well below that of water molecules. In addition, if the classic mechanism (no participation of solvent in the hydrogenation) were to act in aqueous solutions, it would not be possible to explain the selectivity as a function of pH, as it was demonstrated by Delbecq et al.,[21] and observed in our previous studies concerning the regioselective hydrogenation of α,β-unsaturated aldehydes.[15]

### Discussion and Comparison of the Proposed Mechanisms

On the basis of the energetics and other considerations, we can explain the stereoselectivity observed in the current catalytic system. Of the considered mechanisms, Mechanism I and III favour the formation of the (*Z*)-product, while Mechanism II leads to the formation of the (*E*)-product. Mechanism III was shown to be unimportant on the basis of the considerations in the end of the last section. Hence, the stereoselectivity can be explained by comparison of the energetics obtained for Mechanisms I and II.

If we consider the energy changes for the various steps of Mechanism I, it can be seen that the first step of the hydrogenation has a barrier of 7.2 kcal/mol, and after the first step coordination of a $H_2O$ molecule is energetically favourable by 21.4 kcal/mol, and in addition, the second hydrogenation step is characterized by a TS which lies only 1.6 kcal/mol over the corresponding minimum. Nevertheless, the first barrier in Mechanism II is 9.6 kcal/mol, and since the first step does not result in any coordination vacancy, no solvent coordination can give extra stabilization. In addition, the second step has a barrier of 9.1 kcal/mol. Comparing the energy values for the two mechanisms, it is quite clear that Mechanism I features more favourable energetics, thus it accounts for the stereoselectivity observed in acidic aqueous solutions.

## Concluding Remarks

Theoretical methods were applied in this work to describe the mechanism of the aqueous-phase hydrogenation of 1,2-diphenylacetylene with [{$RuCl_2$(*m*tppms)$_2$}$_2$] catalyst. Our study provided realistic mechanistic pathways for the formation of (*Z*)- and (*E*)-stilbene, and in addition the ener-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

getics clearly accounted for the relevant stereoselectivity observed.

The mechanism of the reaction was described by the application of $PH_3$ model ligands for *m*tppms, which was proved to be a reliable substitution in earlier examinations of catalytic reactions with the same catalyst,[15] when phosphane dissociation is not considered as a reaction step. The same catalytically active species were used to provide a theoretical description for the regioselective C=C vs. C=O hydrogenation of α,β-unsaturated aldehydes in the same catalytic system, that is, using the same catalyst dissolved in acidic aqueous solution.

Since the reaction proceeds in water, the effect of the solvent had to be taken into account. In all reaction steps, the effect of the bulk solvent was estimated by the application of the polarizable continuum model (PCM/UA0), whereas in the case of the steps involving the participation of water molecules in proton transfer reactions, small clusters of water molecules were used as models for the solvent environment.

Three different mechanisms were considered for the reaction. Two of the mechanisms (Mechanism I and III) correspond to the formation of the (*Z*)-isomer, while Mechanism II results in the formation of (*E*)-stilbene. On the basis of both the energetics and experimental considerations, Mechanism I and II are thought to be feasible reaction pathways for the formation of the two stereoisomers.

In the course of both reaction mechanisms, the hydrogenation proceeds in two steps: the insertion of one carbon atom of the multiple bond to the Ru–H bond and the protonation of the other carbon atom. The two mechanisms differ in the order of the two hydrogenation steps. In the course of Mechanism I, the first step is the transfer of the hydrido ligand to the adjacent carbon atom of the coordinated substrate, and the hydrogenation is completed by the protonation of the other carbon atom of the multiple bond with hydroxonium ions, which results in the formation of (*Z*)-stilbene. Conversely, Mechanism II involves the protonation of one of the carbon atoms by the surrounding hydroxonium ions as the first step, which is followed by the insertion of the other carbon to the Ru–H bond. This latter mechanism yields the (*E*)-isomer as product. We mention that this (*E*)-isomer is the main alkene product under basic conditions; however, it is unlikely to form by the aforementioned mechanism, since the concentration of $H_3O^+$ is very low in basic solutions. We assume that $OH^-$ participation leads to reversed stereoselectivity in alkaline solutions.

The stereoselectivity observed in the reaction system was explained by the lower barriers and the more favourable energetics calculated for Mechanism I.

The calculations also highlighted again that water presents a distinct reaction environment in the case of organometallic processes, since the solvent molecules (and its ions) can take part in the reaction and make unconventional pathways possible. Water molecules can coordinate to the metal centres of the complexes, as was also considered in the course of the above investigation. In addition, water molecules can act as proton donors or acceptors, thus forming hydrogen or dihydrogen bonds with the ligands and taking part in proton transfer reactions with the metal complexes.

In summary, the present work provided a detailed mechanistic picture for the stereoselective hydrogenation of disubstituted alkynes with a water-soluble phosphane complex of ruthenium. It was found that the two important pathways corresponding to the formation of the two stereoisomers differ in the order of the two hydrogenation steps (insertion and protonation), and the calculated energetics is consistent with the experimentally observed stereoselectivity.

# Metallated Phthalocyanines as the Core of Dendrimers – Synthesis and Spectroscopic Studies

**Julien Leclaire,[a] Rodolphe Dagiral,[a] Anna Pla-Quintana,[a] Anne-Marie Caminade,*[a] and Jean-Pierre Majoral*[a]**

**Keywords:** Dendrimers / Phthalocyanine / Phosphorus / UV/Vis spectroscopy / Cobalt

The complexation of a first-generation dendrimer possessing a metal-free octasubstituted phthalocyanine as its core has been carried out with copper and cobalt chlorides. In the case of the cobalt complex, the synthesis of the dendrimer has been pursued up to the eighth generation. The progressive influence of the branches upon the core has been studied with dendrimers from generation 1 to generation 7, using UV/Vis spectroscopy. These data indicate a progressive isolation of the core.

## Introduction

Phthalocyanines[1] possess unique physico-chemical properties, which led to widespread potential applications in various fields such as photodynamic therapy,[2] solar energy conversion,[3] various optoelectronic devices,[4] or catalysed photooxidation of pollutants.[5] The main intrinsic problem when using such compounds is their strong stacking tendency to form dimers and other aggregated species in solution,[6] which induces a significant decrease in the photosensitising efficiency. Thus, much effort has been put into synthesizing nonaggregated phthalocyanines, generally by grafting bulky substituents, which also increase the solubility. One interesting way to achieve this goal consists of grafting dendritic substituents. Several examples have been reported since the first one published in 1997.[7] The phthalocyanine core can be either free,[8] or more generally complexed by a metal (in particular zinc),[7] or connected to a silicon derivative bearing dendritic stoppers.[9] In most cases, these phthalocyanines are tetrasubstituted, and only a few publications have reported the synthesis of octasubstituted dendritic phthalocyanines.[10,11] This is surprising in view of the advantages offered by the octasubstitution over the tetrasubstitution, in particular the absence of regioisomers, and a higher steric hindrance, which should facilitate the isolation of the core (preventing aggregation), even for low-generation dendritic substituents. This observation prompted us to report the synthesis of an octasubstituted metal-free phthalocyanine, which we used as the core for growing phosphorus-containing dendritic branches[12] up to generation 5, including a water-soluble series.[13] Having in hand a series of dendrimers possessing a metal-free phthalocyanine as a core, it appeared interesting to study their complexation ability, and the consequences of the complexation upon their spectroscopic properties. We report here the synthesis and characterization of a series of dendritic phthalocyanine complexes from generation 1 to generation 8, their UV/Vis properties, and the structural information deduced from these data.

## Results and Discussion

The complexation could have been carried out with any of the generations from 0 to 5 of the dendrimer having a free phthalocyanine as a core that we have previously synthesized;[12,13] however, from a practical point of view the first generation appears to be the most suitable. Indeed, it is more soluble than generation zero, and it is sufficiently small to ascertain a quantitative complexation. We decided to study the complexation of two metals that were very rarely incorporated into the core of phthalocyanine-containing dendrimers: copper (one example of a first generation only)[14] and cobalt (one example of first and second generations).[15] In both cases the reaction is carried out with the corresponding dichloride derivatives, in the presence of triethylamine as a base in THF (Scheme 1). The complexation reaction is mainly controlled by the disappearance of the band at 3250 $cm^{-1}$ in the infra-red spectra, corresponding to the pyrrolic NH bonds. Indeed, we have previously shown that triethylamine (and even DBU) are unable to deprotonate the phthalocyanine in THF,[12] thus the absence of N–H bonds is exclusively due to the complexation.

We expected that the paramagnetism due to the presence of $Cu^{II}$ could induce an enlargement of the signals detected

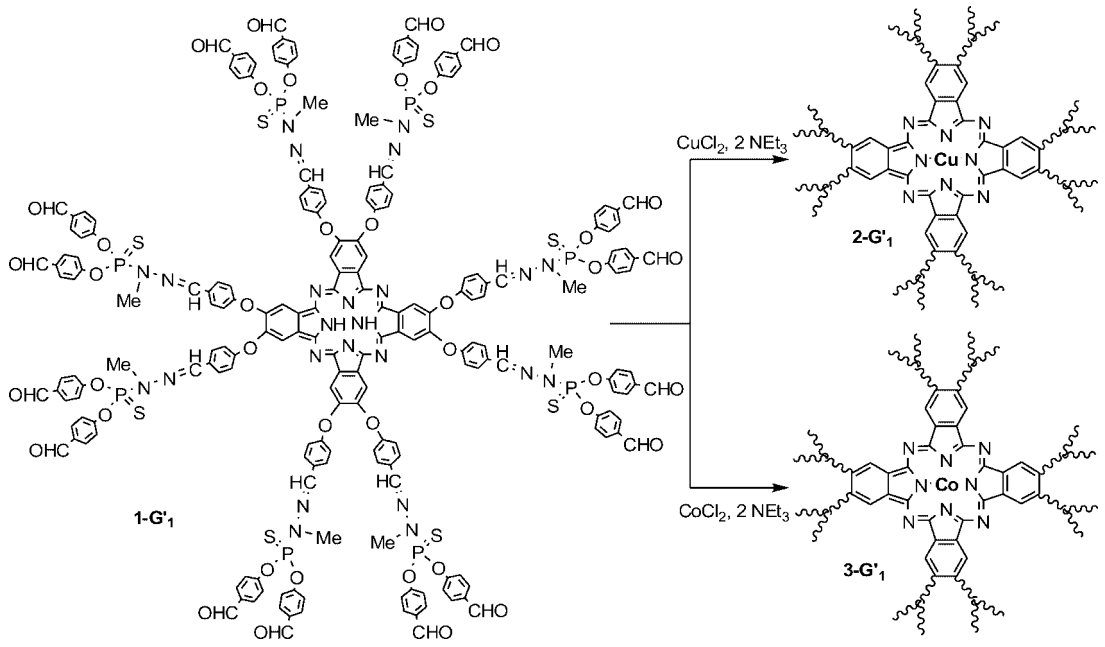


Scheme 1.

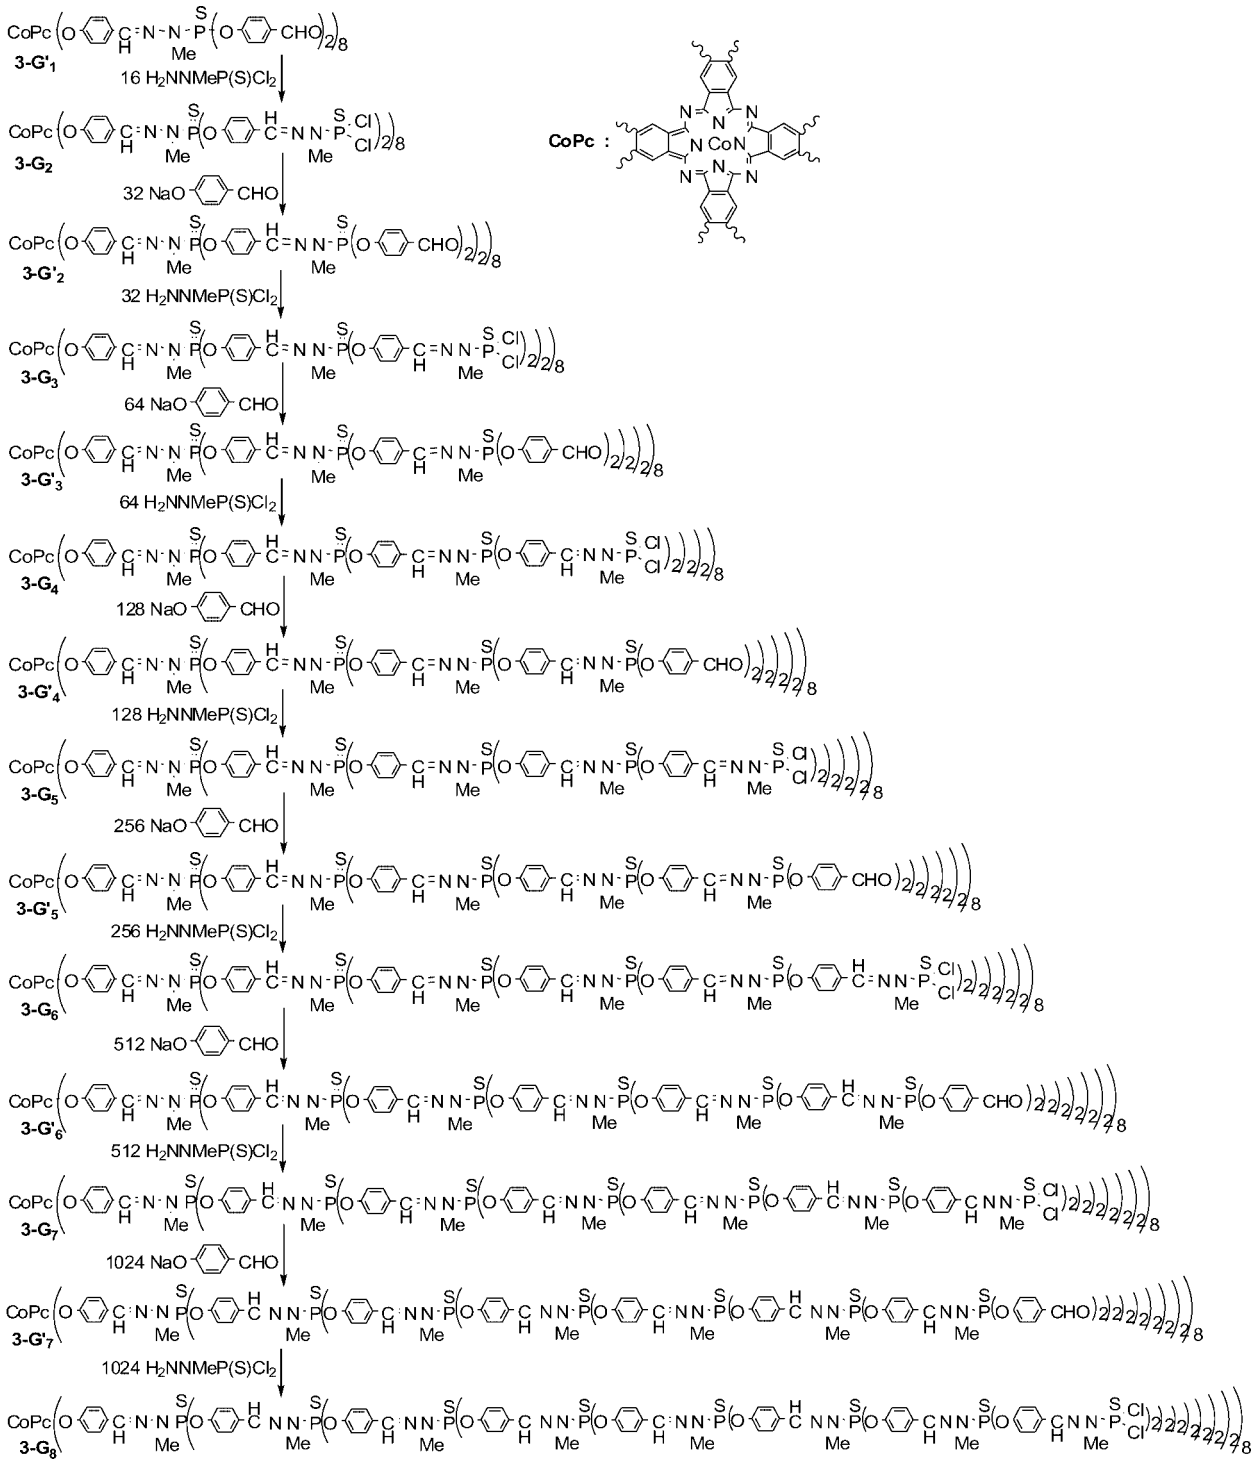
by NMR; such a phenomenon is observed and is particularly important for $^1$H NMR, as mentioned in the single existing example reported so far.[14] On the other hand, $Co^{II}$ in $CoCl_2$ is not paramagnetic, but we observed an enlargement of the NMR signals, indicating that the resulting complex is paramagnetic. No NMR spectroscopic data were reported for the single previous example of a dendritic phthalocyanine cobalt complex,[15] but such paramagnetism is known for cobalt complexes of nondendritic phthalocyanines.[16] The perturbation being less important with the cobalt complex than with the copper one, we decided to grow the dendrimer only from the cobalt complex **3-G′$_1$**, using our classical method of synthesis of phosphorus-containing dendrimers,[12,17] i.e. the repetition of condensation reactions between aldehyde endgroups and the phosphorhydrazide $H_2NNMeP(S)Cl_2$, and substitution reactions of the chlorine atoms by the sodium salt of 4-hydroxybenzaldehyde (Scheme 2). The completion of the condensation reactions is easily shown by $^1$H NMR, with the disappearance of the singlet corresponding to the aldehyde groups (also detected by $^{13}$C NMR and IR). The substitution reaction is monitored by $^{31}$P NMR, which firstly displays a signal at ca. 74 ppm, corresponding to the monosubstitution [P(S)-Cl($OC_6H_4CHO$)], as well as the signal corresponding to unreacted $P(S)Cl_2$ at $\delta$ = 63.3 ppm. Both signals disappear when the reaction has gone to completion, on behalf of the appearance of a signal at $\delta$ = 60.5 ppm. The precision of the NMR techniques to ascertain the completion of these reactions is estimated to be 0.5%. These syntheses have been carried out up to the eighth generation **3-G$_8$** [$P(S)Cl_2$ endgroups]. This is not the highest generation obtainable (no particular broadening of signals is observed); however, the series of dendrimers synthesized up to this generation is large enough to study the progressive influence of the branches upon the core, and is the largest series of dendritic phthalocyanines reported in the literature to date, thus we decided to stop at this stage.

The phthalocyanine core is a sensitive probe and sensor, thus it appeared interesting to study the UV/Vis and fluorescence properties of this family of dendritic phthalocyanine complexes. All experiments are carried out with dendrimers with aldehyde endgroups (from **3-G′$_1$** to **3-G′$_7$**), which are more stable than the $P(S)Cl_2$ endgroups. The π-π* transitions of the phthalocyanine ring should afford two types of absorption bands centred at about 300 nm (B-band) and about 670 nm (Q-band) in the UV/Vis spectra.

The B band is not very useful to study the behaviour of the core, since there is a superposition with the absorption band characteristic of the arylhydrazones constituting the branches of the dendrimers. However, this area is interesting to study the dependence of the molar absorption coefficient ($\varepsilon$) on the number of chromophoric units. We have already shown that there is a linear correlation between $\varepsilon$ and the number of aryl groups for the dendrimers built from the free phthalocyanine core, at least up to generation four.[12] The question of the linearity remains open for high generations, but plotting the measured values of $\varepsilon$ vs. the theoretical number of aryl groups gives a straight line even up to generation seven (Figure 1). Such behaviour both confirms that each arylhydrazone group is electronically independent (no overcrowding on the periphery) and that the expected number of arylhydrazones is indeed present (no large defects, even for high generations), confirming the information deduced from NMR spectroscopic data.

The Q-band of phthalocyanines is in an area where the dendritic skeleton is totally transparent, thus it is able to provide very interesting information concerning the symmetry and the environment of the core. Indeed, free neutral phthalocyanines have a $D_{2h}$ symmetry, inducing a splitting of the Q-band into two components [$Q_y(0,0)$ and $Q_x(0,0)$]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

giving two main absorptions (ca. 670 and 700 nm). On the other hand, the complexation of a metal induces a $D_{4h}$ symmetry, which should give a single Q-band. The UV/Vis spectrum of the first generation **3-G′$_1$** in the area 650–700 nm displays a single band [$\lambda$ = 674 nm, Q(0,0)], accompanied as usual by a vibrational band [$\lambda$ = 610 nm, Q(0,1)] (Figure 2). However, a broad band is also clearly visible between both bands, usually attributed to an aggregation phenomenon. This attribution is confirmed by the fact that it progressively disappears when the number of the generation increases. In the spectrum corresponding to the seventh generation **3-G′$_7$** (see the insert in Figure 2), only the Q(0,0) and Q(0,1) bands are visible, and the intermediate band has totally disappeared; obviously, any aggregation is unlikely for a seventh generation in which the core should be totally protected by the branches.

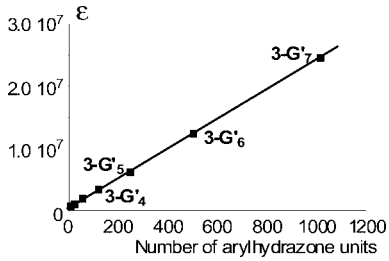

Figure 1. Variation of $\varepsilon$ ($mol^{-1}$ L $cm^{-1}$) at 268 nm with the number of arylhydrazone groups in $CHCl_3$.

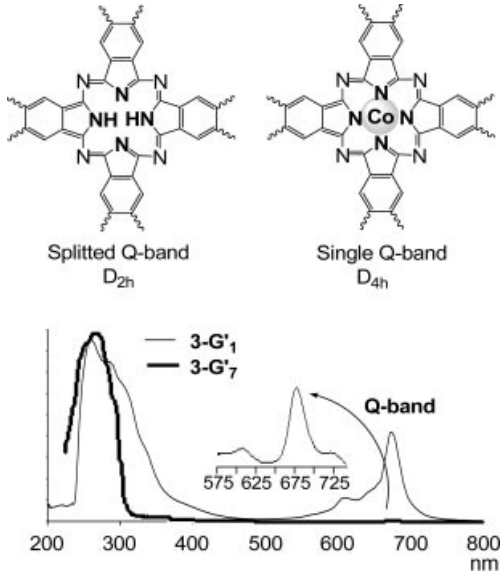

Figure 2. (top) Symmetry of free and complexed phthalocyanine cores, and spectroscopic consequences. (bottom) UV/Vis spectra of the first (**3-G′$_1$**) and seventh (**3-G′$_7$**) generations of the complexed cobalt phthalocyanine; both spectra are normalized to have the same intensity at 268 nm. The insert is an enlargement of the area of the Q-band of **3-G′$_7$** in THF.

The area of the Q-band provides other proofs of the progressive isolation of the core when the generation increases. Indeed, the value of $\varepsilon_{max}$ for the Q-band increases linearly from generation 1 to generation 5, and more smoothly from generation 5 to generation 7 (Figure 3). Such behaviour corresponds to a progressive isolation of the core, as shown by an analogous increase of $\varepsilon$ already reported for chromophores encapsulated in liposomes.[18] Furthermore, the value of $\lambda_{max}$ for the Q-band also increases linearly (bathochromic effect) from generation 1 to generation 5, and is practically constant from generation 5 to generation 7. Reichardt has proposed a relationship between solvatochromism and polarity.[19] We may interpret the bathochromic effect observed here as a consequence of the increase of the local polarity induced by the branches (constituted of arylhydrazones) towards the core. We already observed the same phenomenon for dendritic metal-free phthalocyanines up to generation 4.[12] The major (and unprecedented) information obtained here is that this increase is stopped after the fifth generation. We may interpret this phenomenon as a consequence of the steric hindrance around the core: it is already totally encapsulated by the branches of the fifth generation, and the presence of additional branches has no influence on it.

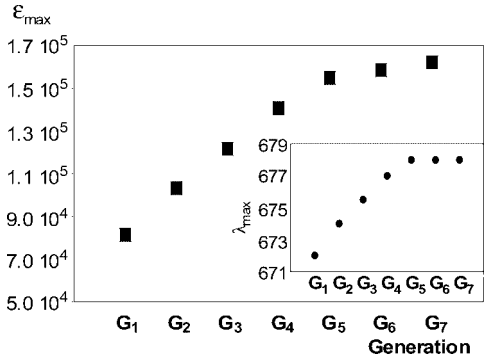

Figure 3. Variation of $\varepsilon_{max}$ of the Q-band with the generation. Insert: variation of $\lambda_{max}$ of the Q-band with the generation for compounds **3-G′$_n$** ($n$ = 1–7), in THF.

Fluorescence also might be particularly suitable to detect the variation of the response of the dendrimer core upon modifications of its local environment. Thus, we tried to study the fluorescence of the series **3-G′$_n$** in THF, via excitation at the beginning of the Q-band at 646 nm and using 3,3′-diethyloxatricarbocyanine iodide (DOTCI) in absolute ethanol as a reference.[20] However, no fluorescence is observed. Such behaviour may seem surprising; indeed, dendritic zinc phthalocyanines in organic solvents have a relatively intense quantum yield ( ≈ 0.30) even for small generations (0–2),[21] but a complete lack of fluorescence has been observed for some cobalt phthalocyanines.[22] Such behaviour is due to the unfilled d-orbitals of $Co^{II}$ that couple with the π orbital system of the phthalocyanine, providing additional and very efficient channels for π* deactivation.[22] Thus, it is not surprising to observe the absence of fluorescence in our case; indeed, this intrinsic deactivation obviously cannot be prevented by the presence of the dendritic branches, whatever the generation of the dendrimer.

## Conclusions

The synthesis of the largest series of dendritic phthalocyanines to date (up to generation 8), and the study of their spectroscopic properties provide interesting insights into the nanoenvironment around the phthalocyanine core and into the role of the dendritic branches. A progressive protection of the core can be deduced from the UV/Vis spectra as expected. The shielding effect of the branches induces an increase of the intensity ($\varepsilon$) of the Q-band specific of phthalocyanines. Furthermore, an increase of the local polarity induced by the arylhydrazone branches constituting the skeleton of the dendrimers is observed, as shown by the bathochromic shift of the Q-band. Both phenomena are observed up to generation 5, but ceased for generations 6 and 7. Such behaviour indicates that the branches of the fifth generation provide a maximum shielding and crowding of the core, and that the influence of additional layers (generations) cannot be detected by the core.

## Experimental Section

**General:** All manipulations were carried out with standard high vacuum and dry-argon techniques. The solvents were freshly dried and distilled (THF and ether over sodium/benzophenone, pentane and $CH_2Cl_2$ over phosphorus pentoxide). All the vessels were wrapped in aluminum foil to protect the compounds from light. Classical $^1H$, $^{13}C$, $^{31}P$ NMR spectra were recorded with Bruker AC 200, AC 250, DPX 300 or AMX 400 spectrometers. References for NMR chemical shifts are 85% $H_3PO_4$ for $^{31}P$ NMR, $SiMe_4$ for $^1H$ and $^{13}C$ NMR spectroscopy. The attribution of $^{13}C$ NMR signals has been done using $J_{mod}$, two-dimensional HMBC, and HMQC, Broad Band or CW $^{31}P$ decoupling experiments when necessary. The numbering used for NMR assignments is depicted in Figure 4. The acquisition of mass spectra (MALDI-TOF) was attempted for the higher generations with a Voyager DE-ST spectrometer (Perseptive Biosystems), but could not afford any data concerning the purity of these compounds, due to rearrangements of the hydrazone linkages, as already observed.[23] UV/Vis spectra were recorded with a Specord 205 spectrophotometer (Analytik Jena).

**Dendrimer 2-G′$_1$: 1-G′$_1$** (0.150 g, 0.036 mmol),[12] $CuCl_2$ (0.0049 g, 0.036 mmol) and triethylamine (11.6 μL, 0.083 mmol) in THF (1.5 mL) were heated at 100 °C whilst stirring in a sealed Schlenk tube for 3 h. The mixture was then cooled to room temperature and was filtered through celite. The resulting solution was evaporated to dryness to afford **2-G′$_1$** as a blue powder in 98% yield (0.149 g). $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 60.6 (s, $P_1$) ppm. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.37 (br. s, 24 H, $CH_3$-N), 7.34 (br. s, 48 H, $C_{0-1}{}^2$-H), 7.79 (br. s, 64 H, $C_{0-1}{}^3$-H, CH=N, CHPc), 9.86 (br. s, 16 H, CHO) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 32.8 (d, $^2J_{CP}$ = 12.6 Hz, $CH_3$-N-$P_1$), 115.2 (s, $C^2$), 117.7 (s, $C_0{}^2$, $C^1$), 122.0 (d, $^3J_{CP}$ = 4.6 Hz, $C_1{}^2$), 128.7 (s, $C_0{}^3$), 129.9 (s, $C^3$), 131.4 (s, $C_1{}^3$), 131.6 (s, $C_0{}^4$), 133.6 (s, $C_1{}^4$), 139.9 (d, $^3J_{CP}$ = 11.9 Hz, CH=N-N-$P_1$), 149.8 (s, $C^4$), 150.0 (s, $C_0{}^1$), 155.1 (d, $^2J_{CP}$ = 7.8 Hz, $C_1{}^1$), 190.8 (br. s, CHO) ppm. IR (KBr): $\tilde{\nu}$ = 1702 $cm^{-1}$ $\nu_{CHO}$. $C_{208}H_{152}CuN_{24}O_{40}P_8S_8$ (4195.5): calcd. C 59.55, H 3.65, N 8.01; found C 59.27, H 3.81, N 7.96.

**Dendrimer 3-G′$_1$: 1-G′$_1$** (0.666 g, 0.161 mmol), $CoCl_2$ (0.0209 g, 0.161 mmol) and triethylamine (49.4 μL, 0.354 mmol) in THF (6 mL) were heated at 110 °C whilst stirring in a sealed Schlenk tube for 3 h. The mixture was then cooled to room temperature overnight and was concentrated under reduced pressure. Then dichloromethane (20 mL) was added and the resulting mixture was filtered through celite. The resulting solution was evaporated to dryness to afford **3-G′$_1$** as a dark green powder in 87% yield (0.585 g). $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 60.7 (s, $P_1$) ppm. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.42 (br. s, 24 H, $CH_3$-N), 7.36 (br. s, 48 H, $C_{0-1}{}^2$-H), 7.76 (br. s, 64 H, $C_{0-1}{}^3$-H, CH=N, CHPc), 9.89 (br. s, 16 H, CHO) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 32.9 (br. s, $CH_3$-N), 118.0 (br. s, $C_0{}^2$), 122.1 (br. s, $C_1{}^2$), 128.6 (br. s, $C_0{}^3$), 131.5 (br. s, $C_1{}^3$), 133.8 (br. s, $C_1{}^4$), 140.0 (br. s, CH=N-N-$P_1$), 155.2 (br. s, $C_1{}^1$), 190.7 (br. s, CHO) ppm. IR (KBr): $\tilde{\nu}$ = 1702 $cm^{-1}$ $\nu_{CHO}$. $C_{208}H_{152}CoN_{24}O_{40}P_8S_8$ (4190.9): calcd. C 59.61, H 3.66, N 8.02; found C 60.36, H 3.71, N 8.07.

**General Procedures for the Synthesis of Dendrimers 3-G$_n$ and 3-G′$_n$**

**Dendrimers 3-G$_n$:** A freshly prepared solution of dichlorothiophosphorhydrazide (0.25 M in $CHCl_3$) was added dropwise to a solution of **3-G′$_{n-1}$** [0.500 g; $n$ = 2 (0.1193 mmol), $n$ = 3 (0.0526 mmol), $n$ = 4 (0.0248 mmol), $n$ = 5 (0.0121 mmol), $n$ = 6 (0.0059 mmol), $n$ = 7 (0.00296 mmol), $n$ = 8 (0.00147 mmol)] in THF (5 to 10 mL). The resulting mixture was stirred overnight then evaporated to dryness. The residue was washed with 20 mL of diethyl ether/pentane (1:1) then dried under vacuum. Dendrimers **3-G$_n$** were obtained as coloured powders from dark green for the lowest generations to light green for the highest generations.

**Dendrimers 3-G′$_n$:** 4-Hydroxybenzaldehyde sodium salt (5% excess) was added to a solution of **3-G$_n$** [0.600 g; $n$ = 2 (0.0887 mmol), $n$ = 3 (0.0409 mmol), $n$ = 4 (0.0197 mmol), $n$ = 5 (0.0097 mmol), $n$ = 6 (0.0048 mmol), $n$ = 7 (0.00239 mmol)] in THF (10 to 20 mL). The resulting mixture was stirred overnight, and then centrifuged. The solution was concentrated under reduced pressure and the residue was washed with 20 mL of THF/diethyl ether/pentane (1:2:2), then twice with 20 mL of diethyl ether/pentane (1:1). Dendrimers **3-G′$_n$** were obtained as coloured powders (from dark green for the lowest generations to light green for the highest generations) after drying under vacuum.

**3-G$_2$:** 79% Yield, 0.638 g. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 62.3 (br. s, $P_1$), 63.3 (br. s, $P_2$) ppm. $^1H$ NMR ($CDCl_3$): $\delta$ = 3.36 (m, 72 H, $CH_3$-N-$P_{1-2}$), 7.25 (br. s, 48 H, $C_{0-1}{}^2$-H), 7.66 (br. s, 80 H, $C_{0-1}{}^3$-H, CH=N-N-$P_{1-2}$, CHPc) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 31.9 (d, $^2J_{CP}$ = 12.3 Hz, $CH_3$-N-$P_2$), 33.0 (d, $^2J_{CP}$ = 13.2 Hz, $CH_3$-N-$P_1$), 115.5 (s, $C^2$), 117.6 (br. s, $C_0{}^2$, $C^1$), 121.9 (br. s, $C_1{}^2$), 128.7 (br. s, $C_0{}^3$, $C_1{}^3$), 129.8 (s, $C^3$), 131.4 (br. s, $C_0{}^4$, $C_1{}^4$), 139.7 (br. s, CH=N-N-$P_1$), 140.7 (d, $^3J_{CP}$ = 17.9 Hz, CH=N-N-$P_2$), 150.3 (br. s, $C_0{}^1$), 151.9 (br. s, $C_1{}^1$) ppm. $C_{224}H_{200}Cl_{32}CoN_{56}O_{24}P_{24}S_{24}$ (6767): calcd. # Zirconium(IV) Tris(phosphinoamide) Complexes as a Tripodal-Type Metalloligand: A Route to Zr–M (M = Cu, Mo, Pt) Heterodimetallic Complexes

**Takashi Sue,[a] Yusuke Sunada,[a,b] and Hideo Nagashima*[a,b]**

**Keywords:** Phosphinoamide / Heterodimetallic / Tripodal ligands

Treatment of $ZrCl_4$ with 3 equiv. of Li($PPh_2NR$) (R = *t*Bu, *i*Pr) gives tris(phosphinoamide)zirconium complexes, $(PPh_2NR)_3$-ZrCl [R = *t*Bu (**1a**), *i*Pr (**1b**)], in high yield. Crystal structures of **1a**,**b** show that three phosphorus atoms are coordinated to the zirconium center in the solid state, whereas variable temperature NMR studies indicate a reversible coordination/dissociation process of three phosphorus atoms in the solution state. Reaction of **1a**,**b** with CuCl give rise to the formation of Zr–Cu heterodimetallic complexes, $ClCu(Ph_2PNR)_3$-ZrCl [R = *t*Bu (**2a**), *i*Pr (**2b**)]. The molecular structures of **2a**,**b** show that the Cu atom adopts a pseudotetrahedral coordination geometry with tripodal phosphorus moieties and a chlorine atom, whereas the ligand arrangement around the Zr atom is trigonal bipyramidal with the linear Cl–Zr–Cu axis at the apical site. A Zr–Mo heterodimetallic complex, $(CO)_3$-$Mo(Ph_2PNiPr)_3ZrCl$ (**3**), is synthesized from **1b** and $Mo(CO)_3$-$(CH_3CN)_3$, in which the ligands around the Mo center are arranged octahedrally, and three phosphorus moieties are coordinated in the *fac*-$P_3$ fashion. The reaction of **1b** with a square planar $Pt^{II}$ precursor, such as $(COD)PtCl_2$, is unique and gives ($\kappa^2$-$Ph_2PNiPr$)$Pt(Ph_2PNiPr)_2ZrCl_3$ (**4**), which is the first example of a Zr–Pt zwitterionic heterodimetallic complex. The reaction involves intramolecular migration of two chlorine atoms from Pt to Zr as well as that of a $Ph_2PNiPr$ moiety from Zr to Pt.

## 1. Introduction

It is well-known in coordination chemistry that ligand design is important for the synthesis of transition-metal complexes with unique structures and properties. Phosphanes are one of the most investigated ligands, especially in their application to homogeneous catalysis. Numerous monodentate and bidentate phosphane ligands have been developed, and their ligation to appropriate transition metals has contributed to the opening of new aspects in catalytic transformations of organic molecules and polymers.[1] Electronic and steric effects of these phosphane ligands are well-documented by using Tolman's $\chi$ values and cone angles for monodentate phosphanes and bite angles for bidentate phosphane ligands.[2] Thus, the chemical properties of most transition-metal complexes having monodentate and/or bidentate phosphane ligands are predictable in modern organometallic chemistry. Although relatively little has been studied compared with chemistry of mono- and bidentate phosphane ligands, tridentate phosphane ligands have attracted the attention of organometallic chemists as a result of their special structural and chemical properties.[3] Tridentate tertiary phosphane ligands can be classified into two types according to their preferred coordination geometries: one is the *fac*-$P_3$ (tripodal) coordination mode, whereas the other is the *mer*-$P_3$ coordination mode. The phosphane 1,1,1-tris[(diphenylphosphanyl)methyl]ethane (triphos) is the best-known *fac*-$P_3$ tripodal-type phosphane ligand for transition metals.[4] For instance, treatment of triphos with CuCl or $Mo(CO)_3(CH_3CN)_3$ reportedly gives (triphos)CuCl[4a] or (triphos)$Mo(CO)_3$, respectively.[4b] These examples clearly demonstrate that the tripodal ligands rigidly coordinate to a single transition-metal center in the *fac*-$P_3$ fashion so as to stabilize the mononuclear transition-metal complexes with tetrahedral and octahedral coordination geometries. This feature is different from the *mer*-$P_3$ ligands that are often used to stabilize a multimetallic framework, which bridges over the dual metals by virtue of its structural flexibility.

An interesting recent development used to control the electronic properties of the phosphane ligand is the introduction of a Lewis acid center in the ligand backbone.[5] As shown in Figure 1, the "amphoteric ligand" reported by Labinger is a typical example, in which both the Lewis acidic $R_2Al$ moieties and Lewis basic $R_2P$ units are included in one molecule; unique reactivity of the aluminum phosphinoamide $Ph_2PNtBuAlEt_2$ was discovered in the reaction with several transition-metal carbonyls.[6,7] The bi-

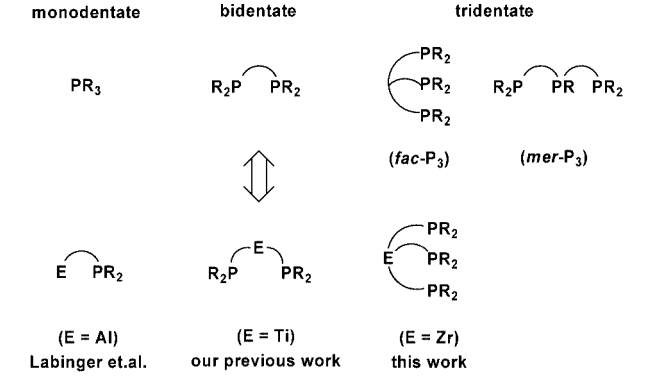
dentate version of the amphoteric ligand was lately reported by Bourissou and coworkers who reported the synthesis of diphosphanylborane ($o$-$i$Pr$_2$P-C$_6$H$_3$)$_2$B(Ph) and its ligation to the RhCl moiety in the reaction with [Rh(nbd)Cl]$_2$.[8,9] We reported earlier a titanium version of bidentate amphoteric ligands, (Ph$_2$PNR)$_2$TiCl$_2$ (R = $t$Bu, $i$Pr), which are good precursors to Ti–Pt and Ti–Ru heterodimetallic complexes, YY′Pt(Ph$_2$PN$t$Bu)$_2$TiCl$_2$ (Y, Y′ = Cl; Y = Me, Y′ = Cl; Y = $p$-Tol, Y′ = Cl; Y, Y′ = Me) and Cp*Ru(μ-Cl)(Ph$_2$PN$t$Bu)$_2$Ti = O as shown in Scheme 1.[10] The Ti–Pt complexes have a trigonal bipyramidal titanium and a square planar platinum center,[10a] whereas the Ti–Ru complex has titanium and ruthenium atoms with trigonal bipyramidal and tetrahedral geometries, respectively.[10b] Synthesis of a tridentate amphoteric ligand was examined by the design of the *fac*-P$_3$ tripodal-type compounds containing a cyclopentadienyl or tris(pyrazolyl)hydroborate zirconium moiety in the molecule; Cp*Zr(OCH$_2$PPh$_2$)$_3$ or TpZr(OCH$_2$PPh$_2$)$_3$ acts as a tripodal-like ligand in Cp*Zr(OCH$_2$PPh$_2$)$_3$Ni(CO), Cp*Zr(OCH$_2$PPh$_2$)$_3$RhMe, and TpZr(OCH$_2$PPh$_2$)$_3$Mo(CO)$_3$.[11]



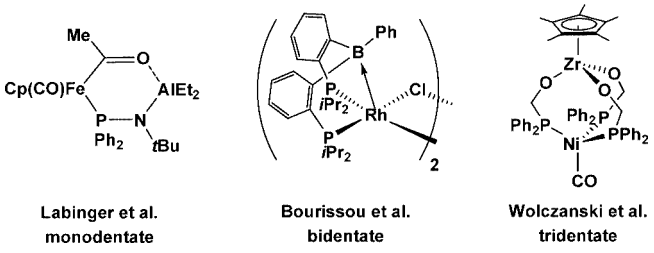


Figure 1. Monodentate, bidentate, and tridentate phosphorus ligands containing a Lewis acidic center.

We were interested in the fact that the cyclopentadienyl group in previous examples of the *fac*-P$_3$ tripodal-type amphoteric ligands reduced the Lewis acidity of the zirconium center. As described above, we synthesized the titanium phosphinoamides as a bidentate amphoteric ligand, which was successfully ligated to organoruthenium or platinum species to give the corresponding Ti–Ru and Ti–Pt complexes. Of interest are the structures of these heterodimetallic complexes: the Ti–Ru compound has a bridging chlorine atom, whereas the existence of a Pt→Ti dative bond is suggested from the crystal structure of the Ti–Pt complexes. The Lewis acidity of the titanium center is probably the reason for these structural features. In this context, we examined the synthesis of (PPh$_2$NR)$_3$TiCl (R = $i$Pr, $t$Bu) by the reaction of TiCl$_4$ with 3 equiv. of LiNRPPh$_2$; however, (PPh$_2$NR)$_2$TiCl$_2$ was the only product at room temperature and only a small amount of the species assignable to the desired (PPh$_2$NR)$_3$TiCl (R = $i$Pr, $t$Bu) was detectable by NMR spectroscopy when the reaction mixture was heated at 70 °C. In sharp contrast, the reaction of 3 equiv. of lithium phosphinoamide with ZrCl$_4$ successfully led to the formation of tris(phosphinoamide)zirconium, (PPh$_2$NR)$_3$ZrCl [R = $t$Bu (**1a**), $i$Pr (**1b**)]. In this paper, we describe the preparation, molecular structure, and solution dynamics of **1a**,**b** and their coordination behavior to several late transition metals. The heterodimetallic complexes ClCu(Ph$_2$PNR)$_3$ZrCl and (CO)$_3$Mo(Ph$_2$PN$i$Pr)$_3$ZrCl showed that these zirconium phosphinoamides behave as a *fac*-P$_3$ tripodal ligand which effectively stabilizes the late-transition-metal complexes with tetrahedral and octahedral geometries. A unique reaction involving complicated intermetallic ligand rearrangement occurred in the reaction of **1b** with (COD)PtCl$_2$, which afforded a zwitterionic dimetallic complex, ($\kappa^2$-Ph$_2$PN$i$Pr)Pt(Ph$_2$PN$i$Pr)$_2$ZrCl$_3$ (**4**).

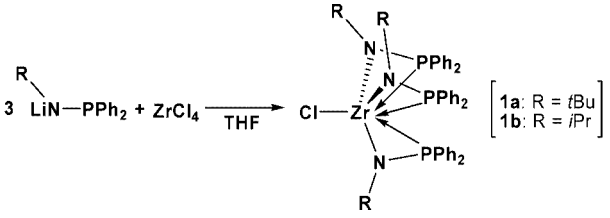
## 2. Results and Discussion

### 2.1 Synthesis and Characterization of Tris(phosphinoamide)-zirconium Complexes (Ph$_2$PN$t$Bu)$_3$ZrCl (1a) and (Ph$_2$PN$i$Pr)$_3$ZrCl (1b)

Treatment of 3 equiv. of Li(Ph$_2$PNR) (R = $t$Bu, $i$Pr) with zirconium tetrachloride in THF afforded tris(phosphinoamide)zirconium complexes, (Ph$_2$PNR)$_3$ZrCl [R = $t$Bu (**1a**), $i$Pr (**1b**)], in 86 and 84% yield, respectively, as colorless crys-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tals (Scheme 2). A single $^{31}P$ NMR resonance appeared for **1a**,**b** at –11.8 and –12.0 ppm, respectively, which were 34.4 and 46.5 ppm shifted to higher field relative to that of the phosphinoamide ligands $Ph_2PNHtBu$ and $Ph_2PNHiPr$.[12] Although dynamic behavior was observed, as described later in detail, $^1H$ and $^{13}C$ NMR spectroscopy clearly showed signals assignable to $Ph_2P$ and *t*Bu or *i*Pr groups. The molecular structures of **1a**,**b** were determined by X-ray diffraction analysis and are shown in Figure 2; representative bond lengths and angles for **1a**,**b** are summarized in Table 1. The asymmetric unit of **1a** contains three crystallographically independent but chemically equivalent molecules. Ambiguous value of the Flack parameter (0.42) suggests the structure of **1a** is inversion twinned, which is sometimes seen in a trigonal space group. There is a threefold axis along with the Zr–Cl bond in the solid-state structure of all three independent molecules of **1a**. One of the molecular structures of **1a** is described in Figure 2. Three phosphinoamide ligands are connected to the zirconium center by a Zr–N bond and all of the three phosphorus moieties are coordinated. Both **1a**,**b** assume a distorted tetrahedral geometry with one chlorine atom and three centers of the N–P bonds. In the solid-state structure, all three phosphorus atoms are oriented away from the chlorine atom, and no isomer was found in the crystal. The N–P bond lengths are comparable to those seen in Eisen's zirconium tetrakis(phosphinoamide) complex, $Zr(Ph_2PNPh)_4$,[13] our previously reported titanium complexes, $(Ph_2PNR)_2TiCl_2$ (R = *t*Bu, *i*Pr), and other known phosphinoamide or related complexes.[14] The Zr–N bond lengths around 2.15 Å are slightly longer than those found in previously reported zirconium amide complexes,[15] whereas the Zr–P bond lengths are somewhat shorter than those of known zirconium phosphane complexes.[16]



Scheme 2.

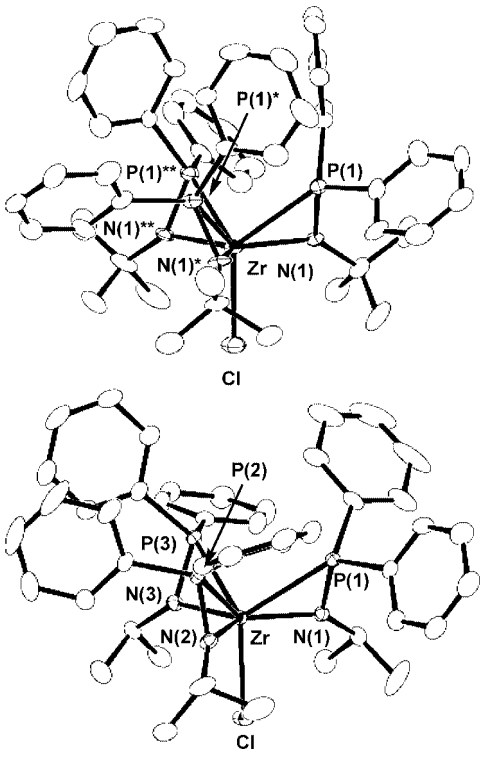


Figure 2. Molecular structures of $(Ph_2PNtBu)_3ZrCl$ (**1a**) (top) $(Ph_2PNiPr)_3ZrCl$ (**1b**) (bottom) with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

Although all of the three phosphorus atoms are bonded with the zirconium center in the solid state, NMR spectroscopic studies suggested a dynamic coordination/dissociation process of these three phosphorus atoms that is similar to that of titanium phosphinoamide, $(Ph_2PNR)_2TiCl_2$,[10a] and $Zr(Ph_2PNPh)_4$.[13] In a representative example, $^1H$ NMR spectra of **1a** are dependent on the temperature measured: at room temperature, three broad signals at $\delta$ = 6.99–7.17 ppm and one singlet at $\delta$ = 1.47 ppm were seen, which are assignable to the protons of the Ph group and the methyl portion of the *t*Bu group. At –90 °C, the spectrum consists of six signals at $\delta$ = 6.53 (m, 2 H), 6.66 (t, 2 H), 6.95 (t, 1 H), 7.20 (t, 2 H), 7.24 (m, 2 H), and 7.29 (t, 1 H) ppm and a slightly broadened singlet at $\delta$ = 1.37 ppm, which are assignable to two sets of phenyl signals

Table 1. Representative bond lengths and angles for **1a**,**b**.

| Bond lengths [Å] | | | Bond angles [°] | | |
|---|---|---|---|---|---|
| | **1a** | **1b** | | **1a** | **1b** |
| Zr–Cl(1) | 2.505(2) [2.488(2), 2.525(2)] | 2.4865(9) | Cl–Zr–N(1) | 91.09(13) [91.07(12), 89.70(11)] | 86.28(7) |

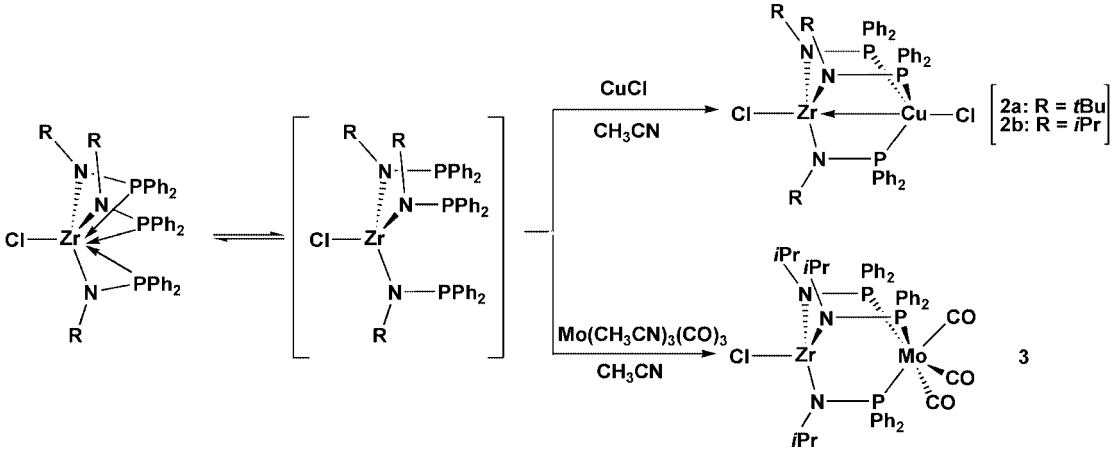
of the *ortho*-, *meta*-, *para*-, *meta*-, *ortho*-, and *para* protons, respectively, and a signal for the *t*Bu group. $^1$H NMR spectroscopic resonances due to the phenyl moieties were unequivocally assigned by a $^1$H–$^1$H selective decoupling measurement. The spectrum is explained by the existence of three magnetically equivalent phosphinoamide ligands, in which two phenyl groups bonded with each phosphorus atom are inequivalent. Similar variable temperature NMR studies of **1b** also showed dynamic behavior; two signals due to the Ph group [$\delta$ = 7.12–7.17 (m, 12 H), 7.22–7.26 (m, 18 H) ppm] appeared at room temperature, which were broadened at –90 °C to show three broad signals. Similarly, the methyl and methine signals of the *i*Pr group were gradually broadened at lower temperatures, and only a single set of broad signals was seen even at –90 °C. Because **1b** is not very soluble in $CD_2Cl_2$ at low temperatures, the well-resolved spectra below –90 °C, in which two doublets due to the inequivalent methyl groups should appear, were unable to be obtained because of technical problems. These spectral changes are consistent with the fact that phosphorus atoms are coordinated to the zirconium center at lower temperatures, whereas reversible dissociation takes place at higher temperatures in solution states; this is favorable for the possible usage of **1** as a tripodal metalloligand as described later.[17]

In close analogy to these results, Eisen and coworkers reported the preparation and structure determination of $Zr(Ph_2PNPh)_4$, which also showed dynamic behavior in variable temperature NMR studies.[13] The four phosphinoamide ligands are bonded to the zirconium atom by Zr–N and Zr←P bonds in the solid state. In solution, the coordination of the phosphorus atoms is reversible. Although the synthetic method of Eisen's complex is similar to that of **1**, neither $Zr(Ph_2PN$*t*$Bu)_4$ nor $Zr(Ph_2PN$*i*$Pr)_4$ was detected in our experiments. As a representative experiment, $ZrCl_4$ was treated with 4 equiv. of $Li(Ph_2PN$*i*$Pr)$ in THF at room temperature overnight; $^1$H and $^{31}$P NMR spectra of the crude product showed the formation of **1b** as a single product; $Zr(Ph_2PN$*i*$Pr)_4$ was not detected. This is presumably attributable to the steric bulkiness of the *t*Bu and *i*Pr groups, which prevents the reaction of **1** to the corresponding zirconium tetrakis(phosphinoamide). It should be noted that we have never seen the formation of $(Ph_2PNR)_2ZrCl_2$ (R = *t*Bu, *i*Pr) even in the reaction of $ZrCl_4$ with less than 2 equiv. of $Li(Ph_2PNR)$, though Zhang et al. recently reported the synthesis of bis(phosphinoamide)zirconium complexes, $(Ph_2PNR)_2ZrCl_2$ (R = *t*Bu, Ph), by the reaction of 2 equiv. of $Li(Ph_2PNR)$ (R = *t*Bu, Ph) with $ZrCl_4$; no detailed spectroscopic data were described.[18] Repeated attempts to reproduce the result of Zhang were unsuccessful. In a typical example, 2 equiv. of $Li(Ph_2PN$*t*$Bu)$ was reacted with $ZrCl_4$ in THF from which only complex **1a** was obtained in 30~50% yield and unreacted $ZrCl_4$ was recovered as a THF adduct. This is interesting in comparison with our previous result that the reaction of $TiCl_4$ with 2 equiv. of $Li(Ph_2PNR)$ resulted in the exclusive formation of $(Ph_2PNR)_2TiCl_2$.

### 2.2 Use of 1 as a Tripodal-Type Metalloligand: Construction of Zr–Cu and Zr–Mo Heterodimetallic Complexes $ClCu(Ph_2PNR)_3ZrCl$ [R = *t*Bu (2a), *i*Pr (2b)] and $(CO)_3Mo(Ph_2PN$*i*$Pr)_3ZrCl$ (3)

As described above, the fluxional behavior of **1** in the variable temperature $^1$H NMR spectroscopic studies suggested that **1** was a *fac*-$P_3$ tripodal-type metalloligand. It is known that the *fac*-$P_3$ tripodal-type is suitable as the ligand of complexes with tetrahedral or octahedral geometry.[3] As a representative model of a tetrahedral complex, $Cu^I$ complexes were prepared. Treatment of **1** with 1 equiv. of CuCl in $CH_3CN$ at room temperature afforded Zr–Cu heterodimetallic complexes, $ClCu(Ph_2PNR)_3ZrCl$ [R = *t*Bu (**2a**), *i*Pr (**2b**)], as yellow crystals in 78 and 82% yield, respectively (Scheme 3). The products were unequivocally characterized by NMR spectroscopy, in which no dynamic behavior was visible in the temperature range from –90 to 30 °C. In a typical example, the $^1$H NMR spectrum of **2a** gave signals due to the *ortho*-, *meta*-, and *para* protons of six magnetically equivalent Ph groups in an integral ratio of 12:12:6, and one singlet at $\delta$ = 1.50 ppm, which is assignable to the methyl protons of the *t*Bu group. In the $^{13}$C NMR spec-



Scheme 3.

trum, four signals at $\delta$ = 127.9 (*meta*-Ph), 129.5 (*para*-Ph), 132.8 (*ortho*-Ph), and 134.5 (*ipso*-Ph) ppm are observed, which are assignable to the six magnetically equivalent phenyl groups, along with two signals at $\delta$ = 34.8 ($CMe_3$) and 61.8 ($CMe_3$) ppm due to the three magnetically equivalent *t*Bu groups. This clearly demonstrates the $C_{3v}$ symmetry of the molecule. A singlet appeared at $\delta$ = –30.6 ppm in the $^{31}P$ NMR spectrum of **2a**; peak broadening due to the interaction with the quadrupolar copper center is good evidence of the coordination of three phosphorus moieties to the Cu atom. Spectral data of **2b** is analogous to those of **2a** in the points that three $Ph_2PN$*i*Pr ligands are magnetically equivalent (the integral ratio of methyl and methine protons of *i*Pr and three Ph protons is 18:3:12:12:6) and broadening of the $^{31}P$ NMR spectroscopic resonance ($\delta$ = –11.2 ppm) is ascribed to the coordination of the phosphorus moiety to the copper center. The $C_{3v}$ symmetric structure deduced from these spectroscopic features is confirmed by X-ray diffraction analysis of **2a**,**b** of which the ORTEP drawings are shown in Figure 3, and selected bond lengths and angles are summarized in Table 2.

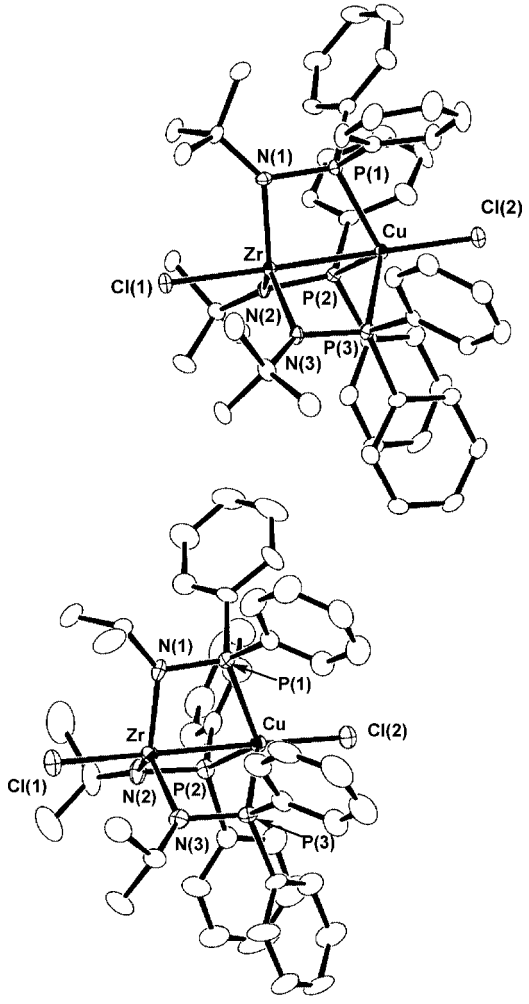

Figure 3. Molecular structures of $ClCu(Ph_2PNtBu)_3ZrCl$ (**2a**) (top) and $ClCu(Ph_2PNiPr)_3ZrCl$ (**2b**) (bottom) with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

The asymmetric unit of **2b** contains two crystallographically independent but chemically equivalent molecules. Bond lengths and angles of the second molecule are given in brackets in Table 2. The molecular structures show that two metal centers are linked by three phosphinoamide ligands. The zirconium center adopts a trigonal bipyramidal coordination geometry with the three nitrogen atoms in the basal position and the Cl(1)–Zr–Cu as the apical axis. The sum of the equatorial angles around the zirconium atom is ca. 357 °. Alternatively, the geometry around the copper is distorted tetrahedrally because of the effective stabilization of tetrahedral geometry given by tripodal-type $P_3$ coordination. The Cl(1)–Zr–Cu–Cl(2) axis is arranged linearly, the bent angles of Cl(1) and Cl(2) from the Zr–Cu axis are 0.77(2)° and 3.12(4)°, respectively, in **2a**. The N–P bond lengths of **2a**,**b** are approximately 0.1 Å shorter than the normal N–P single bonds, but comparable to those of starting zirconium complexes **1a**,**b**, which reflect the partial N–P double bond character. This was supported by the sum of the three angles at the N atom (359.3–359.9°), which is close to the theoretical value of 360° for the planar $sp^2$-hybridized nitrogen atom. The shorter bond lengths of N–P were also observed in our Ti–Pt and Ti–Ru phosphinoamide complexes,[10] $Zr(Ph_2PNPh)_4$,[13] and related complexes.[14] The Cu–P [2.3126(12)–2.3626(11) Å] bond lengths are slightly longer than those of (triphos)CuCl (2.282–2.299 Å),[4e] but comparable to related copper phosphane complexes such as $(PPh_3)_3CuCl$ (2.348 Å).[19]

Reaction of **1b** with an octahedrally arranged molybdenum precursor led to the formation of Zr–Mo heterodimetallic complex **3** (Scheme 3). In **3**, ligands around the molybdenum center are arranged octahedrally, to which the zirconium phosphinoamide moieties are coordinated in a facial coordination mode. Treatment of **1b** with $Mo(CO)_3(CH_3CN)_3$ in $CH_2Cl_2$ at room temperature resulted in the replacement of the $CH_3CN$ ligands by three phosphorus atoms of **1b** to give a Zr–Mo heterodimetallic complex, $(CO)_3Mo(Ph_2PNiPr)_3ZrCl$ (**3**), in 70% yield as pale yellow crystals. The $^1H$ NMR spectrum of **3** showed signals for three magnetically equivalent $Ph_2PNiPr$ moieties, which indicates the $C_{3v}$ symmetric structure of **3** in solution. No dynamic behavior was observed in variable temperature NMR spectroscopic experiments. The $^{31}P$ NMR spectrum of **3** showed a singlet at $\delta$ = 36.3 ppm, which is low-field shifted by ca. 20 ppm relative to $(triphos)Mo(CO)_3$ ($\delta$ =16.8 ppm). The IR spectrum of **3** shows characteristic C≡O stretching bands at 1987 and 1913 $cm^{-1}$, which is 50–70 $cm^{-1}$ shifted to higher frequencies relative to those of $(triphos)Mo(CO)_3$ (1937, 1844 $cm^{-1}$).[4b] The back-donation from molybdenum to the $\pi^*$ orbital of CO in **3** is apparently weaker than that in $(triphos)Mo(CO)_3$. There are two possible explanations for this: one is direct through-space interaction between Lewis acidic Zr and Mo atoms; the other is through-bond interaction by way of the Zr–N–P–Mo bond.[20]

The molecular structure determined by X-ray diffraction analysis is depicted in Figure 4, and representative bond lengths and angles are summarized in Table 2.The two

| N(3)–P(3) | 1.659(3) | 1.668(3) [1.668(3)] | 1.671(2) | 1.615(4) | | | | | |

[a] The asymmetric unit of **2b** consists of two crystallographically independent but chemically equivalent molecules. Bond lengths and angles of the second molecule are given in brackets.

metal centers are connected by three phosphinoamide bridges and three phosphorus atoms are coordinated to the molybdenum center in a *fac*-$P_3$ fashion. The Mo–P bond lengths of **3** [2.5783(7)–2.5796(8) Å] are slightly longer relative to those found in previously reported (triphos)-$Mo(CO)_3$ [2.516(1) Å],[4b] whereas C–O bond lengths of 1.140(3) Å are comparable to those of (triphos)-$Mo(CO)_3$ [1.155(3) Å].[4b] The Mo–Zr and Mo–P distances suggest that the above-described shift of the $\tilde{\nu}$(C≡O) band to higher frequencies can be better explained by through-bond interactions.

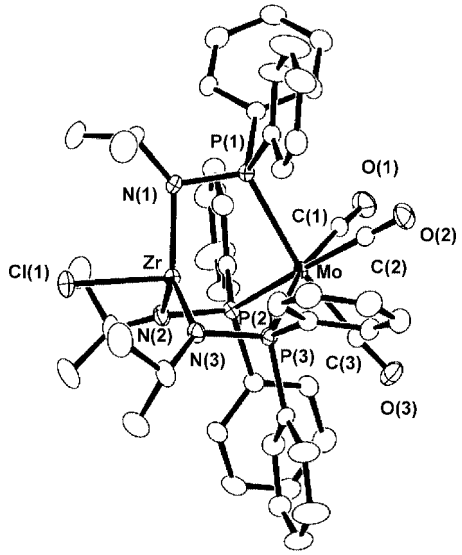

Figure 4. Molecular structure of $(CO)_3Mo(Ph_2PNiPr)_3ZrCl$ (**3**) with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

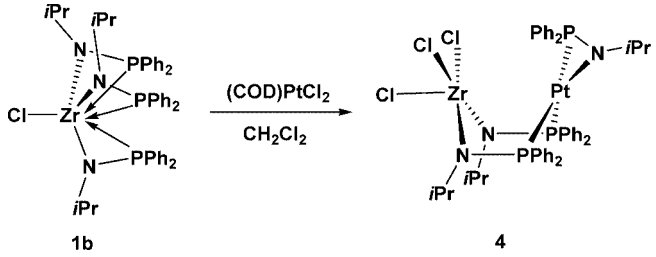
### 2.3 Construction of Zr–Pt Heterodimetallic Complexes with the Use of $Pt^{II}$ Precursors that Do Not Provide Suitable Coordination Geometries for *fac*-$P_3$ Ligands

In the above-described two types of heterodimetallic complexes, the zirconium phosphinoamides act as the *fac*-$P_3$ tripodal-type ligand. The tetrahedral geometry of the $Cu^I$ and octahedral structure of the $Mo^0$ are suitable for the *fac*-$P_3$ tripodal-type coordination. One question concerns the fate of the zirconium phosphinoamides in the reaction with the second metal complex fragment that does not have the appropriate coordination geometry for the *fac*-$P_3$ tripodal-type coordination. To resolve this question, we chose a square-planar arranged $Pt^{II}$ precursor as the reactant in the reaction with **1**. Treatment of **1b** with $(COD)PtCl_2$ in $CH_2Cl_2$ at room temperature for 1 h afforded a novel Zr–Pt heterodimetallic complex, ($\kappa^2$-$Ph_2PNiPr$)$Pt(Ph_2PNiPr)_2$-$ZrCl_3$(**4**) in 75% yield (Scheme 4). The $^{31}P$ NMR spectrum of **4** showed the presence of three different phosphorus atoms with a satellite signal due to the coupling with $^{195}Pt$, $\delta$ = 12.9 ($J_{P,P}$ = 6.7, 286 Hz, $J_{Pt,P}$ = 3153 Hz), 3.4 ($J_{P,P}$ = 6.7, 13.9 Hz, $J_{Pt,P}$ = 3403 Hz), and –32.5 ppm ($J_{P,P}$ = 13.9, 286 Hz, $J_{Pt,P}$ = 1578 Hz). In contrast to the $C_{3v}$ symmetric structures of the Zr–Cu and Zr–Mo complexes giving a sin-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gle $^{31}P$ NMR spectroscopic resonance, the $^{31}P$ NMR spectrum of **4** clearly demonstrates that three $Ph_2PNiPr$ ligands in **4** are magnetically inequivalent and the complex has no symmetry. The nonsymmetric structure of **4** is also supported by the $^1H$ NMR spectrum of **4**; in a typical example, there exists three doublets at $\delta$ = 0.71, 1.15, and 1.45 ppm, which are due to the methyl protons of the *i*Pr group. It is noteworthy that one of them ($\delta$ =0.71 ppm) is significantly shifted to a higher field (vide infra).



Scheme 4.

The molecular structure of **4** was established by X-ray study. Figure 5 shows the ORTEP view of **4** and selected bond lengths and angles of **4** are listed in Table 2. Two metal centers are linked by two phosphinoamide bridges in a boat form similar to Ti–Pt and Ti–Ru phosphinoamide complexes. Ligand arrangement around the zirconium atom is pseudooctahedral with two nitrogen atoms and two chlorine atoms at the basal plane and Cl(1) and Pt at the apical position. Geometry around the platinum atom is distorted square planar with the Pt atom out of the plane defined by P(1), P(2), and the center of N(3)–P(3) (ca. 0.077 Å). A similar distorted structure was also observed in $YY'Pt(Ph_2PNtBu)_2TiCl_2$ complexes in which the Pt atom is out of the plane by ca. 0.181–0.328 Å. The N(3)–P(3) bond length of 1.615(4) Å is ca. 0.03 Å shorter than those of the bridging phosphinoamide ligands, which indicates that there is a slightly increased double bond character of the N(3)–P(3) bond. The ligand arrangement indicates that **4** is formally considered to have a zwitterionic form with $Zr^{IV-}$ and $Pt^{II+}$ centers. To the best of our knowledge, this is the first example of a zwitterionic Zr–Pt heterodimetallic complex. The molecular structure provided clues for understanding the NMR spectroscopic data, which included three magnetically inequivalent methyl and methine signals of the *i*Pr group that were observed in the $^1H$ NMR spectrum and three $^{31}P$ NMR spectroscopic resonances with different chemical shifts and $^{31}P$–$^{195}Pt$ coupling constants. The nonsymmetric structure of **4** is reasonable in giving three doublets at $\delta$ = 0.71, 1.15, and 1.45 ppm that are due to the methyl protons of the *i*Pr group. An unusual upfield shift of one of the three doublets due to the methyl group in the *i*Pr moieties can be ascribed to the methyl proton of the *i*Pr of $\kappa^2$-coordinated phosphinoamide moiety, which is effectively shielded by one of the phenyl rings of the $PPh_2$ group of the bridging phosphinoamide ligand. The signal at $\delta$ = 3.4 ppm in the $^{31}P$ NMR spectrum is *trans* to the N atom of the $\kappa^2$-coordinated phosphinoamide and the other two are *trans* to each other. The value of each coupling constant is consistent with this interpretation.

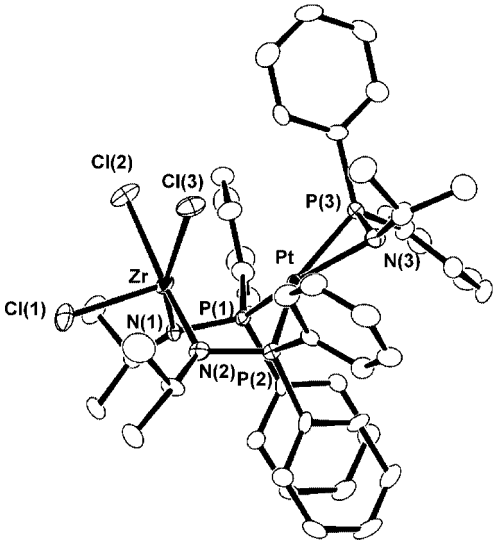


Figure 5. Molecular structure of ($\kappa^2$-$Ph_2PNiPr$)$Pt(Ph_2PNiPr)_2$-$ZrCl_3$(**4**) with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

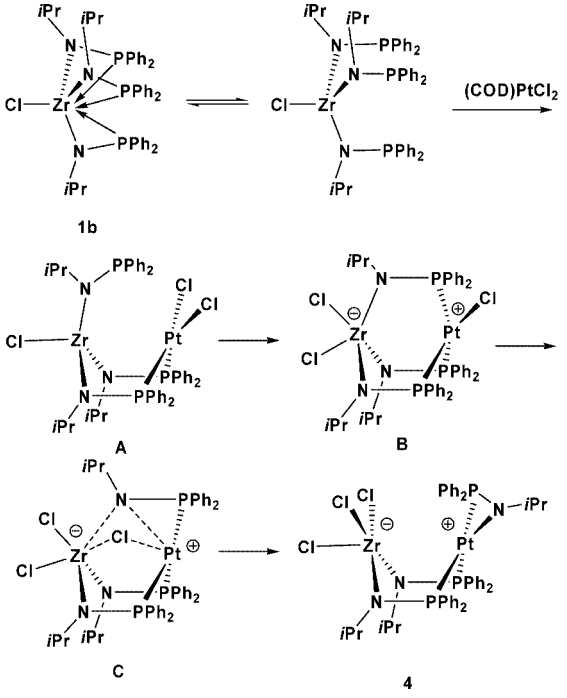
This unusual ligand rearrangement in the reaction of **1b** with a square planar platinum complex fragment provided some mechanistic insight. The reaction is likely to occur intramolecularly and the ligand migration is internuclear. The dimetallic structure of **4**, in which the Zr and Pt exist close enough to exchange their individual ligands, is the key to accomplish the rearrangement. The possible mechanism is illustrated in Scheme 5. Three phosphorus atoms of zirco-



Scheme 5.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nium phosphinoamide **1b** reversibly dissociate to their uncoordinated forms in solution and two of them react with a square-planar $Pt^{II}$ species to form **A**. Coordination of the remaining phosphorus atom to the $Pt^{II}$ center results in internuclear migration of a chlorine atom from Pt to Zr to give zwitterionic intermediate **B**. The tricyclic structure of **B** generates significant ring strain that triggers the cleavage and recombination of the Zr–N and Pt–Cl bonds to form **4**. These results clearly demonstrate that zirconium phosphinoamides **1a**,**b** behave as *fac*-$P_3$ tripodal-type metalloligands in the reaction with transition metals that are able to attain a tetrahedral or octahedral geometry while coordinated to the metal center with a square planar structure. This geometry is unfavorable for the coordination of the tripodal-type ligand and as such an internuclear ligand arrangement is induced to release the ring strain of the primarily formed intermediates.

## 3. Concluding Remarks

As described above, we attained success in the preparation of tris(phosphinoamide)zirconium complexes, $(Ph_2PNR)_3ZrCl$ [R = *t*Bu (**1a**), *i*Pr (**1b**)], which reacted with a second metal complex fragment to form heterodimetallic complexes, $ClCu(Ph_2PNR)_3ZrCl$ (**2**) and $(CO)_3Mo(Ph_2PN{\it i}Pr)_3ZrCl$ (**3**). In the Zr-Cu and Zr-Mo complexes, the coordination geometry around the late-transition-metal center is defined as pseudotetrahedral and octahedral, respectively, owing to the effective coordination of they $P_3$-moiety of **1** in the tripodal fashion. The reaction of **1b** with square planar arranged $(COD)PtCl_2$ is unique and gives a zwitterionic heterodimetallic complex ($\kappa^2$-$Ph_2PN{\it i}Pr)Pt(Ph_2PN{\it i}Pr)_2ZrCl_3$ (**4**); this reaction involves intramolecular migration of two chlorine atoms from Pt to Zr as well as that of a $iPrNPPh_2$ moiety from Zr to Pt. In heterodimetallic complexes **2**–**4**, the Lewis acidic zirconium and the late-transition-metal atoms are closely located; this realized the internuclear ligand arrangement seen in the formation of **4**. The driving force for the rearrangement can be attributed to the fact that the hard chlorine atom preferred the hard zirconium center, whereas the soft phosphinoamide ligand preferred the soft platinum atom. Of interest is the possible dative interaction of the late transition metal to the zirconium atom. As reported earlier, we proposed the Ti←Pt interaction in the $YY'Pt(Ph_2PN{\it t}Bu)_2TiCl_2$ complexes from the crystal structures. There is an occupied $d_{z^2}$ orbital in the platinum atom, and this possibly interacted with the Lewis acidic titanium center. The Ti←Pt bond lengths decrease in the order $Cl_2Pt(Ph_2PN{\it t}Bu)_2TiCl_2$ [2.8358(6) Å] > $MeClPt(Ph_2PN{\it t}Bu)_2TiCl_2$ [2.7547(10) Å] > $Me_2Pt(Ph_2PN{\it t}Bu)_2TiCl_2$ [2.6860(11) Å]; this is explained by assuming that the higher electron dense platinum complex moiety can make a stronger dative bond interaction. The molecular structure of **2** revealed that the Zr–Cu bond length of **2a** [2.6069(7) Å] is slightly shorter than the sum of the van der Waals radii of Zr and Cu (ca. 2.74 Å)[21] (ca. 95% of the sum of the radii). In contrast, the Zr–Mo and Zr–Pt distances of 2.9741(5) and 2.964(4) Å in complexes **3** and **4**, respectively, are nearly identical to the sum of the van der Waals radii of Zr–Mo and Zr–Pt (ca. 3.05 Å)[21] (98 and 97% of the sum of the radii, respectively). The Rh–B interaction is proposed in Bourissou's complex, $\{[(o\text{-}{\it i}Pr_2P\text{-}C_6H_3)_2B(Ph)]RhCl\}_2$, from chemical shifts of the $^{11}B$ NMR spectroscopic resonance and the Rh–B distance found from X-ray crystallography. This was supported by DFT calculations {BP86/[CEP-31G(Rh), 6-31G*(other elements)]}, in which bonding interaction was observed at the HOMO of the complex.[8] However, our preliminary theoretical calculations (single-point calculation of the structure of **2a**/HF/LanL2DZ) did not provide clear evidence for the bonding interaction at the HOMO level. Thus, further theoretical studies with a higher functional level, including those of **3**, **4**, previously reported Ti–Pt heterodimetallic complexes, and related complexes, should be performed to discuss metal–metal interactions.

In summary, **1** is useful as a metalloligand for the formation of Zr–M heterodimetallic compounds, though the coordination mode of **1** was dependent on the preferred coordination environment of the second transition–metal centers. Current efforts are directed towards the synthesis of novel heterodimetallic complexes with several second transition-metal complex fragments having other coordination geometries. Their systematic results, including structural properties and dynamic behaviors, are expected to open the way to construct novel heterodimetallic complexes with unique structures, electronic properties, and reactivities.

## Experimental Section

**General:** Manipulation of air- and moisture-sensitive organometallic compounds was carried out under a dry argon atmosphere by using standard Schlenk tube techniques associated with a high-vacuum line, or with the nitrogen filled glove box. All solvents were distilled from appropriate drying reagents prior to use (THF, hexane; $Ph_2CO$/Na, $CH_3CN$, $CH_2Cl_2$; $CaH_2$). $^1H$, $^{13}C$, and $^{31}P$ NMR spectra were recorded with a JEOL Lambda 600 or a Lambda 400 spectrometer at ambient temperature unless otherwise noted. $^1H$, $^{13}C$, and $^{31}P$ NMR chemical shifts ($\delta$ values) were given in ppm relative to the solvent signal ($^1H$, $^{13}C$) or standard resonances ($^{31}P$; external 85% $H_3PO_4$). IR spectra were recorded with a JASCO FT/IR-550 spectrometer. Melting points were measured with a Yanaco SMP3 micro melting point apparatus. Elemental analyses were performed by the Elemental Analysis Center, Faculty of Science, Kyushu University, or with a Perkin–Elmer 2400/CHN analyzer. Starting materials, phosphinoamide,[12] $[Mo(CO)_3(CH_3CN)_3]$,[22] and $(COD)PtCl_2$[23] were synthesized by the method reported in the literature.

**$(Ph_2PNR)_3ZrCl$ [R = *t*Bu (1a), *i*Pr (1b)]:** In a 100-mL Schlenk tube, $Ph_2PNH{\it t}Bu$ (2589 mg, 10.06 mmol) was dissolved in THF (30 mL). A hexane solution of *n*BuLi (1.56 M, 6.5 mL, 10.14 mmol) was added to the solution at –78 °C, and the solution was slowly warmed to room temperature. After stirring at room temperature for 3 h, the mixture was cooled to –78 °C and a THF (15 mL) solution of $ZrCl_4$ (800 mg, 3.43 mmol) was added dropwise. The slightly yellow solution turned off white in color and a white solid precipitated. After 12 h, all of the volatiles were removed under

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vacuum, and the formed crude product was dissolved in $CH_2Cl_2$ (20 mL). The insoluble materials were filtered off through a G3 filter, and the resulting filtrate was concentrated to a volume of 5 mL. Hexane (20 mL) was added to this supersaturated $CH_2Cl_2$ solution. The desired product was obtained as colorless crystals in 86% yield (2580 mg, 2.88 mmol). In a similar fashion, **1b** was obtained in 84% yield as colorless crystals. **1a**: M.p. 108 °C (dec). $^1H$ NMR (600 MHz, $CD_2Cl_2$): $\delta$ = 1.47 (s, 27 H, *t*Bu), 6.99–7.17 (br., 30 H, Ph) ppm. $^{13}C$ NMR (150 MHz, $CD_2Cl_2$): $\delta$ = 34.1 ($CMe_3$), 60.0 (m, $CMe_3$), 127.5 (m, *meta*-Ph), 128.8 (*para*-Ph), 133.4 (m, *ortho*-Ph), 136.75 (*ipso*-Ph) ppm. $^{31}P\{^1H\}$ NMR (243 MHz, $CD_2Cl_2$): $\delta$ = –11.8 (s) ppm. $C_{48}H_{57}ClN_3P_3Zr$ (895.59): calcd. C 64.37, H 6.42, N 4.69; found C 64.14, H 6.42, N 4.45. **1b**: M.p. 107–108 °C (dec). $^1H$ NMR (600 MHz, $CD_2Cl_2$): $\delta$ = 1.20 [d, $J_{H,H}$ = 6.6 Hz, 18 H, $(CH_3)_2CH$], 3.89 [sept, $J_{H,H}$ = 6.6 Hz, 3 H, $(CH_3)_2CH$], 7.12–7.17 (m, 12 H, *meta*-Ph), 7.22–7.26 (m, 18 H, *ortho* and *para*-Ph) ppm. $^{13}C$ NMR (150 MHz, $CD_2Cl_2$): $\delta$ = 26.8 [$(CH_3)_2CH$], 53.2 [$(CH_3)_2CH$], 128.1 (*meta*-Ph), 129.3 (*para*-Ph), 133.4 (m, *ortho*-Ph), 136.9 (m, *ipso*-Ph) ppm. $^{31}P\{^1H\}$ NMR (243 MHz, $CD_2Cl_2$): $\delta$ = –12.0 (s) ppm.$C_{45}H_{51}ClN_3P_3Zr$ (853.51): calcd. C 63.32, H 6.02, N 4.92; found C 63.34, H 6.52, N 5.40.[24]

**$ClCu(Ph_2PNR)_3ZrCl$ [R = *t*Bu (2a), *i*Pr (2b)]:** A 20-mL Schlenk tube was charged with **1a** (44 mg, 0.050 mmol) and CuCl (5 mg, 0.051 mmol), and the atmosphere was replaced by argon. The mixture was dissolved in $CH_3CN$ (5 mL). The color of the solution changed immediately from colorless to yellow, from which a yellow precipitate was separated. After removal of the solvent in vacuo, the solid was washed with hexane (3 × 2 mL). The crude product was dissolved in warm $CH_2Cl_2$, and the insoluble materials (unreacted CuCl) were filtered off. The filtrate was cooled to –30 °C to form yellow microcrystals of **2a** in 78% yield (38 mg, 0.038 mmol). In a similar fashion, **1b** was obtained in 82% yield as yellow microcrystals. **2a**: M.p. 116–117 °C (dec). $^1H$ NMR (600 MHz, $CD_2Cl_2$): $\delta$ = 1.50 (s, 27 H, *t*Bu), 6.96 (t, *J* = 7.4 Hz, 12 H, *meta*-Ph), 7.15 (t, *J* = 7.4 Hz, 6 H, *para*-Ph), 7.42 (br., 12 H, *ortho*-Ph) ppm. $^{13}C$ NMR (150 MHz, $CD_2Cl_2$): $\delta$ = 34.8 ($CMe_3$), 61.8 (m, $CMe_3$), 127.9 (*meta*-Ph), 129.5 (*para*-Ph), 132.8 (*ortho*-Ph), 134.5 (m, *ipso*-Ph) ppm. $^{31}P\{^1H\}$ NMR (243 MHz, $CD_2Cl_2$): $\delta$ = –30.6 (br) ppm. $C_{48}H_{57}Cl_2CuN_3P_3Zr$ (994.59): calcd. C 57.97, H 5.78, N 4.22; found C 57.51, H 5.94, N 4.32. **2b**: M.p. 117–118 °C (dec). $^1H$ NMR (600 MHz, $CD_2Cl_2$): $\delta$ = 1.38 [d, $J_{H,H}$ = 6.6 Hz, 18 H, $(CH_3)_2$-CH], 3.85 [m, 3 H, $(CH_3)_2CH$], 6.98 (t, $J_{H,H}$ = 7.7 Hz, 12 H, *meta*-Ph), 7.19 (t, $J_{H,H}$ = 7.7 Hz, 6 H, *para*-Ph), 7.34 (br., 12 H, *ortho*-Ph) ppm. $^{13}C$ NMR (150 MHz, $CD_2Cl_2$): $\delta$ = 27.2 [$(CH_3)_2CH$], 53.2 [$(CH_3)_2CH$], 128.1 (*meta*-Ph), 130.0 (*para*-Ph), 133.7 (m, *ortho*-Ph), 134.8 (m, *ipso*-Ph) ppm. $^{31}P\{^1H\}$ NMR (243 MHz, $CD_2Cl_2$): $\delta$ = –11.2 (br) ppm. $C_{45}H_{51}Cl_2CuN_3P_3Zr$ (952.52): calcd. C 56.74, H 5.40, N 4.41; found C 56.87, H 5.80, N 4.59.

**$(CO)_3Mo(Ph_2PNiPr)_3ZrCl$ (3):** A 20-mL Schlenk tube was charged with **1b** (428 mg, 0.501 mmol) and $Mo(CO)_3(CH_3CN)_3$ (155 mg, 0.511 mmol), and the atmosphere was replaced by argon. The mixture was dissolved in $CH_2Cl_2$ (5 mL), and the solution was stirred at room temperature for 1 h. The color of the reaction mixture changed from yellow to red. The solution was kept at –30 °C to form pale yellow microcrystals of **3** in 70% yield (365 mg, 0.353 mmol). M.p. 227–228 °C (dec). $^1H$ NMR (600 MHz, $CD_2Cl_2$): $\delta$ = 1.11 [d, $J_{H,H}$ = 6.8 Hz, 18 H, $(CH_3)_2CH$], 3.67 [m, 3 H, $(CH_3)_2CH$], 7.25–7.28 (m, 12 H, *meta*-Ph), 7.36–7.41 (m, 18 H, *para* and *ortho*-Ph) ppm. $^{13}C$ NMR (150 MHz, $CD_2Cl_2$): $\delta$ = 26.0 [$(CH_3)_2CH$], 53.0 [$(CH_3)_2CH$], 128.9 (m, *meta*-Ph), 129.8 (*para*-Ph), 133.4 (m, *ortho*-Ph), 138.0 (m, *ipso*-Ph), 218.3 (m, CO) ppm. $^{31}P\{^1H\}$ NMR (243 MHz, $CD_2Cl_2$): $\delta$ = 36.3 (s) ppm. IR (KBr pellet): $\tilde{\nu}$ = 1987 (C≡O), 1913 (C≡O) $cm^{-1}$.$C_{48}H_{51}Cl_2MoN_3O_3P_3Zr$ (1033.49): calcd. C 55.78, H 4.97, N 4.07; found C 55.48, H 4.91, N 4.00.

**($\kappa^2$-$Ph_2PNiPr$)$Pt(Ph_2PNiPr)_2ZrCl_3$ (4):** A 20-mL Schlenk tube was charged with **1b** (50 mg, 0.059 mmol) and $(COD)PtCl_2$ (21 mg, 0.056 mmol), and the atmosphere was replaced by argon. The mixture was dissolved in $CH_2Cl_2$ (5 mL), and the solution was stirred at room temperature for 1 h. The color of the reaction mixture changed from yellow to red. The solution was cooled to –30 °C to form pale yellow crystals of **4** in 75% yield (47 mg, 0.042 mmol). M.p. 126–128 °C (dec). $^1H$ NMR (600 MHz, $CD_2Cl_2$): $\delta$ = 0.71 [d, $J_{H,H}$ = 6.8 Hz, 6 H, $(CH_3)_2CH$], 1.15 [d, $J_{H,H}$ = 6.0 Hz, 6 H, $(CH_3)_2CH$], 1.45 [d, $J_{H,H}$ = 6.0 Hz, 6 H, $(CH_3)_2CH$], 2.97 [m, 1 H, $(CH_3)_2CH$], 3.47 [m, 1 H, $(CH_3)_2CH$], 3.62 [m, 1 H, $(CH_3)_2CH$], 6.75–6.80 (m, 4 H, Ph), 6.90–6.97 (m, 4 H, Ph), 7.07–7.12 (m, 2 H, Ph), 7.13–7.17 (m, 4 H, Ph), 7.22–7.27 (m, 2 H, Ph), 7.37–7.42 (m, 4 H, Ph), 7.51–7.60 (m, 10 H, Ph) ppm. $^{13}C$ NMR (150 MHz, $CD_2Cl_2$): $\delta$ = 25.2 [$(CH_3)_2CH$], 25.8 [$(CH_3)_2CH$], 27.0 [$(CH_3)_2CH$], 49.2 [$(CH_3)_2CH$], 54.2 [$(CH_3)_2CH$], 54.7 [$(CH_3)_2CH$], 127.5 (Ph), 128.2 (Ph), 129.0 (Ph), 130.5 (Ph), 130.7 (Ph), 133.0 (Ph), 133.1 (Ph), 133.4 (Ph), 134.1 (Ph) ppm. $^{31}P\{^1H\}$ NMR (243 MHz, $CD_2Cl_2$): $\delta$ = 12.9 (dd, $J_{P,P}$ = 6.7, 286 Hz, $J_{Pt,P}$ = 3153 Hz), 3.4 (dd, $J_{P,P}$ = 6.7, 13.9 Hz, $J_{Pt,P}$ = 3403 Hz), –32.5 (dd, $J_{P,P}$ = 13.9, 286 Hz, $J_{Pt,P}$ = 1578 Hz) ppm.$C_{45}H_{51}Cl_3N_3P_3PtZr$ (1119.51): calcd. C 48.28, H 4.59, N 3.75; found C 48.14, H 4.66, N 3.68.

**X-ray Data Collection and Reduction:** Single crystals of all complexes were grown from $CH_2Cl_2$/pentane. X-ray crystallography was performed with a Rigaku Saturn CCD area detector with graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71070A). The reflection data were collected at 123(2) K by using ω scan in the $\theta$ range of $3.1 \leq \theta \leq 27.5°$ (**1a**), $3.0 \leq \theta \leq 27.5°$ (**1b**), $3.0 \leq \theta \leq 27.5°$ (**2a**), $3.1 \leq \theta \leq 27.5°$ (**2b**), $3.1 \leq \theta \leq 27.5°$ (**3**), $3.1 \leq \theta \leq 27.5°$ (**4**). The data obtained were processed with Crystal-Clear (Rigaku) on a Pentium computer, and were corrected for Lorentz and polarization effects. The structures was solved by direct methods (SIR 97[25] for **1a**,**b**, and **2b**, SIR 92[26] for **2a**, **3**, and **4**) and expanded by using Fourier techniques.[27] The non-hydrogen atoms were refined anisotropically, and the hydrogen atoms by using the riding model. The final cycle of full-matrix least-squares refinement on $F^2$ was based on 10782 observed reflections and 563 variable parameters for **1a**, 9605 observed reflections and 529 variable parameters for **1b**, 10146 observed reflections and 580 variable parameters for **2a**, 20685 observed reflections and 1113 variable parameters for **2b**, 10383 observed reflections and 599 variable parameters for **3**, and on 10368 observed reflections and 556 variable parameters for **4**. Neutral atom scattering factors were taken from Cromer and Waber.[28] All calculations were performed with the CrystalStructure[29,30] crystallographic software package. Details of the final refinement are summarized in Tables 3 and 4, and the numbering scheme employed is shown in Figures 2, 3, 4, and 5 which was drawn with ORTEP at 50% probability ellipsoids. Unsatisfactory quality of the crystal in the crystallographic analysis of **1a** provided two large residual densities near the Zr atom. However, the data obtained are reliable enough to discuss the atom connectivity, bond lengths, and angles. CCDC-632038 (**1a**), -632039 (**1b**), -632040 (**2a**), -632041 (**2b**), -632042 (**3**), and -632043 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.au.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Variable temperature NMR spectroscopic data (**1a**,**b**) and $^1$H, $^{13}$C, and $^{31}$P NMR spectroscopic data (**1a**,**b**, **2a**,**b**, **3**, **4**).

[5] It is well-known that the reaction of a Lewis acidic boron center with an appropriate anion gives the corresponding borate. Peters et al. described the synthesis of a new type of bidentate and *fac*-$P_3$ tripodal phosphanes containing a borate anion, bis or tris[(diphenylphosphanyl)methyl]borate such as $[Ph_nB(CH_2PPh_2)_{4-n}]^-$ ($n$ = 1, 2). They successfully ligate to various transition metals such as Fe, Co, Ni, Pd and Pt complex fragments. Seea) S. J. Thomas, J. C. Peters, *J. Am. Chem. Soc.* **2001**, *123*, 5100–5101; b) T. A. [17] One of the reviewers suggested that the dynamic behavior observed here could also be interpreted as the twisting of the phosphinoamide ligand without dissociation of the phosphorus moiety from the Zr center. Although this possibility could not be ruled out, we consider the coordination/dissociation process of the phosphinoamide ligands to be reasonable for the following reasons. First, a similar process was also proposed in the solution dynamics of $Zr(Ph_2PNPh)_4$ and $(Ph_2PNR)_2TiCl_2$. Second, the facile reaction with CuCl and other complex fragments suggests the existence of uncoordinated phosphorus atoms in solution.

[20] One reviewer suggested that the CO stretching vibration in the IR spectrum could also be shifted as a result of the geometric constrains given by the tripodal phosphorus ligand. This cannot be ruled out.

# Transfer Hydrogenation Reactions Catalyzed by Free or Silica-Immobilized $[RuCl_2(ampy)\{RN(CH_2PPh_2)_2\}]$ Complexes

**Alessandro Del Zotto,*[a] Carla Greco,[a,b] Walter Baratta,[a] Katia Siega,[a] and Pierluigi Rigo[a]**

**Keywords:** Ruthenium / Transfer hydrogenation / Heterogeneous catalysis / Silica / Ketones

The complexes *cis*-$[RuCl_2(ampy)\{R^1N(CH_2PPh_2)_2\}]$ [ampy = (2-aminomethyl)pyridine, $R^1$ = $C_6H_5$ or $(CH_3CH_2O)_3Si(CH_2)_3$] showed very high catalytic activity in the homogeneous transfer hydrogenation of acetophenone (TOF > 300000 $h^{-1}$) with the use of 2-propanol as the hydrogen donor and in the presence of sodium isopropoxide. The ligand $(CH_3CH_2O)_3Si(CH_2)_3N(CH_2PPh_2)_2$ (ATM) was prepared in high yield by reacting (3-aminopropyl)triethoxysilane, paraformaldehyde, and diphenylphosphane in toluene heated at 80 °C. The $-N(CH_2PPh_2)_2$ function was attached to the surface of three different kinds of silica by means of two alternative methods. Thus, MA-Si-150 and mesoporous MA-Si-MCM-41 were prepared by the reaction of the inorganic matrix with ATM, whereas MA-Si-60 was synthesized by reaction of the commercially available 3-aminopropyl-functionalized silica gel with HCHO and $PHPh_2$ in refluxing toluene. The $-(CH_2)_3N(CH_2PPh_2)_2$ functionalized inorganic materials were used to anchor the $RuCl_2(ampy)$ moiety; thus, three different silica-immobilized versions of the *cis*-$[RuCl_2(ampy)(ATM)]$ complex were obtained. The silica-anchored complexes were tested in the transfer hydrogenation of acetophenone, which was found to be fast and quantitative; the effect of the nature of the silica support on the activity of the catalyst was almost negligible. It was possible to reuse the catalytic system for a second cycle without a decrease in the activity, but the efficiency of the catalyst considerably diminished in successive reuses.

## Introduction

The catalytic transfer hydrogenation of ketones has recently emerged as a useful and convenient method to prepare secondary alcohols, including chiral compounds.[1] Several transition-metal complexes have been found to catalyze the reduction of ketones by using 2-propanol as a hydrogen donor or the system formic acid/triethylamine. In particular, significant results were obtained, mainly by Noyori and co-workers, using ruthenium(II) complexes with monotosylated diamines[2] or amino alcohols.[3] These catalysts, as well as those based on rhodium and iridium with the same type of ligands, have been largely investigated in recent years by several research groups.[4] Many efforts have been made to design highly efficient catalysts but, for large-scale applications, increasing activity and productivity of the catalytic reactions is still a target of primary importance as is the ability to separate, recover, and recycle the catalyst.

Recently, we reported the synthesis of a series of phosphanyl–$Ru^{II}$ complexes bearing the (2-aminomethyl)pyridine (ampy)[5–8] ligand or the related 6-(4′-methylphenyl)-2-pyridylmethylamine ligand,[9,10] and examined their ability to catalyze the reduction of ketones. Among complexes with the ampy ligand, exceptionally high catalytic activity was observed for complexes also bearing diphosphane ligands (Figure 1) with the *cis* isomer showing higher efficiency. TOF values up to $4 \times 10^5$ $h^{-1}$ and *ee* values up to 94% with the use of chiral diphosphane ligands were obtained.[7] The analogous species with two triphenylphosphane ligands was less active;[7] however, they seemed to be suitable precursors for the anchoring of the $RuCl_2(ampy)$ moiety to a solid support. The grafting of a complex active in the homogeneous phase to an inert solid support is find-

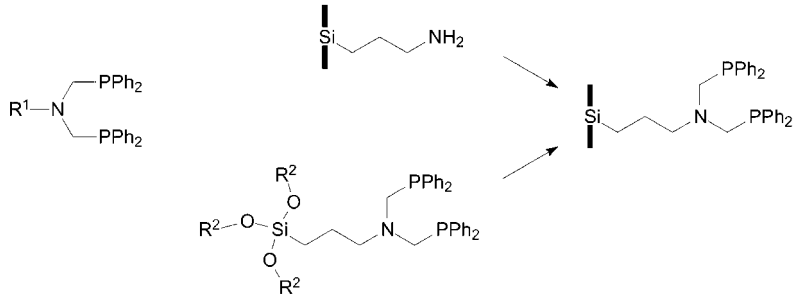


Scheme 1.

ing fast growing interest because the use of immobilized catalysts can provide a significant improvement to overcome the problems of separation and recycling of the catalyst. Silica is the most common support for the heterogenization of molecular catalysts[11] owing to its high stability, inertness, and low cost, all of which render this matrix attractive for medium-scale synthesis and industrial applications. However, the use of catalysts immobilized on inorganic supports for the transfer hydrogenation of ketones is still rare.

With the very active *cis*-[$RuCl_2$(ampy)(dppp)][7] [dppp = 1,3-bis(diphenylphosphanyl)propane] complex in mind, we turned our attention to the $R^1N(CH_2PPh_2)_2$ ligand (Scheme 1), which is topologically analogous to dppp, easily prepared, and used to anchor the $RuCl_2$(ampy) moiety to a solid support. A suitable choice for the $R^1$ group, as in the case of $(OR^2)_3Si(CH_2)_3$–, allows the diphosphane to be conveniently grafted onto a silica support. Alternatively, the $–N(CH_2PPh_2)_2$ function linked to the inorganic matrix can be obtained by reacting a suitable amino-functionalized silica with $H_2CO$ and $PPh_2H$ (Scheme 1).

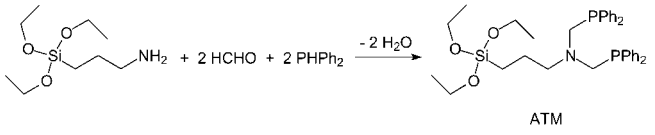
Similar $Ru^{II}$-functionalized silicas, where the metal is surrounded by a $Cl_2N_2P_2$ donor set, were prepared by Kumar and Ghosh starting from supports with ethylenediamino arms.[12] Such catalytic systems were successfully applied to the hydrogenation of carbonyl compounds. Furthermore, Reek, van Leeuwen, and co-workers used silica-immobilized $Ru^{II}$ complexes for the asymmetric reduction of acetophenone where the metal was anchored to the inert support by chelation to an aminoalcohol moiety.[13] Finally, Tu and co-workers investigated the asymmetric transfer hydrogenation of different prochiral ketones by using $Ru^{II}$ complexes immobilized on amorphous or mesoporous silicas functionalized through chiral diamine arms.[14]

In this paper, we present the preparation and characterization of the $Ru^{II}$ complexes [$RuCl_2$(ampy){$R^1N(CH_2PPh_2)_2$}] [$R^1$ = $C_6H_5$ or $(CH_2)_3Si(OCH_2CH_3)_3$] as well as of three different $–N(CH_2PPh_2)_2$ functionalized silicas along with the corresponding $Ru^{II}$ derivatives containing the $RuCl_2$(ampy) moiety. Furthermore, the catalytic application of both free and immobilized complexes to the transfer hydrogenation of acetophenone by using 2-propanol as the hydrogen source is reported and discussed.

## Results and Discussion

### Synthesis and Characterization of the Diphosphanes and Diphosphanyl-Functionalized Silicas

Following a known synthetic method,[15] the diphosphane (3-{bis[(diphenylphosphanyl)methyl]amino}propyl)-triethoxysilane (ATM) was obtained as a colorless oil by reacting (3-aminopropyl)triethoxysilane with paraformaldehyde and diphenylphosphane in a 1:2.5:2 molar ratio in toluene heated at 80 °C [Equation (1)]. Unreacted paraformaldehyde was easily eliminated by filtration after dissolving the crude product in ethyl ether. The product, which was isolated in high yield, showed a single resonance at $\delta$ = –28.0 ppm in the $^{31}P\{^1H\}$ NMR spectrum and a clean $^1H$ NMR spectrum, which confirmed its very high purity.

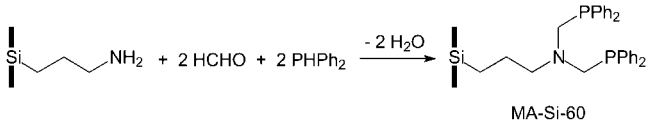


(1)

As the morphology of the inorganic support (surface area and porosity) as well as the distance between the catalytic sites could influence the activity of the anchored transition-metal complex,[11] we prepared three different silica-immobilized versions of the ATM ligand. The first one was synthesized according to Equation (2) by starting from the commercially available 3-aminopropyl-functionalized silica gel (mean pore size: 60 Å, surface area: 550 $m^2 g^{-1}$, loading: 1 $mmol g^{-1}$), which was heated at reflux in toluene for 48 h together with HCHO and $PHPh_2$. The product, 3-{bis-[(diphenylphosphanyl)methyl]amino}propyl-functionalized silica gel (MA-Si-60) was obtained as a white cream powder, which was characterized by elemental analysis (C, H, N, P), TGA measurements, and CP-MAS $^{31}P$ NMR spectroscopy. The latter confirmed the presence of the anchored diphosphane function (broad singlet at $\delta$ = –25.3 ppm). Two minor broad signals centered at $\delta$ = 20.3 and 30.8 ppm, within the range for the P=O resonances, and a shoulder on the high-field signal were indicative of the formation of small amounts of products resulting from the oxidation of the ligand.[16] Furthermore, from the elemental analysis of ni-

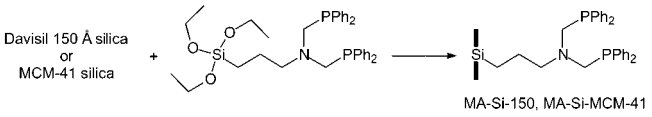
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trogen and phosphorus, it was possible to determine 0.86 and 0.70 mmol $g^{-1}$ loading, respectively. The relative P/N molar ratio (1.6) is lower than that expected (2.0) for total conversion of the $–NH_2$ functions to $–N(CH_2PPh_2)_2$. This finding could be reasonably explained in terms of a material still showing about 20% of the amine function unchanged. The possibility of formation of $HNCH_2PPh_2$ functions on the inorganic surface seems to be excluded by the NMR spectroscopic data, though the presence of both $–NHCH_2PPh_2$ and $–N(CH_2PPh_2)_2$ groups cannot be excluded as the resonances of the P nuclei could be superimposed. It should be noted that no appreciable variation in the loading was observed when the reaction time was increased, whereas a lower value (0.49 mmol $g^{-1}$, based on P analysis) was determined when the reaction was stopped after 24 h. Two further preparations of MA-Si-60 confirmed the good reproducibility of the synthesis.



(2)

Two other 3-{bis[(diphenylphosphanyl)methyl]amino}-propyl-functionalized silicas, namely, MA-Si-150 and MA-Si-MCM-41, were conveniently prepared starting from Davisil silica with a 150 Å mean pore size and a surface area of 300 $m^2 g^{-1}$ and MCM-41 mesoporous silica with a surface area of 1000 $m^2 g^{-1}$, respectively. Both were obtained by combining ATM and the appropriate matrix in toluene heated at 80 °C according to Equation (3). As per MA-Si-60, the two products were characterized by elemental analysis. The calculated loading, based on phosphorus, was 0.46 mmol $g^{-1}$ for MA-Si-150 and 0.59 mmol $g^{-1}$ for MA-Si-MCM-41. As observed for MA-Si-60, the syntheses of MA-Si-150 and MA-Si-MCM-41 showed very good reproducibility. Compounds MA-Si-60, MA-Si-150, and MA-Si-MCM-41 were also characterized by TGA measurements, which were run under an atmosphere of argon in the temperature range 20–800 °C. From 20 to ca. 250 °C, all samples showed about 5% weight loss due to water release, whereas the progressive weight decrease above 250 °C was attributed to organic material release only. Thus, in the range 250–800 °C, MA-Si-60, MA-Si-150, and MA-Si-MCM-41 lost 24, 15, and 20% of their weight, respectively. These data, combined with the relative amounts of $–(CH_2)_3NH_2$ and $–(CH_2)_3N(CH_2PPh_2)_2$ groups, present in each material, calculated from the P/N molar ratio, allowed MA-Si-60, MA-Si-150, and MA-Si-MCM-41 to be obtained following the loading 0.64, 0.39, and 0.50 mmol $g^{-1}$, respectively. Such values are lower than those obtained from the elemental analysis of phosphorus.



(3)

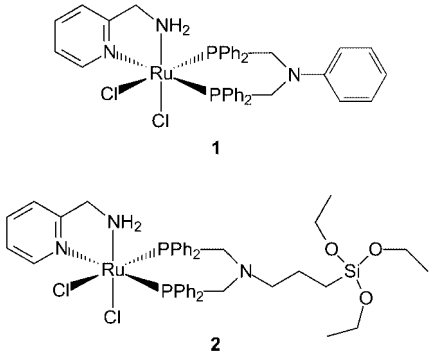


Figure 2. $Ru^{II}$–ampy complexes with the ligands $PhN(CH_2PPh_2)_2$ and ATM.

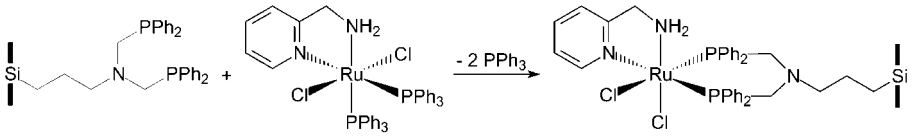
## Synthesis of the Ruthenium(II)–ampy Complexes

The synthesis of the six-coordinate *cis*-$[RuCl_2(ampy)\{R^1N(CH_2PPh_2)_2\}]$ [$R^1 = C_6H_5$ **1**, $R^1 = (CH_2)_3Si(OCH_2CH_3)_3$ **2**] (Figure 2) complexes was carried out as described previously for analogous compounds starting from $[RuCl_2(PPh_3)_3]$, ampy, and the diphosphane in a 1:1:1 molar ratio.[7] The complexes precipitated spontaneously as sand yellow microcrystals from hot solutions of toluene and were almost insoluble in common solvents. However, acceptable quality $^{31}P\{^1H\}$ NMR spectra were recorded from saturated $CD_2Cl_2$ solutions. The spectra of **1** and **2** appeared as AB spin systems with a coupling constant of about 45 Hz; the doublets of **1** were centered at $\delta$ = 39.7 and 43.2 ppm and those of **2** at $\delta$ = 37.8 and 45.9 ppm. As the NMR spectroscopic parameters agree with those found for the *cis*-$[RuCl_2(ampy)(dppp)]$[7] complex, we propose for complexes **1** and **2** the same stereochemistry to that shown by *cis*-$[RuCl_2(ampy)(dppp)]$, with P-*trans*-Cl and P-*trans*-N(pyridine) arrangements. As a matter of fact, this represents the common stable geometry shown by several complexes bearing ampy and different diphosphane ligands with $C_3$ and $C_4$ backbones.[7]

## Synthesis and Characterization of Silica-Immobilized Ruthenium(II) Complexes

As depicted in Equation (4), by reacting the appropriate functionalized silica and the *trans,cis*-$[RuCl_2(PPh_3)_2(ampy)]$ complex in boiling 2-propanol, three different $Ru^{II}$-based immobilized catalysts, namely, Ru-MA-Si-60, Ru-MA-Si-150, and Ru-MA-Si-MCM-41, were prepared. The catalysts were thoroughly washing with dichloromethane to eliminate all traces of physisorbed metal–organic species from the inert support. All materials appeared as yellow to yellow–orange microcrystalline solids, which were characterized by

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

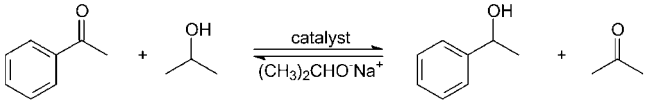


(4)

elemental analysis (C, H, N, Ru) and TGA measurements in the range 20–800 °C to assess the metal loading. The yield of the reaction (based on ruthenium), was generally high (88, 91, and 84% for Ru-MA-Si-60, Ru-MA-Si-150, and Ru-MA-Si-MCM-41, respectively). The calculated loading values were 0.35, 0.29, and 0.33 mmol $g^{-1}$ of complex, in the respective order. To address the reaction to the formation of the *cis* dichloro isomer immobilized on silica, the reagents were heated at reflux and allowed to react for 2 h. In the case of Ru-MA-Si-60, a $^{31}P$ CP/MAS NMR spectroscopic investigation was undertaken. The spectrum showed, in addition to signals due to uncoordinated diphosphane and the corresponding oxide, two signals at $\delta$ = 47 and 53 ppm. The rather large line width may be the reason for the lack of observable coupling between the two inequivalent P nuclei. The NMR measurements are in agreement with the presence of a unique $Ru^{II}$ species immobilized on the inert support.

### Transfer Hydrogenation of Acetophenone in the Homogeneous Phase

The metal-catalyzed transfer hydrogenation of ketones was accomplished by using 2-propanol as the hydrogen donor heated at reflux [Equation (5)]. It is well-documented that the presence of a strong base as a cocatalyst enhances the rate of the reaction.[17] Accordingly, all catalytic tests were run in the presence of sodium 2-propoxide generated by dissolution of metallic sodium into the alcohol.



(5)

As complexes **1** and **2** showed only partial solubility in 2-propanol, even when heated at reflux and in catalytic conditions, we turned our attention to in situ prepared catalytic systems. Thus, the catalytic reactions were carried out with the use of a 0.1 M solution of acetophenone in 2-propanol in the presence of 0.05 mol-% of the *cis,cis*-[$RuCl_2(PPh_3)_2$(ampy)] complex, 0.06 mol-% of the appropriate $R^1N(CH_2PPh_2)_2$ ligand, and 2 mol-% of $(CH_3)_2CHO^-Na^+$ (substrate/Ru/base = 2000:1:40) under reflux conditions. $^{31}P$ NMR spectroscopic monitoring of a dilute $CDCl_3$ solution containing *trans,cis*-[$RuCl_2(PPh_3)_2$(ampy)] and the ligand ATM in a 1:1 molar ratio showed that on increasing the temperature the $PPh_3$ ligands are completely replaced by the diphosphane ligand and that after prolonged heating the only Ru-containing species detectable in solution was complex **2**. Analogous results were obtained by monitoring the *trans,cis*-[$RuCl_2(PPh_3)_2$(ampy)]/[$C_6H_5N(CH_2PPh_2)_2$] system, for which the exclusive formation of **1** was observed. These findings confirm that the in situ prepared catalytic systems effectively correspond to isolated complexes **1** and **2**, which are obtained in almost insoluble form in refluxing toluene.

A comparison of the catalytic efficiency of the complexes bearing $R^1N(CH_2PPh_2)_2$ ligands with that of isostructural *cis*-[$RuCl_2$(ampy)(dppp)] shows that the modification of the diphosphane by substitution of the central carbon atom of the P–C–C–C–P skeleton with a N–$R^1$ moiety has only a little influence on the activity of the relative ruthenium complex. As a matter of fact, by using complexes **1** and **2**, the catalytic reduction of acetophenone was completed (98%) within 1 min (Table 1, Entries 1 and 2), and the corresponding very high TOF values (>300000 $h^{-1}$ at 50% conversion) were of the same magnitude to that found for *cis*-[$RuCl_2$(ampy)(dppp)] (220000 $h^{-1}$).[7]

### Transfer Hydrogenation of Acetophenone in the Heterogeneous Phase

All three silica-immobilized ruthenium complexes were examined as catalysts in the transfer hydrogenation of acetophenone. Standard reactions were carried out by using 500:1 and 20:1 acetophenone/Ru and $(CH_3)_2CHO^-Na^+$/Ru molar ratios, respectively, at the reflux temperature of 2-propanol (82 °C). The results are collected in Table 1. Although, as expected, the immobilized complexes were much less active than their counterparts in the homogeneous phase, a quantitative conversion of the substrate into 1-phenylethanol was observed within 90 min (Table 1, Entries 3–5), and the results showed that the nature of the inorganic support played an almost negligible role on the performance of the catalyst. An analogous behavior was observed for ruthenium complexes anchored on mesoporous MCM-41 and MCM-48 and amorphous silicas.[12] The concentration of the strong base is crucial for the activity of the supported complex. In fact, a decrease in the $(CH_3)_2CHO^-Na^+$/Ru molar ratio from 20:1 to 5:1 resulted in a 94% conversion achieved in 8 h by using Ru-MA-Si-MCM-41 (Table 1, Entry 6). It should be stressed that the stability of the functionalized silicas Ru-MA-Si-60, Ru-MA-Si-150, and Ru-MA-Si-MCM-41, as well as that of the precursor 3-aminopropyl-functionalized silica gel, towards $(CH_3)_2CHO^-Na^+$ was analyzed. All samples, after treatment with a 20-fold excess of base for 2 h at 100 °C showed a 15–20% reduction in the linked organic moiety (based on nitrogen analysis). These results are in agreement with the metal

[a] The values reported in parenthesis for Entries 7 and 8 indicate the successive reuses of the catalyst. [b] Substrate/catalyst(Ru) molar ratio. [c] Base/catalyst molar ratio. [d] The yield of 1-phenylethanol was determined by GC. [e] Reaction run in the homogeneous phase, Ru/ligand, 1:1.2 molar ratio. [f] TOF = 320000 $h^{-1}$ (turnover frequency = mol of acetophenone converted to 1-phenylethanol per mole of catalyst per hour at 50% conversion). [g] TOF = 340000 $h^{-1}$. [h] At 40 °C.

leaching measured after the first use of the catalyst (see below).

Recycling tests were run on all three silica-immobilized ruthenium complexes with the use of both the 500:1 and the 100:1 substrate/ruthenium molar ratios. As almost identical results were observed with the three different silica supports, only those obtained with the representative Ru-MA-Si-150 catalyst are presented in Table 1. By using a high substrate/ruthenium molar ratio, such as 500:1, the activity of the recycled catalyst in the second run resulted reduced [Table 1, Entries 7 and 7(1)], although complete conversion of acetophenone into 1-phenylethanol was achieved. In the next reuse, only low amounts of product were obtained, which indicates that there is a breakdown in the catalytic system [Table 1, Entry 7(2)]. The measurements were repeated by using a lower substrate/ruthenium molar ratio (100:1). As can be seen in Table 1 [Entries 8–8(3)], the efficiency of the catalyst was apparently retained in the first reuse, but then it drastically decreased; however, in the third run the substrate underwent complete transformation into 1-phenylethanol. It should be stressed that in each successive catalytic trial, the recovered catalyst was mixed not only with acetophenone and solvent, but also with a 20-fold excess of $(CH_3)_2CHO^-Na^+$ with respect to the amount of ruthenium effectively present. It is important to note that the efficiency of the catalyst did not appreciably fade from the first to the second use. This finding should be compared with the observed breakdown in the activity of complexes **1** and **2**, as well as of all similar derivatives,[7] when reused as homogeneous catalysts.

As decomposition processes should be reduced by working at low temperature, the catalytic potential of Ru-MA-Si-MCM-41 was verified at 40 °C. In this case, the reaction proceeded at an extremely low rate as only 6% conversion was observed after 12 h (Table 1, Entry 9). ICP MS measurements carried out on both Ru-MA-Si-150 and Ru-MA-Si-MCM-41 systems treated at 100 °C for 2 h in the presence of a strong excess of $(CH_3)_2CHO^-Na^+$ (20:1 with respect to the metal) indicated that for both samples about 15% of the ruthenium present in the immobilized catalyst was released into the solution. Not surprisingly, analogous results concerning the metal leaching were obtained by measuring the ruthenium amount in solution after the first catalytic trial. By contrast, an almost negligible metal leaching (<2%) was measured in the successive reuse of the catalyst. Thus, as the activity of the immobilized complex remained unchanged from the first to the second use, one can conclude that the ruthenium released into the solution is present in a catalytically inactive form. It should be noted that $^{31}P$ NMR spectroscopic measurements run on the recovered solutions did not give any useful information about the decomposition pattern of the catalyst. The neat decline of the efficiency of the catalyst in the successive reuses can be ascribed to a decomposition of the structure of the supported metal complex.

## Conclusions

We have shown that the *cis*-[$RuCl_2$(ampy)-{$R^1N(CH_2PPh_2)_2$}] complexes are highly efficient homogeneous catalysts in the transfer hydrogenation of acetophenone with 2-propanol and that they may have great potential for a broad application in the reduction of carbonyl compounds. We have also demonstrated that the anchoring of the $RuCl_2$(ampy) moiety to a silica support can be easily accomplished when the surface of the inorganic matrix is prior functionalized with $-N(CH_2PPh_2)_2$ arms. Such a modification of the support was done by two alternative pathways, which allowed the syntheses of three different mesoporous or amorphous silicas and of the relative immobilized ruthenium(II) complexes. These systems have shown to be catalytically active in the transfer hydrogenation of acetophenone, which is rapidly and quantitatively transformed into 1-phenylethanol. Recovery and recycling of the inorganic material still resulted in good catalytic perform-

ance but only for the first reuse as decomposition of the catalyst limited successive reuses.

## Experimental Section

**General:** All reagents were purchased from Aldrich and used without further purification. Commercial reagent grade solvents were dried according to standard methods and freshly distilled under an atmosphere of argon before use. All syntheses and manipulations were carried out under an atmosphere of argon by using either standard Schlenk or glove box techniques. The diphosphane $PhN(CH_2PPh_2)_2$[15b] and the complexes $[RuCl_2(PPh_3)_3]$,[18] *trans*,*cis*-$[RuCl_2(PPh_3)_2(ampy)]$,[7] and *cis*,*cis*-$[RuCl_2(PPh_3)_2(ampy)]$[7] were synthesized according to literature procedures. The solution of $(CH_3)_2CHO^-Na^+$ in 2-propanol used in the catalytic trials was prepared by dissolving 46 mg of freshly cut Na into 20 mL of solvent and kept under an atmosphere of argon in the dark. The $^1H$ and $^{31}P$ NMR spectra in solution (at 200.13 and 81.02 MHz, respectively) were recorded with a Bruker AC 200 F QNP spectrometer. The $^1H$ chemical shifts were referenced to $SiMe_4$, whereas positive $^{31}P$ NMR chemical shifts are reported downfield from 85% $H_3PO_4$ as an external standard. The NMR characterization of solid samples was performed with a Bruker AC 200 spectrometer equipped for solid state analysis. Samples were spun at 7000 Hz in 7 mm diameter zirconia rotors with Kel-F caps. $^{31}P$ SPE MAS NMR spectra were obtained at 80.90 MHz by using a single pulse experiment and high-power proton decoupling, with 120 s relaxing delay. $^{31}P$ NMR chemical shifts were externally calibrated with respect to solid triphenylphosphane at $\delta = -7.2$ ppm and were referenced to 85% $H_3PO_4$. The GC analyses of the catalytic mixtures were run with a Fisons GC 8000 Series gas chromatograph equipped with a Supelco PTA-5 column [30 m long, 0.53 mm i.d., coated with a 3.0 μm poly(5% diphenyl-95% dimethylsiloxane) film] Injector temperature was kept at 250 °C and the column temperature was programmed from 50 °C to 170 °C with a gradient of 8 °C min$^{-1}$. The elemental analyses (C, H, N) were carried out at the Microanalytical Laboratory of the Dipartimento di Scienze e Tecnologie Chimiche, Università di Udine, with a Carlo Erba 1106 elemental analyzer. Phosphorus and ruthenium quantitative determination were carried out at the Dipartimento di Scienze e Tecnologie Chimiche and the Dipartimento di Scienze Agrarie e Ambientali, Università di Udine by using a Varian Vista MPX axial Inductively Coupled Plasma-Optical Emission spectrometer (for the determination of P) and a Spectro Analytical Instruments Spectromass 2000 Type MSDIA10B Inductively Coupled Plasma Mass spectrometer (for the determination of Ru). Samples (20 mg) were digested on a microwave apparatus MILESTONE Mega 1200 by use of 1 mL of 65% $HNO_3$, 0.4 mL of 30% $H_2O_2$ and 0.1 mL of 40% HF with a mineralization program at 650 W for 20 min in Teflon vessels. Thermogravimetric analyses were performed by using a TA Instrument (Waters) TGA Q500 apparatus. Weight loss was measured in the range 20–800 °C with a heating rate of 10 °C min$^{-1}$, under an argon atmosphere.

**(3-{Bis[(diphenylphosphanyl)methyl]amino}propyl)triethoxysilane (ATM):** A mixture of (3-aminopropyl)triethoxysilane (0.89 g, 4.0 mmol), paraformaldehyde (0.30 g, 10 mmol) and diphenylphosphane (1.49 g, 8.0 mmol) was stirred in toluene (20 mL) and heated at 80 °C for 1 h with complete dissolution of solid paraformaldehyde. The solvent was removed under vacuum. The resulting oil was treated with ethyl ether (20 mL), the mixture was filtered, and the product was recovered from the solution as a colorless oil by elimination of the solvent under vacuum. Yield: 2.18 g (88%). $^1H$ NMR (200 MHz, $CDCl_3$, 295 K): $\delta$ = 7.1–7.5 (m, 20 H, *phenyl*), 3.73 (q, $J_{H,H}$ = 7.0 Hz, 6 H, $CH_2CH_3$), 3.55 (d, $J_{P,H}$ = 3.3 Hz, 4 H, $NCH_2P$), 2.82 (m, 2 H, $CH_2CH_2N$), 1.48 (m, 2 H, $CH_2CH_2CH_2$), 1.16 (t, $J_{H,H}$ = 7.0 Hz, 9 H, $CH_3$), 0.46 (m, 2 H, $CH_2Si$) ppm. $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$, 295 K): $\delta$ = 138.2 (d, $J_{C,P}$ = 12.8 Hz, $C^i$), 133.0 (d, $J_{C,P}$ = 18.3 Hz, $C^o$), 128.3 ($C^p$), 128.2 (d, $J_{C,P}$ = 8.5 Hz, $C^m$), 59.2 (t, $J_{C,P}$ = 9.2 Hz, $CH_2CH_2N$), 58.6 (dd, $J_{C,P}$ = 5.5, 9.1 Hz, $NCH_2P$), 58.2 ($CH_2CH_3$), 19.7 ($CH_2CH_2CH_2$), 18.3 ($CH_2CH_3$), 7.6 ($CH_2Si$) ppm. $^{31}P\{^1H\}$ NMR (81 MHz, $CDCl_3$, 295 K): $\delta$ = –28.0 ppm.

***cis*-[$RuCl_2$(ampy){$PhN(CH_2PPh_2)_2$}] (1):** $[RuCl_2(PPh_3)_3]$ (384 mg, 0.40 mmol) and 2-(aminomethyl)pyridine (45 mg, 0.42 mmol) were mixed in toluene (15 mL), and the slurry was heated at reflux for 2 h. The ligand $PhN(CH_2PPh_2)_2$ (196 mg, 0.40 mmol) was then added, and the mixture was heated at reflux for another 20 h. Upon cooling, a sand yellow powder precipitated, which was isolated by filtration, washed with ethyl ether, and dried under reduced pressure. Yield: 225 mg (73%). $C_{38}H_{37}Cl_2N_3P_2Ru$ (769.66): calcd. C 59.30, H 4.85, N 5.46; found C 59.23, H 4.66, N 5.31. $^{31}P\{^1H\}$ NMR (81 MHz, $CD_2Cl_2$): $\delta$ = 39.7 (d, $J_{P,P}$ = 44.7 Hz), 43.2 (d, $J_{P,P}$ = 44.7 Hz) ppm.

***cis*-[$RuCl_2$(ampy)(ATM)] (2):** As for **1**, but with the use of the ATM ligand instead of $PhN(CH_2PPh_2)_2$. Sand yellow solid. Yield: 246 mg (68%). $C_{41}H_{53}Cl_2N_3O_3P_2RuSi$ (897.90): calcd. C 54.84, H 5.95, N 4.68; found C 54.01, H 5.92, N 4.59. $^{31}P\{^1H\}$ NMR (81 MHz, $CD_2Cl_2$): $\delta$ = 37.8 (d, $J_{P,P'}$ = 46.2 Hz), 45.9 (d, $J_{P,P'}$ = 46.2 Hz) ppm.

**Preparation of 3-{Bis[(diphenylphosphanyl)methyl]amino}propyl-Functionalized Silica Gels**

**MA-Si-60 from Silica with 60 Å Mean Pore Size:** A mixture of 3-aminopropyl-functionalized silica gel (60 Å mean pore size) (1.00 g, 1.0 mmol of amine), paraformaldehyde (90 mg, 3.0 mmol), and diphenylphosphane (465 mg, 2.5 mmol) was stirred in toluene (20 mL) and heated at reflux for 48 h. A cream white product was recovered by filtration, washed with ethyl ether, and dried under vacuum. Yield: 1.15 g. Composition found: C 19.90, H 2.30, N 1.21, P 4.32. TGA analysis (20–800 °C, under argon): $\Delta w$ = 24% (water loss excluded).

**MA-Si-150 from Silica with 150 Å Mean Pore Size:** A mixture of Davisil silica gel (150 Å mean pore size) (510 mg), which was activated by heating at 150 °C under vacuum for 15 h, and ATM (302 mg) was stirred in toluene (10 mL) and heated at 110 °C for 20 h. The pale yellow mixture was cooled, filtered, washed with toluene, dichloromethane, ethanol, and ethyl ether, and finally dried under reduced pressure to obtain a cream white solid. Yield: 782 mg. Composition found: C 13.01, H 1.56, N 0.77, P 2.83. TGA analysis (20–800 °C, under argon): $\Delta w$ = 14% (water loss excluded).

**MA-Si-MCM-41 from MCM-41 Mesoporous Silica:** A mixture of MCM-41 mesoporous silica gel (440 mg) which was activated by treatment at 150 °C under vacuum for 2 h, and ATM (310 mg) was stirred in toluene (10 mL) and heated at 110 °C for 18 h. After cooling, the mixture was filtered, and the white solid was washed with toluene, dichloromethane, ethanol, and ethyl ether. The white product was then dried under reduced pressure. Yield: 714 mg. Composition found: C 19.87, H 2.21, N 0.96, P 3.64. TGA analysis (20–800 °C, under argon): $\Delta w$ = 20% (water loss excluded).

**Synthesis of Silica-Supported $Ru^{II}$ Complexes**

**$Ru^{II}$ Complex Supported on MA-Si-60 Silica (Ru-MA-Si-60):** A suspension of silica MA-Si-60 (100 mg) and *trans*,*cis*-$[RuCl_2(PPh_3)_2(ampy)]$ (32 mg) was heated at reflux in 2-propanol (5 mL) for 2 h.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

After cooling, the mixture was filtered, and the solid was carefully washed with 2-propanol, dichloromethane (until the discarded solvent resulted colorless), and ethyl ether to give a yellow powder, which was dried under reduced pressure. Yield: 102 mg. Composition found: C 21.29, H 2.47, N 1.55, Ru 3.48. TGA analysis (20–800 °C, under argon): $\Delta w$ = 20% (water loss excluded).

**$Ru^{II}$ Complex Supported on MA-Si-150 Silica (Ru-MA-Si-150):** Ru-MA-Si-150 was prepared as indicated above for Ru-MA-Si-60 from silica MA-Si-150 (100 mg) and *trans*,*cis*-[$RuCl_2(PPh_3)_2$(ampy)] (26 mg). The isolated product is a yellow powder. Yield: 92 mg. Composition found: C 15.38, H 1.70, N 1.10, Ru 3.22. TGA analysis (20–800 °C, under argon): $\Delta w$ = 16% (water loss excluded).

**$Ru^{II}$ Complex Supported on MA-Si-MCM-41 Silica (Ru-MA-Si-MCM-41):** Ru-MA-Si-MCM-41 was prepared as indicated above for Ru-MA-Si-60 from functionalized mesoporous silica MA-Si-MCM-41 (100 mg) and *trans*,*cis*-[$RuCl_2(PPh_3)_2$(ampy)] (32 mg). The product is a yellow–orange microcrystalline powder. Yield: 99 mg. Composition found: C 20.95, H 2.18, N 1.34, Ru 3.41. TGA analysis (20–800 °C, under argon): $\Delta w$ = 20% (water loss excluded).

**Studies on the Stability of the Functionalized Silicas Towards Sodium Isopropoxide:** A 25-mL Schlenk was charged with silica (3-aminopropyl-functionalized silica gel, MA-Si-60, MA-Si-150, or MA-Si-MCM-41) (15 mg), 2-propanol (10 mL), and the suitable amount of a 0.1 M solution of $(CH_3)_2CHO^-Na^+$ in 2-propanol to obtain a 1:20 molar ratio between the organic function linked to silica and base. The mixture was warmed under an atmosphere of argon, at 100 °C for 2 h. After cooling, the solid was filtered off, washed with 2-propanol and dichloromethane, dried, and analyzed (C, H, N).

**Catalytic Transfer Hydrogenation of Acetophenone in Homogeneous Phase:** Two solutions containing (a) acetophenone and (b) *cis*,*cis*-[$RuCl_2(PPh_3)_2$(ampy)]/ATM were prepared as follows: (a) a 50-mL Schlenk was charged with acetophenone (240 μL, 2 mmol) and 2-propanol (19 mL), and the vessel was put into an oil bath at 100 °C; (b) a 10-mL Schlenk was charged with *cis*,*cis*-[$RuCl_2(PPh_3)_2$(ampy)] (4.0 mg, 5 μmol), ATM (6.8 mg, 10 μmol), 2-propanol (3 mL), and $(CH_3)_2CHO^-Na^+$ (0.1 M in 2-propanol, 2 mL). The mixture was then gently warmed until complete dissolution of the complex was achieved. Finally, 1 mL of solution (b) was added to solution (a) kept at reflux, with immediate starting of the catalytic reaction. For the GC analysis of the reaction mixture, 0.2 mL of the solution was extracted by means of a syringe, cooled, mixed with ethyl ether (2 mL), and the resulting suspension was passed through a microcolumn filled with silica gel to eliminate any inorganic material.

**General Procedure for the Transfer Hydrogenation of Acetophenone with Silica-Supported Catalysts:** Under an argon atmosphere, a 25-mL Schlenk was charged with the silica-anchored ruthenium(II) complex ($10^{-3}$ mmol of metal). Then, 2-propanol (10 mL) and $(CH_3)_2CHONa$ (0.1 M in 2-propanol, 0.2 mL) were added and the mixture was heated at reflux. Finally, by addition of acetophenone (0.5 mmol) the catalytic reaction started. Samples for the GC analysis were prepared as indicated above.

**General Procedure for Recycling of Silica-Supported Catalysts:** The mixture recovered after the first catalytic trial was centrifuged, and the solution was discarded. The solid was washed with dichloromethane and 2-propanol and vacuum dried. It was then weighed and transferred into a 25-mL Schlenk, which was charged under an atmosphere of argon, with 2-propanol and $(CH_3)_2CHO^-Na^+$ (0.1 M in 2-propanol). The mixture was warmed to reflux, and the catalytic reaction was started by the addition of acetophenone. Amounts of solvent, base, and substrate were based on the weight of the recovered catalyst to maintain a constant substrate/metal/base ratio. Analogous procedures were adopted for successive reuses of the catalysts.

## Acknowledgments

The authors are indebted to Federchimica, Rome, Italy for a fellowship to C. G. We thank Prof. C. de Leitenburg, Dr. F. Tubaro, and Mr. P. Polese (Dipartimento di Scienze e Tecnologie Chimiche, University of Udine) for carrying out TGA measurements, ICP-MS, and elemental analyses, respectively. We also thank Dr. A. Sassi (Dipartimento di Processi Chimici dell′Ingegneria, University of Padua) and Dr. M. Contin (Dipartimento di Scienze Agrarie e Ambientali, University of Udine) for performing solid state NMR and ICP-OE measurements, respectively.

# Pyridine Carboxylate Complexes of $Mo^{II}$ as Active Catalysts in Homogeneous and Heterogeneous Polymerization

**Maria Vasconcellos-Dias,[a] Carla D. Nunes,*[a] Pedro D. Vaz,[a] Paula Ferreira,[b] and Maria José Calhorda*[a]**

**Keywords:** Molybdenum / Lamellar materials / Polymerization / Heptacoordination / Catalysis / ROMP

New lamellar materials intercalated with molybdenum(II) complexes with potential catalytic properties were prepared by a stepwise procedure. The lamellar material was first calcined at 823 K for four hours to eliminate all the carbonate ions; the layered structure was reconstructed after treatment with a solution of either pycH (pyridine-2-carboxylic acid) or $pydcH_2$ (pyridine-2,6-dicarboxylic acid) in a KOH solution of dmf at 343 K. Impregnation with a solution of the organometallic precursor $[Mo(CO)_3I_2(NCCH_3)_2]$ led to substitution of the nitrile groups by two pyridine ligands. All the materials were characterized by powder X-ray diffraction, FTIR, and $^{13}C$ CP MAS and $^{27}Al$ MAS solid-state NMR spectroscopy. Similar $Mo^{II}$ complexes were also prepared by using pycH or $pydcH_2$ and characterized by elemental analysis as well as FTIR and $^1H$ and $^{13}C$ solution NMR spectroscopy. These new materials and the complexes of pyc or pydc ligands containing 4.54 wt.-% and 6.33 wt.-% of Mo respectively, catalyze the ring-opening-metathesis polymerization of norbornene and the polymerization of styrene at 333 K, their performance increasing upon the addition of methylalumoxane (MAO) as cocatalyst.

## 1. Introduction

Heterogeneous catalysis allows an easy separation of the products of a given reaction from the catalyst, being therefore favored in many industrial processes. The combination of organometallic complexes and a selected support has received much attention in recent years owing to the new perspectives it opens, since the first are known for their capabilities in selective and efficient promotion of many reactions in solution, while the latter optimize recovery and recycling of the catalysts.[1,2]

The choice of the supporting material and the incorporation of the organometallic precursor must be handled with care. In particular, porous materials are very promising candidates for such purposes, as they offer a large surface area inside the pores, but they must be designed by taking into consideration the need to afford a stable (and reactive) material without blocking the pores, so that the reaction can proceed and a good contact between the reactants is promoted.

Layered materials such as clays have been successfully used as hosts for the intercalation of other species. Layered double hydroxides (LDH), available as minerals or from synthesis and known as anionic clays, are very versatile. They can be thought of as descending from a $M(OH)_2$ hydroxide, such as $Mg(OH)_2$, with a structure built from layers of $Mg(OH)_6$ edge-sharing octahedra; if some of these $Mg^{2+}$ dications are replaced by $M^{3+}$ cations, the layers become positively charged, and anions are needed to balance this charge. They occupy, along with water molecules, the space between layers, and can be exchanged with other anions, organic or inorganic. Hydrotalcite (HTC) is an anionic clay from this family, based on Mg and Al cations, but a wide range of compositions $[M^{2+}_{1-x}M^{3+}_x(OH)_2](A^{m-})_{x/m}\cdot nH_2O$ ($M^{2+}$ = $Mg^{2+}$, $Zn^{2+}$, $Ni^{2+}$, etc., $M^{3+}$ = $Al^{3+}$, $Cr^{3+}$, $Ga^{3+}$, etc.) is possible.[3,4]

A rich intercalation chemistry can be obtained not only from the anion exchange process, but also from the substitution of the di- and trivalent cations in the layers. When sizes are not too different, the initial type of structure (brucite) does not change. The value of $x$, measuring the amount of $M^{3+}$ relative to ($M^{3+}$ + $M^{2+}$), is related to the distance between layers. This distance changes when other anions are introduced, although the layered structure is able to swell in the case of large anions, making space available between layers. Among the possible strategies for exchanging anions, rehydration of a calcined precursor has proved advantageous compared to direct anion exchange,[3] as competition between anions can be more efficiently pre-

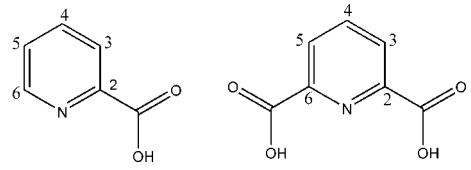
vented as long as carbonate, the anion found in the minerals, is excluded. Several groups have worked along these lines, intercalating organic and inorganic anions, from simple to complicated biological ones.[3–5] In another interesting route, the synthesis of the double hydroxide is carried out in the presence of the anions chosen to belong to the final structure.[6,7]

These anions, despite their origin, can undergo several reactions, namely coordination to a metal center, provided that suitable functional groups are present. The calcined HTC itself has also been shown to catalyze reactions such as the aziration of oxiranes.[8] In this work, we studied the intercalation of pyridine-2-carboxylate and pyridine-2,6-dicarboxylate in a Mg/Al HTC and the reaction of the supported anions with a $Mo^{II}$ precursor $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**), in order to evaluate the catalytic activity of the final materials in the heterogeneous polymerization of olefins. This was compared with the catalytic activity of the homogeneous analogue in the same reaction and the activity of related $Mo^{II}$ complexes supported in other matrices.[9]

## 2. Results and Discussion

### 2.1. Characterization of the Complexes

The precursor complex $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**)[10] was allowed to react with two equivalents of either pycH or $pydcH_2$ (Scheme 1), affording the complexes formulated as $[Mo(CO)_3I_2(pycH)_2]$ (**2**) and $[Mo(CO)_3I_2(pydcH_2)_2]$ (**3**), respectively, as outlined in Scheme 2.[11,12]

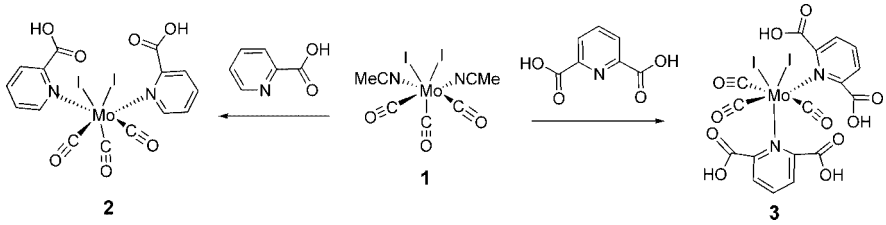


Scheme 1.

The $^1H$ NMR spectrum of $[Mo(CO)_3I_2(pycH)_2]$ (**2**) shows clear differences from those of the precursor complex **1** and the pycH ligand, namely the absence of a resonance at ca. 2.0 ppm assigned to the acetonitrile ligands of **1**, reflecting the loss of both acetonitrile ligands.

The four signals of the 6-H, 4-H, 3-H, and 5-H atoms (see numbering in Scheme 1) of the coordinated pycH ligand are observed at 8.99, 8.71, 8.66, and 8.37 ppm, respectively, clearly shifted relative to the corresponding signals in the free ligand at 8.76, 8.03, 8.10, and 7.67 ppm. The downfield shift experienced by the signals of the complexed ligand can be explained by the coordination to the electron-rich Mo center. The $^{13}C$ NMR spectrum confirms the above observations. Indeed, in the coordinated pycH, the resonances at 149.5, 144.2, 142.4, 131.3 and 129.0 ppm are assigned to the C-6, C-4, C-2, C-5, and C-3 atoms of the pyridine ring, while the carboxylate carbon atom appears at $\delta$ = 161.2 ppm. These values are shifted relative to those for the free ligand by small [149.4 ppm (C-6), 124.6 ppm (C-3)] and large amounts [137.4 (C-4), 148.4 (C-2), 126.7 (C-5), 166.1 ppm (carboxylate carbon)]. All these values are collected in Table 1.

The FTIR spectrum of $[Mo(CO)_3I_2(pycH)_2]$ (**2**) also reveals the absence of the $\nu_{C\equiv N}$ stretching modes at ca. 2300 $cm^{-1}$ (Table 2). Another strong evidence for the substitution of the nitrile ligands is the strong redshift (lower wavenumbers) experienced by the $\nu_{C\equiv O}$ modes relative to the bands in complex **1**. The appearance of four bands at 2018, 1959, 1900, and 1845 $cm^{-1}$, assigned to the $\nu_{C\equiv O}$ modes, when only three were expected, was ascribed to the existence of another isomer in the solid. This situation has also been reported previously for the parent compound (Figure 1).[13] In order to evaluate the possible fluxionality between both isomers, complex **2** was dissolved in methanol, and the vibrational spectrum of this solution was recorded. The four bands are still visible in solution, as shown in Figure S1 in the Supporting Information, and are reflected in the difference spectrum compared with that of $[Mo(CO)_3I_2(pycH)_2]$ (**2**).



Scheme 2.

Table 1. $^1H$ and $^{13}C$ NMR chemical shifts [ppm] for the ligands pycH and $pydcH_2$, and the complexes **2** and **3**.

Table 2. FTIR wavenumbers of the $\nu_{C\equiv O}$, $\nu_{C=O}$, and $\nu_{C=N}$ modes for the ligands pycH and $pydcH_2$, and the complexes **1**, **2**, and **3**.

| Complex or ligand | $\nu_{C\equiv O}$ [$cm^{-1}$] | $\nu_{C=O}$ [$cm^{-1}$] | $\nu_{C=N}$ [$cm^{-1}$] |
|---|---|---|---|
| $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**) | 2017 (vs), 1924 (broad, vs) | – | – |
| pycH | – | 1722 (vs) | 1609 (vs), 1596 (vs) |
| $pydcH_2$ | – | 1701 (vs) | 1468 (s), 1416 (s) |
| $[Mo(CO)_3I_2(pycH)_2]$ (**2**) | 2018 (m), 1959 (s), 1900 (s), 1845 (s) | 1740 (s) | 1654 (s), 1612 (m) |
| $[Mo(CO)_3I_2(pydcH_2)_2]$ (**3**) | 2071 (s), 2011 (s), 1943 (s) | 1696 (vs) | 1458 (m), 1413 (m) |

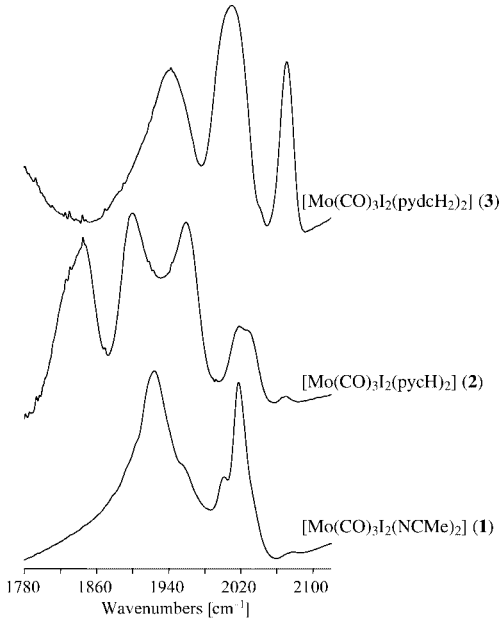

Figure 1. FTIR spectra of $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**), $[Mo(CO)_3I_2(pycH)_2]$ (**2**), and $[Mo(CO)_3I_2(pydcH_2)_2]$ (**3**).

The vibrational spectrum of complex **3** also supports its formulation as $[Mo(CO)_3I_2(pydcH_2)_2]$. The FTIR spectrum of $[Mo(CO)_3I_2(pydcH_2)_2]$ (**3**) shows only three narrow bands assignable to a single isomer, a fact that can be explained by the larger bulk of the two nitrogen ligands. They are slightly shifted relative to those of the precursor complex **1**. The $\nu_{C=O}$ mode of the $pydcH_2$ ligand shifts from 1701 $cm^{-1}$ (in the free ligand) to 1696 $cm^{-1}$ in complex **3**, while two bands assigned to the $\nu_{C=N}$ mode at 1468 ($\nu_{sym}$) and 1416 $cm^{-1}$ ($\nu_{asym}$) in the free ligand undergo a redshift to 1458 and 1413 $cm^{-1}$, respectively, after binding.

In what concerns the ligand, the major changes should involve the $\nu_{C=N}$ of the ring and $\nu_{C=O}$ of the COOH group. The band at 1740 $cm^{-1}$ ($\nu_{C=O}$ modes of the COOH group) in **2** shows a small blueshift of ca. 18 $cm^{-1}$, suggesting no involvement in hydrogen bonding. The $\nu_{C=N}$ modes of the free pycH ligand (1596 and 1609 $cm^{-1}$) shift upon complexation to 1612 and 1654 $cm^{-1}$, respectively.

The most relevant spectroscopic features of complex **2** are summarized in Table 2, as well as the corresponding data for complex **3**, the precursor complex **1**, and the ligands pycH and $pydcH_2$.

The $^1H$ NMR spectrum of complex $[Mo(CO)_3I_2(pydcH_2)_2]$ (**3**) is similar to the one described for **2**, with resonances at $\delta$ = 8.39 (3-H, 5-H) and 8.27 ppm (4-H), shifted to higher $\delta$ values relative to those observed for the free ligand ($\delta$ = 8.28 ppm for 3-H and 5-H; 8.23 ppm for 4-H). The pyridine signals in the $^{13}C$ NMR spectrum appear at 150.2, 141.2, and 130.0 ppm, being assigned to C-2/C-6, C-4, and C-3/C-5, respectively, while the COOH carbon is observed at $\delta$ = 167.1 ppm. All the signals are shifted downfield in comparison with free $pydcH_2$ [148.0 (C-2/C-6); 139.2 (C-4), and 127.4 ppm (C-3/C-5); COOH 165.4 ppm].

### 2.2. Intercalation of the Ligands and the Organometallic Fragment in Hydrotalcite

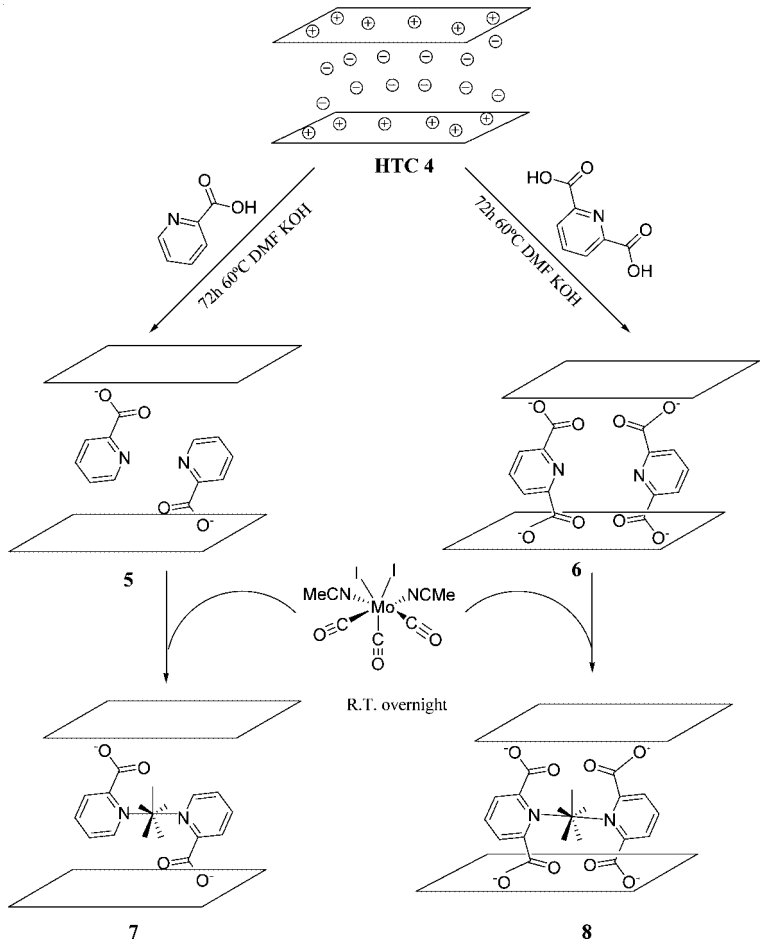
Prior to the intercalation experiments, the commercial HTC (**4**) lamellar material was submitted to a calcination process at 823 K for 4 h to eliminate the $CO_3^{2-}$ anions in the interlayer region, as described previously.[8] The structure of the lamellar material collapses, but it is rebuilt in the following step, when the deprotonated ligands pyc and pydc are intercalated inside the intergallery space by using dmf at 343 K.[6] This procedure made possible the preparation of composite materials HTC–pyc (**5**) and HTC–pydc (**6**), containing the anions in the interlayer space, according to Scheme 3.

The results of elemental analyses of materials **5** and **6** show that the C/N mol ratios are 5.6 and 6.6, respectively, which are slightly higher than the expected values, 5.2 in pyc and 6.0 in pydc. On the other hand, the C/H mol ratios are 3.4 and 2.6, much lower than the expected values of 7.2 and 6.0. This suggests that incorporation of some carbonate during reconstruction of the layered structure leading to a multiphase sample does not take place.[14] Instead, the high content of hydrogen may be explained by the uptake of OH groups. On the basis of the amount of nitrogen for the two materials **5** and **6**, the contents of pyc and pydc ligands incorporated are 57% and 63%, respectively.

These functionalized materials were then allowed to react with the organometallic precursor **1** in dry $CH_2Cl_2$ for 24 h at room temperature, affording the new materials HTC–pyc–Mo (**7**) and HTC–pydc–Mo (**8**) after filtration and drying. The molybdenum loadings for the organometallic composite materials **7** and **8** were found to be 4.54 wt.-% and 6.3 wt.-% (0.43 mmol $g^{-1}$ and 0.66 mmol $g^{-1}$), respectively, showing that higher metal quantities were incorporated in comparison to immobilization in a mesoporous support.[9] These results indicate the coordination of the available supported ligands to molybdenum to form 2:1 complexes, such as **2** and **3**.

All the new materials were characterized by powder XRD, FTIR, and solid-state $^{13}C$ and $^{27}Al$ NMR spectroscopic techniques.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3.

The powder XRD patterns obtained for these lamellar materials are typical of this type of reasonably well-ordered materials, exhibiting sharp and symmetric 003 reflections (Figure 2).[15]

The peaks were indexed to a rhombohedral symmetry. There was evidence of $Al(OH)_3$ in the lamellar materials, arising from the presence of gibbsite, at $2\theta$ = 17.5, 28.9, and 39.2°. The calculated *d* parameters were 15.3 Å for the lamellar material **5** and 12.2 Å for material **6**. The 15.3 Å value found for material **5** corresponds to a gallery height of 10.5 Å, assuming the HTC sheets to be 4.8 Å thick.[3] Considering the longest dimension of the pycH guest to be approximately 8.8 Å, the value estimated for benzoate,[3] the XRD results suggest that a bilayer-like structure is assembled within the gallery. Furthermore, since the gallery height is only slightly superior to the size of the guest, the bilayer arrangement might consist of superimposed guest molecules, as schematized in Figure 3. Similar proposals have already been discussed by some authors.[3,15]

In the case of material **6**, the gallery height was found to be 7.4 Å. Assuming the length of the $pydcH_2$ guest (similar to a terephthalate anion) to be 9.9 Å, it is most likely that the molecules cannot be upright. They may either lie in a

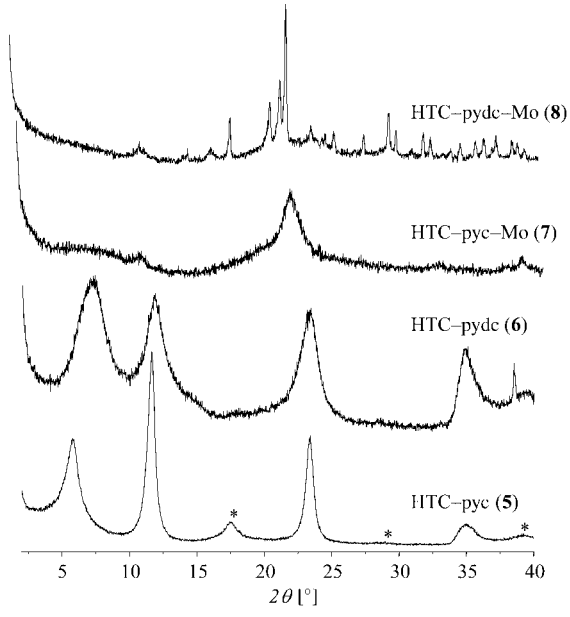


Figure 2. Powder XRD patterns of HTC–pyc (**5**), HTC–pydc (**6**), HTC–pyc–Mo (**7**), and HTC–pydc–Mo (**8**); * denotes peaks from gibbsite.

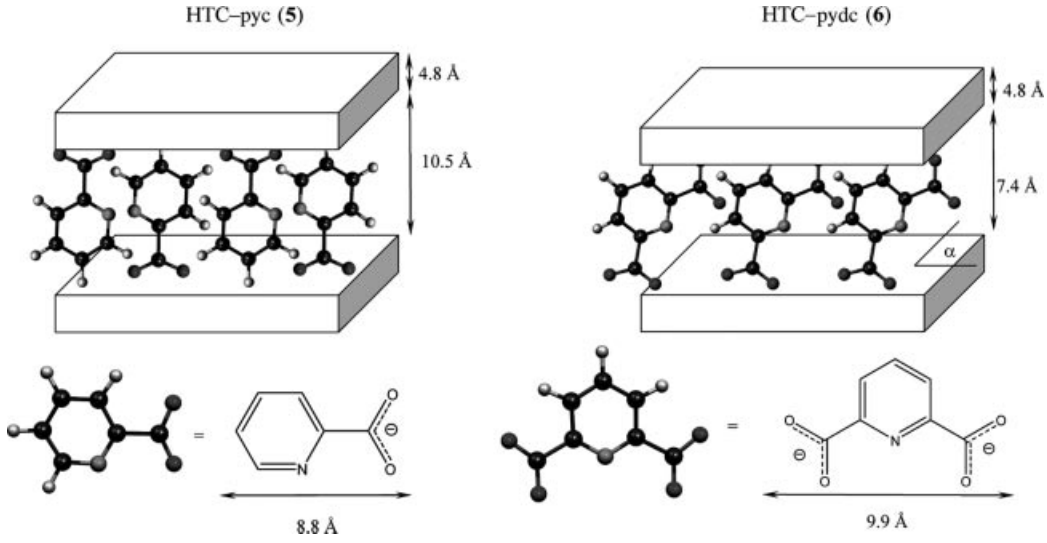

Figure 3. Models for the interlayer arrangement of the guest species of the materials HTC–pyc (**5**) and HTC–pydc (**6**); a color version of this figure is part of the Supporting Information.

horizontal arrangement, such as described in previous works,[3,15] or prefer tilted positions, up to a maximum tilt angle of 48° ($\alpha$ in Figure 3). This is also supported by the large full width at half height of the diffraction peaks.[15] The XRD patterns of materials **5** and **6** are very similar in terms of the number and positions of peaks, and differ mainly in the band width: broader peaks are observed for material **6**.

For materials **7** and **8**, obtained after treatment with complex **1**, the 001 reflections are significantly reduced in intensity. These changes can be attributed to a marked increase in the electron density at the midpoint of the interlayers due to the presence of the Mo centers at a high loading (4–6 wt.-%). This is in line with previous reports.[16,17] It is also possible, according to other reports, that the structure has partially disrupted owing to exfoliation, especially in material **8**.[18]

The FTIR spectrum of the HTC host material is similar to that of other materials of the same type. In the high-frequency region (4000–2000 $cm^{-1}$), it is dominated by broad bands at about 3400 $cm^{-1}$, assigned to the O–H stretches of weakly hydrogen-bonded water molecules and layer hydroxy groups. Some carbonate groups, from the air and humidity, may be responsible for the band at around 1400 $cm^{-1}$.The derivatized materials HTC–pyc (**5**) and HTC–pydc (**6**), resulting from the treatment of HTC with pyc and pydc anions, respectively, showed new bands in their vibrational spectra relative to the host material HTC. For HTC–pyc (**5**), a band at 3458 $cm^{-1}$ is assigned to the O–H stretches of the structure of HTC and water molecules, as described above, the bands at 1598 and 1594 $cm^{-1}$, to the $\nu_{C=N}$ of the pyridine ring, and the band at 1632 $cm^{-1}$ to the $\nu_{C=O}$ group of the carboxylate group of the ligand. Some of these bands show a deviation relative to the free ligand, because the ligand is deprotonated and held inside the gallery of the material. For HTC–pydc (**6**), it is possible to assign the bands at 2982 and 2977 $cm^{-1}$ to the $\nu_{C-H}$ of the ring and the $\nu_{C=N}$ mode of the pyridine ring at 1439 and 1376 $cm^{-1}$ (at 1468 and 1416 $cm^{-1}$ in the free ligand). The band at 1607 $cm^{-1}$ can be assigned to the $\nu_{C=O}$ mode of the ligand (1701 $cm^{-1}$ in the free ligand). The small changes observed in the bands of both composite materials suggest that the structures of the anionic ligands were not affected during immobilization in the material.

Treatment of the composite materials **5** and **6** with the organometallic complex $[Mo(CO)_3I_2(NCCH_3)_2]$ led to the new materials HTC–pyc–Mo (**7**) and HTC–pydc–Mo (**8**). In the composite material **7**, the vibrations of the carbonyl groups ($\nu_{C\equiv O}$) at 2022, 1950, and 1880 $cm^{-1}$ are shifted relative to those of complex **2**, probably as a result of specific host–guest interactions between the $Mo(CO)_3$ core and the layers of the HTC-derivatized host material. The $\nu_{C=N}$ modes of the pyridine ring appear at 1640 and 1630 $cm^{-1}$. These values are higher than those for the free ligand (1609 and 1596 $cm^{-1}$) and are close to those for complex **2**, indicating chelation to the metal center. The same trends are observed in HTC–pydc–Mo (**8**), with the $\nu_{C\equiv O}$ modes of the $Mo(CO)_3$ fragment at 2037, 1955, and 1892 $cm^{-1}$, and the $\nu_{C=N}$ modes of the pyridine ring at 1442 and 1395 $cm^{-1}$, values slightly lower than those for the free ligand (1468 and 1416 $cm^{-1}$), and close to the values for complex **3**. No bands that might be assigned to the $\nu_{C\equiv N}$ modes, observed at 2304 and 2277 $cm^{-1}$ in the precursor **1**, corresponding to the acetonitrile ligands, were detected in either HTC–pyc–Mo (**7**) or HTC–pydc–Mo (**8**).

The $^{13}C$ CP MAS NMR spectra of the lamellar materials **5**–**8** (Figure 4) exhibit several resonances in the $120 < \delta < 150$ ppm range assigned to carbon atoms of the pyridine ring, and a single peak in the $160 < \delta < 170$ ppm range assigned to the carboxylate carbon atoms. These results indicate that the ligands are inside the interlamellar space of hydrotalcite for materials **5** and **6**. The sharp signals ob-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

served for material **5** are similar to those found in solution for the pycH ligand, and can therefore be assigned: 124.7 (C-3), 128.0 (C-5), 139.8 (C-2), 146.6 (C-4), and 150.9 (C-6), and 170.1 ppm (*C*OO$^-$ group). In material **6**, the spectrum is not so well resolved. Three peaks at $\delta$ = 125.1, 139.2, and 150.2 ppm are attributed to the pyridine ring of the pydc ligand, and another at $\delta$ = 170.5 ppm for the *C*OO$^-$ group.

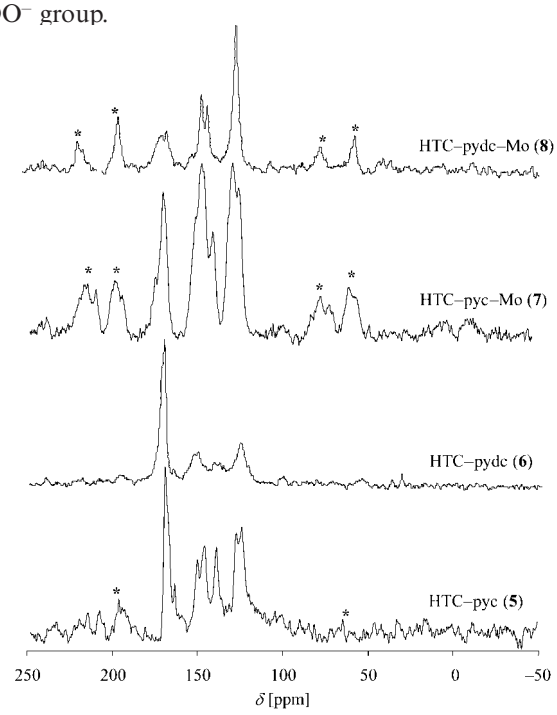

Figure 4. $^{13}$C CP MAS NMR spectra for the materials HTC–pyc (**5**), HTC–pydc (**6**), HTC–pyc–Mo (**7**), and HTC–pydc–Mo (**8**); * denotes spinning side bands.

In materials **7** and **8**, no resonances of the acetonitrile ligands of precursor **1** are detected, and signals from the C≡O ligands are not visible, since they have a long relaxation time. On the other hand, the signals of the pyc ligand in **7** are not as clear as in the precursor **5**: 170.3 (*C*OO$^-$ group), 124.9 (C-3), 128.6 (C-5), 140.4 (C-2), and 147.0 ppm (C-4), whereas C-6 is convoluted with C-4. In material **8**, only three signals are resolved, namely the signals of the pyridine ring at $\delta$ = 127.1, 143.9, and 147.2 ppm, and that of the COO$^-$ group at $\delta$ = 167.4 ppm, as also observed for material **6**.

The $^{27}$Al MAS NMR spectra of all the lamellar materials are very similar. A sharp peak is observed at ca. 9 ppm, with a broad downfield shoulder, assigned to octahedral aluminum. Similar spectra are described in the literature.[19] The first site, corresponding to the sharp peak, displays a distribution of isotropic chemical shifts and is probably due to the presence of a range of slightly different local Al environments generated by the random insertion of Al in the layers. The low-frequency shoulder corresponds essentially to undistributed Al species, but it has an average quadrupole coupling constant that is larger than that of the first site. This has been ascribed previously to small clusters of Al atoms in the brucite-like layers.[7]

### 2.3. Polymerization Catalytic Studies

Following the interest in the study of olefin polymerization catalyzed by Mo$^{II}$ and W$^{II}$ systems over the last years,[11–15] complex **1** has been tested for ring-opening-metathesis polymerization (ROMP) catalysis of norbornene and norbornadiene (NBE and NBD, respectively; polyNBE and polyNBD denote the corresponding polymer product).[11] ROMP of NBD has been successfully carried out by complexes $[Mo(CO)_3(NCCH_3)_2X_2]$ at room temperature for X = Br, while for X = I, a cocatalyst such as $ZrCl_4$ or $AlCl_3$ is required in order to initiate polymerization.[11] Recently, some of these Mo$^{II}$ and W$^{II}$ complexes immobilized in a MCM–41 material have also shown weak activity towards the ROMP reactions of NBE and NBD.[9] MAO has been successfully used as a cocatalyst in heterogeneous clay/metal systems as described in previous publications addressing olefin polymerization.[20,21]

In the present work, complexes **2** and **3** as well as materials **7** and **8** were tested for ROMP catalysis of NBE and polymerization of styrene (STY) at 333 K, and the results are collected in Table 3. The effect of addition of a cocatalyst (MAO) on the catalytic performance and the nature of the polymer were also checked. Complexes **2** and **3** show comparable activities towards both olefins, stressing that there is no beneficial effects of using either pycH or $pydcH_2$ ligands. This same trend is observed when MAO is used.

In absence of the cocatalyst, the composite materials **7** and **8** are slightly more active catalysts for the polymerization reaction of STY than the homogeneous counterparts **2** and **3**, while the results are comparable in the case of ROMP of NBE. The presence of aluminum in the sheets of the host material may contribute to a higher Lewis acidity and therefore induce a more efficient catalysis. This situation has already been discussed previously.[9,22–24]

Neither the calcined HTC host material nor the derivatized materials **5** and **6** possess catalytic activity towards the polymerization reactions of the olefins, indicating that the active species must contain molybdenum.

For all metal-containing catalysts and in the absence of the cocatalyst, the polymerization of STY is easier to accomplish than ROMP of NBE. Nevertheless, when MAO is used, the performances are boosted, more significantly for NBE than for STY, and polymer yields of polyNBE are higher than those found for polySTY. In fact, addition of MAO increases the yield of polySTY by an average factor of 3, while for polyNBE this factor reaches an average of 27.5. This general increase in yield is expected because of the role of MAO as a radical initiator, promoting the formation of the initial active species that binds to the metal center where the propagation and/or termination steps occur.

Another interesting factor is the local structure of the polymer, as homotactic isomers are preferred, namely in the case of polySTY, because of their industrial importance.[22,23] For polyNBE, a reasonable *cis* content is achieved in all the catalytic processes, but the *cis* content rises significantly in the presence of MAO. Thus, addition

Table 3. Results for the polymerization reactions of NBE and STY initiated by isolated and immobilized $[Mo(CO)_3I_2(L)_2]$ complexes at 333 K.

| Catalyst | Cocatalyst | PolyNBE | | PolySTY | |
|---|---|---|---|---|---|
| | | Yield [%] | *cis* [%] | Yield [%] | *syndio* [%] |
| $[Mo(CO)_3I_2(pycH)_2]$ (**2**) | – | 3 | 50 | 9 | 20 |
| | MAO | 99 | 50 | 31 | 20 |
| $[Mo(CO)_3I_2(pydcH_2)_2]$ (**3**) | – | 3 | 45 | 8 | 62 |
| | MAO | 91 | 60 | 24 | 65 |
| HTC–pyc–Mo (**7**) | – | 4 | 33 | 23 | 22 |
| | MAO | 95 | 44 | 60 | 65 |
| HTC–pydc–Mo (**8**) | – | 4 | 38 | 25 | 47 |
| | MAO | 94 | 56 | 61 | 42 |
| MCM–DAB–Mo[a] | – | 36 | – | – | – |
| | MAO | 59 | – | – | – |

[a] DAB = $(OEt)_3Si(CH_2)_3N{=}C(Ph){-}C(Ph){=}N(CH_2)_3Si(OEt)_3$, Mo = $MoBr_2(CO)_3$; from ref.[9]

of MAO is helpful not only in terms of reaction initiation, but also in directing the formation of homotactic polymer structures.

In the case of polySTY, the trend in the percentage of the syndiotactic polymer structure is not as clear, and MAO does not seem to influence the percentage of homotactic structures very much. As a general rule, and despite some good values of syndiotactic polymer yield (see Table 3, entries 3, 4, and 6), there is a general tendency towards the preparation of *syndio*-rich atactic polymers.

All the species described above exhibit higher catalytic activities towards the ROMP of NBE than the related $Mo^{II}$ and $W^{II}$ complexes immobilized in a MCM–41 material (Table 3, last entry).

## 3. Conclusions

The intercalation of heptacoordinate halocarbonylmolybdenum(II) complexes in organic–inorganic hybrid clay materials was successfully accomplished by first intercalating carboxylic acid derivatives of pyridine, under basic conditions, into the interlayer spacing of previously calcined hydrotalcite clay and subsequently introducing an organometallic fragment. This scheme was confirmed by several analytical techniques. For instance, FTIR spectra exhibited the bands assigned to $\nu_{C\equiv O}$ modes, reflecting the incorporation of the organometallic *fac*-$Mo(CO)_3$ core, and others showing the coordination of Mo to the pyridine ligand. Powder X-ray diffraction patterns, on the other hand, revealed the reconstruction of the HTC layered structure.

The catalytic activity in the ROMP reaction of NBE and polymerization of STY improves upon going from the homogeneous-phase complexes **2** and **3** to the corresponding heterogenized catalysts (**7** and **8**). In general, the conversions are higher for STY than for NBE. When MAO is added as a cocatalyst, the polymer yields are increased for both, so that the only obvious advantage of the heterogeneous catalysts seems to be the ease of separation.

A high content of *cis* polymer is detected for polyNBE, and the *cis* content increases when the reaction is carried out in the presence of MAO. There is no such simple trend for polySTY. The local structures of the polySTY may be better defined as *syndio*-rich atactic polymer chains.

## Experimental Section

**General:** All preparations and manipulations were performed by using standard Schlenk techniques under nitrogen. Commercial grade solvents were dried and deoxygenated by standard procedures ($Et_2O$ over Na/benzophenone ketyl; $CH_2Cl_2$, dmf, and $CH_3CN$ over $CaH_2$), distilled under nitrogen, and kept over 4 Å molecular sieves (3 Å for $CH_3CN$). Picolinic acid (pycH), pyridine-2,6-dicarboxylic acid ($pydcH_2$), methyl alumoxane (MAO), and Mg,Al-hydrotalcite (HTC) were purchased from Aldrich Co. Prior to the intercalation experiments, commercial hydrotalcite was calcined (823 K for 4 h) in order to eliminate all the carbonate anions.[8] The precursor organometallic complex $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**) was also prepared according to literature methods.[10]

Powder XRD data were collected with a Phillips PW1710 diffractometer by using graphite-filtered Cu-$K_\alpha$ radiation. FTIR spectra were measured with a Nicolet Nexus 6700 FTIR spectrometer by using KBr pellets (for complexes) in the transmission mode and also with diffuse reflectance (for clay materials). Solution spectra were measured in a liquid cell with KBr windows and by using dry methanol as solvent. All FTIR spectra were measured with 2 $cm^{-1}$ resolution.

$^1H$ and $^{13}C$ solution NMR spectra were obtained at 400.13 MHz and 100.62 MHz, respectively, with a Bruker Avance 400 spectrometer by using $CD_3OD$ as solvent. Chemical shifts are quoted in ppm from TMS.

$^{27}Al$ and $^{13}C$ solid-state NMR spectra were recorded at 104.26 MHz and 100.62 MHz, respectively, with a (9.4 T) Bruker Avance 400P spectrometer. $^{13}C$ solid-state NMR spectra were also recorded at 125.76 MHz with a Bruker Avance 500P spectrometer. $^{27}Al$ MAS NMR spectra were acquired by using short and powerful radio-frequency pulses (0.6 μs, corresponding to π/12 pulses), a spinning rate of 14 kHz, and a recycle delay of 1 s. Chemical shifts are quoted in ppm relative to $[Al(H_2O)_6]^{3+}$. $^{13}C$ CP MAS NMR spectra were recorded with a 4.5-μs $^1H$ 90° pulse, 2-ms contact time, a spinning rate of 8 kHz, and 4-s recycle delays. Chemical shifts are quoted in ppm from TMS. Microanalyses were performed at the University of Vigo and the University of Aveiro.

**Catalytic Studies:** The complexes and materials reported herein were tested in the ROMP of norbornene (NBE) and polymerization of styrene (STY) under a $N_2$ atmosphere at 333 K and by using toluene as solvent. The catalytic reactions with complexes **2** and **3** were carried out by using a catalyst/olefin mol ratio of 1:200. In the studies with the composite materials **7** and **8**, a Mo/olefin mol ratio of 1:200 (based on the metal loadings as determined by ICP–

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

AES) was used. For the catalytic reaction with MAO as cocatalyst, the Mo/Al/olefin mol ratio was 1:3:200. In a typical experiment, a certain amount of the materials containing olefin (18.5 mmol) was mixed in toluene (10 mL) at 333 K. All the reactions were stopped after 48 h. This was accomplished by separating the catalysts by filtration, followed by the addition of methanol to the toluene solution in order to precipitate the polymer. The polymers were precipitated by addition of methanol at the end of the reaction, i.e., after 48 h and upon catalyst separation. The solid polymer was separated by filtration, and the polymers were dried in vacuo before being weighed. The yields were calculated on the basis of the initial weight of olefin used. The identification of the polymers was accomplished by $^1$H NMR spectroscopy, and the *cis* content (NBE) and tacticity (STY) were estimated from $^1$H and $^{13}$C NMR spectroscopic data.[24,25–29]

**Preparation of the Complexes $[Mo(CO)_3I_2L_2]$ (L = pycH or pydcH$_2$) (2, 3):** A solution of $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**) (0.50 mmol, 258 mg) in $CH_2Cl_2$ (10 mL) was treated with a solution of the ligand pycH or pydcH$_2$ (1 mmol; 123 or 167 mg) in $CH_2Cl_2$ (5 mL). The resulting solution was stirred for 14 h at room temperature. The desired complex precipitated, and the solvent was filtered off. The complex was then washed with hexane and dried under vacuum.

**$[Mo(CO)_3I_2(pycH)_2]$ (2):** Yield: 92%. $C_{15}H_{10}I_2MoN_2O_7$ (680.00): calcd. C 26.49, H 1.48, N 4.12; found C 26.05, H 1.62, N 4.27. IR (KBr): $\tilde{\nu}$ = 3094 (m), 3052 (w), 2069 (vw), 2018 (m), 1959 (m), 1900 (m), 1845 (m), 1740 (s), 1654 (s), 1612 (vs), 1576 (m), 1559 (m), 1460 (s), 1340 (m), 1294 (s), 1206 (m), 1166 (m), 1092 (m), 962 (m), 757 (vs), 708 (m), 690 (m), 656 (w), 448 (w) cm$^{-1}$. $^1$H NMR (400.13 MHz, $CDCl_3$, room temp.): $\delta$ = 8.99 (d, $J_{5,6}$ = 5.6 Hz, 1 H, pyc), 8.71 (t, $J_{4,5}$ = 8.0 Hz, 1 H, pyc), 8.66 (d, $J_{3,4}$ = 7.6 Hz, 1 H, pyc), 8.37 (t, $J_{5,6}$ = 6.6 Hz, 1 H, pyc) ppm. $^{13}$C NMR (100.62 MHz, $CDCl_3$, room temp.): $\delta$ = 161.2 (COOH), 149.5 (C-6), 144.2 (C-4), 142.4 (C-2), 131.7 (C-5), 129.0 (C-3) ppm.

**$[Mo(CO)_3I_2(pydcH_2)_2]$ (3):** Yield: 96%. $C_{17}H_{10}I_2MoN_2O_{11}$ (768.02): calcd. C 26.59, H 1.31, N 3.65; found C 26.09, H 1.26, N 3.44. IR (KBr): $\tilde{\nu}$ = 3447(w), 3068 (w), 2901 (w), 2624 (w), 2546 (w), 2071 (w), 2011 (m), 1943 (m), 1696 (vs), 1654 (s), 1575 (m), 1458 (m), 1413 (m), 1331 (m), 1298 (m), 1266 (m), 1176 (w), 1080 (m), 997 (m), 915 (m), 855 (m), 752 (s), 702 (s), 648(s) cm$^{-1}$. $^1$H NMR (400.13 MHz, $CDCl_3$, room temp.): $\delta$ = 8.27 (d, $J_{3,4}$ = 7.2 Hz, 1 H, pydc), 8.39 (d, $J_{4,5}$ = 7.6 Hz, 2 H, pydc) ppm. $^{13}$C NMR (100.62 MHz, $CDCl_3$, room temp.): $\delta$ = 167.1 (COOH), 150.2 (C-2, C-6), 141.2 (C-4), 130.0 (C-3, C-5) ppm.

**Preparation of the Materials HTC–L (L = pyc or pydc) (5, 6):** A mixture of pycH (7.30 mmol) or pydcH$_2$ (3.60 mmol) in freshly distilled dmf (10 mL) and deionized water (20 mL) with NaOH (1 equiv. for pycH or 2 equiv. for pydcH$_2$) was stirred until complete solubilization. This solution was then added to a suspension of calcined HTC (1.00 g) in freshly distilled dmf (25 mL) at 343 K, and the reaction mixture was stirred at the same temperature for 48 h. All the manipulations were carried out under a $N_2$ atmosphere to prevent the uptake of carbonate anions. The resulting material was then filtered off, washed with deionized water (3 × 20 mL), and dried in a desiccator under vacuum.

**HTC–pyc (5):** Elemental analysis found: C 13.65, H 4.05, N 2.41. IR (KBr) $\tilde{\nu}$ = : 3458 (vs), 1632 (s), 1598 (s), 1476 (m), 1374 (s), 1293 (w) cm$^{-1}$. $^{13}$C NMR CP MAS NMR: $\delta$ = 124.7 (C-3), 128.0 (C-5), 139.8 (C-2), 146.6 (C-4), 150.9 (C-6), 170.1 (COOH) ppm. $^{27}$Al MAS NMR: $\delta$ = 9.47 ppm.

**HTC–pydc (6):** Elemental analysis found: C 10.19, H 3.98, N 1.55. IR (KBr): $\tilde{\nu}$ = 2982 (vs), 2977 (vs), 2907 (s), 1607 (s), 1563 (s), 1439 (m), 1376 (vs), 1269 (w), 1174 (w), 1083 (w), 957 (m), 771 (s), 676 (s), 566 (m), 450 (s) cm$^{-1}$. $^{13}$C NMR CP MAS NMR: $\delta$ = 125.1 (C-3, C-5), 139.2 (C-4), 150.2 (C-2, C-6), 170.5 (COOH) ppm. $^{27}$Al MAS NMR: $\delta$ = 9.28 ppm.

**Preparation of the Materials HTC–L–Mo (L = pyc or pydc) (7, 8):** A solution of $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**) (0.34 g, 0.65 mmol) in dry $CH_2Cl_2$ (5 mL) was added to a suspension of the HTC intercalated material HTC–L (**4** or **5**) (1.00 g) in dry $CH_2Cl_2$ (20 mL). The reaction mixture was stirred under a $N_2$ atmosphere at room temperature for 24 h. The resulting material was then filtered off, washed with $CH_2Cl_2$ (2 × 20 mL), and dried in a desiccator under vacuum.

**HTC–pyc–Mo (7):** Elemental analysis found: C 7.36, H 2.66, Mo 4.54, N 1.32. IR (KBr) $\tilde{\nu}$ = 3460 (vs), 2972 (w), 2947 (w), 2875 (w), 1950 (m), 1640 (s), 1630 (s), 1480 (m), 1380 (m), 1300 (w), 962 (m), 679 (s), 447 (s) cm$^{-1}$. $^{13}$C CP MAS NMR: $\delta$ = 124.7 (C-3), 128.0 (C-5), 139.8 (C-2), 146.6 (C-4), 150.9 (C-6), 170.1 (COOH) ppm. $^{27}$Al MAS NMR: $\delta$ = 9.97 ppm.

**HTC–pydc–Mo (8):** Elemental analysis found: C 5.19, H 3.14, Mo 6.33, N 0.96. IR (KBr): $\tilde{\nu}$ = 3480 (m), 2180 (m), 2180 (w), 2037 (vw), 1955 (vw), 1892 (vw), 1680 (vs), 1617 (vs), 1442 (m), 1395 (s), 1294 (m), 1198 (w), 1084 (m) cm$^{-1}$. $^{13}$C CP MAS NMR: $\delta$ = 127.1 (C-3, C-5), 143.9 (C-4), 147.2 (C-2, C-6), 164.66 (COOH) ppm. $^{27}$Al MAS NMR: $\delta$ = 9.67 ppm.

**Supporting Information** (see footnote on the first page of this article): FTIR spectra of $[Mo(CO)_3I_2(NCCH_3)_2]$ (**1**), $[Mo(CO)_3I_2(pycH)_2]$ (**2**), complex **2** in MeOH solution and the difference spectrum of complex **2** and MeOH; color version of Figure 3.

# Gold(I) and Palladium(II) Thiolato Complexes Containing Water-Soluble Phosphane Ligands

Elena Vergara,[a] Susana Miranda,[b] Fabian Mohr,[c] Elena Cerrada,[a] Edward R. T. Tiekink,[d] Pilar Romero,[a] Aránzazu Mendía,*[b] and Mariano Laguna*[a]

**Keywords:** Phosphane ligands / Palladium / Gold / Thiolato complexes

Water-soluble gold(I) and palladium(II) complexes containing different thiolates and the phosphanes 1,3,5-triaza-7-phosphaadamantane (PTA) and 3,7-diacetyl-1,3,7-triaza-5-phosphabicyclo[3.3.1]nonane (DAPTA) are described. The complexes were characterised by spectroscopic techniques including 2D NMR experiments, and the complexes $[Au(S_2CNEt_2)(PTA)]$, *trans*-$[Pd(SC_5H_4N)_2(PTA)_2]$ and *trans*-$[Pd(SC_5H_4N)_2(DAPTA)_2]$ were additionally characterised by X-ray crystallography; the latter complex is one of the few structurally characterised DAPTA complexes.

## Introduction

Water as a solvent for chemical transformations is experiencing a renaissance which has mainly been driven by environmental and, to some extent, economical concerns. The use of water as a solvent, however, requires the development of new catalysts or reagents that are compatible (stable) and soluble in water.[1,2] Gold thiolato complexes dispersed in different solvents, including natural resins, have been used as a gold source for decorating ceramic tiles and glasses after heating.[3] Because these dispersions are liquid, they are commonly referred to as "liquid gold" and, when other late transition metals are involved, the name "liquid precious metal" is used. To avoid the use of toxic and volatile solvents, there is an increasing interest in the development of water-soluble "liquid metals" and thus for water-soluble thiolato complexes.[4] The main strategy employed in this area is either the use of thiolato ligands with solubilising groups or the replacement of traditional phosphane ligands with other water-soluble analogues such as the mono-, di- and tri-sulfonated triphenylphosphanes.[4] Herein, we describe the use of the water-soluble phosphanes 1,3,5-triaza-7-phosphaadamantane (PTA) and 3,7-diacetyl-1,3,7-triaza-5-phosphabicyclo[3.3.1]nonane (DAPTA). PTA was first prepared about thirty years ago[5] and some gold complexes were studied by Fackler Jr.[6–9] and some of us.[10–13] A review and recent reports of new coordination modes of this ligand illustrate the rich and varied coordination chemistry displayed by this compound.[13–16] The diacetate derivative of PTA known as DAPTA has only been reported recently[17] and to date only a very limited number of complexes with this ligand have been described.[11,17]

In this paper we report the synthesis and structures of some water-soluble gold(I) and palladium(II) complexes containing PTA and DAPTA with various thiolato ligands.

## Results and Discussion

### Gold Complexes

The thiolato gold(I) complexes $[Au(SR)(PR'_3)]$ (SR = various thiolato derivatives as shown in Scheme 1; $PR'_3$ = PTA, DAPTA) were easily prepared in good yields by treating the complexes $[AuCl(PR'_3)]$ with the thiol derivatives in the presence of base (Scheme 1). The complexes [AuCl(PTA)][6] and [AuCl(DAPTA)] were prepared by replacement of tetrahydrothiophene (tht) from [AuCl(tht)] with the appropriate phosphane.

The thiolato complexes were characterised by spectroscopic techniques and in the case of $[Au(S_2CNEt_2)(PTA)]$ by X-ray diffraction. All of the $[Au(SR)(PR'_3)]$ complexes reported here show singlet resonances in their $^{31}P\{^1H\}$ NMR spectra displaced to a lower field relative to those of the free phosphanes.[5,17] The $^1H$ NMR spectra of the phosphane resonances merit some comments. The N$CH_2$P resonances appear as doublets in free PTA and as singlets in the thiolato derivatives, whilst the N$CH_2$N resonances appear as singlets in free PTA and as an AB system in the thiolato complexes. This behaviour has been observed in

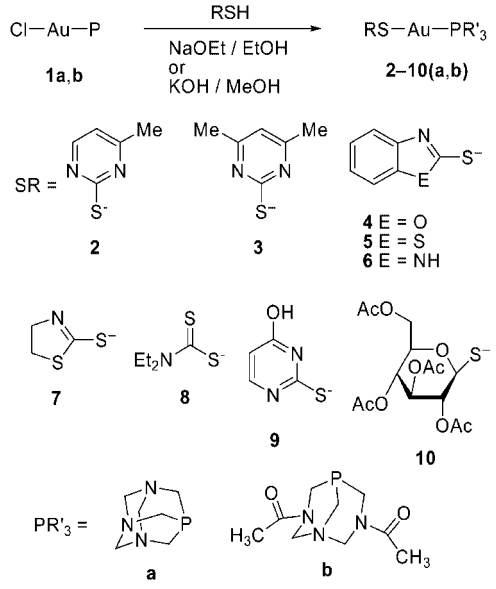

Scheme 1.

other PTA gold derivatives and was confirmed by 2D NMR spectroscopic techniques in the palladium complexes.[18] The $^1$H NMR spectra of the DAPTA thiolato derivatives are much more complicated and show a similar pattern to that of the free ligand (Figure 1a). The assignment of the originally reported $^1$H NMR spectrum of DAPTA[17] is incorrect so we provide a corrected assignment for all the signals on the basis of various 2D NMR methods here. The N*CH*$_2$P signals of DAPTA appear as five resonances, four of which integrate as one proton and the other as two protons, which is due to the nonsymmetry of the compound. Further assignment of these signals was conducted by $^1$H-, $^{13}$C- and $^1$H–$^{31}$P{$^1$H} HSQC experiments. The latter, in addition to the $^1$H{$^{31}$P} NMR spectrum (Figure 1b), show that all these protons are coupled with the phosphorus atom, although some of them with very small coupling constants.

The $^1$H–$^{13}$C HSQC spectrum permits the assignment of the resonances of each of the diastereotopic methylene protons, one pair at $\delta$ = 5.25 (dd) and 3.20 (dt) ppm, the other at $\delta$ = 4.28 (d) and 3.79 (ddd) ppm. The third methylene N*CH*$_2$P is not diastereotopic, hence it appears as a doublet at $\delta$ = 3.51 ppm. In addition, $^1$H–$^1$H homodecoupling experiments point to some coupling between protons of different methylene groups. The two N*CH*$_2$N methylene groups are diastereotopic and appear at $\delta$ = 5.79(d) and 3.95(d) ppm and the other at $\delta$ =4.93(d) and 4.53(d) ppm. The mass spectra of the gold(I) thiolato complexes show in all cases the parent peak, which confirms the proposed stoichiometry. In some cases higher mass adducts formed by the addition of Au(PTA) or Au(DAPTA) fragments can be observed, which is typical behaviour in mass spectra of thiolate gold(I) complexes.[19,20]

The water solubility of complexes **2** and **7** are quite high at 115 g/L for **2a**, 125 g/L for **2b**, 42 g/L for **7a** and 51 g/L for **7b**. The rest of complexes that are insoluble in water

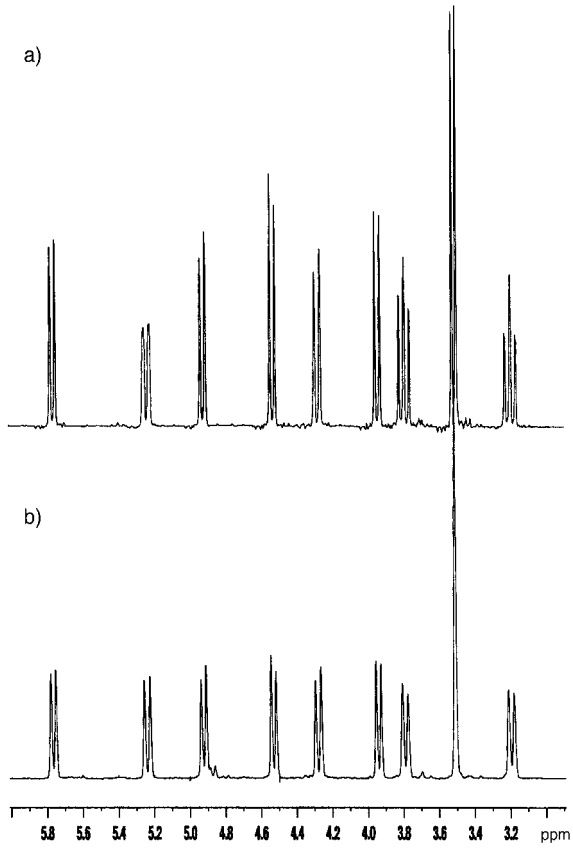

Figure 1. $^1$H NMR spectrum showing the $CH_2$ region of DAPTA; a) P coupled spectrum, b) P decoupled spectrum.

tend to be quite soluble in MeOH or MeOH/$H_2O$ mixtures. The solid gold(I) thiolato complexes are stable at room temperature but start to decompose around 200 °C and ultimately give metallic gold at ca. 750–800 °C as shown by thermal analysis experiments. Attempts to grow single crystals of any of the water-soluble complexes proved unsuccessful, in part owing to the decomposition of the solutions that occurred over a period of 1–2 weeks. However, we were successful in obtaining X-ray quality crystals of the *N*,*N*-diethyldithiocarbamate complex [Au($S_2CNEt_2$)(PTA)], the molecular structure of which is shown in Figure 2.

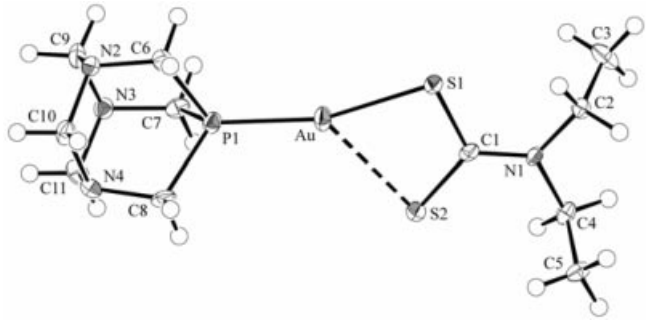

Figure 2. Molecular structure of [Au($S_2CNEt_2$)(PTA)]. Ellipsoids show 50% probability levels. Bond lengths [Å] and angles [°]: Au–P1 2.2310(14), Au–S1 2.3840(13), Au···S2 2.7806(15); S1–Au–P1 163.54(5), S2···Au–P1 126.96(5).

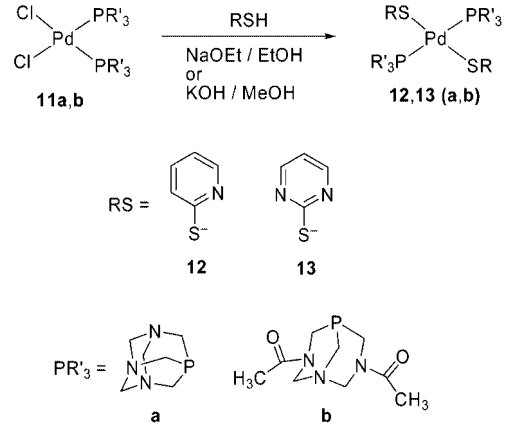
To a first approximation, the molecule of [Au($S_2CNEt_2$)(PTA)] comprises a linear gold atom geometry defined by the S1 and P1 atoms. The relatively close approach of the S2 atom [Au–S2 2.7806(15) Å] is responsible for the significant distortion away from the ideal linear geometry, the angle P1–Au–S1 measures 163.54(5)°. There are several related monophosphane gold(I) dithiocarbamate structures available in the literature[21] and these, along with related xanthate ($S_2COR$)[22] and dithiocarboxylate ($S_2CR$)[23] structures, feature significantly more linear geometries at the gold atom as the S2 atom forms Au···S2 distances greater than 3.0 Å in these structure. Thus, the structure of [Au($S_2CNEt_2$)(PTA)] is exceptional. For the dithiocarbamate structures,[21] the Au–S1, Au···S2 and Au–P1 distances fall in the ranges 2.3256(16)–2.3388(1), 3.0150(2)–3.1068(11) and 2.2430(14)–2.2600(4) Å, respectively. It is evident that the Au–P1 distance is significantly shorter in [Au($S_2CNEt_2$)(PTA)], which is consistent with the strong σ bonding ability of this ligand. This interaction pushes the S1 atom away from the gold centre and allows close approach of the S2 atom.

### Palladium Complexes

The chlorido palladium(II) complexes *cis*-[$PdCl_2$(PTA)$_2$] (**11a**) and *cis*-[$PdCl_2$(DAPTA)$_2$] (**11b**) were easily prepared by reacting $PdCl_2$ directly with stoichiometric quantities of the corresponding phosphanes. The *cis* geometry can be deduced from the presence of two ν(Pd–Cl) and ν(Pd–P) bands in the far-IR spectrum. This is consistent with the *cis* geometry of *cis*-[$PdCl_2$(PTA)$_2$], which was structurally characterised.[24,25] Thiolato palladium(II) complexes are easily prepared from the above dichlorido precursor complexes by reaction with the thiol derivatives in the presence of base. This synthetic approach was previously used by us[26] in the preparation of new palladium(II) and platinum(II) complexes showing novel thiolate coordination modes. The palladium thiolato complexes [Pd(SR)$_2$(PR′$_3$)$_2$] (SR = 2-$SC_5H_4N$, 2-$SC_4H_3N_2$ and PR′$_3$ = PTA, DAPTA) were prepared in good yields and were characterised by various spectroscopic techniques as well as X-ray crystallography (Scheme 2). The [Pd(SR)$_2$(PR′$_3$)$_2$] complexes show only one ν(Pd–P) and ν(Pd–S) band in the far-IR spectrum, which suggests a *trans* configuration about the palladium. This was indeed confirmed by an X-ray crystallographic study of *trans*-[Pd(2-$SC_5H_4N$)$_2$(PTA)$_2$] (**12a**) and *trans*-[Pd(2-$SC_5H_4N$)$_2$(DAPTA)$_2$] (**12b**). Molecular structures of these two complexes are shown in Figures 3 and 4, respectively.

The $^{31}P\{^1H\}$ NMR singlet resonances of the complexes are shifted to a higher field than those of the chlorido derivatives; furthermore, there is little difference in the chemical shift between the 2-pyridine and 2-pyrimidine derivatives. Like in the above-mentioned gold(I) complexes, the $^1H$ NMR spectra show singlet resonances due to equivalent $NCH_2P$ protons of the PTA ligand as well as the AB system assigned to the $NCH_2N$ protons. The DAPTA complexes show geminal H–H coupling for the $NCH_2N$ and $NCH_2P$ protons and, in addition, the P–H and H–H coupling patterns are identical to those observed in the free ligand. In addition, the mass spectra LSIMS+ agree with the mononuclear structures of the four thionate derivatives. No peaks due to any aggregation of metal–phosphane fragments comparable to gold(I) derivatives **1**–**10** are observed.



Scheme 2.

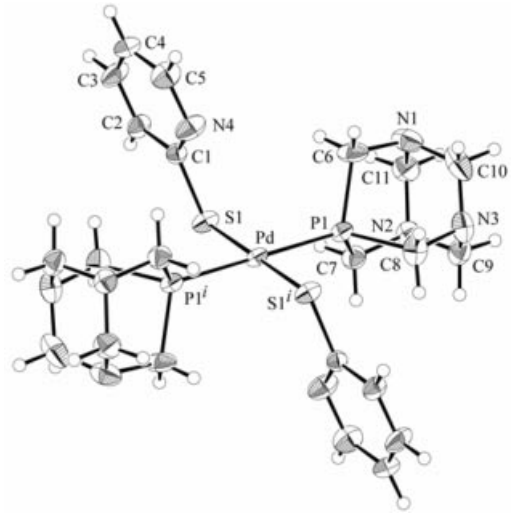


Figure 3. Molecular structure of *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$]. Ellipsoids show 35% probability levels. Primed atom related by the symmetry operation *i*: 1 – *x*, 1 – *y*, 1 – *z*. Selected bond lengths [Å] and angles [°]: Pd–S1 2.3411(13), Pd–P1 2.2832(13), S1–C1 1.745(5); S1–Pd–P1 87.44(5).

Compounds **12**–**13** did not show any sign of decomposition even after several months at room temperature. They are insoluble in solvents such as methanol, ethanol, acetone and hexane, and they are partially soluble in $CH_2Cl_2$, $CHCl_3$, DMSO and $H_2O$. The solubility in $H_2O$ is similar for all four complexes and is about 10 g/L. It is known that incorporation of the highly water-soluble DAPTA ligand into the coordination sphere of group 10 metal centres leads to water insoluble compounds.[17] We show here that the combination of thiolate and triazaphosphane ligands is a good ligand combination for the synthesis of water-soluble compounds of this group with attractive properties for new applications.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

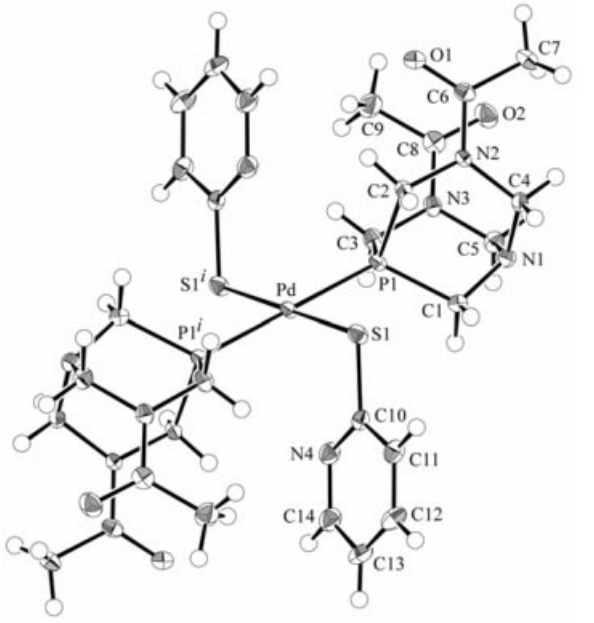

Figure 4. Molecular structure of *trans*-[Pd($SC_5H_4N$)$_2$(DAPTA)$_2$]. Ellipsoids show 50% probability levels. Primed atom related by the symmetry operation *i*: 1 – *x*, 1 – *y*, 1 – *z*. Selected bond lengths [Å] and angles [°]: Pd–S1 2.3421(4), Pd–P1 2.2962(4), S1–C1 1.7536(18); S1–Pd–P1 87.092(16).

The palladium atom in *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$] (**12a**) lies on a crystallographic centre of inversion and lies within a *trans* $N_2S_2$ donor set that defines a square-planar geometry. The structure of *trans*-[Pd($SC_5H_4N$)$_2$(DAPTA)$_2$] (**12b**) is virtually identical to that just described, which allows the differences in chemistry, and shows virtually the same geometric parameters about the palladium save for the Pd–P1 bond length that is longer than that in *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$]. In each case, the pyridine nitrogen atom is directed towards the central palladium atom but the Pd···N4 separations of 3.307(5) and 3.1564(16) Å are not considered to represent significant bonding interactions. Arguably, the most closely related complex in the literature available for comparison is that of *trans*-[Pd($SC_5H_5$)$_2${P(H)$Cy_2$}$_2$][27] for which two independent centrosymmetric molecules comprise the asymmetric unit. Here, the two Pd–S bond lengths are 2.3366(2) and 2.3393(17) Å, with Pd–P of 2.3056(18) and 2.3121(18) Å. These distances are shorter and longer, respectively, than those found in each of *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$] and *trans*-[Pd($SC_5H_4N$)$_2$(DAPTA)$_2$]. There are no analogous *trans*-$PdN_2S_2$ structures containing either PTA or DAPTA in the crystallographic literature. However, a protonated form of PTA is found in the crystal structure of *trans*-[Pd($NCS$)$_2$($PTAH$)$_2$]($NCS$)$_2$[28] with Pd–S and Pd–P distances of 2.3509(8) and 2.2940(8) Å, respectively, in the centrosymmetric molecule. Both of these distances are longer than the analogous bonds in *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$]. In the crystal structure of *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$], molecules associate through C–H···S interactions to form a chain motif along the *a* direction. From symmetry, each molecule forms two donor and two acceptor C–H···S interactions with geometric parameters: C7–H7a···S1$^{ii}$ = 2.74 Å, C7···S1$^{ii}$ = 3.663(5) Å and angle at H7a of 160°; *ii*: –*x*, 1 – *y*, 1 – *z*. By contrast, a three-dimensional architecture is found in the crystal structure of [Pd($SC_5H_4N$)$_2$(DAPTA)$_2$] owing to the presence of C–H···O interactions. The O1 atom is bifurcated and forms interactions with the H1b and H5a atoms. The geometric parameters defining these interactions are C1–H1b···O1$^{ii}$ = 2.47 Å, C1···O1$^{ii}$ = 3.357(2) Å and angle at H1b of 152° for *ii*: *x*, 3/2 – *y*, –1/2 + *z*; the parameters for the C5–H5a···O1$^{ii}$ interaction are 2.48 Å, 3.359(2) Å and 151°, respectively.

As commented for the gold complexes, the palladium derivatives were analysed by thermogravimetric analysis showing decomposition to metal (gold or palladium) around 750 °C. This behaviour permits their use as "liquid metal" when deposited on tiles and heated around 800 °C. The water solubility avoids the use of toxic organic solvents for this purpose. As an alternative to thermally induced decomposition, the use of a YAG laser beam focused on the complexes also leads to metal deposition as recently reported by some of us and others.[29,30] The development and optimisation of better metal deposition conditions are in progress.

## Conclusions

We report here water-soluble thiolato complexes of gold(I) and palladium(II) that could be used for the preparation of "liquid metals" for metallic deposition. The structures of some derivatives were determined by X-ray crystallography and show a pseudolinear coordination of gold(I) in [Au($S_2CNEt_2$)(PTA)] and *trans* square-planar coordination of palladium in *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$] and *trans*-[Pd($SC_5H_4N$)$_2$(DAPTA)$_2$]; the latter complex is one of the few structurally characterised examples of a compound containing DAPTA.

## Experimental Section

**General:** NMR spectra were recorded with 400 MHz Varian Inova or 400 or 500 MHz Bruker Avance spectrometers. Chemical shifts are quoted relative to external TMS ($^1$H, $^{13}$C) or 85% $H_3PO_4$ ($^{31}$P). FAB mass spectra were measured with a Micromass Autospec spectrometer in positive ion mode by using NBA as matrix. IR spectra were recorded as KBr or polyethylene disks with Nicolet Impact 410 or JASCO FTIR (far-IR) spectrometers. Elemental analyses were obtained in-house by using a LECO CHNS-932 microanalyser. The phosphanes PTA,[31] DAPTA[17] and [AuCl(tht)][32] as well as [AuCl(PTA)][6] were prepared according to published methods.

**DAPTA:** $^1$H NMR (500 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.03 (s, 3 H, CO*Me*), 2.02 (s, 3 H, CO*Me*), 3.20 (dt, $J_{H,H} \approx J_{P,H}$ = 15.2 Hz, $^4J_{H,H}$ = 2.5 Hz, 1 H, NC$H_2$P), 3.51 (d, $J_{P,H}$ = 11.4 Hz, 2 H, NC$H_2$P), 3.79 (ddd, $^2J_{H,H}$ = 15.4 Hz, $J_{P,H}$ = 14.7 Hz, $^4J_{H,H}$ = 2.8 Hz 1 H, NC$H_2$P), 3.95 (d, $J_{H,H}$ = 14.0 Hz, 1 H, NC$H_2$N), 4.28 (d, $J_{H,H}$ = 15.4 Hz, 1 H, NC$H_2$P), 4.53 (d, $J_{H,H}$ = 13.8 Hz, 1 H, NC$H_2$N), 4.93 (d, $J_{H,H}$ = 13.8 Hz, 1 H, NC$H_2$N), 5.25 (dd, $J_{H,H}$ = 15.2 Hz, $J_{P-H}$ = 2.0 Hz, 1 H, NC$H_2$P), 5.79 (d, $J_{H,H}$ = 14.0 Hz, 1 H,

NC$H_2$N) ppm. $^{31}P\{^1H\}$ NMR (202 MHz, $CDCl_3$, 25 °C): $\delta$ = –81.06 ppm. MS EI: *m/z* = 143 [M – 2$CH_3CO$]$^+$, 186 [M – $CH_3CO$]$^+$, 229 [M]$^+$, 230 [M + H]$^+$.

**Preparation of [AuCl(DAPTA)] (1b):** To a solution of [AuCl(tht)] (0.500 g, 1.56 mmol) in $CH_2Cl_2$ (ca. 50 mL) was added DAPTA (0.357 g, 1.56 mmol). After stirring the mixture for ca. 2 h, the solid products were isolated by filtration, washed with $CH_2Cl_2$ and $Et_2O$ and dried in vacuo. Yield: 99%, colourless solid. $^1H$ NMR (400 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 2.05 (s, 3 H, CO*Me*), 2.08 (s, 3 H, CO*Me*), 3.84 (d, *J* = 15.7 Hz, 1 H, NC$H_2$P), 4.12 (s, 2 H, NC$H_2$P), 4.24 (d, *J* = 14.1 Hz, 1 H, NC$H_2$N), 4.42 (dt, *J* = 15.7, 2.6 Hz, 1 H, NC$H_2$P), 4.79 (d, *J* = 14.2 Hz, 1 H, NC$H_2$N), 4.97 (dd, *J* = 15.2, 7.9 Hz, 1 H, NC$H_2$P), 5.05 (d, *J* = 14.2 Hz, 1 H, NC$H_2$N), 5.54 (dd, *J* = 15.6, 9.5 Hz, 1 H, NC$H_2$P), 5.63 (d, *J* = 14.0 Hz, 1 H, NC$H_2$N) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, [D$_6$]acetone, 25 °C): $\delta$ = –25.65 ppm. FAB MS: *m/z* = 426 [M – Cl]$^+$, 462 [M]$^+$, 655 [M – Cl + DAPTA]$^+$, 887 [M + AuDAPTA]$^+$. $C_9H_{16}AuClN_3O_2P$ (461.6): calcd. C 23.42, H 3.49, N 9.10; found C 24.01, H 3.31, N 9.21.

**Preparation of [Au(SR)(PR′$_3$)] Complexes:** To a solution of KOH (0.022 g, 0.385 mmol) in MeOH (ca. 10 mL) containing the thiol compound (0.308 mmol) was added [AuCl(PR′$_3$)] (PR′$_3$ = PTA, DAPTA) (0.100 g, 0.257 mmol). After stirring the mixture for ca. 20 h, the solid products were isolated by filtration, washed with $H_2O$, MeOH and $Et_2O$ and dried in vacuo. In some cases, the [Au(SR)(P)] complexes were soluble in MeOH so a different work up procedure was used. The solution was evaporated to dryness in vacuo, and the residue was extracted with $CH_2Cl_2$ (3 × 10 mL). The combined extracts were passed through Celite and concentrated in vacuo to ca. 5 mL. Addition of pentane or $Et_2O$ precipitated the products, which were isolated by filtration and dried in air.

**[Au(SMepyrim)(PTA)] (2a):** Yield: 49%, colourless solid. $^1H$ NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.26 (s, 3 H, Me), 4.36 (s, 6 H, C$H_2$P), 4.40 (d, *J* = 13.1 Hz, 3 H, C$H_2$N), 4.50 (d, *J* = 13.1 Hz, 3 H, C$H_2$N), 6.85 (d, *J* = 5.3 Hz, 1 H, pyrim-H$^5$), 8.18 (d, *J* = 5.1 Hz, 1 H, pyrim-H$^6$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = –48.29 ppm. FAB MS: *m/z* = 480 [M]$^+$, 833 [M + AuPTA]$^+$. $C_{11}H_{17}AuN_5PS$ (479.3): calcd. C 27.57, H 3.58, N 14.61; found C 27.50, H 3.75, N 14.30.

**[Au(SMepyrim)(DAPTA)] (2b):** Yield: 63%, colourless solid. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.08, 2.09 (s, 3 H, DAPTA-Me), 2.39 (s, 3 H, Me), 3.75 (dd, *J* = 16.0, 6.3 Hz, 1 H, NC$H_2$P), 4.03 (s, 2 H, NC$H_2$P), 4.04 (d, *J* = 15.2 Hz, 1 H, NC$H_2$N), 4.35 (m, 1 H, NC$H_2$P), 4.64 (d, *J* = 14.1 Hz, 1 H, NC$H_2$N), 4.80 (m, 1 H, NC$H_2$P), 4.90 (d, *J* = 13.9 Hz, 1 H, NC$H_2$N), 5.64 (dd, *J* = 15.2, 7.4 Hz, 1 H, NC$H_2$P). 5.74 (d, *J* = 14.2 Hz, 1 H, NC$H_2$N), 6.75 (d, *J* = 5.3 Hz, 1 H, pyrim-H$^5$), 8.19 (d, *J* = 5.3 Hz, 1 H, pyrim-H$^6$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = –24.88 ppm. FAB MS: *m/z* = 552 [M]$^+$, 978 [M + AuDAPTA]$^+$. $C_{15}H_{24}AuN_5O_2PS$ (551.4): calcd. C 30.50, H 3.84, N 12.70; found C 30.41, H 3.79, N 12.64.

**[Au(SMe$_2$pyrim)(PTA)] (3a):** Yield: 89%, colourless solid. $^1H$ NMR (400 MHz, $D_2O$, 25 °C): $\delta$ = 2.50 (s, 6 H, Me), 4.55 (s, 6 H, C$H_2$P), 4.93 (d, *J* = 12.9 Hz, 3 H, C$H_2$N), 4.86 (d, *J* = 12.9 Hz, 3 H, C$H_2$N), 7.12 (s, 1 H, pyrim-H$^5$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $D_2O$, 25 °C): $\delta$ = –35.73 ppm. FAB MS: *m/z* = 494 [M]$^+$, 857 [M + AuPTA]$^+$. $C_{12}H_{19}AuN_5PS$ (493.3): calcd. C 29.22, H 3.88, N 14.20; found C 29.12, H 3.77, N 14.55.

**[Au(SMe$_2$pyrim)(DAPTA)] (3b):** Yield: 57%, colourless solid. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.10 (s, 6 H, DAPTA-Me), 2.35 (s, 6 H, Me), 3.72 (d, *J* = 15.4 Hz, 1 H, NC$H_2$P), 4.01 (s, 2 H, NC$H_2$P), 4.08 (d, *J* = 13.7 Hz, 1 H, NC$H_2$N), 4.32 (d, *J* = 15.4 Hz, 1 H, NC$H_2$P), 4.66 (d, *J* = 14.7 Hz, 1 H, NC$H_2$N), 4.75 (dd, *J* = 15.0, 9.5 Hz, 1 H, NC$H_2$P), 4.93 (d, *J* = 15.1 Hz, 1 H, NC$H_2$N), 5.65 (dd, *J* = 16.3, 7.3 Hz, 1 H, NC$H_2$P), 5.77 (d, *J* = 14.2 Hz, 1 H, NC$H_2$N), 6.60 (s, 1 H, pyrim-H$^5$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = –24.82 ppm. FAB MS: *m/z* = 566 [M]$^+$, 991 [M + AuDAPTA]$^+$. $C_{16}H_{26}AuN_5O_2PS$ (565.4): calcd. C 31.87, H 4.10, N 12.39; found C 31.82, H 3.99, N 12.18.

**[Au(benzoxazole)(PTA)] (4a):** Yield: 85%, pale yellow solid. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 4.37 (s, 6 H, C$H_2$P), 4.50 (d, *J* = 10.7 Hz, 3 H, C$H_2$N), 4.53 (d, *J* = 10.7 Hz, 3 H, C$H_2$N), 7.10 (m, 2 H, benzoxazole-H$^2$,H$^3$), 7.34 (d, *J* = 7.8 Hz, 1 H, benzoazole-H$^1$), 7.46 (d, *J* = 7.8 Hz, 1 H, benzoazole-H$^4$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, 25 °C): $\delta$ = –52.00 ppm. FAB MS: *m/z* = 505 [M]$^+$, 858 [M + AuPTA]$^+$. $C_{13}H_{16}AuN_4OPS$ (504.3): calcd. C 30.96, H 3.20, N 11.11; found C 30.95, H 3.25, N 11.30.

**Crystallography:** Intensity data for [Au($S_2CNEt_2$)(PTA)] (**8a**), *trans*-[Pd($SC_5H_4N$)$_2$(PTA)$_2$] (**12a**) and *trans*-[Pd($SC_5H_4N$)$_2$-(DAPTA)$_2$] (**12b**) were measured at 293, 230 and 293 K, respectively, with a Xcalibur Oxford Diffraction in the case of **12b** and on a Bruker CCD for **8a** and **12a** fitted with Mo-$K_\alpha$ radiation so that $\sigma_{max}$ was 28.4, 25.0 and 32.2°, respectively. The structures were solved by heavy-atom methods (SHELXS97) [33] and refinement was on $F^2$ (SHELXL97)[33] with the use of data that was corrected for absorption effects with an empirical procedure,[34] with non-hydrogen atoms modelled with anisotropic displacement parameters, with hydrogen atoms in their calculated positions, and by using a weighting scheme of the form $w = 1/[\sigma^2(F_o^2) + (aP)^2]$ where $P = (F_o^2 + 2F_c^2)/3$. Disorder was noted in the structure of [Au($S_2CNEt_2$)(PTA)] so that two distinct positions were determined for the gold atom. Refinement showed that the major component had a site occupancy factor = 0.807(3). The absolute configuration of [Au($S_2CNEt_2$)(PTA)] was determined on the basis of differences in Friedel pairs included in the data sets and confirmed by the near zero value of the Flack parameter [i.e. –0.003(7)].[35] A residual electron density peak of 1.12 e/Å$^3$ was noted in the final difference map for *trans*-[Pd($SC_5H_4N$)$_2$(DAPTA)$_2$], this was located between the Pd and S1 atoms. Molecular structures are shown in Figures 1, 2 and 3 and were generated with ORTEP.[36] Data analyses were performed with PLATON.[37] Crystallographic data and refinement details are given in Table 1. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We thank the Ministerio de Ciencia y Tecnologia (Spain) and FEDER (CTQ2005-08099-CO3-01), as well as the Junta de Castilla y Leon and the University of Burgos (BU033A06 and 112-541A-487.01) for financial support. F. M thanks the University of Burgos for a visiting fellowship and E. V. is grateful to the CSIC for a I3P research grant.

# Photoinitiation of Acrylate Polymerization with (Arene)chromium Complexes

E. Peter Kündig,*[a] Long-He Xu,[a] Mikhail Kondratenko,[a] Allan F. Cunningham Jr.,*[b] and Martin Kunz[b]

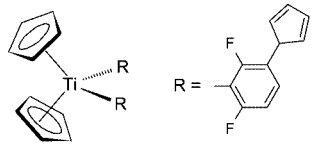
**Keywords:** Acrylate polymerization / Photoinitiators / Arene complexes / Chromium / Radiation curing

Photoinitiation of acrylate polymerization by [Cr($\eta^6$-arene)-$(CO)_3$] complexes in the presence of an organic chloro compound was investigated. For the bimolecular system, a good correlation between activity and metal–arene and metal–carbonyl bond strength was observed. The highest efficiency was found for an initiator in which the organic chloro compound was tethered to the complexed arene: [Cr($\eta^6$-$C_6H_5CH_2OCOCCl_3$)$(CO)_3$]. The initial steps of the photoinitiation were probed and provided evidence for metal–arene bond cleavage in an Cr($\eta^2$-acrylate)($\eta^6$-arene)$(CO)_2$ complex. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

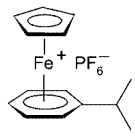
## Introduction

Photoinitiated polymerization, commonly termed radiation curing, is an important industrial process employed for the fabrication of a wide variety of products ranging from floor coatings to integrated circuit boards. Among the advantages of this technology are lower energy costs and the concomitant reduction in the use of organic solvents, issues of ever-increasing importance.[1]

One of the key elements in a radiation-curable system is the photoinitiator.[2] Most of the commercially available photoinitiators are organic compounds which absorb in the UV and near-UV regions of the electromagnetic spectrum. Prompted by a potential further reduction in energy costs through the use of standard light sources and the increased availability of visible-light lasers which are required for technically advanced applications, efforts to develop photoinitiators sensitive to visible light have multiplied. In this domain, transition-metal organometallic chemistry offers special opportunities, as most organometallic compounds absorb in the visible region because of the partial occupation of the metal d orbitals. In addition, the absorption characteristics of such complexes can be manipulated by modifying the nature of the metal-bound ligands.[2] The commercialization of two organometallic photoinitiators, Irgacure 784, a titanocene suitable for the polymerization of acrylate-based systems with the argon laser, and Irgacure 261, a ferrocenium salt which provides a Lewis acid upon irradiation and is used to cure epoxy resins, attest to the viability of this approach.[3,4]



Irgacure 784



Irgacure 261

The photochemistry of a large number of organometallic compounds under varying conditions has been investigated, and, in some cases, the generation of radicals or acidic species has been observed.[3,5] One well-documented example is the combination of carbonylmetal complexes with carbon tetrachloride, which serves to photoinitiate the polymerization of acrylates via the production of the trichloromethyl radical. Whereas the initial work of Bamford and coworkers concentrated on the homoleptic carbonylmetal complexes, decacarbonyldimanganese and decacarbonyldirhenium,[6] it was later extended to include organometallic derivatives of manganese[7] and (arene)tricarbonylchromium complexes.[8]

An abbreviated version of the mechanism of radical production proposed by Bamford for the bimolecular photoinitiator composed of (benzene)tricarbonylchromium (**1**) and carbon tetrachloride is shown in Scheme 1. Irradiation of **1** in the presence of methyl methacrylate (mma) is presumed to give rise to an exciplex of the acrylate and **1**, which undergoes further transformation to the (mma)chromium complexes **2** and **3**. The former, being at best a 16-electron complex when one assumes coordination of both the double bond and the ketone of mma to the metal, can interact directly with carbon tetrachloride and thereby provide an initiating trichloromethyl radical and, formally, a chromium(I) species. In the case of complex **3**, ligand dissociation, which also occurs in the dark but is greatly accelerated by irradiation, must precede radical generation, unless, of course, through-space electron transfer can occur. Accord-

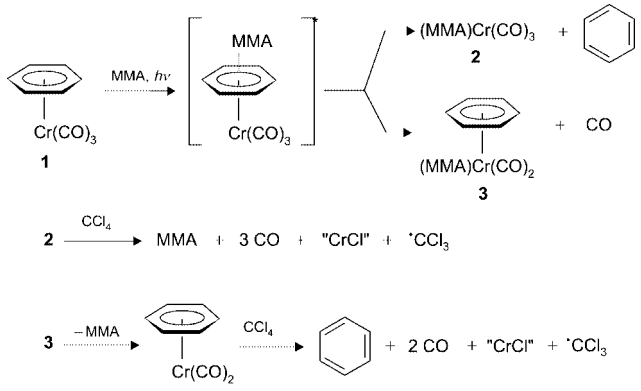
 InterScience © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing to this mechanism, the formation of one initiating radical is accompanied by the liberation of one molecule of arene. Indeed, this is observed experimentally in that the quantum yield for decomposition of the arene complex is indistinguishable from the quantum yield for initiation of polymerization. In addition, these quantities are dependent on the nature of the arene complex: the stronger the arene–chromium bond, the slower the rate of polymerization (and decomposition).



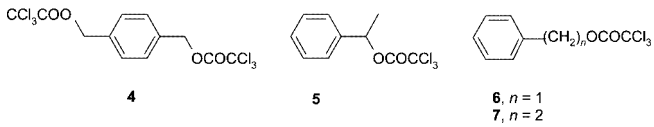
Scheme 1. Mechanism proposed by Bamford for the photoinitiation of methyl methacrylate (MMA) polymerization in the presence of [Cr(benzene)(CO)$_3$] (**1**)/$CCl_4$.[6]

A major drawback of the (arene)tricarbonylchromium/carbon tetrachloride photoinitiator system, from an industrial viewpoint, is the use of the highly volatile and carcinogenic carbon tetrachloride as coinitiator. Furthermore, the intermolecular nature of the radical production requires the use of a great excess of this component. One approach toward the resolution of both of these problems is to attach a functional group capable of producing radicals upon reduction directly to chromium. In addition to decreasing the volatility of the system, the presence of an intramolecularly bound coinitiator should lead to an increase in photoinitiator activity, since a high effective concentration of the coinitiator in the vicinity of the metal is assured. We have analyzed this approach and now report our results on the design, synthesis, and reactivity of a new class of unimolecular organometallic photoinitiators.

## Results and Discussion

### Bimolecular Photoinitiators

Initial work was aimed at the identification of an appropriate substitute for carbon tetrachloride which would exhibit similar reactivity in the presence of (benzene)tricarbonylchromium (**1**). On the basis of literature reports of the photoinitiator activity of decacarbonyldimanganese and ethyl trichloroacetate,[9] and the crosslinking of poly(vinyl trichloroacetate) with this carbonylmetal complex,[9a,10] phenalkyl trichloroacetates were targeted as potential coinitiators. The presence of a phenyl group was desired in order to allow introduction of the tricarbonylchromium moiety by using well-documented methodology.[11,12]



**4** **5** **6**, $n = 1$ **7**, $n = 2$

Synthesis of the trichloroacetates **4**–**7** was carried out by the reaction of the corresponding alcohols with trichloroacetyl chloride and pyridine in dichloromethane.[13] The coinitiator activity of these acetates in the presence of **1** was assessed under typical industrial conditions. The photoinitiator system to be tested was added to a clear lacquer consisting of a mixture of polyfunctional acrylates and vinylpyrrolidinone (for details, see Exp. Sect.). A 60–70-μm layer of the resulting formulation was applied to a sheet of aluminum, then covered first with a polyester foil and finally with a 21-step optical wedge. The sample was then placed at a distance of 30 cm from a 4-kW Xenon lamp and irradiated for 20 s. The reactivity of the various photoinitiator combinations, quantified as the number of completely hardened (cured) steps after development in ethanol, is shown in Figure 1. It should be noted at this point that a difference of two steps corresponds to a twofold increase in reactivity; i.e., the transmittance of light at step 1 is two times that at step 3. It is evident that even **1** alone is a photoinitiator, albeit of very low activity (step 0, which is 100% transparent, is cured). Given the fact that dissolved oxygen is present in the formulation and that one component of the formulation contains hydroxy groups (dipentaerythritol monohydroxypentacrylate), the unimolecular photoinitiator activity of the complexes may be due to oxidative ligand exchange rather than radical polymerization of the acrylate units. Wagner and Purbrick[14] previously reported that **1** promotes the photochemical crosslinking of polymers containing pendant hydroxy groups in the presence of oxygen. The formation of O–$Cr^{III}$ bonds between polymer molecules was suggested to account for this observation (Scheme 2).

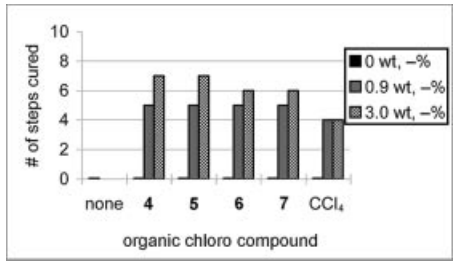


Figure 1. Reactivity of 0.3 wt.-% **1** in the presence of organic chlorides **4**–**7** and $CCl_4$ (0, 0.9, and 3.0 wt.-%) in a clear lacquer. 20-s irradiation with a 4-kW Xenon lamp through a 21-step optical wedge.

The addition of an organic chloro compound results in a substantial increase in activity. The most efficient coinitiators are the bis(trichloroacetate) **4** and 2-phenethyl trichloroacetate (**5**). They are 1.5 to 3 times more reactive than carbon tetrachloride over the concentration range studied (increase of 1–3 cured steps, Figure 1). The increased reactivity of the trichloroacetates can be ascribed to the forma-

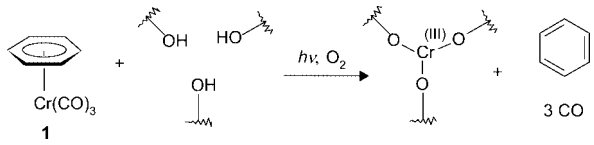

Scheme 2. Formation of $Cr^{III}$ species from the reaction of **1** with polymers containing pendant hydroxy groups in the presence of oxygen.

tion of a resonance-stabilized α-carbonyloxy radical. In the absence of **1**, all the trichloroacetates as well as carbon tetrachloride were inactive. As expected from the work of Bamford discussed previously, enhanced reactivity is observed for all the trichloroacetates when **1** is replaced with the chlorobenzene complex **8**, which has a weaker chromium–arene bond (Figure 2). In this case, however, trichloroacetates **4**, **6**, and **7** are twice as effective as **5** (increase of 2 cured steps). Surprisingly, carbon tetrachloride exhibits more or less the same coinitiator activity with both complexes. This may indicate that the rate-determining step in the case of carbon tetrachloride is its reaction with the active chromium species to provide the trichloromethyl radical rather than the generation of the latter from **1** or **8**.

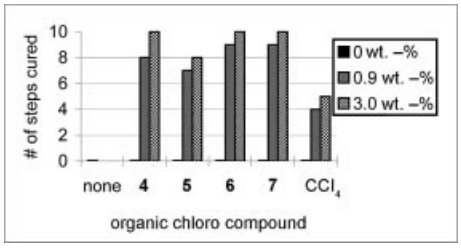

Figure 2. Reactivity of 0.3 wt.-% **8** in the presence of organic chlorides **4**–**7** and $CCl_4$ (0, 0.9, and 3.0 wt.-%) in a clear lacquer. 20-s irradiation with a 4-kW Xenon lamp through a 21-step optical wedge.

It is apparent from the order of reactivity that neither the nature of the tether between the phenyl and trichloroacetate groups nor the number of trichloroacetate groups per molecule has a significant effect on the rate of polymerization.

At this point, the influence of the arene substituent of the chromium complex upon its activity in the presence of **4** was investigated. Other than **13**, which was obtained via lithiation of **9** followed by treatment with hexachloroethane,[15] all complexes were prepared by direct ligand exchange in hexacarbonylchromium [11] or tricarbonyl(naphthalene)chromium.[16] With the exception of **14**, which can cure 2 steps, crosslinking of the formulation is negligible when the complexes are employed alone (at 100% transmittance, 0 steps). The superior photoinitiator activity of **14** may be connected to the lower oxidative stability of the 16-electron chromium fragment resulting from loss of carbon monoxide. In contrast, the phosphane complex **15**, which could formally yield a similar unsaturated fragment, does not undergo direct photodissociation of carbon monoxide.[17] When **4** is present, the highest reactivity is observed for the halogenated complexes **13** and **9** (9 steps). In general, complexes containing one electron-withdrawing group exhibit higher reactivity than that of the parent benzene complex **1**. The anisole complex **12** is about as active as **1**, whereas the phosphane- and phosphite-substituted complexes **14** and **15** are less reactive than **1** (Figure 3).

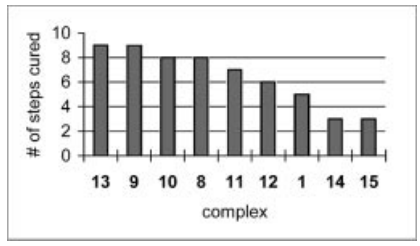

Figure 3. Reactivity of 0.9 wt.-% **4** and 0.3 wt.-% [Cr(arene)$(CO)_3$] complexes in a clear lacquer. 20-s irradiation with a 4-kW Xenon lamp through a 21-step optical wedge.

The results obtained with the (arene)tricarbonylchromium complexes are in accord with those of Bamford: reactivity increases with decreasing arene–chromium bond strength. Although the absolute bond strengths of all the complexes employed in this study are not reported in the literature, the bond strengths are directly related to the energy of the HOMOs of the complexes and, in turn, their oxidation potentials and their carbonyl stretching frequencies.[18] In fact, very good correlation is obtained between νCO and the number of steps cured. A higher carbonyl stretching frequency, indicative of a lower M–CO bond strength, results in higher reactivity. As proposed by Bamford, this can be explained by the more facile substitution of the arene or CO by acrylate, thus leading to higher concentrations of the active intermediates **2** and **3** (Scheme 1). It should be noted, however, that the photochemical generation of species related to **2** from (arene)tricarbonylchromium is not expected to be an important pathway as irradiation of (arene)tricarbonylchromium leads almost exclusively to loss of CO.[17a]

The effect of substituting a carbonyl ligand of **1** with phosphane or phosphite is a marked decrease in bimolecular photoinitiator activity. The combinations of complexes **14** and **15** with **4** exhibit the lowest reactivity of all the systems studied. Inspection of the carbonyl stretching frequencies indicates that these compounds have the strongest chromium–carbonyl bonds (νCO: 1915 and 1857 $cm^{-1}$ for **14** and 1890 and 1831 $cm^{-1}$ for **15** vs. 1974 and 1894 $cm^{-1}$ for **1**), which is consistent with the mechanism based on initial carbonyl dissociation. Given that the drastic decrease in carbonyl stretching frequency is due to direct resonance of the phosphorus ligand with the carbonyl ligands through the metal atom and not to interactions with the benzene substituent, it is difficult to compare these complexes with the tricarbonyl series. There are indications, however, that the arene–chromium bond in such complexes is also

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stronger than that in **1**. For example, arene exchange reactions with dicarbonyl(naphthalene)(triphenylphosphane)-chromium have not been successful,[19] whereas arene exchange in tricarbonyl(naphthalene)chromium is a well-proven, widely applied, mild method for the synthesis of (arene)tricarbonylchromium complexes.[12,16,20]

### Unimolecular Photoinitiators

Having defined the factors affecting the bimolecular generation of radicals from (arene)chromium complexes and phenalkyl trichloroacetates, we then focused our attention on the synthesis and reactivity of the following unimolecular system: the tricarbonylchromium complexes of phenalkyl trichloroacetates. Of initial interest was the effect of the distance between the phenyl and trichloroacetate functionalities on the photoinitiating efficiency. The required complexes were prepared in two steps by starting from the phenalkyl alcohols. Ligand exchange of hexacarbonylchromium with the alcohols provided the complexes **16a**–**d** which were acetylated under standard conditions to afford complexes **17a**–**d** (Scheme 3).

These compounds were then evaluated in the acrylate formulation at a concentration of 0.3 wt.-% as described previously (Figure 4). The most active photoinitiator is the benzyl trichloroacetate complex **17a** (11 steps) which is 1.5 times more effective than the bimolecular combinations of 0.3 wt.-% **8** and 3.0 wt.-% organic chloride. Upon lengthening the chain by one carbon, as in **17b**, a fourfold decrease in activity results. Although the replacement of the ethylene bridge in **17b** by a propylene bridge (in **17c**) again causes a reduction in activity, further increases in chain length are without effect. It is interesting to note that the advantage of attaching the coinitiator directly to the chromium complex is lost when the methylene tether is longer than two carbons: the photoinitiator activity of **17c** and **17d** are exactly the same as that of the bimolecular combination of **1** and 0.9 wt.-% **4** or **6** (Figure 1). The fact that addition of 0.9 wt.-% of the bis(trichloroacetate) **4** to formulations containing the photoinitiators **17** leads to a slight increase in activity in almost all cases may indicate that decomplexation of the arene occurs prior to radical generation.

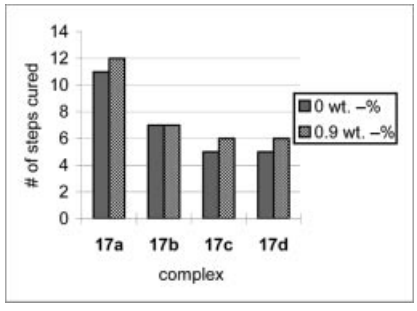

Figure 4. Reactivity of 0.3 wt.-% **17a**–**d** alone or with 0.9 wt.-% **4** in a clear lacquer. 20-s irradiation with a 4-kW Xenon lamp through a 21-step optical wedge.

Retaining the basic structure of complex **17a** as a template, two general strategies were employed in an attempt to enhance the photoinitiator activity of this class of compounds: (1) monitoring the orientation and number of trichloroacetate functionalities and (2) substitution of the arene moiety. With the first strategy, it is clear that the trichloroacetate group must be in proximity to the metal center to allow the generation of initiating radicals. Therefore, any interaction or structural constraint that forces these groups into a *syn* geometry should also result in higher reactivity.

With this in mind, we undertook the synthesis of the derivatives of **17a** having methyl substitution at the benzyl carbon. The higher steric volume of the methyl group should lead compounds such as **19a** and **19b** to exhibit preferred conformations in which the acetate functionality resides on the same face of the arene as the tricarbonylchromium moiety.

Unfortunately, these two compounds were unstable and could not be evaluated in the acrylate-based lacquer. Although the arene complexes **18a** and **18b** could be obtained in good yields, their subsequent reactions with trichloroacetyl chloride led, in the first case, to an oil which decomposed at room temperature and, in the second case, to elimination to afford the methylstyrene complex **20** (Scheme 4).[21] A derivative with the desired structural constraint was found in the *syn*-1-tetrahydronaphthol complex *syn*-**21**.[22] Reaction with trichloroacetyl acetate furnished the desired trichloroacetate **22** in 93% yield. Attempted trichloroacetylation of the corresponding *anti* isomer (*anti*-**21**) led to decomposition via the metal-stabilized benzyl cation.[23] The assessment of **22** in the acrylate lacquer revealed that the structural constraint has little effect on the photoinitiator activity (Figure 5). It is feasible that the advantage gained by this modification is offset by the deactivating influence of the additional alkyl group.

Neither does the increase in the number of trichloroacetate groups of the photoinitiator have a measurable effect on its activity. Bis(trichloroacetate) **24**, prepared via the complexed diol **23**, exhibits the same activity as **17a** (11

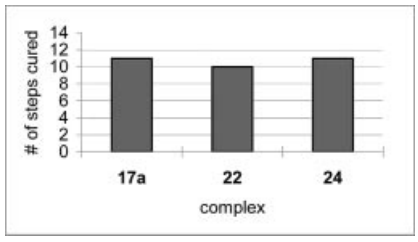

Figure 5. Reactivity of 0.3 wt.-% [Cr(arene)(CO)$_3$] complexes **17a**, **22**, and **24** in a clear lacquer. 20-s irradiation with a 4-kW Xenon lamp through a 21-step optical wedge.

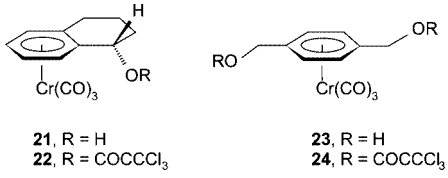

steps, Figure 5). This is in accord with results obtained with the bimolecular photoinitiator systems which show that the coinitiator activity of **4** and **6** are approximately the same.

Since the bimolecular activity of the chromium complexes exhibited a strong dependence on the nature of the arene substituent, it was hoped that the activity of **17a** could be modified in the same fashion. The di- and trisubstituted tricarbonylchromium complexes **25** and **26** were prepared as usual. The direct reaction of *o*-chlorobenzyl alcohol with $Cr(CO)_6$ afforded complex **27a**[24] in low yield (19%). Protection of the alcohol functionality as its *tert*-butyldimethylsilyl ether prior to complexation gave a slightly improved yield of **27b** (27%) and, using [$Cr(CO)_3$-(naphthalene)] as the Cr(CO)3 source, this yield was raised to 40%.[16a] The complexes were then converted into their respective trichloroacetates **28**–**30** and compared to **17a** as photoinitiators in the acrylate lacquer. In contrast to the bimolecular photoinitiators, a slight decrease in activity was observed upon introduction of an *ortho*-methoxy or an *ortho*-chlorine substituent in **17a**: both **29** and **30** allow the curing of only 10 steps vs. 11 steps for **17a** (Figure 6). A further erosion of activity is found when a second alkoxy group is introduced: the catechol derivative **28** is four times less reactive than **17a**. Apparently, the upper limit of reactivity is already attained with complex **18a**. This could imply that the rate-determining step of radical production, at high levels of activity, is the interaction of the trichloroacetate with the metal fragment. With complexes of lower activity, the rate of radical production would be defined by the rate of ligand dissociation.

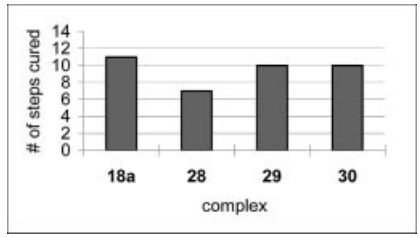

Figure 6. Reactivity of 0.3 wt.-% [Cr(arene)(CO)$_3$] complexes **18a**, **28**–**30** in a clear lacquer. 20-s irradiation with a 4-kW Xenon lamp through a 21-step optical wedge.

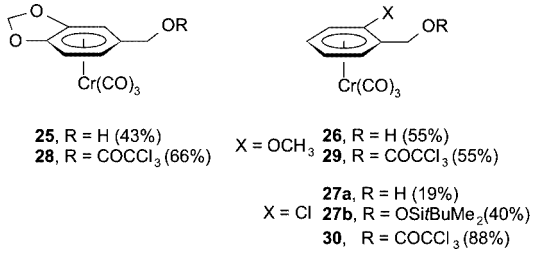

Having established that complex **17a** possessed optimum reactivity and synthetic accessibility, we then probed its photochemistry in the absence of polymerizable acrylates with the goal of identifying the initiating species. It is important to note that the test results obtained with the series of phenalkyl trichloroacetate complexes **17a**–**17d** can be rationalized in terms of initial carbonyl loss or arene loss. Dissociation of a carbonyl ligand would allow direct coordination of a chlorine atom of the trichloroacetate to chromium (Scheme 5, path a). Subsequent oxidation and fragmentation would engender an unstable 17-electron $Cr^I$ arene complex containing a carboxydichloromethyl radical. As the energetics of the intramolecular interaction is clearly dependent upon the chain length, one would expect the highest reactivity with **17a**, as is observed. Likewise, postulating initial arene dissociation, the trichloroacetate moiety of **17a** would remain closer to the metal than in **17b**–**d** which have longer methylene chains.

First attempts to trap a radical intermediate were carried out in benzene solution in the presence of excess methyl 2-*tert*-butyl-2-propenoate (**31**).[25] Acrylate **31** has previously been employed to identify the initiating radicals for a

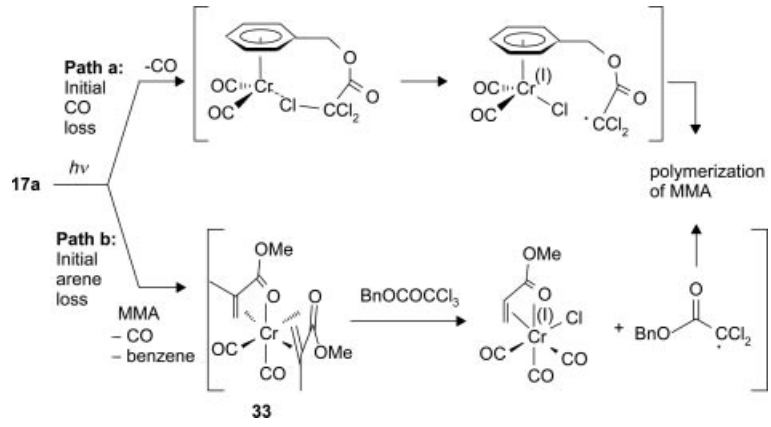


Scheme 5. Possible pathways of radical generation by irradiation of the Cr complex **17a** in methyl methacrylate.

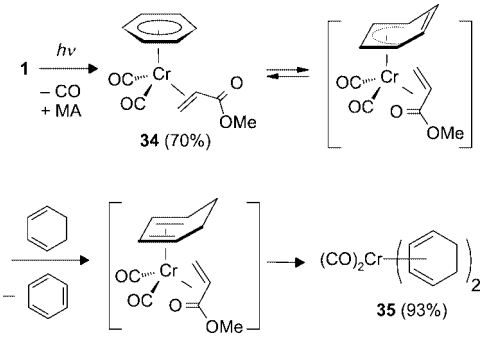
**31** **32**

number of photoinitiators, as radical addition to **31** does not lead to polymerization.[26] Irradiation of a 0.25-M solution of **17a** containing 4 equiv. **31** at 350 nm (four lamps of 24 W each) in a Rayonet apparatus for 12 h led to the isolation of one new product, the benzyl chloride complex **32** in 17% yield along with 19% recovered starting material.

No trace of a radical addition product to **31** could be detected. An analogous result was obtained upon photolysis of **17a** in the absence of **31**. At a concentration of 0.25 M, **32** was obtained in 41% yield after irradiation for 2 d, whereas only a trace of **32** could be detected at a concentration of 0.08 M. These results show that **31** does not play a role in the formation of complex **32** and that it is unlikely that **32** is formed from **17a** by an intramolecular process. These results then appear to rule out path a (Scheme 5).

The failure to trap any radical species in the aforementioned photolysis of **17a** and **32** suggests that the polymerizable acrylate is an important component of this photoinitiator system. The role of the acrylate may be to displace the arene from the chromium complex, thereby generating an intermediate (a diacrylate complex of chromium, e.g. **33**) which is more reactive toward the organic halide (path b). This process is initiated by the loss of CO and olefin coordination of mma. Slippage of the arene from the $\eta^6$ to the $\eta^4$ coordination mode concomitant with $\eta^4$ coordination of mma leads to an intermediate that should readily undergo further association of mma with liberation of benzene. Photoinitiation of polymerization via initial loss of CO was dismissed by Bamford in order to explain the higher rates of decomposition of **1** (evolution of benzene) in mma as compared to isooctane *in the absence of an organic chloro compound* ($CCl_4$). It is unclear whether these observations are related to the generation of initiating radicals. In any event, it can been readily seen that the enhanced arene formation reported could also arise from the mode of substitution of arene by mma shown in Scheme 5, path b.

Neither the direct irradiation of **17a** in the presence of methyl methacrylate (mma) or methyl acrylate (ma) nor the two-step procedure based on cyclooctene[27] afforded the desired alkene complexes. Turning to the parent complex **1**, mma again yielded no isolable complex. However, as communicated earlier from this laboratory,[28] the two-step procedure, when combined with the use of ma, gave the acrylate complex **34** in good yield. The acrylate ligand strongly labilizes the metal–arene bond, presumably by a haptotropic rearrangement as shown in Scheme 6. The arene ligand in **34** is more labile than the acrylate, and **34** undergoes arene exchange at ambient temperature.[28] Mono- and dihapto ligands displace first the arene, and then the acrylate. An example pertinent to the subject of the present investigation is the reaction of **34** with 1,3-cyclohexadiene at ambient temperature to give [$Cr(CO)_2(\eta^4$-1,3-cyclohexadiene$)_2$] (**35**) in high yield.[28–30]



Scheme 6. Substitution of both benzene and methyl acrylate in **1** by cycohexadiene to give **35**.

The reactivity of **34** was then assayed under various conditions. In the absence of the organic chloro compound **4** in the dark, no polymerization of ma was observed. Nonetheless, after 3 h at room temp. complex **34** could no longer be detected, and this indicates an exchange of benzene for ma as previously noted by Bamford. Upon addition of **4** to the solution of **34** in ma in the absence of light, rapid polymerization of ma occurred. In contrast, the combination of **4** with complex **1** does not lead to polymerization in the absence of irradiation.

This provides substantial evidence for the intermediacy of an acrylate complex in the photopolymerization of acrylates with the arene chromium complex/organic chloro compound initiator system. Photoinitiation starts by CO substitution for an acrylate. The acrylate ligand, which can interconvert between an $\eta^2$ and an $\eta^4$ binding mode, renders the arene–metal bond labile. Arene displacement leads to a reactive intermediate, e.g. **33**, which can reduce suitable organic chlorides, thereby generating initiating radicals. Incorporation of the organic chloro compound in the chromium complex results in a more efficient photoinitiator, as the essential components remain in close proximity throughout the initiating process.

## Experimental Section

All manipulations involving organometallic compounds were carried out under an atmosphere of purified nitrogen by using an inert gas/vacuum double manifold and standard Schlenk techniques. Solvents for the preparation of chromium complexes were dried and distilled under nitrogen immediately before use. Methyl acrylate was purified by washing twice with NaOH (5% aq.) to remove inhibitors, then twice with water, and then dried with $CaCl_2$, $Na_2CO_3$, $MgSO_4$, and finally distilled from CaH. Complexes **8**,[11] **9**,[11] **10**,[31] **12**,[11] **14**,[32] **15**[33] were prepared as described in the literature. A high pressure Hg-lamp (Philipps-125W) was used for the synthesis of phosphane- or phosphitechromium complexes. Photolysis of methyl acrylate in the presence of a chromium complex was carried out for mechanistic investigations by using a photochemical reactor (Rayonet-CAT NO RPR-100) equipped with RPR-3500 Å lamps (Southern New England Ultraviolet Company, USA). Analytical and preparative TLC: Merck silica gel 60 $F_{254}$ plates. Flash column chromatography: silica gel 60, (Merck). M.p.: Büchi 510, not corrected. IR: Mattson Polaris or Perkin–Elmer 1650 FT-IR spectrometer, NaCl solution cells. $^1$H and $^{13}$C-NMR: Bruker 400 MHz or Varian-XL-200 spectrometer. MS: Varian CH 4 or SM 1, 70 eV; high-resolution MS (HRMS): VG analytical 7070E mass spectrometer.

**4-(2,2,2-Trichloroacetoxymethyl)benzyl Trichloroacetate (4):** To a mixture of 1,4-phenylenedimethanol (690 mg, 5 mmol) and pyridine (988 mg, 12.5 mmol) in dry $CH_2Cl_2$ (80 mL) was added dropwise trichloroacetyl chloride (2.0 g, 11 mmol) at 0 °C. The resulting mixture was stirred at room temp. for 1 h before removing the solvent. The residue was purified by chromatography on silica gel (pentane/diethyl ether 2/1) to give **4** as a white solid (1.56 g, 76%). M.p. 82–84 °C. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1766, 1227, 982, 831, 685 cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 5.37 (s, 4 H, $CH_2$), 7.44 (s, 4 H, ArH) ppm. $^{13}$C NMR (100 MHz, CDC $l_3$): $\delta$ = 70.1, 89.7, 128.6, 134.6, 161.8 ppm. MS: *m*/*z* (%) = 428 (4) $[M]^+$, 393 (4), 335 (4), 281 (12), 265 (100), 231 (5), 119 (17), 104 (42), 91 (25), 77 (11), 36 (8), 28 (4). $C_{12}H_8Cl_6O_4$ (428.91): calcd. C 33.60, H 1.88; found C 33.61, H 1.88.

**Tricarbonyl(4-hydroxymethylphenylmethanol)chromium (23):**[34] Under $N_2$, a degassed mixture of (4-hydroxymethylphenyl)methanol (1.38 g, 10 mmol) and (naphthalene)tricarbonylchromium (2.64 g, 10 mmol) in thf (50 mL) was heated for 15 h at 60 °C. Solvent removal followed by chromatography on silica gel with diethyl ether and recrystallization in toluene afforded **23** (2.49 g, 90%). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1969, 1892 cm$^{-1}$. $^1$H NMR (400 MHz, $CD_3COCD_3$): $\delta$ = 4.43 (s, 4 H, $CH_2$), 4.66 (s, 2 H, OH), 5.73 (s, 4 H, ArH) ppm. $^{13}$C NMR (100 MHz, [$D_6$]Acetone): $\delta$ = 62.1, 92.6, 112.5, 233.7 ppm. MS: *m*/*z* (%) = 274 (20) $[M]^+$, 218 (6), 190 (22), 172 (20), 104 (100), 78 (12), 52 (50), 28 (40). $C_{11}H_{10}CrO_5$ (274.19): calcd. C 48.19, H 3.68; found C 48.18, H 3.65.

**General Procedure for the Synthesis of Chromium Complexes (Method A11) Tricarbonyl($\eta^6$-1,2,3,4-tetrahydro-1-naphthol)chromium(0) (*syn*-21):**[22] A degassed solution of 1,2,3,4-tetrahydro-1-naphthol (2.25 g, 15.20 mmol), $Cr(CO)_6$ (4.00 g, 18.17 mmol), and thf (4 mL) in $Bu_2O$ (80 mL) was heated under reflux (oil bath $T$ = 160 °C) for 40 h. After cooling to room temperature, the solution was filtered through Celite, then evaporated under reduced pressure. The yellow solid was recrystallized from $CH_2Cl_2$/hexane to give 2.85 g *syn*-**21**. The mother liquor was concentrated, and the residue chromatographed on silica gel (diethyl ether/hexane = 1:1) to give two fractions (0.61 g *syn*-**21** and 0.27 g *anti*-**21**). The total yield was 86%, and the ratio *syn*/*anti* was 93:7. Complex *syn*-**21**: IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1963, 1885 cm$^{-1}$. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 1.55–2.20 (m, 5 H, OH and $CH_2$), 2.45–2.85 (m, 2 H, $PhCH_2$), 4.40–4.65 (m, 1 H, CHOH), 5.00–5.25 (m, 2 H, ArH), 5.50 (t, $J$ = 6.2 Hz, 1 H, ArH), 5.82 (d, $J$ = 6.4 Hz, 1 H, ArH) ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 19.2, 27.5, 32.1, 66.6, 89.0, 90.2, 93.5, 95.1, 112.8, 113.8, 233.3 ppm.

***anti*-21:** $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 1.45–2.20 (m, 4 H, $CH_2$), 2.45–2.85 (m, 3 H, OH and $PhCH_2$), 4.45–4.68 (br, 1 H, CHOH), 5.20 (d, $J$ = 6.2 Hz, 1 H, ArH), 5.24 (t, $J$ = 5.8 Hz, 1 H, ArH), 5.33 (t, $J$ = 6.2 Hz, 1 H, ArH), 5.66 (d, $J$ = 5.8 Hz, 1 H, ArH) ppm. $^{13}$C NMR (50 MHz, $CDCl_3$): $\delta$ = 18.1, 28.0, 31.5, 67.0, 91.1, 92.2, 93.6, 94.4, 108.7, 110.0, 233.1 ppm.

**Method B16b (Complex 27b):** A degassed mixture of (2-chlorobenzyloxy)-*tert*-butyldimethylsilane (2.05 g, 8 mmol) and naphthalenetricarbonylchromium (1.06 g, 4 mmol) in thf/diethyl ether (5 mL, 4:1) was heated in a Carius tube with an o-ring tap for 22 h at 70 °C. Solvent removal followed by chromatography on silica gel (hexane/diethyl ether) afforded **27b** (628 mg, 40%). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1910, 1978 cm$^{-1}$. $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 0.04 (s, 3 H, SiMe), 0.09 (s, 3 H, SiMe), 0.97 (s, 9 H, *t*Bu), 4.14 (t, $J$ = 6.3 Hz, 1 H, ArH), 4.29 (t, $J$ = 6.3 Hz, 1 H, ArH), 4.46 (s, 2 H, CH2), 4.66 (d, $J$ = 6.3 Hz, 1 H, ArH), 5.37 (d, $J$ = 6.3 Hz, 1 H, ArH) ppm.

**Method C: Tricarbonyl($\eta^6$-1-chloro-2-fluorobenzene)chromium(0) (13):**[15] *n*BuLi (1.57 N in hexane, 0.70 mL, 1.1 mmol) was added dropwise to a solution of complex **9** (0.232 g, 1.0 mmol) in thf (10 mL) at –78 °C. The solution was slowly warmed to –45 °C over 45 min. After recooling to –78 °C, hexachloroethane (1.19 g, 5.0 mmol) was added, and the reaction mixture was warmed to room temp. over a period of 3 h. After concentration of the solution, the residue was dissolved in diethyl ether, washed with water, then dried with $MgSO_4$. Removal of volatiles and chromatography on silica gel yielded complex **13** (180 mg, 68%). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1986, 1914 cm$^{-1}$. $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 3.57–3.66 (m, 1 H, ArH), 3.87–3.97 (m, 1 H, ArH), 4.30–4.38 (m, 1 H, ArH), 4.58–4.65 (m, 1 H, ArH) ppm. $^{13}$C NMR (100 MHz, $C_6D_6$): $\delta$ = 78.9 (d, $J$ = 21.0 Hz), 86.1, 89.7 (d, $J$ = 6.6 Hz), 92.5, 100.4, 141.9 (d, $J$ = 265 Hz), 230.7 ppm.

Complexes **16a**–**d**, **18a**,**b**, **25**, and **26** were obtained by method A.

**($\eta^6$-Benzyl alcohol)tricarbonylchromium(0) (16a):**[35] IR (diethyl ether): $\tilde{\nu}$ = 1972, 1896 cm$^{-1}$. $^1$H NMR (400 MHz, $C_6D_6$): $\delta$ = 1.40–1.70 (br, 1 H, OH), 3.83 (s, 2 H, $CH_2OH$), 4.37 (t, $J$ = 5.6 Hz, 1 H, ArH), 4.53 (t, $J$ = 5.6 Hz, 2 H, ArH), 4.67 (d, $J$ = 5.6 Hz, 2 H, ArH) ppm. $^{13}$C NMR (100 MHz, $C_6D_6$): $\delta$ = 62.8, 90.8, 91.4, 92.9, 111.8, 233.5 ppm.

0.75 (br, 1 H, OH), 1.98 (t, $J$ = 6.0 Hz, 2 H, $PhCH_2$), 3.16 (t, $J$ = 6.0 Hz, 2 H, $CH_2OH$), 4.25–4.60 (m, 5 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 37.9, 62.6, 90.6, 93.4, 110.4, 233.7 ppm.

**Tricarbonyl(η⁶-3-phenylpropan-1-ol)chromium(0) (16c):** IR (diethyl ether): $\tilde{\nu}$ = 1970, 1896 $cm^{-1}$. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 0.75–1.05 (br, 1 H, OH), 1.34 (m, 2 H, $CH_2$), 2.05 (t, $J$ = 8.0 Hz, 2 H, $PhCH_2$), 3.15–3.25 (br, 2 H, $CH_2OH$), 4.36 (t, $J$ = 6.3 Hz, 1 H, ArH), 4.46 (d, $J$ = 6.3 Hz, 2 H, ArH), 4.58 (t, $J$ = 6.3 Hz, 2 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 31.3, 33.8, 61.2, 90.2, 92.6, 93.7, 113.9, 233.5 ppm.

**Tricarbonyl(η⁶-4-phenylbutan-1-ol)chromium(0) (16d):** Yellow oil. IR (diethyl ether): $\tilde{\nu}$ = 1971, 1896 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 0.85–1.40 (br, 5 H, OH and $CH_2$), 1.75–2.05 (m, 2 H, $PhCH_2$), 3.10–3.40 (m, 2 H, $CH_2OH$), 4.20–4.65 (m, 5 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 62.8, 90.8, 91.4, 93.0, 111.8, 233.5 ppm.

**Tricarbonyl(η⁶-1-phenylethanol)chromium(0) (18a):**[37] Yellow oil. IR ($C_6H_6$): $\tilde{\nu}$ = 1968, 1892 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 1.18 (d, $J$ = 6.5 Hz, 3 H, $CH_3$), 2.65–2.75 (br, 1 H, OH), 4.18–4.50 (br, 1 H, CHOH), 4.53–4.77 (m, 4 H, ArH), 5.25 (d, $J$ = 6.5 Hz, 1 H, ArH) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 25.2, 67.6, 90.8, 91.3, 92.5, 92.7, 92.9, 116.5, 118.0, 233.9 ppm.

**Tricarbonyl(η⁶-2-phenyl-2-propanol)chromium(0) (18b):** Yellow oil. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1967, 1888 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 1.16 (s, 6 H, $CH_3$), 1.59 (s, 1 H, OH), 4.43 (t, $J$ = 6.2 Hz, 2 H, ArH), 4.55 (t, $J$ = 6.2 Hz, 1 H, ArH), 5.05 (d, $J$ = 6.2 Hz, 2 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 31.3, 70.3, 91.0, 91.7, 93.4, 121.4, 233.8 ppm.

**(η⁶-1,3-Benzo[1,3]dioxol-5-methanol)tricarbonylchromium(0) (25):**[38] Yellow oil. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 1.40–1.65 (br, 1 H, OH), 3.60–3.80 (br, 2 H, $CH_2OH$), 4.20 (d, $J$ = 5.9 Hz, 1 H, ArH), 4.72 (d, $J$ = 5.9 Hz, 1 H, ArH), 4.91 (s, 2 H, $OCH_2O$), 5.09 (s, 1 H, ArH) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 62.7, 75.9, 76.5, 84.4, 100.3, 106.3, 129.6, 233.7 ppm.

**Tricarbonyl(η⁶-2-methoxybenzyl alcohol)chromium(0) (26):**[39] IR (diethyl ether): $\tilde{\nu}$ = 1966, 1890 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 1.45–1.85 (br, 1 H, OH), 2.91 (s, 3 H, $OCH_3$), 3.80–4.25 (m, 3 H, $CH_2OH$ and ArH), 4.34 (d, $J$ = 6.2 Hz, 1 H, ArH), 4.64 (t, $J$ = 6.2 Hz, 1 H, ArH), 5.30 (d, $J$ = 5.7 Hz, 1 H, ArH) ppm.

**General Procedure for the Synthesis of Trichloroacetate Derivatives: Tricarbonyl(η⁶-1,2,3,4-tetrahydro-1-naphthyl trichloroacetate)chromium(0) (22):** To a mixture of complex **21** (1.34 g, 4.70 mmol) and $Et_3N$ (0.86 mL, 6.12 mmol) in $CH_2Cl_2$ was added dropwise trichloroacetyl chloride (0.58 mL, 5.10 mmol) at 0 °C. The resulting mixture was stirred at room temp. for 1 h, then poured into water, and extracted with $CH_2Cl_2$. The organic solution was dried with $MgSO_4$ and then concentrated. The residue was purified by chromatography on silica gel (diethyl ether/hexane = 1–2:2) to give 1.89 g (94%) of **22** as a light yellow crystalline solid. M.p. 81.0–81.5 °C. IR (hexane): $\tilde{\nu}$ = 1982, 1920, 1908, 1766 $cm^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 1.75 (m, 4 H, $CH_2$), 2.60–2.90 (m, 2 H, $PhCH_2$), 5.05 (d, $J$ = 6.6 Hz, 1 H, ArH), 5.09 (t, $J$ = 6.6 Hz, 1 H, ArH), 5.50 (t, $J$ = 6.6 Hz, 1 H, ArH), 5.56 (d, $J$ = 6.6 Hz, 1 H, ArH), 5.80 (dd, $J$ = 6.6, 6.8 Hz, 1 H, PhCHOH) ppm. $^{13}C$ NMR (50 MHz, $C_6DCl_3$): $\delta$ = 18.3, 27.5, 27.9, 73.6, 87.6, 88.8, 92.9, 94.7, 104.1, 111.9, 161.8, 232.1 ppm.

**1-Phenethyl Trichloroacetate (5):** IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1763, 1496, 1453, 1248, 1059, 883, 828 $cm^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 1.60 (d, $J$ = 6.8 Hz, 3 H, $CH_3$), 5.90 (q, $J$ = 6.8 Hz, 1 H, OCH), 7.20–7.35 (m, 5 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$): $\delta$ = 21.8 78.2, 99.3, 126.0, 128.6, 128.7, 139.5 161.1 ppm.

**Benzyl Trichloroacetate (6):** IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1766, 1498, 1456, 1228, 965, 829.0 $cm^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 5.37 (s, 2 H, $PhCH_2O$), 7.30–7.45 (m, 5 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$): $\delta$ = 70.7, 99.3, 128.3, 128.8, 129.0, 133.7, 161.8 ppm.

**(η⁶-Benzyl trichloroacetate)tricarbonylchromium(0) (17a):** Yellow solid. M.p. 98.50–100 °C. IR (hexane): $\tilde{\nu}$ = 1987, 1923, 1774 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 4.10–4.37 (br, 5 H, ArH and $CH_2O$), 4.37–4.56 (br, 2 H, ArH) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 68.9, 91.6, 92.0, 93.1, 100.9, 161.5, 232.2 ppm. $C_{12}H_7Cl_3CrO_5$ (389.54): calcd. C 37.00, H 1.81; found C 37.15, H 1.81.

**Tricarbonyl(η⁶-phenethyl trichloroacetate)chromium(0) (17b):** Yellow solid. M.p. 85.5–86.0 °C. IR (diethyl ether): $\tilde{\nu}$ = 1973, 1900, 1772 $cm^{-1}$. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 1.90 (t, $J$ = 6.0 Hz, 2 H, $PhCH_2$), 3.96 (t, $J$ = 6.0 Hz, 2 H, $CH_2O$), 4.16–4.55 (m, 5 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 33.7, 68.5, 90.1, 91.5, 92.6, 93.2, 107.1, 161.5, 233.1 ppm. $C_{13}H_9Cl_3CrO_5$ (403.57): calcd. C 38.69, H 2.25; found C 38.66, H 2.21.

**Tricarbonyl(η⁶-3-phenylpropyl trichloroacetate)chromium(0) (17c):** Yellow solid. M.p. 57.50–58.0 °C. IR (diethyl ether): $\tilde{\nu}$ = 1973, 1900, 1791 $cm^{-1}$. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 1.17–1.40 (br, 2 H, $CH_2$), 1.70–1.98 (br, 2 H, $PhCH_2$), 3.58–3.87 (br, 2 H, $CH_2O$), 4.15–4.42 (br, 3 H, ArH), 4.42–4.68 (br, 2 H, ArH) ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 29.1, 30.8, 67.8, 90.2, 92.1, 93.4, 111.3, 161.8, 233.4 ppm. $C_{14}H_{11}Cl_3CrO_5$ (417.59): calcd. C 40.27, H 2.65; found C 40.30, H 2.65.

**Tricarbonyl(η⁶-4-phenylbutyl trichloroacetate)chromium(0) (17d):** Yellow oil. IR (diethyl ether): $\tilde{\nu}$ = 1971, 1896, 1770 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 0.70–1.40 (br, 4 H, $CH_2$), 1.50–2.00 (br, 2 H, $PhCH_2$), 3.45–4.00 (br, 2 H, $CH_2O$), 4.15–4.43 (br, 3 H, ArH), 4.43–4.85 (br, 2 H, ArH) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 27.0, 27.5, 34.2, 68.6, 90.2, 92.2, 93.6, 112.6, 161.9, 233.5 ppm. MS: $m/z$ (%) = 430 (85) $[C_{13}H_9Cl_3CrO_6]^{+\cdot}$, 346 (18), 311 (14), 236 (100), 117 (16), 91 (100), 52 (53). HRMS: $m/z$ calcd. for $C_{15}H_{13}Cl_3CrO_5$ 429.9233; found 429.9268.

**Tricarbonyl(η⁶-1-phenethyl trichloroacetate)chromium(0) (19a):** Yellow oil. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1974, 1898, 1767 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 1.14 (d, $J$ = 3.98 Hz, 3 H, $CH_3$), 4.20–5.50 (m, 6 H, ArH and CHO) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 20.3, 75.6, 90.6, 91.1, 91.2, 91.5, 92.6, 107.8, 160.7, 232.4 ppm.

**Tricarbonyl(η⁶-α-methylstyrene)chromium(0) (20):** IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1968, 1891 $cm^{-1}$. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 1.65 (dd, $J$ = 0.8, 1.4 Hz, 3 H, $CH_3$), 4.40–4.50 (m, 3 H, ArH), 4.70–4.78 (m, 2 H, ArH), 4.78 (d, $J$ = 1.4 Hz, 1 H, C=$CH_2$), 5.02 (d, $J$ = 0.8 Hz, 1 H, C=$CH_2$) ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 20.4, 90.3, 91.7, 91.8, 109.2 114.3, 139.6, 233.4 ppm.

**Tricarbonyl[4-(2,2,2-trichloroacetoxymethyl)benzyl trichloroacetate]chromium(0) (24):** Yellow solid. M.p. 98.5–100 °C. IR ($C_6H_6$): $\tilde{\nu}$ = 1979, 1912, 1770 $cm^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 5.14 (s, 4 H), 5.53 (s, 4 H) ppm. $^{13}C$ NMR (100 MHz, $CDCl_3$): $\delta$ = 68.4, 89.3, 91.8, 100.8, 161.6, 230.5 ppm. MS: $m/z$ (%) = 564 (1) $[M]^+$, 438 (2), 265 (8), 139 (40), 104 (100), 52 (15), 28 (36). $CrC_{15}H_8Cl_6O_7$ (564.94): calcd. C 31.89, H 1.43; found 31.86, H 1.42.

**(η⁶-Benzo[1,3]dioxol-5-ylmethyl trichloroacetate)tricarbonylchromium(0) (28):** Yellow crystals. M.p. 75 °C (decomp.). IR ($CH_2Cl_2$): $\tilde{\nu}$ = 1971, 1894, 1768 $cm^{-1}$. $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 4.92 (d, $J$ = 12.2 Hz, 1 H, $CH_2O$), 5.01 (d, $J$ = 12.2 Hz, 1 H, $CH_2O$), 5.11 (d, $J$ = 6.3 Hz, 1 H, ArH), 5.50 (d, $J$ = 6.3 Hz, 1 H, ArH), 5.65 (s, 1 H, ArH), 5.77 (s, 1 H, $OCH_2O$), 6.00 (s, 1 H, $OCH_2O$) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 69.4, 71.4, 75.8, 78.0, 88.0, 95.3, 95.3, 101.5, 129.2, 129.8, 162.1, 232.4 ppm.

**Tricarbonyl(η⁶-2-methoxybenzyl trichloroacetate)chromium(0) (29):** Yellow solid. M.p. 95 °C (decomp.). IR (diethyl ether): $\tilde{\nu}$ = 1975, 1902, 1770 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 2.4–3.15 (br, 3 H, $OCH_3$), 3.52–4.20 (br, 2 H, $PhCH_2O$), 4.20–5.40 (br, 4 H, ArH) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 55.4, 65.0, 73.0, 84.2, 89.9, 90.1, 94.2, 97.0, 142.5, 161.5, 232.4 ppm. MS: *m*/*z* (%) = 418 (1.62) $[C_{13}H_9Cl_3CrO_6]^{+\cdot}$, 257 (2.39), 173 (3.89), 157 (3.13), 121 (100), 91 (50.95), 52 (45.6). HRMS: *m*/*z* calcd. for $C_{13}H_9Cl_3CrO_6$ 417.8955; found 417.8893.

**Tricarbonyl(η⁶-2-chlorobenzyl trichloroacetate)chromium(0) (30):** IR (diethyl ether): $\tilde{\nu}$ = 1985, 1920, 1773 $cm^{-1}$. $^1H$ NMR (200 MHz, $C_6D_6$): $\delta$ = 3.90–4.16 (m, 1 H, ArH), 4.40–4.44 (m, 1 H, ArH), 4.47 (d, *J* = 12.5 Hz, 1 H, $PhCH_2O$), 4.79 (d, *J* = 12.5 Hz, 1 H, $PhCH_2O$), 4.69–4.86 (m, 1 H, ArH) ppm. $^{13}C$ NMR (50 MHz, $C_6D_6$): $\delta$ = 66.7, 87.3, 89.9, 90.7, 93.0, 94.4, 97.5, 113.8, 161.2, 230.9 ppm.

**Evaluation of Photoinitiator Reactivity in an Acrylate Formulation:** A base formulation of the following composition was prepared: 50 g Actylan 200 (urethane acrylate, Akcros), 10 g Sartomer SR 399 (dipentaerythritol monohydroxypentaacrylate), 15 g TPGDA (Tripropyleneglycol diacrylate), 10 g TMPTA (Trimethylolpropane triacrylate), 15 g *N*-vinylpyrrolidone, 0.3 g BYK 300 (silicon resin for scratch resistance, 50% polymer in a mixture of xylene/butanol).

The photoinitiator component(s) were incorporated into a portion of the base formulation by stirring at 60 °C. The formulation was coated on an 300 μm aluminum foil with an electrical applicator equipped with a 100-μm wire-wound rod. The resulting film was successively laminated with a 76-μm Mylar foil, which serves as an oxygen barrier, a Stouffer 21-step optical wedge, which allows the determination of the relative reactivity of the photoinitiator systems, and a UV-transparent polyester foil, and then fixed on a vacuum table. Broad-band exposure was performed with a 4-kW Xenon lamp at a distance of 30 cm with a fixed dose of 291 mJ $cm^{-2}$. After exposure, the laminated foils were removed, and the film was developed in an ultrasonic bath of ethanol for 10 s. The number of fully cured steps, which serves as a measure of reactivity, was determined after drying for 5 min at 40 °C. Step 0 of the Stouffer optical wedge is 100% transparent. From step 1 to step 21, the transparency decreases from 89.13 to 0.09%, whereby every 2 steps corresponds to a halving of the transparency. Thus, a photoinitiator system which can cure 10 steps is twice as reactive as one which effects the curing of 8 steps.

**Irradiation of Complex 17a to Give (η⁶-Benzyl chloride)tricarbonylchromium (32):**[40] A solution of **17a** (0.385 g, 0.99 mmol) in benzene (5 mL) was irradiated in a Rayonet photoreactor (Four 3500 Å lamps) until complete disappearance of starting material (2 d, followed by TLC). The reaction mixture was filtered (Celite) and concentrated. Chromatography on silica gel (eluent hexane/EtOAc = 5:1) afforded complex **32** as a yellow solid (0.107 g, 41%). 1H NMR (200 MHz, $C_6D_6$): $\delta$ = 3.47 (s, 2 H, $CH_2Cl$), 4.15–4.40 (m, 5 H, ArH) ppm. MS: *m*/*z* (%) = 262 (11) $[M^+]$, 178 (26), 143 (8), 91 (100), 52 (60). HRMS: *m*/*z* calcd. for $C_{10}H_7ClCrO_3$ 261.9489; found 261.9477.

**(η⁶-Benzene)dicarbonyl(η²-methyl acrylate)chromium(33b):** Following a literature method,[27] a solution of (η⁶-benzene)(η²-*cis*-cyclooctene)$Cr(CO)_2$ was prepared by photolysis (Philips, HPK 125) of complex **1** (0.642 g, 3 mmol) in benzene (200 mL)/cyclooctene (16 mL). Methyl acrylate (270 μL, 3 mmol) was added to the reaction mixture after completion of the irradiation. After 16 h, the mixture was filtered through Celite. Volatiles were removed in vacuo. The residue was taken up in hexane/benzene (20:1) and recrystallized at –40 °C to give red-orange crystals of **33b** (0.586 g, 72%). M.p. 82–83 °C. IR (hexane): $\tilde{\nu}$ = 1948 (s), 1896 (s), 1704 (m) $cm^{-1}$. 1H NMR ($C_6D_6$, 200 MHz): $\delta$ = 4.35 (s, 6 H, $C_6H_6$), 3.56 (s, 3 H, $OCH_3$), 2.93 (dd, *J* = 11.3, 7.7 Hz, 1 H, C=C*H*-$CO_2$Me), 2.76 (dd, *J* = 11.3, 0.8 Hz, 1 H, $CH_2$=C), 2.37 (dd, *J* = 7.7, 0.8 Hz, 1 H, $CH_2$=C) ppm. 13C NMR ($C_6D_6$, 50 MHz): $\delta$ = 246.6, 245.9, 177.2, 95.9, 50.1, 41.4, 38.6 ppm. MS: *m*/*z* (%) = 272 (0.4) $[M^+]$, 186(4), 158(7), 130(18), 78(100), 52(65). $C_{12}H_{12}CrO_4$ (272.22): calcd. C 52.95, H 4.44; found C 52.72, H 4.36.

**Keywords:** Grids / Ditopic acylhydrazones / Component assembly / Crystal structures

Ditopic bis(acylhydrazone) ligands, derived from the reactions of carbohydrazides with 2-phenylpyrimidine-4,6-dicarbaldehyde and designed for grid formation with octahedrally coordinating transition-metal ions, exhibit a varied coordination chemistry depending upon the degree of their deprotonation. The neutral acylhydrazones are relatively poor ligands and are seemingly involved in multiple, labile complexation equilibria varying with the solvent and the particular metal salt in solution; nevertheless, grid complexes of different forms can be isolated in the solid state. Although only limited study has been made of the singly deprotonated ligands, grid species appear to be much more readily isolated. With the doubly deprotonated ligands, grid formation is strongly favoured in both the solution and solid states. As a consequence, the grid structures form spontaneously in the presence of a base by self-assembly from their components without need to preform the ditopic ligands. Extensive structural studies have been carried out both to establish the grid structures and to analyse the nature of the supramolecular interactions possible for neutral and charged grid species.

## Introduction

Metallosupramolecular chemistry has developed a wide range of fascinating multicomponent coordination architectures generated by self-assembly from suitably designed ligands and specific metal ions.[1–12] The structure of the ligand bears the molecular information, as a message in molecules, that is processed through the coordination algorithm of the metal ion. Grid-type metallosupramolecular entities are of special interest, as they represent regularly positioned arrays of metal ions that may display novel optical, electronic and magnetic properties.[8,12,13] In particular, [2×2] tetranuclear grids have been extensively studied by our group.[8] We describe here developments towards classes of [2×2] grids presenting novel structural and functional characteristics.

### Design Features

The "parent" [2×2] grid architectures incorporate ditopic ligands based on pyridine (py) and pyrimidine (pym) groups in a py-py-pym-py-py sequence amounting to two tridentate terpyridine-type coordination centres (structure **L**).[8] Replacement of a py group by an isosteric hydrazone unit presents considerable synthetic advantages as well as other novel properties. It may be achieved by condensation of a central pyrimidine-4,6-dicarbaldehyde with either a pyridine-2-hydrazine or a hydrazide (Figure 1, routes leading to products **A** and **B**, respectively), thus generating ditopic ligands incorporating two hydrazone functions as central groups of two tridentate metal coordination centres. Ligands containing two unsubstituted hydrazone units (Figure 1) possess two ionisable sites[12,14–19] that may serve to modulate (i) the coordination properties of the ligands, (ii)

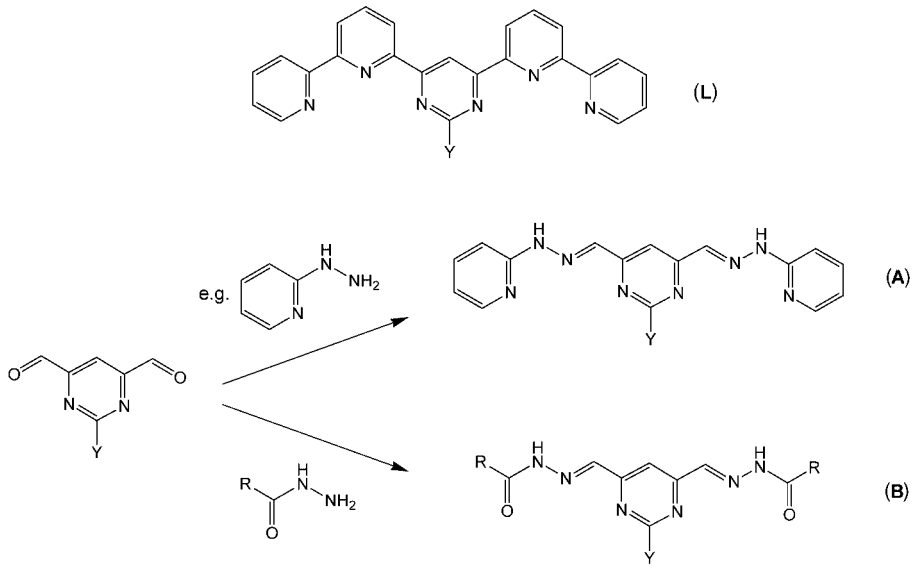

Figure 1. The parent [2×2] grid-forming bis(bipyridyl)pyrimidine ligand **L** and synthetic pathways to isosteric hydrazone (**A**) and acylhydrazone (**B**) analogues. Note that the bis(tridentate) form shown is but one of the configurations possible for such ligands.

the optical electronic and magnetic properties of the grid complexes, as well as (iii) the communication between external effectors and the metal centres.

In addition, the py-hydrazone ligands (**A** in Figure 1) may be fitted with side chains that will extend along the axis perpendicular to the mean plane of the four metal cations in the grid,[20] whereas for the grids formed from acylhydrazone ligands (**B** in Figure 1), the R side chains extend laterally. Thus, grid formation from these two types of ligands results in multiple "axial" and "lateral" functionalisation. Furthermore, the acylhydrazone groups may also bear axial side chains, resulting in grids presenting a total of sixteen substituents that can be of two different types.

Finally, the hydrazone-based ligands need not to be preformed, as they may form directly from their components and the metal ions in a single overall process in the course of the self-organisation of the grid architecture (Figure 2). Component self-assembly has a long history in coordination chemistry involving carbonyl condensation reactions.[21] Multicomponent/multinuclear self-assembly has been shown to take place in the spontaneous build-up of another type of [2×2] grid[22] and has been further exploited recently.[11]

Grid-type complexes formed from hydrazone-containing ligands display several features of great interest: (i) easy synthetic access from preformed ligands or by component

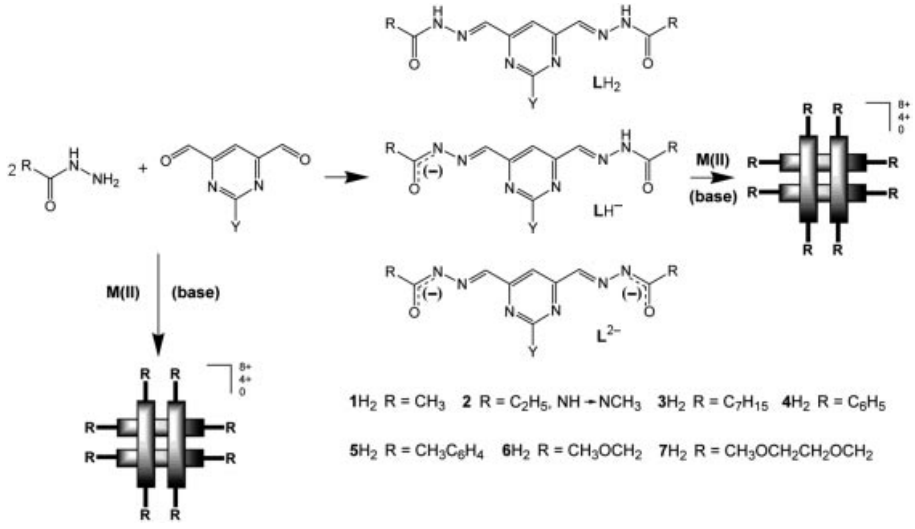

Figure 2. Formation and ionisation of a bis(acylhydrazone) derived from a pyrimidinedicarbaldehyde, with an idealised representation of the laterally functionalised grid, which may be formed by complexation either from the preformed ligand or by reaction with its constituents. Only the bis(tridentate) form of the ligand is shown. The seven particular acylhydrazones studied in the present work are listed (Y = phenyl in all cases).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

self-assembly; (ii) multiple functionalisation; (iii) response to external effectors. We have undertaken studies towards the exploration and the exploitation of these different aspects of the potentialities offered by such grid complexes of the [2×2] type as well as of other types.

The readily ionised ligands of type **B** (Figure 2) provide functionalised grid complexes, giving rise to quartets of pairs of "lateral" functional groups. Crystal structure determinations on a range of these complexes with $M^{II}$ transition-metal ions give indications of a variety of labile interactions possible in grid systems, which might be exploited in supramolecular chemistry.

## Results and Discussion

### 1. Bis(acylhydrazone) Ligand Synthesis and Characterisation

The neutral, protonated forms of the bis(acylhydrazone) ligands presently described have all been obtained by double-condensation reactions of 2-phenylpyrimidine-4,6-dicarbaldehyde with carbohydrazides (designated henceforth as acylhydrazines). It is possible to conduct these reactions with a much greater variety of acylhydrazines, work which will be the subject of other publications,[23] and, of course, to vary the nature of the dicarbaldehyde. Characterisation of the reactions between the phenylpyrimidinedicarbaldehyde and acylhydrazines in homogeneous solution is complicated by the low solubility of the products in most solvents, as well as by changes in the form of the dicarbaldehyde in different solvents (Figure 3). The dicarbaldehyde, as obtained directly from the partially aqueous final synthetic medium,[24] is hydrated to a degree and thus present as a mixture of forms, even though it does crystallise well from diethyl ether. In aprotic solvents such as chloroform or acetonitrile, the $^1$H NMR spectrum shows predominantly peaks attributable to the true aldehyde only (even in the presence of low concentrations of water present in the undried solvents), whereas in methanol only an extremely weak –CHO signal of the aldehyde species can be discerned, and the bulk (99%) of the compound appears to be present as its bis(hemiacetal), giving rise to a CH resonance at $\delta$ = 5.54 ppm, a similar weak resonance at $\delta$ = 5.53 ppm along with the aldehyde peak at $\delta$ = 10.09 ppm, consistent with the presence of ca. 1% mono(hemiacetal)monoaldehyde. We presume that, in the absence of an acid catalyst, further reactions to give acetal species must be very slow.

Fortunately, the hemiacetals are labile, since addition of an acylhydrazine to a methanol solution of the dicarbaldehyde results in the appearance of new peaks corresponding to hydrazide-*N* addition products within the time required for mixing the reagents and recording the spectrum. Typically after a period of some tens of minutes at room temperature for 2:1 molar mixtures of acylhydrazine and dicarbaldehyde, the bis(acylhydrazone) derivatives of the dicarbaldehyde begin to precipitate from such solutions, indicating that elimination reactions of the addition intermediates are also relatively rapid. The insolubility of the bis(acylhydrazone) is commonly such that it is the material precipitated even from solutions in which the molar ratio of reactants is 1:1. Consistent with an inhibition of the reaction by acetal formation in methanol, product precipitation occurs much sooner (within a few minutes) in acetonitrile. In the particular case of benzoylhydrazine, the initial precipitate obtained from acetonitrile solvent appears to be amorphous and even oily but slowly (over days) transforms largely into clusters of pale yellow needles, indicating that the immediate product could be a mixture of stereoisomers.[25,26] A further indication of this is that, in the presence of some $M^{II}$ ions (M = Mn, Zn), the precipitate, which still does not contain the metal ions, deposits more slowly and appears to be entirely crystalline. Perhaps this is because the precipitation of one form is retarded by complexation, even though complexation by both stereoisomers is well-established for simple acylhydrazones,[26,27] and (see below) at least two forms are still present in the precipitate. Up to the point of precipitation in solutions not containing

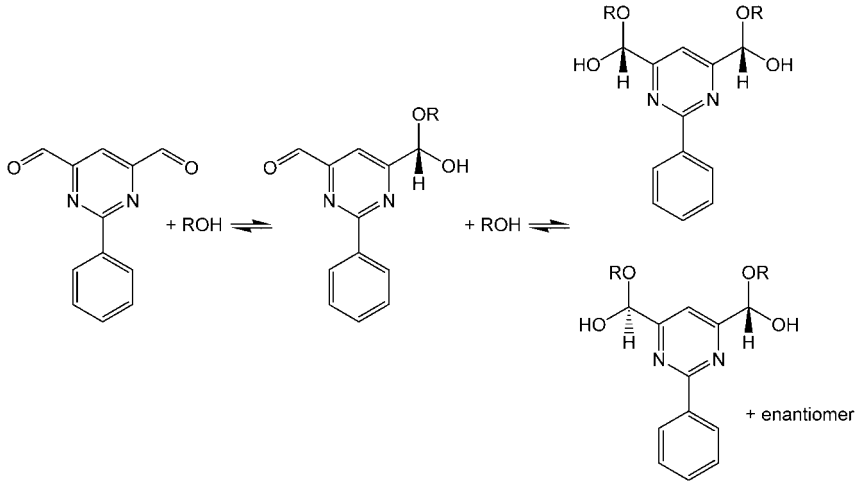

Figure 3. Hydrate (R = H) and hemiacetal (R = alkyl) formation reactions of 2-phenylpyrimidine-4,6-dicarbaldehyde.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metal ions, strong signals near $\delta$ = 5.7 ppm are consistent with the fact that addition intermediates are the dominant solution species, at least two being apparent.

For the hydrazides derived from methoxy- and methoxyethoxyacetic acid, solvents can be found in which all components stay soluble up to the point of homogeneous equilibrium. Here, at concentrations of ca. $5 \times 10^{-3}$ mol L$^{-1}$, NMR spectroscopy shows that small but detectable concentrations of species containing a tetrahedral methine centre are present even after several days at room temperature in acetonitrile, and over relatively short time periods (at least 1 h) in this solvent, the methoxyacetyl system seems simply to be involved in an addition equilibrium where a significant fraction of dicarbaldehyde is present. The addition of a metal ion such as $Zn^{II}$ to a mixture of acylhydrazine and dicarbaldehyde has multiple effects, including an initial release of dicarbaldehyde, presumably as a consequence of coordination of the acylhydrazine reactant, though ultimately there is a modest acceleration of the formation of the acylhydrazone. The situation is simpler in dimethyl sulfoxide solvent, where an addition equilibrium appears to be very rapidly established and is then very slowly displaced towards the elimination products (hydrazones) unless $Zn^{II}$ is added, in which case, for the addition of one molar equivalent, the spectrum changes over a period of minutes at ambient temperature towards that of the "free" bis(acylhydrazone) in this solvent. If $Ga^{III}$ is used as catalyst, the reaction seems to be complete within the time of mixing of the reagents. Thus, it can be deduced that there is efficient Lewis acid catalysis of acylhydrazone formation in dmso.

The solids that precipitate commonly from preparative mixtures can be dissolved in solvents such as dmso and do not show $^1$H spectral resonances near $\delta$ = 5.7 ppm, nor do they appear to react with the low concentrations of water present in such solvents. In most cases, however, at least two NH resonances of different intensity are detectable, indicating that stereoisomers are present (Figure 4). For related grid-forming ligands derived from thiocarbonodihydrazide,[19b] it has been established by a crystallographic study that the most readily crystallised isomer is not that ultimately found in the grid complexes, intramolecular hydrogen bonding being suggested as a factor favouring the form observed. That the proton complex of the anionic ligand has coordination characteristics very different from those of its transition-metal complexes is hardly surprising and has, of course, a great number of precedents.

While isomerism of acylhydrazones is usually considered to be associated with configuration about the hydrazone C=N bond, restricted rotation about the acyl-C–N bond is also possible; furthermore, there is evidence that intermolecular hydrogen bonding can give rise to multiple species in solution.[28] For bis(acylhydrazone)s, *E*/*Z* isomerisation about the hydrazone bond could give rise to at least three isomeric forms, and in several of the present hydrazones (e.g. **1**H$_2$, R = CH$_3$) the $^1$H NMR spectra show multiple NH (and other) resonances consistent with the presence of at least two forms. For the ligand **6**H$_2$ (R = CH$_3$OCH$_2$), one NH resonance is strongly dominant, but there are pairs of methyl and methylene peaks of similar intensity, indicating that this molecule is largely in the (*E*,*Z*) form. This may also apply for the ligand **5**H$_2$ (R = CH$_3$C$_6$H$_4$), for which the spectrum shows two sets of resonances of very different intensity, although for the closely related benzoylhydrazine derivative **4**H$_2$ (R = C$_6$H$_5$), the $^1$H NMR spectrum in [D$_6$]-

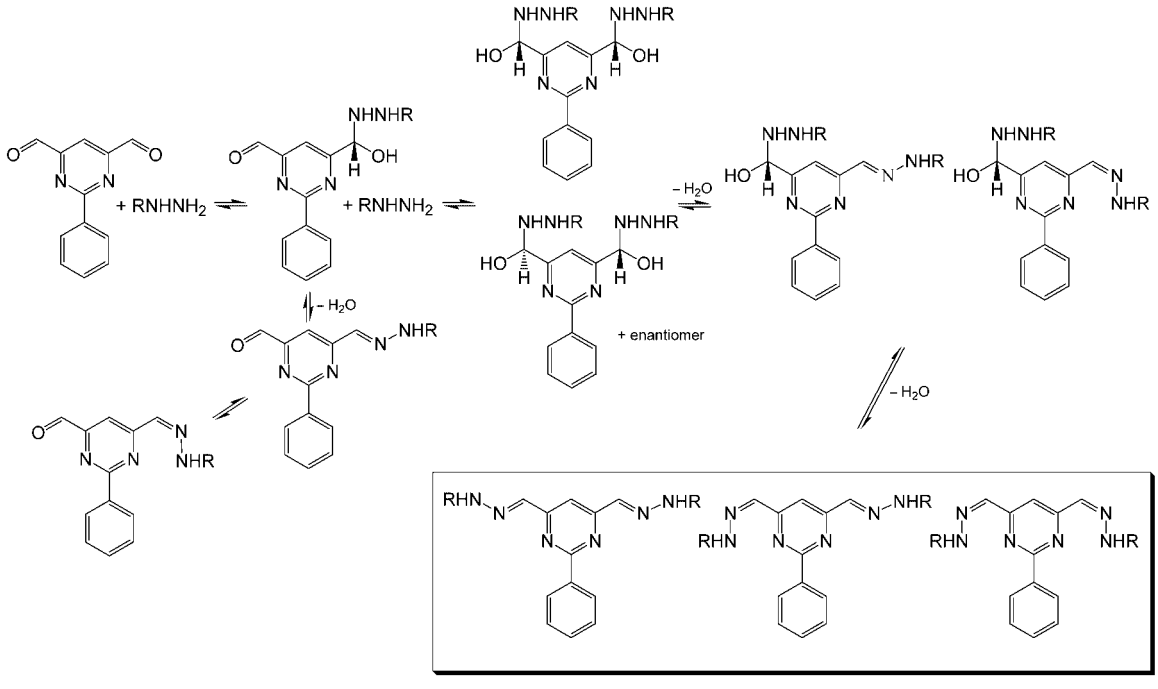

Figure 4. Species possibly present in reaction mixtures formed from 2-phenylpyrimidine-4,6-dicarbaldehyde and acylhydrazines in non-nucleophilic solvents; each stereoisomer may, of course, have other conformations than those shown.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dmso shows a single, relatively sharp NH resonance ($\delta$ = 12.40 ppm), and the NOESY spectrum (Figure 5) can be interpreted in terms of a single conformation of the (*E*,*E*) isomer. Thus, the correlation between the NH protons, C, and the CH=N protons, B, establishes the (*E*) configuration of the hydrazone link, while the correlation of C with the aromatic protons, D, is consistent with the (*E*) configuration of the amide bond. Assuming that a *trans* conformation of the unsaturated-N substituents on the C(aromatic)–C(hydrazone) single bond would be favoured, the configuration deduced for this molecule is that shown in Figure 5.

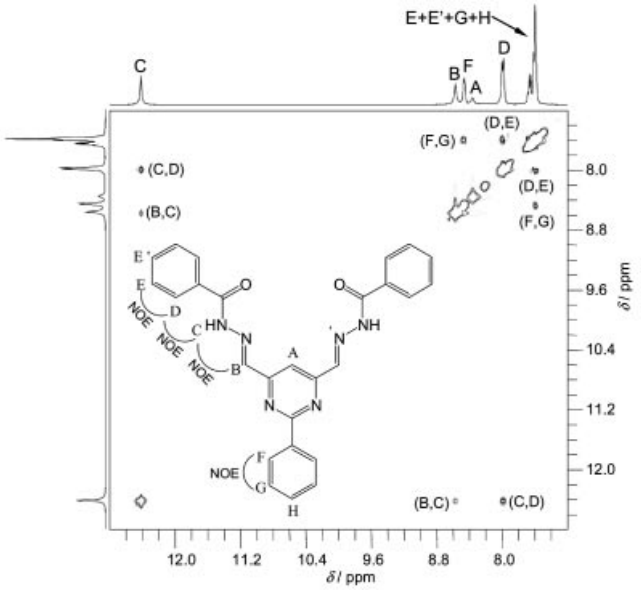

Figure 5. $^1$H-NOESY spectrum (300 MHz, [D$_6$]dmso) for the compound **4**H$_2$; the observed correlations and the configuration deduced are shown in the inset.

This conclusion is supported by the NOESY spectrum of ligand **2** (Figure 6), which shows several important similarities to that of **4**H$_2$. A crystal structure determination for ligand **2** (Figure 7) has established not only proton locations consistent with the spectrum, but has also shown the anticipated arrangement about the C(aromatic)–C(hydrazone) single bonds. The correlation (B,C) between the methyl protons, C, and the hydrazone proton, B, is in agreement with the (*E*) configuration of the C=N hydrazone bond and with an *s-trans* conformation of the N–N bond substituents. Moreover, a correlation (B,F) between the hydrazone proton, B, and the phenyl protons, F, on C2 and C2′ confirms the *s-trans* conformation of the bond connecting the hyz group to the pym ring. The correlation (A,D) between the pyrimidine proton, A, on C5 and the methylene protons, D, suggests the *s-cis* conformation of the amide bond, a difference from the conformation in **4**H$_2$, which may be attributable to both steric and electronic differences between phenyl and ethyl substituents. The weak correlation (A,B) between the pyrimidine proton, A, on C5 and the hydrazone, B, shows that, in solution, the *s-trans* conformation of the C(aromatic)–C(hydrazone) bond is partially twisted because of the steric hindrance between the two acyl arms of the ligand.

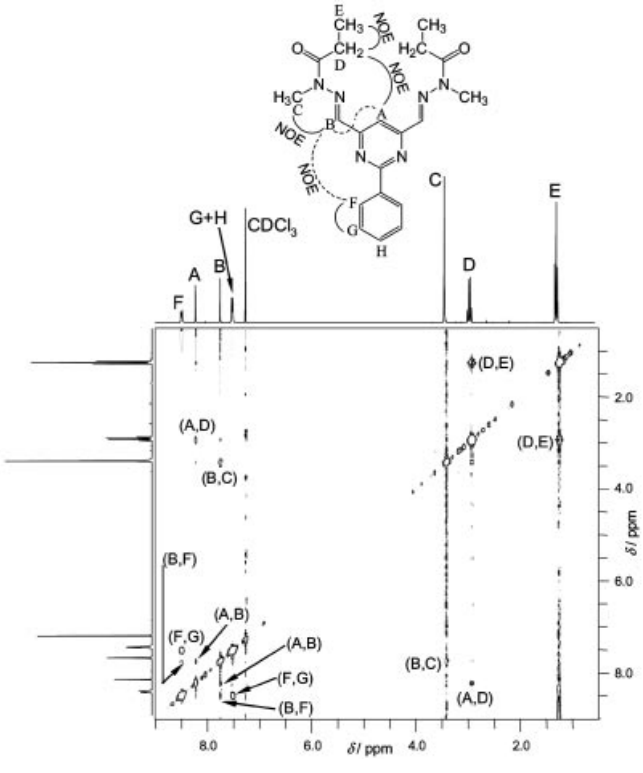

Figure 6. $^1$H-NOESY spectrum (300 MHz, $CDCl_3$) of compound **2**; proton correlations and the deduced configuration of the molecule are shown in the inset.

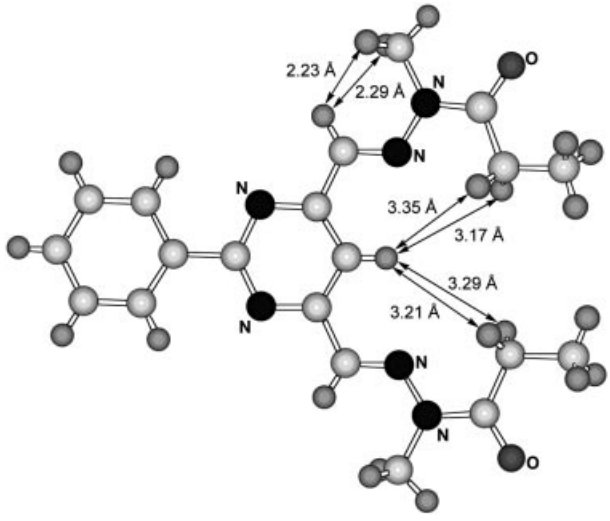

Figure 7. One molecule of **2** as found in the crystal lattice. Several intramolecular H···H separations are indicated.

## 2. Complexation of the Bis(acylhydrazone) Ligands

As the first transition-metal series provides a number of labile M$^{II}$ species commonly showing octahedral coordination but with a variety of electronic properties, the most readily available members, viz. Mn$^{II}$, Fe$^{II}$, Co$^{II}$, Ni$^{II}$, Cu$^{II}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and $Zn^{II}$, were chosen for our initial investigations. $Mn^{II}$ proved to be complicated to study, presumably because of both the relatively low stability of its complexes, as reflected by its position in the Irving–Williams series,[29] and its susceptibility to undergo multiple oxidation processes, even though mass spectra provided evidence that the expected grids were the initial products of synthesis. The present focus is therefore upon the remaining five metal ions, although $Cu^{II}$ also provided some difficulties. In view of its diamagnetism, and hence the feasibility of recording high-resolution NMR spectra, $Zn^{II}$ was generally chosen as the first metal ion to be investigated, though of course it was not expected to necessarily give the most stable complexes. As anticipated and confirmed by structural and spectroscopic studies, the bis(acylhydrazone) ligands do generate 2×2 grid complexes.

### *(a) Complex Formation from the Preformed Bis(acylhydrazone) Ligands*

A limited degree of binding of the neutral ligands to $M^{II}$ ions even in pure methanol or acetonitrile solvents is suggested by the fact that acylhydrazones dissolve quite readily in these solvents when, for example, the metal triflate is added, to give appreciably coloured solutions. In the case of ligand $\mathbf{7}H_2$ (R = $CH_3OCH_2CH_2OCH_2$), which shows some solubility in $CH_3CN$, addition of one equivalent $Zn^{II}$ causes significant changes in the $^1H$ NMR spectrum, and in general the spectra of mixtures of the neutral ligands with $Zn^{II}$ vary somewhat with the metal ion concentration. Nevertheless, the spectra are poorly resolved and complex, showing slow, minor changes over time, indicating that several species may be present, and evaporation of the solvent generally results in reprecipitation of the free ligand. If, however, the initial reaction mixture containing $Zn^{II}$ (as its triflate) is immediately diluted with a poorly ligating solvent such as diethyl ether, the colour changes from pale yellow to red, presumably indicating some degree of metal complexation, and ultimately both yellow (ligand) and red crystalline materials deposit from the solution. If nitromethane is used as the solvent for the reaction, complexation of the acylhydrazone appears to be more favoured than in acetonitrile, in that the solution formed has a clear red colour, but at least for bis(benzoylhydrazone) it is still the free acylhydrazone which precipitates most readily from the solution. This precipitation can be inhibited by increasing the amount of $Zn(CF_3SO_3)_2$ present, ultimately enabling the deposition of a red 2:1 complex. In the $^1H$ NMR spectrum of this species in acetonitrile (in which the ligand itself is completely insoluble), the *ortho* protons of the central phenyl ring appear to have undergone strong shielding, which is consistent with the binding of metal ions and the resulting rotation of the phenyl group. More interesting is the observation that with tetrafluoroborate in place of triflate, a 1:1 complex precipitates, as it does in the case of $Ni^{II}$ when perchlorate is the associated anion. Note, however, that $Ni^{II}$ does not guarantee success in the isolation of a neutral ligand complex, as, while $Ni(BF_4)_2$ and ligand $\mathbf{3}H_2$ (R = $C_7H_{15}$) dissolve in boiling methanol to give an orange solution, it is the ligand which precipitates on cooling, and with $Ni(NO_3)_2$ and ligand $\mathbf{4}H_2$, the red complex which precipitates contains partly deprotonated ligand.

Overall, these observations indicate that there is a delicate balance of various solvent- and anion-dependent equilibria, including acid dissociation, involved in the interactions of neutral acylhydrazones with $M^{II}$ transition-metal ions, complications which of course are undesirable in relation to the ultimate goal of using the complexes in solution chemistry. Both of the 1:1 complexes referred to above have the form of grids in the solid state (see crystallographic discussion) but they are nonetheless quite different, the Ni species having only the (*E*,*E*) form of the ligand while the Zn species has a 1:1 mixture of (*E*,*E*) and (*Z*,*Z*) isomers.
